Résumé : On a fait appel à des méthodes de la fonctionnelle de la densité (B3LYP, B3PW91, B3P86, MPWB95) et on a utilisé des méthodes avec des ensembles de base 6–31G** et des bases complètes pour étudier les énergies de dissociation de liaisons (EDL) O–NO_2 pour des composés sept *O*-nitroalcools en solution dans l'acétonitrile. On a aussi utilisé les méthodes B3LYP/6–31G**, (RO)B3LYP/6–311++G(2df,2p) et B3LY/6–311G(d,p). Par comparaison avec les données expérimentales, la méthode B3LYP/6–31+G** est la plus précise pour calculer des valeurs fiables pour les EDL des composés étudiés. On a analysé les effets de substituants sur les valeurs de EDL O–NO_2. On a observé que les groupes électro-attracteurs augmentent la valeur des EDL du produit de base alors que les groupes électro-répulsifs diminuent les valeurs de EDL du produit de base. De pus l'analyse des orbitales naturelles de liaison montre qu'il existe une bonne corrélation linéaire entre $E^{(2)}$ et les constantes de Hammett, l'EDL et la différence des énergies de stabilisation du deuxième ordre $E^{(2)}$ de $1pO_3 \rightarrow BD^*(O_1–N_1)$ et $1pO_3 \rightarrow BD^*(O_2–N_1)$.

Mots-clés : théorie de la fonctionnelle de la densité, modèle du continuum polarisé, composés *O*-nitroalcools, énergie de dissociation de liaison, analyse de l'orbitale naturelle de liaison.

Introduction

In the last two decades, the chemistry and biochemistry of nitrogen oxides (N*x*O*y*) have regained tremendous research attention,[1] because of the recent discoveries on the significant roles of N*x*O*y* in many important natural processes. Among various kinds of N*x*O*y*, nitric oxide (NO) is one of the smallest known biologically active messenger molecules and it plays key roles in regulating many important physiological functions in living bodies.[2–5] However, the importance of nitrogen dioxide (NO_2) has largely been overshadowed or even overlooked during the same period.

In chemistry, NO_2 is considered a strong oxidant and nitrating reagent for organic synthesis. Recent research shows that NO_2 is found to be associated with many destructive processes in living bodies, and the significant functions of NO_2 and nitrite ion (NO_2^-) in mammalian biology have slowly been accumulated.[6–9] Therefore, the research on the functions of NO_2 and NO_2^- has started to draw increasing attention recently. Espey et al.[10] and Pfeiffer[11] et al. thought that a wide spectrum of diseases is related to the exogenously and endogenously generated NO_2. In addition, NO_2^- plays a crucial role in many NO-mediated processes and gene expression.[12–14]

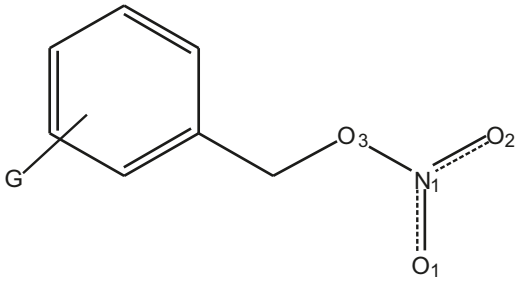
To understand the mechanistic details of NO_2 in chemical or biological processes, the basic information concerning quantitative energetic changes in NO_2-related bond cleavage in solution should be of great value because it provides the necessary information on the thermodynamic driving forces of NO_2 carrier molecules to release, capture, or transfer a NO_2 moiety.[15] The binding force of NO_2 with a particular active site can therefore be represented by the bond energy of the Y–NO_2 type, where Y represents the atom in a carrier to which NO_2 is directly attached. Recently, Li et al.[15] report a series of determined O–NO_2 homolytic bond energies of some *O*-nitroalcohols in acetonitrile solution by using titration calorimetry combined with relevant electrochemical data through proper thermodynamic cycles. The structures of the selected *O*-nitroalcohols are shown in Fig. 1.



Because a rapid cleavage of the Y–NO_2 bond upon one-electron reduction of a nitro compound has been observed for years,[16–18] this kind of bond energy scale should also be useful for the study of the stability and shock sensitivity of the Y–NO_2-type energetic materials[19,20] and for estimating the nitrating ability of nitro-releasing compounds in synthetic chemistry.[21,22] However, our library survey shows that there are very few reports on the bond dissociation energies (BDEs) for the Y–NO_2 bond energies in any solvent system where the NO_2-related chemical and biological activities are likely to take place. If we can find an accurate calculational method to compute the BDEs of the Y–NO_2 bond, it would be possible to use this method to predict those molecules whose experimental BDEs are not available. In addition, the Y–NO_2 bond energy data bank can deepen our understanding of the board range of NO_2-related activities. This has also spurred us to initiate research on the O–NO_2 bond energies of molecules in solution.

Computational methods derived from density functional theory (DFT) are currently more practical for BDE calculation because of their favorable scaling and reasonable CPU cost. Among these DFT methods, B3LYP, B3PW91, and B3P86 are highly popular because of their advantages in BDE calculation. Previous research shows that the C–N BDEs for imidazole derivatives computed by the B3LYP/6–31G** method are in excellent agreement with their experimental values.[23] The B3P86 method revealed the best agreement with available experimental data in predicting the C–NO BDE.[24] Furthermore, Fu et al.[25] computed the BDEs of Y–NO bonds (Y = C, N, O, and S) for X–Y–NO (X = H, CH_3, C_2H_5, OCH_3, $COCH_3$, and Ph) molecules by the B3LYP method.

However, recent studies from a more general perspective demonstrated that these popular DFT methods could tend to underestimate BDEs by 2–6 kcal/mol (1 cal = 4.184 J).[26] Obviously, these failures are due to deficiencies of the approximate exchange-correlation functionality used for different calculating systems. So it is important to shed light on their systematic performance for a particular computational target.

In the present work, our objective was to perform a systematic comparison of the O–NO_2 BDEs of seven *O*-nitroalcohols compounds in acetonitrile solution. All the BDEs were calculated by employing hybrid DFT (B3LYP, B3PW91, B3P86, and MPWB95) methods and the complete basis set (CBS-4M) method. By comparing the calculated results with the available experimental values, a suitable method to compute O–NO_2 BDEs was obtained. The natural bond orbital (NBO) analysis was also performed for the title compounds.

Theory and computational details

All calculations were performed with the Gaussian03 computational package.[27] Geometry optimizations and subsequent normal mode analyses were performed for the products of the different bond scission reactions in which a single NO_2 group was removed from the parent structure. The equilibrium geometries and BDEs were obtained at the Becke-style three-parameter DFT[28] with the Lee–Yang–Parr correlation function(LYP),[29,30] Perdew–Wang's 91 expression (PW91),[31] and Perdew's 86(P86).[32] One recently developed DFT method – one-parameter hybrid meta-GGA functional MPWB95[33] was also used in this paper. All calculations were performed at the 6–31G** basis set. The normal mode analysis for each structure resulted in no imaginary frequencies for the $3N - 6$ vibrational degrees of freedom, where N is the number of atoms in the system. This indicates that the structure of each molecule corresponds to a local minimum on the potential energy surface.

Generally, computed BDEs are reported for gas-phase conditions and it is expected that these values suffer variation in different environments such as those in living organisms. Therefore, it would be interesting to know what happens to these dissociation energies in the presence of a solvent such as acetonitrile.

The polarized continuum model (PCM) developed by Tomasi and co-workers[34–36] was employed. In this PCM model, the atomic radii of the spheres used to build the molecular cavity were adjusted by introducing chemical considerations such as hybridization, formal charge, and first-neighbor inductive effect. The effect of the escaped electronic charge outside the cavity was corrected with an additional set of charges on the cavity surface distributed according to the solute electronic density in each point of the surface.

For the CBS-4M model,[37–39] geometry optimization and zero-point energy computations were carried out first in Hartree–Fock theory. Then, the energy was evaluated with the second-order of Møller–Plesset (MP2) theory with a larger basis set and a CBS extrapolation to correct the energy through the second order. The MP4SDQ/6–31G calculation was used to approximate higher orders of contributions. There are also empirical corrections for spin contamination and a size-consistent higher order correction.

[a]The values in the parentheses are the deviations from the computed BDE for the experimental value.
[b]The data are from ref. 15.

The O–NO_2 bond strength was obtained by calculating the homolytic BDE, which is defined as the enthalpy change of the dissociation reaction

$$[1] \qquad R{-}X \rightarrow R^{\bullet} + X^{\bullet}$$

For the *O*-nitroalcohols studied here, the BDE is defined as the difference between the zero-point-corrected energy of the parent molecule and that of the products of the unimolecular dissociation in which a NO_2 group is removed. For example, for 4-CH_3–$C_6H_4CH_2O$–NO_2 the BDE is

$$[2] \qquad BDE_{O-NO_2} = E(C_8H_9O) + E(NO_2) - E(C_8H_9NO_3)$$

The average errors of the BDEs for the B3LYP, B3PW91, and B3P86 methods were determined by calculating the average absolute error (ε_{aae}), defined as

$$[3] \qquad \varepsilon_{aae} = \frac{1}{N}\sum_{i=1}^{N} |x_i - c_i|$$

where x_i represents the experimental data, c_i denotes the calculated values, and N is the number of experimental or calculated data.

Results and discussion

The N–O bond length

First, we examined the N_1–O_3 bond length of seven *O*-nitroalcohol compounds by various computational methods. The experimental equilibrium bond distances for the N_1–O_3 bond distances of the seven title compounds were not available. To have a comparison, we listed the N_1–O_3 experimental value[40] for $C_2H_5ONO_2$. It is noted from Table 1 that the N_1–O_3 bond lengths computed by the B3LYP functional are the biggest among those calculated by the B3LYP, B3PW91, B3P86, and MPWB95 methods with the 6–31G** basis set, and the N_1–O_3 bond lengths calculated by the MPWB95/6–31G** method are the smallest. The N_1–O_3 bond lengths computed by the CBS-4M method are slightly smaller than those computed by the B3LYP/6–31G** method except for 4-OCH_3–C_6H_4–CH_2ONO_2.

Compared with the corresponding experimental value, the B3LYP/6–31G** method produces the best result for $C_2H_5ONO_2$ with an N_1–O_3 bond length of 1.391 Å, only a 0.014 Å deviation from the experimental value, whereas the MPWB95/6–31G** method gives the worst result for $C_2H_5ONO_2$ with an N_1–O_3 bond length of 1.363 Å. In Table 1, we listed the results computed by Gong et al.[41] with the MP2/6–311G* method.

In addition, we computed the N_1–O_3 bond lengths of the selected compounds by using the BLYP/6–31+G**method. Through a comparison of the computational results, it is noted that the use of the diffuse function will improve the result. The deviation from the experimental value increases in the presence of the function.

[b]The data are from ref. 15.

The BDEs of *O*-nitroalcohols in acetonitrile

The BDE results computed by using the B3LYP, B3P86, and B3PW91 three-parameter hybrid DFT methods with the 6–31G** basis set are presented in Table 2. The available experimental values[15] are also included. The BDEs of seven *O*-nitroalcohols are compared with the corresponding experimental results for the system. Detailed analysis reveals that the BDEs calculated by the B3LYP, B3P86, and B3PW91 methods all overestimated BDE, which disagrees with previous research asserting that DFT methods usually underestimate BDE systematically.

It is noted that the BDEs calculated by the B3P86 method for the seven molecules are all very poor, and all of the B3P86 calculated results overestimate the BDEs for the studied compounds. The O–NO_2 BDEs for the studied molecules have a considerable difference when compared with the experimental values. The average absolute difference for the B3P86 method is 12.1 kcal/mol, which is outside our desired target accuracy for chemical predictions. In Table 2, the largest error is found for 4-CF_3–C_6H_4–CH_2ONO_2 and 4-Cl–C_6H_4–CH_2ONO_2 (14.6 kcal/mol).

The mean absolute deviation between B3PW91 results and the experimental is 9.6 kcal/mol, which is smaller than that for the B3P86 method. From Table 2, we can see that the B3PW91 calculated results also overestimate the BDEs for the studied compounds. The maximum difference for the B3PW91 method is 11.6 kcal/mol for the BDE of compound 4-CF_3–C_6H_4–CH_2ONO_2. Thus, while the B3PW91 method with the 6–31G** basis set yields good results for some systems, it is clear that this method is not suitable for predicting accurate BDEs for the N_1–O_3 bond.

In Table 2, we can also see that the values obtained with the B3LYP method are closer to the experimental values than those obtained with the B3PW91 and B3P86 methods, with a mean absolute deviation between the B3LYP results and the experimental values of 7.3 kcal/mol. It is also noted that the mean absolute error reduces from 12.1 to 7.3 kcal/mol when the B3P86 method is replaced by the B3LYP method, which proves that the N_1–O_3 BDE for the studied compounds is sensitive to the calculational methods. Comparing the three DFT methods, it is noted that B3LYP method is the best procedure to compute the N_1–O_3 BDE among the selected methods, although the N_1–O_3 BDEs calculated by the B3LYP/6–31G** method for the studied molecules are considerably different when compared with the experimental values.

To determine whether the B3LYP method is sensitive to the basis sets, we computed the BDEs of the *O*-nitroalcohol compounds with the B3LYP method at the 6–31+G** basis set. In addition, to give an extensive comparison, the CBS-4M and MPWB95/6–31G** methods were also employed to predict the BDEs for the seven compounds. All calculated results are presented in Table 3.

As can be seen in Table 3, the N_1–O_3 BDEs performed by CBS-4M method are drastically deviated from the experimental values, with an average absolute deviation of 14.7 kcal/mol and a maximum deviation of 18.4 kcal/mol. For the seven compounds, the deviations between computational and experimental values are all greater than 3.0 kcal/mol. Therefore, the CBS-4M method is not suitable for predicting the BDEs for the studied compounds. For the

Table 4. Computed bond dissociation energies (BDEs, kcal/mol; 1 cal = 4.1.84 J) in MeCN for the removal of an NO_2 group in *O*-nitroalcohol molecules by using the (RO)B3LYP/6–311++G(2df,2p) and B3LYP/6–311G(d,p) methods.

		Method[a]		
Entry	Compound	(RO)B3LYP/6–311++G(2df,2p)	B3LYP/6–311G(d,p)	Expt.[b]
1	4-H–C_6H_4–CH_2ONO_2	32.9 (2.5)	34.2 (3.8)	30.4
2	4-CH_3–C_6H_4–CH_2ONO_2	34.7 (3.4)	35.6 (5.3)	30.3
3	4-Cl–C_6H_4–CH_2ONO_2	30.3 (–0.5)	35.7 (4.9)	30.8
4	4-NO_2–C_6H_4–CH_2ONO_2	31.4 (–8.2)	36.2 (–3.4)	39.6
5	4-Br–C_6H_4–CH_2ONO_2	35.0 (3.9)	35.5 (4.4)	31.1
6	4-CF_3–C_6H_4–CH_2ONO_2	35.0 (3.6)	35.8 (4.4)	31.4
7	4-OCH_3–C_6H_4–CH_2ONO_2	33.2 3.1)	33.3 (3.2)	30.1
Mean absolute deviation		3.6	4.2	

[a] The values in parentheses are the deviations from computed BDEs for the experimental values.
[b]The data are from ref. 15.

MPWB95/6–31G** method, the average absolute deviation is 12.4 kcal/mol, which is slightly smaller than that obtained by the CBS-4M method. For the B3LYP method, the use of the diffuse function can greatly improve the results. The deviations from experimental values drastically decrease in the presence of the diffuse function.

In view of the importance of the study on the BDEs of the Y–NO_2 type of compounds and whether the B3LYP/6–31+G** method can give satisfactory BDEs for other types of Y–NO_2 bonds, such as *N*-nitroacylamides, we computed the N–NO_2 BDEs of several *N*-nitroacylamides by the B3LYP/6–31+G** method. The computed results are listed in Table 3. From Table 3, it is noted that the B3LYP/6–31+G** method gave the better BDEs for the *N*-nitroacylamides. All the deviations are within 1.0 kcal/mol, the maximum deviation is 0.9 kcal/mol, and the mean absolute deviation is 0.4 kcal/mol.

Chandra et al.[42] estimated accurate S–H BDEs by using the (RO)B3LYP/6–311++G(2df,2p) method. Nam et al.[43,44] estimated accurate P–H BDEs by the (RO)B3LYP/6–311++G(2df,2p) method and C–H BDEs of toluene derivatives by using the (RO)B3LYP/6–311++G(2df,2p) and B3LYP/6–311G(d,p) methods. To determine whether the (RO)B3LYP/6–311++G(2df,2p) and B3LYP/6–311G(d,p) methods can obtain accurate O–N BDEs of the studied *O*-nitroalcohol compounds, we computed the O–N BDEs of the *O*-nitroalcohol compounds by using the (RO)B3LYP/6–311++G(2df,2p) and B3LYP/6–311G(d,p) methods. The computed results are all listed in Table 4. According to Table 4, it is interesting to point out that, although the (RO)B3LYP/6–311++G(2df,2p) and B3LYP/6–311G(d,p) methods gave accurate P–H BDEs and C–H BDEs, the two methods seem to give poor results for the studied molecules. For 4-NO_2–C_6H_4–CH_2ONO_2, the (RO)B3LYP/6–311++G(2df,2p) method produced a BDE of 31.4 kcal/mol, a 8.2 kcal/mol deviation from the experimental value. For the other six compounds, there are four compounds for which the deviations between computational and experimental values are greater than 3.0 kcal/mol. A similar analysis was made for the computed results by the B3LYP/6–311G(d,p) method.

Here, we should note that the B3LYP/6–31+G** method is able to accurately predict the BDE of the N–O bond for the selected alcohol compounds, but it is not a suitable method for estimating the transition metal – OH bond energies. Numerous studies show that the best method for calculating bond energies of transition-metal complexes is CCSD(T).[45] Dapprich et al.[46] calculated the BDEs of transition-metal complexes and found that CCSD(T) results were in good agreement with experimental data, whereas the bond energies at the HF level were too low and the MP2 results were too high.

[a]Energy difference between donor (*i*) and acceptor (*j*) NBO orbitals.
[b]$F(i,j)$ is the Fock matrix element between *I* and *J* NBO orbitals.

From Tables 1 and 3, through analysis of the O_3–N_1 bond lengths and the BDEs calculated by the B3LYP/6–31+G** method, we found that the N_1–O_3 BDE is in a good linear relationship with the N_1–O_3 bond length and the correlated coefficient is 0.95. Figure 2 plots the correlation between the O_3–N_1 BDE and bond lengths.

Substituent effects on the BDEs of the O–NO_2 bond

From the analysis in the previous section, we know that B3LYP/6–31+G** is the best procedure for computing the dissociation energies for the N_1–O_3 bond in acetonitrile. Using this method, we studied the substituent effect on the N_1–O_3 BDEs for the studied molecules, where substituted groups include both the electron-donating and -withdrawing groups such as 4-Cl, 4-Br, 4-NO_2, 4-CH_3, and 4-CH_3O. The calculated BDEs for the selected compounds are shown in Table 5. The results show that the substituent effects on the BDEs of the selected compounds are insignificant.

An interesting point observed in the selected molecules is the change of BDEs and ΔBDE with the Hammett constant σ_p values of the substituent on the benzene. The Hammett constants[47] of the OCH_3, CH_3, H, Cl, Br, CF_3, and NO_2 groups are –0.27, –0.07, 0.00, 0.23, 0.23, 0.54, and 0.78, respectively. It is noted that electron-withdrawing groups increase the BDE of the parent compound 4-H–C_6H_4–CH_2ONO_2, while electron-donating groups decrease the BDE of the parent compound. On the one hand, we think this is because the benzene ring shows a strong negative inductive effect and a negative conjugative effect when the substituted group is connected with the benzene ring, which makes the density of the electric cloud change greatly and has an effect on the properties of the parent compound. On the other hand, it may occur because both groups may cause spin delocalization from the radical center formed by a single NO_2 group leaving the parent structure.

NBO analysis

NBO analysis provides an efficient method for studying intra- and inter-molecular bonding and interaction among bonds, and it also provides a convenient basis for investigating charge transfer or conjugative interaction in molecular systems. Some electron orbitals, acceptor orbitals, and the interacting stabilization energy that resulted from the second-order microdisturbance theory are reported.[48,49] The larger the $E^{(2)}$ value, the more intensive is the interaction between electron donors and electron acceptors, i.e., a tendency toward donating from electron donors to electron acceptors and a greater extent of conjugation of the whole system. Delocalization of the electron density between occupied Lewis-type (bond or lone pair) NBO orbitals and formally unoccupied (antibond or Rydberg) non-Lewis NBO orbitals correspond to a stabilizing donor–acceptor interaction. NBO analysis was carried out at the B3LYP/6–31+G** level to elucidate the intramolecular rehybridization and delocalization of electron density within the molecule. The important second-order stabilization energies ($E^{(2)}$) are reported in Table 6.

From Table 6, we can see that the $E^{(2)}$ of 4-OCH_3–C_6H_4–CH_2ONO_2 is the largest among the studied compounds. This shows that the interactions between electron donors and electron acceptors, $lpO_3 \rightarrow BD^*(O_1–N_1)$ and $lpO_3 \rightarrow BD^*(O_2–N_1)$, are

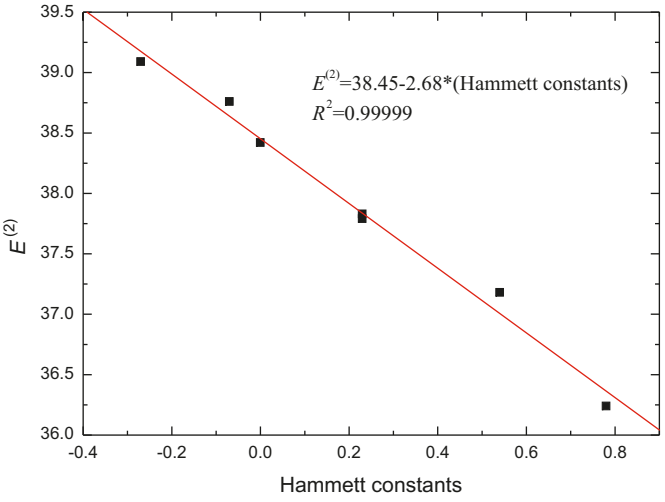
Fig. 3. Dependence of the second-order stabilization energy ($E^{(2)}$) on Hammett constants for the title compounds in acetonitrile solution.



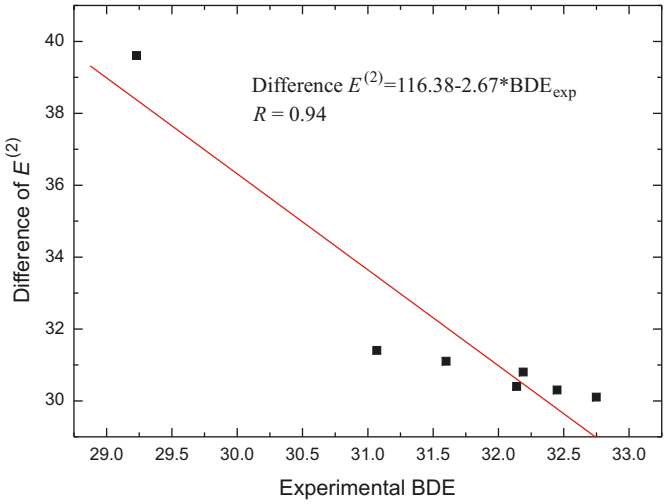


Fig. 4. Dependence of the difference of the second-order stabilization energy ($E^{(2)}$) on the experimental bond dissociation energies (BDEs) for the title compounds in acetonitrile solution.

very strong, which result in a shorter O_3–N_1 bond length. The Hammett constants[41] of the OCH_3, CH_3, H, Cl, Br, CF_3, and NO_2 groups are –0.27, –0.07, 0.00, 0.23, 0.23, 0.54, and 0.78, respectively. From the data in Table 6, it is noted that the $E^{(2)}$ of $lpO_3 \rightarrow BD^*(O_1–N_1)$ is successfully correlated with the Hammett constants. Figure 3 gives the correlation between $E^{(2)}$ and the Hammett constants.

In addition, it is noted that the BDEs of the title compounds have a better linear correlation with the difference between the $E^{(2)}$ of $lpO_3 \rightarrow BD^*(O_1–N_1)$ and $lpO_3 \rightarrow BD^*(O_2–N_1)$. The experimental BDE values of the title compounds are plotted against $E^{(2)}$ in Fig. 4. The correlation coefficient reached was 0.94.

Conclusions

In this paper, the BDEs of the O–NO_2 bonds for seven *O*-nitroalcohol compounds in acetonitrile solution were calculated by the B3LYP, B3PW91, B3P86, and MPWB95 methods with the 6–31G** basis set. The B3LYP/6–31+G**, (RO)B3LYP/6–311++G(2df,2p), B3LYP/6–311G(d,p), and CBS-4M methods were also used. By comparing all of the computed results with the experimental ones, we obtained the following conclusions:

1. The N_1–O_3 BDEs calculated by meta GGA functional MPWB95/6–31G** drastically deviate from the experimental values; the average absolute deviation is 12.4 kcal/mol.
2. Comparing the N_1–O_3 BDEs calculated by various methods, the B3LYP/6–31+G** method is the best procedure for computing dissociation energies for the N_1–O_3 BDE bonds among the selected methods; it has an average absolute deviation of 2.9 kcal/mol and a maximum deviation of 4.7 kcal/mol.
3. The analysis of substituent effects on the BDEs shows that electron-withdrawing groups increase the BDE of the parent compound 4-H–C_6H_4–CH_2ONO_2 and electron-donating groups decrease the BDE of the parent compound. The related reasons are further analyzed.
4. A good linear correlation exists between $E^{(2)}$ and the Hammett constants and a better correlation exists between the BDEs and the difference between the $E^{(2)}$ of $lpO_3 \rightarrow BD^*(O_1–N_1)$ and $lpO_3 \rightarrow BD^*(O_2–N_1)$.

We believe that such bond information should be useful in understanding the biological functions of nitrogen dioxide, especially its reactions with amino acids in vivo.

Abstract: 4,22-Dimethoxy[2.10]metacyclophan-1-yne was prepared by bromination of [2.10]metacyclophan-1-ene followed by the dehydrobromination of the bromine adduct with KOBu-*t*. Treatment of 4,22-dimethoxy[2.10]metacyclophan-1-yne with BBr_3 in CH_2Cl_2 at room temperature led to the demethylation and a successive intramolecular cyclization reaction to afford a novel [10](2,9)-5a,11a-benzofuro-5a-bora-11-bromochromenophane in good yield. Similar treatment of a mixture of the corresponding *meso*- and *dl*-1,2-dibromo-4,22-dimethoxy[2.10]metacyclophane with BBr_3 in CH_2Cl_2 under the same conditions described above afforded *cis*-4b,9b-dihydro[10]benzofuro[3,2-*b*]benzofuranophane in 83% yield.

Key words: metacyclophan-1-ene, dehydrobromination, metacyclophan-1-yne, double intramolecular cyclization, benzofuranophane.

Résumé : On a préparé le 4,22-diméthoxy[2,10]métacyclophan-1-yne par une bromuration du 4,22-diméthoxy[2,10]métacyclophan-1-ène suivie d'une déshydrobromuration de l'adduit bromé à l'aide de *tert*-butylate de potassium. La réaction du 4,22-diméthoxy[2,10]métacyclophan-1-yne avec du BBr_3, en solution dans le CH_2Cl_2, à la température ambiante, conduit successivement à une déméthylation et une réaction de cyclisation intramoléculaire qui fournit un nouveau [10](2,9)-5a,11a-benzofuro-5a-bora-11-bromochrométhénophane, avec un bon rendement. Un traitement semblable d'un mélange de *méso*- et de *dl*- 1,2-dibromo-4,22-diméthoxy[2,10]métacyclophane avec du BBr_3, en solution dans le CH_2Cl_2, dans les conditions décrites plus haut, conduit au 4b,9b-dihydro[10]benzofuro[3,2-*b*]benzofuranophane, avec un rendement de 83 %.

Mots-clés : métacyclophan-1-ène, déshydrobromuration, métacyclophan-1-yne, double cyclisation intramoléculaire, benzofuranophane.

Introduction

Cyclophanes belong to one of the remarkable compound classes that has attracted extensive studies.[1–3] In 1982, Psiorz and Hopf reported the identification of some elusive strained paracyclophyne intermediates, which were indirectly confirmed by the fact that giving Diels–Alder adducts were produced with dienophiles or that trimerization to the hexaphenyl benzene derivatives occurred.[4–8] Later, Meijere and Wong[5] reported the existence of the strained cyclophynes as an intermediate, which was established by a trapping method. Ramming and Gleiter[9] reported the syntheses of [*n*]MCP-diynes (MCP = metacyclophane) and their transformation of propargylic moieties into allenic moieties, as well as reactions with strong bases. Recently, Kawase and co-workers[10–12] reported the synthesis of [2_n]MCP-*n*-ynes by bromination–dehydrobromination of the corresponding MCP-*n*-enes, which were considerably strained with bent triple bonds. Although we attempted to prepare [2.3]- and [2.4]-MCP-1-ynes by the dehydrobromination of the corresponding 1,2-dibromo[2.3]- and [2.4]-MCPs,[13] no formations of the desired [2.3]- and [2.4]-MCP-ynes were observed because of the considerably strained bent triple bonds. Instead, only 1-bromo[2.3]- and [2.4]-MCP-1-enes, along with [2.3]- and [2.4]-MCP-1-ones, were obtained. On the other hand, we succeeded in preparing the larger ring sized 8,22-dimethoxy[2.8]- and 8,24-dimethoxy[2.10]-MCP-1-ynes with bent triple bonds by the bromination–dehydrobromination of the corresponding [2.*n*]MCP-1-enes.[13]

On the other hand, recently, Yamaguchi and co-workers[14–18] reported the double intramolecular cyclizations of diarylacetylenes to construct a series of fully ring-fused ladder π-conjugated skeletones with various main group elements, such

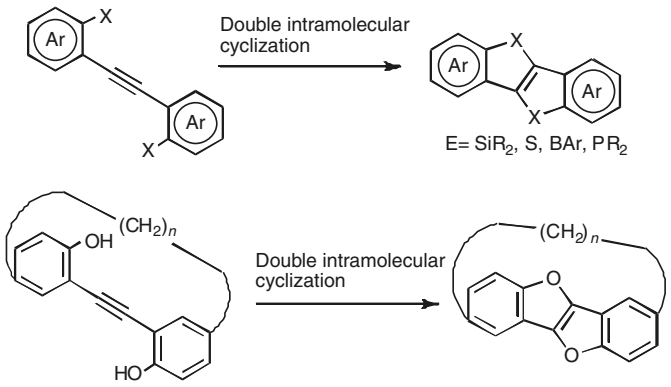
as Si, B, P, and S, as the bridging moieties. Thus, there is substantial interest in the synthesis of the larger sized [2.*n*]MCP-1-ynes having nucleophilic substituents such as OH and OMe groups at the ortho position to the acetylenic linkage, which can afford convenient starting materials for the attempted preparation of a series of fully ring-fused [2.*n*]cyclophanes by the double intramolecular cyclizations of the diarylacetylene moiety (Scheme 1). In this paper, we describe the first preparation of 4,22-dimethoxy[2.10]MCP-1-ene using the low-valent titanium-induced McMurry reaction and their conversion to 4,22-dimethoxy[2.10]MCP-1-yne, which was treated with BBr_3 to afford a novel [10](2,9)-5a,11a-benzofuro-5a-bora-11-bromochromenophane by the intramolecular cyclizations of the diarylacetylene moiety.

Results and discussion



1,10-Bis(4-methoxyphenyl)decane (**2**) was prepared according to our previous reports.[19–24] The cross-coupling reaction of 4-methoxyphenylmagnesium bromide with 1,10-dibromodecane was carried out in the presence of cuprous bromide as a catalyst in a mixture of hexamethylphosphoric triamide (HMPA) and tetrahydrofuran (THF) at reflux temperature to give the desired 1,10-bis(4-methoxyphenyl)decane (**2**) in 82% yield. The $TiCl_4$-catalysed formylation of compound **2** with Cl_2CHOMe at 20 °C led to regioselective formylation at the meta positions of the 1,10-diphenylalkane, affording the desired 1,10-bis(3-formyl-4-methoxyphenyl) decane (**3**) in 83% yield. Compound **3** was subjected to reductive coupling by the McMurry reaction.[25–43] The novel desired [2.10]MCP-1-ene (**4**) was obtained in 94% yield along with the corresponding 1,2-diol (**5**). The ^{1}H NMR spectrum of **4** shows two kinds of methoxy protons, each as a singlet. By careful column chromatography (silica gel, Wako C-300), two isomers, (*E*)-**4** and (*Z*)-**4** (Scheme 2), were separated in 52% and 42% yield, respectively.

The structures of products (*E*)-**4** and (*Z*)-**4** were determined on the basis of their elemental analyses and spectral data. ^{1}H NMR signals of the olefinic protons for *E*- and *Z*-olefins should be observed at $\delta > 7.4$ ppm (*E*) and $\delta < 6.9$ ppm (*Z*).[44] The ^{1}H NMR spectrum of (*E*)-**4** in $CDCl_3$ shows a singlet at δ 7.36 ppm for olefinic protons and a doublet ($J = 2.4$ Hz) at δ 7.30 ppm for one aromatic proton ($H_{8,24}$), which is in a strongly deshielding region of the bridged double bond. In contrast, the ^{1}H NMR spectrum of (*Z*)-**4** in $CDCl_3$ shows a singlet at δ 6.70 ppm for olefinic protons and a set of doublets ($J = 2.4$ Hz) at δ 6.76, 6.98, and 7.03 ppm for the aromatic protons, which were observed at higher field owing to the strong shielding effect of the opposing benzene ring. These data strongly support that the structure of (*E*)-**4** is the E configuration and the structure of (*Z*)-**4** is the Z configuration, both having syn conformation. The structure of the syn-confomer is also readily assigned from the chemical shift of the internal proton Hi at δ 7.30 ppm for (*E*)-**4** and δ 7.03 ppm for (*Z*)-**4**.

Single-crystal X-ray diffraction structures of (*E*)-**4** recrystallized from hexane are illustrated in Fig. 1 with the atom-numbering system.

Compound (*E*)-**4** crystallized in the monoclinic space group *P*121/*a*. Compound (*E*)-**4** was located at general positions in the asymmetric unit of the crystal structure. The X-ray crystallographic analyses of (*E*)-**4** clearly show that the compound also adopts the anti conformation in the solid state. In addition, the double bond adopts the E configuration. These results seem to indicate that the double bond in (*E*)-**4** plays an important role in the fixation of the conformation in the solid state.

Scheme 1. Double intramolecular cyclization of diarylacetylenes and hydroxy[2.*n*]metacyclophan-1-ynes

In (*E*)-**4** the bond distance of C_1–C_2 is 1.341 Å, which is almost the same value as the distance between carbon atoms in ethylene. The bond distances of C_2–C_3 and C_1–C_{23} are 1.472 and 1.474Å, respectively, which are slightly shorter than those of C_7–C_9 (1.545 Å) and C_{18}–C_{19} (1.524 Å). The dihedral angles of C_9–C_{10}–C_{11}–C_{12}–C_{13}–C_{14}–C_{15}–C_{16}–C_{17}–C_{18}–C_1–C_2 between C_3–C_4–C_5–C_6–C_7–C_8 and C_{19}–C_{20}–C_{21}–C_{22}–C_{23}–C_{24} are different values, 3.15° and 0.15°, respectively, showing that the aromatic rings adopt the asymmetrical conformation in the molecule. This reflects the bond angles in the ethylenic bridge chain; the bond angles of C_1–C_2–C_3 and C_{23}–C_1–C_2 are different values (131.74° and 122.49°) that are larger than those of ethylene.

The structure of diol **5** was also determined on the basis of its elemental analyses and spectral data. Thus, we reported[44] the structure of *anti*-1,2-dihydroxy-6,13-dimethoxy[2.3]MCP and assigned it as a *trans*-diol with a exo–exo arrangement. We assigned the structure of **5** in a similar fashion. However, in the case of **5**, the similar upfield shift of the internal aromatic proton (δ 4.95 ppm for *anti*-1,2-dihydroxy-6,13-dimethoxy[2.3]MCP)[1–3,45,46] was not observed, but appeared in the normal aromatic region at δ 6.72 ppm ($J = 2.4$ Hz). This observation strongly suggests **5** adopts a syn conformation, different from that in *anti*-1,2-dihydroxy-6,13-dimethoxy[2.3]MCP. The other two aromatic protons was observed at δ 6.72 ($H_{5,21}$, $J = 8.4$ Hz) and 6.95 ($H_{6,20}$, $J = 2.4$, 8.4 Hz) ppm, respectively. Furthermore, the bridged methine protons show a downfield shift at δ 4.81 ppm as a doublet ($J = 2.1$ Hz), whereas those of 1,2-dihydroxy-6,13-dimethoxy[2.3]MCP are at δ 4.34 ppm. Thus, the bridged methine protons of **5** are in a strongly deshielding region of the oxygen atom of the methoxy groups on the benzene ring. These observations are strongly supported because the two OH groups are in an exo, exo arrangement and, therefore, **5** was found to be a *cis*-diol.

Attempted bromination of (*Z*)-4,22-dimethoxy[2.10]MCP-1-ene (*Z*)-**4** with an equimolar amount of benzyltrimethylammonium tribromide (BTMA Br_3), which was found to be a convenient solid brominating agent,[47] carried out in a

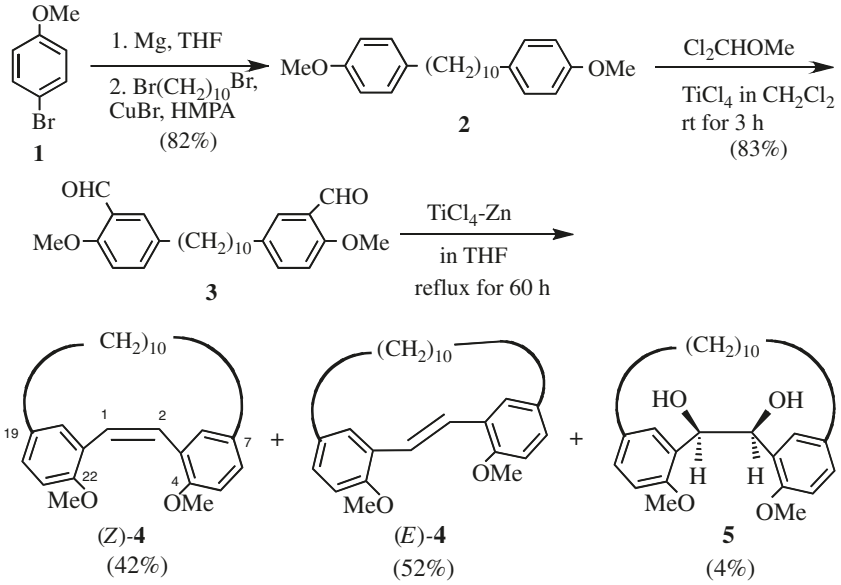
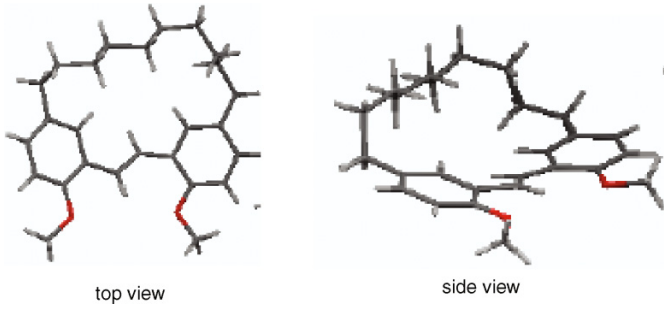
Scheme 2. Synthesis of (*Z*)- and (*E*)-4,22-dimethoxy[2.10]MCP-1-ene, (*Z*)-**4** and (*E*)-**4.**





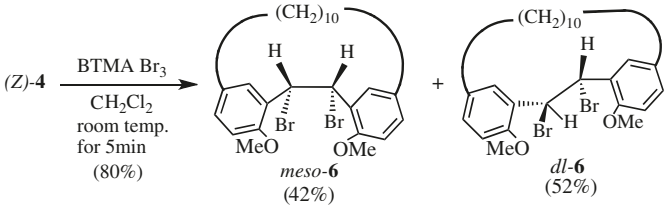


Fig. 1. Single-crystal X-ray diffraction structures of (*E*)-**4**. Hydrogen atoms are omitted for clarity.

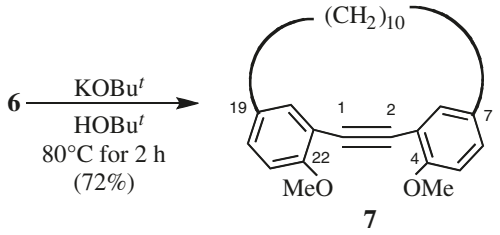
Scheme 3. Bromination of (*Z*)-**4** with BTMA Br_3.



dichloromethane solution at room temperature for 5 min led to the expected cis- and trans-adducts **6** (*endo–endo*–Br and *endo–exo*–Br) to the bridged double bond in a ratio of 45:55 in 80% yield. Similar treatment of (*E*)-**4** with BTMA Br_3 under the same reaction conditions afforded a mixture of *meso*-**6** and *rac*-**6** (Scheme 3) in 91% yield in a ratio of 45:55.

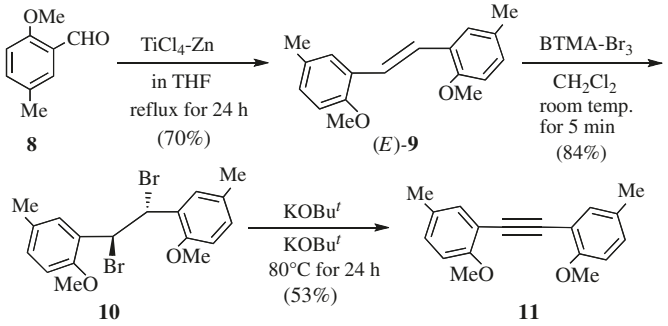
When treated with potassium *tert*-butoxide in refluxing HOBu-*t* at 80 °C for 2 h, bromine adduct **6** gave the didehydrobromination product [2.10]MCP-1-yne (**7**) in 72% yield.

The structure of **7** was determined on the basis of its elemental analysis and spectral data. The ^{1}H NMR spectrum of **7** shows two internal protons as a doublet at δ 7.39 ($H_{8,24}$, J = 2.1 Hz) ppm and two aromatic protons at δ 6.78 ($H_{5,21}$, J = 8.4 Hz) and 7.03 ($H_{6,20}$, J = 2.1, 8.4 Hz) ppm. The chemical shift for the internal protons at normal aromatic protons strongly supports that the structure of **7** is the syn-conformer. A deshielded internal proton was observed in the NMR spectrum of **7** at δ 7.39 ppm in comparison with other aromatic protons, which is in a strongly deshielding region owing to the π-electrons of the triple bond. The chemical shifts of the ^{1}H and ^{13}C NMR signals arising from the benzene rings of **7** are comparable to those of the acyclic reference compound **11**,[13] which was prepared from 2-formyl-5-methylanisole (**8**) in three. steps, the same procedure as that for **7** (Scheme 4). Interestingly, the signals of the acetylenic carbons were observed at slightly lower field (δ 91.48 ppm for **7**) than that of **11** (δ 89.69 ppm, Scheme 5); this reflects the relatively small strain in the triple bond owing to bending and is almost the same value of that of [2_4]MCP-1,9,17,25-tetrayne (δ 92.20 ppm), but much lower than that of 1,5-cyclooctadiyne (δ 95.8 ppm)[48] or [2_3]MCP-1,9,17-triyne (δ 99.86 ppm).[11]

Single-crystal X-ray diffraction structures of **7** recrystallized from hexane are illustrated in Fig. 2 with the atom-numbering system. Compound **7** crystallized in the monoclinic space group $P21/a$ (Z = 8). All remaining hydrogen atoms are not shown for clarity. The structure was solved by direct-methods (Sir2002) and refined using the full-matrix least-squares method and Fourier synthesis. The X-ray structure determination of **7** clearly indicates that the structure of **7** is also the syn-conformer in the solid state, and the two methoxy groups are lying on the same side of the inner ring toward the outer direction to avoid steric repulsion with the bridge chain, the same as in (*E*)-**4**. The bond distance of C_1–C_2 is 1.20 Å, which is almost equal to the distance between carbon atoms in acetylene. The bond distances of C_2–C_3 and C_1–C_{23} are 1.43 and 1.43 Å, respectively, which are much shorter than those of C_7–C_9 (1.52 Å) and C_{18}–C_{19} (1.51 Å). Interestingly, the acetylenic moiety in the bridge chain does not adopt a different linear structurethan reference compound **11**; the bond angles of C_1–C_2–C_3 and C_2–C_1–C_{23} are unusual values, 169.6°and 170.2°. Thus, this clearly shows that **7** is a slightly bent molecule and supports the lower field shifts of

Scheme 4. Didehydrobromination of **6** with potassium *tert*-butoxide.

Scheme 5. Synthesis of acyclic reference compound **11**.



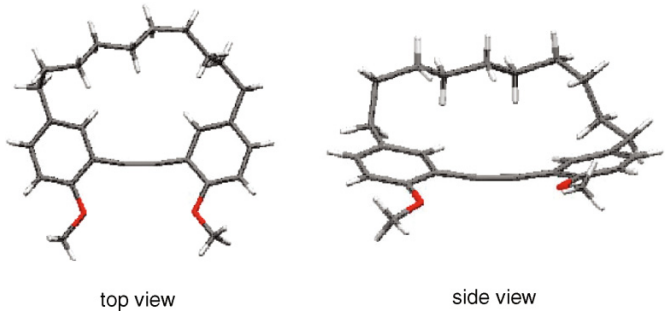


Fig. 2. Single-crystal X-ray diffraction structures of **7**. Hydrogen atoms are omitted for clarity.

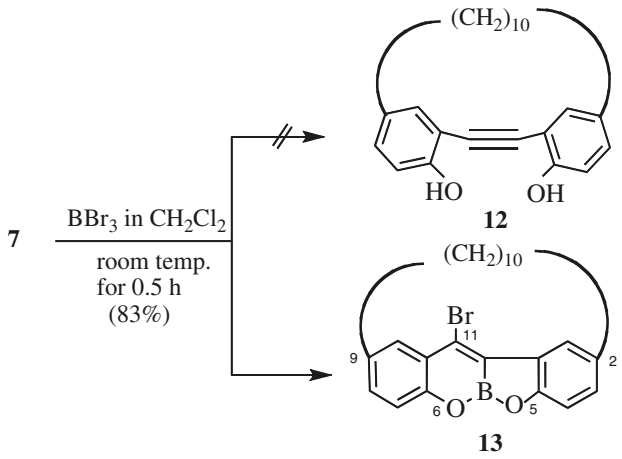


the signals of the acetylenic carbons in its ^{13}C NMR spectrum.

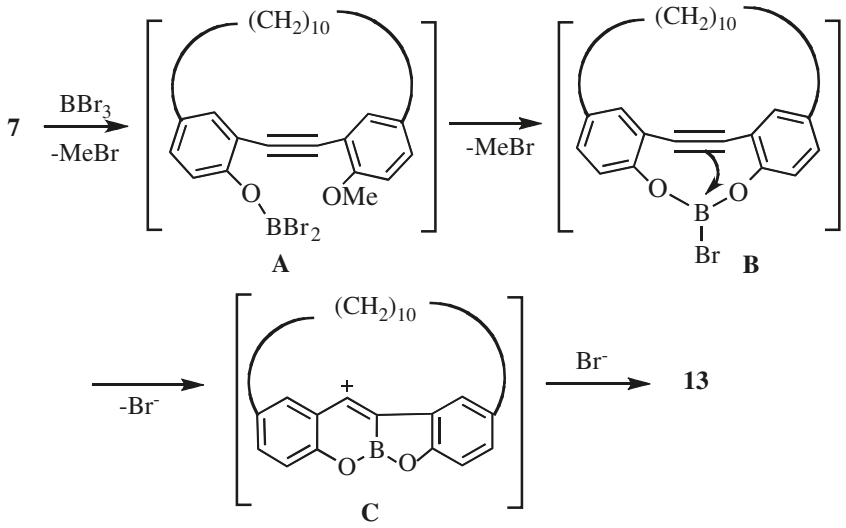
Attempted demethylation of **7** to afford **12** with trimethylsilyl iodide in acetonitrile solution[42–52] under various conditions failed. Only an intractable mixture of products was obtained. Interestingly, treatment of **7** with BBr_3 in CH_2Cl_2 at room temperature for 0.5 h afforded a novel [10](2,9)-5a,11a-benzofuro-5a-bora-11-bromochromenophane (**13**) in 83% yield (Scheme 6). No formations of the expected 4,22-dihydroxy[2.10]MCP-1-ene (**12**) or [10]benzofuro[3,2-*b*]benzofuranophane (Scheme 1) derived from the double intramolecular cyclizations of diarylacetylene and the OH groups of **12** were observed under the conditions used.

The structure of **13** was elucidated based on its elemental analysis and spectral data. Especially, the mass spectral data for **13** (M^+ = 435, 437) strongly supports one bromine atom containing product. The ^{1}H NMR spectrum in $CDCl_3$ exhibited six aromatic protons at δ 6.84 (d, J = 8.4), 6.86 (d, J = 2.4 Hz), 7.01 (dd, J = 2.4, 8.4 Hz), 7.18 (d, J = 8.4 Hz), 7.23 (dd, J = 1.2, 8.4 Hz), and 7.95 (d, J = 1.2 Hz) ppm, which were clearly associated with the unsymmetrical structure of **13**. On the basis of the spectral data, compound **13**

Scheme 6. Treatment of **7** with BBr_3 in CH_2Cl_2.

was assigned the structure, [10](2,9)-5a,11a-benzofuro-5a-bora-11-bromochromenophane.

Although the detailed mechanism of formation of [10]benzofurochromenophane (**13**) is not clear at the present stage, one might assume the reaction pathway as shown in Scheme 7. The present BBr_3-induced transformation from **7** to **13** probably occurred by demethylation of one methoxy group to afford the corresponding intermediate **A** followed by the second demethylation reaction along with the intramolecular cyclization reaction to afford the intermediate **B**, from which the electrophilic attack to the triple bond to generate the vinyl cation intermediate **C** occurred. Succesively, the nucleophilic attack to the vinyl cation intermediate **C** afforded compound **13** (Scheme 7). The present cyclization of the intermediate **B** to **C** might be attributable to conformational flexibility of the intermediate **B** and a short distance among the ethynyl group and boron atom as an electrophile owing to the *syn*-MCP skeletone. In fact, similar treatment of reference compound **11** with BBr_3 under the same conditions afforded only the intractable mixture of products. No formation of the corresponding benzofurochromene was observed under the conditions used.



To study the present [10]benzofurochromenophane formation reaction in more detail, we attempted to carry out the treatment of dibromide **6** with BBr_3. In fact, the treatment of a mixture of *meso*- and *dl*-**6** with BBr_3 in CH_2Cl_2 under the same conditions described above afforded *cis*-4b,9b-dihydro [10]benzofuro[3,2-*b*]benzofuranophane (**15**) in 83% yield, but not [10]benzofurochromenophane (Scheme 8).

The present BBr_3-induced transformation from **6** to **15** probably occurred by the demethylation of methoxy groups to afford the corresponding phenol derivative **D**, followed by a nucleophilic attack by phenolic oxygen to the bromide carbon at the C_2 carbon to afford the benzofuran intermediate **E**, from which the second nucleophilic attack to the bromide carbon at the C_3 position of benzofuran occurred to afford benzofuro[3,2-*b*]benzofuranophane skeletone intermediate **G**. The second cyclization of the intermediate **E** to **F** might be attributable to conformational flexibility of the intermediate **E** around the diaryl linkage of 2-arylbenzofuran. Deprotonation from the intermediate **G** afforded compound **15** (Scheme 9). From this proposed reaction mechanism for the BBr_3-induced transformation of **6** to **15**, one might assume the importance

Scheme 7. Proposed reaction mechanism for the formation of **13**.

Scheme 8. Reaction of a mixture of *meso*- and *dl*-**6** with BBr_3 in CH_2Cl_2.

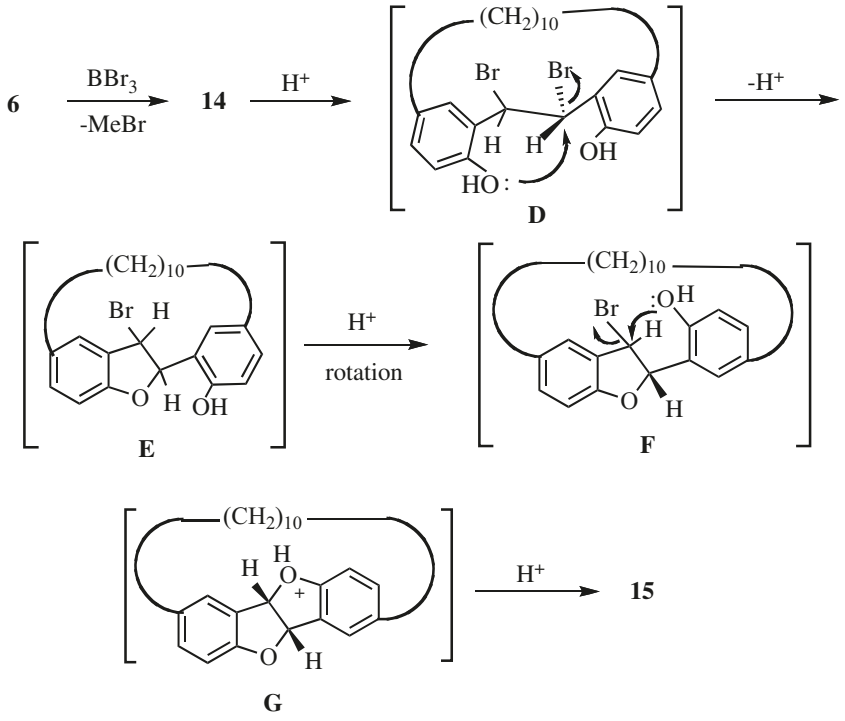
of the intramolecularly cyclized nine-membered intermediate **B** to afford **13** during the demethylation of **7** with BBr_3.

Conclusions

We have demonstrated a convenient preparation of 4,22-dimethoxy[2.10]MCP-1-yne (**7**) and conversion to a novel [10]benzofurochromenophane (**13**) by treatment with BBr_3 in CH_2Cl_2 at room temperature via demethylation and a successive intramolecular cyclization reaction. Interestingly, similar treatment of a mixture of the corresponding *meso*- and *dl*-1,2-dibromo-4,22-dimethoxy[2.10]MCP (**6**) with BBr_3 in CH_2Cl_2 under these same conditions afforded *cis*-4b,9b-dihydro[10]benzofuro[3,2-*b*]benzofuranophane (**15**) in 83% yield by double intramolecular cyclization. Further studies on the chemical properties of [10](2,9)-5a,11a-benzofuro-5a-bora-11-bromochromenophane **13** and *cis*-4b,9b-dihydro[10]benzofuro[3,2-*b*]benzofuranophane **15** are now in progress.

Experimental

All melting points were uncorrected. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Nippon Denshi JEOL FT-300 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JIR-AQ2OM mass spectrometer at an ionization energy of 70 eV using a direct-inlet system through GLC; *m*/*z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed with a Yanaco MT-5. Gas–liquid chromatograph (GLC) analyses were performed with a Shimadzu GC, GC-14A (silicone OV-1, 2 m; programmed temperature rise, 12 °C min^{-1}; carrier gas, nitrogen, 25 mL min^{-1}).



Preparation of 1,10-bis(4-methoxyphenyl)decane (2)

To a solution of 9.52 g (0.39 mol) of magnesium and a small amount of iodine in THF (10 mL) was added a solution of 4-bromoanisole (**1**) (33.7 g, 0.18 mol) in THF (40 mL) and the mixture was refluxed for 12 h. To a solution of 1,10-dibromodecane (18 g, 60 mmol) and CuBr (2.0 g, 14 mmol) in HMPA (10 mL) was added dropwise a solution of 4-methoxyphenylmagnesium bromide with gentle refluxing. After the reaction mixture was refluxed for an additional 24 h, it was quenched with a 10% aqueous ammonium chloride solution and extracted with CH_2Cl_2 (100 mL × 3). After the combined CH_2Cl_2 extracts were dried over Na_2SO_4, the solvent was evaporated in vacuo, and the residue was washed with methanol (100 mL) to afford 19 g of crude **2** as a colorless solid. Recrystallization from hexane gave **2** (17.5 g, 82%) as colorless prisms, mp 64–65 °C. ^{1}H NMR ($CDCl_3$) δ: 1.27 (broad s, 12H, *CH*$_2$), 1.54 (s, 4H, *CH*$_2$), 2.54–2.59 (m, 4H, *CH*$_2$), 3.78 (s, 6H, O*Me*), 6.82 (d, J = 8.8 Hz, 4H, Ar–*H*), 7.08 (d, J = 8.8 Hz, 4H, Ar–*H*). MS *m*/*z* (%): 354 (M^+). Anal. calcd for $C_{24}H_{34}O_2$ (354.53): C 81.31, H 9.67; found: C 81.42, H 9.54.

Preparation of 1,10-bis(3-formyl-4-methoxyphenyl)decane (3)

To a solution of 1,10-bis(4-methoxyphenyl)decane (**2**, 7.08 g, 20 mmol) and Cl_2CHOCH_3 (4.86 mL, 56 mmol) in CH_2Cl_2 (40 mL) was added a solution of $TiCl_4$ (6.7 mL,

Scheme 9. Proposed reaction mechanism for BBr_3-induced transformation from **6** to **15**.

61 mmol) in CH_2Cl_2 (40 mL) at 0 °C. After the reaction mixture was stirred at room temperature (rt) for 3 h, it was poured into a large amount of ice water (200 mL) and extracted with CH_2Cl_2 (100 mL × 2). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was chromatographed over silica gel (Wako C-300, 500 g) with hexane – ethylacetate (4:1) as eluent to give crude **3**. Recrystallization from hexane gave 6.82 g (83%) of 1,10-bis(3-formyl-4-methoxyphenyl)decane (**3**) as colorless prisms, mp 63–64 °C. IR (KBr, cm^{-1}) ν_{max}: 1683 (C=O). ^1H NMR ($CDCl_3$) δ: 1.26 (broad s, 12H, *CH*$_2$), 1.55 (s, 4H, *CH*$_2$), 2.54–2.59 (m, 4H, *CH*$_2$), 3.91 (s, 6H, *OMe*), 6.10 (d, *J* = 8.4 Hz, 2H, Ar*H*), 7.36 (dd, *J* = 2.1, 8.4 Hz, 2H, Ar*H*), 7.63 (d, *J* = 2.1 Hz, 2H, Ar–*H*), 10.4 (s, 2H, C*H*O). MS *m*/*z* (%): 410 (M^+). Anal. calcd for $C_{26}H_{34}O_4$ (410.56): C 76.06, H 8.35; found: C 76.14, H 8.27.

McMurry coupling reaction of 3

The McMurry reagent was prepared from $TiCl_4$ (13.75 mL, 125 mmol) and Zn powder (18 g, 275 mmol) in dry THF (500 mL), under nitrogen. A solution of 1,10-bis(3-formyl-4-methoxyphenyl)decane (**3**, 4.72 g, 11.5 mmol) in dry THF (250 mL) was added within 60 h to the black mixture of the McMurry reagent by using a high-dilution technique with continuous refluxing and stirring. The reaction mixture was refluxed for an additional 8 h, cooled to rt, and hydrolysed with aqueous 10% K_2CO_3 (500 mL) at 0 °C. The reaction mixture was extracted with CH_2Cl_2 (300 mL × 3). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was chromatographed over silica gel (Wako C-300, 500 g) with hexane – ethyl acetate (4:1) and ethyl acetate as eluents to give a mixture of (*E*)-**4** and (*Z*)-**4** as a colorless oil and **5** as a colorless solid. Recrystallization of hexane – ethyl acetate (4:1) eluents from hexane afforded (*E*)-**4** (2.28 g, 52%). The filtrate was condensed in vacuo to afford (*Z*)-**4** (1.83 g, 42%) as a colorless oil. The material obtained from the ethyl acetate eluent was recrystallized from hexane and afforded **5** (190 mg, 4%) as colorless prisms.

(*E*)-4,22-Dimethoxy[2.10]metacyclophan-1-ene ((*E*)-4)

(*E*)-**4** was obtained as colorless prisms (hexane), mp 102–103 °C. ^1H NMR ($CDCl_3$) δ: 1.46 (broad s, 12H, *CH*$_2$), 1.69 (broad s, 4H, *CH*$_2$), 2.55–2.67 (m, 4H, *CH*$_2$), 3.89 (s, 6H, O*Me*), 6.79 (d, *J* = 8.4 Hz, 2H, Ar*H*), 6.98 (dd, *J* = 2.4, 8.4 Hz, 2H, Ar–*H*), 7.30 (d, *J* = 2.4 Hz, 2H, Ar–*H*), 7.36 (s, 2H, =C*H*). ^{13}C NMR ($CDCl_3$) δ: 26.87, 28.35, 29.27, 29.99, 31.75, 55.47, 110.74, 126.62, 128.33, 128.53, 129.62, 133.41, 155.30. MS *m*/*z* (%): 378 (M^+). Anal. calcd for $C_{26}H_{34}O_2$ (378.55): C 82.49, H 9.05; found: C 82.41, H 8.99.

(*Z*)-4,22-Dimethoxy[2.10]metacyclophan-1-ene ((*Z*)-4)

(*Z*)-**4** was obtained as a colorless oil. ^1H NMR ($CDCl_3$) δ: 1.26 (m, 12H, *CH*$_2$), 1.43 (m, 4H, *CH*$_2$), 2.33–2.42 (m, 4H, *CH*$_2$), 3.69 (s, 6H, O*Me*), 6.70 (s, 2H, =C*H*), 6.76 (d, *J* = 8.4 Hz, 2H, Ar–*H*), 6.98 (dd, *J* = 2.4, 8.4 Hz, 2H, Ar–*H*), 7.03 (d, *J* = 2.4 Hz, 2H, Ar–*H*). MS *m*/*z* (%): 378 (M^+). Anal. calcd for $C_{26}H_{34}O_2$ (378.55): C 82.49, H 9.05; found: C 82.64, H 9.07.

1,2-Dihydroxy-4,22-dimethoxy[2.10]metacyclophane (5)

Compound **5** was obtained as colorless prisms (hexane), mp 116–117 °C. ^1H NMR ($CDCl_3$) δ: 1.24 (broad s, 12H, *CH*$_2$), 1.42–1.46 (m, 4H, *CH*$_2$), 2.37–2.44 (m, 4H, *CH*$_2$), 3.53 (s, 6H, O*Me*), 3.86 (d, *J* = 2.1 Hz, 2H, O*H*), 4.81 (d, *J* = 2.1 Hz, 2H, C*H*), 6.61 (d, *J* = 8.1 Hz, 2H, Ar–*H*), 6.72 (d, *J* = 2.4 Hz, 2H, Ar–*H*), 6.95 (dd, *J* = 2.4, 8.1 Hz, 2H, Ar–*H*). ^{13}C NMR ($CDCl_3$) δ: 26.3, 26.5, 29.7, 34.5, 55.2,

109.8 100.1, 127.3, 127.8, 128.1, 130.3, 155.2. MS *m/z* (%): 394 ($M^+ - H_2O$). Anal. calcd for $C_{26}H_{36}O_4$ (412.57): C 75.69, H 8.8; found: C 75.73, H 8.78.

Bromination of (*Z*)-4 with BTMA Br_3

To a solution of (*Z*)-**4** (200 mg, 0.53 mmol) in CH_2Cl_2 (20 mL) was added BTMA Br_3 (220 mg, 0.58 mmol) at rt. After the reaction mixture was stirred at rt for 5 min, it was poured into a large amount of ice water (50 mL) and extracted with CH_2Cl_2 (50 mL × 2). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was recrystallized from hexane and gave 228 mg (80%) of a mixture of 1-*endo*-bromo-2-*exo*-bromo-4,22-dimethoxy[2.10]metacyclophane (*rac*-**6**) and 1,2-di-*endo*-bromo-4,22-dimethoxy[2.10]-metacyclophane (*meso*-**6**) in a ratio of 55:45 as colorless prisms, mp 148–149 °C. ^{1}H NMR ($CDCl_3$) (*rac*-**6**) δ: 1.36 (broad s, 12H, *CH*$_2$), 1.45 (m, 4H, *CH*$_2$), 2.41–2.46 (m, 4H, *CH*$_2$), 3.73 (s, 3H, O*Me*), 3.78 (s, 3H, O*Me*), 5.64 (d, *J* = 10.2 Hz, 1H, *CH*), 6.60 (d, *J* = 7.8 Hz, 1H, *Ar–H*), 6.70 (d, *J* = 10.2 Hz, 1H, *CH*), 6.87–6.92 (m, 5H, Ar–*H*); *meso*-**6** δ: 1.36 (broad s, 12H, *CH*$_2$), 1.45 (m, 4H, *CH*$_2$), 2.41–2.46 (m, 4H, *CH*$_2$), 3.91 (s, 6H, O*Me*), 6.36 (s, 2H, *CH*), 6.65 (d, *J* = 7.8 Hz, 2H, *ArH*), 6.89 (dd, *J* = 1.2, 7.8 Hz, 2H, *Ar–H*), 7.08 (d, *J* = 1.2 Hz, 2H, Ar–*H*). MS *m/z* (%): 536, 538, 540 (M^+). Anal. calcd for $C_{26}H_{34}Br_2O_2$ (538.35): C 58.01, H 6.37; found: C 58.27, H 6.42.

Similar treatment of (*E*)-**4** with BTMA Br_3 under the same conditions as noted in the previous paragraph afforded a mixture of *rac*-**6** and *meso*-**6** in 91% yield in a ratio of 55:45 as colorless prisms.

Dehydrobromination of 6 with KOBu-*t*

To a solution of a mixture of *meso*- and *dl*-**6** (180 mg, 0.33 mmol) in HOBu-*t* (24 mL) was added KOBu-*t* (1.18 g, 10.5 mmol) at rt. After the reaction mixture was stirred at 80 °C for 2 h, it was poured into a large amount of ice water (50 mL) and extracted with CH_2Cl_2 (100 mL × 2). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was recrystallized from methanol and gave 89 mg (72%) of 4,22-dimethoxy[2.10]metacyclophan-1-yne (**7**) as colorless prisms, mp 113–114 °C. IR (KBr, cm^{-1}) ν_{max}: 2899, 2866, 2830, 2050 (C≡C), 1495, 1463, 1258, 1100, 1025, 802. ^{1}H NMR ($CDCl_3$) δ: 1.41 (m, 12H, *CH*$_2$), 1.60–1.72 (m, 4H, *CH*$_2$), 2.61–2.69 (m, 4H, *CH*$_2$), 3.89 (s, 6H, O*Me*), 6.78 (d, *J* = 8.4, 2H, Ar-*H*), 7.03 (dd, *J* = 8.4, 2.1 Hz, 2H, Ar*H*), 7.39 (d, *J* = 2.1 Hz, 2H, Ar–*H*). ^{13}C NMR ($CDCl_3$) δ: 26.65, 28.31, 29.17, 29.63, 31.76, 55.76, 91.48 (*sp*-C), 110.68, 112.11, 130.15, 133.52, 134.80, 156.56. MS *m/z* (%): 376 (M^+). Anal. calcd for $C_{26}H_{32}O_2$ (376.53): C 76.06, H 8.57; found: C 82.87, H 8.50.

McMurry coupling reaction of 8

The McMurry reagent was prepared from $TiCl_4$ (11.0 mL, 100 mmol) and Zn powder (14.4 g, 220 mmol) in dry THF (300 mL), under nitrogen. A solution of 2-formyl-5-methylanisole (**8**, 5.0 g, 33.3 mmol) in dry THF (70 mL) was added within 24 h to the black mixture of the McMurry reagent by using a high-dilution technique with continuous refluxing and stirring. The reaction mixture was refluxed for additional 8 h, cooled to rt, and hydrolysed with aqueous 10% K_2CO_3 (500 mL) at 0 °C. The reaction mixture was extracted with CH_2Cl_2 (300 mL × 3). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was treated with hexane (100 mL) to afford a colorless solid. Recrystallization from hexane afforded (*E*)-1,2-bis(2-methoxy-5-methylphenyl)ethene ((*E*)-**9**, 3.15 g, 70%) as colorless prisms, mp 123–125 °C. ^{1}H NMR ($CDCl_3$) δ: 2.34 (s, 6H, *CH*$_3$), 3.85 (s, 6H, O*Me*), 6.78 (d, *J* = 8.3 Hz, 2H, Ar–*H*), 7.02 (dd, *J* = 2.2, 8.3 Hz, 2H, Ar–*H*), 7.42 (s, 2H, =C*H*), 7.45 (d, *J* = 2.2 Hz, 2H, Ar*H*). ^{13}C NMR ($CDCl_3$) δ: 20.6, 55.6, 110.8, 123.1, 123.3, 126.9, 128.8, 129.8, 154.7. MS *m/z* (%): 268 (M^+). Anal. calcd for $C_{18}H_{20}O_2$ (268.36): C 80.56, H 7.51; found: C 80.41, H 7.69.

Bromination of (*E*)-9 with BTMA Br_3

To a solution of (*E*)-**9** (1.0 g, 3.73 mmol) in CH_2Cl_2 (100 mL) was added BTMA Br_3 (1.74 g, 4.46 mmol) at rt. After the reaction mixture was stirred at rt for 5 min, it was poured into a large amount of ice water (300 mL) and extracted with CH_2Cl_2 (100 mL × 2). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was treated with hexane (100 mL) to afford a colorless solid. Recrystallization from hexane afforded 1,2-bromo-1,2-bis(2-methoxy-5-methylphenyl)-ethane (**10**, 1.35 g, 84%) as colorless prisms, mp 146–148 °C. ^{1}H NMR ($CDCl_3$) δ: 2.18 (s, 6H, *CH*$_3$), 3.74 (s, 6H, O*Me*), 6.11 (s, 2H, *CH*), 6.52 (d, *J* = 8.1 Hz, 2H, Ar–*H*), 7.12 (dd, *J* = 2.0, 8.1 Hz, 2H, Ar–*H*), 7.38 (d, *J* = 2.0 Hz, 2H, Ar–*H*). MS *m/z* (%): 426, 428, 430 (M^+). Anal. calcd for $C_{18}H_{20}Br_2O_2$ (428.17): C 50.61, H 4.76; found: C 50.49, H 4.71.

Dehydrobromination of 10 with KOBu-*t*

To a solution of a mixture of **10** (680 mg, 1.59 mmol) in HOBu-*t* (68 mL) was added KOBu-*t* (1.78 g, 15.9 mmol) at rt. After the reaction mixture was stirred at 80 °C for 24 h, it was poured into a large amount of ice water (50 mL) and extracted with CH_2Cl_2 (100 mL × 2). The combined extracts were washed with water, dried with Na_2SO_4, and concentrated. The residue was chromatographed over silica gel (Wako C-300, 500 g) with hexane as eluents to give a colorless solid. Recrystallization from hexane afforded 1,2-bis(2-methoxy-5-methylphenyl)ethyne (**11**, 223 mg, 53%) as colorless prisms, mp 114–115 °C. ^{1}H NMR ($CDCl_3$) δ: 2.28 (6H, s, *CH*$_3$), 3.89 (s, 6H, O*Me*), 6.78 (d, *J* = 8.4 Hz, 2H, Ar*H*), 7.07 (dd, *J* = 2.4, 8.4 Hz, 2H, Ar–*H*), 7.33 (d, *J* = 2.2 Hz, 2H, Ar–*H*). ^{13}C NMR ($CDCl_3$) δ: 20.27, 56.04, 89.69 (*sp*-C), 110.6, 112.46, 129.60, 130.04, 133.96, 157.86. MS *m/z* (%): 266 (M^+). Anal. calcd for $C_{18}H_{18}O_2$ (266.34): C 81.17, H 6.81; found: C 81.03, H 6.92.

Reaction of 7 with BBr_3

To a solution of **7** (60 mg, 0.16 mmol) in CH_2Cl_2 (6 mL) at 0 °C was gradually added a solution of BBr_3 (0.087 mL, 0.922 mmol) in (0.1 mL). After the reaction mixture was stirred at rt for 0.5 h, it was poured into ice water (10 mL) and then extracted with CH_2Cl_2 (10 mL × 3). The combined extracts were washed with water (10 mL × 2), dried over Na_2SO_4, and concentrated in vacuo to leave a residue. The residue was chromatographed over silica gel (Wako C-300, 100 g) with hexane–$CHCl_3$ (4:1) as eluent to give crude **13** as a colorless solid. Recrystallization from EtOH gave

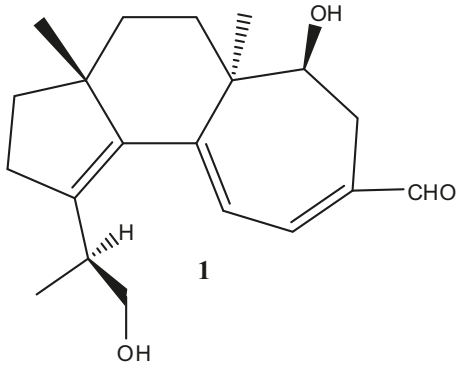
Abstract: The synthesis of a large number of β- and β,β-substituted keto esters was successful by the use of the Knoevenagel condensation reaction. The stereoselectivity of these reactions was improved by alteration of various substituent groups. Although there were few examples of complete Z selectivity, the use of *tert*-butyl acetoacetate with either aromatic or aliphatic aldehydes afforded Z selectivity. The selective reductions of these substituted keto esters was successfully achieved by using a combination of $NaBH_4$ and $CeCl_3 \cdot 7H_2O$ or $Yb(OTf)_3$, which allowed a facile synthesis of a large number of stereochemically pure substituted Morita–Baylis–Hillman adducts, including β,β-substituted adducts.

Key words: Morita–Baylis–Hillman, Knoevenagel, reduction, β,β-substituted.

Résumé : On a effectué avec succès la synthèse d'un grand nombre d'esters β- et β,β-substitués en faisant appel à la condensation de Knoevenagel. On a amélioré la stéréosélectivité de ces réactions en procédant à l'altération de divers substituants. Même s'il n'y a que peu d'exemples de sélectivité Z complète, l'utilisation de l'acétoacétate de *tert*-butyle avec des aldéhydes aromatiques ou aliphatiques conduit à la formation de produits avec une sélectivité Z. On a effectué avec succès les réductions sélectives de ces cétoesters substitués en utilisant une combinaison de $NaBH_4$ et de $CeCl_3 \cdot 7H_2O$ ou de $Yb(OTf)_3$; ceci a permis de réaliser une synthèse facile d'un grand nombre d'adduits de Morita-Baylis-Hillman substitués et stéréochimiquement purs, y compris des adduits β,β-substitués.

Mots-clés : Morita–Baylis–Hillman, Knoevenagel, réduction, β,β-substitué.



[Traduit par la Rédaction]

Introduction

There is significant interest in the field of natural product synthesis for the purpose of developing methodology for the synthesis of compounds with medicinal properties. Sarcodonin A (**1**) is a natural product found in the fungus *Sarcodon scabrosus*, which has been found to possess antibacterial and anti-inflammatory properties.[1] The cyanthane diterpenes are characterized by a fused 5,6,7-tricyclic array (Fig. 1), with most containing a C-3 isopropyl group that is not functionalized. Sarcodonin A is an exception, as it has an alcohol functionality at C-19, which generates a chiral centre at C-18. This increased level of oxidation makes the synthesis of sarcodonin A significantly more difficult than other members of the cyanthane family, since it requires controlling the configuration of a stereogenic centre on a pendant side chain relative to which it is attached. Since this particular type of stereochemical arrangement has been proven to be particularly troublesome to handle synthetically, this compound provides an interesting target to address this challenge.

Recently, the MaGee group[2] demonstrated that enantioselective deprotonation can be used to help address this problem. To implement this strategy for the synthesis of sarcodonin A, a potential symmetry in the molecule had to be delineated. Upon close examination it was envisioned that the left-hand portion of sarcodonin A could be constructed from the [3.2.1]-bicyclic diketone **4** (Scheme 1), thus, compounds like **2** became the lynchpin for our proposed synthesis.

Fig. 1. Sarcodonin A.

1

There appeared to be several approaches for the construction of this type of structure; these included: (1) addition of an allyl cation, or equivalent, to a conjugated diene;[3] (2) [3 + 3] carbocyclization of a nitroallylic ester and an enamine;[4] and (3) an α,α′-annulation strategy[5] involving reaction between a cyclic enamine and a biselectrophile (i.e., a compound that could serve as both an alkylation and Michael addition agent) (Fig. 2). For our purposes, however, each

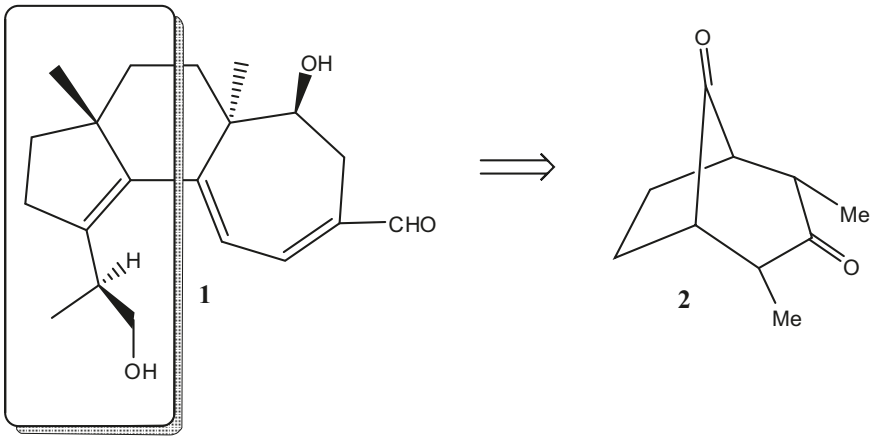
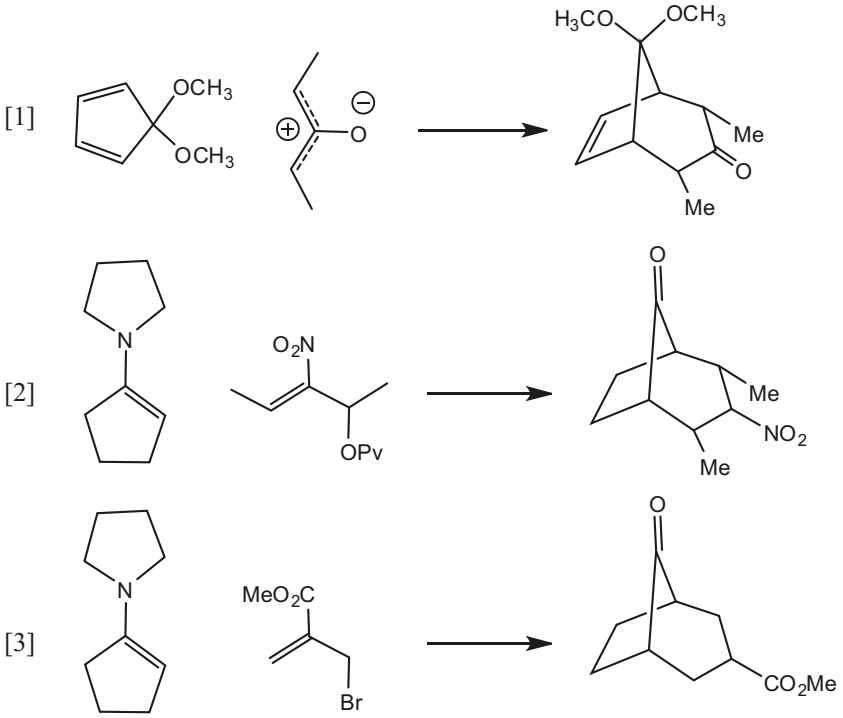
Scheme 1. Retrosynthetic analysis of sarcodonin A.





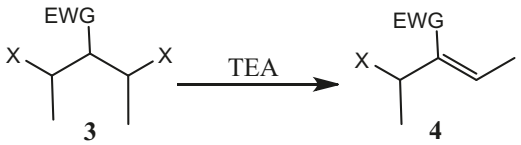


Fig. 2. Various approaches to construct [3.2.1]-bicyclic ketones.

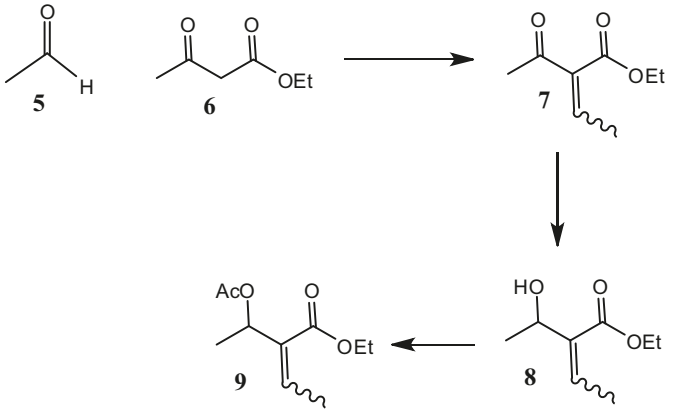
approach had limitations. For instance, oxyallyl cation addition to 1,1-diethoxycyclopentadiene proceeds in very poor yield, which is unacceptable as the first step in a total synthesis. The [3 + 3]-carbocyclization route using nitroallylic esters proceeds in acceptable yields and is easily scaled up, however, all attempts to perform a Nef reaction failed.[6] Finally, the α,α′-annulation strategy efficiently generates compounds such as [3.2.1]-bicyclic ketones, however, it is underfunctionalized, and the ability to synthesize and use more highly substituted derivatives to participate in the annulation reaction has not been demonstrated.



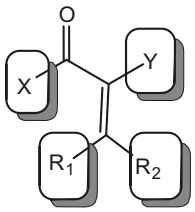
To solve the issue of underfunctionalization, compounds like **4** (Scheme 2) were required, and it was felt that these can potentially be accessed from Morita–Baylis–Hillman (MBH) adducts.[7] Unfortunately, β-branched MBH adducts are difficult to obtain using classical conditions, therefore, several chemical solutions have been reported.[8–15] Although each has their own advantages, they all have the limitation in requiring reactive organometallic and (or) toxic reagents and not being very amenable to scale up.

Scheme 2. An α,β-unsaturated compound suitably substituted for use in an α,α′-annulation sequence for sarcodonin A synthesis.

Given these limitations, an alternative route for the synthesis of the targeted annulation agent was sought. It was felt that the Knoevenagel reaction[16] between an aldehyde and ethyl acetoacetate would give rise to an α,β-unsaturated keto ester like **7**, and that upon reduction with an appropriate reducing agent would provide the MBH adduct **8** (Scheme 3). Although there was precedent for this approach,[17] in our

Scheme 3. Synthesis of Morita–Baylis–Hillman (MBH) adducts using the Knoevenagel condensation/reduction two-step protocol.

hands we routinely obtained low yields (>30%). If more substituted examples were used (e.g., Ph substituted on the alkene rather than methyl) then a much slower reduction occurred and did not have complete conservation of stereochemistry. Given these difficulties, we decided to investigate the breadth and scope of this reaction focusing on different substitution patterns, electron-withdrawing groups, and reduction conditions. Herein we report our study on the preparation of MBH adducts by this two-step protocol and show that it is rapid and generally applicable to the formation of β- and β,β-disubstituted MBH compounds.



Results and discussion

The first step was the synthesis of the intermediate keto esters via a Knoevenagel condensation reaction. Literature reports have demonstrated this method to be appropriate for reactions between aromatic and aliphatic aldehydes, as well as different 1,3-dicarbonyl compounds[16] such as acetoacetates. The breadth of this reaction was attractive, since it would allow for the construction of a wide variety of adducts and thus permit the exploration of the scope of this two-step process.

In deciding what compounds should be generated, consideration was given to each quadrant of the alkene (Fig. 3). For instance, if Y were an ester then it could be easily varied from *tert*-butyl to methyl or benzyl to probe the sterics. It was also envisaged that electron-withdrawing groups (EWGs, Y) other than esters could be explored, such as a SO_2Ph, a ketone, or a cyano group. The ketone (X) could also be varied from a methyl to a branched or long-chain aliphatic ketone or to an aromatic ketone. Altering this quadrant allowed one to explore the effect of sterics on both the E:Z ratios obtained in the Knoevenagel condensations, as well as the ease of hydride reduction. Moving to the other quadrants of the double bond, R_1 and (or) R_2 could be replaced with branched or long-chain aliphatic or aromatic units. Finally, if both R_1 and R_2 were replaced with carbons then this would provide access to β,β-substituted adducts that could then be transformed into β,β-substituted MBH adducts; these are little known or studied compounds.

It is important to note that all of these alterations were important for obtaining a variety of substituted symmetrical and unsymmetrical compounds that have the potential to be very useful α,α′-annulation agents (biselectrophiles) for not only

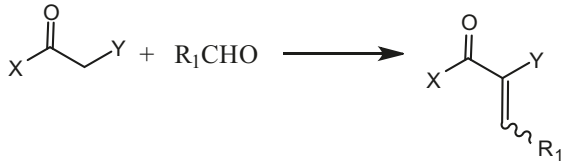
Fig. 3. Different quadrants of the Knoevenagel condensation product.

the formation of substituted [3.2.1]-bicyclic diketones, but also a variety of other natural products. With this in mind, 18 different Knoevenagel products were synthesized following general procedures (Tables 1 and 2).

It was decided to first investigate what effect, if any, aromatic and aliphatic aldehydes had on the E and Z stereoselectivity when condensed with 1,3-dicarbonyl compounds. Thus, condensation of different acetoacetates with various aliphatic aldehydes (Table 1, entries 1–6) showed that regardless of whether a methyl, isopropyl, pentyl, or cyclohexyl group was on the terminus of the double bond, all condensations afforded roughly the same mixture of isomers (1.5–2.3:1) with Z being favoured over the E isomer in most cases. The exception to this was entry 6 where a *tert*-butyl group was able to confer complete stereochemical control, albeit in low chemical yield.

Other notable results obtained are entries 7–9 (Table 1), where the ester functionality was varied from methyl to *tert*-butyl to benzyl. It was found that increasing the bulk of the EWG group also increased the selectivity of the reaction in favour of the Z isomer. This was surprising, since it was expected that E stereoselectivity would be preferred as one increased the size of the ester group.[18] However, Tanikaga et al.[19] demonstrated that the stereoselectivity of the Knoevenagel product is affected by slight differences in steric requirements between the two EWGs and when the differences between X, Y, and R_2 (Fig. 3) are rather small then selectivity in favour of the Z isomer is preferred.

The effect of EWGs other than esters was also investigated. In entry 11 (Table 1), a sulfone was used for comparison and, as reported by Tanikaga et al.,[20] an overwhelming preference for the E-isomer was observed. However, as expected,[21] use of a cyano group (Table 1, entry 14) in place of an ester preferentially gave the Z-isomer.



Continuing with this survey of different combinations, various alkyl groups were substituted on the ketone (Table 1, entries 10, 12, and 13) to assess if improved selectivity could be obtained and if the reduction would tolerate increased steric hindrance near the ketone. Not surprisingly, as the steric hindrance around the ketone increased there was an improvement in the stereochemical purity. This increase in stereoselectivity came at a price as the yield of Knoevenagel product decreased substantially as the acetoacetate became bulkier.

With a large number of aldehydes screened, a decision was made to look at the possibility of doing the condensation with a number of ketones ranging from straight-chain aliphatic (symmetric and unsymmetric), to cyclic aliphatic, to heterocyclic. These were condensed with ethyl acetoacetate to form β,β-substituted Knoevenagel products (Table 2).

With a number of Knoevenagel condensation products in hand, the stage was set to look at the critical 1,2-hydride reduction. Upon examination of the literature there appeared to be several approaches. The first method to be studied was reduction using Luche conditions.[22] The advantage of this method was that selective 1,2-reduction could be obtained under conditions that did not affect other functional groups such as carboxylic acids, esters, amides, or nitro groups.[19] Furthermore, the reaction could be conducted at room temperature without the special exclusion of air or moisture. Even though there was a lot of precedent literature that consistently showed that Luche conditions were the appropriate choice for the selective 1,2-reduction of α-enones, it was not clear how it was going to perform on keto esters like **7**, as there were few reports of its use for the reduction of β′-oxocarbonyl compounds.[23] Regardless, following the procedure outlined by Luche, compounds **16** and **17** were treated with 1 mol equiv of sodium borohydride and cerium trichloride in methanol at 0 °C and room temperature (to assess the influence of temperature on the yield) to provide allylic alcohols **29** and **30** in 34%–80% overall yield (Table 3). From these results it was clear that effecting the reduction at room temperature gave the best results.

Of note in this preliminary investigation was the fact that, even though the reaction was started with a 1:1 mixture of isomers, the final stereoisomeric ratio of the products was found to be 2:3. There were several possibilities to account for this. Firstly, if the reduction of one isomer was faster than the other and the rate of isomerization of the starting materials was approximately the same as the reduction, then this would lead to a preponderance of one isomer. A second possibility was that there was some isomerization that took place after the reduction had occurred, presumably this would lead to a predominance of the thermodynamic product. Finally, it is possible that the reduction of one isomer was much more efficient than the other.

Table 3. Reduction of Knoevenagel condensation products **16** and **17** to allylic alcohols **29** and **30** using Luche conditions.

Starting material (E:Z isomer ratio)	Temp. (°C)	Time (h)	Product	Yield (%)	Isomer ratio (E:Z)
16 (1:1)	0	2	**29**	50	2:3
16 (1:1)	25	2	**29**	80	2:3
17 (2:3)	0	2	**30**	34	2:3
17 (2:3)	25	2	**30**	77	2:3

With the optimal conditions for the Luche reduction obtained, other reducing agents were investigated to see if greater success could be realized; these included lithium tri-*tert*-butoxyaluminium hydride (LATB-H),[24] borane methyl sulfide complex (BMS),[25] and $Yb(OTf)_3$[26] (Table 4). Of these, only $Yb(OTf)_3$ consistently reduced the ketone; however, the yields were substantially inferior to the yields under Luche conditions.

Based on the optimized conditions, all of the compounds in Tables 1 and 2 were reduced using the Luche method, and the results are summarized in Table 5. It was observed that as the substituent on the terminus of the alkene increased in size, the yield of the reduction product improved (Table 5, entries 1–7). This was presumably due to a diminution of competing side reactions such as Michael addition, self-condensation, or 1,4-reduction. This was especially true for the methyl-substituted compound (Table 5, entries 1 and 2) where it was observed that good yields could only be realized if the reduction was allowed to run for only a few seconds. It was also observed that in most cases it was possible to obtain pure isomers when starting with either pure E or Z starting material. The exception to this was the phenyl ketone **16**, for which the same isomer ratio of products was obtained after reduction regardless of the isomer ratio of the starting ketones.

Another notable result was the reduction of the cyano compound (Table 5, entry 18). It was found that the desired reduction product (Z-isomer) along with the fully reduced product, in which the double bond was also reduced, was obtained in approximately a 1:1 ratio. Although the desired product was present, the two compounds were found to be inseparable by column chromatography; thus, pure MBH adduct could not be achieved by this method.

Having succeeded with the reduction of the β-substituted Knoevenagel condensation products, the reduction of the β,β-substituted 1,3-dicarbonyl compounds was examined (Table 5). All the ketones (**24**–**28**) reduced very efficiently and in a short period of time (15 min) to produce the β,β-substituted MBH adducts in good to excellent yields. Of particular note is entry 23 (Table 5) where compound **52** was obtained in 71%; this result shows that additional functional groups may be present without adversely affecting the reduction.

α,α′-Annulation strategy for construction of the [3.2.1]-bicyclic ketone

With a suitable method available to generate amounts of alcohol **31** in hand, investigation into transforming it to the targeted annulation agent **57** was undertaken (Scheme 4). Fortunately, when alcohol **31** was treated with triphenylphosphine and *N*-bromosuccinimide (NBS)[27] at –30 °C, allylic bromide **55** was obtained in 48% yield as a 1:1 mixture of E- and Z-isomers. Alternatively, **31** could be efficiently acylated with acetyl chloride, pivaloyl chloride, and methyl chloroformate in 71%, 65%, and 73% yields, respectively.[4,17] Treatment of each of these biselectrophiles with 1-pyrrolidino-1-cyclopentene (**56**) with and without triethylamine in refluxing ethanol or acetonitrile provided variable success, with the desired cycloadducts, **57a** and **57b**, being most efficiently produced in 43% yield as a 1:1 mixture of isomers using bromide **55**.

Table 4. Reduction of selected Knoevenagel products with tri-*tert*-butoxyaluminium hydride (LATB-H), borane methyl sulfide complex (BMS), and $Yb(OTf)_3$.

Reducing agents	Starting material (E:Z isomer ratio)	Time (h)	Product	Yield (%)	Isomer ratio (E:Z)

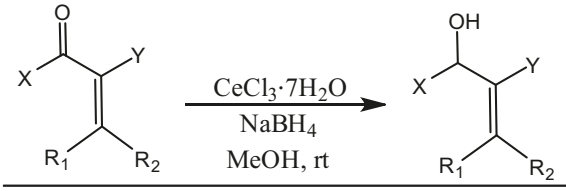
	19 (0:1)	2	**43**	nr	—-

Note: nr, no reaction.

The isolated products were determined to be an approximately 50:50 mixture of symmetric and asymmetric esters based on an analysis of the ^1H and ^{13}C NMR spectra. The stereochemistries of the esters were assigned on the basis of correlations observed in the NOESY spectrum of the mixture. For the symmetric ester, the methine hydrogens on the carbons bearing the methyl groups were assigned as equatorial based on NOESY correlations observed between these hydrogens and the axial methylene hydrogens. The ester was assigned as axial based on NOESY correlations observed between the axial methyl hydrogens and the methine hydrogen on the carbon bearing the ester group (Fig. 4, **57a**).



A similar analysis for the asymmetric ester determined the ester group to be axial. For the side of the molecule with the methyl group axial, NOESY correlations similar to those for the symmetric ester were observed, with an additional NOESY correlation observed between the methyl hydrogens and the axial methine hydrogen on the carbon bearing the equatorial methyl group. In addition, NOESY correlations were observed between the equatorial methyl hydrogens and one of the axial methylene hydrogens (Fig. 4, **57b**).

Conclusion

In conclusion, a large number of β- and β,β-substituted α,β-unsaturated keto esters were synthesized using the Knoevenagel condensation. For the synthesis of the β-keto esters, it was demonstrated that the stereoselectivity of the reaction was improved by alteration of various substituents on the ketone, ester group, and various aldehydes. From our results, a Z-selective Knoevenagel condensation can be achieved by the use of *tert*-butyl acetoacetate with either aromatic or aliphatic

aldehydes. An added advantage of the *tert*-butyl ester derivatives was that it allowed for easy chromatographic separation of the stereoisomers. Although there were a few examples of complete Z selectivity, for the most part ratios of approximately 70:30 were routinely obtained. A number of β,β-substituted Knoevenagel condensation products were also obtained by the use of various symmetrical and unsymmetrical ketones with $TiCl_4$ or zinc chloride. In the case of an unsymmetrical ketone a 1:1 mixture of isomers was obtained.

These β- and β,β-substituted keto ester compounds were subjected to a variety of different reducing conditions to generate substituted MBH products, many of them previously unknown and inaccessible via traditional MBH methods. It was found that the reduction of these β-oxoesters was most successful using Luche conditions with good to excellent yields (40%–92%) being obtained within a few minutes at room temperature. In most cases, it was determined that there was no scrambling of the stereochemistry when either pure E- or Z-isomers were reduced. Since it is well-documented that Knoevenagel products are readily isomerized by simple heating,[28] this is important because, coupled with the ability to separate them by chromatography, it offers the potential of cycling both β-oxoester compounds to either MBH product in a stereochemically pure fashion.

Studies aimed at using these substituted MBH adducts for a variety of different synthetic endeavors are currently underway and results will be communicated in due course.

General experimental procedures

All reactions were carried out in flame-dried round bottom flasks (RBF) or in oven-dried glassware (pyrex) (140 °C, 1 h) unless stated otherwise. Temperatures indicated refer to an external bath. All reactions were magnetically stirred, unless stated otherwise. Standard techniques were used for solvent purifications. Anhydrous reaction solvents were available via the use of Grubbs-type columns. Air- and moisture-sensitive reagents were handled via standard techniques. Reagents were purchased from common suppliers and used as received unless stated otherwise. SiO_2 flash chromatography was performed using Silicycle silica gel (30–60 μm particle size). Nuclear magnetic resonance (NMR) spectroscopy was performed on a Varian INOVA 300 MHz or on a Varian UNITY 400 MHz (referred to proton resonance frequency). ^{1}H NMR spectroscopic data are presented in parts per million (δ) relative to tetramethylsilane as an internal standard. All proton–proton NMR coupling constants (*J*) are expressed in Hertz (Hz). ^{13}C NMR data are presented in parts per million (δ) relative to $CDCl_3$ (77.16 ppm) as an internal standard unless otherwise stated. Infrared spectra (IR) were recorded on a NEXUS 470 FTIR. Main peaks are reported as wavenumbers in cm^{-1}. High-resolution mass spectra (HRMS) were recorded using a Waters Xevo Q-Tof mass spectrometer. Samples were dissolved into a mixture of acetonitrile / deionized water / formic acid (50%:50%:0.1% composition), filtered on a 0.2 μm membrane filter, and then immediately introduced into the instrument by infusion at a rate of 10 μL/min. The ionization mode was electrospray positive (ESI+), which predominantly produced protonated cations ($[M + H]^+$ species). High-resolution spectra were acquired using a sodium formate solution as a lock mass reference solution and used as a mass correction when acquiring the sample spectra. ESI$^+$ conditions were optimized with a capillary voltage between 2 kV, a sample cone of 30, an extraction cone of 3.0, a source temperature of 120 °C, a desolvation temperature of 200 °C, a desolvation gas flow of 500 L/h, and a cone gas flow of 10 L/h. The MS data were acquired over a range of 20–1000 *m/z* with a scan duration of 1 s. Melting points were measured on a Gallenkamp melting point apparatus and all melting points are uncorrected.

General procedure for the synthesis of α,β-unsaturated dicarbonyl compounds 10–13

To a cooled (0 °C) mixture of aldehyde (50 mmol) and acetoacetate (15 mmol) was added a mixture of piperidine (0.03 mL) and EtOH (0.025 mL). The mixture was stirred at 0 °C for 12 h, and the reaction was quenched with cold aqueous 20% tartaric acid. The products were extracted with ethyl acetate, and the extracts were washed with brine, dried ($MgSO_4$), and concentrated under reduced pressure. The crude product was purified by column chromatography (SiO_2, hexane–AcOEt 10:1).

Preparation of tert*-butyl (*E*)- and (Z)-2-acetyl-but-2-enoate (10)*

Following the general procedure, esters **10a** and **10b** were formed in 83% yield (2.2 g) as a 1.2:3 mixture of E- and Z-isomers.[16]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

Preparation of **tert-*butyl* (E)-** *and* **(Z)-2-acetyl-4-methylpent-2-enoate (11)**

Following the general procedure, esters **11a** and **11b** were formed in 70% yield (2.23 g) as a 1.2:3 mixture of E- and Z-isomers.[16]

Preparation of **tert-*butyl* (E)-** *and* **(Z)-2-acetyloct-2-enoate (12)**

Following the general procedure, esters **12a** and **12b** were formed in 80% yield as a 2:3 mixture of E- and Z-isomers. (Z)-Isomer **12a**: IR (neat, cm^{-1}): 2985, 1724, 1657, 1625, 1577, 1497, 1448, 1394, 1234, 1213, 1043, 949, 890, 757, 695. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.93 (t, 3H, J = 7.0 Hz), 1.21–1.51 (m, 8H), 1.52 (s, 9H), 2.31 (s, 3H), 6.82 (t, 1H, J = 9.5 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 22.0, 29.8, 52.0, 70.0, 126.0, 128.7, 129.6, 130.5, 133.3, 135.8, 139.9, 168.6. HRMS (M^+ + H) calcd for $C_{14}H_{25}O_3$: 241.1801; found: 241.1803. (*E*)-Isomer **12b**: IR (neat, cm^{-1}): 2985, 1724, 1657, 1625, 1577, 1497, 1448, 1394, 1234, 1213, 1043, 949, 890, 757, 695. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.89 (t, 3H, J = 6.8 Hz), 1.21–1.40 (m, 8H), 1.50 (s, 9H), 2.33 (s, 3H), 6.80 (t, 1H, J = 7.8 Hz). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 13.9, 22.3, 28.0, 29.1, 31.0, 31.4, 81.8, 137.2, 147.6, 163.7, 201.6. HRMS (M^+ + H) calcd for $C_{14}H_{25}O_3$: 241.1804; found: 241.1804.

Preparation of methyl **(E)-** *and* **(Z)-2-(cyclohexylmethylene)-3-oxobutanoate (13)**

Following the general procedure, esters **13a** and **13b** were formed in 84% yield as a 2:3 mixture of E- and Z-isomers.[23]

General procedure for the synthesis of α,β-unsaturated dicarbonyl compounds 14–22 using the Knoevenagel condensation reaction

1,3-Dicarbonyl compound (10 mmol), benzene (50 mL), aldehyde (10 mmol), glacial acetic acid (1 mmol), and piperidine (1 mmol) were placed in an oven-dried RBF equipped with a Dean–Stark apparatus. The mixture was heated to reflux and maintained there until TLC showed the complete consumption of starting material. Upon cooling to room temperature, the solution was diluted with diethyl ether (50 mL) and water (25 mL). The organic layer was separated and washed with water (25 mL), 1 mol/L HCl solution (2 × 25 mL), and then sodium hydrogen carbonate solution until neutrality was reached. The organic layer was dried (Na_2SO_4), filtered, and the solvent evaporated in vacuo. The crude product was purified by flash chromatography (hexane – diethyl ether).

Preparation of methyl **(E)-** *and* **(Z)-2-acetyloct-2-enoate (14)**

Following the general procedure, esters **14a** and **14b** were formed in 70% yield as a 1:2 mixture of E- and Z-isomers.[16]

Preparation of ethyl **(Z)-2-acetyl-4,4-dimethylpent-2-enoate (15)**

Following the general procedure, ester **15** was formed in 24% yield as a single Z-isomer.[29]

Preparation of methyl **(E)-** *and* **(Z)-2-benzylidene-3-oxobutanoate (16)**

Following the general procedure, esters **16a** and **16b** were formed in 80% yield as a 1:1 mixture of E- and Z-isomers.[16]

Preparation of benzyl **(E)-** *and* **(Z)-2-benzylidene-3-oxobutanoate (17)**

Following the general procedure, esters **17a** and **17b** were formed in 77% yield as a 2:3 mixture of E- and Z-isomers.[30]

Preparation of **tert-*butyl* 2-benzylidene-3-oxobutanoate (18)**

Following the general procedure, ester **18** was formed in 50% yield as a single Z-isomer.[31]

Preparation of ethyl **(Z)-2-benzoyl-3-phenylacrylate (19)**

Following the general procedure, ester **19** was formed in 70% yield as a single Z-isomer.[16,32]

Preparation of **(E)-1,3-diphenyl-2-(phenylsulfonyl)prop-2-en-1-one (20)**

Following the general procedure, ester **20** was formed as a brown solid that was recrystalized from ethanol to give 2.7 g (78% yield) of the E-isomer.[7] mp 135–136.5 °C (lit.[7] 136 °C).

Preparation of methyl **(E)-** *and* **(Z)-2-isobutyryl-3-phenylacrylate (21)**

Following the general procedure, ester **21** was formed in 60% yield as an 1.8:1 mixture of E- and Z-isomers.[16,33]

Preparation of methyl **2-benzylidene-4,4-dimethyl-3-oxopentanoate (22)**

Following the general procedure, ester **22** was formed in 18% yield as a Z-isomer.[34]

Preparation of (Z)-3-cyclohexyl-2 (benzo)acrylonitrile (23)

In a RBF under argon was added benzoylacetonitrile (1.45 g 10.0 mmol) and ethanol (30 mL). To this, L-proline (0.23 g, 2.0 mmol) and cyclohexane carboxaldehyde (1.21 mL, 10.0 mmol) were added. The mixture was allowed to stir at room temperature for 48 h. It was then concentrated in vacuo and purified via SiO_2 chromatography (15:1 hexane – ethyl acetate) to give 1.19 g (50% yield) of **23** as a clear yellow oil.[35]

Preparation of ethyl α-isopropylidine acetoacetate (24)

Ethyl acetoacetate (13.0 g, 0.100 mol), acetone (8.7 g, 0.15 mol), acetic anhydride (12.8 mL), and fused zinc chloride (1.9 g) were heated under reflux for 72 h. After cooling, diethyl ether (25 mL) was added and the resulting solution was washed with water (4 × 25 mL). The combined water washings were extracted with Et_2O (50 mL), and the combined organic extracts were dried with $MgSO_4$, filtered, and the solvent evaporated under reduced pressure. The oily residue was purified via SiO_2 chromatography (10:1 hexane – AcOEt) to give 7.42 g (42%) of **17** as a yellow oil.[36]

General procedure for the synthesis of α,β-unsaturated dicarbonyl compounds 25–28 using $TiCl_4$

CH_2Cl_2 (20 mL) and THF (20 mL) were placed in a RBF cooled to 0 °C. To this $TiCl_4$ (2.2 mL, 20 mmol) was carefully added dropwise, followed by ketone (10 mmol) and ethyl acetoacetate (1.08 mL, 10 mmol) in THF (5 mL). After complete addition, pyridine (3.2 mL, 40 mmol) was added and the solution was allowed to slowly warm to room temperature and stir for 16 h. The reaction mixture was diluted with H_2O and ethyl acetate (1:1, 100 mL) and the aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

phase was separated. The organic phase was washed with H_2O (3 × 50 mL), $NaHCO_3$, and brine and then dried over $MgSO_4$, filtered, and the solvent removed under reduced pressure. The oily residue was purified via SiO_2 chromatography (7:1 hexane – ethyl acetate).

Preparation of ethyl α-cyclohexylidine acetoacetate (25)

Following the general procedure, ester **18** was formed in 38% yield (0.75 g) as a pale yellow oil.[37]

Preparation of ethyl α-cyclopentylidine acetoacetate (26)

Following the general procedure, ester **19** was formed in 28% yield (0.55 g) as a pale yellow oil.[38]

Preparation of methyl 4-(1-(ethoxycarbonyl)-2-oxopropylidine)piperdine-1-carboxylate (27)

Following the general procedure, ester **20** was formed in 32% yield (0.8 g) as a pale yellow oil.[39]

Preparation of ethyl (*E*)- and (*Z*)-2-acetyl-3-methyldec-2-enoate (28)

Following the general procedure, esters **28a** and **28b** were formed in 27% yield (0.64 g) as colourless oils in a 1.25:1 mixture of E- and Z-isomers. *Z*-Isomer **28a**: IR (neat, cm^{-1}): 2954, 2929, 2857, 1725, 1700, 1624, 1466, 1354, 1225, 1119, 1053. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.88 (t, 3H, J = 7.1 Hz), 1.22–1.38 (m, 8H), 1.30 (t, 3H, J = 7.0 Hz), 1.42–1.55 (m, 2H), 1.95 (s, 3H), 2.28 (s, 3H), 2.34–2.42 (m, 2H), 4.24 (q, 2H, J = 7.2 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.3, 21.3, 22.8, 28.2, 29.2, 29.9, 30.8, 31.8, 31.9, 36.8, 60.9, 132.1, 157.4, 166.3, 200.3. HRMS (M^+ + H) calcd for $C_{15}H_{27}O_3$: 255.1961; found: 255.1960. *E*-Isomer **28b**: IR (neat, cm^{-1}): 2928, 2857, 1725, 1722, 1625, 1466, 1355, 1273, 1225, 1118, 1056. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.87 (t, 3H, J = 7.0 Hz), 1.18–1.35 (m, 8H), 1.29 (t, 3H, J = 7.2 Hz), 1.42–1.60 (m, 2H), 2.08 (s, 3H), 2.14–2.21 (m, 2H), 2.28 (s, 3H), 4.22 (q, 2H, J = 7.0 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.26, 14.3, 20.8, 22.8, 28.3, 29.2, 29.9, 31.2, 31.9, 37.1, 60.9, 132.2, 157.4, 165.9, 201.0. HRMS (M^+ + H) calcd for $C_{15}H_{27}O_3$: 255.1961; found: 255.1960.

General procedure for the reduction of Knoevenagel adducts using Luche conditions

Adducts **10**–**28** (1 mmol) and $CeC1_3{\cdot}7H_2O$ (1 mmol) were dissolved in methanol (2.5 mL) and $NaBH_4$ (38 mg, 1 mmol) was added in one portion with stirring. A vigorous gas evolution occurred and then stirring was continued for the specified time before the pH was adjusted to neutrality with dilute aqueous HCl. The mixture was extracted with diethyl ether (3 × 15 mL), the combined organic extracts were dried over $MgSO_4$, and the solvent evaporated under reduced pressure. The crude product was analyzed for quantitative isomer determination by ^1H NMR. It was then purified by column chromatography and identified by the usual spectroscopic methods.

Preparation of methyl (E)- and (Z)-2-benzylidene-3-hydroxybutanoate (29)

Following the general procedure (15 min), alcohols **29a** and **29b** were formed in 80% yield as a 2:3 mixture of E- and Z-isomers.[40]

Preparation of benzyl (E)- and (Z)-2-benzylidene-3-hydroxybutanoate (30)

Following the general procedure (15 min), alcohols **30a** and **30b** were formed in 77% yield as a 2:3 mixture of E- and Z-isomers. Z-Isomer **30a**: IR (neat, cm^{-1}): 3421, 3031, 2974, 1718, 1497, 1455, 1385, 1212, 1142, 1014, 921, 751, 697. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.44 (d, 3H, J = 6.5 Hz), 2.35 (d, 1H, J = 6.2 Hz), 4.64 (q, 1H, J = 6.3 Hz), 5.16 (s, 2H) 6.85 (s, 1H), 7.23–7.60 (m, 10H). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 22.4, 66.8, 69.9, 128.1, 128.2, 128.4, 128.5, 132.7, 135.0, 135.4, 137.5, 168.8. HRMS (M^+ + H) calcd for $C_{18}H_{19}O_3$: 283.1334; found: 283.1334. E-Isomer **30b**: IR (neat, cm^{-1}): 3421, 3031, 2974, 1718, 1497, 1455, 1385, 1212, 1142, 1082, 1014, 921, 751, 697. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.48 (d, 3H, J = 6.5 Hz), 2.20 (s, 1H, J = 6.3 Hz), 4.84 (q, 1H, J = 5.9 Hz), 5.16 (s, 2H), 7.21–7.43 (m, 10H), 7.85 (s, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 23.3, 65.0, 66.8, 128.3, 128.5, 128.6, 128.7, 128.9, 129.2, 134.5, 135.6, 140.0, 167.5. HRMS (M^+ + H) calcd for $C_{18}H_{19}O_3$: 283.1334; found: 283.1334.

Preparation of* tert-*butyl (E)-2-(1-hydroxyethyl)-but-2-enoate (31)

Following the general procedure (15 s), E-alcohol **31** was formed in 66% yield as a colourless oil. IR (neat, cm^{-1}): 3508, 2977, 2932, 1683, 1645, 1456, 1368, 1322, 1291, 1149, 1060, 988, 897, 761. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.39 (d, 3H, J = 6.7 Hz), 1.51 (s, 9H), 1.80 (d, 3H, J = 7.4 Hz), 3.80 (b, 1H), 4.70 (q, 1H, J = 6.7 Hz), 6.69 (q, 1H, J = 7.4 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 13.7, 23.4, 28.4, 64.9, 81.5, 136.2, 136.8, 166.9. HRMS (M^+ + H) calcd for $C_{10}H_{19}O_3$: 187.1334: found: 187.1332.

Preparation of* tert-*butyl (Z)-2-(1-hydroxyethyl)-but-2-enoate (32)

Following the general procedure (15 s), Z-alcohol **32** was formed in 68% yield as a colourless oil. IR (neat, cm^{-1}): 3462, 2977, 1684, 1645, 1456, 1368, 1291, 1148, 1104. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.34 (d, 3H, J = 6.5 Hz), 1.53 (s, 9H), 1.95 (d, 3H, J = 7.2 Hz), 4.40 (q, 1H, J = 6.5 Hz), 6.15 (q, 1H, J = 7.2 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 15.5, 22.5, 28.5, 70.3, 81.8, 134.7, 137.4, 167.4. HRMS (M^+ + H) calcd for $C_{10}H_{19}O_3$: 187.1334; found: 187.1332.

Preparation of* tert-*butyl (E)-2-(1-hydroxyethyl)-4-methylpent-2-enoate (33)

Following the general procedure (1 min), E-alcohol **33** was formed in 79% yield as a colourless oil. IR (neat, cm^{-1}): 3514, 2969, 2932, 2871, 1684, 1641, 1457, 1368, 1324, 1276, 1153, 1120, 1065, 900, 773. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.98 (d, 3H, J = 6.7 Hz), 1.03 (d, 3H, J = 6.7 Hz), 1.38 (d, 3H, J = 6.7 Hz), 1.50 (s, 9H), 2.60–2.75 (m, 1H), 3.71 (d, 1H, J = 10.9 Hz), 4.61–4.72 (m, 1H), 6.35 (d, 1H, J = 10.3 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 22.4, 22.5, 24.0, 27.3, 28.4, 65.3, 81.5, 133.1, 148.5, 167.3. HRMS (M^+ + H) calcd for $C_{12}H_{23}O_3$: 215.1647; found: 215.1647.

Preparation of* tert-*butyl (Z)-2-(1-hydroxyethyl)-4-methylpent-2-enoate (34)

Following the general procedure (1 min), Z-alcohol **34** was formed in 66% yield as a colourless oil. IR (neat, cm^{-1}): 3514, 2969, 2932, 2871, 1684, 1641, 1457, 1368, 1324, 1276, 1153, 1120, 1065, 900, 773. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.03 (d, 3H, J = 6.7 Hz), 1.38 (d, 3H, J = 6.7 Hz), 1.50 (s, 9H), 2.70 (d, 1H, J = 6.2 Hz), 3.00–3.06 (m, 1H), 4.61–4.72 (m, 1H), 6.35 (d, 1H, J = 10.3 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 22.65, 22.78, 22.79, 28.39, 28.44, 65.3, 81.8, 134.4, 146.0, 167.6. HRMS (M^+ + H) calcd for $C_{12}H_{23}O_3$: 215.1647; found: 215.1647.

Preparation of* tert-*butyl (E)-2-(1-hydroxyethyl)oct-2-enoate (35)

Following the general procedure (5 min), E-alcohol **35** was formed in 75% yield as a colourless oil. IR (neat, cm^{-1}): 3471, 2960, 2930, 2857, 1686, 1454, 1368, 1277, 1148, 1066, 850. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.91 (t, 3H, J = 7.0 Hz), 1.30–1.51 (m, 8H) 1.62 (s, 9H), 2.80 (bs, 1H) 2.28 (s, 3H), 4.41 (q, 1H, J = 6.5 Hz), 6.61 (t, 3H, J = 6.7 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 13.9, 22.5, 28.1, 28.3, 32.0, 82.2, 137.7, 146.9, 148.0, 163.1, 166.1, 195.0. HRMS (M^+ + H) calcd for $C_{14}H_{27}O_3$: 243.1961; found: 243.1961.

Preparation of* tert-*butyl (Z)-2-(1-hydroxyethyl)oct-2-enoate (36)

Following the general procedure (5 min), Z-alcohol **36** was formed in 72% yield as a colourless oil. IR (neat, cm^{-1}): 3430, 2960, 2930, 2859, 1713, 1458, 1368, 1250, 1153, 846. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.91 (t, 3H, J = 6.5 Hz), 1.20–1.51 (m, 8H) 1.52 (s, 9H), 2.28 (s, 3H), 2.80 (d, 1H, J = 6.3 Hz), 4.41 (q, 1H, J = 7.0 Hz) 6.10 (t, 1H, J = 6.7 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 13.9, 22.4, 26.9, 28.3, 32.0, 82.2, 138.2, 146.9, 148.0, 163.1, 165.1, 195.0. HRMS (M^+ + H) calcd for $C_{14}H_{27}O_3$: 243.1961; found: 243.1961.

Preparation of ethyl (Z)-2-(1-hydroxyethyl)-4,4-dimethylpent-2-enoate (37)

Following the general procedure (1 min), Z-alcohol **37** was formed in 66% yield as a colourless oil. IR (neat, cm^{-1}): 3441, 2959, 2872, 1725, 1661, 1464, 1380, 1271, 1235, 1194, 1140, 1071, 1028. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.15 (s, 9H), 1.35 (t, 2H, J = 7.2 Hz), 2.28 (s, 3H), 4.23 (q, 3H, J = 6.7 Hz), 5.65 (s, 1H). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.3, 22.5, 29.6, 33.3, 60.0, 61.0, 134.7, 141.3, 169.1. HRMS (M^+ + H) calcd for $C_{11}H_{21}O_3$: 201.1491; found: 201.1491.

Preparation of methyl (E)-2-(1-hydroxyethyl)oct-2-enoate (38)

Following the general procedure (15 min), E-alcohol **38** was formed in 40% yield as a colourless oil. IR (neat, cm^{-1}): 3447, 2959, 1718, 1496, 1436, 1367, 1226, 1139, 1012, 753, 697. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.85 (t, 3H, J = 6.9 Hz), 1.52–1.60 (m, 6H, J = 6.7 Hz), 1.39 (d, 3H, J = 6.5 Hz), 2.40 (q, 1H, J = 7.3 Hz), 2.59 (bs, 1H) 3.80 (s, 3H), 4.52 (t, 2H, J = 6.4 Hz), 6.79 (t, 1H, J = 7.4 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 13.0, 22.0, 33.0, 51.8, 80.5, 128.2, 129.0, 134.4, 135.4, 141.5, 167.0. HRMS (M^+ + H) calcd for $C_{11}H_{21}O_3$: 201.1491; found: 201.1491.

Preparation of methyl (Z)-2-(1-hydroxyethyl)oct-2-enoate (39)

Following the general procedure (15 min), Z-alcohol **39** was formed in 49% yield as a colourless oil. IR (neat, cm^{-1}): 3447, 2959, 1718, 1496, 1436, 1367, 1226, 1139, 1012, 753, 697. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.85 (t, 3H, J = 7.0 Hz), 1.51–1.60 (m, 6H), 1.39 (d, 3H, J = 6.5 Hz), 2.40 (q, 1H, J = 7.4 Hz), 2.59 (bs, 1H), 3.80 (s, 3H), 4.52 (t, 2H, J = 6.4 Hz), 6.19 (t, 1H, J = 7.7 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 13.0, 20.2, 33.5, 52.0, 74.8, 128.6, 129.0, 134.0, 135.2, 141.5, 167.4. HRMS (M^+ + H) calcd for $C_{11}H_{21}O_3$: 201.1491; found: 201.1491.

Preparation of methyl (E)-2-cyclohexzylidene-3-hydroxybutanoate (40)

Following the general procedure (5 min), E-alcohol **40** was formed in 52% yield as a colourless oil. IR (neat, cm^{-1}): 3447, 2959, 1718, 1496, 1436, 1367, 1226, 1139, 1012, 753, 697. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.80–1.38 (m, 10H), 1.40 (d, 3H, J = 6.7 Hz), 1.41–1.80 (m, 1H), 2.50 (bs, 1H) 3.80 (s, 3H), 4.71 (t, 1H, J = 9.9 Hz), 6.53 (d, 1H, J = 9.2 Hz). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 24.3, 25.6, 25.8, 26.0, 32.5, 37.4, 52.0, 65.5, 132.3, 148.6, 168.4. HRMS (M^+ + H) calcd for $C_{12}H_{21}O_3$: 213.1491; found: 213.1491.

Preparation of methyl (Z)-2-cyclohexzylidene-3-hydroxybutanoate (41)

Following the general procedure (5 min), Z-alcohol **41** was formed in 56% yield as a colourless oil. IR (neat, cm^{-1}): 3447, 2959, 1718, 1496, 1436, 1367, 1226, 1139, 1012, 753, 697. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.80–1.38 (m, 10H, J = 6.5 Hz), 1.39 (d, 3H, J = 6.5 Hz), 1.40–1.80 (m, 1H), 2.50 (bs, 1H) 3.80 (s, 3H), 4.71 (t, 1H, J = 9.7 Hz), 5.93 (d, 1H, J = 9.7 Hz). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 22.6, 25.5, 26.0, 26.1, 32.5, 37.9, 51.3, 69.5, 133.0, 146.4, 168.1. HRMS (M^+ + H) calcd for $C_{12}H_{21}O_3$: 213.1491; found: 213.1491.

Preparation of* tert-*butyl (Z)-2-benzylidene-3-hydroxybutanoate (42)

Following the general procedure (15 min), Z-alcohol **42** was formed in 50% yield.[41]

Preparation of ethyl (Z)-2-(hydroxyl(phenyl)methyl)-3-phenylacrylate (43)

Following the general procedure (15 min), (*Z*)-alcohol **43** was formed in 64% yield.[28]

Preparation of (E)-1,3-diphenyl-2-(phenylsulfonyl)prop-2-en-1-ol (44)

Following the general procedure (15 min), with the exception that a 4 mol equiv excess of sodium borohydride and cerium trichloride were used, alcohol **44** was formed in 40% yield as a colourless solid based on reacted starting material. mp 145–147 °C. IR (neat, cm^{-1}): 3478, 1619, 1493, 1446, 1298, 12589, 1142, 1089, 1049, 1029, 773, 698, 611. ^1H NMR ($CDCl_3$, 300 MHz) δ: 4.03 (bs, 1H), 6.09 (s, 1H), 7.02–7.14 (m, 4H), 7.25–7.32 (m, 3H), 7.38–7.54 (m, 8H),

For personal use only.

8.14 (s, 1H). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 69.6, 126.0, 127.5, 127.6, 128.3, 129.0, 129.1, 129.6, 130.3, 132.7, 132.9, 139.2, 141.3, 143.0, 143.5. HRMS (M^+ + H) calcd for $C_{21}H_{19}O_3S$: 351.1055; found: 351.1055.

Preparation of methyl (E)-2-benzylidene-3-hydroxy-4-methylpentanoate (45)

Following the general procedure (15 min), E-alcohol **45** was formed in 65% yield as a colourless oil. IR (neat, cm^{-1}): 3447, 2959, 1718, 1496, 1436, 1367, 1226, 1139, 1012, 753, 697. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.69 (d, 3H, J = 6.7 Hz), 1.04 (d, 3H, J = 6.7 Hz), 2.03 (m, 1H), 3.22 (d, 1H, J = 2.7 Hz), 3.85 (s, 3H), 4.22 (t, 1H, J = 9.9 Hz), 7.26–7.43 (m, 5H), 7.80 (s, 1H). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 18.0, 19.5, 33.0, 51.8, 80.5, 128.2, 129.0, 134.4, 135.4, 141.5, 167.4. HRMS (M^+ + H) calcd for $C_{14}H_{19}O_3$: 235.1334; found: 235.1334.

Preparation of methyl (Z)-2-benzylidene-3-hydroxy-4-methylpentanoate (46)

Following the general procedure (15 min), Z-alcohol **46** was formed in 71% yield as a colourless oil. IR (neat, cm^{-1}): 3447, 2959, 1718, 1496, 1436, 1367, 1226, 1139, 1012, 753, 697. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.86 (d, 3H, J = 6.7 Hz), 1.02 (d, 3H, J = 6.7 Hz), 1.92 (m, 1H, J = 2.7 Hz), 2.10 (s, 1H), 3.63 (s, 3H), 4.06 (d, 1H, J = 9.9 Hz), 6.83 (s, 1H), 7.23–7.40 (m, 5H). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 19.6, 33.5, 52.0, 74.8, 128.6, 128.67, 129.0, 133.2, 134.0, 141.5, 167.4. HRMS (M^+ + H) calcd for $C_{14}H_{19}O_3$: 235.1334; found: 235.1334.

Preparation of (Z)-3-cyclohexyl-2-(hydroxy(phenyl)methyl) acrylonitrile (48)

Following the general procedure (5 min), alcohol **48** and its saturated analogue were formed in 52% yield as a yellow oil that was inseparable by SiO_2 chromatography. IR (neat, cm^{-1}): 3444, 3063, 3031, 2926, 2853, 2221, 1450, 1047, 701. ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 1.67–1.76 (m, 10H), 2.17 (d, 1H, J = 4.0 Hz), 2.51–2.62 (m, 1H), 5.27 (d, 1H, J = 4.0 Hz), 6.37 (d, 1H, J = 10.0 Hz), 7.25–7.41 (m, 5H). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 25.4, 25.8, 32.1, 40.7, 74.6, 126.4, 126.5, 126.7, 128.9, 128.95, 129.0, 153.2. HRMS (M^+ + H) calcd for $C_{16}H_{20}NO$: 242.1546; found: 242.1545.

Preparation of methyl 2-(1-hydroxyethyl)-3-methylbut-2-enoate (49)

Following the general procedure (15 min), alcohol **49** was formed in 91% yield as pale yellow oil. IR (neat, cm^{-1}): 3450, 2970, 2931, 2856, 1715, 1448, 1372, 1300, 1253, 1210, 1146, 1108, 916, 733. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.34 (t, 3H, J = 7.1 Hz), 1.35 (d, 3H, J = 6.6 Hz), 1.83 (s, 3H), 1.9 (s, 3H), 2.80 (d, 1H, J = 1.4), 4.28 (q, 2H, J = 7.0 Hz), 4.74 (p, 1H, J = 6.9 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.4, 20.8, 22.5, 23.2, 60.5, 66.1, 131.9, 140.0, 169.3. HRMS (M^+ + H) calcd for $C_8H_{15}O_3$: 159.1021; found: 159.1021.

Preparation of ethyl 2-cyclohexylidene-3-hydroxybutanoate (50)

Following the general procedure (15 min), alcohol **50** was formed in 69% yield as a pale yellow oil. IR (neat, cm^{-1}): 3456, 2980, 2931, 2856, 1718, 1656, 1448, 1367, 1300, 1263, 1210, 1146, 1108, 1025, 916, 733. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.32 (d, 3H, J = 7.2 Hz), 1.36 (t, 3H, J = 6.8 Hz), 1.53–1.71 (m, 6H), 2.20–2.35 (m, 4H), 2.49 (d, 1H, J = 7.3 Hz), 4.26 (q, 2H, J = 7.2 Hz), 4.80 (p, 1H, J = 6.7 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.4, 23.0, 26.5, 28.0, 28.1, 30.4, 33.4, 60.6, 65.9, 129.6, 145.1, 169.8. HRMS (M^+ + H) calcd for $C_{12}H_{21}O_3$: 213.1491; found: 213.1491.

Preparation of ethyl 2-cyclopentylidene-3-hydroxybutanoate (51)

Following the general procedure (15 min), alcohol **51** was formed in 94% yield as a pale yellow oil. IR (neat, cm^{-1}): 3447, 2976, 2931, 2856, 1717, 1448, 1367, 1300, 1263, 1210, 1146, 1108, 916, 733. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.32 (t, 3H, J = 7.2 Hz), 1.39 (d, 3H, J = 6.7 Hz), 1.60–1.78 (m, 4H), 2.28–2.40 (m, 2H), 2.66–2.72 (m, 2H), 3.64 (d, 1H, J = 10.4 Hz), 4.24 (q, 2H, J = 7.0 Hz), 4.6 (p, 1H, J = 6.6 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz δ): 14.2, 25.9, 26.1, 30.3, 34.8, 34.82, 60.8, 128.1, 166.4, 169.2, 199.2. HRMS (M^+ + H) calcd for $C_{11}H_{19}O_3$: 199.1334; found: 199.1334.

Preparation of methyl 4-(1-(ethoxycarbonyl)-2-hydroxypropylidene)piperidine-1-carboxylate (52)

Following the general procedure, alcohol **52** was formed in 71% yield as a pale yellow oil. IR (neat, cm^{-1}): 3455, 2980, 2873, 1684, 1456, 1412, 1371, 1213, 1132, 1095, 1071, 1024, 862, 769. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.32 (t, 3H, J = 7.0 Hz), 1.37 (d, 3H, J = 6.7 Hz), 2.54–2.46 (m, 5H), 3.46–3.58 (m, 4H), 3.70 (s, 3H), 4.26 (q, 2H, J = 7.2 Hz), 4.75 (p, 1H, J = 6.5 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.5, 23.1, 29.6, 32.0, 44.1, 44.4, 52.9, 61.0, 65.4, 132.2, 140.8, 156.0, 168.9. HRMS (M^+ + H) calcd for $C_{13}H_{22}NO_5$: 272.1498; found: 272.1498.

Preparation of ethyl (Z)-2-(1-hydroxyethyl)-3-methyldec-2-enoate (53)

Following the general procedure (15 min), Z-alcohol **53** was formed in 82% yield as a pale yellow oil. IR (neat, cm^{-1}): 3509, 3419, 2929, 2857, 1720, 1624, 1465, 1366, 1272, 1164, 1117, 1056, 967, 779, 722. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.88 (t, 3H, J = 7.2 Hz), 1.24–1.48 (m, 10H), 1.33 (t, 3H, J = 7.2 Hz), 1.35 (d, 3H, J = 6.7 Hz), 1.80 (s, 3H), 2.14–2.22 (m, 2H), 2.67 (d, 1H, J = 8.4 Hz), 4.25 (q, 2H, J = 7.2 Hz), 4.71 (p, 1H, J = 7.4 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.3, 14.5, 18.6, 22.6, 22.8, 28.4, 29.4, 29.8, 32.0, 37.1, 60.6, 66.3, 76.5, 132.0, 143.7, 169.4. HRMS (M^+ + H) calcd for $C_{15}H_{29}O_3$: 257.2117; found: 257.2118.

Preparation of ethyl (E)-2-(1-hydroxyethyl)-3-methyldec-2-enoate (54)

Following the general procedure (15 min), E-alcohol **54** were formed in 82% yield as a pale yellow oil. IR (neat, cm^{-1}): 3515, 3419, 2929, 2857, 1720, 1700, 1624, 1465, 1354, 1224, 1172, 1118, 1052, 970, 859, 781, 668, 646, 563. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 0.88 (t, 3H, J = 6.8 Hz), 1.32 (t, 3H, J = 7.0 Hz), 1.35 (d, 3H, J = 6.5 Hz), 1.88 (s, 3H), 2.04–2.22 (m, 2H), 2.81 (d, 1H, J = 8.0 Hz), 4.27 (q, 2H, J = 7.2 Hz), 4.72 (p, 1H, J = 6.3 Hz). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 14.3, 14.5, 21.4, 22.8, 28.4, 29.3, 29.9, 31.9,

35.0, 60.7, 65.9, 131.6, 144.8, 169.6. HRMS ($M^+ + H$) calcd for $C_{15}H_{29}O_3$: 257.2117; found: 257.2117.

General procedure for the reduction of Knoevenagel adducts using BMS

In a 50 mL three-neck flask equipped with a magnetic stirring bar and a reflux condenser, THF (3 mL) and β-keto ester (0.5 mmol) were added. To this well-stirred solution under an argon atmosphere was added BMS (0.50 mmol). After stirring for 75 min, excess hydride was quenched by the addition of methanol (0.5 mL), and the solution was diluted with water (25 mL) and extracted with diethyl ether (6 × 10 mL). The combined organic extracts was dried over $MgSO_4$ and, after filtration and evaporation of solvent, the crude product was purified by silica gel chromatography.

Preparation of methyl 2-benzylidene-3-hydroxybutanoate (29)

Two isomers were obtained: E and Z (2:3); 40% yield.

Preparation of* tert*-butyl 2-benzylidene-3-hydroxybutanoate (42)

1,2- and 1,4-addition products and two isomers (E and Z) were obtained in 10% yield.

Preparation of ethyl (Z)-2-(hydroxyl(phenyl)methyl)-3-phenylacrylate (43)

No reduction.

Preparation of methyl (E)- and (Z)-2-isobutyryl-3-phenylacrylate (45)

Two isomers were obtained (E and Z in a ratio of 2:3) in 10% yield, but they were not separable.

General procedure for the reduction of Knoevenagel adducts with sodium borohydride and $Yb(OTf)_3$

The keto ester (0.05 g, 1 mmol), MeOH (3 mL), and $Yb(OTf)_3$ (1.1 equiv) were added to a RBF and stirred at room temperature for 30 min. The solution was cooled to –78 °C and then $NaBH_4$ (1.1 equiv) was added slowly. The resulting mixture was stirred for 30 min at this temperature and then quenched by the addition of saturated aqueous ammonium chloride (10 mL). The reaction mixture was extracted with CH_2Cl_2 (3 × 5 mL), and the combined organic extract was dried over anhydrous $MgSO_4$. After filtering, the solvent was evaporated under reduced pressure and the product purified by flash column chromatography.

Preparation of methyl 2-benzylidene-3-hydroxybutanoate (29)

Two isomers were obtained: E and Z (2:3); 20% yield.

Preparation of* tert*-butyl 2-benzylidene-3-hydroxybutanoate (42)

The Z-isomer was obtained in 40% yield.

Preparation of ethyl (Z)-2-(hydroxyl(phenyl)methyl)-3-phenylacrylate (43)

No reduction.

Preparation of *tert*-butyl 2-(1-bromo-ethyl)-but-2-enoate (55)

To a RBF, under argon, was added alcohol **31** (3.29 g, 20.8 mmol) and CH_2Cl_2 (30 mL). The solution was cooled to –30 °C and triphenylphosphine (5.8 g, 22.1 mmol) was added, followed by NBS (3.9 g, 21.9 mmol). When the reaction was deemed complete using TLC, ~4 h at –30 °C, the solution was diluted with CH_2Cl_2, washed with $NaHCO_3$ (2×), brine, and then dried over $MgSO_4$. It was then filtered and solvent was removed in vacuo. The product was then purified via column chromatography using hexane – ethyl acetate (10:1) as eluent to yield bromide **55** as a yellow oil (2.2 g, 48%) that was immediately used in the next reaction. IR (neat, cm^{-1}): 2981, 2927, 1720, 1640, 1445, 1387, 1262, 1153, 1095, 1033, 913, 763, 734. ^1H NMR ($CDCl_3$, 300 MHz) δ: 6.92 (q, 0.33 H, J = 7.4 Hz) and 6.35 (qd, 0.66 H, J = 0.9, 7.2 Hz), 5.23 (q, 0.33H, J = 7.1 Hz), 5.11 (qt, 0.66 H, J = 0.9, 7.1 Hz), 4.29 (m, 2H), 2.05–1.85 (m, 6H), 1.32 (m, 3H). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 166.2, 140.3, 136.4, 60.8, 37.9, 24.3, 15.7, 14.2.

Preparation of 2,4-dimethyl-8-oxo-bicyclo[3.2.1]octane-3-carboxylic acid *tert*-butyl ester (57)

To a RBF, under argon, was added enamine **56** (1.36 g, 9.95 mmol), CH_3CN (15 mL), and triethylamine (1.2 g, 11.9 mmol). To this solution was then added bromoalkene **55** (2.2 g, 9.95 mmol) in CH_3CN (10 mL). After complete addition, the solution was heated at reflux for 20 h, cooled, and then water (15 mL) was added and heating at reflux was continued for 1.5 h. After cooling to room temperature, the solution was extracted with CH_2Cl_2 (4×). The combined organic phases were washed with brine, dried over $MgSO_4$, and filtered. The solvent was removed in vacuo to yield a brown oil that was purified via column chromatography using hexane – ethyl acetate (4:1) as eluent to yield ketone **57** as a yellow oil (0.79 g, 36%). IR (neat, cm^{-1}): 2975. ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.76 (m, 0.5H), 2.63 (dp, J = 2.9, 7.4 Hz, 0.5H), 2.45 (m, 1H), 2.26 (dd, J = 2.6, 7.7 Hz, 0.5H), 2.16–1.94 (m, 3H), 1.92–1.78 (m, 2.5H), 1.71 (t, J = 8.4 Hz, 1H), 1.48 (s, 4.5H), 1.47 (s, 4.5H), 1.17 (d, J = 7.3 Hz, 1.5H), 1.08 (d, J = 7.1 Hz, 4.5H). ^{13}C NMR ($CDCl_3$, 300 MHz) δ: 220.1, 219.6, 174.7, 173.4, 81.0, 80.8, 52.2, 49.9, 49.5, 48.8, 48.4, 45.8, 43.0, 39.0, 28.23, 28.2, 25.1, 22.6, 22.0, 21.5, 17.7, 17.4. HRMS ($M^+ + H$) calcd for $C_{15}H_{25}O_3$: 253.1804; found: 253.1805.

Acknowledgments

Financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) for a Discovery Grant and the University of New Brunswick (UNB), Fredericton, New Brusnwick, is gratefully acknowledged. S.R. would like to thank the Botswana International University of Science and Technology (BIUST) for supporting her studies in Canada. Helpful discussions with Dr. Larry Calhoun (UNB) are gratefully acknowledged. We would like to thank Gilles Vautour for his assistance in running the mass specs and Elena McIntyre for her assistance in making some starting materials.

Abstract: The catalytic activity of highly thermal stable, hydrophobic, and complete heterogeneous propylsulfonic acid functionalized nanostructured SBA-15 for excellent acetylation of alcohols and phenols with acetic anhydride at ambient temperature in solvent-free conditions was examined under environmentally benign reaction conditions. The salient features of this protocol are the absence of solvent, a green experimental procedure, and simple reusability of the catalyst (at least five reaction cycles).

Key words: solid sulfonic acid, SBA-15, heterogeneous catalyst, acetylation, solvent-free.

Résumé : Le SBA-15 est un produit nanostructuré à base d'acide propylsulfonique fonctionnalisé qui est très stable vis-à-vis de la chaleur, hydrophobe et totalement hétérogène. On a étudié son activité catalytique comme excellent catalyseur pour la réaction d'acétylation d'alcools et de phénols à l'aide d'anhydride acétique, à la température ambiante, dans des conditions expérimentales sans solvant et écologiques. Ce protocole est principalement caractérisé par l'absence de solvant, par son caractère écologique et la facilité de réutilisation du catalyseur (dans au moins cinq cycles réactionnels).

Mots-clés : acide sulfonique solide, SBA-15, catalyseur hétérogène, acétylation, sans solvant.

[Traduit par la Rédaction]

Introduction

The use of protecting groups is highly significant in organic synthesis and is often the key to the success of many synthetic enterprises. Among the various protecting groups used for the hydroxyl function, acetyl is the most common group in view of its facile introduction, being stable to the acidic reaction conditions, and also being easily removable by mild alkaline hydrolysis.[1] The acetylation of alcohols and phenols provides an efficient route for protecting –OH groups during oxidation, peptide coupling, and glycosidation reactions.[2] The most common and cheap acetylating regent is activated carboxylic acid derivative acetic anhydride[3] in the presence of amine bases like pyridine,[4] 4-diaminopyridine (DMAP),[5] triethylamine,[3] and 4-pyrrolidinopyridine.[4] Protic acids are also known to catalyze the acetylation process.[6] Additionally, various Lewis acids including $Sc(OTf)_3$,[7] $In(OTf)_3$,[8] $Ce(OTf)_3$,[9] $Gd(OTf)_3$,[10] $Al(OTf)_3$,[11] $Fe(ClO_4)_3$,[12] $Mn(OAc)_2$,[13] I_2,[14] $La(NO_3)_36H_2O$,[15] $Sn^{IV}(TPP)(BF_4)_2$,[16] $TiCl_3(OTf)$,[17] $H_{14}[NaP_5W_{29}MoO_{110}]$,[18] and borated zirconia[19] have also been investigated to meet the demand for more efficient methods. However, some of the base catalysts are toxic and possess offensive odours,[3–5] and the other methods have some serious drawbacks such as harsh reaction conditions, long reaction times, poor yields of the desired products, and tedious workup procedures. Another disadvantage is that most of these catalysts need organic solvents as media for acylation, thereby generating large amounts of corrosive and toxic waste. On the other hand, there are some toxicity and difficulties in separating conventional homogeneous catalysts from products.

One of the most promising solutions to these problems seems to be immobilization of catalysts or using ecofriendly solvent-free reaction conditions. Heterogeneous catalysts give generally higher selectivity and typically require easier workup procedures. Along this line, alumina-supported MoO_3,[20] $NaHSO_4{\cdot}SiO_2$,[21] polymer-supported $Gd(OTf)_3$,[22] cobalt(II) salen complex,[23] and sulfuric acid ([3-(3-silicapropyl)sulfanyl]propyl)ester[24] were also reported as heterogeneous catalysts for acylation of alcohols. Despite a number of improvements, some of these procedures still suffer from long reaction times,[22,23] high temperatures,[23] the use of toxic organic solvents,[21] and nonrecoverable catalysts,[21] which result in the generation of a large amount of toxic waste. Thus, introduction of inexpensive and green catalysts for this purpose is still in much demand.

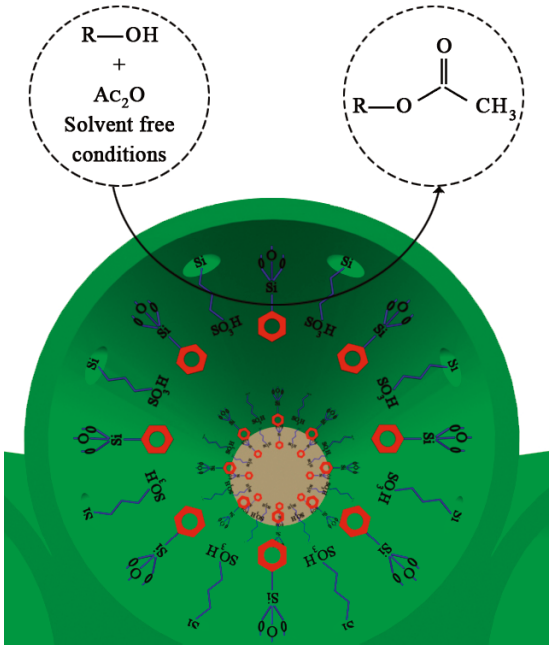
Experimental section

General acetylation procedure

In a round-bottom flask (10 mL) equipped with a magnetic stirrer, SBA-15–Ph–Pr–SO_3H (12 mg, 2 mol %) was added to the substrate (1 mmol) and acetic anhydride (1.2 mmol), and the mixture was stirred at room temperature for the period of time indicated in Table 1. After completion of the reaction (TLC), the reaction mixture was filtered and the catalyst was rinsed with ethyl acetate and then was recovered. After the organic layer was washed with saturated $NaHCO_3$ and water, the aqueous layer was extracted with ethyl acetate and dried over anhydrous Na_2SO_4, filtered, and evaporated. The combined organic layer was subjected to column chromatography on silica gel to afford pure acetate. Characterization of some products was achieved by ^1H and ^{13}C NMR.



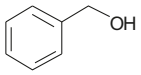
Results and discussion

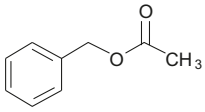
Recently, we have prepared and used heterogeneous and hydrophobic sulfonic acid SBA-15–Ph–Pr–SO_3H as an efficient recoverable catalyst in some organic reactions.[25,26] Therefore, as a part of our continuing interest in the development and utility of this catalyst, having both acidic sites and phenyl groups inside the mesochannel of SBA-15, herein, we wish to report the applicability of SBA-15–Ph–Pr–SO_3H as an efficient, environmentally benign, and reusable catalyst in the promotion of the acetylation of alcohols and phenols with acetic anhydride. All reactions were performed in solvent-free reactions at room temperature and under complete heterogeneous reaction conditions in excellent yields (Scheme 1 and Table 1; also see the Supplementary data).

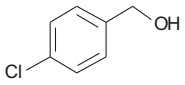
Initially, the effect of catalyst was investigated in the model reaction of benzyl alcohol with acetic anhydride, and several sets of reaction conditions were examined. Benzyl alcohol (1 mmol) was treated with acetic anhydride (1.2 mmol) in the absence of catalyst. As can be seen in Table 1, the corresponding product was obtained in 30% GC yield after 10 min (Table 1, entry 1). To evaluate the quantity of SBA-15–Ph–Pr–SO_3H, 1, 2, and 3 mol % of catalyst was used in the acetylation of benzyl alcohol for 10 min under solvent-free reaction conditions. It was observed that this reaction goes well in the presence of 2 mol % of catalyst (Table 1, entry 1). Use of a higher amount of catalyst (3 mol %) neither improves the yield nor the reaction time. Further studies have showed that all procedures work well with a 1:1.2 molar ratio of substrate to Ac_2O in the presence of 2 mol % of SBA-15–Ph–Pr–SO_3H without solvent at room temperature. On the basis of these results, we investigated the scope of the substrate alcohols and phenols with respect to the SBA-15–Ph–Pr–SO_3H catalyst-mediated acetylation, and the results obtained are summarized in Table 1.

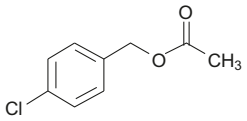
The general efficiency of this reaction is evident from the fact that a variety of hydroxy compounds, including primary (aromatic and aliphatic), secondary (acyclic, cyclic, and benzylic), tertiary alcohols, and phenols, acetylated with acetic anhydride in the presence of 0.02 mmol of catalyst at room temperature were obtained in excellent yields during a short reaction time (Table 1). Primary benzylic alcohols with electron-releasing and electron-withdrawing groups were acylated, and the corresponding acetates were obtained in excellent yields (Table 1, entries 1–5). Secondary aromatic alcohols

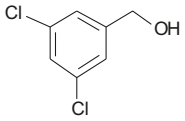
Scheme 1. Schematic representation for solvent-free acylation of alcohols with Ac_2O using SBA-15–Ph–Pr–SO_3H.

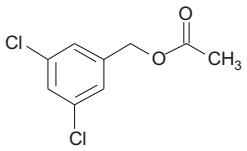


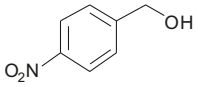


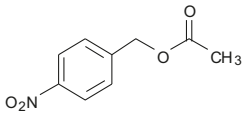


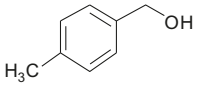


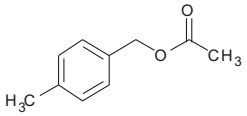


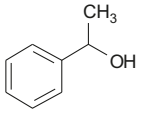


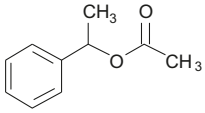


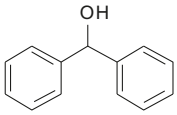


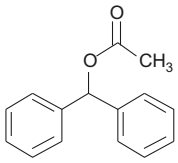


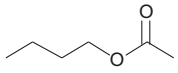


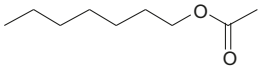


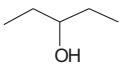


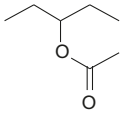


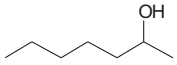


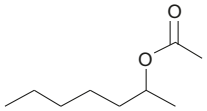


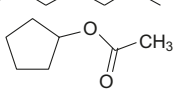


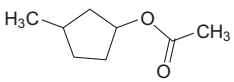


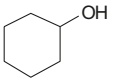


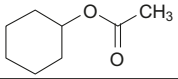












were also transformed to the respective acetates (Table 1, entries 6 and 7). Meanwhile, acetylation of primary and secondary aliphatic alcohols was performed in excellent yields in short reaction times (Table 1, entries 8–16). Phenol (Table 1, entry 17) and its derivatives (Table 1, entries 18–23) were also subjected to acetylation satisfactorily. It was also found that SBA-15–Ph–Pr–SO_3H effectively catalyzed the acetylation of diols and triols (Table 1, entries 24–26). Interestingly, adamantanol was also converted to the corresponding acetate as a model for acetylation of the hindered tertiary alcohols (Table 1, entry 27). The assigned structures were established from their spectral properties (^1H and ^{13}C NMR) and by comparison with available authentic data.

To clarify the merit of the catalyst, we compared the results of acetylation reaction of alcohols with some heterogeneous catalysts.[21–23] It can be concluded that the higher conversion of starting materials, shorter reaction times, and solvent-free reaction conditions for catalyst SBA-15–Ph–Pr–SO_3H might likely be attributed to the larger pore size of ordered SBA-15 and the beneficial influence of phenyl groups in close proximity to the sulfonic acid groups. Based on these observations, it is clear that the pore size and hydrophobic character of the catalyst are crucial parameters in the effectiveness of sulfonic acid based catalysts for the catalysis of the acetylation reaction, especially in solvent-free reaction conditions.

Reuse of the catalyst is an important aspect of any industrial process. Compared with traditional methods using volatile toxic solvents and nonrecoverable catalysts, which are energy consuming and environmentally malign, the ease of recycling is an attractive property of catalyst SBA-15–Ph–Pr–SO_3H for environmental protection and economic reasons. The catalyst could be stored and handled under open air conditions. To test the recyclability of the catalyst, the reaction was conducted with benzyl alcohol in the presence of catalyst

for 10 min, which gave a conversion of 96%. The catalyst was quantitatively recovered by simple washing and filtration methods and proved to be reusable up to five times without any appreciable loss of catalytic activity. It is noteworthy that the catalyst-free solution was then left for 10 h, but no further reaction took place. This reusability demonstrates the high stability and turnover of catalyst under the conditions employed.

Conclusions

In summary, we have introduced highly efficient, hydrophobic, and reusable catalyst SBA-15–Ph–Pr–SO_3H as an active catalyst for solvent-free acetylation of alcohols at ambient temperature. In the presence of this catalyst, an almost stoichiometric amount of AC_2O is necessary. Moreover, this catalyst offers mild reaction conditions with short reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

times, performing the acylation reactions under neat conditions. Besides, the catalyst kept its activity after five catalytic cycles. Accordingly, the methodology employed is a clean alternative for the acetylation reaction, tending toward ecoefficiency due to the use of solvent-free reaction conditions and recoverable catalyst, which can easily be prepared in the laboratory and stored for an extended period of time.

Abstract: The double addition of bis(trimethylsilyl) ketene acetals (**1a**–**1b**, $R_1 = CH_3$, $-(CH_2)_5-$) to 2-substituted pyrazines promoted by triflic anhydride leads to γ-lactones in a single step. A systematic study involving electron-withdrawing and electron-donating groups (R_2 = CN, COOMe, PhCH=CH, Cl, Me, OMe) in the pyrazine ring reveals a strong dependence of electronic effects on the regiochemistry of nucleophilic addition.

Key words: pyrazines, γ-lactones, N-activation.

Résumé : La double addition des acétals de bis(trimethylsilyl) cétènes (**1a**–**1b**, $R_1 = CH_3$, $-(CH_2)_5-$) sur les pyrazines substituées en 2 et activées par l'anhydride triflique conduit à la formation de γ-lactones en une seule étape. Une étude systématique utilisant des substituants électro-attracteurs et des électro-donneurs (R_2 = CN, COOMe, PhCH=CH, Cl, Me, OMe) sur l'anneau de la pyrazine a révélé une forte dépendance des effets électroniques sur la régio-chimie de l'addition nucléophilique.

Mots-clés : pyrazines, γ-lactones, N-activation.

Introduction

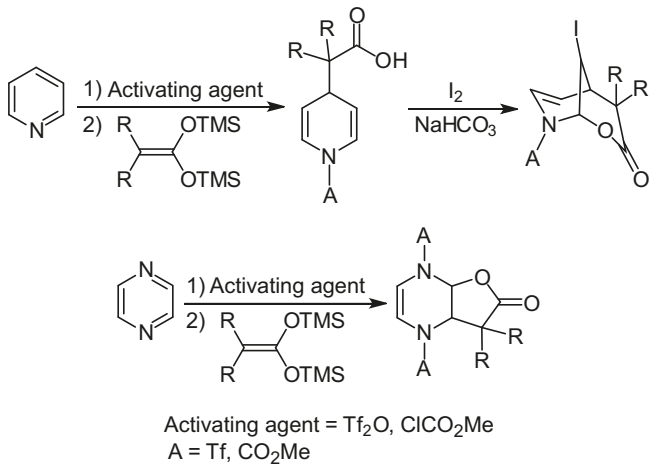
Nitrogen heterocycles are abundant in nature and are of great significance to life because their structural subunits exist in many natural products such as vitamins, hormones, antibiotics, and alkaloids, as well as in pharmaceuticals, herbicides, and dyes.[1,2] The functionalization of azaheterocycles is therefore a powerful tool for synthesizing natural products and bioactive substances. Among the synthetic strategies that exist for carrying out such transformations, we have focused our efforts on the activation of the aromatic substrates by coordinating their double bonds to a transition metal and the activation of the aza-aromatics that occurs through nitrogen atoms via their pyridinium salts.[3] Following these approaches, we and other research groups have described the synthesis of functionalized γ- and δ-lactones via a double nucleophilic addition of bis(TMS)–ketene acetals to chromium(0) complexes,[4] allyl acetates,[5] tropylium ions,[6] and some azaheterocycles using methyl chloroformate[7] or triflic anhydride[8] as activating agents, and the appropriated halogen to induce the formation of the corresponding halolactones.

In the case of diazaheterocycles, there are important differences in their reactivity. When this reaction is extended to diazines such as pyrazine, quinoxaline, and pyrimidine, the ring-closure reaction takes place in one step (Scheme 1).[9–11]

In continuation of our studies on the activation of different diazaheterocyclic compounds and their reactivity towards nucleophiles, we herein report the full details on the regiochemistry of the nucleophilic addition of bis(TMS)–ketene acetals to different monosubstituted pyrazines previously activated with triflic anhydride. This systematic study involves both electron-withdrawing and electron-donating groups on the pyrazine ring.

Results and discussion

Reactivity of pyrazines containing electron-withdrawing groups



We started our study by using substituted pyrazines containing electron-withdrawing groups; thus, triflic anhydride (2 equiv) was added by syringe to a solution of corresponding pyrazine (**2**–**5**) in dry CH_2Cl_2 at –30 °C, followed by 2 equiv of bis(trimethylsilyl)ketene acetal **1**; the reaction

Scheme 1.

mixture was stirred for 12 h (Scheme 2). The results are shown in Table 1. This reaction leads to the formation of two regioisomers (**A** and **A'**) depending on the nucleophilic attack of the TMS–ketene acetal. As can be seen, the reaction proceeds in a regioselective mode leading to products **A**. This behavior includes pyrazines containing strongly or moderated electron-withdrawing groups (Table 1, entries 1–8).

The assignment of the structure of all compounds was performed through spectroscopic methods. For example, the ^{1}H NMR spectrum of compound **2a** (mp 173 °C) confirms the double nitrogen activation and the ring closure in one step, leading to a *cis*-γ-lactone, which is consistent with two coupled signals shifted at 6.69 ppm (H6) and 5.12 ppm (H5) with $J = 8$ Hz. The ^{13}C NMR spectrum displays representative signals at 174.4 (lactone C=O), 85.9 (C6), 68.6 (C5), and 124.6 ppm (C3). Similar results were observed in the case of **2b** (mp 138 °C). Long-distance correlation (^3J) between H6 with C2, C7, and C8, as well as H5 with C3 using a heteronuclear multiple-bond correlation spectroscopy (HMBC) experiment, provides evidence of the correct position of the nitrile group, which is bonded to C2 (Fig. 1).

The structure of **4a** was fully established through an X-ray diffraction analysis (Fig. 2) and confirmed that a γ-lactone cis-fused to a tetrahydropyrazine had been formed.

In accordance with spectroscopic data, we can establish that the first nucleophilic attack toward pyrazine occurs on C5 once the nitrogen at position 4 has been activated, leading to intermediate **D**. This regiospecific activation is due to the fact that N4 is more basic as compared with N1, because of the neighboring electron-withdrawing group. A second activation promoted by another triflic anhydride molecule then takes place at N1, leading to **E**, which favors the ring-closure reaction, to give **2a** and **2b** (Scheme 3).

The introduction of chlorine as a substituent on the pyrazine ring leads to different behavior (Table 1, entries 7 and 8). As can be seen, products **5a** and **5b** were formed in moderate yield, and the new compounds **7a** and **7b**, containing an amide group in their structure (**B**), were also obtained. This is probably because the second nitrogen activation is not as fast, leading to a side reaction between the acetal **1** and triflic anhydride. The formation of **7a** and **7b** probably follows a similar reaction mechanism, as previously proposed by us in a related γ-lactone, using pyridazine as starting material and triflic anhydride as the activating agent (Scheme 4).[10]

The IR spectrum of product **7a** shows two absorption bands at 1791 and 1705 cm^{-1}, which indicates the presence of two different carbonyl groups. This result was confirmed in the ^{13}C NMR spectrum by the signals at 176.1 and 176.9 ppm, assigned to a lactone and an amide group, respectively. Two groups of signals shifted upfield in the ^{1}H NMR spectrum indicate the presence of four methyl groups, two of them as singlets, and the others as doublets coupled with a heptet signal shifted at 2.91 ppm, integration for one proton, which suggests an isopropyl group. This was in accordance with the introduction of 2 equiv of (TMS)–ketene acetal. The relative position of chlorine with respect to the lactone ring was assigned by the long-distance interaction observed in the HMBC experiment (Fig. 1).

The structure of **7a** was fully established through an X-ray diffraction analysis (Fig. 3) and confirmed that a γ-lactone cis-fused to a tetrahydropyrazine had been formed, one nitrogen bearing a trifluoromethanesulfonyl group, as expected from the NMR spectroscopic data, and the other surprisingly bearing an acyl group, which comes from an additional ketene acetal moiety.[10]

Reactivity of pyrazines containing electron-donating groups

To gain insight into the factor that controls the regiochemistry by electron-donating groups, we started screening this reaction using 2-methylpyrazine (**6**) and the (TMS)–ketene acetal **1a** (Table 1, entry 9) under similar reaction conditions. We obtained products **A** and **A'** in a 5:1 ratio, with a yield of 96%.[12] The major product was identified as **6a**, whose ^{1}H NMR spectrum showed two doublets at 6.53 and 4.79 ppm for H6 and H5 with $J = 8$ Hz, corresponding to a cis-fused lactone; this signal pattern concurs with previous results. Structure **6a'** was assigned to the minor product and, in this case, the vinyl protons H5 and H6 were displayed as a multiple signal with the integration of two protons. The ^{13}C NMR spectrum for this compound revealed a signal at 88.0 ppm assigned to quaternary carbon C2, consistent with a nucleophilic addition of (TMS)–ketene acetal over C3 and C2 of **6**. Two-dimensional NMR experiments are in agreement with the structure of **6a'**.

Similar to that observed for electron-withdrawing groups, the first activation occurs at the N4 despite increasing basic character in N1; we thought that the steric effect plays an important role in the first stage of the reaction. On the other hand, a loss in the selectivity of nucleophilic addition is observed and a mixture of products **6a** and **6a'** is obtained when acetal **1a** is used. When the same reaction was carried out with acetal **1b**, we only obtained the analogous compound **6b**. These results using the more sterically encumbered acetal substrate **1b** suggest that steric hindrance controls both the regioselectivity and yield of the nucleophilic addition product.

Finally, we carried out this reaction on 2-methoxypyrazine (**8**), which, once activated with triflic anhydride, led to three products after workup: two were identified as lactones **8'** and **9** and the other as carboxylic acid **10** (Scheme 5). The three products were formed by the regioselective nucleophilic addition of TMS–ketene acetal on C3, and in the case of **8'** and **9**

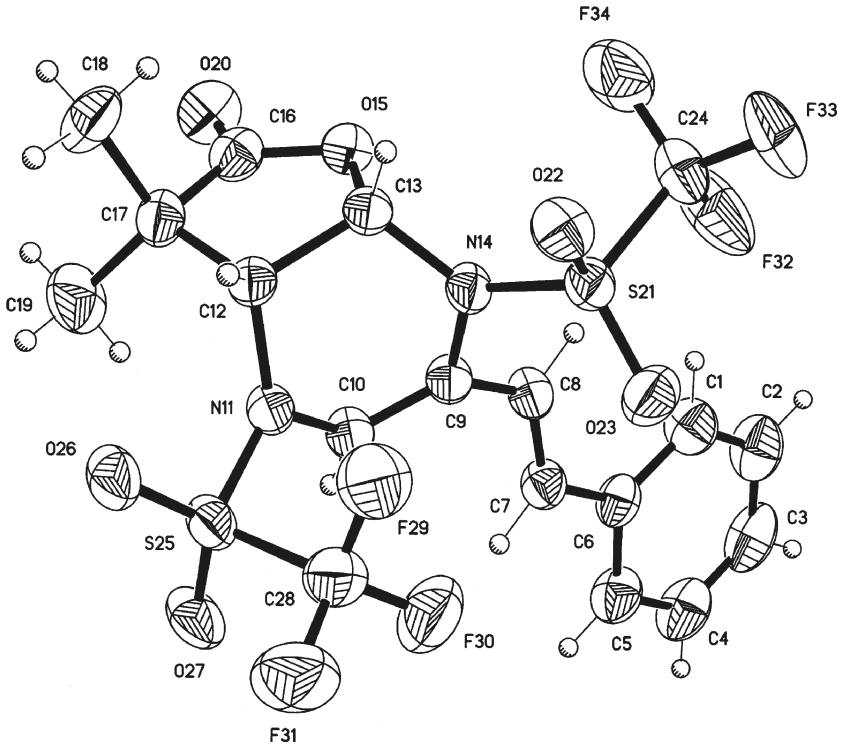
with a ring-closure on C2, which is evidenced by the signals observed on the ^{13}C NMR spectra of these compounds around 100 ppm. These results reveal a high influence of the methoxy group in modifying the reactivity of the pyrazine. Additionally, a close relationship can be seen between the structure of **9a**–**9b** and the results obtained for compounds **7a**–**7b**, where an *N*-trifluoromethanesulfonyl moiety is bonded to an acyl group from 1 additional equiv of ketene acetal. The IR spectra of **9** showed two absorption bands around 1800 and 1700 cm^{-1}, consistent with a lactone and an amide group. The NMR spectroscopic data agree with this assessment. We fully confirmed the structure of **9a** through X-ray diffraction analyses (Fig. 4).

The IR spectra of the more polar compounds **10a** and **10b** showed the characteristic absorption band for the CO*OH* group, confirmed by the signals displayed in the ^1H NMR spectra at 10.70 and 10.08 ppm, respectively. We also observed the signals for the carboxyl groups in the ^{13}C NMR spectra at 179.8 and 178.9 ppm, respectively. A final assessment of the **10b** structure was obtained through an X-ray single crystal analysis (Fig. 5), which revealed that the first activation occurs on N4 of pyrazine followed by nucleophilic attack of the ketene acetal on C3; this compound is analogous to the first intermediate proposed in the reaction mechanism (**E**) (Scheme 3).

In accordance with the experimental results, a possible mechanism for the formation of **8'**, **9**, and **10** can be suggested (Scheme 6): the first nitrogen activation occurs on the nitrogen at the 4-position, then (TMS)–ketene acetal is nucleophilic added at the 3-position, leading to **F**, which is the key intermediate that gives rise to the three products. The hydrolysis of **F** thus leads to **10**. A subsequent nitrogen activation of **F** with a second equivalent of triflic anhydride favors the ring-closure reaction to **8'**. Alternatively, **F** might react with a second equivalent of ketene acetal, which is in excess, probably through a tandem reaction giving the amide **9**, as we have previously suggested.[10]



To understand the regiochemistry of the first nucleophilic addition on the pyrazines with triflic anhydride (C), we calculated the Fukui indices at the B3LYP/6–31G(d,p) level of theory. Figure 6 shows f^+ values for the substituted pyrazinium ions CN (**2C**), Me (**6C**), and MeO (**8C**). Geometry optimizations were carried out for each triflated compound.

On the basis of the calculated values for **2C** and **8C**, nucleophilic addition is carried out on C5 and C3, respectively. However, in the case of **6C**, we obtained close values of Fukui indices in both carbon atoms, showing a similar probability of nucleophilic attack by the TMS–ketene acetal. These theoretical findings agree with the experimental results and explain the loss of regioselectivity.

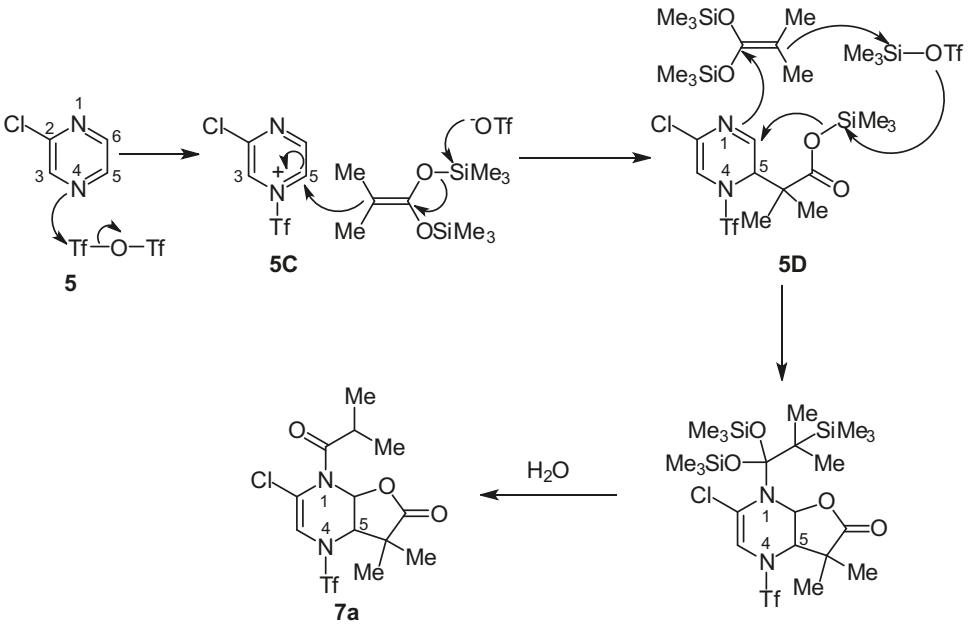
Scheme 3.

Mechanism insight

In an attempt to trap the intermediates proposed in the pathway to obtain **8**–**10**, we carried out three experiments in which we modified the stoichiometry of the ketene acetal as well as its structure. In the first assay, we performed the reaction using 1 equiv of triflic anhydride plus 2 equiv of ketene acetal **1b**. We obtained **10b** as the only product in 98% yield, thus confirming that **F** is the crucial intermediate in the reaction (Scheme 7).

Since the course of the reaction involves the formation of intermediate **F** as an initial step, we modified the structure of the ketene acetal by selecting the *O*-(TMS) ester **1c**. When we used an equimolar amount of Tf_2O and **1c**, the only product obtained was **11c**, which is formed through the nucleophilic addition at the 3-position on preactivated pyrazine (Scheme 8 and Table 2, entry 1). The spectroscopic data for **11c** confirms this result. In particular, the protons of the double bond gave the double signals at 6.37 and 6.09 ppm with $J = 5$ Hz and two singlets with the integration of three protons assigned to the methyl groups observed in the ^{1}H NMR spectrum. Furthermore, in the ^{13}C NMR spectrum we observed two signals at 172.7 and 157.8 ppm, assigned to an ester group and N=C, respectively. If the same reaction is carried out in a 2:1 ratio of Tf_2O–**1c** (Scheme 8 and Table 2, entry 2), **11c**, and **12c** were obtained in nearly equal amounts (38% and 48%, respectively). The IR spectrum

Scheme 4.



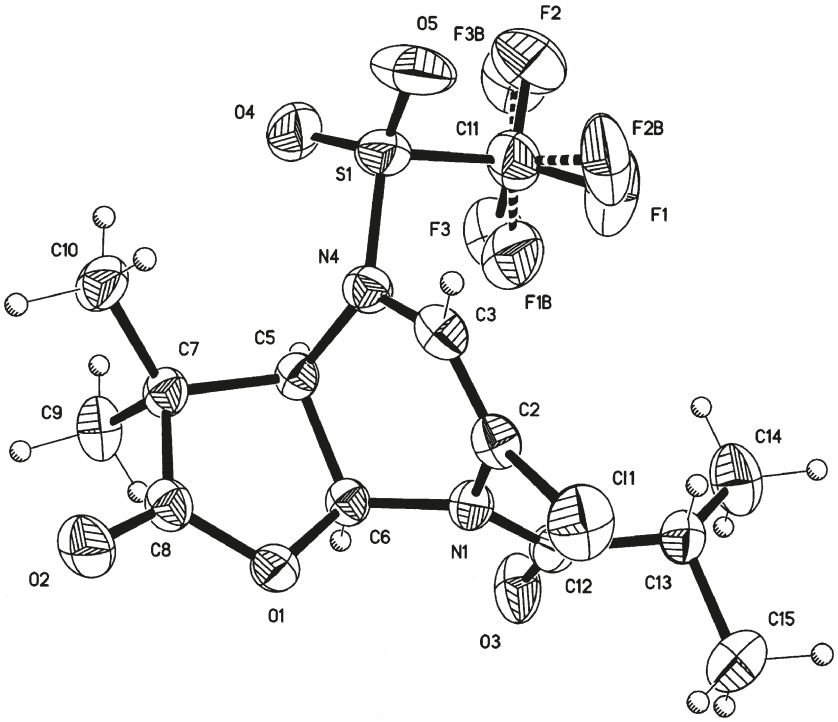


Fig. 3. ORTEP view of compound **7a**. Only one of two independent molecules is displayed. Thermal ellipsoids are at the 30% probability level.

of **12c** displays two absorption bands for carbonyl groups. As characteristic signals in the ^{1}H NMR spectrum, we observe those corresponding to the double bond C=C and the methyl group of the ester. The ^{13}C NMR spectrum shows two quartets with $J = 323$ Hz, indicating the presence of two different CF_3SO_2 bonded to both nitrogen atoms, which concurs with the mass spectrometry analysis. We can fully establish the structure of **12c** through X-ray diffraction analyses (Fig. 7).

These results confirm that the successive activation on the pyrazine ring takes place in steps, the crucial step being the formation of intermediate **F**, after which a consecutive activation promoted by a second molecule of triflic anhydride can promote the ring-closure reaction if a bis(TMS)–ketene acetal is used as a nucleophile.

For **12c**, we propose the following pathway (Scheme 9): as in preceding cases, the first nitrogen activation occurs on the nitrogen at the 4-position, then (TMS)–ketene acetal is nucleophilic-added at the 3-position, leading to **11c**, which reacts with a second equivalent of triflic anhydride, giving as a possible intermediate an iminiun salt that after work-up

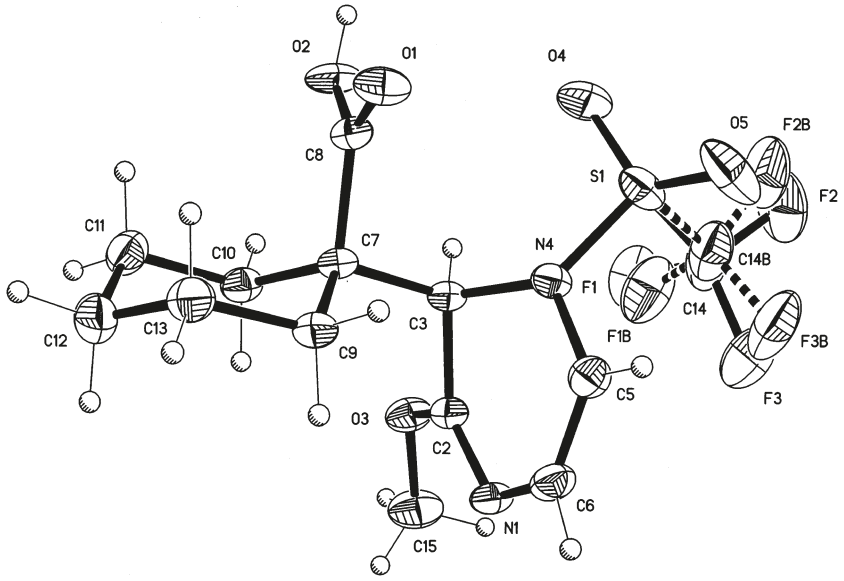
leads to the hemiacetal **G**, which after hidrolysis is transformed into the pyrazinone **12c**.

Conclusions

In all cases it was possible to obtain the γ-lactone through a one-pot reaction. The first N-activation of the diazine takes place on the nitrogen atom furthest from the substituent. This behavior can be attributed to the steric effect of the activating agent. The nucleophilic addition of the TMS–ketene acetal over the pyrazinium ring strongly depends on the substituents. Electron-withdrawing groups thus favor the addition on C5, even though strong donating groups such as methoxy modify the regiochemistry to the C3-position. In the case of the methyl group, we observe a loss of the regioselectivity of the nucleophilic addition. Calculated Fukui indices reflect the observed orientations upon the formation of the lactones through nucleophilic addition of the nucleophiles employed. Some suggested intermediates were trapped, which enabled us to propose a reasonable mechanism.

Experimental section



Materials

Anhydrous solvents were obtained by distillation under an inert atmosphere over sodium benzophenone for THF and anhydrous $CaCl_2$ for dichloromethane. Column chromatography was performed using 70–230 mesh silica gel. All reagents and solvents were obtained from commercial suppliers and used without further purification. All compounds were

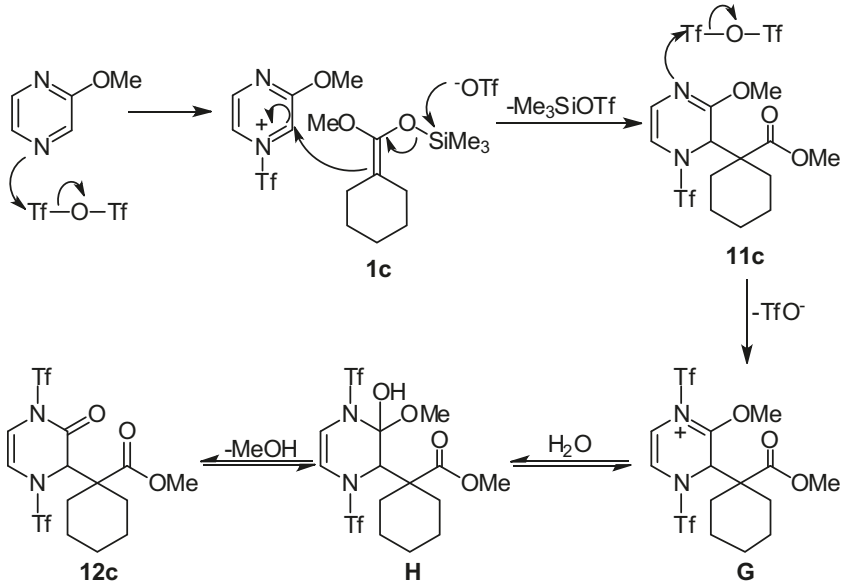
characterized by IR spectra, recorded on a PerkinElmer 283B or 1420 spectrophotometer using the KBr technique; all data are expressed in wavenumbers (cm^{-1}). Melting points were obtained on a Melt-Temp II apparatus and are uncorrected. NMR spectra were measured with a JEOL Eclipse +300 and a Varian Inova (500 MHz), using $CDCl_3$ and acetonitrile-D_3 as solvents. Chemical shifts are in ppm (δ) relative to TMS. The MS-FAB and MS-EI spectra were obtained on a JEOL SX 102A. The ketene acetals **1a–1c** were prepared according to published methods.[13]

Computational details



All computations were carried out using the Gaussian09 suite of programs.[14] Natural population analyses were performed with the NBO 3.1 program included in the aforementioned

Gaussian09 suite. The Berny optimization algorithm was employed in optimizing the geometry of all compounds. Fukui indices were later calculated for all the molecules following the regular procedure,[15] by using the results in the Natural Population Analysis (NPA).[16]

Structure determination by X-ray crystallography

Suitable X-ray quality **4a**, **7a**, **9a**, **10b**, and **12c** crystals were grown through slow evaporation of a dichloromethane–*n*-hexane solvent mixture at –5 °C. Single white crystals of compounds **4a**, **7a**, **9a**, **10b**, and **12c** were mounted on a glass fiber at room temperature. The crystals were then placed on a Bruker SMART APEX CCD diffractometer, equipped with Mo Kα radiation; decay was negligible in all cases. Data collections for all crystals were obtained at room temperature. Details of crystallographic data collected on compounds **4a**, **7a**, **9a**, **10b**, and **12c** are provided in Table 3. Systematic absences and intensity statistics were used in space group determination. The structures were solved using direct methods.[17] Anisotropic structure refinements were

achieved using full-matrix least-squares techniques on all non-hydrogen atoms. All hydrogen atoms — except H2 in compound **10b** — were placed in idealized positions, based on hybridization, with isotropic thermal parameters fixed at 1.2 or 1.5 times the value of the U_{eq} of the parent carbon atom. Structure solutions and refinements were performed using SHELXTL v 6.10 (see the Supplementary data).[18]

2-Benzylidene pyrazine (**4**) was prepared according to a modification of the reported method[19] as follows: In a 150 mL two-neck round-bottom flask fitted with a magnetic stirrer and reflux condenser, 1 equiv of potassium *tert*-butoxide (0.56 g, 5.5 mmol) was placed in 30 mL of anhydrous THF under nitrogen. After that, 1 equiv of 2-methylpyrazine (0.5 mL, 5.5 mmol) was added and the mixture was refluxed. Then, a solution of 1 equiv of benzaldehyde (0.6 mL, 5.5 mmol) in 20 mL of anhydrous THF was slowly added. The reaction mixture was refluxed for 24 h. Finally, 30 mL of brine was added and the product extracted with CH_2Cl_2 (2 × 50 mL). The combined organic layers were dried with anhydrous Na_2SO_4, and the solvent was removed in vacuo. The product was purified by neutral alumina chromatography. Elution with hexane – ethyl acetate (98:2). ($C_{12}H_{10}N_2$, M = 261 g/mol, white solid, mp 116–120 °C (0.68 g, 3.74 mmol, 68%). General procedure

Synthesis of lactones

In a 100 mL flask fitted with a magnetic stirrer, the corresponding monosubstituted pyrazine was dissolved in 30 mL of anhydrous dichloromethane and placed under nitrogen at –30 °C. After that 2 equiv of triflic anhydride were added, showing the formation of a precipitate, and subsequently 2 equiv of bis(trimethylsilyl)–ketene acetal **1** was added. The reaction mixture was allowed to reach room temperature and left stirring for 12 h. Finally, 40 mL of distilled water was added, the organic phase was recovered, and then dried with anhydrous sodium sulfate and filtered. The solvent was evaporated under vacuum. The products were purified using silica gel column chromatography, eluting with hexanes – ethyl acetate (98:2).

Abstract: Density functional theory (DFT) calculations were performed on the geometries and energies of $CO_3^{1-/2-}(CO_2)_n$ clusters with n = 1–5. For small clusters (n = 1 or 2), coupled cluster energies were obtained. Up to three CO_2 molecules are bound covalently to the dianion. Only weak electrostatic bonds were found in the monoanions. Calculated binding energies for the monoanions are in reasonable agreement with experimental values. The calculated adiabatic electron detachment energy for the dianion is –0.07 eV at n = 5, indicating that at least six CO_2 molecules will have to be added to CO_3^{2-} before the dianionic cluster becomes, in the gas phase, more stable than the monoanionic one. In comparison, for sulfate – carbon dioxide clusters, stabilization occurs at n = 2. Carbonate clusters are compared with sulfate clusters for three solvent molecules: CO_2, SO_2, and H_2O. Carbonate clusters have larger binding energies than sulfate clusters. For a given dianion, binding energies are largest for SO_2 and smallest for H_2O. However, in all cases, stabilization of the carbonate dianion by clustering is more difficult to achieve than stabilization of the sulfate dianion.

Key words: carbonate – carbon dioxide clusters, monoanions, dianions, density functional theory, dianion stabilization, solvation energies, binding energies, comparison with sulfate clusters.

Résumé : On a effectué des calculs suivant la théorie de la fonctionnelle de la densité sur les géométries et les énergies d'agrégats $CO_3^{1-/2-}(CO_2)_n$ dans lesquels n = 1–5. Pour les petits agrégats (n = 1 ou 2), il a été possible d'évaluer les énergies de couplage des agrégats. Le dianion peut se lier d'une façon covalente avec un maximum de trois molécules de CO_2. On n'a trouvé que de faibles liaisons électrostatiques dans les monoanions. Les énergies de liaisons calculées pour les monoanions sont en accord raisonnable avec les valeurs expérimentales. L'énergie calculée pour le détachement adiabatique d'un électron est de –0,07 eV pour n = 5; ceci indique que, en phase gazeuse, il faut ajouter au moins six molécules de CO_2 à l'anion CO_2^{2-} avant que l'agrégat dianionique devienne plus stable que l'agrégat monoanionique. Par comparaison, pour les agrégats sulfate – dioxyde de carbone, la stabilisation se produit avec n = 2. On a comparé les agrégats du carbonate avec ceux du sulfate pour trois molécules de solvant : CO_2, SO_2 et H_2O. Les énergies de liaison des agrégats du carbonate sont plus élevées que celles des agrégats du sulfate. Pour un dianion donné, les énergies de liaison sont les plus élevées pour le SO_2 et les plus faibles avec H_2O. Toutefois, dans tous les cas, la stabilisation du dianion carbonate par le biais de la formation d'agrégat se fait plus difficilement que la stabilisation du dianion sulfate.

Mots-clés : agrégats carbonate – dioxyde de carbone, monoanions, dianions, théorie de la fonctionnelle de la densité, stabilisation du dianion, énergies de solvatation, énergies de liaison, comparaison avec les agrégats du sulfate.

[Traduit par la Rédaction]

Introduction

Anionic clusters involving carbon dioxide have received considerable attention, with experiments going back to the 1970s. In 1977, Klots and Compton[1] obtained $(CO_2)_n^{1-}$ clusters for n = 2–6 by electron attachment to $(CO_2)_n$ in a time-of-flight mass spectrometer. More recent references report mass spectrometric, IR, and photoelectron work on clusters like $(CO_2)_n^{1-}$ and $O^-(CO_2)_n$;[2] $Cl^-(CO_2)_n$;[3] $F^-(CO_2)_n$;[4] $CO_3^{1-}(CO_2)_n$; $O_2^-(CO_2)_n$; $NO_2^{1-}(CO_2)_n$,[5] $O^-(CO_2)_n$, $(CO_2)_n^{1-}$;[6] $X^-(CO_2)$ with X = F, Cl, Br, and I;[7,8] $I_2^{1-}(CO_2)_n$;[9] $H_2O^{1-}(CO_2)_n$;[10] and $(CO_2)_n$.[11]

The present paper, dealing with anionic clusters of carbonate with carbon dioxide and of type $CO_3^{1-/2-}(CO_2)_n$, serves several purposes. For one, monoanionic clusters play an important role in the negative ion chemistry of the lower atmosphere.[12] Dianionic carbonate– carbon dioxide clusters, while not stable in the gas phase for small n, eventually become stabilized (more stable than corresponding monoanions) with

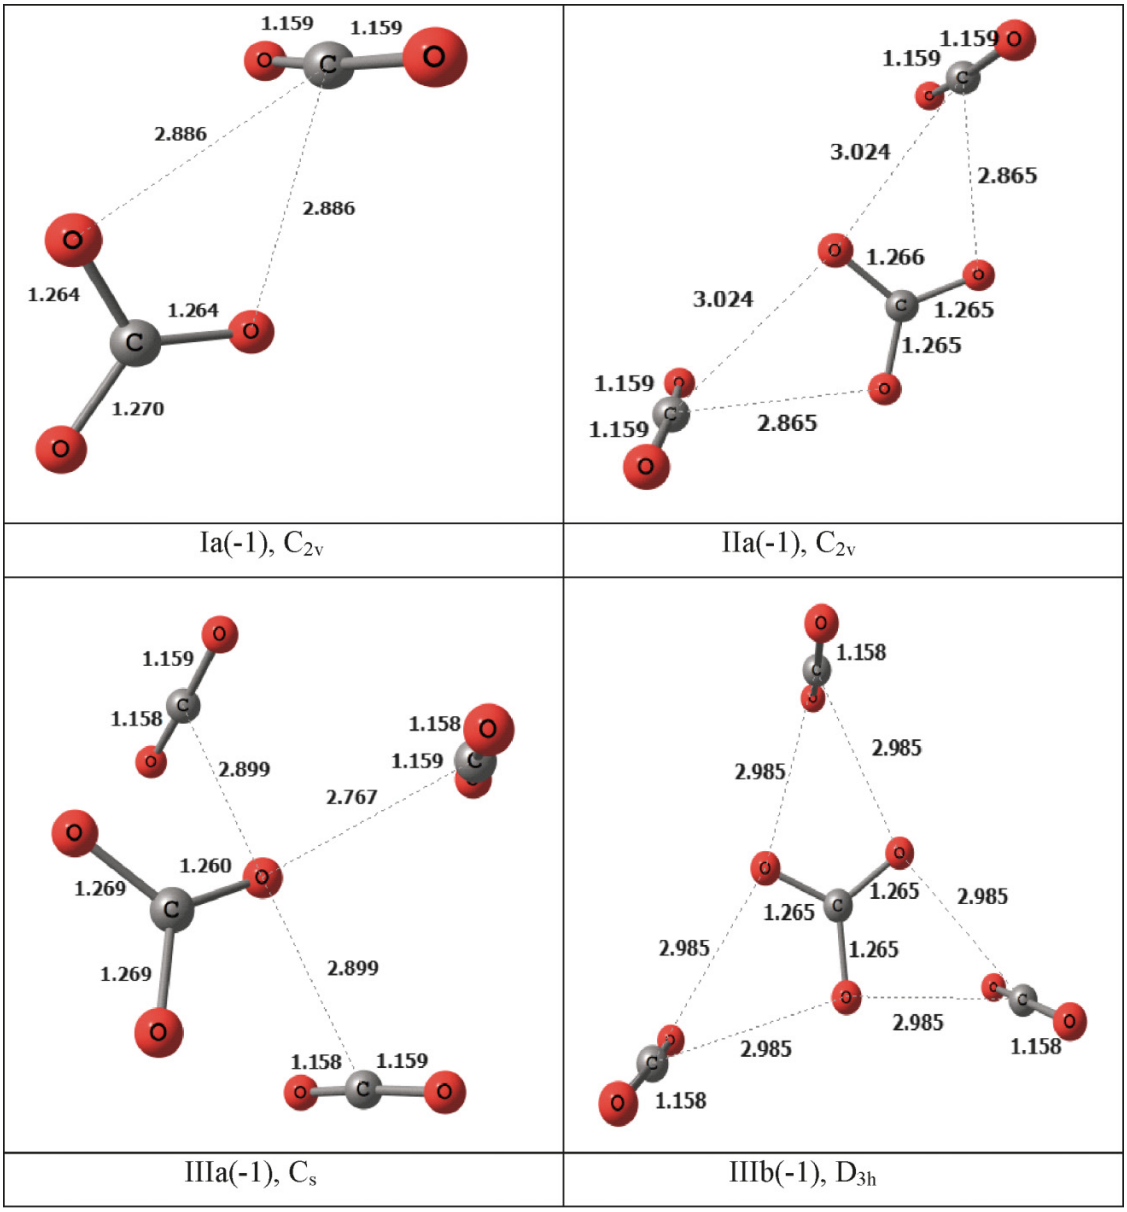
Note: For B3PW91 calculations the basis set was 6–311+G(3df) and, for CCSD and CCSD(T) calculations, the 6–311+G(d) basis set was used.

the addition of a sufficient number of carbon dioxide molecules. A better knowledge of such clusters, in terms of binding energies, electron detachment energies, types of bonding, and covalent bonding versus electrostatic interactions, is of interest both for environmental reasons and for basic research. This knowledge also allows for comparison with related clusters, such as sulfate – carbon dioxide,[13] carbonate – sulfur dioxide,[14] and sulfate – sulfur dioxide[15] clusters, which were the subject of previous studies by this group.

