

# On the role of lysine in the active site Ser-X-X-Lys region of penicillin-recognizing enzymes

Saul Wolfe and Kiyull Yang

**Abstract:** Using Autodock, docking of penicillin G to the crystal structures of penicillin-recognizing enzymes leads to an alignment in the active site Ser-X-X-Lys region consisting of the serine hydroxyl group, the terminal amino group of lysine, a second hydroxyl group, and the N-C=O of the  $\beta$ -lactam. This alignment is consistent with the notion that acylation of the serine hydroxyl group proceeds by a one-step cooperative mechanism in which C-O bond formation and proton transfer to the  $\beta$ -lactam nitrogen take place through a heteroatom bridge. For the cooperative ring opening of penam by two molecules of methanol and one molecule of methylamine or one molecule of water, density functional theory with the B3LYP DFT gradient-corrected functional and the 6-31G(d) basis set reproduces the alignment seen in the docked structures. Methylamine lowers the barrier calculated at MP2/6-31G(d) from the DFT-optimized geometries by 3 kcal/mol; water increases the barrier by 4 kcal/mol. The function of the conserved lysine in the active sites of penicillin-recognizing enzymes is therefore to catalyze the formation of an acyl enzyme by a cooperative mechanism.

**Key words:** Autodock, cooperative mechanism, density functional theory (DFT), acyl enzyme.

**Résumé :** Les simulations à l'aide du programme Autodock montrent que l'arrimage de la pénicilline G aux structures cristallines des enzymes reconnaissant la pénicilline conduit à un alignement dans la région du site actif Ser-X-X-Lys formé du groupe hydroxyle de la lysine, du groupe aminé terminal de la lysine, du second groupe hydroxyle et du N-C=O du  $\beta$ -lactame. Cet arrangement est en accord avec la notion selon laquelle l'acylation du groupe hydroxyle de la lysine se produit par un mécanisme coopératif en une étape dans lequel la formation de la liaison C-O et le transfert de proton à partir de l'azote du  $\beta$ -lactame se produit par un pont hétéroatomique. Pour l'ouverture de cycle coopérative du pénam par deux molécules de méthanol et une molécule de méthylamine ou une molécule d'eau, l'utilisation de la théorie de la fonctionnelle de la densité, TFD, avec une fonctionnelle corrigée pour le gradient, B3LYP, et un ensemble de base 6-31G(d) permet de reproduire l'alignement observé dans les arrimages de structures. Pour la méthylamine la barrière calculée au niveau MP2/6-31G(d) est abaissée de 3 kcal/mol par rapport à la valeur obtenue par la TFD avec des géométries optimisées.

**Mots-clés :** Autodock, mécanisme coopératif, théorie de la fonctionnelle de la densité (TFD), enzyme acyle.

[Traduit par la Rédaction]

Penicillin-binding proteins (PBPs), the targets of  $\beta$ -lactam antibiotics,<sup>1</sup> and  $\beta$ -lactamases, which defend bacteria from the action of  $\beta$ -lactam antibiotics,<sup>2</sup> are related to each other structurally,<sup>3</sup> kinetically,<sup>4</sup> and in their evolution from a common ancestor.<sup>5</sup>

Structurally, PBPs and  $\beta$ -lactamases are serine peptidases whose catalytic serine is followed by lysine three residues towards the carboxyl terminus (Ser-X-X-Lys). PBPs and  $\beta$ -lactamases exhibit the same kinetics (Fig. 1), but with different rate constants:  $k_2 \gg k_3$  in a PBP and  $k_2 \approx k_3$  in a  $\beta$ -lactamase, and this difference is responsible for their different functions.

In the case of a PBP, the acyl enzyme cannot catalyze the final step of the synthesis of the peptidoglycan component

**Fig. 1.** Formation of acyl enzymes.

of the bacterial cell wall, which is weakened, and the internal osmotic pressure causes the cell to burst. In the case of a  $\beta$ -lactamase, hydrolysis of the acyl enzyme regenerates the enzyme and the antibiotic is inactivated as a result of the net hydrolysis of the  $\beta$ -lactam bond. This is an important mechanism of bacterial resistance to  $\beta$ -lactam antibiotics.

All of these reactions involve addition to a carbonyl group, the  $\beta$ -lactam carbonyl group in the formation of the acyl enzyme, and the carbonyl group of an ester in the hydrolysis of the acyl enzyme. There are many publications dealing with the mechanisms of these reactions, especially the roles of Lys73, Glu166 of  $\beta$ -lactamases, and a water

molecule.<sup>6</sup> Most of these publications propose stepwise ionic processes for these reactions. Our contrarian view regarding such mechanisms follows from the demonstration<sup>7</sup> that the aqueous hydration of an aldehyde or ketone does not proceed in a stepwise ionic manner but, rather, by a cyclic (cooperative) mechanism, with concurrent C–O bond formation and proton transfer to oxygen taking place through a solvent and (or) catalyst bridge. *The neutral hydrolysis of an ester also proceeds by a one-step cooperative mechanism.*<sup>8</sup>

Our interest in the cooperative mechanism evolved from a computational examination of the methanolysis of azetidinones,<sup>9</sup> which led to the conclusions that in the low-dielectric gas phase, an O-protonation pathway **1**, leading to a tetrahedral intermediate, is disfavoured relative to an N-protonation pathway **2**, that one water molecule provides over 10 kcal/mol of catalysis, that penam provides 5 kcal/mole of catalysis over *N*-methylazetidinone, and the 3 $\alpha$ -carboxyl group of the penicillin nucleus also provides 5 kcal/mol of catalysis.

The data of ref. 9 were obtained by geometry optimization at the 3–21G(d) level followed by single-point calculation of energies at the MP2/6–31G(d) level.<sup>10</sup> We have now repeated these calculations using density functional theory with the B3LYP DFT gradient-corrected functional and the 6–31G(d) basis set,<sup>11</sup> and have confirmed the earlier trends.

Very significantly, in our view, structure **2** is now seen to resemble **3** and **4**, in which penicillin G has been docked<sup>12</sup> to the crystal structures of an exocellular PBP from *Streptomyces* R61,<sup>13</sup> and the RTEM Class A  $\beta$ -lactamase from *Escherichia coli*.<sup>14</sup> When the unprotonated terminus of the lysine residue of the Ser-X-X-Lys motif is included in these structures, the function of this conserved amino acid becomes clear.

Structures **5–7** are mono and stereo views of the active site regions of penicillin G docked to the crystal structures of *Streptomyces* R61 (**5**), the RTEM  $\beta$ -lactamase (**6**), and PBP1a from *Streptococcus pneumoniae* **7**.<sup>15</sup>

Each of these structures resembles the reactant complex of a cooperative process in which proton transfer from the hydroxyl groups of Ser62, Ser70, or Ser370 to the unprotonated<sup>16</sup> amino groups of Lys65, Lys73, or Lys373, proton transfer from these amino groups to the hydroxyl oxygens of Tyr159, Ser130, or Ser428, and proton transfer from these hydroxyl oxygens to the  $\beta$ -lactam nitrogen are accompanied by attack of the hydroxyl oxygens of Ser62, Ser70, or Ser370 on the carbon of the  $\beta$ -lactam carbonyl group.

On the basis of these observations, structures **8–10** are mono and stereo views of the reactant complexes, calculated using density functional theory with the B3LYP DFT gradient-corrected functional and the 6–31G(d) basis set, of the cooperative methanolysis of penam by two methanol molecules (**8**), two methanol molecules and one molecule of methylamine (**9**), and two methanol molecules and one molecule of water (**10**). The MP2/6–31G(d) barriers, calculated using the DFT-optimized geometries,<sup>17</sup> are the following: **8**, 28.64 kcal/mol, **9**, 25.77 kcal/mol, and **10**, 32.49 kcal/mol. Thus, methylamine catalyzes the cooperative reaction by

nearly 3 kcal/mol, but water inhibits the reaction by nearly 4 kcal/mol.

We conclude that the acyl enzymes formed in the reaction of penicillin G with penicillin-recognizing enzymes are produced by a cooperative mechanism, and that the uncharged amino group of the conserved lysine of the ubiquitous Ser-X-X-Lys motif catalyzes this process.

## Supplementary data

Supplementary data for this article (the coordinates of the docked structures, calculated reactant complexes, and calculated transition structures) are available on the journal Web site ([canjchem.nrc.ca](http://canjchem.nrc.ca)) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. # The effect of substituent rotation on aromatic quadrupole moments

Michael Lewis, Shana Beg, Aimee Clements, Dianne Tran, and Kristine Waggoner

**Abstract:** We recently reported substituent constants for the accurate prediction of molecular quadrupole moments of mono-, di-, tri- and tetra-substituted aromatics. Four of the substituents in the study,  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$ , and  $-\text{CH}_3$ , were polyatomic and for these groups the substituent constants only hold for the lowest energy, or near-lowest energy, geometries. Herein, we report a computational investigation of the effect of rotation of  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$ , and  $-\text{CH}_3$  groups on the aromatic quadrupole moment,  $\Theta_{zz}$ . As expected, rotation of these substituents significantly affects the aromatic  $\Theta_{zz}$  value; however, the effects are clearly periodic. Additionally, we have modified the methods to best employ our substituent constants.

**Key words:** aromatic quadrupole moment, substituent constants, substituent rotation, cation–arene complexes.

**Résumé :** On a récemment rapporté des constantes de substituant permettant de faire des prédictions précises de moments quadripolaires moléculaires de produits aromatiques mono-, di-, tri- et tétrasubstitués. Quatre des substituants examinés dans cette étude,  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$  et  $-\text{CH}_3$ , sont polyatomiques et pour ces groupes les constantes de substituant ne sont valables que pour les géométries de plus basse énergie ou près de la plus basse énergie. Dans ce travail, on rapporte une étude théorique de l'effet de rotation des groupes  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$  et  $-\text{CH}_3$  sur le moment quadripolaire aromatique,  $\Theta_{zz}$ . Tel qu'on s'y attendait, la rotation de ces substituants affecte d'une façon significative la valeur aromatique  $\Theta_{zz}$ , toutefois les effets sont clairement périodiques. De plus, on a modifié les méthodes qui permettent d'utiliser au mieux nos constantes de substituant.

**Mots-clés :** moment aromatique quadripolaire, constantes de substituant, rotation des substituants, complexes cation–arène.

[Traduit par la Rédaction]

## Introduction

Noncovalent interactions involving aromatic  $\pi$ -electron density<sup>1</sup> are ubiquitous in chemistry and biology with demonstrated importance in organic reaction development,<sup>2</sup> protein folding,<sup>3</sup> enzyme-substrate recognition,<sup>4</sup> solid-state organization,<sup>5</sup> the function of ion channels,<sup>6</sup> and in the design of organic semiconductors.<sup>7</sup> The aromatic molecular quadrupole moment,  $\Theta_{zz}$ , is widely used to explain the nature of the cation–arene complex (cation– $\pi$  interaction), the anion–arene complex (anion– $\pi$  interaction), and the arene–arene complex.<sup>1</sup> Dougherty and co-workers<sup>8</sup> showed that the aromatic electrostatic potential is all that need be considered when predicting the cation-binding energy of substituted aromatics, and we recently showed that the cation binding of substituted aromatics is directly related to the aromatic quadrupole moment,  $\Theta_{zz}$ .<sup>9</sup>

The relationship between the aromatic  $\Theta_{zz}$  value and cation–arene binding led our group to develop substituent constants for the accurate prediction of molecular quadrupole moments of mono-, di-, tri-, and tetra-substituted aromatics, which in turn allows for the prediction of cation–

arene binding energies based solely on the aromatic substitution pattern.<sup>10</sup> For polyatomic groups ( $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$ , and  $-\text{CH}_3$ ) the substituent constants only predict the aromatic quadrupole moment,  $\Theta_{zz}$ , if the substituents are at, or near, the lowest energy geometry. Of course, in highly anisotropic environments it is common for polyatomic substituents to assume geometries significantly distorted from gas-phase or solution-phase lowest energy geometries. For instance, solid-state structures of the electronic materials perylene diimides show significant rotation about the imide C–N bond.<sup>11</sup> In substituted nitrobenzenes, having a methyl or methoxy substituent at the ortho position,<sup>12</sup> or even a formyl group,<sup>13</sup> causes nitro group rotation in the solid state, and this area has been reviewed.<sup>14,15</sup> Aromatic substituent rotation also affects reactivity. Aromatic amines with large ortho groups undergo deamination or substitution more readily than nonsterically hindered amines and this is thought to be due to the rotation of the amino group.<sup>16–18</sup> 2,4-Dinitrochlorobenzenes partake in  $\text{S}_{\text{N}}\text{Ar}$  reactions less effectively when there is an alkyl group between the nitro substituents causing the nitro groups to rotate out of the plane of the aromatic.<sup>19,20</sup> Similarly, substituted bromothiophenes have been shown to undergo piperidinobromination significantly slower when a carboxamido group is adjacent to the bromo substituent, and this has been attributed to rotation of the carboxamido group.<sup>21</sup>

In an effort to begin understanding the effects of substituent rotation on the aromatic  $\Theta_{zz}$  value, herein, we report the effect of  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$ , and  $-\text{CH}_3$  group rotation on the

aromatic quadrupole moment tensor component values. In the course of performing this study we have re-evaluated the initial approach we employed to determine aromatic quadrupole moments using our substituent constants, and here we present a modified approach.

## Theoretical background

The aromatic quadrupole moment,  $\Theta_{zz}$ , is a  $3 \times 3$  tensor (eq. [1]) and for planar aromatics the off-diagonal elements are zero and eq. [2] determines  $\Theta_{zz}$ . Therefore, any effort to understand the affect of aromatic substitution on the overall aromatic  $\Theta_{zz}$  value is inherently an effort to understand the effect of substituents on the aromatic quadrupole moment diagonal tensor components. By considering the effects of aromatic substitution on the aromatic quadrupole moment diagonal tensor components we were able to develop substituent constants for the accurate prediction of the aromatic  $\Theta_{zz}$  value of mono-, di-, tri-, and tetra-substituted aromatics.<sup>10</sup>

$$[1] \quad \Theta_{zz} = \begin{bmatrix} Q_{xx} & Q_{yx} & Q_{zx} \\ Q_{xy} & Q_{yy} & Q_{zy} \\ Q_{xz} & Q_{yz} & Q_{zz} \end{bmatrix}$$

$$[2] \quad \Theta_{zz} = Q_{zz} - 0.5(Q_{xx} + Q_{yy})$$

A central assumption in the development of these substituent constants was that the aromatic substituents assume the lowest energy geometry of the relevant monosubstituted aromatic. For example, a nitro-substituted benzene with a substituent ortho to the nitro group may have a geometry where the  $-\text{NO}_2$  is in the same relative position as in the monosubstituted nitrobenzene (Fig. 1b compared to Fig. 1a). Conversely, the ortho substituent may affect the position of the nitro group by electrostatic repulsion, as seen by contrasting (c) and (a) in Fig. 1. In determining aromatic quadrupole moment substituent constants for F, Cl, Br, I, CN, OH,  $\text{CH}_3$ ,  $\text{NO}_2$ , and  $\text{NH}_2$ , the assumption that substituent positions in di-, tri- and tetra-substituted aromatics were approximately the same as they would be in the relevant monosubstituted aromatics proved to be quite reasonable.<sup>10</sup> The only cases where the assumption failed was when a highly electronegative group (F, Cl, and  $\text{NO}_2$ ) was ortho to a nitro group and electrostatic repulsion resulted in the substituent positions differing from the relevant monosubstituted aromatic, as depicted in Fig. 1c, or when OH and  $\text{NH}_2$  groups were ortho to an amino group and hydrogen-bonding resulted in the substituent positions differing from the relevant monosubstituted aromatic. While the affect illustrated in Fig. 1c was rarely observed for F, Cl, Br, I, CN, OH,  $\text{CH}_3$ ,  $\text{NO}_2$ , and  $\text{NH}_2$  substituents in di-, tri-, and tetra-substituted aromatics, it is important to note these were gas-phase calculations in a vacuum. As noted above, in highly anisotropic environments such as the solid-state, enzymes, proteins and nucleic acids the substituent positions of polysubstituted aromatics may vary greatly from the gas-phase, vacuum lowest energy geometry of the relevant monosubstituted aromatic. Of course, the most likely variation would be expected for the polyatomic substituents  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$ , and  $-\text{CH}_3$  since these groups all have

**Fig. 1.** (a) Nitrobenzene. (b) Ortho-substituted nitrobenzene with the nitro group position unaffected by the ortho substituent, and in the same relative position as in nitrobenzene (a). (c) Ortho-substituted nitrobenzene with the nitro group position affected by the ortho substituent, and not in the same relative position as in nitrobenzene (a).

low energy rotations that could easily be initiated by the environment.

## Computational methods

All calculations, including structure optimizations, frequency calculations, and quadrupole moment tensor component calculations were performed at the RHF/6-311G\*\* level of theory. In comparison to more rigorous theoretical methods, such as the correlated MP2 and QCISD(T) methods, and more flexible basis sets that included diffuse functions and increased polarization functions, the RHF/6-311G\*\* level of theory was shown to give the best agreement with experiment for calculating aromatic quadrupole moments.<sup>22</sup> The experimental  $\Theta_{zz}$  value for benzene is  $-8.7 \pm 0.5$  DÅ and for hexafluorobenzene it is  $+9.5 \pm 0.5$  DÅ;<sup>23</sup> the RHF/6-311G\*\* calculated values are  $-8.76$  DÅ and  $+10.06$  DÅ.<sup>10</sup> All calculations were performed using the Gaussian03 suite of programs.<sup>24</sup>

## Results and discussion

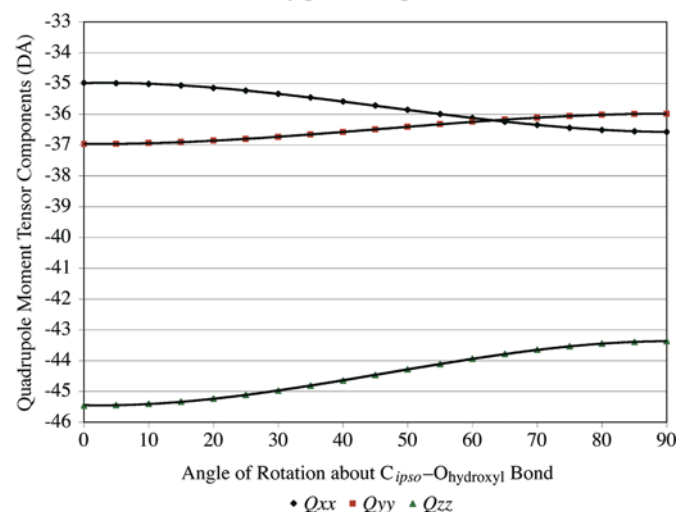

### Effects of aromatic substituent rotation on the quadrupole moment

The  $\text{C}_{\text{ipso}}$ -substituent bonds in phenol ( $-\text{OH}$ ), nitrobenzene ( $-\text{NO}_2$ ), aniline ( $-\text{NH}_2$ ), and toluene ( $-\text{CH}_3$ ) were rotated about the plane of the aromatic ring as shown in Fig. 2. For phenol, nitrobenzene, and aniline the substituents were rotated by  $90^\circ$  since this covers the unique, nonrepeating portion of the rotation. For toluene, the unique portion of the rotation is covered by a  $60^\circ$  rotation of the methyl carbon atom about the plane of the aromatic ring. In all cases, the rotations were performed in  $5^\circ$  increments and the quadrupole moment tensor components,  $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$ , were determined for each point. Importantly, the calculations were performed such that the dihedral angle corresponding to the substituent rotation was held constant, but all other geometric variables were optimized. Figures 3–6 show the plots for phenol, nitrobenzene, aniline, and toluene. Tables containing the numerical results are in the Supplementary data. The  $0^\circ$  dihedral angles in Figs. 3–6 represent the optimized geometries. For phenol (Fig. 3) this means the  $\text{H}_{\text{hydroxyl}}-\text{O}_{\text{hydroxyl}}-\text{C}_{\text{ipso}}-\text{C}_{\text{ortho}}$  dihedral angle is  $0^\circ$ , for nitrobenzene (Fig. 4) the  $\text{O}_{\text{nitro}}-\text{N}_{\text{nitro}}-\text{C}_{\text{ipso}}-\text{C}_{\text{ortho}}$  dihedral angle is  $0^\circ$ , and for toluene (Fig. 6) one of the  $\text{H}_{\text{methyl}}-\text{C}_{\text{methyl}}-\text{C}_{\text{ipso}}-\text{C}_{\text{ortho}}$  dihedral angles is  $0^\circ$ . For aniline, the optimized structure is pyrami-

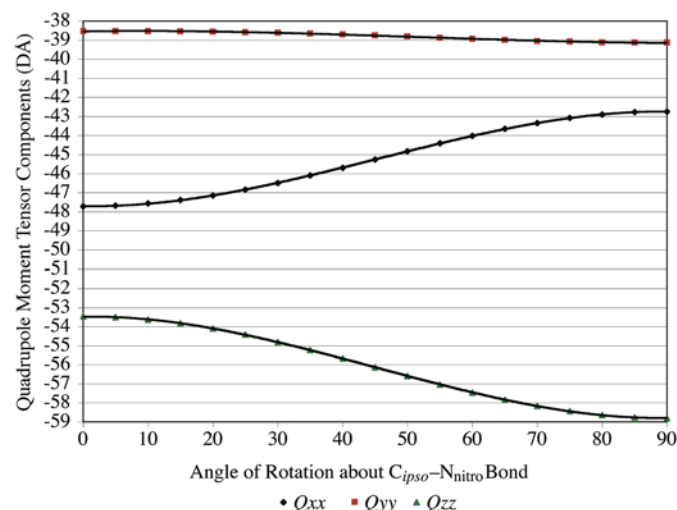

**Fig. 2.** The effect of aromatic  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2$ , and  $-\text{CH}_3$  substituent rotation was investigated by rotating about the aromatic ring plane the  $\text{C}_{\text{ipso}}-\text{O}_{\text{hydroxyl}}$  bond of phenol by  $90^\circ$ , the  $\text{C}_{\text{ipso}}-\text{N}_{\text{nitro}}$  bond of nitrobenzene by  $90^\circ$ , the  $\text{C}_{\text{ipso}}-\text{N}_{\text{amino}}$  bond of aniline by  $90^\circ$ , and the  $\text{C}_{\text{ipso}}-\text{C}_{\text{methyl}}$  bond of toluene by  $60^\circ$ .

**Fig. 3.** Plot of the aromatic quadrupole moment tensor components ( $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$ ) vs. the angle of rotation of the  $\text{C}_{\text{ipso}}-\text{O}_{\text{hydroxyl}}$  bond about the aromatic ring plane for phenol.

**Fig. 4.** Plot of the aromatic quadrupole moment tensor components ( $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$ ) vs. the angle of rotation of the  $\text{C}_{\text{ipso}}-\text{N}_{\text{nitro}}$  bond about the aromatic ring plane for nitrobenzene.

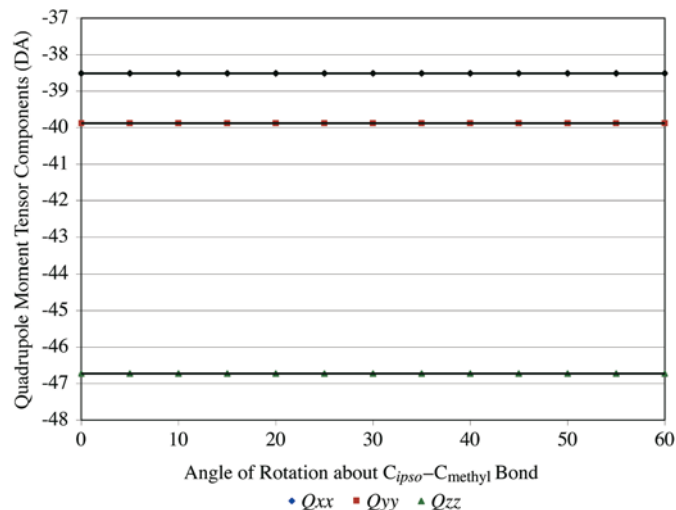

dal about the aniline nitrogen atom and thus the dihedral angle of  $0^\circ$  in Fig. 5 represents a  $\text{H}_{\text{amino}}-\text{N}_{\text{amino}}-\text{C}_{\text{ipso}}-\text{C}_{\text{ortho}}$  dihedral angles of  $45^\circ$ .

For phenol, nitrobenzene, and aniline, rotation about the

**Fig. 5.** Plot of the aromatic quadrupole moment tensor components ( $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$ ) vs. the angle of rotation of the  $\text{C}_{\text{ipso}}-\text{N}_{\text{amino}}$  bond about the aromatic ring plane for aniline.

**Fig. 6.** Plot of the aromatic quadrupole moment tensor components ( $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$ ) vs. the angle of rotation of the  $\text{C}_{\text{ipso}}-\text{C}_{\text{methyl}}$  bond about the aromatic ring plane for toluene.

$\text{C}_{\text{ipso}}$ -substituent bond results in the quadrupole moment tensor components varying by approximately 1–6 DA. However, for toluene this is not the case; rotation about the  $\text{C}_{\text{ipso}}-\text{C}_{\text{methyl}}$  bond results in essentially no change in the quadrupole moment tensor components, with variations between 0.001 and 0.004 DA (Fig. 6). The lack of variation of the quadrupole moment tensor components for toluene upon rotation of the  $\text{C}_{\text{ipso}}-\text{C}_{\text{methyl}}$  bond is easily explained by recognizing that the quadrupole moment tensor components,  $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$ , describe the distance electron density extends from the molecular center of mass in the  $x$ ,  $y$ , and  $z$  directions, respectively. Rotation of the methyl group does not significantly change the electron density distribution in any of the three Cartesian directions because there is always a hydrogen atom above or below the plane of the aromatic regardless of the methyl group geometry. Furthermore, there is little electron density about a hydrogen atom,

so the minor deviations in the H-atom positions as a result of methyl-group rotation are rendered even less significant.

The variations in the quadrupole moment substituent constants for phenol, nitrobenzene, and aniline upon substituent rotation can also be explained by considering the effects on the electron density distribution; however, there are notable differences between the three substituted aromatics and toluene. First, as evidenced by Figs. 3–5, rotation of the substituent does significantly affect the quadrupole moment tensor components. Second, it is not only the orientation of the hydrogen atoms that is important, but additionally the position of the heteroatom lone pairs upon substituent rotation must also be considered to give the best rationale for the variations in the quadrupole moment tensor components. Figure 7 helps explain the quadrupole moment tensor component variations for phenol (Fig. 3). The tensor component  $Q_{xx}$  becomes more negative upon  $90^\circ$  rotation of the  $-\text{OH}$  group with respect to the plane of the aromatic. Thus, electron density extends further in the  $x$  direction upon rotation of the substituent. One explanation for  $Q_{xx}$  being more negative upon  $-\text{OH}$  group rotation is that in the optimized structure the oxygen lone pairs of phenol are largely orthogonal to the arene  $\pi$ -electron density; this is best viewed via the Newman projections at the bottom of Fig. 7. After a  $90^\circ$  rotation of the  $-\text{OH}$  group, the lone pairs should overlap with the arene  $\pi$ -cloud; however, this would obviously be quite repulsive. The result is that the aromatic  $\pi$ -electron density repels the lone pairs into the  $x$  direction, making  $Q_{xx}$  more negative.

The tensor component  $Q_{yy}$  is more positive upon rotation of the  $-\text{OH}$  group in phenol (Fig. 3) and thus the electron density in the  $y$  direction becomes more contracted. This can be explained using the top view of Fig. 7. As the  $-\text{OH}$  hydrogen atom becomes parallel with the arene  $\pi$ -electron density it can partake in hydrogen bonding and move closer to the aromatic. Thus, electron density moves closer to the molecular center of mass, making  $Q_{yy}$  more positive.

The quadrupole moment tensor component  $Q_{zz}$  is more positive upon rotation of the  $-\text{OH}$  group in phenol (Fig. 3), signifying the electron density extends less in the  $z$  direction. The Newman projections at the bottom of Fig. 7 clearly show that the hydrogen atom electron density extends more in the  $z$  direction upon rotation of the  $-\text{OH}$  group and this would make  $Q_{zz}$  more negative. However, as we noted in our explanation of the variation of the  $Q_{xx}$  tensor component, the oxygen atom lone pairs are repelled towards the  $x$  direction and away from the  $z$  direction by the aromatic  $\pi$ -electron density. Since  $Q_{zz}$  is less negative upon rotation of the  $-\text{OH}$  group, the repulsion of the oxygen atom lone pairs in the  $x$  direction must be greater than the electron density of the hydrogen atom.

The explanation for the variation of the quadrupole moment tensor components of nitrobenzene upon  $90^\circ$  rotation of the nitro group is simpler than the above explanation for phenol. The change in the  $Q_{yy}$  tensor component upon rotation of the nitro group about the plane of the aromatic ring in nitrobenzene is negligible (Fig. 4). This can be explained using Fig. 8 where it is evident that there is little change in the extension of the electron density in the  $y$  direction upon nitro group rotation; the lone pairs of the oxygen atoms extend in the  $y$  direction to approximately the same extent re-

**Fig. 7.** View of phenol, with lone pairs, down the  $x$  plane (top) and down the  $y$  plane (bottom). In the top view the solid line is the aromatic ring. The bottom view is a Newman projection viewed down the  $\text{O}_{\text{hydroxyl}}-\text{C}_{\text{ipso}}$  bond.

**Fig. 8.** Rotation of the nitro group in nitrobenzene about the plane of the aromatic ring.

gardless of the nitro group orientation. The  $Q_{xx}$  quadrupole moment tensor component becomes more positive by approximately 5 DA upon rotation of the nitro group by  $90^\circ$  and Fig. 8 clearly shows why this is the case; as the nitro group is rotated the lone pairs of the oxygen atoms extend less in the  $x$  direction. Conversely, nitro group rotation results in the lone pairs of the oxygen atoms extending more in the  $z$  direction and this explains why the  $Q_{zz}$  tensor component becomes more negative by about 5 DA as the nitro group is rotated  $90^\circ$  about the plane of the aromatic ring.

The variation in the quadrupole moment tensor components of aniline upon  $90^\circ$  rotation of the  $-\text{NH}_2$  group about the plane of the aromatic ring (Fig. 5), much like for rotation of the nitro group in nitrobenzene, is relatively easily explained. The  $Q_{xx}$  tensor component becomes more negative upon rotation of the amino group and, as is evidenced by Fig. 9, this is because the nitrogen atom lone pair extends more in the  $x$  direction upon rotation. The  $Q_{yy}$  tensor component becomes more positive with amino group rotation (Fig. 5) and this too can be attributed to the orientation of the nitrogen atom lone pair. In the optimized geometry of aniline the aromatic ring  $\pi$ -electron density repels the nitrogen atom lone pair in the  $y$ -direction. In the structure where the amino group is rotated  $90^\circ$  the lone pair is orthogonal to the aromatic ring  $\pi$ -electron density and is therefore not repelled in the  $y$  direction. Thus, electron density extends less in the  $y$  direction upon amino group rotation and, consequently,  $Q_{yy}$  becomes more positive. The rotation of the amino group lone pair also results in electron density extending less in the  $z$  direction, as is obvious from Fig. 9, and this results in a more positive  $Q_{zz}$  quadrupole moment tensor component (Fig. 5).

**Fig. 9.** Rotation of the amino group in aniline about the plane of the aromatic ring.

### Modified approach to employing quadrupole moment tensor component substituent constants

In our initial report detailing the development of quadrupole moment tensor component substituent constants for the prediction of aromatic quadrupole moments, we provided  $Q_{xx}$ ,  $Q_{yy}$ , and  $Q_{zz}$  substituent constants for substituents in the ipso, ortho, meta, and para positions and this amounted to 12 sets of substituent constants.<sup>10</sup> Upon reconsideration, this can be significantly simplified to seven sets of substituent constants. The  $Q_{zz}$  tensor component describes the electron density distribution in the  $z$  direction, and Fig. 10 shows that the effect on  $Q_{zz}$  should not be related to the position the substituent occupies. Thus, there is no need for  $Q_{zz,i}$ ,  $Q_{zz,o}$ ,  $Q_{zz,m}$ , and  $Q_{zz,p}$  substituent constants, as we initially reported, and one average value,  $Q_{zz}$ , would suffice. Table 1 lists the average  $Q_{zz}$  values for each substituent. There is a very small standard deviation for these values, generally on the order of a hundredth to a tenth DA, supporting the notion that the position of the substituent is inconsequential. To a lesser extent, simplification is also in order for the  $Q_{xx}$  quadrupole moment tensor component substituent constants. It is apparent from Fig. 10 that the electron density distribution in the  $x$  direction should be affected equally by ipso and para substitution and equally by ortho and meta substitution. Thus, instead of the four  $Q_{xx,i}$ ,  $Q_{xx,o}$ ,  $Q_{xx,m}$ , and  $Q_{xx,p}$  substituent constants,  $Q_{xx,ip}$  and  $Q_{xx,om}$  are all that is needed. The  $Q_{xx,ip}$  and  $Q_{xx,om}$  tensor component substituent constants, obtained by averaging the  $Q_{xx,i}$  and  $Q_{xx,p}$  values and the  $Q_{xx,o}$  and  $Q_{xx,m}$  values, respectively, are given in Table 1, and again, small standard deviations for these values support this approach. Finally, Fig. 10 shows that substituent position is important in determining electron density distribution in the  $y$  direction, and thus,  $Q_{yy}$  substituent constants are required for the four unique aromatic positions, ipso ( $Q_{yy,i}$ ), ortho ( $Q_{yy,o}$ ), meta ( $Q_{yy,m}$ ), and para ( $Q_{yy,p}$ ). These were reported in our initial study<sup>10</sup> and are shown in Table 1.

As we noted above, a central assumption in the development of these substituent constants was that the aromatic substituents assume the lowest energy geometry of the relevant monosubstituted aromatic, and that interactions with neighboring substituents are minimal.<sup>10</sup> This assumption broke down for penta- and hexa-substituted aromatics; however, it worked very well for mono-, di-, tri-, and tetra-substituted arenes. In the course of the present study, we recognized another important assumption that was unintentionally made in our initial study:<sup>10</sup> the center of mass of a substituted aromatic is the same as the average center of mass of the relevant monosubstituted aromatics. For instance, our approach assumed that the center of mass of 1-bromo-3-chloro-5-fluorobenzene is equal to the average of the center of masses of bromobenzene, chlorobenzene, and fluorobenzene; this assumption is obviously not true.

**Fig. 10.** Substituent positions used to determine effects on aromatic quadrupole moment tensor component substituent constants.

Further underlying the error of this assumption, constitutional substituted-benzene isomers would have the same center of mass; 1-bromo-3-chloro-5-fluorobenzene would have the same center of mass as 1-bromo-2-chloro-5-fluorobenzene. Again, this is obviously not true. Since our initial aim was to develop substituent constants that could be used to predict, with relative ease, the quadrupole moment of substituted aromatics, rather than complicate the approach by adding a center-of-mass component, we offer the set of rules in Table 2 on how to orient the substituted aromatics before employing the substituent constants in Table 1. The rules in Table 2 minimize our erroneous center of mass assumption by making sure the substituent with the greater number of atoms or, if the substituents have the same number of atoms, the heavier substituent is placed at the ipso position. The ipso position discussed in Table 2 represents the position shown in Fig. 10 ( $S_i$ ).

Going back to our initial assumption, that the aromatic substituents assume the lowest energy geometry of the relevant monosubstituted aromatic,<sup>10</sup> we now realize this affects more than just the  $\Theta_{zz}$  prediction of penta- and hexa-substituted aromatics. It also precludes predicting the  $\Theta_{zz}$  values of aromatics where three nonhydrogen atoms are adjacent to each other, as in a 1,2,3-trisubstituted aromatic or a 1,2,3,5-tetrasubstituted aromatic. For instance, using the substituent constants in Table 1 and placing either the heaviest atom or the polyatomic group with the most atoms in the ipso position, the predicted  $\Theta_{zz}$  values of 1,3-dichloro-2-nitrobenzene and 1-bromo-2-chloro-3-cyanobenzene are  $-10.59$  and  $-5.45$  DA, respectively. The calculated values are  $-0.82$  and  $+12.49$  DA, respectively. Given that we can predict the  $\Theta_{zz}$  values of 1,3,5-trisubstituted aromatics quite well, *vide infra*, the only explanation for this result is steric crowding, the same explanation we gave for the inability to predict penta- and hexa-substituted aromatics using our approach. The one caveat here is that if three substituents are adjacent to one another, and one of them is a fluorine atom, then the substituent constants (Table 1) and the orientation rules (Table 2) still work. Given the very small size of a fluorine atom this supports the notion that sterics are the primary factor in precluding  $\Theta_{zz}$  prediction of congested aromatics, where a congested aromatic can be defined as having three nonhydrogen atoms adjacent to each other, at least for the purpose of predicting aromatic  $\Theta_{zz}$  values. These insights about congested aromatics and the special consideration of fluorine atoms are accounted for in Table 2.

Using the simplified quadrupole moment substituent constants (Table 1) and the orientation rules (Table 2), we pre-

**Table 2.** Orientation rules for how to orient di-, tri-, and tetra-substituted aromatics when predicting  $\Theta_{zz}$  values using the substituent constants in Table 1.

Substituted aromatic	Orientation rules <sup>a</sup>
Disubstituted, 1,3,5-trisubstituted, and 1,2,4,5-tetrasubstituted aromatics	The substituent with the greater number of atoms should be in the ipso position. If the substituents have the same number of atoms, the heavier one should be in the ipso position.
1,2,3-Trisubstituted aromatics	Only works if at least one substituent is F (sterics). Otherwise, see above rules for disubstituted and 1,3,5-trisubstituted aromatics.
1,2,4-Trisubstituted aromatics	One of the substituents in the 1- or 2-position must be ipso. Otherwise, see above rules for disubstituted and 1,3,5-trisubstituted aromatics.
1,2,3,4-Tetrasubstituted aromatics	Only works if F is in the 2- or 3-position (sterics). For the two nonfluorine substituents that are vicinal to each other, see above rules for disubstituted and 1,3,5-trisubstituted aromatics.
1,2,3,5-Tetrasubstituted aromatics	Only works if F is in either 1-, 2-, or 3-position (sterics). For the two nonfluorine substituents in the 1-, 2-, or 3-position, see above rules for disubstituted and 1,3,5-trisubstituted aromatics.

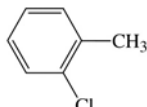

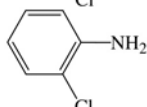

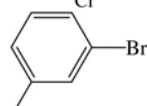

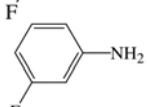

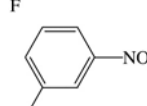

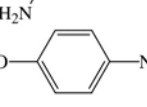

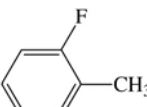

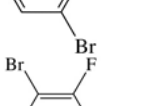

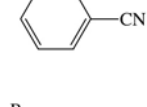

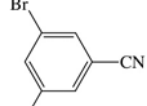

<sup>a</sup>The ipso position is defined by Fig. 10.

dicted the quadrupole moments for randomly substituted di-, tri-, and tetra-substituted aromatics, six examples of each (A–R), and these are compared to the calculated  $\Theta_{zz}$  values in Table 3. Our previous work illustrates exactly how the substituent constants are employed for predicting aromatic  $\Theta_{zz}$  values. For the disubstituted aromatics the predicted  $\Theta_{zz}$  values are almost identical to the calculated values. The only instances where caution should be taken in predicting aromatic quadrupole moments of disubstituted aromatics using the substituent constants in Table 1 is when the nature of atoms ortho to each other is such that they will cause their positions to change relative to the relevant monosubstituted aromatics. For instance, 1-fluoro-2-nitrobenzene has two highly electronegative groups ortho to each other and electrostatic repulsion would cause the position of the fluorine to not be the same as in fluorobenzene, and the position of the nitro group to not be the same as in nitrobenzene. This is exemplified by comparing the calculated quadrupole moment of 1-fluoro-2-nitrobenzene,  $\Theta_{zz} = -1.35$  DÅ, to the value predicted using the substituent constants in Table 1 and the orientation rules in Table 2,  $\Theta_{zz} = -9.85$  DÅ. This has nothing to do with the center of mass assumption and the resulting orientation rules, and instead is a result of the assumption from our original paper<sup>10</sup> that the aromatic substituents assume the lowest energy geometry of the relevant monosubstituted

tuted aromatic, and that interactions with neighboring substituents are minimal. As we noted in our original paper, the neighboring group interactions that would lead to this assumption failing include electronic repulsion by highly electronegative atoms being ortho to each other and hydrogen bonding from groups such as amino and hydroxyl being ortho to each other. As can be seen with ortho-chlorotoluene, A, and ortho-chloroaniline, B, in Table 3, the approach outlined in Tables 1 and 2 for predicting the  $\Theta_{zz}$  values of ortho-substituted aromatics where the groups are not highly electronegative, and not involved in hydrogen bonding, is excellent. Likewise, this approach also gives excellent results predicting the  $\Theta_{zz}$  values of meta (C–E) and para disubstituted aromatics (F), as shown in Table 3.

The 1,2,3-, 1,2,4-, and 1,3,5-substitution patterns are the three general possibilities for trisubstituted aromatics. As discussed above, and specified in Table 2, for 1,2,3-trisubstituted aromatics, one of the three substituents must be a fluorine atom, and when this is the case the  $\Theta_{zz}$  value can be predicted using Tables 1 and 2, as shown in Table 3 for aromatics G and H. For 1,3,5- (I) and 1,2,4-trisubstituted aromatics (J–L) the steric concern of having three adjacent substituents is moot and we see decent agreement between the calculated and predicted  $\Theta_{zz}$  values (Table 3). For the tetrasubstituted aromatics, both the 1,2,3,4- (M and N) and 1,2,3,5-substitu-

tion patterns (**O** and **P**) have the possibility for steric crowding: however, so long as one of the substituents is a fluorine atom, the constants in Table 1 and the rules in Table 2 give predicted  $\Theta_{zz}$  values in good agreement with the calculated values (Table 3). Finally, the 1,2,4,5-tetrasubstituted aromatics (**Q** and **R**) do not have the problem of steric crowding and the predicted and calculated values are in good agreement.

Throughout the discussion of the results in Table 3, we have stated that the agreement between the calculated and predicted  $\Theta_{zz}$  values is good. Ultimately, the greatest value of the substituent constants in Table 1 and the orientation rules in Table 2 lie in being able to predict relative  $\Theta_{zz}$  values, although in many cases in Table 3 the agreement in absolute terms is quite good. Still, since the aromatic  $\Theta_{zz}$  value is an excellent predictor of how well an aromatic will

bind a cation,<sup>9</sup> the ability to predict relative  $\Theta_{zz}$  values would allow one to say that a certain substitution pattern will allow for greater, or poorer, cation binding. As a means of quantifying how well the relative  $\Theta_{zz}$  value is predicted using the constants in Table 1 and the rules in Table 2, we

**Table 4.** Ranking of the calculated ( $\Theta_{zz,calc}$ ) and predicted ( $\Theta_{zz,pred}$ )  $\Theta_{zz}$  values for aromatics **A–R** and the absolute value of the difference between the rankings.

Aromatic	$\Theta_{zz,calc}$ rank	$\Theta_{zz,pred}$ rank	$ \Delta(Rank) $
<b>A</b>	5	6	1

ranked the aromatics in Table 3 based on the calculated ( $\Theta_{zz,calc}$ ) and predicted ( $\Theta_{zz,pred}$ )  $\Theta_{zz}$  values and the results are collected in Table 4. The rankings give the aromatic with the most negative  $\Theta_{zz}$  value the number 1 and the most positive  $\Theta_{zz}$  aromatic is ranked 18. By calculating the absolute value of the difference between the two sets of rankings,  $|\Delta(rank)|$  (Table 4), we can quantify how well the predicted values perform in determining relative  $\Theta_{zz}$  values. As shown in Table 4, for two-thirds of the 18 aromatics in Table 3 the  $\Theta_{zz,calc}$  and  $\Theta_{zz,pred}$  rankings are exactly the same ( $|\Delta(rank)| = 0$ ), or they differ by one ( $|\Delta(rank)| = 1$ ). The average  $|\Delta(rank)|$  value for the 18 aromatics is 1.4. Thus, for the purposes of predicting relative  $\Theta_{zz}$  values and, subsequently, relative cation binding affinities, the predictive scheme outlined in Tables 1 and 2 performs quite well.

One final caveat should be noted. The amino group quadrupole moment substituent constants were developed from aniline and disubstituted anilines. Aniline, of course, is  $sp^3$  hybridized and pyramidal at the nitrogen atom; however many substituted anilines, such as para-nitro-aniline, have the amino nitrogen atom  $sp^2$  hybridized and conjugated with the aromatic ring such that the geometry about the nitrogen atom is planar. Thus, care should be taken when applying the approach outlined here for the prediction of the  $\Theta_{zz}$  values of substituted anilines that are planar about the amino nitrogen atom. Furthermore, a similar point can be made for substituted phenols. The H–O–C bond angle in phenol is  $111.1^\circ$  at the RHF/6-311G\*\* level of theory, and thus, the oxygen atom is  $sp^3$  hybridized. However, it is not difficult to envision substituents causing one of the phenol oxygen atom lone pairs to become conjugated with the aromatic ring, making the oxygen atom  $sp^2$  hybridized. This, of course, would have repercussions for the prediction of aromatic  $\Theta_{zz}$  values of substituted phenols. The issue of OH and  $NH_2$  conjugation with the aromatic, and how this conjugation is increased or decreased with substitution, will certainly make it a challenge to translate the success we have demonstrated in

predicting aromatic  $\Theta_{zz}$  values into successfully using the predicted  $\Theta_{zz}$  values to predict cation-substituted arene binding energies where one of the substituents is rotated. We are currently addressing this issue, and the preliminary results are encouraging. We look forward to reporting this work when it is complete.

## Conclusion

The rotation of an aromatic methyl group does not significantly affect the quadrupole moment tensor components; however, there is a noticeable change in these values when a hydroxyl, nitro, or amino group is rotated. These changes would ultimately change the molecular quadrupole moment in aromatics with rotated groups; however, since the change in quadrupole moment tensor components upon substituent rotation is periodic, it seems reasonable that the  $\Theta_{zz}$  value of aromatics with substituents at non-lowest energy geometries could possibly be predicted. Such prediction could be an extension of the substituent constants and orientation rules we present here, a modification of our previous work,<sup>10</sup> and current work in our group is directed at this problem. Certainly, the modified approach we present here for predicting aromatic  $\Theta_{zz}$  values works very well in predicting relative  $\Theta_{zz}$  values, and would therefore be useful in predicting cation–arene binding energies via simple inspection of the aromatic substitution pattern.

## Supplementary data

# Highly stereoselective facile synthesis of $\beta$ -amino carbonyl compounds via a Mannich-type reaction catalyzed by $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/MeSO<sub>3</sub>H (alumina/methanesulfonic acid: AMA) as a recyclable, efficient, and versatile heterogeneous catalyst

Hashem Sharghi and Mahboubeh Jokar

**Abstract:** Mannich reaction of ketones, aromatic aldehydes, and aromatic amines catalyzed efficiently by  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/MeSO<sub>3</sub>H (alumina/methanesulfonic acid: AMA) as a heterogeneous catalyst, which were carried out in EtOH at ambient temperature to afford the corresponding  $\beta$ -amino ketones in good yields and high stereoselectivities in favor of the anti isomer, was described for the first time. It was found that this catalyst could be completely recovered and reused without loss of its catalytic activities and is thus environmentally conscious. Furthermore, the use of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/CH<sub>3</sub>SO<sub>3</sub>H (AMA) catalyst is feasible because of its easy preparation, easy handling, stability, easy recovery, reusability, good activity, stereoselectivity, and eco-friendliness. The use of this method provides a novel and improved modification of the three-component Mannich reaction in terms of mild reaction conditions and clean reaction profiles, using a very small quantity of catalyst and a simple workup procedure.

**Key words:** Mannich reaction,  $\beta$ -amino ketones, methanesulfonic acid,  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/MeSO<sub>3</sub>H (alumina/methanesulfonic acid: AMA), stereoselectivity, recyclable catalysis

**Résumé :** Opérant à la température ambiante, en solution dans l'éthanol, on a effectué des réactions de Mannich de cétones, d'aldéhydes aromatiques et d'amines aromatiques catalysées efficacement par un catalyseur hétérogène formé de  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/MeSO<sub>3</sub>H (alumine/acide méthanesulfonique: AAM) qui conduisent à la formation des  $\beta$ -aminocétone correspondantes, avec de bons rendements et par la première fois à des stéréosélectivités élevées en faveur de l'isomère anti. On a observé que le catalyseur peut être récupéré complètement sans perte de son activité catalytique et qu'il est écologique. De plus, l'utilisation du catalyseur  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/MeSO<sub>3</sub>H (alumine/acide méthanesulfonique) est possible en raison de sa facilité de préparation, de manutention, de récupération et de réutilisation ainsi que de sa bonne activité, de sa stéréosélectivité et de son caractère écologique. L'utilisation de cette méthode donne accès à une modification nouvelle et améliorée de la réaction de Mannich à trois composants en termes de conditions réactionnelles douces, avec des profils réactionnels propres, qui n'utilisent que de très faibles quantités de catalyseur et une méthode simple de récupération des produits.

**Mots-clés :** réaction de Mannich,  $\beta$ -aminocétone, acide méthanesulfonique,  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>/MeSO<sub>3</sub>H (alumine/acide méthanesulfonique: AAM), stéréosélectivité, catalyseur recyclable

## Introduction

Mannich-type reactions are very important C–C bond-forming reactions in organic synthesis and one of the most widely utilized chemical transformations for the formation of  $\beta$ -amino ketones and other  $\beta$ -amino carbonyl compounds, which in turn are important synthetic intermediates for various pharmaceuticals and natural products, such as alkaloids

and polyketides.<sup>1,2</sup>  $\beta$ -Amino carbonyl compounds and their derivatives are used for the synthesis of amino alcohols, peptides, and lactams, and as precursors for optically active amino acids. Therefore, the development of new synthetic methods leading to  $\beta$ -amino carbonyl compounds or their derivatives has attracted much attention. However, the classic Mannich reaction has limited applications. To overcome the drawbacks of the classic method, numerous modern versions of the Mannich reaction using electrophiles, such as imines and stable nucleophiles, such as enolates, enol ethers, and enamines,<sup>3</sup> have been developed. But the preferred route is to use a one-pot, three-component strategy that opens a wide range of structural variations. Furthermore, only a few one-pot procedures on the use of unmodified aldehydes or ketones have been reported in the literature and a variety of

catalysts, such as  $\text{Zn}(\text{OTf})_2$ ,<sup>4</sup>  $\text{H}_3\text{PW}_{12}\text{O}_{40}$ ,<sup>5</sup>  $\text{ZrOCl}_2 \cdot 8\text{H}_2\text{O}$ ,<sup>6</sup> (*S*)-serine,<sup>7</sup> DBSA,<sup>8</sup>  $\text{SDS-HCl}$ ,<sup>9–11</sup>  $\text{Bi}(\text{OTf})_3 \cdot 4\text{H}_2\text{O}$ ,<sup>12</sup> sodium tetrakis(3,5-trifluoromethylphenyl) borate,<sup>13</sup>  $\text{PS-SO}_3\text{H}$ ,<sup>14</sup> L-proline,<sup>3h</sup>  $\text{NbCl}_5$ ,<sup>15</sup>  $\text{HClO}_4\text{-SiO}_2$ ,<sup>16a</sup> and silica sulfuric acid,<sup>16b</sup> have been investigated.

However, most Lewis acids cannot be used in this one-pot reaction because of the presence of free amines and  $\text{H}_2\text{O}$  produced in the imine formation.

Within recent years, the use of reusable heterogeneous catalysts has received considerable importance in organic synthesis because of their environmental, economical, and industrial aspects.<sup>6b,17</sup> Up to now several reusable and heterogeneous catalysts have been designed and used in various reactions. Metal colloids,<sup>18a</sup> mineral clays,<sup>18b</sup> and supported reagent on silica gel,<sup>18c,18d</sup> alumina,<sup>19</sup> and other solid supports are some common examples of heterogeneous catalysts that have extensive applications in organic transformations.

Aluminum oxides constitute an important technological material that can be widely used in catalytic processes. In particular,  $\gamma\text{-Al}_2\text{O}_3$  is used as both a catalyst and support because of its acid-base properties and mechanical and high-temperature resistance.<sup>6b</sup> This study is part of our ongoing interest in a mixture of the  $\gamma\text{-Al}_2\text{O}_3/\text{MeSO}_3\text{H}$  (alumina/methanesulfonic acid: AMA) catalyst in the Fries rearrangement,<sup>19</sup> Beckmann rearrangement,<sup>20</sup> direct conversions of aromatic aldehydes to the corresponding glycol monoesters,<sup>21</sup> hydration of nitriles into amides,<sup>22</sup> syntheses of macrocyclic polyether-diester,<sup>23</sup> syntheses of new hydroxythioxanthone derivatives,<sup>24</sup> direct sulfonylation of phenols with *p*-toluenesulfonic acid,<sup>25a</sup> and synthesis of coumarin derivatives.<sup>25b</sup> We report herein our results in the three-component  $\gamma\text{-Al}_2\text{O}_3/\text{MeSO}_3\text{H}$  (AMA) catalysed Mannich-type reaction.

## Results and discussion

In this research, we report a new, simple, mild, and effective procedure for the one-pot synthesis of  $\beta$ -amino carbonyl compounds via a multicomponent reaction between aryl aldehydes, anilines, and cyclohexanone or cyclopentanone in the presence of  $\gamma\text{-Al}_2\text{O}_3/\text{MeSO}_3\text{H}$  (AMA) as catalyst (Scheme 1).

To establish the optimum conditions for this reaction, initially, the three-component Mannich reaction of benzaldehyde (2.0 mmol), aniline (2.0 mmol), and cyclohexanone (2.2 mmol) was examined. To find out the optimum quantity of  $\gamma\text{-Al}_2\text{O}_3$ -supported methanesulfonic acid (AMA), the Mannich reaction was carried out at room temperature using different quantities of the catalyst (Table 1 and Fig. 1).

The reaction does not proceed if no catalyst is employed, despite prolonged reaction times (Table 1, entry 1). It should

<sup>a</sup>Yield of isolated products.

<sup>b</sup>Anti/syn ratio was determined by  $^1\text{H}$  NMR.

<sup>c</sup>The same catalyst was used for each of the four runs.

**Fig. 1.** A plot of the yield of 2-[anilino(phenyl)methyl]cyclohexanone (**4a**) versus the amount of  $\gamma\text{-Al}_2\text{O}_3$ /methanesulfonic acid (AMA) as catalyst using benzaldehyde (2.0 mmol), aniline (2.0 mmol), and cyclohexanone (2.2 mmol) in ethanol at room temperature.

be noted that the optimal catalyst loading effect obtained from towards the  $\beta$ -amino carbonyl compounds peaked at a concentration of 0.05 mol% (Table 1, entry 4). A lower catalyst loading gave decreased yields (Table 1, entries 2 and 3), and increasing the catalyst loading also led to decreased yields (Table 1, entries 5–7). Thereafter, the reaction was carried out by varying the amount of cyclohexanone and aniline. The optimum ratio of benzaldehyde, cyclohexanone, and aniline was found to be 2:2.2:2, respectively, and 0.1 g AMA (equal to 0.05 mol%  $\text{H}^+$ ). Entry 4 of Table 1 described the yields of four consecutive reactions leading to

2-[anilino(phenyl)methyl]cyclohexanone (**4a**). In these experiments, the reaction mixture was diluted with AcOEt, and the catalyst was removed by filtration and washed with hot EtOH. The filtrate was dried at 120 °C for 24 h to give recycled AMA. Thus, the recovered catalyst, which always works the same, begins reloading with fresh reagents for further runs. No significant decrease in the yield was observed demonstrating the efficiency of AMA as a catalyst in the synthesis of  $\beta$ -amino carbonyl compounds.

With AMA as an effective catalyst for the Mannich-type reaction, conditions using various solvents such as MeCN, 1,4-dioxane, Et<sub>2</sub>O, THF, toluene, CHCl<sub>3</sub>, and EtOH were examined (Table 2). Benzaldehyde, aniline, and cyclohexanone were chosen as representative substrates. Interestingly, the Mannich reaction showed an intriguing solvent effect, and it was found that the solvent has an important role in terms of reaction rate, yields, and stereoselectivity. Among various solvents tested, toluene, MeCN, Et<sub>2</sub>O, CH<sub>2</sub>Cl<sub>2</sub>, and MeOH gave moderate yields of the expected product (Table 2, entries 1–5) and the reaction in 1,4-dioxane afforded a very poor yield (Table 2, entry 7, 27%). Excellent anti selectivity was observed in MeCN whereas the yield of the reaction exhibited was low (Table 2, entry 1, 55%) compared to EtOH that showed a high yield and excellent stereoselectivity. Obviously, EtOH is the solvent of choice with its fast reaction rate, high yield, excellent anti selectivity, cheapness, and environmental acceptability. According to step II of the mechanism for this reaction, which involves the formation of a Schiff base, we expected EtOH to stand out as the favorite solvent, since EtOH has proved to be one of the suitable solvents for the synthesis of Schiff bases.<sup>26</sup>

To optimize the temperature we carried out a model study with benzaldehyde (2 mmol), aniline (2 mmol), and cyclohexanone (2.2 mmol) using a catalyst (0.1 g, equal to 0.05 mol % H<sup>+</sup>) in EtOH at various temperatures (Table 3). Increasing the temperature to 80 °C favored side reactions and the formation of deeply colored products. If the reaction runs at refluxing temperature, no Mannich-reaction bases (**4**) can be isolated. Decreasing the temperature decreases the rates of the reaction, and also the rates of the side reactions. Table 3 clearly demonstrates that room temperature is an effective temperature in terms of reaction time and yield obtained.

Encouraged by the remarkable results obtained with the above reaction conditions, and to show the generality and scope of this new protocol, we used various aldehydes and amines (Table 4). A variety of aromatic aldehydes, including electron-withdrawing and electron-donating groups, were tested using our new method in EtOH in the presence of AMA. It was found that the electronic effect of substitutes had an influence on the yields. In this case, both the electron-rich and the electron-deficient benzaldehydes gave good to excellent anti selectivity at room temperature (Table 4, entries 1–14). However, when aryl aldehyde bearing an electron-withdrawing substituent was subjected to the reaction under standard conditions, there was a lower yield of desired adducts formed (Table 4, entry 9). An important feature of this procedure was the survival of a variety of functional groups, such as ethers, nitro, hydroxyl, halides, cyanide, etc., under the reaction conditions. Acid-sensitive

substrates like 4-cyanobenzaldehyde also reacted in high yields without the formation of any side products (Table 4, entry 13). Heteroaryl aldehydes, such as 2-thiophenecarboxaldehyde (Table 4, entry 10), was well-tolerated in these mild conditions. The highly electron-deficient 4-nitroaniline almost did not work (Table 4, entry 15). By using <sup>1</sup>H NMR to monitor the reaction, we realized that the imine intermediate, 4-nitrobenzylidenephénylamine, was not formed during the reaction. Furthermore, the use of alkyl aldehydes (such as butylaldehyde) also failed to give the desired product, which implies that this reaction is limited to nonenolizable imines (Table 4, entry 16). A three-component reaction of benzaldehyde, aniline, and cyclopentanone did not produce the desired adduct, probably because of the polyaminoalkylation of cyclopentanone,<sup>27</sup> and in this case, another procedure was adopted in which benzaldehyde and aniline were first mixed to produce imine in situ before ketone was added. As is shown in Table 4, the desired adduct was generated with very good yields and excellent diastereoselectivities.

With the help of different probe molecules, surface properties of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> have been the object of many experimental works.<sup>28a</sup> Under atmospheric conditions, the surfaces adsorb

<sup>a</sup> Yield of isolated products.<sup>b</sup> Anti/syn ratio was determined by <sup>1</sup>H NMR.<sup>c</sup> The reaction was carried out on a 100 mmol scale.

water both molecularly<sup>28b,28c</sup> and dissociatively, giving rise to surface hydroxyls that persist even at temperatures higher than 1000 °C.<sup>28d,28e</sup> Surface characterization experiments have been monitored by IR<sup>28f</sup> and DRIFTS<sup>28g</sup> spectroscopies that show the presence of different hydroxyl groups, which are assigned primarily to the different possibilities for coordination of surface aluminum cations and, for a given coordination number, to the different environments of the site (Fig. 2).<sup>6b,28h,28i</sup>

With regard to the latest articles about adsorption of some alcohols such as methanol, ethanol, propanol, and isopropanol on the  $\gamma$ -alumina surface,<sup>28j,28k</sup> we assume that methanesulfonic acid (MeSO<sub>3</sub>H) chemisorbs to the alumina surface with hydrogen bonding when they come close to the surface with suitable orientation between the OH hydrogen of

MeSO<sub>3</sub>H with a surface oxygen atom of  $\gamma$ -alumina, which is in turn close to a cation vacancy.

To explore the mechanism of the reaction, we monitored aldehyde consumption by GC analysis and found that the Schiff base is formed (within the first 20 min of the beginning of the reaction) and the rate determining step (RDS) was found to be the attack of in situ generated enolate I on the in situ generated aldimine II as shown in Scheme 2.<sup>6a,6b</sup> AMA, used in catalytic amounts, is recycled in the reaction and can be reused for subsequent reactions.

High anti selectivity was obtained with various substituted benzaldehydes (Table 4, entries 1–14). The two most stable possible transition states are shown in Scheme 2. Transition state III (Scheme 2) provides the anti isomer, whereas the syn isomer forms via V (Scheme 2). In V (Scheme 2), the

**Fig. 2.** Dry  $\gamma$ - $\text{Al}_2\text{O}_3$  where small circles:  $\text{Al}^{+3}$ , gray and white circles:  $\text{O}^{2-}$ , and black circles:  $\text{OH}^{2-}$  (**8i**).

two phenyl groups of aldimine are syn to each other, so they are unfavorable. Also in V (Scheme 2), steric repulsion exists between the hydrogen atoms of cyclohexanone's methylene and phenyl groups. The phenyl groups of aldimine in III (Scheme 2) are anti to each other; therefore, III (Scheme 2) should be more stable than V (Scheme 2) and is the most stable transition state that produces the anti isomer.<sup>16,17,29</sup>

The anti/syn ratio was determined by  $^1\text{H}$  NMR, using the intensity of the  $H_a$  (Scheme 3). The  $J_{H_a,H_b}$  signal of the anti isomer is higher than that of the syn isomer. According to the  $^1\text{H}$  NMR spectrum, the  $H_a$  signal for the anti isomer has a lower  $\delta$  value than that for the syn isomer. For instance, in the  $^1\text{H}$  NMR spectra of 2-[anilino(phenyl)methyl]cyclohexanone (**4a**), the signal at  $\delta = 4.63$  ppm ( $J = 7.1$  Hz) is contributed by the anti isomer, while the one at  $5.4$  ppm ( $J = 3.6$  Hz) is contributed by the syn isomer.<sup>6,16,17</sup>

To access the feasibility of applying this method in a preparative scale, we carried out the one-pot, three-component Mannich reaction of benzaldehyde with aniline and cyclohexanone on a 100 mmol scale (Table 4, entry 17). As expected, the reaction proceeded similarly to the case in Table 4 (entry 1) in a smaller scale, and the desired  $\beta$ -amino ketone was obtained in 98% isolated yield in 100 min.

The reaction proceeded not only for cycloalkanones but also for acyclic ketones such as acetophenones. As illustrated in Scheme 4, AMA did catalyze the Mannich reaction of acetophenones, substituted benzaldehydes, and anilines to yield the desired  $\beta$ -amino ketone products.

The optimum ratio of benzaldehyde, acetophenone, and aniline was found to be 2:2.2:2, respectively, and 0.2 g AMA (equal to 0.1 mol%  $\text{H}^+$ ). The expected products were obtained in good-to-high yields under these conditions. Acyclic ketones were less reactive than cyclohexanone and needed much more catalyst and a longer reaction time to afford the desired products (Table 5).

The reaction worked well with a variety of aldehydes including those bearing electron-withdrawing groups, and the corresponding  $\beta$ -amino ketones (**6**) were obtained in good yields (Table 5, entries 2, 3, and 7). Several electron-rich aromatic aldehydes led to the desired products in very good yields (Table 5, entries 4, 5, 8, 9, and 15).

The presented method has the ability to tolerate other functional groups such as methoxy, halides, and nitro on aryl aldehyde (Table 5).

The scope of our method could be extended to substituted anilines. Although para-substituent aromatic amines gave good results, ortho-substituent aromatic amines such as 2-methylaniline (Table 5, entry 12) failed to yield any product because of the steric effects. Furthermore, amines with electron-withdrawing groups, such as 4-chloroaniline, 4-fluoroaniline, and 4-bromoaniline, gave the desired product in good yields (Table 5, entries 10, 11, and 14).

To show the simplicity and efficiency of the over presented catalyzed Mannich reaction of benzaldehydes, anilines, and ketones, including acetophenones and cycloalkanones, they are compared with the reported works in Table 6.

## Conclusion

In conclusion, the present procedure provides an efficient and improved modification of Mannich type reactions. This new catalytic method provides a protocol that enables the synthesis of  $\beta$ -amino carbonyl compounds in a highly stereoselectivity pure form, while displaying good functional group tolerance. No toxic reagent(s) or byproduct(s) were involved. This procedure is ideally suited for automated application since the entire synthetic sequence can be carried out at room temperature in the presence of a reusable and heterogeneous catalyst. Mild reaction condition, low loading of catalyst, ease of workup, high yields, stability and recyclability of the catalyst, general applicability of both acyclic and cyclic ketones and aldehydes, large-scale synthesis, and simple procedure are features of this new protocol. Quite a number of products are insoluble in EtOH, which can be obtained by filtration and recrystallization. This simple work-up procedure is also beneficial in this method. These conditions are also environmentally friendly, cost effective, and possess high generality, making our methodology a valid contribution to the existing processes in the field of  $\beta$ -amino ketone synthesis. Further applications of this catalyst to other transformations are currently under investigation.

## Experimental

### Instrumentation, analysis, and starting material

NMR spectra were recorded on a Bruker Avance DPX-250 ( $^1\text{H}$  NMR 250 MHz and  $^{13}\text{C}$  NMR 62.9 MHz) spectrometer in pure deuterated solvents with tetramethylsilane as an internal standard. IR spectra were obtained using a Shimadzu FTIR 8300 spectrophotometer. Mass spectra were determined on a Shimadzu GCMS-QP 1000 EX instruments at 70 or 20 eV. Melting points were determined in open capillary tubes in a Büchi-535 circulating oil melting point apparatus. Elemental analyses were performed by Thermo Finnigan CHNS-O analyzer, 1112 series. The purity deter-

**Scheme 2.** Proposed reaction mechanism for the Mannich reaction of benzaldehyde, aniline, and cyclohexanone and the possible transition states leading to the anti isomer.

mination of the substrates and reaction monitoring were accomplished by TLC on silica gel PolyGram SILG/UV 254 plates. Column chromatography was carried out on short columns of silica gel 60 (70–230 mesh) in glass columns (2–3 cm diameter) using 15–30 g of silica gel per one gram of crude mixture. Chemical materials were either prepared in our laboratories or purchased from Fluka, Sigma-Aldrich, and Merck Companies. Acidic  $\gamma$ -alumina ( $\gamma$ - $\text{Al}_2\text{O}_3$ ) type 540 C was purchased from the Fluka Company.

#### Preparation of AMA (0.1 g, equal to 0.05 mol% $\text{H}^+$ )

Methanesulfonic acid (1.62 mL, 25 mmol) was added dropwise over a period of 90 min at 40 °C to a mixture of  $\gamma$ -alumina (50 g, 500 mmol) in dichloromethane (30 mL). After the addition was complete, the mixture was stirred for 2 h and then the solvent was evaporated under reduced pressure. After removal of  $\text{CH}_2\text{Cl}_2$  in a rotary evaporator, the solid powder was kept at 120 °C for 72 h. A white solid of 65.0 g was obtained.

**Scheme 3.** Identification of anti and syn isomers by  $^1\text{H}$  NMR spectroscopy.

#### General procedure for synthesis of $\beta$ -amino carbonyl compounds 4

A mixture of the aldehyde (2 mmol), amine (2 mmol), and a solution of the catalyst (0.1 g, equal to 0.05 mol%  $\text{H}^+$ ) in EtOH (4–6 mL) was placed in a test tube and the reaction mixture was vigorously stirred at room temperature. Cyclohexanone or cyclopentanone (2.2 mmol) was then added to the mixture and after completion of the reaction as

**Scheme 4.** One-pot, three-component Mannich reaction of aromatic aldehydes (2 mmol) and anilines (2.0 mmol) with acetophenones (2.2 mmol).

indicated by TLC (Table 4), the reaction mixture was diluted with ethyl acetate, and the catalyst was removed by filtration. The organic phases were combined and dried over  $\text{Na}_2\text{SO}_4$ . The solvent was removed under reduced pressure to give the desired products. The residual crude product was purified by column chromatography on neutral silica gel (ethyl acetate/petroleum ether 1:5) or by recrystallization with  $\text{CH}_2\text{Cl}_2$ /petroleum ether or hexane to give the pure  $\beta$ -aminoketone as a mixture of diastereoisomers. The syn/anti ratio was determined by  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR analysis.

#### General procedure for synthesis of $\beta$ -amino carbonyl compounds 6

A mixture of the aldehyde (2 mmol), amine (2 mmol), and acetophenone (2.2 mmol) was added to a solution of the catalyst (0.2 g, equal to 0.1 mol%  $\text{H}^+$ ) in EtOH (4–6 mL) was placed in a test tube and the reaction mixture was vigorously stirred at room temperature for the appropriate time (Table 5). The reaction was monitored by TLC. The products precipitated from the reaction mixture. The precipitate was filtered off, dissolved in hot EtOH, and the catalyst was removed by hot filtration. The filtrate was kept at room temperature, was triturated with hexane (10 mL) and then filtered and was crystallized with EtOH/ $\text{H}_2\text{O}$  (2:1).

#### Recycling of $\gamma\text{-Al}_2\text{O}_3/\text{CH}_3\text{SO}_3\text{H}$ (AMA)

$\gamma\text{-Al}_2\text{O}_3/\text{CH}_3\text{SO}_3\text{H}$  (AMA) was prepared according to the abovementioned procedure. The catalyst was separated from the reaction mixture and washed with EtOH and dried at  $120^\circ\text{C}$  for 24 h to give recycled  $\gamma\text{-Al}_2\text{O}_3/\text{CH}_3\text{SO}_3\text{H}$  (AMA). The remaining catalyst begins reloading with fresh reagents for further runs. The reaction of benzaldehyde, aniline, and cyclohexanone was repeated with recycled catalyst and the yields were found to remain in the range of 96%–97% for four recycles.

All runs produced  $\beta$ -amino ketones characterized by detailed structural data using IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and elemental analysis as given below.

Anal. calcd. for  $C_{25}H_{21}NO$  (351.440; %): C 85.44, H 6.02, N 3.99; found: C 85.49, H 6.08, N 3.94.

### 3-Anilino-3-(4-nitrophenyl)-1-phenyl-1-propanone (6g)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6g** as a pale green powder in an 80% yield; mp 108–110 °C (lit. value<sup>34</sup> mp 108–109 °C). <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>)  $\delta$ : 8.1 (2H, d,  $J$  = 8.8 Hz), 7.89 (1H, d,  $J$  = 8 Hz), 7.6 (2H, d,  $J$  = 8.5 Hz), 7.57 (2H, t,  $J$  = 7.3 Hz), 7.44 (2H, t,  $J$  = 7.8 Hz), 7.11 (2H, t,  $J$  = 7.5 Hz), 6.70 (1H, d,  $J$  = 7.3 Hz), 6.55 (2H, d,  $J$  = 7.8 Hz), 5.1 (1H, t,  $J$  = 6.0 Hz), 3.5 (2H, d,  $J$  = 6.0 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>)  $\delta$ : 45.5, 54.4, 114.1, 118.8, 123.6, 124.1, 124.2, 125.7, 127.5, 128.6, 128.8, 129.3, 129.6, 133.4, 133.8, 136.3, 141.5, 145.9, 147.2, 150.5, 197.1. Anal. calcd. for  $C_{21}H_{18}N_2O_3$  (346.379; %): C 72.82, H 5.24, N 8.09; found: C 72.78, H 5.29, N 8.15.

### 3-Anilino-3-(4-methoxyphenyl)-1-phenyl-1-propanone (6h)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6h** as a colorless powder in a 91% yield; mp 148–150 °C (lit. value<sup>34</sup> mp 150–152 °C). <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>)  $\delta$ : 7.92 (2H, d,  $J$  = 8.3 Hz), 7.88 (1H, t,  $J$  = 8.5 Hz), 7.45 (2H, t,  $J$  = 7.8 Hz), 7.34 (2H, d,  $J$  = 8.8 Hz), 7.10 (2H, t,  $J$  = 7.5 Hz), 6.8 (2H, d,  $J$  = 8.8 Hz), 6.68 (1H, t,  $J$  = 8.0 Hz), 6.60 (2H, d,  $J$  = 7.5 Hz), 4.97 (1H, t,  $J$  = 6.5 Hz), 3.80 (3H, s), 3.47 (2H, d,  $J$  = 5.8 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>)  $\delta$ : 46.2, 54.5, 55.2, 114.1, 114.2, 118.0, 123.2, 124.3, 124.9, 127.1, 127.5, 128.2, 128.7, 129.1, 133.3, 134.6, 136.1, 141.2, 145.8, 148.0, 158.8, 198.4. Anal. calcd. for  $C_{22}H_{21}NO_2$  (331.408; %): C 79.73, H 6.39, N 4.23; found: C 79.70, H 6.43, N 4.20.

### 3-Anilino-3-(4-methylphenyl)-1-phenyl-1-propanone (6i)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6i** as a colorless powder in a 92% yield; mp 134–135 °C (lit. value<sup>34</sup> mp 131–132 °C). <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>)  $\delta$ : 7.92 (2H, d,  $J$  = 7.3 Hz), 7.56 (1H, t,  $J$  = 8.8 Hz), 7.44 (2H, t,  $J$  = 7.8 Hz), 7.32 (2H, d,  $J$  = 8.0 Hz), 7.06–7.14 (4H, m), 6.64 (1H, t,  $J$  = 7.3 Hz), 6.58 (2H, d,  $J$  = 8.8 Hz), 4.98 (1H, t,  $J$  = 6.0 Hz), 3.50 (2H, d,  $J$  = 5.5 Hz), 2.23 (3H, s, 3H). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>)  $\delta$ : 21.1, 46.2, 54.7, 114.0, 114.9, 118.0, 124.4, 126.3, 127.3, 127.9, 128.2, 128.6, 129.1, 129.4, 133.2, 136.3, 139.0, 141.7, 145.5, 147.9, 159.0, 199.1. Anal. calcd. for  $C_{22}H_{21}NO$  (315.408; %): C 83.78, H 6.71, N 4.44; found: C 83.81, H 6.75, N 4.40.

### 3-(4-Bromoanilino)-1,3-diphenyl-1-propanone (6j)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6j** as a colorless powder in a 90% yield; mp 182–184 °C (lit. value<sup>32</sup> mp 182–184 °C). <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>)  $\delta$ : 7.86 (2H, d,  $J$  = 8.3 Hz), 7.51 (2H, t,  $J$  = 7.3 Hz), 7.39 (2H, t,  $J$  = 7.5 Hz), 7.35 (2H, d,  $J$  = 7.5 Hz), 7.20–7.28 (4H, m), 6.77 (2H, d,  $J$  = 8.8 Hz), 4.99 (1H, t,  $J$  = 6.5 Hz), 3.85 (2H, d,  $J$  = 6.5 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>)  $\delta$ : 43.7, 59.1, 114.0, 114.9, 120.7, 121.2, 124.1, 127.9, 128.1, 128.6, 128.7, 128.9, 132.2, 133.6, 136.2, 137.6, 138.0, 139.3, 144.9, 162.9, 196.6. Anal. calcd. for  $C_{21}H_{18}BrNO$  (380.278; %): C 66.33, H 4.77, N 3.68; found: C 66.29, H 4.70, N 3.71.

### 3-(4-Fluoroanilino)-1,3-diphenyl-1-propanone (6k)<sup>35</sup>

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6k** as a colorless powder in an 89% yield; mp 158–160 °C. <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>)  $\delta$ : 7.89 (2H, d,  $J$  = 7.3 Hz), 7.23–7.56 (8H, m), 6.78 (2H, t,  $J$  = 8.8 Hz), 6.49 (2H, d,  $J$  = 9.0 Hz), 4.91 (1H, t,  $J$  = 7.0 Hz), 3.45 (2H, d,  $J$  = 5.3 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>)  $\delta$ : 46.3, 55.6, 114.9, 115.1, 115.3, 115.7, 116.0, 126.4, 127.5, 128.2, 128.5, 128.7, 128.9, 133.5, 136.6, 142.6, 143.1, 145.1, 154.1, 158.0, 198.2. Anal. calcd. for  $C_{21}H_{18}FNO$  (319.372; %): C 78.98, H 5.68, N 4.39; found: C 78.94, H 6.61, N 4.35.

### 3-Anilino-1-(4-chlorophenyl)-3-phenyl-1-propanone (6m)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6m** as a colorless powder in a 90% yield; mp 119–120 °C (lit. value<sup>32</sup> mp 119–120 °C). <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>)  $\delta$ : 7.74 (2H, d,  $J$  = 8.5 Hz), 7.45 (3H, d,  $J$  = 8.3 Hz), 7.1–7.37 (4 H, m), 6.90 (2H, t,  $J$  = 8.0 Hz), 6.55 (3H, d,  $J$  = 8.3 Hz), 5.02 (1H, t,  $J$  = 6.8 Hz), 3.80 (2H, d,  $J$  = 6.3 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>)  $\delta$ : 44.2, 59.0, 111.3, 118.35, 121.5, 122.7, 127.6, 128.3, 128.5, 128.8, 128.9, 129.0, 129.7, 129.9, 130.7, 134.7, 138.6, 139.9, 145.4, 178.9, 195.7. Anal. calcd. for  $C_{21}H_{18}ClNO$  (335.826; %): C 75.11, H 5.40, N 4.17; found: C 75.05, H 5.44, N 4.21.

### 3-(4-Bromoanilino)-1-(4-chlorophenyl)-3-phenyl-1-propanone (6n)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6n** as a pale yellow powder in an 85% yield; mp 139–140 °C (lit value<sup>32</sup> mp 139–141 °C). <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>) δ: 7.80 (2H, d, *J* = 8.5 Hz), 7.32–7.42 (4H, m), 7.27 (3H, t, *J* = 8.0 Hz), 7.12 (2H, d, *J* = 8.8 Hz), 6.43 (2H, d, *J* = 8.8 Hz), 4.92 (1H, t, *J* = 5.8 Hz), 3.42 (2H, d, *J* = 7.3 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>) δ: 46.0, 54.8, 109.7, 111.0, 113.2, 114.5, 115.5, 122.1, 126.3, 127.6, 128.9, 129.0, 129.6, 129.1, 130.4, 131.8, 134.9, 140.1, 142.1, 145.7, 196.9. Anal. calcd. for C<sub>21</sub>H<sub>17</sub>BrClNO (414.723; %): C 60.82, H 4.13, N 3.38; found: C 60.89, H 4.07, N 3.41.

### 3-Anilino-3-(2-methoxyphenyl)-1-phenyl-1-propanone (6o)

The filtrate was triturated with hexane (10 mL), filtered, and then recrystallization with EtOH/H<sub>2</sub>O (2:1) gave compound **6o** as a pale green powder in an 85% yield; mp 122–124 °C. IR (KBr, cm<sup>-1</sup>) ν: 3375, 1681, 1600, 1519, 1234, 748, 690, 574. <sup>1</sup>H NMR (250 MHz, CDCl<sub>3</sub>) δ: 7.91 (2H, d, *J* = 8.5 Hz), 7.39 (3H, t, *J* = 9.0 Hz), 7.21 (2H, t, *J* = 9.0 Hz), 7.05 (2H, t, *J* = 7.5 Hz), 6.84–6.92 (2H, m), 6.63 (1H t, *J* = 7.5 Hz), 6.53 (2H, d, *J* = 8.5 Hz), 5.22 (1H, dd, *J*<sub>1</sub> = 8.5 Hz, *J*<sub>2</sub> = 4.5 Hz), 3.92 (3H, s), 3.64 (1H, dd, *J*<sub>1</sub> = 15.0 Hz, *J*<sub>2</sub> = 4.8 Hz), 3.20 (1H, dd, *J*<sub>1</sub> = 15.0 Hz, *J*<sub>2</sub> = 8.3 Hz). <sup>13</sup>C NMR (62.9 MHz, CDCl<sub>3</sub>) δ: 44.5, 50.7, 55.4, 110.5, 113.5, 113.9, 117.7, 118.0, 121.0, 127.5, 128.33, 128.9, 129.1, 129.7, 129.8, 134.9, 135.0, 139.7, 140.1, 146.9, 156.5, 197.9. MS *m/z* (%): 333 (M<sup>+</sup> + 2, 1.0), 331 (M<sup>+</sup> + 1, 3.5), 330 (M<sup>+</sup>, 1.9), 279 (3.4), 257 (1.8), 241 (2.0), 212 (47.0), 167 (11.3), 149 (37.9), 119, 93 (17.6), 69 (100.0). Anal. calcd. for C<sub>22</sub>H<sub>21</sub>NO<sub>2</sub> (331.408; %): C 79.73, H 6.39, N 4.23; found: C 79.70, H 6.35, N 4.29.

# Ionophilic phosphonium-appended carbopalladacycle catalyst for Suzuki–Miyaura and Heck cross-coupling catalysis

Jocelyn J. Tindale and Paul J. Ragogna

**Abstract:** An ionic liquid, covalently tethered to an efficient transition-metal catalyst in the presence of an ionic liquid reaction medium, can utilize ionophilic interactions to improve catalyst activity, recyclability, and product isolation while decreasing catalyst leaching. Given the greater stability of phosphonium salts in comparison to imidazolium ionic liquids under basic conditions, phosphonium-tagged oxime carbopalladacycle salts were prepared and employed in both Heck and Suzuki–Miyaura reactions. The desired product was obtained in good yields for up to four catalyst cycles in the case of the Suzuki–Miyaura reaction. While taking advantage of the non-volatile nature of ionic liquids, the product was isolated through simple sublimation from the reaction mixture, eliminating issues associated with catalyst leaching, and the remaining ionic liquid solvent–catalyst mixture was ready for further catalysis.

**Key words:** phosphonium, ionic liquids, ionophilic catalysis, carbopalladacycle, ionic tag.

**Résumé :** Un liquide ionique lié d'une façon covalente à un catalyseur efficace à base d'un métal de transition, en présence d'un milieu réactionnel formé d'un liquide ionique, peut utiliser les interactions ionophiles pour améliorer l'activité du catalyseur, sa capacité à être recyclé et la facilité d'isoler le produit tout en diminuant la lixiviation du catalyseur. Se basant sur la plus grande stabilité des sels de phosphonium par comparaison aux liquides ioniques à base d'imidazolium dans des conditions basiques, on a préparé des sels à base carbocycles contenant du palladium sels et portant des phosphonium d'oximes comme étiquette ionique et on les a utilisés dans des réactions de Heck et de Suzuki–Miyaura. Le produit désiré a été obtenu avec de bons rendements pour au moins quatre cycles catalytiques dans le cas de la réaction de Suzuki–Miyaura. En tirant avantage de la nature non volatile des liquides ioniques, on a pu isoler le produit par simple sublimation à partir du milieu réactionnel, éliminant ainsi les problèmes associés avec la lixiviation du catalyseur et alors que le mélange solvant liquide ionique/catalyseur est prêt à être réutilisé pour d'autres réactions catalytiques.

**Mots-clés :** phosphonium, liquides ioniques, catalyse ionophile, carbocycles contenant du palladium, marquage ionique.

[Traduit par la Rédaction]

## Introduction

The use of ionic liquids (ILs) as an alternative solvent in catalysis has become popular over the last ten years as a means of rendering the reaction “green”.<sup>1</sup> This notion predominantly stems from the ionic nature of the salts, which give rise to a negligible vapor pressure. However, given recent reports on the toxicity of some ILs, their potential application as “green” solvents has faltered.<sup>2,3</sup> Nevertheless, many of their properties beyond non-volatility do render these materials highly amenable to many chemical reactions and applications. High thermal stabilities, wide liquid temperature ranges, and unique solubility parameters give rise to ionic liquids as good alternative solvents. Ionic liquids generally have the ability to dissolve many organic and organometallic compounds and are often immiscible with non-polar organic solvents.<sup>4</sup> The breadth of potential appli-

cations is further amplified given the general framework of common ionic liquids, such as imidazolium or pyridinium salts, is susceptible to chemical modification to attain a desired function while concomitantly maintaining the intrinsic properties of the low melting salts.

The ease of dissolution of transition metals in ionic liquids and the immiscibility observed with some organic solvents are both phenomena associated with ionic liquids that are often exploited in catalysis. These properties enable an improvement in the isolation of the organic product from the catalyst during simple extraction procedures.<sup>5,6</sup> Unfortunately, in some cases, the catalyst activity quickly decreases after several runs.<sup>7</sup> This is often a result of catalyst leaching during the extraction of the product from the reaction mixture or in the purification of the ionic liquid before the initiation of the next reaction cycle. To ensure retention of the catalyst within the ionic liquid phase and consequently improve the recyclability of the system and the isolation of products, modifications to the catalyst are required. A current methodology includes preparing a catalyst that mimics the physico-chemical properties of the ionic medium, thus increasing the ionophilicity of the catalyst. Shreeve et al. have synthesized a (carbene)palladium(II) catalyst that resembles the skeletal structure of the imidazolium ionic liquid reaction medium and was used successfully to facili-

**Chart 1.** Illustration of the decomposition of an imidazolium cation in the presence of base resulting in the formation of a carbene, **1**, and alternative imidazolium cations protected at the C-2 position, **2** and **3**.

tate C–C bond forming reactions.<sup>8,9</sup> A more prevalent strategy to increase a catalyst's ionophilicity is to covalently integrate an ionic fragment into the catalyst framework. A critical review highlighting various successes employing ionic liquid ligands for the preparation of ionophilic catalysts has recently been published.<sup>10,11</sup>

Carbon–carbon bond forming reactions, such as Heck and Suzuki–Miyaura, are some of the most important reactions in organic synthesis. Substantial effort has been put forth to convert the successful homogeneous methodology into a heterogeneous system with enhanced catalyst recyclability. Recently, ionophilic ionic-liquid-tagged catalysts have been reported as a means of achieving this goal.<sup>12,13</sup> The ubiquitous imidazolium cation has been employed as an ion tag; however, it is susceptible to degradation under basic conditions, a requirement for the Heck and Suzuki–Miyaura reactions. The subsequent formation of a carbene, **1**, leads to poor yields, unwanted side-products, and inactive catalysts.<sup>14–16</sup> One approach to avoid this problem is the substitution of a metal-binding ligand such as a pyridine, **2**, or phosphine, **3**, at the C-2 position on the imidazolium cation (Chart 1).<sup>17,18</sup>

Our methodology, inspired by the work of Corma et al.,<sup>19</sup> also evades the susceptibility of imidazolium salts towards decomposition in the presence of base. Utilizing the ionophilic ionic-liquid-appended catalyst concept, a phosphonium salt was tethered to an oxime carbopalladacycle moiety, which was previously noted as an exceptional catalyst for Suzuki–Miyaura cross-coupling of aryl halides and arylboronic acids.<sup>20,21</sup> Phosphonium salts do not share the same vulnerability to basic conditions as observed for imidazolium cations and have been successfully used as alternative solvent media in Suzuki and Heck reactions without any signs of decomposition products such as Wittig-type reagents.<sup>22–26</sup> In this context, a phosphonium-tagged oxime carbopalladacycle catalyst precursor **8** has been synthesized and comprehensively characterized. It is important to note here that Singer et al. have prepared similar ionophilic ligands derived from oximes with pendant imidazolium salts. The salts were designed as capturing devices for sequestering metals from aqueous solutions, and their use as cross-coupling pre-catalysts was not investigated.<sup>27</sup> Herein, cross-coupling reactions catalyzed by the ionophilic catalyst,

**8**, were conducted using trihexyltetradecylphosphonium chloride, [P<sub>66614</sub>][Cl], as the reaction medium. Increased isolated yields and catalyst recyclability were noted as significant improvements to previous reports of ionophilic oxime carbopalladacycle cross-coupling catalysis.

## Experimental section

### Materials

The solvents were obtained from Caledon Laboratories. Dichloromethane, *N,N*-dimethylformamide, and toluene were dried using an Innovative Technologies Inc. Solvent Purification System, which utilizes dual-alumina columns, and were stored under a nitrogen or argon atmosphere in Strauss flasks or stored in the glovebox over 4 Å molecular sieves. Methanol was dried by storing over 3 Å molecular sieves. The trihexyltetradecylphosphonium chloride (Strem), styrene (Aldrich), *p*-methoxyphenyl boronic acid (Aldrich), and iodobenzene (Aldrich) were used as received and stored in a nitrogen-filled MBraun Labmaster 130 glovebox. The palladium dichloride (Pressure Chemicals), K<sub>3</sub>PO<sub>4</sub> (Riedel-deHaën), and LiCl (Caledon) were used as received and stored in a desiccator. Deuterated NMR solvents (CDCl<sub>3</sub>, DMSO) were purchased from Cambridge Isotope Laboratories and were stored over 4 Å molecular sieves. Tri-*n*-butyl phosphine was generously donated by Cytec Industries and was distilled prior to use. Manipulations involving the use of <sup>n</sup>Bu<sub>3</sub>P and the catalysis experiments were performed either in the glovebox or by using standard Schlenk techniques. The precursors 4-hydroxyacetophenone oxime and 4-(5-bromopentoxo)acetophenone oxime were synthesized using literature methods.<sup>19</sup>

### Measurements

Solution <sup>1</sup>H, <sup>31</sup>P{<sup>1</sup>H} and <sup>13</sup>C{<sup>1</sup>H}, gHMBC, and gHSQC NMR spectra were recorded on a Varian INOVA 400 MHz, Varian INOVA 600 MHz, or Mercury 400 MHz spectrometer. All samples for <sup>1</sup>H NMR, <sup>13</sup>C{<sup>1</sup>H}, gHMBC, and gHSQC spectroscopy were referenced to the residual protons in the solvent relative to (CH<sub>3</sub>)<sub>4</sub>Si (δ (ppm): <sup>1</sup>H: CDCl<sub>3</sub> 7.26, DMSO 2.50; <sup>13</sup>C{<sup>1</sup>H}: CDCl<sub>3</sub> 77.0, DMSO 39.52). Phosphorus-31 NMR chemical shifts were reported relative to an external standard (85% H<sub>3</sub>PO<sub>4</sub> δ = 0.00 ppm). Mass spectrometry measurements were recorded in positive and negative ion modes using an electrospray ionization Micro-mass LCT spectrometer. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada.

The decomposition temperatures were determined using thermogravimetric analysis (TGA) on a Q600 SDT TA Instrument for **7** or on a TGA/SDTA 851e Mettler Toledo instrument for **8**. A 0.005–0.010 g sample was heated in a 40 µL alumina crucible at a rate of 10 °C/min over a temperature range of 100–600 °C. Melting and glass transition points were determined using differential scanning calorimetry (DSC) on a Q20 DSC TA instrument for **7** or on a DSC 822e Mettler Toledo instrument for **8** using aluminum sample pans. For **7**, a 0.005–0.010 g sample was cooled to –90 °C and then heated to 200 °C at 10 °C/min, cooled to –90 °C at 10 °C/min, and finally reheated to 200 °C at 10 °C/min. The glass-transition temperatures were taken

from the final heat cycle. For **8**, a 0.005–0.010 g sample was cooled to  $-70\text{ }^{\circ}\text{C}$  where the temperature was sustained for 15 min, followed by heating to  $500\text{ }^{\circ}\text{C}$  at  $10\text{ }^{\circ}\text{C}/\text{min}$ . All thermal analysis experiments were conducted in a  $\text{N}_2(\text{g})$  atmosphere.

## Synthesis

### Preparation of **7**

To a solution of 4-(5-bromopentoxo)acetophenone oxime (0.970 g, 3.220 mmol) in DMF (17 mL)  $n\text{Bu}_3\text{P}$  (0.716 g, 3.542 mmol) was added, and the mixture was heated at  $70\text{ }^{\circ}\text{C}$  for 48 h under a flow of nitrogen. DMF was removed in vacuo, and the resulting viscous yellow liquid was dissolved in a minimal amount of  $\text{CH}_2\text{Cl}_2$ , which was extracted first with hexanes ( $2 \times 15\text{ mL}$ ) and then with THF ( $1 \times 15\text{ mL}$ ). The residual solvent was removed in vacuo yielding **7** as a viscous clear yellow liquid (1.083 g, 2.155 mmol, 67%).  $T_d = 343\text{ }^{\circ}\text{C}$ ;  $T_g = -2\text{ }^{\circ}\text{C}$ .  $^{31}\text{P}\{^1\text{H}\}$  NMR (161.96 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 30 (s).  $^1\text{H}$  NMR (599.69 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.57 (d, 2H,  $^3J = 9.0\text{ Hz}$ ), 7.42 (s, br, 1H), 6.86 (d, 2H,  $^3J = 8.4\text{ Hz}$ ), 4.00 (t, 2H,  $^3J = 6.0\text{ Hz}$ ), 2.60–2.55 (m, 2H), 2.48–2.43 (m, 6H), 2.25 (s, 3H), 1.87 (quintet, 2H,  $^3J = 6.6\text{ Hz}$ ), 1.74–1.64 (m, 4H), 1.56–1.51 (m, 12H), 0.97 (s, 9H).  $^{13}\text{C}\{^1\text{H}\}$  NMR (100.60 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 159.2, 153.6, 129.1, 126.8, 113.9, 67.2, 28.2, 27.1 (d,  $^3J_{\text{P-C}} = 13\text{ Hz}$ ), 23.5 (d,  $^3J_{\text{P-C}} = 12\text{ Hz}$ ), 23.4 (d,  $^2J_{\text{P-C}} = 3\text{ Hz}$ ), 21.3 (d,  $^2J_{\text{P-C}} = 4.6\text{ Hz}$ ), 19.1 (d,  $^1J_{\text{P-C}} = 47.5\text{ Hz}$ ), 18.7 (d,  $^1J_{\text{P-C}} = 47.0\text{ Hz}$ ), 13.2, 11.6. FTIR (drop-cast on KBr;  $\text{cm}^{-1}$ (ranked intensity)): 510(20), 561(14), 634(12), 725(11), 838(3), 924(4), 1006(7), 1094(16), 1182(9), 1250(1), 1304(10), 1376(15), 1464(8), 1515(6), 1610(5), 1673(21), 2870(17), 2959(2), 3169(13), 3207(19), 3263(18). MS (ESI)  $m/z^{+/-}$  (%): 422.3 (100) [ $\text{M}^+ - \text{Br}$ ], 923.6<sup>5</sup> [ $\text{M}_2\text{Br}^+$ ], 582.2 (35) [ $\text{MBr}_2$ ].

### Preparation of **8**

The  $\text{Li}_2\text{PdCl}_4$  was first prepared by the addition of  $\text{PdCl}_2$  (0.212 g, 1.193 mmol) to a solution of  $\text{LiCl}$  (0.101 g, 2.387 mmol) in  $\text{MeOH}$  (0.6 mL), which was then heated at  $60\text{ }^{\circ}\text{C}$  for 30 min until all the reagents dissolved. Sodium acetate (0.049 g, 0.597 mmol) and **7** (0.300 g, 0.597 mmol) in  $\text{MeOH}$  (0.65 mL) were then added dropwise to the resulting red methanolic  $\text{Li}_2\text{PdCl}_4$  solution, and the mixture was stirred at room temperature for 36 h. Methanol was then added (2 mL), and the heterogeneous mixture was centrifuged and the supernatant was decanted. The solids were washed with  $\text{MeOH}$  ( $4 \times 4\text{ mL}$ ) followed by acetone ( $4 \times 4\text{ mL}$ ) to selectively remove the red-brown solid. The acetone fractions were combined and cooled to  $-30\text{ }^{\circ}\text{C}$ . Upon precipitation of a beige solid, the mixture was centrifuged, the supernatant was removed, and the solid was dried in vacuo giving **8** as a beige powder (0.144 g, 0.112 mmol, 19%).  $T_d = 290\text{ }^{\circ}\text{C}$ ;  $T_m = 160\text{ }^{\circ}\text{C}$ .  $^{31}\text{P}\{^1\text{H}\}$  NMR (161.96 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 30 (s).  $^1\text{H}$  NMR (400.09 MHz,  $\text{DMSO}$ )  $\delta$  (ppm): 10.5 (s, br, 1H), 7.17 (s, br, 1H), 7.06 (d, 2H,  $^3J = 8.4\text{ Hz}$ ), 6.54 (d, 2H,  $^3J = 8.4\text{ Hz}$ ), 3.93 (t, 2H,  $^3J = 6.4\text{ Hz}$ ), 2.22–2.15 (m, 11H), 1.73 (quintet, 2H,  $^3J = 6.0\text{ Hz}$ ), 1.53–1.35 (m, 16H), 0.90 (t, 9H,  $^3J = 6.8\text{ Hz}$ ).  $^{13}\text{C}\{^1\text{H}\}/\text{gHSQC}/\text{gHMBC}$  (599.44 MHz,  $\text{DMSO}$ )  $\delta$  (ppm): 163.4, 157.5, 153.6, 138, 129, 120.8, 109.5, 66.8, 27.8, 26.7

(d,  $^3J_{\text{P-C}} = 14.9\text{ Hz}$ ), 23.3 (d,  $^3J_{\text{P-C}} = 17\text{ Hz}$ ), 22.6 (d,  $^2J_{\text{P-C}} = 3.9\text{ Hz}$ ), 20.4 (d,  $^2J_{\text{P-C}} = 3.8\text{ Hz}$ ), 17.5 (d,  $^1J_{\text{P-C}} = 46.1\text{ Hz}$ ), 17.3 (d,  $^1J_{\text{P-C}} = 47.7\text{ Hz}$ ), 13.2, 10.9. FTIR (CsI pellet;  $\text{cm}^{-1}$ (ranked intensity)): 227(21), 248(19), 280(26), 304(25), 440(24), 639(9), 722(20), 807(12), 917(17), 959(14), 1043(6), 1100(8), 1209(2), 1227(18), 1266(7), 1308(13), 1339(5), 1378(10), 1459(3), 1560(11), 1582(1), 1629(16), 1648(27), 2872(15), 2934(23), 3446(22). ### Preparation of 4-methoxy-biphenyl via Suzuki–Miyaura cross-coupling reaction

A 5 mol% mixture of the catalyst **8** (0.025 g, 0.019 mmol) in trihexyltetradecylphosphonium chloride (0.700 g, 1.348 mmol) was dissolved in  $\text{CH}_2\text{Cl}_2$  (1.5 mL) to facilitate the transfer of the mixture to a small, narrow Schlenk tube. The bulk of the solvent was removed in vacuo at room temperature, and the remaining residual solvent was removed at  $70\text{ }^{\circ}\text{C}$ . The mixture was cooled to room temperature, and neat  $\text{K}_3\text{PO}_4$  (0.275 g, 1.294 mmol), *p*-methoxyphenyl boronic acid (0.066 g, 0.431 mmol), and iodobenzene (0.080 g, 0.392 mmol) were added followed by the addition of toluene (0.1 mL) and distilled and  $\text{N}_2$ -purged  $\text{H}_2\text{O}$  (0.2 mL). The reaction mixture was stirred and heated at  $70\text{ }^{\circ}\text{C}$  for 5 h, and then the volatile solvents were removed in vacuo at room temperature. A cold finger was fitted to the Schlenk tube and the product was isolated from the ionic liquid mixture by sublimation at  $80\text{ }^{\circ}\text{C}$  for 14 h, yielding 4-methoxy-biphenyl as a white solid (0.057 g, 0.309 mmol, 99%).  $^1\text{H}$  NMR (400.09 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.56 (m, 4H), 7.42 (t, 2H,  $^3J = 7.6\text{ Hz}$ ), 7.30 (t, 1H,  $^3J = 7.6\text{ Hz}$ ), 6.98 (d, 2H,  $^3J = 8.8\text{ Hz}$ ), 3.86 (s, 3H).

### Preparation of trans-stilbene via Heck cross-coupling reaction

A 2 mol% mixture of the catalyst **8** (0.015 g, 0.012 mmol) in trihexyltetradecylphosphonium chloride (0.300 g, 0.578 mmol) was dissolved in  $\text{CH}_2\text{Cl}_2$  (1.5 mL) to more easily facilitate the transfer of the mixture to a small, narrow Schlenk tube and to assist in the dispersion and solvation of **8** in the ionic liquid solvent. The bulk of the solvent was removed in vacuo at room temperature, and the remaining residual solvent was removed at  $70\text{ }^{\circ}\text{C}$ . The mixture was cooled to room temperature, and neat styrene (0.094 g, 0.900 mmol), iodobenzene (0.122 g, 0.600 mmol), and  $\text{K}_3\text{PO}_4$  (0.255 g, 1.200 mmol) were added, followed by the addition of toluene (0.1 mL) and distilled,  $\text{N}_2$ -purged,  $\text{H}_2\text{O}$  (0.2 mL). The reaction mixture was stirred and heated at  $90\text{ }^{\circ}\text{C}$  for 5 h, and then the volatile solvents were removed in vacuo at room temperature. A cold finger was fitted to the Schlenk tube and the product was isolated from the ionic liquid mixture by sublimation at  $80\text{ }^{\circ}\text{C}$  for 14 h, yielding 4-methoxy-biphenyl as a white solid (0.106 g, 0.588 mmol, 98%).  $^1\text{H}$  NMR (400.09 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.52 (d, 4H,  $^3J = 8.4\text{ Hz}$ ), 7.36 (t, 4H,  $^3J = 7.6\text{ Hz}$ ), 7.26 (t, 2H,  $^3J = 7.6\text{ Hz}$ ), 7.12 (s, 2H).

### Procedure for recycling the catalyst and the ionic liquid

Upon completion of the catalysis, the product was isolated following the same procedure as noted. Proton NMR spec-

**Scheme 1.** Synthesis of phosphonium-functionalized oxime carbopalladacycle **8**.

troscopy of the resulting IL mixture confirmed the complete removal of the product. The reagents were then added in the same amounts, following the initial reaction conditions, and the catalysis was repeated.

## Results and discussion

### Synthesis

The synthetic route towards the preparation of the phosphonium salt catalyst **8** is summarized in Scheme 1. Compounds **4** through **6** were prepared according to literature procedures.<sup>19</sup> Given the likely reactivity of  $n\text{-Bu}_3\text{P}$  with palladium, the generation of the phosphonium salt **7** was completed first, followed by formation of the carbopalladacycle phosphonium salt **8**. The quaternization of tri-*n*-butylphosphine with **6** was monitored by  $^{31}\text{P}\{^1\text{H}\}$  NMR spectroscopy until the full consumption of  $n\text{-Bu}_3\text{P}$  ( $\delta = -32$  ppm) was observed.<sup>28</sup> The complete formation of the phosphonium salt ( $\delta = 35$  ppm) was detected within 48 h at 70 °C. The DMF was removed in vacuo, and the product was purified by extractions with hexanes and THF, respectively. Comprehensive characterization ascertained the formation of the phosphonium ionic liquid **7** as a yellow, clear, viscous liquid. Thermal analysis of **7** revealed a glass transition temperature of  $-2$  °C and a thermal decomposition temperature of 343 °C. The addition of **7** and NaOAc to methanolic  $\text{Li}_2\text{PdCl}_4$  resulted in immediate precipitation of a red-brown solid. Upon stirring for 3 days, a beige precipitate also formed. The solids were isolated and washed with MeOH followed by acetone and were finally recrystallized in acetone. The beige powder was fully characterized to confirm the formation of the carbopalladacycle using the following analytical and spectroscopic methods: 1D and 2D NMR spectroscopy, FTIR spectroscopy, UV-vis spectroscopy, electrospray ionization mass spectrometry, differential scanning calorimetry, thermogravimetric analysis, and elemental analysis. The most salient feature in the  $^1\text{H}$  NMR spectrum was the change in the pattern of the aromatic protons from AA'BB' to ABC, which was indicative of the formation of the aryl carbopalladacycle environment (Fig. 1).<sup>19,29</sup> The phosphonium carbopalladacycle **8** was isolated as a white powder in a modest yield (19%). Compound **8** was soluble in DCM, DMSO, acetone, and trihexyltetradecylphosphonium chloride,  $[\text{P}_{66614}][\text{Cl}]$ , and was insoluble in  $\text{CHCl}_3$  and apolar solvents, such as alkanes and ethers.

The FTIR spectrum for **7** displayed a characteristic C=N

stretching vibration of  $1673\text{ cm}^{-1}$ , and the corresponding C=N vibration in **8** was shifted by  $26\text{ cm}^{-1}$  (observed at  $1648\text{ cm}^{-1}$ ), which suggested N-Pd coordination (Fig. 2).<sup>30</sup> Analysis by UV-vis spectroscopy provided further evidence of the presence of the carbopalladacycle in **8**. An absorption at  $\lambda_{\text{max}}$  262 nm and an absorption band at  $\lambda_{\text{max}}$  307 nm with a broad shoulder peak corresponded to ligand centered absorptions on the phosphonium salt. Ionic liquid **7** displayed only one absorption band at  $\lambda_{\text{max}}$  260 nm. The absorption band at  $\lambda_{\text{max}}$  307 nm symbolized charge-transfer transitions, which were specific to metal-ligand orbital interactions, and was in accordance with literature results (Fig. 3).<sup>19</sup>

A typical oxime carbopalladacycle is often a chloro-bridged dimer, which occurs to fulfill the favorable four-coordinate geometry about the palladium centre. However, the imidazolium-tagged oxime carbopalladacycle was found to be monomeric. The last coordination site was filled by the imidazolium, preventing the formation of a dimer.<sup>19</sup> Evidence for both the monomer and dimer phosphonium analogues, **8**, were observed in ESI-MS with the most intense peak attributed to the monomer. The dimer was the most likely conformation, since there was no donor capability at the phosphonium centre in contrast to the imidazolium example. Attempts to grow crystals of suitable quality for X-ray diffraction studies resulted in microcrystalline powders or clusters; thus, solid-state characterization was not possible. No conclusive statement could be made from these results to declare the coordination environment about the palladium.

### Catalysis studies

To examine the catalytic ability of the phosphonium carbopalladacycle, two C-C bond forming cross-coupling reactions, Heck and Suzuki-Miyaura, were carried out. The evaluation of the Heck reaction was accomplished using styrene and iodobenzene with  $\text{K}_3\text{PO}_4$  and, the Suzuki-type reaction was carried out using *p*-methoxyphenylboronic acid and iodobenzene with  $\text{K}_3\text{PO}_4$  as the base. The reaction conditions including solvents, bases, reaction times, temperature, catalyst loading, and isolation techniques were varied, and the results are summarized in Table 1.

Oxygen-free conditions were required, as reactions carried out in the absence of an inert atmosphere resulted in low yields (Table 1, entries 1, 2, and 14). It was observed that a small amount of toluene and water were required to assist the dissolution of the reagents in the ionic liquid medium,

**Fig. 1.** Stacked  $^1\text{H}$  NMR spectra for **7** (bottom) and **8** (top), which clearly display the change in the environment about the phenyl protons, indicative of the incorporation of the palladium metal.

**Fig. 2.** FTIR spectrum of **7** (top) displays a C=N vibration at  $1673\text{ cm}^{-1}$ , and the FTIR spectrum of **8** (bottom) shows the shift of the C=N vibration to  $1648\text{ cm}^{-1}$  revealing N–Pd coordination.

as the reaction performed using solely  $[\text{P}_{66614}][\text{Cl}]$  yielded only trace amounts of the desired product (Table 1, entry 14). To attain a minimal reaction time under mild temperatures, the ideal catalyst loading was found to be 5 mol% (Table 1, entry 13) for the Suzuki reaction and 2 mol% for the Heck reaction (Table 1, entry 19).

With the use of viscous, non-volatile ionic liquids as solvents in chemical transformations, modifications to the conventional approaches to synthesis and product isolation are necessary. Previously reported product isolation techniques for Suzuki reactions performed in phosphonium ionic liquids were assessed, including aqueous and organic solvent extractions, followed by filtration through silica (Table 1, entries 2, 15, and 16) or alternatively, direct filtration of the reaction mixture through a silica plug (Table 1, entries 1 and 14); all of which proved unsatisfactory for various reasons. Separation of the product by extraction into organic solvent increased volatile solvent use, which is to be avoided if possible. Subsequent filtration through silica increased the steps required to obtain a pure product, which can reduce the final yield. The filtration of the ionic liquid mixture was formerly deemed necessary, since extracting

**Fig. 3.** UV–vis spectra of **7** (solid line) and **8** (dotted line). The emergence of a second band for **8** is indicative of a metal–ligand interaction.

the reaction mixture with hexanes does not always completely remove all of the biaryl product, given some of the biaryl species remains in the ionic liquid phase.<sup>22</sup> This filtration strategy is limited by the inability to reuse the catalyst and solvent because the phosphonium salts predominantly remain coordinated to the silica. However, it is important to note, that herein, no evidence of the phosphonium catalyst **8** was present in the hexanes extractions.

In this context, it was ascertained that the best way to isolate the products was through sublimation. One can take advantage of the non-volatility of the reaction medium and catalyst and simply remove the volatile product by sublimation. Initial experiments were carried out in a small vial ( $15 \times 48\text{ mm}$ ) with a septum cap for the delivery of  $\text{N}_{2(g)}$  by a needle, given the volume of the reaction mixture was small. Upon completion of the reaction, the mixture was dissolved in  $\text{CH}_2\text{Cl}_2$  and transferred to a Schlenk flask. The volatile solvent was removed under reduced pressure, the flask was then fitted with a cold finger, and the product was sublimed at  $0.5\text{ mm Hg}$  and  $80\text{ }^\circ\text{C}$ . To further optimize the isolation procedure, an unconventionally shaped Schlenk tube was designed not only to accommodate the small reaction volume, but also to include the capacity to fit a cold finger to the flask (Fig. 4). Under the optimized reaction conditions and with the appropriate glassware, high-yielding Suzuki and Heck cross-coupling reactions were achieved (Table 1, entries 13 and 19).

### Catalyst recyclability studies

While employing the optimized conditions, the recyclability of the ionophilic catalyst was demonstrated. For both the Heck and Suzuki reactions, upon completion of the reactions, the residual toluene and water were removed in vacuo at room temperature, and subsequently, a cold finger was inserted into the flask and the product was sublimed at  $0.5\text{ mm Hg}$  at  $80\text{ }^\circ\text{C}$  overnight.  $^1\text{H}$  NMR spectroscopy of the remaining IL mixture confirmed the absence of any product or starting reagents. If residual product was observed in the IL, then a second sublimation was performed. Without removal of any residual borates or phosphates, the starting reagents, not including fresh catalyst, were again added to the ionic liquid mixture and the catalysis was repeated at the optimized conditions, and the results are summarized in Table 2.

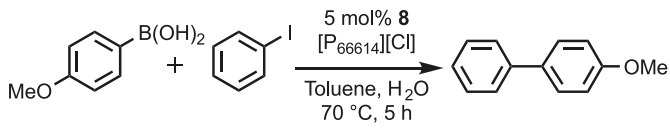

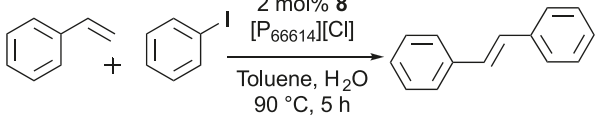

**Fig. 4.** Sublimation of *trans*-stilbene from the ionophilic catalyst **8** – [P<sub>66614</sub>][Cl] reaction mixture using the specially designed reaction tube.

The ionophilic catalyst **8** – [P<sub>66614</sub>][Cl] mixture was recycled three times before any decrease in activity was observed for the Suzuki reaction. After the third reuse of the catalyst, the IL mixture changed from yellow to black. This

is likely due to the formation of Pd black and is probably associated with the decrease in conversion. The phosphonium catalyst **8** exhibited good catalytic activity in Heck reaction as well; however, the recyclability of the catalyst was poor. The yields decreased by 20% on the second cycle and continued to diminish rapidly over the subsequent cycles. Again, the colour of the reaction mixture changed from yellow to a red-black on the first cycle, indicative of the initiation of catalyst decomposition. However, it is important to note that while **8** exhibits moderate recyclability, the imidazolium carbopalladacycle ionophilic catalyst by Corma et al. displayed quite low reactivity. The Heck and Suzuki coupling reactions exhibited yields ranging from 3%–25% on the first run, and therefore, the catalyst was not recyclable.<sup>19</sup> They proposed that the imidazolium tag was unstable under the basic conditions required, and the formation of carbene by deprotonation at C-2 on the imidazolium prevailed. The resulting carbene would then coordinate to the palladium and ultimately result in the decomposition of the catalyst, the formation of Pd black, and poor catalytic activity. Therefore, the substitution of a phosphonium salt for an imidazolium cation proves to be a more effective route towards the generation of an ionophilic tag for oxime carbopalladacycle cross-coupling reaction catalysts, given basic conditions are required for these types of reactions.

## Conclusions

A phosphonium-tagged oxime carbopalladacycle catalyst **8** has been synthesized and comprehensively characterized. The catalyst displayed ionophilic properties in the C–C bond forming cross-coupling Heck and Suzuki reactions conducted in an ionic liquid medium. Based on the ionic nature of **8**, the catalyst selectively partitioned into the ionic liquid reaction phase, and furthermore, the ionic catalyst – solvent media allowed the isolation of the reaction products simply by sublimation without the need to use volatile organic solvents for extraction/separation techniques. This straightforward product-isolation methodology enabled and simplified the recycling of the catalyst and the reaction solvent. The substitution of a phosphonium appendage on an oxime carbopalladacycle as opposed to an imidazolium functionality resulted in increased tolerance towards the basic conditions required in Heck and Suzuki reactions and therefore increased catalytic activity.

# Synthesis and electrochemical behavior of triazole-containing nicotinamide adenine dinucleotide analogs

Wujun Liu, Shuhua Hou, and Zongbao Kent Zhao

**Abstract:** The coupling of 2',3'-di-*O*-acetyl nicotinamide mononucleotide with 3-butyne-1-ol in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride quantitatively afforded a terminal alkyne-containing intermediate. Furthermore, copper(I)-mediated Huisgen [3 + 2] cycloaddition with a series of azido compounds in a two-phase solvent system gave eight triazole-containing nicotinamide adenine dinucleotide analogs with yields over 88%. The cyclic voltammetric behaviors of these novel analogs were investigated with a glassy carbon electrode, and structural features of these analogs on their electrochemical properties were briefly discussed.

**Key words:** nicotinamide adenine dinucleotide, analog, click chemistry, cyclic voltammetry.

**Résumé :** Le couplage du mononucléotide du 2',3'-di-*O*-acétylnicotinamide avec le but-3-yn-1-ol, en présence de chlorure de 2,4,6-triisopropylbenzènesulfonyle conduit à la formation pratiquement quantitative d'un intermédiaire comportant un alcyne terminal. Une cycloaddition ultérieure [3 + 2] de Huisgen, catalysée par le cuivre(I), avec une série de composés azide, dans un système liquide à deux phases, conduit à la formation, avec des rendements globaux supérieurs à 88 %, d'analogues dinucléotides d'adénine nicotinamide contenant un triazole en position 8. On a étudié les comportements en voltampérométrie cyclique de ces nouveaux analogues à l'aide d'une électrode de carbone vitreux et on discute brièvement des caractéristiques structurales de ces analogues sur leurs propriétés électrochimiques.

**Mots-clés :** dinucléotide de l'adénine nicotinamide, analogue, chimie par clic, voltampérométrie cyclique.

[Traduit par la Rédaction]

## Introduction

Nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and its reduced form, NADH, are involved in numerous biological systems, especially as cofactors for enzymes mediating oxidoreductive reactions.<sup>1</sup> In those oxidoreductive reactions, NAD(H) transfers hydrogen and electron shuttles, along with chemical potential change. The chemical potential of NAD<sup>+</sup> or its derivatives play critical roles in calcium homeostasis,<sup>2</sup> cross-membrane transportation,<sup>3</sup> oxidative stress resistance,<sup>4,5</sup> and reactive oxygen species clearance.<sup>6</sup> Although electrochemical studies have been done on a few model compounds,<sup>7</sup> and on applying a novel method<sup>8</sup> or materials<sup>9</sup> for modification of the surface of the electrode to improve the sensitivity of electrode response to NAD(H), there are few reports on testing the electrocatalytic reduction of synthetic NAD<sup>+</sup> analogs.

NAD<sup>+</sup> is a coupled product of the nicotinamide mononucleotide (NMN) part and the adenosine monophosphate (AMP) moiety (Fig. 1). The NMN part bestows its oxidoreductive property, whereas the AMP moiety is largely involved in binding in the biological environment. Early

study showed that a simple phosphodiester-type NAD<sup>+</sup> analog could be recognized by horse liver alcohol dehydrogenase, and that the system could be applied for reduction of prochiral ketones in moderate yields.<sup>10,11</sup> Thus, it is essential to have the NMN part in NAD<sup>+</sup> analogs so that their prospects as a redox chemistry mediator can be further explored. In these reactions, a synthetic cofactor was regenerated with valuable rhodium complexes, but low-cost electrochemical or photo driven regeneration of the NAD<sup>+</sup> cofactor led to a complex reaction.<sup>12,13</sup> One strategy to overcome these deficiencies is to modify the structure of the cofactor to improve electrode reaction activity.

We were recently interested in the preparation of NAD<sup>+</sup> analogs in which one phosphorus atom is removed from the original skeleton to meliorate electrode reaction activity of the natural coenzyme. In this work, we wish to report our efforts on the construction of 1,2,3-triazole-containing NAD<sup>+</sup> analogs (Fig. 1) and their electrochemical properties. We developed an efficient synthetic strategy for synthesis of these analogs based on CuSO<sub>4</sub>/sodium ascorbate-mediated Huisgen's 1,3-dipolar cycloaddition, or click reaction.<sup>14</sup>

**Scheme 1.** Synthesis of triazole-containing NAD<sup>+</sup> analogs. Reagents and conditions: (i) Ac<sub>2</sub>O/Py (1:1), 0–5 °C, 24 h, 98%; (ii) 3-butyn-1-ol (3 equiv.), TIPS-Cl (3 equiv.), DMF/Py (1:1), RT, 3 h, 99%; (iii) (a) R–N<sub>3</sub>, CuSO<sub>4</sub>/sodium ascorbate, H<sub>2</sub>O/DCM (1:1), RT, 0.5–6 h, 90%–98%, (b) NH<sub>4</sub>HCO<sub>3</sub> (1 mol/L), in H<sub>2</sub>O/MeOH (1:10), 98%. Data in the parentheses indicate the total isolated yield of each compound on Ac<sub>2</sub>NMN.

Compared to NAD<sup>+</sup>, these analogs showed relatively low reductive peak potentials ( $E_p$ ) and a distinct improvement of the electrode reaction rate constant ( $K_s$ ).

## Results and discussion

### Synthesis of triazole-containing NAD<sup>+</sup> analogs

Our in-house preparation of NMN was realized via selective hydrolysis of NAD<sup>+</sup> using ZrCl<sub>4</sub> as catalyst.<sup>15</sup> To synthesize the triazole-containing NAD<sup>+</sup> analogs, we originally tried to couple NMN with the corresponding alkynyl alcohol followed by click reaction with azides (Fig. 1). Because NMN is liable to form an inactive inner salt and has notoriously low solubility in most organic solvents (i.e., DMF (dimethylformamide), pyridine, MeCN), it was difficult to find an appropriate solvent system to realize the coupling reaction. Moreover, C–N bond breakage of the NMN molecule was substantial in many experiments. We then treated NMN with a mixture of Ac<sub>2</sub>O and pyridine at 0–5 °C, leading to the acetylated product of NMN, 2',3'-di-*O*-acetyl nicotinamide mononucleotide (Ac<sub>2</sub>NMN). It turned out that Ac<sub>2</sub>NMN had much better solubility and higher activity. Thus, the coupling of Ac<sub>2</sub>NMN with excess 3-butyn-1-ol in DMF/Py (1:1, *v/v*) in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride (TIPS-Cl) at room temperature for 3 h afforded the key intermediate of 2',3'-di-*O*-acetyl β-nicotinamide ribose-5'-3-butynyl phosphate, **3**, in a 99% yield based on <sup>31</sup>P NMR analysis (Scheme 1).

To convert compound **3** into triazole-containing NAD<sup>+</sup> analogs, we prepared eight azides (Scheme 1). These compounds were selected to mimic the adenine moiety of the NAD<sup>+</sup> structure, mainly depending on their accessibility and aromatic ring structures. Azides **a–c** were obtained from the corresponding halides via a nucleophilic substitution using sodium azide, whereas azides **d–h** were made via acylation of the corresponding amines with 5-chloropentanoyl chloride followed by a nucleophilic substitution reaction using sodium azide.<sup>16</sup>

With intermediate **3** and azide compounds in hand, we

**Fig. 1.** Structures of NAD<sup>+</sup> and its triazole-containing analogs.

carried out cycloaddition experiments in the presence of copper sulfate and sodium ascorbate according to the strategy described by Sharpless and co-workers.<sup>17</sup> Upon testing a couple of solvent systems, i.e., water mixed with DMSO, DMF, DCM, THF, MeCN, or *t*-BuOH, we found that there was no significant difference whether the organic solvent was soluble or insoluble in water. This was likely because compound **3** and the coupled products had excellent solubility in water. To facilitate an easier recycling of azides, our synthesis was carried out in a two-phased system made of DCM and H<sub>2</sub>O. Using this strategy, we were successful in coupling azides **a–h** with **3** at room temperature in over 90% yields within 6 h. For most reactions, 5 mol% Cu(I) catalyst was enough to convert **3** within 2 h. The bulky azides **f** and **h** required 4 h for better yields. Because azide **g** had a poor solubility, up to 6 h was necessary to achieve

excellent conversion. We also tried the combination  $\text{CuSO}_4/\text{Cu}$  to mediate the coupling reaction. However, the products seemed liable to coordinate with copper, leading to a tedious purification process and low isolated yields.

It was interesting to note that those triazole-containing intermediates could be easily deacetylated by 1 mol/L  $\text{NH}_4\text{HCO}_3$  solution in  $\text{H}_2\text{O}/\text{MeOH}$  (1:10, v/v). Thus, crude compound **4** was achieved during the reverse phase silica gel chromatography purification.

Because  $\text{NAD}^+$  analogs are amphiphilic molecules containing both positive and negative charges, purification usually presents a major barrier to achieve an appreciable quantity of target compounds in the lab. Thus, successful procedures varied from case to case for the isolation of analogs **4a–4h**. Chromatography with various supporting materials, including activated charcoal, silica gel, octyl-functionalized silica gel, ion exchange resins, and Bio-Gel P-2 resin has been applied in different combinations to fulfill valid purification. Compound **4a** was purified with octyl-functionalized silica gel and  $201 \times 2 \text{ HCO}_2^-$  form of the anion resin followed by Bio-Gel P-2 resin. For compounds **4b**, **4d**, and **4e**, chromatography on octyl-functionalized silica gel and anion resin, at different elution conditions, gave the best results. For compounds **4c** and **4f–4h**, chromatography on octyl-functionalized silica gel and Bio-Gel P-2 resin gave our target molecules.

### Electrochemical behavior of triazole-containing $\text{NAD}^+$ analogs

With novel analogs in hand, we investigated their electrochemical performance on a glassy carbon (GC) electrode in aqueous solution. Oxido-reductive behaviors of these triazole-containing  $\text{NAD}^+$  analogs were estimated by cyclic voltammetry. The redox curves were also a two electron mechanism according to the Angulo et. al method.<sup>18</sup> Upon a reversal scan of the  $\text{NAD}^+$  analogs, both the reduction peak and reoxidation peak were observed, albeit the latter was much weaker than the former. The corresponding reoxidation peaks were stronger than that of  $\text{NAD}^+$  under the same conditions. Thus, the overall processes are not reversible.

The reductive potential ( $E_p$ ) of the triazole-containing analog (−1.141 V) was much lower than that of natural  $\text{NAD}^+$  (−1.269 V; Table 1). Upon four cyclic reversal scans, marginal decreases in the reductive peak currents of  $\text{NAD}^+$  analogs were observed, and the decrease range of **4h** was much smaller than that of  $\text{NAD}^+$  under the same conditions (Fig. 2). This indicated that triazole-containing analogs had relatively weak absorption on GC than natural  $\text{NAD}^+$ .

The cathodic peak currents ( $i_p$ ) of triazole-containing analogs increased curvilinearly with the square root of the scan rate ( $v$ ), an upper warp curve in the range of 20–200  $\text{mV s}^{-1}$ . All the upper data resulted in the reduction of triazole-containing  $\text{NAD}^+$ , which was an absorption-controlled irreversible process under our conditions.

According to Laviron theory,<sup>19</sup> absorption-controlled irreversible process potential ( $E_p$ ) is determined based on the following equation:

$$[1] \quad E_p = E^\circ - (RT/\alpha nF) \ln(\alpha nF/RTK_s) - (RT/\alpha nF) \ln v$$

where  $E^\circ$ ,  $\ln v$ ,  $R$ ,  $T$ ,  $F$ ,  $n$ ,  $K_s$ , and  $\alpha$ , represent the standard

**Table 1.** Electrochemical dynamic constants of triazole-containing  $\text{NAD}^+$  analogs (**4a–4h**) and related compounds.

Compound	$E_p$ (V)	$K_s$ ( $\text{s}^{-1}$ )	$\alpha$
<b>4a</b>	−1.157	0.24	0.39
<b>4b</b>	−1.145	0.23	0.38
<b>4c</b>	−1.148	0.23	0.36
<b>4d</b>	−1.154	0.23	0.35
<b>4e</b>	−1.159	0.20	0.34
<b>4f</b>	−1.142	0.23	0.36
<b>4g</b>	−1.145	0.23	0.36
<b>4h</b>	−1.141	0.24	0.40
$\text{NAD}^+$	−1.269	0.11	0.22
NMN	−1.183	0.12	0.28
NAR	−1.211	0.12	0.21

**Note:** All data were the average value of three replicates.

**Fig. 2.** Overlay of the continuous reductive curves of  $\text{NAD}^+$  and **4h** under the same conditions.

potential, logarithm of the scan rate ( $v$ ), gas constant, absolute temperature, Faraday constant, the transfer electron number ( $n = 2$  for  $\text{NAD}^+$  or its derivatives), electrode reaction rate constant, and electron transfer coefficient, respectively. The value of  $E^\circ$  of all compounds (vs the standard calomel electrode (SCE)) was obtained from the intercept of the plot of  $E_p$  vs.  $v$  (data not shown). The electrode reaction rate constant ( $K_s$ ) and the electron transfer coefficient ( $\alpha$ ) were calculated from the slope and intercept of  $E_p$  vs.  $\ln v$  according to the above equation (Fig. 3a). Accordingly, all triazole-containing  $\text{NAD}^+$  analogs and related compounds were tested and results were listed in Table 1.

It was obvious that analogs with bulky aromatic rings and **4b** have relatively low reductive peak potentials. Compound **4a** and **4h** have the largest  $K_s$  and  $\alpha$ . Compound **4e** shows the lowest  $K_s$  and  $\alpha$  in tris(hydroxymethyl)aminomethane (Tris)/NaCl buffer, which may be due to the presence of aromatic fluorine atoms in the molecule. To investigate the electrochemical property in more detail, we carried out additional experiments on **4h**.

To make a comparison, we also obtained the correlative constants of  $\text{NAD}^+$ , NMN, and nicotinamide ribose (NAR) under identical conditions. It was clear that  $\text{NAD}^+$  and NAR had similar reduction peak potentials ( $E_p$ ) and NMN had a more positive  $E_p$  value. However, all  $\text{NAD}^+$  analogs had even more positive  $E_p$  values. Thus, substitution of

**Fig. 3.** (a) Linear plot of  $E_p$  vs.  $\ln v$  of NAD<sup>+</sup> analog **4h** ( $r = 0.9986$ ). (b) Linear plot of  $E_p$  vs. pH of the NAD<sup>+</sup> analog **4h**.

AMP moiety of the NAD<sup>+</sup> skeleton with a triazole-containing structure could increase the  $E_p$  of the corresponding product.

$K_s$  and  $\alpha$  of **4h** were more than twofold larger than that of other compounds, especially to natural NAD<sup>+</sup>. That indicated that the reduction of NAD<sup>+</sup> analog **4h** on a GC electrode was faster than natural NAD<sup>+</sup> and related compounds. Thus, modification of pyrophosphate made NAD<sup>+</sup> reduce at a relatively lower potential and the triazole ring in the analog molecule made it reduce faster than natural NAD<sup>+</sup>. The triazole ring increased the charge transfer efficiency, which is similar to Zhou et al.'s<sup>20</sup> results. Thus, we concluded that triazole-containing NAD<sup>+</sup> analogs were more liable to be reduced than other compounds on a GC electrode.

To investigate the reoxide stability of **4h** at different pHs, the peak reductive potential of the NAD<sup>+</sup> analog was measured in 1 mol/L phosphate buffer containing  $10^{-3}$  mol/L **4h** at different pHs (pH = 4–9). It was found that the  $E_p$  increased linearly with pH and that reduction of **4h** would be much easier at a higher pH (Fig. 3b). It should be noted that **4h** was stable at these selected pHs and could be recovered by reverse-phase column chromatography in a 96% yield. However, no such correlations were observed for NAD<sup>+</sup>, NMN, or NAR at identical conditions (data not shown).

Based on the  $pK_a$  of nicotinamide and triazole, the amino group of nicotinamide and nitrogen atom of the triazole ring was protonated below pH 6. Thus, the NAD<sup>+</sup> analogs existed as an inner salt in solution at a wide range of pHs. The triazole ring had an interaction with H<sup>+</sup> and promoted conductance of the charge at a relatively high concentration of H<sup>+</sup>, so a higher  $E_p$  was needed to reduce analogs. When the pH was higher than 7, interaction between the triazole ring and proton on the NAD<sup>+</sup> analog gradually disappeared. The repulsion of the triazole ring with the hydroxide anion made analog **4h** reduce at a relatively lower potential.

## Conclusion

An efficient strategy to prepare novel triazole-containing NAD<sup>+</sup> analogs was developed. These compounds had a triazole ring and phosphatediester linkage as mimics of the adenosine heterocyclic ring and pyrophosphate, respectively.

These analogs were more liable to reduce than NAD<sup>+</sup> on a GC electrode in Tris/NaCl buffer. Triazole analogs showed a stable redoxide property at different pHs. The reductive peak potential of **4h** increased linearly with the solution pH. The triazole-containing analogs could be broadly applied in cofactor regeneration or biosensor. We are now exploring other special biological functions with these compounds in a wide variety of chemical and biological areas, and results will be reported in due course.

## Experimental section

### General

All reagents were analytical grade, obtained from commercial suppliers (ABCR, ACROS, or Sigma-Aldrich), and used without further purification. NMR spectra were measured with a Bruker DRX-400 spectrometer (400.3 MHz for <sup>1</sup>H NMR, 100.6 MHz for <sup>13</sup>C NMR, 160.1 MHz for <sup>31</sup>P NMR, and 376 MHz for <sup>19</sup>F NMR) at 298 K. High resolution mass spectroscopy was obtained on a LC/Q-TOF-MS and operated with an electrospray source in positive ion mode. F254 thin-layer and silica gel (400 mesh) were purchased from Yantai Jiangyou Silica Co., Ltd., China. Octyl-functionalized silica gel was purchased from Sigma-Aldrich. Ion exchange resin (100–200 mesh) was purchased from the Chemical Plant of Nankai University, Tianjin, China. Bio-Gel P-2 resin (45  $\mu$ m) was obtained from Bio-Rad Laboratories, Inc. All reactions were carried out under a nitrogen atmosphere. UV-vis spectra were obtained at room temperature on a JASCO V-530 UV-vis spectrophotometer. The electrochemical measurements were performed with a CHI 600C electrochemical analyzer (CH Instruments, USA) connected to a personal computer. All experiments were performed using a conventional three-electrode system with a glassy carbon (GC) disc (CHI 104, 3 mm diameter) working electrode, a saturated calomel reference electrode (CHI 150), and a platinum wire as the counter electrode (CHI 115).

### Preparation of Ac<sub>2</sub>NMN (2)

To a mixture of pyridine (7.5 mL) and Ac<sub>2</sub>O (7.5 mL) was added NMN (275 mg, 0.82 mmol) in H<sub>2</sub>O (160  $\mu$ L)

at  $-5\text{ }^{\circ}\text{C}$ . The suspension was kept at  $0\text{ }^{\circ}\text{C}$  until all solids dissolved. The solvents were removed and the residue was dissolved in a mixture of  $\text{H}_2\text{O}$  (2 mL) and pyridine (2 mL). The yellow solution was stirred at room temperature for 2 h and the solvents were evaporated at reduced pressure. The residue was lyophilized to give  $\text{Ac}_2\text{NMN}$  as an amorphous solid, which was used directly in the next reaction without additional purification.<sup>21</sup>

### Preparation of alkynyl ester (3)

$\text{Ac}_2\text{NMN}$  (344 mg, 0.82 mmol) and 3-butyn-1-ol (3 equiv. to  $\text{Ac}_2\text{NMN}$ ) were dissolved in  $\text{Py}/\text{DMF}$  (1:1,  $v/v$ ) under a nitrogen atmosphere.  $\text{TIPS-Cl}$  (3 equiv. to  $\text{Ac}_2\text{NMN}$ ) was added and the mixture was stirred at room temperature for 3 h in a 99% yield based on  $^{31}\text{P}$  NMR. The solvent was removed, and the residue was added to 10 mL of  $\text{H}_2\text{O}$  and extracted with  $\text{DCM}$  (15 mL  $\times$  3). The aqueous solution was concentrated, purified via ion exchange column chromatography on anion resin ( $201 \times 2$ ,  $\text{HCO}_2^-$  form) eluted with  $\text{H}_2\text{O}$ . Fractions were concentrated and lyophilized to give crude **3**, and it was used in the next reaction without further purification.

### General method for the preparation of azide compounds (a–h)

Azides (**a–c**) in Scheme 1 were synthesized via a nucleophilic substitution using sodium azide, whereas azides **d–h** were made via acylation of the corresponding amines with 5-chloropentanoyl chloride followed by a nucleophilic substitution reaction using sodium azide.<sup>16</sup>

### General method for the preparation of $\text{NAD}^+$ analogs (4a–4h)

A solution of compound **3** in  $\text{H}_2\text{O}$  and azide in  $\text{DCM}$  (or other solvent) was mixed. To the mixture was added an appropriate amount of  $\text{CuSO}_4/\text{sodium ascorbate}$  (5 mol%) in one portion. After the reaction was stirred at room temperature for 0.5–6 h, the organic layer was removed, and the aqueous phase was purified by octyl-functionalized silica gel eluted with water and 1 mol/L  $\text{NH}_4\text{HCO}_3$  solution in  $\text{CH}_3\text{OH}/\text{H}_2\text{O}$  (1:10,  $v/v$ ) to give the crude product. The product was further purified via anion resin ( $201 \times 2$ ,  $\text{HCO}_2^-$  form) or size-exclusion chromatography Bio-Gel® P-2 Gel polyacrylamide gel. The corresponding fractions were pooled and freeze dried to give the triazole-containing analogs.

#### Compound 4a

Compound **4a** was purified by anion resin ( $\text{HCO}_2^-$  form) column chromatography eluted with  $\text{H}_2\text{O}$  and the fraction was concentrated, followed by size-exclusion chromatography Bio-Gel® P-2 Gel polyacrylamide gel, eluted with a 25 mmol/L  $\text{NH}_4\text{HCO}_3$  water solution, to give **4a** as a colorless syrupy solid in a 96% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 2.46 (q, 2H), 2.85 (t,  $J = 6.16$  Hz, 2H), 3.83 (ddd,  $J = 11.96, 5.00, 2.2$  Hz, 1H), 3.94 (q, 2H), 3.96 (ddd,  $J = 11.96, 4.56, 2.4$  Hz, 1H), 4.22 (dd,  $J = 4.96, 2.72$  Hz, 1H), 4.29 (t,  $J = 6.68$  Hz, 2H), 4.34 (t,  $J = 5.2$  Hz, 1H), 4.41 (t,  $J = 2.44$  Hz, 1H), 4.82 (dd,  $J = 8.84, 1.48$  Hz, 1H), 4.87 (d,  $J = 1.52$  Hz, 1H), 5.62 (ddd,  $J = 23.96, 17.28, 10.44$  Hz, 1H), 6.06 (d,  $J = 5.44$  Hz, 1H), 7.72 (s, 1H), 8.12 (t,  $J = 6.48$  Hz,

1H), 8.84 (d,  $J = 8.12$  Hz, 1H), 9.09 (d,  $J = 6.28$  Hz, 1H), 9.28 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 168.05, 162.82, 148.47, 147.04, 144.86, 142.22, 136.41, 136.28, 130.95, 126.58, 120.34, 102.28, 89.59, 89.51, 80.13, 73.30, 67.21, 66.76, 52.03, 36.21, 28.83, 28.75, 22.56.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.067. HR-MS (ESI) calcd. for  $\text{C}_{19}\text{H}_{26}\text{N}_5\text{O}_8\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 484.1597; found: 484.1588.

#### Compound 4b

Compound **4b** was purified by anion resin ( $\text{HCO}_2^-$  form) column chromatography eluted with water to give **4b** as a colorless solid syrup in a 94% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 2.84 (t,  $J = 5.92$  Hz, 2H), 3.52 (ddd,  $J = 1.84, 4.64, 11.88$  Hz, 1H), 3.70 (ddd,  $J = 2.24, 4.40, 12$  Hz, 1H), 3.91 (dd,  $J = 5.92, 11.84$  Hz, 2H), 4.10 (dd,  $J = 2.48, 4.76$  Hz, 1H), 4.15 (t,  $J = 2.16$  Hz, 1H), 4.25 (t,  $J = 5.16$  Hz, 1H), 5.35 (s, 2H), 5.93 (d,  $J = 5.48$  Hz, 1H), 7.2 (m, 5H), 7.76 (s, 1H), 7.98 (dd,  $J = 6.48, 7.76$  Hz, 1H), 8.73 (d,  $J = 8.12$  Hz, 1H), 8.94 (d,  $J = 7.88$  Hz, 1H), 9.16 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 168.0, 148.42, 147.53, 144.70, 142.22, 142.22, 137.50, 136.43, 131.64, 131.26, 130.95, 130.72, 126.67, 102.29, 89.52, 80.15, 73.33, 67.20, 66.71, 56.33, 28.82.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.01. HR-MS (ESI) calcd. for  $\text{C}_{22}\text{H}_{27}\text{N}_5\text{O}_8\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 520.1597; found: 520.1617.

#### Compound 4c

Compound **4c** was purified by size-exclusion chromatography Bio-Gel® P-2 Gel polyacrylamide gel, eluted with 25 mmol/L  $\text{NH}_4\text{HCO}_3$  water solution, to give **4c** as a colorless solid syrup in a 92% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 2.91 (t, 2H), 3.61 (t, 2H), 3.94 (dd,  $J = 10.64, 5.16$  Hz, 1H), 3.99 (dd,  $J = 2.76$  Hz, 1H), 4.02 (t, 2H), 4.07 (t, 1H), 5.51 (d,  $J = 2.76$  Hz, 1H), 5.56 (d,  $J = 4.36$  Hz, 1H), 7.31 (d,  $J = 8.6$  Hz, 1H), 7.35 (dd,  $J = 6.16, 3.0$  Hz, 2H), 7.47 (t,  $J = 7.52$  Hz, 1H), 7.62 (m, 4H), 7.90 (s, 1H), 8.39 (d,  $J = 6.16$  Hz, 1H), 8.44 (d,  $J = 8.04$  Hz, 1H), 8.61 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 167.32, 147.92, 147.49, 143.43, 141.31, 135.46, 134.98, 134.84, 131.22, 130.33, 130.14, 130.02, 129.94, 129.43, 128.38, 126.41, 101.91, 89.46, 79.93, 73.32, 67.04, 66.83, 56.36, 28.83.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.14. HR-MS (ESI) calcd. for  $\text{C}_{26}\text{H}_{28}\text{N}_5\text{O}_8\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 570.1754; found: 570.1735.

#### Compound 4d

Compound **4d** was purified by anion resin ( $\text{HCO}_2^-$  form) column chromatography eluted with water to give **4d** as a colorless solid syrup in a 95% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 1.35 (m, 2H), 1.68 (m, 2H), 2.15 (t, 2H), 2.77 (t, 2H), 3.70 (ddd,  $J = 2.08, 5.08, 11.96$  Hz, 1H), 3.78–3.86 (m, 3H), 4.13–4.18 (m, 3H), 4.26 (t, 1H), 5.87 (d,  $J = 5.24$  Hz, 1H), 6.92 (m, 1H), 7.10 (d, 5H), 7.64 (s, 1H), 7.94 (t,  $J = 6.6$  Hz, 1H), 8.67 (d,  $J = 8.12$  Hz, 1H), 8.89 (d,  $J = 6.24$  Hz, 1H), 9.08 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 177.13, 173.46, 168.11, 167.85, 162.90, 148.26, 147.17, 144.61, 142.04, 139.20, 136.22, 131.55, 130.84, 127.82, 126.42, 124.07, 102.17, 89.34, 80.01, 73.10, 67.21, 66.68, 52.33, 37.96, 31.24, 28.70, 24.51.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.01. HR-MS (ESI) calcd. for  $\text{C}_{26}\text{H}_{33}\text{N}_6\text{O}_9\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 605.2125; found: 605.2103.

**Compound 4e**

Compound **4e** was purified by anion resin ( $\text{HCO}_2^-$  form) column chromatography, eluted with 5%  $\text{HCO}_2\text{NH}_4$  solution, followed by octyl-functionalized silica gel eluted with water, to give **4e** as a colorless solid syrup in a 95% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 1.48 (m, 2H), 1.80 (m, 2H), 2.31 (t, 2H), 2.86 (t, 2H), 3.80 (dd,  $J = 3.72$ , 10.6 Hz, 1H), 3.91–3.96 (m, 3H), 4.13–4.18 (m, 3H), 4.20 (s, 1H), 4.26–4.32 (m, 3H), 4.38 (s, 1H), 6.02 (d,  $J = 5.24$  Hz, 1H), 6.84–6.91 (m, 2H), 7.28 (dd,  $J = 2.72$ , 8.76 Hz, 1H), 7.31 (s, 1H), 8.09 (t,  $J = 6.72$  Hz, 1H), 8.81 (d,  $J = 8.12$  Hz, 1H), 9.05 (d,  $J = 6.28$  Hz, 1H), 9.24 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 178.13, 168.01, 148.45, 144.82, 142.19, 136.40, 130.94, 130.05, 126.52, 114.00, 113.78, 107.08, 106.83, 106.58, 102.30, 89.56, 80.13, 73.30, 67.26, 66.81, 52.38, 37.43, 31.26, 28.78, 24.60.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.08.  $^{19}\text{F}$  NMR (376 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : -111.8, -118.9. HR-MS (ESI) calcd. for  $\text{C}_{26}\text{H}_{31}\text{F}_2\text{N}_6\text{O}_9\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 641.1936; found: 641.1960.

**Compound 4f**

Compound **4f** was purified by size-exclusion chromatography Bio-Gel<sup>®</sup> P-2 Gel polyacrylamide gel, eluted with 25 mmol/L  $\text{NH}_4\text{HCO}_3$  water solution, to give **4f** as a colorless solid syrup in a 90% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ )  $\delta$ : 1.36 (m, 2H), 1.54 (m, 2H), 2.10 (t, 2H), 2.82 (t, 2H), 3.80 (ddd,  $J = 11.96$ , 5.16, 1.92 Hz, 1H), 3.94 (m, 3H), 4.05 (t, 2H), 4.17 (dd,  $J = 4.52$ , 2.64 Hz, 1H), 4.22 (t, 1H), 4.34 (s, 1H), 4.52 (s, 2H), 5.88 (d,  $J = 5.32$  Hz, 1H), 7.32–7.17 (m, 4H), 7.44 (s, 1H), 7.64 (d,  $J = 2.44$  Hz, 1H), 7.66 (dd,  $J = 3.6$  Hz, 1H), 7.87 (t,  $J = 7.64$  Hz, 1H), 8.58 (d,  $J = 8.08$  Hz, 1H), 8.87 (d,  $J = 6.24$  Hz, 1H), 9.04 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ )  $\delta$ : 178.03, 167.54, 162.80, 148.02, 146.99, 144.49, 141.87, 135.85, 135.46, 132.88, 131.16, 130.64, 129.01, 128.66, 128.40, 128.12, 126.13, 125.48, 102.21, 89.37, 80.05, 73.11, 67.21, 66.74, 52.18, 43.43, 37.40, 31.21, 28.81, 24.82.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.11. HR-MS (ESI) calcd. for  $\text{C}_{31}\text{H}_{37}\text{O}_9\text{N}_6\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 669.2438; found: 669.2444.

**Compound 4g**

Compound **4g** was purified by size-exclusion chromatography Bio-Gel<sup>®</sup> P-2 Gel polyacrylamide gel, eluted with 25 mmol/L  $\text{NH}_4\text{HCO}_3$  water solution, to give **4g** as a colorless solid syrup in an 88% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 1.46 (m, 2H), 1.70 (m, 2H), 2.18 (t,  $J = 6.96$  Hz, 2H), 2.80 (t,  $J = 6.62$  Hz, 2H), 3.77 (dd,  $J = 11.36$ , 4.04 Hz, 1H), 3.88–3.93 (m, 3H), 4.17–4.22 (m, 5H), 4.27 (t,  $J = 5.16$  Hz, 1H), 4.32 (s, 1H), 5.90 (d,  $J = 5.48$  Hz, 1H), 7.16 (d,  $J = 7.96$  Hz, 2H), 7.21 (d,  $J = 7.12$  Hz, 1H), 7.27 (t,  $J = 7.24$  Hz, 2H), 7.41 (m, 5H), 7.64 (s, 1H), 8.01 (t,  $J = 6.88$  Hz, 1H), 8.72 (d,  $J = 8.08$ , 1H), 8.98 (d,  $J = 6.2$  Hz, 1H), 9.16 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 177.21, 167.63, 148.39, 144.79, 142.09, 141.24, 140.09, 136.32, 131.16, 130.97, 130.33, 129.61, 129.02, 128.81, 102.36, 89.63, 80.17, 73.23, 67.15, 66.76, 52.15, 44.87, 37.43, 31.51, 28.98, 24.88.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.01. HR-MS (ESI) calcd. for  $\text{C}_{33}\text{H}_{39}\text{N}_6\text{O}_9\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 695.2594; found: 695.2569.

**Compound 4h**

Compound **4h** was purified by size-exclusion chromatography Bio-Gel<sup>®</sup> P-2 Gel polyacrylamide gel, eluted with 25 mmol/L  $\text{NH}_4\text{HCO}_3$  water solution, to give **4h** as a colorless solid syrup in a 91% yield.  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 1.45 (m, 2H), 1.62 (m, 2H), 2.17 (t,  $J = 7$  Hz, 2H), 2.86 (t,  $J = 6$  Hz, 2H), 3.75 (dd,  $J = 11.4$ , 4.15 Hz, 1H), 3.92–4.11 (m, 3H), 4.14 (t,  $J = 6.8$  Hz, 2H), 4.18 (t,  $J = 2.4$  Hz, 1H), 4.24 (t,  $J = 5.4$  Hz, 1H), 4.35 (s, 1H), 5.91 (d,  $J = 5.2$  Hz, 1H), 7.28–7.39 (m, 5H), 7.5 (s, 3H), 7.68 (d,  $J = 7.8$  Hz, 2H), 7.75 (t,  $J = 8.2$  Hz, 2H), 7.91 (t,  $J = 6.8$  Hz, 2H), 8.63 (d,  $J = 8.08$  Hz, 1H), 8.92 (d,  $J = 6.16$  Hz, 1H), 9.08 (s, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 176.29, 167.64, 148.39, 146.84, 144.82, 143.86, 142.1, 136.33, 130.95, 129.60, 126.01, 102.35, 89.66, 80.16, 73.22, 67.16, 66.76, 59.23, 52.04, 37.19, 31.47, 28.94, 24.83.  $^{31}\text{P}$  NMR (160 MHz,  $\text{D}_2\text{O}$ , ppm)  $\delta$ : 0.15. HR-MS (ESI) calcd. for  $\text{C}_{33}\text{H}_{39}\text{N}_6\text{O}_9\text{P}$  [ $\text{M} + \text{H}$ ] $^+$ : 695.2594; found: 695.2615.

**Electrochemical experiment**

All data were recorded on a CHI 600C electrochemical analyzer, and further processed using the software Origin 8.0 when necessary.<sup>22</sup> The working concentration of analytes was  $2 \times 10^{-3}$  mol/L. Solutions of either 0.01 mol/L Tris/NaCl (0.005 mol/L) or phosphate (1 mol/L) buffer were used as supporting electrolytes. The pH was adjusted with NaOH or  $\text{H}_3\text{PO}_4$ . Stock solutions of all compounds were stored at 4 °C to avoid decomposition. Solutions were sonicated and purged with purified nitrogen and the temperature was kept at  $25 \pm 0.2$  °C.

To use this electrode it was necessary to activate its surface. For this purpose, several methods were tried, namely, polishing with alumina powder, sonication, activation with sulfochromic mixture, etc. The treatment selected for the electrode, made before each measurement, was the following: washing with distilled water, putting the electrode into a sulfochromic mixture for 30 s, washing with distilled water, polishing with 0.3  $\mu\text{m}$  alumina powder and 0.05  $\mu\text{m}$  alumina powder, sonication for 2 min in distilled water, washing with distilled water, and drying with soft paper. Under such conditions measurements were highly reproducible.

To maintain the activity of  $\text{NAD}^+$ , all buffer pHs must be in the range of 5–7. Tris/NaCl (pH 7) was a better choice than the same pH phosphate for a sensitive GC electrode response. In NaCl (0.01 mol/L) / Tris (0.005 mol/L) buffer at pH 7, peak currents was invariable. The potential range used for  $\text{NAD}^+$  analog detection was -0.4 to -1.4 V, which was the most suitable (small peak current changes). The scan rate was 0.1 V/s.

Cyclic voltammogram for determination of dynamic constants was performed with a glassy carbon electrode vs. SCE in supporting electrolyte (0.01 mol/L NaCl / 0.005 mol/L Tris, pH 7). The response to  $2 \times 10^{-3}$  mol/L  $\text{NAD}^+$  analogs and corresponding compounds were measured in 10 mL of supporting electrolyte at  $298 \pm 0.2$  °C under a nitrogen atmosphere.

The cyclic voltammogram for pH dependence of **4h** was performed in 1 mol/L phosphate buffer at different pHs (pH 4–9) containing  $2 \times 10^{-3}$  mol/L **4h**.

# On the microwave-assisted synthesis of acylphenothiazine derivatives — Experiment versus theory synergism

**Luiza Gaina, Dan Porumb, Ioan Silaghi-Dumitrescu, Castelia Cristea, and Luminita Silaghi-Dumitrescu**

**Abstract:** The microwave-assisted synthesis of a series of acylphenothiazine derivatives is described. 10*H*-Phenothiazine-3-carbaldehyde derivatives were obtained in moderate yields by the Duff formylation reaction, and 10-acetyl-phenothiazine derivatives were obtained in excellent yields by acetylating phenothiazine derivatives with acetic anhydride. A theoretical explanation for the chemoselectivity and regioselectivity of these acylation reactions applied to phenothiazine substrates was attempted by molecular-modeling analyses based on molecular mechanics, and semi-empirical and DFT calculations.

**Key words:** phenothiazine, microwave-assisted organic synthesis (MAOS), Duff formylation, acetylation, DFT calculations, electrostatic potential.

**Résumé :** On décrit la synthèse assistée par des microondes d'une série de dérivés de l'acylphénothiazine. On a obtenu le 10*H*-phénothiazine-3-carbaldéhyde avec des rendements modérés en faisant appel à une réaction de formylation de Duff alors que les dérivés de la 10-acétylphénothiazine ont été obtenus avec d'excellents rendements par acétylation des dérivés de la phénothiazine à l'aide d'anhydride acétique. On a essayé de trouver une explication théorique de la chimiosélectivité et de la régiosélectivité de ces réactions d'acylation appliquées à des substrats phénothiazines en faisant appel à des analyses de modelages moléculaires basés sur des calculs de mécanique moléculaire, semi-empiriques ou des calculs basés sur la théorie de la fonctionnelle de densité.

**Mots-clés :** phénothiazine, synthèses organiques assistées par des microondes (SOAM), formylation de Duff, acétylation, calculs basés sur la théorie de la fonctionnelle de densité (TFD), potentiel électrostatique.

## Introduction

The increased popularity of the microwave-assisted organic synthesis (MAOS) technique in chemical synthesis on a laboratory scale is based on particularly efficient heating processes which afford shorter reaction times and offer the possibility of rapid optimization of the reaction conditions. An increasing number of published papers, several books,<sup>1,2</sup> and review articles show that almost all conventionally heated reactions, including synthesis and functionalization of heterocyclic compounds, were performed using this technique.<sup>3,4,5</sup> Since 1986, when Gedye<sup>6</sup> and Giguere<sup>7</sup> carried out the first reported organic syntheses using sealed vessels heated in domestic microwave ovens, several methods have been developed for the preparation of samples (with or without solvent) in both pressurized or open vessel systems; meanwhile dedicated multimode or monomode microwave reactors have been designed. Phenothiazine de-

rivatives were obtained by microwave-assisted thiation of diarylamines in reactions of neat reactants or adsorbed onto inorganic supports such as alumina and bentonite,<sup>8,9</sup> and in water as a solvent.<sup>10</sup> Chalcones containing phenothiazine units were successfully synthesized by microwave-assisted condensation of (hetero)aromatic carbonyl derivatives.<sup>11</sup>

One aim of this work was to optimize the microwave-assisted reaction conditions, as an eco-friendly approach for the synthesis of acyl-phenothiazine derivatives. These derivatives might prove to be useful substrates in the formation of coupled heterocyclic systems, by forming new C=C bonds in condensation reactions. Suitable substituted phenothiazine derivatives are candidates for developing potentially interesting organic solid-state properties (such as unconventional physical, nonlinear optical, magnetic, and (or) electrical properties), based on the well-known electron donor effect of the phenothiazine nucleus characterized by low and highly reversible first oxidation potential and a pronounced tendency to form stable cation-radicals.<sup>12</sup> Furthermore, when the 10*H*-phenothiazine unit appears unsubstituted at the heterocyclic nitrogen atom, the cation-radical formed by single-electron oxidation may be involved in protolytic equilibria as well, thus generating the isoelectronic conjugate base, the neutral radical.<sup>13–15</sup> Potential new materials may be obtained using such redox-active and pH-sensitive heterocyclic building blocks.

## Experimental techniques

To ensure highly reproducible reaction conditions, the experimental technique employed for the microwave-assisted syntheses of acylphenothiazine derivatives described below is based on microwave power processing of materials using a microwave instrument Synthos 3000; this system provides multi-mode heating in sealed vessels equipped with built-in magnetic stirrer, pressure sensors, and internal temperature measurement. The instrument ensures cooling mechanisms, online power, and temperature control using the feedback from IR thermography. Software operation provides high-precision reaction control.

## Results and discussion

The chemical reactivity of phenothiazine towards electrophilic substitution was demonstrated in the preparation of numerous examples of N- or C-substituted derivatives. Chemical syntheses of acylphenothiazine derivatives were previously performed under conventional heating techniques which required long reaction times and usually generated mixtures of constitutional isomers. Although phenothiazine carbaldehydes were obtained by Vilsmeier formylation<sup>16</sup> and Bergman formylation<sup>17</sup> of *N*-alkyl-phenothiazine derivatives, this method is inappropriate for the C-formylation of 10*H*-phenothiazine because of the formation of *N*-formyl-phenothiazine derivatives in competitive reactions. We wish to report here a direct and C-regioselective formylation of 10*H*-phenothiazine substrates, based on the Duff reaction,<sup>18</sup> as the only reaction strategy generating good yields of 10*H*-phenothiazin-3-yl-carbaldehydes. Our promising results obtained by the microwave-assisted Duff formylation of unsubstituted 10*H*-phenothiazine<sup>11</sup> encouraged us to continue to apply this mild formylation reaction to several other substrates such as methyl-, halogeno-, and trifluoromethyl-10*H*-phenothiazine.

### Microwave-assisted synthesis of 10*H*-phenothiazine-3-carbaldehyde derivatives

The microwave-assisted synthesis of 3-formyl-10*H*-phenothiazine derivatives was performed in the resonance cavity of a Synthos 3000 instrument by multimode microwave irradiation in pressurized systems (sealed quartz vessels) using acetic acid, a polar solvent which ensures a medium absorption efficiency and heating rate ( $\tan\delta = 0.174$ , dielectric loss  $\epsilon'' = 1.079$ ).<sup>19</sup>

3-Formyl-10*H*-phenothiazine (**1**) was synthesized in moderate yields by the microwave-assisted reaction of 10*H*-phenothiazine with urotropine in acetic acid solution. The same regioselectivity for substitution in position 3 of the heterocyclic substrate was observed in the microwave-assisted Duff formylation of some alkyl-substituted 10*H*-phenothiazine derivatives such as 3-methyl-phenothiazine, 10-methyl-phenothiazine, and 1,6-bis-(phenothiazin-10-yl)-hexane (Scheme 1).

The microwave-assisted Duff formylation reactions of some 2-substituted phenothiazine derivatives were also performed. As shown in Scheme 2, different carbaldehyde regioisomers may be formed according to the influence exerted by the substituent.

Electron-withdrawing substituents such as chlorine or tri-

Scheme 1.

fluoromethyl group attached in position 2 of the phenothiazine substrate does not reduce the reactivity for electrophilic aromatic substitution in position 3, so that 3-formyl- and 7-formyl-phenothiazine derivatives were obtained. When 2-chlorophenothiazine was subjected to the Duff formylation reaction, the two monoformyl derivatives 2-chloro-7-formyl-phenothiazine (**5a**) and 2-chloro-3-formylphenothiazine (**5b**) were obtained in 1.5:1 ratio.

2-Trifluoromethyl-phenothiazine generated the 3,7-di-formyl-2-trifluoromethylphenothiazine (**6**) as the main reaction product, in moderate yields.

The reaction conditions employed for these microwave-assisted syntheses (reaction temperature, reaction time, and ramp time to achieve the prescribed temperature) are shown in Table 1. Temperature-controlled experiments in the temperature range 150–190 °C show enhanced reactivity of unsubstituted phenothiazine as compared to substituted derivatives. Similar reaction conditions (time, temperature) were required for the formylation of alkyl-, 2-chloro-, and 2-trifluoromethyl-phenothiazine derivatives. Despite the alkyl chain length or its position in the substrate, mono formyl-derivatives were isolated, even in the case of 1,6-bis-(phenothiazin-10yl)-hexane which contains two equivalent phenothiazine units. Good yields of diformyl-phenothiazine derivative were obtained in the formylation of 2-trifluoromethyl-phenothiazine.

The regioselectivity of this reaction was experimentally proved by the failure of the formylation reaction when 3,7-dibromo-10-methylphenothiazine was subjected to a microwave-assisted Duff formylation reaction.

The structure assignments of compounds **1–6** are supported by spectroscopic data. FTIR spectroscopy indicates the stretching vibration of N–H bond in compounds **1**, **2**, **5**, and **6**, by the absorption band situated near 3300 cm<sup>–1</sup>. The substitution in position 3 of the phenothiazine units was unambiguously assigned according to the NMR spectra. The coupling patterns of the aromatic protons observed for the <sup>1</sup>H NMR signals were assigned using the 2D homocorrelation COSY–45 spectra for each of products **1–6**. <sup>13</sup>C NMR spectra together with 2D NMR heterocorrelation spectra HMQC and HMBC afforded the complete structural assignments.

### Microwave-assisted synthesis of acetyl-10*H*-phenothiazine derivatives

Acetylation of 10*H*-phenothiazine derivatives using acetic anhydride generates different *N*-acetyl-10*H*-phenothiazine

Scheme 3.

and *C*-acetyl-10*H*-phenothiazine regioisomers according to the reaction conditions applied.<sup>20,21</sup>

The microwave-assisted acetylation of phenothiazine substrates was found to be highly chemoselective; *N*-acetylphenothiazine derivatives were obtained in almost quantitative yields. Scheme 3 presents the reactions of phenothiazine derivatives with acetic anhydride in the presence of catalytic amounts of phosphoric acid.

In the microwave-assisted acetylation of 10-methylphenothiazine, 3-acetyl-10-methylphenothiazine (**10**) was obtained in excellent yields. Table 2 summarizes the experimental conditions employed for the microwave-assisted acetylation of phenothiazine derivatives.

As expected, the less-reactive substrate in the acetylation reaction was *N*-methylphenothiazine. When longer reaction

time was allowed, 3,7-diacetyl-10-methylphenothiazine (**11**) was obtained in good yields.

Spectroscopic data support the structure assignment of acetyl-derivatives **7–11**. The recorded 300 MHz  $^1\text{H}$  NMR spectra show the diagnostic appearance of a singlet signal for the acetyl group protons situated at 2.5. Complete structural assignment for the aromatic protons and carbon atoms was performed by 2D NMR correlation spectra (COSY-45, HMQC and HMBC).

## Molecular modeling

The chemoselectivity and regioselectivity of these acylation reactions of the phenothiazine nucleus observed by experimental results were compared with theoretical data generated by DFT calculations.

The minimum energy geometry of each phenothiazine derivative employed as a substrate in acylation reactions was obtained starting with molecular mechanics optimization of the conformers generated within the Confanal module of Spartan'06,<sup>22</sup> followed by semi-empirical (PM3) and 6–31G(d) B3LYP DFT<sup>23–25</sup> calculations on all such obtained conformers. The following discussion applies to the lowest energy conformers.

Theoretical explanations for the regioselectivity of the Duff formylation reaction and the chemoselectivity of the acetylation reaction, respectively, applied to substituted phenothiazine substrates may be formulated on the basis of the electrophilic aromatic substitution reaction mechanism. The soft electrophile  $\text{H}_2\text{C}=\text{N}^+ \leftrightarrow \text{H}_2\text{C}^+-\text{N}^-$  generated by urotropine during the Duff formylation reaction may selectively attack heterocyclic carbon atoms in positions characterized by high electron density, whereas the acylium ion  $\text{H}_3\text{C}-\text{CO}^+$  generated by the acetic anhydride in acidic media is a hard electrophile and it is preferentially attached to the heterocyclic nitrogen atom. Here, we adopt the electrostatic charges derived from the electrostatic potential as an indicator of the preferred reaction site on the ring. These atomic charges given in Table 3 show the highest (negative) value on the nitrogen atom (position 10 of the heterocyclic substrate), followed by the values assigned to the carbon atoms in positions 3 and 7, for each phenothiazine substrate employed in experimental acylation reactions.

The electrostatic potential surfaces (−18 kcal/mol isovalues) for relevant alkylphenothiazine substrates are also shown in Fig. 1. In each case, it can be noticed that the region around position 3 of the substrate exhibits a relatively high area of negative electrostatic potential, thus supporting the availability of this atom to electrophilic attack, in agreement with experimental data regarding the regioselective aromatic electrophilic substitution performed by the soft electrophile (see Schemes 1 and 2). Notable is the shape of the −18 kcal/mol electrostatic potential surface for 1,6-bis(phenothiazin-10-yl)-hexane (Fig. 1b) located only on one of the phenothiazine rings suggesting that only one of the rings is subjected to a possible electrophilic attack. Indeed, experimental data show that only a monocarbaldehyde **4** is formed under the experimental conditions within this work.

The formation of a mixture of carbaldehydes **5a** and **5b** in a 1.5:1 ratio (Table 1) during the formylation of 2-chlorophenothiazine is understandable in view of the electrostatic charges (Table 3) in positions 7 (−0.213) and 3 (−0.201). The generated electrostatic potential surface (isovalue −15 kcal/mol) for 2-chloro-10*H*-phenothiazine is shown in Fig. 2b and may also suggest the slightly higher preference for the formation of **5a**. Moreover, once position 3 (or 7) is substituted, no significant negative electrostatic potential is noticed in position 7 or 3 (Fig. 2a or 2c). According to Figs. 2a and 2c further electrophilic attack is suppressed since no negative electrostatic potential in position 7 of **5a**

**Fig. 1.** Generated electrostatic potential (grayish envelope denotes negative electrostatic potential at isovalue  $-18$  kcal/mol) for (a) 10*H*-phenothiazine, (b) 1,6-bis(phenothiazin-10-yl)-hexane, (c) 10-methylphenothiazine, (d) 3-methyl-10*H*-phenothiazine.

(Fig. 2a), or in position 3 of **5b** (Fig. 2c) is displayed. Thus, the formation of a 3,7-dicarbaldehyde derivative of 2-chloro-10*H*-phenothiazine is not expected and the experimental procedures applied to the formylation of 2-chlorophenothiazine confirmed the theoretical hypothesis by leading only to monocarbaldehydes **5a** and **5b**.

In contrast, the experimental formation of 3,7-dicarbaldehyde (**6**) is supported by possible formylation of 2-trifluoromethyl-10*H*-phenothiazine-monocarbaldehyde intermediates. Note in Fig. 3 that negative electrostatic potential surfaces appear around the carbon atoms in position 7 of the 3-carbaldehyde intermediate (Fig. 3c) and in position 7 of the 7-carbaldehyde intermediate, respectively (Fig. 3b).

**Fig. 2.** Generated electrostatic potential (grayish envelope denotes negative electrostatic potential at isovalue  $-15$  kcal/mol); (a) 2-chloro-3-formyl-10*H*-phenothiazine (**5b**), (b) 2-chloro-10*H*-phenothiazine, (c) 2-chloro-7-formyl-10*H*-phenothiazine (**5a**).

## Conclusions

The Duff formylation reaction of phenothiazine derivatives appears for the moment as the only efficient alternative for obtaining new 10*H*-phenothiazine-3-carbaldehyde derivatives containing a free amino group able to participate in protolytic equilibria, as well as in redox processes characteristic for this heterocycle. The microwave-assisted Duff formylation reaction of phenothiazine derivatives is a technique which gives satisfactory experimental results affording good yields of 10*H*-phenothiazine-3-carbaldehyde derivatives.

The microwave-assisted acetylation reaction produced good to almost quantitative yields, in most of the experiments performed using phenothiazine substrates. Comparison of microwave-assisted synthesis with the conventional synthetic methods demonstrates advantages related to shorter reaction times and higher regioselectivity.

The electrostatic potential surfaces generated on the basis of 6-31G(d) B3LYP calculations support the preference for electrophilic attack and explain the regioselectivity of formylation reactions.

## Experimental section

The reactions were performed using a microwave installation Synthos 3000. Reagents from Merck were used. TLC was used to monitor the reaction progress (Merck silica gel F 254 plates). NMR spectra were recorded using a 300 MHz Bruker Avance NMR spectrometer. FTIR spectra were recorded using a Bruker Vector 22 FTIR spectrometer. Elemental analysis was carried out on a Thermo FlashEA 1112 Series instrument. The lowest-energy conformers generated

**Fig. 3.** The electrostatic potential surface (grayish envelope denotes negative electrostatic potential at isovalue  $-10$  kcal/mol); (a) 2-trifluoromethyl-10H-phenothiazine, (b) 7-formyl-2-trifluoromethyl-10H-phenothiazine, (c) 3-formyl-2-trifluoromethyl-10H-phenothiazine.

by using the MMFF force field implemented in Spartan'04 have been further fully optimized using the 6-31G(d) B3LYP hybrid DFT method.<sup>23–25</sup>

#### General procedure for microwave-assisted Duff formylation reaction of phenothiazine derivatives

The reaction mixture (5 mmol phenothiazine derivative and 7.5 mmol urotropine) dissolved in 20 mL acetic acid was introduced into the quartz reaction vessel, which was then sealed and subjected to microwave irradiation in the resonance cavity of the microwave power system. Prescribed sample temperatures were automatically monitored during the irradiation (Table 1). TLC was used to monitor the reaction progress. After irradiation, the reaction mixture was poured into water and neutralized with  $\text{Na}_2\text{CO}_3$ . Organic products were extracted in dichloromethane ( $3 \times 20$  mL). The combined organic layers were dried on anhydrous  $\text{Na}_2\text{SO}_4$  and concentrated to dryness. The product was purified by column chromatography (silica gel, toluene).

### General procedure for microwave-assisted acetylation reaction of phenothiazine derivatives

The reaction mixture (phenothiazine derivative – acetic anhydride ratio 1:10 and phosphoric acid in catalytic amounts) was introduced into the quartz reaction vessel, which was then sealed and subjected to microwave irradiation in the resonance cavity of the microwave power system. Prescribed sample temperatures were automatically monitored during the irradiation (Table 2). TLC was used to monitor the reaction progress. After irradiation, the reaction mixture was poured on ice and neutralized. The precipitate formed was filtered and thoroughly washed with water. The product was purified by recrystallization in toluene.

# Phytochemical constituents of *Cardamine diphylla*

Sabine Montaut, René S. Bleeker, and Carine Jacques

**Abstract:** From the methanol extract of the *Cardamine diphylla* rhizome, methylethyl- (1), 2-methylbutyl- (2), 3-methylpentyl- (4), 3-indolylmethyl- (5), 1-methoxy-3-indolylmethyl- (6), 4-methoxy-3-indolylmethyl- (7) glucosinolates, and desulfo-2-methylbutylglucosinolate (3) were isolated. The structure elucidation of the compounds was performed by spectroscopic methods. The toxicity on brine shrimp larvae of the methanol extract of the *C. diphylla* rhizome was evaluated. In addition, the free-radical-scavenging activity of the crude extract was carried out by the 1,1-diphenyl-2-picrylhydrazyl (DPPH) assay.

**Key words:** Brassicaceae, *Cardamine diphylla*, aliphatic glucosinolates, indole glucosinolates, desulfoglucosinolate, *Artemia salina*, toxicity, free-radical-scavenging activity, 1,1-diphenyl-2-picrylhydrazyl (DPPH).

**Résumé :** À partir de l'extrait méthanolique du rhizome de *Cardamine diphylla*, le méthyléthyl- (1), le 2-méthylbutyl- (2), le 3-méthylpentyl- (4), le 3-indolylméthyl- (5), le 1-méthoxy-3-indolylméthyl- (6), le 4-méthoxy-3-indolylméthyl- (7) glucosinolates et le désulfo-2-méthylbutylglucosinolate (3) ont été isolés. L'élucidation de la structure des composés a été réalisée au moyen de méthodes spectroscopiques. La toxicité sur les larves de crevettes *Artémia*, de l'extrait méthanolique du rhizome de *C. diphylla*, a été évaluée. De plus, l'activité de piégeage de radicaux libres sur l'extrait brut a été réalisée avec le test au 1,1-diphényl-2-picrylhydrazyl (DPPH).

**Mots-clés :** Brassicaceae, *Cardamine diphylla*, glucosinolates aliphatiques, glucosinolates indoliques, désulfoglucosinolate, *Artemia salina*, toxicité, activité de piégeur de radicaux libres, 1,1-diphényl-2-picrylhydrazyl (DPPH).

## Introduction

*Cardamine diphylla* (Michx.) A. Wood (Brassicaceae) (syn. *Dentaria diphylla* Michx.) is a wild endemic perennial plant found in Canada (New Brunswick, Nova Scotia, Quebec, and Ontario) and in the United States of America (from Michigan to Kentucky, South Carolina to Wisconsin, Tennessee, and Pennsylvania).<sup>1</sup> This uncommon species grows in fresh to dry and sandy to loamy tolerant hardwood stands. It can also be found in moist, clayey, intolerant, mixed wood stands.<sup>2</sup> *C. diphylla* has a long root that is all in one piece and often branched. A stem with two stalked and opposite leaves grows from the root. The white flowers are followed by long upright seed pods.<sup>2</sup> This plant is commonly referred to as toothwort, crinkleroot, and pepper-root, due to the pleasant, pungent taste of the rhizome.<sup>2</sup> The North American aboriginal people ate the roots raw or cooked. The roots were used for food and medicine, and in spring, the whole plant was used for medicine.<sup>3</sup> *C. diphylla* was of great medicinal importance for several North American First Nations. For example, the Algonquin gave an infusion of the plant to children with fevers, the Cherokee gargled an infusion of the root to aid sore throats, the Delaware used an infusion of the root as a stomach remedy and as a venereal aid when combined with other plants, and the Iroquois used an infusion of

the plant as a pulmonary aid for chest pains and also as a remedy for the first stages of tuberculosis.<sup>3</sup>

Only one previous phytochemical study has been conducted on *C. diphylla*.<sup>4</sup> During this investigation, the gas chromatography (GC) analysis of the hydrolyzed products of the compounds extracted from the rhizome, shoot, and leaf showed the presence of methylethyl-, 2-butyl-, and 2-methylbutyl isothiocyanates. These assignments were confirmed by comparison with authentic standards. This information suggested that the plant contained methylethyl- (1), 2-butyl-, and 2-methylbutyl glucosinolates (GLs) (2) (Fig. 1).

GLs are plant secondary metabolites, whose general structure consists of a  $\beta$ -D-thioglucose group with a sulfonated oxime moiety and a variable side chain derived from amino acids.<sup>5</sup> Aliphatic GLs are mainly derived from methionine, alanine, leucine, or valine. Indolic GLs are derived from tryptophan.<sup>6</sup> GLs can be hydrolyzed, by the plant enzyme myrosinase (thioglucoside glucohydrolase, EC 3.2.3.147), during cell damage, to produce isothiocyanates, nitriles, epithionitriles, oxazolidine-2-thiones, and thiocyanates.<sup>7</sup> The hydrolyzed products possess several different biological activities and in particular health-promoting effects.<sup>8</sup>

As part of our continued interest in the chemistry of the Brassicaceae, we initiated an investigation on the phytochemical content of the *C. diphylla* rhizome, probing the plant crude extract for some biological activities. This work describes the isolation and elucidation of the structure of two new intact GLs and one new desulfoGL together with four known GLs from the methanol extract of the *C. diphylla* rhizome. Furthermore, we present the results of the toxicity of the methanol extract on brine shrimp larvae and the free-radical-scavenging activity on 1,1-diphenyl-2-picrylhydrazyl (DPPH).

## Results and discussion

The investigation of the methanol extract of the rhizome of *C. diphylla* led to the isolation and identification of seven compounds (See the Materials and methods section).

Compound **1** was attributed to methylethylGL or isopropylGL or glucoputranjivin (**1**) (Fig. 1) by comparison of spectroscopic data (Tables 1 and 2) with published data.<sup>9</sup> The presence of compound **1** was expected because the methylthylisothiocyanate has already been detected, in this plant by GC, by Feeny and Rosenberry.<sup>4</sup> In our study, we have shown for the first time the presence of the intact GL.

Compound **2** displayed a UV spectrum characteristic of a nonaromatic compound with a  $\lambda_{\max}$  at 225 nm. From the high-resolution mass spectrum, the molecular formula C<sub>12</sub>H<sub>22</sub>NO<sub>9</sub>S<sub>2</sub> was established. FTIR absorption bands were found at 3391 (OH), 2964 (CH), 1652 (CN), 1054 (CO), 877 (sulfonic acid), and 617 (CS) cm<sup>-1</sup>. The <sup>1</sup>H NMR spectral data were indicative of the presence of two methyl groups ( $\delta_{\text{H}}$  0.85 and 0.91 ppm), two CH<sub>2</sub> groups  $\alpha$  to a stereocenter, each giving an AB coupling system ( $\delta_{\text{H}}$  A 2.47, B 2.18 and A 1.35, B 1.24 ppm) and one CH group ( $\delta_{\text{H}}$  1.86 ppm). These signals indicated that **2** possessed a branched aliphatic chain. In addition, signals attributable to a glucose unit were observed (Table 1). The doublet of the anomeric proton, H-1', at 4.57 ppm, with a coupling constant of 10.2 Hz, was assigned to a  $\beta$ -linked glucopyranosyl moiety.<sup>10</sup> The assignment of carbons and protons, achieved

by HMBC and HMQC 2D shift correlations, led us to propose that compound **2** was 2-methylbutylGL (Fig. 1). The presence of this GL was also expected because Feeny and Rosenberry<sup>4</sup> had already detected 2-methylbutylisothiocyanate, by GC, in this plant. This is the first time that the intact GL has been isolated from *C. diphylla*. In addition, we report for the first time the spectroscopic data of this intact GL.

The UV and FTIR spectroscopic data obtained for compound **3** were similar to that observed for compound **2**, which indicated that they had similar structures. The high-resolution mass spectrum suggested that the molecular formula was C<sub>12</sub>H<sub>22</sub>NO<sub>6</sub>S. The difference between the masses of **2** and **3** was 80 amu, which was consistent with **3** being the desulfo-2-methylbutylGL. As in the case of **2**, the <sup>1</sup>H NMR spectrum exhibited the presence of two methyl groups ( $\delta_{\text{H}}$  0.92 and 0.95 ppm), two CH<sub>2</sub> groups  $\alpha$  to a stereocenter, each giving an AB coupling system ( $\delta_{\text{H}}$  A 2.59, B 2.41 and A 1.46, B 1.21 ppm), and one CH group ( $\delta_{\text{H}}$  1.87 ppm). These signals indicated that **3** possessed a branched aliphatic chain. In addition, signals attributable to a glucose unit were observed (Table 1).<sup>10</sup> The coupling constant of 9.8 Hz determined from the doublet of the anomeric proton, H-1', at 4.98 ppm, was indicative of a  $\beta$ -linked glucopyranosyl moiety.<sup>10</sup> Support for **3** being a desulfoGL came from the <sup>13</sup>C NMR spectrum. The chemical shifts for the C-1 of desulfoGLs reported in the literature have been found between 155.3 to 156.3 ppm.<sup>11</sup> We observed a  $\delta_{\text{C}}$  at 156.0 ppm (Table 2), which was in this range. The assignment of carbons and protons, using HMBC and HMQC 2D shift correlations confirmed that compound **3** was desulfo-2-methylbutylGL (Fig. 1). It is the first time that this compound has been isolated from *C. diphylla* and we report for the first time the spectroscopic data of this desulfoGL. Moreover, it is worth noting that desulfoGLs are not common naturally occurring products in plants.<sup>12</sup> In addition, this metabolite seems to be the biosynthetic precursor of 2-methylbutylGL (**2**).<sup>6</sup>

The UV spectrum and IR data of **4** indicated that the metabolite was also an aliphatic GL. From the high-resolution mass spectrum, the molecular formula C<sub>13</sub>H<sub>24</sub>NO<sub>9</sub>S<sub>2</sub> was established. The difference between the masses of **2** and **4** was 14 amu, which corresponded to one CH<sub>2</sub> group. The <sup>1</sup>H NMR spectrum exhibited the presence of two methyl groups ( $\delta_{\text{H}}$  0.78 and 0.82 ppm), three CH<sub>2</sub> groups, two of them each giving an AB coupling system because they were  $\alpha$  to a stereocenter ( $\delta_{\text{H}}$  A 1.61, B 1.46 and A 1.29, B 1.10 ppm), and one CH group ( $\delta_{\text{H}}$  1.36 ppm). These signals indicated that **4** possessed a branched aliphatic chain. In addition, signals attributable to a  $\beta$ -linked glucopyranosyl moiety (Table 1) were observed.<sup>10</sup> The assignment of carbons and protons, using HMBC and HMQC 2D shift correlations, suggested that compound **4** was 3-methylpentylGL (Fig. 1). It is the first time that this intact GL has been isolated from a plant in the *Cardamine* genus. The structure of this branched-chain GL, previously found in *Coiccyia*, *Erucas-trum*, and *Hirshfeldia* genera, was inferred from the mass and partial <sup>1</sup>H NMR spectroscopic data of the desulfo-3-methylpentylGL obtained by sulfatase treatment of native GLs in extracts.<sup>11</sup> We report for the first time all the spectroscopic data of this intact GL.

Despite the fact that Feeny and Rosenberry<sup>4</sup> detected 2-butylisothiocyanate in *C. diphylla*, which would indicate that 2-butylGL was present in the plant, we were not able to detect this GL in our extract. This may be attributed to genetic, climatic, and soil differences.