A brief review of the literature pertinent to this investigation will be given. Keesee et al.[16] obtained gas-phase $\Delta H°$ and $\Delta S°$ values for the reaction $CO_3^{1-} + CO_2 \rightarrow CO_3^{1-}(CO_2)$, using high-pressure mass spectroscopy. Hiraoka and Yamabe[5] reported $\Delta H°$ values for the formation of $CO_3^{1-}(CO_2)_n$ clusters, with n = 1–7. The experimental $\Delta H°$ values will be given in the Results and discussion section and are compared with energies calculated in the present work. These authors also performed spin-restricted open-shell Hartree–Fock (ROHF) calculations to establish the structures of $CO_3^{1-}(CO_2)_n$ clusters with n = 1–3, all of which were found to have C_{2v} symmetry, with long chelate bonds (about 2.8 Å) coordinating the carbon of CO_2 with two oxygens of CO_3^{1-}. Shkrob[17] performed B3LYP/6–31G* geometry optimizations on CO_3^{1-} and $CO_3^{1-}(CO_2)$. Six starting geometries were tested for $CO_3^{1-}(CO_2)$. The lowest energies were obtained for C_s structures. In a recent paper by Bruna et al.,[18] structures of the dianionic clusters $CO_3^{2-}(CO_2)_n$ (n = 1–6) with C_2 symmetry were investigated by density functional theory (DFT) methods.

Table 3. Calculated incremental energy differences ($\Delta E_{n-1,n}$) vs. experimental incremental enthalpy differences ($\Delta H°_{n-1,n}$, kcal/mol; 1 cal = 4.184 J) for gas-phase clusters $CO_3(CO_2)_n^{1-}$.

Cluster	$\Delta E_{n-1,n}$	$\Delta H°_{n-1,n}$[a]
$CO_3^{1-}(CO_2)_1$	–4.83[b]	–5.94
$CO_3^{1-}(CO_2)_2$	–4.18	–5.73
$CO_3^{1-}(CO_2)_3$	–3.79	–5.50
$CO_3^{1-}(CO_2)_4$	–2.82	–5.22
$CO_3^{1-}(CO_2)_5$	–3.11	–4.80



[a]See ref. 5 for experimental values.

[b]Calculated $\Delta H°_{1,2}$ = –3.97 kcal/mol. Enthalpies were not calculated for higher n values.

Experimental and theoretical studies were also reported on clusters of the anions CO_3^{1-} and CO_3^{2-} with molecules other than CO_2. Experimental $\Delta H°$ and $\Delta S°$ results are available for the reaction $CO_3^{1-} + nH_2O \rightarrow CO_3^{1-}(H_2O)_n$, n = 1–4.[19] Theoretical results for this reaction were obtained by Cappa and Elrod[20] and Pathak and Maity[21]; theoretical results for $CO_3^{2-} + nH_2O \rightarrow CO_3^{2-}(H_2O)_n$ were obtained by Pathak et al.;[22] and theoretical results for

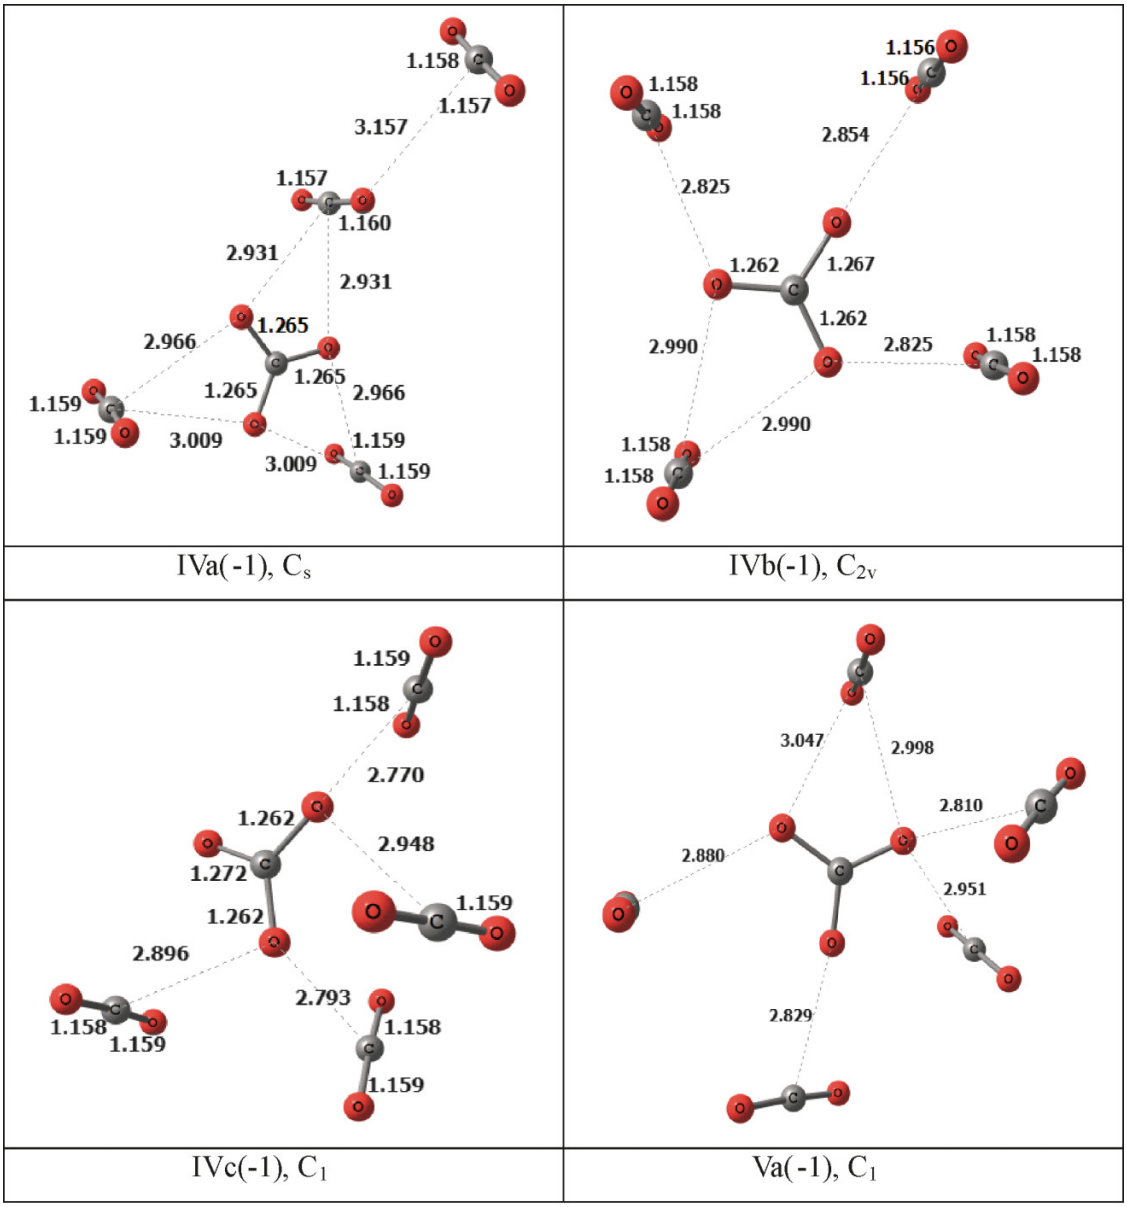
Fig. 1. Structures of monoanions, $CO_3^{1-}(CO_2)_n$. Distances are in Å.

$CO_3^{1-/2-} + nSO_2 \rightarrow CO_3^{1-/2-}(SO_2)_n$, n = 1–4, were obtained by Grein et al.[14]



Methods

All DFT calculations were performed with the B3PW91[23,24] functional and the 6–31+G(3df) basis set, using the Gaussian03 computer programs.[25] For smaller clusters, coupled cluster methods with single, double (CCSD), and noniterative triple excitations (CCSD(T)) and second-order Møller–Plesset perturbation (MP2) methods, were applied. The choice of basis set, especially the use of diffuse functions, is critical for calculating geometries and energies of anions. Overly diffuse functions may lead to near separation of an electron from a dianion that is unstable in the gas phase, and therefore lead to energies and geometries close to that of the monoanion. On the other hand, diffuse functions are necessary for the description of stable anions. In the present case, as calculations on both mono- and di-anions are to be performed, a common basis set is required, and we chose a moderately diffuse basis set. We were encouraged in using such a basis set as theoretical values in the literature have been tested against experimental results. For example, Wang et al.[26] calculated ADE and VDE values for $SO_4^{2-}(H_2O)_n$, n = 1–6, using the aug-cc-pVTZ basis set, and obtained excellent agreement with experimental values for the stable clusters with n = 4–6.

Several starting geometries were used for the $CO_3^{1-}(CO_2)_n$ clusters, all initially having no symmetry constraints. Optimized structures were checked for symmetry, and the calculations were repeated with a symmetry constraint if found appropriate. Following the method described in previous papers,[13–15] the structures are labeled by a Roman numeral, indicating the number of CO_2 molecules added, and a small letter, where "a" is used for chainlike structures and "b" and "c" for branched structures. The energies listed in the tables

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12

Fig. 1 (*continued*).

are electronic energies without zero-point vibrational corrections. In checking several cases, such corrections would decrease the binding energies by less than 0.1 eV (absolute). No imaginary frequencies were encountered when checking the most stable mono- and di-anionic clusters up to three additions.

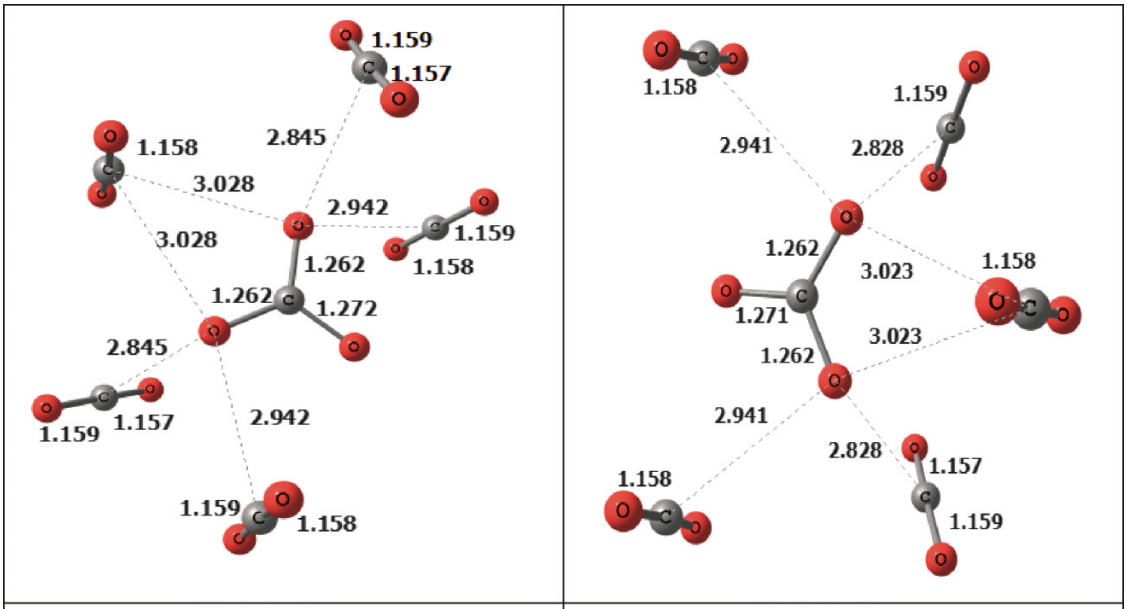
Results and discussion

Structure of CO_3^{1-} and CO_3^{2-}

As described in the CO_3–SO_2 paper,[14] CO_3^{2-} is calculated by all methods to have D_{3h} symmetry, in agreement with experiment. However, the structure of CO_3^{1-} has been controversial. Hartree–Fock (HF) methods result in C_{2v} symmetry,[5] whereas DFT methods lead to D_{3h} symmetry.[14,17,20] It can be shown that HF and other methods are subject to symmetry breaking, from D_{3h} to C_{2v} symmetry. In a systematic investigation using methods from HF to MP2 to CCSD, CCSD(T), and DFT, Cappa and Elrod[20] concluded that the true ground state of CO_3^{1-} has D_{3h} symmetry, similar to that of the well-studied isoelectronic NO_3 radical.

Energies of carbonate – carbon dioxide clusters

In Table 1, B3PW91/6–311+G(3df) energies (E) and binding energies $\Delta E(-1)$ and $\Delta E(-2)$ are given for the optimized structures of $CO_3^{1-}(CO_2)_n$ and $CO_3^{2-}(CO_2)_n$, with n from 0 to 5. The binding energies are defined by



$$[1] \qquad \Delta E(-1) = E[CO_3{}^{1-}(CO_2)_n] - E[CO_3{}^{1-}] - nE[CO_2]$$

$$[2] \qquad \Delta E(-2) = E[CO_3{}^{2-}(CO_2)_n] - E[CO_3{}^{2-}] - nE[CO_2]$$

Symmetries are also indicated. Two structures are given for $n = 3$ and three each for $n = 4$ and 5.

Fig. 1 (*concluded*).

Vb(-1), C_2 | Vc(-1), C_s

Binding energies of the monoanions are small, ranging from –0.21 eV for $n = 1$ to –0.81 eV for $n = 5$. However, they are much larger for the dianions, with values from –2.40 to –4.43 eV. Differences in binding energies, for a given n, are small. Energies of the structures Va(–1) to Vc(–1) differ by only 0.01 eV, whereas energies of the corresponding dianionic clusters differ by 0.04 eV.

Adiabatic (ADE) and vertical (VDE) electron detachment energies are listed in Table 2. They are defined in eqs. [3] and [4], with

$$[3] \qquad \mathrm{ADE} = E_0[{CO_3}^{1-}(CO_2)_n] - E_0[{CO_3}^{2-}(CO_2)_n]$$

using the calculated energies (E_0) of the lowest energy structures of the mono- and di-anions, and

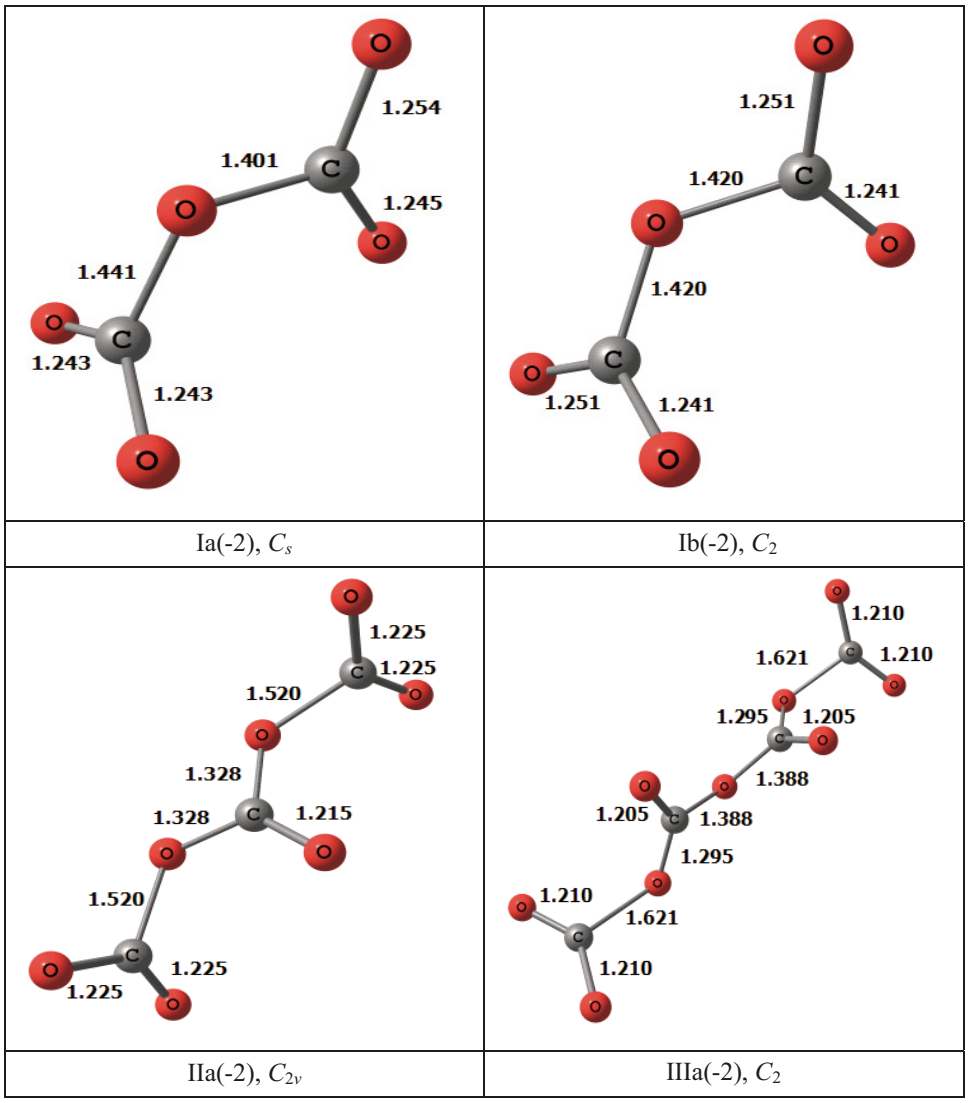
$$[4] \qquad \mathrm{VDE} = E_{\mathrm{vert}}[{CO_3}^{1-}(CO_2)_n] - E_0[{CO_3}^{2-}(CO_2)_n]$$

where the energy of the anionic cluster ${CO_3}^{1-}(CO_2)_n$ is calculated at the optimized geometry of the lowest energy dianion ${CO_3}^{2-}(CO_2)_n$ for the given n. As defined, ADE and VDE are negative if the dianion is less stable than the monoanion, and positive otherwise.

The ADE value (in DFT) is –3.69 eV for ${CO_3}^{2-}$, implying that ${CO_3}^{2-}$ is adiabatically 3.69 eV less stable than ${CO_3}^{1-}$. As expected, ADE values move toward zero as CO_2 molecules are added to ${CO_3}^{2-}$. However, contrary to ${SO_4}^{1-/2-}(CO_2)_n$[12] and other systems studied before, even at $n = 5$ ADE is still negative, although only by the small amount of 0.07 eV. (For the other systems studied in this series, the dianionic cluster stabilizes at $n = 2$ or 3.) VDE values are still negative at $n = 1$, but become positive starting with $n = 2$. This implies that ${CO_3}^{2-}(CO_2)_2$ is more stable than ${CO_3}^{1-}(CO_2)_2$ at the optimized geometry of ${CO_3}^{2-}(CO_2)_2$. Coupled cluster CCSD and CCSD(T) energies have been obtained at the DFT-optimized geometries for $n = 0$–2. They show the same trend as the DFT values. For $n = 2$, ADE is more negative by 0.2–0.3 eV. On the other hand, VDE values in CCSD and CCSD(T) are more positive. However, the switch from negative to positive VDEs still occurs at $n = 2$, as with DFT.

In Table 3, calculated incremental energies differences ($\Delta E_{n-1,n}$) for the monoanionic clusters are compared with experimental incremental enthalpy differences ($\Delta H°_{n-1,n}$) obtained by Hiraoka and Yamabe.[5] ΔH values were calculated for $n = 1$, but not for larger clusters. Calculated $\Delta E_{n-1,n}$ values are 1–2 kcal/mol (1 cal = 4.184 J) lower than experimental $\Delta H°_{n-1,n}$. As n increases, the drop-off in experimental enthalpies is much slower than that of the calculated energies. Theoretical values do not decrease in a regular fashion, and an irregular decrease is seen at $n = 4$. A search for $n = 4$ structures of ${CO_3}^{1-}(CO_2)_n$ with lower energy was not successful. Overall, however, considering such small energy differences, the agreement of theoretical with experimental values can be considered to be reasonable. Keesee et al.[16] obtained an enthalpy change of –7.1 ± 0.2 kcal/mol for ${CO_3}^{1-} + CO_2$, somewhat larger than that found by Hiraoka and Yamabe.[5]

Structure of monoanionic clusters



In all monoanionic clusters, shown in Fig. 1, the ${CO_3}^{1-}$ stays essentially intact, with weak electrostatic bonding (bond distances of 2.79–3.05 Å) to the carbon monoxides. As also seen for ${SO_4}^{1-}(CO_2)_n$,[12] the CO_2 molecules are slightly bent, with their oxygens pointing away from ${CO_3}^{1-}$, owing to electric repulsion of negative charges. Despite the long bonds, a remarkable number of clusters show symmetry, from C_s to D_{3h}. In agreement with the findings by Hiraoka and Yamabe,[5] the CO_2 carbons preferably bond to two oxygens of ${CO_3}^{1-}$. While these authors also found C_{2v} symmetry for the $n = 3$ clusters, in this work the D_{3h} structure for $n = 3$ optimized at lower energy.

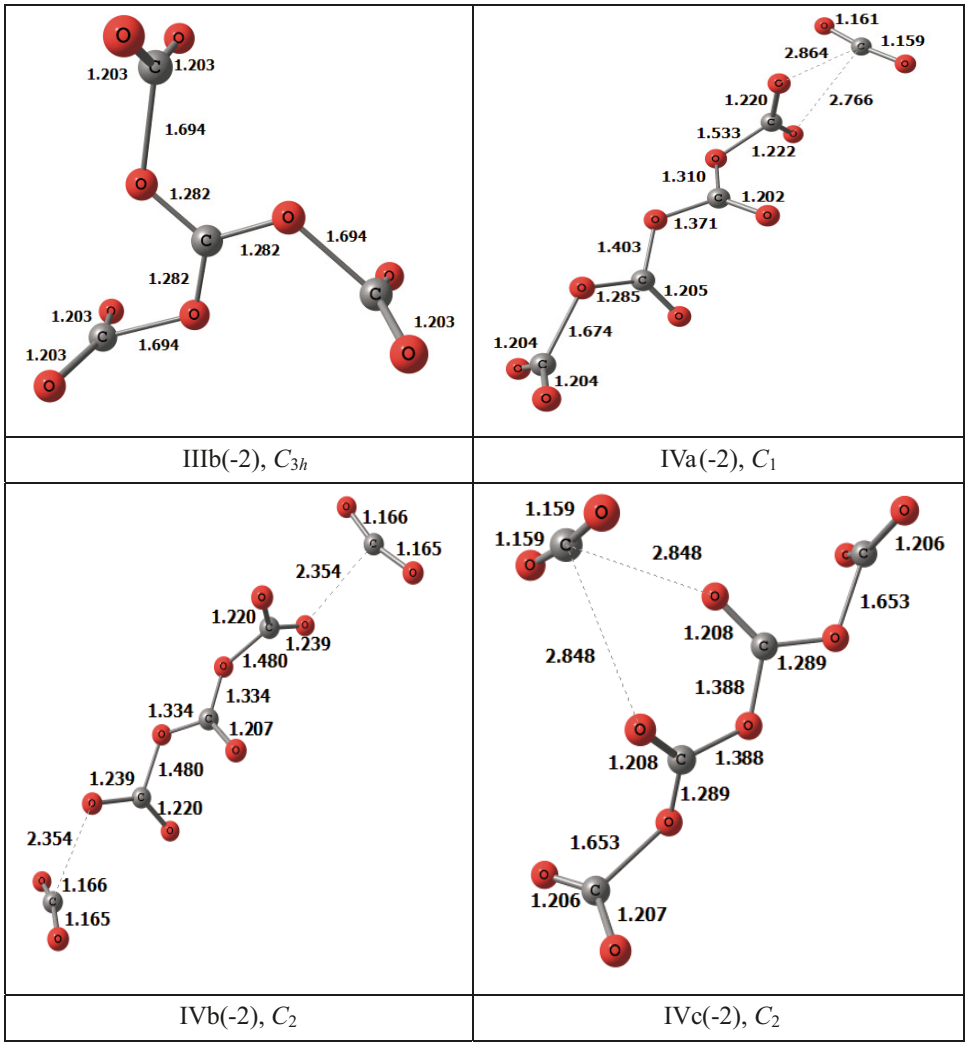
Structure of dianionic clusters

The structures of dianionic clusters are displayed in Fig. 2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

Fig. 2. Structures of dianions, $CO_3^{2-}(CO_2)_n$. Distances are in Å.

Covalently bonded structures were found for dianions containing up to four carbon atoms. One to three oxygens of CO_3^{2-} are shared with neighboring CO_2 molecules, to form chainlike $O_2C–O–CO_2$, $O_2C–O–C(O)–O–CO_2$, and $O_2C–O–C(O)–O–C(O)–O–CO_2$ dianions, as well as a threefold paddlewheel structure (IIIb(–2)) with a carbon in the centre. The structures for $n = 4$ and 5 show one to three weakly bonded CO_2s. It is interesting that two structures for $[O_2C–O–CO_2]^{2-}$ ($n = 1$) have nearly identical energies, one being of C_s symmetry (Ia(–2)) and the other of C_2 symmetry (Ib(–2)). The central C–O bond distances are different in the C_s case (1.40 and 1.44 Å), but identical (1.42 Å) in the C_2 case. The most stable structures for each n have C_2 symmetry, in agreement with the structures found by Bruna et al.,[18] except for the C_1 structure IVa(–2), which is 0.02 eV lower than the C_2 structure IVb(–2).



Comparison of carbonate – carbon dioxide with sulfate – carbon dioxide clusters

In Table 4, the results for the $CO_3^{1-/2-}(CO_2)_n$ (system **A**) clusters are contrasted to the $SO_4^{1-/2-}(CO_2)_n$ (system **B**) clusters from ref. 13. Both clusters have CO_2 as solvent, but differ in the anion. Table 4 shows that **A** has higher binding energies than **B**, both for the monoanions and the dianions. As n increases, the differences in binding energies between dianions and monoanions increase more strongly for system **A** than **B**. For system **A** such differences are about 2.2 eV for $n = 1$, rising up to 3.5 eV for $n = 4$. For system **B**, however, the differences are about 1.2 eV for $n = 1$ and 2.0 eV for $n = 4$. Despite the faster increase of the dianionic binding energies in system **A** compared with system **B**, it is more difficult to stabilize the dianion over the monoanion in system **A** because of the large ADE of CO_3^{2-} (–3.69 eV), compared with the much smaller (absolute) value for SO_4^{2-} (–1.75 eV).

Comparison of carbonate clusters with sulfate clusters

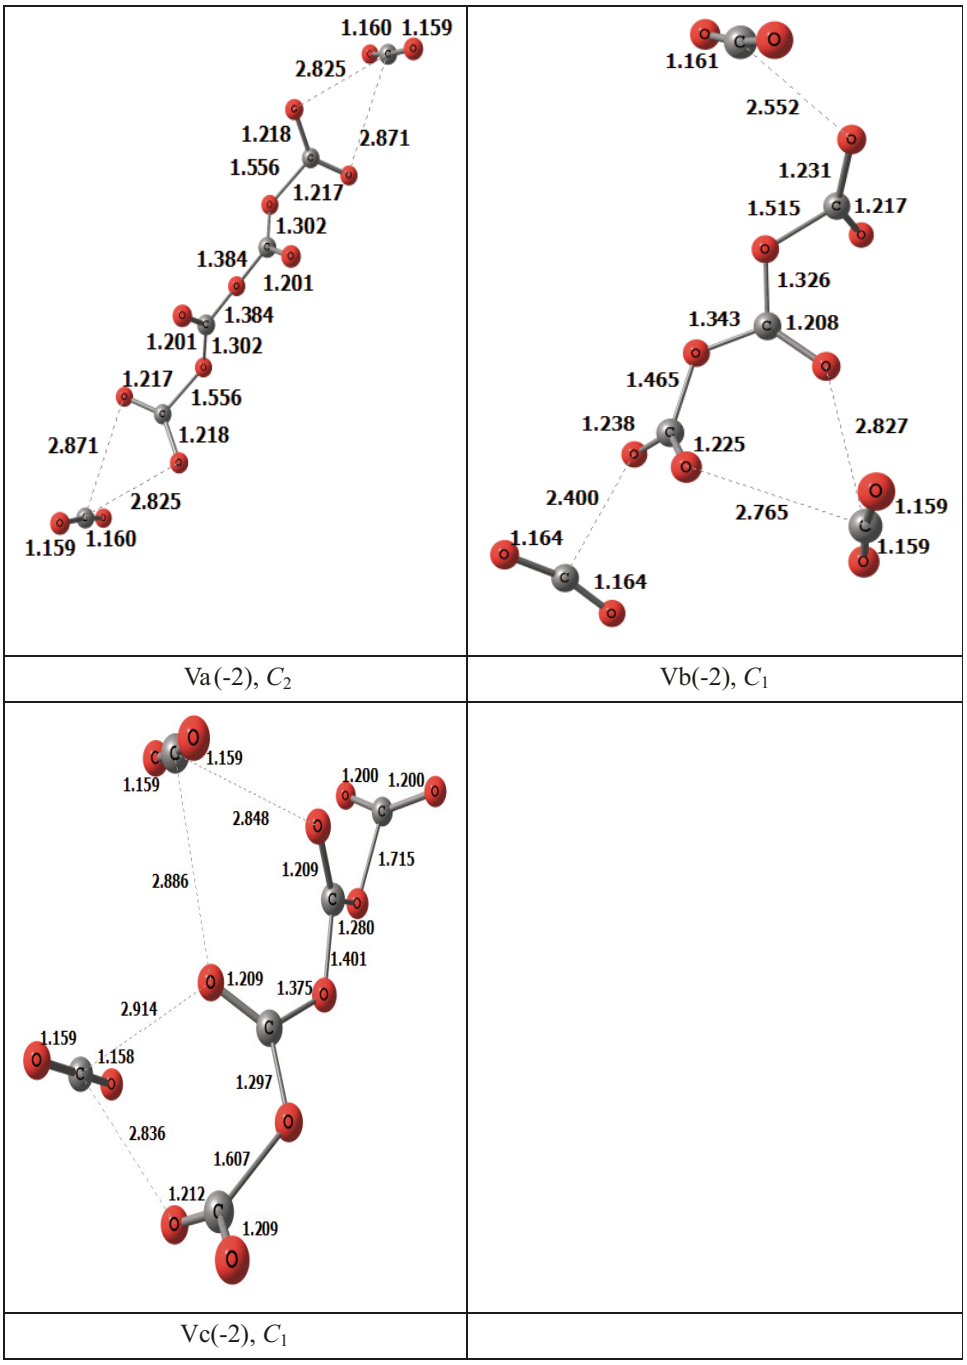
Earlier, carbonate clusters were compared with sulfate clusters, both having carbon dioxide as solvent. However, the problem of slower stabilization of carbonate clusters is not restricted to CO_2, but also applies to other solvents such as SO_2 and H_2O. Experimental and theoretical studies on $SO_4^{2-}(H_2O)_n$ clusters, for example, showed that here stabilization

Fig. 2 (*continued*).

IIIb(-2), C_{3h} | IVa(-2), C_1

IVb(-2), C_2 | IVc(-2), C_2

occurs at $n = 3$, with an experimental ADE at $n = 3$ of about 0.4 eV.[26] From the earlier discussion, one would predict that the carbonate–water clusters $CO_3^{2-}(H_2O)_n$ would stabilize at $n > 3$. No experimental studies of such clusters could be found in the literature. Pathak et al.[22] published theoretical results for IR spectra of $CO_3^{2-}(H_2O)_n$ clusters with n values from 1 to 6. However, for lower values of n such clusters are not expected to be stable in the gas phase, as they lose an electron by autodetachment. A calculation done here for $n = 1$ resulted in an ADE of –2.65 eV.



Based on the results obtained so far, we found it interesting to compare carbonate with sulfate clusters for the three solvent molecules CO_2, SO_2, and H_2O. These molecules span a wide range of dielectric constants, from a small 1.6 for CO_2 to a medium 15.4 for SO_2 and to a large 77.4 for H_2O. However, there are differences in bonding. Whereas dianionic clusters with CO_2 and SO_2 have mainly covalent bonding, those with water have hydrogen bonding.

The comparison is shown in Table 5. Data for $SO_4^{2-}(SO_2)_n$ are taken from Chan and Grein[15] and data for $CO_3^{2-}(SO_2)_n$ are taken from Grein et al.[14] Generally, the binding energies of the dianions are higher for the carbonate than for the sulfate clusters. For a given anion, the binding energies at $n = 1$ are highest for SO_2 and lowest for H_2O. Of the six clusters shown, $CO_3^{2-}(SO_2)$ has the highest binding energy and $SO_4^{2-}(H_2O)$ has the lowest binding energy. The ADEs for $n = 1$ are more negative for the carbonate than for the sulfate clusters, as was discussed earlier. For a given dianion, the water cluster has the most negative ADE. Overall, $CO_3^{2-}(H_2O)$ has the most negative ADE and $SO_4^{2-}(SO_2)$ has the least negative ADE at $n = 1$.

Solvation energies of dianions and monoanions in the three solvents were calculated with the PCM model.[27] They are shown in the last three columns of Table 5. Obviously, the solvation energies increase with the dielectric constant in the order CO_2, SO_2, and H_2O. For a given solvent, the solvation energies are higher for carbonates than for sulfates, both for the dianion and the monoanion. However, despite CO_3^{2-} in CO_2 solution having a higher solvation energy than SO_4^{2-} in CO_2 solution, such energy is not sufficient to overcome the large negative ADE of CO_3^{2-}. Contrary to the usual situation, where dianions in solution become stabilized over the monoanion, according to our calculations the dianion CO_3^{2-} solvated in CO_2 is less stable than the monoanion CO_3^{1-}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12

Fig. 2 (*concluded*).

solvated in CO_2. The last column of Table 5 shows the energy difference between the solvated dianion and monoanion (ΔE_{dian}), with positive numbers indicating that the solvated dianion is more stable. The value for CO_3^{2-}–CO_2 is –0.76 eV (3.92 – 0.99 – 3.69). The findings of solvation energy calculations for carbonate in CO_2 solution appear to disagree somewhat with the findings of our step-by-step calculations, whereby the carbonate dianion should eventually become stabilized (by the addition of about six CO_2 molecules).

On the other hand, calculations on $SO_4^{2-}(CO_2)_n$, which has a calculated reversal of stabilities at $n = 2$, show the solvation energy of SO_4^{2-} in CO_2 to be 3.64 eV, lower than the solvation energy of CO_3^{2-} in CO_2, but much in excess of –1.77 eV, the ADE of SO_4^{2-}. The total energy of the solvated dianion is lower than that of the solvated monoanion by 0.97 eV, in qualitative agreement with our step-by-step calculations.

The n value for which stabilization of the dianion first occurs (n_{Stabil}) is always higher for the carbonate than for the sulfate clusters and, within each group, it is highest for H_2O. For the carbonate clusters, n_{Stabil} was found to be 3 for SO_2,[14] and is predicted to be 6 for CO_2 (this work); it is estimated to be 4 or 5 for H_2O. This estimate of n_{Stabil} for $CO_3^{1-/2-}(H_2O)_n$ is based on the fact that it has to be greater than $n_{Stabil} = 3$,

the value for hydrated sulfate, but not much greater owing to the large solvent stabilization energy of the dianion (ΔE_{dian} = 4.08 eV). The corresponding sulfate numbers are 2 for CO_2 and SO_2[13,15] and 3 for H_2O, as found experimentally and confirmed by calculations.[26]

According to Table 5, the (negative) binding energies for the dianionic clusters are ordered $SO_2 > CO_2 > H_2O$. However, combining the values given for the dianions with ADE(CO_3^{2-}) or ADE(SO_4^{2-}), shows that the binding energies of the monoanionc clusters are ordered $SO_2 > H_2O > CO_2$, with CO_2 and H_2O interchanged. The reason can be seen in the bonding character. Whereas clusters with SO_2 always have covalent bonding, the dianionic clusters with SO_2 and CO_2 have covalent bonding, and the monoanionic ones have only weak electrostatic bonds. Obviously, hydrogen bonds, while being weaker than covalent bonds, are still stronger than the electrostatic interactions.

Summary and conclusion

In this contribution, geometries were optimized for monoanionic and dianionic clusters of carbonate with carbon dioxide, using DFT methods. The monoanion CO_3^{1-} shows only weak electrostatic bonds with carbon dioxide molecules and corresponding small binding energies. The carbonate dianion, on the other hand, binds covalently to CO_2, up to a limit of three molecules. The binding energy is 2.4 eV for the first bond and rapidly declines for successive bonds. It will take at least six carbon dioxide molecules to stabilize the dianionic cluster over the monoanionic one.

This is the fourth paper in a series of studies exploring clusters of carbonate and sulfate with carbon dioxide and sulfur dioxide (for previous papers see refs. 13–15), allowing for a comparison of clusters and for extracting trends in properties. It was found that binding energies for dianionic clusters are higher for carbonates than for sulfates. Up to three CO_2s are covalently bonded in $CO_3^{2-}(CO_2)_n$ clusters, whereas only two are bonded in $SO_4^{2-}(CO_2)_n$. However, stabilization of dianionic clusters is more difficult for carbonates. Whereas sulfate – carbon dioxide clusters stabilize at $n = 2$ (addition of two CO_2s), carbonate – carbon dioxide clusters do not yet stabilize at $n = 5$. Calculated solvation energies on carbonate and sulfate dissolved in CO_2 confirm these trends.

In a more general comparison, clusters of carbonate and sulfate with water molecules have been added to clusters with CO_2 and SO_2. Clusters with water molecules have lower binding energies owing to hydrogen bonding compared with covalent bonding for the other systems. Stabilization requires

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

the addition of three H_2O molecules to sulfate and four or five to carbonate. Experimental results for dianionic clusters are available only for water as solvent. It is hoped that experiments will be conducted using other solvents such as SO_2 and CO_2.

Abstract: This account intends to cover recent literature on radical perfluoroalkylation reactions of aromatic nuclei in organic and aqueous media. Emphasis will be placed on radical aromatic perfluoroalkylation reactions in water or aqueous media, with the aim of exploring aromatic radical reactivity in a benign environment.

Key words: radical perfluoroalkylation, radicals in aqueous media, aromatic radical perfluoroalkylation.

Résumé : Dans ce travail, on passe en revue la littérature récente sur les réactions de perfluoroalkylation radicalaires de noyaux aromatiques, dans des milieux organiques ou aqueux. On met l'emphase sur les réactions de perfluoroalkylation aromatiques dans l'eau ou les milieux aqueux afin d'évaluer la réactivité radicalaire des produits aromatiques dans un environnement bénin.

Mots-clés : perfluoroalkylation radicalaire, radicaux en milieu aqueux, perfluoroalkylation radicalaire aromatique.

Aromatic perfluoroalkylation reactions in organic conventional media

Introduction

Several important review articles involving radical perfluoroalkylation reactions of aromatic compounds have appeared in the literature in the past.[1,2] Radical metal-promoted aromatic perfluoroalkylation reactions are rare. Among them, the reactions where the metals employed (e.g., Cu, Zn, Fe)[2] are not directly involved in the Ar–R_f bond formation step, but are needed to generate the perfluoroalkyl radical from R_fX (X = I, Br), will not be the subject of this review article.

The $C_4F_9^\bullet$ and other perfluoroalkyl radicals show a clear-cut electrophilic character in aromatic substitution, as already reported for the addition to alkenes,[3,4] but the low regio- and chemo-selectivities suggest that the polar effect is not the main factor in determining the high reactivity of perfluoroalkyl radicals toward aromatics (10^5–10^6 $(mol/L)^{-1}$ s^{-1}, two to three orders of magnitude more reactive than alkyl radicals). The enthalpic factor, related to the involved bond energies, appears to be the major cause of the increased reactivity. The polar effect is considered as related more to the polarizability than to the polarity of a radical (the σ-perfluoroalkyl radicals are considered less polarizable and hence less sensitive to polar effects than σ-radicals).[5] Thus, it is not surprising that electron-rich aromatic nuclei showed the highest reactivity toward R_f radicals.

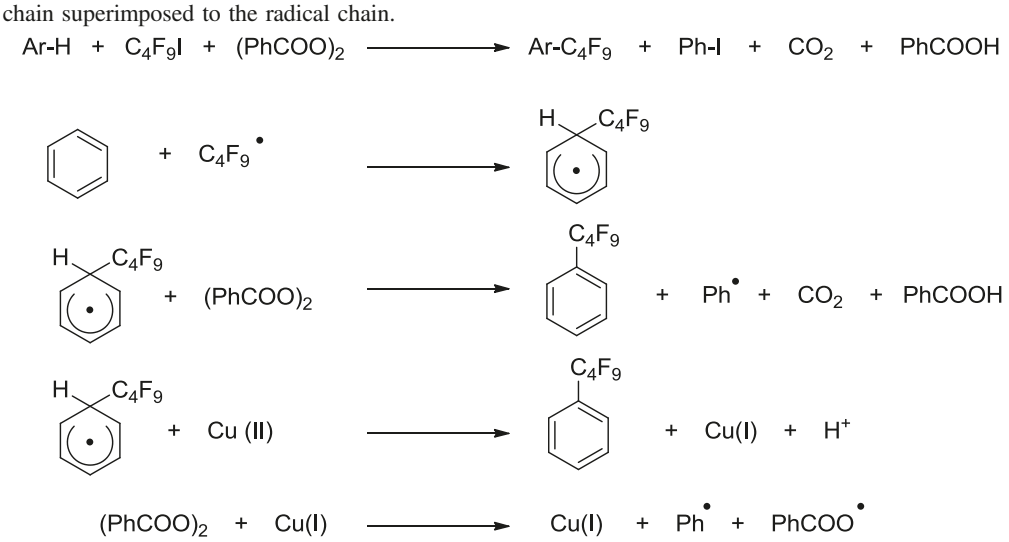
Aromatic radical perfluoroalkylation triggered by thermal initiators

Minischi and co-workers[5] used a series of initiation techniques to generate perfluoroalkyl radicals ($R_f^\bullet$) such as (*i*) benzoyl peroxide; (*ii*) *t*-BuOOH and Fe(III) salts; (*iii*) H_2O_2 and acetone; and (*iv*) H_2O_2, DMSO, and Fe(II) salt. Table 1 summarizes the perfluorobutylation of aromatics employing benzoyl peroxide as the radical initiation technique.

The reaction mechanism according to procedure (*i*) clearly involves homolytic decomposition of benzoyl peroxide with the formation of phenyl radical; the reaction of this according to eq. [1] appears to be much faster ($>10^8$ $(mol/L)^{-1}$ s^{-1}) than the hydrogen abstraction from the solvent (10^5 $(mol/L)^{-1}$ s^{-1}) or the addition to the aromatic ring (10^5 $(mol/L)^{-1}$ s^{-1}) because no significant aromatic phenylation was observed.

[1] $R_fI + Ph^\bullet \longrightarrow R_f^\bullet + PhI$

The radical $C_4F_9^\bullet$ adds to the aromatic ring, and the radical adduct is then oxidized in a chain process. The presence of a catalytic amount of Cu(II) salt increases the reaction rate because a redox chain is superimposed to the radical chain (Scheme 1).



Minischi and co-workers[5] argue that the solvent is important for the efficiency of the aromatic perfluoroalkylation, because perfluoroalkyl radicals can effectively abstract hydrogen from C–H bonds of the solvent (the rates of abstraction by $Rf^\bullet$ are $>10^3$ larger than those of the analogue hydrocarbon radicals).[6]

Scheme 1. Redox chain superimposed to the radical chain.

Thus, the rate of hydrogen abstraction by n-C_7F_{15}• from THF, whose α-C–H bond to the oxygen ring is particularly activated by both enthalpic and polar factors toward electrophilic radicals, has been evaluated at 6.1×10^5 $(mol/L)^{-1}$ s^{-1}. The authors[5] expected significantly lower rate constants for hydrogen abstraction from AcOH, DMSO, and MeCOMe by R_f•, always for enthalpic and polar reasons. The competition of hydrogen abstraction from the used solvents (AcOH, DMSO, and MeCOMe) appears to be negligible with activated aromatic substrates, and the efficiency of aromatic n-perfluoroalkylation is high, as shown by the comparable yields of PhI and n-C_4F_9–Ar.[1]

However, with deactivated aromatic substrates, such as $PhNO_2$ or PhCN,[5] the conversion of the aromatic compound is significantly lower than the yield, always high, of PhI; in these cases, it would appear that hydrogen abstraction from the solvent by n-C_4F_9• competes with the addition to the deactivated aromatic ring, even if an analysis of the volatile reaction products was not carried out.[5]

Aromatic substitution by procedures (*ii*)–(*iv*) is generally cleaner than the previously reported substitutions by thermolysis of R_fI or by homolysis of $(t\text{-BuO})_2$. The main reason is related to the lower efficiency of the rearomatization of the intermediate cyclohexadienyl radical, which, under these conditions, can also undergo disproportionation and dimerization leading to high-boiling derivatives.

The oxidation of cyclohexadienyl radicals by Cu(II) or Fe(III) are, on the contrary, very fast and selective in all cases, and they are always preferable when a catalytic redox chain can be achieved.

No substitution takes place with pyridine in AcOH solution,[5] whereas nitrobenzene and benzonitrile are attacked by the C_4F_9• radical. The fact that alkyl radicals, generated from alkyl iodides by the same procedures, do not react with homocyclic aromatic substrates suggested that perfluoroalkyl radicals must be much more reactive than alkyl radicals.[5]

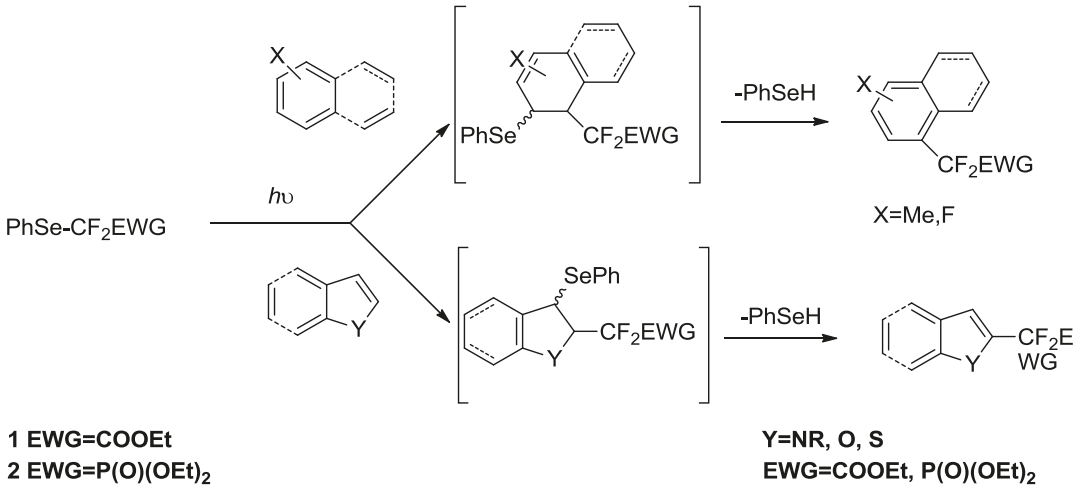
On the other hand, protonated pyridine gives good results with alkyl radicals, but is quite unreactive toward C_4F_9• under the same conditions. This would indicate that alkyl and perfluoroalkyl radicals have opposite behavior because of their opposite polar character (electrophilic and nucleophilic, respectively, for perfluoroalkyl and alkyl radicals).

Table 1. Homolytic aromatic radical n-perfluoroalkylation.

Aromatic substrate	Orientation (%) relative substitution			Yield (%)
Benzene				94.7
Anisole	*o* (14.7)	*m* (45.5)	*p* (39.6)	93.3
Diphenyl ether	*o* (18.1)	*m* (24.4)	*p* (57.5)	90.9
Toluene	*o* (46.1)	*m* (30.3)	*p* (23.3)	90.1
Chlorobenzene	*o* (41.7)	*m* (39.6)	*p* (18.7)	47.1
Benzonitrile	*o* (20.5)	*m* (52.2)	*p* (27.3)	41.4
Nitrobenzne	*o* (31.1)	*m* (36.7)	*p* (32.2)	42.3
Biphenyl	*o* (25.1)	*m* + *p* (74.9)		97.2
Naphthalene	α (80.4)	β (19.6)		99.1
Thiophene	α (86.5)	β (13.1)		97.6

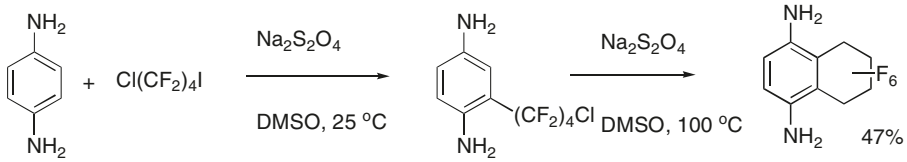
The electrophilic character of C_4F_9• radical is, however, scarcely reflected on the orientation of the substitution.

The ortho, meta, and para positions of toluene, chlorobenzene, anisole, diphenyl ether, benzonitrile, and nitrobenzene are substituted with low selectivity (Table 1), without a macroscopic influence of the polar character of the substituent, the ortho position being, obviously, affected by steric effects (e.g., the isomer distribution in chlorobenzene is characterized by 52% in the ortho position by CF_3•, but only 14% by the n-$C_{10}F_{21}$• radical). Substitution of naphthalene, biphenyl, thiophene, and pyrrole is, on the opposite, more selective. It would appear that the orientation is related more to the stabilization of the intermediate radical adducts than to the electron availability of the ring position.[5]



Aromatic radical perfluoroalkylation triggered by photochemical methods

A photochemical method was successfully employed to effect perfluoroalkylation reactions of aromatic and heteroaromatic compounds to provide substitutions with corresponding α-aryl-α,α-difluoroacetates and α-aryl-α,α-difluoromethylphosphonates in good to moderate yields.[7]



Aromatic and heteroaromatic substitutions with difluoromethyl radicals photogenerated from ethyl α-(phenylseleno)-α,α-difluoroacetate (**1**) and diethyl α,α-difluoromethyl-α-(phenylseleno)phosphonate (**2**) as shown in Scheme 2.

Scheme 3. Perfluoroalkylation of aromatic amines with $Cl(CF_2)_4I$ in DMSO.

Scheme 4. Introduction of polyfluoroalkoxy and polyfluoroalkylthio substituents in aromatic rings.

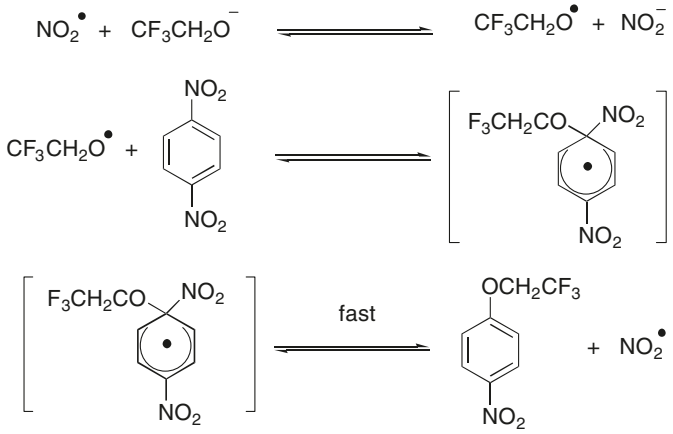
Aromatic radical perfluoroalkylation triggered by sulfinatodehalogenation reactions

Chen and co-workers[8] achieved the radical perfluoroalkylation reaction of aromatic amines by the substitution of aromatic H for R_f groups in DMSO as solvent, triggered through the decomposition of $Na_2S_2O_4$, according to Scheme 3 (see the Aromatic radical perfluoroalkylation reactions in aqueous media section for the mechanism of the sulfinatodehalogenation reactions).

A nonradical perfluoroalkylation reaction of activated ($ArNH_2$) aromatic nuclei has recently been accomplished through Pd catalysis in benzene as solvent.[9]

Aromatic radical perfluoroalkylation triggered by electron-transfer reactions

More recently, Yamakawa and co-workers[2h,10] accomplished the fluorination of aromatic compounds using Fenton reagent in DMSO as solvent. They attempted a series of simple substituted aromatic and heteroaromatic compounds with CF_3I and ethoxycarbonyl difluoromethyl bromide as fluorinating agents.



Introduction of polyfluoroalkoxy and polyfluoroalkylthio substituents in aromatic rings can be achieved with mild conditions and short times through the reaction of concentrated solutions of dinitrobenzenes in DMF with polyfluoroalcohols and polyfluorothiols in moderate excess in the presence of excess tetrabutylammonium fluoride as a base.[11] Terejo et al.[11]

Table 2. Introduction of polyfluoroalkoxy and polyfluoroalkylthio substituents in aromatic rings.

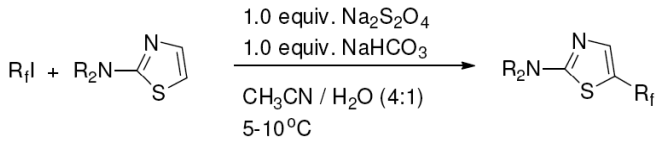
postulated an operable fast radical chain mechanism. This mechanism is elicited from the oxidation of a Meisenheimer complex and proceeds through a radical aromatic substitution with the polyfluoroalkoxy or the polyfluoroalkylthio radicals as key intermediates. At low concentrations, entrainment can be achieved with the superoxide anion (Scheme 4).

The series of substituted products obtained under these conditions are illustrated in Table 2.

In Scheme 5, the proposed propagation mechanism is described, accounting for product formation.

Indeed, the mechanism corresponds to a typical radical aromatic substitution.[12] It is known that superoxide anion is a good oxidant for relatively acidic protic substrates to the corresponding radical through a process that includes dismutation.[13,14]



Terejo et al.[11] managed to generate the trifluoroethanol radical alternatively by the action of superoxide anion on trifluoroethanol ($pK_a = 23.6$ in DMSO).[15] The fast reaction between *p*-DNB and trifluoroethanol could be triggered by the addition of a catalytic amount of KO_2 (and an equimolecular amount of 18-crown-6 ether to achieve its solubilization in DMF). This represents a good example of entrainment, and considering the superoxide anion has no outer sphere electron-transfer oxidant properties,[13] this result strongly supports the operation of the trifluoroethoxy radical as an intermediate.

Aromatic radical perfluoroalkylation reactions in aqueous media

As opposed to radical perfluoroalkylation addition reactions of unsaturated compounds,[16,17] fluoroalkyl radical substitution

Scheme 9. Radical perfluoroalkylation of 2-aminothiazole derivatives.[21]

on the aromatic ring has received little attention. Furthermore, aromatic radical perfluoroalkylation in aqueous mixtures is restricted to a few examples of sulfinatodehalogenation reactions.

Recently, Barata-Vallejo and Postigo[18] summarized radical perfluoroalkylation reactions in aqueous media. In particular, activated aromatic nuclei, such as 1,3,5-trimethoxybenzene were employed in perfluoroalkyl substitution radical reactions in aqueous media. When a mixture of 1,3,5-trimethoxybenzene and 1-chloro-1-bromo-2,2,2-trifluoroethane was treated under sulfinatodehalogenation reaction conditions ($Na_2S_2O_4$/$NaHCO_3$ in CH_3CN/H_2O), a radical substitution reaction of H for R_f was achieved, as shown in Scheme 6.[19]

Dmowski et al.[19] postulated a radical mechanism such as that depicted in Scheme 7.

In another report by Dmowski et al.,[20] the aromatic substitution of trimethoxybenzenes and pyrrols with $BrCF_2CF_2Br$ was attempted as shown in Scheme 8.

More recently, Lu and co-workers[21] accomplished the polyfluoroalkylation of 2-aminothiazoles, as shown in Scheme 9. Reactions of 2-aminothiazole with *n*-C_4F_9I under sulfinatodehalogenation reaction conditions gave the substitution product in 80% yield with total selectivity at the 5-position of 2-aminothiazole (Scheme 9). A number of N-substituted 2-aminothiazoles also reacted with R_fI and R_fBr in yields ranging from 58% to 90%.[21]

While defluorination of polyfluoroalkyl-substituted arenes followed by nucleophilic attack from water has been well documented,[22] very few reductive defluorinations of polyfluoroalkyl-substituted arenes under mild conditions have been previously reported, and no other such reaction has been documented in aqueous media.

Conclusions

It becomes apparent that aromatic radical perfluoroalkylation reactions progress in good yields under different reaction and medium conditions. The types of reactions explored encompass simple aromatic radical substitutions triggered by the thermal decomposition of thermal initiators, photochemical initiation, metal-entrainment reactions, sulfinatodehalogenation reactions, and electron-transfer initiation. Remarkably, some of these initiations can be carried out in aqueous media, lowering the environmental impact of aromatic radical homolytic and ipso substitutions.

Abstract: Chlorodiphenylphosphine, imidazole, and molecular iodine in refluxing dichloromethane are used for the efficient preparation of amides under mild reaction conditions. This reagent system also shows excellent selectivity for mono-N-alkylation of amines with alcohols. In this system, the resulting phosphorus byproduct (diphenylphosphinic acid) is easily removed by extraction using an aqueous basic solution in the workup processes, which avoids the tedious and time-consuming chromatographic methods.

Key words: benzylation, amidation, imidazole, amine, alcohol, carboxylic acid, chlorodiphenylphosphine, iodine.

Résumé : On a utilisé un mélange de chlorodiphénylphosphine, d'imidazole et d'iode moléculaire dans le dichlorométhane au reflux pour préparer des amides d'une façon efficace, dans des conditions douces. Ce système de réactifs présente aussi une bonne sélectivité pour la mono-N-alkylation d'amines avec des alcools. Dans ce système, il est facile d'éliminer le sous-produit phosphoré, l'acide diphénylphosphinique, par extraction du mélange réactionnel à l'aide d'une solution basique aqueuse qui évite les méthodes chromatographiques lentes et ennuyeuses.

Introduction

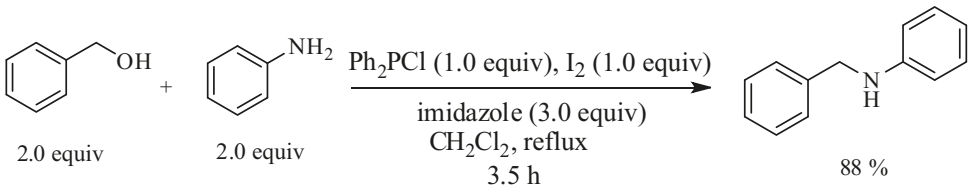
For many years, phosphines as reagents or catalysts have been employed for various organic transformations. Among these, soluble triphenylphosphine (TPP) has found significant attention, and several applications of this reagent have been demonstrated. This reagent has widespread use in organic chemistry in reactions such as the Staudinger reduction,[1] the Mitsunobu reaction,[2] the Wittig reaction,[3] halogenation of a hydroxyl group,[4] formylation reactions,[5] and nitrile and amide formation.[6] A common drawback of all these systems is the formation of stoichiometric amounts of phosphine oxides as byproducts, of which their separation from the reaction mixtures is usually a difficult task, and time-consuming chromatographic purification of the product is necessary to obtain pure compounds. Speed and efficiency in chemical separation are at the heart of parallel synthesis and combinatorial chemistry and are increasingly important in traditional synthesis as well.

As a solution to this problem, in recent years many efforts have been directed toward modifying TPP to facilitate the isolation and purification of the desired product. In this way, the use of expensive and not easily available reagents such as polymer-supported TPP,[7] PEG-supported (PEG = polyethyleneglycol) phosphine,[8] polystyryldiphenylphosphine,[9] diphenyl(2-pyridyl)phosphine,[10] (4-dimethylaminophenyl)diphenylphosphine,[11] Silphos,[12] tris[4-(1*H*,1*H*-perfluorooctyloxyphenyl)] phosphine[13] have been reported. Therefore, development of simple, efficient, and useful methods for the easy synthesis of organic compounds using readily available reagents is one of the major research demands in organic synthesis.

We have recently reported that chlorodiphenylphosphine (CDP), a commercially available reagent, is practically effective for the conversion of carboxylic acids, phenols, and thiols to their corresponding esters in the presence of molecular iodine.[14] In this system, the resulting phosphorus byproduct (diphenylphosphinic acid) is easily extracted with an aqueous basic solution in the workup processes without the need of using tedious and time-consuming chromatographic methods.

In continuation of our earlier work, we present a very easy and efficient method for N-alkylation and amidation of amines with alcohols or carboxylic acids.

The reaction of amines has been a topic of immense research owing to their synthetic utility and biological activity.[15] They are also widely used as intermediates to prepare solvents, fine chemicals, agrochemicals, and catalysts.[16]



The nucleophilic attack of alkyl halides by primary amines is useful for the preparation of secondary amines, but the reaction is invariably slow and gives rise to a mixture of secondary and tertiary amines.[17] However, the toxicity of some

Scheme 1. Formation of *N*-benzyl aniline using the Ph_2PCl/I_2/imidazole system.

alkylating agents and also the control of monoalkylation can be problematic. To obviate these problems, reductive amination of the carbonyl compounds,[18] amide reduction,[19] and the use of catalytic systems in the presence of alcohols, such as ruthenium, rhodium, iridium, zinc, palladium, and γ-alumina, have been reported. These conditions require strong reducing reagents or dangerous hydrogen gas and, in many cases, are not always selective and generate tertiary amines and (or) quaternary ammonium salts as byproducts. In addition, most of these catalytic systems require high reaction temperatures, and the applicable amines and alcohols are very restricted.[20] Recently, Iranpoor et al.[21] reported selective methods for N-monoalkylation of amines using the TPP system. In these methods, careful chromatography is necessary for isolation of the desired products from TPP oxide and the reaction mixture.

Due to the wide biological, synthetic, and industrial applications of amides, the amidation reaction is considered an important transformation in organic synthesis.[22,23] Different synthetic methodologies have been developed in the past two decades for the formation of an amide bond, with the focus on design and development of innovating coupling reagents. The most popular methods for the synthesis of amides involve the conversion of carboxylic acid to a more reactive functional group, such as acyl chloride, acyl azide, acylimidazoles, mixed anhydride, active esters, etc., followed by aminolysis with amine or via an in situ activation of the carboxylic group by using coupling reagents.[24] Although good results have been obtained with both approaches, they often need expensive coupling reagents, some of which are moisture-sensitive and sometimes lead to the formation of byproducts requiring further separation. These drawbacks usually limit their extensive application and give rise to the need for development of new types of condensing reagents.

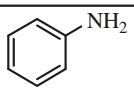
Results and discussion

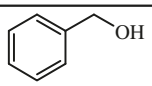
First, we investigated N-alkylation of aniline with benzyl alcohol using the Ph_2PCl/imidazole/I_2 system under various reaction conditions (Scheme 1). The optimization study revealed that 1.0 equiv of both Ph_2PCl and I_2 and 3.0 equiv of imidazole were sufficient to complete the reaction between 2.0 equiv of alcohol and 2.0 equiv of amine in refluxing dichloromethane. Similar to our previous work, it was observed that the presence of imidazole in the reaction mixture[14] not only neutralizes the liberated halogen acids, but also enhances the reactivity of the reagent system.

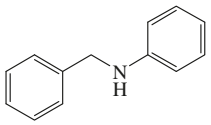
With the optimized conditions in hand, we screened a representative range of structurally different alcohols and amines for the reaction. Representative results are summarized in Table 1.

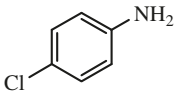
As shown by the data reported in Table 1, N-alkylation of anilines with benzyl alcohols bearing electron-donating and electron-withdrawing substituents at the aromatic ring proceeded to give benzyl aniline derivatives in good to excellent yields. As the results show, the reaction works best with the electron-rich benzyl alcohols. The electron-poor benzyl alcohols also provided the corresponding products, but with longer reaction times (Table 1, compare entries 5 and 9 with entries 6 and 10). In addition to the electronic factors, steric effects also affected the reaction in terms of time and yield. Comparison of entries 6 and 7 in Table 1 indicate that the existence of an ortho substituent on the phenyl ring slightly decreases the yield and increases the time of the reaction.

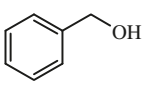
Treatment of 1-phenyl ethanol with this mixed reagent system (Table 1, entries 13–15) showed that this system is also suitable for the conversion of the secondary benzylic alcohols to their corresponding products. In the case of primary and secondary aliphatic alcohols such as 1-octanol and 2-octanol (Table 1, entries 20 and 21), no desired product was formed even after reflux in acetonitrile for a prolonged reaction time. These results exhibited that the reaction of non-benzylic alcohols with aniline in the presence of our reagent system does not occur.

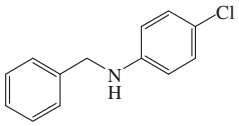


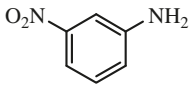


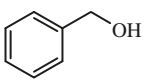


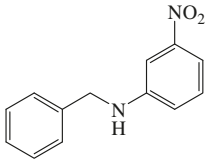


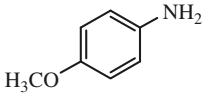


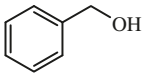


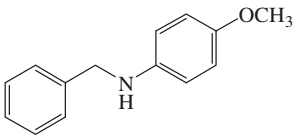


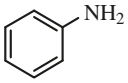


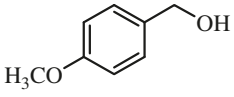


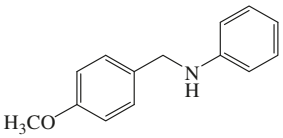


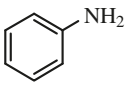


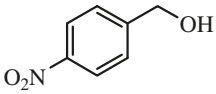


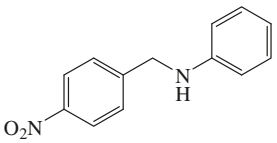


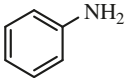


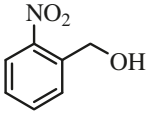


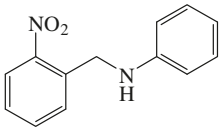


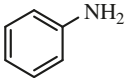


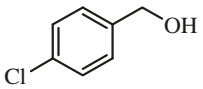


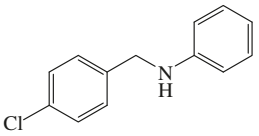


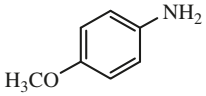


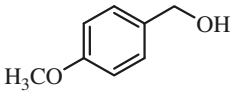


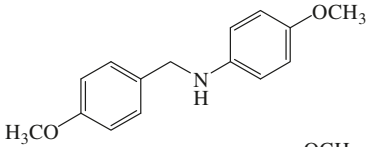


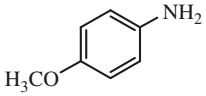


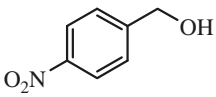


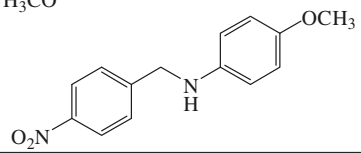












Similar to the alcohols, the nature of the substitution of the aromatic ring in aniline was also briefly studied. Both electron-donating and electron-withdrawing substituents react under our reaction conditions, and the overall yields in all cases are excellent. The reaction of benzyl alcohol with electron-rich anilines such as *p*-anisidine (Table 1, entry 4) gave the *N*-benzyl-4-methoxybenzenamine after 1.5 h, whereas a longer reaction time was observed for anilines bearing electron-withdrawing groups on the phenyl moiety (Table 1, entries 2 and 3).

In addition to this, in the reaction with benzyl alcohol, the more nucleophilic *N*-methylaniline produced better results as compared with the poor nucleophilic aromatic amines such as aniline (Table 1, compare entry 1 with entry 12).

Aliphatic amines were also tested to N-alkylation, but our attempts for alkylation of the primary aliphatic amines under the aforementioned conditions were unsuccessful, and the product was not obtained in this way even after refluxing in CH_3CN for 48 h. Secondary aliphatic amines (Table 1, entries 18 and 19) produced their corresponding tertiary amines in moderate yields. These reactions did not complete under the reaction conditions after 24 h and led to the desired product with lower yield possibly because of the steric effects. These results are not surprising based on the nucleophilicity of the amines. For the reaction to proceed, it is important to have amines as the reactive nucleophile and the secondary aliphatic amines are stronger nucleophiles than the primary amines. In the case of the aromatic amines, the stronger acidity of the amino group in aniline derivatives resulted in the easier formation of amine anions, which are strong nucleophiles.

To have more insight into the applicability, selectivity, and limitations of this new method, we performed an experiment using binary mixtures of equimolar amounts of aniline and different primary or secondary aliphatic amines and primary ones with benzyl alcohol. The results of this study are presented in Table 2.

As expected, reaction of a binary mixture of aniline and a primary aliphatic amine such as butyl amine proceeded smoothly to give the benzanilide as the single product in 90% yield (Table 2, entry 1). Benzyl amine was found to be unreacted under the reaction conditions (Table 2, entry 2). Furthermore, the alkylation of a secondary aliphatic amine in a dual mixture with benzyl amine as a primary aliphatic amine also proceeded to give tribenzylamine in moderate yield (Table 2, entry 3). The most important point regarding this method is that aromatic and secondary aliphatic amines

Scheme 2. Synthesis of benzanilide from the reaction of benzoic acid and aniline using the Ph_2PCl/I_2/imidazole system.

can be converted to their corresponding alkylated products in the presence of primary aliphatic amines in binary mixtures with excellent selectivity using the same stoichiometric amounts of the reagents and substrates as before.

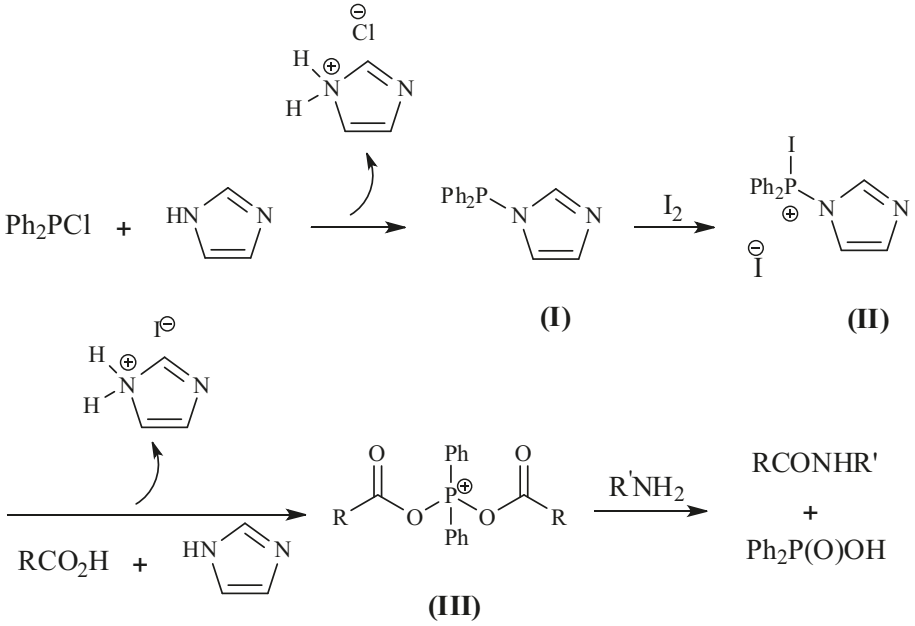
To extend the applicability of our methodology and find out the limitations encountered in this new system, we sought conditions for performing direct amidation of carboxylic acids with amines, as an important transformation. In the amidation process, we examined the reaction of benzoic acid with aniline as a model reaction. Of the various stoichiometric amounts, the ratio of 1.5:4.5:1.5:2.0:2.0 for Ph_2PCl/imidazole/I_2/$PhCO_2H$/$PhNH_2$ in refluxing CH_2Cl_2 was found to be the best condition and resulted in benzanilide in 90% yield (Scheme 2). This transformation occurred conveniently with the easy removal of the produced phosphine oxide (diphenylphosphinic acid) by a simple extraction.

By using this system, the amidation of carboxylic acids with amines was also performed in a similar manner of amination and is shown in Table 3.

These results clearly demonstrate that the direct amidation was successful for both aliphatic and aromatic amines and acids.

With the variation of substituents in both acids and amines, it was observed that the reaction depended on the acidity of the benzoic acid derivatives and the nucleophilicity of the aromatic amines. As shown in Table 3, for most cases, better results were observed for the reaction of electron-withdrawing substituted aromatic acids (stronger aryl acids) with the activated aromatic amines carrying electron-donating substithents (stronger nucleophiles). For instance, reaction of *p*-nitrobenzoic acid with aniline proceeded to afford the desired product after 20 min (Table 3, entry 3), whereas longer reaction times were required when benzoic or *p*-methylbenzoic acid were employed in the reaction (Table 3, entries 1 and 2). Treatment of *p*-methoxyaniline and benzoic acid led to a clean reaction affording the desired amide after 30 min (Table 3, entry 4); however, the use of aniline bearing an electron-withdrawing group such as nitro, lead to the desired product in a relatively longer reaction time (2 h) and lower yield (75%) because of the low nucleophilicity of the amine (Table 3, entry 9).

As shown in Table 3, aliphatic amines (entries 10 and 11) and also aliphatic acids (Table 3, entry 15) are suitable substrates for synthesis of their corresponding amides. To show the generality of the present method, we examined the reaction of aliphatic and aromatic thiocarboxylic acids with aniline. In these cases, the successful transformation of thioacids to their corresponding thioamides was observed using the same reaction conditions as for carboxylic acids (Table 3, entries 16 and 17).



As previously reported,[14] we suggest that this reaction might be proceeding initially by formation of 1-(diphenylphosphino)imidazole (**I**), which in the second step reacts with iodine. The imidazole and iodine in the produced phosphonium salt are then exchanged by carboxylate anion to form the the acyloxyphosphonium ion (**III**). Finally the attack of the amine at the carbonyl carbon atom of this intermediate gives the corresponding amide along with diphenylphosphinic acid as a byproduct (Scheme 3).

Conclusion

In conclusion, we have developed a new, efficient, and mild method for mono-N-benzylation of amines with alcohols and also for amidation of carboxylic acids with aliphatic and aromatic amines. It should be noted that the present N-alkylation proceeds with high selectivity for mono-N-alkylation. In each reaction, monoalkylated aniline was formed as a single product and no formation of dialkylated aniline was observed. Therefore, one crucial feature embedded in this protocol is the excellent chemoselectivity. High yields, mild

Scheme 3. Proposed mechanism for the amidation reaction.

reaction conditions, a simple and convenient procedure, commercially availablity of the reagents, no need for a catalyst, and no prior activation in amidation are the advantages of this system. This system also has the further advantage that the reagent-derived byproduct (diphenylphosphinic acid) can be removed easily by a simple aqueous workup, which provides quick workup procedures instead of using the tedious and time-consuming chromatographic methods.

Experimental section

General methods

Solvents were dried and purified by standard procedures. Melting points were determined in open capillary tubes in a Buchi 530 circulating oil apparatus and are not corrected. NMR spectra were recorded on a Bruker Avance DPX-250 (^{1}H NMR, 250 MHz; ^{13}C NMR, 62.9 MHz) spectrometer in $CDCl_3$ or DMSO-d_6 using TMS as an internal standard. Determination of the purity of the products and the reaction monitoring were carried out on silica gel 254 analytical sheets or by GLC on a Shimadzu model GC-10A instrument. Column chromatography was carried out by silica gel 60 Merck (30–270). All compounds had been reported previously, and their identities were confirmed by comparison of their melting points and spectroscopic data with the reported data.

General procedure for the conversion of amines to *N*-benzyl amines

Benzyl alcohol (2.0 mmol) was added to a mixture of chlorodiphenylphosphine (1.0 mmol), imidazole (3.0 mmol), and iodine (1.0 mmol) in refluxing dichloromethane. Amine (2.0 mmol) was then added to the reaction mixture. After completion of the reaction, the residue was washed with saturated aqueous sodium carbonate (3 × 5 mL) until all diphenylphosphinic acid was removed from the organic phase. The aqueous phase was separated, and the organic phase was washed with aqueous sodium thiosulfate (2 × 5 mL) to remove the excess iodine and then washed with water, dried, and concentrated. Flash chromatography of the organic residue was performed on silica gel using *n*-hexane / ethyl acetate as eluent to give the pure products.

4-Chloro*-N-*(1-phenylethyl)aniline

mp 59 °C (lit.[25k] 62 °C). δ_H (250 MHz, $CDCl_3$): 7.29–7.33 (m, 4H, Ph), 7.21–7.25 (m, 1H, Ph), 7.00–7.02 (m, 2H, Ph), 6.40–6.43 (m, 2H, Ph), 4.41 (q, 1H, J = 6.6 Hz, C*H*), 4.03 (s, 1H, N*H*), 1.53 (d, 3H, J = 6.6 Hz, *Me*). δ_C (62.9 MHz, $CDCl_3$): 145.7, 144.6, 128.9, 128.7, 127.0, 125.7, 121.8, 114.3, 53.5, 24.9. HRMS (EI+) calcd for $C_{14}H_{14}ClN$: 231.0815; found: 231.0809 (Table 1, entry 14).

***4-Methoxy*-N-*(1-phenylethyl)aniline*[25k]**

δ_H (250 MHz, $CDCl_3$): 7.20–7.38 (m, 5H, Ph), 6.66–6.69 (d, 2H, J = 8.4 Hz, Ph), 6.44–6.47 (d, 2H, J = 8.4 Hz, Ph), 4.42 (q, 1H, J = 6.6 Hz, C*H*), 3.60 (S, 3H, O*Me*), 1.47 (d, 3H, J = 6.6 Hz, *Me*). δ_C (62.9 MHz, $CDCl_3$): 151.9, 144.4, 141.5, 128.6, 126.8, 125.9, 114.7, 114.5, 55.7, 54.2, 25.0. HRMS (EI+) calcd for $C_{15}H_{17}NO$: 227.131; found: 227.130 (Table 1, entry 15).

Tribenzylamine

mp 91 °C (lit.[25l] 91 °C). δ_H (250 MHz, $CDCl_3$): 7.44–7.21 (m, 15H, Ph), 3.56 (s, 6H, CH_2). δ_C (62.9 MHz, $CDCl_3$): 140.1, 129.2, 128.6, 127.3, 58.3. HRMS (EI+) calcd for $C_{21}H_{21}N$: 287.1674; found: 287.1670 (Table 1, entry 18).

N-*Benzylmorpholine*

mp 168 °C (lit.[25l] 170 °C). δ_H (250 MHz, $CDCl_3$): 7.20–7.29 (m, 5H, Ph), 3.68 (t, 4H, J = 4.8 Hz, CH_2), 2.41 (t, 4H, J = 4.6 Hz, CH_2), 3.45 (s, 2H, PhCH_2). δ_C (62.9 MHz, $CDCl_3$): 137.7, 129.2, 128.2, 127.1, 67.0, 63.5, 53.6. HRMS (EI+) calcd for $C_{11}H_{15}NO$: 177.1154; found: 177.1148 (Table 1, entry 19).

General procedure for the conversion of acids to amides

To a stirred solution of Ph_2PCl (1.5 mmol) and imidazole (4.5 mmol) in 5 mL dichloromethane at reflux were added iodine (1.5 mmol) and acids (2.0 mmol), successively. Amines (2.0 mmol) were then added to the reaction mixture. After completion of the reaction, the organic layer was washed with saturated aqueous sodium carbonate (3 × 5 mL) and then aqueous sodium thiosulfate (2 × 5 mL), and then dried. The residue was subjected to flash chromatography over silica gel by using *n*-hexane / ethyl acetate as eluent to give the pure amides.

Benzanilide

mp 161 °C (lit.[25a] 163 °C). δ_H (250 MHz, $CDCl_3$): 7.15–8.08 (complex, 11H, Ph). δ_C (62.9 MHz, $CDCl_3$): 165.8, 137.9, 133.6, 131.8, 128.8, 128.4, 127.0, 124.6, 120.3. HRMS (EI+) calcd for $C_{13}H_{11}NO$: 197.0841; found: 197.0835 (Table 3, entry 1).

4-Methyl*-N-*phenylbenzamide

mp 147 °C (lit.[26a] 145 °C). δ_H (250 MHz, $CDCl_3$): 7.90 (s, 1H, N*H*), 7.68 (d, 2H, J = 8.0 Hz, Ph), 7.59 (d, 2H, J = 7.6 Hz, Ph), 7.42 (t, 2H, J = 7.8 Hz, Ph), 7.25 (d, 2H, J = 8.2 Hz, Ph), 7.23 (t, 1H, J = 7.4 Hz, Ph), 2.38 (s, 3H, *Me*). δ_C (62.9 MHz, $CDCl_3$): 167.2, 142.5, 137.8, 131.6, 129.5, 129.1, 128.4, 124.6, 119.8, 21.3. HRMS (EI+) calcd for $C_{14}H_{13}NO$: 211.0997; found: 211.0988 (Table 3, entry 2).

4-Nitro*-N-*phenylbenzamide

mp 211–213 °C (lit.[26b] 211–212 °C). δ_H (250 MHz, d_6-DMSO): 10.54 (s, 1H, N*H*), 8.36 (d, 2H, J = 8.8 Hz, Ph), 8.16 (d, 2H, J = 8.8 Hz, Ph), 7.76 (d, 2H, J = 8.3 Hz, Ph), 7.36 (m, 2H, Ph), 7.10–7.15 (m, 1H, Ph). δ_C (62.9 MHz, $CDCl_3$): 164.2, 157.5, 134.1, 133.8, 129.2, 128.7, 124.1, 123.5, 120.4. HRMS (EI+) calcd for $C_{13}H_{10}N_2O_3$: 242.0691; found: 242.0680 (Table 3, entry 3).

N-*(4-Methoxyphenyl)benzamide*

mp 154 °C (lit.[26c] 156–157 °C). δ_H (250 MHz, $CDCl_3$): 7.77 (d, 2H, J = 8.1 Hz, Ph), 7.64 (s, 1H, N*H*), 7.39–7.61 (m, 5H, Ph), 6.78 (d, 2H, J = 8.5 Hz, Ph), 3.85 (s, 3H, O*Me*). δ_C (62.9 MHz, $CDCl_3$): 165.7, 155.9, 137.1, 132.3, 131.2, 128.9, 127.5, 122.0, 114.9, 55.4. HRMS (EI+) calcd for $C_{14}H_{13}NO_2$: 227.0946; found: 227.0940 (Table 3, entry 4).

N-*(4-Methoxyphenyl)-4-nitrobenzamide*

mp 198–200 °C (lit.[26d] 199–201 °C). δ_H (250 MHz, d_6-DMSO): 10.45 (s, 1H, N*H*), 8.33 (d, 2H, J = 8.7 Hz, Ph), 8.16 (d, 2H, J = 8.7 Hz, Ph), 7.70 (d, 2H, J = 8.9 Hz, Ph), 6.93 (d, 2H, J = 8.9 Hz, Ph), 3.74 (s, 3H, O*Me*). δ_C (62.9 MHz, d_6-DMSO): 163.3, 155.8, 149.0, 140.6, 131.7, 129.0, 123.4, 122.0, 113.7, 55.1. HRMS (EI+) calcd for $C_{14}H_{12}N_2O_4$: 272.0797; found: 272.0785 (Table 3, entry 5).

N-*(4-Methoxyphenyl)-4-methylbenzamide*

mp 166 °C (lit.[26e] 166 °C). δ_H (250 MHz, $CDCl_3$): 9.35 (s, 1H, N*H*), 7.88 (d, 2H, J = 8.4 Hz, Ph), 7.73 (d, 2H, J = 9.3 Hz, Ph), 7.28 (d, 2H, J = 8.4 Hz, Ph), 6.90 (d, 2H, J =

Studies on the reaction of nitric oxide with α,β-unsaturated hydrazones

Desuo Yang, Xiaolin Luo, Haiyun Zhu, Yaning Guo, and Longmin Wu

Abstract: α,β-Unsaturated arylhydrazones (**1**) reacted with nitric oxide (NO) in the presence of a trace of oxygen to give α-(**2a**–**2c**, **2e**, and **2f**) or β-nitro (**2d** and **2g**) unsaturated hydrazones in good yield and with high stereoselectivity. The reaction occurs most likely by an electrophilic addition of NO_2 to the carbon–carbon double bond of **1** at its α- or β-position.

Key words: α,β-unsaturated hydrazone, nitric oxide, nitration reaction, electrophilic addition.

Résumé : Les arylhydrazones α,β-insaturées (**1**) réagissent avec l'oxyde nitrique (NO), en présence d'une trace d'oxygène pour conduire à la formation d'α- (**2a**–**2c**, **2e** et **2f**) ou de β-nitrohydrazones (**2d** et **2g**) insaturées, avec des bons rendements et une grande stéréosélectivité. La réaction se produit très probablement par une addition électrophile de NO_2 sur les positions α ou β de la double liaison carbone–carbone du composé **1**.

Mots-clés : hydrazone α,β-insaturée, oxyde nitrique, réaction de nitration, addition électrophile.

Introduction

Studies on nitric oxide (NO) associated with life processes have attracted more attention from scientists. The proper regulation of NO levels has been proposed as a desirable target for developing new medicines.[1] Therefore, intensive investigations have been directed toward reactions of NO with biological molecules[2] and various organic molecules, such as alkenes,[3] Schiff bases or oximes,[4] epoxides,[5] polycyclic aromatic hydrocarbons,[6] chalcone derivatives,[7] coumarins,[8] flavanones,[9] and hydrazones.[10]

Hydrazone compounds with an active imine double bond are widely used to construct chiral configurations and certain specific skeletons in organic synthesis.[11] In recent years, some hydrazones and their complexes have been found to have good bioactivity in the anticancer,[12] antimalarial,[13] and antiviral aspects.[14] As part of continuing efforts to explore biological applications of NO chemistry and ongoing studies on the reaction of NO with organic molecules, we studied the reaction of NO with saturated arylhydrazones in the presence of trace oxygen. It was found that the reaction of NO with aldehyde arylhydrazones provided exclusively C(1′)-nitrohydrazones with E-configurations,[15] and that ketone arylhydrazones afforded mononitrated azo-compounds.[16]

Gillis and LaMontagne[17] studied the oxidation of cinnamaldehyde monomethylhydrazone with lead tetraacetate and obtained the corresponding *N*-acetylcinnamic acid methylhydrazide. Kamitori et al.[18] reported that the trifluoroacetylation of dialkylhydrazones of α,β-unsaturated aldehydes occurred at the terminal carbon of the conjugate system. In conjunction with alkenes and simple hydrazones, the reaction of α,β-unsaturated hydrazones with NO is suggested to occur by a different mechanism from saturated hydrazones because of the existence of both C=C and C=N bonds in α,β-unsaturated hydrazones. In the present work we will report research on the reaction of NO with α,β-unsaturated aldehyde and ketone arylhydrazones.

α,β-Unsaturated arylhydrazones (**1**) were prepared by the reaction of an α,β-unsaturated ketone with 2,4-dinitrophenylhydrazine in ethanol. The crude products were obtained after removal of the solvent. Further purifications were done according to literature procedure.[19] The products were characterized by NMR, MS, and IR. The reaction of NO with **1** was examined in the presence of trace oxygen in CH_2Cl_2 at room temperature (Scheme 1). The unique products, α-nitrohydrazones (**2a**–**2c**, **2e**, and **2f**) or β-nitrohydrazones (**2d** and **2g**), were obtained in high yield. In the case of **1e** a small quantity of α-nitro alkenyl azo-compound (**2e′**) was also obtained. These results indicate that the reaction of NO with **1** occurs in a different way, compared with those of saturated hydrazones. It is proposed that the π bond of the C=C of **1** breaks during the reaction and a fresh C=C double bond is regenerated by an elimination reaction.

Results and discussion

Nitration reaction of NO with α,β-unsaturated arylhydrazones

Under similar conditions, compound **1** reacted with NO in the presence of minute amounts of oxygen affording a more complex pattern of products than the saturated hydrazones.[15,16] One hydrogen atom at the C=C bond of **1** was

exclusively substituted by a nitro group in all cases. It was also found that the nitro group replaces an α-hydrogen atom at the C=C bond with two hydrogen atoms in trans-positions (**2a**–**2c**), whereas the nitro group replaces a β-hydrogen atom (**2d**) when these two hydrogen atoms lay in cis-positions. It was found that **1e** reacted with NO to give **2e** and, in addition, a small amount of an α-nitro alkenyl azo-compound (**2e′**), where the substitution of a hydrogen atom at the C=C bond by a nitro group did not occur.

The nitration reaction of **1** with NO is assumed to occur by an electrophilic addition of NO_2 to the C=C double bond of **1**, most likely similar to that of alkenes.[3,20] At first, NO is oxidized with oxygen to give nitrogen dioxide (NO_2). NO_2 then undergoes an electrophilic addition to either the α-carbon (**1a**–**1c**, **1e**, and **1f**) or β-carbon (**1d** and **1g**) at the C=C bond of **1**, leading to the formation of a carbon radical. Afterwards, the resulting carbon radical couples with three molecules of NO to give a *N*-nitroso-*N*-nitrite compound,[15] followed by a rearrangement, an elimination of HNO_3, and an expulsion of N_2, giving compound **2** (Table 1).

As such, the amount of O_2 in the whole system would play a key role and is closely related to the composition of products and the reaction rate. No product was obtained when oxygen was rigorously excluded from the system.[15]

Identification of products

MS and HR-MS detections show that all the products were formed by loss of a hydrogen atom from **1** and by introduction of a nitro group. Except for **2e**′, the ν_{N-H} of –NH stretching bands is observed at ~3300 cm^{-1} in the IR spectra of **2**. The observations of a singlet peak at δ ~ 11.0 ppm for one hydrogen and another singlet peak and two doublet peaks at δ 7.2–9.2 ppm in the ^{1}H NMR spectra of **2** are assigned to –NH and 2,4-dinitrophenyl protons, respectively. ^{1}H NMR spectra of **2a**–**2d** also exhibit the loss of one hydrogen at the C=C bond in **1a**–**1d**. These detections indicate that the 2,4-dinitrophenylamino group remains unchanged, and the reaction occurs at the C=C bond rather than at the C=N bond.

A doublet peak at δ ~ 7.20 ppm and a multiplet peak at δ ~ 2.71 ppm are assigned to an isopropyl group (Scheme 1). An NOE enhancement was observed at the CH_3 (δ 2.30 ppm) protons in **2a** upon irradiation of the NH proton (δ 11.32 ppm). This indicates that NH is related to the $–CH_3$ at the C=N bond, i.e., $–CH_3$ and the NH–Ar groups are on the same side of the C=N bond with an E-configuration. When the =CH (δ 7.19 ppm) proton was irradiated, the signal of $–CH_3$ (δ 2.30 ppm) at the C=N bond was enhanced, indicating the nitro and the isopropyl groups are on the same sides of the C=C bond with a Z-configuration.

To determine the position of the nitro group at the C=C bond in **2b**, gHSQC and HMBC experiments were performed (Figs. 1 and 2). Three types of hydrogen, 2,4-dinitrophenyl (H3, H5, and H6), CH_3 (H16), and –NH (H7) in the ^{1}H NMR spectrum of **2b** are easily assigned. A singlet peak at δ ~ 8.20 ppm for one hydrogen is assigned to =CH (H11), and a group of multiple peaks at 7.39–7.49 ppm are assigned

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

to the hydrogens on the substituted phenyl (H13 and H13′, H14 and H14′, and H15). DEPT and gHSQC experiments indicate that H11 connects to C11 (~136.8 ppm). It can also be seen from the HMBC that H11 at the C=C bond is obviously related to a substituted phenyl (7.39–7.49 ppm) (Fig. 2). Similarly, C9 and C10 are relevant to H16 and H11, respectively. Thus, the nitro group can be deduced to lie at the α-position of **2b**. An NOE enhancement establishes the Z-configuration at the C=C bond.

The ^{1}H NMR spectrum of **2c** shows a singlet at δ 8.15 ppm assigned to the proton at the C=C double bond (=CH) and manifests, from its HMBC spectrum, that the =CH proton is related to the substituted phenyl protons (7.06–7.33 ppm). Therefore, the nitro group in **2c** is thought to be also connected to the α-position. NOE enhancements were observed at the phenyl protons of C=N bond upon irradiation of the NH proton (~11.38 ppm) and the proton at the C=C bond. These observations indicate that the phenyl and –NHAr groups are on the same side of the C=N bond and the $-NO_2$ and =CH groups are on opposite sides of the C=C bond. Therefore, a Z-configuration at the C=C bond of **2c** is assigned.

The ^{1}H NMR spectrum of **2d** shows a singlet at δ 7.66 ppm assigned to the =CH proton. Thus, the nitro group is thought to be connected to the β-position. An NOE enhancement was observed at the α-CH_2 protons (~2.64 ppm) of the C=N bond upon irradiation of the NH proton (~11.50 ppm). An E-configuration is assigned to the C=N bond of **2d**.

There is one hydrogen atom at the C=C bonds of **1e**–**1g**. ^{1}H NMR spectra of their products (**2e**–**2g**) display no proton linking at the C=C bond. The ^{13}C NMR spectra of **2e**–**2g** show that the proton of the double bond was replaced by a nitro group. An NOE experiment for **2e** shows its α-CH_2 proton (~2.68 ppm) at the C=N bond was related to the proton of NH (~11.20 ppm). Thus, the C=N group of **2e** with an E-configuration is established.

Compound **1e** reacted with NO to give a small amount of **2e**′ in addition to **2e**. MS and HR-MS detections show **2e**′ and **2e** have the same molecular formula. The ^{1}H NMR spectrum of **2e**′ displays a singlet at δ 7.28 ppm assigned to the =CH, and its ^{13}C NMR spectrum shows a singlet at δ_c 87.1 ppm assigned to a quaternary carbon associated with an NO_2. IR and ^{1}H NMR spectra indicate that there is no NH group in **2e**′. Therefore, product **2e**′ may be inferred to be an azo-compound.

Crystal structure of 2e

X-ray crystallography data for **2e** are shown in Table 2 (see the Supplementary data). Crystal structure and a packing diagram of **2e** are illustrated in Fig. 3, and the selected bond lengths and bond angles are summarized in Table 3. The analytical results indicate that the nitro group is linked at C-5, i.e., the α-carbon (Fig. 3*a*) and the N(3)–C(5) is a single bond (1.476(2) Å). Both the C(4)–C(5) bond length of 1.334(2) Å and the N(1)–C(6) bond length of 1.288(2) Å are assigned to an ethylenic bond and an imine double bond, respectively, in **2e**.

The C(1)–C(2)–C(3)–C(4)–C(5)–C(6) six-membered ring is an envelope-type structure. The vertical distance from C2 to the plane constructed by the remaining five carbon atoms is 0.5 Å. The dihedral angle between the nitro group at C5 (α-carbon) and the six-membered ring plane is 78°. A hydrogen bond exists between the hydrogen atom of NH and the oxygen atom of the *ortho*-nitro group on the benzene ring (Table 4; Fig. 3*b*).

Conclusion

The present study reports that the reaction of NO with α,β-unsaturated arylhydrazones (**1**) in the presence of a trace of oxygen at room temperature gives α-nitro (**2a**–**2c**, **2e**, and **2f**) or β-nitro (**2d** and **2g**) unsaturated hydrazones in good yield and with high stereoselectivity. The nitration reaction is most likely initiated by an electrophilic addition reaction of NO_2 to the C=C double bond of substrate **1**. A small quantity of α-nitro alkenyl azo-compound (**2e**′) was also formed in the case of **1e**. The nitration reaction discussed herein offers an efficient method for preparing α,β-nitro unsaturated hydrazones and α,β-nitro unsaturated ketones.

Experimental

All solvents were distilled prior to use according to standard procedures. Methylene dichloride was dehydrated with CaH_2 by refluxing.

^1H and ^{13}C NMR spectra were recorded on a Bruker Avance 400 (^1H, 400 MHz; or ^{13}C, 100 MHz; δ downfield from TMS). IR analysis was performed on a Nicolet NEXUS 670 FT-IR. Mass data were obtained on a HP-5988A GC–MS, and HR-ESI-MS data were obtained on a Bruker Daltonics APEx II FT-ICR. Melting points were determined with an XT_4-100X micromelting point apparatus and not corrected.

X-ray analysis on single crystals was carried out at 293(2) K on a Nonius CAD4 automatic diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). Structural solutions and full-matrix least-squares refinements based on F^2 were performed with the SHELXS-97 and SHELXL-97 program packages,[21] respectively. All the non-hydrogen atoms were anisotropically positioned. Hydrogen atoms were placed in geometrical positions and constrained to ride on their parent atoms. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated (see the Supplementary data for crystallographic data (excluding structure factors)).[22]

General procedure for the synthesis of 2a–2g

A solution of **1** was prepared by dissolving **1** (0.5 mmol) in 100 mL of anhydrous dichloromethane. NO was produced by dropwise addition of 1 mol L^{-1} H_2SO_4 solution to a stirred saturated aqueous solution of $NaNO_2$ under an argon atmosphere. NO gas was purified by passing through a series of scrubbing bottles containing 4 mol L^{-1} NaOH, distilled water, and anhydrous $CaCl_2$ pellets in this order. The purified NO was bubbled through the stirred solution of **1**, which was previously degassed by argon for approx. 5–10 min and kept at a pressure of up to +10 mm H_2O column over local atmospheric pressure, at ambient temperature for 8–14 h. In the course of the reaction, the argon flow rate was controlled by regulating the flow meter at 0.8 L min^{-1}. A rough estimate of the total amount of NO passing through the solution was about 1000 mmol at the local atmosphere pressure using the ideal gas law. The progress of the reaction was monitored by TLC. After the reaction was complete, the mixture was dried over anhydrous $MgSO_4$, concentrated under vacuum, and purified by column chromatography on silica gel (200–300 mesh; ethyl acetate – petroleum ether, 1:6 v/v), giving pure product **2** (Table 1).

(E)-1-(2,4-Dinitrophenyl)-2-((Z)-5-methyl-3-nitrohex-3-en-2-ylidene)hydrazine (2a)

Yellow needles, mp 129–130 °C. ^1H NMR (400 MHz, $CDCl_3$, ppm) δ: 1.15(d, 6H, *J* = 4.6 Hz), 2.30 (s, 3H), 2.67–2.73 (m, 1H), 7.21 (d, *J* = 12.8 Hz, 1H), 7.89 (d, *J* = 9.6 Hz, 1H), 8.39 (dd, *J* = 9.6, 2.8 Hz, 1H), 9.18 (d, *J* = 2.8 Hz, 1H), 11.32 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$, ppm) δ: 16.6, 22.1, 28.4, 63.4, 116.5, 123.2, 130.3, 130.4, 139.2, 144.4, 144.5, 146.9, 147.6. Abstract: Copper hydroxide (oxide) / multiwalled carbon nanotubes nanocomposite-modified glassy carbon electrode ($Cu_{hydroxide/oxide}$/MWCNTs/GCE) was successfully prepared by a novel film plating / cyclic voltammetry (CV) method, which exhibited marked synergistic catalytic effects on the electro-oxidation of NO_2^-. The preparation process, impedance behavior, and surface morphology of $Cu_{hydroxide/oxide}$/MWCNTs/GCE were investigated by CV, electrochemical impedance spectroscopy, and scanning electron microscopy (SEM), respectively. The optimum preparation and test conditions for the electrode to have high catalytic activity were acquired. The linear range between the anodic current (Δi_a, μA) and NO_2^- concentration (c, mmol L^{-1}) was 1.0×10^{-4} to 14.0 mmol L^{-1}, and the corresponding calibration curve was $\Delta i_a = -0.1504 + 57.954c$ (R = 0.9990, n = 32) with a detection limit of 0.03 μmol L^{-1} (S/N = 3). The $Cu_{hydroxide/oxide}$/MWCNTs/GCE prepared in the optimal conditions showed good stability, high selectivity, low detection limit, and quick response (<0.2 s) to NO_2^- in phosphate buffer (pH 5.29) at 0.78 V, which has been successfully applied to the determination of NO_2^- in pickled vegetables with satisfactory results.

Key words: copper hydroxide / oxide, multi-walled carbon nanotube, nitrite, catalytic oxidation.

Résumé : On a réussi à préparer une électrode d'hydroxyde (oxyde) de cuivre / nanotubes de carbone vitreux multicloisonné nanocomposite modifié ($Cu_{hydroxyde/oxyde}$/MWCNTs/GCE) en faisant appel à une nouvelle méthode de plaquage de film / voltampérométrie cyclique (VC) qui présente des effets marqués de synergie catalytique sur l'oxydation électrolytique du NO_2^-. On a étudié le processus de préparation, le comportement d'impédance et la morphologie du $Cu_{hydroxyde/oxyde}$/MWCNTs/GCE en faisant appel respectivement à la VC, à spectroscopie d'impédance électrochimique et à la microscopie électronique à balayage. On a déterminé les conditions optimales de préparation et vérification pour que l'activité catalytique soit optimale. La plage linéaire entre le courant anodique (Δi_a, μA) et la concentration de NO_2^- (c, mmol L^{-1}) est de $1{,}0 \times 10^{-4}$ à 14,0 mmol L^{-1} et la courbe de calibration correspondante est décrite par l'équation $\Delta i_a = -0{,}1504 + 57{,}954\ c$ (R = 0,9990, n = 32), avec une limite de détection de 0,03 mmol L^{-1} (S/N = 3). Le $Cu_{hydroxyde/oxyde}$/MWCNTs/GCE préparé dans des conditions optimales présente une bonne stabilité, une sélectivité élevée, une limite de détection faible et un temps de réponse rapide (<0,2 s) vis-à-vis du NO_2^- dans un tampon de phosphate (pH de 5,29), à 0,78 V et il a été utilisé avec des résultats satisfaisants pour la détermination du NO_2^- dans des légumes marinés.

Mots-clés : hydroxyde / oxyde de cuivre, nanotube de carbone multicloisonné, nitrite, oxydation catalytique.

[Traduit par la Rédaction]

Introduction

Pollution to the soil and groundwater owing to the extensive use of nitrogenous fertilizer and nitrogen-containing pesticides results in a higher nitrate content in plants, especially leafy vegetables such as cabbage, kale, spinach, etc. During the storage of vegetables, nitrate can be reduced to nitrite by the nitrate reductase produced by the microorganisms propagated profusely in vegetables.[1] Vegetable pickling, one of the most common and most popular processing methods of fresh vegetables, will also produce a lot of nitrite in the pickled vegetables because of improper curing process control (inadequately pickled or deterioration).[2] Nitrite as a preservative and color fixative in meat processing (bacon, sausage, salted fish, etc.) is widely used to inhibit the propagation of *Clostridium botulinum* and produces a distinct color and flavor.[3] Nitrite may also indirectly enter the milk for a variety of reasons, such as the digestion of forage itself and feeding process.[4] Therefore, nitrite widely exists and is closely related to our daily lives.

However, numerous studies have shown that excessive nitrite is hazardous to human health. An intake of 0.2–0.5 g nitrite can lead to poisoning of an adult and ingestion of 3 g

can lead to death. Nitrite in the blood can cause the irreversible oxidation of hemoglobin to methemoglobin, which lacks the capacity for oxygen transport and eventually will lead to death by respiratory failure.[5] Moreover, nitrite can react with amines and amides in the stomach to produce carcinogenic *N*-nitrosamine compounds, which mainly induce the digestive system canceration.[6] Nitrosamines also have teratogenic effects on the fetus, in particular on the central nervous system and the production of skeletal system abnormalities. To control the nitrite content in food and daily intake, it is of great importance to further develop a reliable alternative method for fast and sensitive determination of nitrite.

So far, many methods, such as UV–vis spectroscopy, fluorescence spectroscopy, chromatography, capillary electrophoresis, polarography, and potentiometry, have been used for nitrite determination in recent years.[7] However, most of these conventional approaches need complicated processes and expensive instruments. Furthermore, they are not suitable for the real-time monitoring of nitrite required for strict environmental control. In contrast, electrochemical methods for nitrite determination possess many unique advantages, such as simplicity, low cost, fast response, and the potential for real-time monitoring applications.[8] When the nitrite content was determined by measuring the current caused by the direct oxidation or reduction of nitrite on a substrate electrode, severe interferences could be produced because of the existence of higher overpotential.[9] At the same time, some species could poison the electrode surface and decrease the response sensitivity and reproducibility. To improve the selectivity of nitrite determination, the working electrode potential should be as close to zero as possible, which can be obtained by modifying a suitable electrocatalyst on the surface of the substrate electrode.

A variety of materials, such as metal nanoparticles,[10] metal oxides,[11] amino acids,[12] organic dyes,[13] conductive polymers,[14] carbon nanotubes (CNTs),[15] complexes,[16] and enzymes,[17] have been used to prepare chemically modified electrodes (CME) as sensors for nitrite determination. They all have demonstrated greater analytical performance than bare electrodes. In recent years, composite-modified electrodes have acquired increasing interest with quite different catalytic activity from those of single material. Some composites, such as CNTs/polyvanillin,[18] Pt nanoparticles / thionine / MWCNTs,[19] and Pt nanoparticles / poly(3-methylthiophene) nanorods,[20] have been reported for nitrite determination, which either improved the sensitivity, selectivity, and stability or extended the linear range of the calibration curve.

Transition-metal oxides as modified electrode materials show explicit characteristics of high activity, stability, and low cost, whereas CNTs exhibit high chemical stability, good electrical conductivity, and excellent biocompatibility, which makes them attractive for the construction of various electrochemical biosensors.[21,22] Based on the above considerations, we developed a copper hydroxide (oxide) / MWCNTs nanocomposite-modified glassy carbon electrode ($Cu_{hydroxide/oxide}$/MWCNTs/GCE) by a novel film plating / cyclic voltammetry (CV) method that was easier for the control of the number of active sites and made the film uniform and closely integrated with the electrode compared with the other methods reported. Marked synergistic catalytic effects on the electro-oxidation of NO_2^- were found. The effects of the preparation and testing conditions on the properties of the modified electrode were studied in detail. The results not only provided a sensitive electrochemical method for the determination of nitrite in real samples, but also embodied a novel idea for nanocomposite-modified electrode preparation and laid a good basis for the development of a high-performance miniature electrochemical sensor.

Fig. 1. (A) Cyclic voltammograms of glassy carbon electrode (GCE, curve 1) and multiwalled carbon nanotubes (MWCNTs) / GCE (curve 2) in 0.1 mol L^{-1} KCl solution. (B) Cyclic voltammogram of MWCNTs/GCE in 0.1 mol L^{-1} KCl solution containing 3.0 mmol L^{-1} $CuCl_2$ at 50 mV s^{-1}.

Results and discussion

Preparation of $Cu_{hydroxide/oxide}$/MWCNTs/GCE

Figure 1A shows the typical cyclic voltammograms of GCE (curve 1) and MWCNTs/GCE (curve 2) in 0.1 mol L^{-1} KCl. Non-Faradaic current at the MWCNTs/GCE increased significantly compared with that at GCE, indicating that MWCNTs had been successfully casted on the GCE surface. Figure 1B shows the cyclic voltammogram of $CuCl_2$ on MWCNTs/GCE in 0.1 mol L^{-1} KCl solution. Two pairs of well-defined redox peaks (O_1/R_1, O_2/R_2) were observed, which can be attributed to the quasi-reversible reaction of Cu^0/Cu^I and Cu^I/Cu^{II} redox couples, respectively. As can be

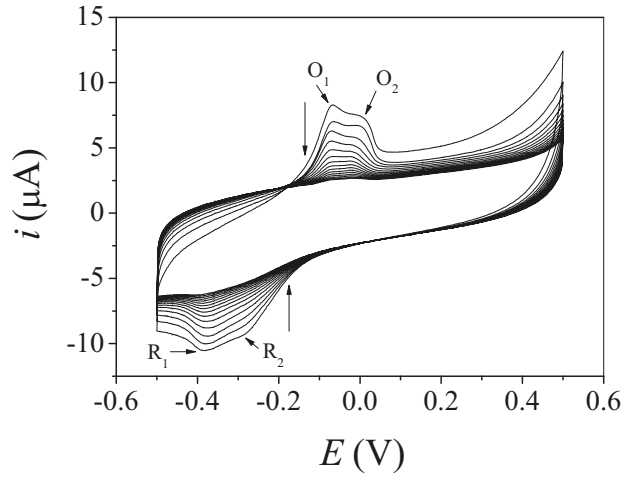
Fig. 2. Repetitive cyclic voltammograms of Cu / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) in 0.1 mol L^{-1} NaOH solution at 40 mV s^{-1}.



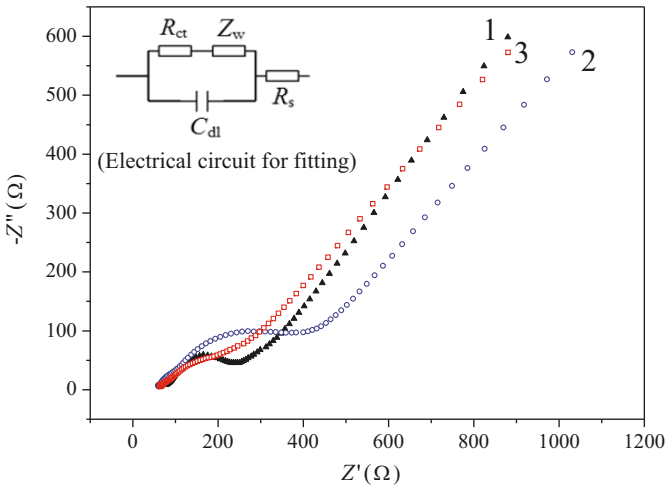


Fig. 3. Electrochemical impedance spectroscopy (EIS) of glassy carbon electrode (GCE, curve 1), $Cu_{hydroxide/oxide}$/GCE (curve 2), and $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / GCE (curve 3) in 0.1 mol L^{-1} KCl containing 10 mmol L^{-1} $[Fe(CN)_6]^{4-/3-}$ for 0.01–10^5 Hz at 0.28 V.

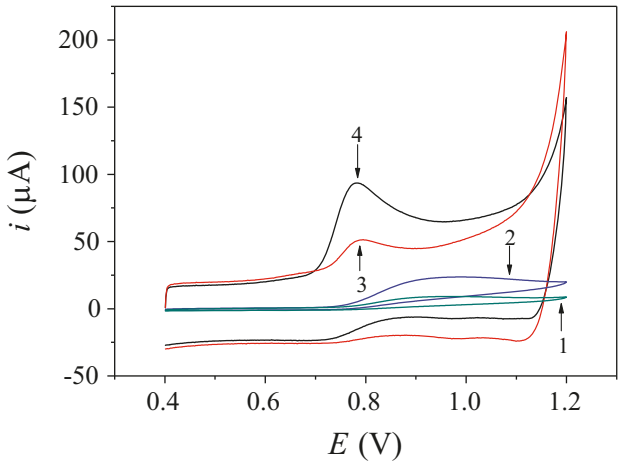
seen, Cu^{II} starts to be deoxidized at 0.30 V to Cu^{I}, which is further deoxidized to Cu^0 at –0.13 V, meaning that the deposition potential of Cu^0 particles on MWCNTs/GCE must be lower than –0.13 V.

Figure 2 shows the repetitive cyclic voltammograms of Cu/MWCNTs/GCE in 0.1 mol L^{-1} NaOH solution, by which $Cu_{hydroxide/oxide}$/MWCNTs/GCE was successfully prepared. As the potential scan proceeded, all redox peak current decreased, indicating that copper was converted to copper hydroxide / oxide on MWCNTs/GCE surface. The possible mechanism involving the electrochemical process can be expressed as follows: peak pair (O_1/R_1), $2Cu + 2OH^- - 2e = Cu_2O + H_2O$; peak pair ($O_2/R_2$), $2Cu_2O + 2OH^- + H_2O - 2e = 2Cu(OH)_2$.

Electrochemical impedance spectroscopy (EIS) is an efficient method for the investigation of electrochemical properties of modified electrode surface, with their graph comprising a semicircle and a straight line. The electron-

Fig. 4. Cyclic voltammograms of bare glassy carbon electrode (GCE, curve 1), $Cu_{hydroxide/oxide}$/GCE (curve 2), multiwalled carbon nanotubes (MWCNTs) / GCE (curve 3), and $Cu_{hydroxide/oxide}$/MWCNTs/GCE (curve 4) in 0.07 mol L^{-1} PBS + 0.2 mol L^{-1} KCl (pH 5.29) solution containing 2.5 mmol L^{-1} nitrite at 20 mV s^{-1}.



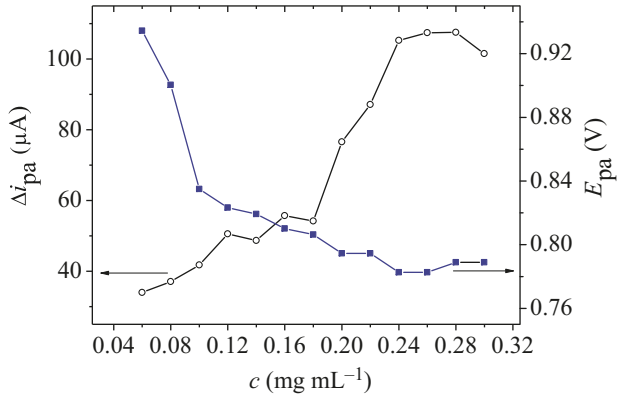


Fig. 5. The effect of multiwalled carbon nanotubes (MWCNTs) concentration on oxidation peak potential (E_{pa}) and current (Δi_{pa}) of 2 mmol L^{-1} nitrite on $Cu_{hydroxide/oxide}$ / MWCNTs / glassy carbon electrode (GCE) in 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl solution at 20 mV s^{-1}.

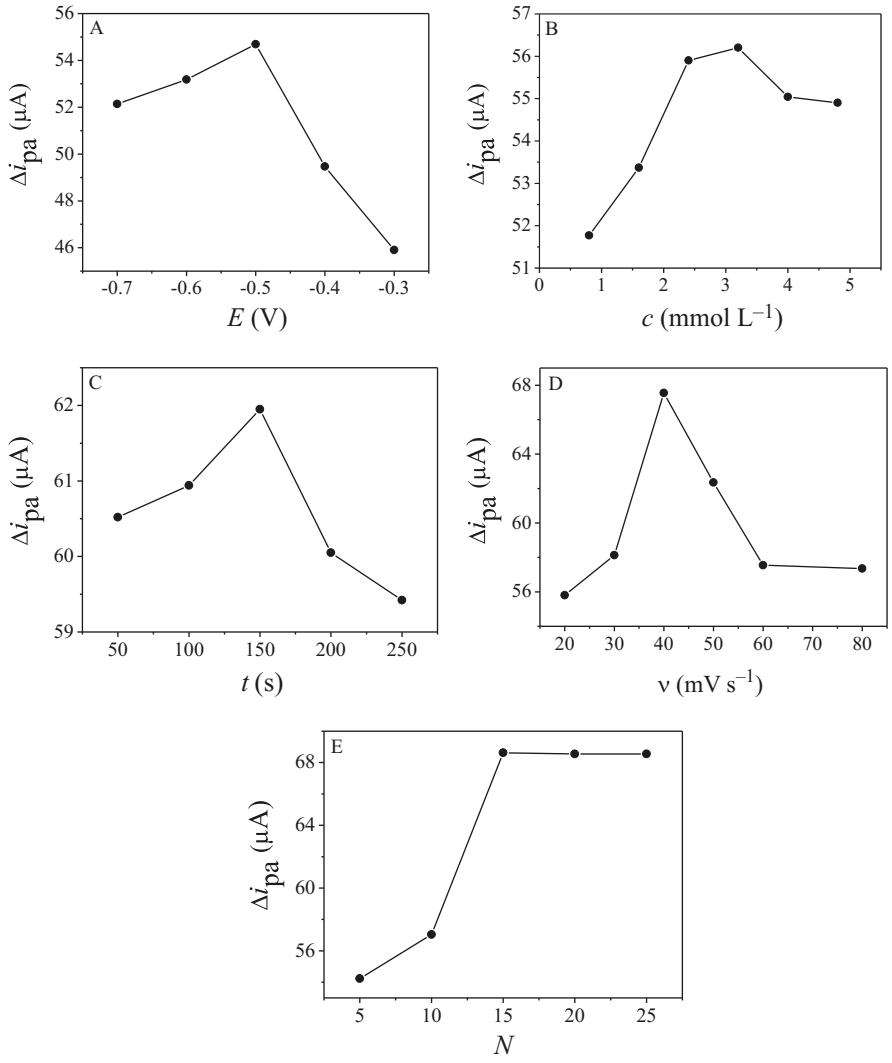


transfer resistance (R_{ct}) at the electrode surface is equivalent to the semicircle diameter. To obtain accurate R_{ct} values, an electrical circuit (inset, Fig. 3) was used to fit the EIS. Figure 3 shows the EIS measured on bare GCE (curve 1), $Cu_{hydroxide/oxide}$/GCE (curve 2), and $Cu_{hydroxide/oxide}$/MWCNTs/GCE (curve 3) in the presence of 10 mmol L^{-1} $[Fe(CN)_6]^{4-/3-}$ at 0.28 V. As shown, the EIS of $Cu_{hydroxide/oxide}$/GCE exhibited a larger semicircle portion (R_{ct} = 230.6 Ω) compared with that of bare GCE (R_{ct} = 145.9 Ω), suggesting that the resistance to the anion redox reaction increased at $Cu_{hydroxide/oxide}$/GCE. However, the semicircle portion (R_{ct} = 169.4 Ω) on $Cu_{hydroxide/oxide}$/MWCNTs/GCE significantly decreased because of the good conductivity of $Cu_{hydroxide/oxide}$/MWCNTs composite, which potentially improves the sensitivity of the sensor. The results from the EIS further proved that copper hydroxide / oxide was effectively deposited on MWCNTs surface.

Optimization of preparing conditions

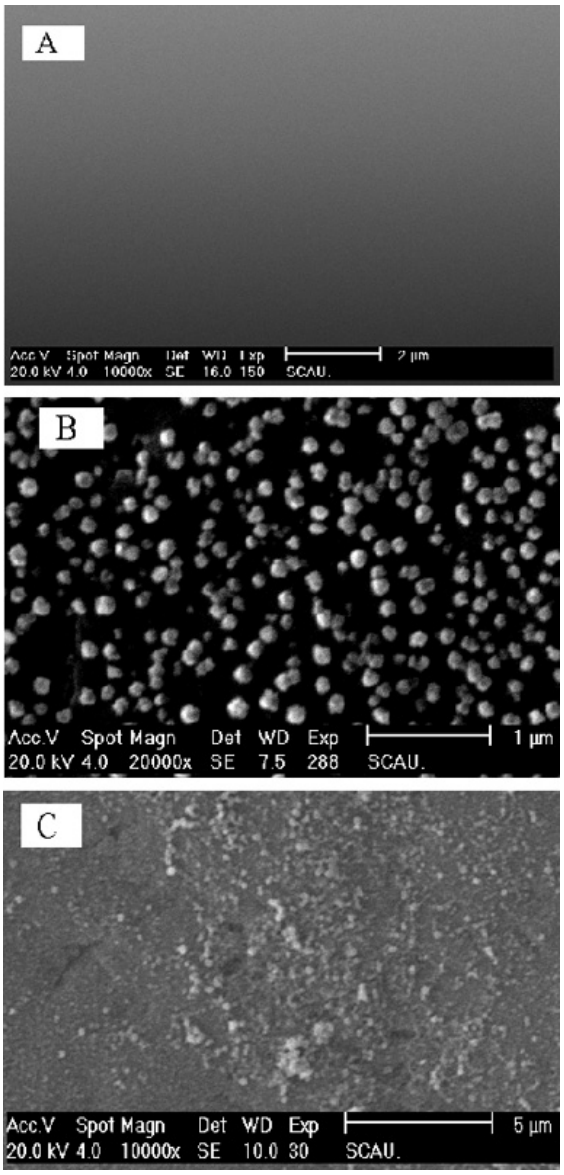
Figure 4 shows the cyclic voltammograms obtained by four different GCEs in phosphate buffer solution (pH 5.29)

Fig. 6. Effects of copper deposition potential (A), Cu^{2+} concentration (B), deposition time (C), scan rate (D), and the number of scanning cycles (E) on the electrocatalytic activity of $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE). Supporting electrolyte: 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl + 2 mmol L^{-1} $NaNO_2$.

containing 2.5 mmol L^{-1} nitrite at 20 mV s^{-1}. The nitrite underwent an irreversible oxidation. The peak potentials were about 0.97 V and the peak currents of nitrite oxidation on bare GCE and $Cu_{hydroxide/oxide}$/GCE were about 7.5 and 22.1 μA, respectively. The increase in peak current indicated that copper hydroxide / oxide had evident electrocatalytic activity toward the oxidation of nitrite. A remarkable shift in peak potential to the negative side (0.78 V) was noticed on MWCNTs/GCE, indicating that MWCNTs have strong electrocatalytic activity for nitrite oxidation. Interestingly, a larger increase in peak current (70.9 μA) was observed after electrodepositing copper hydroxide / oxide onto the MWCNTs/GCE, which can be attributed to the synergic catalytic effect of $Cu_{hydroxide/oxide}$/MWCNTs nanocomposite and the decrease of R_{ct}.

H^+ was proven to be involved in the catalytic reaction process, and the active species should be HNO_2 instead of NO_2^-. Nitrite is oxidized through a 2e process with the final product (NO_3^-) in aqueous solution. The mechanism for nitrite oxidation at solid electrodes is described as follows.[9,23,24]

$$H^+ + NO_2^- = HNO_2$$



$$HNO_2 + H_2O - 2e = NO_3^- + 3H^+$$

The electrocatalytic activity of $Cu_{hydroxide/oxide}$/MWCNTs/GCE was affected by many factors such as the amount of MWCNTs, copper hydroxide / oxide, and electrochemical parameters. Figure 5 depicts the effect of MWCNTs concentration on the oxidation peak potential (E_{pa}) and current response to 2 mmol L^{-1} $NaNO_2$ at $Cu_{hydroxide/oxide}$/MWCNTs/GCE. With increasing MWCNTs concentration, the peak potential shifted to negative values and the peak current gradually increased. When the concentration of MWCNTs was in the range of 0.24–0.28 mg mL^{-1}, the peak potential and current had no significant changes, which might be due to the excellent synergistic effect of copper hydroxide / oxide and MWCNTs and lower R_{ct}. Insufficient or redundant MWCNTs may result in fewer active centers or the formation of clusters. Therefore, 0.24 mg mL^{-1} MWCNTs was chosen for subsequent experiments.

Fig. 7. Scanning electron microscopy (SEM) images of glassy carbon electrode (GCE; A), $Cu_{hydroxide/oxide}$/GCE (B), and $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / GCE (C).

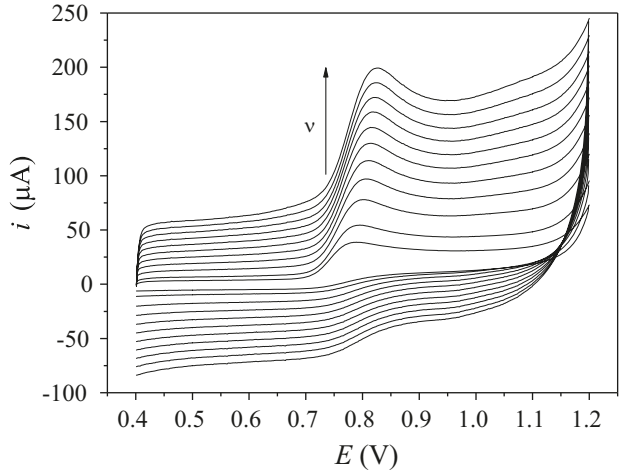
The effect of copper particle deposition potential on the electrocatalytic activity is shown in Fig. 6A. The more negative the deposition potential, the higher the catalytic activity, indicating that the amount of copper hydroxide / oxide particles played a major role. However, the catalytic ability slowly decreased when the deposition potential was lower than –0.5 V, which may be attributed to the increase of resistance of ion transfer for charge balance in the process of film oxidation and reduction. The maximum response current was obtained at –0.5 V. Therefore, –0.5 V was selected as the optimum deposition potential. The Cu^{2+} concentration in the deposition bath had significant effect on the performance of the sensor. As can be seen from Fig. 6B, the peak current rises sharply with the increasing concentration of Cu^{2+} and the maximum response is approached at 3 mmol L^{-1}. Thus, 3 mmol L^{-1} Cu^{2+} was chosen as the optimal concentration for the sensor preparation. Figure 6C depicts the effect of

Fig. 8. Cyclic voltammograms of $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) in different pH solutions containing 1.5 mmol L^{-1} nitrite at 0.1 V s^{-1}.

electrodeposition time of copper particles on the electrocatalytic activity. The current response increases with the electrodeposition time increasing from 50 to 150 s and subsequently decreases, which further proves that the amount of copper hydroxide / oxide particles had a synergistic effect.

The influence of scan rate on the conversion of copper into copper hydroxide / oxide is shown in Fig. 6D. The magnitude of scan rate might influence the size, morphology, and uniform distribution of copper hydroxide / oxide particles on MWCNTs. The maximum response current was obtained at 40 mV s^{-1}. The function of the number of scanning cycles is to ensure the complete conversion of copper into copper hydroxide / oxide. The peak current increases sharply with an increase of the number of scanning cycles and the maximum response is approached after 15 cycles (Fig. 6E).

Characterization of $Cu_{hydroxide/oxide}$/MWCNTs/GCE



The surface morphology of $Cu_{hydroxide/oxide}$/MWCNTs/GCE (Fig. 7C) prepared in the optimized conditions was characterized by scanning electron microscopy (SEM). It can be seen that copper hydroxide/oxide particles were distributed homogeneously on MWCNTs with obvious differences to copper hydroxide/oxide particles directly deposited on GCE (Fig. 7B), which can be attributed to the completely different nucleation and growth process.

To find the optimal pH for nitrite oxidation on $Cu_{hydroxide/oxide}$/MWCNTs/GCE, cyclic voltammograms were recorded in different pH (1.00–9.19) solutions containing 1.5 mmol L^{-1} nitrite at 0.1 V s^{-1} (Fig. 8). The E_{pa} shifted negatively with increasing pH from 1.00 to 5.29 and remained stable at pH 5.29–9.18, indicating that H^+ takes part in the electrochemical reaction. Since a higher peak current was obtained at pH 5.29, pH 5.29 was selected for the subsequent experiments.

Figure 9 shows the cyclic voltammograms of $Cu_{hydroxide/oxide}$/MWCNTs/GCE in pH 5.29 PBS containing 2 mmol L^{-1} nitrite at various scanning rates (5–100 mV s^{-1}). The E_{pa} shifted positively with increasing scan rate, indicating a kinetic control for the oxidation of nitrite at the redox sites of $Cu_{hydroxide/oxide}$/MWCNTs/GCE electrode. The anodic peak current increased linearly with the square root of scan

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

Fig. 9. Cyclic voltammograms of $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) in 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl solution containing 2 mmol L^{-1} nitrite at scanning rates of 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100 mV s^{-1}.

rate (v) in the range of 5–100 mV s^{-1} (i_{pa} = –12.658 + 20.633$v^{1/2}$, R = 0.9954), suggesting that the kinetics of the overall process was controlled by diffusion.

Determination of NO_2^- on $Cu_{hydroxide/oxide}$/MWCNTs/GCE

Linear range and detection limit

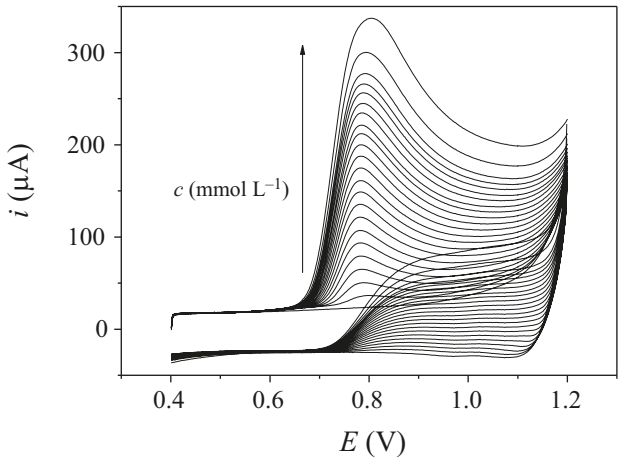
Figure 10 shows the typical cyclic voltammograms obtained at $Cu_{hydroxide/oxide}$/MWCNTs/GCE in 0.07 mol L^{-1} PBS + 0.2 mol L^{-1} KCl solution containing different concentrations of $NaNO_2$. With the addition of $NaNO_2$, the peak current gradually increased and the potential was almost unchanged, suggesting that the sensor's response was very stable. A linear relationship between the peak current and the concentration of $NaNO_2$ was acquired in the range of 0.02–7.0 mmol L^{-1} (Δi_{pa} = 1.481 + 27.155c, R = 0.9993).

A current vs time curve at constant potential is a much more accurate and sensitive means for the determination of current than cyclic voltammetry (CV), which is usually employed to estimate the lower detection limit. Figure 11 shows a typical steady-state amperometric response of $Cu_{hydroxide/oxide}$/MWCNTs/GCE with the successive addition of $NaNO_2$ into the continuously stirred solution of PBS (pH 5.29) and KCl at 0.78 V. The linear regression equation is Δi_a = –0.1504 + 57.954c (R = 0.9990, n = 32) over the range of 1.0 × 10^{-4} to 14.0 mmol L^{-1} with a detection limit of 0.03 μmol L^{-1} (S/N = 3).

Effect of interferants

Selectivity is important in the practical use of sensors. The interference of foreign substances, such as Na_2SO_3, $CuSO_4$, $Mg(NO_3)_2$, and $(NH_4)_2CO_3$, on the determination of nitrite can be examined by adding them in turn into PBS solution (pH 5.29) (Fig. 12). When the tolerance limit was taken as the concentration of diverse species causing less than a 5% relative error, a 200-fold quantity of Na^+, K^+, Ca^{2+}, Mg^{2+}, Al^{3+}, Fe^{3+}, Zn^{2+}, Cu^{2+}, Ni^{2+}, F^-, Cl^-, Br^-, NO_3^-, SO_4^{2-}, CO_3^{2-}, PO_4^{3-}, glucose, fructose, L-glutamic acid, ethanol, and H_2O_2, and a 50-fold quantity of I^-, S^{2-}, SO_3^{2-}, SCN^-, L-tryptophan, and guanine, did not produce interference for 0.3 mmol L^{-1} nitrite. However, a 10 times greater presence of ascorbic acid, uric acid, dopamine, norepinephrine, and L-tyrosine in 0.3 mmol·L^{-1} nitrite interfered with the determination. In this case, differential pulse voltammetry could be used to determine the content of nitrite owing to their difference in peak potential. Therefore, the $Cu_{hydroxide/oxide}$/MWCNTs/GCE possessed high selectivity for nitrite.

Fig. 10. Cyclic voltammograms of $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) in 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl solution containing different concentrations (c) of NO_2^- at 20 mV s^{-1}. c (mmol L^{-1}): 0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 6.5, 7.0, 7.5, 8.0, 8.5, 9.0, 9.5, 10.0, 11.0, and 13.0.



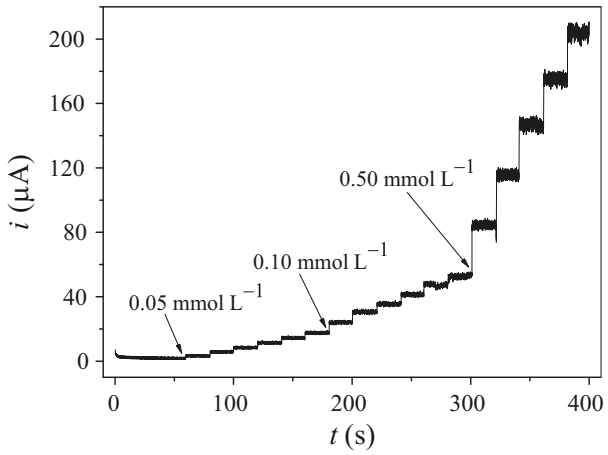


Fig. 11. A current vs time curve for nitrite oxidation on $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) in 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl at 0.78 V.

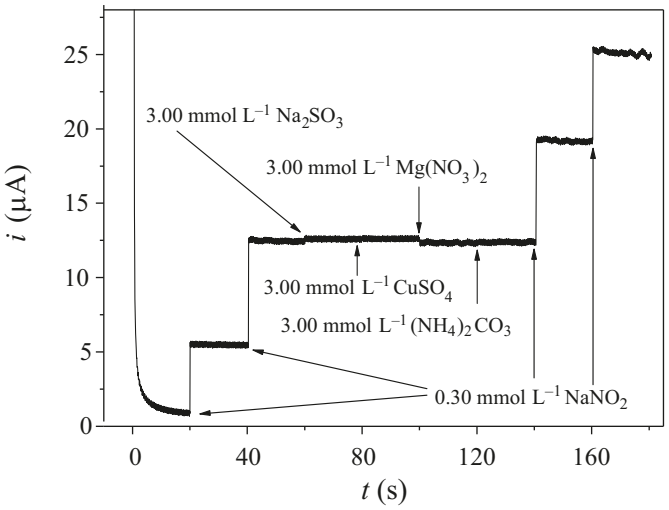

Response time and stability

The $Cu_{hydroxide/oxide}$/MWCNTs/GCE showed very fast response (<0.2 s) to the addition of nitrite at 0.78 V and produced a steady-state signal within 1 s (Fig. 13A). Figure 13B shows the amperometric response to 0.5 mmol L^{-1} $NaNO_2$ during a prolonged 3300 s experiment. The response remained stable throughout the experiment, indicating that the $Cu_{hydroxide/oxide}$/MWCNTs/GCE had high stability.

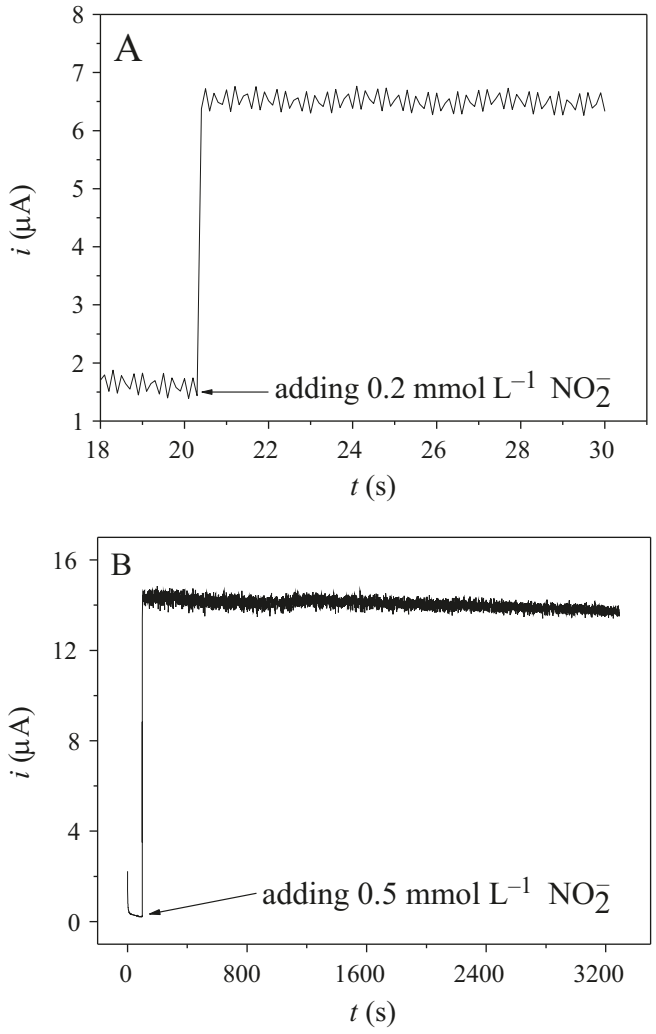
Fig. 12. A current vs time curve recorded on $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) in 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl by adding different species at 0.78 V. Arrows stand for the point of sample addition.



Five different $Cu_{hydroxide/oxide}$/MWCNTs/GCEs were prepared under the same conditions to estimate the fabrication reproducibility. The relative standard deviation (RSD) of amperometric responses to 0.20 mmol L^{-1} $NaNO_2$ was 2.2%, indicating that the reproducibility of electrode fabrication was excellent. The service life of $Cu_{hydroxide/oxide}$/MWCNTs/GCE electrode was evaluated by assaying 0.20 mmol L^{-1} $NaNO_2$ every day for 60 days and the relative change in current response was less than 5%. The storage stability of $Cu_{hydroxide/oxide}$/MWCNTs/GCE electrode was also investigated by placing it in a refrigerator (4 °C) after the first test. Six months later, the current response to 0.20 mmol L^{-1} $NaNO_2$ retained 92% of the initial value. In short, fast response and good stability provided a guarantee for the practical application.

Amperometric determination of $NaNO_2$ in real samples

To verify the performance and feasibility of the proposed method for the analysis of nitrite in pickled vegetables (purchased from local supermarkets), the $Cu_{hydroxide/oxide}$/MWCNTs/GCE was applied to the determination of nitrite in pickled radish, potherb mustard, and cucumber by a current vs time curve method at 0.78 V. The pickled vegetable was chopped and homogenized with a food mill. Two grams of the homogenized sample (weighed accurately to 0.1 mg) was placed in a 10 mL flask and extracted for 30 min by a supersonic method to keep the solid phase completely dispersed. The flask was kept in a water bath (75 °C) for 5 min to further promote the extraction of nitrite and then allowed to cool at ambient temperature. The sample was diluted with deionized water to the scale mark of the volumetric flask and filtered with filter paper. After the filtrate was centrifuged for 15 min at 10 000 rpm, the supernatant was used for electrochemical analysis.

Amperometric determinations were carried out by directly adding the standard sample and supernatant in turn into the electrochemical cell containing 10 mL of 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl. All the data presented are the means of five parallel determinations. Table 1 summarizes

Fig. 13. Response time (A) and stability (B) of $Cu_{hydroxide/oxide}$ / multiwalled carbon nanotubes (MWCNTs) / glassy carbon electrode (GCE) to 0.2 mmol L^{-1} (A) and 0.5 mmol L^{-1} $NaNO_2$ (B) in 0.07 mol L^{-1} PBS (pH 5.29) + 0.2 mol L^{-1} KCl at 0.78 V.

the results of the three samples. As can be seen, the RSD for each sample was less than 3%, and the recoveries ranged from 96.9% to 103.7%, indicating that the $Cu_{hydroxide/oxide}$/MWCNTs/GCE could be efficiently used for the determination of nitrite in food samples. To further estimate the efficiency of this sensor, a standard spectrophotometric method (*Chinese National Food Safety Standard*, GB 5009.33-2010) was adopted for the determination of nitrite in the same batch of samples and these results were consistent with those obtained by this work.

Conclusions

In this paper, we developed a copper hydroxide (oxide) / MWCNTs nanocomposite modified GCE by film plating / CV, which exhibited marked synergistic catalytic effects on the electrooxidation of NO_2^- in PBS (pH 5.29) solution. The concentration of MWCNTs, the thickness of the copper film, and the electrolyte pH had significant effects on electrocatalytic activity of GCE. The nitrite sensor possessed many advantages, such as easy preparation, fast response, long-term

Table 1. Nitrite content in pickled vegetables.

Sample	Initial nitrite content (mg kg^{-1})	Spiked nitrite content (mg kg^{-1})	Measured total nitrite content (mg kg^{-1})	RSD (%, $n = 5$)	Recovery (%)	Nitrite content obtained by the spectrophotometric method (mg kg^{-1})
Pickled radish	5.61	1.10	6.69	2.6	98.2	5.52
Pickled potherb mustard	7.36	5.80	12.98	3.0	96.9	7.41
Pickled cucumber	4.08	4.90	9.16	2.9	103.7	4.19

Note: RSD, relative standard deviation.

stability, high selectivity, wide linear range, and low detection limit. It has been applied to the determination of NO_2^- in pickled vegetables with satisfactory results.

Experimental section

Reagents

MWCNTs (purity, >97%; o.d., <10 nm; length, 5–15 μm) were purchased from Shenzhen Nanotech Port Co., Ltd., Shenzhen, P.R. China. Analytical grade $NaNO_2$, $CuCl_2{\cdot}2H_2O$, KCl, and *N*,*N*-dimethylformamide (DMF) were all purchased from Shanghai Chemical Reagent Company, Shanghai, P.R. China) and used without further purification. Stock solutions were all prepared with doubly distilled water.

Instrumentation

CV, EIS, and the current vs time curve method were carried out on a CHI 660C electrochemical analyzer (Shanghai Chenhua Co., P.R. China). A three-electrode configuration consisted of a modified GCE (3.0 mm diameter) as a working electrode, a reference electrode (Ag/AgCl satd. KCl), and a counterelectrode (Pt wire, 5 mm length, 1 mm diameter). Environmental SEM images (ESEM) were obtained on the GCE electrode with a detachable electrode tip using a XL-30 microscope (Philips Co., Netherlands). The solution pH values were determined on a pHS-3C meter (Precision Instruments Co., Ltd., Shanghai, P.R. China).

Preparation of $Cu_{hydroxide/oxide}$/MWCNTs/GCE and electrochemical measurement

The GCE surface was cleaned by ultrasonic cleaning in dilute nitric acid (1:1, *v*/*v*), ethanol, and deionized water, sucessively. First, a 10 μL suspension of MWCNTs in DMF obtained by ultrasound for 2 h was dripped on the GCE surface and dried at room temperature to obtain a MWCNTs/GCE. Then, copper nanoparticles were electrodeposited on MWCNTs/GCE surface by maintaining –0.5 V in 0.1 mol L^{-1} KCl solution containing $CuCl_2$. Last, the electrode was put in 0.1 mol L^{-1} NaOH solution to convert copper nanoparticles to copper hydroxide (oxide) by scanning repetitively.

The CV, current vs time curve, and EIS of $Cu_{hydroxide/oxide}$/MWCNTs/GCE were carried out in an electrochemical cell holding 10.0 mL different electrolyte solution. EIS measurements were carried out in the 0.01–10^5 Hz frequency range at 0.28 V. During all experiments, the electrolyte was prepurged with high-purity N_2 for 10 min to remove O_2, and a continuous flow of N_2 gas was maintained over the solution. All experiments were performed at room temperature (25 ± 1 °C).

Abstract: The performance of various density functional theories (B3LYP, B3PW91, B3P86, B1LYP, BMK, MPWB1K, PBE0, and MPWB95) was examined for calculating N–NO_2 bond dissociation energies (BDEs) of 10 *N*-nitroacylamide compounds. The CBS-4M method was also used. By comparing the calculated results with the experimental values, it was observed that B1LYP/6–31G** and B3LYP/6–31+G** provided accurate BDEs. Especially, B3LYP/6–31+G** was recommended because of its smaller maximum absolute deviation. Further, substituent effects based on the B3LYP/6–31+G** method were analyzed. The result shows that an electron-donating group increases the BDE of the parent C_6H_5–$CON(CH_3)NO_2$, while an electron-withdrawing group decreases the BDE of the parent C_6H_5–$CON(CH_3)NO_2$. Subsequently, the BDEs of the other *N*-nitroacylamindes were estimated.

Key words: density functional theory, polarized continuum model, *N*-nitroacylamides compounds, bond dissociation energy, substituent effects.

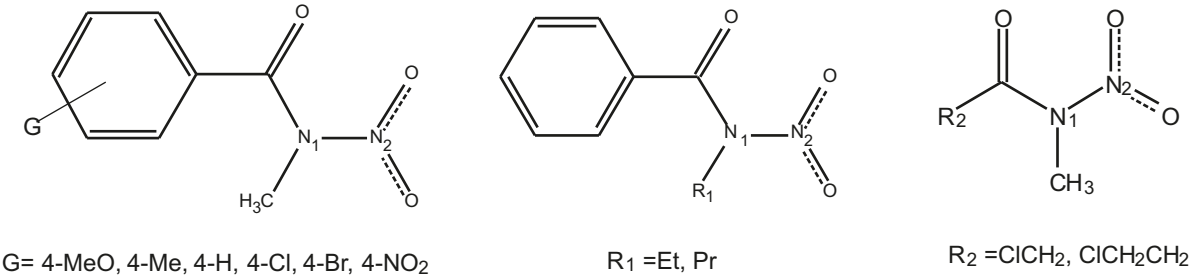
Résumé : On a examiné les performances relatives de diverses variantes de la théorie de la fonctionnelle de la densité (B3LYP, B3PW91, B3P86, B1LYP, BMK, MPWB1K, PBE0 et MPWB95) pour calculer les énergies de dissociation de la liaison (EDL) N–NO_2 de composés de la famille de 10 *N*-nitroacylamides. On a aussi fait appel à la méthode CBS-4M. Une comparaison des résultats des calculs avec les résultats expérimentaux a permis d'observer que les méthodes B1LYP/6–31G** et B3LYP/6–31+G** conduisent aux énergies de dissociation de liaison les plus exactes. On recommande particulièrement la méthode B3LYP/6–31+G** en raison du fait que sa déviation absolue est la plus faible. On a de plus analysé l'effet de substituant par la méthode B3LYP/6–31+G**. Les résultats montrent qu'un groupe électrodonneur augmente l'énergie de dissociation de la liaison du composé fondamental, C_6H_5–$CON(CH_3)NO_2$, alors qu'un groupe électroattracteur la diminue. Finalement, on a aussi évalué les énergies de dissociation de liaison d'autres *N*-nitroacylamides.

Mots-clés : théorie de la fonctionnelle de la densité, modèle du continuum polarisé, composés de la famille des *N*-nitroacylamides, énergie de dissociation de la liaison, effets de substituant.

[Traduit par la Rédaction]

Introduction

Nitric oxide (NO) is a free-radical gas and one of the smallest known biologically active messenger molecules, which plays key roles in regulating a diverse range of physiological processes, including cellular differentiation and apotosis.[1–4] However, the importance of nitrogen dioxide (NO_2) has largely been overshadowed or even overlooked during the same period. Nitrogen dioxide has long been known in chemistry as a strong oxidant and nitrating reagent for organic synthesis, but not until very recently was it found to be associated with many destructive processes in living bodies. A wide spectrum of diseases has been suggested to be related to the exogenously and endogenously generated NO_2.[5,6] Conversely, it is also reported that NO_2^- plays a crucial role in many NO-mediated processes, such as hypoxic vasodilation and cytoprotection from cardiac and liver ischemia–reperfusion injury, and in gene expression.[7] Nitrite is also suggested to be a potential therapeutic in the treatment of various diseases.[8,9]



To understand the mechanistic details of NO_2 or NO_2^- in chemical or biological processes, the basic information concerning quantitative energetic changes in NO_2^- related bond cleavage in solution should be of great value because it provides the necessary information on the thermodynamic driving forces of NO_2^- carrier molecules to release, capture, or

transfer an NO_2 (or NO_2^-) moiety.[6] The binding force of NO_2 with a particular active site can therefore be represented by the bond energy of the Y–NO_2 type, where Y represents the atom in a carrier to which NO_2 is directly attached. Recently, Li et al.[10] reported the first series of experimentally determined N–NO_2 homolytic bond energy scales of some *N*-nitroacylamides compounds by using titration calorimetry in acetonitrile solution. The 10 *N*-nitroacylamide compounds are 4-MeO–$C_6H_4CON(CH_3)NO_2$ ($C_9H_{10}O_4N_2$), 4-CH_3–$C_6H_4CON(CH_3)NO_2$ ($C_9H_{10}O_3N_2$), $C_6H_5CON(CH_3)NO_2$ ($C_8H_8O_3N_2$), 4-Cl–$C_6H_4CON(CH_3)NO_2$ ($C_8H_7O_3N_2Cl$), 4-Br–$C_6H_4CON(CH_3)NO_2$ ($C_8H_7O_3N_2Br$), 4-NO_2–$C_6H_4CON(CH_3)NO_2$ ($C_8H_7O_5N_3$), $C_6H_5CON(C_2H_5)NO_2$ ($C_9H_{10}O_3N_2$), $C_6H_5CON(C_3H_7)NO_2$ ($C_{10}H_{12}O_3N_2$), $ClCH_2CON(CH_3)NO_2$ ($C_3H_5O_3N_2Cl$), and $ClCH_2CH_2CON(CH_3)NO_2$ ($C_4H_7O_3N_2Cl$). The structures of the selected *N*-nitroacylamide compounds are shown in Fig. 1.

Since a rapid cleavage of the Y–NO_2 bond (releasing a nitrite) upon one-electron reduction of a nitro compound has been observed for years,[11–13] this kind of bond energy scale should also be useful for the study of the stability and shock sensitivity of the Y–NO_2-type energetic materials[14,15] and for estimating the nitrating ability of nitro-releasing compounds in synthetic chemistry.[16,17] However, to our knowledge, no systematic work has been reported on the theoretical determinations of N–NO_2 bond energies in any solvent system where the NO_2-related chemical and biological activities are likely to take place.

Density functional theory (DFT) is currently more practical for bond dissociation energy (BDE) calculations because of their favorable scaling and reasonable CPU cost. Among these DFT methods, B3LYP, B3PW91, and B3P86 are highly popular because of their advantages in BDE calculation. Previous research has shown that the C–N BDEs for imidazole derivatives computed by the B3LYP/6–31G** method are in excellent agreement with their experimental values.[18] Furthermore, B3P86 values revealed the best agreement with available experimental data in predicting C–NO BDE.[19] Baciu and Gauld[20] obtained the best reliable BDEs for a range of *S*-nitrosothiols by the B3P86/6–311++G(2df,p) method, which is agreement with values obtained with higher accuracy methods, e.g., CBS-Q. However, recent cstudies from a more general perspective demonstrated that these popular DFT methods could tend to underestimate BDEs by 2–6 kcal/mol (1 cal = 4.184 J).[21] Obviously, the failures are due to deficiencies of the approximate exchange–correlation functionality used for different calculating systems. Therefore, it is important to shed light on their systematic performance for a particular computational target, particularly for the N–NO_2 BDEs of the title compounds.

In the present work, the performance of a variety of DFT functions, including B3LYP, B3PW91, B3P86, B1LYP, BMK, MPWB1K, PBE0 and MPWB95, was examined for the calculation of the N–N BDEs for several *N*-nitroacylamide compounds with the available experimental data. The complete basis set (CBS-4M) method is also used. The focus is on investigating their suitability and identifying low-cost alternative methods. If we can find an accurate calculational method to compute BDEs of the N–NO_2 bond, it would be possible to use this method to predict those molecules whose experimental BDEs are not available.

Computational methodology

All calculations were performed with the Gaussian03 computational package.[22] Geometry optimizations and subsequent normal-mode analyses at the corresponding equilibrium structures were performed for the products of the different bond scission reactions in which a single NO_2 group was removed from the parent structure. The equilibrium geometries and BDEs were obtained using the Becke-style three-parameter DFT[23] with the Lee–Yang–Parr correlation function (LYP),[24,25] the Perdew–Wang 91 expression (PW91),[26] and the Perdew 86 expression (P86).[27]

In addition, we applied two hybrid meta DFT methods called MPWB95 and MPWB1K, which were proposed by Zhao and Truhlar.[28] MPWB95 and MPWB1K have been developed in such a way that the functionals depend on the electron density, density gradient, Hartree–Fock exchange, and the Kohn–Sham orbitals in the form of a kinetic energy density, whereas the functionals of the hybrid DFT depend on the electron density, density gradient, and Hartree–Fock exchange only.[28] The MPWB1K method, which was developed for kinetics calculations, has been shown to be more accurate than the previously introduced MPW1K method.[28]

For the CBS-4M model,[29–31] a geometry optimization and a zero-point-energy computations were carried out in Hartree–Fock theory. Then, the energy was evaluated with the second-order of Møller–Plesset (MP2) theory with a larger basis set and a CBS extrapolation to correct the energy through the second order. The MP4SDQ/6–31G calculation was used to approximate higher orders of contributions. There are also empirical corrections for spin contamination and a size-consistent higher order correction. It must be noted that the new DFT method, the BMK functional, consists of modified original exchange and correlation functionalities. The BMK functionality is rather different from the others as it simulates a variable exact exchange by combining

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

exact exchange (42%) and terms depending on the kinetic energy density. This allows it to be developed for various applications, ranging from accurate heat of formation prediction to calculation of rate coefficients.[32]

In the PBE0 functional, there is only one coefficient, which is theoretically adjusted to 0.25, reflecting the mix of Hartree–Fock or exact exchange and the DFT exchange, which is represented by the PBE density functional.[33] The correlation part is also represented by the PBE correlation functional with the coefficient equal to one.

The polarized continuum model (PCM) developed by Tomasi and co-workers[34–36] was employed. In this PCM model, the atomic radii of the spheres used to build the molecular cavity were adjusted by introducing chemical consideration such as hybridization, formal charge, and first-neighbor inductive effect. The effect of the escaped electronic charge outside the cavity was corrected with an additional set of charges on the cavity surface distributed according to the solute electronic density in each point of the surface.

All calculations were performed at the 6–31G** basis set except the CBS-4M method. The normal mode analysis for each structure resulted in no imaginary frequencies for the $3N - 6$ vibrational degrees of freedom, where N is the number of atoms in the system. This indicates that the structure of each molecule corresponds to a local minimum on the potential energy surface.

Generally, computed BDEs are reported for gas-phase conditions and it is expected that these values suffer variation in different environments such as those in living organisms. So, it would be interesting to know what happens to these dissociation energies in the presence of a solvent such as acetonitrile.

The $N–NO_2$ bond strength is obtained by calculating the homolytic bond dissociation energy, which is defined as the enthalpy change of the dissociation reaction.

$$[1] \qquad R - X \rightarrow R^{\bullet} + X^{\bullet}$$

For the *N*-nitroacylamide compounds studied here, the BDE is defined as the difference between the zero-point-corrected energy (E) of the parent molecule and that of the products of the unimolecular dissociation in which an NO_2 group is removed. For example, for 4-CH_3–$C_6H_4CON(CH_3)NO_2$, the BDE is

$$[2] \qquad BDE_{N-NO_2} = E(C_9H_{10}ON) + E(NO_2) - E(C_9H_{10}O_3N_2)$$

The average error is determined by calculating the average absolute error (ε_{aae}), defined as

$$[3] \qquad \varepsilon_{aae} = \frac{1}{N}\sum_{i=1}^{N} |x_i - c_i|$$

where x_i represents the experimental data, c_i denotes the calculated values, and N is the number of experimental or calculated data.

Results and discussion

The N–N bond length

First, we examine the $N_1–N_2$ bond lengths of the 10 *N*-nitroacylamide compounds by various computational methods. For the $N_1–N_2$ bond distances of the 10 title compounds, the experimental equilibrium bond distances are not available. To have a comparison, we listed the N–N experimental bond distance[37] for NH_2NO_2.

It is noted from Table 1 that the $N_1–N_2$ bond lengths computed by the B3LYP functional are the largest among those calculated by various computational methods and the $N_1–N_2$ bond lengths calculated by the MPWB1K/6–31G** method are the smallest. The $N_1–N_2$ bond lengths computed by the CBS-4M method are slightly larger than those computed by the MPWB1K/6–31G** method. Compared with the corresponding experimental value, the B3LYP/6–31G** method produces the best result for NH_2NO_2 with an N–N bond length of 1.394 Å, only a 0.033 Å deviation from the experimental value. The CBS-4M method gives the worst result for NH_2NO_2 with an N–N bond length of 1.354 Å, because the method is based upon geometries optimized at the HF/3–21G* level of theory.

In addition, we computed the $N_1–N_2$ bond lengths of the selected compounds by using the B3LYP/6–31+G** method. Through a comparison of the computational results, it is noted that using diffuse function does not improve the result. The deviation from experimental value increases in the presence of diffuse function.

Performance of various computational methods for the $N–NO_2$ BDEs of *N*-nitroacylamides in acetonitrile

The BDE results computed by using the B3LYP, B1LYP, B3P86, and B3PW91 hybrid DFT methods with the 6–31G** basis set are presented in Table 2. The available experimental values[10] are also included. The BDEs of the 10 *N*-nitroacylamide compounds are compared with the corresponding experimental results for the system. Figure 2 gives the overall maximum and mean absolute deviations of the various methods.

It is noted from Table 2 and Fig. 2 that the B3PW91 and B3P86 methods failed to provide an accurate description of the N–O BDEs for the *N*-nitroacylamide compounds. The two methods deviated from the experimental data by as much as 13.9 kcal/mol, and the mean absolute deviations were 5.9 and 9.2 kcal/mol for the B3PW91 and B3P86 methods, respectively. Compared with the B3PW91 and B3P86 methods, the mean absolute deviation of the B3LYP method is 3.7 kcal/mol and the maximum deviation is 8.1 kcal/mol, which indicates that the B3LYP method is a better method for predicting the $N–NO_2$ BDEs among the three DFT methods. Table 2 also demonstrates that the B1LYP method gives the best BDEs for the $N–NO_2$ bonds of the title compounds. The maximum absolute and the mean absolute deviations are 5.68 and 1.2 kcal/mol, respectively.

In addition, detailed analysis reveals that the BDEs calculated by the B3LYP, B3P86 and B3PW91 methods were overestimated, which disagrees with previous research asserting that DFT methods usually underestimate BDE systematically. For example, the largest deviation (13.9 kcal/mol) between the BDEs and the experiment for the B3P86 method occurs for $ClCH_2CON(CH_3)NO_2$ ($C_3H_5O_3N_2Cl$). The maximum deviation between the B3PW91 computational results and the experimental values was 10.1 kcal/mol for $ClCH_2CON(CH_3)NO_2$ ($C_3H_5O_3N_2Cl$). The B1LYP method

[a]Values in parentheses are the deviations of the computed BDEs from the experimental ones.
[b]The data are from ref. 6.

gave both negative and positive deviations. Comparing the calculation results of the B1LYP and B3LYP methods, we can see that the B3LYP method did not give the better results, which means that not all of the complicated methods can obtain accurate results. For the different systems, it is important to found a suitable method to obtain the BDEs.

To determine whether the B3LYP method is sensitive to the basis set, we computed the BDEs of the *N*-nitroacylamides with the B3LYP method at the 6–31+G** basis set. In addition, to give an extensive comparison, the CBS-4M method and the BMK, MPWB95, MPWB1K, and PBE0 methods with the 6–31G** basis set were also employed to predict the BDEs for the 10 compounds. All calculated results are presented in Table 3.

As demonstrated in Table 3, the BMK, MPWB95, MPWB1K, PBE0 and CBS-4M methods all failed to provide accurate N–NO_2 BDEs. The mean absolute deviations of these methods versus the experiment are as follows: 9.3, 4.7, 5.0, 6.5, and 11.6 kcal/mol, respectively. Of the DFT methods, the B3LYP/6–31+G** method provides the best performance with the least mean absolute deviation. This shows that the use of diffuse functions can greatly improve the results. The deviations from experimental values drastically decrease in the presence of diffuse functions. As shown in Fig. 2, the maximum absolute deviations of B3P86 and BMK, B3PW91 and MPWB1K, and B3LYP and MPWB95 are almost at the same height, whereas the mean absolute deviation of MPWB95 is as large as that of MPWB1K. For PBE0, the maximum absolute deviation and mean absolute deviation are 11.0 and 6.5 kcal/mol, respectively. This shows that the PBE0 method is not the ideal method for the prediction of the N–NO_2 BDEs of *N*-nitroacylamide compounds.

From Fig. 2, it is clear that the B3LYP/6–31+G** and B1LYP/6–31G** methods are the ideal methods for estimating the N–NO_2 BDEs of the title compounds.

In summary, these DFT methods and the CBS-4M method exhibited different performances for calculating the N–NO_2 BDEs of the title compounds. The B3LYP/6–31+G** and B1LYP/6–31G** methods provided accurate values, and the B3LYP/6–31+G** method was found to be the best method because of the smaller maximum absolute deviation. Here, we must acknowledge that there are insufficient experimental data in the present work, specifically, the performance attributes for the particular computational targets.

From Tables 1 and 3, through analysis of the N_1–N_2 bond lengths and its BDEs calculated by the B3LYP/6–31+G** method, we found that the N_1–N_2 BDE is in a good linear relationship with the N_1–N_2 bond length and the correlated coefficient is 0.96. Figure 3 plots the correlation between the N_1–N_2 BDEs and bond lengths.

Substituent effects on the BDE of the N–NO_2 bond

In a comparison of the various computational methods from the analysis in the previous section, we know that the B3LYP method at the 6–31+G** basis set is the best procedure for the computation of the dissociation energies for the N–NO_2 bond in acetonitrile. Using this method, we studied the substituent effect on the N–NO_2 BDEs for the studied molecules, where substituted groups include both the electron-donating and -withdrawing groups such as 4-Cl, 4-Br, 4-NO_2, 4-CH_3, and 4-CH_3O. The calculated BDEs for the

Fig. 3. Dependence of N_1–N_2 bond dissociation energy (BDE) on bond length for some *N*-nitroacylamides in acetonitrile solution.

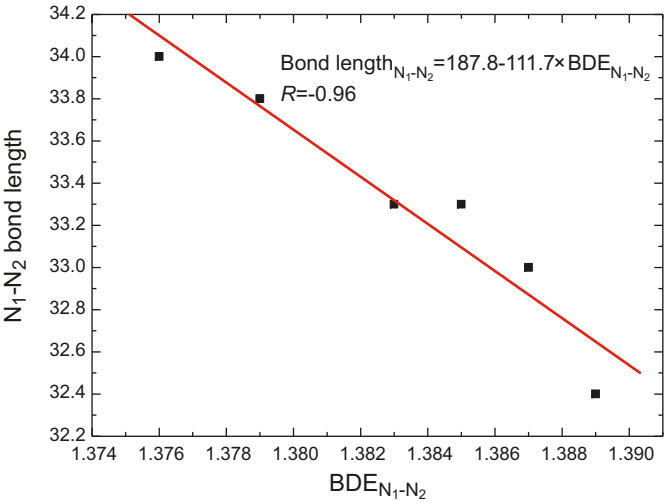

Table 4. Substituent effects on the bond dissociation energies (BDEs) of N–NO_2 homolysis (kcal/mol; 1 cal = 4.184 J) by using the B3LYP/6–31+G** method for Y–C_6H_4–CON(CH_3)NO_2, C_6H_5–CON(Y)NO_2, and Y–CON(CH_3)NO_2 in acetonitrile, where Y is 4-OCH_3, 4-CH_3, 4-H, 4-Cl, 4-Br, 4-NO_2, Et, Pr, $ClCH_2$, $ClCH_2CH_2$.

Y	BDE (kcal/mol)	ΔBDE (kcal/mol)
Y–C_6H_4–CON(CH_3)NO_2		
4-OCH_3	34.0	0.7
4-CH_3	33.8	0.5
4-H	33.3	0
4-Cl	33.3	0
4-Br	33.0	–0.3
4-NO_2	32.4	–0.9
C_6H_5–CON(Y)NO_2		
Et	32.4	0
Pr	32.0	–0.4
Y–CON(CH_3)NO_2		
$ClCH_2$	36.4	0
$ClCH_2CH_2$	36.2	–0.4

selected compounds are shown in Table 4. The results show that the substituent effects on the BDEs of the selected compounds are significant.

An interesting point observed in the selected molecules is the change of the BDEs and ΔBDE with the Hammett constant (σ_p) values of the substituent on the benzene. The Hammett constants[38] of the OCH_3, CH_3, H, Cl, Br, and NO_2 groups are –0.27, –0.17, 0.00, 0.23, 0.23, and 0.78, respectively. It is noted that BDE and ΔBDE decrease with the augment of the σ_p values for the 4-position substituted Y–C_6H_4–CON(CH_3)NO_2. Figure 4 plots the correlation between the N–NO_2 BDE of the 4-position substituted YC_6H_4–CON(CH_3)NO_2 and the Hammett constants. That is to say that an electron-donating group, such as 4-CH_3O, increases the BDE of the parent C_6H_5–CON(CH_3)NO_2, whereas an electron-withdrawing group, such as 4-NO_2, decreases the BDE of the parent C_6H_5–CON(CH_3)NO_2, because these groups always destabilize a radical.

Fig. 4. The correlation between the N–NO_2 bond dissociation energy (BDE) of the 4-position substituted Y–C_6H_4–CON(CH_3)NO_2 and the Hammett constant.

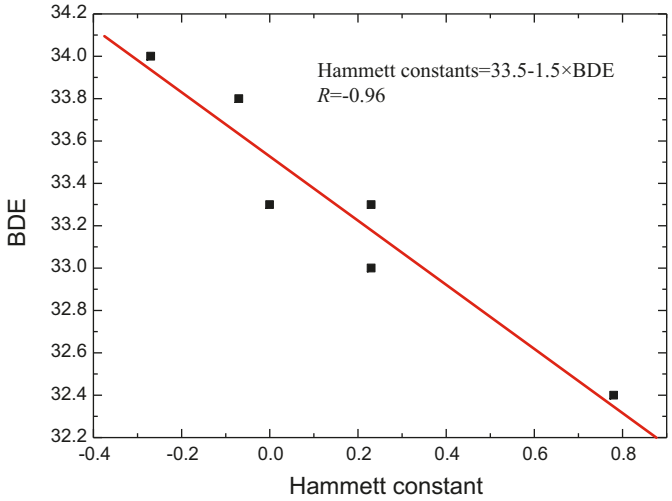

Table 5. Computed bond dissociation energies (BDEs, kcal/mol; 1 cal = 4.184 J) in MeCN for the removal of an NO_2 group in the other *N*-nitroacylamides by using B3LYP/6–31+G** methods.

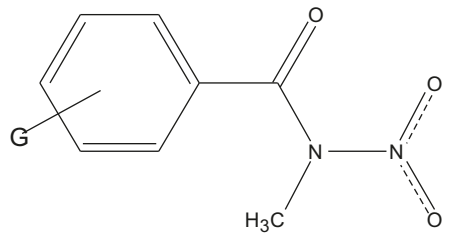

Compound	BDE (kcal/mol)
3-OMe–C_6H_4CON(CH_3)NO_2	34.7
3-CH_3–C_6H_4CON(CH_3)NO_2	32.8
3-Cl–C_6H_4CON(CH_3)NO_2	32.0
3-Br–C_6H_4CON(CH_3)NO_2	29.6
3-NO_2–C_6H_4CON(CH_3)NO_2	31.3
2-OMe–C_6H_4CON(CH_3)NO_2	33.0
2-Me–C_6H_4CON(CH_3)NO_2	33.0
2-Cl–C_6H_4CON(CH_3)NO_2	34.0
2-Br–C_6H_4CON(CH_3)NO_2	35.4
2-NO_2–C_6H_4CON(CH_3)NO_2	33.1

The polarization effects of the Et and Pr groups on the nitrogen atom are –0.49 and –0.54, respectively. Obviously, the BDE increases with the augment of the polarization effect. Similar analysis can be made on the Y–CON(CH_3)NO_2 compound, where Y is $ClCH_2CH_2$ or $ClCH_2$.

The prediction of the N–NO_2 BDEs of the other *N*-nitroacylamides in acetonitrile

In view of the importance of the study on the bond energies of the N–NO_2 type of compounds, this study aims not only to identify a suitable DFT method for *N*-nitroacylamides but also to estimate the BDEs of the other *N*-nitroacylamides through the chosen method, for which there are no experimental BDEs. The geometric molecular structures of the other *N*-nitroacylamides are optimized at the B3LYP/6–31+G** method. Their molecular structures are listed in Fig. 5. The N–NO_2 BDEs calculated by the B3LYP/6–31+G** method are listed in Table 5. It is noted that the BDE decreases with the augment of the σ_p value for the 3-position substituent groups, whereas the BDE changes slightly with the augment of the σ_p value for the 2-position substituent groups. In addition, comparing the calculated N–NO_2 BDEs of the 4-position substituted Y–C_6H_4–CON(CH_3)NO_2 compounds

Fig. 5. The structures of the other *N*-nitroacylamide compounds.

G= 3-Me, 3-OMe, 3-CH_2CH_3, 3-Cl, 3-Br, 3-NO_2
2-CH_2CH_3, 2-Me, 2-OMe, 2-Cl, 2-Br, 2-NO_2

listed in Table 3 with the calculated N–NO_2 BDEs in Table 5, we note that the position of the substituted groups has little effect on the BDEs.

Conclusion

In this paper, a systematic test was performed to study the performance of various DFT methods and the CBS-4M method for the N–NO_2 BDE calculation of *N*-nitroacylamide compounds. It was observed that the B1LYP/6–31G** and B3LYP/6–31+G** methods predicted accurate values and significantly outperformed CBS-4M and other popular DFT methods, including B3LYP, B3PW91, B3P86, BMK, MPWB1K, PBE0, and MPWB95 with the 6–31G** basis set. Because of the smaller maximum absolute deviation, we think that the B3LYP/6–31+G** method yields the most accurate BDEs compared with the experimental data; the mean absolute and maximum absolute deviations are 1.2 and 4.5 kcal/mol, respectively. The substituent effect shows that an electron-donating group increases the BDE of the parent C_6H_5–$CON(CH_3)NO_2$, whereas an electron-withdrawing group decreases the BDE of the parent C_6H_5–$CON(CH_3)NO_2$. Using the B3LYP/6–31+G** method, we estimated the BDEs of the other *N*-nitroacylamindes.

Abstract: The chemiluminescent reactions of bis(2,4,6-trichlorophenyl)oxalate (TCPO) and bis(2-nitrophenyl)oxalate (2-NPO) with hydrogen peroxide in acetonitrile/water micellar systems (anionic, cationic, and non-ionic) and γ-cyclodextrin were studied in the presence of fluoranthene or 9,10-diphenylanthracene, imidazole, and two buffer solutions, $HTRIS^+$/TRIS and $H_2PO_4^-/HPO_4^{2-}$. The relative chemiluminenscence (CL) intensity is higher in the presence of the cationic (DDAB, CTAC, DODAC, and OTAC), anionic (SDS), and non-ionic (Tween 80) surfactants. In the presence of some non-ionic surfactants (Brij 35, Brij 76, and Tween 20), the CL intensity was partially quenched compared with the reaction with no surfactant. The sensitivity for hydrogen peroxide determination in the range 0.01×10^{-4} to 1.0×10^{-4} mol L^{-1}, considering the slope of the calibration curves (maximum peak height of CL vs. concentration), improved with the introduction of DDAH, CTAB, and SDS in $HTRIS^+$/TRIS buffer.

Key words: TCPO, 2-NPO, surfactant, chemiluminescence, hydrogen peroxide.

Résumé : On a étudié les réactions chimiluminescentes de l'oxalate de bis(2,4,6-trichlorophényle) (OTCP) et de l'oxalate de bis(2-nitrophényle) (O-2NP) avec le peroxyde d'hydrogène dans des systèmes micellaires d'acétonitrile/eau (anionique, cationique et non-ionique) et de γ-cyclodextrine, en présence de fluoranthène et de 9,10-diphényanthracène, d'imidazole et de deux solutions tampons, $HTRIS^+$/TRIS et $H_2PO_4^-/HPO_4^{2-}$. L'intensité relative de la chimiluminescence (CL) est plus élevée en présence des agents de surface cationiques (DDAB, CTAC, DODAC et OTAC), anionique (SDS) et non-ionique (Tween 80). En présence de quelques agents de surface non-ioniques (Brij 35, Brij 76 et Tween 20), l'intensité de CL est partiellement piégée par rapport à la réaction sans agent de surface. Si on se base sur la pente des courbes de calibration (hauteur maximale du pic de la CL vs. concentration), la sensibilité de la détermination du peroxyde d'hydrogène dans la plage de concentration allant de $0{,}1 \times 10^{-4}$ à $1{,}0 \times 10^{-4}$ mol L^{-1} augmente avec l'introduction de DDAH, de CTAB et de SDS dans le tampon $HTRIS^+$/TRIS.

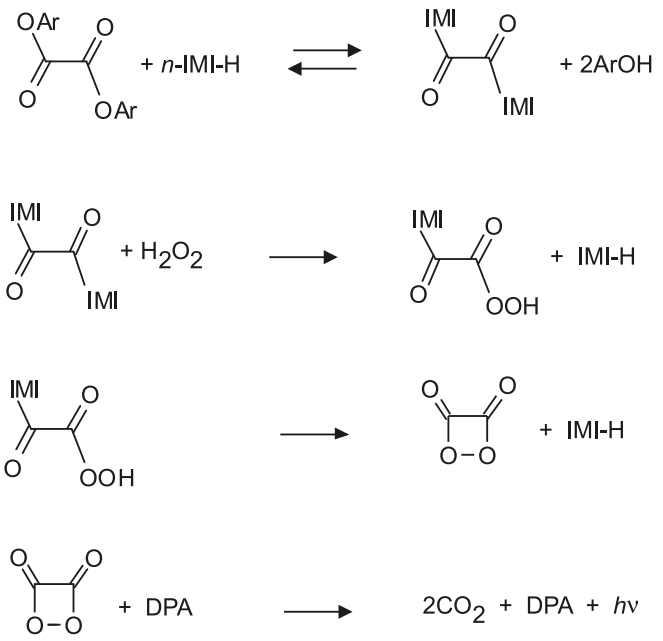
Mots-clés : oxalate de bis(2,4,6-trichlorophényle) (OTCP), oxalate de bis(2-nitrophényle) (O-2NP), agent de surface, chimiluminescence, peroxyde d'hydrogène.

[Traduit par la Rédaction]

Introduction

The chemiluminescent reactions of bis(2,4,6-trichlorophenyl)oxalate (TCPO) and bis(2,4-dinitrophenyl)oxalate (DNPO) in the presence of hydrogen peroxide have been widely used for the detection of fluorescent compounds (fluorophores) at fmol levels. Most of the analytical applications of these systems refer to indirect methods for the determination of species, which generates hydrogen peroxide in a parallel reaction (for instance enzymes) or derivatization reaction using fluorophores as a label.[1–22]

Applications of the peroxyoxalate system, as a post-column reagent in chemiluminescence (CL) detection, in liquid chromatography,[23] and electrophoresis,[24] for clinical, pharmaceutical, environmental, and food analyses, combines the selectivity of the separation methods with the sensitivity of this detection technique.



A critical review of the influence of Cr^{III}, Zn^{II}, and Pb^{II} on the chemiluminescent reactions of TCPO and bis(2-nitrophenyl)oxalate (2-NPO) with hydrogen peroxide in the presence of 3-aminofluoranthene, as fluorophore, and imidazole

Scheme 1. Simplified mechanism for the chemiluminescent reaction of bis(2,4,6-trichlorophenyl)oxalate (TCPO) with hydrogen peroxide, catalyzed by imidazole, in ethyl acetate anhydrous medium.[31] Ar = (2,4,6-trichlorophenyl) for TCPO and (2-nitrophenyl) for NPO.

(IMI), as catalyst, showed that the metal ions had no influence when the experiments were carried out in buffer solutions such as tris(hydroxymetyl)aminomethane ($HTRIS^+$/TRIS, pH 6.9–8.0) or $H_2PO_4^-/HPO_4^{2-}$ (pH 7.0–8.0).[25,26]

According to Motoyoshiya and Maruyama,[27] zinc and copper ions markedly enhanced the CL efficiencies in the presence of the chelator *N*-phenyl-*N*′,*N*′-bis(2-pyridinylmethyl)-1,2-ethanediamine, owing to the interaction of this ligand with the metal ion and the fluorophore.

A detailed study of several parameters such as acidity, water and acetonitrile (ACN) contents, and concentrations of TCPO, 2-NPO, IMI, hydrogen peroxide, and metal ions was reported by our group.[25,26] Among these factors, the catalytic effect of IMI depends very much on the unprotonated imidazole concentration and the acidity. The complex formation of these metal ions with IMI may change the acidity by disturbing the acid–base equilibrium of $HIMI^+$/IMI. As the CL efficiency sharply decreases at pH higher than 7.5, small variations of the acidity conditions can lead to several errors in the interpretation of the data. Some alternative methods described in the literature using flowing streams, such as continuous flow, flow injection[28–30] analysis, and liquid chromatography, require an appropriated optimization of the experimental parameters.

Some authors have intensively studied the possible mechanisms and intermediates for the chemiluminescent reaction of peroxyoxalate (PO-CL) catalyzed by IMI. The main reactions of the mechanism for the system TCPO, hydrogen peroxide, IMI, and 9,10-diphenylanthracene (DPA), in anhydrous ethyl acetate medium, involved the formation of an IMI-substituted peracid and an energy-rich intermediate (1,2-dioxetane-3,4-dione), which excited the fluorophore DPA, leading to light emission and CO_2 formation (Scheme 1).[31–34]

The main disadvantage of these systems is the insolubility of these compounds in water and their instability towards hydrolysis, which requires the use of organic solvents. The application of micelles has been studied to solve these problems, to use these systems for analytical purposes, decreasing the amount of organic solvents, or even avoiding IMI.

The results of the proposed CL systems in micellar media showed that enhancement on the CL intensity could arise by the solubilization of the reagents, the electrostatic effect of the ionic surfactant, and the alteration of the pH and the microenviroment of the CL reaction.[35,36]

There are some studies on analytical applications for the determination of fluorophores, proteins, and hydrogen peroxide in aqueous samples using the PO-CL reaction with the introduction of the micelles.[28–30,37–44]

Sodium dodecyl sulfate (SDS) micellar medium was used as a carrier to avoid the rapid degradation of TCPO in water in a flow-injection analysis,[28–30,41] allowing the use of TCPO in the absence of organic solvent.

Some groups have reported on the effect of micellar medium.[40,42,45] Steijger et al.[42] compared the stability of TCPO in ACN micellar systems and ACN/water phosphate buffer solution (80–20, *v*/*v*) with perylene as fluorophore. They investigated the effect of several types of surfactants, such as the anionic SDS and the cationic hexadecyltrimethylammonium bromide (CTAB). All analyzed micelles had a total or partial quencher effect compared with ACN buffer (no surfactant). The TCPO/H_2O_2 chemiluminescent reaction did not occur in CTAB, which may be the result of the quenching of CL intensity by the bromide ion of CTAB, and the intensity in SDS anionic micelles was appreciably less than that in neutral micellar solutions.

Based on the enhancement of PO-CL CL intensity by some surfactants in H_2O_2/TCPO/rhodamine, Wada et al.[43] proposed a method to detect commercially available detergent. The enhancement may occur by a notable change of pH by adding surfactants, such as a buffer solution was used. The effect of the buffer cations can be important because of the interaction of the polar surface of micelles and the cations, which can provide an electrostatic attraction for the hydrogen peroxide anions that penetrate into non-ionic micelles.[40] Several surfactants might play a catalytic effect, and the fluorescent impurities of some surfactants may contribute to this enhancement.[43]

Liang et al.[35] studied the synergetic effect of SDS, CTAB, and gold nanoparticles on the system H_2O_2 / TCPO / sodium citrate / Au nanoparticles. The CL intensity enhanced sharply with 5×10^{-3} mol L^{-1} CTAB and became reasonably constant when the concentration of 2.5×10^{-2} mol L^{-1} CTAB was used. However, a too high concentration of surfactant depressed the CL. According to the authors,[35] the CL of TCPO is enhanced by the cationic surfactant CTAB because the solubilities of TCPO and its excited intermediate in an aqueous micellar system are greater than that in pure ACN. The electrostatic effect of the ionic surfactant helps to concentrate the counterion, and the citrate anion was adsorbed onto the surface of the gold nanoparticles, which resulted in the stability of the Au colloid. In the presence of CTAB, Au nanoparticles are linked to CTAB by electrostatic attraction. The cage structure of the micelle is helpful for stabilizing the excited state and preventing it from quenching.

The present work reports the effect of different types of micelles (anionic, cationic, and non-ionic) and γ-cyclodextrin

(γ-CD; as further discussed) on the reaction of TCPO or 2-NPO with hydrogen peroxide in the presence of fluoranthene (FA) or DPA, as fluorophores, and two buffer solutions $HTRIS^+$/TRIS and $H_2PO_4^-/HPO_4^{2-}$. We carried out the experiments in three different media, with 25%, 37%, and 62% (*v*/*v*) ACN, since the stock solutions of TCPO, DPA, and IMI must be prepared in ACN. The CL intensity–time (*t*) profile was examined by varying the water content, acidity, IMI, hydrogen peroxide concentration, and fluorophore. Our results are reported in terms of the maximum peak height (I_{max}, relative light unit/second) and the area (*A*) under the curve of relative CL intensity (relative light unit) vs *t*. The total *t* refers to the time for the complete CL signal decay.

Experimental

Apparatus, reagents, and chemicals

All reagents were used as received without purification. Aqueous solutions were prepared with deionized water from the Milli-Q system (Millipore).

The buffers used were $HTRIS^+$/TRIS (0.12 mol L^{-1} tris(hydroxymethyl)aminomethane, pH 6.8, 8.3, and 8.7; (Kanto Chemical Co.) and $H_2PO_4^-/HPO_4^{2-}$ (0.10 mol L^{-1}, pH 6.6, 7.6, and 8.4; Kanto Chemical Co.). The pH of the buffers was adjusted with sodium hydroxide or nitric acid. The pH measurements were done with a pH meter (Metrohm, model 713) with a glass electrode (filled with saturated NaCl).

2-NPO was prepared according to the procedure in ref. 46.

Solutions of 4.5×10^{-4} mol L^{-1} TCPO (TCI Tokyo Kasei), 4.5×10^{-4} mol L^{-1} 2-NPO, 1.0×10^{-3} mol L^{-1} DPA (TCI Tokyo Kasei), 6.0×10^{-3} and 1.2×10^{-2} mol L^{-1} IMI (Sigma-Aldrich), and 1.0×10^{-3} mol L^{-1} FA (Nakalai Chemicals Ltd.) were prepared in ACN (Mallinckrodt) every day.

Diluted hydrogen peroxide solutions were prepared every day in water from hydrogen peroxide stock solution (30%, *m*/*m*, Merck). The stock solution of 0.100 mol L^{-1} hydrogen peroxide was standardized by titration with $KMnO_4$ standard solution in acid medium.

The surfactant (from Sigma-Aldrich, Kanto Chemical Co., and Merck) solutions were prepared in water or buffer solution (as indicated in the text): Brij 35 (polyoxyethylene(23) lauryl ether; critical micelle concentration (cmc) = 1×10^{-4} mol L^{-1}), Brij 76 (polyoxyethylene(10) stearyl ether; cmc = 3×10^{-3} mol L^{-1}), Tween 20 (polyoxyethylene (20) sorbitan monolaurate; cmc = 5×10^{-5} mol L^{-1}), Tween 80 (polyoxyethylene(20) sorbitan monooleate; cmc = 1.2×10^{-5} mol L^{-1}), TDTAB (tetradecyltrimethylammonium bromide; cmc = 3.5×10^{-3} mol L^{-1}), DDAB (dododecyldimethylammonium bromide; cmc = 1.8×10^{-4} mol L^{-1}), CTAC (cetyltrimethylammonium chloride; cmc = 1.3×10^{-3} mol L^{-1}), DODAC (dioctadecyldimethylammonium chloride) and OTAC (octadecyltrimethylammonium chloride; cmc = 3.4×10^{-4} mol L^{-1}), CTAB (cmc = 9×10^{-4} mol L^{-1}, SDS (cmc = 8.1×10^{-3} mol L^{-1}), DDAH, (3-(dimethyldodecylammonio)-propane-1-sulfonate; cmc = 1.2×10^{-3} mol L^{-1}).[47]

γ-CD (cyclooctaamylose, 0.01 mol L^{-1}; Sigma-Aldrich) solution was prepared in buffer medium.

Sample preparation

The experiments were done in the presence of two fluorophores, FA and DPA.

Table 1. Effect of some cationic surfactants on maximum emission intensity (I_{max}) in the reactions of bis(2-nitrophenyl)oxalate (2-NPO) or bis(2,4,6-trichlorophenyl)oxalate (TCPO) with H_2O_2.

	Oxalate

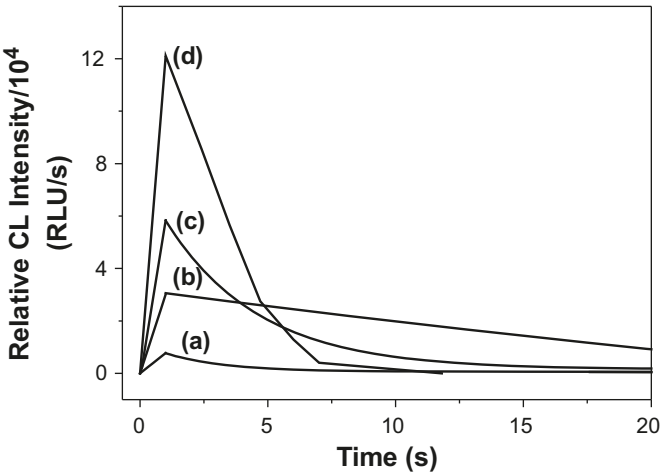
DDAB	10	45	0.19	45
CTAC	14	60	0.72	45
DODAC	18	60	1.8	60
OTAC	21	60	1.2	45

Note: [2-NPO] = 5.6×10^{-5} mol L^{-1}, [TCPO] = 5.6×10^{-5} mol L^{-1}, [H_2O_2] = 1.6×10^{-3} mol L^{-1}, [FA] = 1.2×10^{-4} mol L^{-1}, % ACN = 25, [surfactant] = 10cmc; *t* refers to the time for the complete chemiluminescence (CL) signal decay. TDTAB, tetradecyltrimethylammonium bromide; DDAB, dododecyldimethylammonium bromide; CTAC, cetyltrimethylammonium chloride; DODAC, dioctadecyldimethylammonium chloride; OTAC, octadecyltrimethylammonium chloride; FA, fluoranthene; ACN, acetonitrile.

Table 2. Effect of surfactant on maximum emission intensity (I_{max}) in the reaction of bis(2-nitrophenyl)oxalate (2-NPO) with H_2O_2.

Surfactant	Peak height ($I_{max}/10^4$)	*t* (s)
None	3.5	30
Non-ionic		
Brij 35	2.2	60
Brij 76	1.9	75
Tween 20	1.6	60
Tween 80	4.6	75
Anionic		
SDS	4.5	75



Note: [2-NPO] = 5.6×10^{-5} mol L^{-1}, [H_2O_2] = 1.6×10^{-3} mol L^{-1}, [FA] = 1.2×10^{-4} mol L^{-1}, % ACN = 25, [surfactant] = 10cmc; *t* refers to the time for the complete chemiluminescence (CL) signal decay. FA, fluoranthene; ACN, acetonitrile.

In the experiments with FA, the CL intensity profile was obtained with a Lumicounter 1000 (Microtec Nichi-on) and the signal recorded with a Shimadzu 135 recorder. The emission began just after the addition of the oxalate solution. The emission intensity is represented as the peak height (I_{max}) and the total emission time of reaction as (*t*). The sequence of the addition of the solutions was 0.1 mL of water, buffer, or surfactant solution (10 times the surfactant cmc), and 0.02 mL of 1.0×10^{-3} mol L^{-1} FA, 0.02 mL IMI (when used), 0.02 mL hydrogen peroxide, and 0.02 mL of 4.5×10^{-4} mol L^{-1} oxalate (2-NPO or TCPO). The sequence influences the emission intensity because the peroxyoxalates hydrolyze in aqueous solution. The concentrations of the final solutions (0.16 mL) are indicated in Tables 1 and 2.

In the experiments with DPA, the procedure for the CL intensity measurements involved mixing the reagents in a 3 mL glass flask placed in the luminometer (Lumat LB 9507, Berthold

Technologies), positioned in front of the photomultiplier tube.

Because the peroxyoxalates hydrolyze in aqueous solution, the following mixing orders for the different reagents were used: 25% ACN (*v*/*v*): 50 μL of water or H_2O_2 (0.1×10^{-5} to 10×10^{-5} mol L^{-1}), 50 μL of 1.0×10^{-3} mol L^{-1} DPA, and 250 μL of surfactant (in water or buffer) were introduced into the glass flask, followed by automatic jet-injection, after 10 s, of 50 μL of 4.5×10^{-4} mol L^{-1}TCPO. As the DPA and TCPO solutions were prepared in ACN, the final solutions after mixing were 25% ACN (*v*/*v*); 37% ACN (*v*/*v*): 50 μL of water or H_2O_2 (0.1×10^{-5} to 10×10^{-5} mol L^{-1}), 50 μL of 1.0×10^{-3} mol L^{-1} DPA, 50 μL of 6.0×10^{-3} mol L^{-1} IMI, and 200 μL of water or surfactant (in water or buffer) were introduced into the glass flask, followed by automatic jet-injection, after 10 s, of 50 μL of 4.5×10^{-4} mol L^{-1} TCPO. As the DPA, TCPO, and IMI solutions were prepared in ACN, the final solutions after mixing were 37% ACN (*v*/*v*); 62% ACN (*v*/*v*): 50 μL of water or H_2O_2 (0.1×10^{-5} to 10×10^{-5} mol L^{-1}), 50 μL of 1.0×10^{-3} mol L^{-1} DPA, 100 μL of 1.2×10^{-2} mol L^{-1} IMI, 50 μL of ACN, and 100 μL of water or surfactant (in water or buffer) were introduced into the glass flask, followed by automatic jet-injection, after 10 s, of 50 μL of 4.5×10^{-4} mol L^{-1} TCPO. As the DPA, TCPO, and IMI solutions were prepared in ACN, the final solutions after mixing were 62% ACN (*v*/*v*). The concentrations of the final solutions (0.40 mL) are indicated in Figs. 1–4.

Results and discussion

The effects on the I_{max} and *A* values of different types of surfactants (anionic, cationic, and non-ionic), with different charged groups and hydrophobic chain lengths, were evaluated. We conducted experiments in the presence of fluorophores (FA or DPA) and oxalates (2-NPO or TCPO), as they were used in previous research[22] and showed different CL intensity–time profiles.

Fig. 2. Effect of pH and H_2O_2 concentration on maximum emission intensity (I_{max}) and emission area (*A*). Reaction of bis(2,4,6-trichlorophenyl)oxalate (TCPO) in acetonitrile (ACN) / water (25% ACN), at different pH values in $HTRIS^+$/TRIS and $H_2PO_4^-/HPO_4^{2-}$ buffers. No surfactant. [TCPO] = 5.6×10^{-5} mol L^{-1}, [DPA] = 1.2×10^{-4} mol L^{-1}. (*a*) Unbuffered medium (■). (*b*) $H_2PO_4^-/HPO_4^{2-}$, pH 6.6 (●). (*c*) $H_2PO_4^-/HPO_4^{2-}$, pH 7.6 (▲). Experiments in the presence of FA

The data for the 2-NPO reaction are reported in Tables 1 and 2. In the presence of the cationic surfactants (DDAB, CTAC, DODAC, and OTAC; Table 1) I_{max} and *t* increased. TDTAB and DDAB have bromide ions (reactive counterion), which can react with hydrogen peroxide in solution; even so, DDAB (with a larger hydrophobic chain length) had a positive effect on the CL intensity. The non-ionic Tween 80 and anionic SDS surfactants (Table 2) also showed higher I_{max}, whereas Brij 35, Brij 76, and Tween 20 had one partial quencher effect compared with the ACN/water systems with no surfactant.

The 2-NPO/H_2O_2 reaction was very much affected by the medium acidity and the buffer nature. Some experiments

(*f*) 25% ACN; HTRIS$^+$/TRIS, pH 8.7; no IMI (■). DPA, 9,10-diphenylanthracene.

(data not shown) were carried out with 3.5×10^{-5} mol L^{-1} 2-NPO, 7.7×10^{-4} mol L^{-1} H_2O_2, and 7.7×10^{-5} mol L^{-1} FA in the presence of Brij 76 (10cmc) and HTRIS$^+$/TRIS (pH 8.3) or $H_2PO_4^-$/HPO_4^{2-} (pH 8.5) medium. In the presence of Brij 76 and HTRIS$^+$/TRIS buffer, the I_{max} value was twice the value of the one obtained in $H_2PO_4^-$/HPO_4^{2-} buffer.

The data reported in Table 1 show that, for the same experimental conditions, the reaction with 2-NPO has a higher I_{max} than the reaction with TCPO, in the presence or absence of cationic surfactants. In the cationic surfactants (especially CTAC, DODAC, and OTAC) intense peaks were observed for 2-NPO/ H_2O_2 and TCPO/H_2O_2 reactions, which had very low signals in the absence of surfactant.

Comparing the effect of the cationic micelles (CTAC and OTAC) (Table 1), CTAC, which has the smallest hydrophobic chain, showed a lower I_{max} value than OTAC. However, in DODAC medium, which forms vesicle micelles, the I_{max} value was in between CTAC and OTAC with a higher t. The increase of the hydrocarbon chain length of the surfactant results in an increase of both A and I_{max}). The length of the hydrocarbon chain of the surfactant influences the size of the micelles and the depth of penetration is different. This process may be favored by longer chain surfactants, which form looser micelles.

Experiments with TCPO in the presence of DPA

Additional experiments were carried out with DPA replacing FA. The acidity and micelle effects on the TCPO chemiluminescent reaction with hydrogen peroxide were investigated by analyzing the values of I_{max} and A.

Some CL intensity–time profiles, in the absence of IMI, are represented in Fig. 1. The emission began just after the addition of TCPO. The presence of 6.2×10^{-3} mol L^{-1} γ-CD had no effect. However SDS, DDAH, and CTAB increased the CL intensity. The results are shown in Figs. 2–5.

Fig. 5. Effect of H_2O_2 concentration on maximum emission intensity (I_{max}) and emission area (A). Reaction of bis(2,4,6-trichlorophenyl) oxalate (TCPO) in acetonitrile (ACN) / water (62% ACN) in unbuffered medium with different surfactants. [TCPO] = 5.6×10^{-5} mol L^{-1}, [DPA] = 1.2×10^{-4} mol L^{-1}, [IMI] = 3.0×10^{-3} mol L^{-1}. (*a*) [DDAH] = 10cmc (▲). (*b*) [CTAB] = 10cmc (◆). (*c*) [γ-CD] = 2.5×10^{-3} mol L^{-1} (★). (*d*) [SDS] = 10cmc (►). (*e*) No surfactant (●). DPA, 9,10-diphenylanthracene; IMI, imidazole; DDAH, 3-(dimethyldodecylammonio)-propane-1-sulfonate; CTAB, hexadecyltrimethylammonium bromide; γ-CD, γ-cyclodextrin; SDS, sodium dodecyl sulfate; cmc, critical micelle concentration.

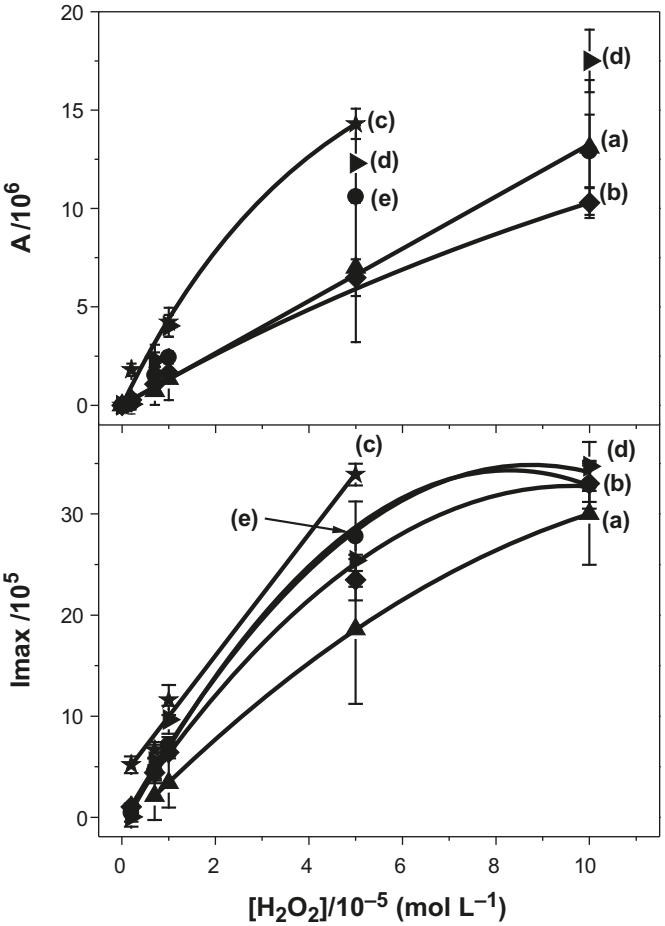

Figure 2 shows the effect of $H_2PO_4^-/HPO_4^{2-}$ and HTRIS+/TRIS buffers and the pH in the absence of surfactant. There was one smaller increase on the signals (I_{max} and A) in $H_2PO_4^-/HPO_4^{2-}$ medium compared with the unbuffered medium. The considerable enhancement in HTRIS+/TRIS buffer might be due to the catalytic effect of TRIS, as reported by Hayakawa et al.[37]

Figure 3 shows the effect of some of the surfactants. SDS (anionic) and γ-CD (0.01 mol L^{-1}) completely suppressed the signal in unbuffered and $H_2PO_4^-/HPO_4^{2-}$ media (data not shown). However, as TRIS has some catalytic effect, a relatively high increase occurs on the A and I_{max} values in HTRIS+/TRIS buffer solution (pH 8.7) in the presence of these surfactants (compare Figs. 1 and 2). The special combination of TRIS and CTAB (cationic) showed the highest increase of the I_{max} value (Fig. 2*b*). The following is the order for the I_{max} values: CTAB (cationic) > DDAH (amphiprotic) > SDS (anionic) > γ-CD; and the following is the order for the area (A): SDS (anionic) > CTAB (cationic) > DDAH (amphiprotic) > γ-CD.

Some relatively small signals were observed in the experiments in unbuffered medium in the presence of DDAH and CTAB (data not shown). When $H_2PO_4^-/HPO_4^{2-}$ (pH 7.6) was used, one relatively small signal was observed only in the presence of CTAB.

By comparing Figs. 2 (no surfactant) and 3, I_{max} and A were higher when the surfactants were present in HTRIS+/TRIS (pH 8.7), except when γ-CD was used (Fig. 2*c*). For the same hydrogen peroxide concentration, SDS had the most positive effect only on A, however, CTAB and DDAH also had good effects on I_{max} and A values, respectively.

1-Aroxalylimidazole and 1,1′-oxalyldiimidazole (Scheme 1) have been suggested as the relevant high-producing intermediates in aqueous ACN.[31,32] The catalytic effect of IMI on the TCPO/H_2O_2 reaction can be seen from the data in Fig. 3, as a large increase in the signals was observed.

As TCPO is easily hydrolyzed, I_{max} and A increase in the medium with the higher percentage of ACN. There is no linearity of I_{max} and A with the concentration of hydrogen peroxide in 62% ACN and HTRIS+/TRIS (Figs. 4*a* and 4*b*). However, in the presence of 37% and 25% ACN a linear dependence was observed (Figs. 4*c*–4*e*).

In the presence of IMI and 62% ACN, γ-CD had the highest effect on the I_{max} and A values (compare Figs. 3*c* and 5*c*); at 1×10^{-4} mol L^{-1} hydrogen peroxide, these values were so high that they could not be measured with the equipment that was used, showing one marked effect with the concentrations of hydrogen peroxide higher than 5×10^{-4} mol L^{-1}. In the presence of IMI the effect of surfactants is not marked (compare Fig. 5*e* without surfactant and Figs. 5*a* and 5*b* with DDAH and CTAB), since the catalytic effect of IMI (better than TRIS) is the dominant influence. There is no linearity of I_{max} and A with hydrogen peroxide concentration, which would not be suitable for analytical purposes.

The use of α-CD, γ-CD, and β-CD was suggested by Kojo et al.[38] to obtain better sensitivity in the analytical method for the determination of dansyl acid and glucose based on the glucose oxidase / H_2O_2 reaction in the presence of TCPO. γ-CD had better sensitivity in the phosphate buffer (pH 7.0), and the produced hydrogen peroxide was measured after 1 min with stirring at 37 °C. The detection limit corresponded to 1 pmol of hydrogen peroxide.

Inclusion in the CD cavity, which has a hydrophobic nature, is known to significantly affect the luminescent properties.[39] Woolf and Grayeski[39] reported the aqueous peroxyoxalate reactions of 4,4′-[oxalylbis[(trifluoromethylsulfonyl) imino]ethylene]bis[4-methylmorpholinium trifluoromethane sulfonate with hydrogen peroxide in the presence of several fluorophores and α-, γ- and β-CD. The enhancement due to the CDs was attributed to the increase in reaction rate and excitation and fluorescence efficiencies of the emitting species.

In Table 3, analytical parameters for H_2O_2 determination are represented for some selected experimental conditions. The detection limit is defined as three times the standard deviation of the linear coefficient divided by the angular coefficient value. The background signal and the standard deviation of the linear coefficient also increased, which restricts the improvement of the detection limits (10^{-6} mol L^{-1})

Table 3. Analytical parameters for H_2O_2 determination.

		Slope/10^{10}		Detection limit/10^6 (mol L^{-1})	
Medium/%ACN	Surfactant	I_{max}	A	I_{max}	A
HTRIS$^+$/TRIS (pH 8.7) / 25%	No	0.16	0.20	0.158	0.924
HTRIS$^+$/TRIS (pH 8.7) / 25%	DDAH	1.07	4.17	2.51	4.11
	CTAB	1.97	5.16	1.74	0.686
	γ-CD	0.14	0.14	2.09	7.80
	SDS	0.54	8.16	2.00	1.17
No buffer ([IMI] = 6.0×10^{-3} mol L^{-1}) / 37%	No	1.00	3.87	0.730	0.716
HTRIS$^+$/TRIS (pH 8.7) ([IMI] = 6.0×10^{-3} mol L^{-1}) / 37%	No	0.66	0.71	12.6	12.8

Note: Linear range 0.01×10^{-4} to 1.0×10^{-4} mol L^{-1}. IMI, imidazole; DDAH, 3-(dimethyldodecylammonio)-propane-1-sulfonate; CTAB, hexadecyltrimethylammonium bromide; γ-CD, γ-cyclodextrin; SDS, sodium dodecyl sulfate.

in the presence of the surfactants. In the presence of IMI, as a catalyst, the buffer HTRIS$^+$/TRIS had a negative effect; however, one better detection limit was obtained in the absence of surfactant and HTRIS$^+$/TRIS. The slopes of the calibration curves (A vs $[H_2O_2]$ and I_{max} vs $[H_2O_2]$), which represent the sensitivity, increase in the presence of DDAH, CTAB, and SDS in HTRIS$^+$ /TRIS buffer (pH 8.7, 25% ACN), whereas γ-CD had a small effect.

The analytical parameters reported by Dan et al.,[40] obtained for the chemiluminescent reaction of METQ with hydrogen peroxide in the presence of Brij 35 or CTAB, showed one detection limit of about 10^{-3} mol L^{-1}; so in the present work better results were obtained.

Conclusion

Under the experimental conditions of the present work, the presence of some surfactants causes an increase in the I_{max} and A signals. The effect on the increase is dependent on the nature of the fluorophore and hydrophobicity, charge differences, and concentration of the surfactant.

The effect of surfactants on the CL reaction is still unclear and depends on several parameters, and the comparison of different studies is not possible. The complexity of the system does not allow a definitive assignment of the species involved. However, based on the available literature and the data from Table 3, the sensitivity for hydrogen peroxide determination, considering the slope of the calibration curves (Table 3), improved with the introduction of some surfactants (DDAH, CTAB, and SDS) in HTRIS$^+$/TRIS buffer.

Abstract: Mannich-type addition of the titanium enolate derived from 2′-hydroxypropiophenone to *N*-tosylimines provided the corresponding β-aminoketones in good to excellent yields (60%–90%) and with >99 : <1 anti diastereoselectivity. A model for synthesis of *anti* β-aminoketone as a predominant isomer based on the titanium enolate has been developed. High anti selectivity is not independent of the electron-donating and electron-withdrawing groups on the phenyl ring of the *N*-tosylimines. Noteworthy is the observation that the influence of a second Lewis acid on the Mannich-type reaction based on the titanium enolate is opposite to that obtained from other titanium enolates reported. A reasonable mechanism has been proposed to explain the high anti diastereoselectivity and the effect of a second Lewis acid on yield.

Key words: Mannich-type reaction, 2′-hydroxypropiophenone, titanium enolate, *N*-tosylimine.

Résumé : L'addition de type Mannich de l'énolate de titane obtenu à partir de la 2′-hydroxypropiophénone avec des *N*-tosylimines conduit à la formation des β-aminocétones correspondantes, avec des rendements allant de bons à excellents (60 % à 90 %) et un diastéréosélectivité anti >99 : <1. On a développé un modèle, basé sur l'utilisation d'un énolate de titane, qui permet de réalise la synthèse d'une β-aminocétone dans laquelle l'isomère anti est prépondérant. La sélectivitéanti élevée n'est pas indépendante du caractère électroaffinitaire ou électrodonneur des groupes présents sur le noyau phényle des *N*-tosylimines. Il est important de prendre note du fait que l'addition d'un second acide de Lewis au milieu réactionnel de la réaction de type Mannich déjà catalysée par un énolate de titane conduit à une influence opposée à celle obtenue avec d'autres énolates de titane. On propose un mécanisme raisonnable pour expliquer la diastéréosélectivité anti élevée et l'effet d'un deuxième acide de Lewis sur le rendement.

Mots-clés : réaction de type Mannich, 2′-hydroxypropiophénone, énolate de titane, *N*-tosylimine.

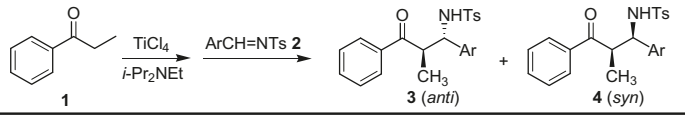
[Traduit par la Rédaction]

Introduction

The Mannich-type reaction is one of the most widely utilized chemical transformations for the construction of carbon–carbon bond.[1] High diasteroselectivity in the process is desirable. Numerous achievements have been accomplished in the area.[2,3a] Over the past 15 years, carbon–carbon bond-forming reactions involving additions of titanium enolates to the C=N bond of imines have emerged as powerful tools in organic synthesis.[3] In principle, these Mannich-type reactions of titanium enolates generate synthetically and biologically important β-aminocarbonyl compounds. Therefore, there is considerable attention on the development of methodologies for diastereocontrol. The ideal outcome is to form only syn- or anti-product with a series of imines. However, most of the reported addition reactions usually gave a mixture of syn- and anti-isomers, and high diastereoselectivity relied considerably on the substitution patterns of the imines.[4]

The aldol condensation of simple and commercially available propiophenone with aldehydes using $TiCl_4/Et_3N$ was reported by Harrison.[5] In the procedure, the enolization of the aromatic ketone gave the corresponding titanium enolates by treatment with $TiCl_4$ and triethylamine in CH_2Cl_2 at 0 °C, followed by the addition to aldehydes, affording aldol adducts with good to excellent diastereoselectivity. However, these conditions have not been applied to Mannich-type reactions with imines. We adopted the $TiCl_4$ / diisopropylethylamine (DIPEA) system and expanded it to Mannich-type reactions with *N*-tosylimines.

Results and discussion



The initial investigation of the reaction of representative *N*-tosylimines (**2**) with the titanium enolate, derived from propiophenone by treating the aromatic ketone with $TiCl_4$/DIPEA at –20 °C in CH_2Cl_2, afforded the expected products (**3** and **4**) in acceptable yields as a mixture of anti- and syn-stereoisomers (Table 1, entries 1 and 2). The treatment of *N*-(furan-2-ylmethylene)-4-methylbenzenesulfonamide with titanium enolate gave the sole anti-isomer **3c** (Table 1, entry 3). It

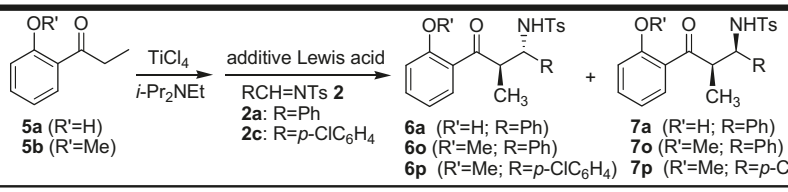
showed that diastereoselectivity of the Mannich-type reaction still depended on the substitution patterns of the imines. The levels of selectivity were similar to those possible with titanium enolates that were previously reported.

Recently, chemists have taken an interest in titanium-mediated Mannich-type reactions based on α- or β-functionalized carbonyl compounds, since high stereoselection of the addition reaction is easily achieved by the use of internal metal chelation. For example, titanium-mediated addition reactions of α-alkoxyacetate ester,[6] α-alkoxy amide,[7] β-silyloxy thioester,[8] β-hydroxy ester,[9] α-sulfenylacetates,[10] α-phenylseleno esters,[11] and α-chloro and cyanoethyl acetates[12] to imines, have been developed. The corresponding β-aminocarbonyl compounds have been prepared with predictably high stereoselectivity.

The recent success in the diastereoselective synthesis of *syn*- and *anti*-β-aminocarbonyl compounds by addition of titanium enolates to imines encouraged us to redesign a model of aromatic ketone for the acceleration of diastereoselection in the Mannich-type reaction. This idea was to introduce hydroxy at the 2-position on the phenyl ring of propiophenone. Although the titanium enolate, derived from 2′-hydroxypropiophenone, has been applied to diastereoselective synthesis of a 1-β-methylcarbapenem intermediate by condensation with 4-acetoxy-β-lactam,[13] diastereoselective Mannich-type reaction of the titanium enolate with *N*-tosylimines has not been exploited so far. Herein, we further describe Mannich-type reactions of 2′-hydroxypropiophenone (**5a**), compare its diastereoselection with that of the propiophenone. Although this resulted only in a moderate yield of the corresponding β-aminocarbonyl compound (Table 2, entry 1), the formation of the sole anti-product **6a** was attractive to us.

It is well-known that a Lewis acid activates an aldimine and that nucleophilic additions are accelerated.[14] Thus, we began to investigate the effect of a second Lewis acid on the addition reaction. In the condensation reaction of **5a** with imine **2a**, utilization of additive Lewis acids, such as $TiCl_4$, Ti(OPr-*i*)Cl_3, Ti(OPr-*i*)$_2Cl_2$, Ti(OPr-*i*)$_3$Cl, Ti(OPr-*i*)$_4$, $AlCl_3$, and BF_3·OEt_2, gave the sole anti product **6a** in all cases. In contrast with the results anticipated, yields were lower than those in the cases without any additive Lewis acids (Table 2, entries 2–8). In the absence of additive Lewis acid, Mannich-type reactions of the enolate derived from 2′-methoxypropiophenone (**5b**) with *N*-tosylimines **2a** and **2c** provided the corresponding products with high anti selectivity and in 47% and 49% yield, respectively (Table 2, entries 9 and 10). In contrary to those of the enolate derived from **5a**, yields were enhanced when using 1 equiv of additive Lewis acid such as titanium tetrachloride (Table 2, entries 11 and 12).

Under these optimal conditions, the Mannich-type reaction of the titanium enolate derived from **5a** occurred with a series of *N*-tosylimines as substrates, affording the expected products. The configuration to *anti*-**3** and *anti*-**6** and syn-isomers **4** was assigned on the basis of chemical shift and coupling constant trends and secured by comparison with similar ^{1}H NMR spectrum data already reported in the literature.[15–17] Furthermore, the relative stereochemistry was determined by decomposition of compound **6a** using ozone[13] into a known *anti*-β-amino acid (**8**) (Scheme 1).



As shown in Table 3, the substituent group on the phenyl ring of the *N*-tosylimines did not have any influences on diastereoselectivity. Electron-donating and electron-withdrawing groups always gave the predominant anti-products **6** (Table 3, entries 1–12). Obviously, the hydroxy group at the ortho position on the phenyl ring of the aromatic ketone played an important role in the Mannich-type reaction, leading to higher anti selectivity.

The formation of the predominant *anti*-β-aminoketones **6** can be rationalized in terms of the addition of the *Z*-enolate[18] to the C=N double bond of the *N*-tosylimine via an accepted six-membered chelated chairlike transition state proposed by Zimmerman and Traxler.[19] In the transition state **TS-1** which is hexacoordinate at titanium,[20,21] the titanium center is coordinated to the enolate oxygen, phenol oxygen, and imine nitrogen, and has negative polarity as shown in Scheme 2. Thus, the enolate addition occurs from the anti-conformation[22] of the imine R with the titanium enolate methyl group to give the anti-product **6**.

As described in the previous paragraph, the Mannich-type reaction can be retarded by a second Lewis acid. Perhaps the most novel and interesting mechanistic issue arising from the current studies relates to the factors governing the sense of the reactive behavior in the carbon–carbon bond formation process. According to the literature,[20] we believe that the role of the second Lewis acid is to abstract chloride ion from the enolate-bound Ti(IV), thereby converting the trichlorotitanate transition state **TS-1** to the corresponding electroneutral dichlorotitanium enolate transition state **TS-2**, in which the enolate oxygen, phenol oxygen, imine nitrogen, and *N*-tosyl group oxygen are coordinated to titanium as

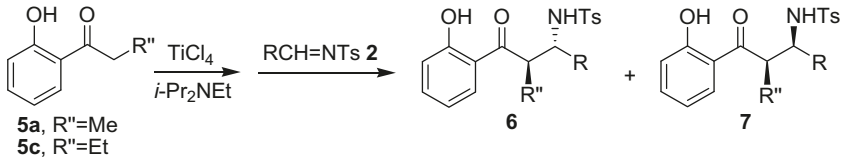
outlined in Scheme 3. The new Ti(IV)-enolate species in **TS-2** are possibly different from that the Ti(IV)-enolate in **TS-1** initially formed. In **TS-2**, although the imine can be further activated because of the coordination of the *N*-tosyl group oxygen to titanium, the nucleophilicity of the electroneutral enolate moiety considerably decreases. Thus, the use of another second Lewis acid always results in poor Mannich-type reactions in our titanium enolate model.

With the titanium enolate derived from 2′-methoxypropiophenone, the effect of a second Lewis acid on yield is obviously different from those of **5a**. These results strongly suggest that the anti-isomers were obtained through a different pathway. It is known that $TiCl_4$ can form dimeric structures that involve bridging chlorine atoms[23,24]. Therefore, we speculate that the transition state **TS-3** formed in additive $TiCl_4$-mediated reactions in which the two chlorine atoms serve as bridges for the two transition metals (Scheme 4). In **TS-3**, the 2′-methoxy group oxygen on the phenyl ring of the enolate is not coordinated to titanium, and the elimination of Cl^- by MX_n should not occur. The aldimine would be activated by the coordination of the tosyl group oxygen with the additive Lewis acidic Ti(IV) center, resulting in higher yield.

Finally, while we have no direct information regarding the transition states of these reactions, Scheme 2, Scheme 3 and Scheme 4 depict simple models for rationalizing the observed anti stereochemistry and effect of a second Lewis acid on yield.

Conclusions

In summary, we have described a highly diastereoselective Mannich-type reaction of the titanium enolate derived from 2′-hydroxypropiophenone with a wide range of *N*-tosylimines. An efficient methodology for synthesis of *anti*-β-aminoketone as the sole isomer has been disclosed. The key to the success is the introduction of a hydroxy group at the ortho position on the phenyl ring of aromatic ketone. A working hypothesis based on the crucial role played by the stereochemistry of the enolate complexes has been proposed to account for the aforementioned results. The basic idea of controlling diasteroselectivity as shown here can be applied to many other nucleophilic addition reactions. Work along this line and the deprotection of the Ts group of products **6** are now in progress.



Experimental section

General procedures

The melting points reported are uncorrected and were determined using a super capillary point apparatus. IR spectra were recorded on a Nicolet Nexus TT-IR spectrophotometer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance-500 spectrometer with chloroform-*d* as a solvent and TMS as reference. EIMS and HRMS spectra were recorded on a GC–MS QP2010 and a Bruker APEX IV, respectively. Elemental analyses were obtained using a Thermofinnigan Flash-EA 1112 series apparatus. CH_2Cl_2 was dried on CaH_2, and other solvents were distilled prior to use.

*2-Methyl-1-phenyl-3-(***p***-chlorophenyl)-3-(tosylamino) propan-1-one (3b and 4b)*

Yield: 40% (anti:syn up to 75%:25%); colorless solid, mp 126–127 °C (hexane/EtOAc). Data for **3b**: ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ: 7.80 (d, J = 8.0 Hz, 1H), 7.73 (d, J = 7.0 Hz, 2H), 7.45–7.51 (m, 3H), 7.36 (d, J = 8.0 Hz, 2H), 7.26 (d, J = 8.0 Hz, 1H), 6.96–7.05 (m, 4H), 6.60 (d, J = 9.5 Hz, 1H), 4.70 (dd, J = 9.5, 6.0 Hz, 1H), 3.89 (dq, J = 7.0, 6.0 Hz, 1H), 2.33 (s, 3H), 1.16 (d, J = 7.0 Hz, 3H). ^{13}C NMR (125.8 MHz, $CDCl_3$, ppm) δ: 203.26, 143.23, 139.25, 137.70, 136.05, 133.61, 133.07, 129.21, 128.71, 128.35, 128.29, 127.16, 126.94, 60.02, 45.84, 21.50, 16.50. Data for **4b**: ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ: 7.80 (d, J = 8.0 Hz, 1H), 7.68 (d, J = 7.0 Hz, 2H), 7.45–7.51 (m, 3H), 7.34 (d, J = 8.0 Hz, 2H), 7.26 (d, J = 8.0 Hz, 1H), 6.96–7.05 (m, 4H), 6.02 (d, J = 8.5 Hz, 1H), 4.60 (t, J = 8.5 Hz, 1H), 3.82 (qd, J = 8.5, 7.0 Hz, 1H), 2.31 (s, 3H), 1.25 (d, J = 7.0 Hz, 3H). ^{13}C NMR (125.8 MHz, $CDCl_3$, ppm) δ: 201.52, 143.45, 138.19, 137.93, 136.95, 133.35, 132.68, 129.68, 128.65, 128.30, 128.12, 127.13, 126.40, 59.21, 46.57, 21.39, 14.93. Data for a mixture of **3b** and **4b**: IR (KBr, cm^{-1}): 3241, 1688, 1592, 1495, 1437, 1328, 1154, 1089, 974, 916, 819, 664, 561. MS (EI): 428 (M^+), 384, 362, 322, 297, 294 (100), 272, 229, 178, 155, 134, 91, 77, 39. HRMS calcd for [$C_{23}H_{22}O_3S$ + H]: 408.1633; found: 408.1637. Anal. calcd for $C_{24}H_{25}O_3S$: C 70.73, H 6.18, N 3.44; found: C 70.68, H 6.20, N 3.48.

2-Methyl-1-phenyl-3-(2-furyl)-3-(tosylamino)propan-1-one (4c)

Yield: 38%; colorless solid, mp 88–90 °C (hexane/EtOAc). IR (KBr): 3340, 2964, 1668, 1593, 1521, 1455, 1209, 1167, 1023, 989, 820, 703, 559 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ: 7.82 (d, J = 8.0 Hz, 2H), 7.63 (d, J = 8.0 Hz, 2H), 7.56 (t, J = 8.0 Hz, 1H), 7.43 (t, J = 8.0 Hz, 2H), 7.32 (d, J = 8.0 Hz, 1H), 7.18 (d, J = 8.0 Hz, 2H), 7.06 (d, J = 8.0 Hz, 1H), 6.13 (d, J = 9.0 Hz, 1H), 5.86 (d, J = 3.0 Hz, 1H), 4.79 (dd, J = 9.0, 5.0 Hz, 1H), 4.06 (dq, J = 7.0, 5.0 Hz, 1H), 2.37 (s, 3H), 1.24 (d, J = 7.0 Hz, 3H). ^{13}C NMR (125.8 MHz, $CDCl_3$, ppm) δ: 207.09, 154.83, 149.39, 143.08, 136.52, 129.89, 128.02, 128.73, 126.83, 126.35, 119.19, 118.62, 113.89, 53.92, 43.89, 21.50, 15.90. MS (EI): 383 (M^+), 314, 290, 274, 250, 237, 228, 198, 155, 133, 105 (100), 91, 77, 65, 51, 39. HRMS calcd for [$C_{21}H_{21}NO_4S$ + H]: 384.1270; found: 384.1273. Anal. calcd for $C_{21}H_{21}NO_4S$: C 65.78, H 5.52, N 3.65; found: C 65.79, H 5.49, N 3.67.

Typical procedure for the synthesis of 6 and 7

To a stirred solution of the 2′-hydroxyprophenone (1 mmol, 0.150 g, 138 μL) in dry CH_2Cl_2 (10 mL), cooled at –20 °C under N_2, was added $TiCl_4$ (1 mmol, 0.188 g, 110 μL). After 2 min, i-Pr_2NEt (2 mmol, 0.258 g, 330 μL) was added dropwise. After 1 h of stirring at –20 °C, a solution of *N*-tosylimines (0.5 mol, 0.130 g) in anhydrous CH_2Cl_2 (2 mL) was added, and the mixture was stirred for another 10 h at 0 °C. The reaction was quenched by addition of saturated NH_4Cl (5 mL), and the resulting slurry was washed with H_2O (50 mL). The combined organic extracts were dried over Na_2SO_4, filtered, and concentrated in vacuo to afford a brown solid. The residue was purified by flash chromatography on silica (petroleum ether / EtOAc, 7:1) to afford **6a** (0.140 g, 68%; **6a**:**7a** up to 100%:0%) as a colorless solid.

2-Methyl-1-(2-hydroxyphenyl)-3-phenyl-3-(tosylamino) propan-1-one (6a)

Yield: 68%; colorless solid, mp 116–117 °C (hexane/EtOAc). ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ: 12.00 (s, 1H), 7.52 (d, J = 8.5 Hz, 1H), 7.48 (d, J = 8.0 Hz, 2H), 7.38–7.42 (m, 1H), 7.08–7.10 (m, 3H), 7.04 (d, J = 8.0 Hz, 2H), 7.03 (d, J = 8.0 Hz, 2H), 6.91 (d, J = 8.5 Hz, 1H), 6.74–6.78 (m, 1H), 6.13 (d, J = 9.0 Hz, 1H), 4.72 (dd, J = 9.0, 6.0 Hz, 1H), 3.90 (dq, J = 7.0, 6.0 Hz, 1H), 2.31 (s, 3H), 1.21 (d, J = 7.0 Hz, 3H). ^{13}C-NMR (125.8 MHz, $CDCl_3$, ppm) δ: 208.84, 163.13, 142.90, 139.01, 137.69, 136.96, 129.79, 129.18, 128.39, 127.44, 126.93, 126.65, 119.02, 118.76, 60.44, 45.46, 21.39, 16.76. IR (KBr, cm^{-1}): 3300, 1719, 1619, 1432, 1325, 1160, 1082, 924, 760, 674, 575. MS (EI): 409 (M^+), 286, 260, 254, 238, 223, 207, 195, 181, 165, 155, 150, 134, 121, 104, 91 (100), 77, 65, 51, 39. HRMS calcd for [$C_{23}H_{23}NO_4S$ + H]: 410.1426; found: 410.1429. Anal. calcd for $C_{23}H_{23}NO_4S$: C 67.46, H 5.66, N 3.42; found: C 67.51, H 5.64, N 3.45.

Procedure[13] for the transformation of 6a to methyl-3-(4-methylphenylsulfonamido)-3-phenylpropanoic acid (8)

A solution of **6a** (0.5 mmol, 0.205 g) in 50 mL of dichloromethane was added to 5.0 g of silica gel (80–120 mesh), followed by the removal of the solvent under reduced pressure. Ozone was passed through the silica gel preadsorbed with **6a** in a 500 mL Erlenmeyer flask at –78 °C for 15 min, followed by warming of the flask to room temperature. The silica gel was washed with ethyl acetate, filtered, and concentrated under reduced pressure. The residue was purified by flash chromatography on silica (petroleum ether / EtOAc, 2:1) to afford **8** (0.101 g, 61%) as a colorless solid, mp 132–133 °C (hexane/EtOAc) (lit[25] mp 131–133 °C). Spectral data (^{1}H and ^{13}C NMR and IR) of **8** are identical with those reported.[25] ^{1}H NMR (500 MHz, $CDCl_3$, ppm) δ: 7.48 (m, 2H), 7.11 (m, 3H), 7.03 (m, 4H), 6.19 (d, J = 9.2 Hz, 1H), 4.51 (dd, J = 7.2, 8.8 Hz, 1H), 2.89 (quint, J = 6.8 Hz, 1H), 2.28 (s, 3H), 1.17 (d, J = 6.8 Hz, 3H). ^{13}C NMR (125.8 MHz, $CDCl_3$, ppm) δ: 178.61, 143.32, 138.90, 138.02, 129.50, 128.72, 127.91, 127.33, 127.10, 60.49, 46.11, 21.70, 15.72. IR (KBr, cm^{-1}): 3265, 1715, 1162.

Abstract: The present work demonstrates the fabrication of unique gold cellular networks inside water-soluble sodium alginate sol. In conjunction with control experiments, UV–vis spectra and TEM images structurally give a piece of robust evidence that Au(III) and sodium alginate combined with preparation parameters synergically favor the formation of gold cellular networks. From the viewpoint of green chemistry, the cheap and safe reactant sodium alginate and the friendly aqueous medium make the present method possible for applications in large-scale production of metallic cellular networks. Thus, coupled with facile and green creation, the gold cellular networks open new opportunities for noble metal nanostructures, with different morphologies, as biological labels, energy transfer pairs, and other nanoscale electronics.

Key words: biopolymer, cellular network, gold.

Résumé : Dans ce travail, on présente une méthode de préparation de réseaux cellulaires uniques d'or à l'intérieur d'un sol d'alginate de sodium soluble dans l'eau. En relation avec des expériences de contrôle, les spectres UV–vis et les images obtenues par microscopie électronique à transmission (MET) donnent un appui de taille au fait que le Au(III) et l'alginate de sodium se combinent avec des paramètres de préparation qui favorisent par synergie la formation des réseaux cellulaires d'or. Du point de vue de la chimie verte, l'alginate de sodium peu dispendieux et facilement accessible et le milieu réaction aqueux écologiquement correct font que la présente méthode pourrait s'appliquer sans problème à la production à grande échelle de réseaux cellulaires métalliques. Les réseaux cellulaires d'or, qui peuvent être obtenus facilement et d'une façon écologiquement correcte, ouvrent donc de nouvelles possibilités pour la production de nanostructures de métaux nobles comportant des morphologies différentes qui pourraient être utilisés comme marqueurs biologiques, paires de transfert d'énergie et d'autres combinaisons électroniques à l'échelle nano.

Mots-clés : biopolymère, réseau cellulaire, or.

[Traduit par la Rédaction]

Introduction

Nanoparticles are nanometer-size materials with unique physical and chemical properties and have been widely used for many years.[1] Meanwhile, it has been well-demonstrated that their physical and chemical properties are closely related to their size and shape.[2,3] Therefore, there has been an increasing interest in developing new methods for fabricating shape-controlled nanoparticles. For example, Ag and Au with different shapes such as nanorods,[3,4] nanoplates,[5–12] nanodisks,[13–16] sponges,[17] three-dimensional (3D) thorny nanostructures,[18] and hollow microspirals[19] have been synthesized. However, the procedure for porous metallic nanostructures is still a great challenge for materials scientists, although nanomaterials with very abundant pores have become increasingly attractive in the area of materials science,[20] which is fueled by their use in catalysis, gas storage, and separation.[21,22]

Biopolymers belong to a class of materials that can swell largely in water other than organic solvents and maintain their 3D network structure on a nanometer length scale in the swollen state. This makes them have many potential applications including high-surface-area supports for catalysts, separation media, and templates for the synthesis of other nanoscopic materials, which undoubtedly motivates the preparation of nanostructural materials inside biopolymers.[23,24] In fact, a sol-gel-derived 3D network of nanoscale particles (aerogel/ambigel),[25] and a 3D (hierarchically) ordered macroporous (3DOM) solid with an inverted opal structure have already been created by a combination of sol-gel chemistry and templating.[26,27] Among biopolymers that are widely used is Sodium alginate is a biopolymer that is widely in use. It is a popular additive and naturally derived linear anionic copolymer of 1,4-linked β-D-mannuronic acid (M block) and α-L-guluronic acid (G block) residues arranged in a nonregular blockwise pattern of varying proportionsof GG, MG, and MM blocks.[28–31] The chemical structure of sodium alginate is shown in Scheme 1. The extensive number of carboxyl groups present in sodium alginate can make cross-linked hydrogels form in the presence of cations via an ionic interaction between the acid groups on the G blocks and the chelating ions, generally, Ca^{2+}.[32,33] As a result, it is plausible

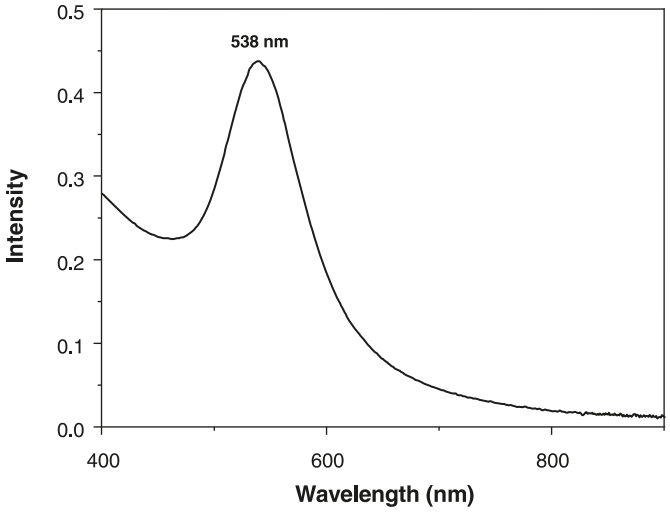

Scheme 1. Chemical structure units of sodium alginate (M = mannuronic acid and G = guluronic acid).

that Au(III) ions can play a significant role in guiding the supramolecular organization among sodium alginate sol, which results in the nanogold formation upon the reduction. That is to say, sodium alginate sol can act as nanoreactor to template and stabilize nanoparticles in the cross-linked system. However, little attention has been paid to the application of their cross-linked systems as nanoreactors.

In conjunction with the biocompatible nature and unique optical properties of gold nanoparticles, we report herein on the generation of gold cellular networks through the in situ reduction of the gold precursor existing inside the 3D network structure in sodium alginate sol. This bulky natural sodium alginate sol allows the stabilization of the porous nanostructues. UV–vis spectra and TEM images structurally witness the formation of gold cellular networks. Control experiments give a piece of robust evidence that Au(III) and the cheap and safe sodium alginate reactant combined with preparation parameters synerically favor the formation of gold cellular networks. Thus, coupled with facile and green creation, the gold cellular networks open new opportunities for noble metal nanostructures with different morphologies

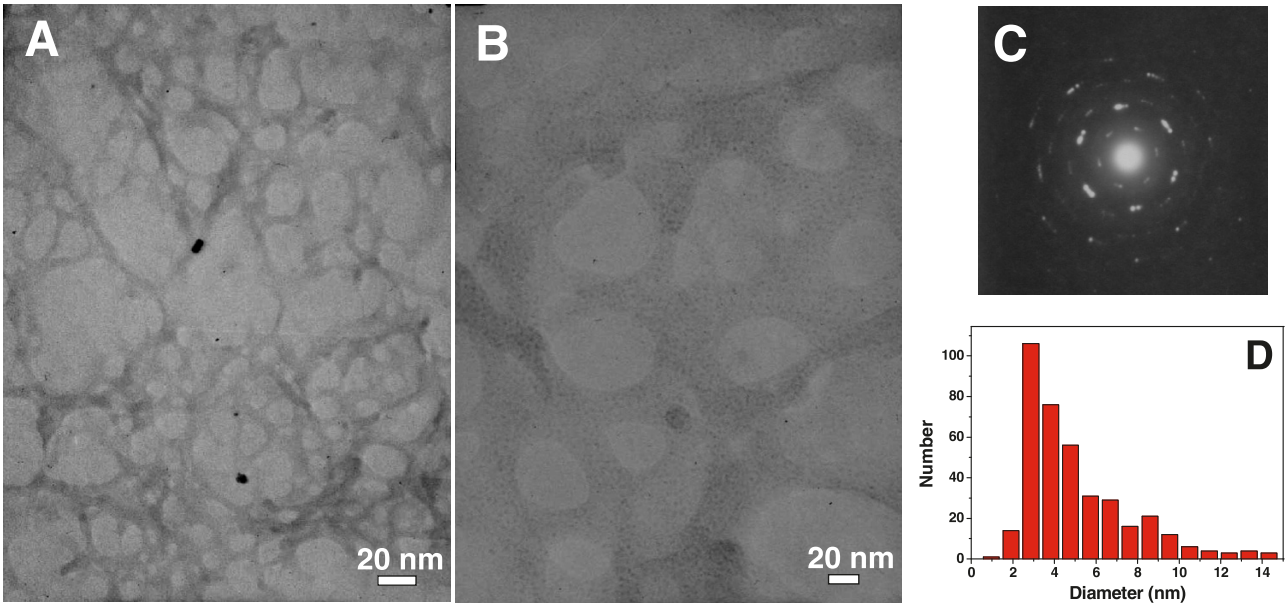
as biological labels, energy transfer pairs, and other building blocks in nanoscale electronics.

Materials and methods



Sodium alginate was purchased from Sigma-Aldrich. All other reagents are of analytic grade and used as received without further purification. All water used in this investigation was deionized by a Nanopure filtration system to a resistivity of 18 MΩ cm. The preparation of gold cellular networks is quite straightforward. In a typical preparation, a 0.5 mL aliquot of a 0.0254 mol/L aqueous solution of $HAuCl_4$ was added to 10 mL of a 0.055% (wt) aqueous solution of soluble sodium alginate. The mixture was heated to 90 °C and was maintained at this temperature for 30 min. After the subsequent dropwise introduction of 0.2 mL of freshly prepared 0.1 mol/L aqueous sodium borohydride, the solution turned red, indicating the formation of gold nanoparticles. They were structurally investigated by UV–vis spectra, TEM images, selected area electron diffraction (SAED), and X-ray diffraction (XRD) to obtain detailed information on their nanometer-scale morphology. The UV–vis spectra were collected on a UV–vis spectrophotometer (Beijing Purkinje General Instrument Co., Ltd.). TEM and SAED measurements were made on a JEOL 2010 transmission electron microscope operated at an accelerating voltage of 200 kV. The XRD pattern was collected on a Rigaku-D/Max 2500 V/PC X-ray diffractometer using high-intensity Cu Kα1 radiation (λ = 1.54056 Å). Samples for TEM and XRD characterization were prepared by placing the gold colloidal sample on carbon-coated copper grid and glass substrates, respectively, and dried at room temperature.

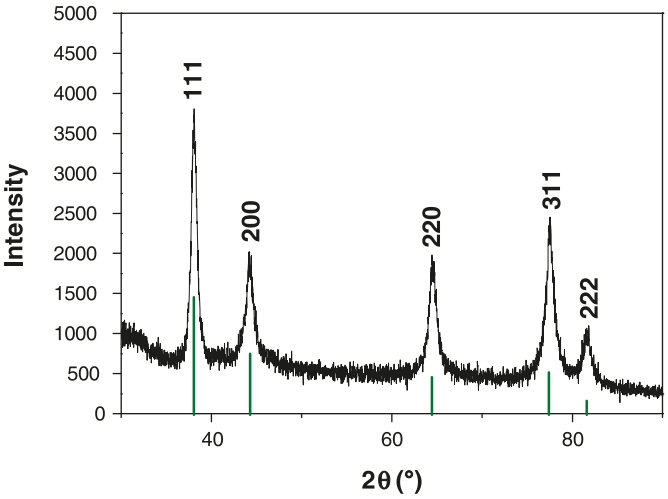
Results and discussion

UV–vis absorption observations

The synthesis of gold cellular networks is carried out by the reduction of Au(III) to Au(0) in heated sodium alginate/$HAuCl_4$ aqueous solution. Gold nanoparticles exhibit strong plasmon resonance absorption that is dependent on particle size and shape. For roughly spherical gold nanoparticles, the fingerprint surface plasmon absorbance band generally falls

Fig. 2. Low magnification TEM Image (A), high magnification TEM image (B), SAED (C) of the gold cellular networks, and the size distribution (D).

between 520 and 530 nm.[27,34–36] The formation of gold colloid in our system was confirmed by the UV–vis spectrum, displaying a plasmon band maximum at 538 nm (2.31 eV) (shown in Fig. 1). The slight red shift to longer waves was observed for the sample, presumably stemming from the collective network behavior. It is worthwhile mentioning that the colloidal sample is stable for a month or longer without any observable aggregation, indicating that sodium alginate can serve as a very effective protective agent for the formation of gold colloid. There was quick color change from light yellow to purple, accompanied by the observable aggregation, for the control experiment with no sodium alignate in the solution performed. This simultaneously proved the protective agent role of sodium alginate in the formation of gold colloid.



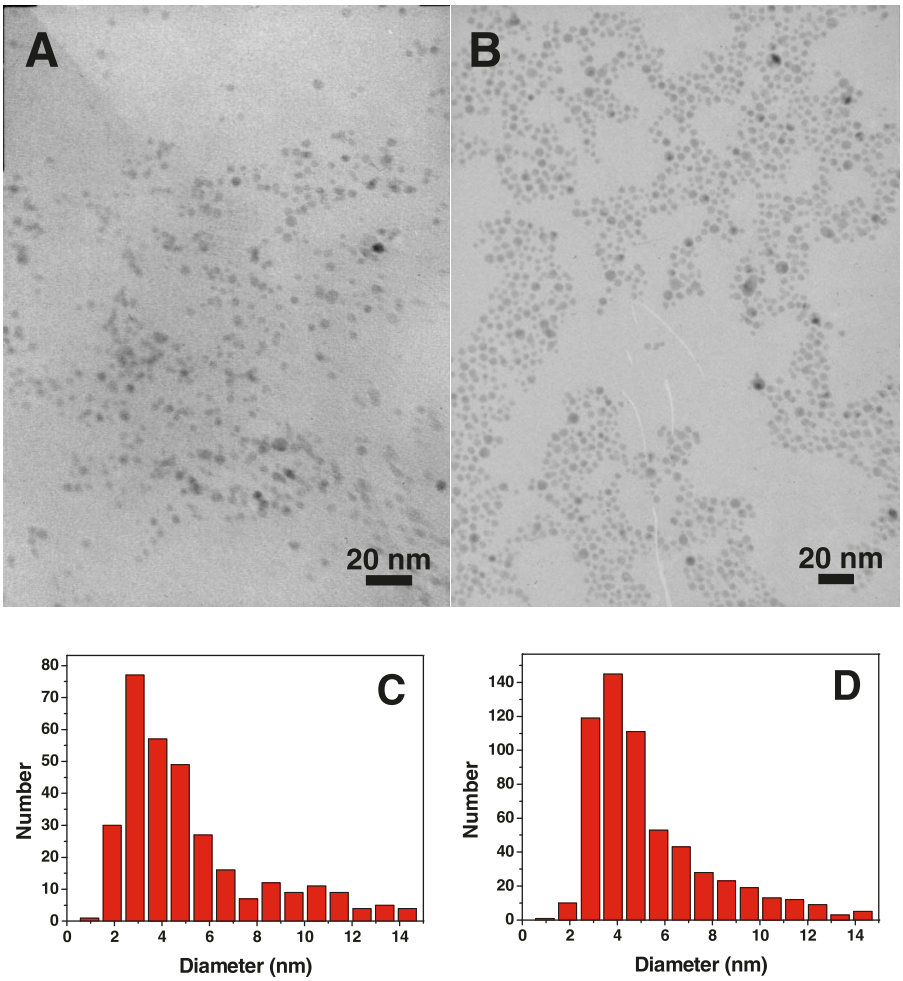
TEM measurements

Figure 2 shows the typical TEM images of the obtained gold cellular networks. The lower magnification image (Fig. 2A) indicates that the product consists of porous cellular networks. The higher magnification image (Fig. 2B) shows that the cellular networks are composed of discrete gold nanoparticles with average diameters of 3 nm. Figure 2D shows the size distributions. In general, the particles are isotropic (i.e., low aspect ratio) in shape. These results illustrate the synthesis of Au(0) nanoparticles through the reduction of Au(III) inside the cross-linked nanoscopic sodium alginate templates. The massive carboxyl groups act as stabilization and passivation contacts for the stabilization of the nanoparticles formed inside these templates. The related SAED pattern (Fig. 2C) obtained by focusing the electron beam on porous cellular networks on the TEM grid gives a piece of powerful evidence of the gold component. The SAED pattern reveals a ringlike pattern, suggesting that the gold nanoparticles are multicrystalline.

XRD measurement

Whereas SEM and TEM often sample only a small portion

Fig. 3. XRD pattern of the gold cellular networks. The vertical lines represent the data of JPCDS file, card No. 04-0784.



of the products, XRD can be used to assess the overall quality and purity of the product.[37] The XRD pattern recorded on the product is compiled in Fig. 3. The observed five Bragg reflections clearly correspond to the face-centered cubic structure of metallic gold with space group *Fm*3*m* (JPCDS file, card No. 04-0784). The observation of all the expected diffraction peaks substantiates the formation of crystalline gold.[38] The nanometer size of the gold crystallites is evidenced by the broad X-ray reflection peaks. From the well-known Scherrer formula, the average crystallite size (L) is

$$L = \frac{K\lambda}{B_m \cos\theta}$$

where λ is the X-ray wavelength, θ is the diffraction angle, B_m is the line width of the "pure" diffraction profile resulting from small crystallite size, and K is a constant approximately

equal to unity and related to crystallite shape. According to the Scherrer formula, the average crystallite size of gold cellular networks is 5 nm, which is consistent with that calculated from the TEM images.

Control experiments

To clarify the effect of the reaction temperatures on the special morphology of the product, we conducted experiments by changing the reaction temperature to room temperature and 50 °C under otherwise identical conditions. The TEM image (Fig. 4) indicates that the particles invariably show 2D arrays consisting of close-packed and well-separated spherical particles, with an average particle size of 3.7 nm (Fig. 4A) and 4 nm (Fig. 4B), respectively. This indicates that the gold nanoparticles are capped by sodium alginate, which prevents physical contact between the particles and also provides sufficient hydrophobicity to the gold nanoparticles to enable their dispersion in water. More importantly, it suggests that the reaction temperature plays a vital role in the formation of cellular networks. This is presumably attributed to its well-stretched state resulting from heating treatment. The stretched state offers enough space for metal ions to approach carboxyl, thus facilitating the cross-linked system and the nanoparticles more stable. By this token, heat treatment in the present case is employed not only to increase the reaction velocity and narrow the particle-size distributions,[39] but also for the formation of the cross-linked system. This is a distinct feature superior to conventional stabilizers.

To make clear the role of the reactant concentrations in the formation of the porous networks, we also investigated the effect of the molar ratios of sodium alginate to Au on the morphology of the product, whereby we conducted the experiment by changing the molar ratio of sodium alginate / $HAuCl_4$ to 10:1 and 1:1 under otherwise identical conditions. The TEM image (Fig. 5) indicates that the particles also invariably show 2D arrays consisting of close-packed and well-separated spherical particles, with the average particle size of 4 nm (Fig. 5A) and 6.4 nm (Fig. 5B), respectively. This likewise indicates that the gold nanoparticles are capped by sodium alginate, which prevents physical contact between the particles and also provides sufficient hydrophobicity to the gold nanoparticles to enable their dispersion in water. The disappearance of cellular networks under the present conditions suggests that the molar ratios of sodium alginate to Au have evident effect on the formation of cellular networks. This is presumably attributed to the fact that the biopolymers swell enough to form the cross-linked system

Fig. 5. Representative TEM images when the molar ratios of sodium alginate/$HAuCl_4$ are changed to 1:1 (A) and 10:1 (B) under the otherwise identical conditions and the corresponding size distributions: C from A and D from B.

through metal ions bridging only at an appropriate concentration.

Conclusion

In conclusion, the results from UV-vis absorption spectra, TEM images,and XRD are in agreement, and provide robust evidence to support the successful fabrication of gold cellular networks. The cheap and safe of sodium alginate reactant combined with easy control of preparing parameters makes the present method possible for applications in large-scale production of metallic cellular networks. Control experiments show that both the reaction temperatures and reactant concentrations play a vital role in the formation of the cellular networks. Intense work aimed at supporting this sol-template-controlled synthesis strategy for other porous systems, particularly for nanomagnets is in progress.

A key issue in nanotechnology is the development of conceptually simple construction techniques for the mass fabrication of identical nanoscale structures. The present approach relies on the exploitation of specific cross-linking interactions between biopolymer and metal ions and is one of the key building principles of all living organisms. It is thus obvious to search for more biological structures that can be used as templates for directing and perfecting the self-assembly.[40]

Abstract: A facile approach to the synthesis of some side-chain-protected amino acids via oxalic acid dihydrate as the copper sequestering reagent is presented. The copper in the amino acid complex reacted with oxalic acid dihydrate to form insoluble cupric oxalate, with the free amino acid released. Compared with conventional methods, this method is convenient, inexpensive, and environmentally friendly.

Key words: side-chain-protected amino acid, oxalic acid dihydrate, cupric oxalate, synthesis.

Résumé : On a mis au point une approche simple à la synthèse des divers acides aminés à chaîne latérale protégée impliquant le dihydrate de l'acide oxalique comme réactif de séquestration de du cuivre. Le cuivre du complexe avec l'acide aminé réagit avec le dihydrate de l'acide oxalique pour former l'oxalate cuivrique insoluble et la libération de l'acide aminé libre. Par comparaison avec les autres méthodes conventionnelles, cette méthode est pratique, peu coûteuse et écologique.

Mots-clés : acide aminé à chaîne latérale protégée, dihydrate de l'acide oxalique, oxalate cuivrique, synthèse.

Introduction

Since the emergence of glycylglycine synthesis from a diketopiperazine by Fischer and Fourneau[1] in 1901, peptide synthesis has undergone tremendous progress and it is now possible to routinely synthesize a protein consisting of over 200 amino acids. However, when the amino acids involved are trifunctional, such as lysine, ornithine, etc., it is necessary to protect their side-chain functional groups. This is accomplished by first reacting the primary amino acids with cupric ions to form the stable chelate complex, followed by a reaction with acylation reagents to facilitate selective protection of the side-chain functional group.

To recover the side-chain-protected amino acids, it is necessary to decompose the copper – amino acid complexes, for which several methods are available involving several important reagents including EDTA,[2,3] potassium cyanide,[4] 8-quinolinol,[5] hydrogen sulfide,[6,7] thioacetamide,[8] sodium borohydride,[9] and sodium sulfide.[10] EDTA is one of the most widely employed copper-sequestering reagents. However, the resultant copper–EDTA complex during the course of the reaction is water-soluble, which can lead to effluent problems with the water-soluble side-chain-protected amino acids. When copper is removed from the complexes using KCN, H_2S, or thioacetamide, there is a marked drawback in that these reagents are highly toxic and, thioacetamide in particular, is a potential cancer-causing chemical. When copper is removed from the complexes employing 8-quinolinol, there is a low yield of protected amino acids, with the cost greatly increased. Similarly, in the case of copper removal using sodium borohydride, issues such as heat generation during bulk production of protected amino acids also result. Despite the fact that recent research has confirmed the efficiency of sodium sulfide in the detachment of copper from the complexes, its serious hazards to the environment are noteworthy.

Given the limitations of the methods concerning the copper(II) deprotection discussed previously, it is difficult to realize the industrialization. Several studies have shown that oxalic acid can be preferable for its inexpensiveness and friendliness to the environment and can form complexes with copper.[11–13] In this paper, we report a highly convenient and efficient method in which oxalic acid dihydrate is employed to detach the copper(II) complexes, to prepare the side-chain amino-protected acetyl, Boc, Fmoc, and Z (benzyloxy carbonyl) ornithines,and lysines, respectively.

Results and discussion

The behavior of copper in oxalic acid solutions has been well-studied. The results have shown that copper ions with oxalate can easily form complexes; however, the complexation ability in the solution depends on pH (1–1.5).[13] In continuation of our efforts towards the decoppering reaction, we employed oxalic acid dihydrate to sequester copper from the copper – amino acid complexes. In general, cupric oxalate is insoluble in water or diluted hydrochloric acid. To accelerate

8	H-Lys(Boc)-OH	**h**	63	96.9

[a]All compounds were characterized by ^{1}H NMR and elemental analysis.

the reaction, diluted hydrochloric acid was selected as the vehicle, with the concentrations of the acid investigated. It was observed that, with the acid maintained at a concentration of 0.01 mol/L, the method for the removal of copper ions by oxalic acid dihydrate was effective and could completely eradicate the sulfide problem during the course of the reaction (the pH of the solutions is ~1.1). The results in Table 1 show that the oxalic acid dihydrate-mediated detachment of copper ions from all the copper amino acid complexes resulted in protected amino acids of high purity with no racemization.

The copper complexes of the following amino acids were prepared in accordance with the methods in literature: N^{ε}-Boc–lysine,[14] N^{δ}-Boc–ornithine,[15] N^{ε}-*Z*–lysine, N^{δ}-*Z*–ornithine,[8] N^{ε}-Fmoc–lysine, N^{δ}-Fmoc–ornithine,[16] N^{δ}-acetyl–ornithine, and N^{ε}-acetyl–lysine.[17]

The copper – amino acid complexes were treated with oxalic acid dihydrate in diluted hydrochloric acid for 1–2 h at 80 °C to afford side-chain-protected amino acids **a**–**j** in yields of 55%–80% (Scheme1 and Table 1). The isolated products were characterized by ^{1}H NMR and elemental analyses.

Conclusion

In conclusion, we have confirmed that oxalic acid dihydrate is a useful reagent in removing copper from amino acid copper complexes during the preparation of several side-chain-protected amino acids. This method may also be applicable to bulk production of side-chain-protected amino acids.

Experimental

Melting points were measured in open capillaries and are uncorrected. Optical rotations were measured on a PerkinElmer model 341 automatic polarimeter. Elemental analysis was performed on a PerkinElmer CHNS analyzer. ^{1}H NMR spectra were recorded in CD_3SOCD_3 on a Bruker Avance 500 spectrometer; chemical shifts (δ) are reported in parts per million (ppm) relative to tetramethylsilane (TMS), serving as an internal standard. Solvents and reagents were purchased from respective suppliers and used without further purification.

General procedure for the preparation of side-chain-protected amino acids a–h

To dissolve the copper – amino acid complex (10.0 mmol) in a capped flask at ambient temperature, diluted hydrochloric acid (30 mL, 0.01 mol/L) was added, followed by the addition of oxalic acid dihydrate (10.3 mmol), and the resulting mixture was stirred at 80 °C (the pH of the solutions was ~1.1 at this time). At the end of stirring for 1–3 h, the consequent cupric oxalate precipitate was filtered. The filtrate was neutralized with dilute NaOH. The resulting precipitate was isolated by filtration and then rinsed with distilled water (50 mL × 4) to obtain the side-chain-protected amino acids **a**–**f**. The water-soluble products (**g**–**h**) were isolated by the removal of the solvent and extraction of the residue with acetone.

H-Orn (*Z*)-OH (compound a)

White crystals (70%), mp 248–250 °C, $[\alpha]_D^{20}$ +17.6° (lit.[18] mp 228–230 °C, $[\alpha]_D^{20}$ +17.5°, *c* 0.01, water/acetone = 1:1, and equal volumes of hydrochloric acid). ^{1}H NMR δ: 7.35–7.45 (m, 5H, Ar-H), 5.08 (s, 2H, Ar–CH_2), 3.37–3.44 (m, 1H, α-H), 3.19–3.23 (m, 2H, δ-H), 1.81–1.86 (m, 2H, γ-H), 1.65–1.70 (m, 2H, β-H). Abstract: Three kinds of nano-baskets including 1,2-alternate and cone conformers of di-ionizable *p-tert*-butylcalix[4]arene-1,2-crown-3 and the cone conformer of *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 were synthesized and the competitive solvent extractions of alkali and alkaline earth metal cations were studied. The novelty of this study is including three binding units of the calixarene's bowl, the crown ether's ring, and electron-donor ionizable moieties in a unique scaffold, in which their sizes were selected based upon their complexation ability to show equal binding tendency towards the cations. The objective of this work is to assess the extraction efficiency, selectivity, and $pH_{1/2}$ of such complexes. The results of solvent extraction experiments indicated that these compounds were effective extractants of alkali and alkaline earth metal cations. Their selectivities were greatly influenced by the acidity of the solution and the conformations of the calixcrown. One conformer was highly selective to Na^+ and the other to Ba^{2+} in acidic and basic solutions, respectively.

Key words: nano-baskets, competitive extraction, calix[4]crown-3, s-block metals.

Résumé : On a réalisé la synthèse de trois nouveaux types de nano-paniers, dont les conformères 1,2-alternés et à cône du *p-tert*-butylcalix[4]arène-1,2-couronne-3 et de son conformère en cône, le *p-tert*-butylcalix[4]arène-1,2-thiacouronne-3 et on en a étudié les capacités d'extraction compétitive par solvants de cations alcalins et alcalinoterreux. La nouveauté de cette étude réside dans le fait qu'elle inclut trois unités de fixation, soit le bol du calixarène, le noyau de l'éther couronne et les portions ionisables d'un électrodonneur dans un échafaudage unique dans lequel leurs grandeurs ont été choisies en raison de leur habilité à former à tous former des complexes avec les cations avec autant de facilité. L'objectif de ce travail était d'évaluer l'efficacité d'extraction, la sélectivité et le $pH_{1/2}$ de tels complexes. Les résultats des expériences d'extraction par les solvants indiquent que ces composés permettent d'extraire d'une façon efficace les cations métalliques alcalins et alcalino-terreux. Leurs sélectivités sont fortement influencées par l'acidité de la solution et de la conformation du calixarène couronne. Un conformère est très sélectif pour la Na^+ et l'autre pour la Ba^{2+} dans des solutions respectivement acides et basiques.

Mots-clés : nano-paniers, extraction compétitive, calix[4]couronne-3, métaux du bloc s.

[Traduit par la Rédaction]

Introduction

Nano-baskets of calixarenes and calixcrowns are a versatile class of macrocycles that have been subject to extensive research in the development of many extractants, transporters, and stationary phases (using a gas chromatograph, Teif Gostar Faraz Co.).[1–6] Functionalization of calix[4]arenes at both the upper rim and the lower rim has been extensively studied.[7,8] Attaching donor atoms to the lower rim of a calix[4]arene can improve the binding strength of the parent calixarene dramatically.[9–19] The two main groups of lower rim-functionalized calix[4]arenes are calix[4]arene podands and calixarene-crown ethers.[20,21] Distal hydroxyl groups can be connected to give 1,3-bridged calix[4]crowns, whereas connection between proximal hydroxyl groups leads to 1,2-bridged calix [4]crowns.

It was found that the 1,3-bridged calix[4]crowns exhibit high binding affinity and selectivity toward alkali and alkaline earth metal cations,[22] whereas the research on 1,2-bridged calix[4]crowns lags far behind. Combining crown ethers with calix[4]arenes increases the cation binding ability of the parent calixarenes, and control of the selectivity is obtained through the modulation of the crown ether size. Attachment of proton-ionizable groups to calixcrowns can further improve their extraction properties because the ionized group not only participates in metal ion coordination but also eliminates the need to transfer aqueous phase anions into the organic phase. Ungaro et al.[23] reported the first diproton-ionizable calix[4]crown-5 in 1984 and it showed a quite high efficiency in the extraction of divalent cations from water into dichloromethane. Combining crown ethers with calix[4]arenes increases the cation binding ability of the parent calixarenes.[24–26] The selectivity can be affected by the crown ether size, the identity of donor atoms on the crown ether moiety, and the conformation of the calixarene platform. To further explore the influence of these factors on the extraction characteristics of *p-tert*-butylcalix[4]arene-1,2-crown ethers toward metal ions, a series of di-ionizable *p-tert*-butylcalix[4]arene-1,2-crown-3 compounds in the cone

and the 1,2-alternate conformations, as well as *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 in the cone conformation, were synthesized.

There are two kinds of side chains in the calixcrown skeleton that were studied including two ionizable carboxylic acid moieties and the crown-ether moieties. The ionizable moieties not only participate in cooperative metal ion coordination but also eliminate the need to transfer the anions from the aqueous phase into the organic phase by operating in a cation-exchange mode with the metal cation. In this work, two proton-ionizable functional groups were incorporated into the calix[4]arene scaffold. A special feature of this modification is that the acidity of the ionizable moiety can be tunable by changing the functional group from hydroxyl to other groups because of the different electron-withdrawing abilities of the functional group. A wide range of pH environments can be examined when these ionizable groups are incorporated into the calixcrown skeleton. These extractants exhibit excellent extraction selectivity for alkali and alkaline earth metals.

In this work, three nano-baskets of calixcrowns with different proton-ionizable moieties were synthesized including cone *p-tert*-butylcalix[4]arene-1,2-crown-3 diacid, 1,2-alternate *p-tert*-butylcalix[4]arene-1,2-crown-3 diacid, and cone *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 diacid. Competitive solvent extractions of alkali metal cations and alkaline earth metal cations were performed using these calixcrowns in which 1.0 mmol/L solutions of di-ionizable calix[4]arene ligands in chloroform as well as the plots of cation loading of the organic phase vs. the equilibrium pH of the aqueous phase were presented. In the following, the synthesis and the extraction procedures of the three conformers are presented.

Experimental methods

Materials and apparatus

Reagents were obtained from commercial suppliers and used directly, unless otherwise noted. Acetonitrile (MeCN) was dried over CaH_2 and distilled immediately before use. Tetrahydrofuran (THF) was dried over sodium with benzophenone as an indicator and distilled just before use. Cs_2CO_3 was activated by heating at 150 °C overnight under high vacuum and stored in a desiccator. Melting points were determined with a Mel-Temp melting point apparatus. Infrared (IR) spectra were recorded with a PerkinElmer model 1600 FT-IR spectrometer as deposits from CH_2Cl_2 solution on NaCl plates. The ^1H and ^{13}C NMR spectra were recorded with a Varian Unity INOVA 500 MHz FT-NMR (^1H, 500 MHz; and ^{13}C, 126 MHz) spectrometer in $CDCl_3$ with Me_4Si as internal standard unless mentioned otherwise. Chemical shifts (δ) are given in ppm downfield from TMS and coupling constants (*J*) are in Hz.

Preparation of *p-tert*-butylcalix[4]arene-1,2-crown-3 (**2**)

To a mixture of *p-tert*-butylcalix[4]arene (6.50 g, 10 mmol), diethylene glycol (1.59 g, 15 mmol), and triphenylphosphine (TPP, 8.00 g, 30 mmol) in 200 mL of toluene, a 40% solution of diethylazodicarboxylate (DEAD, 5.22 g, 30 mmol) in toluene was added dropwise. The mixture was stirred at room temperature for 0.5 h and then the solution was evaporated to dryness and the residue was extracted with hexane (3 × 30 mL) followed by evaporation and subsequent stirring in hexane and ethyl acetate. The precipitate was filtered and the filtrate was purified by chromatography on silica gel with hexane–EtOAc (9:1) as eluent to give a white solid (3.90 g, 54%) with mp 198–199 °C. IR (deposit from CH_2Cl_2 solution on a NaCl plate, cm^{-1}) ν_{max}: 3342 (O–H), 1249 and 1124 (C–O). ^1H NMR ($CDCl_3$) δ: 1.20 (s, 18H, CH_3), 1.21 (s, 18H, CH_3), 3.26–3.45 (m, 4H, $ArCH_2Ar$), 4.01 (t, J = 10.5 Hz, 2H, OCH_2CH_2O), 4.12 (t, J = 11.0 Hz, 2H, OCH_2CH_2O), 4.28–4.46 (m, 7H, OCH_2CH_2O, $ArCH_2Ar$), 4.82 (d, J = 12.0 Hz, 1H, $ArCH_2Ar$), 6.94–7.06 (m, 6H, ArH), 7.15 (d, J = 2.0 Hz, 2H, ArH), 8.87 (s, 2H, OH). ^{13}C NMR ($CDCl_3$) δ: 31.30, 31.50, 32.66, 33.01, 33.90, 34.18, 75.32, 125.31, 125.58, 125.60, 126.45, 128.32, 128.84, 129.15, 133.88, 134.62, 142.81, 147.42, 149.14, 150.34. Anal. calcd for $C_{48}H_{62}O_5$ (%): C 80.18, H 8.69; found: C 80.08, H 8.37.

Preparation of cone *p-tert*-butylcalix[4]arene-1,2-crown-3 diester (**3**)

p-tert-Butylcalix[4]arene-1,2-crown-3 (**2**) (5.00 g, 6.95 mmol) in 50 mL of THF was added dropwise into a mixture of NaH (0.85 g, 35.4 mmol) in 50 mL of THF. After stirring for 2 h, ethyl bromoacetate (6.95 g, 41.7 mmol) was added and the reaction mixture was stirred overnight. The reaction was monitored by TLC. After 48 h, the reaction was quenched by careful addition of dilute HCl and evaporated in vacuo. The residue was dissolved in CH_2Cl_2, the solution was washed with dilute HCl and water, dried over $MgSO_4$, and the solvent was evaporated in vacuo. Chromatographic purification on silica gel with hexane–EtOAc (2:8) as eluent gave an oil (3.81 g, 61%). IR (deposit from CH_2Cl_2 solution on a NaCl plate, cm^{-1}) ν_{max}: 1760 (C=O), 1253 and 1128 (CO). ^1H NMR ($CDCl_3$) δ: 1.04 (s, 18H, CH_3), 1.12 (s, 18H, CH_3), 1.34 (t, J = 7.0 Hz, 6H, OCH_2CH_3), 3.09 (d, J = 12.0 Hz, 1H, $ArCH_2Ar$), 3.18 (d, J = 12.0 Hz, 2H, $ArCH_2Ar$), 3.24 (d, J = 13.0 Hz, 1H, $ArCH_2Ar$), 3.83–3.92 (m, 2H, OCH_2CH_2O), 4.07 (d, J = 12.0, 2H, OCH_2CH_2O), 4.20 (m, 2H, OCH_2CH_2O), 4.27 (q, J = 7.0, 4H, OCH_2CH_3), 4.42 (d, J = 10.5 Hz, 2H, OCH_2CH_2O), 4.54–4.65 (m, 3H, $ArCH_2Ar$, OCH_2Ar), 4.88 (d, J = 15.5 Hz, 2H, OCH_2CO), 4.96 (d, J = 12.0 Hz, 1H, $ArCH_2Ar$), 6.76–6.84 (m, 4H, ArH), 6.86 (d, J = 2.5 Hz, 2H, ArH), 6.92 (d, J = 2.0 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$) δ: 14.33, 31.02, 31.32, 31.42, 33.82, 33.88, 53.42, 60.62, 72.03, 73.04, 75.24, 124.35, 125.39, 125.55, 132.72, 134.03, 134.35, 134.81, 144.84, 145.34, 152.88, 152.93, 170.28. Anal. calcd for $C_{56}H_{74}O_9$ (%): C 75.47, H 8.37; found: C 75.22, H 8.23.

Preparation of cone *p-tert*-butylcalix[4]arene-1,2-crown-3 diacid (**4**)

p-tert-Butylcalix[4]arene-1,2-crown-3 diester (**3**) (3.00 g, 3.05 mmol) in 60 mL of THF and 60 mL of 10% Me_4NOH was refluxed overnight. The solvent was evaporated in vacuo and the residue was dissolved in 100 mL of CH_2Cl_2. The organic layer was washed with 1 N HCl solution until pH 1 and then washed with 60 mL of brine and 60 mL of water, dried over $MgSO_4$, and evaporated in vacuo to give a white solid (2.49 g, 88%) with mp 255–256 °C. IR (deposit from CH_2Cl_2 solution on a NaCl plate, cm^{-1}) ν_{max}: 3217 (O–H),

1761 (C=O), 1203 and 1121 (C–O). ^{1}H NMR ($CDCl_3$) δ: 1.07 (s, 18H, CH_3), 1.11 (s, 18H, CH_3), 3.12 (d, J = 12.0 Hz, 1H, $ArCH_2Ar$), 3.22–3.36 (m, 3H, $ArCH_2Ar$), 3.81–3.92 (m, 2H, OCH_2CH_2O), 4.11 (d, J = 12.5 Hz, 2H, OCH_2CH_2O), 4.20 (t, J = 11.0 Hz, 2H, OCH_2CH_2O), 4.25–4.38 (m, 4H, OCH_2CH_2O, $ArCH_2Ar$), 4.49 (d, J = 13.0 Hz, 1H, $ArCH_2Ar$), 4.58 (d, J = 16.5 Hz, 2H, OCH_2CO), 4.79 (d, J = 16.5 Hz, 2H, OCH_2CO), 5.19 (d, J = 12.5 Hz, 1H, $ArCH_2Ar$), 6.83–6.91 (m, 4H, ArH), 6.93 (d, J = 2.0 Hz, 2H, ArH), 6.99 (d, J = 2.5 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$) δ: 30.30, 30.60, 30.80, 31.24, 31.34, 33.90, 33.98, 53.41, 71.62, 73.63, 124.49, 125.47, 126.11, 126.19, 133.12, 133.25, 133.54, 134.94, 145.45, 146.80, 151.23, 152.71, 171.56. Anal. calcd for $C_{52}H_{66}O_9$ (%): C 74.79, H 7.97; found: C 74.50, H 7.95.

Preparation of 1,2-alternate *p-tert*-butylcalix[4]arene-1,2-crown-3 diester (5)

Calix[4]arene-1,2-crown-3 (**2**) (6.00 g, 8.34 mmol) in 60 mL of THF was added dropwise to a mixture of KH (4.17 g, 40% in mineral oil, 41.7 mmol) in 60 mL of THF. After stirring for 2 h, ethyl bromoacetate (8.34 g, 50.04 mmol) was added and the reaction mixture was stirred for 3 days. The reaction was quenched by careful addition of dilute HCl. The mixture was washed with dilute HCl and water, dried over $MgSO_4$, and evaporated in vacuo. Chromatographic purification on silica gel with hexane–EtOAc (1:19) as eluent gave a white solid (3.60 g, 48%) with mp 205–206 °C. IR (deposit from CH_2Cl_2 solution on a NaCl plate, cm^{-1}) ν_{max}: 1760 (C=O), 1205 and 1132 (C–O). ^{1}H NMR ($CDCl_3$) δ: 1.09 (t, J = 7.0 Hz, 6H, SO_2CH_3), 1.31 (s, 18H, CH_3), 1.33 (s, 18H, CH_3), 2.48, (t, J = 10.0 Hz, 2H, OCH_2CH_2O), 3.15, (d, J = 12.5 Hz, 1H, $ArCH_2Ar$), 3.30–3.44 (m, 3H, $ArCH_2Ar$, OCH_2CH_2O), 3.53–3.65 (m, 6H, OCH_2CH_2O, OCH_2CO), 3.83 (d, J = 17.0 Hz, 2H, OCH_2CO), 3.89–4.04 (m, 6H, OCH_2CH_3, OCH_2CO), 4.07 (d, J = 16.5 Hz, 2H, $ArCH_2Ar$), 4.54 (d, J = 12.0 Hz, 1H, $ArCH_2Ar$), 4.77 (d, J = 13.5 Hz, 1H, $ArCH_2Ar$), 6.97 (d, J = 2.5 Hz, 2H, ArH), 7.07 (d, J = 2.0 Hz, 2H, ArH), 7.32 (d, J = 2.5 Hz, 2H, ArH), 7.42 (d, J = 2.0 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$) δ: 14.12, 29.20, 31.54, 31.58, 31.73, 34.07, 34.10, 39.14, 60.14, 69.37, 73.01, 74.43, 125.12, 125.43, 125.73, 125.89, 132.47, 133.06, 134.20, 135.24, 144.57, 145.57, 152.84, 152.96, 170.14. Anal. calcd for $C_{56}H_{74}O_9$ (%): C 75.47, H 8.37; found: C 75.50, H 8.06.

Preparation of 1,2-alternate *p-tert*-butylcalix[4]arene-1,2-crown-3 diacid (6)

The *p-tert*-butylcalix[4]arene-1,2-crown-3 diester (4.00 g, 4.07 mmol) in 150 mL of THF and 150 mL of 10% Me_4NOH was refluxed overnight. The solvent was evaporated in vacuo and the residue was dissolved in 200 mL of CH_2Cl_2. The organic layer was washed with 1 N HCl until pH 1 and then with brine (100 mL) and water (100 mL), dried over $MgSO_4$, and evaporated in vacuo to give a white solid (3.60 g, 96%) with mp > 300 °C. IR (deposit from CH_2Cl_2 solution on a NaCl plate, cm^{-1}) ν_{max}: 3391 (O–H), 1760 (C=O), 1207 and 1128 (C–O). ^{1}H NMR ($CDCl_3$) δ: 1.30 (s, 18H, CH_3), 1.33 (s, 18H, CH_3), 2.38, (t, J = 11.0 Hz, 2H, OCH_2CH_2O), 3.19, (d, J = 12.5 Hz, 1H, $ArCH_2Ar$), 3.24, (d, J = 13.0 Hz, 1H, $ArCH_2Ar$), 3.49, (t, J = 10.0 Hz, 2H, OCH_2CH_2O), 3.54–3.66 (m, 4H, OCH_2CH_2O), 3.85 (d, J = 17.5 Hz, 2H, $ArCH_2Ar$), 3.94 (t, J = 17.0 Hz, 2H, $ArCH_2Ar$), 4.09 (d, J = 15.5 Hz, 2H, OCH_2CO), 4.15 (d, J = 16.0 Hz, 2H, OCH_2CO), 4.55 (d, J = 12.0 Hz, 1H, $ArCH_2Ar$), 4.71 (d, J = 12.5 Hz, 1H, $ArCH_2Ar$), 6.98 (d, J = 2.0 Hz, 2H, ArH), 7.00 (d, J = 2.0 Hz, 2H, ArH), 7.34 (d, J = 2.5 Hz, 2H, ArH), 7.38 (d, J = 2.0 Hz, 2H, ArH). ^{13}C NMR ($CDCl_3$): 29.54, 31.40, 31.59, 34.13, 34.20, 38.98, 68.32, 72.80, 74.47, 124.40, 125.22, 125.57, 126.54, 131.40, 131.86, 134.18, 134.84, 146.49, 146.52, 151.45 152.13, 170.37. Preparation of cone *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 (7)

To a mixture of *p-tert*-butylcalix[4]arene (**4**) (23.00 g, 35.49 mmol), 2,2′-thiodiethanol (6.49 g, 53.24 mmol), and TPP (27.92 g, 106.47 mmol) in 600 mL of toluene, a 40% solution of DEAD (46.35 g, 106.47 mmol) in toluene was added dropwise and the mixture was stirred at room temperature for 3 h. After the reaction was complete the solution was evaporated to dryness and the residue was extracted with hexane (3 × 300 mL). After filtration, the solvent was evaporated in vacuo. Purification by chromatography on silica gel with hexane–EtOAc (49:1) as eluent gave a white solid (7.55 g, 29%) with mp 110–115 °C. IR (deposit from CH_2Cl_2 solution on a NaCl plate, cm^{-1}) ν_{max}: 3338 (O–H), 1247 (CO). ^{1}H NMR ($CDCl_3$) δ: 1.19 (s, 18H, CH_3), 1.21 (s, 18H, CH_3), 3.17–3.26 (m, 2H, OCH_2CH_2S), 3.29–3.41 (m, 6H, $ArCH_2Ar$, OCH_2CH_2S), 3.93 (t, J = 10.0 Hz, 2H, OCH_2CH_2S), 4.33 (d, J = 13.0 Hz, 2H, $ArCH_2Ar$), 4.35 (d, J = 13.5 Hz, 1H, $ArCH_2Ar$), 3.62–4.68 (m, 2H, OCH_2CH_2S), 5.05 (d, J = 12.0 Hz, 1H, v), 6.99 (d, J = 2.5 Hz, 2H, ArH), 7.01 (d, J = 2.5 Hz, 2H, ArH), 7.02 (d, J = 2.5 Hz, 2H, ArH), 7.14 (d, J = 2.5 Hz, 2H, ArH), ^{13}C NMR ($CDCl_3$) δ: 31.21, 31.28, 31.49, 32.68, 33.00, 33.90, 34.17, 36.90, 53.36, 125.28, 125.54, 125.90, 126.36, 128.78, 128.90, 133.57, 134.75, 142.92, 147.48, 149.04, 150.19. Anal. calcd for $C_{48}H_{62}O_4S$ (%): C 78.43, H 8.50; found: C 78.75, H 8.41.

Preparation of cone *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 diester (8)

p-tert-Butylcalix[4]arene-1,2-thiacrown-3 (**7**) (2.00 g, 2.72 mmol) in 40 mL of THF was added dropwise to a mixture of NaH (0.96 g, 8.16 mmol) in 40 mL of THF. After stirring for 2 h, ethyl bromoacetate (2.72 g, 16.32 mmol) was added and the reaction mixture was stirred overnight. The reaction mixture was monitored by TLC. The reaction was quenched with dilute HCl, washed with dilute HCl and water, dried over $MgSO_4$, and evaporated in vacuo. Chromatographic purification on silica gel with 3% EtOAc in hexanes gave a white solid (1.13 g, 46%) with mp 61–63 °C. IR (deposit from CH_2Cl_2 solution on a NaCl plate,cm^{-1}) ν_{max}: 1759 (C=O), 1248 and 1128 (C–O). ^{1}H NMR ($CDCl_3$) δ: 1.04 (s, 18H, CH_3), 1.12 (s, 18H, CH_3), 1.34 (t, J = 7.0 Hz, 6H, CH_2CH_3), 3.02–3.09 (m, 2H, OCH_2CH_2S), 3.12 (d, J = 12.5 Hz, 1H, $ArCH_2Ar$), 3.17 (d, J = 12.5 Hz, 2H, $ArCH_2Ar$), 3.25 (d, J = 12.5 Hz, 1H, $ArCH_2Ar$), 3.46–3.54

Results and discussion

Synthesis of calix[4]crown-3 conformers

The commonly employed method, which involves the reaction of *p-tert*-butylcalix[4]arene (**1**) and diethylene glycol ditosylate in the presence of strong base, failed to give *p-tert*-butylcalix[4]arene-1,2-crown-3 (**2**). Variations of the base, as well as elevating reaction temperature, were performed, but no detectable levels of compound **2** were found. Another entirely different method was utilized for the synthesis of compound **2** (Scheme 1). Under Mitsunobu reaction conditions, *p-tert*-butylcalix[4]arene (**4**) was treated with TPP and DEAD and reacted with diethylene glycol to form compound **2**. The reaction was quenched after 0.5 h and gave a 54% yield. Compared with the commonly used methods, the Mitsunobu reaction had a much shorter reaction time with a reasonable yield. Also, conversion of the diethylene glycol into diethylene glycol ditosylate was not necessary. Compound **2** was treated with sodium hydride in THF and reacted with ethyl bromoacetate at room temperature for 2 days to form *p-tert*-butylcalix[4]arene-1,2-crown-3 diester (**3**) in the cone conformation in 61% yield. The synthesis procedure is shown in Scheme 1. The resulting diester **3** was hydrolyzed with aqueous tetramethylammonium hydroxide in THF under reflux to give diacid **4** in 88% yield. Compound **2** was treated with KH in THF and reacted with ethyl bromoacetate at room temperature for 3 days to form *p-tert*-butylcalix[4]arene-1,2-crown-3 diester (**5**) in the 1,2-alternate conformation in 48% yield. The synthesis is depicted in Scheme 1. The resulting diester **5** was hydrolyzed with aqueous tetramethylammonium hydroxide in THF under reflux to give diacid **6** in 96% yield.

There were no peaks between 35–40 ppm in the ^{13}C NMR spectra for compound **4**, revealing that all four benzene rings have syn arrangements. In the ^{1}H NMR spectra for this compound, the bridging methylene protons are split into three pairs of doublets with an integration ratio of 1:2:1.

The ^{13}C NMR spectra for compound **6** showed peaks at both 31 and 38 ppm, revealing that the benzene rings have both syn and anti arrangements. In the ^{1}H NMR spectra for this compound, the bridging methylene protons are split into three pairs of doublets, with the integration ratio being 1:1:2.

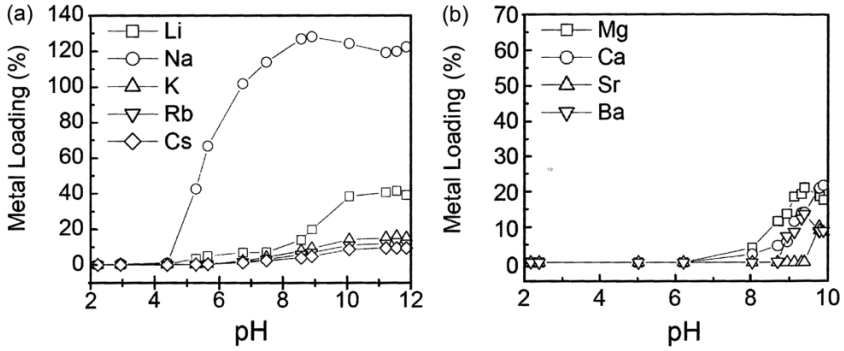

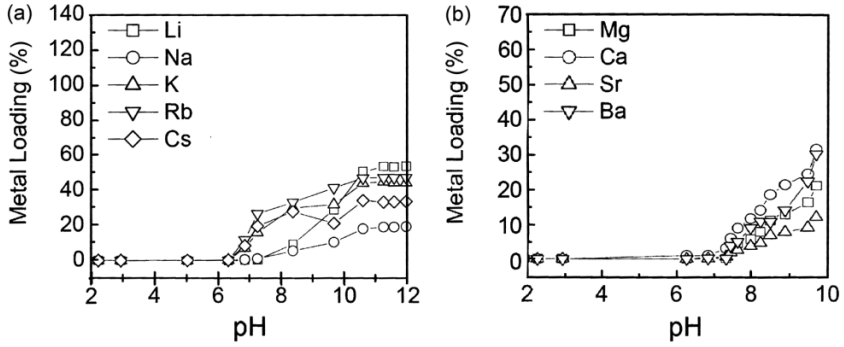

Fig. 2. Percentage of (*a*) metal loading vs. (*b*) equilibrium pH of the aqueous phase for competitive solvent extraction of alkali and alkaline earth metal ions into chloroform using conformer **6**.

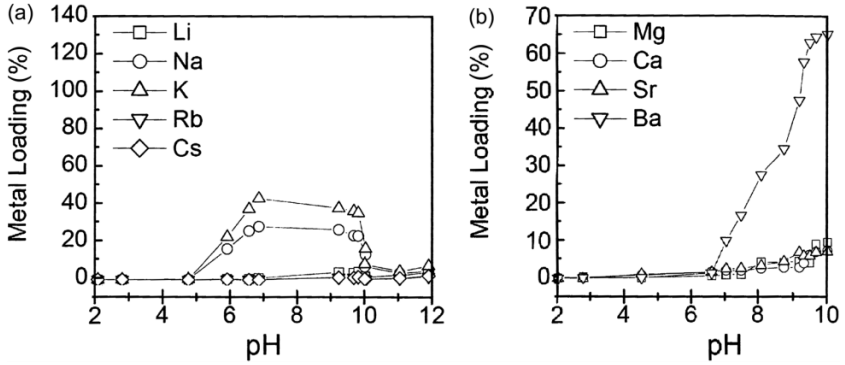
Synthesis of cone calix[4]thiacrown-3

The *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 (**7**) was synthesized following the method used for making compound **2** (Scheme 2). Under Mitsunobu reaction conditions, *p-tert*-butylcalix[4]arene (**1**) was treated with TPP and DEAD and reacted with 2,2′-thiodiethanol to form compound **7** in 29% yield.

Compound **7** was treated with sodium hydride in THF and reacted with ethyl bromoacetate at room temperature overnight to form *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 diester (**8**) in the cone conformation in 61% yield. The synthesis is presented in Scheme 2. The resulting diester **8** was hydrolyzed with aqueous tetramethylammonium hydroxide in THF under reflux to give diacid **9** in 91% yield.

There are no peaks at 35–40 ppm in the ^{13}C NMR spectra for compound **9**, revealing that all four benzene rings have syn arrangements. In the ^{1}H NMR spectra for this compound, the bridging methylene group protons are split into three pairs of doublets, with an integration ratio of 1:2:1.

Competitive solvent extractions by ligand 4



For competitive extraction of such metal cations, di-ionizable *p-tert*-butylcalix[4]arene-1,2-crown-3 ligand **4** exhibits very different selectivity from its *p-tert*-butylcalix[4]arene-1,2-crown-4 and -crown-5 analogues. All five alkali metal cations and four alkaline earth metal cations were detectably extracted into the chloroform phase and the selectivity order was $Na^+ > Li^+ > K^+ \approx Rb^+ \approx Cs^+$ and $Mg^{2+} > Ca^{2+} \approx Ba^{2+} > Sr^{2+}$ for ligand **4**, respectively. The pH for half loading ($pH_{1/2}$) is a measure of the acidity of the ligand. For compound **4**, the $pH_{1/2}$ value was 6 for binding to Na^+ and 9.6 for binding to Li^+, K^+, Rb^+, and Cs^+. The $pH_{1/2}$ values for binding to alkaline earth metal cations were determined to be in the range of 9–9.5. Figure 1 depicts the plots of metal ion loading of the organic phase vs. the equilibrium pH of the aqueous phase using ligands **4**.

Competitive solvent extractions by ligand 6

For competitive solvent extractions of aqueous alkali and

Fig. 3. Percentage of (*a*) metal loading vs. (*b*) equilibrium pH of the aqueous phase for competitive solvent extraction of alkali and alkaline earth metal ions into chloroform using conformer **9**.

alkaline earth metal cation (10.0 mmol/L in each) solutions by 1.0 mmol/L solutions of di-ionizable *p-tert*-butylcalix[4]arene-1,2-crown-3 ligand (**6**) in chloroform, plots of metal ion loading of the organic phase vs. the equilibrium pH of the aqueous phase are presented in Fig. 2.

For competitive extraction of alkali and alkaline earth metal cations, di-ionizable *p-tert*-butylcalix[4]arene-1,2-crown-3 ligand (**6**) exhibits versatile selectivities for alkali and alkaline earth metal ion species. All five alkali metal cations and four alkaline earth metal cations were detectably extracted into the chloroform phase. The selectivity order was $Li^+ > Rb^+ > K^+ > Cs^+ > Na^+$ and $Ca^{2+} > Ba^{2+} > Mg^{2+} > Sr^{2+}$ for ligand **6**, respectively. For compound **6**, the $pH_{1/2}$ value was 7 for binding to K^+, Rb^+, and Cs^+ and 9 for binding to Li^+ and Na^+. The $pH_{1/2}$ values for binding to alkaline earth metal cations were determined to be 8.5.

Competitive solvent extractions by ligand 9

Ligand **9** exhibited very different selectivity from its *p-tert*-butylcalix[4]arene-1,2-crown-3 analogues in cone and 1,2-alternate conformers. All five alkali metal cations and four alkaline earth metal cations were detectably extracted into the chloroform phase and the selectivity order was $K^+ > Na^+ >> Li^+ \approx Rb^+ \approx Cs^+$ and $Ba^{2+} >> Mg^{2+} \approx Ca^{2+} \approx Sr^{2+}$ for ligand **9**, respectively. The loading of K^+ and Na^+ passed through a maximum value and decreased to initial values, respectively. The peak points in the loading of K^+ and Na^+ by ligand **9** were determined to be 40% and 30%, respectively. These maximum loading conditions were observed in the pH range of 7–10. The $pH_{1/2}$ value was 6 for binding to Na^+ and K^+, whereas the other alkali metal cations (Li^+, Rb^+, and Cs^+) showed no loading. The $pH_{1/2}$ values for binding to alkaline earth metal cations were determined to be 9. Figure 3 shows the plots of metal ion loading of the organic phase vs. the equilibrium pH of the aqueous phase using ligands **9**.

Conclusions

1. Proton di-ionizable *p-tert*-butylcalix[4]arene-1,2-crown-3 conformers in the cone and the 1,2-alternate conformations, as well as a *p-tert*-butylcalix[4]arene-1,2-thiacrown-3 compound in the cone conformation, were synthesized as potential metal ion extractants.
2. The conformations and regio-selectivities of the new ligands were verified by ^1H and ^{13}C NMR spectroscopy, IR spectroscopy, and elemental analysis.
3. For each of the studied conformers, the average loading percentage for alkali metal cations were twice the loading percentage for alkaline earth metal cations.
4. Inserting the soft element of sulfur in the crown ether ring enhanced the loading percentage of soft cations (Ba^{2+}) dominantly.
5. Ligand **4** was selective to Na^+ at pH 8, ligand **6** was not selective to any cations at any pH points, and ligand **9** was selective for Ba^{2+} at pH 10.
6. The $pH_{1/2}$ values not only depended on the structures of the conformers but also were a function of the trapped cation.

Abstract: In this paper, the results obtained in the synthesis of thioamides and α-ketothioamides by a modification of the Willgerodt–Kindler reaction, under solvent-free and noncatalyst conditions using IR energy as a source of activation, are presented. The use of IR energy in these reactions has been shown to lead to a mixture of thioamide and α-ketothioamide as the main products in most cases, with the latter predominating. The yields of α-ketothioamides from most of these reactions are better than those reported previously. To the best of our knowledge, this is the first time that IR energy has been applied to promote the Willgerodt–Kindler reaction.

Key words: Willgerodt–Kindler modification, α-ketothioamides, solvent-less conditions, IR energy, noncatalyst.

Résumé : Dans ce travail, on rapporte les résultats obtenus lors de la synthèse de thioamides et de α-cétothioamides, par le biais d'une modification de la réaction de Willgerodt–Kindler dans des conditions qui n'impliquent aucun solvant et aucun catalyseur et qui utilisent l'énergie infrarouge comme source d'activation. On a démontré que l'utilisation de l'infrarouge dans ces réactions conduit, dans la plupart des cas, à des mélanges contenant comme produits principaux un thioamide et un α-cétothioamide et que ce dernier est prédominant. Les rendements en α-cétothioamides, pour la plupart des réactions, sont meilleurs que ceux rapportés antérieurement. Au meilleur de nos connaissances, c'est la première fois que l'énergie de l'infrarouge a été utilisée pour la promotion de la réaction de Willgerodt–Kindler.

Mots-clés : modification de la réaction de Willgerodt-Kindler, α-cétothioamides, conditions expérimentales sans solvant, énergie infrarouge, sans catalyseur.

[Traduit par la Rédaction]

Introduction

Thioamides are among the most extensively studied chalcogen-containing compounds. They are known to demonstrate biological activity,[1] are used as synthetic intermediates in organic chemistry,[2] have been found in natural products, and have many applications in materials science and industrial processes.[3] They are also employed as insecticides[4] because they are well tolerated by plants and have low toxicity in higher animals, and they are used in medical applications, for example, in tuberculosis treatment,[5] as painkillers,[6] and as antioxidants.[7]

Currently, it is possible to find several methods for the synthesis of thioamides, most of which employ Lawesson's reagent.[8] However, there are also publications concerning the Willgerodt–Kindler method for the generation of these compounds,[9] but this method has some limitations, i.e., long reaction times are required and low yields are achieved. This reaction is characterized by the use of alkyl aryl ketones or aldehydes, elemental sulfur, and amines, with morpholine being the most commonly used amine. When ketones are used in this methodology, the carbonyl group is reduced to a methylene group and the terminal methyl group is oxidized to a thiocarbonyl group (**I**, Scheme 1).

Previous studies using thermal energy for the activation of reactions have yielded some unexpected results, with the most common problem being the failure to reduce the carbonyl group in the alkyl aryl ketone used, leading to the formation of the α-ketothioamide **II** as a reaction byproduct. Dauben and Rogan,[10] Harris et al.[11] Harrowven and Lucas,[12] and Liu et al.[13] encountered this problem and generated **II** in yields of 3%–20% when using reaction times of 8–24 h. In

Scheme 1. General reaction conditions for the synthesis of thioamides. Dauben and Rogan:[10] Acetophenone (2.0 g, 12.3 mmol), elemental sulfur (0.40 g, 12.3 mmol), morpholine (1.08 g, 12.3 mmol); R_1 = Me, R_2 = Me, R_3 = H, R_4 = Me; yield (**II**) = 20%; 8 h. Harris et al.:[11] Acetophenone (5.0 g, 20.4 mmol), elemental sulfur (1.0 g, 31.25 mmol), morpholine (2.82 g, 32.4 mmol); R_1 = OC_6H_5, R_2 = H, R_3 = Cl, R_4 = H; yield (**I**) = 46%, **II** not isolated; 20 h. Harrowven and Lucas:[12] Acetophenone (23.3 g, 142 mmol), elemental sulfur (6.8 g, 213 mmol), morpholine (18.5 g, 213 mmol); R_1 = OMe, R_2 = Me, R_3 = H, R_4 = H; yield (**I**) = 57%, yield (**II**) = 10%; 24 h. Liu et al.:[13] Acetophenone (12.2 g, 100 mmol), elemental sulfur (4.8 g, 150 mmol), morpholine (11.3 g, 130 mmol); R_1 = R_2 = R_3 = R_4 = H; yield (**I**) = 66%, yield (**II**) = 3%; 20 h.

these reports, the reactions were performed at reflux, in the absence of solvent, employing acetophenones, elemental sulfur, and morpholine. However, the methodology developed in these studies cannot be considered to be a general synthetic route to α-ketothioamides **II**, because this unexpected product of the Willgerodt–Kindler reaction was only generated in isolated cases.

Other published routes to α-ketothioamides have employed α-chloroketones,[14] α-oxonitryl,[15] thioacetomorpholides,[16] pinacolone (3,3-dimethyl-2-butanone),[17] α-chlorosulfonyl and trisulfane intermediates,[18] or *N*,*N*-(dialkyl)aroylmethylamines.[19] However, like the Willgerodt–Kindler reaction, these methodologies are not general for the synthesis of α-ketothioamides. The reaction conditions employed are also dangerous or require expensive reagents and long reaction times. In general, thermal energy is used as the activation source for the Willgerodt–Kindler reaction. The use of alternative energy sources such as ultrasound[20] and microwaves[21] has recently been explored, and microwave activation has attracted particular attention. To the best of our knowledge, however, the use of IR energy as an activation source for the Willgerodt–Kindler reaction has not yet been reported. IR energy has been demonstrated to be useful in organic synthesis,[22] and has been used in the synthesis of 1,3,5-trioxanes from aldehydes,[23] in the Biginelli[24] and Knoevenagel[25] reactions, and for the synthesis of diindolylmethanes[26] and 3,4-dihydro-2(1*H*)-pyridones.[27] When investigating the synthesis of ε-caprolactam from cyclohexanone and hydroxylamine using bentonic clay under solvent-less conditions, we explored the use of several energy sources for activation of the reaction and found that IR energy performed better than thermal, microwave, or ultrasound energies.[28]

Results and discussion

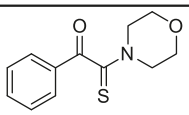
We set out to explore the use of IR energy for the activation of the Willgerodt–Kindler reaction, employing acetophenone, elemental sulfur, and morpholine. After extensive experimentation, we found that a stoichiometric ratio for the starting materials of 1:1:1, solvent-less conditions, and irradiation with IR energy at a wavelength of 1100 nm (near-IR) for 1 h at 100 °C[29] were optimal conditions for the generation of the corresponding α-ketothioamide. In this way, the desired product was obtained exclusively in 56% yield.

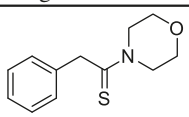
This result encouraged us to study the reaction using other acetophenones and amines, to establish this method as a general route to synthesize α-ketothioamides **3** (Scheme 2).

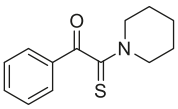
We found that, under these conditions, this reaction ensured that the α-ketothioamides **3a**–**3h** (Table 1) were generated as the main products in most cases, and the yields were higher than those obtained (3%–20%) by other synthetic methods previously reported in the literature. The Willgerodt–Kindler products **4a**–**4h** were also detected in yields ranging from 0%–42% as a second product. Thus, with the methodology employed in this work, the outcome of the Willgerodt–Kindler reaction can be regarded as unclassical.

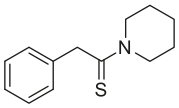
The products **3a**–**3h** were obtained in yields close to or higher than 50%, although when 2-methylpiperidine was used as the amine, a yield of only 20% was obtained, which may be attributed to steric factors. In entries 1–5 of Table 1, the products were synthesized from unsubstituted acetophenone, and the amine used was either morpholine, piperidine, or methylated regioisomers of the latter.

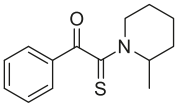
When the reaction was carried out with *p*-chloroacetophenone, a crystalline product was formed, and a single crystal could be used for X-ray diffraction study[30] (Fig. 1).

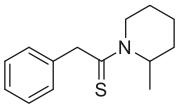


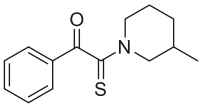


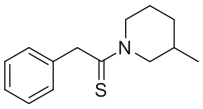


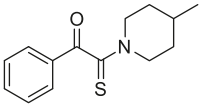


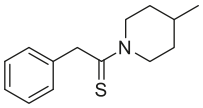


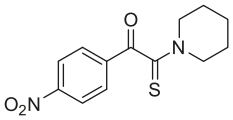


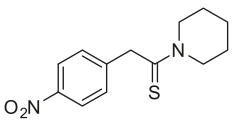


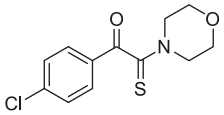


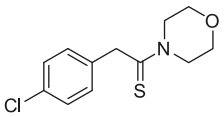


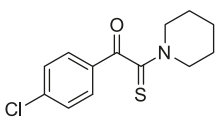


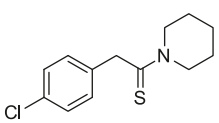












It is important to mention that the low yields of **3** shown in entries 7 and 8 in Table 1 were due to a competitive S_NAr reaction resulting in the formation of *p*-morpholino- or *p*-(1-piperidinyl)acetophenone[31] in yields of 20% and 19%, respectively, along with the corresponding thioamides from the Willgerodt–Kindler reaction, compounds **4g** and **4h** (Scheme 2; Table 1).

We also studied the reactions leading to the synthesis of **3a**–**3h** at room temperature, to determine the influence of temperature and energy source on their outcomes. The reactions were monitored for 48 h by TLC, and the conversion percentages were measured by gas chromatography coupled with mass spectrometry (Table 2). More than 50% of the acetophenone remained unreacted in some cases (Table 2, entries 7 and 8), and the behavior of these reactions was similar when IR energy was used. These results clearly demonstrated that the reactions proceeded better when activated with IR energy than when conducted at room temperature, and established the importance of IR energy in the synthesis of α-ketothioamides **3**. The formation of **4a**–**4h** was detected and the results are summarized in Table 2.

To compare the use of thermal conditions and IR energy for the synthesis of α-ketothioamides, we performed the reactions to obtain **3a** and **3b** under reflux conditions. After 5 h of reaction, with hourly monitoring by TLC, no formation of the corresponding α-ketothioamides could be detected. This behavior is consistent with the reported results by Liu et al.[13] for the reaction employing acetophenone, elemental sulfur, and morpholine at reflux temperature (83–85 °C), whereby **3** was obtained in just 3% yield after 20 h of reaction. In contrast, in the present study, the same compound (Table 1, entry 1) was obtained in 56% yield in a reaction time of 1 h. Moreover, Carmack et al.[32] reported similar reaction conditions to those used in the present paper (100 °C, elemental sulfur, morpholine, and solvent-less conditions) for

the reaction of linear and cyclic aliphatic ketones, using thermal energy, and obtained only the Willgerodt–Kindler product and carbonyl group isomerization products. Considering all of these results, it is proposed that IR energy is responsible for the synthesis of **3** as the principal product, and not the thermal heating that comes from the lamp employed in this work (see the Supplementary data).

The use of IR energy gives very efficient heat transfer similar

to that provided by microwave irradiation because both are electromagnetic waves and the behavior is comparable. The main effect produced by IR energy is thus an overheating in the reaction mixture that favors the formation of **3**. Mechanistically, we are in agreement with the reaction mechanism proposed by Darabi et al.[33]

Conclusion

In summary, we have described a new methodology for the synthesis of α-ketothioamides as the principal products, employing a multicomponent reaction activated by IR energy under solvent-less conditions. As far as we are aware, this is the first report of the use of IR energy for activation of the Willgerodt–Kindler reaction. We have established the utility of this method for the generation of α-ketothioamides, a reaction that could not previously be reliably accomplished by the Willgerodt–Kindler protocol when thermal energy was used. In all cases reported in this study, the α-ketothioamides were produced in yields ranging from moderate to good, depending on the substituents on the acetophenone aromatic ring.

This new methodology can be considered as a useful addition to the synthetic organic chemistry tool kit, as, to the best of our knowledge, no method has hitherto been reported to give α-ketothioamides in a one-pot reaction in yields better than those reported here.

Experimental section

General

All reagents were from Sigma-Aldrich and used from its commercial presentation, ^{1}H and ^{13}C NMR spectra were recorded by use of $CDCl_3$ or acetone-d_6 in Varian Mercury 200 and 300 MHz instruments, chemical shifts were reported in ppm from TMS with the solvent resonance as the internal standard, and coupling constants (*J*) are given in hertz, where s was assigned to single, d for doublet, t for triplet, m for multiple, and br for broad signals. The GC–MS analyses were conducted with gas chromatograph model 6850 and mass spectrometer 5975C by Agilent Technologies, employing a J&W HP-5MS capillary column. GC conditions: capillary column (30 m × 0.25 mm i.d., 0.25 μm film), helium as carrier gas at a constant flow velocity of 35 cm/s, and injector temperature 250 °C. MS data were reported as *m/z* (relative intensity). HRMS were recorded in an MStation JMS-700 JEOL at 70 eV. Melting points were obtained on a Fisher-Johns apparatus and are uncorrected. Analytical TLC was performed using Kieselgel 60 F_{254} silica gel plates (Merck, Darmstadt, Germany). A Buchi pump controller C-610 and a Buchi pump module C-601 were employed for flash chromatography. Elemental analyses were carried out with an Elementar Vario EL III element analyser.

IR equipment

The equipment used for irradiation with IR energy was created by employing an empty cylindrical metal vessel in which an Osram lamp (bulb model Thera-Therm, 250 W, 125 V) was inserted. This lamp is special short-wave IR lamp (IR-A) for use in body care and wellness applications, with a maximum radiation at a wavelength of about 1100 nm. The lamp instantly emits a full thermal output as soon as it is switched on. For controlling the temperature, a Digi-Sense variable-time power controller was used. This time controller turned the output load on and off and then repeated the cycle.

Typical procedure for the Willgerodt–Kindler reaction employing IR energy

For the synthesis of **3a**, the following were placed in a tube: acetophenone **1a** (100 mg, 0.83 mmol), elemental sulfur (27 mg, 0.83 mmol), and amine **2a** (73 mg, 0.83 mmol). This tube was then sealed and placed inside of the IR equipment at 3–5 cm above the IR lamp. The reaction mixture was irradiated at a wavelength of 1100 nm with IR energy at 100 °C for the appropriate time (30–150 min according to Table 1) and monitored using TLC. The products obtained as brown dark oils were purified using preparative plates or flash chromatography with silica gel as a stationary phase and a mixture of hexane – ethyl acetate as a mobile phase;

[a]Percentage of conversion was measured by GC–MS.
[b]Unreacted raw material.

recrystallization processes were not necessary and pure products were characterized by ^{1}H and ^{13}C NMR and mass spectrometry. Syntheses of **3b**–**3h** were carried out with the same procedure. Products **4a**–**4h** were isolated and characterized from the mixture of the reactions for the synthesis of **3a**–**3h**.

Typical procedure for the Willgerodt–Kindler reaction at room temperature

For the formation of **3a**, elemental sulfur (184 mg, 5.7 mmol) was added to 500 mg (5.7 mmol) of amine **2a**, the reaction mixture was stirred for 2 h until the sulfur was completely dissolved in the amine, and then acetophenone **1a** (690 mg, 5.7 mmol) was added to the amine–sulfur mixture and stirred at room temperature for 48 h. The reaction was monitored by TLC and the conversion rates were determined by GC–MS. Compounds **3b**–**3h** were obtained, replacing the corresponding acetophenones **1a**–**1c** and amines **2a**–**2e** following the typical procedure for **3a**.

2-Morpholino-1-phenyl-2-thioxoethanone (3a)[13,14,16]

Yield: 109 mg (56%); pale yellow solid, mp 107–109 °C. R_f (70% Hex/AcOEt): 0.42. ^{1}H NMR (200 MHz, $CDCl_3$, Me_4Si) δ_H: 8.01–7.97 (2H, m), 7.34–7.31 (3H, m), 4.37–4.33 (1H, t, J = 9.8 Hz), 3.76–3.71 (1H, t, J = 9.8 Hz), 3.65–3.60 (1H, t, J = 9.6 Hz), 3.40–3.35 (1H, t, J = 9.6 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ_C: 199.9 (C=S), 187.8 (C=O), 135.7, 128.9, 127.7, 127.1, 66.3, 50.7, 50.5, 50.1. MS (EI) m/z: 235 ($M^{+\bullet}$, 15%), 221 (100), 130 (35), 105 (5). HRMS-EI calcd for $C_{12}H_{13}O_2NS$: 235.0667; found: 235.0655.

1-Phenyl-2-(piperidin-1-yl)-2-thioxoethanone (3b)[14,19]

Yield: 97 mg (50%); pale yellow solid, mp 53–55 °C. R_f (90% Hex/AcOEt, eluted twice): 0.48. IR (KBr, cm^{-1}): 2944, 2862, 1666, 1590. ^{1}H NMR (300 MHz, $CDCl_3$, Me_4Si) δ_H: 7.99–7.96 (1H, m), 7.62–7.56 (2H, m), 7.50–7.44 (2H, m), 4.25–4.22 (2H, m), 3.54–3.50 (2H, m), 2.16 (2H, s), 1.82–1.73 (2H, br), 1.62–1.60 (2H, br). ^{13}C NMR (75 MHz, $CDCl_3$) δ_C: 194.2 (C=S), 187.9 (C=O), 134.1, 133.2, 129.6, 128.7, 52.9, 48.0, 26.3, 25.2, 23.9. 1-(4-Nitrophenyl)-2-(piperidin-1-yl)-2-thioxoethanone (3f)

Yield: 91 mg (54%); yellow solid, mp 123–125 °C. R_f (66% Hex/acetone): 0.46. ^{1}H NMR (300 MHz, $CDCl_3$, Me_4Si) δ_H: 7.77–7.74 (2H, m), 6.62–6.59 (2H, m), 4.43 (2H, m), 4.23 (2H, m), 3.53 (2H, m), 1.77 (2H, br), 1.74 (2H, br). ^{13}C NMR (75 MHz, $CDCl_3$) δ_C: 195.5 (C=S), 187.7 (C=O), 152.6, 132.5, 122.8, 113.9, 53.0, 48.2, 26.5, 25.4, 24.1. MS (EI) m/z: 278 ($M^{+\bullet}$, 48%), 150 (6), 128 (100), 84 (96). Anal. calcd for $C_{13}H_{14}N_2O_3S$ (278.3): C 56.10, H 5.07, N 10.06; found: C 60.49, H 6.19, N 10.23.

1-(4-Chlorophenyl)-2-morpholino-2-thioxoethanone (3g)[16]

Yield: 33 mg (19%); yellow solid, mp 150–152 °C. R_f (73% Hex/AcOEt): 0.25. ^{1}H NMR (300 MHz, $CDCl_3$, Me_4Si) δ_H: 7.94–7.91 (2H, d, J = 8.7 Hz), 7.48–7.45 (2H, d, J = 9 Hz), 4.33–4.30 (1H, t, J = 9.9 Hz), 3.91–3.88 (1H, t, J = 9.9 Hz), 3.71–3.68 (1H, t, J = 9 Hz), 3.60–3.57 (1H, t, J = 9.3 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ_C: 194.8 (C=S), 186.3 (C=O), 140.9, 131.1, 129.2, 125.7, 66.4, 66.3, 51.9, 47.1. MS (EI) *m/z*: 269 ($M^{+\bullet}$, 12%), 139 (33), 130 (100), 86 (76). Anal. calcd for $C_{12}H_{12}ClNO_2S$ (269.7): C 53.43, H 4.48, N 5.19; found: C 53.33, H 5.47, N 4.35.

1-(4-Chlorophenyl)-2-(piperidin-1-yl)-2-thioxoethanone (3h)[19]

Yield: 21 mg (12%); yellow solid, 120–122 °C. R_f (70% Hex/AcOEt): 0.18. IR (KBr, cm^{-1}): 2949, 2858, 1665, 1586. ^{1}H NMR (300 MHz, acetone-d_6, Me_4Si) δ_H: 8.00–7.97 (2H, d, J = 9 Hz), 7.61–7.58 (2H, d, J = 8.7 Hz), 4.26 (2H, m), 3.63–3.59 (2H, t, J = 11.4 Hz), 2 (2H, m) 1.81–1.77 (2H, m) 1.62 (2H, m). ^{13}C NMR (75 MHz, acetone-d_6) δ_C: 194.0 (C=S), 186.9 (C=O), 140.5, 133.3, 132.0, 129.9, 53.5, 48.4, 27.2, 25.9, 24.5. MS (EI) *m/z*: 267 ($M^{+\bullet}$, 30%), 138 (17), 128 (36), 84 (100). Anal. calcd for $C_{13}H_{14}ClNO_2S$ (267.7): C 58.31, H 5.27, N 5.23; found: C 58.20, H 7.26, N 2.91.

2-Phenyl-1-(piperidin-1-yl)ethanethione (4b)

Yield: 72 mg (39%); pale yellow solid, mp 55–57 °C. R_f (90% Hex/AcOEt, eluted twice): 0.51. ^{1}H NMR (300 MHz, $CDCl_3$, Me_4Si) δ_H: 7.33–7.18 (5H, m), 4.32 (2H, s), 4.26–4.23 (2H, m, J = 10.5 Hz), 3.57–3.53 (2H, m, J = 11.1 Hz), 2.02–1.97 (2H, bs), 1.64–1.61 (2H, m), 1.30–1.26 (2H, m). ^{13}C NMR (75 MHz, $CDCl_3$) δ_C: 198.1, 136.0, 128.7, 127.7, 126.7, 51.5, 50.9, 26.1, 25.1, 23.7. MS (EI) *m/z*: 219 ($M^{+\bullet}$, 100%), 128 (75), 91 (80). Anal. calcd for $C_{13}H_{17}NS$ (219.3): C 71.18, H 7.81, N 6.39; found: C 64.47, H 7.01, N 6.34.

2-(4-Chlorophenyl)-1-morpholinoethanethione (4g)

Yield: 69 mg (42%); yellow solid, mp 125–127 °C. R_f (73% Hex/AcOEt): 0.31. ^{1}H NMR (300 MHz, $CDCl_3$, Me_4Si) δ_H: 7.30–7.23 (5H, m), 4.34–4.31 (1H, t, J = 9.9 Hz), 4.28 (2H, s), 3.74–3.71 (1H, t, J = 9.9 Hz), 3.61–3.58 (1H, t, J = 9.6 Hz), 3.43–3.40 (1H, t, J = 9.9 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ_C: 199.2, 134.1, 132.8, 129.1, 129.0, 66.2, 66.0, 50.6, 50.0, 49.6. MS (EI) *m/z*: 255 ($M^{+\bullet}$, 100%), 130 (55), 125 (35). Anal. calcd for $C_{12}H_{14}ClNOS$ (255.7): C 56.35, H 5.52, N 5.48; found: C 57.07, H 6.33, N 4.75.

M[P(1,2-$O_2C_6H_4)_3$] (M = K or Na) — Synthesis, characterization, and use in halide abstraction

Paul W. Siu and Derek P. Gates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

Abstract: Alkali metal salts of the tris(*o*-phenylenedioxy)phosphate anion, K[P(1,2-$O_2C_6H_4)_3$] (K[**1**]) and Na[P(1,2-$O_2C_6H_4)_3$] (Na[**1**]), were prepared by treating Et_3NH[**1**] with KH or NaH, respectively. X-ray crystallographic analysis of K[**1**], crystallized in the presence of DMSO, revealed a dimeric structure of formulation $K_2(DMSO)_6$[**1**]$_2$·C_7H_8. In contrast, the crystal structure of K[**1**] grown from MeCN consists of fascinating hexagonal macrocycles with formulation {K$(MeCN)_2$[**1**]}$_6$ with an outside diameter of about 25 Å and a very small hole (≤2.5 Å). Remarkably, these hexagonal macrocycles stack one upon the other with a spacing of about 9.4 Å. The salt, K[**1**], is an effective halide abstraction agent reacting with (dppp)$PdCl_2$ (dppp = 1,3-bis(diphenylphosphino)propane) (1:1 ratio) or [(cod)RhCl]$_2$ (2:1 ratio) to afford [(dppp)Pd(μ-Cl)]$_2$[**1**]$_2$ and (cod)Rh[**1**], respectively. The molecular structures of each complex were determined.

Key words: anions, phosphorus, palladium, rhodium, macrocycles.

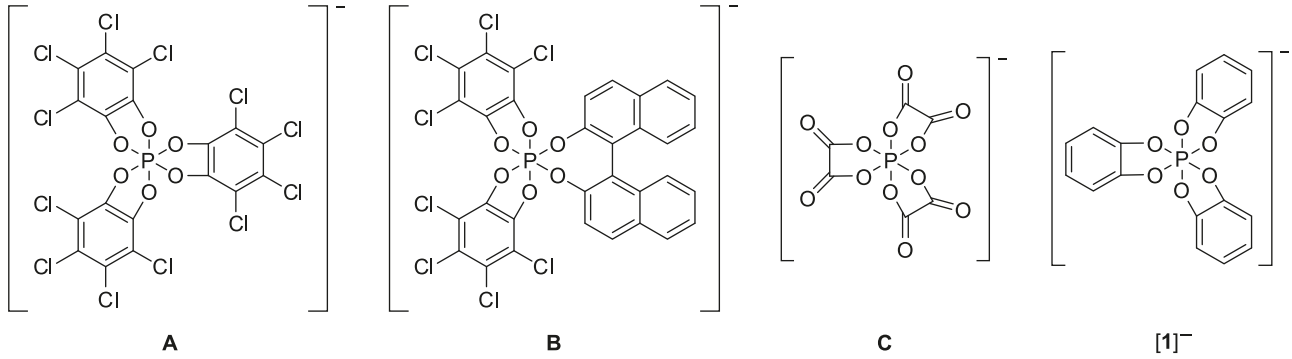
Résumé : On a préparé les sels de sodium et de potassium de l'anion tris(*o*-phénylènedioxy)phosphate, K[P(1,2-$O_2C_6H_4)_3$] (K[**1**]) et Na[P(1,2-$O_2C_6H_4)_3$] (Na[**1**]) par traitement du produit Et_3NH[**1**] respectivement avec du KH ou du NaH. Le composé K[**1**] recristallisé à partir du DMSO a fait l'objet d'une étude par diffraction des rayons-X et l'analyse des données révèle qu'il existe sous une structure dimère de formule $K_2(DMSO)_6$[**1**]$_2$·C_7H_8. Toutefois, la structure cristalline du composé K[**1**] obtenu par recristallisation à partir de l'acétonitrile est formée de macrocycles hexagonaux fascinants de formule {K$(MeCN)_2$[**1**]}$_6$ de diamètres extérieurs d'environ 25 Å et un très petit trou (≤2,5 Å). Il est remarquable que les macrocycles hexagonaux s'empilent les uns sur les autres avec un espacement de 9,4 Å. Le sel K[**1**] est un agent très efficace pour enlever des halogènes; il réagit avec le (dppp)$PdCl_2$ (dppp = 1,3-bis(disphénylphosphino)propane) (rapport de 1 :1) ou le [(cod)RhCl]$_2$ (rapport de 2 : 1) pour conduire à la formation respectivement de [(dppp)P(μ-Cl)]$_2$[**1**]$_2$ et de (cod)Rh[**1**]. On a déterminé les structures moléculaires de chaque complexe.

Mots-clés : anions, phosphore, palladium, rhodium, macrocycles.

[Traduit par la Rédaction]

Introduction

The development and investigation of hexacoordinate compounds of phosphorus is an area of widespread fundamental interest. Although such species can be cationic or neutral depending on the nature of the substituents,[1–3] by far the most prevalent are anionic species of the form $[PX_6]^-$, led by $[PF_6]^-$ and $[PCl_6]^-$. Within this subclass, the family of chiral hexacoordinate phosphorus(V)-based anions bearing chelating dianionic ligands such as tris(tetrachlorobenzenediolato) phosphate (TRISPHAT, **A**),[4a] bis(tetrachlorobenzenediolato) mono([1,1′]-binaphthalenyl-2,2′-diolato)phosphate (BINPHAT, **B**),[4b] and tris(oxalato)phosphate (TOP, **C**)[4c] (Chart 1) are of considerable interest.[5] Of these, perhaps the most widely studied is TRISPHAT (**A** in Chart 1),[6] which can be resolved into pure enantiomers and is employed in NMR enantiodifferentiation and resolution of chiral cations.[7,8] Interestingly, the non-halogenated tris(*o*-phenylenedioxy)phosphate anion, [**1**]$^-$, which was the first example of a hexacoordinate organophosphate anion,[9–11] cannot be resolved into pure enantiomers due to acid-catalyzed, one-ended dissociation leading to pseudorotation and racemization.[12] This parent system has received limited attention with the exception of some electrochemical studies of Li[**1**] pertaining to applications in lithium batteries,[13–15]



We have been interested in using [**1**]$^-$ as an anion for the stabilization of highly reactive cations and have synthesized and isolated Brønsted acids of [**1**]$^-$, namely $H(DMSO)_2$[**1**] and $H(DMF)_2$[**1**].[16] These compounds are attractive because of their simple and convenient synthesis from cheap and readily available starting materials and their potential utility in the generation of reactive cations in the presence of [**1**]$^-$, a relatively weakly coordinating anion. Indeed, we have shown that $H(DMF)_2$[**1**] may be utilized to protonate metal–alkyl bonds, a key step in the generation of numerous active catalyst species.[17–19] Based upon our investigation of the IR stretching frequencies of the ammonium salts, the coordination ability of [**1**]$^-$ should be comparable to that of $[BF_4]^-$.[16] Therefore, we hypothesized that alkali metal salts of [**1**]$^-$ may be of interest as halide abstracting reagents to generate reactive cations. Although the Li^+ salt of [**1**]$^-$ has been prepared,[15] the heavier alkali salts of [**1**]$^-$ have not been reported.

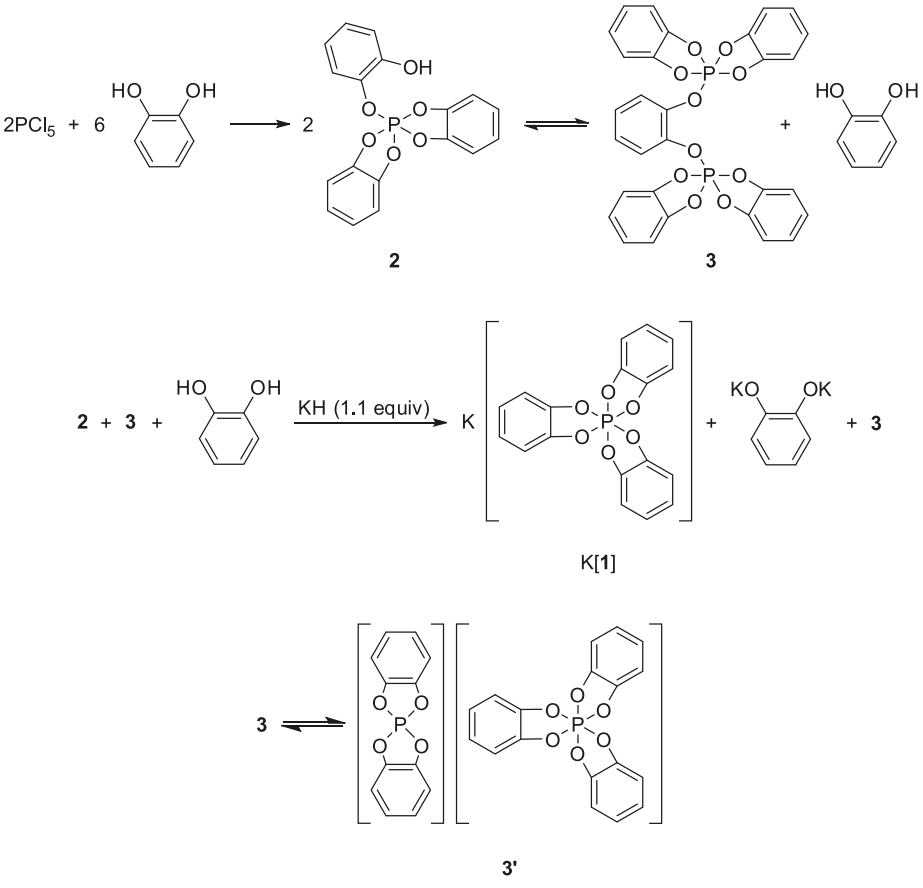

Chart 1. Selected samples of chiral hexacoordinate phosphorus(V)-based anions.

Herein, we report the synthesis and characterization of sodium and potassium salts of the anion [**1**]⁻ and our preliminary investigations of their use as halide abstracting reagents. The molecular structures of four new compounds containing [**1**]⁻ are reported: $K_2(DMSO)_6[\mathbf{1}]_2 \cdot C_7H_8$, $\{K(MeCN)_2[\mathbf{1}]\}_6$, $[(dppp)Pd(\mu\text{-}Cl)]_2[\mathbf{1}]_2$ (dppp = 1,3-bis(diphenylphosphino) propane), and (cod)Rh[**1**].

Discussion

It is well-established that the reaction of phosphorus(V) chloride with catechol (3 equiv) affords a mixture of **2** and **3**.[20] The salt Li[**1**] has previously been prepared by treating this mixture with *n*-BuLi.[14,15] Since *n*-BuK is not readily available, we attempted to prepare K[**1**] by treating a mixture of **2** and **3** in THF with potassium hydride (1.1 equiv). The ^{31}P NMR spectrum of the reaction mixture exhibits signals assigned to starting material **3** ($\delta = -27$)[20,21] and to a product with a chemical shift consistent with the [**1**]⁻ anion ($\delta = -83$),[15,16,22–25] tentatively assigned to K[**1**]. Interestingly, upon isolation and redissolution of the crude product in DMSO-d_6 the ^{31}P NMR spectrum showed signals at 13 and –83 ppm, suggesting the formation of the known **3′**.[20] Unfortunately, we have been unable to isolate pure K[**1**] from this mixture.

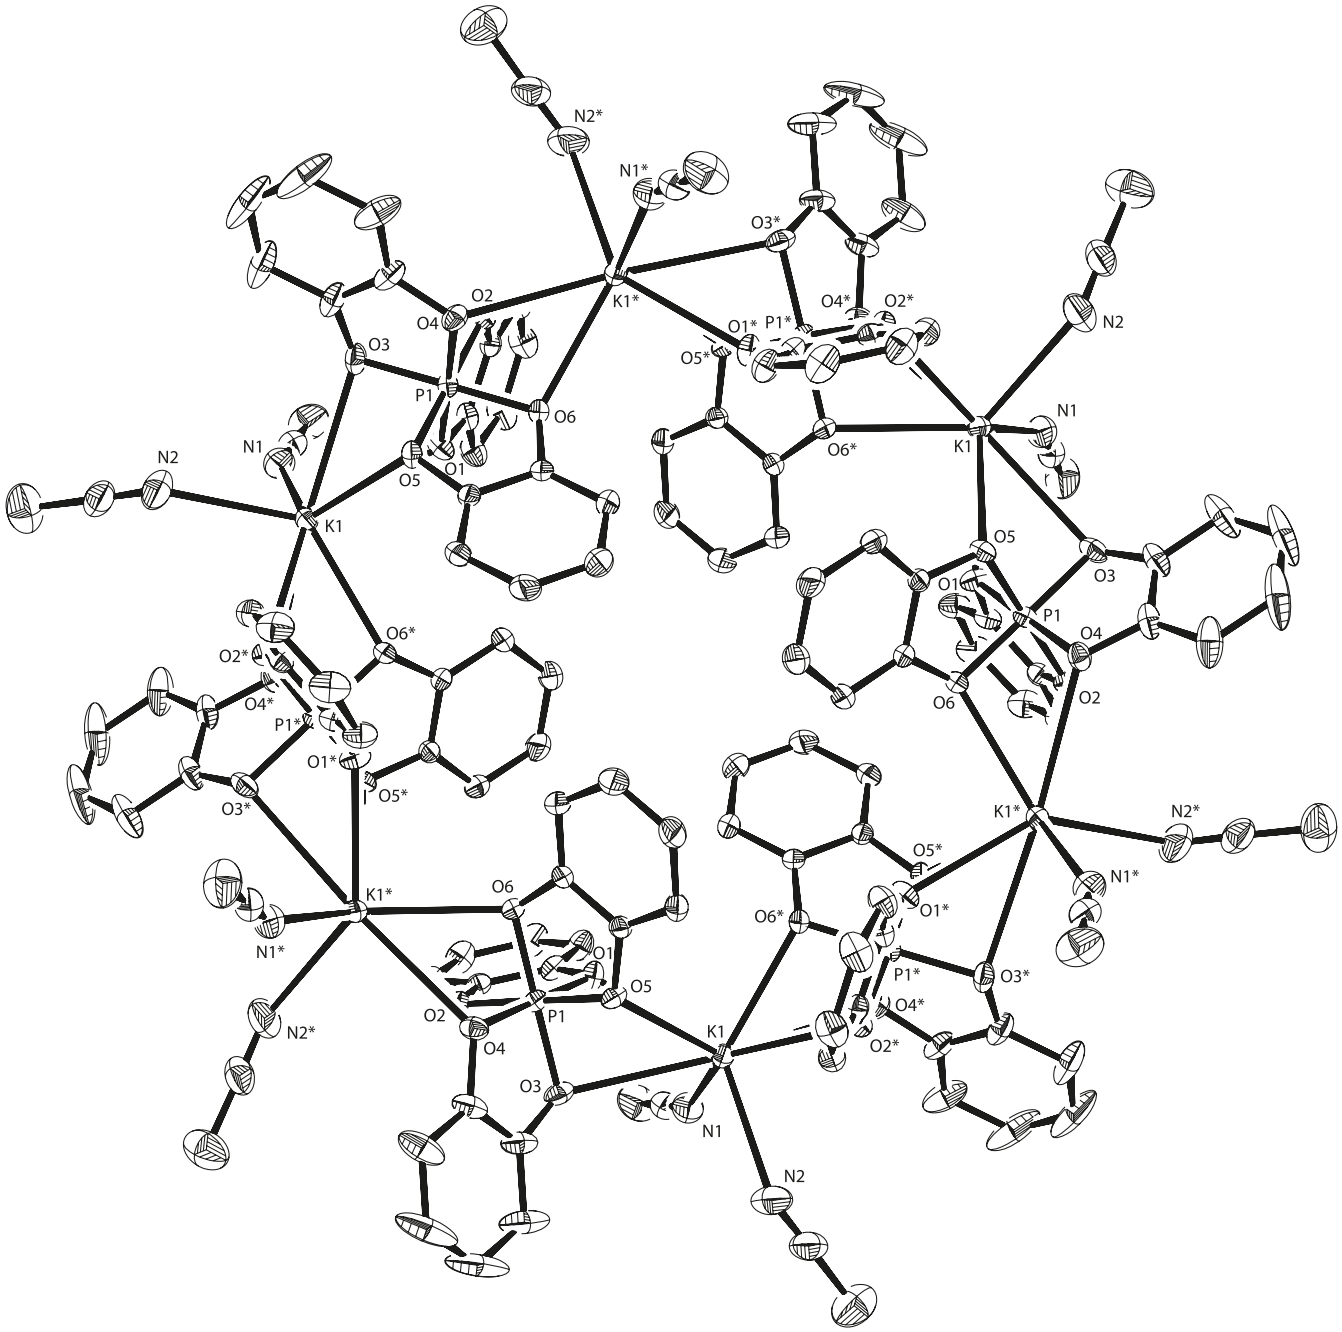
Fig. 1. Molecular structure of the Δ,Δ-$K_2(DMSO)_6[\mathbf{1}]_2$ (50% probability ellipsoids, the Λ,Λ-isomer is not shown). All hydrogen atoms and the solvent of crystallization (C_7H_8) are omitted for clarity. Selected bond lengths (Å): P(1)–O(1) = 1.714(1); P(1)–O(2) = 1.722(1); P(1)–O(3) = 1.707(1); P(1)–O(4) = 1.721(1); P(1)–O(5) = 1.708(1); P(1)–O(6) = 1.717(1); P(2)–O(7) = 1.710(1); P(2)–O(8) = 1.718(1); P(2)–O(9) = 1.708(1); P(2)–O(10) = 1.715(1); P(2)–O(11) = 1.708(1); P(2)–O(12) = 1.735(1); K(1)–O(2) = 2.876(1); K(1)–O(4) = 2.846(1); K(1)–O(6) = 2.801(1); K(1)–O(13) = 2.696(2); K(1)–O(14) = 2.666(2); K(1)–O(15A) = 2.766(5); K(1)–O(16A) = 2.779(7); K(2)–O(8) = 2.754(1); K(2)–O(10) = 2.965(1); K(2)–O(12) = 2.887(1); K(2)–O(13) = 2.678(2); K(2)–O(14) = 2.681(2); K(2)–O(17) = 2.670(2); K(2)–O(18A) = 2.729(8). Selected bond angles (°): O(1)–P(1)–O(2) = 90.88(6); O(3)–P(1)–O(4) = 91.04(6); O(5)–P(1)–O(6) = 90.67(6); O(7)–P(2)–O(8) = 90.51(6); O(9)–P(2)–O(10) = 91.44(6); O(11)–P(2)–O(12) = 90.76(6).



As an alternate strategy to synthesize K[**1**], the deprotonation of the known ammonium salt Et_3NH[**1**][9–11] with a slurry of KH (1.1 equiv) in acetonitrile was attempted. After workup, the desired product (K[**1**]) was obtained as a white solid. Characterization by ^{31}P NMR spectroscopy in CD_2Cl_2 revealed a singlet resonance at –86.1 ppm, consistent with the presence of the [**1**]$^-$ anion. The ^1H and $^{13}C\{^1H\}$ NMR spectra show only signals in the aromatic region as expected for K[**1**]. In particular, three signals are observed in the $^{13}C\{^1H\}$ NMR spectrum, which is consistent with the symmetrical [**1**]$^-$ anion. Satisfactory elemental microanalysis was obtained for K[**1**]. Following an analogous procedure, the sodium salt (Na[**1**]) was prepared and characterized by ^{31}P, ^1H, and $^{13}C\{^1H\}$ NMR spectroscopy and elemental analysis.

Efforts to obtain single crystals of K[**1**] from CH_2Cl_2 proved unsuccessful; however, crystals obtained from slow diffusion of toluene into a DMSO solution of the crude product were suitable for X-ray diffraction. The molecular structure is shown in Fig. 1 and reveals a dimeric structure of formulation $K_2(DMSO)_6[\mathbf{1}]_2{\cdot}C_7H_8$. Interestingly, each of the

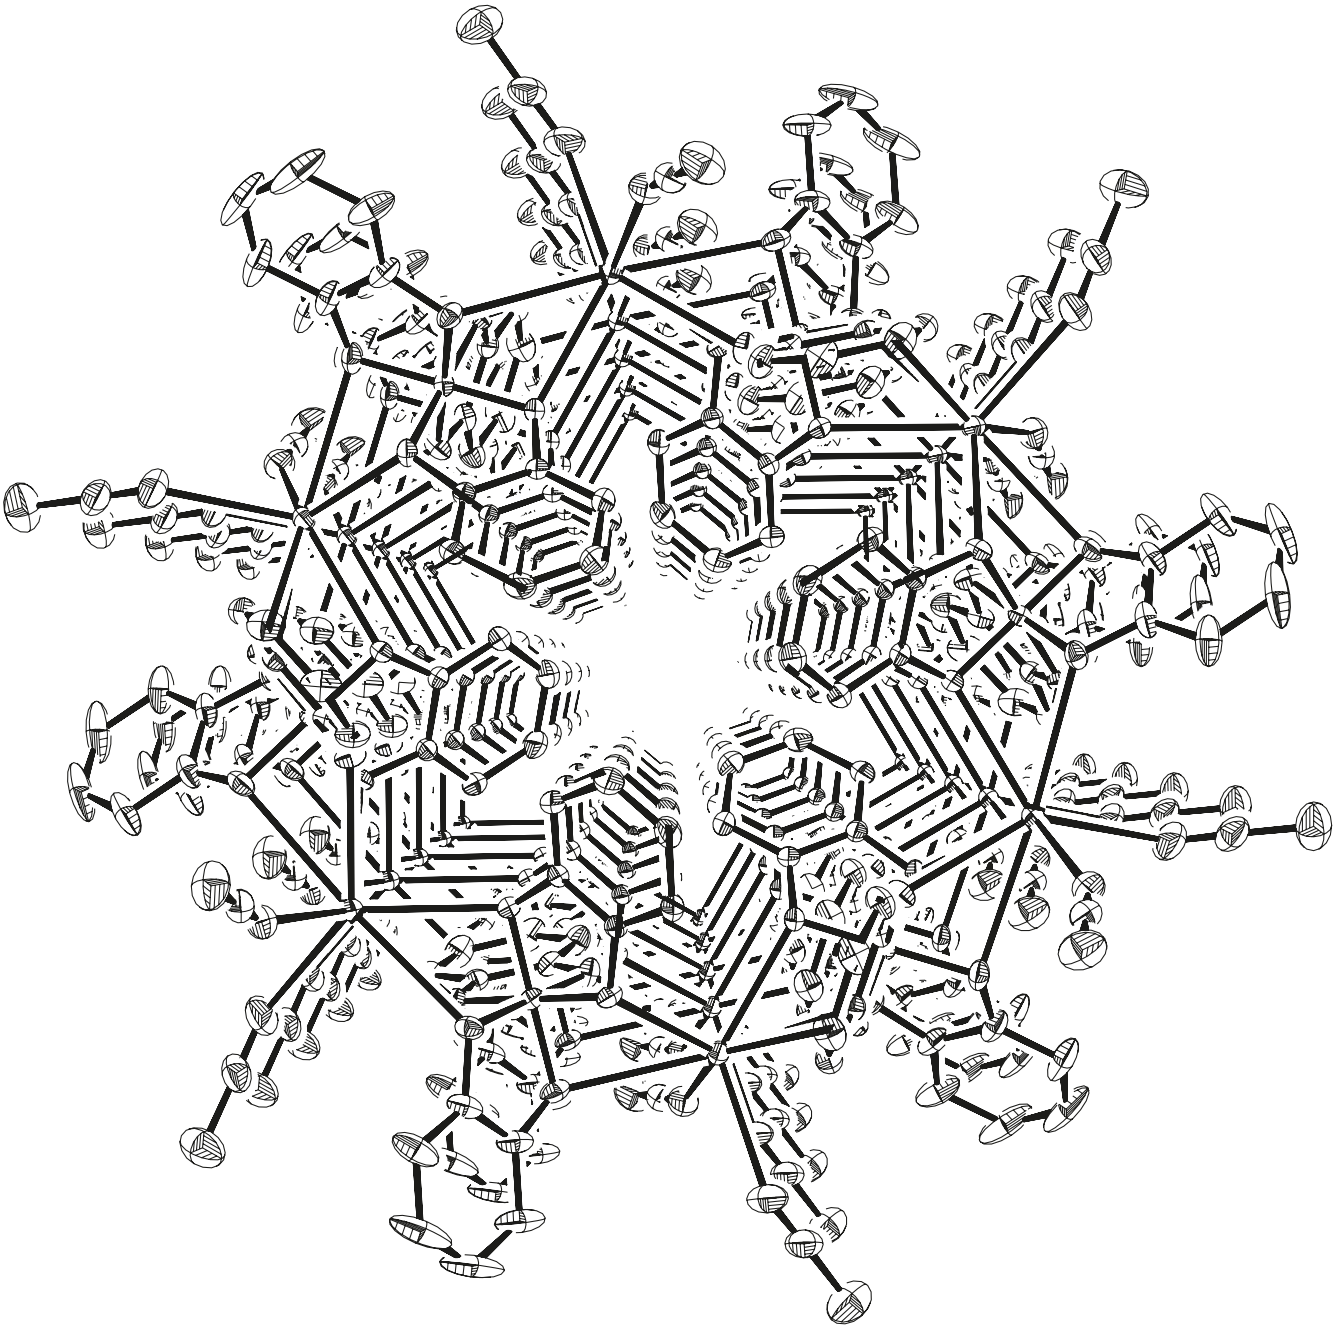

Fig. 2. Molecular structure of $\{K(MeCN)_2[\mathbf{1}]\}_6$ (50% probability ellipsoids). All hydrogen atoms are omitted for clarity. Selected bond lengths (Å): O(1)–P(1) = 1.7149(9); O(2)–P(1) = 1.7111(9); O(3)–P(1) = 1.7189(9); O(4)–P(1) = 1.7207(9); O(5)–P(1) = 1.7058(9); O(6)–P(1) = 1.7024(9); K(1)–O(1) = 2.7770(9); K(1)–O(3) = 3.019(1); K(1)–O(5) = 2.8244(9); K(1*)–O(2) = 2.8832(9); K(1*)–O(4) = 3.024(1); K(1*)–O(6) = 2.7705(9). Selected bond angles (°): O(1)–P(1)–O(2) = 91.06(4); O(3)–P(1)–O(4) = 91.11(5); O(5)–P(1)–O(6) = 91.53(4).

potassium ions are seven-coordinate, being bound by two terminal DMSO ligands, two bridging DMSO ligands, and three oxygen atoms of the $[\mathbf{1}]^-$ anion. The $[\mathbf{1}]^-$ anion is slightly perturbed by binding to K^+ with the three bound P–O bonds (avg. 1.721(3) Å, range 1.715(1) to 1.735(1) Å) being slightly longer than the three unbound P–O bonds (avg. 1.709(3) Å, range 1.707(1) to 1.714(1) Å). Overall, the average P–O bond (1.715(5) Å) and the average endocyclic O–P–O angle (90.9(2)°) within the anion $[\mathbf{1}]^-$ are similar to those found in previously reported compounds containing $[\mathbf{1}]^-$, namely: $Et_3NH[\mathbf{1}]$ (1.708(4) Å, 91.4(2)°),[11] $H(DMSO)_2[\mathbf{1}]$ (1.716(3) Å, 90.91(9)°),[16] $H(DMF)_2[\mathbf{1}]$ (1.711(3) Å, 90.8(1)°),[16] [(dppe)Pd(NCMe)Me][**1**] (dppe = 1,2-bis(diphenylphosphino)ethane; 1.709(7) Å, 91.0(2)°),[16] and $[(dppe)Pd(NCMe)_2][\mathbf{1}]_2$ (1.713(6) Å, 90.8(2)°).[16] The K–O distances involving the $[\mathbf{1}]^-$ ion (avg. 2.855(3) Å) are longer than those involving the DMSO moiety ($avg._{terminal}$ = 2.741(2) Å; $avg._{bridging}$ = 2.680(3) Å).

Recrystallization of K[**1**] from acetonitrile gave quite a different structure (Fig. 2). Remarkably, the molecular structure consists of fascinating macrocyclic hexamers of formulation $\{K(MeCN)_2[\mathbf{1}]\}_6$ with S_6 point group symmetry. The K^+ ions bridge two κ^3-bound $[\mathbf{1}]^-$ anions and have two acetonitrile

Fig. 3. Three-dimensional stacking of the $\{K(MeCN)_2[\mathbf{1}]\}_6$ (50% probability ellipsoids). All hydrogen atoms are omitted for clarity.

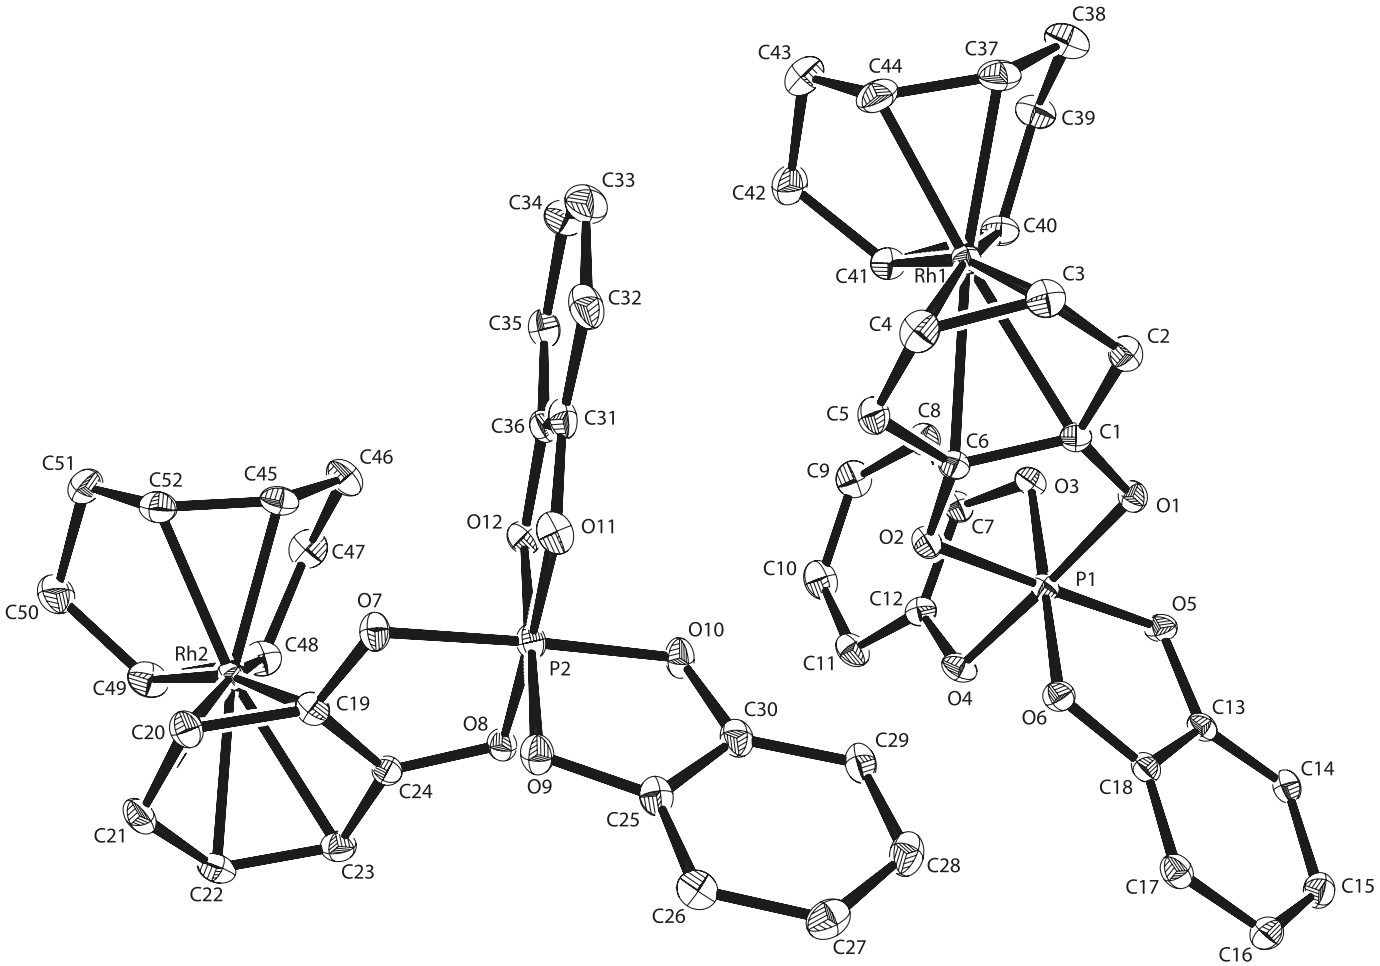
ligands making the K^+ ions eight coordinate. The K–O distances (avg. 2.883(2) Å) are slightly longer than the corresponding K–O distances in $K_2(DMSO)_6[\mathbf{1}]_2{\cdot}C_7H_8$ (avg. 2.855(3) Å). The $[\mathbf{1}]^-$ anions are situated at the vertices of a hexagon and their stereochemistry alternates between Λ and Δ around the ring. The metrical parameters within the anion $[\mathbf{1}]^-$ (avg. P–O = 1.712(2) Å and avg. O–P–O = 91.23(8)°) are comparable to those found in $K_2(DMSO)_6[\mathbf{1}]_2{\cdot}C_7H_8$ (avg. P–O = 1.715(5) Å and avg. O–P–O = 90.9(2)°). Particularly striking is the stacking of the hexagonal $\{K(MeCN)_2[\mathbf{1}]\}_6$ macrocycles one upon the other in the crystalline lattice (Fig. 3). The macrocycles each have an outside diameter of about 25 Å and a very small hole (≤2.5 Å) and are spaced by about 9.4 Å to form a one-dimensional array.

As a starting point to testing the efficacy of K[**1**] as a halide abstracting agent, a mixture of (dppp)$PdCl_2$ and solvent-free K[**1**] were mixed and dissolved in chloroform. The ^{31}P NMR spectrum of the yellow reaction solution, after filtration to remove KCl, showed singlet resonances at 12.4 and –84.2 ppm. Single crystals suitable for X-ray diffraction were obtained on slow evaporation of the reaction mixture. The molecular structure of the chloro-bridged dimer $[(dppp)Pd(\mu\text{-}Cl)]_2[\mathbf{1}]_2$ is shown in Fig. 4 and confirms the successful abstraction of a Cl^- ion with K[**1**]. There is a crystallographically imposed inversion centre between the Pd atoms. The metrical parameters of $[(dppp)Pd(\mu\text{-}Cl)]_2[\mathbf{1}]_2$ are unremarkable, being similar to those of related dimeric structures (e.g., $[(dppp)Pd(\mu\text{-}Cl)]_2[SO_4]_2$,[26] $[(dppe)Pd(\mu\text{-}Cl)]_2[X]_2$ (X = ClO_4^-,

Fig. 4. Molecular structure of $[(dppp)Pd(\mu_2\text{-}Cl)]_2[\mathbf{1}]_2$ (50% probability ellipsoids). All hydrogen atoms and the solvent of crystallization ($2 \times CHCl_3$) are omitted for clarity. Selected bond lengths (Å): P(1)–O(1) = 1.713(2); P(1)–O(2) = 1.710(2); P(1)–O(3) = 1.713(2); P(1)–O(4) = 1.708(2); P(1)–O(5) = 1.724(2); P(1)–O(6) = 1.720(2); Pd(1)–P(2) = 2.2489(5); Pd(1)–P(3) = 2.2598(5); Pd(1)–Cl(1) = 2.4024(5); Pd(1)–Cl(1*) = 2.4004(5). Selected bond angles (°): O(1)–P(1)–O(2) = 90.88(7); O(3)–P(1)–O(4) = 91.24(7); O(5)–P(1)–O(6) = 90.93(7); P(2)–Pd(1)–P(3) = 91.10(2); Cl(1)–Pd(1)–Cl(1*) = 83.22(2). dppp, 1,3-bis(diphenylphosphino)propane.

BF_4^-),[27,28] $[(dppen)Pd(\mu\text{-}Cl)]_2[CF_3SO_3]_2$ (dppen = 1,2-bis(diphenylphosphino)ethene),[29] $[(o\text{-}C_6H_4(CH_2PPh_2)_2)Pd(\mu\text{-}Cl)]_2[PF_6]_2$,[30] and $[(Ph_3P)_2Pd(\mu\text{-}Cl)]_2[BF_4]_2$).[31] Significantly, the molecular structure suggests weak interactions are present between the cation and the $[\mathbf{1}]^-$ anion. The closest contact is between an oxygen of the $[\mathbf{1}]^-$ anion and a hydrogen of the CH_2 moiety within the dppp ligand (O(1)···H(33b) = 2.208(1) Å) and is within the sum of the van der Waals radii for oxygen and hydrogen (r_{vdw} = 2.72 Å).[32] The metrical parameters within the anion $[\mathbf{1}]^-$ (avg. P–O = 1.715(4) Å and avg. O–P–O = 91.0(1)°) are consistent with those found in $K_2(DMSO)_6[\mathbf{1}]_2{\cdot}C_7H_8$ and $\{K(MeCN)_2[\mathbf{1}]\}_6$. Noteworthy is the fact that the molecular structure is consistent with the aforementioned ^{31}P NMR spectroscopic data for the reaction mixture with equivalent phosphine moieties of dppp (δ = 12.4) and the free $[\mathbf{1}]^-$ anion (δ = –84.2). It was not possible to dissolve the crystals in weakly coordinating solvents (e.g., $CDCl_3$ or CD_2Cl_2) so the crystals were dissolved in acetonitrile-d_3 for further spectroscopic analysis. Interestingly, the CD_3CN solution showed inequivalent phosphine moieties (δ = 15.1 (br s), 10.3 (br s)) and the $[\mathbf{1}]^-$ anion (δ = –81.7). These data are consistent with the solution structure being $[(dppp)PdCl(NCMe)][\mathbf{1}]$, which appears to be in equilibrium with $[(dppp)Pd(\mu\text{-}Cl)]_2[\mathbf{1}]_2$, since in some instances signals assigned to both species are observed.



Given that K[**1**] is an effective halide abstraction agent for palladium(II) chloride bonds, we tested the efficacy of K[**1**] as a halide abstraction agent with the rhodium(I) dimer, $[(cod)RhCl]_2$. To a mixture of $[(cod)RhCl]_2$ with K[**1**] (2 equiv) was added acetonitrile and the yellow mixture was stirred overnight. Recrystallization of the crude product from dichloromethane afforded orange crystals. The molecular structure is shown in Fig. 5 and shows that the $[\mathbf{1}]^-$ anion is η^6-bound to the rhodium(I) centre to afford zwitterionic (cod)Rh[**1**]. Similar cation–anion interactions have been noted in the solid-state structures of similar rhodium(I) complexes containing the weakly coordinating anions $[BPh_4]^-$ and $[B(Ar_F)_4]^-$ (Ar_F = 3,5-bis(trifluoromethyl)phenyl).[33,34] The distance between the centroid of the η^6-bound aromatic ring and Rh(I) is approximately 1.9 Å and is similar to that found in Rh(dppe)$[BPh_4]$ and (cod)Rh$[B(Ar_F)_4]$. The anion–cation interaction results in a lowering of the symmetry about phosphorus with the four P–O bonds of the uncoordinated catechol (avg. 1.700(7) Å) being shorter than the P–O bonds of the coordinated catechol (avg. 1.745(4) Å). The crystals were further characterized by ^1H and ^{31}P NMR spectroscopy and elemental microanalysis. The ^{31}P NMR spectrum (CD_2Cl_2) displayed a singlet resonance at –79.9 ppm, which is shifted downfield compared with K[**1**] (δ = –86.1) and consistent with the retention of the coordination complex in solution. The ^1H NMR spectrum was consistent with a loss of symmetry for

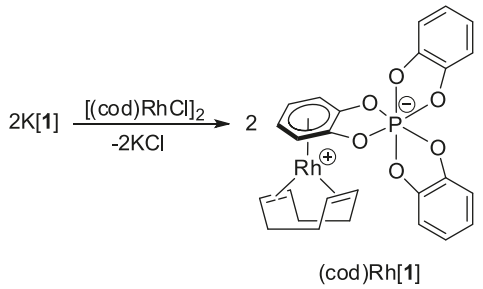

Fig. 5. Molecular structure of (cod)Rh[**1**]. Ellipsoids are drawn at the 50% probability level. All hydrogen atoms and solvents of crystallization (2.5 × CH_2Cl_2) are omitted for clarity. Selected bond lengths (Å): P(1)–O(1) = 1.747(3); P(1)–O(2) = 1.746(3); P(1)–O(3) = 1.695(2); P(1)–O(4) = 1.699(3); P(1)–O(5) = 1.706(3); P(1)–O(6) = 1.702(2); P(2)–O(7) = 1.746(3); P(2)–O(8) = 1.739(3); P(2)–O(9) = 1.703(2); P(2)–O(10) = 1.702(3); P(2)–O(11) = 1.697(3); P(2)–O(12) = 1.697(2); Rh(1)vC(1) = 2.405(4); Rh(1)–C(2) = 2.373(4); Rh(1)–C(3) = 2.262(3); Rh(1)–C(4) = 2.280(3); Rh(1)–C(5) = 2.355(4); Rh(1)–C(6) = 2.371(4); Rh(1)–C(37) = 2.127(5); Rh(1)–C(40) = 2.151(3); Rh(1)–C(41) = 2.136(3); Rh(1)–C(44) = 2.130(5); Rh(2)–C(19) = 2.364(3); Rh(2)–C(20) = 2.307(3); Rh(2)–C(21) = 2.286(3); Rh(2)–C(22) = 2.254(4); Rh(2)–C(23) = 2.357(5); Rh(2)–C(24) = 2.431(3); Rh(2)–C(45) = 2.125(4); Rh(2)–C(48) = 2.136(3); Rh(2)–C(49) = 2.124(3); Rh(2)–C(52) = 2.146(5). Selected bond angles (°): O(1)–P(1)–O(2) = 89.4(1); O(3)–P(1)–O(4) = 91.7(1); O(5)–P(1)–O(6) = 91.7(1); O(7)–P(2)–O(8) = 89.7(1); O(9)–P(2)–O(10) = 91.6(1); O(11)–P(2)–O(12) = 91.8(1).

the aryl H moieties and provides a further evidence that the complex structure of (cod)Rh[**1**] is retained in solution.

Summary

Synthetic procedures to access alkali metal salts containing the tris(*o*-phenylenedioxy)phosphate anion [**1**]$^-$, Na[**1**] and K[**1**], have been presented. Both compounds were characterized spectroscopically. In addition, X-ray crystallographic analysis of K[**1**], recrystallized in the presence of either DMSO or MeCN, revealed two distinct crystal structures: a dimeric structure of formulation $K_2(DMSO)_6[\mathbf{1}]_2 \cdot C_7H_8$ and a hexagonal macrocycle with formulation $\{K(MeCN)_2[\mathbf{1}]\}_6$. Solvent-free K[**1**] was shown to be an effective halide abstractor for (dppp)$PdCl_2$ (1:1) and $[(cod)RhCl]_2$ (2:1 ratio) to generate the dimeric $[(dppp)Pd(\mu\text{-}Cl)]_2[\mathbf{1}]_2$ and the zwitterionic (cod)Rh[**1**], both of which were structurally characterized.

(cod)Rh[**1**]

Experimental section

General procedures

All manipulations were performed using standard Schlenk or glove box techniques under nitrogen atmosphere. THF was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

dried over sodium / benzophenone ketyl and distilled prior to use. Triethylamine, dichloromethane, acetonitrile, and CD_3CN (Cambridge Isotope Laboratories Inc.) were dried over calcium hydride and distilled prior to use. CD_2Cl_2 was purchased from Cambridge Isotope Laboratories Inc. in 1 g sealed ampules and used as received. DMSO was dried over 3 Å molecular sieves and distilled prior to use. Et_2O and toluene were deoxygenated with nitrogen and dried by passing through a column containing activated alumina. PCl_5 (Sigma-Aldrich) was sublimed prior to use. Potassium hydride (30 wt % dispersion in mineral oil) was purchased from Sigma-Aldrich, washed with hexanes, and dried in vacuo prior to use. Sodium hydride (dry, 95%) was purchased from Sigma-Aldrich and used as received. Mixture **2** / **3**[20] and [(dppp)$PdCl_2$][35] were prepared following literature procedures. ^{1}H, ^{13}C{^{1}H}, and ^{31}P NMR spectra were recorded at room temperature on Bruker Avance 300 or 400 MHz spectrometers. H_3PO_4 (85%) was used as an external standard (δ 0.0) for ^{31}P NMR spectra. ^{1}H NMR spectra were referenced to residual protonated solvent, and ^{13}C{^{1}H} NMR spectra were referenced to the deuterated solvent. Elemental analyses were performed in the University of British Columbia Chemistry Microanalysis Facility, Vancouver, British Columbia.

Synthesis of K[**1**]

To a stirred mixture of **2** and **3** (1.8 g, 5.1 mmol) in THF (15 mL) was added triethylamine (0.58 g, 5.7 mmol). An immediate precipitate was observed. The reaction mixture was stirred for 30 min, the precipitate was isolated by centrifugation and the solid was dried in vacuo. To a suspension of this colourless solid in acetonitrile (10 mL) was added potassium hydride (0.23 g, 5.7 mmol). The evolution of a gas was observed. After the mixture was stirred for 30 min, the solvent was removed in vacuo and the resultant white residue dissolved in THF (40 mL). The solution was filtered to remove insoluble salts and the filtrate was evaporated to dryness to afford a white solid. The solid was dissolved in minimal dichloromethane (3 mL) and Et_2O (100 mL) was added to precipitate the product, which was collected by filtration and dried in vacuo at 130 °C. Yield: 1.4 g (70%). ^{31}P NMR (121 MHz, CD_2Cl_2) δ: –86.1 (s). ^{1}H NMR (300 MHz, CD_2Cl_2) δ: 6.65–6.59 (m, 6H, Ar-*H*), 6.57–6.53 (m, 6H, Ar-*H*). ^{13}C{^{1}H} NMR (101 MHz, CD_2Cl_2) δ: 144.5 (d, J_{CP} = 4 Hz), 121.3 (s), 110.8 (d, J_{CP} = 16 Hz). Anal. calcd for $C_{18}H_{12}KO_6P$: C 54.82, H 3.07; found: C 54.58, H 3.20. X-ray quality crystals of $K_2(DMSO)_6$[**1**]$_2$ were obtained from slow diffusion of toluene into a DMSO solution of K[**1**] for about 1 week. X-ray quality crystals of {K(NCMe)$_2$[**1**]}$_6$ were obtained from slow evaporation of a concentrated solution of K[**1**] in toluene/MeCN for 8 days.

Synthesis of Na[**1**]

To a stirred mixture of **1** and **2** (0.55 g, 1.5 mmol) in THF (5 mL) was added triethylamine (0.18 g, 1.8 mmol). An immediate precipitate was observed. The reaction mixture was stirred for 15 min and the precipitate was isolated by centrifugation and the solid was dried in vacuo. To a suspension of this white solid in acetonitrile (10 mL) was added sodium hydride (0.039 g, 1.6 mmol). The evolution of a gas was observed. After the mixture was refluxed for 30 min, the solvent was removed in vacuo and the resultant white residue dissolved in THF (15 mL). The solution was filtered to remove insoluble salts and the filtrate was evaporated to dryness to afford a white solid. The solid was dried in vacuo at 120 °C. Yield: 0.47 g (80%). ^{31}P NMR (162 MHz, CD_3CN) δ: –82.9 (s). ^{1}H NMR (400 MHz, CD_3CN) δ: 6.67–6.65 (m, 12H, Ar-*H*). ^{13}C{^{1}H} NMR (101 MHz, CD_2Cl_2) δ: 146.4 (d, J_{CP} = 5 Hz), 120.5 (s), 110.5 (d, J_{CP} = 17 Hz). Anal. calcd for $C_{18}H_{12}NaO_6P$: C 57.16, H 3.20; found: C 57.50, H 3.44.

Synthesis of [(dppp)Pd(μ-Cl)]$_2$[**1**]$_2$

To a solid mixture of (dppp)$PdCl_2$ (50 mg, 0.085 mmol) and K[**1**] (34 mg, 0.086 mmol) was added chloroform (2 mL). The yellow reaction solution was stirred overnight and filtered through celite. The ^{31}P NMR spectrum of the reaction mixture showed singlet resonances at 12.4 and –84.2 ppm. Slow evaporation of the yellow solution afforded yellow crystals suitable for X-ray diffraction. The sample was dried in vacuo prior to analysis. Yield: 32 mg (41%). ^{31}P NMR (162 MHz, CD_3CN) δ: 15.1 (br s, dppp), 10.3 (br s, dppp), –81.7 (s, anion). ^{1}H NMR (400 MHz, CD_3CN) δ: 7.69–7.45 (m, 20H, Ar-*H* of dppp), 6.64–6.58 (m, 12H, Ar-*H* of anion), 2.67 (br s, 4H, PCH_2), 2.15–1.99 (m, 2H, $CH_2CH_2CH_2$). ^{13}C{^{1}H} NMR (101 MHz, CD_3CN) δ: 146.9 (d, J_{CP} = 5 Hz), 134.3 (d, J_{CP} = 11 Hz), 133.4 (s), 130.18 (s), 128.5 (s), 127.9 (s), 120.0 (s), 110.9 (d, J_{CP} = 17 Hz), 24.1 (br s), 19.2 (s). Anal. calcd for $C_{45}H_{38}ClO_6P_3Pd$: C 59.42, H 4.21; found: C 59.06, H 4.00.

Synthesis of (cod)Rh[**1**]

To solid mixture of K[**1**] (83 mg, 0.21 mmol) and [(cod)RhCl]$_2$ (51 mg, 0.10 mmol) was added acetonitrile (3 mL). The resulting cloudy yellow mixture was stirred overnight, followed by the removal of all volatiles in vacuo. The yellow residue was dissolved in dichloromethane (3 mL) and filtered to remove a small amount of insoluble material. Slow evaporation of the solution afforded orange crystals suitable for X-ray diffraction. Yield: 33 mg (52%). ^{31}P NMR (161 MHz, CD_2Cl_2) δ: –79.9 (s). ^{1}H NMR (400 MHz, CD_2Cl_2) δ: 6.94–6.91 (m, 2H, Ar-*H*), 6.76–6.64 (m, 8H, Ar-*H*), 5.56–5.50 (m, 2H, Ar-*H*), 5.33 (s, 1.25H, CH_2Cl_2), 4.69–4.39 (m, 4H, *H*C=C*H* in COD), 2.44–2.03 (m, 8H, CH_2 in COD). Anal. calcd for $C_{26}H_{24}O_6PRh \cdot 1.25CH_2Cl_2$: C 48.67, H 3.97; found: C 48.53, H 3.95.

X-ray crystallography

All single crystals were immersed in oil and were mounted on a glass fiber. Data were collected on a Bruker X8 APEX II diffractometer with graphite-monochromated Mo Kα radiation. All structures were solved by direct methods and subsequent Fourier difference techniques. Unless noted, all non-hydrogen atoms were refined anisotropically, whereas all hydrogen atoms were included in calculated positions but not refined. All data sets were corrected for Lorentz and polarization effects. Calculations were performed using PARST[36,37] and SHELXL-97.[38,39] All refinements were performed using the SHELXTL[39,40] crystallographic software package from Bruker-AXS.

The molecular structure of $K_2(DMSO)_6$[**1**]$_2$ contains five disordered molecules of DMSO bound to K(1) and K(2). Each of the disordered DMSO molecules was modeled in two orientations and refined with combinations of SADI,

Abstract: The geometrical and electronic structures of a series of six monosilacyclobutane and 1,3-disilacyclobutane radical cations were systematically studied using ab initio and density functional theories. It was shown that all six radical cations possess an asymmetrically distorted structure in their ground electronic states. In the asymmetrically distorted C_1 structure of monosilacyclobutane cations, one Si–C bond was elongated and the other was shortened. For the disilacyclobutane cations, two ring bonds were elongated and the other two contracted. The asymmetrical distortion was enhanced by exocyclic methyl substitutions and weakened by endocyclic Si substitution. The unpaired electron was localized mainly in the elongated σ(Si–C) ring bond(s) in all six cations. Studies of the excited electronic states of the cations provided strong support that the asymmetrical distortion in the four-membered-ring cations originates from the second-order Jahn–Teller effect. It was found that the puckered ring structures in the monosilacyclobutane molecules were maintained upon ionization, whereas 1,3-disilacyclobutane cations changed to a planar ring structure. Examination of the potential energy surfaces of all six cations showed that the Si–C ring bond elongation is the main contributor to the significant difference in the geometry change between monosilacyclobutane and disilacyclobutane species upon ionization.

Key words: silacyclobutane, radical cation, second-order Jahn–Teller effect, potential energy surfaces, structures.

Résumé : Faisant appel à des calculs théoriques ab initio et d'autres dérivés de la théorie de la fonctionnelle de la densité, on a fait une étude systématique des structures géométriques et électroniques d'une série de six cations radicaux dérivés de monosilacyclobutanes et 1,3-disilacyclobutanes. Il a été permis de démontré que, dans leurs états électroniques fondamentaux, ces six cations radicaux possèdent une structure avec distorsion asymétrique. Dans la structure C_1 à distorsion asymétrique des cations radicaux du monosilacyclobutane, une des liaisons Si–C est allongée alors que l'autre est raccourcie. Dans le cas des cations radicaux du disilacyclobutane, les deux liaisons du cycle sont allongées alors que les deux autres sont contractées. La distorsion asymétrique est rehaussée par des substitutions de groupes méthyles exocycliques et affaiblie par une substitution endocyclique du silicium. Pour chacun des six cations radicaux, l'électron non apparié est principalement localisé dans les liaisons allongées σ(Si–C) du cycle. Les études des états électroniques excités des cations radicaux supportent fortement la distorsion dans les cations radicaux des cycles à quatre chaînons qui trouvent leur origine dans l'effet Jahn–Teller du deuxième ordre. On a trouvé que les structures repliées des cycles des molécules de monosilacyclobutane sont maintenues lors de l'ionisation alors que celles des cations radicaux dérivés du 1,3-disilacyclobutane se transforment en une structure dans laquelle le cycle est plan. L'examen des surfaces d'énergie potentielle des six cations radicaux montre que l'élongation de la liaison Si–C du cycle est la principale cause de la différence significative dans le changement de géométrie entre les espèces monosilacyclobutanes et disilacyclobutanes lors de leur ionisation.

Mots-clés : silacyclobutane, cation radical, effet Jahn–Teller du deuxième ordre, surfaces d'énergie potentielle, structures.

[Traduit par la Rédaction]

Introduction

The study of the geometrical and electronic structures of alkane radical cations has attracted much attention over the past few decades because of their fundamental chemical importance.[1–3] A variety of alkane radical cations, including both acylic[1,2,4,5] and cyclic[6–11] alkanes, have been studied by the low-temperature halocarbon matrix isolation electron spin resonance (ESR) spectroscopic techniques since the method was developed in the 1970s. Two types of electronic structures, i.e., a delocalized type and a localized type, were found based on the distributions of the unpaired electron. The *n*-alkane and unsubstituted cycloalkane (c-C_nH_{2n}, $3 \leq n \leq 8$) radical cations are characterized as delocalized σ-radical cations, in which the unpaired electron in the σ-molecular orbital delocalizes over the entire normal alkane chain and the equatorial plane of the cycloalkane ring, respectively. The

radical cations of branched alkanes and methyl-substituted cycloalkanes assume the localized electronic structure where the unpaired electron is more confined to a particular σ(C–C) bond.

The Jahn–Teller effect[12] plays an important role in determining the geometric structures of the alkane radical cations. Among the variety of acyclic and cyclic alkane cations studied, it has generally been found that the alkane molecules that are Jahn–Teller active, i.e., have a degenerate HOMO orbital, all undergo structure distortion by lowering the symmetry after one-electron oxidation to form the radical cations, whereas the geometric structures of the Jahn–Teller inactive alkane molecules can be maintained in their corresponding radical cations.[1–3,6] However, studies of methyl-substituted cycloalkane radical cations have revealed some interesting results. Shiotani and co-workers[7–11] found that, even if the precursor neutral molecules are Jahn–Teller inactive, their radical cations take an asymmetrically distorted geometrical structure in which one of the two ring C–C bonds connected to the methyl substituent is elongated and the symmetry of the cations is lowered.

Shiotani and co-workers then extended their low-temperature halocarbon matrix isolation ESR studies to silacycloalkane molecules, including silacyclohexane,[13] 1-methylsilacyclohexane,[14] and silacyclobutane and its methyl-substituted derivatives.[15] Theoretical studies of the ESR spectra and structures of silacyclobutane radical cations have also been reported recently.[16,17] It was found that removing one electron from these silacycloalkane molecules lowers the symmetry in the geometrical structures. The radical cations of the aforementioned silacycloalkanes possess an asymmetrically distorted C_1 structure with one of the Si–C bonds elongated where the unpaired electron mainly resides. The structural distortion observed in both methyl-substituted cycloalkane and silacycloalkane radical cations can be explained by the second-order Jahn–Teller theory, also known as the pseudo Jahn–Teller effect.[13,18–20] This theory predicts a specific way in which any molecule with electronic states that are close to each other (within about 4 eV) will react upon activation. In this case, the vibronic coupling, which is inversely proportional to the energy difference between the ground and excited electronic states, can induce the structural distortion of Jahn–Teller inactive molecules. The ESR studies of the radical cations of the open-chain ethylsilanes, including $SiEt_2H_2$, $SiEt_3H$, $SiEt_4$, and $SiEt_2MeH$ (Et, ethyl; Me, methyl), in low-temperature halocarbon matrices have confirmed that, owing to the pseudo Jahn–Teller effect, all cations adopt asymmetrically distorted structures with only one of the Si–C bonds elongated and the unpaired electron is largely localized in the elongated Si–C bond.[21] Toriyama et al.[22,23] revisited the radical cation structures of propane and *n*-pentane / branched pentane[24] and found that they also undergo similar structural distortion to those of ethylsilanes. Therefore, it is believed that the asymmetrically distorted structure originating from the pseudo Jahn–Teller effect is an intrinsic nature of the alkane and silaalkane radical cations whose precursor neutral molecules possess certain symmetry elements such as C_s, C_2, or C_{2v}.

The four-membered-ring silacycloalkane molecules have recently attracted a lot of research interest because of their wide range of applications in chemistry[25] and materials science.[26] The high ring strain energy and reactivity of these molecules have made them excellent choices as single-source precursors for producing silicon carbide thin films using chemical vapor deposition (CVD) techniques.[27–33] The structures of the neutral four-membered-ring silacycloalkane molecules have been extensively investigated by various experimental techniques and theoretical calculations.[34–38] Unlike their neutral equivalents, the structures of the radical cations of these four-membered-ring compounds are much less studied, although they are very important for their activities in the process of plasma-enhanced CVD[39] and other chemical reactions.[25] Only the ESR spectra accompanied by theoretical studies using ab initio and density functional theory (DFT) of silacyclobutane and its methyl-substituted derivatives have been reported in the literature.[15–17] The silacyclobutane radical cation possesses the asymmetrically distorted structure with one of the ring Si–C bonds elongated. However, the effect of the exocyclic methyl substitution on the electronic and geometric structures of silacyclobutane radical cation has not been systematically studied. Furthermore, it remains unclear how the asymmetrical distortion due to the pseudo Jahn–Teller effect changes in the radical cations upon introducing a second Si in the four-membered ring (endocyclic substitution).

In this work, to explore the effect of both exocyclic methyl substitution and endocyclic Si substitution on the structures of the radical cations of the four-membered-ring silacycloalkanes, we have systematically examined the electronic and geometric structures of a series of monosilacyclobutane (MonoSCB) and 1,3-disilacyclobutane (DiSCB) radical cations using ab initio and DFT methods. The three MonoSCB molecules investigated in this work include 1-silacyclobutane (SCB), 1-methyl-1-silacyclobutane (MSCB), and 1,1-dimethyl-1-silacyclobutane (DMSCB). 1,3-Disilacyclobutane (DSCB), 1,1-dimethyl-1,3-disilacyclobutane (DMDSCB), and 1,1,3,3-tetramethyl-1,3-disilacyclobutane (TMDSCB) belong to DiSCB molecules. The molecular structures of SCB (I), MSCB (II), DMSCB (III), DSCB (IV), DMDSCB (V), and TMDSCB (VI) are represented in the following.

The puckering potential energy surfaces (PESs) of all six cations were also studied to help understand the structural difference between MonoSCB and DiSCB radical cations. In addition, we studied some of the electronic transitions of the six radical cations. Comparison of the energy difference between the ground and excited electronic states of the radical cations provides strong support of the pseudo Jahn–Teller effect as the origin of the asymmetrical distortion in the four-membered-ring cations.

Computational details

All calculations in this work were performed using the Gaussian 03 program.[40] The previous studies from our group[38] and others[37] have shown that calculations using the second-order Møller-Plesset (MP2) perturbation theory work very well in predicting the geometric structures of neutral MonoSCB and DiSCB molecules, since the correlation energy is small in these single-bonded molecules. The structures of the six MonoSCB and DiSCB radical cations have not been reported in the literature except for that of SCB. The geometric structures of the SCB radical cation were investigated using MP2 and DFT with the B3LYP hybrid functional.[16,17] To confirm the lowest energy geometric structures of all six radical cations to be studied in this work, both MP2 and the B3LYP hybrid functional were used for the geometry optimization of radical cations using the 6–311++G(d,p) basis set. For all geometry optimizations, the frozen core approximation was employed. The frequency calculations at the harmonic level were performed on the optimized geometries to ensure that they belonged to the stable structures, not transition states.

Figure 1 shows the labels and numbering of atoms in both MonoSCB (compounds I–III) and DiSCB (compounds IV–VI) radical cations. The definitions of puckering angle (φ) and puckering coordinate (x) are shown in Fig. 2. φ is the dihedral angle between two planes, i.e., planes 1-2-4 and 3-2-4, in the ring, and x is half of the perpendicular distance between two ring diagonals. The PESs of the puckering motion and the barriers to planarity for each of the six radical cations were obtained by keeping the puckering dihedral angle, $\varphi(Si_1–C_2–C_4–C_3)$, at varied fixed values in the range of –60° to 60° at a step size of 5° while optimizing all the remaining parameters using MP2/6–311++G(d,p). The coordinate x was calculated at the optimized structures with different dihedral angles, so that the parameters of potential energy function could be obtained by polynominal fitting of the potential energy as a function of the x values.

To shed light on the origin of the asymmetrically distorted structures assumed by the radical cations, the first excited electronic states of all six radical cations were calculated on the MP2-optimized structures by time-dependent DFT, in which the hybrid functional B3LYP was employed with a basis set of 6–311++G(d,p).

Results and discussions

Geometry optimization — Asymmetrically distorted and localized ground electronic states

The search for the ground electronic states of the six radical cations was performed using the MP2 methods with the 6–311++G(d,p) basis set. From the geometry optimization of the SCB radical cation, two stable structures were found with C_1 and C_{2v} symmetry. The two structures are shown in Fig. 3. In the asymmetrically distorted C_1 structure, labeled as SCB$^{+\bullet}$-C_1 (Fig. 3*a*), one of the Si–C bonds was elongated and the other was contracted, whereas the C_{2v} structure shown in Fig. 3*b* has a planar ring structure with both Si–C bonds elongated to the same extent. The energy of SCB$^{+\bullet}$-C_1 is found to be 3.00 kcal/mol (1050 cm^{-1}) lower than that of SCB$^{+\bullet}$-C_{2v}. Therefore, the ground electronic state of the SCB radical cation has an asymmetrically distorted structure of C_1 symmetry with a puckered ring. This is in agreement with previous studies on the SCB radical cation[15–17] and other silaalkane cations.[13,14,21] The ground-state cationic structure for SCB was calculated using both MP2 and B3LYP methods. Comparison of the calculated structural parameters, including the bond lengths, bond angles, and puckering angles, for the ground electronic state of the SCB radical cation (SCB$^{+\bullet}$-C_1) using different methods can be found in Table 1. The results from previous calculations in the literature are also listed in Table 1. Our calculations show good agreements with those reported in the literature. All methods predict that the SCB radical cation has a puckered ring structure in its ground state. However, the DFT method seems to underestimate the dihedral angle by 7.6° when compared with the MP2 method. According to the previous results,[17] such underestimation was believed to be an artefact due to the B3LYP optimization. The calculated structural parameters were similar when using B3LYP and MP2 except for the underestimation of dihedral angle in the former. In addition, the energies for the ground-state SCB radical cation calculated at MP2/6–311++G(d,p) and B3LYP/6–311++G(d,p) were found to be –407.42276 and –408.33246 hartree, respectively. The energy calculated at the MP2 level of theory is much closer to the single-point energy of –407.52135 hartree calculated using CCSD(T)/6–311++G(3d,2p) on the optimized structure with MP2/6–311++G(d,p). Therefore, the following discussions will be based on the results from the MP2 calculations for consistency.

Similar asymmetrical distortions were found in the ground electronic structures of MSCB and DMSCB radical cations. MSCB has two conformers, i.e., the equatorial form (MSCB-*e*) and the axial form (MSCB-*a*). The geometry optimization found two stable structures with C_1 and C_s symmetry for the radical cation of each conformer. The C_1 structure shows an asymmetrical distortion with one of the ring Si–C bonds elongated and the other contracted, whereas both ring Si–C bonds are elongated in the planar C_s structure. The energy of the C_1 structure is 3.96 and 3.64 kcal/mol lower than that of the C_s structure for the MSCB-$e^{+\bullet}$ and MSCB-$a^{+\bullet}$, respectively. The MSCB-$a^{+\bullet}$-C_1 structure is calculated to be 0.33 kcal/mol (114 cm^{-1}) higher in energy than MSCB-$e^{+\bullet}$-C_1. Therefore, the ground electronic state of MSCB radical cation has an asymmetrically distorted C_1 structure in the equatorial form. The asymmetrically distorted C_1 structure of the ground-state DMSCB$^{+\bullet}$ is 4.54 kcal/mol lower in energy than the planar C_{2v} structure. The total energies for the different structures of the three MonoSCB radical cations calculated at MP2/6–311++G(d,p) and the energy difference between the two stable structures of each species are listed in Table 2.