Compounds **5–7** were identified as 3-indolylmethylGL or glucobrassicin (**5**), 1-methoxy-3-indolylmethylGL or neoglucobrassicin (**6**), and 4-methoxy-3-indolylmethylGL or 4-methoxyglucobrassicin (**7**) (Fig. 1), respectively, by comparison of spectroscopic data (Tables 1 and 2) with published data for intact GLs<sup>13,14</sup> and desulfoGLs.<sup>15</sup> Desulfo **5** and **7** have been detected previously in 10–15 day-old seedlings of *C. chenopodiifolia* Pers. by HPLC analysis of desulfoGLs.<sup>16</sup> In addition, desulfo **7** has been detected in leaves of *C. amara* L. by HPLC and LC–MS analysis of desulfoGLs.<sup>17</sup> Nevertheless, it is the first time that the intact GLs **5–7** were isolated from the *Cardamine* genus. We report for the first time the <sup>13</sup>C NMR, IR, and optical rotation data of intact **6** and the <sup>13</sup>C NMR and IR data of intact **7**. The occurrence of **5–7** in *C. diphylla* is very significant because **5** and the mixture of **5–7** have been shown to induce an increase in the CYP1A protein (phase I enzyme involved in detoxification of chemical carcinogens) levels and activities in rats.<sup>18</sup> However, no study has probed the potential of aliphatic GLs for health benefits.

The brine shrimp lethality test showed that the crude ex-

tract of *C. diphylla* was inactive against *Artemia salina* larvae at the tested concentrations (10, 100, and 1000 ppm).

The half-maximal scavenging concentration, SC<sub>50</sub>, of the methanolic crude extract of *C. diphylla*, in the DPPH assay, was 766 µg/mL (±3 µg/mL). The extract did not seem to exhibit strong free-radical-scavenging capabilities compared to ascorbic acid that showed a half-maximal scavenging concentration, SC<sub>50</sub>, of 7 µg/mL (±2 µg/mL) under our experimental conditions.

Bioassays on the effects of *C. diphylla* crude extract on phase I and phase II enzymes should be investigated to evaluate the potential effect of this wild crucifer in cancer chemoprevention.

## Materials and methods

### General experimental procedures

All solvents were ACS (American Chemical Society) grade and used as such, except for CHCl<sub>3</sub>, which was redistilled. All deuterated solvents were purchased from Cambridge Isotopes Laboratories, Inc. (Andover, MA). DMSO (dimethyl sulfoxide), ascorbic acid (reagent grade), and DPPH were purchased from Sigma-Aldrich (Oakville, ON). Formic acid was purchased from BDH (Toronto, ON). HPLC-grade MeOH, Et<sub>3</sub>N (reagent grade), and thymol were purchased from Fisher Scientific (Whitby, ON). HPLC-

<sup>a</sup>150 MHz.<sup>b</sup>125 MHz.<sup>c</sup>Superimposable.

grade  $\text{H}_2\text{O}$  was generated in the laboratory through a Nanopure Diamond Ultrapure water system by Barnstead (Dubuque, IA). Kieselgel 60 F254 analytical TLC aluminum sheets were purchased from EM Science (Gibbstown, NJ); compounds were visualized under UV light and by dipping the plates in sulfuric acid thymol solution containing 1% (w/v) thymol, 10% (v/v)  $\text{H}_2\text{SO}_4$ , and EtOH (95%), followed by heating. Preparative TLC was performed on precoated 20 cm  $\times$  20 cm silica gel 60 (0.5 mm thickness, Merck) plates. Flash column chromatography (FCC) was carried out using 70–230 mesh 60 Å normal phase silica gel (Sigma-Aldrich). Sephadex<sup>®</sup> LH-20 was purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). C-18 silica gel cartridges (Mega Bond Elut<sup>®</sup> Flash, 10 g sorbent mass, 60 mL volume) were obtained from Varian, Inc. (Mississauga, ON). LC-MS analysis was performed by injecting a 20  $\mu\text{L}$  aliquot of the solution of crude extract or fraction into an Agilent Technologies HP 1100 (New Castle, DE) high-performance liquid chromatograph equipped with a quaternary pump, automatic injector, diode-array detector (wavelength range 190–600 nm), degasser, and a Hypersil ODS column (5  $\mu\text{m}$ , 4.6 mm  $\times$  200 mm). The two mobile phase solvents, MeOH and  $\text{H}_2\text{O}$ , were prepared with 0.15%  $\text{Et}_3\text{N}$  and 0.18%  $\text{HCO}_2\text{H}$ , added as ion-pairing reagents. Both solutions were filtered using 0.45  $\mu\text{m}$  nylon membranes. The initial mobile phase was 100% HPLC-grade  $\text{H}_2\text{O}$ . At 10 min, the mobile

phase was switched to a linear gradient of 100%  $\text{H}_2\text{O}$  to 100% MeOH over 60 min. After each run, the initial mobile phase conditions were set and the system was allowed to equilibrate. The flow rate was kept constant at 1 mL/min. The column temperature was held at room temperature.<sup>19</sup> The HPLC was interfaced to an Agilent model 6120 mass spectrometer (Toronto, ON) with a Chemstation data system LC-MSD B.03.01. The electrospray interface was a standard ES source operating with a capillary voltage of 4 kV and temperature of 350 °C. The system was operated in the negative and positive ion electrospray modes. Nitrogen was used as nebulizing and drying gas at a flow rate of 10 L/min (35 psig). The mass spectrometer was programmed to perform full scans between  $m/z$  100 and 1000 amu. Lyophilization was done in a Labconco Freezone 12 freeze dryer system. UV spectra were determined on a Biochrom Ultraspec 2100 pro UV–visible spectrophotometer (Cambridge, England). The specific rotation  $[\alpha]_D$  was measured with a Rudolph Research Corporation Autopol<sup>®</sup> II automatic polarimeter (Flanders, NJ), at ambient temperature, using a 20 cm path length cell. The specific rotation is expressed in units of  $10^{-1}$  deg  $\text{cm}^2 \text{g}^{-1}$  and the concentration ( $c$ ) in g/100 mL. Infrared spectra were recorded with a PerkinElmer Paragon 1000PC IR spectrometer (Waltham, Massachusetts, USA) using KBr (VWR, Mississauga, ON) disks. NMR spectra were recorded on a Bruker Avance

spectrometer at 600 MHz ( $^1\text{H}$ ) and 150 MHz ( $^{13}\text{C}$ ) at the Saskatchewan Structural Science Centre (Saskatoon, Canada) or on a Bruker DRX 500 spectrometer at 500 MHz ( $^1\text{H}$ ) and 125 MHz ( $^{13}\text{C}$ ) at Laurentian University (Sudbury, Canada);  $\delta$  values were referenced to  $\text{D}_2\text{O}$  at 4.80 ppm. HR-ESI-MS measurements were recorded using an API Qstar XL mass spectrometer at the Saskatchewan Structural Science Centre (Saskatoon, Canada). The measurements of free-radical-scavenging ability were done on a Biotek Powerwave XS and the data was interpreted using KC (Keneticalc. for Windows) 3.4 Rev. 21.

### Plant material

Fresh rhizome of *C. diphylla* was obtained from Semences et plantes internationales (Cantley, QC). A voucher specimen (number 21024) was deposited at the Department of Biology Herbarium at Laurentian University (Sudbury, Canada).

### Extraction and isolation

Freeze-dried rhizomes (431 g) were frozen in liquid  $\text{N}_2$ , ground in a mortar, and immediately extracted three times with MeOH (1.2 L for the first extraction, 0.8 L for the other extractions) for 30 min. The methanolic solution was filtered and concentrated to dryness (49.4 g). This extract was dissolved in  $\text{H}_2\text{O}$  (600 mL) and submitted to liquid-liquid extractions with solvents of increasing polarity, i.e.,  $\text{CHCl}_3$ , EtOAc, and BuOH. Each organic layer was concentrated ( $\text{CHCl}_3$  fraction 2.3 g, EtOAc fraction 1.1 g, and BuOH fraction 6.4 g), and the aqueous layer was lyophilized (37.5 g). The BuOH was separated by FCC column 1 (normal phase, gradient  $\text{CHCl}_3$ -MeOH, 8:2 and 7:3 v/v, 20 mL fractions). Fractions 27 to 130, obtained from the FCC column 1, were combined (2.3 g) and fractionated on a Sephadex LH-20 column 1 ( $\text{H}_2\text{O}$ -MeOH, 100:0 and 0:100 v/v, 5 mL fractions). Fractions 3 to 5, obtained from the Sephadex LH-20 column 1, were combined (2.1 g) and submitted to a FCC column 2 (normal phase, gradient acetone-MeOH, 95:5 and 90:10, v/v, 15 mL fractions). Fractions 1 to 12, from the FCC column 2, were combined (80 mg) and submitted to solid-phase separation 1 (C18 cartridge,  $\text{H}_2\text{O}$ -MeOH, 100:0 and 0:100 v/v, 3 mL fractions) yielding compound **1** (3.7 mg,  $8.6 \times 10^{-4}$  % of dry weight) in fractions 6 and 7. The combined fractions 11 to 54 (30 mg) were submitted to preparative TLC ( $\text{CHCl}_3$ -MeOH- $\text{H}_2\text{O}$ , 65:45:10, two successive migrations) yielding compound **3** (3.7 mg,  $8.6 \times 10^{-4}$  % of dry weight). The combined fractions 25 to 102, obtained from FCC column 2, submitted to solid-phase separation 2 (C18 cartridge,  $\text{H}_2\text{O}$ -MeOH, 100:0 and 0:100 v/v, 3 mL fractions) yielded compound **2** (26.1 mg,  $6.0 \times 10^{-3}$  % of dry weight) in fractions 12 to 15. Fractions 6 and 7, obtained from the Sephadex LH-20 column 1, were combined (110 mg) and submitted to solid-phase separation 3 (C18 cartridge,  $\text{H}_2\text{O}$ -MeOH, 100:0 and 0:100 v/v, 5 mL fractions). Fractions 33 to 58, obtained from the solid-phase separation 3, were combined (48 mg) and submitted to preparative TLC ( $\text{CHCl}_3$ -MeOH- $\text{H}_2\text{O}$ , 65:45:10) yielding **5** (20.4 mg,  $4.7 \times 10^{-3}$  % of dry weight) after filtration. The combined fractions 59 to 73, obtained from the solid-phase separation 3, yielded compound **4** (5.5 mg,  $1.3 \times 10^{-3}$  % of dry weight). The combined fractions 74 to 78 (28.1 mg), ob-

tained from the solid-phase separation 3, were submitted to preparative TLC ( $\text{CHCl}_3$ -MeOH- $\text{H}_2\text{O}$ , 65:45:10) and yielded compound **6** (3.2 mg,  $7.4 \times 10^{-4}$  % of dry weight) and compound **7** (5.3 mg,  $1.2 \times 10^{-3}$  % of dry weight).

#### 1-Methylethylglucosinolate (1)

White, amorphous powder. HPLC  $t_R$  = 17.5 min.  $[\alpha]_D^{22}$  -115.4 (c 0.052, MeOH). UV (MeOH)  $\lambda_{\text{max}}$  (nm, log  $\epsilon$ ): 225 (3.6). FTIR (KBr,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3412, 2923, 1738, 1628, 1448, 1276, 1089, 1059, 869, 790, 630. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 600 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 150 MHz) data see Table 2. HR-ESI-MS  $m/z$  calcd. for  $\text{C}_{10}\text{H}_{18}\text{NO}_9\text{S}_2$ : 360.0423; found: 360.0427  $[\text{M}]^-$ .

#### 2-Methylbutylglucosinolate (2)

Yellowish, amorphous powder. HPLC  $t_R$  = 25.2 min.  $[\alpha]_D^{22}$  -20.1 (c 0.324, MeOH). UV (MeOH)  $\lambda_{\text{max}}$  (nm, log  $\epsilon$ ): 225 (3.7). FTIR (KBr,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3391, 2964, 1732, 1652, 1558, 1540, 1507, 1457, 1400, 1223, 1054, 877, 777, 617, 591. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 600 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 150 MHz) data see Table 2. HR-ESI-MS  $m/z$  calcd. for  $\text{C}_{12}\text{H}_{22}\text{NO}_9\text{S}_2$ : 388.0741; found: 388.0732  $[\text{M}]^-$ .

#### Desulfo-2-methylbutylglucosinolate (3)

Yellowish, amorphous powder. HPLC  $t_R$  = 28.8 min.  $[\alpha]_D^{22}$  -19.2 (c 0.078, MeOH). UV (MeOH)  $\lambda_{\text{max}}$  (nm, log  $\epsilon$ ): 223 (3.6). FTIR (KBr,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3378, 3008, 2932, 1572, 1458, 1416, 1046, 1016, 926, 658, 616. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 500 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 125 MHz) data see Table 2. HR-ESI-MS  $m/z$  calcd. for  $\text{C}_{12}\text{H}_{22}\text{NO}_6\text{S}$ : 308.1173; found: 308.1174  $[\text{M}]^-$ .

#### 3-Methylpentylglucosinolate (4)

Yellowish, amorphous powder. HPLC  $t_R$  = 30.2 min.  $[\alpha]_D^{22}$  -67.3 (c 0.052, MeOH). UV (MeOH)  $\lambda_{\text{max}}$  (nm, log  $\epsilon$ ): 219 (3.3). FTIR (KBr,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3393, 2929, 2858, 1725, 1648, 1467, 1089, 1042. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 600 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 150 MHz) data see Table 2. HR-ESI-MS  $m/z$  calcd. for  $\text{C}_{13}\text{H}_{24}\text{NO}_9\text{S}_2$ : 402.0898; found: 402.0890  $[\text{M}]^-$ .

#### 3-Indolylmethylglucosinolate (5)

Yellowish, amorphous powder. HPLC  $t_R$  = 26.0 min.  $[\alpha]_D^{22}$  -36.8 (c 0.204, MeOH). UV (MeOH)  $\lambda_{\text{max}}$  (nm, log  $\epsilon$ ): 221 (4.4), 274 (3.6). FTIR (KBr,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3381, 2964, 2922, 1671, 1614, 1459, 1282, 1233, 1099, 1056, 802, 731, 604. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 600 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 150 MHz) data see Table 2. HR-ESI-MS  $m/z$  calcd. for  $\text{C}_{16}\text{H}_{19}\text{N}_2\text{O}_9\text{S}_2$ : 447.0537; found: 447.0534  $[\text{M}]^-$ .

#### 1-Methoxy-3-indolylmethylglucosinolate (6)

Yellowish, amorphous powder. HPLC  $t_R$  = 32.6 min.  $[\alpha]_D^{22}$  -33.0 (c 0.106, MeOH). UV (MeOH)  $\lambda_{\text{max}}$  (nm, log  $\epsilon$ ): 221 (4.4), 275 (3.6). FTIR (KBr,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3369, 2952, 2927, 1710, 1509, 1456, 1270, 1058, 953, 876, 797, 743, 693, 633. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 500 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 125 MHz) data see Table 2. HR-ESI-MS  $m/z$  calcd. for  $\text{C}_{12}\text{H}_{22}\text{NO}_9\text{S}_2$ : 477.0643; found: 477.0629  $[\text{M}]^-$ .

#### 4-Methoxy-3-indolylglucosinolate (7)

Yellowish, amorphous powder. HPLC  $t_R$  = 30.0 min. UV

(MeOH)  $\lambda_{\max}$  (nm): 221, 271. For  $^1\text{H}$  NMR ( $\text{D}_2\text{O}$ , 500 MHz) data see Table 1. For  $^{13}\text{C}$  NMR ( $\text{D}_2\text{O}$ , 125 MHz) data see Table 2. HR-ESI-MS  $m/z$  (calcd. for  $\text{C}_{17}\text{H}_{21}\text{N}_2\text{O}_{10}\text{S}_2$ : 477.0643; found: 477.0663  $[\text{M}]^-$ ).

### Brine shrimp lethality assay

Brine shrimp eggs were hatched, harvested, and the nauplii dispensed in a manner similar to that described by McLaughlin et al.<sup>20</sup> Several concentrations (10, 100, and 1000 ppm) of *C. diphylla* crude extract were prepared in triplicate by serial dilution using artificial seawater containing 1% DMSO. These solutions were added to live nauplii and following 24 h of drug treatment, at 22 °C, the brine shrimp lethality was measured by counting the number of dead (nonmotile) nauplii per vial. The results were obtained from three independent experiments. Seawater with 1% DMSO was used as the negative control. A positive assay was the death of all brine shrimp with 100  $\mu\text{mol/L}$  thymol.

### DPPH assay

Radical-scavenging activity was determined spectrophotometrically by reaction with DPPH radicals, as described by Gerhäuser et al.<sup>21</sup> Several concentrations (187.5, 375, 750, and 1000  $\mu\text{g/mL}$ ) of *C. diphylla* crude extract in 100% DMSO were treated with a solution of 100  $\mu\text{mol/L}$  DPPH in ethanol for 30 min at 37 °C. Scavenging activity was compared with a solvent control (0% radical-scavenging activity) and ascorbic acid (250  $\mu\text{mol/L}$  final concentration, 100% radical-scavenging activity, used as a positive control). The results were obtained from experiments run in triplicate and from three independent experiments. The half-maximal scavenging concentration,  $\text{SC}_{50}$ , was determined using the following formula:

$$[1] \quad \% \text{ scavenging activity} = \frac{(\text{negative control endpoint absorption} - \text{trial endpoint absorption}) / (\text{negative control endpoint absorption} - \text{positive control endpoint absorption})}{1}$$

### Acknowledgements

Financial support from the Natural Sciences and Engineering Research Council of Canada (Discovery grant), Laurentian University (Start-up funds, Placement Centre, Laurentian University Research Funds, and teaching assistantship and scholarship to R.B.), the Ontario Ministry of Northern Development and Mines (Summer Jobs Service Program), Canadian Foundation for Innovation (Leaders Opportunity Fund) – Ontario Research Fund is gratefully acknowledged by S.M. We also thank Dr. T.C. Tai for allowing us to use his multiplate reader, and Prof. H. Joly for her comments on the manuscript.

# Hydration of acetone in the gas phase and in water solvent

Kiyull Yang, Yih-Huang Hsieh, Chan-Kyung Kim, Hui Zhang, and Saul Wolfe

**Abstract:** In water solvent, the hydration of acetone proceeds by a cyclic (cooperative) process in which concurrent C–O bond formation and proton transfer to oxygen take place through a solvent and (or) catalyst bridge. Reactivity is determined primarily by the concentration of a reactant complex and not the barrier from this complex. This situation is reversed in the gas phase; although the concentrations of reactive complexes are much higher than in solution, the barriers are also higher and dominant in determining reactivity. Calculations of isotope effects suggest that multiple hydron transfers are synchronous in the gas phase to avoid zwitterionic transition states. In solution, such transition states are stabilized by solvation and hydron transfers can be asynchronous.

**Key words:** hydration of acetone, isotope effects, MP2/6-31+G(d)//B3LYP/6-31G(d).

**Résumé :** En solution dans l'eau, l'hydratation de l'acétone se produit par un processus cyclique (coopératif) dans lequel la formation concurrente d'une liaison C–O et d'un transfert de proton vers l'oxygène se produit avec l'aide d'un pont avec un solvant ou un catalyseur. La réactivité est déterminée principalement par la concentration d'un complexe du réactant et non par une barrière à partir de ce complexe. Cette situation est inversée en phase gazeuse; même si les concentrations des complexes réactifs sont beaucoup plus élevées que celles en solution, les barrières sont aussi plus élevées et elles sont dominantes dans la détermination de la réactivité. Des calculs d'effets isotopiques suggèrent que de multiples transferts d'hydrons sont synchrones en phase gazeuse dans le but d'éviter les états de transitions zwitterioniques. En solution, de tels états de transition sont stabilisés par la solvation et les transferts d'hydrons peuvent être asynchrones.

**Mots-clés :** hydratation de l'acétone, effets isotopiques, MP2/6-31+G(d)//B3LYP/6-31G(d).

[Traduit par la Rédaction]

We have recently reported that the neutral,<sup>1</sup> acetic acid catalyzed,<sup>2</sup> and 2-hydroxypyridine (2-pyridone)-catalyzed<sup>3</sup> hydrations of acetone in water solvent do not proceed via ionic intermediates. Instead, as seen in Fig. 1, the reactant complexes of the principal channels of these aqueous reactions, there is in each case a cyclic (cooperative) process<sup>4</sup> in which concurrent C–O bond formation and proton transfer to oxygen take place through a solvent and (or) catalyst bridge. As originally suggested by Eigen,<sup>4a</sup> this mechanism overcomes the requirement that charged species undergo continuous solvation and desolvation as they appear and disappear.

The realization that an ionic mechanism is not obligatory in water solvent seems to have consequences. For example,<sup>2</sup> “it is necessary to reexamine the dogma<sup>5–10</sup> that multistep ionic mechanisms are operative in the *low* dielectric media that exist at the active sites of hydrolytic enzymes.” It is

also necessary to reexamine the notion<sup>11</sup> that hydrolytic enzymes manifest their catalytic effect via cooperative multiple-proton-transfer reactions coupled to tautomerism<sup>12</sup> at nonpolar active sites.<sup>13</sup> In water solvent, the availability of a multiple-proton-transfer pathway and (or) the existence of a low barrier do not seem to be necessary to catalyze the hydration of acetone.

Although four protons are in flight in the neutral reaction and three in the catalyzed reactions, the aqueous barrier of the 2-pyridone-catalyzed reaction (11.97 kcal/mol) is calculated<sup>3</sup> to be only slightly higher than that of the neutral reaction (11.34 kcal/mol) and significantly higher than that of the acetic acid catalyzed reaction (8.14 kcal/mol). Nonetheless, 2-hydroxypyridine, as its tautomer 2-pyridone dihydrate, exhibits a catalytic effect ( $k_{\text{cat}}/k_{\text{neut}}$ ) of  $4 \times 10^7$ , and acetic acid exhibits a catalytic effect of  $2 \times 10^6$ .

**Fig. 2.** Structures **1a–1d**, the reactant complexes of the gas-phase hydration of acetone by one, two, three, or four water molecules. Values in parentheses are the activation energies and Gibbs energies of activation at 298 K, respectively.

**Fig. 3.** Structures **2a–2j**, the reactant complexes of the acetic acid catalyzed gas-phase hydration of acetone by one, two, or three water molecules. Values in parentheses are the activation energies and Gibbs energies of activation at 298 K, respectively.

The reason is that, in contrast to the conventional view of the origin of *enzymatic* catalysis,<sup>14</sup> reactivity in water solvent is determined primarily by the concentration of the reactant complex not the reaction barrier.

These findings raise a number of questions, including the following:

- (i) Is the action of two or more functional groups an important factor in catalysis?<sup>15</sup>

**Fig. 4.** Structures **3a–3i**, the reactant complexes of the 2-hydroxypyridine- and 2-pyridone-catalyzed gas-phase hydration of acetone by one or two water molecules. Values in parentheses are the activation energies and Gibbs energies of activation at 298 K, respectively.

**Note:** Calculated rate (M s<sup>-1</sup>) = 9.887 × 10<sup>-10</sup> ( $\Delta G^\ddagger$  = 28.92 kcal/mol). Calculated  $k_{\text{HA}}$  (M<sup>-1</sup>s<sup>-1</sup>) = 9.887 × 10<sup>-7</sup>. Calculated  $k_0$  (s<sup>-1</sup>) = 1.794 × 10<sup>-15</sup>.

(ii) Does the hydration of a carbonyl group in water differ mechanistically from that in the gas phase?<sup>16</sup>

(iii) Does the enzymatic catalysis require a medium of low dielectric constant?<sup>17</sup>

(iv) Do acetic acid and 2-hydroxypyridine catalyze the hydration of acetone in the gas phase?

These questions have led to the present work, a Gaussian 03 examination<sup>18</sup> of the gas-phase neutral, acetic acid catalyzed, and 2-hydroxypyridine/2-pyridone-catalyzed hydration of acetone. A necessary first objective was the selection of a computational strategy that would reproduce experimental gas-phase data such as the dimerization energy of water,<sup>19</sup> the dimerization energy of acetic acid,<sup>20</sup> and the tautomerization energy of 2-hydroxypyridine<sup>21</sup> (Table 1). As summarized in Table 1, this has been achieved by B3LYP/6–31G(d) optimization of geometries,<sup>22,23</sup> followed by single-point MP2/6–31+G(d) calculation of energies, which are converted to Gibbs energies at 298 K using eq. [1],

$$[1] \quad G = H - TS_{\text{vib}}$$

where  $H$  is the sum of the MP2 single-point energy and the zero-point and thermal correction energies obtained from the B3LYP/6–31G(d) frequency calculations, and  $S_{\text{vib}}$  is the vibrational entropy calculated at B3LYP/6–31G(d). With all calculations carried out at MP2/6–31+G(d)//B3LYP/6–31G(d), Fig. 2 shows the reactant complexes **1a–1d** for the neutral cooperative hydration of acetone by one, two, three or four water molecules, Fig. 3 shows the reactant complexes **2a–2j** for the acetic acid catalyzed cooperative hydration of acetone by one (**2a**), two (**2b–2d**), or three (**2e–2j**) water molecules, and Fig. 4 shows the reactant com-

**Note:** Calculated rate (M s<sup>-1</sup>) = 2.876 × 10<sup>-10</sup> ( $\Delta G^\ddagger$  = 30.48 kcal/mol). Calculated  $k_{\text{HA}}$  (M<sup>-1</sup>s<sup>-1</sup>) = 1.438 × 10<sup>-6</sup>. Calculated  $k_0$  (s<sup>-1</sup>) = 7.204 × 10<sup>-15</sup>.

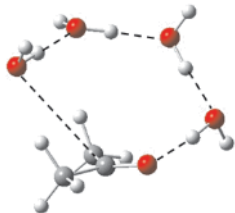

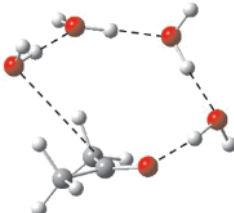

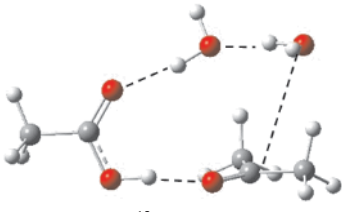

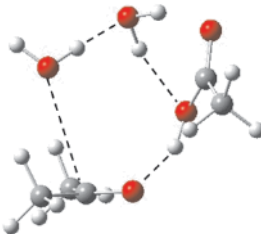

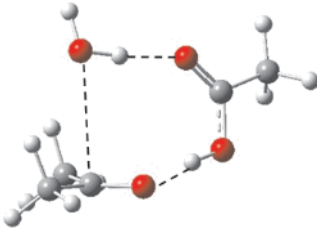

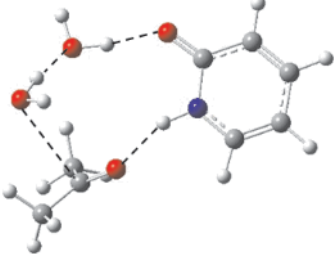

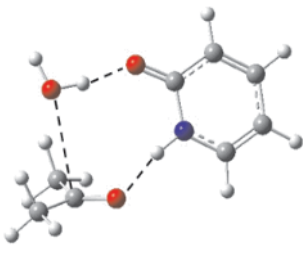

plexes **3a–3i** for the 2-hydroxypyridine (**3a–3f**) and 2-pyridone (**3g–3i**) catalyzed cooperative hydration of acetone by one (**3a, 3g**) or two (**3b–3f, 3h, and 3i**) water molecules.

On the basis of these data, Table 2 provides the kinetic analysis of the gas-phase cooperative hydration of a 1 mol/L acetone solution, and Tables 3 and 4 summarize the catalytic effects of 1 mmol/L acetic acid or 0.2 mmol/L 2-hydroxypyridine/2-pyridone on the gas-phase hydration of a 1 mol/L acetone solution.<sup>24</sup> Table 5 summarizes what we have found for the hydration of acetone in water solvent and in the gas phase at the concentrations listed above. The second column of the table lists the experimental Gibbs energies of activation in solution at 298 K. The third column shows the structures of the principal calculated reactant complex(es) in solution, the concentrations of these complexes, and the barriers from these complexes. The fourth column provides the calculated gas-phase Gibbs energies of activation (from Tables 2–4), and the fifth column shows the structures of the principal reactant complexes, the concentrations of these complexes, and the barriers from these complexes.

The principal findings of Table 5 are that *all Gibbs energies of activation are much higher in the gas phase despite the much higher gas-phase concentrations of the principal reaction channels*. In contrast to the situation in solution, the gas-phase rates are determined by the barriers, not the concentrations of the reactant complexes. The specific answers to questions (i)–(iv) are therefore as follows:

(i) In the gas-phase, as well as in solution, the presence of two or more functional groups contributes to catalysis, but only one molecule of water is required for such catalysis.

**Table 5.** Gibbs energies of activation (kcal/mol) in the gas phase and in solution.

Reaction	In solution		In the gas phase	
	$\Delta G^\ddagger^a$	Principal channel <sup>b</sup>	$\Delta G^\ddagger^b$	Principal channel <sup>b</sup>
Neutral	24.34	 1.629 × 10 <sup>-10</sup> mol/L, 11.34 kcal/mol	36.75	 2.383 × 10 <sup>-5</sup> mol/L, 31.28 kcal/mol
Acetic acid catalyzed	20.89	 3.93 × 10 <sup>-12</sup> mol/L, 7.74 kcal/mol  9.76 × 10 <sup>-12</sup> mol/L, 8.14 kcal/mol	28.92	 4.749 × 10 <sup>-6</sup> mol/L, 22.48 kcal/mol
2-HP (2-PD)-catalyzed	21.39	 4.78 × 10 <sup>-8</sup> mol/L, 11.97 kcal/mol	30.48	 2.160 × 10 <sup>-6</sup> mol/L, 23.60 kcal/mol

<sup>a</sup> Experimental result.<sup>b</sup> Calculated result.**Fig. 5.** Calculated isotope effects in the gas phase (upper numbers) and in water solvent (lower numbers). The imaginary frequencies are 1328i cm<sup>-1</sup> in the gas phase and 504i cm<sup>-1</sup> in water.

(ii) The neutral reaction is the same in the gas phase and in solution, but the catalyzed reactions require less water.

(iii) There is no evidence that enzymatic catalysis requires a medium of low dielectric constant.

(iv) When compared to the neutral reaction, acetic acid and 2-pyridone catalyze the hydration of acetone in the gas phase.

Why are the gas-phase barriers so much higher? Fig. 5, which examines the solvent isotope effects in the neutral reactions, suggests the explanation. Hydron movement is synchronous in the gas-phase reaction to avoid a high-energy zwitterionic transition state.

Such structures are stabilized in solution and the hydron of the attacking water molecule makes the dominant contribution to the transition state.

## Supplementary data

Supplementary data (the coordinates of the calculated reactant complexes and transition structures) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5298. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub\_e.shtml.

(24) Kinetic analyses for the neutral and 2HP/2PD-catalyzed hydration reactions were performed using the strategies of refs. 1b and 3. For acetic-acid catalysis, the kinetic analysis was

performed using the strategy of ref. 2, including consideration of the dimerization of acetic acid.

# Trends in the frequencies of $\nu(\text{AsO}_x\text{H}_{x-1})$ [ $x = 2-4$ ] in selected As(V)-containing compounds investigated using quantum chemical calculations

Adrian Adamescu, Holly Gray, Katherine M.E. Stewart, I.P. Hamilton, and Hind A. Al-Abadleh

**Abstract:** The application of computational chemistry to studies in geochemistry is increasingly becoming invaluable in explaining experimentally observed trends for surface interactions of pollutants with sorbents ubiquitous in the environment. We report computational results on factors that affect the force constant of  $\text{AsO}_x$  bonds in As(V)-containing compounds relevant to geochemical environments. Geometries, atomic charges, and stretching frequencies of  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moieties in these molecules were calculated using semi-empirical methods (PM3) and density functional theory (B3LYP) for both isolated (gas phase) molecules and hydrated complexes in which the molecules are surrounded by four water molecules. We found that the number of organic substituents has a relatively smaller effect on the force constant of  $\text{AsO}_x$  bonds than protonation. The increase in resonance effect with deprotonation causes As–O bond lengths to increase, and the decrease in resonance in fully deprotonated species with increasing organic substitution causes As–O bond lengths to decrease. In the absence of the resonance effect in fully protonated species, As–O bond lengths increase with more organic substituents. Also, increasing organic substitution causes the charge on the central arsenic atom to decrease. Charges on oxygen atoms in As–OH bonds are more sensitive to deprotonation than to resonance relative to other oxygen atoms in As–O bonds. As expected, frequencies of  $\nu(\text{AsO}_x)$  show an inverse relationship with As–O bond lengths upon deprotonation and organic substitution. Our results have implication for the interpretation of infrared and X-ray absorption spectra of adsorbed As(V)-containing compounds.

**Key words:** organoarsenicals, arsenate, organic oxyanions, computational chemistry, optimized geometries, infrared frequencies, AsO stretching vibration, DFT/B3LYP

**Résumé :** L'application de la chimie théorique aux études de la géochimie devient de plus en plus indispensable pour expliquer les tendances observées expérimentalement les interactions superficielles de polluants avec des sorbants omniprésents de l'environnement. Dans ce travail, on rapporte les résultats de calculs sur les facteurs qui affectent la constante de force des liaisons  $\text{AsO}_x$  dans des composés contenant de l'arsenic pentavalent, As(V), intéressant pour les environnements géochimiques. On a calculé les géométries, les charges atomiques et les fréquences d'élongation des portions  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) de ces molécules en faisant appel à des méthodes semi-empiriques (PM3) et à la théorie de la fonctionnelle de la densité (B3LYP) tant pour des molécules isolées (phase gazeuse) que pour des complexes hydratés dans lesquels les molécules sont entourées de quatre molécules d'eau. On a trouvé que, comparativement à la protonation, le nombre de substituants organiques n'a que peu d'effet sur la constante de force des liaisons  $\text{AsO}_x$ . L'augmentation de l'effet de résonance avec la déprotonation provoque une augmentation de la longueur de la liaison As–O alors que la diminution de résonance dans les espèces totalement déprotonées par une augmentation de la substitution organique cause une diminution dans les longueurs des liaisons As–O. En l'absence d'effet de résonance dans les espèces totalement protonées, les longueurs des liaisons As–O augmentent avec une augmentation du nombre de substituants organiques. De plus, une augmentation de la substitution organique provoque une diminution de la charge sur l'atome d'arsenic central. Par comparaison aux autres atomes d'oxygène dans les liaisons As–O, les charges sur les atomes d'oxygène des liaisons As–OH sont plus sensibles à la déprotonation qu'à la résonance. Tel que prévu, les fréquences  $\nu(\text{AsO}_x)$  présentent une relation inverse avec les longueurs des liaisons As–O lors d'une déprotonation ou une substitution organique. Les résultats obtenus dans ce travail ont des implications pour l'interprétation des spectres d'absorption infrarouge ou de rayons-X des composés adsorbés contenant du As(V).

## Introduction

The application of computational chemistry to studies in geochemistry has been the subject of a number of excellent reviews,<sup>1–3</sup> which highlight the usefulness of quantum chemical calculations in explaining trends observed experimentally. In general, studies in geochemistry focus on pollutant origins and impacts, and are motivated by regulations designed to lower levels of contaminants in water and soil. Hence, the fate of contaminants, whether introduced to the environment naturally or anthropomorphically, needs to be quantified through properties such as transport and bioavailability. It is well-established that the interaction of pollutants with soil particles controls these properties.<sup>4</sup> This interaction is a surface phenomenon occurring at the water/solid interface, which necessitates the utilization of surface-sensitive techniques for quantifying thermodynamics and kinetics of binding, and for obtaining structural data on geometries of surface complexes. The most commonly used techniques are attenuated total internal reflectance Fourier transform infrared (ATR-FTIR)<sup>5</sup> and extended X-ray absorption fine structure (EXAFS)<sup>6</sup> spectroscopies, which have proven to be powerful in studying surface complexes under environmentally relevant conditions. For spectroscopic results to be useful in building models for predicting transport and bioavailability of pollutants in the environment, experimental data need to be complemented with computational results. Computational results can verify the interpretation of experimental data and minimize the parameterization of fits used to extract structural information. As an example, Kubicki et al. calculated frequencies, structures, and Gibbs free energy of adsorption ( $\Delta G_{\text{ads}}$ ) of oxyanion complexes of carbon, phosphorus, sulfur, and arsenic on iron and aluminum oxide clusters.<sup>7</sup> Computational results agreed with spectral data from infrared, X-ray absorption, and binding thermodynamics experiments, suggesting that model clusters of surface complexes are useful theoretical models of real systems.

There are, however, fewer theoretical studies on the surface chemistry of organic oxyanions in general, and organoarsenicals in particular. Kubicki and co-workers pioneered the use of hybrid molecular orbital/density functional theory (MO/DFT) for calculating the surface structure of glyphosate (an organophosphorus compound) on FeOOH.<sup>8</sup> For methylated organoarsenicals, the effect of methyl substituents on the AsO force constant (and bond order) was calculated by Gründler et al.,<sup>9</sup> who found that, for the fully deprotonated anions, the force constant (as well as the bond order) increases in this order:  $\text{AsO}_4^{3-} < \text{CH}_3\text{AsO}_3^{2-} < (\text{CH}_3)_2\text{AsO}_2^-$ . They attributed the increase in force constant to increasing As–O bond polarity and decreasing degree of multiple bonding upon oxygen substitution with carbon. Vansant et al.<sup>10</sup> calculated the As–O bond lengths for  $\text{CH}_3\text{AsO}_3\text{H}^-$  and  $\text{CH}_3\text{AsO}_3^{2-}$  species to be 1.65 and 1.69 Å, respectively, and 1.71 Å for As–OH in the former species. It is important to note here that these calculations were done for isolated molecules, which do not accurately reflect the geometry of solvated molecules. Myneni et al.<sup>11</sup> have shown, using quantum chemical calculations, that increasing the number of water molecules from one to four, to simulate solvated arsenate ions, results in decreasing the As–O bond lengths. Similar results were obtained from ab initio calculations by Pye and Rudolph on the geometries of hydrated phosphate ions,

where it was observed that increasing water molecules from one to six to simulate hydration causes an overall decrease in the P–O distances.<sup>12</sup> Such changes to bond distances have consequences for the stretching frequency of the As–O and P–O bonds,  $\nu(\text{AsO}_4)$  and  $\nu(\text{PO}_4)$ .

To accurately interpret the ATR-FTIR spectra of organoarsenicals surface complexes, factors that affect the IR-active vibrational modes of the  $\text{AsO}_x$  moiety in the bulk aqueous phases of these molecules must be understood. This is because binding of organoarsenicals to metal (oxyhydr)oxides occurs via a ligand-exchange mechanism between the  $\text{AsO}_x$  moiety in these molecules and metal cations, and factors such as protonation, hydrogen bonding, and the presence of organic substituents impact the number of infrared bands observed experimentally. We recently reported the ATR-FTIR and Raman spectra of a number of As(V)-containing organoarsenicals of importance in geochemical environments in bulk solid and aqueous phases, and compared these results with those for arsenic acid ( $\text{iAs(V)}$ ,  $\text{H}_3\text{AsO}_4$ ).<sup>13</sup> These compounds include monomethylarsonic acid ( $\text{MMA(V)}$ ,  $\text{CH}_3\text{AsO}_3\text{H}_2$ ), *p*-arsanilic acid ( $\text{p-AsA(V)}$ ,  $\text{H}_2\text{NC}_6\text{H}_4\text{AsO}_3\text{H}_2$ ), and dimethylarsinic acid ( $\text{DMA(V)}$ ,  $(\text{CH}_3)_2\text{AsO}_2\text{H}$ ). We observed, from the analysis of the aqueous phase infrared spectra that increasing the number of organic substituents on the  $\text{AsO}_x$  moiety (where  $x = 2\text{--}3$ ) results in increasing the frequency of  $\nu(\text{AsO}_x)$  for completely deprotonated anions, whereas the opposite trend is observed for completely protonated molecules. We also observed that for a given As(V)-containing compound, the decrease in the protonation state with increasing pH results in red shifting the frequency of  $\nu(\text{AsO}_x)$ . These observations were explained in light of the aforementioned studies<sup>9–11</sup> on the extent of the resonance effect as a result of replacing oxygen with carbon and the decrease in the number of hydrogen atoms bonded to oxygen.

In the present study, we report results from semi-empirical PM3 and DFT calculations on the equilibrium geometries, atomic charges, and vibrational frequencies of hydrated  $\text{iAs(V)}$ ,  $\text{MMA(V)}$ ,  $\text{p-AsA(V)}$ , and  $\text{DMA(V)}$  in order of increasing organic substitution. Due to the acidic nature of the  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2\text{--}4$ ) moiety, each of these compounds can exist in multiple protonation states governed by their  $\text{pK}_a$  values.<sup>13,14</sup> Calculations were performed for these compounds in the isolated (gas phase) and hydrated (surrounded with four water molecules to simulate the first hydration sphere) clusters. The results are discussed in light of the resonance effect on calculated As–O bond lengths, atomic charges on arsenic and oxygen atoms, and frequencies of vibrations assigned to  $\nu(\text{AsO}_x)$ .

## Computational methods

Quantum chemical calculations were performed using Spartan 04 (v. 1.0.3)<sup>15</sup> for As(V)-containing compounds that include  $\text{iAs(V)}$ ,  $\text{MMA(V)}$ ,  $\text{p-AsA(V)}$ , and  $\text{DMA(V)}$ . These calculations were done on isolated and hydrated clusters. Hydration of As(V)-containing compounds was modeled by explicitly adding four water molecules. Calculations were also performed using Spartan 08 on fully protonated and deprotonated clusters to implicitly solvate them through a polarizable continuum model that simulates an aqueous environment. The water molecules were added one at a time,

and the geometry of the complex was optimized at each addition. All nuclear coordinates in the complex were relaxed to minimum potential-energy positions with no constraints on symmetry or structural parameters. Semi-empirical calculations using the PM3 method<sup>16</sup> were performed first to calculate the equilibrium geometry and vibrational frequencies. This method was used by Myneni et al.<sup>11</sup> for modeling iAs(V) clusters. We show below that this method overestimates vibrational frequencies when compared with experimental values. Hence, coordinates from these calculations were used as input for DFT calculations, which (as noted earlier) produced accurate results for oxyanion surface complexes. These calculations were performed with the B3LYP functional<sup>17,18</sup> using the 6-31G\* basis set,<sup>19</sup> and were followed by calculations using the larger 6-311+G\*\* basis set.<sup>20</sup> The latter basis set has diffuse functions on heavy atoms but not hydrogen. Throughout this paper, results reported are those for the larger basis set unless noted otherwise. After ensuring that all vibrational frequencies were real, adjustments to the optimized structure were made (typically by rotating one or more water molecules), and the resulting structure was re-optimized. This process was repeated until we were reasonably sure that we had found the minimum-energy equilibrium geometry.

Many methods have been proposed for calculating atomic charges, of which the best known is probably Mulliken population analysis.<sup>19</sup> However, it is well-known that Mulliken atomic charges are strongly basis-set-dependent. For greater consistency between the 6-31G\* and 6-311+G\*\* basis sets, we therefore use natural population analysis ( $Q_{\text{NPA}}$ ),<sup>21</sup> which has been shown to resolve largely the basis-set-dependence problem. As expected, results for  $Q_{\text{NPA}}$  from DFT calculations are similar with the two basis sets, 6-31G\* and 6-311+G\*\*, and values reported are those for the larger basis set.

Calculated vibrational frequencies are usually scaled by a factor,  $F$ , to correct for anharmonicity.<sup>21</sup> While a single scaling factor can typically be used for hydrocarbon vibrations, several authors have concluded that for metal systems, independent scaling factors should be used for each vibration involving the metal atom.<sup>22–24</sup> Scaling factors used here to correct harmonic frequencies corresponding to  $\nu(\text{AsO}_x)$  are  $F = 1.0199$  in iAs(V), and  $F = 0.9787$  in organoarsenicals MMA(V),  $p$ -AsA(V), and DMA(V). The former factor was used by Jensen et al.<sup>23</sup> to correct  $\nu(\text{As–O–As})$  in tetraarsenic

hexoxide ( $\text{As}_4\text{O}_6$ ), and the latter factor was used to correct  $\nu(\text{As=O})$  in trimethylarsine oxide  $[(\text{CH}_3)_3\text{AsO}]$ .<sup>24</sup> Kubicki et al.<sup>7</sup> used a factor of 0.96 to scale calculated frequencies for hydrated iAs(V) and iAs(III) and their surface complexes on iron and aluminum oxide clusters. These scaling factors for As(V)-containing compounds change frequency values by  $\pm 2\%$ – $4\%$ . According to Stewart and Seiler,<sup>16,25</sup> vibrational frequencies were not used in developing the PM3 method, and hence no scaling factors were used to correct frequencies from PM3 calculations.

## Results and discussion

### Equilibrium geometries of isolated and hydrated As(V)-containing compounds

Table 1 summarizes the As–O bond lengths from DFT(B3LYP) calculations on isolated As(V)-containing compounds along with values reported previously for iAs(V).<sup>10,11</sup> Analyzing trends in structural parameters for isolated species is important when discussing the effect of hydration and hydrogen bonding on these parameters for the same compounds (vide infra). Minimum-energy geometries of all protonation states of the  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moiety in each compound were calculated so that correlations could be drawn between the extent of charge delocalization (i.e., resonance) and As–O bond lengths. Bond lengths calculated for fully protonated and deprotonated species using DFT(B3LYP/6-31G\*) and a polarizable continuum model are within 0% to  $\pm 2\%$  of those calculated for the gas-phase species. Fully protonated As(V)-containing compounds have no resonance effect among the As–O bonds. For these molecules, increasing the number of organic substituents on the  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moiety slightly increased the length of the As=O<sub>1</sub> bond from 1.62 Å in  $\text{H}_3\text{AsO}_4$  to 1.64 Å in  $(\text{CH}_3)_2\text{AsO}_2\text{H}$ , and caused a more dramatic increase in the As–OH bond length from 1.76 Å in  $\text{H}_3\text{AsO}_4$  to 1.81 Å in  $(\text{CH}_3)_2\text{AsO}_2\text{H}$ . This trend may be attributed to the electron-donating abilities (to the central As atom) from methyl (in MMA and DMA) and phenyl groups (in  $p$ -AsA) causing a relative increase in electrostatic repulsion with the –OH group, hence increasing its distance from the central As atom.

Moreover, for a given isolated As(V)-containing compound, the increase in charge delocalization upon deprotona-

tion has a pronounced effect on the As–O bond lengths, i.e., As=O1 and As–OH bonds increase in length until all bond lengths become equal for the fully deprotonated species. For example, the lengths of the As=O1 and As–OH bonds in  $\text{CH}_3\text{AsO}_3\text{H}_2$  are 1.63 and 1.78 Å, which increase to 1.67 and 1.86 Å in  $\text{CH}_3\text{AsO}_3\text{H}^-$ . For  $\text{CH}_3\text{AsO}_3^{2-}$ , all As–O bonds are 1.71 Å in length. Also, bond lengths of the fully deprotonated species in each of the As(V)-containing compounds studied decrease in the following order:  $\text{AsO}_4^{3-} > \text{CH}_3\text{AsO}_3^{2-} \approx \text{H}_2\text{NC}_6\text{H}_4\text{AsO}_3^{2-} > (\text{CH}_3)_2\text{AsO}_2^-$ . This trend can be explained by the fact that charge delocalization occurs over four bonds in  $\text{AsO}_4^{3-}$  compared with three and two in  $\text{CH}_3\text{AsO}_3^{2-}$ ,  $\text{H}_2\text{NC}_6\text{H}_4\text{AsO}_3^{2-}$ , and  $(\text{CH}_3)_2\text{AsO}_2^-$ , respectively. Hence, lower degree of resonance shortens the As–O bonds with increasing organic substitution.

Since the goal of this study is to model the experimental infrared spectra of aqueous As(V)-containing compounds, explicit addition of water molecules to the isolated compounds is necessary to simulate an aqueous environment. Semi-empirical (PM3) and DFT(B3LYP) calculations were completed for all possible protonation states of the  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moiety in each As(V)-containing compound surrounded by four water molecules. Figure 1 shows energy-minimized geometries of these hydrated As(V)-containing clusters using DFT(B3LYP/6-311+G\*\*) from fully protonated (left side) to fully deprotonated (right side), and in order of increasing the number of organic substituents (top to bottom). Calculated values of the As–O bond lengths are summarized in Table 2, and also plotted as a function of the protonation state for each As(V)-containing compound in Fig. 2. Semi-empirical PM3 calculations were performed with eight water molecules for fully protonated and fully deprotonated species of each As(V)-containing compound, and results are listed in Table 2 and shown as empty circles in the left panel of Fig. 2. Bond-length values from our calculations on clusters of four  $\text{H}_2\text{O}$  molecules are close to those reported previously.<sup>11</sup> Kubicki et al.<sup>7</sup> calculated the optimized geometries of  $\text{H}_2\text{AsO}_4^-$  and  $\text{HAsO}_4^{2-}$  molecules surrounded by eight water molecules using a hybrid molecular orbital (MO/DFT) method and basis sets similar to those in our study, but the results of their calculations were not shown in the paper for comparison. Trends observed for these arsenic molecules are similar to those observed by Pye and Michels for the corresponding phosphorus molecules.<sup>26,27</sup>

Our results indicate that the four water molecules can be regarded as the first “hydration shell” through forming direct hydrogen bonds with the  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moiety in each As(V)-containing compound with  $\text{OH}\cdots\text{O}$  distances varying from 1.67 to 2.09 Å as in clusters XI and IV (Fig. 1), respectively. These hydrogen-bonding values are indicative of moderate-strength hydrogen bonds.<sup>28</sup> Table 3 lists the calculated hydrogen-bond distances in hydrated As(V)-containing clusters. Additional water molecules interact more strongly with each other and with the first “hydration shell”, with no direct interaction with the  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moiety. This might explain the insignificant change in the As–O bond lengths for clusters containing eight relative to four waters. Solid lines are shown in Fig. 2 to highlight trends in the As–O bond lengths in hydrated As(V)-containing clusters as a function of protonation

state and organic substitution, and their slopes are nearly similar using PM3 and DFT methods. These trends are also similar to those observed for isolated As(V)-containing compounds listed in Table 1 and explained earlier, namely, the increase in resonance effect with deprotonation causing As–O bonds to increase in length, and the decrease in resonance in fully deprotonated species with increasing the number of organic substituents causing As–O bonds to be shorter. The most obvious difference among As–O bond lengths for isolated and hydrated As(V)-containing compounds is the inequality observed for fully deprotonated and hydrated species. This is clearly due to the influence of hydrogen bonding between water molecules in the first hydration shell and the  $-\text{AsO}_x^{x-1}$  ( $x = 2-4$ ) moieties on charge delocalization among As–O bonds. The section below analyzes in detail the effect of protonation state and organic substitution on atomic charges in hydrated As(V)-containing compounds.

### Charge distribution in hydrated As(V)-containing compounds

To quantify the charge distribution as a function of protonation state and organic substitution, calculated charges derived from natural population analysis ( $Q_{\text{NPA}}$ ) on central arsenic atoms, oxygen atoms in As=O, and As–OH bonds, respectively, are shown in Fig. 3 for each hydrated As(V)-containing compound. The values of atomic  $Q_{\text{NPA}}$  were obtained from semi-empirical PM3 and DFT calculations, and the results are summarized in Table 4. It may be seen that, as expected, the PM3 calculations underestimate the magnitude of the charges on the arsenic and oxygen atoms relative to the DFT calculations. We note that, at least for oxygen atoms, an accurate procedure for correcting PM3 charges has been developed,<sup>29</sup> but for our systems, it was unnecessary to consider this procedure because DFT calculations are feasible and more accurate.

Values of atomic  $Q_{\text{NPA}}$  reveal that, for a given hydrated As(V)-containing compound, the partial positive charge on As changes little with decreasing protonation. The strongest effect on  $Q(\text{As})_{\text{NPA}}$  is the number of organic substituents, which as noted earlier, are electron-donating groups. For a given protonation state of the hydrated As(V)-containing compound, positive values of  $Q(\text{As})_{\text{NPA}}$  decrease in this order:  $\text{iAs(V)} > \text{MMA(V)} \approx \text{p-AsA(V)} > \text{DMA(V)}$ , consistent with the increase in electron donation from organic substituents to the central As atom, which is proportional to the number of substituents. In addition, Fig. 3b shows that the negative charge on O1, which is double bonded to the central As atom, becomes more negative with decreasing protonation, suggesting relatively more electron density on O1 in fully deprotonated species compared with the fully protonated species. This trend can be explained by the fact that the loss of protons from neighboring As–OH pumps electron density into As–O bonds. Oxygen atoms involved in resonance will experience additional negative charge on top of their own non-bonding lone pairs of electrons. It is interesting to note that the degree of organic substitution has minimal effect on  $Q(\text{O1})_{\text{NPA}}$ , compared with that on  $Q(\text{As})_{\text{NPA}}$ , which is likely due to the minimum orbital overlap between O1 and carbon atoms. The above interpretation explains why the value of  $Q(\text{O1})_{\text{NPA}}$  is the same for the first deprotonation state of all the hydrated As(V)-containing compound:

**Fig. 1.** Minimum-energy equilibrium geometries of hydrated As(V)-containing clusters using DFT(B3LYP/6-311+G\*\*) from fully protonated (left side) to fully deprotonated (right side). Atoms of different elements are shown in different colors: arsenic, blue; oxygen, red; hydrogen, light gray; carbon, dark gray; and nitrogen, light purple. The chemical formula of each cluster is listed in Table 2.

**Fig. 2.** Calculated As–O bond lengths in hydrated As(V)-containing clusters surrounded by four H<sub>2</sub>O molecules (filled circles) using PM3 (left), DFT(B3LYP/6–31G\*) (centre), and DFT(B3LYP/6–311G\*\*) (right), respectively. The *x*-axis represents the possible protonation states of the –AsO<sub>*x*</sub>H<sub>*x*–1</sub> (*x* = 2–4) moiety in iAs(V), MMA(V), *p*-AsA(V), and DMA(V) (from top). Me = CH<sub>3</sub> and Ar = H<sub>2</sub>NC<sub>6</sub>H<sub>4</sub>. The empty circles in the left panel are the As–O bond lengths in hydrated As(V)-containing clusters surrounded by eight H<sub>2</sub>O molecules. Trend lines are shown to guide the eye.

$AsO_3^{2-} \approx Ar-AsO_3^{2-}$  and are more negative than that in  $HAsO_4^{2-}$ . While the degree of resonance among As–O bonds is the same in these species, it is likely that this trend in  $Q(O1)_{NPA}$  is due to the electron-donating abilities of

methyl and aromatic substituents compared with the electron-withdrawing abilities of the OH group in  $HAsO_4^{2-}$ . It is interesting to note that  $Q(O1)_{NPA}$  in fully deprotonated iAs(V),  $AsO_4^{3-}$ , is the same as that in  $CH_3-AsO_3^{2-}$  and  $Ar-$

**Table 3.** Calculated hydrogen-bond lengths in hydrated As(V)-containing compounds between water molecules and  $-\text{AsO}_x\text{H}_{x-1}$  ( $x = 2-4$ ) moiety.

**Note:** The reader is referred to Fig. 1 for numbers of oxygen atoms.

$\text{AsO}_3^{2-}$ , suggesting that the loss of the last proton caused a relative increase in electron density in a manner similar to electron donation by organic substituents.

Moreover, Fig. 3c shows trends in the atomic  $Q(\text{Ox})_{\text{NPA}}$  ( $x = 2-4$ ) in hydrated disubstituted ( $x = 2$ ), monosubstituted ( $x = 3$ ), and unsubstituted ( $x = 4$ ) As(V)-containing compounds, respectively. These oxygen atoms are bonded to hydrogen (i.e., As–OH) and are the last ones to deprotonate. Values of  $Q(\text{Ox})_{\text{NPA}}$  ( $x = 2-4$ ) are clearly sensitive to deprotonation, and relatively insensitive to resonance among other As–O bonds. These atomic charge values become ~25% higher (i.e., more negative) in fully deprotonated and hydrated As(V)-containing compounds relative to the fully protonated species, compared with ~6% increase due to deprotonation of other As–OH bonds and the enhancement in resonance as a result. Judging from the relative values of  $Q(\text{Ox})_{\text{NPA}}$  ( $x = 2-4$ ) in fully protonated and deprotonated species, we conclude that the effect of the degree of organic substitution on these atomic charges is insignificant. It is interesting to note that when comparing values of  $Q(\text{O1})_{\text{NPA}}$  and  $Q(\text{Ox})_{\text{NPA}}$  ( $x = 2-4$ ) for fully deprotonated species, one would expect relative agreement due to resonance (i.e., same

charge values on O1 and Ox). This is indeed the case for  $\text{AsO}_4^{3-}$ ,  $\text{CH}_3-\text{AsO}_3^{2-}$ , and  $\text{Ar}-\text{AsO}_3^{2-}$ . For  $(\text{CH}_3)_2\text{AsO}_2^-$ ,  $Q(\text{O2})_{\text{NPA}}$  is larger (i.e., more negative) than  $Q(\text{O1})_{\text{NPA}}$  by a factor of 1.2, suggesting that the charge gained due to deprotonation is more localized. This observation might be explained by the lesser degree of resonance among the two As–O bonds in  $(\text{CH}_3)_2\text{AsO}_2^-$  compared with other fully deprotonated species, and also by the fact that O2 is involved in two hydrogen bonds with water in the first hydration shell compared with one hydrogen bond by O1 (Table 3). The involvement of oxygen atoms in hydrogen bonding makes their electron density less available for delocalization among other bonds. This interpretation can also explain the relatively small decrease in  $Q(\text{O1})_{\text{NPA}}$  for  $(\text{CH}_3)_2\text{AsO}_2^-$  compared with  $(\text{CH}_3)_2\text{AsO}_2\text{H}$  (Fig. 3b). Calculations performed using a polarizable continuum model on hydrated fully protonated and deprotonated clusters resulted in  $Q_{\text{NPA}}$  values that are in close agreement with those shown in Fig. 3. As illustrated in the next section, these trends in charge delocalization with its impact on bond lengths (and order) change the force constant of As–O bonds and consequently frequencies of  $\nu(\text{AsO}_x)$ .

**Fig. 3.** Calculated atomic charges,  $Q_{\text{NPA}}$ , for (a) As, (b) O1, and (c) O $_x$  ( $x = 2-4$ ), in hydrated As(V)-containing compounds. The  $x$ -axis shows the chemical formula of the clusters with increasing organic substitution (top to bottom) and deprotonation state (left to right); Ar =  $\text{H}_2\text{NC}_6\text{H}_4$ .

### Effect of protonation state and organic substitution on $\nu(\text{AsO}_x)$ in hydrated As(V)-containing compounds

Frequency calculations were performed on the optimized geometries of each hydrated As(V)-containing compound shown in Fig. 1 to identify vibrations in the spectral range 600–1100  $\text{cm}^{-1}$  containing  $\nu(\text{AsO}_x)$ . These frequencies were calculated using semi-empirical (PM3) and DFT(B3LYP), and the results are presented in Table 5. Filled circles in Fig. 4 show trends in the calculated and scaled frequencies of  $\nu(\text{AsO}_x)$  as a function of the protonation state of a given As(V)-containing compound and degree of organic substitution. Scaling factors,  $F$ , were used to correct calculated frequencies for anharmonicity as described in the Computational methods section. The most-intense spectral component assigned to  $\nu(\text{AsO}_x)$  in a given cluster is labeled by a superscript and was used to normalize the intensities of all spectral components assigned to the same vibration. Only spectral components with intensities greater than 11% of the most-intense  $\nu(\text{AsO}_x)$  component are reported in Table 5. Some of these components are found to be coupled to other vibrational modes such as frustrated rotation (i.e., librational mode) of water molecules in the first hydration shell;<sup>30</sup>

**Fig. 4.** Calculated vibrational frequencies of As–O bonds in hydrated As(V)-containing clusters calculated using DFT(B3LYP/6–31G\*) (filled circles) compared with the experimental values (empty circles) taken from ref. 13. The *x*-axis represents the possible protonation states of the AsO<sub>*x*</sub> group in iAs(V), MMA(V), *p*-AsA(V), and DMA(V) (from left). Trend lines are shown to guide the eye.

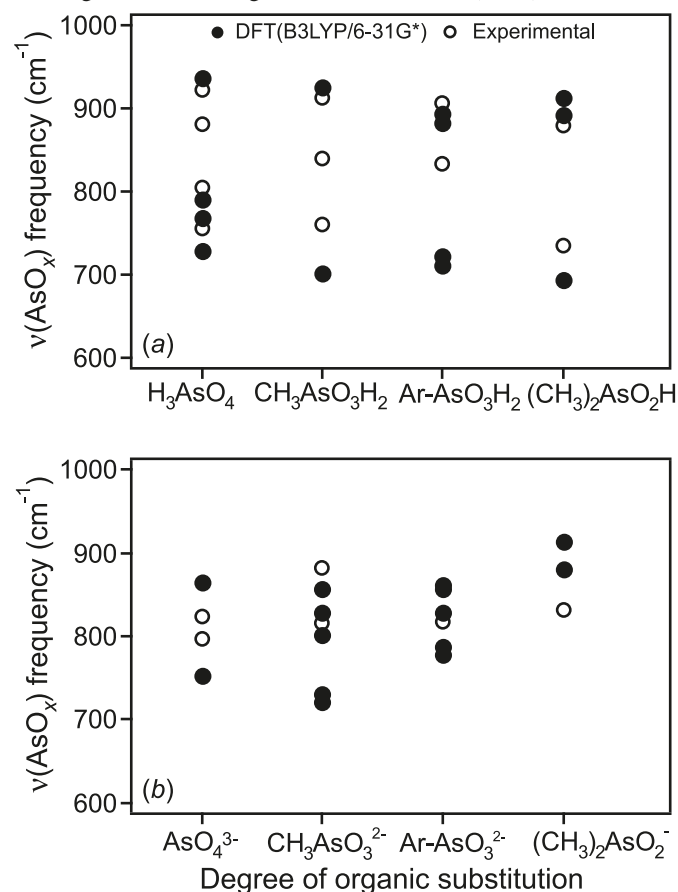

bending vibration of AsOH,  $\delta(\text{AsOH})$ ; rocking vibration of methyl group,  $\rho(\text{CH}_3)$ ; bending vibration of aromatic –CH groups,  $\delta(\text{CH})$ ; bending vibration of aromatic amine substituent,  $\delta(\text{NH}_2)$ ; and stretching vibration of aromatic C–C bonds,  $\nu(\text{C–C})$ . Vibrations coupled to  $\nu(\text{AsO}_x)$  were identified using the visualization tool in Spartan, and only those having similar intensities to that of  $\nu(\text{AsO}_x)$  were labeled in Table 5.

For a given hydrated As(V)-containing compound, calculated frequencies in Table 5 were compared with the experimental frequencies (empty circles in Fig. 4) of aqueous phase As(V)-containing compounds reported as a function of pH using ATR-FTIR.<sup>13</sup> The differences between the scaled frequencies from DFT(B3LYP/6–31G\*) calculations (filled circles) and the spectral components identified experimentally are within 10–80  $\text{cm}^{-1}$ , depending on the cluster. These differences between experimental and calculated frequencies are mainly due to the limitations and assumptions inherent in any computational method including DFT.<sup>31</sup> For hydrated iAs(V) compounds, Table 5 also shows that the frequencies of  $\nu(\text{AsO}_x)$  from our PM3 calculations are in close agreement with those reported by Myneni et al.<sup>11</sup> for

these systems. However, it is clear from Table 5 and Fig. 4 that the PM3 method overestimated the frequencies of  $\nu(\text{AsO}_x)$  when compared with the experimental values. Overall, the calculated frequencies show trends similar to those observed experimentally,<sup>13</sup> namely, inverse relationships of  $\nu(\text{AsO}_x)$  with deprotonation. These results are consistent with the explanation provided above on the effect of deprotonation on the degree of resonance among As–O bonds, i.e., increasing resonance among As–O bonds causes an overall increase in As–O bond lengths (Fig. 2) and a decrease in the force constant of these bonds with deprotonation. For PM3 frequency calculations completed on As(V)-containing compounds surrounded by eight water molecules, results shown in Table 5 agree fairly well with calculations on compounds surrounded by four water molecules. For some clusters with eight water molecules, there are extra spectral components with appreciable intensity compared with the four-water case, which most likely arise from a reduction in the symmetry of the cluster with additional water molecules. The number of spectral components becomes important when spectral fitting is done on the experimental spectra of a given As(V)-containing compound.<sup>32</sup> An in-

**Fig. 5.** Calculated vibrational frequencies of AsO bonds in hydrated As(V)-containing clusters calculated using DFT(B3LYP/6-31G\*) compared with the experimental values (empty circles) taken from ref.13 for (a) fully protonated and (b) fully deprotonated states showing the effect of organic substitution on  $\nu(\text{AsO}_x)$ .

creased number of spectral components assigned to  $\nu(\text{AsO}_x)$  was also observed for hydrated fully protonated and deprotonated As(V)-containing compounds when calculated using DFT(B3LYP/6-31G\*) and a polarizable continuum model. Frequency values are in very close proximity to those shown in Fig. 4. Hence, we conclude that the number of components shown in the filled circles in Fig. 4 is the minimum number needed to fit the experimentally observed data.

Figure 5 also shows frequencies of  $\nu(\text{AsO}_x)$  in hydrated As(V)-containing compounds calculated using DFT(B3LYP/6-31G\*) and compared with the experimental values (empty circles) taken from ref.13 for fully protonated (a) and fully deprotonated (b) states. The data in Fig. 5 are the same as those in Fig. 4, but plotted so as to show the effect of organic substitution on calculated  $\nu(\text{AsO}_x)$ . For fully protonated clusters, the resonance effect does not play a role in explaining trends in  $\nu(\text{AsO}_x)$ , and arsenic-oxygen interactions exist as well-defined As=O and As-OH bonds, giving rise to high frequency ( $>850\text{ cm}^{-1}$ ) and low frequency ( $<800\text{ cm}^{-1}$ ) spectral components. The slight decrease in calculated  $\nu(\text{AsO}_x)$  among fully protonated compounds with increasing number of organic substituents might be due to the increase in electrostatic repulsion with -OH groups that causes an increase in As=O and As-OH bond lengths (vide supra). Frequency trends shown in Fig. 3b for fully de-

protonated species can be explained by the relative degree of resonance among As-O bonds with increasing number of organic substituents. In this case, As-O<sup>-</sup> bonds in  $\text{AsO}_4^{3-}$  are replaced by one As-C bond in  $\text{CH}_3\text{AsO}_3^{2-}$  and  $\text{ArAsO}_3^{2-}$ , and two As-C bonds in  $(\text{CH}_3)_2\text{AsO}_2^-$ . The experimental and calculated frequencies show relatively higher  $\nu(\text{AsO}_x)$  for the latter hydrated compound, which is indicative of more charge localization and minimum resonance in this case. Overall, these results suggest that the number of organic substituents has a lesser effect on the values of  $\nu(\text{AsO}_x)$  compared with the number of -OH groups. This conclusion is consistent with that from the analysis of atomic charges on oxygens of the  $\text{AsO}_x\text{H}_{x-1}$  moiety in hydrated As(V)-containing compounds (Fig. 3). The implications of these results are presented in the following section.

## Conclusions and geochemical implications

In this paper, we reported results from theoretical calculations on the geometries, atomic charges, and vibrational frequencies of a number of As(V)-containing compounds relevant to geochemical environments. Results from quantum chemical calculations aid in the interpretation of the experimental data obtained using ATR-FTIR for characterization of surface complexes. As noted earlier, surface-sensitive measurements from infrared experiments are important for a molecular-level understanding of surface complexation of these compounds, which affects their transport and bioavailability properties. The compounds studied herein were surrounded by four water molecules, which we found to be reasonable for simulating an aqueous environment. These results have important implications for understanding the factors that affect the force constant of  $\text{AsO}_x$  bonds in these compounds, which include bonding to protons and carbon atoms. Protonation (i.e., binding to  $\text{H}^+$ ) of  $\text{AsO}_x$  bonds occurs in neutral and acidic environments and has a strong effect on charge distribution for O<sup>-</sup> atoms in the  $\text{AsO}_x$  moiety, and the overall symmetry of compounds containing this group. This results in increasing the number of IR-active spectral components. We found that the number of organic substituents has a relatively smaller effect on the force constant of  $\text{AsO}_x$  bonds than protonation. Additionally, binding of the  $\text{AsO}_x$  moiety to metal centres in minerals such as  $\text{Fe}^{3+}$  and  $\text{Mg}^{2+}$  instead of protons will also impact the force constant of AsO bonds depending on the nature of the metal cation. Myneni et al.<sup>11</sup> calculated (using the PM3 method)  $\nu(\text{AsO}_x)$  to be  $750\text{--}830\text{ cm}^{-1}$  for As-OM (M = complexing cation), which is blue-shifted relative to that in  $\text{AsO}_4^{3-}$ . We recently reported similar results from the adsorption of *p*-AsA(V) on iron (oxyhydr)oxides.<sup>33,34</sup>

We found, from the comparison of bond lengths and vibrational frequencies, using PM3 and DFT(B3LYP/6-31G\*) methods, that the latter method produces results that agree reasonably better with experimental data and trends expected from chemical intuition. Hence, the number of spectral components assigned to  $\nu(\text{AsO}_x)$  obtained from DFT(B3LYP/6-31G\*) calculations on hydrated As(V)-containing compounds can be used in spectral fitting routines of experimental infrared spectra of aqueous-phase As(V)-containing compounds. This way, the choice of the number of components has a physical basis and is not arbitrarily

chosen. Fitting experimental data is also done routinely when analyzing EXAFS spectra of adsorbed oxyanions on metal cations.<sup>6,35</sup> Spectra collected from standard compounds containing the element of interest in a given oxidation state are needed to obtain a good fit, so that information on the bond lengths in surface complexes and the number of nearest neighbors can be extracted. In the absence of spectra from standards (compounds in bulk aqueous and solid phases), it becomes challenging to fit EXAFS spectra of adsorbed complexes. Results from quantum chemical calculations are invaluable in these cases because they yield structural information on model adsorbed clusters. DFT calculations on the binding of organoarsenicals to metal oxide complexes are currently ongoing in our laboratory to simulate inner-sphere binding configurations similar to those used as model clusters for inorganic oxyanions.<sup>7</sup>

# Rate constants for decarboxylation reactions calculated using no barrier theory

J. Peter Guthrie, Sriyawathie Peiris, Margaret Simkin, and Yun Wang

**Abstract:** No barrier theory (NBT) provides both a qualitative way of thinking about what makes a reaction fast or slow and a quantitative way of calculating the rate constant (free energy of activation) corresponding to a particular mechanism. The origin and development of this idea are reviewed and examples of its use for qualitative understanding are presented before applying it to a set of decarboxylations. From the literature, a set of best values for rate constants for decarboxylation was picked. Detailed mechanistic models were developed for reactions leading to delocalized “anions” or to localized anions. It was necessary to have  $pK_a$  values for ionization of the carbon acids corresponding to all of these species and these were selected from the literature or estimated by linear free energy relations (or occasionally calculated from proton exchange data). Over the entire range of measured decarboxylation rate constants, a range of  $10^{25}$  in rate constant, the calculated values were in good agreement with experiment, with two exceptions: malonate dianion, which has been reported but probably not measured, and glycine, where it is possible that a different mechanism is being followed, unfortunately, one which we do not yet know how to treat by NBT. NBT is both a qualitatively and quantitatively useful tool for understanding chemistry.

**Key words:** decarboxylation, no barrier theory, reaction mechanism, intrinsic barrier.

**Résumé :** La théorie sans barrière fournit d'une part une façon qualitative de réfléchir sur ce qui fait qu'une réaction est rapide ou lente et d'autre part une façon quantitative de calculer la constante de vitesse (énergie libre d'activation) correspondant à un mécanisme particulier. On passe en revue l'origine et le développement de cette idée et on présente des exemples de son utilisation dans la compréhension qualitative avant de l'appliquer à un ensemble de décarboxylations. On a tiré de la littérature un ensemble des meilleures valeurs pour les constantes de vitesse de décarboxylation. Des modèles de mécanismes réactionnels détaillés ont été développés pour des réactions conduisant à des anions délocalisés ou localisés. Il était nécessaire d'avoir les valeurs de  $pK_a$  pour l'ionisation des acides carboniques correspondants à chacune des espèces et celles-ci ont été sélectionnées à partir de la littérature ou elles ont été évaluées par des relations d'énergie linéaires ou elles ont été occasionnellement calculées à partir de données d'échange de proton. Sur l'ensemble complet des constantes de vitesse de décarboxylation, une plage de constantes de vitesse relatives s'étalant de 1 à  $10^{25}$ , les valeurs calculées ont en bon accord avec les valeurs expérimentales, à deux exceptions près: le dianion de l'acide malonique a été rapporté, mais qui n'a probablement pas été mesuré et la glycine pour laquelle il est possible qu'un mécanisme différent soit impliqué, un mécanisme qu'on ne peut malheureusement pas encore traiter par la théorie sans barrière. La théorie sans barrière (TSB) est un outil qualitativement et quantitativement utile pour la compréhension de la chimie.

**Mots-clés :** décarboxylation, théorie sans barrière, mécanisme réactionnel, barrière intrinsèque.

## Introduction

Over the past ten years, we have been developing an approach to calculating rate constants for chemical reactions, which also provides a useful way to think about why

a particular reaction is inherently fast or slow. Because the essential idea is that for any process in which only one thing happens there is no barrier, the approach is called “no barrier theory”, NBT. We will first review how this idea arose, and then look at how it can be applied to a well-known, but inherently difficult reaction, decarboxylation.

Our approach to thinking about reactions developed from Marcus theory<sup>1-7</sup> and uses the same model, focusing on the actual transformation, which begins with an encounter complex of starting materials, with all atoms in position for the bond transformation to come, but with none of this transformation yet occurred, and ends with an encounter complex of products, with all atoms in the positions corresponding to the just completed bond transformation; this is illustrated in

**Fig. 1.** General model of a reaction used for Marcus theory and no barrier theory. The reactants, A and B, must come together to form an encounter complex, (A, B), with all atoms in position and ready to begin the bond transformation, which constitutes the chemical reaction. The cost in free energy of bringing A and B together is the work term,  $w_R$ . The reaction passes over a barrier with height  $\Delta G_{\text{corr}}^\ddagger$  and leads to the encounter complex of the products, (C, D). These then dissociate to give the products in their standard state. The cost in free energy of bringing C and D together in this complex is another work term,  $w_P$ . The free energy change for the reaction, beginning and ending with all species in their standard states,  $\Delta G^\circ$ , is generally different from the free energy change for reaction within the encounter complex,  $\Delta G_{\text{corr}}^\circ$ , just as the directly measurable free energy of activation,  $\Delta G_{\text{obs}}^\ddagger$ , is generally different from the free energy of activation within the encounter complex,  $\Delta G_{\text{corr}}^\ddagger$ .

Fig. 1. The Marcus “work terms”,  $w_R$  and  $w_P$  represent all the costs in free energy to bring the starting materials and products from their equilibrium state in dilute solution to the encounter complexes. These work terms may include the entropic cost of bringing species together: conformational changes if the reactive conformation of starting material or product is not the equilibrium conformation, partial desolvation if one reactant must lose a solvent molecule to come into contact, proton transfer if the reactive species is not the tautomer favored at equilibrium, and so on. The Marcus equation, eq. [2],<sup>8</sup> allows prediction of rate from equilibrium if one knows the “intrinsic barrier”,  $\tilde{G}$ . One way of achieving this is the assumption of transferable intrinsic barriers, approximately the same for a set of similar reactions. This approach proved quite useful<sup>5,9–39</sup> but did require an empirical intrinsic barrier for each family of reactions. Furthermore, it is known that this approximation breaks down for wide enough ranges of equilibrium constants.<sup>31,32,40,41</sup>

$$[1] \quad \Delta G^\ddagger = w_r + \tilde{G} \left( 1 + \frac{\Delta G^\circ - w_r + w_p}{4\tilde{G}} \right)^2$$

$$[2] \quad \Delta G_{\text{corr}}^\ddagger = \tilde{G} \left( \frac{1 + \Delta G_{\text{corr}}^\circ}{4\tilde{G}} \right)^2$$

As a first step towards lessening the number of empirical values that had to be evaluated to extend this approach to more complicated reactions, multidimensional Marcus theory was developed.<sup>42</sup> In this approach a concerted reaction was regarded as the resultant of two simpler reactions each with its own intrinsic barrier, and the postulate that each section through the multidimensional reaction energy surface would obey the Marcus equation (eq. [2]). This approach was applied to the E2 elimination<sup>43</sup> (with the simpler reactions being the E1/S<sub>N</sub>1 ionization to an ion triple, and the E1cb deprotonation to a carbanion; see Fig. 2), and concerted acyl transfer<sup>44</sup> (with the simpler reactions being nucleophilic addition to give a tetrahedral intermediate and ionization to give an acylium ion; see Fig. 3).

An interesting conjecture arising from the multidimensional Marcus theory approach is that other things being equal, the more reaction dimensions required to describe a chemical transformation the higher will be the kinetic barrier for that transformation.<sup>42</sup> This can be proven in a very simple case<sup>42</sup> but a more general proof is more difficult and has not yet been achieved. This idea leads to the general proposition (with apologies to William Lyon McKenzie King) that reactions are “Concerted if necessary, but not necessarily concerted”. A reaction will be concerted if necessary to avoid high energy intermediates, but will not be concerted without necessity because the more elaborate path for the concerted reaction is inherently more difficult than a simpler reaction path where fewer things must happen in a concerted fashion.

A reaction is concerted if all the stepwise intermediates are bad, but comparably bad, so that the only way to avoid any bad intermediate is to avoid all. If one intermediate is very bad the reaction will be stepwise or a lower dimensional concerted process, avoiding the bad intermediate, but not constrained to be fully concerted. If one intermediate is relatively unbad, then reaction will be stepwise by way of that intermediate. This principle is a generalization of ideas that have been around for some time, such as the Libido Rule of Jencks:<sup>45</sup> Concerted general acid base catalysis of a reaction occurs when the reaction converts a proton transfer from unfavorable to favorable with respect to the catalyst. If a stepwise process, involving either preliminary proton transfer or proton transfer only after the heavy atom bond formation, would require having an unstable intermediate on the reaction path, then the reaction will proceed with concerted proton transfer.

In Figs. 2 and 3, the behavior of energy along the diagonal linking the two stepwise intermediates controls what will happen. If the energy at some point along the diagonal is lower than either stepwise intermediate then the reaction will be concerted; if the reaction is concerted then the energy at some point along the diagonal must be lower than either intermediate. Things are a bit more complicated because of the intrinsic barriers for the edge reactions, but if the corner species are high energy intermediates, then the kinetic barrier to break down to starting materials or products must be small and the above must be approximately correct. The idea is that if a corner intermediate is bad then moving

**Fig. 2.** E2 elimination as an example of a potentially concerted reaction. The two stepwise alternatives are the E1/S<sub>N</sub>1 ionization to an ion triple, and the E1c<sub>b</sub> deprotonation to a carbanion.

**Fig. 3.** Concerted acyl transfer as an example of a potentially concerted reaction. The two stepwise alternatives are nucleophilic addition to give a tetrahedral intermediate and ionization to give an acylium ion.

away from it towards the center of the diagram will make things better but proceeding too far along the diagonal leads to the other bad corner and raises the energy again. If one corner intermediate becomes increasingly worse than the other then a point will be reached where any motion away from the less bad intermediate towards the more bad intermediate leads to an increase in energy. In such a case, the reaction is constrained to be stepwise by way of the less bad intermediate. These ideas are illustrated in Fig. 4. This argument implies that anyone proposing a concerted reaction mechanism needs to present arguments that the stepwise intermediates being avoided are comparably bad; this is not always done. Arguments of this sort have been applied to potentially concerted phosphoryl and sulfonyl transfers.<sup>46</sup>

The next step was to do away with the need for an empirical intrinsic barrier by extending the approach of multidimensional Marcus theory and considering all reactions as the resultant of a set of “simple” reaction dimensions, where a simple reaction dimension is one for which with a

suitable progress variable the energy is a quadratic function of that progress variable. Thus, for such a simple process, “if only one thing happens then there is no barrier to that process” and the energy simply rises following a quadratic law for some suitable progress variable. This can be illustrated for the ionization of *tert*-butyl chloride, a two dimensional process, as shown in Fig. 5. The reaction dimensions are bond breaking and geometry change. The assumptions that all one dimensional processes follow quadratic laws allows us to draw in the four edges of the energy surface for a two dimensional reaction, as shown in Fig. 6. The additional assumption that all such parabolas have their minimum at the low energy end, allows us to fill in the entire energy surface. One needs then to find the minimum energy saddle point connecting the initial and final corners and this will be the transition state.

This new approach, no barrier theory, avoids the need for empirical intrinsic barriers, which constrained the application of Marcus theory or multidimensional Marcus theory to

**Fig. 4.** A series of parabolas of constant length passing through two points with different relative heights. This illustrates the behavior expected when there are two alternative, relatively high energy, intermediates through which a reaction could pass. If both are comparably high then the preferred path is a concerted avoidance of both. If one is much higher than the other then the reaction proceeds by way of the lower energy intermediate. This can also be illustrated by holding a short piece of rope and changing the relative heights of the ends.

organic reactions, and also, in effect, provides a procedure to calculate the intrinsic barrier for any reaction. This also provides an interpretation of the intrinsic barrier, and allows a useful qualitative analysis since a reaction that requires more reaction dimensions will be inherently slow, and can only be fast with a large thermodynamic driving force.

This can be illustrated for a set of reactions using data from the literature. In each case the qualitative facts are surprising based on usual ways of thinking but seem quite predictable using no barrier theory. The reactions to be compared are shown in Table 1. The naïve expectation (if intrinsic barriers were similar for both reactions in each pair) is that for  $K \approx 1$ ,  $\Delta \log(k) \approx 0.5 \Delta \log(K)$ ; if  $K \gg 1$ , then  $\Delta \log(k) \ll 0.5 \Delta \log(K)$ ; if  $K \ll 1$ , then  $\Delta \log(k) \approx \Delta \log(K) \gg 0.5 \Delta \log(K)$ . These expectations are not met for any of the examples. Clearly the intrinsic barriers are not comparable, and the challenge is to explain why this is so.

Hydrogen atom transfer is inherently faster (for similar equilibrium constants) from phenol than from ethyl benzene. The difference is that there is an additional reaction dimension needed for ethyl benzene: the geometry change at carbon. Other reaction dimensions should be comparable: the actual hydrogen atom transfer and the bond length changes accompanying delocalization.

The addition of hydroxide to a carboxylate ester (to form an anionic tetrahedral intermediate) is inherently faster than the addition of hydroxide to a phosphate ester (to form an anionic trigonal bipyramidal intermediate). The reason can be seen by examining the angular distortions involved in the NBT analysis of this reaction; see Fig. 7. For the carboxylate ester, the distorted ester has three angles that would like to be  $120^\circ$  but are forced to be  $109^\circ$ , for  $11^\circ$  of distortion for each. For the phosphate ester, there are three angles that would like to be  $109^\circ$  but are forced to be  $120^\circ$ , for  $11^\circ$  of distortion for each, and three that would like to be  $109^\circ$  but are forced to be  $90^\circ$ , for  $19^\circ$  of distortion for each. For the carboxylate adduct, there are three angles that would like to be  $109^\circ$  but are forced to be  $120^\circ$  for  $11^\circ$  of distortion for each, and three that would like to be  $109^\circ$  but are forced to be  $90^\circ$ , for  $19^\circ$  of distortion for each. For the phosphate adduct, there are three angles that would like to be  $120^\circ$  but are forced to be  $109^\circ$ , for  $11^\circ$  of distortion for each, three that would like to be  $90^\circ$  but are forced to be  $109^\circ$ , for  $19^\circ$  of distortion for each, and three that would like to be  $90^\circ$  but are forced to be  $71^\circ$ , for  $19^\circ$  of distortion for each. For both the distorted ester and distorted adduct, the angular distortion is greater for the phosphate than for the carboxylate. Using the approximation that all bending force constants are the same (the basis for the principle of least motion), the pure distortion corners must be higher in energy for the phosphate reaction and thus the intrinsic barrier must be higher.

Acid-catalyzed addition of water to an amide, though itself a slow reaction, is inherently faster than acid-catalyzed addition of water to a nitrile, even though the equilibrium constant for the latter reaction is much less unfavorable. This is again a result of the difference in angular distortion; see Fig. 8. For the amide reaction, the distortions are the same as for the ester example above: three times  $11^\circ$  for each angle for the amide itself, and three times  $11^\circ$  plus three times  $19^\circ$  for each angle for the adduct. For the nitrile, the distorted form has an angle that would like to be  $180^\circ$  but is forced to be  $120^\circ$  for a distortion of  $60^\circ$ ; for the adduct there is one angle that wants to be  $120^\circ$  and is forced to be  $180^\circ$  and two that want to be  $120^\circ$  and are forced to be  $90^\circ$ , leading to one distortion of  $60^\circ$  and two of  $30^\circ$ . Since the energetic cost of an angular distortion depends on

**Fig. 5.** Ionization of *tert*-butyl chloride in water, a two dimensional process. The reaction dimensions are bond formation (with no geometry change) and geometry change (with no bond formation).

**Fig. 6.** Energy surface for the ionization of *tert*-butyl chloride, based on the assumption that at the edges (where one coordinate varies and the other is zero or one) the energy has a parabolic dependence on reaction coordinate (—) and further, for every section through the diagram where only one coordinate changes the energy is a parabola with its minimum at the lower energy end (—). This defines the energy surface, and the energy of the saddle point relative to the starting point is the free energy of activation. The curve from starting material to product traces a reaction path through the transition state

the square of the distortion, the distortion energies for the nitrile reaction are quite large and thus the intrinsic barrier is high.

The preceding discussion emphasized the qualitative utility of the ideas behind no barrier theory, but even more important is its ability to predict free energies of activation (rate constants) for a wide range of reactions.<sup>47-53</sup>

The goal of our research program is to develop a set of detailed mechanistic models for reactions that permit the rates of these reactions to be calculated from the equilibrium constants. These models must be internally consistent for a particular family of reactions, and consistent over the whole range of chemistry, which can be treated by the no barrier theory approach.

This paper will examine decarboxylation reactions over a wide range of reactivity as an illustration of the application of no barrier theory. This reaction is inherently slow, as shown by the experimental rate constants from the literature gathered in Table 2. Decarboxylation can be compared with an analogous retroaldol reaction<sup>11,70</sup> using two reactions of fairly similar thermodynamic driving force; the decarboxylation is much slower; see Table 1. Qualitatively, the difference lies in the much greater angular distortion for a change from  $sp^2$  to  $sp$  geometry than for a change from  $sp^3$  to  $sp^2$  geometry; see Fig. 9. For the retroaldol reaction, distortion of the starting material at the carbon, which is to become a carbonyl, forces three angles that want to be  $109^\circ$  to be  $120^\circ$ , for a distortion of  $11^\circ$ . In the product, three angles wanting to be  $120^\circ$  would be forced to be  $109^\circ$ , again for a distortion of  $11^\circ$ . In the decarboxylation reaction, distortion of the starting material at the carbon, which is to leave as  $CO_2$ , forces one angle that wants to be  $120^\circ$  to be  $180^\circ$  and two that want to be  $120^\circ$  to be  $90^\circ$ , giving one distortion of  $60^\circ$  and two of  $30^\circ$ . The energy cost of the distortions re-

**Table 1.** Reactions where the relation between equilibrium and rate is puzzling by traditional viewpoints but is readily given a qualitative explanation by no barrier theory.

Reaction	log <i>K</i>	log <i>k</i>

quired for the decarboxylation is higher and thus the intrinsic barrier is higher than for the retroaldol.

## Results and discussion

The no barrier theory approach calculates the rate corresponding to a particular model for the mechanism of the reaction. This model includes not only the detailed reaction path as specified in the “curly arrow mechanism” but also issues of whether partial desolvation is postulated for certain corners, and how one deals with the structure of ionic intermediates, which are often unstable in the gas phase, even though they have a lifetime (perhaps short) in solution. This latter problem is a consequence of the current not fully satisfactory state of computational chemistry. We have attempted to find ways of dealing with this problem with manageably small computational demands. In particular, for anions which decarboxylate readily, we add water molecules (one per lone pair) and minimize this structure. For zwitterions we also add a water solvating the acidic hydrogen, and,

where possible, arrange to have this water also form a hydrogen bond to one of the waters solvating an anionic oxygen. Then we remove the waters from the structure, and carry out a single point calculation to serve as the reference energy for distortion calculations, in all of which the geometrical features defining the reaction centers will be locked at either the initial or final values. Where the equilibrium structure with explicit waters did not correspond to one where the C–CO<sub>2</sub><sup>−</sup> bond was orthogonal to the plane of the delocalized “carbanion” (for those reactions where the loss of CO<sub>2</sub> left a delocalized lone pair) we carried out calculations with explicit waters and with this orthogonality enforced. To avoid needless crowding in some of the distortion structures, we also locked the conformation of the CO<sub>2</sub><sup>−</sup> so that this group was orthogonal to the electron withdrawing group in compounds where there was a delocalized carbanion product. These two constraints gave the “reactive conformation” and the unconstrained calculation gave the “equilibrium conformation”. The carbanions left behind when CO<sub>2</sub> departed differed in whether solvation might oc-

**Fig. 7.** Why phosphate esters are inherently slower to add hydroxide than carboxylate esters despite a smaller thermodynamic barrier. The distortions in starting material and product are compared for methyl acetate and trimethyl phosphate. There are more angles distorted in the phosphate case, and the total angular distortion is greater for addition to phosphate.

cur at the carbon from which  $\text{CO}_2$  departed (phenyl anion, uracil anion, methide, trichloromethide, trifluoromethide, ammoniomethide, water) or not (acetone enol or its enolate, acetic acid enol or its mono- or di-anionic forms, nitromethide ion, cyanomethide ion, 1-*H*-2-methylenedihydropyridine, 1-*H*-4-methylenedihydropyridine). The carbanions of the second class are extensively delocalized and solvation is expected to take place predominantly at the heteroatoms, which bear the charge or lone pair. (The carbanion may be an enolate or an enol or an enamine, for all of which carbanion resonance forms can be written.) For carbanions of the first class, if the measured or estimated  $\text{p}K_{\text{a}}$  refers to aqueous solution then it presumably refers to the species with hydrogen bonding solvation to the carbanion center, and in the immediate product of decarboxylation this solvation will be missing. In these cases, a correction for the cost of desolvation must be included. This is done following a model previously described,<sup>43</sup> and is summarized in Appendix A. If the measured or estimated  $\text{p}K_{\text{a}}$  refers to a nonaqueous,

nonhydrogen bonding solvent such as DMSO then the immediate product of decarboxylation in water corresponds to the conjugate base used in the definition of  $\text{p}K_{\text{a}}$  used and no correction for desolvation is needed. The  $\text{p}K_{\text{a}}$  values used here, which refer to DMSO as solvent, are for benzene and methane.

We have already reported two studies of decarboxylation reactions, of acetoacetic acid<sup>49</sup> and carbonic acid.<sup>51</sup> For the reaction of acetoacetic acid no barrier theory could be used as a mechanistic criterion: reaction by the textbook mechanism, eq. [3], did not lead to a free energy of activation consistent with experiment, but to a much higher value, and reaction by way of the zwitterion led to a free energy of activation that was consistent with experiment. The same result was obtained either for a cyclic model with two bridging waters or with the zwitterion; for the cyclic mechanism the proton transfers were complete at the transition state, and the mechanism was actually the zwitterion mechanism. For the decarboxylation of bicarbonate the opposite

**Fig. 8.** Why acid hydrolyses of nitriles are inherently slower than for analogous amides despite a smaller thermodynamic barrier. The distortions in starting material and product are compared for acetonitrile and *N,N*-dimethylacetamide. The total angular distortion is greater for the nitrile.

situation was obtained; the zwitterion mechanism gave a free energy of activation higher than experiment, while the cyclic mechanism led to good agreement, and corresponded to a concerted mechanism with only partial proton transfer

at the transition state. This difference in behavior is presumably the result of the relative stabilities of zwitterionic and neutral forms of the starting materials:  $\text{p}K_z = 9.57$  (from values in Table 3) for acetoacetic acid and 13.09 (from values

**Table 2.** Rate constants for decarboxylation reactions.

Starting material	Rate constant at 25 °C	Selected rate constant
Nitroacetate anion	$2.02 \times 10^{-3}{}^a$ $2.50 \times 10^{-3}{}^c$	$2.50 \times 10^{-3}{}^b$

in ref. 51) for carbonic acid. For a not too bad intermediate (acetoacetic acid case), the lowest energy path can go by this species and avoid the high intrinsic barrier concerted path. When the intermediate becomes less stable, the concerted path becomes preferable despite its higher intrinsic barrier and the bad intermediate can be avoided.

**Fig. 9.** Why decarboxylation is inherently slower than an analogous retroaldol reaction (itself a slow reaction). The angular distortion for  $sp^2$  to  $sp$  geometry is much larger than for  $sp^3$  to  $sp^2$  geometry, and the energy cost is proportional to the square of the angular distortion.

Rate constants for the decarboxylation reactions considered are collected in Table 2. Where there were multiple values we either averaged the values (taking account of the uncertainty in the reported values) or selected the value based on the shortest extrapolation from higher temperature.

Although decarboxylation of the pyridyl acetic acids has been studied several times, there seem to be no rate constants at 25 °C in water, nor rate constants at a set of higher temperatures allowing extrapolation to 25 °C. Values have been reported for decarboxylation of both acids at 90 °C in water; the two were very similar at each of three pH values.<sup>82</sup> From kinetics data in aqueous dioxane at 25 °C we can extrapolate to aqueous solution by plotting  $\ln(k)$  versus %dioxane. Empirically, this gives a reasonable line ( $r^2 = 0.976$ ); there is slight curvature, which suggests that the true value in water may be somewhat slower than the value given by linear interpolation. We will take the rate for both 2- and 4-pyridylacetic acids to be the same.

For trifluoroacetate decarboxylation, the rate constant at 25 °C was obtained (following an approach used by Zhang and Minear<sup>64</sup>) by extrapolation of an Arrhenius plot of data at elevated temperatures in ethylene glycol.<sup>65</sup> A small correction for the solvent effect was taken from the corresponding extrapolation of data for decarboxylation of trichloroacetate in ethylene glycol<sup>65</sup> and the value for water from Table 2.<sup>58</sup>

Where possible, we used experimental thermodynamic quantities to calculate equilibrium free energy changes. Table 4 gives the thermodynamic quantities, experimental and computational, for all compounds involved in the reactions considered. For each reaction (except for glycine where the problem of calculating solvation energies is extreme), we calculated heats of formation of carboxylic acids and neutral decarboxylation products using the G3MP2B3 method, entropies at the B3LYP/6-31+G\*\* level with the hindered-rotor option where possible (this does not always succeed) and solvation energies by our parameterized IPCM method.<sup>100</sup> There were problems with computed solvation energies of ketoacids and ketoesters. The values calculated were very sensitive to conformation, and there was very little barrier to rotation about the C–CO bonds. In one case, the IPCM calculation failed to converge with the normal isodensity parameter. For the keto tautomer of ethyl acetoacetate and for dimethyl malonate the computational solvation energies are much more negative than values derived from experiment (by correcting to the keto tautomer for ethyl acetoacetate, and from diethyl to dimethyl malonate). The previously reported value for acetoacetic acid is given in Table 4. For malonic acid we used the enthalpy of formation and standard entropy of the solid acid, and activity coefficients calculated from an equation reported by Clegg and Seinfeld.<sup>94</sup> From the activity coefficient we calculated the free energy change for

diluting a saturated solution (which by definition has the same free energy as the solid) to 0.01 mol/L solution, which was taken as dilute enough to be treated as ideal. We then calculated the free energy change for increasing the concentration from 0.01 mol/L to 1 mol/L ideal solution. These two combined gave the desired free energy change for the transformation from solid to 1 mol/L aqueous solution.

For the four cases where computational and experimental free energies of decarboxylation can both be calculated, the values agreed with an rms error of 1.92 kcal/mol, and a maximum absolute error of 2.87 kcal/mol for  $\text{CF}_3\text{COOH}$ ; see Table 5. In these calculations the experimental value for  $\text{CO}_2$  was used in all cases. Based on this agreement, we conclude that the computational values are adequate for the present purposes. To assume, as was implicitly done above, that all the error is in the computed values, is of course unrealistic; the experimental values are also subject to significant uncertainty.

$pK_a$  values used in this work are collected in Table 3. Various  $pK_a$  values, for which there are not experimental values, had to be estimated as described in what follows.

### $pK_a$ for $\text{CH}_3\text{NH}_3^+$ as a carbon acid

We can estimate this  $pK_a$  using a linear free energy relation. For fluoroform<sup>72</sup> and chloroform,<sup>71</sup> rate constants for exchange have been measured and thus a  $pK_a$  can be calculated; a  $pK_a$  value for methane has been estimated.<sup>74a</sup> For methylammonium ion acting as a carbon acid, there is no direct evidence. Richard et al.<sup>74a</sup> reported an upper limit on the rate constant for exchange of  $(\text{CH}_3)_4\text{N}^+$ ,  $4 \times 10^{-8} (\text{mol/L})^{-1} \text{s}^{-1}$ . Doering,<sup>74b</sup> working at higher temperatures, reported rate constants from which a value, extrapolated to 25 °C, of  $1 \times 10^{-14} (\text{mol/L})^{-1} \text{s}^{-1}$  can be derived. For ethane, a  $pK_a$  based on a computational approach has been reported. Taking the available data for  $pK_a$  values and  $\sigma^*$  values for the substituents (see Table 6) we get the plot shown in Fig. 10. Not surprisingly,  $\text{CHCl}_3$  deviates: heavy atoms are known to have special carbanion stabilizing power when directly attached.<sup>102</sup> From the line defined by three points we can estimate a  $pK_a$  for methylammonium of 43. The slope of the line is in reasonable agreement with expectation based on the generalization proposed by Perrin et al.;<sup>101</sup> predicted 3.2, observed 2.52.

### $pK_a$ values for malonic acid

For protonated malonic acid to neutral, we start with acetic acid for which  $pK_{\text{BH}^+} = -6.56^{103}$  and correct for the effect of the neighboring  $\text{COOH}$  as was done for acetoacetic acid.<sup>49</sup> This leads to a  $pK_{\text{BH}^+} = -8.84$  for protonated malonic acid. For protonated malonic acid to zwitterion, start with the first  $pK_a$  of malonic acid = 2.83,<sup>73</sup> which after correcting for the number of ionizable protons, gives the per proton value, 2.53. The effect of a neighboring positive charge was estimated as was done for acetoacetic acid.<sup>49</sup> This leads to a  $pK_a = 0.90$  for ionization of protonated malonic acid to the zwitterion, and consequently to a  $pK_Z$  (neutral to zwitterion) = 9.74. The  $pK_a$  for zwitterion to anion is easily calculated to be -6.91.

### $pK_a$ values for acetoacetic acid

$pK_a$  values for acetoacetic acid were taken from previous work,<sup>49</sup> except for the  $pK_a$  for zwitterion to anion, which can be calculated from the other  $pK_a$  values.

### $pK_a$ values for acetic acid enol

We have previously reported a value estimated from that for mandelic acid enol by an argument based on substituent effects; the value was 6.6.<sup>104</sup> An alternative estimation starts

<sup>z</sup>Calculated from free energies of formation from parts (a) or (b) of this table and  $pK_a$  values from Table 2.

from the  $pK_a$  for acetone enol, 10.94.<sup>77</sup> Using the general estimation procedure for  $\rho^*$  proposed by Perrin et al.,<sup>101</sup> we take  $\rho^* = 3.2$ ;  $\sigma^*$  for  $\text{CH}_3$  is 0.0 and  $\sigma^*$  for OH is 1.34. With these values the estimated  $pK_a$  for acetic acid enol is  $10.94 - 3.2 \times 1.34 = 6.65$ . The second  $pK_a$  can be approximately estimated by invoking Pauling's rule,<sup>105</sup> that successive  $pK_a$  values for  $\text{Z}(\text{OH})_n$  increase by 5  $pK_a$  units; this leads to a value of 12.

### $pK_a$ value for $\text{CHF}_3$

We used the rate constant for hydroxide-catalyzed hydrogen exchange reported by Symons and Clermont;<sup>72</sup> they measured the rate of reaction at higher temperatures and determined  $E_a = 32.0 \pm 1.6$  kcal/mol,  $\Delta H^\ddagger = 31.4 \pm 1.6$  kcal/mol, and  $\Delta S^\ddagger = 18 \pm 5$  cal/mol/K. From these values  $\Delta G^\ddagger = 26.04 \pm 2.19$  kcal/mol at 25 °C, or  $k = 5.15 \times 10^{-7}$  (mol/L<sup>-1</sup>) s<sup>-1</sup>. For the reverse reaction, expected to be very fast, we use the rate constant for the relaxation of water,  $1 \times 10^{11}$  s<sup>-1</sup>.<sup>106,107</sup> These two rate constants lead to a  $pK_a$  of 31.3.

### $pK_a$ values for benzene

Streitwieser et al.<sup>80</sup> have made various attempts to determine the  $pK_a$  of benzene, generally by extrapolation techniques. In 1972,<sup>80</sup> a value based on cesium cyclohexylamide in cyclohexylamine and referenced to 9-phenylfluorene of  $43.0 \pm 0.2$  was reported. The use of 9-phenylfluorene is significant because the conjugate base of this acid is highly delocalized and thus unlikely to be hydrogen bonded even in a protic solvent. In 1996,<sup>108</sup> values based on ion pair equilibration in THF were reported. The values were cesium ion pairs, benzene  $pK_a = 44.8$  at 25 °C; lithium ion pairs, benzene  $pK_a = 39.5$ . These experiments used highly delocalized indicator acids of known  $pK_a$ . Thus, experimental values lead to values of  $44 \pm 1$  as the  $pK_a$  of benzene in aprotic solvents. Shen et al.,<sup>109</sup> in a careful computational study of hydrocarbon and heterocycle  $pK_a$  values in DMSO reported the  $pK_a$  of benzene as 44.7.

### $pK_a$ values for methane

Bordwell<sup>110</sup> estimated a value for methane in DMSO by

**Table 5.** Comparison of experimental and equilibrium free energies of decarboxylation.

Reaction	Computational	Experimental	Difference

$\text{Cl}_3\text{CH}$	8.88	25	32.46
$\text{CH}_3\text{NH}_3^+$	4.74		42.90

**Note:** At 25 °C in water;  $\sigma^*$  values from ref. 101, and  $\text{p}K_a$  values from Table 3.

**Fig. 10.** Estimation of a  $\text{p}K_a$  for CH in methylammonium ion. Known  $\text{p}K_a$  values (see text) for ethane, tetramethylammonium, fluoroform, and chloroform are plotted against  $\sigma^*$  values (Table 6). The line was fitted by least squares with the point for chloroform ( $\square$ ) omitted: chlorine is expected to stabilize an anion by mechanisms not captured by  $\sigma^*$ . ( $\blacktriangle$ ) Experimental  $\text{p}K_a$  values; ( $\triangle$ )  $\text{p}K_a$  for  $\text{H-CH}_2\text{-NH}_3^+$  estimated using this correlation.

an extrapolation procedure and obtained a  $\text{p}K_a$  of 56. Richard et al.<sup>74a</sup> estimated a value in water of  $\text{p}K_a = 49$  based on a computational value for ethane<sup>74a,111</sup> corrected for the number of hydrogens. These values are roughly consistent: the expected desolvation energy for the anion (see below) is 13 pK units, leading to a  $\text{p}K_a$  in DMSO of 62. Bearing in mind that the independent  $\text{p}K_a$  estimates in water and DMSO have uncertainties of at least 2 kcal, and that the desolvation energy represents a considerable extrapolation and must also have a substantial uncertainty, this is about as good as one is entitled to hope for.

#### $\text{p}K_a$ values for N-protonation of 1-*H*-2-methylene-dihydropyridine and 1-*H*-4-methylene-dihydropyridine

Given the absence of any other information, we assume that an enol (e.g.,  $\text{p}K_a$  for  $\text{CH}_2=\text{CH}(\text{OH}) = 10.50$ ,<sup>77</sup>  $\text{p}K_a$  for  $\text{CH}_2=\text{C}(\text{CH}_3)(\text{OH}) = 10.94$ <sup>77</sup>) is similar in  $\text{p}K_a$  to a phenol ( $\text{p}K_a$  for  $\text{C}_6\text{H}_5(\text{OH}) = 9.95$ <sup>73</sup>), so an N-protonated enamine should be similar to a protonated aniline ( $\text{p}K_a$  for  $\text{C}_6\text{H}_5(\text{NH}_3^+) = 4.58$ <sup>73</sup>), and use  $\text{p}K_a$  values of 5 for N-protonated forms of both 1-*H*-2-methylene-dihydropyridine and 1-*H*-4-methylene-dihydropyridine.

The set of decarboxylation reactions to be considered involves several different types of compounds, which will be treated separately. The first set of reactions involves compounds where decarboxylation produces a delocalized carbanion, which may in fact be neutral if the starting material was a zwitterion. The reactions are the decarboxylations of acetoacetic acid (as the zwitterion), acetoacetate anion, malonic acid (as the zwitterion), malonate monoanion, malonate dianion, nitroacetate anion, cyanoacetate anion, pyridine-2-acetic acid, and pyridine-4-acetic acid, both of the last two as the zwitterions. The model for these reactions is discussed below. The results, Table 7 and Fig. 11, show that agreement is quite good except for malonate dianion. Examination of the origins of this number<sup>61</sup> shows that although it has been reported it has probably not been measured. It was assumed<sup>61</sup> that for a solution in which the dianion was the major species it was also the kinetically significant species. Since the monoanion can reasonably be expected to be much more reactive, this is not a safe assumption and only a demonstration that the rate is pH independent for a pH range where the dianion is the major species would allow the assignment of the observed rate to the dianion reaction.

The detailed model of the reaction is that the overall transformation involves two or three dimensions: geometry change at the carboxylate, geometry change at the carbanion carbon if there is a delocalized carbanion, and bond breaking. For some classes of reaction, bond length is a dimension but for other reactions it leads to excessively high

<sup>c</sup>Calculated from  $\Delta G_{\text{rds}}$  and  $\Delta G_{\text{calc}}^{\ddagger}$ .

<sup>d</sup> $\Delta G_{\text{pre}}$  for zwitterion formation.

<sup>e</sup>These data are impossible; the free energy of activation is less than the free energy change for product formation. This suggests that the mechanism is different and leads to a different product than is assumed here.

<sup>f</sup>As discussed in the text, it seems likely that the rate of this reaction has not yet been measured.

intrinsic barriers. The key feature seems to be whether both ends of a bond are tied to the solvent structure by hydrogen bonding. Thus, simple carbonyl additions require bond length as a coordinate but decarboxylations or aldol additions do not. In a simple carbonyl addition both the nucleophile and the carbonyl oxygen are hydrogen bonded and linked to the solvent structure. In decarboxylation, both the C–O bonds of the carboxylate and (for delocalized carbanions) the bond to the electron withdrawing group change length, but only the termini of the entire reacting system are hydrogen bonded, and the carbons of the scissile bond (which are also the termini of the bonds that change length) are not tied to solvent. Desolvation must be allowed for when a localized carbanion is formed and is missing hydrogen bonding assumed to be present in the definition of the  $pK_a$  used to calculate the corner energy.

Normally, we would try for an equilibrium conformation as contrasted with the reactive conformation defined by the stereoelectronic demands of the mechanism. However, in the case of zwitterions there are additional problems. There is a strong anomeric effect, which favors the reactive conformation, tending to alter the geometry in the direction of product and lengthen the scissile bond. In the absence of explicit solvation or constraints this goes to completion. Conversely, there is a tendency, in the absence of explicit waters, for the conformation to change to one with an intramolecular hydrogen bond, or even to undergo a proton transfer. Such an intramolecular hydrogen bond is strongly stabilizing in the gas phase but this is spurious, because the estimated  $pK_a$

values on which the zwitterion content was based do not include this hydrogen bond even in its much weaker solution form. Such hydrogen bonds are much weaker in solution and are not even present in the reactive conformation. In most cases, there will not be a meaningful alternative conformation, nor should there be much difference in conformational energy (less electrostatic interactions, which are difficult to account for computationally).

As an attempt to resolve these difficulties, the fully hydrated zwitterion was allowed to optimize without constraints and the result of these calculations was taken as the equilibrium form. These optimizations with multiple waters are very slow, so we normally stopped when the length of the scissile bond stabilized. The waters were then removed and a single point calculation was carried out to give the equilibrium energy.

Geometries and bond lengths for zwitterionic species were determined by optimization with enough waters to form hydrogen bonds to each acidic hydrogen and basic lone pair, with cyclic chains of hydrogen bonds wherever possible. This amount of explicit solvation allowed the zwitterions to stay together with modest C–C bond lengthening.

Desolvation energies for anions were estimated based on the change in  $pK_a$  from DMSO to water per hydrogen bond in the conjugate base for a series of alcohols with increasing numbers of fluorines, as described in Appendix A.

The next set of decarboxylation reactions to be considered involves arenecarboxylates, specifically benzoate and 1-methylorotate; see Fig. 12. For these reactions, the product

**Fig. 11.** Comparison of observed and calculated values of  $\Delta G^\ddagger$  for decarboxylation reactions. ( $\square$ ) Reactions that generate a delocalized "anion". (+) Reactions of arenecarboxylates. ( $\triangle$ ) Reactions that generate a localized  $sp^3$  anion. Filled symbols represent points that deviate significantly; arrows indicate points where the experimental value is a lower limit.

is a localized arenecarboxylate. The  $pK_a$  values of such ions can be determined, albeit indirectly, by measuring rates of exchange. Data are available for two reactions, the decarboxylations of benzoate and 1-methylorotate. In the case of 1-methylorotate, the  $pK_a$  for the product is actually available for 1,3-dimethyluridine but the extra methyl should make only a small difference to the  $pK_a$ . The calculated rate constants are in good agreement with experiment; benzoate is in fact the lower limit of reactivity for which the rate has been experimentally measurable to date.

Finally, we examined a number of cases where decarboxylation leads to an  $sp^3$  hybridized carbanion with a localized charge. There are experimental data for trifluoro- and trichloroacetate, and for glycine, and an upper limit for the rate constant for acetate.

The calculated free energies of activation are in good agreement with experiment for trifluoro- and trichloroacetate, and consistent with the reported upper limit for acetate. For glycine, the predicted free energy of activation is significantly too high; this may mean that the mechanism is not the simple decarboxylation assumed. It may be possible for

decarboxylation to be accompanied by a water mediated proton switch from nitrogen to carbon, leading directly to neutral methylamine as product. The intrinsic barrier calculated, assuming this is the process (zwitterion of glycine going directly to neutral methylamine), is much higher than that calculated assuming that the zwitterion of glycine leads to the zwitterion of methylamine. At present, we do not know how to treat the concerted electrophilic substitution at  $sp^3$  carbon, which would be involved in such a process, so this can only be a speculation.

Equilibrium free energy changes and free energies of activation for the reactions to be considered are gathered in Table 7. The corresponding empirical intrinsic barriers implied by the Marcus equation (eq. [2]) are also given in Table 7. Comparison of related reactions show that acetoacetate zwitterion has a lower intrinsic barrier than acetoacetate anion, and malonate zwitterion has a lower barrier than malonate monoanion. This can be explained in terms of an enhanced anomeric effect in the zwitterion, with lone pair electrons from the carboxylate ion feeding into the antibonding  $\sigma^*$  orbital for the C–C bond which is to break and from this to the  $\pi^*$  antibonding orbital for the protonated carbonyl, leading to a shift in bond lengths and geometry closer to those of the product. In the corresponding anion there is a poorer electron sink and consequently less hyperconjugation and less shift in bond lengths and geometry; see Fig. 13. To the extent that the geometry shifts towards the product, the distortion energies for the one thing at a time corners will be smaller and consequently the intrinsic barrier will be lower. To calculate these hyperconjugation induced geometry changes by molecular orbital (MO) theory requires explicit solvation because zwitterions are so unstable in gas that they would inevitably fall apart. The addition of five water molecules proved sufficient, with four solvating the carboxylate and one solvating the protonated carbonyl and also forming a bridging hydrogen bond to a water solvating the carboxylate; see Fig. 14.

The estimated values of  $\Delta G^\circ$  and the NBT values of  $\Delta G^\ddagger$  for acetate and glycine lead to intrinsic barriers of 24.15 and 24.79 kcal/mol, respectively, which is in good agreement with the values observed for other decarboxylations leading to localized carbanions (benzoate, orotate, trichloroacetate), though the value for trifluoroacetate is surprisingly low. This supports the idea that glycine reacts by a different mechanism, leading to a faster reaction than the one assumed for the NBT calculation. This cyclic path has a much lower thermodynamic barrier so it is faster despite the very high intrinsic barrier.

In summary, the NBT method has successfully predicted rate constants over the entire range reported to date, and can call attention to places (malonate dianion) where the literature may be incorrect. It also allows a choice to be made when literature values lead to strikingly different rate constants at 25 °C, as for trichloroacetate and trifluoroacetate where values based on the literature differ by four orders of magnitude. The faster rate constants are based on high temperature studies in metal cells (stainless steel or titanium),<sup>59,63</sup> and may be subject to transition metal catalysis.

NBT represents both a useful qualitative way to think about why some reactions are fast and some are slow, but also a quantitative way of calculating rates of reactions,

**Fig. 12.** Decarboxylation of aromatic carboxylic acids: benzoic acid and 1-methylorotic acid.**Fig. 13.** Hyperconjugation as an explanation for the lower intrinsic barrier in zwitterions of  $\beta$ -keto acids. This is illustrated using both hyperconjugation and bond–no-bond resonance.**Fig. 14.** Explicit solvation of the zwitterion of acetoacetic acid by five water molecules, four solvating the carboxylate and one the protonated carbonyl. The optimized structure (b3lyp/6-31+G\*\*) is shown.

which is much less computationally demanding than the traditional “brute force” approach of calculating the energy of the solvated transition state directly. We are now engaged in extending the range of reactions to which the method can be applied and also improving the computer programs used to

carry out the calculations in hopes of making the whole process easier and more accessible.

## Computational methods

All molecular orbital calculations were carried out using Gaussian03.<sup>112</sup> Heats of formation were calculated using the G3MP2B3 keyword, and the G3MP2 enthalpy was converted to heat of formation by way of the heat of atomization, using calculated G3MP2 enthalpies for the atoms and experimental heats of formation of the atoms. Entropies were calculated using B3LYP/6-31+G\*\*/freq// B3LYP/6-31+G\*\* or where possible B3LYP/6-31+G\*\*/freq=hindrot// B3LYP/6-31+G\*\*. Solvation energies were calculated using B3LYP/6-31+G\*\*/scrf=ipcm// B3LYP/6-31+G\*\* and then corrected using the set of parameters we have reported.<sup>100</sup>

The Supplementary data contains optimized geometries for all G3MP2B3 calculations, optimized geometries for all entropy calculations (the same geometries were used for solvation calculations), initial and final corner structures used for NBT calculations, and tables containing all the energy contributions to the final corner energies used to find the free energy of activation.

## Supplementary data

Supplementary data for this article are available on the journal Web site ([canjchem.nrc.ca](http://canjchem.nrc.ca)) or may be purchased

from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5326. For more information on obtaining material, refer to [cisti-icist.nrc-cnrc.gc.ca/cms/unpub\\_e.shtml](http://cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml).

## Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support of this work and the Shared Hierarchical Academic Research Computing Network (SHARCNET) for computing resources.

## Appendix A Calculation of desolvation energies for anions

The desolvation cost of an anion was taken as the difference in  $pK_a$  per hydrogen bond between water, where it is assumed that there are three hydrogen bonds per lone pair of an alkoxide, and DMSO, where there are no hydrogen bonds. The pH dependence of the desolvation energy was estimated based on the pH dependence of the desolvation energy, using a set of alcohols, which should have no confounding interactions. The data used are summarized in Table A1. These data

lead to a linear relationship,  $\Delta pK_a/nHB = 0.333 \pm 0.099 + 0.266 \pm 0.008 pK_a^{H_2O}$ .

This relation can then be used to estimate the desolvation cost for loss of a hydrogen bond from any localized anion. This has been done for the anions of interest in this work.

**Table A1.** Correlation of  $\Delta pK_a$  per hydrogen bond (HB) with the  $pK_a$  of the conjugate acid.

Acid	$pK_a^{H_2O}$	$pK_a^{DMSO}$	$\Delta pK_a/nHB$

# Synthesis, characterization, and application of palladium complexes containing 8-quinolyphosphinite ligands

Earl Cook, Jason D. Masuda, and Aibing Xia

**Abstract:** Palladium complexes containing 8-quinolyphosphinite ligands have been synthesized and characterized. Their solid state structures were determined by single-crystal X-ray diffraction. They were found to be active catalysts for Suzuki coupling reactions of phenylboronic acid and various aryl halides.

**Key words:** palladium complexes, unsymmetrical ligands, quinoline, the Suzuki reaction.

**Résumé :** On a effectué la synthèse et caractérisé des complexes du palladium avec des ligands 8-quinolyphosphiniques. On a déterminé leur structures à l'état solide par diffraction des rayons X par un cristal unique. On a trouvé qu'ils sont actifs comme catalyseurs dans les réactions de couplage de Suzuki entre l'acide phénylboronique et divers halogénures d'aryle.

**Mots-clés :** complexes du palladium, ligands non symétriques, réaction de Suzuki.

## Introduction

Unsymmetrical ligands with two or more different donors have attracted increasing attention due to their bonding versatility and catalytic applications. The combination of a soft donor and a hard donor induces different interactions between the metal centers and the unsymmetrical donors, which may lead to hemilabile properties.<sup>1–3</sup> The weak donors in the hemilabile ligands can dissociate from the metal center to facilitate substrate interaction, and rebind to the metal center to stabilize the reactive intermediates during catalytic cycles.

P,N-type ligands, containing strong donors such as phosphines and weak donors such as amines,<sup>4–9</sup> pyrazoles,<sup>10,11</sup> and pyridines<sup>12–19</sup> have been investigated in a variety of catalytic transformations. Recently Walther and co-workers<sup>20</sup> reported nickel complexes containing phosphinite ligands based on 8-hydroxyquinoline (Fig. 1, R = Ph, <sup>i</sup>Pr). The nickel diisopropylphosphinite complex was isolated, yet the diphenyl analogue was unstable and a tetrameric nickel complex was obtained instead. Very recently Crociani et al.<sup>21</sup> reported the synthesis of quinolyphosphinite palladium complexes containing di-*tert*-butyl groups (R = <sup>t</sup>Bu) and their catalytic applications. Here, we wish to report the synthesis, characterization, and catalytic applications of three new palladium complexes containing 8-quinolyphosphinites (R = Ph, <sup>i</sup>Pr, Cy).

## Experimental

### General

All experiments were performed under an argon atmosphere unless otherwise specified. All anhydrous solvents were purchased from Sigma-Aldrich Canada Ltd. and stored over 4 Å molecular sieves prior to use. 8-Hydroxyquinoline, chlorodiphenylphosphine, chlorodiisopropylphosphine, potassium hydride, and 4-*N,N*-dimethylaminopyridine (DMAP) were purchased from Sigma-Aldrich Canada Ltd. Bis(benzonitrile)dichloropalladium(II) and chlorodicyclohexylphosphine were purchased from Strem Chemicals, Inc. <sup>1</sup>H and <sup>31</sup>P NMR spectra were recorded on a Bruker Avance 500 spectrometer and referenced to SiMe<sub>4</sub> and 85% H<sub>3</sub>PO<sub>4</sub>, respectively. Infrared spectra were collected on a Nicolet Avatar 330 FT-IR spectrometer. Elemental analyses were carried out by Guelph Chemical Laboratories in Guelph, Ontario. Melting points were recorded on a Mel-Temp (Electrothermal) Apparatus and were uncorrected.

### Complex 1

8-Hydroxyquinoline (0.145 g, 1.00 mmol) and DMAP (0.122 g, 1.00 mmol) were dissolved in THF (10 mL). Chlorodiphenylphosphine (0.221 g, 1.00 mmol) in THF (5 mL) was added dropwise. The mixture was stirred overnight and filtered. A solution of bis(benzonitrile)dichloropalladium(II) (0.384 g, 1.00 mmol) in CH<sub>2</sub>Cl<sub>2</sub> (5 mL) was added to the filtrate. Yellow solids were formed after completion of the addition. The mixture was stirred overnight and filtered. The yellow solids were washed with hexane (2 × 5 mL). Yield 0.470 g (93%), mp 209 °C (dec). IR (KBr, cm<sup>-1</sup>) ν: 2924 (m), 1655 (w), 1560 (w), 1508 (s), 1464 (m), 1437 (m), 1310 (m), 1253 (m), 1105 (s), 927 (w), 828 (m), 762 (w), 694 (w), 539 (w), 492 (w). <sup>1</sup>H NMR (500.13 MHz, CDCl<sub>3</sub>, ppm) δ: 10.59 (dd, *J* = 1.5, 5.4 Hz, 1H, quinoly1), 8.44 (dd, *J* = 1.6, 8.3 Hz, 1H, quinoly1),

### Complex 3

In a procedure similar to the preparation of **2**, complex **3** was obtained as yellow solids. Yield 0.490 g (94%), mp 235 °C (dec). IR (KBr, cm<sup>-1</sup>)  $\nu$ : 2931 (s), 2850 (m), 1593 (w), 1510 (m), 1465 (w), 1448 (w), 1388 (w), 1311 (w), 1258 (m), 1170 (w), 1101 (m), 1043 (w), 1002 (w), 933 (w), 886 (w), 856 (w), 831 (m), 762 (w), 726 (w), 696 (w), 571 (w), 560 (w), 531 (w). <sup>1</sup>H NMR (500.13 MHz, CDCl<sub>3</sub>, ppm)  $\delta$ : 10.48 (dd, *J* = 1.5, 5.4 Hz, 1H, quinolyl), 8.44 (dd, *J* = 1.4, 8.3 Hz, 1H, quinolyl), 7.72 (dd, *J* = 1.4, 8.2 Hz, 1H, quinolyl), 7.64 (t, *J* = 7.9 Hz, 1H, quinolyl), 7.58–7.55 (m, 2H, quinolyl), 2.69–2.61 (m, 2H, Cy), 1.91–1.72 (m, 12H, Cy), 1.41–1.25 (m, 6H, Cy). <sup>31</sup>P NMR (202.47 MHz, CDCl<sub>3</sub>, ppm)  $\delta$ : 155.82. Anal. Calcd. for C<sub>21</sub>H<sub>28</sub>Cl<sub>2</sub>NOPPd: C 48.62, H 5.44, N 2.70; found: C 48.35, H 5.22, N 2.35.

### X-ray crystallography

Crystals of **1–3** were grown by slow evaporation of solutions in CH<sub>2</sub>Cl<sub>2</sub>/hexane at room temperature. Single crystals were mounted in thin-walled capillaries. The data were collected using the Bruker APEX2 software package<sup>22</sup> on a Siemens diffractometer equipped with an APEXII CCD detector, a graphite monochromator, and MoK $\alpha$  radiation ( $\lambda$  = 0.71073 Å). A hemisphere of data was collected in 1664 frames with 10 s exposure times. Data processing and absorption corrections were applied using the APEX2 software package.<sup>22</sup> The structure was solved (direct methods) and all

nonhydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions using an appropriate riding model and coupled isotropic temperature factors. Thermal ellipsoid diagrams (50% probability level) were produced using Ortep-3 for Windows.<sup>23</sup>

### Suzuki coupling reaction

General procedures for Suzuki reactions: a 20 mL reaction tube was charged with an aryl halide, phenylboronic acid, the palladium complex, and a base in 3 mL of solvent under argon and heated to 100 °C for 18 h. The mixture was then cooled to room temperature. The volatiles were removed under a reduced pressure. The organic product was extracted with ether and analyzed on an Agilent 6890 GC-FID instrument. The GC yield was calculated based on unreacted aryl halide and calibrated relative to standards containing aryl halide starting material and biphenyl product.

## Results and discussion

### Synthesis

The syntheses of 8-quinolylphosphinite ligands and their palladium complexes were outlined in Scheme 1. Deprotonation of 8-hydroxyquinoline with DMAP or potassium hydride, followed by reactions with chlorophosphines, gave the phosphinites. Due to their air-sensitive nature,<sup>21</sup> the phosphinites were used directly without further purification to react with bis(benzonitrile)dichloropalladium(II) to afford the corresponding palladium quinolylphosphinite complexes (**1–3**). All the complexes are air stable and can be stored and handled in air. They were also thermally robust, showing no

sign of decomposition under 200 °C in air. They were characterized by  $^1\text{H}$  and  $^{31}\text{P}$  NMR spectroscopy and infrared (IR) spectroscopy. The solid state structures of the palladium complexes (**1–3**) were determined through X-ray diffraction studies. The elemental analysis results matched well with the expected values.

### Characterization

The  $^1\text{H}$  NMR spectra of the three palladium complexes contained chemical shifts for the quinolyl hydrogen around 10.5 ppm. This reflected a downfield shift of 1.5 ppm from the signal in the reported free ligands.<sup>20,21</sup> Other quinolyl hydrogens showed smaller shifts. The methyl groups in the isopropyl moieties in complex **2** became nonequivalent, reflecting the restriction of rotation of the isopropyl in the palladium complexes. The  $^{31}\text{P}$  signals ranged from 115 to 162 ppm.

Suitable crystals of **1–3** for X-ray analysis were grown from slow evaporation of solutions of dichloromethane and hexane. The molecular structures of the complexes were almost identical. A representative structure of **1** is shown in Fig. 2. The structural data of **2** and **3** were included in the Supplementary data. Selected bond lengths and angles are listed in Table 1. Crystal data and structure refinement data are listed in Table 2. The structure of **1** showed a distorted square-planar geometry around the palladium ion, which bonded to the quinolylphosphinite P and N atoms as well as two Cl atoms. The bond angles of N–Pd–Cl(1) and P–Pd–Cl(2) are 175.5° and 170.8°, respectively. The bond lengths for Pd–P (2.177 Å), Pd–N (2.080 Å), and Pd–Cl (2.288 and 2.381 Å) are comparable to the reported values in related *tert*-butyl quinolylphosphinite palladium complexes.<sup>21</sup> The Pd–Cl(2) distance trans to the phosphorus is slightly longer than the Pd–Cl(1) distance trans to the nitrogen atom, suggesting a stronger trans effect of the phosphinite donor.

### Catalytic studies

We evaluated the efficiency of the palladium phosphinite complexes in the Suzuki coupling reaction, one of the most important palladium-catalyzed cross-coupling carbon–carbon bond forming reactions in organic synthesis.<sup>24–26</sup> The results are listed in Table 3. For screening purposes, we used **1** as the palladium catalyst and chose 4-bromoanisole, a rather inert aryl bromide, as the organic substrate. We screened a few commonly used solvents and bases and found that  $\text{Cs}_2\text{CO}_3$  and DMF led to the best yield (96%, Table 3, entry 6).

Under similar conditions, the palladium complexes gave moderate yields for the coupling of 4-chloronitrobenzene, an activated aryl chloride (Table 3, entries 7 and 8). When the palladium loading was increased to 2 mol%, excellent yields were obtained with all three complexes (Table 3, entries 9–11). However, the complexes were ineffective toward 4-chlorotoluene, a neutral aryl chloride (Table 3, entries 12–14). In comparison, the recently reported *tert*-butyl analogue gave complete conversion of both activated and nonactivated aryl chlorides in toluene.<sup>21</sup> When toluene was used as the solvent and  $\text{K}_2\text{CO}_3$  as the base, **1–3** gave only low to modest yields for the coupling of 4'-chloroacetophenone (Table 3, entries 15–17). The higher efficiency of the *tert*-butyl analogue is likely due to its stronger donating ability

and larger steric hindrance, which are beneficial factors for the Suzuki reactions of more challenging aryl chlorides.<sup>25,26</sup>

### Conclusion

In summary, we have synthesized and characterized three palladium complexes containing 8-quinolylphosphinite ligands. The palladium complexes were easy to synthesize and stable in air. They were investigated in the Suzuki coupling reaction and showed excellent activity towards a deactivated aryl bromide but lower activity towards aryl chlorides.

# Cytotoxic phenolic compounds in leaf buds of *Populus tremuloides*

André Pichette, Azadeh Eftekhari, Patricia Georges, Serge Lavoie, Vakhtang Mshvildadze, and Jean Legault

**Abstract:** Phytochemical investigations of the EtOH extract of *Populus tremuloides* leaf buds led to the isolation of 19 phenolic compounds. Among them, (1*S*,2*S*)-1-[4-*O-E*-coumaroyl- $\beta$ -D-glucopyranosyloxy]cyclohexanediol was reported for the first time, and its structure was determined by spectroscopic (NMR and MS) and chemical methods. Seventeen of the isolated compounds were tested for their cytotoxicity against lung carcinoma (A549) and colorectal adenocarcinoma (DLD-1) human cell lines. Antibacterial activity was also evaluated against *Escherichia coli* and *Staphylococcus aureus*.

**Key words:** quaking aspen, coumarate, flavonoids, NMR.

**Résumé :** Une étude phytochimique d'un extrait éthanolique des bourgeons de feuilles du *Populus tremuloides* a permis d'isoler 19 composés phénoliques, dont le (1*S*,2*S*)-1-[4-*O-E*-coumaroyl- $\beta$ -D-glucopyranosyloxy]cyclohexanediol, un produit qui n'a jamais été rapporté antérieurement et dont la structure a été déterminée par des méthodes chimiques et spectroscopiques (RMN et spectrométrie de masse). Les propriétés cytotoxiques de 17 de ces produits ont été évalué contre des lignées de cellules humaines de carcinome du poumon (A549) et d'adénocarcinome (DLD-1). Leur activité antibactérienne a aussi été évalué contre l'*Escherichia coli* et le *Staphylococcus aureus*.

**Mots-clés :** peuplier faux-tremble, coumarate, flavonoïdes, RMN.

## Introduction

The buds exudates of many plant species of *Populus* genus are known as raw material processed by bees into propolis.<sup>1</sup> The latter product has been widely used in popular medicine as antibacterial,<sup>2–4</sup> anti-inflammatory,<sup>5</sup> antioxidant,<sup>6,7</sup> and cytostatic treatments.<sup>8</sup> The biological activity of propolis samples is mainly due to phenolic compounds like flavonoids, aromatic acids, and diterpenic acids,<sup>9,10</sup> which are the principal constituents of the buds of *Populus* species.<sup>11–13</sup> Recently, studies in the northern-type propolis showed a potential source of biologically active substances in *Populus tremuloides*,<sup>14</sup> which are widely spread across North America.<sup>15</sup> In spite of its use as ointment by Amerindian traditional medicine to treat numerous diseases, such as coughs, colds, and irritated nostrils,<sup>16</sup> few studies were carried out on the medicinal applications of *P. tremuloides*. In the present study, the isolation and structure elucidation of a new phenolic compound from *P. tremuloides* Michaux, along with 18 known products are described.

## Results and discussion

The leaf buds of *Populus tremuloides* were extracted with

EtOH and EtOH/H<sub>2</sub>O under reflux. After evaporation of EtOH in vacuo, the aqueous phase was successively partitioned with hexane and *n*-BuOH. The *n*-BuOH soluble extract was purified on an open Diaion® column with a gradient of decreasing polarity, and three fractions were obtained. Each fraction was investigated for in vitro cytotoxic and antibacterial biological activities. Cytotoxic activity evaluations were carried out on human lung cancer (A549), human colorectal cancer (DLD-1), and normal skin fibroblasts (WS1) using the resazurin reduction test as previously described in the literature.<sup>17</sup> Antibacterial activity was evaluated against *Escherichia coli* and *Staphylococcus aureus*. The results (Table 1) show that the last fraction C was found to exert a weak cytotoxic activity against A549 (IC<sub>50</sub>, 96 ± 7 µg mL<sup>-1</sup>) and DLD-1 (IC<sub>50</sub>, 89 ± 6 µg mL<sup>-1</sup>), but was inactive toward bacterial cell lines. Thus, bioassay-guided fractionation of fraction C was undertaken with a combination of different chromatographic techniques leading to the isolation of a new compound **1** together with 18 known compounds: chaenomeloidin (**2**),<sup>18</sup> prunin (**3**),<sup>19</sup> echinacin (**4**),<sup>20</sup> echinacin (**5**),<sup>21</sup> tremulacin (**6**),<sup>22</sup> salicine (**7**),<sup>23</sup> tremuloidin (**8**),<sup>24</sup> genkwanin (**9**),<sup>25</sup> rhamnocitrin (**10**),<sup>26</sup> sakuranetin (**11**),<sup>27</sup> acacetin (**12**),<sup>28</sup> kaempferide (**13**),<sup>29</sup> aromadendrin (**14**),<sup>30</sup> phenylmethyl coumarate (**15**),<sup>31</sup> phenethyl *p*-coumarate (**16**),<sup>32</sup> cinnamyl coumarate (**17**),<sup>33</sup> phenylmethyl caffeine (**18**),<sup>34</sup> and *trans*-ferulic acid (**19**)<sup>35</sup> (Fig. 1). Known compounds were identified by comparison of their spectroscopic data with the values found in the literature. NMR spectroscopic data for phenethyl *p*-coumarate (**16**), which was also isolated from buds of *P. tremuloides*, were not available. Therefore, complete <sup>1</sup>H and <sup>13</sup>C NMR spectroscopic data for **16** are also reported.

The molecular formula (C<sub>21</sub>H<sub>28</sub>O<sub>9</sub>) of **1**, a white amorphous powder, was determined from its HR-ESI-MS spec-

trum (positive-ion mode) on the basis of a quasimolecular ion peak at  $m/z$  447.1623  $[M + Na]^+$  (calcd. 447.1631). Infrared absorption bands at 3328, 1602, 1160, 982, and 833  $\text{cm}^{-1}$  suggested the presence of hydroxyl groups, aromatic system, and an ester carbonyl groups.  $^{13}\text{C}$  NMR spectrum displayed 19 carbon signals (Table 2) separated by DEPT spectrum into five methylenes, seven aliphatic oxy-methines, four unsaturated methines, and three quaternary carbons (one for an ester carbonyl). Among them, six resonances could be assigned to a sugar moiety.  $^1\text{H}$  NMR spectrum confirmed the presence of a hexose moiety with anomeric proton at  $\delta_{\text{H}}$  4.45 (1H, d,  $J = 7.8$  Hz).  $^1\text{H}$  NMR spectrum also shows the presence of two *trans*-olefinic protons at  $\delta_{\text{H}}$  7.66 (1H, d,  $J = 15.9$  Hz) and  $\delta_{\text{H}}$  6.37 (1H, d,  $J = 15.9$  Hz) and a 1,4-disubstituted aromatic ring with four protons at  $\delta_{\text{H}}$  7.47 (2H, d,  $J = 8.6$  Hz) and 6.81 (2H, d,  $J = 8.6$  Hz). HMBC correlations at  $\delta_{\text{H}}$  7.47 (H-2'', H-6'') and  $\delta_{\text{C}}$  147.3 (H-7''),  $\delta_{\text{H}}$  6.81 (H-3'', H-5'') and  $\delta_{\text{C}}$  161.5 (C-4''), and  $\delta_{\text{H}}$  7.66 (H-7'') and  $\delta_{\text{C}}$  168.6 (C-9'') suggested the presence of a coumaroyl moiety. Analysis of the COSY, HSQC, and HMBC spectra led to the identification of a third aglycone system: the cyclohexane-1,2-diol. HMBC correlation between the methine proton at  $\delta_{\text{H}}$  4.87 (H-4') and the carbonyl group at  $\delta_{\text{C}}$  168.6 (C-9'') suggested the linkage between the glucose and the coumaroyl moiety. Finally, the correlation between  $\delta_{\text{H}}$  4.45 (H-1') and  $\delta_{\text{C}}$  79.4 (C-1) indicated the linkage site of the glucose moiety to the aglycone.

Acidic hydrolysis of **1** and TLC analysis of the aqueous phase afforded identification of glucose as the sugar component. Absolute configuration of the glucose as D was determined by optical rotations in comparison with authentic standard. The presence of *p*-coumaric acid in the organic phase was confirmed by TLC in comparison with authentic standard. Cyclohexane-1,2-diol was also detected in the organic phase using GC-MS and NMR analysis.<sup>36</sup> The absolute configuration of cyclohexane-1,2-diol could be determined directly from the organic phase, since the other aglycon part, namely, *p*-coumaric acid, is optically inactive. The organic phase showed positive value in optical activity measurement meaning that (1*S*,2*S*)-cyclohexane-1,2-diol has been isolated.<sup>37</sup> The structure of **1** was thus confirmed as (1*S*,2*S*)-1-[4-*O*-*E*-coumaroyl- $\beta$ -D-glucopyranosyloxy]cyclohexanediol.

Compound **16** has been identified by many authors, but surprisingly, no complete NMR assignment was given.<sup>38</sup> Therefore, complete  $^1\text{H}$  and  $^{13}\text{C}$  characterization was accomplished using  $^1\text{H}$ ,  $^{13}\text{C}$ , and 2D spectra (Table 3). First, the same *p*-coumaroyl moieties as in **1** were identified with  $\delta_{\text{H}}$  at 6.29 (1H, d,  $J = 15.9$  Hz, H-8), 6.85 (2H, d,  $J = 8.1$  Hz, H-3 and H-5), 7.42 (2H, d,  $J = 8.1$  Hz, H-2 and H-6), and 7.62 (1H, d,  $J = 15.9$  Hz, H-7) and  $\delta_{\text{C}}$  at 115.5 (C-8), 115.9 (C-3 and C-5), 127.3 (C-1), 130.0 (C-2 and C-6), 144.6 (C-7), 157.7 (C-4), and 167.4 (C-9). Additionally, five overlapped  $^1\text{H}$  NMR signals between  $\delta_{\text{H}}$  7.20–7.30 along with two methylene triplets at 3.02 (2H, t,  $J = 6.9$  Hz, H-7') and 4.42 (2H, t,  $J = 6.9$  Hz, H-8') were attributed to a phenethyl moiety. The HMBC correlation between H-8' and C-9 confirmed the link between the phenethyl and the *p*-coumaroyl groups.

Compounds **10** and **13** were isolated as a mixture. Separation of each constituent was not performed due to their small amounts. Therefore, careful examination of NMR

spectra ( $^1\text{H}$ ,  $^{13}\text{C}$ , DEPT, and HSQC) and comparison with literature allowed the identification of these components as rhamnocitrin (**10**)<sup>29</sup> and kaempferide (**13**).<sup>26</sup> Moreover, the biological results were obtained using commercial pure products. Because of the low isolated yields of compounds **3** and **19**, those compounds were also tested from commercial materials.

All isolated compounds, except compounds **2** and **4**, were evaluated using resazurin reduction test for their cytotoxicity against human lung cancer (A549), human colorectal cancer

(DLD-1), and normal skin fibroblasts (WS1).<sup>17</sup> Results presented in Table 4 are expressed as the concentration of product inhibiting cell growth by 50% (IC<sub>50</sub>). Etoposide was used as positive control with IC<sub>50</sub> of 2.8 and 2.0 µmol/L against A549 and DLD-1 cell lines, respectively. The phenolic compounds were regarded as active when the IC<sub>50</sub> was smaller than 100 µmol/L.<sup>39</sup> The compound **9** was found to be the most active with IC<sub>50</sub> ranging from 5.8 to 9.2 µmol/L. Moreover, compounds **10**, **12**, and **15** were moderately active against cancer cells with IC<sub>50</sub> ranging from 19 to 37 µmol/L. In contrast to compounds **9**, **12**, and **15**, compound **10** was significantly selective toward cancer cells with IC<sub>50</sub> of 31 µmol/L for A549 and 37 µmol/L for DLD-1 in comparison with 87 µmol/L for normal cells, WS1. Although the cytotoxicity of compounds **9** and **12** were known on A549 cells,<sup>40,41</sup> the activity on human colorectal adenocarcinoma DLD-1 was never reported. Finally, compounds **13** and **18** were found weakly cytotoxic, and all the other compounds tested were inactive. As far as structure–activity relationships are concerned, these in vitro results suggest that the addition of a double bond in C-2 position in molecule **9**, with regard to compound **11**, increases the cytotoxic activity. Similarly, the presence of a methoxy group in C-7 position and a hydroxyl in C-4' position in the flavone **9** seem to have a beneficial effect on the cytotoxic activity in comparison with the acacetin (**12**), where the inversion of these groups reduces the activity. On the other hand, the presence of hydroxyl group in R<sup>2</sup> of compounds **10** and **13** is detrimental for the activity in comparison with compounds **9** and **12**, respectively. In the case of compounds **15–19**, only molecules bearing a benzyl group exhibited cytotoxicities (**15** and **18**). Moreover, the hydroxyl group in R<sup>1</sup> of compound **18** reduces significantly the cytotoxicity in comparison with **15**. All compounds were also evaluated for their antibacterial activities against *S. aureus* and *E. coli*, but no significant activity was observed.

## Concluding remarks

In conclusion, the structure of a new compound **1** was described and 19 compounds were identified from *P. tremuloides*. Among them, compounds **2** and **5** were reported for the first time in *Populus* genus and compounds **3**, **4**, **9**, **10**, **12**, **16**, and **17** for the first time in *P. tremuloides*. Compound **9** was found to be the most cytotoxic against lung carcinoma cell (A549) and colorectal adenocarcinoma (DLD-1) human cell lines. Interestingly, compound **10** was selective toward both cancer cell lines in comparison with normal cells. Finally, all compounds tested do not possess antibacterial activity.

## Experimental

### General

Optical rotations were measured with an automatic polarimeter Rudolph Research Analytical Autopol IV. FTIR spectra were recorded with a PerkinElmer SpectrumOne. High resolution electrospray ionization mass spectrum was conducted in positive mode with an Applied Biosystems/MDS Sciex QSTARXL QqTOF MS system. 1D and 2D NMR spectra (<sup>1</sup>H–<sup>1</sup>H COSY, HSQC, and HMBC) were performed using an Avance 400 Bruker spectrometer equipped with a 5 mm QNP-probe. Chemical shifts were expressed in δ

(ppm) units relative to TMS as an internal standard, and coupling constants were given in Hz. Preparative HPLC was performed on an Agilent 1100 liquid chromatography system, equipped with a solvent delivery system, an auto-sampler and a UV-MWD detector. Samples were eluted in an Intertsil prep-ODS column C18 (20 × 250 mm; 10 µm) at room temperature with a flow rate of 10 mL min<sup>-1</sup>. GC–MS analyses were performed with an instrument (Agilent Technologies 6890N) fitted with a mass-selective detector (Agilent Technologies 5973), a split–splitless injection port, and an apolar capillary column DB-5MS (30 m × 0.25 mm × 0.25 µm).

Analytical thin-layer chromatography (TLC) was performed with silica gel 60 F<sub>254</sub>, 0.25 mm pre-coated TLC plates (Silicycle, Québec, Canada). Flash column chromatographies (CC) were performed on silica gel (40–63 µm with indicator F<sub>254</sub>, Silicycle, Québec, Canada) and on C<sub>18</sub> reversed-phase silica gel (carbon 11%, 40–69 µm, Silicycle, Québec, Canada). Polyamide CC-6 was purchased from Macherey-Nagel (Germany) and Diaion HP-20 from Supelco. Detection of the phenolic compounds was carried out by spraying TLC plates with polyethylene glycol (NP/PEG) reagent followed by heating at 110 °C and detected by UV absorption at 254 and 365 nm. TLC identification of monosaccharides was performed with CH<sub>2</sub>Cl<sub>2</sub>/MeOH/H<sub>2</sub>O (50:25:5) solvent system. The compounds were visualized by spraying an orthophosphoric acid solution of naphtorescinal 5% in EtOH, followed by heating at 110 °C.

The commercial samples used for biological tests, namely, prunin (**3**), kaempferide (**13**), and *trans*-ferulic acid (**19**), were purchased from Indofine Chemical Company (USA). Rhamnocitrin (**10**) was purchased from Apin Chemicals Ltd. (UK).

### Plant material

Leaf buds of *P. tremuloides* Michaux were collected in the boreal forest to the south of Chicoutimi, Québec, Canada, in April 2006. Samples were identified by Patrick Nadeau (Département des sciences fondamentales, Université du Québec à Chicoutimi). A voucher specimen (QFA-A540466) was deposited at the Herbarium Louis-Marie of Université Laval, Québec, Canada.

### Extraction and isolation

The buds of *P. tremuloides* (1 kg) were exhaustively extracted with EtOH (3 L, 60 °C, three times, 2 h each time) followed by EtOH/H<sub>2</sub>O (7:2). The extracts were filtered and pooled. After evaporation of EtOH in vacuo, the aqueous phase was extracted successively with hexane (500 mL × 5) and saturated *n*-BuOH with H<sub>2</sub>O (500 mL × 5). The *n*-BuOH phase was decanted and evaporated in vacuo. The residue (80 g) was fractionated using an open Diaion® column eluted with H<sub>2</sub>O/MeOH with 30%, 50%, and 80% of MeOH. Three fractions were obtained: A (6.46 g), B (7.24 g), and C (58.96 g).

Fraction C was purified on silica gel CC, eluted with CHCl<sub>3</sub>/MeOH gradient (60:1 → 5:1, v/v), and three fractions were obtained: C1, C2, and C3.

Fraction C1 (16.73 g) was subjected to silica gel using a gradient of CHCl<sub>3</sub>/MeOH (90:1 → 60:1, v/v) as eluent. Subfraction C1.1 (384 mg), obtained from CHCl<sub>3</sub>/MeOH

(90:1), was separated on silica gel CC with CHCl<sub>3</sub>/MeOH (80:1) as eluent, to give three fractions: C1.1A, C1.1B, and C1.1C. Subfraction C1.1A was purified by preparative HPLC with a gradient elution of MeOH/H<sub>2</sub>O (50:50 → 85:15, v/v) yielding compounds **15** (249 mg), **16** (5 mg), and **17** (41 mg). Subfraction C1.1B (2.36 g) was applied successively on a silica gel CC and a reversed-phase CC using MeOH/H<sub>2</sub>O gradient (50:50 → 70:30, v/v) as eluent to give **11** (160 mg). Compound **9** (3 mg), **12** (18 mg), and a mixture of **10** and **13** (27 mg) were isolated after a silica gel CC eluted with CHCl<sub>3</sub>/MeOH (90:1) and a preparative HPLC (isocratic CH<sub>3</sub>CN/H<sub>2</sub>O 40:60) of fraction C1.2. Compound **18** (50 mg) was obtained from fraction C1.3 (294 mg) after repeated silica gel CC (CHCl<sub>3</sub>/MeOH, 75:1) and polyamide flash column (MeOH/H<sub>2</sub>O, 50:50 → 75:25).

Fraction C2 was chromatographed on silica gel CC with a gradient elution of CHCl<sub>3</sub>/MeOH (75:1 → 15:1, v/v) to give eight fractions: C2.1–C2.8. Subfraction C2.7 (558 mg) was separated by preparative HPLC using an isocratic mobile phase of CH<sub>3</sub>CN/H<sub>2</sub>O/HCOOH (40:60:1) to afford **2** (19 mg) and **14** (3 mg).

Fraction C3 (5.4 g) was purified on silica gel using a gradient of CHCl<sub>3</sub>/MeOH (25:1 → 7:1) for elution to give five subfractions: C3.1–C3.5. C3.2 was separated on silica gel CC with CHCl<sub>3</sub>/MeOH (20:1) giving **6** (289 mg). Some purifications on different silica gel CC of subfraction C3.2.1 permitted to obtain **19** (2 mg). Subfraction C3.4 (418 mg) was separated by preparative HPLC using an isocratic mobile phase of CH<sub>3</sub>CN/H<sub>2</sub>O (30:70) to afford compounds **1** (20 mg), **3** (8 mg), **4** (14 mg), and **8** (37 mg). Subfraction

C3.5 (482 mg) was separated by HPLC using a gradient of MeOH/H<sub>2</sub>O (10:90 → 100:0) to give **5** (21 mg) and **7** (35 mg).

#### (1S,2S)-1-[4-O-E-coumaroyl-β-D-glucopyranosyloxy]cyclohexanediol (**1**)

White amorphous powder. [α]<sub>D</sub><sup>25</sup> −35.3° (c 1.0, MeOH). IR (neat) ν<sub>max</sub>: 3328, 2935, 1696, 1602, 1160, 1080, 1024, 982, and 833 cm<sup>−1</sup>. <sup>1</sup>H and <sup>13</sup>C NMR spectroscopic data: see Table 2. HR-ESI-MS *m/z*: 447.16225 [M + Na]<sup>+</sup> (calcd. for C<sub>21</sub>H<sub>28</sub>O<sub>9</sub>Na: 447.16310).

#### Acid hydrolysis of **1**

Compound **1** was dissolved in HCl 10% and heated at 110 °C for 4 h. The resulting hydrolysate was extracted with CHCl<sub>3</sub>. The organic phase was dried (MgSO<sub>4</sub>) and the solvent evaporated under reduced pressure. The presence of *p*-coumaric acid was confirmed with standard sample on TLC (CHCl<sub>3</sub>/MeOH 10:1 as eluent and developing with NP/PEG reagent). The presence of cyclohexane-1,2-diol in the organic phase ([α]<sub>D</sub> + 3.4) was confirmed with a GC-MS analysis: Injector temperature, 250 °C; ionization voltage, 70 eV (EI-MS); column temperature, 40 °C for the initial 2 min followed by an increase of 15 °C min<sup>−1</sup> up to 350 °C; carrier gas, He; column flow rate, 1 mL min<sup>−1</sup>. Cyclohexane-1,2-diol was detected at *R*<sub>t</sub> 7.55 min. The aqueous phase was neutralized with *N,N*-diethylmethylamine (10% in CHCl<sub>3</sub>), and the solvents were evaporated under reduced pressure. The residue contained the monosaccharide D-glucose ([α]<sub>D</sub> + 24.8).

#### Cell lines and culture conditions

Lung carcinoma (A549), colorectal adenocarcinoma (DLD-1), and normal skin fibroblast (WS1) human cell lines were obtained from the American Type Culture Collection (ATCC). All cell lines were cultured in minimum essential medium containing Earle's salts and L-glutamine (Mediatech Cellgro, VA) to which were added 10% fetal bovine serum (Hyclone), vitamins (1X), penicillin (100 IU mL<sup>−1</sup>) and streptomycin (100 μg mL<sup>−1</sup>), essential amino acids (1X), and sodium pyruvate (1X) (Mediatech Cellgro, VA). Cells were kept at 37 °C in a humidified environment containing 5% CO<sub>2</sub>.

#### Cytotoxicity assay

Exponentially growing cells were plated in 96-well microplates (BD Falcon) at a density of 5 × 10<sup>3</sup> cells per well in 100 μL of culture medium (DMEM with 10% SVF) and were allowed to adhere for 24 h before treatment. Increasing concentrations of each compound in MeOH or DMSO were then added (100 μL per well), and the cells were incubated for 48 h. The final concentration of MeOH or DMSO in the culture medium was maintained at 0.25% (v/v) to avoid solvent toxicity. Cytotoxicity was assessed using resazurin<sup>17</sup> on an automated 96-well Fluoroskan Ascent F1™ plate reader (Labsystems) using excitation and emission wavelengths of 530 and 590 nm, respectively. Fluorescence was proportional to the cellular metabolic activity in each well. Survival percentage was defined as the fluorescence in experimental wells compared to that in control wells after subtraction of blank values. Each experiment was carried

out three times in triplicate. IC<sub>50</sub> results were expressed as means  $\pm$  standard deviation.

### Antibacterial assays

Antibacterial activity was evaluated using the microdilution method<sup>42</sup> but with some modifications: exponentially growing bacteria were plated in 96-well flat bottom microplates (BD Flacon) at a density of  $5 \times 10^3$  Gram-negative *E. coli* (ATCC 25922) or  $40 \times 10^3$  Gram-positive *S. aureus* (ATCC 25923) per well in 100  $\mu$ L nutrient broth (Difco). The concentration of ethanol in the culture medium was maintained at 0.25% (v/v) to avoid solvent toxicity. Fifty microliters of 4% resazurin was added to each well, and the microplates were incubated for 6 h at 37 °C. Fluorescence was measured after 6 h on an automated 96-well Fluoroskan Ascent Fl<sup>TM</sup> plate reader (Labsystems) using excitation and emission wavelengths of 530 nm and 590 nm, respectively.

### Acknowledgement

The financial support of Fonds Québécois de la Recherche sur la Nature et les Technologies (FQRNT, fonds forestiers 02) is gratefully acknowledged. The authors wish to thank Carole Grenon for the HPLC separations, Catherine Dussault and Maxime Lebrun for biological assays. Finally, the authors also thank Dr Richard Menini for his corrections and helpful comments on this manuscript

# Solid-state $^{27}\text{Al}$ nuclear magnetic resonance investigation of three aluminum-centered dyes

Kamal H. Mroué, Abdul-Hamid M. Emwas, and William P. Power

**Abstract:** We report the first solid-state  $^{27}\text{Al}$  NMR study of three aluminum phthalocyanine dyes: aluminum phthalocyanine chloride,  $\text{AlPcCl}$  (**1**); aluminum-1,8,15,22-tetrakis(phenylthio)-29*H*,31*H*-phthalocyanine chloride,  $\text{AlPc}(\text{SPh})_4\text{Cl}$  (**2**); and aluminum-2,3-naphthalocyanine chloride,  $\text{AlNcCl}$  (**3**). Each of these compounds contains  $\text{Al}^{3+}$  ions coordinating to four nitrogen atoms and a chlorine atom. Solid-state  $^{27}\text{Al}$  NMR spectra, including multiple-quantum magic-angle spinning (MQMAS) spectra and quadrupolar Carr–Purcell–Meiboom–Gill (QCPMG) spectra of stationary powdered samples have been acquired at multiple high magnetic field strengths (11.7, 14.1, and 21.1 T) to determine their composition and number of aluminum sites, which were analyzed to extract detailed information on the aluminum electric field gradient (EFG) and nuclear magnetic shielding tensors. The quadrupolar parameters for each  $^{27}\text{Al}$  site were determined from spectral simulations, with quadrupolar coupling constants ( $C_Q$ ) ranging from 5.40 to 10.0 MHz and asymmetry parameters ( $\eta$ ) ranging from 0.10 to 0.50, and compared well with the results of quantum chemical calculations of these tensors. We also report the largest  $^{27}\text{Al}$  chemical shielding anisotropy (CSA), with a span of  $120 \pm 10$  ppm, observed directly in a solid material. The combination of MQMAS and computational predictions are used to interpret the presence of multiple aluminum sites in two of the three samples.

**Key words:** aluminum phthalocyanine dyes, solid-state  $^{27}\text{Al}$  NMR, electric field gradient tensor, aluminum chemical shift anisotropy, quantum chemical calculations.

**Résumé :** On a réalisé la première étude RMN du  $^{27}\text{Al}$  en phase solide de trois colorants à base de phthalocyanine d'aluminium, soit le chlorure de phthalocyanine d'aluminium,  $\text{AlPcCl}$  (**1**), le chlorure de la 1,8,15,22-tétrakis(phénylthio)-29*H*,31*H*-phthalocyanine d'aluminium,  $\text{AlPc}(\text{SPh})_4\text{Cl}$  (**2**) et le chlorure de la 2,3-dinaphthalocyanine d'aluminium,  $\text{AlNcCl}$  (**3**). Chacun de ces composés contient des ions de  $\text{Al}^{3+}$  coordonnés à quatre atomes d'azote et un atome de chlore. Les spectres RMN de l'aluminium-27 en phase solide, y compris les spectres multiquantiques à l'angle magique de rotation (« MQMAS ») et les spectres quadripolaires de Carr–Purcell–Meiboom–Gill (« QCPMG ») d'échantillons de poudres solides, ont été obtenus à des forces de champs magnétiques élevés diverses (11,7, 14,1 et 21,1 T) dans le but de déterminer leur composition et le nombre de sites d'aluminium et on les a analysés pour en extraire de l'information détaillée relative au gradient du champ électrique (GCE) de l'aluminium ainsi que les tenseurs de blindage du champ magnétique. On a déterminé les paramètres quadripolaires de chacun des sites d'aluminium-27 par simulations spectrales; les constantes de couplage quadripolaires ( $C_Q$ ) qui varient de 5,40 à 10,0 MHz et les paramètres d'asymétrie ( $\eta$ ) qui s'étalent de 0,10 à 0,50 se comparent bien avec les résultats obtenus pour ces tenseurs par le biais de calculs théoriques. On a aussi observé une anisotropie de blindage chimique (ABC) de l'aluminium-27 de  $120 \pm 10$  ppm qui correspond à la valeur la plus élevée jamais observée dans un matériel solide. On a utilisé une combinaison des valeurs expérimentales observées dans les spectres multiquantiques à l'angle magique de rotation avec les prédictions théoriques pour interpréter la présence de multiples sites d'aluminium dans deux des trois échantillons.

**Mots-clés :** colorants à base de phthalocyanine d'aluminium, RMN du  $^{27}\text{Al}$  en phase solide, tenseur du gradient du champ électrique, anisotropie du déplacement chimique de l'aluminium, calculs théoriques à base de chimie quantique.

[Traduit par la Rédaction]

## Introduction

Phthalocyanine complexes (Pcs), and the structurally related naphthalocyanines (Ncs), together with their metal-

centered derivatives, constitute an important class of macrocyclic compounds, which play a vital role in many modern practical and technological applications.<sup>1</sup> These materials have been intensively used in dyes, pigments, fuel and solar cells, electrophotography, semiconductors, liquid crystals, data-storage devices, photosensitizers for photodynamic therapy, and nonlinear optical materials, among others. This wide variety of applications is due mainly to their intense green-blue color, combined with their exceptional stability to acids, alkalis, heat, light, and common solvents. These properties and applications, among others as well, are discussed in several excellent monographs about phthalocyanines and their derivatives.<sup>2–8</sup>

Numerous techniques have been used to study these mate-

rials, such as X-ray diffraction, mass spectrometry, Raman, IR, UV-vis, electronic absorption/emission, Mössbauer, electron paramagnetic, and nuclear magnetic resonance (NMR) spectroscopies, among others. Studies of these materials by liquid-state NMR have involved mainly the use of  $^1\text{H}$  and  $^{13}\text{C}$  NMR as identification tools.<sup>9,10</sup> Direct NMR observation of the metal nuclei in solid metal-centered phthalocyanines has been limited to few studies, including a  $^{59}\text{Co}$  NMR study of four hexacoordinated cobalt(III) phthalocyanines,<sup>11</sup> a  $^{25}\text{Mg}$  NMR study of monopyridinated aqua(magnesium) phthalocyanine,<sup>12</sup> and a recent  $^{71}\text{Ga}$  NMR study of gallium phthalocyanine chloride,  $\text{GaPcCl}$ .<sup>13,14</sup>

From a spectroscopic perspective, solid-state nuclear magnetic resonance (SSNMR) represents an ideal and powerful tool to probe the metal centre in a metalophthalocyanine. The advantages of NMR over other techniques, such as X-ray and neutron diffraction, is that while the latter techniques rely on the long-range order in the crystal lattice and require the availability of high-quality single crystals suitable for analysis, SSNMR focuses on the local electronic environment around the nucleus of interest without the necessity of single crystals. Given the limited solubility of metalophthalocyanines in both inorganic and organic solvents, and their large molecular weights, their analysis by single-crystal X-ray diffraction can be quite cumbersome, if at all possible. Moreover, the ability of SSNMR to characterize disordered and amorphous solid materials has been well-established and demonstrated in numerous instances (vide infra). Recently, the increasing availability of ultra-high-magnetic-field NMR spectrometers, together with the advances in instrumental hardware, and the introduction of new pulse sequences have also facilitated the application of SSNMR to study such poorly crystalline materials.<sup>15,16</sup>

Among the various metalophthalocyanines, aluminum-centered ones are well-suited for SSNMR experiments. This is due to the very favorable NMR properties that  $^{27}\text{Al}$  enjoys, including its high natural abundance (100%), large magnetogyric ratio ( $\gamma = 6.9762 \times 10^7 \text{ rad T}^{-1} \text{ s}^{-1}$ , close to  $^{13}\text{C}$ ), and a sizable chemical shift range of about 300 ppm.<sup>17</sup> However, the quadrupolar nature of  $^{27}\text{Al}$  (spin  $I = 5/2$ ) introduces various challenges in SSNMR studies of this nucleus. The most distinctive challenge arises from the nonzero nuclear quadrupole moment [ $Q(^{27}\text{Al}) = 14.66 \times 10^{-30} \text{ m}^2$ ],<sup>18</sup> which couples strongly with any electric field

gradient (EFG) arising naturally from lack of spherical symmetry in charge distribution around the aluminum nucleus. Such quadrupolar interactions have considerable effects on  $^{27}\text{Al}$  NMR spectra, often beyond those described under first-order perturbation theory. Usually, only the central transition (CT,  $+1/2 \leftrightarrow -1/2$ ) is observed in a SSNMR experiment of a polycrystalline powdered sample, and it is unaffected to first-order but is substantially broadened by second-order quadrupolar effects.<sup>19,20</sup> In addition to the quadrupolar interaction,  $^{27}\text{Al}$  is also sensitive to the chemical shift/shielding interaction. The EFG and chemical shift (CS) are both orientation-dependent NMR interactions that can provide reliable information about the local electronic environment of the nucleus of interest, and can potentially yield structural details not typically available from other techniques.<sup>21,22</sup>

Despite the complications caused by second-order quadrupolar broadening, solid-state  $^{27}\text{Al}$  NMR has been used frequently to study a wide variety of materials, most of which are inorganic and disordered solids such as glasses, zeolites, aluminosilicates, molecular sieves, cements, ceramics, as well as natural and synthetic minerals.<sup>23–38</sup> In these studies,  $^{27}\text{Al}$  magic-angle-spinning (MAS) NMR has been used primarily to narrow the central transition line shapes, and to enhance the spectral resolution to differentiate among tetrahedral, penta-coordinate, and octahedral local aluminum coordination environments (mainly in aluminum-(oxygen)<sub>n</sub> coordination,  $n = 4, 5, 6$ ) based on the different  $^{27}\text{Al}$  chemical shift ranges of each environment.<sup>15,39</sup> In the case of disordered and (or) amorphous solids, the conventional one-dimensional MAS spectrum does not give well-defined second-order quadrupolar line shapes. These lines are rather featureless and asymmetric, from which it is quite challenging to extract any information related to the chemical shift and quadrupolar interactions arising from overlapping signals.<sup>40–42</sup> For such materials, the two dimensional multiple-quantum magic-angle-spinning (MQMAS) experiment<sup>43,44</sup> is used to resolve overlapping resonances in multi-site systems, based on the difference in the chemical shift and quadrupolar parameters experienced by each site. In many instances, MQMAS makes it possible to not only resolve the different sites present in the system, but also allows extraction of sufficient information about the  $^{27}\text{Al}$  NMR parameters associated with each unique site.

In contrast to the plethora of inorganic and glassy materials investigated by solid-state  $^{27}\text{Al}$  NMR, it is surprising that only a handful of aluminum-containing organic compounds have been studied by this technique. Wasylishen and co-workers reported solid-state  $^{27}\text{Al}$  NMR spectra of tris(acetylacetonato)aluminum(III), tris(tropolonato)aluminum(III), and tris(2,2,6,6-tetramethyl-3,5-heptanedionato)aluminum(III).<sup>45</sup> The aluminum atoms in these compounds are each coordinated to six oxygen atoms in a distorted octahedral geometry, where small  $^{27}\text{Al}$  chemical shift anisotropy (CSA) values were observed for the three complexes. Gang Wu and co-workers also recorded solid-state  $^{27}\text{Al}$  NMR spectra of three blue-luminescent aluminum compounds containing terminal 7-azaindole ligands, in which the aluminum ions are in distorted tetrahedral coordination environments.<sup>46</sup> The same group successfully applied  $^{27}\text{Al}$  3QMAS spectroscopy to the identification of disorder and isomerism in two blue-luminescent aluminum compounds, in which the Al centres exhibit five-coordinated geometries.<sup>47</sup> Utz et al. studied the  $^{27}\text{Al}$  spectra of three different polymorphs of solid tris(8-hydroxyquinoline)aluminum(III) under MAS conditions.<sup>48</sup> These same systems were reinvestigated recently by Nishiyama et al. using  $^{27}\text{Al}$  1D MAS and 2D MQMAS NMR experiments.<sup>49</sup> Schurko et al. reported a very small  $^{27}\text{Al}$  quadrupolar interaction but a large aluminum chemical shielding anisotropy, with a span of 83 ppm, in the bis(pentamethylcyclopentadienyl)aluminum cation.<sup>50</sup> Schurko and co-workers applied the frequency-stepped technique in Hahn-echo and QCPMG pulse sequences to acquire ultrawide-line  $^{27}\text{Al}$  NMR spectra of stationary samples of three- and five-coordinate organoaluminum complexes.<sup>51</sup>

In this work, we investigate the solid-state  $^{27}\text{Al}$  NMR spectra of three aluminum-centered organic dyes: aluminum phthalocyanine chloride,  $\text{AlPcCl}$  (**1**); aluminum-1,8,15,22-tetrakis(phenylthio)-29*H*,31*H*-phthalocyanine chloride,  $\text{AlPc}(\text{SPh})_4\text{Cl}$  (**2**); and aluminum-2,3-naphthalocyanine chloride,  $\text{AlNcCl}$  (**3**) (Fig. 1). In addition to our main interest in the SSNMR of phthalocyanines (for the reasons mentioned above), these compounds have been chosen because they exhibit aluminum in penta-coordinate geometries, which is much less common than the four- and six-coordinate motifs. In all three systems, the  $\text{Al}^{3+}$  ions are coordinated to four isoindole nitrogen atoms and one chlorine atom in a square-pyramidal geometry. Such coordination geometry is relatively rare in solid-state  $^{27}\text{Al}$  NMR studies, both in inorganic and organic systems. We also report extensive density functional theory (DFT) and restricted Hartree–Fock (RHF) quantum chemical calculations of aluminum NMR interactions in molecular models of these complexes in an attempt to examine the orientation of NMR tensors within molecular frames and to help rationalize the origin of experimentally measured aluminum NMR parameters.

## Experimental

### Sample preparation

The three complexes were purchased from Aldrich Chemical Company. The dye contents are ~ 85%, 90%, and 80% for compounds **1**, **2**, and **3**, respectively. Attempts to obtain the pure compounds by recrystallization from a variety of

organic solvents or by vacuum sublimation were unfruitful. Hence, they were used as purchased. Samples of each complex were ground into fine powders with a mortar and pestle for X-ray powder diffraction experiments, and subsequently packed into 2.5 and 4.0 mm o.d. zirconia rotors for SSNMR experiments. Powder X-ray diffraction data were collected using an INEL powder diffractometer with a position-sensitive detector and Cu  $\text{K}\alpha_1$  radiation ( $\lambda = 1.54056 \text{ \AA}$ ). The operating conditions were 30 kV and 30 mA, with an exposure time of 5–10 min over the  $2\theta$  range from 0.0 to  $120^\circ$ .

### Solid-state $^{27}\text{Al}$ NMR spectroscopy

$^{27}\text{Al}$  solid-state NMR experiments were performed at Larmor frequencies of 130.3 MHz (11.75 T), 156.4 MHz (14.1 T), and 234.5 MHz (21.1 T) using Bruker Avance (11.75 and 14.1 T) and Avance II (21.1 T) consoles. The experiments at 11.75 and 14.1 T were performed at the University of Waterloo; experiments at 21.1 T were performed at the National Ultrahigh-Field NMR Facility for Solids at the National Research Council (NRC) in Ottawa, Ontario, Canada. Standard Bruker 2.5 mm double-resonance MAS probes were used at 14.1 and 21.1 T, whereas a Bruker 4 mm double-resonance MAS probe was used at 11.75 T. Pulse calibration and chemical shift referencing were performed using a 1.0 mol/L  $\text{Al}[(\text{H}_2\text{O})_6]^{3+}$  aqueous solution set at 0.0 ppm. A solid echo ( $\pi/2 - \tau_1 - \pi/2 - \tau_2 - \text{ACQ}$ ) and quadrupolar Carr–Purcell–Meiboom–Gill (QCPMG)<sup>52,53</sup> pulse sequences were used to acquire spectra of non-spinning samples. For experiments performed under MAS conditions, the sample spinning speed was 20.0 kHz at 14.1 T and 21.1 T, and 15.0 kHz at 11.75 T. A very short pulse ( $\pi/12$ ) was used in the one-dimensional MAS spectra to ensure quantification of all species. For the solid-echo and QCPMG experiments, a selective  $\pi/2$  pulse of 1.20–1.40  $\mu\text{s}$  was used.

Two-dimensional  $^{27}\text{Al}$  triple-quantum MAS (3QMAS) spectra of the three complexes were obtained at 21.1 T using a spinning rate of 20.0 kHz. The  $z$ -filtered 3QMAS pulse sequence was used,<sup>54</sup> consisting of excitation (1.90  $\mu\text{s}$ ) followed by evolution of the triple-quantum coherence during  $t_1$  followed by a conversion pulse (0.80  $\mu\text{s}$ ), a 20  $\mu\text{s}$   $z$ -filter, and a selective  $\pi/2$  pulse (7.50  $\mu\text{s}$ ) followed by acquisition during  $t_2$ . A total of 240 transients were obtained for each  $t_1$  increment; 64 complex points were acquired in  $t_1$ , with a  $t_1$  increment of 25  $\mu\text{s}$ , which corresponds to half the rotor period. Exponential apodization of 300 Hz was applied in both dimensions prior to zero-filling and Fourier transformation. A shearing transformation was performed during data processing to obtain the isotropic dimension along F1 and the anisotropic MAS dimension along F2. Recycle delays of 2.0 s, 3.0 s, and 5.0 s were sufficient at 11.75, 14.1, and 21.1 T, respectively. The 1D NMR spectra used for line-shape analysis were simulated with SIMPSON.<sup>55</sup> Spectral simulations were carried out iteratively and simultaneously at multiple fields, and the errors in the extracted parameters were determined by visual comparison of the resulting fit at each field with the corresponding experimental spectrum. Each parameter was optimized independently by varying it in both directions away from its best-fit value, while all other parameters were held fixed, until a visible difference

between experimental and simulated spectra was observed. Stack plots were generated with DMFit.<sup>56</sup>

### Quantum chemical calculations

All quantum chemical calculations were performed using Gaussian 03<sup>57</sup> running on the SHARCNET facility for high performance computing.<sup>58</sup> In an attempt to understand the experimentally observed <sup>27</sup>Al NMR parameters, three models for calculations of NMR interaction tensors were constructed for compound **1**: The first model was built using atomic coordinates obtained from the X-ray single-crystal study of Hasegawa and Sato,<sup>59,60</sup> and used directly for NMR calculations. Two additional models were constructed by the addition of either a chlorine atom or a water molecule below the phthalocyanine ring in an axial position to complete the octahedral coordination around the aluminum atom. The geometries of both models were then fully optimized at the RHF/6–311G\*\* method. Since there are no crystal structures reported for compounds **2** and **3**, the structures used in NMR calculations were derived from the reported structure of molecule **1** of compound **1**<sup>59,60</sup> by adding either four thiophenyl groups (**2**) or four naphthalo groups (**3**) in their respective peripheral positions, as depicted in Fig. 1. The two structures were then fully optimized at the RHF/6–311G\*\* method. Aluminum electric field gradient and nuclear magnetic shielding tensors were subsequently calculated for the resulting structures using both the restricted Hartree–Fock (RHF) and density functional theory (DFT) methods. The B3LYP exchange functional<sup>61,62</sup> was employed in the DFT calculations. The following standard Pople-type basis sets were employed on all atoms: 6–31G\*\*, 6–31++G\*\*, 6–311G\*\*, 6–311++G\*\*, and 6–311+G (2d, p). The nuclear magnetic shielding tensors were calculated using the gauge-including atomic orbitals (GIAO) method.<sup>63,64</sup> Because there is no established absolute magnetic shielding scale for <sup>27</sup>Al, the calculated <sup>27</sup>Al isotropic chemical shieldings ( $\sigma_{\text{iso}}$ ) were converted into the corresponding isotropic chemical shifts ( $\delta_{\text{iso}}$ ) using the formula  $\delta_{\text{iso}} = \sigma_{\text{ref}} - \sigma_{\text{iso}}$ , where  $\sigma_{\text{ref}}$  is the calculated isotropic shielding constant of  $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$  cation, the reference species.<sup>17</sup> The geometry of this cation was fully optimized at the RHF/6–311G\*\* level. To avoid basis-set dependence of the calculated <sup>27</sup>Al chemical shifts, the reference chemical shielding  $\sigma_{\text{ref}}$  was computed for each basis set used. The calculated <sup>27</sup>Al EFG and CS parameters were extracted from the Gaussian output files using the EFGShield program (version 2.3) developed in the laboratory of D.L. Bryce.<sup>65</sup>

### Solid-state <sup>27</sup>Al NMR conventions

Prior to commencing the discussion of the <sup>27</sup>Al NMR results of this study, it is convenient to recall some NMR concepts and definitions relevant to the systems currently investigated, keeping in mind that the SSNMR theory for half-integer quadrupolar spins is detailed more elegantly elsewhere.<sup>19–22</sup> Aside from the Zeeman interaction, the spectrum of a half-integer quadrupolar spin (such as <sup>27</sup>Al,  $I = 5/2$ ) is dominated by the nuclear quadrupole interaction and the nuclear magnetic shielding interaction. The high-field approximation, in which the Zeeman interaction is assumed

to be at least ten times stronger than both interactions, is always applied in the interpretation of SSNMR spectra of these nuclei.

Nuclear magnetic shielding is the interaction between the nuclear spins and the local magnetic field induced by surrounding electrons, and depends on the orientation of the molecule with respect to the external applied magnetic field,  $\mathbf{B}_0$ ; in other words, it is anisotropic. Thus, it can be described by a second-rank tensor, denoted by  $\sigma$ . In its principal axis system (PAS), the symmetric component of  $\sigma$  is diagonal, and has three eigenvalues labeled and ordered such that:  $\sigma_{33} \geq \sigma_{22} \geq \sigma_{11}$ . Experimentally, the magnetic shielding at a nucleus is measured in terms of the chemical shift,  $\delta_{ii}$ , which gives the difference in ppm between the sample signal and that of a reference compound. Since chemical shielding and chemical shift vary conversely with frequency, the three principal components of the CS tensor are ordered as:  $\delta_{11} \geq \delta_{22} \geq \delta_{33}$ . Although the magnitude of the shielding (or shift) tensor can be fully described by its three eigenvalues, an alternative convention is used in which the magnitude of the tensor is fully described by: its isotropic chemical shift  $\delta_{\text{iso}} = (\delta_{11} + \delta_{22} + \delta_{33})/3$ ; its span  $\Omega = \sigma_{33} - \sigma_{11} \approx \delta_{11} - \delta_{33}$ ; and its skew  $\kappa = 3(\sigma_{\text{iso}} - \sigma_{22})/\Omega = 3(\delta_{\text{iso}} - \delta_{22})/\Omega$ , where  $-1.0 \leq \kappa \leq +1.0$ .<sup>66,67</sup> The span reflects the breadth of the powder pattern due to shielding anisotropy, while the skew describes the shape of the shielding tensor, with  $\kappa = \pm 1.0$  indicating an axially symmetrical CS tensor. It is very important to mention that the span of the CS tensor, represented by  $\Omega$ , scales linearly (when measured in Hz) with  $\mathbf{B}_0$ . This means that the effects of CSA are observed more clearly at high magnetic fields than at lower ones.

The quadrupolar interaction results from the coupling of the quadrupole moment of a nucleus with any electric field gradient (EFG) at that nucleus. The EFG is represented by a second-rank traceless and symmetric tensor. In its PAS, it has three components ordered as:  $|V_{33}| \geq |V_{22}| \geq |V_{11}|$ , with  $V_{11} + V_{22} + V_{33} = 0$ . Two parameters are sufficient to quantify the magnitude of the quadrupolar interaction: the quadrupolar coupling constant ( $C_Q$ ) to measure its size (strength), and the asymmetry parameter ( $\eta$ ) to measure the degree of axial asymmetry of the EFG tensor. They are given by  $C_Q = (eQV_{33})/h$  and  $\eta = (V_{11} - V_{22})/V_{33}$ . Here,  $e$  is the charge of an electron,  $Q$  is the nuclear quadrupole moment, and  $h$  is Planck's constant.  $C_Q$  is measured in Hz, while  $\eta$  is unitless and can take any value between 0 and 1 ( $\eta = 0$  corresponds to axial symmetry of the EFG tensor). The quadrupolar interaction can be treated as a second-order perturbation of the Zeeman interaction when the quadrupolar frequency,  $\nu_Q = 3C_Q/(2I(2I - 1)) = 0.15 C_Q$  for <sup>27</sup>Al, is less than 10% of the Larmor frequency,  $\nu_L$ .<sup>68</sup> This has two direct consequences for solid-state <sup>27</sup>Al NMR spectroscopy. First, the satellite transitions,  $(\pm 5/2 \leftrightarrow \pm 3/2)$  and  $(\pm 3/2 \leftrightarrow \pm 1/2)$ , often extend over a large spectral range so that they are difficult to both excite and detect; hence, experimentally only the central transition is typically observed. Second, the second-order quadrupolar breadth of the central transition line shape is directly proportional to  $C_Q^2/\nu_L$ .<sup>68,69</sup> This means that the second-order quadrupolar broadening (in Hz) scales inversely with  $\mathbf{B}_0$ , making it advantageous to acquire NMR spectra of half-integer quadrupolar nuclei at the highest pos-

sible magnetic field strengths to minimize such broadening. Another very important consequence of second-order quadrupolar effects is that the centre of gravity of the central transition ( $\delta_{cg}$ ) does not coincide with the true isotropic chemical shift ( $\delta_{iso}$ ). Rather, it is shifted away by the so-called isotropic second-order quadrupole induced shift ( $\delta_{qis}$ ). For a spin-5/2 nucleus such as  $^{27}\text{Al}$ ,  $\delta_{qis}$  of the central transition is given, in ppm, by<sup>15,70</sup>

$$[1] \quad \delta_{qis} = \delta_{cg} - \delta_{iso} = -6000 \frac{P_Q^2}{\nu_L^2}$$

where  $P_Q = C_Q(1+\eta^2/3)^{1/2}$  is the second-order quadrupole effect (SOQE) parameter, and sometimes is simply termed the quadrupolar product.

Of equal importance to the magnitudes of the CS and quadrupolar interactions is the information pertaining to the relative orientation of these two tensor quantities. This unique information is contained in three fixed Euler angles ( $\alpha$ ,  $\beta$ , and  $\gamma$ ) that describe the counter-clockwise rotations needed to bring the EFG PAS into coincidence with the CS PAS. The so-called “zyz” convention is usually used, where  $\alpha$  describes the counter-clockwise rotation about the initial  $z$  axis ( $V_{33}$ ) of the coordinate system, followed by a rotation about the new  $y'$  axis ( $V_{22}$ ) by  $\beta$ , followed by a rotation about the final  $z''$  axis ( $V_{33}$ ).<sup>71</sup>

## Results and discussion

Preliminary studies of compounds **1–3** using MQMAS at 21.1 T indicated that both compounds **1** and **2** were composed of multiple components, while compound **3** was composed largely of a single component (Fig. 2). All three spectra indicate one component with a signal near  $30 \pm 5$  ppm in each dimension, which can be described by an aluminum site with a quadrupolar coupling constant near 10 MHz and an isotropic chemical shift near 27 ppm, as well as a common minor impurity with a narrow peak near 10 ppm (vide infra). Therefore, for clarity, compound **3** will be described first, and those results will be used to help illustrate the situation for compounds **1** and **2**. This is completely consistent with the results of powder X-ray diffraction (provided in the Supplementary data), in which compound **1** displayed a multi-component nature with a number of overlapping reflections, **2** displayed no crystalline reflections (indicating an amorphous nature), while compound **3** displayed a clear diffraction pattern consistent with a single-phase crystalline sample.