Table 3 lists the calculated structural parameters of the ground electronic states (C_1) and the C_s/C_{2v} structures for the three MonoSCB radical cations. The structural parameters for the three neutral molecules are also listed for comparison. In the asymmetrically distorted C_1 structures, one Si–C ring bond ($r(Si_1–C_4)$ = 2.273–2.326 Å) was elongated by around 20% and the other Si–C ring bond ($r(Si_1–C_2)$ = 1.843–1.853 Å) was contracted a little when compared with the neutral MonoSCBs (r(Si–C) = 1.893–1.896 Å). The two unequal endocyclic bond angles ∠SiCC ($\angle Si_1–C_2–C_3$ = 79.1°–79.4°; $\angle Si_1–C_4–C_3$ = 92.5°–94.6°) in the C_1 structures also

suggest the asymmetrical distortion of MonoSCB radical cations in comparison with the two equal bond angles in their neutral forms ($\angle Si_1–C_2–C_3 = \angle Si_1–C_4–C_3$ = 86.1°–86.4°). The similar puckering angles between the MonoSCB neutral and cationic C_1 structures indicate that the puckered structure was conserved upon ionization into the ground states. It is also interesting to note how the degree of asymmetrical distortion is affected by exocyclic methyl substitution in MonoSCB cations. The difference in the bond length between two Si–C ring bonds becomes larger with methyl substitution, as shown in Table 3, i.e., 0.430 Å for $SCB^{+\bullet}$; 0.452 Å for MSCB-$e^{+\bullet}$; and 0.473 Å for $DMSCB^{+\bullet}$. This type of trend implies that the distortion becomes slightly larger by replacing the exocyclic Si–H bonds with Si–CH_3 connections.

For the geometry optimization of the DSCB radical cation, the two stable structures shown in Figs. 4*a* and 4*b* were found with C_{2v} and D_{2h} symmetry, respectively. The former has an asymmetrically distorted structure with two elongated Si–C ring bonds and the other two shortened, whereas the latter has four elongated Si–C ring bonds to the same extent as compared with its neutral form. By comparing the energy between these two structures, the C_{2v} structure is 3.46 kcal/mol lower in energy than the one with D_{2h} symmetry. Thus, the ground electronic state of the DSCB radical cation has an asymmetrically distorted C_{2v} structure. Similar to $DSCB^{+\bullet}$, the ground electronic state of the $TMDSCB^{+\bullet}$ radical has an asymmetrically distorted C_{2v} structure that is 2.70 kcal/mol lower in energy than the D_{2h} structure. For the DMDSCB radical cation, the two optimized stable structures have C_s and C_{2v} symmetry, respectively, and are shown in Figs. 4*c* and 4*d*. The C_s structure is asymmetrically distorted with two elongated Si–C ring bonds, however, the two elongated Si–C bonds are of different lengths. The Si–C bond connected to the two methyl groups is more significantly elongated. The C_{2v} structure has all four Si–C ring bonds elongated, but not to the same extent. It was found that the $DMDSCB^{+\bullet}$-C_s structure is 3.78 kcal/mol lower in energy than its C_{2v} counterpart, and thus the asymmetrically distorted C_s structure is the ground state of the DMDSCB radical cation. The energy comparison for the different structures of the three DiSCB radical cations calculated at MP2/6–311++G(d,p) can be found in Table 2.

The calculated structural parameters of the ground electronic states (C_{2v} for $DSCB^{+\bullet}$ and $TMDSCB^{+\bullet}$ and C_s for $DMDSCB^{+\bullet}$) and the next higher energy stable structures for the three DiSCB radical cations are listed in Table 4. The structural parameters for the three neutral DiSCB molecules are also listed in the same table for comparison. In the asymmetrically distorted ground state of C_s symmetry for $DMDSCB^{+\bullet}$, one Si–C ring bond ($r(Si_1–C_4)$ = 2.243 Å) attached to the methyl groups was elongated by around 18%, but the other Si–C ring bond ($r(Si_1–C_2)$ = 1.841 Å) attached to the methyl groups was shortened. The $Si_3–C_4$ bond length was slightly elongated, whereas the remaining Si–C ring bond was almost unchanged with respect to the neutral DMDSCB (r(Si–C) = 1.899 Å). On the other hand, the ground electronic states for both $DSCB^{+\bullet}$ and $TMDSCB^{+\bullet}$ have two elongated Si–C ring bonds (2.058 Å for $DSCB^{+\bullet}$ and $TMDSCB^{+\bullet}$) to the same extent by ~8% in comparison with their neutral forms (1.901 Å for DSCB and 1.904 Å for TMDSCB), and the other two Si–C ring bonds contracted a little (1.862 Å for $DSCB^{+\bullet}$ and 1.866 Å for $TMDSCB^{+\bullet}$). Similar to the three MonoSCB radical cations, the asymmetric distortion in the ground cationic states of DiSCBs can be reflected in the two unequal endocyclic bond angles ∠Si–C–C. Furthermore, it is noted that the change in ring bond angles ∠C–Si–C upon ionization into the ground states is different among the three DiSCB radical cations. One ring bond angle (∠C–Si–C) changes significantly in $DMDSCB^{+\bullet}$ ($\angle C_2–Si_3–C_4$ = 99.2°) in comparison with its neutral ($\angle C_2–Si_3–C_4$ = 90.3°), and the other remains almost constant ($\angle C_2–Si_1–C_4$ = 90.9° and 89.9° for the cationic and neutral form, respectively). However, the two ring bond angles ∠C–Si–C are equal in $DSCB^{+\bullet}$ and $TMDSCB^{+\bullet}$ ($\angle C_2–Si_1–C_4 = \angle C_2–Si_3–C_4$ = 97.0° for $DSCB^{+\bullet}$; $\angle C_2–Si_1–C_4 = \angle C_2–Si_3–C_4$ = 96.4° for $TMDSCB^{+\bullet}$). This is due to the different asymmetric distortion assumed by DMDSCB and DSCB/TMDSCB radical cations. In $DMDSCB^{+\bullet}$-C_s, the two elongated Si–C ring bonds are of different lengths, whereas the symmetric plane crossing two ring C atoms was maintained in $DSCB^{+\bullet}$ and $TMDSCB^{+\bullet}$ with one pair of Si–C ring bonds elongated and another pair shortened, both to the same extent.

[c]Calculations from ref. 17.

One significant change in the geometry upon ionization for all three DiSCB species is that their dihedral angles were reduced to zero, i.e., all three $DiSCB^{+\bullet}$ have planar ring structures in their ground states. This is in sharp contrast to the behavior observed with the three MonoSCB cations where the puckered ring structures are maintained in the ground states. The reason for the difference in the geometry assumed by $MonoSCB^{+\bullet}$ and $DiSCB^{+\bullet}$ will be explained later. It is also interesting to note that the bond length difference of 0.196 Å between the two pairs of ring Si–C bonds in the ground-state $DSCB^{+\bullet}$ is much reduced as compared with 0.430 Å for the ground-state $SCB^{+\bullet}$. Moreover, the difference in the bond lengths of the two ring Si–C bonds connected to the methyl substituent is smaller in the ground-state $DMDSCB^{+\bullet}$ (0.402 Å) than in the ground-state $DMSCB^{+\bullet}$ (0.473 Å). Therefore, the endocyclic Si substitution seems to lessen the extent to which the four-membered ring undergoes the asymmetric distortion upon ionization.

Table 5 lists the calculated spin density distributions on the four ring atoms in the six asymmetrically distorted ground-state radical cations using DFT and MP2 with the 6–311++G(d,p) basis set. It is clear that most of the spin densities in the

$MonoSCB^{+\bullet}$ with C_1 symmetry are localized mainly in the elongated σ(Si–C) ring bond as a result of the structural distortion. This agrees very well with the previous results that demonstrated that the unpaired electron resided predominately on the elongated σ(Si–C) ring bond(s) in silacyclobutane and silacyclohexane radical cations by low-temperature EPR studies.[13–17] The same was found for the $DMDSCB^{+\bullet}$-C_1 structure where the majority of the spin densities are confined to the one significantly elongated σ(Si–C) ring bond attached to the methyl groups. For the remaining two $DiSCB^{+\bullet}$, most of the total spin density is localized to the two σ(Si–C) ring bonds, i.e., Si_1–C_4 and Si_3–C_4. This is because both of the $DSCB^{+\bullet}$-C_{2v} and $TMDSCB^{+\bullet}$-C_{2v} structures have a pair of two Si–C ring bonds elongated. Therefore, all six radical cations form the localized asymmetrically distorted structures in their ground states.

Origin of the structure distortions — Pseudo Jahn–Teller effect

The structural distortion observed in the ground states of the six radical cations studied in this work can be explained by the pseudo Jahn–Teller effect. This theory suggests that the structural distortion in the radical cations of Jahn–Teller inactive molecules originates from the vibronic–electronic coupling, which is inversely proportional to the energy difference between the ground and excited electronic states. This is shown in the expression of the energy of a species, after a small distortion from the stable configuration, written as eq. [1] based on the second-order perturbation theory.[13,18–20]

$$[1] \qquad E = E_0 + \frac{Q^2}{2}\langle\psi_0|\frac{\partial^2 U}{\partial Q^2}|\psi_0\rangle + \sum_k \frac{\left(Q\langle\psi_0|\frac{\partial U}{\partial Q}|\psi_k\rangle\right)^2}{(E_0 - E_k)}$$

where E_0 is the energy of the structure without distortion, Q is the displacement of the normal coordinate from the original position, U is the nuclear–nuclear and nuclear–electronic potential energy, and ψ_0 and ψ_k are the wave functions for the ground electronic state and excited state, respectively. The first energy correction term in eq. [1] to the undistorted energy E_0 is always positive, and the second correction term is always negative. It is, therefore, the sum of the last two terms that determines whether a distorted structure is preferable or not; that is, when the sum is negative, the distorted structure is energetically favourable. As shown in eq. [1], the absolute value of the second correction term is inversely proportional to the energy difference between the ground state and the excited state. As Bader[18] suggested, the pseudo Jahn–Teller effect generally induces geometrical distortion when the energy difference between the electronic ground state and the low-lying electronic excited state is within 4 eV and that only the lowest lying excited state seems to be important in the summation of eq. [1].

Time-dependent DFT calculations were then used to calculate the electronic transition energy in the six radical cations. Table 6 lists the calculated electronic transition energy between the electronic ground state and the first excited electronic state for both MonoSCB and DiSCB radical cations at B3LYP/6–311++G(d,p). The lowest electronic transition energies calculated for the six neutral molecules are also listed in the same table for comparison. It was found that the lowest electronic transition mainly involves the HOMO and SOMO in the cations (97.3%–99.8%) and HOMO and LUMO in the neutral form (68.6%–70.1%). As shown in Table 6, the lowest electronic transition energy for the MonoSCB and DiSCB radical cations varies from 2.17 to 2.78 eV, which is less than 4 eV. Therefore, the predominant second energy-correction term in eq. [1] is expected to reduce the energy of the radical cations after structural distortion. In other words, the structures of MonoSCB and DiSCB cations get stabilized by the asymmetrical distortion in geometry. The lowest electronic transition energy for the six neutral molecules, on the other hand, ranges from 5.73 to 6.50 eV, which is significantly higher than those for the radical cations, and more importantly, higher than 4 eV. This explains why the structural distortion due to the pseudo Jahn–Teller effect does not occur in the neutral MonoSCBs and DiSCBs.

As mentioned in the previous section, the asymmetrical distortion is enhanced by exocyclic substitution of methyl groups on the ring Si atom and weakened by the endocyclic Si substitution for the six four-membered-ring radical cations. This type of trend was also observed in the radical cations of silacyclohexane and its methyl derivatives.[13] Creve and Nguyen[41] showed in their study of halogenated phosphine radical cations that an increasing number of substituents with high electronegativity can strengthen the pseudo Jahn–Teller effect. Since the C atom is more electronegative with respect to the Si atom, methyl substitution should result in a stronger

pseudo Jahn–Teller effect by further localizing the charge distribution on the elongated σ(Si–C) ring bond. Following the same argument, replacing a ring C atom with Si weakens the pseudo Jahn–Teller effect, consequently resulting in the structural distortion.

The asymmetrical distortion in the geometrical structures due to the pseudo Jahn–Teller effect generally lowers the molecular symmetry. For example, the radical cations of SCB, MSCB, and DMSCB all belong to the C_1 point group, which is lower than the C_s symmetry in their corresponding neutral forms. This is because the symmetric plane is distorted because of the pseudo Jahn–Teller effect upon ionization. However, the three DiSCB radical cations seem to escape from this general rule. The molecular symmetry is maintained upon ionization even though the ring structure has been asymmetrically distorted, which destroys the symmetry plane crossing the two ring Si atoms. This exception is due to the fact that the ring structure of the three DiSCB molecules changes from puckered to planar upon ionization.

Puckering potential energy surface (PES)

Although both MonoSCB and DiSCB cations possess the asymmetrically distorted structures in their ground states, there is one significant difference in the geometry change between these two types of species upon ionization. The puckered ring structures are maintained in MonoSCB cations, whereas DiSCB cations change to a planar ring structure. These two distinct structures are well-represented in the PESs as a function of dihedral angles, as shown in Fig. 5. In Fig. 5*a*, the puckered MonoSCB cations have double-well potential energy curves, in which the maximum energy structures correspond to the planar transition states. For SCB and DMSCB radical cations, the two minima are of equal energy. Two nonequivalent minima were found for the MSCB radical cation, and the equatorial conformer (MSCB-$e^{+\bullet}$) is more stable than the axial one (MSCB-$a^{+\bullet}$). The energy difference between the two conformers was determined to be 114 cm^{-1}. This is consistent with our previous calculation on the neutral molecule of MSCB, whose stable structure is also in equatorial form.[38] In Fig. 5*b*, the potential energy curves of the DiSCB cations have a single-well shape, which reflects the planar structure.

As has been well-established in the literature,[34] the puckering PES can be described by a one-dimensional potential energy function shown in eq. [2], if the planar ring has a plane of symmetry.

$$[2] \qquad V(x) = Ax^4 + Bx^2$$

where A is a positive constant, B can be either a positive or negative constant, and x is the puckering coordinate defined

[a]Results from ref. 38 calculated using the B3LYP/6–311++G(3df,p) level.

in Fig. 2. If B is negative, the function is a symmetric double-minimum type with an energy barrier height of $B^2/4A$ separating the equivalent minima. If B is positive, the function has only one minimum. The planar ring of $MSCB^{+\bullet}$ does not have a plane of symmetry. For this species, the asymmetry can be introduced into $V(x)$ by including the odd-powered terms of x. Since the maximum energy structure in the PES of $MSCB^{+\bullet}$ is planar coinciding with $x = 0$, the linear term can be omitted and the puckering potential energy for $MSCB^{+\bullet}$ can be represented by eq. [3].

$$[3] \qquad V(x) = Ax^4 + Bx^2 + Cx^3$$

where C is a constant. Among the six radical cations studied, C only has a nonzero value in $MSCB^{+\bullet}$. The potential function in eq. [3] has two nonequivalent minima. The sign of C determines which minimum is lower in energy than the other, and its magnitude reflects the energy difference between the two minima. The A, B, and C parameters in $V(x)$ for the six radical cations were determined in this work by fitting the calculated PES in the form of a polynomial function of x. The value of x at a specific dihedral angle was calculated using the corresponding geometric parameters, including the bond length and bond angles. The values of A, B, and C thus obtained for the six radical cations are listed in Table 7. The three parameters for the six neutral molecules are listed in the same table for comparison. The barrier height to planarity has also been reported with its corresponding dihedral angle and x value.

As shown in Table 7, the parameters of A remain positive upon ionization for all six species. The three MonoSCB radical cations have negative B values, which result in the puckered ring structures. However, the barrier heights are reduced in the cations as compared with their neutral counterparts. It is important to note that the B parameters for the DiSCBs change their sign from negative to positive upon ionization. The positive B values in the DiSCB cations suggest that they now have planar ring structures. The sign change in B originates from the fact that the balance between the torsional strain and the angle strain determines the ring planarity.[34] The torsional strain ordinarily favors a puckered ring to relieve the repulsion between hydrogen atoms in the eclipsed planar conformation, whereas the angle strain prefers to a planar ring in which the compressed and strained ring angles are at maximum.

The potential function in eq. [2] can be rewritten in terms of angle strain (V_d) and torsional strain (V_t).[34]

$$[4] \qquad V(x) = V_d + V_t = (A_d + A_t)x^4 + (B_d + B_t)x^2 = Ax^4 + Bx^2$$

where A_d and B_d are the angle strain contributions to the quartic and quadratic terms, respectively, and A_t and B_t are the torsional strain contributions to the quartic and quadratic terms, respectively. The expressions for the four constants are given in eqs. [5]–[8].

$$[5] \qquad A_d = \sum_i \frac{1}{2} k_i c_i$$

[a]The errors for the *A*, *B*, and *C* parameters (eq. [3]) were obtained from the polynomial fittings.

[b]Results from ref. 38.

[c]The barrier height was calculated from puckered MSCB-*e* (equatorial form) to its planar structure.

$$[6] \qquad A_t = \frac{27}{16}\sum_i h_i^4 V_3^i$$

$$[7] \qquad B_d = \sum_i k_i s_i c_i$$

$$[8] \qquad B_t = -\frac{9}{4}\sum_i h_i V_3^i$$

Here, i represents each single bond in a ring, k is the angle-bending force constant, s is the angle strain inherent in the planar ring, c and h are both positive constants, and V_3 is the torsional barrier to a torsional motion about a ring bond. According to eqs. [7] and [8], B_d is always positive, since s_i is positive for the four-membered rings, whereas B_t is always negative. Therefore, the sign of B is determined by the relative magnitudes of B_d and B_t.

As is seen from Table 7, the B constants are all negative in the six neutral molecules; this suggests that B_t predominates over B_d in the neutral forms. The magnitude of B_t is proportional to the torsional barrier height (V_3) about the ring bonds. The value of V_3 about a particular bond was reported to decrease with increasing bond length, as was illustrated in ethane (1013.069 cm^{-1}), methylsilane (591.370 cm^{-1}), and disilane (404.344 cm^{-1}).[42] Among these three molecules, the bond length increases with Si substitution, i.e., σ(C–C) < σ(Si–C) < σ(Si–Si).[43] As we discussed in our previous study,[38] the neutral DiSCB molecules are less puckered than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

MonoSCBs, since there are four Si–C ring bonds in the former, but only two in the latter. This makes the *B* constants less negative in DiSCBs. Owing to the σ(Si–C) ring bond(s) elongation arising from the structural distortion, the V_3 values of all six molecules are expected to decrease in magnitude upon ionization. The resultant decrease in the magnitude of B_t leads to the overall positive *B* values in the DiSCB radical cations. The overall *B* values remain negative in MonoSCB radical cations, since the starting values of B_t are more negative in their neutral forms. Therefore, the Si–C ring bond elongation due to the pseudo Jahn–Teller effect upon ionization is believed to be the main reason why endocyclic Si substitution in silacyclobutane rings gives a planar ring in the DiSCB radical cations.

The exocyclic methyl substitution is found to affect the shape of the puckering PES. As shown in Fig. 5*b*, the TMDSCB radical cation has a larger curvature at the minimum when compared with the DSCB and DMDSCB radical cations. This is due to an increase in the magnitude of the positive *B* values upon exocyclic methyl substitution, as shown in Table 7. The change in *B* can again be understood by the change in V_3 upon methyl substitution. Previous studies of methyl-substituted silanes showed that the V_3 about the Si–C bond decreased upon methyl substitution, e.g., CH_3SiH_3 (V_3 = 591.370 cm^{-1}),[44] $(CH_3)_2SiH_2$ (V_3 = 577.437 cm^{-1}),[45] and $(CH_3)_4Si$ (V_3 = 476.476 cm^{-1}).[46] This leads to the decreasing magnitude of B_t, which in turn results in a more positive *B* value upon methyl substitution. Therefore, upon exocyclic methyl substitution the PESs of the DiSCB radical cations behave more like that of the harmonic oscillators.

Conclusions

A systematic study of the geometrical and electronic structures of three monosilacyclobutane (SCB, MSCB, and DMSCB) and three 1,3-disilacyclobutane (DSCB, DMDSCB, and TMDSCB) radical cations was performed using ab initio and DFT methods. The ground electronic states of all six radical cations have an asymmetrically distorted structure. Those of the MonoSCB radical cations are all of C_1 symmetry with one Si–C ring bond elongated and the other shortened. In the asymmetrically distorted structures of DiSCB radical cations, a pair of Si–C ring bonds are elongated and the other pair shortened. Of the three DiSCB radical cations, the pairs of bonds are elongated to the same extent in $DSCB^{+\bullet}$ and $TMDSCB^{+\bullet}$, whereas the two elongated Si–C bonds are of different lengths in $DMDSCB^{+\bullet}$. The next higher energy stable structures of the six radical cations all have a planar ring structure, where two ring Si–C bond lengths are increased to the same extent for MonoSCBs. The general feature in the geometry of the next higher energy stable structures of the three DiSCB radical cations is that all four ring Si–C bonds are elongated; however, all ring Si–C bonds are of the same length in $DSCB^{+\bullet}$ (D_{2h}) and $TMDSCB^{+\bullet}$ (D_{2h}), whereas the C_{2v} structure of $DMDSCB^{+\bullet}$ has two pairs of equal ring Si–C bonds.

In the asymmetrically distorted ground states, the unpaired electrons reside predominantly on the elongated σ(Si–C) ring bond(s) in the six radical cations, indicating a localized structure. This is in agreement with previous studies on silacycloalkane cations. In examining the effect of the exocyclic substitution of methyl groups on the ring Si atom and the replacement of a ring C atom by Si, it was found that the asymmetrical structural distortion is enhanced by exocyclic methyl substitution and weakened by endocyclic Si substituion. The asymmetrical structural distortions upon ionization of MonoSCBs and DiSCBs are believed to be due to the second-order Jahn–Teller effect. Our studies of the lowest lying excited electronic states of both MonoSCB and DiSCB radical cations using time-dependent DFT methods showed that they all lie above the ground states by an energy gap ranging from 2.17 to 2.78 eV. Therefore, the structural distortion due to the second-order Jahn–Teller effect stabilizes the cationic structures. It is also noted that there is one significant difference in the geometry change between MonoSCBs and DiSCBs upon ionization, i.e., the puckered ring structures are maintained in MonoSCB cations, whereas DiSCB cations change to a planar structure. The investigation on the PESs of the radical cations shows that MonoSCB cations possess double-well potential energy curves, whereas those of DiSCB cations are of a single-well shape. The difference is explained in terms of the competition between the torsional strain and the angle strain that determines the ring planarity. The elongation of Si–C ring bond(s) and the consequent decrease in the torsional barrier height lead to a planar ring structure in DiSCB radical cations.

Abstract: The aim of this study was to provide syntheses of optically pure (*R*)-1-phenylethanol and (*R*)-1-phenylpropanol from ethylbenzene and propylbenzene, respectively, using the fungal mycelia of new fungal species, namely *Aspergillus flavus* MTCC-1783 and *Aspergillus flavus* MTCC-1884, as catalysts. The mycelia of *A. flavus* MTCC- 1783 and *A. flavus* MTCC-1884 were prepared by growing the fungal strains in liquid culture medium containing ethylmethylketone as the sole carbon source. The mycelia were suspended in potassium phosphate buffer pH 7.0. The suspensions of mycelia were used for the transformations of ethylbenzene and propylbenzene. Ethylbenzene and propylbenzene were converted to (*R*)-1-phenylethanol and (*R*)-1-phenylpropanol, in 100% and 99% ee, respectively. The mycelia of *A. flavus* MTCC-1783 and *A. flavus* MTCC-1884 can be used for the preparation of (*R*)-1-phenylethanol and (*R*)-1-phenylpropanol in 100% and 99% ee, respectively, from ethylbenzene and propylbenzene, respectively. The studies report convenient methods for the syntheses of optically pure isomers, (*R*)-1-phenylethanol and (*R*)-1-phenylpropanol, which are important chiral building blocks in the preparations of fine chemicals and pharmaceuticals. The reactions are ecofriendly, occur at 30 °C, and the time required was 24 h.

Key words: Aspergillus flavus, benzylic hydroxylation, biocatalyst, (*R*)-1-phenylethanol, (*R*)-1-phenylpropanol.

Résumé : On a réalisé la synthèse des (*R*)-1-phényléthanol et (*R*)-1-phénylpropanol, à partir respectivement de l'éthylbenzène et du propylbenzène, en présence de mycélium fongiques provenant de nouvelles espèces fongiques, soit l'*Aspergillus flavus* MTCC-1783 et l'*Aspergillus flavus* MTCC-1884, utilisées comme catalyseurs. Les mycélium d'*A. flavus* MTCC-1783 et d'*A. flavus* MTCC-1884 ont été préparés en procédant à la culture des souches fongiques dans des milieux de culture liquide ne contenant que de l'éthylméthylcétone comme source de carbone. Les mycélium ont été suspendus dans un tampon de sulfate de potassium, de pH 7,0. On a ensuite utilisé les suspensions de mycélium pour les transformations de l'éthylbenzène et du propylbenzène. L'éthylbenzène et le propylbenzène ont été convertis en (*R*)-1-phényléthanol et en (*R*)-(1)-phénylpropanol avec des excès énantiomères respectivement de 100 % et 99 %. En conclusion, les mycélium d'*A. flavus* MTCC-1783 et d'*A. flavus* MTCC-1884 peuvent être utilisés dans la préparation de (*R*)-1-phényléthanol et (*R*)-(1)-phénylpropanol avec des excès énantiomères respectivement de 100 % et 99 %, à partir respectivement l'éthylbenzène et du propylbenzène. Les études décrites dans ce travail rapportent la mise au point de méthodes commodes de synthèses d'isomères optiquement purs de (*R*)-1-phényléthanol et de (*R*)-(1)-phénylpropanol qui sont des synthons chiraux importants dans les préparations de produits chimiques fins et pharmaceutiques. Les réactions sont écologiques; elles se produisent à 30 °C et les temps requis sont de l'ordre de 24 heures.

Mots-clés : Aspergillus flavus, hydroxylation benzylique, biocatalyseur, (*R*)-1-phényléthanol, (*R*)-(1)-phénylpropanol.

[Traduit par la Rédaction]

Introduction

Chiral alcohols are important intermediates and are structural elements in the syntheses of biologically active compounds and natural products.[1–5] The optically active 1-phenylethanol is used as a chiral building block and synthetic intermediate in fine chemicals and in pharmaceutical industries.[6–8] (*R*)-1-Phenylethanol is widely used as a fragrance in the cosmetic industry because it has a mild floral odour. Other applications include use as a salvatochromic dye,[9] use as an opthalic preservative, and use as an inhibitor of cholesterol intestinal absorption.[10] β-Aminoalcohols have been used for the syntheses of 1-phenylethanol-2-[(2-phenyl-1-alkylethyl)amino]ethanol derivatives, a new important class of antidiabetic agents.[11] A large genus of mushroom flies has been reported to be attracted to 1-phenylethanol in field tests.[12] Thus, secondary alcohols act as pheromones also. However, the chemical methods for their syntheses are not

convenient and ees are generally low.[13] On the other hand, biocatalytic methods are convenient and enantiomeric excesses are high.[14]

Several biocatalytic methods to synthesize enantiomeric pure secondary alcohols have been developed during the recent past owing to the increasing demand for these valuable compounds.[5] Stereoselective reduction of ketones[14] and enantioselective oxidation of racemic secondary alcohols have been studied for the preparations of pure enantiomeric secondary alcohols. Although the hydroxylation of nonactivated centres in hydrocarbons is one of the most useful biotransformations, so far it has been used mainly for the hydroxylation of steroids and terpeniods.[3,13] The biotransformation of ethylbenzene to 1-phenylethanol has rarely been studied.[15–20] The conversion of ethylbenzene and a number of its para-substituted derivatives to the corresponding optically active 1-phenylethanols with enantiomeric excesses varying between 5% and 40% using the fungus *Mortierella isabellina* have been reported.[15] The fungi *Cunninghamella echinulata* var. *elegans* and *Heminthosporium* were also capable of performing some of these transformations.[15] The hydroxylation of ethylbenzene almost exclusively at the secondary carbon atom giving 1-phenylethanols in the ratio 2:1 of the R and S isomers using cytochrome P450camp has been reported.[16] Seventeen fungi and two yeast species that could hydroxylate ethylbenzene and propylbenzene to 1-phenylethanol and 1-phenylpropanol, respectively, have been reported.[17] One potent strain, *Fusarium moniliforme*, oxidizes ethylbenzene and propylbenzene to the corresponding benzylic alcohols with enantiomeric excesses of 98% in the (R) (+) form.[17] The involvement of cytochrome P450 in this transformation has been demonstrated.[18] Szaleniec et al.[19] reported the oxidation of ethylbenzene to (*S*)-(–)-1-phenylethanol by the denitrifying bacterium *Azoarcus* species strain EbN1. A nobel Mo–Fe–S enzyme, anaerobic ethylbenzene dehydrogenase, has been isolated and characterized.[20] Keeping in mind the potential for the biotransformation of ethylbenzene to optically pure isomers of 1-phenylethanol, we initiated a search for the fungal strains that could carry out these useful transformations. In this communication, we report two fungal strains, namely *Aspergillus flavus* MTCC-1783 and *Aspergillus flavus* MTCC-1884, which transform ethylbenzene to (*R*)-1-phenylethanol and propylbenzene to (*R*)-1-phenylpropanol in 100% and 99% ee, respectively.

Materials and methods

Chemicals

Methylbenzene, ethylbenzene, propylbenzene, ethylmethylketone, racemic (±)-1-phenylethanol, (*R*)-1-phenylethanol, racemic (±)-1-phenylpropanol, and (*R*)-1-phenylpropanol were purchased from Sigma-Aldrich Chemicals Private Limited, New Delhi, India. All other chemicals were purchased either from S.D. Fine-chem Ltd., Mumbai, India, or from Qualigens Chemicals, Mumbai, India, and were used without further purification.

Fungal strains

Both fungal strains were procured from the Microbial Type Culture Collection Centre and Gene Bank, Institute of Microbial Technology, Chandigarh, India, and were maintained on Bennett's agar medium,[17] which consisted of 1.5% (*w*/*v*) glucose, 0.5% peptone, 0.2% yeast extract, 0.2% Ehlrich's beef extract, and 1.5% agar in tap water.

Preparation of mycelia

The microorganisms were cultivated in 100 mL of basal medium I (BM I) containing 1 mL of unsterilized ethylmethylketone (*v*/*v*) in 250 mL Erlenmeyer flasks at 30 °C on a rotary shaker at 150 rpm for 3 days. BM I contained 10 g of $NaNO_3$, 2 g of NH_4Cl, 2 g of KH_2PO_4, 3 g of K_2HPO_4, 2 g of NaCl, 0.2 g of $MgSO_4{\cdot}7H_2O$, 0.5 g of yeast extract, and 2 mL of metal solution having pH 7.0 in 1 L of deionized water. The metals solution consisted of 400 mg of $MnCl_2{\cdot}2H_2O$, 350 mg of $FeCl_2{\cdot}4H_2O$, 200 mg of $ZnCl_2$, 20 mg of $CoCl_2$, 20 mg of $CuCl_2{\cdot}H_2O$, 10 mg of $Na_2MoO_4{\cdot}2H_2O$, 10 mg of $Na_2B_4O_7{\cdot}10H_2O$, and 2 mL of concentrated HCl in 100 mL of deionized water. The mycelia were collected by filtration on ordinary filter papers, washed twice with 30 mL of 25 mmol/L potassium phosphate buffer (KPB, pH 7.0), and were used fresh.

Biotransformation reactions

The biotransformation reactions were performed using the reported method.[17] Wet mycelia (0.1 g) were suspended in 2 mL of 25 mmol/L KPB in test tubes (17 mm in diameter and 150 mm in height), and 200 μmol of ethylbenzene (21 μL) was added. The test tubes were closed with stoppers and incubated at 30 °C in a reciprocal shaker at 200 rpm. After 24 h, the reaction solutions were acidified by the addition of 0.2 mL of 6 N HCl. The products formed in the reaction solution were extracted thrice using 2.0 mL of *n*-hexane each time. Biotransformations of propylbenzene and methylbenzene were also studied using the above method. The extracts were analysed for 1-phenylethanol, 1-phenylpropanol, and benzylalcohol by using HPLC as mentioned in the following. In one typical scale-up experiment, 7.5 g of the mycelia of *A. flavus* MTCC-1884 suspended in 100 mL of 25 mmol/L KPB and 1.5 mL of ethylbenzene were reacted for 24 h at 25 °C and then extracted with 30 mL of *n*-hexane; 20 μL of the extract was subjected to HPLC analysis. In another experiment, 14 g of the mycelia of *A. flavus* MTCC-1783 suspended in 100 mL of KPB and 3.0 mL of ethylbenzene at 25 °C was reacted for 24 h, then extracted with 30 mL of *n*-hexane, and then 20 μL of the extract was subjected to HPLC analysis. Similar experiments were performed with propylbenzene.

HPLC analysis

HPLC analyses were done using a Waters HPLC (model 600E) and a Spherisorb C_{18} 5 UV (4.5 mm × 250 mm) column. The eluent phase was a methanol–water mixture in a 1:1 (*v*/*v*) ratio at 1 mL/min. The *n*-hexane extracts of the products (20 μL) were injected and the detections were made using a Waters UV detector (model 2487) at 254 nm.

Spectroscopic analysis

The identifications of the biotransformation products were done by IR and ^1H and ^{13}C NMR spectroscopic techniques.

^1H NMR

The ^1H NMR spectra of the biotransformation products

were recorded using a Jeol AL 300 MHz spectrometer in $CDCl_3$ using TMS as the internal standard reference at the Department of Chemistry, Banaras Hindu University, Varanasi, India.

^{13}C NMR

The ^{13}C NMR spectra of the biotransformation products were recorded on a Jeol-ECX 500 Hz spectrophotometer in $CDCl_3$ using TMS as the internal standard reference at the Department of Chemistry, Indian Institute of Technology, Kanpur, India. The chemical shift values were reported in ppm.

IR

The IR spectra of the biotransformation products were recorded on a Bruker IR-VERTEX Flash 70 spectrometer in the range of 400–4000 cm^{-1} at the Department of Chemistry, Indian Institute of Technology, Kanpur, India.

GC–MS

Products were analysed by GC–MS using an HP GC–MS model No. 5975C-inert MSDS with triple axis detector using helium gas (5 mL/min) as the mobile phase at the Department of Chemistry, Indian Institute of Technology, Kanpur, India.

Determination of ee

The ees were determined using a Chiralcel OD column (4.6 mm × 250 mm) manufactured by Daicel Chiral Technologies Pvt. Ltd. (Japan) using a 90:10 (*v*/*v*) mixture of *n*-hexane and isopropylalcohol as the eluent phase at a flow rate of 0.5 mL/min at the Department of Chemistry, Indian Institute of Technology, Kanpur, India.

Results and discusion

The results of the identification of the biotransformation products, (*R*)-1-phenylethanol and (*R*)-1-phenylpropanol, using the suspensions of fungal mycelia of the strains *A. flavus* MTCC-1783 and *A. flavus* MTCC-1884 are given in the Supplementary data. The fungal mycelia of *A. flavus* MTCC-1783 converted ethylbenzene to (*R*)-1-phenylethanol in 100% enantiomeric excess and propylbenzene to (*R*)-1-phenylpropanol in 99% enantiomeric excess. The reaction times were 24 h and no ethylbenzene and propylbenzene were detected at the end of transformation reactions showing that ethylbenzene and propylbenzene were fully transformed to their corresponding biotransformation products. Methylbenzene was also transformed to benzylalcohol by these two fungal strains showing that hydroxylations occur at benzylic carbon centre. In typical scale up experiments as mentioned in the materials and methods section (Biotransformation reactions) 1.5 mL of ethylbenzene and 3.0 mL of propylbenzene were fully converted to (*R*)-1-phenylethanol and (*R*)-1-phenylpropanol, respectively, showing the feasibility of the method on laboratory scale.

Supplementary data

Supplementary data are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v2012-034.

Abstract: A new third-generation thermoresponsive amphiphilic dendron consisting of a hydrophobic poly(benzyl ether) dendritic core and hydrophilic oligo(ethylene glycol) peripheries was synthesized by an efficient convergent approach. Its structure was confirmed by ^{1}H NMR, ^{13}C NMR, IR, GPC, MALDI-TOF MS, and elemental analysis. Turbidity and dynamic light scattering (DLS) measurements demonstrated that the dendron showed a reversible temperature-dependent phase-transition behavior in aqueous solution and its lower critical solution temperature (LCST) was lower than that of the corresponding second-generation dendron, indicating the dependence of LCSTs on the generation of dendrons. Fluorescent spectroscopy and TEM studies revealed that the dendron would self-assemble into nanospherical micelles with a very low critical micelle concentration (CMC) in water. The core-shell structure of the micelles was proved by ^{1}H NMR analyses of the micelles in D_2O. The drug-loading capacity of the dendron micelles is about 29 wt % for podophyllotoxin (POD) used as a model drug, and in vitro release tests showed a desired thermoresponsive drug-release behavior. These results indicate that the dendron is promising as stimuli-responsive material for biomedical applications.

Key words: amphiphilic dendron, poly(benzyl ether) dendritic core, oligo(ethylene glycol) peripheries, thermoresponsive micelles, controlled drug release.

Résumé : Utilisant une approche impliquant une synthèse efficace et convergente, on a réalisé la synthèse d'un nouveau dendron amphiphile thermosensible de troisième génération formé d'un coeur dendritique, un poly(éther benzylique) hydrophobe, et des périphéries hydrophiles à base d'oligo(éthylèneglycol). On en a confirmé la structure résonance magnétique nucléaire du ^{1}H et du ^{13}C, infrarouge, chromatographie en phase gazeuse, spectrométrie de masse en temps de vol avec ionisation par désorption au laser d'une matrice (« MALDI-TOF MS ») et par analyse élémentaire. Des mesures de turbidité et de diffusion de la lumière dynamique (DLD) ont permis de démontrer que, en solution aqueuse, le dendron donne lieu à un comportement impliquant une transition de phase réversible en fonction de la température et que sa température de solution critique la plus basse (TSCB) est plus basse que celle du dendron correspondant de deuxième génération, ce qui met en évidence que la température de solution critique la plus basse (TSCB) varie en fonction de la génération des dendrons. Des études de spectroscopie de fluorescence et de microscopie électronique de transmission (MET) mettent en évidence le fait que, dans l'eau, le dendron pourrait donner un auto-assemblage en micelles nanosphèriques avec une concentration micellaire critique (CMC) très basse. Faisant appel à des analyses de RMN du ^{1}H, on a pu déterminer que, dans le D_2O, la structure des micelles correspond à coeur en forme de coquille. La capacité de charge de médicament par les micelles de dendron est d'environ 29 % en poids pour la podophyllotoxine (POD) utilisée comme médicament modèle et des essais d'émission in vitro ont permis de démontrer un comportement recherché d'émission thermosensible des médicaments. Ces résultats indiquent que le dendron est un matériel stimuli-sensible prometteur pour des applications biomédicales.

Mots-clés : dendron amphiphile, poly(éther benzylique) à coeur dendritique, oligo(éthylèneglycol), périphéries, micelles thermosensibles, émission contrôlée de médicament.

[Traduit par la Rédaction]

Introduction

In recent years, a growing interest has been evident in the development of dendrimers that are responsive to external stimuli, such as pH,[1,2] temperature,[3,4] light,[5,6] and redox state.[7,8] One of the most appealing stimuli-responsive species is the thermoresponsive dendrimer, since such a system combines the advantages of temperature sensitivity and dendritic effect[9] for applications such as biomedicine and catalysis.[10–13] Thermoresponsive dendrimers can be constructed by attaching thermoresponsive groups or polymers to the periphery or the core of the dendrimer. Dendrimers with properly balanced hydrophilic and hydrophobic units can also act as temperature-sensitive dendrimers.[14] Poly(*N*-isopropylacrylamide) (PNIPAM) is a representative polymer exhibiting thermoresponsive behavior. It shows a dissolution–precipitation transition

in aqueous solution at 32 °C. *N*-Isopropylacrylamide (NIPAM) has been incorporated into linear and dendritic macromolecules to obtain thermoresponsive copolymers and dendrimers.[15–20] For example, Kimura et al.[21] prepared the first thermoresponsive dendrimer by polymerization of NIPAM from the termini of a poly(propyleneimine) dendrimer with terminal thiol groups. The core of the dendrimer was a cobalt complex, which catalyzed oxidation of the thiol compounds.

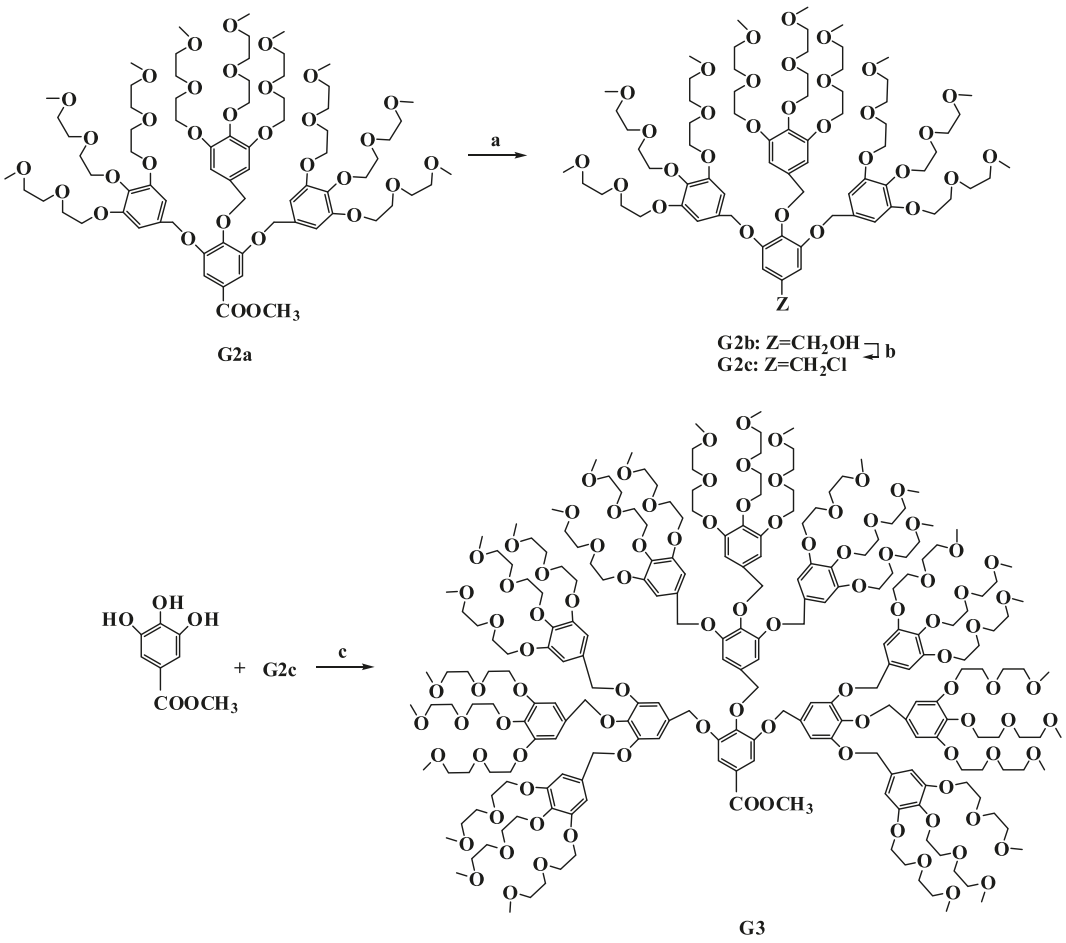
Polyethylene glycol (PEG), an uncharged, nontoxic, and nonimmunogenic water-soluble polymer, has found diverse applications in biological sciences, personal care products, and industrial additives.[22] However, PEG possesses a lower critical solution temperature (LCST) above 100 °C, which is too high and may be a limitation to its widespread use in the biomedical field.[23] Recently, PEGylated polymers have been explored by incorporating PEG or oligo(ethylene glycol) (OEG) units into other macromolecules. They show lower LCSTs and are promising alternatives to PNIPAM for applications in drug delivery systems.[24–28] PEG is also useful for the preparation of temperature-sensitive dendrimers. For example, Li et al.[29] synthesized dendrimers containing temperature-sensitive oligoethylene glycol as a building block. These unique dendrimers showed fast and sharp transitions around their LCSTs. Their thermoresponsive behaviors are dependent on both the generation and the terminal structure.

Some amphiphilic PEGylated dendrons that are parts of dendrimers have temperature-dependent phase-transition behavior. Moreover, these dendrons, composed of hydrophobic and hydrophilic parts, can self-assemble into dendritic micelles. For instance, Asthmanikandan et al.[9] reported on thermosensitive biaryl-based dendrons with a pentaethylene glycol monomethyl ether and a decyl chain. These amphiphilic dendrons exhibited generation-dependent temperature sensitivity and were capable of forming micelles and reverse micelles in polar and apolar solvents, respectively. Chang and Dai[30] synthesized dendrons consisting of hydrophobic oligo (*p*-phenylene vinylene) core branches and hydrophilic oligo (ethylene oxide) terminal chains. These dendrons showed a LCST and the critical micellization behavior. The unusual properties of these amphiphilic PEGylated dendrons are attractive for potential application in controlled drug delivery systems.

Usually, the purification of synthesized dendrons or dendrimers requires column chromatography, which not only is tedious to perform but also unavoidably leads to losses of product. In this paper, we described the column-free synthesis, and thermoresponsive and micellar behaviors of a third-generation amphiphilic dendron containing a hydrophobic poly(benzyl ether) dendritic core and 27 hydrophilic diethylenoxy methyl ethers at its periphery. The controlled release of the model drug podophyllotoxin (POD) using the thermoresponsive micelles was also studied in detail.

Results and discussion

Synthesis and characterizations of dendrons



The synthetic procedures of the dendrons are summarized in Scheme 1. The second-generation dendron **G2a** was synthesized according to our previously reported method.[31] **G2a** was reduced with lithium aluminum hydride (LAH) to give the second-generation dendron alcohol **G2b**. Chlorination of **G2b** with $SOCl_2$ afforded the corresponding chloride **G2c**. In this study, each dendron was purified simply by solvent extraction or dialysis to remove the earlier generation dendron. Compared with the synthetic strategy of the corresponding first-generation dendron, the reaction conditions to synthesize **G2b** were modified by adjusting the molar ratio of LAH to **G2a** from 2:1 to 3:1 and prolonging the reaction time from 16 to 20 h. The reaction time of **G2b** with $SOCl_2$ was also prolonged from 3 to 4 h. As a result, the purification of **G2b** and **G2c** required only solvent extraction. The alkylation of methyl gallate with **G2c** by using K_2CO_3 as the base in *N*, *N*-dimethylformamide (DMF) provided analytically pure third-generation dendron **G3**, requiring only a dialysis workup. None of the dendrons required column chromatography for analytically pure material, thus facilitating scale-up. All new compounds were obtained as oily liquids and their structures were characterized by ^{1}H NMR and ^{13}C NMR spectra (Supplementary data Figs. S1–S3; Fig. 1), FT-IR, as well as ESI-MS or MALDI-TOF MS. **G3** was further characterized by GPC and elemental analysis. GPC analysis of **G3** showed a single peak (PDI = 1.05, Fig. 2). The M_n measured by GPC for **G3** was much lower than the calculated one using calibration with linear polystyrene. This is attributed to the difference between the hydrodynamic volumes of polystyrene and **G3** and is consistent with the studies of polyether dendrimers by Fréchet and coworkers.[32] However, MALDI-TOF MS of **G3** showed a single signal at m/z ($[M + Na]^+$) = 4624 (calcd mass, 4599), indicating the formation of **G3**.

Formation of micelles

The presence of a hydrophobic poly(benzyl ether) branch unit and hydrophilic oligo(ethyleneoxy) periphery means that these amphiphilic dendrons can potentially be precursors to nanoparticles with an oligo(ethyleneoxy) corona and a poly (benzyl ether) core upon dissolution in water, which is a selective solvent. The formation of the hydrophobic poly(benzyl ether) domain can be confirmed by ^{1}H NMR spectra with $CDCl_3$ and D_2O as locking solvents for **G3**. In $CDCl_3$, where micellar formation was not expected, all ^{1}H NMR resonances attributed to poly(benzyl ether) and oligo(ethyleneoxy) units were detected as shown in Fig. 1*a*. However, the ^{1}H NMR spectrum in D_2O showed an intensity reduction of poly(benzyl ether) resonances resulting from the suppressed molecular motion of the aggregated hydrophobic branch units (Fig. 1*b*). The small broad signals in the NMR spectrum indicate restricted motions of these protons within the core of nanoparticles. This result is evidence for a core-shell type formation with a hydrophobic inner core and a hydrophilic shell. Similar trends in ^{1}H NMR spectra are consistent with amphiphilic block copolymer systems.[33,34]

The formation of micelles from the third-generation dendron **G3** was also examined by the detection of critical micelle concentration (CMC) relying on a fluorescence technique with pyrene as the probe because pyrene preferentially partitions into the hydrophobic core of micelles from water.[35] The intensity ratio of I_{341}/I_{337} vs the logarithm of concentrations of **G3** in the pyrene excitation spectra was plotted in Fig. 3*a*. It is seen that the I_{341}/I_{337} ratios remain fairly constant below a certain concentration and then increase

remarkably above that concentration, indicating the formation of micelles. From this plot, a CMC of 7.7×10^{-6} mol/L was obtained from the intersection of two straight lines: the baseline and the rapidly rising I_{341}/I_{337} line (Fig. 3*b*), which is lower than the one of the second-generation dendron **G2a** (2.2×10^{-5} mol/L).[31] This could be attributed to the fact that **G3** is larger than **G2a**, which facilitates the aggregation of the dendron. These CMC values are comparable to those reported for some other amphiphilic dendrons and linear copolymers.[9,36] The low CMC values mean that the dendrons can self-assemble to form nanoscaled core-shell micelles at a lower compound concentration, which is suitable for drug delivery in very dilute aqueous milieux such as body fluids.[37]

Micelle morphology was investigated by transmission electron microscopy (TEM). It can be seen from Fig. 4 that dendron **G3** forms spherical micelles with a core-shell (corona) structure and an average diameter of about 60 nm. The micelles made from **G3** were bigger than those from **G2a**[31] because of its larger core and peripheries.

Thermoresponsive behavior

To investigate whether the third-generation dendron **G3** exhibits a thermal response, we examined the optical transmittance of a **G3** aqueous solution as a function of temperature. The concentration dependence of the LCST was also investigated in the range of 0.1–2.1 mg/mL and the results are plotted in Fig. 5. For comparison, the respective curve of dendron **G2a**[31] was also added (Fig. 5*b*). Dendron **G3** displayed an obvious phase transition in water and its LCST values decreased with increasing concentration from 0.3 to 1.5 mg/mL. Compared with dendron **G2a**, **G3** shows lower LCSTs at all concentrations tested, demonstrating the dependence of LCSTs on the generation of dendrons, which was in correspondence with the report by Aathimanikandan et al.[9] The reason may arise from the increased size of the dendrons with the increasing generation; thus, the interaction of the peripheral oligo(ethyleneoxy) groups would take place more efficiently with the increasing generation of the dendron, which leads to the dehydration of the terminal oligo (ethyleneoxy) groups at a lower temperature with increasing generation.[3]

The thermoresponsive behavior of dendrons **G2a** and **G3** was also analyzed by dynamic light scattering (DLS). The hydrodynamic diameter (D_h) of the dendrons are apparently influenced by the temperature, as shown in Fig. 6. At temperatures lower than the LCSTs, the two dendrons are easily solubilized in water so that the amphiphilic dendrons self-assemble into core-shell micelles with a low D_h of approximately 50–60 nm. However, a dramatic increase in D_h was

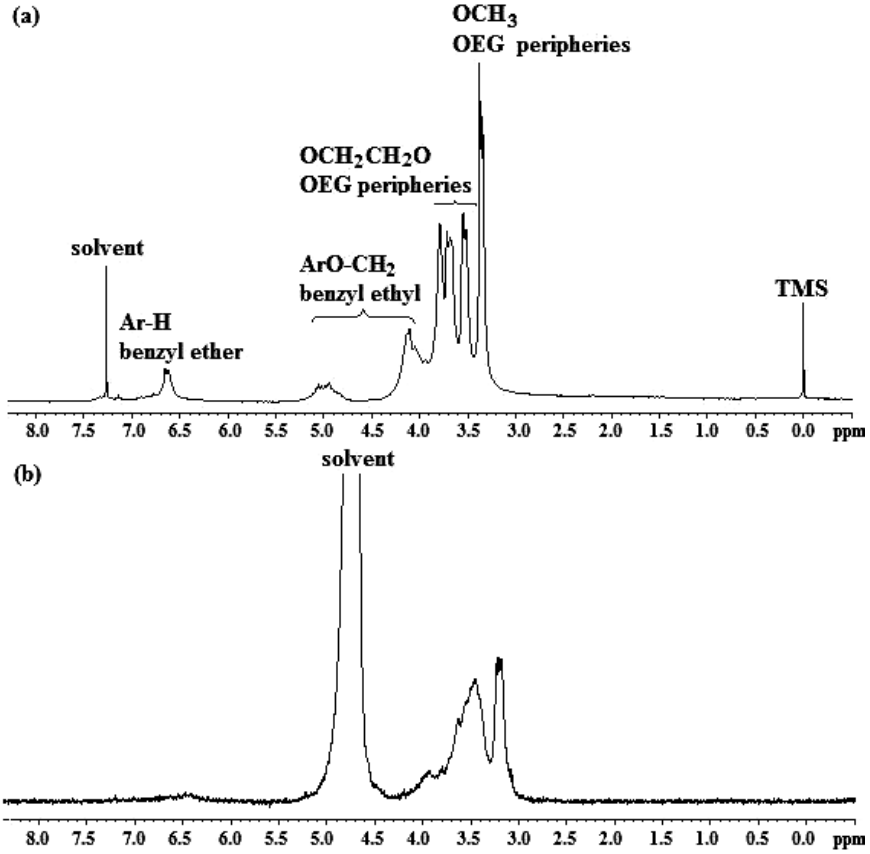
Fig. 1. ^{1}H NMR spectra of **G3** in $CDCl_3$ (*a*) and D_2O (*b*).



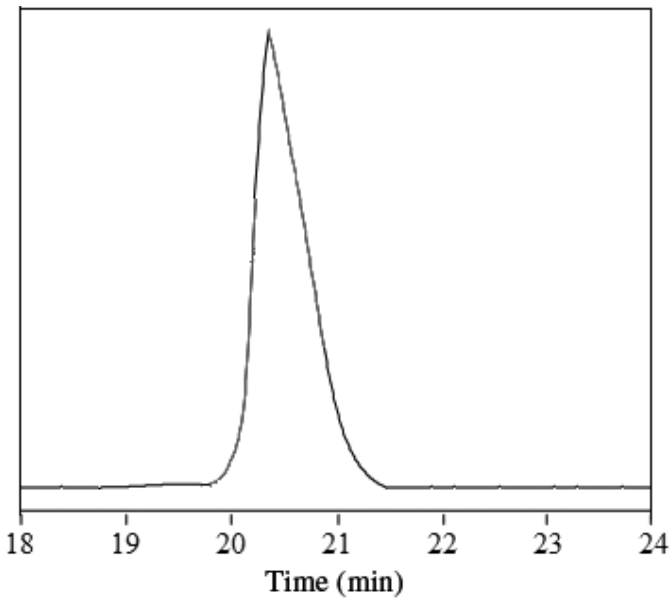


Fig. 2. GPC trace of **G3** with M_n (theory) = 4599 Da and M_n (GPC) = 1666.

observed once the temperature increased to near the LCST (58 and 54 °C, respectively), which indicated dendron aggregation. Dendron **G2a** requires a higher temperature to induce aggregation than dendron **G3** does. The aggregation process was completely reversible, and the aggregates became soluble again below the onset temperature. These are consistent with the results of turbidimetry measurement.

Controlled drug release

Hydrophobic drugs can be physically incorporated and stabilized in the micellar hydrophobic inner core by hydrophobic interaction. Podophyllotoxin (POD), an anticancer drug with poor solubility in water, was used as a model drug to investigate the potential application of dendron **G2a** and **G3** micelles in controlled drug release. The amount of drug incorporated into the micelles was measured by a UV spectrometer. The results showed that POD was successfully incorporated into micelles of **G2a** and **G3**, and the drug-loading content (DLC) and entrapment efficiency (EE) were about 21.24% and 77.81% for **G2a**, and 28.71% and 94.95% for **G3**, respectively, which are higher than those of the traditional micelles.[37] Furthermore, the amount of POD introduced into the micelle was dependent on the generation of the dendrons. The DLCs and EEs of **G3** with more hydrophobic phenyl groups are higher than those of **G2a** with fewer hydrophobic phenyl groups. To obtain information about the release of POD from **G2a** and **G3** micelles, the drug-loaded **G2a** and **G3** micelles were dissolved in PBS and dialyzed against PBS. Figure 7 shows the release profile of POD from **G2a** and **G3** micelles. In contrast with the rapid release of the free drug from a cellulose membrane (99% released in 4 h), the release from the dendritic micelles was slow and showed sustained characteristics. The generation of dendrons also affects drug release. The amount of drug released and the rate of release were greater for **G3** than for **G2a** micelles. This could be ascribed to steric hindrance of crowded end functional groups in higher generations and weaker interaction between these functional groups

Fig. 3. (*a*) Excitation spectra of pyrene in water at different concentrations of **G3**. (*b*) Plot of the intensity ratio I_{341}/I_{337} vs the logarithm of the concentration of **G3**.

and the drug molecules. A similar trend was observed in linear-dendrimer block copolymers containing PEG studied by Adeli et al.[38] To evaluate the effect of the temperature stimulus on release of POD from the thermoresponsive micelles, the POD release from **G3** micelles was examined in PBS solution at 25, 37, and 55 °C. As shown in Fig. 8, the POD release rate and amount increased with increasing temperature under constant pH (7.4) . A slow release was observed owing to the greater stability of micelles when the temperature was below the LCST (20 and 37 °C). However, when the temperature was above the LCST (55 °C), drug release was accelerated because of the temperature-induced structure change of the micelles. At a temperature above the LCST, the hydrophilicity of the micellar shell, comprised of oligo(ethyleneoxy) chains, was weakened, resulting in the deformation of the structure of the micelles. Thus, the drug release was faster above the LCST than below the LCST. Unfortunately, there was little change in the release rate of POD from **G3** micelles as a function of temperature, probably because the drug would be retained in the hydrophobic aggregates above the LCST. Therefore, this may not be an ideal system for thermally triggered drug release. However, it is expected that a less hydrophobic drug may be more readily released from **G3** micelles above the LCST.

Conclusions

We synthesized a novel third-generation thermoresponsive amphiphilic dendron with a hydrophobic poly(benzyl ether) dendritic core and hydrophilic oligo(ethylene glycol) peripheries using a simple convergent approach. The dendron exhibited a thermally induced phase transition in aqueous solution and its LCST increased with decreasing concentration over the range of 0.3–2.1 mg/mL of the dendron in aqueous solution. Studies of the association behavior of the synthesized dendron in aqueous solution revealed that the dendron is capable of forming spherical micelles of around 60 nm in diameter. Compared with its second-generation counterpart, the dendron exhibited lower LCST and CMC. The self-assembled dendron micelles exhibited high drug-loading capacity and thermoresponsive drug release behavior. These results indicate that the thermosensitive amphiphilic dendron possesses promising potential applications in the biomedical field.

Experimental

Instruments and materials

^{1}H NMR and ^{13}C NMR spectra were determined on a Bruker DRX-500 with TMS as internal standard. ESI-MS spectra were obtained on a Finnigan LCQ-Advantage mass spectrometer. Matrix-assisted laser desorption ionization (time of flight) mass spectrometry (MALDI-TOF MS) was carried out on a Bruker Biflex III MALDI-TOF spectrometer with α-cyano-4-hydroxylcinnamic acid (CCA) as the matrix. The GPC system consisted of a Waters 2690D separations module and a Waters 2414 refractive index detector (RI). Styragel HR1 THF and HR2 THF columns (Waters) were used at 40 °C with polystyrene as the standard and tetrahydrofuran (THF) as the mobile phase at a flow rate of 0.3 mL/min. FT-IR spectra were taken on a Nicolet AVATAR 360 FT-IR spectrometer.

Methyl 3,4,5-tris(3,4,5-tris(2-(2-methoxyethoxy)ethoxy) benzyloxy) benzoate (**G2a**) was synthesized according to the method previously reported.[31] Methyl gallate was purified by recrystallization from methanol. THF was refluxed on sodium and distilled from sodium benzophenone. DMF and dichloromethane (DCM) were distilled from anhydrous calcium chloride for drying. Other reagents were used as received.

Synthesis of 3,4,5-tris(3,4,5-tris(2-(2-methoxyethoxy) ethoxy)benzyloxy) benzyl alcohol (G2b)

Dendron **G2b** was prepared by the reduction of **G2a** with

another 3 h. After being washed with aqueous $NaHCO_3$ solution and saturated NaCl, the organic phase was dried over $MgSO_4$ and filtered, and the solvent was rotoevaporated, affording **G2c** as a pale yellow oil, yield 92.4%. IR (KBr) *ν:* 2929 (s), 2879 (s), 1589 (s, ν(Ar)), 1499 (m, ν(Ar)), 1112 (s, ν_{as}(COC)). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 6.63–6.65 (m, 8H, Ar H), 5.00 (s, 6H, CH_2), 4.46–4.49 (m, 2H, CH_2), 3.98–4.19 (m, 18H, CH_2), 3.77–3.87 (m, 18H, CH_2), 3.65–3.72 (m, 18H, CH_2), 3.51–3.64 (m, 18H, CH_2), 3.34–3.38 (m, 27H, CH_3). ESI-MS *m/z*: 1531 $[M + Na]^+$.

Synthesis of methyl 3,4,5-tris(3,4,5-tris(3,4,5-tris(2-(2-methoxyethoxy)ethoxy)benzyloxy)benzyloxy)benzoate (G3)

G3 was obtained by the alkylation of methyl gallate with **G2c**. A mixture of methyl gallate (0.09 g, 0.5 mmol), **G2c** (2.41 g, 1.6 mmol), and K_2CO_3 (0.69 g, 5.0 mmol) in dry DMF was stirred and heated to 70 °C for 24 h under a nitrogen atmosphere. After filtration and then evaporation of DMF in vacuo, the residue was dissolved in a small amount of distilled water, which was dialyzed against distilled water for 3 days. The water in the dialyzed solution was removed under reduced pressure, affording **G3** as a pale yellow oil, yield 62.3%. IR (KBr) *ν*: 2937 (m), 2878 (m), 1723 (m, ν(C=O)), 1589 (m), 1503 (m), 1110 (s, ν_{as}(COC)) ^{1}H NMR (500 MHz, $CDCl_3$) δ: 6.61–6.66 (m, 26H, Ar H), 4.94–5.07 (m, 24H, CH_2), 3.92–4.13 (m, 54H, CH_2), 3.78–3.79 (m, 57H, CH_2 + CH_3), 3.68–3.71 (m, 54H, CH_2), 3.52–3.55 (m, 54H, CH_2), 3.35–3.38 (m, 81H, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 166.72 (C=O), 154.66, 153.64, 153.02, 152.79, 151.85, 149.46, 142.49, 141.52, 138.31, 136.42, 133.74, 133.02, 132.71, 131.85, 131.65, 110.19, 109.60, 107.46, 107.05, 75.86, 75.33, 73.27, 72.89, 72.70, 72.34, 72.26, 70.87, 70.66, 69.99, 69.15, 60.46, 59.20, 58.29, 52.50. MALDI-TOF MS *m/z* calcd for $C_{227}H_{350}O_{95}$: 4599; found: 4624 $[M + Na]^+$. Anal. calcd for $C_{227}H_{350}O_{95}$: C 59.28, H 7.67; found: C 59.01, H 7.81.

Fluorescence measurements

Fluorescence spectra were obtained on a Hitachi F-4500 luminescence spectrophotometer using pyrene as a fluorescent probe. Aliquots of pyrene solution (5.9×10^{-6} mg/mL in acetone, 50 μL) were added to volumetric flasks and the acetone was evaporated overnight. Then, aqueous solutions of **G3** at different concentrations were added to the flasks. The final pyrene concentration in each sample was 5.9×10^{-7} mg/mL. The solutions were kept at room temperature for 24 h to equilibrate the pyrene and the micelles. The emission spectra were recorded from 250 to 500 nm with an excitation wavelength of 390 nm.

TEM measurements

A drop of aqueous dendron solution (1 mg/mL) was placed on a Formwar-coated copper grid and dried in air. TEM observation of the micelles was conducted on a Hitachi H-600 instrument operating at an acceleration voltage of 80 kV.

LCST measurement

The LCST was determined by cloud point measurement. Dendron **G3** was dissolved in deionized water at different concentrations. The temperature of the solutions was raised at a constant rate (0.4 °C/min) and the optical transmittance of the polymer solution was measured at 500 nm with a UV–vis spectrophotometer (Cary 50, Varian). The LCST was defined as the temperature corresponding to the initial break points in the resulting transmittance vs temperature curve.[39]

Dynamic light-scattering (DLS) experiments

The D_h of the micelles was determined by DLS as a function of temperature. The measurements were performed with a Zetasizer ZEN 3600 instrument (Malvern, UK) using a light-scattering apparatus equipped with a He–Ne laser. The scattering angle was kept at 173° (backscattering), and the wavelength in the vacuum was set as 633 nm during the whole experiment. Solutions of dendrons **G3** and **G2a** in deionized water (1.0 mg/mL) were filtered with a 0.45 μm filter prior to use. Three replicates were performed for each measurement and an average value was obtained.

Drug loading and in vitro release

Dendron **G2a** or **G3** (50 mg) and POD (15 mg) were dissolved in 10 mL of acetone. Deionized water (10 mL) was added dropwise to the solution under vigorous stirring. The solution was stirred in an open air system overnight to remove acetone by evaporation. The precipitate of unbound POD was removed by centrifugation at 4000 rpm for 30 min. The amount of POD entrapped in the dendron micelles was determined by measuring the absorbance at 292 nm, using a standard calibration curve experimentally obtained with POD–ethanol solutions. The DLCand EE were calculated from the following equations:[37] DLC (wt %) = 100(mass of POD in micelles / mass of POD-loaded micelles); EE (%) = 100(mass of POD in micelles / mass of POD initially loaded).

To study in vitro drug release, a dialysis bag (molecular weight cut off = 3500 Da) containing 15 mL of the drug-loaded micelles in suspension was immersed in a phosphate buffer solution (150 mL, 0.01 mol/L, pH 7.4) at 20, 37, or 55 °C. At predetermined time intervals, 2 mL aliquots of the aqueous solution were withdrawn from the release media for UV–vis analysis, and the same volume of a fresh buffer solution was added. The amount of drug released from micelles at different temperatures was measured by UV absorbance at 292 nm.

Abstract: A novel multilayer film based on gold nanoparticles (AuNPs), thionine (Thi), and TiO_2–graphene (TiO_2–Gr) was exploited to develop a highly sensitive amperometric immunosensor for detecting carcinoembryonic antigen (CEA). Firstly, Nafion–TiO_2–Gr homogeneous composite was dropped on the surface of a glassy carbon electrode (GCE). Then Thi was chemisorbed by the TiO_2–Gr–Nafion composite. Furthermore, the negative ly charged AuNPs were chemisorbed onto Thi film through the electrostatic force with the amino groups of Thi. Cyclic voltammetry (CV) was employed to characterize the assembly process and the performance of the immunosensor. Because of the synergistic effect of the AuNPs, Thi, and the unique properties of TiO_2–Gr, the obtained immunosensor exhibited a wide linear response to CEA in two ranges from 0.1 to 10.0 ng mL^{-1} and from 10.0 to 120.0 ng mL^{-1} with a relatively low detection limit of 0.01 ng mL^{-1} (S/N = 3), as well as good stability and repeatability.

Key words: TiO_2–graphene, gold nanoparticles, thionine, carcinoembryonic antigen, immunosensor.

Résumé : On a mis à profit un nouveau film à couches multiples, à base de nanoparticules d'or (NPAu), de thionine (Thi) et de TiO_2–graphène (TiO_2–Gr), pour développer une sonde immunologique ampérométrique ultrasensible pour la détection de l'antigène cancéroembryonique (ACE). Dans une première étape, le composite homogène Nafion–TiO_2–Gr est déposé sur la surface d'une électrode de carbone vitreux (ECV). La thionine est alors chimisorbée par le composite Nafion–TiO_2–Gr. Les nanoparticules d'or, chargées négativement, sont ensuite chimisorbées sur le film de thionine par la force électrostatique des groupes aminés de la thionine. On a fait appel à la cyclovoltampérométrie pour caractériser le processus d'assemblage et la performance de la sonde immunologique. En raison des effets de synergie des nanoparticules d'or, de la thionine et des propriétés uniques du TiO_2–Gr, la sonde immunologique obtenue présente des plages étendues de réponse linéaire à l'antigène cancéroembryonique (ACE) de 0,1 à 10,0 ng mL^{-1} et de 10,0 à 120,0 ng mL^{-1}, avec une limite de détection relativement faible de 0,01 ng mL^{-1} (S/N = 3), ainsi qu'une bonne stabilité et répétabilité.

Mots-clés : TiO_2–graphène, nanoparticules d'or, thionine, antigène cancéroembryonique, sonde immunologique.

Introduction

Increasing attention has been focused on the development of immunoassay because it has become a major analytical tool in clinical diagnosis. Many diseases are closely related to some proteins that are called as biomarkers, such as carcinoembryonic antigen (CEA) and α-fetoprotein (AFP). However, sensitive detection of protein biomarkers remains a great challenge as some biomarkers present at ultralow levels in the early stages of diseases.[1,2] It is very important to explore new methods for signal amplification to increase the sensitivity of the detection. Different methods for signal enhancement have been investigated such as enzyme labeling,[3] rolling circle amplification,[4] and nanomaterial labeling.[5] Among these methods, nanomaterial labeling is gaining growing interest because of the intrinsic advantages of nanomaterials, such as low cost, good thermal stability, and large surface area.[6,7]

3Graphene (Gr) has recently received attention from materials scientists because of its unique qualities including fast electron transportation and good biocompatibility, which result in promising applications in electrochemical sensors and biosensors.[8–10] However, many of the interesting and unique properties of Gr can only be realized after it is integrated into more complex assemblies. Some Gr-based hybrid materials have shown greater versatility as advanced electrode materials for the fabrication of electrochemical sensors and biosensors.[11,12]

TiO_2 is a metal oxide that has been widely used in the fabrication of electrochemical biosensors and biosensors[13,14] owing to its good biocompatibility and high conductivity. For example, TiO_2 was employed as a support matrix for immobilizing enzymes and the results showed that the TiO_2-based composite can facilitate the direct electron transfer and enhance the catalytic activity of enzymes.[15] Most recently, we

reported a TiO_2–graphene (TiO_2–Gr) nanocomposite used in electrochemical biosensor construction and its application in some biomolecule sensing, such as dopamine, glucose, adenine, and guanine.[16–18] TiO_2–Gr based analytical methods showed excellent performance, such as high selectivity, broad dynamic range, and low detection limit, owing to the characteristics and advantages of the TiO_2–Gr nanocomposite, and it opened a new platform for electrochemical sensor and biosensor design.

CEA, an acidic glycoprotein with a molecular weight of about 200 kDa, is one of the most extensively used tumor markers.[19] The normal range for CEA in an adult nonsmoker is <2.5 ng mL^{-1} and the normal range for a smoker is <5.0 ng mL^{-1}. An elevated CEA level in serum may be an early indication of lung cancer, ovarian carcinoma, colon cancer, breast cancer, and cystadenocarcinoma.[20,21] In this work, a sensitive electrochemical immunosensor for the detection of CEA based on a signal amplification of gold nanoparticles (AuNPs), thionine (Thi), and TiO_2–Gr is reported. Nafion–TiO_2–Gr composite was employed to form a stable and uniform film on the cleaned glassy carbon electrode (GCE) surface. Furthermore, Thi could be adsorbed on the Nafion–TiO_2–Gr film based on the electronic exchange between Nafion and cationic dye Thi. Moreover, AuNPs, which were utilized to immobilize the biomolecule for its biocompatibility and to provide satisfactory conductive capability, were adsorbed on Thi film through opposite-charged adsorption and the interaction between AuNPs and the amino groups of Thi. In this case, an efficiently conductive multilayer was formed on the electrode surface, which was responsible for the satisfactory current and amplified sensitivity. The whole route of this novel immunosensor immobilization was very simple and time-saving. This developed immunoassay showed good performance in areas such as high sensitivity, improved stability, good selectivity, and wider linear range owing to the synergic effects of TiO_2–Gr, Thi, and AuNPs. This strategy could be further developed for practical clinical detections of CEA and other important tumor markers.

Experimental

Materials

Chloroauric acid, sodium citrate, graphite powder, hydrazine solution (50 wt %), and ammonia solution (28 wt %) were obtained from the Shanghai Chemical Reagent Corporation (Shanghai, P.R. China). Bovine serum albumin (BSA), CEA, prostate-specific antigen (PSA), low-density lipoprotein (LDL), and human immunoglobulin (HIgG) were obtained from Sigma-Aldrich (Saint Louis, Missouri). AFP was purchased from Biocell (Zhengzhou, P.R. China). Gold nanoparticles were produced by reducing gold chloride tetrahydrate with citric acid.[22] The mean size of the prepared Au colloids was about 18 nm. The acetate buffer solutions with various pH values were prepared with 0.1 mol/L HAc–NaAc containing 0.1 mol/L KCl. Double-distilled water was used throughout this study

Instruments

A CHI660D electrochemical workstation (CH Instruments, Shanghai, P.R. China) and a standard three-electrode cell containing a platinum wire auxiliary electrode, a saturated calomel reference electrode (SCE), and a modified electrode as the working electrode were employed for the electrochemical studies. All of the potentials were with respect to the SCE. The pH measurements were made with a pH meter (MP 230, Mettler–Toledo, Greiffensee, Switzerland).

Preparation of TiO_2–Gr nanocomposite

Graphene oxide (GO) was prepared from graphite powder by the modified Hummers method.[22] Graphite was put into a mixture of 12 mL of concentrated H_2SO_4, 2.5 g of $K_2S_2O_8$, and 2.5 g of P_2O_5. The solution was heated to 80 °C and kept stirring for 5 h using an oil bath. Next, the mixture was diluted with deionized water (500 mL). The product was obtained by filtering using a 0.2 μm nylon film and then dried in air. The product was reoxidized by using the Hummers and Offeman method to produce the GO. Exfoliation was carried out by sonicating 0.1 mg/mL of the GO dispersion for 1 h. TiO_2–Gr nanocomposite was prepared according to the method provided in previous work.[16] In short, 20 mg of GO was dispersed in a mixed solution of H_2O (10 mL) and ethanol (5 mL) under ultrasonication for 1 h to get a homogenous colloidal suspension of exfoliated GO. Then, 0.2 mL of Ti(O*i*-Pr)$_4$ was added to the GO suspension and ultrasonicated for another 1 h. The resultant mixture was transferred to a 25 mL Teflon-sealed autoclave and kept at 130 °C for 12 h. The final product was isolated by filtration and rinsed thoroughly with water and then ethanol. After rinsing, the product was dried in vacuum. The TiO_2–Gr nanocomposite was obtained in the form of a black powder.

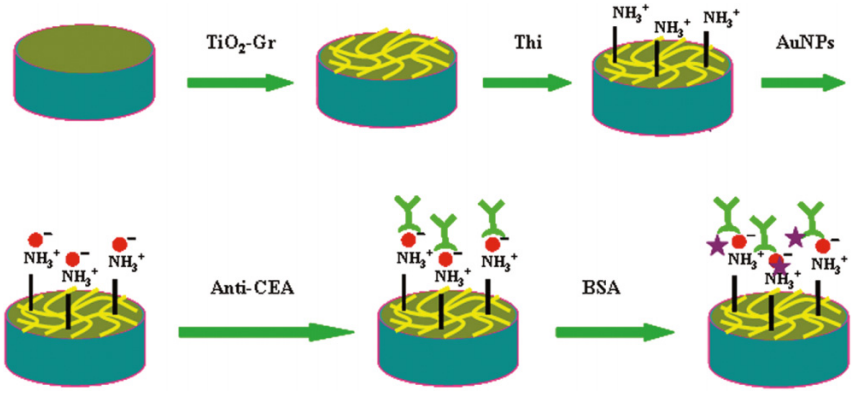
Fabrication of the immunosensor

One milligram of the as-prepared TiO_2–Gr nanocomposite was dispersed in 10.0 mL of 0.25 wt % Nafion solution under ultrasonication for 30 min to obtain a homogeneous, well-distributed suspension of Nafion–TiO_2–Gr composite. Prior to the modification, the bare GCE (3 mm diameter) was carefully polished to obtain a mirrorlike surface with 0.3 and 0.05 μm alumina slurries, followed by successive sonication in water and ethanol for 5 min and then the GCE was dried in air. Subsequently, 20 μL of the prepared Nafion–TiO_2–Gr was dropped on the clean GCE, which was then soaked in Thi solution (3 mmol/L) for 10 min. Following that it was incubated in gold colloids for 2 h. Twenty microlitres of anti-CEA antibody was then dropped on the surface of the AuNPs / Thi / Nafion–TiO_2–Gr / GCE and incubated for 6 h at 4 °C. The as-prepared immunosensor (assigned as anti-CEA / AuNPs / Thi / Nafion–TiO_2–Gr / GCE) was incubated in 0.25 wt % BSA for 60 min to eliminate nonspecific binding effects and block the remaining active groups. The process for the assembly of the immunosensor is presented in Scheme 1.

Electrochemical measurements

The immunosensor was then placed in an unstirred electrochemical cell containing 0.1 mol/L HAc–NaAc buffer (pH 5.0) at room temperature. The detection of the current response change before and after the antigen–antibody reaction was carried out by cyclic voltammetry (CV) measurements, with the potential range from –0.6 to 0.2 V (vs SCE). After

Scheme 1. The stepwise fabrication process of the immunosensor.



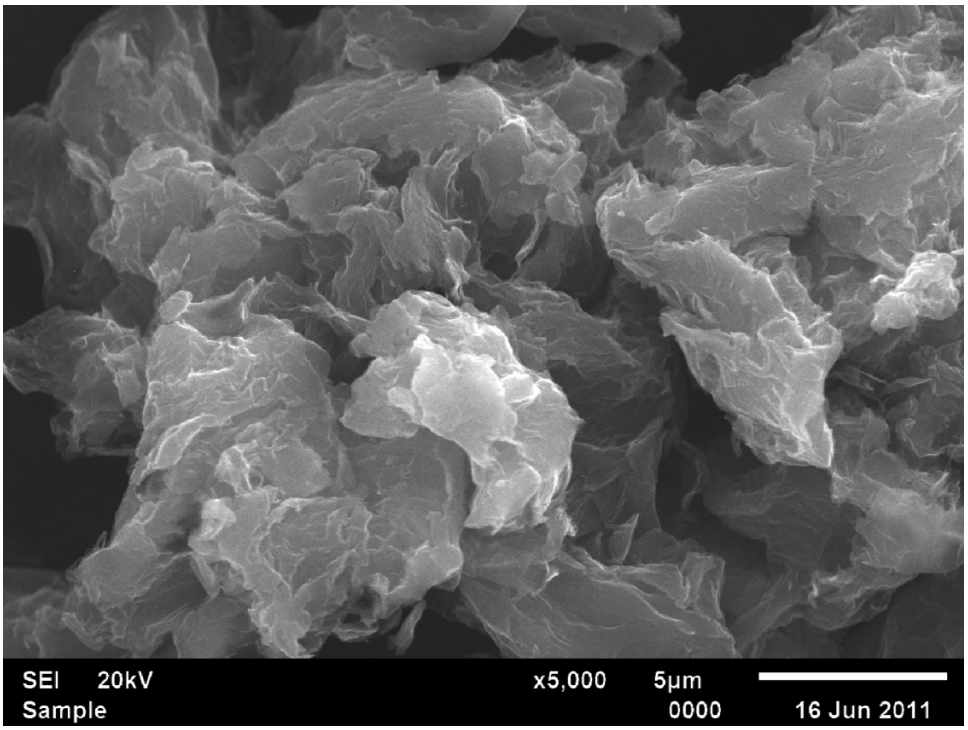


Fig. 1. SEM images of graphene (Gr).

incubation in antigen, the peak current response of the immunosensor was expected to decrease, because the antigen–antibody immunocomplex should hinder the access of the electron to the electrode. The amount of immunocomplex increased when the concentration of antigen increased, and this resulted in a decrease in the current response.

Results and discussion

Characteristics of Gr and TiO_2–Gr

The SEM image of the Gr (Fig. 1) reveals a typical crumpled and wrinkled Gr sheet structure. The integration between TiO_2 and Gr can be visualized from Fig. 2, in which TiO_2 nanoparticles of approximately 20–30 nm are uniformly and compactly embedded on the Gr substrate. The XRD patterns of the TiO_2–Gr are given in Fig. 3. The peaks in these diffraction patterns correspond to the anatase phase of TiO_2 (JCPDS file No. 21-1272), suggesting the complete formation of anatase TiO_2 during the hydrothermal process. However, the diffraction peaks of Gr are not distinguishable in the XRD patterns of TiO_2–Gr. This phenomena has also been observed in other relevant works, and it can be ascribed to the much lower crystalline extent of Gr than that of TiO_2, which results in the shielding of the Gr peaks by those of TiO_2.[23]

Electrochemical behaviors of modified electrodes

Cyclic voltammetrywas chosen to investigate the changes in the electrode behavior before and after each assembly step. Almost no CV peaks were detected at either the bare GCE or the Nafion–TiO_2–Gr modified GCE (Fig. 4, curves a and b). The background current of the TiO_2–Gr modified electrode is stronger than that of the bare GCE. This is most likely becaused the TiO_2–Gr nanocomposite could increase the effective surface area of the electrode. A pair of typical redox peaks can be observed after the adsorption of the electrochemically active Thi onto the Nafion–TiO_2–Gr film

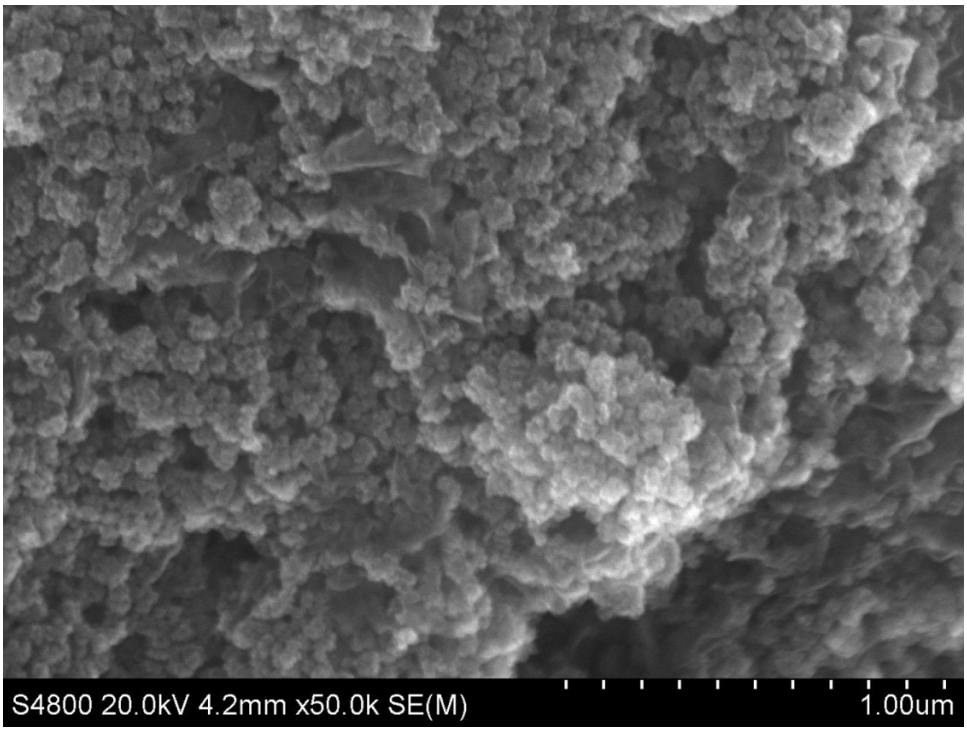

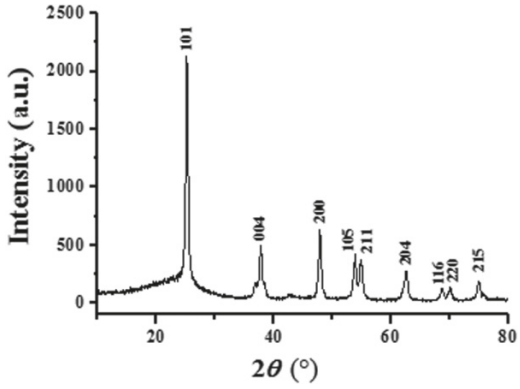

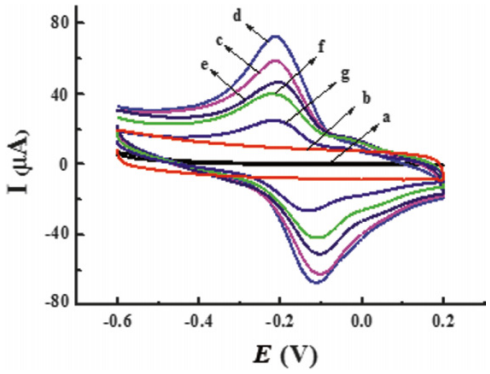

Fig. 3. XRD patterns of TiO_2 – graphene (Gr).

(Fig. 4, curve c). After the formation of the AuNPs monolayer on the modified electrode, the current response increases (Fig. 4, curve d). AuNPs can act as an electron shuttle, which makes it easier for the electron transfer to take place.[24] After the anti-CEA molecules are adsorbed onto the AuNPs, the peak currents obviously decrease, which suggests that the anti-CEA protein severely reduced the effective area and the active sites for electron transfer (Fig. 4, curve e). When BSA was immobilized to block the remaining active groups, a further decrease of the peak currents was found. This presumably was caused by the BSA hindrance of the access of Thi to the electrode surface, which resulted in a lower CV peak current. Lastly, a decrease of the peak current was found after CEA reactrf with BSA/anti-CEA/AuNPs/Thi/Nafion–TiO_2–Gr/GCE.

To further verify the conclusion previously mentioned and the electrochemical behaviors of the electrode during the modification, the electrochemical impedance spectroscopy (EIS) of variously modified electrodes wwas monitored in

5 mmol/L $Fe(CN)_6^{3-/4-}$ solution containing 0.1 mol/L KCl (Fig. 5). The high-frequency region of the impedance plot shows a semicircle related to the redox probe $Fe(CN)_6^{3-/4-}$, followed by a Warburg line in the low-frequency region, which corresponds to the diffusion step of the overall process.[25] The bare GCE displays an almost straight line in the Nyquist plot of impedance spectroscopy, characteristic of a diffusion-limited electron-transfer process (Fig. 5, curve a). When Nafion–TiO_2–Gr was modified on the GCE surface, a high resistance was obtained (Fig. 5, curve b). The resistance

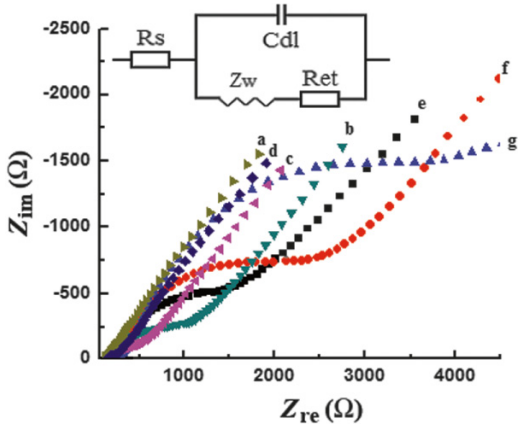

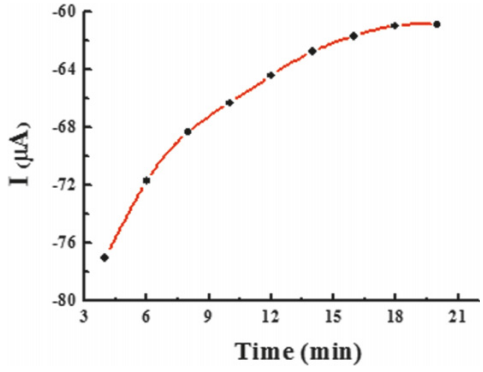

Fig. 6. Influence of incubation time.

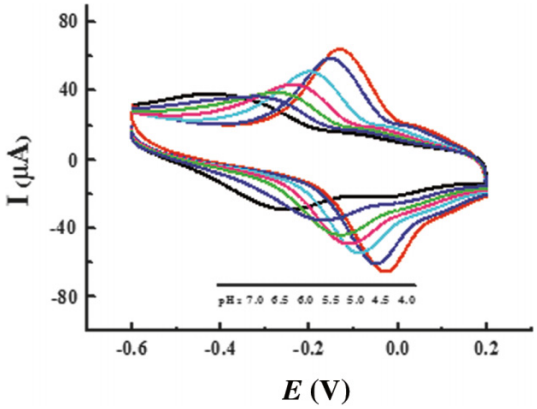
decreased after Thi was assembled on the surface of Nafion–TiO_2–Gr (Fig. 5, curve c). This may occur because Thi as a mediator could facilitate the electron transfer and the positively charged Thi could attract the negatively charged Fe $(CN)_6^{3-/4-}$. In contrast, the resistance decreased again at the AuNPs/Thi/Nafion–TiO_2–Gr/GCE (Fig. 5, curve d), which is mainly attributed to the high conductivity of AuNPs. Anti-CEA antibody is a biomacromolecule with weak electroactivity and its assembly resulted in a resistance increase (Fig. 5, curve e). After the electrode was blocked with BSA, the resistance increased (Fig. 5, curve f), which can be attributed to the fact that the outer protein membrane insulates the conductive support and counteracts the interfacial electron transfer. After immobilization of CEA onto the electrode surface, a remarkable increase in the resistance was observed (Fig. 5, curve g). The reason is that the immunocomplex layer on the electrode acts as the electron communication and mass-transfer blocking layer, further insulating the conductive support and significantly hindering the access of the redox probe to the electrode surface.

Fig. 7. The immunosensor response in the detection solution (BSA) at various pH values (4.0, 4.5, 5.0, 5.5, 6.0, 6.5, and 7.0).



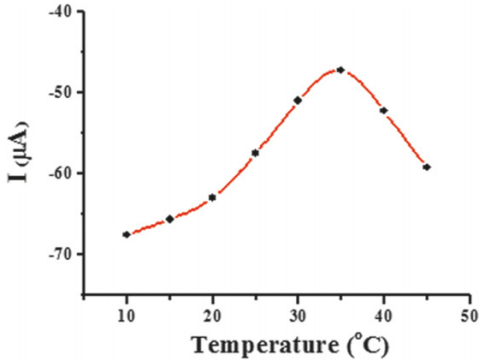


Fig. 8. Influence of incubation temperature on current response. All potentials are given versus a saturated calomel reference electrode (SCE) and the scan rate was 50 mV s^{-1}.

Optimizing conditions for immunoassay

The incubation time is a block to the improvement of immunoassay efficiency, which is usually controlled by the mass transport of immunoreagents and the kinetics of immunoreaction. Figure 6 displays the electrochemical responses of the immunosensor in pH 5.0 BSA after incubation with 30 ng mL^{-1} CEA for various times. The peak currents increase with the increasing incubation time and then tends to level off after 18 min, and a longer incubation time does not improve the response. Thus, 18 min was used for the antigen–antibody reaction. Figure 5*b* shows the CVs of the immunosensor in 0.1 mol/L BSA with various pH values at 50 mV s^{-1} after incubation with 30 ng mL^{-1} CEA. As indicated in Fig. 7, the peak currents decrease with an increase in pH from 4.0 to 7.0, while the potential separation of the anodic peak and cathodic peak increases. At BSA pH 5.0, the electrochemical immunosensor exhibits a quasireversible redox process. Meanwhile, we also considered that higher or lower pH might affect the bioactivity of the immobilized proteins. So, ABS pH 5.0 was selected for the detection of CEA. The effect of incubation temperature on the peak currents

Table 2. Interference studies with the immunosensor ($n = 6$).

Interference	Current ratio	Interference	Current ratio
PSA	0.94±0.02	Ascorbic acid	1.03±0.07
AFP	0.89±0.05	Dopamine	0.90±0.05
HIgG	0.92±0.06	Glucose	0.96±0.02
BSA	1.04±0.01	Tryptophan	0.95±0.02
LDL	0.96±0.02	Tyrosine	1.03±0.05
Arginine	1.01±0.06	Histidine	0.98±0.03

Note: PSA, prostate-specific antigen; LDL, low-density lipoprotein; HIgG, human immunoglobulin; AFP, α-fetoprotein; BSA, bovine serum albumin.

was studied over a temperature range from 10 to 45 °C. The maximum response appears at an incubation temperature of 35 °C (Fig. 8). However, considering the activity of the biomolecule and the lifetime of the immunosensor, a temperature of 25 °C was used for the experiment.

Analytical performance of the immunosensor

Under optimal conditions, the immunosensor was incubated in a CEA solution of different concentrations for 18 min and then the measurements were performed at a scan rate of 50 mV s^{-1} in BSA (pH 5.0) at 25 °C. The calibration graph for the determination of CEA was obtained using BSA/anti-CEA/AuNPs/Thi/Nafion–TiO_2–Gr/GCE as an immunosensor. The results show that the decrease in peak current is proportional to CEA concentration in two ranges, from 0.1 to 10.0 ng mL^{-1} and from 10.0 to 120.0 ng mL^{-1}, with correlation coefficients of 0.990 and 0.995, respectively. The detection limit was 0.01 ng mL^{-1} (S/N = 3). The results are compared with those of other immunoassay biosensing systems, which have been developed to monitor the levels of CEA, as shown in Table 1. The comparative data suggests the superiority of the present sensor over some earlier reported immunosensors, especially the characteristics of sensitivity and the detection limit. The possible reason is that Nafion–TiO_2–Gr and AuNPs/Thi film may increase the electrocatalytic active area and the immobilization amount of anti-CEA, as well as promote electron transfer between multilayer films and the electrode.

Stability, repeatability, reproducibility, and specificity

The reproducibility of the immunosensor was evaluated by intra-assay and interassay coefficients of variation (CVs). The intra-assay precision was evaluated by assaying the CEA level for 20 determinations of 1 sample with the same immunosensor. The intra-assay CVs of this method were 6.9% and 4.8% at CEA concentrations of 1 and 10 ng mL^{-1}, respectively. The interassay precision was estimated by determining the CEA level in one sample with six immunosensors. The interassay CV was 6.1% at a CEA concentration of 10 ng mL^{-1}. Thus, the precision and reproducibility of the proposed immunosensor were acceptable.

The storage stability of the sensors was evaluated over a period of 30 days by storing the sensor in 0.01 mol/L phosphate-buffered solutions (PBS, pH 7.0) at 4 °C. No obvious amperometric changes were observed after storage. The sensor retained about 98.1%, 96.2%, and 86.3% of the original value after storage periods of 10, 20, and 30 days, respectively. The good stability may be ascribed to the fact that the anti-CEA molecules were absorbed firmly on the surface of the AuNPs/Thi/Nafion–TiO_2–Gr composite film, which provided a good biocompatible microenvironment.

The reproducibility of the immunosensor plays a key factor in the development of a practical immunosensor. A regeneration study of the prepared immunosensor was implemented by using regeneration solutions to break the antibody–antigen linkage. In this study, the immunosensor that had been incubated in 10 ng mL^{-1} CEA for 18 min was immersed in a stirred 0.2 mol/L glycine–hydrochloric acid (Gly–HCl) solution (pH 2.8) and a stirred 4 mol/L urea solution for 5 min, in succession. A relative standard deviation (RSD) of 4.0% was acquired (five regenerations and measurement).

Selective determination of target analytes plays an important role in analyzing biological samples in situ without separation. The effect of substances that might interfere with the response of the immunosensor was investigated. The evaluation of the selectivity of the immunosensor was carried out by incubating the immunosensor in 10.0 ng mL^{-1} CEA containing some potential co-existing species with CEA, such as PSA, AFP, HIgG, LDL, BSA, ascorbic acid, dopamine, L-glucose, arginine, histidine, tryptophan, and tyrosine. Table 3. Comparison of the results of the analyses of serum samples using two different methods.

	Sample (ng mL^{-1})				
Method	1	2	3	4	5
ELISA	5.1±0.2	14.3±0.2	21.6±0.6	40.4±0.5	70.3±0.8
Method described in this work	4.8±0.3	14.9±0.6	20.2±0.3	42.9±0.5	74.1±0.7
Relative standard deviation (%)	–5.9	4.2	–6.5	6.2	5.4

degree of interference from these substances can be judged from the value of the current ratio. Herein, the current ratios can be obtained from the current reading of the immunosensor incubated in 10.0 ng mL^{-1} CEA and 10.0 ng mL^{-1} interfering substances versus the current reading with the immunosensor incubated in 10.0 ng mL^{-1} CEA. The results are listed in Table 2. The results suggested that the substance selected did not interfere remarkably. Moreover, these nonspecific species did not lead to a significant current shift or current change. Therefore, the immunosensor had a good selectivity to CEA.

Application

To investigate the reliability of the immunosensor for actual samples, six human serum samples were diluted to different concentrations with PBS (pH 7.0) and were assayed using the immunosensor with reference to the ELISA method. The results are shown in Table 3. The relative deviations of the two methods ranged from –6.5% to 6.2%, which indicated that the results obtained by the immunosensor were in agreement with that obtained by the ELISA. Therefore, the proposed immunosensor could be reasonably applied in assaying actual samples.

Conclusions

This work developed a novel strategy for an amperometric immunosensor for CEA based on the antibody adsorbed in AuNPs/Thi/Nafion–TiO_2–GR/GCE. The combination of the good conductivity and a large surface area with TiO_2–Gr, and the advantages of the AuNPs/Thi film, including biocompatibility and amplification, significantly enhanced the sensitivity of the immunosensor. The biosensor possesses good bioactivity, comparable detection limit and linear range, and acceptable storage stability. The results showed that the method was simple and sensitive enough for determination of CEA in human serum samples with good precision and accuracy. A new goal based on this work is to construct a new TiO_2–Gr-based bionanolabel for the amplification of the assay signal. This research could open new avenues in the application of TiO_2–Gr-based nanocables for clinical immunoassays, and could provide a convenient platform to modify for clinical testing and drug screening.

Nonperturbative time-dependent density functional theory (TDDFT) and time-dependent electron localization function (TDELF) study of the ionization of OCS and CS_2 with ultrashort intense laser pulses — Orientational effects

Emmanuel Fowe Penka and André Dieter Bandrauk

Abstract: The nonlinear nonperturbative response of OCS and CS_2 to ultrashort (few cycles) intense laser pulses was studied numerically by time-dependent density functional theory (TDDFT) methods to understand molecular ionization as a function of laser–molecule orientation. A time-dependent electron localization function(TDELF) was used to visualize the nonlinear nonperturbative electron transfer occurring during the laser pulse. It was found that, for intensities $I > 3.5 \times 10^{14}$ W/cm^2, the inner shell Kohn–Sham (KS) molecular orbitals contribute significantly to the ionization, whereas for the intensity $I < 3.5 \times 10^{14}$ W/cm^2, the highest occupied molecular orbital (HOMO) shows the dominant response to the field. In general, the ionization rate maxima correspond to the alignment of maximum KS orbital densities with the laser pulse polarization instead of orbital ionization potentials (IP). These findings are corroborated through analysis of the TDELF images, where the ionization occurs from the lone pair or bond regions of the corresponding molecules.

Key words: molecular ionization, ionization potential, electron localization function, density functional theory.

Résumé : Faisant appel aux méthodes de la théorie de la densité fonctionnelle dépendante du temps (TDFDT), nous avons étudié d'une façon numérique la réponse non linéaire et non perturbatrice du OCS et du CS_2 aux pulsations laser ultracourtes (quelques cycles) et intenses dans le but d'étudier l'ionisation moléculaire en fonction de l'orientation laser–molécule. Nous avons utilisé la fonction de localisation de l'électron dépendante du temps (FLEDT) pour visualiser le transfert d'électron non linéaire et non perturbé qui se produit au cours de la durée du pulse laser. On a trouvé que, pour des intensités $I > 3{,}5 \times 10^{14}$ W/cm^2, les orbitales moléculaires Kohn–Sham (KS) de la couche interne contribuent d'une façon significative à l'ionisation alors que, lorsque l'intensité $I < 3{,}5 \times 10^{14}$ W/cm^2, c'est l'orbitale moléculaire haute occupée (OMHO) qui provoque la réponse dominante du champ. En général, les maxima du taux d'ionisation correspondent à un alignement des densités des orbitales KS avec la polarisation de la pulsation laser plutôt que les potentiels d'ionisation (PI) des orbitales. Ces observations sont corroborées par une analyse des images de la fonction de localisation de l'électron dépendante du temps (FLEDT) dans lesquelles l'ionisation se produit à partir d'une paire non partagée ou des régions de liaisons des molécules correspondantes.

Mots-clés : ionisation moléculaire, potentiel d'ionisation, fonction de localisation d'électron, théorie de la fonctionnelle de la densité.

Introduction

Recent developments in the generation and characterization of ultrashort laser pulses[1,2] provide the tools necessary for investigating electron dynamics in atoms and molecules at the electron's natural time scale, the attosecond (1 as = 10^{-18} s).[2] Such ultrashort pulses offer the possibility of creating coherent electron wavepackets (CEWPs) inside molecules on the as time scale and subnanometer size.[3] Currently, the main source of as pulses is high-order harmonic generation (HHG) from atoms and (or) molecules exposed to ultrashort (few cycles) laser pulses at intensities $I \geq 10^{14}$ W/cm^2 and IR frequencies ($\omega = 0.0567$ au, $\lambda = 800$ nm). The atomic unit, au of intensity $I = 3.54 \times 10^{16}$ W/cm^2, corresponds to the au of electric field strength, $E = 5 \times 10^9$ V/cm, the field at the au of radius $a_0 = 0.0525$ nm of the H atom. Current laser intensities approach the au of I, thus requiring nonlinear nonperturbative treatments of laser–molecule interactions. A most promising approach to treating such problems is a nonlinear

Fig. 1. DFT/LB94 orbital energies (E_{KS}) and experimental ionization potentials (IPs) of the molecular orbitals of OCS and CS_2. Only the three highest relevant occupied molecular orbitals, HOMO, HOMO-1, and HOMO-2, are shown. Atom colours: carbon (black), sulfur (yellow), and oxygen (red) (please see the Web version of this paper for the colour figure).

nonperturbative time-dependent density functional theory method (TDDFT), using functionals that can accurately give ionization potentials (IPs) of molecular orbitals.[4] Such an approach has also been generalized to introduce coherent control algorithms for optimizing laser–molecule responses.[5] In the present work, we extend our previous study[6] of CO_2 in intense laser fields to CS_2 and the nonsymmetric OCS to compare the nonlinear nonperturbative laser–molecule response of symmetric and nonsymmetric systems. Effective single active electron (SAE) models are currently used for orbital imaging of CO_2 in intense laser fields.[7] TDDFT methods will allow us to address the accuracy of these models and include inner shell excitation–ionization shown previously to be non-negligible at high intensities.[8]

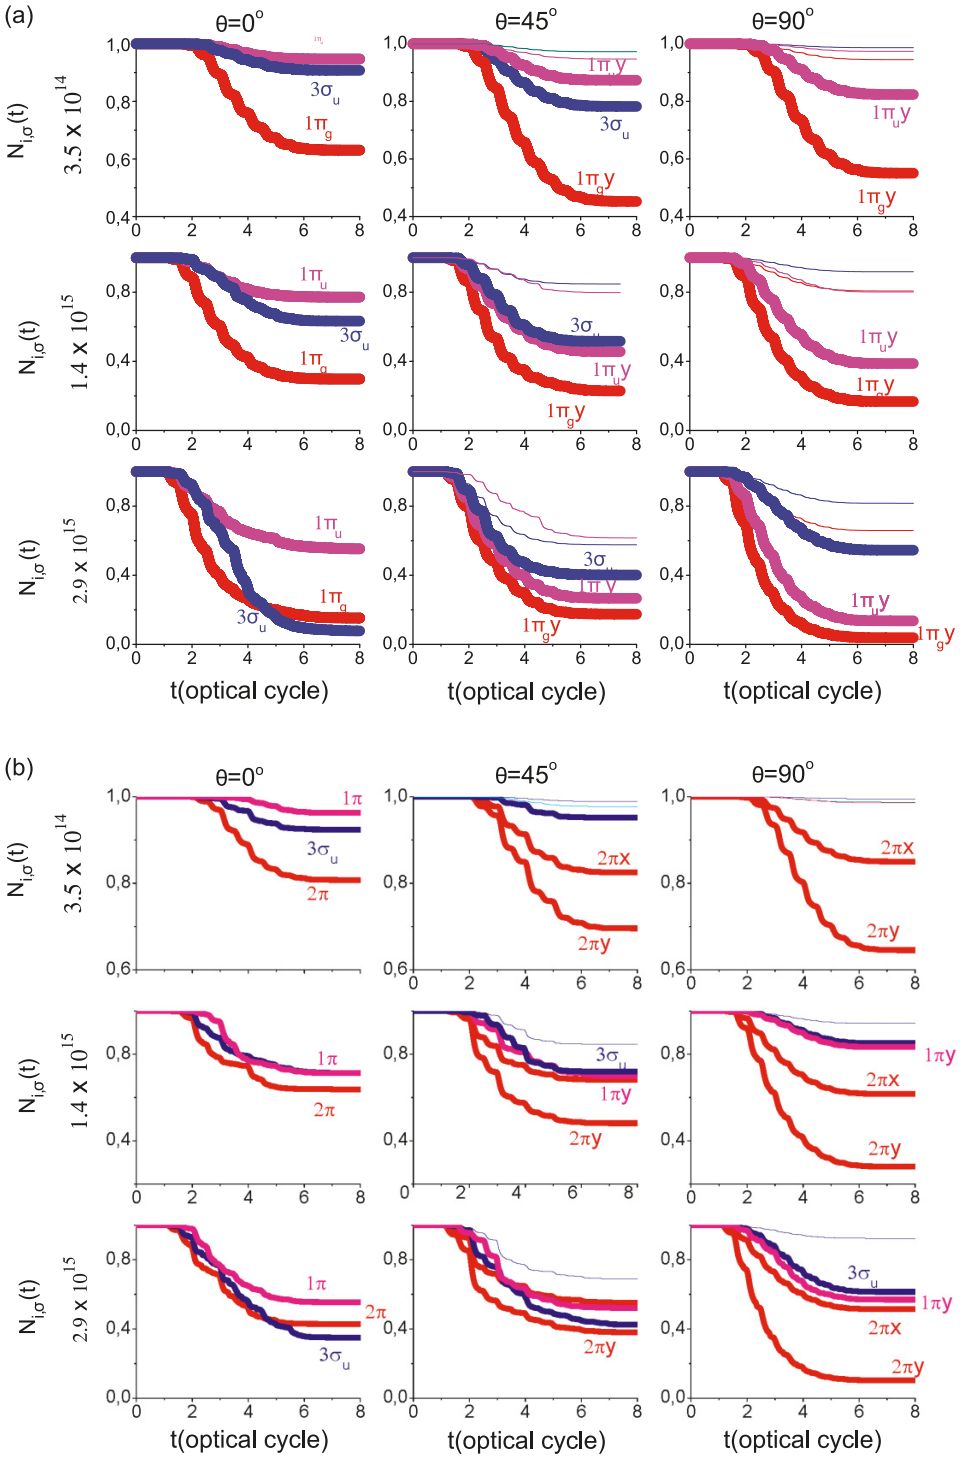
Methods — Nonperturbative TDDFT Kohn–Sham formalism

The TDDFT method provides the most detailed and feasible ab initio approach for tackling many-body problems in external time-dependent fields. DFT, as first introduced by Hohenberg and Kohn,[9] and extended by Kohn and Sham[10] (KS), is based on the existence of an exact mapping between one-particle density and external potentials. This leads to the density of the interacting system being obtained from the density of an auxiliary system of noninteracting particles moving in an effective local single-particle potential. A time-dependent generalization of DFT was provided by Runge and Gross,[11] showing that there is a one-to-one correspondence between the external (time-dependent) potential, $\upsilon_{ext}(r, t)$, and the time-dependent one-electron density, $n(r, t)$ for many-body systems evolving from a fixed initial state. The time-dependent electronic density is written as[12]

$$[1] \qquad n(r,t) = \sum_{\sigma=\uparrow,\downarrow} n_\sigma(r,t) = \sum_{\sigma=\uparrow,\downarrow} \sum_{i}^{N_\sigma} |\psi_{i\sigma}(r,t)|^2$$

where N_σ is the number of the occupied KS orbital in spin state σ and $\psi_{i\sigma}(r,t)$ is the orbital obtained through the time-dependent KS equations (in au)

$$[2] \qquad i\frac{\partial}{\partial t}\psi_{i\sigma}(r,t) = \left[-\frac{1}{2}\nabla^2 + \upsilon_{\text{eff}}(r,t)\right]\psi_{i\sigma}(r,t)$$



where

$$\upsilon_{\text{eff}}(r,t) = \upsilon_{\text{ext}}(r,t) + \upsilon_h(r,t) + \upsilon_{\text{xc},\sigma}(r,t)$$

The first term is the external potential due to the interaction of the electron with an external laser field and the nuclei, the second term accounts for the classical Hartree electrostatic interaction between electrons, and the third term is the exchange correlation potential (υ_{xc}), which includes all nontrivial many-body effects, and has an extremely complex (and essentially unknown) functional dependence on the density. When an intense low-frequency electric field is applied to a molecule, electrons tend to ionize from the higher ionization potential (IP) orbitals. Therefore, the choice of an approach that accurately reproduces the experimental IP is essential for analysis of ionization processes. In this work, we have used the Van Leeuwen and Baerends[13] potential (LB94), which introduces a gradient correction to the LDA exchange correlation so as to reproduce the Coulomb asymptotic behaviour of the potential. The LB94 potential yields excellent estimates of the IP for atoms and small molecules, as shown in Fig. 1, especially in the framework of the linear response TDDFT excitation energy.[14] This model potential significantly corrects the higher moments of the density, notably for diffuse outer orbitals involved in excitations and, in our case, in ionization. The LB94 also includes partial and considerable self-interaction correction (SIC) resulting from an interaction of an electron with itself, of importance to electronic transport.[15] Such corrections can produce spurious oscillations in photoionization calculations,[16] but little is known about the corrections for strong fields in the nonperturbative regime. We focus on the LB94 potential generally, which offers accurate IPs for most molecular orbitals, an essential starting point for accurate ionization. Previous other approaches have used optimized effective potentials[17] (OEP) with exact exchange and also effective local potentials for excited states.[18,19] Furthermore, at high intensities, excited states have very short lifetimes, thus reducing considerably the nonadiabatic effects. The neglect of nonadiabatic effects, which is a major difficulty of linear TDDFT, is implicit in the strong field approximation (SFA)[20] a current simple nonperturbative model that neglects excited states. The generally accurate KS orbital IPs with the LB94 potential suggest that these orbitals simulate Dyson orbitals[21] for which no exact

in space using finite-difference (FD) grid techniques as reported in our previous work.[6] The bond length was set to its experimental[22–25] value. For OCS, bond lengths are CS = 0.156 nm, CO = 0.1157 nm, and CS= 0.155 nm for CS_2 as compared with CO_2.[6] The molecule was placed in a large three-dimensional (3D) rectangular grid cell (au are used) of dimension $|z_{max}| = 90$ au (1 au = 0.0529 nm) and $|x_{max}| = |y_{max}| = 25$ au if the laser is oriented parallel to the molecular z axis. The uniform FD grid spacing ($\Delta z = \Delta x = \Delta y = 0.34$ au) was used and the convergence of the calculations was checked against results that used a larger grid spacing. The size of the grid was determined by the maximum radius $\alpha = E/m\omega^2$ of an electron in a time-dependent electric field of maximum amplitude E. Thus, at $E = 0.1$ au corresponding to an intensity $I = 3.50 \times 10^{14}$ W/cm^2, $\alpha = 30$ au at $\lambda = 800$ nm and $\omega = 0.057$ au. Thus, since α is the size of the recolliding electron trajectory, $z_{max} = 90$ au >> α ensures that all recolliding electrons are collected in the numerical procedure.[26] The laser intensity is related to the field strength by $I = \frac{1}{2}\varepsilon_o cE^2$, where ε_o is the permittivity of free space and c is the speed of light. The angle (θ) between the linear polarized laser and the main molecular z axis varies from 0° to 90°. The total pulse area condition $\int_{-\infty}^{+\infty} E(t)dt = 0$ was verified to ensure no spurious static effects for pulses satisfying Maxwell's equations.[26,27] The external potential created by an intense laser field is assumed to arise from an oscillating electric field with a cosine envelope. When the laser is linearly polarized parallel to the molecular axis z, $\upsilon_{ext}(r, t)$ is given by

$$[3] \qquad \upsilon_{ext}(r,t) = zE\cos^2\left(\frac{\pi t}{T}\right)\sin(\omega t) \qquad (0 \prec t \prec T)$$

T determines the laser pulse duration. The time-dependent equations (eq. [2]) are solved using the Crank–Nicolson scheme,[22,24] with $\Delta t = 0.02$ au (1 au = 24×10^{-18} s) as the time step. All calculations were done using eight optical cycle pulse duration on an Intel multiprocessor parallel machine at Compute Canada's Sherbrooke centre. To absorb the ionized charge density and avoid reflections at the boundary of the box owing to ionization during the propagation, we employ a mask function. By using this technique, the KS wave function is multiplied at each time step at grid boundaries by a function $M(z)$, which is 1 in the inner simulation region and gradually goes to 0 at the boundaries. The time-dependent ionization probability ($P_{i,\sigma}(t)$) of an individual KS spin orbital is calculated as[4]

$$[4] \qquad P_{i,\sigma}(t) = 1 - N_{i,\sigma}(t)$$

where $N_{i,\sigma}(t) = \langle\psi_{i,\sigma}(r,t)|\psi_{i,\sigma}(r,t)\rangle$ is the time-dependent population (survival probability) of the i,σ-th occupied spin population.

Time-dependent electron localization function (TDELF)

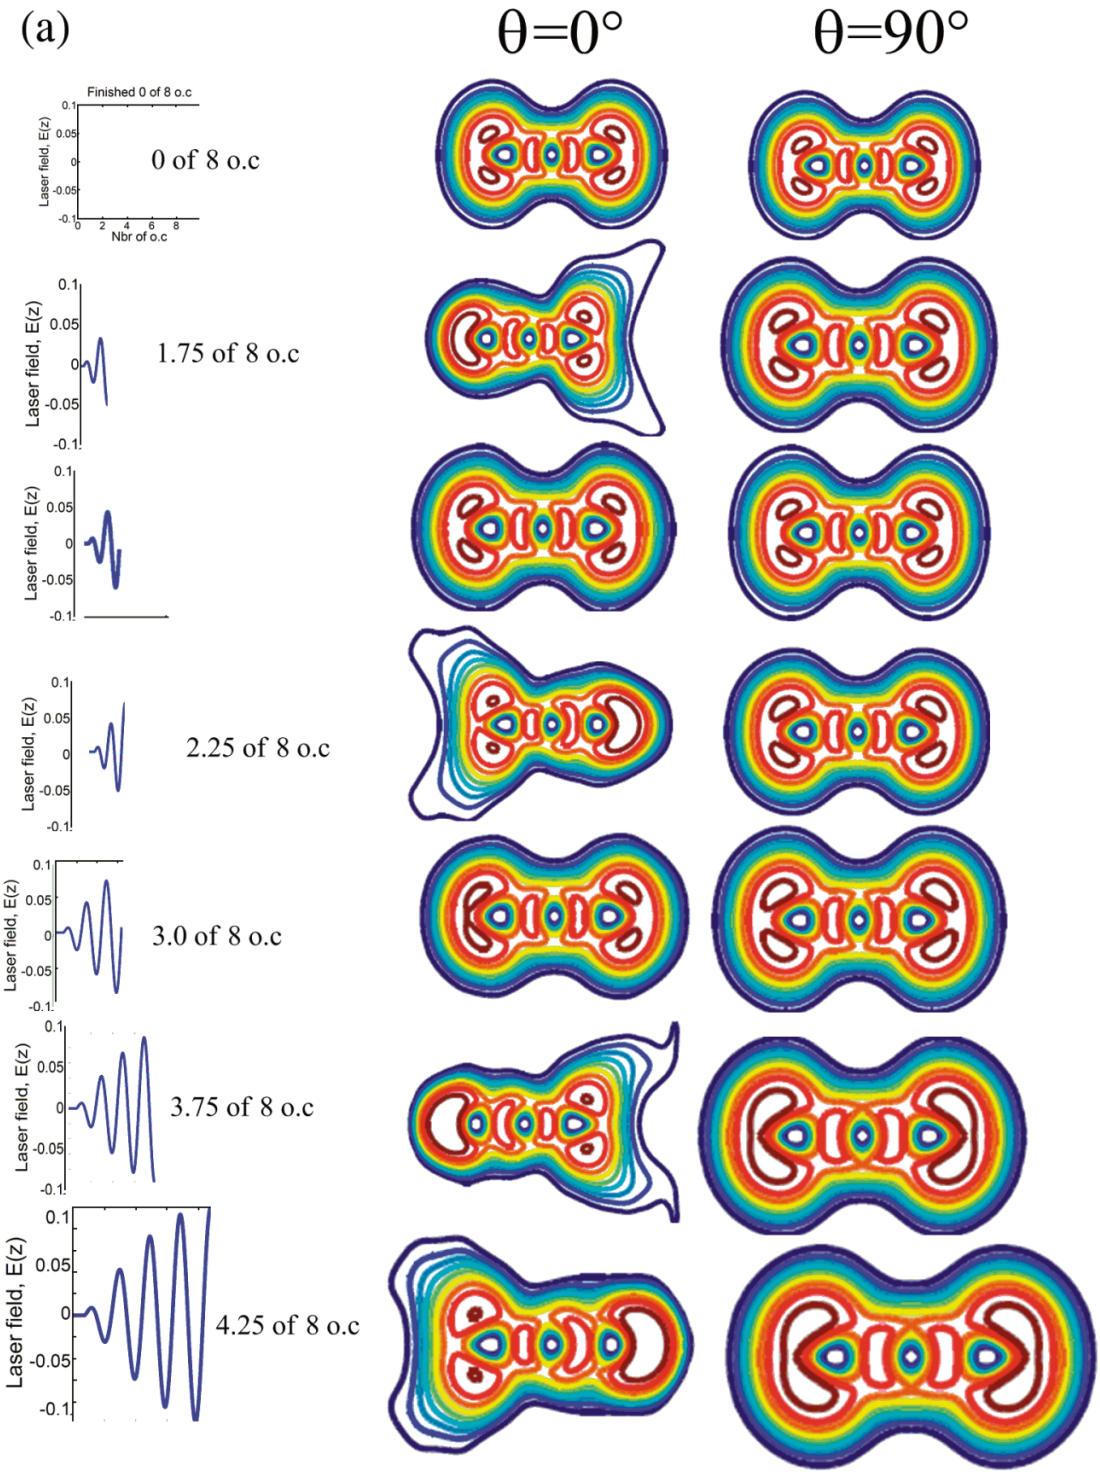
The ELF is a method for the mapping of the pair-electron probability in multielectron systems. It was first introduced by Becke and Edgecombe[28] as a descriptor of electronic localization, using arguments based on the conditional same-spin pair-probability function. Our recent work shows that the ELF is a useful tool for identifying and visualizing lone-pair and bonding-pair electrons.[6] Here, we briefly recall the definitions of the extension of the ELF for time-dependent processes. The time-dependent ELF, or TDELF ($\eta(r, t)$) is given as

$$[5] \qquad \eta(r,t) = \frac{1}{1 + \left(\frac{C(r,t)}{C_h(r,t)}\right)^2}$$

where

$$[6] \qquad C(r,t) = \sum_\sigma \left\{ \sum_{i=1}^{N_\sigma} |\nabla\psi_{i\sigma}(r,t)|^2 - \frac{1}{4}\frac{[\nabla n_\sigma(r,t)]}{n_\sigma(r,t)} - \frac{j_\sigma^2(r,t)}{n_\sigma(r,t)} \right\}$$

$$[7] \qquad C_h(r,t) = \frac{3}{5}(6\pi^2)^{2/3} n_\sigma(r,t)^{5/3}$$



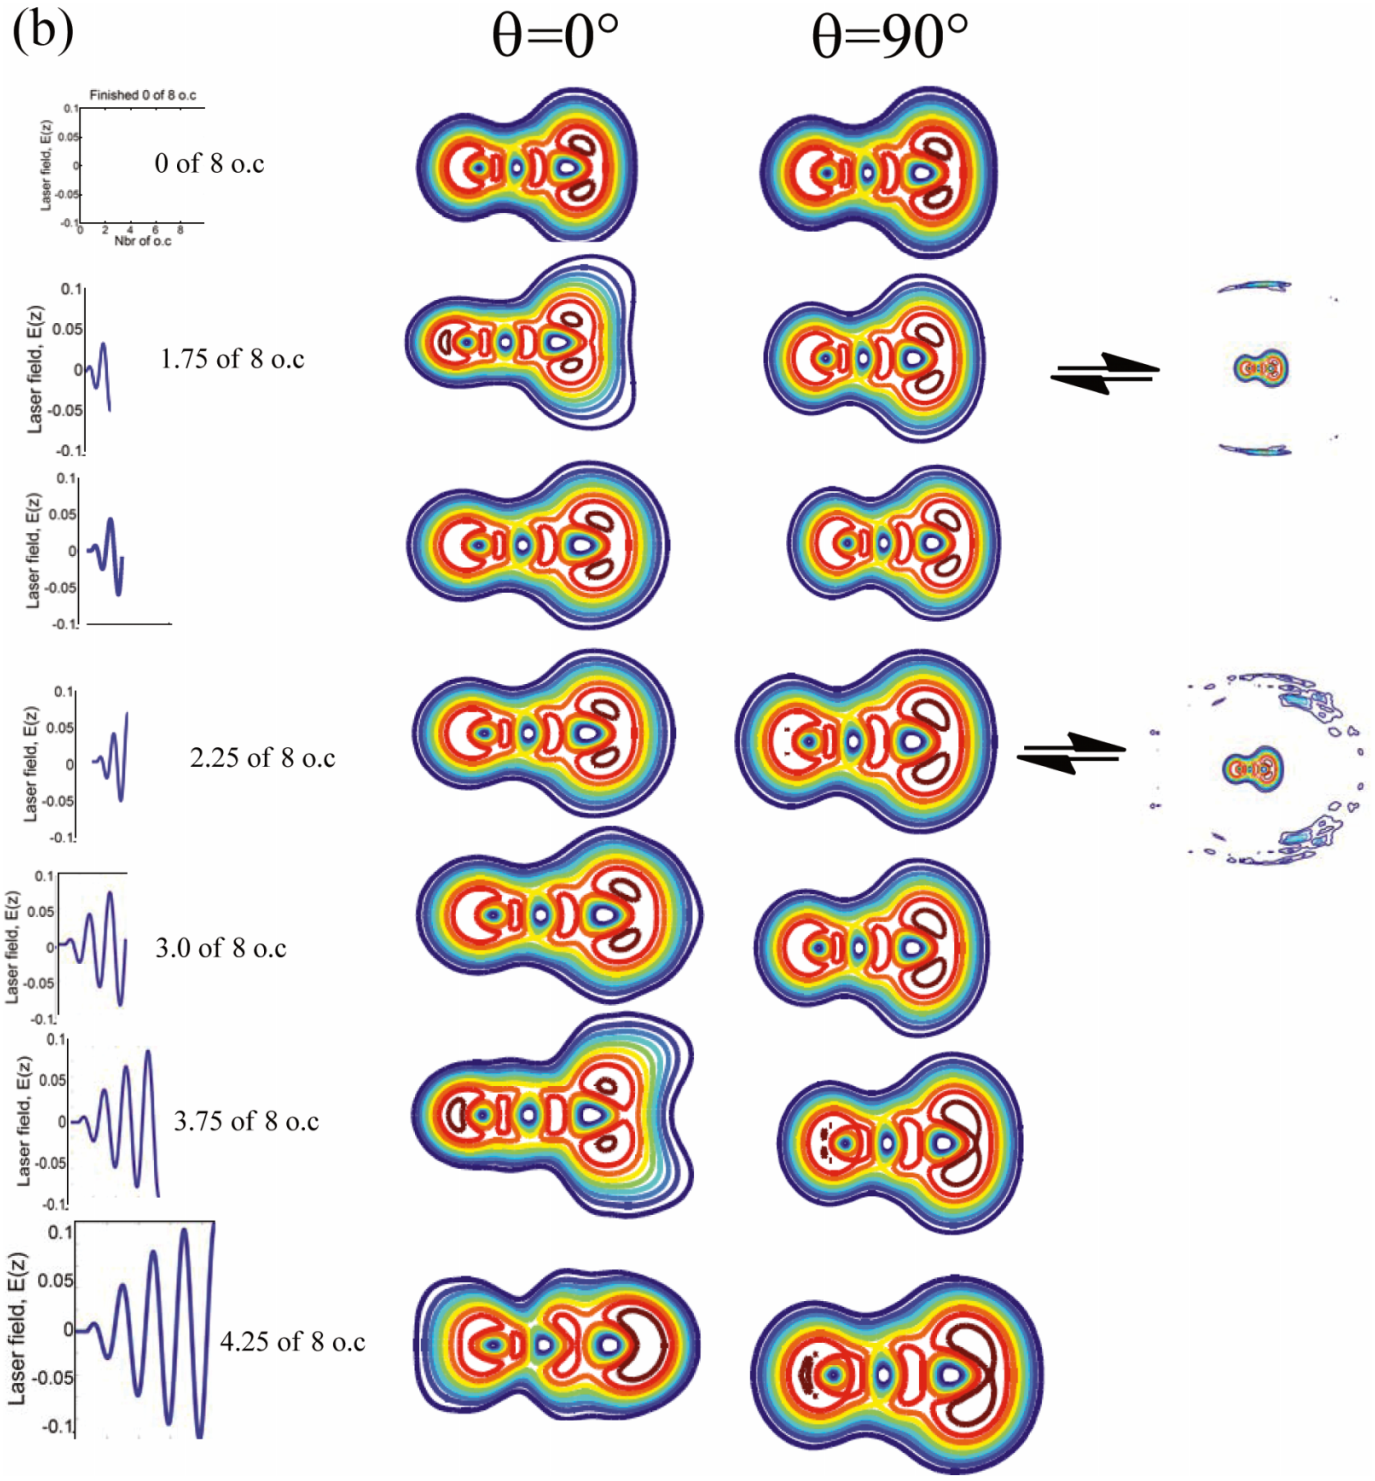
The term j_σ^2 is the squared modulus of the current density depending on the phase of the orbitals and is the time-dependent correction to the original ELF.[28] $C(r, t)$ measures the probability of finding one electron in the near vicinity of a reference like-spin electron at position r and time t. Thus, the Pauli repulsion between two like-spin electrons, described by the smallness of $C(r, t)$, is taken as a measure of the electron localization. $C_h(r, t)$ is the corresponding factor found for a uniform electron gas, i.e., a homogeneous electron gas whose density is the same as that of the real system. The TDELF would be used for the time-resolved observation of the molecular ionization and can thus provide a visual understanding of the electron-transfer dynamics (most notably lone-pair and bond electrons) under strong laser pulses.

Results and discussion

Electronic analysis and ionization

The electronic structure from the DFT–KS calculation is depicted in Fig. 1, where the three highest occupied KS MOs HOMO, HOMO-1, and HOMO-2 with their phases and energies, are presented. For the CS_2 molecule, one finds that the HOMO is an antibonding type ($1\pi_g$) formed of π lobes lying perpendicular to the internuclear axis and located on the sulfur atoms for CS_2, whereas the orbitals forming the HOMO (2π) of OCS are mostly located on the sulfur atom. One sees that the computed KS orbital energies are, except

Fig. 4. (*a*) Snapshot of the isosurface of the TDELF images for $I = 3.5 \times 10^{14}$ W/cm^2 as the CS_2 molecule evolves in a laser field of eight optical cycles (o.c.). Calculations are done for with $\theta = 0°$ and 90°. (*b*) Snapshot of the isosurface of the TDELF images for $I = 3.5 \times 10^{14}$ W/cm^2 as the OCS molecule evolves in a laser field of eight optical cycles (o.c.). Calculations are done for with $\theta = 0°$ and 90° (including the ionized distribution on right-hand side).



for OCS, in general in agreement with the available experimental IPs. Thus, the CS_2 KS orbital energies respect the experimentally observed IP order, whereas, for OCS, the order between the 3σ and 1π orbitals is inverted, but the energy separation of 1 eV is the same. We further investigated the time evolution in the presence of intense pulses of some relevant KS orbitals using eq. [4]. Three angular orientations were considered ($\theta = 0°$, 45 °, and 90°), where θ is the angle between the molecular *z* axis and the laser polarization.

Time-dependent KS populations, ($N_{i,\sigma}(r, t)$) using three laser intensities ranging from 3.50×10^{14} to 3.0×10^{15} W/cm^2, are displayed in Figs. 2*a* and 2*b* for, respectively, the CS_2

Fig. 4. (*concluded*).

and the OCS molecules. Evidence of a strong dependence of the KS remaining orbital population on the laser intensity was observed. It emerges that, in general, the KS MO ionization is the most important for CS_2 owing to its lower IP as compared with OCS. When $\theta = 0°$, for symmetry reasons the two components of each 2π or $1\pi_g$ orbital have the same behaviour because they are degenerate. For the lower laser intensity $I = 3.50 \times 10^{14}$ W/cm^2, one sees that the HOMO shows the dominant response to the laser field, as expected. It is followed, respectively, by the inner shell orbitals $3\sigma/3\sigma_u$ (HOMO-1 for OCS and HOMO-2 for CS_2). As the laser intensity increases, it emerges that the HOMO does not remain the most affected by the external laser field. Instead, our calculation shows that the ionization of the inner $3\sigma/3\sigma_u$ molecular orbital dominates. Such relatively small ionizations of the HOMOs under high laser intensity is related to their nodal plane containing the molecular axis. This gives rise to a low ionization yield when aligned parallel to the laser electric

field, whereas $3\sigma_u/3\sigma$ has the right symmetry (MO shape) to interact with the laser field as its density is maximum parallel to the field. At angles $\theta = 45°$ and 90°, the symmetry behaviour of the different components of the π orbitals is broken (i.e., degeneracy is removed) and we have renamed them as follows: components of the $1\pi_g$ of CS_2 are $1\pi_g x$ and $1\pi_g y$ and those of the 1π of the OCS are $1\pi x$ and $1\pi y$. When $\theta = 45°$, the main ionization occurs from the HOMO, followed by that of the inner $1\pi_u/1\pi$ and $3\sigma_u/3\sigma$ MO orbital. The enhanced ionization of the HOMO is the result of the combined effects of its lower IP and its alignment along the laser polarization axis at $\theta = 45°$ as reported[29] previously in H_2^+. Finally, when $\theta = 90°$, once again, one finds that the KS MOs of CS_2 ionize more than in OCS and the HOMO remains the most affected by the field at lower intensity. For higher laser-peak intensities, the ionization is dominated by the bonding $1\pi_u/1\pi$ orbital. We find that those orbitals that have maximum density in the direction of laser polarization will most strongly influence or dominate in ionization and in the MHOHG processes. However, for the OCS molecule, one sees that as the laser intensity is increasing, the two components of the HOMO ($2\pi y$, $2\pi x$) present the dominant response to the laser field. This is because in comparison with the CS_2 MOs, the HOMO and the HOMO-2 of the OCS have almost the same shape (density). As a consequence, its HOMO ionizes faster as the laser intensity is increasing owing to its lower IP.

In conclusion, we find that the KS HOMO ionization increases from $\theta = 0°$ and reaches a maximum when the molecule is aligned at an angle around 45° with respect to the direction of the laser polarization, and then decreases at larger angles towards 90°. The ionization rate maxima as a function of the angle follow the maxima in electron density, and the minima reflect the nodal structure of the orbitals. Such a nonlinear response in ionization at high intensities has been predicted by the tunnelling ionization model.[30]

Electron localization analysis

ELF versus density

In Fig. 3*a*, we display the field free ELF of OCS and CS_2 molecules in a plane containing the three atoms. The bond (b) and the lone pair location (a) are shown.

The ELF value for the lone pair is higher than for the chemical bond. This arises from the fact that the lone pair (HOMO) is more localized than the CO bond (HOMO-1 and HOMO-2) as shown in Fig. 1. The lone pair electron density HOMO ($1\pi_g/2\pi$ region (a)), is visible, whereas the HOMO-1 and the HOMO-2 are essentially located in bonding region (b). Such clear separation between the HOMO and the relevant inner orbitals enables us to get a deep insight into the real time MO behaviour when the molecule is under an external field. The angles $\theta = 0°$ and $\theta = 90°$ weren considered and the results are shown next. We note that, in the CS moiety, the lone pair appears as two distinct regions at angles of 45° with respect to the molecular z axis. This reflects the major density of the π orbitals of the sulfur atoms.

TDELF of CS_2

At $\theta = 0°$, the laser polarization is parallel to the molecular z axis and, at the initial time step, the ELF picture corresponds to the ground-state image. As the time propagation evolves, the first major laser perturbation occurs on the lone-pair region of the sulfur (Fig. 3*b*) after 1.75 optical cycles (o.c.).

The electric field being negative, the major perturbation consists of a lengthening of the lone-pair region followed by the appearance of a hole in the left atom, reflecting the depletion by ionization or the electron transfer (ET) of the electron density. At 2.25 o.c., where the electric field is positive, a perturbation as exactly described in the folllowing arises on the right atom. The same asymmetric perturbation behaviour is observed, respectively, at 3.75 and 4.25 o.c., where the size of the perturbation increases with the electric field. The observed nonsymmetrical perturbation of the electron density on the two sulfur (CS_2) atoms indicates that these atoms feel the presence of the external field differently. The images show that the major part of the perturbation is located in the region corresponding to the lone-pair region (HOMO) of the molecule. As the time propagation evolves, the intensity of the perturbation in the lone-pair region increases as well, reaching a maximum for the field extrema (minimum, i.e., 3.75 o.c. ($E < 0$); or maximum, i.e., 4.25 o.c. ($E > 0$)) of the external electric field and seems to disappear around the zero values of the external field (e.g., at 3.0 o.c.). Classical models of electron recollision predict such recollisions to occur near zero fields.[31,32] For the perpendicular configuration $\theta = 90°$, the first noticeable perturbation occurs after 1.75 o.c., where the field is negative. This is manifested by the lengthening or increased diffuseness of the lone-pair region on the sulfur atoms for CS_2. The perturbation is found symmetrically distributed; this effect reflects the fact that the sulfur atoms feel simultaneously or instantaneously the same effect of the laser field. As the time propagation evolves (3.75 and 4.25 o.c.), one sees that the dominant response comes from the lone-pair region. Most notably, one observes that, during the propagation, the electronic perturbation is characterized by an interaction between the outer lone pair and the inner bonding CS region and the perturbation disappears whenever the external electric field vanishes. Large depletion of electron density occurs at 2.25 and 4.25 o.c. in the opposite direction to that of the field and is illustrated as dark "holes" in Fig. 4*a*. Thus, in CS_2, the loss of an electron via ionization occurs in the lone-pair sp^2 hybrids of S. Simultaneously, the bonding C–S region expands opposite to the whole region.

TDELF of OCS

One of the most interesting points in the study of the OCS molecule with the TDELF function lies in the fact that its HOMO is nonsymmetric (as opposed to the CS_2 case) and is mainly located on two different atoms, oxygen (nearly 20%) and sulfur (nearly 70%), each bearing a different IP. In Fig. 4*b*, the oxygen is easily recognized by having one lobe, whereas the sulfur bears two owing to considerable sp^2 hybridization. For $\theta = 0°$, where the laser polarization and molecular axis are parallel, at 1.75 o.c. ($E < 0$) with a negative electric field and with electron displacement toward S, the perturbation appears on the lone-pair position of the oxygen atom. At 4.25 o.c. ($E > 0$) with a positive electric field, the results show that the perturbation now appears on the lone-pair region of the sulfur atom, whereas the corresponding lone-pair region on the oxygen atom has expanded owing to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

electron transfer in that direction. As the propagation is evolving, the intensity of the perturbation on the lone-pair region is increasing as well, reaching a maximum at the electric field maxima or minima.

For $\theta = 90°$, the two atoms are feeling exactly the same laser intensity at the same time, and the ionization (see 1.75 and 2.25 o.c.) is much higher from the sulfur moiety than from the oxygen one, owing to the IP difference of the sulfur and the oxygen atoms. As expected, the perturbation on the different lone-pair regions is getting higher as the laser intensity is increasing. Figure 4*b* shows that the OCS behaves in the presence of the laser as a superposition of the moieties, one from CS_2 and the other from CO_2, giving rise to a nonsymmetric perturbation on the system when the laser is oriented parallel ($\theta = 0°$) or perpendicular ($\theta = 90°$) to the laser field. On the latter, a double-hole structure appears on the O moiety, as observed before in CO_2,[6] suggesting increasing sp^2 hybridization.

In conclusion, we find that at the lower intensity ($I = 3.50 \times 10^{14}$ W/cm^2) laser-peak intensity, the lone-pair region (HOMO) of linear molecules is the most affected by the field, in good agreement with our finding in the KS–MO ionization analysis in the previous section. For CS_2, the lower IP of the sulfur orbitals shows that these holes remain localized (Fig. 4*a*), reflecting rapid electron ionization (Fig. 2*b*) in the opposite direction to that of the laser-field phase. For the perpendicular orientation ($\theta = 90°$), the holes on each atom are split symmetrically as seen in Figs. 4*a* (CS_2) and 4*b* (OCS). On the latter, the O lone-pair distribution behaves distinctly differently from that of S owing to the smaller radius of the O orbitals.

Conclusion

The nonlinear nonperturbative TDDFT calculations presented in this paper for symmetric CS_2 and nonsymmetric OCS triatomics present a TDELF analysis of MO ionization at high laser intensities where linear TDDFT is not applicable. As major results, we find that at equilibrium distance R and at intensities $I > 3.5 \times 10^{14}$ W/cm^2, lower inner highest occupied molecular orbitals contribute significantly to ionization. This is due to the symmetry of these orbitals, even though such lower inner shell orbitals have higher IPs. At particular angles, ionization probabilities of different orbitals cross in magnitude. These findings are confirmed with the TDELF representation through the analysis in terms of density perturbations appearing on the TDELF images of each molecule. For $\theta = 0°$ and at a lower laser intensity ($I = 10^{14}$ W/cm^2), one sees that the HOMO is the most affected by the laser field and a large asymmetric density is found, i.e., one finds that during each half cycle, the laser perturbation occurs alternatively from one nucleus to another (favouring minimal interference), whereas for $\theta = 90°$, both nuclei simultaneously feel the same perturbation from the laser field (favouring maximal interference).[33] Our simulations also show that the local LB94 potential gives reliable orbital energies,[34] and IPs in near agreement with experimental data of individual orbitals, thus suggesting that the KS orbitals are close to Dyson orbitals,[21] which are the exact many-body orbitals for ionization. The relation between time-dependent Dyson and LB94 KS orbitals requires further exploration and also the effect of long range – short range correlation models on the nonlinear nonperturbative response[35] of molecules to intense laser pulses.

Abstract: (*Z*)-1,2-Dihaloalkenes are thermodynamically disfavoured of the two stereoisomers. This paper reports the synthesis of some (*Z*)-1,2-dichloroalkene analogues from mucochloric acid. A more versatile approach involved the chloroboration of terminal alkynes to yield corresponding (*Z*)-chloroboronic acid as a first step. Treatment of the organoboronic acid with potassium hydrogen difluoride followed by tetrabutylammonium trichloride gave (*Z*)-1,2-dichloroalkenes in moderate to good yields in a stereospecific manner.

Key words: cis-dichloroalkene, chloroboration, chlorodeboronation, NOE, terminal alkyne.

Résumé : Dans les séries de 1,2-dihalogénoalcènes, les isomères (*Z*)- sont thermodynamiquement défavorisés. Dans ce travail, on a réalisé la synthèse de quelques analogues de (*Z*)-1,2-dichloroalcènes à partir de l'acide mucochlorique. Une approche encore plus versatile implique une première étape de chloroboration d'alcynes terminaux qui conduit à l'acide (*Z*)-chloroboronique correspondant. Le traitement de l'acide organoboronique avec du difluorure de potassium et d'hydrogène, suivi d'une réaction avec du trichlorure de tétrabutylammonium fournit les (*Z*)-1,2-dichloroalcènes d'une manière stéréospécifique, avec des rendements allant de modérés à bons.

Mots-clés : cis-dichloroalcène, chloroboration, chlorodéboronation, effet Overhauser nucléaire (EN), alcyne terminal.

[Traduit par la Rédaction]

Introduction

1,2-Dihaloalkenes are useful precursors in organic synthesis, particularly in the carbon–carbon bond-forming reactions.[1] Of the two stereoisomers, (Z)-isomers have found applications in reactions such as the Bergman cyclization.[2] In this respect, challenges remain in the preparation of 1,2-(*Z*)-dihaloalkenes as the (E)-isomers are thermodynamically favoured and are formed predominantly in direct electrophilic halogenation of alkynes.[3–5] A few methods have been reported for the stereoselective synthesis of 1,2-dihaloalkenes,[6–9] including a recent report on the synthesis of (*Z*)-dibromoalkenes by a bromodeboronation sequence of potassium bromoalkenyl – trifluoroborates;[10] however, as far as we are concerned, the only known reliable stereospecific approach to (*Z*)-1,2-dichloroalkene derivatives is the use of mucochloric acid (**1**) as the starting material.[11] We now report a chlorodeboronation methodology that is applicable to the synthesis of (*Z*)-1,2-dichloroalkenes.

Results and discussion

Synthesis of (*Z*)-1,2-dichloroalkenes from mucochloric acid

As mentioned previously, the only known stereospecific method for the preparation of (*Z*)-1,2-dichloroalkenes utilized mucochloric acid (**1**) as starting material. Upon treatment with sodium hydroxide, 2,3-(*Z*)-dichloropropenoic acid (**2**) was obtained. This latter compound can be transformed into corresponding alcohol **3**, allyl chloride **4**, anhydride **5**, or ester **6** (Scheme 1). However, this process is rather limited in scope, requiring complex transformations to access higher carbon derivatives.

Stereoselectivity of bromodeboronation reaction from potassium bromoalkenyl – trifluoroborates

It was recently shown[10] that (*Z*)-1,2-dibromoalkenes can be prepared in a stereospecific manner from a sequence of transformations using terminal alkynes as starting materials. This approach (Scheme 2) begins with the addition of boron tribromide across the triple bond to give (*Z*)-bromovinylboron dibromide (**8**).[12] Upon hydrolysis, bromovinylboronic acid (**9**) was obtained, which was subsequently transformed into corresponding potassium trifluoroborate (**10**) by treatment with potassium hydrogen difluoride.[10,12] Final bromodeboronation with tetrabutylammonium tribromide gave (*Z*)-1,2-dibromoalkenes (**11**) with retention of stereochemistry.[10]

With a model compound ((*Z*)-3,4-dibromobutenyl *p*-tosylate, **12**), we were able to confirm the stereochemistry with crystal

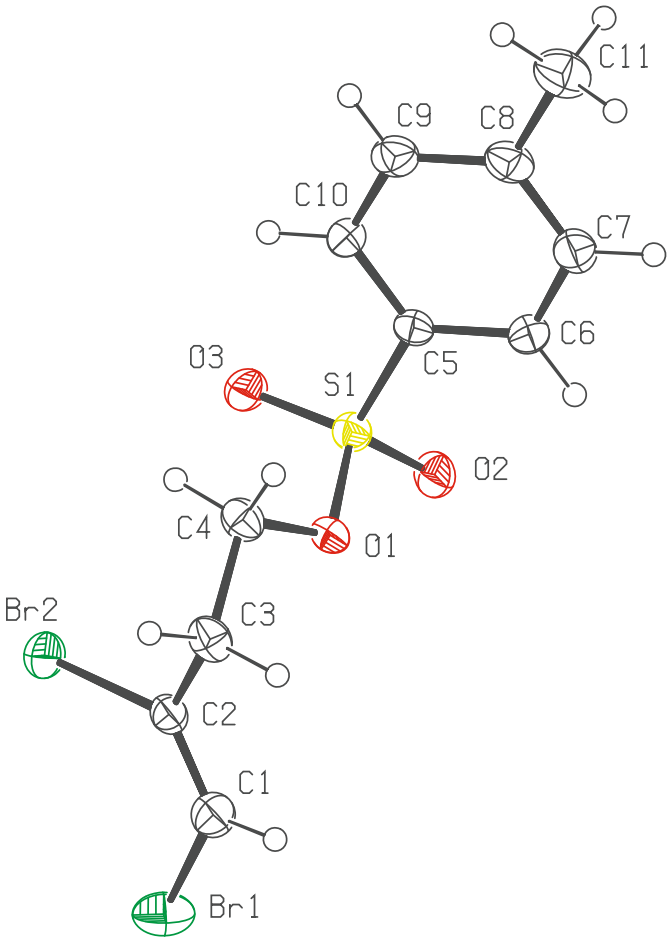
structure (Fig. 1), where the two bromines are clearly in a Z-configuration.



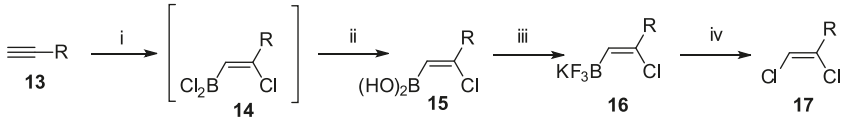
The chemistry described in this section extends its scope to both aliphatic and aromatic alkynes and therefore represents a versatile approach for the access of (*Z*)-1,2-dibromoalkenes.

Preparation of (*Z*)-1,2-dichloroalkenes from terminal alkynes

In our search for suitable 1,2-dihaloalkenes as Sonogashira reaction precursors, a versatile approach for the synthesis of (*Z*)-1,2-dichloroalkenes was required. It occurred to us that it is highly likely that a strategy similar to the bromodeboronation sequence described previously would provide access to the desired (*Z*)-1,2-dichloroalkenes. Indeed, it was reported previously that treatment of phenylacetylene with boron trichloride gave corresponding (2-chloro-2-phenylvinyl)dichloroborane.[14] To our satisfaction, this approach gave (*Z*)-1,2-dichloroalkenes from terminal alkynes in moderate to good yields and in a stereospecific manner (Scheme 3).

The transformations began with the treatment of terminal alkynes with boron trichloride, followed by hydrolysis to give corresponding chlorovinylboronic acid (**15**). Upon formation of the corresponding potassium trifluoroborate (**16**), chlorodeboronation was effected using tetrabutylammonium

Fig. 1. The molecular structure of (*Z*)-3,4-dibromobutenyl *p*-tosylate (**12**) with 30% probability displacement ellipsoids (prepared with PLATON).[13]



trichloride. This latter reagent is not commercially available, however, it can be readily prepared as a stable solid by bubbling chlorine gas into a solution of tetrabutylammonium chloride in dichloromethane.[15,16] The results for chlorodeboronation of some substrates are shown in Table 1. It is noted that some of the lower yields shown in Table 1 were most likely due to the relatively low boiling points of the products.

To illustrate the stereochemistry of the transformations, 3,4-(*E*)-dichlorobutenol (**18**) was prepared using a literature procedure.[3] Thus, treatment of 3-alkynol with copper(II) chloride and lithium chloride (Scheme 4) gave **18** almost as the sole product.

The two stereoisomers **17a** and **18** displayed different ^1H NMR chemical shifts (Fig. 2*a*), and in NOE experiments, the clear NOE signal present in **17a**, which is absent in **18**, clearly confirmed the (Z)-configuration.

The utility of this method can be extended to the preparation of 1,2-(*Z*)-bromochloro (or chlorobromo) alkenes from 1,2-terminal alkynes. As exemplified in Scheme 5, treatment of 4-bromo-1-butyne (**19**) with either BCl_3 or BBr_3 followed by hydrolysis gives the corresponding (*Z*)-2-chloro-4-bromo-1-butenylboronic acid (**15e**) or (*Z*)-2-bromo-4-bromo-1-butenylboronic acid (**20**). Transformation of these two organoboronic acids into the corresponding potassium trifluoroborates

16e and **21**, respectively, was readily effected by treatment with potassium hydrogen difluoride. Subsequent bromo- (or chloro-) deboronation gave 1,2-(*Z*)-bromochloro (or chlorobromo) alkenes **23** and **22**, respectively. It is anticipated that these 1,2-(*Z*)-dihaloalkenes could find synthetic utilities in sequential coupling reactions because of the different reactivity between vinyl chlorides and bromides. This aspect of the application is being explored in our laboratory to access the enediyne moieties with different substituents on 1,2-alkenes.

Conclusion

In conclusion, tetrabutylammonium trichloride-based chlorodeboronation of potassium bromoalkenyl trifluoroborates represents an efficient approach to the synthesis of (*Z*)-1,2-dichloroalkenes from terminal alkynes. This method provides access to these thermodynamically less stable alkenes as important synthetic intermediates.

Experimental details

^1H NMR spectra were measured at 300 and 600 MHz with Bruker AV300 and AV600 spectrometers, respectively; tetramethylsilane was used as an internal standard; *J* values are given in Hz. ^{13}C NMR spectra were measured at 75.5 or 150.9 MHz with the same spectrometers. Chemical shifts are given in ppm. Low- and high-resolution mass spectra were obtained with a Kratos Concept 1S high-resolution mass spectrometer using electron impact or fast atom bombardment sources interfaced with a DART 32 bit acquisition system through a Sun Sparcstation 10 and Mach 3 software. Desican 230–400 mesh silica gel 60 was used for flash column chromatography. Chemicals were purchased from Sigma-Aldrich or TCI America and used without further purification unless stated otherwise. Dichloromethane, diethyl ether, and tetrahydrofuran were purified by a Pure-Solv solvent purification system (Innovative Technology), and stored over activated 4 Å molecular sieves.

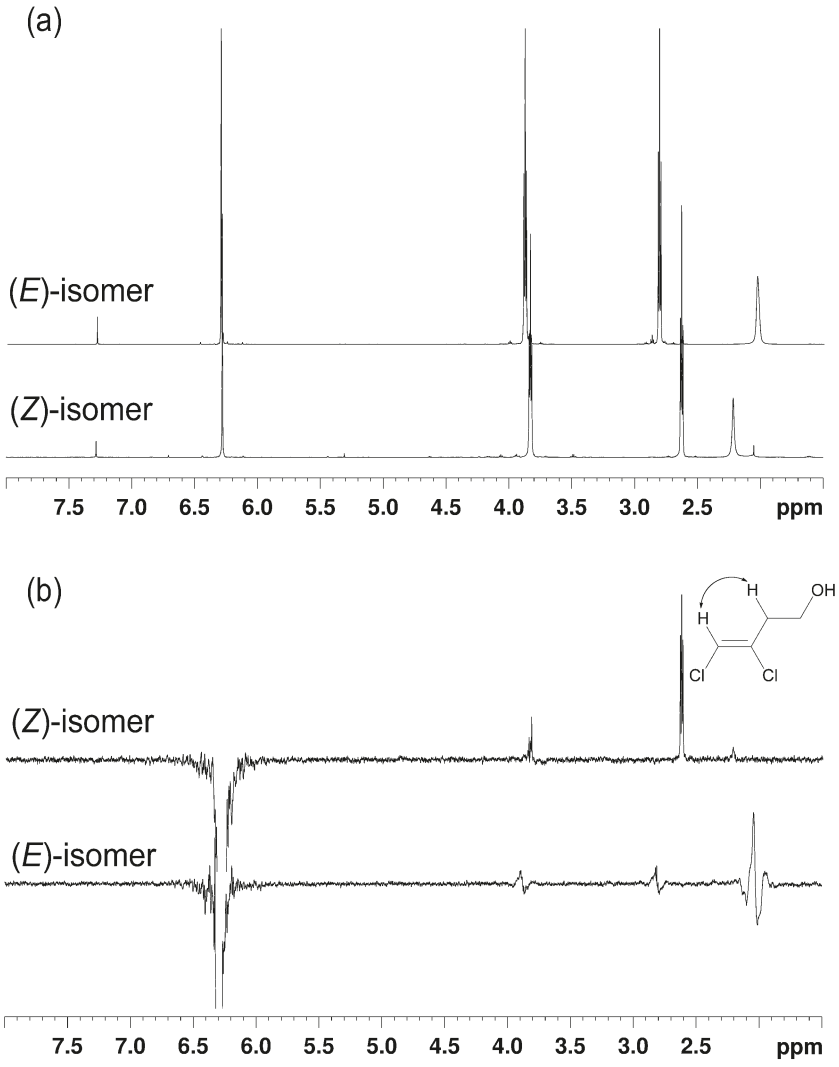
Experimental procedures for the synthesis of **17a** and corresponding intermediates are described in the following. Synthetic procedures for **17b–17d** and corresponding intermediates can be found in the Supplementary data.

(*Z*)-2-Chloro-4-hydroxy-1-butenylboronic acid (15a)

To a solution of boron trichloride in dichloromethane (1 mol/L, 8.0 mL, 8.0 mmol) was added dropwise a solution of 3-butyn-1-ol (0.48 g, 6.85 mmol) in dry dichloromethane (10 mL) at 0 °C under nitrogen. After the reaction mixture was stirred for 20 h at room temperature, the products were transferred via cannulation to a stirred mixture of diethyl ether and water (20 mL, 1:1 *v*/*v*) at 0 °C. The resulting mixture was stirred for 4 h at room temperature and then concentrated to dryness under reduced pressure. The residue was purified by column chromatography on silica gel. The appropriate fractions, which were eluted with dichloromethane, were pooled and concentrated under reduced pressure to yield the title compound as a colourless oil (0.48 g, 47%). δ_H (D_2O): 2.47 (2 H, t, J = 5.8 Hz), 3.63 (2 H, t, J = 5.9 Hz), 5.49 (s, 1H). δ_C (D_2O): 43.9, 58.5, 120.6 (br), 145.6.

Potassium (*Z*)-2-chloro-4-hydroxy-1-butenyl trifluoroborate (16a)

To a solution of the organoboronic acid **15a** (0.31 g, 2.06 mmol) in methanol (8 mL) was added dropwise a solution of potassium hydrogen difluoride (0.80 g, 10.2 mmol) in water (8 mL) at 0 °C. After the reaction mixture was stirred at room temperature for 3 h, the products were concentrated to dryness under reduced pressure. The resulting solid was extracted with acetone (5 × 30 mL), aided by sonication. The acetone extracts were combined and evaporated at room temperature under reduced pressure to give the title compound as a light brown solid (0.31 g, 1.44 mmol, 71%). δ_H (D_2O): 2.48 (2 H, t, J = 6.1 Hz), 3.69 (2 H, t, J = 6.1 Hz), 5.44 (1 H, q, J = 4.5 Hz). δ_C (D_2O): 44.1, 59.0, 129.0 (br), 138.7 (q).



(*Z*)-3,4-Dichloro-3-buten-1-ol (17a)

To a solution of potassium trifluoroborate **16a** (0.20 g, 0.94 mmol) in aqueous tetrahydrofuran (12 mL, 1:1 *v*/*v*) was added tetrabutylammonium trichloride (0.68 g, 1.95 mmol) at room temperature. After the mixture was stirred for 3 h, the products were diluted with water (20 mL) and extracted with dichloromethane (3 × 30 mL). The combined organic layers were dried ($MgSO_4$) and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel. Evaporation of the combined fractions, which

Fig. 2. NMR spectra of the (Z)- and (E)-stereoisomers **17a** and **18**. (*a*) ^{1}H NMR spectra of **17a** and **18**. (*b*) NOE of **17a** and **18**.

Scheme 5. Reagents and conditions: (*i*) (*a*) BBr_3, CH_2Cl_2; (*b*) H_2O; (*ii*) (*a*) BCl_3, CH_2Cl_2; (*b*) H_2O; (*iii*) KHF_2, CH_3OH, H_2O; (*iv*) $Bu_4N^+Cl_3^-$, aq THF; (*v*) $Bu_4N^+Br_3^-$, aq THF.

were eluted with hexanes – ethyl acetate (9:1 *v*/*v*), gave the title compound as a colourless oil (68 mg, 51%). δ_H ($CDCl_3$): 2.18 (1 H, s), 2.62 (2 H, t, J = 5.8 Hz), 3.83 (2 H, t, J = 5.9 Hz), 6.28 (s, 1H). δ_C ($CDCl_3$): 40.7, 59.2, 115.7, 133.8. HR-MS (EI) calcd for $C_4H_6Cl_2O$: 139.97957; found: 139.97914.

(*Z*)-2,3-Dichloropropenoic acid (**2**)

To a cooled (ice water bath) solution of sodium hydroxide in distilled water (24.00 g NaOH in 120 mL water, 0.600 mol) was added mucochloric acid (40.00 g, 0.237 mol) in small portions to maintain a light yellow mixture. The resulting clear yellow solution was heated at 50 °C for 2 h. Upon cooling (ice water bath), concentrated hydrochloric acid (37%, 40 mL) was added slowly under stirring. After the reaction mixture was stirred for 1 h at 0 °C, the solid that formed was collected by filtration, followed by washing with small portions of ice-cold water (2 × 30 mL). The pale yellow solid was dissolved in diethyl ether (50 mL) and dried ($MgSO_4$). Evaporation of solvents under reduced pressure gave the title compound as a yellow oil that solidified upon standing as a creamy solid (23.3 g, 70%). δ_H ($CDCl_3$): 7.83 (1 H, s), 10.57 (1 H, s). δ_C ($CDCl_3$): 126.8, 135.4, 166.3. HR-MS (EI) calcd for $C_3H_2O_2Cl_2$: 139.94318; found: 139.94348.

Reduction of (*Z*)-2,3-dichloropropenoic acid (2) to (*Z*)-1,2-dichloro-3-hydroxy-1-propene (17c or **3**)

To a cooled (ice water bath) suspension of lithium aluminum hydride (0.84 g, 95% purity, 21 mmol) in dry diethyl ether (20 mL) was added dropwise a solution of (*Z*)-2,3-dichloropropenoic acid (**2**, 3.00 g, 21.3 mmol) in dry diethyl ether (20 mL). After stirring, first at 0 °C for 20 min and then at room temperature for 2 h, the reaction mixture was cooled (ice water bath), followed by sequential addition of methanol (0.5 mL) and water (20 mL). When the evolution of hydrogen gas ceased, dilute hydrochloric acid (approximately 3 N) was added to acidify the mixture until all precipitate dissolved. The layers were separated and the aqueous layer was back-extracted with diethyl ether (50 mL). The combined organic layers were washed with brine (2 × 20 mL), dried ($MgSO_4$), and evaporated under reduced pressure. The residue was distilled to give (*Z*)-1,2-dichloro-3-hydroxy-1-propene as a colourless oil (1.62 g, 45–48 °C/2 mm Hg (1 mm Hg = 133.3224 Pa), 61%). The NMR spectra were identical to those of **17c**.

(*Z*)-1,2,3-Trichloro-propene (4)

To a cooled (ice water bath) solution of (*Z*)-1,2-dichloro-3-hydroxy-1-propene (**3**, 3.00 g, 23.6 mmol) in dry dichloromethane (12 mL) and dry pyridine (2.7 mL) was added dropwise thionyl chloride (2.4 mL, 33 mmol). After the reaction mixture was stirred, first at 0 °C for 20 min and then at room temperature for 2 h, nitrogen gas was bubbled into the reaction mixture. The products were then evaporated under reduced pressure, and the residue was extracted with diethyl ether (3 × 50 mL). The combined ether layers were concentrated under reduced pressure. The residue was purified by column chromatography on silica gel. The appropriate fractions, which were eluted with hexanes–dichloromethane (3:2 *v*/*v*), were evaporated under reduced pressure to give the title compound as a colourless oil (1.30 g, 38%). δ_H ($CDCl_3$): 4.67 (2 H, s), 6.64 (1 H, s). δ_C ($CDCl_3$): 63.5, 120.9, 130.7. HR-MS (EI) calcd for $C_3H_3Cl_3$: 143.93003; found: 143.92975.

(*Z*)-3,4-Dibromo-3-buten-1-tosylate (12)

To a cold (ice water bath) solution of (*Z*)-3,4-dibromo-3-buten-1-ol (**11**,[10] 0.20 g, 0.87 mmol) in dry pyridine (3.5 mL) was added *p*-tosyl chloride (0.33 g, 1.73 mmol). After 24 h, the products were concentrated under reduced pressure, and the residue was taken up in dichloromethane (20 mL) and washed successively with water (20 mL) and brine (20 mL), and dried ($MgSO_4$). Evaporation of solvents gave a yellow oil that was purified by column chromatography on silica gel. The appropriate fractions, which were eluted with petroleum ether – ethyl acetate (9:1 *v*/*v*), were combined and evaporated under reduced pressure to give the title compound as a colourless oil that solidified upon standing (0.15 g, 45%). δ_H ($CDCl_3$): 2.47 (3 H, s), 2.84 (2 H, dt, J = 1.1 and 6.0 Hz), 4.21 (2 H, t, J = 6.0 Hz), 6.69 (1 H, t, J = 1.1 Hz), 7.27 (2 H, d, J = 8.0 Hz), 7.78 (2 H, d, J = 8.0 Hz). δ_C ($CDCl_3$): 21.7, 40.5, 66.6, 109.6, 127.2, 128.0, 130.0, 132.7, 145.1. HR-MS (EI) calcd for $C_{11}H_{12}O_3Br_2S$: 383.88547; found: 383.88595.

Single crystal growth: Single crystals of the tosylate **12** were obtained by slow evaporation of a solution of **12** in hexanes.

X-ray diffraction experiment

Data were collected on a Nonius Kappa-CCD diffractometer using monochromated Mo Kα radiation and were measured using a combination of ϕ scans and ω scans with κ offsets, to fill the Ewald sphere. The data were processed using the Denzo-SMN package.[17] Absorption corrections were carried out using SORTAV.[18] The structure was solved and refined using SHELXTL V6.1[19] for full-matrix least-squares refinement that was based on F^2. All H atoms were included in the calculated positions and allowed to refine in riding-motion approximation with U_{iso} tied to the carrier atom.

Supplementary data

Supplementary data are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v2012-041. CCDC 859121 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via http://www.ccdc.cam.ac.uk/products/csd/request (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 33603; or e-mail: depost@ccdc.cam.ac.uk.

Conclusion

In conclusion, an approach for the synthesis of the thermodynamically disfavoured (*Z*)-1,2-dichloroalkenes was developed. Chloroboration of terminal alkynes gives corresponding (*Z*)-chloroboronic acids, which are readily transformed into potassium trifluoro organoborate. Subsequent chlorodeboronation gives (*Z*)-1,2-dichloroalkenes in a stereospecific manner.

Abstract: An ab initio calculation of the low-lying electronic states of zirconium nitride (ZrN) were performed by using a complete active space self-consistent field with multireference single and double excitation configuration interaction (MRSDCI). The potential energy curves of 21 low-lying electronic states of the ZrN molecule with different spin and spatial symmetries, in the representation $^{2s+1}\Lambda^{(+/-)}$ and below 30 000 cm^{-1}, were identified. The harmonic frequency (ω_e), the equilibrium internuclear distance (R_e), the rotational constants (B_e), the electronic energy with respect to the ground state (T_e), and the permanent dipole moment (μ) were calculated for the considered electronic states. The comparison of these values with those available in the literature shows a very good agreement with either theoretical or experimental data. Fifteen new electronic states were studied here for the first time.

Key words: ab initio calculation, electronic structure, spectroscopic constants, potential energy curves.

Résumé : On a fait des calculs ab initio des états électroniques de faible intensité du nitrure de zirconium (ZrN) en utilisant un champ auto-cohérent avec un espace complètement actif et des interactions de configuration à excitation simple et double à multiples références (« MRSDCI »). On a identifié les courbes d'énergie potentielle de vingt et un états électroniques de faible intensité de la molécule de ZrN avec divers spins et symétries spatiales, de représentation $^{2s+1}\Lambda^{(+/-)}$ et apparaissant en-dessous de 30 000 cm^{-1}. On a calculé la fréquence harmonique (ω_c), la distance internucléaire d'équilibre (R_c), les constantes rotationnelles (B_c), l'énergie électronique par rapport à l'état fondamental (T_c), ainsi que le moment dipolaire permanent (μ), de chacun des états électroniques considérés. La comparaison de ces valeurs avec celles rapportées dans la littérature montre qu'il existe un bon accord entre les valeurs expérimentales et théoriques. Quinze nouveaux états électroniques ont été étudiés pour la première fois.

Mots-clés : calculs ab initio, structure électronique, constantes spectroscopiques, énergie potentielle, courbes.

Introduction

The zirconium nitride molecule (ZrN) is one of the transition-metal nitrides (TMNs), which are metallic compounds with outstanding physical properties. They are chemically very stable with high corrosion resistance, high melting temperatures, and are extremely hard.[1] These TMNs are widely used in information storage technology, cutting tools, high power energy industry, and optoelectronics. ZrN has a cubical crystal structure where the metallic atoms form the face-centered cubic lattice and nonmetallic atoms occupy the interstitial positions.[2–13] The nitrides of group IV metals are finding increased importance in the semiconductor industry. Titanium, zirconium, and hafnium nitrides are excellent diffusion barrier layers in silicon semiconductors because of their slow diffusion rates and high conductivity. In recent years, the electronic structures, dynamics of formation, and bonding in bulk and gas-phase cluster materials have become of significant interest to materials scientists and chemists.[14–17] In industrial processes, ZrN is one of the materials that has the best mechanical properties and is deposited by physical vapor deposition to coat medical devices, industrial parts, automotive and aerospace components, and other parts subject to high wear and corrosive environments.[18–21]

Some of the transition-metal elements are known to occur in S- and M-type stars in the form of metal monoxides.[22] It is possible that the corresponding TMNs are also present in a stellar atmosphere. Transition-metal-containing diatomics represent simple metal systems where d electrons participate in the bonding.[22] These molecules provide models for understanding the bonding and reactivity in transition-metal systems.[23] The spectroscopic study of this transition-metal diatomic is difficult particularly because of the high density of the low-lying electronic states associated with partially occupied d orbitals[24,25] to the large nuclear spin associated with transition-metal atoms, which could give rise to complex magnetic hyperfine structure patterns in the spectra of these molecules.[26–28] Although the electronic structure of many gaseous transition-metal oxides, carbides, and hydrides are relatively well-characterized, only a few nitrides are known.

The theoretical ab initio methods are helpful in this respect, since they provide the experimentalist with useful and accurate data on the electronic structure of this class of molecules.

In the literature, most of the bands (0,0),[28,29] (1,1),[30–32] (2,2)[32,33] of the vibrational transitions $A^2\prod \leftarrow X^2\sum$ and $B^2\sum^+ \leftarrow X^2\sum$ of the ZrN molecule were heavily perturbed, and thus only partial analysis of the spectrum was performed.[32–34] Li et al.[35] studied the magnetic hyperfine structure of the $X^2\sum^+$ state for the isotopomer ^{91}ZrN, recording the laser-induced fluorescence spectrum of the $A^2\prod - X^2\sum^+$ vibrational transition (0 – 0). DeVore and Gallaher[36] performed an IR spectroscopic and density functional investigation for the reaction between transition metals Ti, Zr, and Hf and nitrogen atoms. Kushto et al.[37] performed an IR vibrational spectroscopy of the group IV transition-metal diatomic gaseous nitrides TiN, ZrN, and HfN. The ZrN molecule is isoelectronic with YO[38] and has a valence electronic configuration similar to TiN[39–41] and ScO;[42–45] in view of the perturbations observed in the spectra of these isovalent molecules,

it is not surprising that the spectrum of ZrN is also perturbed. Chen et al.[28] conducted a theoretical study on the ZrN molecule on the six lowest lying electronic states.

The important connection between energy relations of solids and molecules[46] and the absence of theoretical study of the higher excited states of the ZrN molecule stimulated us, in the present work, to investigate more extensive ab initio calculation of ZrN. Based on our previous theoretical calculations,[47–53] the potential energy curves and the spectroscopic constants of the 21 low-lying electronic states were calculated where 15 new electronic states have been studied here for the first time.

Calculation method

The energies of the ground and low-lying excited states of

ZrN were calculated by employing the complete active space self-consistent method (CASSCF) to generate the orbitals for the multireference single and double excitation configuration interaction (MRSDCI) computation. The CASSCF method included a full CI space of configurations within the active space chosen, obtained by distributing seven valence electrons of ZrN among the Zr (4d, 5s, 5p) and N (2s, 2p) orbitals. As the CASSCF method does not include dynamic correlation, we performed MRSDCI calculations to provide DCI optimizations. The Davidson correction, noted as MRSDCI + Q, was then invoked to account for quadruple excitations.

The spectroscopic constants R_e, ω_e, T_e, D_e, and B_e obtained from all of these curves are given in Table 1, where R_e is the equilibrium internuclear distance, ω_e is the harmonic frequency around the equilibrium, T_e is the transition energy relative to the ground state, B_e is the rotational constant, and D_e is the centrifugal distortion constant. These constants were calculated by fitting the potential energy curves around the internuclear distance at equilibrium R_e. All of the calculations were carried out in the C_{2v} symmetry with the ZrN molecular axis lying along the z axis of the coordinate system. The CASSCF active space contains 4σ(Zr, 5s, $4d_0$, $5p_z$; N, $2p_z$), 3π(Zr, $4d_{\pm2}$, $5p_{x,y}$; N, $2p_{x,y}$), and 1δ(Y, $4d_{\pm1}$) orbitals, this corresponds to five $a1$, three $b2$, three $b1$, and one $a2$ orbitals [5,3,3,1]. The potential energy curves of 21 low-lying electronic states of ZrN were generated using the MRSDCI + Q calculations. The zirconium species is treated in an all electron scheme; the 40 electrons of the Zr atom are considered using the contracted Huzinaga basis set from the literature[54,55] for s, p, and d functions; this basis set (27s, 20p, 17d) was contracted to (18s, 16p, 11d) and to which we have added one f function (18s, 16p, 11d, 1f). The exponent of this f function was taken to be 0.08. The nitrogen species was treated as a system of seven electrons by using the Rydberg2 (Dunning–Hay DZP + Rydberg)[56] basis set for s, p, and d functions (9s, 5p, 1d). Among the 47 electrons considered for the ZrN molecule, 40 electrons were frozen in subsequent calculations so that seven valence electrons were distributed over all the active molecular orbitals. Although the atomic structure of the nitrogen atom is relatively simple, with ^{4}S state for its ground electronic state and ^{2}D for the first excited state at about 19174.22 cm^{-1} higher,[57] the electronic states of the zirconium atom are more complicated. The lowest electronic state of Zr is ^{3}F, but the first excited state, namely, ^{3}P ($4d^25s^2$), lies at about 4269.89 cm^{-1} higher.[57] The doublet and quartet low-lying electronic states $\sum^+$, $\prod$, Φ, Δ, and Γ of ZrN have been obtained by the combination of the atoms Zr and N. It is obvious that even if we consider the nitrogen atom only in its ground state, there will be a plenty of electronic states generated from the low-lying atomic Zr electronic states, which could also split further by

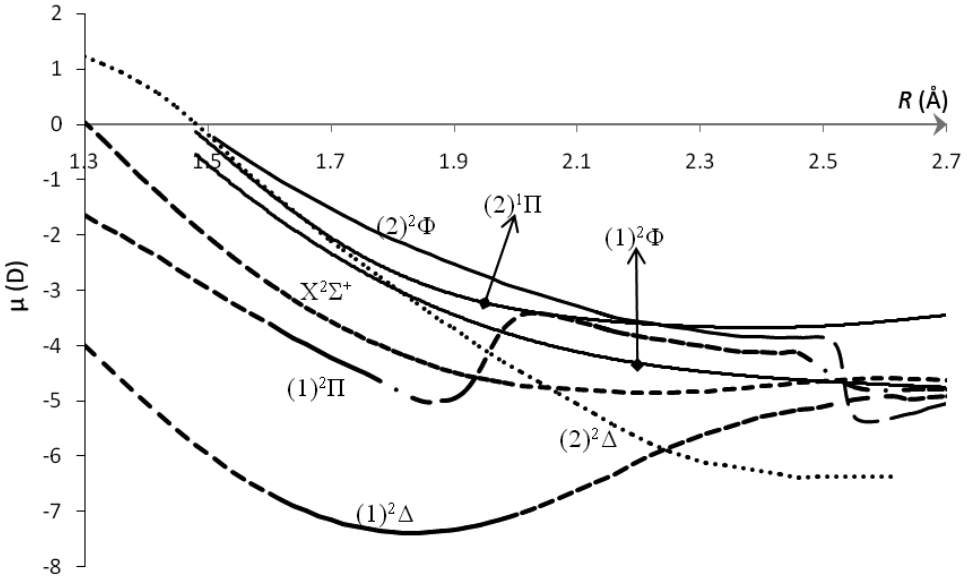
spin orbit coupling.[58,59] To facilitate a thorough exploration of the complicated manifold of electronic states of the ZrN molecule, multiple roots for every possible multiplicity were considered for each symmetry in the C_{2v} group at the CASSCF/MRSDCI level. Depending on the space and spin symmetries of the electronic states, the size of the wave functions used varied from 10 248 to 14 251 configuration state functions in CASSCF calculations and from 770 000 to 977 500 configuration state functions in MRSDCI calculations.



Results

The potential energy curves for 21 low-lying electronic states in the representation $^{2s+1}\Lambda^{(\pm)}$ of the ZrN molecule were obtained from MRSDCI + Q calculations performed at 40 internuclear distances equally distributed between 1.3 and 2.5 Å. Figures 1–4 show the potential curves of 12 low-lying doublet and 9 low-lying quartet states, respectively. The energy scale of all figures is relative to the energy minimum of the ground electronic states predicted here to be $^2\sum^+$. The ground state of ZrN is $X^2\sum^+$, resulting from the distribution of seven valence electrons over molecular orbitals $1\sigma^2 1\pi^4 2\sigma^1$, leading to a $\Lambda = 0$, with one unpaired electron ($S = 1/2$), giving a doublet multiplicity (2s+1) ground state.

The comparison between the values of the present work with the theoretical results available in the literature[30] shows a very good agreement with a percentage relative difference of $3.2\% \leq \delta T_e/T_e \leq 11\%$, $2.4\% \leq \delta\omega_e/\omega_e \leq 7.4\%$, and $1.4\% \leq \delta R_e/R_e \leq 3\%$ for the states $X^2\Sigma^+$, $(1)^2\Delta$, $(2)^2\Sigma^+$, $(3)^2\Sigma^+$, $(1)^2\Pi$, and $(1)^4\Delta$. The experimental results available in the literature for ZrN for the states $X^2\Sigma^+$, $(3)^2\Sigma^+$, and $(1)^2\Pi$ are reproduced in our calculations with a percentage relative difference of 3.4% (ref. 31) $\leq \delta T_e/T_e \leq$ 6.2% (ref. 35), 0.8% (ref. 37) $\leq \delta\omega_e/\omega_e \leq$ 4.5% (ref. 33), 2.1% (ref. 38) $\leq \delta B_e/B_e \leq$ 9.8% (ref. 38), and 1.5% (ref. 33) $\leq \delta R_e/R_e \leq$ 2.1% (ref. 30). The experimental values[30–32,34] of the rotational constant D_e are in good agreement with our results for the ground $X^2\Sigma^+$ state, with a relative difference of 9.3% (ref. 32) $\leq \delta D_e/D_e \leq$ 10% (ref. 34); this agreement becomes less for the $(1)^2\Pi$ state, where the relative difference is 17% (ref. 31) $\leq \delta D_e/D_e \leq$ 18.3% (ref. 34). In Table 1, the experimental value of the transition energy T_e for the state

Fig. 5. Permanent dipole moments (μ) of the ground and doublet excited considered electronic states of the ZrN molecule.

$(1)^2\prod$ reported in ref. 31 was estimated by using the relation $T_e = T_v - \omega_e (v+1/2)$, and the energy value 17318.76 was averaged over the two spin components $\prod_{1/2}$ and $\prod_{3/2}$ reported in ref. 34. Table 2 gives a list of 24 configurations labeled from (A) to (Z), which have weight ≥ 2% in the CMRCI wave functions as detailed in Table 3. The configuration weights are calculated as the squares of the corresponding CI coefficients. Table 2 characterizes each configuration in terms of electron promotions with respect to the ground configuration ($1\sigma^2 1\pi^4 2\sigma^1$) and also reports the arising electronic states. The $(1)^2\prod$ state arises from the promotion of the $2\sigma^1$ electron into a $2\pi^1$ orbital with an increase in energy of about 16 298.08 cm^{-1}. The $(2)^2\sum^+$ state ($1\sigma^2 1\pi^4 3\sigma^1$) arises from the promotion of a 2σ electron to a 3σ orbital, which corresponds to an energy increase of 17 562.94 cm^{-1}, whereas the $(3)^2\sum^+$ state ($1\sigma^1 1\pi^4 2\sigma^1 3\sigma^1$) arises from the promotion of the 1σ electron into the 3σ orbital with an energy increase of 23 524.67 cm^{-1}. The lowest quartet state $(1)^4\Delta$ ($1\sigma^2 1\pi^2 2\sigma^1 3\sigma^2$) arises from the promotion of two 1π electrons into a 3σ orbital with an energy change of 16 435.04 cm^{-1}. In this study, we calculated the spectroscopic properties of the low-lying $(1)^4\Pi$ and $(1)^4\Phi$ states for which a heavy mixing was reported in ref. 30 The $(1)^4\Pi$ state was found to be 86 cm^{-1} separated from the $(1)^4\Phi$ state; this is not surprising, since both states have the same electronic configuration ($1\sigma^2 1\pi^3 2\sigma^1 3\sigma^1$) that arises from the excitation of a 1π electron into a 3σ orbital with an average energy change of 16 652.57 cm^{-1}.

Chen et al.[25] studied the (0,0) band of the $(3)^2\sum^+ \leftarrow X^2\sum^+$ transition through the laser spectroscopy technique, reporting the presence of severe perturbations in the rotational energy spectra of the investigated transition. As the nature of the perturbing state could not be identified, this suggests that the $(3)^2\sum^+$ state and its perturbing state have close potential energy curves with a low vibrational $v = 0$ quantum number for this perturbing state. From the potential energy curves of the present work, we identified the nature of the perturbing state to be a $(3)^2\Delta$ state whose potential energy curve crosses that of the $(3)^2\sum^+$ state at $r = 1.66$ Å.

Recent experimental studies of photodissociation dynamics show that the potential energy curve crossing plays a deterministic role in the choice of the channel of dissociation.[48] Then, in the range of r considered, some crossings and avoided crossings between the different electronic states occur; these are reported in Table 4 with the position of the crossings r_c and avoided crossings r_{av} together with their energy gap separation, ΔE_{av}. Several perturbations have been detected experimentally in the vibronic band systems for $v = 0$, 1, and 2 for the $(1)^2\prod$ electronic state.[26,27,33] These perturbations were not clear, since the nature of the perturbing states could not be resolved. Our theoretical potential energy curves show the avoided crossing of the $(1)^2\prod$ state with the $(2)^2\prod$ state at $r = 1.83$ Å and the crossing with the $(1)^2\Phi$ state at $r = 1.84$ Å. This crossing and avoided crossing may be responsible for the experimental vibrational perturbations occurring in the spectra of the $(1)^2\prod$ electronic state. A similar avoided crossing has been detected between the $(1)^2\prod$ and the $(2)^2\prod$ states in the YO molecule,[22] which is isoelectronic to the ZrN molecule.

For the ground and the considered doublet electronic states, the permanent dipole moments were calculated in terms of the internuclear distance (R) and are plotted in Fig. 5. In this figure we notice that the $(1)^2\Delta$ state attains the largest dipole moment of 7.385 D at $R = 1.82$ Å. The permanent dipole moments at the equilibrium internuclear distances for the studied states are given in Table 3. The comparison of these values with other results in the literature is not possible, since, to the best of our knowledge, these values are given here for first time.

Conclusion

The potential energy curves of 21 low-lying electronic states of the ZrN molecule were computed using the CASSCF and MRSDCI + Q methods. To the best of our knowledge, only six states have been characterized in the literature. Several experimental perturbations in the vibronic structures of the $(3)^2\sum^+ \leftarrow X^2\sum^+$ and $(1)^2\prod \leftarrow X^2\sum^+$ systems

have been resolved as the identities of the perturbing states were revealed. Many low-lying quartet states ($^4\prod$ and $^4\Phi$) were detected for the first time. The potential energy curves and the spectroscopic constants were obtained for the investigated states where the comparison with the available experimental and theoretical data in the literature showed very good agreement. In this work, 15 new low-lying electronic states in the doublet and quartet manifolds were studied for the first time. Because of the importance of the ZrN molecule in several areas of science, we expect that the results of the present work will invoke further experimental investigations of the electronic structure of the ZrN molecule. The values of the permanent dipole moments of the investigated electronic states are reported here for the first time.

Abstract: Quantitative structure–property relationship (QSPR) studies were performed for the prediction of gas-phase reduced ion mobility constants (K_0) of diverse compounds based on three-dimensional (3D) molecular structure representation. The entire set of 159 compounds was divided into a training set of 120 compounds and a test set of 39 compounds according to Kennard and Stones algorithm. Multiple linear regression (MLR) analysis was employed to select the best subset of descriptors and to build linear models, whereas nonlinear models were developed by means of an artificial neural network (ANN). The obtained models with five descriptors involved show good predictive power for the test set: a squared correlation coefficient (R^2) of 0.9029 and a standard error of estimation (s) of 0.0549 were achieved by the MLR model, whereas by the ANN model, R^2 and s were 0.9292 and 0.496, respectively. The results of this study compare favorably to previously reported prediction methods for the ion mobility constants. In addition, the descriptors used in the models are discussed with respect to the structural features governing the mobility of the compounds.

Key words: QSPR, ion mobility constants, three-dimensional descriptors, multiple linear regression, artificial neural network.

Résumé : On a effectué des études de relation structure/propriétés quantitatives (RSPQ) dans le but de prédire les constantes de mobilité ionique réduites en phase gazeuse (K_0) de divers composés en fonction de la représentation tridimensionnelle (3D) de leur structure moléculaire. On a fait appel à l'algorithme de Kennard et Stones pour diviser un ensemble de 159 composés en bloc de 120 composés utilisés pour développer la méthode et un autre bloc de 39 composés utilisés pour la vérifier. On a utilisé une méthode d'analyse de régression linéaire multiple (RLM) pour choisir le meilleur sous-ensemble des descripteurs et pour développer les modèles linéaires; les modèles non-linéaires ont été développés à l'aide d'un réseau neural artificiel (RNA). Les modèles obtenus en impliquant cinq descripteurs permettent d'obtenir un bon pouvoir de description pour l'ensemble à vérifier : faisant appel à une analyse de régression multiple, le coefficient de corrélation quadratique (R^2) est égal à 0,9029 et l'erreur d'évaluation standard (s) est égale à 0,0549 alors que, par l'utilisation du réseau neural artificiel conduit à des valeurs de R^2 et s de 0,0202 et de 0 496 respectivement. Les résultats de cette étude se comparent favorablement avec les résultats rapportés antérieurement à l'aide d'autres méthodes de prédiction des constantes de mobilité ionique. De plus, on discute des descripteurs utilisés dans les modèles en fonction des caractéristiques structurales qui gouvernent la mobilité des composés.

Mots-clés : relation structure–propriétés quantitatives (RSPQ), constantes de mobilité ionique, descripteurs tridimensionnels, régression linéaire multiple, réseau neural artificiel.

Introduction

The use of ion mobility spectrometry (IMS) has attracted significant interest as a tool for the separation of mixtures of components because of its high speed, excellent detection limits, amenability to miniaturization, and ruggedness for field operation.[1–3] When coupled with time-of-flight mass spectrometry, IMS also can be used for high-throughput drug screening,[4] proteomics,[5–7] glycomics,[8,9] and metabolomics studies.[10]

The basic concept of IMS is that an ion will drift at a constant velocity when exposed to an electric field at ambient pressure. The ion accelerates in the electric field before colliding with a neutral molecule and stopping.[11] The continuous series of accelerations and collisions leads to the apparent constant velocity. Ion mobility (K) is the ratio of

the ion drift velocity (v) to the applied electric field (E), which is the most important parameter governing the separation of solutes in IMS. The value of K in most IMS instruments can be derived from the following equation:[12]

$$[1] \qquad K = \frac{L^2}{Vt}$$

where L is the length of the drift tube region of the spectrometer, V is the applied voltage, and t is the drift time of the ion. For the purpose of standardization, the reduced mobility constant (K_0) is typically reported for any particular analyte ion. K_0 values are calculated using the following equation:[12]

$$[2] \qquad K_0 = K\left(\frac{273}{T}\right)\left(\frac{P}{760}\right)$$

where T is the operating temperature of the instrument and P is the current ambient pressure. Direct comparison and estimation of K_0 values measured under different conditions are made possible by using this normalization.

The ability to predict K_0 values is of great importance for several reasons.[13] First, the determination of K_0 values by experiment is often expensive and time-consuming. Second, the reported experimental K_0 values are limited. Third, the predicted K_0 values can provide an initial value for algorithms used to calibrate instrument-specific measurements. Finally, a prediction equation could provide valuable insights into the principle dynamics that have the greatest effects on ion mobility.