The sheared 3QMAS spectrum of  $\text{AlNcCl}$  (**3**) at 21.1 T (Fig. 2c) clearly shows a unique Al site flanked with spinning sidebands. This ridge lies in a direction parallel to the F2 axis, a consequence of the strong quadrupolar interaction experienced by  $^{27}\text{Al}$  nuclei in this site. Another small ridge lies at the diagonal CS axis, with a very small intensity relative to the main peak, indicating that it corresponds to an aluminum-containing impurity. This impurity also appears as a low-frequency “shoulder” in the 1D MAS line shape, shown on top of the 2D spectrum. The 1D MAS spectra of  $\text{AlNcCl}$  at the three magnetic fields are all shown in Fig. 3, along with their corresponding simulations. Unlike the two other complexes, the MAS spectra of compound **3** reveal a polycrystalline and non-disordered powdered sample, despite

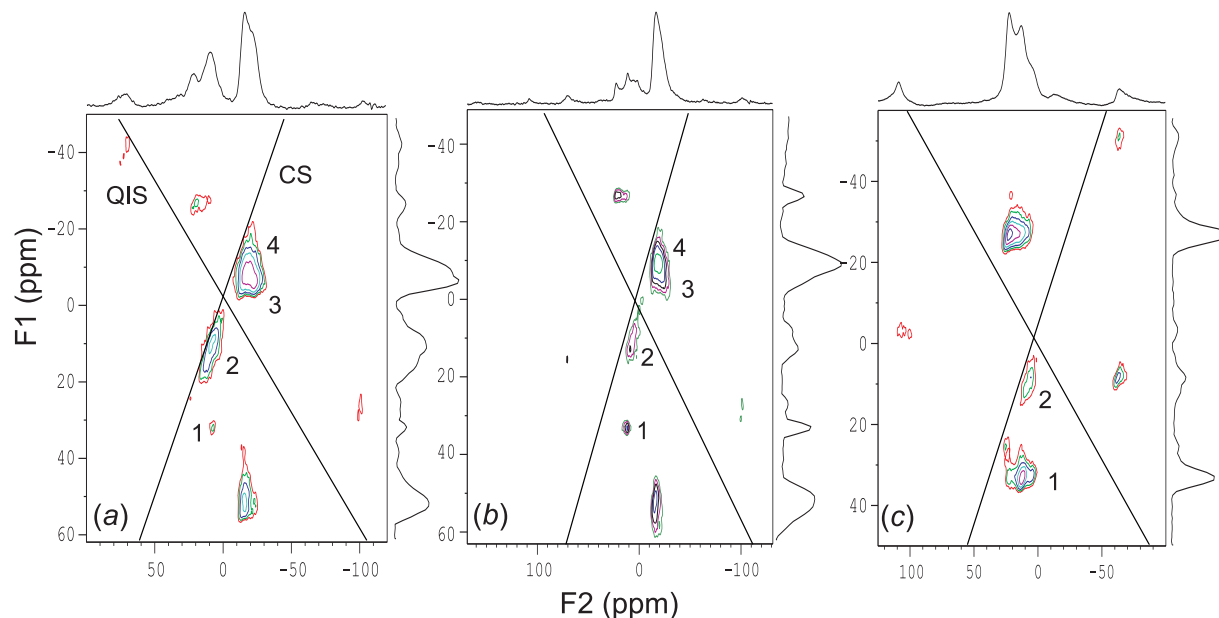

the presence of an impurity. It is obvious that the presence of this impurity hinders the exact agreement between the experimental line shapes and the simulated ones, notably at 21.1 T (Fig. 3a) due to the inherent higher sensitivity at this ultrahigh field. Simultaneous simulation of the three MAS spectra yields the best-fit values of 27.0 ppm, 9.80 MHz, and 0.10 for  $\delta_{iso}$ ,  $C_Q$ , and  $\eta$ , respectively, for the dominant component (Table 1).

In addition to the MAS spectra,  $^{27}\text{Al}$  QCPMG and solid-echo NMR spectra of a stationary powder sample of  $\text{AlNcCl}$  were acquired at 14.1 and 21.1 T, the results of which are shown in Fig. 4. Comparing the line widths of the static spectra at both fields, it can be readily observed that these line widths are almost equal when measured in Hz. This indicates that CSA has a significant contribution to the powder line shape, and is comparable to the second-order quadrupolar broadening. Had the spectra been dominated by the latter interaction only, then the line width at 21.1 T would have been equal to two thirds of that at 14.1 T. Clearly, this is not the case. To determine the contribution of the CSA to the line shape, the  $\delta_{iso}$ ,  $C_Q$ , and  $\eta$  values determined from the MAS experiments were used in the simultaneous simulation of the static spectra at both fields, and the experimental spectra could be reproduced fairly well with the inclusion of a span of  $120 \pm 10$  ppm and a skew of  $0.85 \pm 0.10$ . It is also important to mention that the line shape is very sensitive to the Euler angle  $\beta$ , which is the angle between  $V_{33}$  (the largest component of the EFG tensor) and  $\delta_{33}$  (the most shielded component of the CS tensor). The small experimental value of  $5^\circ$  for this angle indicates that these two components lie almost in the same direction, nearly perpendicular to the plane of the phthalocyanine ring.

A number of studies have noted the presence and characteristics of penta-coordinated Al sites in aluminum oxide derived materials.<sup>72–76</sup> In accord with the results of those studies, isotropic  $^{27}\text{Al}$  chemical shifts of 30–40 ppm are observed, falling midway between the common shift ranges of tetrahedral and octahedral aluminum sites encountered in such materials. Quadrupolar coupling constants vary greatly but are generally smaller than what has been observed with these materials, and chemical shift anisotropies in oxide materials are expected to be small.<sup>45</sup> The most relevant comparisons to be made to the results reported here are from other metal-centered complexes involving heterocyclic ligands. Both reports of solid-state  $^{27}\text{Al}$  NMR characterizations of penta-coordinated Al sites, in 7-azaindolyl complexes by Aschenhurst et al.<sup>47</sup> and in bis-tetrahydrofurfuryloxide complexes by Tang et al.,<sup>51</sup> correspond to square-pyramidal geometries about the aluminum centre, similar to the compounds investigated here. However, due to structural distortions in these other compounds, there are some clear differences in the results, particularly with respect to quadrupolar coupling; these were smaller in the azaindolyl complexes, 5.5–6.8 MHz, while much larger in tetrahydrofurfuryloxide complexes, 19.6–19.9 MHz. Chemical shift data were unreported in ref. 51 as such influences on the acquired NMR spectra were no doubt negligible compared with the very large quadrupolar coupling; however, Aschenhurst et al. reported slightly higher  $^{27}\text{Al}$  chemical shifts of 43–56 ppm in azaindolyl complexes, compared with what has been found here. Of interest in the azaindolyl

**Fig. 2.** Triple-quantum MAS  $^{27}\text{Al}$  NMR spectra of the studied compounds acquired at 21.1 T with a spinning speed of 20.0 kHz. (a) compound **1**,  $\text{AlPcCl}$ ; (b) compound **2**,  $\text{AlPc}(\text{SPh})_4\text{Cl}$ ; and (c) compound **3**,  $\text{AlNcCl}$ . The unique Al sites are marked with numbers. The other peaks are spinning sidebands. To facilitate the interpretation of the spectrum, the chemical shift (CS) axis of gradient +1, and the quadrupole induced shift (QIS) axis with a gradient of  $-10/17$  are also drawn to scale.

**Fig. 3.** Experimental and simulated  $^{27}\text{Al}$  MAS NMR spectra of a powder sample of compound **3** acquired at three magnetic fields. Spinning rates are 20.0 kHz in (a) and (b), and 15.0 kHz in (c). The upper trace in (a) shows the simulation for each individual site, where site 1 is in blue and site 2 is in red. All simulated spectra were calculated using the parameters reported in Table 1.

complexes is the apparent absence of any chemical shift anisotropy;  $^{27}\text{Al}$  NMR spectra obtained at 11.7 T could be simulated well without any inclusion of its effects. Clearly, in the square-pyramidal geometry encountered in the phthalocyanine complexes, chemical shift anisotropy has a much greater influence, a fact confirmed by both multiple-field NMR spectra and the computational chemistry results. This may be a reflection of the electron-rich nature of the macrocyclic ring or its rigid steric influence. Indeed, the  $^{27}\text{Al}$  chemical shift anisotropy measured for compound **3** and predicted for all compounds from calculations are the largest reported directly from  $^{27}\text{Al}$  NMR data of a solid material. The only anisotropies available in the literature that are

larger have been derived from gas-phase spin-rotation data for  $\text{AlNC}$  and  $\text{AlCl}$ , at 405.6 and 477.4 ppm, respectively.<sup>45</sup>

To gain more insight into the structure of compound **3** and to relate the experimental data to that structure, a series of quantum chemical calculations of the  $^{27}\text{Al}$  chemical shielding and EFG tensors were performed using a geometry-optimized model of this compound. The results of these calculations, using various basis sets at the RHF and B3LYP levels, are listed in Table 2. Also shown for comparison are the experimentally measured parameters for the major component (site 1) of this compound determined in the present solid-state study. A striking observation of the calculations is the lack of quantitative agreement between the experi-

**Table 1.** Experimental  $^{27}\text{Al}$  solid-state NMR data obtained from the MAS spectra of the three compounds studied.

**Fig. 4.** Experimental QCPMG and solid-echo  $^{27}\text{Al}$  NMR spectra of a stationary powder sample of compound **3** acquired at 21.1 and 14.1 T. Spectra simulated using the experimental parameters with and without CSA are presented above the experimental spectra.

mental and theoretical values of the  $^{27}\text{Al}$  quadrupolar coupling constant. For both the RHF and DFT methods, all of the calculated  $C_Q$  values are significantly smaller than the experimental value. The largest predicted value of 7.96 MHz, which is obtained with the RHF/6–311+G(2d, p) level, is 18% smaller than the lower experimental limit value of 9.70 MHz. The data also show that for a given basis set, the calculations using RHF and B3LYP methods give similar results for  $C_Q$ , with the former method giving slightly larger values. This indicates that electron correlation is not important for the system under study. The calculations also indicate that the sign of  $C_Q$  is positive. The value of  $C_Q$  is also observed to increase as the size of the basis set is increased. The discrepancy between the calculated and observed values of  $C_Q$ , and of other reported  $^{27}\text{Al}$  NMR parameters as well, may be due to the fact that the atomic coordinates used in the calculations were obtained from a computationally optimized model of the compound, and not from the more realistic single-crystal XRD structure (which

are unavailable for this compound). Other important factors that may cause such discrepancies originate from the fact that calculations were performed on a single isolated rigid molecule in the gas phase (no rovibrational averaging included) and do not take into account the long-range intermolecular interactions in the solid state (which are believed to be very small for the Al site at the centre of the molecule). Also, the limited sizes of the basis sets used may be a factor. It is particularly satisfying to note that theoretical calculations predict an EFG tensor that is nearly axially symmetric, as shown in the tabulated values of the quadrupolar asymmetry parameter  $\eta$ . These are in good agreement with the observed value of  $0.1 \pm 0.1$ , especially with the B3LYP method employing large basis sets. The calculated B3LYP results for  $\eta$  converge to the value of 0.16, in excellent accord with experiment.

Aside from the isotropic chemical shift values, both RHF and B3LYP calculations of the  $^{27}\text{Al}$  CS tensor parameters show very good agreement with experiment. Both methods

overestimate the isotropic chemical shift by at least 10 and 14 ppm for the B3LYP/6-31G\*\* and RHF/6-31G\*\* methods, respectively. With larger basis sets in both methods, the predicted values become even farther from that observed. The availability of an absolute shielding scale enables the most successful test of the ability of theoretical calculations to reproduce experimentally observed isotropic chemical shifts. In lieu of such a scale for  $^{27}\text{Al}$ , it is not surprising to find that the observed isotropic chemical shift,  $27.0 \pm 1.0$  ppm, is not well-reproduced by the calculations at both levels of theory. As mentioned in the Experimental section of this report, the calculated isotropic chemical shifts are derived by subtracting the calculated isotropic  $^{27}\text{Al}$  shielding constant in compound **3** from that in  $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ . Hence, the considerable difference between the predicted and observed values of  $\delta_{\text{iso}}$  is attributed to deficiencies in the geometrically optimized model of the reference cation. Geometry optimization using a larger basis set and (or) different theory than RHF (B3LYP or MP2) of this reference compound may be needed to establish better agreement between the experimental and calculated values of  $\delta_{\text{iso}}$ . Sykes et al. have reported a series of calculated isotropic shielding constants that converge near 613 ppm for  $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$  at the RHF level<sup>77</sup> (an observation we have confirmed in our own calculations). Using their value as an absolute shielding reference for our calculated results gives  $\delta_{\text{iso}}$  values that are similar to those reported in Table 2, with values ranging from 20 to 47 ppm instead of 41 to 47 ppm at the RHF level, but, unsurprisingly, yields  $\delta_{\text{iso}}$  values that are in very poor agreement, ranging from 42 to 80 ppm at the B3LYP level (a different computational method) in going from the 6-31G\*\* to the 6-311+G(2d, p) basis sets. Our own results indicate a difference between the two computational methods, RHF vs. B3LYP, of calculating  $^{27}\text{Al}$  absolute chemical shielding ranging from 25 to 40 ppm, depending on the basis sets used.

As the size of the basis set is augmented, the calculated span of the aluminum CS tensor converges to a value of 100 ppm and 136 ppm at RHF and B3LYP levels, respectively. It is apparent that the DFT/B3LYP method yields span values that are closer to the observed one of  $120 \pm 10$  ppm than the RHF method. It is also interesting to find that both methods predict with high accuracy the skew of the aluminum CS tensor. All basis sets, in both methods, yield skew values that fall within the uncertainty limits indicated by the experimental value of  $0.85 \pm 0.10$ .

The calculated Euler angles, which define the rotations required to bring the PAS of the EFG tensor into coincidence with that of the CS tensor, are in good agreement with the experimental results at both levels of theory. In particular, calculations predict a small value for angle  $\beta$ , which is the angle between the largest EFG component ( $V_{33}$ ) and the most shielded CS component ( $\delta_{33}$ ), in close agreement with the observed value of  $5 \pm 1^\circ$ . Indeed, this is expected, as the observed and predicted pseudo-axial symmetry of both the EFG and CS tensors, with the skew of the latter being close to unity, dictate that approximate coincidence of their unique components,  $\delta_{33}$  and  $V_{33}$ . The absolute orientations of the  $^{27}\text{Al}$  EFG and CS tensors in the molecular framework, calculated at the B3LYP/6-311+G(2d, p) level, are shown in Fig. 5. The most shielded component of the chemical shift tensor,  $\delta_{33}$ , lies exactly along the Al–Cl bond axis, and the other two CS components,  $\delta_{11}$  and  $\delta_{22}$ , are perpendicular to it, and lie in the plane of the naphthalocyanine ring. The EFG tensor exhibits essentially the same orientation as the CS tensor, with  $V_{33}$  being  $8^\circ$  off the Al–Cl bond, and the other EFG components ( $V_{11}$  and  $V_{22}$ ) in the plane of the ring. On the basis of these results and the molecular structure of compound **3**, one can safely suggest that the Al–Cl bond acts as a pseudo- $C_4$  rotation axis, leading to aluminum being in an approximate square-pyramidal coordination environment. These orientations are in line with what has been observed in other phthalocyanine complexes with cobalt,<sup>11</sup> magnesium<sup>12</sup>, and gallium,<sup>13,14</sup> although ring geometry and coordination number can play an important role in the degree of axial symmetry displayed.

In contrast to the two sites observed in compound **3**, Figs. 2a and 2b reveal four distinct aluminum sites in each of compounds **1** and **2**. The presence of four non-equivalent sites, particularly for compound **1**, does not agree with its published crystal structure that reveals two unique and discrete  $\text{AlPcCl}$  molecules, in which each Al atom is involved in square-pyramidal coordination geometry.<sup>59</sup> Indeed, such disagreement is expected since the samples investigated here are in a poorly crystalline state. An attempt to understand the existence of additional sites in both compounds is discussed later in this report (vide infra). Estimated values for the isotropic chemical shift ( $\delta_{\text{iso}}$ ) and quadrupolar product ( $P_Q$ ) for each site in **1** and **2** were extracted from the sheared 3QMAS spectra using a combination of eq. [1] and the following equations for a spin-5/2 nucleus:<sup>78</sup>

**Fig. 5.** Calculated orientations of the  $^{27}\text{Al}$  chemical shift (in red) and electric field gradient (in blue) tensors in the molecular frame of compound **3**, as superimposed on views from the (a) side and (b) top. Only part of the molecular structure that depicts aluminum coordination environment is shown. Hydrogens are omitted for clarity. Aluminum is shown in orange, chlorine in green, nitrogen in blue, and carbon in grey.

**Fig. 6.** Experimental and simulated  $^{27}\text{Al}$  MAS NMR spectra of a powder sample of compound **1** acquired at three magnetic fields. Spinning rates are 20.0 kHz in (a) and (b), and 15.0 kHz in (c). The upper trace in (a) shows the simulation for each individual site (site 1: blue, site 2: red, site 3: green, and site 4: pink). All simulated spectra were calculated using the parameters reported in Table 1.

$$[2] \quad \delta_{\text{iso}} = \frac{17\delta_1 + 10\delta_2}{27}$$

$$[3] \quad P_Q = \nu_L \sqrt{-\frac{\delta_{\text{qis}}}{6000}} = \nu_L \sqrt{\frac{17(\delta_1 - \delta_2)}{162000}}$$

where  $\delta_1$  and  $\delta_2$  are the experimental chemical shifts of the centre of gravity of the peak in F1 and F2 dimensions of the sheared 3QMAS spectrum,  $\nu_L$  is the Larmor frequency,  $P_Q$  and  $\nu_L$  are in MHz, and  $\delta$  is in ppm. These estimated values were subsequently used in the simulation of the one-dimensional MAS spectra acquired at multiple fields. These spectra are shown in Figs. 6 and 7 for compounds **1** and **2**, respectively. The best-fit parameters obtained from the simultaneous simulation of the 1D MAS spectra at three fields are listed in Table 1.

Quantum chemical calculations were also performed on

compounds **1** and **2**, the results of which are given in Tables 3 and 4, respectively. Table 3 shows the calculated results obtained for the two  $\text{AlPcCl}$  molecules present in the asymmetric unit of compound **1**. Comparing these results with the experimental values obtained for site 1 of this compound, one observes fair agreement, within experimental error, between the experimental values of  $\delta_{\text{iso}}$ ,  $C_Q$ , and  $\eta$  and the calculated values at both the RHF and B3LYP levels. Most notably, the calculations predict an almost axially symmetric  $^{27}\text{Al}$  EFG tensor, in perfect accord with experiment. The same can be said about the predicted results of compound **2**, as shown in Table 4. The B3LYP calculations accurately reflect the experimental value of  $0.10 \pm 0.10$  for  $\eta$  observed for site 1 of **2** at all basis sets used, though it should be noted that they were carried out on a geometrically optimized model of **2** and not on an actual crystal structure, as none exists.

**Fig. 7.** Experimental and simulated  $^{27}\text{Al}$  MAS NMR spectra of a powder sample of compound **2** acquired at three magnetic fields. Spinning rates are 20.0 kHz in (a) and (b), and 15.0 kHz in (c). The upper trace in (a) shows the simulation for each individual site (site 1: blue, site 2: red, site 3: green, and site 4: pink). All simulated spectra were calculated using the parameters reported in Table 1.

In light of this successful agreement between experiment and calculation for the major component of **3**, attempts were then made to use calculated predictions to guide interpretation of both the impurity peak common to all three compounds and to the additional sites apparent in compounds **1** and **2**. On the basis of both the simulated best-fit parameters for these additional sites, as given in Table 1, with  $^{27}\text{Al}$  chemical shifts falling in the expected range for octahedral Al species, and the chemical nature of these related dye molecular frameworks, it was appropriate to focus on possible octahedral derivatives of the parent penta-coordinate species. Calculated results were obtained for optimized structures composed of the original species with an additional axial ligand, either Cl or  $\text{H}_2\text{O}$ , completing the octahedral coordination of Al by occupying the empty site below the phthalocyanine ring. These calculated results are given in Tables 5 and 6. While exact agreement is not possible, it is clear that the trends are consistent with two likely assignments: sites 3 and 4 of compounds **1** and **2** are likely associated with additional Cl ligands interacting with the central Al, resulting in a low-frequency movement of the  $^{27}\text{Al}$  chemical shift to approximately -12 ppm; and site 2 of all three compounds is likely associated with a different ligand, possibly  $\text{H}_2\text{O}$  or another light coordinating atom (OH,  $\text{NH}_3$ , and so forth) resulting in a  $^{27}\text{Al}$  chemical shift near 10 ppm. In each case, it seems quite clear that a completion of the octahedral coordination sphere of Al may be responsible for the additional components.

## Conclusions

A combination of solid-state  $^{27}\text{Al}$  NMR experiments and quantum chemical calculations has been used to study anisotropic  $^{27}\text{Al}$  NMR interaction tensors in three commercially obtained aluminum-centered phthalocyanine dyes. The  $^{27}\text{Al}$  CS and EFG tensors, including their relative orientations, were determined for aluminum-2,3-naphthalocyanine chloride. The span of the aluminum chemical shift tensor in this compound is the largest measured directly by  $^{27}\text{Al}$  SSNMR spectroscopy. RHF and DFT calculations have provided more insight into the  $^{27}\text{Al}$  CS and EFG tensors, and their orientation with respect to the molecular frame, indicating that their largest components,  $\delta_{33}$  and  $V_{33}$ , are perpendicular to the macrocyclic ring of this compound. The use of a 21.1 T NMR spectrometer has offered an excellent opportunity for visible manifestation of the aluminum chemical shift anisotropy in experiments performed on stationary polycrystalline samples. In addition, the use of such an ultrahigh-field magnet, combined with the state-of-art triple-quantum MAS experiment, was vital for the resolution of the different non-equivalent aluminum sites present in powder samples of the three related compounds.

## Supplementary data

Supplementary data for this article are available on the journal Web site ([canjchem.nrc.ca](http://canjchem.nrc.ca)) or may be purchased from the Depository of Unpublished Data, Document Deliv-

ery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5313. For more information on obtaining material, refer to [cisti-icist.nrc-cnrc.gc.ca/cms/unpub\\_e.shtml](http://cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml).

## Acknowledgements

The authors are grateful to the Natural Sciences and Engineering Research Council (NSERC) of Canada for financial support through Discovery and Equipment Grants to W.P.P. Access to the 900 MHz NMR spectrometer was provided by the National Ultrahigh-Field NMR Facility for Solids (Ottawa, Canada), a national research facility funded by the Canada Foundation for Innovation, the Ontario Innovation Trust, Recherche Québec, the National Research Council Canada, and Bruker BioSpin and managed by the University of Ottawa ([www.nmr900.ca](http://www.nmr900.ca)). NSERC is acknowledged for a Major Resources Support grant. Dr. Victor Terskikh and Dr. Eric Ye are thanked for NMR spectrometer assistance and for helpful remarks. We also thank Mr. Michael J. Ditty, Mrs. Janet Venne, and Dr. Claude Lemaire for their assistance on the NMR spectrometers at the University of Waterloo.

# 1D and 2D NMR investigations of the interaction between oppositely charged polymers and surfactants

Aleisha A. McLachlan and D. Gerrard Marangoni

**Abstract:** Proton chemical shifts and two-dimensional COSY and NOE spectroscopy (NOESY) experiments have been used to examine the interaction of various oppositely charged surfactant and polyelectrolyte systems, namely, the cationic surfactant dodecyltrimethylammonium bromide (DTAB) and a series of alkanediyl- $\alpha,\omega$ -bis(alkyldimethylammonium bromide) surfactants (Gem 12-*s*-12, where *s* is the length of the methylene spacer group) with the anionic polyelectrolyte poly(styrene sulfonate) or PSS. In all cases, we observe substantial aromatic-solute-induced chemical shifts (ASIS) in the surfactant peaks of the polymer/surfactant complexes versus that of the pure surfactant spectra. In the case of the DTAB/PSS system, the chemical-shift changes as a function of changing ratio of surfactant to polymer are interpreted in terms of structural changes that occur in the complex with increasing polymer concentration. For the Gem 12-*s*-12/PSS systems, the interaction of these gemini surfactants with the anionic polyelectrolyte, as deduced from the interpretation of the  $^1\text{H}$  ASIS shifts and the NOESY cross peaks, is dependent on the length of the methylene spacer. From the NOESY experiments, we observed significant NOESY cross peaks that correlated well with the expected mechanism of interaction as observed in the literature for the single-tailed surfactant/polymer system. NMR techniques are shown to provide information on the molecular arrangement of these molecules in aqueous solution.

**Key words:** polymers, surfactants, complexes, ASIS experiments, 2D NOESY.

**Résumé :** On a fait appel à des expériences déplacements chimiques du proton et de spectroscopie de corrélation bidimensionnelle (« COSY ») et de spectroscopie d'effets Overhauser nucléaire (NEOSY) pour étudier l'interaction entre divers systèmes formés d'un agent de surface et de polyélectrolytes de charges opposés, en particulier de micelles cationiques de l'agent de surface dodécyltriméthylammonium (DTAB) et une série de bromures d'alcanediyl- $\alpha,\omega$ -bis(alkyldiméthylammonium) (Gem 12-*s*-12 dans lesquels *s* correspond à la longueur du groupe espaceur méthylène) avec le polyélectrolyte anionique sulfonate de poly(styrène), SPS. Dans tous les cas, on observe d'importants déplacements anisotropiques induits par le solvant (DAIS) dans les pics des complexes polymère/agent de surface par rapport aux spectres de l'agent de surface pur. Dans le cas du système DTAB/SPS, les changements dans le déplacement chimique en fonction d'un changement dans le rapport d'agent de surface au polymère sont interprétés en fonction de changements structuraux qui se produisent dans le complexe avec une augmentation dans la concentration du polymère. Pour les systèmes Gem 12-*s*-12/SPS, l'interaction entre ces agents de surface jumeaux avec le polyélectrolyte anionique, telle que déduite de l'interprétation des déplacements anisotropiques induits par le solvant pour le  $^1\text{H}$  et des croisements de pics (NEOSY), est dépendante de la longueur de l'espaceur méthylène. À partir des expériences (NEOSY), on a observé des croisements de pics (NEOSY) importants qui donnent une bonne corrélation avec le mécanisme attendu d'interaction tel qu'observé dans la littérature pour le seul système agent de surface polymère étudié. On a donc démontré que les techniques de la RMN peuvent fournir de l'information relative à l'arrangement moléculaire de ces molécules dans une solution aqueuse.

**Mots-clés :** polymères, agents de surface, complexes, déplacements anisotropiques induits par le solvant (DAIS), spectroscopie d'effets Overhauser nucléaire bidimensionnelle (NEOSY).

[Traduit par la Rédaction]

## Introduction

The interaction of polymers and surfactants has received a substantial amount of attention in the literature from both an academic and an industrial standpoint.<sup>1–28</sup> The manner in

which surfactants bind to polymers is critically dependent on the charges of the polymers and the surfactants. Oppositely charged polymer/surfactant complexes have been shown to be extremely surface-active, as evidenced by the efficient lowering of surface tension at very low concentrations of surfactant and polymer. Much of the literature has focused on the determination of the binding isotherms of the surfactants to the polymers via electromotive force measurements, NMR relaxation and chemical-shift studies, luminescence probing experiments, calorimetry, and partition-constant determinations. For example, the interactions between poly(styrenesulfonate) (PSS) and dodecyltrimethylammonium bromide (DTAB) have been investigated by sur-

factant-selective electrodes,<sup>29,30</sup> luminescence probing,<sup>31</sup> and NMR spectroscopy.<sup>32,33</sup>

Dimeric and oligomeric surfactants are novel surfactants that are presently attracting considerable interest from both academic and industrial research groups. The term gemini surfactant, coined by Menger,<sup>34</sup> has become accepted in the surfactant literature for describing dimeric surfactants, that is, surfactant molecules that have two hydrophilic (chiefly ionic) groups and two tails per surfactant molecule.<sup>35</sup> Gemini surfactants possess a number of superior properties when compared with conventional single-headed, single-tailed surfactants, such as lower cmc values (by at least an order of magnitude) and increased surface activity ( $C_{20}$ ),<sup>36–38</sup> in addition to improved hard-water tolerance, superior wetting times, and better cold-water solubility. Cationic gemini surfactants of the *m-2-m* type have been investigated with luminescence probing and neutron scattering.<sup>39</sup> In all cases, the results are consistent with the combination of electrostatic and hydrophobic interactions being the driving forces in the formation of the polymer/surfactant aggregates.

A number of surfactant formulations often contain water-soluble polymers and additional surfactants. In most studies of polymer/surfactant systems, the binding of the surfactant to the polymers is discussed in terms of the nature and types of interactions; these depend greatly on the nature of the surfactant and polymer. Cooperative binding always occurs above a surfactant concentration referred to as *cac* (critical aggregation concentration), which is lower than the value of the surfactant cmc in a polymer-free system.<sup>29,30,40–42</sup> With surfactant/nonionic polymers, the *cac* is usually only slightly smaller than the cmc of the surfactant.<sup>43</sup> With ionic polymers like PSS, the *cac* can be as much as 100 to 1000 times smaller than the cmc.<sup>40</sup> Although a number of papers have examined the cooperativity of polymer/surfactant binding using various techniques, there are very few papers in the literature where detailed spectroscopic information is used to assess the manner in which these systems self-assemble.<sup>33,44</sup>

In the case of the *m-2-m* gemini surfactants/PSS systems, synergistic lowering of the surface tension at very low surfactant concentrations was observed, due to the electrostatic interactions between the positive surfactant head groups and sulfonate groups of the polymer.<sup>39</sup> This leads to both the surfactant and polymer adsorbing at the air/water interface, and forming highly surface-active complexes. However, the adsorption of gemini surfactants at the air/water interface depends greatly on the spacer length,<sup>37</sup> which would indicate that the manner in which gemini surfactants complex with PSS would also depend on spacer length.

Aromatic-solute-induced chemical shifts (ASIS effects) have been shown to be sensitive indicators of the structure in micellar and polymer/surfactant systems.<sup>44–48</sup> When coupled with two-dimensional nuclear Overhauser enhancement experiments (2D NOESY),  $^1\text{H}$  NMR experiments have been shown to provide significant information on both the intra- and inter-molecular proximity of protons.<sup>49</sup> There are a few papers in the literature dealing with the application of the 2D NOESY technique to probe micellar solubilization and polymer/surfactant systems.<sup>48–52</sup> In the case of oppositely charged surfactants and polymers, a detailed analysis of NOESY cross peaks should yield significant insights into the manner in which the polymer and surfactant interact with each other forming complexes and mixed micellar systems. In this paper, we report our results on the changes in the  $^1\text{H}$  NMR chemical shifts that occur when cationic surfactants are bound to the anionic polymer sodium poly(styrenesulfonate). The cationic surfactant systems investigated were (a) dodecyltrimethylammonium bromide (DTAB) and (b) alkanediyl- $\alpha,\omega$ -bis(alkyldimethylammonium bromide) (12-*s*-12). In all cases, we observe significant ASIS effects in the 1D NMR spectra. For the gemini cationic surfactants, the NMR chemical shifts indicate that the manner in which the gemini surfactants self-assemble with the polymer is dependent on the spacer length of the surfactant. The cross-peaks between the polymer and the surfactant protons in the NOESY con-

**Fig. 2.**  $^1\text{H}$  NMR spectrum for (a) 0.065 mol/L DTAB; (b) 0.065 mol/L DTAB/0.232 mol/L PSS.

four plots are consistent with the electrostatic interactions between the surfactant and polymer chains dominating the complex formation in micellar solution.

## Experimental

Dodecyltrimethylammonium bromide (DTAB) was obtained from the Sigma Chemical Company, and it was purified by at least three recrystallizations from an acetone/ethanol mixture. The gemini surfactants 12-*s*-12 were prepared by refluxing 2 mol equivalents of *N,N*-dimethyldodecyl amine (with a 10% excess) with the appropriate  $\alpha,\omega$ -dibromoalkane in either acetone or acetonitrile. The shorter spacer surfactants were recrystallized from acetonitrile, while the longer spacer gemini surfactants were recrystallized from acetone. The purity of the surfactants was confirmed by MS. The structure of the 12-4-12 gemini surfactant is given below.

High purity sodium poly(styrene sulfonate) was from Aldrich Chemical Company with a molecular mass of about

**Fig. 3.** Changes in proton chemical shifts of DTAB upon formation of DTAB/PSS aggregates ( $\Delta\delta = \delta(\text{DTAB/PSS}) - \delta(\text{DTAB})$ ) for varying concentrations and ratios of DTAB/PSS. (◆) 0.033 mol/L DTAB/0.116 mol/L PSS. (▲) 0.065 mol/L DTAB/0.116 mol/L PSS. (■) 0.065 mol/L DTAB/0.232 mol/L PSS. (\*) 0.130 mol/L DTAB/0.232 mol/L PSS. (●) Literature values from ref. 33.

70 000 g/mol; D<sub>2</sub>O (99.8%) was purchased from Aldrich or CDN Isotopes.

The 1D and 2D NMR spectra (<sup>1</sup>H) for the polymer/surfactant systems were obtained on a Bruker Avance 500 NMR spectrometer operating at 500.13 MHz for protons at the Atlantic Region Magnetic Resonance Centre (ARMRC) at Dalhousie University, or a Bruker Avance-II 400 NMR spectrometer operating at 400.13 MHz at St. Francis Xavier University. A typical <sup>1</sup>H spectrum for the system 0.116 mol/L PSS (in terms of the monomer concentration) is given in Fig. 1. The <sup>1</sup>H spectra were referenced to the HOD peak, which was assigned a value of  $\delta = 4.750$  ppm. For the phase-sensitive 2D NOESY spectra, 128 transients of either 8 or 16 scans over 512 complex data points were acquired with suppression of the HOD peak at 4.75 ppm. The mixing times were varied between 0.20 s and 1.5 s, and the delay times were kept fixed at 5.0 s. The data were zero-filled once in dimension 1 and multiplied by a shifted sine-bell function in F1 and F2 before transformation. Stock solutions of the surfactants and the polymers were prepared in sample vials; the appropriate quantities of the stock solutions were transferred to NMR tubes in the presence of a small amount of NaCl. All prepared solutions were clear and stable towards precipitation.

## Results and discussion

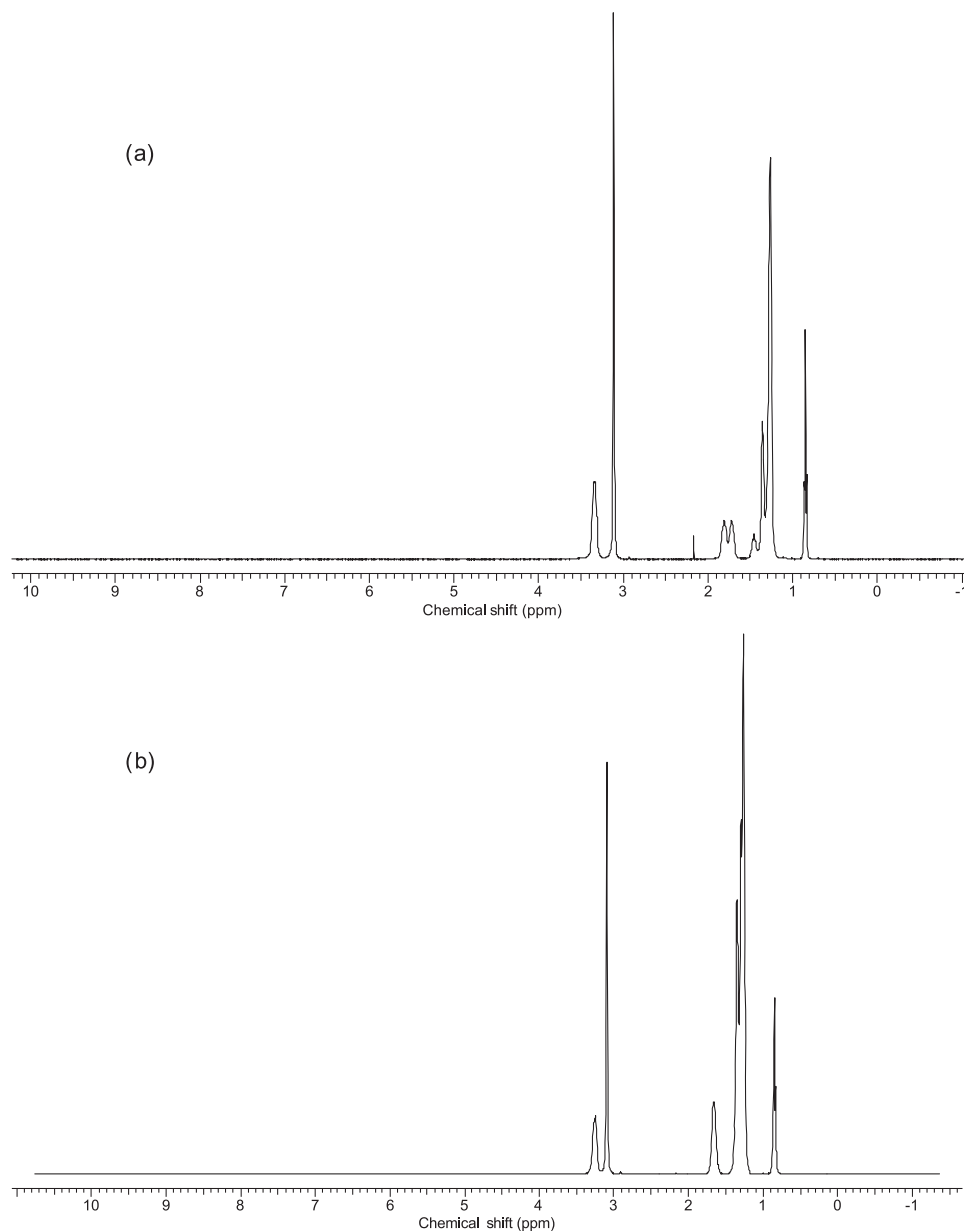

### <sup>1</sup>H chemical-shift changes

In Fig. 2, the <sup>1</sup>H NMR spectrum of a 0.065 mol/L DTAB solution is compared to the spectrum of the same concentration of surfactant mixed with 0.232 mol/L PSS. Significant broadening is seen in the DTAB resonances in the presence of the polymer, which is consistent with the NMR work of Gao et al.<sup>32</sup> We also note that there are considerable high- and low-frequency shifts for the DTAB protons in the polymer/surfactant complex, due to the presence of the aromatic head group in the polymer. Figure 3 gives the chemical-shift

differences for the protons of the DTAB surfactant in the presence and absence of the PSS polymer at various ratios of the polymer to surfactant concentrations. The intermolecular ring current shifts we observe here for the system 0.065 mol/L DTAB/0.116 mol/L PSS (i.e., at a polymer/surfactant ratio of 4:1) are identical to those reported by Gao et al.<sup>32,33</sup> In these oppositely charged polyelectrolyte/surfactant systems, the positively charged surfactant head groups are expected to be in the vicinity of the negatively charged aromatic head group; this will lead to large ring-current shifts for the chain protons on the surfactant molecules as well as for the  $-\text{CH}_3$  protons located in the surfactant head group. We note that for most of the concentrations of polymer and surfactant studied here, large high-frequency shifts are observed for the chain protons and the  $\omega$ -methyl protons, whereas large low-frequency shifts are obtained for the  $\alpha$ ,  $N$ -methyl, and  $\beta$  protons of the DTAB surfactant chain. We note that the magnitudes of the shift changes are almost identical at all the concentrations of polymer and surfactant investigated here, indicating that the microstructure of the polymer/surfactant complex does not vary significantly with changing amounts of polymer or surfactant. For the 0.130 mol/L DTAB/0.232 mol/L PSS system, high-frequency shifts are again observed for  $\omega$ -methyl protons and the chain protons, and low-frequency shifts are obtained for the  $\alpha$ ,  $\beta$ , and the  $N$ -methyl protons. However, it is worth noting that the magnitudes of the shift differences for all protons except the  $\beta$  protons are smaller than the shift differences observed for the other DTAB/PSS systems investigated here. This is consistent with a change in the orientation of the surfactant protons on DTAB with respect to the plane of the aromatic ring on the PSS backbone for the complex, due to a saturation of the polymer with surfactant chains or the interaction of small micelles with the polyanion.

The sign and the magnitude of aromatic-ring-current shifts are dependent on the orientation of the aromatic ring plane with respect to the various DTAB protons. For exam-

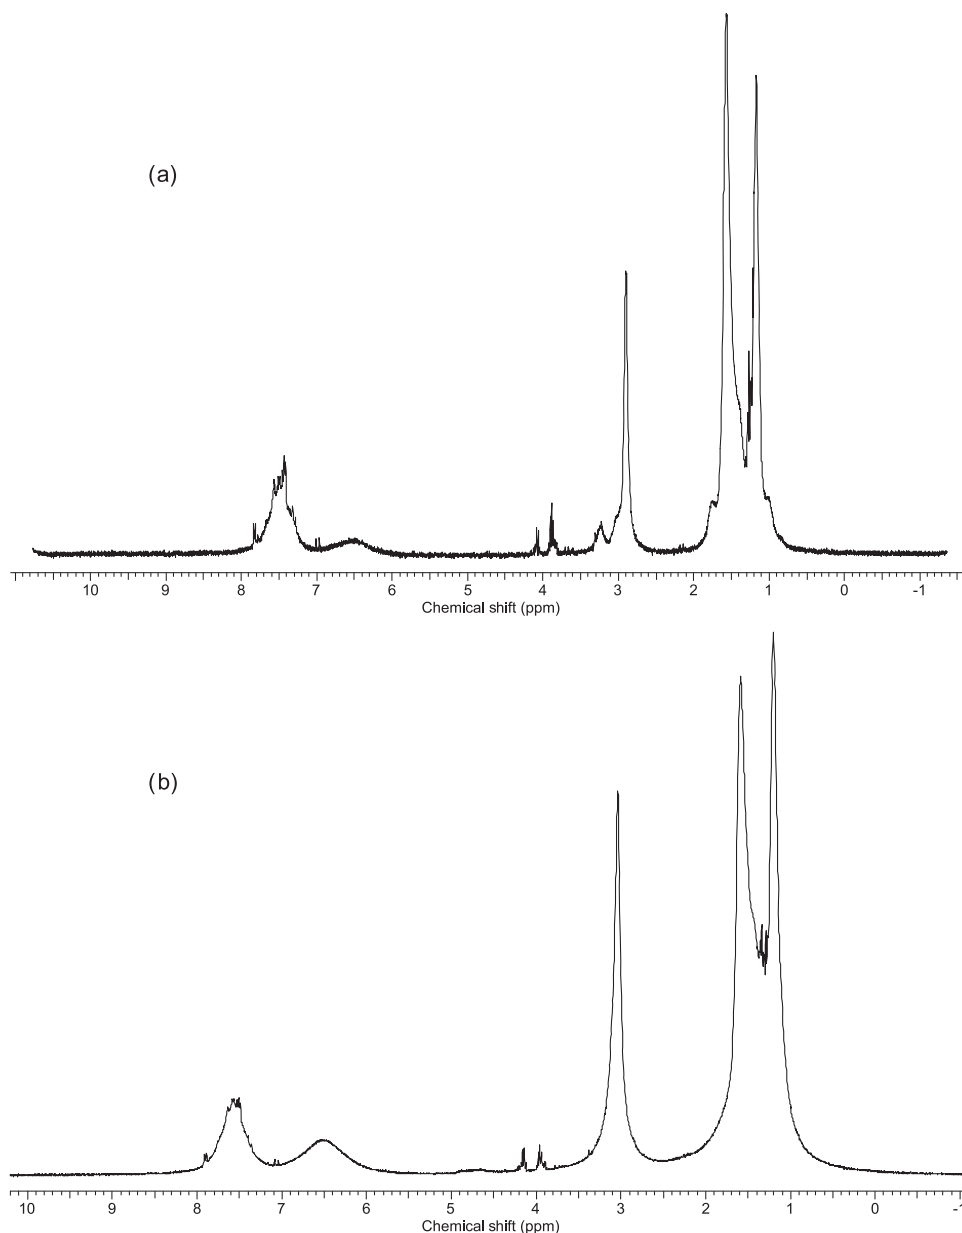

**Fig. 4.**  $^1\text{H}$  NMR spectrum for (a) 0.010 mol/L 12-5-12; (b) 0.0070 mol/L 12-12-12.

ple, if the protons on the DTAB chain are, on average, in the plane of the aromatic ring, their shielding constant is decreased and the result is a high-frequency chemical-shift change. On the other hand, if the average orientation of the protons is above the plane of the aromatic rings, their shielding constant is increased and a low-frequency shift change results. Hence, we can interpret Fig. 3 in terms of the structure of the polymer/surfactant aggregates. According to Gao et al.<sup>33</sup> and Abuin and Scaiano,<sup>31</sup> at the concentrations of surfactant and polymer investigated in this paper, we would expect that the aggregate sizes are small with the micelles interacting with the hydrophobic phenyl ring of the polymer. Hence, the large high-frequency shifts for the protons nearest the surfactant head group are consistent with the surfactant head group electrostatically interacting with the polyelectrolyte, while the  $\omega\text{-CH}_3$  and the chain protons

( $n$ -protons) are on average located in the plane of the aromatic group. We note that in most cases, as the ratio of the surfactant to polymer concentration is changed, the similarity in the ring-current shifts for the DTAB head-group protons indicates that the average orientation of the surfactant with respect to the polymer is essentially unchanged. This is in good agreement with the results of Gao et al.<sup>32,33</sup> However, the large differences in the ring-current shifts for the  $\beta$  protons in the 0.130 mol/L DTAB/0.232 mol/L PSS suggest that the environment of the DTAB protons is different at that concentration from the other complexes investigated here. This is consistent with a difference in the structure of the complexes as the amount of surfactant increases. Abuin and Scaiano<sup>31</sup> have stated that for higher ratios of polymer to surfactant, most of the surfactant ( $\geq 90\%$ ) is polymer-bound. Hence, in the case of the highest concentration of

**Fig. 5.**  $^1\text{H}$  NMR spectrum for (a) 0.010 mol/L 12-5-12/0.055 mol/L PSS; (b) 0.0070 mol/L 12-12-12/ 0.055 mol/L PSS.

surfactant investigated here, the presence of additional amphiphile molecules likely leads to an almost complete saturation of the polymer, with the remaining surfactant self-assembling into free micelles. This is consistent with the fact that the magnitudes of all the chemical-shift differences for DTAB are somewhat reduced in this system, as the solutions will consist of a mixture of polymer/surfactant complexes of slightly larger surfactant aggregation numbers and some free-surfactant micelles. As the exchange between the complexes and the free micelles will be fast on the NMR timescale, the averaged NMR spectrum will reflect the distribution of surfactant molecules between the bound complexes and free micelles. The increase in the aggregation number of the surfactant in the polymer/surfactant complexes, coupled with the appearance of free micelles, leads to a more micelle-like environment in the complex with a

corresponding change in the ASIS chemical-shift profiles as a function of the surfactant concentration.

Typical  $^1\text{H}$  NMR spectra for the gemini surfactants 0.010 mol/L 12-5-12 and 0.0070 mol/L 12-12-12 are shown in Fig. 4. Indicated on the Figures are the chemical shifts of the protons on the 12-carbon chains of the gemini surfactants and in the  $n$ -methylene spacer groups.  $^1\text{H}$  NMR spectra for the same concentrations of both surfactants in a 0.055 mol/L solution of PSS are presented in Fig. 5. We can again clearly see that there are large ASIS effects induced for both the chain protons and for the spacer protons of the gemini surfactants in the presence of the anionic polyelectrolyte.

The  $^1\text{H}$  chemical shifts for the chain protons of the 12-s-12/PSS systems are presented in Fig. 6. From the plot of the  $\Delta\delta$  of the chain protons, we observe that there are differences in the manner in which the gemini surfactants in-

**Fig. 6.** Changes in proton chemical shifts of 12-*s*-12 gemini surfactant chain protons upon formation of 12-*s*-12/PSS aggregates ( $\Delta\delta = \delta(12\text{-}s\text{-}12/\text{PSS}) - \delta(12\text{-}s\text{-}12)$ ). **Fig. 7.** Changes in proton chemical shifts of 12-*s*-12 gemini surfactant spacer protons upon formation of 12-*s*-12/PSS aggregates ( $\Delta\delta = \delta(12\text{-}s\text{-}12/\text{PSS}) - \delta(12\text{-}s\text{-}12)$ ). (◆) 0.010 mol/L 12-4-12/0.055 mol/L. (▲) 0.010 mol/L 12-5-12/0.055 mol/L PSS. (■) 0.0070 mol/L 12-10-12/0.055 mol/L PSS. (☆) 0.0070 mol/L 12-12-12/0.055 mol/L PSS.

interact with the polyelectrolyte as a function of the length of the methylene spacer. For the shorter-spacer gemini surfactants 12-4-12 and 12-5-12, we note that the magnitude of the shift of the *N*-methyl protons is comparable to that of both DTAB and the longer-spacer gemini surfactants, whereas the chemical-shift differences for the  $\alpha$ -chain and the  $\beta$ -chain protons of the surfactant are different for the shorter- and longer-chain spacer gemini surfactants. This indicates that the manner in which the gemini surfactants self-assemble with the polyelectrolyte is different for short-

spacer gemini surfactants from longer-spacer gemini amphiphiles. In fact, when we examine the chemical-shift patterns for the chains of the longer-spacer gemini surfactants, they are identical to those of the DTAB/PSS systems shown above. This is consistent with the longer-spacer gemini surfactants self-assembling with the polyelectrolyte in a manner similar to DTAB, indicating that with the longer-spacer-length gemini surfactants, there is enough distance between the surfactant head groups that they behave essentially independently and are easily able to interact with adjacent PSS monomers on the polymer.

The chemical-shift differences for the spacer protons are presented in Fig. 7. We note that for the short-spacer-length gemini surfactants (12-4-12 and 12-5-12), very small changes are observed for the  $\alpha$  and  $\beta$  protons. However, as the spacer length increases (i.e., for 12-10-12 and 12-12-12), we note that the  $\Delta\delta$  values for the  $\alpha$ - and  $\beta$ -chain protons become more negative, indicating that the first few spacer protons are likely more constrained for the short gemini spacers than for the longer spacers. Given the short spacer length in the 12-4-12 and the 12-5-12 surfactants, when the cationic head groups interact with adjacent sulfonate groups on the polymer chain, this will lead to a more rigid environment for the spacer protons on the short-spacer gemini surfactants, keeping them in intimate contact with the aromatic chains. For the long-spacer gemini surfactants, the positive shift difference for those spacer protons in the middle of the chain indicate that they are outside of the ring current set up by the circulating  $\pi$  electrons, leading to a high-frequency shift for those protons. This would be consistent with the protons in the middle of the long-spacer chain having considerably more freedom of movement than the spacer protons of the short chains. We would expect that given the short spacer length of the 12-4-12 and the 12-5-12 system, the interactions with the two head groups of the gemini surfactant with the sulfonate groups on adjacent monomers would lead to crowding of the benzene rings on adjacent monomers in the complex; this steric crowding would lead to a decrease in the entropy of the system and would contribute to destabilization of the complex. For the long-spacer gemini surfactants, given the freedom of motion of the two chains that make up the cationic gemini surfactant, the reduction of the steric crowding in the complex would lead to an increase of the binding constants over those of the short-spacer gemini amphiphiles. We are currently determining the binding contacts for these species using emf measurements; they will be reported in a future publication. It should be noted that similar results were observed by Wettig et al. for the interaction of gemini surfactants of differing spacer lengths with DNA; their results indicated that the spacer length of the gemini impacted the manner in which cationic head groups were able to interact with negatively charged moieties at the surface of the DNA biopolymer. These subtle differences in binding resulted in differing transfection efficiencies for differing spacer lengths of their gemini-surfactant-based nanoparticles.<sup>53</sup>

### NOESY spectra

NMR NOESY experiments were performed for the following systems: 0.065 mol/L DTAB/0.116 mol/L PSS (Fig. 8), 0.010 mol/L 12-4-12/0.055 mol/L PSS (Fig. 9), 0.010 mol/L

**Fig. 8.** 2D NOESY contour plot for the system 0.065 mol/L DTAB/0.117 mol/L PSS.**Fig. 9.** 2D NOESY contour plot for the system 0.010 mol/L 12-4-12/0.055 mol/L PSS.

12-5-12/0.055 mol/L PSS (Fig. 10), 0.0070 mol/L 12-10-12/0.055 mol/L PSS (Fig. 11), 0.0070 mol/L 12-12-12/0.055 mol/L PSS (Fig. 12). 2D NOESY experiments have been shown to give excellent insights into the nature of the self-assembly process in a number of aggregated systems.<sup>48,50,52,54,55</sup> When we examine the NOESY contour plots for the system 0.065 mol/L DTAB /0.116 mol/L PSS (Fig. 8), it is clear that significant cross peaks occur between the protons of the surfactant and the polymer, indicating that at least some of the protons in both the polymer and the surfactant are within a spatial proximity of 0.5 nm. For the PSS/DTAB systems investigated here, we observe strong cross peaks between the aromatic protons of the polymer and the *N*-methyl protons of the DTAB, which we would expect for the presence of strong electrostatic interactions between the surfactant and polyanionic system. We note, as well, that there are

significant cross peaks between the chain protons of the surfactant and the charged head groups of the polymer, indicating that the chains of the surfactants are interacting strongly with the aromatic ring systems of the polymer. This is consistent with the condensation of a small number of molecules on the polymer backbone and the subsequent hydrophobic interactions of these molecules in the condensed structures. The very strong cross peaks that are observed between the terminal methyl group of the cationic surfactant and the aromatic ring systems signify the spatial proximity of these groups within the self-assembled complex. We note that when we compare the NOESY spectra of the individual 12-*s*-12 gemini systems with the polyanion, we observe very little difference in the nature of the cross peaks in all these systems, and also when compared to the DTAB/PSS system. This indicates that the manner in which these cationic surfactants self-

**Fig. 10.** 2D NOESY contour plot for the system 0.010 mol/L 12-5-12/0.055 mol/L PSS.**Fig. 11.** 2D NOESY contour plot for the system 0.0070 mol/L 12-10-12/0.055 mol/L PSS.

assemble with the polyanion is fundamentally identical. We also note that, in all cases, we observe cross peaks between many of the chain protons of the cationic surfactants and the aromatic ring of the polyanion, which is consistent with the ring-current shift measurements reported above. The existence of cross peaks between the aromatic resonances and the  $\omega$ -CH<sub>3</sub> protons in the cationic surfactants must indicate that these surfactant molecules have a significant amount of rotational freedom, in excellent agreement with the <sup>13</sup>C relaxation data of Gao et al.<sup>33</sup>

From the chemical-shift differences and the NOESY spectra of all the cationic surfactant PSS systems, we would con-

clude that the carbons near the head groups of all the cationic surfactants complexed with the PSS are more spatially restricted in the polymer/surfactant system than in the free surfactants themselves, in excellent agreement with the literature. Given the strong correlations in the 2D NOESY spectrum as well as the large, positive ASIS effects for the protons attached to the carbons near the end of the chain, we anticipate that the motions of the carbons in this region would be isotropic in nature. For the alkyl chain carbons near the head group, the strong NOESY correlations as well as the large, negative ASIS effects clearly indicate a spatially restricted environment for these groups in the complex

**Fig. 12.** 2D NOESY contour plot for the system 0.0070 mol/L 12-12-12/0.055 mol/L PSS.

compared to the micellar solution. Clearly, the binding between the polyanion and the cationic surfactants leads to a more rigid environment near the surface of the complexes compared to the DTAB micelle. These results suggest that the structure of all the cationic surfactant/PSS complexes are similar in that they consist of a highly ordered region near the aggregate surface and a much more micelle-like fluid hydrocarbon region in the core. The ASIS shifts appear to indicate that there are some additional constraints on the formation of these complexes when the spacer arm of the gemini surfactant is short.

## Summary

The  $^1\text{H}$  NMR chemical shifts and the NOESY spectra for a number of cationic surfactants complexed with an aromatic-containing polyanion (PSS) have been determined for several ratios of the surfactant and the polymer. All the NMR results support the existence of the structure where all the cationic surfactant/PSS complexes consist of a highly ordered region near the aggregate surface and a much more micelle-like fluid hydrocarbon region in the core. The  $^1\text{H}$  chemical differences indicate that the manner in which the DTAB and the long-spacer gemini surfactants interact with the PSS are fundamentally similar, whereas the shorter-spacer gemini surfactants have a different  $^1\text{H}$  chemical-shift difference pattern for the spacer and chain protons; this may indicate subtle differences in the nature of the binding of these cationic surfactants to the polyanion.

# 1,3-Dibromo-5,5-dimethylhydantoin as an efficient homogeneous catalyst for the synthesis of 2-arylthiazolines and 2-arylimidazolines

Seyedeh Fatemeh Hojati, Iraj Mohammadpoor-Baltork, Behrooz Maleki, Mostafa Gholizadeh, Fatemeh Shafiezhadeh, and Mahnaz Haghdoust

**Abstract:** A simple, facile, and efficient procedure for the synthesis of 2-arylthiazolines and 2-arylimidazolines has been developed by the simple condensation of nitriles with 2-aminoethanethiol or ethylenediamine catalyzed by 1,3-dibromo-5,5-dimethylhydantoin under solvent-free conditions. Selective preparation of bithiazolines and monoimidazolines from dinitriles and also selective conversion of aryl nitriles to their corresponding 2-arylthiazolines or imidazolines in the presence of alkyl nitriles can be considered as considerable advantages of this method.

**Key words:** thiazoline, imidazoline, 1,3-dibromo-5,5-dimethylhydantoin, solvent-free

**Résumé :** On a mis au point une méthode simple, facile et efficace de réaliser la synthèse de 2-arylthiazolines et de 2-arylimidazolines impliquant une condensation simple de nitriles avec le 2-aminoéthanethiol ou l'éthylènediamine catalysée par la 1,3-dibromo-5,5-diméthylhydrantoïne dans des conditions sans solvant. La préparation sélective de bis-thiazolines et de mono-imidazolines, à partir de dinitriles, ainsi que la conversion sélective d'arylnitriles en 2-arylthiazolines ou 2-arylimidazolines, en présence d'alkylnitriles, peut être considérée comme un avantage considérable pour cette méthode.

**Mots-clés :** thiazoline, imidazoline, 1,3-dibromo-5,5-diméthylhydrantoïne, sans solvant

[Traduit par la Rédaction]

## Introduction

Thiazolines and imidazolines are very important structural moieties, because they are found in a large number of biologically active natural products.<sup>1,2</sup> The most significant examples are thiagazole,<sup>3</sup> tantazole B,<sup>3</sup> lissoclinamides,<sup>4</sup> curacin A,<sup>5</sup> naphazoline,<sup>6</sup> xylometazoline,<sup>7</sup> and oxymetazoline,<sup>8</sup> which are anti HIV-1 and 2, antineoplastic and antimicrobial agents,  $\alpha$ -adrenergic agonists, nasal decongestants, and  $\alpha$ -1 and  $\alpha$ -2 agonist topical decongestants, respectively. Antidiabetic,<sup>9</sup> antihypertensive,<sup>10</sup> antihypercholesterolemic,<sup>11</sup> and anti-inflammatory<sup>12</sup> activities are some other properties which have been reported for the natural and synthetic thiazoline and imidazoline containing compounds.

Optically active mono- and bis-derivatives of these heterocycles have been efficiently used as both auxiliaries and ligands in asymmetric transformations.<sup>13</sup> Furthermore, thiazoline derivatives have found industrial applications due to their ability to enhance the flavor and (or) aroma of various materials.<sup>14</sup>

Different methods have been developed for the synthesis

of these biologically active heterocycles.<sup>15–21</sup> Various precursors, catalysts, and reaction conditions have been applied for this purpose. Although some of these protocols efficiently generate the desired compounds, most of them suffer from one or more drawbacks such as long reaction times,<sup>16</sup> harsh reaction conditions,<sup>17</sup> low yields of products,<sup>18</sup> use of expensive reagents<sup>17c,19</sup> or toxic solvents,<sup>20</sup> and using multi-step syntheses.<sup>15e,18b,21</sup> Therefore, the design of a new, simple, safe, and efficient method for the preparation of thiazolines and imidazolines is still challenging.

1,3-Dibromo-5,5-dimethylhydantoin (DBH) is a five-membered heterocycle, which had been known as a bromination agent,<sup>22</sup> but it has recently gained special attention as an efficient homogeneous catalyst in organic transformations.<sup>23</sup>

However, we were interested in examining the catalytic activity of DBH on our previous work<sup>15d,24</sup> on the synthesis of 2-arylthiazoline and 2-arylimidazoline derivatives (Scheme 1).

**Scheme 1.** Synthesis of 2-arylthiazolines and 2-arylimidazolines catalyzed by DBH.

## Results and discussion

The catalytic synthesis of thiazolines and imidazolines from nitriles by DBH was studied. At first, cyclocondensa-

tion of benzonitrile with 2-aminoethanethiol was carried out in the presence of different amounts of DBH. The temperature and solvent effects were also investigated (Table 1). The best result was obtained with 1:1.1:0.01 molar ratios of benzonitrile/2-aminoethanethiol/DBH at 110 °C under solvent-free conditions. 2-Phenylthiazolines was obtained in 95% yield after 7 min. To show the catalytic activity of DBH, when benzonitrile was reacted with 2-aminoethanethiol in the absence of catalyst under the same reaction conditions, only 15% yield was obtained after 7 min. Thus, DBH is an efficient homogeneous catalyst for the synthesis of 2-substituted thiazolines. Furthermore, the turnover number of the catalyst in the present reaction (TON = 95) exhibits the high catalytic activity of DBH in the synthesis of 2-thiazolines. The applicability of this method was investigated by the reaction of different nitriles with 2-aminoethanethiol in the presence of 1 mol% DBH. Results are summarized in Table 2 (entries 1–10). Nitrogen-containing analogues of thiazolines were also prepared satisfactorily by the current procedure (Table 2, entries 11–16). As shown in Table 2, both electron-donating and -withdrawing substituted nitriles reacted very well and produced corresponding 2-thiazolines and 2-imidazolines in good to excellent yields.

It is noteworthy that bisthiazolines and monoimidazolines were selectively generated by this method (Table 3). As illustrated in Table 3, reactions of 1,3- and 1,4-dicyanobenzene with 2-aminoethanethiol produced bisthiazolines in 97% and 85% yield, respectively, whereas the same substrates, when reacted with ethylenediamine, gave exclusively monoimidazolines in 96% and 95% yield, respectively. Bismidazolines were not obtained even by increasing the reaction times to 10 h.

It is also important to note that alkyl nitriles did not react with 2-aminoethanethiol and ethylenediamine under the same reaction conditions. So, several competitive reactions were performed between aryl nitriles and alkyl nitriles (Scheme 2), which showed an interesting selectivity. Only 2-arylthiazolines and 2-arylimidazolines were obtained after appropriate times, and alkyl nitriles remained intact in the reaction mixture. Consequently, the present method is potentially applicable for the chemoselective conversion of aryl nitriles to their corresponding 2-arylthiazolines and 2-arylimidazolines in the presence of alkyl nitriles.

Although the actual mechanism of the reaction is unclear, a reasonable explanation due to the high catalytic activity of DBH and mechanistic operation of DBH in similar reactions<sup>23c,25</sup> is shown in Scheme 3. 1,3-Dibromo-5,5-dimethylhydantion produces the bromonium ion (Br<sup>+</sup>) and activates the nitrile group by the formation of nitrogen cation **A**. The reaction follows by nucleophilic attack of 2-aminoethanethiol or ethylenediamine on activated nitrile **B** to afford **C** and **D** which are both N-activated by Br<sup>+</sup>. Finally, the corresponding 2-thiazoline or 2-imidazoline is produced by releasing NH<sub>3</sub> and bromonium ion, which returns to the catalytic cycle (Scheme 3).

In conclusion, we have demonstrated a mild and efficient protocol for the preparation of 2-arylthiazolines and 2-arylimidazolines using DBH as a homogeneous catalyst. Chemoselectivity, short reaction times, easy work-up, and high yields of products are noteworthy advantages of this protocol. Furthermore, the use of an inexpensive, approximately

non-toxic, commercially available, and highly efficient catalyst under solvent-free conditions makes the current method economically acceptable and industrially applicable. We have also proposed a plausible mechanism for the present reaction.

## Experimental

All materials are commercial reagent grade and were obtained from Merck or Fluka. <sup>1</sup>H NMR spectra were recorded on a Bruker AVANCE 500 MHz or on a Bruker AW 80 MHz, and TMS was used as an internal standard in a 80 MHz spectrometer. Melting points were taken on a Stuart Scientific SMP2 apparatus. Elemental analyses were performed using a Heraeus CHN-O-Rapid analyzer. Mass spectra were recorded on a PLATFORM 8379E in 70 eV.

### General procedure for the preparation of 2-thiazolines and 2-imidazolines

A mixture of nitrile (2 mmol), 2-aminoethanethiol (2.2 mmol) or ethylenediamine (8 mmol), and DBH (0.02 mmol) was refluxed (110 °C) under solvent-free conditions for the appropriate time according to Table 2. After completion of the reaction as indicated by TLC (2:1 *n*-hexane/EtOAc for thiazolines and 4:1 EtOAc/CH<sub>3</sub>OH for imidazolines), the mixture was cooled to room temperature and the pure product was isolated by column chromatography.

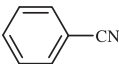

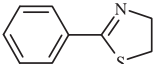

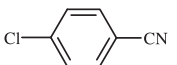

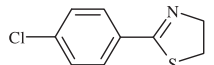

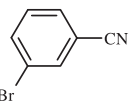

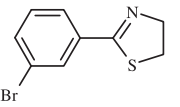

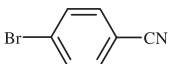

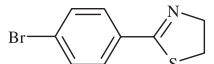

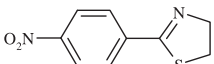

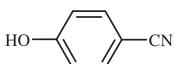

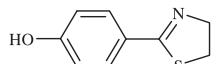

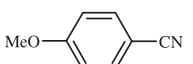

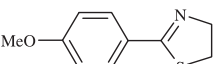

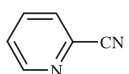

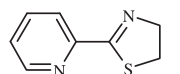

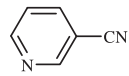

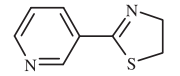

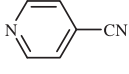

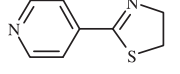

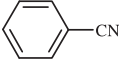

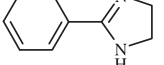

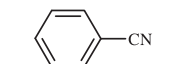

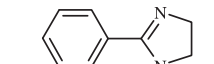

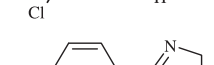

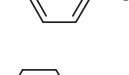

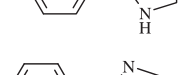

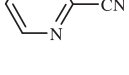

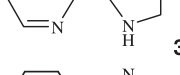

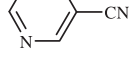

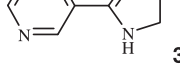

### General procedure for the synthesis of bisthiazolines and monoimidazolines

To a mixture of dinitrile (2 mmol) and 2-aminoethanethiol (5 mmol) or ethylenediamine (16 mmol) was added DBH (0.04 mmol) and the mixture stirred at 110 °C for the appropriate time according to Table 3. The progress of the reaction was monitored by TLC (2:1 *n*-hexane/EtOAc for thiazolines and 4:1 EtOAc/CH<sub>3</sub>OH for imidazolines). After completion of the reaction, the mixture was cooled to room temperature and the crude product purified via silica gel column chromatography.

MS  $m/z$ : 164 [ $M^+$ ]. Anal. calcd. for  $C_8H_8N_2S$ : C 58.51, H 4.91, N 17.06; found C 58.58, H 4.95, N 17.00.

### 2-(4-Pyridyl)thiazoline (3j)

Solid; mp 74–76 °C.  $^1H$  NMR ( $CDCl_3$ , 500 MHz)  $\delta$ : 3.48 (t,  $J = 8.5$  Hz, 2H,  $CH_2-S$ ), 4.51 (t,  $J = 8.5$  Hz, 2H,  $CH_2-N$ ), 7.68 (dd,  $J = 1.5$  and 4.5 Hz, 2H, ArH), 8.71 (dd,  $J = 1.5$  and 4.5 Hz, 2H, ArH). MS  $m/z$ : 164 [ $M^+$ ]. Anal. calcd. for  $C_8H_8N_2S$ : C 58.51, H 4.91, N 17.06; found C 58.49, H 4.85, N 17.13.

### 2-Phenylimidazoline (3k)

Solid; mp 100–102 °C.  $^1H$  NMR ( $CDCl_3$ , 80 MHz)  $\delta$ : 3.75 (s, 4H,  $2CH_2$ ), 4.8 (s, 1H, NH), 7.3–7.4 (m, 3H, ArH), 7.7–7.8 (m, 2H, ArH). MS  $m/z$ : 146 [ $M^+$ ]. Anal. calcd. for  $C_9H_{10}N_2$ : C 73.94, H 6.89, N 19.16; found C 73.95, H 6.85, N 19.18.

**2-(3-Chlorophenyl)imidazoline (3l)**

Solid; mp 134–136 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 80 MHz)  $\delta$ : 3.76 (s, 4H,  $2\text{CH}_2$ ), 4.25 (s, 1H, NH), 7.22–7.75 (m, 4H, ArH). MS  $m/z$ : 180, 182 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_9\text{H}_9\text{ClN}_2$ : C 59.84, H 5.02, N 15.51; found C 59.78, H 5.10, N 15.45.

**2-(4-Chlorophenyl)imidazoline (3m)**

Solid; mp 186–188 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 80 MHz)  $\delta$ : 3.75 (s, 4H,  $2\text{CH}_2$ ), 4.22 (s, 1H, NH), 7.3 (d, 2H, ArH), 7.93 (d, 2H, ArH). MS  $m/z$ : 180, 182 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_9\text{H}_9\text{ClN}_2$ : C 59.84, H 5.02, N 15.51; found C 59.88, H 5.06, N 15.49.

**2-(2-Pyridyl)imidazoline (3n)**

Solid; mp 100–102 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 80 MHz)  $\delta$ : 3.81 (s, 4H,  $2\text{CH}_2$ ), 5.38 (s, 1H, NH), 7.22–7.38 (m, 1H, ArH), 7.62–7.85 (m, 1H, ArH), 8.12 (d, 1H, ArH), 8.55 (d, 1H, ArH). MS  $m/z$ : 147 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_8\text{H}_9\text{N}_3$ : C 65.29, H 6.16, N 28.55; found C 65.20, H 6.17, N 28.61.

**2-(3-Pyridyl)imidazoline (3o)**

Solid; mp 106–108 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 80 MHz)  $\delta$ : 3.78 (s, 4H,  $2\text{CH}_2$ ), 4.54 (s, 1H, NH), 7.2–7.38 (m, 1H, ArH), 8.02–8.15 (m, 1H, ArH), 8.6–8.67 (m, 1H, ArH), 8.92 (s, 1H, ArH). MS  $m/z$ : 147 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_8\text{H}_9\text{N}_3$ : C 65.29, H 6.16, N 28.55; found C 65.25, H 6.14, N 28.63.

**2-(4-Pyridyl)imidazoline (3p)**

Solid; mp 134–136 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 80 MHz)  $\delta$ : 3.79 (s, 4H,  $2\text{CH}_2$ ), 4.3 (s, 1H, NH), 7.61 (d, 2H, ArH), 8.65 (d, 2H, ArH). MS  $m/z$ : 147 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_8\text{H}_9\text{N}_3$ : C 65.29, H 6.16, N 28.55; found C 65.33, H 6.21, N 28.49.

**2-(3-(Thiazolin-2-yl)phenyl)thiazoline (3q)**

Solid; mp 111–113 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz)  $\delta$ : 3.46 (t,  $J = 8.4$  Hz, 4H,  $2\text{CH}_2\text{-S}$ ), 4.49 (t,  $J = 8.4$  Hz, 4H,  $2\text{CH}_2\text{-N}$ ), 7.48 (t,  $J = 7.8$  Hz, 1H, ArH), 7.95 (dd,  $J = 1.5$  and 7.8 Hz, 2H, ArH), 8.27 (s, 1H, ArH). MS  $m/z$ : 248 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_{12}\text{H}_{12}\text{N}_2\text{S}_2$ : C 58.03, H 4.87, N 11.28; found C 58.06, H 4.84, N 11.32.

**2-(4-(Thiazolin-2-yl)phenyl)thiazoline (3r)**

Solid; mp 105–107 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz)  $\delta$ : 3.45 (t,  $J = 8.3$  Hz, 4H,  $2\text{CH}_2\text{-S}$ ), 4.49 (t,  $J = 8.3$  Hz, 4H,  $2\text{CH}_2\text{-N}$ ), 7.88 (s, 4H, ArH). MS  $m/z$ : 248 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_{12}\text{H}_{12}\text{N}_2\text{S}_2$ : C 58.03, H 4.87, N 11.28; found C 58.11, H 4.79, N 11.21.

**3-(Imidazolin-2-yl)benzonitrile (3s)**

Solid; mp 133–134 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz)  $\delta$ : 3.81 (s, 4H,  $2\text{CH}_2$ ), 4.2 (s, 1H, NH), 7.51 (t,  $J = 7.8$  Hz, 1H, ArH), 7.71 (d,  $J = 7.7$  Hz, 1H, ArH), 8.01 (d,  $J = 7.9$  Hz, 1H, ArH), 8.05 (s, 1H, ArH). MS  $m/z$ : 171 [ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_{10}\text{H}_9\text{N}_3$ : C 70.16, H 5.30, N 24.54; found C 70.22, H 5.34, N 24.50.

**4-(Imidazolin-2-yl)benzonitrile (3t)**

Solid; mp 207–209 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz)  $\delta$ : 3.83 (s, 4H,  $2\text{CH}_2$ ), 4.2 (s, 1H, NH), 7.71 (d,  $J = 8.4$  Hz, 2H, ArH), 7.90 (d,  $J = 8.4$  Hz, 2H, ArH). MS  $m/z$ : 171

[ $\text{M}^+$ ]. Anal. calcd. for  $\text{C}_{10}\text{H}_9\text{N}_3$ : C 70.16, H 5.30, N 24.54; found C 70.15, H 5.33, N 24.52.

# Threshold ionization and dissociation of *t*-butylamine

Paul M. Mayer, Martyn F. Guest, Emma E. Rennie, Louise Cooper,  
Larisa G. Shpinkova, David M.P. Holland, and David A. Shaw

**Abstract:** The threshold photoelectron spectrum of *t*-butylamine, recorded between 8 and 28 eV, is reported for the first time. The spectrum was compared to orbital ionization energies calculated at the OVGF/cc-pVTZ level of theory. The adiabatic and vertical ionization energies of the outermost orbital (made up primarily of the nitrogen p orbital) are  $8.48 \pm 0.02$  and  $9.40 \pm 0.02$  eV, respectively. Threshold photoelectron photoion coincidence spectra were recorded between 8.5 and 35 eV, and appearance energies for 15 fragment ions were obtained. The lowest energy dissociation is the loss of a methyl group to form the  $(\text{CH}_3)_2\text{CNH}_2^+$  ion. RRKM fitting of this dissociation leads to a  $\Delta_f H_{298}$  for  $(\text{CH}_3)_2\text{CNH}_2^+$  of  $603 \pm 3$  kJ mol<sup>-1</sup>. This value is  $\sim 10$  kJ mol<sup>-1</sup> higher than the previously derived value of Lossing et al. (based on an electron ionization appearance energy value) and the G3B3 estimate. Together with the proton affinity value of 932.3 kJ mol<sup>-1</sup>, the present  $\Delta_f H_{298}$  leads to a  $\Delta_f H_{298}$  for 2-propanimine  $(\text{CH}_3)_2\text{C}=\text{NH}$  of 5.3 kJ mol<sup>-1</sup>, which can be compared to a value of  $-5.7$  kJ mol<sup>-1</sup> (based on the Lossing et al.  $(\text{CH}_3)_2\text{CNH}_2^+$   $\Delta_f H_{298}$ ) and a G3B3 value of  $-0.3$  kJ mol<sup>-1</sup>. At photon energies above 26 eV, there is evidence for the dissociative double ionization of *t*-butylamine forming either the singlet or triplet state of the dication.

**Key words:** *t*-butylamine ions, ab initio molecular orbital calculations, density functional calculations, ionization energies, threshold photoelectron photoion coincidence spectroscopy, activation energies, activation entropies.

**Résumé :** Les spectres photoélectroniques de seuil de la *t*-butylamine ont été enregistrés entre 8 et 28 eV et sont rapportés pour la première fois. Les spectres sont comparés aux énergies d'ionisation des orbitales calculées au niveau OVGF/cc-pVTZ de la théorie. Les énergies d'ionisation adiabatique et verticale des orbitales les plus loin du noyau, qui comprennent principalement les orbitales p de l'azote, sont respectivement égales à  $8,48 \pm 0,02$  et  $9,40 \pm 0,02$  eV. Les spectres de coïncidence photoélectronique de seuil des photoions ont été enregistrés entre 8,5 et 35 eV et on a obtenu les énergies d'apparition de quinze fragments ioniques. La dissociation d'énergie la plus faible correspond à la perte d'un groupe méthyle conduisant à la formation de l'ion  $(\text{CH}_3)_2\text{C}=\text{NH}_2^+$ . Un ajustement de cette dissociation par la méthode de Rice, Ramsperger, Kassel et Marcus (RRKM) conduit à une valeur de  $603 \pm 3$  kJ mol<sup>-1</sup> pour le  $\Delta_f H_{298}$  de l'ion  $(\text{CH}_3)_2\text{C}=\text{NH}_2^+$ . Cette valeur est environ 10 kJ mol<sup>-1</sup> plus élevée que celle obtenue antérieurement par Lossing et al. sur la base de la valeur de l'énergie d'apparition d'une ionisation électronique ainsi que celle évaluée par la méthode G3B3. Combinée à la valeur de 932,3 kJ mol<sup>-1</sup> pour l'affinité du proton, la valeur de  $\Delta_f H_{298}$  trouvée dans cette étude conduit à une valeur de 5,3 kJ mol<sup>-1</sup> pour le  $\Delta_f H_{298}$  de la 2-propanimine,  $(\text{CH}_3)_2\text{C}=\text{NH}$ ; cette valeur est à comparer à la valeur de  $-5,7$  kJ mol<sup>-1</sup> rapportée par Lossing et al. sur la base de sa valeur du  $\Delta_f H_{298}$  pour l'ion  $(\text{CH}_3)_2\text{C}=\text{NH}_2^+$ , et à la valeur de  $-0,3$  kJ mol<sup>-1</sup> évaluée par la méthode G3B3. À des énergies photoniques supérieures à 26 eV, il y a des indications à l'effet qu'il se produit une double ionisation dissociative de la *t*-butylamine conduisant à l'état singulet ou triplet du dication.

**Mots-clés :** ions de la *t*-butylamine, calculs d'orbitales moléculaire ab initio, calculs de la fonctionnelle de la densité, énergies d'ionisation, spectroscopie de coïncidence photoélectronique de seuil des photoions, énergies d'activation, entropies d'activation.

## Introduction

Primary amines such as *n*-butylamine and *iso*-butylamine display significant molecular ions ( $\sim 10\%$  of the base peak,  $m/z$  30  $\text{CH}_2\text{NH}_2^+$ ) in their electron ionization (EI) mass spectra, while the molecular ion of *sec*-butylamine is only  $\sim 1\%$  of the base peak ( $m/z$  44). *t*-Butylamine is one of many *t*-butyl-containing molecules that exhibit almost no molecular ion in their EI mass spectrum (the list includes *t*-butanol, *t*-butyl methyl ether, *t*-butyl halides, and related compounds such as *t*-pentylamine and trimethylsilylether, among others).<sup>1</sup> The lack of a molecular ion in  $(\text{CH}_3)_3\text{CR}$  systems is due primarily to a large geometry difference between the neutral and ionized molecule, in the form of a long C–C bond between the quaternary carbon and one of the methyl groups, driven by the formation of a stable  $(\text{CH}_3)_2\text{CR}$  moiety in the radical cation (when R is a charge/spin stabilizing group, such as  $\text{CH}_3$ ,<sup>2</sup>  $\text{NH}_2$  (see Results),  $\text{OH}$ ,<sup>3</sup>  $\text{OCH}_3$ ,<sup>2</sup> and  $\text{CN}$ <sup>4</sup>). Vertical ionization of the neutrals produces highly excited ions. Coupled with what are often small activation energies,  $E_0$ , for dissociation, the generated molecular ions simply cannot survive on the microsecond timescale of most mass spectrometers. To probe this issue further with *t*-butylamine, we have employed threshold photoelectron spectroscopy to explore the ionization of molecular orbitals with binding energies up to 28 eV and threshold photoelectron photoion coincidence spectroscopy to determine appearance energies for all ion dissociation channels up to a photon energy of 34 eV. The lowest energy dissociation channel, methyl radical loss, was modeled to extract thermochemical information for the  $(\text{CH}_3)_2\text{CNH}_2^+$  cation.

## Experimental procedures

The pulsed TPEPICO spectrometer<sup>5</sup> in which the dissociation, kinetic, and threshold photoelectron studies were performed, and the 5 m normal incidence monochromator,<sup>6</sup> attached to the Daresbury Laboratory synchrotron radiation source, have been described in detail previously. Briefly, the coincidence spectrometer employs a pulsed extraction technique,<sup>7</sup> the principal advantage of which is that threshold electrons can be detected with a high energy resolution, whilst also allowing the associated ions to be collected with a high mass resolution. In the present arrangement,<sup>5</sup> a very low electric field is applied initially across the interaction region to extract threshold electrons, the detection of which triggers the application of a high voltage ( $\sim 1$  kV) pulse across the interaction region to draw the ion towards the drift tube, initiating the (time-of-flight) TOF measurement. The time between the arrival of the electron and the associated ion is measured electronically, with the summation of many events producing a TOF spectrum. With the present apparatus, the minimum residence time has been measured as  $1.116 \pm 0.050$   $\mu\text{s}$ , using the experimental procedure described in Holland et al.<sup>5</sup>

The threshold photoelectron spectrum was recorded in the binding-energy range from 8 to 28 eV using only the electron-detection part of the coincidence spectrometer. The spectrum was normalized to the incident photon intensity using the signal from a photomultiplier monitoring the radiation after it impinged upon a sodium salicylate coated screen. The threshold photoelectron spectrum was measured

at a photon resolution of 0.1 nm FWHM ( $\sim 18$  meV at  $h\nu = 15$  eV). Lithium fluoride or indium filters could be inserted into the photon beam exiting the monochromator to help suppress higher order radiation. The binding-energy scale was calibrated by recording a threshold photoelectron spectrum of a gas mixture comprising *t*-butylamine, argon, and krypton.

## Computational procedures

Standard ab initio molecular orbital and density functional theory calculations<sup>8</sup> were carried out with the Gaussian 98 suite of programs.<sup>9</sup> Vibrational frequencies were calculated for all optimized geometries (B3-LYP/6–31+G(d,p)) to verify that they corresponded to equilibrium structures. Vibrational frequency scaling factors were chosen from the computational chemistry comparison and benchmark database.<sup>10</sup> Single-point energy calculations at the geometries specified in the text were performed with the G3B3<sup>11,12</sup> composite method, employing B3-LYP/6–31+G(d,p) geometries and zero-point vibrational energies (ZPEs). Neutral and ion enthalpies of formation were derived using the atomization method outlined by Nicholaides and Radom.<sup>13</sup> Thermal corrections incorporated standard  $(H_{298} - H_0)$  terms for the elements.

Vertical ionization energies and their relative spectral intensities (pole strengths) of *t*-butylamine were obtained using the outer valence Green's function (OVGF) approach.<sup>14</sup> The calculations employed the GAMESS-UK<sup>15,16</sup> suite of programs, with a variety of basis sets. For consistency, the geometries were fully optimized at the MP2 level using both cc-pVTZ and cc-pVDZ basis sets.<sup>17–20</sup> The OVGF calculations were performed at the cc-pVTZ-optimized equilibrium geometry of  $C_s$  symmetry using both the cc-pVDZ and cc-VTZ basis sets. Five inner-shell orbitals (the 1s functions on each C and N) were frozen. The cc-VTZ results are listed in Table 1, together with the distribution analysis derived from a Mulliken population analysis of the single configuration (the Hartree–Fock SCF wave function) generated at the same geometry used in the OVGF calculations.

The TPEPICO breakdown curve for the lowest energy-dissociation channel was modeled as described previously.<sup>21–27</sup> In the absence of a kinetic shift, the curve shape is dictated by the parent-ion thermal (rotational and vibrational) energy, the monochromator band pass function (photon resolution  $\sim 8$  meV), and the threshold electron analyzer transmission function ( $\sim 9$  meV full width at half-maximum) derived from a threshold electron spectrum obtained from the photoionization of krypton in the region of the  $^2\text{P}_{1/2}$  ionization limit under the conditions used in the TPEPICO measurements.<sup>21–23</sup> A kinetic step function is used to allow the activation energy,  $E_0$ , to be varied until a satisfactory fit to the experimental breakdown curves was obtained. This kinetic step function was obtained using an RRKM calculation<sup>28,29</sup> according to the standard equation:

$$[1] \quad k(E) = \frac{\sigma N^\ddagger (E - E_0)}{h \rho(E)}$$

where  $\sigma$  is the reaction symmetry number,  $h$  is Planck's constant, and  $N^\ddagger$  and  $\rho$  are the transition state sum-of-states and molecular ion density of states, respectively. The transition-

<sup>a</sup>Cs refers to the s orbital on carbon, Cdf refers to d and f orbitals on carbon, and so forth.

state vibrational frequencies were chosen to be the same as those calculated for the molecular ion (see above), less one, arbitrarily chosen, mode to represent motion over the col. The calculated rotational constants of the molecular ion were used for both molecular ion and transition state when calculating the ro-vib densities and sums of states (which were calculated by the direct count algorithm).<sup>30</sup> The uncertainties quoted for  $E_0$  reflect (i) the uncertainty in the adiabatic IE chosen to convert photon energy to ion internal energy and (ii) the range of  $E_0$  values that gave satisfactory fits to the experimental breakdown curves.

## Results and discussion

### The geometry of *t*-butylamine

The structures of neutral and ionized *t*-butylamine are shown in Fig. 1 along with selected geometrical parameters. As was previously found for *t*-butyl-containing species,<sup>2</sup> the ion exhibits a long C–C bond (1.621 Å) between the (CH<sub>3</sub>)<sub>2</sub>CNH<sub>2</sub> moiety and a methyl group. This is accompanied by an increased planarity of the carbons involved in the long bond and the amino group. The bond elongation allows the (CH<sub>3</sub>)<sub>2</sub>CNH<sub>2</sub> moiety to more closely resemble a delocalized system with a partial (CH<sub>3</sub>)<sub>2</sub>C–NH<sub>2</sub> double bond (evident from the bond length in Fig. 1).

### Threshold photoelectron spectrum

The valence-shell threshold photoelectron spectrum of *t*-butylamine is plotted in Fig. 2, together with the OVGF ionization energies and relative spectral intensities. The predicted ionization energies for the outer valence orbitals agree remarkably well with the observed values, thereby enabling structure in the experimental spectrum to be associated with ionization from specific molecular orbitals. A similar correlation is also feasible for the more tightly bound 4a', 1a'', 3a', and 2a' orbitals, although the calculated ionization energies of these inner valence orbitals are slightly higher than the experimental values. It is noticeable that the

**Fig. 1.** B3-LYP/6–31+G(d,p) optimized geometries for neutral and ionized *t*-butylamine and the fragmentation product  $m/z$  58, along with selected geometric parameters. Bond lengths are in Å.

peaks occurring at 18.3, 21.9, and 23.9 eV are less intense than those associated with the outer valence orbitals and are superimposed upon a continuum. This indicates that the molecular orbital model of ionization<sup>31</sup> no longer holds for these inner valence orbitals and that electron correlation leads to the intensity associated with a particular orbital being redistributed amongst numerous satellite states. It is the superposition of these satellites that results in the observed continuum. Table 1 lists the experimental vertical ionization energies (IE<sub>v</sub>) obtained through inspection of the threshold photoelectron spectrum.

**Fig. 2.** The threshold photoelectron spectrum of *t*-butylamine together with the theoretical results (Table 1). The height of the bar is proportional to the calculated relative spectral intensity (pole strength).

To the best of our knowledge, neither a HeI-excited nor a threshold photoelectron spectrum of *t*-butylamine has been published. Al-Joboury and Turner<sup>32</sup> quote adiabatic ionization energies ( $IE_a$ ) of 8.83, 9.81, 12.46, and 15.11 eV, but they neither show a spectrum nor attempt to relate these energies with specific orbitals. Their values do not agree well with either the present experimental or the calculated OVGf results. From inspection of the threshold photoelectron spectrum, we obtain adiabatic and vertical ionization energies of the outermost  $10a'$  orbital of  $8.48 \pm 0.02$  and  $9.40 \pm 0.02$  eV, respectively. The corresponding values given by Aue et al.<sup>33</sup> are 8.46 and 9.25 eV, respectively, and are thus in good agreement. The G3B3  $IE_a$  is significantly higher at 8.69 eV (Table 2). According to the OVGf calculations, the vertical ionization of the outermost orbital is  $\sim 2.2$  eV lower than that of the next ( $6a''$ ) orbital. These theoretical predictions correlate satisfactorily with the experimental spectrum because the peak at 11.42 eV, associated with the  $6a''$  orbital, leads to a separation of 2.0 eV between the bands corresponding with the  $10a'$  and  $6a''$  orbitals. It is noticeable that the threshold photoelectron yield remains finite across the Franck–Condon gap between the  $(10a')^{-1} \tilde{X}^2A'$  and the  $(6a'')^{-1} \tilde{A}^2A'$  state bands. This is due to resonant autoionization from super-excited states lying in the relevant energy region.

Ionization from the  $9a'$  orbital gives rise to a shoulder at 11.92 eV in the experimental spectrum. The next four orbitals ( $8a'$ ,  $5a''$ ,  $4a''$ , and  $7a'$ ) have similar binding energies and ionization results in overlapping bands, which form the most intense feature in the experimental spectrum. It should be noted that the very sharp peak at 14 eV is due to krypton, which was used to calibrate the energy scale. Ionization from each of the next three orbitals ( $3a''$ ,  $6a'$ , and  $5a'$ ) produces a distinct maximum (at 14.65, 15.14, and 15.79 eV, respectively), whereas ionization from the  $2a''$  orbital, with a predicted ionization energy of 16.54 eV, gives rise to no discernible feature.

The overall shape of the threshold photoelectron spectrum of *t*-butylamine is typical of those observed for small polyatomic molecules.<sup>34,35</sup> Experimentally, it has been found that

the relative intensities of photoelectron bands associated with weakly bound orbitals tend to be greater in conventional spectra than those in threshold photoelectron spectra, whereas the converse holds for the more tightly bound orbitals. The enhancement in the latter bands can be attributed to resonant autoionization from numerous super-excited (Rydberg or valence) states.

The charge-distribution analysis given in Table 1 may be used to characterize the molecular orbitals in terms of atomic populations. In molecules of low symmetry, such as the  $C_s$  symmetry applicable to *t*-butylamine, it is often useful to group together individual contributions into smaller molecular species relevant to that particular molecule. The charge distributions listed in Table 1 are presented in this manner. The results show that the electron density associated with the outermost  $10a'$  orbital is concentrated on the nitrogen atom and arises mainly from the 2p orbital. The electron densities for the following nine orbitals are similar to one-another, with the major contributions being C 2p and H 1s from the  $(Me)_3$  group. The composition of the next orbital ( $2a''$ ) is different in that the principal contributions arise from the N 2p and H 1s orbitals of atoms located at the opposite end of the molecule. The inner valence  $4a'$  orbital is the first to possess a significant C 2s component. Finally, the  $1a''$  and  $3a'$ , and to a lesser extent the  $2a'$ , orbitals contain substantial contributions from the C 2s and H 1s orbitals on the  $(Me)_3$  group whilst N 2s provides the principal component to the most tightly bound inner valence orbital  $1a'$ .

### Threshold photoelectron photoion coincidence spectroscopy

Threshold photoelectron photoion coincidence spectra were acquired from 8.54 to 34.04 eV. Table 3 lists the appearance energies (AEs) for each ion, obtained from inspection of their threshold for appearance. Breakdown curves for all ions except  $m/z$  73 (*t*-butylamine,  $(CH_3)_3CNH_2^+$ ) and 58 ( $(CH_3)_2CNH_2^+$ ) are shown in Fig. 3. The threshold region including  $m/z$  73 and 58 is presented in Fig. 4. The experimentally derived  $IE_a$  (Table 1) was employed to correct the experimental TPEPICO photon energy to ion internal energy

for subsequent data fitting. Ionized *t*-butylamine (*m/z* 73) dissociates by loss of a methyl radical to form (CH<sub>3</sub>)<sub>2</sub>CNH<sub>2</sub><sup>+</sup>, *m/z* 58. This is the analogous reaction to the formation of CH<sub>2</sub>NH<sub>2</sub><sup>+</sup> from ionized primary alkyl amines.<sup>36</sup> The reaction has no kinetic shift, and a fit was generated with the thermal population of neutral *t*-butylamine convoluted with the monochromator band pass and electron transmission functions. The latter shifts the precursor ion disappearance point higher than the true 0 K threshold, and so this threshold cannot be simply read straight off the breakdown curve in Fig. 4. The so-derived 0 K  $E_0$  of  $0.48 \pm 0.02$  eV corresponds to a 0 K energy of  $8.96 \pm 0.04$  eV relative to the neutral molecule (the 0 K appearance energy,  $AE_0$ ). This value can be corrected to a 298 K value of  $9.01 \pm 0.04$  eV employing the theoretical temperature corrections for the species involved. This AE can be used with the literature  $\Delta_f H$  values for neutral *t*-butylamine and the methyl radical (Table 2) to yield a  $\Delta_f H_{298}$  for (CH<sub>3</sub>)<sub>2</sub>CNH<sub>2</sub><sup>+</sup> of  $603 \pm 3$  kJ mol<sup>-1</sup>. This value is  $\sim 10$  kJ mol<sup>-1</sup> higher than

**Fig. 3.** TPEPICO breakdown curves for all observed ions other than *m/z* 73 and 58.

the previously derived value of Lossing et al.<sup>37</sup> (based on an electron ionization appearance energy value) and the G3B3 estimate. The  $\Delta_f H_{298}$  of CH<sub>2</sub>NH<sub>2</sub><sup>+</sup> is 750.3 kJ mol<sup>-1</sup> and

**Fig. 4.** Threshold breakdown curves for  $m/z$  73 and 58 (points) along with representative fits to the data (solid lines).

that of the mono-methyl-substituted ion  $\text{CH}_3\text{CHNH}_2^+$  is  $665 \pm 1.4 \text{ kJ mol}^{-1}$ .<sup>36,38</sup> These values indicate a successive methyl-substitution effect on the  $\text{CH}_2\text{NH}_2^+$  ion  $\Delta_f H_{298}$  of 85 and 62  $\text{kJ mol}^{-1}$ . This compares to, and is consistent with, the diminishing effect observed in the analogous alcohol system of  $\text{CH}_2\text{OH}^+$ ,  $\text{CH}_3\text{CHOH}^+$ , and  $(\text{CH}_3)_2\text{COH}^+$  of 119 and 90  $\text{kJ mol}^{-1}$  (based on their  $\Delta_f H_{298}$  values of 711, 592, and 502  $\text{kJ mol}^{-1}$ , respectively).<sup>39</sup> A  $\Delta_f H_{298}$  for  $(\text{CH}_3)_2\text{CNH}_2^+$  of 592  $\text{kJ mol}^{-1}$  (from the G3B3 calculations and the previous EI AE study) gives a somewhat smaller drop in the successive methyl-substitution effect of 85 and 73  $\text{kJ mol}^{-1}$ .

Employing a  $\Delta_f H_{298}$  for  $(\text{CH}_3)_2\text{CNH}_2^+$  of  $603 \pm 3 \text{ kJ mol}^{-1}$ , and the proton affinity (PA) value of  $932.3 \text{ kJ mol}^{-1}$ ,<sup>1</sup> leads to a  $\Delta_f H_{298}$  for 2-propanimine  $(\text{CH}_3)_2\text{C}=\text{NH}$  of  $5.3 \pm 3 \text{ kJ mol}^{-1}$ , which to our knowledge is the first report of this value. The  $\Delta_f H_{298}$  for  $(\text{CH}_3)_2\text{CNH}_2^+$  of 592  $\text{kJ mol}^{-1}$ , together with the experimental PA value of  $932.3 \text{ kJ mol}^{-1}$ ,<sup>1</sup> leads to a  $\Delta_f H_{298}$  for 2-propanimine of  $-5.7 \text{ kJ mol}^{-1}$ . Each compares well with, but are on opposite sides of, the G3B3  $\Delta_f H_{298}$  of  $-0.3 \text{ kJ mol}^{-1}$ . While it again would be useful to examine the methyl-substitution effect, this time on neutral methylenimine, the reported uncertainties in the  $\Delta_f H_{298}$  for  $\text{CH}_2\text{NH}$  ( $69 \pm 8 \text{ kJ mol}^{-1}$ )<sup>40</sup> and that of  $(\text{CH}_3)\text{CH}=\text{NH}$  ( $24 \pm 8 \text{ kJ mol}^{-1}$ )<sup>40</sup> are so large as to make the exercise impractical.

### Charge-separation reactions in doubly ionized *t*-butylamine cations

The G3B3 calculations predict vertical double-ionization energies of 26.4 and 26.6 eV for the singlet and triplet states, respectively, of the *t*-butylamine dication, whilst the corresponding adiabatic energies are 21.3 and 24.9 eV, respectively. For the singlet dication, the computations show that there is a large shift in geometry, putting one of the methyl groups over the  $\text{NH}_2$ . However, the doubly charged parent ion is not observed experimentally, indicating that it is unstable in relation to the microsecond timescale of the measurements, and fragments into two singly charged ions together with a neutral species.

**Fig. 5.** Ion TOF spectra of *t*-butylamine recorded at photon energies of (a) 22 eV and (b) 32 eV.

Ion TOF spectra of *t*-butylamine, recorded at photon energies of 22 and 32 eV, are plotted in Fig. 5, and it is noticeable that the widths of some of the peaks, particularly those associated with  $m/z$  15, 41, 42, and 43, are broader in the spectrum recorded at 32 eV than in that recorded at 22 eV. The peak width is dependent upon the fragment-ion initial kinetic energy and can be used to deduce double-ionization thresholds. In previous work,<sup>2,21,41,42</sup> we have shown that the width of the  $m/z$  15 peak provides a reliable estimate of the double-ionization threshold in molecules where the doubly charged parent ion is not observed experimentally because it appears that this fragment is often formed in combination with another small fragment ion in the dissociation of the doubly charged parent ion.

The TOF spectrum of *t*-butylamine recorded at 32 eV reveals two interesting features. First, the  $m/z$  15 peak profile contains several distinct components. One of these components coincides with the single peak observed in the TOF spectrum recorded at 22 eV, and therefore corresponds to an  $m/z$  15 fragment formed with very low kinetic energy. The appearance of the other components indicates that, at a photon energy of 32 eV,  $m/z$  15 fragments are produced through additional dissociation processes with the release of at least two distinct kinetic energies. Second, at 32 eV, the TOF peak profiles associated with the  $m/z$  41 and 43, and probably also 42, fragments are doublets. This is unusual at such relatively low excitation energies and demonstrates that these heavier fragment ions, presumably formed as the sec-

ond ionic species in the charge-separation reaction, carry away significant kinetic energy. In our previous charge-separation studies,<sup>2,21,41,42</sup> although the width of the TOF peak of the heavier ion was broader than that corresponding to a thermal ion, a doublet was not observed. The evidence from the TOF spectra of *t*-butylamine suggests that charge-separation reactions in the dication lead to the formation of fragment ions with *m/z* 15, together with *m/z* 41, 42 or 43, and an accompanying neutral species. Both the *m/z* 15 and the heavier fragment ion possess substantial kinetic energy.

The present results for *t*-butylamine show that the fragment peak broadening becomes evident at excitation energies of 26 eV, and above, thereby placing an upper limit on the double-ionization energy. Thus, the experimental value is in satisfactory agreement with the calculated vertical double-ionization energies of the singlet and triplet states of the dication. The present experimental result is also in accord with measurements of 26.1 eV for the vertical double-ionization energies of both the singlet and triplet states of *n*-butylamine.<sup>43,44</sup>

## Conclusion

The threshold photoelectron spectrum of *t*-butylamine was recorded between 8.5 and 28 eV. Threshold photoelectron photoion coincidence spectra were recorded between 8.5 and 35 eV and appearance energies for 15 fragment ions were obtained. The lowest energy dissociation is the loss of a methyl group to form the (CH<sub>3</sub>)<sub>2</sub>CNH<sub>2</sub><sup>+</sup> ion. RRKM fitting of this dissociation leads to a  $\Delta_f H_{298}$  for (CH<sub>3</sub>)<sub>2</sub>CNH<sub>2</sub><sup>+</sup> of 603 ± 3 kJ mol<sup>-1</sup>. This value is ~10 kJ mol<sup>-1</sup> higher than the previously EI-AE-derived value of Lossing et al.<sup>37</sup> and the G3B3 estimate. The present  $\Delta_f H_{298}$ , combined with the previously reported value and the results of G3B3 calculations, leads to a recommended  $\Delta_f H_{298}$  for 2-propanimine 0 ± 5 kJ mol<sup>-1</sup>, which to our knowledge is the first report of this value.

# Task-specific ionic-liquid-catalyzed efficient synthesis of indole derivatives under solvent-free conditions

Sudarshan Das, Matiur Rahman, Dhiman Kundu, Adinath Majee, and Alakananda Hajra

**Abstract:** A sulfonic-acid-functionalized ionic liquid is used as a Brønsted acid catalyst for the efficient synthesis of indole derivatives in good-to-high yields at room temperature under solvent-free conditions. The catalyst can be reused for ten consecutive runs without significant loss of activity.

**Key words:** functionalized ionic liquid, indole derivatives, bis(indolyl)methanes, Michael adduct, recycling.

**Résumé :** On a utilisé un liquide ionique à base d'acide sulfonique fonctionnalisé comme catalyseur acide de Brønsted pour développer des synthèses efficaces de dérivés de l'indole obtenus avec des rendements allant de bons à élevés, dans des conditions sans solvant. Le catalyseur peut être réutilisé jusqu'à dix fois sans perte significative de son activité.

**Mots-clés :** liquide ionique fonctionnalisé, dérivés de l'indole, bis(indolyl)méthanés, adduit de Michael, recyclage.

[Traduit par la Rédaction]

## Introduction

Michael reaction is one of the most important carbon-carbon bond-forming reactions.<sup>1</sup> The syntheses and the reactions of indole derivatives have received much interest for over a century because a number of their derivatives occur in nature and show versatile biological activities.<sup>2</sup> Since the 3-position of indole is the preferred site for electrophilic substitution reaction, 3-substituted indoles are versatile intermediates for the synthesis of a wide range of indole compounds.<sup>3</sup> Till date, several catalysts were used to catalyze the Michael addition of indoles to electron-deficient olefins; however, most of them were Lewis acids.<sup>4–20</sup> Many Lewis acids are deactivated or sometimes decomposed by nitrogen-containing reactants. Even when the desired reactions proceed, more than stoichiometric amounts of Lewis acids are required because the acids are deactivated by the nitrogen atom of indoles. However, the acid-catalyzed conjugate addition of indoles requires careful control of acidity to prevent side reactions such as dimerization and polymerization. For this reason, the need of a less expensive catalyst is desirable to secure catalytic activity, low toxicity, moisture, and air tolerance.

The application of Brønsted acidic task-specific ionic liquids (TSILs) as catalytic materials is growing continuously in the field of catalysis. Combining the useful charac-

Scheme 1.

teristics of solid acids and mineral acids, TSILs have been synthesized to replace traditional mineral liquid acids, such as hydrochloric acid and sulfuric acid, in chemical reactions. In view of green chemistry, the substitution of harmful liquid acids by reusable TSILs is the most promising catalytic system in chemistry.<sup>21–23</sup> Some “greener” halogen-free ionic liquids that involve phosphate or octyl sulfate anions have been reported, and effects of the anion and toxicology have been studied.<sup>24–26</sup> The use of Brønsted acidic TSILs to catalyze organic reactions is an area of ongoing activity and TSILs have been successfully used for various chemical transformations.<sup>27–29</sup> In continuation of our interest in ionic-liquid-mediated reactions,<sup>30</sup> we have explored the utility of a functionalized ionic liquid, 1-butane sulfonic acid-3-methylimidazolium tosylate, [BSMIM]Ts, as a catalyst for the conjugate addition of indoles with electron-deficient alkenes to produce 3-substituted indole derivatives under solvent-free conditions at room temperature (Scheme 1). To the best of our knowledge, this is the first report of a functionalized ionic liquid catalyzed Michael addition of various indoles to electron-deficient alkenes.

## Results and discussion

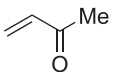

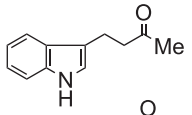

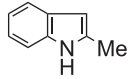

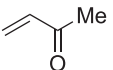

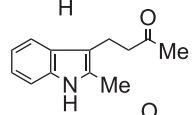

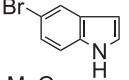

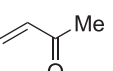

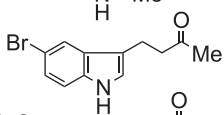

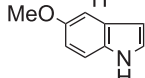

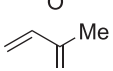

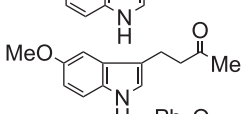

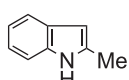

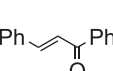

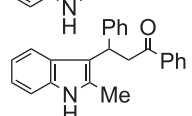

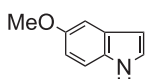

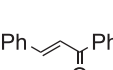

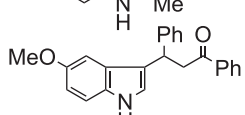

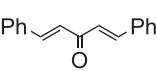

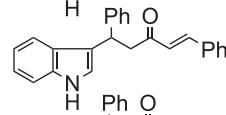

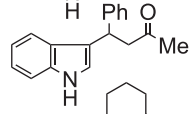

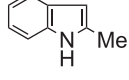

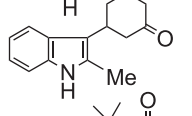

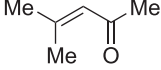

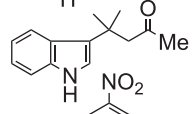

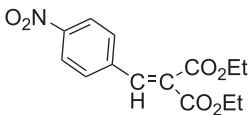

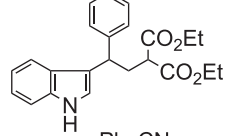

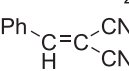

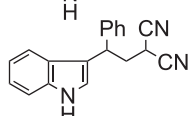

The experimental procedure is very simple. In a preliminary experiment, indole (2 mmol) was treated with methyl vinyl ketone (2 mmol) in the presence of TSIL (5 mol%) under solvent-free conditions at room temperature, providing the corresponding Michael adduct, exclusively, within 5 min

<sup>a</sup> Yields refer to those of pure isolated products fully characterized by spectral and physical data.

in 95% yield. The structure of the product was settled from the spectral data. The crude product obtained after ether extraction was found to be pure, as there was no detectable amount of impurities or starting material in the <sup>1</sup>H NMR of the crude product. We next examined the generality of the present reaction conditions to a series of substituted indoles and electron-deficient alkenes. The results are summarized in Table 1.

Electron-deficient olefins, such as chalcone, benzalacetone, cyclohexenone, and dibenzylidene acetone, afforded the products in good-to-excellent yields. The reaction of dibenzylidene with indole gave mono-addition product in 82% yield. A hindered enone, mesityl oxide, which is difficult for conjugate addition, is also reacted to produce Michael ad-

duct in fairly good yield (Table 1, entry 10). By using substituted indoles, good-to-excellent yields were obtained. The substituents did not affect the reactivity of indoles significantly. The catalytic system also worked well with benzylidene malonate to produce the corresponding product in 82% yield (Table 1, entry 11). For benzylidene malononitrile, the corresponding Michael adduct was obtained in low yield under the same conditions even after a prolonged reaction time (Table 1, entry 12). The present protocol could be used on a 100 mmol scale using 2 mol% of the catalyst, which could be reused several times.

Generally, the reactions are clean, and the products are obtained in high yields without the formation of any side products, such as *N*-alkylation products. However, under the

present reaction conditions,  $\alpha,\beta$ -unsaturated aldehydes and esters did not afford the corresponding Michael addition products. Furthermore, the indole nitrogen did not require prior protection, and the avoidance of strong bases for deprotection permitted compatibility with a wide range of functional groups. The procedure did not require any inert atmospheric condition.

The efficacy and generality of the present protocol can be realized by comparing some of the results presented here with recently reported two ionic-liquid-based methods<sup>31,32</sup> as shown in Table 2, which compares reaction time, yields, and reaction conditions. Thus, it is clear from Table 2 that the present protocol can act as an effective method with respect to reaction times, yields, and reaction conditions.

We extended the utility of catalyst for Michael addition of aniline and benzyl amine to methyl vinyl ketone under the present reaction conditions (Scheme 2). Surprisingly, both reactions proceeded very well in short times (25 min and 8 min, respectively), and the adducts were isolated in excellent yields. The results indicate that the catalyst can catalyze the Michael addition of both aromatic and aliphatic amines. This is a clear advantage over the recent reported ionic-liquid-catalyzed conjugate addition of aliphatic amines to electron-deficient alkenes.<sup>28</sup>

Synthesis of bis(indolyl)methanes is a subject of continuous interest to synthetic organic/medicinal chemists, as indoles and their derivatives have versatile biological activities and are widely present in various biologically active natural products.<sup>33</sup> The catalyst is also effective for the preparation of indole derivatives such as bis(indolyl)methane from benzaldehyde under present reaction conditions (Scheme 3). We found that 10 mg of the catalyst was sufficient to obtain the desired bis(indolyl)methane in 96% yield within 5 min at room temperature in neat conditions. Thus, this acidic ionic liquid is a versatile catalyst for various chemical transformations.

The reusability of the catalyst is an important benefit, especially for commercial applications. Thus, the recovery and reusability of the catalyst were investigated. After completion, the mixture was extracted with ether ( $3 \times 5$  mL) to obtain the desired products. The catalyst, left in the reaction vessel, was dried under vacuum and was reused for subsequent reactions. It showed the same activity as a fresh catalyst in term of yields. After ten recycles, the catalyst had a high activity and gave the desired product in fairly good yield (91%; Table 1, entry 1). Thus, this makes the process more cost-effective.

In conclusion, we have developed a mild, simple, environment-friendly, and cost-advantageous procedure for the Michael addition of indoles to electron-deficient alkenes using a recyclable task-specific acidic ionic liquid under solvent-free conditions. We believe that this procedure will provide a better and more practical alternative to the existing methodologies for the synthesis of 3-substituted indole derivatives. The catalyst is also effective for Michael addition of both aromatic and aliphatic amines as well as the synthesis of bis(indolyl)methane derivatives. Further procedures to broaden the scope of this methodology towards pharmaceuticals and biologically active compounds are under investigation.

Scheme 3.

## Experimental

The synthesis of the ionic liquid was carried out using a method similar to the reported.<sup>34</sup>

### Typical procedure for the synthesis of 4-(1*H*-indol-3-yl)-butan-2-one (Table 1, entry 1)

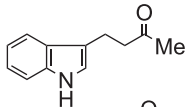

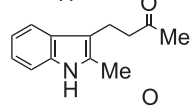

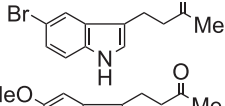

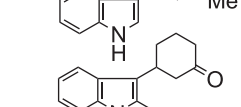

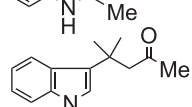

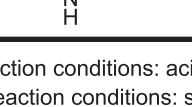

A mixture of indole (234 mg, 2 mmol) and MVK (162  $\mu$ L, 2 mmol) was stirred in presence of acidic ionic liquid (39 mg, 5 mol%) at room temperature for 5 min (TLC). After completion, the reaction mixture was extracted with diethyl ether ( $3 \times 10$  mL). Evaporation of solvent furnished the addition product as a solid (355 mg, 95%) whose spectroscopic data (IR and <sup>1</sup>H NMR) are in good agreement with those reported.<sup>5</sup> The catalyst left in the reaction vessel was dried under vacuum and was reused for the subsequent reaction. This procedure was followed for the synthesis of 3-substituted indoles listed in Table 1. Small amount of ethanol (0.5 mL) was added to the reaction mixture when both indoles and alkenes are solids. Analytically pure compound was obtained by silica gel chromatography using *n*-hexane/EtOAc as eluent. The spectral and elemental analyses of the compound, which are not readily available, are provided here.

The typical procedure for entry 1 (Table 1) was followed for 100 mmol scale reaction, taking a mixture of indole (11.7 g), MVK (8.1 mL), and acidic ionic liquid (780 mg). The pure product was obtained in 96% yield (17.90 g).

# Circular dichroism and fluorescence spectroscopic study on the interaction of bisdemethoxycurcumin and diacetylbisdemethoxycurcumin with human serum albumin

Fakhrossadat Mohammadi, Abdol-Khalegh Bordbar, Khosro Mohammadi, Adeleh Divsalar, and Ali Akbar Saboury

**Abstract:** The interactions of bisdemethoxycurcumin (BDMC) as a bioactive constituent of turmeric and diacetylbisdemethoxycurcumin (DABC) as a novel synthetic derivative of curcumin with human serum albumin (HSA) have been investigated by fluorescence and circular dichroism (CD) spectroscopy. The binding parameters, including the number of substantive binding sites and the binding constants, have been estimated from the analysis of fluorescence measurements. The estimated binding parameters indicated that BDMC has higher affinity than DABC to bind HSA, suggesting the essential role of the phenolic OH groups of BDMC, which are acetylated in DABC. It was found that the binding site for BDMC and DABC is located in the vicinity of Trp-214 in subdomain IIA, which is the same as binding site for curcumin (CUR). The minor changes on the far-UV circular dichroism spectra resulted in partial changes in the calculated secondary structure contents of HSA. The negligible alteration in the secondary structure of HSA indicated that ligand-induced conformational changes are localized in the binding site and do not involve considerable changes in the protein folding. The visible CD spectra indicated that the optical activity observed during the ligand binding is due to induced-protein chirality.

**Key words:** bisdemethoxycurcumin (BDMC), diacetylbisdemethoxycurcumin (DABC), human serum albumin (HSA), fluorescence, circular dichroism (CD).

**Résumé :** Faisant appel à la spectroscopie de fluorescence et au dichroïsme circulaire (DC), on a étudié les interactions entre l'albumine sérique humaine (ASH) et le bisdéméthoxycurcumin (BDMC), un constituant bioactif de l'acide turmérique, ainsi que le diacétylbisdéméthoxycurcumin (DABC), un nouveau dérivé de synthèse du curcumin. Les paramètres de fixation, dont le nombre de sites de fixation substantifs ainsi que les constantes de fixation ont été évaluées à partir de l'analyse des mesures de fluorescence. Les paramètres de fixation évalués indiquent que l'affinité de fixation du BDMC pour l'ASH est plus élevée que celle du DABC ce qui suggère que les groupes phénoliques OH du BDMC, qui sont acétylés dans la DABC, sont essentiels. On a trouvé que le site de fixation pour le BDMC et le DABC est situé à proximité du Trp-214 dans la sous-domaine IIA; il s'agit du même site de fixation que celui pour le curcumin (CUR). Les changements mineurs dans les spectres de dichroïsme circulaire dans l'UV lointain résultent de changements partiels dans les teneurs en structure secondaire calculée de l'ASH. L'altération négligeable dans la structure secondaire de l'ASH indique que les changements conformationnels induits par le ligand sont localisés dans le site de fixation et n'impliquent pas de changements considérables dans le replis de la protéine. Les spectres de dichroïsme circulaire dans le visible indique que l'activité optique observée durant la fixation du ligand résulte d'une chiralité induite par la protéine.

**Mots-clés :** bisdéméthoxycurcumin (BDMC), diacétylbisdéméthoxycurcumin (DABC), albumine sérique humaine (ASH), fluorescence, dichroïsme circulaire (DC).

## Introduction

Curcumin, [1,7-bis(4-hydroxy-3-methoxyphenyl)1,6-heptadiene-3,5-dione] (Scheme 1a), is an active principle of the perennial herb *Curcuma longa* Linn. (commonly known as turmeric). The yellow-pigmented fraction of turmeric contains bioactive substances called curcuminoids, such as curcumin (CUR), demethoxycurcumin (DMC), bisdemethoxycurcumin (BDMC) (Scheme 1b), and the recently identified cyclocurcumin.<sup>1,2</sup> According to numerous studies, curcuminoids display anticarcinogenic,<sup>3,4</sup> antioxidant,<sup>5,6</sup> anti-inflammation,<sup>7</sup> and antiangiogenic properties,<sup>8,9</sup> and modulation of multi-drug-resistance gene and protein function.<sup>10,11</sup> The antimetastasis,<sup>12</sup> and also antitumor and antioxidant activity<sup>13</sup> of BDMC, is much greater than CUR and DMC. Hoehle et al.<sup>14</sup> studied the metabolism of CUR, DMC, and BDMC and their results on enzymatic hydrolysis under various conditions revealed that CUR and DMC are chemically less stable than BDMC, whereas reductive metabolites of all three curcuminoids are stable compounds. The anti-inflammatory properties of DMC and BDMC were attributed to the inhibition of inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) expression, as initiated by the inhibition of nuclear factor-kappaB (NF-kappaB) activity. Additionally, both of them significantly inhibited carrageenan-induced paw edema in mice.<sup>15</sup> Diacetyl-bisdemethoxycurcumin (DABC) (Scheme 1c) is a new synthetic acetylated derivative of curcumin and has been shown to display moderate cytotoxicity ( $IC_{50} \sim 10 \mu\text{mol/L}$ ).<sup>16</sup>

Human serum albumin (HSA) is the major soluble protein constituent of blood plasma with many physiological functions. It contributes to colloid osmotic blood pressure and has an essential role in transport and disposition of many drugs, which are poorly soluble in water. The X-ray crystallographic measurements have shown that HSA is a globular protein and consists of a single polypeptide chain of 585 amino acid residues. HSA consists of three homologous domains (I, II and III). Each domain contains two separate helical subdomains (A and B), which are formed from six and four  $\alpha$ -helical, respectively. Terminal regions of sequential domains contribute to the formation of interdomain helices linking domain IB to IA, and IIB to IIIA, respectively. The secondary structure of HSA at pH 7.4 contains 65%  $\alpha$ -helix, 7%  $\beta$ -sheet, and 28% are the remaining structures (random coil and turn structures). The fluorophore groups of HSA include one tryptophan (residue 214 in domain IIA) and eleven tyrosine residues, of which seven are in domain I and four of them are in domain III. As can be deduced from the crystal structure of HSA, Trp-214 acts as an important stabilizer (by hydrophobic packing force) for the interface between subdomain IIA and IIIA. There are 35 cysteine residues in HSA, 34 of which form 17 disulfide bridges. Sixteen of these residues participate in the formation of eight so-called double disulfide bridges. Cys-34 does not participate in any disulfide bridge. The disulfide bridges, tryptophan, tyrosine, and phenylalanine residues, are the main chromophore groups in the circular dichroism spectra of HSA.<sup>17</sup> The crystal structure analyses have indicated that the principal regions of ligand binding sites of albumin are relocated in hydrophobic cavities in subdomain IIA (site I) and IIIA (site II). Remarkably, warfarin, an anticoagulant drug, and ibuprofen, a nonsteroidal anti-inflammatory agent, are considered stereotypical ligands for sites I and II, respec-

tively. HSA is capable of binding seven equivalents of long-chain fatty acids at multiple binding sites (IB, IIIA, IIIB, and subdomain interfaces) with different affinities.<sup>18–20</sup>

The serum albumin as a transport protein has an essential role in pharmacokinetic properties of drugs. Hence, study on the interaction of curcuminoids with HSA provides useful information for the formulation of these drugs. There are some reports on the interaction of curcumin with human and bovine serum albumin.<sup>21–27</sup> As a brief summary, these studies showed that the primary binding site of CUR is located in site I of HSA. The red-shifted absorption band and the binding of CUR to HSA in a right-handed chiral conformation is due to the dissociation of highly acidic phenolic OH groups of CUR. The interaction of diacetylcurcumin (DAC) and isoxazolcurcumin with BSA has been studied by Sahoo et al.<sup>28</sup> Their experimental results indicated minor conformational changes of BSA because of binding to these two derivatives of CUR and their binding location is in a hydrophobic cleft close to Trp-213.<sup>28</sup> However, there is no report on the interaction of BDMC and DABC with human serum albumin. In this research, we have studied the interaction of BDMC, as one of the natural polyphenol constituents of turmeric, and DABC, as a novel synthetic derivative of curcumin, with human serum albumin using fluorescence and circular dichroism (CD) spectroscopies.

## Experimental

### Materials

HSA (free fatty acid fraction V) was purchased from Sigma-Aldrich.

BDMC was separated from curcumin and DABC was synthesized based on a previously reported method.<sup>16</sup> Ethanol was obtained from Merck Company. All other materials and reagents were of analytical grade. Double distilled water was used for preparing the buffer solution.

### Preparation of the HSA solution

HSA was weighed and dissolved in 0.05 mol/L of pH 6.4 phosphate ( $\text{Na}_2\text{HPO}_4$  and  $\text{NaH}_2\text{PO}_4$ ) buffer solution. The exact concentrations of HSA were determined spectrophotometrically using the molar absorption coefficient of  $\epsilon_{278 \text{ nm}} = 35\,700 \text{ (mol/L}^{-1}\text{) cm}^{-1}$ .<sup>29</sup>

### Preparation of BDMC and DABC solutions

Stock solutions were prepared by dissolving BDMC and DABC in ethanol and different diluted solutions were made from the stock solutions with ethanol and their UV-vis absorption spectra were recorded between 250–600 nm. From the absorption versus concentration graph at the  $\lambda_{\text{max}}$  point (using the Beer-Lambert law), the molecular absorption coefficient of BDMC was found to be  $\epsilon_{417 \text{ nm}} = 46\,193 \text{ (mol/L}^{-1}\text{) cm}^{-1}$  and for DABC the result was  $\epsilon_{395 \text{ nm}} = 19\,122 \text{ (mol/L}^{-1}\text{) cm}^{-1}$ .

### Fluorescence measurements

HSA solution (3 mL, 3  $\mu\text{mol/L}$ ) in a 0.05 mol/L, pH 6.4 phosphate buffer was prepared in a 1 cm rectangular cell. BDMC and DABC solutions (1 mmol/L), which were prepared in ethanol, were consecutively added in  $\mu\text{L}$  volumes using a trace Hamiltonian syringe to the cell placed in the

**Scheme 1.** (a) Chemical structure of curcumin (CUR). (b) Chemical structure of bisdemethoxycurcumin (BDMC). (c) Chemical structure of diacetylbisdemethoxycurcumin (DABC).

sample chamber of the Shimadzu RF-5000 (Kyoto, Japan) spectrofluorimeter. Both the excitation and emission slit widths were set at 5 nm. The excitation wavelength was adjusted to 280 nm and the emission spectra were recorded for all of the samples in the range of 290–450 nm at 25 °C with a scan speed of 200 nm/min. Integration of spectra was done in the range of 290–390 nm to obtain the peak area. During the fluorescence measurements, ethanol that was added with the ligand never exceeded 3% (v/v). The presence of ethanol at 25% induces no major changes in the structure of HSA.<sup>30</sup> However, a control experiment was done on HSA with ethanol and proved the negligible effect of ethanol on the fluorescence intensity of HSA up to 3% (v/v) of ethanol (data are not shown). The other control experiments have also been done and proved that inner filter effect corrections are not required for the fluorescence data.

### CD measurements

All the CD spectra were recorded using Aviv spectropolarimeter model 215 (Proterion Corp., USA) at 25 °C. The scan speed was 20 nm/min and each spectrum was the average of four accumulated spectra. The CD spectra, recorded in the far-UV region (190–260 nm) using a 1 mm path length cell, were used to investigate the changes in the secondary structure of HSA. The protein concentration in the experiments for the far-UV region was 4.0 µmol/L. The results were expressed in molar ellipticity,  $[\theta]$  (deg cm<sup>2</sup> dmol<sup>-1</sup>). The CD software was used to predict the secondary structure of the protein according to the statistical method.<sup>31,32</sup>

The CD spectra recorded between 260–550 nm (near-UV

to visible range) using a cuvette of 1 cm path length were also studied. The induced CD is defined as the CD of the mixture of protein and ligand minus the CD of the protein alone at the same wavelengths and is displayed as  $\theta$  (ellipticity) in units of millidegrees (mdeg). The concentration of HSA solution in induced CD experiments was 15.04 µmol/L. During the CD spectroscopic measurements, ethanol content (added with the ligand) never exceeded 1.5% (v/v). It has been controlled and we observed no considerable changes due to the addition of alcohol.

## Results and discussion

### Fluorescence studies

Fluorescence quenching is a procedure that decreases the fluorescence quantum yield of fluorophores by a variety of molecular interactions such as excited state reactions, energy transfer, molecular rearrangement, formation of a nonfluorescent ground state complex (static quenching), and collisional encounter between the fluorophore and quencher (dynamic quenching). The fluorescence quenching technique can reveal the nature of binding of small molecules with proteins. The fluorescence quenching data can be analyzed by the Stern–Volmer equation as follows:<sup>33</sup>

$$[1] \quad \frac{F_0}{F} = 1 + k_Q \tau_0 [Q] = 1 + K_{SV} [Q]$$

where  $F_0$  and  $F$  are the fluorescence intensities of fluorophore in the absence and presence of a quencher, respectively,  $[Q]$  is the quencher concentration, and  $K_{SV}$  is the Stern–Volmer quenching constant, which can be written as

**Fig. 1.** The fluorescence spectra of HSA (3  $\mu\text{mol/L}$ ) at different concentrations of BDMC: (a) 0  $\mu\text{mol/L}$ , (b) 0.7  $\mu\text{mol/L}$ , (c) 1.4  $\mu\text{mol/L}$ , (d) 2.2  $\mu\text{mol/L}$ , (e) 2.8  $\mu\text{mol/L}$ , (f) 3.5  $\mu\text{mol/L}$ , (g) 4.2  $\mu\text{mol/L}$ , (h) 4.9  $\mu\text{mol/L}$ , (i) 5.6  $\mu\text{mol/L}$ , (j) 6.3  $\mu\text{mol/L}$ , and (k) 7.0  $\mu\text{mol/L}$  measured in 0.050 mol/L phosphate buffer, pH 6.4,  $\lambda_{\text{ex}} = 280 \text{ nm}$ .

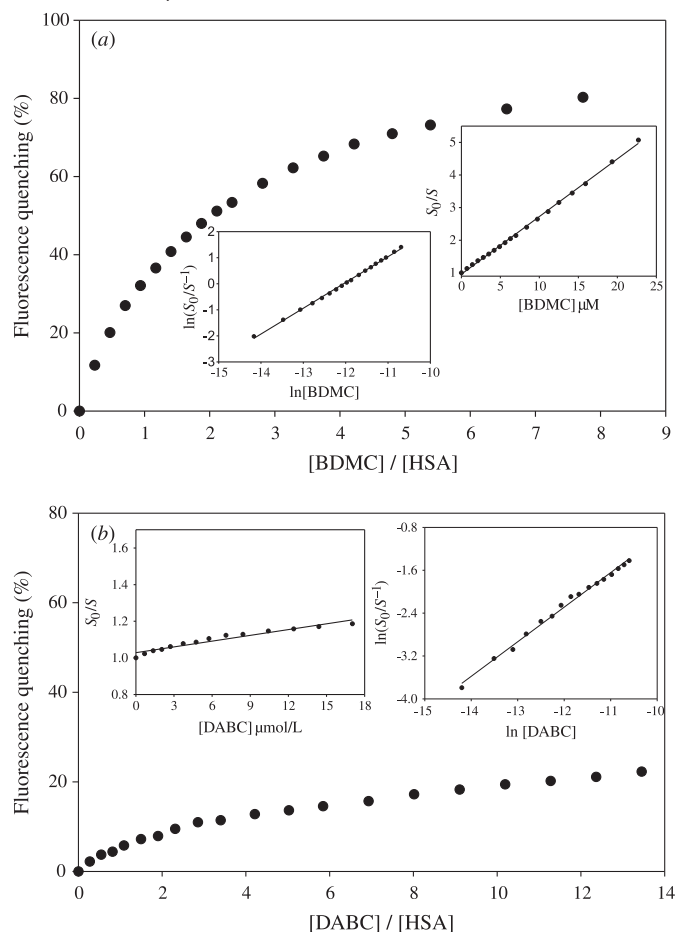

$K_{\text{SV}} = k_{\text{Q}}\tau_0$ , where  $k_{\text{Q}}$  is the bimolecule quenching rate constant and  $\tau_0$  is the average lifetime of the biomolecule without a quencher ( $\tau_0 = 10^{-8}\text{s}$ ).<sup>34</sup> The concentration of a quencher should be the free concentration, but in our experiments, the total concentration of the ligand (BDMC or DABC) was used. The total fluorescence intensity is usually expressed by the peak height, but it is more reasonable to use the total area of the fluorescence emission. So, in our results, we used the peak area of protein fluorescence spectra without or with ligand,  $S_0$  and  $S$ , respectively, instead of  $F_0$  and  $F$  in the Stern–Volmer equation.

It has been shown that both of the considered ligands in the current study (BDMC and DABC) have a quenching effect on the fluorescence emission of HSA. Only one tryptophan, Trp-214, located in subdomain IIA, is the predominant source of fluorescence emission in the UV region. However, minor contribution of tyrosine residue in fluorescence emission could be eliminated by adjusting the excitation wavelength at 295 nm. Figure 1 shows the quenching effect of BDMC on the fluorescence emission of HSA (data for DABC is not shown).

Figure 2 shows the percentage of quenching versus molar ratios of the ligand to protein (L/P) and the corresponding Stern–Volmer plots. As can be seen, the extent of quenching of HSA by BDMC is considerably greater than that by DABC. The estimated  $K_{\text{SV}}$  values are listed in Table 1. It is clear that quenching rate constants initiated by BDMC and DABC are greater than the maximum scatter quenching constant of various quenchers with the biopolymers ( $k_{\text{Q}} = 2 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$ ).<sup>35</sup> So, the fluorescence quenching was not related to dynamic collision but it results from the formation of a nonfluorescent compound.

Based on the assumption that the fluorescence quenching of protein is a static process, and there are  $n$  substantive binding sites on protein to accommodate the ligand mole-

**Fig. 2.** Fluorescence quenching of HSA by (a) BDMC and (b) DABC in 0.050 mol/L phosphate buffer, pH 6.4,  $\lambda_{\text{ex}} = 280 \text{ nm}$  and  $[\text{HSA}] = 3 \mu\text{mol/L}$ .

**Table 1.** The Stern–Volmer constant,  $K_{\text{SV}}$ , bimolecule quenching rate constant,  $K_{\text{Q}}$ , number of substantive binding sites,  $n$ , and the binding constant,  $K_{\text{A}}$ , for the interaction of BDMC and DABC with HSA obtained from the fluorescence quenching measured in 0.050 mol/L phosphate buffer, pH 6.4 at  $\lambda_{\text{ex}} = 280 \text{ nm}$  and  $[\text{HSA}] = 3 \mu\text{mol/L}$ .

	BDMC	DABC
$K_{\text{SV}} ((\text{mol/L})^{-1})$	$1.77 \times 10^5$	$2.60 \times 10^4$
$K_{\text{Q}} ((\text{mol/L})^{-1} \text{ s}^{-1})$	$1.77 \times 10^{13}$	$2.60 \times 10^{12}$
$n$	0.99	0.63
$K_{\text{A}} ((\text{mol/L})^{-1})$	$1.49 \times 10^5$	$4.08 \times 10$

cules, the equilibrium between free and bound molecules can be given by the following equation:<sup>36</sup>

$$[2] \quad \ln \frac{F_0 - F}{F} = \ln K_{\text{A}} + n \ln [Q]$$

where  $F_0$ ,  $F$ , and  $[Q]$  are the same as the parameters in the Stern–Volmer equation.  $K_{\text{A}}$  is the apparent binding constant reflecting the reaction extent of protein and ligand. The value of  $n$  specifies the number of ligand molecules bound to a HSA macromolecule. The values of  $K_{\text{A}}$  and  $n$  derived from the intercept and slope of  $\ln \frac{F_0 - F}{F}$  versus  $\ln [Q]$  plot (Fig. 2) are listed in Table 1. From the values of  $n$ , it can be inferred

that there is one binding site on HSA for BDMC and DABC. The values of  $K_A$  reveal lower binding affinity of DABC than BDMC to HSA. The considerable different binding affinities of BDMC and DABC toward binding to HSA indicates the important role of the phenolic OH groups of BDMC, which are acylated in DABC, in the binding process.

We predict that the only fluorophore, Trp-214, is buried to some extent inside the protein in the hydrophobic environment. This prediction is based on the fact that the emission  $\lambda_{\max}$  of Trp-214 was 330 nm (Fig. 1), which is the emission region of hidden tryptophan molecules that are known to be usually around 320–325 nm,<sup>37</sup> while fluorescence emission of the exposed tryptophan molecules is around 340 nm due to solvent relaxation. The HSA conformation seems to bury Trp-214 in a hydrophobic environment. The alteration in fluorescence intensity of Trp-214 in the presence of a ligand may arise as a direct quenching effect or as a result of conformational changes induced after ligand binding. In the case of the DABC ligand, the emission  $\lambda_{\max}$  at 330 nm is not changed. No spectral shift was observed for the emission spectra upon DABC–HSA interaction, indicating that Trp-214 was not exposed to any alteration in polarity. For BDMC–HSA, the emission  $\lambda_{\max}$  slightly shifted to shorter wavelengths (Fig. 1). If the tryptophan residue becomes hydrogen bonded or exposed to water, the maximum emission shifts to longer wavelengths.<sup>32</sup> Hence, if tryptophan moves to a more hydrophilic environment upon binding to the drugs, it is expected to observe a redshift in the emission maximum. Due to the slightly blueshifted emission spectra of HSA in the presence of BDMC, it can be concluded that the binding of BDMC to HSA has changed the Trp-214 to a more hydrophobic environment.

Since there is no report on the interaction of BDMC and DABC with HSA, we compared our findings in the present work with the results of CUR or its derivatives binding to HSA. A recently published study by Mandeville et al.<sup>38</sup> revealed the moderate binding affinity of CUR to HSA with the association binding constant,  $K = 5.5 \times 10^4$  (mol/L)<sup>-1</sup>, which is comparable to the values reported by Pulla Reddy et al.,<sup>21</sup>  $K = 2.0 \times 10^5$  (mol/L)<sup>-1</sup>, Kunwar et al.,<sup>25</sup>  $K = 6.1 \times 10^4$  (mol/L)<sup>-1</sup>, and also Zsila et al.,<sup>22</sup>  $K = 0.93 \times 10^5$  (mol/L)<sup>-1</sup>. The results of these studies indicated that the most probable binding site for CUR on HSA is in the vicinity of Trp-214 in a hydrophobic cavity of subdomain IIA.

The order of the current calculated binding constant between BDMC and HSA,  $K = 1.49 \times 10^5$  (mol/L)<sup>-1</sup>, is comparable to that of CUR. Also, the number of substantive binding sites for BDMC,  $n = 0.99$ , is comparable to that of CUR ( $n = 1.33$ ) reported by Mandeville et al.<sup>38</sup> using the same double logarithmic plot of  $\ln \frac{F_0 - F}{F}$  versus  $\ln[Q]$ . Therefore, we deduced that the binding mode, binding affinity, and binding site of BDMC on HSA are very similar to those of CUR. This conclusion implies that the methoxy groups of CUR have a negligible role in the interaction with HSA, and the phenolic hydroxyl groups play an important role in the drug–protein interactions. This implication can be confirmed by comparing the results of a CUR derivative such as DABC, which lacks the methoxy groups and its phenolic OH groups are acetylated. Both the apparent binding constant value,  $K = 4.08 \times 10^5$  (mol/L)<sup>-1</sup>, and number of the

bound DABC to HSA,  $n = 0.63$ , reflect the weak drug–protein interaction.

In a similar way, we analyzed the binding interaction of CUR and DAC with HSA and BSA.<sup>39</sup> We showed that there was a great difference between CUR and DAC in their binding affinity toward both serum albumins. The association binding constants for DAC were of the order of  $10^2$ , whereas for CUR, they were in the range of  $10^5$ – $10^6$  (in accordance with the previous studies). So, the main conclusion on the essential role of the phenolic hydroxyl groups of CUR in the binding process can be confirmed on the basis of the great difference between binding parameters of CUR and DAC, and also BDMC and DABC. It is of considerable interest to notice that the difference between our approaches and that of others is that they have carried out the experiments at neutral and alkaline pH, in which CUR has low stability and decomposes relatively fast.<sup>40</sup> Though there is no evidence on the stability of CUR derivatives compounds such as BDMC, DAC, and DABC at different pHs, we have done all the experiments at pH 6.4 to remove the interference of probable decomposition products of CUR or its derivatives and also to gain logical comparison for the considered ligands. The interaction of DAC with BSA has been studied by Sahoo et al.<sup>28</sup> They obtained a binding constant in the range of  $10^5$  (mol/L)<sup>-1</sup>, which is in contrast with our results. This discrepancy may have arisen from the experimental procedures, for instance, they analyzed the UV absorption spectra to calculate the binding constant, whereas we analyzed the fluorescence spectra.

### Energy transfer from HSA to BDMC

The fluorescence quenching of HSA, after its binding with BDMC, indicated the occurrence of energy transfer between ligand and protein. It is important to recognize that the valuable parameters concerning the molecular details of the donor–acceptor pair can be obtained by using fluorescence resonance energy transfer (FRET).<sup>33</sup> FRET occurs whenever the emission spectrum of the fluorophore (donor) overlaps with the absorption spectrum of another molecule (acceptor). The extent of overlap between the emission spectrum of the donor (protein) and the absorption spectrum of the acceptor (ligand), and the relative orientation of the donor and acceptor transition dipoles determine the rate of energy transfer. Due to the important effect of the distance between the donor and acceptor on the extent of energy transfer, numerous applications of energy transfer in biochemical research have been found. According to Förster's theory, the efficiency of energy transfer,  $E$ , is described by the following equation:<sup>41</sup>

$$[3] \quad E = 1 - \frac{F}{F_0} = \frac{R_0^6}{R_0^6 + r^6}$$

where  $F$  and  $F_0$  are the fluorescence intensity of the donor in the absence and presence of an equal amount of acceptor,  $r$  is the distance from the bound ligand on protein to the tryptophan residue, and  $R_0$  is the Förster critical distance at which 50% of the excitation energy is transferred to the acceptor and can be calculated by the following equation:

$$[4] \quad R_0^6 = 8.8 \times 10^{-2} K^2 N^{-4} \Phi J$$

**Fig. 3.** Fluorescence emission and UV–vis absorption of solutions containing BDMC as ligand and HSA as protein measured in 0.050 mol/L phosphate buffer, pH 6.4,  $\lambda_{\text{ex}} = 280$  nm, and  $[\text{HSA}] = [\text{BDMC}] = 6 \mu\text{mol/L}$ .

where  $K^2$  is a factor describing the relative orientation of the transition dipoles of the donor and acceptor (for a random orientation as in fluids,  $K^2 = 2/3$ ),  $N$  is the average refractive index of the medium in the wavelength range where spectral overlap is significant,  $\Phi$  is the fluorescence quantum yield of the donor, and overlap integral,  $J$ , expresses the extent of overlap between the normalized fluorescence emission spectrum of the donor and the acceptor absorption spectrum.  $J$  is given by the following equation:

$$[5] \quad J = \frac{\sum F(\lambda)\varepsilon(\lambda)\lambda^4\Delta\lambda}{\sum F(\lambda)\Delta\lambda}$$

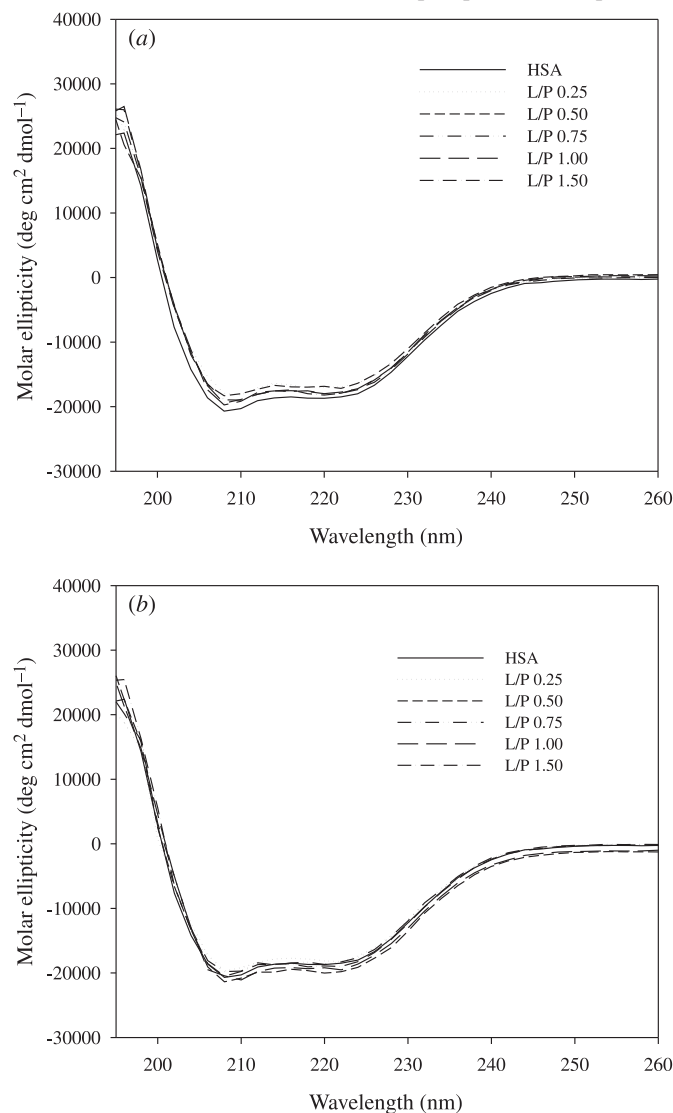

In this equation,  $F(\lambda)$  is the fluorescence intensity of the fluorescent donor at wavelength  $\lambda$  and is dimensionless,  $\varepsilon(\lambda)$  is the molar absorption coefficient of the acceptor at wavelength  $\lambda$ .

In our recent study, we prepared the solutions containing equimolar concentrations of ligand (BDMC or DABC) and HSA and recorded their UV–vis absorption spectra. As the fluorescence emission of protein is affected by the excitation light at 280 nm, the spectrum ranged from 300 to 500 nm and was chosen to obtain the overlapping integral. As shown in Fig. 3, the overlapping between the fluorescence emission of free HSA and absorption spectrum of BDMC is considerable. The UV–vis spectrum of the solution containing DABC and HSA did not show any absorption in the wavelength range of 300–500 nm (data are not shown), so, the energy transfer could not be calculated. The efficiency of energy transfer and overlapping integration can be easily calculated using eqs. [3] and [5]. For calculating the Förster critical distance in eq. [4],  $K^2$  is  $2/3$ ,  $N$  is 1.336, and  $\Phi$  is 0.118.<sup>42</sup> By using the obtained value for  $R_0$  from eq. [4] and  $E$  from eq. [3], the  $r$  value can be calculated. HSA has a single tryptophan residue (Trp-214) and the determined  $r$  is the distance from the bound ligand to this residue. The determined parameters for the interaction of human serum albumin with BDMC using FRET are reported in Table 2. It can be seen from this table that the distance from the bound ligand to tryptophan are less than 7 nm, indicating a nonradiative energy transfer mechanism for quenching.<sup>33</sup> However, the value of  $r$  is higher than the respective critical

**Table 2.** Förster critical distance,  $R_0$ , the binding distance to the tryptophan residue of protein,  $r$ , the overlap integral,  $J$ , and the energy transfer efficiency,  $E$ , upon the interaction of BDMC with HAS using fluorescence resonance energy transfer (FRET) measured in 0.050 mol/L phosphate buffer, pH 6.4,  $\lambda_{\text{ex}} = 280$  nm, and  $[\text{HSA}] = [\text{BDMC}] = 6 \mu\text{mol/L}$ .

$R_0$ (nm)	$r$ (nm)	$J$ ( $\text{cm}^3 \text{mol/L}$ )	$E$

**Fig. 4.** Far-UV circular dichroism spectra of 4.0  $\mu\text{mol/L}$  HSA in the absence and presence of different concentrations of (a) BDMC and (b) DABC measured in 0.050 mol/L phosphate buffer, pH 6.4.

distance ( $R_0$ ), so, the static quenching is more likely responsible for fluorescence quenching than the other mechanism of nonradiative energy transfer.

The  $R_0 = 2.167$  nm and  $r = 2.816$  nm for the binding of BDMC to HSA and are comparable to the  $R_0 = 2.744$  nm and  $r = 3.095$  nm for the case of CUR–HSA reported by Barik et al.,<sup>26</sup> which are in good agreement with our results for CUR–HSA ( $R_0 = 2.80$  nm and  $r = 3.10$  nm) and CUR–BSA ( $R_0 = 2.94$  nm and  $r = 3.16$  nm).<sup>39</sup> The calculated För-

**Table 3.** Content of the secondary structure of HSA upon interaction with (a) BDMC and (b) DABC in different molar ratios of ligand to protein measured in 0.050 mol/L phosphate buffer, pH 6.4 and [HSA] = 4.0  $\mu$ mol/L.

Ligand to protein molar ratios	(a) BDMC				(b) DABC			
	$\alpha$ -Helix (%)	$\beta$ -Sheet (%)	$\beta$ -Turn (%)	Random coil (%)	$\alpha$ -Helix (%)	$\beta$ -Sheet (%)	$\beta$ -Turn (%)	Random coil (%)
0	62.9	7.5	13.3	16.3	62.9	7.5	13.3	16.3
0.25	56.7	9.2	14.0	20.1	59.4	8.5	13.8	18.3
0.50	58.1	8.8	13.9	19.2	64.8	6.9	12.7	15.6
0.75	59.9	8.2	13.6	18.3	62.1	7.7	13.3	16.9
1.00	60.7	8.0	13.4	17.9	65.0	6.8	12.6	15.6
1.50	60.2	8.2	13.5	18.1	63.8	7.1	13.0	16.1

ster critical distance ( $R_0$ ) and distance between the donor and acceptor ( $r$ ) in the BDMC–HSA interaction are in the range of 2–3 nm, which are really close distances. This indicates that the energy transfer from Trp-214 to BDMC occurs with high possibility.

### Circular dichroism studies

Circular dichroism (CD) spectroscopy is a chiroptical method to study the binding of biologically active natural and synthetic compounds to biomacromolecules, including proteins, nucleic acids, and polysaccharides. Various aspects of protein structure and their ligand-binding characteristics can be explored by CD technique. The secondary structure of proteins can be investigated in the far-UV region (190–250 nm). The main absorbing groups in this region are peptide bonds. In the near-UV region, the aromatic amino acid side chains are placed in a chiral environment by the tertiary folding of the polypeptide chain and thus, rise to CD spectra, which can serve as characteristic finger prints of the native structure.<sup>43,44</sup> The induced optical activity of the achiral ligand molecules during the reversible binding interaction can be monitored by CD spectroscopy in the visible range of light absorption. The conformational adaptation of ligand to its asymmetric binding site(s), and also the interaction between ligand molecules held in chiral arrangement relative to each other by the protein sites, results in one or more induced CD bands with a different shape, sign, and intensity, which are called Cotton effects.<sup>45</sup>

The far-UV circular dichroism spectra of HSA in six L/P molar ratios (0, 0.25, 0.50, 0.75, 1.00, and 1.50) of two studied ligands in this research are shown in Figs. 4a and 4b and the secondary structure contents are listed in Table 3. The far-UV CD spectra of HSA exhibited characteristic features of the typical  $\alpha$ -helical structure of the protein and its complex to BDMC and DABC with negative bands at 208 nm and 220 nm (Figs. 4a and 4b). According to Fig. 4a and Table 3, the  $\alpha$ -helix content of HSA in the presence of different concentrations of BDMC is less than that of free HSA. The most decreasing in the  $\alpha$ -helix content is in the case of 0.25 L/P and with increasing the L/P ratios the  $\alpha$ -helix content gradually increases. The minor decrease in the  $\alpha$ -helix structure is accompanied by an increase in the  $\beta$ -sheet and random coil contents, whereas the turn content is not changed. Reduction of the  $\alpha$ -helix content and increase of the random coil structure represents the protein unfolding. The changes in the secondary structure contents of HSA in the presence of different concentrations of DABC

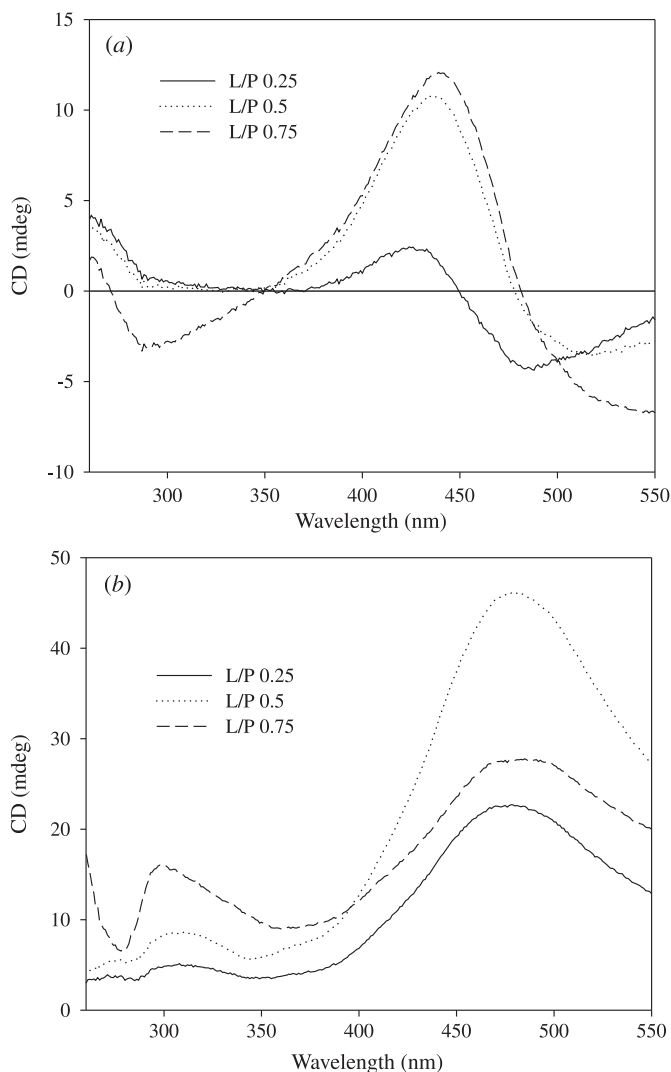

are not regular. The  $\alpha$ -helix content in 0.25 L/P is decreased, in the case of 0.75 L/P is not changed and in other L/P values is increased again. However, these unusual changes in the secondary structure of HSA during the binding to BDMC and DABC are not considerable. The minor changes in the secondary structure contents of HSA indicated that ligand-induced conformational changes are localized in the binding site and do not involve great alterations in protein folding.

The far-UV CD results that showed the minor alteration in the secondary structure content of HSA are consistent with the recent study on the CUR–HSA interaction by Mandeville et al.<sup>38</sup> The results of the binding of the two CUR derivatives, DAC and isoxazolcurcumin, to BSA also represented minor changes in BSA conformation during the binding process.<sup>28</sup>

The near-UV and visible range CD spectra (260–550 nm) in addition to the far-UV region, was investigated in the presence of the two studied ligands. The induced CD spectra are presented in Fig. 5. The results of control experiments show that both BDMC and DABC are achiral molecules and do not exhibit any CD spectra (data are not shown). The optical activities shown in Fig. 5 indicate the well-known phenomenon of protein-induced chirality, which arises from conformational adaptation to the asymmetric protein binding sites. This phenomenon can also be caused by the interaction between ligand molecules held in chiral arrangement relative to each other by the protein sites. Consequently, being bound to the protein, BDMC and DABC behave as chiral molecules and exhibit optical activities. From Fig. 5a, we can see that in the near-UV range (260–350 nm), there is a very weak positive band for 0.25 and 0.5 molar ratios. This positive band disappears and a new negative band appears at 0.75 L/P. In the visible range close to 350 nm, there are two opposite signed Cotton effects. The positive Cotton band is centered around 430 nm and its intensity increases with increasing L/P molar ratio. The negative Cotton band does not show a definite trend with increasing of L/P molar ratios.

From Fig. 5b, it can be seen that unlike BDMC, induced CD spectra of DABC have an intense positive Cotton effect centered at 480 nm. The intensity of this band has no regular increasing trend with increasing DABC concentration. Another positive Cotton band with much lower intensity in the near-UV region at 300 nm can be detected with considerable intensities in 0.5 and 0.75 L/P. The difference between the induced CD spectra of BDMC and DABC

**Fig. 5.** Induced CD spectra of HSA complex with (a) BDMC and (b) DABC measured in 0.050 mol/L phosphate buffer, pH 6.4 and [HSA] = 15.04  $\mu$ mol/L.

indicated the different configuration of these ligands in the binding site of HSA.

# Silica-bonded *S*-sulfonic acid as a recyclable catalyst for the silylation of hydroxyl groups with hexamethyldisilazane (HMDS)

Khodabakhsh Niknam, Dariush Saberi, Hajar Molaei, and Mohammad Ali Zolfigol

**Abstract:** Silica-bonded *S*-sulfonic acid (SBSSA) was prepared by the reaction of 3-mercaptopropylsilica (MPS) and chlorosulfonic acid in *tert*-butylmethyl ether, and used as a catalyst for the silylation of hydroxyl groups. A good range of primary, secondary alcohols and phenolic hydroxyl groups were effectively converted into their corresponding trimethylsilyl ethers with hexamethyldisilazane (HMDS) in the presence of catalytic amounts of SBSSA under mild conditions at room temperature with short reaction times and in good-to-excellent yields. An excellent chemoselective silylation of hydroxyl groups in the presence of other functional groups was also observed. The heterogeneous catalyst was recycled for 30 runs upon the reaction of benzyl alcohol with HMDS without losing its catalytic activity.

**Key words:** silylation, silica-bonded *S*-sulfonic acid, hydroxyl groups, alcohols, catalyst.

**Résumé :** On a préparé de l'acide *S*-sulfonique lié à de la silice par (ASSLS) par réaction du 3-mercaptopropylsilicium (MPS) et de l'acide chlorosulfonique dans le éther de *tert*-butylméthyle et on l'a utilisé comme catalyseur pour la silylation de groupes hydroxyles. On a ainsi pu transformer un ensemble représentatif de groupes hydroxyles d'alcools primaires et secondaires et phénoliques en éthers triméthylsilyles correspondants par réaction avec de l'hexaméthylidisilazane (HMDS) en présence de quantités catalytiques d'acide *S*-sulfonique lié à de la silice, dans des conditions douces, à la température ambiante, avec des courts temps de réaction et avec des rendements allant de bons à excellents. On a pu aussi observer une excellent silylation chimiosélective de groupes hydroxyles en présence d'autres groupes fonctionnels. Le catalyseur hétérogène a pu être recyclé au moins trente fois, sans perte d'activité, pour la réaction de l'alcool benzylique avec le HMDS.

**Mots-clés :** silylation, acide *S*-sulfonique lié à de la silice, groupes hydroxyles, catalyseur.

## Introduction

In recent years, there has been much attention on the search for environmentally benign chemical processes or methodologies, because they are essential for the conservation of the global ecosystem. The development of heterogeneous catalysts for fine chemical synthesis has become a major area of research, as the potential advantages of these materials (facile recovery and reusability; the potential for incorporation in continuous reactors and micro reactors) over homogeneous systems can lead to novel environmentally benign chemical procedures for academia and industry.<sup>1</sup> Application of solid acids in organic transformations is desirable, owing to their simplicity in handling, decreased reactor and plant corrosion problems, and more environmentally safe disposal.<sup>2–10</sup> Green chemistry not only requires the use of environmentally benign reagents and solvents, but

also requires the use of recyclable catalysts. One way to overcome the problem of recyclability of the traditional acid catalysts is to chemically anchor their reactive center onto an inorganic solid carrier with a large surface area to create new organic–inorganic hybrid catalyst.<sup>5,6</sup> The reactive centers in these solid-supported catalysts are highly mobile similar to homogeneous catalysts, and at the same time have the advantage of recyclability like heterogeneous catalysts. In this view, several types of solid sulfonic-acid-functionalized silica (both amorphous and ordered) have been synthesized and applied as an alternative to traditional sulfonic acid resins and homogeneous acids in catalyzing chemical transformations.<sup>5,7</sup>

Herein, we wish to describe the preparation of silica-bonded *S*-sulfonic acid (SBSSA) as illustrated in Scheme 1, and its use as catalyst for the conversion of alcohols into corresponding trimethylsilyl ethers. Sulfur content of SBSSA by conventional elemental analysis was 16.12%. Typically, a loading at ~0.35 mmol/g is obtained. On the other hand, when the washed sulfonated product **2** was placed in an aqueous NaCl solution, the pH of the solution dropped virtually instantaneously to pH 1.85, as ion exchange occurred between protons and sodium ions (proton exchange capacity: 0.33 mmol/g of sulfonic acid **2**), which is in good agreement with the result obtained from TGA and titration.

Protection and deprotection of functional groups are in-

**Scheme 1.** Preparation of silica-bonded S-sulfonic acid.

evitable processes for the synthesis of polyfunctional compounds. Silylation of alcohols and polyols is one of the most commonly used methods for their protection.<sup>11</sup> Trimethylsilylation is a classic way to produce volatile derivatives of alcohols and polyols, as required for their vapor-phase chromatography/mass spectrometric analysis.<sup>12</sup> Another application is the conversion of trimethylsilyl ethers into the corresponding ethers.<sup>13</sup> Generally, the formation of trimethylsilyl ethers has been carried out by treatment of alcohols with trimethylsilyl chloride or trimethylsilyl triflate in the presence of a base,<sup>14</sup>  $\text{Li}_2\text{S}$ ,<sup>15</sup> and sometimes a nonionic super base catalyst.<sup>16</sup> However, some of these methods have frequently suffered from drawbacks, such as lack of reactivity or the difficulty in removal of amine salts derived from the reaction of by-produced acid and co-bases during the silylation reaction. 1,1,1,3,3,3-Hexamethyldisilazane (HMDS) is a stable, commercially available, and inexpensive reagent for trimethylsilylation of hydrogen-labile substrates,<sup>17</sup> giving ammonia as the only byproduct. On the other hand, silylation, using this silazan-type reagent, is nearly neutral and does not need any special precautions. However, the weak silylating ability of HMDS is a main drawback for its application, which needs forceful conditions and long reaction times in many instances. A variety of catalysts, such as  $(\text{CH}_3)_3\text{SiCl}$ ,<sup>18</sup> silica chloride,<sup>19</sup>  $\text{ZnCl}_2$ ,<sup>20</sup>  $\text{LiClO}_4$ ,<sup>21</sup> H- $\beta$  zeolite,<sup>22</sup> tungstophosphoric acid,<sup>23</sup> poly(*N*-bromobenzene-1,3-disulfonamide),<sup>24</sup> ultrasound,<sup>25</sup>  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and  $\text{Cu}(\text{OTf})_2$ ,<sup>26</sup>  $\text{Al}(\text{HSO}_4)_3$ ,<sup>27</sup>  $\text{KBr}$ ,<sup>28</sup> silica-supported perchloric acid,<sup>29</sup> sulfonic-acid-functionalized silica,<sup>30</sup> silica sulfuric acid,<sup>31</sup> 1,3-dibromo-5,5-diethylbarbituric acid,<sup>32</sup> tribromoiso-cyanuric acid and DABCO- $\text{Br}_2$ ,<sup>33</sup>  $\text{Fe}(\text{F}_3\text{CCO}_2)_3$ ,<sup>34</sup> tetrabutylammonium bromide,<sup>35</sup> tribromomelamine,<sup>36</sup> and alumina sulfuric acid<sup>37</sup> have been reported for the silylation of hydroxyl groups using HMDS. In addition to the previously reported procedures, the facile and general synthetic methodology for the silylation of alcohols under essentially neutral conditions is desirable, so this subject encouraged us to develop an efficient, convenient, and practical procedure for the protection of hydroxyl groups under mild and heterogeneous conditions.

## Results and discussion

The trimethylsilylation of hydroxyl groups is easily carried out at room temperature under mild conditions in the presence of SBSSA as a catalyst (Scheme 2). First, we studied the reaction of 4-bromobenzyl alcohol with HMDS

**Scheme 2.** Conversion of different kinds of hydroxyl groups into corresponding silyl ethers

in the presence of SBSSA in  $\text{CH}_3\text{CN}$  at room temperature. The optimal amount of the catalyst was 0.015 g per 1 mmol of 4-bromobenzyl alcohol and 0.8 mmol of HMDS. Next, we prepared a range of silyl ethers under the following reaction conditions: hydroxyl compound (1 mmol), HMDS (0.8 mmol), SBSSA (0.015 g), and acetonitrile (2 mL) (Table 1). A wide range of alcohols underwent silylation by this procedure to provide the corresponding TMS ethers in good-to-excellent yields. Generally, benzylic alcohols, phenols, and primary and secondary alcohols are faster than tertiary alcohols. Trimethylsilylation of hydroxyl groups produce corresponding trimethylsilylated compounds under these conditions, whereas substituted thiophenol, 1-butan-1-ol (Table 1, entries 8, 25, and 26), aniline derivatives, aliphatic amines (Table 1, entries 22–24), and *N*-phenyl acetamide (Table 1, entry 27) remained intact under the reaction conditions. It is worth mentioning that in the case of *p*-aminophenol, only the phenolic group reacted under these conditions and the amino group remains intact (Table 1, entry 19).

We investigated the selective silylation of different binary mixture of alcohols and also alcohols and phenols in the presence of amine, amide, and thiols. This method was shown to be highly selective for primary alcohols, such as benzyl alcohol and 2-phenylethanol. Primary alcohols were completely converted to the corresponding silyl ethers, while tertiary alcohols were converted to the corresponding silylated products with 0% yield (Scheme 3).

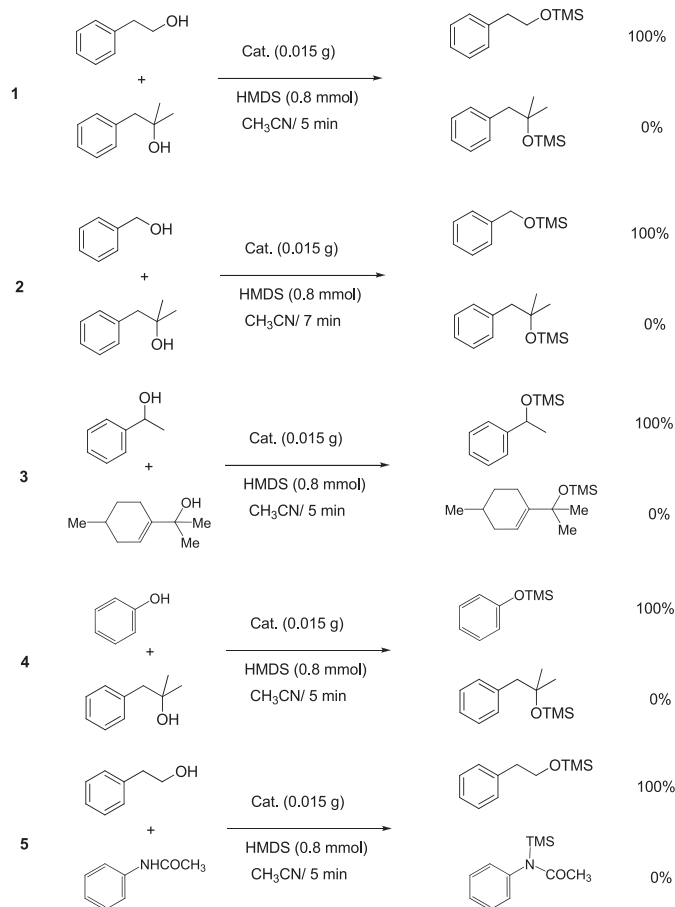

Excellent chemoselectivity was also observed for the conversion of secondary alcohols and phenols in the presence of tertiary alcohols such as  $\alpha$ -terpinene, 1-phenyl-2-methyl-2-propanol (Scheme 3). We also explored the chemoselectivity of SBSSA in the silylation method. Alcohols and phenols in the presence of an amine, amide, and thiols were completely converted to the corresponding trimethylsilyl ethers as sole product.

To show the efficiency of the SBSSA in comparison with previously reported procedures, Table 2 compares some of our results with  $\text{LiClO}_4/\text{SiO}_2$ ,<sup>21</sup> H- $\beta$  zeolite,<sup>22</sup>  $\text{HClO}_4/\text{SiO}_2$ ,<sup>29</sup> sulfonic-acid-functionalized silica,<sup>30</sup> silica sulfuric acid,<sup>31</sup> and alumina sulfuric acid<sup>37</sup> with respect to reaction times and yields of obtained products. It is clear from the results shown in Table 2, that silylation reactions carried out with SBSSA require shorter reaction times and lower catalyst loading.

In all reactions studied, fast evolution of ammonia gas was observed (HMDS is stronger base than  $\text{NH}_3$ ). With this observation, we have proposed a mechanism in which the generation of  $\text{NH}_3$  and catalytic role of SBSSA in a catalytic cycle is clarified (Scheme 4).<sup>29,34</sup>

The possibility of recycling the catalyst was examined. For this purpose, the reaction of benzyl alcohol and HMDS

**Scheme 3.** Chemoselectivity between primary, secondary alcohols, and phenols in the presence of tertiary alcohols and amides using SBSSA with HMDS.

**Scheme 4.** Proposed mechanism for the conversion of alcohols into the corresponding silyl ether by using SBSSA.

was studied in acetonitrile at room temperature in the presence of SBSSA. When the reaction was complete, the mixture was filtered and the solid was washed with dichloromethane, and the recycled catalyst was saved for the next reaction. The recycled catalyst could be directly reused 30 times without any treatment. No observation of appreciable loss in its catalytic activities was noticed (Fig. 1).

**Fig. 1.** Recyclability of solid silica-bonded *S*-sulfonic acid as catalyst in the silylation reaction of benzyl alcohol (1 mmol) and HMDS (1 mmol) at room temperature. Reaction time = 5 min.

## Conclusion

In conclusion, a practical, efficient, and convenient method for the silylation of hydroxyl compounds was described. One major advantage of our described method is using very low molecular ratio of the catalysts in comparison with the reported procedures in the literature. Therefore, we think that this method can be a useful addition to the present methodologies for the silylation of hydroxy groups.

## Experimental

### General

Chemicals were purchased from Merck, Fluka, and Aldrich Chemical Companies. IR spectra were run on a Shimadzu IR-435 FTIR spectrophotometer.  $^1\text{H}$  NMR was run on JEOL NMR spectrometer (FX 90Q) and Bruker Avance (DRX 500 MHz). Melting points were recorded on a Melting Point SMP1 apparatus in open capillary tubes and are uncorrected. The progress of reaction was followed with TLC, using silica gel SILG/UV 254 plates. All the products are known and were characterized by comparison of their spectral (IR,  $^1\text{H}$  NMR), TLC, and physical data with those reported in the literature.<sup>22–36</sup> 3-Mercaptopropylsilica **1** (MPS) was prepared according to the previously reported procedure.<sup>5a</sup>

### Catalyst preparation

To a magnetically stirred mixture of 3-mercaptopropylsilica **1** (5 g) in *tert*-butylmethyl ether (20 mL), chlorosulfonic acid (1.00 g, 9 mmol) was added dropwise at 0 °C for 2 h. After addition was complete, the mixture was stirred for 2 h until HCl gas evolution was stopped. Then, the mixture was filtered and washed with methanol (30 mL) and dried at room temperature to obtain silica-bonded functionalized sulfonic acid **2** (SBSSA) as cream powder (5.22 g). Sulfur content of the samples was 16.12% by conventional elemental analysis. TGA analysis of SBSSA shows a first mass loss due to the desorption of water below 100 °C (Fig. 2). This

**Fig. 2.** TGA diagram for a sample of silica-bonded *S*-sulfonic acid under nitrogen stream.

is followed by a second mass loss starting at 140 °C, corresponding to the loss of the covalently bound organic group. From this mass loss, it is calculated that the loading of the organic group bound to silica surface was 1.78 mmol g<sup>-1</sup>.

#### **pH analysis of the SBSSA**

To an aqueous suspension of 0.1 g SBSSA, NaOH (1.8 mL, 0.1 mol/L) was added. This is equal to a loading of 1.8 mmol SO<sub>3</sub>H g<sup>-1</sup>. So, all of the SH functional groups in 3-mercaptopropylsilica **1** were sulfonated. According to previous reports,<sup>5</sup> the loading of 3-mercaptopropylsilica **1** is 0.33 mmol/g.

#### **General procedure for the silylation of alcohols**

To a stirred solution of the compound containing hydroxyl groups (1 mmol) and HMDS (0.8 mmol) in CH<sub>3</sub>CN (2 mL) was added SBSSA (0.015 g) and stirred at room temperature. When the reaction was complete by GC (or TLC, *n*-hexane/EtOAc, 9:1) analysis, CH<sub>2</sub>Cl<sub>2</sub> was added (10 mL), and SBSSA was removed by filtration. The solvent was evaporated and the trimethylsilyl ether was isolated almost as a pure crude product. Further purification was carried out by short column chromatography on silica gel eluting with ethyl acetate/petroleum ether, if necessary.

<sup>a</sup> Isolated Yield.

<sup>b</sup> GC Yield.

#### Trimethyl(4-methylphenoxy) silan (Table 1, entry 15)

Purified on short column of silica gel using petroleum ether/ethyl acetate (10:1) as eluent. Colorless liquid;<sup>29</sup> bp 206 °C/760 torr. <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>, ppm) δ: 0.32 (s, 9H), 2.33 (s, 3H), 6.80 (d, 2H, *J* = 8.1 Hz), 7.08 (d, 2H, *J* = 8.0 Hz).

#### Trimethyl(2-naphthalenoxy) silan (Table 1, entry 16)

Purified on short column of silica gel using petroleum ether/ethyl acetate (10:1) as eluent. Colorless liquid;<sup>29</sup> bp 282 °C/760 torr. <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>, ppm) δ: 0.41 (s, 9H), 7.18 (dd, 1H, *J*<sub>1</sub> = 8.8 Hz, *J*<sub>2</sub> = 2.3 Hz), 7.31 (d, 1H, *J* = 2.1 Hz), 7.41 (t, 1H, *J* = 7.3 Hz), 7.50 (dt, 1H, *J*<sub>1</sub> = 7.6 Hz, *J*<sub>2</sub> = 0.8 Hz), 7.77–7.85 (m, 3H).

#### Trimethyl(2,4,6-trimethylphenoxy) silan (Table 1, entry 17)

Purified on short column of silica gel using petroleum ether/ethyl acetate (10:1) as eluent. Colorless liquid;<sup>40</sup> bp 241 °C/760 torr. <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>, ppm) δ: 0.25 (s, 9H), 2.17 (s, 6H), 2.23 (s, 3H), 6.78 (s, 2H). <sup>13</sup>C NMR (125 MHz, CDCl<sub>3</sub>, ppm) δ: 1.37, 18.02, 20.94, 128.51, 129.47, 130.70, 150.63.

#### Trimethyl(4-chloro-3-methylphenoxy) silan (Table 1, entry 18)

Purified on short column of silica gel using petroleum ether/ethyl acetate (10:1) as eluent. Colorless liquid;<sup>39</sup> bp 243 °C/760 torr. <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>, ppm) δ: 0.26 (s, 9H), 2.32 (s, 3H), 6.62 (dd, 1H, *J*<sub>1</sub> = 8.6 Hz, *J*<sub>2</sub> = 2.8 Hz), 6.72 (d, 1H, *J* = 2.8 Hz), 7.17 (d, 1H, *J* = 7.9 Hz).

<sup>13</sup>C NMR (125 MHz, CDCl<sub>3</sub>, ppm) δ: 0.58, 20.60, 119.13, 122.96, 127.10, 130.03, 137.42, 154.14.

#### Trimethyl(4-aminophenoxy) silan (Table 1, entry 19)

Purified on short column of silica gel using petroleum ether/ethyl acetate (10:1) as eluent. Colorless liquid;<sup>29</sup> bp 255 °C/760 torr. <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>, ppm) δ: 0.22 (s, 9H), 3.34 (s, 2H), 6.51 (d, 2H, *J* = 8.5 Hz), 6.61 (d, 2H, *J* = 8.5 Hz).

#### Trimethyl(4-fluorophenoxy) silan (Table 1, entry 20)

Purified on short column of silica gel using petroleum ether/ethyl acetate (10:1) as eluent. Colorless liquid;<sup>29</sup> bp 208 °C/760 torr. <sup>1</sup>H NMR (500 MHz, CDCl<sub>3</sub>, ppm) δ: 0.25 (s, 9H), 6.75–6.77 (m, 2H), 6.89–6.92 (m, 2H). <sup>13</sup>C NMR (125 MHz, CDCl<sub>3</sub>, ppm) δ: 0.53, 116.10, 121.26, 151.52, 159.08.

# Engineering of nanometer-sized cross-linked hydrogels for biomedical applications

Jung Kwon Oh

**Abstract:** Microgels/nanogels (micro/nanogels) are promising drug-delivery systems (DDS) because of their unique properties, including tunable chemical and physical structures, good mechanical properties, high water content, and biocompatibility. They also feature sizes tunable to tens of nanometers, large surface areas, and interior networks. These properties demonstrate the great potential of micro/nanogels for drug delivery, tissue engineering, and bionanotechnology. This mini-review describes the current approaches for the preparation and engineering of effective micro/nanogels for drug-delivery applications. It emphasizes issues of degradability and bioconjugation, as well as loading/encapsulation and release of therapeutics from customer-designed micro/nanogels.

**Key words:** microgels, nanogels, hydrogels, drug delivery, degradation, bioconjugation.

**Résumé :** Les microgels/nanogels (micro/nanogels) correspondent à des systèmes prometteurs d'administration des médicaments (SAM) en raison de leurs propriétés particulières, dont des structures physiques et chimiques accordables, de bonnes propriétés mécaniques, un niveau élevé d'eau et leur biocompatibilité. Ils comportent aussi des tailles ajustables jusqu'à des dizaines de nanomètres, des grandes surfaces de surface et des réseaux intérieurs. Ces propriétés démontrent le grand potentiel de micro/nanogels comme systèmes d'administration des médicaments, l'ingénierie des tissus et la bionanotechnologie. Cette minirevue décrit les approches actuelles à la préparation et à l'ingénierie de micro/nanogels adaptés pour les applications d'administration des médicaments. Elle fait ressortir les sujets de dégradabilité et de bioconjugaison ainsi que de chargement/encapsulation et de libération des produits thérapeutiques pour des microgels/nanogels répondant à des spécificités imposées par un client.

**Mots-clés :** microgels, nanogels, hydrogels, administration des médicaments, dégradation, bioconjugaison.

[Traduit par la Rédaction]

## Introduction

Hydrogels can form a cross-linked polymer network that has tunable chemical and physical structures, good mechanical properties, high water content, and biocompatibility. These unique properties suggest the enormous potential of their use in regenerative medicine, tissue engineering, biomedical implants, and drug delivery.<sup>1–7</sup> Recently, the design and preparation of unique hydrogels has also been explored

for the development of biosensors,<sup>8</sup> intracellular thermometry,<sup>9</sup> drug conjugates,<sup>10</sup> microfluidic biomaterials,<sup>11–13</sup> and photonic crystals.<sup>14</sup>

Microgels are a class of hydrogels that are submicron-sized cross-linked particulates.<sup>15</sup> The term “nanogel” is defined as a nanometer-sized microgel. While microgels share the unique properties of hydrogels, micro/nanogels have additional unique features: they are of a size tunable to tens of nanometers; have a large surface area; and possess an inte-

**Fig. 1.** Chemical structures of disulfide-functionalized cross-linkers used for preparation of degradable microgels/nanogels.**Fig. 2.** Chemical structures of acetal-functionalized cross-linkers used for preparation of degradable microgels/nanogels.

rior network.<sup>16</sup> Micro/nanogels have great potential for various biorelated applications, including drug delivery, tissue engineering, and bionanotechnology, because of these properties.<sup>17–20</sup> Micro/nanogels are compositionally classified into two categories: synthetic and biopolymer-based.<sup>21</sup> Synthetic nanogels are based on hydrocarbon-based water-soluble or water-swelling (hydrophilic) polymers. In contrast, biopolymer-based micro/nanogels (biomicro/nanogels) are based on naturally occurring biopolymers including polysaccharides, such as chitosan (CS), hyaluronan (HA), dextran (Dex), cellulose (CeL), pullulan (PuL), chondroitin sulfate (ChS), and alginate (Alg), as well as proteins, gelatins, and poly(amino acids).<sup>22,23</sup> Such biopolymers are intrinsically biodegradable, abundant in nature, renewable, and nontoxic. They also possess a large amount of functional groups that can be utilized for further bioconjugation.<sup>24–26</sup>

Many strategies for the preparation of effective micro/nanogels have been developed. They have been designed and engineered to achieve a high degree of control over several criteria for in vitro and in vivo biomedical applications. Controllable features include dimension (diameter < 200 nm), degradability, bioconjugation to target disease cells, high-loading efficiency, and controllable release of encapsulated biomolecules (therapeutics), stability for prolonged circulation in blood, and non-toxicity to cells. This mini-review will describe the current approaches for the preparation and engineering of micro/nanogels for drug-delivery applications, with an emphasis on recent advances in

degradability, bioconjugation, loading/encapsulation, and release.

## Preparation of micro/nanogels

Current approaches for the preparation of cross-linked micro/nanogels can be largely classified into physical cross-linking, chemical cross-linking, and heterogeneous controlled/living radical cross-linking polymerization (CRCP).