The mass/inverse mobility correlation has been used to predict the K_0 of homogeneous series of compounds with some success. However, the obtained results were not satisfactory when applied to a diverse set of compounds.[14–17] The quantitative structure–property relationship (QSPR) provides an alternative method for predicting K_0 using descriptors derived solely from the molecular structure to fit experimental data. The QSPR method is based on the assumption that the variation of the behavior of the compounds, as expressed by any measured properties, can be correlated with numerical changes in structural features of all compounds, termed "molecular descriptors".[18–24] The advantage of this method lies in the fact that it requires only the knowledge of the chemical structure and is not dependent on any experimental properties. The QSPR method has been successfully applied to predict the chemical and physical properties of compounds. Wessel and Jurs[25] developed an artificial neural network (ANN) model, which predicted K_0 values with over 99% accuracy for a defined set of relatively simple compounds and a somewhat lower (i.e., 91.1%) accuracy for an expanded set containing more diverse compounds.[12] Although this model has good predictive ability, it is difficult to interpret the relationship between the inputs and response. Tolley and co-workers[1] built several models using the multiple linear regression (MLR) method for different series of compounds. A squared correlation coefficient (R^2) value of 80.1% between the calculated K_0 values and measured K_0 values was obtained for 162 compounds. These models are difficult to generalize because different equations are proposed for different groups of compounds. In addition, these models were not tested with the external set, thus, their true prediction ability for new compounds not used for model development was not clear. Actually, the external validation is a crucial aspect of any QSPR modeling.[26] Recently, Yao and co-workers[13] developed linear and nonlinear models for predicting K_0 of diverse compounds based on the descriptors calculated from the CODESSA software. Although much has been done, the accuracy and cost of predictions, as well as their clear physical interpretations, are still matters of concern.

Molecular descriptors can be defined as the final result of a logic and mathematical procedure that transforms chemical information encoded within a symbolic representation of a molecule into a useful number.[27] Molecular descriptors play an important role in the quantitative description of chemical structure to find appropriate predictive models. Based on the dimensionality of the molecular representation, molecular descriptors can be classified into zero-dimensional (0D), one-dimensional (1D), two-dimensional (2D), three-dimensional (3D), and even higher dimensional groups. The good predictive abilities of 3D descriptors in QSPR studies have been demonstrated in recent years,[28–35] since the higher dimensional structure of a molecule contains more information.

No reports on 3D descriptors for QSPR studies on ion mobility constants can be found in the literature. The scope of this work is to evaluate the explanatory ability of 3D descriptors to represent the effect of molecular structure on the ion mobility. A diverse set of 159 compounds previously collected were re-examined. Linear and nonlinear models are developed by means of MLR and ANN. Furthermore, the structural factors affecting the mobility behavior of these compounds in ion mobility spectrometry are discussed in detail on the basis of descriptor contribution analysis.

Materials and method

Data set

The K_0 values of 162 compounds with diverse structures were taken from the literature.[1] Chloroacetophenone, 3-xylyl bromide (3-methylbenzyl bromide), and dichloro(2-chlorovinyl) arsine were excluded from the data set,[13] and the rest of the 159 compounds with K_0 values ranging from 1.23 to 2.97 (Table 1) were studied.

Descriptor generation

The molecular structures of these compounds were optimized using the MM+ molecular mechanics method (Polak–Ribiere algorithm) and the semiempirical AM1 method at a restricted Hartree–Fock level with no configuration interaction in the HYPERCHEM program (version 6.01).[36] A gradient norm limit of 0.01 kcal $Å^{-1}$ mol^{-1} (1 cal = 4.184 J) was chosen as the stopping criterion for the optimization. The resulting lowest energy geometry for each compound was then submitted to the DRAGON software (version 5.4)[37] for calculation of the 735 3D descriptors.

To reduce redundant and nonuseful information, constant or near constant values and descriptors found to be highly correlated pairwise (one of any two descriptors with a correlation greater than 0.99[38]) were excluded in a prereduction step. Consequently, 404 descriptors remained to undergo subsequent descriptor selection.

Kennard and Stones algorithm

Kennard and Stones algorithm[39] has been considered as

*Compounds in the test set.

one of the best ways to build training and test sets.[40,41] The advantages of this algorithm are that the training samples always map the measured region of the input variable space completely with respect to the induced metric and that the no test samples fall outside the measured region. Using Kennard and Stones algorithm, the entire data set was divided into two subsets: a training set of 120 compounds and a test set including the remaining 39 compounds.

Model development and validation

Linear models were developed by applying stepwise MLR analysis with leave-one-out (LOO) cross-validation to the training set. The quality of the models was measured by the R^2, the adjusted R^2, the cross-validated R^2, the F ratio values, the standard error of estimation (s), and the significance level value (p). A variance inflation factor (VIF) was calculated to test if multicollinearities existed among the descriptors, which is defined as

$$[3] \qquad \mathrm{VIF} = \frac{1}{1 - R^2_j}$$

where R^2_j is the squared correlation coefficient between the jth coefficient regressed against all the other descriptors in the model. Models would not be accepted if they contained descriptors with VIF above a value of five.[42] To exclude the possible existence of fortuitous correlations, the proposed MLR model was also checked by Y-randomization tests.

Nonlinear models were then developed by submitting the selected descriptors from MLR to a three-layer, fully connected, feed-forward ANN. The number of input neurons was equal to that of the descriptors in the linear model. The number of hidden neurons was optimized by a trial and error procedure on the training process. One output neuron was used to represent the experimental K_0. The network was trained using the quasi-Newton Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm.[25] To avoid overtraining, one-tenth of the data from the training set were randomly selected as a separate validation set for monitoring the training process, i.e., during the training of the network the performance was monitored by predicting the values for the systems in the validation set. When the results for the validation set ceased to improve, the training was stopped.

Validation of the linear and nonlinear models was further performed by using the external test set composed of data not used to develop the prediction model. The external $R^2_{\mathrm{CV,ext}}$ for the test sets was determined as

$$[4] \qquad R^2_{\mathrm{CV,ext}} = 1 - \frac{\sum (y_i - \tilde{y}_i)^2}{\sum (y_i - \bar{y}_{\mathrm{tra}})^2}$$

where y_i and $\tilde{y}_i$ are the observed and the calculated values, respectively, and $\bar{y}_{\mathrm{tra}}$ is the averaged value for the response variable of the training set. According to Tropsha and coworkers,[26,40] a QSPR model is successful if it satisfies several criteria as follows:

$$[5a] \qquad R^2_{\mathrm{CV,ext}} > 0.5$$

$$[5b] \qquad r^2 > 0.6$$

$$[5c] \qquad (r^2 - r_0^2)/r^2 < 0.1 \quad \text{or} \quad (r^2 - r_0'^2)/r^2 < 0.1$$

$$[5d] \qquad 0.85 \leq k \leq 1.15 \quad \text{or} \quad 0.85 \leq k' \leq 1.15$$

where r is the correlation coefficient between the calculated and experimental values in the test set, r_0^2 (calculated versus observed values) and $r_0'2$ (observed versus calculated values) are the coefficients of determination, and k and k' are the slopes of the regression lines through the origin of the calculated versus observed values and the observed versus calculated values, respectively. Detailed mathematical definitions of these parameters can be found in Golbraikh and Tropsha.[26]

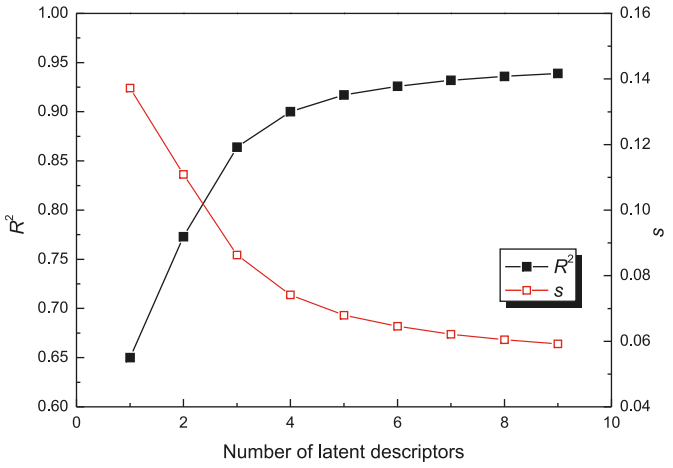
Applicability domain analysis

The applicability domain (AD) of a QSPR model[40,43] must be defined if the model is to be used for screening new compounds. In this work, the structural AD was verified by the leverage approach. The leverage (h_i)[43] is defined as follows:

$$[6] \qquad h_i = \mathbf{x}_i^{\mathrm{T}} (\mathbf{X}^{\mathrm{T}} \mathbf{X})^{-1} \mathbf{x}_i$$

where $\mathbf{x}_i$ is the descriptor row-vector of the ith compound, $\mathbf{x}_i^{\mathrm{T}}$ is the transpose of $\mathbf{x}_i$, $\mathbf{X}$ is the descriptor matrix, and $\mathbf{X}^{\mathrm{T}}$ is the transpose of $\mathbf{X}$. The warning leverage (h^*) is, generally, fixed at $3(m + 1)/n$, where n is the total number of samples in the training set and m is the number of descriptors involved in the correlation.

The Williams plot (the plot of leverage values versus standardized residuals) was used to give a graphical detection of both the response outliers (Y outliers) and the structurally influential compounds (X outliers). In this plot, the two horizontal lines indicate the limit of normal values for Y outliers (i.e., samples with standardized residuals greater than 3.0 SD units, $\pm 3.0s$); the vertical straight lines indicate the limits of normal values for X outliers (i.e., samples with leverage values greater than the threshold value, $h > h^*$). For a sample in the external test set whose leverage value is greater than h^*, its prediction is considered unreliable, because the prediction is the result of a substantial extrapolation of the model. Conversely, when the leverage value of a compound is lower than the critical value, the probability of accordance between predicted and experimental values is as high as that for the compounds in the training set. It is noteworthy that the response outliers can be highlighted only for compounds with known responses and the possibility of a compound to be out of the structural AD of a model can be verified for every new compound, the only knowledge needed being the molecular structure information represented by the molecular descriptors selected in the model.



Results and discussion

MLR model

Stepwise MLR analysis with LOO cross-validation was used to develop linear models from the training set, and the number of descriptors in the final model was determined on the basis of the R^2, the adjusted R^2, the cross-validated R^2, the significance test F, and the standard error s. The plots of R^2 and s versus the number of the latent descriptors are shown in Fig. 1. The R^2 value increased gradually with an increasing number of descriptors. The optimum subset size was reached when the addition of another descriptor did not significantly improve the performance of the model. To avoid overparameterization of the models, such as those that contain an excess of descriptors and are difficult to interpret in terms of physical interactions, an increase of the R^2 value of less than 0.01 was chosen as the breakpoint criterion. Thus,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12

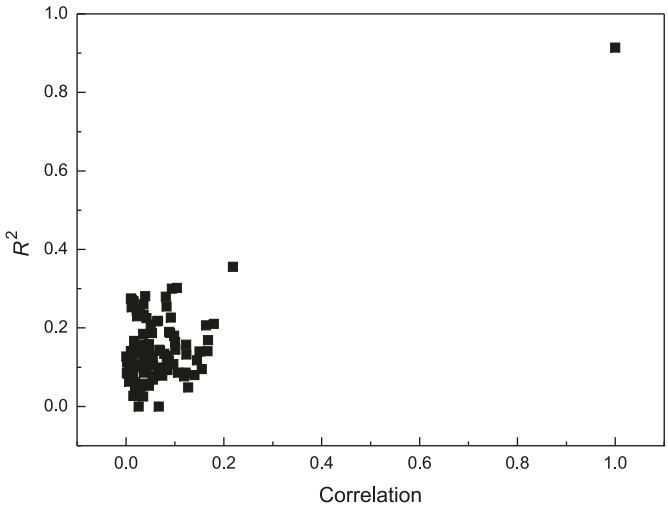
Fig. 1. R^2 and standard error (s) vs the number of latent descriptors in the best multiple linear regression (MLR) models.



the five-parameter model was selected as the best model, which can be described as

$$[7] \quad K_0 = -0.637(\text{DISPe}) - 0.0326(\text{RDF050m}) + 0.421(\text{E3p}) + 0.485(\text{Dm}) - 0.243(\text{HIC}) + 2.748$$

for $n = 120$, $R^2 = 0.9171$, $R_{CV}{}^2 = 0.9056$, $R_{adj}{}^2 = 0.9107$, $s = 0.0680$, $F = 252.3$, and $p < 0.0001$. Here, DISPe is the d COMMA2 value / weighted by atomic Sanderson electronegativities, RDF050m is the radial distribution function – 5.0 / weighted by atomic masses, E3p is the third component accessibility directional weighted holistic invariant molecular (WHIM) index / weighted by atomic polarizabilities, Dm is the D total accessibility index / weighted by atomic masses, and HIC is the mean information content on the leverage magnitude. More information about these descriptors can be found in the DRAGON software user's guide[37] and the refs. therein.

In general, the larger the magnitude of the F ratio, the better the model prediction of the property values in the training set. The large F ratio of 252.3 indicates that eq. [7] does an excellent job of predicting the K_0 values of the training set. Equation [7] has an adjusted R^2 value of 0.9107, which indicates good agreement between the correlation and the variation in the data. The cross-validated correlation coefficient $R_{CV}{}^2 = 0.9056$ illustrates the reliability of the model by focusing on the sensitivity of the model to the elimination of any single data point. The model was further validated by applying the randomization tests, and the obtained R^2 vs the correlation coefficient between the original and permuted response data are plotted in Fig. 2. The lower R^2 values indicate that the good results of the original model are not due to chance correlation or structural dependency of the training set. Some important statistical parameters shown in Table 2 were used to valuate the involved descriptors. The t value of a descriptor measures the statistical significance of the regression coefficients. The high absolute t values shown in Table 2 express that the regression coefficients of the descriptors involved in the MLR model are significantly larger than the standard deviation. The t probability of a descriptor can describe the statistical significance when combined together within an overall collective QSPR model (i.e., descriptors' interactions). Descriptors with t probability values

Fig. 2. R^2 vs the correlation coefficient between the original and permuted response data (average value of R^2 is 0.138).

below 0.05 (95% confidence) are usually considered statistically significant in a particular model, which means that their influence on the response variable is not merely by chance.[44] The smaller t probability suggests the more significant descriptor. The t probability values of the 5 descriptors are very small, indicating that all of them are highly significant descriptors. Furthermore, all the VIF values are less than five, suggesting that these descriptors are weakly correlated with each other. Thus, the model can be regarded as an optimal regression equation.

The calculated K_0 values from the MLR model for the training and test sets are shown in Table 1 and Fig. 3. The errors are distributed on both sides of the zero point; thus, one may conclude that there is no systematic error in the model development. The following statistical parameters were obtained for the test set ($s = 0.0549$), which obviously satisfy the generally accepted condition and thus demonstrate the predictive power of the present model.

$$R^2{}_{CV,ext} = 0.8945 > 0.5$$
$$r^2 = 0.9029 > 0.6$$
$$(r^2 - r_0{}^2)/r^2 = (0.9029 - 0.9919)/0.9029 < 0.1$$
$$\text{or} \quad (r^2 - r_0'^2)/r^2 = (0.9029 - 0.9952)/0.9029 < 0.1$$
$$0.85 \le k = 1.007 \le 1.15$$
$$\text{or} \quad 0.85 \le k' = 0.992 \le 1.15$$

ANN model

The ANN has become an important and widely used nonlinear modeling technique for QSPR studies. The mathematical adaptability of ANN commends it as a powerful tool for pattern classification and building predictive models. A particular advantage of ANN is its inherent ability to incorporate nonlinear dependencies between the dependent and independent variables without using an explicit mathematical function. Among the neural network learning algorithms, the back-propagation (BP) method[45] is one of the most commonly used methods. The drawback of BP is that the training processes slowly, because the gradient-descent algorithm is usually

Table 2. Characteristics of the descriptors selected in the optimal multiple linear regression (MLR) model.

Descriptor	Descriptor type	Coefficient	Error	*t* value	*t* probability	VIF
Constant		2.748	0.065	42.396	0.0000	
DISPe	Geometrical descriptors	–0.637	0.050	–12.789	0.0000	1.139
RDF050m	RDF descriptors	–0.0326	0.004	–7.903	0.0000	1.632
E3p	WHIM descriptors	0.421	0.093	4.518	0.0002	2.175
Dm	WHIM descriptors	0.485	0.101	4.788	0.0000	2.569
HIC	GETAWAY descriptors	–0.243	0.016	–15.627	0.0000	2.451

Note: VIF, variance inflation factor; DISPe, d COMMA2 value / weighted by atomic Sanderson electronegativities; RDF050m, radial distribution function – 5.0 / weighted by atomic masses; E3p, third component accessibility directional WHIM index / weighted by atomic polarizabilities; Dm, D total accessibility index / weighted by atomic masses; and HIC is the mean information content on the leverage magnitude; GETAWAY, geometry, topology, and atom-weights assembly. The *t* value of a descriptor measures the statistical sifnificance of the regression coefficients. The *t* probability of a descriptor can describe the statistical significance when combined together within an overall collective quantitative structure–property relationship (QSPR) model.

Fig. 3. Calculated vs experimental reduced mobility constant (K_0) values by the multiple linear regression (MLR) model.

used for minimizing the sum-of-squares error. In this study, the quasi-Newton BFGS algorithm[25] was used to develop nonlinear models. The advantages of the BFGS algorithm are that specifying rate or momentum is not necessary and the training is much more rapid.[46] The five descriptors from the MLR model were used as inputs to the network. The number of hidden neurons is an important parameter influencing the performance of the ANN. The usual rule of thumb is that the weights and biases should be less than the samples so that the model achieved by the network is stationary.[47] Consequently, a 5–5–1 network configuration, which gives the best prediction, was obtained after the trial and error procedure.

The present three-layer feed forward neural network with the sigmoidal transfer function can be simplified in the form of eq. [8].

$$[8] \qquad y_{\text{calcd}}(i) = \{\mathbf{W}_2[1.2/\left(1 + e^{-(\mathbf{W}_1\mathbf{T}_i)-\mathbf{b}_1}\right) - 0.1]\} + \mathbf{b}_2$$

where $\mathbf{T}$ is the input matrix of dimension of $m \times n$, where m is the number of molecular descriptors involved and n is the number of compounds available in the training set; $\mathbf{T}_i$ is the ith-column of $\mathbf{T}$; $\mathbf{W}_1$ is the first weight matrix of the three-layer network and has the dimension nhidden $\times$ m, where nhidden is the number of neurons in the hidden layer; $\mathbf{b}_1$ is the first bias matrix of dimension nhidden $\times$ 1; $\mathbf{W}_2$ is the second weight matrix of the output layer and has the dimension 1 $\times$ nhidden; $\mathbf{b}_2$ is the second bias matrix of the output layer, which is a number; and $y_{\text{calcd}}(i)$ is the ith output of this network, which must be compared with the ith response. The values of $\mathbf{W}_1$, $\mathbf{W}_2$, $\mathbf{b}_1$, and $\mathbf{b}_2$ (shown in Table 3) were obtained by the minimization of an objective function, which is commonly the mean-squared error between the outputs of the neural network and the target values.

The predictive results from the ANN model for the entire data set are given in Table 1 and Fig. 4. The R^2, R_{CV}^2, and s for the training set are 0.9631, 0.9622, and 0.0446, respectively. The proposed ANN model is predictive as it satisfies the conditions for the test set ($s = 0.0496$).

$$R^2_{\text{CV,ext}} = 0.9215 > 0.5$$
$$r^2 = 0.9292 > 0.6$$
$$(r^2 - r_0^2)/r^2 = (0.9292 - 0.9896)/0.9029 < 0.1$$
$$\text{or} \quad (r^2 - r_0'^2)/r^2 = (0.9292 - 0.9922)/0.9029 < 0.1$$
$$0.85 \le k = 1.009 \le 1.15$$
$$\text{or} \quad 0.85 \le k' = 0.990 \le 1.15$$

By comparison of the models obtained by MLR and ANN, it can be seen that the performance of ANN is better than that of MLR, which confirms the nonlinear relationship between the structural information and the K_0. To further test the suitability of the proposed models, the obtained results were compared with those calculated by other reported models[13] (Table 4) for the same set of compounds. The present models developed on the basis of 3D molecular representation are comparable in quality to the models described by Yao and co-workers[13] This fact confirms the potency of 3D descriptors as a useful tool for the structural characterization and prediction of the mobility behavior in IMS.

Applicability domain

It needs to be pointed out that no matter how robust, significant, and validated a QSPR model may be, it cannot be expected to reliably predict the modeled property for the entire universe of compounds. Therefore, before a QSPR model is put into use for screening compounds, its AD must be defined and predictions for only those compounds that fall in this domain can be considered as reliable. The model AD was analyzed in the Williams plot (shown in Fig. 5). Three

compounds (carbonic dichloride, nitrochloroform, and ammonia) were found to be X outliers (with leverage values higher than the warning leverage limit of 0.150). In the Williams plot, X outliers can be explained as compounds with peculiar features poorly represented in the data set, which could affect the variable selection for a better modeling of those compounds. Ammonia is the only inorganic compound in the data set, nitrochloroform is the unique nitro compound with strong polarity, and arbonic dichloride is of the unstable structure feature. These three compounds were well predicted by the present models and thus reinforced the models.

Fig. 5. Williams plots of the developed models: (*a*) multiple linear regression (MLR) and (*b*) artificial neural network (ANN).

Generally, if the residual value is larger than ±3.0s, the sample can be considered a response outlier (Y outlier), which could be associated with errors in the experimental values. On analyzing the AD of the developed models in the Williams plot, there is no response outlier for the MLR model. For the ANN model, *tert*-amyl alcohol would be recognized as a response outlier and it also shows a relatively large standard residual (close to 3s) for the MLR model. However, the majority of the samples within the model AD were calculated accurately, which provided another indication of the reliability of the predictions.

Because of their high predictive abilities, the proposed models could be used to screen existing databases or virtual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

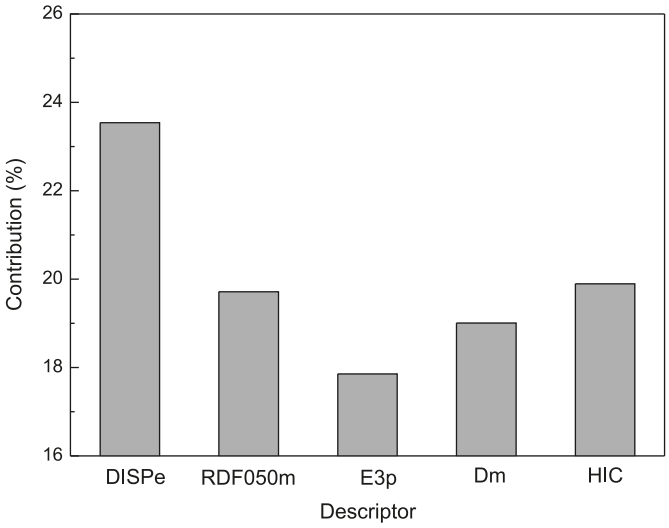
chemical structures to identify compounds with the desired ion mobility constants. In this case, the AD will serve as a valuable tool to filter out "dissimilar" chemical structures.

Descriptor contribution analysis and interpretation

The descriptors appearing in the present models encode 3D aspects of the molecular structure and can be classified as follows: (1) a geometrical descriptor, DISPe; (2) an RDF descriptor, RDF050m; (3) two WHIM descriptors, E3p and Dm; and (4) a GETAWAY (geometry, topology, and atom-weights assembly) descriptor, HIC.

It is not a trivial task to interpret the nonlinear models because of their complex modeling procedure and vague output, although the nonlinear models could give better predictive results. Thus, the descriptor interpretation was carried out on the basis of the MLR model. Based on a previously described procedure,[48] the relative contributions of the five descriptors to the MLR model were determined and are plotted in Fig. 6. The significance of the descriptors involved in the MLR model decreases in the following order: DISPe (23.5%) > HIC (19.9%) > RDF050m (19.7%) > Dm (19.0%) > E3p (17.9%). The difference in descriptor contribution between any two descriptors used in the models is not significant, indicating that all of the descriptors are indispensable in generating the predictive models.

The most significant descriptor in the MLR model is DISPe, a COMMA2[49] descriptor. DISPe is a measure of displacement between the geometric and the electronegativity (e) centers in the molecule, calculated with respect to the molecular principal axes. This descriptor can reflect how charge is distributed in the molecule and loosely show molecular size as well. The negative regression coefficient of this descriptor suggests that an increasing separation between geometric and electronegativity centers is detrimental to the K_0. Thus, this descriptor could be an indicator for compounds that have a small K_0 value.



The second important descriptor is HIC, the mean information content on the leverage magnitude. HIC is calculated as follows:[50]

$$[9] \qquad \mathrm{HIC} = -\sum_{i=i}^{n\mathrm{AT}} \frac{h_{ii}}{D} \log_2 \frac{h_{ii}}{D}$$

where nAT is the number of molecule atoms, D is the rank of the molecular matrix equal to 1, 2, and 3 for linear, planar, and nonplanar molecules, respectively. This descriptor is able to catch more specific information with regard to molecular complexity than the total and standardized information content on the leverage equality. For example, HIC can recognize the different substituents in a series of monosubstituted benzenes. HIC is also sensitive to the presence of multiple bonds. The emergence of HIC in the model reflects the importance of molecular shape of a compound during the IMS separation process.

The third descriptor, RDF050m, is one of the RDF descriptors, which have been proposed based on a radial distribution function. The RDF descriptors can be interpreted as the probability distribution of finding an atom in a spherical volume of radius r. The general form of the radial distribution function is represented by

Fig. 6. Relative contributions of the descriptors to the multiple linear regression (MLR) model.

$$[10] \qquad \mathrm{RDF}rw = f \sum_{i=1}^{n\mathrm{AT}-1} \sum_{j=i+1}^{n\mathrm{AT}} w_i w_j e^{-\beta(r-r_{ij})^2}$$

where f is a scaling factor (assumed equal to one in the calculations) and w is the characteristic property of the atom.[51] RDFrw is generally calculated at a number of discrete points with defined intervals. Besides information about interatomic distances in the entire molecule, RDF050m provides further information about atomic masses. The negative correlation coefficient for RDF050m indicates that a compound with a larger value for this descriptor would have smaller K_0 value.

WHIM descriptors[52,53] are based on principal component analysis of the weighted covariance matrix obtained from the atomic Cartesian coordinates. WHIM descriptors can capture 3D information regarding molecular size, shape, symmetry, and atom distribution with respect to the molecule as a whole. E3p and Dm were calculated by eqs. [11] and [12], respectively, where λ refers to eigenvalues of the weighted covariance matrix and t refers to atomic coordinates with respect to the principal axes.

$$[11] \qquad Ekw = \frac{\lambda_k^2 n\mathrm{AT}}{\sum t_{jk}^4}$$

$$[12] \qquad D = E1w + E2w + E3w$$

Dm indicates a global measure of the degree of participation in intermolecular interactions, based on the projections of the atoms through principal axes or principal components. This descriptor points to the influence of the molecular conformation during the IMS separation process. The coefficient of Dm is positive, meaning that the K_0 increases when this descriptor increases. E3p conveys information about the distribution of electronic charge within the molecule, which has a positive effect on K_0.

Conclusions

In this paper, the QSPR method was employed to predict the ion mobility constants of 159 diverse compounds based on 3D descriptors. A five-parameter linear model was developed by MLR, with $R^2 = 0.9171$ and $s = 0.0680$ for the training set. The nonlinear model built by ANN appeared to be more reliable than the linear model, where R^2 was 0.9631 and s was 0.0446 for the training set. Satisfactory prediction results for the test set were obtained with both the linear and nonlinear models. The descriptors involved in the models indicate that the major factors determining the mobility of the compounds are molecular size, shape, and charge distribution. The proposed models are predictive and could be used to estimate the ion mobility constants of compounds in IMS because all the descriptors involved can be directly calculated from the molecular structure.

Abstract: Glucolesquerellin (**2**), glucohesperin (**3**), quercetin 3-*O*-sophoroside (**4**), and quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**), isolated from the fruit of *Dithyrea wislizenii*, were quantified by HPLC. The fruit extract and flavonoids were not found to be toxic by using a brine shrimp lethality assay. The fruit extract and the flavonoids and glucosinolates were submitted to a free-radical scavenging activity assay with the diphenylpicrylhydrazyl radical (DPPH$^{\bullet}$). The concentration of quercetin (**6**) (a positive control for the flavonoids) able to scavenge 50% of DPPH$^{\bullet}$ (SC_{50}) was 32 ± 2 μmol/L (or 4 ± 1 μg/mL), which was about 27 times more potent than the crude extract. Compounds **4** and **5** had a SC_{50}, the concentration of the compound required to scavenge 50% of the DPPH$^{\bullet}$, of 78 ± 1 μmol/L and 113 ± 10 μmol/L, respectively. The positive control for the glucosinolates, glucoraphasatin, (**1**) had a SC_{50} of 1768 ± 60 μmol/L. The glucosinolates **2** and **3** had a SC_{50} of 7819 ± 1968 and 970 ± 63 μmol/L, respectively.

Key words: Dithyrea wislizenii, Brassicaceae, flavonoids, glucosinolates, free-radical scavengers.

Résumé : La glucolesquerelline (**2**), la glucohespérine (**3**), la quercétine 3-*O*-sophoroside (**4**), et la quercétine 3-*O*-sophoroside-7-*O*-glucoside (**5**), isolées à partir des fruits de *Dithyrea wislizenii*, ont été quantifiés par HPLC. L'extrait de fruit et les flavonoïdes n'ont pas montré de toxicité en utilisant le test de mortalité de la crevette de saumure. L'extrait de fruit, les flavonoïdes et les glucosinolates ont été soumis à un test d'activité anti-radicalaire à l'aide du radical diphénylpicrylhydrazyle (DPPH$^{\bullet}$). La concentration de quercétine (**6**) (un contrôle positif pour les flavonoïdes) capable de piéger 50 % de DPPH$^{\bullet}$ (SC_{50}) était 32 ± 2 μmol/L (ou 4 ± 1 μg/mL), ce qui était environ 27 fois plus puissant que l'extrait brut. Les composés **4** et **5** avaient des SC_{50} de 78 ± 1 μmol/L et 113 ± 10 μmol/L, respectivement. Le contrôle positif pour les glucosinolates, la glucoraphasatine, (**1**) avait une SC_{50} de 1768 ± 60 μmol/L. Les glucosinolates **2** et **3** avaient des SC_{50} de 7819 ± 1968 et 970 ± 63 μmol/L, respectivement.

Mots-clés : Dithyrea wislizenii, Brassicaceae, flavonoïdes, glucosinolates, piégeurs de radicaux libres.

Introduction

The antioxidant properties of plant extracts originating from members of the Brassicaceae family were first attributed to polyphenolic compounds.[1] However, there have been reports that nonphenolic compounds can also contribute to the antioxidant activity of some *Brassica* sp.[2] In fact, the glucosinolate (GL), 4-methylsulfanyl-3-butenylGL (**1**), was shown to have free-radical scavenging activity towards the radical cation 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS$^{\bullet+}$) and the diphenylpicrylhydrazyl (DPPH$^{\bullet}$) free radical.[3,4]

Dithyrea wislizenii Engelm. (Brassicaceae) (syn. *Dimorphocarpa wislizenii* (Engelm.) Rollins), an endemic annual plant found in Nevada, Colorado, Utah, Arizona, New Mexico, and Texas, grows in open sandy soil of dry grasslands and deserts. This branched or unbranched, greyish, hairy plant has pinnately lobed leaves, white flowers in dense, thick racemes, and is commonly referred to as "spectacle pod".[5] Many Native American tribes used this plant as food for animals,[6] as a drug to reduce swelling, to treat delirium, on wounds, and in miscellaneous ceremonies.[7]

In previous phytochemical studies, the fatty acid content of the seed oil of *D. wislizenii* was investigated.[8,9] In addition, a GC analysis of the hydrolysis products of the compounds extracted from the seeds showed the presence of 5-methylsulfanylpentyl-, 6-methylsulfanylhexyl-, 7-methylsulfanylheptyl-, 5-methylsulfinylpentyl-, and 6-methylsulfinylhexyl isothiocyanates (ITCs), which suggests that the seeds contain the parent GLs.[10] Recently, our group analyzed the fruit extract of *D. wislizenii* for desulfoGLs and intact GLs using HPLC–APCI-MS and HPLC–ESI-MS, respectively. 2-PropenylGL (sinigrin) was shown to be present in the extract. 6-MethylsulfanylhexylGL (glucolesquerellin, **2**), 6-methylsulfinylhexylGL (glucohesperin, **3**), 7-methylsulfanylheptylGL, and 5-methylsulfanylpentylGL (glucoberteroin) were isolated from the extract and characterized by UV, IR, and NMR spectroscopies, and mass spectrometry.[11] Finally, the indole alkaloid, dithyreanitrile (7-methoxy-α,α-bis(methylsulfanyl)-1*H*-indole-3-acetonitrile), was isolated from the seeds of

D. wizlizenii. This compound was shown to inhibit the feeding of the fall armyworm (*Spodoptera frugiperda* Smith) and the European corn borer (*Ostrinia nubilalis* Hbn.) larvae.[12]

Here we report the isolation, structure elucidation, and quantification of two flavonoids present in the fruit extract of *D. wislizenii*. In addition, we have quantified the two major GLs (**2** and **3**) in the extract. The toxicity on brine shrimp larvae of the fruit extract and of the flavonoids was probed. The free-radical scavenging activity of the fruit extract and of the isolated flavonoids was evaluated by electron spin resonance (ESR) spectroscopy. Seeing that some GLs have been implicated in the free-radical scavenging activity of plant extracts, but not many have been studied, we determined the free-radical scavenging activity of the GLs found in the fruit extract of *D. wislizenii*.

Results and discussion

To use the plant extract in health-benefit applications or in animal and human nutrition, its lack of lethality was probed against *Artemia salina* L. (brine shrimp) larvae. The brine shrimp lethality test showed that the fruit extract was not lethal against *A. salina* larvae at the tested concentrations.[13] This was expected, since this plant was given to animals as food.[6]

To test free-radical scavenging activity, the *D. wislizenii* fruit extract was added to solutions containing a known concentration of the stable free radical, DPPH•. The average amount of *D. wislizenii* fruit extract able to scavenge 50% of the DPPH• (SC_{50}) was 110 ± 11 μg/mL (Table 1). We decided to determine which natural products contributed to this activity; hence, we have isolated the major secondary metabolites in the extract and probed their free-radical scavenging activity.

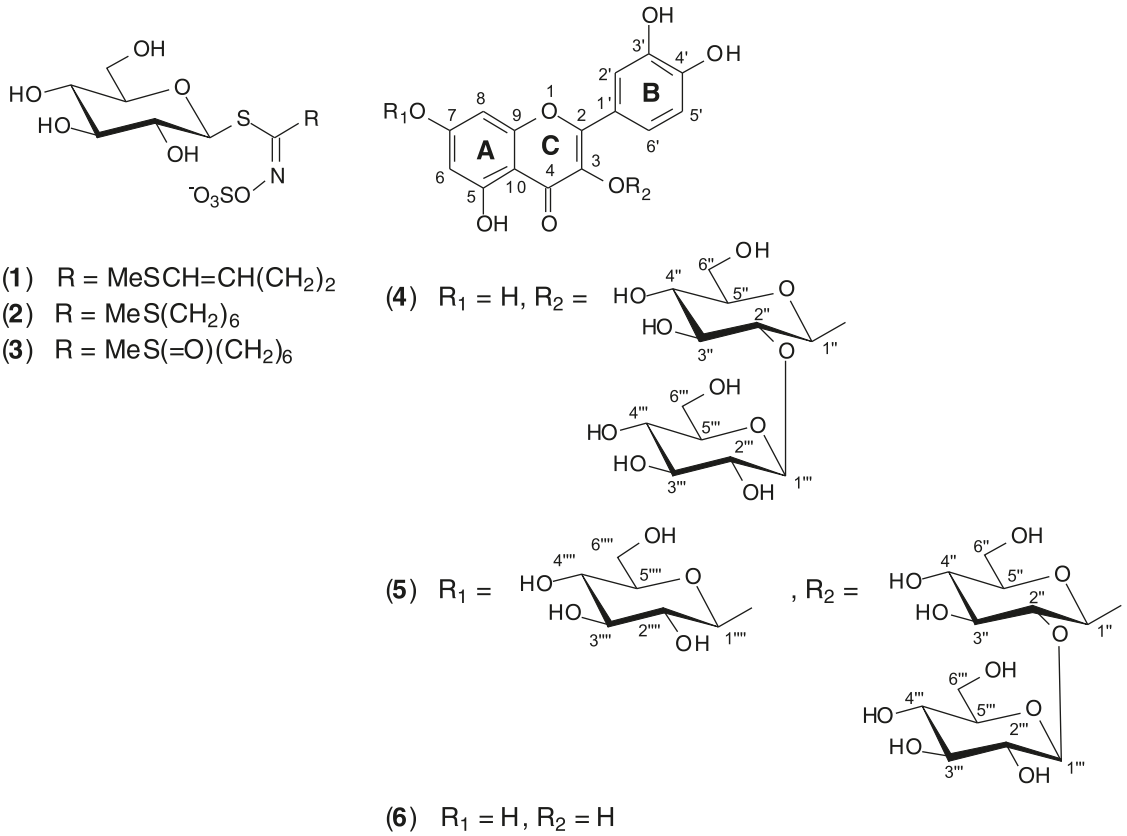
Several peaks were detected in the HPLC chromatogram of the extract of *D. wislizenii* fruit (Fig. S1, Supplementary data), using the experimental conditions described in the literature.[14] In addition to the previously reported occurrence of sinigrin, glucohesperin, glucoberteroin, glucolesquerellin, and 7-methylsulfanylheptylGL,[11] the plant extract contained two compounds eluting at retention times (t_R) of 36.8 min (compound **4**) and 29.8 min (compound **5**). These two compounds were isolated from the extract using the chromatographic separations outlined in the Experimental section. The spectroscopic data of compound **4** were in agreement with those published in the literature for the 3-*O*-β-D-(2-*O*-β-D-glucopyranosyl)glucopyranoside of quercetin, also known as quercetin 3-*O*-sophoroside (**4**)[15–19] (Fig. 1; Table S1, Supplementary data) and the data of compound **5** were in agreement with those published in the literature for quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**) (Fig. 1; Table S1, Supplementary data).[15–17,20,21]

Although **4** and **5** have been found in several members of the Brassicaceae family, it is the first time that they have been observed in the *Dithyrea* sp. For example, quercetin 3-*O*-sophoroside has been previously identified in the genus *Brassica*[22] and in watercress,[23] and quercetin 3-*O*-sophoroside-7-*O*-glucoside has been found in canola and tronchuda cabbage.[19–21,24–28]

The major compounds found in the *D. wislizenii* extract, namely **2**–**5** were quantified by HPLC. The quantities of **2**, **3**, **4**, and **5** in the plant extract were estimated to be 12.4, 6.0, 2.1, and 18.0 μmol/g of dried fruit, respectively.

The free-radical scavenging activities of the natural products isolated from *D. wislizenii* were tested (Table 1). Quercetin (**6**) and glucoraphasatin (**1**), compounds known to have free-radical scavenging activity against DPPH•, were used as the positive control for the flavonoids and GLs isolated from *D. wislizenii*, respectively. The SC_{50} of **6** has been expressed in both μg/mL and μmol/L to allow for comparison with the activity of the crude extract and the isolated flavonoids and GLs. The SC_{50} of compound **6** is 27 times smaller than that of the crude extract of *D. wislizenii*. This means that compound **6** scavenges DPPH• better than the crude extract. This is not surprising as the extract is a complex mixture of compounds, many of which do not possess free-radical scavenging activity. Flavonoids **4** and **5** have weaker free-radical scavenging activities than **6** (Table 1). Compound **6** is 2.5 times better at scavenging free-radicals than **4**, and 3.6 times better than **5**. This finding is consistent with the trolox equivalent antioxidant capacity (TEAC) values obtained for **6** and **4**. The TEAC value of **6** was reported to be 3 times higher than that of **4**.[1] Furthermore, in our investigation, **4** was found to be 1.5 times better at scavenging free-radicals than **5**, which means that the latter had the weakest free-radical scavenging activity among the flavonoids tested.

The three main structural features in flavonoids that determine their overall free-radical scavenging activity are (*i*) the *o*-dihydroxyl groups in the B ring, (*ii*) the double bond between C(2) and C(3) in the C ring, which is conjugated to the 4-oxo group (C=O) in the C ring, and (*iii*) the presence of additional OH groups at positions 3 and 5.[29] The presence of these three main structural features in **6** explains why it possesses a high free-radical scavenging activity. The substituents at positions 3 and 7 are glucose residues that affect the ability of the B-ring hydroxyl groups to donate one hydrogen in **4** and **5**.



The SC_{50} of **1** was found to be 4 times smaller than that of **2**, whereas the SC_{50} of **3** was 2 times lower than the SC_{50} of **1** and 8 times smaller than that of **2**. This means that **3** is a better free-radical scavenger than **1** and that **1** is a better scavenger than **2** (Table 1). The SC_{50} of **2** has a relatively large standard deviation because it demonstrated relatively weak free-radical scavenging activity. Although the mechanism for the reaction of DPPH• with GLs is not known, Barillari and co-workers[4] proposed that the reaction of DPPH• with 4-methylsulfanyl-3-butenyl ITC, also called raphasatin, the degradation product of **1**, proceeds via two pathways (Fig. 2). These involve abstraction of the hydrogen atom α to the allylic functional group, –CH=CHSCH$_3$, (path 1) and abstraction of the hydrogen atom that is α to the –N=C=S (path 2). Presumably, –CH=CHSCH$_3$ and –N=C=S are responsible for the weakening of the respective C–H bonds. Abstraction of a second hydrogen in both of the proposed pathways leads to a conjugated ITC. In the case of the intact GLs used in the present study, one could propose a similar mechanism (Fig. 3). The hydrogen atoms most likely to react with the DPPH• are those α to the *O*-sulfated *Z*-thiohydroximate functional group as well as those α to –CH=CHSCH$_3$ (for **1**), SCH$_3$ (for **2**), and SOCH$_3$ (for **3**). For **2** and **3**, the sulfanyl and sulfinyl groups are separated from the *O*-sulfated

Table 1. Free-radical scavenging activities of the fruit extract of *Dithyrea wislizenii*, glucolesquerellin (**2**), glucohesperin (**3**), quercetin 3-*O*-sophoroside (**4**), and quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**), against diphenylpicrylhydrazyl (DPPH•).

Extract/product	DPPH[a]	Average SC_{50} ± SD (% error)[b]
Quercetin (**6**)	160	4±1 μg/mL (21.8)
Dithyrea wislizenii fruit extract	160	110±11 μg/mL (10.2)
Quercetin (**6**)	350	32±2 μmol/L (7.6)
Quercetin 3-*O*-sophoroside (**4**)	350	78±1 μmol/L (1.3)
Quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**)	350	113±10 μmol/L (9.1)
Glucoraphasatin (**1**)	350	1768±60 μmol/L (3.4)
Glucolesquerellin (**2**)	350	7819±1968 μmol/L (25.2)
Glucohesperin (**3**)	350	970±63 μmol/L (6.5)

Fig. 1. Structure of glucolesquerellin (**2**), glucohesperin (**3**), quercetin 3-*O*-sophoroside (**4**), and quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**) isolated from *Dithyrea wislizenii*.

Z-thiohydroximate functional group by six methylene groups. The effect of the *O*-sulfated *Z*-thiohydroximate functional group, if any, on the α-C–H bond strength would be comparable. Therefore, the difference in the SC_{50} must be primarily dependent on the SCH_3 and $SOCH_3$ groups. The sulfinyl group is more electron-withdrawing than the sulfanyl group, which makes the adjacent hydrogen atoms in **3** more acidic than in **2**.[30] Furthermore, the S=O bond will delocalize the unpaired electron over the π bond. This allows **3** to donate the hydrogen atoms easily, resulting in a higher free-radical scavenging activity than those of **2** and **1**. For **1**, the C=C bond is electron-withdrawing and will make the adjacent hydrogen atom more acidic and easier for the free radical to abstract. Moreover, the C=C bond allows the free electron to be delocalized over the π bond. This results in a higher free-radical scavenging activity than that of **2**. Our observations suggest that the presence of a sulfinyl group and C=C bond contributes to the overall scavenging activity of certain GLs. Papi et al.[4] studied the free-radical scavenging activity of raphasatin and its intact GL (**1**) towards DPPH• and found the ITC to be 3 times more active than the intact GL. This suggests that the ITC group is the major contributor to this

increased activity. Because **3** was found to be twice as active as **1**, we expect that its corresponding ITC hesperin would be twice as active as raphasatin.

It is worth noting that other natural products, such as the ones in garlic containing a sulfoxide functional group such as alliin and thiosulfinates such as allicin, have also been shown to possess some free-radical scavenging properties.[31] Finally, all the GLs we tested were weaker free-radical scavengers than the flavonoids we analyzed. Glucohesperin (**3**), the best GL among the ones we tested, was 8.6 times less active than **5**, the poorest free-radical scavenger among the flavonoids we tested. Overall, our results indicated that the flavonoids strongly contributed to the free-radical scavenging activity of *D. wislizenii* fruit extract, whereas the GLs contributed to the activity to a lesser extent.

Conclusions

In this study, we have isolated and identified quercetin 3-*O*-sophoroside (**4**) and quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**) representing the first report of the presence of flavonoids in a *Dithyrea* species. The crude extract, **4**, and **5** were not lethal against *A. salina* at the concentrations tested. Both isolated flavonoids and GLs contributed to the free-radical scavenging activity of *D. wislizenii*. It was revealed that the flavonoids were stronger free-radical scavengers than the GLs and, hence, the major contributors to the free-radical scavenging activity of *D. wislizenii*. From the structures of the flavonoids, we confirmed that the more glycosylated the flavonoid, the weaker its free-radical scavenging activity. From the structures of the GLs, we proposed that the presence of the sulfanyl and sulfinyl groups would contribute to the free-radical scavenging activity of the tested GLs. Further investigations of the free-radical scavenging activity of the plant extract and of the major natural products isolated should be carried out against the superoxide anion ($O_2^{\bullet -}$) and hydroxyl radical ($HO^{\bullet}$). Such a study could contribute to understanding the anti-inflammatory properties of the plant metabolites (most probably the flavonoids) initially observed by many Native North American tribes who used the plant to reduce swelling. Because the plant extract and its components display free-radical scavenging ability, other studies could be directed towards probing the potential cancer-preventive effects of *D. wislizenii*. Furthermore, the free-radical scavenging activity of lesquerellin and hesperin, the ITCs of **2** and **3**, could be investigated as they are expected to be better scavengers than their parent GLs. In fact, raphasatin, the glucoraphasatin ITC, has been shown to be 3 times more potent as a scavenger of $DPPH^{\bullet}$ than glucoraphasatin.[4] In conclusion, *D. wislizenii* is a good source of free-radical scavengers.

Experimental

Materials

All solvents were ACS grade and used as such except for $CHCl_3$, which was redistilled. All deuterated solvents were purchased from Cambridge Isotopes Laboratories, Inc. (Andover, Massachusetts). Formic acid, L-(+)-arabinose, D-(+)-galactose, D-glucose, D-(+)-xylose, NaOH, and EtOAc were purchased from BDH (Toronto, Ontario). HPLC-grade MeOH, absolute EtOH, and triethylamine (reagent grade) were purchased from Fisher Scientific (Whitby, Ontario). Sinigrin, D-(+)-mannose, DMSO, NaOAc, and quercetin dihydrate were purchased from Sigma-Aldrich (Oakville, Ontario). $DPPH^{\bullet}$ was purchased from Sigma-Aldrich and stored at 5 °C. Glacial AcOH was purchased from Anachemia Canada Inc. (Montreal, Quebec). HCl was purchased from Stanchem (Etobicoke, Ontario). H_3BO_3 was bought from Matheson, Coleman, and Bell Manufacturing Chemists (Norwood, Ohio). $AlCl_3$ was from the McArthur Chemical Co., Ltd. (Montreal, Quebec). Isopropanol and thymol were purchased from EM Science (Gibbstown, New Jersey). HPLC-grade H_2O was generated in the laboratory through a Nanopure Diamond Ultrapure water system by Barnstead (Dubuque, Iowa). Kieselgel 60 F_{254} analytical TLC aluminum sheets were purchased from EM Science; compounds were visualized under UV light and by dipping the plates in sulfuric thymol solution containing 1% (*w*/*v*) thymol, 10% (*v*/*v*) H_2SO_4, and 95% EtOH, followed by heating. Flash column chromatography (FCC) was carried out using 70–230 mesh 60 Å normal-phase silica gel (Sigma-Aldrich). Sephadex LH-20 was purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). C-18 silica gel was purchased from Alltech (Guelph, Ontario). C-18 silica gel cartridges (Mega Bond Elut Flash, 10 g sorbent mass, 60 mL volume) were obtained from Varian, Inc (Mississauga, Ontario).

Instrumentation

UV spectra were recorded on a Biochrom Ultrospec 2100 pro UV–vis spectrophotometer (Cambridge, UK). Specific rotations ($[\alpha]_D$) were measured with a Rudolph Research Corporation Autopol II automatic polarimeter (Flanders, New Jersey) at ambient temperature using a 20 cm path length cell; the units are 10^{-1}deg cm^2 g^{-1} and the concentrations (*c*) are reported in grams per 100 millilitres. IR spectra were recorded with a PerkinElmer Paragon 1000PC IR spectrometer (Waltham, Massachusetts) or a Bruker Optics Tensor 27 FTIR instrument (Boston, Massachusetts) using KBr disks. NMR spectra were recorded on a Bruker Avance spectrometer at 600 MHz (^{1}H) and 150 MHz (^{13}C) at the Saskatchewan Structural Science Centre (Saskatoon, Saskatchewan), or on a Bruker DRX 500 spectrometer at 500 MHz (^{1}H) and 125 MHz (^{13}C) at Laurentian University (Sudbury, Ontario); δ values were referenced to D_2O at 4.80 ppm and to DMSO-d_6 at 2.50 ppm for ^{1}H NMR spectra and at 39.5 ppm for ^{13}C NMR spectra. High-resolution electrospray mass spectrometric (HR-ESI-MS) measurements were recorded using an API Qstar XL mass spectrometer at the Saskatchewan Structural Science Centre. A Varian E109 EPR spectrometer operating at X-band was used to measure the free-radical scavenging activity of the antioxidants. ESR spectra were recorded at room temperature (21–23 °C) at centre field, 3257; field sweep, 100 G; and microwave power, 2 mW. For a given experiment, the receiver gain was kept constant.

Plant material

Dry *Dithyrea wislizenii* fruit was obtained from the Plants of the South West company (Santa Fe, New Mexico). A voucher (No. 21023) was deposited at the Department of Biology Herbarium, Laurentian University. Cherry Belle radish

seeds (Gardener's choice) were purchased from a local store in Sudbury, Ontario.

HPLC-ESI-MS analysis

Dithyrea wislizenii extract (50 mg) was dissolved in 2 mL of MeOH and filtered through a plug of cotton prior to analysis by HPLC. Analysis was performed by injecting a 20 μL aliquot of the solution of crude extract into an Agilent Technologies HP 1100 (New Castle, Delaware) HPLC equipped with a quaternary pump, automatic injector, diode-array detector (wavelength range 190–600 nm), degasser, and a Hypersil ODS column (5 μm, 4.6 mm × 200 mm). The two mobile-phase solvents, MeOH and H_2O, were prepared with 0.15% triethylamine and 0.18% formic acid added as ion-pairing reagents. Both solutions were filtered using 0.45 μm nylon membranes. The initial mobile phase was 100% HPLC-grade H_2O. At 10 min, the mobile phase was switched to a linear gradient of 100% H_2O to 100% MeOH over 60 min.[14] After each run, the initial mobile-phase conditions were set and the system was allowed to equilibrate. The flow rate was kept constant at 1 mL/min. The column temperature was held at room temperature. The HPLC was interfaced to an Agilent model 6120 MS with a Chemstation data system (LC–MSD B.03.01). The ES interface was a standard ES source operating with a capillary voltage of 4 kV and temperature of 350 °C. The system was operated in the negative and positive ion ES modes. Nitrogen was used as nebulizing and drying gas at a flow of 10 L/min (35 psig, 1 psi = 6.894 kPa). The MS was programmed to perform full scans between *m/z* 100 and 1000 amu.

Extraction and isolation

Dithyrea wislizenii fruits (347 g) were frozen in liquid N_2, ground in a mortar, and immediately extracted 3 times with boiling MeOH (1.4 L for the first extraction and 1.05 L for the other extractions) for 30 min. The methanolic solution was filtered and concentrated to dryness (33 g). This extract was dissolved in H_2O (200 mL) and submitted to liquid–liquid extractions with solvents of increasing polarity, $CHCl_3$, EtOAc, and BuOH. Each organic layer was concentrated ($CHCl_3$ fraction, 15.2 g; EtOAc fraction, 1.2 g; and BuOH fraction, 6.1 g) and the aqueous layer was lyophilized (11.7 g). The BuOH fraction (3.6 g) was fractionated by FCC (normal phase; gradient $CHCl_3$/MeOH 8:2, 7:3, and 0:10 *v/v*; 25 mL fractions). Fractions 22–35, obtained from the FCC column, eluted with $CHCl_3$/MeOH 7:3 (*v/v*), were combined (210 mg) and fractionated on a Sephadex LH-20 column (H_2O/MeOH 10:0 and 0:10 *v/v*, 5 mL fractions). Fractions eluted with MeOH were combined and yielded quercetin 3-*O*-sophoroside (**4**, 64.6 mg). Fractions 126–177, obtained from the FCC (normal phase) mentioned previously, eluted with MeOH, were combined (611 mg) and subjected to Sephadex LH-20 column (H_2O/MeOH 10:0 and 0:10 *v/v*, 5 mL fractions) fractionations. Fractions 4–8, eluted with H_2O from the Sephadex LH-20 column, were combined (175 mg) and submitted to a solid-phase separation (C18 cartridge; H_2O/MeOH 100:0, 95:5, 90:10, 80:20, and 0:100 *v/v*; 5 mL fractions). Fractions 69–82, eluted with H_2O/MeOH 80:20 (*v/v*), yielded quercetin 3-*O*-sophoroside-7-*O*-glucoside (**5**, 56.6 mg).

Acid hydrolysis of flavonoids and identification of aglycones and carbohydrates

The flavonoid was mixed with 6% aq HCl (5 mL). The solution was heated for 45 min. After cooling, the solution was extracted 3 times with EtOAc (3 × 5 mL). Evaporation of the aqueous layer yielded the sugars that were analysed by TLC (isopropanol/AcOH/H_2O, 3:1:0.5 *v/v/v*). The carbohydrate composition was determined according to the TAPPI test method T249-cm-85 by FPInnovations-Paprican division (Pointe-Claire, Quebec).[17] Arabinose, xylose, mannose, galactose, and glucose were used as reference compounds. The organic layer, after drying over sodium sulfate, was evaporated. Quercetin was identified in this layer by LC–MS analysis by comparison of the t_R, UV, and mass spectra with those of a commercial standard.

Quercetin 3-O-sophoroside (4H-1-benzopyran-4-one, 2-(3,4-dihydroxyphenyl)-3-[(2-O-β-D-glucopyranosyl-β-D-glucopyranosyl)oxy]-5,7-dihydroxyflavone; 4)

Yellow amorphous powder. HPLC, t_R = 36.8 min. $[\alpha]^{26}_D$ – 147 (*c* 0.08, MeOH). Purification of glucoraphasatin (1)

Cherry Belle radish seeds were soaked for 1 min in 1% sodium hypochlorite and rinsed with distilled H_2O. Seeds were laid on two sheets of filter paper in Petri dishes and were incubated at room temperature (23 ± 2 °C) under an 8 h day / 16 h night photoperiod. The sprouts were watered twice a day with H_2O. Fresh nine-day-old Cherry Belle radish seedlings (899 g) were frozen in liquid N_2, ground in a mortar, and immediately extracted 3 times with boiling MeOH (3 × 3 L) for 30 min. The methanolic solution was filtered and concentrated to dryness (35 g). This extract was dissolved in H_2O (100 mL) and subjected to liquid–liquid extractions with solvents of increasing polarity, EtOAc and BuOH. Each organic layer was concentrated (EtOAc fraction, 1.1 g; and BuOH fraction, 3.4 g) and the aqueous layer was dried (29.4 g). The aqueous fraction (3 g) was purified using column

For personal use only.

chromatography (C18 reverse phase, gradient H_2O/MeOH 10:0 and 0:10 *v*/*v*, 23 mL fractions). Fractions 18–84, eluted with H_2O from the C18 reverse-phase column, were combined (232 mg) and subjected to solid-phase separation (C18 cartridge, H_2O/MeOH 10:0 and 0:10 *v*/*v*, 3 mL fractions). Fractions 7–34, eluted with H_2O yielded glucoraphasatin (**1**, 101 mg). The purity of the amorphous solid **1** was assessed by HPLC, and the compound was characterized by ^{1}H and ^{13}C NMR spectroscopies. The spectroscopic data were consistent with the ones previously published.[3]

Purification of glucolesquerellin (2) and glucohesperin (3)

These GLs were isolated and characterized as previously reported.[11]

Flavonoid and glucosinolate quantification

Several solutions of **2** and **3** (5×10^{-3}, 10^{-3}, 2×10^{-4}, and 4×10^{-5} mol/L), **4** (9.8×10^{-4}, 4.9×10^{-4}, and 2.45×10^{-4} mol/L), and **5** (10^{-2}, 5×10^{-3}, 10^{-3} mol/L) were prepared via serial dilution in MeOH. Each solution was injected (20 µL) into the HPLC. Calibration curves were then constructed using Microsoft Excel from data obtained from three independent experiments run in triplicate.

Brine shrimp lethality assay

Brine shrimp eggs were obtained from a local store and were hatched in artificial sea water. The hatching, harvesting, and dispensing of nauplii were performed in a manner similar to that of Solis et al.[13] *Artemia salina* eggs were hydrated in a 200 mL beaker containing artificial sea water (table salt, 38 g/L). Eggs were sprinkled into the darkened half of the beaker and separated from the aerated, illuminated other half by a plastic divider. The hatching time was ~48 h. *Artemia salina* nauplii that accumulated in the illuminated part of the beaker were transferred into a 96 well microplate (VWR International Inc., Mississauga, Ontario) (10 nauplii per 100 microlitres of artificial sea water per well). *Dithyrea wislizenii* fruit extract, **4**, and **5** were added to live nauplii and, after a 24 h exposure time at 22 °C, the brine shrimp lethality was measured by counting the number of dead (nonmotile) nauplii per well, using a binocular microscope. One hundred microlitres of MeOH were then added to each well and, after 15 min, the total number of shrimp in each well was counted. The crude extract was tested at 125, 250, and 500 ppm. Compounds **4** and **5** were tested at 125, 250, 500, and 1000 µmol/L. Sea water was used as the control. A positive assay was the death of all brine shrimp with 100 µmol/L of thymol. The results were obtained from three independent experiments in triplicate.

DPPH• assay

Solution preparation

The SC_{50} for **6** (positive control for flavonoids), **1** (positive control for GLs), and compounds **2**–**5** were extracted from the linear regression line of plots of % scavenging activity (SA) vs compound concentration (µmol/L). The SC_{50} was determined from the linear regression line. SC_{50} values represent the mean of three independent experiments, run in triplicate, and are expressed as the mean ± SD, calculated using Microsoft Excel. The solutions tested for SA using the ESR method outlined as follows were prepared by the serial dilution of stock solutions of **1**–**6**. EtOH was used as the solvent in the dilutions. A 981.5 µmol/L quercetin (**6**) stock solution was used to prepare five solutions with concentrations between 12.6 and 196.3 µmol/L. A 6900 µmol/L stock solution of **4** in DMSO was used to prepare four solutions with concentrations between 22.8 and 284.3 µmol/L. A 172 µmol/L stock solution of **5** in DMSO was used to prepare four solutions with concentrations between 22 and 275 µmol/L. A 7129 µmol/L stock solution of **1** in DMSO was used to prepare four solutions with concentrations between 1643 and 4277 µmol/L. A stock solution (about 26 227 µmol/L) of **2** was prepared in DMSO. From the stock solution, three serial dilutions in EtOH resulted in solution concentrations between 7 787 and 22 958 µmol/L. The stock solution and the three solutions were tested for free-radical scavenging activity. A 3147 µmol/L stock solution of **3** in DMSO was used to prepare three solutions with concentrations ranging from 201 to 1259 µmol/L. These as well as the stock solution were tested for free-radical scavenging activity.

General procedure

In general, 100 µL of a 700 µmol/L DPPH• solution was transferred to a 4 mL vial (Supelco 2-7138) containing a stirring bar. The antioxidant solution (100 µL) being tested was added to the vial. The timer was started and the vial was capped and placed on the stir plate. The reaction was carried out at room temperature (21–23 °C). At the 30 min mark, a portion of the contents of the vial were transferred with a glass syringe (Hamilton 80801) to a 3 cm long capillary tube (fabricated by cutting a Kimble No. 345059 (VWR) capillary tube to the desired length). The capillary tube was sealed with paraffin. The capillary was placed in an ESR tube (Wilmad), which was subsequently inserted in the cavity of the Varian X-band ESR spectrometer. The ESR spectrum was recorded at a frequency of ~9120 MHz and a microwave power of 2 mW. The center field and field sweep were set at 3257 and 100 G, respectively. The area under the ESR spectrum of DPPH• was determined by using the double integration (DI) feature in the ESR software known as EPRware (Scientific Software Services, Northville, Michigan). The DI is related to the concentration of DPPH• in the tube. The %SA is defined as shown in eq. [1].

$$[1] \qquad \%SA = 100(1 - DI_S/DI_{NC})$$

DI_S and DI_{NC} are the double integration of the DPPH• spectrum in the presence and absence, respectively, of the compound being tested for the free-radical scavenging activity.

Supplementary data

Supplementary data (Fig. S1 and Table S1) are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v2012-042.

Abstract: Surfactant-free magnetic nano-octahedrons were successfully synthesized by the alkaline hydrothermal decomposition of ferric nitrate salt ($Fe(NO_3)_3{\cdot}9H_2O$) in a water–ethanol mixed solvent with a variety of alkaline concentrations. High-resolution scanning electron microscope (SEM) pictures demonstrated the formation of octahedron-structured magnetic nanoparticles at a 10 mol/L alkaline concentration. A possible synthesis mechanism of the magnetic nano-octahedron was discussed. An alternating current magnetic field to induce hyperthermia cancer cell killing was investigated. Maximum hyperthermia cancer cell killing (~100%) was found with 10 mol/L alkaline-synthesized nano-octahedrons, whereas that with 2 mol/L alkaline gave ~40%.

Key words: magnetic materials, chemical synthesis, electron microscopy, X-ray diffraction, magnetic properties, hyperthermia cancer cell killing.

Résumé : On a réalisé avec succès la synthèse de nanoparticules magnétiques à structure octaédrique ne comportant aucun agent de surface en procédant à la décomposition hydrothermique alcaline du sel de nitrate ferrique (($Fe(NO_3)_3{\cdot}9H_2O$) dans un mélange eau–éthanol agissant comme solvant pour des concentrations variées de produit alcalin. Des images obtenues par microscopie électronique à balayage (MEB) à haute résolution ont permis de démontrer la formation de nanoparticules magnétiques à structure octaédrique lors des traitements par des solutions alcalines à une concentration de 10 mol/L. On discute aussi du mécanisme de synthèse potentiel des nanoparticules magnétiques à structure octaédrique. On a examiné la possibilité de détruire des cellules cancéreuses par hyperthermie induite par un champ magnétique à courant alternatif. La destruction maximale des cellules cancéreuses par hyperthermie (environ 100 %) a été observée avec les nanoparticules magnétiques à structure octaédrique obtenues lors de la synthèse à l'aide d'une solution alcaline à concentration de 10 mol/L alors que la destruction observée avec celles obtenues à une concentration de 2 mol/L n'est que d'environ 40 %.

Mots-clés : matériaux magnétiques, synthèse chimique, microscopie électronique, diffraction des rayons X, propriétés magnétiques, destruction de cellules cancéreuses par hyperthermie.

[Traduit par la Rédaction]

Introduction

Magnetic nanostructural materials have been studied as novel imaging, diagnostic, and therapeutic agents due to their unique properties.[1] Magnetic nanoparticles (MNPs) have attracted tremendous attention because of their various biomedical applications.[2] In particular, magnetite (Fe_3O_4) has been considered recently as an ideal candidate for biological applications, both as a tag for sensing and imaging and as an activity agent for antitumor therapy.[3] Magnetic properties of magnetite nanoparticles are particularly attractive for application in cancer cell killing and magnetic recording.

A number of preparation techniques have been reported for high-quality magnetite nanoparticles, such as the reduction of Fe_2O_3,[4] microwave hydrothermal reaction,[5] coprecipitation method,[6] sonochemical reduction,[7] etc. The traditional approach to iron oxide colloids has relied on the aqueous precipitation or hydrolysis of Fe^{2+} and (or) Fe^{3+} salt(s); these materials can be poorly crystalline and polydispersive in many cases.[8] In general, among almost all the methods, stabilizing reagents are introduced during the preparation for acquiring colloidal dispersions. In our case, we used only the hydrothermal method without using any stabilizing agent or surfactant.

We have studied how to grow nano-sized single crystals of magnetic materials in a mixed solvent of ethanol and water. A thorough literature search revealed that no single crystals of magnetic materials were grown in a large scale production using KOH hydrothermal reduction of ferric nitrate. To grow bulk-scale single crystals, the growth conditions have to be optimized accordingly. Hence, in the present work, attempts have been made to investigate the nucleation parameters of magnetic nanomaterials, which are the prerequisite for investigating the growth mechanism of bulk-scale single crystals. The magnetic octahedron-shaped nanoparticles in a mixture

of alcohol and water were prepared for the first time and thereby the possibility of growing bulk-scale magnetic single crystals was also examined. In addition, the effects of reaction conditions such as the molar concentration of alkali on morphology and magnetic properties of magnetic octahedron-structured nanoparticles were investigated. The ability to create octahedron-shaped morphologies with interesting magnetic properties enhances the prospects for application of magnetic nanostructures in a wide range of scientific and technological fields, including medicine, biochemistry, and electronics.

Here, we report a new generation of compact, uniform, surfactant-free magnetic nano-octahedrons and their successful utilization for hyperthermia cancer cell killing under an alternating current (AC) magnetic field. Moreover, the magnetic octahedron-shaped nanoparticles in a mixture of alcohol and water were prepared for the first time and their hyperthermia cytotoxicity is also reported for the first time.

Experimental

Material and methods

Ferric(III) nitrate nonahydrate ($Fe(NO_3)_3{\cdot}9H_2O$), ethanol, methanol, and potassium hydroxide (KOH) were purchased from Wako Pure Chemical Industries Ltd. All chemicals were used as received without further purification. The water used was purified through a Millipore system. The magnetic nanoparticles were synthesized using a hydroxide oxidation–reduction method under autoclave hydrothermal conditions.

Preparation

MNPs were synthesized using ferric(III) nitrate fixed at 0.03 mol/L and the concentration of KOH was varied at 2, 4, 6, 8, and 10 mol/L. $Fe(NO_3)_3{\cdot}9H_2O$ (0.03 mol/L) was dissolved in a 40 vol% ethanol–water solution. Under vigorous stirring, fresh KOH was mixed with the $Fe(NO_3)_3{\cdot}9H_2O$ containing water–ethanol solution. Finally, the mixture was transferred into a Teflon-lined stainless steel autoclave with a capacity of 200 mL for hydrothermal treatment at 200 °C for 12 h. After the reduction was complete, the autoclave was allowed to cool to room temperature. Next, the solution was centrifuged and the particles were separated by washing with distilled water and absolute methanol and dried in a vacuum at 80 °C.

Characterization

The UV–vis reflectance spectra of the MNPs were recorded with a UV–vis spectrophotometer (Shimadzu Corporation, UV-2450, Japan) and barium sulfate ($BaSO_4$) was used as a standard. The reflectance band was automatically changed to the absorption band by UV-2450 instrument software. The average diameters and size distributions of the magnetic nanoparticles were obtained from the enlarged photographs of a scanning electron microscope (SEM) (SU-70, Hitachi). The crystal structure identification was made by X-ray diffraction (XRD) using a PANalytical Advance X-ray diffractometer with Cu Kα radiation. The quantitative chemical composition of the nanoparticles' surface was also measured using an energy dispersive X-ray spectrometer (EDX) attached to the SEM. Magnetic measurements were performed using a superconducting quantum interference device (SQUID) magnetometer (Quantum Design model MPMS-5).

Cancer cell culture and killing method

Potential cancer cell killing effects of MNPs towards a human carcinoma (HeLa) cell line were studied by incubating the cells in different concentrations of MNPs. HeLa cells were cultured in a minimum essential medium (MEM) solution with 10% newborn calf serum (NBS) in a humidified incubator under an atmosphere of 5% CO_2 in air at 37 °C. The HeLa cells were plated at a concentration of about 3×10^5 in 40 mm Petri dishes and allowed to grow for 2 days. An AC magnetic field (handmade, picture shown in the Supplementary data as Fig. S4, frequency 560 kHz, AC voltage 7 V, AC current 0.8 A, monitor voltage 3.2 Vp (6.2 mT = 5 kA/m)) was induced for 10 min for the hyperthermia effect on HeLa cells. Hyperthermia-elevated temperature for every dish was measured by using a digital thermometer (^{SK}SATO, Model SK-250WP II-R). After the AC magnetic field was induced, the medium was removed and the cells were washed twice with phosphate-buffered saline (PBS) and the cells were counted using an automated cell counter (Bio-Rad, Model TC 10) with trypan blue staining. The images were taken using an Olympus inverted CKX41 microscope with an attached digital camera (DP21).

Results and discussion

UV–vis reflectance absorption spectra analysis of magnetic nanoparticles

The UV–vis reflectance spectra of MNPs are shown in Fig. S1 in the Supplementary data. The characteristic absorption shoulders are found at around 600–700 nm. The shoulder bands may depend on the individual particle property including size, shape, and solvents and reducing agents employed. Figure S1 (Supplementary data) shows that the absorption shoulders increase with increasing KOH alkaline agent (absorption band b–f in Fig. S1). The alkaline agent (KOH) can impact the absorption properties of MNPs as shown in Fig. S1 (Supplementary data). The broadness of the absorption shoulders (Fig. S1 in the Supplementary data) probably arises from the wide size distribution of MNPs at the high alkaline concentration (10 mol/L). The comparison of absorption spectra with reference commercial α-Fe_2O_3 and Fe_3O_4 are also shown in Figs. S1*a* and S1*g* (Supplementary data), respectively.

Morphological and structural characterization of MNPs

The SEM images for the MNPs are shown in Fig. S2 and reveal many irregular particles (Figs. S2*a*–S2*d*; Supplementary data) when the KOH concentration was varied in aqueous solution, keeping other conditions constant. This difference suggests that the KOH concentration plays an important role in the formation of octahedron MNPs. As seen in Figs. S2*e*–S2*f* (Supplementary data; [KOH] = 10 mol/L), the average sizes of most of the particles are less than or around 400 nm and the nanocrystals have an octahedron structure. Very small amounts of spherical nanocrystals and triangles were also observed in some images. The reproducibility of the formation of the nano-octahedron was observed through independent experiments under identical conditions at

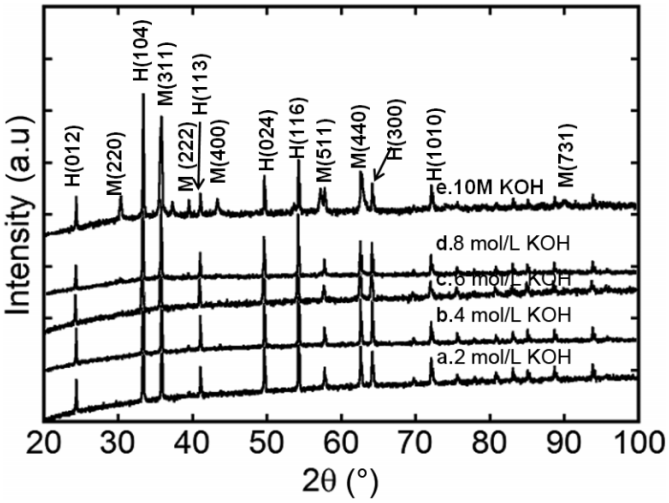
Fig. 1. The X-ray powder diffraction (XRD) patterns of 2–10 mol/L alkali-synthesized nanoparticles. H, hematite; M, magnetite.



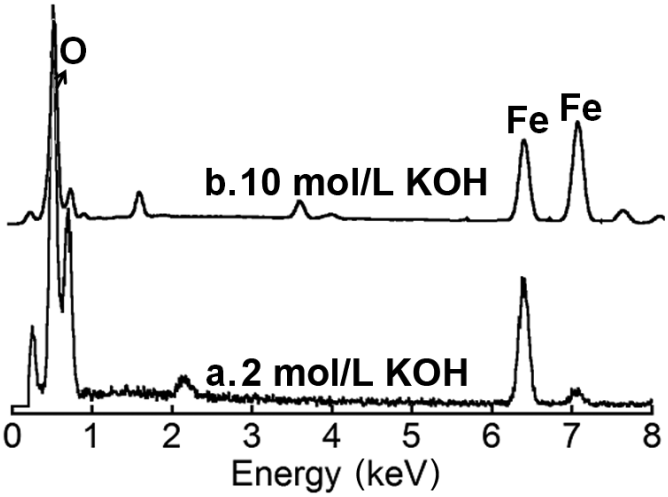


Fig. 2. Energy dispersive X-ray spectrometer (EDX) spectrum of (*a*) 2 mol/L and (*b*) 10 mol/L alkali-synthesized nano-octahedron.

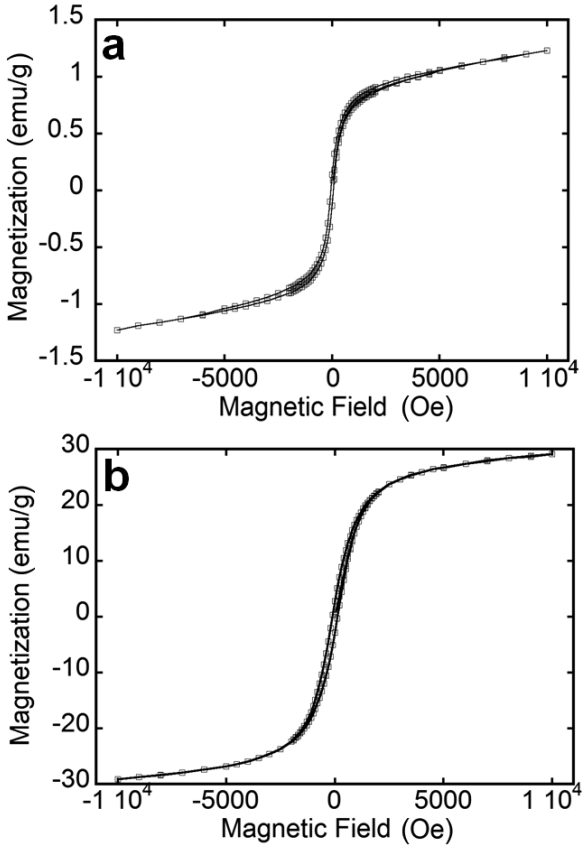


[KOH] = 10 mol/L. The shape of these structures is characteristic of the face-centered cubic (fcc) structure of MNPs. Magnetite has a cubic inverse spinel structure with oxygen forming fcc closed packing and Fe cations occupying interstitial tetrahedral sites and octahedral sites.[9]

The X-ray diffraction patterns of the MNPs synthesized at different alkaline concentrations are shown in Fig. 1. The peaks at the (220), (311), (222), (400), (511), (440), and (731) planes belong to the fcc metallic magnetite (Joint Committee on Powder Diffraction Standards (JCPDS) file No. 01-075-0033) as shown in Fig. 1*e*. The other peaks (Fig. 1*e*) and the spectra peaks of Figs. 1*a*–1*d* belong to hematite (JCPDS file No. 00-013-0534), indicating that hematite also partly coexists with magnetite particles. It can be seen that hematite (α-Fe_2O_3) products are obtained when the KOH concentration is less than 8 mol/L as shown in Figs. 1*a*–1*d* and, when the KOH concentration is 10 mol/L, the product is almost completely changed to magnetite (Fe_3O_4) withsome α-Fe_2O_3 coexisting as shown in Fig. 1*e*.

EDX was employed to obtain the quantitative elemental information of the amount and the distribution of Fe and O species in the sample. The elemental analysis by EDX (Fig. 2) confirms the presence of Fe and O elemental signatures of the product obtained at 2 (Fig. 2*a*) and 10 mol/L (Fig. 2*b*) KOH reduction. The elemental analysis showed that the products have iron oxides with the atomic ratios of 68.49:30.48 and 72.61:27.39 (%) for Fe/O at 2 and 10 mol/L KOH reduction materials, respectively, as expected for the nearly stoichiometric composition of magnetite with coexisting hematite.

Fig. 3. Magnetic hysteresis curves measured at room temperature for (*a*) 2 mol/L alkali-synthesized nanoparticles and (*b*) 10 mol/L alkali-synthesized nano-octahedrons.

Magnetic measurement of MNPs

The magnetic properties of 2 and 10 mol/L alkali-synthesized MNPs were investigated at room temperature. A change of magnetic saturation was observed when the alkaline concentration was varied from 2 to 10 mol/L. Figure 3 shows that the magnetic saturation value (M_s) is 0.9 emu/g for 2 mol/L alkali-synthesized (Fig. 3*a*) nanoparticles, whereas it is 24 emu/g for 10 mol/L alkali-synthesized (Fig. 3*b*) nano-octahedrons. Such phenomena can be closely related to the phase change of magnetic particles from hematite to magnetite. The magnetic state hysteresis residual magnetization at a zero external field was also varied by the alkaline concentration. The remanent magnetization (M_r) was found to be 0.13 emu/g for 2 mol/L and 3.33 emu/g for 10 mol/L, and coercivity (H_c) was 59.0 Oe for 2 mol/L and 111.00 Oe for 10 mol/L, respectively, as shown in the Supplementary data (Figs. S3*a* and S3*b*). Hysteresis loops of the nano-octahedron show

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

that the octahedron is ferromagnetic (Hc = 111.00 Oe) at room temperature.

An XRD study also proved that the magnetite particles are partially replaced in place of hematite at the 10 mol/L alkaline concentration, which results in an increase in the magnetization. The experimental results also indicate that the MNPs alkalization at the higher 10 mol/L possesses high magnetization. It is reasonable to conclude that the alkaline concentration also has tunable properties for the magnetization.

Synthesis mechanism of MNPs

We prepared the ferromagnetic nanoparticles by the oxidation–reduction of ferric nitrate salt in the ethanol–water solvent. Firstly, $Fe(NO_3)_3{\cdot}9H_2O$ dissociates slowly into Fe^{3+} and NO_3^- ions due to their weak dissociation tendency under the aqueous hydrothermal conditions.

$$[1] \quad Fe(NO_3)_3 \rightarrow Fe^{3+} + 3NO_3^-$$

Also, most of the metal nitrate salts (e.g., $Fe(NO_3)_3$) decompose via hydrolysis to the hydroxides.[10]

$$[2] \quad Fe(NO_3)_3 + 3H_2O \rightarrow Fe(OH)_3 + 3HNO_3$$

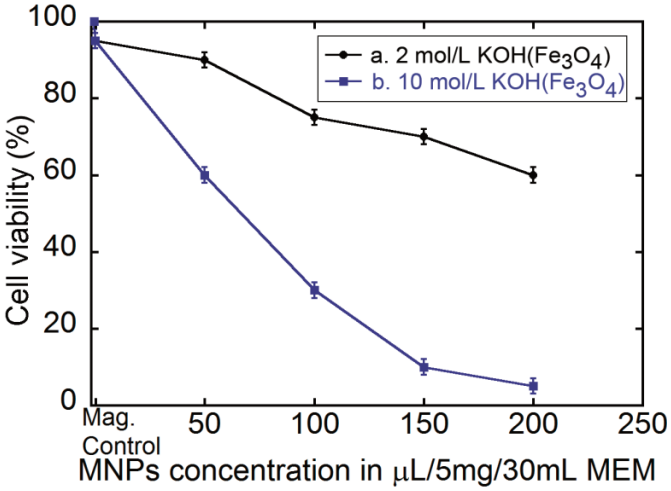
Or, the available Fe^{3+} ions (eq. [1]) are subsequently depleted to form $Fe(OH)_3$ or FeOOH in an alkaline condition.

$$[3] \quad Fe^{3+} + H_2O \rightarrow Fe(OH)_3 \rightarrow FeO(OH) \quad (H_2O \text{ oxidation})$$

The resulting $Fe(OH)_3$ or FeOOH quickly decomposes into α-Fe_2O_3 in an alkaline solution.

$$[4] \quad Fe(OH)_3/FeO(OH) \rightarrow \alpha\text{-}Fe_2O_3$$

Finally, α-Fe_2O_3 can be transformed into Fe_3O_4 in the reaction of an alkaline solution under high temperature and pressure.



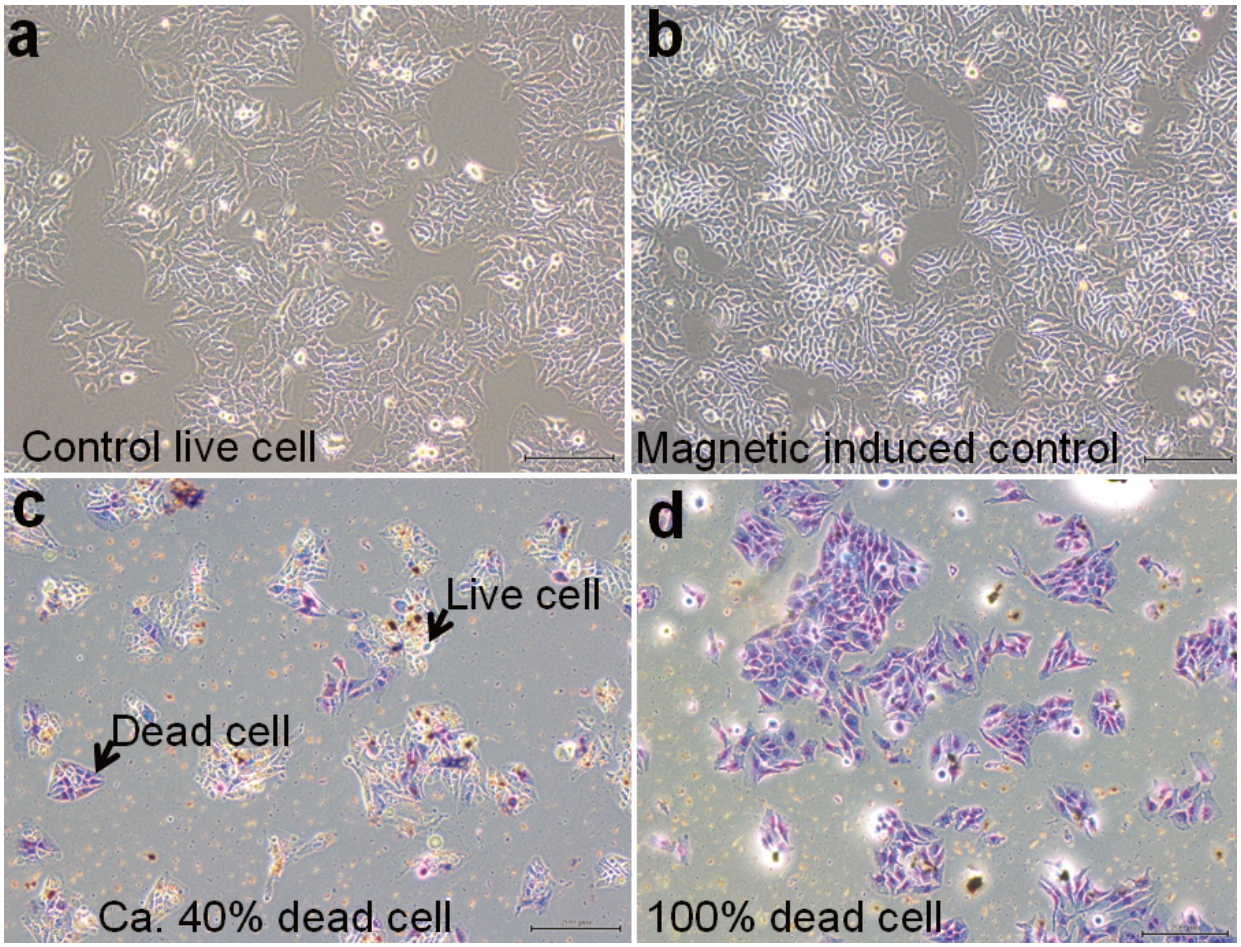
$$[5] \quad \alpha\text{-}Fe_2O_3 \rightarrow Fe_3O_4 \quad (\text{Reduction})$$

Through the experiments we find that the concentration of the alkali has a key influence on the octahedron-shape growth morphology. When the alkaline concentration (10 mol/L) is high in the reaction, mainly Fe_3O_4 nano-octahedrons and some coexisting Fe_2O_3 particles can be produced (Fig. 1*e*). This is in good agreement with the synthesis of the alkali-tunable ferromagnetic nanoparticles (Fig. 1).

Enhanced magnetic hyperthermia cancer cell killing

It is also well-known that hematite shows antiferromagnetic behavior. In our case, 10 mol/L alkali-synthesized magnetic nano-octahedrons also have some coexisting hematite as shown in the XRD data (Fig. 1*e*). The ferromagnetic (Fe_3O_4) and antiferromagnetic (α-Fe_2O_3) behavior of nanoparticles can increase the localized temperature (hyperthermia) inside a tumor,[11] which promotes cancer cell death. From the comparative studies (Fig. 4) on cancer treatments, the cancer cell killing efficiency was found to be ~40% (Fig. 4*a*) for 2 mol/L synthesized MNPs with a hyperthermia temperature (~45 °C), whereas for 10 mol/L synthesized MNPs it was found to be ~100% (Fig. 4*b*) with a hyperthermia temperature of ~50 °C. To investigate the colloidal stability of MEM-containing MNPs, the MNPs (5 mg) were dispersed in MEM (10 mL) by sonication. As shown in the Supplementary data in the absence (Fig. S5*a*) and presence (Fig. S5*b*) of a permanent magnetic field, as-prepared nano-octahedrons are well dispersed in the MEM media without any aggregation and (or) precipitation and firmly dragged by the permanent magnetic force.

Fig. 4. Surviving fractions of HeLa cells in the presence of 2 mol/L alkaline-synthesized nanoparticles and 10 mol/L alkaline-synthesized magnetic nanoparticles (MNPs). One hundred percent of cells were killed in the presence of 200 μL of the 10 mol/L alkaline-synthesized MNPs solution, whereas the 2 mol/L alkaline-synthesized nanoparticles gave only 40%. In the vertical scale, 100% means the control dish, bars represent the average region of three times the measured data, and the points represent the mean value from three measurements.



MNPs (5 mg) were dispersed in 30 mL of MEM supplemented with 10% NBS. Then the solution was sonicated for about 5 min and the nanoparticle-containing solution was filtered by a 40 μm cell strainer (BD Falcon). To compare the magnetic field induced cell killing, cell dishes were incubated for 24 h with different amounts of MEM-containing MNPs solutions (50, 100, 150, and 200 μL), and another dish without a nanoparticle solution (magnetic-induced control dish) was also incubated for 24 h. The cell viability under a 10 min AC magnetic field induction without MNPs (magnetic control) was more or less 95%. The cell killing ability under a 10 min AC magnetic field induced with 200 μL MEM containing 2 mol/L alkaline-synthesized nanoparticles and 10 mol/L alkaline-synthesized nanoparticles was ~40% and ~100%, respectively (Fig. 4).

The microscopic images of HeLa cells before and after magnetization induction are shown in Figs. 5*a* and 5*b*–5*d*, respectively. Figures 5*a* and 5*b* show that the cell morphology is largely unchanged after a 10 min magnetization. Figures 5*c* and 5*d* show that the HeLa cells suffer severe hyperthermia injury under a 10 min magnetization with the MNPs, indicated by the trypan blue stain, which confirms cell death.

Conclusions

In summary, we synthesized surfactant-free octahedron-shaped Fe_3O_4 with coexisting Fe_2O_3 under variable alkaline

Fig. 5. Microscopic images of HeLa cells. (*a*) No nanoparticles nor magnetization. (*b*) After a 10 min magnetic field induction without nanoparticles. (*c*) After a 10 min magnetic field induction with 2 mol/L alkaline-synthesized nanoparticles; trypan blue stained image. concentrations by hydrothermal decomposition of $Fe(NO_3)_3 \cdot 9H_2O$ in a water–ethanol mixed solvent. Through the experiments we found that the concentration of alkali has a key influence on the octahedron-shape growth morphology. The study also revealed that these alkaline concentrations influence the phase, shape, and magnetization of nanoparticles. We found a reproducible octahedron shape with high magnetization of nanoparticles synthesized at high alkaline concentration (10 mol/L). Also, we found that the cancer cell killing with high alkaline (10 mol/L) synthesized nanoparticles was more efficient than that with lower alkaline (2 mol/L) synthesized nanoparticles.

Abstract: This work addresses the remediation of nitrate-contaminated water using electrodes made of Ebonex (a titanium oxide ceramic with a wide range of potential stability). The objective was the complete denitrification of solutions containing nitrate ion. Denitrification was achieved in about 50% yield with unreactive supporting electrolytes when Ebonex was used as both cathode and anode, the remaining product being ammonia. Ammonia could be re-oxidized at the Ebonex anode, but this was much less efficient than the reduction step. A more efficient electrolytic denitrification was possible for solutions containing chloride; this is oxidized anodically to hypochlorite, which then oxidizes ammonia chemically to N_2. The overall rate of denitrification was highest at moderate concentrations of chloride ion, because hypochlorite also re-oxidizes reduction intermediates such as nitrite back to nitrate. Complete denitrification was achieved at all stages of the reaction using Ebonex cathode and a dimensionally stable anode based on Ti/IrO_2 or Ti/RuO_2, because the DSA oxidizes chloride ion more efficiently than Ebonex. Cathode fouling by water sources that are high in hardness cations can be prevented by using one DSA and a pair of Ebonex electrodes that undergo periodic polarity reversal.

Key words: nitrate reduction, Ebonex cathode, reverse polarity, electrolytic denitrification.

Résumé : Ce travail a pour but de présenter une méthode de réhabilitation de l'eau contaminée par des nitrates en faisant appel à des électrodes faites à partir d'Ebonex (de la céramique à base d'oxyde de titane qui présente une stabilité de potentiel sur une très grande plage). L'objectif était d'obtenir une dénitrification complète de solutions contenant l'ion nitrate. Lorsque l'Ebonex a été utilisé soit comme cathode ou comme anode avec des électrolytes de support non réactifs, la dénitrification a été réalisée avec un rendement d'environ 50 % et le produit résiduel était l'ammoniac. L'ammoniac ne peut pas être réoxydé sur une anode d'Ebonex, mais ce processus est beaucoup moins efficace que l'étape de réduction. Une dénitrification électrolytique plus efficace est possible avec les solutions contenant l'ion chlorure qui est oxydé à l'anode en hypochlorite et qui oxyde ensuite l'ammoniac d'une façon chimique en N_2. Le taux maximal de dénitrification est maximal avec des concentrations modérées d'ion chlorure, parce que l'hypochlorite reoxyde aussi des intermédiaires de la réduction, tel le nitrite en nitrate. On a réalisé une dénitrification totale à toutes les étapes de la réaction en utilisant une cathode d'Ebonex et une anode de dimension stable à base de Ti/IrO_2 ou Ti/RuO_2, parce que le DSA (Dirty Sandstone Acid)™ oxyde l'ion chlorure d'une façon plus efficace que l'Ebonex. Il est possible de prévenir l'encrassement de la cathode par des eaux de source riches en cations provoquant de la dureté en utilisant un DSA et une paire d'électrodes Ebonex qui est soumise périodiquement à une inversion de polarité.

Mots-clés : réduction de nitrates, cathode Ebonex, inversion de polarité dénitrification.

[Traduit par la Rédaction]

Introduction

Nitrate is an almost ubiquitous contaminant of ground water in areas of intensive agriculture due to run off from fertilizer and to biological transformation of nitrogenous runoff from feedlots. This poses a toxicity problem when ground water is to be used as a source of drinking water for both municipal consumers and those with residential wells.[1,2] The toxicity of nitrate is of special concern for young children, because the fetal and infant form of hemoglobin binds to nitrate to produce an inefficient oxygen transport molecule, leading to the condition methemoglobinemia. In most jurisdictions, the maximum allowable level for nitrate in drinking water is 45 mg L^{-1}, often expressed as 10 mg N L^{-1}. A further problem is the release of the potent greenhouse gas N_2O as a result of incomplete denitrification.[3,4] Other sources of nitrate contamination include industrial and nuclear processing waste waters.[5]

Electrochemical reduction of nitrate has been studied for many different cathodes as a possible remediation method for waters that contain sufficient electrolytes to carry the current.[5–7] The optimal outcome would be the complete elimination of nitrogen in the form of N_2, especially for potable water, but in most cases the major reduction product is ammonia, and elemental nitrogen is only a minor product (eqs. [1]–[2]). This has the effect of exchanging one pollutant for another. The options for an electrochemical technology to

remove nitrate are to find conditions that favour the formation of N_2 over NH_3 or to couple the electrochemical reduction of nitrate with a process for removing ammonia as it is formed.

[1] $NO_3^- + 10H^+ + 8e^- \rightarrow NH_4^+ + 3H_2O$

[2] $NO_3^- + 6H^+ + 5e^- \rightarrow 1/2N_2 + 3H_2O$

Kyriacou and Katsounaros[6] have summarized the results of nitrate electroreduction for a wide variety of cathodes. The proportions of N_2 and NH_3 depend on the choice of cathode, the cathode potential, and the supporting electrolyte. The best yield of nitrogen reported, 92% N_2 and 6% N_2O, was found at a tin cathode, at very negative potentials.[8] The detailed chemistry is complex because of the large number of nitrogenous species of different oxidation states that must be considered as possible intermediates.

Although the ammonia product can be removed from aqueous solutions by gas stripping, this process is most effective when pH > pK_a of NH_4^+ (9.25), which is outside the pH range of drinking water. It would be impractical to implement domestically, while for municipal or industrial applications there would remain the problem of treating the volatilized ammonia to avoid air pollution.

The 3-electron electrochemical oxidation of ammonia to nitrogen (eq. [3]) can in principle be coupled to the 8-electron reduction of nitrate ion to ammonium ion (eq. [1]).

[3] $NH_3 \rightarrow 1/2N_2 + 3H^+ + 3e^-$

The oxidation of ammonia to elemental nitrogen is also much more facile in alkaline solution, because NH_3 is much more easily oxidized than NH_4^+[9]. High chemical and current efficiencies are possible using noble metal anodes, such as platinized platinum, and carefully controlled potential.[9] Attempts to use anodes not based on noble metals at pH values relevant to drinking water have had limited success.[9,10] Recently, denitrification has been studied with pairs of identical electrodes made of Cu-Ni alloy[11] or boron-doped diamond[12] using polarity reversal. In the latter case, low (but not zero) concentrations of ammonia were achieved in the remediation of high nitrate – low chloride waste water from hydroponic operations.

Break-point chlorination (eqs. [4]–[5]) is routinely used to remove ammonia from potable water simultaneously with disinfection.[13,14] Analogous chemistry can be initiated by electrochemical oxidation of chloride ion to HOCl.[15–18] The combination of cathodic reduction of nitrate and chloride-mediated electrochemical oxidation achieves the desired conversion of NO_3^- to N_2, although chloride salts cannot be added to potable water. In addition, the cycle eq. [6]–eq. [5] is not entirely catalytic in chloride: further oxidation of hypochlorite gives toxic chlorine oxyanions: ClO_2^- promotes erythrocyte lysis;[19] ClO_3^- is a nitrate antagonist in plants;[20] ClO_4^- is a thyroid hormone mimic.[21,22]

[4] $Cl_2 + H_2O \rightarrow HCl + HOCl$

[5] $3HOCl + 2NH_3 \rightarrow N_2 + 3HCl + 3H_2O$

[6] $Cl^- + H_2O \rightarrow HOCl + H^+ + 2e^-$

The present research was initially directed towards the use of Ebonex electrodes for the simultaneous reduction of nitrate and oxidation of ammonia, as a possible one-step chloride-free denitrification. Ebonex is a conductive and corrosion-resistant ceramic with optimal electrical conductivity at the composition Ti_4O_7, which is usually conceptualized as alternating layers of TiO: $3TiO_2$.[23,24] Ebonex has excellent stability with respect to water decomposition under both anodic (>2 V vs. SCE) and cathodic (~ –1.4 V vs. SCE) polarization and is extremely corrosion-resistant,[25–28] suggesting its possible use as both anode and cathode for such a process. In practice, the combination of Ebonex cathode – Ebonex anode was rather inefficient. Instead, a novel chloride-mediated protocol was developed — a Ti/RuO_2 anode promoted efficient oxidation of chloride, and a pair of Ebonex electrodes was used with periodic polarity reversal. This gave efficient reduction, even in the presence of hardness cations, which otherwise foul the cathode.

Materials and methods

Sodium hydroxide, sodium chloride, calcium chloride, sodium nitrate, and sodium nitroprusside were obtained from Fisher Scientific (Toronto, Ontario, Canada). Sigma-Aldrich (Oakville, Ontario, Canada) provided ammonium sulfate, sodium sulfate, sodium citrate, sodium perchlorate, and phenol. Commercial Alcohols Inc. (Brampton, Ontario, Canada) supplied ethanol, and Ultra Bleach (sodium hypochlorite) was obtained from Loblaws (Toronto, Ontario, Canada). The Ebonex electrode materials were obtained from Vector Corrosion (Stoney Creek, Ontario, Canada), and Ti/IrO_2-Ta_2O_5 and Ti/RuO_2 electrodes were supplied by ELTECH Systems Corporation (Painesville, Ohio, USA). All solutions were prepared using deionized water.

Electrolyses using Ebonex as both the cathode and anode were performed in a rectangular Plexiglas cell (internal dimensions: 2.9 cm × 2.9 cm × 7.5 cm) whose lid (also Plexiglas) held four cylindrical Ebonex electrodes (7.5 cm length and 1 cm diameter, external dimensions), with each immersed area of 20 cm^2. The electrodes were connected in diagonal pairs and operated (in most experiments) with periodically reversed polarity. In this cell, for example, an applied current of 40 mA represents a current density of 1 mA cm^{-2}. The inter-electrode gap was 5 mm between cathode and anode, and 10 mm between the 2 anodes or the 2 cathodes. A Princeton Applied Research Model 363 Potentiostat Galvanostat was used as the power supply, with a Siemens LOGO! 12/24 RC switcher used to reverse polarity between the electrodes. Cell voltage was monitored using a Wavetek DM5XL multimeter.

Batch electrolyzes using a Ti/RuO_2 anode (surface area of 6 cm^2 immersed in solution) were performed in a 100 mL Pyrex beaker, using 38 mL of solution in each experiment. An Ebonex cathode was used (7.5 cm length × 1 cm diameter), with an inter-electrode gap of 1 cm. In this cell, the cathode current density for 40 mA applied current was 2 mA cm^{-2}, and the anode current density was 6.7 mA cm^{-2}. Electrolyses were carried out amperostatically and under gentle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

stirring, using a magnetic stir bar and a Fisher Scientific Thermix stirrer.

The progress of the electrolyzes was monitored by taking 0.5 mL samples every hour, diluting the sample to 10 mL with deionized water, and analyzing the sample for total nitrogen with a Shimadzu TOC analyzer, using the TOC + TN method. The analyzer gave a result in ppm of nitrogen, which was converted to mmol L^{-1} of N after dividing by the molar mass of nitrogen (14 g mol^{-1}) and multiplication by the 20× dilution factor.

Ammonia concentrations were determined spectrophotometrically,[29] using phenol, nitroprusside, and alkaline citrate to form indophenol blue, whose intensity at 640 nm is proportional to the ammonia concentration. A Pharmacia LKB-Novaspec II spectrophotometer was used to measure absorbance. A calibration curve was produced using standards, from which absorbance values of unknown samples could be converted to ammonia concentration.

Nitrate concentration was determined by subtracting the concentration of ammonia from the concentration of TN for a given sample. In some cases, nitrate concentration was also determined spectrophotometrically,[30] with agreement always observed between the two methods. A Shimadzu UV 160U Spectrophotometer was used to measure the absorbance of the samples at 275 and 220 nm.

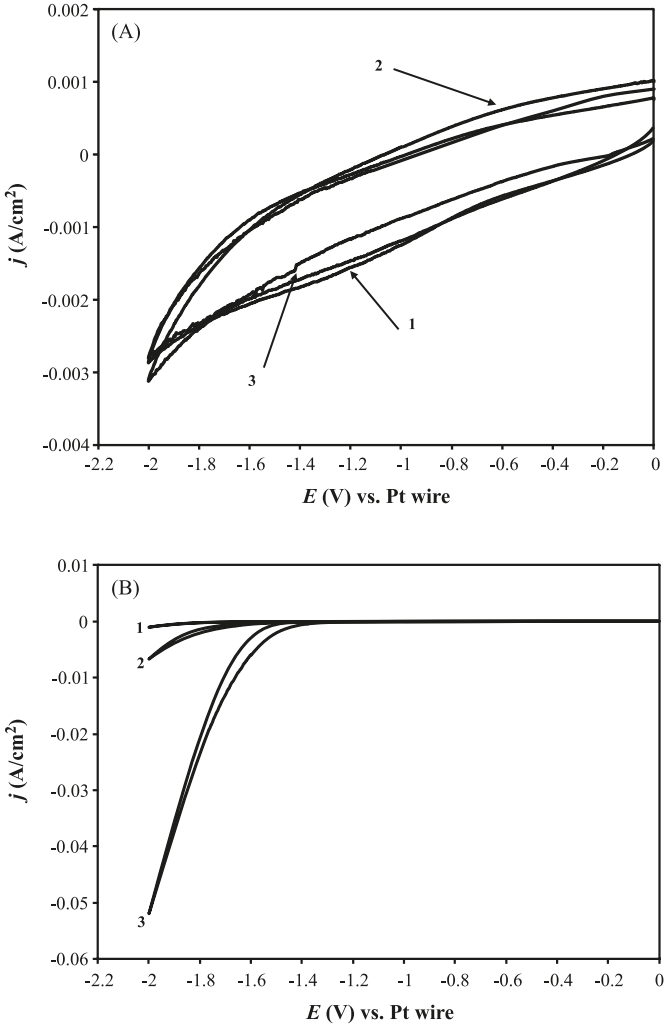
Results and discussion

Ebonex cathode and Ebonex anode in the absence of chloride

Cyclic voltammetry at an Ebonex electrode revealed that there was no cathodic current until –1.8 V vs. Pt wire reference electrode, and that the current was independent of the nitrate concentration (Fig. 1A). This observation is compatible with the conclusions of Katsounaros and Kyriacou for tin,[31] where there is a high overvoltage for hydrogen evolution, and the cathodic current is ascribed to the formation of sorbed hydrogen rather than reduction of nitrate. Tentatively, a similar explanation may be applicable to Ebonex. For graphite, in contrast, the onset of the cathodic current began at less negative potentials, and the current increased with the nitrate concentration (Fig. 1B).

Preliminary electrolyzes showed that reduction of nitrate was efficient at Ebonex, but oxidation of ammonia was inefficient. These experiments employed Ebonex as both anode and cathode, and the polarity was reversed every 30 min, because we have previously shown that an Ebonex anode otherwise loses its activity through oxidation of the surface.[32,33] Anodic deactivation can be conceptualized as oxidation of the Ti_4O_7 surface layer to Ti_4O_8 (= TiO_2), in competition with oxidation of water or other substrate. Periodic reversal of the polarity allowed the activity of a pair of Ebonex electrodes to be sustained, with the additional advantage of avoiding the deposition of carbonate scale on the cathode when the supporting electrolyte contains hardness cations. Cathode fouling is the result of high pH near the cathode surface due to the reduction of water to H_2 and OH^-.[34] A control electrolysis without nitrate, in which the supporting electrolyte contained calcium (0.5 mol/L $CaCl_2$), indeed showed the development of a lime deposit unless the polarity was reversed.

Fig. 1. Cyclic voltammetry at 50 mV/s using 50 mmol/L $NaClO_4$ of supporting electrolyte: 1, background; 2, 25 mmol/L $NaNO_3$; 3, 0.5 mol/L $NaNO_3$. (A) Ebonex electrode (8 mm^2). (B) Graphite pencil lead electrode (63 mm^2).



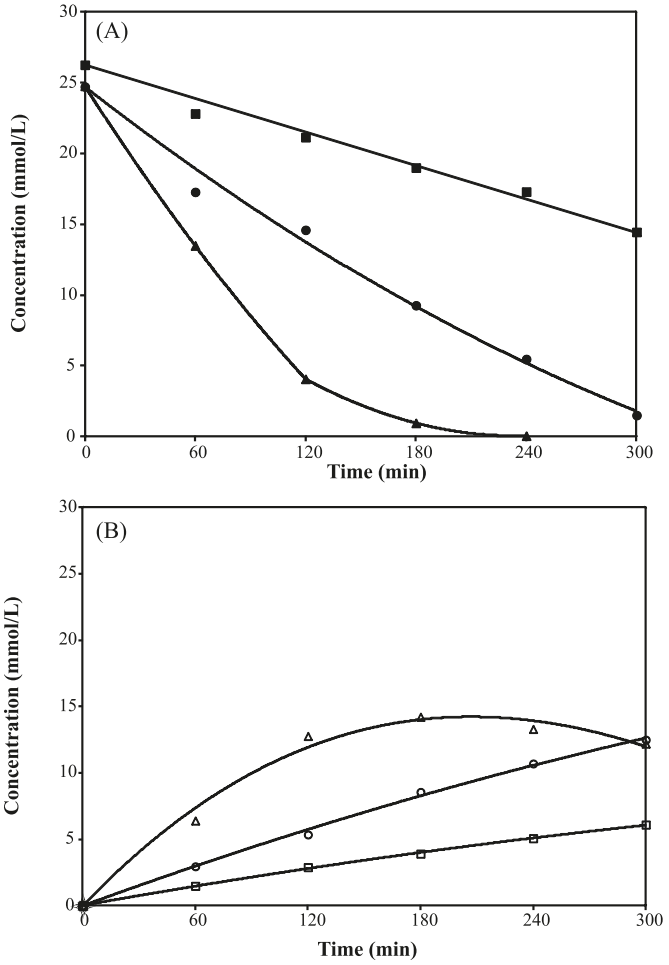


Figure 2 shows the results of electrolysis of 25 mmol/L $NaNO_3$ at different currents, with 0.1 mol/L $NaClO_4$ as an unreactive supporting electrolyte. Ammonia was in all cases a significant product, as observed at most other cathodes.[6] Loss of total nitrogen (TN) is a direct measure of denitrification. The loss of nitrate, represented by the difference between TN and $c(NH_3)$, followed the expected nearly zero order (current-controlled) kinetics until late in the reaction because of the low current densities (0.67 to 3.0 mA cm^{-2}). This was shown by the initial rates (linear portion of Fig. 2, panel A) of 0.038 ± 0.001, 0.081 ± 0.010, and 0.17 ± 0.01 mmol/L min^{-1} at 30, 60, and 120 mA, which were proportional to the applied current (Supplementary data Fig. S1). When $c(NO_3^-)$ was measured directly, there was no difference between this value and [TN - $c(NH_3)$], showing that significant concentrations of other nitrogen species were not present. An experiment in which 25 mmol/L $NaNO_3$ was electrolyzed in 0.1 mol/L $NaClO_4$ supporting electrolyte at 120 mA, with or without reversing the polarity, showed that the reduction of nitrate was not affected by polarity reversal. From this, we conclude that Ebonex cathodes are not inactivated by

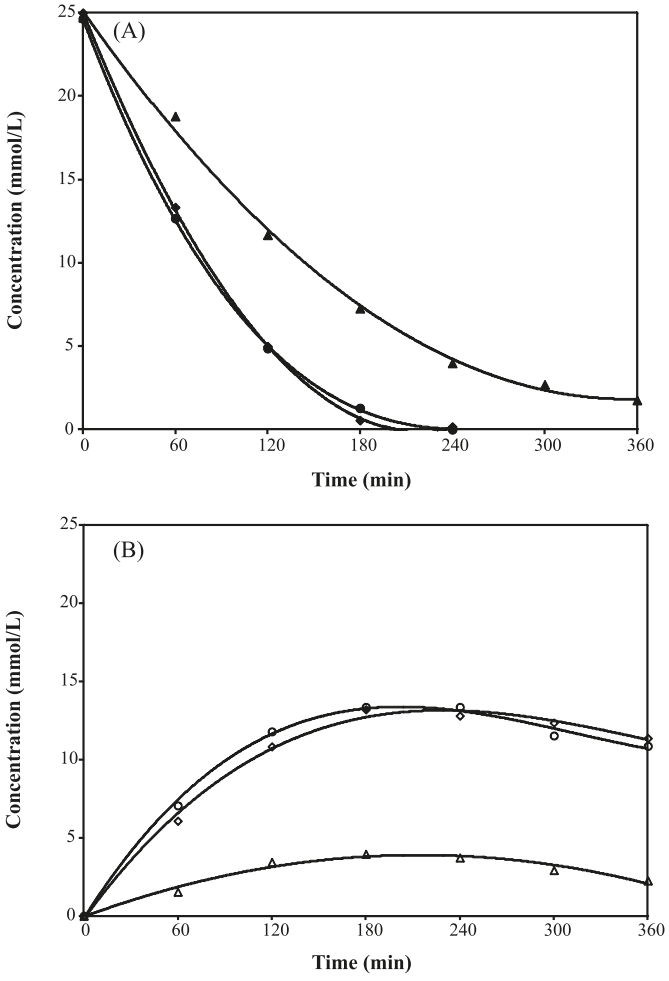
Fig. 2. Electrolysis of 25 mmol/L $NaNO_3$ with 0.1 mol/L $NaClO_4$ supporting electrolyte at different currents. (A) Nitrate. (B) Ammonia. 120 mA (▲/△), 60 mA (●/○), 30 mA (■/□)

"over-reduction" in the way that Ebonex anodes are inactivated by overoxidation.[32] Periodic polarity reversal is not detrimental to the current efficiency, however, and is useful when solutions contain hardness cations.

In the foregoing experiment at 120 mA, the concentration of ammonia was 14 mmol/L after 3 h; this accounted for almost all the TN (the residual concentration of nitrate was ~1 mmol/L). Of the total 1296 C (0.0134 mol electrons), 4.3×10^{-3} mol e^- were used to form ammonia according to eq. [1] and 2.7×10^{-3} mol e^- for forming N_2 by eq. [2], for a total current efficiency of 52%. The product ratio NH_3:N_2 was independent of current, namely 1.1, 1.2, and 1.0 for 30, 60, and 120 mA, respectively. In experiments that were continued overnight, the residual ammonia concentrations were zero at 120 mA, 9 mmol/L at 60 mA, and 10 mmol/L at 30 mA. These experiments were carried out under conditions where any ammonia stripped from the solution was trapped — there was no significant loss of ammonia by this route. The rate of oxidation of ammonia was at least 10-fold slower than the reduction of nitrate; therefore, the initial phase of denitrification cannot be explained by a mechanism in which nitrate is reduced to ammonia at the cathode and then reoxidized at the anode. This conclusion was confirmed in experiments starting with ammonia, again using Ebonex as both anode and cathode, even when the reaction conditions were modified to the highly alkaline pH values that are customarily used at noble metals. For example, there was still 7 mmol/L ammonia remaining even after 21 h electrolysis of 25 mmol/L ammonia (in the form of ammonium perchlorate) at 120 mA in alkaline solution (Supplementary data Fig. S2).

Voltammetry does not offer straightforward answers concerning the mechanism of cathodic reduction of nitrate. A clear reduction peak for nitrate was seen at Pt in acidic solution.[35] A complication is that the progress and mechanism of nitrate reduction are pH dependent, as emphasized by Milhano and Pletcher.[5,44] In other work, no reduction current was seen unless the solution also contained a small concentration of nitrite ion, and the second cycle of a cyclic voltammogram gave larger currents than the first, suggesting that nitrite formation causes the reduction to be autocatalytic.[36] Katsounaros and Kyriacou found that the reduction current, in neutral solution at a tin cathode, commenced at ~ –1.5 V vs. Ag/AgCl and increased with the concentration of $NaNO_3$, but no peak current was seen even at –2.2 V.[31]

A high overpotential for hydrogen formation is not the only factor that determines the selectivity between N_2 and NH_3. Tin, Ebonex, and boron-doped diamond all have a high overpotential for hydrogen evolution, but only tin has a high selectivity for N_2.[6,8] The electrochemical reduction of nitrate (and the analogous biological process)[37] are mechanistically complex, not least because many intermediates exist as acid-base conjugates.[5,6]



At most cathodes, the initial product of nitrate reduction is nitrite ion, initiated by addition of e^-/H^+. For tin, no hydrogen gas was evolved until well into the electrolyzes, especially at higher initial concentrations of nitrate, suggesting that nascent hydrogen, assumed to be equivalent to a sorbed hydrogen atom, is the active reductant under these conditions.[31] The intermediate product is NO_2, which is reduced to nitrite by either e^- or H(ads). Analogous reactions can convert nitrite to NO and thence HN=O (nitroxyl). Nitroxyl is the key intermediate in determining whether the final product is monomeric (NH_4^+) or dimeric (N_2O and (or) N_2) both electrochemically and biologically.[37] HNO dimerizes rapidly in aqueous solution to give hyponitrous acid $H_2N_2O_2$.[38] Katsounaros and Kyriacou showed experimentally that $H_2N_2O_2$ is formed during the reduction of nitrate at a tin cathode and proposed that it spontaneously produces N_2O, which can reduce further to N_2.[39] However, HNO also undergoes a pair of e^-/H^+ reactions that lead to hydroxylamine (which is reducible to ammonium ion); in addition, HNO is a reaction partner for hydroxylamine, forming N_2. The reaction between ammonium ion and nitrite (N_2O_3 is the active nitrosating agent at moderate pH values) (eq. [7]), is too slow to account for significant loss of TN from the solution on the time-scale and reactant concentrations of our experiments.[40]

$$[7] \qquad NO_2^- + NH_4^+ \rightarrow N_2 + 2H_2O$$

Katsounaros and Kyriacou observed that the relative yield of nitrogen and the total faradaic current efficiency were concentration-dependent, increasing from 70% to 83% as the concentration of nitrate was raised from 100 to 1500 mg L^{-1}.[31] Taking into account that the highly negative polarization of the tin cathode (–2.8 V vs. Ag/AgCl) would repel the

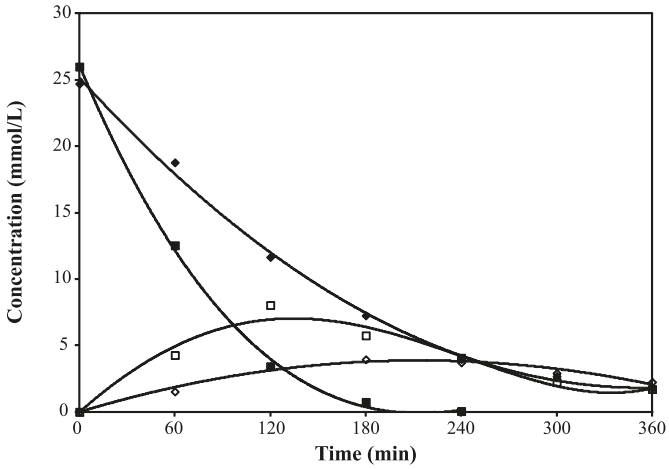
Fig. 3. Electrolysis of $NaNO_3$ 25 mmol/L at 120 mA with different supporting electrolytes. (A) Nitrate. (B) Ammonia. NaCl 0.05 mol/L (▲/△), $NaClO_4$ 0.05 mol/L (●/○), Na_2SO_4 0.05 mol/L (◆/◇).



approach of nitrate anions, they proposed a mechanism involving the approach of $M^+\cdots NO_3^-$ ion pairs to the cathode and fitted the concentration dependence of the rate of reduction at constant potential to a Langmuir association model.[39]

To conclude this section, our experiments show that it is possible to achieve complete electrochemical denitrification of a nitrate solution using Ebonex as both anode and cathode, although the overall current efficiency is disappointingly low.

Ebonex cathode and Ebonex anode in the presence of chloride

Figure 3 compares electrolyzes of 25 mmol/L nitrate in 0.05 mol/L supporting electrolytes $NaClO_4$, Na_2SO_4, and NaCl. The NaCl solution gave the fastest loss of TN, the slowest rate of loss of nitrate, and the lowest chemical yield of ammonia. These observations are consistent with the well-known intervention of oxidation to hypochlorite and a mediated oxidation in the presence of chloride. The explanation for the slower reduction of nitrate in the presence of chloride is that hypochlorite re-oxidizes partly reduced intermediates back to nitrate. As in the chloride-free solutions, the measured $c(NO_3^-)$ was equal to [TN – $c(NH_3)$], showing the absence of significant concentrations of other nitrogen species. The apparent current efficiency in NaCl solution was 30%. The current efficiency for N_2 was calculated on the basis of a $5e^-$ change (not $8e^-$ followed by reoxidation), both to compare with the chloride-free system and because the ultimate practicality of such as remediation method is kWh per kg nitrate, irrespective of the reaction mechanism.

Fig. 4. 25 mmol/L $NaNO_3$ + 50 mmol/L NaCl electrolyzed at 120 mA. Nitrate (black shapes), ammonia (white shapes). Polarity reversal every 180 min (■/□), polarity reversal every 30 min (◆/◇).

In contrast with chloride-free solution, polarity reversal every 30 min decreased the rate of reduction of nitrate and increased the yield of ammonia ($[Cl^-]$ = 500 mmol/L; $[NO_3^-]$ = 25 mmol/L) (Fig. 4). This observation is consistent with observations on the oxidation of sulfide at Ebonex anodes.[33] Polarity reversal maintains the activity of the anode towards oxidation of chloride to hypochlorite, giving a higher steady-state concentration of hypochlorite, and thus increasing the rate of oxidation of ammonia to N_2. It also speeds up re-oxidation of partly reduced intermediates to nitrate, so the net rate of reduction of nitrate is slower.

In a series of experiments carried out in the cell with two pairs of Ebonex electrodes at $[Cl^-]$ = 500 mmol/L; $[NO_3^-]$ = 25 mmol/L, the initial (linear) rates of loss of TN for currents 20, 40, 60, 120 mA (= 1:2:3:6) were 0.012, 0.022, 0.033, and 0.080 mmol/L min^{-1} = 1:1.8:2.7:6.7; those for loss of nitrate were similar: 0.014, 0.032, 0.044, and 0.109 min^{-1} = 1:2.4:3.1:7.8 (Fig. 5). The increasing curvature of the data with increasing current suggests a current controlled reaction at low current, moving towards mixed and (or) mass transport control at 120 mA. As in the absence of chloride, the ammonia concentration only begins to decline once $c(NO_3^-)$ has become negligible, showing that nitrate reduction is more efficient than ammonia oxidation. Throughout the reaction, TN ~ $c(NH_3)$.

A study of the effect of the chloride concentration at constant $[NO_3^-]$ and constant current (120 mA) indicated an optimum range for $c(Cl^-)$. Our initial experiments were carried out without controlling the ionic strength (Supplementary data Fig. S3), at which the rate of ammonia formation followed the order: Control < 0.01 < 0.05, 0.2, and 0.5 mol/L NaCl. At a constant ionic strength of 500 mmol/L, varying from 100% $NaClO_4$ to 100% NaCl, there was little change in

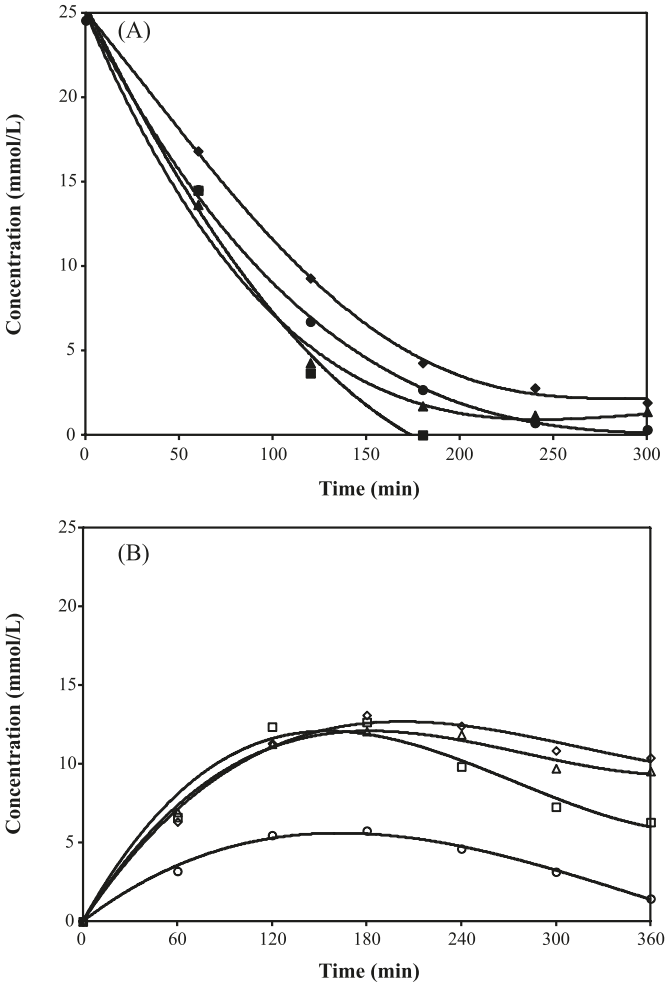

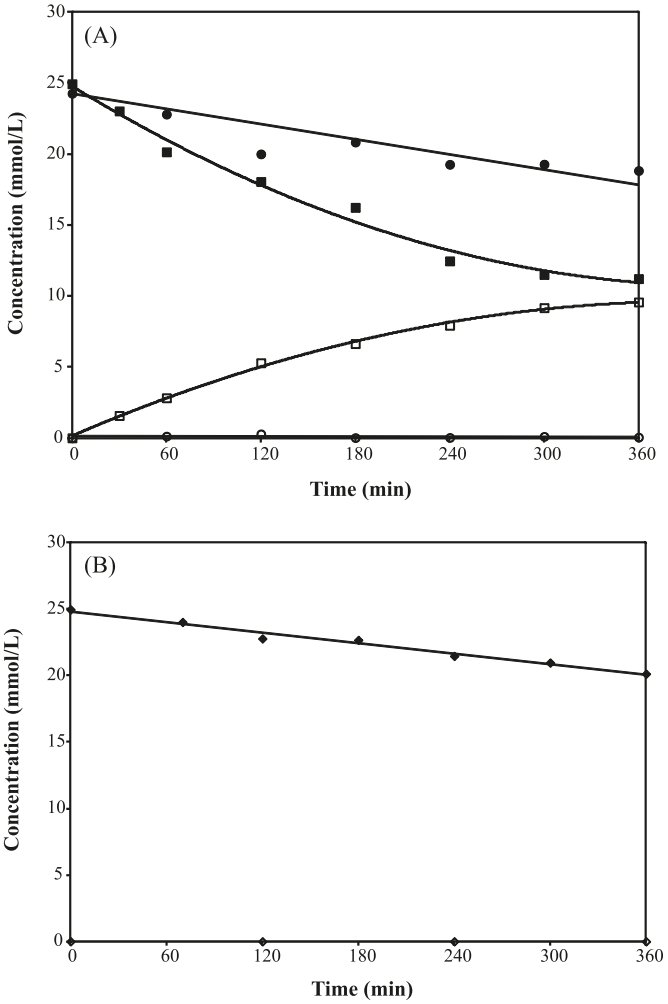

Fig. 7. Electrolysis of $NaNO_3$ 25 mmol/L at 40 mA with one Ebonex. Nitrate (filled symbols), ammonia (open symbols). (A) Ti/IrO_2-Ta_2O_5 anode/Ebonex cathode, (B) Ti/RuO_2 anode/ Ebonex cathode. NaCl 0.5 mol/L (●/○), Na_2SO_4 0.5 mol/L (■/□).

the rate of reduction of nitrate and a gradual (but incomplete) reduction in the build-up of ammonia at intermediate stages of denitrification (Fig. 6).

Ebonex cathode and dimensionally stable anode in the presence of chloride

Because the inefficiency of ammonia oxidation in the foregoing experiments can be attributed to the relative inefficiency of Ebonex as an anode material, we carried out experiments with an Ebonex cathode and either Ti/IrO_2-Ta_2O_5 or Ti/RuO_2 anode. On the anode side, DSAs have previously been used in this application by Li et al.[41] Reversal of polarity was not employed in these experiments, because it is unnecessary for the Ebonex cathode (see above) and inappropriate for the metal oxide-based anodes. In a series of experiments using 500 mmol/L [Cl^-], 25 mmol/L [NO_3^-], and an applied current of 40 mA, the loss of nitrate was 0.014 and 0.013 mmol/L min^{-1} at Ti/RuO_2 or Ti/IrO_2-Ta_2O_5 anodes, respectively, and total denitrification was achieved at all stages of the electrolyzes (Figs. 7A and 7B). For comparison, the loss of nitrate (initial rate 0.048 mmol/L min^{-1}) at Ti/IrO_2-Ta_2O_5 in 500 mmol/L Na_2SO_4 was faster than in

Table 1. Comparison of DSA and Ebonex anodes (Ebonex cathode) in the reduction of nitrate in unreactive supporting electrolytes and in NaCl.

Anode	Supporting electrolyte	Initial rate (mmol/L min^{-1})	Ammonia concentration	Notes
Ebonex	0.1 mol/L $NaClO_4$	0.050	5 mmol/L at 180 min	Interpolated from Figs. S1 and 2B
Ebonex	0.5 mol/L NaCl	0.032	2 mmol/L at 180 min	Figure 5

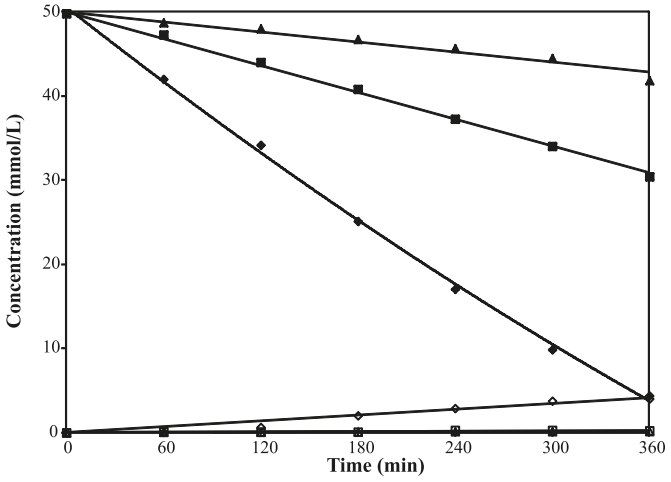

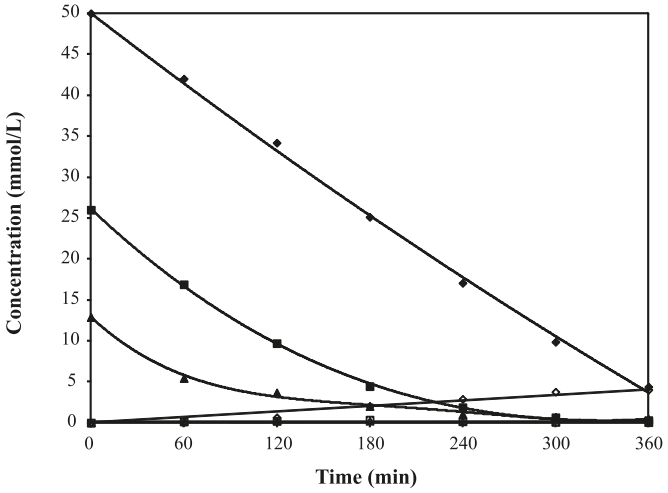

Fig. 9. Batch cell electrolysis at 120 mA. Ti/RuO_2 anode; pair of Ebonex cathodes with polarity reversal every 30 min. Nitrate (filled symbols), ammonia (open symbols). 50 mmol/L $NaNO_3$ + 50 mmol/L NaCl + 425 $NaClO_4$ (♦ /◇), 25 mmol/L $NaNO_3$ + 50 mmol/L NaCl + 450 mmol/L $NaClO_4$ (■/□), 12.5 mmol/L $NaNO_3$ + 50 mmol/L NaCl + 462.5 mmol/L $NaClO_4$ (▲/△).

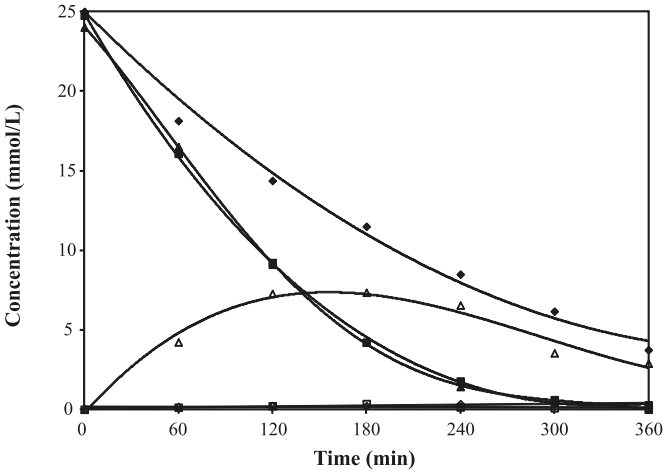
NaCl, but ammonia was present at intermediate stages of electrolysis. As explained previously, anodic formation of hypochlorite promotes the oxidation of both ammonia to N_2 and reduction intermediates back to nitrate, lowering the net rate of reduction of nitrate.

Table 1 summarizes results at 40 mA, 500 mmol/L [Cl^-], 25 mmol/L [NO_3^-] for the systems Ebonex–Ebonex and DSA–Ebonex for loss of nitrate, along with the ammonia concentrations at an arbitrarily chosen reaction time of 180 min. The rate of loss of nitrate was consistently slower when an unreactive supporting electrolyte was replaced by NaCl, as explained by re-oxidation of intermediate reduction products. The DSAs catalyze the oxidation of ammonia and reduction intermediates of nitrate through the hypochlorite reaction more efficiently than Ebonex. At the DSAs, ammonia is absent at all stages of the reaction when NaCl is present, unlike at Ebonex anodes. However, the net rate of nitrate reduction is slower using the DSA than at Ebonex for the same chloride concentration.



Two Ebonex electrodes with periodic polarity reversal and one DSA in the presence of chloride

In this section, we introduce the idea of using Ti/RuO_2 as the anode, without polarity reversal, and a pair of Ebonex electrodes that switched between cathodic and anodic polarization every 30 min. This method combines the superior efficiency of Ti/RuO_2 over Ebonex for oxidizing chloride to hypochlorite, with the ability to reverse the polarity to prevent the accumulation of lime deposits on the cathode when the water contains hardness ions.[11,12,42] Its high stability under both anodic and cathodic polarization makes Ebonex a good choice for this application.

Figure 8 shows the influence of changing the applied current in the system 50 mmol/L $NaNO_3$, 50 mmol/L NaCl, and 425 mmol/L $NaClO_4$. For currents 30, 60, and 120 mA, the rate of loss of nitrate was proportional to the current (Supplementary data Fig. S4). Ammonia was completely absent from the solution at all stages of the reaction at 30 and 60 mA but built up late in the reaction at 120 mA, presumably because the oxidation of chloride could not keep pace with the reduction of nitrate at this low chloride concentration. Overall current efficiencies (again based on $5e^-$ for nitrate to N_2 and $8e^-$ for nitrate to ammonia) were 26%, 29%, and 38% at 30, 60, and 120 mA. Consistent with this explanation, a series of electrolyses at constant current (120 mA), chloride (50 mmol/L), and $NaClO_4$ adjusted to keep the ionic strength constant showed that lowering the starting concentration of nitrate led to complete denitrification even at 120 mA (Fig. 9). The initial rates of loss of nitrate (first 60 min) were almost independent of the nitrate concentration.

Fig. 10. Batch cell electrolysis of 25 mmol/L $NaNO_3$ at 120 mA in different concentrations of NaCl. Ti/RuO_2 anode; pair of Ebonex cathodes with polarity reversal every 30 min. Nitrate (filled symbols), ammonia (open symbols). All solutions electrolyzed were at equal ionic strength ($NaClO_4$ was used). 0.5 mol/L NaCl (◆/◇), 0.05 mol/L NaCl (■/□), 0.01 mol/L NaCl (▲/△).

As observed in the Ebonex cathode – Ebonex anode experiments above, the rate of loss of nitrate was slower in NaCl solution than in $NaClO_4$ or Na_2SO_4 at the same ionic strength, and there was a significant build-up of ammonia (maximum 9–10 mmol/L from 25 mmol/L $NaNO_3$ in the latter two experiments) at intermediate conversion of nitrate (Supplementary data Figs. S5A and S5B).

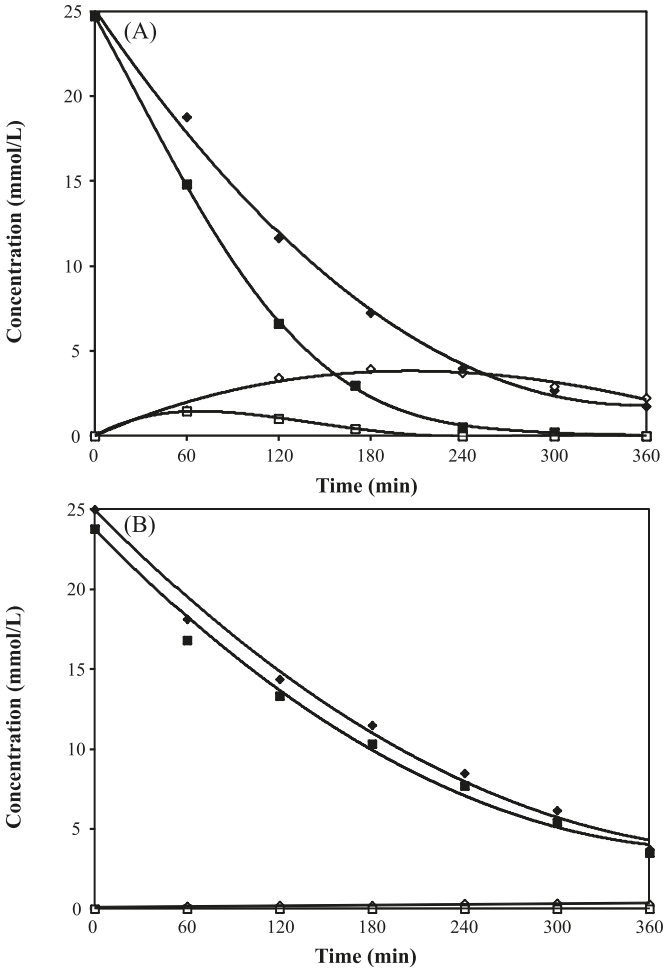

Figure 10 (which represents an series of experiments parallel to those in Fig. 6 for Ebonex–Ebonex) illustrates the effect of changing the chloride concentration at constant nitrate (25 mmol/L) and current (120 mA). At and above 50 mmol/L chloride, no ammonia is formed at any stage of the reaction. The net rate of loss of nitrate is independent of the chloride concentration at the two lower chloride concentrations but is inhibited at the high chloride concentration of 500 mmol/L. Finally, Fig. 11 gives a comparison of experiments carried out at 250 mmol/L $CaCl_2$ and 500 mmol/L NaCl for both Ebonex anode – Ebonex cathode and Ti/RuO_2 anode – two Ebonex electrodes with reversing polarity. The presence of the hardness cation Ca^{2+} slowed the reduction of nitrate and the overall rate of denitrification at Ebonex–Ebonex due to the accumulation of a lime deposit (Fig. 11A), but there was no inhibition of either process for Ti/RuO_2 anode/two Ebonex electrodes (Fig. 11B).

Conclusions

The use of Ebonex as both cathode and anode allowed a partial solution to the problem of remediating nitrate without the use of chloride. The reduction step gave ammonia in maximum yields of about 50% of the starting concentration of nitrate. Re-oxidation of ammonia at the Ebonex anode allowed complete denitrification, but the oxidation step was considerably more demanding in terms of the total charge required.

A simpler and more efficient electrolytic process was possible for solutions that contain chloride. Reduction at the Ebonex cathode once again gave a mixture of ammonia and

Fig. 11. Electrolysis of 25 mmol/L $NaNO_3$ at 120 mA with different supporting electrolytes: (A) Ebonex anode–Ebonex cathode; (B) Ti/RuO_2 anode and two Ebonex electrodes with periodically reversed polarity. Nitrate (filled symbols), ammonia (open symbols). NaCl 0.5 mol/L (◆/◇), $CaCl_2$ 0.25 mol/L (■/□).

N_2, but anodic oxidation of chloride to hypochlorite allowed efficient removal of ammonia. The hypochlorite-mediated process could be achieved using Ebonex cathode and anode as before, but even more efficiently if the anode was a dimensionally stable anode based on Ti/IrO_2 or Ti/RuO_2 — the types of anodes used for the industrial oxidation of chloride. The presence of chloride inhibited the apparent rate of loss of nitrate, because the hypochlorite thus formed re-oxidized reduction intermediates such as nitrite back to nitrate, and so the overall efficiency of denitrification was highest at moderate concentrations of chloride ion. The use of one DSA and two Ebonex electrodes, with the polarity of the Ebonex electrodes being periodically reversed, prevented cathode fouling for water sources that are high in hardness cations. The advantage of using Ebonex in this application is the ability to reverse the polarity, and hence to operate with an undivided cell, which avoids the need for a membrane that can be subject to fouling. A slightly different approach to indirect reduction has been described by Wang et al.,[43] who produced Ti(II) and Ti(III) species at a sacrificial titanium anode. The soluble titanium species can reduce nitrate anion in the bulk solution.

Abstract: Inhibition of checkpoint kinase-1 (Chk1) by small molecules is of great therapeutic interest in the field of oncology and for understanding cell-cycle regulations. This paper presents a model with elements from docking, pharmacophore mapping, the 3D-QSAR approaches CoMFA, CoMSIA and CoRIA, and virtual screening to identify novel hits against Chk1. Docking, 3D-QSAR (CoRIA, CoMFA and CoMSIA), and pharmacophore studies delineate crucial site points on the Chk1 inhibitors, which can be modified to improve activity. The docking analysis showed residues in the proximity of the ligands that are involved in ligand–receptor interactions, whereas CoRIA models were able to derive the magnitude of these interactions that impact the activity. The ligand-based 3D-QSAR methods (CoMFA and CoMSIA) highlight key areas on the molecules that are beneficial and (or) detrimental for activity. The docking studies and 3D-QSAR models are in excellent agreement in terms of binding-site interactions. The pharmacophore hypotheses validated using sensitivity, selectivity, and specificity parameters is a four-point model, characterized by a hydrogen-bond acceptor (A), hydrogen-bond donor (D), and two hydrophobes (H). This map was used to screen a database of 2.7 million druglike compounds, which were pruned to a small set of potential inhibitors by CoRIA, CoMFA, and CoMSIA models with predicted activity in the range of 8.5–10.5 log units.

Key words: anticancer agents, checkpoint kinase-1 (Chk1), docking, CoRIA, CoMFA, CoMSIA, pharmacophore modeling, database screening.

Résumé : L'inhibition de la kinase-1 du point de vérification (Chk-1) par de petites molécules est d'un grand intérêt dans le domaine de l'oncologie et dans la compréhension de la régulation du cycle cellulaire. Dans ce travail on a mis au point un modèle avec des éléments de jonction, de cartographie pharmacophore, des approches de relation quantitative structure activité tridimensionnelle (RQSA-3D) telle l'analyse comparative de champ moléculaire (ACoCM), l'analyse comparative des indices de similarité moléculaire (ACoISM), l'analyse comparative des interactions entre résidus (ACoIR) et une visualisation virtuelle afin d'identifier de nouvelles touches pour l'inhibition de la kinase-1 du point de vérification (Chk-1). Les éléments de jonction, les approches de relation quantitative structure activité tridimensionnelle (RQSA-3D) (analyse comparative de champ moléculaire (ACoCM), analyse comparative des indices de similarité moléculaire (ACoISM), analyse comparative des interactions entre résidus (ACoIR)) et les études de pharmacophore ont permis de délimiter les sites ponctuels critiques des inhibiteurs Chk-1 qui peuvent être modifiés pour en améliorer l'activité. Les analyses des éléments de jonction ont permis de préciser la nature des résidus à proximité des ligands qui sont impliqués dans les interactions ligand–récepteur alors que les analyses comparatives des interactions entre résidus (ACoIR) ont permis de déterminer l'amplitude des interactions qui influencent l'activité. Les méthodes de relation quantitative structure activité tridimensionnelle (RQSA-3D) basées sur des ligands, telle l'analyse comparative de champ moléculaire (ACoCM) et l'analyse comparative des indices de similarité moléculaire (ACoISM), permettent de mettre en évidence superficies clés des molécules qui ont des effets avantageux et (ou) préjudiciables à leur activité. Les études des éléments de jonction et les méthodes RQSA-3D sont en excellent accord en termes d'interactions de sites de liaisons. Les hypothèses tirées de la cartographie pharmacophore et validées en faisant appel à des paramètres de sensibilité, de sélectivité et de spécificité correspondent à un modèle à quatre points qui est caractérisé par un accepteur de liaison hydrogène (A), un donneur de liaison hydrogène (D) et deux hydrophobes (H). On a utilisé cette carte pour évaluer une base de données de 2,7 millions de composés ressemblant à des médicaments qui ont été élagués par l'analyse comparative de champ moléculaire (ACoCM), l'analyse comparative des indices de similarité moléculaire (ACoISM) et l'analyse comparative des interactions entre résidus (ACoIR) de façon à obtenir un petit ensemble d'inhibiteurs potentiels avec une activité prédite de 8,5 à 10,5 unités logarithmiques.

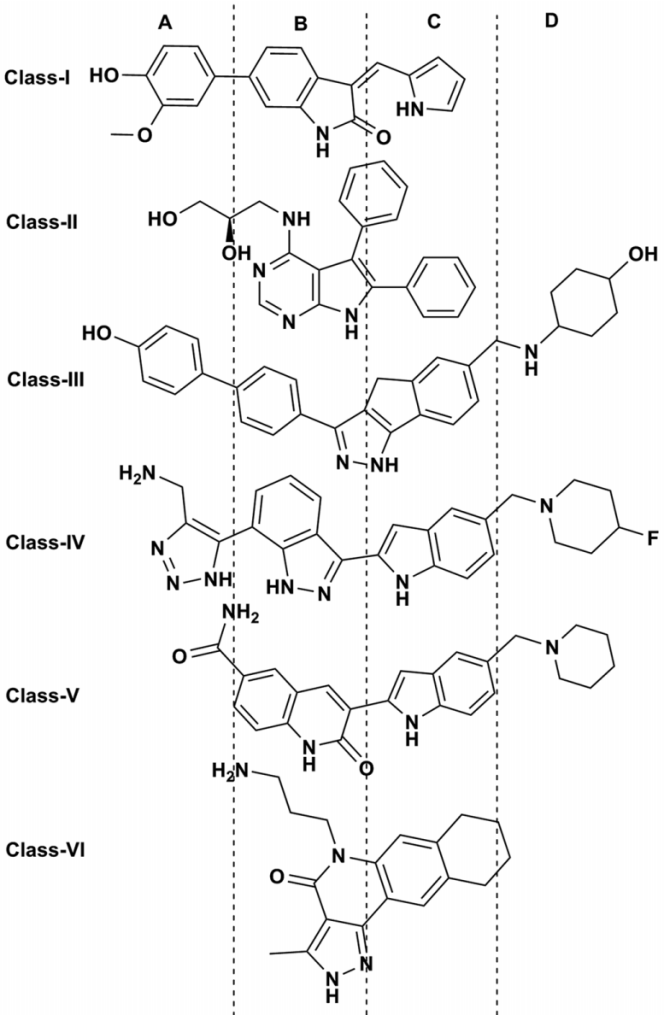
Introduction

The cellular response to DNA damage involves a delay in the cell cycle and an increase in repair and apoptosis.[1] Many of the current cancer therapies are based upon apoptosis as an outcome of induced DNA damage by the anticancer agents, but the development of resistance is a significant limitation in treatment. One important mechanism of drug resistance is the result of cell-cycle delays, which provide opportunities for cancer cells to repair DNA damage. A number of kinases respond to DNA damage in normal cells so as to arrest cycle progression. This allows the repair of DNA damage to occur either at the cell-cycle G1 phase mediated by the tumor suppressor protein p53 and (or) at the G2 and S phases mediated by the checkpoint kinase-1 (Chk1). However, tumor cells often are deficient in DNA repair at the G1 phase due to loss of the p53 function (an estimated 50%–70% of all cancers) and relies on Chk1 to induce arrest at the S and G2 phases for survival. Consequently, p53-deficient cancers are more vulnerable to Chk1 inhibition, which results in abrogation of DNA-damage-induced arrest and premature progression into mitosis, resulting in mitotic damage and apoptosis.

Several chemical classes of natural and synthetic origin have been reported as Chk1 inhibitors, for example, debromohymenialdisine,[1–3] 9-staurosporine,[4,5] 3-ethylidene-1,3-dihydro-indol-2-ones,[6] 1,4-dihydroindeno[1,2-*c*]pyrazoles,[7] 3-(indol-2-yl)indazoles,[8] thioquinazolinones,[9] pyrazoloquinolinones,[10] 6-substituted indolylquinolinones,[11] and substituted furo[2,3-*d*]pyrimidines.[12] In spite of the diverse classes of Chk1 inhibitors that have been identified, there is a need to identify inhibitors that can be developed as drugs.

Molecular modeling studies have provided insights into the ligand–Chk1 receptor recognition process and in the development of potential Chk1 inhibitors. Many such endeavors include computational studies such as classical and multidimensional quantitative structure–activity relationships (QSARs),[13] docking, de novo drug design,[14] molecular dynamics (MD) simulations,[15] and pharmacophore modeling.[16–19] Comprehensive reviews have been published recently that summarize the use of computational techniques in the development of Chk1 inhibitors.[12,18,20,21] Although a few studies[12,18,21] have hypothesized the involvement of selected amino acid residues in the receptor to be vital for ligand binding, the important residue types and the nature of interactions involved in ligand–receptor binding remain to be established.

Chen et al.[18] reported a ligand-based, four-point pharmacophore model for a set of active Chk1 inhibitors (22 molecules with an activity span of 4 log units). The model is comprised of a hydrogen-bond acceptor, a hydrogen-bond donor, and two hydrophobes along with an excluded volume. Chen et al.[19] also proposed a pharmacophore model based on a consensus study of an overlay of 35 X-ray crystal structures, with additional information extracted from the target enzyme of Chk1. Although both the reported models have the same four features, the second hypothesis includes shape and 12 excluded volume features. The hydrogen-bond features located on the ligand are designed to bond with the backbone CO of Glu85 and the backbone NH of Cys87 of Chk1, whereas the two hydrophobes were mapped to the aromatic cores of the molecule.



The present study is a step-by-step approach to identify novel Chk1 inhibitors. To state briefly, 70 molecules from different structural classes were docked into the active site of Chk1 to identify probable binding poses. Models equating the activity to interaction elements like van der Waals (vdW), coulombic forces, and hydrogen bonding were built using the 3D-QSAR tool, comparative residue–ligand interaction analysis (CoRIA).[22–24] Several other activity models using only ligand features were recognized with the 3D-QSAR tools, comparative molecular field analysis (CoMFA)[25] and comparative molecular similarity indices analysis (CoMSIA),[26] based on the alignment strategy derived by the previously conducted docking studies. Having built the necessary models to predict active molecules, we extended the studies to develop pharmacophore models that could be used to screen databases of druglike molecules not amenable to 3D-QSAR approaches. The pharmacophore models for Chk1 were developed using both the receptor- and ligand-based approaches to realize similarities and differences in the two approaches. The hypotheses were developed based upon five different crystal structures of Chk1 bound with potent ligands and were validated using a database of both active and inactive molecules. Subsequently, the same set of ligands was used to build further hypotheses using the ligand-based pharmacophore approach involving (*i*) the receptor-bound conformations of the ligand ignoring the receptor conformation and (*ii*) generation of multiple conformers. All hypotheses (receptor- and ligand-based) were screened against a decoy data set spiked with actives, and the resulting enrichment factor (EF) was calculated. Finally, a large database of druglike compounds was screened using the best hypothesis (receptor-based) leading to a set of virtual hits, whose activities were predicted using the earlier developed CoMFA, CoMSIA, and CoRIA models. The ligands predicted to be active are suitable for experimental investigations based on the predicted absorption, distribution, metabolism, and excretion (ADME) properties.

Materials and methods

The docking studies were carried out with the docking program Glide v5.6[27–29] in the Schrödinger Suite 2010 (Schrödinger LLC, USA) running on an Intel Xeon processor-based workstation with CentOS Enterprise Linux 5.5. The CoRIA models were built based on the docked poses of

the ligands with Cerius2 (v4.11; Accelrys Inc., USA) running on an AMD Athlon processor-based workstation with CentOS Enterprise Linux 4.9. The 3D-QSAR (CoMFA and CoMSIA) studies were accomplished with Sybyl v7.1 (Tripos Inc., USA) running on an AMD Athlon processor-based workstation with CentOS 4.9 Enterprise Edition Linux 4.9. Pharmacophore mapping and database screening were done with the pharmacophore module in Discovery Studio (v3.0; Accelrys Inc.) running on an eight-node high-performance computing cluster (HCL Infosystems Ltd., India) with an Intel Xeon processor and CentOS Enterprise Linux 5.4.

Chk1 inhibitors

Chk1 inhibitors and their activities were compiled from literature reports.[6–8,10–12,21] Six different classes of Chk1 inhibitors were considered for this study (Fig. 1 and Table 1): class I, 3-ethylidene-1,3-dihydroindol-2-ones; class II, substituted furo[2,3-*d*]pyrimidines; class III, 1,4-dihydroindeno [1,2-*c*]pyrazoles; class IV, 3-(indol-2-yl)indazoles; class V, 6-substituted indolylquinolinones; and class VI, pyrazoloquinolinones, along with other miscellaneous compounds that exhibit pronounced Chk1 inhibition (Table 1). The molecules were then partitioned into training (50) and test (20) sets with the ratio of molecules at approximately 3:1. The segregation of molecules into training and test sets was based on structural diversity, physicochemical properties, and span of activity and was carrid out with the "ligand diversity selection" tool in Discovery Studio v3.0. The structures of the molecules in the training (50) and test (20) sets are provided in Table S1 of the Supplementary data.

Protein and ligand preparation

The X-ray crystal structures (PDB codes: 2AYP, 2BRB, 2C3L, 2C3K, 2C3J, 2E9O, 2HOG, 2HY0, and 2QHN) of Chk1 bound to different inhibitors were obtained from the Protein Data Bank (http://www.rcsb.org/pdb). The structures were prepared for the docking studies with the Protein Preparation Wizard in the Schrödinger Suite of programs. The crystal waters were removed, hydrogen atoms were added, and atom types and partial charges were assigned based on the OPLS2005 force field. The formal charges for the acidic and basic amino acids were set according to the physiological pH 7.4. The N- and the C-terminii were capped with the acetyl (ACE) and the *N*-methylamino (NMA) groups, respectively. Subsequently, the system was relaxed using energy minimization until an energy gradient of 0.01 kcal/mol/Å (1 cal = 4.184 J) was reached with the OPLS2005 force field.

The Chk1 inhibitors used in docking studies were prepared using the LigPrep v2.4 in Maestro (Schrödinger 2010 Suite). The atom types and partial charges were assigned based on the OPLS2005 force field, corresponding to the physiological pH 7.4. A set of diverse conformations and tautomeric states were generated for the ligands using the LigPrep in Schrödinger Suite.

Docking studies

In the initial phase of docking, the grid was generated with the bound ligand defining the grid center. The inner grid box was set to 10 Å and the outer grid was set to 20 Å in size, thus providing ample space for the generation of diverse ligand conformations in the binding pocket by the search and score algorithm. The vdW radius was scaled to 1.0 Å to soften the potential over the nonpolar areas of the enzyme that lie within the grid extents and the partial atomic charges were set to 0.25 of the exact value. The receptor atoms beyond the extent of the grid were unscaled. To maximize the probability of forming hydrogen bonds between the residues in the enzyme active site and the ligand, the side-chain hydroxyl groups of the amino acids serine, threonine, and tyrosine were allowed to rotate. The docking settings were validated based on the protocol's ability to reproduce the X-ray conformation of the bound ligand in the enzyme active site. On optimization of the protocol, the Chk1 inhibitors were docked to find the best poses, which were scored on-the-fly with scoring function GlideScore SP. Energies associated with electrostatic, van der Waals, and hydrogen-bonding interactions were computed between every amino acid in the active site and the ligand. These energies formed the input for the development of the CoRIA models.

with the inhibitors, were probed with CoRIA.[22–24] The CoRIA descriptors, i.e., the nonbonded interaction energies (vdW, coulombic (Coul), and hydrogen bond) of Chk1 inhibitors with individual residues in the active site of the Chk1, were computed using Glide v5.6 on the individual enzyme–ligand complexes. These descriptors were then correlated with the biological activity using G/PLS as the chemometric method in Cerius2 v4.11.[30,31] Initially, 500 equations were randomly generated on a training set of 50 molecules. These solutions were evolved for 20 000 generations through a process of crossover and mutation to generate the final models. The models were optimized for the number of PLS components and the length of the equations, which were varied from 2 to 6 and 4 to 10, respectively. The final models were validated using leave-group-out (LGO) and randomization. The models were also tested for their predictive power on an external test set of 20 molecules.[30,31] Additional metrics like r^2_m (for training and test sets) and r^2_p (for randomization) were implemented to assess the robustness of the models.[32,33]

CoMFA and CoMSIA studies

The 3D-QSAR studies CoMFA[25] and CoMSIA[26,34–36] were carried out on the receptor-based alignment, an overlay of the molecules obtained from the docking studies. The steric and electrostatic fields were computed with the default settings of the 3D cubic lattice, grid spacing, the probe atom, and the cutoff. For the CoMFA studies, only steric and electrostatic fields were computed, whereas, for CoMSIA, hydrophobic, and hydrogen-bond donor and acceptor fields were computed in addition to the steric and electrostatic fields. The CoMFA and CoMSIA descriptors were used as independent variables and the pIC_{50} ($-\log(IC_{50})$ in molar concentration) values as the dependent variable in a partial least-squares (PLS) regression analysis[37] to derive the 3D-QSAR models. The optimal number of components was determined by SAMPLS,[38] which was subsequently used to derive the final QSAR models. In addition to q,[2] the conventional correlation coefficient r^2, the standard errors (SE), and the F value were also computed. The robustness of the models was gauged by cross-validation using the leave-one-out (LOO) and the LGO of 10 groups and bootstrap[30,39] carried out with 100 runs. Additional validation metrics as suggested by Roy and co-workers[32,33] were also carried out.

Pharmacophore modeling

Pharmacophore generation

The pharmacophore models were built in Discovery Studio v3.0 using two approaches. The first approach, referred to as the receptor–ligand pharmacophore generation protocol, is a receptor-dependent technique that dwells on the information on features extracted from enzyme–ligand complexes. In the present study, the pharmacophore hypotheses were developed using the X-ray structures with PDB codes 2AYP, 2E9O, 2HOG, 2HY0, and 2QHM. In the pharmacophore modeling, all standard features, i.e., hydrogen-bond acceptor, hydrogen-bond donor, hydrophobic feature, negative and positive ionizable features, and aromatic ring, were considered. The minimum number of features was set to 4 and the maximum to 10. The pharmacophore models were ranked using a rule-based scoring function. The scoring function is based on a GFA model, which is a function of all the features in the pharmacophore model and the corresponding distances between them. The effect of the shape constraint was also evaluated during the study. The pharmacophore models were validated using a defined set of active and inactive ligands. A flexible-fit approach was used to achieve correspondence between the ligands used for validation and the pharmacophoric features of the models. A ligand-dependent technique known as common feature pharmacophore was also used as a complementary approach. The hypotheses were generated either from the receptor-bound conformations or from multiple conformations of the ligands generated by a systematic search ensuring maximum coverage of conformational space. A set of 10 hypotheses was generated in each case.

Validation of pharmacophore hypotheses

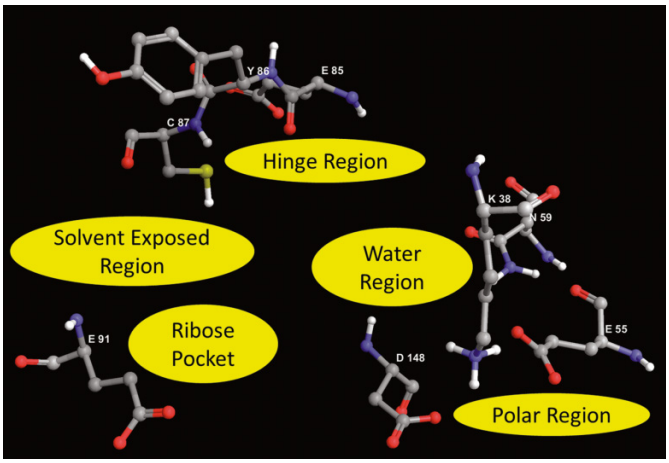
The selectivity and sensitivity of the hypotheses were determined based on the efficiency of the models to select known actives and inactives for the target enzyme (Chk1). Also, all hypotheses were screened against a decoy data set of 2000 molecules with an average MW of 300, which was spiked with 25 actives ($pIC_{50} \geq 6.0$). Subsequently, the enrichment ratio (EF) was determined for all hypotheses as given by

$$[1] \qquad EF = (H_a D_t)/(H_t D_a)$$

where H_a is the number of actives, H_t is the total number of hits, D_t is the total number of molecules in the database, and D_a is the total number of active molecules in the database.

Database screening

The best pharmacophore model (receptor-based model) was used to screen the '"iResearch Database" (ChemNavigator, USA) having approximately 2.7 million druglike compounds. The fished out virtual hits were docked into the active site of Chk1 in their pharmacophore-constrained conformation. The activities of the hits were further predicted by the previously validated 3D-QSAR models of CoRIA, CoMFA, and CoMSIA. A few representative molecules with activities (consensus) predicted in the 8.5–10.5 range are depicted in Table 2. The hits obtained from the virtual screen have a Tanimoto similarity coefficient in the range 0.4–0.6 with reference to the training set molecules.



Results and discussion

The ATP-binding pocket of Chk1 can be roughly divided into five regions: the solvent-exposed region, the hinge region, the water pocket, the polar region, and the ribose-binding pocket (Fig. 2). The solvent-exposed region is adjacent to the hinge region, and the introduction of the polar group in this region is expected to enhance kinase activity and also improve biophysical characteristics.

The water pocket, which is unique to Chk1, is occupied by three water molecules and buried at the periphery of the ATP binding site. It has been demonstrated that filling this pocket with functional groups can confer ligands with an enhanced affinity for Chk1. In addition, to obtain high potency, it is required that the ligands form hydrogen bonds with amino acid residues in the polar region. Ligands that can participate in ionic interactions with the acidic residue Glu91 or form

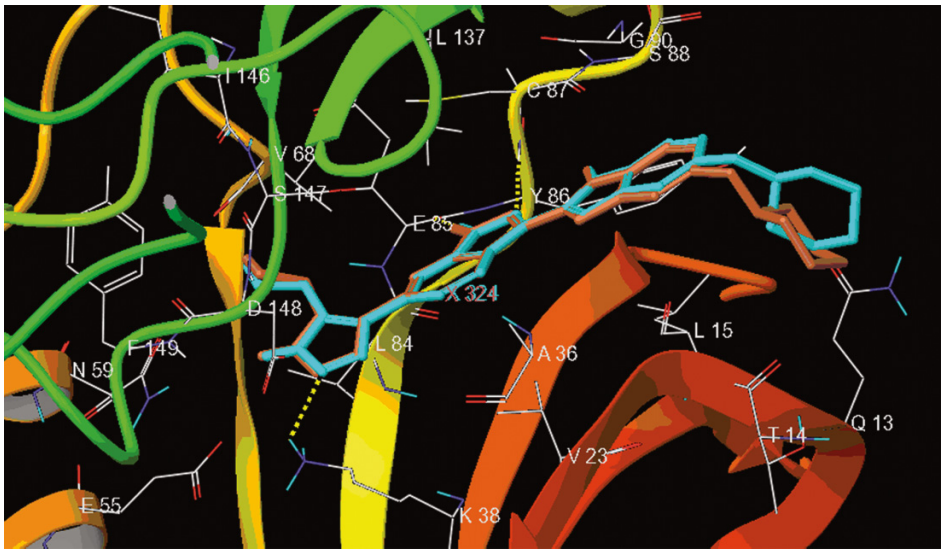
Fig. 2. The ATP binding site of checkpoint kinase-1 (Chk1) depicting critical regions of amino acids that bind ligands and water molecules.

hydrogen bonds with the side-chain carbonyl oxygen of Glu91, situated in the ribose binding pocket, can potentially enhance the potency of the compound. It has been revealed that this region is of great significance, since functional groups designed to interact with residues in or in proximity to the ribose-binding pocket are desirable, although not a specific requirement for inhibition of Chk1.

The docking and 3D-QSAR studies reported by Du et al.[13] were based on 5,10-dihydrodibenzo[*b*,*e*]-1,4-diazepin-11-ones as Chk1 inhibitors. The study revealed strong hydrophobic interactions between the inhibitors and residues Leu15, Val23, Tyr86, Leu137, and Asp148 in the enzyme. The molecules also form hydrogen bonds with the backbone CO or NH groups of the amino acids Thr14 and Cys87. The CoMFA analysis also highlighted the fact that amine or amide groups placed at the terminal fragment of the molecules (polar region) strongly modulate the activity.

Chen et al.[18] reported a five-point pharmacophore model with a hydrogen-bond acceptor, hydrogen-bond donor, two hydrophobes, and an excluded volume, which was developed by a multiple conformation approach. These features were mapped onto the active site of Chk1 using (*i*) the hydrogen-bond interactions in the hinge region involving the carbonyl group at the second position on the quinolin-2(1*H*)-one moiety with the backbone NH of Cys87 and (*ii*) the N^1H of the quinolin-2(1*H*)-one with the backbone CO of amino acid Glu85, which make up the hydrogen-bond acceptor and donor features, respectively. The two hydrophobic regions are mapped to the aromatic ring (fragment C in Fig. 1) that binds in the pocket formed by Leu15, Gly89, and Gly90. The second hydrophobic region is located on the 6-chlorine substitution on the quinol-2-one nucleus (fragment B in Fig. 1), which binds in the region lined by the amino acids Val40, Val68, Phe70, Leu82, and Leu84. Another pharmacophore hypothesis by Chen et al.[18] was developed by clustering multiple structure-based pharmacophore models that have been derived from different Chk1 ligand complexes in comparable binding modes. Similar to the earlier model, the hydrogen-bond acceptor and donor features were positioned in the hinge region of the active site, whereas one hydrophobe was located near the amino acids Tyr20 and Val23 and the other near Leu15 and Leu137. In addition, Chen et al.[18] also proposed that the positive ionizable feature on the ligand that interacts with the ribose-binding site had no significant contribution to activity. In our study, the quality of the hypothesis has been further improved by the inclusion of excluded volumes.

Docking studies



In our study, the binding modes were analyzed and compared based on the six structural classes by docking the inhibitors into the active site of Chk1. The active site of Chk1 is a groove that is formed by a bundle of β-strands and an α-helix composed of hydrophobic amino acids, namely, Leu15, Val23, Ala36, Val68, Leu84, Cys87, Gly90, Leu137, and Phe149, a positively charged amino acid Lys38, negatively charged amino acids Glu55, Glu85, and Asp148, and polar amino acids Gln13, Thr14, Tyr86, Ser88, Asn135, and Ser147. Before docking the inhibitors, the protocol was tested on the X-ray crystal structures with PDB codes 2AYP, 2BRB, 2E9O, 2HOG, 2HY0, and 2QHN.[6–8,10–12,21] Upon analysis, it was observed that the docking poses had a root-mean-squared displacement (RMSD) less than 1.0 from the crystal pose (Fig. 3). Following this, all Chk1 ligands (structures provided in Supplementary data Table S1) were docked and the classwise binding interactions analyzed (Table 3).

Based on the overlay of the crystal structures, the binding-site analysis revealed that fragment A of ligands with groups such as hydroxy, hydroxymethyl, amine, or methylamine are able to interact with various amino acids in the polar region through prominent and regular hydrogen bonds, namely, with the ω-nitrogen of Lys38 and the δ-carboxylate of Glu55 and hydrogen bonds with the γ-carboxamide of Asn59, β-hydroxy of Ser147, and the backbone NH of Asp148 and Phe149. For most ligands, fragment A is surrounded by hydrophobic amino acids (Leu62, Val68, Leu82, Leu84, Ile146, and Phe149), of which the prominent interactions were with Val68, Leu84, and Phe149. However, these interactions are missing in class VI molecules as they do not have fragment A. Hydrogen-bond interactions involving fragment B are seen in the hinge region of the Chk1 active site formed by the backbone of amino acids Glu85 and Cys87. This is a crucial interaction for Chk1 inhibition irrespective of the class, which has also been highlighted by Chen et al.[18] Hydrophobic interactions of fragment B are seen with Val23, Ala36, and Leu137. The hydrogen-bonding interactions for fragment C are sparse and almost absent for fragment D. The hydrophobic amino acids Leu15, Val23, and Tyr86 are in close proximity to fragment C. Fragment D is seen to surface out from the binding pocket of Chk1 as a result of which the binding-site analysis does not reveal any specific interaction for fragment D. However, it can be noted that the molecules bearing fragment D have pIC_{50} values greater than 8 log units. The presence of fragment D in a molecule simply alters the partition coefficient through an increase in the hydrophobicity and this causes an increase in the activity. This aspect cannot be deciphered from the docking studies.

CoRIA studies

CoRIA models were developed using the interaction energies Coul, vdW, hydrogen bond, and total energy (E_{Int}) between the

Fig. 3. A view of the docking pose in relation to the crystal structure for the ligand 5-{3-[5-(piperidin-1-yl-methyl)-1*H*-indol-2-yl]-1*H*-indazol-6-yl}-2*H*-1,2,3-triazol-4-yl)methanol.

ligands and residues in the enzyme active site as descriptors. These were correlated to the biological activity through G/PLS.[30,31] Statistically significant models were obtained by optimization of the training-set molecules, the number of PLS components, and the length of the equations. The best models were obtained on a training set of 50 diverse sites (structural fingerprints and physicochemical properties), with four and five PLS components and with five to eight terms, respectively. The CoRIA models have acceptable regression coefficients (r^2), which lie in the range 0.81–0.87, and cross-validation coefficients (q^2) between 0.69–0.71. Some representative CoRIA models along with their statistics are presented in Table 4. Additional computed metrics, such as r^2_m and r^2_p, also have values greater than 0.5, indicating robustness of the model[32,33] (Table 4). The plots for experimental versus predicted activity are given in Fig. 4.

The use of a genetic algorithm in model building permitted the visualization of the rise and decay of descriptors (the evolution) during the model-building process. The descriptors that were retained after genetic evolution and formed part of the final CoRIA models helped in analysing and interpreting the type and point of interaction between the ligands and amino acids in the active site. The significant descriptors evolved over the 500 models were classified into two groups (major and minor) based on their frequency of appearance in the models so as to understand their influence on the activity.

The amino acids that predominantly appeared with coulombic interactions with the inhibitors are Tyr20, Gly21, Val35, Ile39, Val68, Lys132, and Leu137, whereas Asn143, Leu144, Lys145, and Ser147 exhibited vdW interactions that enveloped fragments A and B. The amino acids Leu15, Gly21, Leu64, Glu85, Thr170, and Ser193 exhibited both Coul and vdW interactions. Analysis of models 1 and 2 given in Table 4, showed that the total E_{Int} with amino acids Leu15 and Gly21 had a negative coefficient, which indicates that enhancing this interaction would improve the activity. Amino acids Leu15 and Gly21, which appeared in the vicinity of fragments C and D and resulting in classes II and VI molecules being devoid of fragment D, showed lower activity. The coefficients of terms associated with vdW interaction, e.g., for Tyr20 and Lys145, were positive and negative, respectively. This meant that vdW interaction with Tyr20 can have a negative impact on the activity owing to a steric clash with fragment A. On the other hand, the Coul interaction of molecules with Val35 had a positive impact on the activity.

Statistical analysis revealed that there are two molecules predicted as outliers by model 2 (Table 4) and one molecule by model 1 (Table 4), by 2 log order deviation from the reported experimental activity. This residual in the prediction arises from the large vacuous nature of the binding pocket. This means that the outlier molecules have adopted conformations different from similar molecules in their series. This deviation in the binding pose has a direct impact on the computed binding site interactions, which further impacts the activity predicted by the QSAR models.

In summary, our studies suggest that structural modifications that enhance the E_{Int} for fragment C with residues Leu15 and Gly21 (characteristic for most active molecules) and decrease the vdW interaction of fragment A with Tyr20 (prominent in the low active molecules) will help in improving the activity (Table 5).

3D-QSAR (CoMFA and CoMSIA) studies

The CoMFA and CoMSIA models were generated over a training set of 50 Chk1 inhibitors belonging to six classes. The molecules in the training and test sets were aligned based on the receptor-based overlay,[40] a technique that has been proven better over the standard atom-fit alignment. The standard atom-fit alignment cannot be implemented for the Chk1 inhibitors as their cores are structurally diverse, and hence the 3D-QSAR studies were carried out on the receptor-based alignment (Fig. 5). Different models were generated using Gasteiger, Gasteiger–Hückel, and MMFF94 charges. All models were internally validated by LOO, LGO, and bootstrap analysis. The results indicate that CoMFA models have poor statistics compared with CoMSIA models, which is probably because of the inability of CoMFA to explicitly

with respect to the most active and least active molecules in the training set to understand differences in the field distribution associated with the different fragments and their correlation with the activity of the molecules. The contours are depicted in Figs. 6 and 7 for the CoMFA and CoMSIA models, respectively. The steric and electrostatic contours positioned in the Chk1 active site show that the nature of the contours complements the nature of the amino acids over which they superimpose, and it now becomes possible to comprehend the 3D-QSAR results in light of the protein–ligand interactions (Fig. 8).

Steric field

The CoMFA steric fields around the molecule are represented by green and yellow contours that differentiate bulk in a favourable or unfavourable way, respectively (Fig. 6). Inspection of the contours around the most active molecule reveals that bulk is favoured around fragment D; this fragment, which is absent in classes I, V, and VI, is responsible for their low activity, which is <5 log units. In Fig. 6, patches of green in the vicinity of the terminal portion of fragment A indicate that fragments with one or two carbon units, namely, methyl or ethyl, can be accommodated in this region. This observation is supported by the more active molecules. The yellow contours, which represent the disfavoured bulk brackets of the molecule at fragments B and C, indicating that the substitution at this area would cause steric hindrance as the fragment B–C itself snugly fits among hydrophobic residues in this region of the active site of Chk1. Similar steric contours are seen in case of the CoMSIA model (Fig. 7).

Electrostatic field

The Chk1 inhibitors studied here have fragments B and C composed of heteroaromatic rings that are linearly linked to each other. The blue electrostatic contours (Fig. 6) seen in these fragments arise from the acidic nitrogen atoms in the heteroaromatic cores. This part of the molecule is involved in hydrogen-bond interaction with the amino acids Glu85 and Cys87, which form the part of the hinge region in the active site. In the least active molecules, fragments B–C have electronegative groups (e.g., NO_2), which are incompatible with the blue contours in CoMFA. The electrostatic contours in CoMSIA (Fig. 7) depict small red patches that represent electronegative atoms near fragment A, which has electronegative groups, e.g., the electronegative pyrazole ring atoms in the more active molecules. This represents the electronegative microenvironment that is desirable for interaction (hydrogen bonds) with the positively charged amino acid Lys38.

Hydrophobic field

CoMSIA contours provide information about the hydrophobic characteristics of Chk1 molecules. The yellow contours (Fig. 7) that characterize hydrophobic fields enclose the aromatic cores of fragments A, B, and C, which snugly fit the active site. The contours that represent hydrophilic fields (white) are concentrated near the heteroatoms of fragments A and B. The hydrophilic contours are in line with the characteristics of the Chk1 active site, which has an anchoring polar site, a water region (with Lys38), and a hinge

region (with Glu85 and Cys87). A relationship also exists between the hydrophobic contours and the remaining portion of the active site.

Hydrogen-bond donor and acceptor fields

The Chk1 inhibitors interact with the active-site residues using significant numbers of hydrogen-bonding interactions. Thus, QSAR contours that depict hydrogen bonds and their characteristics (acceptor or donor) can help correlate the relationship between H-bonding interactions and biological activity.

The hydrogen-bond donor fields are represented by cyan and purple contours (Fig. 7). Cyan-coloured contours are seen near the heteroatom (acidic nitrogen atom) on fragment

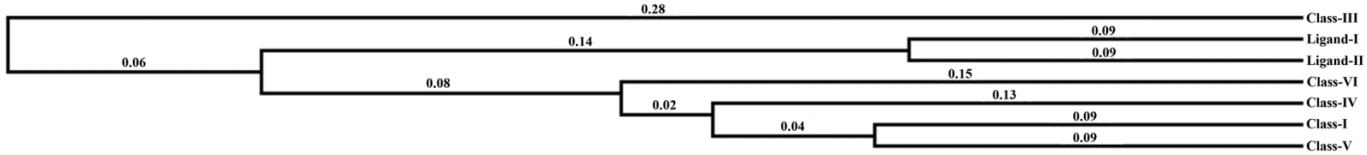
Fig. 10. Dendrogram showing the clustering of the seven pharmacophore hypotheses.



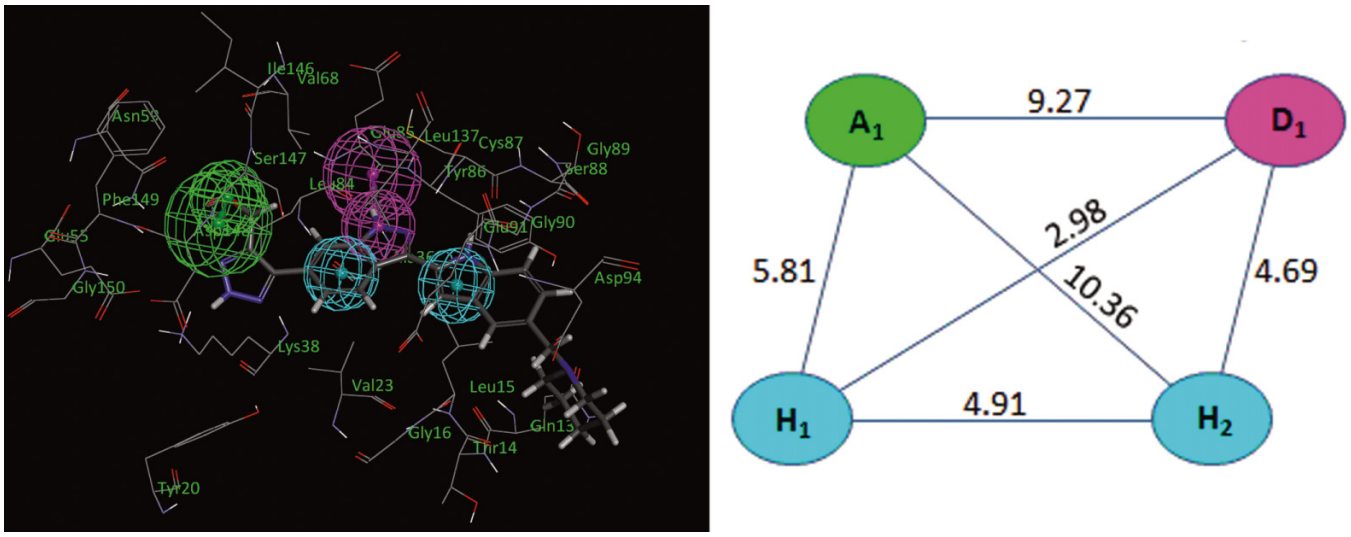


Fig. 11. Features and distances for the best pharmacophore hypotheses (ADHH). A, hydrogen-bond acceptor; D, hydrogen-bond donor; and H, hydrophobe.

B, which can be correlated with the hydrogen bond with the backbone CO of Glu85 (Fig. 7 and Table 3). There seems to be no additional requirement for hydrogen-bond donor groups in the remaining region of the molecule as seen by the absence of purple contours.

Extending the analysis further to hydrogen-bond acceptor fields, magenta contours are concentrated at the basic nitrogen or oxygen atoms on fragments A and B and the amine (–NH–) bridge that links fragment C with D. This primarily represents the interaction of Chk1 inhibitors with amino acids like Lys38, the backbone NH of Asp148 or Phe149 for fragment A, and the backbone NH of Cys87 for fragment B (Fig. 7 and Table 3).

Pharmacophore-modeling studies

The current study used both receptor-dependent and -independent techniques to develop pharmacophore models. In the receptor-based technique, the features in the Chk1 ligand complexes that correspond to significant interactions were transformed into hypotheses. In the ligand-based approach, models were developed using both rigid and flexible conformations for a selected set of active ligands. Overall, it was found that, irrespective of the approach used for hypothesis development, the models possessed the same set of pharmacophoric features, namely, hydrogen-bond donor, hydrogen-bond acceptor, and two hydrophobes, which also correspond to the models reported by Chen et al.[18] However, the major differences between the hypothesis generated in the current study and that reported by Chen et al.[18] are related to the spatial location and interfeature distances. The specificity and selectivity of these models were computed for a set of Chk1 analogs categorized as actives and inactives. A comparative analysis of the pharmacophores developed by the two approaches shows that the receptor-based pharmacophore evolves as a superior hypothesis, which is attributed to the fact that the method captures crucial ligand–receptor interactions besides ligand configuration.

Receptor–ligand pharmacophore

Based on the ligand features that correspond to receptor–ligand interactions, a set of pharmacophoric hypotheses were generated for each of the five X-ray crystal structures (PDB codes 2AYP, 2E9O, 2HOG, 2HY0, and 2QHM). The hypotheses were subsequently validated using a set of both active and inactive ligands. The pharmacophore hypothesis generated for each class is discussed as follows.

Class I (3-ethylidene-1,3-dihydroindol-2-ones)

Among 18 pharmacophoric features that were detected for the ligand 2AYP, only seven involved interactions with amino acids in the Chk1 active site. Among the set of 10 pharmacophore hypotheses generated, the DDHH hypothesis was mapped most frequently to the ligand and its interactions with the active site (Table 7). The best four-point model (DDHH, Fig. 9) mapped to the ligand (3*Z*)-6-(4-hydroxy-3-methoxyphenyl)-3-[(1*H*-pyrrol-2-yl)methylene]-1,3-dihydro-2*H*-indol-2-one (class I, Fig. 1) has two hydrogen-bond donor features (D) that involve the 4-hydroxyl group of the phenyl ring (fragment A) and the 1-NH group of the indol-2-one ring (fragment B) with one vector oriented towards the δ-carboxylate of the amino acid Glu55 (polar region) and the second vector pointing to the carbonyl group in of the backbone of Glu85 (hinge region). The two hydrophobes (H) are closely spaced and appear on the phenyl ring (fragment A) and the 3-methoxy substituent that interacts with

Asn59, Val68, Phe70, and Phe149. Validation of this hypothesis using a decoy data set showed an above average (>0.60) sensitivity and excellent selectivity (>0.90), (Table 7). The EF for this model is, however, in the range of average acceptable value (<0.60). A set of 30 excluded volume features were found to align the binding pocket of the Chk1 active site, except for the areas where the significant amino acids that interact with the ligand are located.

No validated pharmacophore hypothesis could be generated for class II ligands using the receptor-based approach and will not bediscussed further.

*Class III (1,4-dihydroindeno[1,2-*c*]pyrazoles)*

Of the 19 pharmacophoric features identified for the Chk1 ligand complexes, five could be mapped to significant enzyme–ligand interactions, namely, AHHH, where A is the hydrogen-bond acceptor. This gives two models, each with four features that map the ligand interactions with the active site. The statistically acceptable four-point model (AHHH) is mapped to the ligand 4-(6-{[(4-methylcyclohexyl)amino]methyl}-1,4-dihydroindeno[1,2-*c*]pyrazol-3-yl)benzoic acid as follows: the hydrogen-bond acceptor feature is mapped to the 4-carboxylate group on fragment A that associates as an hydrogen bond with the side-chain NH_3^+ group in Lys38. The hydrophobes are located over the centroid of the phenyl ring (fragment A) and the centroid of the dihydroindeno[1,2-*c*]pyrazole nucleus (fragment B/C). The interacting hydrophobic amino acids are Leu15, Val23, Ala36, Val68, Leu84, Tyr86, and Leu137. In all, 25 excluded volumes were mapped to the binding pocket for residues that do not have any significant interactions. The class III hypothesis (AHHH) is different from the class I hypothesis (DDHH). In this case, statistics reveal an EF value with sensitivity and specificity above average (>0.70).

Class IV (3-(indol-2-yl)indazoles)

The most active Chk1 inhibitors belong to class IV. Seven significant features, namely, AADDHHH, which represent the essential receptor–ligand interactions, were mapped to the ligand 5-{3-[5-(piperidin-1-yl-methyl)-1*H*-indol-2-yl]-1*H*-indazol-6-yl}-2*H*-1,2,3-triazol-4-yl)methanol from among the 33 pharmacophoric features. All the 10 hypotheses are different, but as per the statistics, ADHH is the best-fit hypothesis developed for this class, which was also reported by Chen et al.[18,19] However, these features appear to be located at different sites in the ligand with different interfeature distances in comparison with the model reported and discussed by Chen et al.[18,19] A has been mapped to the hydroxymethyl group on the triazole nucleus (fragment A), which forms a hydrogen bond with the backbone NH of Asp148, whereas D is the NH^1 group of indazole (fragment B), which interacts with the backbone CO of Glu85. The two Hs are present on the phenyl ring of indazole (fragment B) and the pyrrole ring of indole (fragment C). Nearly 27 excluded volume features are found to align the binding site. The hypothesis ADHH built on the class IV ligand has an excellent EF value with high sensitivity and selectivity.

Class V (6-substituted indolylquinolinones)

There are about 18 pharmacophoric features for the ligand 3-[5-(piperidin-1-yl)methyl]-1*H*-indol-2-yl-6-(1*H*-pyrazol-4-yl)quinolin-2(1*H*)-one, of which the four-feature hypothesis that matches the receptor–ligand interactions is AHHH. The best model among the six has A pointing to the carbonyl function of the quinolone nucleus (fragment B) and is oriented towards Cys87 in the hinge region of the receptor. The three hydrophobic points are located at the centroids of the quinolone ring (fragment B), the indole nucleus (fragment C), and the pyrrole ring of the indole nucleus (fragment C), which are surrounded by Leu15, Val23, Ala36, Val68, Leu84, and Leu137; also lining the active site are 25 excluded volumes. This hypothesis (ADHH) shows an excellent EF value (77%) with high sensitivity and selectivity.

Class VI (pyrazoloquinolinones)

In this case, unlike other classes, only one hypothesis model was built for the ligand (3-endo)-8-methyl-8-azabicyclo[3.2.1]oct-3-yl-1*H*-pyrrolo[2,3-*b*]pyridine-3-carboxylate. Of the 12 pharmacophore features for the ligand, only a single hypothesis could be formed with four features, namely, ADHP. The A feature is depicted by the nitrogen atom of the pyridine ring of the pyrrolopyridine nucleus of fragment B. This group forms a cohesive bond with the backbone NH of Ala36 and Tyr86. The D feature is based at the acidic proton NH^1 of the pyrrolopyridine nucleus, with Lys38/Glu85 amino acids as the acceptors. The third important feature, the hydrophobic site, is located at the pyridine ring of the pyrrolopyridine nucleus, which closely interacts with Val23. A positive ionizable feature is seen over the 8-azabicyclo[3.2.1]octane ring (fragment C), which is surrounded by Glu134, Asn135, and Lys136. Even though the hypothesis shows excellent overlay with the corresponding features in the ligands and the receptor, it has a poor EF value because of the absence of fragments A and D.

Common feature pharmacophore

The hypotheses were initially generated using the bound-state conformations of the ligands, which involved the overlay of the Chk1 inhibitors in rigid conformation only allowing a translation or rotation of the molecules to search for the overlap of a common feature among the inhibitors. Only three pharmacophoric features were found to be in agreement with the various models, namely, two Hs and one A. Of the 10 models, the best model had a good fit over the ligands 2HOG, 2HY0, 2AYP, and 2QHM. The 2E9O ligand did not fit the hypothesis, probably because of the rigidity seen in the tricyclic indazole ring. With a three-point pharmacophore model as a query, the chances of obtaining a "false positive" during virtual screen is higher compared with a four- or five-point pharmacophore hypothesis. As a result, the usefulness of the model was not considered for developing new pharmacophore models.

Alternative strategies were generated with a search for low-energy conformations of ligands that were then overlaid to develop other hypotheses. By this strategy, it was possible to develop models with four pharmacophoric features, namely, two Hs and two As. In this study, 10 hypotheses were generated, nine as four-point models and the 10th as a three-point model. Seven of the hypotheses had features that were identical to the models developed using the receptor–ligand strategy. The best four-point pharmacophore model possessed one hydrogen-bond donor, one hydrogen-bond acceptor, and two hydrophobe features (ADHH), with a good fit over all

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

the selected ligands (2AYP, 2E9O, 2HOG, 2HY0, and 2QHM). The common feature model, which was based on the sampling of multiple conformations for the molecules, has features and spatial distances similar to the best receptor-based hypothesis, except that the hydrogen-bond donor and acceptor features are swapped in fragment B. The EF statistics for this model are the same as that for the model built using the 2HOG crystal structure.

Comparison of pharmacophore models

The best pharmacophore model developed for Chk1 ligands using the ligand- and receptor-based hypotheses were clustered to assess similarity in the features and the interfeature distances. For the purpose of clustering seven hypotheses, five belonging to the receptor-based category and two to the ligand-based category were selected. Based on the RMSD between the matching features, a distance function (d_{ij}) was generated to cluster the hypotheses, which split the models into five bins (Fig. 10). The first cluster had the receptor-based hypotheses for both class I (DDHH, 3-ethylidene-1,3-dihydroindol-2-ones) and class IV (ADHH, 3-(indol-2-yl)indazoles) with $d_{ij} = 0.09$, as both have the features DHH in common. The second bin contained the lone receptor-based hypothesis developed on class V (ADHH, 6-substituted indolylquinolinones) with $d_{ij} = 0.13$, and the third bin covered the lone receptor-based hypothesis of class VI (ADHP, pyrazoloquinolinones) with $d_{ij} = 0.15$; the last bin shares the ADH features with cluster 1. Similarly, the hypotheses generated from theligand-based approach were clustered as a fourth group with $d_{ij} = 0.08$, with the ADH features in common with clusters 1, 2, and 3. The class III hypothesis (AHHH, 1,4-dihydroindeno[1,2-*c*]pyrazoles) stands in Ccluster 5 with $d_{ij} = 0.28$, indicating the distal relationship with other clusters.

The consensus from the pharmacophore models revealed that, for significant Chk1 inhibition, two hydrophobes, one hydrogen-bond donor, and one hydrogen-bond acceptor with interfeature distances as mentioned in Fig. 11 are vital.

Database screening

The receptor-based pharmacophore hypothesis was used to screen a database of 2.7 million druglike compounds. The molecules identified from this screen have druglike characteristics with respect to log *P*, molecular weight, and hydrogen-bond acceptor and donor groups. The structural cores that have been identified as hits are different from the training set molecules. Some of these molecules can be classified as quinolone analogs, isoquinoline analogs, *N*,*N*′-disubstituted urea analogs, coumarin analogs, phenyl hydrazine analogs, benziminopyran analogs ,and quinazolines analogs. The activities of these molecules were subsequently predicted by the 3D-QSAR models. The structures of these ligands, along with the predicted pIC_{50} values, are provided in Table 2. They are predicted to be potential inhibitors of Chk1 and are worthy of experimental investigation as judged by their predicted activities and ADME properties.

Conclusions

In conclusion, docking, 3D-QSAR (CoRIA, CoMFA, and CoMSIA), and pharmacophore studies delineated crucial site points on the Chk1 inhibitors, which can be modified to improve activity.

The docking analysis showed residues in the proximity of the ligands that are involved in ligand–receptor interactions, whereas CoRIA models were able to derive the magnitude of these interactions that impact the activity. The ligand-based 3D-QSAR methods (CoMFA and CoMSIA) highlight key areas on the molecules that are beneficial and (or) detrimental for activity. The docking studies and 3D-QSAR models are in excellent agreement in terms of binding-site interactions. Pharmacophore modeling with or without knowledge of the receptor provided hypotheses with comparable results. The statistical data with regards to sensitivity, selectivity, and RMSD scores for hypotheses generated by the receptor-based approach were better than the data obtained with the ligand-based approach. From the QSAR studies, we conclude that the absence of fragments A or D on these molecules results in a decrease in the activity. Although fragment D does not seem to have a significant role in the binding pocket, it is responsible for improving the overall lipophilicity of the molecule. From our 3D-QSAR studies and pharmacophore-modeling studies, it is clear that the best Chk1 inhibitor has hydrophobic features on fragment A that can interact with the amino acids Leu15, Val23, Ala36, Leu82, Leu84, and Tyr86. In addition, fragment B should interact with Leu62, Val67, Val68, Ile146, Phe149, and Leu137 through hydrophobic interactions. In addition, hydrogen-bond acceptor groups located on fragment A can interact with the ω-ammonium group of Lys38 and the backbone NH of Asp148. Similarly, the hydrogen-bond donor and (or) acceptor groups on fragment B can interact either with the backbone CO group of Glu85 or with the backbone NH of Cys87 in the hinge region of the Chk1 active site.

Finally, the active compounds predicted from the database screen of the pharmacophore models using the CoRIA, CoMFA, and CoMSIA approaches, coupled with in-silico ADME/toxicity profiles, are worthy of further experimental investigations.

Abstract: The synthesis and characterization of the first heteroleptic pyrrolide/2,2′-bipyridyl complexes of ruthenium(II) are reported. Pyrroles substituted at the 2-position with X = O functionality react with $Ru(bipy)_2Cl_2{\cdot}2H_2O$ to form complexes in which the pyrrolide ligands chelate to Ru(II). The library of pyrroles includes 2-formyl, 2-keto, 2-carboxylato, 2-sulfinyl, and 2-sulfonyl derivatives.

Key words: ruthenium complexation, formyl pyrrole, keto pyrrole, chelation.

Résumé : On a effectué la synthèse et caractérisé les premiers complexes hétéroleptiques pyrrolidure/2,2′-bipyridyle du ruthénium(II). Les pyrroles substitués en position 2 par une fonctionnalité X = O réagissent avec le $Ru(bipy)_2Cl_2{\cdot}2H_2O$ pour former des complexes dans lesquels les ligands pyrrolidures se chélatent au Ru(II). La bibliothèque de pyrroles comprend les dérivés 2-formyle, 2-céto, 2-carboxylato, 2-sulfinyle et 2-sulfonyle.

Mots-clés : complexation du ruthénium, formylpyrrole, cétopyrrole, chélation.

[Traduit par la Rédaction]

Introduction

The chemistry of the cyclopentadienyl unit as a ligand in transition metal chemistry is well-established.[1,2] However, the ability of isoelectronic and geometrically comparable pyrrolide ligands to coordinate to transition-metal centres is significantly underdeveloped.[3,4] It was frequently believed that pyrrolide–metal complexes were intrinsically unstable, based on attempts to prepare complexes of various transition metals using sodium pyrrolide that met only with disappointment.[5] Subsequently, π-cyclopentadieneyl-π-pyrrolyliron complexes (azaferrocenes) were discovered[5,6] following the synthesis of π-pyrrolide manganese tricarbonyl, apparently the first example of a pyrrolide–metal complex.[7] Numerous pyrrole-based metal complexes have since been reported, but the ligands are often cyclopyrrolic[8] (macrocycles containing pyrrole units), particularly tetrapyrrolic,[9] with limited examples of simple pyrrolic systems.

Pyrrolides may coordinate in several alternative modes: π coordination (η^5), involving the entire π system; an N-σ mode (η^1); and a C-σ mode (η^1). Most pyrrolide transition-metal complexes correspond to the N-σ η^1 mode. However, there are also examples of η^2 coordination to rhenium, tungsten, and osmium,[10,11] as well as examples of η^1 complexation to rhenium through the 2-position of pyrrole.[12,13]

Although pyrrolide complexes of transition metals such as rhenium[14,15] and molybdenum[16] have been reported, there are few examples reported with ruthenium(II).[17–20] For example,[18] a pyrrolide–ruthenium complex has been observed through the use of a bidentate α-substituted pyrrole, producing N,O-coordinated pyrrolide–ruthenium complexes as models for catalytic intermediates in the Murai coupling reaction (**A**, Fig. 1). These results lead us to postulate that there may be increased success with pyrrolide–metal complexation using bidentate α-substituted pyrroles. Furthermore, chelation facilitates the coordination of pyrrolyldipyrrinato ligands to tin(IV) complexes that feature a pyrrolide and a dipyrrinato unit.[21] Coordination of pyridylpyrrolides to K, Cu, Ag, Au, and Rh has recently been reported.[22] Bidentate coordination of pyrrole to ruthenium has also been accomplished through the reaction of TpRu(CO)(NCMe)(Me) with pyrrole, which results in the formation of product **B**.[19] The product contains an *N*-pyrrolide ligand with a coordinating pendant imine that arose from addition to the previously coordinated acetonitrile unit, presumably via metal-mediated N–H/C–H activation of the pyrrole, accompanied by the release of methane. Interestingly, lithium pyrrolide displaced triflate from TpRu(CO)(NCMe)(OTf) to give TpRu(*N*-pyrrolide)(CO)(NCMe), without C–H activation, akin to reactions previously reported for rhenium.[12,13] A similar approach has been utilized to prepare ruthenium complexes of azoferrocenes that, of course, feature a pyrrolide ligand.[18]

Within the context of dipyrrinato complexes,[23] dipyrrinato-

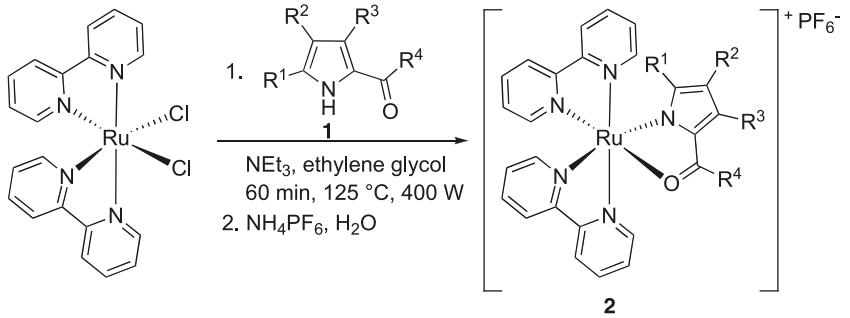

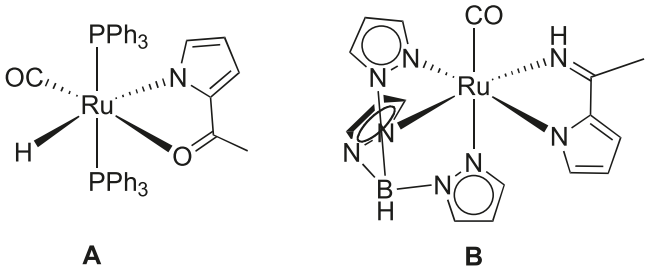

Fig. 1. Literature examples of bidentate pyrrolide–ruthenium(II) complexes.

bound ruthenium(II) complexes[24] have been reported recently, with two bipyridyl units further supporting the metal centre. Ruthenium complexes bearing bipyridyl ligands are very common, and are useful because of their photochemical and photophysical properties.[25] We herein report the synthesis and properties of the first heteroleptic pyrrolide 2,2′-bipyridyl (bipy) complexes of ruthenium(II).

Results and discussion

2-Formyl and 2-keto pyrroles

Cognisant of the dipyrrinato scaffold, whereby anionic pyrrolide and neutral azafulvene (imine) units act synergistically to chelate ruthenium(II) in bis(2,2′-bipy) complexes,[24] we first investigated 2-formyl and 2-keto pyrroles (Scheme 1) as potential sources of pyrrolide ligands. Pyrrole **1a**, fully substituted around the pyrrole ring and bearing a formal group in the 2-position, served as our first candidate. Following a modified literature procedure,[24] 1.1 equiv of the pyrrole were reacted with $[Ru(bipy)_2Cl_2]$ in ethylene glycol under microwave irradiation in the presence of triethyl amine. The resulting reaction mixture was then added to a solution of NH_4PF_6 so that the complex could be isolated as the PF_6^- salt via precipitation. Other counterions were employed, including triflate, tetraphenyl borate, and 3-TMS-1-propane sulfonate, but hexafluorophosphate provided complexes that precipitated the most readily.

Purification was achieved through the dissolution of the crude precipitate in dichloromethane (DCM), washing the solution with brine, and then drying the organic fraction over sodium sulfate. The solvent was removed in vacuo, and the resulting film was triturated with hexanes to give a solid that could be collected using a Millipore filter. Microwave irradiation was essential for the formation of these complexes, since conventional heating methods gave no complexation products. The temperature and time of reaction were both optimized for the microwave system (Table 1), using pyrrole **1a**. The literature procedure[24] suggests a reaction time of 35 min at 100 °C for complexation of dipyrrinato ligands to ruthenium(II), but optimum reaction conditions for the formation of pyrrolide–ruthenium(II) complexes were found to be 60 min at 125 °C.

Table 1. The optimization of time and temperature for the formation of complex **2a**.

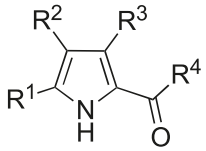
Trial	Time (min)	Temp. (°C)	Isolated yield (%)
1	30	100	20
2	60	100	25
3	60	125	93
4	90	100	54
5	90	125	45

The optimized conditions were then applied to 2-formyl pyrroles (Table 2, entries 1–6) and 2-keto (Table 2, entries 7–9) pyrroles **1b**–**1i**, with high yields achieved throughout. Various alkyl groups were used as substituents around the pyrrole ring, with one example containing a halogen substituent. Fully substituted pyrroles (**1a**, **1b**, **1f**–**1g**, and **1i**) were tolerated well by the reaction, as were pyrroles featuring unsubstituted positions (**1c**–**1e** and **1h**). In most cases, small amounts of pyrrolic starting material remained after the reaction, but these were easily removed upon work-up and purification as described previously.

2-Carboxylate pyrroles

We then pursued complexation reactions with pyrroles containing a carboxylate functionality in the 2-position (Scheme 2), as the flanking chelating moiety appears to be the key to success. Initial attempts garnered little success (Table 3, entries 1 and 2), presumably via destabilization of the Ru–O bond courtesy of the presence of the OEt/OBn moiety; such instability has been previously reported in pyrrole–rhenium complexes.[14]

As such, we sought to use pyrroles that featured a halide substituent, especially as complex **2h** (Table 2, within the formyl series) had been prepared in essentially quantitative yield. Several 2-carboxylato-functionalized pyrroles of this genre were subsequently complexed to ruthenium(II) (Table 3, entries 3–5), albeit in yields lower than for the aldehydes and ketones.



2-Sulfinyl and 2-sulfonyl pyrroles

The final set of ligands contained a sulfinyl moiety at the

2-position (Scheme 3). These 2-(arylsulfinyl)pyrroles[26] are of special interest as they contain a chiral centre at the sulfoxide. Each ligand was synthesized as a racemate. Various aryl groups were substituted on the sulfur centre, with little substitution around the pyrrole ring, and these ligands were successfully complexed (Table 4, entries 1–3), although in yields generally lower than those for complexes containing pyrrolyl ligands bearing 2-carbonyl moieties. Diastereoselectivity within the complexation reaction was not observed.

For pyrroles **5d** and **5e** a formyl group was introduced at the 5-position to investigate binding competition between the two potential coordination sites (Table 4, entries 4 and 5). Comparing the carbonyl stretching frequencies of pyrrole **5d** to complex **6d** reveals that the frequency is red-shifted from 1670 cm^{-1} in the free ligand to 1545 cm^{-1} in the complex. A similar result is found when comparing the carbonyl stretching frequencies of pyrrole **1a** (1619 cm^{-1}) with that of complex **2a** (1578 cm^{-1}). As such, coordination must occur through the formyl group in each case, indicating that this coordination site is more favourable than the sulfinyl group.

Complexes **6f** and **6g** were synthesized using 2-(arylsulfenyl) and 2-(arylsulfonyl) pyrroles, respectively, to demonstrate that complexation can occur with pyrroles bearing 2-sulfur substituents at the sulfenyl, sulfinyl, and sulfonyl oxidation states (Table 4, entries 6 and 7).

All complexes **2**, **4**, and **6**, are air- and moisture-stable. They are deep red in the solid state and appear dark burgundy in solution, except complexes **6d**–**6f**, which are red-orange in solution. Each product was fully characterized using ^{1}H NMR, ^{13}C NMR, and UV–vis spectroscopy, as well as ESI-MS. Futhermore, several complexes were characterized using X-ray crystallography.

The absorption spectra of these complexes are characterized by intense $\pi \rightarrow \pi^*$ intraligand transitions in the UV range

and metal-to-ligand charge transfer (MLCT) transitions, $d_\pi(Ru)\rightarrow\pi^*(L)$, in the visible region[27–29] (Fig. 2). The spectrum for complex **2a** shows the general trend of the absorption spectra for these complexes, consisting of the intense $\pi\rightarrow\pi^*$ bipy-localized transitions below 300 nm,[28] as well as lower energy bands ($S_o\rightarrow S_1$) between 300 and 400 nm. Each complex exhibits a broad MLCT transition containing a shoulder, explained by the overlapping $d_\pi(Ru)\rightarrow\pi^*$ absorptions from the bipyridyl and pyrrolide ligands, and these bands are located above 450 nm.

X-ray crystallographic data were collected for several of the new complexes (**2a**, **2b**, **2d**, **2g**, and **4e**), with structures being obtained for pyrrolide 2-formyl, 2-keto, and 2-carboxylate ruthenium(II) complexes. The structural details for **2b** and **2d** are included in the Supplementary data, as are those for **1a** and **1d**. Complex **2a** (2-formyl group) crystallizes in the

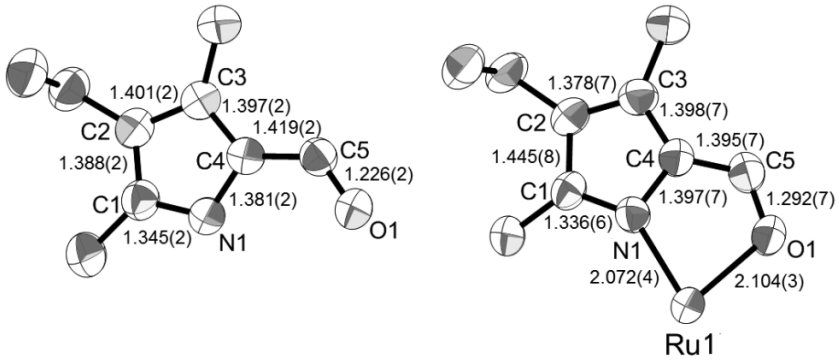
Fig. 4. Thermal ellipsoid diagrams (50%) showing bond lengths of the parent pyrrole (left, **1a**) and the corresponding coordinated pyrrolide (right, partial structure of **2a**); hydrogen atoms are omitted for clarity.



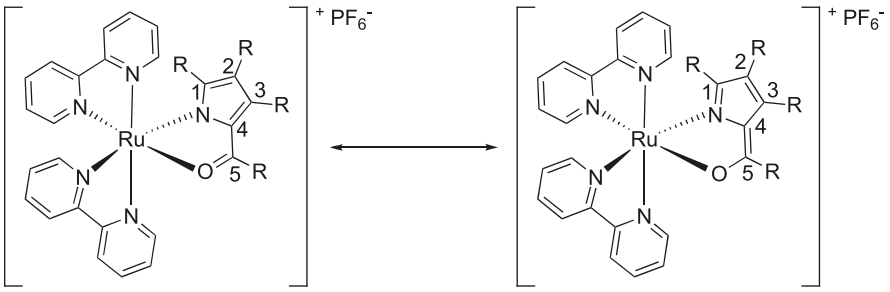


Fig. 5. Resonance structures of complexed pyrrolide (left, pyrrole; right, azafulvenium).

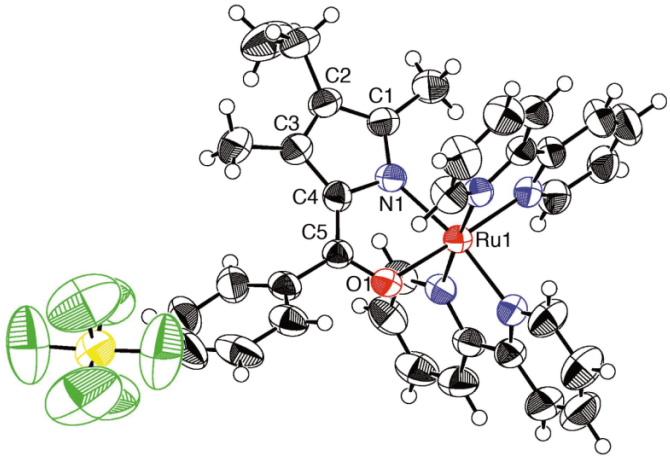


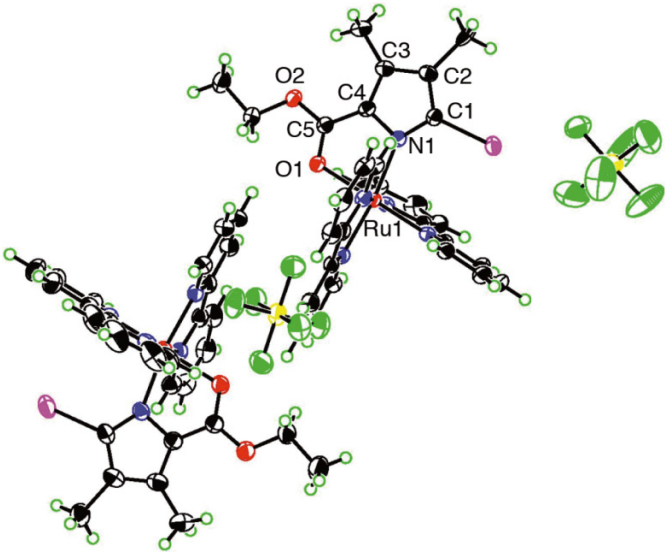
space group *P*-1, with one enantiomer of the complex occupying the asymmetric unit. The geometry of the ruthenium(II) centre was found to be distorted octahedral (Fig. 3).

The Ru–N_{bipy} bond lengths are in the range of 2.029(2)–2.065(1) Å and the Ru–$N_{pyrrole}$ bond length is 2.076(2) Å. The Ru–O bond length is longer at 2.097(2) Å. These Ru–O and Ru–N bond lengths are shorter than those found in similar pyrrole–ruthenium complexes.[18] To enable comparison of the structures of the uncoordinated pyrrole with the pyrrolide ligand within the complex, X-ray crystallographic data were obtained for the pyrrole **1a** (Fig. 4).

Analysis of the structures reveals that there is a lengthening of the C–O bond in the complex **2a** (1.292(7) Å) with respect to the C–O bond of the pyrrole **1a** (1.226(2) Å). Furthermore, the C4–C5 bond length (1.395(7) Å) in **2a**, which is formally a C–C single bond from the pyrrole to the carbonyl carbon atom, is shorter than in the corresponding bond in the parent pyrrole **1a** (1.419(2) Å). The formal C1–C2 C=C double bond of the pyrrole ring (1.445(8) Å) is longer in **2a** than the pyrrole **1a** (1.388(2) Å) (Fig. 4). It appears that all bonds have taken on double bond character, as is typical for an aromatic system. However, the increased C–O and C1–C2 bond lengths in **2a** suggest that the major resonance form of the pyrrolide ligand is the azafulvenium variant (Fig. 5).

Complex **2g** (2-keto group) crystallizes in the space group $P2_1/n$ with the geometry at the ruthenium(II) centre again being distorted octahedral (Fig. 6). The Ru–N_{bipy} bonds fall in the range of 2.035(2)–2.059(2) Å, and the Ru–$N_{pyrrole}$ and Ru–O bond lengths were both found to be 2.076(2) Å. The C–O bond length of pyrrole **1g**[22] (1.2434(9) Å) is shorter than the same bond in complex **2g** (1.284(3) Å). It appears that this ligand follows the same trend shown in complex **2a**. The C1–C2 and C4–C5 bond lengths in pyrrole **1g** (1.397(1) and 1.441(1) Å, respectively) undergo a similar increase and decrease upon complexation (1.423(5) and 1.399(4) Å, respectively, for complex **2g**).

Fig. 6. Thermal ellipsoid diagram (50%) of **2g**.



Complex **4e** (2-carboxylate) also crystallizes in the space group $P2_1/n$ with distorted octahedral geometry at the ruthenium(II) centre (Fig. 7). The Ru–N_{bipy} bond lengths are between 2.016(2) and 2.053(3) Å and the Ru–$N_{pyrrole}$ bond lengths are 2.087(2) and 2.088(3) Å. The Ru–O bond lengths are 2.1281(19) and 2.134(2) Å, which are much longer than those of the 2-formyl and 2-keto pyrrole–ruthenium complexes.

Conclusion

In summary, the first heteroleptic pyrrolyl 2,2′-bipyridine complexes of ruthenium(II) are reported, along with a reliable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12

Fig. 7. Thermal ellipsoid diagram (50%) of **4e**.

route for their high-yielding syntheses. A wide variety of pyrrolyl ligands containing numerous functionalities have been successfully coordinated to ruthenium(II) producing air- and moisture-stable complexes. The general synthetic method described should provide a route to pyrrolide–ruthenium complexes of various bidentate pyrroles and potentially a pathway to alternative pyrrolide-bound transition-metal complexes.

Experimental section

General experimental

All ^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz) spectra were recorded on a Bruker Avance AV-500 spectrometer. Chemical shifts are expressed in parts per million (ppm) using the solvent signals ($CDCl_3$, ^{1}H NMR 7.26 ppm; CD_2Cl_2, ^{1}H NMR 5.26 ppm, ^{13}C NMR 53.8 ppm; DMF-d_7, ^{1}H NMR 2.74 ppm, ^{13}C NMR 30.1 ppm) as an internal reference for ^{1}H and ^{13}C. Splitting patterns are indicated as follows: br, broad; s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; and app, apparent. All coupling constants (J) are reported in Hertz (Hz). Mass spectra were obtained using ion trap (ESI) instruments operating in positive mode. All microwave reactions were performed using a Biotage Initiator laboratory microwave apparatus. The following compounds were prepared according to literature procedures: **1a**,[30] **1b**,[30] **1c**,[2] **1d**,[30] **1e**,[31] **1g**,[32] **1h**,[33] **3c**,[34] **3d**,[35] **3e**,[36] and **5a**–**5g**.[26] Measurements were made on a Rigaku Raxis rapid-imaging plate area detector with graphite-monochromated Mo Kα radiation. The structures were solved by direct methods[37] and expanded using Fourier techniques.[38] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model. Calculations were performed using the CrystalStructure[39,40] crystallographic software package.

General procedure for the synthesis of ruthenium complexes (GP1)

To a solution of the pyrrole (0.19 mmol) and $Ru(bipy)_2Cl_2{\cdot}2H_2O$ (0.17 mmol) in ethylene glycol (16 mL) was added triethylamine (0.5 mL). The resulting solution was reacted in a laboratory microwave at a controlled temperature of 125 °C for 60 min and then cooled to room temperature with a pressurized air supply. The cooled reaction mixture was added to a solution of NH_4PF_6 (3.1 mmol) in deionized water (100 mL). The suspension was stirred overnight and the resulting precipitate was then collected via suction filtration. Purification was achieved by dissolving the precipitate in DCM (80 mL), washing with brine (80 mL), and drying the organic fraction with sodium sulfate. After filtration, the solvent was removed in vacuo. The resulting film was triturated with hexanes and the resulting solid was collected using a Millipore filter.

Representative synthesis

*Bis(2,2′-bipyridyl)-(4-ethyl-2-formyl-3,5-dimethyl-*N*-pyrrolato)ruthenium(II) hexafluorophosphate (2a)*

Complex **2a** was synthesized using GP1 and pyrrole **1a** and was isolated as a microcrystalline dark burgundy solid (0.115 g, 93%). Crystals suitable for X-ray diffraction analysis were grown via the diffusion of hexane into a concentrated chloroform solution. UV–vis (DCM) λ_{max} (nm): 296 ε 115 000 L mol^{-1} cm^{-1}, 375 ε 40 000 L mol^{-1} cm^{-1}, 536 ε 20 000 L mol^{-1} cm^{-1}. δ_H (500 MHz, $CDCl_3$): 8.63 (1H, d, J = 4.9), 8.39 (1H, d, J = 8.0), 8.36 (1H, d, J = 8.2), 8.30 (1H, d, J = 8.2), 8.26 (1H, d, J = 8.1), 8.21 (1H, s), 7.99–7.95 (2H, m), 7.89 (1H, d, J = 5.7), 7.79–7.72 (3H, m), 7.54–7.51 (1H, m), 7.49 (1H, d, J = 5.6), 7.46–7.44 (1H, m), 7.18–7.16 (2H, m), 2.29–2.23 (5H, m, CH_2 + CH_3), 1.26 (3H, s), 0.95 (3H, t, J = 7.5). δ_C (125 MHz, DMF-d_7): 176.0, 160.0, 159.4, 158.8, 158.3, 153.9, 153.7, 152.5, 152.5, 151.3, 142.5, 136.9, 136.7, 136.1, 135.4, 133.2, 130.5, 127.6, 127.4, 127.4, 127.1, 124.5, 124.1, 124.1, 123.9, 18.1, 15.3, 12.3, 10.1. m/z [M – PF_6 + H$^+$]: 564.1. Crystal data for complex **2a**: $C_{30}H_{29}N_5OPF_6RuCl_3$, MM = 827.99 g/mol, dark-red needle crystal, 0.31 mm × 0.13 mm × 0.06 mm; primitive triclinic, space group P-1; a = 9.8219(4) Å; b = 13.6422(5) Å; c = 13.7188(3) Å; α = 73.941(8); β = 73.983(11); γ = 87.603(12)°; V = 1696.72(15) Å^3; Z = 2; ρ = 1.621 g/cm^3; μ(Mo Kα) = 0.8115 mm^{-1}; 22 241 reflections (11 932 unique, R_{int} = 0.052); $R(F)$ = 0.0596; $Rw(F)$ = 0.0713; GoF = 1.120.

*Bis(2,2′-bipyridyl)-(4-ethyl-3,5-dimethyl-2-benzoyl-*N*-pyrrolato)ruthenium(II) hexafluorophosphate (2g)*

Complex **2g** was synthesized using GP1 and pyrrole **1g** and was isolated as a microcrystalline dark burgundy solid (0.110 g, 80%). Crystals suitable for X-ray diffraction analysis were grown via the slow evaporation of solvent from a concentrated methanol solution. UV–vis (DCM) λ_{max} (nm): 296 ε 125 000 L mol^{-1} cm^{-1}, 330 ε 35 000 L mol^{-1} cm^{-1}, 540 ε 25 000 L mol^{-1} cm^{-1}. δ_H (500 MHz, DMF-d_7): 8.87 (1H, d, J = 8.0), 8.84 (1H, d, J = 8.1), 8.81 (1H, d, J = 8.2), 8.79–8.76 (2H, m), 8.21–8.18 (2H, m), 8.16–8.14 (1H, m), 8.09 (1H, d, J = 5.3), 8.00–7.98 (2H, m), 7.84–7.81 (1H, m), 7.78 (1H, d, J = 5.6), 7.73–7.70 (1H, m), 7.49–7.46 (1H, m), 7.44–7.40 (6H, m), 2.26 (2H, m, J = 7.1), 1.81 (3H, s), 1.39 (3H, s), 0.90 (3H, t, J = 7.5). δ_C (125 MHz, CD_2Cl_2): 186.2, 159.3, 158.8, 158.3, 157.8, 153.5, 152.9, 152.2, 151.6, 151.1, 138.6, 136.2, 136.0, 135.3, 134.6, 133.0,

Abstract: Sulfonated multiwalled carbon nanotubes (MWCNTs) were synthesized by chemical vapor deposition (CVD) as a new and facile one-pot method using acetylene (as the CNT precursor), thiophene (as the sulfur precursor), and ferrocene (for in situ liberation of metal nanoparticles as the CNT nanocatalyst). A low catalytic amount of the resulting sulfonated MWCNTs with a turnover number (TON) up to 980 and a turnover frequency (TOF) up to 11 160 h^{-1} was utilized as a new and recyclable heterogeneous nanocatalyst for the efficient one-pot synthesis of various amines (secondary and tertiary) by direct reductive amination of aldehydes and ketones using $NaBH_4$. The catalyst was easily isolated from the reaction mixture by simple filtration and reused at least five times without significant degradation in activity.

Key words: multiwalled carbon nanotubes, nanocatalyst, sulfonic acid, amine, reductive amination.

Résumé : On a réalisé la synthèse de nanotubes de carbone sulfonés à parois multiples (NTCPM) par une nouvelle méthode monotope simple de dépôt de vapeurs chimiques (DVC) implication l'acétylène comme précurseur des nanotubes de carbone, le thiophène comme précurseur du soufre et le ferrocène (pour la libération in situ des particules métalliques agissant comme nanocatalyseur dans la formation de nanotubes de carbones). On a utilisé une faible quantité catalytique des nanotubes de carbone sulfonés à parois multiples (NTCPM) ainsi obtenu, avec des nombres de renouvellement allant jusqu'à 980 et des fréquences de renouvellement allant jusqu'à 11 160 h^{-1}, comme nouveau catalyseur hétérogène recyclable pour la synthèse monotope efficace de diverses amines (secondaires et tertiaires) par amination réductrice directe d'aldéhydes et de cétones à l'aide de $NaBH_4$. On peut facilement isoler le catalyseur du mélange réactionnel, par simple filtration, et l'utiliser à nouveau au moins cinq fois sans dégradation significative de son activité.

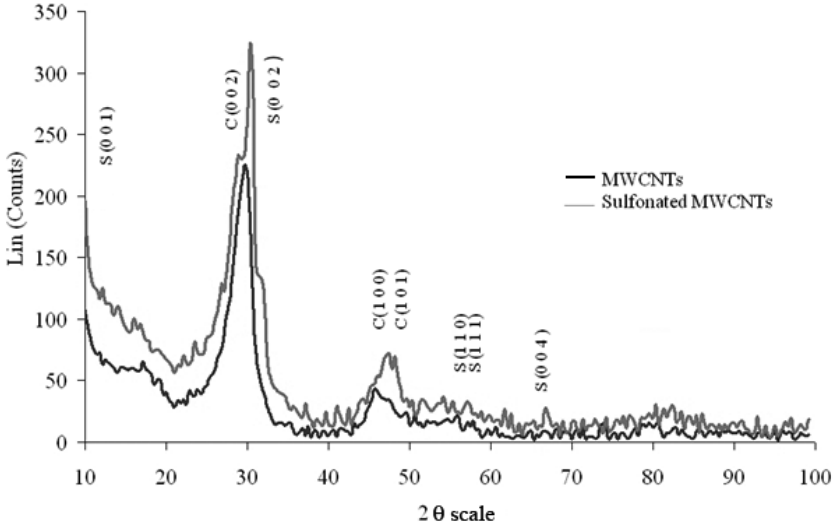
Mots-clés : nanotubes de carbone sulfonés à parois multiples (NTCPM), nanocatalyseur, acide sulfonique, amination réductrice.

[Traduit par la Rédaction]

Introduction

Amines are of high importance in organic chemistry because of their presence in high quantities in biological and natural molecules, such as alkaloids, amino acids, nucleic acids, dyes, and fine chemicals.[1–4] Synthetic methodologies for amines vary depending on the location of the amine in the original source and the type of the amine. Often, there are multiple processes used for the synthesis of a particular amine or family of amines.[5–8] Among these processes, direct reductive amination is the most practical and convenient approach, since it allows the conversion of carbonyl functionality to structurally diverse secondary and tertiary amines.[9–12] This reaction offers compelling advantages over amine synthesis, including brevity, wide availability of commercial substrates, synthesis of an alkylated amine of higher order and generally mild reaction conditions. Several reagents, which affect reductive amination, have been recently developed.[13–18] However, most of the reagents may have one or more drawbacks such as hard reaction conditions, a tedious workup procedure, and the use of unrecyclable or unstable catalysts, which would eventually produce toxic waste. Therefore, the development of a new method to overcome these shortcomings remains an ongoing challenge for the synthesis of these significant scaffolds.

Heterogeneous catalysts for the synthesis of fine chemicals have attracted considerable attention from both the environmental and economical points of view because they offer several advantages in organic synthesis, e.g., simplification of reaction procedures, easy separation of products, long catalytic life, ease of catalyst recyclability, and thermal stability.[19]



Carbon nanotubes (CNTs) appear to be one of the most promising nanomaterial supports for different functional

groups and nanocatalysts because of their properties such as their unique surface structure, small diameter, large active surface area, inherent size and hollow geometry, basal and edge plane sites, desirable chemical stability, high electric conductivity, and excellent mechanical and thermal properties.[20–23] On the other hand, the functionalization of CNTs decreases the hydrophobic character of the CNTs, caused by strong intertubular van der Waals forces, and modifies the physical and chemical properties of the CNTs. Sulfonic acid is one of the ideal grafting functional groups to the CNTs surface. Acid-assisted thermal decomposition and electrochemical modification and reduction are the typical synthetic routes for the preparation of sulfonated CNTs.[24] Generally, acid-assisted thermal decomposition involves refluxing the CNTs with concentrated acid under high temperatures. Such aggressive treatments may lead to severe damage to the CNTs backbone.[25] The electrochemical modification route allows mild operational conditions and its utility is only restricted to electrically contacted CNTs on the confined electrode surface.[26,27] In the case of aryl-functionalized CNTs, synthesized by conventional chemical reduction methods, the procedure is usually time-consuming because it involves especially complex processes or multiple steps.[28,29]

The most popular and widely used method for CNTs synthesis is chemical vapor deposition (CVD). It is because of its low setup cost, high production yield, ease of scale up, ability to harness plenty of hydrocarbons in each state (solid, liquid, or gas), ability to enable the use of various substrates, one-pot covalent functionalization, and ease of CNTs growth either in different forms (powder, thin or thick films, aligned or entangled, or straight or coiled nanotubes) or in a desired architecture of nanotubes on predefined sites of a patterned substrate.[30]

Because of the need for a clean and green recovery of the heterogeneous catalyst, especially acid catalysts, we wish to introduce a new method for the one-pot synthesis of sulfonated multiwalled carbon nanotubes (MWCNTs) by CVD using acetylene, thiophene, and ferrocene as C, S, and Fe precursors, respectively. We also studied the utility of the synthesized sulfonated MWCNTs as a new and recyclable heterogeneous catalyst for one-pot synthesis of different amines.

Results and discussion

For the synthesis of sulfonated MWCNTs, acetylene (as the CNT precursor), thiophene (as the sulfur precursor), and ferrocene (for in situ liberation of metal nanoparticles as the CNT nanocatalyst) were mixed with hydrogen and argon in a furnace at ~1300 °C. The sulfur-doped carbon nanostructure was produced and purified directly from any amorphous carbon via oxygen purging and the introduction of hydrogen peroxide into the setup. This process was carried out in a second furnace at ~500 °C. Oxygen converts sulfurous species and amorphous carbon to oxidized sulfurous compounds and carbon dioxide, respectively. During the purification process, sulfonated MWCNTs were produced in situ by further oxidation of sulfur-doped carbon nanostructures by a hydrogen peroxide aerosol. The oxidation process was followed by UV and MW irradiations. These irradiations simply provide the necessary energy to cleave the C–C bond, which leads to defect creation in the CNT matrix.

The synthesized sulfonated MWCNTs were then characterized by various methods including X-ray diffraction (XRD), Raman, scanning electron microscopy (SEM), transmission electron microscopy (TEM), and FT-IR. The amount of sulfonic acid loaded on the surface of the MWCNTs was determined by thermogravimetric analysis (TGA) and confirmed further by back titration.

XRD analysis

According to the XRD pattern (Fig. 1), the strong peaks positioned at $2\theta = 28°$, 42°, and 48° are related to C (002), C (100), and C (101), respectively. The peaks appearing at $2\theta = 12°$, 30°, 56°, 58°, and 66° belong to S (001), S (110), S (111), and S (004), respectively. The XRD pattern reveals the presence of sulfur atoms in the MWCNT matrix.

Raman spectra

A significant change in the defect of the Raman spectra of sulfonated MWCNTs compared with that of the MWCNTs,

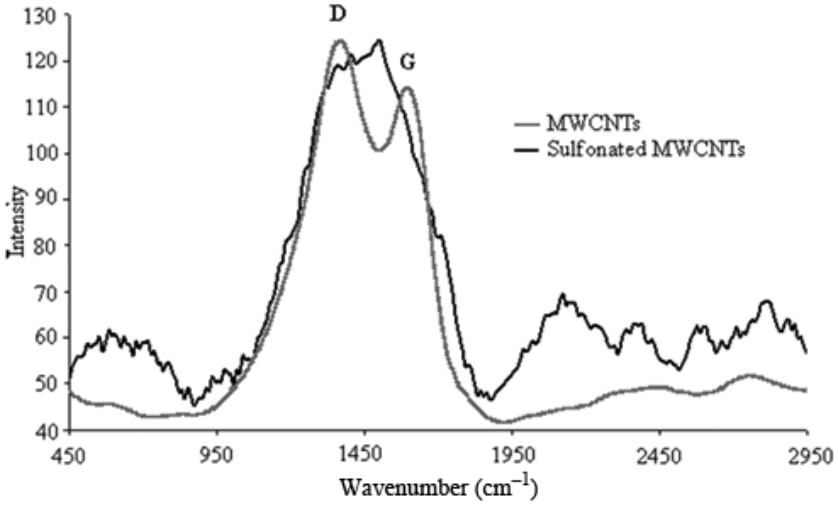
Fig. 2. Raman spectra of sulfonated multiwalled carbon nanotubes (MWCNTs) (black) and MWCNTs (gray).



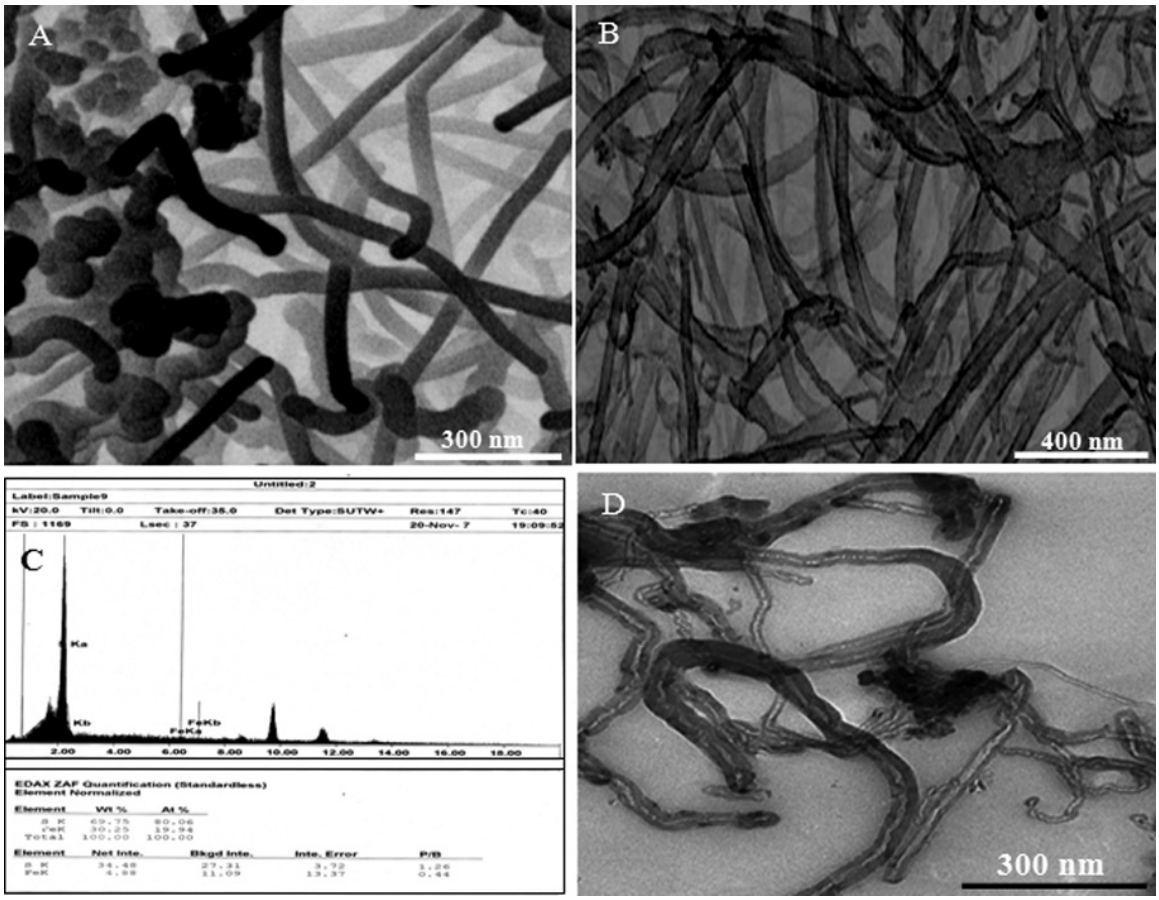


Fig. 3. Electronic microscopic images including (A) SEM, (B and D) TEM, and (C) EDX analysis of sulfonated MWCNTs.

shows the presence of sulfur atoms in the CNT matrix (Fig. 2).

SEM and TEM

The size and structure of the sulfonated MWCNTs were determined using SEM and TEM. According to the SEM (Fig. 3A) and TEM (Figs. 3B and 3D), it is clear that the synthesized sulfonated MWCNTs have a nanodimension ranging from ~10 to 30 nm.

FT-IR spectroscopy

The appearance of peaks at 1130 and 1531 cm^{-1} in the FT-IR spectrum of sulfonated MWCNTs (Fig. 4A) is ascertained to the C–S (in which carbon is available in the MWCNTs backbone) and S=O bonds, respectively. These two peaks are not observed in the spectrum of MWCNTs (Fig. 4B). This observation indicates the existence of C–SO_3H in the sulfonated MWCNTs. Two bands positioned at 3436 and 1635 cm^{-1} belong to the O–H stretching and bending

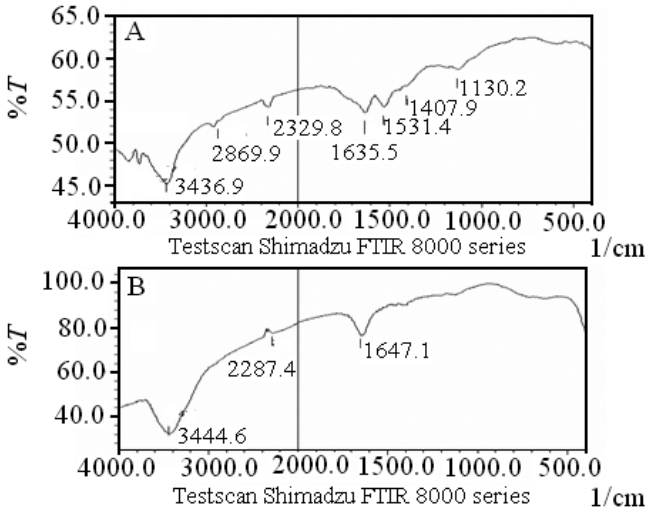
Fig. 4. FT-IR spectra of (A) sulfonated multiwalled carbon nanotubes (MWCNTs) and (B) MWCNTs.



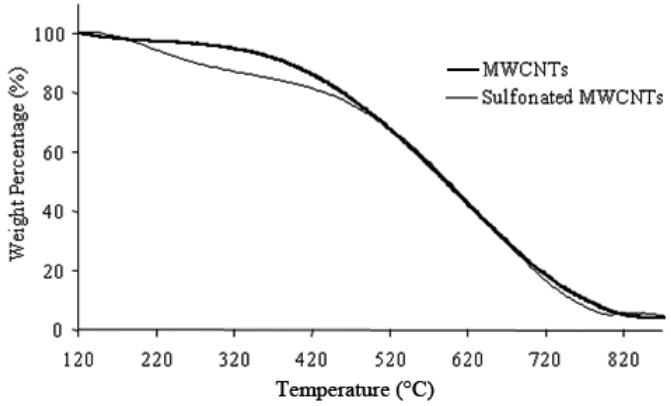


Fig. 5. Thermogram of sulfonated multiwalled carbon nanotubes (MWCNTs, gray) and MWCNTs (black).

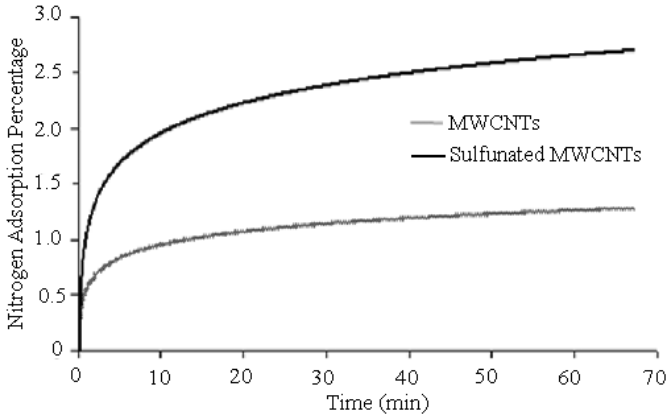
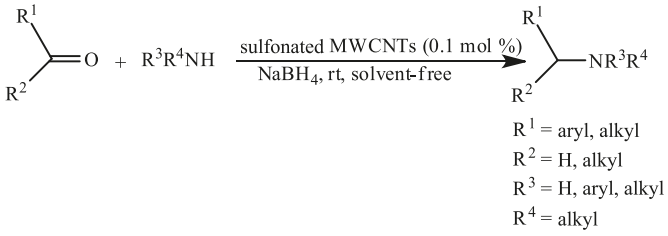
vibrations, respectively. The OH group was produced during the activation of the MWCNTs and the formation of sulfonate functional groups.

TGA



The thermal behavior of sulfonated MWCNTs and pure MWCNTs is shown in Fig. 5. A significant decrease in the weight percentage of the sulfonated MWCNTs at ~170 °C is related to the desorption of the sulfonate functional group from the catalyst surface. A sharp decrease in the weight percentage at ~620 °C is due to the decomposition of the MWCNTs. According to the thermogram, the amount of sulfonic acid functionalized on the MWCNTs is ~8.29% (*w*/*w*). This result is in agreement with back-titration analysis.

Nitrogen adsorption isotherm



N_2 adsorption isotherms of the sulfonated MWCNTs and pure MWCNTs at 25 °C by using a homemade TGA system are shown in Fig. 6.

According to the N_2 adsorption isotherms, a significant increase (up to ~591 m^2 g^{-1}) in the active surface area of the MWCNTs was observed owing to the defects of the CNT matrix during the sulfonation process.

Fig. 6. Nitrogen adosorption isotherm of sulfonated multiwalled carbon nanotubes (MWCNTs, black) and MWCNTs (gray).

Scheme 1.

Catalytic activity of sulfonated MWCNTs in the one-pot synthesis of amines

As a part of our continuing research on the development of new applications of solid acids as heterogeneous catalysts in organic reactions,[31–34] we used sulfonated MWCNTs as a heterogeneous catalyst for the one-pot synthesis of amines by direct reductive amination of aldehydes and ketones (Scheme 1 and Table 1).

As shown in Table 1, substituted anilines or aliphatic (primary and secondary) amines underwent direct reductive amination with benzaldehyde and produced the corresponding secondary and tertiary amines in 75%–98% yields (Table 1, entries 1–8). In addition, the reaction of aniline with cyclopentanone and cyclohexanone gave high yields of the corresponding secondary amines (Table 1, entries 9 and 10).

In these transformations, turnover number (TON) and turnover frequency (TOF) were in the range of 750–980 and 830 – 11 160 h^{-1}, respectively, which demonstrates the high efficiency of sulfonated MWCNTs for the synthesis of a wide range of amines.

After performing the reductive amination of benzaldehyde with aniline under the conditions described in Table 1, EtOH was added to the reaction mixture and the catalyst was filtered off and reused for another reaction. This process was carried out for five runs without any noticeable reduction in the catalytic activity of the catalyst. The average isolated yield for at least five successive runs was 94.6%, which clearly demonstrates the practical reusability of the catalyst (Fig. 7).

Conclusion

In conclusion, sulfonated MWCNTs were synthesized via a new and facile one-pot method by CVD using acetylene (as

the CNT precursor), thiophene (as the sulfur precursor), and ferrocene (for in situ liberation of metal nanoparticles as the CNT nano catalyst). The synthesized sulfonated MWCNTs were applied as a new recyclable heterogeneous catalyst for the direct reductive amination of benzaldehyde and ketones with aromatic or aliphatic amines under solvent-free conditions at room temperature. Use of a small amount (0.1 mol %) of sulfonated MWCNTs as a water-tolerant and thermally stable catalyst, short reaction times, high yields, and recyclability of the catalyst without loss of reactivity for at least five reaction cycles are the remarkable properties of this work. Further investigations on the development of organic transformations using this new heterogeneous catalyst are ongoing in our laboratory.

Experimental section

Synthesis of sulfonated MWCNTs

Acetylene gas with a flow rate of ~50 mL min^{-1} was bubbled into a solution containing ferrocene (0.30 g) in benzene–thiophene (25 mL, volume ratio, 1:10). This solution was mixed with hydrogen and argon (flow rates = 0.5 and 800 mL min^{-1}, respectively). The resulting reaction mixture was introduced into a quartz tube and passed through a 80 cm tubing furnace with temperature of 1300 °C. The sulfur-doped carbon nanostructures were then directly purified from any amorphous carbon via oxygen purging and introducing hydrogen peroxide into the setup followed by online activation using UV and microwave (MW) irradiations.

General procedure for the reductive amination of aldehydes and ketones

An aldehyde or a ketone (5.0 mmol) was ground with a mixture of an amine (5.0 mmol) and sulfonated MWCNTs (0.1 mol %) in a mortar by a pestle at room temperature. $NaBH_4$ (5.5 mmol) was added to the resulting mixture, which was ground for an appropriate time (Table 1). EtOH (30 mL) was then added to the reaction mixture and the catalyst was filtered, washed by EtOH (2 × 20 mL), dried, and recycled for the similar reaction. The filtrate solvent was removed under reduced pressure and the resulting crude product was purified by column chromatography and eluted with *n*-hexane–EtOAc (20:1–2:1).

Abstract: Density functional theory (DFT) was used to study the β-myrcene ozonolysis reaction. The reactants, intermediates, transition states, and products were optimized at the MPWB1K/6–31G(d,p) level. The single-point energies were performed at the MPWB1K/6–311+G(3df,2p) level. The profiles of the potential energy surfaces were constructed and the rate constants of the reaction steps were analyzed. The possible reaction mechanisms for the ozonolysis intermediates in real atmosphere are also discussed. Based on quantum chemistry information, the rate constants were calculated using Rice–Ramsperger–Kassel–Marcus (RRKM) theory and the canonical variational transition-state theory (CVT) with small curvature tunneling effect (SCT). Arrhenius equations of rate constants over the temperature range of 200–800 K are provided, and the lifetimes of the reaction species in the troposphere were estimated according to rate constants.

Key words: myrcene ozonolysis, DFT, RRKM theory, CVT/SCT, rate constant.

Résumé : On a fait appel à la théorie de la fonctionnelle de la densité (TFD) pour étudier la réaction d'ozonolyse du myrcène. On a optimisé les réactifs, les intermédiaires, les états de transition et les produits au niveau MPWB1K/6–31G(d,p) de la théorie. On a déterminé des énergies ponctuelles au niveau MPWB1K/6–311+G(3df,2p) de la théorie. On a construit les profils d'énergie potentielle et on a analyse des constantes de vitesse des diverses étapes réactionnelles. On discute aussi des mécanismes potentiels des intermédiaires d'ozonolyse dans un atmosphère réel. Sur la base des informations obtenues par la chimie quantique, on a calculé les constantes de vitesse à l'aide de la théorie de Rice–Ramsperger–Kassel–Marcus (RRKM) et de la théorie d'un état de transition variationnel et canonique (TVC) comportant un effet tunnel avec faible courbure (TFC). On a obtenu les équations d'Arrhenius des constantes de vitesse sur la plage de température allant de 200 à 800 K et on a évalué les temps de vie des espèces réactionnelles dans la troposphère à l'aide de ces constantes de vitesse.

Mots-clés : ozonolyse du myrcène, théorie de la fonctionnelle de la densité (TFD), théorie de RRKM, théorie d'un état de transition variationnel et canonique (TVC) comportant un effet tunnel avec faible courbure (TFC), constante de vitesse.

[Traduit par la Rédaction]

Introduction

β-Myrcene (7-methyl-3-methylene-1,6-octadiene) is an important member of the monoterpene family. Myrcene is produced by the mevalonic acid pathway of plants and emitted into the atmosphere through diffusion.[1]

Myrcene has three double bonds, including conjugated double bonds. It could easily react with O_3, OH, NO_3, and other species in the atmosphere and generate a series of oxidation products.[2] Ozonolysis of ethene, including the formation of primary and secondary ozonides, has been thoroughly researched with a theoretical method.[3–6] Several monoterpenes, including myrcene, reacted with ozone and hydroxyl radical to produce acetone at room temperature and 1 atm (1 atm = 101.325 kPa). The isobutenyl group of the monoterpenes might react with ozone to form acetone, which would account for the majority of the products in the first step of the reaction.[7,8] It has been reported that monoterpenes react more easily with O_3 than with the OH radical, and that the lifetime of myrcene is about 28 min under 50 ppb O_3.[9] The OH radicals, released from the gas-phase reactions of ozone with a series of monoterpenes, were scavenged by 2-butanol and reported to accelerate ozonolysis reactions to some extent.[10,11]

It was reported that three products, hydroxyacetone, formaldehyde, and acetone, were formed during the myrcene ozonolysis reaction.[12] Moreover, two kinds of mechanisms for the reaction between the Criegee intermediate and water were put forward.[13] The ozonolysis products of myrcene, such as 4-methylene-5-hexenal, were detected at room temperature.[14]

The gas-phase oxidation products and secondary organic aerosol yields from terpene reactions with ozone have been investigated experimentally. Wolkoff and co-workers[8,15–17] performed the experiment for the ozonolysis of monoterpenes and researched primary and secondary ozonides. The yield of

aldehydes and ketones was reported and secondary organic aerosol yield (by mass, at 293 K) of the myrcene ozonolysis accounted for 11%. The ozonolysis aerosol yield of the terpenes with exocyclic double bonds, such as myrcene and linalool, was less than that of the one with endocyclic double bonds, such as limonene.[18] Up to now, no report has presented the calculation of the ozonolysis mechanisms of myrcene with the quantum chemistry method.

This paper is partially based on previous experimental data. A theoretical study was performed to reveal the reaction mechanisms of myrcene with ozone using the density functional theory (DFT) method. The thermodynamic parameters of the reaction steps, such as reaction barriers, enthalpies, and Gibbs free energies, were carefully analyzed. The rate constants were calculated using the Rice–Ramsperger–Kassel–Marcus (RRKM) theory and the canonical variational transition-state theory (CVT) with small curvature tunneling effect (SCT) (CVT/SCT) method, based on quantum chemistry information. Arrhenius equations of the rate constants with a temperature range of 200–800 K are given, and the lifetimes of the reaction species in the troposphere are estimated according to the rate constants.

Computational methods

Geometry optimization

DFT has become a powerful calculation tool because of its merits.[19,20] In this paper, the MPWB1K functional[21] and the 6–31G(d,p) basis set[22] were combined to optimize structures of stationary points and calculate vibrational frequencies. The single-point energies were determined at the MPWB1K/6–311+G(3df,2p) level. Each transition state was verified to connect the specific reactants with products by performing an intrinsic reaction coordinate (IRC) analysis. The profiles of potential energy surfaces were constructed. All work was carried out using the Gaussian 03 suite of programs.[23]

Kinetic calculation

Based on the geometry information from Gaussian output files, including coordinates, gradients, and force constants or Hessian matrix, the rate constants with the tunneling effects were calculated. The CVT/SCT effect correction is a useful method to calculate rate constants, which have been successfully applied to a great deal of research.[24–26] The RRKM method was used to calculate the rate constants of reactions that have no barrier or very low barriers. All kinetic calculations were carried out using the Polyrate 9.7 program[27] and the RRKM-TST program.[28]

In this paper, these methods were employed to study the rate constants of reaction steps over the range of 200–800 K and to discover the relationship between temperature and rate constants. It is obvious that most of the calculated rate constants can be fitted by Arrhenius equations, i.e., $k(T) = A \exp(-E_a/RT)$.

Results and discussion

The reactions of myrcene with O_3

The main possible channels of the myrcene ozonolysis reaction are provided in Fig. 1. Three main O_3 addition channels exist in myrcene ozonolysis reactions.

Reaction channel A of myrcene with O_3

The profile of the potential energy surface for myrcene ozonolysis channel A and subsequent reactions are provided in Fig. 2. In channel A, ozone is added to the C_1=C_2 double bond and forms a van der Waals complex (VdW) IM1, acting as a shallow well in the reaction. Then IM1 isomerizes to intermediate IM2 (primary ozonide, POZ) via transition state TS1 in rn. [1]; the reaction barrier and exothermic energy are 3.8 and 69.1 kcal mol^{-1} (1 cal = 4.184 J), respectively. In the subsequent reactions, two kinds of decomposition processes are identified from IM2. IM2 can decompose into IM3 and formaldehyde via transition state TS2 in rxn. [2]. Formaldehyde and its derivative formic acid have been detected in previous experiments.[18] The reaction barrier of this decomposition channel is 26.9 kcal mol^{-1}. Another reaction channel for IM2 exists, i.e., the decomposition of IM2 to P1 and CH_2O_2 via TS3 in rxn. [3]. The barrier is 28.1 kcal mol^{-1}, and 6.1 kcal mol^{-1} of energy was absorbed.

From the two competitive reactions, it can be concluded that rxn. [2] has a barrier 1.2 kcal mol^{-1} lower than that in rxn. [3]. The rate constant of rxn. [2] was calculated and proved to be larger than that of rxn. [3]. The geometry parameters are listed in Fig. 3.

Reaction channel B

The profile of the potential energy surface for myrcene ozonolysis channel B and subsequent reactions are provided in Fig. 4. The ozone addition channel B begins with the formation of IM4 (VdW), i.e., the association of O_3 and myrcene. Next, ozone is added to the C=C double bond in $>C_7$=$C_8(CH_3)_2$ via transition state TS4 and primary ozonide IM5 is formed in rxn. [4]. Channel B is similar to channel A. These two channels share two common traits, the formation of a five-membered ring adduct of myrcene with ozone and the carbonyl oxides, referring to Criegee intermediates (CH_2O_2, IM3, IM6, and $C_3H_6O_2$). The products consist of IM6 and acetone in rxn. [5] and P2 (4-methylene-5-hexenal) and $C_3H_6O_2$ in rxn. [6]. 4-Methylene-5-hexenal was reported by Reissell et al.[14] The geometry parameters are listed in Fig. 3, and the potential energy surface of channel B is provided in Fig. 4. The reaction channels are described in the following reactions (ΔE_b stands for barrier, and ΔE_r for reaction heat).

[1] $C_{10}H_{16} + O_3 \rightarrow IM4 \rightarrow TS4 \rightarrow IM5$
($\Delta E_b = 0.7$ kcal mol^{-1}, $\Delta E_r = -74.0$ kcal mol^{-1})

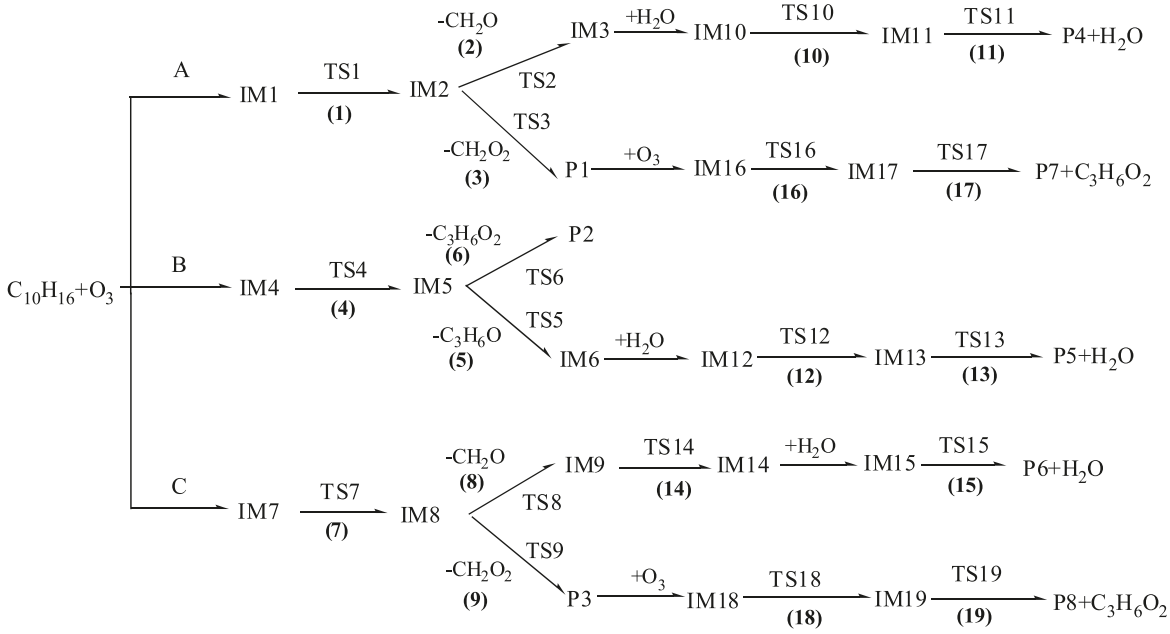
[2] $IM5 \rightarrow TS5 \rightarrow IM6 + C_3H_6O$
($\Delta E_b = 26.0$ kcal mol^{-1}, $\Delta E_r = -5.3$ kcal mol^{-1})

[3] $IM5 \rightarrow TS5 \rightarrow P2 + C_3H_6O_2$
($\Delta E_b = 24.8$ kcal mol^{-1}, $\Delta E_r = -8.6$ kcal mol^{-1})

Reaction channel C

The profile of the potential energy surface for myrcene ozonolysis channel C and subsequent reactions are provided in Fig. 5. The ozone addition channel C of myrcene is similar to channels A and B. After the barrierless association of myrcene and ozone to form IM7, the ozone is added to the

Fig. 1. The main possible reaction channels for the reaction of myrcene with O_3 and subsequent reactions.



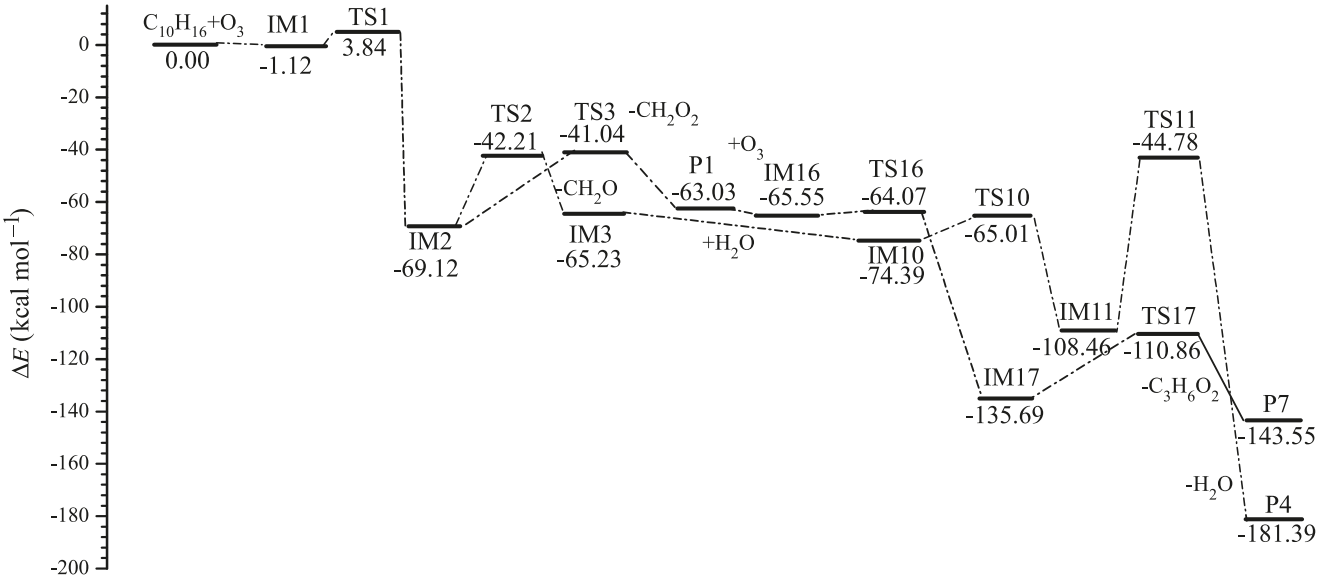


Fig. 2. The profile of the potential energy surface for myrcene ozonolysis channel A and subsequent reactions (energy unit, kcal mol^{-1}; 1 cal = 4.184 J).

C_3=C_4 double bond via transition state TS7 in rxn. [7], and primary ozonide IM8 was obtained. The subsequent competitive reactions produced IM9 (Criegee intermediate) and formaldehyde in rxn. [8] and P3 and CH_2O_2 in rxn. [9]. The geometry parameters are listed in Fig. 3. The reaction channels are given in the following reactions.

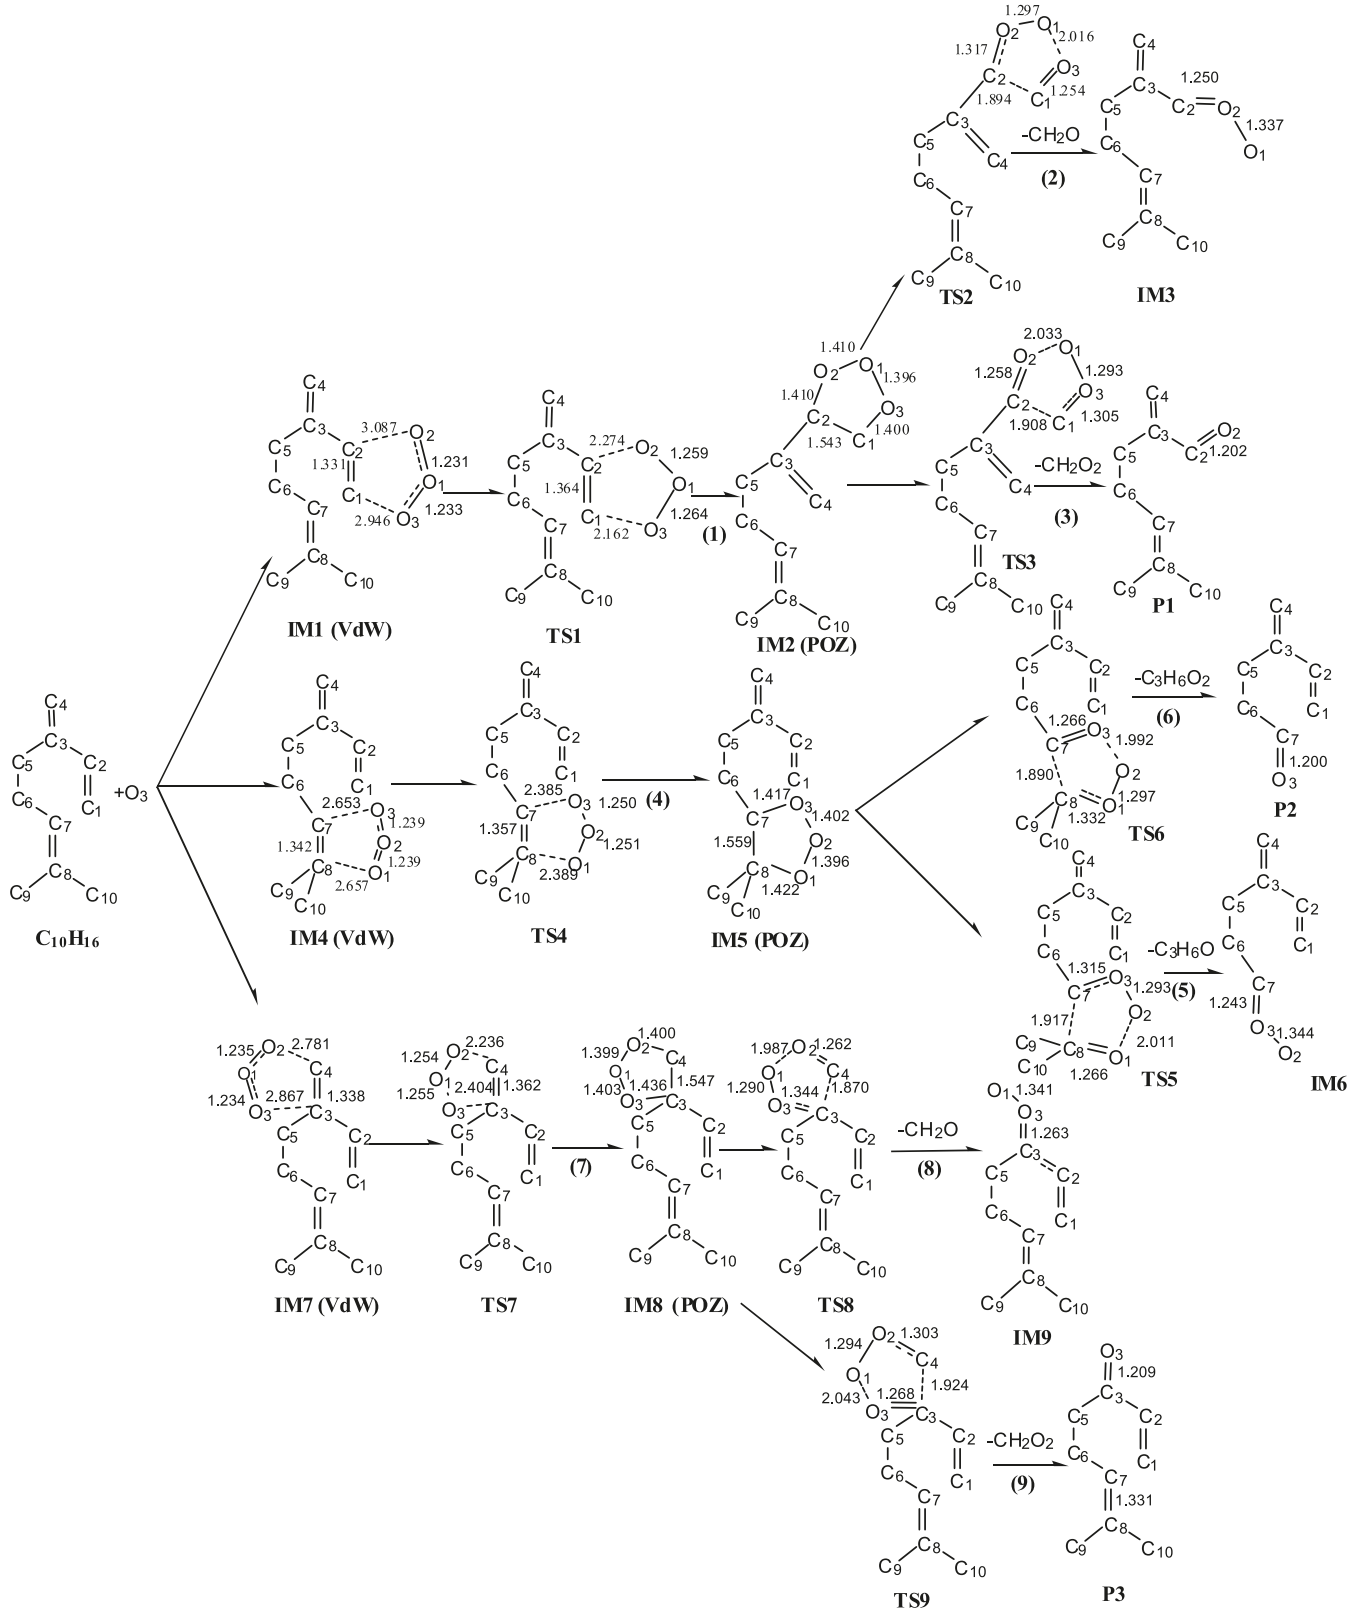
[4] $C_{10}H_{16} + O_3 \rightarrow IM7 \rightarrow TS7 \rightarrow IM5$
($\Delta E_b = 2.5$ kcal mol^{-1}, $\Delta E_r = -67.0$ kcal mol^{-1})

[5] $IM8 \rightarrow TS8 \rightarrow IM9 + CH_6O$
($\Delta E_b = 23.9$ kcal mol^{-1}, $\Delta E_r = -8.3$ kcal mol^{-1})

[6] $IM8 \rightarrow TS9 \rightarrow P3 + CH_2O_2$
($\Delta E_b = 29.7$ kcal mol^{-1}, $\Delta E_r = -0.4$ kcal mol^{-1})

Comparing reaction channels, we see that rxn. [8] has a lower barrier than rxn. [9]; therefore, rxn. [8] should have the larger rate constant at 298.13 K.

The subsequent reactions under atmospheric conditions



The reaction in the presence of H_2O

The H_2O molecule plays an important role in the secondary organic aerosol (SOA) formation.[29,30] The optimized geometries of the reactants, intermediates, transition states, and products for subsequent reactions of Criegee intermedi-

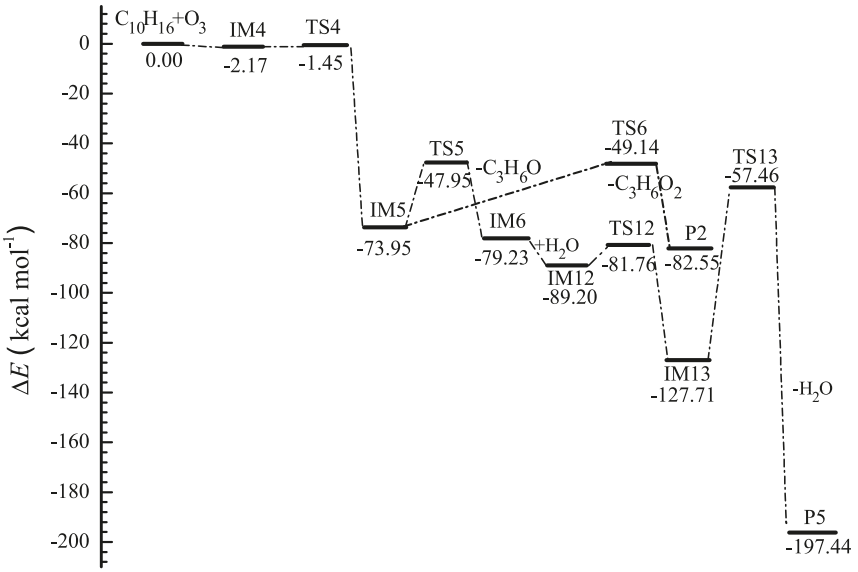
Fig. 3. The diagram of primary ozonide formation and subsequent decompositions.

ates with water are shown in Fig. 6. In channel A, the IM3 reacts with a H_2O molecule to form IM10 through a barrierless association, via transition state TS10 in rxn. [10]. An unstable hydroxyalkyl hydroperoxide (IM11) was formed (Fig. 6). Then, P4 was produced by removing an H_2O molecule from IM11 via transition state TS11 in rxn. [11]. This process includes the following details: after the rupture of the C_2–H_3 and O_2–O_1 bonds and the formation of the O_1–H_3

Fig. 4. The profile of the potential energy surface for myrcene ozonolysis channel B and subsequent reactions (energy unit, kcal mol^{-1}; 1 cal = 4.184 J).



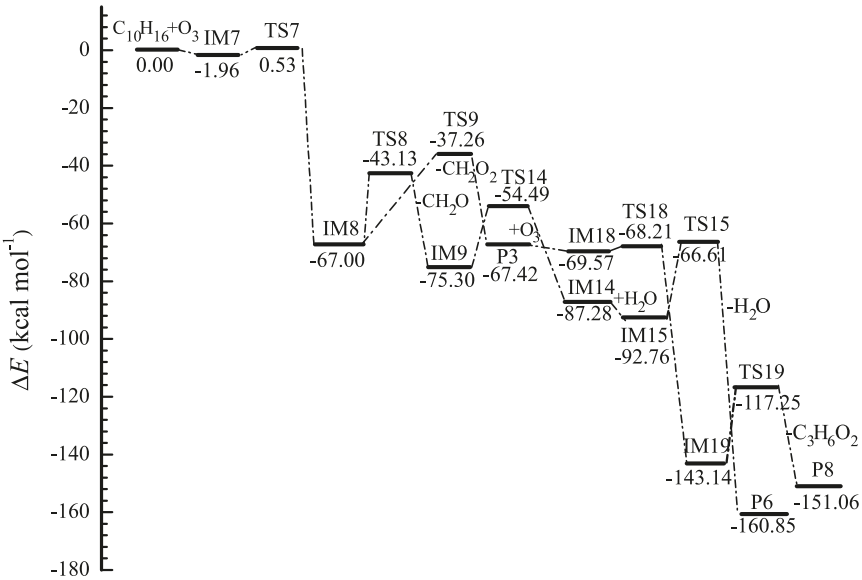


Fig. 5. The profile of the potential energy surface for myrcene ozonolysis channel C and subsequent reactions (energy unit, kcal mol^{-1}; 1 cal = 4.184 J).

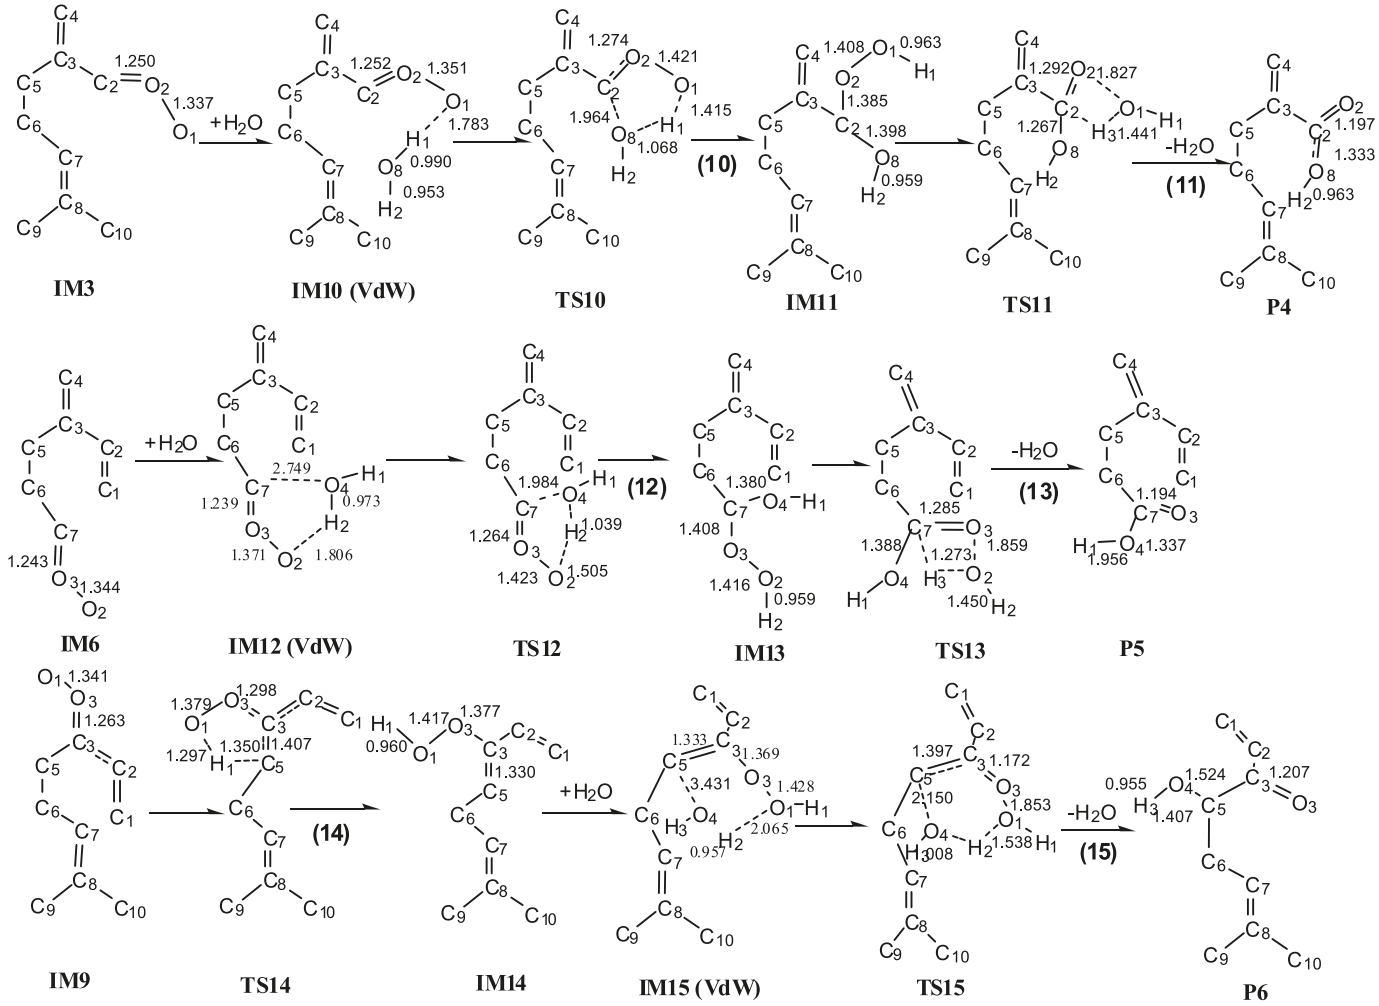
bond, the O_1–H_1 hydroxyl group and the H_3 atom can form an H_2O molecule (Fig. 6). The result shows that the dehydration reaction has a higher reaction barrier than that of the H_2O addition reaction in rxn. [10]. It is implied that the dehydration reaction is the rate-determining reaction step. The profile of the potential energy surface is included in Fig. 2. The reaction channels are described in the following reactions.

[7] $\mathrm{IM3} + \mathrm{H_2O} \rightarrow \mathrm{IM10} \rightarrow \mathrm{TS10} \rightarrow \mathrm{IM11}$
($\Delta E_b = 9.4$ kcal mol^{-1}, $\Delta E_r = -34.1$ kcal mol^{-1})

[8] $\mathrm{IM11} \rightarrow \mathrm{TS11} \rightarrow \mathrm{P4} + \mathrm{H_2O}$
($\Delta E_b = 63.7$ kcal mol^{-1}, $\Delta E_r = -72.9$ kcal mol^{-1})



In channel B, IM6 can associate with a water to produce IM12 (VdW). In TS12, the O_4 atom of H_2O transfers to the C_7 atom and the H_2 atom of the H_2–O_4 tends to link to the O_2 atom. IM13 is obtained via TS12. Similarly, a H_2O is removed and P5 is obtained via TS13 in rxn. [13]. P5 is a carboxylic acid with two unsaturated double bonds (Fig. 6). The potential energy surface is shown in Fig. 4. The reaction channels are described by

[9] $\mathrm{IM6} + \mathrm{H_2O} \rightarrow \mathrm{IM12} \rightarrow \mathrm{TS12} \rightarrow \mathrm{IM13}$
($\Delta E_b = 7.4$ kcal mol^{-1}, $\Delta E_r = -38.5$ kcal mol^{-1})

[10] $\mathrm{IM13} \rightarrow \mathrm{TS13} \rightarrow \mathrm{P5} + \mathrm{H_2O}$
($\Delta E_b = 70.3$ kcal mol^{-1}, $\Delta E_r = -69.7$ kcal mol^{-1})

Fig. 6. The diagram of subsequent reactions of Criegee intermediates with water.

As for channel C, intramolecular hydrogen migration takes place in IM9, i.e., the H1 atom conjoined to the C_5 atom transfers to the O_1 atom via transition state TS14 in rxn. [14]. IM14 is associated with an H_2O, which forms IM15 (VdW), and then another H_2O and the product P6 are obtained via transition state TS15 in rxn. [15] (Fig. 6). The potential energy surface is shown in Fig. 5. The detailed reaction mechanism is represented by

[11] $\text{IM9} \rightarrow \text{TS14} \rightarrow \text{IM14}$
$(\Delta E_b = 20.8 \text{ kcal mol}^{-1},\ \Delta E_r = -12.0 \text{ kcal mol}^{-1})$

[12] $\text{IM14} + H_2O \rightarrow \text{IM15} \rightarrow \text{TS13} \rightarrow \text{P6} + H_2O$
$(\Delta E_b = 20.7 \text{ kcal mol}^{-1},\ \Delta E_r = -73.6 \text{ kcal mol}^{-1})$

The reaction in the presence of excessive O_3

The double bond in product P1 can also react with oxidizing species in the atmosphere. The reaction mechanism between ozone and P1 is presented in the following discussion. IM16, a VdW complex of ozone and P1, is used as the subsequent reactant. Next, an ozone molecule is added to the isobutenyl double bond, generating a primary ozonide IM17 via transition state TS16 in rxn. [16]. IM17 is ruptured via transition state TS17 and then P7 and $C_3H_6O_2$ are obtained. The profile of the potential energy surface is shown in Fig. 2. The reaction channels are represented by

[13] $\text{P1} + O_3 \rightarrow \text{IM16} \rightarrow \text{TS16} \rightarrow \text{IM17}$
$(\Delta E_b = 1.5 \text{ kcal mol}^{-1},\ \Delta E_r = -70.1 \text{ kcal mol}^{-1})$

[14] $\text{IM17} \rightarrow \text{TS17} \rightarrow \text{P7} + C_3H_6O_2$
$(\Delta E_b = 24.8 \text{ kcal mol}^{-1},\ \Delta E_r = -7.9 \text{ kcal mol}^{-1})$

To continue the reactions in channel C, another molecule of ozone can be added to the $>C_7{=}C_8(CH_3)_2$ double bond in P3. The profile of the potential energy surface is shown in Fig. 5. The subsequent reactions (rxns. [18] and [19]) are described by

[15] $\text{P3} + O_3 \rightarrow \text{IM18} \rightarrow \text{TS18} \rightarrow \text{IM19}$
$(\Delta E_b = 1.4 \text{ kcal mol}^{-1},\ \Delta E_r = -73.6 \text{ kcal mol}^{-1})$

[16] $\text{IM19} \rightarrow \text{TS19} \rightarrow \text{P8} + C_3H_6O_2$
$(\Delta E_b = 25.9 \text{ kcal mol}^{-1},\ \Delta E_r = -7.9 \text{ kcal mol}^{-1})$

The final products presented in the previous discussion can be categorized into four groups, including aldehydes (P1, P2,

Note: Arrhenius equations for the reactions: rxn. [4], $k = 5.34 \times 10^{-15}$ exp(–2830.18/T) for this work and $k = 2.21 \times 10^{-15}$exp[–(520 ± 109)/T] in a previous experiment (ref. 31); rxn. [5], $k = 5.07 \times 10^{12}$ exp(–12312/T); rxn. [6], $k = 4.18 \times 10^{12}$ exp(–11788/T); rxn. [12], $k = 6.25 \times 10^{-15}$ exp(299.85/T); rxn. [13], $k = 4.96 \times 10^{12}$ exp(–33623/T).

and P7), ketones (P3), carboxylic acid (P4 and P5), ketone with a hydroxyl group (P6) and ketone with an aldehyde group (P8). P2 ($C_7H_{10}O$) (4-methylene-5-hexenal) has been detected in previous experiments[18] and proved to exist in the atmosphere. Further investigation into secondary ozonide (SOZ) formation is needed. The NO oxygen abstraction reaction with hydrocarbon peroxide is possible in urban areas with the NO_x pollutants from automobile exhaust.

Rate constants

The rate constant results achieved with the CVT/SCT method are reported for the five reaction steps in reaction channel B and listed in Table 1.

In this discussion, the barriers for all types of ozone addition reactions are low, but the rate constants of rxn. [4] are not high enough in contrast to the result from the experiments of Kim et al.[31] As one of the possible reasons, the energy released from the POZ formation was not considered for the subsequent decompositions in the Polyrate 9.7 and RRKM-TST programs. The magnitudes of the rate constants for decomposition rxns. [5] and [6] are 10^{-6} and 10^{-5}, respectively, at room temperature. It can be concluded that the rate constants of the IMb2 (POZ) rupture stay at a moderate level if calculated as an individual reaction.

The barrier for H_2O addition in rxn. [12] is low and the rate constant is 1.70×10^{-14} cm^3 $molecule^{-1}$ s^{-1} at room temperature. The rate constants of rxn. [13] are so low that it may take a long time for this dehydration reaction to complete. But this reaction can release a large amount of heat. Further research is still needed to get the dehydration mechanism to proceed in real conditions.

The equations for the rate constants are shown in the note for Table 1. The correlative coefficient R^2 is above 0.994. These equations are beneficial for the kinetic study of the ozonolysis of volatile terpenes. Based on experiment data, the Arrhenius equation for the gas-phase reaction of β-myrcene and ozone,[29] over the temperature range of 298∼318 K and 1 atm, was reported in previous research:[29]

$$k = (2.21^{+0.94}_{-0.66}) \times 10^{-15} \exp[-(520 \pm 109)/T]$$

where the rate constant k is in units of cm^3 $molecule^{-1}$ s^{-1} and the temperature T is in Kelvin.

The lifetimes of the reactants in rxns. [4]–[6], [12], and [13] were obtained over the range of 200–800 K and are listed in Table S3 of the Supplementary data.

Conclusions

1. The three reaction barriers in POZ formation for myrcene are different from each other. The reaction in the >C=C(CH_3)$_2$ site may take up a larger proportion than those in stable conjugated double bonds, which is also supported in the experiments.
2. The Criegee intermediates, such as CH_2O_2 and $C_3H_6O_2$, are formed in the myrcene ozonolysis mechanisms.
3. In the water addition reactions, H_2O acts as the catalyst of the OH migration and may promote the reactions to happen faster.
4. The barrier of ozone addition in POZ formation is low. However, the CVT/SCT rate constants are low. The barriers of the water addition to carbonyl oxides (Criegee intermediates) are low and the reactions tend to occur. However, the dehydration reaction of unstable hydroxyalkyl hydroperoxides formed by water addition has to overcome such a high barrier that the reaction occurs with difficulty. An alternative reaction channel for Criegee intermediates may exist, such as the formation of OH radicals to accelerate the reaction.

Abstract: The ceric sulfate dosimeter is based on the radio-induced reduction of Ce^{4+} in acidic medium. For low linear energy transfer (LET) radiation, the yield of Ce^{3+} is 2.4 molecules / 100 eV, regardless of the presence of oxygen. To investigate the reaction mechanisms of the ceric sulfate dosimeter, we simulated the chemical reaction kinetics curves and the evolution of $G(Ce^{3+})$, $G(O_2)$, and $G(H_2)$ in the ceric sulfate solution with and without oxygen. Studies of $G(Ce^{3+})$ as function of the initial concentration of Ce^{3+} and of the LET were also done. One important finding of this study is that $^{\bullet}OH$ radicals are scavenged by the reaction $^{\bullet}OH + HSO_4^- \rightarrow SO_4^{\bullet-} + H_2O$, rather than by the reaction $^{\bullet}OH + Ce^{3+} \rightarrow Ce^{4+} + OH^-$.

Key words: ceric sulfate dosimeter, radiolysis, free-radical and molecular yields, linear energy transfer (LET), Monte Carlo simulations.

Résumé : Le dosimètre cérique est basé sur la réduction radio-induite de Ce^{4+} en milieu acide. Pour les radiations de faible transfert d'énergie linéaire (TEL), le rendement de Ce^{3+} est 2,4 molécules / 100 eV, indépendamment de la présence d'oxygène. Pour étudier les mécanismes du dosimètre cérique, nous avons simulé l'évolution temporelle de $G(Ce^{3+})$, $G(O_2)$ et $G(H_2)$ dans une solution de sulfate cérique avec et sans oxygène. Des études des rendements en fonction de la concentration initiale de Ce^{3+} et du TEL ont également été réalisées. Une découverte importante de cette étude est que les radicaux $^{\bullet}OH$ sont captés par la réaction $^{\bullet}OH + HSO_4^- \rightarrow SO_4^{\bullet-} + H_2O$, plutôt que par la réaction $^{\bullet}OH + Ce^{3+} \rightarrow Ce^{4+} + OH^-$.

Mots-clés : dosimètre cérique, radiolyse, rendements radicalaires et moléculaires, transfert d'énergie linéaire (TEL), simulations Monte Carlo.

Introduction

The ceric sulfate dosimeter has been extensively studied and widely accepted. In fact, the International Commission on Radiological Units and Measurements rated this system as the next most useful to the ferrous sulfate dosimeter and recommended its use as a reference standard for radiation doses exceeding 500 Gy.[1] This dosimeter is based on the reduction of Ce^{4+} in acidic medium by the oxidizing species produced by the radiolysis of water. The yield (the number of molecules created or destroyed)[2] of Ce^{3+} for low linear energy transfer (LET) radiations is ~2.4 molec. / 100 eV of deposited energy, regardless of the presence or absence of oxygen.[3] The purpose of this work is to study the reaction mechanisms and kinetics occurring in the ceric sulfate dosimeter.

Experimentally, optimal results are obtained by using a solution of 0.4 mol/L H_2SO_4, 3×10^{-5} mol/L of Ce^{4+}, and 1×10^{-5} mol/L of Ce^{3+}.[3] The irradiation of the system leads to the production of radiolytic species such as $H^{\bullet}$, $^{\bullet}OH$, H_2, H_2O_2, e^-_{aq}, $HO_2^{\bullet}/O_2^{-\bullet}$.[4] Following their formation, these species chemically react with each other during the nonhomogeneous chemical phase, up to ~10^{-6} s after the track structure formation.[5,6] The contributions of these chemical reactions to radiolytic yields in neutral water has been previously discussed.[6] In the ceric dosimeter, there are reactions between radiolytic species, sulfuric acid, Ce^{3+}, and Ce^{4+}.[7]

The radiolytic species are scavenged in the ceric sulfate solution by the following mechanisms. As in the Fricke dosimeter, in acidic medium, the hydrated electrons react with protons to give $H^{\bullet}$ radicals. In the presence of oxygen, the following chemical reaction may happen:

[1] $\quad H^{\bullet} + O_2 \rightarrow HO_2^{\bullet}$

$HO_2^\bullet$ then reacts with Ce^{4+}:

[2] $$HO_2^\bullet + Ce^{4+} \rightarrow H^+ + Ce^{3+} + O_2$$

Similarly, $^\bullet OH$ radicals react with Ce^{3+} as follows:

[3] $$^\bullet OH + Ce^{3+} \rightarrow Ce^{4+} + OH^-$$

Hydrogen peroxide undergoes a Fenton-type reaction:

[4] $$H_2O_2 + Ce^{4+} \rightarrow Ce^{3+} + H^+ + HO_2^\bullet$$

Using rxns. [1]–[4], the material balance equation for the yields of Ce^{3+}, O_2, and H_2 is obtained.

[5] $$\begin{aligned} G(Ce^{3+}) &= 2G_{H_2O_2} - G_{^\bullet OH} + G_{H^\bullet} \\ G(O_2) &= G_{H_2O_2} \\ G(H_2) &= G_{H_2} \end{aligned}$$

where G_X is the primary yield[8] of species X. For ^{60}Co γ-irradiated 0.4 mol/L sulfuric acid aqueous solutions at room temperature (pH ~ 0.46), representative values of the primary free-radical and molecular product yields are[7]

[6] $$\begin{aligned} G_{e^-_{aq}+H^\bullet} &= 3.66 \\ G_{H_2O_2} &= 0.78 \\ G_{H_2} &= 0.40 \\ G_{^\bullet OH} &= 2.84 \\ G_{HO_2^\bullet} &= 0.02 \end{aligned}$$

Using material balance eq. [5] and the primary yields of the radiolytic species (eq. [6]), the values $G(Ce^{3+}) = 2.4$, $G(O_2) = 0.8$, and $G(H_2) = 0.4$ were obtained. These values are in good agreement with experimental data.[3,9]

It is known that the dose rate of the radiation may influence the yield values. At high dose rate, the chemical species formed in spurs are closer to those originating from different radiation tracks and may interact. This can change the radiation chemistry and, consequently, the radiolytic yields. Therefore, the highest dose rate used for the standard ceric dosimeter is usually ~10 Gy/s. In our calculations, since individual tracks are simulated, the dose is much smaller that 1 Gy, and the dose rate is much lower than 10 Gy/s.

In this work, Monte Carlo simulation of the irradiation of the ceric dosimeter by low-LET radiation was performed. The following studies were done: (*i*) the time evolution of the yields of Ce^{3+}, O_2, and H_2 for the ceric dosimeter with oxygen; (*ii*) the time evolution of the yields of Ce^{3+}, O_2, and H_2 for the ceric dosimeter without oxygen; (*iii*) the effect of the initial concentration of Ce^{3+} on the yields of Ce^{3+}; and (*iv*) the effect of the LET of the radiation on the yield of Ce^{3+}. In general, the results of the calculations are in good agreement with experimental data.

Materials and methods

Monte Carlo simulation techniques were used to model the complex succession of events that are generated in irradiated liquid water, sulfuric acid, and ceric sulfate solutions. To simulate the fast electrons or ^{60}Co γ-radiolysis, short (~100 μm) segments of 300 MeV proton tracks, over which the LET value obtained in simulation is nearly constant and equal to ~0.3 keV/μm were used. This approximation is adequate, since the spurs formed by low-LET protons and fast electrons are similar and in general are created too far from each other to influence the radiolytic yields before the end of spur expansion. The number of proton histories (~150) was chosen to ensure small statistical fluctuations of the results while keeping acceptable computer time limits.

Monte Carlo simulations of the ceric dosimeter

The detailed description and implementation of the Monte Carlo simulation codes that were used for this work were previously described.[5,6,10–12] Briefly, all stages of the track development (physical, $<10^{-15}$ s; physicochemical, 10^{-15}–10^{-12} s; nonhomogeneous chemical, 10^{-12}–10^{-6} s; and homogeneous chemical, $>10^{-6}$ s) were modeled on an event-by-event basis. The code IONLYS (which replaces the codes previously called TRACPRO and TRACELE) was used to simulate all events of the early physical and physicochemical stages in the track development. The description of the cross sections, transport models, and other relevant information has been published.[10] These codes have been modified and improved over the years,[13,14] notably to include the new electron cross-sections data by Michaud et al.[15] and the cross sections for multiple ionization (MI) of water molecules by ions.[14] In this study, the simulations were performed using short (10–100 μm) $^1H^+$ ion track segments of LET varying from ~0.3 to 65 keV/μm, for which the contribution of MI can be neglected.

The simulation of the chemistry was performed using the step-by-step (IONLYS-SBS) code.[5,11] The theory used for this code and the implementation of the IONLYS-SBS program has been discussed in previous work.[5,12] Briefly, the program simulates the Brownian motion of the chemical species and evaluates the probabilities of reactions of the particles during small time steps (~10^{-13} s). To avoid unnecessary long calculation times, the time steps were increased exponentially during the simulation. The possibility of occurrence of reactions for each pair of particles was evaluated at each time step by using their respective probabilities of reactions. Similarly, the particles were allowed to react with chemical species distributed in the bulk of the solution. Following chemical reactions, the reactants were removed from the list of particles and newly formed products were added. The diffusion-reaction process was repeated until the time corresponded to the end of the simulation. The parameters used by the IONLYS-SBS program, such as the diffusion coefficients of the particles and the reaction rate constants, are also given.[5] As is the case for the Fricke dosimeter, the full reaction kinetics for the ceric dosimeter was obtained by simulating the chemistry up to 50 s.[7]

Modeling the solution of the ceric sulfate dosimeter

The ceric sulfate dosimeter is a solution comprising Ce^{3+}, Ce^{4+}, and H_2SO_4, with or without oxygen. The concentrations of these compounds can be varied. The cerous ion concentration initially present affects the degree of linearity of the response of the dosimeter to radiation.[16] The higher the initial concentration, the more linear the response. However, unnecessarily high total cerium concentrations should be

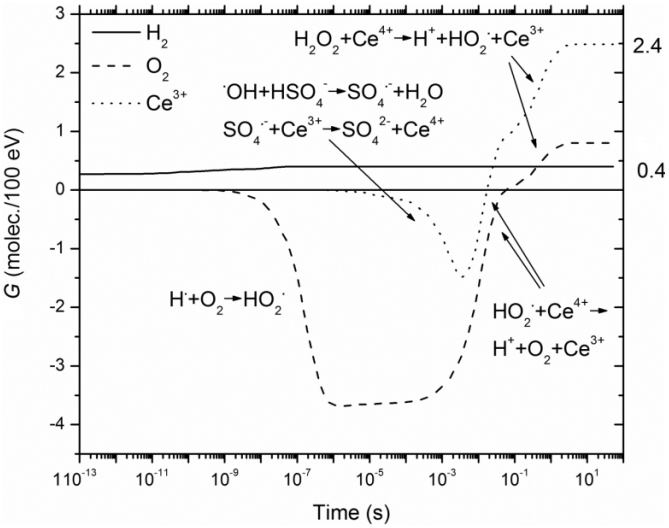
avoided because of possible errors due to the build-up factor ratio when the ^{60}Co energy spectrum is degraded.[17] Consequently, a study was done as a function of the initial concentration of Ce^{3+} in the second part of this work.

Sulfuric acid (H_2SO_4) is a diprotic acid which dissociates according to

$$[7] \qquad H_2SO_4 \underset{pK_{a_1}}{\overset{H^+}{\rightleftarrows}} HSO_4^- \underset{pK_{a_2}}{\overset{H^+}{\rightleftarrows}} SO_4^{2-}$$

with $pK_{a_1} = -3$ and $pK_{a_2} = 1.987$ at 25 °C.[7] The pH of the solution was ~0.46; at this pH, ionic strength affects all reactions between ions, except the bimolecular self-recombination of hydrated electrons for which there is no evidence of such an effect.[18] Ionic strength effects were taken into account in the IONLYS-SBS program by using the equation obtained from the Brønsted–Bjerrum model of ionic reactions and the extended Debye–Hückel theory of ionic solutions. This equation is

$$[8] \qquad \log\left(\frac{k}{k_0}\right) = 1.02 Z_a Z_b \left(\frac{I^{1/2}}{1 + I^{1/2}}\right) - 2bI$$



where k is the rate constant at ionic strength I, k_0 is the rate constant in the limit of zero ionic strength (i.e., infinite dilution), Z_a and Z_b are the algebraic numbers of the charges on the reactants, and b is a parameter taken as ($0.15\ Z_aZ_b$).[19] I is defined as

$$[9] \qquad I = \frac{1}{2}\sum_i Z_i^2 C_i$$

where Z_i is the charge number and C_i is the concentration of the ith ion.[19] The sum runs through all ions present in solution. The reactions added to the IONLYS-SBS code to simulate the ceric dosimeter, along with the rate constants and scavenging power, are presented in Table 1.

The reaction rate constants were obtained from several references and are known with some uncertainty. It is not uncommon for some reaction rate constants to have an uncertainty of up to an order of magnitude. The rate constants used in the simulations were taken from previous work.[12] The values of the rate constants are not expected to influence the stoichiometry of the reactions of the ceric dosimeter, but may alter the time profile of the calculated reaction kinetics.

Fig. 1. Time evolution of $G(Ce^{3+})$, $G(O_2)$, and $G(H_2)$ in the radiolysis of an air-saturated solution of 0.4 mol/L H_2SO_4, 3×10^{-5} mol/L of Ce^{4+}, and 1×10^{-5} mol/L of Ce^{3+} at 25 °C by 300 MeV protons. The concentration of dissolved oxygen is 2.5×10^{-4} mol/L. The values shown on the right are the experimental values of $G(Ce^{3+})$ and $G(H_2)$.

Results and discussion

The ceric dosimeter with oxygen

The simulation results are shown in Figs. 1 and 2 for the ceric dosimeter with $[O_2] = 2.5 \times 10^{-4}$ mol/L.

The most striking result in Fig. 1 is the time evolution of the yield of O_2. The $H^{\bullet}$ radicals are scavenged by oxygen through rxn. [1]; consequently, the yield of O_2 decreases to approximately –3.7, which is similar to the value of $G_{e^-_{aq}+H^{\bullet}} = 3.66$.[20] At ~$10^{-3}$ s, rxn. [2] will release an oxygen molecule for each $HO_2^{\bullet}$ molecule; hence, rxns. [1] and [2] have no net effect on oxygen production. On the other hand, rxn. [4] also starts approximately at this time, producing $HO_2^{\bullet}$, which will generate molecular oxygen through rxn. [2]. Therefore, $G(O_2)$ rises up to 0.8, corresponding to $G_{H_2O_2} = 0.78$. The most significant result of this study is the scavenging of the $^{\bullet}OH$ radicals, which is believed to occur through rxn. [3].[24] However, the curves depicted in Fig. 2 show that this reaction plays only a minor role, if any. In fact, the simulations indicate that $^{\bullet}OH$ is preferentially scavenged by rxn. [10].

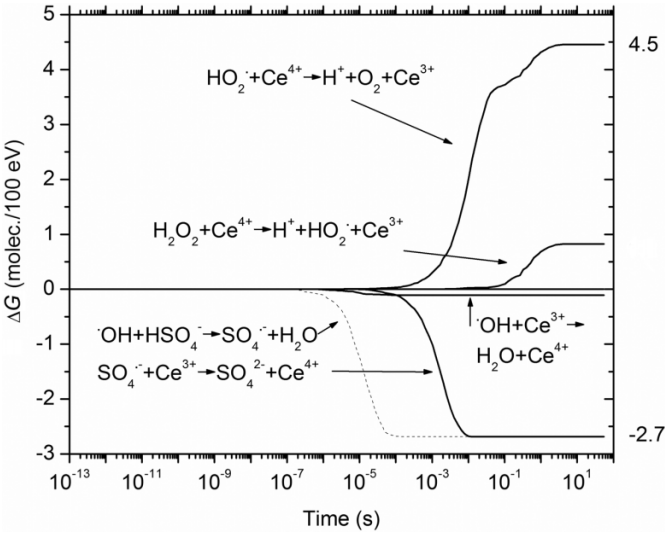
Fig. 2. Time dependence of the extents ΔG (in molecules / 100 eV) of the main reactions involved in the formation (or decay) of Ce^{3+} and O_2, calculated from the simulations of the radiolysis of aerated ceric sulfate solution by ~300 MeV protons.



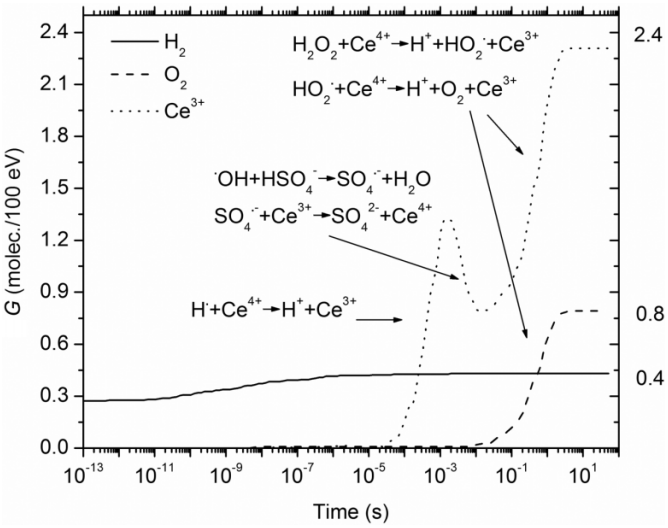


Fig. 3. Time evolution of $G(Ce^{3+})$, $G(O_2)$, and $G(H_2)$ (in molecules / 100 eV) in the radiolysis of deoxygenated solutions of 0.4 mol/L H_2SO_4, 3×10^{-5} mol/L of Ce^{4+}, and 1×10^{-5} mol/L of Ce^{3+} at 25 °C by 300 MeV protons. The values shown on the right are the experimental values of $G(Ce^{3+})$ and $G(H_2)$.

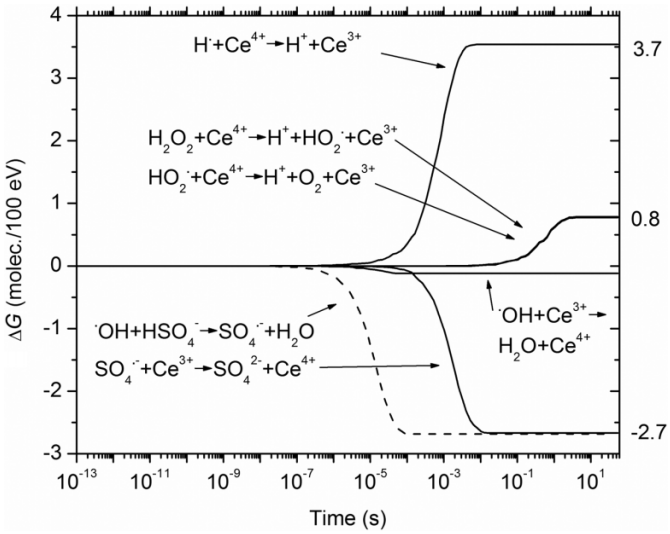


[10] $$^{\bullet}OH + HSO_4^- \rightarrow SO_4^{\bullet-} + H_2O$$

The rate constant of rxn. [3] is larger than the one of rxn. [10], but the concentration of H^+ in the ceric dosimeter is very high so the scavenging power of the latter is ~20 times higher (see Table 1). Following rxn. [10], the $SO_4^{\bullet-}$ radical oxidizes Ce^{3+} to Ce^{4+}.

[11] $$SO_4^{\bullet-} + Ce^{3+} \rightarrow SO_4^{2-} + Ce^{4+}$$

Actually, if rxn. [11] is not included in the IONLYS-SBS code, the calculated yields are not in agreement with the experimental results. The ΔG for this reaction is approximately –2.7, which shows that most of the $^{\bullet}OH$ radical follows this reaction scheme. The effect of this reaction is to reduce $G(Ce^{3+})$.

Fig. 4. Time dependence of the extents ΔG (in molecules / 100 eV) of the main reactions involved in the formation (or decay) of Ce^{3+} and O_2, calculated from the simulations of the radiolysis of deaerated solutions of 0.4 mol/L H_2SO_4, 3×10^{-5} mol/L of Ce^{4+}, and 1×10^{-5} mol/L of Ce^{3+} at 25 °C by 300 MeV protons.

Another consequence of this reaction for the simulation is that a background concentration of Ce^{3+} is necessary for this reaction to occur. If a simulation is attempted with diffusion-based chemistry programs such as IONLYS-IRT[6] or IONLYS-SBS[5,11] without Ce^{3+}, $SO_4^{\bullet-}$ is not scavenged, and therefore it is impossible to find adequate values of $G(Ce^{3+})$.

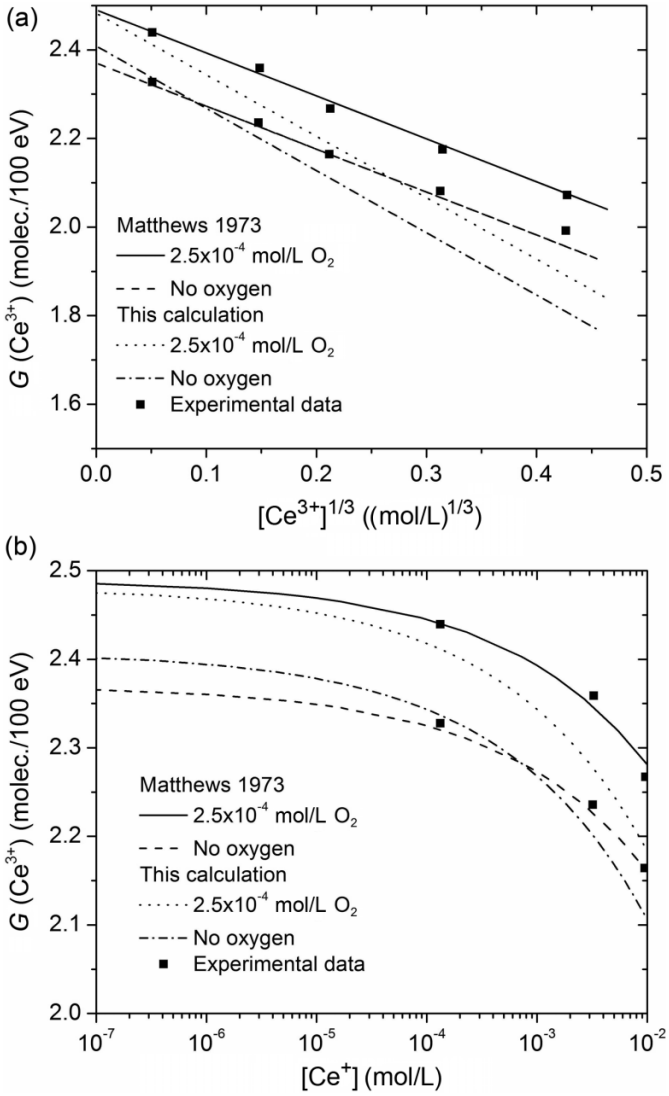
The ceric dosimeter without oxygen

The yields of Ce^{3+}, O_2, and H_2 are similar to those obtained in the ceric dosimeter with oxygen, but the kinetics curves are quite different (Figs. 3 and 4).

In this case, the yield of $HO_2^{\bullet}$ produced by the radiolysis of water is very small, therefore, rxn. [2] will only intervene for $HO_2^{\bullet}$ produced via rxn. [4]. The $H^{\bullet}$ radicals are directly scavenged by Ce^{4+}.

[12] $$H^{\bullet} + Ce^{4+} \rightarrow H^+ + Ce^{3+}$$

The major difference in the kinetics curves comes from rxn. [12], which intervenes much later than rxn. [1]. In this case, oxygen is produced from H_2O_2 via rxns. [2] and [4]. In both cases (with and without oxygen), molecular hydrogen does not react with the other chemical species; thus, $G(H_2) = G_{H_2} = 0.40$.



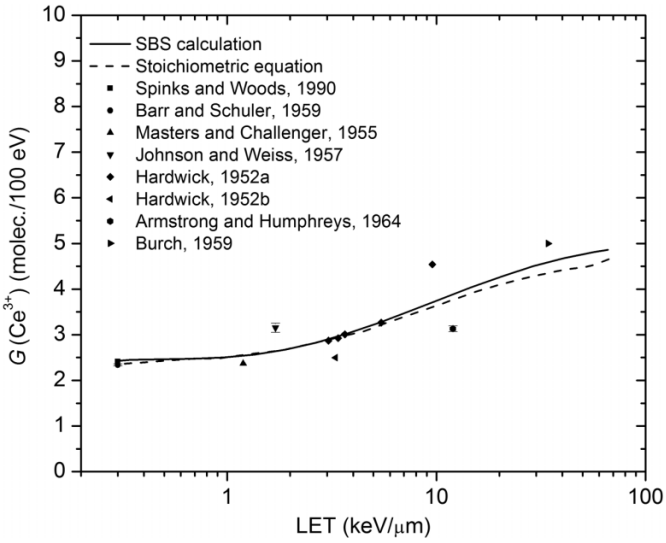
A difference in the yield of Ce^{3+} between aerated and deaerated solutions has been reported in the literature. Matthews[16] reported the following values:

[13] $$G(Ce^{3+})_{ox} = 2.49 - 0.97[Ce^{3+}]^{1/3}$$

[14] $$G(Ce^{3+})_{deox} = 2.37 - 0.87[Ce^{3+}]^{1/3}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by UNIVERSITAT DE VALENCIA on 10/20/12
For personal use only.

Fig. 5. Effect of the initial ceric ion concentration on $G(Ce^{3+})$ in the radiolysis of a solution of 0.4 mol/L H_2SO_4 and 1×10^{-4} mol/L Ce^{4+}, with and without oxygen at 25 °C by 300 MeV protons. The results are compared with the reported values of Matthews.[25]



The values $G(Ce^{3+})_{ox} = 2.47$ and $G(Ce^{3+})_{deox} = 2.35$ are obtained by using $[Ce^{3+}] = 1 \times 10^{-5}$ mol/L. A small difference was also found in our calculated yields: $G(Ce^{3+})_{ox} = 2.48$ and $G(Ce^{3+})_{deox} = 2.31$. We try to explain this difference as follows. In the aerated system, the scavenging power of rxn. [1] is ~3×10^6 s^{-1}. There, the typical reaction time is ~3×10^{-7} s. Thus, rxn. [1] competes with rxns. [15] and [16] in the aerated system.

[15] $H^{\bullet} + {}^{\bullet}OH \rightarrow H_2O$

[16] $H^{\bullet} + H^{\bullet} \rightarrow H_2$

In fact, the ΔG values for rxns. [15] and [16] are 1.01 and 0.077 molec. / 100 eV in the oxygenated system and 1.13 and 0.11 molec. / 100 eV in the deoxygenated system. The net effect on the yield of Ce^{3+} by changing the ΔG of these reactions is not clear, since $H^{\bullet}$ and $^{\bullet}OH$ have opposite effects

Fig. 6. $G(Ce^{3+})$ (in molecules / 100 eV) for aerated 0.4 mol/L H_2SO_4 solutions, 3×10^{-5} mol/L of Ce^{4+}, and 1×10^{-5} mol/L of Ce^{3+} (ceric sulfate dosimeter), at 25 °C, with linear energy transfer (LET) in the range ~0.3–65 keV/μm.

on the yield of Ce^{3+}, and many reactions can be affected by this change. The difference in the ΔG of rxn. [16] between the oxygenated and deoxygenated systems is ~0.035 molec. / 100 eV, which would explain the difference of 0.07 molec. / 100 eV.

[17] $^{\bullet}OH + {}^{\bullet}OH \rightarrow H_2O_2$

It is very tempting to use rxn. [17] to explain the decrease of $G(Ce^{3+})$, because there is more $^{\bullet}OH$ available in the oxygenated system. However, the difference in ΔG between the oxygenated and deoxygenated solutions for this reaction is only ~0.01, which should contribute to a 0.04 rise in $G(Ce^{3+})$ in oxygenated solutions. Therefore, the decrease in $G(Ce^{3+})$ in deoxygenated solutions cannot be fully explained.

Effect of the concentration of Ce^{3+}

As reported in the previous section, $G(Ce^{3+})$ decreases with the concentration of Ce^{3+} as ~$[Ce^{3+}]^{1/3}$. A study was performed as a function of the concentration of Ce^{3+} to verify this assumption. The results are shown in Fig. 5*a*.

The trend is a linear decrease of $G(Ce^{3+})$ with $[Ce^{3+}]^{1/3}$, both in oxygenated and deoxygenated solutions, with slopes that are slightly different from those reported by Matthews.[25] However, because the abscissa is $[Ce^{3+}]^{1/3}$, the graphic can be misleading. The leftmost part of the graphic (up to 0.1 $(mol/L)^{1/3}$) covers concentrations of Ce^{3+} up to 10^{-3} mol/L. The agreement of our calculations with the data of Matthews[25] is better in this region. In fact, Hardwick[26] considered that the yield of cerous ion is independent of the ceric ion concentration over the range of 2×10^{-6} to ~10^{-2} mol/L. This is illustrated in Fig. 5*b*, where the abscissa is $[Ce^{3+}]$. There is some difference with the results of Matthews[25] at $[Ce^{3+}]$ higher than 10^{-3} mol/L. At these concentrations, the scavenging power of rxn. [3] is greater than 3×10^5 s^{-1}; therefore, the typical reaction time is less than ~3.3×10^{-6} s. At these time values, it is possible for rxn. [3] to compete

Can. J. Chem. Downloaded from www.nrcresearchpress.com by UNIVERSITAT DE VALENCIA on 10/20/12
For personal use only.

with $^{\bullet}OH + {}^{\bullet}OH \rightarrow H_2O_2$, leading to a decrease in the production of H_2O_2, which results in a decrease in $G(Ce^{3+})$.

Effect of LET on radiolytic yields

Most of the experimental work on the ceric sulfate system has been done with ^{60}Co γ-rays. Much less experimental data are available on this system for radiation of different LETs. As mentioned by Barr and Schuler,[27] $G(Ce^{3+})$ values increases with LET. This can be explained by noting that at a higher LET, more recombination of the radicals occurs, notably via the reaction $^{\bullet}OH + {}^{\bullet}OH \rightarrow H_2O_2$. Therefore, $G_{H_2O_2}$ increases and $G_{^{\bullet}OH}$ decreases with increasing LET, resulting in an increase in $G(Ce^{3+})$ as indicated by stoichiometric eq. [5]. For example, our previous calculations in acidic pH gave the values $G_{e^-_{aq}+H^{\bullet}} = 1.43$, $G_{H_2O_2} = 1.73$, and $G_{^{\bullet}OH} = 0.24$ at 65 keV/μm.[11] Using these values in eq. [5] yields $G(Ce^{3+}) = 4.64$.

To study the effect of LET on the yield of Ce^{3+}, simulations of the ceric dosimeter by proton tracks segments of energies from ~300 to 0.2 MeV, corresponding to LETs varying from ~0.3 to 65 keV/μm were performed. To ensure small statistical fluctuations on the results, 150 histories were simulated. The simulated $G(Ce^{3+})$ values were compared with the available experimental data from the literature and with calculations using the stoichiometric equation[28] (Fig. 6).

The simulation results show that $G(Ce^{3+})$ increases from ~2.45 molec. / 100 eV at 0.3 keV/μm to ~4.85 molec. / 100 eV at 65 keV/μm.[29] In general, the simulation results compare well with the experimental data, despite the relatively wide spread of measured G values and the scarcity of data for $G(Ce^{3+})$ in this LET range. However, it should be noted that different ions, such as $^4He^{2+}$ ions, were used in the experimental studies.[30]

Conclusion

Monte Carlo simulations of the ceric dosimeter with and without oxygen by low-LET radiation were performed. In both cases, the calculations are able to correctly reproduce the yields of Ce^{3+}, O_2, and H_2. The reaction kinetics curves indicate that $^{\bullet}OH$ radicals are scavenged mainly by HSO_4^-, yielding $SO_4^{\bullet-}$ radicals. The latter then oxidize a Ce^{3+} ion. The net effect on the yield of Ce^{3+} is the same as the direct reaction of $^{\bullet}OH$ with Ce^{3+}, but the reaction mechanism is different. These findings support an affirmation of Spinks and Woods,[24] which states that the mechanism of rxn. [3] has been simplified and reactions of the primary radicals with H_2SO_4 and its anions should not affect the stoichiometry of the reaction. Therefore, it may be useful to do an experiment to determine how $^{\bullet}OH$ radicals are scavenged in the ceric dosimeter. The good overall agreement between calculated and experimental yield values strongly supports the consistency and validity of the model used in this study.

Abstract: The nitrosation of cysteamine ($H_2NCH_2CH_2SH$) to produce cysteamine-*S*-nitrosothiol (CANO) was studied in slightly acidic medium by using nitrous acid prepared in situ. The stoichiometry of the reaction was $H_2NCH_2CH_2SH + HNO_2 \rightarrow H_2NCH_2CH_2SNO + H_2O$. On prolonged standing, the nitrosothiol decomposed quantitatively to yield the disulfide, cystamine: $2H_2NCH_2CH_2SNO \rightarrow H_2NCH_2CH_2S–SCH_2CH_2NH_2 + 2NO$. NO_2 and N_2O_3 are not the primary nitrosating agents, since their precursor (NO) was not detected during the nitrosation process. The reaction is first order in nitrous acid, thus implicating it as the major nitrosating agent in mildly acidic pH conditions. Acid catalyzes nitrosation after nitrous acid has saturated, implicating the protonated nitrous acid species, the nitrosonium cation (NO^+) as a contributing nitrosating species in highly acidic environments. The acid catalysis at constant nitrous acid concentrations suggests that the nitrosonium cation nitrosates at a much higher rate than nitrous acid. Bimolecular rate constants for the nitrosation of cysteamine by nitrous acid and by the nitrosonium cation were deduced to be 17.9 ± 1.5 $(mol/L)^{-1}$ s^{-1} and 6.7×10^4 $(mol/L)^{-1}$ s^{-1}, respectively. Both Cu(I) and Cu(II) ions were effective catalysts for the formation and decomposition of the cysteamine nitrosothiol. Cu(II) ions could catalyze the nitrosation of cysteamine in neutral conditions, whereas Cu(I) could only catalyze in acidic conditions. Transnitrosation kinetics of CANO with glutathione showed the formation of cystamine and the mixed disulfide with no formation of oxidized glutathione (GSSG). The nitrosation reaction was satisfactorily simulated by a simple reaction scheme involving eight reactions.

Key words: nitric oxide, nitrosation, thiols, cysteamine, kinetics.

Résumé : Opérant en milieu légèrement acide et utilisant de l'acide nitreux préparé in situ, on a étudié la réaction de nitrosation de la cystéamine ($H_2NCH_2CH_2SH$) conduisant à la cystéamine-*S*-nitrosothiol (CANO). La stoechiométrie de la réaction est $H_2NCH_2CH_2SH + HNO_2 \rightarrow H_2NCH_2CH_2SNO + H_2O$. Laissé longtemps au repos, le nitrosothiol se décompose quantitativement avec formation du disulfure, cystamine : $2H_2NCH_2CH_2SNO \rightarrow H_2NCH_2CH_2S–SCH_2CH_2NH_2 + 2NO$. Le NO_2 et le N_2O_3 ne sont pas les agents de nitrosation primaires puisque leur précurseur, le NO, n'a pas été détecté au cours du processus de nitrosation. La réaction est du premier ordre en acide nitreux, ce qui implique qu'il est l'agent de nitrosation majeur dans des conditions de pH légèrement acides. L'acide catalyse la nitrosation après une saturation par l'acide nitreux et ceci implique que, dans des environnements d'acidité élevée, le cation nitrosonium (NO^+) peut agir comme espèce nitrosante. La catalyse acide, à des concentrations constantes d'acide nitreux, suggère que le cation nitrosonium provoque la nitrosation avec une constante de vitesse beaucoup plus élevée que ce l'acide nitreux. On a déduit que les constantes de vitesse bimoléculaires pour la nitrosation de la cystéamine, par l'acide nitreux et par le cation nitrosonium, sont respectivement de $17{,}9 \pm 1{,}5$ $(mol/L)^{-1}$ s^{-1} et $6{,}7 \times 10^4$ $(mol/L)^{-1}$ s^{-1}. Les ions Cu(I) ainsi que Cu(II) sont tous les deux efficaces comme catalyseurs pour la formation et la décomposition du nitrosothiol de la cystéamine. Les ions Cu(II) catalysent la nitrosation de la cystéamine dans des conditions neutres alors que les ions Cu(I) ne la catalysent que dans des conditions acides. La transnitrosation du CANO avec du glutathion donne lieu à la formation de cystamine et du disulfure mixte, sans formation du produit doxydation du glutathion (GSSG). On peut simuler d'une façon satisfaisante la réaction de nitrosation par un schéma réactionnel simple impliquant huit réactions.

Mots-clés : oxyde nitrique, nitrosation, thiols, cystéamine, cinétique.

Introduction

Nitric oxide (NO) is a simple gaseous molecule with fascinating biological functions.[1] It is one of the most versatile bioactive molecules ever identified. Unlike other free radicals, it is relatively stable, but becomes unstable in biological systems due to its reaction with oxygen, superoxide anion ($O_2^{\bullet-}$), and haem proteins.[2] Nitrite (NO_2^-) is the major end product of its reaction with oxygen. Nitrite can also release NO on acidification and by the reductase activity of the enzyme, xanthine oxidoreductase, at pH conditions lower than 6.0.[3–5]

Nitric oxide has been the focus of many research groups in recent years, probably because of the realization that it is synthesized by mammalian cells and can act both as a physiological messenger and as a cytotoxic agent.[6] It is an essential physiological signaling molecule necessary for cell-to-cell communication and it is also involved in the regulation of gene expression and modification of sexual and aggressive behavior.[7,8] It is actively involved in smooth muscle relaxation due to its ability to activate guanosine 3′,5′-cyclic monophosphate (cGMP) in smooth muscle tissue.[9,10] The role of nitric oxide in the physiological system at any given time significantly depends on its concentration and its environment. It is known to perform most of its beneficial roles, such as vasorelaxation[11,12] and neurotransmission,[13,14] at low concentrations, on the order of 5–10 nmol/L.[15] At this concentration range it cannot effectively compete with superoxide dismutase (SOD) for $O_2^{\bullet-}$.

NO also readily reacts with $O_2^{\bullet-}$ to produce the highly damaging and genotoxic oxidant (peroxynitrite, $ONOO^-$):

$$[R1] \qquad NO + O_2^{\bullet-} \rightarrow ONOO^-$$

The bimolecular rate constant for rxn. [R1] is 6.7×10^9 $(mol/L)^{-1}$ s^{-1}.[15,16] Superoxide anion radical concentrations in the physiological environment are in the order of 4–10 μmol/L.[15] When NO concentrations are in the micromolar range, rxn. [R1], which produces the deleterious peroxynitrite, becomes competitive with the deactivating reaction that removes superoxide anion radical.

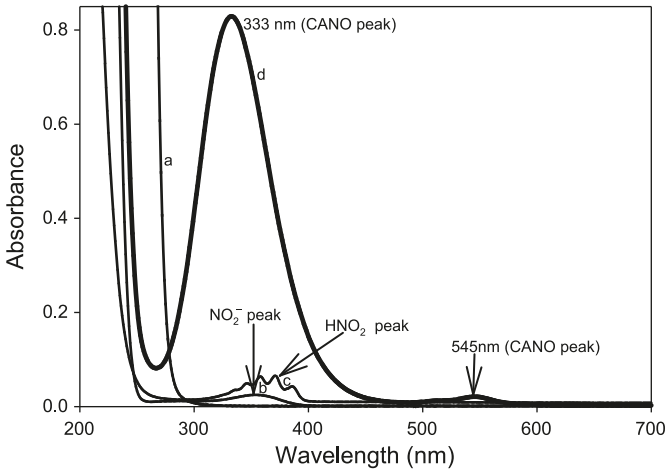
Excessive production of nitric oxide has thus been linked to so many cytotoxic activities such as septic shock and liver injury.[17,18] It is necessary to have processes that can reduce NO concentrations to beneficial levels in the physiological environment. Such processes would include its reaction with thiols to form *S*-nitrosothiols (RSNOs). For example, RSNOs have been shown to improve end-organ recovery in models of ischemia–reperfusion injury in the heart and liver.[19,20] Biological nitrosothiol formation is a post-translational modification of biological thiols that is subsequently linked to all those functions that are attributed to nitric oxide.[21] Possible roles of S-nitrosation include the regulation of apoptosis through glyceraldehyde-3-phosphate dehydrogenase modification[22] as well as involvement in the pathogenesis of Parkinson's disease.[23] There are several studies on nitrosothiol formation by Williams,[24–33] but these studies dwell on formations and characterizations and not so much on the mechanisms and kinetics. Despite the potential benefits of the relevance of the mechanistic basis of nitrosations (both S- and N-nitrosations),[34] very few studies have been directed at elucidating these mechanisms.

Cysteamine (2-aminoethanethiol) is a very important physiologically active β-aminothiol. It is produced in vivo by degradation of coenzyme A. Coenzyme A is a cofactor in many enzymatic pathways, which include fatty acid oxidation, heme synthesis, synthesis of the neurotransmitter acetylcholine, and amino acid catabolism.[35] Cysteamine is medically known as Cystagon and can be used as oral therapy for the prevention of hypothyroidism and as a growth enhancer in patients with nephropathic cystinosis.[36] Cysteamine and its disulfide (cystamine) can also be used in topical eye drops to dissolve corneal cystine crystals.[37,38] It has also been shown to be an effective molecule against hepatotoxicity caused by excessive production of nitric oxide.[17]

Although a series of studies have been performed on the metabolism of this thiol and its metabolites with respect to oxidation by reactive oxygen species,[39–41] nothing has been done on the elucidation of its mechanism of nitrosation by NO and (or) NO-derived metabolites (N_2O_3 and NO^+). Its nitrosation is well-known and has been reported in several manuscripts,[42,43] but the exact mechanistic details are still unknown. We report herein on the detailed kinetics and mechanism of the nitrosation of cysteamine. The nitrosating agent is produced in situ, by premixing H^+ and NO_2^- and utilizing a double-mixing stopped-flow spectrophotometer. This manuscript also reports on detailed product analysis as well as on transnitrosation kinetics. The most prevalent thiol-based antioxidant in the physiological environment is glutathione. It is envisaged that, in any discussion of S-nitrosation, glutathione would be a major player.

Experimental

Materials



Cysteamine hydrochloride (CA, 2-aminoethanethiol hydrochloride) 98%, cystamine, cysteine (99+%), sodium perchlorate (Acros), glutathione, sodium nitrite, sodium chloride, perchloric acid (72%), ferrous sulfate (Fisher Scientific), cuprous chloride, and cupric chloride (GSF chemicals) were used as purchased. Stock solutions of CA and nitrite were prepared just before use. Reagent solutions were prepared with distilled and deionized water from a Barnstead Sybron Corporation water purification unit. Inductively coupled plasma mass spectrometry (ICP–MS) was used to show that our aqueous reaction medium did not contain enough transition-metal ions to affect the overall reaction kinetics and mechanism The highest metal ion concentration was cadmium at 1.5 ppb followed by lead at 0.43 ppb. Copper was virtually undetectable.

Methods

All experiments were carried out at 25.0 ± 0.1 °C and at a constant ionic strength of 1.0 mol/L ($NaClO_4$). The progress of the nitrosation reaction was monitored spectrophotometrically by following the absorbance of *S*-nitrosocysteamine (CANO) at its experimentally determined absorption peak of 545 nm, where an absorptivity coefficient of 16.0 ± 0.1 $(mol/L)^{-1}$ cm^{-1} was evaluated. Although CANO has a second absorption peak at 333 nm, with a much higher absorptivity coefficient of 536.0 $(mol/L)^{-1}$ cm^{-1}, its maximum absorption at 545 nm was used owing to the lack of interference

Fig. 1. UV–vis spectral scan of reactants 0.01 mol/L cysteamine hydrochloride (CA, a), 0.001 mol/L $NaNO_2^-$ (b), 0.001 mol/L HNO_2 (c), and product 0.001 mol/L *S*-nitrosocysteamine (CANO, d).

from the absorption peaks of nitrogen species (NO_2^-, NO^+, and HNO_2) at this absorption wavelength (see Fig. 1).

Product identification and verification was achieved by complementary techniques: UV–vis spectrophotometry, HPLC, quadrupole time-of-flight mass spectrometry (TOF-MS), and electron paramagnetic resonance (EPR) spectrometry. Kinetics measurements for fast reactions were performed on a Hi-Tech Scientific double-mixing SF61-DX2 stopped-flow spectrophotometer. For slower reactions, a PerkinElmer Lambda 25 UV–vis spectrophotometer was used.

Stoichiometric determinations were performed by mixing excess perchloric acid and nitrite with a fixed amount of CA such that CA was the limiting reagent. The reaction was allowed to proceed to completion while rapidly scanning the reacting solution between 200 and 700 nm. The concentration of CANO was deduced from its maximum absorption at 545 nm.

HPLC technique

The HPLC system utilized a Shimadzu Prominence (Columbia, Maryland) SPD-M10A VP diode array detector, dual LC 600 pumps, LPT-6B LC–PC interface controller, SIL-10AD auto injector, and Class-VP chromatography data system software. All samples were loaded on a reversed phase Discovery 5 μm C18 column (Supelco, Bellefonte, Pennsylvania). They were run isocractically at 0.15% trifluoroacetic acid (TFA) / H_2O to 10% methanol / H_2O, and CANO was detected at 545 nm (for selective scans) with maximum spectral scan mode employed to detect all eluents. A flow rate of 1 mL/min was maintained. All solutions for HPLC analysis were made with Milli-Q Millipore purified water and filtered with Whatman Polypropylene 0.45 μm pore-size filter devices before injection (10 μL) into the column using the auto injector. To curb the interaction of the protonated amines on the analytes with the silanol groups on the stationary phase (which was causing tailing of peaks), the sodium salt of 1-octanesulfonic acid (0.005 mol/L) was incorporated into the aqueous mobile phase as an HPLC ion-pairing agent. This was sufficient to neutralize the protonated amines and produce good resolution while eliminating peak tailing.

TOF-MS

Mass spectra were acquired on a Micromass QTOF-II (Waters Corporation, Millford, MA) quadrupole time-of-flight mass spectrometer. Analytes were dissolved in 50:50 acetonitrile / water – 1% formic acid mixture, and analyte ions were generated by positive-mode electrospray ionization (ESI) at a capillary voltage of 2.8 kV and a flow rate of 5 μL/min. The source block was maintained at 80 °C and the nitrogen desolvation gas was maintained at 150 °C and at a flow rate of 400 L/h. Data were visualized and analyzed with the Micromass MassLynx 4.0 software suite for Windows XP (Water Corporation, Millford, Massachusetts).

EPR Measurements

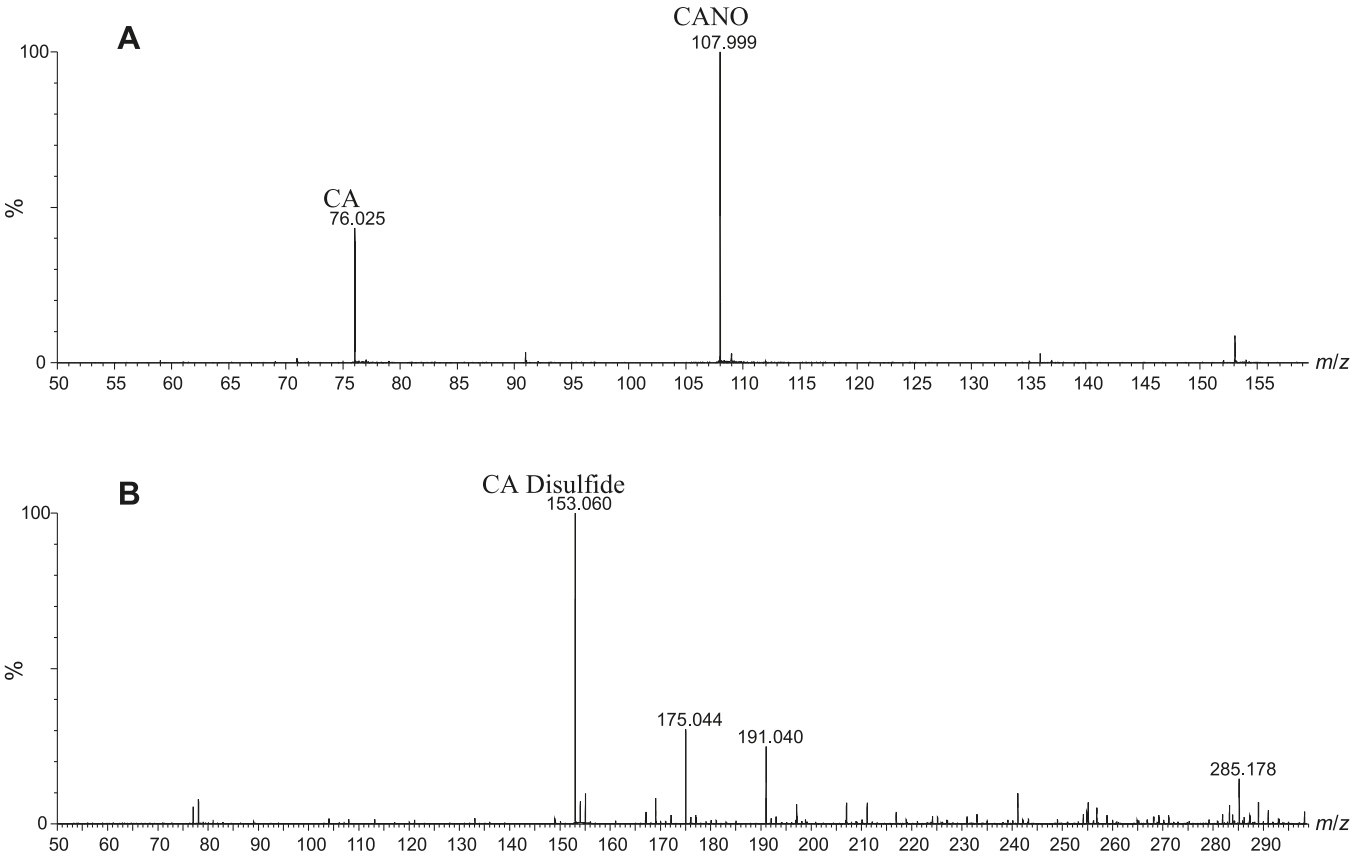
A Bruker e-scan EPR spectrometer (X-band) was used for the detection of radicals and to confirm the release of NO upon the decomposition of CANO. Detection of NO was through the use of the NO-specific spin trap, *aci*-nitroethane.[44] The following settings were used for a typical run: microwave power, 19.91 mW; modulation amplitude, 1.41 G; receiver gain, 448; time constant, 10.24 ms; sweep width, 100 G; and frequency, 9.78 GHz. All measurements were taken at room temperature.

Results

The major reaction studied was a simple nitrosation of cysteamine through in situ production of nitrous acid as the nitrosating agent. The yield of CANO varied, based on the order of mixing reagents. The highest yield, which gave quantitative formation of CANO, was obtained by premixing nitrite with acid and incubating the solution for approximately 1 s before subsequently reacting this nitrous acid with cysteamine in a third reagent stream of the double-mixing stopped-flow spectrophotometer. The value of the absorptivity coefficient of CANO at 545 nm adopted for this study of 16.0 mol/L^{-1} cm^{-1} was derived from this mixing order. Premixing CA with acid before the addition of nitrite gave a lower yield of CANO. The available protons are reduced by the protonation of CA.

$$[R2] \qquad H_2NCH_2CH_2SH + H^+ \leftrightarrow [H_3NCH_2CH_2SH]^+$$

This subsequently reduces the amount of the immediately available nitrosating agent, HNO_2.



Stoichiometry and product analysis

The stoichiometry, in conditions of excess acid and nitrite over CA, was strictly 1:1.

$$[R3] \qquad H_2NCH_2CH_2SH + HNO_2 \rightarrow H_2NCH_2CH_2S-NO + H_2O$$

Stoichiometry rxn. [R3] is attained within a minute of mixing the reagents at high acid concentrations, and a little longer in lower acid concentrations. High acid concentrations rapidly form the product (CANO), which also rapidly decomposes. A resolvable mass spectrum is taken at low acid concentrations, and this generally will show both the reagent (CA) and the single product (CANO). This mass spectrum is shown in Fig. 2A. There are no other peaks that can be discerned from the reaction mixture, apart from those belonging to the reagent and the product. Incubation of the product of

Fig. 2. Mass spectrometry analysis of the product of nitrosation of cysteamine hydrochloride (CA) showing (A) formation of *S*-nitrosocysteamine (CANO), m/z = 107.9999; (B) product of decomposition of CANO after 24 h. Cystamine, a disulfide of CA was produced with a strong peak, m/z = 153.0608.

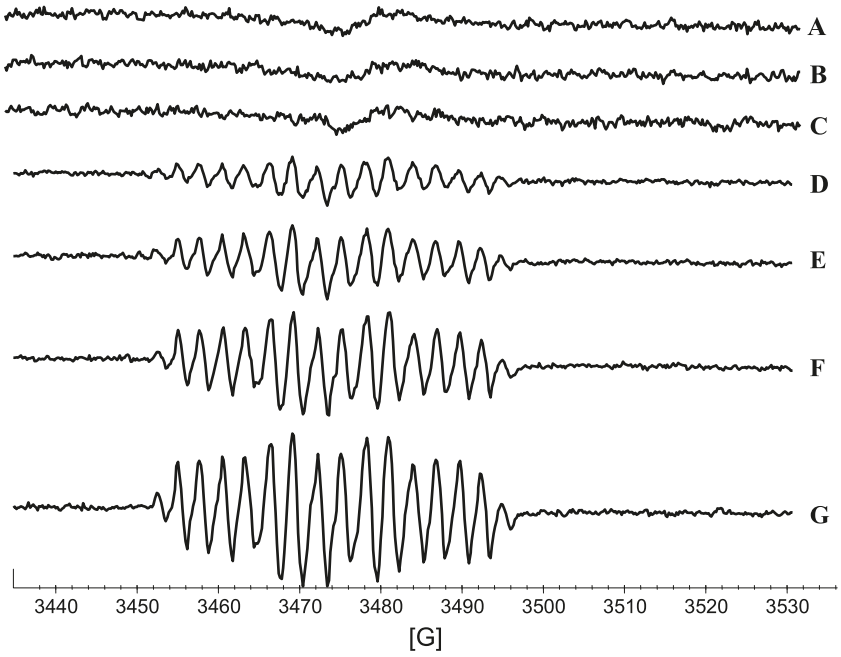
nitrosation overnight shows a final conversion of the CANO into the disulfide, cystamine ($H_2NCH_2CH_2S–SCH_2CH_2NH_2$, Fig. 2B).

$$[R4] \quad 2H_2NCH_2CH_2S-NO \rightarrow H_2NCH_2CH_2S-SCH_2CH_2NH_2 + 2NO$$

Nitric oxide can be trapped and observed by EPR techniques through the use of a nitroethane trap.[44] The aci-anion of this trap, formed in basic environments, generates a long-lived spin adduct with NO, which is detectable and quantifiable by its distinct EPR spectrum pattern and g value.



$$[R5] \quad CH_3CH=NO_2^- + {}^{\bullet}NO + OH^- \rightarrow [CH_3C(NO)(NO_2)]^{\bullet 2-} + H_2O$$

This adduct ($[CH_3C(NO)(NO_2)]^{\bullet 2-}$) is EPR-active. No peaks were obtained in the EPR spectrum when the nitroethane trap was utilized during the formation of CANO, indicating that NO is not released during the S-nitrosation and that it is not a major nitrosation agent in this mechanism. Upon use of the trap, however, during the decomposition of CANO, a strong EPR spectrum indicating the presence of NO was obtained, proving stoichiometry [R4]. Figure 3 shows a series of EPR spectra that proves the presence of NO in the decomposition of CANO. The first three spectra show that, on their own, nitroethane, CA, and NO_2^- cannot generate any active peaks that can be attributed to NO. In excess concentrations of the trapping reagent, heights of the spectral peaks can be used, after a standardization, as a quantitative measure of the available NO. NO has a very poor solubility in water, and so the technique is limited only to low NO concentrations.

Reaction kinetics

The reaction has a very simple dependence on cysteamine concentrations (see Figs. 4A and 4B). There is a linear first-order dependence on the rate of nitrosation with CA concentrations with an intercept kinetically indistinguishable from zero. The reaction kinetics are more reproducible in the format utilized in Fig. 4 in which concentrations of acid and nitrite are equal and in overwhelming excess over CA concentrations. The effect of nitrite is also simple and first-order (see Figs. 5) when nitrite concentrations do not exceed the initial acid concentrations. Effectively, under these conditions, all N(III) species in the reaction environment are in the form of protonated HNO_2. Acid effects are much more complex and are dependent on the ratio of initial acid to nitrite concentrations. The nitrosation response to acid differs, depending on whether initial proton (H_3O^+) concentrations exceed initial nitrite concentrations. The most important parameter affecting the rate of nitrosation is the concentration of HNO_2. A set of kinetics traces that encompass a proton concentration variation, which ranges from concentrations

Fig. 3. Electron paramagnetic resonance (EPR) spectra of the NO radical generated during the decomposition of *S*-nitrosocysteamine (CANO) using 0.5 mol/L nitroethane (NE) in 1.0 mol/L NaOH solution as the spin trap. (A) 0.5 mol/L NE, (B) 0.01 mol/L NO_2^-, (C) 0.04 mol/L cysteamine hydrochloride (CA), (D) [CANO] = 0.01 mol/L, (E) [CANO] = 0.02 mol/L, (F) [CANO] = 0.03 mol/L, and (G) [CANO] = 0.04 mol/L.

that are lower than nitrite to those that exceed, was performed. A simple plot of added acid to the rate of nitrosation shown in Fig. 6A clearly displays a discontinuity at the point where acid exceeds nitrite concentrations. By utilizing the dissociation constant of HNO_2, the final concentrations of H_3O^+, NO_2^-, and HNO_2 can be calculated for each set of initial concentrations. These data are shown in Table 1 for the input concentrations used for the set of kinetics experiments. Close examination of the data in Table 1 shows that the kinetics of the reaction are vastly different depending on whether initial acid concentrations exceed initial nitrite concentrations. When nitrite is in excess (the first four readings), there is a sharp nonlinear increase in the rate of nitrosation with nitrous acid concentrations (Fig. 6B), and a saturation in rate with respect to the actual proton concentrations despite the recalculation of the concentrations undertaken in Table 1. Figure 6B would strongly indicate second-order kinetics in nitrous acid, and a plot of nitrosation rate versus nitrous acid to the second power is linear (plot not shown). Table 1 shows that, in the series of data plotted for Fig. 6B, nitrous acid concentrations and excess proton concentrations increase while nitrite concentrations decrease, and the final observed rate of nitrosation is derived from these three species concentrations and not isolated to nitrous acid. At acid concentrations that exceed initial nitrite concentrations, there is a linear dependence in rate on acid concentrations (Fig. 6C). Note that a saturation would have been achieved in nitrous acid concentrations as would be expected in this format in which the nitrous acid saturates at 50 mmol/L. The increase in nitrosation rate with an increase in acid after saturation of HNO_2 indicates that other nitrosants apart from HNO_2 exist in the reaction environment.

Effect of copper

Copper has been implicated in many reactions involving organosulfur compounds.[45–47] Cu(I) is known to be much more active than Cu(II). It is easier to assay for Cu(II) and the addition of Cu(II) to organosulfur reactions involves its initial conversion to the more active Cu(I). Figure 7A shows that addition of Cu(II) rapidly increases the nitrosation reaction. Cu(II) ions, however, also catalyze the decomposition of CANO. A plot of the rate of nitrosation versus Cu(II) concentrations shows the sigmoidal rate increase followed by an abrupt saturation, which is typical of catalytic mechanisms (figure not shown). No nitrosation occurs in the presence of nitrite without acid (which is necessary to generate the HNO_2). Figure 7B, however, shows that, even in the absence of acid, Cu(II) ions can still effect the nitrosation of CA. Cu(I) ions, however, could not effect nitrosation in the absence of acid. Figure 7C shows the catalytic effect of Cu(II) ions on the decomposition of CANO. CANO was prepared in situ from two feed streams of the double-mixing stopped flow ensemble. Cu^{2+} ions derived from cupric chloride were next added from a third feed stream after complete production of CANO. All feed streams were buffered at pH 7.4. The two control experiments (traces a and b) show the slow decomposition expected from CANO solutions at pH 7.4. Trace b was treated with EDTA to sequester all metal ions in the reaction solution. This trace is identical to the one without EDTA (trace a), confirming the absence of metal ions in reagent solution, which can affect the decomposition kinetics. Addition of micromolar quantities of Cu(II) ions effects a big acceleration in the rate of decomposition. Higher Cu(II) concentrations give a strong autocatalytic decay of the nitrosothiol (trace f in Fig. 7C). The catalytic effect of Cu(II) ions on the decomposition can also be

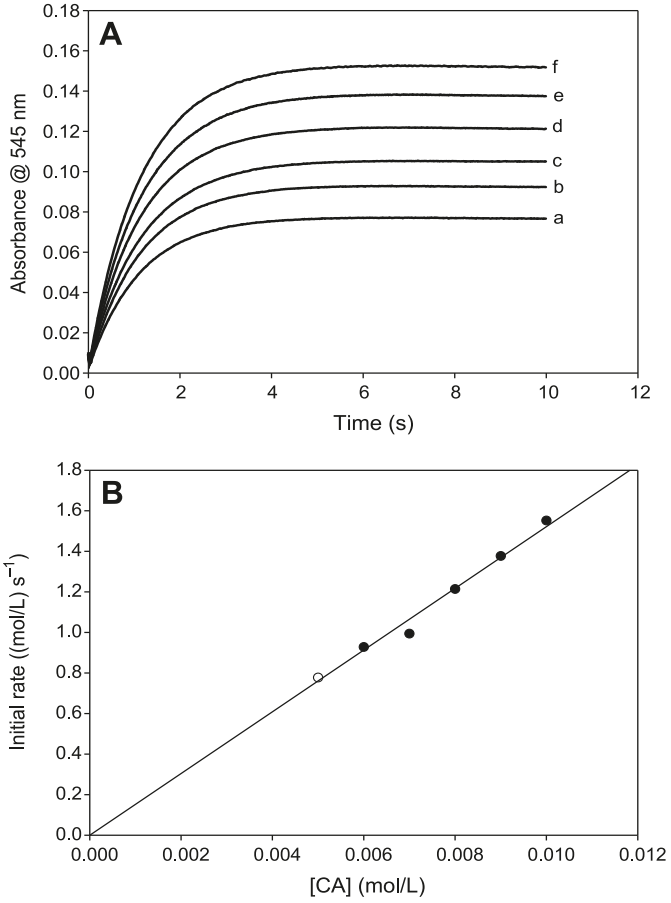
Fig. 4. (A) Absorbance traces showing the effect of varying cysteamine hydrochloride (CA) concentrations. The reaction displays first-order kinetics in CA. $[NO_2^-]_0 = 0.10$ mol/L; $[H^+]_0 = 0.10$ mol/L; and (a) $[CA]_0 = 0.005$ mol/L; (b) $[CA]_0 = 0.006$ mol/L; (c) $[CA]_0 = 0.007$ mol/L; (d) $[CA]_0 = 0.008$ mol/L; (e) $[CA]_0 = 0.009$ mol/L; and (f) $[CA]_0 = 0.010$ mol/L. (B) Initial rate plot of the data in Fig. 4A. The plot shows the strong first-order dependence of the rate of formation of *S*-nitrosocysteamine (CANO) on CA, with an intercept kinetically indistinguishable from zero.



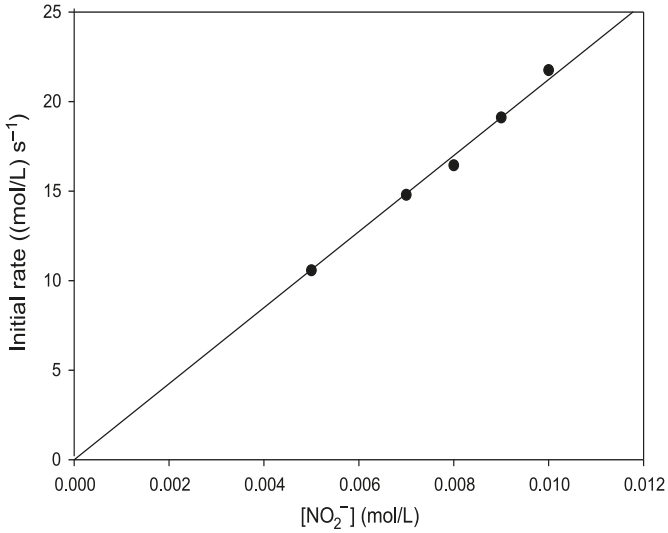


Fig. 5. Initial rate plot from the data derived from varying nitrite ion concentrations in excess acid over nitrite. $[CA]_0 = 0.10$ mol/L; $[H^+]_0 = 0.10$ mol/L; and $[NO_2^-]_0$ was varied from 0.005 to 0.010 mol/L. The plot shows strong first-order dependence on initial rate of formation of *S*-nitrosocysteamine (CANO) on nitrite. CA, cysteamine hydrochloride.

evaluated through the rate of production of nitric oxide, which is known to be the major product, together with the disulfide, of nitrosothiol decompositions. Figure 7D shows EPR spectra using the nitroethane trap, of the enhanced production of NO with addition of Cu(II) ions. All three spectra were taken after the same time lapse from CANO incubation, and thus the peak heights of the NO-induced spectra can be correlated with the extent of reaction.

Transnitrosation

The most abundant thiol in the physiological environment is glutathione (GSH). A pertinent reaction to study would be the interaction of any nitrosothiol formed in the physiological environment with glutathione. There is a crucial question about the lifetimes of the nitrosothiols formed. If thiols are carriers of NO from the point of production to the point of its usage, the nitrosothiols formed should be stable enough and have a long enough lifetime to enable them to perform this activity. Spectrophotometric study of transnitrosation is rendered complex by the fact that many nitrosothiols seem to absorb around the same wavelength and with similar absorptivity coefficients. Figure 8A shows a series of superimposed spectra of four well-known nitrosothiols, which show nearly identical spectra. Figure 8B shows the spectrophotometric characterization of possible transnitrosation in mixtures of CANO and GSH. GSNO has a higher absorptivity coefficient than CANO at the same wavelength,[48] and this explains the initial increase in absorbance on addition of GSH to CANO. LC–MS data have shown that the reaction mixture can transiently (before attainment of the equilibrium mixture) contain any of at least six components at varying times and concentrations: CANO, *S*-nitrosoglutathione (GSNO), GSH, CA–CA (cystamine), GSSG (oxidized glutathione), and CA–GS (mixed disulfide). The rate of transnitrosation will be difficult to evaluate owing to the presence of the mixed disulfide. Figure 8B shows that, relatively, CANO is more stable than GSNO because of the rapid rate of consumption of GSNO upon its formation as compared with the much slower CANO decomposition with or without EDTA. Figure 9 shows a GC–MS spectrum of mixtures of CANO and GSH. This involved a 3:5 ratio of CANO to GSH, which is also trace f in Fig. 8B. The remarkable aspect of this spectrum is the absence of the GSSG, whose precursor is GSNO. Thus, GSNO, when formed, rapidly decomposes by reacting with CA to form the mixed disulfide and releasing NO. The cystamine formed and observed in the spectrum is derived from the normal decomposition of CANO (see rxn. [R10], vide infra).

Mechanism

The overall rate of nitrosation is dependent on the rate of formation and accumulation of the nitrosating agents. A number of possibilities have been suggested, and these include HNO_2, NO, NO_2, N_2O_3, and the nitrosonium cation, ^+NO. Some nitrosants cannot exist under certain conditions; for

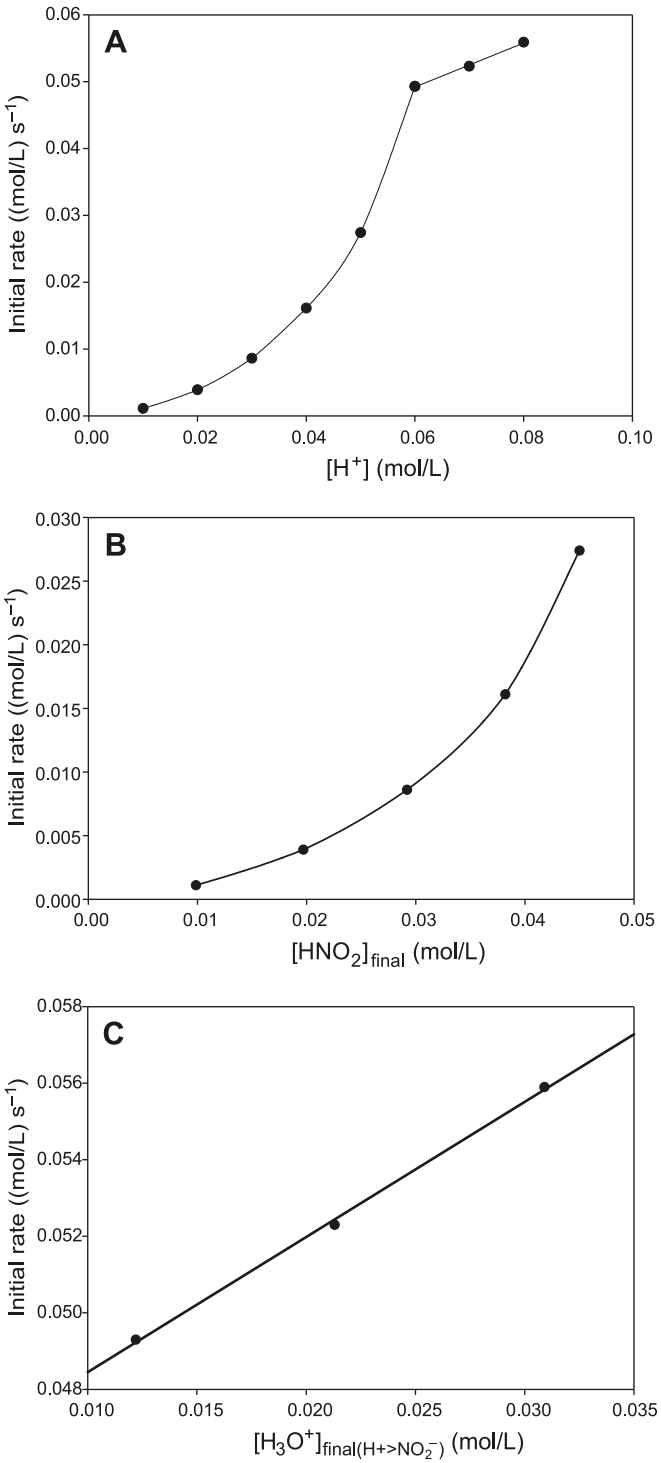

Fig. 6. (A) Plot of the raw kinetics data for the effect of added acid on the rate of nitrosation.$[CA]_0 = 0.05$ mol/L; $[NO_2^-]_0 = 0.05$ mol/L; and $[H^+]_0$ was varied between 0.01 and 0.08 mol/L. For the first four data points, $[NO_2^-]_0 > [H^+]_0$. The linear potion of the plot represents excess proton concentrations over nitrite. Acid concentrations plotted here are those experimentally added and not calculated. (B) Plot of initial rate versus nitrous acid concentrations of the experimental data in Fig. 6A and calculated in Table 1. This plot involves the region at which initial nitrite concentrations exceed acid concentrations. (C) Plot showing the linear dependence of the rate of formation of *S*-nitrosocysteamine (CANO) on $[H_3O^+]$ in high acid concentrations, where initial acid concentrations exceed nitrite concentrations. Nitrous acid concentrations are nearly constant in this range (see Table 1).

example, the ^+NO cannot exist at high pH[49] conditions and NO_2 cannot be produced in strictly anaerobic conditions. Figure 10 shows two nitrosation reactions at equivalent conditions except that one was run in solutions that had been degassed with argon and immediately capped. Aerobic environments can form NO_2 from NO and subsequently N_2O_3 will also be formed.[50]

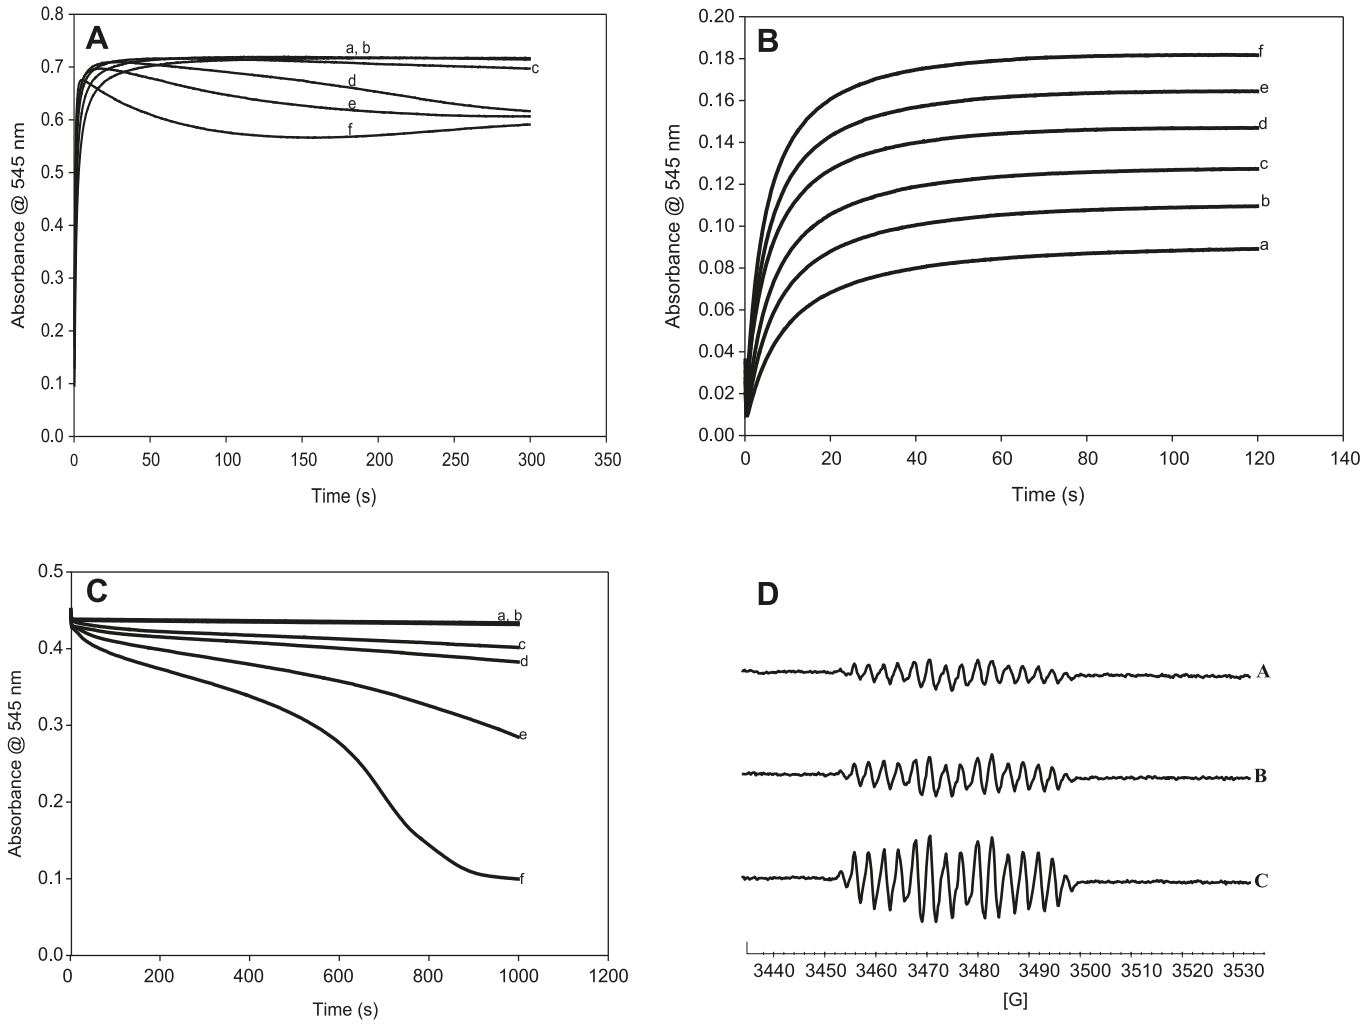
[R6] $\quad NO + 1/2O_2 \rightarrow NO_2$

[R7] $\quad NO + NO_2 \rightarrow N_2O_3$

Both NO_2 and N_2O_3 are potent nitrosating agents.[29] There is a slightly higher rate of nitrosation in aerobic environments when compared with those in anaerobic environments. This is a reflection of the low dissolved oxygen concentrations available in aqueous solutions at approximately 2×10^{-4} mol/L. Thus, although formation for these nitrosants is favored, their viability is hampered by the low concentrations of oxygen as well as NO, which is only produced during the decomposition of the nitrosothiol. NO was not detected during the formation of CANO. In the aqueous environment utilized for these experiments, reaction of aqueous N_2O_3 to nitrous acid would be overwhelmingly dominant. This is a rapid equilibrium reaction that favors the weak acid, HNO_2.

[R8] $\quad N_2O_3(aq) + H_2O(l) \leftrightarrow 2HNO_2(aq); \quad K_H$

Early studies by Bunton and Steadman[51] had erroneously estimated a value for $K_H^{-1} = 0.20$ (mol/L)$^{-1}$, which would indicate appreciable amounts of N_2O_3(aq) over nitrous acid. A more accurate evaluation by Markovits et al.[52] gave a more realistic value of $K_H^{-1} = 3.03 \times 10^{-3}$ (SD 0.23×10^{-3}) (mol/L)$^{-1}$. According to Turney,[53] appreciable amounts of N_2O_3 can only exist in highly acidic environments, in the region of 5 mol/L perchloric acid. Such conditions are not applicable for the physiological environment. Most nitrosation studies in aerobic NO environments neglect the contribution to nitrosation by NO_2 and only concentrate on NO and N_2O_3. NO_2 concentration will always be negligibly low because of rxn. [R6], which is two orders of magnitude greater than the rate of nitrosation by NO_2 (1.1×10^9 (mol/L)$^{-1}$ s^{-1} vs 2.0×10^7 (mol/L)$^{-1}$ s^{-1}, respectively),[54,55] is hampered by the low concentrations of oxygen available. In the presence of NO, it is more unstable with respect to N_2O_3.



All nitrosation kinetics show first-order dependence in both thiol and nitrite with a complex dependence on acid. Data in Figs. 4 and 5 show this strong first-order dependence on CA and on nitrite. In conditions in which acid concentrations are less than initial nitrite concentrations, the effect of nitrite is more difficult to interpret, since a change in its concentrations concomitantly induces a change in both acid and HNO_2 concentrations, and thus its sole effect cannot be isolated. First-order kinetics in nitrite strongly suggest that the major nitrosant at the beginning of the reaction is HNO_2, since there is a direct correlation between nitrite concentrations and HNO_2, especially when there is consistently excess

Fig. 8. (A) Superimposed spectra of four well-known nitrosothiols (a) CysNO, (b) *S*-nitrosocysteamine (CANO), (c) *S*-nitrosoglutathione (GSNO), and (d) nitrosothiol of penicillamine (SNAP). Three of them nearly have the same ε at 545 nm. The observed separation in the absorbances of these three at 545 nm is due to staggering of the time lag before acquiring the spectrum. (B) The effect of glutathione (GSH) on the stability of CANO in a pH 7.4 phosphate buffer. All experimental traces have $[CA]_0 = 0.03$ mol/L, $[NO_2^-]_0 = 0.03$ mol/L, and $[H^+]_0 = 0.05$ mol/L. (a) [GSH] = 0, (b) [GSH] = 0, (c) [GSH] = 0.01 mol/L, (d) [GSH] = 0.02 mol/L, (e) [GSH] = 0.03 mol/L, and (f) [GSH] = 0.05 mol/L. Traces a and b are controls. Trace a has no EDTA. Trace b is the same as trace a with 10 μmol/L of EDTA. There is no significant difference between traces a and b, indicating that the water used for preparing reagent solutions did not contain enough trace metal ions to affect the kinetics. Ten microlitres of EDTA was added to

acid over nitrite. After performing calculations for the relevant reactive species in the reaction medium (Table 1), the plot of the initial rate of nitrosation versus nitrous acid concentrations shows a parabolic dependence, which erroneously suggests second-order kinetics in HNO_2 (Fig. 6B) for the region in which initial nitrite concentrations exceed acid. As mentioned in the Results section, the data in Table 1 show that HNO_2 is not changing in isolation. Both nitrite and acid are also concomitantly changing, and so the effect observed in rate is not solely attributable to changes in HNO_2 concentrations. When acid is in excess over nitrite, the amount of HNO_2 saturates, but as can be seen in Fig. 6C, the rate keeps increasing linearly with an increase in acid, indicating the presence of multiple nitrosating agents apart from HNO_2. The simplest rate law that can explain this nitrosation rate involves ^+NO and HNO_2. ^+NO can be formed from the protonation of HNO_2:

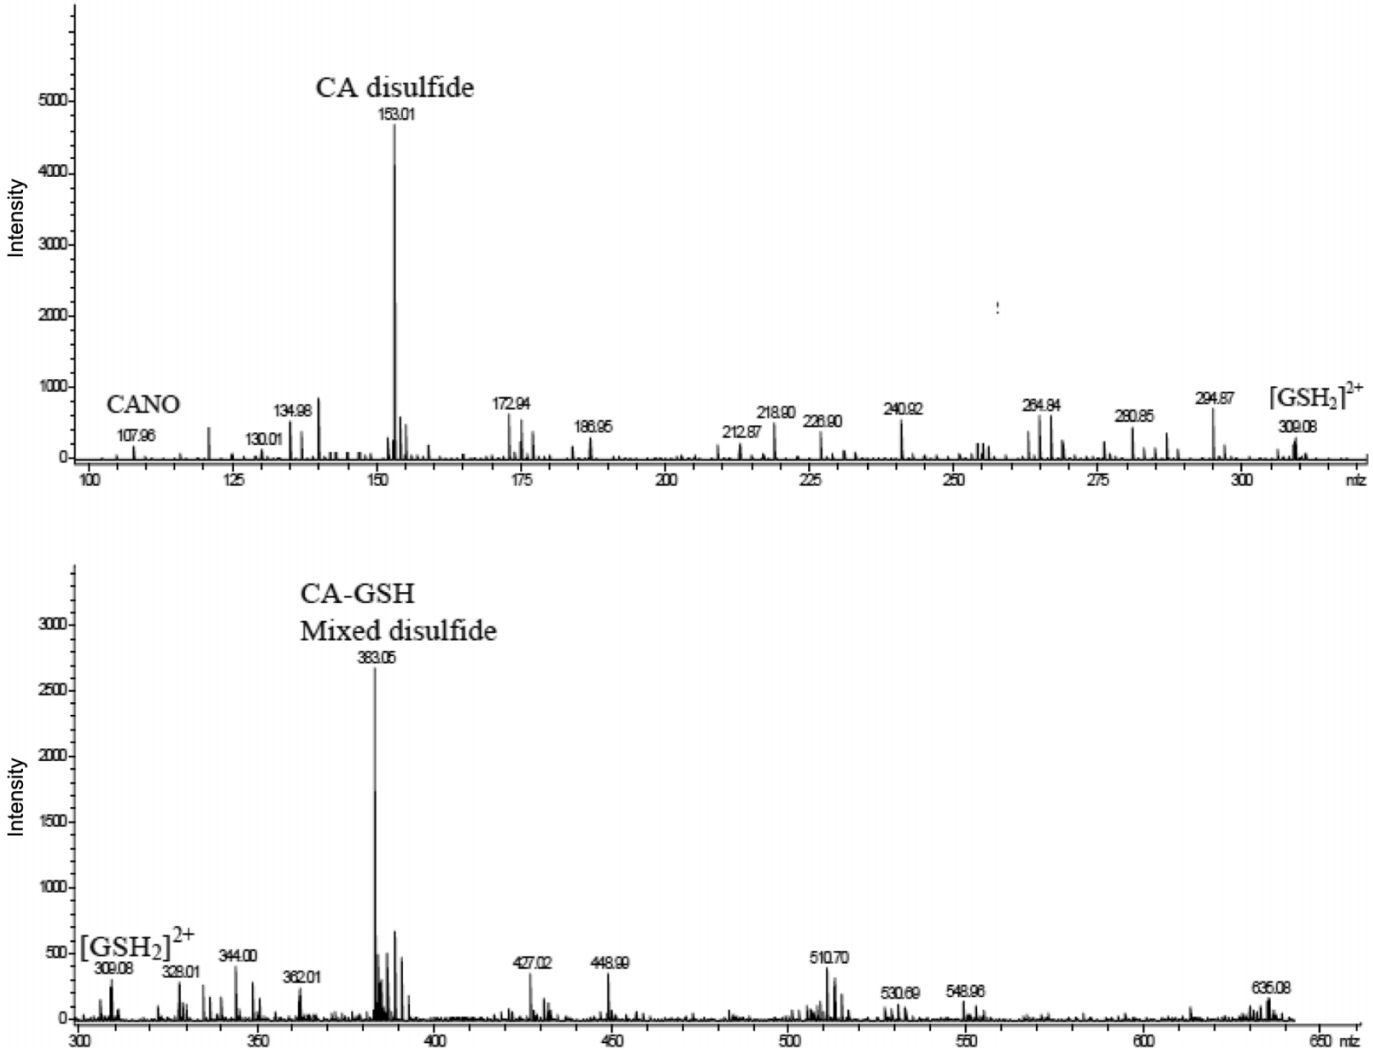
[R9] $$HNO_2 + H_3O^+ \leftrightarrow H(OH)N{=}O^+ + H_2O; \quad K_b$$

($H(OH)N{=}O^+$ is a hydrated nitrosonium cation, $^+NO + H_2O$).

The overall rate of reaction, using these two nitrosants gives

[1] $$\text{Rate} = \left(\frac{[H^+][N(III)]_T}{[H^+] + K_a}\right)[CA](k_1 + k_2K_b[H^+])$$

where $[N(III)]_T$ is the total concentrations of nitrous acid and nitrite as calculated in Table 1 (columns 4 and 5) and $[H^+]$ is the calculated acid concentration in column 6 of Table 1. K_a is the acid dissociation constant of nitrous acid, K_b is the equilibrium for the protonation of nitrous acid (rxn. [R9]), k_1 is the bimolecular rate constant for the nitrosation of CA by HNO_2, and k_2 is the bimolecular rate constant for the nitrosation by ^+NO. K_a was taken as 5.62×10^{-4} $(mol/L)^{-1}$ and, thus, at high acid concentrations, a plot of Rate/$[N(III)]_T$ [CA] vs $[H^+]$ should give a straight line with slope k_2K_b and intercept k_1. This type of plot only applies to conditions of excess acid over nitrite (Fig. 6C). One can derive values for k_1 and product k_2K_b from these series of plots. A value of $k_1 = 17.9 \pm 1.5$ $(mol/L)^{-1}$ s^{-1} was derived from a series of several complementary experiments. k_2 was deduced as 6.70×10^4 $(mol/L)^{-1}$ s^{-1} after assuming a K_b value of 3.16×10^{-2} $(mol/L)^{-1}$.



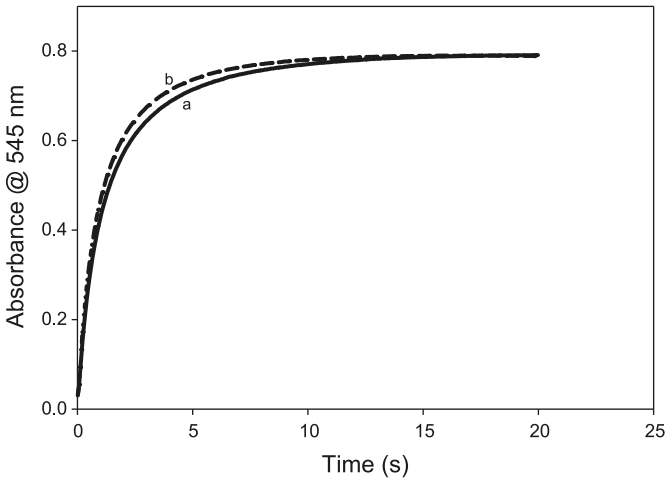
Decomposition of CANO

RSNOs differ greatly in their stabilities, and most of them have never been isolated in solid form. Homolysis of the S–N bond occurs both thermally and photochemically, but, generally, these processes are very slow at room temperature and in the absence of radiation of the appropriate wavelength. In vivo decomposition of RSNOs is likely to proceed through other pathways apart from these two. The presence of trace amounts of Cu(II) or Cu(I) can efficiently catalyze RSNOs to disulfide and nitric oxide (see Figs. 7A–7D).

[R10] $$2RSNO \rightarrow RSSR + 2NO$$

The characterization of the S–N bond is crucial in determining the stability of RSNOs, and, unfortunately, very little work has been performed in this area. The little crystallographic data available on isolable RSNOs indicate that the S–N bond is weak, sterically unhindered, elongated at between 0.17 and 0.189 nm,[56] and exists as either the cis (syn) or trans (anti) conformers. These conformers are nearly isoenergetic but separated by a relatively high activation barrier of ~11 kcal mol^{-1} (1 cal = 4.184 J). CANO is a primary *S*-nitrosothiol, with primary and secondary nitrosothiols known to be kinetically unstable to decomposition when compared with tertiary nitrosothiols.[57,58] *S*-Nitroso-*N*-acetylpenicillamine is the most well-known stable tertiary nitrosothiol.[59] The mechanism of decomposition of nitrosothiols was believed to

Fig. 9. A GC–MS spectrum of a 3:5 ratio of *S*-nitrosocysteamine (CANO) to glutathione (GSH); trace f in Fig. 8B. Final products were predominantly the mixed disulfide and cysteamine with no evidence of oxidized glutathione (GSSG). CA, cysteamine hydrochloride.



proceed through the homolytic cleavage of this weak S–N bond. Computed S–N bond dissociation energies for nitrosothiols show very little variation, however, between primary, secondary, and tertiary nitrosothiols, resulting in very similar homolysis rates of reaction at elevated temperatures for all nitrosothiols. The computed activation parameters for thermal homolysis to occur are prohibitively high for this to be a dominant pathway under normal biological conditions. For example, assuming an approximate S–N bond energy of 31 kcal,[58] a rough calculation will indicate that if decomposition was to proceed solely through homolysis, the half-life of a typical nitrosothiol would be in the region of years instead of the minutes to hours that are observed.[60] This analysis does not support the work reported by Roy et al.[61] in which they established homolysis as the major decomposition pathway. They also managed to trap the thiyl radical, RS·. Close examination of their reaction conditions show high trap concentrations (0.2 mol/L DMPO) and nitrosothiol (0.1 mol/L). Such conditions would catch even very low concentrations of thiyl radical, but would not necessarily indicate that this was the dominant pathway and whether it was derived solely from homolytic cleavage of the S–N bond. Nitrosothiol decomposition rates in the absence of metal ions are known to be mostly zero order[57] and this is inconsistent with an S–N bond homolysis-driven decomposition,[62] which would have been expected to be first order. In the presence of excess thiol, however, decomposition of nitrosothiols proceeds via a first-order decay process.[59] The absence of first-order decay kinetics in the decomposition of CANO also rules out homolysis as a dominant pathway. For a series of nitrosothiols, the homolysis-dependent decomposition rates are not dependent on the bulkiness of the substituent groups attached to the nitrosothiols, which seems to enhance the calculations that showed no discernible difference in the S–N bond energies irrespective of whether the nitrosothiol was primary, secondary, or tertiary.[63] In aerated solutions, the decay was autocatalytic, thus implicating N_2O_3 as the autocatalytic propagating species (see rxns. [R6] and [R7]). Nitrosothiol decompositions were much slower in solutions in which NO was not allowed to escape, implicating NO as a possible retardant of nitrosothiol decomposition.[25] This can be explained by the recombination of the thiyl radical with NO in the reaction cage after initial cleavage. Elimination of NO from the medium by bubbling air forces rxn. [R11] to the right.

Fig. 10. Evaluating the effect of oxygen on the rate of nitrosation of cysteamine. The solutions purged with argon (trace a) give a very slightly lower rate of nitrosation, indicating a small and insignifant contribution of nitrosation by N_2O_3. $[CA]_0 = 0.05$ mol/L; $[H^+]_0 = 0.08$ mol/L; and $[NO_2^-]_0 = 0.07$ mol/L. CA, cysteamine hydrochloride.

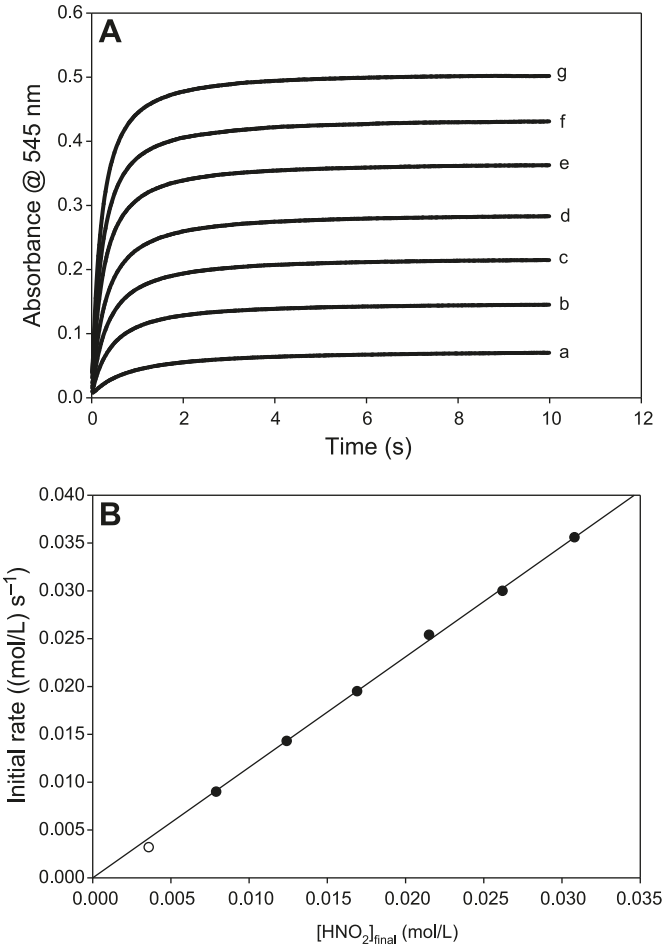
[R11] $\mathrm{RSNO} \leftrightarrow \mathrm{RS}^{\bullet} + \mathrm{NO}$

No mechanism has yet been proposed for the implication of N_2O_3 in the autocatalytic mechanism. One can assume that N_2O_3 should assist in the cleavage of the S–N bond, thus accelerating the rate of homolytic decomposition of RSNOs.

In aerated solutions, NO then undergoes rxns. [R6] and [R7] to yield N_2O_3.