### Physical cross-linking approach

Physical cross-linking approach is achieved through electrostatic interactions, hydrogen bonds, crystallized domains, hydrophobic interactions, stereocomplexation, temperature-induced sol–gel transitions, host–guest interactions, aggregations, and self-assembly/self-associations. Physical cross-linking has two primary advantages: reversibility and no requirement that other chemicals be used to link chains. Several methods of physical cross-linking have been developed for the successful preparation of micro/nanogels. One general method involves aqueous homogeneous gelation. In most experiments, electrostatic interactions of polysaccharide-based polymers with various polyelectrolytes in water have been explored. These polyelectrolytes include polyethyleneimine (PEI),<sup>27</sup> sodium tripolyphosphate (TPP),<sup>28–30</sup> poly(ethylene oxide) (PEO)-*b*-poly(*N,N*-dimethylaminoethyl methacrylate) block copolymer,<sup>31</sup> and biopolymer-based polyelectrolyte<sup>32</sup> to yield CS-based nanogels. In addition, various other polysaccharide-based microgels have been

prepared. They include cyclodextran (CyDex)-based nanogels and core-cross-linked Alg-based microcapsules for cell encapsulation in water,<sup>33,34</sup> mannose-bearing CS micro-spheres containing PEI/DNA complexes in emulsion,<sup>27</sup> and Dex-based microgels in double emulsion.<sup>35</sup>

A microfluidic method has also been employed for the preparation of physically cross-linked microgels. Microfluidic devices are designed with inlets for monomers, continuous liquids and optional cross-linkers, microchannels, and a tapered junction. Ionic cross-linking by external cross-linking appears to be a promising method for the microfluidic preparation of Alg-based microgels. Carboxylic acid residues (COOH) of Alg have been cross-linked with  $\text{Ca}^{2+}$  ions in droplets, yielding shape- and size-controlled Alg-microgels,<sup>36–38</sup> cell-encapsulated microgels,<sup>39</sup> and microcapsules with controlled morphology.<sup>40,41</sup>

Polysaccharide derivatives have also been modified with hydrophobic molecules or oligomers, yielding amphiphilic biopolymers that can self-assemble in water to form micellar

nanoparticles. Such nanoparticles include hydroxyethylcellulose (HECeL),<sup>42</sup> cellulose acetate (CeL-Ac),<sup>43</sup> PuL,<sup>44–47</sup> PuL acetate (PuL-Ac),<sup>48</sup> glycol CS,<sup>49</sup> and Dex.<sup>50</sup> Further, self-association of two polymers in water yields supramolecular nanogels. Examples include inclusion of  $\beta$ -CyDex with lauryl-modified Dex in water,<sup>51,52</sup> hydrogen bonds between poly(vinyl pyrrolidone) (PVP) and poly(acrylic acid)-cysteine (PAA-Cys),<sup>53</sup> HPCeL with carboxylic-acid-containing surfactant,<sup>54</sup> and temperature (or heat)-induced self-association of hydroxypropyl cellulose (HPCeL) in water.<sup>55–57</sup> In addition, the reverse micellar method has produced Alg-based microgels that are physically cross-linked with  $\text{Ca}^{2+}$  ions for the controlled delivery of vascular endothelial growth factor (VEGF).<sup>58</sup>

#### Chemical cross-linking approach

The chemical cross-linking approach is the general method for the preparation of micro/nanogels. Specific techniques of this approach have included polycondensation re-

actions as well as radical polymerizations in water and heterogeneous media. Polycondensation reactions are mainly utilized for the preparation of biomicro/nanogels. This is because functional groups are plentiful in polysaccharides, gelatins, and proteins and can react with external cross-linkers such as glutaraldehyde, divinyl sulfone, and adipic dihydrazide. In addition, the residual functional groups can be further used for bioconjugation with cell-targeting biomolecules, allowing for the exploration of specific biological processes. Various water-in-oil (W/O) heterogeneous gelation methods, including inverse miniemulsion,<sup>59–68</sup> inverse microemulsion,<sup>69,70</sup> and membrane emulsification,<sup>71–73</sup> have been explored for the preparation of HA, CS, and Alg-based micro/nanogels. Other methods include aqueous homogeneous gelation<sup>74,75</sup> and continuous reactive extrusion.<sup>76</sup> Details of these methods have been described in a recent review.<sup>21</sup>

Heterogeneous free-radical polymerization (FRP) of hydrocarbon-based water-soluble monomers in the presence of multifunctional cross-linkers has been extensively explored for the preparation of synthetic micro/nanogels. Typical FRP methods include precipitation, inverse (mini)emulsion, and inverse microemulsion polymerization. Precipitation polymerization in water has been utilized for the preparation of hydrogels and microgels based on poly(*N*-isopropylacrylamide) (PNIPAM)<sup>77–82</sup> and, more recently, poly[oligo(ethylene glycol) monomethyl ether methacrylate] (POEOMA) including its copolymers with 2-(2-methoxyethoxy)ethyl methacrylate (MEO<sub>2</sub>MA),<sup>83,84</sup> for biomedical applications. The thermosensitive properties of these polymers, which undergo volume change at a lower critical solution temperature (LCST) in water, make them good candidates for use in vivo. Above the LCST, they are hydrophobic and expel water; below LCST, they are hydrophilic and swell in water. These unique properties facilitate the loading of drugs into microgels and enhance the controllable release of encapsulated drugs.<sup>85</sup> In addition, copolymerization of NIPAM with various functional monomers under precipitation-polymerization conditions has been shown to yield functional microgels.<sup>86</sup> Examples of comonomers include more hydrophilic or hydrophobic monomers for tuning the volume phase transition of the resultant microgels<sup>87,88</sup> and acid-containing monomers such as AA, methacrylic acid, and undecanoic acid for targeted drug delivery<sup>16,89–91</sup> as well as for use as a glucose sensor.<sup>92–94</sup> (4-Vinyl-4'-methyl-2,2'-bipyridine)-bis(2,2'-bipyridine)ruthenium(II) complex has also been incorporated into PNIPAM-based nanogels for self-flocculating/self-dispersing oscillation.<sup>95</sup>

Inverse emulsion, miniemulsion, and microemulsion polymerization have been explored for the preparation of cross-linked micro/nanogels. This interest is due to the facile confinement of water-soluble drugs in aqueous droplets dispersed in continuous organic solvents. Examples include micro/nanogels based on PNIPAM,<sup>96</sup> polyacrylamide (PAAm),<sup>97</sup> acrylated triblock copolymer of poly(ethylene glycol)-*b*-poly(propylene glycol)-*b*-poly(ethylene glycol) (PEO-*b*-PPO-*b*-PEO),<sup>98</sup> poly(magnesium acrylate),<sup>99</sup> and diacrylated Pluronic-oligo(lactic acid) copolymer<sup>100,101</sup> by inverse (mini)emulsion polymerization. In addition, well-defined nanogels based on PAAm,<sup>102</sup> PVP,<sup>103,104</sup> poly(hydroxyethyl acrylate-*co*-2-acryloxyethyltrimethylammonium chloride),<sup>105</sup> and  $\alpha,\beta$ -poly(*N*-2-hydroxyethyl)-D,L-as-

partamide<sup>106</sup> have been prepared by inverse microemulsion polymerization.

Particle replication in nonwetting templates (PRINT)<sup>107</sup> was developed to fabricate submicron-sized microgels with control over particle size, shape, and composition. This method uses photolithography to create photocurable perfluoropolyether (PFPE) replica molds, in which various multifunctional monomers are cross-linked by photo-radical polymerization. PRINT has yielded monodisperse microgels of poly(ethylene glycol diacrylate) (PEGDA), triacrylate resin, polylactide (PLA), and polypyrrole, with sizes ranging from 200 nm to micron-scale in diameter and achieving various shapes, such as trapezoidal, bar, conical, and arrow.

### Heterogeneous controlled/living radical cross-linking polymerization

The utilization of controlled/living radical polymerization (CRP) techniques<sup>108–113</sup> allows for the development of cross-linked microgels, nanogels, and hydrogels with well-controlled polymer segments and high swelling ratios.<sup>114–119</sup> Few papers have reported on the use of CRP methods to prepare well-defined micro/nanogels. Atom transfer radical polymerization (ATRP)<sup>120,121</sup> in water has yielded PNIPAM nanogels at 25 °C.<sup>122</sup> Reversible addition fragmentation transfer (RAFT) polymerization<sup>123,124</sup> has produced poly(vinyl acetate)-based nanogels,<sup>125</sup> acid-cleavable core-shell nanoparticles,<sup>126</sup> and thermally responsive<sup>127</sup> and double hydrophilic<sup>128</sup> block copolymer nanogels. Recently, an effective method utilizing ATRP, inverse miniemulsion polymerization, and disulfide–thiol exchange has been developed for the preparation, functionalization, and application of well-defined biodegradable nanogels for the goal of targeted drug delivery. The novel approach has allowed for the preparation of biomaterials with many useful features. They include uniform network, high loading efficiency, novel distributed functionality of bromine end groups, and degradation by hydrolysis or through a disulfide–thiol exchange.<sup>129–135</sup> The details are reported elsewhere.<sup>136</sup>

### Degradation

Degradation cannot only modulate the release of encapsulated biomolecules, such as drugs, for a desired period of time, but also can enable the removal of an empty device after drug release from the body. Degradation is generally achieved by introducing degradable linkages as multifunctional cross-linkers into micro/nanogels. These degradable linkages are then cleaved in response to external stimuli, such as chemicals, pH, hydrolysis, enzymes, and light. Consequently, a significant amount of work has been directed toward the development of cross-linkers functionalized with degradable linkages, leading to degradable micro/nanogels for targeted drug-delivery applications.

Disulfides have been degraded into the corresponding thiols in the presence of water-soluble reducing agents, such as dithiothreitol<sup>137–139</sup> and glutathione,<sup>140</sup> through the disulfide–thiol change. In particular, glutathione is a biocompatible tripeptide found within cells at millimolar concentrations.<sup>141,142</sup> It has been reported that the viability of C2C12 cells in the presence of 10 mmol/L glutathione was over

91% for 2 days, suggesting that, at this concentration, glutathione exhibits insignificant cytotoxicity.<sup>130</sup> Nanogels prepared in the presence of disulfide-functionalized cross-linkers can be degraded in the presence of glutathione in cellular environments, releasing anticancer drugs to kill cancer cells. Well-defined nanogels of POEOMA have been prepared by inverse miniemulsion ATRP in the presence of dithiopropionyl poly(ethylene glycol) dimethacrylate.<sup>129,130</sup> Trojan horse PRINT particles have also been prepared in the presence of *N,N'*-cystamine bisacrylamide.<sup>143</sup> Figure 1 shows the chemical structures of disulfide-functionalized cross-linkers.

An acetal is an acid-labile linkage that can be degraded under acidic conditions ( $\text{pH} < 6.5$ ).<sup>144</sup> Acetal chemistry is extremely promising for targeted drug-delivery applications because acid-labile linkages can be sufficiently stable to sustain drugs in the bloodstream ( $\text{pH} = 7\text{--}7.5$ ), but then cleaved in cancer cells ( $\text{pH} < 5.7$ ), releasing drugs to kill a tumor.<sup>145,146</sup> Several reports have described the preparation of acetal-functionalized micro/nanogels mainly by inverse emulsion polymerization. Examples include nanogels based on PAAm and its copolymers prepared in the presence of acetal-functionalized diacrylamide cross-linkers,<sup>147–150</sup> poly(2-hydroxymethyl methacrylate) microgels with acetal-functionalized dimethacrylates,<sup>151</sup> and poly(*N*-vinylformamide) nanogels with 2-bis[2,2-*N*-vinylformamido]ethyl propane.<sup>152</sup> Figure 2 shows the chemical structures of acetal-functionalized cross-linkers.

Microgels cross-linked with oligolactate linkages have been prepared by inverse suspension polymerization of oligolactate-functionalized diacrylates. In this case, the microgels were degraded upon hydrolysis of oligolactate linkages in physiological conditions at  $\text{pH} = 7.0$  at  $37^\circ\text{C}$ .<sup>100</sup> Enzyme-responsive microgels were prepared by precipitation copolymerization of AAm with an amine-functionalized AAm derivative in water. The amine groups in the microgels reacted with enzyme-cleavable peptide linkers that were cleaved in the presence of a protease enzyme.<sup>80,81</sup> Light-responsive microgels were prepared by photo-induced dimerization ( $\lambda > 310\text{ nm}$ ) of coumarin groups in micellar nanoparticles produced from amphiphilic block copolymers consisting of PEO hydrophilic block and pendent coumarin-containing hydrophobic block.<sup>153</sup> Upon the irradiation of light ( $\lambda < 260\text{ nm}$ ), the dimers of coumarin side groups were cleaved, leading to microgel degradation.<sup>153</sup>

In addition, many reports have demonstrated the preparation of effective degradable hydrogels cross-linked with disulfides,<sup>140,154</sup> acetals,<sup>155,156</sup> peptides,<sup>157–160</sup> oligolactate esters,<sup>85,161–164</sup> and other degradable linkages, including periodates,<sup>165</sup> polyphosphoesters,<sup>166,167</sup> anhydrides,<sup>168</sup> polyperoxides,<sup>169</sup> and poly(3-hydroxybutyrate).<sup>170</sup>

## Bioconjugation

Bioconjugation of micro/nanogel surfaces with specific ligands that can recognize receptors on diseased cells has allowed for active targeting to specific cells. Effective ligands for cancer cells include folic acid derivatives, peptides, proteins, and antibodies. To achieve effective bioconjugation, a novel functionality must be incorporated into micro/nanogels. CS-based microgels physically cross-linked with TPP were prepared by aqueous homogeneous gelation. They

were bioconjugated with transferrin in water. The bioconjugation was characterized using ninhydrin solution.<sup>171</sup> Microgels of P(NIPAM-AA) had a hydrodynamic diameter of 110 and 156 nm at  $\text{pH} = 4.5$  and  $7.4$ , respectively. Acid groups in microgels reacted with amino groups of proteins, such as albumin and transferrin, yielding microgel–protein bioconjugates. Interestingly, only transferrin-conjugated microgels entered HeLa cancer cells through receptor-mediated endocytosis (Fig. 3).<sup>16</sup> The preparation of P(NIPAM-AA) microgels bioconjugated with folic acids have also been reported.<sup>89</sup>

Well-defined biodegradable OH-functionalized nanogels of POEOMA have been prepared by ATRP in inverse miniemulsion. Two approaches have been proposed: copolymerization of OEOMA with OH-functional monomers, particularly 2-hydroxyethyl acrylate (HEA),<sup>130</sup> and the use of OH-functionalized ATRP initiators such as 2-hydroxyethyl 2-biromisobutyrate (OH-EBiB).<sup>132</sup> Hydroxyl (OH) groups of nanogels have been reacted with carboxylic acid groups of biotins. The resulting biotin-functionalized nanogels were subsequently bioconjugated with avidin through a specific biotin–avidin interaction.<sup>130</sup> Biotin-functionalized nanogels can also be conjugated with an avidin-functionalized antibody for receptor-mediated endocytosis. In addition, OH groups in POEOMA nanogels have been converted to the corresponding carboxylic acids. The resulting COOH-POEOMA nanogels were subsequently conjugated with RGD-NH<sub>2</sub> tripeptide, yielding RGD-conjugated POEOMA nanogels.<sup>132</sup> Recently, the reversible surface switching of CS-based nanogels triggered by temperature was prepared by cross-linking reaction of CS with TPP at physiological  $\text{pH} = 7.4$ . The nanogels were conjugated with transferrin in aqueous media for receptor-mediated endocytosis.<sup>171,172</sup>

## Loading/encapsulation and release

Micro/nanogels have an interior network for the incorporation of biorelated molecules. Several methods have been utilized to incorporate various water-soluble and dispersible biomolecules into nanogels. They include physical loading and in situ physical incorporation. The entrapment of bioactive molecules in the polymeric network as well as their in vitro release have been extensively investigated as possible routes for drug delivery in biomedical applications. In general, load/release is achieved through electrostatic interactions, hydrophobic and hydrophilic interactions, stimuli response, and degradation.<sup>21</sup>

Physical loading has generally been utilized for low molecular weight bioactive molecules. Examples include anticancer drugs, like doxorubicin (Dox)<sup>16,143,173,174</sup> and methotrexate,<sup>75,171</sup> as well as polypeptides including insulin.<sup>175</sup> To accomplish physical loading, micro/nanogels are mixed with drugs in water. Excess drugs are removed by centrifugation or dialysis. In one study, a hydrophilic and hydrophobic interaction was utilized to load Dox into biodegradable POEOMA nanogels cross-linked with disulfide linkages in water. Here, the loading level of Dox was determined using the extinction coefficient of Dox ( $\epsilon = 7600\text{ mol/L}^{-1}\text{ cm}^{-1}$  at  $\lambda = 497\text{ nm}$ ) in water. It increased from 5.4 to 16.4 wt% as the initial ratio of Dox/nanogel in the mixture increased from 0.07/1 to 0.35/1.<sup>130</sup>

Results were similar to those for nanogels based on Pluronic F127 containing hydrophobic poly(propylene glycol). The amount of Dox loaded into the nanogels increased from 2.7 to 8.9 wt% as the initial ratio of Dox/nanogel increased from 0.1/1 to 0.2/1.<sup>98</sup> Thermoresponsiveness was also utilized to load Dox into P(NIPAM-AA) microgels at pH = 7.4 where the microgels were swollen. However, at pH = 4.5, the microgels shrank and Dox was then released.<sup>16</sup> The loading and release of insulin into PNIPAM-based microgels by thermal responsiveness has also been explored.<sup>175</sup>

In situ physical incorporation has been utilized to load relatively high molecular weight biomolecules, such as proteins, carbohydrates, and genes. In this case, the pore size of micro/nanogels is not sufficiently large to allow high molecular weight biomolecules to diffuse into the network. Two methods are generally employed. The more promising method involves the use of inverse (mini)emulsion and inverse microemulsion polymerization where water-soluble biomolecules are confined in water-soluble droplets. As an example, plasmid DNA was loaded into acid-labile PAAm-based microgels prepared by inverse emulsion polymerization. Subsequently, the plasmid DNA was released from the microgels upon degradation in response to pH change. The release behavior was characterized using agarose gel electrophoresis (Fig. 4).<sup>149</sup> In addition, ovalbumin,<sup>148</sup> BSA,<sup>133</sup> lysozyme,<sup>152</sup> and antisense<sup>105</sup> as well as various carbohydrate model drugs<sup>103,104,131</sup> have also been incorporated into micro/nanogels using the same method. The second method involves the use of aqueous gelation by physical cross-linking. Bioactive molecules are incorporated into micro/nanogels during gelation in aqueous solution. Examples include insulin loaded in microgels based on CS/CyDex hybrid<sup>34</sup> and PVP/PAA,<sup>53</sup> as well as BSA<sup>172</sup> and Dex<sup>29</sup> in CS-based microgels. Meta-tetra(hydroxyphenyl)chlorine has also been encapsulated into PAAm nanogels for photodynamic therapy (PDT).<sup>176</sup>

## Incorporation of inorganic nanoparticles into micro/nanogels

The incorporation of inorganic nanoparticles (NPs) into micro/nanogels allows for the retention of the unique structural and optical properties that have been attributed to nanoscale phenomena of inorganic NPs.<sup>177,178</sup> Examples of colloidal inorganic NPs include quantum dots (QDs) for fluorescent imaging, iron oxide NPs for magnetic resonance imaging (MRI), and silver and gold NPs for optical imaging and therapy. Three approaches are generally utilized: physical loading, in situ polymerization, and in situ formation.

For physical loading, the pH-responsive swelling property of P(NIPAM-VP) in water at pH = 3 has been utilized to incorporate water-soluble CdTe QDs into microgels, yielding CdTe-loaded microgels for multicolor-coded microspheres. At pH > 11, QDs have been released by thermal-responsiveness (shrinking) of P(NIPAM-VP) (Fig. 5).<sup>179</sup> Similarly, CdTe-loaded PNIPAM gels,<sup>180</sup> poly(NIPAM-AA),<sup>181</sup> and P(NIPAM-vinyl imidazole)<sup>182</sup> microgels have been prepared in response to temperature and pH stimuli. In addition, Au nanorods have been incorporated into P(NIPAM-AA) microgels for photodynamic therapy.<sup>183</sup> As an example of in situ polymerization, dispersion and inverse emulsion polymeriza-

tion of NIPAM in the presence of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> NPs yielded magnetic PNIPAM-based microgels loaded with  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> NPs.<sup>184</sup> Magnetic PHEMA-based microgels have been similarly prepared.<sup>185</sup>

For in situ formation of inorganic NPs inside the microgel network, ionic precursors of inorganic NPs are added first to react with functional groups such as amines and carboxylic acids in microgels. A subsequent addition of counter ions yields inorganic NPs inside the microgel network. Examples include PNIPAM microgels loaded with Au NPs,<sup>186</sup> poly(*N*-vinyl caprolactam) microgels loaded with poly(3,4-ethylenedioxythiophene) nanorods,<sup>187</sup> P(NIPAM-AA) microgels with Ag NPs,<sup>188</sup> and P(NIPAM-AA-HEA) microgels with CdS QDs, Ag, and Fe<sub>3</sub>O<sub>4</sub> NPs.<sup>189</sup> Recently, magnetic P(NIPAM-AA-HEA) microgels containing Fe<sub>3</sub>O<sub>4</sub> NPs were utilized as stimuli-responsive emulsifiers for the remote control of separation and stability of oil-in-water emulsions.<sup>190</sup>

## Summary

Various methods for the preparation of micro/nanogels for drug-delivery applications have been developed using physical cross-linking, chemical cross-linking, and heterogeneous CRCP approaches. Micro/nanogels have been designed and engineered to achieve a high degree of control of properties for biomedical applications. To accomplish this high level of control, nanogel diameters should be <200 nm. This facilitates cellular uptake through receptor-mediated endocytosis to cross cell membranes, and reduces nanoparticle uptake by the mononuclear phagocyte system (MPS). Second, degradability enables modulation of drug release for a desired period of time and enables the removal of the empty device after drug release. This has generally been achieved by introducing degradable linkages as multifunctional cross-linkers into micro/nanogels. The degradable linkages can then be cleaved in response to external stimuli. Effective degradable linkages include disulfide (glutathione); acid-labile groups, including acetal, polyphosphoester, and hydrazone (pH change); oligolactate (hydrolysis); peptide (enzyme); and photo-cleavable groups (light). Third, functionality allows for the bioconjugation of microgel surfaces with specific ligands that can recognize receptors on diseased cells. Effective ligands for cancer cells include folic acid derivatives, peptides, proteins, and antibodies. Fourth, loading and release of biorelated molecules is achieved through electrostatic interactions, hydrophobic and hydrophilic interactions, stimuli-responsiveness, and degradation. General methods include (i) physical loading for both low molecular weight, bioactive molecules, and polypeptide, and (ii) in situ physical incorporation for relatively high molecular weight biomolecules, including proteins, carbohydrates, and genes. In addition, inorganic nanoparticles (NPs) have been incorporated into micro/nanogels for fluorescence, MRI, optical imaging, and therapy. In the future, more research effort will be directed toward the design and development of effective nanogels with better control over those criteria most critical for in vivo drug-delivery applications.

# A sensitive fluorescence method for monitoring the kinetics of microemulsion polymerization

Haike Feng, Yi Dan, and Yue Zhao

**Abstract:** We present a fluorescence method that allows one to monitor the kinetics of microemulsion polymerization of very low monomer contents (water-to-monomer ratio can readily be superior to 1000). The microemulsion polymerization of methyl methacrylate (MMA) was investigated using *N*-(2-anthracene)methacrylamide (AnMA) as the probe whose fluorescence emission intensity was proportional to the conversion of MMA into the polymer. The real-time-measurement results show that in the regime of very low monomer contents, the surfactant exerted a profound effect on the kinetic process. In a microemulsion containing 0.1 wt% of MMA with respect to water, with the anionic surfactant of sodium dodecyl sulfate (SDS), the fast polymerization was preceded by an induction period whose length increased with reducing the concentration of the water-soluble initiator of potassium persulfate (KPS). By contrast, with the non-ionic surfactant of polyoxyethylene (20) oleyl ether (Brij98), the induction period was short and the decrease in the KPS concentration mainly resulted in a decrease of the reaction rate. The unprecedented sensitivity of this fluorescence method made it possible to access kinetic data of microemulsion polymerization with very low monomer contents for the first time, providing new insight into the effects of surfactant and initiator on this heterophase polymerization process.

**Key words:** microemulsion polymerization, reaction kinetics, fluorescence spectroscopy, characterization method.

**Résumé :** On a mis au point une méthode de fluorescence qui permet de suivre la cinétique de polymérisation en microémulsion à des teneurs très faibles de monomères dans lesquelles le rapport d'eau à monomère peut facilement être supérieur à 1000. On a étudié la polymérisation en microémulsion de méthacrylate de méthyle (MAM) en utilisant le *N*-(2-anthracène)méthacrylamide (AnMA) comme sonde dont l'intensité d'émission de fluorescence était proportionnelle à la conversion du méthacrylate de méthyle en polymère. Les résultats de mesures en temps réel montrent que dans le régime impliquant de très faibles teneurs en monomère, l'agent de surface exerce un effet important sur le processus cinétique. Dans une microémulsion contenant 0,1 % en poids de MAM par rapport à l'eau et du dodécylsulfate de sodium (DSS) comme agent de surface anionique, la polymérisation rapide est précédée d'une période d'induction dont la longueur augmente avec la réduction de la concentration du persulfate de potassium (PSK), l'initiateur soluble dans l'eau. Par opposition, avec l'éther oléyle du polyoxyéthylène (20) (Brij98), un agent de surface non ionique, la période d'induction est courte et une diminution de la concentration de persulfate de potassium conduit à une réduction de la vitesse de réaction. La sensibilité sans précédent de cette méthode de fluorescence permet d'obtenir pour la première fois des données cinétiques pour la polymérisation en microémulsion avec de très faibles teneurs en monomère et d'en tirer des conclusions sur les effets des agents de surface et de l'initiateur sur le processus de polymérisation en hétérophase.

**Mots-clés :** polymérisation en microémulsion, cinétique de la réaction, spectroscopie de fluorescence, méthode de caractérisation.

[Traduit par la Rédaction]

## Introduction

The kinetics of microemulsion polymerization has been extensively investigated.<sup>1–10</sup> Generally, to monitor the kinetics, aliquots of the oil (monomer) in water (o/w) reaction mixture are removed over the course of polymerization at

various time intervals; by measuring the polymer concentration formed over time, kinetic data can be obtained. Using this method, understandably, one needs a large volume of the reaction solution and a high monomer content (e.g., > 3 wt% with respect to water) to obtain data with an appreciable precision. There are also several real-time monitoring

**Fig. 1.** Chemical structures of the monomers and schematic illustration of the microemulsion-polymerization-induced fluorescence emission.

techniques that have been utilized to study the kinetics of microemulsion (and miniemulsion) polymerizations. These include the dilatometry that measures the volume change of the reaction liquid in a capillary upon polymerization,<sup>3</sup> the reaction calorimetry that measures the heat released from the polymerization over time,<sup>8,9</sup> and the laser Raman spectroscopy that probes the breaking of C=C double bonds in a vinyl polymerization.<sup>2</sup> In terms of sensitivity, the calorimetric method is better, allowing the use of low monomer contents around 0.5 wt%.<sup>8</sup>

Although a microemulsion is a thermodynamically stable, transparent solution, the polymerization is a heterophase reaction process, since it takes place inside nanometer-sized monomer droplets (~5–10 nm) stabilized by a large number of surfactant molecules. In a microemulsion, there are also empty micelles, dissolved surfactant molecules, and either a water-soluble or monomer-soluble initiator.<sup>1–10</sup> It is of fundamental interest to know what happens when the monomer content becomes very low. For instance, is the polymerization kinetics affected by reducing the monomer concentration while keeping the same concentrations of surfactant and initiator? Can the kinetics reveal some sort of transition from a heterogeneous to homogeneous polymerization when the monomer concentration is extremely diluted? The above-mentioned experimental techniques cannot access this regime of very low monomer contents. In this paper, we report a very sensitive fluorescence-based method that can yield kinetic data on microemulsion (or miniemulsion) polymerization using monomer content as low as 0.0035 wt% (or water-to-monomer ratio of 28 000)!

The method used is based on previous reports of Warman and co-workers.<sup>11–14</sup> They have developed a series of fluorescent probes and used them to study radiation-induced polymerization. The fluorescent probes are polymerizable monomers (with a C=C double bond) and have the distinct feature to be completely nonfluorescent in the monomer

form but become fluorescent upon polymerization as the double bond is saturated. In particular, Frahn et al. showed that *N*-(2-anthracene)methacrylamide (AnMA) could be used as a fluorescent probe to monitor the Gamma-ray induced free-radical polymerization of methyl methacrylate (MMA) in bulk and in solution, and found that the ratio of the chain-propagating rate constants for the reactions of an MMA free radical with AnMA and with MMA is 0.96.<sup>14</sup> This means that the increase in the fluorescence emission intensity over time could reflect closely the kinetic process of the free-radical polymerization of MMA. In the present study, we used AnMA as the probe to investigate the microemulsion polymerization of MMA with very low monomer contents. The great sensitivity of the fluorescence appearing upon polymerization, as schematically illustrated in Fig. 1, allowed us to access kinetic data in this regime for the first time. Among the results, the real-time measurements show a more important effect of the used surfactant on the kinetics with very low monomer content than with relatively high monomer content.

## Experimental

### Materials

Unless otherwise stated, all chemicals were purchased from Aldrich. For the monomers, methyl methacrylate (MMA, 98%) was passed through a basic alumina column prior to use. *N*-(2-Anthracene)methacrylamide (AnMA) was synthesized using a literature method,<sup>13</sup> it was purified by recrystallization from a methylene chloride/hexane mixture (4:1, v/v). The two used surfactants were sodium dodecyl sulfate (SDS, 99%), which is an anionic surfactant, and polyoxyethylene (20) oleyl ether (Brij98, 99%), which is a non-ionic surfactant. For the free-radical initiators, the water-soluble potassium persulfate (KPS, 99.99%) was used as received, and the water-insoluble 2,2'-azobis(isobutyronitrile) (AIBN) (from Polysciences) was recrystallized twice from ethanol. For

other chemicals, tetrahydrofuran (THF, 99%) was distilled from sodium benzophenone, while hexadecane (99%) and hexyl alcohol (98%) were used without further purification.

### Preparation and monitoring of microemulsion polymerization

An example of experiment is detailed as follows: SDS (0.3 g, 1.04 mmol) was dissolved in 10 g of deionized water (0.56 mol) in a 25 mL round-bottom flask. AnMA (0.15 mg, 0.00057 mmol) was dissolved in a solution of hexyl alcohol, a costabilizer, (0.03 g, 0.29 mmol), and MMA (0.3 g, 3 mmol). Then, the liquid mixture of monomers containing AnMA was added dropwise into the aqueous solution at room temperature. After 5 min ultrasound sonication (60 W, 40 KHz), KPS (5 mg, 0.0185 mmol) was added. After another 1 min sonication, an aliquot of the microemulsion was transferred into a standard quartz fluorescence cuvette (1 cm × 1 cm × 3 cm), purged with argon gas for 15 min and sealed with a Teflon stopper and a Parafilm tape. Afterwards, the cuvette was placed in the spectrometer's sample holder, pre-heated to 60 °C, and the fluorescence emission (whole spectrum or intensity at a wavelength) was recorded after 1 min required for thermal equilibrium of the solution.

In case where Brij98 was the surfactant, hexadecane was used as costabilizer (10 wt% with respect to Brij98). In all reactions, the same extremely low fluorescent-probe concentration was used (0.19 mmol AnMA in 1 mol MMA) to ensure that AnMA remained part of the monomer even with a very low monomer content in the microemulsion. In the control test using relatively high monomer content, the increase in the amount of polymer over time was determined by using the conventional method. Aliquots of the reaction solution were taken at various time intervals, poured into cold methanol (cooled by ice), and the precipitated polymer was filtered, dried under vacuum, and weighed to calculate the monomer conversion defined as:  $\text{Conversion (\%)} = W_p/W_m \times 100\%$ , where  $W_p$  is the mass of the obtained PMMA and  $W_m$  is the known mass of the monomer. In this paper, the monomer content and the surfactant concentration are mass-percentages with respect to water, while the concentration of initiator is mass-percentage with respect to the monomer.

### Characterizations

Steady-state fluorescence emission spectra were recorded using a fluorescence spectrophotometer (Varian Cary Eclipse). The excitation and emission slit widths were set at 5 nm, and the scan rate was 10 nm s<sup>-1</sup>. Real-time monitoring of the emission intensity at a chosen wavelength could also be carried out. For all measurements, the excitation wavelength was 337 nm; and for the kinetic data, the emission intensity at 425 nm was measured. Unless otherwise stated, the reported fluorescence intensities were not scaled. They were recorded under the same conditions (same volume of reaction solution, same excitation and emission slit widths). Since the concentration of AnMA was kept constant in MMA, the different fluorescence intensities result from different monomer concentrations in the microemulsion.

## Results and discussion

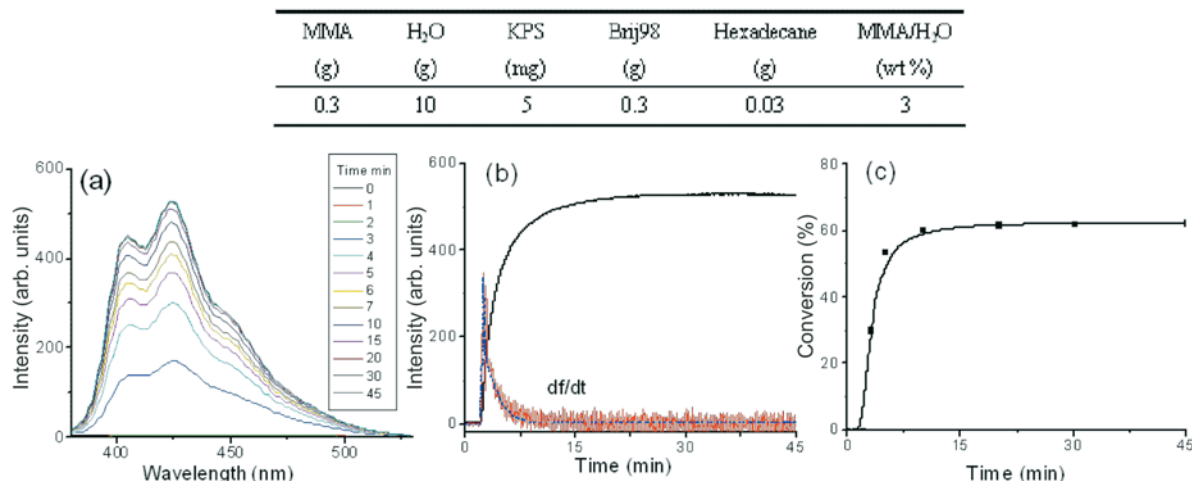

We first attempted to validate the fluorescence method by

using a microemulsion containing 3% of the monomer, with which the conventional method can be utilized to determine the reaction kinetics. Figure 2 shows the results, together with the composition of the solution. In Fig. 2a, the fluorescence emission spectra of the solution were recorded as a function of time. While the solution was virtually nonfluorescent before the reaction, the fluorescence emission increased over time, indicating a growing number of AnMA monomers polymerized with MMA. In Fig. 2b, the plot of fluorescence intensity,  $f$ , at 425 nm vs. time is given, showing a fast increase within the first 10 min before reaching a plateau. The first derivative of the plot,  $df/dt$ , yielded the change of the reaction rate over time (the profile of the rate curve is better seen from the smoothed line). The result is typical of a microemulsion polymerization, showing that the polymerization rate rose to a maximum value and then decreased to zero without an interval of constant reaction rate. Shown in Fig. 2c is the conversion curve obtained by measuring the polymer concentrations at various reaction times. It is seen that within experimental error, the plot of fluorescence intensity vs. time corroborates well the kinetics measured using the conventional method. However, it should be emphasized that the fluorescence result represents better the reaction kinetics due to its sensitivity. Using the conventional method, oligomers can be washed away upon polymer precipitation, while with the fluorescence method, they can be detected. Apparently, the maximum fluorescence intensity corresponds to a monomer conversion of about 60%. These results indicate that this fluorescent probe reveals correctly the kinetics of microemulsion polymerization of MMA. We mention that for the experiments with very low monomer contents to be discussed below, we were mainly focused on the kinetic aspects. Due to the few nanoparticles formed, the characterizations of actual conversion, molecular masses, and particle morphology could not be performed with certainty.

Before discussing the results obtained with low monomer contents, Fig. 3 is meant to emphasize that, with the used surfactant concentration, all polymerizations were performed with a microemulsion. The highest MMA content used was 3%, and with 3% of either SDS or Brij98, the solutions are basically transparent (Fig. 3, images A and B), in contrast with, for comparison, a solution with only 0.3% of SDS (Fig. 3, image C). However, the microemulsion with the non-ionic surfactant Brij98 appears less transparent than the solution with the anionic surfactant SDS, reflecting the difference between the two surfactants. The surfactant concentration was kept the same with lower MMA contents.

In a microemulsion, with the same concentrations of surfactant and water-soluble initiator, what could be the effect on the kinetics by diluting the monomer to a very low concentration? Fig. 4 shows the results obtained with a set of experiments designed to answer the question, using two different surfactants and, for each of them, three monomer concentrations (actual compositions of the solutions are shown in the figure). The fluorescence curves obtained with 0.5% and 0.1% of MMA are magnified by a factor as indicated in the figure, since a lower monomer content means less fluorescent AnMA units in the polymer. While the kinetics appears similar with the two surfactants at the rather high monomer content of 3%, it is drastically different at the low

**Fig. 2.** (a) Fluorescence emission spectra ( $\lambda_{\text{ex}} = 337$  nm) recorded at various polymerization times; (b) plots of fluorescence emission intensity at 425 nm, ( $f$ ) and the first derivative ( $df/dt$ ) vs. time; and (c) plot of conversion (%) vs. time for a microemulsion containing 3 wt% of MMA with respect to water (the composition of the reaction solution is indicated).

**Fig. 3.** Photographs of a microemulsion containing 3% MMA with 3% SDS (image A), a microemulsion containing 3% MMA with 3% Brij98 (image B), and an emulsion containing 3% MMA and 0.3% SDS (image C).

B	0.3	10	0	0.3	0	0.03
C	0.3	10	0.03	0	0.003	0

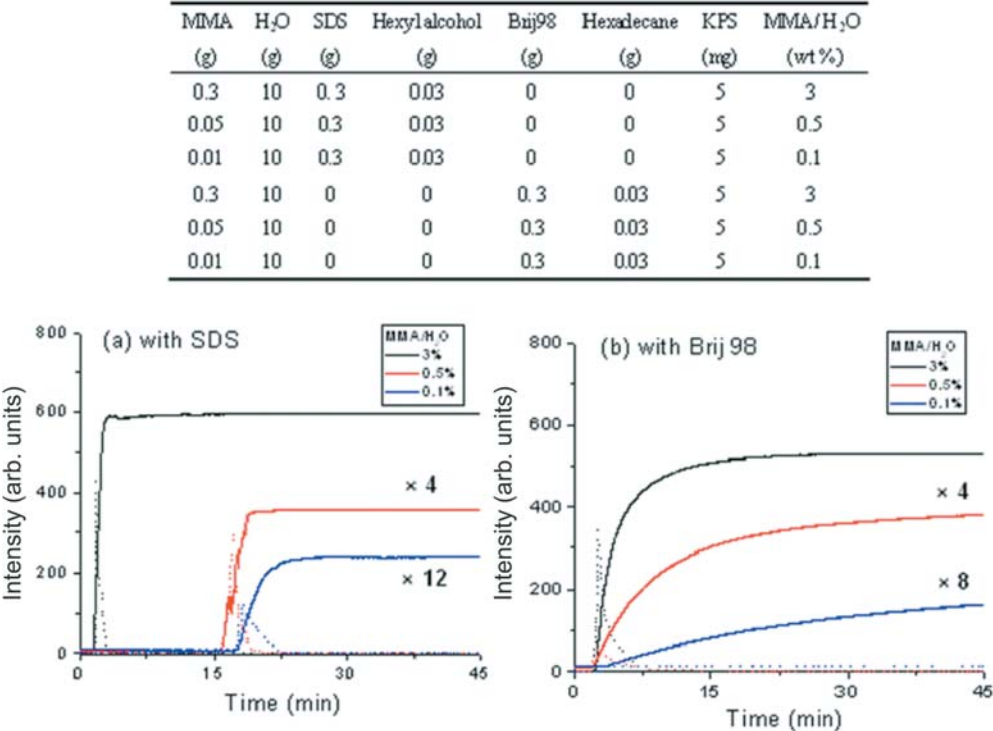

contents of 0.5% and 0.1%. With SDS as the surfactant, there appeared an induction period before the reaction took place, which became longer with reducing the monomer concentration. By contrast, using Brij98 as the surfactant, the reduction of the monomer concentration resulted in a decrease in the rate of polymerization. In all cases, the polymerization rate profiles (dotted lines) are also shown. A couple of analyses can be made. On the one hand, with the same surfactant, if only the number of monomer droplets was diminished with lower monomer content (more empty micelles in the solution), each droplet would be surrounded by initiator molecules of the same concentration and, consequently, the kinetics should not be changed. The results in Fig. 4 show that this is not the case, suggesting that at a very low concentration of monomer, the monomer droplet

size and the concentration of surfactant molecules adsorbed at the interface may be different, which changes the dynamic nature of the monomer-swollen micelles and the entry of primary free radicals in the droplets to initiate the polymerization. On the other hand, the very different kinetic behaviours observed with the two surfactants should reflect, among others, their different micellization abilities and interaction natures with MMA. The kinetic results indicate that the initiation of polymerization takes place more rapidly with Brij98 than with SDS, but after the initiation, the polymerization rate is slower with the former than with the latter. With SDS, the monomer droplets are covered by an outer layer of anionic sulfate groups, while with Brij98, they are surrounded with nonionic ethylene glycol units. The two surfactants are also very different in size (molar mass of 288 g for SDS as compared with about 1150 for Brij98), which means, at the same mass-based concentration, very different numbers of surfactant molecules interacting with the monomer droplets. These differences could affect the number and size of monomer droplets and the entry of primary radicals required to initiate the polymerization. It may appear more reasonable to use the same molar concentration for the two surfactants, but still this may just have a different effect on the number and size of monomer droplets, and on the density of adsorbed surfactant molecules. Clearly, it is the combination of those factors that dictates the reaction kinetics. At this point, we can only speculate the reasons for the observed differences; a clear understanding requires further studies by varying systematically the reaction conditions.

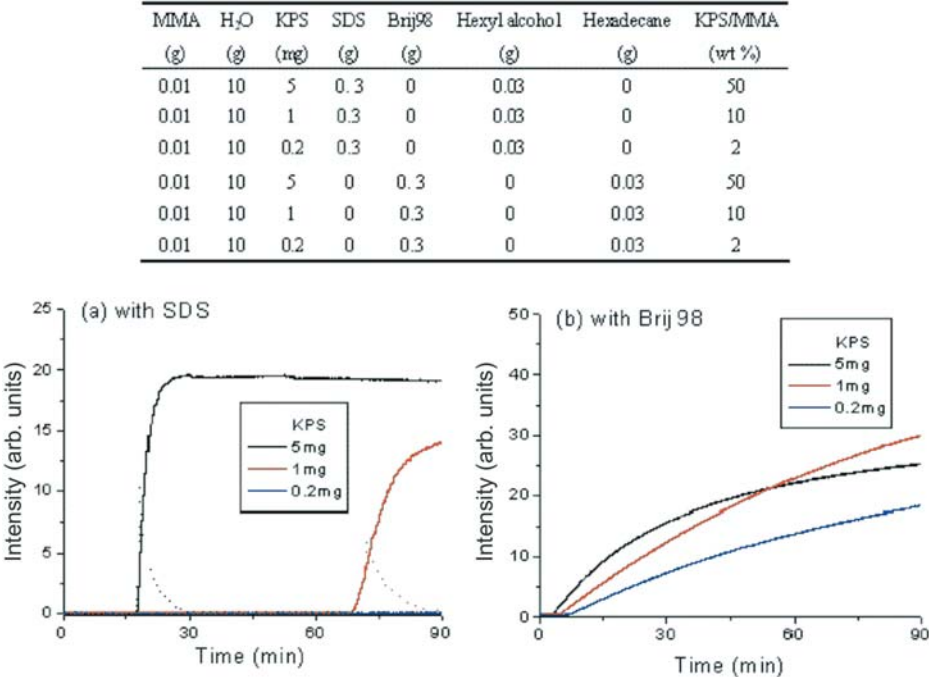

We then investigated the effect of the initiator concentration on the kinetic process with a very low monomer content of 0.1%, while keeping the surfactant concentration unchanged. Again, the two surfactants were utilized, and the results are shown in Fig. 5. With SDS as surfactant, the decrease of the water-soluble initiator concentration resulted in an increase in the induction period preceding the starting of polymerization and a slight decrease in the polymerization rate as well. At the lowest KPS concentration (2% with respect to the monomer), no polymerization was observed

**Fig. 4.** Fluorescence emission intensity at 425 nm ( $\lambda_{\text{ex}} = 337 \text{ nm}$ ) vs. reaction time for microemulsions containing 3%, 0.5%, and 0.1% MMA with (a) SDS and (b) Brij98 as surfactant. All solutions have the same surfactant and initiator (KPS) concentrations. The curves obtained at lower monomer contents are magnified by a factor as indicated in the figure.

**Fig. 5.** Fluorescence emission intensity at 425 nm ( $\lambda_{\text{ex}} = 337 \text{ nm}$ ) vs. reaction time for microemulsions containing 0.1% MMA and three different initiator (KPS) concentrations with (a) SDS and (b) Brij98 as surfactant. The compositions of all reaction solutions are shown.

after 90 min, indicating the great difficulty in starting the polymerization when both monomer and initiator concentrations are small. While with Brij98 as surfactant, the decrease in the initiator concentration mainly resulted in a decrease in the polymerization rate and, on a closer inspection, a slight

increase of the induction period (the polymerization rate profiles are not shown for the sake of clarity). The effect of surfactant in this regime of very low monomer contents is evident for all initiator concentrations, but most strikingly at the lowest initiator concentration (2% with respect to mono-

**Fig. 6.** Fluorescence emission intensity at 425 nm ( $\lambda_{\text{ex}} = 337$  nm) vs. reaction time for microemulsions containing 0.1% MMA with three successive additions of the monomer: (a) with SDS and (b) with Brij98 as surfactant.

It is known that when more monomers are added into the solution at the end of a microemulsion polymerization, the reaction could resume, resulting in more polymer particles. We found that this could also happen with very low monomer contents. Figure 6 shows the result obtained with a solution containing 0.1% of MMA, with both SDS and Brij98 as the surfactant. In the case of SDS, after the fluorescence intensity reached the plateau level for some time, the same

amount of MMA was injected into the solution using a syringe through a parafilm covering the cuvette containing the solution; it took about 1 min before resuming the fluorescence intensity measurement (in other words, there was a 1 min delay between the cycles of polymerization). The result shows that within experimental error, at the end of the initial microemulsion polymerization, the two successive additions of more monomers proceeded with the same kinetics and a similar conversion degree, but with no induction period. This observation suggests that at the end of the first polymerization cycle, free radicals could be in empty micelles of the surfactant, so that once more monomers were added in the solution and solubilized by the micelles, new polymerization could take place immediately. Basically, the same conclusion can be drawn with Brij98 even though the kinetic process is different (slower polymerization rate with almost no induction period).

With an extremely low monomer content and in the presence of an excess amount of surfactant molecules, can the microemulsion polymerization get close to a homogeneous (single-phase) polymerization? An experiment was conducted with 0.1% MMA to get an answer to the question. Figure 7 compares the apparent kinetics of the polymerization of 0.1% MMA in a microemulsion with Brij98 as surfactant and in THF, with AIBN as initiator in both cases. The polymerization in THF solution started quickly but proceeded very slowly due to the low monomer concentration, while the microemulsion polymerization was much faster but started only after an induction period. These results indicate that at this low monomer content, the microemulsion polymerization is still a heterophase polymerization. The reaction inside monomer droplets is faster than the reaction in a homogeneous solution in which monomer molecules are much diluted. This result also gives a hint on the different kinetics by using SDS and Brij98 (Figs. 4 and 5). It would be possible that with very low monomer content, the reaction solution with Brij98 was closer to a homogeneous system than the solution with SDS, which accounts for the different induction periods. Finally, to highlight the unprecedented sensitivity of this fluorescence method in monitoring the kinetics of microemulsion polymerization, Fig. 8 shows the result obtained with 0.0035% of MMA, i.e., at a water-to-monomer ratio > 28 000! Even with this extremely low content of monomer, the typical kinetic process of the microemulsion polymerization of MMA with SDS as surfactant could still be detected, with of course a weak fluorescence signal. In principle, the sensitivity can further be improved by increasing the concentration of AnMA in the monomer.

## Conclusions

We presented a fluorescence method that made it possible to monitor the kinetics of microemulsion polymerization with very (or even extremely) low monomer contents. Using AnMA as the fluorescent probe, kinetic data of polymerization of MMA in a microemulsion with a water-to-monomer ratio as high as 28 000 could be obtained. The results show that with low monomer content, such as 0.1% of MMA with respect to water, the surfactant had a more profound effect on the kinetics than with a relatively high monomer content,

such as 3%. Using the anionic surfactant of SDS, the polymerization rate was fast, but there was an induction period, while with the non-ionic surfactant of Brij98, the polymerization started much earlier, but the reaction rate was slower. A decrease in the concentration of the water-soluble initiator KPS either further lengthened the induction period or slowed down the polymerization. With the unprecedented sensitivity, this fluorescence method is well-suited for kinetic study in the regime of low monomer contents. It can also be explored for monitoring polymerization systems, for which other methods are inaccessible or can be utilized with difficulties.

# Design, synthesis, and properties of benzobisthiadiazole-based donor- $\pi$ -acceptor- $\pi$ -donor type of low-band-gap chromophores and polymers

Gang Qian and Zhi Yuan Wang

**Abstract:** A novel low-band-gap chromophore (**5**, 0.86 eV) having fluorene as a donor, benzobisthiadiazole (BBTD) as an acceptor, and pyrrole as a  $\pi$ -spacer was successfully designed and synthesized, to probe the effect of  $\pi$ -spacer on the band-gap level of the donor- $\pi$ -acceptor- $\pi$ -donor type of chromophores. Compared with the thiophene spacer analogue (in compound **3**), the intramolecular hydrogen bonding between the pyrrole and the neighboring BBTD unit pushes the absorption maximum and fluorescence emission of chromophore **5** into the near-infrared spectral region with a red shift of 172 and 158 nm, respectively. The same red-shift phenomenon can also be realized by addition of Lewis acid (e.g.,  $\text{BF}_3$ ) to the BBTD-containing chromophores with other spacers. Attempt of using low-band-gap chromophore **5** in bulk heterojunction (BHJ) solar cells was made, showing a non-optimized photovoltaic device with the power conversion efficiency of 0.01%. A precursor approach to introduction of the alkaline-labile BBTD acceptor into the polymer backbone has been demonstrated by successful synthesis of low-band-gap polymer **P2**. The same strategy can be in principle applied to the synthesis of a series of low-band-gap chromophores or polymers with strong acceptors.

**Key words:** donor- $\pi$ -acceptor- $\pi$ -donor, chromophore, low band gap, bulk heterojunction (BHJ), precursor polymer.

**Résumé :** Afin de pouvoir étudier l'effet d'un espaceur  $\pi$  sur le niveau d'énergie interbande des chromophores de type donneur- $\pi$ -accepteur- $\pi$ -donneur, on a développé et synthétisé un nouveau chromophore de basse énergie interbande (**5**, 0,86 eV) comportant un fluorène comme donneur, un benzobisthiadiazole (BBTD) comme accepteur et un noyau pyrrole comme espaceur  $\pi$ . Par comparaison avec l'analogue comportant un espaceur thiophène (dans le composé **3**), la liaison hydrogène intramoléculaire entre le pyrrole et l'unité adjacente BBTD déplace le maximum d'absorption et l'émission de fluorescence du chromophore **5** dans la région spectrale du proche infrarouge avec des déplacements vers le rouge de respectivement 172 et 158 nm. On peut observer le même phénomène de déplacement vers le rouge par l'addition d'un acide de Lewis (tel le  $\text{BF}_3$ ) à des chromophores comportant du BBTD et d'autres espaceurs. On a essayé d'utiliser le chromophore **5** à faible énergie interbande dans des cellules solaires à hétérojonction globale (HJG); on a obtenu un dispositif non voltaïque non optimisé ayant une efficacité de conversion de pouvoir de 0,01 %. On a démontré l'applicabilité d'une autre approche à l'introduction de l'accepteur BBTD labile aux produits alcalins dans le squelette d'un polymère en effectuant avec succès la synthèse du polymère **P2** de faible énergie interbande. En théorie, la même stratégie peut être appliquée à la synthèse d'une série de chromophores ou de polymères de faible énergie interbande avec des accepteurs forts.

**Mots-clés :** donneur- $\pi$ -accepteur- $\pi$ -donneur, chromophore, faible énergie interbande, hétérojonction globale (HJG), polymère précurseur.

## Introduction

Research on low-band-gap organic materials (e.g., chromophores and polymers), whose band-gap levels, defined as the difference between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) energy levels, are typically below 1.8 eV, has been the focal point in a number of technologically impor-

tant areas. Low-band-gap organic materials absorb light with wavelengths longer than 700 nm or within the near-infrared (NIR) spectral region of 750–2000 nm.

In the area of solar-energy conversion, it is essential that the absorption of the light-harvesting material matches the spectral characteristics of the sun.<sup>1</sup> For the polythiophene (P3HT)-based bulk heterojunction (BHJ) solar cells, P3HT has a band gap of ~1.90 eV and a rather narrow absorption

<sup>1</sup>Corresponding author (e-mail: wayne\_wang@carleton.ca).

band (FWHM  $\approx$  150 nm) and can absorb only a limited fraction of the solar photons ( $\sim$ 30%). Thus, the NIR-absorbing chromophores and polymers have the possibility to improve the efficiency of organic BHJ solar cells owing to a better overlap with the solar spectrum.<sup>2</sup>

Near-infrared fluorescent organic materials may find applications as NIR-fluorescent tags for bio-imaging<sup>3</sup> and chemical sensing<sup>4</sup> or emitters in NIR light-emitting diodes (LED) for information-secured display and background lighting. To date, most of organic materials that have been shown to emit the light around 700–1000 nm are mainly with lanthanide complexes,<sup>5</sup> transition-metal complexes,<sup>6</sup> ionic dyes,<sup>7</sup> and low-band-gap polymers.<sup>8</sup> NIR organic photovoltaic materials have recently been demonstrated for use in NIR photodetectors.<sup>9</sup>

Among various types of low-band-gap organic materials, much effort has been focused on the design and synthesis of the chromophores and polymers consisting of powerful electron donor (D) and acceptor (A) units. Some of the best-performing BHJ organic solar cells are fabricated with the D–A type of conjugated polymers.<sup>10</sup> Some of these D–A polymers contain benzo-2,1,3-thiadiazole (BT) as the acceptor unit.<sup>11</sup> Recently, we have shown that the D– $\pi$ –A– $\pi$ –D type of chromophores, where  $\pi$  is a spacer or linking unit, can absorb light with the wavelength around 1000 nm and fluoresce above 1000 nm, such as compounds **1–3** in Fig. 1.<sup>12</sup> The band-gap levels of this class of chromophores depend on the strength of the donor and acceptor. Those containing a strong electron-withdrawing heterocyclic quinoid, namely, benzo[1,2-*c*:4,5-*c'*]bis([1,2,5]thiadiazole) (BBTD), tend to have a lower band gap than other acceptor-containing chromophores, since the BBTD unit is known to possess a substantial quinoidal character within a conjugated backbone, allowing for greater electron delocalization, and thus lowering the band gap.<sup>13</sup> However, the scope and limitations of the acceptor strength and the role of the spacer in tuning the band gap are still not fully understood. For example, a recent work shows that the band gap of the D–A type of benzothiadiazole (BT)-containing chromophores can be significantly lowered by the introduction of Lewis acids as a result of changing the electronic properties of the BT fragment via interactions with Lewis acids that bind nitrogen.<sup>14</sup>

Considering the D– $\pi$ –A– $\pi$ –D system such as compounds **1–3**, by diminishing the electron density on the nitrogen of the BBTD unit, a further decrease in band gap or red shift in absorption and emission spectra of the chromophores should be expected. Conceivably, the BBTD acceptor strength can be increased through either the intermolecular or intramolecular interaction by addition of Lewis acid or other electron-accepting species. In this work, we intend to show that by the introduction of pyrrole as a spacer, the band gap of the D– $\pi$ –A– $\pi$ –D chromophores can be further lowered due to the intramolecular hydrogen bonding with the neighboring BBTD unit, which is similar to the effect of adding a Lewis acid to the chromophores having other spacers. Accordingly, a new D– $\pi$ –A– $\pi$ –D chromophore (**5**, Fig. 1) is designed, synthesized, and characterized. Furthermore, for potential applications in thin-film devices, such as polymer BHJ solar cells, a new general approach to low-

band-gap polymers having the D– $\pi$ –A– $\pi$ –D unit in the backbone is demonstrated.

## Experimental section

### Materials

All chemicals and reagents were used as received from commercial sources without purification. Solvents for chemical synthesis were purified by distillation. All chemical reactions were carried out under an argon atmosphere. 2-Bromo-9,9-dioctylfluorene (**6**),<sup>15</sup> *N*-(*tert*-butoxycarbonyl)-2-(trimethylstannyl) pyrrole (**7**),<sup>16</sup> 4,8-dibromobenzo[1,2-*c*:4,5-*c'*]bis([1,2,5]thiadiazole) (**10**),<sup>13d</sup> 4,7-bis[4-(*N*-phenyl-*N*-(4-methylphenyl)amino)phenyl]-5,6-diamino-2,1,3-benzothiadiazole (**11**),<sup>12b</sup> and 9,9-dioctyl-2,7-bis(trimethyleneboronate)fluorene (**13**)<sup>17</sup> were prepared according to literature methods.

### Methods

<sup>1</sup>H NMR spectra were recorded using a Bruker Avance 300 NMR spectrometer. The high-temperature NMR experiments were performed on a Varian Unity-400 MHz spectrometer. High-resolution mass spectrometry (HRMS) was obtained from 7.0 T Actively Shielded Fourier Transform Ion Cyclotron Resonance Mass Spectrometers. The number- and weight-average molecular weights of the polymers were determined by gel-permeation chromatography (GPC) with a Waters 410 instrument and polystyrene as a standard and THF as eluent. Absorption and fluorescence spectra were recorded with a Shimadzu UV-3600 or Lambda 900 Perkin-Elmer spectrophotometer and a PTI fluorescence spectrophotometer, respectively. IR spectra were recorded on a Bio-Rad FTS-135 spectrophotometer. Cyclic voltammetry (CV) was performed on a CHI660b electrochemical workstation, in dry dichloromethane containing *n*-Bu<sub>4</sub>NPF<sub>6</sub> (0.1 mol/L) with a scan rate of 50 mV/s at room temperature under argon, using a Pt disk (2 mm diameter) as the working electrode, a Pt wire as the counter electrode and a Ag/AgCl electrode as the reference electrode.

### Photovoltaic device fabrication and characterization

The solar-cell devices were fabricated with the device structure of [indium tin oxide (ITO)/poly(3,4-ethylene dioxathiophene):poly(styrenesulfonate) (PEDOT:PSS)/Compound **5**:PCBM/Al]. The ITO glass was pre-cleaned and coated with PEDOT:PSS. Then, the active layer was spin-coated from the chlorobenzene solution of compound **5** and PCBM (1:1, w/w) on the substrate. Finally, the Al cathode was deposited at a vacuum level of  $4 \times 10^{-4}$  Pa. The effective area of the unit cell is 16 mm<sup>2</sup>. The current–voltage (*I*–*V*) measurement of devices was conducted on a computer controlled Keithley 236 Source meter. A xenon lamp (500 W) with AM 1.5 filter was used as the white light source, and the optical power at the sample was 100 mW/cm<sup>2</sup>.

### *N*-(*tert*-Butoxycarbonyl)-2-(9,9-dioctylfluorene-2-yl)pyrrole (**8**)

2-Bromo-9,9-dioctylfluorene (**6**) (4.7 g, 10 mmol), *N*-(*tert*-butoxycarbonyl)-2-(trimethylstannyl)pyrrole (**7**) (6.6 g, 12 mmol), and tetrakis(triphenylphosphane) palladium(0) (115.5 mg, 0.1 mmol) were dissolved in a mixture of tol-

**Fig. 1.** Chemical structures of D- $\pi$ -A- $\pi$ -D chromophores **1–5**.

uene (20 mL) and a 1 mol/L aqueous solution of sodium carbonate (20 mL). The mixture was stirred at 110 °C for 60 h. After cooling, the resulting solution was extracted with dichloromethane. The combined organic layers were washed with water and dried with anhydrous  $\text{MgSO}_4$ . Evap-

oration of the solvent and subsequent column chromatography (silica gel, dichloromethane/petroleum ether = 1/5) afforded the product as pale yellow oil (1.1 g, 20%).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.74–7.68 (m, 2H), 7.40–7.26 (m, 6H), 6.30–6.24 (m, 2H), 1.98 (t, 4H,  $J$  =

8.37 Hz), 1.41 (s, 9H), 1.40–1.10 (m, 20H), 0.89–0.87 (m, 6H), 0.73–0.61 (m, 4H).

**Tributyl[*N*-(*tert*-butoxycarbonyl)-5-(9,9-dioctylfluoren-2-yl)pyrrole-2-yl]stannane (9)**

A 100 mL three-necked flask was charged with dry THF (20 mL) and 2,2,6,6-tetramethylpiperidine (1.85 mL, 11 mmol). The mixture was cooled to  $-78^{\circ}\text{C}$  and *n*-BuLi (2.5 mol/L in hexane, 4.8 mL, 12 mmol) was added dropwise. The mixture was stirred at  $-78^{\circ}\text{C}$  for 10 min, then warmed to  $0^{\circ}\text{C}$  and stirred for additional 10 min. At this point, the mixture was cooled again to  $-78^{\circ}\text{C}$ , a solution of *N*-(*tert*-butoxycarbonyl)-2-(9,9-dioctylfluoren-2-yl)pyrrole (8) (5.5 g, 10 mmol) in dry THF (10 mL) was added, and the mixture was stirred for 1.5 h while keeping the temperature below  $-65^{\circ}\text{C}$ .  $\text{Bu}_3\text{SnCl}$  (3.7 mL, 13 mmol) was added dropwise. The mixture was stirred for 40 min at  $-75^{\circ}\text{C}$  and for additional 40 min at  $0^{\circ}\text{C}$ , and then for 12 h at room temperature. The mixture was poured into water and extracted with diethyl ether. The organic extracts were dried over anhydrous  $\text{MgSO}_4$ . Upon evaporation of the solvent, the crude product was obtained as pale yellow oil and used for the next step without further purification.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.75–7.67 (m, 2H), 7.40–7.24 (m, 5H), 6.44 (d, 1H,  $J = 3.75$  Hz), 6.33 (d, 1H,  $J = 3.00$  Hz), 1.99 (t, 4H,  $J = 8.10$  Hz), 1.65–1.62 (m, 6H), 1.40–1.37 (m, 6H), 1.24 (s, 9H), 1.18–1.08 (m, 26H), 0.97–0.92 (m, 9H), 0.89–0.83 (m, 6H), 0.73–0.61 (m, 4H).

**4,8-Bis[*N*-(*tert*-butoxycarbonyl)-5-(9,9-dioctylfluoren-2-yl)-2-pyrrolyl]benzo[1,2-*c*:4,5-*c'*]bis([1,2,5]thiadiazole) (4)**

To a solution of compound 9 (1.0 g, 1.2 mmol) and 4,8-dibromobenzo[1,2-*c*:4,5-*c'*]bis([1,2,5]thiadiazole) (10) (0.18 g, 0.5 mmol) in toluene (40 mL) was added  $\text{Pd}(\text{PPh}_3)_4$  (71 mg, 0.061 mmol). The mixture was stirred for 36 h at  $110^{\circ}\text{C}$ . After cooling, the mixture was poured into water and extracted with dichloromethane. The organic layer was washed with saturated aqueous potassium fluoride and brine before being dried over anhydrous  $\text{MgSO}_4$ . After evaporation of the solvent, the residue was purified by column chromatography on silica gel with dichloromethane/petroleum ether (1:1) as the eluent to afford the product (0.13 g, 20%) as black solid.  $^1\text{H}$  NMR (400 MHz,  $o\text{-C}_6\text{D}_4\text{Cl}_2$ , 403 K)  $\delta$  (ppm): 7.78–7.72 (m, 4H), 7.54–7.46 (m, 4H), 7.41–7.35 (m, 6H), 7.05 (d, 2H,  $J = 3.5$  Hz), 6.56 (d, 2H,  $J = 3.5$  Hz), 2.05–2.00 (m, 8H), 1.59 (s, 18H), 1.29–1.00 (m, 40H), 0.86 (t, 12H,  $J = 6.7$  Hz), 0.70 (br, 8H).

**4,8-Bis[5-(9,9-dioctylfluoren-2-yl)-2-pyrrolyl]benzo[1,2-*c*:4,5-*c'*]bis([1,2,5]thiadiazole) (5)**

Thermolysis of compound 4 (98 mg) at  $200^{\circ}\text{C}$  under reduced pressure ( $10^{-5}$  torr, 30 min) (1 torr = 133.322 Pa) afforded 92 mg (94% yield) of product as black solid.  $^1\text{H}$  NMR (400 MHz,  $o\text{-C}_6\text{D}_4\text{Cl}_2$ , 403 K)  $\delta$  (ppm): 11.72 (br, 2H), 8.04 (br, 2H), 7.78–7.67 (m, 8H), 7.55–7.37 (m, 6H), 6.96 (br, 2H), 2.15–2.11 (m, 8H), 1.23–1.15 (m, 40H), 0.85–0.80 (m, 20H). HRMS (for  $[\text{M}]^+$ ) calcd.: 1100.65119; found: 1100.64015.

**4,7-Bis[4-(*N*-(4-bromophenyl)-*N*-(4-methylphenyl)amino)phenyl]-5,6-diamino-2,1,3-benzothiadiazole (12)**

A solution of tetrabutylammonium tribromide (0.96 g, 2.0 mmol) and 4,7-bis[4-(*N*-phenyl-*N*-(4-methylphenyl)amino)phenyl]-5,6-diamino-2,1,3-benzothiadiazole (11) (0.61 g, 9.0 mmol) in freshly distilled dichloromethane (45 mL) was stirred at room temperature for 3 h. The precipitates were filtrated and washed with dichloromethane. The solid was dried under vacuum to give the product as orange solid (0.55 g, 73%).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.43 (d, 4H,  $J = 8.3$  Hz), 7.34 (d, 4H,  $J = 8.7$  Hz), 7.19 (d, 4H,  $J = 8.5$  Hz), 7.12 (d, 4H,  $J = 8.6$  Hz), 7.08 (d, 4H,  $J = 9.1$  Hz), 7.04 (d, 4H,  $J = 8.7$  Hz), 2.33 (s, 6H).

**Polymer P1**

To a mixture of 9,9-dioctyl-2,7-bis(trimethyleneboronate)-fluorene (13) (0.279 g, 0.500 mmol) and 4,7-bis[4-(*N*-(4-bromophenyl)-*N*-(4-methylphenyl)amino)phenyl]-5,6-diamino-2,1,3-benzothiadiazole (12) (0.419 g, 0.500 mmol) was added Aliquat 336 (0.120 g),  $\text{Pd}(\text{PPh}_3)_4$  (7.9 mg, 0.007 mmol), degassed toluene (7 mL), and aqueous 2 mol/L potassium carbonate (3 mL) under a dry argon atmosphere. The mixture was heated to  $95^{\circ}\text{C}$  and stirred in the dark for 48 h. After cooling, the mixture was poured into methanol. The precipitate was collected by filtration and then dissolved in dichloromethane. The solution was washed with water, dried with anhydrous  $\text{MgSO}_4$ , and then concentrated to an appropriate volume. The fiber-like brown polymer (0.500 g, 94%) was obtained by pouring the concentrated solution into methanol.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 7.74 (d, 2H,  $J = 7.9$  Hz), 7.61–7.55 (m, 8H), 7.47 (d, 4H,  $J = 8.7$  Hz), 7.29–7.25 (m, 8H), 7.20–7.13 (m, 8H), 2.36 (s, 6H), 2.00 (br, 4H), 1.20–1.00 (m, 20H), 0.80–0.75 (m, 10H).

**Polymer P2**

To a solution of polymer P1 (0.107 g, 0.1 mmol) in dry pyridine (10 mL) was added *N*-sulfinylaniline (0.5 mL, 4 mmol) and chlorotrimethylsilane (0.5 mL, 3.6 mmol) in argon atmosphere. The mixture was heated to  $80^{\circ}\text{C}$  and stirred overnight. After workup, excess chlorotrimethylsilane was distilled off. The solution was concentrated to 5 mL and poured into methanol. The fiber-like dark blue polymer P2 (98.0 mg, 89%) was collected by filtration, washed with ethanol, and dried under vacuum.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 8.20 (d, 4H,  $J = 8.5$  Hz), 7.75 (d, 2H,  $J = 7.4$  Hz), 7.63–7.56 (m, 8H), 7.34–7.16 (m, 16H), 2.37 (s, 6H), 2.06 (br, 4H), 1.06 (br, 20H), 0.80–0.75 (m, 10H).

## Results and discussion

### Design and synthesis of low-band-gap chromophores

#### Design concept and synthesis

The concept for designing low-band-gap chromophores is based on the use of a strong electron acceptor, namely, benzobisthiadiazole, and electron donors that are linked through a  $\pi$ -conjugated spacer. In particular, the D- $\pi$ -A- $\pi$ -D type of chromophores, such as compounds 1–3 (Fig. 1), previously reported by our group,<sup>12a</sup> is the focal point of design

**Scheme 1.** Synthetic route to intermediates and chromophores **4** and **5**. Reagents and conditions: (i)  $\text{Pd}(\text{PPh}_3)_4$ ,  $\text{Na}_2\text{CO}_3$  (aq., 1 mol/L), toluene,  $110^\circ\text{C}$ , 60 h; (ii) *N*-lithium-2,2,6,6-tetramethylpiperidine,  $-70^\circ\text{C}$ ,  $(\text{Bu})_3\text{SnCl}$ , THF,  $-70^\circ\text{C}$  to room temperature; (iii)  $\text{Pd}(\text{PPh}_3)_4$ , toluene,  $110^\circ\text{C}$ , 36 h; (iv)  $200^\circ\text{C}$ , 30 min,  $10^{-5}$  torr.

and study. With the same acceptor, the absorption wavelength of chromophores **1–3** varies according to the strength of donors and the nature of spacer. Between compounds **2** and **3**, the difference in band-gap levels is attributed to the different donors. However, a larger difference in the band-gap levels or absorption ( $\Delta\lambda_{\text{max}} = 157$  nm) between chromophores **1** and **2** is clearly due to the presence of different  $\pi$ -spacers (thiophene vs. benzene or nil). Therefore, the  $\pi$ -spacer or linking moiety in the D- $\pi$ -A- $\pi$ -D type of chromophores can play an important role in band-gap tuning, which may lead to further band-gap lowering or spectral red shift relative to chromophores **1–3**. Accordingly, in this work, pyrrole was introduced as  $\pi$ -spacer in a new chromophore **5** (Fig. 1) to study the scope and limitations of the  $\pi$ -spacer regarding the band-gap tuning. Any additional contribution to a better D-A interaction or lowering the LUMO level of the acceptor unit that may be brought by the use of a new  $\pi$ -spacer is likely to result in a further red shift in absorption in reference to the structurally analogous chromophore **3** ( $\lambda_{\text{max}} = 848$  nm).

Scheme 1 outlines the synthetic route to compounds **4** and **5**. Compound **4** was readily synthesized by the Stille coupling reaction of dibromo-BBTD **10** with tributyltin compounds **9** derived from the donor. It should be noted that aqueous sodium carbonate solution was not added, as required to suppress the C-Sn bond cleavage in the Stille coupling reaction,<sup>18</sup> due to instability of the BBTD group in alkaline solution, which caused a rather poor yield (20%) for compound **4**. Removal of the *tert*-butoxycarbonyl (*t*-Boc) protecting group in **4** by heating under reduced pressure afforded the target compound **5** with high yield.

#### Optical and electrochemical properties

The absorption and photoluminescence of compounds **4** and **5** in toluene are shown in Fig. 2, and the data are presented in Table 1. As for compounds **1–3**, compound **5** has mainly two absorption bands. The peaks from 300 to 500 nm are attributed to the  $\pi$ - $\pi^*$  transition and the possible  $n$ - $\pi^*$  transition of the conjugated aromatic segments, and those at longer wavelengths are due to the intramolecular charge transfer (ICT) transitions between the donor and acceptor. Compared with compound **3**, the maximum absorption of compound **4** is blue-shifted. Since pyrrole is more electron-donating than thiophene, the observed blue

**Fig. 2.** Normalized absorption ( $10^{-5}$  mol/L) and fluorescence emission ( $10^{-4}$  mol/L) spectra of compounds **4** and **5** in toluene.

shift is mainly due to non-planarity between the BBTD and the pyrrole induced by *t*-Boc group. After removal of the *t*-Boc group, both the maximum absorption and emission wavelengths were red-shifted dramatically (about 183 and 121 nm, respectively; Fig. 2) relative to its precursor **4**. The pyrrole spacer and the neighboring BBTD core in compound **5** are expected to be completely coplanar by virtue of hydrogen bonding (Fig. 3), which should facilitate the charge transfer from donor to acceptor, and thus lowers the band-gap level. This intramolecular hydrogen bonding also contributes to altering the energy level of the BBTD acceptor by sharing or removing partial electrons on the nitrogen in BBTD. In the  $^1\text{H}$  NMR spectra of compound **5**, the pyrrole N-H signal is found at the low field ( $\delta = 11.68$ , Fig. 4), which is an indication for strong intramolecular hydrogen bonding.<sup>19</sup>

Similar to the effect of hydrogen-bonding interaction, addition of Lewis acids should also alter the band gap as a result of binding with the nitrogen in BBTD. Figure 5 shows the absorption spectra of compound **3** and a mixture of **3** with excess  $\text{BF}_3$ . The spectrum of compound **3** exhibits an absorption maximum ( $\lambda_{\text{max}}$ ) at 834 nm with an onset ( $\lambda_{\text{onset}}$ ) at 958 nm. Upon addition of an excess of  $\text{BF}_3$ , a color change took place immediately, going from yellowish green

<sup>a</sup>Measured in toluene with a concentration of  $10^{-5}$  mol/L.<sup>b</sup>Measured in toluene with a concentration of  $10^{-4}$  mol/L. Excitation wavelengths for **1–4** are at their maximum absorption wavelengths, and at 980 nm for **5**.<sup>c</sup>Fluorescence quantum yield measured relative to IR-125 ( $\Phi_f = 0.13$  in DMSO).<sup>d</sup>Calculated from the formula,  $E_{(\text{HOMO})} = -(E_{\text{ox}} + 4.34)$  (eV),  $E_{(\text{LUMO})} = -(E_{\text{red}} + 4.34)$  (eV).<sup>e</sup>See ref. 12a.**Fig. 3.** Hydrogen bonding in compound **5** and the **3**-BF<sub>3</sub> adduct.**Fig. 4.** <sup>1</sup>H NMR spectra (400 MHz, *o*-C<sub>6</sub>D<sub>4</sub>Cl<sub>2</sub>, 403 K) of compounds **4** and **5**.

to dark blue visually. Consequently, the  $\lambda_{\text{max}}$  and  $\lambda_{\text{onset}}$  of compound **3**-BF<sub>3</sub> adduct appeared at 1260 nm and 1580 nm, being red-shifted by 426 nm and 622 nm, respectively. According to the confirmed structure of the complex of benzothiadiazole derivatives with Lewis acid,<sup>14</sup> in the **3**-BF<sub>3</sub> adduct, BF<sub>3</sub> should bind to the nitrogen of each thia-

**Fig. 5.** Normalized absorption spectra of compound **3** ( $10^{-4}$  mol/L in THF) and a mixture of **3** with excess BF<sub>3</sub>.

diazole rings (Fig. 3), effectively pulling the electron density away from the BBTD unit, enhancing the ICT transition between peripheral donor and acceptor core, and thus leading to a significant bathochromic shift in absorption. Additionally, there is a synergistic lowering of the absolute energies of the two frontier molecular orbitals, thereby giving rise to the narrower band gap.

Considering the potential application of the D- $\pi$ -A- $\pi$ -D type of low-band-gap chromophores in photovoltaic cells, compound **5** was blended with PCBM and cast into films. Figure 6 shows the absorption spectrum of the blend film (1:1, w/w; solid line) and displays mainly three peaks centered at 333, 428, and 1046 nm, respectively. Compared with the absorption spectrum of **5**, the peak at 333 nm increases, which was due to the absorption of PCBM. Additionally, the ICT transition peak becomes broad and is red-shifted (about 26 nm). Thus, there is additional charge transfer interaction in the blend, which is likely due to the one between the acceptor and PCBM and similar to the effect of adding a Lewis acid to the chromophores.

The electrochemical properties of compounds **4** and **5** were investigated by CV (Fig. 7), and the data are summarized in Table 1. They are all electrochemically active, having two reversible oxidation and two reduction waves in the cyclic voltammogram, respectively. The first reduction potential is from the reduction of the BBTD core, and the first

**Fig. 6.** Absorption spectra of the blend film of compound **5** with PCBM (1:1, w/w; solid line) and compound **5**.

**Fig. 7.** Cyclic voltammograms of compounds **4** and **5** (1 mmol/L concentration).

oxidation wave is attributed to the oxidation of the donors and  $\pi$ -spacers. For chromophore **5**, the first oxidation potential increases significantly (about 0.2 eV); however, the reduction potentials keep nearly unchanged. The HOMO and LUMO levels of compounds **4** and **5** were calculated according to empirical equations of  $E_{(\text{HOMO})} = -(E_{\text{ox}} + 4.34)$  (eV) and  $E_{(\text{LUMO})} = -(E_{\text{red}} + 4.34)$  (eV), respectively. As shown, compound **5** has the band gap of 0.86 eV and absorbs at the longest wavelength (1020 nm) among chromophores **1–5**.

#### Photovoltaic property

Organic BHJ photovoltaic cells were fabricated using compound **5** as electron donor and PCBM as electron acceptor, with a structure configuration of ITO/PEDOT:PSS/**5**:PCBM/Al. Typical performance data of the devices are listed in Table 2, and the corresponding current–voltage curves are illustrated in Fig. 8. Without optimization, the device gave power conversion efficiency (PCE) of 0.01% with an open-circuit voltage ( $V_{\text{oc}}$ ) of 0.27 V and a short-circuit

**Table 2.** Performance of photovoltaic device under illumination of 100 mW/cm<sup>2</sup> white light.

Material	$V_{\text{oc}}$ (V)	$J_{\text{sc}}$ (mA/cm <sup>2</sup> )	FF	PCE (%)
<b>5</b> :PCBM (1:1, w/w)	0.27	0.13	0.28	0.01

**Fig. 8.** Current density–voltage curves of solar-cell devices in dark and under illumination of 100 mW/cm<sup>2</sup> white light. Inset: Proposed energy-level scheme of compound **5** and PCBM.

current ( $J_{\text{sc}}$ ) of 0.13 mA/cm<sup>2</sup> under AM 1.5 solar simulator (100 mW/cm<sup>2</sup>). Accordingly, a fill factor (FF) was calculated to be 0.28. For BHJ devices,  $V_{\text{oc}}$  is linearly correlated with the energy difference of the HOMO of the donor and the LUMO of the acceptor. Our result (0.27 V) coincides well with the empirical calculation.<sup>20</sup> The relatively low  $V_{\text{oc}}$  is likely due to the high HOMO level of the donor (Fig. 8, inset). The  $J_{\text{sc}}$  is determined by the amount of absorbed light and the internal conversion.<sup>21</sup> The absorption profile of the active layer shows a quiet mismatch to the solar photon flux, thus leading to the quite low  $J_{\text{sc}}$ . Nevertheless, the device based on low-band-gap chromophore **5** is still comparable well to some other solution-processed molecular BHJ solar cells.

#### Design and synthesis of low-band-gap polymer

The band gap of polymers can be reduced by incorporating alternating donor and acceptor moieties in the polymer main chain. BBTD is a strong electron acceptor and can be used by design to construct many different kinds of low-band-gap polymers. However, because the BBTD unit is unstable in alkaline solution and readily attacked by nucleophiles (e.g., OH<sup>−</sup>), the polymers containing the BBTD moiety are often difficult to be synthesized by the Suzuki coupling reaction or other methods that need to use a base. Up to now, several polymers containing BBTD have been reported,<sup>22</sup> and are mainly synthesized by the Stille coupling reaction or electrochemical polymerization. However, the required tributylstannane monomers for the Stille polymerization are toxic and difficult to purify, and electrochemical polymerization is difficult to produce high-molecular-weight soluble polymers. Therefore, it remains a challenge to synthesize high-molecular-weight low-band-gap polymers containing BBTD unit.

**Scheme 2.** Synthetic routes to polymers **P1** and **P2**. Reagents and conditions: (i) Bu<sub>4</sub>NBr<sub>3</sub>, CH<sub>2</sub>Cl<sub>2</sub>, 25 °C, 3 h; (ii) Pd(PPh<sub>3</sub>)<sub>4</sub>, K<sub>2</sub>CO<sub>3</sub> (aq., 2 mol/L), toluene, Aliquat 336, 95 °C, 24 h; (iii) PhNSO, TMSCl, pyridine, 80 °C, overnight.

**Fig. 9.** <sup>1</sup>H NMR spectra (300 MHz, CDCl<sub>3</sub>) of polymers **P1** and **P2**.

In this work, we intend to explore a precursor approach to introduction of the BBTD unit in polymers. The feasibility of such a precursor approach is based on the fact that the monomers containing the 1,2-diaminophenylene group can be utilized in the Suzuki coupling reaction to produce high-molecular-weight polymers,<sup>23</sup> and the 1,2-diaminophenylene group can be converted into various electron-deficient groups (e.g., quinoxaline and benzothiadiazole).<sup>24</sup> Therefore, we demonstrated this precursor strategy by making the precursor polymer **P1** and subsequently converting to the BBTD-containing polymer **P2** (Scheme 2). The monomer **12** was prepared by bromination of compound **11** with tetrabutylammonium tribromide. Because of the presence of the

**Fig. 10.** IR spectra of polymers **P1** and **P2**.

methyl group on one of the two phenyl groups, bromination only takes place at one of the phenyl rings of the diphenylamino moiety in **11**. Using the Suzuki cross-coupling reaction, polymerization of monomers **12** and **13** gave the precursor polymer **P1**. By simple treatment of **P1** with *N*-sulfinylaniline and chlorotrimethylsilane in dry pyridine, the target low-band-gap polymer **P2** was readily obtained with high yield (89%).

#### Structural characterization

The chemical structures of polymers **P1** and **P2** were fully characterized by NMR and IR spectroscopic methods. Fig-

<sup>a</sup>Determined by GPC.<sup>b</sup>Measured in chlorobenzene, excitation wavelengths for **P1** and **P2** are at their maximum absorption wavelengths.<sup>c</sup>Optical band gap, estimated from the onset wavelength of optical absorption spectra.<sup>d</sup>Shoulder peak.

ure 9a shows the  $^1\text{H}$  NMR spectrum of polymer **P1**. A peak at  $\delta$  4.18 ppm is assigned to the amine hydrogen and the aliphatic and aromatic hydrogens are observed at  $\delta$  0.6–2.5 and  $\delta$  7.1–7.7 ppm, respectively. After conversion of the diamine into the thiadiazole group, the peak at  $\delta$  4.18 disappeared (Fig. 9b), indicating that the transformation reaction was successful and the amino group was converted completely. A new peak at  $\delta$  8.20 is assigned to the hydrogens in the phenylene that is adjacent to the BBTD core ( $\text{H}^a$  shown in Scheme 2). Because of the strong electron-withdrawing BBTD unit, the signal of  $\text{H}^a$  shifted to a lower field. The observed chemical shift ( $\delta$  8.20) coincides well with that of a small compound with similar structure ( $\delta$  8.18),<sup>12b</sup> further demonstrating the formation of the BBTD unit in **P2**. The IR spectrum of polymer **P1** (Fig. 10) shows two distinct  $\nu(\text{NH})$  bands at 3442 and 3357  $\text{cm}^{-1}$ , which, as expected, are absent in the spectrum of **P2** (Fig. 10).

The molecular weights were estimated by gel-permeation chromatography (THF as eluent) relative to polystyrene standards. Polymer **P1** shows high molecular weight with the number-average molecular weight ( $M_n$ ) of 56 000 g/mol and a polydispersity index of 3.2 (Table 3). The apparent  $M_n$  of **P2** was found to be only 28 000 g/mol, although it should be the same or similar to that of **P1**, which was mainly due to poor solubility of the high-molecular-weight fraction of **P2** in THF.

### Optical property

The absorption and photoluminescence of polymers **P1** and **P2** were recorded in chlorobenzene. Without a strong acceptor or strong intramolecular charge transfer, **P1** absorbs in the visible spectral region with a maximum ( $\lambda_{\text{max}}$ ) at 440 nm and emits at 558 nm. In comparison, owing to the presence of the BBTD acceptor, the absorption and emission maxima of **P2** were red-shifted dramatically to 749 and 980 nm, respectively (Table 3 and Fig. 11). Similar to chromophores **1–5**, the absorption bands of polymer **P2** mainly have two parts. The peaks in the higher energy region are attributed to the  $\pi$ – $\pi^*$  and also possible  $n$ – $\pi^*$  transitions of the conjugated aromatic segments. The high molar extinction coefficient (Log  $\epsilon$  = 4.39) of the ICT band of **P2** is ideal for photovoltaic application. The optical band-gap levels of **P1** and **P2** were estimated from the onset wavelength ( $\lambda_{\text{onset}}$ ) of the optical absorption spectra to be 2.7 and 1.4 eV, respectively.

### Conclusions

A novel D– $\pi$ –A– $\pi$ –D type of low-band-gap (0.86 eV) chromophore **5** has been successfully designed and synthesized. The use of pyrrole as  $\pi$ -spacer is proven to be effective and beneficial in further lowering the band-gap level of

**Fig. 11.** Absorption and fluorescence emission of polymer **P2** in chlorobenzene.

and beneficial in further lowering the band-gap level of the D– $\pi$ –A– $\pi$ –D chromophores. Compared with the thiophene spacer (in compound **3**), the pyrrole spacer provides the intramolecular hydrogen bonding to the BBTD acceptor, which pushes the absorption maximum and fluorescence emission of chromophore **5** into the near-infrared spectral region with a red shift of 172 and 158 nm, respectively. A precursor approach to the introduction of the alkaline-labile BBTD acceptor into the polymer backbone has been demonstrated by successful synthesis of low-band-gap polymer **P2**. The same strategy can be in principle applied to the synthesis of a series of low-band-gap polymers with the structures and properties similar to chromophores **1–5**.

# NMR imaging study of cross-linked high-amylose starch tablets — The effect of drug loading

Y.J. Wang, F. Ravenelle, and X.X. Zhu

**Abstract:** NMR imaging techniques were used to study the effect of drug loading in cross-linked high-amylose starch tablets. The tablets contained acetaminophen with loading levels from 10 to 40 wt%. The absolute amount of the drug released increased with a larger amount of drug loading, but the percentages of drug released had only minor differences for the different tablets, probably due to the rapid formation of a gel layer for all the tablets, which slowed down drug release significantly. The release of drugs from the tablets in all cases is dominated by a diffusion mechanism before the disappearance of the dry core of the tablets. Radial and axial swelling and water uptake were found to increase with the amount of drug loading. The diffusion rates of water were comparable at the initial stage for all the tablets with different loadings, but became faster later for the tablets with higher amounts of drug loading as water diffusion may be facilitated by the hydrophilicity of the drug.

**Key words:** NMR imaging, diffusion coefficient, high-amylose starch, drug loading.

**Résumé :** Les techniques d'imagerie RMN ont été utilisées pour étudier l'effet de la charge en médicament dans les tablettes d'amidon réticulés riche en amylose. Les tablettes contenaient un médicament, l'acétaminophène, de 10 à 40 pour-cent en poids. La quantité absolue du médicament libéré augmente avec une augmentation de la charge en médicament, mais les pourcentages de médicament libéré n'ont que des différences mineures pour les différentes tablettes, probablement à cause d'une formation rapide d'une couche de gel autour de toutes les tablettes qui ralentit d'une façon significative la libération du médicament. Les libérations de médicaments sont dominées dans tous les cas par un mécanisme de diffusion avant la disparition du cœur sec des tablettes. On a trouvé que les gonflements radiaux et axiaux ainsi que l'absorption d'eau augmentent avec une augmentation de la charge en médicament. Les vitesses de diffusion de l'eau dans la période initiale sont comparables pour toutes les tablettes comportant des charges différentes de médicament, mais plus tard elles deviennent plus rapides pour les tablettes portant une quantité plus élevée de médicament, probablement en raison du fait que la diffusion est peut-être facilitée par le caractère hydrophile du médicament.

**Mots-clés :** imagerie RMN, coefficient de diffusion, amidon à forte concentration d'amylose, charge en médicament.

## Introduction

Cross-linked high-amylose starch (CHAS) has been demonstrated to be an effective controlled release matrix.<sup>1-4</sup> Once the CHAS tablets are hydrated, a consistent gel layer is formed very rapidly around the tablet core, leading to retarded release of drugs.<sup>5</sup> The integrity of the CHAS tablets is sustained for over 48 h.<sup>6</sup> We have used NMR imaging to study the effects of tablet size, temperature, and drug loading on the tablet swelling and water diffusion.<sup>5-8</sup> The effect of moisture content on the swelling of high-amylose starch films was also studied by the use of NMR imaging by Russo et al.<sup>9</sup> In addition, the conversion from V-type (single helix) to B-type (double helices), which limits the swelling of starch, was also revealed by CP-MAS <sup>13</sup>C solid-state NMR spectroscopy.<sup>10</sup>

The drug release mechanism is classified into three cases:

diffusion mechanism, polymer relaxation mechanism, and a mechanism that lies between the two cases. It was found for ethyl cellulose tablets that drug release is controlled by a diffusion mechanism at a high loading of acetaminophen (APAP, 49.5 wt%), while the effect of the polymer relaxation becomes significant at a low loading (9.9 wt%).<sup>11</sup> In the case of poly(ethylene oxide) (PEO) tablets, the drug dissolution and diffusion through the swollen gel layer controlled the release at loading levels of 39% and 20%, respectively.<sup>12</sup> Previously, we have studied the release of two drugs, ciprofloxacin and acetaminophen, loaded at 10 wt% in CHAS.<sup>5</sup> The amount of drug loading may also have a significant effect on the amount released from the polymer tablets. APAP is an analgesic (pain reliever) and an antipyretic (fever reducer), which has been used as a probe to study controlled release properties of some matrices, including hydroxypropyl methyl cellulose (HPMC),<sup>13</sup>

**Fig. 1.** NMR images of CHAS tablets immersed in water at 37 °C for 1, 2, 5, 10, 15, and 20 h. The purple part at the bottom of images is the Teflon support.

HPMC-polyvinylpyrrolidone,<sup>14</sup> and high-amylose sodium carboxymethyl starch matrices.<sup>15</sup> We also chose APAP in this study with loadings of 10, 20, and 40 wt% in the CHAS tablets. In vitro drug release from the matrix tablets was determined and the results were correlated with swelling and water uptake of the tablets. The diffusion coefficients of water can be obtained from profile fitting and diffusion-weighted NMR images.

## Experimental

### Preparation of tablets

The polymer (CHAS) was made of chemically modified high-amylose starch (70% amylose), cross-linked with 0.075 wt% phosphorous oxychloride in a mild alkaline medium first and further functionalized with 6 wt% of propylene oxide followed by washing and drying. Gelatinization of the starch under 160 °C and 5.5 bar (1 bar = 100 kPa) was then conducted immediately prior to spray drying. An appropriate amount of granulated acetaminophen (Compap, MW 151 g/mol,  $R_h$  0.37 nm) and CHAS were mixed for 4 min. The blend was compressed to form tablets of 200 mg, each with a dimension of 9.0 mm × 3.0 mm. To achieve the target weight and thickness for the tablets, the press parameters were adjusted to 1330 kg/cm<sup>2</sup> for 10–20 wt% drug loadings and 785 kg/cm<sup>2</sup> for 40 wt% drug loading along the axial direction. Dosages with drug loadings of 10, 20, and 40 wt% were obtained.

### NMR imaging

All NMR imaging experiments were carried out at 37.0 °C on a Bruker Advance-400 NMR spectrometer operating at a frequency of 400.27 MHz for protons equipped with a microimaging probe having a 20 mm inner diameter. A standard spin-echo pulse sequence was used to obtain spin density images of the tablets in a 20 mm o.d. NMR tube containing 20 mL of distilled water. A slice of 0.5 mm in thickness was selected either perpendicular or parallel to the main magnetic field using a sinc-shaped pulse. Eight scans were accumulated to obtain 128 × 128 pixel images for a field of view of 2.0 cm, leading to an in-plane resolution of 156 μm. An echo time (TE) of 3 ms and a repetition time (TR) of 1 s were fixed leading to an acquisition time of about 17 min for each image.

Diffusion-weighted images were acquired by combining the spin-echo pulse sequence with the pulsed-gradient spin-echo (PGSE) pulse sequence developed by Stejskal and Tanner.<sup>16</sup> The diffusion time ( $\Delta$ ) and the length of the gradient pulse ( $\delta$ ) were 10 ms and 2 ms, respectively. The gradient strength varied from 5 to 100 G/cm.

### Solubility tests of CHAS

The CHAS powder (300 mg) was mixed with 20 mL distilled water in a 50 mL centrifuge tube, which was then placed in a shaking bath and agitated at 100 rpm and 37 °C for 30 min. The samples were centrifuged (4000 rpm, 1 h) and the supernatant was collected and dried at 70 °C for soluble fraction quantification. The test was performed in triplicate.

### Water uptake experiments

Water uptake studies were carried out in a water bath at 37 °C with mild agitation. Each tablet was immersed in 20 mL distilled water and the weight was measured in triplicate at predetermined time intervals. The percentage of mass uptake is defined as

$$[1] \quad S_t = \frac{M_t - M_0}{M_0} \times 100\%$$

where  $S_t$  is the water uptake in percentage,  $M_0$  and  $M_t$  are the initial weight of a tablet and its weight at time  $t$ , respectively.

### In vitro drug release tests

The tablets were placed individually in 900 mL of distilled water at 37 °C in a U.S.P. XXIV dissolution apparatus 2 (Distek Premiere 5100 dissolution system) equipped with a rotating paddle (100 rpm). The amount of drug released from the tablet in 24 h was determined spectrophotometrically (244 nm) at intervals of 30 min. The sampling liquid flowed back to the vessels. All tablets were tested in triplicate.

The fitting of the data from NMR imaging experiments and of the drug release tests was carried out with Microsoft Excel 2003 using the Newton method to minimize the sum of the squared errors. A summation of 30 roots of the Bessel function was used.

**Fig. 2.** (A) Mass uptake, (B) radial swelling, and (C) axial swelling of the CHAS tablets loaded with 10% ( $\square$ ), 20% ( $\circ$ ), and 40% ( $\nabla$ ) acetaminophen. Note that the mass uptake is the combined effect of the mass gain by the absorption of water and the mass loss by the release of the drug.

## Results and discussion

Figure 1 shows the NMR images of CHAS tablets acquired from 1 to 20 h in water at 37 °C. A gel layer formed quickly, within a few minutes after the tablets came into contact with water. All three images at 1 h clearly show the gel layer, the hydrated layer, and the dry core (with the lowest water signal). The formation of the gel layer is essential for the controlled release of the CHAS tablets. The apparent high water signal shown by the reddish periphery of the tablets is caused by the shorter longitudinal relaxation time,  $T_1$  (ca. 800 ms), of the hydrated layer compared with that of the free water (the green-bluish part, ca. 5 s). As the water front advanced towards the center, the dry core gradually diminished in dimension with immersion time. The effect of drug loading levels is visible on the images acquired at 5 h

**Fig. 3.** The water proton spin density profile (solid line) and the fit to eq. [2] (dashed line) of a CHAS tablet with 20% acetaminophen swelled in water at 37 °C for 30 min.

and onward. At 20 h, water is distributed almost evenly in the tablet of 40% APAP, while the tablet of 10% APAP is still far from reaching equilibrium (Fig. 1). NMR imaging experiments showed the tablets with 10% APAP loading reached equilibrium after 50 h. Therefore, the diffusion of water inside the tablets depends on the amount of APAP inside. It is to be noted that the movement of water into the tablet in the presence of the drug may not be strictly diffusional as the contribution of osmotic convection at the beginning stages of the process is present.

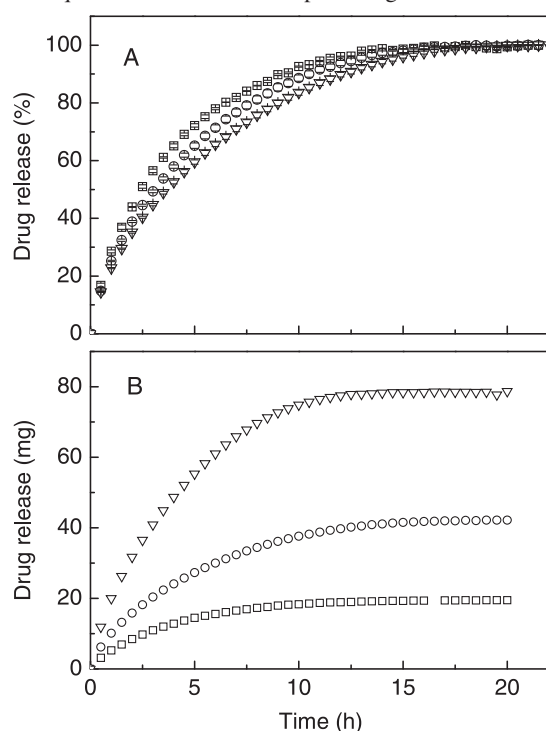

Figure 2A shows the mass uptake of tablets. Overall, the amount of mass change is contributed by the weight gain due to water diffused into the tablets and by the weight loss due to drug release from the tablets. The solubility of CHAS in water (2.6 mg/mL) is much lower than that of APAP (14.5 mg/mL, U.S.P. XXIV) so that the amount of dissolved CHAS can be neglected, but frequent manipulations may also cause weight loss and thus the mass uptake may be underestimated. In general, the tablets with a higher amount of drug loading had a lower gain in mass. The difference between the mass uptake at equilibrium is close to the difference between drug loading levels. The tablet with low drug loading had a faster increase in mass and reached an equilibrium earlier in time. Clearly, the tablets of 40% APAP undergo the highest weight loss due to drug release. In addition, the gel layers formed on these tablets are softer than the gel layers formed on tablets with lower drug loading levels, which is clearly visible, so these layers are less resistant to erosion.

Figures 2B and 2C show the radial and axial swelling of the tablets, respectively. The extent of axial swelling is almost three times that of the radial swelling for all the tablets, which has been observed for the CHAS tablets with and without the drug.<sup>5,6</sup> The higher axial swelling is caused by the compression along the axial direction during the preparation process. To prevent the floating and movement of the tablets in the liquid media, a piece of cotton ball was placed above the tablet to keep it in place during the NMR imaging experiments, which may have caused the relatively higher standard deviations of axial swellings in comparison to those of radial swellings. The tablets with 10% loading have the lowest swelling, while the other two swell at a similar rate and reached a similar size. The drug APAP has a

**Fig. 4.** Diffusion coefficients of water in the inner core of the tablets loaded with 10% (□), 20% (○), and 40% (▽) acetaminophen obtained by diffusion-weighted imaging. The values corresponding to the hydrated gels of the tablets are shown by closed symbols.**Fig. 5.** Release of drugs of CHAS tablets loaded with 10% (□), 20% (○), and 40% (▽) acetaminophen. The amount of the drug released is quite different while the percentage remained similar.

higher hydrophilicity than the matrix, which facilitates the penetration of water and enhances the overall swelling in both axial and radial directions.

The measurement of diffusion coefficients of water ( $D$ ) inside of the CHAS tablets may provide quantitative information on the effect of drug loading on the mobility of the polymer matrix. The initial diffusion coefficient of water can be obtained from the water proton image profiles, an example of which is shown in Fig. 3. At the initial stage of swelling, a tablet can be treated as an infinite cylinder in which water diffusion follows Fick's second law of diffusion.<sup>6,17</sup> The initial diffusion coefficients of water (shown in Table 1) can be obtained from fitting the data to

$$[2] \quad \frac{C}{C_0} = 1 - 2 \sum_{n=1}^{\infty} \frac{J_0(x\alpha_n/r)}{\alpha_n J_1(\alpha_n)} e^{-D \frac{\alpha_n^2}{r^2} t}$$

where  $C$  and  $C_0$  are the concentrations of water at distance  $x$  and at the surface of the cylinder, respectively,  $r$  is the radius of the cylinder,  $D$  the diffusion coefficient of water,  $t$  the immersion time,  $J_0$  the Bessel function of the first kind of the order 0,  $J_1$  the Bessel function of the first kind of the order 1, and  $\alpha_n$  the  $n$ th root of  $J_0 = 0$ .<sup>18–21</sup>

At the beginning of immersion, the assumption of infinite cylinder is applicable and good fits to eq. [2] can be easily obtained, as exemplified by Fig. 3. The initial diffusion coefficients of water in CHAS tablets are comparable for all three tablets with different drug loading levels along both directions (Table 1). But the cylinder assumption becomes invalid with the further advancement of water inside the tablets. Alternatively, the average diffusion coefficient ( $\bar{D}$ ) can be calculated from the mass uptake by substituting the  $k_d$  value obtained from eq. [3] into eq. [4]:<sup>17,22</sup>

$$[3] \quad \frac{M}{M_\infty} = k_d t^n$$

$$[4] \quad \bar{D} = \left( \frac{k_d \pi r}{4} \right)^2$$

where  $M$  and  $M_\infty$  are the amount of water penetrated in a tablet at time  $t$  and at equilibrium, respectively, and  $k_d$  is a parameter related to the diffusion.

Mass uptake could be obtained from either gravimetric analyses or the integration of water signals in NMR images. The tablets become fragile after immersion in water, and manipulations during the weighing process may introduce errors, yielding less consistent results than the integration of signals of the NMR images. The latter method may also be difficult to apply for the system here since eq. [3] becomes invalid at ca. 60% of water uptake,<sup>9,23</sup> which can be accomplished within 3 h for the tablets. The rapid water uptake

during the first 3 h and the long acquisition time of each image with good S/N ratio (17 min) add up to the difficulty of obtaining an accurate  $\bar{D}$ .

To overcome such difficulties, diffusion-weighted images were acquired from which average diffusion coefficients may be obtained. This method produces images weighted with the local characteristics of water diffusion. The diffusion coefficients of both the gel part and the core of the tablets with various drug loading levels are shown in Fig. 4. Reliable values of  $D$  cannot be obtained for an immersion time of less than 10 h when the signal attenuation is too low to be accurately detected even if a high gradient strength is applied. Figure 4 shows that the self-diffusion coefficients of water in the outer gel changes only slightly with time and the values are comparable for different tablets, while those in the inner part of the tablets changed with time and vary significantly with different drug loading levels. The signal in the core for the tablets with 40% drug loading increased faster than the tablets of lower loadings. The faster water diffusion in these tablets agrees well with the faster swelling of the tablets. Since APAP is more hydrophilic than the CHAS matrix, a higher loading of APAP facilitates the diffusion of water towards the core.

The percentage of drug released at 37 °C (Fig. 5A) shows only minor differences among the tablets of different drug loading levels, even though the absolute amount of the drug released are very different (Fig. 5B). A small initial burst could be attributed to the release of the drug at the surface and surface erosion of the matrix prior to the formation of a gel layer. The drug release curves can be fitted to the equation  $F = kt^n$ . The value of the power index,  $n$ , serves as a criterion to determine whether the release is controlled by a diffusion mechanism ( $n = 0.5$ ) or polymer relaxation mechanism ( $n = 1$ ). For the CHAS tablets with 10%, 20%, and 40% APAP, the  $n$  values are found to be 0.51, 0.55, and 0.56, respectively, indicating the drug release process is dominated by a diffusion mechanism in all the tablets.

The average diffusion coefficients ( $\bar{D}$ ) may be obtained by fitting the dissolution test results to the following equation:<sup>24</sup>

$$[5] \quad \frac{M(t)}{M(\infty)} = 1 - \frac{8}{l^2 \alpha^2} \sum_m \alpha_m^{-2} \exp(-D\alpha_m^2 t) \times \sum_n \beta_n^{-2} \exp(-D\beta_n^2 t)$$

where  $M(t)$  and  $M(\infty)$  are the amount of drug released at time  $t$  and infinite time, respectively,  $l$  is the half-thickness of the tablet,  $r$  the radius, and  $D$  the diffusion coefficient;  $\alpha$  and  $\beta$  are parameters defined in  $J_0(r\alpha) = 0$  and  $\beta_n = \frac{(2n+1)\pi}{2l}$ , where  $J_0$  is a zero-order Bessel function. The model is applicable to tablets of a shape ranging from a flat disk to a cylinder. It is important to note that the validity of the equation is based on the hypotheses that there is no dimension change of the tablets, no variation of the diffusion coefficient of water from the outer gel to inner core, and no gradual increase of diffusion coefficients of water in the tablets over time. For comparison purposes, the fitting was performed on two stages, yielding the “initial” average diffusion coefficient ( $\bar{D}_0$ ) using the initial dimension of the tablet ( $l$  and  $r$ ) during the drug release of 0%–60% (cor-

responding to an immersion time from 0 to 3.5 or 4 h, depending on the amount of drug loading) and the average diffusion coefficient at equilibrium ( $\bar{D}_\infty$ ) using the final dimension during the drug release of 80%–100% (corresponding to an immersion time period of ca. 7–18 h). The results are shown in Table 1. The assumption of a constant diffusion coefficient leads to lower  $\bar{D}_0$  values than those obtained by spin density profile fitting, but still in the same order of magnitude. Moreover, the values for 10%–40% drug loadings are similar to each other, which is consistent with the trend obtained from NMRI profile fitting. At equilibrium, the water diffuses much faster than at the beginning and thus  $\bar{D}_\infty$  is almost an order of magnitude higher than  $\bar{D}_0$ . The trend is also reflected by the diffusion-weighted imaging experiments (Fig. 4). The difference between the two series of diffusion coefficients may be explained by the low repetition time used during the diffusion-weighted imaging experiments. Strictly speaking, this model is not applicable because of the gradual size change of the tablets and the heterogeneous diffusion process involved.

## Conclusion

We have studied the effect of drug loading for the case of cross-linked high-amylose starch with APAP. In this case, the amount of drug released is higher with a higher level of drug loading, but the percentage of the drug released remained similar, making the prediction of drug release easier. This is likely due to the formation of a protective gel layer upon hydration of the tablets, which serves as a key factor in such a controlled release process. The NMR imaging results also show that the radial and axial swelling and water uptake of the CHAS tablets increased with the drug loading level. Diffusion of water is faster for the tablets of high drug loadings due to the hydrophilicity of APAP, especially at a later stage of the release process. The dissolution tests demonstrated that the release of APAP from the CHAS tablets followed a diffusion mechanism. The results of this study may be useful in the study of the controlled release of drugs from pharmaceutical tablets made of starch.

# Mixed micelles of poly(styrene-*b*-3-(methacryloylamino)propyltrimethylammonium chloride-*b*-ethylene oxide) and anionic amphiphiles in aqueous solutions

Jingjing Liu, Airi Yoneda, Dian Liu, Yuuichi Yokoyama, Shin-ichi Yusa, and Kenichi Nakashima

**Abstract:** The micelles of poly(styrene-*b*-3-(methacryloylamino)propyltrimethylammonium chloride-*b*-ethylene oxide) (PS-*b*-PMAPTAC-*b*-PEO) have been successfully prepared in aqueous solutions. The micelles have a PS core, cationic PMAPTAC shell, and PEO corona. Due to the short PS chain (degree of polymerization = 8), the formation of micelles is difficult at a low concentration, and the micelles are detected only at concentrations higher than 1 g L<sup>-1</sup>. The addition of anionic amphiphiles, such as sodium dodecyl sulfate (SDS) and poly(methacrylic acid) (PMAA), induces the formation of mixed micelles at a low concentration level of the polymer (~0.005 g L<sup>-1</sup>). This can be ascribed to insolubilization of the cationic PMAPTAC block due to charge neutralization by the anionic amphiphiles. The binding of SDS or PMAA to the PMAPTAC block is confirmed by zeta-potential measurements. The mixed micelles are characterized by dynamic light scattering (DLS), scanning electron microscopy (SEM), and fluorescence measurements. Based on DLS measurements, it is revealed that the hydrodynamic diameter of the mixed micelles falls in the range of 120–130 nm. SEM measurements provided clear pictures of mixed micelles with a spherical morphology. The kinetics of exchange of organic dyes between the micelle particles was investigated by fluorescence techniques. The result indicates that the exchange of the dyes between the micelle particles takes place within a time scale of seconds.

**Key words:** polymeric micelles, amphiphilic ABC triblock copolymer, mixed micelles, sodium dodecyl sulfate (SDS), poly(methacrylic acid) (PMAA).

**Résumé :** Opérant en solutions aqueuses, on a préparé avec succès des micelles de poly(styrène- chlorure de *b*-3-(méthacryloylamino)propyltriméthylammonium- *b*-oxyde d'éthylène) (PS-*b*-CPMAPTA-*b*-POE). Les micelles comportent un squelette de polyéthylène (PS), une coquille cationique de chlorure de polyméthacryloylaminopropyltriméthylammonium (CPMAPTA) et une couronne de polyoxyde d'éthylène (POE). En raison de la courte longueur de la chaise de polystyrène (degré de polymérisation = 8), la formation de micelles est difficile à faible concentration et les micelles ne peuvent être détectées qu'à des concentrations supérieures à 1 g L<sup>-1</sup>. L'addition d'amphiphiles anioniques, tel le dodécylsulfate de sodium (DSS) et l'acide poly(méthacrylique) (APMA), induisent la formation de micelles mixtes à des niveaux de concentration faible de polymère (environ 0.005 g L<sup>-1</sup>). Ce comportement peut être attribué à l'insolubilisation du bloc cationique de chlorure de polyméthacryloylaminopropyltriméthylammonium (CPMAPTA) provoquée par la neutralisation de la charge par les amphiphiles anioniques. La fixation du DSS ou de l'acide poly(méthacrylique) sur le bloc CPMAPTA est confirmée par des mesures de potentiel zêta. Les micelles mixtes ont été caractérisées par des mesures de diffraction dynamique de la lumière (DDL), de microscopie électronique à balayage (MEB) et de fluorescence. Sur la base de mesure de diffraction dynamique de la lumière, on a pu établir que le diamètre hydrodynamique des micelles mixtes se situe entre 120 et 130 nm. Les mesures de microscopie électronique à balayage permettent d'établir clairement que les micelles mixtes possèdent une morphologie sphérique. On a étudié les cinétiques d'échange de colorants organiques entre les particules de micelles par les techniques de fluorescence. Les résultats indiquent que l'échange des colorants entre les particules de micelles se fait sur une échelle de temps de secondes.

## Introduction

The synthesis of nanoparticles with a unique size and shape finds potential applications in areas such as optics, electronics, catalysis, and storage devices. For their synthesis, templates are often indispensable and it is an important issue to stabilize these nanoparticles or to arrange them into superstructures. For this purpose, amphiphilic block copolymers with hydrophilic and hydrophobic blocks turned out to be advantageous as each block performs different functions.<sup>1–4</sup> In most cases, the block copolymers are dissolved in a selective solvent that is poor for one block and good for the other block(s), which results in spherical micelles with a core-shell or multilayer structure.<sup>5</sup>

Very recently, core-shell-corona micelles from ABC triblock copolymers in aqueous solutions have attracted much attention. This type of micelle consists of a hydrophobic dense core surrounded by a hydrophilic shell, and an outer hydrophilic corona, which protects the micelles stability in an aqueous environment.<sup>6–9</sup> A typical example of a well-defined core-shell-corona micelle is the micelle of poly(styrene-*b*-2-vinylpyridine-*b*-ethylene oxide) (PS-*b*-P2VP-*b*-PEO) triblock copolymer, which has a PS core, P2VP shell, and PEO corona in aqueous solutions.<sup>10,11</sup> It was found that the micelles undergo a pH-sensitive morphological change from shrunken to extended spheres as the pH of the micellar solution is lowered below 5. This is due to the protonation of the P2VP block at a pH lower than 5, which causes an electrostatic repulsion between the protonated P2VP chains. Such a morphological change was also induced when the positive charge of the protonated P2VP was cancelled by the negative additives including dodecyl sulfate, dextran sulfate, and tungstate.<sup>12–15</sup>

It is important to note that the P2VP shell in the micelle of PS-*b*-P2VP-*b*-PEO is ionized only in a limited pH range, which restricts its potential applications in diverse material synthesis.<sup>16,17</sup> To overcome this difficulty, we synthesized a new ABC triblock copolymer, poly(styrene-*b*-3-(methacryloylamino)propyltrimethylammonium chloride-*b*-ethylene oxide) (PS-*b*-PMAPTAC-*b*-PEO) by a reversible addition-fragmentation chain transfer (RAFT) controlled radical polymerization.<sup>18</sup> We confirmed the formation of core-shell-corona micelles of PS-*b*-PMAPTAC-*b*-PEO in aqueous solutions.<sup>18</sup> The central PMAPTAC block is ionized over a wide pH range in contrast to the P2VP block, which is important when we employ these micelles as nanoreactors. The reactants can be incorporated into the PMAPTAC shell of the PS-*b*-PMAPTAC-*b*-PEO micelles at almost any pH in contrast to the P2VP shell of the PS-*b*-P2VP-*b*-PEO micelles.

In our previous study,<sup>18</sup> the micelles of PS-*b*-PMAPTAC-*b*-PEO with a longer PS chain (degree of polymerization, DP = 80) were already investigated in aqueous solutions. We now report the studies of micelles of the PS-*b*-PMAP-

TAC-*b*-PEO triblock copolymer with a short PS chain (DP = 8, Scheme 1). With a short PS chain, the formation of micelles is often quite difficult at low concentrations, and therefore the mixed micelle formation was also investigated in the presence of counter ions, such as sodium dodecyl sulfate (SDS) and poly(methacrylic acid) (PMAA). The counter ions with a negative charge are expected not only to stabilize the micelles through electrostatic binding with a positively charged PMAPTAC shell, but also to offer some interesting morphological changes to the micelles. Therefore, some new functional mixed micelles were also expected from these molecular self-assemblies. The micelles of the neat triblock copolymer and its mixed micelles were characterized by various techniques including dynamic light scattering (DLS), electrophoretic light scattering (ELS), scanning electron microscopy (SEM), and fluorescence spectroscopy.

## Experimental

### Chemicals

(3-(Methacryloylamino)propyl)trimethylammonium chloride (MAPTAC) (50 wt% in water) from Sigma-Aldrich was passed through an inhibitor-remover column. 4,4'-Azobis(4-cyanopentanoic acid) (V-501) (98%) from Wako Pure Chemicals Industries, Ltd. (Wako) was used as received without further purification. 2,2'-Azobis(isobutyronitrile) (AIBN) (98%) from Wako was recrystallized from methanol. The styrene was washed with an aqueous alkaline solution and distilled from calcium hydride under reduced pressure. The *N,N*-dimethylformamide (DMF) was dried over 4 Å molecular sieves and distilled under reduced pressure. The methanol was dried over 4 Å molecular sieves and distilled. Pyrene (Sigma-Aldrich), titan yellow (TY, Wako), fluorescein (FL, Sigma-Aldrich), and SDS (Wako) were used without further purification. The PMAA homopolymer (Scientific Polymer Products, Inc.) was used as supplied. The molecular weight of PMAA is 15 000.

### Synthesis of PS-*b*-PMAPTAC-*b*-PEO

The poly(ethylene oxide) (PEO) based chain transfer agent (PEO-CTA) was synthesized according to the method reported by McCormick and co-workers.<sup>19</sup> The diblock copolymer, PEO-*b*-PMAPTAC, was synthesized via RAFT radical polymerization as previously reported.<sup>20</sup> The molecular weight distribution ( $M_w/M_n$ ) value determined by gel-permeation chromatography (GPC) was 1.02. The number-average degree of polymerization (DP) for the PEO and PMAPTAC blocks were estimated to be 47 and 106, respectively. A procedure for the synthesis of the triblock copolymer, PS-*b*-PMAPTAC-*b*-PEO is as follows: Styrene (525 mg, 5.04 mmol), 2,2'-azobis(isobutyronitrile) (3.30 mg, 0.02 mmol), and PEO-*b*-PMAPTAC (1.22 g, 0.05 mmol) were dissolved in methanol (105 mL). The mixture was de-

**Scheme 1.** The structure of PS-*b*-PMAPTAC-*b*-PEO employed in this study.

gassed by purging with Ar gas for 30 min. The polymerization was carried out at 60 °C for 24 h. The polymerization mixture was then poured into a large excess of ethyl acetate to precipitate the resulting polymer. The polymer was purified by reprecipitating from dimethyl sulfoxide (DMSO) into a large excess of ethyl acetate. The obtained triblock copolymer was dried in a vacuum oven for 24 h (1.02 g). The DP values for the PS block and number-average molecular weight ( $M_n$ ) of PS-*b*-PMAPTAC-*b*-PEO were 8 and  $2.65 \times 10^4$ , respectively, as estimated by  $^1\text{H}$  NMR in DMSO- $d_6$  at 100 °C. The detailed characterization method was described in our previous report.<sup>18</sup>

#### Gel-permeation chromatographic measurements

The gel-permeation chromatographic (GPC) measurements of PS-*b*-PMAPTAC-*b*-PEO were performed using a refractive index (RI) detector equipped with a Shodex 10  $\mu\text{m}$  bead size GPC K-806 mol/L column (exclusion limit  $\sim 10^7$ ) working at 40 °C. DMSO containing 10 mmol L<sup>-1</sup> LiBr was used as the eluent at a flow rate of 0.5 mL min<sup>-1</sup>.

PS-*b*-PMAPTAC-*b*-PEO cannot be completely dissolved except in DMSO. Although the unimodal GPC elution curve was detected for PS-*b*-PMAPTAC-*b*-PEO, the molecular weight could not be determined due to the insolubility of standard polystyrene samples in the eluent.

#### Dynamic light scattering measurements

The dynamic light scattering (DLS) was measured by an Otsuka ELS-800 at a fixed 90° scattering angle. Correlation functions were analyzed by a histogram method and used to determine the diffusion coefficient ( $D$ ) of the nanocomplexes in the test sample. The hydrodynamic diameter ( $D_h$ ) was calculated from  $D$  using the Stokes–Einstein equation:

$$[1] \quad D_h = \frac{k_B T}{3\pi\eta D}$$

where  $k_B$  is the Boltzmann constant,  $T$  is the absolute temperature, and  $\eta$  is the solvent viscosity.

#### Light scattering measurements

The light scattering measurements were carried out using a JASCO FP-6500 fluorescence spectrophotometer. The samples were irradiated with 400 nm light from a 150 W

Xe-lamp and the scattered light was detected at a right angle configuration.

#### Zeta-potential measurements

The electrophoresis mobility (EPM) was measured with an Otsuka ELS-800. The zeta potential was calculated from the EPM using Smoluchowski's equation:

$$[2] \quad \mu_E = \frac{\zeta \epsilon}{\eta}$$

where  $\mu_E$  is EPM,  $\zeta$  is the zeta potential, and  $\epsilon$  is the solvent permittivity.

#### Fluorescence spectroscopy

The fluorescence spectra were recorded by a JASCO FP-6500 fluorescence spectrophotometer using right-angle geometry.

#### Scanning Electron Microscopy

SEM measurements were carried out using a Hitachi S-3000N electron microscope at an accelerating voltage of 15 kV. The samples were prepared by dropping the micelle solution onto a carbon seal (Nisshin Em Co.) attached to the glass plate, followed by drying in air for 24 h.

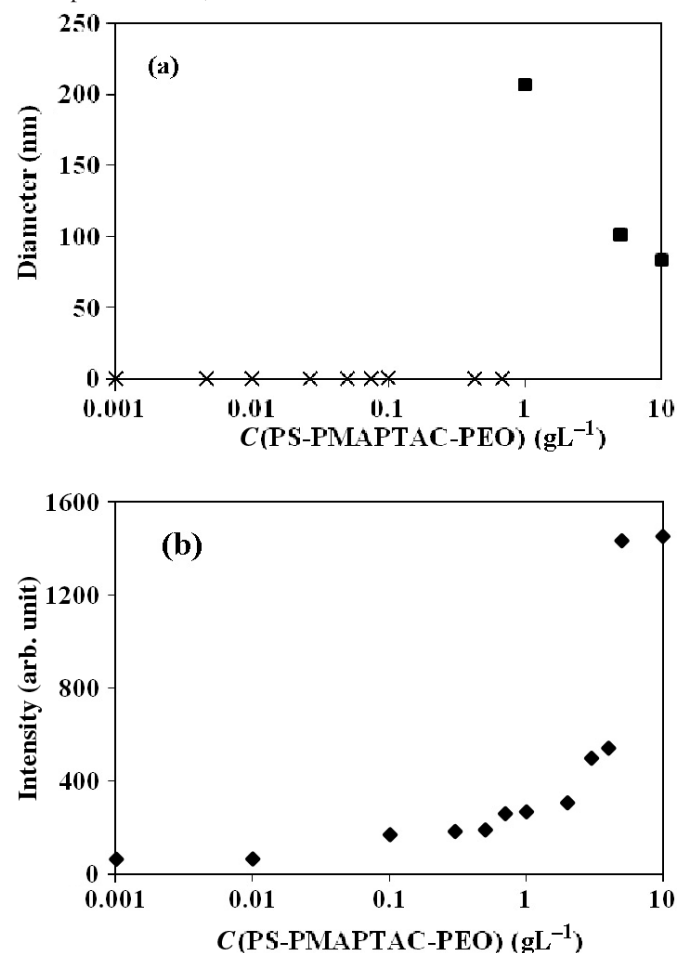

## Results and discussion

#### Micelle formation of PS-*b*-PMAPTAC-*b*-PEO

We first investigated the micellar behavior of PS-*b*-PMAPTAC-*b*-PEO in an aqueous solution without adding any amphiphiles. Figure 1a shows the hydrodynamic diameter ( $D_h$ ) of the micelles with respect to different polymer concentrations. For the polymer concentration ranging from 1 to 5 g L<sup>-1</sup>, reasonable hydrodynamic diameters were obtained by the DLS method and no reliable data were obtained for concentrations below 1 g L<sup>-1</sup>. The weak scattered light intensity is the reason for the lack of reliable data below 1 g L<sup>-1</sup> and it should be noted in Fig. 1a that the  $D_h$  values on the  $x$  axis do not correspond to 0 nm, but indicates that stable data were not obtained.

To determine the critical micelle concentration (cmc), an important parameter of polymeric micelles, we have carried out light scattering measurements because the sensitivity of the DLS measurement is not high enough to determine the

**Fig. 1.** (a) The hydrodynamic diameter ( $D_h$ ) of the micelles of PS-*b*-PMAPTAC-*b*-PEO as a function of the polymer concentration. (b) The light scattering intensity of micellar solutions of PS-*b*-PMAPTAC-*b*-PEO as a function of the polymer concentration. It should be noted that in Fig. 1a the  $D_h$  values on the  $x$  axis do not correspond to 0 nm, but indicate that stable data were not obtained.

cmc. It is noted from Fig. 1b that the light intensity increased with the increasing polymer concentration, and a drastic change occurred at 5  $\text{g L}^{-1}$ . However, this value does not seem to be the cmc, because this concentration is almost the same as the concentration at which the DLS intensity was significantly enhanced.

As we could not get a clear cmc value from the DLS or from light scattering method, we carried out fluorescence measurements using pyrene as a probe.<sup>21</sup> It is reported by Winnik and co-workers<sup>21</sup> that the intensity ratio (so-called  $I_1/I_3$  ratio) between the 0–0 band (band 1) and the  $b_{1g}$  vibronic band (band 3) in monomer fluorescence gives the upper bound of the cmc of a polymeric micelle, and the excitation spectra gives an exact cmc value. However, we could not observe any significant change in both the  $I_1/I_3$  ratio and excitation spectra (see Fig. S1 in the Supplementary data). One of the possible reasons may be that the core of the micelles is not hydrophobic enough to provide a nonpolar environment to the pyrene molecule because the PS chain is very short.

**Fig. 2.** The SEM image of the micelles of PS-*b*-PMAPTAC-*b*-PEO. The SEM sample was prepared at 25 °C from a polymer solution with a concentration of 1  $\text{g L}^{-1}$ .

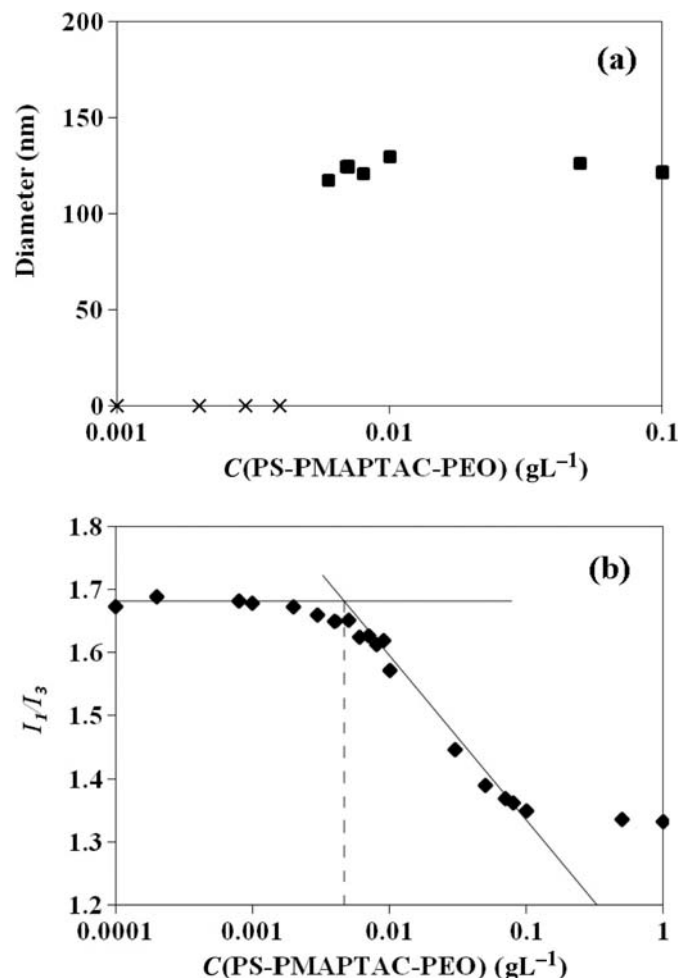

**Fig. 3.** Variation in the  $D_h$  of the micelles of PS-*b*-PMAPTAC-*b*-PEO vs temperature. All the measurements were made from a polymer solution at a concentration of 5  $\text{g L}^{-1}$ .

The micelle formation of the PS-*b*-PMAPTAC-*b*-PEO polymer was confirmed by SEM observations. Figure 2 shows the SEM image of the sample having spherical micelle particles. Thus, the SEM result provided concrete evidence for micelle formation of the present block copolymer and the estimated diameter from the SEM (around 100 nm) matches well with that obtained by DLS.

The temperature dependence of the hydrodynamic diameter of these polymeric micelles was also investigated and shown in Fig. 3. The diameter was measured by DLS at different temperatures starting from room temperature to 50 °C. Initially, the observed diameter was found to be approximately 100 nm until the temperature reached 35 °C. A further increase in temperature led to a sharp increase in the micelle's diameter up to 350 nm. The rapid increase in size may be due to the dehydration of the PEO block, which results in a secondary aggregation. The sharp increase in  $D_h$  around 35 °C may open some applications because this temperature is close to human body temperature.

**Fig. 4.** (a) The effect of concentration over the  $D_h$  for SDS/PS-*b*-PMAPTAC-*b*-PEO mixed micelles (ADN = 50%). (b) The effect of concentration over the  $I_1/I_3$  ratio of pyrene in SDS/PS-*b*-PMAPTAC-*b*-PEO solution (ADN = 50%). The fluorescence measurements were carried out at an excitation wavelength of 334 nm, and the excitation and emission band passes are 5 and 1 nm, respectively. It should be noted in Fig. 4a that the  $D_h$  values on the  $x$  axis do not correspond to 0 nm, but indicate that stable data were not obtained.

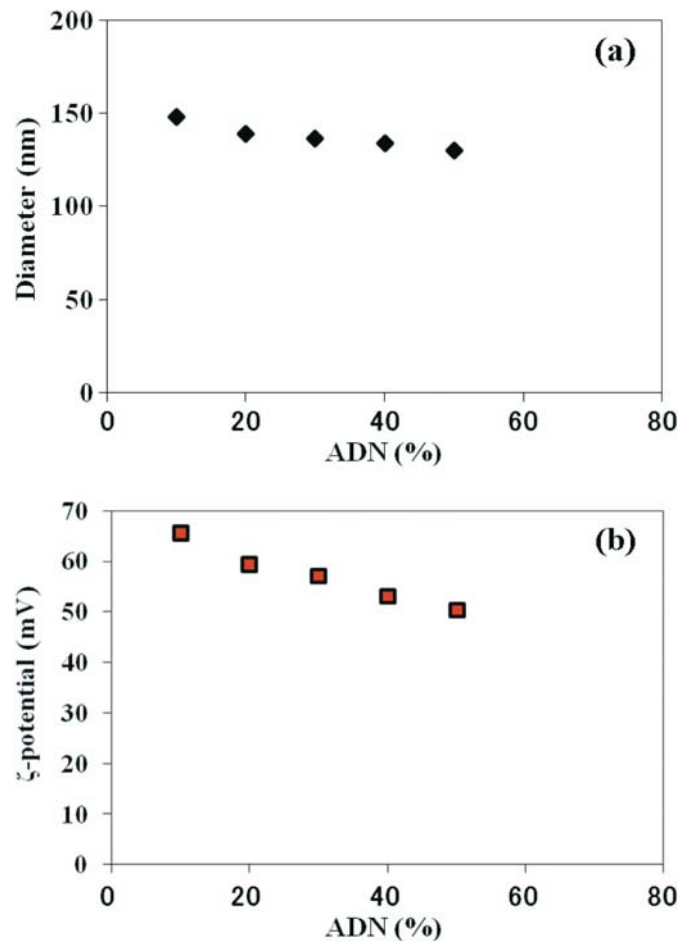

#### Mixed micelles of PS-*b*-PMAPTAC-*b*-PEO and SDS

The formation of mixed micelles based on an electrostatic interaction between the positively charged PMAPTAC block in PS-*b*-PMAPTAC-*b*-PEO and the added surfactants was also examined in the present study. For the investigation, we employed an anionic surfactant (SDS), which is expected to interact with the positively charged PMAPTAC shell. To express the amount of added SDS, we introduced the concept of *apparent degree of neutralization* (ADN), which is defined by

$$[\text{3}] \quad \text{ADN (\%)} = \frac{\text{Amount of added SDS in mole unit}}{\text{Amount of trimethylammonium group of the PMAPTAC block in mole unit}} \times 100$$

**Fig. 5.** (a) Variation in the  $D_h$  and (b) zeta potential ( $\zeta$ ) of mixed micelles of SDS/PS-*b*-PMAPTAC-*b*-PEO as a function of ADN. The concentration of PS-*b*-PMAPTAC-*b*-PEO was fixed at 0.1 g L<sup>-1</sup> for both experiments.

**Fig. 6.** The SEM image of the micelles SDS/PS-*b*-PMAPTAC-*b*-PEO. The SEM sample was prepared from a polymer solution at the polymer concentration of 0.1 g L<sup>-1</sup> and ADN = 50%.

**Fig. 7.** Variation in the  $D_h$  for the mixed micelles of PMAA/PS-*b*-PMAPTAC-*b*-PEO with respect to concentration of PS-*b*-PMAPTAC-*b*-PEO (ADN = 50%). It should be noted that the  $D_h$  values on the  $x$  axis do not correspond to 0 nm, but indicate that stable data were not obtained.

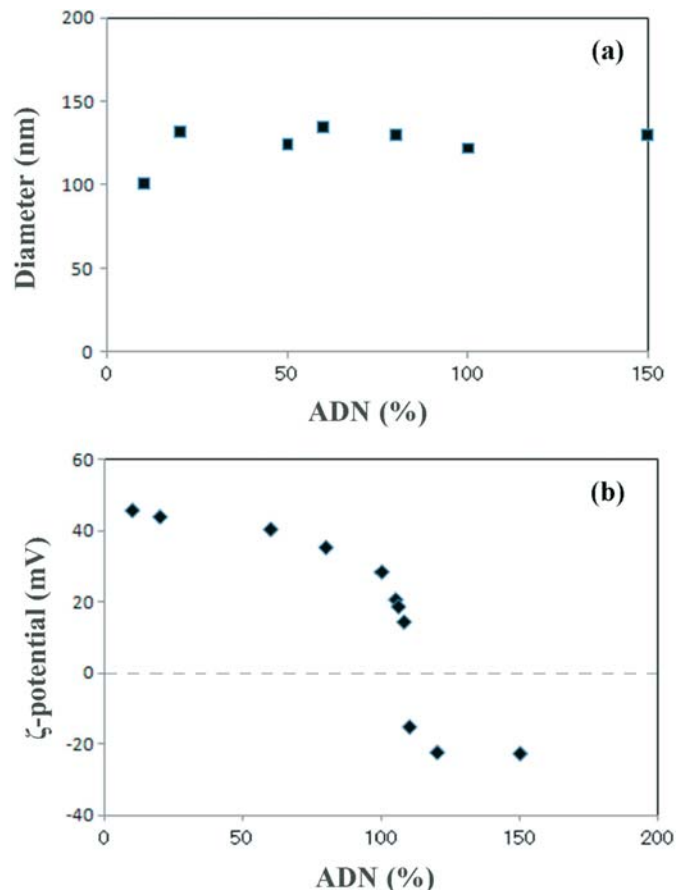

Figure 4a shows the  $D_h$  of the mixed micelles as a function of the polymer concentration at 50% ADN. A nearly uniform micelle size of about 125 nm was obtained when the polymer concentration level was above 0.006 g L<sup>-1</sup> and no reliable DLS data were obtained below that concentration. The formation of mixed micelles was also confirmed by the vibronic fine structure of the pyrene fluorescence spectra (Fig. 4b). The sudden decrease in the  $I_1/I_3$  ratio above 0.005 g L<sup>-1</sup> indicates the upper bound of the critical aggregate concentration (cac).<sup>21</sup> It should be noted that in the presence of SDS, the cac, value is significantly low indicating the smooth formation of the mixed micelles. The main significance of using SDS is that by neutralizing the positive charge of the PMAPTAC block, it increases the hydrophobicity, which facilitates the formation of core as well as stable micelles.

We have also explored the PS-*b*-PMAPTAC-*b*-PEO micelles for possible stimuli-induced morphological changes in the presence of SDS. In the absence of SDS, the PMAPTAC block of the PS-*b*-PMAPTAC-*b*-PEO micelles is expected to exist in an extended conformation due to the repulsion between the positive charges; whereas binding of SDS to the PMAPTAC block may lead to a shrunken conformation due to the cancellation of the charges. Figure 5a shows the variation in the hydrodynamic diameters of the mixed SDS/PS-*b*-PMAPTAC-*b*-PEO micelles with different ADN values. With the addition of SDS, the  $D_h$  gradually decreased and the solution turned turbid at 60% ADN. The reduction in the hydrodynamic diameter of the micelles clearly indicates that the SDS effectively binds with the cationic PMAPTAC and eliminates the repulsive forces between the PMAPTAC blocks.

The variation in the zeta potential with ADN is shown in Fig. 5b. The successive addition of SDS resulted in a continuous decrease in the zeta potential from 67.3 to 51.8 mV. This result indicates that the positive charges on the PS-*b*-PMAPTAC-*b*-PEO micelle particle are neutralized due to electrostatic binding of the oppositely charged species.

Figure 6 shows the SEM image of the SDS/PS-*b*-PMAP-

**Fig. 8.** Variation in the (a)  $D_h$  and (b) zeta-potential ( $\zeta$ ) of mixed micelles of PMAA/PS-*b*-PMAPTAC-*b*-PEO at different ADNs. The concentration of PS-*b*-PMAPTAC-*b*-PEO is fixed at 0.1 g L<sup>-1</sup> for both experiments.

TAC-*b*-PEO mixed micelles at 50% ADN, and spherical particles with a good dispersivity are clearly observed. This image provides clear evidence for the formation of the mixed micelles of PS-*b*-PMAPTAC-*b*-PEO and SDS.

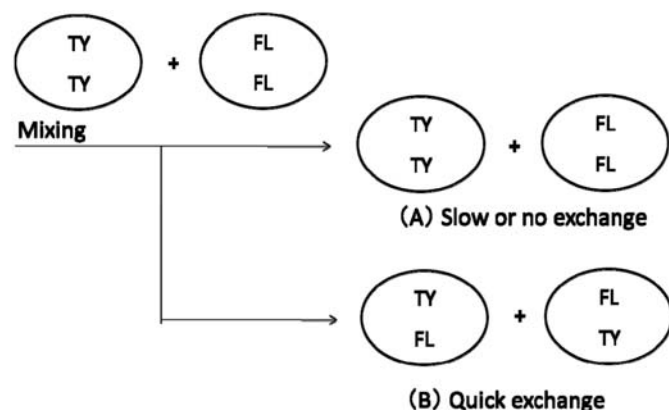

#### Mixed micelles of PS-*b*-PMAPTAC-*b*-PEO and PMAA

Impressed by the above results, we have extended our studies using the combination of the PS-*b*-PMAPTAC-*b*-PEO copolymer and PMAA, where the latter is expected to have application in biological and medical fields, e.g., controlled release of insulin after oral administration.<sup>22</sup> Figure 7 shows the  $D_h$  of mixed micelles over a range of polymer concentrations at 50% ADN. Nearly uniform micelles with a size of about  $120 \pm 5$  nm were obtained when the polymer concentration was raised above 0.006 g L<sup>-1</sup> indicating the formation of the mixed micelle in the presence of PMAA. Figure 8a shows the change in the hydrodynamic diameter of mixed micelles, PMAA/PS-*b*-PMAPTAC-*b*-PEO, at different ADNs. When PMAA was added to the aqueous solution of PS-*b*-PMAPTAC-*b*-PEO, the  $D_h$  rapidly increased to about 100 nm at 10% ADN and then the increase in the micelle size was rather slow with a further neutralization. The moderate increase in the  $D_h$  at a low degree of neutralization is attributed to the partial charge neutralization of the PMAPTAC blocks by PMAA. Unlike the case of SDS, no

**Fig. 9.** The SEM image of the mixed micelles of PMAA/PS-*b*-PMAPTAC-*b*-PEO. The SEM sample was prepared from a 0.1 g L<sup>-1</sup> polymer solution; ADN = 50%.

**Fig. 10.** The schematic representation for two model cases of the exchange of TY and FL dyes between the micelle particles.

morphological change from the extended to shrunken conformation was observed, and also, the micellar solution did not become turbid even after 150% ADN. The lack of turbidity formation may be due to the hydrophilicity of the residual carboxyl groups present in the methacrylic acid after neutralization. The hydrophilic nature of the mixed micelles is implied from the change in the  $I_1/I_3$  ratio in the pyrene fluorescence spectra (see Fig. S2 in the Supplementary data). The  $I_1/I_3$  ratio shows a very slight change upon going from low (0.0001 g L<sup>-1</sup>) to high (0.1 g L<sup>-1</sup>) polymer concentrations.

Additional proof for the effective binding of PMAA was obtained from the zeta-potential measurements (Fig. 8b). The positive charge of the PS-*b*-PMAPTAC-*b*-PEO micelle particles is gradually neutralized during the binding of the oppositely charged PMAA resulting in a continuous decrease in the zeta potential up to 0 mV at about 100% ADN. However, the addition of more PMAA caused a further decrease in the zeta potential to -22.9 mV indicating the presence of excess negative charges in the mixed micelle system. The above results indicate that, in addition to the electrostatic interaction, there could be another type of interaction between the triblock copolymer and PMAA. Although the exact nature of the interaction is not known, it may be (1) a hydrophobic interaction between PMAA and

**Fig. 11.** The fluorescence spectra of FL and TY in the mixed micelles of PS-*b*-PMAPTAC-*b*-PEO and PMAA. The solid line indicates the fluorescence spectrum of FL (40 μmol/L) incorporated in the micelles. The dotted line shows the fluorescence spectra of TY (2 μmol/L) and FL (20 μmol/L), which are premixed before being incorporated in the micelles. The polymer concentration and ADN are fixed at 0.1 g L<sup>-1</sup> and 30%, respectively, throughout the experiments. The samples are excited at 350 nm, and both the excitation and emission band passes are 3 nm. It should be noted that the concentration of FL in the solid line spectrum is two times higher than that in the dotted line spectrum.

**Fig. 12.** Time dependence of FL fluorescence in the mixed micelle solutions of PMAA/PS-*b*-PMAPTAC-*b*-PEO. The concentration of PS-*b*-PMAPTAC-*b*-PEO is 0.1 g L<sup>-1</sup> and ADN is 30% throughout the experiment. The concentration of FL is 40 μmol L<sup>-1</sup> at point A. The concentrations of FL and TY at the end (at point C) are 20 and 2 μmol/L, respectively.

the PS-*b*-PMAPTAC-*b*-PEO or (2) hydrogen bonding between PMAA and the PEO block. The morphology and dispersivity of these mixed micelle systems is recorded by SEM, which is shown in Fig. 9.

#### Kinetics of the exchange of organic dyes between the micelle particles

It is interesting to investigate the kinetics of the exchange of organic dyes between the micelle particles, because the exchange kinetics can be related to the drug release from the container micelles. One of the methods to study the exchange kinetics is to use electronic energy transfer.<sup>23</sup> This

idea is schematically shown in Fig. 10. We prepared two kinds of micelle solutions: one only contains FL and the other only contains TY. It is known that the electronic energy of TY is transferred to FL by a dipole–dipole interaction, resulting in quenching of the TY fluorescence and the sensitization of the FL fluorescence.<sup>24,25</sup> The critical energy transfer distance is usually less than 10 nm. Therefore, the energy transfer quenching of the TY fluorescence and sensitization of the FL fluorescence will effectively occur when both TY and FL are incorporated in the same micelle particle, while they will not occur when TY and FL are partitioned among the different particles. We monitored the fluorescence intensity of FL before and after the mixing of the two micelle solutions. If the exchange of the incorporated dyes occurs within the time scale of seconds or less (case B in Fig. 10), then we will observe a quick increase in the fluorescence intensity of FL. If it takes hours or a much longer time for the exchange to occur (case A in Fig. 10), we will not observe any significant intensity change.

To investigate the exchange kinetics of the organic dyes between the micelle particles, we employed the mixed micelles of PS-*b*-PMAPTAC-*b*-PEO and PMAA. Before we examined the time profile of the fluorescence intensity of FL, we measured the fluorescence spectra of TY and FL in the mixed micelle solutions of PS-*b*-PMAPTAC-*b*-PEO and PMAA (Fig. 11). In the absence of TY (Fig. 11, solid line), there is only one band (around 520 nm) corresponding to the fluorescence of FL. When TY is also present in the micelle (Fig. 11, dotted line), we observe two bands, one is assigned to TY (around 425 nm), and the other is assigned to FL (around 520 nm). If we compare the two spectra (i.e., the solid and dotted lines), we realize that the fluorescence of FL is significantly sensitized by TY. This fact indicates that the energy transfer from TY to FL effectively occurs in the micelle particle, because such a high sensitization does not occur in the absence of the micelles (see Fig. S3 in the Supplementary data). In the bulk aqueous solution (i.e., in the absence of the micelles), the fluorescence of FL is not increased, but decreased by the presence of TY, because the intensity increase due to the sensitization by TY is much lower than the intensity decrease due to the inner filter effect of TY.

Figure 12 shows a time profile of the fluorescence intensity of FL in the mixed micelle solution. At point A in Fig. 12, the sample contains only FL. We quickly added the solution containing TY at point B in Fig. 12. The fluorescence intensity increased rapidly to the level of point C in Fig. 12, indicating that the TY and FL in different micelle particles rapidly mixed with each other in the same micelle particle. Therefore, we can conclude that the exchange of the incorporated dyes takes places within a time scale of seconds.

## Conclusions

The micelles of PS-*b*-PMAPTAC-*b*-PEO have been successfully prepared in aqueous solutions. Due to the short PS chain (DP = 8), the formation of micelles is difficult at low concentrations, and the micelles are detected by DLS and light scattering only at concentrations higher than 1 g L<sup>-1</sup>. This concentration is considerably higher than that (0.0015

g L<sup>-1</sup>) found previously for the same type of triblock copolymer with a longer PS chain (DP = 80).<sup>18</sup>

The addition of anionic amphiphiles, such as SDS and PMAA, induces the formation of mixed micelles at a low concentration level of the polymer (~0.005 g L<sup>-1</sup>). This can be ascribed to the insolubilization of the cationic PMAAPTAC block due to charge neutralization by the anionic amphiphiles. The binding of SDS or PMAA to the PMAAPTAC block is confirmed by the zeta-potential measurements. The zeta potential decreases with an increase in the amount of the added SDS or PMAA, reflecting the charge neutralization of the cationic PMAAPTAC block with anionic SDS or PMAA. The mixed micelles were characterized by DLS, SEM, and fluorescence measurements. The DLS measurements give  $D_h = 125$  nm for the SDS/PS-*b*-PMAPTAC-*b*-PEO mixed micelles and  $D_h = 120$  nm for the PMAA/PS-*b*-PMAPTAC-*b*-PEO mixed micelles. The SEM measurements provided clear pictures of the mixed micelles with a spherical morphology for both SDS/PS-*b*-PMAPTAC-*b*-PEO and PMAA/PS-*b*-PMAPTAC-*b*-PEO systems. The significant difference between the two systems is that the SDS/PS-*b*-PMAPTAC-*b*-PEO system undergoes precipitation when ADN exceeds 50%, while the PMAA/PS-*b*-PMAPTAC-*b*-PEO system does not undergo precipitation even after the ADN exceeds 100%. This difference may be attributed to the hydrophilicity of the residual carboxyl groups present in PMAA after neutralization.

The exchange kinetics of organic dyes between the micelle particles of the PMAA/PS-*b*-PMAPTAC-*b*-PEO system was investigated by a fluorescence technique, which is based on electronic energy transfer from TY to FL. This result indicated that the exchange of the dyes between the micelle particles takes places within a time scale of seconds.

## Supplementary data

Supplementary data for this article (additional figures of the dependence of the  $I_1/I_3$  ratio on the polymer concentration are available for the solution of PS-*b*-PMAPTAC-*b*-PEO micelles and PMAA/PS-*b*-PMAPTAC-*b*-PEO mixed micelles and fluorescence spectra of FL and TY in aqueous solutions) are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. # How switching the substituent of a pyrene derivative from a methyl to a butyl affects the fluorescence response of polystyrene randomly labeled with pyrene

Mark Ingratta, Manoj Mathew, and Jean Duhamel

**Abstract:** A series of polystyrenes randomly labeled with 1-pyrenebutanol were prepared by copolymerizing styrene and 1-pyrenebutylacrylate yielding the CoBuE-PS series. Solutions of CoBuE-PS were prepared in nine organic solvents having viscosities ranging from 0.36 to 5.5 mPa·s and the fluorescence spectra and pyrene monomer and excimer fluorescence decays were acquired. Analysis of the fluorescence spectra yielded the  $I_E/I_M$  ratio, whereas analysis of the fluorescence decays with the fluorescence blob model (FBM) yielded the parameters  $N_{\text{blob}}^0$ ,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$ , and  $k_{\text{blob}}^0$ . These parameters were compared to those obtained with two other series of pyrene-labeled polystyrenes, which had been studied earlier, namely CoA-PS and CoE-PS where pyrene was attached to the polymer backbone via a methylamide and benzyl methyl-ether linker, respectively. Although the parameters  $I_E/I_M$ ,  $N_{\text{blob}}^0$ ,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$ , and  $k_{\text{blob}}^0$  took different values according to the specific nature of the linker connecting pyrene to the polystyrene backbone, they exhibited trends that were quite similar for all the pyrene-labeled polystyrene constructs. The excellent agreement between the parameters retrieved for the three different types of pyrene-labeled polystyrenes suggests that the FBM accounts satisfyingly for differences in the nature of the label used, while still retrieving information pertinent to the polymer of interest.

**Key words:** polymer chain dynamics, fluorescence, polystyrene, pyrene.

**Résumé :** La série CoBuE-PS de polystyrènes marqués aléatoirement par du 1-pyrènebutanol a été préparée par copolymérisation du styrène avec de l'acrylate de 1-pyrènebutyle. Des solutions de CoBuE-PS ont été préparées dans neuf solvants organiques dont les viscosités s'échelonnent de 0,36 à 5,5 mPa s. Les spectres de fluorescence ont été mesurés ainsi que les déclins de fluorescence du monomère et de l'excimère du pyrène. L'analyse des spectres de fluorescence a permis de déterminer les valeurs des rapports  $I_E/I_M$  alors que l'analyse des déclins de fluorescence à l'aide du modèle (« FBM ») conduit aux paramètres,  $N_{\text{blob}}^0$ ,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  et  $k_{\text{blob}}^0$ . Ces paramètres ont été comparés à ceux obtenus avec deux autres séries de polystyrènes marqués par du pyrène étudiées antérieurement, soit les séries CoA-PS et CoE-PS dans lesquels les unités de pyrène étaient respectivement attachés à un squelette de polymère par des groupes méthylamide et oxide de benzométhyle. Même si les paramètres  $I_E/I_M$ ,  $N_{\text{blob}}^0$ ,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  et  $k_{\text{blob}}^0$  varient suivant la nature spécifique des groupes qui relient le pyrène au squelette de polystyrène, ils présentent tous des tendances assez similaires pour tous les polymères de polystyrène marqué par du pyrène. L'excellent accord entre les paramètres obtenus à partir de trois types différents de polystyrènes marqués par du pyrène suggère que le modèle (« FBM ») permet d'expliquer d'une façon satisfaisante les différences dans la nature du marqueur utilisé tout en permettant d'en tirer l'information pertinente relative au polymère sous étude.

**Mots-clés :** dynamique de chaîne de polymère, fluorescence, polystyrène, pyrène.

## Introduction

In the late 1970s and early 1980s, the research groups of Winnik<sup>1-7</sup> in Toronto, Canada, and Cuniberti and Perico<sup>8,9</sup> in Genova, Italy, conducted pioneering experiments that demonstrated how the process of excimer formation between pyrene pendants covalently attached onto a polymer in solu-

tion provides information at the molecular level on the flexibility of the polymer backbone. Among the various scientific breakthroughs made during that period was the use by the Winnik group in Toronto<sup>1</sup> of time-resolved fluorescence decays to obtain a direct measure of the rate constant of pyrene encounters between two pyrenes attached at the opposite ends of a monodisperse polymer. The bulk of

<sup>1</sup>Corresponding author (e-mail: [jduhamel@uwaterloo.ca](mailto:jduhamel@uwaterloo.ca)).

the work carried out by Winnik and co-workers<sup>1–7</sup> and Cuni-berti and Perico<sup>8,9</sup> was done with pyrene end-labeled monodisperse polymers to take advantage of the observation made in 1974 by Wilemski and Fixman<sup>10,11</sup> that the process of end-to-end cyclization can be described by a single rate constant,  $k_{cy}$ , if the chain is monodisperse.

The majority of these early cyclization experiments used pyrene due to its ability to form an excimer.<sup>12</sup> Upon excitation, an excited pyrene can either decay as a pyrene monomer with its lifetime,  $\tau_M$ , or it can encounter a ground-state pyrene to form an excimer that emits with a lifetime  $\tau_E$ . The pyrene monomer and excimer are two distinct species that represent, respectively, the reactants and the product of the cyclization undergone by a pyrene end-labeled polymer. Thus monitoring the rate of excimer formation provides a measure of  $k_{cy}$ . In turn, the cyclization experiments could draw from earlier studies conducted by Birks<sup>12</sup> that established the validity of a kinetic scheme now referred to as the Birks' scheme that provides a robust procedure to determine the rate constant of excimer formation from fluorescence decay measurements acquired for the pyrene monomer and excimer. Finally, the fact that pyrene acts both as the chromophore upon excitation and as the quencher while in the ground-state simplifies substantially the labeling chemistry since no special arrangement needs to be made in terms of reacting groups to ensure specific labeling of the chain with either the chromophore or the quencher.

As mentioned earlier, most cyclization experiments carried out with pyrene-labeled polymers used pyrene end-labeled monodisperse polymers due to the simplifications associated with the use of a unique rate constant,  $k_{cy}$ , to describe end-to-end cyclization.<sup>10,11</sup> As a matter of fact, the strict relationship predicted by Wilemski and Fixman<sup>10,11</sup> that was found to exist between polymer chain length and  $k_{cy}$  made it quite difficult to study end-labeled polydisperse polymers or randomly labeled polymers, since the process of excimer formation needed to be handled by a distribution of rate constants, with one rate constant corresponding to each and every polymer length spanning every two pyrenes. In turn, this complication prevented the use of randomly labeled polymers to study polymer chain dynamics in solution despite their easier preparation and dramatic enhancement of pyrene–pyrene encounters over what is typically observed with pyrene end-labeled monodisperse polymers.<sup>13</sup>

In 1999, this laboratory introduced the fluorescence blob model (FBM) as an analytical tool to study polymers randomly labeled with pyrene.<sup>14</sup> In a series of studies, the FBM was shown to be surprisingly robust, enabling the experimentalist to retrieve reliable quantitative information about polymer chain dynamics for different polymer backbones,<sup>15,16</sup> polymer architectures,<sup>17</sup> and in solutions of different solvent quality toward the polymer,<sup>13,15,16</sup> viscosity,<sup>18</sup> or polymer concentration.<sup>19</sup> In an interesting recent development, the rather complex FBM was found to yield trends in terms of polymer chain dynamics that perfectly matched those obtained with end-labeled monodisperse polymers, providing an appealing alternative to study polymers that cannot be easily prepared with a narrow molecular weight distribution and (or) end-labeled.<sup>13,18</sup>

So far, the entire work carried out by this laboratory on

polymers randomly labeled with pyrene used a 1-pyrene-methyl derivative with an alcohol or amine functionality to label the polymer of interest, whereas a large number of studies found in the literature use a 1-pyrenebutyl derivative.<sup>20–29</sup> This state of affair is unfortunate because the fluorescence response of a given pyrene-labeled polymer construct has been found to be extremely sensitive, among other factors, to the nature of the linker connecting the pyrene derivative to the chain.<sup>17</sup> Although the FBM accounts for these differences, FBM analysis yields parameters that cannot be directly compared if two polymers are labeled with different linkers and pyrene derivatives. Consequently, the parameters retrieved from the analysis of fluorescence data acquired with polymers randomly labeled with pyrene will take different absolute values whether the polymer is labeled with a 1-pyrene-methyl or -butyl derivative, making direct comparison between such constructs difficult. This manuscript remedies this gap by conducting a FBM analysis on a series of polystyrene samples randomly labeled with pyrene (Py–PS) where pyrene is connected to the chain via a butyl ester linker. This type of Py–PS construct is referred to as CoBuE–PS in this report. The CoBuE–PS series was studied in nine organic solvents. The results obtained from the FBM analysis were compared to those obtained earlier with two other Py–PS constructs, the CoA–PS and CoE–PS series where pyrene is linked to the chain via a methyl amide and a benzyl methyl ether linker, respectively.<sup>13,17,18</sup> The results obtained with the CoA–PS and CoE–PS series have already been published,<sup>18</sup> but they are presented in this study to enable direct comparison between the results obtained with CoBuE–PS. Although the parameters retrieved from the FBM took different values for the three Py–PS constructs, the trends obtained with the FBM parameters pertaining to CoBuE–PS are quite similar to those obtained with CoA–PS and CoE–PS, demonstrating that the FBM accounts satisfyingly for the differences in chemical nature of the pyrene-to-backbone linker that were introduced in those Py–PS constructs. The results obtained with CoBuE–PS are expected to provide a useful reference point that can be used to compare the chain dynamics of other polymers labeled with the commonly encountered 1-pyrenebutyl derivative.

## Theory

Excimer formation between pyrenes covalently attached onto a polymer can be viewed as a two step mechanism as depicted in Scheme 1.<sup>17</sup> In the first step, the polymer chain brings two pyrenes via diffusion within striking range with a rate constant  $k_1$ . The second step corresponds to the rapid rearrangement of the pyrenes to form an excimer with a rate constant  $k_2$ . The first and second steps are controlled by the dynamics of the polymer backbone and that of the pyrene-to-backbone linker, respectively. Although Scheme 1 suggests that diffusive encounters between polymer segments can be described by a single rate constant,  $k_1$ , this is not the case when the fluorophores are attached randomly onto the polymer as for the case at hand.<sup>30–32</sup>

For randomly labeled polymers, an encounter between any two polymer segments bearing a pyrene label is characterized by a rate constant  $k_1$  that depends on the length of polymer spanning the two segments. As a result, there exists

**Scheme 1.** The effect of backbone and side chain motion on the kinetics of excimer formation.

a distribution of rate constants  $k_1$ , which somewhat complicates the analysis of the fluorescence data. In the case of excimer formation between pyrenes randomly attached onto a polymer, this distribution of rate constants  $k_1$  has been described by a function,  $f(t)$ , whose derivation follows from the fluorescence blob model (FBM).<sup>33</sup> Furthermore, Scheme 1 can be simplified by noting that pyrene excimer dissociation is negligible so that  $k_{-2}$  can be set equal to zero and that  $k_2$  being substantially larger than  $k_{-1}$ ,  $k_{-1}$  can be neglected.<sup>12</sup>

Based on Scheme 1, several pyrene species are expected to be present in solution.<sup>33</sup> They include those excited pyrenes ( $\text{Py}^*_{\text{diff}}$ ) that diffuse slowly in solution until they find themselves within striking range of a ground-state (GS) pyrene. Those nearby pyrene pairs constitute the species of excited pyrenes,  $\text{Py}^*_{k_2}$ , that forms an excimer,  $\text{E0}^*$ , rapidly with a rate constant  $k_2$ . Both  $\text{Py}^*_{\text{diff}}$  and  $\text{Py}^*_{k_2}$  emit with the monomer lifetime  $\tau_M$ , whereas  $\text{E0}^*$  emits with the excimer lifetime  $\tau_{\text{E0}}$ . Also, the random labeling of the polymer backbone induces the formation of pyrene-rich and pyrene-poor pockets where excimer formation is, respectively, enhanced or reduced. In the pyrene-poor pockets, some excited pyrenes will not be able to encounter a GS pyrene during their lifetime and they emit as isolated, unattached “free” pyrenes do and are thus referred to as  $\text{Py}^*_{\text{free}}$ . Finally, the steric constraints induced by the covalent attachment of a pyrene moiety onto the polymer has sometimes been found to generate some improper stacking of the pyrene moieties

resulting in the formation of either short- ( $\text{ES}^*$ ) or long- ( $\text{EL}^*$ ) lived pyrene dimers that emit with a lifetime  $\tau_{\text{ES}}$  and  $\tau_{\text{EL}}$ , respectively. The time-dependent behavior of the concentrations of the different pyrene species in solution can be described by the following set of differential equations.

$$[1] \quad \frac{d[\text{Py}^*_{\text{diff}}]}{dt} = -f(t) - \frac{1}{\tau_M} [\text{Py}^*_{\text{diff}}]$$

$$[2] \quad \frac{d[\text{Py}^*_{\text{free}}]}{dt} = -\frac{1}{\tau_M} [\text{Py}^*_{\text{free}}]$$

$$[3] \quad \frac{d[\text{Py}^*_{k_2}]}{dt} = f(t) - \left(k_2 + \frac{1}{\tau_M}\right) [\text{Py}^*_{k_2}]$$

$$[4] \quad \frac{d[\text{E0}^*]}{dt} = k_2 [\text{Py}^*_{k_2}] - \frac{1}{\tau_{\text{E0}}} [\text{E0}^*]$$

$$[5] \quad \frac{d[\text{ES}^*]}{dt} = -\frac{1}{\tau_{\text{ES}}} [\text{ES}^*]$$

$$[6] \quad \frac{d[\text{EL}^*]}{dt} = -\frac{1}{\tau_{\text{EL}}} [\text{EL}^*]$$

The concentration,  $[\text{Py}^*_{\text{diff}}]_{(t)}$ , is obtained by applying the FBM. The FBM postulates that while it remains excited, an excited pyrene probes a finite volume called a blob.<sup>14,32</sup> A blob is then taken as a volume unit, which is used to arbitrarily divide the polymer coil into a cluster of blobs. The random labeling of the chain with pyrene implies that the chromophores distribute themselves randomly among the blobs according to a Poisson distribution. The encounter between two polymer segments bearing a pyrene pendant occurs with a rate constant  $k_{\text{blob}}$ . The exchange of segments bearing pyrene moving in and out of the blobs is handled by  $k_e[\text{blob}]$ , which is the product of the exchange rate constant and the blob concentration inside the polymer coil. The average number of labels per blob is given by  $\langle n \rangle$ . Based on the above,  $[\text{Py}^*_{\text{diff}}]_{(t)}$  has been derived and its expression is given in eq. [7].<sup>14</sup>

$$[7] \quad [\text{Py}^*_{\text{diff}}]_{(t)} = [\text{Py}^*_{\text{diff}}]_0 \exp \left[ -\left(A_2 + \frac{1}{\tau_M}\right)t - A_3 \left(1 - \exp(-A_4 t)\right) \right]$$

In eq. [7], the parameters  $A_2$ ,  $A_3$ , and  $A_4$  are functions of  $k_{\text{blob}}$ ,  $\langle n \rangle$ , and  $k_e[\text{blob}]$  as shown in eq. [8].

$$[8] \quad A_2 = \langle n \rangle \frac{k_{\text{blob}} k_e [\text{blob}]}{k_{\text{blob}} + k_e [\text{blob}]} \quad A_3 = \langle n \rangle \frac{(k_{\text{blob}})^2}{(k_{\text{blob}} + k_e [\text{blob}])^2} \quad A_4 = k_{\text{blob}} + k_e [\text{blob}]$$

The same equation had already been derived to handle the exchange of chromophores between surfactant micelles.<sup>34</sup> Equation [7] can then be used to determine  $f(t)$  in eqs. [1] and [3]. Knowing  $f(t)$  allows one to integrate eq. [3] to get an expression for  $[\text{Py}^*_{k_2}]_{(t)}$ . Knowing the expression of  $[\text{Py}^*_{k_2}]_{(t)}$  enables one to integrate eq. [4] to get  $[\text{E0}^*]_{(t)}$ . Integration of eqs. [2], [5], and [6] is trivial. A more thorough description of the derivation used to find the overall time-dependent profile of the pyrene monomer  $[\text{Py}^*]_{(t)}$  and excimer  $[\text{E}^*]_{(t)}$  can be found in an earlier publication.<sup>33</sup> The final result is shown in eqs. [9] and [10].

$$\begin{aligned}
 [9] \quad [\text{Py}^*]_{(t)} &= [\text{Py}_{\text{diff}}^*]_{(t)} + [\text{Py}_{k_2}^*]_{(t)} + [\text{Py}_{\text{free}}^*]_{(t)} \\
 &= [\text{Py}_{\text{diff}}^*]_0 \exp \left( - \left( A_2 + \frac{1}{\tau_M} \right) t - A_3 \left( 1 - \exp(-A_4 t) \right) \right) \\
 &\quad + \left( [\text{Py}_{k_2}^*]_0 + [\text{Py}_{\text{diff}}^*]_0 e^{-A_3} \sum_{i=0}^{\infty} \frac{A_3^i}{i!} \frac{A_2 + iA_4}{A_2 + iA_4 - k_2} \right) \exp \left( - \left( k_2 + \frac{1}{\tau_M} \right) t \right) \\
 &\quad - [\text{Py}_{\text{diff}}^*]_0 e^{-A_3} \sum_{i=0}^{\infty} \frac{A_3^i}{i!} \frac{A_2 + iA_4}{A_2 + iA_4 - k_2} \exp \left( - \left( A_2 + iA_4 + \frac{1}{\tau_M} \right) t \right) + [\text{Py}_{\text{free}}^*]_0 \exp \left( - \frac{t}{\tau_M} \right)
 \end{aligned}$$

$$\begin{aligned}
 [10] \quad [\text{E}^*]_{(t)} &= [\text{E0}^*]_{(t)} + [\text{ES}^*]_{(t)} + [\text{EL}^*]_{(t)} \\
 &= k_2 \left( \left( [\text{Py}_{k_2}^*]_0 + [\text{Py}_{\text{diff}}^*]_0 e^{-A_3} \sum_{i=0}^{\infty} \frac{A_3^i}{i!} \frac{A_2 + iA_4}{A_2 + iA_4 - k_2} \right) \times \frac{\exp \left( - \frac{t}{\tau_{\text{E0}}} \right) - \exp \left( - \left( k_2 + \frac{1}{\tau_M} \right) t \right)}{k_2 + \frac{1}{\tau_M} - \frac{1}{\tau_{\text{E0}}}} \right. \\
 &\quad \left. + [\text{Py}_{\text{free}}^*]_0 e^{-A_3} \sum_{i=0}^{\infty} \frac{A_3^i}{i!} \frac{A_2 + iA_4}{A_2 + iA_4 - k_2} \frac{\exp \left( - \left( A_2 + iA_4 + \frac{1}{\tau_M} \right) t \right) - \exp \left( - \frac{t}{\tau_{\text{E0}}} \right)}{A_2 + iA_4 + \frac{1}{\tau_M} - \frac{1}{\tau_{\text{E0}}}} \right) \\
 &\quad + [\text{E0}^*]_0 \times \exp \left( \frac{t}{\tau_{\text{E0}}} \right) + [\text{ES}^*]_0 \times \exp \left( - \frac{t}{\tau_{\text{ES}}} \right) + [\text{EL}^*]_0 \times \exp \left( - \frac{t}{\tau_{\text{EL}}} \right)
 \end{aligned}$$

It must be noted that if  $k_2$  in Scheme 1 is very large, eq. [9] reverts back to eq. [11], which is the equation typically used for the FBM analysis of the fluorescence decays of the pyrene monomer.<sup>14,32</sup>

$$[11] \quad [\text{Py}^*]_{(t)} = [\text{Py}_{\text{diff}}^*]_0 \exp \left[ - \left( A_2 + \frac{1}{\tau_M} \right) t - A_3 \left( 1 - \exp(-A_4 t) \right) \right] + [\text{Py}_{\text{free}}^*]_0 \exp(-t/\tau_M)$$

Fitting the monomer decays with eq. [9] yields the fractions  $f_{\text{Mdiff}}$ ,  $f_{\text{Mk}_2}$ , and  $f_{\text{Mfree}}$ , which represent the molar fractions of the  $\text{Py}_{\text{diff}}^*$ ,  $\text{Py}_{k_2}^*$ , and  $\text{Py}_{\text{free}}^*$  species contributing to the monomer decays, whereas fitting the excimer decays with eq. [10] yields the fractions  $f_{\text{Ediff}}$ ,  $f_{\text{Ek}_2}$ ,  $f_{\text{EE0}}$ ,  $f_{\text{EES}}$ , and  $f_{\text{EEL}}$ , which represent the molar fractions of the  $\text{Py}_{\text{diff}}^*$ ,  $\text{Py}_{k_2}^*$ ,  $\text{Py}_{\text{free}}^*$ ,  $\text{E0}^*$ ,  $\text{ES}^*$ , and  $\text{EL}^*$  species contributing to the excimer decays. In turn, the fractions  $f_{\text{Mdiff}}$ ,  $f_{\text{Mk}_2}$ ,  $f_{\text{Mfree}}$ ,  $f_{\text{Ediff}}$ ,  $f_{\text{Ek}_2}$ ,  $f_{\text{EE0}}$ ,  $f_{\text{EES}}$ , and  $f_{\text{EEL}}$  can be rearranged to yield the molar fractions  $f_{\text{diff}}$ ,  $f_{k_2}$ ,  $f_{\text{free}}$ ,  $f_{\text{E0}}$ ,  $f_{\text{ES}}$ , and  $f_{\text{EL}}$  of all the pyrene species present in solution.

## Experimental

### Materials

Copolymerization of styrene with either 1-pyrenemethylacrylamide, 1-pyrenebutylacrylate, or 4-(1-pyrenyl)methoxymethylstyrene yielded the Py-PS constructs shown in Table 1 and are referred to as CoA-PS, CoBuE-PS, and CoE-PS, respectively. The polymerization of CoA-PS and CoE-PS has already been reported<sup>13,18</sup> along with their number-average molecular weight ( $M_n$ ), polydispersity index (PDI), molar fraction of pyrene-labeled monomer ( $x$ ), and pyrene content ( $\lambda_{\text{Py}}$  expressed in moles of pyrene per gram of polymer). The copolymerization of CoBuE-PS was conducted in the same manner as that of CoA-PS and CoE-PS using 1-pyrenebutylacrylate as the pyrene-labeled monomer. The synthesis of 1-pyrenebutylacrylate was conducted according to ref. 35. The  $M_n$ , PDI,  $x$ , and  $\lambda_{\text{Py}}$  values of the CoBuE-PS are listed in Table 2. Table 2 lists the solvents used

**Table 1.** Chemical structures of the pyrene-labeled polystyrenes.

CoE-PS	CoA-PS	CoBuE-PS

in this study and their quality towards polystyrene has been described in earlier publications.<sup>13,18</sup>

### Fluorescence measurements

Fluorescence spectra and decays of the CoBuE-PS samples were acquired and analyzed by following the same protocol used in earlier publications.<sup>13,18</sup> The pyrene monomer fluorescence decays were fitted with eq. [11], whereas the pyrene monomer and excimer fluorescence decays could be analyzed globally using eqs. [9] and [10]. The monomer lifetimes,  $\tau_M$ , used to fit the fluorescence decays are listed in Table 3. They were determined in earlier publications.<sup>13,18</sup>

**Table 2.** Number-average molecular weight ( $M_n$ ), polydispersity index (PDI), molar fraction of pyrene-labeled monomers ( $x$ ), and pyrene content ( $\lambda_{Py}$  in mol g<sup>-1</sup>) for the CoBuE-PS constructs.

**Simulations of fluorescence decays**

Equations [9] and [10] depend on 13 independent parameters which are  $k_{\text{blob}}$ ,  $\langle n \rangle$ ,  $k_e[\text{blob}]$ ,  $k_2$ ,  $\tau_{E0}$ ,  $\tau_{ES}$ ,  $\tau_{EL}$ , and the concentrations  $[\text{Py}^*_{\text{diff}}]_0$ ,  $[\text{Py}^*_{k_2}]_0$ ,  $[\text{Py}^*_{\text{free}}]_0$ ,  $[\text{E0}^*]_0$ ,  $[\text{ES}^*]_0$ , and  $[\text{EL}^*]_0$ . If no short- and long-lived dimer can be detected as is the case in the present study,  $[\text{ES}^*]_0$ ,  $[\text{EL}^*]_0$ ,  $\tau_{ES}$ , and  $\tau_{EL}$  do not need to be optimized and the number of independent parameters reduces to nine. Although one might question the reliability of fitting globally a monomer and excimer fluorescence decays with nine adjustable parameters, it must be pointed out that the same number of nine adjustable parameters is also used when fitting globally a monomer and excimer fluorescence decays with a sum of three exponentials, where the three decay times are coupled in the analysis. Global analysis of a monomer and excimer fluorescence decays with three exponentials has become a routine procedure in the scientific literature.<sup>36,37</sup>

Nevertheless, an error analysis of the parameters retrieved from the global analysis of the fluorescence decays was conducted as follows. The parameters retrieved from the global analysis of each pair of monomer and excimer fluorescence decays were used to generate 20 pairs of monomer and excimer decays having different Poisson noise patterns. The 20 pairs of decays were analyzed globally with eqs. [9] and [10]. The parameters retrieved from the analysis were averaged and their standard deviation was calculated. The errors on the parameters reported in Tables SI.1–SI.6 in the Supplementary data represent the larger value of the standard deviation or the difference between the actual input parameter minus the averaged value of the parameter retrieved from the analysis of the 20 pairs of simulated decays. Except for  $k_e[\text{blob}]$ , which is the parameter that always exhibits the largest errors,<sup>14</sup> and the fractions  $f_{M\text{free}}$  and  $f_{E0}$ , which took very small values, the errors on all the other parameters

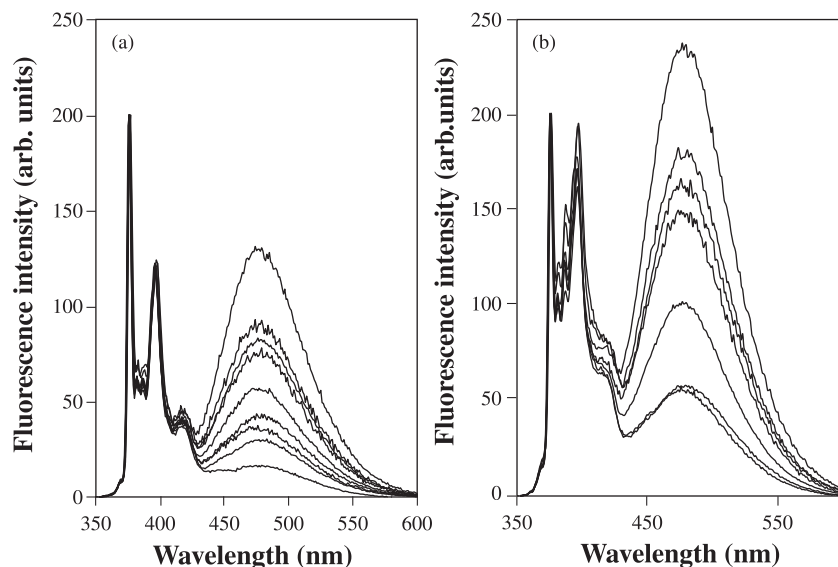

were smaller than 5% in the vast majority of cases, being as large as 10% in a few isolated cases.

**Results and discussion**

The structures of the three pyrene-labeled polystyrene constructs referred to as CoA-PS, CoBuE-PS, and CoE-PS are shown in Table 1. The pyrenyl pendants of CoE-PS are connected to the PS backbone via a flexible and long ether linker that holds the chromophore away from the backbone. In the CoA-PS constructs, pyrene is connected to the PS backbone via a short and rigid amide linker. Earlier studies of the pyrene fluorescence of CoA-PS and CoE-PS have reflected the differences in chemical structure of those constructs, showing that an excited pyrene attached to the CoE-PS backbone probes a larger volume than when attached to CoA-PS.<sup>17,18</sup> Furthermore, a 1-pyrenemethyl derivative was used to prepare CoA-PS and CoE-PS. In the case of CoBuE-PS, an ester bond was used to connect a 1-pyrenebutyl linker to the PS backbone.

As shown in Fig. 1, the fluorescence spectrum of the pyrene monomer observed between 370 and 430 nm is strongly affected by the nature of its substituent. The intensity ratio of the first to the third fluorescence peak, the  $I_1/I_3$  ratio, takes a value between 2.9 and 3.3 for all CoBuE-PS spectra shown in Fig. 1. By comparison, the  $I_1/I_3$  ratio of the CoA-PS samples takes a smaller value between 1.4 and 2.1. Similar  $I_1/I_3$  ratios were obtained for the CoE-PS series. In the case of molecular pyrene, the  $I_1/I_3$  ratio shows a clear correlation with solvent polarity increasing from 1.1 to 1.81, a 60% change as the solvent dielectric constant  $\epsilon$  increases from 2.4 in toluene to 36.7 in DMF.<sup>38</sup> This correlation is dampened and not as consistent for the 1-pyrenemethyl derivative where the  $I_1/I_3$  ratio of CoA-PS changes by less than 50% between dioxane ( $\epsilon = 2.2$ ) and DMA ( $\epsilon = 38.9$ )

**Fig. 1.** Fluorescence spectra of (A) CoEBu-PS with a pyrene content of 3.1 mol% and (B) CoA-PS with a pyrene content of 3.7 mol%. Solvents from top to bottom: methyl acetate, methyl ethyl ketone, dichloromethane, toluene, tetrahydrofuran, *N,N*-dimethylformamide, dioxane, dimethylacetamide, and benzyl alcohol.

and is non-existent for the 1-pyrenebutyl pendant since the same change in  $\epsilon$  results in a 10% change for the  $I_1/I_3$  ratio of CoBuE-PS. These observations have already been reported.<sup>39,40</sup> The fluorescence emission corresponding to the  $I_1$  band at  $\sim 375$  nm has been reported as being symmetry forbidden and is repressed in apolar solvents for pyrene.<sup>41</sup> Aromatic<sup>41</sup> and polar<sup>38,42,43</sup> solvents appear to enhance the emission at 375 nm, as well as substituents that reduce the symmetry of pyrene such as the methyl<sup>44</sup> or butyl substituents of the 1-pyrenemethyl and 1-pyrenebutyl pendants used in this study. Spectral differences between the 1-pyrenemethyl and 1-pyrenebutyl pendants have also been compared for different constructs of pyrene-labeled poly(L-glutamic acid).<sup>45</sup>

Most importantly, the differences in the  $I_1/I_3$  ratio of CoA-PS and CoBuE-PS indicate that the spectral features of the 1-pyrenemethyl and 1-pyrenebutyl derivatives are different. Since the first peak of the pyrene monomer at  $\sim 375$  nm is taken as a measure of the pyrene monomer flu-

orescence intensity by any experimentalist dealing with pyrene fluorescence, the different spectral features exhibited by the two pyrene derivatives make it literally impossible to use the  $I_E/I_M$  ratio obtained from the steady-state fluorescence spectra to compare how much excimer is generated by a given polymer, whether or not that polymer has been labeled with a 1-pyrenemethyl or 1-pyrenebutyl derivative. As a matter of fact, a rapid analysis of the fluorescence spectra shown in Fig. 1 leads to the conclusion that CoBuE-PS generates less excimer than CoA-PS. This statement is confirmed in Fig. 2 that shows the  $I_E/I_M$  ratio of the three constructs as a function of the inverse of solvent viscosity ( $\eta^{-1}$ ). Although the  $I_E/I_M$  ratio increases with increasing  $\eta^{-1}$  regardless of the construct and as expected, since a smaller viscosity enhances excimer formation, it is noticeable that CoBuE-PS yields the smallest  $I_E/I_M$  ratio at all viscosities. Since the  $I_E/I_M$  ratio is typically taken as a measure of backbone flexibility, a smaller  $I_E/I_M$  ratio would suggest that CoBuE-PS is the construct that is the least efficient at producing excimer. In turn, this result is somewhat unexpected because the backbone being the same in both constructs, namely polystyrene, the longer and more flexible butyl ester linker of CoBuE-PS is expected to facilitate excimer formation when compared to the shorter and more rigid amide linker of CoA-PS. More realistically, the smaller  $I_E/I_M$  ratios obtained for CoBuE-PS must be a consequence of the larger  $I_M$  values obtained with the 1-pyrenebutyl derivative. The above discussion clearly illustrates the difficulties encountered when directly comparing the  $I_E/I_M$  ratios obtained with macromolecules labeled with different pyrene derivatives. In such a case, comparison of the process of excimer formation in CoA-PS, CoBuE-PS, and CoE-PS can only be achieved from the quantitative analysis of the monomer and excimer fluorescence decays.

To this end, the fluorescence decays of the pyrene monomer and excimer of all CoBuE-PS samples were acquired in nine organic solvents. The monomer decays could be fitted satisfyingly with eq. [11], but global analysis of the mono-

**Fig. 3.** Monomer (left,  $\lambda_{em} = 375$  nm) and excimer (right,  $\lambda_{em} = 510$  nm) decays acquired for the CoBuE-PS sample excited at 344 nm and labeled with 5.4% pyrene in dioxane. The decays were analyzed globally with eqs. [9] and [10] yielding  $\chi^2 = 1.02$ .

**Fig. 4.**  $N_{blob}$  as a function of the corrected pyrene content obtained through the global analysis of the monomer and excimer fluorescence decays with eqs. **Fig. 7.**  $k_{\text{blob}} \times N_{\text{blob}}$  as a function of  $\eta^{-1}$  for CoE-PS (■), CoBuE-PS (◇, analysis of the monomer decays with eq. [11]), CoBuE-PS (□, global analysis of the monomer and excimer decays with eqs. [9] and [10]), and CoA-PS (▲). Inset:  $k_{\text{blob}} \times N_{\text{blob}}$  multiplied by 0.52, 0.72, 0.86, and 1.0 for the trends obtained with CoE-PS (■), CoBuE-PS (◇, analyzed with eq. [11]), CoBuE-PS (□, analyzed globally with eqs. [9] and [10]), and CoA-PS (▲), respectively.

mer and excimer fluorescence decays of the five CoBuE-PS samples in each solvent were analyzed with eqs. [9] and [10] where the rate constant  $k_2$  was allowed to float. However, the  $k_2$  values retrieved in this manner showed some scatter. Consequently, the  $k_2$  values obtained for the five CoBuE-PS samples were averaged, and the averaged  $k_2$  was fixed in the analysis. In all cases, the fits were good with the analysis of the decays resulting in  $\chi^2$  smaller than 1.30 and residuals and autocorrelation function of the residuals randomly distributed around zero. The parameters retrieved from the analysis of the decays either globally with eqs. [9] and [10] or individually for the monomer decays with the FBM equation (i.e., eq. [11] with  $k_2 \rightarrow \infty$ ) are

**Fig. 8.**  $k_{\text{blob}}^0$  as a function of  $\eta^{-1}$  for CoE-PS (■), CoBuE-PS (◇, analysis of the monomer decays with eq. [11]), CoBuE-PS (□, global analysis of the monomer and excimer decays with eqs. [9] and [10]), and CoA-PS (▲).

listed in Tables SI.1–SI.8 in the Supplementary data. An example of the quality of the fits can be seen in Fig. 3.

For CoBuE-PS, the global analysis of the monomer and excimer fluorescence decays could only be achieved with eqs. [9] and [10], whereas for CoA-PS and CoE-PS, global analysis could be done with the simpler version of eqs. [9] and [10] obtained by assuming  $k_2 \gg k_1$  (i.e., eq. [11] for the pyrene monomer).<sup>13,18</sup> One reason why  $k_2$  could take smaller values for CoBuE-PS than for CoA-PS and CoE-PS might be due to the longer butyl linker used with CoBuE-PS compared to the short methyl linker used for CoA-PS and CoE-PS (Table 1). As shown in Scheme 1, the encounter of two polymer segments is followed by the quick rearrangement of the pyrene units into a conformation that allows optimal stacking of the pyrenes for excimer formation. The butyl linker might enable the pyrene pendants to adopt more conformations that do not lead to excimer formation, a process reflected by a smaller  $k_2$  value. The methylene linker used for CoA-PS and CoE-PS might reduce the number of inefficient conformations adopted by the pyrene pendants resulting in a faster rearrangement with  $k_2 \gg k_1$  in Scheme 1.