[R12] $\mathrm{RSNO} + \mathrm{N_2O_3} \rightarrow \mathrm{RSN(NO_2)O}^{\bullet} + \mathrm{NO}$

The incorporation of the NO_2^- group in the nitrosothiol would weaken the S–N bond, leading to its easy cleavage and regeneration of the N_2O_3 molecule, which will further catalyze the decomposition.



[R13] $\mathrm{RSN(NO_2)O}^{\bullet} \rightarrow \mathrm{RS}^{\bullet} + \mathrm{N_2O_3}$

The sequence of rxns. [R11]–[R13] will deliver autocatalysis in N_2O_3, since rxn. [R13] produces N_2O_3, which recycles back into rxn. [R12].

Recent results have suggested a novel pathway for the decomposition of nitrosothiols that involves an initial internal rearrangement to form an N-nitrosation product.[64] Typical nitrosothiol decomposition products after such an internal rearrangement would include thiiranes and 2-hydroxy-mercaptans. This mechanism has been used successfully to explain the production of a small but significant quantity of 2-hydroxy-3-mercaptopropionic acid (apart from the dominant product cystine) in the decomposition of *S*-nitrosocysteine. The GC–MS spectrum shown in Fig. 2, however, gives a dominant signal for dimeric cystamine, with very little evidence of any other significant products, indicating very little initial N-transnitrosation.

The copper-catalyzed decomposition of nitrosothiols has been well-documented.[65–67] The varying rates of nitrosothiol decompositions reported by different research groups can be traced possibly to adventitious metal ion catalysis from the water used in preparing reagent solutions. Even in our case, with the maximum metal ion concentrations of 0.43 ppb in Pb^{2+}, small differences can be observed in EDTA-laced reaction solutions and those that are not (see traces a and b in Fig. 7C). Nitrosothiol decompositions have also implicated other metal ions and not just specifically copper.[66] Although Cu(II) ions are used to catalyze nitrosothiol decomposition, the active reagent is Cu(I). In this catalytic mechanism, Cu redox cycles between the +2 and +1 oxidation states. Only trace amounts of Cu(I) are needed to effect the catalysis, and these can be generated from the reduction of Cu(II) ions from minute amounts of thiolate anions that exist in equilibrium with the nitrosothiol.

Fig. 11. (A) Evaluation of unambigous nitrous acid dependence by employing $[H^+]_0 = [NO_2^-]_0$ and varying both at the same equimolar concentrations. $[CA]_0$ fixed at 0.25 mol/L. (a) $[H^+]_0 = [NO_2^-]_0 = 0.005$ mol/L, (b) $[H^+]_0 = [NO_2^-]_0 = 0.010$ mol/L, (c) $[H^+]_0 = [NO_2^-]_0 = 0.015$ mol/L, (d) $[H^+]_0 = [NO_2^-]_0 = 0.020$ mol/L, (e) $[H^+]_0 = [NO_2^-]_0 = 0.025$ mol/L, (f) $[H^+]_0 = [NO_2^-]_0 = 0.030$ mol/L, and (g) $[H^+]_0 = [NO_2^-]_0 = 0.035$ mol/L. (B) Plot of initial rate of nitrosation versus initial nitrous acid concentrations as calculated in Table 2 and derived from the data in Fig. 11A. This plot is linear, as opposed to Fig. 6C.

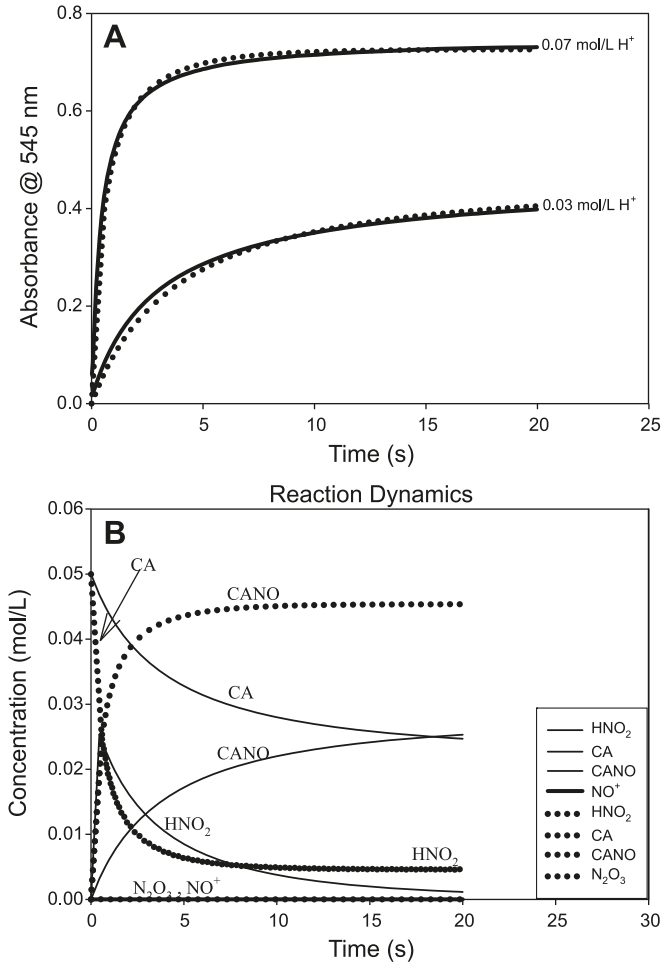
Note: k_f, forward rate constant; k_r, reverse rate constant.

$$[R17] \qquad [RS(Cu)NO]^+ \rightarrow RS^- + NO + Cu^{2+}$$

The cascade of rxns. [R14]–[R17] continues until the nitrosothiol is depleted and converted to the disulfide. The complex formed in rxn. [R16] has been justified through density functional theory studies that report that Cu(I) binds more strongly to the S center than to the N center of the nitrosothiol.[65] This preferential binding weakens and lengthens the S–N bond, thus facilitating its cleavage. It is difficult to extrapolate this proposed mechanism into the physiological environment, but some experimental results have shown that protein-bound Cu^{2+} catalyzed nitric oxide generation from nitrosothiols, but not with the same efficiency as the free hydrated ion.[68] Further studies are needed to evaluate the efficiency of this catalysis, especially in copper-based enzymes.

Effect of Cu(II) on the nitrosation of cysteamine (Fig. 7B)

The fact that Cu(II) ions can assist in nitrosating CA from nitrite in the absence of acid while Cu(I) ions are unable to effect this can be explained by recognizing that nitrosation is an electrophilic process, where NO effectively attaches as the (formally) positive charge, while eliminating a positively charged proton. Cu(II), in this case, acts by complexing to the nitrite and forming a nitrosating species that will release the Cu(II) ions after nitrosation.



Further experiments on the effect of nitrous acid

Since nitrous acid is the major nitrosation species, another series of experiments were undertaken in which the effect of nitrous acid could be unambiguously determined. For the data shown in Fig. 11A, nitrite and acid were kept at equimolar concentrations and varied with that constraint. Final proton and nitrite concentrations after dissociation are also equal for electroneutrality (see Table 2). Thus, if our simple mechanism is plausible, a plot of nitrous acid versus initial nitrosation rate should be linear with the expected slight tailing at either extreme of the nitrous acid concentrations owing to nonlinear generation of the free acid derived from the quadratic equation. Using the same rate law as eq. [1], a value of k_1 can be derived and compared with values obtained from the Fig. 6C plot. Kinetics constants derived from the Fig. 11B plot are not expected to be as accurate as those from Fig. 6C, but should deliver values close to those from high acid environments. For the case of nitrous acid as the nitrosating agent (too low a concentration of excess H_3O^+ to effect equilibrium of rxn. [R9]), data derived from Fig. 11B delivered an upper limit rate constant for k_1 that was higher than that derived from Fig. 6C-type data, but well within the error expected for such a crude extrapolation. Other sets of kinetics data were derived in which CA concentrations were varied while keeping the nitrous acid concentrations constant. Varying nitrous acid concentrations were used and, for each, a CA dependence was plotted (data not shown). These were straight lines through the origin and with the slope determined by the concentration of nitrous acid and the free protons existing in solution after the dissociation of nitrous acid. For these kinetics data, eq. [1] had to be evaluated completely, since $K_a \approx [H_3O^+]$ and no valid approximation could be made. The values of k_1 and k_2K_b were utilized in eq. [1] to recalculate initial rates and slopes with respect to CA

Fig. 12. (A) Simulation of the short set of reactions shown in Table 3. Solid lines are experimental data and the symbols indicate simulations. The mechanism is dominated by the value of the bimolecular rate constant for the nitrosation of cysteamine hydrochloride (CA) by HNO_2 (k_1). $[CA]_0 = [NO_2^-]_0 = 0.05$ mol/L. (B) Results from the modeling that delivered simulations of the two traces shown in Fig. 12A. These simulations show the concentration variations of those species that could not be experimentally monitored. Neither N_2O_3 nor NO^+ rise to any significant concentration levels.

concentrations. These values were utilized to check the accuracy of the kinetics constants derived from high-acid-dependent experiments. It was noted that, within experimental error, these values checked and were generally robust.

Simulations

A small set of simple reactions was utilized to simulate the nitrosation kinetics. This set is shown in Table 3. At low acid concentrations, the nitrosation is dominated by HNO_2 as the nitrosant, and as acid concentrations are increased, both nitrous acid and the nitrosonium cation are involved in the nitrosation. Even though Table 3 includes nitrosation by N_2O_3, the lack of oxygen (approximately kept constant at 2.0×10^{-4} mol/L) and its most favored and rapid reaction to nitrous acid made the nitrosation by N_2O_3 insignificant. N_2O_3 is the dehydrated form of HNO_2 (rxn. [R8]), while reaction conditions were in an overwhelming excess of water. Its insignificant concentration ensured that the simulations were insensitive to value of the bimolecular nitrosation constant for N_2O_3 (k_{M8}). Figure 12B clearly shows that the concentration of N_2O_3 never rises to a level where it would be significant. The rate constants adopted for rxn. [M1] (Table 3) were not crucial for as long as they were fast (in both directions) and were connected by K_a. Increasing the forward and reverse rate constants while maintaining K_a only slowed the simulations, but did not alter the simulation results. Reaction [M2] (Table 3) was also a rapid hydration reaction that strongly favored HNO_2, thus rapidly depleting any N_2O_3 formed or merely keeping these concentrations depressed should the tandem rxns. [R6] + [R7] have been added to the mechanism. These were not utilized for this simulation because EPR experiments had not detected NO at the beginning of the reaction and had only detected NO during the decomposition of the nitrosothiol. There are no reliable thermodynamics parameters for rxn. [M3] (Table 3), since this would be heavily dependent on the pH of the medium. For the purposes of this simulation and some of our previous estimates, the equilibrium constant for rxn. [M3] was set at 3.16×10^{-2} $(mol/L)^{-1}$. Kinetics constants for rxns. [M4] and [M5] (Table 3) were derived from this study. In the absence of significant concentrations of N_2O_3, the simulations were insensitive to the kinetics constants utilized for rxns. [M6] and [M8] (Table 3). Reaction [M7] (Table 3) was assumed to be slow and, in the absence of Cu(II) ions or other adventitious ions, this is indeed so (see Figs. 7A and 7C). The simulations are shown in Fig. 12A, which gives a reasonably good fit from such a crude mechanism. Figure 12B is provided to show the concentration variation of some of the species that could not be experimentally determined. Of note is that N_2O_3 concentrations are depressed throughout the lifetime of the nitrosation. Even though ^+NO is also depressed in concentration, this can be explained by its high rate of nitrosation as soon as it is formed and an equilibrium that favors its hydration back to HNO_2 once the thiol is depleted.

Conclusion

This detailed kinetics study has shown that, even though there are several possible nitrosating agents in solution, in the physiological environment, with its slightly basic pH and low oxygen concentrations, the major nitrosant is HNO_2. Furthermore, the lifetime of CANO is not long enough to be able to be effectively used as a carrier of NO. GSH, which has been touted as a possible carrier of NO, appears to have a shorter lifetime than CANO. However, because of its overwhelming concentration in the physiological environment it might still be a major carrier of NO when it is compared with other thiols. Protein thiols, it appears, would be the best carriers by either intra- or inter-molecular transfer of NO through protein nitrosothionylation through exposed and accessible cysteine groups.[69]

Abstract: Facile and convenient procedures for the synthesis of dibenzo[*a*,*i*]xanthene-diones have been described. The process employs one-pot condensation of aldehydes, 2-hydroxynaphthalene-1,4-dione, and 2-naphthol/2,7-dihydroxynaphthalene/2,6-dihydroxynaphthalene using catalytic sulfuric acid in water under reflux. Task-specific ionic liquid, 1-butyl-3-methylimidazolium hydrogen sulfate ([bmim]HSO_4), has also been found to be an effective catalyst for this transformation. The protocols defined herein prove to be efficient in terms of high yields, operational simplicity, easy workup, and short reaction time. Also, these compounds were screened for antioxidant activity by 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging assay.

Key words: benzoxanthene, synthesis in water, task-specific ionic liquid, antioxidant activity, DPPH assay.

Résumé : On décrit une méthode simple et commode de synthèse des dibenzo[*a*,*i*]xanthènediones. Le procédé implique l'utilisation d'une condensation monotope d'aldéhydes, de 2-hydroxynaphtalène-1,4-dione et de 2-naphtol/2,7-dihydroxynaphtalène/2,6-dihydroxynaphtalène, en faisant appel à une catalyse par l'acide sulfurique dans l'eau, sous reflux. On a trouvé que le liquide ionique à tâche spécifique, le sulfate acide du 1-butyl-3-méthylimidazolium ([bmim]HSO_4) peut aussi être utilisé comme catalyseur efficace pour cette transformation. Les protocoles définis dans ce travail se sont avérés efficaces en termes de rendements élevés, simplicité d'opération, facilité d'extraction et de temps de réaction court. De plus, l'activité antioxydante de tous ces composés a été examinée par le biais de l'essai au piégeage du radical 2,2-diphényl-1-picrylhydrazyle (DPPH).

Mots-clés : benzoxanthène, synthèse en milieu aqueux, liquide ionique à tâche spécifique, activité antioxydante, essai au DPPH.

Introduction

Xanthenes and benzoxanthenes, being the structural motifs of a large number of naturally occurring as well as synthetic derivatives, hold a prominent position in medicinal chemistry.[1] Benzoxanthenes exhibit a broad spectrum of biological activities such as antiviral,[2] antibacterial,[3] anti-inflammatory, and [4] zoxazolamine antagonists,[5] as well as efficacy in photodynamic therapy.[6] These compounds can also be used as dyes,[7] pH-sensitive fluorescent materials for visualization of biomolecules,[8] and in laser technologies.[9] Moreover, natural and synthetic xanthenes and xanthones are also known for their antioxidant activity.[10] However, limited methods have been reported for the synthesis of dibenzo[*a*,*i*]xanthene-diones.[11] Development of improved and environmentally benign methodologies for the synthesis of xanthenes containing naphthoquinone fragments is an interesting challenge.

Multicomponent reactions (MCRs)[12] have emerged as an efficient and powerful tool for the synthesis of heterocyclic scaffolds and are useful for the construction of diverse chemical libraries of "druglike" molecules. The design of MCRs in nontoxic and nonvolatile media, such as ionic liquids, polyethylene glycol, and water, has gained significant impetus owing to environmental concerns. The advantages of conducting organic reactions in water include an enhancement in rate, ease of operation, and an improved safety profile.[13] Also, organic reactions in water exhibit unique reactivity and selectivity that is different from reactions in organic solvents.[14] In continuation of our studies on the development of new routes for the heterocyclic systems,[15] we have investigated the synthesis of dibenzo[*a*,*i*]xanthene-8,13-diones in aqueous medium and task-specific ionic liquid. Moreover, phenolic- and quinone-based compounds are known to show potent antioxidant activity that is attributed to their redox properties.[16] Therefore, we decided to screen the synthesized dibenzoxanthene-diones for their antioxidant activity by 2,2-diphenyl-1-picrylhydrazyl radical (DPPH) scavenging assay.

Results and discussion

We report herein an efficient synthetic route for the synthesis of 14-aryl-14*H*-dibenzo[*a*,*i*]xanthene-8,13-diones in aqueous media using H_2SO_4 as catalyst under reflux and also by utilizing the task-specific ionic liquid, 1-butyl-3-

methylimidazolium hydrogen sulfate ([bmim]HSO_4), at 60 °C. Furthermore, the assessment of radical scavenging activity towards the DPPH radical was measured, and these compounds were found to scavenge the DPPH free radical efficiently.

The reaction conditions were optimized by the reactions of 4-methoxybenzaldehyde (1.0 mmol), 2-naphthol (1.0 mmol), and 2-hydroxynaphthalene-1,4-dione (1.0 mmol) in different media in the presence of acid catalysts like HCl, HNO_3, CH_3COOH, and H_2SO_4. The best result was obtained when the reaction was carried out in water in the presence of a catalytic amount of sulfuric acid (0.1 mmol) under reflux. The reaction underwent completion in 30 min yielding 92% of 14-(4-methoxyphenyl)-14*H*-dibenzo[*a,i*]xanthene-8,13-dione (**1a**) after a simple work up. In the absence of any catalyst, we did not observe any product formation even after 16 h of reflux. The synthesis of **1a** in different solvents such as EtOH, CH_2Cl_2, and CH_3CN under reflux using H_2SO_4 as catalyst yielded 85%, 40%,and 26% of 14-(4-methoxyphenyl)-14*H*-dibenzo[*a*,*i*]xanthene-8,13-dione (**1a**), respectively. Subsequently reactions of variously substituted aromatic aldehydes with 2-naphthol and 2-hydroxy-1,4-naphthoquinone were carried out in water using 10 mol % of H_2SO_4 as catalyst under reflux. The reactions proceeded efficiently, yielding the corresponding xanthene derivatives (**1a**–**1k**) in excellent yields (Scheme 1). The results have been summarized in Table 1 (method A, entries 1–11).

This cyclocondensation reaction was then investigated with different dihydroxynaphthalenes. The reaction of 4-methoxybenzaldehyde (1.0 mmol), 2,7-dihydroxynaphthalene (1.0 mmol), and 2-hydroxy-1,4-naphthoquinone (1.0 mmol) in water using H_2SO_4 as catalyst under reflux yielded 91% of 2-hydroxy-14-(4-methoxyphenyl)-14*H*-dibenzo[*a*,*i*]xanthene-8,13-dione (**2a**) after 30 min. Subsequently, reactions of other aldehydes also yielded the corresponding novel xanthene derivatives (**2a**–**2k**) (Table 1, method A, entries 12–22) in excellent yields. Replacement of 2,7-dihydroxynaphthalene with 2,6-dihydroxynaphthalene also led to the successful condensation under similar conditions to afford novel xanthene derivatives (**3a**–**3b**) in high yields (Table 1, method A, entries 23 and 24). None of the reactions of 2,7-dihydroxynaphthalene and 2,6-dihydroxynaphthalenes showed the formation of any bis-condensation product. Reactions using double molar concentrations of aldehydes and 2-hydroxy-1,4-naphthoquinone with 2,7-dihydroxynaphthalene and 2,6-dihydroxynaphthalenes did not show formation of bis-condensation products even after prolonged reaction times. Even reactions of initially formed **2** with aldehyde and 2-hydroxy-1,4-naphthoquinone to give bis-condensation products were unsuccessful. Reactions using 1,5-, 1,6-, and 1,7-dihydroxynaphthalenes led to the formation of 3,3′-(arylmethylene)bis(2-hydroxynaphthalene-1,4-dione) derivatives rather than desired xanthene-diones.

Reactions were then attempted using task-specific acidic ionic liquid [bmim]HSO_4. It was observed that the reaction of 4-methoxybenzaldehyde (1.0 mmol), β-naphthol (1.0 mmol), and 2-hydroxynaphthalene-1,4-dione (1.0 mmol) proceeded efficiently in [bmim]HSO_4 at 60 °C, yielding 91% of the corresponding xanthene derivative **1a** in 30 min without any other catalyst. The effect of the amount of ionic liquid on the reaction time and yields was also examined. A maximum yield of **1a** was obtained with 20 mol % of [bmim]HSO_4, which acted both as medium and catalyst. A further increase in the amount of [bmim]HSO_4 did not have any significant effect on product yield and reaction time. The condensation reactions of other diversely substituted aromatic aldehydes with 2-naphthol and 2-hydroxy-naphthalene-1,4-dione using 20 mol % of [bmim]HSO_4 under the standardized conditions gave excellent yields of the corresponding xanthene derivatives (Table 1, method B, entries 1–11). Also, on replacing 2-naphthol with 2,7- and 2,6-dihydroxynaphthalenes, the reactions underwent successful completion in [bmim]HSO_4 (Table 1, method B, entries 12–24). All attempts to achieve bis condensation under these conditions were unsuccessful.

We also examined the reusability of [bmim]HSO_4 by studying the catalytic activity of the recycled ionic liquid for the synthesis of **1a**. After separation of the product by filtration, the filtrate containing the ionic liquid was rinsed with ether and further vacuumed to dryness at 90 °C for 2 h to remove any moisture. The recovered [bmim]HSO_4 was reused directly for the next run. It was found that the ionic liquid can be used for the reactions for up to three runs without any appreciable loss of efficiency.

To survey the possible biological activities of these highly coloured 14-aryl-14*H*-dibenzo[*a*,*i*]xanthene-8,13-diones, these compounds (Table 1, entries 1–24) were subjected to a test of antioxidant activity. The antioxidant activity is represented by their capacities for scavenging the DPPH radical, and the results are summarized in Table 2 and Fig. 1.

Among the synthesized dibenzoxanthene-diones, compounds **2a**–**2k** and **3a** and **3b** showed potent DPPH radical-scavenging activity, comparable to that of the standard (butylated hydroxyl toluene, BHT) at higher concentrations of the tested compounds. Further, it was observed that the antioxidant property of dibenzoxanthene-diones was enhanced by introducing aldehydes having an electron-donating functionality.

Conclusion

In conclusion, we have devised efficient synthetic approaches for the synthesis of 14-aryl-14*H*-dibenzo[*a*,*i*]xanthene-8,13-dione derivatives. The three-component condensation has been proficiently performed in water as a "green" solvent using H_2SO_4 as catalyst. The ionic liquid, [bmim]HSO_4 also efficiently catalyses the cyclocondensation reaction. The antioxidant activity of these compounds was evaluated by DPPH free-radical scavenging assay, and we found them to be efficient DPPH free-radical scavengers.

Experimental

All the chemicals used were purchased from Sigma-Aldrich and used as received. Silica gel 60 F_{254} (precoated aluminium plates) from Merck was used to monitor reaction progress. The melting points were determined on a Tropical Labequip apparatus and are uncorrected. IR (KBr) spectra were recorded on PerkinElmer FTIR spectrophotometer and the values are expressed as ν_{max} (cm^{-1}). Absorbance measurements were made using an Analytikjena Specord 250 spectrophotometer. Elemental analysis was performed by a Vario EL III Elementar analyzer. Mass spectral data were recorded on a Jeol-Accutof JMS-T100 mass spectrometer having a DART

[a]Ethanol was used for recrystallization.
[b]Known compound, but the mp is reported for the first time.

source. The ^1H and ^{13}C NMR spectra were recorded on a Bruker Spectrospin spectrometer and a Jeol JNM ECX-400P at 300 MHz and 400 MHz, respectively, using TMS as an internal standard. The chemical shift values are recorded on a δ scale, and the coupling constants (*J*) are in Hertz. [bmim]HSO_4 was prepared by the reported procedure.[17] The melting point, IR, ^1H NMR, and elemental analysis of all known compounds were found to be identical with those described in the literature.[11]

General procedure for the synthesis of 14-aryl-14*H*-dibenzo[*a*,*i*]xanthene-8,13-dione derivatives

Method A

A mixture of aldehyde (1.0 mmol), 2-naphthol (or 2,7-/2,6-dihydroxynaphthalene) (1.0 mmol), 2-hydroxynaphthalene-1,4-dione (1.0 mmol), H_2SO_4 (0.1 mmol), and 10 mL of water was stirred magnetically under reflux for the appropriate time as mentioned in Table 1. The progress of the reaction was monitored by TLC using petroleum ether – ethyl acetate (70:30, *v*/*v*) as eluent. After completion of the reaction, the reaction mixture was allowed to cool to room temperature. The precipitate formed was collected by filtration at pump, washed with cold dilute ethanol and recrystallized from ethanol to afford the pure xanthene derivative. The products were identified by spectral analysis.

Method B

A mixture of aldehyde (1.0 mmol), 2-naphthol (or 2,7-/2,6-dihydroxynaphthalene) (1.0 mmol), 2-hydroxynaphthalene-1,4-dione (1.0 mmol), and [bmim]HSO_4 (20 mol %) was stirred magnetically in an oil bath maintained at 60 °C for

Note: A 0.1 mmol/L methanolic solution of DPPH was used for all the experiments.

[a]The solutions of compounds were prepared in a mixture of methanol–acetone (1:1).

[b]Butylated hydroxyl toluene (BHT) was used as a reference compound.

an appropriate time as mentioned in Table 1. After completion of the reaction as monitored by TLC using petroleum ether – ethyl acetate (70:30, *v*/*v*) as eluent, the reaction mixture was allowed to cool to room temperature and then quenched with water (~5 mL). The precipitate formed was collected by filtration at the pump, washed with cold dilute ethanol, and recrystallized from ethanol to afford the pure xanthene derivative. The filtrate was rinsed with ether, concentrated under reduced pressure, and dried at 90 °C to recover the ionic liquid for subsequent reuse.

DPPH free-radical scavenging assay

A methanol solution of DPPH was used as a reagent for the spectrophotometric assay with modifications.[18] Solutions of different concentrations of dibenzoxanthene-diones (i.e., 0.8 and 0.4 (μmol/L)/mL) were prepared using a mixture of methanol–acetone (1:1). One millilitre of a 0.1 mmol/L methanolic solution of DPPH was added to 3 mL of the solution of the compounds and the mixture was shaken vigorously using a vortex mixer. Absorbance was read against a blank at 517 nm after incubation of the reaction mixtures for 60 min in the dark at room temperature. BHT was used as a reference compound. The radical-scavenging activities were expressed as an inhibition percentage and were calculated using the formula:

$$\text{Radical scavenging activity (\%)} = [(A_0 - A_1)/A_0 \times 100]$$

where A_0 is the absorbance of the control (blank, without compound) and A_1 is the absorbance of the compound. All the tests were carried out in triplicate and the results were averaged.

Fig. 1. 2,2-Diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity (%) of 14-aryl-14*H*-dibenzo[*a*,*i*]xanthene-8,13-dione derivatives.

*14-(4-Nitrophenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1e)*

Orange solid, mp > 300 °C (lit.[11a] 332–333 °C). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 336 nm (2.43×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 2914, 1703, 1663, 1635, 1590, 1518, 1349, 1212. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.20 (d, J = 7.6 Hz, 1H, Ar), 8.15 (d, J = 7.6 Hz, 1H, Ar), 8.05 (d, J = 8.8 Hz, 2H, Ar), 7.97–7.79 (m, 4H, Ar), 7.66–7.46 (m, 6H, Ar), 6.05 (s, 1H, CH). Anal. calcd for $C_{27}H_{15}NO_5$: C 74.82, H 3.49, N 3.23; found: C 74.84, H 3.51, N 3.24.

*14-(3-Nitrophenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1f)*

Orange solid, mp > 300 °C (lit.[11a] 304–305 °C). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 337 nm (2.50×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 2922, 1702, 1656, 1637, 1575, 1529, 1347, 1214. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.21 (d, J = 8.0 Hz, 1H, Ar), 8.13 (d, J = 8.1 Hz, 1H, Ar), 8.10 (s, 1H, Ar), 8.00–7.82 (m, 6H, Ar), 7.66–7.61 (m, 2H, Ar), 7.52–7.41 (m, 3H, Ar), 6.06 (s, 1H, CH). Anal. calcd for $C_{27}H_{15}NO_5$: C 74.82, H 3.49, N 3.23; found: C 74.80, H 3.46 H 3.20.

*14-(2,4-Dichlorophenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1g)*

Orange solid, mp > 300 °C (lit.[11a] 301–302 °C). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 340 nm (2.75×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3056, 1662, 1637, 1591, 1577, 1466, 1362, 1288. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.20 (d, J = 7.8 Hz, 1H Ar), 8.15–8.11 (m, 2H, Ar), 7.89–7.79 (m, 3H, Ar), 7.65–7.43 (m, 4H, Ar), 7.32–7.26 (m, 2H, Ar), 7.10 –7.03(m, 1H, Ar), 6.15 (s, 1H, CH). Anal. calcd for $C_{27}H_{14}Cl_2O_3$: C 70.91, H 3.09; found: C 70.89, H 3.06.

*14-(2-Chlorophenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1h)*

Orange solid, mp 280–282 °C (lit.[11a] 281–282 °C). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 338 nm (2.51×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3068, 1666, 1638, 1591, 1577, 1361, 1289. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.23–8.12 (m, 2H, Ar), 8.14 (d, J = 7.5 Hz, 1H, Ar), 7.87–7.78 (m, 3H, Ar), 7.63–7.26 (m, 6H, Ar), 7.09–7.00 (m, 2H, Ar), 6.20 (s, 1H, CH). Anal. calcd for $C_{27}H_{15}ClO_3$: C 76.69, H 3.58; found: C 76.66, H, 3.56.

*14-(4-Fluorophenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1i)*

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 340 nm (2.52×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 2923, 2852, 2699, 1661, 1637, 1590, 1502, 1368, 1214. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 7.93–7.83 (m, 3H, Ar), 7.80–7.75 (m, 1H, Ar), 7.60–7.42 (m, 4H, Ar), 7.37–7.33 (m, 2H, Ar), 7.29–7.18 (m, 4H, Ar), 5.91 (s, 1H, CH). Anal. calcd for $C_{27}H_{15}FO_3$: C 79.79, H 3.72; found: C 79.76, H 3.70.

*14-(2-Naphthyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1j)*

Yellow solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 340 nm (2.25×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 2925, 1635, 1586, 1365, 1216. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 8.23 (d, J = 7.56 Hz, 1H, Ar), 8.13 (d, J = 8.48 Hz, 1H, Ar), 8.016 (d, J = 9.20 Hz, 1H, Ar), 7.93–7.84 (m, 4H, Ar), 7.77–7.62 (m, 5H, Ar), 7.44–7.32 (m, 5H, Ar), 5.91 (s, 1H, CH). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 178.28, 177.91, 156.70, 147.33, 141.58, 135.57, 133.18, 132.28, 131.97, 130.92, 130.86, 130.63, 130.26, 129.22, 128.98, 128.54, 128.26, 127.97, 127.82, 127.68, 127.23, 126.69, 126.41, 125.96, 125.02, 124.05, 117.92, 117.00, 115.88, 35.62. MS (ESI) m/z calcd for $C_{31}H_{18}O_3$: 438.13; found: 439.20 [M^+ + H]. Anal. calcd for $C_{31}H_{18}O_3$: C 84.92, H 4.14; found: C 84.90, H 4.12.

*14-(4-Bromophenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (1k)*

Orange solid, mp 284–295 °C (lit.[11c] 294–298 °C). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 339 nm (2.25×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3075, 1704, 1663. ^{1}H NMR (300 MHz, DMSO-d_6) δ: 8.18– 8.11 (m, 2H, Ar). 7.93–7.86 (m, 3H, Ar), 7.80 (t, J = 7.6 Hz, 1H, Ar), 7.62–7.50 (m, 2H, Ar), 7.45–7.40 (m, 2H, Ar). 7.34–7.26 (m, 4H, Ar), 5.87 (s, 1H, CH). Anal. calcd for $C_{27}H_{15}BrO_3$: C 69.39, H 3.24; found: C 69.37, H 3.22.

*2-Hydroxy-14-(4-methoxyphenyl)-14*H*-dibenzo[a,i]xanthene-8,13-dione (2a)*

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 357 nm (1.08×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3297, 2924, 1700, 1650, 1627, 1591, 1377, 1210. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 9.90 (s, 1H, OH), 8.18 (d, J = 7.56 Hz, 1H, Ar), 7.94 (d, J = 7.56 Hz, 1H, Ar), 7.86–7.62 (m, 4H, Ar), 7.44 (d, J =

For personal use only.

8.96 Hz, 1H, Ar), 7.20–7.17 (m, 3H, Ar), 6.97–6.95 (m, 1H, Ar), 6.74 (d, J = 8.72 Hz, 2H, Ar), 5.45 (s, 1H, CH), 3.58 (s, 3H, OCH_3). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 177.98, 177.78, 157.95, 156.70, 156.35, 147.42, 135.77, 135.35, 132.32, 131.57, 130.63, 130.34, 130.25, 129.57, 129.32, 128.66, 126.03, 124.56, 117.74, 116.14, 115.16, 113.88, 105.55, 55.10, 34.03. MS (ESI) m/z calcd for $C_{28}H_{18}O_5$: 434.12; found: 435.20 [M^+ + H].

2-Hydroxy-14-(4-bromophenyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2b)

Orange solid, mp > 300 °C(decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 344 nm (1.62×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3307, 2923, 1701, 1654, 1627, 1379, 1210; ^1H NMR (400 MHz, DMSO-d_6) δ: 9.93 (s, 1H, OH), 8.17 (d, J = 7.76 Hz, 1H, Ar), 7.95 (d, J = 7.80 Hz, 1H, Ar), 7.85–7.64 (m, 4H, Ar), 7.45 (d, J = 8.68 Hz, 1H, Ar), 7.39–7.16 (m, 5H, Ar), 6.99–6.96 (m, 1H, Ar), 5.50 (s, 1H, CH). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 178.19, 177.93, 157.26, 157.84, 147.80, 143.26, 135.53, 132.61, 131.99, 131.74, 131.23, 131.00, 130.85, 130.54, 130.05, 128.95, 126.38, 124.94, 120.27, 118.20, 115.62, 114.65, 114.20, 105.77, 35.03. MS (ESI) m/z calcd for $C_{27}H_{15}BrO_4$: 482.02; found: 483.02 [M^+ + H], 485.02 [M^+ + H + 2].

2-Hydroxy-14-(4-methylphenyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2c)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 349 nm (1.19×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3359, 2924, 1701, 1653, 1629, 1592, 1378, 1212. ^1H NMR (400 MHz, DMSO-d_6) δ: 9.94 (s, 1H, OH), 8.19 (d, J = 7.76 Hz, 1H, Ar), 7.96 (d, J = 7.76 Hz, 1H, Ar), 7.88–7.64 (m, 4H, Ar), 7.47 (d, J = 8.72 Hz, 1H, Ar), 7.23–7.19 (m, 3H, Ar), 7.00–6.98 (m, 3H, Ar), 5.48 (s, 1H, CH), 2.13 (s, 3H, CH_3). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 178.25, 178.08, 157.07, 156.75, 141.09, 136.32, 135.66, 132.69, 131.93, 130.91, 130.65, 130.59, 129.70, 129.43, 129.00, 128.81, 126.37, 124.91, 118.09, 116.38, 115.41, 114.19, 105.99, 34.98, 20.98. MS (ESI) m/z calcd for $C_{28}H_{18}O_4$: 418.12; found: 419.12 [M^+ + H].

2-Hydroxy-14-(4-chlorophenyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2d)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$), λ_{max} (ε): 354 nm (1.76×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3227, 1618, 1597, 1377, 1212. ^1H NMR (400 MHz, DMSO-d_6) δ: 9.93 (s, 1H, OH), 8.19 (d, J = 7.76 Hz, 1H, Ar), 7.95 (d, J = 7.80 Hz, 1H, Ar), 7.87–7.64 (m, 4H, Ar), 7.46 (d, J = 8.68 Hz, 1H, Ar), 7.31–7.17 (m, 5H, Ar), 6.99–6.97 (m, 1H, Ar), 5.52 (s, 1H, CH). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 178.20, 177.94, 157.26, 156.85, 147.82, 142.84, 135.54, 132.62, 132.00, 131.73, 131.00, 130.85, 130.56, 130.04, 128.96, 128.82, 126.38, 124.95, 118.19, 115.70, 114.73, 114.21, 105.77, 34.94; MS (ESI) m/z calcd for $C_{27}H_{15}ClO_4$: 438.07; found: 439.10 [M^+ + H], 441.10 [M^+ + H + 2].

2-Hydroxy-14-(4-nitrophenyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2e)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 349 nm (2.25×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3306, 2924, 1702, 1628, 1592, 1379, 1210. ^1H NMR (400 MHz, DMSO-d_6) δ: 9.99 (s, 1H, OH), 8.23 (d, J = 7.76 Hz, 1H, Ar), 8.10 (d, J = 8.68 Hz, 2H, Ar), 7.98–7.67 (m, 5H, Ar), 7.62 (d, 2H, J = 8.68 Hz, Ar), 7.52 (d, J = 8.72 Hz, 2H, Ar), 7.19 (s, 1H, Ar), 7.02–7.00 (m, 1H, Ar), 5.70 (s, 1H, CH). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 177.56, 177.29, 156.88, 156.51, 150.62, 147.31, 146.12, 134.98, 132.07, 131.60, 130.54, 130.46, 129.91, 128.42, 125.87, 124.51, 123.54, 117.74, 114.38, 113.74, 113.47, 105.17, 35.1. MS (ESI) m/z calcd for $C_{27}H_{15}NO_6$: 449.09; found: 450.10 [M^+ + H].

2-Hydroxy-14-(2-chlorophenyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2f)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 358 nm (2.36×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3298, 2924, 1700, 1623, 1591, 1375, 1210. ^1H NMR (400 MHz, DMSO-d_6) δ: 9.91 (s, 1H, OH), 8.22 (d, J = 7.8 Hz, 1H, Ar), 7.95 (d, J = 7.92 Hz, 1H, Ar), 7.88–7.64 (m, 4H, Ar), 7.43 (d, J = 8.72 Hz, 1H, Ar), 7.32–7.06 (m, 5H, Ar), 7.01–6.99 (m, 1H,Ar), 5.79 (s, 1H, CH). MS (ESI) m/z calcd for $C_{27}H_{15}ClO_4$: 438.07; found: 439.07 [M^+ + H], 441.07 [M^+ + H + 2].

2-Hydroxy-14-(isopropyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2g)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 355 nm (2.38×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3354, 2966, 1702, 1625, 1591, 1570, 1398, 1211. ^1H NMR (400 MHz, DMSO-d_6) δ: 9.93 (s, 1H, OH), 8.09 (d, J = 7.36 Hz, 1H, Ar), 7.99 (d, J = 7.32 Hz, 1H, Ar), 7.83–7.76 (m, 3H, Ar), 7.67–7.63 (m, 1H, Ar), 7.34–7.28 (m, 2H, Ar), 7.05–7.02 (m, 1H, Ar), 4.51 (s, 1H, CH), 2.04 (m, 1H, $CH(CH_3)_2$), 0.86 (d, J = 6.88 Hz, 3H, CH_3), 0.63 (d, J = 6.88 Hz, 3H, CH_3). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 178.84, 177.77, 159.38, 156.67, 148.64, 135.03, 132.33, 131.24, 130.47, 130.28, 130.20, 128.42, 125.88, 124.01, 117.65, 115.74, 113.63, 113.33, 104.77, 34.57, 33.39, 20.75, 17.71. MS (ESI) m/z calcd for $C_{24}H_{18}O_4$: 370.12; found: 371.17 [M^+ + H].

2-Hydroxy-14-(thienyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2h)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 347 nm (2.10×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3295, 1698, 1658, 1624, 1589, 1381, 1213. ^1H NMR (400 MHz, DMSO-d_6) δ: 9.99 (s, 1H, OH), 8.18 (d, J = 7.76 Hz, 1H, Ar), 7.99 (d, J = 7.32 Hz, 1H, Ar), 7.89–7.87 (m, 2H, Ar), 7.82 (d, J = 8.72 Hz, 1H, Ar), 7.70–7.66 (m, 1H, Ar), 7.46 (d, J = 9.16 Hz, 1H, Ar), 7.27–7.22 (m, 2H, Ar), 7.05 (dd, $J^{1,2}$ = 2.28 Hz, $J^{1,3}$ = 8.72 Hz, 1H, Ar), 6.89–6.82 (m, 2H, Ar), 5.87 (s, 1H, CH). MS (ESI) m/z calcd for $C_{25}H_{14}O_4S$: 410.06; found: 411.06 [M^+ + H].

2-Hydroxy-14-(3-bromophenyl)-14H-dibenzo[a,i]xanthene-8,13-dione (2i)

Orange solid, mp > 300 °C (decomp.). UV (4×10^{-5} mol/L solution in $CHCl_3$) λ_{max} (ε): 340 nm (2.25×10^4 L mol^{-1} cm^{-1}). IR (ν_{max} cm^{-1}, KBr): 3329, 2926, 1700, 1626, 1569, 1592, 1376, 1208. ^1H NMR (400 MHz, DMSO-d_6) δ: 10.01 (s, 1H, OH), 8.20 (d, J = 7.36 Hz, 1H, Ar), 7.98 (d, J = 6.60 Hz, 1H, Ar), 7.93–7.75 (m, 3H, Ar), 7.70 (m, 1H, Ar),

Abstract: It was recently discovered that easily available $CuSO_4 \cdot 5H_2O$ could be employed as an efficient catalyst towards the coupling reactions of terminal alkynes with *H*-phosphonates, which finally led to the formation of a large variety of novel alkynylphosphates.

Key words: terminal alkynes, coupling, $CuSO_4 \cdot 5H_2O$, alkynylphosphonates.

Résumé : On a découvert récemment que le $CuSO_4 \cdot 5H_2O$, qui est facilement disponible, peut être utilisé comme catalyseur efficace pour les réactions d'alcynes vrais avec des *H*-phosphonates qui conduisent éventuellement à la formation d'une grande variété de nouveaux alcynylphosphates.

Mots-clés : alcynes vrais, couplage, $CuSO_4 \cdot 5H_2O$, alcynylphosphonates.

[Traduit par la Rédaction]

Introduction

The reactivity and versatility of alkynylphosphonates provide some biological activities,[1] but they also make them valuable precursors for other phosphonates,[2] and particularly for the synthesis of heterocycles by [2+2],[3] [3+2],[4] and [4+2][5] cycloaddition reactions. There are four traditional reaction categories useful for the preparation of alkynylphosphonates: the "apparent" Michaelis–Arbuzov[6] and Michaelis–Becker reactions,[7] the phosphite–allenylphosphonate rearrangement,[8] the carbanionic displacements at pentavalent phosphorus centers,[9] and conversions of vinyl- to alkynyl-phosphonates by addition–elimination reactions.[10] The increasing importance of phosphorus compounds in organic synthesis, materials science, and chemical biology always welcomes novel, efficient phosphorus involved bond-forming reactions for the construction of structurally sophisticated phosphorus compounds that are not readily available by classic methods. Metal-catalyzed cross-coupling reactions are among the most powerful reactions available for formation of carbon–heteroatom bonds, especially for that of the carbon–phosphorus bond. Metal-salt-catalyzed cross-coupling of *H*-phosphonates with carbon–carbon unsaturated compounds is one of the most straightforward ways of preparing phosphorus-containing compounds, which have wide applications in organic synthesis and industrial processes.[11] Lera and Hayes[12] demonstrated a method for the palladium-catalyzed synthesis of alkynylphosphonates from 1,1-dibromo-1-alkenes with H(O)$P(OR)_2$. Zhao and co-workers[13] disclosed a new methodology for catalytically constructing C–P bonds, an aerobic oxidative coupling of terminal alkynes with *H*-phosphonates that is catalyzed by Cu to generate alkynylphosphonates. Three easily oxidized copper(I) salts, including CuI, CuBr, and CuCl, and relatively expensive copper(II) salt – $Cu(OAc)_2 \cdot H_2O$ have been employed by Zhao's group to act as the catalysts for the C–P cross-coupling reaction of terminal alkynes with *H*-phosphonates. To the best of our knowledge, $CuSO_4 \cdot 5H_2O$, as a relatively benign and inexpensive reagent that can be stored and handled in the laboratory using normal laboratory methods, has not yet been employed as the catalyst for such air-induced C–P bond-forming reactions. Propargyl aryl ethers can react with a gold catalyst to furnish various allenes,[14] an important starting reactant leading to a variety of functionalized compounds, including important benzopyrans.[15] Herein, we wish to report an efficient method for the construction of alkynylphosphonates using $CuSO_4 \cdot 5H_2O$ as the catalyst of the reaction of terminal alkynes with *H*-phosphonates. By this method, we have synthesized a variety of novel alkynylphosphonates.

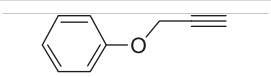
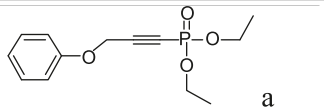
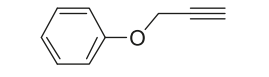
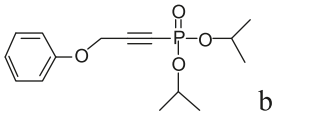
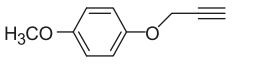
Results and discussion

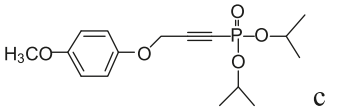


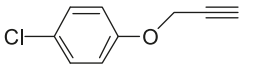


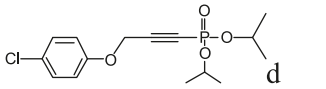


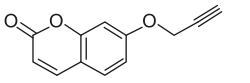


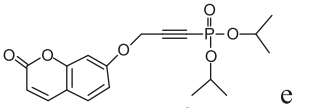


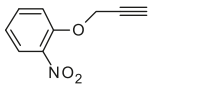


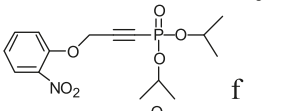


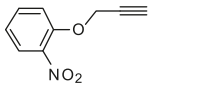


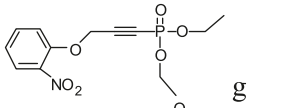


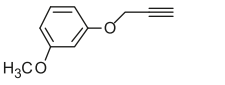


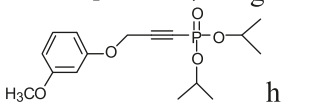


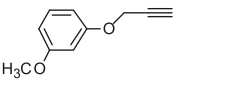


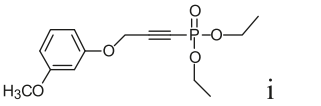


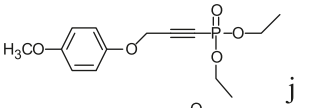


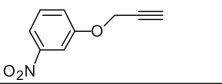


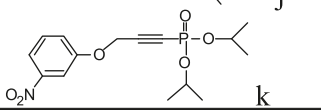






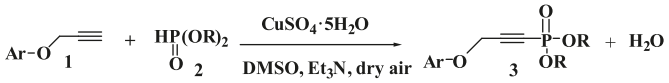






To find the optimal reaction conditions for this coupling reaction, we examined a variety of conditions for the reaction. The easily accessible terminal alkyne (propargyl phenyl ether) was chosen as a model substrate to determine the appropriate reaction conditions for this aerobic oxidative coupling. The principal results of this optimization study are complied in Table 1. We first focused our attention to the amount of the catalyst to be used. The optimum catalyst loading was found to be 20 mol % (based on Table 1, entry 3), whereas reducing it to 10 mol % (Table 1, entry 1) led to a significant drop in the yield of the product. At a 15 mol % catalyst loading (Table 1, entry 2) a slight decrease in the yield was obtained, but at 25 mol % (based on Table 1, entry 4) there was almost no change in the yield. At 30 mol % loading (Table 1, entry 5) a slight drop in the yield of the product was observed. After various solvents were examined, the polar aprotic solvents DMF (Table 1, entry 6) and DMSO gave the best value for the reaction and MeCN, THF, toluene, CH_2Cl_2, and $CHCl_3$ (Table 1, entries 7–11) produced only a trace amount of the product; therefore, DMSO was chosen as the solvent for this reaction. Bases, such as Et_3N, $HNEt_2$, K_2CO_3, tri-*n*-propylamine, tri-*n*-butylamine, and Cs_2CO_3 (Table 1, entries 3 and 12–16) were used in this study. Interestingly, using these bases gave the product in a good yield, except for K_2CO_3 (obtained in 46% yield). Comparing Table 1 entry 2 with entries 17–20, we found that using a reaction temperature of 55 °C produced better results than other temperatures.

After the optimization process for the loading amounts of catalyst, solvents, bases, and temperatures, we conclude that the optimal reaction conditions for this coupling reaction are as follows: a mixture of 0.6 mmol propargyl phenyl ether and 0.5 mmol diisopropyl phosphite in 1.5 mL of DMSO in the presence of 20 mol % $CuSO_4 \cdot 5H_2O$ and 30 mol % Et_3N, heated to 55 °C and stirred for 28 h in the dry air.



With the optimized conditions in hand, the scope of the reactants was then enlarged to use various terminal alkynes and two different *H*-phosphonates, as shown in Table 2. Generally, the coupling reaction proceeded well to afford the desired products in good yields, no matter which substituted propargyl aryl ethers, containing electron-rich groups (OCH_3 and $NHCOCH_3$) or electron-deficient groups (Cl and NO_2), were employed. Perhaps owing to the steric hindrance, there was a slightly observed decrease in yield when coumarin-containing propargyl aryl ethers (Table 2, entries 5, 13, and 16) instead of phenyl propargyl ethers were employed as the corresponding reactants. When the yields of these same propargyl aryl ethers reacted with two different *H*-phosphonates (Table 2, entries 1 and 2, 6 and 7, 8 and 9, 11 and 12, and 14 and 15), the isopropyl *H*-phosphonate always gave better yield than the ethyl *H*-phosphonate. A broader range of terminal alkynes, including phenyl acetylene (Table 2, entries 17 and 18), *p*-ethylphenylacetylene (Table 2, entry 19), 1-ethynyl-4-phenylbenzene (Table 2, entry 20), cyclopropyl

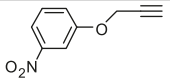
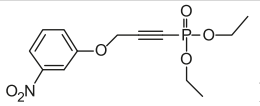
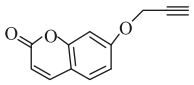
acetylene (Table 2, entry 21), and phenyl-diprop-2-ynylamine (Table 2, entry 22) were employed as the non-ether alkynes, which finally effectively led to a series of corresponding coupling products using inexpensive catalyst–$CuSO_4 \cdot 5H_2O$, demonstrating true versatility of the methodology.

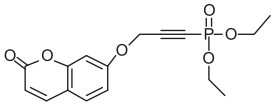
A tentative mechanism for this coupling reaction, catalyzed by copper(II) salt – $CuSO_4 \cdot 5H_2O$, is proposed as shown in Scheme 1. The copper acetylide **4**, which was insoluble during the reaction procedure and disappeared completely at the end of the reaction, was formed by a reaction among propargyl aryl ether, $CuSO_4 \cdot 5H_2O$, and Et_3N. The trivalent phosphate **2′** (tautomer of the *H*-phosphonate **2**) then acted as a nucleophile to attack the copper(II) of **4**, forming intermediates **5**. The intermediate **6** was formed following an attack of alkynide anion (**5**) on the phosphorus cation (**5**). The product **3** was finally formed following the oxidation of **6** in dry air.

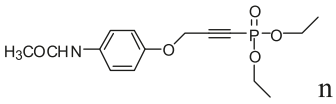
Conclusion

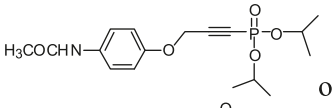


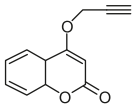


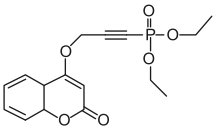


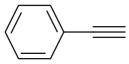


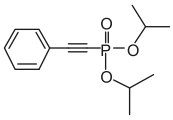


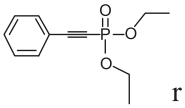


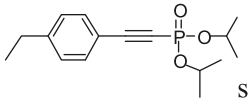


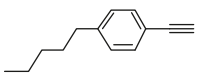


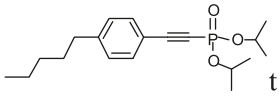


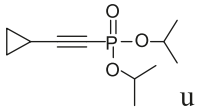


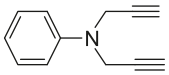


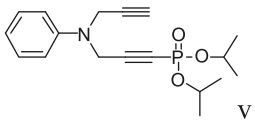












In summary, we have found an efficient and cheap catalytic system ($CuSO_4 \cdot 5H_2O$ / Et_3N / dry air) for the reaction of terminal alkynes with *H*-phosphonates. The method has the following advantages: (*i*) an inexpensive catalytic system, (*ii*) good functional group tolerance (bearing various substituents at the aryl positions), (*iii*) easy work-up procedure, and (*iv*) very mild reaction conditions (without exclusion of air and 55 °C). The method described in this paper can be used successfully for the straightforward synthesis of alkynylphosphonates.

reagents were reagent grade, commercially available, and used without further purification. All reagents were weighed and handled in air at room temperature. Flash column chromatography was performed on silica gel (200–300 mesh), and thin layer chromatography (TLC) analyses were performed on silica gel plates (GF 254). ^1H and ^{13}C NMR spectra were recorded on a Bruker 400 MHz spectrometer with $CDCl_3$ as the solvent and TMS as an internal standard. ^{31}P NMR spectra were recorded on the same instrument with 85% H_3PO_4 as an external standard. ESI-MS spectra were recorded on a Bruker Esquire 3000. IR spectra were recorded on a Shimadazu IR-408. High-resolution mass spectra were performed on a Micromass Q-TOF MicroTM mass spectrometer with an ESI source (Waters, Manchester, UK).

Typical experimental procedure for the oxidative coupling of terminal propargyl aryl ethers with *H*-phosphonates

Scheme 1. Proposed reaction path.

DMSO (1.5 mL) were added to a round bottom flask (25 mL) at 55 °C under a dry-air atmosphere, immediately generating a yellow suspension. After stirring for about 28 h, the insoluble materials disappeared to produce a clear green solution in a short time, The resulting reaction solution was cooled down to room temperature, 20 mL of water was added, and then the target product was extracted with ethyl acetate. Following that, the organic layer was washed three times with saturated sodium chloride solution and then concentrated by a rotary evaporator. In the purification process, most of the liposoluble products were extracted in the organic layer and most of DMSO in water. In the end, the reaction solvent DMSO can be effectively washed away. The crude product was finally purified by column chromatography on silica gel by using petroleum ether/ethyl acetate as eluent to give the desired product. Spectroscopic data for these products are consistent with the proposed structures (spectra and characterization data can be found in the Supplementary data).

Flavonol glycosides from *Cardamine komarovii*

Seung Young Lee, Il Kyun Lee, and Kang Ro Lee

Abstract: Two new flavonol glycosides (**1** and **2**) were isolated from a MeOH extract of the aerial parts of *Cardamine komarovii* Nakai (Cruciferae) together with 13 known phenolic compounds (**3**–**15**). The structures of **1** and **2** were determined by spectroscopic methods including 1D and 2D NMR (COSY, HMQC, HMBC, NOESY, and TOCSY) and HR-FAB-MS data.

Key words: Cardamine komarovii, Cruciferae, flavonol glycosides.

Résumé : Les produits d'extractions des tiges de *Cardamine komarovii* Nakai, cruciféracée, par le méthanol ont permis d'isoler deux nouveaux glucosides (**1** et **2**) ainsi que 13 composés phénoliques connus (**3**–**15**). Les structures des **1** et **2** ont été déterminées par des méthodes spectroscopiques, dont la RMN 1D et 2D (« COSY », « HMQC », « HMBC », « NEOSY » et « TOSY ») et des données de spectrométrie de masse avec bombardement avec des atomes rapides et à haute résolution (SM-BAR-HR).

Mots-clés : Cardamine komarovii, cruciféracée, glucosides de flavonol.

Introduction

Cardamine komarovii Nakai (Cruciferae) is widely distributed throughout Asia.[1] The aerial parts of this plant have been used for the treatment of respiratory diseases and hemostasis in Chinese folk medicine.[2] In Korea, this indigenous herb is an edible wild vegetable and is also used as a folk medicine for the control of blood pressure.[2] As part of our continuing search for biologically active compounds from Korean medicinal plants, we investigated the constituents of the aerial parts of *C. komarovii* and reported their cytotoxic constituents, including megastigmane,[3] and flavonoids.[4] In our ongoing search on this source, we have further isolated two new flavonol glycosides (**1** and **2**) together with 13 known phenolic compounds (**3**–**15**).

Results and discussion

The 80% MeOH extract of the aerial parts of *C. komarovii* was subjected to repeated column chromatography on silica gel to afford **1** and **2** together with **3**–**15** (Fig. 1). The identification and structural elucidation of **1** and **2** were based on 1D- and 2D-NMR and HR-FAB-MS data.

Cardamoside A (**1**) was isolated as a yellowish gum with a molecular formula of $C_{48}H_{57}O_{27}$ on the basis of the $[M + H]^+$ peak at *m/z* 1065.3086 (calcd for $C_{48}H_{57}O_{27}$, 1065.3087) in the HR-FAB-MS. The IR spectrum of **1** indicated the presence of a hydroxyl group (3356 cm^{-1}), a carbonyl group (1657 cm^{-1}), and an aromatic ring (1451 cm^{-1}). The ^1H NMR spectrum of **1** showed an aglycone characterized by two doublet signals at δ 7.99 (d, J = 8.8 Hz, H-2′, 6′) and 6.89 (d, J = 8.8 Hz, H-3′, 5′), which were assigned to two aromatic protons of the B ring, with two meta-coupled doublets at δ_H 6.78 (d, J = 2.0 Hz, H-8) and 6.47 (d, J = 2.0 Hz, H-6) for the A ring. In the ^{13}C NMR spectrum, 15 carbon signals of an aglycone appeared at δ 161.0 (C-4′), 131.6 (C-2′, 6′), 115.9 (C-3′, 5′), and 121.2 (C-1′) of the B ring, as well as other signals at δ 178.2 (C-4), 163.3 (C-7), 161.6 (C-5), 158.2 (C-9), 156.8 (C-2), 134.2 (C-3), 106.5 (C-10), 100.2 (C-6), and 95.4 (C-8) of the A and C rings (Table 1). These spectral data implied that **1** was a kaempferol derivative.[5] In addition, the four anomeric protons appeared at δ 5.38, 4.15, 5.27, and 4.43 in the ^1H NMR spectrum, which showed correlations with anomeric carbons at δ 101.7, 104.2, 100.3, and 101.3 in the ^{13}C NMR spectrum by the HMQC, respectively. The characteristic coupling constant of anomeric protons at δ 5.38 (d, J = 7.8 Hz), 5.27 (d, J = 7.8 Hz) and 4.15 (d, J = 7.8 Hz) implied three β-D-glucopyranoses (Glc I, Glc II, and Glc III), and another anomeric proton at δ 4.43 (s) identified α-L-rhamnopyranose (Rha). The glycosidic position was established by an HMBC experiment, in which the long-range correlations were observed between the H-1″ (δ 5.38) of Glc I and the C-3 (δ 134.2) of aglycone, H-1‴ (δ 4.15) of Glc II and the C-4" (δ 80.9) of Glc I, H-1⁗ (δ 4.43) of Rha and the C-6″ (δ 66.7) of Glc I, and H-1⁗′ (δ 5.27) of Glc III and C-7 (δ 163.3) of aglycone (Fig. 1). The ^1H and ^{13}C NMR spectra of **1** also showed *trans-p*-coumaroyl unit signals[6] (δ 7.56 (d, J = 15.6 Hz, H-7⁗′), 7.55 (d, J = 8.8 Hz, H-2⁗′, 6″), 6.79 (d, J = 8.8 Hz, H-3⁗′, 5⁗′), and 6.43 (d, J = 15.6 Hz, H-8⁗′); δ 166.8 (C-9⁗′), 160.5 (C-4⁗′), 145.2 (C-7⁗′), 130.9 (C-2⁗′, 6⁗′), 125.9 (C-1⁗′), and 116.5 (C-3⁗′, 5⁗′)). The *trans-p*-

Fig. 1. Chemical structures of compounds **1**–**15**.

coumaroyl group linkage was confirmed by an HMBC experiment, in which a correlation was observed between the H-3′′′′′ (δ 5.03) of Glc III and the C-9′′′′′′ (δ 166.8) of the *trans*-*p*-coumaroyl group as shown in Fig. 2. The downfield shift of the signals at H-3′′′′′ (δ 5.03) and C-3′′′′′ (δ 77.9), as well as concomitant upfield shifts of the adjacent carbon signals at C-2′′′′′ (δ 71.9) and C-4′′′′′ (δ 68.2), suggested that the *trans*-*p*-coumaroyl group should be placed at C-3′′′′′ of **1**.[6] Alkaline hydrolysis of compound **1** afforded *trans*-*p*-coumaric acid,[6] together with kaempferol 3-*O*-β-D-glucopyranosyl-(1′′′→4′′)-[α-L-rhamnopyranosyl(1′′′′→6′′)]-β-D-glucopyranosyl-7-*O*-β-D-glucopyranoside (**1a**), which was confirmed by comparison of its ^{1}H NMR and FAB-MS data with literature values.[4] Acid hydrolysis of **1a** yielded kaempferol and sugar residues.[4] Kaempferol was confirmed by comparison of its ^{1}H NMR and FAB-MS data with literature values.[5] The sugar residues, D-glucopyranose and L-rhamnopyranose, were identified by co-TLC with authentic sugars ($CHCl_3$–MeOH–H_2O = 6:4:1; R_f value of D-glucopyranose, 0.31 and L-rhamnopyranose, 0.60) and by GC analysis of their corresponding trimethylsilylated L-cysteine adducts.[7] Thus, the structure of **1** was determined as kaempferol 3-*O*-β-D-glucopyranosyl-(1′′′→4′′)-[α-L-rhamnopyranosyl-(1′′′′→6")]-β-D-glucopyranosyl-7-*O*-(3′′′′-*O*-*trans*-coumaroyl)-β-D-glucopyranoside and it was named cardamoside A.

Cardamoside B (**2**) was isolated as a yellowish gum. Its molecular formula was determined as $C_{49}H_{58}NaO_{28}$ from the $[M + Na]^+$ peak at *m/z* 1117.3021 (calcd for $C_{49}H_{58}NaO_{28}$, 1117.3012) in the HR-FAB-MS spectrum. The IR, UV, and ^{1}H and ^{13}C NMR spectra of **2** were similar to those of **1**. The difference in NMR spectra was the acyl moiety, that is the *trans*-*p*-coumaroyl group in **1** was replaced with the *trans*-feruloyl group[8] (δ 7.50 (d, *J* = 15.9 Hz, H-7′′′′′′), 7.21 (d, *J* = 1.8 Hz, H-2′′′′′′), 7.01 (dd, *J* = 8.8, 1.8 Hz, H-6′′′′′′), 6.74 (d, *J* = 8.8 Hz, H-5′′′′′′), 6.40 (d, *J* = 15.9 Hz, H-8′′′′′′), 3.77 (s); δ 167.2, 150.1, 148.6, 145.9, 126.2, 123.9, 116.2, 114.8, 111.7, 56.3) in **2** (Table 1). The *trans*-feruloyl group linkage was confirmed by HMBC data, in which a correlation was observed between the H-6′′′′′ (δ 4.20, 4.45) of Glc III and the C-9′′′′′′ (δ 167.2) of the *trans*-feruloyl group as shown in Fig. 2. Moreover, the downfield shift of the signals at H-6′′′′′ (δ 4.20, 4.45) and C-6′′′′′′ (δ 63.8), as well as concomitant upfield shifts of the adjacent carbon signal at C-5′′′′′ (δ 73.9), suggested that the *trans*-feruloyl group should be placed at the C-6′′′′′ of **2**.[9] Alkaline hydrolysis of compound **2** afforded *trans*-ferulic acid[8] and kaempferol 3-*O*-β-D-glucopyranosyl-(1′′′→4′′)-[α-L-rhamnopyranosyl(1′′′′→6′′)]-β-D-glucopyranosyl-7-*O*-β-D-glucopyranoside (**2a**) (same as **1a**), which was confirmed by comparison of its ^{1}H NMR and FAB-MS data with literature values.[4] Acid hydrolysis of **2a** yielded kaempferol and a sugar residue. Kaempferol was confirmed by comparison of its ^{1}H NMR, and FAB-MS data with literature values, and D-glucopyranose and L-rhamnopyranose were identified by co-TLC with authentic sugars and by GC analysis of their corresponding trimethylsilylated L-cysteine adducts.[7] Thus, the structure of **2** was determined as kaempferol 3-*O*-β-D-glucopyranosyl-(1′′′→4′′)-[α-L-rhamnopyranosyl(1′′′′→6′′)]-β-D-glucopyranosyl-7-*O*-(6′′′′′-*O*-*trans*-feruloyl)-β-D-glucopyranoside and it was named cardamoside B.

Thirteen other known compounds obtained in this investigation were identified as *p*-anisic acid (**3**),[10] *p*-hydroxybenzaldehyde (**4**),[11] benzoic acid (**5**),[8] 4-methoxy-*trans*-cinnamic acid (**6**),[12] 4-methoxy-*cis*-cinnamic acid (**7**),[13] *p*-coumaric acid (**8**),[6] caffeic acid (**9**),[6] ferulic acid (**10**),[8] 3,4-dimethoxycinnamic acid (**11**),[14] benzyl glucopyranoside (**12**),[15] phenylethyl glucopyranoside (**13**),[15] *p*-hydroxy phenylethyl glucopyranoside (**14**),[15] and *p*-*trans*-sinaposyl glucopyranoside (**15**),[16] by comparing their spectroscopic data with those in the literature (Fig. 1). The known compounds **3**–**15** are reported from this plant source for the first time.

Experimental

General experimental procedures

IR spectra were recorded on a Bruker IFS-66/S FT-IR spectrometer. FAB and HR-FAB mass spectra were obtained on a JEOL JMS700 mass spectrometer. NMR spectra, including ^{1}H–^{1}H COSY, HSQC, HMBC, NOESY, and TOCSY experiments, were recorded on a Varian Unity Inova 500 NMR spectrometer operating at 500 MHz (^{1}H) and 125 MHz (^{13}C), with chemical shifts given in ppm (δ). Preparative HPLC was conducted using a Gilson 306 pump with a Shodex refractive index detector. Chromatographic separation was performed on an Apollo Silica 5 μm column (250 × 10 mm i.d.) or an Optimapak ODS-A (250 × 10 mm i.d.). Gas chromatography was carried out using a ZB-1MS capillary column (30 cm × 0.25 mm × 0.25 μm, Zebron); column temperature, 230 °C; injection temperature, 250 °C; and carrier gas, He. Silica gel 60 (Merck, 70–230 mesh and 230–400 mesh) and RP-C_{18} silica gel (Merck, 230–400 mesh) were used for column chromatography. The packing material for molecular sieve column chromatography was Sephadex LH-20 (Pharmacia Co.). Merck precoated silica gel F_{254} plates and RP-18 F_{254s}

plates were used for TLC. Spots were detected on TLC under UV light or by heating after spraying with 10% H_2SO_4 in C_2H_5OH (*v*/*v*).

Plant material

The aerial parts of *C. komarovii* were collected at Goseung-gun in Gangwon-Do province, Korea, in August 2008, and the plants were identified by one of the authors (K.R.L.). A voucher specimen (SKKU 2008-11) has been deposited in the herbarium of the School of Pharmacy, Sungkyunkwan University, Suwon, Korea.

Extraction and Isolation

The aerial parts of *C. komarovii* (1.7 kg) were extracted using 80% aqueous MeOH at room temperature. The solvent was evaporated under reduced pressure to give a crude extract (120 g). The crude extract was dissolved in distilled water (800 mL) and successively extracted with *n*-hexane, $CHCl_3$, EtOAc, and *n*-BuOH to provide *n*-hexane (12 g), $CHCl_3$ (13 g), EtOAc (3 g), and *n*-BuOH (26 g) extracts. The $CHCl_3$-soluble fraction (13 g) was subjected to normal-phase column chromatography (CC) over a silica gel using $CHCl_3$/MeOH of increasing polarity (40:1 to 1:1) to give seven fractions (C1–C7). Fraction C3 (1.0 g) was isolated by Sephadex LH-20 chromatography (80% MeOH) and was purified with a silica gel preparatory HPLC with a solvent system of *n*-hexane/EtOAc (15:1) to yield **3** (5 mg). Fraction C3 (2.0 g) was isolated by Sephadex LH-20 chromatography (80% MeOH) and was subjected to reversed-phase CC over a RP-C_{18} silica gel using MeOH/H_2O (9:1) to provide four subfractions (C31–C34). Subfraction C32 (70 mg) was separated by preparative normal-phase HPLC using a solvent system of $CHCl_3$/MeOH (20:1) to obtain **4** (5 mg), **5** (4 mg), **6** (6 mg), and **7** (5 mg). Fraction C4 (2.5 g) was isolated by Sephadex LH-20 chromatography (80% MeOH) and was purified with a RP-C_{18} HPLC with a solvent system of MeOH/H_2O (1:1) to yield **8** (4 mg), **9** (4 mg), **10** (4 mg), and **11** (7 mg). The *n*-BuOH soluble fraction (26 g) was subjected to CC over HP-20 resin using 100% H_2O and 100% MeOH to give two fractions (B1 – 100% H_2O and B2 – 100% MeOH). Fraction B2 (9.7 g) was subjected to normal-phase CC over a silica gel using $CHCl_3$/MeOH/H_2O (10:4:0.5) to give 14 fractions (B21–B214). Fraction B22 (120 mg) was purified by preparative RP-C_{18} HPLC using a solvent system of MeOH/H_2O (2:3) to afford **15** (5 mg). Fraction B22 (500 mg) was isolated by Sephadex LH-20 chromatography (90% MeOH) and was purified over a silica gel CC using MeCN/H_2O (1:4) to yield **12** (3 mg), **13** (9 mg), and **14** (11 mg). Fraction B212 (500 mg) was isolated by Sephadex LH-20 chromatography (70% MeOH) and was purified over a silica gel CC using MeOH/H_2O (1:4) to yield **1** (13 mg), and **2** (15 mg).

Cardamoside A (1)

Yellowish gum. UV (MeOH) λ_{max} (log ε): 317 (4.1), 267 (3.8). IR (KBr, cm^{-1}) ν_{max}: 3356, 2941, 2832, 1657, 1602, 1451, 1167, 1032, 802, 670. ^{1}H NMR (DMSO-d_6, 500 MHz) and ^{13}C NMR (DMSO-d_6, 125 MHz): see Table 1. HR-FAB-MS *m*/*z*: 1065.3086 $[M + H]^+$ (calcd for $C_{48}H_{57}O_{27}$, 1065.3087).

Cardamoside B (2)

Yellowish gum. UV (MeOH) λ_{max} (log ε): 323 (4.0), 267 (3.9). IR (KBr, cm^{-1}) ν_{max}: 3355, 2947, 2832, 1452, 1032, 797, 670. ^{1}H NMR (DMSO-d_6, 500 MHz) and ^{13}C NMR (DMSO-d_6, 125 MHz): see Table 1. HR-FAB-MS *m*/*z*: 1117.3021 $[M + Na]^+$ (calcd for $C_{49}H_{58}NaO_{28}$, 1117.3012).

Alkaline hydrolysis of 1 and 2

Compounds **1** (10 mg) in 0.05 mol/L KOH (2 mL) was stirred at room temperature for 2 h. The hydrolysate was extracted with $CHCl_3$, and the $CHCl_3$ extract was evaporated in vacuo. The $CHCl_3$ extract was purified using HPLC (Optimapak ODS-A, 250 × 10 mm; mobile phase, 40% MeOH; detector, RI; and flow rate, 2.0 mL/min) to yield *trans-p*-coumaric acid (1.2 mg) and **1a** (7 mg). Compound **2** (10 mg) was treated using the same method to give **2a** (=**1a**) (6.5 mg) and *trans*-ferulic acid (1.3 mg).

1a (**2a**): yellowish gum. ^{1}H NMR (DMSO-d_6, 500 MHz) δ: 7.95 (d, J = 8.8 Hz, H-2′,6′), 6.87 (d, J = 8.8 Hz, H-3′,5′), 6.73 (d, J = 2.0 Hz, H-8), 6.44 (d, J = 2.0 Hz, H-6), 5.37 (d, J = 7.8 Hz, Glc I), 5.06 (d, J = 7.8 Hz, Glc III), 4.43 (s, Rha), 4.16 (d, J = 7.8 Hz, Glc II). FAB-MS *m*/*z*: 917 $[M - H]^-$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by UNIVERSITAT DE VALENCIA on 10/20/12
For personal use only.

Acid hydrolysis of 1a and 2a

Compounds **1a** (=**2a)** (5 mg) was heated in an ampoule with 1 mL of aq. 1.5 mol/L HCl at 80 °C for 2 h. After cooling, the reaction mixture was extracted with EtOAc. The EtOAc solvent was evaporated in vacuo, and the residue was purified by HPLC (Optimapak ODS-A, 250 × 10 mm; mobile phase, 50% MeOH; detector, RI; and flow rate, 2.0 mL/min) to yield kaempferol (1.5 mg). The structure was identified by ^{1}H NMR and MS spectral analysis.

Determination of the sugars of compounds 1 and 2

The sugar residues (each ~2.0 mg) obtained from the hydrolysis of **1** and **2** were dissolved in anhydrous pyridine (0.1 mL) and L-cysteine methyl ester hydrochloride (2 mg) was subsequently added. The mixture was stirred at 60 °C for 1.5 h. After the reaction mixture was dried in vacuo, the residue was trimethylsilylated with 1-trimethylsilylimidazole (0.1 mL) for 2 h. The mixture was partitioned between *n*-hexane and H_20 (0.3 mL each), and the organic layer (1 μL) was analyzed by GC–MS. Identification of D-glucopyranose, and L-rhamnopyranose for **1** and **2** were detected in each case by co-injection of the hydrolysate with standard silylated samples, giving single peaks at D-glucopyranose (10.11 min) and L-rhamnopyranose (5.54 min) for **1**, and at D-glucopyranose (10.19 min) and L-rhamnopyranose (5.49 min) for **2**. Retention times of authentic samples treated in the same way with 1-trimethylsilylimidazole in pyridine, were D-glucopyranose (10.14 min) and L-rhamnopyranose (5.51 min).

A simple and straightforward approach toward selective C=C bond reduction by hydrazine

Hao Chen, Jianmin Wang, Xuechuan Hong, Hai-Bing Zhou, and Chune Dong

Can. J. Chem. Downloaded from www.nrcresearchpress.com by UNIVERSITAT DE VALENCIA on 10/20/12
For personal use only.

Abstract: A simple and straightforward method for reducing the C=C double bond with hydrazine is described. A number of representative C=C bonds in various steric and electronic environments were examined. Substituted alkenes can be selectively reduced in EtOH in the presence of hydrazine to give the corresponding products in up to 100% yields.

Key words: hydrazine, reduction, C=C double bond.

Résumé : On décrit une méthode simple et directe de réduire une double liaison C=C à l'aide d'hydrazine. On a appliqué la méthode à un certain nombre de doubles liaisons typiques, dans des environnements stériques et électroniques variés. Il est possible de réduire sélectivement des alcènes substitués dans l'éthanol, en présence d'hydrazine, pour conduire aux produits correspondants avec des rendements allant jusqu'à 100 %.

Mots-clés : hydrazine, réduction, double liaison C=C.

[Traduit par la Rédaction]

Introduction

The reduction of functionalized alkenes is one of the most fundamental reactions in organic chemistry.[1] In recent decades, various transition-metal catalysts such as Rh, Pt, and Pd were generally applied for the selective reduction of alkenes to the corresponding alkanes.[2,3] Despite the important progress in this field, these reported processes not only had harsh conditions and limited selectivity, but also produced significant amounts of inorganic and organic wastes that are of environmental concern. Thus, the development of more efficient, environmentally friendly, and economical nonmetal reagents for selective reduction of functionalized alkenes is of interest to the organic synthesis and medicinal chemistry communities as well.

In contrast, diimide reduction appears to offer an attractive solution, since NH=NH acts as a mild reducing agent for a variety of unsaturated bonds.[4,5] This reduction process has the potential to be environmentally benign, since nitrogen gas is the sole waste product. Imada et al.[6] reported the first green method for aerobic hydrogenation; the olefins can be reduced by treatment with hydrazine in the presence of $FLEt{\cdot}ClO_4$ under an O_2 atmosphere to give the product in excellent yields, with environmentally benign water and molecular nitrogen as the only waste products. *o*-Nitrobenzenesulfonylhydrazide (NBSH) is known to be another convenient precursor of diimide, since the *o*-nitrobenzene sulfinate is a good leaving group under mild conditions. In 2009, Marsh and Carbery[7] demonstrated NBSH forming the simple and efficient diimide alkene's reductions protocol. Meanwhile, it was also recognized that when the level of substitution of alkenes increases, the reaction becomes less efficient and low conversion is observed. Obviously, these methods provide improved results over traditional methods. However, the limitation of scope and the presence of organo or metal catalysts all preclude the straightforward approach to selective C=C double bond reduction.[8] Therefore, the development of more efficient, commercial available, and simple reducing agents is highly desirable.

To the best of our knowledge, there has not been a report on the facile reduction of the C=C double bond by hydrazine under mild conditions. Herein, we wish to report an unexpected reduction reaction of functionalized alkenes with commercially available hydrazine under simple thermal conditions that leads to a general and efficient method for selective C=C double bond reduction of substituted alkenes.

Results and discussion

Our studies were initiated by the reaction of 2-allylphenol **1a** with commercial hydrazine hydrate **2**. The reaction was carried out in air. To our delight, when 8 equiv of **2** was used, **1a** was fully converted to 2-propylphenol **3a** (Table 1, entry 7). As reasonably expected, no product was observed when the reaction was run under an argon atmosphere (Table 1, entry 10), which clearly indicates that diimide reduction occurred. After a brief survey of the reaction conditions, it was found that solvents and the amount of hydrazine were critical for the reaction efficiency (Table 1). 2-Allylphenol was treated with 2 equiv of hydrazine in EtOH at 80 °C, leading to trace amounts of the desired product after 14 h (Table 1, entry 9). Further study indicated that a 34% yield

[b]The reaction was run under an argon atmosphere.

of product was obtained when 4 equiv of **2** was employed (Table 1, entry 8). Additionally, among the tested solvents, ethanol was identified as the solvent of choice. Acetonitrile gave an inferior result, but dichloromethane, THF, and toluene were observed to be ineffective (Table 1, entries 1–6).

Having identified the optimal reaction conditions, we next explored the scope and limitations of this reduction reaction with hydrazine using various alkenes derivatives (**1b**–**1r**). The results are summarized in Table 2. Clearly, our reduction system proved rather effective for the selective reduction of a wide variety of substituted alkenes, providing the corresponding product in excellent yields. In addition to 2-allylphenol **1a**, terminal alkenes **1b** and **1c** also reacted smoothly with hydrazine giving the corresponding products in excellent yields (Table 2, entries 2 and 3). Additionally, a polarized alkene, such as **1d**, was efficiently reduced by hydrazine in 5.5 h, forming product **3d** in excellent yield (Table 2, entry 4). Aromatic alkenes with the phenyl ring substituted with an electron-donating or an electron-withdrawing group also performed well in this reduction (Table 2, entries 5–13). For example, *p*-methoxyl methyl cinnamate (**1i**) and *p*-trifluoromethyl cinnamic acid (**1l**) underwent smooth reduction (Table 2, entries 9 and 12). It can be clearly seen that when the level of th ealkene substitution increases, the reduction becomes less efficient. Tetra-substituted alkene **1r** remained inert under the same reaction conditions (Table 2, entry 18). Interestingly, in the case of styrene, a 16% yield of enthylbenzene was obtained (Table 2, entry 17), which indicates that, for mono-substituted alkenes, conjugation might play an important role in hydrazine-promoted reduction.

Clearly, this reduction system offers synthetic advantages with respect to metal-catalyzed hydrogenation and other reducing systems as well.

Conclusions

In conclusion, a simple, efficient, and highly selective C=C double bond reduction protocol has been developed. The hydrazine-mediated reducing system has been successfully applied to various substituted alkene reductions to form the desired products in excellent yields. We believe this reduction method, from a synthetic point of view, is a valuable alternative not only for the laboratory but also for industry.

Experimental section

General information

All reagents and solvents were obtained from commercial sources and were used without further purification. The hydrazine hydrate used in this study was 80% solution. Column chromatography was performed with silica gel (300–400 mesh). NMR spectroscopy was performed on a Bruker (400 MHz) spectrometer using TMS as the internal standard. Products were characterized by comparison of their ^{1}H NMR spectroscopic data with those reported in the literatures.

General procedure for reduction reactions with hydrazine hydrate

To 1 mmol of substrate **1** dissolved in 1.0 mL of solvent was added 8 mmol of hydrazine **2** and the mixture was heated to reflux for 5.5–24 h in air. After the reaction finished, the solvent was removed and the residue was extracted three times with ethyl acetate (3 × 5 mL) and dried over $MgSO_4$. The product was characterized by NMR.

Abstract: Salicylaldehyde benzoylhydrazone (H_2sb) has a variety of biological activities including anticancer activity. The Cu(II) complexes of H_2sbs possess enhanced anticancer activity as compared with their free ligands. A quantitative structure–activity relationship (QSAR) analysis was performed on a series of H_2sb ligands and their corresponding Cu(II) complexes to capture the structural requirements that are responsible for the bioactivity. The predictive QSAR models were developed using statistical techniques such as multiple linear regression (MLR) and principal component regression analysis (PCRA). We used different combinations of various descriptors such as a physicochemical descriptor, electrotopological state atom (ETSA) indices, and descriptors derived from density functional theory (DFT) calculations. The DFT-derived descriptors used for QSAR analysis are HOMO and LUMO energies, atomic charges, chemical potential, and hardness. Our developed models showed the importance of the lipophilicity index (ClogP), ETSA indices, and atomic charges for anticancer activities of the H_2sb analogs and their Cu(II) complexes. In addition, our MLR models revealed that, while the global lipophilicity index and hardness are important for anticancer activity of H_2sb ligands, chemical potential and HOMO energy are important for the anticancer activity of Cu(II) complexes.

Key words: salicylaldehyde benzoylhydrazone, copper(II) complexes, DFT, ETSA index, QSAR.

Résumé : La benzoylhydrazone du salicylaldéhyde (H_2sb) possède une grande variété d'activités biologiques, dont une activité anticancéreuse. Les complexes du Cu(II) avec la H_2sb possèdent une activité anticancéreuse amplifiée par rapport à celle des ligands non liés à un métal. On a effectué une analyse de relation structure–activité quantitative (RSAQ) sur une série de ligands dérivés de la H_2Sb ainsi que sur les complexes correspondants du Cu(II) afin de déterminer quelles caractéristiques structurales sont responsables de cette bioactivité. On a développé les modèles prédictifs de RSAQ en faisant appel à des techniques statistiques telles que l'analyse de la régression linéaire multiple (RLM) et l'analyse de la régression de la composante principale (ARCP). On a utilisé diverses combinaisons de descripteurs différents, tel un descripteur physicochimique, les indices électrotopologiques de l'état de l'atome (ETEA) et des descripteurs dérivés de calculs de la théorie de la fonctionnelle de la densité (TFD). Les descripteurs dérivés de la TFD qui ont été utilisés pour les analyses RSAQ sont l'énergie de l'orbitale moléculaire (OM) haute occupée (HO) ou basse vacante (BV), les charges atomiques, le potentiel chimique et la dureté. Les modèles qui ont été développés mettent en évidence l'importance de l'indice du caractère lipophile (ClogP), des indices électrotopologiques de l'état de l'atome (ETEA) et des charges atomiques sur les activités anticancéreuses des analogues de la H_2sb et de leurs complexes de Cu(II). De plus, nos modèles de régression linéaire multiple (RLM) démontrent l'importance de l'indice du caractère lipophile et de l'énergie de l'orbitale moléculaire HO sur l'activité anticancéreuse des complexes du Cu(II).

Mots-clés : benzoylhydrazone du salicylaldéhyde, complexes du cuivre, théorie de la fonctionnelle de la densité (TFD), indice électrotopologique de l'état de l'atome (ETEA), relation structure–activité quantitative (RSAQ).

[Traduit par la Rédaction]

Introduction

The biological activities of salicylaldehyde benzoylhydrazone (H_2sb) analogs have received great attention in the past years. H_2sb was first found to have promising bacteriostatic activity and later it was found that they are able to inhibit DNA synthesis and cell growth in a broad range of human and rodent cell lines.[1,2] In addition, H_2sb analogs have also been reported to have significant antitumor activities against a variety of cancer cell lines.[3,4] Interestingly, they also have been shown to be an effective copper chelator, and their Cu(II)

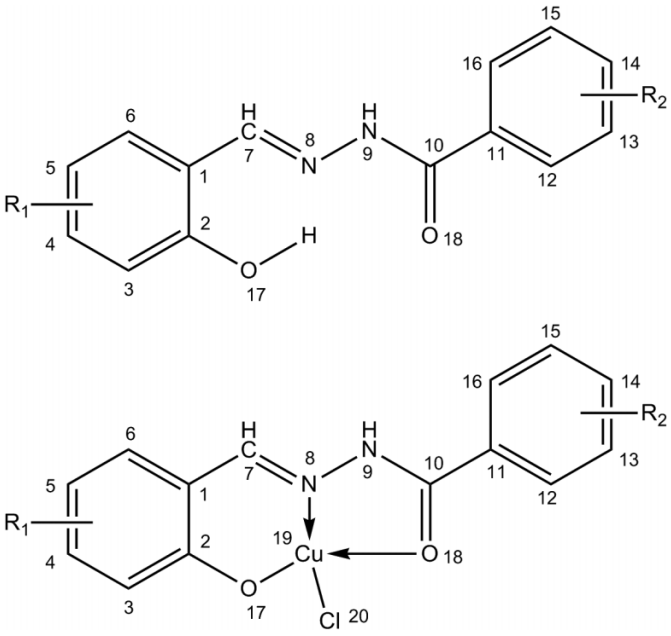
complexes possess enhanced antitumor activities when compared with the free H_2sb ligands.[3,4] Over the years, a significant amount of studies have been done on the Cu(II) complexes for their potential anticancer activity.[5,6] The main reason is that the Cu(II) complexes can serve as an alternative for the renowned platinum-based drugs (e.g., cisplatin and carboplatin), which have undesirable side effects and drug-resistance problems.[7] In 1998, Ainscough et al.[4] synthesized a series of H_2sb ligands and their Cu(II) complexes that showed promising antitumor activity against the human colon cancer cell line. To date, the mechanism for anticancer activity of H_2sb analogs and their Cu(II) complexes is still unclear. Thus, a detailed understanding on the properties of these compounds at the molecular level, such as steric and electronic properties, may provide important insights into the anticancer properties.[8] Among the diversified descriptors, the quantum chemical descriptors based on density functional theory (DFT) and semiempirical methods have been found useful in several quantitative structure–activity relationship (QSAR) studies conducted recently.[9–11] The net atomic charges, frontier molecular orbital energies (i.e., highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO)),[12] and DFT-based reactivity descriptors, such as global hardness, electronegativity, and chemical potential, have been demonstrated to correlate well with various biological activities. A preliminary QSAR study was performed by Ainscough et al.[4] on the H_2sb ligands using the octanol–water partition coefficient and the Hammett σ parameters for antitumor activity. However, they were unable to conduct QSAR analysis on the Cu(II) complexes because of the lack of accurate and transferable linear free energy relationship (LFER) parameters for the complexes. To the best of our knowledge no QSAR studies have been performed on Cu(II) complexes of H_2sb ligands. Moreover, very few QSAR studies on copper complexes for other bioactivities have been reported[5] owing to the lack of specific metal–ligand parameters in most of the common force fields, which generally do not predict the structure of metal complexes accurately.[13]



Thus, in the present study, we performed the QSAR analysis on the H_2sb analogs and their Cu(II) complexes to develop predictive QSAR models and to capture the structural changes that are responsible for the cancer inhibitory activity. We used the electrotopological state atom (ETSA) indices, physiochemical properties like the hydrophobicity index, DFT-derived descriptors such as E_{HOMO} and E_{LUMO}, chemical potential, global hardness, the global electrophilicity index, and atomic charges as descriptors for the QSAR studies. We performed multiple linear regression (MLR) analysis and principal component regression analysis (PCRA) to develop the QSAR models for the H_2sb analogs and their Cu(II) complexes.

Materials and methods

Molecular modelling

The general structures and arbitrary atom numberings for the H_2sb analogs and their Cu(II) complexes are illustrated in Fig. 1. All calculations were performed by the DFT[14,15] B3LYP (Becke's three-parameter hybrid function[16] with the nonlocal correlation of the Lee–Yang–Parr[17]) method with

Fig. 1. General structures of salicylaldehyde benzoylhydrazone ligands and their corresponding Cu(II) complexes with arbitrary numberings.

the 6–31G(d) basis set.[18] The calculations were carried out using the Gaussian 03 suite of programs.[19] Full geometry optimizations were performed on both the H_2sb ligands and their Cu(II) complexes at the B3LYP/6–31G(d) level (past studies[20–22] justified that the 6–31G(d) basis set is sufficient for current systems). Frequency analyses were performed on the optimized geometries to confirm that they are at minima (no imaginary frequency). The optimized stable structures of the H_2sb ligands and their Cu(II) complexes were used for the calculations of reactivity descriptors for the QSAR analysis. Natural population analysis (NPA)[23,24] was performed to obtain the natural atomic charges.

Data set and descriptor calculations

The anticancer activity data (IC_{50}, μmol) of H_2sb and their Cu(II) complexes were collected from the published work of Ainscough et al.[4] The IC_{50} (μmol) values taken from Ainscough et al. were first converted to IC_{50} (mol). The IC_{50} values were then converted to the logarithmic scale ($pIC_{50} = -\log IC_{50}$) and used as response variables to develop the QSAR models (see Table 1). The calculations of the *n*-octanol–water partition coefficient (ClogP), molar refractivity (MR), and geometrical parameters, such as Connolly accessible area (CAA), Connolly molecular area (CMA), and volume (*V*), were performed using the Chem 3D Ultra 11.0 software package.[25] ClogP and MR were calculated according to Ghose and Crippen's fragmentation method.[26] The ETSA index introduced by Kier and Hall and co-workers[27–29] was employed in the QSAR analysis for the exploration of atoms or regions of the compounds that modulate the activity comparatively to a greater extent. The ETSA index of a skeletal atom is defined as $S_i = I_i + \Delta I_i$, where I_i is the intrinsic electronic and topological character of an atom and ΔI_i is the perturbation effect of the molecular topological environment of each atom in the molecule. The I_i value of an atom is

defined as $I_i = [(2/N)^2\delta^v + 1]/\delta$, where N is the principal quantum number, δ^v and δ are the counts of the valence electrons and σ electrons, respectively, associated with the atom i in the hydrogen-suppressed graph. The general expression for the perturbation term is $\Delta I_i = \sum (I_i - I_j)/r_{ij}^2$, where I_i and I_j are the intrinsic state values for atoms i and j, respectively, and r_{ij} is the number of atoms through atom i to atom j, including the atoms i and j.

The energies of the highest occupied molecular orbital (E_{HOMO}) and lowest unoccupied molecular orbital (E_{LUMO}) are often used as quantum mechanical parameters to characterize the reactivity of molecules in many chemical reactions. Based on Koopmans' theorem,[30] ionization potential and electron affinity can be approximated as the $-E_{HOMO}$ and $-E_{LUMO}$, respectively. With the approximations according to Koopmans' theorem and the finite difference approach, the following set of DFT-based reactivity descriptors were derived and used in our QSAR study: (*i*) the global electrophilicity index ($\omega = \frac{\mu^2}{2\eta}$),[31] (*ii*) the chemical potential ($\mu = \frac{E_{LUMO}+E_{HOMO}}{2}$),[32] and (*iii*) the hardness $\eta = \frac{E_{LUMO}-E_{HOMO}}{2}$.[33]

Statistical analysis

Two statistical methods, MLR[34] and PCRA,[35] were employed to develop QSAR models. The leave-one-out (LOO) cross-validation method[36] was carried out to validate the predictive abilities of the MLR equations. The statistical qualities of the developed MLR equations were judged by using parameters such as square of the correlation coefficient (R^2), explained variance (R^2_a), variance ratio (F), probability factor related to the F ratio (p), the standard error of estimate (s), and predicted residual sums of squares (PRESS). All the statistical analyses were performed using MINITAB[37] software.

Results and discussion

MLR analysis

QSAR models for H_2sb ligands

The selected ETSA indices, natural atomic charges, lipophilicity indices, and quantum chemical descriptors derived from the DFT study for the H_2sb ligands and their Cu(II) complexes, used to deduce the QSAR models, are listed in Tables 2 and 3. All descriptors were subjected to correlation analysis, and highly intercorrelated descriptors were removed based on their correlation. MLR analysis was performed the on the H_2sb ligand's data set for anticancer activity. All possible combinations of the selected descriptors were taken into account during the model derivation. The QSAR models obtained from the MLR analysis for the H_2sb ligands were selected based on statistical measures such as R^2, the adjusted R^2 (R^2_a), the LOO cross-validated square of the correlation coefficient (Q^2), s, and the overall F statistics for the addition of each successive term (F) and are presented in Table 4. The QSAR models (eqs. [1]–[14]) obtained from the regression analysis for the H_2sb ligands are listed in Table 4.

The best QSAR model (Table 4, eq. [1]) developed with two parameters for the H_2sb ligand's data set shows the positive contribution of ClogP and the negative contribution of η towards the anticancer activity. Equation [1] (Table 4) explains 75.0% and predicts 62.1% of the variance of the activity. This indicates that the variations of lipophilicity and chemical hardness are induced becausee of ortho or para substitution at the salicylaldehyde ring or ortho, meta, or para substitution at the benzoylhydrazone's phenyl ring, which plays an important role in the interaction of the H_2sb compounds with cancer cells. This prompted us to further improve the models with the addition of other descriptors.

We developed four new equations with improved overall statistical qualities (Table 4, eqs. [2]–[5]) by introducing one additional descriptor in eq. [1] (Table 4) such as the electrotopological descriptors (S_{11} and S_{17}) and quantum chemical descriptors (q_1 and q_2). S_{11} and S_{17} are the ETSA indices of atoms 11 and 17, respectively, and q_1 and q_2 are the atomic charges on atoms 1 and 2, respectively. The similar statistical significance of these equations reveals that the descriptors S_{11}, S_{17}, q_1, and q_2 have comparable contributions towards the anticancer activity of H_2sb ligands. The negative coefficients of S_{11} (eq. [2], Table 4) and S_{17} (eq. [3], Table 4) also suggest that an increase in the values of these descriptors is detrimental to the anticancer activity of the H_2sb compounds. Moreover, the negative coefficient of q_1 (eq. [4], Table 4) and the positive coefficient of q_2 (eq. [5], Table 4) show that a decrease of atomic charge on atom 1 and an increase of atomic charge on atom 2 is favourable for the anticancer activity of H_2sb ligands. Equations [6] and [7] (Table 4) are the most statistically significant models constructed with three parameters, which explain 77.5% and 80.7% of the variance of activity,

For personal use only.

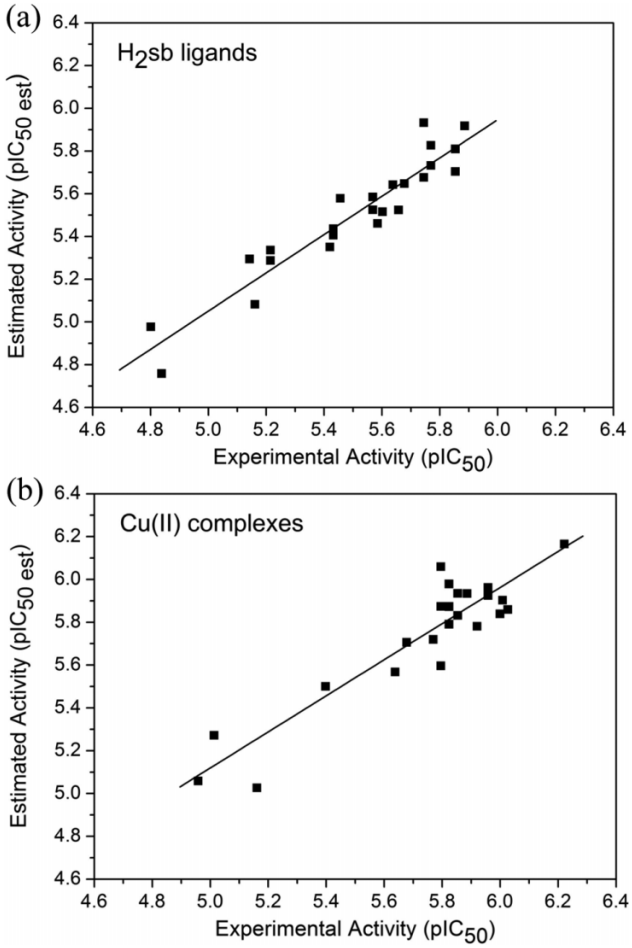
respectively. Both equations show the importance of ω for predicting the cytotoxicity of the H_2sb ligands.

In addition, we derived four-parameter QSAR models (eqs. [8]–[14], Table 4) with improved overall statistical qualities (e.g., eq. [4], $R^2 = 0.832$ and $F = 32.98$; and eq. [10], $R^2 = 0.896$ and $F = 40.79$) by introducing an additional descriptor in eq. [4] (Table 4). The negative coefficient of S_8 (eq. [10], Table 4) suggests that an increase of the ETSA index of the imine N atom will decrease the anticancer activity. The calculated anticancer activity of H_2sb ligands from eq. [10] (Table 4) is plotted against the experimental activity (see Fig. 2*a*). Figure 2 shows the ability of our model to predict the anticancer activity of H_2sb ligands.



The similar statistical qualities of eqs. [8]–[12] (Table 4) reveal that the ETSA indices S_6, S_7, S_8, S_9, and S_{10} have similar contributions to the anticancer activity of H_2sb ligands (Table 4). Since the ETSA indices are derived from the availability of the valence electrons on the atoms plus the effects of the topology of neighbouring atoms, the values of S_2–S_8 are practically interdependent at these positions. The negative coefficients associated with the S_6–S_{10} indices suggest that the increase of the value of ETSA index of atoms 6–10 will decrease the anticancer activity of H_2sb. Moreover, atoms 7–10 are important atoms on the backbone of the H_2sb ligands, which are involved in the electronic conjugation along the H_2sb framework. Successful incorporation of ETSA indices of these atoms in the QSAR models suggests that these atoms may be crucial for the interaction between H_2sb ligands and the cancer cells. Equations [13] and [14] (Table 4) also suggest that the atomic charges on atoms 2 and 18 are important for the prediction of the anticancer activity of H_2sb ligands.

QSAR models for Cu(II) complexes

The QSAR models (eqs. [15]–[31]) for the Cu(II) complexes were developed in the same fashion as for the H_2sb ligands using the MLR technique and are listed in Tables 5 and 6. We used descriptors having low and moderate degrees of correlation based on Pearson's correlation coefficient. In general, if the Pearson's correlation coefficient is $r \in [-0.5, 0.5]$, there was a low degree of correlation between the two descriptors; if $r \in (0.5, 0.8)$ or $r \in (-0.8, -0.5)$, there was a moderate degree of correlation; and if $r \in [0.8, 1]$ or $r \in [-1, -0.8]$, there was a strong correlation between the descriptors.[38] Usually, the descriptors used to derive QSAR models have been selected based on lower correlation among the

Fig. 2. The estimated versus experimental activities of salicylaldehyde benzoylhydrazone (H_2sb) ligands and their Cu(II) complexes using the best equations. Ligands (eq. [10]): $n = 24$ and $R^2 = 0.896$; Cu (II) complexes (eq. [31]): $n = 24$ and $R^2 = 0.843$.

descriptors. However, we observed significant enhancement of the statistical qualities of the QSAR models developed for Cu(II) complexes by using the moderate intercorrelated descriptors. The descriptors having greater correlation with each other are found to have greater R^2 values with lower standard deviations and higher F values (see Tables 5 and 6). The best QSAR equation developed for the Cu(II) complexes contains descriptors S_9, S_{12}, q_{14}, and q_{18}. The descriptors S_{12} and q_{18} each have a correlation coefficient of 0.699. Since the two descriptors are of different types (one is an ETSA index and the other is atomic charge) and from different atoms, we could use them together to develop the QSAR models. Therefore, we developed the QSAR models for Cu (II) complexes using descriptors having low and moderate degrees of correlation.

The positive coefficients of ClogP, S_1, q_{15}, and q_{18} (Table 5, eq. [15]) indicate that the higher value of these parameters may be favourable for the higher anticancer activity of Cu(II) complexes. Equation [16] (Table 5) is built solely using ETSA indices and natural charges on selected atoms, i.e., S_8, q_1, q_{16}, and q_{18}, which explains 68.8% and predicts 55.2% of the variance of activity. The results suggest that the atoms 1, 8, 16, and 18 play an important role for the inhibition of cancer cells. Equations [15]–[18] (R^2_a and Q^2 ranged from 68.8% to 69.5% and 52.6% to 51.1%, respectively) and [19]–[22] (R^2_a and Q^2 ranged from 72.2% to 73.9% and 61.8% to 62.8%, respectively) exhibit comparable statistical qualities. Our results suggest that the electronic interactions of the benzoylhydrazone part to the copper are important for the cytotoxicity of the compounds. In particular, eqs. [21] and [22] (Table 5) show that the increase in the values of S_{18}, S_{20}, q_{10}, and q_{18} are favourable for the anticancer activity of the Cu(II) complexes.

We observe that most of the significant models presented in Table 6 are a combination of S_{12}, S_{18}, q_{12}, and q_{18} parameters, which indicates that atoms 12 and 18 are crucial for the prediction of the anticancer activity of the Cu(II) complexes. Our results also suggest that the substitution of an electron-withdrawing group to the benzoylhydrazone ring might be necessary for the biological activity of the Cu(II) complexes. Moreover, we show the capabilities of quantum chemical descriptors like chemical potential (μ_β) and HOMO energy for the spin down configuration ($E_{\beta\text{-HOMO}}$; eqs. [23] and [24], Table 6) for the prediction of the cytotoxicity of Cu(II) complexes. We also show the importance of S_5, S_8, q_1, q_5, q_7, and q_{14} for the anticancer activity of Cu(II) complexes (eqs. [25]–[29], Table 6).

The two best QSAR models developed for Cu(II) complexes, i.e., eqs. [30] and [31] (Table 6), show that the atoms 4, 9, 12, and 18 are crucial for the prediction of the anticancer activity of Cu(II) complexes. In comparison to the best equation derived for the ligands (Eqs. [10] and [11], Table 4), eqs. [30] and [31] are built solely on ETSA indices and atomic charges, whereas the models for the ligands are a combination of ClogP, η, ETSA indices, and atomic charges. Furthermore, these equations also illustrate the importance of the electronic interaction between atoms 12 and 18 in affecting the anticancer activity. We observe that eq. [31] (Table 6) is statistically better than eq. [30] (Table 6) because the former can predict a much higher variance of the activity than the latter (i.e., $Q^2_{\text{eq. [31]}} = 74.5\%$ and $Q^2_{\text{eq. [30]}} = 53.9\%$). The calculated anticancer activities of Cu(II) from eq. [31] (Table 6) are plotted as a function of experimental activity and are shown in Fig. 2*b*. Our present study shows that besides ClogP, the DFT-derived descriptors and electrotopological state atom index can successfully be used to develop the predictive QSAR models for anticancer activities of the H_2sb and their Cu(II) complexes.

Validation of the developed models

The predictive power of our developed models is validated both internally (using LOO cross validation) and externally (using training and test sets). The observed (Obs.), calculated (Calcd.), residual (Res.), predicted residual (Pres.), and LOO-predicted (Pred.) activities of the best QSAR model (eq. [10], Table 4) are listed in Table 7 (see the Supplementary data for the rest of the equations). We divided the data set of the 24 H_2sb ligands and 24 Cu(II) complexes into a training set (75% of the total data set) and a test set (remaining 25%) randomly for external validation. The compounds **3**, **5**, **11**, **13**, **21**,and **23** were selected as the test set

23 using eqs. [10] and [31] and the predicted values of these compounds (test set) using eqs. [10*tr*] and [31*tr*] are similar. This indicates the significant predictive power of our developed models.

Principal component regression analysis (PCRA)

Principal component analysis (PCA) was carried out on the H_2sb ligand and Cu(II) complex data sets to extract the factor loadings of different variables. The factor loadings (after VARIMAX rotation) of different variables for the data set of H_2sb ligands and Cu(II) complexes are presented in Tables 9 and 10, respectively. The nine factors were extracted from the PCA considering the eigenvalues greater than or equal to one. Factor loadings >0.70 are shown in boldface. The nine factors of H_2sb ligands and the copper complexes' descriptors account for 89.1% and 86.7% of the variance of the activity for the H_2sb ligands and Cu(II) complexes, respectively. When the factor scores are used as independent variables in MLR analysis, the following MLR equation is obtained for the H_2sb ligands:

$$[32] \quad pIC_{50}\ (\text{ligand}) = 5.501\ (\pm 0.025) + 0.100\ (\pm 0.026)F_1 - 0.107\ (\pm 0.026)F_3 + 0.239\ (\pm 0.026)F_7$$

where $n = 24$, $s = 0.123$, $R^2 = 0.856$, $R^2_a = 0.834$, $Q^2 = 0.641$, PRESS = 0.760

Equation [32] explains 83.4% and predicts 64.1% of the variance of the activity. The values mentioned in the parentheses are the 95% confidence intervals of the regression coefficients. All regression coefficients are significant at the 95% level as supported by their t and p values (see Table 11). All the factors contain the important information from a different combination of descriptors. The positive coefficients of

Note: MR, molar refractivity; CAA, Connolly accessible area; CMA, Connolly molecular area; ClogP, *n*-octanol–water partition coefficient; *V*, volume; η, hardness; ω, global electrophilicity index; μ, chemical potential; E_{HOMO}, energy of the highest occupied molecular orbital; E_{LUMO}, energy of the lowest unoccupied molecular orbital; *S*, ETSA index; *q*, atomic charge.

F_1 and F_7 indicate that the higher the values of these parameters, the better the anticancer activity, whereas the negative coefficient of F_3 indicates an opposite effect. The factor score 1 shows the importance of the ETSA indices of atoms 1, 2, 6, 7,and 8, the atomic charges on atoms 8 and 17, and the energy of HOMO. Similarly, the factor score 3 signifies the importance of the atomic charges on atoms 7 and 15, the energy of LUMO, and the hardness. The factor score 7 indicates the importance of ClogP of the H_2sb ligands for anticancer activity.

The following MLR model was derived for the Cu(II) complexes using the factor scores as independent descriptors in MLR analysis.

Fig. 3. Structure of the salicylaldehyde benzoylhydrazone (H_2sb) ligand showing the fragment (atoms enclosed by the broken line) necessary for anticancer activities.

20 for the inhibitory activity of cancer cells. The factor score 3 indicates the importance of atomic charges on atoms 10, 11, and 15 and the energies of α-LUMO and β-LUMO, whereas the factor score 5 shows the importance of the ETSA index and atomic charge on atom 12. The factor score 7 signifies the importance of the atomic charge on atom 1. According to the PCRA results, we can divide the compound's structure into two parts (separated by atom 8), the salicylaldehyde part and the benzoylhydrazone part. We observe that upon copper coordination, the benzoylhydrazone part (especially atoms 9, 10, 11, 12, 15, 16, 18, and 20) becomes important for anticancer activity, whereas, for the ligands, the salicylaldehyde ring part (especially atoms 1, 2, 6, 7, and 17) is more interactive with the biomolecules. Since the factor scores are used as independent variables instead of the original variables in PCRA, the loss of information during the MLR analysis can be avoided and the quality of the developed equations can also be improved. This is because each factor score contains information from all of the original descriptors. For instance, factor scores shown in eq. [32] have included all the important descriptors that influenced the bioactivity of the H_2sb ligands, which was also found in the MLR analysis (Table 4). Furthermore, the PCRA analysis of H_2sb ligands pointed out the importance of the ETSA indices on atoms 1 and 2, which are not captured by MLR analysis. In summary, our present work shows that the cytotoxicity of substituted salicylaldehyde benzoylhydrazones and their Cu(II) complexes can be modelled successfully by using quantum chemical and topological descriptors. In addition, our developed QSAR models may be used for the prediction of anticancer activities of substituted salicylaldehyde benzoylhydrazones and their Cu(II) complexes, and may help to design new compounds with potentially higher cytotoxicities.

The QSAR models developed for 24 H_2sb ligands show the importance of the ETSA indices of atoms 6–11 and the atomic charges of atoms 1, 2, 8, and 18. This indicates that the benzoylhydrazone fragments (see Fig. 3) of the ligands are necessary for anticancer activities. Our QSAR results suggest that the strong correlation effect among the atoms on the benzoylhydrazone framework is consistent to our previous studies,[8] showing that there is strong conjugation along the molecular plane of the ligand. The strong conjugation effect along the benzoylhydrazone framework allows these atoms to have mutual effects toward each other when a different substitution group is added to the benzene ring. As a result, the ETSA indices of atoms 6–11 are mutually important for anticancer activity. Since the atomic charge on atom 2 is positive and negative on atom 1, our developed model shows that an increase in positive charge on atom 2 and in negative charge for atom 1 will increase the anticancer activities of H_2sb ligands. This indicates that the addition of electron-withdrawing groups near position 2 (e.g., position 3) and electron-donating groups near position 1 (e.g., position 5 and 6) is required for the anticancer activity of H_2sb ligands. Based on our QSAR study, more negative charge on atom 18 is favorable for the anticancer activities of H_2sb ligands. Thus, we need to modify the compounds in such a way that it will increase the negative charge on atom 18 and thus the anticancer activities. Since there is a local conjugation system between carbonyl oxygen atom 18 and the neighboring atoms (i.e., atoms 11 and 12), the addition of an electron-donating group to atom 12 will increase the charge density of atom 18 through the conjugation system and hence lead to improved activities. This can be further explained by the Cu(II) complexes of the H_2sb ligands. Atom 18 is the carbonyl oxygen involved in the complexation of H_2sb ligands with Cu to form their corresponding Cu(II) complexes. The calculated atomic charges of H_2sb ligands and their Cu(II) complexes show that atom 18 of the Cu(II) complexes has more negative charge than the one in their ligands (see Tables 2 and 3). According to our current QSAR analysis, the Cu(II) complexes will have enchanced anticancer activities, which is supported by the experimental finding that the Cu(II) complexes of H_2sb ligands have a better anticancer activity than their ligands.[4] Thus, the complexation of the ligands with Cu is essential for increasing the anticancer activity of the H_2sb ligands.

Conclusions

We have developed statistically significant QSAR models for the H_2sb ligands and their corresponding Cu(II) complexes for their anticancer activity using MLR and PCRA techniques. We used different combinations of various descriptors such as physicochemical and ETSA indices and molecular descriptors such as chemical hardness, chemical potential, and natural population (NPA) charges, derived from DFT calculations. Our developed models show the importance of ClogP, ETSA indices, and atomic charges for the anticancer activities of the H_2sb analogs and their Cu(II) complexes. In addition, our MLR models revealed the importance of the global lipophilicity index and hardness for the anticancer activity of H_2sb ligands, whereas our MLR models revealed the importance of chemical potential and HOMO energy for the spin down configuration for the anticancer activity of Cu(II) complexes. A positive coefficient for ClogP indicated that the increase in ClogP increases the anticancer activities of both the H_2sb ligands and their corresponding Cu(II) complexes. For the H_2sb ligands, we observed that an increase of hardness is detrimental to their anticancer properties, whereas an increase in chemical potential and HOMO energy for the spin down configurations of Cu(II) complexes are favorable for their anticancer activity. In conclusion, we have successfully developed QSAR models for Cu(II) complexes as well as for the ligands. The developed QSAR models may be used for the prediction of anticancer activities and to design new analogs of the H_2sb ligands and their corresponding Cu(II) complexes with potentially higher anticancer activities.

Abstract: Electronic absorption spectra of rhodamine B dye in aqueous solutions and in a polyacrylamide hydrogel matrix with different structural compositions were studied at room temperature. The transport and the solute–solute interactions of rhodamine B in aqueous solutions across the hydrophilic gels were investigated via exploration of the spectral properties of the dye-loaded hydrogel. The nature of the dye pair interactions in these media was discussed using the Kasha exciton theory. In addition, the monomer–dimer equilibrium of rhodamine B molecules in hydrogels with different compositional percentages was studied by means of UV–vis spectroscopy and least-squares fitting methods.

Key words: rhodamine laser dye, polyacrylamide hydrogel, dye aggregation, Kasha exciton theory, guest–host interaction.

Résumé : Opérant à la température ambiante, on a étudié les spectres d'absorption électronique du colorant rhodamine B en solutions aqueuses ainsi que dans diverses matrices d'hydrogels de polyacrylamide de compositions structurales différentes. On a aussi étudié les propriétés de transport et les interactions soluté–soluté de la rhodamine B en solutions aqueuses à travers les gels hydrophiles en explorant les propriétés spectrales d'hydrogel imbibé du colorant. On discute de la nature des interactions de la paire de colorant dans ces milieux en faisant appel à la théorie de l'exciton de Kasha. Faisant appel à la spectroscopie UV–vis et les méthodes d'ajustements par les moindres carrés, on a de plus étudié l'équilibre monomère–dimère des molécules de rhodamine B dans les hydrogels de compositions différentes en pourcentage.

Mots-clés : colorant laser rhodamine, hydrogel de polyacrylamide, agréation de colorant, théorie de l'exciton de Kasha, interaction hôte–invité.

Introduction

Rhodamine dyes are an important class of xanthene dyes. They have great fluorescence quantum yields and large molar absorptions. They have been extensively studied because of their practical applications as the active agent in dye lasers and optical applications.[1–9] The most active rhodamine derivatives are obtained by substituting the hydrogen of the rhodamine skeleton by groups such as alkyls, amines, etc. This substitution changes the ground- and excited-state dipole moments of substituted rhodamine molecules,[10] as well as their other photophysical properties.

One of the appropriate laser dyes is the one that uses rhodamine B (RB) as a lasing agent, which is tunable around 610 nm. Rhodamine laser dyes such as RB can easily form aggregates[11,12] in solution that quench the dye fluorescence emission and, therefore, degrade the lasing ability of dye-laser systems. This quenching process is mainly due to the transfer of excitation energy between monomers and aggregate forms of the dye molecules,[13–16] which subsequently, decays nonradiatively.[17] This means that dye aggregations is extremely important in dye-laser applications.

The aggregation of the dye molecules leads to a strong coupling of the molecular transition dipoles. This electrostatic interaction between molecular transition dipoles of the chromophores splits energy levels of the excited states of the dye molecules. According to the Kasha exciton theory,[18] in an ideal system J- or H-aggregates can be formed depending on the angle between the transition dipoles and the monomer center-connected axis in aggregate form (Fig. 1).[12,19] For H-aggregates (Fig. 1*a*), the chromophores of the participating molecules are in parallel planes, whereas, in J-aggregates, they are in the same plane (Fig. 1*b*)). However, in reality, both cases of the dimer structures are idealistic, and the transition moments are neither parallel nor antiparallel exactly. Appearance of both H- and J-bands[12,18,19] in the dimer spectrum confirms that oblique orientation of the transition dipoles is more feasible (Fig. 1*c*).

In the oblique dimer form, the angle between the transition dipoles of aggregated molecules (α angle) express the J- or H-aggregate characteristic of the dimer structure. The α angle can take values between 0° and 180°, and the shift from J- to H-aggregate occurs at $\alpha = 70.6°$. In this case, the θ angle (the angle between the transition dipoles and the monomer center-connected axis) is 54.7° Fig. 2. An α angle greater than 70.6° is connected with the J-aggregate, whereas an α angle less than 70.6° belongs to the H-aggregate.

Aggregation properties of the dyes can be controlled with different factors such as solvent media effect, concentration, temperature, and the presence of other solutes and cosolvents. We have ecently reported the influence of environment and concentration on the aggregative and photophysical properties of some oxazine, and thiazin dyes.[20–22] It was concluded that the host media affect the electronic absorption and aggregative characteristics of the ionic dyes.

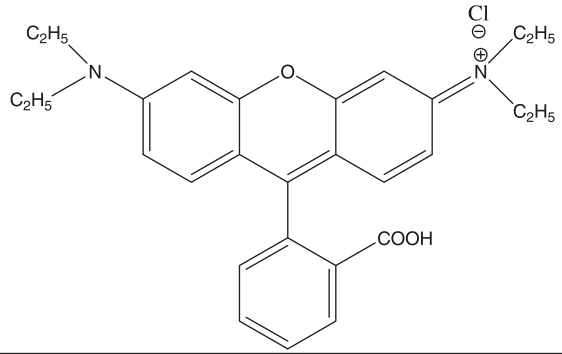
Previously, the aggregation properties of some dyes in liquid solvent have been studied.[14,15,19] The solid-state media effects on the dye aggregation mechanism have been investigated recently.[23,24] All the research noted that the solvent matrix internal association and th einteraction of solvent molecules with the dye molecules are important parameters that determine the characteristics of the aggregate structures.

Polymer gels known as hydrogels, which have both solid- and liquid-like properties, are astonishing and fascinating materials. They are only composed of a cross-linked polymer network and interstitial fluid. These gels contain a great amount of water. The water uptake, the swelling process, is associated with a respective volume change.[20,21,25] Its structural framework is formed from three-dimensional networks of randomly cross-linked polymeric chains.

In this study, the aggregative properties of rhodamine B dye in polyacrylamide (PAAM) hydrogels with different compositional percentages of structural components were studied using optical spectroscopy. It would be interesting to understand the effect of the hydrogel host structure on the solute–solvent and solute–solute interactions and the monomer–dimer equilibrium of the aggregate dyes. This study is intended to provide the information about the effect of PAAM structural composition on guest–host interactions and the aggregative properties of RB in binary solvent systems by means of the exciton theory.

Experimental

Materials



Acrylamide (97%), *N*,*N*-methylenebisacrylamide (≥98%), *N*,*N*,*N*,*N*-tetramethylethylenediamine (≥99%) (TEMED), and ammonium persulfate (≥98%) (APS) were used for synthesizing polyacrylamide gels with different compositional percentages (10%–40% PAAM/Water (*w*/*w*)).[20] All precursors were purchased from Sigma-Aldrich and used as received without any further purification. The laser-grade RB dye (Table 1) was procured from Exciton and used without further purification. Deionized water was used for all the dilutions and the polymerization reactions, as well as for the swelling and spectroscopic studies. Polyacrylamide gels were synthesized by the standard free radical copolymerization method.[26,27] The PAAM gels (with different compositions) were synthesized in cubic cells ($2 \times 2 \times 0.5$ cm^3) and, subsequent to polymerization, the prepared gels were taken out and used. The dye-loaded hydrogels were prepared by soaking the hydrogel hosts in aqueous solutions of RB dye with known concentrations for various durations of time (1 min to 10 h).

Absorption and emission spectroscopy

A double-beam Shimadzu UV-2450 Scan UV–vis spectrophotometer was used for recording the absorption spectra over a wavelength range of 300 to 800 nm, which was combined with a cell temperature controller. Emission spectra of the dye were studied with a JASCOFP-6200.

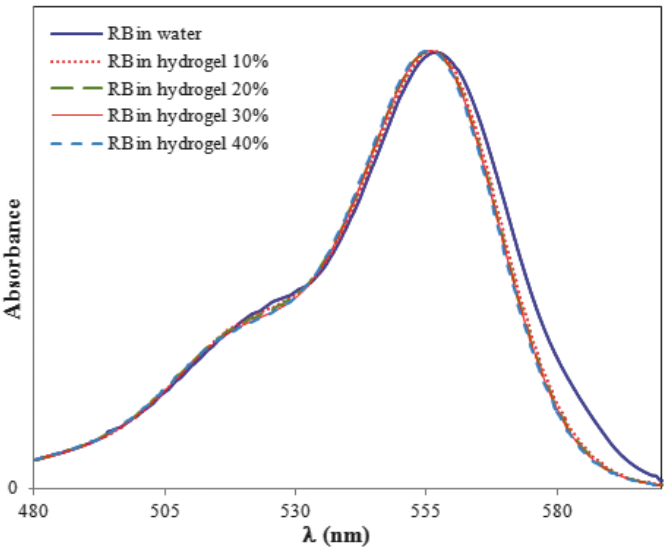
Results and discussion

Absorption spectra of rhodamine B in the hydrophilic gel matrix



RB is a cationic dye and typically possesses doublet bands, i.e., a maximum (λ_{max}) and a shoulder ($\lambda_{shoulder}$).[12] The host nature can strongly influence the position and relative intensity of the doublet absorption bands. The shape variation of the dye optical spectrum might be controlled by distinct phenomena such as solvent–solute and solute–solute (ion pairing and dye aggregation) interactions.[28]

The visible spectra of the dye-loaded hydrogels were recorded at 22 °C. The aqueous solutions of the dye were prepared in a concentration range between 2×10^{-6} and 2×10^{-4} mol/L and the PAAM compositional percentage ranged from 10% to 40% *w*/*w*.

Absorption spectra of aqueous solutions of RB (5×10^{-5} mol/L) and hydrogel hosts (PAAM/water 10%–40% *w*/*w*) were investigated and are compared in Fig. 3. As can be seen from Fig. 3, the monomer absorption wavelengths of RB in aqueous solution is red-shifted as compared with those with different compositions of PAAM in hydrogels. The low absorption shifts of RB in different media means the dye senses same polarity in these media. Furthermore, the amount of the spectral shift for the higher compositional percentages of PAAM (30% and 40% *w*/*w*) as compared with the lower compositional percentages of PAAM (10% and 20% *w*/*w*) demonstrates the relationship between the size of pores in PAAM and the strength of dye–hydrogel interactions. In other words, the network structure and pore size play a key role in the diffusional behavior in hydrogels. The synthesized hydrogel showed a smaller pore size with an increase in concentration of the cross linker. The polymer chains of a higher compositional percentage of PAAM hydrogels are densely packed and provide strictly limited solute transport via the diffusion through free volumes. Therefore, RB dye molecules in the small pores of the hydrogel mostly interacted with active groups of the PAAM chains.

By increasing pore size, with lower compositional percentages of polyacrylamide, diffusion and transportation of RB occurs owing to a combination of molecular diffusion and convection in the water-filled pores. Finally, RB dye interacts with hydrogel water-filled pores in the same manner as the aqueous solution.

Fig. 3. Normalized visible absorption spectra of rhodamine B (RB, 5×10^{-5} mol/L) in aqueous solution and different percentages of polyacrylamide in hydrogels.

Determination of the dimer association constant of RB in hydrophilic gel matrix

Absorption UV–vis spectroscopy is one of the most suitable methods for the quantitative study of dye aggregation as a function of concentration, since, in the concentration range used (10^{-3}–10^{-6} mol/L), mainly monomer–dimer equilibrium can be detected.[19,29]

$$[1] \qquad 2[\mathrm{M}] \underset{K_{\mathrm{dissociation}}}{\overset{K_{\mathrm{association}}}{\rightleftharpoons}} [\mathrm{D}]$$

where [M] and [D] are the monomer and dimer concentrations, respectively. Therefore, the dimer formation equilibrium constant (K) can be calculated.

$$[2] \qquad K = \frac{[\mathrm{D}]}{[\mathrm{M}]^2}$$

At the point, one should consider two more equations based on mass balance and total absorption ($\mathrm{Abs}_{\mathrm{total}}$) in all samples.

$$[3] \qquad \text{Total analytical concentration} \equiv [\mathrm{C}] = [\mathrm{M}] + 2[\mathrm{D}]$$

$$[4] \qquad \begin{aligned} \mathrm{Abs}_{\mathrm{total}}(\lambda) &= \mathrm{Abs}_{\mathrm{monomer}}(\lambda) + \mathrm{Abs}_{\mathrm{dimer}}(\lambda) \\ &= \varepsilon_{\mathrm{m}}(\lambda)[\mathrm{M}]l + \varepsilon_{\mathrm{d}}(\lambda)[\mathrm{D}]l \end{aligned}$$

where $\varepsilon_{\mathrm{m}}(\lambda)$ and $\varepsilon_{\mathrm{d}}(\lambda)$ correspond to the molar absorption coefficients of the monomer and dimer at a given wavelength, respectively, and l is the optical path length. This equilibrium exists even in extremely dilute solutions and, consequently, the pure molar absorption coefficient of the monomer and dimer species at a particular wavelength and their concentrations, as well as the equilibrium constant, cannot be evaluated directly.

Fundamentally, three major routes including linear and nonlinear least-squares fitting and decomposition of the absorption spectra matrix into a product of target and projection matrices[30] have been used for evaluation of these unidentified parameters. In this paper we have used linear least-squares

Can. J. Chem. Downloaded from www.nrcresearchpress.com by UNIVERSITAT DE VALENCIA on 10/20/12
For personal use only.

fitting methods. In this method, dividing eq. [4] by [C]l and defining α as the fraction of dyes present as monomers gives

$$[5] \qquad \alpha = \frac{[M]}{[C]}$$

Combining this with eq. [2] gives

$$[6] \qquad K = \frac{(1-\alpha)[C]}{2\alpha^2[C]^2}$$

$$[7] \qquad \varepsilon_{total}(\lambda) = \varepsilon_m(\lambda)\alpha + \varepsilon_d(\lambda)\left(\frac{1-\alpha}{2}\right) = \left[\varepsilon_m(\lambda) - \frac{\varepsilon_d(\lambda)}{2}\right]\alpha + \frac{\varepsilon_d(\lambda)}{2}$$

Assuming that $\varepsilon_m(\lambda)$ and $\varepsilon_d(\lambda)$ are independent of concentration, variation of $\varepsilon_{total}(\lambda)$ vs α should yield a straight line with intercepts at $\varepsilon_m(\lambda)$ for $\alpha = 1$ and $\varepsilon_d(\lambda)/2$ for $\alpha = 0$ (Supplementary data). By systematic variation of K_d and analyzing the straight-line fitness in a series of wavelengths, one obtains the optimum dimerization constant as well as monomer and dimer spectra.[29]

The calculated dimerization constants for RB in water and in hydrogels with various percentages of constituents at different soaking times were obtained and are presented in Tables 2–5. These data show that dimerization constants for RB in different media and throughout different soaking times are different. In all hydrogels with various percentages of constituents, the dimeric constants are low at initial soaking times and increase with longer soaking times. In addition, the dimerization constants in hydrogels with a lower percentage of PAAM during the final soaking time show the approximate value of the dimerization constant in water. Furthermore, by increasing the percentage of PAAM in the hydrogel structure during the final soaking times, the dimerization constants decrease. These facts can be explained in terms of hydrogel firmness. In other words, in hydrogels with the higher percentage of polyacrylamidePAAM, pores sizes and the amount of free-water molecules in the polymer matrix decrease. It increases the quantity of freezing-water molecules in the pores of hydrogel and, therefore, increases strict hindrance and decreases the values of the dimeric association constants.

Aggregation of RB dye in hydrophilic gel matrix

Absorption spectra of aggregated dye molecules usually show large differences when compared with the individual molecules. By using Kasha exciton theory in its developed form the angle between the transition dipoles of chromophores can be obtained according to the following relationship[19]

$$[8] \qquad \alpha = 2\arctan\sqrt{\frac{\nu_H f_J}{\nu_J f_H}}$$

where ν is the position (in cm^{-1}) and f_i is the oscillator strength of the corresponding transition. The oscillator strengths (f_i) of the monomer and the dimer species were calculated using

$$[9] \qquad f_i = 4.32 \times 10^{-9} \int \varepsilon(\overline{\nu})\mathrm{d}\overline{\nu}$$

where ε is the value of the molar extinction coefficient and $\overline{\nu}$ is the position of the band in wavenumber. The term $\int \varepsilon_\nu \mathrm{d}\nu$ is the experimental value of the corresponding absorption integral. After subtracting the monomer absorption from the total visible spectrum, two Gaussian shaped bands for different forms of the dimeric species were obtained. The characteristics of these bands were used for calculation of the oscillator strengths and the angle between the transition dipoles of the chromophores.

The distance (R in Å) between the monomers in the dimer structure can be found by the following expression:[19]

$$[10] \qquad R = \sqrt[3]{\frac{2.14 \times 10^{10} \cos\alpha f_M}{\nu_M \Delta\nu}}, \qquad \Delta\nu = \nu_H - \nu_J$$

where f_M denotes the oscillator strength of the monomer transition. The difference in energy of the split levels depends on the interaction energy (U) between the dye molecules in the dimer species. The intermonomeric U of the dimer structure can be calculated by using the following relationship:[31]

$$[11] \qquad U = \frac{\nu_H - \nu_J}{2}$$

Moreover, the transition dipole (μ_i) of the monomeric, J- and H-bands (μ_i) can be obtained using the experimental value of the absorption integral according to the following equation

$$[12] \qquad |\mu_i|^2 = \left(\frac{3he^2 f_i}{8\pi^2 m_e \nu}\right)$$

where m_e and e are the mass and charge on the electron, respectively, h is Planck's constant, ν is the frequency at the corresponding band.

The spectral data and the excitonic parameters of the RB dye in aqueous solution and hydrogels (with the different compositional percentage of PAAM) were investigated and compared (Tables 2–5). The spectral properties and aggregation formation of the RB in the hydrogel host are dependent on soaking time. Although the water amount in the hydrogel structure is larger than the water amount in the polymer, the RB in aqueous solution and in the hydrogel matrix showed dissimilar behaviors.

RB in aqueous solution clearly shows H-aggregation and, in the final soaking time of hydrogel with different compositional percentages of PAAM, different values of excitonic parameters were obtained. In other words, the intermonomeric interaction energy of RB in aqueous solution is higher than in hydrogel media. In addition, the distance between the monomers that form the dimer and the α angle in aqueous solution are lower than in all percentages of hydrogel at final soaking time.

The excitonic parameters of RB in different percentages of hydrogels (Tables 2–5) show H-aggregate forms for all soaking times. In addition, an increase in soaking time increases the transition dipole of H-aggregation and the distance between the monomers and also decreases the intermonomeric interaction energy. Moreover, as the compositional percentage of the PAAM in the hydrogel increases, the change rate of aggregative parameters is reduced.

In the case of RB-loaded hydrogel, the degree of aggregation is clearly prevented by the swelling properties of the hydrogel host (K_d). It should be noted that, when hydrogels come in contact with water or an aqueous solution, the solution diffuses into the hydrogel and the hydrogel swells. The water in a hydrogel network exists in a continuum state between two extremes. The bound or freezing water is strongly associated with the hydrogel network through hydrogen bonds, whereas the free or nonfreezing water has a much greater mobility and is unaffected mainly by the hydrogel environment.[21] The free water molecules present in the relatively large pores of the hydrogel may be replaced by the guest dye molecules, whereas the bound water is strongly attached to the gel matrix and is not easily replaceable by the guest molecules. Moreover, the RB is more hydrophilic in nature and its interactions with free water and freezing-water regions in the hydrophilic gel are dissimilar. However, monitoring the time evolution of the replacement of the guest molecules confirms the presence of an equilibrium state between guest molecules preserved into both regions, i.e., if enough time is provided, because of the tendencies of the hydrogel functional groups, some of the guest molecules dissolved in the free water regions can diffuse into the bound water regions and interact with the hydrogel matrix.[20,21]

The obtained excitonic parameters suggest that, in the initial soaking time, the RB molecules interact with the free water of the hydrogel pores. By increasing this time, the RB molecules interact with the active functional groups of the hydrogel in the polymeric chain and freezing water molecules in the hydrogel pores. Furthermore, strict hindrance between hydrogel pores and the associated form of RB, as the soaking time increases, decreases the mobility, aggregation, and intermonomeric interaction energy of the dye molecules. Furthermore, increasing the compositional percentage of PAAM hydrogel (increasing the active sites in the polymer chains), increases the steric privation effect of the dye molecules (decreasing mobility) and, consequently, the aggregation parameters of RB in these media will vary largely as compared towith those in the hydrogels with lower compositional percentages of PAAM hydrogel.

Tables 2–5 demonstrate that the α and U values of dissolved RB in hydrogel hosts are dissimilar. It may be due to an existing dissimilar amount of active polymer sites, freezing water, and free water in various percentages of PAAM hydrogel. The values of U in all hydrogel media decrease with increasing percentages of PAAM. However, a decrease in U between the dye molecules of the dimer species confirms that the steric privation effect increases for the higher compositional percentages of the hydrogel. This confirms an increase in the distance between the monomers in the aggregate form of the dye.

Figure 4 shows the emission spectra of RB in different percentages of PAAM hydrogel and aqueous solution media. We used low concentrations of RB ($C = 2 \times 10^{-5}$ mol/L) for all percentages of PAAM with monomer excitation wavelengths and the standard method for detection of the fluorescence intensity for all the samples.We used these variations as a confirmation of microenvironment viscosity variation. This means that the dye acts as a viscosity sensitive probe in which its quantum yield increases as a result of microenvironment viscosity enhancement. In other words, by increasing the polymeric gel viscosity, RB molecules are protected from quenching and lead to fluorescence of a higher intensity.

Fig. 4. Emission spectra of rhodamine B (RB, 5×10^{-5} mol/L) in different compositional percentages of polyacrylamide with a monomer excitation wavelength.

This supports the decision that increasing the percentage of PAAM in the hydrogel matrix decreases the amount of free water in the hydrogel media and then decreases the ability of the media to solubilize the RB in dimer form and favors solubilization of RB into the hydrogel polymeric matrix in its monomeric form. Subsequently, an increase in the intensity of fluorescence can be observed.

Conclusions

Hydrogels with three-dimensional networks and randomly cross-linked polymeric chains contain active sites for interaction with guest molecules and contain structural water (freezing and free water). Freezing water molecules are strongly associated with the hydrogel network through hydrogen bonds, and free water molecules have a much greater mobility and are less influenced by the hydrogel environment. RB interactions with hydrogel active sites and freezing or free water molecules in polymer environments show different interactions as compared with the dye in aqueous solutions.

The dimerization constants of RB in low percentages of the hydrogel at the final soaking time show the approximate value of the dimeric constant of water. Moreover, as the compositional percentage of the hydrogel increases, the dimeric constants at the final soaking times show smaller values as compared witih those in hydrogels with lower percentages. Therefore, the degree of aggregation is clearly prevented by the pore size and swelling properties of the hydrogel host. The same behaviors were shown in the aggregation parameters. The angle between transition dipoles of aggregate molecules (α) and the transition dipole amount of the H-dimeric bands increase with an increase in soaking time. Furthermore, the values of U in all hydrogel media decrease with increasing percentages of PAAM and soaking times. In other words, a decrease in U between the dye molecules of dimer species confirms that the steric privation effect increases with increasing compositional percentages of hydrogel and the hydrogel swells (increases soaking time). By increasing soaking time and the compositional percentage of the hydrogel, the

steric privations in the hydrogel media increase the distance between the monomers in the aggregate form of the dye.

The obtained results confirm that, at shorter soaking times, RB molecules interact with free water in thr hydrogel pores. By increasing soaking time, RB interacts with the hydrogel interactive functional groups in the polymeric chain and freezing water molecules in the hydrogel pores.

Diphenylphosphinoethane-functionalized polystyrene resin-supported Pd(0) complex — A highly active and recyclable catalyst for the Stille reaction under aerobic conditions

Siavash Bahari, Babak Mohammadi-Aghdam, Rahim Molaei, and Zakiyeh Gharibi

Abstract: The polymer-supported palladium(II) diphenylphosphinoethane complex is a highly active catalyst that could be used for the Stille coupling reaction between aryl iodides and (or) chlorides and organostannanes at room temperature under aerobic conditions. This heterogeneous palladium catalyst is efficient, air-stable, and recyclable.

Key words: Stille coupling, supported palladium catalyst, aryl iodides, aryl chlorides, heterogeneous catalyst.

Résumé : Le complexe de diphényphoslphinoéthane palladium(II) déposé sur un polymère est un catalyseur très actif qui pourrait être utilisé pour la réaction de couplage de Stille entre des iodures ou chlorures d'aryles et des organostannanes, à la température ambiante, dans des conditions aérobiques. Ce catalyseur hétérogène du palladium est efficace, stable à l'air et il peut être recycler.

Mots-clés : couplage de Stille, catalyseur de palladium déposé sur un polymère, iodures d'aryles, chlorures d'aryles, catalyseur hétérogène.

Introduction

The Stille cross-coupling reaction of organohalides with organotin compounds has been proven to be a useful synthetic method for carbon–carbon bond formation in organic synthesis. Consequently, many effective palladium catalytic systems have been developed for the Stille cross-coupling reaction.[1–5] The yields of coupled products are often high, and the organotin reagents can be readily synthesized, purified, and stored. However, the reaction generally proceeds in the presence of a homogeneous palladium catalyst such as $Pd(PPh_3)_4$, $PdCl_2(PPh_3)_2$, or $PdCl_2(MeCN)_2$, which makes the recovery of the metal tedious if not impossible and might result in unacceptable palladium contamination of the product. The forcing conditions are typically at reflux in tetrahydrofuran (THF) or dioxane and the requirement for dry, oxygen-free environments is also a limitation of the Stille reaction. From the standpoint of green chemistry, the development of more environmentally benign conditions for the reaction, for example, the use of a heterogeneous palladium catalyst, would be desirable.[6]

In recent years there has been a tremendous upsurge of interest in various chemical transformations performed under heterogeneous catalysis.[7] Moreover, using inexpensive and noncorrosive heterogeneous catalysts, chemical transformations occur with better efficiency, higher purity of the products, and easier workup, with evident economic and ecological advantages, especially for industrial processes.

The use of heterogeneous catalysts for Stille coupling reactions leads to a reduction in waste. Polymer-supported transition-metal complexes having high activity have attracted significant interest because they can be easily recovered and reused.[6a] Although different methods are available for the Stille reaction, there is still a dearth of efficient processes for this reaction using polymer-supported palladium catalysts. Thus, the study of types of polymer-supported palladium catalysts that might be suitable for the Stille reaction has practical significance.

Resins are one class of polymeric supports originating from organic precursors that are widely employed as catalyst carriers and also in solid-phase organic synthesis. Resin-supported palladium complexes having high activity and selectivity are currently attracting a great interest because of their easy separation and recovery.[6b]

Polymer-supported palladium complex catalysts derived from chloromethyl polystyrene resin have been employed in both the Heck,[8] Suzuki,[9] and Sonogashira[10] reactions, and have shown lower leaching of palladium during cross-coupling. However, to the best of our knowledge, Stille reactions catalyzed by polymer-supported palladium complexes have received less attention.[11] Unfortunately, they have lower

catalytic activity compared with their soluble counterparts in Stille reactions. In addition, the activity of the recycled catalysts gradually decreases because the palladium species leaches from the supporting polymer or silica gel. To overcome these limitations, a novel methodology for creating insoluble and highly active catalysts is needed. This encouraged us to investigate the diphenylphosphinoethane-functionalized polystyrene resin-supported Pd(0) complex,[10] PS-dpp-Pd(0), for the Stille reaction (Scheme 1). Our approach was guided by three imperatives: (*i*) the polymeric reagent should be easily accessible, (*ii*) start from readily available and cheap reagents, and (*iii*) the polymeric ligand should be air-stable, which should allow its storage in normal bottles with unlimited shelf life.

Kamali and co-workers[12] have already reported the use of an ethylenediamine-functionalized polystyrene resin-supported Pd(II) complex as an active and reusable catalyst in Sonogashira reactions.[13] Herein, we develop a mild protocol for the Stille coupling of aryl iodides and aryl chlorides with organostannanes under aerobic conditions with PS-dpp-Pd(0) as catalyst (Scheme 2).

Results and discussion

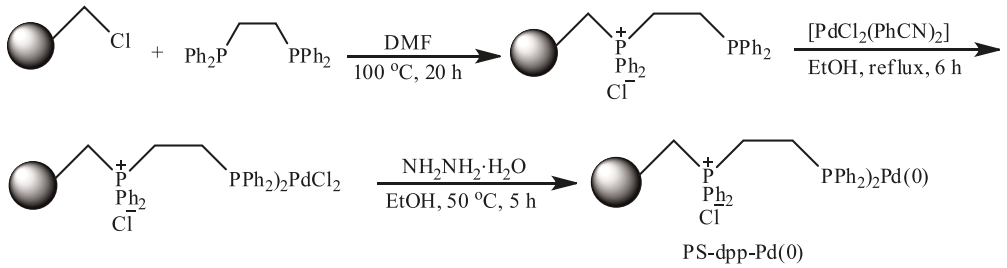
PS-dpp-Pd(0) was prepared according to the literature.[10]

We used known chloromethylated polystyrene cross-linked with 2% divinylbenzene as the support, as it allows grafting of metallic atoms via ligands, which are attached to the polymer beads. Reaction of polystyrene resin with diphenylphosphinoethane in dimethylformamide (DMF) at 100 °C, and then treatment of the phosphinated polystyrene with a solution of $[PdCl_2(PhCN)_2]$ in ethanol, and finally reduction with hydrazine monohydrate resulted in covalent attachment of the palladium complex to give the polymer-supported palladium(0) complex catalyst (Scheme 1).[10] This catalyst is safe, easy to handle, air-stable, and environmentally benign with fewer disposal problems.

Successful functionalization of the polymer was confirmed by elemental analysis. The P content of the resin was found to be 4.25% by inductively coupled plasma (ICP), which indicates that the resin had reacted with diphenylphosphinoethane. The metal loading of the polymer-supported palladium complex, determined by neutron activation analysis (NAA), was 5.42% (0.51 mmol/g).[10]

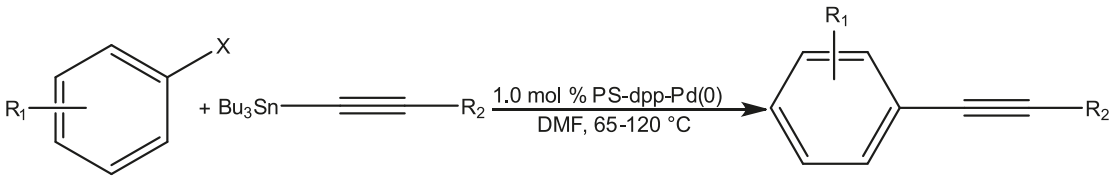
First, we optimized the amount of PS-dpp-Pd(0) catalyst required in the reaction between iodobenzene and 1-(tributylstannyl)-2-phenylethyne (Table 1). For optimization of the reaction conditions, we chose the reaction of 1-(tributylstannyl)-2-phenylethyne with iodobenzene as the model reaction, and the effects of the solvents, temperature, and catalyst were examined. Several solvents were screened for the reaction in the presence of a catalytic amount of PS-dpp-Pd(0). As shown in Table 1, the reaction was influenced significantly by the solvent employed. The reaction worked very well when organic solvents such as DMF and *N*-methylpyrrolidone (NMP) were used (Table 1, entries 4 and 7), with the best result obtained in the case of DMF (Table 1, entry 7). THF, PhH, and CH_3CN were not suitable solvents for this reaction. The optimum amount of PS-dpp-Pd(0) was found to be 2.0 mol % in the presence of iodobenzene (1 mmol) and 1-(tributylstannyl)-2-phenylethyne (1.2 mmol) in DMF (3 mL) at 65 °C under aerobic conditions. Increasing the amount of the palladium catalyst shortened the reaction time but did not increase the yield (Table 1, entry 10). A low palladium concentration prolonged the reaction time and led to a decreased yield (Table 1, entry 9).

To examine the scope of this coupling reaction, a variety of alkynylstannanes were coupled with various aryl iodides and aryl chlorides containing electron-withdrawing or electron-donating groups (Scheme 2). As shown in Table 2, the Stille coupling reactions proceeded smoothly under very mild conditions giving the corresponding products in excellent yields.



The optimized catalyst system was quite general and compatible with a wide range of functional groups, such as nitro, methoxy, carbonyl, and silyl, on either partner. We attempted to carry out the coupling reactions of heteroaryl iodides such as 3-iodopyridine with alkynylstannanes under the same reaction conditions, but this was unsuccessful; no desired coupled product was detected after 30 h of reaction time.

The developed methodology was also applicable for Stille coupling reactions of vinylstannanes with aryl iodides. The Stille coupling of aryl iodides with a variety of vinylstannanes was investigated (Scheme 3); the experimental results are summarized in Table 3. Stille coupling reactions of a variety of aryl iodides with (*Z*)- or (*E*)-vinylstannanes proceeded smoothly in the presence of a catalytic amount of PS-dpp-Pd(0) in DMF at 65 °C to afford the corresponding coupled products in high yields with retention of the configuration (Table 3, entries 1–6).



In a typical experiment, after the reaction was completed, PS-dpp-Pd(0) as a catalyst was isolated from the reaction mixture by simple filtration in the workup stage. The catalyst could be recycled by filtering it from the reaction mixture and then washing the solid reagent with water and acetonitrile, followed by drying in an oven. In every experiment, more than 98% of the PS-dpp-Pd(0) was easily recovered from the reaction mixture. Catalytic activity of the recovered catalyst was tested and showed the same activity as the PS-dpp-Pd(0) used for the first time. The nature of the recovered catalyst was traced by infrared (IR) spectroscopy. The results indicated that the catalyst showed no loss of activity as there was no change in its IR spectrum after being reused five times (Table 2, entry 1). The reusability of the catalyst is one of the most important benefits and makes it useful for commercial applications. The high catalytic activity, excellent reusability, and easy accessibility of PS-dpp-Pd(0) makes it a highly attractive supported palladium catalyst for the parallel solution-phase synthesis of diverse libraries of compounds.

In conclusion, we have developed PS-dpp-Pd(0) as a reusable catalyst for the heterogeneous Stille coupling reaction of alkynylstannane with aryl iodides and aryl chlorides under aerobic conditions. The advantages of our heterogeneous catalytic system over others are as follows: (*i*) the catalyst could be conveniently prepared from commercially available reagents; (*ii*) high yields, mild reaction conditions, and a simple workup procedure; and (*iii*) excellent performance and reusability of the catalyst. PS-dpp-Pd(0) as a catalyst is important from an environmental point of view and from the viewpoint of economic considerations because it produces little waste.

[a]Isolated yield.

Experimental

All reagents were purchased from Merck and Sigma-Aldrich and used without further purification. ^{1}H NMR spectra were recorded on Bruker Avance DRX 300 and 400 MHz instruments, using tetramethylsilane (TMS) as the internal standard. IR spectra were recorded on a Shimadzu 470 spectrophotometer. Melting points were taken in open capillary tubes with a Buchi 510 melting point apparatus and were uncorrected. Thin-layer chromatography (TLC) was performed on Merck precoated silica gel 60-F254 plates.

Typical procedure for the Stille coupling reaction

Aryl iodide or aryl chloride (1.0 mmol), PS-dpp-Pd(0) (1.0 mol %), and DMF (3 mL) were added to a flask, and the resulting mixture was stirred at room temperature for 15 min under aerobic conditions. To this suspension was added organostannane (1.2 mmol) and the reaction mixture was stirred at 65 °C for an appropriate time (TLC). The mixture was dissolved in Et_2O (30 mL). The PS-dpp-Pd(0) catalyst was separated from the reaction mixture by filtration after each experiment, washed with water and acetonitrile, and dried carefully before use in subsequent runs. The ethereal solution was treated with 20% aqueous KF (10 mL) for 30 min before being dried and concentrated. The solvent was removed under vacuum and the residue was purified by flash chromatography on silica gel using ethyl acetate / hexane as eluent to give the desired product.

The pure products were characterized by IR, ^{1}H NMR, and melting point. All the products are known compounds and the spectral data and melting points were identical to those reported in the literature.[14–27]

1-(1-Hexynyl)-4-methoxybenzene (Table 2, entry 10)

Oil.[25] ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.34 (d, J = 8.8 Hz, 2H), 6.81 (d, J = 8.8 Hz, 2H), 3.82 (s, 3H), 2.91 (t, J = 7.1 Hz, 2H), 1.64–1.45 (m, 4H), 0.97 (t, J = 7.4 Hz, 3H).

Trimethyl(2-phenyl-1-ethynyl)silane (Table 2, entry 11)

Oil.[26] ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.47–7.43 (m, 2H), 7.31–7.28 (m, 3H), 0.24 (m, 9H).

Trimethyl[(4-nitrophenyl)ethynyl]silane (Table 2, entry 12)

Oil.[10] ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 8.16 (d, J = 8.7 Hz, 2H), 7.61 (d, J = 8.7 Hz, 2H), 0.18 (s, 9H).

(E)-1-(3-Methoxyprop-1-enyl)benzene (Table 3, entry 1)

Oil.[16] ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.42–7.20 (m, 5H), 6.62 (d, J = 15.9 Hz, 1H), 6.27–6.30 (m, 1H), 4.04 (d, J = 6.1 Hz, 2H), 3.37 (s, 3H).

(E)-1-Methoxy-4-styrylbenzene (Table 3, entry 2)

mp 135–136 °C (lit.[16] mp 134–135 °C). ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 7.52 (d, J = 7.5 Hz, 2H), 7.47 (d, J = 8.6 Hz, 2H), 7.35 (t, J = 7.5 Hz, 2H), 7.27–7.22 (m, 1H), 7.09 (d, J = 16.7 Hz, 1H), 7.00 (d, J = 16.7 Hz, 1H), 6.92 (d, J = 8.7 Hz, 2H), 3.85 (s, 3H).

(Z)-1-Methyl-4-styrylbenzene (Table 3, entry 3)

Oil.[16] ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 7.30–7.20 (m, 5H), 7.17 (d, J = 8.0 Hz, 2H), 7.06 (d, J = 8.0 Hz, 2H), 6.60 (s, 2H), 2.34 (s, 3H).

(E)-1-(Hex-1-enyl)-4-methoxybenzene (Table 3, entry 4)

Oil.[16] ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 7.25 (d, J = 8.5 Hz, 2H), 6.82 (d, J = 8.5 Hz, 2H), 6.29 (d, J = 15.4 Hz, 1H), 5.93 (dt, J = 15.4, 7.0 Hz, 1H), 3.82 (s, 3H), 2.20–2.15 (m, 2H), 1.45–1.33 (m, 4H), 0.91 (t, J = 7.0 Hz, 3H).

(Z)-1-Nitro-4-styrylbenzene (Table 3, entry 5)

mp 60–62 °C (lit.[16] mp 60.5–61.5 °C). ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 8.10 (d, J = 8.7 Hz, 2H), 7.40 (d, J = 8.7 Hz, 2H), 7.25–7.18 (m, 5H), 6.80 (d, J = 12.5 Hz, 1H), 6.60 (d, J = 12.5 Hz, 1H).

(Z)-1-(Hex-1-enyl)-4-nitrobenzene (Table 3, entry 6)

Oil.[16] ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 8.20 (d, J = 8.6 Hz, 2H), 7.40 (d, J = 8.6 Hz, 2H), 6.44 (d, J = 11.5 Hz, 1H), 5.84 (dt, J = 11.5, 7.0 Hz, 1H), 2.35–2.30 (m, 2H), 1.49–1.43 (m, 2H), 1.39–1.33 (m, 2H), 0.89 (t, J = 7.0 Hz, 3H).

MINIREVIEW / MINISYNTHÈSE

Three different mechanisms for azo-ether hydrolyses in aqueous acid[1]

Robin A. Cox and Erwin Buncel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

Abstract: It has been shown recently that most ethers hydrolyze in aqueous acid media not by the traditional A1 or A2 process, but by a mechanism involving rate-determining proton transfer to the substrate, concerted with C–O bond cleavage. The reactions of azoethers are more complicated, because the azo group can be protonated in the acid reaction medium as well. This protonation has to be accounted for in the kinetic analysis. Often it simply ties up the substrate in an unreactive form; the hydrolysis reaction slows down as a result of the azo-protonated compound not being the reactant in the hydrolysis. However, there are other possibilities. If the ether group is suitably located in the substrate the azo-protonated compound can react with three water molecules (a "water wire") in a fast reaction, and the alkoxy group is lost as a result. Depending on the acidity, in this mechanism either the initial three-water attack, or the breakup of the resulting intermediate, can be rate-determining, and both of these were observed. A third possibility is that ring protonation of suitable substrates can occur, giving delocalized carbocations that can form a hydrolysis product in subsequent fast reactions. Thus, three different hydrolysis mechanisms for azoethers in acidic media can be observed. Six azoethers were studied, one of which contained two methoxy groups. Both of these hydrolyzed, but by different mechanisms.

Key words: azo compounds, ethers, hydrolysis, excess acidity, mechanism, acid media.

Résumé : Il a été démontré récemment que l'hydrolyse de la plupart des éthers dans des milieux aqueux ne se fait pas par le processus traditionnel A1 ou A2, mais que l'étape qui détermine la vitesse implique plutôt le transfert d'un proton vers le substrat, en concertation avec le clivage de la liaison C–O. Les réactions des azoéthers sont plus compliquées parce que le groupe azo peut aussi être protoné dans le milieu réactionnel acide. Il faut expliquer cette protonation dans l'analyse cinétique. Il arrive souvent qu'elle ne donne lieu qu'à une simple liaison avec le substrat sous une forme qui n'est pas réactive; il en résulte que la réaction d'hydrolyse s'en trouve ralentie en raison du fait que le composé azo protoné ne donne pas lieu à une hydrolyse. Toutefois, il existe d'autres possibilités. Si le groupe éther est bien situé dans le substrat, le composé azo protoné peut alors réagir avec trois molécules d'eau (une chaîne d'eau) dans une réaction rapide et il en résulte que le groupe alkoxy est ainsi perdu. Dans ce mécanisme, suivant l'acidité du milieu, l'étape déterminante de la vitesse de la réaction peut aussi bien être l'attaque initiale par trois molécules d'eau ou une rupture de l'intermédiaire qui en résulte et les deux cas ont pu être observés. Il existe une troisième possibilité, une protonation du cycle de substrats adéquats peut se produire conduisant à des carbocations délocalisés qui peuvent donner lieu à la formation d'un produit d'hydrolyse dans des réactions rapides subséquentes. Il est donc possible d'observer trois mécanismes différents d'hydrolyse pour les azoéthers en milieu acide. On a étudié six azoéthers, dont un qui contenait deux groupes méthoxy. Ces deux groupes ont été hydrolysés, mais par des mécanismes différents.

Mots-clés : composés azo, éthers, hydrolyse, acidité en excès, mécanisme, milieu acide.

[Traduit par la Rédaction]

In recent papers it has been shown that many ethers hydrolyze, not by a traditional A1 or A2 process, but in a concerted fashion as shown in Scheme 1.[3–5] (In Scheme 1 and subsequently, "aq" is meant to indicate the medium acting as a source or a sink for protons or water molecules; aq does not appear in the kinetic analysis.)[3–5] If the substrate is capable of forming a carbocation which has a long enough lifetime in the medium, it will do so, and the carbocation will then react with water (or presumably with another nucleophile if present), or rearrange and then react, and so on;[3] if the substrate cannot form a stable carbocation, reaction with a nucleophile in the medium (usually water) is concerted

Scheme 1.

with the proton transfer, as shown in Scheme 1 for diethyl ether.[3–5]

The principle at work here was first enunciated by Jencks,[6] as an "enforced mechanism". If an intermediate does not have a long enough lifetime in the reaction medium (i.e., exist there for at least a couple of molecular vibrations, having, say, a lifetime of greater than about 10^{-13} s),[5] it cannot be involved in the reaction, and a mechanism without it is "enforced".[6] Oxygen-protonated intermediates in which the positive charge is localized on the oxygen and cannot be dispersed (usually by resonance) do not have long enough lifetimes to be reaction intermediates.[3–6] Nor do primary and most secondary carbocations.[5] Some carbonyl-protonated species, and some acylium ions, are unlikely to have long enough lifetimes to be reaction intermediates in dilute acid either.[5]

Specific protonated water species, such as H_3O^+, do not exist as such in water. If they had lifetimes long enough to be reaction intermediates they would have detectable IR or Raman spectra, but they do not; this has been discussed in some detail in recent reviews.[4,5] Thus, usually individual protonated water species are not involved in ether hydrolysis in aqueous acid media; the proton source is written as "H^+_{aq}".[3–5]

We have been interested in aromatic azo and azoxy compounds for over 50 years now;[7] most recently, we have looked at azoxypyridine rearrangements.[2] A number of these compounds have been aromatic azoethers,[7–11] and this paper concerns the several different hydrolysis mechanisms that we have found for these. The structures of the compounds dealt with here (**1**–**7**) are given in Scheme 2. (Compound **6** is formed as a result of the first hydrolysis of **5**.)[11] All of the azoethers **1**–**7** protonate on the azo group in relatively dilute acid; some contain a pyridine nitrogen that protonates in the pH region,[9,11] and so the substrates **3**–**6** in Scheme 2 are assumed to be already protonated there. The pK_{SH^+} values for the azo groups must be known before the kinetics can be analyzed. These and the related m^* values are listed in Table 1.

The values for **3**–**7**, determined using the excess acidity technique, are already in the literature;[10,11] no errors were given for **7**.[10] Those for **1** and **2**, which had not been determined that way, were found using eq. [1],[12] substituting eq. [2] into it, and, using the listed UV absorbance difference values (ΔA) as a function of acid concentration,[7] curve-fitting the result.[13]

$$[1] \qquad \log I - \log C_{H^+_{aq}} = m^* X + pK_{SH^+}$$

$$[2] \qquad I = C_{SH^+}/C_S = \frac{\Delta A - \Delta A_S}{\Delta A_{SH^+} - \Delta A} = \text{antilog}\,(m^* X + pK_{SH^+} + \log C_{H^+_{aq}})$$

Scheme 2.

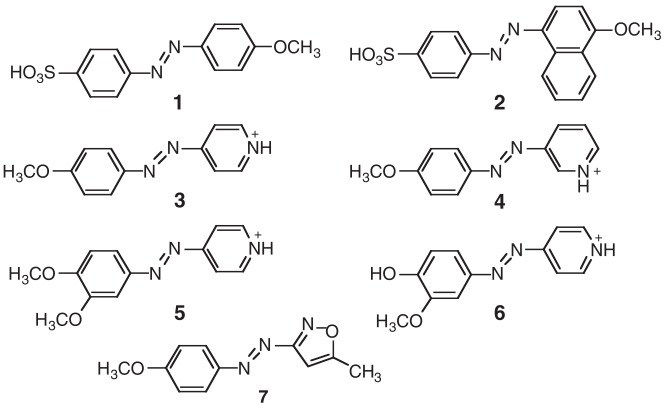

Table 1. Values of pK_{SH^+} and m^* for **1**–**7**.

Note: All compounds were measured at 25 °C in aqueous H_2SO_4 except for **2**, which was measured in aqueous HCl.

In these equations I is the ionization ratio defined in eq. [2], C is molar concentration, S and SH^+ are the substrate and the protonated substrate, respectively, and H^+_{aq} is the solvated proton; its concentration is basically the acid molarity for aqueous HCl and $HClO_4$. Values of these quantities, and of the excess acidity X, were obtained from the literature.[14] The pK_{SH^+} and m^* values obtained are given in Table 1. The slope parameter m^* essentially describes the type of substrate concerned, values being 1.0 for primary amines, 1.3 for tertiary amines, 0.8 for amides, and so on.[12] The pK_{SH^+} values determined at the time, –1.45 for **1** and –0.74 for **2**, are really the H_0 values at half-protonation,[7] and these were deemed not to be sufficiently accurate for this work. Both are insufficiently negative as they do not follow H_0 (which would imply an m^* value of 1.0),[12] and the measured values in this work are closer to 1.5 (Table 1).

The reaction rate data obtained for **1**–**7** are also analyzed using the excess acidity method.[14,15] We have found this to be a very useful technique for determining the mechanisms by which azo and azoxy compounds react in acid media,[2,11,16] and many other organic reactions have been studied as well.[3–5,14,17] Summarizing briefly, this method works as follows.[14,15]

$$[3] \qquad k_\psi C_S = k_0 a_S a_{H^+_{aq}}/f_\ddagger = k_0 C_S C_{H^+_{aq}} \frac{f_S f_{H^+_{aq}}}{f_\ddagger}$$

$$[4] \qquad \log \frac{f_S f_{H^+_{aq}}}{f_\ddagger} = m^\ddagger \log \frac{f_{B^*} f_{H^+_{aq}}}{f_{B^*H^+}} = m^\ddagger X$$

$$[5] \qquad \log k_\psi - \log C_{H^+_{aq}} = \log k_0 + m^\ddagger X$$

Fig. 1. Excess acidity plots of the left-hand side of eq. [6] against X, for **1** and **2**. The theoretical lines are drawn using the slope and intercept values given in Table 2.

Since a proton transfer is part of the rate-determining step in these reactions (Scheme 1), S and H^+_{aq} reacting in the slow step in the mechanism usually referred to by the term A-S_E2, the rate equation that applies is eq. [3], C_S canceling out on both sides.[14] Here, k_ψ are the experimentally observed pseudo-first-order rate constants, k_0 is the rate constant in the standard state (essentially infinite dilution in pure water),[14] a is molar activity, and f is the molar activity coefficient. The excess acidity method then makes the assumption of eq. [4], to which, after testing hundreds of examples, no exceptions have yet been found;[14] B* is a standard base. Taking logs of eq. [3], substituting eq. [4], and rearranging gives the excess acidity equation used in this work (eq. [5]).[3]

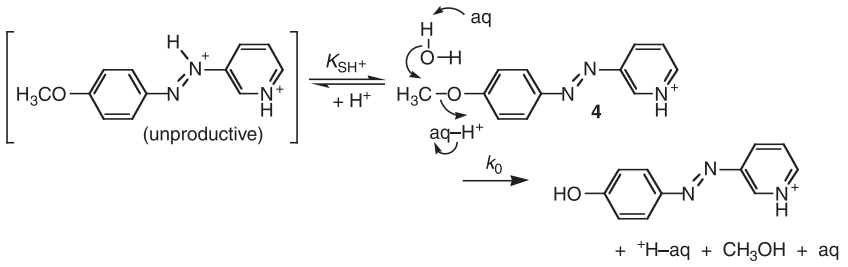
A plot of $\log k_\psi - \log C_{H^+_{aq}}$ against X will be linear if eq. [5] applies to the reaction directly. The slope parameter is given as $m^{\ddagger}$, since it refers to the transition state.[3,4] Examples of this behavior have been found for several ethers, ones capable of forming stable carbocations during hydrolysis under the reaction conditions used.[3] If the eq. [5] plot is not linear, it can be modified to see if any other species is involved in the reaction, along with the substrate and H^+_{aq} (e.g., a water molecule is involved in Scheme 1), by subtracting, for example, the molar water activity a_{H_2O} from the left-hand side. (Updated values of the water activity are listed.[14]) Many examples of this behavior were also found in the ether hydrolysis studies.[3–5]

Here, the azo substrates are also protonated on the azo group in an equilibrium sense, and the degree of protonation is dependent on the medium acidity. This too causes curvature in excess acidity plots, and it can also be accounted for by subtracting a protonation correction term, $\log[C_S/(C_S + C_{SH^+})]$, from the left-hand side of eq. [5].[14]

$$[6] \quad \log k_\psi - \log\frac{C_S}{C_S + C_{SH^+}} - \log C_{H^+_{aq}} - \log a_{H_2O} = \log k_0 + m^{\ddagger}X$$

These modifications produce eq. [6], which, except for the addition of the protonation correction term, is the same rate equation already found to apply to many ethers.[3–5] The protonation correction terms were calculated using eq. [1] and the pK_{SH^+} values given in Table 1. These values, measured at 25 °C, were corrected to the reaction temperature, if this was different, using the assumption that the free energy of protonation is temperature-independent, and the equation $\Delta G^\circ = 2.303\ RT\mathrm{p}K_{SH^+}$, as we have done before.[18] This seems to be a better assumption than assuming that pK_{SH^+} itself is temperature-independent, but there is little evidence either way.[19]

Scheme 3.



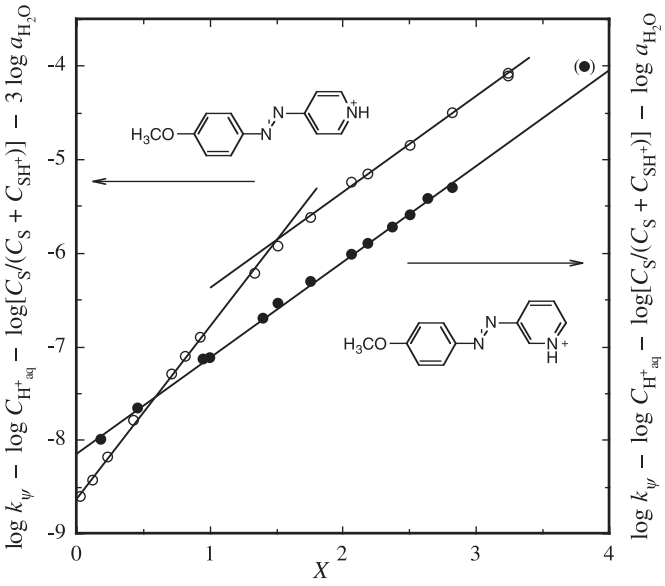


Fig. 2. Excess acidity plots against X, for the hydrolyses of **3** and **4** in aqueous H_2SO_4.

$$[7] \qquad \log k_0 = 10.31883 + \log T - \frac{\Delta G_\Theta^{\ddagger}}{R\Theta \ln 10} + \frac{\Delta H_\Theta^{\ddagger}}{R\Theta \ln 10} \cdot \frac{T - \Theta}{T}$$

If rate constants at only one reaction temperature are available, the quantity $\log k_0$ perforce refers to it. However, if data at several temperatures are available, it can be expanded according to the Clarke and Glew formulation[20] (better in practice than the Eyring equation[21]) as shown in eq. [7]. We find this formulation a more natural one to use, giving numbers with errors that are independent of one another.[20] Here, the absolute reaction temperature is T and Θ is the standard-state temperature of 298.15 K, 25 °C. The gas constant is R (1.98589 cal K^{-1} mol^{-1} here; 1 cal = 4.184 J) and the numerical term contains the Boltzmann and Planck constants required by the theory.[21] The entropy of activation $\Delta S_\Theta^{\ddagger}$ is readily obtained via $\Delta G_\Theta^{\ddagger} = \Delta H_\Theta^{\ddagger} - \Theta \Delta S_\Theta^{\ddagger}$; the subscript Θ means that these values are the standard-state 25 °C values.[20]

All of the rate constant data[7–11] for **1**–**7** were initially analyzed using eq. [6] (and eq. [7], if necessary). A simple linear regression of $\log k_\psi - \log C_{H^+_{aq}} - \log[C_S/(C_S + C_{SH^+})] - \log a_{H_2O}$ vs X was used if data at only one temperature were available; for data at several temperatures, a double linear regression of $\log k_\psi - \log C_{H^+_{aq}} - \log[C_S/(C_S + C_{SH^+})] - \log a_{H_2O} - \log T$ vs X and $(T - \Theta)/T$ was used. The programs used discarded data points that, to 95% confidence, were not part of the same data set as the rest;[22] here, this only happened twice. All of the derived quantities obtained in this work are given in Table 2. The results for **1** and **2** are illustrated in Fig. 1.

As can be seen from Fig. 1, compounds **1** and **2** follow eq. [6] exactly, with intercepts (k_0) that are, within experimental error, the same in both aqueous HCl and aqueous $HClO_4$ media (Table 2). If the protonation correction term is not included, the plots of rate constants against acidity curve downwards,[7,8] which shows that the azo-protonated form is not the reactant; protonation on the azo-group must deactivate the molecule. The slopes are different in the two different acid media, with the hydrolysis reaction being faster in aqueous HCl. This undoubtedly reflects the fact that there is an additional nucleophile present in that medium, chloride ion, which can participate in Scheme 1 too. It would probably be possible to obtain some idea of its catalytic effect by working on the difference between the two acid systems (ClO_4^- not being nucleophilic), but this was not done as the error would be quite high, and the measurement temperatures in the two acids were not quite the same for **1**.[7,8] It is sufficient to see that reaction is in fact faster in aqueous HCl. Amazingly, these are the only ether hydrolyses in the literature in which kinetic measurements in aqueous HCl media are reported.[3] There are none at all reported in aqueous HBr.[3]

Not all of the compounds obeyed eq. [6]. Compounds **1**, **2**, **4**, and **7** did; the excess acidity analyses given here for the Scheme 1 and (or) Scheme 3 mechanism being better than any of the previously reported mechanistic analyses for these compounds.[9,10] Compounds **3** and **5** followed an equation involving three water molecules rather than one (i.e., subtracting three times $\log a_{H_2O}$ rather than one in eq. [6] was required to achieve linearity), and compound **6** did not need the log water activity to be subtracted at all.

Figure 2 gives the excess acidity plots for **3** and **4**. Compound **4** (right-hand axis) also follows eq. [6] exactly; the reaction mechanism for **4** (and **1**, **2**, and **7**) is shown in Scheme 3. However, it is apparent from Fig. 2 that compound **3** follows a different mechanism, as we have found before,[11] one involving three water molecules. This is given here as Scheme 4.[11]

The protonated substrate reacts by adding water at the para position, which is activated by the presence of the positive charge on the azo group. Three water molecules are involved in a five-membered ring; the highly structured aqueous solvent does not need to reorganize first, as the structure is already there.[4] This behavior, involving cycles of two or three water molecules, is quite common;[4] a recent paper refers to this as a "water wire",[23] terminology that may well become more common. We have reported on this before;[11] the data

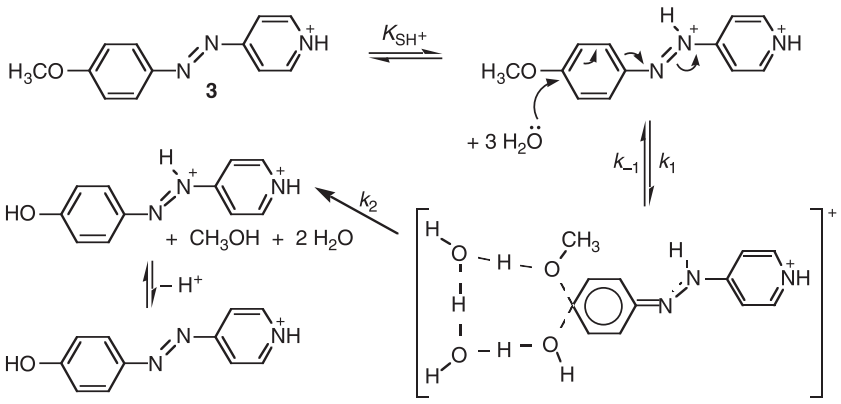
Scheme 4.



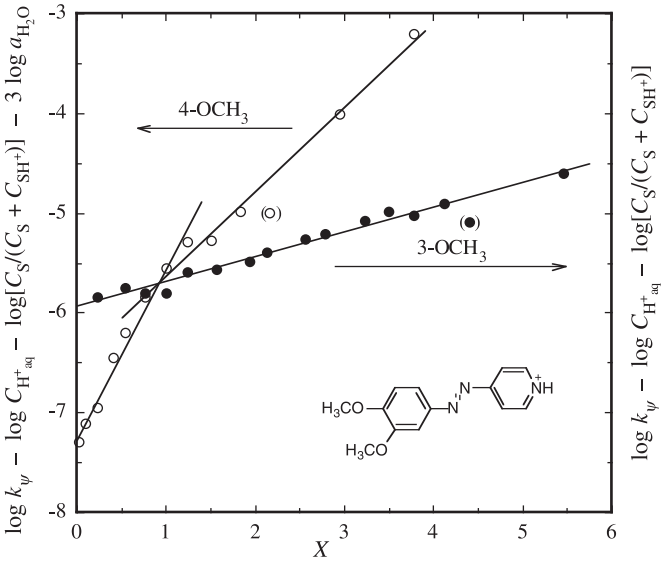


Fig. 3. Excess acidity plots against X for the hydrolyses of **5** (and **6**) in aqueous H_2SO_4.

have been reworked for this paper, as the water activities used previously were not the optimum ones.[14] Using the correct water activities does not change the mechanism at all; only the slope and intercept results, and the activation parameters, are marginally altered. Either k_1 or k_2 can be the rate-determining step, and it is evident from the break in Fig. 2 that both are, at different acidities.

Interestingly, the activation parameters for the k_1 and k_2 processes are not very similar; from the activation parameters in Table 2 one might guess the k_1 process to be the slow step initially, with a more negative entropy of activation, and the k_2 process at the higher ones, where there is less water present. The values given here in Table 1 for **3** and **4** (and **5** and **6**) supercede those given previously.[11]

Looking at compounds **5** (and **6**): as far as the 4-methoxy group is concerned, compound **5** reacts by way of exactly the same mechanism as does compound **3**, giving as a product compound **6**, as we have discussed previously.[11] Both of these reactions are quite fast in the standard state (Table 2), although **5** reacts more quickly than **3**. Presumably the 3-methoxy group in **5** activates the molecule somewhat. Subsequently, the 3-methoxy group in **6** also hydrolyzes, but much more slowly, and by a mechanism that does not involve the water activity. Both hydrolyses are illustrated in Fig. 3.

The mechanism by which the 3-methoxy group is lost involves protonation of one of the aromatic ring carbons as the rate-determining step. This is quite common for aromatic rings with several activating groups in acidic media,[24] and has been observed before for the hydrolysis of the methoxy group of 3,5-dihydroxyanisole.[25] This process has been analyzed,[3] and it was characterized by a shallow $m^{\ddagger}$ slope; the slope observed here (Table 2) is only 0.25. Slow carbon protonations do seem to have shallow $m^{\ddagger}$ slopes associated with them.[22]

The hydrolysis mechanism proposed for **6** is given in Scheme 5.[11] The proton is drawn as attacking the position para to the methoxy group. It is just as likely (perhaps more likely) that the proton attacks at either of the positions ortho to it. Without more experimental evidence (perhaps isotopic substitution studies)[11] it is not possible to say which one is predominantly attacked; in any case, the resulting product will be the same.

Compound **7** hydrolyzes normally, according to Scheme 3. The excess acidity plots at 30 and at 60 °C are given in Fig. 4. As can be seen, the 30 °C plot, covering a range of acidity of 40–80 wt % aqueous H_2SO_4, is accurately linear over an impressive nine orders of magnitude. The 60 °C plot is linear as well, but it is not parallel to the 30 °C one. The reason for this is unclear; this behavior has not been seen before in excess acidity plots, where the same $m^{\ddagger}$ slope usually applies at all temperatures.[14] For instance, the hydrolysis of isopropyl phenyl ether shows five accurately parallel excess acidity plots at 5, 15, 25, 35, and 45 °C.[3] It would be possible to obtain activation parameters in the standard state from the two intercepts, but this was not thought to be a good idea; the values would not be reliable without an understanding of the lack of parallelism.

In more general terms, looking at Table 2 it is apparent that the Scheme 3 process is quite slow, particularly in the case of **1**. Compound **2**, with its naphthyl ring, is more activated and reacts somewhat faster; it is also very easy to protonate on the azo group (Table 1) by comparison with the others. Compound **7** also reacts very slowly in the standard state. In contrast, the three-water-molecule process of Scheme 4 is quite fast. The entropy of activation for compound **4**, reacting via Scheme 3, is much more negative than those of other ethers that react this way, which mostly have

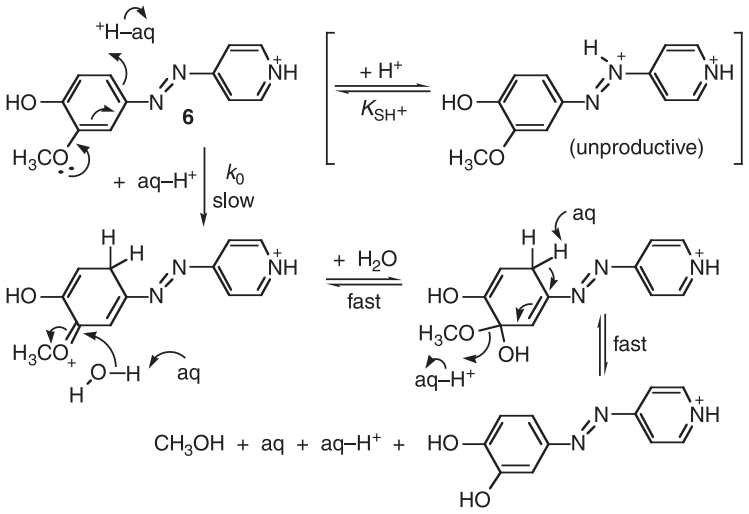
Scheme 5.



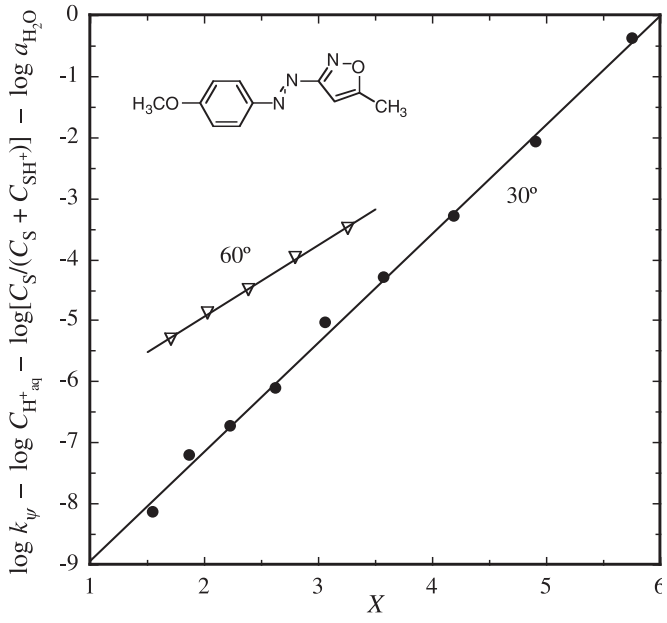


Fig. 4. Excess acidity plots for the hydrolysis of **7** in aqueous H_2SO_4. The theoretical lines are drawn using the slope and intercept values in Table 2.

values a few entropy units on either side of zero.[3] However, this is understandable as **4** contains one (or two) positive charges, and thus the solvent must be more electrostricted than is the case for the neutral ethers studied before.[3]

To summarize, these azoethers have quite interesting hydrolysis mechanisms, if suitably substituted, but many of them hydrolyze by the same Scheme 1 mechanism as do most ethers that cannot form stable carbocations in the medium used.[3,4]

Abstract: A new and convenient method for the synthesis of bis(pyrazolyl)methanes by one-pot tandem Knoevenagel–Michael reaction of 3-methyl-1-phenyl-5-pyrazolone with aryl, heteroaryl, or alkyl aldehydes in the presence of 2-hydroxyethylammonium acetate (2-HEAA) as a task-specific ionic liquid is described. This method was also successfully applied for the synthesis of 2-pyrazolyl-1-nitroalkanes by Michael addition of 3-methyl-1-phenyl-5-pyrazolone with β-nitrostyrenes in short reaction times. The present protocol offers several advantages such as using a reusable and cost-effective ionic liquid, an environmentally benign reaction media, being amenable to scale-up and good to high yields of the products.

Key words: bis(pyrazolyl)methane, ionic liquid, aldehydes, β-nitrostyrene.

Résumé : On a développé une méthode nouvelle et simple de synthèse des bis(pyrazolyl)méthanes par une réaction monotope en tandem de Knoevenagel–Michael de la 3-méthyl-1-phényl-5-pyrazolone avec des aldéhydes d'aryles, d'hétéroaryles ou d'alkyles, en présence d'acétate de 2-hydroxyéthylammonium (acétate de 2-HEA) dans un liquide ionique spécifique pour cette réaction. On a appliqué cette méthode avec succès pour la synthèse de 2-pyrazolyl-1-nitroalcanes par le biais d'une addition de Michael de la 3-méthyl-1-phényl-5-pyrazolone sur le β-nitrostyrène avec un très court temps de réaction. Le présent protocole offre plusieurs avantages, tel l'usage d'un liquide ionique réutilisable et efficace, un milieu réactionnel écologique et la possibilité de pouvoir être amené à produit des grandes quantités de produits avec des rendements allant de bons à élevés.

Mots-clés : bis(pyrazolyl)méthane, liquide ionique, aldéhydes, β-nitrostyrène.

[Traduit par la Rédaction]

Introduction

Pyrazoles are an important class of bioactive drug targets in the pharmaceutical industry, as they are the core structure of numerous biologically active compounds.[1–3] Among the pyrazole derivatives, the synthesis of pyrazolone derivatives has attracted much attention from organic chemists because of their various biological activities, such as antitumor[4,5] and selective COX-2 inhibitory.[6] Pyrazolone derivatives are also used as cytokine inhibitors,[7] human telomerase inhibitors,[8] therapeutics for kinase-mediated inflamatory disorders,[9] and dyes.[10,11] For example, 2,4-dihydro-3*H*-pyrazol-3-one derivatives, including 4,4′-(arylmethylene)bis(3-methyl-1-phenyl-1*H*-pyrazol-5-ol)s, are being used as anti-inflammatory, antipyretic, gastric secretion stimulatory antidepressant, antibacterial, and antifilarial agents.[12–16] Moreover, the corresponding 4,4′-(arylmethylene)bis(1*H*-pyrazol-5-ol)s are applied as fungicides, pesticides, insecticides, dyestuffs, and chelating and extracting reagents for different metal ions.[17–20] The conventional chemical approach to 4,4′-(arylmethylene) bis(3-methyl-1-phenyl-1*H*-pyrazol-5-ol)s involves the successive Knoevenagel synthesis of the corresponding arylidene-pyrazolones and its base-promoted Michael reaction.[17,18,21] One-pot tandem Knoevenagel–Michael reaction of aldehydes with 2 equiv of 5-methyl-2-phenyl-2,4-dihydro-3*H*-pyrazol-3-one, which was performed under a variety of reaction conditions, is another approach for achieving these important scaffolds.[22–33] Even though, 4,4′-(arylmethylene)bis(3-methyl-1-phenyl-1*H*-pyrazol-5-ol)s could be synthesized by these methods, most of the methods suffer from limitations such as low yields, long reaction time, application of hazardous solvents, tedious work-up procedures and noncompliance with green chemistry protocols. On the other hand, a literature survey indicates that the methods for the synthesis of 4-substituted pyrazolones are mainly focused on the condensation reaction of 3-methyl-1-phenyl-5-pyrazolone with aldehydes.[22–33] It also shows that Michael addition of pyrazolone with Michael acceptors such as β-nitrostyrene as possibly the strongest and particularly versatile Michael acceptors has been less explored.[34,35] Therefore, it is necessary to develop an efficient and convenient method for the synthesis of 4-substituted pyrazolones such as bis(pyrazolyl)methanes and 2-pyrazolyl-1-nitroalkanes.

In recent years, room-temperature ionic liquids have received considerable attention as an alternative green reaction medium for numerous organic reactions because of their favorable properties, such as good solvating capability, wide liquid range, negligible vapor pressure, tunable polarity, high thermal stability, and ease of recyclability.[36,37] Ionic liquids, as catalysts, have also played a significant role in controlling these reactions.[38–40] The major concern in using ionic liquids as reaction media in industrial processes is the cost of the ionic liquid, which would be directly dependent on the price of the cations and anions that are used for their production.[41] The currently popular ionic liquids incorporate expensive cations, such as alkyl methyl imidazolium or dialkyl imidazolium, and expensive anions, such as tetrafluoroborate or hexafluorophosphate. Thus, introduction of cost-effective ionic liquids as reaction media should be a priority.

Having this point in mind, and as part of our continued interest in the development of new methods for the synthesis of pyrazolone derivatives,[30,31] herein, we wish to report a new method for environmentally benign synthesis of bis(pyrazolyl)methanes and 2-pyrazolyl-1-nitroalkanes in the presence of 2-hydroxyethylammonium acetate (2-HEAA)[42–44] as a cost-effective and reusable ionic liquid at room temperature.

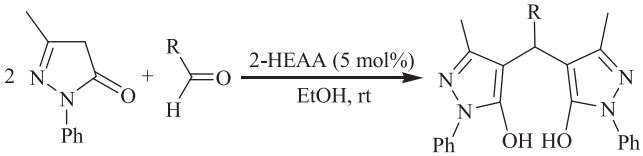
Results and discussion

At first, to find the best solvent, the reaction of benzaldehyde (1 equiv) with 3-methyl-1-phenyl-5-pyrazolone (**1**, 2 equiv) was studied in EtOH, H_2O, CH_3CN, CH_2Cl_2, petroleum ether, and toluene in the presence of 2-HEAA (5 mol %) at room temperature (Table 1, entries 1–6). The results revealed that EtOH was the best solvent for this reaction (Table 1, entry 1). Low yield of the product was obtained in the absence of any solvent (Table 1, entry 7).

In the next step, to show the generality of this method, the reaction of different types of aldehydes with **1** in the presence of 2-HEAA (5 mol %) in EtOH at room temperature was investigated (Scheme 1). The results of these studies are summarized in Table 2.

As shown in Table 2, substituted benzaldehyde with electron-donating and electron-withdrawing groups underwent one-pot tandem Knoevenagel–Michael reaction with 2 equiv of **1** and gave the corresponding products in 74%–95% yields (entries 1–6). Both formyl groups in terphthaldehyde reacted with **1** to produce the desired product in 85% yield (Table 2, entry 7). The reaction of naphthalene-2-carbaldehyde as a polynuclear aromatic aldehyde gave the corresponding product in 40 min (Table 2, entry 8). Acid-sensitive aldehydes, such as thiophene-2-carbaldehyde, underwent smooth reactions without any decomposition or polymerization (Table 2, entry 9). This method is also applicable for the synthesis of bis(pyrazolyl)methanes (**2j** and **2k**) from the reaction of **1** with aliphatic aldehydes (Table 2, entries 10 and 11).

It was observed that the ionic liquid was reusable at least 15 times in multiple sequential condensations by the addition of new samples of benzaldehyde and **1** to the reaction mixture. This protocol was also easily amenable to scale-up. For example, the condensation of benzaldehyde with **1** in a semi scale-up procedure (20 times) was carried out successfully and produced the desired product in 85% yield.



It is important to note that the reports for the condensation reaction of aldehydes with **1** in ionic liquid are rare in the literature.[45,46] In these reports, 4-[(5-hydroxy-3-methyl-1-phenyl-1*H*-pyrazol-4-yl)-phenyl-methyl]-5-methyl-2-phenyl-1,2-dihydropyrazol-3-ones (Fig. 1) were obtained instead of bis(pyrazolyl)methanes (**2**). Therefore, the present method is the first protocol for the synthesis of bis(pyrazolyl)methanes in the presence of an ionic liquid.

R = aryl, alkyl, heteroaryl

To show the catalytic effect of 2-HEAA on the synthesis of bis(pyrazolyl)methanes **2**, the coupling reaction between benzaldehyde and **1** in the absence of ionic liquid at room temperature was considered. This reaction led to the formation of the desired product (**2a**) in low yield (40%) after 20 h (Table 3, entry 1). A similar reaction in the presence of $[CH_3CH_2NH_3^+][AcO^-]$ proceeded with a longer reaction time compared with 2-HEAA and produced the desired product in 81% yield (Table 3, entries 2 and 3). These results showed the role of the hydroxyl group of 2-HEAA in imparting the catalytic property and indicates that 2-HEAA can act as a functionalized or task-specific ionic liquid in this method. We have also found that lengthening of the alkyl chain in $[HO(CH_2)_nNH_3^+][AcO^-]$ has no influence on the efficiency of the ionic liquid (Table 3, entries 4 and 5).