Analysis of the fluorescence decays yielded the average number of pyrenes per blob,  $\langle n \rangle$ , which was used with eq. [12] to determine the size of a blob as the number of styrene units making up a blob,  $N_{\text{blob}}$ .<sup>14,32</sup>

$$[12] \quad N_{\text{blob}} = \frac{\langle n \rangle}{[\lambda_{\text{Py}} / (1 - f_{\text{Mfree}})] \times [M_{\text{Py}}(x) + M_{\text{Sty}}(1 - x)]}$$

In eq. [12],  $\lambda_{\text{Py}}$  is the pyrene content in  $\text{mol} \cdot \text{g}^{-1}$  and  $f_{\text{Mfree}}$  is the fraction of pyrene monomer in the monomer fluorescence decays that do not form excimer (note that  $1 - f_{\text{Mfree}} = f_{\text{Mdiff}} + f_{\text{Mk}_2}$ ). In the case of CoBuE-PS,  $M_{\text{Py}}$  and  $M_{\text{Sty}}$  are the molar masses of a 1-pyrenebutyl acrylate and styrene units equal to 328 and 104  $\text{g} \cdot \text{mol}^{-1}$ , respectively, and  $x$  represents the molar fraction of pyrene labeled monomer in the polymer. A plot of  $N_{\text{blob}}$  as a function of the corrected pyrene content,  $\lambda_{\text{Py}} / (f_{\text{Mdiff}} + f_{\text{Mk}_2})$ , is shown in Fig. 4 when  $\langle n \rangle$  was retrieved from the global analysis of the monomer and excimer fluorescence decays. The trends shown in Fig. 4 in-

dicates that as the solvent viscosity increases and the motion of pyrene is hindered,  $N_{\text{blob}}$  decreases. The trends shown in Fig. 4 were extrapolated to zero-pyrene content to obtain the value of  $N_{\text{blob}}$  that an ideal unlabeled PS backbone would yield, which is referred to as  $N_{\text{blob}}^0$ . A similar procedure was applied to determine  $N_{\text{blob}}^0$  from the  $\langle n \rangle$  values retrieved from the analysis of the monomer decays with eq. [11]. The result of these analyses is shown in Fig. 5.

All trends in Fig. 5 show a similar behavior regardless of the polymer construct, as demonstrated in the inset of Fig. 5 where  $N_{\text{blob}}^0$  was scaled by 1.0, 0.95, 0.70, and 0.64 for CoA-PS, CoBuE-PS (analyzed globally with eqs. [9] and [10]), CoBuE-PS (analyzed with eq. [10]), and CoE-PS, respectively. The good overlap between the trends shown in the inset indicates that the FBM analysis of the fluorescence decays of the different Py-PS constructs satisfyingly handles differences in the nature of the linker and yields parameters such as  $N_{\text{blob}}^0$  and, as will be seen later on,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$ , that describe the chain dynamics of the polymer. The data in Fig. 5 show that  $N_{\text{blob}}^0$  increases with increasing  $\eta^{-1}$ , although that increase appears to be more pronounced for viscosities smaller and greater than 0.4 and 1.9 mPa·s, respectively. The overall increase of  $N_{\text{blob}}^0$  with  $\eta^{-1}$  reflects the enhanced restriction experienced by an excited pyrene moving in a more viscous solvent. In any solvent, CoE-PS yields the largest  $N_{\text{blob}}^0$  values, reflecting the longer reach enabled by the phenyl spacer between pyrene and the PS backbone, which allows pyrene to probe a larger volume,  $V_{\text{blob}}$ . CoA-PS and CoBuE-PS yield smaller  $N_{\text{blob}}^0$  values due to the shorter methyl and butyl pendants of the pyrene derivatives used to prepare these Py-PS constructs. Although the longer butyl linker of CoBuE-PS should theoretically yield a larger  $N_{\text{blob}}^0$  value than for CoA-PS, this is not always observed, certainly because the lifetime of the 1-pyrenebutyl derivative (Table 3) is usually about 50 ns smaller than that of the 1-pyrenemethyl derivative. Since  $V_{\text{blob}}$  is the volume probed by a chromophore while it remains excited, its value depends on both the lifetime and mobility of the excited chromophore. In the case of CoA-PS and CoBuE-PS, the longer lifetime of 1-pyrenemethyl with respect to that of 1-pyrenebutyl compensates to some extent for its reduced mobility associated with the shorter methylene linker.

Analysis of the monomer decays with eq. [11] yields  $N_{\text{blob}}^0$  values that are, on average, about 25% greater than those obtained by the global analysis of the CoBuE-PS decays with eqs. [9] and [10]. This difference in  $N_{\text{blob}}^0$  values appears to be inherent to the different types of analysis and will need to be taken into account when comparing trends obtained in future studies with other pyrene-labeled polymers.

As found in earlier reports,<sup>18,46</sup> the most informative parameter in a FBM analysis is the product  $k_{\text{blob}} \times N_{\text{blob}}$  because it is independent of pyrene content and it represents a measure of chain flexibility. It has also been shown to be much less sensitive to chromophore lifetime than the parameters  $N_{\text{blob}}$  and  $k_{\text{blob}}$ , which should facilitate comparison of the trends obtained with 1-pyrenemethyl and 1-pyrenebutyl.<sup>46</sup> It is plotted in Fig. 6 for CoBuE-PS in a series of solvents as a function of pyrene content using the results obtained from the global analysis of the monomer and excimer fluorescence decays. Similar trends were obtained when the monomer de-

cays were analyzed with eq. [11] (data not shown).  $k_{\text{blob}} \times N_{\text{blob}}$  in Fig. 6 is found to be independent of pyrene content. Its value can be averaged to yield  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$ , which is given in Fig. 7 for both analyses as a function of  $\eta^{-1}$ .

For all constructs and analyses, the product  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  increases linearly with increasing  $\eta^{-1}$  within experimental error. When the trends are scaled by a multiplication factor of 1.0, 0.86, 0.72, and 0.52 for, respectively, CoA-PS, CoBuE-PS (analyzed globally with eqs. [9] and [10]), CoBuE-PS (analyzed with eq. [11]), and CoE-PS, the trends appear to overlap remarkably well (inset in Fig. 7), demonstrating that the FBM analysis yields parameters that describe the chain dynamics of PS regardless of the nature of the Py-PS construct. Furthermore, the product  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  appears to reflect accurately the differences in behavior expected for the Py-PS constructs. CoA-PS with a short and rigid amide linker yields the smallest  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  values in all solvents. The largest  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  is obtained for the CoE-PS constructs that have a long and flexible ether linker. Regardless of the type of analysis used,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  takes intermediate values for CoBuE-PS whose butyl ester linker is longer and more flexible than that of CoA-PS but shorter and less flexible than that of CoE-PS. The  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  values obtained for CoBuE-PS from the analysis of the monomer decays with eq. [11] are, on average, 17% larger than those obtained with the global analysis of the monomer and excimer decays.

Since the rate constant for excimer formation inside a blob,  $k_{\text{blob}}$ , is often found to increase with pyrene content, it is obtained by taking the ratio  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle / N_{\text{blob}}^0$  and is referred to as  $k_{\text{blob}}^0$ .<sup>18,46</sup> The trends of  $k_{\text{blob}}^0$  as a function of  $\eta^{-1}$  are shown in Fig. 8 for all Py-PS constructs. Although scattered,  $k_{\text{blob}}^0$  remains relatively constant as a function of viscosity, taking an average value of  $1.0 \pm 0.3$ ,  $1.0 \pm 0.3$ ,  $1.1 \pm 0.3$ , and  $1.2 \pm 0.2 \times 10^7 \text{ s}^{-1}$  for CoA-PS, CoBuE-PS (analyzed with eq. [11]), CoBuE-PS (globally analyzed with eqs. [9] and [10]), and CoE-PS, respectively. Considering that the viscosity varies more than 10 fold from 0.36 mPa·s in methyl acetate to 5.5 mPa·s in benzyl alcohol, the small variations observed for  $k_{\text{blob}}^0$  with viscosity confirm that this parameter is relatively insensitive to solvent viscosity, an observation that has been already reported and rationalized within the framework of the FBM.<sup>16,18,19,46</sup>

Analysis of the monomer decays with eq. [11] yields  $N_{\text{blob}}^0$  and  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  values that are consistently 25% and 17% larger than those obtained from the global analysis of the monomer and excimer decays with eqs. [9] and [10]. One reason for this trend is that the introduction of  $k_2$  in eqs. [9] and [10] accounts for the early part of the monomer and excimer decays. It is this section of the decays that most affects  $\langle n \rangle$  and, to a lesser extent,  $k_{\text{blob}}$ . A steeper drop in the monomer decay accompanied by a rapid risetime in the excimer decay would result in larger  $\langle n \rangle$  values, and accordingly, larger  $N_{\text{blob}}$  and  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  values. Introducing  $k_2$  accounts for the fast early processes so that smaller  $\langle n \rangle$  values are obtained when using eqs. [9] and [10]. Although the absolute value of  $N_{\text{blob}}$  and  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  might not be known with an accuracy better than 25% and 17%, respectively, the present study demonstrates that a given analysis, either analysis of the monomer decays with eq. [11] or global analysis of the monomer and excimer decays with eqs. [9]

and [10], yields trends that are internally consistent (see insets in Figs. 5 and 7).

## Conclusions

The CoBuE-PS series of polystyrenes randomly labeled with 1-pyrenebutanol was prepared and their steady-state fluorescence spectra and monomer and excimer time-resolved fluorescence decays were acquired. The results obtained with the CoBuE-PS samples were compared with those obtained with the CoA-PS and CoE-PS series. The fluorescence spectra exhibited some noticeable differences in the spectral features of the pyrene monomer, whether or not the Py-PS construct was prepared with a 1-pyrenebutyl or a 1-pyrenemethyl derivative. In particular, the CoBuE-PS constructs prepared with the 1-pyrenebutyl derivative yielded larger  $I_M$  intensities than the Py-PS constructs obtained with the 1-pyrenemethyl derivative, which resulted in lower than expected  $I_E/I_M$  ratios. This observation highlighted the inherent difficulty of comparing trends obtained with polymers labeled with different pyrene derivatives.

If pyrene-labeled polymers are to be used to gain quantitative information on the chain dynamics of a given polymeric backbone in solution, the quantitative analysis of the pyrene monomer and excimer fluorescence decays must be carried out. This was done by using the FBM. FBM global analysis of the pyrene monomer and excimer fluorescence decays of CoBuE-PS highlighted another difference associated with the use of a 1-pyrenebutyl derivative. The rapid rearrangement step characterized by the rate constant  $k_2$  in Scheme 1 needed to be accounted for in the analysis. This had been found to be unnecessary for the CoA-PS and CoE-PS series<sup>17,18,46</sup> where a 1-pyrenemethyl derivative had been used to label polystyrene. Despite this mathematical modification needed to globally analyze the pyrene monomer and excimer fluorescence decays of CoBuE-PS, the trends obtained with the parameters  $N_{\text{blob}}^0$ ,  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$ , and  $k_{\text{blob}}^0$  as a function of  $\eta^{-1}$  matched closely with those found earlier with CoA-PS and CoE-PS (see Figs. 5, 7, and 8). Comparison of the  $N_{\text{blob}}^0$  and  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  values obtained by fitting the monomer fluorescence decays with eq. [11] or the monomer and excimer fluorescence decays globally with eqs. [9] and [10] for CoBuE-PS showed that the former analysis yielded  $N_{\text{blob}}^0$  and  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  values that were, respectively, 25% and 17% larger than those obtained by the latter analysis.

The similar trends obtained for  $N_{\text{blob}}^0$  (Fig. 5),  $\langle k_{\text{blob}} \times N_{\text{blob}} \rangle$  (Fig. 7), and  $k_{\text{blob}}^0$  (Fig. 8) indicate that despite the various changes associated with the use of the 1-pyrenebutyl derivative in terms of a shorter lifetime and the need of a modified FBM analysis that accounts for the rapid rearrangement of the pyrene moieties, the FBM accounts satisfyingly for these changes and retrieves information that describes the behavior of the polymer, not that of the label. Since the 1-pyrenebutyl derivative seems to be commonly used to label macromolecules,<sup>20–29</sup> this study is expected to represent an important reference point to which the behavior of other polymers labeled with a 1-pyrenebutyl derivative can be compared.

# Synthesis of *N*-vinylcarbazole-*N*-vinylpyrrolidone amphiphilic block copolymers by xanthate-mediated controlled radical polymerization

Chih-Feng Huang, Jeong Ae Yoon, and Krzysztof Matyjaszewski

**Abstract:** Amphiphilic block copolymers poly(*N*-vinylcarbazole)-*b*-poly(*N*-vinylpyrrolidone) (PNVK-*b*-PNVP) were prepared by xanthate-mediated reversible addition-fragmentation chain transfer (RAFT) polymerization. Both the PNVK and PNVP macroinitiators and the resulting block copolymers had molecular weights close to theoretical values, predicted for efficient initiation, in the range of  $M_n = 30\,000$  to  $90\,000$ . The block copolymers dissolved in several organic solvents but, depending on their composition, in methanol formed either micelles or large aggregates, as confirmed by dynamic light scattering. The presence of globular aggregates was confirmed by tapping mode atomic force microscopy.

**Key words:** amphiphilic block copolymer, RAFT, living radical polymerization, micelle.

**Résumé :** On a préparé des copolymères à bloc amphiphiles poly(*N*-vinylcarbazole)-*b*-poly(*N*-vinylpyrrolidone) (PNVK-*b*-PNVP) par une réaction de polymérisation de transfert de chaîne avec addition-fragmentation réversible (TCAR) catalysée par le xanthate. Les valeurs des poids moléculaires des deux macroinitiateurs PNVK et PNVP ainsi que des copolymères à bloc qui en ont résulté étaient proches des valeurs théoriques prévues pour une initiation efficace, de l'ordre de  $M_n = 30\,000$  à  $90\,000$ . Les copolymères à bloc se dissolvent dans plusieurs solvants organiques; toutefois, dans le méthanol, suivant leur composition, il y a formation de micelles ou de gros agrégats décelés par la diffusion dynamique de la lumière. La présence d'agrégats globulaires a aussi été confirmée par la spectroscopie en mode de forces atomiques.

**Mots-clés :** copolymère à bloc amphiphile, transfert de chaîne avec addition-fragmentation réversible (TCAR), polymérisation radicalaire vivante, micelle.

## Introduction

The preparation and properties of amphiphilic block copolymers, with hydrophilic and hydrophobic blocks, is currently an area of active study. Amphiphilic block copolymers form various supramolecular structures such as micelles, cylinders, or vesicles through self-organization and self-assembly and are being evaluated in numerous applications including emulsifiers, dispersants, and surfactants.<sup>1</sup> Potential uses also include microcontainers for delivery of hydrophobic materials or templates for syntheses of materials with nanosized features.

The aim of this study is to synthesize amphiphilic block copolymers using *N*-vinylcarbazole and *N*-vinylpyrrolidone (PNVK-*b*-PNVP). PNVK, a carbazole-containing polymer, is a photoconductive material with good charge-transport properties that has found applications as a photoreceptor, light-emitting diode, and photorefractive material.<sup>2</sup> On the other hand, PNVP, the water-soluble block, has been used

in medical, pharmaceutical, and cosmetic applications, due to its low toxicity and good biocompatibility.<sup>3</sup> This indicates that PNVK-*b*-PNVP could be an interesting conductive polymer which could be processed in water. The nanophase separation of the amphiphilic block copolymer could result in a conductive PNVK segment embedded in an insulating PNVP matrix. There are only a few reports on water processable conductive block copolymers because of the difficulties with synthesis.<sup>4</sup> To prepare well-defined amphiphilic block copolymers, a controlled/living polymerization technique is required.<sup>5</sup> Although both NVK and NVP can be polymerized by radical mechanisms, the controlled radical polymerizations of NVK and NVP have not been yet thoroughly studied due to the low reactivity of non-conjugated vinyl monomers.

In general, block copolymers can be prepared by three routes: sequential monomer addition;<sup>6</sup> chain-end coupling of separately prepared blocks;<sup>7</sup> or transformation of chain ends of polymers prepared by one mechanism into initiating moi-

eties for the chain propagation of the second monomer.<sup>8</sup> Previous attempts to prepare well-defined PNVK or PNVP homopolymers using one of the CRP methods has involved a degenerative transfer radical mechanism,<sup>9</sup> ATRP,<sup>10</sup> or Co-mediated polymerization.<sup>11</sup> Only a few studies describe chain extension from either PNVK or PNVP homopolymers to prepare block copolymers.<sup>12</sup> Regardless of the potentially interesting properties, block copolymers of PNVK and PNVP (PNVK-*b*-PNVP) have not been yet prepared, since the synthesis of well defined PNVK-*b*-PNVP block copolymers is challenging, owing to the low reactivity of both NVK and NVP. The low reactivity of NVK and NVP and the low stability of the propagating radicals indicate that a degenerative transfer process, such as reversible addition-fragmentation chain transfer (RAFT) polymerization, could be best suited for conducting a controlled polymerization. For this study, we selected a xanthate-type mediating agent, since it was successfully employed for RAFT polymerization of less active monomers in previous studies.<sup>12d</sup>

## Experimental

### Materials

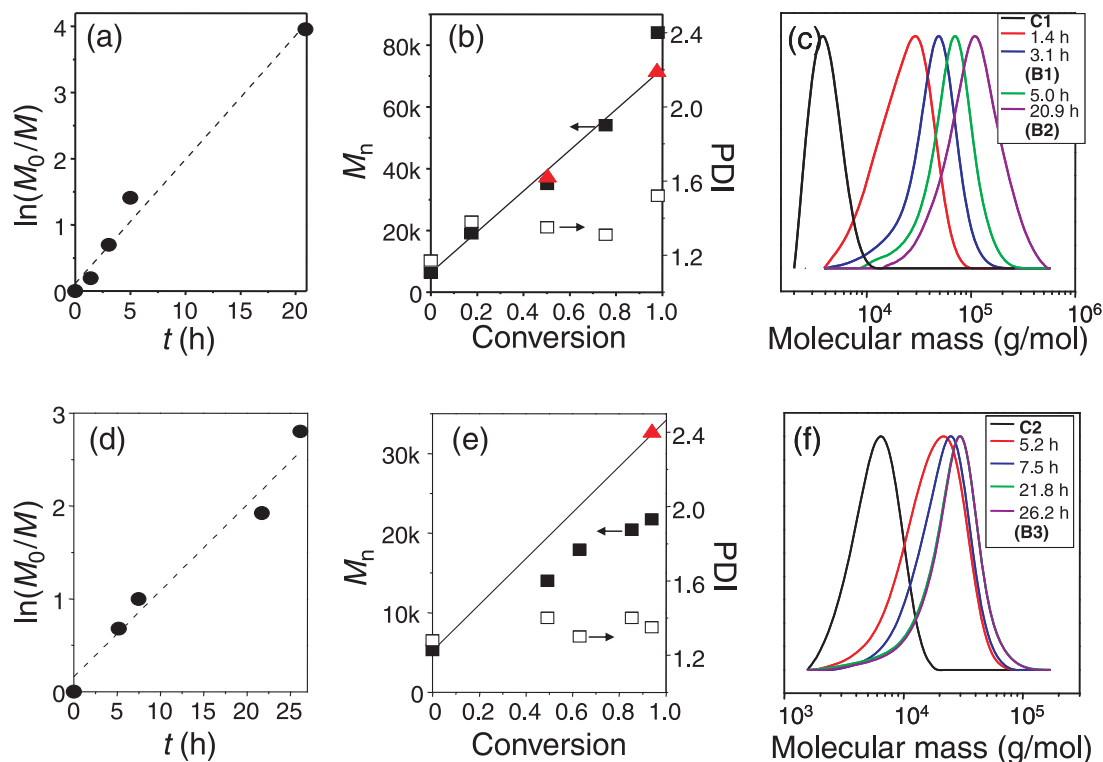

*N*-Vinylpyrrolidone (NVP, 99%, Sigma-Aldrich) was dried over anhydrous magnesium sulfate and purified by dis-

tillation under reduced pressure. *N*-vinylcarbazole (NVK, 97%, Sigma-Aldrich) and 2,2'-azobis(isobutyronitrile) (AIBN, 99%, Sigma-Aldrich) were recrystallized twice from methanol. All solvents were purified by distillation prior to use. *S*-(2-Ethyl propionate)-*O*-ethyl xanthate (EX)<sup>13</sup> was synthesized according to the literature procedure. Briefly, potassium *O*-ethyl xanthate (4.75 g, 2.9 × 10<sup>-2</sup> mol) was dissolved in 25 mL of ethanol with ethyl 2-bromopropionate (4.74 g, 5.3 × 10<sup>-2</sup> mol) for 20 h at room temperature. The crude product was purified by extraction with diethyl ether – water followed by column chromatography using hexane – ethyl acetate 95:5 (v/v) as eluent to give a yellow oil. Yield: 3.0 g (51%). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>, ppm) δ: 4.63 (q, 2H), 4.37 (q, 1H), 4.20 (q, 2H), 1.56 (d, 3H), 1.41 (t, 3H), 1.28 (t, 3H).

### RAFT polymerization of NVK (C1)

3.41 g of NVK (17.6 mmol), 91.0 mg of EX (0.410 mmol), 34.0 mg of AIBN (0.207 × 10<sup>-3</sup> mmol), and 8 mL of anisole were charged to a Schlenk flask. The molar ratio of NVK–EX–AIBN was 43:1:0.5. The mixture was de-oxygenated by three freeze–pump–thaw cycles. The flask was placed in an oil bath thermostated at 60 °C for a required time period. Samples were withdrawn via a syringe for the measurement of monomer conversion and molecular

weight of polymer by GPC with DMF or THF as eluent. The reaction was quenched by placing the flask in an ice bath, exposing to air, and diluting with THF to provide the PNVK-EX macromolecular chain transfer agent (C1). The crude polymer was purified by filtering through an alumina column followed by precipitation in hexane. Conversion = 71% (by NMR);  $M_{n, \text{theor}} = 6200$  g/mol,  $M_{n, \text{THF GPC}} = 6300$  g/mol (PDI = 1.28).

#### RAFT polymerization of NVP (C2)

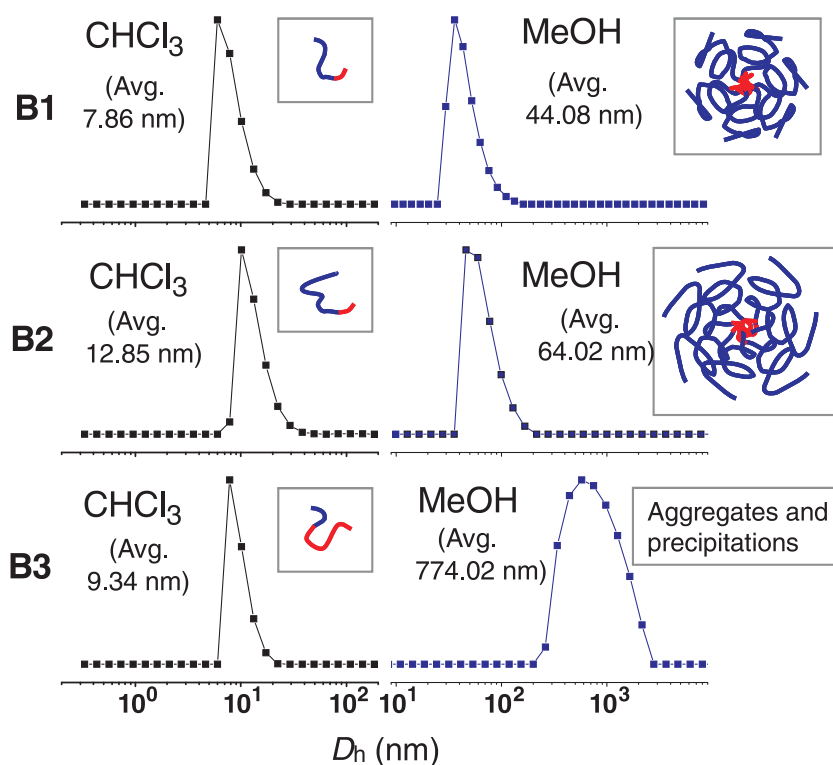

10.0 mL of NVP (10.4 g, 93.7 mmol), 139 mg of EX (0.626 mmol), 4.1 mg of AIBN (0.220 mmol), 2.5 mL of anisole were charged to a Schlenk flask. The mole ratio of NVP-EX-AIBN was 150:1:0.35. The mixture was deoxygenated by three freeze-pump-thaw cycles. The flask was placed in an oil bath thermostated at 60 °C for the desired time period. The rest of the procedure was the same as that for the

preparation of C1. Conversion = 30% (by NMR);  $M_{n, \text{theor}} = 5200$  g/mol,  $M_{n, \text{DMF GPC}} = 5300$  g/mol (PDI = 1.28).

#### Chain extension of PNVK (C1) by RAFT polymerization of NVP forming a block copolymer

3.04 mL of NVP (3.18 g, 28.6 mmol), 0.300 g of C1 ( $M_{n, \text{THF GPC}} = 6300$  g/mol, PDI = 1.28,  $47.6 \times 10^{-3}$  mmol), 3.90 mg of AIBN ( $23.7 \times 10^{-3}$  mmol), and 1.56 mL of anisole were charged to a Schlenk flask. The mole ratio of NVP-C1-AIBN was 600:1:0.5. The mixture was deoxygenated by three freeze-pump-thaw cycles and then was placed in an oil bath thermostated at 60 °C for the required time period. Monomer conversion and molecular weight were tracked by GPC with DMF as eluent. At the desired conversion, the reaction was quenched and the polymer was purified by filtering through an alumina column followed by precipitation in hexane. B1 conversion = 50% (by GPC);  $M_{n, \text{theor}} = 39\,200$  g/mol,  $M_{n, \text{DMF GPC}} = 35\,400$  g/mol

**Fig. 2.** DLS profile for PNVK-*b*-PNVP block copolymer (**B1**, **B2**, and **B3**) in chloroform and methanol. Blue line: PNVP block, Red line: PNVK block.

**Fig. 3.**  $^1\text{H}$  NMR spectra of B1 in different solvents, toluene- $d_8$ , MeOH- $d_4$ , and chloroform- $d$ .

(PDI = 1.35). B2 conversion = 98% (by GPC);  $M_{n, \text{theor}} = 70\,900$  g/mol,  $M_{n, \text{DMF GPC}} = 88\,000$  g/mol (PDI = 1.52).

#### Chain extension of PNVP (C2) by RAFT polymerization of NVK

1.09 g of NVK (5.65 mmol), 0.200 of C2 ( $M_{n, \text{DMF}} = 5300$  g/mol, PDI = 1.28,  $37.7 \times 10^{-3}$  mmol), 3.10 mg of AIBN ( $18.9 \times 10^{-3}$  mmol), and 2.60 mL of anisole were charged to a Schlenk flask. The mole ratio of NVK–C2–AIBN was 150:1:0.5. The mixture was deoxygenated by three freeze–pump–thaw cycles. The flask was placed in an oil bath thermostated at 60 °C for the required time. The rest of the procedure was the same as that for the block copoly-

merization of NVP from PNVK described above. B3 conversion = 94% (by GPC);  $M_{n, \text{theor}} = 32\,400$  g/mol,  $M_{n, \text{DMF GPC}} = 21\,700$  g/mol (PDI = 1.35).

#### Analyses

The molecular weights and molecular-weight distributions were measured using GPC (Polymer Standards Services, columns (guard,  $10^5$ ,  $10^3$ , and  $10^2$  Å)) with DMF (containing 5 mmol/L LiBr) as eluent at 50 °C or with THF as eluent at 35 °C. The flow rate was kept at 1.00 mL/min and a differential refractive index (RI) detector (Waters, 2410) was used. Toluene was used as the internal standard to correct for any fluctuation in eluent flow rate. The molecular weight

**Fig. 4.** 3D images of height mode AFM at different conditions. B1: (a), (b), and (c), B3: (d), (e), and (f).

**Fig. 5.** 3D height mode AFM images (left column) and phase mode AFM images (right column) of B1 (a, b) and B2 (c, d) after drop casting of DMF solution and drying. Phase image size:  $0.6\ \mu\text{m} \times 0.6\ \mu\text{m}$ .

and the molecular-weight distribution were determined with a calibration curve based on linear PMMA (for DMF GPC line) or PS (for THF GPC line) standards using GPCWin software. Conversions were determined by NMR on a Bruker Avance™ 300 MHz instrument or by an internal standard addition, injecting a known amount of monomer into reaction mixtures and following the peak area changes in GPC traces. Particle size and size distribution were measured by dynamic light scattering (DLS) on High Performance Particle Sizer, Model HP5001 from Malvern Instruments, Ltd. DLS measurements provide average diameter,  $D_{\text{av}}$ , and size distribution index, CV (coefficient of variation), which is defined as  $\text{CV} = (S \times 100)/D_{\text{av}}$ , where  $D_{\text{av}}$  is the mean diameter and  $S$  is the size standard deviation. Tapping mode AFM experiments were carried out using a Multimode Nanoscope V system (Veeco instruments). The measurements were performed in air using commercial Si cantilevers with a nominal spring constant and resonance fre-

quency of 40 N/m and 330 kHz, respectively. The height and phase images were acquired simultaneously at a set-point ratio ( $A/A_0$ ), in the range of 0.7–0.9, where  $A$  and  $A_0$  refer, respectively, to the “tapping” and “free” cantilever amplitude.

## Results and discussions

### Synthesis

The synthesis of PNVK-*b*-PNVP block copolymers was conducted sequentially via the two alternative pathways shown in Scheme 1.

First, macromolecular chain transfer agents (CTAs), i.e., macroinitiators, were prepared by RAFT polymerizations using EX as a CTA. The molecular weights of the macroinitiators were measured by GPC and summarized in Table 1. The molecular weight of C1 measured by GPC (in THF using PS standards) ( $M_n = 6300$ ,  $\text{DP} = 31$ ) agreed well with the value estimated from monomer conversion ( $\Delta[M]/[\text{EX}]_0 = 43$ ,  $\text{DP} = 31$  at 71% conversion), assuming quantitative initiation. However, when the molecular weight was measured by GPC in DMF, a much smaller value ( $M_n = 3800$ ,  $\text{DP} = 19$ ) was obtained, presumably due to the formation of more compact polymer coils in DMF. A similar observation concerning a much smaller molecular weight of PS measured in DMF GPC, was reported previously.<sup>14</sup> The molecular weight of C2, determined by GPC (in DMF, PMMA standards), corresponded well to the theoretical molecular weight estimated from monomer conversion ( $\text{DP} = \Delta[M]/[\text{EX}]_0$ ) with the assumption of the quantitative initiation efficiency. The molecular weight of the macroinitiators measured by GPC (in DMF) compared well with the molecular weight calculated by end group analysis of  $^1\text{H}$  NMR spectra. For example, for another PNVP macroinitiator prepared under the same conditions as C2,  $M_n$  was calculated by end group analysis to be 4400 g/mol, and was measured by GPC to be 4500 g/mol (in DMF, PMMA standards). Furthermore, good agreement of experimental and theoretical molecular weights indicated that the number of new chains generated by decomposition of AIBN, coupling with CTA, and transfer process was small.

Chain extensions from the prepared macroinitiators were

performed by RAFT polymerization of the second monomer. The molecular weight and polydispersity of each block copolymer and the block copolymer composition determined by NMR are summarized in Table 1. Figure 1 displays the kinetic plots, the linear change of molecular weight with conversion, and the evolution of GPC traces over time for each block copolymer. The chain extension reactions were carried out to over 90% monomer conversion for both pathways. The molecular weights of B1 and B2 measured by GPC (in DMF, PMMA standards) were very similar to the calculated molecular weights based on monomer conversion and  $^1\text{H}$  NMR analyses. THF could not be used as GPC eluent for PNVP because it is isorefractive with PNVP. The molecular weight of B3, calculated from the  $^1\text{H}$  NMR spectrum, was very close to that based on monomer conversion, assuming quantitative initiation. The values differed from the  $M_n$  by GPC (in DMF, PMMA standard) which can be attributed to the compact structure of the PNVK block (83 wt% in B3) in DMF, as was the case with the PNVK macroinitiator. The observed first-order kinetic plots and the very high efficiency of the chain extensions suggested the negligible contribution of possible side reactions such as formation of NVP dimers or elimination of xanthate end groups.<sup>12e,15</sup> This could be attributed to the simple structure of xanthate (EX), use of purified reagents, and the mild polymerization temperature (60 °C).

### DLS and NMR studies

Particle-size distribution (volume vs. hydrodynamic diameter ( $D_h$ )) of each prepared block copolymer was studied by dynamic light scattering (DLS). Table 2 summarizes particle size distributions in various solvents having different polarities (represented in Table 2 by dielectric constant). The DLS profiles in two representative solvents, chloroform and methanol, are presented in Fig. 2.

All block copolymers displayed  $D_h$  values smaller than 15 nm in medium polarity solvents (chloroform and THF), implying dissolution of the block copolymers without formation of aggregates. However, when methanol was used as the solvent, the average particle size was much larger, ranging from 44 to 64 nm for B1 and B2, and resulted in larger aggregates ( $D_h > 700$  nm) for B3 (some precipitation was visually observed). Methanol, a non-solvent for PNVK and a good solvent for PNVP, resulted in formation of micelles with PNVP as the major block in the outer shell (B1 and B2). With PNVK as the major block (B3), larger aggregates were formed, accompanied by precipitation. Assuming full stretching of PNVP chains, the calculated size of micelles for B1 and B2 should range from 150 nm to 390 nm ( $\text{DP} \times (0.25 \text{ nm}) \times 2$ ), respectively. Observed smaller diameters suggest coiled chains of PNVP, due to a less dense micelle structures (Fig. 2, insets). In contrast to methanol, anisole is a good solvent for PNVK because of aromatic interactions and a poor solvent for PNVP because of its weak hydrogen-bonding ability. As a result, while B3 dissolved as individual chains ( $D_h = 10.3$  nm), B1 and B2, with PNVP as the major block, formed very large aggregates sized over 300 nm (cf. Table 2).

The change of solubility of the block copolymer in selective solvents was further confirmed by  $^1\text{H}$  NMR measurements. The  $^1\text{H}$  NMR spectra of B1 are shown in Fig. 3. In

the spectrum measured in chloroform-*d*, a good solvent for both blocks, peaks from both PNVK block (4.5–8 ppm) and PNVP block (0.5–4.5 ppm) are well resolved. However, the peaks of PNVK block disappear when measured in MeOH-*d*<sub>4</sub>, because of the insolubility of the PNVK block. Toluene-*d*<sub>8</sub> was selected as a nonpolar solvent instead of anisole. No appreciable peak was observed, proving the insolubility of the B1 to toluene owing to the large portion of polar PNVP block.

### AFM studies

The phase separation in block copolymers was also observed by tapping mode AFM (Fig. 4). The block copolymers B1 and B3 were dissolved in chloroform (1 mg/mL) and solutions were drop-cast onto silicon wafers (1 cm  $\times$  1 cm), followed by drying under vacuum at room temperature overnight. The films of block copolymers were studied by AFM. Globular morphologies with dimensions of 37 nm and 49 nm were observed for B1 and B3. Although the dilute chloroform solutions of B1 and B3 did not contain aggregates (cf. DLS studies), they formed aggregates as concentration increased during the solvent evaporation. The polymer films were then annealed at 160 °C (Figs. 4b and 4e) and 190 °C (Figs. 4c and 4f), i.e., above the  $T_g$  of PNVP block ( $\sim 120$  °C) under vacuum. Because the annealing was conducted below the  $T_g$  of the PNVK block ( $\sim 210$  °C), phase separation could not be enhanced by thermal annealing. The aggregates, formed during the film formation, relaxed, as seen from smoothed surfaces after annealing.

The hypothesis that the globular morphology was generated by aggregation of polymers during the drying process was supported by another experiment. This time, block copolymers B1 and B2, with the same PNVK block but different chain length of PNVP, were dissolved in DMF, a good solvent for both blocks. Since DMF evaporates at a slower rate than chloroform, it should provide sufficient time for the copolymers to attain lower-energy morphologies. The height and phase mode AFM images of B1 and B2 in Fig. 5 were measured after drop casting and drying of DMF in a vacuum oven at room temperature. The average domain sizes of B1 and B2, obtained by 2D isotropic power spectral density analysis of height images, were 28 and 33 nm, respectively, indicating that the increase in the size of the domains is correlated with the dimensions of the PNVP blocks ( $\text{DP} = 269$  vs.  $\text{DP} = 573$ ).

### Conclusion

Amphiphilic block copolymers with a hydrophobic PNVK block and a hydrophilic PNVP block were synthesized by xanthate-mediated RAFT polymerization by preparation of PNVK or PNVP macroinitiators and sequential chain extensions with the second monomer, i.e., NVP or NVK. The resulting block copolymers had low polydispersity and the molecular weight, measured by GPC and  $^1\text{H}$  NMR, agreed well with the theoretical values. The particle-size distributions of the prepared block copolymers were measured in various solvents with different polarities. Block copolymers B1 and B2, with longer PNVP blocks, formed micelles in methanol whereas B3, with PNVK as the major block,

formed larger aggregates and precipitates. AFM measurements of film samples revealed the block copolymers aggregated during the drying of films, even though the initial solution did not contain aggregates. Annealing the film samples at a temperature between the  $T_g$  of PNVK (210 °C) and PNVP (120 °C) yielded a smoother surface than before annealing but did not enhance the phase separation.

# Synthesis, photophysics, and electrochemistry of thiophene–pyridine and thiophene–pyrimidine dyad comonomers

Andréanne Bolduc, Stéphane Dufresne, Garry S. Hanan, and W.G. Skene

**Abstract:** A series of new  $\pi$ -conjugated donor (D) and acceptor (A) dyad comonomers were prepared using Suzuki coupling protocols. The D–A comonomers consisting of thiophene/bithiophene as donors and pyridine/pyrimidine as acceptors were prepared to investigate their photophysical and electrochemical properties. The dyads were spectroscopically confirmed to be highly conjugated. This was further supported by the X-ray crystal structure of the bithiophene–pyridine dyad that showed all the heterocycles to be coplanar. It was further found that the fluorescence yields ( $\Phi_f$ ) of the dyads were highly dependent on the number of thiophenes. The bithiophene derivatives exhibited  $\Phi_f$  values  $\geq 0.3$  while the thiophene derivatives did not fluoresce. The suppressed fluorescence observed for the thiophene derivatives was due to their higher triplet energy resulting in efficient intersystem crossing (ISC) to the triplet state with  $\Phi_{ISC} \geq 0.8$ . This was confirmed both by time-resolved and steady-state measurements. The singlet excited state of both thiophene and bithiophene dyads was deactivated solely by either fluorescence and (or) ISC. Owing to their donor and acceptor character, the dyads could be oxidized and reduced both electrochemically and photochemically to afford the radical cation and anion, respectively.

**Key words:** comonomer, thiophene, pyridine, pyrimidine, photophysics, fluorescence.

**Résumé :** À l'aide d'un couplage de Suzuki, une série de comonomères conjugués contenant une fonction donneur d'électrons (D) et une fonction accepteur d'électrons (A) ont été préparés. Ces comonomères, dits D–A, qui utilisent le thiophène/bithiophène comme donneurs d'électrons et la pyridine/pyrimidine comme accepteurs d'électrons, ont été synthétisés dans le but d'analyser leurs propriétés photophysiques et électrochimiques. Il a été évalué spectroscopiquement que les dimères sont grandement conjugués. Ceci est d'ailleurs soutenu par la structure rayons-X du composé bithiophène–pyridine qui montre que tous les hétérocycles sont coplanaires. Il a été déterminé que les rendements quantiques de fluorescence ( $\Phi_f$ ) des composés dépendent du nombre de thiophènes présents dans la molécule. En effet, les dérivés du bithiophène ont des  $\Phi_f \geq 0,3$  tandis que les dérivés du thiophène ne fluorescent pas. Cette absence de fluorescence est causée par la formation d'un état triplet de haute énergie par croisement intersystème (ISC pour « intersystem crossing ») avec un  $\Phi_{ISC} \geq 0,8$ . L'état singulet excité des dimères de thiophène et de bithiophène est uniquement désactivé par la fluorescence ou le ISC. Grâce à leur caractéristique donneur/accepteur, les comonomères ont pu être oxydés et réduits électrochimiquement et chimiquement afin de former le radical cation et le radical anion.

**Mots-clés :** comonomère, thiophène, pyridine, pyrimidine, photophysique, fluorescence.

## Introduction

Conjugated materials have attracted much attention because of their electrochemical and photophysical properties that are ideally suited for plastic electronics, including organic field effect transistor,<sup>1–4</sup> photovoltaics,<sup>5,6</sup> emitting devices,<sup>7,8</sup> and conducting materials,<sup>9,10</sup> to name but a few. Thiophenes have been widely used in these electronic applications owing to their low oxidation potential and their possibility of undergoing electropolymerization resulting in conjugated polymers possessing extremely low oxidation potentials. However, homopolymers of thiophene and its deriv-

atives often have undesirably high HOMO–LUMO energy gaps ( $E_g$ ) and oxidation potentials ( $E_{pa}$ ) that are unsuitable for functional materials, as well as weak fluorescence.

The  $E_g$  and  $E_{pa}$  can be modulated by copolymerizing thiophene with different electron-donating and -accepting monomers. However, homopolymers are solely obtained if the oxidation potentials of both the monomer and thiophene are not closely matched. Although choosing monomers with  $E_{pa}$  that are closely matched to thiophene results in copolymers, the  $E_g$  and  $E_{pa}$  are similar to those of the homopolythiophene. This problem can be overcome with comonomers. The comonomer configuration consisting of a central aro-

**Scheme 1.** Synthetic scheme for **1** and **3** (top) and **2** and **4** (bottom).

matic acceptor (A) core inserted between electron-rich donors (D) simplifies the electropolymerization process that would otherwise require two or three separate monomers to obtain analogous alternating copolymers via other coupling methods.<sup>11,12</sup> The same polymer can also be obtained by cathodic polymerization of a D–A–D comonomer.

Comonomers consisting of electron-deficient heterocycles, such as pyridine, pyrazine, and pyrimidines, are also interesting because they can coordinate with metals. This can be done either prior to- or post-polymerization, affording metal-containing polymers. Property tailoring for a given application is possible by coordinating different metals. *n*-Doping of the electron-deficient-containing compounds is further possible resulting in the both *p*- and *n*-type polymers.

Unlike the polymerization of D–A–D or A–D–A comonomers that can be done in one step, the polymerization of D–A comonomers requires two steps. This can either be done by anodic dimerization followed by cathodic polymerization or the reverse. The added advantage of the stepwise polymerization of D–A comonomers is that the anodically and cathodically coupled dimers can be characterized, and the metal complexes can be isolated and characterized as well. Structure–property relationships are therefore possible in addition to tailoring the properties for a given application. This is in contrast to their triad cousins that are insoluble when polymerized, precluding their spectroscopic and molecular-weight characterization.

Our ongoing investigation of conjugated polymers<sup>13–19</sup> and our previous endeavors in comonomer synthesis<sup>11,20</sup> prompted us to prepare a series of  $\pi$ -rich and  $\pi$ -poor dyad comonomers consisting of thiophenes and both pyridine and pyrimidine. These compounds are of particular interest because they are expected to exhibit mutual *p*- and *n*-doping properties allowing for selective stepwise anodic and cathodic coupling potentially leading to D–A–A–D and A–D–D–A comonomer products, respectively. These can then subsequently be electropolymerized. Furthermore, the  $\pi$ -donor/acceptor arrangement provides the means to tune the HOMO–LUMO energy levels and to tailor the spectroscopic and electrochemical properties.<sup>21–24</sup>

Herein, we present the preparation of new  $\pi$ -donor/acceptor

**Chart 1.** Comonomers synthesized.

dyad comonomers along with their steady-state and time-resolved photophysics and electrochemical characterization. The combined effect of thiophene and bithiophene  $\pi$ -donors coupled with pyridine and pyrimidine  $\pi$ -acceptors for comonomers is presented. Although such compounds are of interest for their electrochemical properties, little work has examined the photophysics for such dyads. Their structure–property relationships and the understanding of their fluorescence deactivation mechanisms are of interest for the design and property tuning of new compounds. For these reasons, the photophysical properties, including the emission yields and excited-state deactivation pathways, of these new comonomers are studied. The investigation of such properties provides valuable information for determining the suitability of such precursors for functional materials and for the design of future compounds.

## Synthesis

The comonomers **2** and **4** (Chart 1) were prepared by standard Suzuki coupling.<sup>25,26</sup> The 2-thiophene boronic acid and 2-bithiophene boronic acid precursors required for Suzuki coupling were obtained by standard aryl anion formation with *n*-BuLi followed by nucleophilic addition to triethylboronate ester starting from inexpensive thiophene and bithiophene, respectively.<sup>27</sup> The boronic acids were

coupled with a chloropyridine by Suzuki coupling in aqueous isopropanol, and this solvent led to homogenous reaction mixtures resulting in higher yields.<sup>11</sup> The reaction proceeded cleanly at 50 °C with only 1 mol% of catalyst. Conversely, **1** and **3** (Chart 1) were less straightforward to prepare, since the required 4-halogenopyrimidine commercially precursor is unavailable and the 2- and the 5-substituted derivatives are expensive. The required pyrimidine precursors for the synthesis of **1** and **3** were therefore prepared by a Michael reaction according to Scheme 1. This route unfortunately required a slow ring-closing step requiring 7 days for completion.<sup>28–30</sup>

## Crystallography

Confirmation of the formation of **4** was obtained by X-ray diffraction (Table 1). Suitable crystals for analysis were obtained from the slow evaporation of **4** in dichloromethane. The resolved structure is shown in Fig. 1. The resolved structure shows disorder of the terminal thiophene consisting of inversion of the thiophene. The thiophene (S1–C1–C2–C3–C4) weights are 76% for the structural representation with the two thiophene adopting an anti conformation. The remaining 24% is attributed to the minor isomer in which the two thiophenes are syn. It should be noted that the heterocycles are nearly coplanar, contributing in part to its high degree of conjugation (vide infra). The torsion angle between the pyridine and the central thiophene is 5.38° while that of two thiophenes is 9.75°, and is consistent with similar structures.<sup>11</sup>

The molecules of **4** in the crystal lattice align along the *a*–*b* axis in a zig-zag fashion as shown in Fig. 2. This arrangement is in part a result of non-conventional H-bonding occurring between C11–H and N1. The distance between C11 and N1 is 3.443 Å, which is within a suitable distance for such a weak interaction. Face-edge  $\pi$ -stacking also oc-

**Fig. 1.** X-ray structure of **4** and the numbering scheme adopted.

curs between S2–C5–C6–C7–C8 and the pyridine through C12 with the two being separated by 3.665 Å. C1 is also directed towards the N1–C9–C10–C11–C12–C13 ring, and they are separated by a distance of 3.427 Å (Fig. 3).

## Spectroscopy

The effect of the number of heterounits in the comonomer on the spectroscopic properties can be seen from the spectroscopic data in Table 2. Both the absorption and fluorescence maxima of **3** and **4** are bathochromically shifted relative to **1** and **2**. The bathochromic shifts imply an increased degree of conjugation resulting from the bithiophene unit relative to thiophene. The increased degree of conjugation of the bithiophene dyad relative to the thiophene is also evident from the *E<sub>g</sub>*, which is lower for **3** and **4** than for **1** and **2**. It is noteworthy that the *E<sub>g</sub>* is larger for pyridine-containing dyads compared with their pyrimidine analogues, owing to the more electron deficient nature of diazines, which perturbs the LUMO level.

Functional materials with high fluorescence yields are of interest for emitting devices. High fluorescence yields are also desired for efficient ligand-to-metal energy transfer. For these reasons, we examined the fluorescence quantum yields for the comonomer dyads. Both the bithiophene dyads are highly fluorescent relative to their thiophene analogues. High fluorescence yields were confirmed by measuring the absolute emissions with an integrating sphere. The advantage of the integrating sphere is that references with similar absorption, emissions, and emission yields to the compounds of study are not required. Even though the fluorescence values measured for **1** and **2** are below the detection limit of the integrating sphere, accurate fluorescence measurements of **3** and **4** are possible. It can be concluded that **1** and **2** are nonfluorescent. The difference in fluorescence between the two sets of dyads implies two different deactivation pathways of the singlet excited state are present. Although both the thiophene and bithiophene dyads exhibit unimolecular fluorescence decays of approximately < 2 ns, an efficient deactivation mode competes with fluorescence for **1** and **2**, resulting in suppressed fluorescence.

Deactivation of the excited state by intramolecular charge transfer (ICT) can lead to suppressed fluorescence. ICT often results from charge separation occurring on separate donor–acceptor moieties. Charge separation can be visualized from the molecular orbitals, which can be accurately calculated by theoretical means. The HOMO and LUMOs of the comonomers were therefore investigated to afford insight into the different excited-state deactivation modes. As

**Fig. 4.** HOMO (left) and LUMO (right) energy levels calculated via DFT of **4** (A), **3** (B), and **2** (C).

seen in Fig. 4, the HOMO and LUMO orbitals calculated from DFT single-point energies from the X-ray crystal coordinates are not isolated on one heterocycles and they are evenly distributed across the heterocycles regardless of the dyad. ICT is therefore not responsible for the different fluorescence yields despite the  $\pi$ -donor/acceptor character.

The singlet excited state deactivation pathways of the comonomers were further investigated using various quenchers. In all cases, the comonomers were self-quenched with diffusion-controlled kinetics in acetonitrile ( $2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ ).<sup>31</sup> All spectroscopic measurements were subsequently done at extremely low concentrations ( $10^{-6} \text{ mol/L}$ ) to avoid self-quenching. An electron acceptor (benzoquinone) and donor (*N,N'*-dimethylaniline) were added to determine whether the comonomers could undergo photoinduced electron transfer. Interestingly, all the comonomers studied were quenched at diffusion-controlled limits by both benzoquinone and *N,N'*-dimethylaniline (Fig. 5). This implies that the comonomers

are capable of generating both radical cations and radicals. This is in contrast to thiophene derivatives that can generate only radical cations while pyridine and pyridimine afford uniquely radical anions. The photoinduced electron-transfer mechanism leading to radical ion intermediates is further supported by the exergonic  $\Delta G_{\text{et}}$  values calculated from the Rehm–Weller equation, shown in Table 2.<sup>31</sup> The dual quenching confirms that the comonomers can potentially be both oxidized and reduced while their increased degree of conjugation relative to their discrete monomers afford the means to tailor the spectroscopic and electrochemical properties.

### Laser flash photolysis

The donor–acceptor character of the comonomers can lead to radical ions upon photoirradiation, as observed by the fluorescence quenching with the electron donor and ac-

**Fig. 5.** Static Stern–Volmer analysis of **3** as a function of benzoquinone. Inset: Decrease in fluorescence intensity of **3** with benzoquinone addition in deaerated acetonitrile.

ceptor. Laser flash photolysis (LFP) was used for spectroscopically detecting these intermediates in addition to any triplets, either of which could be responsible for the reduced fluorescence of **1** and **2**. The transient absorption spectra for the dyads studied are found in the inset of Fig. 6. Both the thiophene and bithiophene comonomers exhibited transient spectra whose absorption maxima are dependent on the number of thiophenes. The unimolecular decay (Fig. 6) implies that the observed transients are triplets. Triplet assignment was further confirmed by the fast quenching of the transients with known triplet quenchers; oxygen, 1,3-cyclohexadiene,  $\beta$ -carotene, and 2-methylnaphthalene (Table 3). The unimolecular decay precludes the formation of radical ions that can be produced by intramolecular photoinduced electron transfer. The observed transients were further assigned to triplets, since they were not quenched by radical ion generators, benzoquinone, or *N,N*-dimethylaminopyridine.

Quantification of the triplet state is possible by LFP according to eq. [1]

$$[1] \quad \Phi_x = \frac{\Delta \text{Abs}_x \cdot \Phi_{\text{ref}} \cdot \varepsilon_x}{\Delta \text{Abs}_{\text{ref}} \cdot \varepsilon_{\text{ref}}}$$

where  $\Phi_{\text{TT}}$  is the quantum yield of triplet formation,  $\varepsilon_{\text{TT}}$  is the triplet–triplet molar absorption coefficient,  $\Delta \text{Abs}$  is the signal intensity monitored at the maximum triplet absorption as a function of laser power, ref refers to the actinometer, and *x* refers to the corresponding comonomer. Either  $\Phi_{\text{TT}}$  or  $\varepsilon_{\text{TT}}$  can be derived by direct comparison of the comonomer triplet signal to the reference, xanthone. Equation [1] can be simplified to eq. [2] for calculating the triplet comonomer yield without knowing  $\varepsilon_{\text{TT}}$ , which is not normally precisely known.

$$[2] \quad \Phi_x = \frac{\Delta \text{Abs}_x \cdot \Phi_{\text{ref}}}{\Delta \text{Abs}_{\text{ref}} \cdot \Phi_x}$$

Equation [2] is valid if both the reference and the comonomer produce a common triplet. This is the case when 2-

**Fig. 6.** Kinetic decay of triplet **4** monitored at 490 nm after excitation at 355 nm. Inset: Transient absorption spectra of **4** monitored at 16  $\mu\text{s}$  (■) and 27  $\mu\text{s}$  (○) after the laser pulse of 355 nm.

methylnaphthalene (MN) is added to both the reference and comonomer samples. In this case, MN quenches the comonomer and xanthone triplet by energy transfer to produce triplet MN that is observed at 420 nm. MN is the quencher of choice because its triplet cannot be produced by direct excitation. More importantly, its triplet can be detected by LFP and its absorption does not overlap with any of the comonomers or with xanthone. Equation [2] is valid if all the triplets produced within the laser pulse are rapidly quenched by energy transfer to produce the triplet methylnaphthalene. The amount of MN required for deactivating at least 95% of the comonomer and xanthone triplets can be calculated by the quenching rate constant derived from Fig. 7.

The  $\Phi_{\text{TT}}$  of the comonomers can be derived from the slope of the maximum triplet signal as a function of laser power relative to xanthone ( $\Phi_{\text{TT}} = 1$ ; Fig. 8) according to the simplified eq. [2] by observing the common triplet MN. The comonomer  $\varepsilon_{\text{TT}}$  can similarly be calculated from the slope of the maximum signal observed at the comonomer absorption maximum as a function of laser power versus xanthone in the absence of MN. The calculated triplet values found in Table 4 show that the  $\varepsilon_{\text{TT}}$  are larger for the bithiophene dyads than for the thiophene comonomers. The larger  $\varepsilon_{\text{TT}}$  implies the bithiophene triplets exhibit a higher degree of conjugation than **1** and **2**.

It is also evident from Table 3 that the comonomers produce appreciable amounts of triplet. From the energy conservation ( $1 = \Sigma \Phi_x = \Phi_{\text{fl}} + \Phi_{\text{ISC}} + \Phi_{\text{IC}}$ ) and the spectroscopic data, it can be concluded that the comonomers deactivate their singlet excited state predominately by two pathways: either fluorescence or intersystem crossing (ISC) to form their triplet state. In the case of the thiophene comonomers, the singlet excited manifold is deactivated predominately by ISC, supported by the fluorescence and LFP data. This is most likely a result of their higher triplet level favoring ISC. The higher triplet energy of **1** and **2** is confirmed by the phosphorescence emissions that are significantly hypsochromically shifted relative to **3** and **4** (Table 4 and

**Table 3.** Triplet-quenching rate constants for the different comonomers with various quenchers measured in anhydrous and deaerated acetonitrile.

sion.<sup>32,33</sup> The steady-state and time-resolved data collectively confirm that the fluorescence can be tuned as a function of comonomer structure and that the excited-state energy can be channeled to the emitting manifolds. Tuning of the spectroscopic properties as a function of structure is therefore possible.

## Electrochemistry

Cyclic voltammetry of each comonomer was done to determine their redox potentials. All the comonomers exhibited both oxidation and reduction potentials corresponding to the radical cation and anion, respectively. The electrochemical data also demonstrate the inherent dual *n*- and *p*-type character of the comonomers. This behaviour is corroborated by the fluorescence quenching data. The HOMO and LUMO values, and the corresponding energy gaps can be calculated from the measured redox potentials by standard methods leading to the values reported in Table 5.<sup>23</sup> It is evident from the calculated values that the  $\pi$ -donating thiophene group affects the LUMO of the  $\pi$ -accepting nitrogen-containing heterocycles. This is supported by the less-negative reductive potentials ( $E_{pc}$ ) of **1–4** compared with pyridine ( $E_{pc} = -2.6 \text{ V}$ ) and pyrimidine ( $E_{pc} = -2.4 \text{ V}$ ).<sup>34,35</sup> Conversely, the oxidation potentials ( $E_{pa}$ ) of the comonomers are unchanged compared to their thiophene ( $E_{pa} = 1.6 \text{ V}$ )<sup>36</sup> and bithiophene ( $E_{pa} = 1.3 \text{ V}$ ) monomers.<sup>37</sup> This is a result of the  $\pi$ -accepting character of the adjacent nitrogen heterocycle, further confirming that the comonomers are conjugated.

Both the reduction and oxidation processes of the comonomers are not reversible, as seen in Fig. 10. This is expected, since the radical ions are highly reactive and can cross-couple to form their corresponding dimers.<sup>38</sup> Electrochemical dimerization using a large-surface-area mesh electrode was used to afford sufficient quantities of dimers for characterization. Unfortunately, only products insoluble in standard organic solvents were obtained. This is most likely a result of multiple radical ion coupling on the same comonomer. This nonetheless confirms that the donor–acceptor dyads are electrochemically active and that D–A–A–D and A–D–D–A products are possible.

## Conclusion

A series of new donor–acceptor dyad comonomers were prepared. The spectroscopic and electrochemical properties can be modulated as a function of structure. The comonomers can both be photochemically and electrochemically oxidized and reduced resulting in radical ions. This dual active behaviour is a result of incorporating both  $\pi$ -donors and  $\pi$ -acceptors to form the comonomers. The singlet excited state was found to deactivate exclusively by either fluores-

cence or intersystem crossing. The deactivation pathway can be tailored by adjusting the triplet energy level, which in turn, is controlled by the degree of conjugation and the number of thiophenes. These novel comonomers are ideal candidates for emitting applications owing to their high fluorescence yields.

## Experimental

### Analyses

#### Spectroscopic measurements

Absorbance measurements were recorded on a Cary-500 spectrometer, while fluorescence measurements were performed with an Edinburgh Instruments FLS-920 fluorimeter after deaerating the sample for 20 min with nitrogen. Fluorescence quantum yields were measured at low sample concentration in dichloromethane by exciting the compounds close to their maximum absorption wavelength and by comparing the emission to bithiophene ( $\Phi_{\text{fl}} = 0.013$ ) at the same wavelength. Phosphorescence measurements were done on a Cary Eclipse at 77 K in a 4:1 ethanol/methanol solvent.

#### Laser flash photolysis (LFP) measurements

Laser flash photolysis experiments were done on a Luzchem mini-LFP system excited at 355 nm with the third harmonic of a Nd-YAG laser. The solutions were prepared with absorbances between 0.3 and 0.5 at the excitation wavelength. Triplet-state quantum yield and triplet–triplet molar absorption coefficients were measured against xanthone in

dichloromethane ( $\Phi_{\text{TT}} = 1$ ,  $\varepsilon_{\text{TT}} = 28\,000 \text{ mol/L}^{-1} \text{ s}^{-1}$ ) and were determined using standard techniques.<sup>39–42</sup>

#### Crystal structure determination

Diffraction data for **4** was collected on a Bruker Smart 6000 diffractometer using graphite-monochromatized Cu K $\alpha$  radiation with 1.54178 Å. The structures were solved by direct methods (SHELXS97). Disorder was found in the terminal thiophene and consisted of a flip of this heterounit. The weight of each isomer was optimized. All non-hydrogen atoms were refined based on Fobs2 (SHELXS97), while hydrogen atoms were refined on calculated positions with fixed isotropic U, using riding model techniques.

#### Electrochemical measurements

Cyclic voltammetry measurements were recorded with a Bio Analytical Systems Ec Epsilon potentiostat. The compounds of study were dissolved in anhydrous and deaerated dichloromethane with 0.1 mol/L TBAPF<sub>6</sub>. A platinum electrode was employed as the working electrode, while a platinum wire was used as the auxiliary electrode. The reference electrode was a saturated Ag/AgCl electrode.

### Syntheses

#### Thiophen-2-ylboronic acid

Thiophene (998 mg, 11 mmol) and butyl lithium 2.5 mol/L (5 mL, 12 mmol) were added to anhydrous THF (25 mL) at 0 °C under nitrogen. Trimethylborate (4.05 mL, 36 mmol) was added dropwise to the solution at –78 °C. The temperature was raised to room temperature, and the solution was stirred for 1 h before 10% H<sub>2</sub>SO<sub>4</sub> (20 mL) was added. The product was extracted with dichloromethane (20 mL), and the organic layer was then washed with 3 mol/L NaOH (50 mL). The pH of the aqueous layer was adjusted to 1 using 3.2 mol/L HCl, then it was washed with dichloromethane (60 mL). The product was isolated as a yellow-orange solid (840 mg, 55%) and was used without additional purification. Mp 137–139 °C. <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 7.71 (d, 1H, <sup>3</sup>J = 4.4 Hz), 7.31 (s, 1H), 7.18 (t, 1H, <sup>3</sup>J = 4.1 Hz), 5.79 (s, 2H). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 136.1, 131.7, 128.4, 128.3.

#### 1-(2,2'-Bithiophen-5-yl)ethanone (**5**)

To anhydrous THF (20 mL) was added 2,2'-bithiophene (1.72 g, 10 mmol), and the reaction solution was cooled to –78 °C. *n*-Butyl lithium (10 mol/L, 1 mL, 10 mmol) was added under nitrogen, then the temperature was raised to room temperature and the mixture was allowed to stir for 1 h. *N,N*-Dimethylacetamide (0.93 mL, 10 mmol) was added, and the reaction was stirred for an additional 2 h at room temperature. The reaction was quenched with water

**Table 5.** Cyclic voltammetry data obtained in 1 mol/L TBAPF<sub>6</sub> in anhydrous and deaerated dichloromethane.

<b>1</b>	1.5	−1.4	5.9	3.0	2.9
<b>2</b>	1.7	−1.6	6.1	2.8	3.3
<b>3</b>	1.4	−1.6	5.8	3.1	2.7
<b>4</b>	1.5	−1.6	5.9	3.2	2.7

**Fig. 10.** Cyclic voltammogram of **4** measured in anhydrous and deaerated dichloromethane with TBAPF<sub>6</sub> at 100 mV/s.

(50 mL), and the organic layer was extracted with dichloromethane (60 mL). The product was purified by flash chromatography eluted with hexanes/ethyl acetate (90:10, v/v) to give a yellow powder (451 mg, 21%). <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 7.80 (d, 1H, <sup>3</sup>*J* = 4), 7.56 (dd, 1H, <sup>3</sup>*J* = 5.2, <sup>5</sup>*J* = 1.2), 7.46 (dd, 1H, <sup>3</sup>*J* = 3.6, <sup>5</sup>*J* = 0.8), 7.34 (d, 1H, <sup>3</sup>*J* = 4), 7.14 (dd, 1H, <sup>3</sup>*J* = 5.2 and 4), 2.52 (s, 3H).

**(2,2'-Bithiophen-5-yl)-3-(dimethylamino)prop-2-en-1-one (6)**

To a 2:1 ethanol/dichloromethane solution (3 mL) was added **5** (110 mg, 0.5 mmol), and the solution was then refluxed for 1 h. *N,N*-Dimethylformamide dimethyl acetal (225 mg, 1.9 mmol) was added, and the reaction was refluxed for 17 h. The reaction was cooled to room temperature, and then hexanes were added and the solution was left to cool in the freezer overnight. The precipitate was filtered to afford the product as an orange solid (102 mg, 75%). The compound was used without any further purification. <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 7.68 (d, 1H, <sup>3</sup>*J* = 12.4), 7.65 (d, 1H, <sup>3</sup>*J* = 3.6), 7.49 (dd, 1H, <sup>3</sup>*J* = 5.2, <sup>5</sup>*J* = 1.2), 7.39 (dd, 1H, <sup>3</sup>*J* = 3.6, <sup>5</sup>*J* = 0.8), 7.27 (d, 1H, <sup>3</sup>*J* = 4), 7.13 (dd, 1H, <sup>3</sup>*J* = 5.2 and 3.6), 5.79 (d, 1H, <sup>3</sup>*J* = 12), 3.21 (s, 3H), 2.98 (s, 3H).

**4-(Thiophen-2-yl)pyrimidine (1)**

To absolute ethanol (25 mL) was added **6** (2.00 g, 11 mmol). The solution was brought to reflux after which time formamidine acetate (3.45 g, 33 mmol) was added, and the solution was refluxed for an additional 10 min. Sodium (0.77 g, 33 mmol) in absolute ethanol (2 mL) was then

added. The mixture was then refluxed for 16 h. The solvent was then evaporated, the solid washed with dichloromethane, and then filtered. The filtrate was purified by flash chromatography using hexanes/ethyl acetate (70:30, v/v) to afford the product as a yellow powder (541 mg, 31%). Mp 54–56 °C. <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 9.05 (s, 1H), 8.74 (d, 1H, <sup>3</sup>*J* = 5.2 Hz), 7.99 (dd, 1H, <sup>3</sup>*J* = 4 Hz, <sup>5</sup>*J* = 1.2 Hz), 7.88 (dd, 1H, <sup>3</sup>*J* = 5.2 Hz, <sup>5</sup>*J* = 1.2 Hz), 7.75 (dd, 1H, <sup>3</sup>*J* = 4.8 Hz, <sup>5</sup>*J* = 0.8 Hz), 7.23 (dd, 1H, <sup>3</sup>*J* = 3.6 Hz and 1.2 Hz). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 160.8, 160.5, 159.4, 144.1, 132.5, 130.5, 130.0, 117.1. HR-MS(+) calculated for [C<sub>8</sub>H<sub>6</sub>N<sub>2</sub>S + H]<sup>+</sup>: 163.03245; found: 163.03303.

**2-Thiophene-2-yl-pyridine (2)**

To isopropanol (40 mL) was added a 2 mol/L Na<sub>2</sub>CO<sub>3</sub> solution in water (5 mL). Thiophene-2-yl-2-boronic acid (459 mg, 36 mmol) and 2-chloropyridine (408 mg, 36 mmol) were then added. Tetrakis (triphenylphosphine) palladium (101 mg, 0.36 mmol) was added under nitrogen under the cover of light. The temperature was raised to 50 °C, and the reaction was stirred at this temperature for 17 h. The product was extracted with dichloromethane and then purified by flash chromatography using hexanes/ethyl acetate (95:5, v/v) followed by 10% ethyl acetate. The product was isolated as a yellow solid (268 mg, 46%). Mp 56–58 °C. <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 8.52 (d, 1H, <sup>3</sup>*J* = 4.8), 7.85 (dd, 1H, <sup>3</sup>*J* = 6.8, <sup>5</sup>*J* = 0.8), 7.79 (td, 1H, <sup>3</sup>*J* = 7.2, <sup>5</sup>*J* = 1.6), 7.74 (dd, 1H, <sup>3</sup>*J* = 4, <sup>5</sup>*J* = 1.2), 7.54 (dd, 1H, <sup>3</sup>*J* = 5.2, <sup>5</sup>*J* = 1.2), 7.24 (dd, 1H, <sup>3</sup>*J* = 4.8, <sup>5</sup>*J* = 1.2), 7.14 (dd, 1H, <sup>3</sup>*J* = 4 and 1.2). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 154.4, 151.3, 147.0, 138.7, 129.9, 126.5, 123.9, 120.3. HR-MS(+) calculated for [C<sub>9</sub>H<sub>7</sub>NS + H]<sup>+</sup>: 162.03719; found: 162.03711.

**4-(2,2'-Bithiophenyl-5-yl)pyrimidine (3)**

In ethanol (25 mL) was added 1-(2,2') bithiophenyl-5-yl-3-dimethylamino-propenone (178 mg, 0.67 mmol), and the solution was refluxed for 1 h. Formamidine acetate was then added (227 mg, 2 mmol), and the reaction was stirred for 10 min followed by the addition of sodium (57 mg, 2.5 mmol) in ethanol (2 mL). The slurry was then refluxed for 7 days. The solvent was evaporated, the product was taken up in dichloromethane, and the remaining inorganic salts were filtered. The product was purified by flash chromatography using hexanes/ethyl acetate (95:5, v/v) to afford the product as a bright yellow solid (144 mg, 87%). Mp 113–115 °C. <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 9.06 (d, 1H, <sup>3</sup>*J* = 1.6), 8.74 (d, 1H, <sup>3</sup>*J* = 5.2), 7.96 (d, 1H, <sup>3</sup>*J* = 4), 7.90 (dd, 1H, <sup>3</sup>*J* = 5.6, <sup>5</sup>*J* = 1.6), 7.53 (dd, 1H, <sup>3</sup>*J* = 5.2, <sup>5</sup>*J* = 1.2), 7.45 (dd, 1H, <sup>3</sup>*J* = 3.6, <sup>5</sup>*J* = 0.8), 7.39 (d, 1H, <sup>3</sup>*J* = 4), 7.15 (dd, 1H, <sup>3</sup>*J* = 3.6 and 1.6). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>):  $\delta$  = 160.8, 160.1, 159.3, 143.7, 142.4, 131.0, 130.3, 128.0, 126.9,

126.8, 116.8. HR-MS(+) calculated for  $[C_{12}H_8N_2S_2 + H]^+$ : 245.02017; found: 245.02088.

### 2-(2,2') Bithiophenyl-5-yl-pyridine (4)

To ethanol (25 mL) was added 2 mol/L  $Na_2CO_3$  (5 mL) followed by (2,2') bithiophenyl boronic dimethyl ester (1.5 g, 7.27 mmol) and 2-chloropyridine (1.65 g, 14.54 mmol) under nitrogen. Tetrakis (triphenylphosphine) palladium (822 mg, 72.7 mmol) was then added under nitrogen and in the absence of light. The reaction mixture was heated to 50 °C for 16 h. The product was extracted with dichloromethane and was purified by flash chromatography using hexanes and increasing the polarity with hexanes/ethyl acetate (90:10, v/v). The product was isolated as a pale orange solid (656 mg, 40%). Mp 124–126 °C.  $^1H$  NMR (acetone- $d_6$ ):  $\delta$  = 8.53 (d, 1H,  $^3J$  = 4.8), 7.83 (d, 1H,  $^3J$  = 8), 7.81 (td, 1H,  $^3J$  = 7.6,  $^5J$  = 2), 7.68 (d, 1H,  $^3J$  = 3.6), 7.46 (dd, 1H,  $^3J$  = 5.2,  $^5J$  = 1.2), 7.37 (dd, 1H,  $^3J$  = 3.6,  $^5J$  = 1.2), 7.29 (d, 1H,  $^3J$  = 3.6), 7.25 (dd, 1H,  $^3J$  = 4.8,  $^5J$  = 0.8), 7.11 (dd, 1H,  $^3J$  = 3.6 and 1.2).  $^{13}C$  NMR (acetone- $d_6$ ):  $\delta$  = 154.0, 151.3, 145.8, 140.9, 139.1, 138.7, 130.1, 127.4, 127.0, 126.428, 126.0, 124.0, 120.2. HR-MS(+) calculated for  $[C_{13}H_9NS_2 + H]^+$ : 244.02492; found: 244.02546.

### Anodic dimerization

The comonomer **2** (20 mg, 0.12 mmol) was dissolved in anhydrous dichloromethane (12 mL) under nitrogen.  $FeCl_3 \cdot 6H_2O$  (166 mg, 0.61 mmol) was added, and the mixture was refluxed for 24 h. After refluxing, an insoluble precipitate formed. The soluble product was extracted with dichloromethane, the solvent evaporated, and taken up into THF for MS analysis.

# The role of molecular volume and the shape of the hole transport molecule in the morphology of model charge transport composites

Ferdous Khan, Shalini Khanna, Ah-Mee Hor, and P.R. Sundararajan

**Abstract:** We present a study of the morphology and molecular interactions in a model charge transport composite with 1,1-bis(di-4-tolylaminophenyl) cyclohexane (TAPC) as the hole transport molecule in bisphenol-A polycarbonate (BPAPC) and cyclohexyl polycarbonate, also known as bisphenol-Z polycarbonate (PCZ). Solution NMR shows that while there is aromatic interaction between the phenyl groups of the polycarbonate and TAPC, the broadening of the peaks corresponding to the latter indicates a decrease in the rotational motion. FTIR spectroscopy also exhibits frequency shifts of the aromatic C–H absorption peaks, which parallels the extent of the depression of the glass transition temperature ( $T_g$ ) of the polycarbonate. These are compared with the previous results for *N,N*-diphenyl-*N,N*-bis(3-methylphenyl)-[1,1-biphenyl]-4,4-diamine (TPD) and tri-*p*-tolylamine (TTA), and the differences are rationalized on the basis of the molecular shape and van der Waals volume of the small molecules. It is proposed that when the polycarbonate is in a random coil conformation, spherical small molecules (e.g., TAPC and TTA) reduce the glass transition temperature much more than a rodlike small molecule (e.g., TPD). Annealing at a temperature just below the  $T_g$  of the polycarbonate was used as a means of simulating accelerated ageing. Upon annealing, phase separation and crystallization of TAPC occurs and leads to a recovery of the  $T_g$  of the polymer significantly. The  $T_g$  recovery in this case is much more significant than in the case of TPD. The average crystal sizes are about ten times smaller than the crystals obtained in the case of TPD for the same temperature of annealing. To enhance the charge mobility, it might actually be advantageous to induce submicron crystals of the small molecule, while keeping the film transparent.

**Key words:** hole transport, charge transport, polycarbonate, phase separation, solvent effect.

**Résumé :** On a étudié la morphologie et les interactions moléculaires dans un modèle de transport de charge composite comportant un 1,1-bis(di-4-tolylaminophényl)cyclohexane « TAPC » comme molécule du trou de transport dans un mélange de polycarbonate de bisphénol-A « BPAPC » et de polycarbonate de cyclohexyle, aussi connu sous le nom de polycarbonate de bisphénol-Z « PCZ ». Les spectres de RMN en solution montrent que, même s'il existe une interaction aromatique entre les groupements phényles du polycarbonate et le « TAPC », l'élargissement des pics correspondants aux derniers suggèrent qu'il se produit une diminution du mouvement rotationnel. Les spectres IR à transformée de Fourier présentent aussi des déplacements de fréquence des pics d'absorption des C–H aromatiques, parallèles au taux de dépression de la température  $T_g$  du polycarbonate. On a comparé ces résultats à ceux obtenus antérieurement avec la *N,N*-diphényl-*N,N*-bis(3-méthylphényl)-[1,1-biphényl]-4,4-diamine « TPD » et la tri-*p*-tolylamine « TTA » et on a rationalisé les différences sur la base de la forme moléculaire et du volume de van der Waals des petites molécules. On suggère que lorsque le polycarbonate se trouve dans une conformation pelote aléatoire, les petites molécules sphériques (telles le « TPAC » et la « TTA ») réduisent beaucoup plus la température de transition vitreuse qu'une petite molécule en forme de bâtonnet (telle la « TPD »). On a utilisé une température de recuisson juste inférieure à la valeur de  $T_g$  du polycarbonate dans le but de stimuler une accélération du vieillissement. Par recuisson, il se produit une séparation de phase et une cristallisation du « TAPC » qui conduit à une récupération significative de la  $T_g$  du polymère. La récupération de la  $T_g$  dans ce cas est beaucoup plus significative que dans le cas de la « TDP ». Les tailles moyennes des cristaux sont environ dix fois plus petites que celles des cristaux obtenus dans le cas de la « TDP » pour la même température de recuisson. Dans le but d'augmenter la mobilité de la charge, il pourrait être avantageux d'induire des cristaux sous-micron de la petite molécule tout en maintenant le film transparent.

## Introduction

Optoelectronic devices employ a complex mixture of functional small molecules dispersed in polymer matrices. Studies on the charge transport molecules (CTM) dissolved in a polymer matrix are of both technological and fundamental interests.<sup>1–3</sup> Such binary solid solution systems enable easy fabrication of films ( $\mu\text{m}$ – $\text{nm}$  thickness range) that are widely used in photoreceptors, organic light emitting diodes, and electrochromic devices. Charge transport occurs via charge transfer between adjacent donor or acceptor molecules, which is described as a one-electron oxidation–reduction process. The charge transport molecules contain one or more subunits, which are strong electron donors or acceptors.<sup>4,5</sup> Charge mobilities of hole transport molecules have strong electric field and temperature dependence.<sup>6–9</sup> It has been shown that the charge transport occurs by a hopping mechanism.<sup>10–13</sup> Several studies also showed that the host polymer has an influence on the charge transport properties of the devices.<sup>14–18</sup> For example, Yuh and Pai<sup>16,17</sup> found that the charge mobility of *N,N*-diphenyl-*N,N*-bis(3-methylphenyl)-[1,1-biphenyl]-4,4-diamine (TPD) was significantly higher with polystyrene than with polycarbonate as the matrix polymer. The charge transport properties of these materials were initially studied for applications in photoreceptor devices. A multilayered structure consisting of a charge transport layer (CTL) and a charge generation layer (CGL) has been commonly used in photoreceptor devices. A high concentration of the charge transport molecule is preferred to improve the overall sensitivity of the device and this must be accomplished without phase separation or crystallization of the charge transport molecule from the matrix.

Whereas the variation of the charge mobility was often interpreted in terms of the matrix–CTM interaction, morphological studies and the phase stability of these systems were not pursued at that time by this community. Several factors influence the phase separation and crystallization of the charge transport molecule, such as the type and nature of CTM and the polymer matrix, and to an extent, the solvent used for the preparation of composites. We<sup>19–22</sup> studied the stability of model CTLs with the two types of charge-transport molecules, such as TPD (*N,N*-diphenyl-*N,N*-bis(3-methylphenyl)-[1,1-biphenyl]-4,4-diamine) and TTA (tri-*p*-tolylamine) with different polymer binders. We used annealing as a means of simulating the ageing behaviour. The TTA-based charge transport composites were highly unstable in morphological aspects than those obtained from the TPD-based system. Using the results of the depression of the glass transition temperature ( $T_g$ ) of the polymer with the charge transport molecule, the FTIR spectroscopy, and molecular volumes, we interpreted the recovery of the  $T_g$  and the extent of phase separation and crystallization of the charge transport molecule, upon annealing, on the basis of molecular interactions. It was also shown that the conformational flexibility of the polymer significantly affects the stability. The type of solvent used

plays a role as well.<sup>22</sup> It was shown that polycarbonate exists in an extended conformation in 1,1,2,2-tetrachloroethane, and the composite films made with this solvent showed different morphological behavior than those made with dichloromethane. Thus, these results were rationalized in terms of the molecular volume of the charge transport molecule, polymer flexibility, and host–guest molecular level interactions.

The above organic semiconductors were originally developed for photoreceptor applications. Although the photoreceptor technology is now considered mature, the charge transport molecules of the type mentioned above are now being studied extensively, both experimentally and theoretically, for applications in organic light emitting diode (OLED) and organic photovoltaic devices.<sup>23</sup> Some recent publications include the studies of field and temperature dependence of hole mobility of TPD–polycarbonate,<sup>24</sup> and TPD–polystyrene,<sup>25</sup> the effect of a radical salt of TPD derivative,<sup>26</sup> the simulation of the effect of disorder and film morphology on charge transport,<sup>27</sup> and two in-depth reviews on charge transport of these organic semiconducting molecular materials.<sup>28,29</sup> Hence, as a continuation of our previous studies, we present the morphological aspects of another charge transport molecule, 1,1'-bis(di-4-tolylaminophenyl) cyclohexane (TAPC, Fig. 1), in polycarbonates and compare them with TPD and TTA.

Borsenberger and co-workers<sup>9,18,30,31</sup> and Young<sup>32</sup> demonstrated that 1,1'-bis(di-4-tolylaminophenyl) cyclohexane (TAPC, Fig. 1) and TAPC-doped bisphenol-A-polycarbonate (BPAPC) are not susceptible to deep trapping as compared to the other hole charge transport molecules, over a wide range of temperatures and fields. This implied that devices could be fabricated over an extended concentration range without crystallization of TAPC.<sup>30</sup>

Although TPD, TTA, and TAPC are based on triphenyl amine groups, their molecular shapes are different. Although TPD is nonplanar, its molecular volume resembles a rodlike structure. The TTA, due to the nonplanarity of the three phenyl groups about the central nitrogen atom, has a spherical shape. The TAPC is a dimeric analog of the tri-*p*-tolylamine (TTA) moieties chemically bridged by a cyclohexane ring. Its molecular volume resembles two spheres anchored to a cyclohexyl group. Although the charge-transport sites of TAPC are identical to that of TTA,<sup>32</sup> their packing will be different due to their pairing in TAPC. From a morphological view, such differences in molecular shapes can be expected to lead to different stability properties when these molecules are dispersed in a polymer matrix.

In this paper, we discuss the molecular level interaction, phase separation, and morphological aspect of TAPC with different types of polycarbonates (PC). The differences and the similarities in morphological behavior of this charge transport molecule will be compared to those of TPD and TTA, which were discussed before.<sup>19–21</sup> Of the two types of polycarbonates, one is bisphenol-A polycarbonate (BPAPC) and the other, cyclohexyl polycarbonate (PCZ). Two differ-

**Fig. 1.** (a) Schematic of the structure of host polymers (BPAPC and PCZ) and the hole transport molecule (TAPC). (b) Molecular models of (from the top) TTA, TPD, and TAPC. The dotted circles are meant to indicate the spherical volume occupied by the triphenyl groups.

ent molecular weights of the latter were used, and these are denoted as PCZ-2 and PCZ-3. The PCZ polycarbonate has a higher  $T_g$  (e.g., between 160–180 °C) than BPAPC, depending on the molecular weight. It is known<sup>33–35</sup> that PCZ is conformationally more restricted compared to BPAPC. The conformational flexibility of these polymers has an influence on the phase separation and crystallization of the charge transport molecule as was demonstrated in Khan and Sundararajan's<sup>19,21</sup> previous investigations (TPD–PC and TTA–PC systems).

## Experimental section

Bisphenol-A polycarbonate (BPAPC) and cyclohexyl polycarbonate (PCZ) were purchased from Bayer Chemicals and Mitsubishi Gas Chemicals, respectively. The charge transport molecule (TAPC) was obtained from H.W. Sands Corporation, USA. The molecular weight ( $M_w$ ) and the polydispersity of the polymers, as measured by GPC, are presented in Table 1. The molecular structures of the materials used in this study are shown in Fig. 1. Films were prepared by dissolving the required amounts of TAPC and the polymer in dichloromethane ( $\text{CH}_2\text{Cl}_2$ ) or tetrachloroethane (TCE) of

laboratory grade. Concentrations ranging from 10 to 50 wt% of TAPC were used with the polycarbonates. Composite films were coated on a glass substrate using an electrically driven film coater and these were then dried at a very low rate of solvent evaporation at ambient conditions for at least 48 h. The thickness of the films was about 10–15  $\mu\text{m}$ . The annealing was performed using a vacuum oven with an accuracy of  $\pm 1$  °C.

A TA Instruments 2010 differential scanning calorimeter (DSC) was used for thermal analysis, at a heating rate of 10 °C  $\text{min}^{-1}$ . DSC thermograms were recorded with about 8–10 mg of sample, under a nitrogen flow of 50  $\text{mL min}^{-1}$ . The crystallinity of the samples was calculated as the ratio of the measured heat of fusion of the composite film corresponding to the melting endotherm of TAPC (normalized to the weight fraction of TAPC in the sample), and the heat of fusion of 100% TAPC.

Fourier transform infrared (FTIR) spectroscopic measurements were performed using a Michelson M120 BOMEM FTIR spectrometer. The BOMEM GRAMS/386 software was used for data collection and analysis. The spectrum of TAPC was obtained in the form of a transparent KBr pellet. A film sample holder was used to record the spectra of the

**Table 1.** Molecular weight and  $T_g$  of polycarbonates used in this study and their films with TAPC.

Sample	$M_w$	Polydispersity	$T_g$ (°C) (Onset)	$T_g$ (°C) (Midpoint)
BPAPC	250 860	1.7	148	154
TAPC–BPAPC (40/60)			65	68
TAPC–BPAPC (50/50)			52	56
PCZ-2	112 800	4.4	174	182
TAPC–PCZ-2 (40/60)			64	67
TAPC–PCZ-2 (50/50)			55	58
PCZ-3	365 500	1.8	178	184
TAPC–PCZ-3 (40/60)			60	62
TAPC–PCZ-3 (50/50)			57	59

polymers and composite films. For each experiment a background spectrum was taken with the identical sample holder and subtracted automatically. A heating stage built in our laboratory was used to investigate the phase transition for composites in the case of the FTIR spectroscopic kinetic study.

$^1\text{H}$  NMR solution spectra were obtained using a Bruker AMX-400 spectrometer. Samples of TAPC, BPAPC, or PCZ-3 (10 mg) were dissolved in deuterated dichloromethane at ambient conditions. In the case of composites (50% TAPC and PC), 5 mg of each was dissolved in the same solvent and conditions. Fourier transformation of 64 K transients and a 4.784 s acquisition time were used to obtain the net spectra.

X-ray diffraction was recorded using a Philips automated powder diffractometer Model PW 1710 with nickel-filtered Cu K $\alpha$  radiation ( $\lambda = 1.5418$  Å). The MDI Data Scan 3.2 software (Materials Data Inc., Livermore, CA) was used for data collection and MDI Jade 5 software to determine the crystallinity ( $X_c$ ). The  $X_c$  was calculated as the ratio of the intensity under the crystalline peaks above the background to the total intensity. A Zeiss Axioplan polarizing optical microscope was used to record optical micrographs. The Northern Eclipse software was used for image analysis.

The charge mobility was measured by the standard time-of-flight (TOF) method<sup>36</sup> with a nitrogen dye laser with a 10 ns pulse at  $\sim 680$  nm as the light source. The photoreceptor samples were prepared by solution coating a charge transport layer (the charge transport molecule/polymer) of thickness ( $L$ )  $\sim 20$  microns onto a phthalocyanine generator layer. Under the applied voltage ( $V$ ), the hole charge carrier is injected from the generator into the transport layer following laser excitation. The transit current versus time is recorded on a digital oscilloscope and the log–log plot of current–time yields the intersection, which defines the transit time ( $t_T$ ) for the arrival of the charge carrier at the counter electrode. The charge mobility ( $\mu$ ) is calculated from the equation

$$[1] \quad \mu = L^2/Vt_T$$

## Results and discussion

We will first discuss the depression of the glass transition temperature of the polymer by the charge transport molecule TAPC, the effect of molecular shape and volume, and the evidence from NMR and FTIR spectroscopy for molecular interaction between the small molecule and the polymer in

solution and in films, as well as the disorder. These results will be compared with those obtained previously with TPD and TTA as the charge transport molecules with the polycarbonates. We will then present the results of annealing and the recovery of the glass transition temperature upon phase separation of the charge transport molecule from the matrix.

### Depression of glass transition temperature

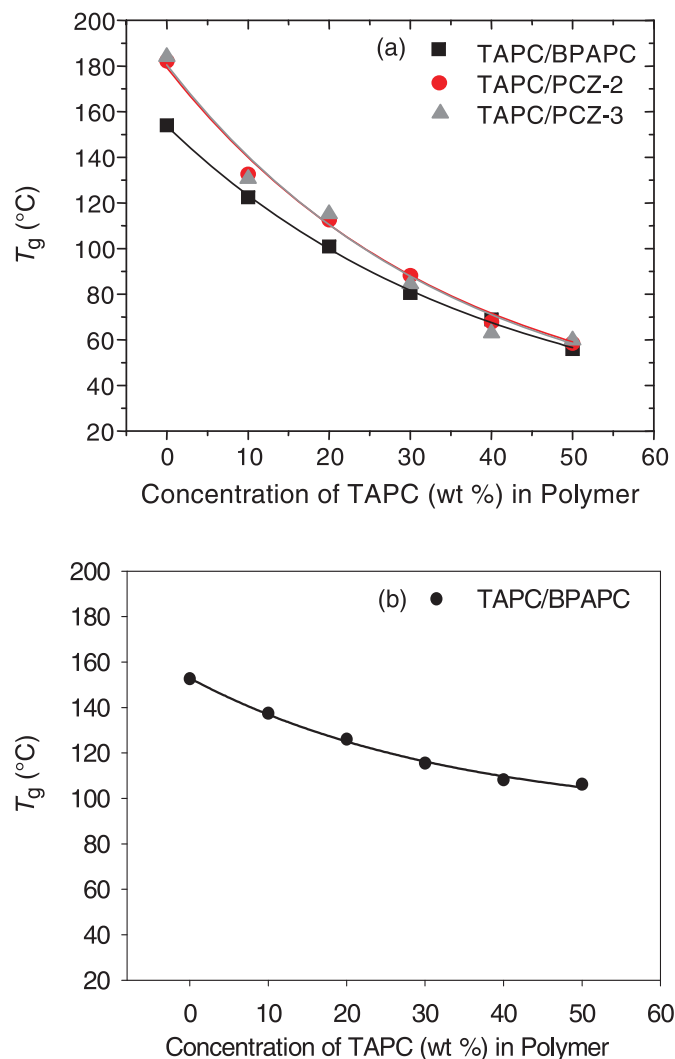

The molecular level interaction between two components is often quantified by measuring the  $T_g$  of the composite, as well as analyzing its dependence on composition. The polymers were amorphous and only glass transition temperatures were detected. Glass transition temperatures of the as-prepared films of BPAPC–, PCZ–, and TAPC–polymer composites are listed in Table 1. For the as-prepared films of BPAPC, PCZ-2, PCZ-3, the midpoint  $T_g$ s are 154, 182, and 184 °C, respectively (Table 1). The addition of TAPC lowers the  $T_g$  of the polymers, as expected. With lower concentrations (up to 30 wt%) of TAPC with BPAPC only a  $T_g$  was observed. However, with concentrations of  $\geq 40$  wt% TAPC an endothermic peak appeared at 178 °C, which corresponds to the melting of TAPC. At a concentration of 50 wt% of TAPC with PCZ-3, no endotherm was detected, and only  $T_g$  was detected for the as-prepared film.

The variation of the  $T_g$ s of BPAPC, PCZ-2, and PCZ-3 with different concentrations of TAPC for the as-prepared films with  $\text{CH}_2\text{Cl}_2$  as the solvent, is presented in Fig. 2a. The effect of the concentration of TAPC in BPAPC, with TCE as the solvent, is shown in Fig. 2b. The films were homogeneous and transparent up to 40 wt% of TAPC in the polymers, as will be discussed in the morphology section (see below).

For the films prepared with  $\text{CH}_2\text{Cl}_2$  (Fig. 2a), with 50 wt% of TAPC, the  $T_g$ s of BPAPC and PCZ-3 are depressed by 98 and 124 °C, respectively. The depression of the  $T_g$  caused by TAPC is less pronounced than with TTA (tri-*p*-tolylamine)<sup>21</sup> for the same concentration. With 50% of TTA with BPAPC and PCZ-3, the depression was 110 and 130 °C, respectively.<sup>21</sup> By comparison, Khan and Sundararajan's<sup>19</sup> studies of TPD–polycarbonate composites showed that the  $T_g$  depression for BPAPC and PCZ-3 was 74 and 88 °C, respectively, for a 50% concentration of the hole transport molecule.

The differences in the  $T_g$  depression mentioned above could be attributed to (i) molecular volume, (ii) the shape of the hole transport small molecule, and (iii) the polymer conformation, which would depend on the solvent used. The differences in the  $T_g$  depression caused by these small

**Fig. 2.** The variation of  $T_g$  of the polycarbonates (a) BPAPC, PCZ-2, and PCZ-3 based films using  $\text{CH}_2\text{Cl}_2$  and (b) BPAPC based films using TCE.

molecules could be due to their molecular packing differences and disorder. With respect to the molecular volume, TAPC is a dimeric analog of TTA with a cyclohexyl group. Using the HyperChem software (Hypercube Inc., Gainesville, FL) the calculated van der Waals volume of TAPC was  $638 \text{ \AA}^3$ , which is noticeably greater than that of TPD ( $513 \text{ \AA}^3$ ), and more than double that of TTA ( $298 \text{ \AA}^3$ ). The addition of the charge transport molecule increases the free volume of the polymer and this leads to enhanced mobility (not necessarily the conformational freedom) of the polymer and the depression of the  $T_g$ . Moreover, the change in free volume of the polymer can occur either on the segment level or at the molecular level as discussed before.<sup>19</sup> Thus, the size of the dopant molecule would have an effect on the extent of the reduction of the  $T_g$ . The differences in the  $T_g$  depression between the cases of TAPC and TTA could be attributed to the higher molecular volume of TAPC, which is about twice that of TTA. The smaller size of TTA would lead to a higher degree of dispersion.

As for the influence of the shape of the transport molecule, TPD is an almost linear rodlike molecule or dumbbell-

like (although nonplanar), whereas TTA is near spherical and TAPC is double spherical. The cyclohexyl group in the latter also enhances the bulkiness. Further, it was shown before<sup>22</sup> that the polycarbonate chain is in a coiled, globular shape in the  $\text{CH}_2\text{Cl}_2$  solution and in an extended shape in TCE. In the former case, spherical small molecules would be more effective in dispersing in the coil and increasing the free volume than a rodlike molecule such as TPD. Hence, the depression of the  $T_g$  by TAPC is larger than that caused by TPD.

As discussed before,<sup>26–28</sup> the PCZ is conformationally more restricted than BPAPC. The present results are in accord with the earlier observations that the higher the rigidity (greater the  $T_g$ ) of the polymer, the larger is the reduction in  $T_g$ . It appears that the free volume created by TAPC, or TTA, or TPD has a much larger effect in the case of PCZ than BPAPC. Such effect is higher in the case of TAPC than TPD.

As for the role of the polymer conformation, in a previous paper, Khan and Sundararajan<sup>22</sup> discussed the effect of the casting solvent on the  $T_g$  of the TPD–polymer composites. It was shown that the polycarbonate chain is in an extended conformation (stretched out) in TCE, and as a result, the depression of the  $T_g$  was larger (as compared with those cast from  $\text{CH}_2\text{Cl}_2$ ), due to the better intercalation of the rodlike TPD with the polymer. However, we find that the decrease in the  $T_g$  recorded for different composites of TAPC–BPAPC, prepared from TCE (Fig. 2b), is not as sharp as that observed in the case of composites prepared using dichloromethane. It is only about  $35^\circ\text{C}$  with 50% of TAPC. It is likely that the bulkiness of this spherical molecule hinders an effective intercalation, if the polymer is extended in its conformation.

The above observations would lead one to conclude that (i) since the BPAPC would be in a coiled conformation in  $\text{CH}_2\text{Cl}_2$ , packing of a near-spherical molecule such as TTA or TAPC would be more effective in the coil and lead to a larger depression of the  $T_g$  of the film than TPD, which is rodlike; (ii) likewise, the BPAPC chain is extended in TCE and the rodlike TPD would pack better than TAPC, which might be the cause of a small depression of the  $T_g$  of the film with TAPC.

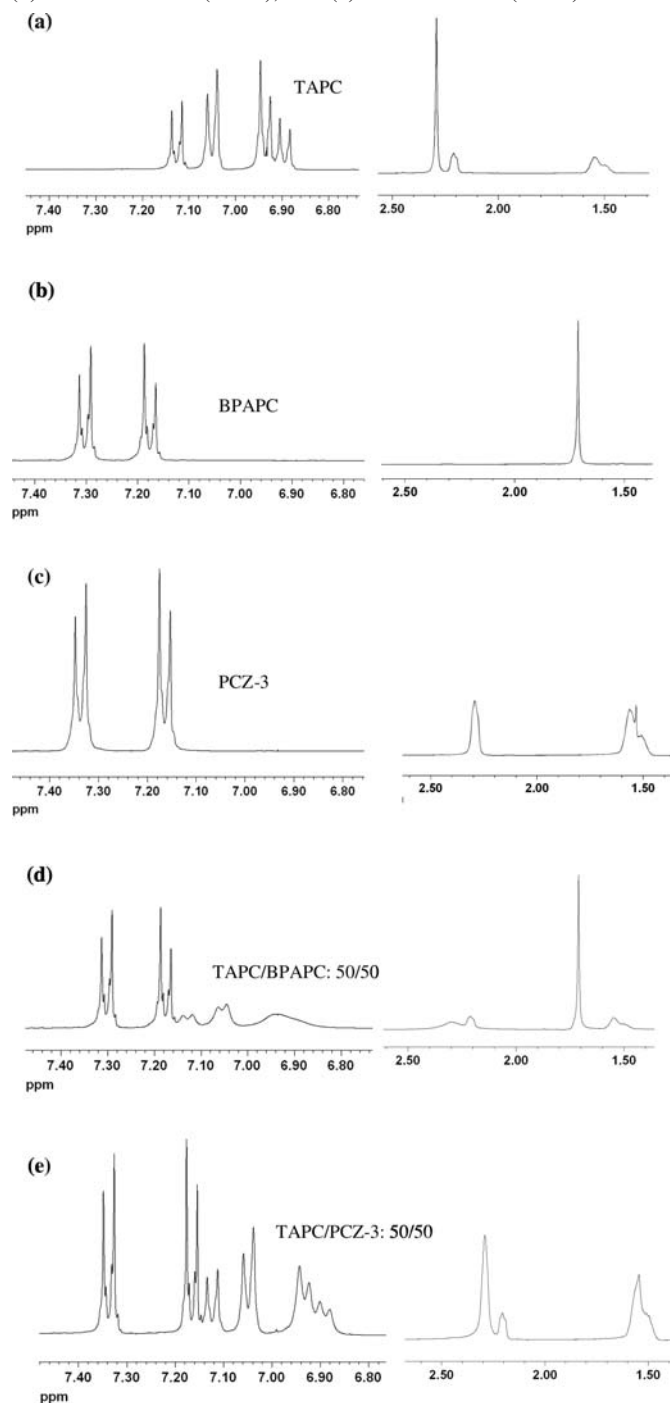

Several authors<sup>37</sup> have shown that the charge transport in polymers such as poly(3,4-ethylenedioxythiophene) (PEDOT), poly(3-methyl thiophene), polypyrroles, and polyanilines depend on the solvent used, and that the interactions that exist in solution (e.g., hydrogen bond, ion pairing, etc.) are manifested in the solid state. We feel that the case is similar with the films prepared from  $\text{CH}_2\text{Cl}_2$  and TCE: the solution conformation of the polycarbonate chain (i.e., a coiled conformation in the former) is retained when the film is cast.

### NMR spectra in solution

We used high-resolution proton nuclear magnetic resonance spectroscopy to probe the interactions, if any, between TAPC and the polycarbonates in solution. FTIR spectroscopy was used for this purpose with the solid films. Figure 3 presents the  $^1\text{H}$  NMR spectra of TAPC, BPAPC, PCZ-3, and mixtures of 50% TAPC with BPAPC and PCZ-3.

The comparison of the  $^1\text{H}$  NMR spectra of TAPC–

**Fig. 3.** The  $^1\text{H}$  NMR spectra of (a) TAPC, (b) BPAPC, (c) PCZ-3, (d) TAPC–BPAPC (50/50), and (e) TAPC–PCZ-3 (50/50).

BPAPC (50/50, Fig. 3d) with the spectra recorded for the individual components indicates that there is no noticeable change observed in the aromatic region of the BPAPC ranging from 7.31 to 7.16 ppm (Fig. 3b). The peaks appearing in the range from 7.1 to 6.9 ppm (Fig. 3d) correspond to the aromatic segments of TAPC. These peaks are broad and less intense as compared to the peaks recorded for individual TAPC (Fig. 3a). In addition, the peaks have shifted slightly downfield and the number of peaks is reduced on mixing with BPAPC (i.e., when TAPC was blended in solution

with BPAPC). In the upfield region ranging from 2.5 to 1.5 ppm there is no difference observed for the protons of  $\text{CH}_3$  groups of BPAPC at 1.7 ppm. However, the peak at 2.3 ppm in the TAPC spectrum becomes less intense on blending with BPAPC. The broadening can be interpreted as due to the decrease in the torsional mobility of the phenyl groups of TAPC due to their interaction with BPAPC.

Figures 3c and 3e show the spectra of PCZ-3 and TAPC–PCZ-3 (50/50) mixture, respectively. The aromatic protons of PCZ-3 give rise to four peaks at 7.35, 7.33, 7.18, and 7.15 ppm. When blended with TAPC, in addition to the peaks corresponding to PCZ-3, some extra peaks are seen at 7.34, 7.33, 7.3, 7.17, and 7.1 ppm. The TAPC spectra showed aromatic proton peaks in the range from 7.13 to 6.88 ppm (Fig. 3a). When TAPC was blended with PCZ-3, the peaks at 7.13, 7.12, and 7.1 ppm are not seen and the remaining peaks shifted slightly towards the upfield (Fig. 3e). Also, we observe a broadening and a reduction in the height of the peaks in the range from 6.94 to 6.88 ppm. The chemical shifts recorded in the range of 2.3 to 1.5 ppm for individual components (TAPC, Fig. 3a and PCZ-3, Fig. 3c) differ significantly in the case of mixtures. The change in the chemical shifts, peak heights, and the number of peaks indicate that molecular level interactions occur between TAPC and both the polycarbonates in solution.

#### Fourier transform IR spectroscopy

FTIR spectra were recorded with various concentrations of TAPC in the host polymer. Figure 4 shows the spectra for the composition of 50% TAPC with BPAPC along with the spectra of TAPC only and BPAPC films. The PCZ-3 spectra are not shown here. The medium absorption band at  $1602\text{ cm}^{-1}$  in both the BPAPC and TAPC spectra is attributed to the para-aromatic ring stretch,<sup>38</sup> which is shifted to a higher frequency by  $3\text{ cm}^{-1}$  with higher intensity along with a new shoulder at  $1581\text{ cm}^{-1}$  (due to TAPC) for the composites. In the case of PCZ-3 (not shown), the band at  $1604\text{ cm}^{-1}$  was shifted to  $1606\text{ cm}^{-1}$ , along with a shoulder at  $1580\text{ cm}^{-1}$ , with higher intensity. The peaks in the region  $3000\text{--}3200\text{ cm}^{-1}$  correspond to aromatic CH stretch.<sup>39</sup> A weak absorption band at  $3042\text{ cm}^{-1}$  in both BPAPC and PCZ-3 spectra shifted to a lower wavenumber, by  $12\text{ cm}^{-1}$ , with higher intensity. The peak at  $2874\text{ cm}^{-1}$  shifted to  $2860\text{ cm}^{-1}$  with higher intensity in TAPC–BPAPC. In this region ( $3000\text{--}3200\text{ cm}^{-1}$ ), such a change was noticeably higher in the case of TTA–BPAPC.<sup>21</sup>

In the BPAPC spectrum, a band at  $1104\text{ cm}^{-1}$  shifted to higher wavenumber by  $5\text{ cm}^{-1}$ . A broad band between  $1130$  and  $1335\text{ cm}^{-1}$  with several peaks at  $1310\text{ cm}^{-1}$ ,  $1290\text{ cm}^{-1}$ , and  $1163\text{ cm}^{-1}$  is attributed to the carbonate segment. This region became broader by  $27\text{ cm}^{-1}$  with a strong peak at  $1320\text{ cm}^{-1}$  and with small peaks at  $1274\text{ cm}^{-1}$ ,  $1192\text{ cm}^{-1}$ , and  $1164\text{ cm}^{-1}$ , similar to the case of TTA–BPAPC<sup>21</sup> and TPD–BPAPC.<sup>19</sup> Similar changes were observed in the case of TAPC–PCZ-3.

Thus, the FTIR spectra show a significant change in the absorption bands of the polycarbonates (both in the aromatic and carbonyl regions) by blending with TAPC. Figure 5a shows the increase in the wavenumber shift of the aromatic CH stretch ( $3042\text{ cm}^{-1}$ ) with TAPC concentration in PCs. A linear increase of peak absorption area of this peak with the

**Fig. 4.** FTIR spectra of TAPC, BPAPC, and TAPC–BPAPC (50/50) composite.

TAPC concentration in the host polymer is seen in Fig. 5b. Although there is no significant difference in the wavenumber shift between the two types of polycarbonates for the same concentration of TAPC, PCZ-3 showed a higher absorption area than the BPAPC. The wavenumber shift and peak absorption area are plotted as a function of  $\Delta T_g$  in

Figs. 5c and 5d, respectively. These results indicate specific interactions between the aromatic groups of the polycarbonate and the TAPC, i.e., the alignment of the phenyl group of the TAPC with those of the polycarbonates. The wavenumber shift observed here is more than that in the case of TPD, consistent with the larger  $T_g$  depression of the matrix. Similarly, the IR frequency shift in the case of TTA–BPAPC was larger than with TAPC or TPD, consistent with the larger  $T_g$  depression. The TPD–polystyrene system did not show significant IR frequency shifts, and the depression of the  $T_g$  was less.<sup>20</sup> Both the  $T_g$  reduction and the IR band shift depend on the concentration of TAPC. In the case of BPAPC, a larger shift for the  $\Delta T_g$  values is due to the smaller depression of the  $T_g$  of BPAPC as compared to the PCZ-3 for the same concentration of TAPC (see Fig. 2). Thus, the changes in the FTIR spectra show that while molecular interactions exist, the broadening of the peaks also indicate disordered packing with the TAPC.

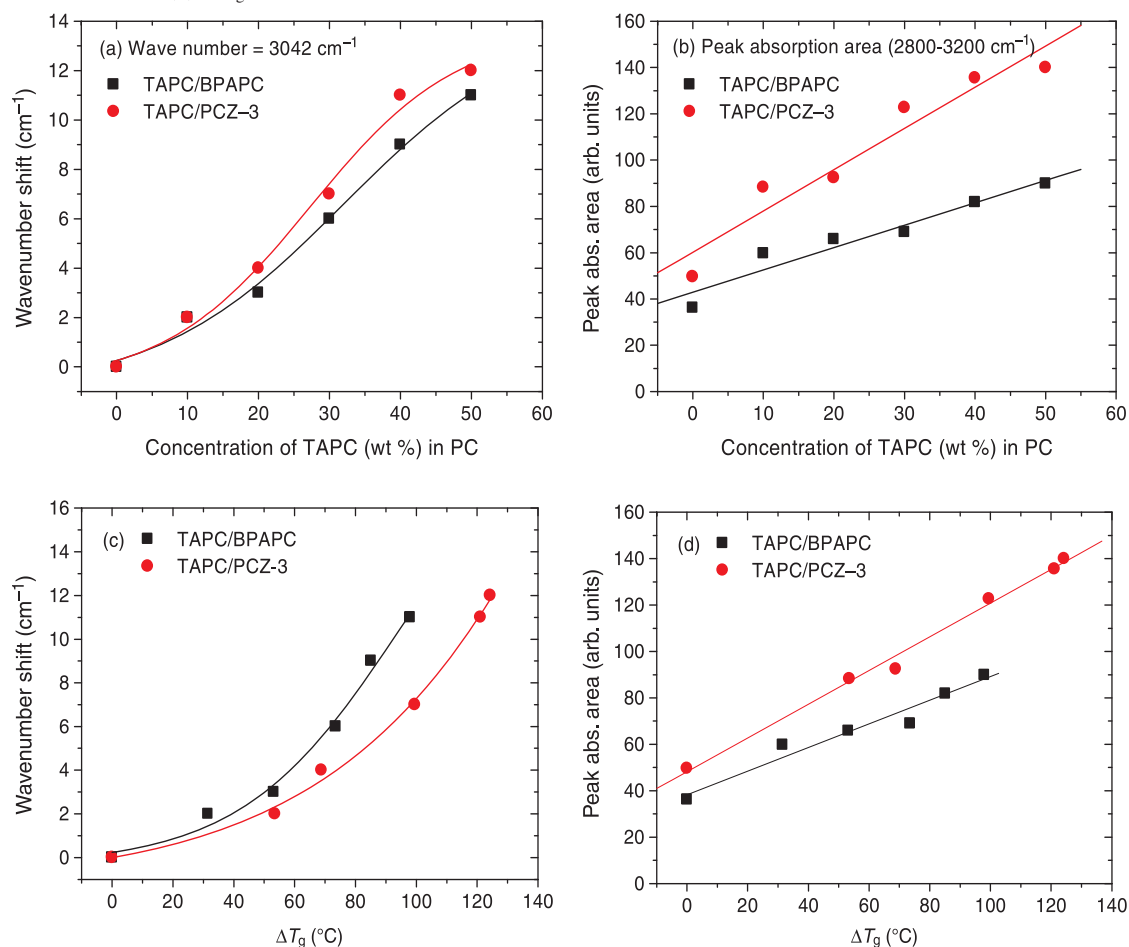

Hence, both NMR spectra in solution and FTIR analysis of the films indicate the presence of molecular interactions and disordered packing. The effect of disorder on the charge transport properties has been studied experimentally and via simulation.<sup>23a,23h,27</sup>

### Phase separation and $T_g$ recovery

Annealing is a common practice to understand the phase separation behavior and morphological stability of a small molecule (e.g., TAPC) in a polymer matrix. Accelerated thermal treatment has been used by several authors to study the ageing of polymers and polymer composites.<sup>40</sup> In previous publications, Khan and Sundararajan<sup>19–22</sup> discussed the annealing induced phase separation behaviour of the charge transport molecule from the host matrices, and rationalized them on the basis of molecular interactions and the molecular flexibility of the polymer. Annealing was performed at a few degrees below the  $T_g$  of the host polymer. We considered this to be similar to accelerated ageing. Although there might not be a standard testing procedure to estimate the ageing effect of charge transport layers, we used thermal annealing as a means to study the phase separation of the hole transport molecule from the charge transport layer. Other factors such as corona charging and other device conditions may also contribute to ageing.

Annealing was performed at 120, 130, and 140 °C for various times for TAPC–PC composites. The phase separation of TAPC from the polymer matrix would lead to a  $T_g$  recovery of the polymer. With a 40 wt% concentration of TAPC in BPAPC, the  $T_g$  recovery was 47 °C upon annealing at 140 °C for 4 h. The recovery of the  $T_g$  was more pronounced in the case of a 50 wt% TAPC concentration in polycarbonates. Figure 6 shows the increase in the  $T_g$  with annealing time and temperatures, for a TAPC concentration of 50 wt% in the two types of polycarbonates (BPAPC and PCZ-3). It is seen in Figs. 6a and 6b, that the rate of increase in the  $T_g$  is sharp during the first half hour of annealing, and it levels off beyond 2 h. The initial large increase indicates that the phase separation is profuse. Since the  $T_g$  recovers significantly during this initial period, further diffusion of the small molecule from the polymer matrix is retarded. With TAPC–BPAPC (50/50) composite, upon annealing at 120, 130, 140 °C for 4 h, the  $T_g$  increases from

**Fig. 5.** The infrared wavenumber shift ( $\text{cm}^{-1}$ ) as a function of (a) TAPC concentration and (c)  $\Delta T_g$ ; the absorption area as a function of (b) TAPC concentration and (d)  $\Delta T_g$ .

53 to 110, 128, and 134  $^{\circ}\text{C}$ , respectively (the onset  $T_g$ s are given here since the transitions were broad and determining the midpoint was difficult). Thus, a maximum  $T_g$  recovery of 81  $^{\circ}\text{C}$  was obtained (upon annealing at 140  $^{\circ}\text{C}$  for 2 and 4 h). This is a significantly higher recovery as compared to the case of 50 wt% TPD with BPAPC, in which the recovery was only 11  $^{\circ}\text{C}$  upon annealing for 4 h at 140  $^{\circ}\text{C}$ . The latter was rationalized on the basis that some of the sub-micron crystals formed during annealing actually exercise a plasticizing effect and keep the  $T_g$  lower.

Figure 6b for the case of TAPC–PCZ-3 (50/50) also shows that the  $T_g$  recovery is rapid in the first half hour of annealing. The maximum recovery is about 52  $^{\circ}\text{C}$  for PCZ-3 (for PCZ-2 also), after 4 h of annealing at 140  $^{\circ}\text{C}$ . Thus, the maximum recovery of  $T_g$  is lower by about 28  $^{\circ}\text{C}$  in the case of PCZ as compared with BPAPC. In contrast, the TPD–PCZ-3 system showed only a negligible 5  $^{\circ}\text{C}$  recovery in  $T_g$  when annealed at these temperatures.

For the case of TTA–BPAPC (50/50), the maximum  $T_g$  recovery was 92  $^{\circ}\text{C}$  when annealed at 140  $^{\circ}\text{C}$ , and it was 69  $^{\circ}\text{C}$  with TTA–PCZ-3. This is a higher  $T_g$  recovery when compared to the TAPC and TPD systems. Apart from the smaller molecular volume of TTA, its melting temperature (111  $^{\circ}\text{C}$ ) is also significantly lower than that of TAPC

(188  $^{\circ}\text{C}$ ) and TPD (171  $^{\circ}\text{C}$ ). The annealing temperatures used were above that of the melting of TTA and this resulted in sublimation of the small molecule.<sup>21</sup> Since TAPC is a dimeric analog of TTA, the  $T_g$  recovery is consistent with the higher van der Waals volume of TAPC when compared to TTA, which would lead to a lower diffusion rate and phase separation upon annealing.

It is expected that the  $T_g$  recovery would depend on the difference between the  $T_g$  of the polymer and the annealing temperature (i.e.,  $\Delta T = T_g - T_{\text{ann}}$ ). Figure 6c shows a plot of the  $T_g$  recovery as a function of  $\Delta T$  for BPAPC and PCZ-3, after annealing (for 4 h at 140  $^{\circ}\text{C}$ ). The trend can be expressed as follows.

$$[2] \quad T_{g(\text{rec})} = 100 - 1.2\Delta T; (\text{TAPC–BPAPC})$$

$$[3] \quad T_{g(\text{rec})} = 62 - 0.2\Delta T; (\text{TAPC–PCZ-2})$$

$$[4] \quad T_{g(\text{rec})} = 71 - 0.4\Delta T; (\text{TAPC–PCZ-3})$$

The slope corresponding to the BPAPC (eq. [2]) is higher than that of PCZ-3 (eq. [4]). These slopes were same in the case of TPD–BPAPC and TPD–PCZ-3 (see Fig. 8a and eq. [2] of ref. 19), which was  $-0.12$ .<sup>19</sup> In the case of the

**Fig. 6.** Recovery of the glass transition temperatures ( $T_g$ ) of (a) TAPC–BPAPC (50/50), (b) TAPC–PCZ-3 (50/50) with annealing time, and (c) the  $T_g$  recovery with  $\Delta T$  (the difference between the temperature of annealing and the  $T_g$  of the polymer).

TTA system, the rate of the  $T_g$  recovery was significantly higher than the TAPC and TPD systems. The corresponding slopes were  $-1.5$  and  $-0.8$  for TTA–BPAPC and TTA–PCZ-3.<sup>21</sup>

**Fig. 7.** Changes in the crystallinity upon annealing: (a) X-ray diffraction profiles, (b) DSC crystallinity of TAPC–BPAPC (50/50), and (c) X-ray crystallinity.

### Crystallinity of phase separated TAPC

The crystallinity was measured from the melting endotherm in the DSC thermogram and from the X-ray diffraction profiles, as described in the Experimental section. No resolved crystalline peak was seen in the X-ray diffraction profile for the as-prepared film. Figure 7a shows the X-ray diffraction profiles as the TAPC–BPAPC (50/50) film was annealed at 140 °C for various times. The crystalline peaks

corresponding to phase separated TAPC begin to appear within 30 min of the annealing time. A significant increase in intensity of such peaks is observed between 0.5 and 2 h. The crystallinities calculated from the DSC thermograms and X-ray diffraction profiles are shown in Figs. 7b and 7c, respectively. It is seen that the values of the crystallinity from X-ray diffraction are significantly lower than those obtained from the DSC measurements. Such a difference in the crystallinity measurement is expected while using two different methods. The trend in the variation of the crystallinity, however, is similar using both methods. The DSC crystallinity was measured with respect to the heat of fusion of TAPC, which is assumed to be that of 100% crystalline material. The results of X-ray diffraction suffer from the fact that the crystals that grow out of the polymer film are not necessarily perfect and not of uniform size. The crystallinities in the case of TAPC-PCZ were far less than those detected in the case of TAPC-BPAPC composites.

### Time dependence of FTIR spectra

It was seen in Fig. 5b that the peak absorption area corresponding to the aromatic CH stretch region increased with the concentration of TAPC in the polycarbonate matrices, indicating disordered packing. A kinetic study of the composite films was performed by keeping the films at 140 °C up to 4 h and collecting IR spectra at intervals of 15 min. Typical changes in the spectral shape with time are shown in Fig. 8, for a TAPC-BPAPC (50/50) film. It is seen in Figs. 8a and 8b that the transmission intensity of the bands decreased with prolonged annealing time. The change in intensity is more pronounced for the bands in the wavenumber range of 2800–3200  $\text{cm}^{-1}$ . These absorption areas were normalized with respect to that obtained from the as-prepared film, and the relative peak absorption areas are shown in Fig. 8c. Figure 8c shows that the increase of the peak absorption area is significantly high in the first hour of annealing time, which is consistent with the rate of increase of  $T_g$  upon annealing (Fig. 6). Annealing beyond this time does not cause any change in the absorption area or the  $T_g$ . The peak absorption area is higher in the case of BPAPC than PCZ-3, suggesting higher phase separation in the former case.

### Morphology of TAPC-polymer composites

Figure 9 shows the optical micrographs of the films under various conditions. We observed that the as-prepared films were transparent with up to 40 wt% of TAPC in the polymer. With 50 wt% of TAPC in BPAPC, PCZ-2, and PCZ-3, some crystals were detected for the as-prepared films (Figs. 9a and 9b). Most of these crystals were fairly uniform in size. The average crystal area was 13  $\mu\text{m}^2$  in the as-prepared film of TAPC-BPAPC (50/50), and it was slightly lower by about 4  $\mu\text{m}^2$  in the case of PCZ-2 and PCZ-3 with the same concentration of TAPC. On annealing these films, the number of crystals increases as seen in Figs. 9c and 9d. Figures 9c and 9d show that the phase separation of TAPC is pronounced in the case of BPAPC compared to PCZ. This could be attributed to the fact that BPAPC has a lower glass transition temperature than PCZ, and its conformation is also more flexible. The crystal size of TPD was about ten times larger in the case of TPD<sup>19</sup> (see also Fig. 8

**Fig. 8.** (a) and (b) Changes in the FTIR spectra and (c) the absorption area as a function of annealing time at 140 °C for the TAPC-BPAPC (50/50) film.

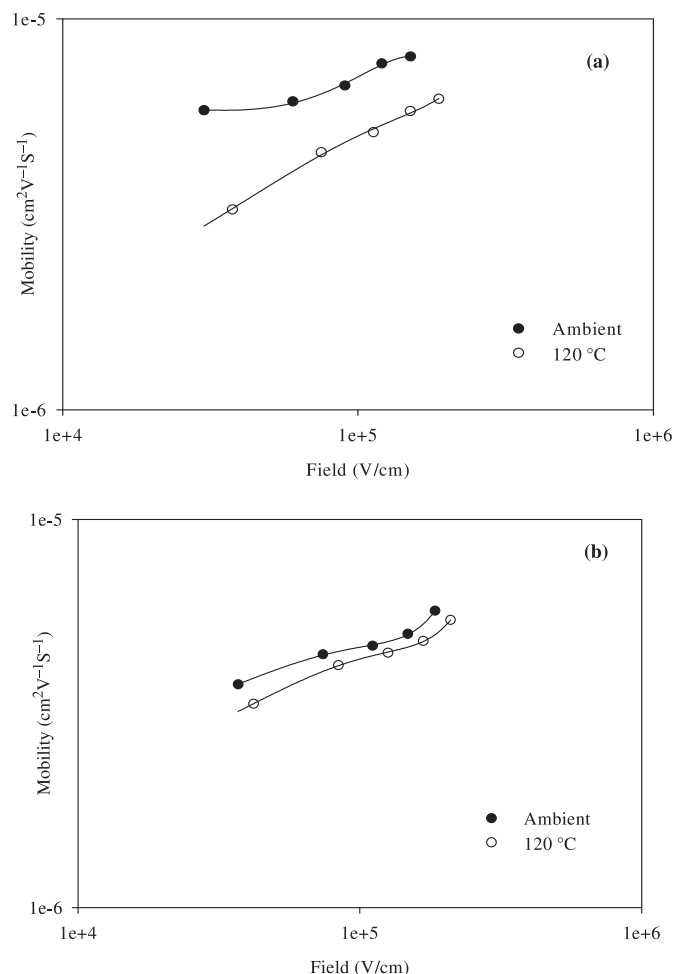

of ref. 20) as compared to TAPC. In the case of TTA-polymer composites, the phase separation was observed at temperatures as low as 80 °C upon annealing. This was attributed to the lower melting temperature of TTA as compared to TPD and TAPC.

**Fig. 9.** Optical micrographs of as-prepared films of (a) TAPC–BPAPC (50/50); (b) TAPC–PCZ-3 (50/50); (c) TAPC–BPAPC (50/50) film annealed at 140 °C for 4 h; (d) TAPC–PCZ-3 (50/50) film annealed at 140 °C for 4 h.

**Fig. 10.** Variation of the charge mobility for the as-prepared and annealed films with 40 wt% TAPC. (a) BPAPC. (b) PCZ-3.

### Charge mobility measurements

The effect of thermal annealing on the charge mobility depends on the type of polymer matrix. Figure 10 shows the charge mobility measurement results for 40 wt% TAPC–BPAPC and 40 wt% TAPC–PCZ composites before and after thermal annealing. After 2 h of annealing at 120 °C, TAPC–BPAPC showed a bigger drop, ~50% in mobility with respect to the unannealed sample. The TAPC–PCZ composite exhibited less than 10% change in mobility for the same treatment. The slower charge transport indicates a reduction of dispersed transport molecules in polymer matrix as they crystallized and phased separate. This seems to correlate very well with the fact that TAPC diffuses more readily in BPAPC and achieves greater phase separation than in PCZ.

It is seen in Fig. 10 that the charge mobility is higher in BPAPC than in PCZ-3. We find that even with 40 wt% TAPC, there is some phase separation with BPAPC as the matrix. The film was still transparent since the crystals were very small. It is likely that hopping between these sub-micron crystals enhances the mobility. Previously, we explained the enhanced charge mobility of TPD in polystyrene as due to the chaining of such submicron crystals.<sup>20</sup> If such is the case, it might actually be advantageous to induce sub-

micron crystals of the small molecule, while keeping the film transparent.

## Conclusions

The phase stability of model charge transport composites depend significantly on the shape of the charge transport molecule. We find that TAPC, which is double spherical and large compared to TPD is more effective in suppressing the  $T_g$  when the composite film is made with  $\text{CH}_2\text{Cl}_2$  as the solvent. The changes in the  $^1\text{H}$  NMR chemical shifts of TAPC and the polycarbonates in solution and the broadening of the peaks show that while aromatic interactions exist in the case of composites, the torsional mobility of TAPC is also reduced. Similarly, the IR spectra show frequency shifts indicative of aromatic interactions between TAPC and the polycarbonate and the areas of the absorption peaks also show an increase in the concentration of the small molecule in the composite.

As mentioned above, the polycarbonate is in an extended conformation in tetrachloroethane and in a random coil conformation in methylene chloride. Films made with TPD (a rodlike molecule) and BPAPC with the former solvent showed a larger depression of the  $T_g$  due to enhanced intercalation of the rodlike small molecule with a polymer in an extended conformation. Hence, our studies published so far indicate that the depression of the  $T_g$  caused by spherical small molecules (TTA and TAPC) in a random-coil polymer is more than that resulting by including a rodlike small molecule (TPD). Likewise, the rodlike TPD is more effective in reducing the  $T_g$  when the polymer is in an extended conformation. Using the spherical molecule (TAPC) with BPAPC in tetrachloroethane led to a smaller  $T_g$  depression of the film.

The crystallinity of TAPC that develops due to phase separation upon annealing is more pronounced in the case of BPAPC than PCZ as the matrix. The phase separation is nearly complete within the first half hour of annealing. The FTIR kinetic study also indicates that the phase separation is pronounced in the case of BPAPC compared to PCZ. The morphology of the crystals also depends on the type of transport molecule. The crystal sizes are about ten times smaller in the case of TAPC based composites as compared to the TPD–polymer composites. It is likely that the near-spherical and bulky shape of the TAPC prevents the growth of large crystals, as compared to the “rodlike” shape of TPD.

In the case of photoreceptors it has been necessary to use a concentration of 50 wt% of the charge transport molecule to achieve sufficient mobility. We show that at such concentrations, there is already some phase separation and that sub-micron crystals form. We suggest that the formation of such submicron crystals might itself be the reason for the enhanced mobility. This has been suggested in other studies as well.<sup>23a,23h,27</sup>

# A study of the intermolecular branch frequency dependence of tie-chain concentration in single-site linear low-density polyethylene blown films by a new FTIR method

Mingtao Wang, Nan Li, Phillip Choi, and Yaolin Zhang

**Abstract:** The relative concentrations of tie chains (TCs) in six single-site linear low-density polyethylene blown films (LLDPE) were measured using a polarized Fourier transform infrared (FTIR) technique along with a newly developed sample preparation strategy. Before the FTIR measurements, the films were first subjected to a tensile strain of 20% using a homemade appliance and then annealed at a temperature of 60 °C over a time period of 24 h to relax all nonTCs in the amorphous phase. The relative TC concentrations were inferred from the FTIR measurement of the orientation order of the amorphous chains in the stretched films. It is believed that a greater concentration of TCs leads to a higher orientation order for the amorphous chains. The results showed that the quantity of TCs is essentially determined by the chains with the appropriate branch frequency (~12 branches per 1000 backbone carbons based upon the films used in this work), especially those of the high molar mass chains as formation of TCs requires suitable ethylene sequence lengths between branches. The dart impact strength of the films appeared to be positively related to the relative concentration of TCs; films with greater concentrations showed higher dart impact strength. No clear correlations were observed between the relative concentration of TCs and the tear resistance of the films. However, the TC concentration seems to be related to the magnitude of the difference between the transverse direction and machine direction tear resistance.

**Key words:** tie chains, polarized Fourier transform infrared (FTIR), linear low-density polyethylene (LLDPE) blown films, dart impact.

**Résumé :** Faisant appel à la technique d'infrarouge à transformée de Fourier polarisée (IR-TF) et à une nouvelle stratégie de préparations des échantillons, on a étudié les concentrations relatives de chaînes liées (CL) de six films soufflés de polyéthylène de faible densité, linéaire et à site unique. Avant d'effectuer les mesures IR-TF, les films ont été soumis à une force tensile de 20 % à l'aide d'un appareil maison et ils ont ensuite été recuits à une température de 60 °C pour une période de 20 heures afin de détendre toutes les chaînes non liées dans la phase amorphe. Les concentrations relatives de chaînes liées ont été déduites de la mesure IR-TF de l'ordre d'orientation des chaînes amorphes dans les films étirés. On croit qu'une concentration plus élevée de chaînes liées conduit à un ordre d'orientation plus élevé pour les chaînes amorphes. Les résultats montrent que la quantité de chaînes liées est essentiellement déterminée par les chaînes comportant la fréquence appropriée de ramification (environ 12 branches par 1000 atomes de carbone dans le squelette si on se base sur les films utilisés dans cette étude), particulièrement pour les chaînes de masse moléculaire élevée puisque la formation de chaînes liées nécessite des longueurs appropriées de séquence d'éthylène entre les branches. Le force d'impact au dard des films semble être liée d'une façon positive à la concentration des chaînes liées; les films en comportant de plus grandes concentrations présentent une force d'impact au dard plus élevée. On n'a observé aucune corrélation entre la concentration relative des chaînes liées et la résistance aux déchirures des films. Toutefois, la concentration des chaînes liées semble être liée à l'amplitude de la différence entre la direction transverse et la direction mécanique de la résistance aux déchirures.

**Mots-clés :** chaînes liées, infrarouge à transformée de Fourier, films soufflés de polyéthylène de faible densité et linéaire, impact au dard.

## Introduction

Among the structural features in polyethylene blown films, tie chains (TCs) are believed to play a significant role in determining their physical properties as TCs bridge adjacent lamellae.<sup>1</sup> A high concentration of TCs results in a significant improvement in the resistance to low-temperature impact,<sup>2</sup> to creep,<sup>3</sup> to slow crack growth,<sup>4</sup> and to tear and puncture.<sup>5</sup> Without TCs, all lamellae would be held by relatively weak van der Waals forces leading to lower dart impact strength and tear resistance, the two most important performance properties of polyethylene blown films. The formation of TCs has been attributed to the random coil dimension in the molten state being larger than the thickness of crystallites formed in the solid state after crystallization.<sup>6,7</sup> Several crystalline lamellae can grow within the sphere of gyration of a chain provided the chain is sufficiently long. Therefore, a long-chain molecule can cross the noncrystalline region and provide the physical bridging for adjacent crystalline lamellae. Since not all chains emanating from a lamella would traverse through the amorphous regions and enter into another lamella, it is difficult to predict *a priori* the absolute concentration of TCs. In fact, some of the chains reenter the original lamella,<sup>8</sup> and others may simply end up in the amorphous regions as loose loops or dangling chains. Obviously, chains below a critical molar mass cannot participate in the TC formation process as these chains are not long enough to have at least two parts of it being involved in two different lamellae, which are connected by the remaining part of the chains. Also, optimal branch frequencies must exist for the formation of TCs for branched polyethylene chains of different lengths. In general, chains with low branch frequency tend not to form TCs even though their molar masses are high. All of the aforementioned findings regarding TCs have been summarized in a review article written by Seguela.<sup>9</sup> To formulate any structure–property relationship for polyethylene blown films, measurement of the absolute TC concentration is most desirable. Unfortunately, such measurement is difficult, if not impossible, as TCs are buried in the amorphous regions with other structural units, a situation that is hard for any analytical methods to differentiate and characterize them. Therefore, at present, no direct analytical method is available for such a purpose. In many cases, researchers tend to infer the relative concentration of TCs in a series of samples based on the measured mechanical properties such as the brittle fracture strength.<sup>10,11</sup> The quest for a reliable method for measuring the concentration of TCs, at least in a relative sense, is still of scientific and practical significance.

The orientation of amorphous chains in polyethylene blown films can be characterized by using a polarized infrared method.<sup>12</sup> Using polarized Fourier transform infrared (FTIR) spectroscopy, Lustiger and Ishikawa<sup>13</sup> measured the relative concentration of TCs in polyethylene blown films. In their work, the authors chlorinated the film specimens to differentiate the signals (peaks) of the amorphous orientation from those of the crystalline orientation.<sup>13</sup> A simpler method of differentiating the amorphous from the crystalline orientations was proposed by Kissin.<sup>14</sup> However, the method suffers from the problem that not all chlorinated branches are associated with the TCs. In fact, the amount of chlorinated

branches that are associated with TCs is unknown in this method. Also, extra efforts have to be spent for the chlorination process as highly toxic chlorinated chemicals must be used.

In the work presented here, we also used a polarized FTIR method employed by Kissin<sup>14</sup> to measure the relative concentration of TCs. However, a new simpler sample preparation strategy was applied to six single-site linear low-density polyethylene (ss-LLDPE) blown films with different molar mass dependence of branch frequency. The samples were chosen such that the experiments not only serve to test the proposed method but also allow us to investigate the effect of interchain branch frequency on the concentration of TCs.

## Theoretical background

When polyethylene blown films are stretched at a temperature above their glass transition temperature,  $T_g$ , both the crystalline and amorphous components oriented towards the stretching direction. Within the amorphous regions, the TCs and chains other than TCs (i.e., loose loops, dangling chains, nonbridging amorphous chains, collectively referred to as NTCs) would be aligned along the stretching direction. The NTCs, however, would relax back to the unoriented states provided that sufficient time and appropriate conditions are given. Since TCs act as bridges between lamellae, they cannot relax. Consequently, it can be assumed that upon relaxation, the orientation order of the amorphous regions mainly originates from the aligned TCs under stretch, and that measurement of the amorphous orientation order of a stretched sample upon relaxation can be directly related to the concentration of TCs. The comparison of such orders among film samples would yield information about which sample would have a relatively higher concentration of TCs. For a uniaxially stretched polyethylene blown film, the dichroic ratio,  $D$ , is defined as<sup>12</sup>

$$[1] \quad D = \frac{A_{//}}{A_{\perp}}$$

where  $A_{//}$  and  $A_{\perp}$  are the absorbance measured with the electric field vector of the polarized radiation parallel and perpendicular to the stretching direction, respectively. To characterize the orientation of the amorphous chains in the stretched samples, Herman orientation function,  $f$ , is used and defined as<sup>12</sup>

$$[2] \quad f = (3\langle \cos^2 \theta \rangle - 1)/2$$

where  $\theta$  is the angle between the stretching direction and the axis of the chain segments. The relationship between  $f$  and  $D$  for a given absorption band is given by eq. [3]:<sup>12</sup>

$$[3] \quad f = \frac{D - 1}{D + 2}$$

where  $D_0$  is given by eq. [4]:<sup>12</sup>

$$[4] \quad D_0 = 2\cos^2 \Phi$$

Here,  $\Phi$  is the angle between the chain axis and the transition moment direction of the vibration mode responsible for the infrared absorption.  $f$  is a function of both the degree of

orientation and the quantity of the orienting elements in a given film sample. Under comparable stretching conditions, the degree of orientation of the aligned elements in the amorphous regions in various films was assumed to be the same, and thus,  $f$  is an indicative of the relative concentration of TCs.

## Experimental

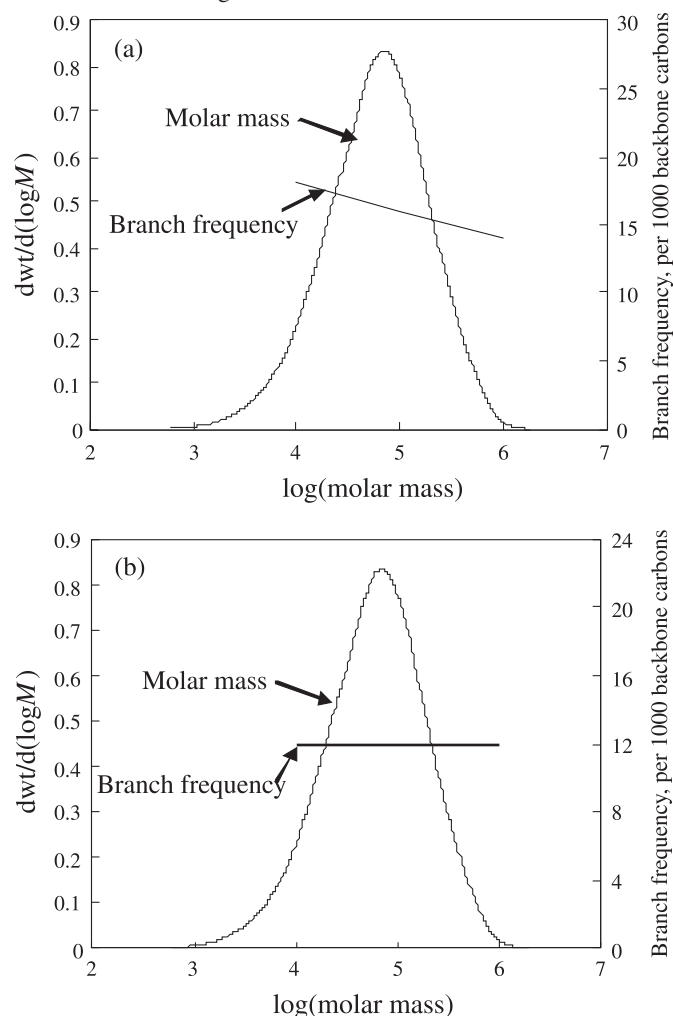

### Materials and blown film preparation

Six single-site linear low-density polyethylene (ss-LLDPE) blown films, hereafter referred to as films A, B, C, D, E, and F, exhibiting wide ranges of dart impact strength and tear resistance, were chosen to test the proposed FTIR method (see Table 1). They were provided by NOVA Chemicals Corporation (Calgary, AB). The films were made from resins with comparable solid-state densities and melt indices and their nominal thickness was about 25  $\mu$ m. As can be seen from Table 1, the molar mass averages and branch frequencies of the resins differ. It should be noted that the same resin was used for films A, C, and D but they were processed under different conditions. Another major difference between films A–D and E–F is their molar mass dependence of branch frequency (see schematics in Fig. 1). As shown, films A–D contain a greater portion of branches in their shorter chains (Fig. 1a), whereas the branches were more or less evenly distributed among chains in films E and F (Fig. 1b).

### Blown film deformation and relaxation of NTCs

The ss-LLDPE blown films were cut into 50 mm  $\times$  10 mm slices (machine direction  $\times$  transverse direction) in the rectangle geometry. The films were then placed in a homemade stretching device (see Fig. 2) and uniaxially stretched along the machine direction (MD) slowly to ensure uniform stretching. After the chosen strains were reached, the films were held in the stretching device and placed in an oven annealed at 60  $^{\circ}$ C for 24 h to relax the NTCs in their amorphous phase. The temperature was chosen so that it is not high enough to cause any destruction of the lamellae, and that it is not too low to result in unnecessary long

**Fig. 1.** Schematics of two types of molar mass dependence of branch frequency: (a) a greater portion of branches are located in shorter chains and (b) branches are evenly distributed among chains of different chain lengths.

**Fig. 2.** An image of the homemade stretching device.

relaxation times. The relaxation time of 24 h was chosen based on the fact that longer relaxation times at 60 °C resulted in no significant changes to the FTIR spectra of the stretched films.

### FTIR measurements

Polarized FTIR measurements were carried out directly on the stretched films held in the fixture using a Nicolet 8700 FTIR spectrometer. The spectra were collected using a polarized beam parallel and perpendicular to the stretching machine direction with 128 scans at the resolution of 2.0 cm<sup>-1</sup>. Background spectra with the polarized beam at 0° and 90° were recorded before the acquisition of the parallel and perpendicular spectra of the stretched ss-LLDPE blown films. The strains of ss-LLDPE blown films along machine direction were reached stepwise (i.e., 0%, 5%, 10%, 15%, 20%, 30%, 50%, and 70%). The polarized FTIR spectra were collected for each relaxed film at each step.

A spectral range of 600–800 cm<sup>-1</sup> was used for the orientation measurements. This range includes three bands. Two of them, one at 730 cm<sup>-1</sup> and the other at 719 cm<sup>-1</sup>, characterize the rocking modes of the chains in the orthorhombic crystalline phase, with each transition moment parallel to the crystallographic *a* and *b* axes, respectively.<sup>12</sup> The third band, at 722 cm<sup>-1</sup>, is attributed to the transition moment perpendicular to the chain axes for the amorphous phase.<sup>12</sup> The doublet at 730/720 cm<sup>-1</sup> was fit with Lorentzian functions

**Fig. 3.** FTIR spectrum of film E with MD parallel to the polarized light. Three peaks at 730, 719, and 722 cm<sup>-1</sup> were resolved from the fitting (see text for details). *R*<sup>2</sup> = 0.992, standard error = 0.010.

into three peaks corresponding to three bands (730, 722, and 719 cm<sup>-1</sup>). Peak fitting was carried out using GRAMS/AI software from Thermal Fisher Scientific. Prior to the curve fitting, the baselines of the spectra were corrected using an offset function. The width of the crystalline bands is approximately 3~4 cm<sup>-1</sup>, and that of the amorphous band is 10~20 cm<sup>-1</sup>. The standard deviation errors of the fittings were smaller than the value of 0.01. Figure 3 shows a polarized FTIR spectrum of film E with the polarized beam parallel to the MD and the corresponding fitting curves.

Since the amorphous component of the 722 cm<sup>-1</sup> band has a transition moment lying perpendicular to the chain axis, the orientation factor (*f*<sub>722</sub>) of the TCs can be determined by eq. [5], which was obtained by combining eqs. [3] and [4]:

$$[5] \quad f_{722} = -2 \frac{D_{722} - 1}{D_{722} + 2}$$

## Results and discussion

### Relative concentration of TCs

The orientation order (*f*<sub>722</sub>) of the amorphous region of each film sample under different tensile strains was determined and the results are shown in Fig. 4. Note that, the *f*<sub>722</sub> values at low strains (5% and 10%) for all six film samples were measured and these values are close to those at 0%; in Fig. 4, only the *f*<sub>722</sub> values at 0% are shown. The near zero or slightly negative *f*<sub>722</sub> values observed at low strains (i.e., <~10%) for all six film samples indicate that their amorphous chains, including both TCs and NTCs, are essentially randomly oriented. As the tensile strain increases, the *f*<sub>722</sub> value increases. At tensile strains approximately above 10%, differences in the *f*<sub>722</sub> value start to manifest among the samples. In particular, films E and F exhibit greater *f*<sub>722</sub> values than do the remaining films. The differences start to diminish when the strain becomes greater than 20% although the *f*<sub>722</sub> values for all six samples keep increasing. It is believed that with strains greater than 20%, the disassembling of the crystalline chains occur, resulting in contributions to the *f*<sub>722</sub> value of the amorphous chains. Beyond 80% of stretching, the recrystallization process may occur because the pulled out crystalline chains start to realign.<sup>15</sup> From Fig. 4, it can be seen that the *f*<sub>722</sub> values are

**Fig. 4.** The orientation orders of the amorphous phases of six ss-LLDPE blown films at varying strains.

almost the same for all six films for strains ranging from 30% to 70%, indicating that portions of crystalline chains were pulled out of the lamellae and into the amorphous regions. This is further confirmed by the results obtained from the tensile testing experiments performed on the films using an INSTRON machine (results are not shown here; the yield strains of these samples are about 20%). Before yield, only the amorphous regions are being stretched leading to the separation of lamellae. Above the yield point, chains in the lamellae are being pulled out to allow higher strains; these chains enter the amorphous phase and increase the orientation order of the amorphous chains. The tensile testing results justified us to use the  $f_{722}$  values at a strain of 20% to signify the concentration of TCs. Finally, it should be noted that the determination of the fraction of each phase from the FTIR spectrum is possible if the corresponding extinction coefficient for each different phase is known. However, since such coefficients for the crystalline and amorphous phases would likely vary differently upon stretching, we did not measure them.

#### Effects of branch content and distribution

The existence, and thus the quantity of TCs are closely related to the content, and the inter- and intra-chain distribution patterns of the short-chain branches (SCBs). And it generally believed that the type of SCBs is of secondary importance in influencing the resultant structures when SCBs contain more than two methylene carbons. As shown in Fig. 4, films E and F made from resins with high  $M_n$  ( $\sim 50\,000$ ) and low branch frequency ( $\sim 12$  per 1000 backbone carbons) exhibited significantly higher  $f_{722}$  values (i.e., higher concentrations of TCs) than did the other four films made from resins with a  $M_n$  of  $\sim 30\,000$  and branch frequency of  $\sim 15$  per 1000 backbone carbons. This suggests that an ethylene sequence between adjacent SCBs should have an optimal length to form TCs, and that a sample consisting of a greater number of long chains and incorporating appropriate levels of SCBs into these long chains enhances the probability of generating more TCs, which are consistent

**Fig. 5.** The dart impact strength vs relative concentration of TCs for six ss-LLDPE blown films.

with the finding by Krishnaswamy et al.<sup>16</sup> On average, if SCBs are more clustered in shorter chains (films A, B, C, and D), a greater quantity of very long branch-free chain segments would occur and give rise to a greater probability of producing larger and thus fewer crystalline lamellae; the probability for shorter chains that contain too many branches to form lamellae is also greatly reduced.<sup>17</sup> These two factors decrease the number of TCs. In contrast, when SCBs are more evenly distributed among chains or a greater portion of SCBs are incorporated into longer chains (films E and F), more homogeneous crystalline lamellae would occur and the two aforementioned unfavorable conditions for the formation of TCs would be largely avoided. In fact, the molar mass dependency of SCBs in films E and F ensures a higher probability of producing lamellae across the whole molar mass range, the optimal condition for the formation of TCs. The data from Fig. 4 may also imply that a branch frequency of  $\sim 12$  per 1000 backbone carbons results in a greater probability of producing TCs than does a branch frequency of  $\sim 15$  per 1000 backbone carbons; this requires more investigations, however, since the average molar mass and branch distribution pattern for the two groups of films investigated here differ.

Results of films A, C, and D demonstrate that processing conditions also influence the formation of TCs to a certain degree. In particular, high blow up ratio and low output rate may increase the chance of forming more TCs. In the case of film B, it is speculated that it contains the appropriate level of branches (it must be less than  $\sim 16$  per 1000 backbone carbons as the average branch frequency of this sample is about 16) in the high molar mass chains (highest  $M_z$  among the resins), and it exhibited a reasonable dart impact and the highest tear resistance.

#### Relationship between the relative concentration of TCs and dart impact

The dart impact strength is an important physical property for LLDPE blown films, and it is closely related to the amount of TCs in the material. Figure 5 shows the relation-

ship between the dart impact strength and the measured relative concentration of TCs of the films used in this study. It is shown that the dart impact strength increases as the concentration of TCs increases. TCs play an important role in connecting different components to form a network in which the imbalance between different components and orientations is reduced. A greater amount of TCs leads to the formation of a high number of smaller crystallites that tend to be more randomly oriented than the larger ones in the unstretched film. As a result, such an isotropic morphology results in higher dart impact strengths.<sup>18</sup> The positive correlation between the dart impact strength and the concentration of TCs observed for six films shows that the presence and quantity of TCs play a major role, if not a dominant one, in determining the dart impact strength of the material.

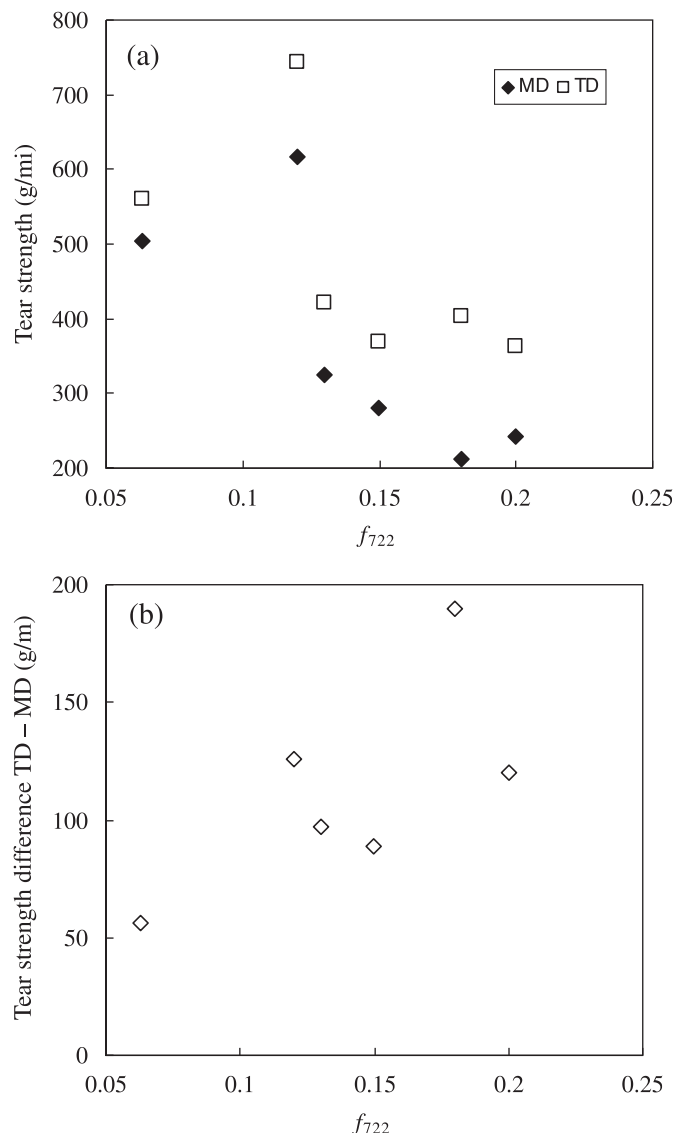

### Relationship between the relative concentration of TCs and tear strength

Tear resistance is another important physical property for LLDPE blown films. In the deformation, tear resistance reflects the energy that is dissipated in the growth of the crack. A certain amount of TCs (depending on machine direction (MD) or transverse direction (TD)) needs to be broken in order for the tear to propagate. As a result, if the crack propagation runs through a greater amount of TCs, stronger tear strength would follow owing to the covalent nature of the TC bonds. A clear correlation between the relative concentration of TCs and the tear resistance of the six films investigated here was not observed (Fig. 6a). Structural features other than TCs, such as the size and orientation of the crystalline lamellae, must be responsible for this observation. It is reported that larger lamellae being oriented along a certain direction result in good tear strengths in that direction.<sup>19</sup> A close examination of our data showed that the quantity of TCs may contribute to the tear resistance discrepancy between the MD and TD of the same film; it appeared that a higher concentration of TCs led to a larger discrepancy (Fig. 6b). This observation agrees with the finding of Chen et al.<sup>20</sup>

### Conclusions

The relative concentrations of tie chains (TCs) in six ss-LLDPE thin blown films were determined via the FTIR measurements of the amorphous orientation of the stretched films upon relaxation. The critical issues are the determination of an appropriate strain and the separation of the amorphous orientation from those of the crystalline chains. We demonstrated that at a strain of 20%, the amorphous chains (most importantly the TCs) were oriented to a significant degree, and the disturbance to the crystalline lamellar layer was limited to the minimum. The separation of the amorphous and crystalline orientations was solved by using the procedure reported by Kissin.<sup>14</sup> The average molar mass and the interchain distribution pattern of SCBs have significant effects on the amount of TCs. An optimal ethylene sequence length between SCBs must exist for the formation of TCs with other structural features remaining similar. The relationship between the relative concentration of TCs and the physical properties of the films showed that the quantity of TCs and the dart impact strength are positively related and

**Fig. 6.** (a) The tear strength vs relative concentration of TCs. (b) The tear strength difference (TD minus MD) vs relative concentration of TCs for six ss-LLDPE blown films.

that no clear correlation between the relative concentration of TCs and the tear strength was observed, indicating that other morphological features, such as lamellar size and orientation, may be more important in determining the tear resistance. The quantity of TCs may contribute to the discrepancy in MD and TD tear resistance of the films.

### Acknowledgements

We are grateful for the financial support from NOVA Chemicals Corporation and the Natural Sciences and Engineering Research Council of Canada through a collaborative research grant as well as to NOVA Chemicals Corporation for providing us the polyethylene film samples and the data shown in Table 1. We would also like to take this opportunity to thank the kind invitation from Professors Willie Leigh and Jean Duhamel at McMaster University and the University of Waterloo, respectively, for this submission to a special issue of the *Canadian Journal of Chemistry* to hon-

our the career contributions of Professor Mitchell A. Winnik at the University of Toronto.

# Conductivity percolation of carbon nanotubes (CNT) in polystyrene (PS) latex film

Ş. Uğur, Ö. Yargi, and Ö. Pekcan

**Abstract:** In this study, the effect of multiwalled carbon nanotubes (MWNT) on film formation behaviour and electrical conductivity properties of polystyrene (PS) latex film was investigated by using the photon transmission technique and electrical conductivity measurements. Films were prepared by mixing PS latex with different amounts of MWNTs, varying in the range between 0 and 20 wt%. After drying, MWNT content films were separately annealed above the glass transition temperature ( $T_g$ ) of PS, ranging from 100 to 270 °C, for 10 min. To monitor film formation behavior of PS–MWNT composites, transmitted light intensity,  $I_{tr}$ , was measured after each annealing step. The surface conductivity of annealed films at 170 °C was measured and found to increase dramatically above a certain fraction of MWNT (4 wt%) following the percolation theory. This fraction was defined as the percolation threshold of conductivity,  $R_c$ . The conductivity scales with the mass fraction of MWNT as a power law with exponent 2.27, which is extremely close to the value of 2.0 predicted by percolation theory. In addition, the increase in  $I_{tr}$  during annealing was explained by void closure and interdiffusion processes. Film formation stages were modeled and the corresponding activation energies were measured.

**Key words:** multiwalled carbon nanotubes, polystyrene, latex, nanocomposites, conductivity, transmission, percolation, film formation.

**Résumé :** Faisant appel à la technique de transmission photonique et à des mesures de conductivité électrique, on a étudié l'effet de nanotubes de carbone à parois multiples (NCPM) sur le comportement de formation de films et sur les propriétés de conductivité électrique de films de latex au polystyrène (PS). Les films ont été préparés en mélangeant du latex de PS avec diverses quantités de nanotubes de carbone à parois multiples allant de 0 à 20 % en poids. Après les avoir soumis au séchage, les films contenant des nanotubes de carbone à parois multiples ont été recuits séparément à une température supérieure à la celle de la de transition de verre ( $T_g$ ) du PS, de 100 à 270 °C, pendant dix minutes. Afin de suivre le comportement de formation des films composites PS/NCPM, on a mesuré l'intensité de la lumière transmise,  $I_{tr}$ , après chaque étape de recuisson. On a aussi mesuré la conductivité de surface des films recuits à 170 °C et on a observé une augmentation dramatique au-dessus d'une certaine fraction (4 % en poids), en accord avec la théorie de percolation. On a défini cette fraction comme le seuil de percolation de conductivité,  $R_c$ . Les échelles de conductivité utilisant la fraction massique des nanotubes de carbone à parois multiples avec une loi de puissance avec un exposant 2,27 sont très près de la valeur de 2,0 prédite par la théorie de la percolation. De plus, l'augmentation de  $I_{tr}$  durant la recuisson peut être expliquée par la fermeture du vide et des processus d'interdiffusion. On a calculé des modèles des stages de formation des films et on a mesuré les énergies d'activation correspondantes.

**Mots-clés :** nanotubes de carbone à parois multiples, polystyrène, latex, nanocomposites, conductivité, transmission, percolation, formation de film.

## Introduction

As a result of worldwide efforts by theorists and experimentalists, a very good understanding of the mechanisms of latex film formation has been achieved.<sup>1</sup> Traditionally, the film formation process of polymer latex is considered in terms of three sequential steps: (i) Water evaporation and subsequent packing of polymer particles. (ii) Deformation of the particles and close contact between the particles if

their glass transition temperature ( $T_g$ ) is less than or close to the drying temperature (soft or low  $T_g$  latex). Latex with a  $T_g$  above the drying temperature (hard or high  $T_g$  latex) stays undeformed at this stage. In the annealing of a hard latex system, deformation of particles first leads to void closure<sup>2–4</sup> and then after the voids disappear, diffusion across particle–particle boundaries starts, i.e., the mechanical properties of hard latex films evolve during annealing, after all solvent has evaporated and all voids have disappeared. (iii) Coales-

cence of the deformed particles to form a homogeneous film<sup>3</sup> where macromolecules belonging to different particles mix by interdiffusion.<sup>5,6</sup>

This understanding of latex film formation can now be exploited to underpin the processing of new types of coatings and adhesives. The blending of latex particles and inorganic nanoparticles provides a facile means of ensuring dispersion at the nanometer scale in composite coatings. Carbon nanotubes (CNT) and monodispersed nanoparticles are two of the most important building blocks proposed to create nanodevices. Recently, CNT-polymer nanocomposites have been widely investigated due to their remarkable mechanical,<sup>6</sup> thermal,<sup>7</sup> and electrical properties.<sup>8</sup> CNT have potential applications in many areas such as biosensors, conducting agents, field-effect transistors, and nanocomposites.<sup>9</sup> The polymeric or ceramic matrix of composites is usually considered nonconductive material because of its extremely low electrical conductivity (in the order of  $10^{-10}$ – $10^{-15}$  S/m). Dispersing conductive materials into the nonconductive matrix can form conductive composites. The electrical conductivity of a composite is strongly dependent on the volume fraction of the conductive phase. At low volume fractions, the conductivity remains very close to the conductivity of the pure matrix. When a certain volume fraction is reached, the conductivity of the composite drastically increases by many orders of magnitude. The phenomenon is known as percolation and can be well explained by percolation theory. The electrical percolation threshold of conductive reinforcements embedded in an insulating matrix is sensitive to the geometrical shape of the conductive phase. The small size and large aspect ratio (length/diameter) help lower the percolation threshold.<sup>10</sup> Depending on the matrix, the processing technique, and the nanotube type used, percolation thresholds ranging from 0.001 wt% to more than 10 wt% have been reported.<sup>11,12</sup> Because carbon nanotubes have tremendously large aspect ratios (100–10 000), many researchers have observed exceptionally low electrical percolation thresholds.<sup>12</sup> The electric current-carrying ability of CNTs may be 1000 times that of copper wires.<sup>13</sup> Due to the high aspect ratio of their external shapes, nanotubes can form percolated networks even at very low filler fractions (<5 wt%) to impart tremendous filler reinforcement effects. There have been many studies on low volume fraction composites where the addition of a very small amount of nanotubes substantially modifies the electrical properties of polymer matrices.<sup>13–16</sup> Thus, carbon nanotubes are excellent candidates to blend with polymers to produce electrostatic dissipative materials and other useful components in electronics.

As for the electrical properties of CNT-polymer composites, it was reported that the use of CNTs as conductive fillers in a polymer matrix implies a very low percolation threshold.<sup>13,15,17</sup> However, as CNTs are generally insoluble in common solvents and polymers, they tend to aggregate and disperse poorly in polymer matrix, resulting in deleterious effects. To overcome these difficulties, several methods have been developed to disperse CNTs in host polymers. CNTs could be dispersed in certain polymer solutions via ultrasonication<sup>18–22</sup> or in the presence of surfactants.<sup>23–25</sup> Several groups have reported electrical resistivity results for multiwalled nanotubes (MWNT) and single-walled nanotube (SWNT) ropes.<sup>26</sup> In a recent study, Gojny et al.<sup>27</sup> concluded

that multiwalled carbon nanotubes offer the highest potential for enhancement of electrical conductivity. The rationale behind this conclusion is that the multiwalled nanotubes usually have a better dispersability than single-walled nanotubes. Measured electrical conductivities for nanotube-based composites typically range from  $10^{-5}$  to  $10^{-2}$  S/m for nanotube contents above the percolation threshold.<sup>28</sup> However, electrical conductivity tailored to the range of 0.01–3480 S/m by varying the nanotube content from 0.11 to 15 wt% has also been reported.<sup>17</sup> Surely, the increase of the nanotube volume fraction can increase the electrical conductivity of composites. Previous studies indicate that the overall resistances of SWNT bundle networks and carbon nanotube-based composites are dominated by the contact resistance.<sup>29</sup> Measurements on crossed SWNTs<sup>30</sup> gave contact resistance of 100–400 k $\Omega$  for metal-metal or semiconducting-semiconducting SWNT junctions and values two orders higher for metal-semiconducting junctions.

Waviness is a dominant feature of carbon nanotubes in composites. Wavy nanotubes dispersed in a matrix tend to have more contact points than straight nanotubes, and therefore, have a considerable effect on electrical conductivity due to the dominant role of contact resistance. Previous studies have only investigated the effect of waviness on percolation threshold and elastic stiffness of composites.<sup>31–35</sup> The basic conclusion reached in these studies is that the waviness tends to increase the percolation threshold but reduces the elastic stiffness. To date, almost all the computational simulations of the electrical conductivity of nanotube-based composites assumed nanotubes as straight sticks.<sup>34</sup> More recently, Li et al.<sup>36</sup> simulated wavy nanotubes using elongated polygons, and the current carrying backbones of percolation clusters in the composite are identified by a direct electrifying algorithm.<sup>37</sup> The tunneling resistance due to an insulating film of matrix material between crossing nanotubes is considered. Results of Monte Carlo simulations indicate that the electrical conductivity of composites with wavy nanotubes is lower than that of composites with straight nanotubes. In experimental measurements of conductivities, researchers have strived to pursue composite systems with well dispersed fillers. Such an “ideal” system forms a basis for the comparison of conductivity percolation thresholds as influenced by factors such as filler aspect ratio, matrix materials, contact resistance, nanotube waviness, and so forth. The anisotropy of conductivity is strongly affected by nanotube alignment, especially when the nanotube contents are small. But the effect of alignment becomes weaker at larger nanotube contents.<sup>38,39</sup>

In the work reported here, we investigated the film formation behavior and electrical conductivity properties of polymer-CNTs depending on the CNTs content using the photon transmission technique and electrical conductivity measurements. In this work, MWNTs were chosen as conductive fillers rather than single-wall carbon nanotubes (SWNTs) since MWNTs are less expensive than SWNTs and polymer-MWNT composites may be more acceptable than polymer-SWNT composites in industrial application. Furthermore, MWNTs are easier to disperse in the polymer matrix compared to SWNTs. Polystyrene (PS) was used as the polymer matrix because its properties are well-known; it is easy to process, it is soluble in a broad range of solvents, and its

clarity allows dispersion of MWNTs to be optically observed at the micron scale. Films were prepared by mixing PS latex with MWNT particles in various compositions and annealing them at temperatures above the glass transition temperature of PS. After each annealing step, the transmitted light intensity,  $I_{tr}$ , was monitored to observe the film formation process. The increase in  $I_{tr}$  up to the healing temperature,  $T_h$ , and above  $T_h$  during annealing was explained by void closure and interdiffusion processes, respectively. From the measurements of the electrical conductivities of the composites, the percolation threshold of conductivity was found to be 4 wt% MWNT.

## Experimental

### Materials

PS particles were produced via surfactant free emulsion polymerization process. The polymerization was performed batch-wisely using a thermostatted reactor equipped with a condenser, thermocouple, mechanical stirring paddle, and nitrogen inlet. The agitation rate was 400 rpm and the polymerization temperature was controlled at 70 °C. Water (100 mL) and styrene (5 g) were first mixed in the polymerization reactor where the temperature was kept constant (at 70 °C). The potassium peroxydisulfate (KPS) initiator (0.1g), dissolved in small amount of water (2 mL), was then introduced to induce styrene polymerization. The polymerization was conducted during 18 h. The polymer has a high glass transition temperature ( $T_g = 105$  °C). The latex dispersion has an average particle size of 400 nm. Figure 1a shows a scanning electron microscope (SEM) image of the PS latex produced for this study.

Commercially available MWNTs (Cheap Tubes Inc., VT, USA, 10–30  $\mu\text{m}$  long, average inner diameter: 5–10 nm, outer diameter: 20–30 nm, the density is approximately 2.1 g/cm<sup>3</sup>, and purity is higher than 95 wt%) were used as supplied in black powder form without further purification. A stock solution of MWNTs was prepared following the manufacturers regulations: nanotubes were dispersed in de-ionized (DI) water with the aid of polyvinyl pyrrolidone (PVP) in the proportions of 10 parts MWNTs, 1–2 parts PVP, 2,000 parts DI water by bath sonication for 3 h. PVP is a good stabilizing agent for dispersions of carbon nanotubes, enabling preparation of polystyrene composites from dispersions of MWNT in polystyrene solution. Figure 1b shows the transmission electron microscope (TEM) image of MWNTs used in this study (www.cheaptubesinc.com).

### Preparation of PS–MWNT composite films

A 15 g/L solution of polystyrene (PS) in water was prepared separately. The dispersion of MWNTs in water was mixed with the solution of PS yielding the required ratio,  $R$ , of MWNTs in PS latex by using the relation

$$R = \frac{M_{\text{MWNT}}}{M_{\text{PS}} + M_{\text{MWNT}}}$$

where  $M_{\text{PS}}$  and  $M_{\text{MWNT}}$  represent the weight of PS and MWNTs in the mixture, respectively. Eighteen different mixtures were prepared with 0, 0.15, 0.45, 0.8, 1, 1.5, 1.8, 2, 2.5, 3, 4, 5, 8, 10, 13, 15, 18, 20 wt% MWNTs by using this relation. Each mixture was stirred for 1 h followed by

**Fig. 1.** (a) SEM image of PS latex and (b) TEM image of multi-walled nanotubes (MWNTs) (www.cheaptubesinc.com) used in this study.

**Fig. 2.** A schematic illustration of sample position and transmitted light intensity ( $I_{tr}$ ).

sonication for 30 min at room temperature. By placing the same number of drops on glass plates with similar surface areas ( $0.8 \times 2.5 \text{ cm}^2$ ) and allowing the water to evaporate at 60 °C in the oven, dry films were obtained. After drying, samples were separately annealed above the  $T_g$  of PS for 10 min at temperatures ranging from 100 to 270 °C. The temperature was maintained within  $\pm 2$  °C during annealing. After each annealing step, films were removed from the oven and cooled down to room temperature. The thickness of the films was determined from the weight and the density of samples and ranged from 6 to 10  $\mu\text{m}$ .

### Measurements

Photon transmission experiments were carried out using model Carry 100 bio UV–visible (UVV) spectrometer from Varian. The transmittances of the films were detected at

500 nm at which the composite's spectra is almost flat, i.e., at this wavelength polystyrene and carbon nanotubes have no specific absorption. This picture is quite common for the polymeric films studied using the optical transmission technique.<sup>40–42</sup> A glass plate was used as a standard for all UVV experiments. The sample position and the transmitted light intensity,  $I_{tr}$ , are presented in Fig. 2.

Scanning electron microscope (SEM) images were taken using LEO Supra VP35 FESEM.

Electrical conductivity was measured by a two-probe method using a Keithley Model 6517a Electrometer with an ultrahigh resistance meter. For the surface resistance measurements, the samples were coated onto thin rectangular glass slabs with typical dimensions of  $2.0 \times 3.0 \text{ cm}^2$ . The electrical contact was made using a silver paste. Electrical resistivities of the composite films were measured by alternating polarity technique with electrometer and a test fixture. The composite films were placed in the test fixture, which have disk shaped electrodes, then their surface resistivities,  $R_s$  ( $\Omega$ ), were measured for 15 s under 100 V alternating potential. All the resistivities of the composite films were determined for four different orientations and measurements were repeated many times to lower the error level. The surface resistivity was converted into surface conductivity.

## Results and discussion

### Film formation process of PS–MWNT composites

Transmitted light intensities,  $I_{tr}$ , versus annealing temperatures are plotted in Fig. 3 for the films with 0, 1.5, 3, 5, 10, and 15 wt% MWNT content. Upon annealing, the transmitted light intensity,  $I_{tr}$ , started to increase for all film samples except for 15 wt% MWNT content film. The increase in  $I_{tr}$  with annealing can be explained by the evaluation of the transparency of the films and surface smoothing upon annealing. Most probably, the increase in  $I_{tr}$  up to  $T_h$  corresponds to the void closure process,<sup>39,43–46</sup> i.e., the polystyrene starts to flow upon annealing and voids between particles can be filled. On the other hand, the increase in  $I_{tr}$  above  $T_h$  corresponds to the interdiffusion process. However, for 15 wt% MWNT content film,  $I_{tr}$  almost doesn't change with annealing, which means that no film formation process occurs, and light transmission is completely blocked by dispersion of the MWNTs in the composite film. On the other hand,  $I_{tr}$  decreases with increasing MWNT content in films at all annealing temperatures, predicting that less transparency occurs at high MWNT content films. The plots of the maximum values of  $(I_{tr})_{max}$  versus MWNT content in Fig. 4a also confirms this picture, i.e., as the MWNT content is increased,  $(I_{tr})_{max}$  first decreases continuously from 70% to 30% at 4 wt% MWNT, and then shows a slight decrease reaching its minimum value (10%) around 15 wt% MWNT.

To see dispersion of MWNTs in PS lattice during annealing, SEM micrographs of composite film with 15 wt% MWNT content were taken after annealing them at 100 and 150 °C (see Fig. 5), respectively. In Fig. 5a, for the 15 wt% MWNT film annealed at 100 °C no deformation in PS particles is observed and PS particles keep their original spherical shapes. After annealing treatment at 150 °C (Fig. 5b), SEM images show that complete particle coalescence has been achieved. It can be clearly seen that the composite

film consists of a network of bundles and indicates significant porosity, which results in strong scattering. The optical transmission of the films versus MWNT content above 15 wt% MWNT (Fig. 4a) is a good indicator of how finely nanotubes are dispersed in the matrix. This result is consistent with the microstructural analysis.

The increase in  $I_{tr}$  intensity below and above the  $T_h$  point in the 0–10 wt% MWNT range can be explained by void closure and interdiffusion processes, respectively.<sup>47</sup> To understand these phenomena, the following mechanisms and their formulations are proposed.

### Voids closure

Latex deformation and void closure between particles can be induced by shearing stress, which is generated by surface tension of the polymer, i.e., polymer–air interfacial tension. The void closure kinetics can determine the time for optical transparency and latex film formation.<sup>48</sup> To relate the shrinkage of a spherical void of radius  $r$  to the viscosity of the surrounding medium,  $\eta$ , an expression was derived and given by the following relation.<sup>48</sup>

$$[1] \quad \frac{dr}{dt} = -\frac{\gamma}{2\eta} \left( \frac{1}{\rho(r)} \right)$$

where  $\gamma$  is surface energy,  $t$  is time, and  $\rho(r)$  is the relative density. It has to be noted here that surface energy causes a decrease in void size and the term  $\rho(r)$  varies with the microstructural characteristics of the material, such as the number of voids, the initial particle size, and packing. Equation [1] is similar to one that was used to explain the time dependence of the minimum film formation temperature during latex film formation.<sup>49</sup> If the viscosity is constant in time, the integration of eq. [1] gives the relation as

$$[2] \quad t = -\frac{2\eta}{\gamma} \int_{r_0}^r \rho(r) dr$$

where  $r_0$  is the initial void radius at  $t = 0$ .

The dependence of the viscosity of the polymer melt on temperature is affected by the overcoming of the forces of macromolecular interaction, which enables the segments of the polymer chain to jump over from one equilibration position to another. This process happens at temperatures at which free volume becomes large enough and is connected with the overcoming of the potential barrier. The Frenkel–Eyring theory produces the following relation for the temperature dependence of viscosity.<sup>50–52</sup>

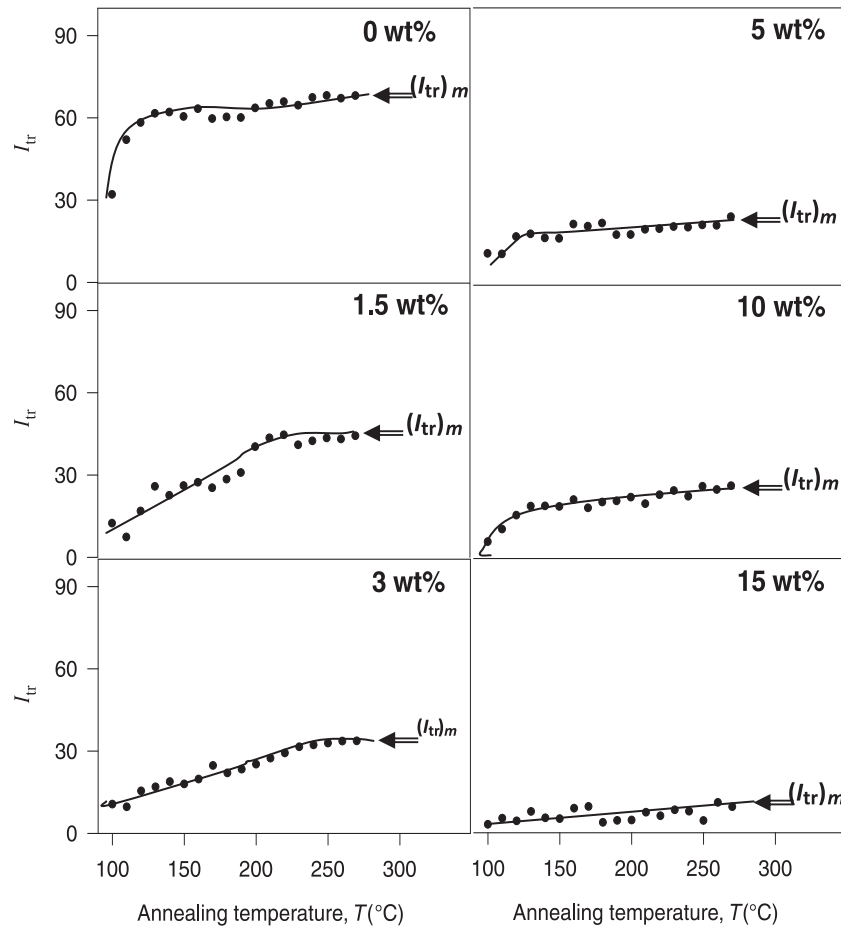

$$[3] \quad \eta = (N_0 h / V) \exp(\Delta G / kT)$$

where  $N_0$  is Avagadro's number,  $h$  is Planck's constant,  $V$  is the molar volume, and  $k$  is Boltzmann's constant. It is known that  $\Delta G = \Delta H - T\Delta S$ , then eq. [3] can be written as

$$[4] \quad \eta = A \exp(\Delta H / kT)$$

where  $\Delta H$  is the activation energy of viscous flow, i.e., the amount of heat that must be given to 1 mol of material for creating the act of a jump during viscous flow.  $\Delta S$  is the entropy of activation of viscous flow. Here,  $A$  represents a constant for the related parameters that do not depend on

**Fig. 3.** Plots of transmitted photon intensities,  $I_{tr}$ , vs. annealing temperatures depending on MWNT content in the films. The numbers on each figure show the MWNT content in the film.

temperature. Combining eq. [2] and [4] the following useful equation is obtained

$$[5] \quad t = -\frac{2A}{\gamma} \exp\left(\frac{\Delta H}{kT}\right) \int_{r_0}^r \rho(r) dr$$

To quantify the above results, eq. [5] can be employed by assuming that the interparticle voids are equal in size and the number of voids stay constant during film formation (i.e.,  $\rho(r) \propto r^{-3}$ ), then integration of eq. [5] gives the relation

$$[6] \quad t = \frac{2AC}{\gamma} \exp\left(\frac{\Delta H}{kT}\right) \left(\frac{1}{r^2} - \frac{1}{r_0^2}\right)$$

where  $C$  is a constant related to the relative density,  $\rho(r)$ .

To quantify the behavior of  $I_{tr}$  curves below  $T_h$  presented in Fig. 3, the void closure model can be applied, where a decrease in void size ( $r$ ) causes an increase in  $I_{tr}/(I_{tr})_{\max}$  ratios and vice versa. If the assumption is made that the  $I_{tr}/(I_{tr})_{\max}$  ratio is inversely proportional to the 6th power of the void radius,  $r$ , then eq. [6] can be written as

$$[7] \quad t = \frac{2AC}{\gamma} \exp\left(\frac{\Delta H}{kT}\right) \left(\frac{I_{tr}}{(I_{tr})_{\max}}\right)^{1/3}$$

Here,  $r_0^{-2}$  is omitted from the relation since it is very

small compared to  $r^{-2}$  values after a void closure process is started. Equation [7] can be solved for  $I_{tr}/(I_{tr})_{\max}$

$$[8] \quad I_{tr}(T) = S(t) \exp\left(\frac{-3\Delta H}{kT}\right)$$

where  $S(t) = (\gamma t / 2AC)^3$  and  $I_{tr} = I_{tr}/(I_{tr})_{\max}$ . For a given time the logarithmic form of eq. [8] can be written as follows

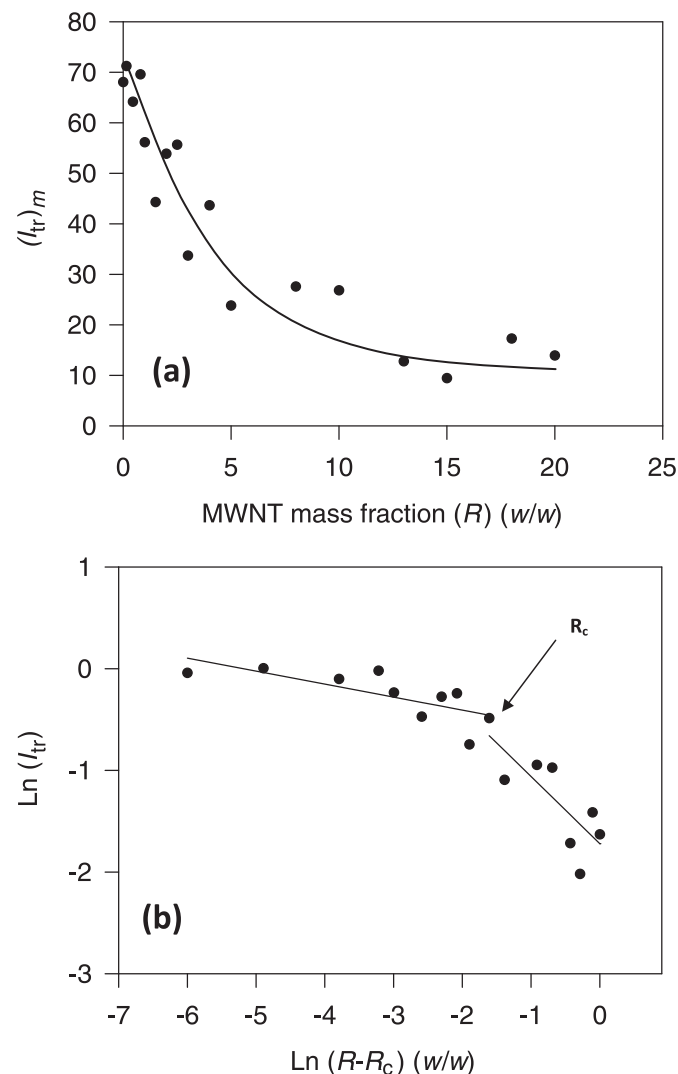

$$[9] \quad \ln I_{tr}(T) = \ln S(t) - \left(\frac{3\Delta H}{k_B T}\right)$$

Equation [9] can now be used to produce viscous flow activation energies,  $\Delta H$ .  $\ln I_{tr}$  versus  $T^{-1}$  plots and their fits to eq. [9] are presented in Fig. 6 (right hand side of the curves) from which  $\Delta H$  activation energies were obtained. The measured void closure,  $\Delta H$  activation energies are listed in Table 1, which are present at a minima around 4 wt%.

### Healing and interdiffusion

The decrease in  $I_{tr}$  was already explained in the previous section, by the increase in transparency of latex film due to the disappearance of deformed particle-particle interfaces. As the annealing temperature is increased above healing temperature,  $T_h$ , some part of the polymer chain may cross the junction surface and particle boundaries start to disappear, as a result,  $I_{tr}$  increases due to the shorter optical and

**Fig. 4.** (a) A plot of the maxima of transmitted light intensities,  $(I_{tr})_{max}$ , in Fig. 3 vs. MWNT content,  $R$  (w/w); (b) log-log plot of  $(I_{tr})_{max}$  vs.  $(R - R_c)$ .

long mean free paths of a photon.<sup>43–47</sup> To quantify these results, the Prager–Tirrell (PT) model<sup>53</sup> for the chain crossing density can be employed. These authors used de Gennes’s<sup>54</sup> “reptation” model to explain configurational relaxation at the polymer–polymer junction where each polymer chain is considered to be confined to a tube in which it executes a random back and forth motion. A homopolymer chain with  $N$  freely jointed segments of length  $L$  was considered by PT, which moves back and forth by one segment with a frequency,  $\nu$ . In time, the chain displaces down the tube by a number of segments,  $m$ . Here,  $\nu/2$  is called the “diffusion coefficient” of  $m$  in one-dimensional motion. PT calculated the probability of the net displacement with  $m$  during time  $t$  in the range of  $n - \Delta$  to  $n - (\Delta + d\Delta)$  segments. A Gaussian probability density was obtained for small times and large  $N$ . The total “crossing density”,  $\sigma(t)$  (chains per unit area), at the junction surface was then calculated from the contributions of  $\sigma_1(t)$  due to chains still retaining some portion of their initial tubes, plus a remainder,  $\sigma_2(t)$ . Here, the  $\sigma_2(t)$  contribution comes from chains that have relaxed at least

**Fig. 5.** SEM images of composite films prepared with 15% MWNT content and annealed for 10 min at (a) 100 and (b) 150 °C temperatures.

once. In terms of reduced time,  $\tau = 2\nu t/N^2$ , the total crossing density can be written as

$$[10] \quad \sigma(\tau)/\sigma(\infty) = 2\pi^{-1/2} \left\{ \tau^{1/2} + 2 \sum_{k=0}^{\infty} (-1)^k [\tau^{1/2} \exp(-k^2/\tau) - \pi^{-1/2} \operatorname{erfc}(k/\tau^{1/2})] \right\}$$

For small  $\tau$  values the summation term of the above equation is very small and can be neglected, which then results in

$$[11] \quad \sigma(\tau)/\sigma(\infty) = 2\pi^{-1/2} \tau^{1/2}$$

This was predicted by de Gennes<sup>54</sup> on the basis of scaling arguments. Here, it should be mentioned that the dependence on time,  $t$ , in eq. [10] goes as  $t^{1/4}$  at early times of healing.<sup>54,55</sup> To compare our results with the crossing density of the PT model, the temperature dependence of  $\sigma(\tau)/\sigma(\infty)$  can be modeled by taking into account the following Arrhenius relation for the linear diffusion coefficient

$$[12] \quad \nu = \nu_0 \exp(-\Delta E_b/kT)$$

Here,  $\Delta E_b$  is defined as the activation energy for backbone motion depending on the temperature interval. Combining eqs. [11] and [12], a useful relation is obtained as

**Fig. 6.** The  $\ln(I_{tr})$  vs.  $T^{-1}$  plots of the data in Fig. 3. The slope of the straight lines produces  $\Delta H$  and  $\Delta E$  activation energies, which are listed in Table 1.

**Table 1.** Experimentally determined activation energy values.

MWNT (wt%)	0	1.5	2	3	4	5	10	15
$\Delta H$ (kcal/mol)	2.1	3.0	1.1	1.8	0.8	2.2	3.7	—
$\Delta E$ (kcal/mol)	0.7	4.6	8.6	4.6	5.5	1.4	2.1	—

$$[13] \quad \sigma(\tau)/\sigma(\infty) = A_0 \exp(-\Delta E_b/2kT)$$

where  $A_0 = (8\nu_0 t/\pi N^2)^{1/2}$  is a temperature independent coefficient.

The increase in  $I_{tr}$  above  $T_h$  is already related to the disappearance of particle–particle interfaces, i.e., as annealing temperature is increased, more chains relax across the junction surface and as a result the crossing density increases. Now, it can be assumed that  $I_{tr}$  is proportional to the crossing density,  $\sigma(\tau)$ , in eq. [13] and then the phenomenological equation can be written as

$$[14] \quad I_{tr}(T)/I_{tr}(\infty) = A \exp(-\Delta E/2kT)$$

Logarithmic plots of  $I_{tr}$  versus  $T^{-1}$  are presented in Fig. 6 (left hand side of the curves) for various MWCNT content. The activation energies,  $\Delta E$ , are produced by least-squares fitting the data to eq. [14] and are listed in Table 1, where it is seen that  $\Delta E$  values present a maximum around 3 wt% MWNT content, while  $\Delta H$  values have a minimum about the same point. In other words, the interdiffusion of polymer chains needs more energy to cross over the junction surface than the amount of heat that was required by 1 mol of polymeric material to accomplish a jump during viscous flow. In

fact, these optimum points correspond to the percolation threshold for the electrical conductivity and for the optical transparency in composite film (see the next section).

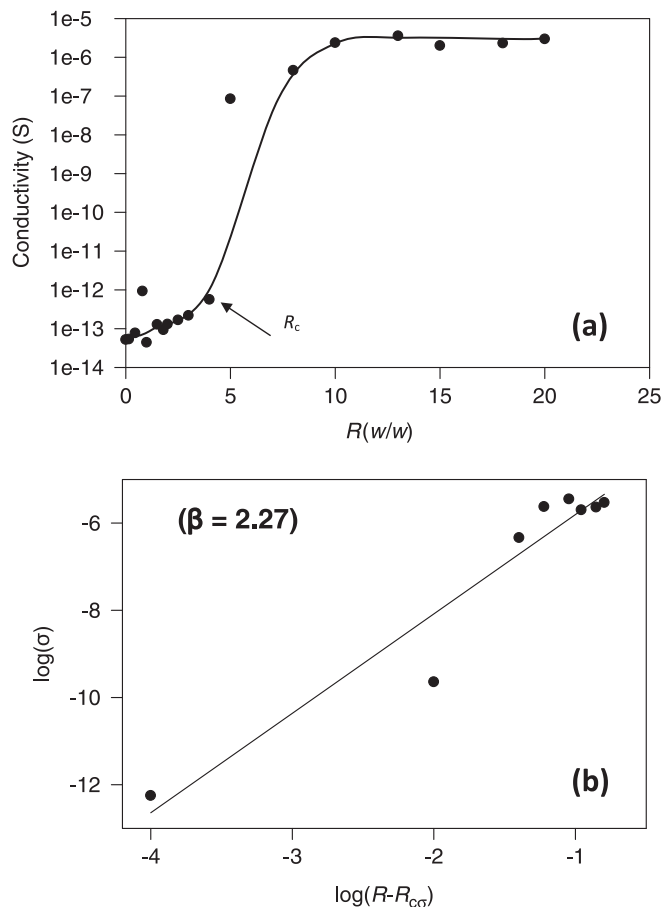

### Electrical conductivity of PS–MWNT composites

The surface conductivity properties of the films were measured at room temperature by using a two probe technique. Figure 7a shows the electrical conductivity ( $\sigma$ ) of PS–MWNT composite films and its best fit as a function of the MWNTs ratio,  $R$ . While low MWNT content composites ( $R < 0.04$ ) show similar conductivity between  $10^{-13}$ – $10^{-12}$  S, the conductivity of high MWNT content films ( $R > 0.04$ ) increase dramatically to  $\sim 10^{-7}$ – $10^{-6}$  S. In other words, above 0.04 MWNTs form an interconnected percolative network. However, below 0.04, clusters of MWNT become separated by the polystyrene layers. From here we could conclude that the electrical conductivity of the films exhibited a type of percolation<sup>56</sup> behavior since below a certain amount of MWNT, called the percolation threshold,  $R_{c\sigma}$  ( $= 0.04$ ), the conductivity exhibited only a very little change ( $10^{-13}$ – $10^{-12}$  S). While for a further increase of MWNTs to above  $R_{c\sigma} = 0.04$ , the conductivity shows a drastic increase ca. 6–7 orders of magnitude ( $10^{-7}$ – $10^{-6}$  S), as compared with low MWNTs content films. Zang and co-workers<sup>57,58</sup> found the percolation threshold is about 4 wt% MWNT for the MWNT–PS composites prepared by the polymerization filling method.

### Percolation theory

The basis of the percolation theory is to determine how a

**Fig. 7.** (a) Conductivity,  $\sigma$ , and its best fitted curve vs. MWNT content,  $R$  (w/w); (b) log-log plot of the best fitted curve of  $\sigma$  vs.  $(R - R_c)$ .

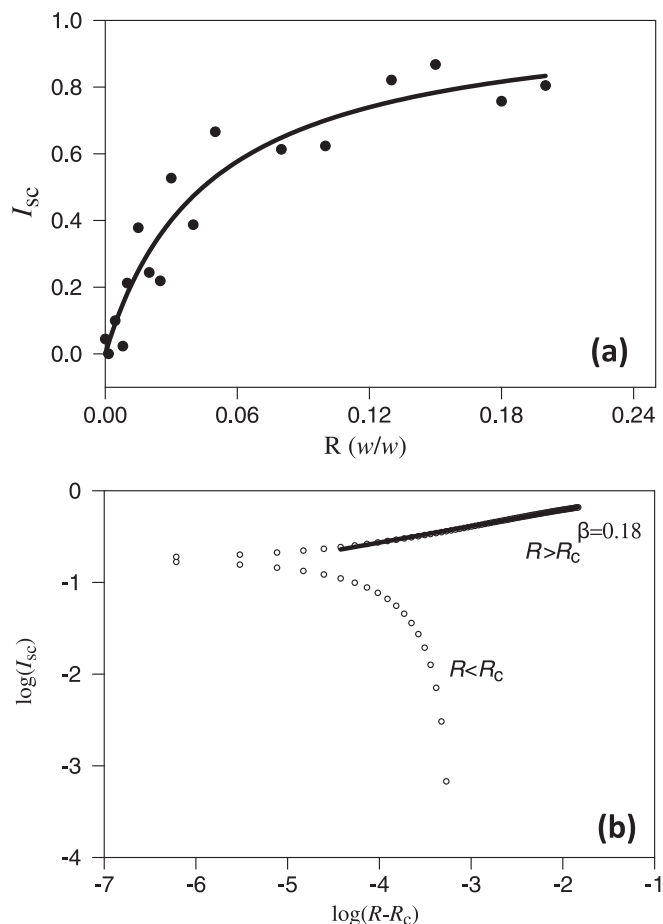

given set of sites, regularly or randomly positioned in some space, is interconnected.<sup>56</sup> At some critical probability, called the “percolation threshold ( $p_c$ )”, a connected network of sites is formed that spans the sample, causing the system to percolate. In 1957, Broadbent and Hammersley,<sup>59</sup> introduced the term “percolation theory” and used a geometrical and statistical approach to solve the problem of fluid flow through a static medium. Initial work focused on the determination of the percolation thresholds in simple two- and three-dimensional geometries. Two types of percolation were considered: site percolation, where sites in a lattice are either filled or empty, or bond percolation, where all the sites in a lattice are occupied, but are either connected or not.<sup>60</sup> Extensive simulations and theoretical work have shown that the percolation probability,  $P_\infty(p)$  vanishes as a power-law near  $p_c$ :

$$[15] \quad p_\infty(p) \approx (p - p_c)^\beta$$

For all volume fractions  $p > p_c$ , the probability of finding a spanning cluster extending from one side of the system to the other side is 1. The largest cluster spans the lattice connecting the left and right edges to the bottom edge, which is called “percolating cluster”. Whereas for all volume fractions  $p < p_c$ , the probability of finding such an infinite cluster is 0.

**Fig. 8.** (a) Scattering light intensity,  $I_{sc}$ , and its best fitted curve vs. MWNT content,  $R$  (w/w); (b) log-log plot of the best fitted curve of  $I_{sc}$  versus  $(R - R_c)$ .

The concept of percolation has been applied to many diverse applications, including the spread of disease in a population, flow through a porous medium, quarks in nuclear matter, and variable range hopping in amorphous semiconductors.<sup>61</sup> Percolation theory has been used to interpret the behaviour in a mixture of conducting and nonconducting components.<sup>62</sup> The sudden transition in such materials from insulator to conductor is evidence of a percolation threshold. The conductivity,  $\sigma$ , of a percolative system is generally described as a function of the mass fraction,  $R$ , by the scaling law in the vicinity of the percolation threshold ( $R_{c\sigma}$ ):

$$[16] \quad \sigma = \sigma_0(R - R_{c\sigma})^{\beta_\sigma}$$

where  $\sigma$  is the composite conductivity (in Siemens),  $\sigma_0$  is the self conductivity of MWNTs film and is equal to 1.  $R$  represents the weight fraction of MWNTs,  $R_{c\sigma}$  represents the percolation threshold of conductivity, and  $\beta_\sigma$  is the critical exponent. This equation is valid at concentrations above the percolation threshold, i.e., when  $R > R_{c\sigma}$ . The value of the critical exponents,  $\beta_\sigma$ , is dependent on the dimensions of the lattice.<sup>59</sup>

To calculate the percolation threshold, eq. [16] was transformed into the logarithmic form:

$$[17] \quad \log(\sigma) = \log(\sigma_0) + \beta_\sigma \log|R - R_c|$$

Then to produce an estimated value for  $R_{c\sigma}$  and the critical exponent  $\beta_\sigma$  we fitted the  $\log(\sigma) - \log|R - R_c|$  data in Fig. 7b for  $R > R_{c\sigma}$  to eq. [17]. Here, due to the limitation on getting more data in critical region, we used the continuous function fitted best to the experimental points in Fig. 7a. The goodness of the fit was around  $r^2 \approx 0.9$ . The value of  $\beta_\sigma$  has been determined from the slope of the linear relation of  $\log(\sigma) - \log|R - R_c|$  plot of the best fitted curve in Fig. 7b and found to be 2.27. This value agrees well with the universal scaling value of  $\beta_\sigma = 2.0$ . The difference between the theoretical and experimental values (13.5%) might be explained with the errors originating from the fitting. In three-dimensional lattice systems<sup>60</sup>  $\beta_\sigma$  values change from 1.3 to 3. The fact that  $\beta_\sigma$  is not significantly greater than 2.0 also suggests that the bundles are not separated by polymer tunneling barriers and shows that the polymer coating observed in Fig. 5 cannot simply coat individual bundles but must coat the network as a whole, allowing intimate contact between bundles at junction sites.

On the other hand, as seen in Fig. 4a, the inclusion of MWNTs into the PS lattice strongly decreases the transmitted light intensity. This finding can be rationalized by first assuming that  $\sigma$  is proportional to the scattered light intensity,  $I_{sc} = 1 - (I_{tr})_{max}$ , by obeying the following relation

$$[18] \quad I_{sc}(R) = (R - R_c)^\beta$$

Here, it should be realized that inclusions of MWNTs into the PS lattice creates a two phase heterogeneous structure, which causes light scattering from the composite film surface, while the conductivity increases in the same fashion. Equation [18] describes the percolation model for MWNTs distribution in the PS lattice where  $R_c$  was produced in Fig. 4b from the intersection of two broken straight lines. When  $R$  approaches  $R_c$ , the largest cluster of MWNTs appears by connecting the left and right edges to the bottom edge of the MWNTs.

The scattered light intensity,  $I_{sc}$ , versus MWNTs content and its best fit are plotted in Fig. 8a, where it is seen that  $I_{sc}$  has increased to large values for all samples above 4 wt% MWNT content. This behavior of scattering light intensity can be explained by percolating MWNT particles in the PS lattice. In Fig. 8b, the log-log plot of eq. [18] is fitted to the data in Fig. 8a, where the slope of the straight line produced the critical exponent,  $\beta = 0.18$ , above  $R_c = 0.04$ , which is not so far from the bond-percolation theory. In a simple cubic lattice  $\beta$  is found to be 0.25 for the bond percolation model.<sup>56</sup>

## Conclusions

We have reported an investigation of the film formation and electrical conductivity of PS-MWNT composites. Below 10 wt% MWNT content, two distinct film formation stages, which are named as void closure and interdiffusion, were observed. However, MWNT concentrations above 10 wt% MWNT, no film formation can be achieved. On the other hand, sample conductivities were observed to depend strongly on the MWNT contents, which are drastically changed with an increase of the MWNT content above the percolation threshold of 4 wt% MWNT. With the introduction of 4 wt% MWNTs, the conductivity presented an in-

crease by 6–7 orders of magnitude compared with low MWNT content films.

Void closure ( $\Delta H$ ) and interdiffusion ( $\Delta E$ ) activation energies presented optimum values around the threshold of the electrical conductivity and optical transparency percolation around 4 wt% MWNT content. Our results are quite similar to other reports on low conductance with CNTs amounts and start to saturate at higher CNTs content. Further investigation of electrical properties of the composite films is underway in our laboratory to understand the behaviors of ( $\Delta H$ ) and ( $\Delta E$ ) activation energies around the percolation point.

# Biomaterials for neural-tissue engineering — Chitosan supports the survival, migration, and differentiation of adult-derived neural stem and progenitor cells

Vanessa I. Scanga, Alex Goraltchouk, Nasser Nussaiba, Molly S. Shoichet, and Cindi M. Morshead

**Abstract:** Neural precursor cells (NPCs or stem and progenitor cells) are promising in transplantation strategies to treat an injury to the central nervous system, such as a spinal cord injury (SCI), because of their ability to differentiate into neurons and glia. Transplantation studies to date have met with limited success for a number of reasons, including poor cell survival. One way to encourage cell survival in injured tissue is to provide the cells with a scaffold to enhance their survival, their integration, and potentially their differentiation into appropriate cell types. Towards this end, four amine-functionalized hydrogels were screened in vitro for adult murine NPC viability, migration, and differentiation: chitosan, poly(oligoethylene oxide dimethacrylate-co-2-amino ethyl methacrylate), blends of poly(oligoethylene oxide dimethacrylate-co-2-amino ethyl methacrylate), and poly(vinyl alcohol), and poly(glycerol dimethacrylate-co-2-amino ethyl methacrylate). The greatest cell viability was found on chitosan at all times examined. Chitosan had the greatest surface amine content and the lowest equilibrium water content, which likely contributed to the greater NPC viability observed over three weeks in culture. Only chitosan supported survival of multipotent stem cells and the differentiation of the progenitors into neurons, astrocytes, and oligodendrocytes. Plating intact NPC colonies revealed greater cell migration on chitosan relative to the other hydrogels. Importantly, long term cultures on chitosan showed no significant difference in total cell counts over time, suggesting no net cell growth. Together, these findings reveal chitosan as a promising material for the delivery of adult NPC cell-based therapies.

**Key words:** biomaterials, chitosan, hydrogels, stem cells, cell viability.

**Résumé :** Les cellules neurales précurseurs (CNP, cellules souches et progéniteurs) sont très prometteuses dans les stratégies de transplantation pour le traitement de blessures au système nerveux central, tel un traumatisme au cordon médullaire (TCM), en raison de leur habilité à différencier les neurones des cellules gliales. Jusqu'à maintenant, les études de transplantation n'ont eu que des succès mitigés en raison de divers facteurs, dont le faible taux de survie des cellules. Une façon d'augmenter ce taux de survie dans les tissus traumatisés est de fournir des cellules comportant un échafaudage permettant d'augmenter leur survie, leur intégration et éventuellement leur différenciation dans les divers types de cellules. À cette fin, quatre hydrogels portant des amines fonctionnalisées, le chitosane, le poly(diméthacrylate de l'oxyde d'oligoéthylène-co-2-aminométhacrylate d'éthyle), des mélanges de poly(diméthacrylate de l'oxyde d'oligoéthylène-co-2-aminométhacrylate d'éthyle) et d'alcool polyvinylique et du poly(diméthacrylate de glycérol-co-2-aminométhacrylate d'éthyle) ont été soumis à une évaluation in vitro, pour la migration, la différenciation et viabilité de cellules neurales précurseurs de murine adulte. Dans tous les cas, la viabilité la plus grande des cellules a été observée avec le chitosane. Le chitosane comporte le degré le plus élevé d'amine de surface et la quantité la plus faible d'eau en équilibre, ce qui a vraisemblablement contribué à la plus grande viabilité des cellules observée au cours de trois semaines en culture. Seul le chitosane a soutenu la survie de cellules souches multipotentes et la différenciation des progéniteurs en neurones, astrocytes et oligodendrocytes. Le plaqage de colonies intactes de NPC a révélé une migration plus grande sur le chitosane par rapport aux autres hydrogels. Importamment, les cultures à long terme sur le chitosane n'ont montré aucune différence significative dans les dénombrements de cellules au cours du temps, suggérant une croissance nette nulle. Ensemble, ces constatations révèlent le chitosane comme un matériau prometteur pour la délivrance de thérapies à base de cellules NPC adultes.

ment contribué à la plus grande viabilité des cellules neurales précurseurs sur une période de trois semaines dans les cultures. Seul le chitosane permet de supporter la survie de cellules souches à plusieurs composantes et de différencier les progéniteurs en neurones, astrocytes et oligodendrocytes. L'examen de plaques de colonies intactes de cellules neurales précurseurs met en évidence que la migration de ces cellules sur le chitosane est beaucoup plus rapide que sur les autres hydrogels. Les cultures à long terme sur le chitosane ne présentent pas de différences significatives dans les comptages totaux de cellules en fonction du temps; cette observation est importante puisqu'elle suggère qu'il ne supporte aucune croissance nette de cellules. Toutes ces observations mettent en évidence le fait que le chitosane est un matériau plein de promesses pour conduire à des thérapies basées sur les cellules neurales précurseurs adultes.

*Mots-clés* : biomatériaux, chitosane, hydrogels, cellules souches, viabilité des cellules.

## Introduction

Traumatic injury to the adult mammalian spinal cord causes irrevocable damage, producing an environment that inhibits regrowth of damaged axons.<sup>1–4</sup> The initial damage to the cord is compounded by a prolonged secondary cascade of injury including the disappearance of growth-promoting cues, the appearance of growth-inhibiting factors, apoptosis, and the formation of a glial scar. This series of post-injury cascades leads to the formation of a cystic cavity, axonal degeneration, and ultimately an inability of the adult cord to self-repair.<sup>5,6</sup> Regeneration of severed central-nervous-system (CNS) axons has been reported for both cellular bridges<sup>7–9</sup> and biomaterial implants;<sup>10–13</sup> however, functional recovery from these single application treatments has been limited. The complicated pathophysiology resulting from spinal cord injury (SCI) likely necessitates a combination strategy to promote axonal repair and regeneration. Neurons, astrocytes, and oligodendrocytes comprise the primary cell types of the CNS and because these cells die at the site of injury after SCI, cell replacement therapies will undoubtedly be key to combination strategies aimed at repairing the damaged spinal cord.

The therapeutic potential of CNS stem cells has received considerable attention.<sup>14–27</sup> The observation that stem-cell populations can be isolated from along the developing and adult neuroaxis<sup>28,29</sup> has led to the development of a number of cell-based therapies to treat SCI. In the context of developing regenerative-medicine strategies, the use of adult-derived populations is a significant step forward as it affords an approach that is independent of ethical concerns. Adult neural stem cells are maintained throughout the life of the animal in both the brain and spinal cord and have the capacity to self-renew and differentiate into astrocytes, oligodendrocytes, and neurons.<sup>28,30–33</sup> Neural stem cells can be isolated and propagated in vitro using a well-described colony-forming assay whereby individual stem cells proliferate in the presence of epidermal growth factor (EGF) and (or) fibroblast growth factor (FGF2) to form free-floating colonies of cells termed “neurospheres”. Individual neurospheres can be dissociated into single cells and replated in the presence of these growth factors to form new neurospheres thereby resulting in an expansion of neural stem-cell-derived cell populations, and demonstrating the cardinal stem cell property of self-renewal. Individual neurospheres are comprised of a mixed population of stem and progenitor cells<sup>31</sup> and are referred to collectively as neural precursor cells (NPCs). Upon exposure to differentiation conditions,

neurosphere-derived cells can differentiate into all of the neural phenotypes comprising the CNS (neurons, astrocytes, and oligodendrocytes), thereby illustrating their multipotentiality. The ability to proliferate and differentiate into CNS-specific cell types makes NPCs promising candidates for cell replacement strategies to replace cells lost after CNS injury.

The extracellular matrix during development influences cell adhesion, growth, differentiation, and motility<sup>34</sup> while at the same time contributing to tissue strength.<sup>35</sup> The regenerative ability in the damaged adult CNS is limited in large part due to the release of inhibitory matrix proteins and a breakdown in the structural scaffolding provided by the extracellular matrix to neurons, astrocytes, and oligodendrocytes.<sup>36,37</sup> Accordingly, bridging strategies provide attractive models of repair following damage to the nervous system and have included the use of nerve guides,<sup>38,39</sup> hydrogel scaffolds,<sup>40</sup> and tissue and cell transplants such as fetal tissue, Schwann cells, olfactory ensheathing glia, neural stem cells, and progenitor cells<sup>27,41–45</sup> as well as macrophages.<sup>46</sup> The partnership of some of these bridging strategies with the administration of neurotrophic<sup>47–49</sup> or survival<sup>50–53</sup> factors have clearly demonstrated the powerful effects of combination therapy in the treatment of this debilitating injury. However, these studies have shown only modest functional improvement. The extent of intrinsic cell renewal following the local delivery of mitogenic agents such as EGF and FGF2 to stimulate endogenous precursor cells<sup>47</sup> has also been insufficient in promoting significant recovery following SCI. Additionally, the poor survival rate of cells transplanted directly into the site of injury following SCI<sup>54</sup> reflects the need to provide a better environment for cell survival. Work by Karimi-Abdolrezaee et al.<sup>14</sup> has shown that combining NPC transplantation and the delivery of growth factors via an osmotic mini-pump leads to a dramatic increase in cell survival and differentiation and, moreover, leads to measurable functional recovery. Hence, we propose that a nerve guidance channel that is biodegradable, biocompatible, supportive of NPC survival and differentiation, and amenable to the incorporation of a drug delivery system will promote axon regeneration following SCI. Towards this end, we set out to identify the microenvironment, and specifically the matrix material, that met the specific criteria of NPC viability, migration, and differentiation.

Four polymeric biomaterials were screened using neurosphere-derived NPCs isolated from the forebrain of adult mice. These biomaterials were required to be biode-

gradable, amine-functionalized (to promote cell adhesion), non-cytotoxic, and capable of being processed into a nerve guidance channel. The following biomaterials were compared in terms of NPC viability, cell migration, and differentiation: (i) chitosan, a naturally-derived polysaccharide; (ii) poly(oligoethylene oxide dimethacrylate-*co*-2-amino ethyl methacrylate), P(PEG-*co*-AEMA); (iii) blends of P(PEG-*co*-AEMA) and poly(vinyl alcohol) (PVA), P(PEG-*co*-AEMA)-PVA; and (iv) poly(glycerol dimethacrylate-*co*-2-amino ethyl methacrylate), P(GDMA-*co*-AEMA). Chitosan was studied because it has already demonstrated some promise in neural-tissue engineering<sup>55</sup> and PEG-AEMA based polymers were synthesized with the understanding that PEG would be biocompatible<sup>56</sup> while AEMA would provide amine functional groups for enhanced cell adhesion.

## Materials and methods

### Materials

All reagents were purchased from Sigma-Aldrich and used as received unless otherwise stated. Poly(ethylene glycol) dimethacrylate (PEGDMA, molecular weight: 400 Da) and poly(vinyl alcohol) (PVA, molecular weight: 6000 Da, hydrolyzed to 80%) were purchased from PolySciences Inc. (Warrington, PA, USA). The MicroBCA Protein Assay Kit was purchased from Pierce (Rockford, IL, USA). Deionized water was obtained from Milli-RO 10 Plus and Milli-Q UF Plus (Bedford, MA, USA) and used at 18 M $\Omega$  resistance.

### Preparation of chitosan films

Deacetylated chitosan films were prepared from chitosan (NovaMatrix, Norway,  $M_w$ : approximately 150 000–400 000 g/mol) by two successive alkaline hydrolysis steps with 40 wt% NaOH solution at 100 °C for 1 h. The hydrolyzed flakes were washed to neutrality with water and lyophilized using the Thermo Savant ModulyoD freeze dryer at –50 °C and 1.5 mbar pressure. Following lyophilization, 5 g of deacetylated chitosan flakes were added to 166.7 mL of 2 wt% acetic acid in water solution (2/3 working solution). A stock neutralization solution was prepared by mixing 30 mL of ammonia with 70 mL of water and 900 mL of ethanol. Five to six g of the chitosan working solution was poured into a 10 cm Petri dish and allowed to stand uncovered for 24 h. The air-dried films were then washed twice with 20 mL of neutralization solution for 1 h each time. The neutralized films were then washed with PBS and allowed to dry overnight (Fig. 1A).

### Synthesis of PEGDMA-*co*-AEMA films

One g of PEGDMA was added to 20 mL of water in a 30 mL vial. The solution was vortexed and 20  $\mu$ L of concentrated phosphoric acid was added to keep the pH below 4.0. One gram of 2-amino ethyl methacrylate (AEMA) was added to the solution and allowed to completely dissolve. Stock solutions of 10 wt% ammonium persulfate (APS) and 10 wt% sodium metabisulfite (SMBS) in water were prepared. After complete dissolution of the monomers, 100  $\mu$ L of each of the APS and SMBS stock solutions were added, and the solution was vortexed and transferred to a 10 cm Petri dish for polymerization at 37 °C for 24 h (Fig. 1B).

**Fig. 1.** Four amine-functionalized polymer films were synthesized to assay neural precursor cell - matrix interaction: (A) chitosan, (B) poly(oligoethylene oxide dimethacrylate-*co*-2-amino ethyl methacrylate [P(PEGDMA-*co*-AEMA)], (C) physically blended poly(vinyl alcohol) and P(PEGDMA-*co*-AEMA) [P(PEGDMA-*co*-AEMA)-PVA], and (D) poly(glycerol dimethacrylate-*co*-2-amino ethyl methacrylate) [P(GDMA-*co*-AEMA)].

The disks were washed 3 times with PBS for 1 h each time and then washed in PBS overnight prior to use. We did not expect any adverse response due to residual APS-SMBS based on previously published results.<sup>55</sup>

### Synthesis of PEGDMA-*co*-AEMA-blend-PVA films

The identical method as described for the synthesis of PEGDMA-*co*-AEMA films was followed with the dissolution of the PEGDMA in 20 mL of a 5 wt% solution of PVA (6000 Da) in water instead of water alone in the first step (Fig. 1C).

### Preparation of GDMA-*co*-AEMA films

One g of glycerol dimethacrylate (GDMA) and 20  $\mu$ L of concentrated phosphoric acid were dissolved in a 1:1 (v/v) mixture of water and acetone. After the pH was lowered to pH < 4.0, to minimize rearrangement of the AEMA monomer via the acyl migration mechanism, 1 g of AEMA was added to the solution. Upon complete dissolution of all the monomers, 100  $\mu$ L of the APS and SMBS stock solutions were added, and the solution was vortexed and transferred to a 10 cm glass Petri dish covered with a glass slide. The dish with the polymerizing mixture was placed in an oven at 83 °C for 40 min. Soon after gelation, but prior to the

change in turbidity, the films were cooled to room temperature and 10 mL of water added (Fig. 1D).

### Analysis of polymer films

Polymer films were analyzed for equilibrium water content (EWC) according to eq. [1].

$$[1] \quad EWC = \frac{m_w - m_d}{m_d}$$

Wet mass ( $m_w$ ) was measured after allowing 5 mm disks of each material to swell in water for 2 weeks. Dry mass ( $m_d$ ) was measured after freeze-drying. The surface chemical composition was analyzed by X-ray photoelectron spectroscopy (XPS) in survey mode and for specific elements (C, N, O) using the Mg K $\alpha$  X-ray photoelectron spectrometer [Leybold (SPECS) Max 200].

### Isolation and culturing neural precursor cells

Neural precursor cells (NPCs) were isolated from the subependyma lining the lateral ventricles in the forebrain of adult CD1 mice (Charles River) as previously described.<sup>57</sup> Bulk cultures were maintained at clonal densities (10 cell/ $\mu$ L) in 1% penicillin–streptomycin serum-free medium (P/S-SFM) supplemented with EGF (20 ng/mL), FGF2 (10 ng/mL), and heparin (7.32 ng/mL) according to Tropepe et al. All supplements were purchased from Sigma-Aldrich (Oakville, ON, CA). The cultures were passaged weekly<sup>57</sup> to a maximum of three weeks.

### NPC plating and immunocytochemistry

Prior to cell plating, the polymer biomaterial films (8.6 mm<sup>2</sup>) were disinfected with 100% ethanol for 5 min, followed immediately by three serial washes in standard phosphate-buffered saline. The films were placed at 37 °C for 2–3 h prior to cell plating. Cell populations were plated at a density of  $3 \times 10^4$  single cells/film by slowly pipetting cells across the surface of the material. At 24 h, the plates were examined to ensure that there was no clumping of cells over the film surface. Cell migration studies involved plating 10 whole neurospheres onto the surfaces of each of the biomaterials tested and comparing to Matrigel™ controls. Cell counts were conducted in five non-overlapping areas of the polymer films as observed in 10 $\times$  fields of view of each sample area. An in-vitro experimental paradigm was established to analyze the viability of cells within a defined time course. Cell-seeded films were exposed to standard neurosphere-forming media described above followed by the addition of fetal bovine serum (+FBS) on day 2 post-plating to induce differentiation. Cultures were maintained for 2, 7, or 19 days after the addition of FBS and cell-seeded discs were analyzed at 4 (2 days with EFH + 2 days with FBS), 9 (2 + 7), and 21 (2 + 19) days post-seeding. Day-21 samples received new media every 7 days. Sample counts of Hoechst-positive cells were made at 10 $\times$  magnification per field of view. To compare cell counts over time and in the center and periphery of the film surfaces, 50% of the total film area was defined as the center area and 50% defined as the perimeter area. In all cases, 6–10 individual wells containing single material discs ( $n \geq 3$  independent trials) were analysed per group, per trial. In a separate set of experi-

ments, cell viability on chitosan was analysed and compared to Matrigel™ using a PicoGreen assay (Invitrogen) on d0, 2, 4, 9, and 21 post-plating ( $n = 3$  discs/trial from 3 independent trials). NPCs were plated in growth factor conditions for 2 days followed by 1% FBS for an additional 2, 7, or 19 days, similar to the Hoechst counting study described above. Cells were lysed off the films, and along with d0 samples, lysates were stored at –80 °C. Lysates were processed according to the manufacturer's instructions and DNA content was measured using a fluorescent microplate reader (excitation 480 nm, emission 520 nm). The concentration of dsDNA per lysate sample was converted to an estimation of total viable cells (6.05  $\mu$ g DNA / diploid mammalian cell).

To determine whether neural stem cells persisted on chitosan following exposure to differentiation conditions, cells plated on chitosan or Matrigel™ for 9 d were lifted from chitosan surfaces by washing three times with standard PBS followed by a 5 min incubation in 500  $\mu$ L of 0.25% trypsin-EDTA at 37 °C. Each well sample was triturated five times using a fire-polished glass pipette to dislodge the cells from chitosan surfaces. Cells were centrifuged for 5 min at 1500 rpm, and the supernatant was replaced with a 10 mg / 15  $\mu$ L solution of trypsin inhibitor (Roche) followed by centrifugation (5 min at 1500 rpm). The supernatant was replaced with 500  $\mu$ L SFM including EGF, FGF2, and heparin. Cells were replated onto non-adherent 24-well plates and neurosphere formation was assayed 7–9 days later. Recovered neurospheres were dissociated and passaged in standard neurosphere culture conditions and the presence of new neurospheres was assayed after 7 days. Neurosphere-derived cells were plated in 1% fetal bovine serum to examine their differentiation profile using standard immunocytochemistry as described below.

Immunocytochemistry was conducted as reported.<sup>57,58</sup> Briefly, single cells derived from dissociated neurospheres were plated onto the surfaces of biomaterials in 1% P/S-SFM containing FBS in the presence of growth factors following the culture conditions described above. Two, 7, and 19 days after plating the cell-seeded materials were fixed with 4% paraformaldehyde for 20 min. Cells were stained with antibodies to glial fibrillary acidic protein (GFAP, 1:400 rabbit polyclonal, Chemicon), nestin (1:1000 mouse monoclonal, Chemicon),  $\beta$ III tubulin (1:500 mouse monoclonal, Sigma-Aldrich) and O<sub>4</sub> (1:75 mouse monoclonal, Chemicon). Hoechst 33258 (0.725  $\mu$ L/mL, Sigma-Aldrich) was used to visualize the nuclei of plated cells to estimate the total number of cells as described above. To determine the percentages of differentiated cell types, the number of immunolabeled cells was counted and expressed as a percentage of the total number of Hoechst positive cells from 5 nonoverlapping fields of view per well ( $\geq 3$  wells/group/antibody,  $n \geq 3$  independent trials). Appropriate secondary antibodies (FITC or Alexa goat anti-rabbit, goat anti-mouse; FITC, or TRITC (1:200) from Jackson, Alexa (1:400) antibodies from Molecular Probes) were used. Secondary-only controls were prepared in the same manner as cell-plated biomaterials with 10% normal goat serum (Jackson) replacing primary antibodies. Cells were visualized on an Olympus IX70 fluorescent microscope with Olympus Microsuite Software.

### Statistical analysis

Student *t* test was performed for statistical analysis with 95% confidence using Microsoft Excel statistical software.

## Results

### Cell counts are greater on chitosan compared with P(PEGDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA)-PVA blends and P(GDMA-*co*-AEMA)

A key limitation with cell transplantation is the poor rate of cell survival following implantation. For improved therapeutic efficacy following nervous system damage, an increased rate of cell survival is key to success. To determine which of the four biomaterials examined (chitosan, P(PEGDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA)-PVA blend, or P(GDMA-*co*-AEMA)) best supports cell adhesion and viability of neurosphere-derived NPCs, the nuclear marker Hoechst was used to compare cell counts at 4 and 9 d post-plating. Cells showed a relatively even distribution on each material surface at 24 h post-plating; however this changed over time, depending on the material. As shown in Fig. 2A, at 4 d there were significantly more NPCs on chitosan at  $2.33 \pm 0.053 \times 10^3$  (comparable to Matrigel™ at  $2.00 \pm 0.01 \times 10^3$ ) than on the other hydrogel polymers studied, with the fewest number of NPCs found on P(GDMA-*co*-AEMA), followed by P(PEGDMA-*co*-AEMA), and P(PEGDMA-*co*-AEMA)-PVA. The low number of NPCs present on the synthetic polymer surfaces between d4 and d9 reflects either poorly maintained cell adhesion or poor cell survival. The lack of cell survival was further highlighted by the appearance of smaller nuclei,<sup>59</sup> which is indicative of poor cell viability, at both d4 and d9 on P(GDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA), and P(PEGDMA-*co*-AEMA)-PVA (Figs. 2B and 2C). Both chitosan and Matrigel™ controls showed greater total numbers of cells surviving on d9 relative to d4, suggesting proliferation of NPCs between these two time points. This proliferation of NPCs observed on chitosan between d4 and d9 prompted the examination of longer survival times in culture because the continued proliferation of cells would be an undesirable attribute of the cell-material interaction. Cell counts on chitosan and Matrigel™ plated for 4, 9, and 21 d in vitro revealed that by d21 the total number of Hoechst-positive cells was not significantly different from the d4 counts on either matrix ( $p = 0.17$  for d4 compared to d21 on Matrigel™ and  $p = 0.21$  for d4 compared to d21 on chitosan). A PicoGreen assay was also performed at 2, 4, 9, and 21 days post-plating to determine the number of viable cells over time and relative to day 0. The assay employs a fluorochrome that selectively binds double-stranded DNA and can be used to extrapolate the numbers of viable cells per sample. We determined the numbers of viable cells at day 2 (prior to the addition of FBS) as a baseline to reflect the amount of cell death that occurred following initial plating. We observed a decrease in the numbers of cells on both chitosan and Matrigel™ on day 2 (Fig. 2D); however, between d4 and d9, we observed a 1.6- and 1.7-fold increase in the numbers of viable cells on chitosan and Matrigel™, respectively, and similar to what was observed with the Hoechst counts (Fig. 2A). As with the Hoechst analysis, the numbers of viable cells on day 21 was not

significantly different from the numbers present on d4. Overall, these data suggest that chitosan supports greater NPC survival and not uncontrolled cell proliferation. While chitosan and Matrigel™ demonstrated similar cell survival, Matrigel™ is derived from a mouse sarcoma and consists of a multitude of proteins and factors that would not be acceptable for implantation. Moreover, unlike chitosan, Matrigel™ cannot be easily processed into a nerve guidance channel. Taken together, these data suggest that chitosan is the most promising of the materials tested in terms of promoting cell adhesion and survival.

### XPS and EWC analyses

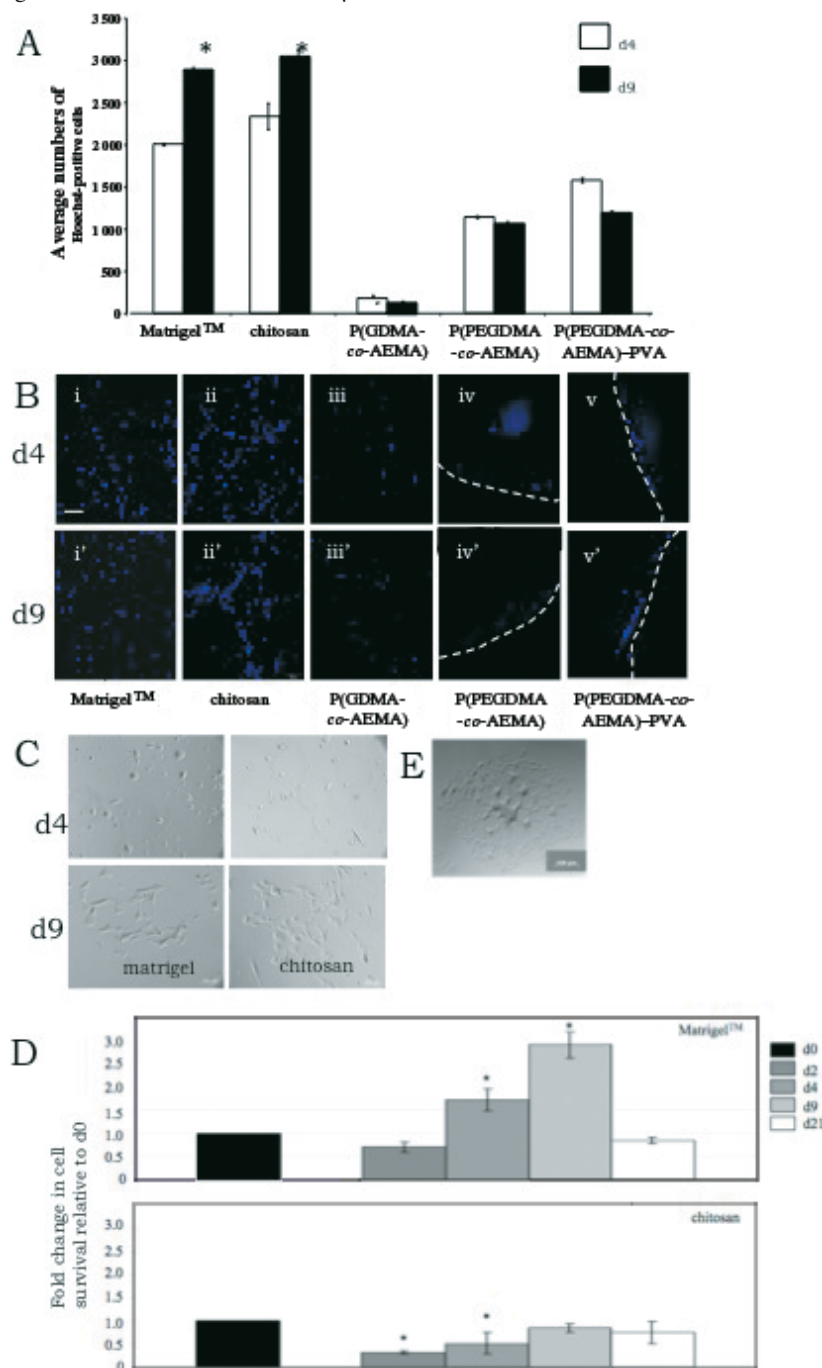

To better understand the NPC-matrix interaction, chitosan, P(GDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA), and P(PEGDMA-*co*-AEMA)-PVA were analyzed by X-ray photoelectron spectroscopy (XPS) for surface composition and bulk equilibrium water content (EWC). As shown in Table 1, of the four biomaterials tested, chitosan had the highest nitrogen content ( $2.75 \pm 0.45$ ) and thus the highest amine surface concentration, reflecting that it is approximately  $99.2 \pm 0.5\%$  deacetylated chitin.<sup>60</sup> Interestingly, chitosan also had the lowest EWC. Our finding that NPC counts are greatest on chitosan is in agreement with Freier et al. who suggested that the higher amine content in chitosan results in increased cell viability relative to films with lower cationic ammonium charge, likely because of non-specific interactions with the negatively charged cell membranes.<sup>60</sup> P(GDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA), and P(PEGDMA-*co*-AEMA)-PVA have significantly greater water content and thus were more hydrophilic than chitosan, reflecting the significant water capacity of PEG and AEMA hydrogels. PEG has been used repeatedly to limit cell adhesion<sup>61</sup> and protein adsorption;<sup>62</sup> thus, despite copolymerization with AEMA to introduce amine functional groups, the high water content likely contributed to the limited cell adhesion and viability observed.

### Neural precursor colony adhesion

Based on the XPS and EWC analysis performed, we hypothesized that a greater initial adhesion of NPCs to the chitosan surface relative to P(GDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA), and P(PEGDMA-*co*-AEMA)-PVA may be a reason for the higher cell counts on chitosan. To test this, we plated 10 intact colonies of NPCs (neurospheres) on each biomaterial surface using identical culture conditions to those used for single cell plating, and examined the number of neurospheres that adhered to each surface at 9 days after cell plating. We observed a greater number of neurospheres adhering to the surface of chitosan relative to the hydrogel polymers (80% on chitosan versus 20%–30% on the other polymers tested). These differences support the hypothesis that the greater amine surface concentration and decreased water content of chitosan, relative to the synthetic hydrogels tested, led to greater cell adhesion and thus greater survival on chitosan.

The plating of whole neurospheres allowed us to look at cell migration on the surfaces of the polymer matrices. A prominent feature of NPCs and their progeny, both in vivo<sup>63–65</sup> and in vitro,<sup>26</sup> is their ability to migrate. We directly tested cell migration on all four biomaterial films

**Fig. 2.** (A) Cell viability was analyzed at d4 and d9 counting Hoechst-positive nuclei. Data are shown as mean  $\pm$  SEM,  $n = 3$  independent trials of 6–10 films. All synthetic materials have significantly reduced numbers of cells present at 4 and 9 days relative to Matrigel™ controls. \* indicates significant difference relative to day 4 ( $p < 0.05$ ) (B) At d4 (top row) and d9 (bottom row) most cells on P(GDMA-*co*-AEMA) (iii, iii'), P(PEG-*co*-AEMA) (iv, iv'), and P(PEG-*co*-AEMA)-PVA (v, v') were notably smaller and regionalized to the perimeter of the discs compared to chitosan (ii, ii') and Matrigel™ controls (i, i'). Dotted lines indicate the edge of the disk where cells were exclusively observed on P(PEG-*co*-AEMA) and P(PEG-*co*-AEMA)-PVA. (C) Bright phase images of cells on chitosan and Matrigel™ showing the morphology of the adherent cells on d4 and d9 post plating single cells. (D) Cell viability analyzed on Matrigel™ and chitosan at 2, 4, 9, and 21 days in culture using the PicoGreen assay and showing the fold change in the numbers of viable cells relative to the numbers of seeded cells on d0. Data represents means  $\pm$  sem. \* = significant difference relative to d0 ( $p < 0.05$ ). (E) Whole neurosphere on chitosan at d9 showing adhesion and migration of cells. Scale bar = 100  $\mu$ m.

compared to Matrigel™ controls by examining the diameter of adherent neurospheres (Fig. 2E). When intact neurospheres of equal diameter (100  $\mu$ m) were plated on day 0

and the diameter of the adherent colony was examined on d4, the cells migrated significantly more on chitosan relative to the other polymeric surfaces tested (chitosan:  $2.13 \pm$

**Table 1.** X-ray photoelectron spectroscopy and water equilibrium content analysis.

Material	Nitrogen surface concentration (%)	Equilibrium water content
Chitosan	2.75 ± 0.45	8.01 ± 1.37
P(GDMA- <i>co</i> -AEMA)	0.35 ± 0.05	56.74 ± 1.81
P(PEGDMA- <i>co</i> -AEMA)	1.65 ± 0.15	50.71 ± 3.51
P(PEGDMA- <i>co</i> -AEMA)-PVA	0.5 ± 0.20	54.68 ± 1.87

0.75 mm; P(GDMA-*co*-AEMA): 0.37 ± 0.18 mm; P(PEGDMA-*co*-AEMA): 0.49 ± 0.14 mm, and P(PEGDMA-*co*-AEMA)-PVA: 0.51 ± 0.36 mm). Hence, chitosan supports cell adhesion and migration to a greater extent than the other biomaterials tested herein, making it a promising material for cell delivery.

### NPC differentiation

Neural precursor cells have the potential to differentiate into astrocytes, oligodendrocytes, and neurons in vitro in the presence of serum on Matrigel<sup>TM</sup>.<sup>29,34</sup> To test the differentiation capacity of NPCs on the candidate matrices, we examined the differentiation profile using immunohistochemistry at various times post-plating. Single NPCs plated onto each biomaterial (and Matrigel<sup>TM</sup> controls) were immunostained for glial fibrillary acidic protein (GFAP) expression to assess for astrocyte formation;  $\beta$ III tubulin for neurons; and O<sub>4</sub> for oligodendrocytes (Figs. 3A and 3B). Strikingly, chitosan was the only candidate material of the four analyzed that supported NPC differentiation regardless of the time in culture (d4, d9, or d21). Moreover, chitosan supported the differentiation of all three cell types (astrocytes, neurons, and oligodendrocytes), similar to what is observed on Matrigel<sup>TM</sup> (Fig. 3A); however, the relative percentages of the differentiated phenotypes varied between the two substrates. Notably, neurons were observed on both chitosan and Matrigel<sup>TM</sup> at d9 and an increase in the percentage of neurons was observed on chitosan over time; oligodendrocytes were present at each time point and the percentage was not statistically different on chitosan over time; however the percentage of oligodendrocytes decreased on Matrigel<sup>TM</sup>, and astrocytes were present at each time point on both chitosan and Matrigel<sup>TM</sup> and comprised the major cell type at all time points. While it is still not known which cell type, or combination of cell types, is best suited for enhancing neural regeneration, the fact that all cell types can be formed on chitosan suggests that it may be advantageous for developing cell transplantation strategies using nerve guidance channels following nervous system damage.

### Neural stem cells persist on chitosan

The neurosphere-derived cells seeded onto the matrices were a mixed population of stem and progenitor cells. Having observed the multipotentiality of the progenitor cells on chitosan, we questioned whether neural stem cells (i.e., the neurosphere-forming cells) also persisted on the matrix. We assayed for the survival of stem cells by lifting the cells off the matrix 9 days post-plating and placing the cells in culture conditions that permit neurosphere formation. We examined the cells in terms of their ability to re-form neurospheres and for the expression of nestin (an intermediate fil-

ament protein that is expressed by virtually 100% of neurosphere-derived NPCs prior to differentiation and continues to be expressed following differentiation in vitro). We observed nestin expression following differentiation on chitosan at d4, d9, and d21 post-plating (Fig. 3), suggesting that undifferentiated precursors were maintained on chitosan. Notably, there was significant overlap in the GFAP- and nestin-expressing populations (ie. single cells expressed both markers) which may reflect an immature phenotype of astrocytes in culture.<sup>66,67</sup> Importantly, we isolated neurosphere-forming cells from chitosan cultures in comparable numbers to those observed on Matrigel<sup>TM</sup>. Similarly, the recovered neurospheres could be passaged and gave rise to neurons, astrocytes, and oligodendrocytes following differentiation. Hence, chitosan supports the differentiation of all three neural cell types in addition to the survival of multipotent stem cells.

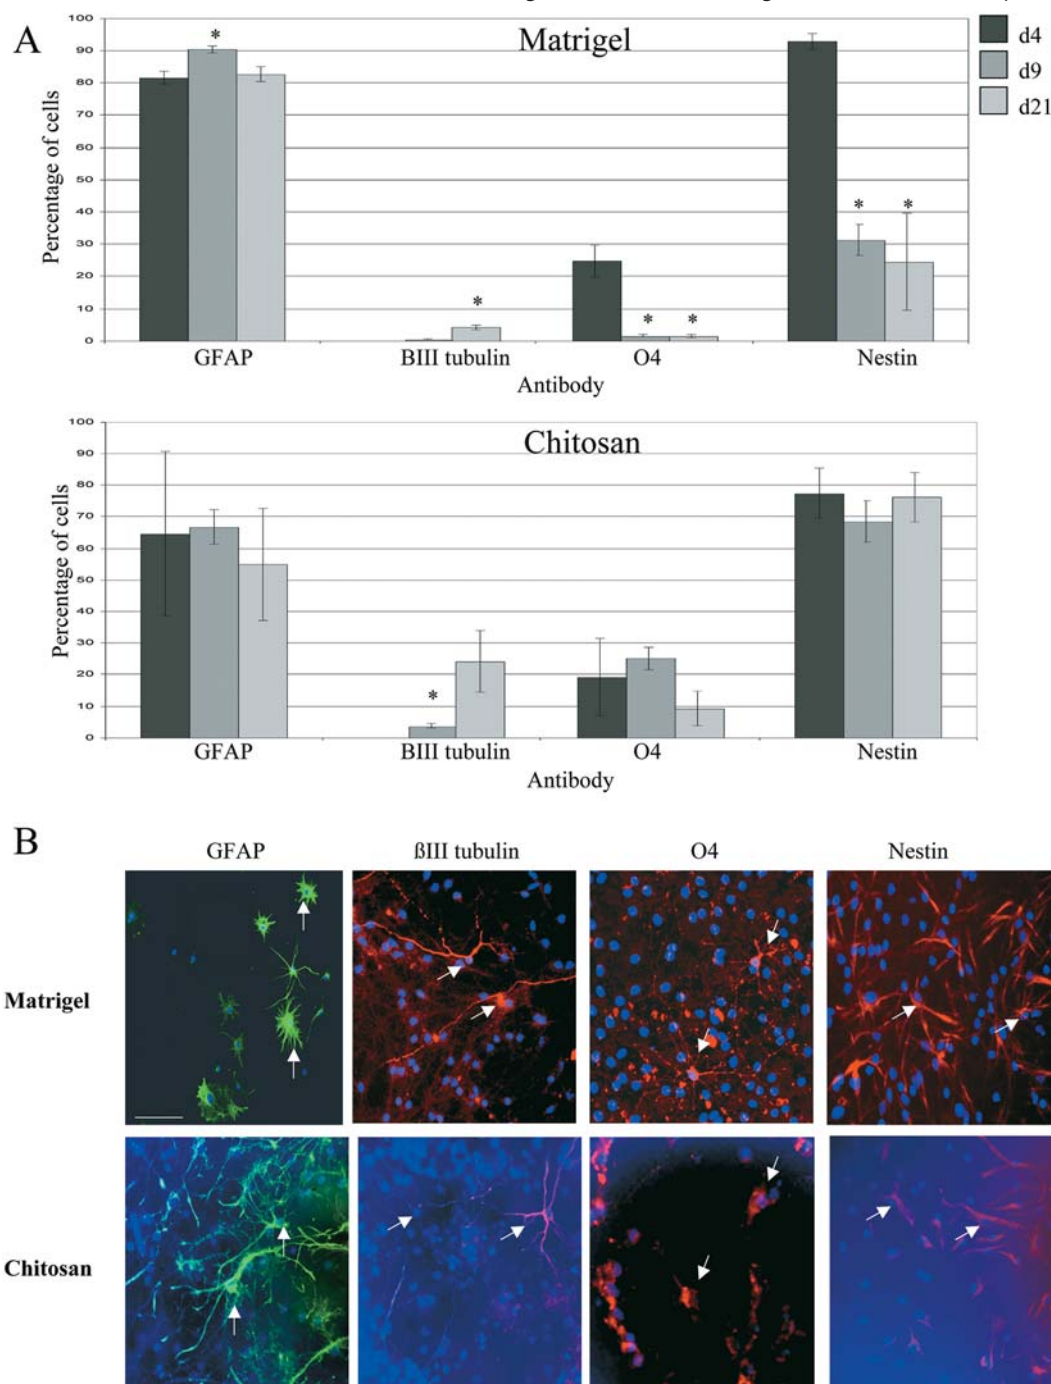

### Discussion

It has been shown that extrinsic factors originating from both diffusible factors<sup>68–71</sup> and cellular interactions<sup>72–74</sup> can regulate the proliferation and differentiation of cells. To our knowledge, this report is the first to show that cell viability, migration, and differentiation of adult murine NPCs differ over time on distinct amine-functionalized polymer surfaces. Moreover, the study identifies adult-derived NPCs and chitosan matrices as promising candidates for surgical implantation strategies aimed at restoring neurological deficits following injury to the nervous system.

Recently, Young et al.<sup>74</sup> reported that chitosan and poly(vinylidene fluoride) (PVDF) substrates could support the proliferation and differentiation of embryonic-derived cortical precursors. Interestingly, their observations using an embryonic-derived starting population of cells generated notable differences from our study when comparing the behaviour of cells plated on chitosan. Our starting population of single adult-derived cells was capable of differentiating into the three neural cell types on chitosan (Fig. 3), which differs from what was found using embryonic cortical precursor populations where single cells were inhibited from proliferating and differentiating on chitosan. This is a good example of the importance of considering both the material and the starting population of cells when designing strategies for tissue repair.

An important criterion in biomaterial selection in this study was the cell-biomaterial interaction. Irrespective of time in culture, NPC counts were significantly greater on chitosan than on the other synthetic hydrogels analyzed, demonstrating the importance of surface composition and water content which is consistent with the observations of others.<sup>27,75–77</sup> P(GDMA-*co*-AEMA), P(PEGDMA-*co*-AEMA), and P(PEGDMA-*co*-AEMA)-PVA hydrogels were either covalently or physically cross-linked to form highly water-swallowable polymer networks. The high water content of these polymeric hydrogels minimized protein adsorption and cell adhesion<sup>78,79</sup> reflecting the high water content associated with PEG.<sup>80</sup> To facilitate cell adhesion, amine-functionalized AEMA was copolymerized with GDMA and PEGDMA; however, this proved insufficient to overcome the low protein- and cell-adhesion properties associated with PEG. In-

**Fig. 3.** (A) The quantification of single-plated neural precursor cells for GFAP (astrocytes), neurons (βIII tubulin), oligodendrocytes (O4) and Nestin (undifferentiated cells) on Matrigel™ controls and chitosan on d4, d9, and d21. \* indicates significant difference relative to day 4 ( $p < 0.05$ ). (B) Immunohistochemistry of neural precursor cells plated on Matrigel™ and chitosan at d9 showing individual cells expressing GFAP (green), βIII tubulin (red), O4 (red), and Nestin (red) as indicated by arrows. Nuclei are Hoechst-positive (blue). Immunohistochemistry captured on chitosan exhibits an increased fluorescent background relative to Matrigel™. Scale bars = 100 μm.

terestingly, there was a progressive increase in cell viability and adhesion with decreasing water content in the polymer films studied and it was water content, not amine functionalization, that had the overriding effect on cell adhesion and thus viability. The low equilibrium water content, coupled with the amine functional groups present on chitosan, rendered chitosan cell-adhesive. Chitosan has also been shown

to be biocompatible and to degrade to non-cytotoxic products,<sup>60,81</sup> making it desirable for further investigation.

Adult NPCs are proliferative cells that migrate along a well-defined pathway to the olfactory bulb where they differentiate into neurons *in vivo*.<sup>58,63,82–85</sup> Proliferation, migration, and differentiation are also well-established characteristics of NPCs *in vitro*.<sup>86</sup> The cell behaviour observed

was dependent on the cell-matrix interaction and accordingly varied significantly between the matrices. Cell proliferation was observed on chitosan and control matrices between d4 and d9 and this coincided with an increase in the total numbers of cells in the center of the film. This mitogenic effect on chitosan surfaces has also been seen with human fibroblast and keratinocyte populations in vitro<sup>87</sup> and is thought to be the result of the highly deacetylated chitosan potentiating the effect of growth factors present in culture. Importantly, the total numbers of cells on d21 did not continue to increase, thereby reducing the likelihood of uncontrolled cell growth in vivo following implantation strategies after CNS damage. The ability of chitosan to promote the differentiation of all cell types (neurons, astrocytes, and oligodendrocytes) may be advantageous because its therapeutic potential as a delivery vehicle could be maximized for CNS injury repair and is attractive for developing regenerative medicine strategies. Importantly, chitosan is amenable to the incorporation of a drug delivery system that will further facilitate the development of specific cell types over time. Taken together, these features make chitosan a promising material for future development in the treatment of nervous system injury. More broadly, our findings provide the necessary framework for combining cellular therapeutics and implantation strategies in tissue engineering repair strategies of the damaged nervous system.

## Conclusions

Of four biomaterials screened, chitosan supported the greatest survival, migration, and multipotent differentiation of adult-derived neural precursors, making it a promising candidate material for cell-biomaterial transplantation studies in CNS applications. Importantly, chitosan supported the survival of multipotent, self-renewing stem cells without uncontrolled proliferation. Taken together, these findings provide the necessary framework for combining cellular therapeutics and implantation strategies to repair the damaged CNS.

## Acknowledgments

We thank Dr. Charles Tator for his insightful discussion and Howard Kim for preparation of chitosan films. We are grateful to the Canadian Institute of Health Research (MSS, CMM), the Natural Sciences and Engineering Research Council of Canada (MSS, CMM), the Ontario Neurotrauma Foundation (VS), CIHR Training in Regenerative Medicine (VS), the Ontario Graduate Scholarship in Science and Technology (AG), and the James F. Crothers Family (VS, AG) for financial support.

# Methods for probing the long-range dynamic of confined polymers in nanoparticles using small-angle neutron scattering

Y. Rharbi, M. Yousfi, Lionel Porcar, and Q. Nawaz

**Abstract:** Motivated by the recent advances in new technologies, a lot of effort has been dedicated to developing methods for quantifying the dynamic of nanoconfined polymers. Particularly, polymers confined in nanoparticles are an important system for several environment-friendly applications such as waterborne coatings and nanoblends. In this work, we discuss two methods to probe the large scale dynamic of nanoconfined polymers in nanoparticles in two situations: (i) nanoblends and (ii) the close-packed structure. In the methods we apply stress at the nanoscopic level around the polystyrene particles and we probe their deformation in real time using small-angle neutron scattering. These methods give new possibilities to probe, in a nonintrusive manner, the dynamic of confined polymers in nanoparticles, which could ultimately bring conclusive insight to this field.

**Key words:** polymer dynamic, confinement, nanoblends, polymer nanoparticles.

**Résumé :** Motivés par les développements récents dans les nouvelles technologies, beaucoup d'efforts ont été déployés dans le but de mettre au point des méthodes permettant de quantifier la dynamique des polymères nanoconfinés. En particulier, les polymères confinés dans des nanoparticules sont des systèmes importants pour plusieurs applications respectueuses de l'environnement, tels les enduits et les mélanges aqueux. Dans ce travail, on discute de deux méthodes d'étudier la dynamique à grande échelle des polymères nanoconfinés dans des nanoparticules, dans deux situations: (i) les nanomélanges et (ii) la structure à grande compacité. Dans ces méthodes, on applique un stress au niveau nanoscopique autour des particules de polystyrène et on étudie leur déformation en temps réel en faisant appel à la diffusion des neutrons à angles faibles. Ces méthodes fournissent de nouvelles possibilités pour étudier, d'une façon non intrusive, la dynamique des polymères confinés dans des nanoparticules et elles pourraient éventuellement permettre d'obtenir un éclairage conclusif pour comprendre ce champ.

**Mots-clés :** dynamique des polymères, confinement, nanomélanges, nanoparticules de polymère.

## Introduction

There are numerous indications that the dynamic of nanoconfined polymers near an interface deviates from that of the bulk.<sup>1–23</sup> This property is of great importance for several nano-technological applications such as the elaboration and stability of nanoscale polymer structures, adhesion, and environment-friendly coatings, among others. By far, thin film is the most studied nanoconfinement geometry<sup>1–19</sup> compared to the other geometries: nanospheres<sup>20–23</sup> and nanotubes.<sup>9</sup> Numerous studies determined the existence of an impressive depression of the nanoconfined glass transition temperature ( $T_g$ ) in supported and free-standing polystyrene (PS) thin films.<sup>1–6</sup> For supported films, the  $T_g$  was found to increase or decrease depending on the nature of the substrate and the polymer.<sup>1,2</sup>

The glass transition temperature in bulk polymers is usually linked to the segmental dynamic, thus, one expects the activation of the dynamic to accompany the observed  $T_g$  reduction in confined systems.<sup>1</sup> Therefore, several methods were proposed to monitor the dynamic of confined polymers at different length scales.<sup>7–19</sup> The segmental dynamic in free-standing PS films measured by means of dielectric relaxation was found to be faster than the bulk, which is coherent with the  $T_g$  reduction.<sup>7,8</sup> On the other hand, the numerous methods used to probe the large scale dynamic yielded different conclusions. For example, Reiter et al.<sup>10</sup> used the dynamic of dewetting of polystyrene on a solid substrate to extract information on the dynamics of polymer chains. Roth and Dutcher<sup>11</sup> investigated the dynamic of thin films using hole-opening experiments. Russell and co-workers<sup>12</sup> used fluorescence recovery after photobleaching to measure the chain

diffusion in polystyrene thin films and found a reduction of the diffusion coefficient with decreasing film thickness. They concluded that chain adsorption on the substrate is what slows chain diffusion. O'Connell and McKenna<sup>13</sup> carried out mechanical tests using the "bubble inflation" technique on ultrathin films and suggested a strong reduction of rubbery compliance as the film thickness decreases, which could mean a higher entanglement density than in the bulk. Bodiguel and Fretigny<sup>14</sup> monitored the dynamic of contraction in free-standing thin films under the action of surface tension and did not find any variation of the rubbery plateau. However, they reported a reduction of the viscosity with decreasing film thickness.<sup>14</sup> Si et al.<sup>15</sup> performed stretching experiments on free-standing films and proposed that intra-chain entanglement decreases with decreasing film thickness. Recently, several researchers investigated the dynamics of the free surface layer of polystyrene films by looking at the time dependence of hole closure.<sup>16–19</sup> Reference 16 suggested that the relaxation of the free surface exhibits a bulk behavior for temperatures close to the bulk  $T_g$  and then strongly deviates from the bulk relaxation for temperatures below the  $T_g$ . To explain the discrepancy between the results of the literature there is still a need to develop new methods to precisely probe the dynamic of confined polymers.

The confinement of polymers in nanoparticles is important in many environmental applications:<sup>20,21</sup> blends, copolymers, nanocomposites, colloids, coatings, and so forth. One example is zero volatile organic compound (VOC) coatings, where polymer nanoparticles are used in the film-making process.<sup>22–26</sup> VOCs are used in coatings to lower the particle  $T_g$  and to soften the particle, which permits the fabrication of crack-free films at room temperature.<sup>20,21</sup> If the polymer dynamic is activated and the  $T_g$  decreases by decreasing the nanoparticle size, the use of VOCs could be avoided, which would have a positive impact on the environment. Another example is in nanoblends, where hard polymer nanoparticles are used to reinforce soft matrices. If confinement in this application causes the reduction of the hard particles'  $T_g$  and the activation of the polymer dynamics, reducing the particle size would be counterproductive for reinforcement since it would cause the softening of the hard particles.<sup>27,28</sup> Thus, there is a real need to develop appropriate methods to measure the dynamics of polymer in nanoparticles.

In this paper, we discuss two methods to monitor the large scale dynamic of polystyrene in nanoparticles in two situations: polymer particles in nanoblends and polymer particles in a close-packed structure. We apply stress to the particles at the nanoscopic level using various procedures and we probe the deformation of the particle in real time by means of small-angle neutron scattering. Particle deformation is then used to quantify the dynamic of confined polystyrene in nanoparticles. Recently, we proposed a method for probing the dynamic of polystyrene nanoparticles in nanoblends<sup>28</sup> and we applied it to a single particle size (80 nm). In the present paper, we first extend these results by discussing the effect of particle. Secondly, we discuss how the void closure between close packed particles could be used to monitor the absolute values of the relaxation time of polymer nanoparticles.

## Experimental

### Materials

Monomers, deuterated styrene ( $D_8$ , Sigma-Aldrich, 99%), nondeuterated styrene (Sigma-Aldrich, 99%), butyl acrylate (Sigma-Aldrich, 99%), butyl methacrylate (Sigma-Aldrich, 99%), and cross-linker, ethylene glycol dimethylacrylate (EGDMA), were used as received. The surfactant, sodium dodecyl sulfate (SDS, Sigma-Aldrich, 99%), the initiator, potassium persulfate (KPS, Sigma-Aldrich, 98%), and buffer sodium bicarbonate were used as received. Double deionized water was used in the emulsion polymerization.

### Synthesis

Poly(butyl methacrylate) (PBMA), poly(butyl acrylate) (PBA), deuterated polystyrene (dPS), and hydrogenated polystyrene (PS) particles were prepared using emulsion polymerization at 80 °C. The polymer concentrations in water were 10 wt% for the PBMA, 10 wt% PS, and 2 wt% for dPS. The PBMA particles were cross-linked at 10% using ethylene glycol dimethylacrylate (EGDMA) during the polymerization. The PBMA and PS nanoparticles were prepared in a standard three-neck round flask (500 mL) with a condenser and a nitrogen inlet. For the preparation of PBMA, the mixture (26 g) of the cross-linker (EGDMA) and monomer (BMA) were added to the predegassed SDS (3 g)/water (250 g) solution, which had previously been heated at 80 °C. The solution was vigorously agitated for 20 min before the initiator was added. A solution of the initiator KPS (33 mg) in water (1.7 g) was added to the reaction. After 4 h, another solution of the KPS (5.4 mg) in water (0.7 g) was added to polymerize all the nonreacted styrene monomer.

The dPS was either prepared from pure deuterated styrene ( $D_8$ ) or from a 50/50 wt% mixture of deuterated styrene ( $D_8$ ) and hydrogenated styrene. The dPS particles were prepared in a 50 mL minireactor equipped with a gas inlet and a homemade minicondenser. The size of the dPS particles was controlled by varying the added amount of surfactant in the reaction. The mixture of water (18 g) and SDS was heated to 80 °C, under nitrogen flux for 20 min and then 0.3 g of styrene monomer (50/50 wt% deuterated and hydrogenated) was added. A solution of the initiator KPS (14 mg) in water (0.5 g) was added to the reaction. After 4 h, another solution of the KPS (1.4 mg) in water (0.25 g) was added to polymerize all the nonreacted styrene monomer. The SDS concentration was varied to control the size of the particles.

The surfactant and free ions were removed from the dispersions using a mixture of anionic and cationic exchange resins (Dowex, Sigma-Aldrich). The suspensions were cleaned a few minutes prior to film preparation.

### Polymer and particle characterization

Particle diameters ( $D$ ) were measured using quasi elastic light scattering (QELS) (Malvern 5000) at a 90° angle. The molecular weight was measured using gas permeation chromatography (GPC) in tetrahydrofuran (THF). The molecular weight of PS-93 was found to be  $M_w \approx 280\,000$  kg/mol and its  $M_n \approx 92\,000$  kg/mol. For dPS-5 the  $M_w = 371\,000$  kg/mol and the  $M_n = 216\,000$  kg/mol.

The bulk glass transition temperature of polystyrene was measured by differential scanning calorimetry (DSC, Mettler

**Table 1.** Properties of the PBMA and PS samples.

Toledo DSC 823) during the heating step at a rate of 10 K/min for polystyrene and 40 K/min for highly cross-linked PBMA. The powder dried at 45 °C, was added to the DSC pan, and annealed for 10 min at 140 °C to remove the thermal history before the first DSC scan. The  $T_g$  is taken as the midpoint in the DSC trace, and in Table 1, we report the  $T_g$  value from the first run. Also in Table 1, we list the properties of dPS and cross-linked PBMA.

### Preparation of the samples for the neutron scattering

The surfactant and free ions were removed from the dispersions using a mixture of anionic and cationic exchange resins (Dowex, Sigma-Aldrich). The dPS-5 suspension was annealed in a stainless steel bomb at 120 °C for 20 min to release their thermal histories.

The nanoblends were prepared by mixing dPS and PBMA dispersions to make dPS concentrations of 2 wt% of the solid PBMA. The blends containing dPS-1 and dPS-6 were prepared using PBMA (lot 2) and dPS-5 was prepared from a PBMA (lot 1). Cracked films were obtained after water evaporation at 56 °C. The hydrogenated PS samples were prepared by drying the PS suspension at 45 °C for 48 h. This yielded a cracked PS powder.

### SANS experiments

The small-angle neutron scattering (SANS) experiments were carried out on spectrometer PAXY of Laboratoire Léon Brillouin (LLB, Saclay, France) at the reactor Orphée Saclay and at D22 and D11 of Institut Laue-Langevin (ILL, Grenoble, France). The scattered neutrons, collected on an XY bidimensional multidetector, were circularly averaged to obtain spectra of intensities ( $I$ ) versus the magnitude of the scattering wave vector ( $Q$ ). Several configurations of the wavelengths and sample-to-detector distances were chosen to yield a range of  $Q$  values between  $2 \times 10^{-3}$  and  $1 \times 10^{-1} \text{ Å}^{-1}$ .

The nanoblend samples were prepared by gently grinding the cracked films into a powder with grains of 0.5 mm beads. This powder (105 mg) was then introduced between two quartz disks separated by a spacer of 12 mm inner diameter and 1.2 mm thickness. The nanoblends were annealed (in situ), the sample was positioned in the neutron beam in a homemade oven equipped with two quartz windows and was heated to the desired temperature during the SANS measurements. The sample temperatures were monitored using a thin thermocouple placed in the proximity of the sample. The sample temperature was found to reach the desired temperature within 2 min. Neutron spectra were taken for 1 min at various annealing times.

The PS samples were separated into several samples of 0.2 g placed in glass bottles. Each of these samples were annealed at  $100 \text{ °C} \pm 0.2 \text{ °C}$  for a given time between 1 min and 2 h. The samples were then gently grinded into 0.5 mm beads. This powder ( $0.09 \pm 0.002 \text{ g}$ ) was then placed between two pieces of aluminum scotch tape (0.1 mm thick)

separated by a spacer of 14 mm inner diameter and 0.8 mm thickness. The powder was then pressed using  $15 \text{ kgf/cm}^2$  ( $1 \text{ kgf/cm}^2 = 98.0665 \text{ kPa}$ ) to obtain a homogeneous film thickness of 0.8 mm.

## Results and discussion

A good protocol to monitor the dynamic of polymer nanoparticles requires (i) that a stress is applied to the particle at the nanoscopic level and (ii) a sensitive method to monitor the change in the particle shape during its deformation. From the time dependence of the particle shape one can deduce the relaxation time of the polymer and its dependence on the temperature and the confinement condition. We apply this procedure to probe the dynamic of polystyrene in two different environments: (i) polystyrene dispersed in nanoblends and (ii) close-packed polystyrene particles.

### Protocol for measuring the dynamic of polystyrene nanoparticles in nanoblends

In a previous report, we proposed a new method to apply the stress locally to the polystyrene nanoparticles dispersed in nanoblends by using the following procedure:<sup>28</sup> Nanoblends composed of colloidal suspensions of cross-linked PBMA and 2% dPS nanoparticles were prepared via water evaporation, see Scheme 1. These blends were prepared at temperatures above the  $T_g$  of cross-linked PBMA particles ( $T_g^{\text{PBMA}}$ ) and well below the  $T_g$  of PS ( $T_g^{\text{PS}}$ ). This should lead to a deformation of the PBMA particles under capillary pressure ( $P_{\text{Lap}} = 12.9\gamma_{\text{aw}}/R \sim 23 \text{ MPa}$ , where  $\gamma_{\text{aw}}$  is the surface tension of air/water and  $R$  is the radius of the particle) filling the voids between them while the glassy dPS nanoparticles remain spherical. With  $P_{\text{Lap}} \sim 23 \text{ MPa}$ , the glassy PS particles with a modulus  $G \sim \text{GPa}$  should remain spherical at the temperature of film formation ( $T^f$ ). The cross-linked PBMA particles, which exhibit an elastic modulus of  $G < 23 \text{ MPa}$  are expected to deform under  $P_{\text{Lap}} \sim 23 \text{ MPa}$  for  $T^f > T_g^{\text{PBMA}}$ . This leads to storage of elastic energy within the PBMA nanoparticles.

After annealing the nanoblends above the  $T_g^{\text{PS}}$ , the PBMA around the PS release the stored elastic energy by partially regaining their spherical shape, which induces the deformation of the PS particles (Scheme 1). SANS is then used to monitor the evolution of the shape of the PS particle and to quantify the dynamic of the confined polystyrene.

### The adequate procedure to obtain individual nanoparticles in nanoblends

To properly study the confined PS in nanoblends, one should first succeed in making films containing PS particles individually dispersed within cross-linked matrices. When the PS and the matrix-forming particles are mixed at low concentrations, they remain stable in water because of electrostatic repulsion. The idealistic situation to obtain a con-

**Scheme 1.** Description of the procedure for measuring the dynamic of PS in nanoblends. Step 1 is the procedure of nanoblends preparation and step 2 is the procedure for annealing the nanoblends (reproduced from ref. 28).

trolled dispersion at the nanoscopic level is that the two particles remain stable throughout the whole water evaporation process. During water evaporation the particle concentration increases, which could affect the stability of the different particles.

In Fig. 1, we compare the SANS spectra of 30 nm dPS particles dispersed in PBA and PBMA matrices. The spectra of dPS in a PBA matrix exhibit a strong scattering for  $q \rightarrow 0$ , which could be fitted to a power law with an exponent of  $-2.85$ . This suggests that dPS particles form large aggregates of dPS particles in the PBA matrix. On the other hand, the spectra of the same dPS particles in PBMA yields a low scattering intensity for  $q \rightarrow 0$ , which suggests that dPS are individually dispersed within the PBMA matrix. As we showed before when the PS and PBMA suspensions are cleaned using the ion exchange procedure, one can obtain nanoblends with perfect dispersion of the PS in the PBMA.<sup>27</sup> On the other hand, we could not obtain individual PS particles in the PBA even when both suspensions are cleaned in the same procedure as in the PS/PBMA. This shows that the ability to obtain nonaggregated particles in the blends depends on the physicochemical properties of the two particles during evaporation. In the following, we focus our discussion on the nanoblends of dPS in the PBMA matrix.

The SANS spectra of blends containing 2 wt% dPS (30, 77, and 80 nm) dispersed in a 10% cross-linked PBMA matrix exhibit a continuously decreasing scattering intensity,  $I(q)$  (Fig. 2). The  $I(q)$  were found to fit well to the  $P(q)$  of polydispersed hard spheres (Fig. 2). The best fit was found to yield for dPS-6 (77 nm) a mean particle diameter of 73 nm and for the dPS-1 (30 nm) a particle diameter of 28 nm. These diameters are similar to those from quasi elastic light scattering. This infers that the dPS nanoparticles are individually dispersed within the PBMA matrices and remain spherical in the blends. The intensity,  $I(q)$ , can be written as  $I(q) = P(q) \cdot S(q)$  where  $P(q)$  is the form factor and  $S(q)$  is the structure factor of the dPS particles.  $S(q) \approx 1$

**Fig. 1.** SANS spectra of films made from 2 wt% deuterated polystyrene particles (30 nm) dispersed in a 10% cross-linked PBA matrix (■) and in 10% cross-linked PBMA matrix (□). The films were prepared via evaporation at 56 °C of a mixture of dPS/PBMA (■) and dPS/PBA (□) suspensions.

because of a low dPS concentration and the absence of selective aggregation. The spectra in Fig. 2 also imply that the cross-linked PBMA particles are deformed under Laplace pressure to fill the interstices. If not, a strong scattering peak from the PBMA matrix at  $q = 2\pi/D_{PBMA} = 0.01 \text{ Å}^{-1}$  would be visible, similar to that observed in glassy PS particles as will be discussed later.

#### Change of the shape of the particle after annealing

When the nanoblends of 77 nm dPS nanoparticles in 10% cross-linked PBMA are annealed above the bulk  $T_g$ , the shape of the dPS particles changes remarkably. The oscillations of the scattering spectra disappear and the intensity,  $I(q)$ , decreases for  $q < 0.01 \text{ Å}^{-1}$  and increases for

**Fig. 2.** SANS spectra of films made from 2 wt% deuterated polystyrene particles dispersed in a 10% cross-linked PBMA matrix: (a) 77 nm dPS (PS-6) and (b) 30 nm dPS (PS-1) particles. The films were prepared from a mixture of two suspensions: 10% cross-linked PBMA particles (56 nm) and dPS nanoparticles. The films were prepared by evaporation at 56 °C (above the  $T_g$  of PBMA and below  $T_g$  of dPS). The SANS curves are fitted to a form factor of (a) polydispersed spheres with a diameter of 73 nm and a polydispersity of PDI = 7% and (b) to polydispersed spheres with a diameter of 28 nm. (Insert: SANS of 80 nm particle (dPS-5) for a wide range of  $q$ , up to  $q = 0.1 \text{ \AA}^{-1}$ , fitted to a factor of spherical particle.)

$q > 0.01 \text{ \AA}^{-1}$ . This observation is found to be the same as the 80 nm dPS sample (dPS-5) reported previously.<sup>28</sup> The 30 nm particle also clearly shows the decrease of the intensity at  $q$  values after annealing. The evolution of the SANS spectra shows that the shape of the dPS nanoparticles evolves during the annealing process. We have shown previously that such change results from a deformation of the individual dPS particles during annealing.<sup>28</sup> One could imagine that the change in the SANS spectra results from penetration of deuterated polystyrene chains in the PBMA matrix or fusion of dPS particles. Fusion is unlikely because it results in large particles with a lower total surface area. This specific interface area between the dPS and the PBMA is estimated using the Porod law as  $q^4 \cdot I(q)$  at large  $q$  values. The average value of  $q^4 \cdot I(q)$  is found to triple after annealing, contrary to what is expected in fusion (Fig. 3 from ref. 28). Furthermore, since fusion yields large particles, a high scattering intensity for  $q \rightarrow 0$  is expected ( $I(0) \sim \phi \cdot V_{\text{part}}$ , where  $\phi$  is the volume fraction and  $V_{\text{part}}$  is the volume of the particles). In fact, the measured  $I(q)$  for low  $q$  after annealing is lower than  $I(q)$  of the nonannealed films in the range of  $q$  values investigated. This could mean that the volume of dPS particles remain unchanged despite the change in their shape. One could also imagine that the change in the SANS spectra results from penetration of deuterated polystyrene chains in the PBMA matrix. Polystyrene and uncross-linked PBMA form an interface which is a few nanometers thick,<sup>29</sup> whereas highly cross-linked PBMA is

likely to inhibit the interpenetration of the polymers. If penetration of dPS into the PBMA matrix is what causes the observed transformation in the SANS spectra, then the change should be more enhanced in low cross-linked PBMA matrices. In contrast with this, the spectra of films made of low cross-linked PBMA matrices remain slightly the same upon annealing (Fig. 4 from ref. 28). It is therefore clear that fusion of dPS nanoparticles and penetration of dPS into the PBMA matrix are not responsible for the observed transformation of the SANS spectra upon annealing. The change of SANS spectra most likely results from the deformation of individual polystyrene nanoparticles, which is dictated by the behavior of the surrounding cross-linked PBMA particles. During annealing, the cross-linked PBMA particles regain their spherical shape and squeeze the dPS particles between them. Such mechanism is likely to produce a dPS nanoparticle with an elongated shape with many branches. The simplest picture is that the dPS nanoparticles deform into a star-like shape with 12 branches according to Scheme 1.

#### *Dynamics of deformation of polystyrene confined in nanoblends at temperatures above the bulk glass transition*

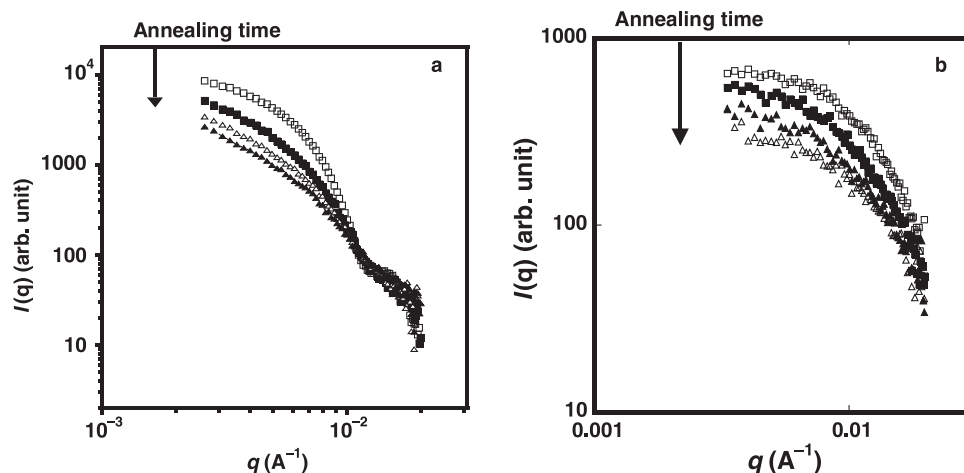

The shape of the spectra of 77 nm dPS in a 10% cross-linked PBMA matrix continuously changes during annealing at 140 °C: the intensity at low  $q$  decreases and that of large  $q$  increases (Fig. 3a). The evolution of the spectra with time reflects the change in the particles' shape during their deformation. Annealing the nanoblends with 30 nm particles at 140 °C gives the same behavior as the 77 nm particles (Fig. 3b): the intensity decreases in the low  $q$  range. This shows that this procedure can be used to test the dynamic of dPS particles in nanoblends for particles as small as 30 nm.

To quantify the dynamics of polystyrene particles in nanoblends, we can either use (i) the change of the scattering intensity at various  $q$  values,  $I(q,t)$ , or (ii) the variation of the gyration radius,  $R_g$ , of the dPS particle with time. In Fig. 4a, we show the scattering intensity at various  $q$  values for 77 nm dPS particles in 10% cross-linked PBMA matrix annealed at 140 °C. These plots fit perfectly to a stretched exponential with an exponent of  $\beta = 0.6$  (Fig. 5) and a relaxation time,  $\tau$ , which depends on the  $q$  value. The reliability of the fit and the estimation of the error bar in  $\beta$  and  $\tau$  are estimated from the width of the minimum of the least-squares plots versus  $\beta$  and  $\tau$ . The magnitude of change in the scattering intensity during annealing decreases when one approaches the minimum of  $P(q)$ , which makes it difficult to monitor the dynamic for  $q > 0.005 \text{ \AA}^{-1}$  for 77 nm and  $q > 0.01 \text{ \AA}^{-1}$  for 30 nm particles.

The  $R_g(t)$  at various annealing times is calculated by fitting the low  $q$  values of  $I(q)$  using the Guinier representation,  $\ln(I(q)) = \ln(I(0)) - q^2 \cdot R_g^2/3$ . The  $R_g(t)/R_g(0)$  decay for 77 nm dPS fits perfectly to a stretched exponential with a decay time of  $\tau_{R_g} = 25 \text{ min}$  and  $\beta = 0.64$  (Fig. 6). This behavior is exactly the same as that found previously on 80 nm particles;<sup>28</sup> however, the exponent was found to be  $\beta = 0.716 \pm 3\%$ , which is slightly higher than that found here. This infers that the exponent depends slightly on the property of the dPS particle and the surrounding matrix.

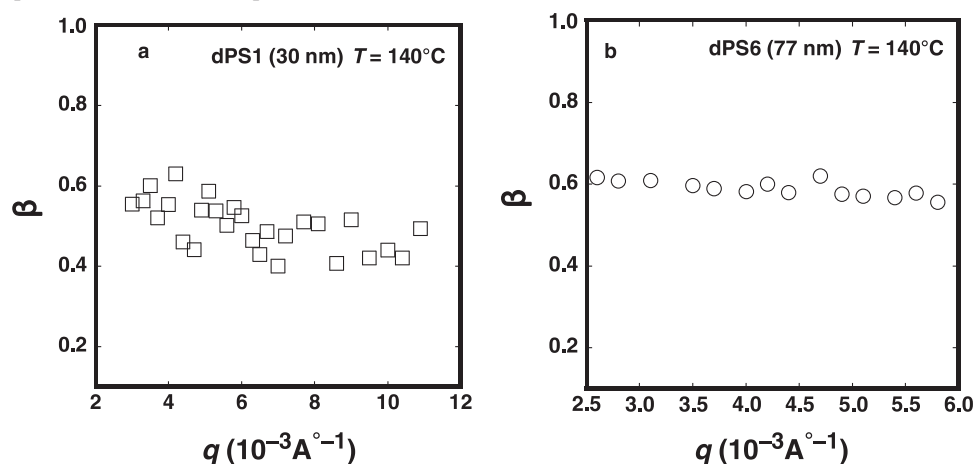

**Fig. 3.** (a) The scattering spectra plotted for various annealing times for 77 nm dPS nanoparticles in a 10% cross-linked PBMA matrix before annealing ( $\square$ ) and at 4 ( $\blacksquare$ ), 17 ( $\triangle$ ), and 37 min ( $\blacktriangle$ ). (b) The scattering spectra plotted for various annealing times for 30 nm dPS nanoparticles in a 10% cross-linked PBMA matrix. The films were annealed at 140 °C.

**Fig. 4.** The evolution of the scattering intensity at various  $q$  values, as a function of the annealing time for blends made from (a) 77 nm dPS nanoparticles and (b) 30 nm particles. The plot is fitted to a stretched exponential (continuous lines).

**Fig. 5.** The exponent  $\beta$  of the fit of the decays ( $I(q, t)$ ) in Fig. 4 to a stretched exponential ( $I(q, t) = I(q, 0) \exp - (t/\tau)^\beta$ ), plotted against the  $q$  values for (a) 30 nm particles and (b) 77 nm particles.

The time decay of the scattering intensity of the 30 nm particle was also found to fit to a stretched exponential with an exponent  $\beta = 5$  for  $q < 0.01 \text{\AA}^{-1}$ , which is slightly lower than that calculated in large particles (Fig. 5). The relaxation of the bulk PS is well-accepted to be a stretched exponential

with an exponent of 0.4.<sup>30</sup> The exponent,  $\beta$ , in our experiment reflects the change in the spreading mechanism of the dPS particle between the PBMA particles and therefore contains information on the exponent of the polymer relaxation as well as other parameters such as the particle size.

**Fig. 6.**  $R_g(t)$  vs. the annealing time for blends made from 77 nm dPS nanoparticles in 10% cross-linked PBMA annealed at 140 °C.  $R_g$  is calculated using the Guinier representation.

The appropriate parameter to characterize the stretched exponential dynamic is the average relaxation time,  $\langle\tau\rangle$ , which is calculated as  $\langle\tau\rangle = \int \exp(-(t/\tau)^\beta) dt$  using the  $\tau$  and  $\beta$  values.<sup>31</sup> The  $\langle\tau(q)\rangle$  in 77 nm dPS particles decreases with increasing  $q$  from 16.6 min to 11.4 min for  $q$  values between  $2.58 \times 10^{-3} \text{ \AA}^{-1}$  and  $5.1 \times 10^{-3} \text{ \AA}^{-1}$  (Fig. 7a). For 30 nm dPS  $\langle\tau\rangle$  was also found to decrease with increasing  $q$  in the same manner as the 77 nm particles (Fig. 7b). Such tendency is similar to that reported previously on dPS-6. Since  $I(q)$  at each  $q$  value portrays the density fluctuations with a size of  $\xi = 2\pi/q$ ,  $\langle\tau(q)\rangle$  also describes the relaxation dynamic of the density fluctuation with a size of  $\xi$ . Larger fluctuations would require more time to change than a smaller fluctuation. Therefore,  $\langle\tau(q)\rangle$  increases with increasing  $\xi$  and thus increases with decreasing  $q$ . For  $q$  approaching  $q = 0$ ,  $\langle\tau(q)\rangle$  converges toward the relaxation time of the gyration radius,  $\langle\tau_{R_g}\rangle$ , which is the largest size of the system,  $\langle\tau(q)\rangle_{R_g} = 34$  min.

The  $\langle\tau(q)\rangle$  of 30 nm particles is found to be larger than the  $\langle\tau(q)\rangle$  of 77 nm when measured at the same  $q$  values (Fig. 7b). The  $\langle\tau(q)\rangle$  and  $\langle\tau_{R_g}\rangle$  describe the dynamic of particle deformation under the applied stress,  $\sigma(t)$ , and depends directly on the relaxation time of the confined polymer ( $\tau_\alpha$ ). During the film formation, PBMA particles around smaller dPS particles undergo a small deformation as compared to around large particles, thus, they store less stress. Therefore, one expects smaller particles to deform more slowly than large ones if the PS behaves dynamically in the same manner in the two particles. To derive  $\tau_\alpha$  from  $\langle\tau(q)\rangle$  and  $\langle\tau_{R_g}\rangle$ , we assume the polymer to exhibit a single exponential relaxation with a time  $\tau_\alpha$  and use the following differential equation (eq. [1]).

$$[1] \quad \frac{d\sigma(t)}{dt} + \frac{\sigma(t)}{\tau_\alpha} = G \frac{d\varepsilon(t)}{dt}$$

where  $G$  is the high shear modulus and the deformation strain,  $\varepsilon(t)$ , defined by  $R_g(t)/R_g(0)$  or  $I(q,t)/I(q,0)$ . Equation [1] applies only if the time and the position dependence of

$\varepsilon(t)$  and  $\sigma(t)$  can be separated. It is easy to accept that the stored strain,  $\sigma(t)$ , decrease with increasing the time in the same manner as  $\varepsilon(t)$ . If we take  $\varepsilon(t)$  and  $\sigma(t)$  as exponential with relaxation time,  $\langle\tau(q)\rangle$  or  $\langle\tau_{R_g}\rangle$ , we found

$$[2] \quad \langle\tau\rangle \approx \frac{G}{\sigma(0)} \tau_\alpha$$

The PBMA particles around small dPS particles undergo a small deformation compared to around large dPS ones. Thus, one expects the stored stress,  $\sigma(0)$ , in the case of small dPS particles to be lower than that in large ones. If we take  $\sigma(0)$  to be proportional to the dPS particle diameter,  $D$  ( $\sigma(0) \propto D$ ), we found  $\tau_\alpha \propto \langle\tau\rangle \cdot D$ . In Fig. 8, we compare the plots  $\langle\tau\rangle \cdot D$  versus  $q$  for 77 nm and 30 nm dPS particles. The  $\langle\tau\rangle \cdot D$  of 30 nm particles is found to be lower than that of 77 nm, which could infer that the relaxation time of confined polystyrene,  $\tau_\alpha$ , of 30 nm is smaller than that of 77 nm.

The decay times,  $\langle\tau(q)\rangle$  and  $\langle\tau_{R_g}\rangle$ , contain useful information about the relaxation time of the confined polystyrene in the nanoparticles in nanoblends. The evolution of these times with temperature and the particle size will be used to obtain information on the effect of confinement on the polymer dynamic.

#### Protocol for measuring the dynamic of polystyrene nanoparticles in a close-packed structure

To apply the stress locally to polymer nanoparticles, we also propose the following procedure: When suspensions of polymer particles are evaporated below the glass transition temperature ( $T_g$ ) of the polymer, the particles remain spherical and form a close-packed structure separated with voids (Scheme 2, stage II). The presence of a large interface area (polymer/air) in the voids makes the particles a confined system, which could affect the polymer dynamic and, consequently, the kinetic of particle deformation and void closure. The presence of the voids applies Laplace pressure in the interstices due to the air/polystyrene surface tension ( $\gamma_{p/a}$ ),  $P_{\text{Lap}} = \alpha\gamma_{p/a}/R$ ,  $\gamma_{p/a} = 0.03 \text{ N/m}^2$ . This tends to deform the particle and close the voids to yield a bulk-like polymer (Scheme 2, stage III). If the particles are glassy, the voids should remain unaffected by Laplace pressure during the time of the experiment, and when the system is annealed above the polymer  $T_g$ , the particles deform and the voids close. If one can probe the closure of the interstices, then this can be used as a nonintrusive method to study the dynamic of confined polymers in nanoparticles. We used the small-angle neutron scattering technique to probe the deformation of the particles during annealing. Previous experiments used atomic force microscopy to monitor the change in the free surface corrugation during annealing of submicron size particles.<sup>32–35</sup> The dynamic of free surface corrugation in polyacrylate was found to be similar to the bulk dynamic.<sup>34,35</sup>

The SANS spectra of films made from 93 nm PS particles at 45 °C before annealing exhibit a well-defined narrow first peak followed by two small peaks (Fig. 9). The position of the first peak,  $q^*$ , corresponds to a characteristic distance of  $D^* = 2\pi(3/2)^{1/2}/q^* = 99 \text{ nm}$ , which is almost equal to the hydrodynamic diameter of the particles measured by dynamic light scattering. It is well-accepted that the drying of

**Fig. 7.** (a) Average relaxation time,  $\langle\tau(q)\rangle$ , plotted against  $q$  for blends of 77 nm dPS particles in 10% cross-linked PBMA matrix.  $\langle\tau(q)\rangle$  is calculated from the fit of the scattering intensities ( $I(q)$  vs. time) to a stretched exponential (Fig. 4). (b) Comparison of the plots  $\langle\tau(q)\rangle$  vs.  $q$  of the 77 nm (dPS-6) (■) and 30 nm dPS-1 (□) particles.  $\langle\tau(q)\rangle$  is calculated from the fit of the scattering intensities ( $I(q,t)$ ) to a stretched exponential.

**Fig. 8.** Relaxation time,  $\langle\tau(q)\rangle \cdot D$  plotted against  $q$  for 77 nm (dPS-6) (■) and 30 nm dPS-1 (□).  $\langle\tau(q)\rangle$  is calculated from the fit of the scattering intensities ( $I(q)$  vs. time) to a stretched exponential.

suspensions of monodispersed particles form a face centered cubic structure (FCC).<sup>25</sup> The contrast in the neutron scattering comes from the difference between the PS in the particles and the voids between them. The strong contrast in the SANS when the suspensions are dried below  $T_g$  infers that the particles remain spherical and separated with voids (Scheme 1, stage II).

#### Dynamic of void closure in 93 nm particles at the bulk $T_g$

When the PS samples are annealed at 100 °C both the first, second, and the third peaks decrease progressively and broaden during annealing (Fig. 9). After 30 min, the second peak disappears while the first peak turns into a broad maximum, and at 60 min both peaks have disappeared. The intensity measured at the first peak decreases steadily during annealing until it becomes purely the incoherent scattering from the PS (Fig. 10). The steady decrease of the intensity results from the progressive closure of the voids under the action of Laplace pressure. The scattering intensity varies as  $I(t) \propto (V_{\text{voids}}(t))^2$ , where  $V_{\text{voids}}$  is the volume of the voids between the particles. A random close-packed structure corresponds to a volume fraction of the solid of 0.64 and frac-

tion of the voids of 0.36.<sup>36</sup> Thus, the intensity can be written as  $I(t) \propto (V_{\text{voids}}(0))^2(0.36 - \varepsilon(t))^2$ , where  $\varepsilon(t)$  is the deformation strain of the sample and  $V_{\text{voids}}(0)$  is the initial volume of the voids or  $I(t)/I(0) \propto ((0.36 - \varepsilon(t))/(0.36 - \varepsilon(0)))^2$ .

Using a generalized Hertzian model<sup>37,38</sup> for the deformation of particles in a close-packed morphology, and assuming film shrinking occurs in the  $z$  direction, the governing equation can be written as eq. [3] when the deformation is averaged over all directions and over the entire film.<sup>36</sup>

$$[3] \quad \frac{6.69(1-\nu)\gamma_{p/a}}{R} = \int_0^t G(t-t') \frac{d\varepsilon^{3/2}}{dt'} dt'$$

where  $G(t)$  is time dependent shear stress,  $\gamma_{p/a}$  is the surface tension between the PS and air,  $\nu$  is the Poisson's ratio of polystyrene ( $\nu = 0.33$ ), and  $R$  is the particle radius.

Near  $T_g$  and for short times, the compliance of PS is dominated by the glassy relaxation process.<sup>47</sup> If we assume the PS in this condition to exhibit a single relaxation time,  $\tau(G(t)$  is an exponential), the  $t_{\text{close}}$  can be calculated from eq. [3] as the time for which  $\varepsilon(t_{\text{close}}) = 0.36$  to give eq. [4]:

$$[4] \quad t_{\text{close}} \approx \frac{0.0479 G}{\gamma_{p/a}} R \cdot \tau$$

where  $G$  is the high frequency shear stress ( $G \sim 1$  GPa) and  $R$  the particle radius. From eq. [4], we can estimate  $\tau \approx 37$  s for  $D = 93$  nm. When the relaxation time was calculated by numerically resolving eq. [3], using the strain  $\varepsilon(t)$  from  $I(t)/I(0) \propto ((0.36 - \varepsilon(t))/(0.36 - \varepsilon(0)))^2$  we found  $\tau \approx 44$  s. The polystyrene dynamic in the glassy regime near the  $T_g$  is more likely to be a stretched exponential ( $G(t) = \exp(-(t/\tau)^\beta)$ ) with an exponent  $\beta = 0.4$ .<sup>30,39</sup> In this case, we estimated the average relaxation time,  $\langle\tau\rangle$  ( $\langle\tau\rangle = \int \exp(-(t/\tau)^\beta) dt$ ), by numerically resolving eq. [3] with  $\varepsilon(t)$  from  $I(t)/I(0) \propto ((0.36 - \varepsilon(t))/(0.36 - \varepsilon(0)))^2$ , which leads to  $\langle\tau\rangle \approx 47$  s. This shows that the various methods for calculating the relaxation time yield similar values.

Contrary to the first method described here, this method gives an absolute value of the relaxation time of the confined polystyrene in nanoparticles. The evolution of  $\langle\tau\rangle$  with a change in temperature and particle size will be used

**Scheme 2.** The three main steps of the film formation process.**Fig. 9.** SANS spectra of film made from 93 nm PS nanoparticles, annealed at 100 °C for various annealing times: 0 (○), 20 (▲), and 60 min (▼).**Fig. 10.** SANS intensity at the first scattering peak,  $I_{\max}(t)$ , of 93 nm PS particles plotted against the annealing time.

in further work to obtain information on the effect of confinement on the polymer dynamic.

## Conclusion

We presented two methods to probe the dynamic of polymers in nanoparticles in two different environments: (i) nanoblends and (ii) close-packed structures. We use neutron scattering to probe the kinetic of nanoparticle deformation under the action of applied stress at the nanoscopic level. For the nanoblends, we prepared the samples by water evaporation of suspensions of glassy PS and elastic PBMA (cross-linked) nanoparticles at  $T_g^{\text{PBMA}} < T^{\text{ev}} < T_g^{\text{PS}}$ . This

leads to storage of elastic stress in the cross-linked PBMA particles around the PS. During annealing at  $T_{\text{annealing}} > T_g^{\text{PS}}$ , the PS particles deform, and this deformation is probed by SANS. The characteristic time from this method can be used to obtain information on the relaxation time of confined PS nanoparticles in nanoblends. In the close-packed structure, the voids between the spherical particles apply Laplace pressure to the particles, which deforms the particle and closes the voids. The kinetic of void closure is used to obtain information on the dynamic of confined PS in nanoparticles. These two methods give new possibilities to probe, in a nonintrusive manner, the dynamic of confined polymers in nanoparticles, which ultimately could bring conclusive insight in this field.

## Acknowledgment

We Acknowledge the Pakistani ministry of education, the Higher Education Commission (HEC) of Pakistani and the French Société Française d'Exportation des ressources Éducatives (SFERE) program for Mr. Nawaz's scholarship. We also thank the French ministry of education and the Cluster Matériaux et Conception pour un Développement durable (MACODEV) program for their financial support. The French neutron facility at the Commissariat à l'Énergie Atomique (CEA) Saclay and the Laboratoire Léon Brillouin (LLB) are gratefully acknowledged for the neutron equipment. We thank Dr. F. Boué (LLB) and Dr. A. Lapp (LLB) for their help in the neutron scattering experiments and for the stimulating discussions. H. Galliard is also acknowledged for her help with these experiments.

# Hybrid microspheres with alternating layers of a polymer and metal nanoparticles

Alla Petukhova, Andrew S. Paton, Ilya Gourevich, Selvakumar V. Nair, Harry E. Ruda, Alexander Shik, and Eugenia Kumacheva

**Abstract:** We studied the optical properties of hybrid multilayer microspheres (HMMs). We prepared multilayer particles with alternating radial layers of gold nanoparticles (NPs) and poly(methyl methacrylate) and achieved control over particle size, the thickness of particle layers, and the surface coverage of gold NPs. We showed the ability to tune the spectral characteristics of the HMMs, which was based on frequency dispersion of the dielectric constant of polymer–metal NP structures. Good agreement between experimental and theoretical extinction properties of the HMMs was obtained. In comparison with multilayer structures synthesized solely from polymers, hybrid multilayer microspheres have a larger refractive layer contrast between adjacent layers, which is important for practical applications in optoelectronic devices.

**Key words:** hybrid polymer–inorganic materials, polymer microspheres, gold nanoparticles, optical properties, extinction spectra.

**Résumé :** On a étudié les propriétés optiques de microsphères multicouches hybrides (MMH). On a préparé les particules à multicouches comportant des couches radiales alternantes de nanoparticules (NP) d'or et de poly(méthacrylate de méthyle) et on a pu contrôler la taille des particules des couches et la surface de la couverture des nanoparticules d'or. On a pu contrôler les caractéristiques spectrales des microsphères multicouches hybrides en ajustant la fréquence de dispersion de la constante de diélectrique des structures des nanoparticules polymère–métal. On a obtenu un bon accord entre les propriétés d'extinction expérimentales et théoriques des microsphères multicouches hybrides. Par comparaison avec les structures multicouches synthétisées uniquement à partir de polymères, les microsphères multicouches hybrides possèdent un plus grand contraste de réfraction par couche entre les couches, propriété importante pour les applications pratiques dans les appareils optoélectroniques.

**Mots-clés :** matériaux hybrides polymère–inorganique, microsphères de polymère, nanoparticules d'or, propriétés optiques, spectres d'extinction.

## Introduction

Polymer microspheres with a multilayer onion-like structure possess optical properties that are useful in photonic crystals,<sup>1,2</sup> optical data storage,<sup>3,4</sup> biometrics,<sup>5,6</sup> and, sensing and single-particle optical limiting.<sup>7–10</sup> Polymer multilayer particles with a radial modulation in the refractive index can also be used as optical-frequency resonators: due to Bragg reflection at the interfaces between the layers, light propagation in the particles at a given wavelength can be suppressed when reflection from the interfaces adds in phase and approaches unity.<sup>11</sup> For this application, the advantage of using polymer multilayer microspheres is their narrow size distribution and precisely controlled thickness of constituent layers, achieved in multistep polymerization proc-

esses.<sup>12,13</sup> The drawback of all-polymer particles is an inherent low refractive index contrast,  $\Delta n$ , between the layers, which requires a large number of layers to be incorporated in the multilayer structure, to achieve suppressed light propagation.<sup>11,14</sup> Fabrication of such multilayer structures, with specific properties of the layers, represents a cumbersome technological procedure. One of the promising approaches to such particles relies on an increase in the refractive index contrast between adjacent layers.

In the present work, this problem is solved by replacing all-polymer multilayer structures with metal–polymer, hybrid multilayer microspheres (HMMs). We synthesized and assembled multilayer particles with alternating layers of gold nanoparticles (NPs) and poly(methyl methacrylate)

(PMMA). The use of layers of NPs (versus homogeneous gold layers) provided the ability to maintain a well-defined wavelength of absorption of the hybrid structures, in comparison with a red-shifted plasmonic resonance peak characteristic for dielectric particles with continuous gold shells.<sup>15</sup> In addition, a strong frequency dispersion of the dielectric constant of polymer-metal NP structures provided the ability to tune the spectral characteristics of the HMMs. We achieved control over particle size, the thickness of particle layers, and the surface density of gold NPs. Experimentally measured and theoretically predicted extinction properties of the HMMs were in good agreement.

## Experimental

### Materials

Methyl methacrylate (99%) was purchased from Fluka Canada. Ethylene glycol dimethacrylate (EGDMA, 98%), 4-vinylpyridine (4VP, 95%), 2,2'-azobis(2-methylpropionamide) dihydrochloride (V-50, 97%), poly(diallyldimethylammonium chloride) (PDDMAC, low molecular weight, 20 wt% in water), poly(sodium 4-styrenesulfonate) (PSS, average  $M_w \approx 70\,000$ ), hydrogen tetrachloroaurate(III) ( $\text{HAuCl}_4$ , 30 wt% solution in dilute hydrochloric acid, 99.99%), tetrakis(hydroxymethyl) phosphonium chloride (THPC, 80% solution in  $\text{H}_2\text{O}$ ) were purchased from Sigma-Aldrich Canada. All chemicals were used as received. Deionized water (18.2 M $\Omega$  cm) was purified by using a Millipore Milli-Q Plus purification system (Millipore Corp.).

### Synthesis of hybrid multilayer microspheres

#### Preparation of gold NPs

Negatively charged gold NPs were prepared by the reduction of tetrachloroauric acid with tetrakis(hydroxymethyl)phosphonium chloride, which was adapted from a method described elsewhere.<sup>16</sup> Briefly, to a vessel (e.g., a 125 mL erlenmeyer flask) containing 96 mL of deionized water, aqueous solutions of sodium hydroxide (1 mol/L, 1.0 mL) and the reducing agent THPC (1.29% w/w in water, 1.5 mL) were added under stirring. There were 4 min allowed between the addition of THPC and tetrachloroauric acid, and then  $\text{HAuCl}_4$  (28 mmol/L, 1 mL) was injected rapidly into the stirring solution. The color of the solution changed to dark brown, indicating the formation of small gold NPs. The NPs were aged for two weeks before the attachment to polymer particles.

#### Synthesis of hybrid multilayer microspheres

The procedure of the synthesis of HMMs is shown schematically in Fig. 1. The latex particles were prepared using a surfactant-free emulsion polymerization procedure described elsewhere.<sup>12,14</sup> All reactions were carried out under nitrogen pressure in a double-walled three-neck flask equipped with a reflux condenser, a nitrogen inlet, and a mechanical stirrer at  $80 \pm 0.1^\circ\text{C}$ .

#### Step 1 — Synthesis of the polymer core

Positively charged 120 nm PMMA-co-P4VP particles (microspheres cores) were synthesized in a batch reaction. The reactor was charged with water (100 g) and mixture of methyl methacrylate (1.5 g), 4-vinylpyridine (0.015 g), and

**Fig. 1.** Schematics of the preparation of hybrid multilayer microspheres (HMMs) (see text).

the cross-linking agent EGDMA (0.015 g) and purged with nitrogen for 30 min. The temperature of the mixture was then increased to  $80 \pm 0.1^\circ\text{C}$ . An aqueous solution of V-50 (0.05 g) was injected into the reactor with a syringe. The reaction was carried out for 3 h. After the 30 min centrifugation cycle at 10 000 rpm (Eppendorf centrifuge 5417R), the supernatant was removed, the precipitated particles were redispersed in deionized water and sonicated for 2–3 min.

#### Step 2 — Attachment of gold NPs to PMMA-co-P4VP polymer particles

To achieve 30% surface coverage of the surface of polymer microspheres with gold NPs, 35 g of the solution of gold NPs were added at pH = 6.0 to 4 g of the dispersion of latex particles synthesized in Step 1 under vigorous stirring for 1 h. The system was then centrifuged at 8000 rpm for 30 min, the sediment was removed and diluted with water up to 50 mL and sonicated for 40 min. To achieve surface coverage lower than 30%, the solution of gold NPs was mixed with PSS with the concentration in the range of 0.01–0.001 wt% and this mixed solution was added to the dispersion of polymer particles, as described above.

#### Step 3 — Adsorption of PDDMAC

An aqueous solution of the cationic polyelectrolyte, PDDMAC (100 mL, 0.1%), was added dropwise at a rate 20 mL/h to the aqueous solution of hybrid microspheres from Step 2 using a fluid-metering pump. Excess PDDMAC was removed by centrifugation of the particles at 10 000 rpm for 30 min. The supernatant was removed and the precipitated particles were redispersed in deionized water and sonicated for 1 h.

#### Step 4 — Synthesis of the PMMA layer on the surface of hybrid particles

The PMMA layer on the surface of hybrid particles was prepared by using a multistage surfactant-free emulsion polymerization method.<sup>12,14</sup> The dispersion of hybrid microspheres (150 g) from Step 3 and water (10 g) were charged in the reaction flask and methyl methacrylate (1 g), EGDMA (0.01 g), and an aqueous solution of V-50 (0.05 g) were introduced using a syringe pump at a rate of 0.144 mL/h. The system was heated to  $80^\circ\text{C}$ , and the polymerization reaction was continued for 1 h after the feeding stage was complete. The latex was purified by centrifugation at 8000 rpm for 30 min, the supernatant was removed, and

the precipitated particles were redispersed in deionized water (100 g) and then sonicated for 2–3 min.

#### Step 5 — Synthesis of the PMMA-co-P4VP layer on the surface of hybrid particles

The synthesis of the PMMA-co-P4VP layer on the surface of hybrid particles was conducted in the same manner as in Step 4. Briefly, after mixing an aqueous solution of hybrid microspheres (70 g) from Step 4 and water (60 g) in the reaction flask, methyl methacrylate (2.5 g), EGDMA (0.025 g), 4-vinylpyridine (0.025 g), and an aqueous solution of V-50 (0.025 g) were introduced into the flask using a syringe pump at a rate of 0.4 mL/h. The system was heated to 80 °C, and the polymerization reaction was continued for 1 h. The centrifugation/redispersion step was repeated as in Step 4.

#### Steps 6–8 — Synthesis of alternating layers of gold and PMMA-co-P4VP layers

The synthesis of alternating layers of gold and PMMA-co-P4VP layers was conducted as in Steps 2–4.

### Characterization of hybrid multilayer microspheres

#### Characterization of particle size, shape, and morphology

Scanning electron microscopy (SEM) imaging was performed on a Hitachi S-5200 microscope operating at an accelerating voltage of 1.0 kV and a current of 10 mA. A drop of dilute latex dispersion was dried on a carbon-coated copper transmission electron microscopy (TEM) grid. Scanning transmission electron microscopy (STEM) was carried out on Hitachi HD-2000 microscope using a high angle annular dark field imaging (HAADF-STEM) detector and operating at an acceleration voltage of 200.0 kV and a current of 40 mA. Prior to the STEM imaging, the microspheres were microtomed with a diamond knife using Leica Ultracut UCT microtome by embedding microbeads in the epoxy resin (5 min epoxy resin 12 Lepage, Henkel Canada Corporation). The 20 nm slices were then placed onto a carbon-coated copper TEM grid.

Particle size was determined by analyzing SEM images using the Image Tool software (University of Texas, Health Science Centre). The error of image analysis was  $\pm 1\%$ . The size distribution of the particles was characterized by the coefficient of variation as  $CV (\%) = (\sigma/D_m) \times 100$ , where  $D_m$  is the mean diameter of the particles and  $\sigma$  is the standard deviation of the particle diameter.

#### Characterization of the extinction properties of HMMs

The extinction spectra of the hybrid multilayer microspheres were recorded with a Varian UV-vis-NIR Cary 5000 spectrophotometer using water as the reference. Prior to the measurements, we ensured that the samples were sufficiently dilute to avoid multiple scattering. The extinction intensity was normalized by the path length of light (equal to 1 cm) and the concentration of particles (which was determined as the number of particles per unit volume). Typically, the concentration of particles varied in the range of  $10^7$  particles/mL (Step 8) to  $10^{10}$  particles/mL (Steps 1–3).

**Fig. 3.** DF-TEM images of (a) the PMMA particles synthesized in Step 1 and PMMA particles coated with (b) 5%, (c) 20%, and (d) 30% of gold NPs (Step 2), using the competition between electrostatically driven attraction of gold NPs and PDDMAC to the PMMA particles. The scale bar is 100 nm.

## Results and discussion

### Synthesis of hybrid microspheres

Figure 1 shows the schematic of the preparation of HMMs with a PMMA core, two alternating layers of gold NPs, and two alternating layers of PMMA. In Step 1, cationic 120 nm diameter latex microspheres were synthesized by emulsion polymerization by copolymerizing methyl methacrylate with 1 wt% of vinyl 4-pyridine (4VP) in the presence of a cationic water-soluble initiator, 2,2'-azo-bis(2-methylpropionamide) dihydrochloride (V-50). The negatively charged  $4 \pm 1$  nm diameter gold NPs stabilized with tetrakis (hydroxymethyl)phosphonium chloride were prepared using a method described elsewhere.<sup>16</sup> Using electrostatically mediated attraction between the anionic NPs and cationic microspheres, the NPs were deposited at pH = 6 on the surface of the latex particles (Fig. 1, Step 2). We stress that copolymerization of methyl methacrylate with a small amount of 4VP was critical to ensure the dense surface coverage and the uniform distribution of the gold NPs on the surface of the microspheres. Figure 2 shows that the positive charge of the latex particles originating solely from the use of the cationic initiator did not result in the dense attachment of gold NP to the particle surface.

Control of the fraction of the polymer surface covered

**Fig. 4.** Dark-field TEM images of HMMs synthesized in (a) Step 4, (b) Step 5, (c) Step 6, and (d) Step 8. Cross-sections of HMMs are shown in (e). Polymer and gold NPs appear dark and bright, respectively. The scale bar is 300 nm.

with gold NPs was achieved by depositing gold NPs on the microspheres in the presence of the anionic polyelectrolyte poly(sodium 4-styrenesulfonate), that is, by using the competition between the adsorption of gold NPs and the polyelectrolyte onto the cationic latex microspheres. When the relative concentration of poly(sodium 4-styrenesulfonate) in the solution of gold NPs changed from 0.01 to 0 wt%, the fraction of the surface of latex microspheres coated with gold NPs increased from 5% to 30%, as determined by the analysis of dark-field transmission electron microscopy images (DF-TEM) of the surface of HMMs (Fig. 3). In Steps 3–8 (Fig. 1) we used PMMA-*co*-P4VP particles with the highest (30%) surface coverage with gold NPs (later in the text, for simplicity, we will refer to these particles as PMMA particles). A cationic polymer poly(diallyldimethyl ammonium chloride) (PDDMAC) was adsorbed onto the polymer particles coated with gold NPs, to minimize the desorption of the NPs from the surface of microspheres in subsequent polymerization reactions. The PDDMAC-coated PMMA microspheres were used as seeds for the starve-fed interfacial polymerization of an outer polymer layer with thicknesses varying from 40 to 100 nm (Fig. 1, Steps 4 and 5, respectively).

To synthesize HMMs with two alternating layers of gold NP and two alternating polymer layers, the procedures of competitive adsorption of gold NPs and PDDMAC and interfacial copolymerization of methyl methacrylate and 4VP were repeated in Steps 6–8 (Fig. 1). The morphology of the microspheres and the presence and location of gold NPs in the HMMs were verified using DF-TEM. Figure 4 shows typical DF-TEM images of the hybrid microspheres produced in Steps 4–6 and Step 8. The multistep synthesis

yielded highly monodisperse HMMs with the alternating radial layers of gold NPs and PMMA-*co*-P4VP, as conceptualized and rationalized in Fig. 1. No evidence of aggregation in the system was observed. Gold NPs placed on the polymer surface were not desorbed in consecutive polymerization steps. Instead, they formed well-defined thin concentric layers. The characteristics of the HMMs such as the diameters and polydispersity of the HMMs and the thicknesses of the polymer and NP layers, all determined by the analysis of the SEM images, are provided in Table 1. We note that to examine the role of the thickness of polymer layers on the optical properties of HMMs, polymerizations in Steps 4 and 5 were carried out to produce the polymer layer with the same composition but with a different thickness.

### Optical properties of hybrid microspheres

Optical properties of the HMMs were examined experimentally and theoretically. Theoretical calculations of the extinction spectra required the knowledge of the effective dielectric constant of the layers of gold NPs placed between the concentric polymer layers or localized at the water–polymer interface (e.g., for the HMMs produced in Steps 2 and 6). Following the procedure described in Appendix A, we obtained the polarizabilities of a gold NP placed at the PMMA–water interface. The calculated polarizabilities,  $\alpha_{\parallel}$  and  $\alpha_{\perp}$ , for the electric field oriented parallel and perpendicular to the interface of a 2 nm diameter gold NP are shown in Fig. 5. Due to anisotropy induced by the interface, the surface plasmon resonance was different for perpendicular and parallel polarizations.

Using the polarizability data we then computed the effective dielectric constant of the composite monolayer of gold NPs using the effective medium model described in Appendix A. For PMMA and water we used reported values of the dielectric constant.<sup>17</sup> Once the dielectric constants of each material constituting the HMMs were determined, the extinction spectra were calculated using an extension of Mie scattering theory to include the radial anisotropy of the dielectric constant of the gold NP layer. The calculated extinction spectra for the structures generated in Step 2 for the different coverage of the PMMA surface with gold NPs are shown as dashed lines in Fig. 6. Experimentally measured extinction spectra are also shown in Fig. 6 as solid lines. The results presented in Fig. 6 show that the magnitude of extinction of HMMs increased with increasing surface coverage of the PMMA particles with gold NPs. A very good agreement between the theoretical and experimental results was obtained for the spectral position of the plasmonic peaks, however, the magnitude of the plasmonic peak was higher in the theoretical spectra. This is most likely due to the approximations in our effective medium theory, which is strictly valid only for dilute composites. In fact, in three-dimensional metal–dielectric composites such effective medium theories are known to overestimate the surface plasmon resonance.<sup>18</sup>

Furthermore, for the 30% coverage of the polymer surface with gold NPs we studied the evolution of the extinction spectra of HMMs by adding new polymer and NP layers (Fig. 1, Steps 3–8) and compared the results of calculations

**Table 1.** Mean diameter,  $D_m$ , coefficient of variation, CV, thickness of layers,  $\delta$ , and types of layers in HMMs.

Step numbers (as in Fig. 1)	1	2	4	5	6	8

Layer	—	Gold NPs	Polymer	Polymer	Gold NPs	Polymer
Thickness of the layer, $\delta$ (nm)	—	4–5	40	100	4–5	55
Coefficient of variation, CV (%)	3	3	3.3	2.8	2.8	2.65

**Fig. 5.** The real and imaginary parts of the polarizability,  $\alpha$ , of a spherical gold NP of radius  $a$  embedded in PMMA at an interface with water for polarization parallel (solid lines) and perpendicular (dashed lines) to the interface. The polarizability is shown scaled by  $a^3$ . The inset shows a schematic of the geometry.

and experiments. Figure 7 shows the following features: First, reasonably good agreement was achieved between the experimental and theoretical extinction spectra. Engulfment of the layer of gold NPs with the polymer layer (Step 2  $\rightarrow$  Step 4) resulted in a red-shift of the plasmon peak from 522 to 550 nm, which was caused by the dependence of the plasmon wavelength on the dielectric environment. The difference in the values of  $\epsilon$  of PMMA and water yielded the 5% shift in the position of plasmon maximum, in agreement with experimental results shown in Fig. 7. Further increase in the thickness of the polymer layer (Step 4  $\rightarrow$  Step 5) did not affect the dielectric environment around the NPs and the position of the plasmonic maximum did not change. The magnitude of the plasmon band increased for the HMMs synthesized in Step 6 and decreased in Step 8. Both of these changes were supported by theory. The experimentally measured and calculated positions of plasmon bands were also in reasonably good agreement.

**Fig. 6.** Comparison of experimental and calculated (solid and dashed lines, respectively) extinction spectra of HMMs dispersed in water for the polymer core (Fig. 1, Step 1) with different surface coverages of gold NPs (Fig. 1, Step 2): (A) 5%, (B) 20%, (C) 30%. The experimental spectra are normalized by the path length (1 cm) and the concentration of particles (the number of particles per unit volume).**Fig. 7.** Comparison of experimental and calculated (solid and dashed lines, respectively) extinction spectra of HMMs dispersed in water for Steps 2, 4, 6, and 8 in Fig. 1. The experimental spectra were normalized by the path length (1 cm) and the concentration of particles (the number of particles per unit volume). For clarity of presentation the data for Step 6 and Step 8 are scaled up by a factor of 100.

## Conclusion

To summarize, we conceptualized and synthesized hybrid multilayer polymer–inorganic microspheres comprising alternating concentric layers of a polymer and gold nanoparticles. The microspheres had a narrow size distribution and the thickness of the radial layers was well-defined. We experimentally characterized the extinction properties of the hybrid multilayer microspheres and compared the experimentally acquired spectra with the theoretical spectra calculated using a generalized classical Clausius–Mossotti (CM) theory. Good agreement was achieved between the experimental and theoretical results.

We emphasize that even in the HMMs with a single or two metal NP layers, the larger refraction index contrast results in noticeable changes in the extinction spectra, compared to all-polymer structures with similar size and number of layers.<sup>12c</sup> This makes the described hybrid multilayer microspheres promising objects for spherical resonators and other optoelectronic devices. For example, when combined with luminescent semiconductor quantum dots,<sup>12c</sup> they have the potential to be used as both passive and active types of devices.

## Appendix A

We used a generalized classical Clausius–Mossotti (CM) theory to construct a model for the effective dielectric constant,  $\varepsilon_{\text{eff}}$ , of a monolayer of spherical NPs at an interface between two different dielectrics. We first consider a single particle of radius  $a$  and dielectric constant,  $\varepsilon_i$ , localized in a medium of the dielectric constant  $\varepsilon_b$  just above the interface with a substrate having the dielectric constant  $\varepsilon_s$ . The value of  $a$  is sufficiently small compared to the wavelength of light that the polarizability of the NP can be obtained from the quasistatic model by calculating the dipole moment induced in the NP by an applied electric field.

The induced dipole moment can be calculated by solving the Laplace equation for the situations when the electric field is either parallel or perpendicular to the interface. We used an analytical solution using bispherical coordinates.<sup>A1,A2</sup> Since the final expressions are cumbersome, we present the polarizability of NPs in the asymmetric system (the gold NPs localized at the interface of PMMA and water) in the numerical form.

We used the reported or experimentally measured values of the dielectric constant of water, PMMA,<sup>A3a</sup> and gold.<sup>A3b</sup> In the latter case, we corrected the experimental data to account for increased momentum relaxation due to the surface scattering as follows: We first fitted the experimentally measured dielectric constant of gold ( $\varepsilon_{\text{expt}}$ )<sup>A3b</sup> in the long-wavelength region to the Drude model and extracted the plasma frequency ( $\omega_p$ ) and relaxation time ( $\tau$ ). This fitting provided the values of  $\hbar\omega_p = 8.98$  eV and  $\hbar/\tau = 75$  meV. The value of  $\varepsilon_i$  of the NPs was then calculated as

$$[A1] \quad \varepsilon_i = \varepsilon_{\text{expt}} + \frac{\omega_p^2}{\omega(\omega - i/\tau)} - \frac{\omega_p^2}{\omega(\omega - i/\tau - i\eta v_F/a)}$$

where  $v_F$  is the Fermi velocity of bulk gold equal to

$1.57 \times 10^8$  cm/s and  $\eta$  is an adjustable parameter of the order 1. The calculated polarizability is shown in Fig. 5. We note that for gold NPs in a uniform background such as PMMA, the polarizability may be calculated using the well-known expression for the spherical particles in a dielectric medium.<sup>A4</sup>

In the next step, the CM theory was applied to the calculation of the effective dielectric constant  $\varepsilon_{\text{eff}}$  of a monolayer of NPs with surface density  $n$ . In terms of symmetry,  $\varepsilon_{\text{eff}}$  is a uniaxial tensor with the components  $\varepsilon_{\text{eff}}^{\perp}$  and  $\varepsilon_{\text{eff}}^{\parallel}$ , which had to be found separately for the applied electric field,  $E_0$ , perpendicular and parallel to the interface. The NPs were treated as point dipoles with a dipole moment,  $\alpha^{\perp\parallel}E_{\text{loc}}$ , where  $E_{\text{loc}}$  is the local electric field at the NP location.

### Perpendicular polarization

The effective dielectric constant of the NP layer,  $\varepsilon_{\text{eff}}^{\perp}$ , was determined by the ratio between the average polarization and the macroscopic electric field,  $E$ , inside the layer. To calculate  $E$ , the induced dipoles were treated as a two-dimensional dipole layer with the dipole density  $D = n\alpha^{\perp}E_{\text{loc}}$  and the thickness  $t$ , so that<sup>A4</sup>

$$[A2] \quad E = E_0 - \frac{4\pi n\alpha^{\perp}E_{\text{loc}}}{t}$$

The local field,  $E_{\text{loc}}$ , was calculated as the sum of the applied field and the field induced by the dipoles as

$$[A3] \quad E_{\text{loc}} = E_0 - \sum_n' \mu/r_n^3$$

where the sum is taken over all dipoles, except the one at the origin, where the local field is being computed,  $r_n$  is the distance from the origin and  $\mu = \alpha^{\perp}E_{\text{loc}}$  is the dipole moment of the  $n$ th dipole. The exact sum over dipoles depends on their microscopic arrangement but its ensemble average scales as  $\mu n^{3/2}\xi$ . The numerical constant,  $\xi$ , is weakly dependent on geometry and is 8.8927 or 9.0336 for the hexagonal or square lattices, respectively.<sup>A5</sup> For the random arrangement of NPs described in the present work, we used  $\xi = 9$ . By eliminating  $E_0$  from eqs. [A2] and [A3], we obtained the average local field

$$[A4] \quad \langle E_{\text{loc}} \rangle = \frac{E}{1 + n^{3/2}\alpha_{\perp}\xi - 4\pi n\alpha_{\perp}/t}$$

and obtained

$$[A5] \quad \varepsilon_{\text{eff}}^{\perp} = \varepsilon_b \left( 1 + \frac{4\pi n\alpha_{\perp}/t}{1 + n^{3/2}\alpha_{\perp}\xi - 4\pi n\alpha_{\perp}/t} \right)$$

### Parallel polarization

In this case, all the dipoles are oriented in the plane of the layer and the macroscopic field is equal to the applied field and

$$[A6] \quad E_{\text{loc}} = E_0 + \sum_n' \mu/2r_n^3$$

so that the effective dielectric constant is given by

$$[A7] \quad \varepsilon_{\text{eff}}^{\parallel} = \varepsilon_b \left( 1 + \frac{4\pi n\alpha_{\parallel}/t}{1 - n^{3/2}\alpha_{\parallel}\xi/2} \right)$$

In the calculations presented above, we assumed that  $t = 2a$ . Since the polarizability of spherical particles is proportional to  $a^3$ , the value of  $\varepsilon_{\text{eff}}$  depends on the geometrical parameters only through the NP area fraction,  $f = \pi a^2 n$ .

## TRIBUTE

### A tribute to Mitch Winnik

Mitch Winnik was born in Milwaukee Wisconsin in 1943. He received his B.A. degree in Chemistry from Yale University in 1965. He carried out his doctoral research under the guidance of Professor Ronald Breslow at Columbia University and received his Ph.D. in organic chemistry in 1969. After postdoctoral studies with Professor George Hammond at the California Institute of Technology, he joined the faculty at the University of Toronto in September 1970 as an organic chemist. In those early days, he saw himself as a physical organic chemist and carried out research in the area of reaction mechanisms. He had a particular interest in intramolecular photochemical reactions of conformationally flexible molecules. Most of these experiments involved measurements of phosphorescence in solution of various benzophenone derivatives. Based on this work, he was promoted to Associate Professor with tenure in 1975. Two years later, while on a sabbatical in France, he met at a conference Walter Stockmayer, who persuaded him that his scientific life would be much richer if he would study similar processes in longer molecules. When he returned to Toronto in 1978, he and his postdoc Tony Redpath began a study of polymer cyclization in solution based upon time-resolved fluorescence measurements of excimer formation of pyrene attached to the chain ends. This turned out to be an enormously rich area of study, since it coincided with blossoming theoretical advances in the description of polymer conformation and dynamics in solution and new techniques to study those processes. It began Mitch's transformation from an organic chemist to a polymer chemist, and pyrene had now replaced benzophenone as his favourite luminescent chromophore.

In the early 1980s, Mitch began working with Mel Croucher at the Xerox Research Centre of Canada on polymer microparticles synthesized by dispersion polymerization. This interaction opened his eyes to the world of polymer materials, taught him about how to interact with scientists in industry, and led to the development of new techniques based upon fluorescence measurements for characterizing polymer morphology. Toward the end of the 1980s, a number of very exciting developments occurred in the Winnik research group. Jose Martinho joined his group and made major contributions to the study of diffusion-controlled reactions. Two key co-workers joined the group at this time, Cheng Le Zhao and Yongcai Wang. They pioneered efforts to apply fluorescence as a tool to study hydrophobically-modified polymers in water, work encouraged by David Bassett at Union Carbide because these polymers were important rheology modifiers for coatings. They also pioneered the Winnik group foray into the study of latex films, in which they developed techniques based upon fluorescence resonance energy transfer (FRET) to study the diffusion of polymer molecules across the boundaries between adjacent latex polymer nanoparticles as they pack in the film upon drying. This is the step that leads to the build-up of useful mechanical properties in the film. This work was initiated with support from ICI Paints and has continued for more than a decade in collaboration with scientists in many companies in the coatings field: ICI, Dow, Union Carbide, 3M, BASF, Air Products, Cytec, Johnson Polymers, and most recently, with Willie Lau at Rohm and Haas. This work has been widely recognized, for example by four First Place Roon awards (1991, 1995, 1998, and 2007) for the top publication in the coating

field, by an American Chemical Society Tess Award (1999), and by the Mattiello lecture award (2001) given by the Federation of Societies for Coatings Technology. These awards recognize that advances in fundamental science can also have an important impact on technology.

In the early 1990s, Ahmad Yekta and Jean Duhamel helped transform the Winnik group in a different direction. They recognized that data from FRET experiments carried out on dyes confined to nanometre-size domains could be interpreted to provide information about the size and shape of those domains. They brought a high level of mathematical rigour to these experiments. This in turn allowed a much deeper richness of information to be obtained from many studies in the Winnik group, on water-soluble polymers, on block copolymer micelles in solution, and on polymer diffusion in latex films. It also opened the possibility to study interfaces where polymers of different compositions meet. These interfaces have widths of only a few nanometers, larger than monomer units and smaller than polymer molecules, domain sizes that could be determined using the concept of energy transfer in restricted dimensions.

A collaboration with Ian Manners on micelles formed by polyferrocenylsilane (PFS) block copolymers began in the late 1990s with the co-supervision of Jason Massey's Ph.D. research. This system is surprisingly rich, with many unexpected discoveries. For example, this seems to be the only known block copolymer that forms fiber-like micelles by a mechanism similar to that of proteins, for example amyloid fibers. Many co-workers made critical contributions here. Several who stand out include Yahya Rharbi, who suggested that the PFS core might be crystalline, Xiaosong Wang, who discovered living self-assembly, Gerald Guerin, who contributed light scattering prowess, and Hai Wang who demonstrated that these nanofibres could serve as templates for the formation of arrays of metal nanoparticles.

A recent turning point in the Winnik group research interests began in 2005 when Mitch was invited to join a project in collaboration with Vladimir Baranov, Olga Ornatsky, and Mark Nitz, based upon the use of inductively coupled mass spectrometry (ICP-MS) for highly multiplexed bioassays. The idea is to use different (lanthanide) metal isotopes as labels to attach to antibodies, in much the same way that others attach fluorescent dyes. The initial focus was on phenotyping human leukemia cells. The Winnik group was asked to synthesize metal chelating polymers to carry many copies of a given metal or single isotope (like  $^{153}\text{Eu}$ ) so that each antibody would carry about 100 metal ions. The long term objective is to be able to measure quantitatively as few as 100 copies of a particular biomolecule in an individual cell. Recent experiments using the new technique of mass cytometry can detect and quantify more than 20 biomarkers cell-by-cell in a single assay.

Over the years, Mitch has been a Visiting Professor at the Université de Bordeaux (1977–1978), a world Trade Scholar at IBM (1982), a JSPS Fellow at the Tokyo Institute of Technology (1985–1986), an Alexander von Humboldt Fellow at the Max Planck Institute for Polymer Science (1996) in Mainz, Germany, and the holder of La Chaire de Paris-Sciences at l'Ecole Supérieure de Physique et Chimie Industrielle (2000) in Paris, France.

Mitch has received numerous awards including the CIC

Award in Polymer Science (1993), the Bell-Canada Forum Award for University-Industry interactions (1995), an Alexander von Humboldt Senior Scientist Award (1996), and the CIC Medal (2004). He was elected a Fellow of the Royal Society of Canada (1996) and of the Polymer and Material Sciences division of the American Chemical Society (2002). In 2006, he was listed as one of the most cited authors in chemistry by the ISI Web of Science. His 550+ publications have been cited more than 14 000 times ( $h^* = 57$ ). At the University of Toronto, he

holds the title University Professor, the University's highest award in recognition of academic excellence.

The number and quality of the papers submitted to this dedicated issue of the *Canadian Journal of Chemistry* attests to the breadth and reach of his influence in the chemistry and polymer science communities.

**Jean Duhamel**

## HOMMAGE

### Hommage à Mitch Winnik

Mitch Winnik est né à Milwaukee, au Wisconsin, en 1943. Il obtient son baccalauréat en chimie de l'Université Yale en 1965. Il poursuit ses études au programme de doctorat sous la direction du professeur Ronald Breslow de l'Université Columbia et reçoit son doctorat en chimie organique en 1969. Après ses études postdoctorales sous la supervision du professeur George Hammond au California Institute of Technology, il joint la faculté de l'Université de Toronto en septembre 1970 à titre d'organicien ou chimiste spécialiste de la chimie organique. À cette époque, il se voit plutôt comme spécialiste de la chimie organique physique et mène des travaux de recherche sur les mécanismes réactionnels, plus particulièrement sur les réactions photochimiques intramoléculaires des molécules présentant une mobilité conformationnelle. La plupart de ces expériences portent sur les mesures de phosphorescence de différents dérivés de la benzophénone en solution. De par ces travaux, il est nommé professeur agrégé permanent en 1975. Deux ans plus tard, alors qu'il est en congé sabbatique en France, il fait la rencontre, à l'occasion d'un congrès, de Walter Stockmayer qui le convainc que sa carrière scientifique serait d'autant plus riche s'il réorientait ses recherches sur les processus similaires dans des molécules plus longues. Dès son retour à Toronto, il entreprend en 1978, avec le concours de son étudiant postdoctoral Tony Redpath, une étude de la cyclisation des polymères en solution; étude qui repose sur des analyses de fluorescence – en temps résolu – de la formation d'excimères du pyrène attaché aux extrémités de la chaîne. Ce domaine d'étude s'avère extrêmement fertile en raison de l'effervescence concomitante d'avancées théoriques dans la description de la conformation et de la dynamique des polymères, et des nouvelles méthodes pour étudier ces processus. C'est ainsi que Mitch délaisse le domaine de la chimie organique au profit de la chimie des polymères, et la benzophénone cède la place au pyrène à titre de chromophore luminescent de prédilection.

Au début des années 1980, Mitch collabore avec Mel Croucher du Centre canadien de recherche Xerox sur la recherche des microparticules de polymères synthétisées par voie de polymérisation par dispersion. Pour lui, cette collaboration est plus qu'une ouverture sur le monde des matériaux polymères. En effet, elle donne lieu à des échanges privilégiés avec les scientifiques de l'industrie et à l'élaboration de nouvelles techniques axées sur les mesures de fluorescence pour la caractérisation de la morphologie des polymères. La fin des années 1980 est marquée par un nombre de changements très importants au sein du groupe de recherche de Winnik. En effet, Jose Martinho se joint au groupe et apporte des contributions majeures à l'étude de réactions contrôlées par la diffusion. De plus, Cheng Le Zhao et Yongcai Wang, deux autres contributeurs clés, se joignent alors au groupe. Ces chercheurs font œuvre de précurseurs en utilisant la fluorescence comme outil dans l'étude des polymères modifiés d'une façon hydrophobe dans l'eau; travail appuyé par David Bassett d'Union Carbide, car ces polymères sont d'importants modificateurs rhéologiques des revêtements. Cheng Le Zhao et Yongcai Wang sont également responsables de l'incursion du groupe de Winnik dans l'analyse des pellicules de latex, ce qui lui permet d'élaborer des techniques de transfert d'énergie par fluorescence de résonance (FRET) pour étudier la diffusion des molécules polymères transfrontalière entre les nano-

particules de latex polymères adjacentes durant leur agglomération en pellicule à l'assèchement. Cette étape mène ensuite à la découverte d'un assortiment de propriétés mécaniques pratiques pour les pellicules. Amorcé avec l'appui d'ICI Paints, ce travail se poursuit pendant plus de 10 ans en collaboration avec les chercheurs de l'industrie, y compris ICI, Dow, Union Carbide, 3M, BASF, Air Products, Cytec, Johnson Polymers, et plus récemment, avec Willie Lau de Rohm and Haas. Les efforts du groupe sont universellement reconnus et primés, comme en témoignent les quatre premières places du prix Roon (1991, 1995, 1998 et 2007) pour la meilleure publication dans le domaine des revêtements, le prix Tess de l'American Chemical Society (1999) et le prix de conférence Mattiello (2001) de la Federation of Societies for Coatings Technology. Ces prix reconnaissent non seulement l'importance des progrès en sciences fondamentales, mais aussi leurs répercussions sur les technologies.

Au début des 1990, Ahmad Yekta et Jean Duhamel insufflent une nouvelle orientation au groupe de Winnik en montrant que les données issues d'expériences par FRET sur des colorants confinés à des domaines de tailles nanométriques pouvaient être interprétées pour fournir des renseignements sur la taille et la forme de ces domaines. Ils inculquent une rigueur mathématique de haut niveau à ces travaux de recherche, ce qui se traduit par une plus grande richesse d'information pour bon nombre d'études réalisées par le groupe de Winnik, y compris les études sur les polymères hydrosolubles, sur les micelles de copolymères séquencés en solution et sur la diffusion des polymères dans les pellicules de latex. Par ailleurs, elle ouvre la voie aux études des interfaces où les polymères de composition variée interagissent. De l'ordre de quelques nanomètres, ces interfaces, qui ont une taille supérieure aux unités de monomères, mais inférieure aux molécules polymères, présentent des tailles de domaine pouvant être déterminées à l'aide du concept de transfert d'énergie dans des dimensions restreintes.

Alors qu'il participe à la supervision des travaux de recherche doctorale de Jason Massey à la fin des années 1990, il établit une collaboration avec Ian Manners sur l'étude des micelles de copolymères séquencés formées par le polyferrocénylsilane (PFS). Ces travaux s'avèrent étonnamment fertiles et débouchent sur un grand nombre de découvertes inattendues. À titre indicatif, il semble être le seul copolymère séquencé connu qui forme des micelles fibreuses par un mécanisme analogue à celui des protéines, comme les fibres amyloïdes. Bon nombre de chercheurs ont apporté des contributions considérables. Au nombre des chercheurs les plus mémorables, mentionnons Yahya Rharbi qui attribue une nature cristalline éventuelle au noyau du PFS; Xiaosong Wang qui découvre l'autoassemblage spontané; Gerald Guerin qui contribue aux prouesses techniques de la diffusion de la lumière; Hai Wang qui montre que ces nanofibres peuvent servir de matrices dans la formation d'une diversité de nanoparticules métalliques.

Un tournant dans les intérêts scientifiques du groupe de Winnik s'est amorcé en 2005 lorsque Mitch est invité à participer à un projet avec Vladimir Baranov, Olga Ornatsky et Mark Nitz; projet qui fait appel à la spectrométrie de masse avec plasma à couplage inductif (ICP-MS) pour les dosages biologiques hautement multiplexés. L'idée ici est d'utiliser différents isotopes métalliques (lanthanide) comme étiquettes pour mar-

quer des anticorps, de façon analogue à l'utilisation de fluorochromes. L'accent est porté initialement sur le phénotypage des cellules leucémiques humaines. On demande ensuite au groupe de Winnik de synthétiser des polymères métallifères pour porter de nombreuses copies d'un métal ou d'un isotope (comme  $^{153}\text{Eu}$ ) donné afin de munir chaque anticorps de quelque 100 ions métalliques. L'objectif à long terme est de mesurer de façon quantitative aussi peu que 100 copies d'une biomolécule particulière dans une cellule donnée. Des expériences récentes faisant appel à cette nouvelle technique de cytométrie de masse peuvent détecter et quantifier plus de 20 biomarqueurs pour chacune des cellules à l'aide d'une seule analyse.

Au fil des années, Mitch est professeur invité à l'Université de Bordeaux (1977–1978), éminent spécialiste du commerce à IBM (1982), boursier JSPS à l'Institut de technologie de Tokyo (1985–1986), boursier Alexander von Humboldt à l'Institut Max Planck pour la recherche sur les polymères (1996) à Mainz, Allemagne, ainsi que titulaire de la chaire de Paris-Sciences à l'École Supérieure de Physique et Chimie Industrielle (2000) de Paris, France.

Mitch est récipiendaire de nombreuses distinctions, y compris le prix de l'Institut de chimie du Canada (ICC) en science des polymères (1993), le prix Forum Bell Canada pour les interactions université-industrie (1995), le prix Alexander von Humboldt pour chercheur principal (1996) et la médaille de l'ICC (2004). Il devient membre de la Société royale du Canada (1996) et de la division des sciences des matériaux polymères de l'American Chemical Society (2002). En 2006, il figure comme l'un des auteurs les plus cités en chimie par le Web of Science de l'ISI Web of Science. Ses quelque 550 publications sont citées plus de 14 000 fois ( $h^* = 57$ ). À l'Université de Toronto, on lui décerne le titre de « Professeur Universitaire », le prix le plus prestigieux de cette université attribué en reconnaissance de l'excellence universitaire.

Le nombre et la qualité des articles de ce numéro dédié de la *Revue canadienne de chimie* sont des gages de l'étendue et la portée de son influence dans le milieu de la chimie et de la science des polymères.

**Jean Duhamel**

# Transfer hydrogenations of benzaldehyde using glycerol as solvent and hydrogen source

Dorith Tavor, Oxana Sheviev, Christina Dlugy, and Adi Wolfson

**Abstract:** Benzaldehyde was successfully reduced by catalytic transfer hydrogenation in glycerol using several ruthenium based complexes and bases. Glycerol was employed as a green solvent and hydrogen source, and it allowed for easy product separation and catalyst recycling and enabled the use of a microwave-assisted reaction.

**Key words:** transfer hydrogenation, catalysis, glycerol, green solvent, benzaldehyde.

**Résumé :** Le benzaldéhyde a été réduit avec succès par une hydrogénation de transfert catalytique, dans le glycérol, en présence de plusieurs complexes et bases à base de ruthénium. Le glycérol a été utilisé à la fois comme source d'hydrogène et de solvant écologique et il permet de séparer facilement le produit, de recycler le catalyseur et d'utiliser les micro-ondes pour faciliter la réaction.

**Mots-clés :** hydrogénation par transfert, catalyse, glycérol, solvant écologique, benzaldéhyde.

[Traduit par la Rédaction]

## Introduction

Carbonyl reduction is a fundamental organic transformation done using a variety of synthetic procedures.<sup>1–3</sup> Metal hydrides, and especially borohydrides, are cheap and simple reducing agents that can easily reduce many carbonyl compounds while producing characteristically high yields and selectivities, but their use is usually accompanied by large amounts of waste. Catalytic hydrogenation with molecular hydrogen, using different homogeneous and heterogeneous metal catalysts, is another potential route; however, it requires extra precautionary measures and special, high pressure equipment. Alternatively, transfer hydrogenation of carbonyl compounds using different organic molecules as the hydrogen source has also been intensively studied and reported in the literature.<sup>4–7</sup>

The transfer hydrogenation of aldehydes and ketones is usually performed in 2-propanol under a homogeneous mode with different ruthenium based complexes and organic or inorganic bases as cocatalysts.<sup>5,6</sup> To overcome the difficulties of the separation and recycling of homogeneous complexes, supported ruthenium catalysts were introduced.<sup>8,9</sup> We recently showed that 2-propanol can be replaced by glycerol, which served as green solvent and hydrogen donor in the transfer hydrogenation of various unsaturated organic compounds and which facilitated easy product separation and catalyst recycling.<sup>10</sup> The promising physical and chemical properties of glycerol enabled its application as a green solvent in many organic reactions, using various homogeneous and heterogeneous chemo- and bio-catalysts.<sup>11–13</sup> As the main byproduct of the conversion of oils and fats in oleochemical production, glycerol is becoming more plentiful,

which reduces its price, due to increases in the production and use of fatty acid derivatives in food, in the cosmetics and drugs industries, and in biofuel synthesis, i.e., biodiesel. As increasingly larger quantities of glycerol are generated by the biodiesel industry, it is vital that economical ways of utilizing glycerol be explored to further defray the cost of biodiesel production. In addition to glycerol's low environmental impact, its replacement of 2-propanol in transfer hydrogenation reactions allowed for experiments to be run at higher temperatures and facilitated easier product separation. Furthermore, during the reaction glycerol is dehydrogenated to dihydroxyacetone, which is a valuable ingredient in sunless tanning products.

In this study, glycerol was used as both solvent and hydrogen donor in the transfer hydrogenation of benzaldehyde as the representative carbonyl compound (Fig. 1). Various ruthenium complexes and different bases were tested as catalysts and promoters, respectively. The effects of catalyst and base types and of loading and reaction temperature on catalytic performance were tested. In addition, catalyst recycling tests and microwave-assisted reactions were also performed.

## Experimental

In a typical procedure, 2.2 mmol of benzaldehyde (0.22 g) and 270  $\mu$ mol of base (KOH, NaOH, or triethyl amine) were added to a vial with 4 g of glycerol (all purchased from Sigma-Aldrich). A corresponding amount of ruthenium catalyst was added, such that the molar ratio of benzaldehyde to ruthenium was in the range of 50–150. The mixture was

**Fig. 1.** Transfer hydrogenation of benzaldehyde in glycerol.

placed in a preheated oil bath and heated to the required temperature (45–75 °C), after which it was magnetically stirred for 5–72 h. At the end of the reaction, the reaction mixture was cooled and extracted with 3 × 5 mL diethyl ether. The organic phase was concentrated under reduced pressure, and the resulting crude product was analyzed by gas chromatography (GC) analysis using an HP-5 column (30 m × 0.25 mm, 0.25 μm thick).

Catalyst recycling experiments were done in a 100 mL Erlenmeyer flask. For the first reaction cycle, 2 g benzaldehyde, 0.12 g Ru(*p*-cumene)Cl<sub>2</sub>-dimer, and 0.17 g KOH were dissolved in 25 g of glycerol, and the reaction mixture was heated in an oil bath to 70 °C for 18 h. At the end of the reaction, the product and the residual substrate were extracted with 3 × 25 mL diethyl ether and the catalyst was recycled by adding fresh benzaldehyde and running the reactions under conditions similar to those of the first run.

The transfer hydrogenation of benzaldehyde under microwave irradiation was carried out using a Ru(*p*-cumene)Cl<sub>2</sub>-dimer as the catalyst and KOH as the base. Experiments were conducted at atmospheric pressure in a domestic microwave oven (Crystal WP900, 900 W) in a 250 mL glass vessel covered with a watch glass. Benzaldehyde (2 g) was dissolved in 25 g of glycerol to which was added 0.12 g of the complex and 0.17 g of KOH. The vessel was covered with the watch glass, and the reaction mixture was heated in the microwave for 3 min from 26 to 72 °C. The vessel was then cooled to room temperature, and the reaction mixture was extracted with diethyl ether for GC analysis.

## Results and discussion

As previously mentioned, the homogeneous catalytic transfer hydrogenation of carbonyl compounds is usually performed with ruthenium complexes and a base. Thus, the investigation began by running the transfer hydrogenation of benzaldehyde in glycerol with different ruthenium catalysts and several bases (Table 1). As expected, performing the reaction in the absence of a base with all types of ruthenium catalysts did not yield any product. In contrast, running the reaction with potassium hydroxide but without a catalyst for 5 h resulted in a 20% yield of benzyl alcohol, but that yield did not change when the reaction was allowed to continue beyond 5 h (Table 1, entry 1). Increasing the amount of base while performing the reaction without catalyst resulted in a faster reaction, but did not change the final yield of benzyl alcohol. Replacing KOH with triethyl amine as a representative organic base and performing the reaction in the absence of the ruthenium complex failed to yield any product (Table 1, entry 2). It was previously reported that the role of the base in transfer hydrogenation–dehydrogenation reactions is to abstract the acidic proton of the hydrogen donor, thereby initiating the catalytic cycle.<sup>14</sup> In addition, it was found that soluble KOH by itself also catalyzed the

transfer hydrogenation of acetophenone in 2-propanol<sup>15</sup> and solid KOH and NaOH were successfully used in the dehydrogenation of aromatic alcohols.<sup>16</sup>

When ruthenium complex and KOH were added together to the reaction mixture, the yield of benzyl alcohol after 5 h was similar to the yield that was detected with KOH alone after 5 h (Table 1, entries 4–6), except in the case of the Ru(*p*-cumene)Cl<sub>2</sub>-dimer that exhibited a 40% higher yield of benzyl alcohol (Table 1, entry 3). Performing a comparative reaction in 2-propanol under similar conditions, using Ru(*p*-cumene)Cl<sub>2</sub>-dimer as catalyst and KOH as base, resulted in a 36% yield of benzyl alcohol, which is 33% higher than the yield in glycerol. It might be attributed to the lower viscosity of 2-propanol or to the difference in the structure of the two solvents that makes their affinity to the catalyst different and thus their ability to transfer proton and hydride. Although the yield of benzyl alcohol with KOH alone did not change after 5 h, the addition of all ruthenium complexes to KOH resulted in an increased yield after 24 h (Table 1, entries 3–6). These results imply that both the base and the ruthenium catalyst are necessary to maintain the catalytic cycle. In addition, no difference was found when the reaction was performed under an inert atmosphere.

The important reaction-initiating role of the base prompted us to test the effect of base type on benzyl alcohol yield (Table 1, entries 7–8). It was found that replacing KOH with either NaOH or triethyl amine did not change the yield. In addition, the yield of benzyl alcohol was only slightly changed at reaction temperatures in the range of 45–75 °C (Table 1, entry 9). Finally, replacing benzaldehyde with 2-octanone and running the reaction under similar reaction conditions resulted in a lower yield, as aliphatic ketones are less active in transfer hydrogenation reactions (Table 1, entry 10).

Reaction progress over time was tested with the Ru(*p*-cumene)Cl<sub>2</sub>-dimer and KOH (Fig. 2). The results show that increasing the reaction time led to a linear increase in the yield of benzyl alcohol. Benzaldehyde conversion was also affected by complex loading (Fig. 3). By decreasing the amount of the complex, thus increasing the substrate to catalyst ratio, the turnover frequency (TOF, the amount of substrate that was converted per each catalyst molecule per hour) increased linearly, thereby revealing that under these conditions, each molecule of complex undergoes more catalytic cycles per hour.

Finally, the efficacy of recycling the Ru(*p*-cumene)Cl<sub>2</sub>-dimer, KOH, and glycerol together was examined. The first reaction cycle was performed at 70 °C for 18 h, and at the end of the reaction the product and the residual substrate were extracted with diethyl ether to reveal a benzyl alcohol yield of 62%. Fresh benzaldehyde was then added to the reaction mixture for the second and third cycles, and the reaction was run under the same conditions as the first cycle. The yields of the second and the third cycles were 54% and

**Table 1.** Transfer hydrogenation of benzaldehyde in glycerol.

Entry	Catalyst type	Base type	Yield after 5 h (%)	Yield after 24 h (%)
1	—	KOH	20	20
2	—	Et <sub>3</sub> N	0	0
3	Ru( <i>p</i> -cumene)Cl <sub>2</sub> -dimer	KOH	27	45
4	RuCl <sub>3</sub> ·H <sub>2</sub> O	KOH	20	38
5	RuCl <sub>2</sub> (TPP) <sub>3</sub> <sup>a</sup>	KOH	20	48
6	RuCl <sub>2</sub> (TPPS) <sub>3</sub> <sup>b</sup>	KOH	20	39
7	Ru( <i>p</i> -cumene)Cl <sub>2</sub> -dimer	NaOH	20	20
8	Ru( <i>p</i> -cumene)Cl <sub>2</sub> -dimer	Et <sub>3</sub> N	19	19
9	Ru( <i>p</i> -cumene)Cl <sub>2</sub> -dimer <sup>c</sup>	KOH	25	42
10	Ru( <i>p</i> -cumene)Cl <sub>2</sub> -dimer <sup>d</sup>	KOH	—	27

**Note:** Reaction conditions: 4 g glycerol, 0.22 g benzaldehyde, S/C = 100, 270 μmol base, 70 °C.

<sup>a</sup>TPP: triphenylphosphine.

<sup>b</sup>TPPS: tris-(3-sulfophenyl)-phosphine trisodium salt.

<sup>c</sup>45 °C.

<sup>d</sup>0.22 g 2-octanone.

**Fig. 2.** The progress of the reaction over time. Reaction conditions: 4 g glycerol, 0.22 g benzaldehyde, S/C = 100, 270 μmol KOH, 70 °C.

42%, respectively. The observed decline in yield may be attributable to partial deactivation of the catalyst or partial loss of base during the reaction. Thus, a recycling experiment with the addition of extra fresh KOH to the second reaction cycle was also tested. It resulted in a slightly higher benzyl alcohol yield of 59% instead of a yield of 54% when fresh base was not added. Finally, because transfer hydrogenation–dehydrogenation reactions are equilibrium reactions, glycerol's role as hydrogen donor could mean that part of it was already dehydrogenated in the former reaction cycles. If so, then the dehydrogenated glycerol would affect the conversion of benzaldehyde in the later cycles.

In addition to its roles as both solvent and hydrogen donor, glycerol also tolerated microwave-promoted heating.<sup>10–13</sup> Based on the ability of the solvent to absorb microwave energy and convert it into heat, microwave heating is ideally suited to the high dielectric constants and high boiling points

of polar solvents with hydroxyl substitution such as glycerol.<sup>17,18</sup> The transfer hydrogenation of unsaturated organic compounds under microwave irradiation has been studied previously.<sup>19–21</sup>

Microwave-promoted transfer hydrogenation of benzaldehyde in glycerol was carried out using a Ru(*p*-cumene)Cl<sub>2</sub>-dimer as the catalyst and KOH or triethyl amine as the base. The experiment was conducted in a domestic microwave oven at atmospheric pressure in a 250 mL glass vessel covered with a watch glass. Benzaldehyde (2 g) was dissolved in 25 g of glycerol after which 0.12 g of the complex and 0.17 g of the bases were added. The reaction mixture was heated in the microwave for 3 min from 26 to 72 °C. At the end of the reaction, the vessel was cooled to room temperature and the reaction mixture was extracted with diethyl ether for GC analysis. The yields were found to be 33% with KOH as the base and 25% with triethyl amine as

**Fig. 3.** The effect of the benzaldehyde to ruthenium complex ratio on catalytic performance. Reaction conditions: 4 g glycerol, 0.22 g benzaldehyde, 270  $\mu\text{mol}$  KOH, 70  $^{\circ}\text{C}$ , 5 h.

the base, but the reaction in the absence of catalyst yielded a much lower conversion. These yields are higher than those detected under conventional heating after 5 h.

## Conclusion

To conclude, benzaldehyde was successfully reduced to benzyl alcohol in catalytic transfer hydrogenation in glycerol using several ruthenium complexes as catalyst and using both organic and inorganic bases. Glycerol was employed as both a green solvent and also as the hydrogen source. As a solvent, glycerol also facilitated easy product separation and catalyst recycling, and it was amenable to microwave-promoted reactions.

# Using the nitro group to induce $\pi$ -stacking in terthiophenes

Wendy A. Sears, Craig D. MacKinnon, Robert C. Mawhinney, Lauren C. Sinnemaki, Matthew J. Johnson, A. John Winter, and Craig M. Robertson

**Abstract:** A new synthetic route to mononitrated oligothiophenes is described, as well as the preparation of halogenated derivatives (Br, I) thereof. An unusual deep red colour is observed and explained, with the aid of DFT calculations, as arising from a significant quinoidal contribution to the molecular structure. The crystal structures of two compounds,  $\text{H}(\text{C}_4\text{H}_2\text{S})_3\text{NO}_2$  and  $\text{Br}(\text{C}_4\text{H}_2\text{S})_3\text{NO}_2$ , are presented. Both compounds have planar sheets held together by intermolecular short contacts (hydrogen bonds and, for the latter,  $\text{NO}_2\cdots\text{Br}$  interactions); the sheets do not directly superimpose, so the effect of the  $\pi$ -stacking is not maximized. Solid-state fluorescence and extended-Hückel band-structure calculations are also presented for these materials.

**Key words:** oligothiophene, organic semiconductor, crystal structure, band structure, nitro-substitution.

**Résumé :** On décrit une nouvelle méthode générale de synthèse des oligothiophènes mononitrés ainsi que la préparation de leurs dérivés bromés et iodés. On a observé une couleur rouge foncé inhabituelle et, en se basant sur des calculs de la théorie de la fonctionnelle de la densité (TFD), on suggère qu'elle résulte d'une importante contribution quinonoidale à la structure moléculaire. On a déterminé les structures cristallines des deux composés  $\text{H}(\text{C}_4\text{H}_2\text{S})_3\text{NO}_2$  et  $\text{Br}(\text{C}_4\text{H}_2\text{S})_3\text{NO}_2$ . Les deux composés se présentent sous la forme de feuillets plans maintenus en place par des contacts intermoléculaires courts (liaisons hydrogènes et, dans le deuxième cas, interactions  $\text{NO}_2\cdots\text{Br}$ ); les feuillets ne sont pas directement superposés et il en résulte que l'effet de superposition  $\pi$  n'est pas maximisé. On rapporte aussi les résultats obtenus pour la fluorescence à l'état solide de ces matériaux ainsi que les calculs étendus de Hückel de leur structure de bande.

**Mots-clés :** oligothiophène, semiconducteur organique, structure cristalline, structure de bande, substitution par un groupe nitro.

[Traduit par la Rédaction]

## Introduction

Organic materials are carbon-based small molecules or polymers with interesting electronic properties. Two of the most studied organic semiconductors are the oligothiophenes<sup>1–3</sup> and the acenes.<sup>4</sup> The promise of organic materials is held in the ability of the compounds to undergo “tuning” of the electronic structures through molecular substitution. Thus, an overwhelming variety of oligomers have been made, from dendrimers to polymers to molecules substituted at every position.

Unsubstituted organic semiconductors are mostly *p*-type (where the charge is carried by positive charges, or holes). Attachment of electron-withdrawing groups can convert them to *n*-type conductors (negative charge carriers), e.g., dihexylsexithiophene is *p*-type while bis(perfluorohexyl)sexithiophene is *n*-type.<sup>5</sup> The lowering of the frontier orbitals upon attachment also increases environmental stability because reactivity with oxygen in the air is reduced. Molecules

substituted with both an electronic acceptor and an electronic donor will contain an internal charge-transfer electronic transition that can be exploited for non-linear optical devices<sup>6,7</sup> or as light-emitting diode dyes.<sup>8</sup> These electronic consequences are well-documented; far less is known of the structural consequences. Perfluorination<sup>9</sup> and  $\alpha,\omega$ -cyano-substitution,<sup>10,11</sup> for example, both lead to a greater degree of  $\pi$ -stacking in the single-crystal structure, which is fortunately a beneficial outcome as  $\pi$ -stacking has been shown to increase mobility in standard device configurations.<sup>12,13</sup>

The nitro group is a typical example of a strong electron-withdrawing group that has been attached to molecular materials.<sup>14–17</sup> While the resultant materials have been well-studied electronically, structural investigations into the consequences of nitro substitution are sparse. Therefore, we have undertaken the synthesis and crystal growth of structurally simple nitro-substituted oligothiophenes. We chose to limit ourselves to mono-nitrated derivatives because these species are of greater synthetic interest, potentially allowing

subsequent substitution to generate more complex molecules. The use of the letter "T" as an abbreviation for the 2,5-disubstituted thienyl ring is common in the oligothiophene literature (see Scheme 1). Using this abbreviation, we report herein the synthesis of several  $\text{XT}_n\text{NO}_2$  species, where  $\text{X} = \text{H}, \text{Br}, \text{or I}$ , and  $n = 2$  (bithiophene) and 3 (terthiophene). We also present the crystal structures of  $\text{HT}_3\text{NO}_2$  and  $\text{BrT}_3\text{NO}_2$ .

## Results and discussion

### Synthesis

The compounds  $\text{HT}_3\text{NO}_2$  and  $\text{BrT}_3\text{NO}_2$  have been previously reported, but experimental details are scanty.<sup>18</sup> Further, we found the reported conditions to be excessively harsh, resulting in loss of regiochemical control, multiple nitrations, or oxidation of the thiophene ring.<sup>19</sup> Therefore, we report a new, milder synthesis of these species. We also report synthesis of the new species  $\text{BrT}_2\text{NO}_2$  and  $\text{IT}_3\text{NO}_2$ , which can be made the same way (although synthesis of  $\text{BrT}_2\text{NO}_2$  by the route  $\text{T}_2 \rightarrow \text{BrT}_2\text{H} \rightarrow \text{BrT}_2\text{NO}_2$  proved to have higher yield and purity). The reaction Scheme summarizes the syntheses. Nitration using nitric acid in acetic anhydride gave the best results, allowing us to heavily favour nitration at one (and only one) of the  $\alpha$ -sites on  $\text{H}_2\text{T}_2$  and  $\text{H}_2\text{T}_3$ . Unfortunately, this could not be extended to longer oligomers (the lack of solubility of  $\text{T}_4$ , for example, required heating the nitration step, leading to inseparable mixtures of regioisomers). Suzuki coupling<sup>20–22</sup> of  $\text{HT}_2\text{B(OH)}_2$  and  $\text{BrT}_2\text{NO}_2$  seemed to be a reasonable alternate route, but the low solubility of the product  $\text{HT}_4\text{NO}_2$  prevented purification by recrystallization or chromatography. Sublimation afforded some material but it was always accompanied by a significant amount of  $\text{H}_2\text{T}_4$  and unidentified decomposition product(s) (probably due to polymerization). The insolubility of  $\text{HT}_4\text{NO}_2$  also prevented the regioselective synthesis of halogenated derivatives. Stille coupling<sup>23–26</sup> was even less useful because it had the same problems as the Suzuki method, with the additional difficulty of stannyl contamination.

### Spectroscopic and computational studies

The most striking characteristic of the nitro-substituted terthiophenes is their deep red colour, in contrast to the pale yellow of unsubstituted  $\text{H}_2\text{T}_3$ . We<sup>10,27</sup> and others<sup>18,28–30</sup> have reported the UV–vis and fluorescence spectra in solution of a variety of oligothiophenes; some of the data are summar-

Scheme 1.

ized in Table 1. It is obvious from these data that the nitro group has an effect on  $\lambda_{\text{MAX}}$  that is larger than it should be based on a simple particle-in-a-box argument, i.e., the  $\text{NO}_2$  group should extend the molecule by only two bonds, the same as the nitrile group. Instead, the  $\lambda_{\text{MAX}}$  of  $\text{HT}_3\text{NO}_2$  is closest to that of  $\text{H}_2\text{T}_5$  (extending the conjugation by eight bonds). We conclude that the  $\text{NO}_2$  substituent helps rigidify the backbone by introducing a quinoidal resonance structure **1Q** to the molecule. This restricts the free rotation (it has a very small energy barrier<sup>35,36</sup>) about the  $\text{C5}–\text{C2}'$  and the  $\text{C5}'–\text{C2}''$  (ring–ring) bonds in the aromatic form **1A**. This rotation disrupts the extended conjugation of the oligomer and shortens the  $\lambda_{\text{MAX}}$ , so the restricted rotation in **1Q** increases the effective average conjugation length. Addition of a second nitro group (e.g., compound **2**) does not have the same effect, presumably because the quinoidalization has already occurred with the first  $\text{NO}_2$  group.

For verification, we turned to DFT calculations. If the resonance form **1Q** is significant, it should lead to a greater degree of  $\pi$ -bonding between C2 and C3 than is present in the aromatic form **1A**. The bonds  $\text{C1}–\text{C2}$  and  $\text{C3}–\text{C4}$  should also lengthen. The results are shown in Table 2, along with experimental bond lengths from crystal structures when available ( $\text{HT}_3\text{NO}_2$  and  $\text{BrT}_3\text{NO}_2$  are reported below for the first time, while the other species have been previously reported). Unfortunately, the ratio derived from the crystal structures is unconvincing, partly due to the fact that the ratio ( $\text{C2}–\text{C3}/\text{C1}–\text{C2}$ ) can vary widely due to crystal packing effects, and partly because the errors in the calculated ratios are within the statistical errors arising from the atomic ESDs. The computational results are more convincing, and may anyway be more representative of the structure in solution (i.e., in the absence of packing effects). For the computed structures, the  $\text{C2}–\text{C3}$  bond decreases in length by 0.012 Å on changing from an H to an  $\text{NO}_2$ . The  $\text{C1}–\text{C2}$  bond lengths also increase slightly, verifying that the resonance structure **1Q** does, in fact, have some influence on the structure of these molecules.

This change is essentially identical no matter what is happening at the other end of the molecule (independent of  $\text{R}^2$ ). This is somewhat counterintuitive because the quinoidal form **1Q** should be stabilized by lone pairs on  $\text{R}^2$ , which could occur when  $\text{R}^2 = \text{Br}$  but not when  $\text{R}^2 = \text{H}$ . We would conclude that the nitro group is such a strong electron-withdrawing substituent that a donor group at the other end is

essentially irrelevant (or, put another way, the far thiophene ring acts as the donor group).

### Solid-state structures

Since we wished to determine the solid-state influence of the nitro group, crystals of both  $\text{HT}_3\text{NO}_2$  and  $\text{BrT}_3\text{NO}_2$  were grown, the former by sublimation and the latter from solution. The pertinent refinement data are given in Table 3. Unfortunately, the crystals for  $\text{BrT}_3\text{NO}_2$  were of low quality.

Because of its low solubility, conversion from  $\text{HT}_3\text{NO}_2$  to  $\text{BrT}_3\text{NO}_2$  required heating and a long reaction time, which created a mixture of brominated products. Purification by repeated recrystallization did not fully separate these substances, so consequently a small amount of disubstituted material remained, which was modeled using partial occupancies as shown in Fig. 1 (the atoms labeled “H/Br2” and “H/Br3” are the partially occupied sites). Repeated sublimation of the product did lead to pure  $\text{BrT}_3\text{NO}_2$  by combustion

**Fig. 1.** Crystal structure of BrT<sub>3</sub>NO<sub>2</sub>. Top left: molecule showing atom numbering and thermal ellipsoids. Top right: two coplanar molecules showing the lack of face-to-face  $\pi$ -stacking between layers. Bottom: the two-dimensional sheet forcing coplanarity on the molecules, showing the short O $\cdots$ Br contacts and hydrogen bonds.

analysis. However, we were unable to obtain even low-quality single crystals of purified BrT<sub>3</sub>NO<sub>2</sub>. Fortunately, the gross structure does give the necessary information on atomic connectivities, and it shows the molecules forming ribbons held together by the halo-nitro supramolecular synthon.<sup>37,38</sup> Contact between the bromo and one oxygen on the nitro (as opposed to both oxygens equally) is typical.<sup>39</sup> The ribbons stack cofacially, but they are offset so that the  $\pi$ -systems overlap very little. Interestingly, rings 1 (C1–C4) and 2 (C5–C8) are mutually syn, while rings 2 and 3 (C9–C12) are anti to each other. While the syn orientation is less common, it is not unheard of (in fact, compound **2** also has mutually syn rings in its crystal structure<sup>31</sup>).

Figure 2 shows the crystal structure of HT<sub>3</sub>NO<sub>2</sub>. In this case, sublimation led to good-quality crystals. The molecules line up in head-to-tail ribbons joined by hydrogen bonds between each nitro oxygen and an aromatic hydrogen. There is also a cross-ribbon hydrogen bond, generating a two-dimensional sheet. These sheets stack in the third dimension, leading to  $\pi$ -stacks, the favored orientation for maximizing carrier mobility in molecular semiconductors. The  $\pi$ -stacking is not fully optimized, however, as consecutive ribbons run in opposite directions in the centrosymmetric space group.

Even though the  $\pi$ -stacking is not optimal in either structure, there are clearly intermolecular interactions that give

**Fig. 2.** Crystal structure of HT<sub>3</sub>NO<sub>2</sub>. Top left: molecule showing atom numbering scheme and thermal ellipsoids. Top right: side view of the  $\pi$ -stack; the top and bottom molecules have one S pointing at the viewer while the middle molecule has two, demonstrating the alternation in the sense of the stacking. Bottom: two-dimensional sheets held together with hydrogen bonds.

rise to intermolecular interactions between molecules in the solid state. The normalized fluorescence spectra for H<sub>2</sub>T<sub>3</sub> and HT<sub>3</sub>NO<sub>2</sub> (in both CH<sub>2</sub>Cl<sub>2</sub> solution and powder solid) are shown in Fig. 3. The  $\lambda_{\text{MAX}}$  for all the solid-state data were presented in Table 1, along with the solution data. The  $\lambda_{\text{MAX}}$  increases significantly for the solids compared with the solutions, demonstrating that the solid-state optical band gap is smaller than the molecular HOMO–LUMO gap.

The electrostatic hydrogen bonds connecting the molecules in the solid state do not contribute to the formation of an extended three-dimensional electronic structure. This is verified by Extended Hückel band structure calculations on RT<sub>3</sub>NO<sub>2</sub> (R = H, Br), the results of which are shown in Fig. 4, along with the same calculation on H<sub>2</sub>T<sub>3</sub>, using the literature crystal structure;<sup>35</sup> numerical data are given in Table 4. The bandwidths are narrow, with little dispersion along any of the reciprocal space axes. In triclinic space groups, in which all these structures crystallize, the directions *X*, *Y*, and *Z* do not correspond to the real-space axes *a*, *b*, and *c*; however, this does not affect the gross conclusion that the dispersion is small. The band gap is significantly lower in the nitro-substituted species than in the unsubstituted molecule, but this is a reflection of the change in the energies of the HOMO and LUMO not a reflection of an increase in the bandwidths. The bandwidths are much narrower than those published for H<sub>2</sub>T<sub>6</sub><sup>41</sup> but are comparable to H<sub>2</sub>T<sub>3</sub>, so longer nitro-substituted oligomers may have significantly larger bandwidths.

## Conclusions

The attachment of one nitro group to a terthiophene oligomer is possible by using the relatively mild conditions of nitric acid in acetic anhydride. The resultant product, HT<sub>3</sub>NO<sub>2</sub> has an unusually small HOMO–LUMO energy gap, which we attribute to the effect of the quinoidal reso-

**Fig. 3.** Normalized solution and powder fluorescence spectra for H<sub>2</sub>T<sub>3</sub> and HT<sub>3</sub>NO<sub>2</sub>.

nance structure. The solid-state crystal structure consists of two-dimensional planes of molecules held together by hydrogen bonds. Although the sheets do not superimpose, there is some  $\pi$ -stacking between the sheets. Bromination and iodination of this molecule is possible, and the BrT<sub>3</sub>NO<sub>2</sub> molecule also has a  $\pi$ -sheet crystal structure, with hydrogen bonds and NO<sub>2</sub>...Br contacts. In this case, there is little  $\pi$ -interaction between the sheets. Neither solid has large dispersion in the band structure, but the bandwidths are similar to unsubstituted H<sub>2</sub>T<sub>3</sub>, so longer nitrated oligomers may have more electronically useful band structures. The band gap is significantly smaller in nitro-substituted species, but this is simply a reflection of the smaller HOMO–LUMO gap. These results suggest that the nitro group is a good candidate for inducing  $\pi$ -stacking in oligothiophenes.

## Experimental

### Materials

Starting reagents were purchased from Aldrich and used

**Fig. 4.** Extended-Hückel band structures of  $\text{H}_2\text{T}_3$ ,  $\text{HT}_3\text{NO}_2$ , and  $\text{BrT}_3\text{NO}_2$ . The dashed line is the Fermi level.**Table 4.** Band structures of selected oligothiophenes.

Compound	Band gap	Valence bandwidth	Conduction bandwidth	Reference
$\text{H}_2\text{T}_3$	2.08	0.013	0.11	This work <sup>a</sup>

$\text{BrT}_3\text{NO}_2^b$	0.60	0.016	0.023	This work
$\text{H}_2\text{T}_4$	2.24	0.52	0.44	40
$\text{H}_2\text{T}_6$	1.94	0.79	0.52	41

<sup>a</sup>The band structure calculation is new to this work, using the literature crystal structure (ref. 35).

<sup>b</sup>The crystal structure contains sites with partial Br occupancy; the band structure calculation has assumed 100% H for those sites.

without purification, except *N*-bromosuccinimide (NBS), which was recrystallized from water. Solvents were purchased from Anachemia or Caledon and purified prior to use: dichloromethane, diethyl ether, and tetrahydrofuran (THF) by passage through an alumina column under  $\text{N}_2$ ; alcohols by distillation from magnesium under  $\text{N}_2$ . Oligothiophenes 2,2'-bithiophene ( $\text{H}_2\text{T}_2$ ); 2,2':5',2''-terthiophene ( $\text{H}_2\text{T}_3$ ); 2,2':5',2'':5'',2'''-quaterthiophene ( $\text{H}_2\text{T}_4$ ); and 2,2':5',2'':5'',2'':5''',2''''-quinquethiophene ( $\text{H}_2\text{T}_5$ ) were synthesized by Grignard couplings of thienylmagnesium bromide ( $\text{HTMgBr}$ ) to 2-bromothiophene ( $\text{BrTH}$ ); 2,5-dibromothiophene ( $\text{Br}_2\text{T}$ ); 5,5'-dibromo-2,2'-bithiophene ( $\text{Br}_2\text{T}_2$ ); and 5,5'-dibromo-2,2':5',2''-terthiophene ( $\text{Br}_2\text{T}_3$ ), respectively, using the Kumada coupling catalyst ( $\text{Ni(dppp)Cl}_2$ ) [1,3-bis(diphenylphosphino)propane]dichloronickel(II).<sup>42</sup> The method of Bäuerle<sup>43</sup> was used for monobromination to create 5-bromo-2,2'-bithiophene ( $\text{BrT}_2\text{H}$ ), and for all dibrominations. 5-Bromo-2,2':5',2''-terthiophene-5'-carbonitrile ( $\text{BrT}_3\text{CN}$ ) was prepared by the literature route.<sup>10</sup> All reactions were performed under an atmosphere of  $\text{N}_2$  (using Schlenk conditions).

### Instruments

FTIR spectra were recorded as nujol mulls on a Nicolet 380 FTIR spectrometer; vibrational frequencies are reported as wavenumbers ( $\text{cm}^{-1}$ ), with an experimental resolution of  $4\text{ cm}^{-1}$ . NMR spectra were recorded on a Varian Unity Inova 500 at room temperature in  $\text{CDCl}_3$  or  $\text{DMSO}-d_6$  solutions, referenced to TMS added to the sample or to the residual protonated solvent peak. Fluorescence measurements were taken on a PerkinElmer LS50B luminescence

spectrometer, while UV-vis absorption spectra were recorded on a PerkinElmer Lambda 11 UV-vis spectrometer; both were recorded as  $\text{CH}_2\text{Cl}_2$  solutions. Combustion analyses were performed on a CEC (SCP) 240-XA Analyzer. Gradient vacuum sublimations and crystal growth for X-ray crystallography were performed on an Applied Test Systems model 3210 split tube furnace attached to a series 2404 three-zone temperature control system. Melting points were recorded on an Electrothermal 9100 apparatus and are uncorrected. Mass spectra were recorded on a Micromass VG Autospec electron impact mass spectrometer at Lakehead University or on a Bruker Reflex III laser desorption/ionization time-of-flight mass spectrometer at the Mass Spectrometry Facility in the Advanced Analysis Centre at the University of Guelph.

### X-ray crystallography

Single-crystal data were collected using the Smart Apex CCD (Bruker) equipped with an area detector utilizing graphite-monochromated  $\text{Mo K}\alpha$  radiation ( $\lambda = 0.71073\text{ \AA}$ ). The data were corrected for Lorentz and polarization effects. Absorption corrections were based on fitting a function to the empirical transmission surface as sampled by multiple equivalent measurements of numerous reflections using the scale function of the APEX II software. The space groups for all compounds were determined on the basis of the systematic absences using symmetry and space group of the APEX II package. Structure solution and refinement using the SHELXTL package of APEX II were successful in the chosen centrosymmetric space groups. The structure solution

via direct method led to the identification of the heavy atoms and the refinement on  $F^2$  using least-square method resulted in good  $R$  values. Full details of the structures have been deposited with the Cambridge Crystallographic Data Centre (see Supplementary data for details).

### Computational details

Calculations used the PBE0 hybrid functional<sup>44–46</sup> and the large basis set 6–311++G(2df, pd)<sup>47,48</sup> as implemented in the Gaussian 03 package.<sup>49</sup>

### Synthesis of 5-bromo-5'-nitro-2,2'-bithiophene ( $\text{BrT}_2\text{NO}_2$ )

Although this compound was often made in the method outlined in the Scheme 1, we found that the following method gave a higher-purity product. In 25 mL of acetic anhydride, 4.79 g (20 mmol) of  $\text{BrT}_2$  was dissolved, and the mixture was cooled to 0 °C. To this solution (maintaining 0 °C) was added dropwise with stirring a mixture of 1.50 g (24 mmol) of nitric acid in 20 mL of acetic anhydride. The resultant mustard-yellow solution was quenched with saturated sodium bicarbonate and extracted into dichloromethane. Rotary evaporation followed by recrystallization (from ethanol) and sublimation (two times) yielded 1.45 g (25.6%) of analytically pure material. Mp 190–193 °C.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  (ppm): 8.12 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 7.56 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 7.45 (d,  $J_{\text{AB}}$  4.0 Hz, 1H), 7.36 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H). Mass spectrum  $m/z$ : 291 ( $\text{M}^+$ , 98%), 261 ( $[\text{M} - \text{NO}]^+$ , 26%), 245 ( $[\text{M} - \text{NO}_2]^+$ , 23%), 201 ( $[\text{M} - \text{SCNO}_2]^+$ , 100%). Anal. calcd. for  $\text{C}_8\text{H}_4\text{BrNO}_2\text{S}_2$ : C 33.12, H 1.38, N 4.83; found: C 32.75, H 1.62, N 4.51%.

### Synthesis of 5-nitro-2,2':5',2''-terthiophene ( $\text{HT}_3\text{NO}_2$ )

In 100 mL of acetic anhydride, 8.75 g (35 mmol) of  $\text{H}_2\text{T}_3$  was dissolved, and the mixture was warmed until the oligothiophene dissolved. To this solution was added dropwise with stirring 2.75 g (44 mmol) of nitric acid. The dark-coloured solution was quenched with saturated sodium bicarbonate, at which time a dark-red precipitate formed. The solid was suction-filtered and washed with toluene and hexanes to give 3.19 g (31%) of an orange powder. Gradient sublimation in a tube furnace (95–70 °C) afforded analytically pure red crystals suitable for X-ray crystallography. Rotary evaporation followed by recrystallization (from ethanol) and sublimation (two times) yielded 1.45 g (25.6%) of analytically pure material. Mp 157–160 °C.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$  (ppm): 8.12 (d,  $J_{\text{AB}}$  4.5 Hz, 1 H), 7.69 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 7.63 (d,  $J_{\text{AB}}$  6.0 Hz, 1H), 7.46 (d,  $J_{\text{AB}}$  4.5 Hz, 2 H), 7.41 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 7.15 (dd,  $J_{\text{AB}} = J_{\text{AC}}$  4.5 Hz, 1 H). Mass spectrum  $m/z$ : 293 ( $\text{M}^+$ , 100%), 247 ( $[\text{M} - \text{NO}_2]^+$ , 25%), 203 (87%). Anal. calcd. for  $\text{C}_{12}\text{H}_7\text{NO}_2\text{S}_3$ : C 49.13, H 2.40, N 4.77; found: C 49.14, H 2.46, N 4.77%.

### Synthesis of 5-bromo-5'-nitro-2,2':5',2''-terthiophene ( $\text{BrT}_3\text{NO}_2$ )

In 100 mL of DMF was dissolved 0.78 g (2.7 mmol)  $\text{HT}_3\text{NO}_2$ . While stirring in the dark, 1.84 g (10 mmol) was added portionwise over the course of 2 h, after which the solution was stirred overnight. Crude material precipitated upon addition of water. The red solid was recrystallized from toluene and repeatedly sublimed (120–90 °C) to obtain analytically pure material. Mp 172–175 °C. Mass spec-

trum  $m/z$ : 373 ( $\text{M}^+$ , 100%), 327 ( $[\text{M} - \text{NO}_2]^+$ , 27%), 283 ( $[\text{M} - \text{SCNO}_2]^+$ , 73%), 145 (33%). Anal. calcd. for  $\text{C}_{12}\text{H}_6\text{BrNO}_2\text{S}_3$ : C 38.72, H 1.62, N 3.76; found: C 38.57, H 1.94, N 3.84%. Crystals suitable for X-ray crystallography were prepared by repeatedly recrystallizing the crude, i. e., isolating and redissolving material in toluene; this had the effect of concentrating the multibrominated byproducts, giving the structure as discussed in the text.

### Synthesis of 5-iodo-5'-nitro-2,2':5',2''-terthiophene ( $\text{IT}_3\text{NO}_2$ )

To a solution of 3.19 g (11 mmol)  $\text{HT}_3\text{NO}_2$  in 250 mL of DMF was added portionwise (in the dark) 2.48 g (11 mmol) of NIS. The mixture was then stirred overnight, followed by precipitation upon addition of water, giving 2.7 g (64%) of red-orange material. This material was purified by sublimation in vacuo. Mp 232–233 °C.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.86 (d,  $J_{\text{AB}}$  4.5 Hz, 1 H), 7.26 (d,  $J_{\text{AB}}$  3.0 Hz, 1 H), 7.20 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 7.09 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 7.07 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H), 6.91 (d,  $J_{\text{AB}}$  4.0 Hz, 1 H). Mass spectrum  $m/z$ : 419 ( $\text{M}^+$ , 100%), 373 ( $[\text{M} - \text{NO}_2]^+$ , 23%), 329 (40%), 293 ( $[\text{M} - \text{I}]^+$ , 11%). Anal. calcd. for  $\text{C}_{12}\text{H}_6\text{INO}_2\text{S}_3$ : C 34.38, H 1.44, N 3.34; found: C 34.50, H 1.65, N 3.11%.

### Supplementary data

Supplementary data for this article (computational data, including optimized geometries, orbital energies, and vertical excitation energies on the series  $\text{R}^1\text{T}_n\text{R}^2$  ( $n = 1–3$ ;  $\text{R}^1 = \text{H}$  or  $\text{Br}$ ,  $\text{R}^2 = \text{H}$  or  $\text{NO}_2$ ) and experimental information on the synthesis of  $\text{XT}_4\text{NO}_2$  ( $\text{X} = \text{H}$ ,  $\text{Br}$ )) are available on the journal Web site (<http://canjchem.nrc.ca>) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5327. For more information on obtaining material, refer to <http://cisti-icist.nrc-cnrc.gc.ca/eng/ibp/cisti/collection/unpublished-data.html>. CCDCs 739773 ( $\text{HT}_3\text{NO}_2$ ) and 739774 ( $\text{BrT}_3\text{NO}_2$ ) contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via <http://www.ccdc.cam.ac.uk/conts/retrieving.html> (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or [deposit@ccdc.cam.ac.uk](mailto:deposit@ccdc.cam.ac.uk)).

### Acknowledgments

Funding for this research was primarily supplied by the Research Corporation (Cottrell College Science Award) and by Lakehead University. RCM would also like to thank SHARCNET for computational facilities. LCS was partially supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) USRA Award. Thanks to Prof. William Sears in the Department of Physics at Lakehead University and to Dr. Abdeljalil Assoud in the Department of Chemistry at the University of Waterloo for some helpful discussions.

# A halogenated pseudopterane diterpene from the Bahamian octocoral *Pseudopterogorgia acerosa*

Abhijeet S. Kate, Kelly Richard, Balaji Ramanathan, and Russell G. Kerr

**Abstract:** Two new pseudopterane diterpenes have been isolated from the gorgonian coral *Pseudopterogorgia acerosa* and have been characterized by NMR and mass spectrometry. These include 15-chlorodeoxypseudopterolide (**1**), the first halogenated pseudopterane diterpene, and 11-*epi*-pseudopteranol (**2**), an epimer of the previously described 11-pseudopteranol. In addition, six known diterpenes were also isolated from this collection including deoxypseudopterolide (**3**), pseudopteradiene (**4**), acerosolide (**5**), pseudopterolide-methanol adduct (**6**), 11-pseudopteranol (**7**), and isogorgiacerodiol (**8**). The cytotoxicity of these eight compounds towards three cancer cell lines (HeLa, PC-3, and HCT116) was assessed and the chlorinated pseudopterane **1** was found to have modest but selective activity against HCT116 (IC<sub>50</sub> 2.7 µmol/L), whereas its nonchlorinated derivative **3** was inactive. This indicates that the halo functionality can modify the cytotoxic activity of pseudopterane diterpenes and potentially other classes of diterpenes.

**Key words:** pseudopterane, diterpene, gorgonian, *Pseudopterogorgia acerosa*, marine natural product.

**Résumé :** On a isolé deux nouveaux diterpènes pseudoptéranoides du corail gorgonien *Pseudopterogorgia acerosa* et on les a caractérisés par MN et spectrométrie de masse. Il s'agit du 15-chlorodésoxypseudoptérolide (**1**), le premier diterpène pseudoptérané halogéné, et le 11-*épi*-pseudoptéranol (**2**), un épimère du 11-pseudoptéranol décrit antérieurement. On a isolé de plus six diterpènes connus à partir de cette collection, sont le désoxypseudoptérolide (**3**), le pseudoptéradène (**4**), l'acérosolide (**5**), l'adduit pseudoptérolide-méthanol (**6**), le 11-pseudoptéranol (**7**) et l'isogorgiacérodol (**8**). On a évalué la cytotoxicité de ces huit composés vis-à-vis de trois lignées de cellules cancéreuses (HeLa, PC-3 et HCT116) et on a trouvé que le pseudoptéranol chloré, **1**, présente une modeste, mais sélective, activité contre la HCT116 (IC<sub>50</sub>, 2,7 µmol/L) alors que son dérivé non chloré, **3**, est inactif. Ces résultats indiquent qu'une fonction halogénée peut modifier l'activité cytotoxique des pseudoptéranoides et éventuellement d'autres classes de diterpènes.

**Mots-clés :** pseudoptérané, diterpène, gorgonien, *Pseudopterogorgia acerosa*, produit marin naturel.

[Traduit par la Rédaction]

## Introduction

Pseudopterane diterpenes represent a biosynthetically intriguing family of diterpenes with a 12-membered carbocyclic skeleton. In 1982, Fenical and Clardy described pseudopterolide as the first pseudopterane and reported that this natural product exhibited considerable activity in the sea urchin antiproliferation assay.<sup>1</sup> Octocorals of the genus *Pseudopterogorgia* are well-known as a rich source of such pseudopterane diterpenes,<sup>2</sup> and *Pseudopterogorgia acerosa* collected from various locations has been found to be a source of a wide spectrum of such compounds.<sup>1–11</sup> We recently reported the isolation of a series of lipidyl pseudopteranes from *P. acerosa* which exhibit selective inhibitory activity against protein tyrosine phosphatase 1B.<sup>11</sup> An examination of the diterpene chemistry of a subsequent collection of *P. acerosa* from the Bahamas has led to the isolation of two new pseudopterane diterpenes along with

six previously described compounds. Herein, we report the isolation of the first halogenated pseudopterane diterpene 15-chlorodeoxypseudopterolide (**1**) and 11-*epi*-pseudopteranol (**2**), an epimer of a previously reported compound, along with six known compounds (**3–8**), five possessing the pseudopterane skeleton and one (**5**) with the 14-membered cembrane skeleton. A literature review revealed that cytotoxicities of only a few of these compounds have been reported,<sup>7,9</sup> and we therefore determined the cytotoxic activity against three cancer cell lines (PC-3, HCT116, and HeLa) for compounds **1–8** (Fig. 1).

## Results and discussion

*Pseudopterogorgia acerosa* was collected from Grand Bahama Island, Bahamas in 2005. Dried material was extracted with ethyl acetate and methylene chloride to yield 26.7 g of crude extract which was subjected to flash column

chromatography over silica using hexanes to ethyl acetate affording 11 fractions. The mid-polar to polar range of these fractions were further purified by either preparative TLC or column chromatography (silica) followed by a semi-preparative HPLC leading to the isolation of eight pure diterpenes (**1–8**).  $^1\text{H}$  NMR, MS, and database searching (MARINLIT) were used to rapidly identify known compounds **3–8**.<sup>3–10</sup>

Compound **1** was obtained as a colorless oil with the molecular formula  $\text{C}_{21}\text{H}_{23}\text{ClO}_5$  suggested by HRESIMS analysis ( $[\text{M} + \text{Na}]^+$   $m/z$ : 413.1101; calculated 413.1126). The MS analysis also revealed the presence of the characteristic chlorine isotopic pattern. The IR spectrum indicated the presence of an unsaturated  $\gamma$ -lactone ( $1756\text{ cm}^{-1}$ ) and a  $\beta$ -carbomethoxyfuran ( $1722\text{ cm}^{-1}$ ) which are common to many pseudopterane diterpenes.<sup>7</sup>  $^1\text{H}$  and  $^{13}\text{C}$  NMR data (Table 1) showed a strong resemblance to that of deoxypseudopterolide (**3**),<sup>9</sup> a previously described metabolite from *P. acerosa*. Careful comparison of the  $^1\text{H}$  NMR of **1** and **3** showed that the olefinic methyl signal of **3** at  $\delta$  1.79 was absent in **1** and was replaced with a signal at  $\delta$  4.20 (2H, s). The chemical shifts of H-14a ( $\Delta 0.32$ ), H-14b ( $\Delta 0.55$ ), H-12a ( $\Delta 0.14$ ), H-12b ( $\Delta 0.14$ ), H-1 ( $\Delta 0.08$ ), H-2a ( $\Delta 0.1$ ), H-2b ( $\Delta 0.09$ ), and H-11b ( $\Delta 0.04$ ) were shifted downfield in **1** with respect to **3** while other signals were almost identical ( $< \Delta 0.02$ ).

The proton signal at  $\delta$  4.20 ppm (H-15) exhibited HMBC correlations with carbons at  $\delta$  39.5 (C-1), 115.8 (C-14), and 147.5 (C-13) confirming the position of the chlorine atom on C-15. Further, the  $^1\text{H}$  chemical shifts of H-15 and H-14 were in accordance with that for 3-chloro-2-methylpropene.<sup>12</sup> Further structural confirmation was achieved by COSY and HMBC correlations (Fig. 2).

The relative configurations of C-7, C-8, and C-1 were deduced by examination of the  $^1\text{H}$ – $^1\text{H}$  coupling constants and NOESY data, along with consideration of the established stereochemistry of known metabolite **3**,<sup>9</sup> the presumed biosynthetic precursor. Notably, the  $^1\text{H}$ – $^1\text{H}$  coupling constant

between H-7 and H-8 of 4.5 Hz was the same as that observed for **3**.

The planar structure of 11-*epi*-pseudopteranol (**2**) was assembled based on  $^1\text{H}$ ,  $^{13}\text{C}$  NMR, COSY, HMQC, HMBC, and MS data. HR-MS analysis of **2** revealed a molecular formula of  $\text{C}_{21}\text{H}_{24}\text{O}_6$  with  $m/z$  of 395.1452 as  $[\text{M} + \text{Na}]^+$  (calculated = 395.1465). The IR spectrum was similar to that of **1** and showed absorptions at  $1754\text{ cm}^{-1}$  and  $1723\text{ cm}^{-1}$  suggesting the presence of an unsaturated  $\gamma$  lactone ring as well as a  $\beta$ -carboxymethoxy furan moiety. The presence of an exchangeable proton in **2** was confirmed by a  $\text{D}_2\text{O}$  exchange experiment. The  $^1\text{H}$  NMR of **2** was found to be very similar to that of the known 11-pseudopteranol (**7**), in which the hydroxyl group at C-11 is in the  $\beta$  orientation and thus has the (*R*)-configuration. The  $^1\text{H}$  NMR showed differences in the proton chemical shifts: H-1 ( $\Delta 0.48\text{ ppm}$ ), H-12a ( $\Delta 0.37\text{ ppm}$ ), and H-11 ( $\Delta 0.15\text{ ppm}$ ) which were downfield in **2** with respect to **7**, while H-9 ( $\Delta 0.37\text{ ppm}$ ) was shifted upfield (Table 2). In compound **7**, the coupling constant between H-11 and H-12b of 11.3 Hz indicated a dihedral angle of approximately  $180^\circ$  while the  $J_{\text{HH}}$  value between the same protons in compound **2** was 3.5 Hz. An  $\alpha$  orientation is therefore suggested for the hydroxyl group at C-11 in **2**. The relative configuration of the other three stereocenters, C-7, C-8, and C-1, of compound **2** was established by comparing  $^1\text{H}$  and  $^{13}\text{C}$  chemical shifts and coupling constants with those of previously reported 11-pseudopteranol (**7**).<sup>10</sup> Assuming that compounds **1–8** share a common biosynthetic origin, it seems reasonable to suggest that the configurations at C-7, C-8, and C-1 are the same in **1** and **2**, and indeed in all members of this series.

Since the cytotoxic activity of many of the known compounds had not been reported, compounds **1–8** were evaluated in a cytotoxicity screen using SYBR Green<sup>13</sup> with HCT-116, HeLa, and PC-3 cells. None of the pseudopteroids showed any activity against PC-3 cells and only minimal activity was observed against the HeLa cell line.

<sup>a</sup> $^{13}\text{C}$  chemical shifts were obtained from  $^{13}\text{C}$  NMR, HMQC, and HMBC experiments.<sup>b</sup> $^{13}\text{C}$  multiplicities were based on DEPTQ and HMQC experiments; nr: not resolved.**Fig. 2.**  $^1\text{H}$ – $^1\text{H}$  COSY and HMBC correlations of compound **1**.

Interesting trends were observed in the activity of **1**–**8** against the HCT-116 cell line (Table 3).

The new chlorinated pseudopteranolide **1** was found to have an  $\text{IC}_{50}$  of 2.7  $\mu\text{mol/L}$  whereas the nonchlorinated analog **3** was inactive, thus indicating that incorporation of a halogen can greatly increase the cytotoxic activity of pseudopteranolides. A similar phenomenon may also hold true for other classes of diterpenes. It is also evident that pseudopteranolides

with an oxygen functionality at C-11 or C-12, or a C-11–C-12 double bond (**2**, **4**–**6**, **8**) generally exhibit modest cytotoxic activity, whereas the derivative that is not functionalized at these locations (**3**) is inactive.

## Experimental section

### General experimental procedures

$^1\text{H}$  (300 MHz and 400 MHz) and  $^{13}\text{C}$  (75 MHz and 100 MHz) NMR data were recorded in  $\text{CDCl}_3$  solution. Spectra were referenced with residual solvent signal with resonances at  $\delta_{\text{H}/^{13}\text{C}}$  at 7.27/77.00 ( $\text{CDCl}_3$ ). UV spectra were measured with a Beckman Coulter – DU 530, Life Science UV/VIS spectrophotometer. The optical rotation  $[\alpha]_{\text{D}}$  values were determined with a Digipol 781, Rudolph Instruments, and IR spectra were measured with Bruker–Equinox 55 (NaCl cell). Flash column chromatography was performed with Silica gel 200–425 mesh size and Silica gel 60  $\text{F}_{254}$  (Whatmann) pre-coated plates were used for preparative TLC. The HPLC experiments were carried out on a PerkinElmer system consisting of a Series 250 pump and LC-235 diode array detector for semi-preparative purpose. A Luna 5  $\mu$  Phenyl-Hexyl 250  $\times$  10 mm Phenomenex column was used for purification of compounds. Thermo Accela™ LC

### Collection and extraction procedure

Diterpenes **1–8** were isolated from the octocoral *Pseudopterogorgia acerosa*, collected at Grand Bahama Island, Bahamas in 2005. Sun-dried coral (367 g) was extracted with EtOAc–CH<sub>2</sub>Cl<sub>2</sub> (1:1) repeatedly until the extract was colorless (8 × 1L) to afford a dark brown oil (27.6 g). The crude extract was subjected to flash chromatography over silica using hexanes–EtOAc mixtures as mobile phase. A total of 11 fractions were collected and the 60% hexanes fraction was further subjected to column chromatography over silica with an isocratic solvent system of hexanes–CH<sub>2</sub>Cl<sub>2</sub>–acetone (64:27:9). Fractions were collected and combined based on TLC into fractions I–VIII. Fraction V was further separated by preparative TLC followed by semi-preparative HPLC to afford **3** (27.7 mg), **4** (3.0 mg), and **1** (1.0 mg). HPLC

purification of the 50% hexanes fraction led to the isolation of **5** (17.3 mg), and the 40% hexanes fraction was purified by preparative TLC and HPLC to give **6** (5.2 mg), and **2** (3.0 mg). HPLC purification of the 30% and the combined 20% and 10% hexane fractions led to **7** (4.0 mg) and **8** (1.9 mg), respectively.

# Heck-type hydroarylations and 1,3-dipolar cycloaddition reactions of new tricyclic hydrazones

Melek Gul and Nuket Ocal

**Abstract:** The C–C coupling of the new tricyclic hydrazones **3–7** with aryl and heteroaryl halides gave under reductive Heck conditions the tricyclic 1-(arylideneamino)pyrrolidine-2,5-diones **8–11a**, **9–11b**, **10c**, and **12**. The [3+2] cycloadditions of **3–7** with *p*-chlorophenyl nitrile oxide (**13**) yielded the bridged isoxazoline derivatives **14–18** with potential biological activity.

**Key words:** tricyclic hydrazone, reductive Heck reactions, C–C coupling, nitrile oxides, isoxazolines.

**Résumé :** Le couplage C–C des nouvelles hydrazones tricycliques **3–7** avec des halogénures d'aryles et d'hétéroaryles, dans les conditions réductrices de Heck, conduisent à la formation des 1-(arylidèneamino)pyrrolidine-2,5-diones tricycles **8–11a**, **9–11b**, **10c** et **12**. Les cycloadditions [3+2] des composés **3–7** avec l'oxyde du *p*-chlorophénylnitrile (**13**) conduisent à la formation des dérivés isoxazolines pontées **14–18** qui peuvent présenter une activité biologique.

**Mots-clés :** hydrazone tricyclique, réactions réductrices de Heck, couplage C–C, oxydes de nitriles, isoxazolines.

[Traduit par la Rédaction]

## Introduction

In a collaborative effort with Kaufmann and co-workers,<sup>1–3</sup> we reported palladium(II) acetate catalyzed asymmetric Heck-type hydroarylations of bicyclic and tricyclic alkenes, such as epibatidine analogs, and their domino–Heck applications by treating with aryl (or heteroaryl) iodides.<sup>4</sup> We then focused on reductive Heck reactions of tricyclic molecules containing a strained C=C bond and an acylamino imide or hydrazide group and possessing potential biological activity.<sup>5,6</sup>

Hydrazones are a versatile class of ligands that have extensive applications in various fields, possessing pronounced biological and pharmaceutical activities as antitumor,<sup>7,8</sup> antimicrobial,<sup>9</sup> antituberculosis,<sup>10</sup> and antimalarial agents.<sup>11</sup> These compounds play an important role in improving the antitumor selectivity and toxicity profile of antitumor agents by forming drug-carrier systems employing suitable carrier proteins.<sup>12</sup> Hydrazones, such as salicylaldehyde and heteroaryl substituted aldo hydrazones, act as orally effective drugs for treatment of iron-overload diseases or genetic diseases like  $\beta$ -thalassemia.<sup>13</sup>

In addition, five-membered heterocycles such as isoxazolines represent a class of compounds of great biological importance. For instance, isoxazolines possess a broad spectrum of biological activity, such as insecticidal, antibacterial, antibiotic, antitumor, and antifungal activities.<sup>14–16</sup>

Scheme 1. Preparation of compound **2**.

Isoxazolines are generally synthesized by 1,3-dipolar cycloadditions of alkenes onto nitrile oxides. 1,3-Dipolar cycloaddition reactions are useful tools for the construction of biologically potent five-membered heterocycles.<sup>17</sup>

There are a few reports in the literature of the synthesis of tricyclic hydrazones and practically no information on their structure analyses.<sup>18,19</sup> Therefore, we became interested in the synthesis of possible bioactive aryl- and hetero-aryl substituted tricyclic hydrazones by reductive Heck reactions and their isoxazoline derivatives via 1,3-dipolar cycloadditions.

## Results and discussion

Our synthesis started with the reaction of *endo*-bicyclo[2.2.1]-hept-5-ene-2,3-dicarboxylic anhydride (**1**) and hydrazine hydrate. The reaction occurred in benzene at room temperature to give *N*-amino-bicyclo[2.2.1]hept-5-ene-2,endo-3-endo-dicarboximide (**2**) as colorless crystals in a yield of 87%<sup>19</sup> (Scheme 1).

Received 15 July 2009. Accepted 24 November 2009. Published on the NRC Research Press Web site at canjchem.nrc.ca on 4 March 2010.

This article is dedicated to Professor Dieter E. Kaufmann on the occasion of his 62nd birthday.

**Scheme 2.** Synthesis of compounds **3–7**.

We carried out the condensation of **2** with aryl- or heteroaryl-substituted aldehydes in dry ethanol to obtain new tricyclic hydrazones (**3–7**) (Scheme 2). The structures of these synthesized compounds were elucidated using FTIR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and mass spectroscopic methods as well as elemental analysis.  $^1\text{H}$  NMR spectroscopy revealed that in  $\text{CDCl}_3$  **4–7** exist as an inseparable mixture of *E* and *Z* isomers pertaining to the stereochemistry about the carbon= nitrogen double bond; the major isomers were tentatively assigned the *E* configuration. In compounds **4–7**, varying ratios of *E/Z* isomers (93:7, 92:8, 78:22, 52:48, respectively) of the C=N bond were observed. The percentages of *E* and *Z* isomers were determined by integration of the  $\text{H}_8$  protons. Assignment of the stereochemistry was based upon the consideration that in the *E* isomer, the proton attached to C=N is in proximity to the imide nitrogen, resulting in an upfield shift compared with the chemical shift of the *Z* isomer. Further evidence for these structures were obtained from the phase-sensitive NOESY measurements. The NOESY experiment confirmed the assigned stereochemistries, showing an interaction between  $\text{H}_2$  and  $\text{H}_3$  and the  $\text{H}_8$ . In addition to the  $^{13}\text{C}$  NMR and FTIR spectral data and elemental analyses which were in agreement with the proposed structures, the mass spectra of all new compounds showed the expected molecular ion peaks.

Treatment of **3** with 4-chloro-1-iodobenzene and 4-methoxy-1-iodobenzene under reductive Heck conditions and subsequent column chromatography on silica gel gave **8a** and **8b** as single diastereomers in isolated yields of 55%–61%. The same reductive Heck arylation conditions were successfully applied to the reaction of **4** with 4-methoxy-1-iodobenzene and 2-chloro-5-iodopyridine to give the new *exo*-arylated heterocycles **9a** and **9b** in good yields after chromatographic separation. We also synthesized **10a**, **10b**, and **10c** from **5** with 2-iodothiophene, 4-chloro-1-iodobenzene, and 2-chloro-1-iodobenzene and prepared **11a** and **11b** from **6** with 1-iodobenzene and 2-iodothiophene (all obtained as *exo*-isomers) under the same conditions. This hydroarylation reaction was also applied successfully to **7** using 4-methoxy-1-iodobenzene to give **12** containing 4-methoxyphenyl group (Table 1 and Scheme 3). All new compounds were observed as *E* forms due to the isomerization of *Z* forms during hydroarylation conditions.

The stereochemistry for each Heck product was inferred from NMR spectra including diagnostic spin–spin interac-

**Scheme 3.** Synthesis of reductive Heck compounds **8–12**.

tions. (Table 2). The *exo*-position of the C–5 substituent was confirmed by the fact that  $\text{H}_5$  showed no significant interaction with  $\text{H}_1$ . The geminal protons on C–6 were identified by vicinal coupling to  $\text{H}_1$ .

Additionally,  $^1\text{H}$ – $^1\text{H}$  COSY spectra showed cross peaks between  $\text{H}_2$  and  $\text{H}_3$  and between  $\text{H}_5$  and  $\text{H}_6$ , respectively. In addition to the  $^{13}\text{C}$  NMR, NOESY, HSQC, and FTIR spectral data and elemental analyses which were in agreement with the proposed structures, the mass spectra of all new compounds showed the expected molecular ion peaks.

Norbornene and its derivatives have figured prominently in organic chemistry. The presence of a rigid bicyclic skeleton gives rise to stereoisomers with fixed spatial orientation of substituents. The double bond in substituted norbornenes is quite reactive toward cycloaddends, in particular toward nitrile oxides in 1,3-dipolar additions. We carried out the [3+2] cycloaddition of **3–7** with 4-chlorophenyl nitrile oxide **13** (generated in situ from 4-chlorobenzaldehyde with  $\text{NaOCl}$ ) to obtain the target compounds **14–18** (Scheme 4), respectively.

The  $^1\text{H}$  NMR spectra of **14–18** are in accord with the proposed structures. To identify the configuration of the isoxazolines with tricyclic hydrazone adducts, we have studied selective  $^1\text{H}$ – $^1\text{H}$  COSY and NOESY spectra obtained from these compounds (Table 3).

$^1\text{H}$ – $^1\text{H}$  COSY spectra show the cross peaks between resonances for  $\text{H}_2$  and  $\text{H}_3$ ;  $\text{H}_{5n}$  and  $\text{H}_{6n}$ . NOESY spectra show that there are appropriate cross-peak resonances ( $\text{H}_1$  and  $\text{H}_2$ ;  $\text{H}_1$  and  $\text{H}_{6n}$ ;  $\text{H}_4$  and  $\text{H}_3$ ;  $\text{H}_4$  and  $\text{H}_{5n}$ ;  $\text{H}_2$  and  $\text{H}_{6n}$ ;  $\text{H}_3$  and  $\text{H}_{5n}$ , respectively) verifying that the six protons are in close spatial proximity and syn. The EI-MS spectra of cycloadducts **14–18** showed the characteristic molecular ion peaks.

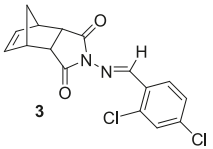

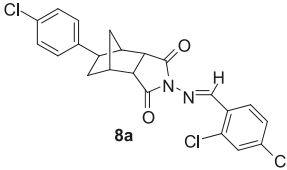

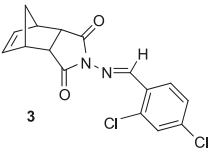

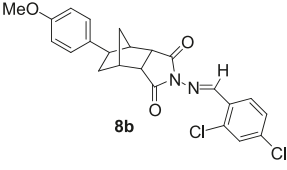

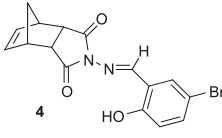

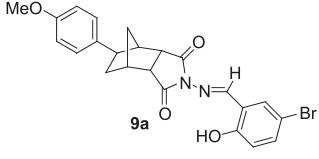

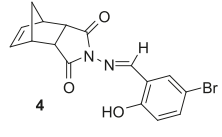

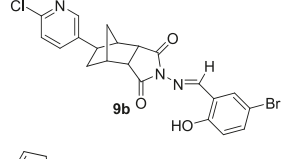

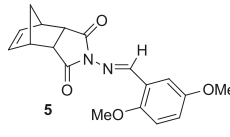

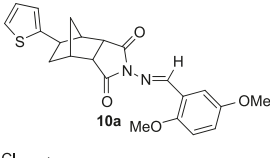

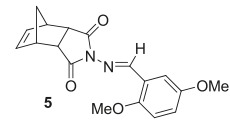

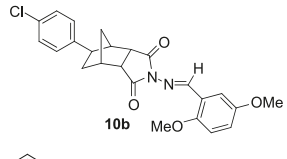

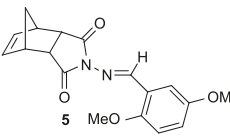

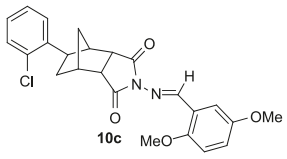

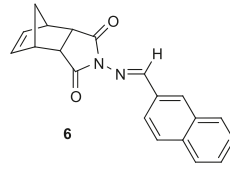

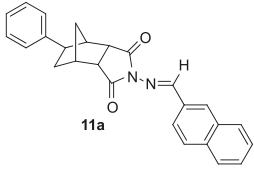

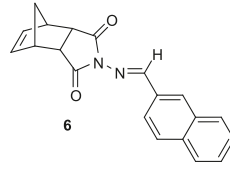

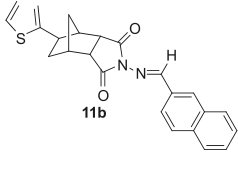

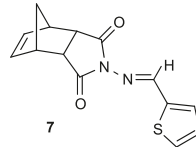

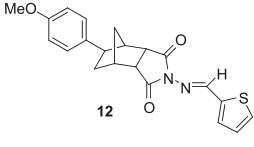

In summary, palladium(II) acetate catalyzed hydroarylation of the readily accessible tricyclic hydrazones **3–7**, in the presence of triphenylarsine as ligand, was shown to be a stereoselective, versatile, and high-yield approach to the synthesis of aryl and heteroaryl derivatives of tricyclic hydrazones. Our results have also demonstrated that the 1,3-dipolar cycloadditions of nitrile oxides onto bridged tricyclic hydrazone derivatives prove useful for the construction of novel heterocycles of potential pharmacological interest.

## Experimental

All the reactions were carried out under nitrogen atmosphere unless otherwise indicated. Reactions were monitored by thin-layer chromatography (TLC). Visualization of the developed chromatograms was performed either with UV light or  $\text{KMnO}_4$  stain. Products were purified by silica gel chromatography with a solvent gradient of 2:1 (ethyl acetate/*n*-hexane) to afford the title compounds. IR spectra were obtained with a PerkinElmer FTIR instrument, and absorption frequencies are reported in  $\text{cm}^{-1}$ . Melting points

were determined with a Gallenkamp digital thermometer equipment. All melting points are uncorrected. NMR spectra were determined with a Bruker Ac-250 MHz NMR, Bruker Ac-400 MHz NMR, or Varian-INOVA-500 MHz instrument. 2D NMR experiments, such as COSY, 2D NOESY, HMBC, and HSQC, were performed with a Bruker Ac-400 MHz instrument. TMS (tetramethylsilane) was used as an internal standard and  $\text{CDCl}_3$  was used as the solvent. Signal multiplicities in the NMR spectra are reported as follows: s, singlet; brs, broad singlet; d, doublet; dd, doublet of doublets; and m, multiplet. Mass spectra were measured either with Agilent LC–MSD Trap SL or MS-ESI. Elemental analyses were carried out with a Thermo Flash EA 1112 Series apparatus.

#### Experimental procedure for the preparation of tricyclic hydrazones, **3–7**

A mixture of **2** (178.85 mg, 1 mmol) and aromatic or heteroaromatic aldehyde (1.00 mmol) in ethanol (50–70 mL) was heated at reflux for 10–12 h under nitrogen. The reaction mixture was concentrated and the residue was chromatographed on silica gel with ethyl acetate/*n*-hexane.

**Experimental procedure for the preparation of 8a–11a, 8b–11b, 10c, and 12**

A solution of Pd(OAc)<sub>2</sub> (5.6 mg, 0.025 mmol) and AsPh<sub>3</sub> (33.7 mg, 0.11 mmol) in dry DMF (3 mL) was stirred in a Schlenk flask under nitrogen at 65 °C for 15 min to form the catalyst complex. Then, aryl iodide (306 mg, 1.5 mmol), hydrazone (3–7; 1.00 mmol), triethylamine (354 mg, 3.5 mmol), and formic acid (138 mg, 3.0 mmol) were added. The mixture was heated to 65 °C for 24–48 h. After cooling down to RT, brine (50 mL) was added, the reaction mixture was extracted with ethyl acetate, and dried over MgSO<sub>4</sub>. The solvent was evaporated, and the residue was purified by chromatography.

**Experimental procedure for the preparation of 14–18**

To a solution of 4-chlorobenzaldoxime (202.25 mg, 1.3 mmol) in dichloromethane was added tricyclic hydrazone **3–7** (1 mmol), and the solution was cooled to 0 °C. Aqueous sodium hypochloride (5.25%, 3.5 g, 2.5 mmol) was added dropwise over 30 min, and the reaction was stirred overnight (0 °C – room temperature). The reaction mixture was extracted with either dichloromethane (3 × 10 mL) or diethyl ether and dried over MgSO<sub>4</sub>. The solvent was evaporated, and the residue was purified by chromatography.

# Microwave-assisted, palladium-catalyzed carbonylative cyclization — Rapid synthesis of 2-quinolones from unprotected 2-iodoanilines and terminal alkynes

Jia-Rong Chen, Jie Liao, and Wen-Jing Xiao

**Abstract:** Palladium-catalyzed cyclocarbonylations of 2-iodoanilines with various terminal alkynes have been carried out by the use of commercially available molybdenum hexacarbonyl as a convenient and solid carbon monoxide source. The reactions were conducted at 160 °C for 30 min under microwave irradiation and in the presence of Et<sub>3</sub>N in THF, affording the corresponding 2-quinolone derivatives in good regioselectivities and yields.

**Key words:** microwave, palladium, carbonylation, 2-iodoaniline, 2-quinolone.

**Résumé :** Faisant appel à des catalyseurs de palladium et de l'hexacarbonyle de molybdène disponible commercialement comme source commode et solide de monoxyde de carbone, on a effectué des cyclocarbonylations de 2-iodoanilines avec divers alcynes en position terminale. Les réactions ont été effectuées à 160 °C, pendant 30 minutes, sous irradiations de micro-ondes et en présence de Et<sub>3</sub>N dans le THF et elles conduisent à la formation des 2-quinoléones correspondantes avec de bons rendements et de bonnes régiosélectivités.

**Mots-clés :** micro-onde, palladium, carbonylation, 2-iodoaniline, 2-quinoléone.

[Traduit par la Rédaction]

## Introduction

Undoubtedly, the transition-metal-catalyzed carbonylation has become one of the most important carbonyl-formation reactions in organic synthesis.<sup>1</sup> Particularly, palladium-catalyzed cyclocarbonylation of unsaturated substrates provides a unique, concise, and efficient approach toward carbo- and hetero-cycles bearing a carbonyl moiety.<sup>2</sup> For example, the insertion of CO into aryl–palladium bond leading to the formation of acylpalladium complex, which could react with various nucleophiles, is a ubiquitous process for the synthesis of aryl carbonyl compounds.<sup>3</sup> Representative examples include palladium-catalyzed carbonylative cyclizations of 2-iodophenols or 2-iodoanilines with unsaturated substrates, such as terminal alkynes, 1,2- and 1,3- dienes, and allenes by the use of gaseous CO.<sup>4</sup>

2-Quinolones are widely distributed in nature and in many biologically important alkaloids, which showed remarkable activities, such as anticancer,<sup>5</sup> antitumor, and antihypertensive properties.<sup>6</sup> In addition, they are useful intermediates in organic synthesis.<sup>7</sup> Conventional methods for the synthesis of 2-quinolones are usually based on the Friedländer synthesis via Schiff base condensation<sup>8</sup> and the Knorr synthesis through acid-catalyzed cyclization of  $\beta$ -ketoanilides.<sup>9</sup> Re-

cently, Kadnikov and Larock reported an elegant approach to 2-quinolones, which was based on palladium-catalyzed carbonylative annulation of terminal or internal alkynes with 2-iodoanilines.<sup>10</sup> However, relatively long reaction time and an additive (e.g., *n*-Bu<sub>4</sub>NCl) are usually required. Moreover, the amino group of 2-iodoanilines has to be protected in the reaction process. Therefore, the development of more rapid and flexible strategy for the synthesis of 2-quinolones is still highly desirable.

Microwave activation as a potential energy source has proven to be a very popular and useful technology in synthetic organic chemistry, especially in the synthesis of heterocyclic compounds.<sup>11</sup> Compared to the traditional heating, the microwave-accelerated reaction has the major advantages of shorter reaction times, cleaner product profiles, and minimal quantities of solvent. As part of our ongoing endeavors on carbo- and hetero-cycle-oriented organometallic catalysis,<sup>12</sup> we recently reported a rapid synthesis of chromen-2-one by microwave-accelerated, palladium-catalyzed carbonylative cyclization of 2-iodophenol with alkynes.<sup>13</sup> This method features the use of commercially available molybdenum hexacarbonyl as a convenient and solid carbon monoxide source.<sup>14</sup> Herein, we extend this carbonylative cyclization strategy as a practical and convenient synthesis

of 3- and 4-substituted 2-quinolones from 2-iodoanilines and terminal alkynes (Scheme 1).

## Results and discussion

The reaction conditions previously used for the carbonylative cyclization reactions of 2-iodophenol with alkynes<sup>13a</sup> were initially applied to the reaction of 2-iodoaniline with 1-octyne (Table 1, entry 1). To our delight, the desired 2-quinolone was obtained in a 59% yield as a mixture of two regioisomers. The structure of 2-quinolone (**1a**) was proposed by NMR and unambiguously confirmed by X-ray crystallographic analysis (Figure 1) (see Supplementary data). Fortunately, these two isomers can easily be separated by flash column chromatography. To optimize the reaction conditions, the effects of the bases, catalysts, ligands, and solvents on the model reaction were further examined.

As can be seen from the results summarized in Table 1, both organic and inorganic bases were effective in this reaction. Among the organic bases screened, trialkylamine gave better results than secondary alkyl amines did (Table 1, entries 2 and 4 vs. entry 3). The use of unhindered pyridines or DMAP as the base resulted in decreased yields but with better regioselectivity (Table 1, entries 5 and 7). A similar effect was also observed in the case of DBU (Table 1, entry 6). The employment of inorganic bases led to low yields and moderate regioselectivity for this reaction. As a result, Et<sub>3</sub>N proved to be the best base, and the desired products were obtained in overall 60% yield with 3.5:1 regioselective ratio. Thereafter, different palladium catalysts, ligands, and solvents were also carefully examined to further improve the yields and regioselectivity with Et<sub>3</sub>N as the base.

Among the three palladium-PPh<sub>3</sub> systems examined, Pd(OAc)<sub>2</sub> exhibited good catalytic activity (Table 2, entry 2). Thus, other common phosphine ligands, such as DPPB, DPPP, DPPE, and DPPF were then examined. It was found that DPPE was the best choice in terms of regioselectivity and yield (**1a:2a** = 4:1, 60%) (Table 2, entry 6). The profile of solvent via reaction efficiency revealed that the reaction in THF gave higher yield and regioselectivity than in other solvents (Table 2, entries 8–12). Thus, the optimized reaction conditions for the microwave-accelerated carbonylative cyclization of 2-iodoaniline and alkynes with Mo(CO)<sub>6</sub> as the CO source have been determined to be 1 mmol of 2-iodoaniline, 2 equiv. of alkyne, 0.5 equiv. of Mo(CO)<sub>6</sub>, 5 mol% Pd(OAc)<sub>2</sub>, and 20 mol% DPPE in the presence of 2 equiv. of Et<sub>3</sub>N in 1 mL of THF under microwave irradiation at 160 °C for 30 min (**1a:2a** = 3.9:1, 62% yield) (Table 2, entry 8).

With the standard conditions in hand, we next investigated the scope and limitation of this process. A series of alkyl/aryl alkynes and differently substituted 2-iodoanilines were subjected to the optimized conditions. Generally, the carbon-

**Note:** Representative experimental procedure: 2-iodoaniline (1 mmol), 1-octyne (2 mmol), base (2 mmol), Pd(OAc)<sub>2</sub> (5 mol%, 0.05 mmol), PPh<sub>3</sub> (20 mol%, 0.2 mmol), and Mo(CO)<sub>6</sub> (0.5 mmol); carried in THF (1 mL) under microwave irradiation at 60 °C for 10 min and then at 160 °C for 30 min.

<sup>a</sup>Isolated yield.

<sup>b</sup>The ratios were determined by GC.

<sup>c</sup>DMAP (1 mmol) and DIPEA (1 mmol) were used.

ylative cyclization proceeded smoothly with good yields. For example, 1-octyne, 1-heptyne, and 1-hexyne were suitable for this protocol (Table 2, entries 16 and 17), affording the 2-quinolones **1** and **2** in 60%, 69%, and 70% overall yields, respectively (Table 3, entries 1–3). Aryl-substituted alkynes can also be employed in this transformation. Importantly, only one regioisomer was isolated in these cases, although the yield was moderate (Table 3, entries 4, 6, 8, and 10–12). Structural variation in the iodoanilines component is also possible. For example, methyl, Cl, and Br can be introduced on the benzene ring at the C(4) position without significant loss in reaction yield or efficiency (Table 3, entries 5–12). As shown in Table 3 (entries 5, 6, and 9–15), we have successfully utilized halogenated 2-iodoaniline substrates in this reaction. Moreover, these products should be valuable for further chemical transformations.<sup>15</sup> Note that the reaction has some limitations. Neither internal alkynes or N-protected 2-iodoanilines can be used in this carbonylative annulation.

## Conclusions

In summary, we have established a rapid and efficient synthesis of 3- or 4-substituted 2-quinolones starting from readily available unprotected 2-iodoanilines and alkynes

under microwave-irradiation conditions. The current methodology is attractive because of the short reaction time, the operational simplicity, and the absence of toxic gaseous carbon monoxide.

## Experimental section

### General methods

Unless otherwise noted, materials were purchased from commercial suppliers and used without further purification. Solvents and liquid organic bases were freshly distilled according to the known procedures.<sup>16</sup> Column chromatography was performed using 200–300 mesh silica gel. All melting points are uncorrected. <sup>1</sup>H NMR spectra were recorded on Varian Mercury 400 (400 MHz) spectrometers. Chemical shifts are reported in ppm from TMS with the solvent resonance as the internal standard (CDCl<sub>3</sub>: δ 7.24, DMSO: δ 2.50). Data are reported as follows: chemical shift, multiplicity (singlet (s), doublet (d), triplet (t), quartet (q), broad (br), or multiplet (m)), coupling constants (Hz). <sup>13</sup>C NMR spectra were recorded on Varian Mercury 400 (100 MHz) with complete proton decoupling spectrophotometers (CDCl<sub>3</sub>: δ 77.7, DMSO: δ 39.5). Elemental analysis was performed on a Vario EL III elemental analysis instrument.

Compounds **1b**, **1c**, **1d**, **1f**, **1j**, **2a**, **2b**, and **2c** are known compounds; and the data of these compounds have been found to be identical with those reported.<sup>10a,17</sup>

All experiments were performed in a Smith Synthesizer producing controlled irradiation at 2450 MHz with a power of 0–300 W.

### Representative procedure for the synthesis of 2-quinolones from unprotected 2-iodoanilines and terminal alkynes

To a 2.0–5.0 mL process vial were added 2-iodoaniline (1 mmol) and Pd(OAc)<sub>2</sub> (0.05 mmol), DPPE (0.2 mmol), Et<sub>3</sub>N (2 mmol), alkyne (2 mmol), Mo(CO)<sub>6</sub> (0.5 mmol), and anhydrous THF (1 mL). The vial was immediately capped with a Teflon septum under N<sub>2</sub> and irradiated with microwave at 60 °C for 10 min, then at 160 °C for another 30 min. After cooling to room temperature, the contents of the vessel were filtered through a short Celite pad, washed with acetone, and then concentrated under reduced pressure. The residue was purified by silica-gel chromatography to afford the desired products.

12 <sup>c</sup>	Br	3-FC <sub>6</sub> H <sub>4</sub>	<b>1l</b>	47	

**Note:** Representative experimental procedure: iodoaniline (1 mmol), alkyne (2 mmol), Et<sub>3</sub>N (2 mmol), Pd(OAc)<sub>2</sub> (5 mol%, 0.05 mmol), DPPE (10 mol%, 0.10 mmol), and Mo(CO)<sub>6</sub> (0.5 mmol); carried out in THF (1 mL) under microwave irradiation at 60 °C for 10 min and then at 160 °C for 30 min.

<sup>a</sup>Isolated yield.

<sup>b</sup>The ratios were determined by GC.

<sup>c</sup>Only the major isomers were detected.

Mp 113–116 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 11.04 (s, 1H), 7.60 (s, 1H), 7.44 (t, *J* = 7.6 Hz, 1H), 7.29 (t, *J* = 10.6 Hz, 1H), 7.19 (t, *J* = 7.6 Hz, 1H), 2.67 (t, *J* = 7.6 Hz, 2H), 1.69 (t, *J* = 7.6 Hz, 1H), 1.64 (s, 2H), 1.43 (s, 2H), 1.35 (m, 4H), 0.90 (t, *J* = 7.0 Hz, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.5, 137.4, 136.5, 134.3, 129.2, 127.0, 122.3, 120.3, 115.6, 31.7, 30.2, 29.1, 28.3, 22.6, 14.1. MS *m/z*: 229 [M<sup>+</sup>]. Anal. calcd. for C<sub>15</sub>H<sub>19</sub>NO: C, 78.56; H, 8.35; N, 6.11. Found: C, 78.60; H, 8.30; N, 6.14.

#### 4-*n*-Hexyl-2-1*H*-quinoline (2a)

White solid (recrystallized from petroleum ether/acetone). Mp 155–157 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 12.33 (s, 1H), 7.73 (d, *J* = 8.0 Hz, 1H), 7.52–7.46 (m, 2H), 7.27–7.22 (m, 1H), 7.60 (s, 1H), 2.86 (t, *J* = 7.8 Hz, 2H), 1.83–1.69 (2H, m), 1.45 (t, *J* = 10.4 Hz, 2H), 1.83–1.69 (m, 2H), 1.36–1.33 (m, 4H), 0.95–0.88 (m, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.7, 153.3, 138.7, 130.2, 124.0, 122.3, 119.8, 119.2, 116.9, 32.2, 31.5, 29.1, 28.7, 22.5, 14.0. MS *m/z*: 229 [M<sup>+</sup>]. Anal. calcd. for C<sub>15</sub>H<sub>19</sub>NO: C, 78.56; H, 8.35; N, 6.11. Found: C, 78.59; H, 8.34; N, 6.14.

#### 3-*n*-Pentyl-2-1*H*-quinoline (1b)

Brown solid (recrystallized from petroleum ether/acetone). Mp 133–136 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 11.83 (s, 1H), 7.62 (s, 1H), 7.53–7.18 (m, 4H), 2.69 (t, *J* = 7.6 Hz, 2H), 1.71 (t, *J* = 1.6 Hz, 2H), 1.43–1.40 (m, 4H), 0.93 (t, *J* = 7.0 Hz, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.6, 137.4, 136.4, 134.2, 129.2, 126.9, 122.2, 120.3, 115.7, 31.6, 30.2, 28.0, 22.6, 14.0. MS *m/z*: 215 [M<sup>+</sup>]. Anal. calcd. for C<sub>14</sub>H<sub>17</sub>NO: C, 78.10; H, 7.96; N, 6.51. Found: C, 78.14; H, 7.92; N, 6.53.

#### 4-*n*-Pentyl-2-1*H*-quinoline (2b)

White solid (recrystallized from petroleum ether/acetone). Mp 142–145 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 600 MHz) δ: 12.75 (s, 1H), 7.71 (d, *J* = 8.0 Hz, 1H), 7.49 (d, *J* = 13.2 Hz, 2H), 7.25–7.21 (m, 1H), 6.59 (s, 1H), 2.84 (t, *J* = 7.6 Hz, 2H), 1.74–1.68 (2H, m), 1.50–1.44 (2H, m), 0.98 (t, *J* = 4.8 Hz, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.6, 153.4, 138.5, 130.3, 124.1, 122.4, 119.8, 119.2, 116.8, 32.2, 31.6, 28.0, 22.5, 14.0. MS *m/z*: 215 [M<sup>+</sup>]. Anal. calcd. for C<sub>14</sub>H<sub>17</sub>NO: C, 78.10; H, 7.96; N, 6.51. Found: C, 78.13; H, 7.98; N, 6.50.

#### 3-*n*-Butyl-2-1*H*-quinoline (1c)

Brown solid (recrystallized from petroleum ether/acetone). Mp 151–154 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 12.20 (s, 1H), 7.62 (s, 1H), 7.53–7.40 (m, 2H), 7.21–7.17 (m, 1H), 2.70 (t, *J* = 7.4 Hz, 2H), 1.74–1.66 (m, 2H), 1.49–1.44 (m, 2H), 0.99 (t, 7.4 Hz, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.6, 137.5, 136.4, 134.2, 126.9, 122.2, 120.3, 115.7, 30.5, 29.9, 22.5, 14.0. MS *m/z*: 201 [M<sup>+</sup>]. Anal. calcd. for C<sub>13</sub>H<sub>15</sub>NO: C, 77.58; H, 7.51; N, 6.96. Found: C, 77.60; H, 7.49; N, 6.99.

#### 4-*n*-Butyl-2-1*H*-quinoline (2c)

Brown solid (recrystallized from petroleum ether/acetone). Mp 112–115 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 12.77 (s, 1H), 7.72 (d, *J* = 5.2 Hz, 1H), 7.48 (d, *J* = 2.4 Hz, 2H), 7.24–7.21 (m, 1H), 6.60 (s, 1H), 2.85 (t, *J* = 5.2 Hz, 2H), 1.73–1.68 (m, 1H), 1.50–1.44 (m, 2H), 0.98 (t, *J* = 4.8 Hz, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.6, 153.4, 138.5, 130.3, 124.1, 122.4, 119.8, 119.2, 116.9, 31.9, 30.9, 22.6, 14.0. MS *m/z*: 201 [M<sup>+</sup>]. Anal. calcd. for C<sub>13</sub>H<sub>15</sub>NO: C, 77.58; H, 7.51; N, 6.96.

C, 77.58; H, 7.51; N, 6.96. Found: C, 77.56; H, 7.53; N, 6.94.

### 3-*n*-Phenyl-2-1*H*-quinoline (1d)

White solid (recrystallized from petroleum ether/acetone). Mp 229–232 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 11.98 (s, 1H), 8.11 (s, 1H), 7.78–7.73 (m, 3H), 7.51–7.20 (m, 6H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 161.1, 138.4, 136.3, 131.6, 130.2, 128.7, 128.1, 128.0, 121.9, 119.6, 114.7. MS *m/z*: 221 [M<sup>+</sup>]. Anal. calcd. for C<sub>15</sub>H<sub>11</sub>NO: C, 81.43; H, 5.01; N, 6.33. Found: C, 81.46; H, 5.04; N, 6.30.

### 3-*n*-Butyl-6-chloro-2-1*H*-quinoline (1e)

White solid (recrystallized from petroleum ether/acetone). Mp 169–172 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 12.76 (s, 1H), 7.48 (d, *J* = 12.8 Hz, 2H), 7.39 (d, *J* = 8.8 Hz, 2H), 2.67 (t, *J* = 3.6 Hz, 2H), 1.69–1.63 (m, 2H), 1.50–1.40 (m, 2H), 0.98 (t, *J* = 7.2 Hz, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.4, 135.9, 135.5, 135.2, 129.4, 127.5, 126.0, 121.2, 117.2, 30.4, 29.9, 22.5, 14.0. MS *m/z*: 238 [M<sup>+</sup>]. Anal. calcd. for C<sub>13</sub>H<sub>14</sub>ClNO: C, 66.24; H, 5.99; N, 5.94. Found: C, 66.26; H, 5.96; N, 5.92.

### 4-*n*-Butyl-6-chloro-2-1*H*-quinoline (2e)

White solid (recrystallized from petroleum ether/acetone). Mp 163–165 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 11.75 (s, 1H), 7.76 (d, *J* = 2.0 Hz, 1H), 7.53 (1H, dd, *J* = 2.0, 2.0 Hz), 7.33 (d, *J* = 8.8 Hz, 1H), 6.60 (s, 1H), 2.79 (t, *J* = 7.6 Hz, 2H), 1.58 (t, *J* = 7.6 Hz, 2H), 1.42–1.37 (m, 2H), 0.93 (t, *J* = 7.2 Hz, 3H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 161.4, 150.8, 137.6, 130.0, 125.8, 123.6, 120.9, 120.0, 117.5, 30.7, 30.4, 21.9, 13.7. MS *m/z*: 238 [M<sup>+</sup>]. Anal. calcd. for C<sub>13</sub>H<sub>14</sub>ClNO: C, 66.24; H, 5.99; N, 5.94. Found: C, 66.27; H, 5.97; N, 5.95.

### 3-Phenyl-6-chloro-2-2*H*-quinoline (1f)

Brown solid (recrystallized from petroleum ether/acetone). Mp 244–247 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 12.11 (s, 1H), 8.09 (s, 1H), 7.84 (d, *J* = 2.4 Hz, 1H), 7.76 (t, *J* = 4.2 Hz, 1H), 7.56–7.34 (m, 5H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 162.8, 137.3, 136.3, 135.6, 133.7, 130.5, 128.9, 128.4, 127.9, 127.0, 121.2, 116.9. MS *m/z*: 256 [M<sup>+</sup>]. Anal. calcd. for C<sub>15</sub>H<sub>10</sub>ClNO: C, 70.46; H, 3.94; N, 5.48. Found: C, 70.48; H, 3.96; N, 5.45.

### 3-Butyl-6-methyl-2-2*H*-quinoline (1g)

White solid (recrystallized from petroleum ether/acetone). Mp 144–147 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 11.67 (brs, 1H), 7.54 (s, 1H), 7.27 (m, 3H), 2.68 (t, *J* = 7.8 Hz, 2H), 2.43–2.38 (m, 3H), 1.72–1.65 (m, 2H), 1.50–1.41 (m, 2H), 1.02–0.96 (m, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.4, 136.2, 135.4, 134.0, 131.7, 130.5, 126.5, 120.2, 115.6, 30.5, 29.9, 22.5, 20.9, 14.0. MS *m/z*: 215 [M<sup>+</sup>]. Anal. calcd. for C<sub>14</sub>H<sub>17</sub>NO: C, 78.10; H, 7.96; N, 6.51. Found: C, 78.14; H, 7.97; N, 6.49.

### 4-Butyl-6-methyl-2-1*H*-quinoline (2g)

Yellow solid (recrystallized from petroleum ether/acetone). Mp 171–174 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 12.52 (s, 1H), 7.56–7.49 (m, 1H), 7.38–7.26 (m, 2H), 7.24–7.21 (m, 1H), 6.59 (d, *J* = 9.6 Hz, 1H), 2.85 (t, *J* = 7.6 Hz,

2H), 2.47–2.42 (t, *J* = 10.0 Hz, 3H), 1.77–1.70 (m, 2H), 1.68–1.43 (m, 2H), 1.03–0.94 (m, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz) δ: 164.5, 153.0, 136.5, 131.8, 131.6, 123.6, 119.7, 119.1, 116.8, 31.8, 30.8, 22.5, 21.2, 13.9. MS *m/z*: 215 [M<sup>+</sup>]. Anal. calcd. for C<sub>14</sub>H<sub>17</sub>NO: C, 78.10; H, 7.96; N, 6.51. Found: C, 78.14; H, 7.97; N, 6.48.

### 3-Phenyl-6-methyl-2-1*H*-quinoline (1h)

White solid (recrystallized from petroleum ether/acetone). Mp 220–223 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 11.90 (s, 1H), 8.02 (t, *J* = 10.0 Hz, 1H), 7.78–7.72 (m, 2H), 7.53 (d, *J* = 10.0 Hz, 1H), 7.46–7.22 (m, 5H), 2.36 (t, *J* = 9.8 Hz, 3H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 161.0, 137.4, 136.4, 131.5, 130.9, 128.8, 128.0, 127.8, 127.6, 119.6, 114.7, 20.5. MS *m/z*: 235 [M<sup>+</sup>]. Anal. calcd. for C<sub>16</sub>H<sub>13</sub>NO: C, 81.68; H, 5.57; N, 5.95. Found: C, 81.70; H, 5.60; N, 5.92.

### 3-Butyl-6-bromo-2-1*H*-quinoline (1i)

White solid (recrystallized from petroleum ether/acetone). Mp 172–174 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 12.36 (s, 1H), 7.65 (d, *J* = 2.4 Hz, 1H), 7.53 (d, *J* = 4.6 Hz, 2H), 7.28 (t, *J* = 8.2 Hz, 1H), 2.68 (t, *J* = 7.8 Hz, 2H), 1.71–1.63 (m, 2H), 1.48–1.42 (m, 2H), 0.98 (t, *J* = 7.2 Hz, 3H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 164.3, 136.2, 135.6, 135.2, 132.0, 129.2, 121.7, 117.4, 114.9, 30.4, 29.9, 22.5, 14.0. MS *m/z*: 281 [M<sup>+</sup>]. Anal. calcd. for C<sub>13</sub>H<sub>14</sub>BrNO: C, 55.73; H, 5.04; N, 5.00. Found: C, 55.70; H, 5.08; N, 5.02.

### 4-Butyl-6-bromo-2-1*H*-quinoline (2i)

White solid (recrystallized from petroleum ether/acetone). Mp 181–184 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 11.78 (1s, H), 7.89 (s, 1H), 7.66 (t, *J* = 4.4 Hz, 1H), 7.28 (d, *J* = 8.8 Hz, 1H), 6.4 (s, 1H), 2.79 (t, *J* = 7.4 Hz, 2H), 1.61–1.54 (m, 2H), 1.43–1.36 (m, 2H), 0.93 (t, *J* = 7.4 Hz). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 164.3, 136.2, 135.6, 135.2, 132.0, 129.2, 121.7, 117.4, 114.9, 30.4, 29.9, 22.5, 14.0. MS *m/z*: 281 [M<sup>+</sup>]. Anal. calcd. for C<sub>13</sub>H<sub>14</sub>BrNO: C, 55.73; H, 5.04; N, 5.00. Found: C, 55.70; H, 5.06; N, 5.01.

### 3-Phenyl-6-bromo-2-1*H*-quinoline (1j)

White solid (recrystallized from petroleum ether/acetone). Mp 256–259 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 12.10 (s, 1H), 7.98 (d, *J* = 2.0 Hz, 1H), 7.74 (d, *J* = 7.2 Hz, 1H), 7.66 (dd, *J* = 2.0, 1.6 Hz, 1H), 7.47–7.40 (m, 3H), 7.28 (d, *J* = 8.8 Hz, 1H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 160.8, 137.4, 136.4, 135.9, 132.7, 130.0, 128.7, 128.1, 128.0, 121.3, 116.8, 113.4. MS *m/z*: 300 [M<sup>+</sup>]. Anal. calcd. for C<sub>15</sub>H<sub>10</sub>BrNO: C, 60.02; H, 3.36; N, 4.67. Found: C, 60.04; H, 3.38; N, 4.65.

### 3-(*p*-Tolyl)-6-bromo-2-1*H*-quinoline (1k)

Yellow solid (recrystallized from petroleum ether/acetone). Mp 255–257 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 12.07 (s, 1H), 8.06 (s, 1H), 7.96 (d, *J* = 2.4 Hz, 1H), 7.64 (dd, *J* = 8.0, 1.6 Hz, 3H), 7.29–7.24 (m, 3H), 2.23 (m, 3H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 160.9, 137.5, 137.2, 135.8, 133.0, 132.3, 129.9, 128.7, 128.5, 121.4, 116.9, 116.7, 113.4, 21.0. MS *m/z*: 314 [M<sup>+</sup>]. Anal. calcd. for C<sub>16</sub>H<sub>12</sub>BrNO: C, 61.17; H, 3.85; N, 4.46. Found: C, 61.20; H, 3.83; N, 4.49.

### 3-(3-Fluorophenyl)-6-bromo-2-1H-quinoline (11)

White solid (recrystallized from petroleum ether/acetone). Mp 279–282 °C. <sup>1</sup>H NMR (DMSO, 400 MHz) δ: 12.16 (s, 1H), 8.19 (s, 1H), 7.98 (d, *J* = 1.6 Hz, 1H), 7.69–7.59 (m, 3H), 7.52–7.47 (m, 1H), 7.30–7.22 (m, 1H). <sup>13</sup>C NMR (DMSO, 100 MHz) δ: 163.0, 160.6, 138.1, 137.5, 133.0, 131.0, 130.0, 124.7, 121.1, 117.0, 115.6, 115.0, 113.5. MS *m/z*: 318 [M<sup>+</sup>]. Anal. calcd. for C<sub>15</sub>H<sub>9</sub>BrFNO: C, 56.63; H, 2.85; N, 4.40. Found: C, 56.67; H, 2.83; N, 4.43.

# AGOA hydration clusters produce the solvation effect on the aziridine...hydrofluoric acid complex — A modern proposal

Boaz G. Oliveira, Regiane C.M.U. Araújo, Antônio B. Carvalho, and Mozart N. Ramos

**Abstract:** The AGOA methodology was used to describe the hydration clusters of the  $C_2H_5N\cdots HF$  heterocyclic hydrogen-bonded complex. Using the TIP4P water-geometry model, the hydration clusters were generated by analyzing the finite gradients of the molecular electrostatic potential (MEP) of the solute ( $C_2H_5N\cdots HF$ ). The results obtained revealed high hydration energies ( $\Delta E^{HC-CORR}$ ) in the positive MEP field, indicating that the water molecules prefer to attack the methyl groups of the aziridine ring upon the formation of the  $C_2H_5N\cdots HF$  hydrogen-bonded complex. Although they are in accordance with the experimental behavior of the aziridine acid-catalyzed open-ring reaction, the theoretical results obtained here provide a new perspective on studies of the solvation effect because the AGOA protocol requires little computational effort to create the hydration-cluster structures.

**Key words:** hydrogen complexes, aziridine, AGOA, clusters, solvation.

**Résumé :** Afin de décrire les agrégats d'hydratation de complexes hétérocycliques  $C_2H_5N\cdots HF$  comportant une liaison hydrogène, on a fait appel à une méthode de calcul théorique dénommée, « AGOA », terme portugais signifiant à l'eau. Utilisant le modèle TIP4P pour la géométrie de l'eau, on a généré des agrégats d'hydratation en faisant une analyse des gradients finis du potentiel électrostatique moléculaire (PEM) du soluté ( $C_2H_5N\cdots HF$ ). Les résultats obtenus mettent en évidence la présence d'énergies d'hydratation élevées ( $\Delta E^{HC-CORR}$ ) dans le champ positif du PEM, ce qui indique que les molécules d'eau préfèrent s'attaquer aux groupements méthyles du noyau aziridine lors de la formation du complexe  $C_2H_5N\cdots HF$  comportant une liaison hydrogène. Même s'ils sont en accord avec le comportement expérimental de la réaction d'ouverture de l'aziridine catalysée par un acide, les résultats théoriques obtenus ici fournissent une nouvelle perspective pour les études d'effet de solvation puisque le protocole « AGOA » ne requiert que de faibles efforts de calculs pour générer les structures des agrégats d'hydratation.

**Mots-clés :** complexes d'hydrogène, aziridine, « AGOA », agrégats, solvation.

[Traduit par la Rédaction]

## Introduction

There can be no doubt that heterocyclic compounds are molecular structures that have properties essential to life,<sup>1</sup> and they are important sources of research into new pharmacological drugs,<sup>2</sup> the development of polymerization processes,<sup>3</sup> and the formation of amorphous metallic structures.<sup>4</sup> In the case of small rings,<sup>5,6</sup> in particular aziridine ( $C_2H_5N$ ), the capacity for reaction with nucleophiles in a basic or acid medium is well-known among organic chemists.<sup>7–10</sup> One example of this is the Wenker synthesis mechanism.<sup>11,12</sup> In short, the catalyzed open-ring reaction in acid medium occurs by a nucleophilic attack on the carbons of the aziridine ring,<sup>13</sup> as demonstrated in Fig. 1.

Using physicochemical studies, it has been demonstrated that acid species cause an acceleration in the reaction.<sup>14</sup> In this situation, the protonation of the aziridine ring weakens

its (C–N) adjacent bonds, inducing a rupture of the ring undergoing an  $S_N2$  mechanism, in which the aziridine cation (**2**) is the subsequent intermediate in the formation of the  $C_2H_5N\cdots HF$  hydrogen-bonded complex (**1**). According to this conjecture, the study of the solvent effect seems to be the key to better understanding of this reaction mechanism.

Over the years, the study of the solvent effect on the aziridine ring has been successfully developed by applying traditional methodologies.<sup>14</sup> In a recent proposal drawn up by Fang and co-workers,<sup>15</sup> interesting parameters relating to the solvent effect on aziridine in the acid-catalyzed open-ring reactions were obtained using SCRF continuum calculations. However, it is very important that a detailed description of the solvent effect be performed. This would involve explicit description of the action of the solvent molecules on the aziridine ring, which would seem to be essential to the

understanding of the acid-catalyzed open-ring reaction, even though it is not related to aziridine-ring protonation, but essentially occurs in the context of the  $C_2H_5N\cdots HF$  hydrogen-bonded complex. Given the ability of the continuum models, this is a task without promising results. A theoretical study of the solvent effect on the  $C_2H_5N\cdots HF$  hydrogen-

bonded complex, which discretely models the water molecules, should therefore be taken into account.<sup>16</sup>

### The most adequate methodology

Historically, the first idea for evaluating the solvent effect

**Fig. 4.** Relationship between hydration-cluster energies and the number of water molecules generated by AGOA to simulate the solvation effect in the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex.

in silico was based on the dielectric model,<sup>17,18</sup> and these were known as continuum methods. From theoretical formulations elaborated by Born,<sup>19</sup> Onsager,<sup>20</sup> and Kirkwood,<sup>21</sup> the continuum approach treats the solute using quantum mechanics, inserting it into a cavity molded as overlapping spheres. Recently, there has been intensive development of modern continuum implementations,<sup>22–24</sup> although these methodologies have serious limitations when it comes to describing specific interactions between solute and solvent.<sup>25</sup> These limitations can be partly overcome by the use of discrete models,<sup>26</sup> such as Monte Carlo or molecular dynamics.<sup>27–30</sup> These models provide an understanding of the real question regarding liquids, which is the association of a

large number of different configurations of the solvent. However, the application of these discrete methods has encountered a number of disadvantages, such as (i) the need for specific force fields, (ii) the dependence on the initial liquid configuration, and (iii) high computational cost.

It was therefore necessary to develop an alternative method of generating hydration clusters involving positioning the solvent molecules around the polar solutes without depending on specific force fields and (or) quantum-mechanical/molecular-mechanical calculations. The AGOA method was developed out of pioneering work carried out by Hernandez et al.,<sup>31</sup> as a way of generating liquid configurations by the analysis of the electrostatic potential of the solute. AGOA was further used to calibrate the force field for computational simulations. As a consequence, Hernandez and Longo<sup>32</sup> suggested another computational methodology called ab initio parametrization (AIPAR). In comparison to the OPLS data,<sup>33,34</sup> AIPAR has been successfully proven to simulate solvation in functional groups, such as methanol, acetone, methyl mercaptan, imidazole, oxazole, and furan. In the case of aziridine, however, the present study will not investigate the solvent effect in the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  hydrogen-bonded complex using traditional discrete techniques, such as Monte Carlo or molecular dynamics. On the contrary, the aim here is to investigate the liquid configurations in the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  hydrogen-bonded complex by way of AGOA. In this way, it is hoped that a suitable explanation of the aqueous stability of this complex will be found, thereby corroborating some aspects of the experimental aziridine acid-catalyzed open-ring reaction.<sup>35</sup>

## Computational details and procedure

The optimized geometry and molecular electrostatic potential (MEP)<sup>36</sup> of the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex were obtained using the density functional theory (DFT)<sup>37,38</sup> and the B3LYP hybrid functional.<sup>39–41</sup> The 6–311++G(d,p) basis set was used and all calculations were performed on the GAUSSIAN 98W program.<sup>42</sup> The hydration-cluster structures (solute:water) were generated by AGOA software, version 2.0.<sup>43</sup> Assuming that the electrostatic effects<sup>44</sup> are the most important interactions between

polar solutes and water molecules, AGOA interprets the MEP of the solute by plotting the solvent accessible surface area (SASA)<sup>45</sup> on a grid of  $20^3 = 8000$  points with the following dimensions:  $20 \times 20 \times 20 \text{ \AA}$ .

For notational purposes alone, the water molecules were distributed at equally spaced intervals in this cube. Single-point calculations for each hydration cluster ( $\Delta E^{\text{HC}}$ ) were then obtained as follows:

$$[1] \quad \Delta E^{\text{HC}} = E^{\text{TOTAL}} - E^{\text{SOLUTE}} - E^{\text{WATER}}$$

where  $E^{\text{TOTAL}}$ ,  $E^{\text{SOLUTE}}$ , and  $E^{\text{WATER}}$  correspond to the hydration-cluster energies of the dimer (solute:water), isolated solute ( $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$ ), and individual water molecules, respectively. All hydration-cluster energies  $\Delta E^{\text{HC}}$  were corrected using Boys and Bernardi's BSSE method,<sup>46</sup> and the values of the corrected hydration-cluster energies  $\Delta E^{\text{HC-CORR}}$  were then determined as follows:

$$[2] \quad \Delta E^{\text{HC-CORR}} = \Delta E^{\text{HC}} - \text{BSSE}$$

## Results and discussion

### Gas phase geometry and molecular electrostatic potential

First, it should be noted that the aim of this study is not to explore the potential-energy surface of the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex. Second, using the B3LYP/6-311++G(d,p) calculations to optimize the geometry of this complex, one particular minimum of the potential-energy surface was identified by analysis of the infrared spectrum in which no imaginary frequency had been detected. The optimized geometry of the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  complex is illustrated in Fig. 2a.<sup>47,48</sup>

In accordance with the AGOA standard protocol,<sup>31</sup> the optimized geometry of the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  complex was used to compute its MEP, whose surface can be seen in Fig. 2b. The maximum (+0.05 au) and minimum (−0.05 au) of the MEP regions are represented by transparent and meshed surfaces, respectively.

### Hydration clusters and interaction energies

AGOA describes hydration clusters by describing the MEP gradient (see eq. [3]) of the solute, and also uses the TIP4P geometry model to orient the water molecules around the solute.<sup>49</sup>

$$[3] \quad E(\text{H}_2\text{O}) = -\nabla\text{MEP}$$

The hydration clusters generated using AGOA for the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  hydrogen-bonded complex are shown in Fig. 3. It can be seen that two groups of 14 water molecules were positioned in the maximum (max) and minimum (min) regions of the MEP, respectively. In this procedure, the AGOA program has internally stored default cutoff radii for the solute and solvent, whose values are listed in Table 1.

The hydration-clusters' structures were obtained in Cartesian coordinates and used to determine the hydration energies  $\Delta E^{\text{HC-CORR}}$ , whose results are presented in Table 2 and graphically illustrated in Fig. 4.

As can be seen in the region of maximum molecular electrostatic potential ( $\text{MEP}_{\text{max}}$ ), the orientation of the water molecules indicates that their oxygen atoms are interacting

with the hydrogen atoms of the methyl groups ( $-\text{CH}_2-$ ). On the other hand, in the region of minimum electrostatic potential ( $\text{MEP}_{\text{min}}$ ), the hydrogen atoms of the water molecules are directly aligned to the fluorine atom of hydrofluoric acid (HF).

Moreover, these hydration clusters provide better stability for the  $\text{MEP}_{\text{max}}$  field because the  $\Delta E^{\text{HC-CORR}}$  values computed in this region are higher, in the range of  $-364.6 \text{ kJ mol}^{-1}$ . This study may be considered consistent with the reproduction of the experimental behavior of aziridine, since cyclic amines are known to be highly reactive compounds.<sup>50</sup> Solely for comparative purposes, a similar experiment was performed to evaluate the solvent effect on the epoxide ring, in particular the  $\text{C}_2\text{H}_4\text{O}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex.<sup>51</sup> Although the hydration-cluster energies of the  $\text{C}_2\text{H}_4\text{O}\cdots\text{HF}$  hydrogen-bonded complex showed values in the range of  $-292 \text{ kJ mol}^{-1}$ , it can be seen that aziridine is more reactive. In other words, the acid-catalyzed open-ring reaction occurs more easily if the formation of the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex is taken into account. The AGOA methodology provides a successful complementary description of the solvation effect, which not only produces interesting results, but can also be achieved at low computational cost, since the analysis of the solute MEP is the single criterion used to form the hydration clusters. In practice, it took only a few seconds to generate the hydration clusters for the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex.

## Conclusions and future research

The theoretical study of the solvation effect in the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  heterocyclic hydrogen-bonded complex has proven that the presence of the water molecules is important for description of the acid-catalyzed open-ring reaction of aziridine. Analysis of the molecular electrostatic potential of the  $\text{C}_2\text{H}_5\text{N}\cdots\text{HF}$  complex revealed two important regions, which correspond to the methyl groups ( $\text{MEP}_{\text{max}}$ ) of the aziridine ( $\text{C}_2\text{H}_5\text{N}$ ) and the fluorine atom ( $\text{MEP}_{\text{min}}$ ) of the hydrofluoric acid, respectively. In the solvation structures generated by the AGOA methodology, the  $\Delta E^{\text{HC-CORR}}$  hydration-cluster energies are higher in the  $\text{MEP}_{\text{max}}$  region. This result concurs well with the experimental acid-catalyzed open-ring reaction, where the nucleophilic attack occurs through the interactions of the water molecules with the methyl groups of the aziridine ring. It should be noted that the AGOA software is for academic purposes,<sup>43</sup> but its potential has been successfully demonstrated<sup>31</sup> in areas such as the theoretical description of the acid/base equilibrium involving alkoxides and ammonium ions<sup>52,53</sup> and hydration-cluster studies of amino acids and protein fragments.<sup>54</sup> In future, we plan to undertake a study of hydration clusters in nanocompounds of biological interest, such as the quantum dots.

# Triazene derivatives of (1,x)-diazacycloalkanes — Part IX. Synthesis and characterization of a series of 1,4-di[2-aryl-1-diazenyl]- 2,6-dimethylpiperazines

Naomi Hunter and Keith Vaughan

**Abstract:** A series of 1,4-di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazines (**5a–5l**), have been synthesized by the reaction of 2,6-dimethylpiperazine with 2 equiv. of the appropriate diazonium salt. The products have been characterized by IR and NMR spectroscopy, and the molecular composition has been verified by high-resolution EI mass spectrometry with accurate mass measurement of the molecular ion. The presence of stereocenters at C2 and C6 of the piperazine ring in the bis-triazene **5** creates two unique pairs of diastereotopic protons in the methylene groups at positions 3 and 5 of the piperazine ring, as evidenced by the complexity of the NMR spectra, which nevertheless can be fully assigned in most cases. The assignment of the proton and carbon signals in the 1,4-di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazines has been aided by the use of 2D NMR HSQC spectroscopy. These results compare favorably with assignments of proton and carbon signals reported previously for triazenes of type **1** and bis-triazenes of type **3**.

**Key words:** triazene, bis-triazene, piperazine, 2,6-dimethylpiperazine, diastereotopic protons, diazonium coupling, 2D NMR, HSQC.

**Résumé :** On a réalisé la synthèse d'une série de 1,4-di-[2-aryl-1-diazenyl]-2,6-diméthylpipérazines (**5a–5l**) par réaction de la 2,6-diméthylpipérazine avec deux équivalents du sel de diazonium approprié. Les produits ont été caractérisés par spectroscopies infrarouge et RMN et on a vérifié la composition moléculaire par spectrométrie de masse à haute résolution et ionisation électronique en effectuant la mesure exacte de la masse de l'ion moléculaire. La présence de stéréocentres dans les positions 2 et 6 du noyau pipérazine du bis-triazène **5** conduit à la création de deux paires distinctes de protons diastéréotopes dans les groupes méthylènes des positions 3 et 5 du noyau pipérazine qui sont mis en évidence par la complexité du spectre RMN qu'on peut toutefois assigner complètement dans la plupart des cas. L'attribution des signaux des atomes d'hydrogène et de carbone dans les 1,4-di-[2-aryl-1-diazenyl]-2,6-diméthylpipérazines a été rendue possible par l'utilisation de la spectroscopie RMN 2D avec corrélation à quantum unique hétéronucléaire (« HSQC »). Ces résultats se comparent favorablement avec les attributions des signaux des atomes d'hydrogène et de carbone rapportées antérieurement pour les triazènes du type **1** et les bis-triazènes de type **3**.

**Mots-clés :** triazène, bis-triazène, pipérazine, 2,6-diméthylpipérazine, protons diastéréotopes, couplage diazonium, RMN 2D, corrélation à quantum unique hétéronucléaire (« HSQC »).

[Traduit par la Rédaction]

## Introduction

This paper is the latest chapter in an extensive study of the synthesis of *N*-aryldiazenylpiperazines and the structural characterization of these triazenes. In Part I of this series,<sup>1</sup> the diazonium coupling reaction of 1-methylpiperazine was explored to synthesize the 4-methyl-1-(2-aryldiazen-1-yl)-piperazines (**1**) (Chart 1). The structure of one compound, namely methyl 4-[(*E*)-2-(4-methylpiperazino)-1-diazenyl]-benzoate, in this series has been verified by X-ray crystallography,<sup>2</sup> which showed that the piperazine ring adopts a

normal chair conformation. In the process of characterizing these triazenes by NMR spectroscopy, the chemical shift parameters of the protons and carbons in the piperazine ring were clearly established and verified by some classical 2D NMR work. This data was used to advantage in characterizing the 4-methyl-1-[aryldiazenyl]-homopiperazines (**2a**) (Chart 1), which have been described, along with the 1,4-di-(2-aryldiazen-1-yl)diazepanes (**2b**), in Part II of this series.<sup>3</sup> The bis-triazenes (**2b**) were obtained by reaction of homopiperazine with the diazonium salt in 1:2 molar proportion.

This bis-diazotization strategy was subsequently explored

Received 23 September 2009. Accepted 9 December 2009. Published on the NRC Research Press Web site at canjchem.nrc.ca on 4 March 2010.

Chart 1.

with piperazine itself and the synthesis of a series of 1,4-di-(2-aryldiazen-1-yl)-piperazines (**3**) (Chart 1) was described in Part III of this series.<sup>4</sup> The bis-triazenes of type **3** were characterized by a range of spectroscopic techniques and the data was compared with some previously published work<sup>5</sup> in which several of the bis-aryldiazenyl-piperazines had already been described. Subsequently, we extended the study of bis-triazenes to the 1,4-di-[2-aryl-1-diazenyl]-2-methylpiperazines (**4**) (Chart 1), which were prepared by diazonium coupling to 2-methylpiperazine.<sup>6</sup>

The work described in this paper is a logical extension of

our previous study<sup>6</sup> of the synthesis of the unsymmetrical bis-triazenes of series **4** to the bis-triazene series **5** (Chart 1), in which an additional methyl substituent is introduced at position six of the piperazine ring. In characterizing the series of bis-triazenes (**3**), we observed that the eight protons of the piperazine ring occur as a single peak. The equivalence of all eight methylene protons in **3** is a little surprising in view of the potential for variation in chemical shift from either (*a*) axial versus equatorial proton environment, or (*b*) syn or anti orientation of the *N*-aryldiazenyl groups, or (*c*) a combination of both of these. We concluded that the

dynamic effects in molecules of type **3** must be occurring faster than the NMR time frame. The presence of a chiral centre at C2 of the piperazine ring in the bis-triazene series **4** created a multitude of diastereotopic protons in the methylene groups of the piperazine ring, as evidenced by the complexity of the NMR spectra, which nevertheless were fully assigned in some cases, such as the tolyl and phenyl derivatives. It was of interest to undertake the synthesis of the symmetrical meso bis-triazenes of series **5** to see the effect of the mirror-image stereocenters at C2 and C6 on the NMR features, in addition to the intellectual curiosity associated with the synthesis of any new molecules.

The presence of two stereocenters in the piperazine ring, as in structure **5**, might have some interesting consequences. In principle, the aryldiazenyl groups in **5** are in nonequivalent environments, and it is an intriguing challenge to see if high field NMR can resolve these nonequivalent aryl groups. Furthermore, there is an element of symmetry in the piperazine ring, which should result in equivalence of the two  $-\text{CH}_2\text{CH}(\text{CH}_3)-$  moieties on each side of the piperazine ring, potentially simplifying the NMR analysis. However, the C2/C6 carbons in **5** are stereocenters, creating the situation where the methylene hydrogens at C3 and C5 are diastereotopic. Thus, the resolution and interpretation of the NMR spectra of the bis-triazenes of type **5** has the potential for being an interesting exercise. These considerations prompted us to explore the effect of introducing two methyl substituents into the piperazine ring of the 1,4-bis(aryldiazenyl)piperazine system and this paper reports the synthesis and characterization of the series of 1,4-di[2-aryl-1-diazenyl]-2,6-dimethylpiperazines (**5a–5l**) (Chart 1), with an in-depth analysis of the NMR spectra of these novel compounds.

## Experimental

All reagents were reagent grade materials purchased from Sigma-Aldrich and were used without further purification. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Infrared spectra were obtained using Nujol mulls with a Bruker Vector 22 spectrometer. <sup>1</sup>H and <sup>13</sup>C NMR spectra were obtained with either (i) Bruker 400 MHz and 500 MHz spectrometers at the Atlantic Regional Magnetic Resonance Center at Dalhousie

University (Halifax, NS), or (ii) the ANASAZI 60 MHz EFT spectrometer at Saint Mary's University (Halifax, NS). Chemical shifts were recorded in CDCl<sub>3</sub> or DMSO-*d*<sub>6</sub> solutions at 20 °C (as specified), and are relative to TMS as internal standard. Accurate mass measurements were made on a CEC 21-110B mass spectrometer operated at a mass resolution of 8000 (10% valley) by computer-controlled peak matching to appropriate PFK reference ions. Spectra were obtained using electron ionization at 70 V and a source temperature of 175 °C, with samples being introduced by means of a heatable quartz probe. The standard deviation of mass measurement is  $\pm 0.0008$  amu, which is an average of 3.6 ppm over the mass range of 100–300 amu.

## 1,4-Di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazines (**5a–5l**)

### General procedure

The aromatic primary amine (0.01 mol) was dissolved in 12 mL of 3 mol/L hydrochloric acid, with the aid of heat if necessary, and the resulting solution was cooled in an ice/salt bath to 0 °C. The solution was diazotized with a solution of sodium nitrite (0.76 g) in water (10 mL) while maintaining the temperature below 5 °C, and then stirred for a further 0.5 h in the cold, reaching a starch–iodide end-point. A solution of 2,6-dimethylpiperazine (0.571 g), dissolved in water (10 mL), was added slowly to the mixture. After stirring for a further 0.5 h, the mixture was neutralized with saturated sodium carbonate solution and then left to stir until precipitation was deemed to be complete (about 1 h). The solid products were filtered under suction, dried and recrystallized from an appropriate solvent to give the 1,4-di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazines (**5a–5g** and **5j–5k**) (Chart 1).

Compounds **5h** and **5l** were formed in the reaction mixture as oils, which were separated from the reaction mixture by extraction into dichloromethane. The dichloromethane solution was purified by washing with water and drying over anhydrous magnesium sulfate. The filtered solution was evaporated under vacuum to afford the compound, **5h** or **5l**, which were spectroscopically pure for characterization.

Physical data and IR spectroscopic bands are listed in Table 1. Table 2 shows the <sup>1</sup>H NMR spectral data (see Scheme 1 for labels), and <sup>13</sup>C NMR data are provided in Table 3 (see Scheme 2). High-resolution mass spectrometric results are tabulated in Table 4.

**Table 2.** <sup>1</sup>H NMR spectroscopic data of the 1,4-di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazines (**5a–5l**) recorded at 300 K and 500 MHz.

## Results and discussion

The target molecules, the 1,4-di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazines (**5a–5l**), were synthesized by reacting 1 equiv. of 2,6-dimethylpiperazine with 2 equiv. of the appropriate diazonium salt. The products are mostly stable, crystalline solids, and the yields are variable in the range of 8%–69%. The products were first characterized by IR spectroscopy to confirm the presence of the aryl substituent, as indicated by the detection of bands from either carbonyl, nitrile, or nitro groups, and the OOP bending vibration characteristic of the substitution pattern. The molecular composition of eight compounds of the series was established by high-resolution EI mass spectrometry with accurate mass measurement of the molecular ion (see Table 4).

However, two compounds of the new series did not exhibit a molecular ion in the mass spectrum; these are the *p*-chloro derivative (**5d**) and the *p*-methoxy derivative (**5g**). Nevertheless, both of these compounds provided evidence in the mass spectra for a well-defined fragment (**6**) consistent with the 1,4-di-[2-aryl-1-diazenyl]-2,6-dimethylpiperazine structure. The common fragmentation pathway is shown in Scheme 3, in which the principle fragmentation is the cleavage of the N–N bond in one of the triazene moieties to give the aryldiazenylpiperazine fragment (**6**). The observed fragment of this pathway is observed at *m/e* 248 for **5g** and *m/e* 252/254 for **5d**. In the mass spectrum of **5g**, the base peak is found at *m/e* 135 (100%), which is assigned to the diazonium ion fragment (ArN<sub>2</sub><sup>+</sup>).

The essential features of the <sup>1</sup>H NMR data are consistent with the assigned structures (**5**). The first point to note is that the methyl groups at C2 and C6 are equivalent, and the signal is found in the range of 1.36–1.66 ppm. The second point is that the C2/C6 methyl signal is consistently a doublet with *J*, in the range of 5.5–7.0 Hz, due to the coupling with the adjacent methine proton, H<sub>a</sub>. The methine proton itself is observed as a broad hump in the range of 4.55–5.0 ppm. The extreme broadness of the methine proton signal, and some other protons, is a result of two factors: (a) the multiplicity of vicinal coupling with the methyl protons and with the diastereotopic methylene protons, H<sub>b</sub> and H<sub>c</sub>, and (b) the dynamic equilibrium associated with rotation around the N–N bond of the triazene moiety. In turn, the signals of the diastereotopic methylene protons, H<sub>b</sub> and H<sub>c</sub>, vary from extremely broad nondescript humps to broad doublets to well-defined doublets of doublets with coupling constants of ~6 and 13 Hz. The doublet of doublets is the expected multiplicity arising from the geminal coupling of H<sub>b</sub> with H<sub>c</sub> and the vicinal coupling (H<sub>a</sub> and H<sub>b</sub> or H<sub>a</sub> and H<sub>c</sub>).

The NMR spectra of the compounds **5b**, **5c**, **5f**, and **5g** also show the expected signals from protons of the substituents in the aryl groups. Indeed, the spectrum of the *p*-tolyl derivative **5f** is exceptional in showing two 3H signals for the tolyl methyl groups, which differ because of the nonequivalence of the aryl groups. The nonequivalence of the aryl groups is also evident from the analysis of the aromatic proton signals. Most of the *p*-substituted compounds in this series (**5a–5g**) show two distinct AA'BB' systems assigned to the two marginally different aryl rings, which arises because of the position of the C2/C6 methyl groups creating a dissymmetry in the molecule. The separation between the sets of signals averages out to ~0.02 ppm. The *o*-substituted analogues (**5j** and **5k**) also show two full sets of aromatic proton signals.

Further evidence for the nonequivalence of the aryl rings in **5** is supplied by analysis of the <sup>13</sup>C NMR spectra of these compounds (Table 2). Several of the *p*-substituted compounds in the series show clearly eight distinct frequencies

<sup>a</sup>Coincident signals, based on HSQC results.

<sup>b</sup>From HSQC spectrum.

**Scheme 2.** Carbon labels for interpretation of  $^{13}\text{C}$  NMR data.

in the aromatic region. The eight signals clearly fall into the pattern of two sets of four aromatic signals. Other features of the  $^{13}\text{C}$  NMR spectra are relevant to the interpretation of structure. The C-methyl carbon (at C3) is observed in the range of 15–19 ppm. The methine carbon (C2) is observed at 51–53 ppm and is always broadened due to the phenomenon of the dynamic equilibrium in the triazene moiety. The signal of the methylene carbon (C1) is also broad at ~50 ppm. Significantly, the nitrile carbons of the *o*-cyano derivative (**5j**) are distinguished at 106.5 and 106.75 ppm. The apparent reverse order of the C1 and C2 signals in **5h** is based on the HSQC spectrum.

The validity of the foregoing assignments is reinforced by the results acquired from the HSQC 2D NMR spectra of several of the compounds in the series **5a–5l**. For example, the HSQC spectrum of the *p*-tolyl derivative **5f** shows a clear correlation of the tolyl methyl carbon at 21.0 ppm with the tolyl methyl protons at 2.37 ppm. Also, in **5f** the methyl carbon signal of the C-methyl carbon at 19.2 ppm correlates with the doublet methyl signal at 1.43 ppm. The carbon peak at 51.6 ppm correlates with the proton signals of H<sub>a</sub> (3.86 ppm), H<sub>b</sub> (4.23 ppm), and H<sub>c</sub> (4.80 ppm), showing

that the C1 and C2 carbon resonances are coincident at 51.6 ppm. The aromatic carbon signals at 120.5/120.6 ppm correlate with the aromatic protons at ~7.38 ppm, whereas the aromatic carbon signals at 129.45/129.50 ppm correlate with the aromatic protons at ~7.20 ppm.

Looking at the HSQC results in general, the aromatic carbon/aromatic hydrogen correlation is observed in the spectra of **5a**, **5b**, **5e**, **5f**, **5g**, **5h**, **5j**, and **5k**. All of the compounds exhibit peaks for the C2 methyl/proton correlation, and the correlation of the C1 signal with protons H<sub>b</sub> and H<sub>c</sub>. The C2/H<sub>a</sub> correlation is shown by compounds **5a**, **5e**, **5f**, **5g**, **5h**, **5j**, and **5k**. The C1/(H<sub>b</sub> + H<sub>c</sub>) correlation is also shown by compound **5a**, which for some reason did not show a C2 methyl/proton correlation. Correlations of the methyl carbon and methyl hydrogens of the substituent X were shown in compounds **5b**, **5f**, and **5g**.

These results compare favorably with the NMR parameters previously observed and assigned in the spectra of triazenes of types **1**,<sup>1</sup> **3**,<sup>4</sup> and **4**.<sup>6</sup> The methylene carbon in the piperazine ring of compounds of type **1** occurs at ~47 ppm, and the methylene protons of structure **1** give rise to proton signals at ~3.9 ppm. The assignments of the resonances of the methine carbons, C2, to the signal at 51–53 ppm, compares with the assignment of C2 in series **4** to the signal at ~53 ppm. The resonance of the equivalent C1 methylene carbon atoms in **5** is observed in the range of 50–51 ppm, which is a little different than the observed methylene resonance at ~46–47 ppm in the bis-triazenes of type **3** and at ~46 ppm in the series of type **4**. The 2 equiv. methyl substituents attached at C2 and C6 of the piperazine ring give rise to a  $^{13}\text{C}$  signal in the range of 15–19 ppm, compared to the methyl resonance at 16.0 ppm in triazenes of type **4**. In the symmetrical bis-triazenes of type **3**, the homotopic methylene protons of the piperazine ring give rise to a proton signal at ~4.1 ppm, which compares with the chemical shift assigned to the diastereotopic methylene protons in **5a–5l** in the range of 3.4–4.3 ppm. Thus, there is significant

**Scheme 3.**

agreement in the NMR parameters among these compounds, but there is an additional degree of complexity in the spectra of compounds of series **5** due to the introduction of the stereocentres at C2 and C6, resulting in the diastereotopic methylene protons, H<sub>b</sub> and H<sub>c</sub>, giving rise to distinct NMR signals in the range of 3.4–4.0 and 4.2–4.4 ppm. However, there is insufficient data available to precisely assign the observed signals to either H<sub>b</sub> or H<sub>c</sub>.

## Conclusion

This paper is part IX in a series that describes the synthesis of a variety of triazenes and bis-triazenes that fit the general classification of 1-aryldiazenyl-(1,*x*)-diazacycloalkanes described by the general structure **7** (Chart 1), where *m* = 1 or 2 and *n* = 2, 3, 4, or 5. Previously, we reported new triazenes derived from imidazolidine (*m* = 1, *n* = 2),<sup>7</sup> hexahydropyrimidine (*m* = 1, *n* = 3),<sup>8</sup> piperazine (*m* = *n* = 2),<sup>1,4,6</sup> and homopiperazine (*m* = 2, *n* = 3).<sup>3</sup> The new piperazines of series **5** fit to the general structure **7** where *m* = 2 and *n* = 2. Future work in this field of chemistry will

endeavour to further extend the family of 1,4-di-(2-aryl-1-diazenyl)piperazines by preparing derivatives with a variety of substituents in the piperazine ring.

# Theoretical study of H bonds of HArF and HF with isoelectronic systems N<sub>2</sub>, CO, and BF

An Yong Li, Li Juan Cao, and Hong Bo Ji

**Abstract:** The H bonds of HArF and HF with N<sub>2</sub>, CO, and BF were studied at the MP2(full)/6-311++G(2d, 2p) level. The results show that only the complexes WY...HArF (WY = N<sub>2</sub>, OC) and WY...HF (WY = N<sub>2</sub>, OC, FB) are stable, the H-bonding WY...HArF leads to contraction of the HAr bond with a concomitant frequency blue shift, but the H-bonding WY...HF causes the HF bond to elongate with a frequency red shift. A quantity  $P$  is defined to measure polarization of the HX bond; the H bonding causes the  $P$  value of the HX bond (X = Ar, F) to increase. The HX bond length change and frequency shift in the H-bonding WY...HArF and WY...HF are mainly caused by intermolecular hyperconjugation,  $n(Y) \rightarrow \sigma^*(HX)$  (X = Ar, F), where electrostatic interaction has only a small contribution. In HArF, the strong intramolecular hyperconjugation,  $n(F) \rightarrow \sigma^*(HAr)$ , can adjust electron density on  $\sigma^*(HAr)$ ; upon formation of H bonding, the HAr stretching frequency blue shift is caused by a decrease of intramolecular hyperconjugation and an increase of the s character of the Ar hybrid in the HAr bond, induced by the intermolecular hyperconjugation. In the H bonds of HF without intramolecular hyperconjugation, the intermolecular hyperconjugation,  $n(Y) \rightarrow \sigma^*(HF)$ , leads to a red shift of the HF bond, although there is also large rehybridization.

**Key words:** H bonds, HArF, hyperconjugation, polarization of bonds.

**Résumé :** Faisant appel à des méthodes de calcul au niveau MP2(complet)/6-311++G(2d,2p), on a étudié les formations de liaisons entre les atomes d'hydrogène des HArF et HF avec N<sub>2</sub>, CO et BF. Les résultats montrent que seuls les complexes WY...HArF (WY = N<sub>2</sub>, OC) et WY...HF (WY = N<sub>2</sub>, OC, FB) sont stables, que la liaison hydrogène WY...HArF conduit à une contraction de la liaison HAr avec un déplacement concomitant de la fréquence vers le bleu alors que la liaison hydrogène WY...HF provoque une elongation de la liaison HF avec un déplacement vers le rouge. On a défini une quantité  $P$  pour mesurer la polarisation de la liaison HX; la liaison hydrogène provoque une augmentation de la valeur de  $P$  pour la liaison HX (X = Ar, F). Le changement de la longueur de la liaison HX et le déplacement de fréquence dans la liaison hydrogène WY...HArF et WY...HF sont causés principalement par une hyperconjugaison intermoléculaire  $n(Y) \rightarrow \sigma^*(HX)$  (X = Ar, F) alors que l'interaction électrostatique ne fait qu'une faible contribution. Dans HArF, la forte hyperconjugaison intramoléculaire  $n(F) \rightarrow \sigma^*(HAr)$  peut ajuster la densité électronique sur  $\sigma^*(HAr)$ ; par formation d'une liaison hydrogène, le déplacement vers le bleu de la fréquence d'elongation de HAr est provoqué par une diminution de l'hyperconjugaison intramoléculaire et une augmentation du caractère s de l'hybride Ar dans la liaison HAr induites par l'hyperconjugaison intermoléculaire. Dans les liaisons hydrogènes du HF sans hyperconjugaison intramoléculaire, l'hyperconjugaison intermoléculaire  $n(Y) \rightarrow \sigma^*(HF)$  conduit à un déplacement vers le rouge de la liaison HF, même s'il n'y a aucune réhybridisation importante.

**Mots-clés :** liaisons hydrogènes, HArF, hyperconjugaison, polarisations des liaisons.

## Introduction

Hydrogen bonding<sup>1-3</sup> and dihydrogen bonding<sup>4,5</sup> have extensive applications in chemistry and biology, and have been important topics in recent years. The most important spectroscopic criterion for the formation of a hydrogen bond, Y...H-X, is the elongation of the HX bond with a concomitant frequency red shift and an increase of IR intensity. It is well-known that a red shift of the HX bond in a H bond is mainly caused by two factors: (1) electrostatic attraction between the positive charge of H and the rich electron end of the proton acceptor and (2) electron density transfer from

the proton acceptor Y to the donor caused by the intermolecular hyperconjugation,  $n(Y) \rightarrow \sigma^*(HX)$ . However, the discovery of blue-shifted H bonds makes the problem much more complicated.<sup>6</sup> The physical and chemical essence of a stretching frequency blue shift of the HX bond in an improper H bond, Y...H-X, has being an important problem in the field of H bonding that remains unaddressed. Several valuable theories have been proposed to explain the blue shift, including the two-step mechanism of Hobza and Havlas,<sup>6</sup> the theory of the balance of attractive and repulsive interactions,<sup>7</sup> and the theory of hyperconjugation and rehybridization of

Alabugin et al.<sup>8</sup> The last theory has attracted the attention of chemists and been developed by introducing intramolecular hyperconjugation.<sup>9</sup>

The H-bonding interaction includes electrostatic interaction, charge transfer and electron exchange repulsion, and so on. They induce changes in the internal electronic and molecular structures in the proton donor, which include the following: (i) Repolarization: polarization of the HX bond enhances, but the polarization strength of the HX bond does not correlate consistently with the strength and length of the HX bond. (ii) Rehybridization: the *s* character in the X hybrid orbital,  $h(sp^n)$ , of the HX bond increases, which causes contraction of the HX bond. (iii) Intramolecular hyperconjugation: as there exists strong intramolecular hyperconjugation,  $n(Z) \rightarrow \sigma^*(HX)$ , in the proton donor H–X–Z, the lone pair,  $n(Z)$ , is like an electron density reservoir and can adjust electron density in  $\sigma^*(HX)$  through the intramolecular hyperconjugation; in some cases, this causes occupancy on  $\sigma^*(HX)$  to decrease so that the HX bond enhances. The bond length change and frequency shift of the HX bond in the equilibrium H-bonding complex is a result of the balance of all these factors: intermolecular electrostatic interaction, charge transfer and repulsion, and adjustment of internal electronic and molecular structures in the proton donor. The decisive factor is different for different kinds of systems, especially for blue-shifted H bonds.

Since the compound HArF was detected in spectroscopy,<sup>10</sup> the rare gas compounds, HRgX (Rg = rare gas such as Ar and Kr, X is an element with high electronegativity), have attracted the attention of experimentalists and theorists.<sup>11–15</sup> Theoretical studies show that HArF contains a covalent bonding of the H–Ar bond and an ion bonding of the Ar–F bond, and has a ion-pair character,  $(HAr)^+F^-$ .<sup>16,17</sup>

HRgX can act as proton donor to participate in H bonding and dihydrogen bonding. It was found<sup>18</sup> that the linear  $N_2 \cdots HArCl$  hydrogen bonding leads to a large blue shift of  $113\text{ cm}^{-1}$  for the HAr bond stretch frequency, and the blue shift was attributed to the enhanced  $(HAr)^+Cl^-$  ion-pair character of the complex resulting in a stronger H–Ar covalent bond. Theoretical<sup>19–21</sup> and experimental<sup>22</sup> studies have shown that the HRg bond enhances and contracts with a concomitant frequency blue shift in the linear H-bonding  $N_2 \cdots HArF$  and  $N_2 \cdots HKrF$ . McDowell<sup>19–21</sup> attributed the blue shift to electron density transfer from  $\sigma^*(HAr)$  to  $n(F)$  caused by a negative quadrupole moment of  $N_2$ , which enhances the  $(HAr)^+F^-$  ion-pair character. This shortening of the HRg bond caused by electron density transfer exceeds elongation caused by electrostatic attraction between the protonated H and the negative-charge end of the quadrupole moment of  $N_2$ . However,  $P_2 \cdots HArF$  is a red-shifted H bond. The author rationalized the red shift by a charge transfer from  $n(F)$  to  $\sigma^*(HAr)$  caused by a positive quadrupole moment of  $P_2$ . This explanation of charge transfer caused by quadrupole moment does not work in the case of the dihydrogen bonding,  $HBeH \cdots HRgF$  (Rg=Ar, Kr).<sup>23</sup>  $HBeH$  has a large negative quadrupole moment three times larger than that of  $N_2$ ; however, the HRg bond weakens and elongates with a concomitant frequency red shift in these complexes. McDowell<sup>19–21</sup> attributed the red shift to the strong electrostatic attraction between the protonated H and the negative-charge end of the quadrupole moment of  $HBeH$ .

Although the H bond  $N_2 \cdots HArF$  is blue-shifted, it is well-known that the H bond  $N_2 \cdots HF$  is red-shifted. Obviously, the different frequency shift character in these two complexes is mainly due to the difference of the proton donors HArF and HF. Compared to the red-shifted dihydrogen bond  $HBeH \cdots HArF$  and H bond  $P_2 \cdots HArF$ , the proton acceptor  $N_2$  is crucial for a blue shift of  $N_2 \cdots HArF$ . What about the frequency shift of the H bonds if  $N_2$  is replaced by its isoelectronic molecules CO or BF? In this article, we theoretically study the H bonds of the proton donors HArF and HF with the acceptors  $N_2$ , CO, and BF, observing the frequency shift character and exploring the mechanism of frequency shift. One of the important purposes is to study the importance of the proton donor structure on frequency shift of the H bonds.

## Computation methods

All the calculations in this article were performed at the MP2(full)/6-311++G(2d, 2p) level by using the Gaussian 03 program.<sup>24</sup> The geometric structures of all the monomers and complexes were completely optimized without freezing any internal coordinate and the frequencies of normal vibrational modes were calculated. The interaction energies were computed with BSSE correction by means of the functional counterpoise method proposed by Boys and Bernardi.<sup>25</sup> We used the AIM2000 program to perform topological analysis of electron density and study properties of chemical bonds.<sup>26–28</sup> The NBO5.0 program<sup>29</sup> was applied to carry out natural bond orbital (NBO) analysis to study polarization of chemical bonds, hybridization of atomic orbitals, and interaction between molecular orbitals. Point charge models were used to mimic the electrostatic field of the proton acceptor and investigate contributions of electrostatic interaction and charge transfer to bond length change and frequency shift in the proton donor upon formation of H bonding.

## Results and discussion

### Changes of bond lengths, frequency shift, and interaction energies

The optimized structures of all the monomers and complexes are linear. The vibrational analysis shows that all the complexes have no imaginary frequency and so are minima in the potential energy surface, except for  $FB \cdots HArF$ , which has two imaginary frequencies and is equivalent to  $(F-B-H)^+ArF^-$ . The bond lengths and vibrational frequencies of the monomers and complexes are listed in Table 1. Upon formation of the H-bonding  $WY \cdots HArF$  with  $WY = N_2$ , CO, OC, and BF, the HAr bond contracts and its stretching frequency increases, and the ArF bond elongates and its stretch frequency decreases. However, the H-bonding  $WY \cdots HF$  with  $WY = N_2$ , CO, OC, BF, and FB leads to elongation of the HF bond with a concomitant frequency red shift. The blue shift of the HAr bond increases in the order of the proton acceptors  $WY = OC$ , BF, CO, and  $N_2$ , but the red shift of the HF bond increases in the order of  $WY = BF$ , CO,  $N_2$ , OC, and FB. Interestingly, in the two classes of complexes, the change of the proton acceptors is consistent. In the complexes  $WY \cdots HArF$  and  $WY \cdots HF$  with  $WY = BF$  and CO, the WY bond length increases and stretching fre-

<sup>a</sup>*ν*(HArF) is the frequency of bent vibration of the bond angle H–Ar–F.

quency decreases; but in the complexes of WY = N<sub>2</sub>, OC, and FB, the WY bond length decreases with a concomitant stretching frequency blue shift. In the red-shifted H-bonding WY...HF, the HF bond length and frequency is a linear correlation; in the blue-shifted H-bonding WY...HArF, the bond length and frequency of the HAr and ArF bonds are also linear correlations, as shown in Fig. 1.

The interaction energies,  $\Delta E_{\text{int}}$ , with BSSE correction and 0 K dissociation energies,  $D_0$ , with BSSE and ZPE corrections for the H bonding are listed in Table 2. In this article the interaction energy is calculated as the sum of energies of the monomers minus the energy of the complex, reversed the common convention, such that positive  $\Delta E_{\text{int}}$  indicates binding. The  $D_0$  value shows that only the five complexes WY...HArF with WY = N<sub>2</sub> and OC and WY...HF with WY = N<sub>2</sub>, OC, and FB are stable. Both for the blue-shifted H-bonding WY...HArF and the red-shifted H-bonding WY...HF, the energy increases in the order of the acceptors WY = BF, CO, N<sub>2</sub>, OC, and FB. This order is the same order of the red shift of the HF bond for the red-shifted H bonds, as shown in Fig. 1d, but is different from the order of the blue shift of the HAr bond for the blue-shifted H bonds, as shown in Fig. 1e.

### Topological analysis of electron density

Electron density topology based on the theory of atoms in molecules (AIM) can characterize chemical bonds. The calculated electron density and Laplacian at BCPs in the monomers and complexes are listed in Table 3. In the monomer HArF, electron density  $\rho > 0.1$  au and Laplacian  $\nabla^2\rho < 0$  at the HAr bond critical point (BCP) show that the HAr bond is a covalent bond, but  $\rho < 0.1$  au and Laplacian  $\nabla^2\rho > 0$  at the ArF BCP show that the ArF bond is a closed interaction, i.e., an ionic bond. The electron density and Laplacian at the intermolecular BCPs show that the H bonding is also a closed interaction.

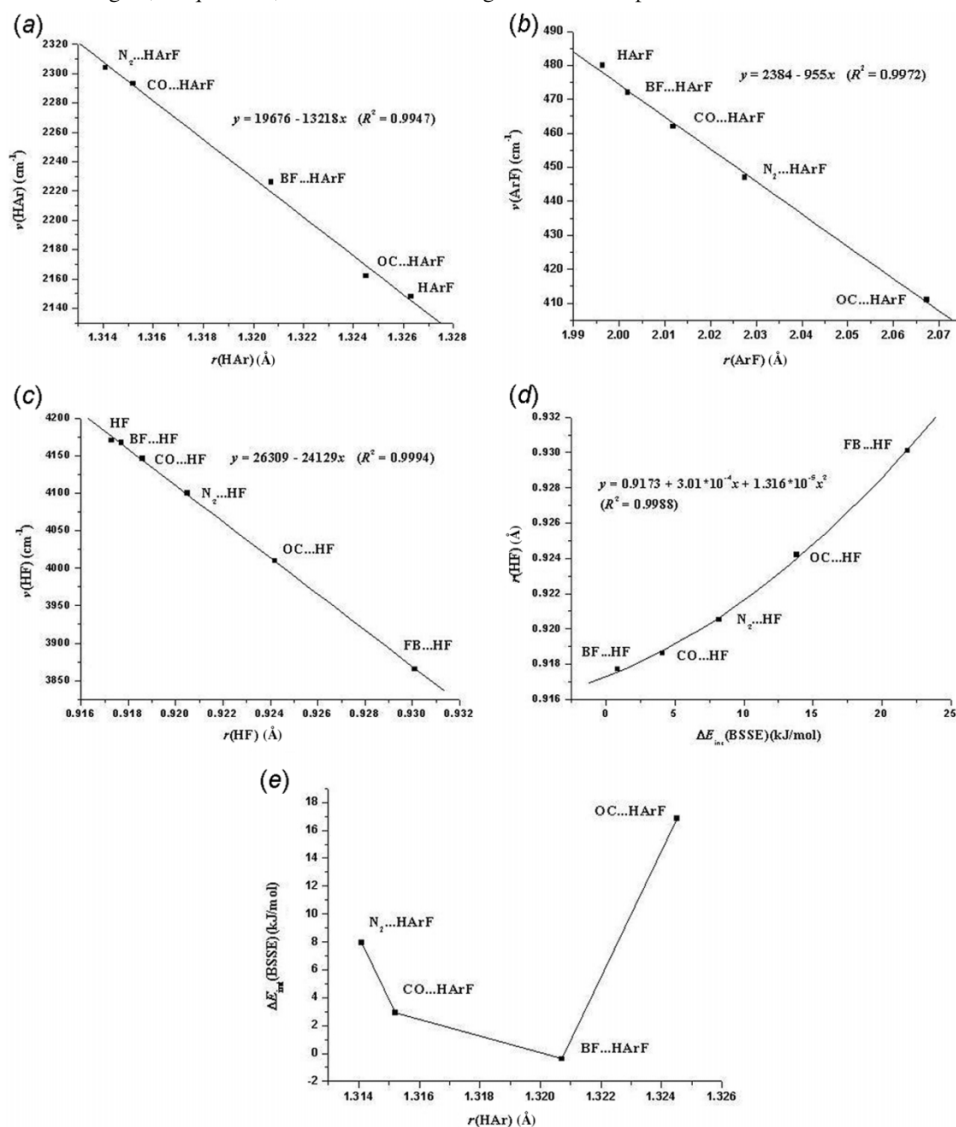

The magnitude of electron density at the BCP can characterize the strength of a chemical bond. In the complexes WY...HArF, electron density at the HAr BCP is larger than that in the monomer HArF, which is consistent with contrac-

tion and frequency blue shift of the HAr bond; electron density at the HAr BCP increases in the order of the blue shift, i.e., OC < BF < CO < N<sub>2</sub>. Moreover, electron density at the ArF bond is smaller than that in the monomer, which is consistent with the red shift of this bond; electron density at the ArF bond decreases in the order of the red shift, i.e., BF > OC > N<sub>2</sub> > CO. In the complexes WY...HF, electron density at the HF BCP is smaller than that in the monomer HF, which is consistent with the elongation and frequency red shift of the HF bond; electron density at the HF BCP decreases in the order of the red shift, i.e., BF > CO > N<sub>2</sub> > OC > FB. Similarly, an increase or decrease of electron density at the WY BCPs compared to the monomer is also consistent with a blue or red shift of this bond. Electron density at the Y...H BCP shows the strength of the H bonding and an increase with the interaction energy, i.e., BF < CO < N<sub>2</sub> < OC < FB. Here, we note that for red-shifted H bonding, changes in all kinds of properties are correlated with each other, but for blue-shifted H bonding, it is not the case. So, the blue-shifted H bonding is more complicated than the red-shifted H bonding.

### Charge transfer and inter- and intra-molecular hyperconjugations

The H-bonding interaction includes electrostatic interaction between permanent and induced multipole moments of the monomers, charge transfer, nuclear and electron exchange repulsions, and so on. The importance of these interactions is different for different kinds of H bonding. Generally, at larger intermolecular distance, there is only electrostatic attraction; at a smaller distance, repulsion is predominant; at equilibrium distance, attractive and repulsive interactions balance, and electrostatic interaction and charge transfer have important contributions to the interaction energy. We first discuss charge transfer.

In a H-bonding Y...HX, charge transfer is a result of intermolecular hyperconjugation between the electron donor,  $n(Y)$ , and acceptor,  $\sigma^*(HX)$ . The hyperconjugation energy is the second order perturbation energy,  $\Delta E^{(2)} = n(Y) \langle n | \text{Flo}^* \rangle^2 / (\epsilon_{\sigma^*} - \epsilon_n)$ , where  $n(Y)$  is the occupancy on

**Fig. 1.** Correlations of bond lengths, frequencies, and interaction energies in the complexes of HArF and HF.**Table 2.** Interaction Energies  $\Delta E_{\text{int}}$  (kJ/mol) with BSSE correction and 0K dissociation energies  $D_0$  (kJ/mol) with BSSE and ZPE corrections.

the lone pair  $n(Y)$ ,  $\langle n|\text{F}| \sigma^* \rangle$  is the Fock matrix element, and  $\epsilon_{\sigma^*}$  and  $\epsilon_n$  are, respectively, the orbital energies of  $\sigma^*(\text{HX})$  and  $n(Y)$ . So, the larger the overlap between the two orbitals and the smaller their energy difference, the larger the hyperconjugation and charge transfer. In Table 4 we list the graphs, energies, and hybridization of the donor orbitals in

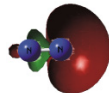

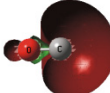

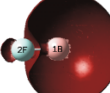

the proton acceptors N<sub>2</sub>, CO, and BF. From F to O to N to C to B, the donor orbital diffuses more and more so that its overlap with the acceptor orbital is larger and larger, and the absolute of energy of the donor orbital is smaller and smaller (the energy of the acceptor orbital is positive), therefore, the hyperconjugation is larger and larger. This conclusion is confirmed by the results of NBO analysis listed in Table 5. Electron density transfer (EDT),  $\Delta n(Y)$  (decrease of occupancy on the lone pair  $n(Y)$ ), and the hyperconjugation energy,  $E\{n(Y) \rightarrow \sigma^*(\text{HX})\}$  ( $X = \text{Ar}, \text{F}$ ), increase in the order of  $\text{WY} = \text{BF}, \text{CO}, \text{N}_2, \text{OC}$ , and  $\text{FB}$ . Since the orbital energy of  $\sigma^*(\text{HAr})$  in the monomer HArF, 0.1714 au, is smaller than that of  $\sigma^*(\text{HF})$  in the monomer HF, 0.7009 au, so  $\sigma^*(\text{HAr})$  is a stronger hyperconjugation acceptor than  $\sigma^*(\text{HF})$ . The hyperconjugation in the H-bonding  $\text{WY} \cdots \text{HArF}$  is larger than that in the H-bonding  $\text{WY} \cdots \text{HF}$  for the same WY.

One of the most important effects of intermolecular hyperconjugation on the monomers is to change occupancy on the involved orbitals. It transfers electron density from  $n(Y)$  to  $\sigma^*(\text{HX})$  so that occupancy on  $n(Y)$  decreases and occupancy

on  $\sigma^*(\text{HX})$  increases. In the H-bonding WY $\cdots$ HF, electron density transfer caused by intermolecular hyperconjugation rationalizes elongation and frequency red shift of the HF bond. However, in the H-bonding WY $\cdots$ HArF, although the intermolecular hyperconjugation is larger than that in the H bonding of HF, the HAr bond length decreases and stretching frequency shifts to blue, which is because in HArF there exists intramolecular hyperconjugation between one lone pair  $n(\text{F})$  and  $\sigma^*(\text{HAr})$  in the ion pair  $(\text{HAr})^+\text{F}^-$ . In the free

monomer HArF, the lone pair on the anion  $\text{F}^-$ ,  $n(\text{sp}^{16.84}) = 0.2362\psi(2s) + 0.9712\psi(2p_z)$ , has large overlap with the antibonding orbital  $\sigma^*(\text{HAr}) = 0.5647h(\text{Ar}, \text{sp}^{15.58}) - 0.8253\psi(\text{H}, 1s)$ , as shown in Fig. 2a. So, the hyperconjugation is very large,  $E\{n(\text{F}) \rightarrow \sigma^*(\text{HAr})\} = 38.31\text{kcal/mol}$ , which transfers large electron density from  $n(\text{F})$  to  $\sigma^*(\text{HAr})$  so that  $\sigma^*(\text{HAr}) = 0.1093 \gg 0$  and  $n(\text{F}) = 1.8608 \ll 2$ , as shown in Fig. 2b. Upon formation of the H bonding, intermolecular hyperconjugation requires large overlap of  $n(\text{Y})$  with  $\sigma^*(\text{HAr})$  and so

**Fig. 2.** (a) Overlap of orbitals and (b) electron density transfer in free HArF. (c) Overlap of orbitals and (d) intra- and inter-molecular electron density transfer in the complex WY...HArF.

attracts the  $\sigma^*(\text{HAr})$  orbital polarizing towards H. Consequently, overlap between  $n(\text{F})$  and  $\sigma^*(\text{HAr})$  decreases, as shown in Fig. 2c, so that intramolecular hyperconjugation decreases and large electron density flows from  $\sigma^*(\text{HAr})$  back to  $n(\text{F})$ , as shown in Fig. 2d. The net change of occupancy on  $\sigma^*(\text{HAr})$  is decided by the two electron density transfers caused by the inter- and intra-molecular hyperconjugations. As shown in Table 5a, except for  $\text{OC}\cdots\text{HArF}$ ,  $\Delta\sigma^*(\text{HAr}) < 0$ , so the HAr bond enhances and contracts and its stretching frequency blue shifts. So, intramolecular hyperconjugation is a decisive factor for a blue shift in the H bonding of HArF. In  $\text{OC}\cdots\text{HArF}$ , intermolecular hyperconjugation is very large, even if intramolecular hyperconjugation also decreases largely, the occupancy on  $\sigma^*(\text{HAr})$  still increases, so that the blue shift in  $\text{OC}\cdots\text{HArF}$  is smallest; however, rehybridization has an important contribution to the blue shift.

Intramolecular hyperconjugation and charge transfer is induced by intermolecular hyperconjugation and charge transfer; the larger the latter, the larger the former. As the proton acceptor WY changes from BF to CO to  $\text{N}_2$  to OC, the intermolecular hyperconjugation energy,  $E\{n(\text{Y}) \rightarrow \sigma^*(\text{HAr})\}$ , is larger and larger so that the intramolecular hyperconjugation energy,  $E\{n(\text{F}) \rightarrow \sigma^*(\text{HAr})\}$ , is smaller and smaller, and intramolecular electron density transfer from  $\sigma^*(\text{HAr})$  to  $n(\text{F})$ ,  $\Delta n(\text{F})$  is larger and larger, as shown in Table 5.

Intermolecular interaction induces changes in the proton donor; generally, there are some electron structures in the donor to diminish these changes. As analyzed above, in the

H bonding of HArF, the intermolecular hyperconjugation,  $n(\text{Y}) \rightarrow \sigma^*(\text{HAr})$ , causes electron density on  $\sigma^*(\text{HAr})$  to increase; however, the intramolecular hyperconjugation,  $n(\text{F}) \rightarrow \sigma^*(\text{HAr})$  decreases and transfers electron density from  $\sigma^*(\text{HAr})$  to  $n(\text{F})$ . So, the lone pair  $n(\text{F})$  in HArF is like an electron density reservoir, which can adjust electron density on  $\sigma^*(\text{HAr})$  through intramolecular hyperconjugation. This self-adjustment in the proton donor HArF is very similar to Le Chatelier's principle on equilibrium shifting of chemical reaction.

### Polarization of the HX bond and hybridization of the X atom

The second important effect of intermolecular hyperconjugation and charge transfer on the proton donor in H-bond  $\text{Y}\cdots\text{HX}$  is to cause polarization of the HX bond to increase. In the free proton donor, the HX bond is formed by overlap of the 1s atomic orbital of H and the  $h(\text{sp}^n)$  hybrid orbital of X. The orthonormal bonding and antibonding orbitals are, respectively,  $\sigma(\text{HX}) = c_X h(\text{sp}^n) + c_H 1s_H$  and  $\sigma^*(\text{HX}) = c_H h(\text{sp}^n) - c_X 1s_H$ , where both  $c_X$  and  $c_H$  are positive. Since electronegativity of X is larger than that of H,  $c_X > c_H$ , the bonding orbital polarizes towards X and the antibonding orbital polarizes towards H. Polarization of the HX bond towards X causes X to be electronegative and H to be electropositive; in Table 6, Ar in HArF is positively charged because F has large electronegativity. Let occupancies on  $\sigma(\text{HX})$  and  $\sigma^*(\text{HX})$  be  $n(\sigma)$  and  $n(\sigma^*)$ , respectively, then electron populations on X and H are  $n(\sigma)|c_X|^2 + n(\sigma^*)|c_H|^2$  and  $n(\sigma)|c_H|^2 + n(\sigma^*)|c_X|^2$ , respectively, and their difference is  $[n(\sigma) - n(\sigma^*)][|c_X|^2 - |c_H|^2]$ . The polarization of the HX bond can be measured by the quantity  $P = [n(\sigma) - n(\sigma^*)][|c_X|^2 - |c_H|^2]/2$ . For diatomic molecules with similar nuclei,  $c_X = c_H = 1/2^{1/2}$ ,  $P = 0$ , and the HX bond is not polarized. For an ionic bond such as NaCl,  $c_X = 1$ ,  $c_H = 0$ , which expresses a lone pair on X; since generally  $n(\sigma) = 2$  and  $n(\sigma^*) = 0$ ,  $P = 1$ , and so the ionic bond has the largest polarization.

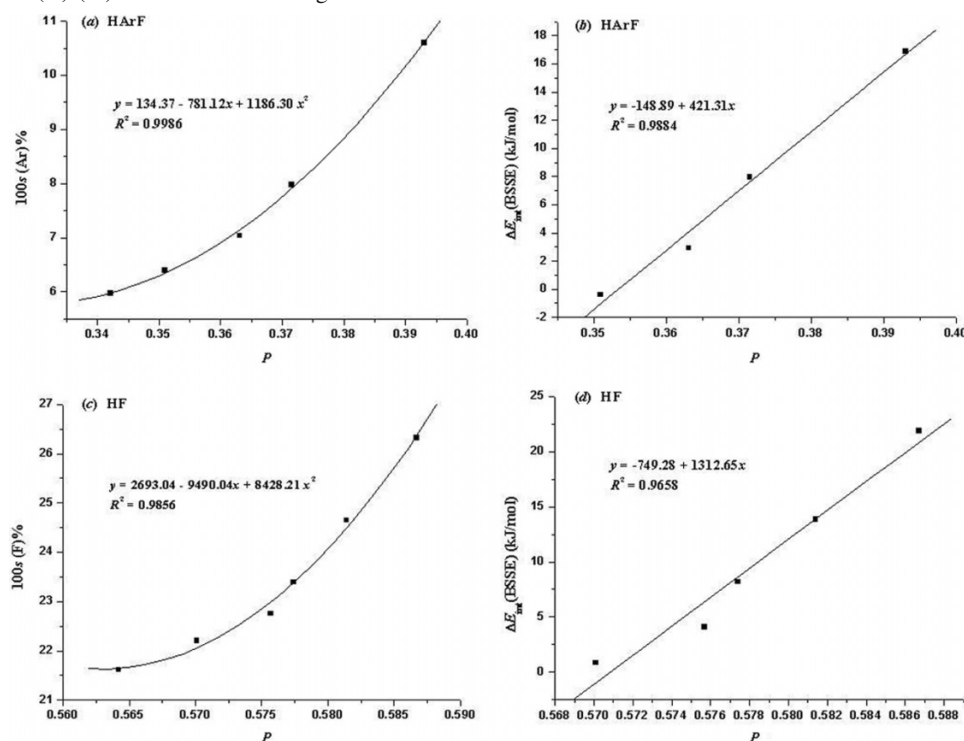

If electronegativity of X is less than H, such as Li, Be, and B, then  $c_X < c_H$ , and the HX bond polarizes towards H so that H is electronegative and X is electropositive. In this case,  $P$  is negative and in the range of  $0 \sim -1$ ; the larger the absolute of  $P$ , the larger the polarization of the HX bond. Weinhold and co-workers<sup>8</sup> use the polarization percentage,  $|c_X|^2$ , to express polarization of the HX bond, however, it cannot distinguish the two cases of the HX bond polarizing towards X and H. In addition, electronegativity of X and H can be quantitatively discussed and derived from electron densities at bond critical points.<sup>30</sup>

Upon formation of H bonding, the intermolecular hyperconjugation requires the largest overlap between  $n(\text{Y})$  and  $\sigma^*(\text{HX})$ , which causes the antibonding orbital  $\sigma^*(\text{HX})$  to further polarize towards H; correspondingly, since  $\sigma(\text{HX})$  and  $\sigma^*(\text{HX})$  are orthogonal,  $\sigma(\text{HX})$  will further polarize towards X. So, the coefficient  $c_X$  increases, the polarization percentage increases, and consequently, the  $P$  value of the HX bond increases, as shown in Table 6. It is observed that the change of occupancy on  $\sigma^*(\text{HX})$  has much less effect on  $P$  than  $c_X$ .

Upon formation of the H bonding, the third important effect of intermolecular hyperconjugation on the proton donor

is that the  $s$  character in the X hybrid,  $h(\text{sp}^n)$ , of the HX bond increases, as shown in Table 6. According to Bent's rule,<sup>31</sup> an increase in the  $s$  character causes contraction of the HX bond, since the larger the  $s$  character, the stronger

the contraction of the  $h(\text{sp}^n)$  hybrid, and the shorter the HX bond to the largest overlap with the  $1s$  orbital of H. In the H-bonding WY...HF, elongation of the HF bond caused by intermolecular hyperconjugation exceeds the shortening

caused by an increase of the s character, so the resulted H bond is red-shifted. In the H-bonding WY...HArF, shortening of the HAr bond caused by an increase of the s character and decrease of intramolecular hyperconjugation is larger than the elongation caused by the intermolecular hyperconjugation, and finally, the H bond is blue-shifted. In OC...HArF, especially, an increase of the s character has a large contribution to the blue shift.

The changes of structure and properties of the monomers in H bonds are induced by intermolecular interaction, so the larger the interaction energy, the larger the changes. For

example, the  $P$  value of the HX bond in H bonds increases with interaction energy, as shown in Fig. 3, so it can be used to express the strength of H bonding. The change of many properties of the proton donor increases with the  $P$  value of the HX bond, such as the s character as shown in Fig. 3, and the red shift for red-shifted H bonds (but for blue-shifted H bonds, the blue shift is not so).

### Electrostatic interaction

To explore the contribution of electrostatic interaction to structure change and frequency shift of the proton donor, we use point charge model (PCM) to mimic the electrostatic field of the free proton acceptor and investigate the change of the donor under this electric field. For CO and BF, two point charges,  $q$  and  $-q$ , are placed at the two atoms, respectively;  $q$  is deduced from the electrostatic potential of the free monomer by use of the CHelpG method with MP2 and SCF densities, or from orbital charge by means of NBO analysis or Mulliken population analysis with SCF density; the dipole moment,  $\mu = ql$ , with  $l$  equal to the bond length of the free monomer for CHelpG and NBO methods. For N<sub>2</sub> without a dipole moment, the electrostatic field of its quadrupole moment is mimicked by three charges,  $q$ ,  $q$ , and  $-2q$ , placed at the two ends and midpoint of free N<sub>2</sub>;  $q$  is deduced from the quadrupole moment,  $Q = ql^2/2$ , where  $l$  is the N–N bond length and  $Q$  is obtained using Mulliken population analysis. The results are listed in Table 7. We noted that for CO only the dipole moment of CHelpG with MP2 density is in good agreement with experimental data, 0.112 D,<sup>32</sup> so for

CO and BF, we use the PCMs obtained by this method to mimic their dipole fields.

In equilibrium structures of the complexes  $\text{WY}\cdots\text{HArF}$  and  $\text{WY}\cdots\text{HF}$ , the proton acceptor WY is replaced by the PCM obtained above; by then fixing the distance  $\text{Y}\cdots\text{X}$  ( $\text{X} = \text{Ar}, \text{F}$ ), we optimize the structure of the proton donor under the electric field of the point charges. The results are listed in Table 8; here we only study the five stable H-bonding complexes. In the PCMs of the H-bonds  $\text{WY}\cdots\text{HF}$ , the HF bond length increases and stretching frequency decreases, similar to the real systems (RSs), but the red shift is much smaller than that of the real system. In the PCM of  $\text{OC}\cdots\text{HArF}$ , the HAr bond contracts and vibrational frequency increases, but the blue shift is much smaller than that of the real system. In the PCM of  $\text{N}_2\cdots\text{HArF}$ , the HAr bond elongates and stretching frequency decreases, qualitatively opposite to the real system; the magnitude of the red shift is much smaller than that of the blue shift in the real system.

In the PCM, there is only electrostatic interaction (EI), without charge transfer and intermolecular hyperconjugation. The NBO analysis shows that EI does not lead to a change of electronic structure and many properties of the proton donors in these two kinds of H-bonding  $\text{WY}\cdots\text{HArF}$  and  $\text{WY}\cdots\text{HF}$ : (1) EI does not lead to repolarization, that is, does not enhance nor diminish the  $P$  value of the HX bond. (2) EI does not lead to rehybridization, i.e., does not change the  $s$  character of the X hybrid of the HX bond. (3) EI does not change the hydrogen atomic charge. (4) For HArF, EI does not induce a change of intramolecular hyperconjugation,  $n(\text{F}) \rightarrow \sigma^*(\text{HAr})$ , so does not change occupancies on  $\sigma^*(\text{HAr})$  and  $n(\text{F})$ . The result of McDowell,<sup>19</sup> that the negative quadrupole moment of  $\text{N}_2$  can cause electron density transfer from  $\sigma^*(\text{HAr})$  to  $n(\text{F})$  is opposite to our result. So, all of the above changes of electronic structure of the proton donors in these H bonds is caused by intermolecular hyperconjugation and charge transfer. The HX bond length change and frequency shift in these H bonds are mainly caused by charge transfer and intermolecular hyperconjugation. The electrostatic interaction has only a small contribution. In the PCM, electrostatic interaction includes attraction between the electropositive H and the negatively charged end of the multipole and repulsion between electron cloud of H and the negatively charged end of the multipole; for the complexes of HF and  $\text{N}_2\cdots\text{HArF}$ , attractive interaction is predominant, so the HX bond is red-shifted; but for  $\text{OC}\cdots\text{HArF}$ , the dipole moment and charge,  $q(\text{C})$ , is small, and the repulsive interaction is more important, so the HAr bond is blue-shifted.

For the complete electron system  $\text{N}_2\cdots\text{HArF}$  and its point charge model, we vary the distance of  $\text{Y}\cdots\text{Ar}$  from 2.5 Å to 7 Å; for each fixed  $\text{Y}\cdots\text{Ar}$  distance, we optimize the structure of the system. Figure 4a shows the correlation of the optimized bond length,  $r(\text{HAr})$ , with the  $\text{N}\cdots\text{Ar}$  distance for both RS and PCM. At large intermolecular distance, only electrostatic interaction works, so the two curves of RS and PCM coincide. As  $r(\text{N}\cdots\text{Ar}) < 4.5$  Å, the two curves begin to separate, so intermolecular hyperconjugation and charge transfer begin to work. For PCM,  $r(\text{HAr})$  increases as  $r(\text{N}\cdots\text{Ar})$  decreases, so electrostatic interaction always leads to a red shift of the HAr bond; however, for the real system,  $r(\text{HAr})$  decreases as  $r(\text{N}\cdots\text{Ar})$  decreases, so charge transfer

always causes a blue shift of the HAr bond. In the PCM, electrostatic interaction is mainly attraction between the negatively charged end of the quadrupole and the positive charge of H, which always causes elongation of the HAr bond. However, in the real system, intermolecular hyperconjugation induces a decrease of intramolecular hyperconjugation and an increase of the  $s$  character of the Ar hybrid of the HAr bond, which always leads to contraction of the HAr bond.

McDowell<sup>19</sup> mimicked the electric field of the quadrupole moment of  $\text{N}_2$  by also using similar PCM at the MP2/6-311G(d, p) level, but  $q = -0.624$  au, which is much larger than ours. He found that the quadrupole electric field leads to a blue shift of the HAr bond at the distance  $r(\text{N}\cdots\text{Ar})$  from 3.5 Å to 7 Å; this result is completely opposite to ours. Obviously, the difference is due to full electron correlation and the diffuse functions used by us. For further confirmation of our result, we vary the charge  $q$  from  $-0.05$  to  $-0.8$  au, but fix the N–N bond length,  $l$ , for the PCM, then optimize the structure of HArF under the quadrupole field for a series of fixed  $r(\text{N}\cdots\text{Ar})$  distances. Figure 4b shows the resulting correlation of the optimized bond length  $r(\text{HAr})$  with  $r(\text{N}\cdots\text{Ar})$  for different  $q$ . We noted that a negative quadrupole moment of the proton acceptor always leads to a red shift of the HAr bond.

For the complete electron system  $\text{N}_2\cdots\text{HF}$  and its PCM, we also vary  $r(\text{N}\cdots\text{F})$  from 2.2 Å to 7 Å; for each fixed  $r(\text{N}\cdots\text{F})$ , we optimize the structure of the system. Figure 5 shows correlation of  $r(\text{HF})$  with  $r(\text{N}\cdots\text{F})$  for RS and PCM. At large distances, the fact that the two curves coincide shows that only electrostatic interaction works. As  $r(\text{N}\cdots\text{F}) < 4.5$  Å, the two curves begin to separate, so charge transfer begins to work. For PCM,  $r(\text{HF})$  always increases with a decrease of  $r(\text{N}\cdots\text{F})$ , so electrostatic interaction always leads to elongation of the HF bond. But for RS,  $r(\text{HF})$  first increases and then decreases with a decrease of  $r(\text{N}\cdots\text{F})$ . At the moderate distance,  $r(\text{N}\cdots\text{F}) = 2.8 \sim 4.5$  Å, charge transfer causes the HF stretching frequency to more of a red shift; but as  $r(\text{N}\cdots\text{F}) < 2.8$  Å, exchange repulsion begins to work, which leads to contraction of the HF bond. Our result is consistent with that of McDowell.<sup>19</sup>

## Conclusions

Our theoretical calculated results on the H bonds of HArF and HF with  $\text{N}_2$ , CO, and BF show that the H bonding leads to a blue shift of the HAr bond but a red shift of the HF bond. The bond length change and frequency shift of the proton donor in the two kinds of H-bonds  $\text{WY}\cdots\text{HArF}$  and  $\text{WY}\cdots\text{HF}$  are mainly caused by intermolecular hyperconjugation and charge transfer; electrostatic interaction has only a small contribution. In HArF, there exists intramolecular hyperconjugation,  $n(\text{F}) \rightarrow \sigma^*(\text{HAr})$ , which can adjust electron density on  $\sigma^*(\text{HAr})$ ; upon the H bonding, intermolecular hyperconjugation induces a decrease of intramolecular hyperconjugation and an increase of the  $s$  character of the Ar hybrid of the HAr bond. These two factors lead to a blue shift of the HAr bond. In HF, however, there is no internal electron structure to adjust electron density on  $\sigma^*(\text{HF})$ , so charge transfer leads directly to an increase of

electron density on  $\sigma^*(\text{HF})$ , which exceeds the effect of re-hybridization so that the resulted H bond is red-shifted.

# Catalytic hypervalent iodine oxidation of alcohols to the corresponding carbonyl compounds using *N*-hydroxyphthalimide (NHPI) and *m*-chloroperbenzoic acid

Chenjie Zhu, Lei Ji, Qian Zhang, and Yunyang Wei

**Abstract:** An efficient, facile, and mild oxidation of alcohols to the corresponding carbonyl compounds with *m*-chloroperbenzoic acid (*m*CPBA) and *N*-hydroxyphthalimide (NHPI) in the presence of a catalytic amount of iodobenzene was reported. The oxidation proceeded in mixed solvent at room temperature to afford carbonyl compounds in excellent yields. A possible mechanism for the oxidation was proposed.

**Key words:** alcohols, oxidation, iodobenzene, *m*-chloroperbenzoic acid (*m*CPBA), *N*-hydroxyphthalimide (NHPI).

**Résumé :** On a mis au point une méthode efficace, facile et douce d'oxydation des alcools en dérivés carbonylés correspondants à l'aide de l'acide *m*-chloroperbenzoïque et le *N*-hydroxyphthalimide, en présence de quantités catalytiques d'iodobenzène. L'oxydation se produit en un solvant mixte, à la température ambiante et elle conduit à la formation des dérivés carbonylés avec d'excellents rendements. On propose un mécanisme possible pour la réaction.

**Mots-clés :** alcools, oxydation, iodobenzène, acide *m*-chloroperbenzoïque, *N*-hydroxyphthalimide.

[Traduit par la Rédaction]

## Introduction

The selective oxidation of alcohols to the corresponding carbonyl compounds is a fundamental transformation both in laboratory synthesis and industrial production.<sup>1</sup> Numerous hypervalent iodine compounds (e.g., DMP, IBX, PhI(OAc)<sub>2</sub>, PhIO, and so forth) in stoichiometric amounts have been traditionally employed to accomplish this transformation.<sup>2</sup> However, some of these reagents are potentially explosive, and the use of stoichiometric amounts of iodine reagents leads to the production of equimolar amounts of organic iodine waste. From economic and environmental perspectives, the development of catalytic systems based on hypervalent iodine has received great attention.<sup>3</sup> Many highly efficient systems have been developed for catalytic hypervalent iodine oxidation using co-oxidants, such as *m*-chloroperbenzoic acid (*m*CPBA),<sup>4</sup> oxone (2KHSO<sub>5</sub>·KHSO<sub>4</sub>·K<sub>2</sub>SO<sub>4</sub>),<sup>5</sup> H<sub>2</sub>O<sub>2</sub>,<sup>6</sup> tetraphenyl-phosphonium monoperoxysulfate (TPPP),<sup>7</sup> NaBO<sub>3</sub>·H<sub>2</sub>O,<sup>8</sup> O<sub>2</sub>,<sup>9</sup> Ru,<sup>10</sup> peracetic acid,<sup>11</sup> or in combination with the nitroxyl radical 2,2,6,6-tetramethyl-piperidyl-1-oxy (TEMPO).<sup>12</sup>

On the other hand, it is well-known that nitroxyl radicals, such as 2,2,6,6-tetramethyl-1-piperidinyloxy free radical (TEMPO) and *N*-hydroxyphthalimide (NHPI) promote the oxidation of various alcohols to the corresponding carbonyl compounds effectively under mild reaction conditions.<sup>13</sup> Piancatelli and co-workers have reported a mild and selective method for the oxidation of primary and secondary alcohols

using TEMPO and stoichiometric bis(acetoxy)iodobenzene (PhI(OAc)<sub>2</sub>) as a reoxidant.<sup>14</sup> However, there are no reports concerning the use of hypervalent iodine as a reoxidant for NHPI.

In continuation of our interest in exploring systems on the oxidation of organic compounds,<sup>15</sup> here, we would like to report a facile procedure for the oxidation of alcohols to the corresponding carbonyl compounds with *m*CPBA in the presence of catalytic amounts of PhI and NHPI (Scheme 1).

**Scheme 1.** Oxidation of alcohols catalyzed by *m*CPBA/PhI/NHPI.

## Results and discussion

The initial experiments were carried out using 4-nitrobenzyl alcohol as the model substrate. When 4-nitrobenzyl alcohol was oxidized with *m*CPBA/PhI/NHPI at room temperature for 3 h, 97% conversion of the alcohol was observed (Table 1, entry 1). As control experiments, the same reaction was carried out in the absence of *m*CPBA, PhI, or NHPI,

**Table 1.** Oxidation of 4-nitrobenzyl alcohol.

Entry	PhI (equiv.)	<i>m</i> CPBA (equiv.)	Additive	Conversion (%) <sup>a</sup>
1	0.1	2	NHPI	97
2	0.1	2	None	<10
3	0.1	None	NHPI	<10
4	None	2	NHPI	<10
5	0.05	2	NHPI	90
6 <sup>b</sup>	0.1	2	NHPI	24
7	0.1	2	CF <sub>3</sub> COOH	25
8	0.1	2	AcOH	29
9	0.1	2	(CF <sub>3</sub> CO) <sub>2</sub> O	<10
10	0.1	2	BF <sub>3</sub> ·Et <sub>2</sub> O	13
11 <sup>c</sup>	0.1	2	3 Å molecular sieves	<10

**Note:** Reactions were performed by using 4-nitrobenzyl alcohol (1 mmol), *m*CPBA (2 mmol), additive (0.2 mmol), and PhI (0.1 mmol) in MeCN/H<sub>2</sub>O (4:1, v/v) at room temperature for 3 h, unless otherwise noted.

<sup>a</sup>GC conversion.

<sup>b</sup>2,6-Di-*tert*-butylphenol (0.2 mmol) was added.

<sup>c</sup>0.1 g of 3 Å molecular sieves was added.

**Fig. 1.** Effect of the amount of *m*CPBA on the oxidation of 4-nitrobenzyl alcohol. Reaction conditions: 4-nitrobenzyl alcohol (1 mmol), *m*CPBA, NHPI (0.2 mmol), and PhI (0.1 mmol) in MeCN/H<sub>2</sub>O (4:1, v/v) at room temperature for 3 h.

respectively. In all cases, the conversion of the alcohol was less than 10% (Table 1, entries 2–4). It was possible to decrease the amount of PhI to as low as 0.05 equiv. without a significant loss in catalytic efficiency (Table 1, entry 5). Moreover, a range of additives were tested for this reaction; however, all of them were unsatisfactory except for NHPI (Table 1, entries 7–11). Besides, we also tested other co-oxidants, such as peracetic acid, NaBO<sub>3</sub>·H<sub>2</sub>O, K<sub>2</sub>S<sub>2</sub>O<sub>8</sub>, NaIO<sub>4</sub>, UHP, and Na<sub>2</sub>CO<sub>3</sub>·3H<sub>2</sub>O<sub>2</sub> in this experiment, all of them were unsuccessful.

To optimize the conditions of the oxidation, the role of *m*CPBA was studied using 1 mmol of 4-nitrobenzyl alcohol as substrate. It was found that the yield of 4-nitrobenzaldehyde reached to maximum when 1 equiv. of *m*CPBA was used. Using more than 1 equiv. of *m*CPBA led to the decrease of the yield of 4-nitrobenzaldehyde and increase of

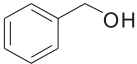

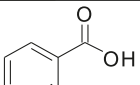

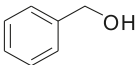

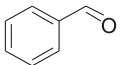

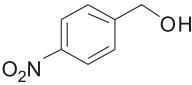

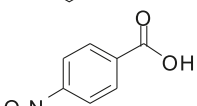

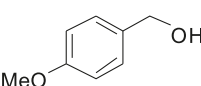

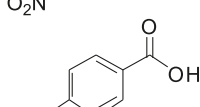

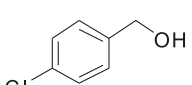

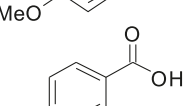

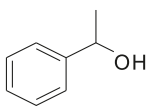

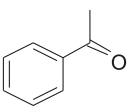

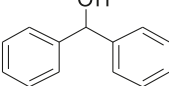

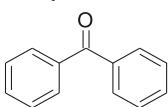

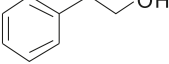

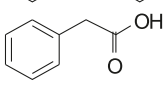

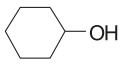

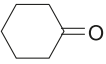

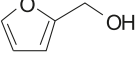

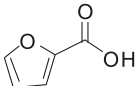

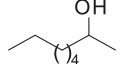

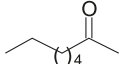

the yield of 4-nitrobenzoic acid. If 3 equiv. of *m*CPBA were used, quantitative yield of 4-nitrobenzoic acid was obtained (Fig. 1).

To evaluate the versatility of this novel catalytic system, we applied the procedure to the oxidation of a wide range of alcohols at room temperature. As shown in Table 2, most alcohols underwent oxidation to afford the corresponding carbonyl compounds in excellent yield. The present protocol afforded carboxylic acids from primary alcohols (Table 2, entries 1, 3–5, 8, 10, 11, and 13) and ketones from the secondary alcohols (Table 2, entries 6, 7, 9, and 12). The use of less amount of *m*CPBA and decreasing the reaction time in the oxidation of primary alcohols also led to the predominant formation of aldehydes (Table 2, entry 2). Benzylic alcohols underwent smooth oxidation (Table 2, entries 1–7). Even secondary alcohols, such as diphenylmethanol, were selectively oxidized to ketones effectively (Table 2, entry 7).

The electronic properties of the substituents in the aromatic ring had relatively minor influence on the oxidation of alcohols (Table 2, entries 3 and 4). Strong electron-withdrawing groups, such as nitro group, improve the oxidation of alcohol (Table 2, entry 3). Strong electron-donating group, such as –OCH<sub>3</sub> group, lowered the reaction rate (Table 2, entry 4). This is different from previously reported procedures, where –OCH<sub>3</sub> group favors alcohols oxidation.<sup>16</sup> It is worth mentioning that together with the good results with benzylic alcohols, the yields of ketones or acids obtained from the oxidation of aliphatic, alicyclic, or heterocyclic alcohols under the same conditions are also quite high (Table 2, entries 8–13).

Table 3 shows the results of the competitive oxidation of primary and secondary alcohols. The competing oxidation of an equimolar mixture of benzyl alcohol and 1-phenylethanol resulted in 95% yield of benzoic acid and less than 10% yield of acetophenone (Table 3, entry 1). Oxidation of an equimolar mixture of octan-1-ol and octan-2-ol gave 81% caprylic acid and less than 5% yield of hexyl methyl ketone, respectively (Table 3, entry 2). These results suggest that chemoselective oxidation of the primary alcoholic functionality in the presence of a secondary alcoholic functionality is possible with the present oxidation system.

**Table 2.** *m*CPBA/PhI/NHPI-catalyzed oxidation of alcohols.

Entry	Alcohols	Products	Time (h)	Yield <sup>a</sup> (%)
1			0.45	Quant.
2			0.5	81 <sup>b,c</sup>
3			3	Quant.
4			5	93
5			3	97
6			2.5	Quant.
7			5	95
8			8	88
9			8	83 <sup>d</sup>
10			4	Quant. <sup>d</sup>
11	$\text{CH}_3(\text{CH}_2)_7\text{OH}$	$\text{CH}_3(\text{CH}_2)_6\text{COOH}$	8	89
12			8	92 <sup>d</sup>
13	$n\text{-C}_{11}\text{H}_{23}\text{-CH}_2\text{OH}$	$n\text{-C}_{11}\text{H}_{23}\text{-COOH}$	10	96

**Note:** Reaction conditions: alcohol (1mmol), *m*CPBA (3mmol), PhI (0.1mmol), NHPI (0.2mmol) MeCN/H<sub>2</sub>O (4:1, v/v), at room temperature.

<sup>a</sup> Yields of isolated products unless otherwise noted. Quant.: Theoretical amount of product was obtained.

<sup>b</sup> *m*CPBA (1 equiv.) was used.

<sup>c</sup> Benzoic acid also formed in 19% yield.

<sup>d</sup> Yields were determined by GC.

A plausible mechanism of this reaction is depicted in Scheme 2. PhI is initially oxidized by *m*CPBA to form the highly reactive hypervalent iodine(III) intermediate **1**, the role of **1** is to regenerate phthalimide-*N*-oxyl radical (PINO) from NHPI, then PINO is responsible for the actual oxidant in this reaction to oxidize alcohol to the corresponding carbonyl compound. Experimental evidence towards catalytic oxidation of PhI to **1** mediated by *m*CPBA has previously been documented,<sup>4a</sup> and the generation and identification of the highly reactive hypervalent iodine(III) intermediate **1** was reported in the literature.<sup>4d</sup> Addition of 2,6-di-*tert*-butylphenol, a free radical scavenger, to the reaction system led to the decrease of the conversion of 4-nitrobenzyl alcohol

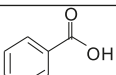

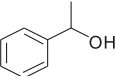

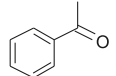

(Table 1, entry 6), which provides an experimental evidence for the generation of PINO during the reaction.

## Conclusion

In summary, a novel and mild catalytic system for the oxidation of alcohols to the corresponding carbonyl compounds with *m*CPBA/PhI/NHPI has been developed. PhI was oxidized by *m*CPBA in situ to highly active hypervalent iodine(III) species, a reoxidant of NHPI, which allowed the oxidation of various kinds of alcohols, including benzylic, aliphatic, alicyclic, and heterocyclic alcohols, to afford carbonyl compounds in excellent yields at room temperature.

**Scheme 2.** Tentative mechanism for the catalytic oxidation of alcohols with *m*CPBA/PhI/NHPI.**Table 3.** Competitive oxidation of primary and secondary alcohols.

Entry	Substrate	Product	Time (h)	Yield <sup>a</sup> (%)
1			0.5	95
				<10
	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>7</sub> OH	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>6</sub> COOH		81
2			4	<5

**Note:** The reactions were carried out on a 1:1 mixture of primary and secondary alcohols, on a 1 mmol scale.

<sup>a</sup>GC yield.

The procedure can be used for the synthesis of carboxylic acids and ketones from primary alcohols and secondary alcohols, respectively. By adjusting the dosage of *m*CPBA, aldehydes can also be obtained from primary alcohols. Selective oxidation of primary alcohols in the presence of secondary alcohols was also achieved.

## Experimental

### General

All chemicals (AR grade) were obtained from commercial sources and used without further purification. Gas chromatography (GC) analysis was performed on an Agilent GC-6820 chromatograph equipped with a 30 m × 0.32 mm × 0.5 μm HP-Innowax capillary column and a flame-ionization detector. Progress of the reactions was followed by TLC using silica-gel polygrams SIL G/UV 254 plates. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus.

### Typical experimental procedure for oxidation of alcohols

To a solution of alcohol (1 mmol), iodobenzene (20 mg, 0.1 mmol), and NHPI (40 mg, 0.2 mmol) in MeCN/H<sub>2</sub>O (4:1, v/v) was added *m*CPBA (700 mg, 65% wet with H<sub>2</sub>O, 3 mmol). The mixture was stirred at room temperature for several hours while checking the reaction progress by gas or thin-layer chromatography. After completion, aqueous sodium thiosulfate and Et<sub>2</sub>O were sequentially added to the residue, and then the mixture was stirred vigorously for 10 min. The organic layer was separated, and the aqueous layer was extracted with Et<sub>2</sub>O. After evaporation, the residue was purified by column chromatography to provide the ana-

lytically pure product. The products were identified either by comparison with authentic samples using gas chromatography or by GC-MS analysis.

# Enantioselective fluorescent sensors for chiral carboxylates based on BINOL — Synthesis and chiral recognition

Kuo-xi Xu, Yu-xia Wang, Shu-yan Jiao, Jin Zhao, and Chao-jie Wang

**Abstract:** The four novel derivatives of 1,1'-bi-2-naphthol (BINOL) have been prepared, and the structures of these compounds have been characterized by IR, MS,  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy, and elemental analysis. The enantioselective recognition of these receptors has been studied by fluorescence titration and  $^1\text{H}$  NMR spectroscopy. The receptors exhibited different chiral-recognition abilities towards some enantiomers of chiral materials and formed 1:1 complexes between host and guest. The receptors exhibit excellent enantioselective fluorescent-recognition ability towards the amino acid derivatives.

**Key words:** receptor, fluorescence, enantioselective recognition, anions, NMR spectroscopy.

**Résumé :** On a préparé quatre nouveaux dérivés du BINOL et on en a déterminé les structures par analyse élémentaire et par spectroscopies infrarouge, de masse et RMN du  $^1\text{H}$  et du  $^{13}\text{C}$ . On a étudié les propriétés de reconnaissance énantiosélective de ces récepteurs par titrage de fluorescence et par spectroscopie RMN du  $^1\text{H}$ . Les récepteurs présentent diverses capacités à reconnaître la chiralité de quelques énantiomères de produits chiraux et ils forment des complexes 1:1 entre molécules hôtes et invitées. Les récepteurs présentent une capacité excellente de reconnaître une fluorescence énantiosélective vis-à-vis des dérivés d'acides aminés.

**Mots-clés :** récepteur, fluorescence, reconnaissance énantiosélective, anions, spectroscopie RMN.

[Traduit par la Rédaction]

## Introduction

Molecular recognition, and in particular chiral recognition, is a fundamental characteristic in the biochemical systems. The study of synthetic model systems could contribute to the understanding of these processes and, at the same time, offer new perspectives for the development of pharmaceuticals, enantioselective sensors, catalysts, and other molecular devices.<sup>1</sup> The basis of any chiral recognition event is the formation of diastereomeric complexes composed of a chiral receptor and a chiral substrate possessing different stabilities.<sup>2</sup> The crucial points in the molecular design of chemosensors are how to achieve the specific recognition of a certain molecule and how to transduce the recognition event into a signal.<sup>3</sup> Many efforts involve the covalent linking of an optical signaling unit (a chromophore or a fluorophore) to a specific receptor for the chiral molecules.<sup>4</sup> Compared with other detection methods, such as NMR, HPLC, CD, or capillary electrophoresis, fluorescence techniques have often been used to study the interaction between enantiomers and receptors because of their sensitivity, selectivity, and versatility.<sup>5</sup> On the basis of their respective advantages, we attempt to design some receptors with optical

response to the enantiomers in the recognition interaction, which may offer a simple method to explore the recognition process for more information. The binaphthyl unit was especially eye-catching for its stable chiral configuration and tunable dihedral angle between the two naphthalene rings. Over the last two decades, binaphthyl derivatives have been shown to exhibit excellent enantioselectivities and turnovers in several types of asymmetric reactions, often matching the enantioselectivities traditionally regarded as being reserved for the enzyme realm.<sup>6</sup> As a naturally occurring chiral source, amino acids generally exhibit biological activity, and their recognition, in particular chiral recognition, attracts considerable interest.<sup>7</sup> Furthermore, they can be easily modified at the amino and carboxylic groups, which can also act as binding sites to form coordinate bonds with chiral molecules, so they were often used in the design and synthesis of artificial chiral receptors,<sup>8</sup> such as different types of acyclic compounds<sup>9</sup> as host molecules. We chose several familiar amino acids (e.g., alanine, phenylalanine) as chiral building blocks and introduced them into the 1,1'-bi-2-naphthol (BINOL) framework to construct the fluorescent receptors (Scheme 1). Herein, we describe the development of BINOL

derivatives bearing amino acid units, and their bonding properties with some enantiomers of chiral materials have been examined by using fluorescence titration experiments in  $\text{CHCl}_3$ . Receptors exhibited good enantioselective recognition abilities towards chiral materials and formed 1:1 complex with the guests in  $\text{CHCl}_3$ .  $^1\text{H}$  NMR experiments suggested that hydrogen-bonding interactions between the host and guest were the main factor in the recognition process.

## Results and discussion

### Synthesis

The synthesis of receptor **S-1** is outlined in Scheme 1. The starting materials binaphthyl dialdehydes were prepared from BINOL.<sup>10</sup> *N*-Boc-protected alanine methyl ester (**2**) were synthesized according to the literature with high yield,<sup>11</sup> and then reacted with excess amount of ethylenediamine to obtain the compound (*S*)-*tert*-butyl-1-(2-aminoethylamino)-1-oxopropan-2-ylcarbamate (**3**). To avoid the partial racemization of **3** in this reaction, the compound **2** and ethylenediamine were dissolved in large amount of methanol and stirring was continued at room temperature. Especially at the end of reaction, the solvent and ethylenediamine should be evaporated under high vacuum at about  $30^\circ\text{C}$ , because a little higher temperature may lead the racemization of compound. Condensation of *S*-binaphthyl dialdehydes with compound **3**, followed by reduction, afforded the disubstituted BINOL **S-1** (Scheme 1). To study how the BINOL and amino acid units in **S-1** influenced the enantioselective fluorescent recognition, **R-1**, **S-5**, and **R-5** were also prepared (Fig. 1). They are readily soluble in common organic solvents, such as  $\text{CHCl}_3$ ,  $\text{CH}_2\text{Cl}_2$ ,  $\text{CH}_3\text{OH}$ , DMSO, and DMF. The structures of all these compounds were characterized by IR, MS,  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy, and elemental analysis.

### Fluorescence spectra study

The properties of the chiral recognition of receptors **S-1** were investigated in the absence and presence of various chiral carboxylates (Fig. 2), such as (*S*)- and (*R*)-mandelate, the  $\alpha$ -phenylglycine anion, *N*-Boc-protected alanine anion (Ala), and *N*-Boc-protected phenylalanine anion (Phe), in which the amino groups were protected by the *tert*-butoxycarbonyl functionality. In each case, tetrabutylammonium was used as the counter cation, which could increase the reaction

**Fig. 1.** Structures of the receptors **R-1**, **S-5**, and **R-5**.**Fig. 2.** Structures of the guests.

between the receptor and guest by hydrogen bondings.<sup>1c</sup> We also chose two amino alcohols, namely, alaninol and phenylalaninol, as guests to compare the associated abilities of the hosts to bind with neutral molecules.

The fluorescence spectra were recorded from a solution of sensor **S-1** ( $1.22 \times 10^{-5}$  mol  $\text{L}^{-1}$ ) in  $\text{CHCl}_3$  in the absence or presence of various enantiomers, (*R*)-, (*S*)-Ala, and Phe anions. Because there was almost no change observed on the UV-vis spectra of receptors upon addition of the anions, the interaction between host and anion was only evaluated by fluorescent spectra.

Upon addition of (*S*)- or (*R*)-Ala or Phe anions, different fluorescent-quenching degrees of **S-1** were observed. The quenching efficiencies of (*S*)-amino acid anions were much higher than the (*R*)-amino acid anions. Figure 3 and Fig. 4 show the fluorescence emission spectra of a mixture of **S-1**

**Fig. 3.** Fluorescence spectra of receptor **S-1** ( $1.22 \times 10^{-5}$  mol L $^{-1}$ ) with (*S*)-Ala anion in CHCl $_3$ . The anion equivalents are: 0, 2, 4, 6, 8, 10, 20, 40, 60, 80, 100, 150, 200, 300, and 500.  $\lambda_{\text{ex}} = 278$  nm. Inset: changes in the fluorescence intensity of **S-1** at 371 nm upon addition of (*S*)-Ala anion. The line shown is a line-fitted curve. The correlation coefficient (*R*) of the nonlinear curve fitting is 0.9994.

and different concentrations of the (*S*)- or (*R*)-Ala anion in CHCl $_3$  ( $\lambda_{\text{ex}} = 278$  nm), respectively. The graphs in the top right corners of Figs. 3 and 4 illustrate the fluorescence intensity change of receptor **S-1** upon addition of (*S*)- and (*R*)-Ala anions, respectively. Figure 5 shows the different fluorescence intensity changes when the same equiv. of (*S*)- or (*R*)-Ala anion were added to the solution of **S-1**, the quenching efficiency was 46.7% when 4 equiv. of (*S*)-Ala anion was added to the solution of **S-1**, while the quenching efficiency was only 8.7% when 4 equiv. of (*R*)-Ala anion was added. The quenched efficiencies ( $\Delta I_S/\Delta I_R = 5.37$ ) indicated that the host **S-1** has a good enantioselective recognition ability between the (*S*)- and (*R*)-Ala anions, respectively. Satisfactory nonlinear curve fitting (the correlation coefficient is over 0.99) confirmed that **S-1** and the (*S*)- or (*R*)-Ala formed a 1:1 complex (see the insets of Fig. 3 and Fig. 4). For a complex of 1:1 stoichiometry, the association constant ( $K_{\text{ass}}$ ) can be calculated by using eq. [1] from the Origin 7.5 software package<sup>12,13</sup>

$$[1] \quad X = X_0 + (X_{\text{lim}} - X_0)/2C_0\{C_H + C_G + 1/K_{\text{ass}} - [(C_H + C_G + 1/K_{\text{ass}})^2 - 4C_H C_G]^{1/2}\}$$

where *X* represents the fluorescence intensity,  $C_H$  and  $C_G$  are the host and guest concentrations, respectively, and  $C_0$  is the initial concentration of the host. The association constants ( $K_{\text{ass}}$ ) and correlation coefficients (*R*) obtained by a nonlinear least squares analysis of *X* vs.  $C_H$  and  $C_G$  are listed in Table 1.

The association constant for the interaction of **S-1** with the (*S*)- and (*R*)-Ala anion is  $(3.60 \pm 0.27) \times 10^4$  and  $(3.54 \pm 0.19) \times 10^3$  M $^{-1}$ , respectively. Receptor **S-1** gives an enantioselectivity  $K_{\text{ass}((S)\text{-Ala})}/K_{\text{ass}((R)\text{-Ala})} = 10.17$ . The dramatically different fluorescent responses and quenching efficiencies observed for the two enantiomers indicate that **S-1** has excellent enantioselective fluorescent-recognition ability towards the Ala anion. Similar phenomena were observed

**Fig. 4.** Fluorescence spectra of receptor **S-1** ( $1.22 \times 10^{-5}$  mol L $^{-1}$ ) with (*S*)-Ala anion in CHCl $_3$ . The anion equivalents are: 0, 2, 4, 6, 8, 10, 20, 40, 60, 80, 100, 200, 300, 400, and 500.  $\lambda_{\text{ex}} = 278$  nm. Inset: changes in the fluorescence intensity of **S-1** at 371 nm upon addition of (*S*)-Ala anion. The line shown is a line-fitted curve. The correlation coefficient (*R*) of the nonlinear curve fitting is 0.9994.

**Fig. 5.** Fluorescence spectra of host **S-1** ( $2.13 \times 10^{-6}$  mol L $^{-1}$ ) with 4.0 equiv. of (*S*)- and (*R*)-Ala anion in CHCl $_3$ .

when (*S*)- or (*R*)-Phe anions were added into a solution of **S-1**. The result of a nonlinear curve fitting (at 371 nm) indicates that a 1:1 complex was formed between receptor **S-1** and (*S*)- or (*R*)-Phe (see Table 1). In addition, the association constants ( $K_{\text{ass}}$ ) were different (see Table 1) ( $K_{\text{ass}((S))} = (3.17 \pm 0.11) \times 10^4$  M $^{-1}$ ,  $\Delta G_0 = -25.69$  kJ mol $^{-1}$ ;  $K_{\text{ass}((R))} = (3.09 \pm 0.08) \times 10^3$  M $^{-1}$ ,  $\Delta G_0 = -19.92$  kJ mol $^{-1}$ ), yielding an *S/R* selectivity [ $K_{\text{ass}((S))}/K_{\text{ass}((R))}$ ] of 10.26 for the Phe anions and a  $\Delta\Delta G_0$  value of  $-5.77$  kJ mol $^{-1}$ , demonstrating that **S-1** has good chiral recognition ability towards the enantiomers of Phe anions.

The binding of **S-1** with mandelate and  $\alpha$ -phenylglycine anion was also carried out, and the association constants of the host **S-1** with mandelate and  $\alpha$ -phenylglycine anion are also listed in Table 1. When **S-1** interacted with  $\alpha$ -phenylglycine anion, the receptor **S-1** exhibited weak enantioselective recognition ability to  $\alpha$ -phenylglycine anion that have been

<sup>a</sup>The data were calculated from the results of fluorescence titrations in  $\text{CHCl}_3$ .<sup>b</sup>All error values were obtained from nonlinear curve fitting.<sup>c</sup>Ala and Phe tetrabutylammonium salts, the amino group was protected by a *tert*-butoxycarbonyl function.

tested (see Table 1). Upon the addition of alaninol or phenylalaninol into a solution of in  $\text{CHCl}_3$ , the fluorescence intensity of **S-1** was slightly quenched by both (*S*)- and (*R*)-enantiomers (see Table 1). This indicates that hydrogen bonding plays an important role in the interaction between

the host and guest and leads to the easier signal transductions of chiral recognition by fluorescence method.

The continuous variation methods were also employed to determine the stoichiometric ratio of the receptor **S-1** with guests [(*S*)- and (*R*)-Ala anions]. The total concentration of

host and guest was constant ( $1.0 \times 10^{-6}$  mol L $^{-1}$ ) in CHCl $_3$ , with a continuously variable molar fraction of host ( $[H]/([H] + [G])$ ). Figure 6 shows the Job plots of receptor **S-1** with (S)- and (R)-Ala anion (at 371 nm,  $\lambda_{\text{ex}} = 278$  nm). When the molar fraction of the host was 0.50, the fluorescence intensity reached a maximum, which demonstrated that receptor **S-1** formed a 1:1 complex with (S)- and (R)-Ala anions, respectively.<sup>14</sup>

The decrease in fluorescence intensity of the excimer upon addition of the anion is similar to the anion-induced fluorescence decrease reported previously.<sup>15</sup> Because of the similar structure of **S-1**, the fluorescent variations of **S-1** showed the same trend. Since there were no changes in the UV-vis spectra of the receptors when treated with (S)- or (R)-anions, a photoinduced electron transfer (PET) process might be responsible for the fluorescent quenching.<sup>16</sup> In the absence of anions, PET between the binaphthyl unit and the electron-withdrawing amide substituents might result in quenched fluorescence. In the presence of guest anions, the fluorescence quenching of receptors **S-1** most likely arose from the change of the free energy ( $\Delta G_{\text{PET}}$ ) of the electron transfer between the excited fluorophore and the receptor.<sup>17</sup> Therefore, fluorescence quenching was observed.

To study how the chirality of the amino acid unit and BINOL groups in **S-1** influenced the enantioselective fluorescent recognition, **R-1**, the diastereomeric compounds of **S-1**, **S-5**, and **R-5** were also prepared by similar methods. We also studied its interaction with mandelate, phenylglycine, Ala and Phe anions, alaninol, and phenylalaninol, which showed the opposite enantioselectivity. That is, the (R)-guest enantiomer quenched the fluorescence of **R-1** more efficiently than (S)-guest. The result of fluorescence titration indicated that a matched chirality between the guest anions center and the chiral BINOL unit led to the enantioselective recognition. The enantiomers of guest anions interacted with **R-1** and **S-1** in the same fashion.

According to Table 1, the interaction of **S-1** with the (S)-Ala and (S)-Phe anions is better than that with the (R)-Ala and (R)-Phe anions, which is probably due to the (S)-amino acid anions having a more complementary structure with receptors **S-1**. The receptors **S-1** and **R-1** all exhibit good chiral recognition ability towards the enantiomers of the Ala and Phe anions, which indicates that the preorganized structure of the chiral center of the binaphthyl unit plays important roles in the enantioselective recognition process.

### <sup>1</sup>H NMR study

<sup>1</sup>H NMR experiments were undertaken to assess the chiral-recognition properties between receptor **S-1** and chiral anionic guest because NMR spectroscopy can provide structural and dynamic information directly.<sup>18</sup> <sup>1</sup>H NMR chiral-recognition studies were carried out with a 400 MHz NMR spectrometer using receptor **S-1** in CDCl $_3$  as chiral solvating agent at room temperature. The spectra of receptor **S-1** and its complexes with equimolar amounts of racemic Ala anions are shown in Fig. 7. When treated with equimolar amounts of receptor **S-1**, the signal of the CH proton of the racemic Ala anion cleaved into a more complicated signal pattern (Fig. 7C) with a downfield shift. The interaction of receptor **S-1** with (S)-enantiomer showed that the CH proton has a larger downfield shift (from  $\delta = 3.85$  to 4.27 ppm,  $\Delta\delta =$

**Fig. 6.** Job plots of receptor **S-1** with (S)- and (R)-Ala anions (367 nm,  $\lambda_{\text{ex}} = 290$  nm). The total concentration of the host [H] and guest [G] is  $1.0 \times 10^{-6}$  mol L $^{-1}$  in CHCl $_3$ .  $I_0$ : fluorescence intensity of **S-1**;  $I$ : fluorescence intensity of **S-1** in the presence of the guest.

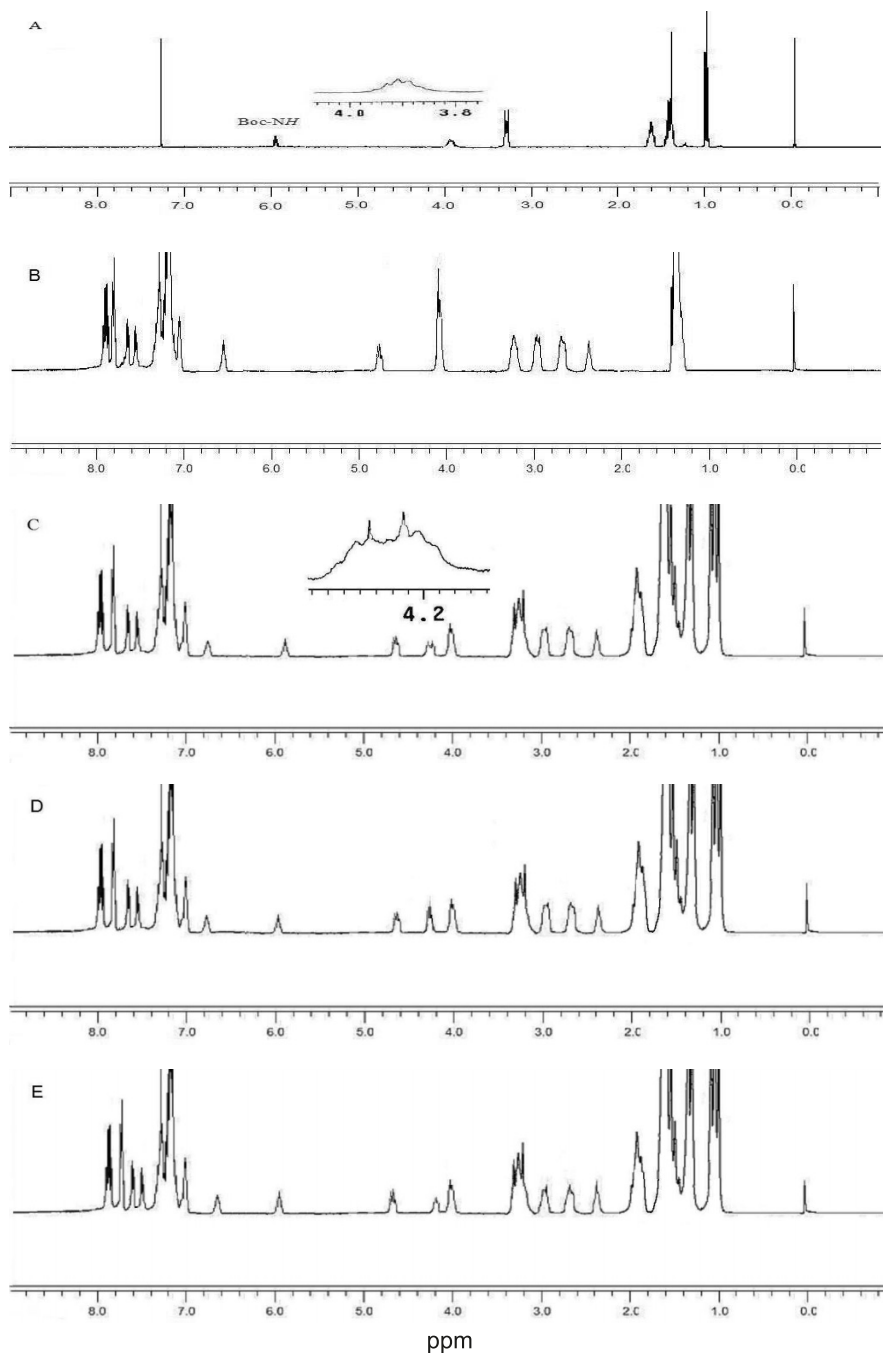

0.42 ppm, Fig. 7D) than that of the CH proton of the (R)-enantiomer (from  $\delta = 3.85$  to 4.19 ppm,  $\Delta\delta = 0.34$  ppm, Fig. 7E). Moreover, the signals of the -OH proton in the <sup>1</sup>H NMR spectra of the receptor **S-1** become weakened obviously and have downfield shift from 6.57 to 6.78 ppm ( $\Delta\delta = 0.21$  ppm, Fig. 7D) or 6.74 ppm ( $\Delta\delta = 0.17$  ppm, Fig. 7E) for (S)- or (R)-Ala anion, respectively, while the signals of the peaks of binaphthyl fragments are downfield-shifted and broadened with the addition of the guest. The signal of the amide (NH) group of Ala linked to the Boc moiety was also clearly downfield-shifted from  $\delta = 5.91$  to 5.98 ppm ( $\Delta\delta = 0.07$  ppm, Fig. 7D) and 5.94 ppm ( $\Delta\delta = 0.03$  ppm, Fig. 7E) for (S)- and (R)-Ala anion, respectively. The above results indicate that **S-1** has a stronger interaction with the (S)-Ala anion than with its (R)-enantiomer. This indicated that the interaction between the host and guest also happened by multiple hydrogen bondings. The results also illustrate that the nature of the receptor, multiple hydrogen-bonding interactions, and complementary chiral-center interactions maybe responsible for the enantiomeric recognition of the amino acid anion.<sup>19</sup>

### Conclusion

In summary, four chiral fluorescent receptors **S-1**, **R-1**, **S-5**, and **R-5** were synthesized, and their enantioselective recognition was studied by fluorescence titration and <sup>1</sup>H NMR spectroscopy. Receptors **S-1** and **R-1** exhibit different chiral-recognition abilities towards some enantiomers of chiral materials and form 1:1 complexes with the guest molecules. It is clear that the nature of the receptor, good structural preorganization, multiple hydrogen-bonding interactions, and complementary chiral-center interactions may be responsible for the enantiomeric recognition of anionic guests.<sup>19</sup> Receptors **S-1** and **R-1** are promising in their use as fluorescence sensors for amino acid anions. The remarkably different fluorescent responses that result from complexation reveal that **S-1** and **R-1** could be used as fluorescent chemosensors for the *N*-Boc-protected alanine anion or *N*-Boc-protected phenylalanine anion in the future.

**Fig. 7.** The  $^1\text{H}$  NMR spectra of **S-1** and its guest complexes at 25 °C ( $[\text{S-1}] = [\text{guest}] = 4.0 \times 10^{-3} \text{ mol L}^{-1}$ ) in  $\text{CDCl}_3$  at 400 MHz. (A) Racemic Ala anion; (B) receptor **S-1**; (C) receptor **S-1** + racemic Ala anion; (D) receptor **S-1** + (*S*)-Ala anion; (E) receptor **S-1** + (*R*)-Ala anion.

## Experimental section

### General

The reagents used were of commercial origin and were employed without further purification. Purifications by column chromatography were carried out over silica gel (230–400 mesh). The IR spectra were performed on a Nicolet 670 FTIR spectrophotometer.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded on a Bruker AV-400 spectrometer. Mass spectra were determined by ESI recorded on a Esquire 3000 LC-MS mass instrument. Optical rotations were taken on a Per-

kinElmer Model 341 polarimeter. Fluorescence spectra were obtained with a F-7000 FL Spectrophotometer. Elemental analyses were performed by the Vario Elemental CHN-O microanalyzer. The anions were used as their tetrabutylammonium salts. The *N*-protected (by the *tert*-butoxycarbonyl functionality) amino acid derivatives were synthesized according to a literature method.<sup>20</sup>

### The synthesis of compound 3

Under  $\text{N}_2$ , excess ethylenediamine (0.60 g, 10 mmol) in 10 mL  $\text{CH}_3\text{OH}$  was added dropwise into a solution (20 mL)

of (*S*)-*N*-Boc-protected alanine methyl ester (**2**) (0.41 g, 2 mmol) in  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (1:10, v/v) in an ice-bath. After the addition, the mixture was stirred at room temperature for 48 h. The solvent was evaporated, and the residual ethylenediamine was removed under reduced pressure. Then,  $\text{CHCl}_3$  (30 mL) was added and washed with  $\text{H}_2\text{O}$  (3  $\times$  30 mL); the organic layer was separated and dried over  $\text{Na}_2\text{SO}_4$ . After filtration, the solvent was removed under reduced pressure to give **3** as colorless ropy oil in 86% yield (0.40 g).  $[\alpha]_{\text{D}}^{20} + 21.84$  ( $c = 0.05$ ,  $\text{CHCl}_3$ ).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.01 (s, 1 H, CONH), 5.47 (s, 1 H, NHBoc), 4.18 (CH), 3.31 (t,  $J = 6.4$  Hz, 2H,  $\text{CH}_2$ ), 2.82 (t,  $J = 6.4$  Hz, 2H,  $\text{CH}_2$ ), 1.72 (s, 2 H,  $\text{NH}_2$ ), 1.44 (s, 9 H,  $\text{CH}_3$ ), 1.35 (t,  $J = 6.8$  Hz, 3 H,  $\text{CH}_3$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 172.8, 155.2, 77.8, 54.1, 41.2, 40.3, 28.8, 27.9. ESI-MS  $m/z$  (%): 232 (100)  $[\text{M} + 1]^+$ .  $\text{C}_{10}\text{H}_{21}\text{N}_3\text{O}_3$  calcd.: C 51.93, H 9.15, N 18.17; found: C 51.66, H 9.22, N 18.04.

### The preparation of *tert*-butyl-2-(2-aminoethylamino)-2-oxoethylcarbamate

*Tert*-butyl-2-(2-aminoethylamino)-2-oxoethylcarbamate was prepared by the same method as that of compound **3** by starting with *N*-Boc-protected glycine methyl ester, and it gave 95% yield.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.11 (s, 1H, CONH), 5.57 (s, 1H, NHBoc), 3.74 (s, 2H,  $\text{CH}_2$ ), 3.39 (t,  $J = 6.4$  Hz, 2H,  $\text{CH}_2$ ), 2.86 (t,  $J = 8.0$  Hz, 2H,  $\text{CH}_2$ ), 1.74 (s, 2 H,  $\text{NH}_2$ ), 1.44 (s, 9 H,  $\text{CH}_3$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 173.3, 155.9, 78.1, 55.7, 41.9, 40.7, 28.9. ESI-MS:  $m/z$  (%) = 218 (100)  $[\text{M} + 1]^+$ .  $\text{C}_9\text{H}_{19}\text{N}_3\text{O}_3$  calcd.: C 49.75, H 8.81, N 19.34; found: C 49.57, H 8.89, N 19.22.

### General procedure for the synthesis of compounds **R-1**, **S-1**, **R-5**, and **S-5**

A mixture of the (*R*) or (*S*)-binaphthyl dialdehyde (0.34 g, 1 mmol) and compound **3** or *tert*-butyl-2-(2-aminoethylamino)-2-oxoethylcarbamate (2.2 mmol) in  $\text{CH}_3\text{OH}$  (30 mL) was stirred for 48 h under  $\text{N}_2$  at room temperature until TLC showed the disappearance of the starting material.  $\text{NaBH}_4$  (0.19 g, 5 mmol) was then added to the mixture in three portions over 3 h, after which it was stirred under  $\text{N}_2$  for another 6 h at 50  $^\circ\text{C}$ . The mixture was poured into 30 mL of 10%  $\text{NaHCO}_3$  after removing the solvent under reduced pressure, and extracted three times with  $\text{CHCl}_3$ . The organic layers were combined and dried over anhydrous  $\text{Na}_2\text{SO}_4$ . After filtration, the solvent was evaporated under reduced pressure, and the residue was purified by column chromatography on silica gel [eluent:  $\text{CHCl}_3/\text{CH}_3\text{CH}_2\text{OH}$ , 50:1 (v/v)]. The pure product was obtained as a pale yellow solid.

### *S-1* and *R-1*

Yield (**S-1**): 76.8%;  $[\alpha]_{\text{D}}^{20} - 34.72$  ( $c = 0.05$ ,  $\text{CHCl}_3$ ). Yield (**R-1**): 79.3%;  $[\alpha]_{\text{D}}^{20} + 117.18$  ( $c = 0.05$ ,  $\text{CHCl}_3$ ).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.87 (s, 2H, CONH), 7.83 (d,  $J = 8.0$  Hz, 2H, Ar-H), 7.76 (d,  $J = 9.6$  Hz, 2H, Ar-H), 7.61 (d,  $J = 8.1$  Hz, 2H, Ar-H), 7.28 (d,  $J = 7.6$  Hz, 2 H, Ar-H), 7.19 (d,  $J = 7.2$  Hz, 2H, Ar-H), 7.13–7.16 (t,  $J = 4.8$  Hz, 2H, Ar-H), 6.52 (s, 2H, OH), 4.76–4.68 (m, 2H,  $\text{CHCH}_2$ ), 4.10 (d,  $J = 8.0$  Hz, 4H, Ar- $\text{CH}_2$ ), 3.00–2.91 (m, 4H,  $\text{CH}_2$ ), 2.73–2.64 (m, 4H,  $\text{CH}_2$ ), 2.36 (s, 2H, NH), 1.42 (s, 18H,  $\text{CH}_3$ ), 1.28 (s, 3H,  $\text{CH}_3$ ), 1.22 (s, 3H,  $\text{CH}_3$ ).  $^{13}\text{C}$  NMR

( $\text{CDCl}_3$ )  $\delta$  (ppm): 172.39, 152.53, 152.51, 134.32, 133.76, 132.91, 132.69, 131.29, 130.69, 130.54, 130.12, 129.94, 128.34, 127.38, 126.95, 126.07, 125.86, 125.59, 125.22, 124.96, 121.02, 57.31, 57.09, 39.89, 24.95, 14.44, 14.14. ESI-MS  $m/z$  (%): 795 (100)  $[\text{M} + \text{Na}]^+$ .  $\text{C}_{42}\text{H}_{56}\text{N}_6\text{O}_8$  calcd.: C 65.26, H 7.30, N 10.87; found (**S-1**): C 65.11, H 7.21, N 10.99; found (**R-1**): C 65.07, H 7.19, N 11.02.

### *S-5* and *R-5*

Yield (**S-5**): 79.6%;  $[\alpha]_{\text{D}}^{20} = -68.32$  ( $c = 0.05$ ,  $\text{CHCl}_3$ ). IR (film,  $\text{cm}^{-1}$ )  $\nu$ : 3402, 3092, 2969, 1679, 1529, 1268, 1234, 752.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.89 (s, 2H, CONH), 7.87 (d,  $J = 8.0$  Hz, 2H, Ar-H), 7.79 (d,  $J = 9.6$  Hz, 2H, Ar-H), 7.64 (d,  $J = 8.1$  Hz, 2H, Ar-H), 7.22 (d,  $J = 7.6$  Hz, 2H, Ar-H), 7.19 (d,  $J = 7.2$  Hz, 2H, Ar-H), 7.17–7.13 (t,  $J = 4.8$  Hz, 2H, Ar-H), 6.55 (s, 2H, OH), 4.12 (d,  $J = 8.0$  Hz, 4H, Ar- $\text{CH}_2$ ), 3.88 (s, 4H,  $\text{CH}_2$ ), 3.03–2.95 (m, 4H,  $\text{CH}_2$ ), 2.79–2.70 (m, 4H,  $\text{CH}_2$ ), 2.38 (s, 2H, NH), 1.44 (s, 18H,  $\text{CH}_3$ ).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 174.03, 153.59, 153.31, 134.99, 133.96, 133.44, 133.17, 132.54, 131.06, 130.86, 130.58, 129.91, 128.71, 127.53, 126.62, 126.01, 125.93, 125.85, 125.73, 124.58, 74.09, 58.39, 58.49, 39.89, 24.92. ESI-MS  $m/z$  (%): 767 (100)  $[\text{M} + \text{Na}]^+$ .  $\text{C}_{40}\text{H}_{52}\text{N}_6\text{O}_8$  calcd.: C 64.50, H 7.04, N 11.28; found (**S-5**): C 64.29, H 7.09, N 11.19; found (**R-5**): C 64.33, H 7.11, N 11.15.

### Preparation of samples for fluorescence measurement

All solutions were prepared using volumetric syringes, pipettes, and volumetric flasks. The tetrabutylammonium salts were prepared by adding 1 equiv. of tetrabutylammonium hydroxide in methanol to a solution of the corresponding carboxylic acid in methanol, and stock solutions of the salts were prepared in  $\text{CHCl}_3$ . The resulting syrup was dried under high vacuum for 24 h, analyzed by NMR spectroscopy, and stored in a desiccator. Compounds **R-1** and **S-1** were prepared as stock solutions in  $\text{CHCl}_3$ . The test solutions were prepared by adding different volumes of anion solution to a series of test tubes, and then the same amount of stock solution of the host compound was added to each of the test tubes and diluted to 3.0 mL with  $\text{CHCl}_3$ . After being shaken for several minutes, the test solutions were analyzed immediately.

### Job Plots

Stock solutions of host **S-1** and the (*S*)- and (*R*)-Ala tetrabutylammonium salts in  $\text{CHCl}_3$  system (the total concentration of the host and guest is  $1.0 \times 10^{-6}$  mol  $\text{L}^{-1}$ ) were freshly prepared. The receptor and Ala solutions were added to the test tubes in ratios of 9:1, 8:2 to 0:10, respectively. After being shaken for several minutes, the working solution could be measured immediately.

### Acknowledgments

We thank the National Natural Science Foundation of China (Grant No. 20872027/B0206) and the Education Department of Henan Province of China (2010B150004) for financial support.

# Electrochemical and in situ spectroelectrochemical investigations into the redox and aggregation behaviours of phthalocyanines bearing octyl 4-phenyloxyacetate moieties

İmran Koç, Meryem Çamur, Mustafa Bulut, and A. Riza Özkaya

**Abstract:** Electrochemical and spectroelectrochemical properties of phthalocyanines (H<sub>2</sub>Pc, ZnPc, NiPc, CuPc, and CoPc) involving octyl 4-phenyloxyacetate moieties have been investigated by cyclic voltammetry and differential pulse voltammetry on Pt in dimethylsulfoxide – tetrabutylammonium perchlorate. These measurements showed that the complexes undergo subsequent one-electron reduction and oxidation processes. In situ UV–vis spectroelectrochemical measurements enabled us to identify the ligand- and metal-based redox processes, and evaluate the effect of aggregation phenomena on these processes. The cobalt complex showed both metal-based and ring-based one-electron redox processes, while the other complexes displayed only ring-based one-electron couples. It was observed that the redox processes of H<sub>2</sub>Pc, NiPc, and CuPc are coupled by aggregation phenomenon, whereas those of ZnPc and especially CoPc are not, probably owing to the difference in their axial coordinating properties.

**Key words:** phthalocyanines, aggregation, electrochemistry, in situ spectroelectrochemistry.

**Résumé :** Faisant appel à la voltampérométrie cyclique et la voltampérométrie pulsée différentielle sur du Pt dans un mélange diméthylsulfoxyde – perchlorate de tétrabutylammonium, on a examiné les propriétés électrochimiques et spectroélectrochimiques de phthalocyanines (H<sub>2</sub>Pc, ZnPc, NiPc, CuPc et CoPc) impliquant des portions 4-phényloxyacétate d'octyle. Ces mesures ont montré que les complexes subissent des processus subséquents de réduction et d'oxydation à un électron. Des mesures spectroélectrochimiques UV–vis in situ ont permis d'identifier les processus redox à base de métal et de ligand et d'évaluer l'effet du processus d'agrégation alors que les autres complexes ne présentent que des couples à un électron à base du noyau. On a observé que les processus redox du H<sub>2</sub>Pc, du NiPc et du CuPc sont couplés par le phénomène d'agrégation alors que ceux du ZnPc et particulièrement celui de CoPc ne le sont probablement pas en raison de la différence dans leurs propriétés de coordination axiales.

**Mots-clés :** phthalocyanines, agrégation, électrochimie, spectroélectrochimie in situ.

## Introduction

There is a strong relationship between the redox properties of phthalocyanines (Pcs) and most of their industrial applications as semiconductors, photovoltaic cells, electrochromic displays, and catalysts, for example.<sup>1,2</sup> Accordingly, the electrochemistry of Pcs has received considerable interest in recent years. Small modifications in Pc molecules may remarkably influence their redox properties since these properties depend on various factors such as the type of the central metal, solvent, axial ligands, substituents, and aggregation.<sup>3–7</sup> It is well-known that Pcs may dimerize and even form larger and more complex aggregates, owing to the extended  $\pi$  system.<sup>8–14</sup> In most cases, the aggregation phenomenon is deleterious to the desired electrical,<sup>15,16</sup> spectroscopic,<sup>17–21</sup>

photophysical,<sup>22–27</sup> and electrochemical<sup>28,29</sup> properties of these compounds. On the other hand, the formation of well-defined Pc dimers and (or) aggregates is useful in materials and catalytic applications where the self-assembly of Pc cores in close proximity is beneficial.<sup>30–34</sup>

Voltammetry is the most widely used electrochemical method to determine the redox properties, whereas the aggregation process of Pcs can be probed using electronic spectroscopy. It is necessary to combine spectroscopic and electrochemical techniques, i.e., carry out in situ spectroelectrochemical measurements, to be able to identify thoroughly the effect of aggregation phenomenon on the redox processes. In most cases, the nature of the redox processes cannot be distinguished by voltammetric methods alone. In

situ spectroelectrochemical measurements allow us to determine whether the redox processes occur in the Pc ring or in the metal center.<sup>35–39</sup>

In a recent study, we have reported on the synthesis and characterization of metal-free and metal phthalocyanines (MPcs) with four 4-phenyloxyacetic acid groups on the periphery, prepared by cyclotetramerization of *p*-(3,4-dicyanophenoxy) phenyl-acetic acid and the corresponding divalent metal salts.<sup>40</sup> Further reactions of these products with thionylchloride and then benzylamine in tetrahydrofuran and octanol in pyridine, gave amide and ester derivatives, respectively. These complexes were observed to have a remarkable tendency to aggregation, a very useful feature for the fabrication of modified electrodes. In the present work, the redox and aggregation behaviours of the metal-free and metal Pcs, bearing octyl 4-phenyloxyacetate moieties and the effect of aggregation phenomena on their redox behaviour have been examined by voltammetry and in situ spectroelectrochemistry.

## Experimental

The electrochemical and in situ spectroelectrochemical measurements were monitored using a Gamry Reference 600 potentiostat–galvanostat controlled by an external PC and utilizing a three-electrode configuration at 25 °C. UV–vis absorption spectra were recorded by an Agilent 8453 diode array spectrophotometer equipped with the potentiostat–galvanostat. The electrochemical measurements were carried in extra pure dimethylsulfoxide (DMSO) containing electrochemical grade tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte at a concentration of 0.10 mol dm<sup>−3</sup>. Metal-free and metal Pcs involving octyl 4-phenyloxyacetate moieties were prepared following a literature procedure<sup>40</sup> (Fig. 1).

For cyclic voltammetry (CV) and differential pulse voltammetry (DPV) measurements, the working electrode was a Pt plate with a surface area of 0.10 cm<sup>2</sup>. A Pt spiral wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode and separated from the bulk of the solution by a double bridge. High purity N<sub>2</sub> was used for deoxygenating the solution at least 20 min prior to each run and to maintain a nitrogen blanket during the measurements. Ferrocene was used as an internal reference, but the potentials were presented versus SCE.

The spectroelectrochemical measurements were carried out by utilizing a thin-layer quartz spectroelectrochemical cell at 25 °C in a three-electrode configuration. The working electrode was transparent Pt gauze. A Pt wire counter electrode separated by a glass bridge and an SCE reference electrode separated from the bulk of the solution by a double bridge were used.

## Results and discussion

Redox properties of the Pc compounds (1–5) in solution were studied by CV and DPV on a platinum working electrode in DMSO–TBAP. Table 1 lists the voltammetric data of the complexes which included the half-peak potentials ( $E_{1/2}$ ), the ratio of anodic to cathodic peak currents ( $I_{pa}/I_{pc}$ ), the peak-to-peak potential separations ( $\Delta E_p$ ), and the differ-

**Fig. 1.** The molecular structure of metal-free and metal Pcs bearing octyl 4-phenyloxyacetate moieties.

ence between the first oxidation and reduction processes ( $\Delta E_{1/2}$ ). Pc compounds undergo successive one-electron reduction and one-electron oxidation to yield the anion and cation radicals.

Figure 2 shows cyclic and differential pulse voltammograms of metal-free Pc **1**. Compound **1** gives a one-electron oxidation and three one-electron reduction processes. All redox processes in Fig. 2 are ring-based since compound **1** is a metal-free Pc. The values of  $I_{pa}/I_{pc}$  for the first and second reduction couples (R1 and R2, respectively, in Fig. 2) are close to unity at 0.010 V s<sup>−1</sup>. The peak-to-peak current ratios and (or) peak potential separations could not be determined for the first oxidation (Fig. 2, couple O1) and third reduction (Fig. 2, wave R3) processes since those occur at the ends of electrolyte-limited potential window.

The general voltammetric behaviour of **2** (ZnPc), **3** (NiPc), and **4** (CuPc) are similar to each other and to that of **1** (H<sub>2</sub>Pc). However, the redox processes of MPcs occur at more negative potential than those of **1** (Table 1). The differences between the  $E_{1/2}$  values can be attributed to the different polarizing powers of central atoms. On the other hand, the similarity in general redox behaviour between metal-free Pc **1** and MPcs **2–4** probably suggests that Zn(II), Ni(II), and Cu(II) behave as redox-inactive metal centers.<sup>41,42</sup> The  $\Delta E_{1/2}$  value corresponds to the energy difference between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) for metal-free Pcs, whereas it is related to HOMO–LUMO gap in MPc species, involving a redox-inactive metal center.  $\Delta E_{1/2}$  values ranging from 1.16 to 1.51 V for **1**, **2**, **3**, and **4** are generally consistent with the values reported in the literature.<sup>41,42</sup> The separation between the first and second ring reductions was found to be approximately 0.25–0.39 V for the complexes having a redox-inactive metal center. These peak separation values are also in agreement with the reported ones for redox processes in similar Pc compounds.<sup>5,41,42</sup> However, the comparison of the redox potentials of the Pcs **1–4** in DMSO (Table 1) with those of the relevant unsubstituted Pcs in a similar

<sup>a</sup> $E_{1/2} = (E_{pa} + E_{pc})/2$  at 0.010 V s<sup>–1</sup>.<sup>b</sup>Cathodic or anodic peak potential for irreversible processes at 0.010 V s<sup>–1</sup>.<sup>c</sup> $E_p = E_{pa} + E_{pc}$  at 0.010 V s<sup>–1</sup>.<sup>d</sup> $I_{pa}/I_{pc}$  for reduction,  $I_{pc}/I_{pa}$  for oxidation processes at 0.010 V s<sup>–1</sup> scan rate. It could not be determined for some redox processes due to ill-defined redox waves.<sup>e</sup> $\Delta E_{1/2} = E_{1/2}$  (first oxidation) –  $E_{1/2}$  (first reduction). This value corresponds to the HOMO–LUMO gap for metal-free and metal Pcs having an electroinactive metal center, but it represents metal-to-ligand charge transfer (MLCT) or ligand-to-metal charge transfer (LMCT) transition gap for MPcs having a redox-active metal center.<sup>f</sup>The process could be recorded only with DPV.<sup>g</sup>Cathodic wave is split, probably due to electron transfer associated with the aggregation–disaggregation equilibrium.**Fig. 2.** Cyclic and differential pulse voltammograms of **1** ( $2.50 \times 10^{-4}$  mol/L) on Pt in DMSO–TBAP. DPV parameters: pulse time 0.050 s; pulse size 0.100 V; step size 0.005 V; sample period 0.100 s.

coordinating solvent, DMF, in the literature<sup>41,42</sup> showed clearly that the redox potentials of the former shift considerably to relatively more positive potentials, because of the electron-withdrawing effect of the octyl 4-phenyloxyacetate substituents. For example, in the case of **2**, the shift in redox potential is 0.23 V for the first reduction, 0.30 V for the second, 0.58 V for the third, and 0.14 V for the first oxidation. A similar behaviour was also observed previously for tetra-substituted Pcs bearing electron-withdrawing 4-phenyloxyacetic acid functionalities,<sup>40</sup> suggesting that the redox potentials, and thus the efficiency of Pcs in various applications, can be changed remarkably by peripheral substituents. For in-

stance, the efficiency of MPcs in electrocatalytic applications is closely related to their redox potentials. The shift in redox potentials of octyl 4-phenyloxyacetate substituted **5** in DMSO towards more positive potentials, compared to those of unsubstituted CoPc in a similar coordinating solvent, DMF, in the literature was also observed.<sup>41,42</sup> However, the shift in the potential of the second reduction process (0.27 V), which is probably based on the Pc ring, was much higher than that in the potential of the first reduction process (0.07 V), which is probably metal-based. It appears that the electron-withdrawing effect of 4-phenyloxyacetate substituents at the periphery is probably more pronounced on the Pc ring than on the metal center.

The redox processes in MPcs are located at the ring and at the metal center.<sup>35–42</sup> Moreover, a general trend for some Pc compounds in this study was their aggregation character implied by splitting or broadening the redox waves. In most cases, it was not possible to identify the nature of the redox processes or to understand the possible aggregation effects on these processes in great detail on the basis of electrochemical measurements alone. For this reason, in situ spectroelectrochemical measurements during the controlled-potential electrolysis of the complexes at suitable potentials were also carried out to provide additional support for the assignment of redox processes and the identification of possible aggregation effects. The shape of the voltammetric peaks of metal-free Pc **1** in Fig. 2 suggests that the redox processes are not associated with the aggregation phenomenon. However, our observations during in situ spectroelectrochemical measurements, although carried out in relatively dilute solutions, indicated the coupling of the redox processes by aggregation–deaggregation transformations. The inset in Fig. 3A shows the effect of increasing concentration on the

**Fig. 3.** In situ UV-vis spectral changes during the controlled-potential electrolysis of **1** at (A)  $-0.56$  V, the former spectral changes (inset shows the effect of increasing concentration on the UV-vis spectra of **1**); (B)  $-0.56$  V, the latter spectral changes; (C)  $-1.00$  V; and (D)  $-1.65$  V vs. SCE.

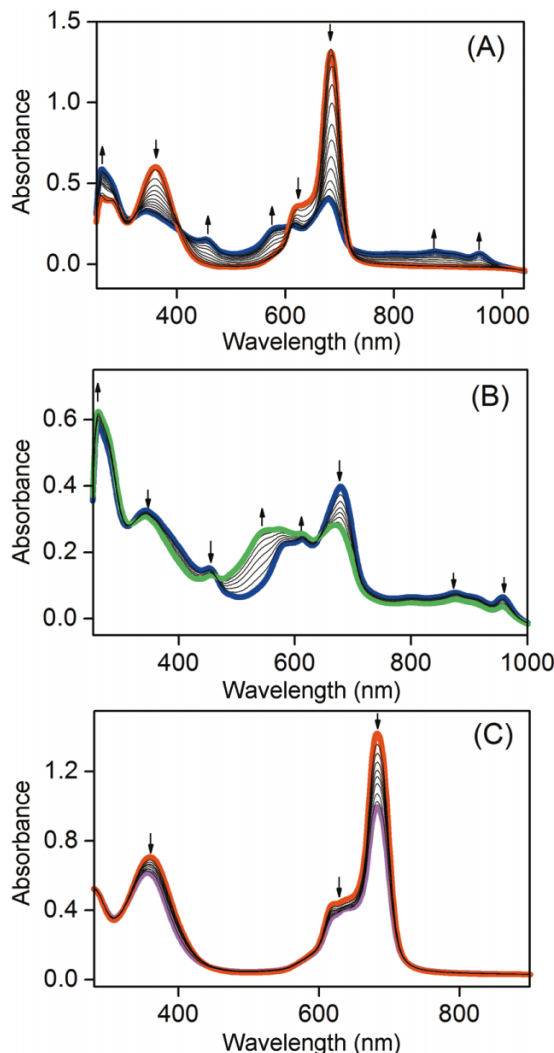

**Fig. 4.** Cyclic and differential pulse voltammograms of **2** ( $2.50 \times 10^{-4}$  mol/L) on Pt in DMSO-TBAP. DPV parameters: pulse time 0.050 s; pulse size 0.100 V; step size 0.005 V; sample period 0.100 s.

shape of the original UV-vis spectrum of **1**. There are two Q-band absorptions at 626 and 680 nm in its spectrum. As the concentration of **1** increases, the intensity of the band with the higher energy also increases and the absorption of

the band at 680 nm becomes a shoulder. This behaviour clearly suggests that the band at 626 nm corresponds to the aggregated species.<sup>43</sup> For metal-free Pcs, the symmetry is usually  $D_{2h}$  and therefore the main Q-band absorption is split. However, the main Q band of **1** at 680 nm is not split, even in the spectrum of the most diluted solution. One reason for the unsplit Q-band absorption is probably the aggregation phenomenon. Another reason is the high acidity of the inner pyrrole hydrogens in strongly basic solvents. When the inner pyrrole hydrogens are acidic enough, they dissociate, resulting in a charged  $Pc^{2-}$  system which becomes symmetric ( $D_{4h}$ ) and thus possesses an unsplit Q band. In situ UV-vis spectral changes during the controlled potential electrolysis of  $H_2Pc$  (**1**) at suitable potentials are shown in Fig. 3. When the working electrode is polarized at  $-0.56$  V vs. SCE, two groups of subsequent spectral changes were monitored. The former changes, accompanied by the formation of clear isosbestic points at 473, 654, and 713 nm, are shown in Fig. 3A. The band at 626 nm, assigned to the aggregated species, decreases in intensity and a new sharp single band at 680 nm appears. The decrease in intensity of the band at 626 nm probably suggests that the former spectral changes correspond to the reduction of aggregated species. During the latter spectral changes

**Fig. 5.** In situ UV-vis spectral changes during the controlled potential electrolysis of **2** at (A)  $-0.85$  V; (B)  $-1.10$  V; and (C)  $+0.80$  V vs. SCE.

(Fig. 3B), the Q-band absorptions at 680 and 626 nm, and the B-band absorption at 345 nm decrease while two new absorption bands appear at 459 and 574 nm. In addition, two weak absorption bands at 880 and 918 nm are observed. These spectral changes, accompanied by the formation of well-defined isosbestic points at 415, 612, and 704 nm, can be attributed to the reduction of disaggregated species. Similar spectroscopic changes for the first reduction of various metal-free Pcs were reported in the literature.<sup>7,37,44–46</sup> Some different spectral changes observed in this study may be attributed to the aggregation effects. During the potential application at  $-1.00$  V vs. SCE, the Q band at 680 nm decreases while two new bands at 540 and 630 nm appear (Fig. 3C), which is characteristic of ring reduction.<sup>43–46</sup> Therefore, the first reduction product,  $[\text{H}_2\text{Pc}(-3)]^-$  is reduced by one electron to form the  $[\text{H}_2\text{Pc}(-4)]^{2-}$  dianion during the second reduction process (couple R2 in Fig. 2). Moreover, the B band and the bands at 880 and 918 nm disappear. The Q band is split again after the second reduction. The spectral changes are accompanied by the formation of clear isosbestic points at 477 and 605 nm, confirming the forma-

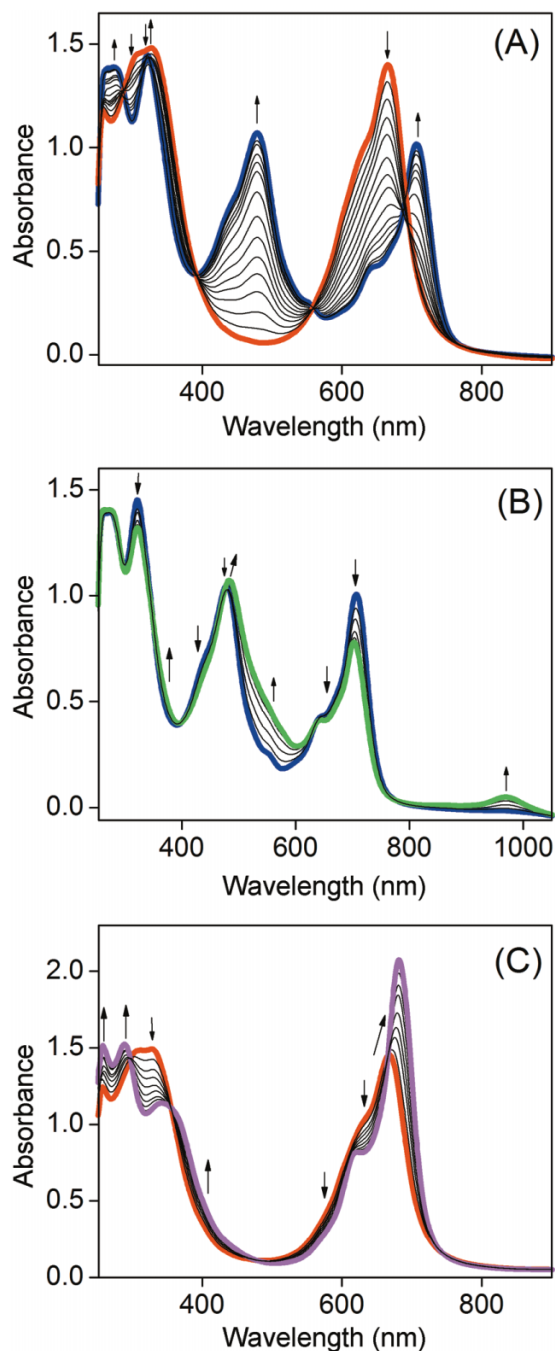

**Fig. 6.** Cyclic and differential pulse voltammograms of **5** ( $5.00 \times 10^{-4}$  mol/L) during (A) the negative potentials sweep and (B) the positive potentials sweep on Pt in DMSO-TBAP. DPV parameters: pulse time 0.050 s; pulse size 0.100 V; step size 0.005 V; sample period 0.100 s.

tion of  $[\text{H}_2\text{Pc}(-4)]^{2-}$  species. We observed net spectral changes even during the third reduction process (couple R3 in Fig. 2) with an applied potential of  $-1.65$  V vs. SCE (Fig. 3D), for the first time to the best of our knowledge. The band at 540 nm decreases in intensity while new bands at 340, 400, and 1022 nm appear. Moreover, the Q band increases with red shift from 630 to 643 nm while the band at 680 nm increases. These spectral changes are accompanied by the formation of clear isosbestic points at 434 and 617 nm, and can be assigned to the  $[\text{H}_2\text{Pc}(-4)]^{2-} \rightarrow [\text{H}_2\text{Pc}(-5)]^{3-}$  process. The spectrum of the triply reduced  $[\text{H}_2\text{Pc}(-5)]^{3-}$  species is split around the Q band region. The formation of a split Q band after the second and third reduction processes probably suggests the formation of completely disaggregated species. During the first oxidation process at 1.05 V vs. SCE, all the bands decreased in intensity without shift. This was probably due to the decomposition of the monocationic  $[\text{H}_2\text{Pc}(-2)]^+$  species after the oxidation, and is consistent with the observation of the relevant redox couple (O1 in Fig. 2) at the end of the solvent-limited potential window.

Figure 4 shows cyclic and differential pulse voltammograms of **2**. It undergoes a one-electron oxidation and three one-electron reductions. Anodic to cathodic peak separations ( $\Delta E_p$ ) of the first two reduction couples at  $0.010$  V s<sup>-1</sup> are approximately equal to 0.060 V, supporting reversible electron transfer. The unity of the  $I_{pa}/I_{pc}$  ratio with the scan rate and linear changes of  $I_{pc}$  with the square root of the scan rate for these couples indicated a purely diffusion-controlled electron transfer mechanism. The first oxidation process could be identified only by DPV, owing to its high positive

**Fig. 7.** In situ UV-vis spectral changes during the controlled potential electrolysis of **5** at (A)  $-0.65$  V, (B)  $-1.45$  V, and (C)  $+0.70$  V vs. SCE.

potential within the available potential range. The third reduction process was ill-defined without the anodic peak. However, well-defined reversible redox waves for the first two reduction processes imply that the redox processes of **2** are not coupled by the aggregation. In situ spectroelectrochemical changes during the controlled-potential electrolysis of **2** at suitable peak potentials are shown in Fig. 5. Figure 5A represents the spectral changes during the first oxidation process. As is clearly evident from an inspection of the spectrum of the original complex at the beginning, the Q-band absorption is rather narrow, suggesting that complex **2**

is in the form of monomers. Unlike compound **1**, the Zn(II) core in **2** probably binds donor DMSO molecules. Thus, the molecules of **2** are kept apart by the axially bound solvent molecules, preventing them from aggregating. After the first reduction at  $-0.85$  V vs. SCE, the absorption of the main Q band at 685 nm, the vibrational band at 616 nm and the B band at 362 nm decrease, while the new bands at 457, 581, 878, and 958 nm appear with the formation of well-specified isosbestic points at 313, 404, 608, and 718 nm. These spectral changes, especially the formation of a new band at 581 nm and the decrease of the Q band without shift, are characteristic for Pc ring reduction and thus confirm the voltammetric assignment of the couple R1 in Fig. 4 to  $\text{Zn(II)Pc}(-2)-[\text{Zn(II)Pc}(-3)]^-$ .<sup>36-39,47,48</sup> During the second reduction, with  $-1.10$  V potential application, the absorption of the main Q band continues to decrease without shift, while a new band around 544 nm appears and the bands at near-IR region decrease slightly without shift (Fig. 5B). These spectral changes, accompanied by the formation of well-defined isosbestic points, correspond to the second-ring reduction with the formation of the  $[\text{Zn(II)Pc}(-4)]^{2-}$  dianion species. During the oxidation at 0.80 V vs. SCE, the absorption of all bands decreases without formation of a new band, which is attributed to the decomposition of the complex immediately after the ring oxidation (Fig. 5C). This is an expected observation owing to the high positive oxidation potential.

Complexes **3** (NiPc) and **4** (CuPc) displayed a one-electron oxidation and three one-electron reduction processes (Table 1). Both electrochemical and spectroelectrochemical data showed that Pc ring-based electron transfer reactions of these complexes are complicated by the high aggregation tendency of these complexes (please see Supplementary data for the relevant figures and explanations).

Figure 6 shows the cyclic and differential pulse voltammograms of **5** (CoPc). The complex **5** undergoes two one-electron oxidations and three one-electron reductions. The  $\Delta E_p$  parameter of the redox couples takes the values within the range of 0.060–0.120 V at a  $0.010 \text{ V s}^{-1}$  scan rate, indicating the reversible or quasi-reversible character of electron-transfer processes. The unity of the peak current ratios ( $I_{pa}/I_{pc}$  for reduction and  $I_{pc}/I_{pa}$  for oxidation) with the scan rate and linear changes of peak currents with the square root of scan rate for the first reduction (R1) and first oxidation (O1) couples indicated a purely diffusion-controlled electron-transfer mechanism for these couples. The metal center in **5** probably prefers six-coordination and thus binds donor DMSO molecules. It is known that six-coordinate MPc species generally do not aggregate since they are kept apart by the axially bound ligands.<sup>41</sup> The peak current ratios for the third reduction (R3) and the second oxidation (O2) couples also appear to be unity. However, these values were not given in Table 1 since these couples, monitored at high potentials at the ends of the solvent-limited potential window, are ill-defined and thus peak current values could not be confirmed. Redox potentials of **5** are remarkably different compared with those of the other Pc compounds (Table 1). The  $\Delta E_{1/2}$  value of **5** is 0.85 V which is much lower than those of **1**, **2**, **3**, and **4**. Thus, it is reduced and oxidized more easily than the others. This distinctive behaviour of **5** can be attributed to the fact that the Co(II) center has

accessible d-orbital levels lying between the HOMO and LUMO gap of the Pc species, so that the metal center can be oxidized and reduced before the ring-based redox processes. However, the electrochemical behaviour of these Pc complexes can vary according to their environment, depending on whether there are any available coordinating species that would stabilize the Co(II) center. The main difference lies in whether the metal or the ring is oxidized first. Donor solvents strongly favour Co(III)Pc(–2) by coordinating along the axis to form six-coordinate species. If such donor solvents are absent, then oxidation to Co(III) is inhibited and ring oxidation occurs first. Thus, the first oxidation and the first reduction processes of **5** are probably metal-based and correspond to Co(II)Pc(–2)–[Co(III)Pc(–2)]<sup>+</sup> and Co(II)Pc(–2)–[Co(I)Pc(–2)]<sup>–</sup> redox couples, respectively, since the voltammetric measurements were carried out in DMSO–TBAP. On the other hand, it is also well-known from the literature that the other reduction processes and the second oxidation process are ring-based.<sup>41,42</sup> Spectroelectrochemical measurements were also carried out to assign the first reduction and the first oxidation processes of **5** with certainty. Figure 7A represents in situ UV–vis spectral changes during the first reduction of **5** at –0.65 V vs. SCE, corresponding to the redox process labeled R1 in Fig. 6. The Q band at 666 nm shifts to 707 nm, while a new band at 479 nm appears with a shoulder around 435 nm. The spectral changes have well-defined isosbestic points at 287, 393, 558, and 691 nm. The band at 479 nm and the shifting of the Q band indicate the formation of [Co(I)Pc(–2)]<sup>–</sup> species, confirming the CV assignment of the couple R1 to the Co(II)Pc(–2)–[Co(I)Pc(–2)]<sup>–</sup> process.<sup>36–39,47–50</sup> During the second reduction at –1.45 V vs. SCE, the Q band at 707 nm and the shoulder at 435 nm decrease without shift (Fig. 7B). At the same time, the absorption at 479 nm increases slightly in intensity with red shift to 484 nm, the absorption between 500 and 600 nm increases, and a new band at 970 nm appears. Clear isosbestic points were observed at 349, 400, 634, and 778 nm. These spectral changes at the potential of the couple R2 are characteristics of a ring-based reduction in a Co(II)Pc complex and confirm our voltammetric assignment of this process to [Co(I)Pc(–2)]<sup>–</sup>–[Co(I)Pc(–3)]<sup>2–</sup>. Figure 7C displays in situ UV–vis spectral changes during the first oxidation process. The Q band at 666 nm increases in intensity with red shift to 681 nm. This process gives clear isosbestic points at 297, 355, 479, and 666 nm. The increase of the Q band with red shift is typical of a metal-based oxidation in CoPc complexes and thus confirms the CV assignment of Co(II)Pc(–2)–[Co(III)Pc(–2)]<sup>+</sup> for couple O1 of **5** in Fig. 6.<sup>36–39,47–50</sup>

## Conclusion

The voltammetric measurements of the Pcs (H<sub>2</sub>Pc **1**, ZnPc **2**, NiPc **3**, CuPc **4**, and CoPc **5**) bearing octyl 4-phenyloxyacetate moieties showed that the compounds undergo one-electron reduction and oxidation processes. In situ spectroelectrochemical measurements enabled us to identify ligand- and metal-based redox processes. In addition, it was concluded from the results of this study that it is not possible to identify the effect of aggregation on the redox processes exactly, without in situ spectroelectrochemical measurements. In situ spectroelectrochemical measurements suggested that the redox processes of **1**, **3**, and **4** are coupled by aggregation

phenomenon, while those of **2** and especially **3** are not. Metal centers in **2** and **5** probably prefer six-coordination and bind donor DMSO molecules. Thus, they are kept apart by the axially bound solvent molecules. This prevents them from aggregating.

# Mean-field study of the synergic effect of the CO–NO reaction on a heterogeneous substrate of interconnected sectors

Joaquín Cortés and Eliana Valencia

**Abstract:** A mean-field theory study is made of the behaviour of a kinetic model of the reduction reaction of NO by CO catalyzed by a surface with simple heterogeneity consisting of two interconnected sectors that differ in their NO dissociation activation energy. A synergistic effect is manifested in the activity, apparent activation energy, and reaction order of the system. This situation, analogous to that observed in the literature in the case of a heterogeneous catalytic particle, is used in the paper to analyze a real case of a bimetallic catalyst.

**Key words:** mean-field model in superficial reaction, catalytic CO–NO reaction, surface heterogeneity in superficial reaction, superficial catalytic reaction, CO–NO reaction over palladium, steps–terraces superficial heterogeneity

**Résumé :** On a effectué une étude, à base de la théorie du champ moyen, du comportement d'un modèle cinétique de la réaction de réduction du NO par le CO, catalysée par une surface comportant une simple hétérogénéité formée de deux secteurs interreliés qui diffèrent par leur énergie d'activation de dissociation du NO. À part d'autres aspects, un effet synergique se manifeste dans l'activité du système, l'énergie d'activation apparente et l'ordre de la réaction. Cette situation, analogue à celle observée dans la littérature dans le cas d'une particule catalytique hétérogène, est utilisée dans ce travail pour analyser un cas réel de catalyseur bimétallique.

**Mots-clés :** modèle du champ moyen dans l'étude d'une réaction superficielle, réaction catalytique CO–NO, hétérogénéité en surface dans une réaction superficielle, réaction catalytique superficielle, réaction CO–NO sur du palladium, hétérogénéité superficielle en paliers et en terrasses

[Traduit par la Rédaction]

## Introduction

Over the last decades, great progress has been made in the knowledge of catalytic surface reactions, owing on the one hand to modern laboratory techniques and on the other to a better understanding of the behaviour of irreversible dynamic systems, of which surface reactions are an example. These kinds of systems have attracted the joint attention of chemists, because of their applications in catalysis, and of physicists, because they are good examples of nonequilibrium models that exhibit interesting complex phenomena such as oscillations, kinetics phase transitions, hysteresis, chaos, and dissipative structures.<sup>1</sup>

There have been advances in developing models and laboratory techniques in surface science to aid in the interpretation of the basic mechanisms of heterogeneous catalysis. In spite of these advances, however, there are still serious difficulties in interpreting the results of industrial catalysis, for two reasons. One reason is related to the fact that industrial experiments take place at about atmospheric pressure, while the models use certain parameters determined under ultra high vacuum conditions (UHV). This difficulty, which has been called the “pressure gap”, is directly related, among other factors, to the interpretation and the use of the con-

stants of the kinetic mechanism as well as to the introduction of lateral interactions between the adsorbed species in the model.

The second reason, called the “material gap”, is related to the fact that in technical catalysis we deal with nanometric metallic particles, as in the case of supported catalysts, while the parameters in model catalysis are usually determined over single crystals that expose a well-defined plane as the catalytic surface. This leads to difficulties in interpreting the heterogeneity existing in the real system, and this has been partially solved by the use of simulations, generally Monte Carlo (MC). However, the theoretical models commonly used by experimenters to interpret their data are, one way or another, mean-field schemes. This difficulty is what basically interests us in this paper.

Both types of techniques, mean field and MC, have been used extensively in the study of surface reactions, and they have been reviewed in some excellent articles by Evans,<sup>2</sup> Albano,<sup>3</sup> Zhdanov and Kasemo.<sup>4</sup> The theoretical study of the CO–NO reaction, which is not a concern in this paper, has an interesting history which began with Yaldran and Khan,<sup>5</sup> Brosilow and Ziff,<sup>6</sup> and Meng, Weinberg and Evans<sup>7</sup> using MC simulations and mean-field theories

(MFT) at the site level, and assuming a simplified mechanism that we have called the BZ model. This system showed an interesting surface-poisoning phenomenon<sup>6,7</sup> that was extended by our group to the study of disordered two- and three-dimensional substrates<sup>8</sup> using MC experiments. From the theoretical standpoint, our group extended the study of this reaction through the MFT model at the pairs level, a method introduced in a classical work by Dickmann for the (CO–O<sub>2</sub>) reaction,<sup>9</sup> for the BZ model,<sup>10</sup> and later for a complete kinetic mechanism,<sup>11</sup> confirming the MFT results with MC simulations. Later, Dickmann et al.<sup>12</sup> extended these analyses to different superficial lattices.

At our laboratory, we have been interested for some time in studying the kinetics of systems that also have practical importance in the catalytic control of motor-vehicle exhaust emissions, like the (CO–O<sub>2</sub>) and (CO–NO) reactions, which we have used as prototypes to relate various mean field models and MC simulations with experimental results.<sup>13,14</sup> Our interest in introducing the heterogeneous factor in a mean-field model, which dates back to our work in the field of adsorption on heterogeneous surfaces mentioned in the monograph of Rudzinski and Everett,<sup>15</sup> led us later to propose a mean-field theory of a surface reaction on a disordered substrate.<sup>16</sup> In the present paper, we propose both a sites and a pairs approximation, characterizing the substrate through set  $\{q_i\}$  of probability that the adsorbed site has  $i$  neighbors that belong to the substrate in the model.

An interesting different approach considered recently by Zhdanov and Kasemo (ZK approach),<sup>17–19</sup> introduces the heterogeneity of the substrate in a mean-field model that analyzes the kinetics of a heterogeneous reaction. The ZK scheme has been applied to the behavior of catalysts formed by particles on an inert support<sup>17,18</sup> and to the determination of the role of the steps of the catalytic surface in the case of the CO–NO reaction,<sup>17</sup> taking into account recent advances that use the density functional theory (DFT) approximation<sup>20</sup> to characterize the activation energy.

Motivated by this way of tackling the problem, in a recent paper, we have analyzed some consequences of the ZK approach.<sup>21</sup> In this paper we develop a mean-field scheme in the case of the CO–NO reaction catalyzed by a heterogeneous substrate consisting of a mixed surface formed by two interconnected sectors. Besides allowing us to analyze some general aspects of the model, such as its behavior with respect to the temperature and pressure of the gas phase, this approach has revealed a synergistic effect of the system that is of general interest.

The model can be applicable to some real systems. Zhdanov et al.<sup>17,18</sup> have used this approach to show that, owing to purely kinetic effects, the activity of a catalytic particle formed by a mixture of (111) and (100) faces can be higher than that calculated by the conventional approximation based on the assumption that the faces operate independently. This kind of synergism experienced by the particle is seen in the example given in the paper for what can be a bimetallic catalyst. The effect, however, may not occur, depending on the kinetic parameters involved. That is the case of the bimetallic catalyst studied in the experiments of Holles et al.<sup>22</sup> for the CO–NO reaction over Pd–Rh–Al<sub>2</sub>O<sub>3</sub>,

which we will analyze below as a possible application of the treatment developed in the paper.

## The kinetic scheme of the CO–NO reaction

The reduction reaction of NO by CO (CO–NO reaction) on rhodium has been studied extensively over the last decades, particularly because of its applications in catalytic converters of automobiles.<sup>23</sup> The determination of the kinetic mechanism of the CO–NO reaction on rhodium has a long and controversial history, since the first papers of Hecker and Bell<sup>24</sup> and followed, among others, by the studies of Oh,<sup>25</sup> Cho,<sup>26</sup> Chiang and Tan,<sup>27</sup> Peden,<sup>28</sup> and Permana,<sup>29</sup> and by those from our laboratory,<sup>30</sup> in the latter case considering recent experiments carried out by Zaera's group.<sup>31</sup> Scheme 1 shows the most frequently used kinetic mechanism, proposed by Peden<sup>28</sup> and Permana<sup>29</sup> for the CO–NO reaction on rhodium. Table 1 shows the parameters used in this paper, chosen from the above references indicated in the table and that we have used recently.<sup>30</sup> For the adsorption constants  $k_{\text{ads}}\{j\}$  of gas  $j$  we use the kinetic theory of gases expression

$$[1] \quad k_{\text{ads}}\{j\} = S_j \sigma (2\pi M_j RT)^{-1/2}$$

where  $M_j$  is the molar mass of  $j$ ,  $S_j$  is the corresponding sticking coefficient, which we have taken to be equal to 1 in this paper, and  $\sigma$  is the area occupied by one mole of metal atoms on the surface of the catalyst.

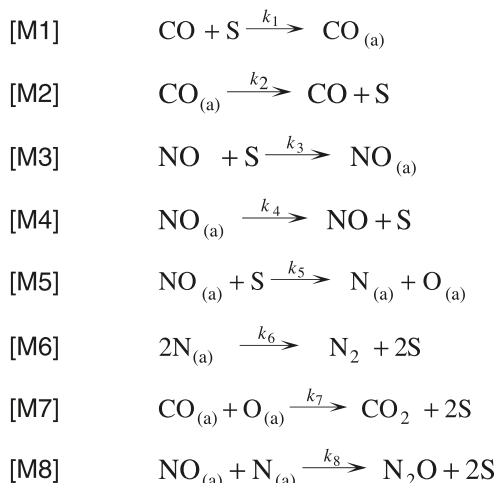

## The mean-field model

Appendix A shows the details of the analytic solution of a mean-field model published earlier by Cortés et al.<sup>14,30</sup> for the mechanism of Scheme 1. It corresponds to the development of the corresponding kinetics equations if it is considered that the surface of the catalyst is uniform. In general, a high superficial diffusion, assumed implicitly in models of the type with which we are concerned, ensure that the mean-field approximation can be a sufficient approximation. Also, if the adsorption–desorption steps are sufficiently fast, as they have been considered in the literature to be for this case,<sup>32</sup> it is possible to accept the approximation of assuming that the CO<sub>(a)</sub> and NO<sub>(a)</sub> adsorbates remain in equilibrium with the gas phase during the process, a condition that has been used to solve the kinetics equations in the previous model included in the appendix and in the procedure of concern in this paper.

The study of the ZK model is very interesting because it allows the application of a mean-field scheme to a catalytic surface with simple heterogeneity, made of few sectors with different energy characteristics. The most obvious examples are surfaces formed by different crystal faces<sup>17,18</sup> or surfaces that have step sites of different activity, presumably more active than the terrace sites of the rest of the surface.<sup>19</sup> The former case may be identified with a typical catalyst of a metal supported on an inert solid, where the surface of its particles is often conceived as a mixture of the most frequent crystal faces of the metal.<sup>33</sup> The latter was the case studied by ZK, motivated by the quantum studies that use the DFT to investigate the role of the steps in the heterogeneous catalysis phenomenon.<sup>20,34</sup>

**Scheme 1.** Mechanism of the CO–NO reaction used in the paper.

Below we will consider the mechanism of Scheme 1 for the CO–NO reaction in the case of a catalytic surface S12 formed by two regions, S1 and S2, that are interconnected. This can be understood if one imagines examples like bi-metallic catalysts, discussed below, or supported metal particles with different crystal faces, considered by Zhadanov.<sup>17,18</sup> The interconnection is defined in the model, for example, in the use of conservation equations applied to the whole surface, in contrast with the existence of some type of barrier in the case of unconnected sectors, in which case the equations are applied separately in each sector. The conservation eqs. [A5] and [A6] of the Appendix, however, which represent steady states for the adsorbed species  $\text{N}_{(\text{a})}$  and  $\text{O}_{(\text{a})}$  ( $d\theta_{\text{N}}/dt = 0$  and  $d\theta_{\text{O}}/dt = 0$ ), now have the following form:

$$\begin{aligned}
 [2] \quad & n^{\text{S2}} k_5^{\text{S2}} \theta_{\text{NO}}^{\text{S2}} \theta_{\text{S}}^{\text{S2}} + n^{\text{S1}} k_5^{\text{S1}} \theta_{\text{NO}}^{\text{S1}} \theta_{\text{S}}^{\text{S1}} = 2n^{\text{S2}} k_6^{\text{S2}} (\theta_{\text{N}}^{\text{S2}})^2 \\
 & + 2n^{\text{S1}} k_6^{\text{S1}} (\theta_{\text{N}}^{\text{S1}})^2 + n^{\text{S2}} k_8^{\text{S2}} \theta_{\text{NO}}^{\text{S2}} \theta_{\text{N}}^{\text{S2}} + n^{\text{S1}} k_8^{\text{S1}} \theta_{\text{NO}}^{\text{S1}} \theta_{\text{N}}^{\text{S1}} \\
 [3] \quad & n^{\text{S2}} k_5^{\text{S2}} \theta_{\text{NO}}^{\text{S2}} \theta_{\text{S}}^{\text{S2}} + n^{\text{S1}} k_5^{\text{S1}} \theta_{\text{NO}}^{\text{S1}} \theta_{\text{S}}^{\text{S1}} = n^{\text{S2}} k_7^{\text{S2}} \theta_{\text{CO}}^{\text{S2}} \theta_{\text{O}}^{\text{S2}} \\
 & + n^{\text{S1}} k_7^{\text{S1}} \theta_{\text{CO}}^{\text{S1}} \theta_{\text{O}}^{\text{S1}}
 \end{aligned}$$

$$[8] \quad F = \frac{(-A(k_8^{\text{S2}} + yk_8^{\text{S1}}) + (A^2(k_8^{\text{S2}} + yk_8^{\text{S1}})^2 + 8AB(k_6^{\text{S2}} + yk_6^{\text{S1}})(k_5^{\text{S2}} + yk_5^{\text{S1}}))^{1/2})}{4(k_6^{\text{S2}} + yk_6^{\text{S1}})}$$

and using conservation eq. [A7] we obtain for the coverage of  $\text{CO}_{(\text{a})}$

$$[9] \quad \theta_{\text{CO}} = 1/(1 + A + B + E + F)$$

The above equations allow the calculation of all the covered fractions  $\theta_i^j$  as a function of the kinetic parameters of the system, which make it possible to determine the average productions  $R_i$  of surface S12. If  $n^{\text{S1}}$  and  $n^{\text{S2}}$  are the number of sites of S1 and S2, respectively, then  $f = n^{\text{S1}}/(n^{\text{S1}} + n^{\text{S2}})$  is the fraction of sites belonging to sector S1. The total production  $R_i$  of species  $i$  will be equal to the weighted sum of productions of S1 and S2, respectively, so

$$[10] \quad R_{\text{CO}_2} = (1 - f)k_7^{\text{S2}} \theta_{\text{CO}} \theta_{\text{O}} + fk_7^{\text{S1}} \theta_{\text{CO}} \theta_{\text{O}}$$

where  $\theta_i$  is the fraction of covered surface and the superscripts refer to the respective sectors S1 and S2. In the development of the model we will assume a rapid diffusion of all the adsorbed species according to the ZK model.<sup>17–19,35</sup> As those authors point out, the values published<sup>35</sup> for the activation energies for the diffusion of adsorbed species, even atomic ones like N and O, are in general smaller than for the other stages  $M_i$  of the mechanism of Scheme 1. This leads to considering as an assumption of the model that the fraction of covered surface of species  $i$  is the same for all the heterogeneous surface S12, i.e.,  $\theta_i^{\text{S2}}$  is equal to  $\theta_i^{\text{S1}}$  for each species  $i$ .

Let us consider also a frequent situation of experimental interest, where the kinetic constants of CO and NO desorption are identical in both sectors. Since eq. [1] also assumes adsorption without activation energy, it means that eqs. [A1]–[A4] in Appendix A are valid for this case. Introducing eq. [A4] into eq. [2] and eq. [3] using the definition  $y = n^{\text{S1}}/n^{\text{S2}}$ , and recalling that  $\theta_i^{\text{S2}} = \theta_i^{\text{S1}} = \theta_i$ , we get

$$[4] \quad k_5^{\text{S2}} AB \theta_{\text{CO}}^2 + yk_5^{\text{S1}} AB \theta_{\text{CO}}^2 = 2k_6^{\text{S2}} \theta_{\text{N}}^2 + 2yk_6^{\text{S1}} \theta_{\text{N}}^2 + k_8^{\text{S2}} A \theta_{\text{N}} \theta_{\text{CO}} + yk_8^{\text{S1}} A \theta_{\text{N}} \theta_{\text{CO}}$$

$$[5] \quad k_5^{\text{S2}} AB \theta_{\text{CO}}^2 + yABk_5^{\text{S1}} \theta_{\text{CO}}^2 = k_7^{\text{S2}} \theta_{\text{CO}} \theta_{\text{O}} + yk_7^{\text{S1}} \theta_{\text{CO}} \theta_{\text{O}}$$

from which it is possible to obtain eq. [6] for the covered fraction of  $\text{O}_{(\text{a})}$

$$[6] \quad \theta_{\text{O}} = E \theta_{\text{CO}}$$

where

$$[7] \quad E = AB(k_5^{\text{S2}} + yk_5^{\text{S1}})/(k_7^{\text{S2}} + yk_7^{\text{S1}})$$

If we also define for  $\theta_{\text{N}}$ , the coverage  $N_{(\text{a})}$ ,  $\theta_{\text{N}} = F \theta_{\text{CO}}$ , from eq. [4] we get that

$$[11] \quad R_{\text{N}_2} = (1 - f)k_6^{\text{S2}} (\theta_{\text{N}})^2 + fk_6^{\text{S1}} (\theta_{\text{N}})^2$$

$$[12] \quad R_{\text{N}_2\text{O}} = (1 - f)k_8^{\text{S2}} \theta_{\text{NO}} \theta_{\text{N}} + fk_8^{\text{S1}} \theta_{\text{NO}} \theta_{\text{N}}$$

## Results and discussion

In this paper, to illustrate the model, we will study the interesting consequences derived from a particular case in which the regions differ only in the value of the activation energy  $E_5$  of the dissociation of NO, keeping unchanged the rest of the system's kinetic parameters. We will discuss the results of the model in the example described below. The kinetic parameters of sector S2 will be those corresponding to

**Table 1.** Kinetics parameters of the CO–NO reaction on Rh<sup>21</sup> and Pd<sup>23</sup> used in the paper.

Events	Activation energy $E_i$ (kcal/mol)		Frequency factor $\nu_i$ (sec <sup>-1</sup> )	
	Rh	Pd	Rh	Pd
CO desorption ( $k_2$ )	31.6		$1.6 \times 10^{14}$	
NO desorption ( $k_4$ )	29.7		$4.6 \times 10^{14}$	
NO dissociation ( $k_5$ )	17.5	34.2	$2.1 \times 10^{10}$	$2.7 \times 10^{14}$
N <sub>2</sub> production ( $k_6$ )	32.6	29	$4 \times 10^{12}$	$6.5 \times 10^{13}$
N <sub>2</sub> O production ( $k_8$ ) (ref. 21)	34.1	34.1	$5.3 \times 10^{13}$	$5.3 \times 10^{13}$
CO <sub>2</sub> production ( $k_7$ )	14.3	33.6	$10^{12}$	$7.1 \times 10^{15}$

Table 1 for Rh, and those of sector S1 differ from them in the value of the activation energy of NO dissociation,  $E_5$ , which we will consider as being 12 250 (cal/mol), 70% lower than that of sector S2. The kinetics mechanism of Scheme 1 is considered valid in both sector S1 and S2 and in the joint surface S12 of interconnected sectors. In this way, the equations that describe the kinetic behaviour of the CO–NO reaction will be given by Appendix A for the separate sectors S1 and S2, and by the model from the previous section for surface S12.

What is interesting here is the synergistic effect that appears in a system of interconnected sectors as a result of the mobility of the adsorbed phase particles, so the dissociation-energy difference chosen for this visualization will in some way be arbitrary. However, we can imagine real situations such as a supported particle whose surface has been conceived as a mixture of various crystalline faces<sup>33</sup> in the case studied by Zhdanov et al.<sup>17,18</sup> Although it is not easy to find in the literature reliable experimental values for the activation energies for the dissociation of NO on various crystalline faces, Michaelides et al.<sup>36</sup> have recently shown a linear relation between the activation energy of dissociation and the corresponding enthalpy changes in surface reactions. On the other hand, periodic density-functional calculations have been carried out for NO dissociation reactions on Rh(111) and Rh(100),<sup>37</sup> showing that the differences in order of magnitude used in our calculations for the hypothetical sectors S1 and S2 seem to be reasonable.

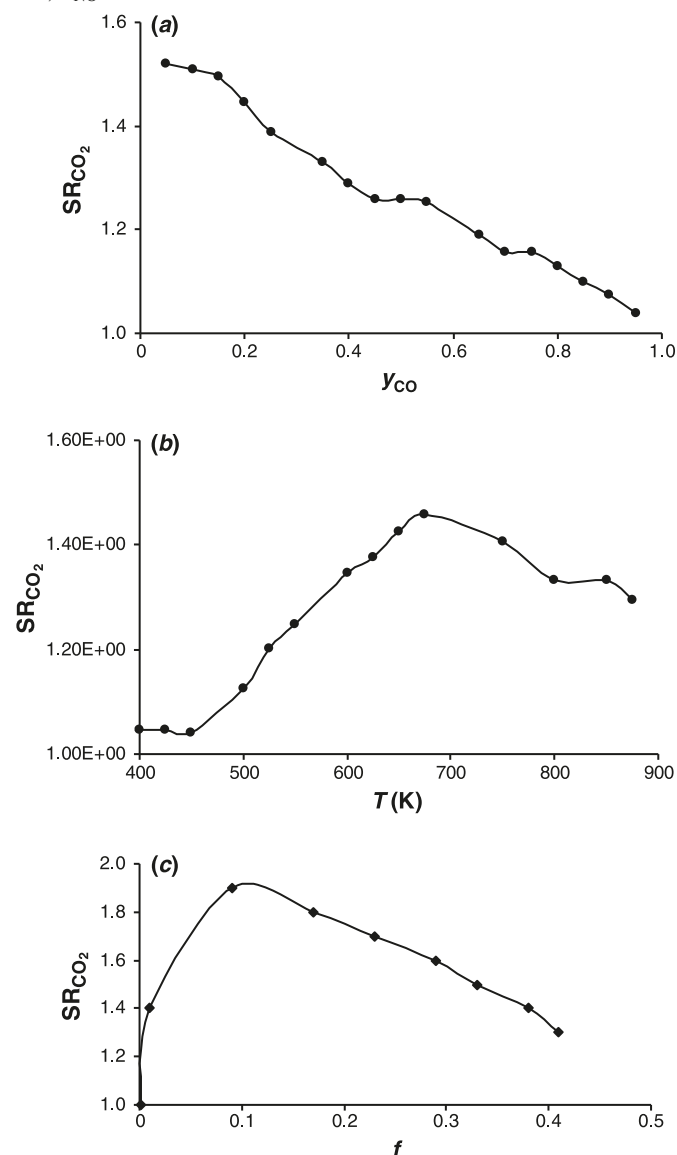

### Synergistic effect of the interconnected sectors system

Figure 1 shows the existence of a synergistic effect observed in the system studied, with changes in temperature, gas-phase concentration, and fraction of sites that belong to sector S1 of the surface. This effect, which we will refer to as the activity of CO<sub>2</sub>, will be described by means of the synergistic factor  $SR_{CO_2}$ , the quotient between the production of CO<sub>2</sub> in the interconnected-sectors system and what it would have if they were completely independent; that is

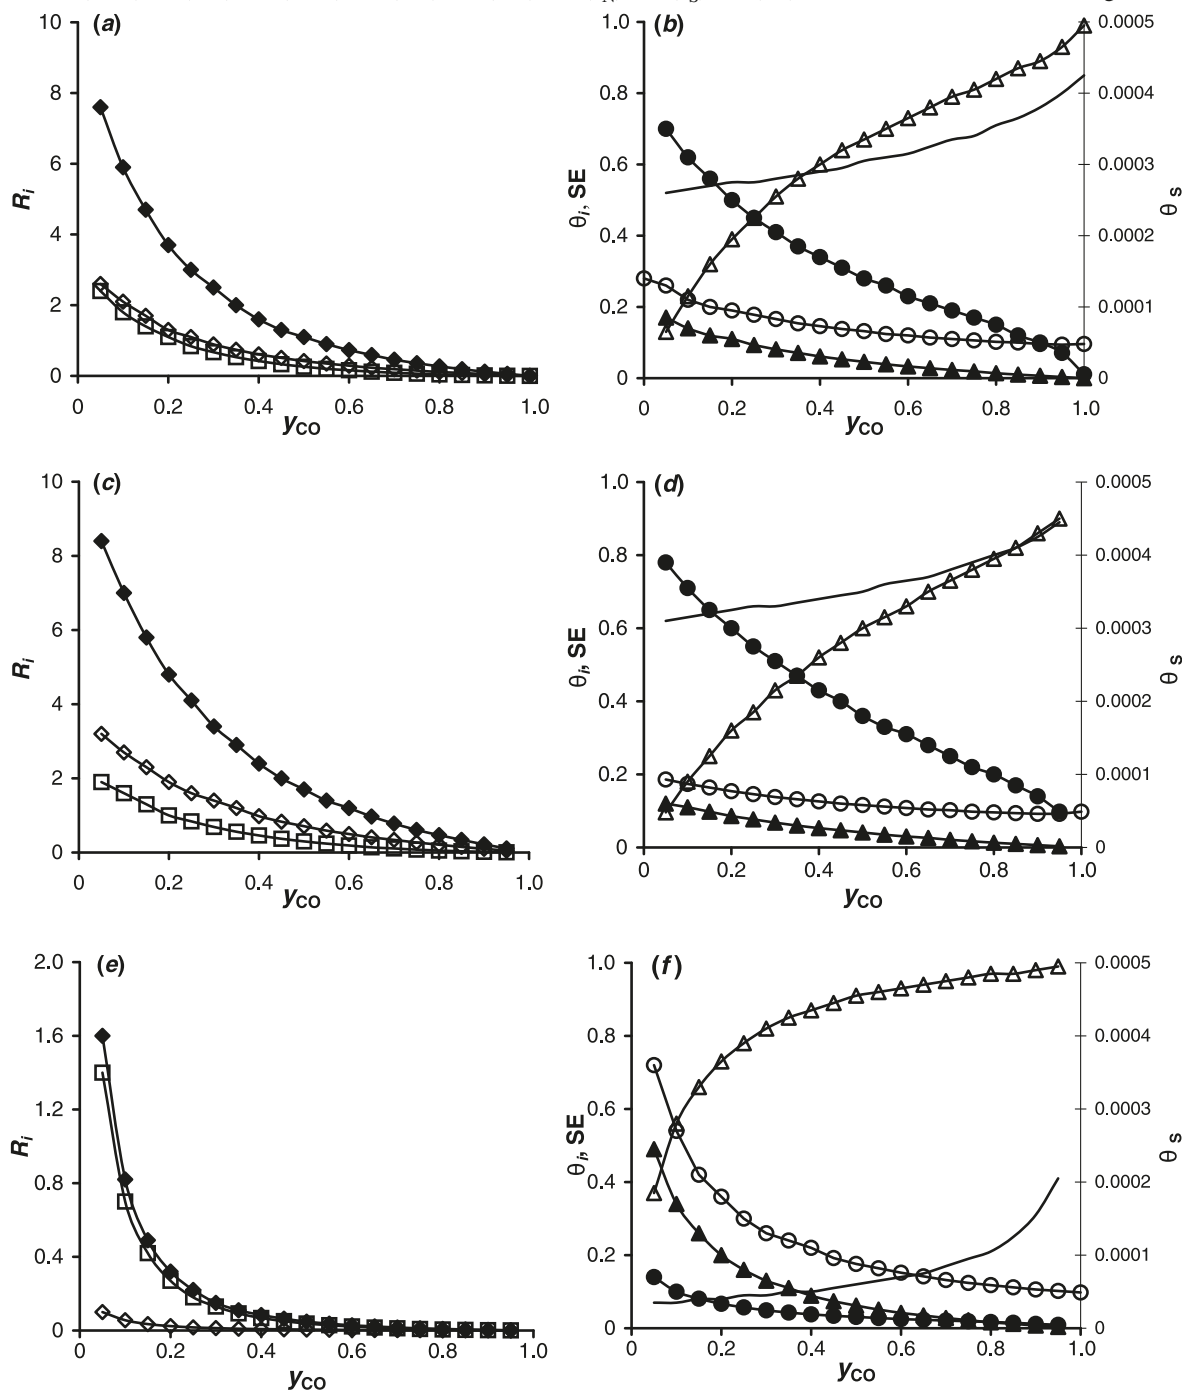

$$[13] \quad SR_{CO_2} = R_{CO_2}/RI_{CO_2}$$

where  $R_{CO_2}$  is determined from eq. [10], and  $RI_{CO_2}$  corresponds to the weighted sum with fraction  $f$  of the productions of both sectors S1 and S2 considered as independent, calculated from the equations of Appendix A using in each case the kinetics parameters corresponding to the sector. In general, the  $SR_{CO_2}$  quotient between the  $R_{CO_2}$  productions determined by the proposed model and  $RI_{CO_2}$  calculated

**Fig. 1.** Relation of CO<sub>2</sub> production between systems of interconnected sectors and sectors assumed to be independent ( $SR_{CO_2}$ ) (synergistic effect).  $E_{dis}(S1) = 12.25$  (kcal/mol),  $E_{dis}(S2) = 17.5$  (kcal/mol); (a) vs. CO concentration  $y_{CO}$ ,  $T = 600$  K,  $f = 0.5$ ; (b) vs. temperature  $T$ ,  $P_{CO} = 20.52$  torr (1 torr = 133.322 Pa),  $P_{NO} = 39.52$  torr,  $f = 0.5$ ; (c) vs. fraction  $f$  of sector S of the surface,  $T = 600$  K,  $P_{CO} = 20.52$  torr,  $P_{NO} = 39.52$  torr.

**Fig. 2.** Production ( $R_i$ ,  $y_{\text{CO}}$ ) and phase diagram ( $x_i$ ,  $y_{\text{CO}}$ ) vs. CO concentration in the gas ( $y_{\text{CO}}$ )  $T = 600$  K; (a, b) interconnected sectors S12,  $f = 0.5$ ,  $E_{\text{dis}}(\text{S1}) = 12.25$  kcal/mol,  $E_{\text{dis}}(\text{S2}) = 17.5$  kcal/mol; (c, d) uniform surface  $E_{\text{dis}} = 12.25$  kcal/mol; (e, f) uniform surface  $E_{\text{dis}} = 17.5$  kcal/mol.  $\blacklozenge$  ( $R_{\text{CO}_2}$ );  $\diamond$  ( $R_{\text{N}_2}$ );  $\square$  ( $R_{\text{N}_2\text{O}}$ );  $\triangle$  ( $\theta_{\text{CO}}$ );  $\blacktriangle$  ( $\theta_{\text{NO}}$ );  $\bullet$  ( $\theta_{\text{N}}$ );  $\circ$  ( $\theta_{\text{S}}$ ); — (SE); the lines have been drawn to guide the eye.

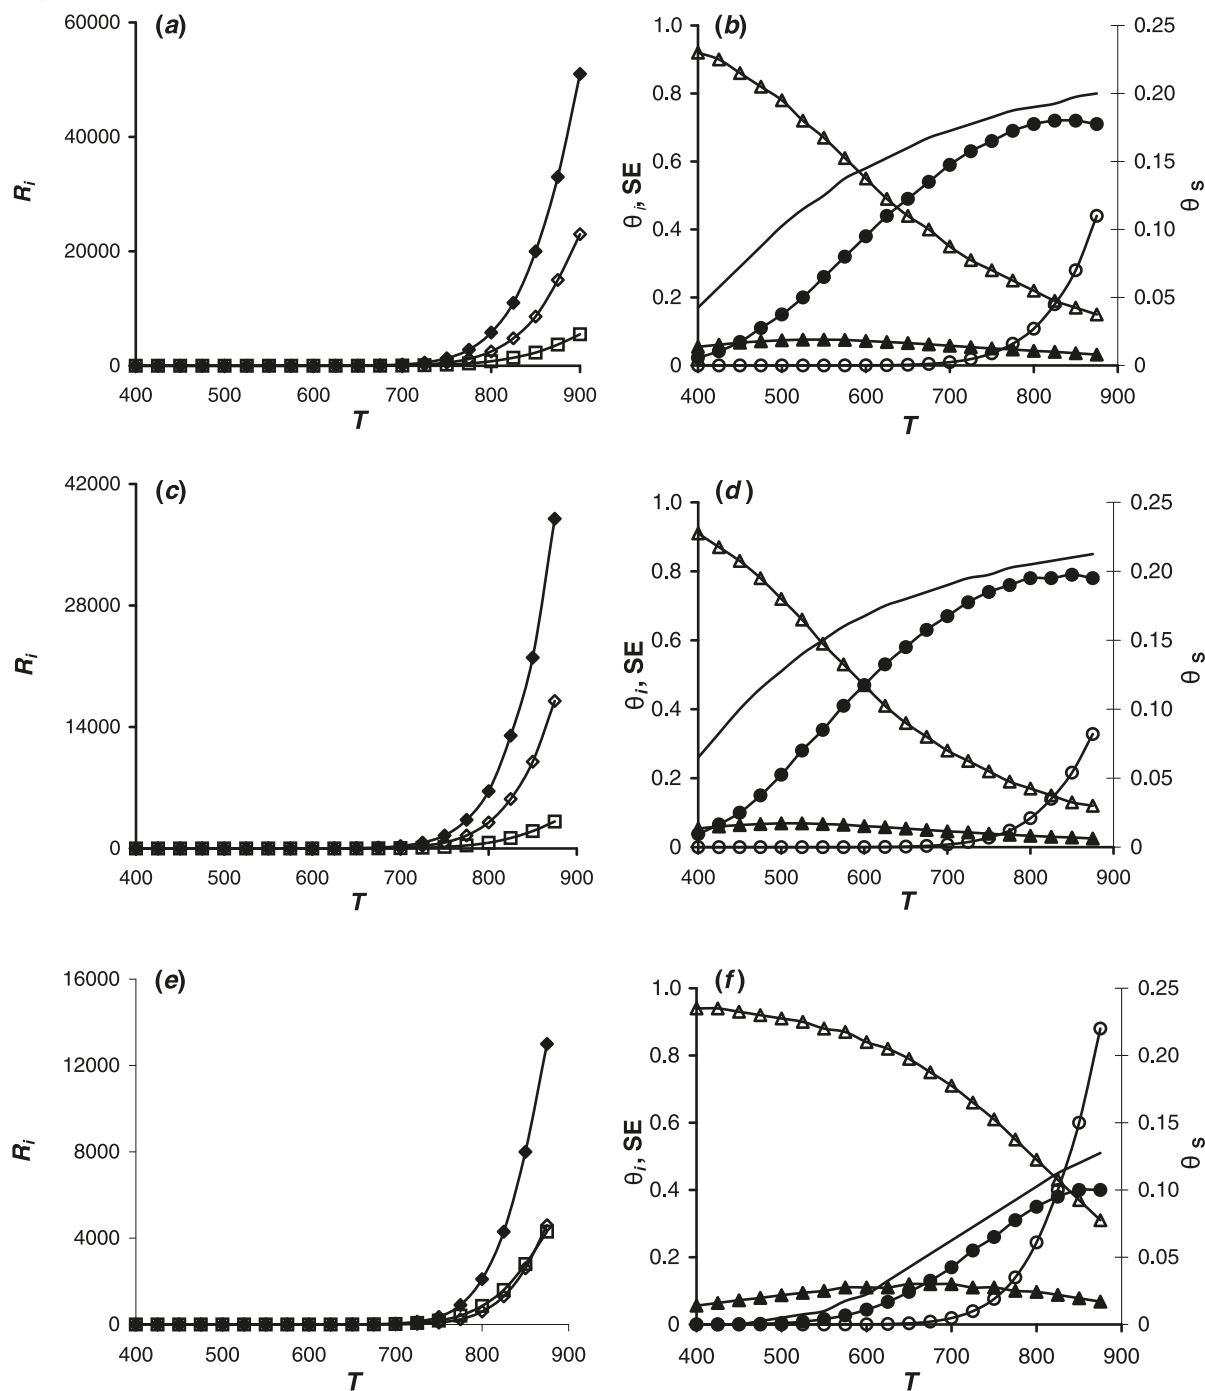

using the previous model developed in Appendix A shows some sensitivity, especially as a function of temperature, because of the rounding-off approximations of the numerical calculations made in each model.

Figure 1a shows an example at  $T = 600$  K, where it is observed that the synergistic effect is large for low concentrations of CO in the gas phase and decreases until it vanishes when that concentration increases up to the extreme situation of pure CO. Factor  $\text{SR}_{\text{CO}_2}$  becomes important when the  $\text{NO}_{(\text{a})}$  fraction of the surface is large. However, if the value

of  $\text{NO}_{(\text{a})}$  is low, which happens at high CO concentrations, the effect of the difference in the activation energy of dissociation on the synergistic effect decreases markedly, as seen in the figure.

On the other hand, Fig. 1b shows that  $\text{SR}_{\text{CO}_2}$  keeps the same order of magnitude for temperatures higher than about 650 K, decreasing at low temperatures. Figure 1c, finally, shows an interesting maximum value for  $\text{SR}_{\text{CO}_2}$  among the extreme situations corresponding to high and low values of fraction  $f$ , which indicate a decrease in the heterogeneity of

**Fig. 3.** The same as Fig. 2 vs. temperature  $T$ ;  $P_{\text{CO}} = 20.52$  torr,  $P_{\text{NO}} = 39.52$  torr.  $\blacklozenge$  ( $R_{\text{CO}_2}$ );  $\diamond$  ( $R_{\text{N}_2}$ );  $\square$  ( $R_{\text{N}_2\text{O}}$ );  $\triangle$  ( $\theta_{\text{CO}}$ );  $\blacktriangle$  ( $\theta_{\text{NO}}$ );  $\bullet$  ( $\theta_{\text{N}}$ );  $\circ$  ( $\theta_{\text{S}}$ ); — (SE).

the surface, and which finally turns uniform in the extreme situations of  $f = 0$  or 1, where  $\text{SR}_{\text{CO}_2} = 1$ .

### Production, selectivity, and phase diagram curves

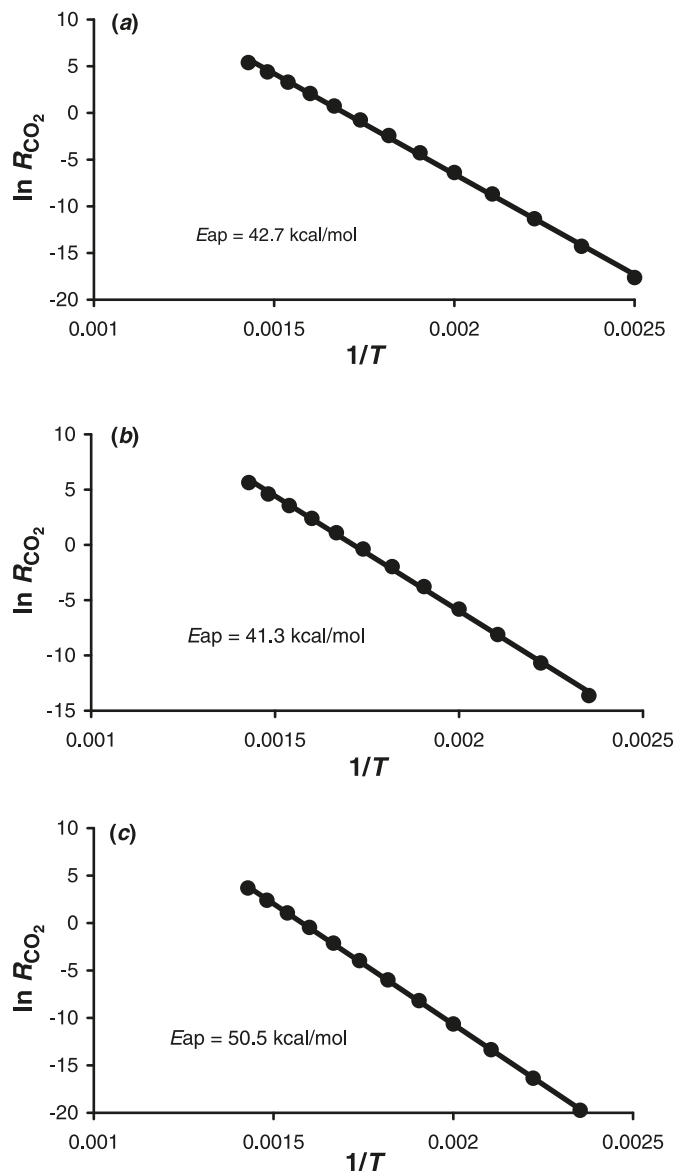

Figure 2 shows the behaviour at 600 K of production and the corresponding phase diagrams of both the heterogeneous system S12 in the case of  $f = 0.5$  and the separate sectors S1 and S2. The same situation is described in Fig. 3 when tem-

perature is varied while keeping CO and NO pressure constant.

Both figures indicate that the reaction, in the range of the kinetic parameters studied, occurs on a small fraction of vacant adsorbed sites. At high CO concentrations in the gas  $y_{\text{CO}}$  and low temperatures  $T$ , the surface is mostly occupied by particles of adsorbed CO. If  $y_{\text{CO}}$  decreases or  $T$  increases, there is an increase in the fraction of vacant sites on the surface  $\theta_{\text{S}}$  and in the particles of adsorbed atomic nitrogen  $\theta_{\text{N}}$ , that react between one another according to stage M6 of the

**Fig. 4.** Arrhenius behavior  $P_{\text{CO}} = 20.52$  torr)  $P_{\text{NO}} = 39.52$  torr; (a) interconnected sectors S12  $f = 0.5$ ,  $E_{\text{dis}}(\text{S1}) = 12.25$  kcal/mol,  $E_{\text{dis}}(\text{S2}) = 17.5$  kcal/mol; (b) uniform surface  $E_{\text{dis}} = 12.25$  kcal/mol; (c) uniform surface  $E_{\text{dis}} = 17.5$  kcal/mol.

kinetics mechanism. This effect is reflected in an increase in the activity of the system, accounting for the decrease in  $\text{CO}_2$  production with the decrease of  $y_{\text{CO}}$  and the decrease of  $T$ .

Comparing the figures corresponding to the uniform surfaces S1 and S2, the expected increase in the order of magnitude of production with the decrease of the activation energy of NO dissociation on surface S1 with respect to S2 is seen. The proportion of the increase of  $R_i$  is maintained at lower temperatures, as for example at 600 K, the temperature chosen in Fig. 2. The increase of  $R_i$ , as noted, correlates with the greater value of  $\theta_{\text{N}}$  on the surface. The greater value of  $\theta_{\text{N}}$  of substrate S1 with respect to S2, on the other hand, also explains the greater selectivity SE for nitrogen in S1, corresponding to the relations between the productions

$R_{\text{N}_2}$  and  $R_{\text{N}_2\text{O}}$ , as shown in both figures for the whole range of CO concentrations and temperatures.

Figures 2 and 3 also show the synergistic effect of the interconnected system S12, which is seen to have a surface configuration of the adsorbed phase similar to surface S1, as a result of the mobility of the adsorbates on the whole surface. This leads to a value greater than one for the synergistic factor  $\text{SR}_{\text{CO}_2}$ , as shown in Fig. 1.

### Arrhenius behavior and reaction orders

Figure 4 shows the Arrhenius straight lines of surfaces S1 and S2 and of the interconnected system S12, with a correlation better than 0.999 in all cases. The values of the apparent activation energy, shown in each of the graphs, is another way of observing the synergistic effect, because the system of interconnected sectors has an activation energy similar to that of sector S1, noticeably lower than that of sector S2.

In regard to the effect of pressure, experimenters usually present their data by means of a semiempirical expression like eq. [14], which in our case defines the order  $m$  with respect to CO and  $n$  with respect to NO:

$$[14] \quad R_{\text{CO}_2} = k_j p_{\text{CO}}^m p_{\text{NO}}^n$$

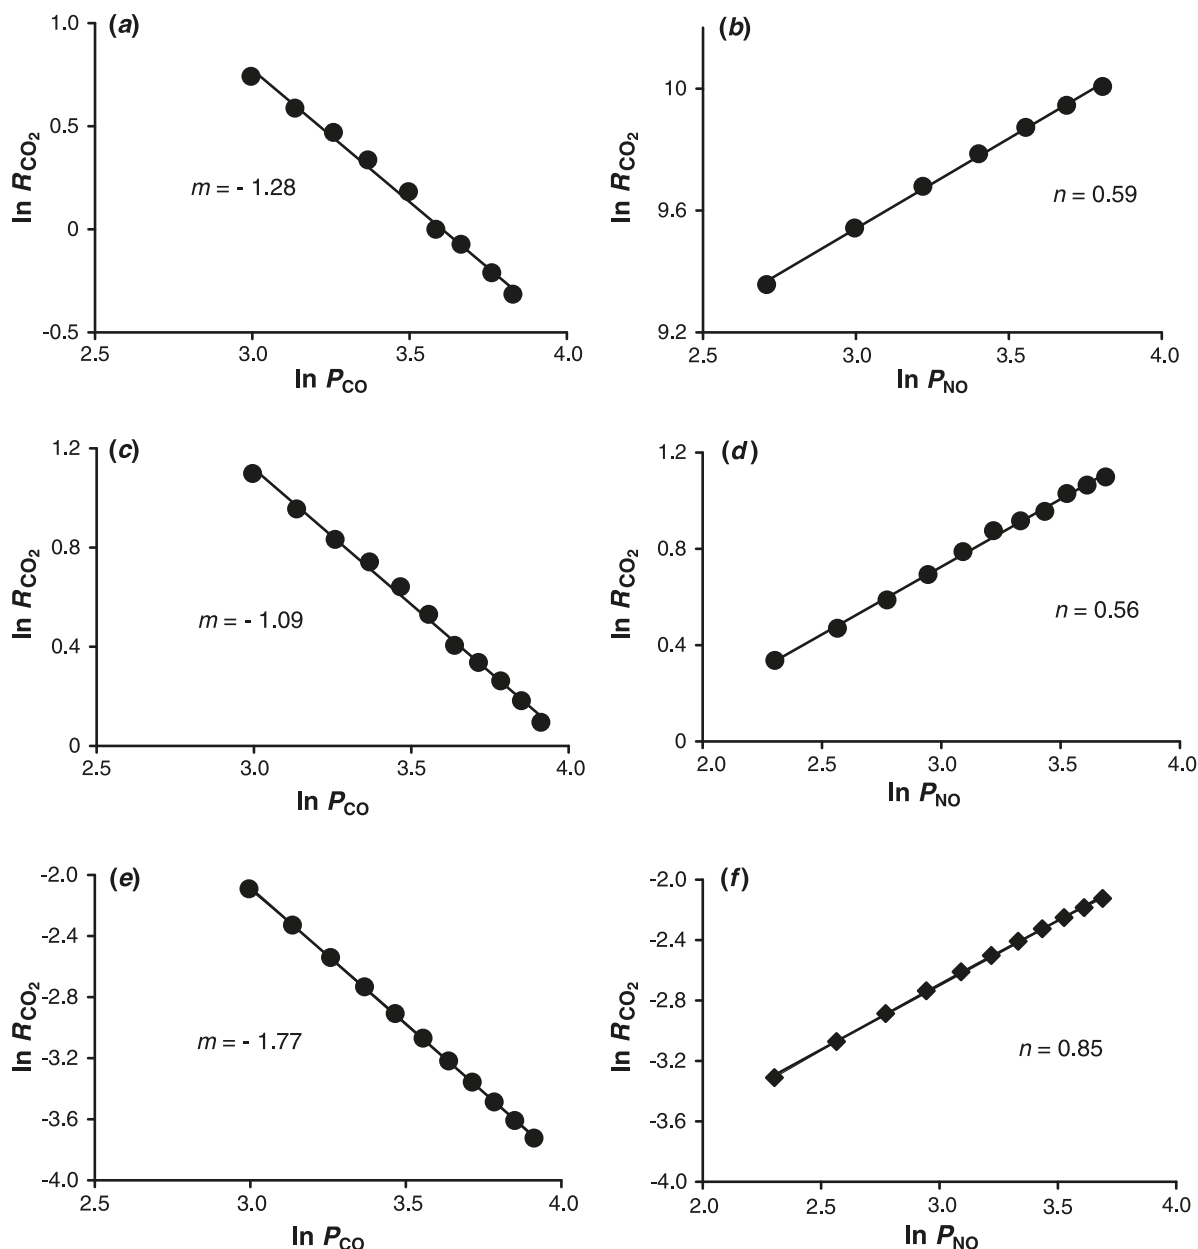

Figure 5 shows straight lines with a high correlation if the logarithm of production is plotted against the logarithm of the corresponding pressure while keeping the other pressure constant, allowing the determination of the corresponding parameters  $m$  and  $n$ . This indicates that on the three surfaces there is an order, decreasing with respect to CO ( $m < 0$ ) and increasing with respect to NO ( $n > 0$ ). The values of  $m$  and  $n$  given in each graph, however, show that the order with respect to both reagents in the interconnected-sector system S12 is similar to that of surface S1 and different from that of sector S2.

### Application of the model in the real case of a bimetallic catalyst

As mentioned in the Introduction, Zhdanov et al.<sup>17,18</sup> found that a catalytic particle shows a synergistic effect between the various faces that make up its surface. In this paper, we are interested in the general behavior of any heterogeneous surface, as in the example that we developed in a previous section, where the synergistic effect illustrated in Fig. 1 is observed. This may be the case of a bimetallic catalyst. However, depending on the parameters of the system, this synergistic effect may not be observed, as in the case of the experiments reported by Holles et al.<sup>22</sup> for the Those authors showed that the turnover frequency on Pd-Rh- $\text{Al}_2\text{O}_3$  was lower than that on either Pd- $\text{Al}_2\text{O}_3$  or Rh- $\text{Al}_2\text{O}_3$ , showing that there is no synergistic effect in that case.

Although Pd and Rh may form an alloy whose properties can explain the phenomenon, it is interesting to go through the exercise of analyzing the situation by means of the model considered in this paper, as shown in the results included in Table 2. It has been assumed that sector S1 corresponds to Pd and S2 to Rh, characterizing both surfaces by the kinetic parameters of stages (M5–M8) of Scheme 1,

**Fig. 5.** Reaction order (eq. [14]; (a)  $\text{CO}_2$  production as a function of CO pressure with a fixed NO pressure of 39.52 torr at 600 K, interconnected sectors S12,  $f = 0.5$ ,  $E_{\text{dis}}(\text{S1}) = 12.25$  kcal/mol, and  $E_{\text{dis}}(\text{S2}) = 17.5$  kcal/mol; (b) the same as (a) as a function of NO pressure with a fixed CO pressure of 20.53 torr; (c) the same as (a) with uniform surface,  $E_{\text{dis}} = 12.25$  kcal/mol; (d) the same as (b) with uniform surface,  $E_{\text{dis}} = 12.25$  kcal/mol; (e) the same of (a) with uniform surface,  $E_{\text{dis}} = 17.5$  kcal/mol; (f) the same as (b) with uniform surface,  $E_{\text{dis}} = 17.5$  kcal/mol.

**Table 2.** Activity  $R_i(\text{TON})$  of the CO–NO reaction on Pd, Rh, and the Pd–Rh bimetallic catalyst (interconnected system) according to the model of the paper;  $f = 0.5$ ,  $P_{\text{CO}} = 20.52$  torr,  $P_{\text{NO}} = 39.52$  torr,  $k_{\text{des}}/k_{\text{ad}}P = 10$ .

T	$R_{\text{CO}_2}$			$R_{\text{N}_2}$			$R_{\text{N}_2\text{O}}$		
	Pd	Rh	Pd–Rh	Pd	Rh	Pd–Rh	Pd	Rh	Pd–Rh
550	0.15	0.76	0.08	0.069	0.34	0.03	0.013	0.075	0.01
600	2	8.3	1.02	0.91	3.4	0.41	0.21	1.5	0.20
650	18	60	9.21	8	21	3.59	2.2	18	2.04
700	120	310	60.61	52	85	22.75	17	140	15.11

whose values are given in Table 1 for Pd and Rh, according to experimental data reported in the literature mentioned there. Given the characteristics of the model that we have developed, for the adsorption-desorption stages we have considered the simplification used by Zhdanov et al.,<sup>17–19</sup> using for the calculation the expression  $k_{\text{des}}/k_{\text{ad}}P = K$  for CO and NO, which implies the assumption that the adsorption equilibrium of both components in both sectors depend only on the corresponding pressures in the gas phase.

The values given in the table in the case of  $K = 10$ , which is the value used by Zhdanov, show the same situation as that reported by Holles et al.,<sup>22</sup> where the activities calculated for the assumption of interacting sectors are lower than on either Pd or Rh, so the bimetallic Rh–Pd system does not show synergism. A similar result, not shown in the paper, is obtained for values of  $K$  equal to 0.1 and 100.

The use of the development of the mean-field model in an experimental example shows the potential importance of using mean-field models on heterogeneous substrates in real situations, and that should encourage extending the frequent case in which the interpretation of the data is done by means of a system of kinetics equations for a catalytic surface assumed to be homogeneous.

## Conclusions

By mean-field theory, a study has been made of the behavior of a kinetic model of the reduction reaction of NO by CO catalyzed by a surface with simple heterogeneity consisting of two interconnected sectors that differ in the activation energy of NO dissociation. As a consequence of the mobility of the adsorbed phase assumed for the model, a synergic effect in the activity of the system is seen that changes with gas phase concentration, temperature, and the relation between the active sites of both sectors of the surface. The system shows an Arrhenius behavior and an order with respect to the pressure of CO and NO, with the effect of the synergy seen in both the apparent activation energy and the reaction orders, if the interacting sectors of the system are compared with the case in which they act independently. This situation, which is similar to that found by Zhdanov et al. in the case of catalytic particles formed by different crystal faces, is also used to explain, in the case of the same reaction on a real bimetallic catalyst, why no synergism was seen.

## Appendix A. Analytical solution of the reaction model used in the paper

In a manner similar to the development shown in one of our previous papers,<sup>14,30</sup> we will derive the equations used in this paper for the mechanism of Scheme 1. Since it is assumed that the CO<sub>(a)</sub> and NO<sub>(a)</sub> adsorbates are in equilibrium with the gas phase, it is possible to write the relations:

$$[A1] \quad \frac{k_1}{k_2} = K_{\text{CO}} = \frac{\theta_{\text{CO}}}{\theta_s P_{\text{CO}}}, \quad \frac{k_3}{k_4} = K_{\text{NO}} = \frac{\theta_{\text{NO}}}{\theta_s P_{\text{NO}}}$$

where the equilibrium constants are expressed as functions of the coverages  $\theta_{\text{CO}}$  and  $\theta_{\text{NO}}$ , and the partial pressures  $P_{\text{CO}}$  and  $P_{\text{NO}}$  of the gas phase, and  $\theta_s$  represents the coverage of the vacant surface sites. The procedure used consists in expressing the coverages  $\theta_i$  as functions of  $\theta_{\text{CO}}$ , for which, if we define

$$[A2] \quad A = \frac{P_{\text{NO}} K_{\text{NO}}}{P_{\text{CO}} K_{\text{CO}}}$$

$$[A3] \quad B = \frac{1}{P_{\text{CO}} K_{\text{CO}}}$$

it is possible to write the relations:

$$[A4] \quad \theta_{\text{NO}} = A\theta_{\text{CO}} \quad \theta_s = B\theta_{\text{CO}}$$

The following conservation equations can be written, where the first two represent the steady state for the surface species N<sub>(a)</sub> and O<sub>(a)</sub> ( $\frac{d\theta_N}{dt} = 0$  and  $\frac{d\theta_O}{dt} = 0$ ):

$$[A5] \quad k_5\theta_{\text{NO}}\theta_s - 2k_6\theta_N^2 - k_8\theta_{\text{NO}}\theta_N = 0$$

$$[A6] \quad k_5\theta_{\text{NO}}\theta_s - k_7\theta_{\text{CO}}\theta_O = 0$$

$$[A7] \quad \theta_s + \theta_{\text{CO}} + \theta_{\text{NO}} + \theta_N + \theta_O = 1$$

If we define the relations

$$[A8] \quad C = (-k_8A + ((k_8A)^2 + 8k_5k_6AB)^{1/2})/4k_6$$

$$[A9] \quad D = k_5AB/k_7$$

it is possible to write

$$[A10] \quad \theta_N = C\theta_{\text{CO}} \quad \theta_O = D\theta_{\text{CO}}$$

so that from eq. [A7] we have

$$[A11] \quad \theta_{\text{CO}} = 1/(1 + A + B + C + D)$$

Therefore, the productions  $R_i$  are the following:

$$[A12] \quad R_{\text{CO}_2} = k_7\theta_{\text{CO}}\theta_O \quad R_{\text{N}_2} = k_6\theta_N^2 \quad R_{\text{N}_2\text{O}} = k_8\theta_{\text{NO}}\theta_N$$

and the selectivity SE for the nitrogen is defined by

$$[A13] \quad \text{SE} = R_{\text{N}_2}/(R_{\text{N}_2} + R_{\text{N}_2\text{O}})$$

# Determining the maximum environmental release limit of the toxic dye, CHPD

Vimal K. Balakrishnan and Virginia Palabrica

**Abstract:** The *Canadian Environmental Protection Act, 1999* (CEPA, 1999) requires the Canadian government to categorize all substances on the Domestic Substances List (DSL). Under the Chemicals Management Plan, the Government of Canada addresses chemicals that had not previously undergone rigorous scientific assessment. One such compound, [[4-[[2-(4-cyclohexylphenoxy)ethyl]ethylamino]-2-methylphenyl]methylene]-, propanedinitrile, commonly known as CHPD (cyclohexylphenoxydinitrile), recently underwent a screening assessment and was declared to be “toxic” to the environment. As a result, the Government of Canada ordered the “virtual elimination” of CHPD from the environment. Thus, CHPD may not be present above the lowest concentration that can be accurately measured using sensitive, but routine, analytical methods. We present a solid-phase extraction (SPE) method to determine CHPD in water and wastewater effluent to establish the maximum environmental release limit for this toxic compound. Optimal extraction was attained using an ENVI-18 cartridge. Extracts were analyzed by HPLC–PDA and HPLC–MS/MS techniques; in both matrices, the PDA method had greater sensitivity, less susceptibility to matrix effects, lower limit of quantitation (LOQ) values, and could be successfully validated at multiple spike levels. The lowest concentration of CHPD that could accurately be measured was found to be 108 ng/L in extracts of pure water, using the HPLC–PDA system. Therefore, this value (108 ng/L) will inform regulations on the maximum environmental release limit for CHPD.

**Key words:** cyclohexylphenoxydinitrile (CHPD), dye, solid-phase extraction (SPE), HPLC–PDA, HPLC–MS, virtual elimination, maximum environmental release limit, Chemical Management Plan.

**Résumé :** La loi canadienne sur la protection de l'environnement (1999) [LCPE (1999)] mandate le gouvernement canadien, par le biais de son ministre de l'environnement, d'établir un registre de toutes les substances sur la liste des substances domestiques (LI et LE, liste intérieure et liste extérieure). Dans le cadre du plan de gestion des produits chimiques, le gouvernement du Canada examine les produits chimiques qui n'ont pas subi antérieurement d'évaluation scientifique rigoureuse. Un de ces produits, le [[4-[[2-(4-cyclohexylphénoxy)éthyl]éthylamino]-2-méthylphényl]méthylène]propanedinitrile, communément connu par l'abréviation « CHPD » (« cyclohexylphénoxydinitrile ») a récemment été soumis à une évaluation de criblage et, par la suite, il a été déclaré toxique pour l'environnement. En conséquence, le gouvernement du Canada a ordonné l'élimination virtuelle du CHPD de l'environnement. Le CHPD ne peut donc plus maintenant être présent dans l'environnement au-delà de la concentration la plus faible pouvant être mesurée à l'aide de méthodes analytiques sensibles, mais de routine. Dans ce travail on présente une méthode par extraction en phase solide (EPS) qui permet de déterminer le CHPD dans l'eau et dans les effluents d'eaux usées dans le but d'établir la limite environnementale maximale pour l'émission de ce produit toxique. L'extraction optimale est obtenue en utilisant une cartouche ENVU-18. Les extraits ont été analysés par des techniques de chromatographie liquide haute performance (CLHP) avec détecteur à barrette à photodiodes ou avec détecteur à SM/SM; dans les deux types de matrices, la méthode aux BPD présente la plus grande sensibilité, le moins de susceptibilité aux effets de matrice, les valeurs les plus faibles de la limite de quantification (LDQ) et elle pu être validée avec succès à de multiples niveaux d'ensemencement. Dans système CLHP–BPD, on a trouvé que pour des extraits dans de l'eau pure, la quantité la plus faible de CHPD qui peut être mesurée est égale à 108 ng/L. En conséquence, cette valeur (108 ng/L) sera utilisée dans les règlements sur la limite d'émission maximale de CHPD dans l'environnement.

**Mots-clés :** cyclohexylphénoxydinitrile (« CHPD »), colorant, extraction en phase solide (« EPS »), chromatographie liquide avec détecteur à barrette à photodiodes (« CL–BPD »), chromatographie liquide avec détecteur à SM/SM (« CL–SM/SM »), élimination virtuelle, limite d'émission maximale dans l'environnement, Plan de Gestion des Produits Chimiques.

## Introduction

Synthetic dyes are extensively used in many fields, including textile industries,<sup>1</sup> leather tanning,<sup>2</sup> paper production,<sup>3</sup> food colouring,<sup>4</sup> and in personal care products<sup>5</sup> (e.g., hair colour, deodorant, and so forth). Furthermore, dyes are used in various engineering and scientific endeavours such as tracers for groundwater,<sup>6</sup> light-harvesting arrays<sup>7</sup> and photoelectrochemical cells.<sup>8</sup> Synthetic dyes exhibit considerable structural diversity, and their release into the environment is both a cause for public concern, and a serious challenge for environmental scientists. Because of their commercial importance, the impact and toxicity of dyes that are released into the environment must be carefully studied.

Many studies<sup>9–12</sup> have shown that dyes and pigments possess significant toxicity and are thus capable of having an impact on the environment. For example, the dye Direct Blue 14 has been shown to form a carcinogenic amine upon exposure to human skin bacteria,<sup>13</sup> while Oros et al.<sup>14</sup> found that 13 diazobenzene dyes had significant antifungal activity. In the course of manufacturing dyes, precursor compounds are often carried over into the final product<sup>15</sup> resulting in a complex mixture containing the dye itself and several other structurally similar compounds. Furthermore, many dyes (e.g., benzidine dyes) have been shown to undergo reduction in natural waterways, with degradation products that include amines, some of which are known carcinogens.<sup>16</sup> These precursors, intermediates, and degradation products are likely hazards due to their potential toxicity and (or) carcinogenicity, and thus knowledge of their environmental fate is of major interest from a risk assessment and risk management perspective. Adding to the complexity of managing the risks associated with environmental exposures to dyes and pigments is the fact that traditional wastewater treatment technologies have proven to be markedly ineffective for handling wastewater from dye manufacturing facilities.<sup>17</sup> Taken together, these findings highlight the importance of more fully evaluating the many dyes and pigments currently in commercial use.

In Canada, the *Canadian Environmental Protection Act, 1999* (CEPA, 1999) requires the Canadian government (through the federal Ministries of Health and Environment) to categorize all substances on the Domestic Substances List (DSL). Further to this activity, the CEPA requires that screening assessments be conducted for substances to determine whether these substances meet the definition of “toxic”, as set out in section 64 of CEPA, 1999. Under the Chemicals Management Plan (CMP), the Government of Canada plans to address legacy chemicals that had not previously undergone rigorous scientific assessment. As part of this plan, the Government of Canada challenged industry and other stakeholders (academics and nongovernmental organizations) to provide information on 193 priority chemical substances and how they are currently used in Canada. The information thus obtained under the CMP would thus facilitate a draft screening assessment under CEPA.

The substance, [[4-[[2-(4-cyclohexylphenoxy)ethyl]ethylamino]-2-methylphenyl]methylene]-, propanedinitrile, more commonly known as CHPD (cyclohexylphenoxydinitrile), was included in Batch 1 of the Challenge under the Chemicals Management Plan. CHPD (Fig. 1) is used as a colorant

**Fig. 1.** Chemical structure of [[4-[[2-(4-cyclohexylphenoxy)ethyl]ethylamino]-2-methylphenyl]methylene]-, propanedinitrile, more commonly known as cyclohexylphenoxydinitrile (CHPD).

in food packaging materials and is not naturally produced in the environment. The initial screening assessment report indicated that “CHPD entered or may be entering the environment in a quantity or a concentration or under conditions that have or may have an immediate or long-term harmful effect on the environment or its biological diversity.”<sup>18</sup> The final report concluded that CHPD met the criteria for persistence and bioaccumulation, and therefore, CHPD was declared a toxic substance.

Given the declaration of toxicity, the Government of Canada declared the ultimate environmental objective for CHPD to be virtual elimination (VE) as specified under subsections 65 and 77(4) of CEPA, 1999. Substances targeted for VE must be added to the Virtual Elimination List along with their level of quantification (LoQ). The LoQ is the lowest concentration that can be accurately measured using sensitive but routine sampling and analytical methods.

Since dyes are thermally unstable and nonvolatile; they are not readily amenable to analysis by GC.<sup>15</sup> Consequently, HPLC methods are typically used for measurements of dyes. The US Environmental Protection Agency (EPA) has validated a method<sup>19</sup> for a variety of azo- and anthra-quinone dyes, based on LC with UV or MS detection. Prior to analysis, samples are extracted using liquid–liquid extraction (LLE) with dichloromethane. However, given that LLE requires high volumes of organic solvent, much research has focused on developing less solvent-intensive alternatives, and applying those alternatives to environmentally relevant matrices.

One extraction technique that resolves problems in the determination of dyes is solid-phase extraction (SPE). For example, Brumley and Brownrigg<sup>20</sup> extracted a mixture of aromatic organic acids containing the sulfonated dyes Trip-tan Blue and Orange II followed by analysis using micellar electrokinetic chromatography, and obtained good recoveries of both from aqueous samples. Meanwhile, Franke et al.<sup>21</sup> applied SPE (using C-18 material) followed by HPLC–fluorescence analysis for the determination of the fluorescent tracers Uranine and Sulphorhodamine B in groundwater, with good recoveries (>80%), coefficients of variance (<20%), and low limits of detection (~300 ng/L). Similarly, SPE coupled to HPLC–FLD techniques were used for the determination of Rhodamine from surface waters.<sup>22</sup> The SPE methodologies used in these studies yielded good recoveries and detection limits in the environmentally relevant part-per-trillion range. Indeed, the robustness of SPE techniques was demonstrated by Mitrowska et al.,<sup>23</sup> who applied SPE (using SCX cartridges) as a clean-up and preconcentration step in

the extraction of malachite green and leucomalachite green from carp muscle.

To the best of our knowledge, no method exists for the determination of CHPD in environmental matrices. In this study, we report on the development and validation of the first solid-phase extraction technique for CHPD determination and we compare the performance of HPLC–PDA and tandem HPLC–MS instruments. Extractions were performed in pure (deionized) water and in wastewater effluent obtained from a water treatment plant in Burlington, ON. The limit of quantitation (LOQ) obtained as a result of this work will be used to establish the maximum environmental release limit for the virtual elimination of CHPD, as mandated under CEPA, 1999.

## Experimental

### Materials

[[4-[[2-(4-Cyclohexylphenoxy)ethyl]ethylamino]-2-methylphenyl]methylene]-, propanedinitrile (CHPD) was purchased (under the trade name Yellow 6G Gran) from Octochem Inc. (St. Louis, IL, lot number: CHSE55902, purity > 95%). A stock solution containing CHPD at a concentration of 100 mg/L was prepared in methanol (MeOH). Standard solutions were prepared by diluting the stock solution with MeOH.

Acetonitrile (CH<sub>3</sub>CN, HPLC grade) and methanol (MeOH, HPLC grade) were purchased from Caledon Laboratories (Georgetown, ON), while deionized water was obtained using a Milli-Q (Millipore) system.

Isotopically labelled <sup>13</sup>C<sub>3</sub>-caffeine was purchased from Cambridge Isotope Laboratories (Cambridge, MA).

### Solid-phase extraction procedures

Solid-phase extractions were performed at room temperature. Three sorbent phases were evaluated: OASIS MCX cartridges (6 mL; Waters Corporation, Milford, MA), STRATA-X cartridges (3 mL; Phenomenex, Torrance, CA), and ENVI-18 cartridges (6 mL, Supelco, Oakville, ON). Since wastewater contains undissolved organic matter, a sample clean-up step (filtration) was incorporated into our method and applied to wastewater samples and to our standard solutions.

The general SPE method used throughout this work was as follows. SPE cartridges were conditioned by passing the following sequence of solutions: methanol (MeOH, 5 mL), H<sub>2</sub>O (10 mL), MeOH/5% NaOH, and H<sub>2</sub>O adjusted to pH 3 (using H<sub>2</sub>SO<sub>4</sub>). Solutions (1 L) were filtered through a 3 cm bed of Celite 545 (Fisher Scientific) on a 1.2 µm GFC filter (VWR Scientific) after which the filtrate was passed through a 0.45 µm Metrical filter (VWR Scientific). The final filtrate was adjusted to pH 3 using concentrated HCl and loaded onto the SPE cartridge, which was then washed with 0.1 N HCl (4 mL). The SPE cartridge was eluted using 15 mL MeOH, a volume that was found to ensure that the CHPD was fully extracted from the sorbent phase (data not shown). The resulting eluate was evaporated under a stream of nitrogen to a final volume of 1 mL.

### Sample collection

Samples of wastewater effluent were collected from a

water treatment plant located in Burlington, ON. All samples were stored at 4 °C in 4 L amber glass bottles, spiked with the appropriate quantity of CHPD, and extracted within 3 d (vide supra). Upon extraction, samples were immediately analyzed as described below.

### Analytical methods

For comparison purposes, all samples were analyzed using two instruments. The first was an HPLC (Agilent LC1100), equipped with a PDA detector set at 423 nm, using a Phenomenex Ultracarb C-18 column (ODS 30, 150 mm × 4.6 mm ID × 5 µm) at 30 °C into which were injected 10 µL sample aliquots. Water (A) and acetonitrile (B) were used as mobile phase solvents for gradient elution at a flow rate of 0.5 mL/min. The gradient was increased from 75% B to 95% B within 1 min, held at 95% B for 10 min, and then immediately returned to the initial conditions (75% B) for the final 14 min of the run, giving a total run time of 25 min.

The second instrument used was a Quattro Ultima tandem LC triple quadrupole mass spectrometer (Micromass, Manchester, UK) equipped with a Z-Spray electrospray ionization (ESI) source and operated in the positive-ion mode. Nitrogen was used as the drying and nebulizing gas at flow rates of 500 and 70 L/h, respectively. Collision induced dissociations were conducted using  $2.5 \times 10^{-3}$  mbar Argon in a hexapole collision cell. MassLynx software (v. 4.1) (Waters Corporation: Milford, MA, 2005) was utilized for both data acquisition and processing. The MS was operated in multiple reaction monitoring (MRM) mode, with a dwell time of 100 ms per ion pair and an interchannel delay of 50 ms. For CHPD, at a cone voltage of 20 kV and collision energy of 15 eV, the precursor ion was found at  $m/z$  414.3, with product ions formed at  $m/z$  of 238.1 (quantitation) and 332.2 (confirmation). The source temperature was set to 120 °C, while that for desolvation was set to 350 °C. The MS apparatus was attached to an Acquity HPLC system (Waters, Milford, MA). Aliquots (10 µL) were injected onto a Phenomenex Ultracarb C-18 column (ODS 30, 150 mm × 4.6 mm ID × 5 µm) at 30 °C. Water (A) and acetonitrile (B) were used as mobile phase solvents for gradient elution at a flow rate of 0.5 mL/min, following the same elution profile as used for the HPLC–PDA runs.

Prior to sample injection, <sup>13</sup>C-labeled caffeine (50 mg/L, prepared in MeOH) was added as an internal standard, such that the final concentration of <sup>13</sup>C-labeled caffeine in all samples was 500 µg/L. MS responses presented throughout this work are normalized against <sup>13</sup>C-labeled caffeine, which had a precursor ion at  $m/z$  = 198.0 and a product ion at  $m/z$  140.0 (at a cone voltage of 30 kV and collision energy of 20 eV).

## Results and discussion

### Development of SPE method

Given that CHPD is a dye with an absorbance maximum at 423 nm, the initial method development was performed using the Agilent HPLC (PDA detector). Once SPE parameters were optimized, method performance samples were analyzed using both the PDA detector and the MS detector.

In SPE, arguably the most important systemic parameter

**Fig. 2.** Sorbent performance for the solid-phase extraction of a 1 L solution of CHPD at a concentration of 20  $\mu\text{g/L}$ , as determined using the PDA detector. Error bars denote the standard deviation about the mean response ( $n = 3$ ).

**Fig. 3.** The impact of filtering aqueous solutions of CHPD through Celite and 0.45  $\mu\text{m}$  filters, as determined using the PDA detector. Error bars denote the standard deviation about the mean response ( $n = 3$ ).

consists of the nature of the sorbent phase onto which the analyte of interest will be extracted. In this work, three sorbent phases were evaluated: ENVI-18 cartridges (reverse phase C-18 that has been polymerically linked to silica); OASIS MCX cartridges (a mixed mode sorbent composed of sulfonate groups, nominally 1 mequiv./g, on polydivinylbenzene-polyvinylpyrrolidone copolymers); and STRATA-X cartridges (a reverse phase polymeric sorbent designed for both polar and nonpolar compounds). When a 1 L aqueous sample of CHPD (20  $\mu\text{g/L}$ ) was passed through each of the sorbents, no evidence of breakthrough was observed. The relative extractability of the 20  $\mu\text{g/L}$  CHPD solution using each of these three sorbent phases is presented in Fig. 2, and was found to proceed as ENVI-18 > OASIS MCX >> STRATA-X. Accordingly, ENVI-18 cartridges were used for all subsequent SPE experiments presented in this work.

Since wastewater contains undissolved organic matter, and that SPE is not, by itself, considered a “clean-up” technique, we deemed it necessary to incorporate a sample clean-up step (filtration) into our method. Briefly, a solution

of CHPD was filtered through a 3 cm bed of Celite 545 on a 1.2  $\mu\text{m}$  GFC filter, after which the filtrate was passed through a 0.45  $\mu\text{m}$  Metrical filter. While the resulting calibration curves (Fig. 3) both had good linearity ( $R^2 > 0.99$ ), it is worth noting that the sensitivity (slope) of the filtered solutions (slope =  $(7.67 \pm 0.21) \times 10^{-2}$ ) was approximately 11% less than that of the unfiltered solutions (slope =  $(8.63 \pm 0.06) \times 10^{-2}$ ). Although small, the observed difference in sensitivity was found to be statistically significant at the 95% confidence interval, indicating that CHPD is somewhat retained by the filter material. Since unfiltered samples are unacceptable for injection into an HPLC column, the method calibration curve must include not only the solid-phase extraction, but also the sample filtration step to correct for the impact of the filter material.

## Method performance

### Calibration curves

In evaluating the SPE method performance, CHPD solutions were filtered through a 3 cm bed of Celite 545 on a 1.2  $\mu\text{m}$  GFC filter after which the filtrate was passed through a 0.45  $\mu\text{m}$  Metrical filter. Thereafter, the filtrate was passed through an ENVI-18 SPE cartridge, and eluted using methanol. A calibration curve was prepared in both deionized water and wastewater effluent containing CHPD at concentrations ranging between the 10 ng/L and 10 000 ng/L. For comparative purposes, extracts were analyzed using both PDA and MS detectors. Water and effluent blanks produced no signals in either detector that coeluted or, in the case of the MS detector, created “cross-talk” with the target analyte. The calibration curves resulting from triplicate measurements are provided in Figs. 4 and 5, and the corresponding figures of merit are given in Table 1.

In general, the PDA response to CHPD in both deionized water and wastewater effluent adhered to a quadratic equation, while the MS detector produced a linear response throughout the entire calibration range. In all cases, coefficients of determination ( $R^2$ ) were found to exceed 0.99, denoting a strong correlation between experimental measurements and the fitted expressions.

In deionized water, it is readily apparent that the PDA detector provides a more sensitive response to CHPD than does the MS detector (Fig. 4). This is not surprising given that CHPD is a dye with a strongly absorbing chromophore. However, in wastewater effluent (Fig. 5), the sensitivity of the PDA detector towards CHPD decreased while the sensitivity of the MS detector increased (as evidenced by the slopes provided in Table 1). We attribute this dichotomous behaviour to matrix effects: for the PDA detector, the presence of other absorbing compounds in the effluent led to a higher background noise that resulted in the decreased sensitivity towards the target analyte; meanwhile, for the MS detector, the presence of effluent resulted in a matrix enhancement of CHPD.

The matrix in which analytes are found is known to exert a powerful effect on electrospray MS by altering the extent to which the analytes of interest are ionized.<sup>24,25</sup> We suggest here that acid–base interactions between CHPD and the humic or fulvic acids normally found in the wastewater effluent enhanced CHPD ionization. Since analyte peak areas in

**Fig. 4.** Method calibration curves for the determination of CHPD in deionized water using both MS and PDA detectors. The response axis represents either the peak area at 423 nm in the case of PDA detection or an area corrected against  $^{13}\text{C}$ -labelled caffeine (500 ng/L) in those instances where an MS detector was used. Error bars denote the standard deviation about the mean response ( $n = 3$ ).

**Fig. 5.** Method calibration curves for the determination of CHPD in wastewater effluent using both MS and PDA detectors. The response axis represents either the peak area at 423 nm in the case of PDA detection or an area corrected against  $^{13}\text{C}$ -labelled caffeine (500 ng/L) in those instances where an MS detector was used. Error bars denote the standard deviation about the mean response ( $n = 3$ ).

electrospray mass spectroscopy are highly variable from one run to another, good laboratory practice dictates that each analyte peak be normalized against an internal standard of a known, constant concentration. Although matrix effects in MS are thought to be largely corrected by dilution using isotopically labelled analogues of the target analyte (i.e., CHPD) as an internal standard,<sup>26</sup> such a correction was not possible in this case given that isotopically labelled CHPD is not commercially available. Consequently, the fact that the selected internal standard ( $^{13}\text{C}_3$ -caffeine) interacts with the fulvic and humic acids in the effluent in a different manner than does CHPD means that the matrix effects will not be fully corrected, as is evident from the differing slopes obtained in deionized water and wastewater effluent (Figs. 4 and 5, Table 1). However, even in those instances where an isotopically labelled analogue of a target analyte is readily available as an internal standard, recent studies in our laboratory using various pharmaceuticals and personal care products

have shown that matrix effects cannot be entirely eliminated.<sup>27,28</sup> Therefore, we recommend that matrix matched calibration curves be employed to ensure the most accurate determination of CHPD in environmental samples.

#### Limits of detection and quantitation (LOD and LOQ)

Limit of detection (LOD) and limit of quantitation (LOQ) values (Table 1) were determined using both PDA and MS detectors by taking  $\text{LOD} = 3\sigma$  and  $\text{LOQ} = 10\sigma$ , where  $\sigma$  was the standard deviation about the mean of a measurement taken at a low CHPD concentration (i.e., where the CHPD concentration in the sample was no greater than ten times the LOD<sup>29</sup>). In deionized water, the measurement was performed at a CHPD concentration of 200 ng/L, whereas for wastewater effluent, the CHPD concentration was set at 500 ng/L.

In all cases, CHPD detection using the PDA detector yielded lower LOD and LOQ values. As expected, LOQ values were lower in deionized water than in wastewater effluent. Interestingly, the presence of wastewater had a greater impact on the MS detector than it did on the PDA detector. In fact, when using the MS detector, the LOQ in wastewater increased from that found for CHPD in pure water by 1160%, whereas the LOQ as determined using the PDA increased only 440%. While the increase in LOQ observed upon proceeding from deionized water to wastewater effluent can be attributed to the effect of a vastly more complicated matrix, the different extents by which the LOQ values increased suggests that the MS detector is more susceptible to matrix effects. In other words, even though CHPD in wastewater effluent is subject to *matrix enhancement* (i.e., increased sensitivity) when determined by MS and *matrix suppression* when determined by PDA (as shown by Figs. 4 and 5, and the slopes of the calibration curves (Table 1)), the MS detector had poorer LOQ results than did the PDA detector. Although this finding may seem counterintuitive, it appears that wastewater effluent enhances CHPD ionization in the MS detector (creating a matrix enhancement and increased sensitivity); the effluent itself is heterogeneous, producing a greater measure of imprecision, and hence, higher LOQs.

#### Method validation

The extraction method was validated at four different CHPD concentrations, in both deionized water and wastewater effluent. Once again, neither water nor effluent blanks produced any signals in either detector that coeluted or, in the case of the MS detector, created cross-talk with CHPD. CHPD was spiked such that the concentration in the sample was half the LOD, twice the LOD, five times greater than LOD, and 10 times greater than LOD. The LOD values used to calculate the spike levels for method validation were premised on the idea that establishing the lowest possible “maximum environmental release limit” and ensuring the virtual elimination of CHPD (as mandated under CEPA) would best be achieved by using the more sensitive PDA detector. Therefore, in deionized water, CHPD concentrations were spiked at 16.5, 66, 165, and 330 ng/L. Meanwhile, wastewater effluent was spiked at 87.5, 350, 875, and 1750 ng/L.

When CHPD was present at a concentration lower than

**Table 1.** SPE method performance for the determination of CHPD in Milli-Q water and wastewater effluent using ENVI-18 cartridges and both PDA and MS detectors.

Matrix	Detector	Equation ( $y = f(X)$ ), where $X = [\text{CHPD}]$	$n$	$R^2$	LOD* (ng/L)	LOQ* (ng/L)
Water	PDA	$(2.24 \times 10^{-6})X^2 + (5.01 \times 10^{-2})X$	9	0.991	32.3	108
	MS	$0.0146X$	9	0.997	46.2	154
Effluent	PDA	$(2.35 \times 10^{-6})X^2 + (1.26 \times 10^{-2})X$	8	0.998	175	583
	MS	$0.0238X$	8	0.996	602	2005

\*For determinations of LOD and LOQ, measurements were taken using a low concentration CHPD standard ( $n = 8$ ).

**Table 2.** Accuracy and precision ( $n = 4$ ) of the SPE method to extract CHPD from pure water and from wastewater effluent.

Matrix	Detector	Spike level (ng/L)	Recovery (%)	CV <sup>a</sup>
Water	PDA	16.5	ND <sup>b</sup>	NA <sup>c</sup>
		66	100.3	19.9
		165	94.9	3.15
		330	99.3	12.1
	MS	16.5	ND	NA
		66	92.7	12.6
		165	94.6	9.60
		330	99.2	3.93
Effluent	PDA	87.5	ND	NA
		350	91.3	16.2
		875	115	10.4
		1750	82.4	1.82
	MS	87.5	82.4	62.8
		350	75.0	51.0
		875	100	23.5
		1750	78.2	15.46

<sup>a</sup>CV = coefficient of variance.

<sup>b</sup>ND = not determined.

<sup>c</sup>NA = not applicable.

the Limit of Detection, CHPD was not found in any matrix (Table 2), except when using MS detection on an extract of wastewater effluent spiked at 87.5 ng/L CHPD. However, the Coefficient of Variance (CV) in that instance was unacceptably high (62.8%). Above the LOD (in both matrices), CHPD recoveries generally exceeded 75%. In fact, aqueous spike recoveries were generally above 90% with both MS and PDA detection at all spike levels above LOD. Furthermore, the CVs obtained in the recovery of aqueous extracts using both MS and PDA detection was typically less than 15%. However, at a spike concentration of 66 ng/L, the coefficient of variance using the PDA detector was 19.9%. Given that 66 ng/L represents a concentration of only twice the LOD, this is an acceptable degree of variance. Indeed, the fact that the method could be validated at only twice the LOD demonstrates the robustness of the method, since 66 ng/L is actually below the LOQ. Therefore, with method accuracy exceeding 80% and CVs no greater than 20%, the method developed herein meets the criteria for successful validation in deionized water.<sup>30</sup>

In analyzing extracts of wastewater effluent using the MS detector, we were unable to validate the method at any spike level. At 350 ng/L, neither the recovery (75%) nor the CV (51%) were acceptable. Meanwhile, at 875 ng/L, the recovery (100%) was acceptable, but the CV (23.5%) proved to be too large. At the final spike level (1750 ng/L), the CV (15.5%) was acceptable, but the recovery (78.2%) was not.

We attribute the failure of the method validation using the MS detector to the fact that the spike levels used in wastewater were all below the LOQ established for MS analyses (2005 ng/L, Table 1). However, when we used the PDA detector at all spike levels above the LOD, errors in accuracy and the CV values were always less than 20%. Hence, we conclude that the SPE extraction method when coupled with detection using a PDA detector is successfully validated.

## Conclusions and environmental implications

Our research has resulted in the development of an SPE extraction technique for the dye CHPD. We compared two HPLC detectors for CHPD determination, and concluded that CHPD is better determined (both in deionized water and wastewater) via SPE extraction using ENVI-18 cartridges followed by analysis on an HPLC–PDA apparatus rather than using an HPLC–MS/MS instrument. The PDA method was found to be more sensitive and less susceptible to matrix effects than was the MS method. Moreover, only determination by PDA could be fully validated in both matrices. Most importantly, the PDA detector produced lower LOQ values than did the MS detector. Accordingly, the PDA detector was used in the recommendation of a maximum environmental release limit for CHPD.

It was readily apparent that the presence of wastewater effluent had a significant impact on method performance, and

thus, we anticipate that the method performance will be impacted in all environmental matrices in a manner unique to each matrix. However, since the method we developed was robust enough to be validated in a matrix as complex as wastewater effluent, it should be readily applicable to the simpler matrices found in natural waters. Even when using matrix matched calibration curves, environmental matrices will tend to suppress the determination of CHPD via a PDA detector by raising the level of background noise. Therefore, any environmental determination of the contaminant would necessarily be at a level that exceeds the limit of quantitation established in pure water. *Consequently, it is our recommendation that the virtual elimination of CHPD (as mandated under the Canadian Environmental Protection Act (1999) and under the auspices of the Chemical Management Plan) is best accomplished by using the LOQ value obtained in pure water with a PDA detector, thereby setting a maximum environmental release limit of 108 ng/L.*

## Acknowledgements

Funding for this research was provided under the Government of Canada's Chemical Management Plan (2006). We gratefully thank Mr. John Toito (Environment Canada) for his valuable technical assistance.

## OBITUARY / NÉCROLOGIE

**Keith Fagnou**, 38, associate professor of chemistry at the University of Ottawa and a rising star in the field of organic chemistry, died suddenly on Nov. 11, 2009. Keith received a B.Ed. from the University of Saskatchewan in 1995. He then earned an M.S. in 2000 and a Ph.D. in synthetic organic chemistry in 2002, both from the University of Toronto under the tutelage of Professor Mark Lautens. Upon completing his degree, he joined the faculty of the University of Ottawa. In 2007, he was promoted to associate professor and appointed University of Ottawa Research Chair in the Development of Novel Catalytic Transformations.

Keith's research program focused on the development of new reactions via the direct functionalization of C–H bonds, and applied these methods to the synthesis of medicinal compounds and small bioactive products. His seminal contributions in the generation of C–C bonds, especially in biaryl compounds, without the need for substrate preactivation, dramatically changed the way chemists approach the generation of carbon-carbon bonds. The excellence of his pioneering work was recognized internationally. He was a gifted lecturer at the undergraduate and graduate levels, and was a sought-after speaker by academic and industry. He gave several named lectures and received numerous awards, including the 2003 Polanyi Prize (Ontario), Sloan Research fellowship, Cottrell Research Scholarship, the Premier's Research Excellence Award (Ontario), and several accolades from pharmaceutical companies (Amgen, AstraZeneca, Boehringer Ingelheim, Eli Lilly, Merck). This past summer, he received the Organometallic Chemistry Directed Towards Organic Synthesis Award, which is presented every two years to a scientist under 40 for outstanding research contributions. In November 2009, Keith posthumously received the Rutherford Memorial

**Keith Fagnou**, 38 ans, professeur agrégé à l'Université d'Ottawa et étoile montante du domaine de la chimie organique, est décédé subitement le 11 novembre 2009. Titulaire d'un B. Éd. de l'Université de la Saskatchewan (1995), Keith a poursuivi ses études supérieures à l'Université de Toronto où il a obtenu une maîtrise (2000) et un doctorat en chimie organique synthétique en 2002, sous la direction du professeur Mark Lautens. Par la suite, il s'est joint à la faculté de l'Université d'Ottawa. En 2007, il est nommé professeur agrégé et occupe la chaire de recherche de l'Université d'Ottawa sur le développement de nouvelles transformations catalytiques.

Dans le cadre de son programme de recherche, il s'attaquait principalement à l'élaboration de nouvelles réactions par la fonctionnalisation directe des liaisons C–H au profit de la synthèse de composés médicinaux et de substances bioactives. L'apport indéniable et majeur de ses travaux à la génération de liaisons C–C, surtout en ce qui a trait aux composés biaryliques, sans préactivation des substrats, a profondément changé la façon dont les chimistes génèrent des liaisons carbone-carbone. L'excellence de ses travaux avant-gardistes est d'ailleurs reconnue mondialement. Il était un enseignant doué, tant au premier cycle qu'aux cycles supérieurs, et un conférencier très sollicité par les milieux universitaire et industriel. En plus d'être invité d'honneur de plusieurs congrès et colloques, Keith a remporté de nombreux prix, y compris le prix Polanyi 2003 (Ontario), une bourse Sloan, une bourse Cottrell, la Bourse du premier ministre pour l'excellence en recherche (Ontario), ainsi que plusieurs éloges d'établissements pharmaceutiques (Amgen, AstraZeneca, Boehringer Ingelheim, Eli Lilly, Merck). L'été dernier, il a remporté le prix « Organometallic Chemistry Directed Towards Organic Synthesis » [chimie organométallique appliquée à la synthèse

Medal of the Royal Society of Canada and was named one of "Canada's Top 40 under 40" by the *Globe & Mail*/Caldwell Partners. Keith was a modest person who was nonetheless a strong advocate for Canadian research excellence. On the personal side, Keith was a dedicated family man and was close to his friends. He will be missed by all. Keith is survived by his wife, Danielle Gervais-Fagnou, and three children, Zachary, Clara, and Samuel.

# Absorption detection using optical waveguide cavities

Hans-Peter Loock, Jack A. Barnes, Gianluca Gagliardi, Runkai Li,  
Richard D. Oleschuk, and Helen Wächter

**Abstract:** Cavity ring-down spectroscopy is a spectroscopic method that uses a high quality optical cavity to amplify the optical loss due to the light absorption by a sample. In this presentation we highlight two applications of phase-shift cavity ring-down spectroscopy that are suited for absorption measurements in the condensed phase and make use of waveguide cavities. In the first application, a fiber loop is used as an optical cavity and the sample is introduced in a gap in the loop to allow absorption measurements of nanoliters of solution at the micromolar level. A second application involves silica microspheres as high finesse cavities. Information on the refractive index and absorption of a thin film of ethylene diamine on the surface of the microresonator is obtained simultaneously by the measurements of the wavelength shift of the cavity mode spectrum and the change in optical decay time, respectively.

**Key words:** cavity ring-down spectroscopy, microresonator, microsphere, fiber loop.

**Résumé :** La spectroscopie à cavité ring-down est une méthode spectroscopique qui utilise une cavité optique de haute qualité pour amplifier la perte optique due à l'absorption de lumière par l'échantillon. Durant cette présentation, nous mettons en évidence deux applications de la spectroscopie à cavité ring-down avec déplacement de phase qui convient aux mesures d'absorption en phase condensée et fait usage de cavités à guide d'onde. Dans la première application, une boucle de fibre est utilisée comme cavité optique et l'échantillon est introduit dans un intervalle de la boucle pour permettre des mesures d'absorption sur des nanolitres de solution au niveau micromolaire. Une seconde application est basée sur des microsphères de silice comme cavités à haute finesse. Des informations sur l'index de réfraction et l'absorption d'un film mince d'éthylène diamine sur la surface d'un micro-résonateur sont obtenues simultanément par des mesures de déplacement de longueur d'onde du spectre modal de la cavité et de changement de temps de décroissance optique, respectivement.

**Mots-clés :** spectroscopie à cavité ring-down, micro-résonateur, microsphère, boucle de fibre.

In the past years, absorption spectroscopy has undergone a rapid change and the absorption spectrometers that are developed in many research labs have little in common with the teaching instruments that most of us were trained on. Indeed, a typical UV-vis absorption spectrometer found in today's undergraduate labs shares many of its basic components with the "spectroscope" devised by Isaac Newton in 1666. It contains a dispersing element, such as a prism or grating, a sample compartment, and a detector that is either placed behind a slit or forms a detection array, such as a photographic plate or photodiode array. Since the experiments by Kirchhoff and Bunsen<sup>1,2</sup> in the 1860s, quantitative absorption spectroscopy relies on the accurate measurement

of a change of transmitted light intensity due to wavelength-dependent attenuation by the analyte of interest. Single pass "direct" absorption detection and spectroscopy remains popular to this day, since it is straightforward to implement and many analytes show absorption features in the UV-vis region of the spectrum, whereas many solvents do not. This makes UV-vis absorption an ideal "label-free" method for detection and quantification of analytes.

On the other hand, direct absorption measurements are not background free, in contrast to fluorescence, photoacoustics, resonant ionization, coherent anti-Stokes Raman spectroscopy (CARS), and other modern spectroscopy methods. Furthermore, as evident from the Beer-Lambert law,  $I/I_0 = \exp(-\epsilon C d)$ ,

the sensitivity of a direct absorption measurement  $dI/dC = -I_0\epsilon d \exp(-\epsilon Cd)$  depends critically on the stability of light sources, optical alignment, and detectors (all expressed through  $I_0$ ).

Because of the need to measure a small intensity change on top of a large, and possibly noisy, intensity background, direct absorption is rather insensitive for low concentrations and (or) short absorption paths. Therefore, a number of approaches have been developed to overcome this limitation, notably the use of multipass cells, preconcentration of the analyte, differential absorption measurements, etc. In gas-phase spectroscopy, only a few of these methods have had an impact comparable to that of the cavity ring-down (CRD) absorption technique, a method that was introduced in 1988 by O'Keefe and Deacon.<sup>3</sup>

### Cavity ring-down spectroscopy

In cavity ring-down spectroscopy, the sample is placed in an optical cavity that is usually made by opposing two highly reflective mirrors at distance  $d$  (Fig. 1). A laser light pulse that is coupled into the cavity will be trapped between the mirrors for a large number of roundtrips while its intensity decays exponentially. The characteristic decay time, or ring-down time,

$$[1] \quad \tau = \frac{t_R}{-2\ln R + \epsilon Cd}$$

depends on the pulses' round trip time,  $t_R = nd/c_0$ , and the reflectivity of the mirrors,  $R$ , but does not depend on the intensity of the light pulse that is coupled into the cavity or on slow fluctuations of the detector response. The ring-down time is large for high mirror reflectivity and decreases with the introduction of absorbing or scattering compounds into the cavity.<sup>4-6</sup> With commercially available "super mirrors", reflectivities higher than 99.99% ( $R > 0.9999$ ) may be achieved, which corresponds to a cavity finesse  $F \approx 2\pi/(1 - R) = 62\,800$ . Since this number can be roughly equated to the number of passes through the cavity medium, one can see that even a desktop cavity with length  $d = 1$  m is equivalent to an absorption cell with an effective path-length of over 60 km! In addition, the sensitivity of the ring-down time measurement,

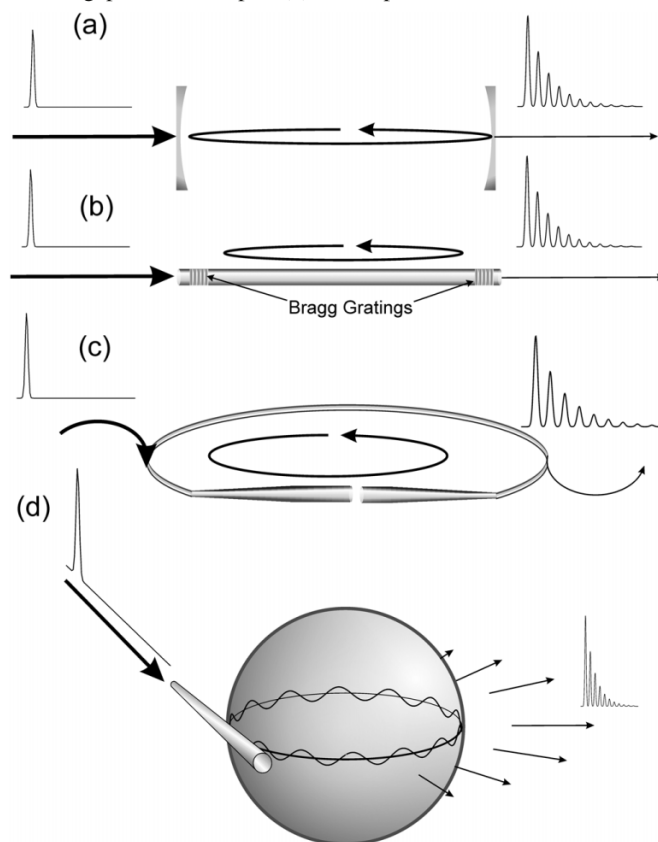

$$[2] \quad \frac{d\tau}{dC} = \frac{-\epsilon d t_R}{(-2\ln R + \epsilon Cd)^2}$$

increases quadratically with decreasing concentration and does not depend on intensity, which is a useful feature for an analytical spectroscopic method.

Not surprisingly, over the last twenty years, CRD spectroscopy and related cavity enhanced absorption methods have gained a larger and larger following, and the number of publications citing "cavity ring-down" in their title or abstract has increased from less than five in 1995 to over 150 in 2008. A large fraction of those publications is concerned with high resolution spectroscopy and detection of gases, of reactive intermediates, or of molecular beam-cooled samples. Since about 2002, an increasing number of research groups, including our own, attempt to adapt CRD detection to liquid samples.

CRD spectroscopy in liquids may be carried out simply by filling the entire optical cavity with liquid<sup>7</sup> or by insert-

**Fig. 1.** (a) Mirror-based cavity ring-down scheme; (b) optical cavity consisting of two fiber Bragg gratings; (c) fiber-loop CRD showing a small gap for the sample; (d) microsphere resonator.

ing a sample cuvette<sup>8-10</sup> or liquid jet<sup>11</sup> into the cavity. CRD detection for HPLC or other systems can similarly be realized by either constructing a very short cavity in which the mirrors are only separated by millimetres or by directing the effluent from the column across the optical axis of the cavity.<sup>12-16</sup> Both methods achieve impressive detection limits, which are limited by their baseline noise level to about  $10^{-5}$  to  $10^{-6}$  absorption units, depending on the mirrors, detection wavelength, and configuration. Also, both require careful optical alignment and a trained operator. In addition, the laser pulse width needs to be shorter than the roundtrip time. This means that millimetre long cavities can only be interrogated with picosecond laser pulses and with fast data acquisition systems. An excellent review describes the implementation of the CRD detection scheme to liquids with particular emphasis on the microliter-sized samples, which are relevant for HPLC.<sup>12</sup>

### CRD in waveguide cavities

In this presentation, we highlight two different types of optical cavities that are based on the waveguiding properties of silica and demonstrate their use for absorption measurements of small (nanoliter-sized) liquid samples.

In a simple analogy to the free-space optical cavity made of two mirrors, a strand of optical fiber that is gold coated at both end facets also acts as a high finesse optical cavity (Fig. 1b). Sigrist and co-workers<sup>17,18</sup> have used such a cavity to determine the concentration of  $H_2$  in the fiber core and to

measure bending losses occurring in the fiber optic cable. Instead of coatings applied to the fiber surface, one may also use fiber Bragg gratings (FBGs) as internal mirrors.<sup>19,20</sup> FBGs are periodic modulations of the refractive index written into the core of a sensitized fiber typically using UV laser radiation. They may have a reflectivity of up to 99.99%. Light propagating along the core of the fiber is reflected from these gratings when the Bragg condition is fulfilled, i.e., when the wavelength of the light is twice as large as the grating period.

An even simpler optical cavity may be formed by connecting the two ends of a strand of optical waveguide to form a continuous loop (Fig. 1c).<sup>21–25</sup> Once light is trapped inside the loop, it will circulate for many roundtrips before its intensity has decayed below the detection threshold. Compared to the linear cavity, the loop offers a number of advantages. First, the operating wavelengths are limited by the transmission spectrum of the waveguide, i.e., for silica from about 1700 nm to about 400 nm, whereas the FBGs have high reflectivity only in a 2–10 nm window, typically at around 1550 nm. Second, the gap between the fiber ends is a natural place to introduce a small liquid sample, for instance by using capillaries or channels in microfluidic devices. Third, the fiber-loop material and core diameter can be tailored to the application, whereas FBGs can be most easily written into single mode silica fibers. On the other hand, coupling light into the loop either requires couplers, which introduce cavity loss, or focusing of laser pulses onto the fiber core, which is a rather inefficient process. By contrast, FBG cavities can be simply spliced on the laser delivery fiber.

Both optical devices, the linear fiber cavity and the fiber loop, have been used in ring-down experiments. Similar to conventional free-space CRD, the ring-down time only depends on the optical loss in the cavity but is largely insensitive to lightsource power fluctuations or even detector response drifts, as long as those changes occur on timescales longer than the ring-down time. A recent review has highlighted the use of these cavities for mechanical and temperature measurements and, to a lesser extent, for refractive index measurements,<sup>26</sup> whereas we will focus on measurements of absorption induced by the interaction of the guided modes with an analyte. For a comprehensive review of cavity ring-down spectroscopic methods and in particular CRD using waveguides, the reader is directed to a 2009 book on cavity ring-down spectroscopy.<sup>6</sup>

### CRD phase-shift measurements

Before discussing different instruments in which waveguide based CRD measurements can be used, we should emphasize the differences between absorption measurements in flow systems and the “static” gas measurements in conventional cavities.

The optical loss in a fiber loop is much higher than in even a low-finesse optical cavity consisting of mirrors. With a mirror pair of a reflectivity of 99.9%, only 0.2% of the light is lost per roundtrip, whereas the insertion loss of fiber–fiber couplers, of fiber splices, and FBGs may easily add up to more than 5%. When measuring the absorption of a sample placed between the two ends of a fiber loop, the

loss is even higher: about 10%–30% of light is lost across the gap even when it is filled with nonabsorbing solvent! For a fiber cavity having the same roundtrip time as a conventional cavity, the ring-down time is therefore much shorter and the sensitivity to changes in the optical loss due to absorption by the analyte is correspondingly lower.

Also, in the analytical separation systems discussed below, the measurement has to take place in real time, while the analyte flows between the two fiber ends, with no opportunity to average multiple “events”. The data acquisition rate has to be matched to the flow rate and the detection volume, such that the detection volume is replaced at a rate that is about 10 times slower than the acquisition rate. Practically, we need to sample a ring-down event every 1–10 ms and determine the ring-down time ( $\tau = 0.1$ – $10 \mu\text{s}$ ) through exponential fitting at the same rate.

In our initial experiments, we used pulsed dye lasers operating at about 800 nm and were restricted in our data acquisition rate by the 10–100 Hz pulse repetition rate of our lasers.<sup>21,22</sup> Also, we had to average about 2000–6000 ring-down events to obtain a reliable ring-down time. The resulting data acquisition rate of  $1/3 \text{ min}^{-1}$  to  $1/10 \text{ min}^{-1}$  (one measurement every 3–10 min) is grossly inadequate for analytical flow measurements. While the rate can be increased considerably by switching to kHz repetition rate lasers, the main problem remains: the duty cycle of the experiment is woefully low. Assuming a 10 kHz repetition rate, light that is injected in the cavity rings down (in about  $10 \mu\text{s}$ ) only for a small fraction of the time, while the remaining time the system does nothing ( $90 \mu\text{s}$ ). Finally, it is neither trivial nor cheap to switch inexpensive lasers or other light sources, such as LEDs, on nanosecond timescales, and it is also costly to read out ring-down transients at high sampling rates.

All three concerns, the fast ring-down times, the poor duty cycle, and the high cost of (sub-)nanosecond switching and readout, may be addressed by applying a simple method that has been used in fluorescence lifetime measurements for many decades. Instead of monitoring the decay of a pulse in the time domain, one can also monitor the phase shift of an amplitude-modulated signal in the frequency domain (Fig. 2).<sup>27,28</sup> If an intensity-modulated signal is continuously fed into a high finesse cavity (or a fluorescent sample), the cavity (or sample) will emit light at the same modulation frequency,  $\omega$ , but with reduced modulation depth and with a phase shift that depends on the ring-down time,  $\tau$  (fluorescence lifetime). For a single exponential decay, the phase shift is<sup>28,29</sup>

$$[3] \quad \tan(\phi - \phi_0) = -\omega\tau$$

Here,  $\phi$  is the phase shift between the light entering and exiting the fiber cavity and  $\phi_0$  is the phase shift resulting from instrumental factors such as electronic time constants and propagation delays. For multiexponential decays, the relation is more complicated but one can still determine the ring-down times and the relative amplitudes of each exponential component from phase-angle measurements at multiple modulation frequencies.<sup>30</sup>

The point is, phase-shift CRD measurements, introduced for spectral analysis by Engeln et al. in 1996,<sup>31</sup> are ideally

**Fig. 2.** Similar to a RC circuit, the response of an optical cavity is different to an impulse (DC, top) or an oscillating input (AC, bottom). An optical cavity, which is driven with a sinusoidally modulated input of angular frequency,  $\omega$ , will emit light with the same modulation frequency but reduced modulation depth and phase shifted to the input.

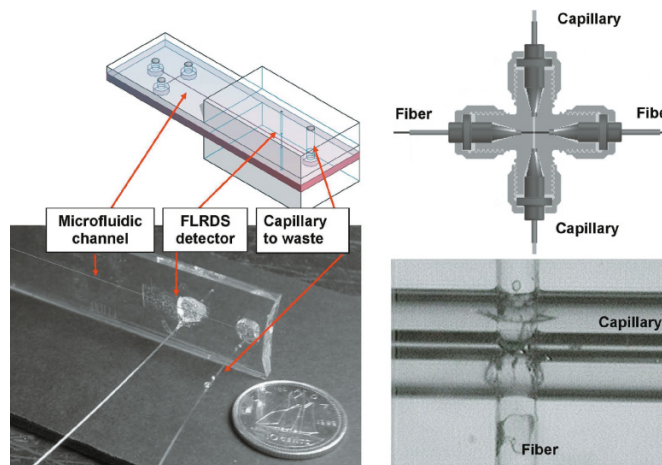

suited for transient absorption detection in low finesse optical cavities.<sup>32</sup> Phase-shift CRD is compatible with short ring-down times, since the modulation frequency may be set to the inverse of ring-down times. Changes in ring-down time as low as a few nanoseconds and picoseconds are readily measurable. Also, the duty cycle of the phase-shift measurement is unity, i.e., there is always light in the cavity. The readout rate is limited only by the ring-down time; “on the fly” exponential fitting is no longer required. Finally, phase comparators are also comparably inexpensive; simple integrated circuits with a  $1^\circ$  resolution may be bought for a few dollars.

Unfortunately, the ring-down times calculated from phase angles are sensitive to scattered light and are also less accurate compared to an exponential fit to a 10 000 point decay trace. Nevertheless, for our applications, the advantages, especially regarding data acquisition rate and cost, outweigh the disadvantages, and in all setups described below, the phase-shift CRD method was employed.

### Fiber-loop ring-down absorption detection

In a 2006 article, we presented three different interfaces between the fiber loop and the flow systems.<sup>33</sup> In one device, a commercial microcross was used to achieve fair coupling of light between the two ends of the fiber loop, which were fixed at a distance of 5–50  $\mu\text{m}$  from each other.<sup>34</sup> Two capillaries were inserted orthogonal to the optical fibers and used to flow samples of cyanine dyes in water between the fiber ends (Fig. 3). A detection limit of 200  $\mu\text{mol/L}$  corresponded to a minimal detectable absorption loss,  $\alpha_{\min}$ ,  $< 50 \text{ cm}^{-1}$ . The flow rate of 10  $\mu\text{L/min}$  and injection

**Fig. 3.** Three interfaces of the fiber loop with a fluidic system. Left: a microfluidic chip into which the fiber loop is inserted; right top: a commercial microcross with the fiber ends and capillary ends inserted normal to each other; right bottom: a 300  $\mu\text{m}$  capillary through which a hole was drilled to insert the two fiber ends. The fiber ends have hemispherical lenses at their ends.

volume of 2  $\mu\text{L}$  are compatible with capillary electrophoresis or micro-HPLC, but unfortunately, the limit of detection (LOD) is too large to be competitive with existing detection methods. Because it is difficult to optimize the optical alignment of the fibers in a microcross and thereby increase the sensitivity, we decided to use a second approach.

A 360  $\mu\text{m}$  capillary (ID: 100  $\mu\text{m}$ ) was embedded in a block of polymethyl methacrylate (PMMA) and a 150  $\mu\text{m}$  hole was drilled through the block and normal to the long axis of the capillary (Fig. 3, right bottom). The fiber ends were inserted to be flush with the inside wall of the capillary and about 60  $\mu\text{m}$  apart and then fixed using epoxy glue. The LOD was improved over the microcross to 50  $\mu\text{mol/L}$  ( $\alpha_{\min} = 10 \text{ cm}^{-1}$ ). The detection limit and sensitivity could be further improved by using hemispherical fiber ends instead of flat fiber end faces. This dramatically increases the coupling efficiency across the sample gap from 60% to about 90%.<sup>33</sup> To create hemispherical lenses, we heated the fiber ends in the electric arc of a fusion splicer.<sup>35</sup> The fiber ends were then inserted as before and placed 30  $\mu\text{m}$  apart before being glued in place. Using lensed fiber ends, the LOD was improved to 10  $\mu\text{mol/L}$  ( $\alpha_{\min} = 1.6 \text{ cm}^{-1}$ ) and protein detection became feasible.

A third interface was created to a microfluidic chip made of glass. Again, the flow channel was first sealed and encapsulated in PMMA and then a 150  $\mu\text{m}$  hole was drilled mechanically perpendicular to the channel. The flat-cut fiber ends were inserted and fixed at a distance of 14  $\mu\text{m}$ . The LOD of 30  $\mu\text{mol/L}$  ( $\alpha_{\min} < 10 \text{ cm}^{-1}$ ) was respectable, especially considering the short absorption path and the small detection volume of 700 pL. Note that the absolute quantity of detected analyte was only 21 fmol at the detection limit.<sup>33</sup>

All experiments above were conducted at 800 nm, i.e., a wavelength that was matched to the absorption maximum of the cyanine dye. At this wavelength, the fiber optic loss is quite low (3 dB/km) and the photomultiplier tubes used to detect scattered light from the loop show high sensitivity. Of course, a practical absorption detector for capillary elec-

trophoresis, microfluidics, or micro-HPLC needs to work at much shorter wavelengths. Because standard fiber optic cables have much reduced transmission at wavelengths shorter than 500 nm, it was believed that fiber-loop ring-down detection is not feasible at the important blue and UV wavelengths.

With recent advances in UV fiber optic materials, fiber CRD detection has now become possible, and in a recent publication we demonstrated the quantification of tartrazine dye, of myoglobin protein, and of a proprietary pharmaceutical ingredient using phase-shift fiber-loop ring-down detection at 405 nm.<sup>36</sup> The experiment was possible because of the low loss of the UV fiber optic loop ( $\alpha = 0.011 \text{ cm}^{-1}$ ) and of a specially designed fiber-optic-fluid interface (shown in Fig. 4), that combined a small detection volume (6 nL) with an even smaller dead volume (estimated at <2 nL). At the same interface, light from the 405 nm laser diode was introduced using a power delivery fiber that irradiated the gap between the fiber ends and thereby allowed for scattered blue light to enter the loop (Fig. 4). Despite the fact that the fiber ends were not lensed and comparatively far apart (190  $\mu\text{m}$ ), the detection limit is improved to 1  $\mu\text{mol/L}$  for myoglobin (Fig. 5) and the minimum detectable absorption loss is lower compared to our best earlier interface by almost an order of magnitude ( $\alpha_{\text{min}} = 0.11 \text{ cm}^{-1}$ ). This is likely due to the improved alignment between the fiber ends and the larger fiber core diameter, both leading to lower optical losses across the sample gap. More importantly, it is likely that the same setup will perform well at even shorter detection wavelengths and we plan to couple light from a 255 nm LED into the fiber loop in the near future.

With the interface displayed in Fig. 4, the detection of single micron-sized particles is also possible. The Mie scattering cross section increases with decreasing scattering wavelength and even the detection of transparent particles is possible if their refractive index differs by more than about 0.15 from the solvent. Indeed, we were able to detect single polystyrene particles of 5  $\mu\text{m}$  diameter that were suspended in water using a detergent (Fig. 5). Since these particles are comparable in size and refractive index to *Escherichia coli* cells, we expect that cytometry and single cell pathogen detection should be feasible using this very inexpensive and compact setup. Earlier experiments with an interface that was far from optimized and the 810 nm detection wavelength were conducted, and showed detection of yeast cells and *E. coli* cells, but not, yet, at the single cell level.<sup>37</sup>

### Microsphere ring-down absorption detection

While the fiber loop is a “long roundtrip/low finesse” optical cavity, microresonators are optical cavities with very high finesse and extremely short roundtrip paths of typically less than a millimetre.<sup>38–41</sup> Microsphere resonators (shown schematically in Fig. 1d) have been used as chemical sensors for many years.<sup>42–52</sup> Light can be coupled tangentially into such a sphere, such that it travels along the “equator”. This so-called “whispering gallery mode (WGM)” can only be excited if the circumference of the sphere is an integer multiple of the excitation wavelength, and if the mode field

**Fig. 4.** Computer rendering of the optical–fluidic interface. The delivery fiber in the foreground illuminates the fiber gap. Capillaries attached to the top and bottom plate feed sample solution through small holes in front of the delivery fiber and out through a hole in the bottom plate.

**Fig. 5.** Detection of transparent 5  $\mu\text{m}$  diameter polystyrene particles (top trace) and detection of myoglobin in buffer solution at 405 nm (bottom) using the interface shown in Fig. 4.

of the whispering gallery mode overlaps with the mode field of the delivery waveguide. A whispering gallery mode can remain localized near the equator of the sphere for a very long time; in an analogy to the acoustic equivalent in the “whispering gallery” of, say, St. Paul’s Cathedral in London. Much like the sound of a whispered voice is guided along the inside of the Cathedral’s dome, light remains guided by total internal reflection. Light may be coupled into the sphere using, for example, tapered fibers (as we have done),<sup>53</sup> evanescent-field access blocks, angled fiber ends, or regular prisms.<sup>40</sup>

Refractive index measurements of analytes adsorbed on such microresonators are comparatively straightforward WGM frequency measurements. Since microresonators are very short, high-finesse cavities; they exhibit a sharp cavity mode spectrum, which depends strongly on the roundtrip length of the whispering gallery modes. The frequency of each WGM is, of course, influenced by the size of the microsphere, i.e., the circumference at the equator, but also by temperature and the refractive index of the immediate environment of the sphere. A thin layer of analyte adsorbed on the surface will effectively increase the circumference of the sphere. Of course, such an adsorbate may also attenuate the WGM intensity and reduce the number of roundtrips that one WGM experiences. Both quantities, the refractive index of the environment and its optical absorption, can therefore be obtained *simultaneously* from the frequency shift of the cavity fringes, and from their associated ring-down time, respectively.<sup>54</sup> Below, we intend to illustrate that such combined absorption and refractive index measurements using silica microsphere resonators are sensitive, but also quite simple.

In separate setups, silica resonators have already demonstrated superb performance for the measurements of both the refractive index and the optical absorption of adsorbed analytes. For example, researchers have used a toroidal microresonator to demonstrate the detection of a single interleukin-2 molecule through a combination of the induced refractive index change and optical absorption of the adsorbed molecule leading to heating and expansion of the sphere, the so-called thermoptic effect.<sup>52</sup> Simultaneous absorption and refractive index measurements of a few monolayers of an adsorbed species are easily feasible.<sup>55</sup> On the other hand, compared to the thermo-optic effect, cavity ring-down experiments provide a more direct measure of the optical absorption of an adsorbed layer but have, to our knowledge, not yet been used in chemical measurements. They were used, however, in characterizing the optical loss in microresonators. For example, Vahala and co-workers<sup>56</sup> conducted the CRD measurement in the time domain and obtained ring-down times of 43 ns for a 90  $\mu\text{m}$  diameter microresonator. The submicrosecond ring-down time highlights the fact that the roundtrip path for such devices is typically less than one millimetre and only about 280  $\mu\text{m}$  in this particular case. It is probably because of the short ring-down times, even for microresonators having a high finesse, that they have been used almost exclusively for refractive index measurements but not for absorption measurements.

On the other hand, a “large” square quartz monolith (7.5 mm  $\times$  7.5 mm  $\times$  5 mm) has been used as a high finesse cavity by Pipino<sup>57</sup> in 1999 and CRD absorption detec-

tion of 0.006% of a monolayer of  $\text{I}_2$  on the quartz surface was realized. Ring-down times of over a microsecond gave a finesse of over 12 500!

The finesse of the 300  $\mu\text{m}$  diameter silica microsphere cavities used in our group is between  $F = 5\,000$ – $100\,000$  and the ring-down times are correspondingly on the order of 4–70 ns, meaning that they will have to be measured with a resolution of picoseconds.

As in the fiber loop experiments, measurements of fast ring-down events at a high duty cycle may be achieved cost efficiently and simply through phase-shift CRD. By setting the modulation frequency,  $\omega = 1/\tau$ , we achieve optimal sensitivity to phase angle changes irrespective of the finesse or ring-down time of the cavity. While their appearance is very different, these microresonators show very similar behaviour compared to “regular” ring-down cavities consisting of two or more mirrors and to the above fiber-loop cavities. For example, in all three types of cavities the overall cavity loss depends on the losses inside the cavity medium *and* the losses that occur when light is coupled in and out of the cavity. The whispering gallery mode can interact with the sample through its evanescent field, i.e., the small part of the mode field that is located *outside* the sphere and decays exponentially over the distance of only a few 100 nm.

Recently, our group has demonstrated phase-shift CRD measurements on a 300  $\mu\text{m}$  microsphere and determined the attenuation that a WGM experiences.<sup>58</sup> In the following, we briefly describe the optical setup and highlight the theoretical and analytical aspects of this work.

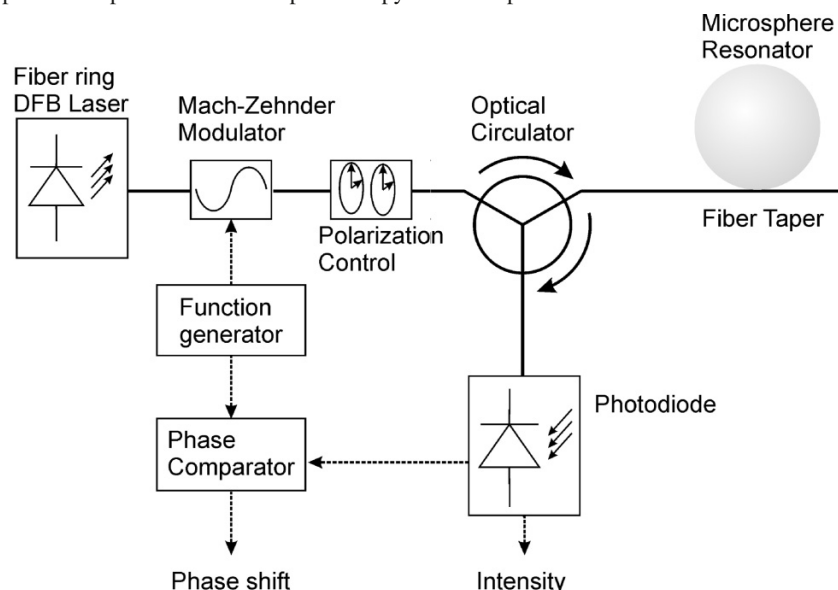

The silica microspheres were formed by fusing the end of a single-mode optical fiber (Corning, single mode fiber, SMF-28) to obtain a sphere with a nominal diameter of about 300  $\mu\text{m}$ . The residual optical fiber stem allows for manipulation and positioning of the microsphere. A tapered single-mode optical fiber, with a waist diameter of about 3–4  $\mu\text{m}$ , was used to couple light into the evanescent field of the microsphere WGM (Figs. 1 and 6). A detailed description of the experimental setup regarding the microsphere and tapered waveguide may be found elsewhere.<sup>53</sup>

Two different lasers were used. A tunable diode laser (Ando AQ 4320D, power: 3 mW) with a linewidth of about 200 MHz was used to optimize the coupling into the sphere and conduct proof-of-concept measurements of the phase angle associated with ring-down events on selected WGMs. An Er-doped fiber-ring DFB laser (Koheras Adjustik E15, linewidth < 1 kHz, power: 100 mW) was employed to interrogate the microsphere when ethylene diamine was deposited onto its surface.

The laser output was sinusoidally intensity modulated using a Mach–Zehnder modulator (JDS Uniphase) up to a modulation frequency of 2 MHz. A polarization controller, positioned after the modulator, allowed the TE and TM resonator modes to be selectively excited, although we were not able to distinguish between these two polarization states. Rayleigh back-scattering from imperfections in the silica microsphere quickly equilibrates degenerate counter-propagating cavity modes.<sup>59</sup> In our previously published work, WGM resonances were observed as dips in the delivery fiber transmission spectrum and as intensity peaks in the scattering spectrum from the microsphere. We also derived expressions (valid for angular modulation frequencies,  $\omega$ ,

**Fig. 6.** Scheme of the setup used for phase-shift CRD spectroscopy of microsphere resonators.

that are much lower than the carrier frequency) for the phase shifts that can be observed by recording the intensity modulated signal of the light transmitted through the fiber taper, and of the light scattered from the sphere.

$$[4] \quad \Delta\phi_{\text{trans}} \approx -\frac{2\omega n_{\text{eff}}L}{c} \frac{2\ln(\Gamma)}{(\ln\Gamma)^2 - (\alpha L/2)^2}$$

$$\Delta\phi_{\text{scatter}} \approx -\frac{2\omega n_{\text{eff}}L}{c} \frac{1}{-2\ln\Gamma + \alpha L}$$

Clearly, the two phase angles have a different dependence on the optical coupling,  $\Gamma$ , between the fiber and the resonator and the optical loss,  $\alpha L$ , of the WGM. Since both phase angles may be recorded simultaneously, we can obtain values for both  $\Gamma$  and  $\alpha L$  for each WGM. As for “regular” cavities, it is possible to transfer nearly all the power into the cavity, i.e., at “critical coupling”. This condition is achieved, here, when  $\Gamma_{\text{critical}} = 0.9998$  and  $\alpha_{\text{critical}} = 0.43 \text{ m}^{-1}$ . At this point, the phase angle of the transmitted light is infinite, and the intensity carried by the fiber taper drops to zero. Phase-angle measurements of the transmitted light are therefore biased to detect WGMs near critical coupling, whereas for scattered light, WGM with the lowest total loss ( $-\ln\Gamma + \alpha L$ ) show the largest phase angles.

With  $-\ln\Gamma$  and  $\alpha L$  one can easily calculate the nominal ring-down time

$$[5] \quad \tau = \frac{n_{\text{eff}}L}{c(-\ln\Gamma^2 + \alpha L)}$$

For the four WGMs that were investigated, we obtained  $\tau = 4 \text{ ns}$  to  $8 \text{ ns}$ , corresponding to quality factors (Q factors) of the order of  $10^6$ – $10^7$ . Most importantly for chemical detection, the attenuation term,  $\alpha$ , will change when an analyte is adsorbed to the microresonator surface and absorbs (or scatters) the WGM.

While the scattered light in previous work was collected through a microscope lens placed above the sphere, we also recorded WGM resonances that were detected through Rayleigh backscattered light. Conveniently, the Rayleigh

backscattered counterpropagating modes are partly coupled back into the delivery waveguide. A fiber optic circulator, positioned before the polarization controller, extracted the backscattered light and directed it to a fiber-coupled, 6 GHz bandwidth InGaAs detector (Thorlabs, Inc. SIR5). A radio-frequency lock-in amplifier (Stanford Research Systems Model SR844) processed the detector output, providing, simultaneously, an intensity and a phase-angle measurement that was referenced to the laser modulation. As the narrow band-width laser was slowly scanned, the lock-in amplifier’s outputs of intensity and phase shift were recorded. The entire optical setup was placed under a Plexiglas™ enclosure and purged with dry nitrogen to reduce contamination. Dry nitrogen was also used to sweep ethylene diamine (Sigma-Aldrich, used without purification) vapour from a flask into the plastic enclosure, with a partial pressure of about 10 Torr. Once a suitable shift in the WGM resonance was observed, the dosing was stopped and the chamber sealed. Ethylene diamine could be removed from the microsphere by purging the chamber with a continuous flow of dry nitrogen.

The presence of ethylene diamine in the vicinity of the silica microsphere surface manifests itself in two ways: through a shift in the cavity resonance position to longer wavelength and through a reduction in the optical lifetime (ring-down time) of the mode. Experimental results are shown in Figs. 7 and 8. The reduction of the ring-down time is also responsible for the decreased amplitude and larger linewidth in the phase-shift spectrum (Fig. 7). The magnitude of the phase shift has been measured for a number of modulation frequencies.

Previously, it has been shown that ethylene diamine adsorbs strongly to silica through interactions with surface silanol groups.<sup>60</sup> We assume, in our case, that the observed perturbations of the cavity resonance are due to adsorbed ethylene diamine, rather than vapour, by virtue of the method by which the compound was introduced. This assumption was confirmed in, as yet, unpublished calculations.

Arnold et al.<sup>43</sup> have derived an expression describing the wavelength shift of a WGM due to molecules adsorbed on a

**Fig. 7.** Redshift of the whispering gallery mode resonance at  $1.56\ \mu\text{m}$  (dashed red line) upon adsorption of ethylene diamine on the microsphere resonator (solid black). The phase shift was recorded at a modulation frequency of  $\omega = 3.77 \times 10^6\ \text{rad/s}$ .

**Fig. 8.** Phase shift of the Rayleigh backscattered light from the microsphere resonator as a function of modulation frequency measured with respect to the forward propagating modes. Due to the increased loss upon adsorption of ethylene diamine (black squares), the ring-down time, i.e., the slope, decreases.

microsphere surface. In our experiment, the observed shift of the WGM resonance upon dosing the microsphere with adsorbate was  $12.8 \pm 0.2\ \text{pm}$  from which a coverage of about 3 monolayers may be estimated using the polarizability of bulk ethylene diamine. Since water vapour is ubiquitous and is also strongly adsorbed on silica, the measured surface concentration of ethylene diamine also indicates that water has been displaced by ethylene diamine.

The surface coverage can also be obtained from the absorption measurement, i.e., from the decrease in phase shift (ring-down time) as the ethylene diamine concentration increases. For a single exponential decay, the phase shift of the intensity-modulated light is related to the ring-down time,  $\tau$ , by eq. [3]. From Fig. 8, the ring-down times with and without ethylene diamine present are  $\tau = 68 \pm 7\ \text{ns}$  and  $\tau_0 = 44 \pm 4\ \text{ns}$ , respectively. Note that this WGM has much lower loss compared to the WGM described previously by

our group.<sup>58</sup> From the ring-down times and using an estimate of the fraction of the evanescent field that can interact with the adsorbed layer, it is possible to again estimate the surface coverage of ethylene diamine as about seven monolayers using the absorption coefficient of bulk ethylene diamine (EDA).

The discrepancy of the value obtained through phase-shift CRD absorption, three monolayers ( $\Sigma_{\text{EDA}} = 3.6 \times 10^{15}\ \text{cm}^2$ ) with the value of seven monolayers ( $\Sigma_{\text{EDA}} = 1.5 \times 10^{15}\ \text{cm}^2$ ) that was obtained using the wavelength shift of the same WGM may be attributed to either a decrease of the ethylene diamine polarizability and (or) an increase of the absorption cross section of ethylene diamine compared to the bulk liquid. This is not surprising as it is well-known that the mid-infrared absorption cross section of ethylene diamine at silica surfaces is markedly higher than that of the bulk liquid.<sup>60</sup> Also, the alignment of the surface complex is normal to the sphere surface and is expected to cause further deviations of the absorption cross section and polarizability from the bulk liquid ethylene diamine values, both of which were obtained in isotropic samples.

In any case, it is possible to estimate the detection limit for the phase-shift CRD microsphere resonator detector. For our particular setup and WGM, we can measure a 10% change of the ring-down time (corresponding to best-fit errors of Fig. 8), and can therefore detect a surface coverage of  $\Sigma_{\text{EDA}} = 6.5 \times 10^{14}\ \text{cm}^2$  corresponding to less than 1.5 monolayers.

Future work will focus on improving this detection limit by using lasers with narrower line widths. Also, a careful survey of the WGM spectrum may yield better suitable WGM with higher Q factors. Finally, we require independent measurements of the surface refractive index and absorption of ethylene diamine to quantify the surface concentration with higher accuracy. Similar measurements should also be possible at different wavelengths, e.g., in the visible region of the spectrum or even in the mid-infrared region given the availability of narrow band lasers and waveguide materials.

While microsphere resonators are well-suited for the optical characterization of thin films, it would be much more difficult to use the optical cavity itself as a tool for chemical identification. Overtone absorption and refractive index of the film are both “broad band” spectroscopic features that carry little information on the exact identity of the chemical composition of the film. Chemical (bio-) detection of targeted molecules is possible, however, by functionalizing the surface such that the analyte of interest adsorbs and then interacts with the optical cavity.

## Conclusions

With this presentation, we intended to show the potential and limitations of two rather exotic applications of absorption spectroscopy. We concentrated this discourse on simple absorption measurements, but it is easily demonstrated that the fiber-loop ring-down method also has other applications, such as the measurements of refractive indices,<sup>61</sup> of loss in fiber optic components, of strain, temperature and pressure.<sup>62–64</sup> Here, the sensitivity of fiber optic devices such as

fiber Bragg gratings and long-period gratings to environmental parameters may be exploited.

Similarly, one can functionalize the surface of microspheres to obtain selectivity to analytes of interest. Refractive index measurements combined with thermooptic response of the cavity have already led to the detection of a single interleukin-2 molecule on silica microtoroid resonator.<sup>52,55</sup> Direct absorption measurements on functionalized spheres have not yet been conducted but are certainly in the realm of phase-shift CRD.

While it appears that CRD absorption measurements using waveguide loops or microresonators are only of limited use for measurements of trace gas concentrations (the strength of mirror-based CRD spectroscopy), and of "large liquid volume" absorption spectroscopy (the strength of direct absorption), the methods may evolve into a useful tool for the measurements of the absorption of small liquid volume and small amounts of adsorbed substances.

## Acknowledgements

The results shown in this presentation are the result of collaborative research initiatives that involved the groups of Professors Brown, Crudden, and Oleschuk (Queen's Chemistry), of Professor Fraser (Queen's Physics), and of Professor Yam (Electrical Engineering). We are particularly indebted to Professor Stephen Brown, who is the co-inventor of the original fiber-loop ring-down technique.

Many gifted students and postdoctoral fellows contributed to the experimental results that were presented here. Of those, we thank especially Zhaoguo Tong, Nicholas Trefiak, Jun Zhang, Mark Wilson, and Klaus Bescherer for their dedication and insights.

Funding for this work was provided by Queen's University, the Province of Ontario (Premier's Research Excellence Award, Photonics Research Ontario, Ontario Centres of Excellence), Canada (Natural Sciences and Engineering Research Council, Canadian Institute for Photonic Innovations), the Consiglio Nazionale delle Ricerche (CNR), Italy, and from industrial partners (Eli-Lilly Canada, PARTEQ Innovations, ITF Labs, Avensys Labs). GG acknowledges financial support by CNR RSTL project and Italian Ministry of Education, University and Research PON project. Finally, HPL thanks MDS Sciex for sponsoring the W.A.E. McBryde Medal and for their support of analytical chemistry research in Canada.

# ATRP grafting of oligo(ethylene glycol) methacrylates from gold surface — Effect of monomer size on grafted chain and EO unit densities

Zhilin Jin, John L. Brash, and Shiping Zhu

**Abstract:** Oligo(ethylene glycol) methacrylate (OEGMA) was grafted from Au surface via surface-initiated atom-transfer radical polymerization (s-ATRP). The initiator density was adjusted by the mole fractions of surface-attachable ATRP initiator and diluting agent. Three OEGMA monomers of  $M_r$  300, 475, and 1100 were used. The Au surfaces before and after modification were characterized by water contact angle and ellipsometry. The effect of monomer  $M_r$  and initiator density on surface chain density and EO unit density was investigated. It was found that at low initiator density (mole fraction of initiator of 2%–5%), poly(OEGMA) grafts had comparable surface chain density independent of OEGMA  $M_r$ . However, at high initiator density (mole fraction of initiator >10%), poly(OEGMA)<sub>1100</sub> had obviously lower chain densities than poly(OEGMA)<sub>300</sub> and poly(OEGMA)<sub>475</sub>, which could be attributed to the size difference of the monomers. The short chain length and low surface chain density of poly(OEGMA)<sub>1100</sub> resulted in its relatively low surface EO unit density.

**Key words:** Au surface, poly(ethylene glycol), atom transfer radical polymerization (ATRP), grafting, surface chain density, surface EO unit density, monomer  $M_r$ .

**Résumé :** On a greffé du méthacrylate d'oligo(éthylèneglycol) (MAOEG) sur une surface d'or par le biais d'une polymérisation radicalaire par transfert d'atome initié par la surface (PRTA-s). La densité de l'initiateur a été ajustée par les fractions molaires de l'initiateur de la PRTA qui peuvent être attachées à la surface et l'agent diluant. On a utilisé trois MAOEG de  $M_r$  300, 475 et 1100. On a caractérisé les surfaces d'or avant et après modification par l'angle de contact de l'eau et par ellipsométrie. On a étudié l'effet du poids moléculaire du monomère et la densité de l'initiateur sur la densité de la chaîne en surface et sur la densité de l'unité d'oligoéthylèneglycol. On a trouvé que pour des densités d'initiateur faibles (fraction molaire d'initiateur allant de 2 % à 5 %), la densité de chaîne en surface des greffes est indépendante du  $M_r$  du MAOEG. Toutefois, à des densités d'initiateur plus élevées (fraction molaire d'initiateur supérieure à 10 %), les densités de chaîne du poly(MAOEG)<sub>1100</sub> sont évidemment plus faibles que celles des poly(MAOEG)<sub>300</sub> et poly(MAOEG)<sub>475</sub> et cette situation peut être attribuée à une différence dans la taille des monomères. La courte longueur de la chaîne et la faible densité de la chaîne de surface du poly(MAOEG)<sub>1100</sub> résultent de la densité relativement faible de l'unité d'oligoéthylèneglycol.

**Mots-clés :** surface d'or, poly(éthylèneglycol), polymérisation radicalaire par transfert d'atome (PRTA), greffage, densité de la chaîne en surface, densité de l'unité d'oligoéthylèneglycol,  $M_r$  du monomère.

## Introduction

Poly(ethylene oxide) (PEO)- and oligo(ethylene glycol) (OEG)-containing polymers (e.g., poly(oligo(ethylene glycol) methacrylate) (poly(OEGMA))) have attracted much attention as a biomaterial coating because of its high ability to resist non-specific protein adsorption, biofouling, and its high biocompatibility.<sup>1</sup> It has been shown that many factors, including PEO chain length, surface chain density, polymer conformation, and surface EO unit density, have strong effects on the protein-resistant and biocompatible perform-

ance.<sup>2–4</sup> However, details of these effects are still a matter of debate. A significant barrier to elucidate these factors to protein resistance and (or) biocompatibility is the lack of techniques to control and accurately measure these properties.

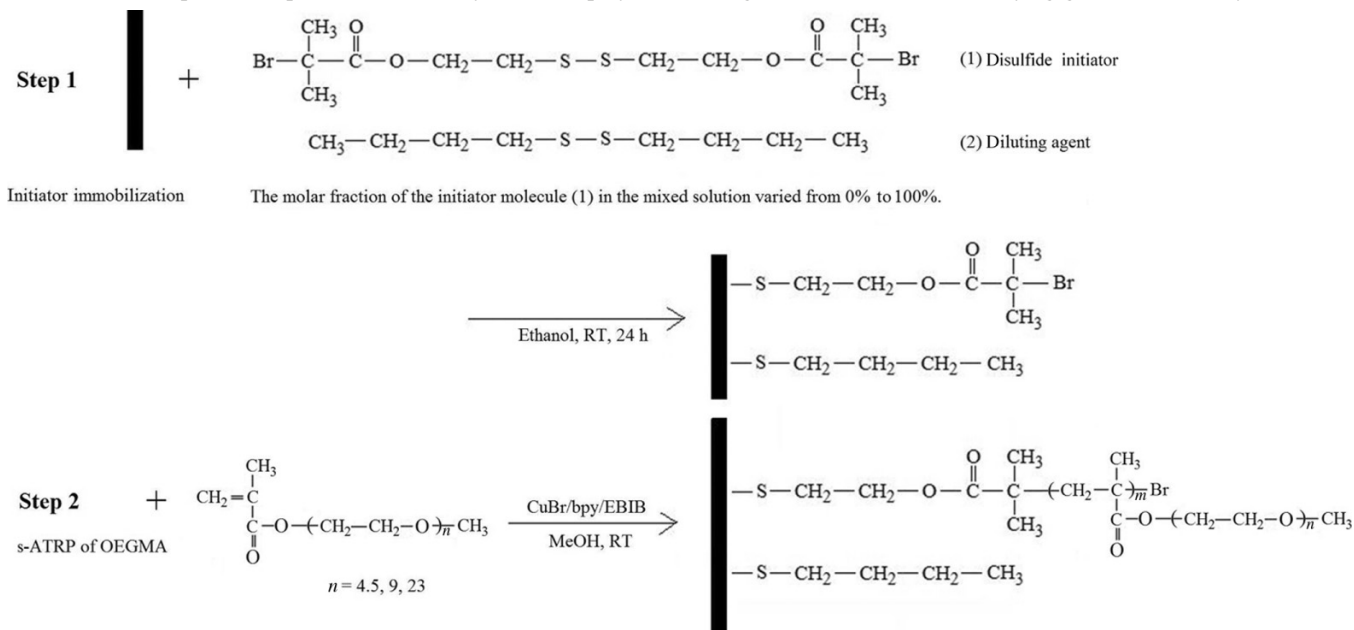

The recent development of atom-transfer radical polymerization (ATRP) method provides a facile way to achieve uniform and tunable graft chain length on surface.<sup>5–8</sup> It has also been found that chain density of polymer grafts can be varied by adjusting the initiator density on surface,<sup>9,10</sup> and

the monomer size has an effect on the polymer chain density formed via surface-initiated ATRP (s-ATRP).<sup>11</sup> Recently, the surface-initiated ATRP of PEO-containing molecules (such as OEGMA) has been performed on well-defined model substrates, such as silicon and gold,<sup>9,10</sup> which allow relatively accurate characterization of polymer grafts via ellipsometry and (or) AFM compared with other substrates, such as polymeric substrates. However, there is very little work where surface chain density and surface EO unit density are finely tuned by varying monomer  $M_r$  and initiator density, and where the effect of monomer  $M_r$  and initiator density was systematically studied.

In this study, oligo(ethylene glycol) methacrylate (OEGMA) was grafted from Au surface via s-ATRP with various initiator densities and three OEGMA monomers of  $M_r$  300, 475, and 1100 (equivalent to 5, 9, and 23 ethylene oxide residues, respectively). The effect of monomer  $M_r$  and initiator density on surface chain density and surface EO unit density was investigated.

## Experimental

### Materials

Gold-coated silicon wafers (500  $\mu\text{m}$  thickness, 100 mm diameter, Au coating layers of 100 nm thickness on both sides) were purchased from SVM (Silicon Valley Microelectronics, Inc.) and cut into 5  $\times$  5 mm pieces using a Micro Ace Series 3 dicer (Loadpoint Ltd., England). Hydrogen peroxide (30%), ammonia solution (30%), and methanol (HPLC grade) were obtained from Caledon Laboratories LTD and used as received. Bis[2-(2'-bromoisobutyryloxy) ethyl] disulfide (the structure shown in Scheme 1) was purchased from ATRP Solutions, Inc. and used as received. Butyl disulfide (97%), ethyl 2-bromoisobutyrate (EBIB) (98%), 2,2'-bipyridyl (bpy) (99%), and  $\text{Cu}^{\text{I}}\text{Br}$  (99.999%) were purchased from Sigma-Aldrich and used as received. OEGMAs with molecular weights ( $M_r$ ) of 300, 475, and 1100 were purchased

from Sigma-Aldrich and passed over a basic alumina column to remove inhibitor. Basic alumina (Brockman Activity 1, mesh 60–325) was purchased from Fisher Scientific and used as received. Deionized water used in this study had a resistivity of 18.2  $\text{M}\Omega\text{cm}$  and nitrogen gas was of ultrahigh-purity (UHP) grade.

### Pretreatment of Au surfaces

Gold-coated silicon chips (5  $\times$  5 mm) were immersed in a 1:1:5 solution of hydrogen peroxide:ammonium hydroxide:water at 80  $^{\circ}\text{C}$  for 5 min, sonicated for 1 min, and rinsed in deionized water to remove any carbonaceous contamination. After cleaning, the gold-coated chips were either used immediately for the formation of the initiator self-assembled monolayer (SAM) or stored in ethanol at room temperature.

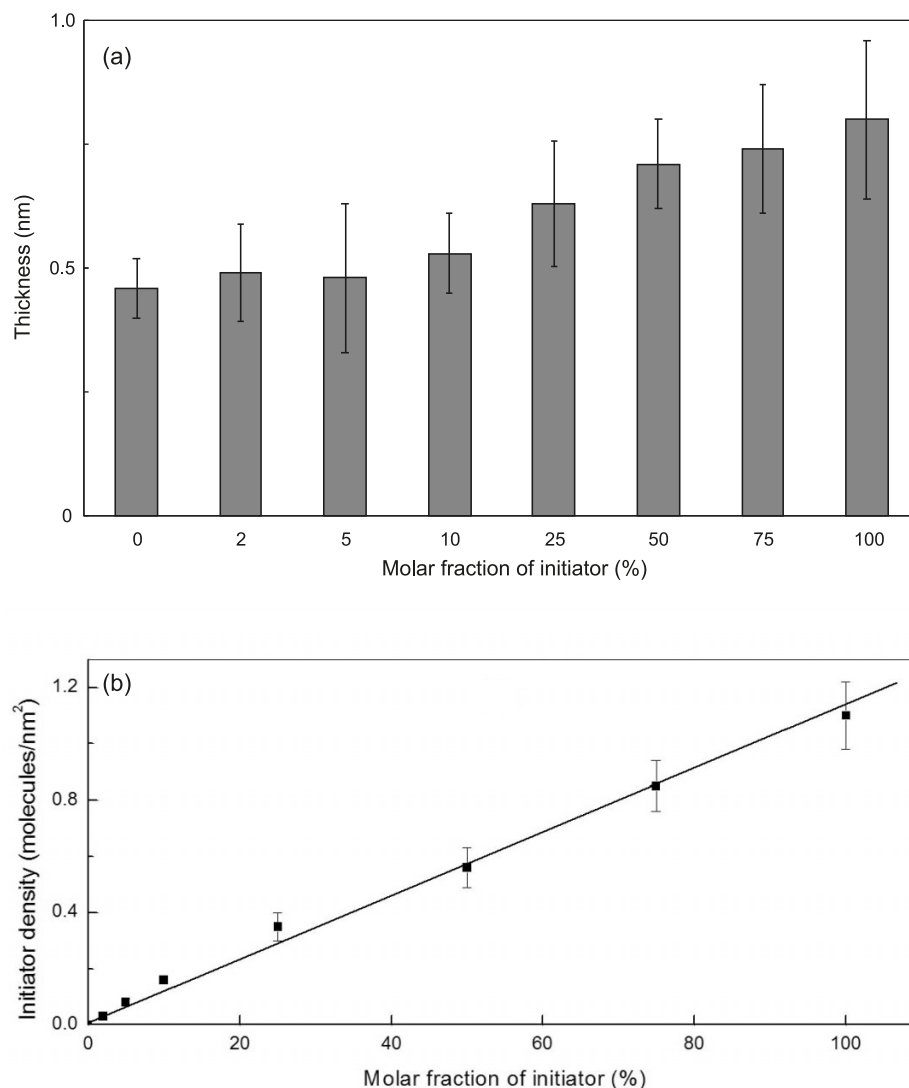

### Formation of initiator monolayer on Au surfaces

The self-assembled monolayer (SAM) of initiator was formed by soaking the freshly cleaned gold-coated chips in an ethanol solution (total concentration: 1 mmol/L) containing disulfides for 24 h without stirring at room temperature. The mixed disulfide solution contained bis[2-(2'-bromoisobutyryloxy) ethyl] disulfide (the initiator molecule **1** in Scheme 1) and butyl disulfide as a diluting agent. The mole fractions of the initiator varied from 0% to 100%. The surfaces were removed from the solution, cleaned ultrasonically for 1 min in pure ethanol, rinsed with THF, and then dried in a nitrogen stream. The gold surfaces with SAMs (referred to as Au/initiator) were either used immediately or stored in glass tubes under nitrogen at room temperature.

### s-ATRP of OEGMA from initiator-functionalized gold surfaces

Poly(OEGMA)s with various side-chain lengths (EO units) or monomer  $M_r$  values (300, 475, and 1100) were grafted from the Au/initiator surfaces via s-ATRP. The detailed procedure was described previously.<sup>12,13</sup> EBIB

was used as a sacrificial initiator. The monomer concentration was fixed at 38% w/v and the molar ratio of OEGMA:EBIB:Cu<sup>I</sup>Br:bpy was 100:1:1:2, with methanol as solvent. 10 g OEGMA was used in an s-ATRP process with 40 pieces of gold-coated chips. The s-ATRP process was performed under nitrogen at room temperature for 48 h. The surfaces were then cleaned ultrasonically for 1 min in methanol, rinsed with methanol, and then dried in a nitrogen stream.

### Characterization

$^1\text{H}$  NMR spectroscopy (Bruker AC-P200 spectrometer, D<sub>2</sub>O solvent) was used to determine OEGMA conversion in the s-ATRP reactions. Gel permeation chromatography (GPC, Waters 2690 separations module with a Waters 2410 refractive index detector, PEO calibration standards) was used to determine the molecular weight and polydispersity index (PDI) of poly(OEGMA) formed in solution. Water contact angle measurements were performed on the gold surfaces

**Fig. 2.** Water contact angles (advancing) of poly(OEGMA)-grafted Au surfaces. The surfaces are named by the mole fraction of initiator (%) (first number) and the monomer  $M_r$  (second number). Error bars represent one standard deviation,  $n = 4$ .

with a Rame-Hart NRL goniometer (Mountain Lakes, NJ) at room temperature, using the sessile drop method.