We also suggest a plausible mechanism for the reaction of **1** and aldehydes in the presence of 2-HEAA (Scheme 2). The process represents a typical tandem reaction in which aldehydes first condensed with **1** to form the Knoevegel product followed by Michael addition with **1** to produce bis(pyrazolyl)methanes **2**. In this reaction, two spontaneous interactions between NH_3^+ and the OH of 2-HEAA with the carbonyl groups of aldehydes and the methylene group of **1** took place. These interactions activated the reactants and facilitated formation of the product.

Successful application of 2-HEAA as a reusable ionic liquid for the one-pot synthesis of bis(pyrazolyl)methanes encouraged us to study the applicability of this method for the synthesis of 2-pyrazolyl-1-nitroalkanes by the reaction of 3-

methyl-1-phenyl-5-pyrazolone with β-nitrostyrene (Scheme 3 and Table 4). As indicated in Table 4, Michael addition of 3-methyl-1-phenyl-5-pyrazolone with β-nitrostyrenes bearing electron-withdrawing or electron-releasing groups proceeded well to afford the corresponding 2-pyrazolyl-1-nitroalkanes in 83%–95% yields.

Conclusions

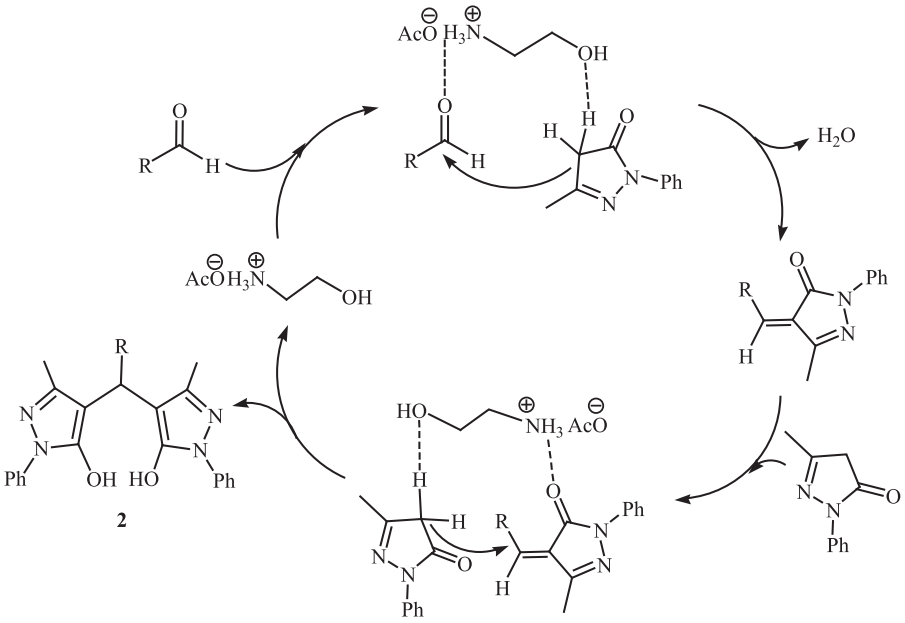
In conclusion, we have successfully developed a new and simple protocol for the synthesis of bis(pyrazolyl)methanes via a one-pot tandem Knoevenagel–Michael reaction in the presence of 2-HEAA as a task-specific ionic liquid. This simple procedure allows a series of bis(pyrazolyl)methanes to be synthesized in good to high yields from the reaction of aryl, heteroaryl, or alkyl aldehydes and 3-methyl-1-phenyl-5-pyrazolone at room temperature. The method was also applicable for the synthesis of 2-pyrazolyl-1-nitroalkanes via Michael addition reaction of 3-methyl-1-phenyl-5-pyrazolone with β-nitrostyrene in short reaction times. The present protocol offers several advantages such as using a reusable and cost-effective ionic liquid, an environmentally benign reaction media, being amenable to scale-up, and good to high yields of the products.

Experimental section

General procedures and materials

Chemicals were purchased from the Merck and Fluka Chemical Companies. Melting points were determined by a Buchi 510 apparatus and are uncorrected. IR spectra were run on a PerkinElmer 780 instrument. NMR spectra were recorded on a Bruker Avance DPX-250, 400, or 500. Mass spectra were recorded on a Shimadzu GC–MS QP5050A spectrometer operating at an ionization potential of 70 eV. Conductivities were measured by an Istek 915PDC apparatus at 25 °C. The electrochemical measurements were performed by a Solartron Electrochemical Interface model 1287 at 25 °C. The purity of the products and the progress of the reactions were accomplished by TLC on silica gel polygram SILG/UV_{254} plates. Elemental analysis for C, H, and N were obtained by using an Elementar Vario EL III.

A typical procedure for the synthesis of 2-HEAA



2-HEAA was prepared according to a previously reported procedure.[43] A solution of acetic acid (50 mmol, 3.00 g) in EtOH (1.5 mL) was added dropwise to a stirring solution of 2-aminoethanol (50 mmol, 3.05 g) in EtOH (1.5 mL) at room temperature within 1 h. The resultant solution was stirred at room temperature for another 20 h. EtOH was removed in vacuo, and the oil residue was dried in vacuo at 50 °C for 48 h to give 2-HEAA as a yellow viscous liquid (pH 7.96 at 25 °C, bp 191 °C, density = 1.11 g cm^{-3} at 25 °C, electrochemical stability between –0.6 and 0.7 V, relative viscosity = 9390.6 at 25 °C, conductivity = 263.3 μs cm^{-1}).

General procedure for the synthesis of bis(pyrazolyl) methanes (2)

2-HEAA (5 mol%) was added to a mixture of aldehyde (1 mmol) and **1** (2 mmol) in EtOH (4 mL) at room temperature. The mixture was stirred at room temperature for the

4,4′-[(isoPropyl)methylene]bis(3-methyl-1-phenyl-pyrazol-5-ol) (2j)

White solid; yield: 92%, 0.37 g; mp 210–212 °C. IR (ν_{max}, cm^{-1}): 3428 (O–H). ^1H NMR (500 MHz, DMSO-d_6) δ_H: 0.84 (6H, d, $^3J_{HH}$ = 7.9 Hz, CH_3), 2.21 (6H, s, CH_3), 2.55–2.69 (1H, m, CH), 2.97–3.08 (1H, m, CH), 7.25–7.28 (2H, m, Ar), 7.40–7.48 (4H, m, Ar), 7.71–7.43 (4H, m, Ar), 11.93 (1H, br s, OH), 13.64 (1H, br s, OH). MS *m/z* (%): 228 (21), 174 (33).

4,4′-[(n-Buthyl)methylene]bis(3-methyl-1-phenyl-pyrazol-5-ol) (2k)

White solid; yield: 83%, 0.34 g; mp 125–127 °C. IR (ν_{max}, cm^{-1}): 3420 (O–H). ^1H NMR (400 MHz, DMSO-d_6) δ_H: 0.85 (3H, t, $^3J_{HH}$ = 7.2 Hz, CH_3), 1.16–1.19 (2H, m, CH_2), 1.27–1.32 (2H, m, CH_2), 1.92–1.96 (2H, m, CH_2), 2.92 (6H, s, CH_3), 3.53 (1H, t, $^3J_{HH}$ = 8.0 Hz, CH), 4.00 (2H, br s, OH), 7.33 (2H, t, $^3J_{HH}$ = 7.2 Hz, Ar), 7.49 (4H, t, $^3J_{HH}$ = 8.0 Hz, Ar), 7.68 (4H, d, $^3J_{HH}$ = 8.0 Hz, Ar). ^{13}C NMR (100 MHz, DMSO-d_6) δ_C: 10.9, 14.3, 22.4, 28.28, 30.0, 31.7, 106.4, 122.6, 127.9, 129.7, 135.0, 145.7, 158.6. MS *m/z* (%): 243 (23.3), 174 (100).

General procedure for the synthesis of 2-pyrazolyl-1-nitroalkanes (3)

2-HEAA (5 mol %) was added to a mixture of β-nitrostyrene (1 mmol) and **1** (1 mmol) in EtOH (4 mL) at room temperature. The mixture was stirred at room temperature for the appropriate time (Table 4). After evaporation of the solvent, water (10 mL) was added to the reaction mixture, and the resulting solid was filtered and washed three times with H_2O (5 mL). The pure product (**3**) was obtained from this solid by recrystallization in EtOH.

3-Methyl-4-[2-nitro-1-(phenylethyl)ethyl]-1-phenyl-5-pyrazolone (3a)

White solid; yield: 83%, 0.32 g; mp 89–90 °C. IR (ν_{max}, cm^{-1}): 2901 (O–H). ^1H NMR (400 MHz, DMSO-d_6) δ_H: 2.51 (3H, s, CH_3), 4.58 (1H, t, $^3J_{HH}$ = 8.0 Hz, CH), 5.31 (1H, dd, $^3J_{HH}$ = 8.0 Hz, $^3J_{HH}$ = 7.6 Hz, CH_2), 5.37 (1H, dd, $^3J_{HH}$ = 8.8 Hz, $^3J_{HH}$ = 6.8 Hz, CH_2), 7.20 (1H, d, $^3J_{HH}$ = 7.2 Hz, Ar), 7.25 (1H, d, $^3J_{HH}$ = 7.2 Hz, Ar), 7.33 (2H, t, $^3J_{HH}$ = 7.6 Hz, Ar), 7.44 (2H, t, $^3J_{HH}$ = 8.0 Hz, Ar), 7.50 (2H, t, $^3J_{HH}$ = 7.6 Hz, Ar), 7.71 (2H, d, $^3J_{HH}$ = 8.0 Hz, Ar), 11.23 (1H, br s, OH).

3-Methyl-4-[2-nitro-1-(2-methoxyphenyl)ethyl]-1-phenyl-5-pyrazolone (3b)

White solid; yield: 91%, 0.32 g; mp 147–149 °C. IR (ν_{max}, cm^{-1}): 2955 (O–H). ^1H NMR (400 MHz, DMSO-d_6) δ_H: 2.16 (3H, s, CH_3), 3.85 (3H, s, OCH_3), 4.95 (1H, dd, $^3J_{HH}$ = 7.6 Hz, $^3J_{HH}$ = 6.8 Hz, CH), 5.15 (1H, dd, $^3J_{HH}$ = 14.2 Hz, $^3J_{HH}$ = 6.6 Hz, CH_2), 5.36 (1H, dd, $^3J_{HH}$ = 8.8 Hz, $^3J_{HH}$ = 6.6 Hz, CH_2), 6.91 (1H, t, $^3J_{HH}$ = 7.6 Hz, Ar), 7.01 (1H, d, $^3J_{HH}$ = 8.4 Hz, Ar), 7.19 (1H, t, $^3J_{HH}$ = 7.6 Hz, Ar), 7.24 (1H, t, $^3J_{HH}$ = 8.0 Hz, Ar), 7.43 (2H, t, $^3J_{HH}$ = 8.0 Hz, Ar), 7.51 (1H, d, $^3J_{HH}$ = 7.2 Hz, Ar), 7.70 (2H, d, $^3J_{HH}$ = 8.6 Hz, Ar). ^{13}C NMR (100 MHz, DMSO-d_6) δ_C: 11.7, 32.1, 56.0, 57.9, 76.1, 102.4, 111.3, 119.1, 120.7, 124.9, 127.5, 128.5, 128.6, 129.3, 137.8, 148.3, 156.5. MS *m/z* (%): 353 (3.6), 173 (30.8), 77 (100), 91 (64.8). Anal. calcd for $C_{19}H_{19}N_3O_4$ (353.14) (%): C 64.58, H 5.42, N, 11.89; found: C 64.64, H 5.48, N 11.91.

3-Methyl-4-[2-nitro-1-(4-methylphenyl)ethyl]-1-phenyl-5-pyrazolone (3c)

White solid; yield: 84%, 0.28 g; mp 80–81 °C. IR (ν_{max}, cm^{-1}): 2994 (O–H). ^1H NMR (400 MHz, $CDCl_3$) δ_H: 1.93

Abstract: Separation of bitumen from oil sands is far more efficient with an organic solvent than with the conventional hot water (Clark) process, but the removal of the organic solvent from the bitumen requires distillation. Distillation is problematic because of the energy cost and the need for a volatile solvent (which is therefore likely to be flammable and smog-forming). A switchable hydrophilicity solvent (SHS) is a solvent that is water-miscible in the presence of an atmosphere of CO_2 but separates from water when CO_2 is absent. Extraction of bitumen from low-grade high-fines oil sands using a SHS ($CyNMe_2$) is efficient, removing 94%–97% of the bitumen. The resulting solids (sand and clay) are dry, free-flowing, and contaminated with only 0.4 wt % of bitumen and as little as 102 ppm of the solvent. No distillation step was required to recover the solvent from the bitumen. Instead, carbonated water extraction removed the solvent from the oil. Losses of the $CyNMe_2$ solvent were, for the best method, 0.06 grams of solvent per gram of bitumen recovered. The method recovers more oil than the Clark process, produces cleaner solids, works with low-grade high-fines oil sands, and requires neither distillation nor a volatile solvent.

Key words: oil sands, solvent, carbon dioxide, extraction, bitumen.

Résumé : La séparation du bitume à partir des sables bitumineux est beaucoup plus efficace avec un solvant organique que par le procédé conventionnel de Clark avec de l'eau chaude; toutefois, la séparation du bitume et du solvant organique nécessite une distillation. La distillation est problématique en raison du coût de l'énergie et de la nécessité d'utiliser un solvant volatil (qui est selon toute vraisemblance plus inflammable et plus susceptible de former du smog). Un solvant dont le caractère hydrophile peut être commutable (SCC) est un solvant qui est miscible dans l'eau en présence d'une atmosphère de CO_2, mais qui se sépare de l'eau quand le CO_2 est absent. L'utilisation d'un SCC ($CyNMe_2$) pour l'extraction du bitume à partir des sables bitumineux extra fins de faible qualité est efficace, enlevant de 94 % à 97 % du bitume. Les solides qui en résultent (sable et argile) sont secs, d'une grande fluidité et ne sont contaminés que par 0,4 % en poids de bitume et aussi peu que 102 ppm de solvant. Aucune étape de distillation n'est nécessaire pour récupérer le solvant du bitume. Il faut plutôt utiliser de l'eau pétillante pour enlever le solvant de l'huile. On a établi que les pertes du solvant $CyNMe_2$ s'élèvent, pour la meilleure méthode, à 0,06 grammes de solvant par gramme de bitume récupéré. La méthode permet de récupérer plus d'huile que le procédé de Clark, elle permet de produire des solides plus propres, elle peut être utilisée pour des sables bitumineux extra fins de faible qualité et elle ne nécessite aucune distillation et aucun solvant volatil.

Mots-clés : sables bitumineux, solvant, dioxyde de carbone, extraction, bitume.

Introduction

Separation of the bitumen from bituminous sand (popularly known as "oil sands") is currently performed as a flotation process using large quantities of hot and alkaline water. The resulting separation is incomplete, leaving sand and clay particles suspended in water and contaminated with bitumen (10% or more of the original amount).[1] The suspension is then left in a tailings pond to settle over years. Wildfowl landing in the tailings ponds have been killed by exposure to the bitumen. The current flotation method is also limited because it is incapable of separating "oil-wet" bituminous sand (meaning that the oil and the solid materials (sand and clay) are in direct contact rather than having an intervening layer of water). About 20% of Canada's geologically accessible deposits and much of those in the US are oil-wet. For these reasons, alternative extraction processes have been sought for many years.

A much cleaner separation of bitumen from sand and clay could be achieved with an organic solvent extraction, but the conventional method of removing organic solvent from product is distillation. Examples of organic solvent-based processes include the Nevtah LES process (using hydrocarbon

solvents),[2] the Dravo Process (heptane/cyclohexane/ethanol mixture),[3,4] the Dow–Kellog process (CH_2Cl_2),[5,6] and the SESA process (naphtha or kerosene).[7,8] In every case, extraction of the bitumen is followed by a distillation step to remove the solvent, which is problematic because it requires both significant energy input and the use of a volatile solvent. Volatile solvents are flammable, contribute to smog, and cause inhalation risks to workers; they can be toxic, carcinogenic, neurotoxic, mutagenic, or narcotic, all by inhalation. In contrast, nonvolatile or low-volatility solvents do not pose these problems, or pose them to a lesser degree, but such solvents are usually avoided because they cannot be removed by distillation. If a nondistillative method for removal of solvent from bitumen could be identified, then organic solvent extraction could be a viable method for the separation of bituminous sand.

In earlier publications, we described several switchable hydrophilicity solvents (SHS),[9,10] including cyclohexyldimethylamine ($CyNMe_2$). An SHS is a solvent that can readily interconvert between two forms; one form is hydrophobic and forms a biphasic mixture when mixed with water (this is the normal behaviour for $CyNMe_2$). The other form is hydrophilic and completely miscible with water. The trigger for the change to hydrophilic is the addition of CO_2 at 1 bar (1 bar = 100 kPa) (which converts $CyNMe_2$ into water-soluble $[CyNHMe_2][HCO_3]$), whereas the trigger for the return to hydrophobic is the removal of the CO_2. These solvents can be used, in the absence of CO_2, for applications that would normally require a hydrophobic solvent, such as the extraction of oil from an oily solid. The SHS can then be washed out of the oil with carbonated water, leaving pure oil product. The separation of the SHS from the carbonated water is triggered by the removal of the CO_2. Thus, product and solvent can be separated from each other without distillation and without requiring a volatile solvent. We have reported this process for the extraction of soybean oil from soybeans[9] and algae lipids from microalgae.[11] Whether this process can be applied to the separation of bitumen from oil sands is the subject of this paper.

Results and discussion

In all experiments described in this report, low-grade, high-fines, water-wet oil sands were used.

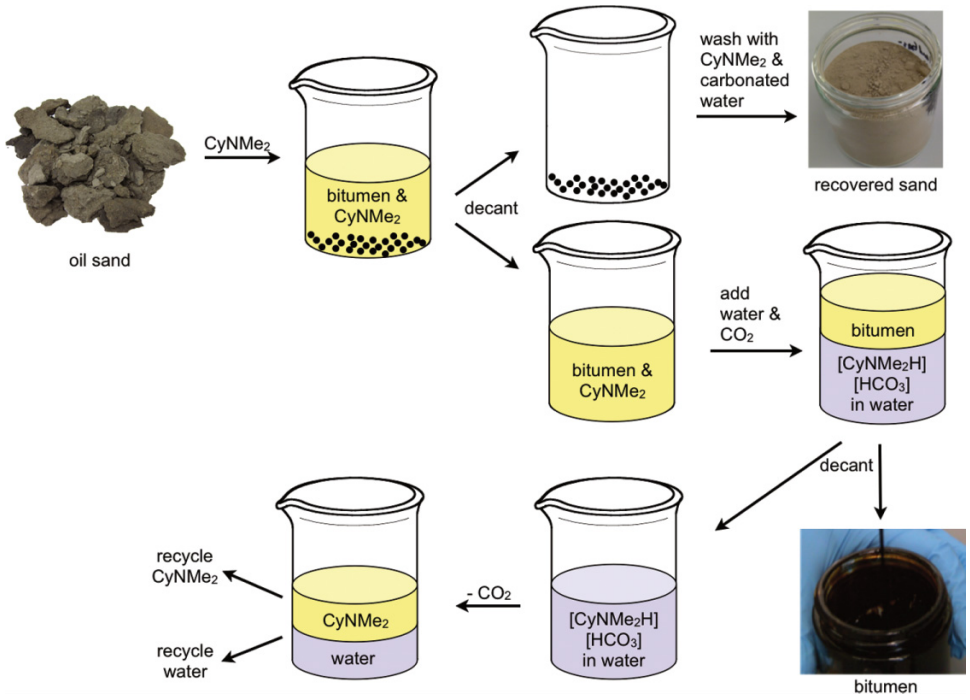
The ability of $CyNMe_2$ to dissolve bitumen from oil sands

First, the ability of $CyNMe_2$ to dissolve bitumen was established. A sample of bitumen was obtained by toluene extraction from oil sands, followed by a Büchner funnel filtration to remove the solids. After removal of the toluene from the bitumen by evaporation, $CyNMe_2$ was added to dissolve the bitumen. The bitumen entirely dissolved, demonstrating that $CyNMe_2$ is able to dissolve all of the toluene-soluble bitumen.

To determine whether the SHS can dissolve asphaltenes, $CyNMe_2$ was used to extract bitumen from oil sands. $CyNMe_2$ was removed by extraction with carbonated water and the bitumen was then mixed with *n*-pentane. A large amount of bitumen remained undissolved. The insoluble solid material was isolated and then heated, causing it to melt into a black tar, showing that the solids were asphaltenes rather than mineral fines. This demonstrates that $CyNMe_2$ is capable of dissolving bitumen containing a substantial amount of asphaltenes.

The time required to extract bitumen from oil sands using an organic solvent depends on the solvent choice. Mixing a lump of oil sand (30–50 g) with solvent (a ratio of 5:1.5 oil sands/solvent by mass) visually demonstrated the effect of solvent choice (see Figs. 1–4 in the Supplementary data). Using hot water, after 15 min without stirring, the oil sands chunk remained intact and no dissolution was observed visually. After stirring, the solid chunk was observed to slowly break up and the water became discoloured. With hexanes, a small amount of dissolution was observed with or without stirring, and again breakup of the solid material was slow. With toluene, good extraction was observed in 15 min but breakup required stirring. With $CyNMe_2$, good extraction was observed in 5 min; the oil sands chunk broke up with minimal stirring, showing that the $CyNMe_2$ was much more efficient at dissolving the bitumen from the oil sands.

Separation of solvent from bitumen



The proposed oil sands separations process (Fig. 1) starts with a conventional extraction of the bitumen from the sand and clay using an SHS ($CyNMe_2$) in its hydrophobic form. After filtration or decantation, the solids are separated from the bitumen/solvent mixture. The solids are washed with fresh solvent and then carbonated water. The bitumen/solvent mixture is then treated with carbonated water to extract the $CyNMe_2$ by converting it to the water-soluble bicarbonate salt $[CyNMe_2H][HCO_3]$. The washed bitumen is then removed by decantation, and the bicarbonate salt solution is heated and treated with either N_2 or air to remove the CO_2. The $CyNMe_2$ solvent separates from the water. Both the amine and the water can be reused.

Because the bitumen content of oil sands varies from sample to sample, tests of the extraction method were performed on six samples and the results averaged. These small-scale tests, using 25 g samples of oil sands, showed that the average mass of bitumen recovered by this process was 1.9 g, although 0.23 g of that material was residual $CyNMe_2$ remaining in the bitumen (12 wt % contamination of the bitumen) and 0.14 g was water (average 7% water content). Thus, the actual mass of bitumen, not including residual solvent and water, was 1.5 g (6% of the original mass of the oil sands sample). The amount of water in the bitumen was insufficient to have carried with it much $CyNMe_2$ or its salt, so the residual $CyNMe_2$ in the bitumen is believed to be dissolved in the oil phase rather than in entrained or emulsified water. The wt % solids in the bitumen was zero, within experimental error. Because of the high viscosity of the bitumen, some losses of bitumen to the sides of the glassware were unavoidable.

The recovered sand/clay mixture was dry and free flowing (mass 22.5 g or 90% of the original mass). Toluene washing of the solids showed that, on average, they contained 0.096 g of residual bitumen (0.4 wt % of the mass of solids). Thus, the removal of bitumen from the oil sand was at least 94% complete. Keeping in mind that some bitumen was lost to the sides of the glassware, the extraction of bitumen was likely somewhat more than 94% complete. A second extraction would presumably greatly increase this value. Simply rinsing the solids with $CyNMe_2$ multiple times while still on the filter,

For personal use only.

Fig. 1. The proposed process for separating bitumen from oil sands.

rather than doing a second extraction, increases the bitumen removal to over 97% complete.

The total recovery of solids and bitumen is 24 g, which is 96% of the original mass of the oil sands sample. Most of the remaining 4% is likely the water content of the oil sands.

The process required a total of 45 mL (53 g) of $CyNMe_2$ to wash the 25 g of oil sands, corresponding to 2.1 grams of solvent per gram of oil sands. Of the 53 g of solvent, 0.23 g (0.4%) was lost to the bitumen and 0.007 g to the sand/clay solid product.

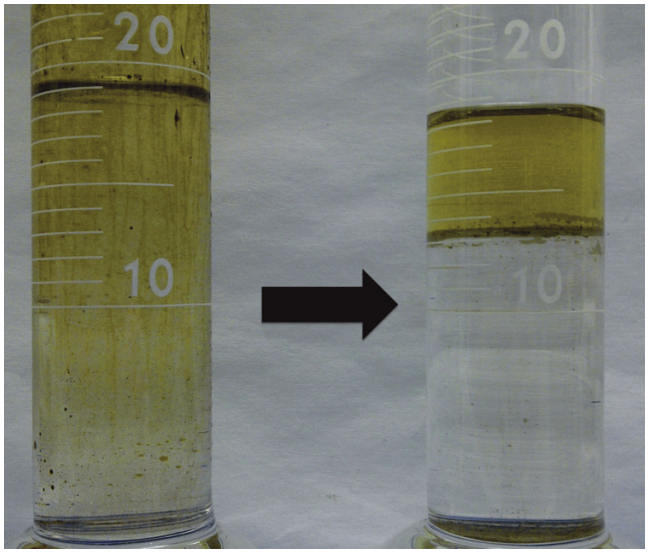
Two large-scale tests, using 500 g samples of oil sands, were performed. To economize on the amount of solvent, these tests were performed with only 213 g of $CyNMe_2$, or 0.42 grams of solvent per gram of oil sands. Nevertheless, the results were similar. The recovered bitumen fraction was 52 g and contained 12 wt % SHS and 14% water; the amount of pure bitumen was therefore 38.5 g (7.7% of the original mass). The recovered sand/clay solid product was 455 g (91% of the original mass).

The mixing method during the treatment of the bitumen/$CyNMe_2$ mixture with carbonated water was merely the agitation caused by the CO_2 bubbling. Tests were also performed with an overhead stirrer at 2500 rpm to see whether better mixing could help lower the concentration of residual amine in the bitumen. Using this method, the average amount of amine remaining in the bitumen was 8 wt %. After the mixture was allowed to settle for 16 h, the amine content was reduced to 5%. This represents a significant improvement, cutting the losses of amine to bitumen by more than half. This blending treatment did not significantly affect the water content of the bitumen, which was still 7%. Thus, the actual bitumen content of this fraction was 88%, and the loss of $CyNMe_2$ was 0.06 grams per gram of recovered bitumen (i.e., 5 grams of solvent per 88 grams of bitumen).

Table 1. Residual solvent content of sand/clay solids after repeated washes with carbonated water.

	$CyNMe_2$ on solids (ppm)	
No. of washings	After 5 min	After 30 min
1	892	646
2	575	314
3	158	—
4	102	—

Note: A 75–80 g sample of contaminated sand/clay mixture containing 6.4 wt % $CyNMe_2$, washed with 100 mL of carbonated water for the times indicated.



Tests were also performed with a blender, which stirs at >15 800 rpm: bitumen contaminated with 12 wt % $CyNMe_2$ was mixed with carbonated water using this blender for 1 min periods followed by 1 min of CO_2 bubbling without mixing. After 15 such cycles, the contamination of the bitumen had dropped to 8 wt %.

Separation of solvent from the sand/clay solids

The solids liberated from the bitumen should have a low amine content (ideally <300 ppm) so that it can be returned to the environment. The solids, immediately after being washed with $CyNMe_2$, contained 6.4 wt % amine (64 000 ppm). Washing a 75 g sample of these contaminated solids with 100 mL normal water (uncarbonated) lowered the contamination to 1.7%. Four such washes brought the contamination down to 480 ppm. Washing with carbonated water is more efficient (Table 1), bringing the amine content to the desired level of ~300 ppm after only two washes. Note that samples below 1500 ppm have no odor.

Fig. 2. The mixture of carbonated water and $CyNMe_2$ after the bitumen has been decanted (left) and the same mixture after the CO_2 has been removed (right). The organic layer is coloured because of residual bitumen.

Separation of solvent from carbonated water

The recovery of $CyNMe_2$ from the carbonated aqueous layer requires the effective removal of the CO_2 from the aqueous phase. Heating the water/$CyNMe_2$/CO_2 mixture to 70 °C for 1 h with continuous bubbling of nitrogen through the liquid, via a gas dispersion tube, caused the amine to form a second liquid phase (Fig. 2). The composition of the aqueous phase was 16 wt % amine. The aqueous phase was reused repeatedly, carrying a constant 16 wt % amine every cycle after the first.

No solids are visible in the aqueous phase before or after amine removal. The wt % solids in the aqueous phase after one use was found gravimetrically to be the same as that in the fresh water supply, within experimental error.

Performing the CO_2 removal with slightly reduced pressure (750 mbar) rather than nitrogen bubbling was not as effective. While an amine phase did appear, the aqueous phase still contained 31 wt % amine.

For the SHS process to be industrially viable, the reuse of solvent is necessary. To determine if the solvent changed at all after multiple uses, $CyNMe_2$ was cycled through the process four times and was studied spectroscopically after each cycle (^{1}H NMR, GC, and IR are shown in the Supplementary data). Overall, no change in the $CyNMe_2$ was observed. Because the solvent is being purified by the treatment with carbonated water and because there is no high-temperature step, there should be no significant degradation of the solvent; the solvent should only need to be topped up with fresh solvent because of losses to the bitumen and the sand/clay solids.

Conclusion

Separation of bitumen from low-grade high-fines oil sands was achieved by using $CyNMe_2$ as a switchable hydrophilicity solvent, as shown in Fig. 1. This solvent dissolves bitumen from the oil sands more readily than toluene or hexanes. The resulting sand/clay solids were dry, free-flowing, and contaminated with only 0.4 wt % of bitumen. The removal of bitumen from the oil sands was 94%–97% complete. Subsequent removal of the solvent from the sand/clay solids by carbonated water rinses brought the solvent content of the solids down as low as 102 ppm. The used carbonated water could then be reused for solids washing or for solvent recovery from the bitumen.

Although $CyNMe_2$ is an oil-miscible organic solvent, no distillation step was required to recover the solvent from the bitumen. Instead, carbonated water extraction removed the solvent from the oil. The isolated bitumen did not contain a detectable quantity of solids but did contain some residual solvent. When the best method was used, losses of the $CyNMe_2$ solvent were 0.06 grams of solvent per gram of solvent-free bitumen recovered.

Further research is being performed to reduce the amount of solvent remaining in the bitumen.

Table 2. Composition and properties of the low-grade high-fines oil sands ore.

Parameter	Value
Bitumen	7.5%

Mg	0.4 ppm

Experimental methods

Equipment and materials

The oil sands samples were low-grade ore having a high fines content, received from the Horizon site of Canadian Natural Resource Ltd., Fort McMurray, Alberta, Canada. The samples were stored in a sealed container in a freezer at –15 °C until needed. Characterization of the oil sands from that part of the formation is given in Table 2. $CyNMe_2$was purchased from Acros Organics and used without further purification. The CO_2 was 99.8% purity or greater. Carbonated water was prepared by bubbling CO_2 via a gas dispersion tube into tap water at 1 atm (1 atm = 101.325 kPa).

After separations, the amount of solvent remaining in the bitumen was determined by ^{1}H NMR spectroscopy. The amount of water remaining in the bitumen was determined with a Karl-Fisher coulometer. The amount of solid matter remaining in the bitumen was determined by thermogravimetric analysis.

NMR and IR spectroscopy and gas chromatography were performed with a Varian 400 MHz NMR spectrometer, a Varian 660 FT-IR in ATR mode, and a Varian 450 GC-FID.

Small-scale extractions

Oil sands (25 g), a magnetic stir bar, and then $CyNMe_2$ (20 mL) were placed in a 150 mL glass beaker and stirred magnetically at 125 rpm for 10 min. The resulting slurry was split between two 125 mL centrifuge bottles with an additional 5 mL of $CyNMe_2$ added to wash any remaining solids in the beaker into the bottles. The sample was centrifuged at 1500 rpm for 30 min followed by decantation of the supernatant, although some fine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

particles remained in the supernatant. To wash the liberated sand/clay solids, fresh $CyNMe_2$ (10 mL) was added to the solids and the mixture was centrifuged at 1500 rpm for 30 min and decanted; this washing procedure was then performed once more. The solids were washed with 30 mL of carbonated water and centrifuged at 1500 rpm for 30 min. The water (containing some solvent and fine particles) was removed by decantation and the solids were allowed to air dry. The combined organic supernatants had a total volume of approximately 45 mL.

The combined organic supernatant layers were filtered using a Büchner funnel with No. 1 filter paper to remove fine particles (Table 1). The filtrate was added to a 250 mL glass graduated cylinder containing 90 mL of precarbonated water. Additional carbon dioxide was bubbled into the aqueous layer via a gas dispersion tube for 90 min at atmospheric pressure. When the solvent switch was complete, the bitumen became very viscous and started to clump together. The bitumen was removed by decantation. The amount of solvent, water, and solid matter remaining in the bitumen was determined.

The extraction was performed six times and the results averaged.

Large-scale extractions

Standard method

Oil sands (500 g) and then $CyNMe_2$ (150 mL, 127 g) were placed in a 2 L glass beaker and stirred using an overhead stirrer impeller at 800 rpm for 10 min. The resulting slurry was transferred to a Büchner funnel with No. 1 filter paper using 50 mL (43 g) of solvent. The beaker was rinsed with an additional 50 mL (43 g) of $CyNMe_2$, which was then passed through the filter, thereby rinsing the sand/clay solids in the filter. The organic filtrate (300 mL) was removed from the apparatus and split into two aliquots. The solids on the filter paper were rinsed with 400 mL of carbonated water.

At this point, the organic filtrate was split in half and the two halves processed differently. The results described previously were obtained with the following method. Half of the organic filtrate (150 mL) was added to 300 mL of carbonated water in a 600 mL PTFE beaker. Carbon dioxide at atmospheric pressure was bubbled through the mixture via a glass gas-dispersion tube until the bitumen layer was clumping together, which took 2–4 h. The bitumen was removed by decantation. The amounts of solvent, water, and solid matter remaining in the bitumen were determined and corrected to represent the entire sample rather than just the half.

The experiment was performed twice and the results averaged.

High shear variation

A portion of the organic filtrate (100 mL) obtained using the standard method was added to 200 mL of carbonated water in a 600 mL PTFE beaker equipped with an overhead stirrer and a gas dispersion tube for carbon dioxide introduction. The solution was mechanically stirred at 2500 rpm and continuously bubbled with carbon dioxide for 2 h. Bitumen samples were taken immediately after bubbling and stirring was stopped and again after the mixture was allowed to sit for 16 h. Samples were analyzed for solvent and water content only.

Using a blender to help remove residual $CyNMe_2$ from the bitumen

Previously isolated bitumen (398 g) was transferred to a blender (Waring model LBC15) and homogenized for several seconds. A small sample was removed and analysed by ^{1}H NMR spectroscopy, which showed the presence of 12.6 wt % $CyNMe_2$. Carbonated water (500 mL), containing 16 wt % $CyNMe_2$ (because it had been used already to remove $CyNMe_2$), was added to the blender and sank below the bitumen. CO_2 was bubbled through the mixture via a gas dispersion tube placed so that the gas would be delivered to the aqueous phase. The bitumen/water mixture was blended at 15 800 rpm for fifteen 1 min intervals with 1 min of rest between each blending cycle, with CO_2 bubbling continued throughout. After the 15 cycles, a sample of the bitumen was removed for analysis by ^{1}H NMR spectroscopy. The bitumen was allowed to settle overnight, after which samples of bitumen were taken for ^{1}H NMR spectroscopy from the cover, wall of the blender, the layer of the bitumen on top of the aqueous phase, and the frit that was used to deliver CO_2.

Observing asphaltene content in recovered bitumen

Testing $CyNMe_2$-extracted bitumen with n*-pentane and toluene*

Bitumen that had been extracted with $CyNMe_2$ (the majority of which was then removed by carbonated water) was weighed into three separate beakers.

In one beaker, 25 mL of *n*-pentane was added to 2.3 g of the bitumen and swirled. A spatula was used to aid in the dissolution by mixing and (or) stirring the bitumen, but some solid material never dissolved. The liquid portion was filtered using a Büchner funnel and an additional 40 mL of pentane was added to the beaker. Even with more stirring, the residual solids did not dissolve in the additional pentane. The material in the beaker was filtered using the Büchner funnel. The residual solids weighed 0.63 g. To confirm that these solids were organic rather than sand or clay, the solids were placed on a watch glass and heated with a heat gun until they melted into a black tar.

Similar experiments were performed with toluene (25 mL of toluene dissolving 2.0 g of bitumen) and with $CyNMe_2$ (25 mL of $CyNMe_2$ dissolving 2.0 g of bitumen) instead of pentane; in both cases, dissolution was complete and no solids were observed visually.

Dissolving toluene-extracted bitumen with $CyNMe_2$

In a beaker, 34 g of oil sands was extracted twice with 10 mL of toluene, using a Büchner funnel to filter the liquids each time. The combined filtrate was transferred to a round-bottom flask and the solvent was removed by rotary evaporation followed by addition of methanol and evaporation of the methanol/toluene azeotrope. $CyNMe_2$ (20 mL) was then added to the resulting bitumen. Dissolution was complete and no solids were observed.

Removal of residual $CyNMe_2$ from the recovered sand/clay solids

Preparation of the sand/clay solids sample

Oil sands were washed with $CyNMe_2$, after which the slightly wet filtered solids were stored in a sealed jar. Small samples were placed into three 4 dram vials and ~2 mL of $CDCl_3$ was added to each vial, followed by 10 μL of ethyl acetate as an internal standard. The samples were shaken vigorously to remove any $CyNMe_2$ from the solids. The supernatant was removed and filtered into an NMR tube.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

Analysis of the liquid by NMR spectroscopy showed that the solids contained an average of 6.4 wt % $CyNMe_2$.

Washing the recovered solids with carbonated water

A 75–80 g sample of the slightly $CyNMe_2$-wet solids was placed into a 600 mL PTFE beaker with 100 mL of tap water. The mixture was stirred at 2400 rpm using an overhead stirrer equipped with a four-blade, 5 cm propeller, for the desired time, with or without CO_2 bubbling during the stirring. If CO_2 was used, it was added to the solution by bubbling through a gas dispersion tube at 1 atm. After the desired time, the solids were filtered using a Büchner funnel and No. 2 filter paper. If additional washes were required, the solids were scraped back into the beaker and a fresh 100 mL of tap water was added. The stirring and bubbling with CO_2 was repeated if necessary. After the final wash, the solids were filtered with the Büchner funnel and an additional 100 mL of tap water was poured over top to push through any residual carbonated water. The solids were scraped into a jar to be kept for analysis of $CyNMe_2$ content. Three samples of the solids were taken for NMR analysis. The samples were made by weighing an amount of the solids into a preweighed 1 dram vial, adding ~1 mL of $CDCl_3$ and 10 μL of EtOAc as an internal standard. The sample was shaken vigorously and the supernatant was filtered into an NMR tube. The wt % of $CyNMe_2$ on the solids was determined from an average of the three samples.

Comparing $CyNMe_2$ with other conventional solvents

Each sample of oil sand (30–50 g) was combined with solvent (1.5 grams of solvent per 5 grams of oil sands and either hexanes, hot water, toluene, or $CyNMe_2$) and visual observations were made every 5 min.

Recovery of solvent from carbonated water

All experiments were repeated at least twice to verify results, unless otherwise stated.

Using vacuum to recover the amine from the aqueous layer

A 32.3 wt % solution of $CyNMe_2$ (in its protonated form) in carbonated water was obtained as the aqueous fraction from an oil sands extraction performed as shown in Fig. 1. A 25 mL sample of this mixture was measured into a 500 mL round-bottom flask. The round-bottom flask was attached to a water condenser that was chilled to 5 °C, using an ethylene glycol/water chiller. A fractionation column was attached on top of the condenser to help with the evaporation problem and then a vacuum adaptor was attached to the top of the fractionation column. Using a diaphragm pump and vacuum controller the vacuum was set to the desired pressure. The round-bottom flask assembly was placed in a preheated oil bath set to the desired temperature. After the desired time, the solution was cooled and the pressure was released. The solution was decanted into a 50 mL graduated cylinder and the volumes of the layers were recorded. The concentration of DMCA in the aqueous layer was measured by removing an aliquot for analysis by NMR (using ethyl acetate as the internal standard and d_3-acetonitrile as the solvent).

Using nitrogen as a purge to recover $CyNMe_2$ from the aqueous layer

A 25 mL sample of the 32.3 wt % solution of $CyNMe_2$ in carbonated water was measured into a 500 mL two-neck round-bottom flask. One neck of the round-bottom flask was attached to a water condenser that was chilled to 5 °C, using an ethylene glycol / water chiller. A fractionation column was attached on top of the condenser, to further inhibit evaporative losses, and left open to the atmosphere. The second neck of the round-bottom flask was attached to a gas dispersion tube to deliver nitrogen at atmospheric pressure. The round-bottom flask was placed in a preheated oil bath set to the desired temperature. After the desired time, the solution was cooled and decanted into a 50 mL graduated cylinder to allow measurement of the volumes of the layers recovered. The concentration of $CyNMe_2$ in the aqueous layer was measured by removing an aliquot for analysis by ^1H NMR (using ethyl acetate as the internal standard and d_3-acetonitrile as the solvent).

Revised mechanism for the hydrolysis of ethers in aqueous acid[1]

Abstract: It has been shown recently that many supposed reaction intermediates in aqueous media do not have lifetimes long enough for them to serve this purpose. Among these are oxygen-protonated species where the positive charge is not delocalized, primary and secondary carbocations, and the commonly written species H_3O^+ and HO^-. This means that the mechanisms for many of the organic reactions that take place in aqueous media are in need of revision. This paper concerns the acid hydrolysis of simple ethers, many of which cannot form carbocations stable enough to exist in water. Rather than an A1 process in which an oxygen-protonated species dissociates into an alcohol and a carbocation, which is then quenched by water, or an A2 process in which a water molecule or another nucleophilic species assists in this, the mechanism for most ethers is a general-acid-catalyzed process in which proton transfer to oxygen is concerted with C–O bond cleavage in cases where a stable carbocation can exist, or additionally concerted with nucleophilic attack for those cases in which stable carbocation formation is not possible. All of the cases for which rate constant data could be found in the literature are analyzed and discussed in this paper, with the exception of the hydrolyses of several azoethers, where additional hydrolysis mechanisms are possible. These will be discussed in a subsequent paper.

Key words: ethers, hydrolysis, excess acidity, mechanism, acid media.

Résumé : Il a été démontré récemment que plusieurs intermédiaires réactionnels potentiels pour des réactions dans des milieux aqueux n'ont pas de temps de vie suffisants pour servir à ces fins. Parmi ceux-ci, les espèces contenant un oxygène protoné dans lesquelles la charge positive n'est pas délocalisée, les carbocations primaires et secondaires et les espèces communément représentées pas les formules H_3O^+ et HO^-. Cette observation implique qu'il faut réviser plusieurs mécanismes de réactions organiques se produisant dans des milieux aqueux. Dans ce travail, on examine particulièrement le cas des catalyses acides d'éthers simples pour lesquels plusieurs ne peuvent pas former de carbocations suffisamment stables pour exister dans l'eau. Plutôt q'un processus A1 dans lequel une espèce contenant un oxygène protoné se dissocie en un alcool et un carbocation qui est ensuite piégé par une molécule d'eau ou un processus A2 dans lequel une molécule d'eau ou une autre espèce nucléophile catalyse ce processus, le mécanisme pour la plupart des éthers est un processus de catalyse acide générale dans lequel le transfert de proton vers l'oxygène est concerté avec la rupture de la liaison C–O dans les cas où un carbocation peut exister ou, dans les cas où la formation d'une carbocation stable n'est pas possible, un processus dans lequel une concertation additionnelle d'une attaque nucléophile se fait sentir. On a analysé et on discute de tous les cas pour lesquels on peut trouver des données relatives à la constante de vitesse dans la littérature, à l'exception des hydrolyses de plusieurs azoéthers pour lesquels des mécanismes d'hydrolyse additionnels sont possibles. Ceux-ci seront discutés dans un travail ultérieur.

Mots-clés : éthers, hydrolyse, excès d'acidité, mécanisme, milieu acide.

[Traduit par la Rédaction]

Introduction

The excess acidity method has been shown to be the best method to use for the analysis of rate constant results obtained in aqueous acid media.[2–5] Recently, it has been found that the very commonly assumed species H_3O^+ does not have a long enough lifetime to act as a reaction intermediate in aqueous solution. This has been discussed at some length in a recent review,[2] and the excess acidity method showed itself to be very amenable to the analysis of rate data in this new situation, being applied to the hydrolyses of trioxane and diethyl ether there.[2]

The current paper amplifies this by covering all of the rate data for ether hydrolyses that could be found in the literature,[6–19] mostly by Lajunen and his group in Finland,[9–18] who used the excess acidity method themselves. Exceptions are some azoethers,[20–22] which are sufficiently different to require a separate paper. In fact, there is amazingly little rate data available; only one study uses aqueous HCl as a hydrolysis medium,[20] and none at all use HBr. Most of the studies were carried out using aqueous $HClO_4$,[6,7,9–20] which only has H_2O as an available nucleophile. The structures of the ethers dealt with in this paper are given as **1**–**19** in Scheme 1.

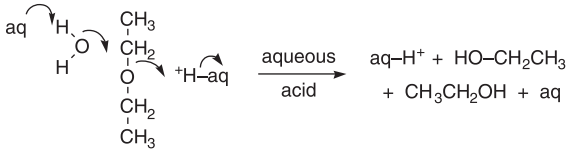
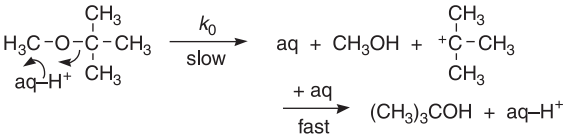
Scheme 1.



It is anticipated that a series of future papers dealing with other reaction mechanisms in need of modification will be required. The principle at work was first enunciated by Jencks[23] in terms of an "enforced mechanism". If an intermediate does not have a long enough lifetime in the reaction medium (i.e., existing there for at least a couple of molecular vibrations, say a lifetime of more than about 10^{-13} s),[24] it cannot be involved in the reaction, and a mechanism without it is "enforced".[23] Only the very latest fast IR technology can detect any kind of structure in protonated water, given as $H_{13}O_6^+$,[25] but even that only accounts for maybe 30% of the solvated protons, the IR spectrum degenerating to a continuum absorption.[26] This structure is by no means undisputed, theoretical calculations in particular suggesting a different one,[27] but the theoreticians agree that the positive charge in a proton cluster cannot be localized,[27,28] it is simply on the cluster as a whole. In terms of reaction mechanism, the actual structure of the solvated proton is unimportant, since all of the possibilities have exceedingly short lifetimes.



As far as ether hydrolysis is concerned, oxygen-protonated species in which the positive charge is not dispersed in some way (usually by resonance) also have lifetimes that are much too short to be reaction intermediates.[2,23] (This is not terribly surprising, one would have thought; $^+NR_4$ species are common enough in water, but $^+OR_3$ species, which are known, cannot exist in water, and $^+FR_2$ ones are not known at all.) This has the interesting consequence that, since the oxygen-protonated species cannot be a reaction intermediate, the pK_{BH^+} value for the site is of lesser importance, since it does not enter into the kinetic analysis.[2] Also, neither primary nor secondary carbocations in which the positive charge is not delocalized can exist in nonacidic aqueous media,[2,29] so they will probably not be reaction intermediates either.

The mechanism found for the hydrolysis of diethyl ether **1** is given in Scheme 2,[2] and Scheme 3 contains the likely mechanism for **3**, where the tertiary *tert*-butyl cation will probably be stable.

Scheme 2.

Scheme 3.

Experimental

$$[1] \qquad k_\psi C_S = k_0 a_S a_{H^+_{aq}} a_{H_2O} / f_\ddagger = k_0 C_S C_{H^+_{aq}} a_{H_2O} \frac{f_S f_{H^+_{aq}}}{f_\ddagger}$$

$$[2] \qquad \log k_\psi - \log C_{H^+} - \log a_{H_2O} = \log k_0 + m^\ddagger X$$

The excess acidity rate equation[5] that applies to Scheme 2 is eq. [1].[2] Here, the observed pseudo-first-order reaction rate constants as a function of acid concentration, and in many cases temperature, are k_ψ; values for **1**–**19** were taken from the literature.[6–19] The substrate concentration (C_S) cancels out on both sides; molar concentration, C; molar activity, a; and molar activity coefficient, f. The solvated proton concentration is $C_{H^+_{aq}}$, the molar water activity is a_{H_2O}, and the excess acidity is X; the published values for all of these in aqueous $HClO_4$, HCl, and H_2SO_4 media were taken from the literature[5] and corrected to the reaction temperature as before.[5] The logarithms of all activity coefficient ratios, such as the one in eq. [1], were assumed to be linear functions of X, no exceptions to this assumption having been found to date,[2,5] and so taking the logarithms of eq. [1] and rearranging results in eq. [2]. The slope parameter is given as $m^\ddagger$, since it refers to the transition state.[5] Since the protonated substrate is not an intermediate, it does not appear in the reaction schemes, and its pK_{BH^+} and m^* values[5] do not apply.

If the reaction in question follows Scheme 3, then the rate equation that is obeyed is eq. [3], which is simply eq. [2] without the water activity.

$$[3] \qquad \log k_\psi - \log C_{H^+} = \log k_0 + m^\ddagger X$$

$$[4] \qquad \log k_0 = 10.31883 + \log T - \frac{\Delta G_\Theta^\ddagger}{R\Theta \ln 10} + \frac{\Delta H_\Theta^\ddagger}{R\Theta \ln 10} \cdot \frac{T - \Theta}{T}$$

The rate constant for the reaction in the standard state, essentially water at 25 °C,[5] is k_0. If rate constants at different temperatures are not available, this quantity, perforce, refers to the reaction temperature. However, if they are available, $\log k_0$ can be expanded according to the Clarke and Glew formulation[30] (performs better in practice than the Eyring equation[31]) as shown in eq. [4]. This formulation has been found to be a more natural one to use, giving better numbers with errors that are independent of one another.[30] Here, the

absolute reaction temperature is T and Θ is the standard-state temperature of 298.15 K, 25 °C. The gas constant is R (1.98589 cal K^{-1} mol^{-1} here; 1 cal = 4.184 J) and the numerical term contains the Boltzmann and Planck constants required by the theory.[31] The entropy of activation $\Delta S_{\Theta}^{\ddagger}$ is easily obtained via $\Delta G_{\Theta}^{\ddagger} = \Delta H_{\Theta}^{\ddagger} - \Theta\Delta S_{\Theta}^{\ddagger}$.

All of the rate constant data[6–19] for **1**–**19** were analyzed according to Schemes 2 and 3, and the actual mechanism followed for the compound under analysis was indicated by the higher correlation coefficients and lower errors on the derived quantities. Data at only one temperature were analyzed by a simple linear regression of $\log k_{\psi} - \log C_{H^+_{aq}}(-\log a_{H_2O})$ vs X, and those at several temperatures by a double linear regression of $\log k_{\psi} - \log C_{H^+_{aq}}(-\log a_{H_2O}) - \log T$ vs X and $(T - \Theta)/T$. The programs used for the correlations will discard data points that, to 95% confidence, were not part of the same data set as the rest;[32] in this work this only happened twice.

Results

All of the statistical information obtained for **1**–**19**, analyzed according to both Schemes 2 and 3, is given in Table 1. This was used to decide on the mechanism followed by each compound, since in many cases plots according to both schemes were linear by eye. If the correlation coefficient was higher, and all of the errors listed in Table 1 (root-mean square deviation between experimental points and fitted line, error on the slope, error on the intercept, and errors on the enthalpy and entropy of activation) were lower, for one scheme over the other, that scheme was chosen as the mechanism which that compound followed. (For the double linear regressions, the F test was also provided by the program used, but since this is calculated using the same information as is used for the correlation coefficient, and thus gives the same result, it is not listed in Table 1.) For some of the simpler ethers (**2**, **3**, **4**, and **7**), there was simply not enough experimental data for this decision to be made, so it was based on likelihood, and the observed similarity in behavior to other compounds in the group. In the case of compounds **16** and **17**, it was not possible to decide between either scheme on any basis.

The experimental results calculated for each compound according to the chosen scheme, slopes, intercepts, and activation parameters, are given in Table 2 (both schemes for **16** and **17**). Also given are the solvent isotope effects found for many of the compounds; since these were all derived from only one measurement obtained in deuterated media,[6–19] the errors on them could not be obtained.

The results obtained for one of the simple ethers studied, isopropyl phenyl ether **6**,[11,12] are illustrated in Fig. 1. Two sets of results obtained by different people at different times were combined, and the agreement between them was excellent, it not being possible to distinguish points obtained in the different studies in the figure. It was found that **6** followed Scheme 3 rather than Scheme 2, so the quantity plotted against X in Fig. 1 is $\log k_{\psi} - \log C_{H^+_{aq}}$.

In Fig. 2, concerning both **10a** and **10b**,[14] plots according to both Scheme 2 (left axis) and Scheme 3 (right axis) are shown, and it can be clearly seen that these ethers follow Scheme 2 (linear) and not Scheme 3 (curves) (see Table 1).

In Fig. 3, for compounds **11** and **12**, plots according to both schemes are also shown, and it is again clear that both of these ethers hydrolyze according to Scheme 2. This is fairly obvious for **12**, but is not nearly so obvious for **11**, just by eyeballing the figure. Lajunen et al., who also used excess acidity plots, also saw this,[9–18] and often could not really decide between the A1 and A2 mechanisms, which at the time were thought to be the only possibilities available. However, the data are quite reliable enough to make the Scheme 2 decision (see Table 1).

Discussion

The simple ethers **1** and **2** clearly hydrolyze according to Scheme 2, a concerted process with a water molecule involved; none of the possible cationic intermediates would be stable under the reaction conditions. The excess acidity method is quite capable of deciding how many water molecules are involved in the reaction; in many cases, where water adds to a carbonyl group (ester hydrolyses,[33] amide hydrolyses,[34] or benzimidate hydrolyses[33]), two water molecules have been found to be involved. Here, however, it is only one. In the acidity region covered by the first set of results in Table 2, 60–90 wt % aqueous H_2SO_4,[6] the water activity is changing rapidly, but the proton concentration is not.[35] Assuming no water involvement leads to strong downward curvature in the excess acidity analysis (Table 1), and assuming two leads to curvature that is just as strong in the upward direction. Only one water molecule leads to the observed perfectly straight line.[2] In Table 2 there are two kinetic studies of the hydrolysis of **1**,[6,7] but they are not strictly comparable, since one of them was performed at 120.1 °C and high pressure,[7] whereas the other, already discussed,[2] was performed at normal pressure and at temperatures of 80–100 °C.[6] It probably would be possible to use the activation parameters in Table 2 to obtain a volume of activation for **1**, but this was not done as there was no way to estimate the error involved, which would probably be considerable. However, the $m^{\ddagger}$ slopes for both of the studies of **1** in Table 2 are, within experimental error, the same.

The other simple ethers (**3**–**7**) do form free carbocations. This is not surprising for **3** and **5**, which can give stable *tert*-butyl cations under the reaction conditions, and **7** gives a variety of reaction products derived from the Claisen rearrangement,[9] which does not require the formation of a detached carbocation.[9] However, **4** gives a wide variety of products derived from the isopropyl cation;[9] presumably, as the *n*-propyl group begins to detach and acquire positive charge it will rearrange to the isopropyl cation, which then attacks the substrate and the other reaction products.[9] The products were not given in the major kinetic study of **6**,[11] but in the other study of **6** various isopropylphenols were identified as reaction products.[12] The conclusion must be that the secondary isopropyl cation is indeed stable enough to be a reaction intermediate under the reaction conditions, which were really quite acidic, 9–10 mol/L aqueous $HClO_4$.[9,11,12] However, it is not formed nearly as readily as is the tertiary *tert*-butyl cation; according to the $\log k_0$ values in Table 1 **4** and **6** react much more slowly than do **3** and **5** (and **7**). Compounds **1** and **2** react much more slowly still and by a different mechanism.

[d]Root-mean-square error between experimental points and the fitted line. All the other errors in the table are standard deviations.

[e]±Error in the slope.

[f]±Error in the intercept.

[g]±Error in the enthalpy of activation (kcal mol^{-1}).

[h]±Error in the entropy of activation (cal deg^{-1} mol^{-1}).

[i]The original data are from ref. 6 and the analysis is from ref. 2.

[j]See text. The actual mechanism does involve a water molecule (see Scheme 4).

Compounds **8** and **9**, *exo*- and *endo*-2-phenoxynorbornane, respectively, were studied to see if the 2-norbornyl cation would be formed under the reaction conditions.[13] Table 2 shows that **8**, unlike **9**, reacts without the involvement of water and that it reacts some 4.5 orders of magnitude faster in the standard state due to the reaction having a much lower enthalpy of activation. Thus, the 2-norbornyl cation is evidently stable in the 4–7 mol/L aqueous perchloric acid reac-

[c]Enthalpy of activation (kcal mol^{-1}) at the standard temperature Θ of 25 °C, 298.15 K.
[d]Entropy of activation (cal deg^{-1} mol^{-1}), at the standard temperature Θ of 25 °C, 298.15 K.
[e]The original data are from ref. 6 and the analysis is from ref. 2.
[f]Impossible to decide between schemes on the basis of the statistical information in Table 1.

tion media,[13] but it can only be formed from the exo compound, presumably via anchimeric assistance by the suitably located C–C bonds. The endo isomer reacts with water according to Scheme 2. (The structure of the 2-norbornyl cation, which used to be described as nonclassical, was the subject of much argument in the literature before 1999, when Werstiuk and Muchall showed that it was T-shaped and that it was a π complex rather than being σ-bridged.)[36]

However, addition of electron-withdrawing groups to the phenyl ring of **8**, as in **10a** and **10b** (Fig. 2), is enough to change the mechanism from Scheme 3 back to Scheme 2; a free carbocation is not formed. Table 2 shows that the reaction is slower for **10a** and **10b** than it is for **8**. Compound **10a** also has a fairly negative entropy of activation in comparison with most of the other table entries. It may be that electron-donating substituents would change the situation, but experimental problems prevented a reliable study of any of these.[14]

Compounds **11** and **12**, norbornanes with methoxy rather than phenoxy substituents (Fig. 3), on the other hand, do not form free carbocations from either the exo- or endo-position. Compound **11** reacts more slowly than does **8**, and has a higher enthalpy of activation, and again the endo compound **12** reacts much more slowly than does the exo-**11**.

Of the five-member ring ethers **13**, **14**, and **15**, only **15** is in a position to give a stable carbocation, delocalized because of the double bond in the ring, and indeed this is how it reacts according to the statistical evaluation in Table 1, although there is not a lot of difference between the three according to the numbers in Table 2. Compound **15** is different from the other two in having a smaller $m^{\ddagger}$ slope and a smaller k_H/k_D value, but what, if anything, this means is not clear without having more information about other compounds to go on.

Compounds **16** and **17**, cyclopentyl and cyclohexyl phenyl ether, would probably be expected to react via Scheme 2, but the experimental data[12] did not permit a decision between Schemes 2 and 3 to be made (Table 1). Both react very slowly owing to a high enthalpy of activation (Table 2) and give phenol and the corresponding alcohols as the major products.[12]

Compounds **18** and **19** are different, not reacting according to Schemes 2 or 3, but preferring to ring-protonate,[19] which may be a good indication of the instability of oxygen-protonated species; these molecules would sooner lose their aromaticity than form undelocalized oxygen-protonated species. However, water is still involved in the slow step (see Table 1), and one possible mechanism for the reaction of these two compounds is given as Scheme 4. There is nothing wrong with protonated alkoxybenzenes as reaction intermediates,[37] but, since a water molecule is clearly involved in this reaction (Table 1), the intermediate in Scheme 4 is written as being

Fig. 1. Excess acidity plot according to Scheme 3 for the kinetics of the hydrolysis of isopropyl phenyl ether (**6**) at several different temperatures. (For clarity, single measurements at 55 and 65 °C[12] are not included in the figure.)

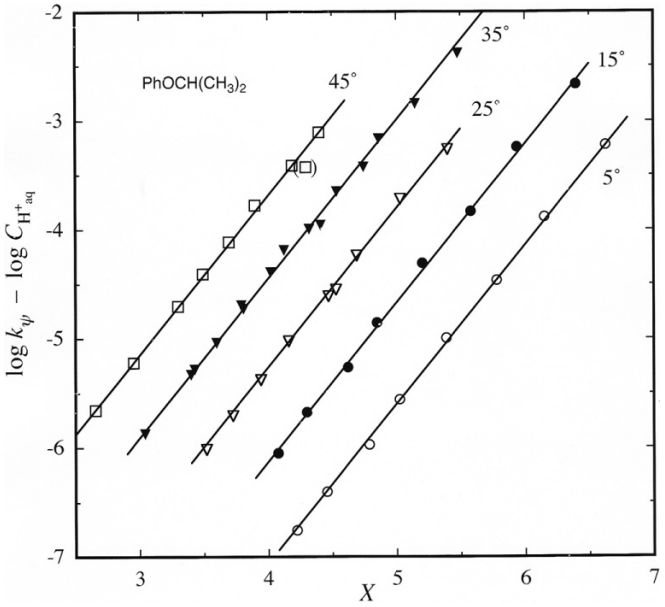

Fig. 2. Excess acidity plots according to Scheme 2 (linear, left axis) and Scheme 3 (curved, right axis) of the kinetics of the hydrolysis of compounds **10a** and **10b**.

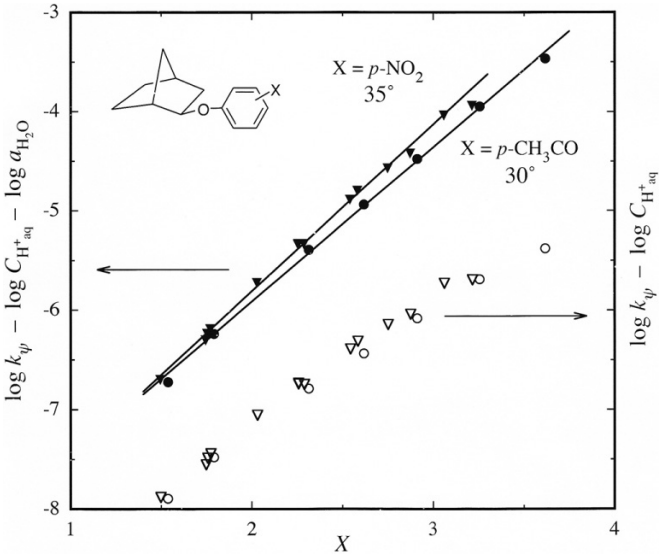

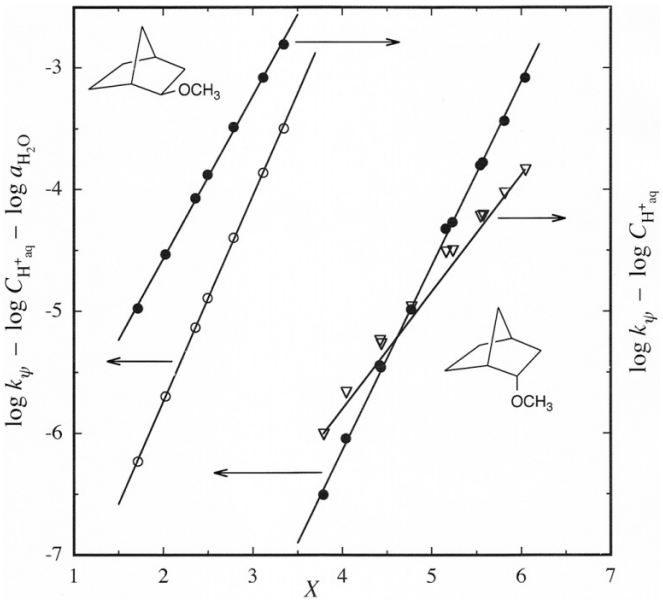

Fig. 3. Excess acidity plots according to Scheme 2 (left axis) and Scheme 3 (right axis) of the kinetics of the hydrolysis of compounds **11** and **12**.

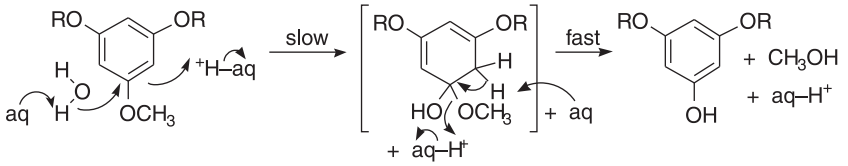
neutral. Compound **18** has an $m^{\ddagger}$ slope value of less than one, and both **18** and **19** have low activation enthalpies and large negative entropies of activation. For both compounds, the bond between the oxygen and the phenyl ring is the one cleaved, according to isotope exchange studies.[19]



All of the reported k_H/k_D values in Table 1 are around 0.5. Two competing effects are at work here. Acids are stronger in D_2O than they are in H_2O, which leads to k_H/k_D values of usually around 0.3 for reactions that are specific-acid-catalyzed (equilibrium protonation).[38] However, for the general acid catalysis seen here, this number would probably be greater than 0.5. D is heavier than H, which would lead to slower reaction in D_2O than in H_2O if proton transfer is involved in the slow step,[38] as it is in Scheme 2. It seems that the stronger acid effect wins out here. The k_H/k_D values for the Scheme 3 mechanism in Table 2, not involving proton transfer, do seem to be smaller than the others.

The slope values in Table 2, referred to as $m^{\ddagger}$, are really all over the place, ranging from a low of 0.9 to nearly 2.3. It was originally hoped[39] that these values would have a useful meaning in interpreting the mechanisms of reactions in acidic media, but it seems that this may not be the case, unlike the m^* slopes referring to equilibrium protonation, which do indeed seem to describe the behavior of different types of base in acidic media.[5,40] It is probably going to be necessary to collect a lot of these $m^{\ddagger}$ slopes for different reactions, particularly with the new interpretation of reaction mechanisms in aqueous media described before[2] and in this paper, and stare at the numbers before deciding whether or not they do in fact have any meaning and, if so, what it is.

In more general terms, Scheme 2 seems improbable on the face of it, since it seems to require several molecules to come together at the transition state. However, this is somewhat illusory. As has been pointed out before,[2] in a highly structured medium such as water,[41] with everything hydrogen-bonded together, all the water molecules and protons needed do not really have to be bought into position first. For instance, the ether oxygen is bound to be hydrogen-bonded to the solvent. The entropies of activation for all of the compounds for which they could be obtained in Table 2 are, with some exceptions, positive, or at least only slightly negative. The only process really contributing to the entropy change is the formation of two species from one, resulting in the small positive entropy of activation observed in most cases.

Reactions are known where solvent reorganization can be important; these often involve very short-lived intermediates.

Scheme 4.

One example is found in the addition of thiol anions to acetaldehyde in acidic media.[42] Here, the trapping by acid of an initially formed anionic addition intermediate with a very short lifetime is thought to be kinetically significant.[42] Another example is found in the hydrations of *cis*- and *trans*-cyclooctene in dilute aqueous acid. These give the cyclooctyl cation with an estimated lifetime of 5×10^{-12} s,[43] short enough not to be solvationally equilibrated. These may have to react by preassociation mechanisms; the cis-isomer is thought to react this way but not the trans.[43] This is not thought to be the case for any of the substrates involved in the work in this paper, but it is certainly a factor to be borne in mind.

In Eigen's[44] famous review the reaction rate constants for proton transfer reactions are given as being of the order of 10^{10} $(mol/L)^{-1}$ s^{-1} (see Table 4 of his review).[44] This implies a lifetime for protonated water species, whatever their structure, of some 10^{-10} s. However, this cannot be the case; if it were, the various individual protonated water species would give rise to identifiable IR or Raman spectra, which they do not.[25,26] On a more careful reading of the review, it becomes apparent that the measured rate constants for proton movement along hydrogen bonds, in ice and in water, actually result in lifetimes of the order 10^{-13} s for individual protonated water species.[44] This is exactly the same as the lifetimes implied by the modern fast IR measurements[25,26] discussed in the Introduction, and consistent with the Grotthuss chain-transfer process[45] for the movement of protons along hydrogen bonds.

The reactions under consideration here are all very slow. Solvent reorganization and proton transfer probably contribute maybe a kilocalorie or two, or the equivalent in entropy terms, to the overall activation energy in each case, but the enthalpy of activation values found in this work (Table 2) are very much higher than that. It is a simplification, of course, but probably the easiest way of thinking about the mechanisms of slow reactions in mainly aqueous media is that the protons and water molecules required by the reaction are pretty much already there. In Schemes 2–4, the frequently used term "aq" is simply meant to imply sources or sinks for protons and water molecules; they are not kinetically involved.

Together with the previous review,[2] the work described in this paper shows quite clearly that many commonly accepted reaction mechanisms in aqueous media are going to have to be revised. Also, it is probably best to write H^+_{aq} or aq–H^+, rather than H^+ or H_3O^+ in reaction schemes. H_3O^+ does not exist in water.[46]

Acknowledgments

Valuable correspondence with Professors Evgenii Stoyanov, Chris Reed, and Dan Singleton is gratefully acknowledged. I also thank the referees for their invaluable comments, which have contributed to making this a far better paper.

Symmetry-adapted perturbation theory study for some magnesium complexes

Mehdi D. Esrafili and Sirous Yourdkhani

Abstract: A systematic theoretical study on Mg–ligand interactions has been carried out employing both ab initio correlated wave function and density functional methods. The interactions of the $Mg(CH_3N_2)_2$ moiety with BF, CO, N_2, NH_3, and H_2O ligands have been investigated by performing calculations at the B3LYP, MP2, MP4, and CCSD(T)/6–311++G(3df,3pd) levels of theory. Results indicate that the interaction energies of the $Mg(CH_3N_2)_2$–L complexes increase in the order $NH_3 > H_2O > BF > CO > N_2$. Symmetry-adapted perturbation theory (SAPT) analysis has been carried out to understand the nature of the forces involved in the bonding. The SAPT results indicate that the stabilities of the Mg–L interactions are attributed mainly to electrostatic effects, while induction and dispersion forces also play a significant role. The evaluated SAPT interaction energies for the $Mg(CH_3N_2)_2$–L complexes are generally in good agreement with those obtained using the supermolecule CCSD(T) methods, suggesting that SAPT is a proper method to study the intermolecular interactions in these complexes. The results also suggest an explanation for the unique role of Mg^{2+} as a carrier of water molecules that mediate enzymatic hydrolysis reactions.

Key words: Mg–ligand interaction, SAPT analysis, ab initio, EDA.

Résumé : On a réalisé une étude théorique systématique des interactions Mg–ligand en faisant appel à des méthodes de fonction d'onde ab initio corrélée et fonctionnelle de la densité. Les interactions de la portion $Mg(CH_2H_2)_2$ avec les ligands BF, CO, N_2, NH_3 et H_2O ont été étudiés en faisant des calculs aux niveaux B3LYP, MP2, MP4 et CCSD(T)/6–0311++G(3df,3pd) de la théorie. Les résultats indiquent que les énergies d'interaction des complexes $Mg(CH_2H_2)_2$–L augmentent dans l'ordre $NH_3 > H_2O > BF > CO > N_2$. On a effectué une analyse selon la théorie de la perturbation adaptée à la symétrie (TPAS) dans le but de comprendre la nature des forces impliquées dans les liaisons. Les résultats de la TPAS indiquent que les stabilités des interactions Mg–L peuvent être attribuées principalement aux effets électrostatiques, alors que les forces d'induction et de dispersion jouent aussi un rôle important. Les énergies d'interactions telles qu'évaluées par la TPAS pour les complexes $Mg(CH_2H_2)_2$–L sont généralement en bon accord avec celles obtenues à l'aide des méthodes de la supermolécule, CCSD(T); ces résultats suggèrent que la méthode TPAS est une méthode qui peut très bien s'appliquer à l'étude des interactions intermoléculaires dans ces complexes. Les résultats suggèrent aussi une explication pour le rôle unique du Mg^{2+} comme porteur de molécules d'eau pour catalyseur les réactions d'hydrolyse enzymatiques.

Mots-clés : interaction Mg–ligand, analyse par la théorie de la perturbation adaptée à la symétrie (TPAS), ab initio, « EDA ».

[Traduit par la Rédaction]

Introduction

It is widely known that metal–ligand interactions are very important for the structures and stabilities of a broad range of biological complexes and crystals.[1–5] Magnesium (Mg) plays a prominent role in many structural and reactive biochemical processes. Over 300 enzymes require Mg ions for their catalytic activity, including all enzymes utilizing or synthesizing adenosine triphosphate (ATP),[6–8] or those that use other nucleotides to synthesize DNA and RNA.[9–11] ATP exists in cells normally as a chelate of ATP and a Mg ion. As the Mg ion has only one valence state, +2, it cannot play a direct role in any redox-mediated enzymatic reactions. The general mode of action of Mg cations in such enzymes appears to be to bind portions of the active site. Mg plays a central role in plants and is necessary for synthesis of chlorophyll and photosynthesis.[12] A combination of different factors, rather flexible coordination geometry and the relatively high charge density, makes divalent Mg, Mg(II), capable of satisfactorily coordinating with the broad spectrum of "hard" and "soft" ligands present in metalloenzymes. Thus, an accurate and well-balanced theoretical description of the ligand binding ability and hydration of Mg(II) ions is required to increase our understanding of Mg enzymology using the tools of computational quantum chemistry.

In principle, the supermolecular ab initio calculations have become very popular tools for the investigation of intermolecular interactions. However, this method does not provide

Fig. 1. Optimized structures and calculated dipole moments of $Mg(CH_3N_2)_2$–L complexes at the MP2/6–311++G(3df,3pd) level of theory, L = BF, CO, N_2, NH_3, and H_2O.

information on the character of these interactions. To get more insight into the physical nature of the interaction one can use the Kitaura–Morokuma (KM) interaction energy decomposition scheme[13] or the perturbation scheme known as the symmetry-adapted perturbation theory (SAPT) method.[14–16] The first step in such an investigation is to find the optimal structure on the intermolecular potential energy surface by a supermolecular method, while the second stage is to perform the SAPT calculations for the minimal configuration. In particular, SAPT provides not only a conceptual basis for understanding intermolecular interactions, but also an efficient computational framework for accurate predictions of interaction energies. In SAPT, the interaction energy is calculated as the sum of terms of distinct physical origin (i.e., the

For personal use only.

first-order electrostatic and the second-order induction and dispersion energies) each of these terms being accompanied by a corresponding exchange correction due to the simultaneous exchange of electrons between the monomers. In the many-body version of SAPT the interacting monomers are described through Møller–Plesset or even coupled cluster theory, depending on the accuracy required for each individual interaction term. The quality of the total interaction energies compares with that obtained from the CCSD(T) method.[17,18]

Several computational studies on Mg–ligand interactions have been published[19–26] in which the application of various density functional theories (DFT) or second-order Møller–Plesset (MP2) perturbation theory was assessed by performing ab initio calculations on small Mg complexes. Among these are Mg–aqua complexes,[19–21] clusters containing one or two formates,[22] and complexes with a single neutral ligand, such as cytosine or a guanine–cytosine base pair.[23,24] In addition, earlier investigations indicated that chlorophyll interacts with nucleophilic ligands and forms stable monosolvates with nucleophiles, such as water, alcohols, amines, ketones, and ethers.[27–30] It was also known that Mg in chlorophyll with coordination number 4 is coordinately unsaturated. It is the coordination unsaturation of the Mg that leads to chlorophyll–nucleophile interactions, and in the absence of extraneous nucleophiles, to self-interactions to form dimers.[31] Thus, in nonpolar solvents, the coordination unsaturation of the Mg is relieved by coordination of the ketone oxygen function of one chlorophyll molecule with the Mg atom of a second chlorophyll molecule to form a dimer. Krauss and Stevens[32] have evaluated the binding energies for a series of hexacoordinated Mg complexes containing one formate and varying numbers of water and formamide ligands. In most cases only the binding energy[20,22–26] or enthalpy[20,21] was calculated, and no systematic high-level study on the nature of ligand to metal binding appears to have been performed to date.

The first goal of this investigation is to provide reliable high-level ab initio results for a set of 1:1 complexes to improve the energetic, structural, and electronic description of the ligand binding ability of a simplified chlorophyll model (Fig. 1). In the model, the combination of the two amidine ligands, $CH_3N_2^-$, has the same charge and bonding geometry as the full porphyrin ring. We hereby investigate the intrinsic properties for binding of L = BF, CO, N_2, H_2O, and NH_3 ligands to the $Mg(CH_3N_2)_2$ complex. A second goal of this study is the analysis of the nature of the metal–ligand bond in the Mg(II) complexes by means of an energy decomposition method. This provides information on the relative importance of the electrostatic, induction, and dispersive contributions to the interaction energy. Altogether our results could be particularly useful for the refinement of molecular mechanics force fields as well as comparison with other partitioning schemes used for the calibration of some molecular mechanics potentials.

Computational details

Ab initio and DFT calculations

All ab initio and DFT calculations were performed using the Gaussian 03 package.[33] The geometry of the investigated $Mg(CH_3N_2)_2L$ complexes was optimized at the MP2 level employing the 6–311++G(3df,3pd) basis set. Then corresponding frequency calculations were carried out at the same level to ensure that the optimized structures are true minima. The interaction energy for each complex was calculated at the HF, MP2, MP4, CCSD(T), and B3LYP levels of theory by using the supermolecule method,[34] which defines it as the difference between the energy of the cluster and those of the individual molecules in isolation

$$[1] \qquad E_{\text{int}} = E_n - \sum_i^n E_i$$

where E_n is the total energy of the cluster of size n, and E_i is the energy of the individual monomers in the cluster geometry. The results of eq. [1] are subject to the basis superposition error (BSSE) as each molecule uses the basis set of the others in the cluster, decreasing the energy and resulting in overestimated interaction energies. Hence, BSSE was corrected by using the Boys and Bernardi counterpoise (CP) method.[35]

Energy decomposition analysis

For SAPT energy decomposition analysis, molecular integrals were first obtained with the DALTON 2.0 package;[36] SAPT partitioning was then performed using the SAPT2008 program.[37] The SAPT interaction energy is represented as a double perturbation expansion of various polarization and exchange contributions.[38]

$$[2] \qquad E_{\text{int}} = \sum_{n=1}^{\infty}\sum_{j=0}^{\infty}\left(E_{\text{pol}}^{(nj)} + E_{\text{exch}}^{(nj)}\right)$$

The polarization corrections of the first order in intermolecular interaction, $E_{\text{elst}}^{(1j)}$, describe the classical electrostatic interaction and are denoted $E_{\text{pol}}^{(1j)}$. The $E_{\text{exch}}^{(1j)}$ is the repulsive first-order exchange component resulting from the antisymmetrization (symmetry adaption) of the wave function. The second-order corrections can be decomposed into the induction and dispersion parts.

$$[3] \qquad E_{\text{pol}}^{(2j)} = E_{\text{ind}}^{(2j)} + E_{\text{disp}}^{(2j)} \quad \text{and} \quad E_{\text{exch}}^{(2j)} = E_{\text{exch-ind}}^{(2j)} + E_{\text{exch-disp}}^{(2j)}$$

The induction component is the energy of interaction of the permanent multipole moments of one monomer and the induced multipole moments on the other, whereas the dispersion part comes from the correlation of electron motions on one monomer with those on the other monomer.

In this study, two different levels of SAPT calculations were used

$$[4] \qquad \text{SAPT0} = E_{\text{elst}}^{(10)} + E_{\text{exch}}^{(10)} + E_{\text{ind,resp}}^{(20)} + E_{\text{exch-ind,resp}}^{(20)} + E_{\text{disp}}^{(20)} + E_{\text{exch-disp}}^{(20)} + \delta E_{\text{int,resp}}^{(\text{HF})}$$

$$[5] \qquad \text{SAPT} = \text{SAPT0} + E_{\text{elst,resp}}^{(12)} + E_{\text{elst,resp}}^{(13)} + {}^tE_{\text{ind}}^{(22)} + {}^tE_{\text{exch-ind}}^{(22)} + \varepsilon_{\text{exch}}^{(1)}(\text{CCSD}) + \varepsilon_{\text{disp}}^{(2)}(2)$$

where $\varepsilon_{\text{exch}}^{(1)}(\text{CCSD}) = E_{\text{exch}}^{(1)}(\text{CCSD}) - E_{\text{exch}}^{(10)}$, and $\varepsilon_{\text{disp}}^{(2)}(2) = E_{\text{disp}}^{(21)} + E_{\text{disp}}^{(22)}$. The subscript "resp" indicates that the induc-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

tion and exchange–induction contributions include the coupled–perturbed HF response.[38] $\delta E_{int,resp}^{(HF)}$ contains the third- and higher-order HF induction and exchange induction contributions. The ${}^{t}E_{ind}^{(22)}$ represents the part of $E_{ind}^{(22)}$ that is not included in $E_{ind,resp}^{(20)}$.

We also performed energy decomposition analysis based on KM method[13]

$$[6] \quad E_{int}(\mathrm{RHF}) = E_{elst} + E_{exch} + E_{CTPLX(Mg\rightarrow L)} + E_{CTPLX(L\rightarrow Mg)} + R$$

where E_{elst} and E_{exch} are electrostatic and exchange, respectively; E_{CTPLX} refers to the charge-transfer and polarization coupled term; and R is the coupling term. All KM analyses were performed using the GAMESS program.[39]

Results and discussion

Geometries and binding energies

Figure 1 shows the optimized structures for the complexes formed between $Mg(CH_3N_2)_2$ moiety and the neutral ligands (L = BF, CO, N_2, NH_3, and H_2O). All the structures were characterized as energy minima on the MP2/6–311++G(3df,3pd) potential energy surface with C_S symmetry. For each complex shown in Fig. 1, the equilibrium Mg–L distance involving the Mg atom and the donor atom of the ligand, Mg–N_A lengths and the optimized $\angle N_A$–Mg–L bond angle are also reported (N_A refers to the amidine nitrogen). The individual distances and angles correspond to fully optimized dimer structures, that is, with both inter- and intra-molecular degrees of freedom relaxed. From Fig. 1, it is apparent that the estimated Mg–L distances are in a range 2.104–2.488 Å, which is much smaller than the sum of van der Waals radii of corresponding counterparts. The binding distance is calculated to be 2.104 Å in the $Mg(CH_3N_2)_2$–H_2O complex that is about 0.4 Å shorter than the $Mg(CH_3N_2)_2$–BF one. More specifically, the optimized Mg–H_2O bond distance is slightly longer than the Mg–O(H_2O) distances in the $[Mg(H_2O)_{6-n}(CH_3OH)_n]^{2+}$ (n = 1–6) complexes[40] and the crystalline structure of $Mg[H_2O]_6^{2+}$[41]. In the $Mg(CH_3N_2)_2$, the Mg atom is in the plane of the amidine ligands. However, the binding of L ligands to Mg lead to very different $\angle N_A$–Mg–L values. It is expected that the $Mg(CH_3N_2)_2$–L complex formation is associated with a dipole moment enhancement due to the charge transfer and electron polarization of the molecules involved in the interaction. Dipole moments (μ) of the free ligands and the $Mg(CH_3N_2)_2$–L complexes are shown in Fig. 1. For all the complexes studied here, the largest dipole moment component is directed along the Mg–L bond. The estimated dipole moments for the $Mg(CH_3N_2)_2$–L complexes are 3.01 D (H_2O), 2.89 D (NH_3), 2.15 D (BF), 0.77 D (N_2), and 0.56 D (CO). One possible explanation for the small dipole moment of the $Mg(CH_3N_2)_2$–CO system may be the unfavorable orientation of individual C=O and $Mg(CH_3N_2)_2$ dipoles in the complex.

Table 1 lists the CP-corrected interaction energies obtained at the HF, MP2, MP4, CCSD(T), B3LYP, SAPT0, and SAPT methods. From a more quantitative point of view, the first important finding is that values of the interaction energies depend appreciably on the method used and (or) the dimer considered. First, it is evident that E_{int}^{HF} is always smaller in magnitude than others. It is clear from Table 1 that the interaction energies of these complexes increase in the order $NH_3 > H_2O > BF > CO > N_2$. A more detailed analysis of these results shows that, in general, the SAPT0 and MP2 methods provide larger stabilization energies than the others. Considering the MP2 results, it is evident that the inclusion of correlation reproduces a stabilization of the complexes as high as 0.8–11.7 kJ/mol. Higher order perturbation (MP4) exhibits only minor variation on the ligand binding energies. As can be seen, the HF method greatly underestimates the interaction energies of the complexes and, in the cases of N_2 ligand, predicts a small binding energy of –0.80 kJ/mol. This indicates that dispersion must play a large role in the stabilization of the $Mg(CH_3N_2)_2$–N_2 complex. The fact that HF interaction energies for the $Mg(CH_3N_2)_2$–NH_3 and $Mg(CH_3N_2)_2$–H_2O are more negative suggests that these interactions may depend more on electrostatic effects than those occurring between the $Mg(CH_3N_2)_2$ and L = BF, CO, and N_2. Previous publications[42,43] demonstrated that the difference between the MP2 and HF energies is mainly assigned to the effects of high-order electrostatic interaction. Consequently, owing to the significant gain of the attraction by electron correlation (0.8–11.7 kJ/mol at the MP2 level), dispersion force plays a considerable role in the stability of the complexes. Focusing on the CCSD(T) results, which are available for each type of system considered, it can be seen that the NH_3 is bound about –53 kJ/mol more strongly than N_2. It should also be noted that the MP2 binding energies are all slightly higher than those of CCSD(T) and that the difference between MP2 and CCSD(T) binding energies increases in the order $N_2 > CO > NH_3 > H_2O > BF$.

Table 1. Calculated binding energies of $Mg(CH_3N_2)_2$–L (L = BF, CO, N_2, NH_3, and H_2O) complexes with different levels of theory using 6–311++G(3df,3pd) basis set.

SAPT	–34.8	–18.5	–11.6	–80.97	–64.43

Note: All interaction energies in –kJ/mol.

Prior to examining the individual contributions to the intermolecular energy, we shall discuss the accuracy of the SAPT0 and SAPT results. From Table 1, it is evident that the SAPT0 binding energies are all slightly higher than those of MP2 as computed using the 6–311++G(3df,3pd) basis set and that the difference between MP2 and SAPT0 energies increases as the interaction between the Mg and ligand becomes more negative. Similar as in supermolecular results, the $Mg(CH_3N_2)_2$–NH_3 is the most stable complex (–94.71 kJ/mol at the SAPT0 level). Table 1 also indicates that the SAPT interaction energies for the title complexes are generally in good agreement with those obtained using the supermolecule MP4 and CCSD(T) methods, suggesting that SAPT is a proper method to study the intermolecular interactions in these studied complexes. The calculated SAPT binding energy for the $Mg(CH_3N_2)_2$–NH_3 complex

is –80.97 kJ/mol, which overestimates CCSD(T) and MP4 energies by about 0.13 and 0.54 kJ/mol, respectively. It is interesting to note that, in the case of the BF ligand, SAPT binding energies are underestimated in relation to MP4.

Figure 2 presents the variation of the interaction energies with the separation distance, $r_{Mg–L}$, for the $Mg(CH_3N_2)_2$–L complexes using different correlated methods. In each case, a distinct minimum is observed; however, for the L = N_2,

the minimum observed is slightly shallow in nature. If one compares the potential energy curves (PECs) obtained with more accurate and sophisticated CCSD(T) results, a close agreement of the CCSD(T) distance with SAPT results is found. On the contrary, the SAPT0 method fails to produce the CCSD(T) results. The MP2 and MP4 methods quite satisfactorily produce the PECs and are in good agreement with the CCSD(T) and SAPT results. A close inspection of Fig. 2 reveals an interesting observation. Because the Mg–CO and Mg–N_2 interactions are dominated by electrostatic and dispersion interactions, the DFT/B3LYP was found unable to yield satisfactory PECs because about 40% of the short-range dispersion energy is neglected by the B3LYP functional.[44] From Fig. 2, we also see that the difference between SAPT0 and SAPT is largest at short distances and dies off to zero at large distances. This suggests that intramolecular correlation effects are significant at short binding distances.

Interaction energies partitioning

To better understand the nature and the extent of different forces contributing to the intermolecular attraction in the $Mg(CH_3N_2)_2$–L complexes, individual energy components of the total interaction energy were obtained using the SAPT. The electrostatic component of the interaction energy is represented here by the sum of $E_{elst}^{(10)}$, $E_{elst,resp}^{(12)}$, and $E_{elst,resp}^{(13)}$. From Table 2, it is evident that the electrostatic energies dramatically increase as we progress from N_2 to NH_3. The electrostatic interaction pulls the two monomers close to each other, which results in large values of all other energy components. For L = N_2, CO, and BF, the exchange energy becomes even larger than the absolute value of the electrostatic energy, but the large attractive induction and dispersion energies lead to a stabilizing interaction. From Table 2, it is found that all contributions of the electrostatic, induction, and dispersion terms have a stabilizing effect. Of course, the major contribution is the electrostatic interaction energy, which presents between 49% and 74% of the total stabilization energy. Considering the SAPT results, it is also found that first-order electrostatic effects ($E_{elst}^{(10)}$) account for about 75% of the overall attraction in the Mg–NH_3 complex. By comparison, the induction component of this interaction represents about 17% of the total attractive forces, whereas dispersion contributes 8% to the stability of this complex. Thus, it can be said that BF, CO, NH_3, and H_2O interactions are remarkably dependent on both electrostatic and induction forces, with electrostatic playing the largest role in their stability. Based on our SAPT results, the electrostatic contribution to the overall attraction energies of L = BF, CO, N_2, NH_3, and H_2O are 66%, 64%, 49%, 74%, and 73%, respectively. The first-order electrostatic effect can be interpreted mainly as the dipole–dipole interaction, which is why $E_{elst}^{(10)}$ is larger for the NH_3 ligand than for N_2. It is clear in the light of the values of the dipole moments of the two molecules (0.00 (N_2) and 1.71 D (NH_3)).

The total first- and second-order exchange contributions (including both induction and dispersion contributions) reduce the stabilizing effect of the terms just discussed. As expected, the major exchange contribution results from the first-order exchange term, which represents 85%–90% of the total exchange contribution at intermediate distances, whereas the second-order induction and dispersion components represented 3%–8% and 1%–3% of the total exchange, respectively. Regarding the total exchange energy, we obtained the

Note: All interaction energies terms in kJ/mol.

following order: BF > NH_3 > H_2O > CO > N_2. For L = BF, CO, and N_2, the exchange repulsion is more than three times the total energy (in absolute value), and it overcompensates the attractive electrostatic term, thus, the first-order energy is repulsive.

The induction contribution to the interaction energy is mainly contained in $E^{(20)}_{ind,resp}$. This is a second-order energy correction that results from the distortion of the charge distribution of one monomer by the electrostatic charge distribution of another monomer, and vice versa. This mutual polarization of the monomer by the static electric field of the other is the polarizabilities of the monomers. Consequently, in the traditional X–Y···Z complex the effect would be larger the more polar the X–Y bond becomes. The leading intramonomer correlation contribution is included in $^tE^{(22)}_{ind}$ and accounts for only 0.5%–3% of the induction energy. The attractive part of the induction energy is substantially quenched by the repulsive exchange-induction energy (represented by $E^{(20)}_{exch-ind,resp}$ and $^tE^{(22)}_{exch-ind}$). It is interesting to note that, although these types of interactions are largely dependent on electrostatic forces, the induction interaction between the $Mg(CH_3N_2)_2$ moiety and L seems to play a significant role in determining the geometric structures and stabilities of these complexes. For the H_2O, NH_3, and CO ligands, the estimated induction energy contribution to the total stabilization energy is about 17%. This contribution is even larger for the L = BF and N_2 complexes. This is probably due to the larger polarizability of N_2 and BF compared with the others.

The other attraction effect comes from dispersion and this term is significantly greater in absolute value for the Mg–NH_3 complex than for others. The ratios of the $E^{(20)}_{disp}$ term to the total SAPT energy are evaluated to be 144% (N_2), 87% (CO), 50% (BF), 24% (NH_3), and 21% (H_2O). In the molecule–molecule interaction involving closed-shell species, the interplay between the induction and dispersion effects may be well-characterized by analyzing the ratio of these two contributions, $E^{(20)}_{exch-disp}/E^{(20)}_{exch-disp,resp}$.[45] The greatest ratio should indicate the system particularly favored by the dispersion ef-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13

fect. The ratios are 1.02, 1.00, 0.34, 0.24, and 0.06 for H_2O, N_2, NH_3, CO, and BF, respectively.

Additionally, for comparison of the two decomposition schemes SAPT and KM, we also performed KM decomposition for the title systems. It may be noted that SAPT contributions are closely related to KM's three-component decomposition of a Hartree–Fock interaction energy into Coulomb, Heitler–London, and CTPLX terms. For a quantitative comparison of SAPT and KM results, all calculations have to be made in the same "Gaussian" basis sets. According to Table 2, the first-order polarization contribution in SAPT exactly equals the E_{elst} term in the KM scheme, as they are defined in the same way. When we compare the relative metal-to-ligand energy for the different Mg–L complexes, we get the following order: BF > NH_3 > CO > N_2 > H_2O. Table 2 also indicates that, for the L = BF, CO, N_2, NH_3, and H_2O ligands, the ligand-to-metal term yields about 5%, 11%, 11%, 8%, and 12% of the total attractive forces, respectively. Therefore, the Mg–L bonds in $Mg(CH_3N_2)_2$–L complexes have more electrostatic than covalent character, especially in the $Mg(CH_3N_2)_2NH_3$ complex. The induction energy can be described as resulting from the interaction between the highest occupied molecular orbital and the lowest unoccupied molecular orbital. The inductive type of molecular orbital interaction can also be correlated to the extent of charge transfer. It would be interesting to examine if the extent of charge transfer can be correlated to the total induction energy. From Fig. 3, it is clear that the total CTPLX term correlates significantly with $E_{ind}^{(20)}$. However, a much better correlation may be found if one considers the $E_{ind,resp}^{(20)} + E_{exch-ind,resp}^{(20)} + \delta E_{int}^{HF}$ term instead of $E_{ind}^{(20)}$. It suggests that the both charge-transfer and polarization effects are important, and their magnitudes depend on the Mg–L interaction under study.

Within the single-exchange approximation, the uncorrelated Hartree–Fock limit leads to a strict coincidence between first-order exchange-repulsion ($E_{exch}^{(10)}$) and the Heitler–London exchange.[46] With approximate Hartree–Fock wave functions for the monomers, a "complementary exchange energy" may be added: $E_{exch}(KM) = E_{exch}^{(10)} + \varepsilon_{compl\text{-}exch}$. The complementary exchange disappears in the full-exchange series beyond the single-exchange approximation, if and only if the monomer ground-state wave functions used in perturbation treatment are the correlated ground-state wave functions. It is also a very useful quantity to evaluate the quality of a given finite basis set for computing intermolecular interactions. Because the exact and single-exchange complementary exchange energies are almost identical for larger intermolecular distances, $\varepsilon_{compl\text{-}exch}$ is a good indicator of how far an approximate SCF wave function built from some given basis set is from the Hartree–Fock limit. In Table 3, we present the values obtained for $\varepsilon_{compl\text{-}exch}$ at a few representative intermolecular distances for the treated different dimers. We also report the values of the Heitler–London exchange energy for comparison. The values obtained for $\varepsilon_{compl\text{-}exch}$ were found to be in good agreement with typical values reported for hydrogen-bonded clusters.[47] This illustrates the good quality of the basis sets used in this work.

Concluding remarks

In summary, we have systematically investigated the interaction of small ligands BF, CO, N2, H_2O, and NH_3 with $Mg(CH_3N_2)_2$. We also focused on the decomposition of the interaction energy into physically meaningful terms and on the basis of the parameters of molecular properties characterized and described the intermolecular interaction. Our results can be summarized as follows:

1. Our results indicated that the interaction energies of the $Mg(CH_3N_2)_2$–L complexes increase in the order NH_3 > H_2O > BF > CO > N_2. A more detailed analysis of these results shows that, in general, the SAPT0 and MP2 methods provide larger stabilization energy than the others. Furthermore, the SAPT interaction energies for the title complexes are generally in good agreement with those obtained using the supermolecule MP4 and CCSD(T) methods, suggesting that SAPT is a proper method to study the intermolecular interactions in these studied complexes.
2. It is evident that the electrostatic energies dramatically increase as we progress from N_2 to NH_3. For L = N_2, CO, and BF, the exchange energy becomes even larger than the absolute value of the electrostatic energy, but the large attractive induction and dispersion energies lead to a stabilizing interaction.
3. The major exchange contribution results from the first-order exchange term, which represents 85%–90% of the total exchange contribution at intermediate distances, whereas the second-order induction and dispersion components represent 3%–8% and 1%–3% of the total exchange, respectively.
4. We found a reasonable correlation between the total KM CTPLX term and the SAPT induction energy. It suggests that the both charge-transfer and polarization effects are important, and their magnitudes depend on the Mg–L interaction under study.
5. The values obtained for $\varepsilon_{compl\text{-}exch}$ were found to be rather small when compared with typical values. This illustrates the good quality of the basis sets used in this work.

Acknowledgments

MDE wishes to thank Professor K. Morokuma, (Fukui Institute for Fundamental Chemistry, Kyoto University, Japan) for many stimulating and helpful discussions as well as technical support.

Theoretical prediction of gas adsorption kinetics based on equilibrium data

Krzysztof Nieszporek and Tomasz Banach

Abstract: Based on the equilibrium adsorption isotherms, new expressions describing the rate of adsorption were developed. The theoretical model takes into account the influence of diffusional effects on the rate of adsorption. Other nonideal effects such as surface energetic heterogeneity or intermolecular interactions can be taken into account by using the adequate equilibrium isotherm. The accuracy of the presented rate equations was verified using real adsorption systems.

Key words: adsorption, kinetics, equilibria, isotherm, thermodynamics.

Résumé : En se basant sur les isothermes d'absorption d'équilibre, on a développé de nouvelles expressions pour décrire la vitesse d'adsorption. Le modèle théorie tient compte de l'influence des effets de diffusion sur la vitesse d'adsorption. L'utilisation de l'isotherme d'équilibre adéquate permet aussi de tenir compte d'autres effets de non-idéalité, telle l'hétérogénéité énergétique de la surface ou les interactions intermoléculaires. On a vérifié le degré d'exactitude des équations de vitesse présentées en faisant appel à des systèmes d'adsorption réels.

Mots-clés : adsorption, cinétique, équilibre, isotherme, thermodynamique.

Introduction

Over the last few decades, the wide application of adsorption phenomena in the chemical, environmental, and biotechnology industries can be observed. Purification and separation using adsorption processes is environmentally friendly and more economical than traditional methods. As the software-controlling apparatus should quickly respond to the changing process conditions, there is a need for analytical expressions describing equilibrium and rate of adsorption.

There are several models for adsorption equilibrium isotherms. The most basic of them is the still being developed Langmuir model.[1] It assumes the lattice of identical adsorption centers on a flat surface, a single adsorption layer, and a lack of interactions between adsorbed molecules. Modifications of the Langmuir isotherm have been carried out in two directions. The first takes into account the interactions between adsorbed molecules. For example, by using the Bragg–Williams approximation, the new Fowler–Guggenheim isotherm was proposed.[2] The other modifications of the Langmuir isotherm deal with surface nonideal effects called energetic heterogeneity. By applying the integral equation approach it has been shown that, for example, the Temkin, Freundlich, and Dubinin–Radushkevich isotherms are the extensions of the Langmuir isotherm for energetically heterogeneous surfaces.[3]

It is well-known that the rate of adsorption can be controlled by two factors: the diffusion effects and the speed of surface reaction depending on the interaction energy of the adsorbed molecules with the surface and neighbouring particles. There are many papers dealing with the theoretical description of the experimental kinetic isotherms,[4] but, in most cases, the authors use old well-known expressions; for example, Lagergren,[5] the pseudo-second-order equation,[6] etc. Although these expressions are based on the surface-reaction model, it is well-known that the transport of substance from the bulk phase to the surface occurs in several steps. Thus, the overall process of adsorption may be controlled by film (or external) diffusion, pore diffusion and adsorption on the surface, or combination of more than one step. The main goal of the present paper is the theoretical description of a kinetics experiment considering the combined mechanism of the adsorption rate. We show a new theoretical model describing the kinetics of gas adsorption by using the equilibrium isotherms. Therefore, to have a thorough representation of adsorption kinetics, it is necessary to use a suitable equilibrium isotherm equation. The proposed expressions are the alternative to those developed by using the statistical rate theory (SRT) of interfacial transport.[7–9]

Our theoretical studies were examined based on the literature experimental adsorption data.[10] They included alkane adsorption data on activated carbons.

Theory

It has been shown that the correct description of adsorption kinetics should take into account the effect of the pressure or concentration gradient in the near-surface region.[11,12] It can be assumed that there exists a subsurface region located close to the surface of adsorbing molecules. In this region the ad-

sorbate pressure (p) differs from that in the bulk phase (p^0), i.e., from the bulk pressure monitored during a kinetics experiment. Pańczyk,[11] then later Nieszporek,[12] described such a model of an adsorption system with different pressure regions of a kinetics experiment. Therefore, the pressure change in the near-surface region can be described by the following equation[12]

$$[1] \qquad \frac{\mathrm{d}p}{\mathrm{d}t} = \alpha(p^0 - p) - \beta\frac{\mathrm{d}\theta}{\mathrm{d}t}$$

where α and β are expressed as follows:

$$[2] \qquad \alpha = \frac{1}{h}\sqrt{\frac{kT}{2\pi m}}, \qquad \beta = N_0\frac{S_A kT}{S_G h}$$

where S_G, S_A, h, and N_0 are the quantities characterizing the properties of the surface of the adsorbing phase. S_G is the area of the interface between the near-surface region and the bulk gas phase, h is the distance between S_G and the area of the adsorbing surface S_A, N_0 is the number of adsorption centers per unit of surface area, and m is the mass of the adsorbing molecule.

Recently, Plazinski[13] studied the applicability of the film-diffusion model for description of the adsorption kinetics at the solid/solution interfaces. By assuming a free molecular flow between the bulk phase and the near-surface region, the diffusion of adsorbing species across the subsurface film can be expressed in terms of Fick's law

$$[3] \qquad \frac{\mathrm{d}c}{\mathrm{d}t} = k_s(c - c_s) - \frac{m}{V_s M}\frac{\mathrm{d}\theta}{\mathrm{d}t}$$

where k_s is the mass-transfer coefficient, V_s is the volume of the subsurface region, M is the maximum adsorbed amount, and c and c_s are the concentrations of sorbate in the bulk and subsurface regions, respectively. It can be seen that by substituting c and c_s with p and p^0, eqs. [1] and [3] become mathematically identical.

In our recent papers,[9,12] we combined eq. [2] with the SRT of interfacial transport[7,8] to describe the rate of pure and mixed-gas adsorption. In the present paper we show another application of eq. [1] to describe the rate of gas (or liquid) adsorption by using any model of adsorption equilibria.

Let us consider the adsorption system in which the overall rate of adsorption is governed only by the rate of the gas particle diffusion in the subsurface region expressed by eq. [1]. This assumption corresponds to the single-resistance model.[14] Because a local equilibrium exists between the adsorbate in the subsurface region and those adsorbed onto the solid, the kinetics of adsorption is influenced by the adsorption isotherm equation linking the surface coverage fraction with the bulk-phase pressure. This assumption is similar to that accepted in the statistical theory approach,[7,8] which links the rate of transport between two phases with different chemical potentials of the molecules in these phases. Thus, the rate of adsorption $\mathrm{d}\theta/\mathrm{d}t$ can be written as follows:

$$[4] \qquad \frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{\mathrm{d}\theta}{\mathrm{d}p}\frac{\mathrm{d}p}{\mathrm{d}t}$$

For our needs, eq. [4] is a general expression helpful in the theoretical description of adsorption kinetics. It makes it possible to use any model of adsorption equilibria and then can take into account the nonideal effects in the adsorbed phase.

It is interesting to note that, by applying eqs. [3] and [4], Plazinski[13] showed a theoretical interpretation of the empirical Lagergren equation. Considering the region of very low adsorbate pressures, the adsorption system is well-represented by Henry's law

$$[5] \qquad \theta = K_H p$$

where K_H is a constant, because

$$[6] \qquad \frac{\mathrm{d}\theta}{\mathrm{d}p} = K_H$$

Equation [4] combined with eqs. [1] and [6] leads to the following expression

$$[7] \qquad \frac{\mathrm{d}\theta}{\mathrm{d}t} = K_H\frac{\mathrm{d}p}{\mathrm{d}t} = K_H\alpha(p^0 - p) - K_H\beta\frac{\mathrm{d}\theta}{\mathrm{d}t}$$

and then

$$[8] \qquad \frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{K_H\alpha}{1 + K_H\beta}(p - p^0)$$

Assuming that during the kinetic experiment the adsorbate pressure above the surface does not vary significantly (the amount of adsorbate in the bulk phase is considerably predominant over the adsorbed amount), p and p^0 can be expressed by Henry's equation and then we arrive at the Lagergren pseudo-first-order equation.

It is well-known that, in real adsorption systems, both surface energetic heterogeneity and interactions between adsorbed molecules exist. One of the most popular theoretical isotherms offering a satisfactory description of the equilibrium of adsorption is the generalized Langmuir–Freundlich (GLF) equation

$$[9] \qquad \theta = \frac{N^{(e)}}{M} = \frac{\left(Kp\ \exp\left\{\frac{\varepsilon^0}{kT}\right\}\right)^{kT/c}\ \exp\left\{\frac{\omega\theta}{c}\right\}}{1 + \left(Kp\ \exp\left\{\frac{\varepsilon^0}{kT}\right\}\right)^{kT/c}\ \exp\left\{\frac{\omega\theta}{c}\right\}}$$

where θ is the partial surface coverage, $K\ \exp\{\varepsilon^0/kT\}$ is the adsorption constant (ε^0 is the most probable energy of adsorption), kT/c is the surface energetic heterogeneity parameter, ω is the product of the interaction energy between two molecules adsorbed on two adjacent sites on a lattice and the coordination number of that lattice, and $N^{(e)}$ is the equilibrium coverage at pressure p. For the mathematical purposes, it is convenient to rewrite eq. [4] as follows:

$$[10] \qquad \frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{\mathrm{d}\theta}{\mathrm{d}\ln p}\frac{\mathrm{d}\ln p}{\mathrm{d}t} = \frac{1}{p}\frac{\mathrm{d}\theta}{\mathrm{d}\ln p}\frac{\mathrm{d}p}{\mathrm{d}t}$$

Rearranging eq. [9] we have

$$[11] \qquad p = \frac{1}{K}\left(\frac{\theta}{1 - \theta}\right)^{c/kT}\ \exp\left\{\frac{\omega\theta}{kT}\right\}$$

and then

$$[12] \qquad \frac{\mathrm{d}\ln p}{\mathrm{d}\theta} = \frac{c}{kT}\frac{1}{\theta(1 - \theta)} + \frac{\omega}{kT}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

Combining eq. [10] with eq. [12] we arrive at the following adsorption rate equation

$$[13] \qquad \frac{d\theta}{dt} = \frac{1}{p}\left[\frac{c}{kT}\frac{1}{\theta(1-\theta)} + \frac{\omega}{kT}\right]^{-1}\left[\alpha(p-p^0) + \beta\frac{d\theta}{dt}\right]$$

which can be simplified as follows:

$$[14] \qquad \frac{d\theta}{dt} = \frac{\alpha(p-p^0)}{p\left[\frac{c}{kT}\frac{1}{\theta(1-\theta)} + \frac{\omega}{kT}\right] - \beta}$$

Equation 14 describes the rate of gas adsorption on energetically heterogeneous surfaces when the interactions between adsorbed molecules are described by the mean field approximation. An unquestionable advantage of eq. [14] is its simple mathematical form and the possibility of simulating (in some range) diffusional effects. This is due to the fact that eq. [14] has been developed by using eq. [1], which directly results from Fick's law. On the other hand, the important disadvantage of eq. [14] is its limited applicability. Namely, GLF (eq. [9]) was obtained by using the condensation approximation (CA), which assumes clear energetic nonideality of molecule–surface interactions. When adsorption occurs such as that on an energetically homogeneous surface ($kT/c \rightarrow 1$), the error connected with CA increases. This inaccurate property of GLF is clearly visible when eq. [9] is used to describe the enthalpic effects accompanying gas adsorption. In that case, the corresponding isosteric heat of adsorption (q^{st}) has the following form

$$[15] \qquad q^{st} = q^{st0} - c\ln\frac{\theta}{1-\theta} + \omega\theta$$

where q^{st0} is the nonconfigurational isosteric heat of adsorption. While assuming a lack of interactions ($\omega/kT = 0$), q^{st} is coverage-dependent even if the surface is energetically homogeneous. Since the adsorption occurs as if it was an energetically homogeneous surface at low adsorbate pressures, eq. [15] should be applied with caution.

Recently, we demonstrated a new isotherm corresponding to the uniform adsorption energy distribution[9]

$$[16] \qquad \theta = \frac{kT}{\Delta\varepsilon}\ln\left(\frac{1 + pK_L^m \exp\left\{\frac{\omega\theta}{kT}\right\}}{1 + pK_L^l \exp\left\{\frac{\omega\theta}{kT}\right\}}\right)$$

where K_L^m and K_L^l are the adsorption constants, and

$$[17] \qquad \Delta\varepsilon = kT\ln\frac{K_L^m}{K_L^l}$$

For our purposes we called it the generalized uniform Langmuir (GUL) isotherm. Equation [16] is the exact solution of the integral equation approach and we do not have to deal with CA error. It means that the GUL isotherm can be used even if the surface is quite energetically homogeneous.

To determine the corresponding kinetic equation, it is convenient to rewrite eq. [16] as follows:

$$[18] \qquad p = \frac{1 - \exp\left\{\frac{\Delta\varepsilon\theta}{kT}\right\}}{\exp\left\{\frac{\omega\theta}{kT}\right\}}\left(K_L^l \exp\left\{\frac{\Delta\varepsilon\theta}{kT}\right\} - K_L^m\right)$$

and, finally, by applying eq. [4] we arrive at the following kinetic expression

$$[19] \qquad \frac{d\theta}{dt} = \frac{\alpha\left(K_L^l \exp\left\{\frac{\Delta\varepsilon\theta}{kT}\right\} - K_L^m\right)\left(\exp\left\{\frac{\Delta\varepsilon\theta}{kT}\right\} + \exp\left\{\frac{\theta(\Delta\varepsilon+\omega)}{kT}\right\}K_L^l p_0 - \exp\left\{\frac{\omega\theta}{kT}\right\}K_L^m p_0 - 1\right)}{\beta\exp\left\{\frac{\omega\theta}{kT}\right\}\left(K_L^m - \exp\left\{\frac{\Delta\varepsilon\theta}{kT}\right\}K_L^l\right)^2 - \frac{\Delta\varepsilon}{kT}\exp\left\{\frac{\Delta\varepsilon\theta}{kT}\right\}(K_L^l - K_L^m)}$$

Summing up, we have shown two new theoretical kinetic isotherms (eqs. [14] and [19]) that can be used to describe the single-gas adsorption rate on energetically heterogeneous surfaces. These new expressions take into account the interactions between adsorbed molecules. Having at our disposal the equilibrium experimental isotherms, most of the parameters in eqs. [14] and [19] can be determined by using eqs. [9] and [16]. Hence, the calculations of the rate of adsorption need only to adjust two best-fit parameters, α and β. The adsorbate pressure (p) can be calculated by using the corresponding equilibrium isotherms (eqs. [9] and [16]) for actual surface coverage.

Results and discussion

To analyze the applicability of the derived kinetics eqs. [14] and [19], we used the experimental data reported by Qiao and Hu.[10] The authors report both equilibrium and kinetics isotherms of simple gases on activated carbon. These data satisfy our requirements: the analysis of experimental equilibrium isotherms gives the values of the best-fit parameters, which then can be used to calculate the adsorption rate.

The practical calculations of the rate of adsorption were done by using Mathematica 7.0 software. For the calculations, we assumed the following boundary conditions: $\theta(t = 0) = 0$ and $p(t = 0) = p^0$. The values of α and β characterizing the geometric properties of the solid phase were calculated by applying the random walk Monte Carlo procedure with 10^6 steps. At each step the values of α and β were generated randomly to find the best agreement of the theoretical curve with the experimental data. Each calculation was repeated a few times with a gradual decrease of the search limits of each parameter. The quality of the adjustment of theoretical kinetics isotherm was characterized by the following error function

$$[20] \qquad AAD\% = \frac{1}{n}\sum_{i=1}^{n}\frac{|N_t^{exp} - N_t^{calcd}|}{N_t^{exp}}100$$

The average absolute deviation (AAD%) has a significant property — the greatest impacts on the value of the error function have deviations at low adsorbate pressures or short times of adsorption. As most of the empirical rate equations show large relative errors for the predicted adsorbed amount at the initial times of adsorption, the AAD% function makes

it possible to assess the applicability of the proposed kinetic equations.

Qiao and Hu[10] reported equilibrium C_2H_6 and C_3H_8 isotherms measured at three temperatures: 303, 333, and 363 K. For the calculations, we mainly assumed that the parameters c/k and ω/k are temperature-independent and are common for all isotherms of a given system. Thus, a few isotherms measured at different temperatures can be adjusted simultaneously. Although this type of assumption makes the calculations significantly more difficult and decreases the quality of the fit, it eliminates the correlations between the values of the best-fit parameters.

During the theoretical analysis of experimental isotherms using the expressions based on the Langmuir model, M should be temperature-independent. However, taking the typical behaviour of experimental isotherms into account, we can see that, with the increasing temperature, adsorption isotherms reach a plateau at lower surface coverage. Hence, M is usually accepted as temperature-dependent to increase the agreement between the theoretical curves and the experimental data.

The results for the calculations of equilibrium and kinetics isotherms for C_2H_6 and C_3H_8 adsorbed at Norit AC by using GLF eqs. [9] and [14] are shown in Table 1 and Figs. 1 and 2.

Figures 1 and 2 confirm the well-known applicability of GLF eq. [9]. Although some deviations of the theoretically calculated isotherms from the experimental data exist, the values of the best-fit parameters M, $K \exp\{\varepsilon^0/kT\}$, c/k, and ω/k seem to be correctly determined. The heterogeneity parameters (c/k) for both gases are similar because ethane and propane have similar chemical properties. It is worth noting that energetic heterogeneity is the property of the entire adsorption system, but not only of the surface, it also reflects the nonideality of adsorbent–adsorbate interaction energy. The interaction parameters (ω/k) have similar values for ethane and propane (the value of ω/k for propane is slightly larger).

While considering the results of the calculations of the rate of alkane adsorption, we should explain the meaning of "fractional uptake" used by Qiao and Hu.[10] The authors defined it as the uptake at any time divided by its value at final equilibrium, i.e., when $t \rightarrow \infty$. Then the values of $\partial\theta/\partial t$

should be multiplied by $M/N^{(e)}$, where $N^{(e)}$ can be calculated by using GLF eq. [9].

Generally, the quality of fit of the kinetic data is quite good. However, the theoretical kinetic isotherm (eq. [14]) is derived from the GLF isotherm (eq. [9]) and then it inherits its limitations. For that reason GLF should not be used for almost energetically homogeneous adsorption systems (i.e., when $kT/c \rightarrow 1$). Table 1 shows that this situation occurs in our case. On the other hand, the experimental data reported by Qiao and Hu[10] were determined in the region of very low adsorbate pressures. It is known that under such pressure conditions, the adsorption occurs as it does on an energetically homogeneous surface.

In the next step of calculations, we used GUL eqs. [16] and [19], corresponding to the uniform energy distribution. The results are shown in Table 2 and Figs. 3 and 4.

It can be stated that GUL eq. [16] describes the equilibrium of adsorption better than GLF eq. [9]. Table 2 shows that all GUL fits are characterized by lower values of AAD %. The application of GUL isotherm eq. [16] indicates evidently stronger interactions between adsorbed alkanes. As eq. [16] is the exact solution of the integral equation approach it has nothing to do with CA error. The analysis of isotherms were performed simultaneously, and the parameters $\Delta\varepsilon/k$ and ω/k characterize the adsorption system.

The results of the calculations for the rate of adsorption by eq. [19] are only just a little bit better than before — the values of AAD% (kin.) are similar for both theoretical models (see Tables 1 and 2).

These calculations were done by assuming the temperature independence of the energetic heterogeneity and interaction energy between adsorbed molecules. Undoubtedly, it seems that the theoretical analysis of single isotherms separately should lead to lower AAD% values. Thus, we finally follow this line and show the agreement between the proposed theoretical models and the experimental data obtained by assuming some temperature dependences of the surface energetic heterogeneity and the interactions between adsorbed molecules. It means that, during the theoretical analysis of equilibrium adsorption, all best-fit parameters are adjusted separately for each experimental isotherm. Tables 3 and 4 show the values of the best-fit parameters determined by ad-

experimental data. Allowing for the temperature dependence of c/k and ω/k results in only a slightly better agreement between the experimental and theoretical kinetics isotherms.

As far as the GUL isotherms (eqs. [16] and [19]) are concerned, we obtained evidently better results. Release of the best-fit parameters $\Delta\varepsilon/k$ and ω/k leads to much better agree-

ment between the theoretically calculated and experimentally measured isotherms. For example, when $\Delta\varepsilon/k$ and ω/k were assumed as temperature-independent and determined during simultaneous adjustment of all equilibrium isotherms, AAD% (eq.) for ethane and propane at 333 K were equal to 3.84 and 1.03, respectively (see Table 2), whereas adjusting for only single isotherms at 333 K, the AAD% (eq.) were equal to 2.56 and 0.86, respectively. An even greater difference between both models of calculations exists in the case of kinetics isotherms. Namely, AAD% (kin.) (determined when $\Delta\varepsilon/k$ and ω/k were temperature-independent) for ethane and propane were equal to 5.21 and 3.56, respectively (Table 2). When these parameters were temperature-dependent, the AAD% (kin.) were equal to 3.05 and 0.98, respectively (Table 4).

Summing up, we have shown two ways for calculations of the theoretical equilibrium and kinetics isotherms differentiated by considering the temperature dependence of some best-fit parameters. It is difficult to state which calculation procedure is recommended. Undoubtedly, simultaneous adjustment of all equilibrium isotherms is more correct. However, the most practical applications of theoretical equilibrium isotherms are characterized by allowing temperature dependence of the adsorption capacity. To get better agreement of theoretical equilibrium and kinetics isotherms with the experimental data, other best-fit parameters in the theoretical isotherms can be released. Unfortunately, in such a case the values of the best-fit parameters are frequently correlated and difficult to interpret.

Conclusions

We proposed a new theoretical description of the rate of gas adsorption. By differentiating a theoretical equilibrium isotherm, it can be easy to determine the corresponding kinetic equation. Plazinski[13] confirmed the correctness of this method by obtaining the theoretical interpretation of the Lagergren pseudo-first-order equation.

By using equilibrium isotherms (eqs. [9] and [16]) we obtained two new theoretical kinetics eqs. [14] and [19]. They have a relatively simple mathematical form and lead to good agreement with the experimentally measured data. The calculations take into account both the surface energetic heterogeneity and the interactions between adsorbed molecules.

Most of the parameters appearing in kinetics isotherms can be obtained from the theoretical analysis of equilibrium data. During calculations of the rate of adsorption, only two best-fit parameters (α and β) must be adjusted. Compared with the corresponding SRT kinetics isotherms,[9,12] this is an unquestionable advantage, because, in the case of the SRT equations, besides α and β an additional two best-fit parameters must be adjusted during the analysis of kinetics experiment.

Undoubtedly, better results have been determined in the case of isotherm eq. [14], especially when each equilibrium isotherm was adjusted separately. It is due to the fact that GLF eq. [9] has been obtained by using the condensation approximation. On the other hand, the GUL isotherm eq. [16] corresponding to the uniform energy distribution is free of such error connected with CA application.

The application of the new rate equations for adsorption from the liquid phase is a separate issue. This is because the adsorption from solutions is a more complicated process than gas adsorption. A solution is typically a system of more than one component, and there are at least two substances that can adsorb. Thus, it is essentially an exchange process and, hence, molecules adsorb not only because they are attracted by solids but also because the solution may reject them. In the case of dilute solutions, it is commonly assumed that all the equations derived from monolayer gas adsorption remain valid after replacing pressure by concentration and modifying the dimensions of some parameters. After such modifications, the new rate eqs. [14] and [19] can be applied to adsorption from liquids.

Kinetics equations determined by eq. [4] can be applied to the adsorption systems when the rate of adsorption is controlled by the surface reaction mechanism. It seems that even when the intraparticle diffusion is the rate-determining step, eq. [4] can still successfully describe the adsorption rate. It is due to the fact that its solution takes into account the variance of pressure in the near-surface region by applying Fick's law.

Abstract: The extraction of dioxouranium (UO_2^{2+}), or uranyl, and strontium (Sr^{2+}) ions from spent nuclear fuel (SNF), often through a biphasic (aqueous / organic solvent) ligand assisted process, is critical for the implementation of a closed-loop nuclear fuel cycle whereby SNF is diverted from permanent geological disposal and the life of the nuclear industry is extended. Deeper understanding of the biphasic extraction process can be achieved through facile electrochemical experiments at a liquid|liquid interface. Of primary importance to developing a quantitative analysis of the ligand assisted or facilitated ion transfer (FIT) (i.e., transfer through interfacial complexation) case is to first quantify the free or simple metal IT; that is the amount of applied potential required to "push" ions across the water|organic interface. This value is, in fact, a constant referred to as the formal transfer potential ($\Delta_o^w\phi^{o'}$), which is unique to each metal ion in the biphasic system. Because of their hydrophilicity they often limit the polarizable potential window. Values for $\Delta_o^w\phi^{o'}$, for the most part, have only been estimated. With a microinterface housed at the tip of a 25 μm capillary it is possible to reduce the Faradaic current to observe their transfer. Herein is described the quantification of $\Delta_o^w\phi^{o'}_{UO_2^{2+}}$ and $\Delta_o^w\phi^{o'}_{Sr^{2+}}$ or the formal transfer potentials for dioxouranium and strontium ions, respectively.

Key words: liquid|liquid electrochemistry, simple ion transfer, formal transfer potential, strontium ion, dioxouranium, uranyl, micropipette.

Résumé : L'extraction des ions dioxouranium (UO_2^{2+}) ou uranyles ou strontium (Sr^{2+}) des combustibles nucléaires irradiés (CNI), souvent par le biais d'un processus en deux phases (aqueuse/solvant organique) assisté par un ligand, est souvent une étape critique dans l'implantation d'un cycle fermé de combustible nucléaire dans lequel le CNI n'est pas immédiatement envoyé à l'élimination géologique définitive en faveur d'une extension de sa vie dans l'industrie nucléaire. On peut obtenir une compréhension profonde du processus d'extraction biphasique par le biais d'expériences électrochimiques simples à une interface liquide|liquide. Dans le développement d'une méthode d'analyse quantitative du transfert d'ion assisté ou facilité (TIF) par un ligand, c'est-à-dire un transfert par le biais d'une complexation interfaciale, il est important de commencer par quantifier le transfert d'un ion (TI) libre ou d'un ion métallique simple; ceci correspond à la quantité de potentiel appliquée requise pour « pousser » les ions à traverser l'interface eau|interface organique. En fait, cette valeur est une constante souvent désignée comme le potentiel de transfert formel ($\Delta_o^w\phi^{o'}$) qui, dans un système biphasique, est unique pour chaque ion métallique. En raison de leur caractère hydrophile, ils limitent souvent la fenêtre du potentiel polarisable. Jusqu'à maintenant, les valeurs de $\Delta_o^w\phi^{o'}$ n'ont pour la plupart qu'été évaluées. Avec une micro-interface montée à la pointe d'un capillaire de 25 μm, il est possible de réduire de courant faradique afin de pouvoir observer le transfert. Dans ce travail, on décrit la quantification des potentiels de transfert formel des ions dixouranium et strontium, respectivement $\Delta_o^w\phi^{o'}_{UO_2^{2+}}$ et $\Delta_o^w\phi^{o'}_{Sr^{2+}}$.

Mots-clés : électrochimie liquide|liquide, transfert d'ion simple, potentiel de transfert formel, ion strontium, dioxouranium, uranyle, micropipette.

Introduction

With the imminent depletion of the world's fossil fuel supply and the long-recognized environmental issues surrounding anthropogenic CO_2 emission,[1] alternative energy sources are being sought; front runners include solar and nuclear power generation. Nuclear power plants, unlike solar, are not an intermittent energy source[1] and, therefore, are considered more reliable. Implementing a closed-loop fuel cycle, whereby spent nuclear fuel (SNF) is recycled instead of — as in the present model — prepared for permanent geologic disposal, could extend the life of the nuclear industry for hundreds of years.[1]

Indeed, the majority of SNF, approximately 95%, is UO_2 suitable for energy production; the other 5% is fission decay products (e.g., ^{90}Sr and ^{137}Cs) that can behave as neutron absorbers, disrupting the fission process and lowering the fuel rod's efficiency.[2] Crucially, these other metals have isotopes

that are valuable in and of themselves for use in nuclear medicine or radioimmunotherapy (RIT).[3–7] ^{90}Y, combined with monoclonal antibodies (mAb), has found some success in targeting and treating cancer.[3,4,6,7] Similarly, ^{82}Rb is used for myocardial perfusion imaging, a diagnostic technique examining the heart and circulatory system.[8] The advantage of ^{90}Y and ^{82}Rb is that they are short-lived isotopes ($t_{1/2}$ = 64 h and 76 s, respectively), which is useful because it means less radiolytic toxicity to patients, but also means that, for these isotopes to be effective, on-site clinical generators are required.[7,9–11] These in-house generators use a parent/daughter strategy and, from the preceding examples, take the form of ^{90}Sr/^{90}Y and ^{82}Sr/^{82}Rb.[7,9–11] Interestingly, strontium is a major component of SNF[2] and, thus, could be a source for parent isotopes.

SNF should not be viewed simply as waste, but as a potential resource. This begs the question as to how to selectively and effectively isolate these materials. ^{90}Sr has been separated from the nuclear waste stream almost since the inception of the civilian nuclear industry because of its use in other applications.[12] However, its recent incorporation into the medicinal field has sparked interest towards improving the purity of ^{90}Sr extraction.

Contemporary methods of metal ion separation involve the use of aqueous/organic biphasic systems with processes like plutonium/uranium extraction (PUREX) and transuranic extraction (TRUEX).[13–15] In either case, a ligand, dissolved in the organic phase, coordinates to the metal center causing it to partition into the organic phase.

Ion partitioning or ion transfer (IT) of metals has been analyzed through a facile electrochemical technique at the interface between two immiscible electrolytic solutions (ITIES), often between water and 1,2-dichloroethane (w|DCE)[16–21] or water and nitrobenzene (w|NB).[22,23] In this method ions are pushed or pulled across the ITIES by an applied potential. Should a potential be administered to either phase, a potential drop or difference would develop across the ITIES, such that $\Delta_o^w\phi = \phi_w - \phi_o$, where ϕ is the potential in phase w (aqueous) or o (organic). A positive potential, administered to the aqueous phase, will repel cations prompting them to cross the interface while attracting anions from the organic phase. If applied to free metal species, this is termed simple IT and shown in eq. [1]

$$[1] \qquad i_w^{z_i} \rightleftharpoons i_o^{z_i}$$

where species i with charge z transfers from w to o. However, if a ligand (L) is dissolved in the organic phase and used to assist IT, the mechanism is called facilitated ion transfer (FIT) and eq. [2] is used.

$$[2] \qquad i_w^{z_i} + nL_o^w \rightleftharpoons iL_o^{z_i}$$

Just as in conventional electrochemistry at a solid electrode where $\Delta G = -zFE^{o'}$, the Gibbs free energy can be related to the potential difference developed across the ITIES in the same manner, $\Delta G = -zF\Delta_o^w\phi^{o'}$. Where $E^{o'}$ is the formal redox potential at a solid electrode, $\Delta_o^w\phi^{o'}$ is the formal transfer potential at an aqueous|organic solvent interface, z is the charge, and F is Faraday's constant.

The theory of FIT at a w|o interface, using cyclic voltammetry (CV), has been developed thoroughly.[18,19,24,25] Equation [3] forms the basis of a diagnostic method for evaluating various ligands and biphasic systems, if we assume that diffusion processes are equal in both phases.

$$[3] \qquad -\frac{zF}{RT}\left(\Delta_o^w\phi_{iL_n^{z+}}^{o'} - \Delta_o^w\phi_{i^{z+}}^{o'}\right) = n\ \ln c_o^* + \ln\beta$$

Equation [3] differentiates between the formal transfer potential of the metal–ligand complex, $\Delta_o^w\phi_{iL_n^{z+}}^{o'}$, and that of the free metal species, $\Delta_o^w\phi_{i^{z+}}^{o'}$; where the latter is a constant and behaves like a point of reference, whereby, with increasing initial ligand concentration, c_o^*, the metal ions transfer more easily. Thus, the formal transfer potential of the metal–ligand complex is linearly dependent on the ligand concentration. The n and β terms are the overall stoichiometry of the interfacial complexation reaction (eq. [2]) and its associated overall complexation constant, respectively. In this way, by varying the ligand concentration in the organic phase and measuring $\Delta_o^w\phi_{iL_n^{z+}}^{o'}$ through CV experiments, n and β can be determined and used as a quantitative measure towards the fitness of various ligand and solvent combinations.

Unfortunately, this is complicated by the fact that most free metal ionic species transfer outside the polarized potential window (PPW) and their formal transfer potential constants are difficult to determine because of their high hydrophilicity. At first, Girault and co-workers,[26,27] working at a large (centimetre scale) ITIES, used the ratio between the current at the edge of scan and the return peak current (I_{eos}/I_{rp}), along with working curves generated through numerical calculations, to estimate the transfer of alkali and other multiply charged metals. Similarly, Samec and co-workers[28,29] implemented sophisticated numerical calculations compared with the profile of the PPW edge to estimate the formal transfer potential.

Later, with improvements towards the micro-ITIES apparatus, a microhole interface was utilized.[30–32] This technique was based on the principle of minimal supporting electrolyte first developed for solid ultramicroelectrodes by Oldham,[33] but later extended to the micro liquid|liquid interface by Wilke.[32] Girault and co-workers[30] examined several cations and anions through direct curve fitting of the experimentally acquired CVs. However, this micro-ITIES is typically supported at a hole formed in a polyamide sheet (25 μm thick) via UV photoablation. It is difficult to ensure a consistent microhole size and geometry while, additionally, the polyamide film can become deformed by absorption of the organic solvent, limiting the number of times it can be used. This approach focused on reducing the interfacial size and the amount of electrolyte in solution to limit the Faradaic current in the hopes of observing simple IT at higher potentials.

Herein, we describe the facile observation of IT of metal species at a micro-ITIES, housed at the tip of a 25 μm diameter silanized borosilicate glass capillary, with the formal transfer potential being obtained directly from differential pulse voltammograms (DPVs). This is made possible by the use of a custom-modified micropipette holder intended for physiological applications, which is equipped with a syringe greatly stabilizing the ITIES at the capillary tip. This apparatus was used to observe the IT of Sr^{2+} and UO_2^{2+} directly, at conventional concentrations, for the first time; in this way determining their formal transfer potential. Additionally, a glass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13

capillary can be used almost indefinitely and our fabrication method ensures a consistent micro-ITIES size of 25 μm in diameter.

Experimental

Chemicals

All chemicals were of reagent grade and utilized without further purification. Uranium nitrate hexahydrate ($UO_2(NO_3)_2{\cdot}6H_2O$) and strontium nitrate ($Sr(NO_3)_2$) were purchased from Fisher Scientific (ThermoFisher Scientific, Ottawa, Ontario) and Sigma-Aldrich (Sigma-Aldrich Canada Ltd., Mississauga, Ontario), respectively. Trihexyltetradecylphosphonium chloride ($P_{66614}Cl$) and potassium tetrakis(pentafluorophenyl)borate (KTB) were obtained from Strem (Strem Chemicals Inc., Newburyport, Massachusetts) and Boulder Scientific (Boulder Scientific Company, Longmont, Colorado), respectively. Aqueous solutions were made up using ultrapure Milli-Q water (18.2 MΩ). The organic phase supporting electrolyte $P_{66614}TB$ was prepared through a simple metathesis reaction between the $P_{66614}Cl$ and KTB salts in dichloromethane using a procedure described elsewhere.[34]

Micropipette

A few recent publications describe the micropipette fabrication,[20,21,34,35] however, a brief outline follows. First, a borosilicate glass capillary (1.0 mm internal and 2.0 mm external diameters, Sutter Instrument Co., Novato, California) was pulled near its center using a Narishige electric puller (model No. PP-83, Japan), which results in two capillaries with tapered ends; these ends were flame annealed using a Bunsen burner so that the small tapered tip was closed. A 1.0–1.5 cm length of Pt wire (25 μm in diameter, Goodfellow Cambridge Ltd., Huntingdon, UK) was then inserted into the top or open end of the capillary and pushed down into the tapered tip. The wire was fixed in place by annealing it, under vacuum, using the electric puller; in this way the wire was encased in approximately 1–2 mm of glass. The sealed end was subsequently polished using a series of grinding and polishing pads (Buehler Canada, Markham, Ontario) until the surface of the glass was smooth and a cross section of the Pt wire was exposed; the quality of the capillary surface was routinely checked using an optical microscope. Polishing was complete when the surface was free of defects and the R_g, that is the ratio of external (r_g) to internal (a) diameter ($R_g = r_g/a$), was greater than 50. The next step was removal of the Pt wire via etching through immersion in aqua regia (3:1 solution of HCl–HNO_3). The capillary tip was silanized using trimethylchlorosilane; in this process Ar gas is bubbled through the capillary in the silane solvent for 5 min and, afterwards, the capillary is dried and baked overnight in an oven at 100 °C.

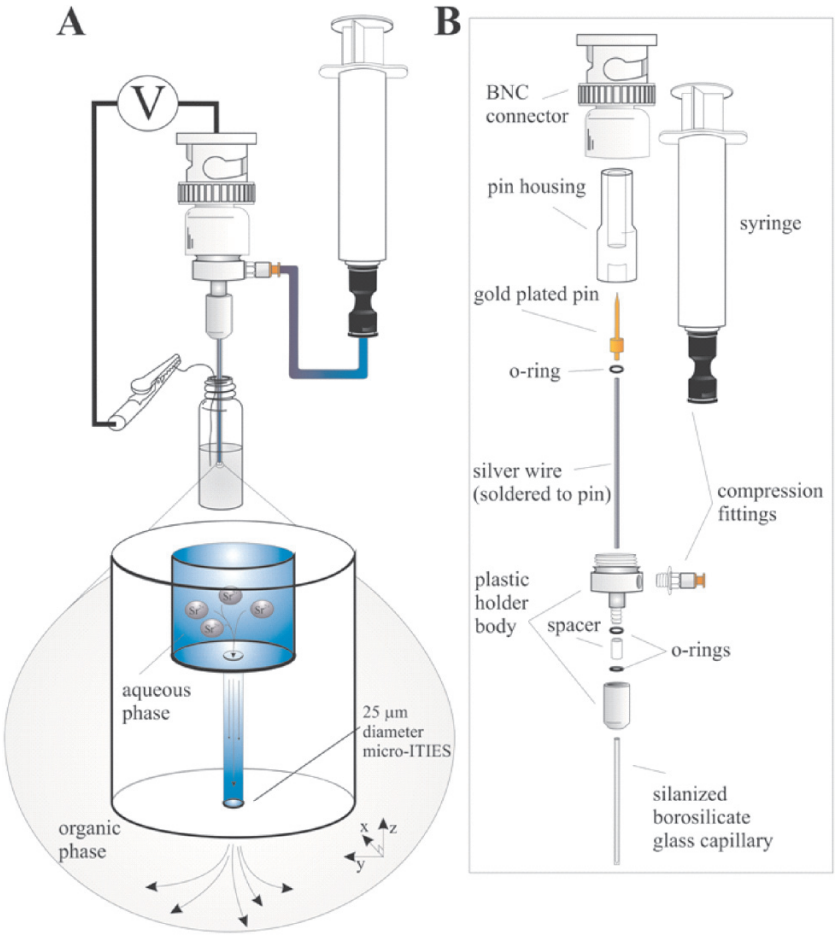
Instrumentation

The Modulab System (Ametek Advanced Measurement Technology, Farnborough, New Hampshire, UK) equipped with a femto ammeter was utilized for all electrochemical experiments. Owing to the reduced current required at a micro-ITIES, a two-electrode system was employed with the working electrode (WE) lead attached to a BNC connector that was subsequently fixed to the micropipette holder. The holder is designed with an incorporated internal silver wire that is sealed with the aqueous phase; the BNC connector provides the external contact. The counter electrode (CE) and reference electrode (RE) leads were coupled together with a standard alligator clip on the end gripping another silver wire immersed in the organic phase. Figure 1 illustrates the disassembled micropipette holder highlighting its components. The following electrochemical cell was used

$$\mathrm{Ag}\,|\,\mathrm{AgNO_3}\,|\,\underset{(aq)}{3\ \mathrm{mM\ X(NO_3)_2}}\,\|\,\underset{(DCE)}{5\ \mathrm{mM\ P_{66614}TB}}\,|\,\mathrm{AgTB}\,|\,\mathrm{Ag}\qquad \text{Cell 1}$$

A CCD camera (Motic Inc., Richmond, British Columbia) fixed to a variable 12× magnification lens assembly (Navitar, Rochester, New York) was used to continuously monitor the ITIES, ensuring it did not fluctuate during experimentation.

Curve fitting was performed using Igor Pro 6.22a (Wavemetric Inc., Portland, Oregon) on an Acer Aspire laptop (Acer America Corporation (Canada), Mississauga, Ontario) with a 1.66 GHz Intel Core 2 Duo processor and 2 GB of DDR2 RAM.



Results and discussion

Figure 2A shows the CV obtained with cell 1 and X equal to Sr^{2+}; the trace was acquired utilizing an initial potential of 0.210 V and scanning in the forward direction to a final potential of approximately 1.200 V, at which point the CV was scanned in the reverse direction towards negative potentials. During this first segment a peak-shaped wave can be seen at roughly 0.786 V. Subsequently, the potential was swept in the reverse direction towards more negative potentials; a sigmoidal-shaped wave can be observed at approximately 0.780 V. The sigmoidal wave is difficult to discern, however, an inflection in the current–potential response of the return sweep at ~0.9 V was deemed to coincide with the limiting or steady-state current (i_l) for the return transfer of Sr^{2+}; thus, the half-wave potential was evaluated by graphing $\ln[(i_l - i)/i]$ vs E and determining the potential at the x-intercept, as described in Bard and Faulkner.[36] These two curve features were attributed to the IT of Sr^{2+} from w to o and back, displaying peak- and sigmoidal-shaped waves, respectively. The asymmetry of IT is a direct result of the pipette geometry.[37,38] Using Sr^{2+} IT as an example, during the forward scan ions in the pipette transfer from w to o, however, the volume of material near the interface is small and rapidly consumed; the current–potential response rises exponentially, but is then followed by an exponential decay as ions must diffuse towards the ITIES from higher up in the microchannel. The voltammogram shows peak-shaped waves. During the reverse scan, material that has crossed the ITIES occupies a relatively large (compared with the volume within the microchannel) hemispherical volume surrounding the micro-ITIES; thus, mass transfer of material towards the interface appears to be faster than its rate of consumption, generating a rise in current followed by a plateau or steady state.

The asymmetric shape of the forward and reverse curves is in good agreement with simple IT of a cation across a w|o interface as described in the literature for a micro-ITIES housed at the tip of a micropipette.[37,38] By convention, the

Fig. 1. (A) Micropipette plus holder with perspective view of micro-ITIES. (B) Component diagram of the micropipette holder.

transfer of a cation from w to o elicits a positive current response.

The scan was continued to the second switching potential of approximately –0.590 V and another peak-shaped curve feature can be observed in this segment at –0.400 V; this has been attributed to the IT of nitrate from w to o. The scan direction was subsequently changed towards increasing potential and progressed until 0.210 V was reached, completing one cycle by returning to the initial potential. For this final portion, a sigmoidal wave can be observed with a half-wave potential of –0.307 V. This observation concerning peak and sigmoidal waves is expected based on diffusion regimes for simple IT at a micropipette.[37,38] Nitrate IT was used to calibrate the polarized potential window (PPW), operating as an internal standard or reference; based on the TATB assumption,[39] or scale, the formal transfer potential of nitrate, $\Delta_o^w\phi^{o'}_{NO_3^-}$, was taken to be –0.380 V.[40] The TATB assumption[39] leads to eq. [4].

$$[4] \qquad \Delta_o^w\phi^{o'}_{X^+} - \Delta_o^w\phi_{1/2,X^+} = \Delta_o^w\phi^{o'}_{NO_3^-} - \Delta_o^w\phi_{1/2,NO_3^-}$$

where the half-wave potentials were obtained from the CV using the peak potentials and eq. [5] from Bard and Faulkner.[36]

$$[5] \qquad \Delta_o^w\phi_{1/2} = \Delta_o^w\phi_p - \frac{0.028\ \text{V}}{z_i}$$

where p denotes the peak potential. It is critical to reiterate that the ITIES was monitored continuously throughout each experiment for any change in its shape or position; none was observed microscopically.

Additionally, the theoretical peak current can be described by the diffusion coefficients obtained from the literature for nitrate[41] and strontium[42] of 1.4 and 1.2 × 10^{-5} cm^2 s^{-1}, respectively, and using the following equation[36]

$$[6] \qquad i_p = 0.4463\left(\frac{F^3}{RT}\right)^{1/2} z_i^{3/2} D^{1/2} c_w^* A v^{1/2}$$

where A is the interfacial surface area, v is the scan rate, and c_w^* is the initial concentration of the ion in the aqueous phase. The expected peak current values for nitrate and strontium were calculated to be 4.2 and 5.1 nA; the nitrate peak at 4.5 nA demonstrates good agreement with the calculated value, however, the strontium peak current was measured to be 17.3 nA, which is higher than the theoretical expectation. This may be due to ion-pair formation at the interface between strontium and TB^- to accelerate the IT.

Interestingly, the simple IT of metal species typically limits the PPW generating a "linear ramp" in the current–potential response. The ability to observe the Sr^{2+} IT of these metals in this case is attributed to the great reduction in the interfacial size to 25 μm, significant improvement surrounding the experimental setup by means of a syringe to backfill the

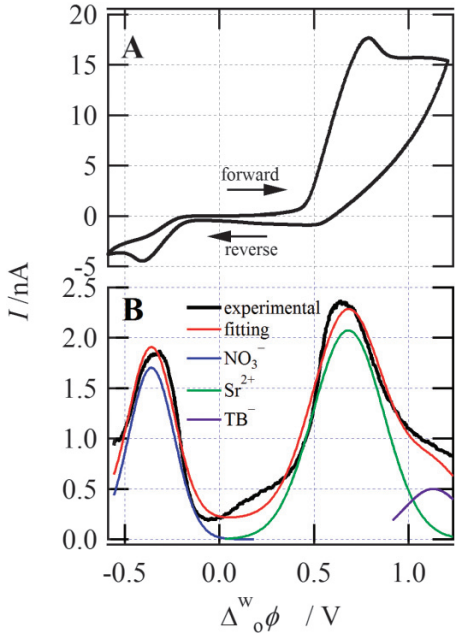
Fig. 2. Using cell 1 with X equal to Sr^{2+}: (A) cyclic voltammogram (CV) obtained with an initial/final potential of 0.210 V, a potential range from approximately –0.590 to 1.200 V, and a scan rate of 0.020 V s^{-1}; and (B) differential pulse voltammogram (DPV) acquired with a potential from –0.590 to 1.200 V; and a step, pulse amplitude, period, and pulse width of 4 mV, 50 mV, 0.1 s, and 0.05 s, respectively.



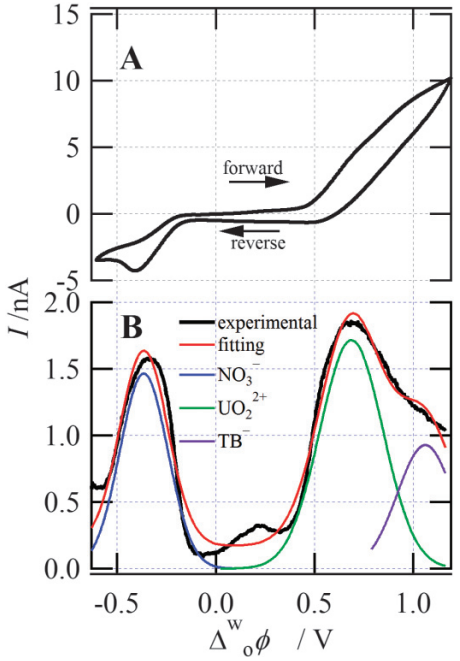


Fig. 3. Using cell 1 with X equal to UO_2^{2+}: (A) cyclic voltammogram (CV) obtained with an initial/final potential of –0.100 V, a potential from approximately –0.600 to 1.200 V, and a scan rate of 0.020 V s^{-1}; (B) differential pulse voltammogram (DPV) acquired with a potential from –0.600 to 1.200 V; and a step, pulse amplitude, period, and pulse width of 4 mV, 50 mV, 0.1 s, and 0.05 s, respectively.

capillary, along with silanization of the outside of the capillary tip, all of which contribute to a highly stable ITIES. From the calibrated CV, the formal transfer potential of Sr^{2+} was estimated to be 0.768 V.

Similarly, dioxouranium was also studied using cell 1 (X = UO_2^{2+}) as shown in Fig. 3A; however, during the forward scan, a familiar exponential increase in current is observed and is typical of metals limiting the PPW. Examining the UO_2^{2+} CV closely, an inflection can be discerned at 0.820 V separating two possible curve features; considering the first to be UO_2^{2+} IT was a peak potential of 0.757 V, $\Delta^w_o\phi^{o'}_{UO_2^{2+}}$ was estimated to be 0.743 V.

Alkali and other metal ion formal transfer potentials limiting the PPW were estimated by Girault and co-workers.[26,27] using a large (centimetre scale) w|DCE interface along with the ratio of the current at the edge of scan to the return peak current (I_{eos}/I_{rp}), which they compared with a working curve derived through numerical calculations. It is important to note that, with the exception of Cs, Girault and co-workers.[26,27] did not strictly observe the IT of these metals. Later, using a microhole apparatus with minimal supporting electrolyte in either phase and a curve-fitting technique,[32,33] IT of Li^+ and Cs^+ were observed,[30] along with UO_2^{2+};[31] $\Delta^w_o\phi^{o'}_{UO_2^{2+}}$ was estimated to be 0.865 V.

The present CV results are similar to those shown previously for alkali metals and dioxouranium,[26,30,31] and both are complicated by the possible simultaneous transfer of the anionic component of the supporting electrolyte in the organic phase, in this case TB^-. Further to this is the question of sufficient electrolyte concentration, since the metal species behaves as both supporting electrolyte and analyte. In the microhole experiment,[30–33] the lack of supporting electrolyte leads to a predictable distortion of the current–potential response, which can mean up to a threefold increase in the observed steady-state current; in the present case, higher electrolyte concentrations are thought to mitigate this phenomenon, however, some uncompensated i_R-drop may still be present.

To confirm the formal transfer potentials obtained using CV, DPVs were also implemented, as illustrated in Figs. 2B and 3B for cell 1 with X equal to Sr^{2+} and UO_2^{2+}, respectively. The instrument parameters included initial and final potentials of approximately –0.590 and 1.250 V, respectively, along with a step, pulse amplitude, pulse period, and pulse width of 4 mV, 50 mV, 0.1 s, and 0.05 s, respectively. Examining the DPVs in Fig. 2B and 3B, only two peaks are observed in each curve. Moving in the forward direction, the first peak, at –0.398 V, is associated with simple nitrate IT, whilst the second peak, at approximately 0.582 and 631 V (for Sr^{2+} and UO_2^{2+}, respectively), is the metal and (or) TB^- IT. Nitrate IT was again employed to calibrate the potential scale, using eq. [1] along with eq. [7] from Girault's book[43]

$$[7] \qquad \Delta^w_o\phi_{max} = \Delta^w_o\phi^{o'} + \frac{RT}{zF}\ln\sqrt{\frac{D_w}{D_o}} - \frac{\Delta E}{2}$$

where ΔE is the pulse amplitude and $\Delta^w_o\phi_{max}$ is the potential at maximum current response (i.e., peak potential); R, T, z, and F are the gas constant, temperature in Kelvin, charge, and Faraday's constant, respectively; and D_w and D_o are the diffusion coefficients in the aqueous and organic phases

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

respectively, these were taken to be equal and, thus, eq. [3] reduces to a simple relation.

In the positive potential region, a transfer peak and a shoulder were observed for both DPVs with $Sr(NO_3)_2$ and $UO_2(NO_3)_2$ in the aqueous phase, respectively (Figs. 2B and 3B). Especially, it is plausible that the shoulder is at the same Galvani potential difference in these figures. Whereas the peak potential values are very close to those for the transfer of the two ions obtained from the CVs in Figs. 2A and 3A, the shoulder was proposed as the TB^- transfer from o to w. To elucidate between strontium/dioxouranium and TB^- IT, a multipeak Gaussian curve fitting was applied directly to the DPVs for each ion; nitrate (blue), metal ion (green), TB^- (purple), and a composite of the three (red). From the curve fitting the formal transfer potential for the strontium and dioxouranium cations was found to be 0.654 and 0.699 V, respectively. The respective $\Delta^{w}_{o}\phi^{o'}_{TB^-}$ for cell 1 with X equal to Sr^{2+} and $UO_2{}^{2+}$ was found to be 1.161 and 1.131 V. The formal transfer potentials for TB^- found here are in good agreement with each other and agree with our recent data using alkali metal ions in place of Sr^{2+} and $UO_2{}^{2+}$.[40]

The difference in formal transfer potentials observed between the two methods is thought to arise from uncompensated i_R-drop present in the CV case, which is mitigated through the DPV experiment. The two cations have a charge of 2+ that might bring more experimental error in determining the formal transfer potential. Especially in the case of Sr^{2+}, the IT is closer to the PPW edge. Therefore, the values obtained from the DPVs are considered to be better estimates.

The formal transfer potential discovered using DPV for Sr^{2+} (0.654) is similar to that shown recently for Rb^+ of 0.562 V.[40] It has been shown, through the alkali metal ions, that with increasing atomic radius down through the periodic table, there is a decrease in the formal transfer potential.[40] Strontium has a van der Waals radius of 2.49 Å compared with that for rubidium of 3.03 Å,[44] however, the increased formal transfer potential is a consequence of increased charge density (1+ versus 2+ on the metal center). Additionally, these two metals should possess similar hydration spheres, since Rb^+ and Cs^+ are proposed to both have eight water molecules coordinated to them in solution; therefore, when comparing Sr^{2+} and Rb^+, this should not play a significant role. Additionally, when Mähler and Persson[45] examined the hydration spheres of the alkali metals using large angle X-ray scattering and double difference IR, they showed that rubidium and cesium were only weakly coordinated; by extension, strontium should also be weakly coordinated.

Conclusion

To the best of our knowledge, the simple ITs of strontium and uranium, which typically limits the PPW, were observed for the first time utilizing a microinterface hosted by a 25 μm diameter micropipette. The determination of the formal transfer potentials for these free metal ions were characterized through the facile use of DPV and CV. $\Delta^{w}_{o}\phi^{o'}_{Sr^{2+}}$ and $\Delta^{w}_{o}\phi^{o'}_{UO_2{}^{2+}}$ were determined to be 0.768 and 0.743 V, respectively, using CV, and 0.654 and 0.699 V, respectively, from DPV, which were resolved from TB^- transfer using a Gaussian multipeak curve-fitting approach.

The observation of simple IT of these heavy metal ions was made possible by the reduction of the micropipette diameter to 25 μm along with our significant improvement on experimental setup, such as the unique design of the micropipette holder and capillary fabrication. This setup offers a facile approach to micropipette fabrication, which generates a consistent, uniform microinterface that can be used repeatedly. The philosophy behind this approach, analogous to the microhole technique,[30] is to decrease the amount of Faradaic current by reducing the interfacial surface area and thus allowing simple IT of metals limiting the PPW to be observed. Interestingly, however, owing to the improved interfacial stability, conventional electrolyte concentrations can be used.

Abstract: In the present work, graphite nanostructures are prepared by thermolysis of a prepared polyacrylamide gel. The gel was prepared by radical chain polymerization and the synthesis of the nanostructures was done by step annealing at different temperatures. The structural of the prepared materials was studied by X-ray diffraction (XRD). The presence of carboxylic and phenolic functional groups on the graphite surface was confirmed by FT-IR analysis. Batch adsorption experiments were conducted to study the effect of equilibration time, initial metal cation concentration, and solution pH for the removal of Cs(I) and Co(II) from aqueous solutions. Kinetic data of Cs(I) adsorption was found to be well fitted with a pseudo-first-order kinetic model. The obtained isotherm data were correlated with the Langumir and Freundlich isotherm models. The effect of temperature on the equilibrium distribution values was utilized to evaluate the change in the standard thermodynamic quantities of enthalpy ($\Delta H°$), entropy ($\Delta S°$), and Gibbs free energy ($\Delta G°$).

Key words: adsorption, Cs(I), Co(II), graphite, aqueous solution.

Résumé : Dans ce travail, on a préparé des nanostructures de graphite par thermolyse d'une préparation de gel de polyacrylamide. Le gel a été préparé par la technique de la polymérisation radicalaire en chaîne alors que la synthèse des nanostructures a été réalisée par la technique de recuisson à diverses températures. Les caractéristiques structurales des matériaux obtenus ont été étudiées par diffraction des rayons-X (DRX). La présence des groupes fonctionnels carboxyliques et phénoliques sur la surface de graphite a été confirmée par analyse infrarouge par transformation de Fourier (IR-TF). On a fait appel à des expériences d'adsorption globale pour étudier l'effet du temps d'équilibre, de la concentration initiale du cation métallique et du pH de la solution pour l'élimination des ions Cs(I) et Co(II) à partir de solutions aqueuses. On a trouvé que les données cinétiques d'adsorption du Cs(I) s'ajustent bien avec un modèle cinétique de pseudo-premier ordre. On a pu établir une corrélation entre les données d'isothermes et les modèles isothermes de Langmuir et Freundlich. On a utilisé l'effet de la température sur les valeurs de distribution d'équilibre pour évaluer le changement des quantités thermodynamiques standard d'enthalpie ($\Delta H°$), d'entropie ($\Delta S°$) et l'énergie libre de Gibbs ($\Delta G°$).

Mots-clés : adsorption, Cs(I), Co(II), graphite, solution aqueuse.

[Traduit par la Rédaction]

Introduction

The toxicity and the biological effects of hazardous materials, which are dangerous to public health and the environment, are attracting progressively more attention. The most hazardous pollutants identified in liquids waste and radioactive liquid waste of low and intermediate levels are Co(II), Cs(I), and Sr(II).[1] These pollutants are routinely and (or) accidentally released. Radioactive cesium has a relatively long half-life of about 30 years; as well, its stable isotope is hazardous to the environment.[2] Stable and radioactive cobalt isotopes are used in nuclear medicine, enamels, semiconductors, grinding wheels, and painting on glass. Acute cobalt poisoning in humans causes damage to the thyroid and liver and may cause mutations (genetic changes) in living cells.[3,4]

The techniques of chemical precipitation, ion exchange, membrane filteration, and reverse osmosis are usually used for the removal of pollutants from wastewaters.[5,6] In special situations, these methods fail to meet the Environmental Protection Agency's requirements;[7] or budget.[8] Among the most promising techniques, adsorption takes the attention because of its efficiency and low-cost operation.

Porous carbons with their large surface area, microporous character, and chemical nature are potential adsorbents for the removal of heavy metals from wastewater.[9] However, applications of porous carbon-based adsorbents with a large fraction of micropores (<2 nm) occupying most of the pore volume can be limited by slow diffusion kinetics.[10,11] Carbon nanostructures have found their place as an alternative for the porous carbon. Their physical properties, combined with their chemical inertness, make them potentially useful for technological applications for removal of hazardous materials.[12–14]

In the present work, graphite nanostructures are prepared

by thermolysis of a polyacrylamide gel. The adsorption behavior of Cs(I) and Co(II) were studied extensively.

Experimental

Chemicals and reagents

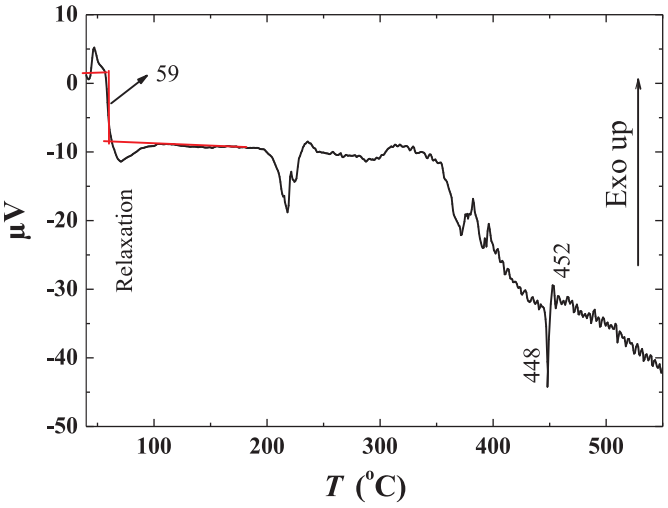
All reagents used in this work were AR grade chemicals and were used without further purification.

Instrumentation

Differential thermal analysis (DTA) was carried out by using a TA50 thermal analyzer (Shimadzu, Japan). The temperature was swapped at a constant rate of 5 °C/min from room temperature to 550 °C under atmospheric conditions. Infrared spectra (FT-IR) for prepared samples were determined using a Bomen Miclson FT-IR spectrophotometer, model MB157 (Canada). Investigation of the crystalline structure was performed using X-ray diffraction (XRD) with a JEOL X-ray diffractometer using Ni-filtered Cu Kα radiation ($\lambda_{K\alpha}$ = 0.154 184 nm). Continuous scanning was applied with a slow scanning speed and a small time constant. Adsorption and uptake of metals were determined by the metal concentration in the sample and solution using an atomic absorption spectrophotometer (Buck Scientific, VGP 210).

Preparation of the gel

Pure acrylamide (AA) powder and ammonium persulfate (APS) were used in the preparation of the organosulfonic acids. Each 56.9 g (0.8 mol) of AA monomer was dissolved in double-distilled water up to 200 mL. A hot plate stirrer was used to dissolve the monomer in water at room temperature at a low frequency. The stirrer was adjusted to heat the solution within the reaction flask to a temperature of 80 °C. The initiator was dissolved in water so that 0.1 mol/L of APS was heated to 80 °C. Mixing of the APS solution and the AA monomer solution took place at 80 °C. The blend was stirred heating for 10 min to ensure complete mixing. In the present work, 1 mL (0.001 mol) of APS solution was added to 20 mL (0.08 mol) of AA solution, i.e., to have a molecular monomer to initiator ratio of 80:1. Only 20 mL of the monomer was used in the preparation of the gel to avoid the overheating that occurs during the exothermic polymerization reaction. Using large amounts of monomer solution would require special attention and the use of a heat sink setup.



Polymerization occurs with complete consumption of the monomer to form the polymers, i.e., there are no effective termination reactions. After the preparation of the gel, the reaction process continued for a long time to degrade the properties of the prepared samples. After preparation of the gel, samples were left to dry at 60 °C for 5 days to ensure the full consumption of the monomer and solidification of the gel.

Differential thermal analysis

The thermal properties were deduced from the DTA curve. Figure 1 shows a discontinuity at 59 °C that represents the glass transition temperature. The enthalpic relaxation peak appearing at about 70 °C resulted from the slow quenching of the samples during the casting process.[15]

Several endothermic peaks were observed between 211 and 391 °C and are associated with the decomposition of the

Fig. 1. Differential thermal analysis curve of the solidified gel sample. The arrow points to the direction of the exothermic processes.

gel into sulfur trioxide, water, carbon monoxide, and carbon dioxide, in addition to a formation of complex organic compounds and direct subsequent volatilization of components such as acrylonitrile, hydrogen cyanide, acrylamide, and diones. The most important is an endothermic peak at 448 °C followed by an exothermic peak at 452 °C, which implies the formation and subsequent crystallization of a material.

Syntheses of graphite

According to the results of the thermal analysis, samples were treated thermally at 250 °C for 3 h at ambient temperature. After annealing, samples were left overnight to complete thermolytic reaction at room temperature. Then the samples were smashed and annealed at 350 °C for an extra 3 h and with extra annealing at 460 °C for 3 h to stimulate the formation of graphite structures. The last two steps were done inside an isolated Pyrex glass bottle to isolate the sample from the ambient atmosphere and then left to cool gradually to room temperature. The maximum uncertainties of the annealing temperature in the oven were 5% according to the position inside the cavity of the oven.

Adsorption experiments

Stock solutions of the metal ions to be examined were prepared by dissolving a known quantity of both cesium and cobalt chloride in double-distilled water. The pH of each solution was adjusted with liquid 1 mol/L NaOH and 1 mol/L HCl solution.

In all experiments, The kinetic behavior of Cs(I) and Co (II) ions on prepared powder was followed up by application of batch technique. The adsorbent (0.1 g) and 10 mL of the desired solution were placed in a horizontal shaker, at room temperature (25 ± 1 °C), for a specified period of contact time. Then a fixed volume (1 mL) of the clear solution was pipetted out for determination of the amount of unsorbed metal ion; the metal concentration retained in the solid phase (mmol/kg) was calculated by using the following equation:

$$[1] \qquad q_t = [(C_0 - C_t)]\frac{V}{m}$$

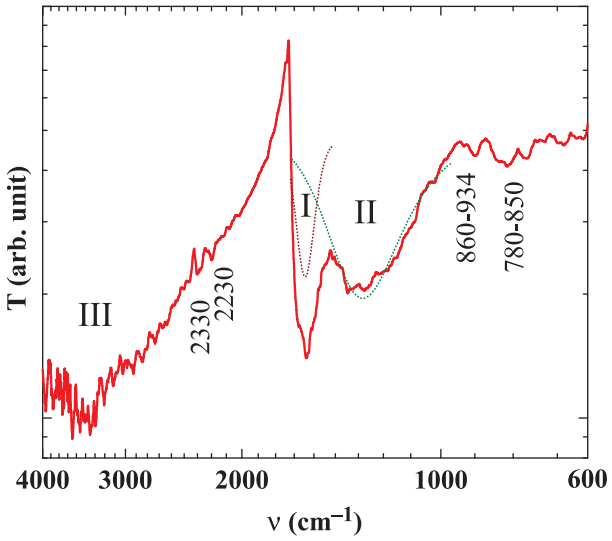
Fig. 2. IR spectra of the prepared material.



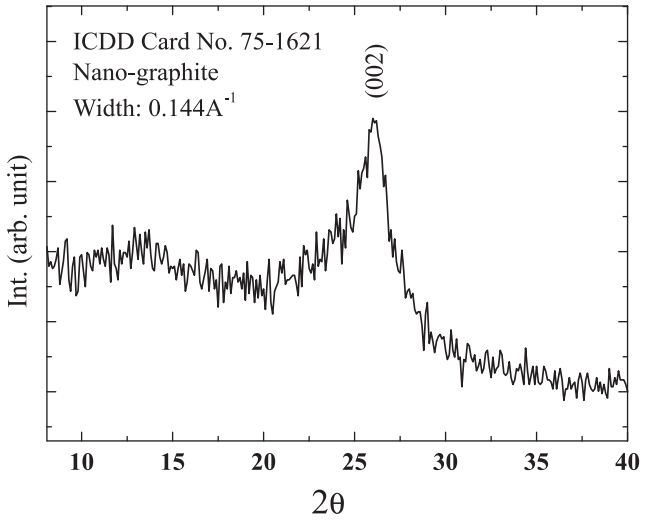


Fig. 3. X-ray diffractogram showing the broad reflection of graphite nanostructure.

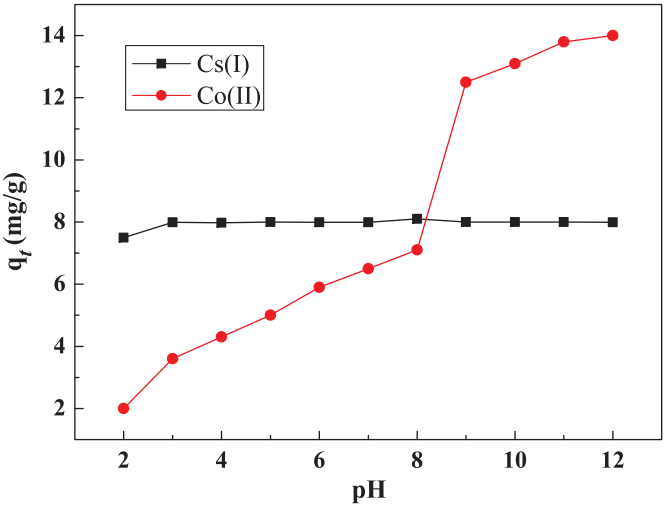
where C_0 and C_t are the initial and time interval concentrations (mmol/L) of metal ion in solution, respectively, V is the volume of the solution in litres, and m is the weight of the adsorbent in grams.

Adsorption isotherms

Batch adsorption studies of Cs(I) and Co(II) ions were performed at different temperatures (25, 40, and 60 °C) to obtain the equilibrium isotherms. The adsorption processes of Cs(I) and Co(II) ions on the prepared powder adsorbent were tested with Langmuir and Freundlich isotherm models. The two empirical adsorption models, Freundlich and Langmuir, which are correspondent to heterogeneous and homogeneous adsorbent surfaces, respectively, were investigated in this study.



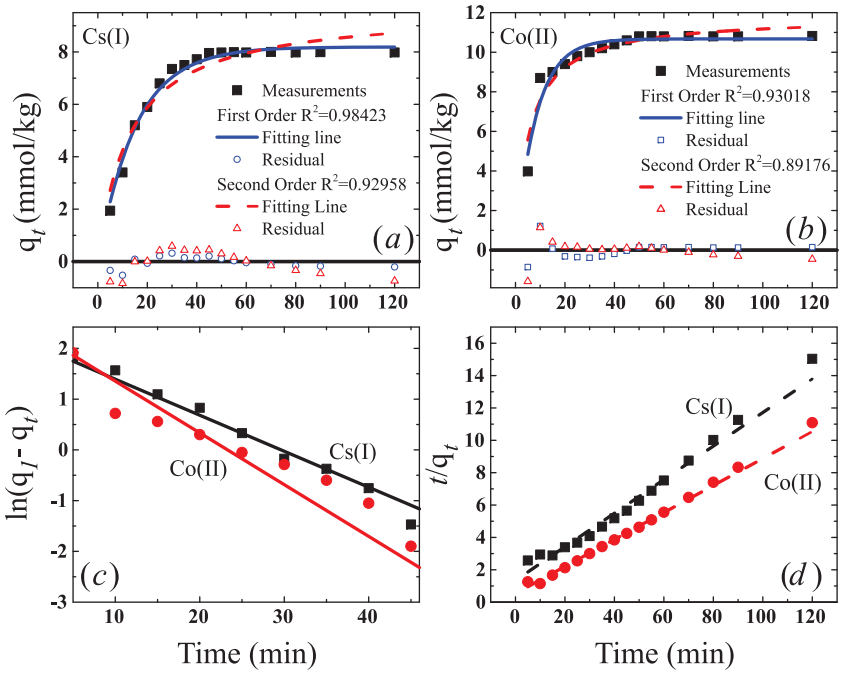
Results and discussion

Characterization of the material

IR spectroscopy of the prepared material was carried out in the range 400–4000 cm^{-1} as shown in Fig. 2. There is a strong absorption region between 1500 and 1700 cm^{-1}, labeled region I. The absorption in that region is attributed to four origins. The first is centered on 1650 cm^{-1} and indicates the presence of a C=O stretching vibration that is associated with an amide. The second source is a medium absorption around 1600 cm^{-1}, which is associated with C–C in the presence of C=O, which is usually found in dienes. The third source of absorption is C=N usually appearing between 1615 and 1700 cm^{-1}, which may be shifted to a lower wavenumber because of a conjunction with C=O. The last source of absorption is the N=O stretching vibration that appeared between 1500 and 1600 cm^{-1}. This type of absorption is accompanied by absorption between 1300 and 1400 cm^{-1} of the bending vibration, which exists in the spectrum.

There is a second broad absorption peak (region II), which consists of complicated absorptions. The first contributing functional group is the N=O bending by absorption between 1300 and 1400 cm^{-1}. The main contributing absorption is the S=O stretching of sulfoxides (1030–1060 cm^{-1}), stretching in sulfonic acids (1345 cm^{-1}), and stretching in sulfates (1350–1450 cm^{-1}). The absorption at 880–995 cm^{-1} is attributed to R=C–H and R=CH_2 stretching vibrations that are shifted to a lower frequency because of a conjunction with a heavy radical, while the absorption at 780–850 cm^{-1} is attributed to its out-of-plane bending of these stretching vibrations.

Fig. 4. Effect of pH value on Cs(I) and Co(II) adsorption.



In region III, the broad absorption band in the range 3290–2750 cm^{-1} is attributed to O–H stretching vibrations of phenolic or alcoholic functional groups. The sharp medium peak at 2230 cm^{-1} is attributed to a conjugated C≡N (nitrile) stretching vibration. The 2330 cm^{-1} absorption is attributed to entrapped CO_2 gas within one or more structures of carbon.[16,17] The CO_2 gas was produced during the thermolysis process.

The hydroxyl, phenol, nitriles, and amides that are formed with the carbon nanostructure, on the surface, provide hydrophilic sites on the hydrophobic surface of the as-produced carbon nanostructures,[18] causing them to be dispersed in aqueous solution.

The synthesized powder was also characterized using XRD as shown in Fig. 3. After annealing at 460 °C, a broad XRD

Fig. 5. Effect of contact time on adsorption of (*a*) Cs(I) and (*b*) Co(II) ions on the prepared carbon at pH 5. Continuous lines represent model approximation (solid line, first-order kinetics; broken line, second-order kinetics). The residuals are represented by open symbols (see text).

reflection was observed that corresponds to the formation of a nonocrystalline graphite structure (tubes, pellets, particles, etc.), see Fig. 3. The average size of the crystallites can be obtained directly from the width of the peak, that is 4 ± 1 nm. Hence, it is possible to perform mass production of the graphite nanostructure using the polyacryloamidic route.

The effect of pH

The value of pH is the key factor that controls the adsorption processes because it controls the electrostatic interactions between the adsorbent and the adsorbate. To investigate the dependence of the maximum removal efficiency of cesium and cobalt on the value of pH, experiments were conducted in the pH range 2–12 (see Fig. 4). The uptake of Co(II) and Cs(I) ions was inhibited in acidic medium (pH < 2.0), which is attributed to the competition between hydrogen ion and the studied ions for adsorption onto the prepared powder.

The uptake of Cs(I) remained almost constant because cesium does not tend to hydrolyze or form complexes readily; hence, over a wide pH range it is present as the Cs ion. However, the exchange properties of the material depend on the pH of the system, not because of any effect on cesium speciation.[19] At pH 2–3, the reduced adsorption is caused by the different solubilities of the constituents of graphite and H^+ competitive adsorption.

The removal of Co(II) from the solution was low at low pH, but increased remarkably with increasing pH. There are many cobalt species that could be present depending on the pH value,[20] such as Co^{2+}, $Co(OH)^+$, $Co(OH)_2$, and $Co(OH)^{3-}$. At low pH, the main species was Co^{2+}. As the pH of an aqueous suspension increases, the surface charge of the powder becomes more negative and thus results in binding the positively charged Co^{2+} ions more strongly. In the present results, up to pH 8, cobalt exists primarily as unhydrolyzed Co(II) ion, but, at pH > 8, it strongly hydrolyzes and starts to precipitate in the form of the insoluble hydroxide, $Co(OH)_2$. All future sorption studies were carried out at pH 5.

The results indicate that cobalt adsorption is favorable with lower ionic strength, higher pH, and lower initial concentration. The mechanisms of heavy-metal ion adsorption on carbon are very complicated and appear attributable to physical adsorption, electrostatic attraction, precipitation, and chemical interaction between the metal ions and surface functional groups.

Kinetic studies

Effect of contact time and temperature

Figure 5 shows the plots of the amount sorbed of Cs(I) and Co(II) ions from aqueous solution onto graphite powders as a function of contact time and at a fixed pH (pH 5) and at room temperature (25 ± 1 °C). The figure shows a high initial rate of removal within the first 30 min of contact (60%–70% removed), followed by a slower subsequent removal rate that gradually approached an equilibrium condition in about 2 h. The rapid uptake of the studied ions by graphite may be due to adsorption and (or) exchange of the ions with some ions on the surface of the graphite.

Adsorption kinetics modeling

In this model, the study of adsorption describes the solute uptake rate and, evidently, this rate controls the residence time of adsorbate uptake at the solid–solution interface. In this part of the study, the kinetics of Cs(I) and Co(II) ion adsorption onto a prepared sample powder were analyzed using pseudo-first-order[21] and pseudo-second-order[22] kinetic models, respectively. The conformity between experimental data and each of the model-predicted values is expressed by the correlation coefficient (R^2). Relatively high R^2 values indicate

Table 1. The calculated parameters of the pseudo-first- and the pseudo-second-order kinetic models.

	First-order kinetics parameter			Second-order kinetics parameter				
Ion	k_1 (min^{-1})	q_1 calcd (mmol/kg)	R^2	k_2 (kg/mmol min^{-1})	q_2 calcd (mmol/kg)	h (mmol/kg min^{-1})	R^2	q_e exp. (mmol/kg)
Cs(I)	0.065	8.19	0.984	0.008	9.64	0.743	0.929	7.98
Co(II)	0.102	10.75	0.980	0.013	11.99	1.868	0.932	10.8

Note: k_1, pseudo-first-order rate constant; q_1, amount of metal ion adsorbed onto the prepared powder at equilibrium; k_2, pseudo-second-order rate constant; q_2, amount of metal ion adsorbed onto the prepared powder at equilibrium by applying second-order kinetics; h, initial adsorption rate;

that the model successfully describes the kinetics of metal ion adsorption.

In the pseudo-first-order model (Lagergren equation),[21] the adsorption kinetics of metal ions from liquid to solid is considered as a reversible reaction with an equilibrium state being established between two phases. A simple pseudo-first-order model[21] was therefore used to correlate the rates of reaction and is expressed as follows:

$$[2] \qquad \frac{dq_t}{dt} = k_1(q_1 - q_t)$$

where q_1 and q_t are the amounts of metal ion adsorbed onto the prepared powder at equilibrium and after time t (in mmol/kg), respectively, and k_1 is the pseudo-first-order rate constant (min^{-1}). After integration and by applying the boundary conditions $t = 0$ to $t = t$ and $q_t = 0$ to $q_t = q_t$, respectively, the integrated form of this equation becomes

$$[3] \qquad \ln(q_1 - q_t) = \ln q_1 - k_1 t$$

The values of $\ln(q_1 - q_t)$ are linearly correlated with t. Therefore, the plot of $\ln(q_1 - q_t)$ vs t should give a linear relationship, from which k_1 and q_1 can be determined by iteration analysis. It is worth mentioning that the direct determination of the equilibrium capacity by experimental procedure can lead to incorrect and (or) misleading results. Instead, by rearranging eq. [3]

$$[4] \qquad q_t = q_1[1 - \exp(-k_1 t)]$$

and by using least-squares fitting to reduce the sum of squares of the deviation from experimentally measured capacities, the values of the amounts of metal ions adsorbed at equilibrium (q_e) and k_1 can be determined.

For the pseudo-second-order model of adsorption, the kinetic rate equation is expressed as

$$[5] \qquad \frac{dq_t}{dt} = k_2(q_2 - q_t)^2$$

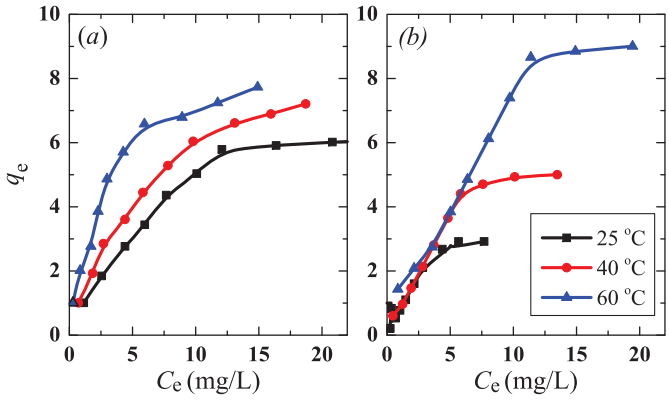
where k_2 (kg mmol^{-1} min^{-1}) is the rate constant of the pseudo-second-order equation. For the boundary conditions $t = 0$ to $t = t$ and $q_t = 0$ to $q_t = q_t$, the integrated form of eq. [5] becomes

$$[6] \qquad \frac{1}{(q_2 - q_t)} = \frac{1}{q_2} + k_2 t$$

Equation [5] can be rearranged to obtain a linear form equation

$$[7] \qquad q_t = q_2\left(1 - \frac{1}{1 + q_2 k_2 t}\right)$$

Fig. 6. Adsorption isotherms of (*a*) Co(II) and (*b*) Cs(I) ions from aqueous solution onto prepared graphite.



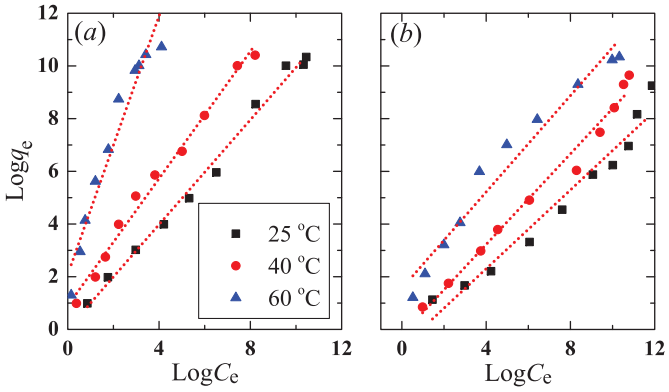


Fig. 7. Freundlich isotherm plots for adsorption of (*a*) Cs(I) and (*b*) Co(II) ions from aqueous solution onto prepared graphite.

$$[8] \qquad \frac{t}{q_t} = \frac{1}{k_2 q_2^2} + \frac{t}{q_2}$$

The plot of (t/q_t) and of t should give a linear relationship from which q_2 and k_2 can be determined or, alternatively, by the technique mentioned before.

Comparisons of the the experimental results with the model fitting for the material capacity (q_t) for both Cs(I) and Co(II) are shown in Fig. 5. The results show that the adsorption capacity of Cs(I) increased rapidly with an increase in contact time until about 40 min, and then the increasing rate slowed down gradually until the material was saturated. The model fitting shows that the pseudo-first-order model is suitable for sorption of Cs(I) on the prepared material. This observation suggests a fast monolayer adsorption onto the nanostructure material. The first-order reaction is associated mainly with diffusion through the organic foam that holds

Table 2. Langmuir and Freundlich isotherm parameters for the adsorption of Cs(I) and Co(II) ions onto prepared graphite at different temperatures.

		Langmuir model parameter			Freundlich model parameter		
Ions	Temp. (°C)	$Q°$ (mmol/kg)	$b\times10^{-3}$ (l/mol)	R^2	$1/n$	K_f (mmol/kg)	R^2
Cs(I)		67.3	35.7	0.9966	0.991	1.22	0.991
	40	72.2	48.7	0.9956	0.542	4.01	0.986
	60	86.5	97.1	0.9830	0.263	7.90	0.973
Co(II)	25	114.4	25.4	0.9981	0.914	4.87	0.995
	40	205.5	49.9	0.9939	0.859	11.62	0.986
	60	226.5	171.8	0.9969	0.748	36.39	0.985

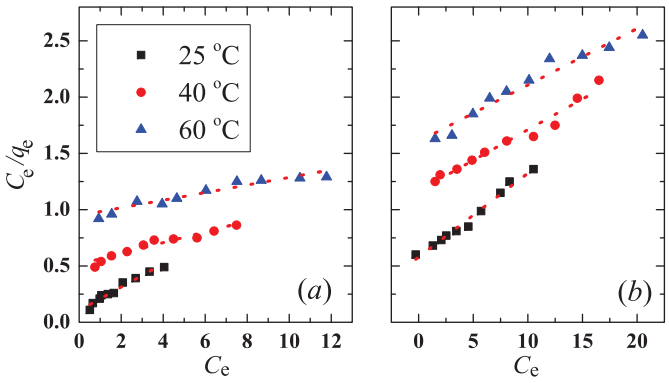
Note: $Q°$, Langmuir constant representing maximum monolayer capacity; b, Langmuir constant related to energy of adsorption; n, Freundlich constant related to intensity of adsorption; K_f, Freundlich constant related to adsorption capacity.

the carbon nanostructures; the foam is an organic substance that is associated with the synthesis of the carbon nanostructures. The rate constant of the prepared nanostructure carbon is very high and reached 0.0652 min^{-1} in comparison with porous activated carbon.[23]

In the case of cobalt at pH 5, pseudo-first-order model fitting shows a reasonable value of R^2 as compared with the pseudo-second-order model (Fig. 5*b*). The kinetics of the mechanism may be more complicated. A kinetic model with a correlation coefficient (R^2) closer to one would be more desirable. However, the greater weight of first-order fitting is after 40 min; therefore, and as shown in Fig. 5*c*, the fitting is not appreciable for the first 40 min. That suggests a strong contribution of second-order and higher kinetics to the ion-exchange processes rather than pseudo-first-order kinetics at the beginning of the adsorption process. In Table 1, the product $k_2q_2^2$ is the initial adsorption rate represented as $h = k_2q_2^2$. Furthermore, the theoretical and experimental q_e values are in good accordance with each other.

Adsorption isotherms

The equilibrium isotherm is important for describing how solutes interact with the adsorbent and, therefore, is critical in optimizing the use of the adsorbent. In this respect, the adsorption isotherms for the removal of Cs(I) and Co(II) ions from aqueous solution onto prepared graphite at three different temperatures were determined and are shown in Fig. 6. The amount of Cs(I) and Co(II) ions adsorbed per unit mass of the graphite increased with the initial metal concentration until the plateau values, representing saturation of the active groups that are available for interaction with Cs(I) and Co(II) ions on the material, were reached. Two commonly used empirical adsorption models, Freundlich and Langmuir models, which correspond to heterogeneous and homogeneous adsorbent surfaces, respectively, were employed in this study.



Freundlich isotherm model

The Freundlich equation was derived to model the multilayer sorption and for sorption onto heterogeneous surfaces. The logarithmic form of the Freundlich equation may be written as

$$[9] \qquad \log q_e = \log K_f + (1/n)\log C_e$$

where C_e is the remaining concentration in the aqueous phase, and K_f and n are the Freundlich constants related to adsorption capacity and intensity of adsorption, respectively. The plot of $\log q_e$ vs $\log C_e$ is shown in Fig. 7, which suggests that adsorption of Cs(I) and Co(II) ions onto graphite obeys the Freundlich isotherm over the entire range of adsorption concentration. The numerical values of the constants $1/n$ and K_f were computed from the slope and intercepts using the linear least-squares fitting method and are given in Table 2. The $1/n$ value is usually dependent on the nature and strength of the adsorption process as well as on the distribution of active sites. The numerical values of K_f represent the adsorption capacities of Cs(I) and Co(II) ions onto graphite.

Fig. 8. Langmuir isotherm plots for adsorption of (*a*) Cs(I) ions and (*b*) Co(II) ions from aqueous solution onto prepared graphite.

Langmuir isotherm model

The Langmuir isotherm model assumes maximum adsorption occurs when the surface is covered by the adsorbate. The linear form of the Langmuir equation is given by the following formula

$$[10] \qquad \frac{C_e}{q_e} = \left(\frac{1}{Q°b}\right) + \left(\frac{1}{Q°}\right)C_e$$

where q_e (mmol/kg) is the amount adsorbed at equilibrium concentration (C_e, mmol/L), $Q°$ (mmol/kg) is the Langmuir constant representing maximum monolayer capacity, and b is the Langmuir constant that is related to energy of the adsorption. The isotherm data has been fitted to a linear relationship using the Langmuir equation and is shown in Fig. 8. The regression constants are tabulated in Table 2. The Langmuir constants $Q°$ and b increased with temperature, showing that the sorption capacity and intensity of adsorption are en-

Fig. 9. Plot of $\ln K_c$ vs $1/T$ for adsorption of Cs(I) and Co(II) ions onto prepared graphite.

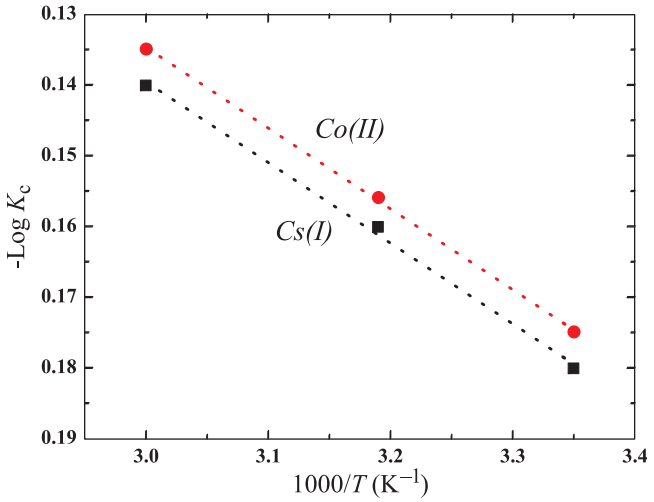

Table 3. Thermodynamic parameters of Cs(I) and Co(II) on prepared graphite.

Metal	$\Delta H°$ (kJ/mol)	$\Delta S°$ (J/mol K^{-1})	$-\Delta G°$ (KJ/mol) At 25 °C	At 40 °C	At 60 °C
Cs(I)			2.9	6.8	15.5
Co(II)	40.7	98.6	9.7	12.5	14.6

hanced at higher temperatures. This increase in adsorption capacity with temperature suggests that the active surfaces available for adsorption have increased with increasing temperature.[24]

Effect of temperature

The effects of temperature on the adsorption behavior of Cs(I) and Co(II) onto graphite powder were studied using van't Hoff's equations, which take the form

$$[11] \quad \log K_c = -\frac{\Delta H^\circ}{2.303RT} + \frac{\Delta S^\circ}{2.303R}$$

$$[12] \quad \Delta G^\circ = -RT \ln K_c$$

where K_c is the adsorption equilibrium constant, R is the gas constant, and T is the absolute temperature in Kelvin. The values of K_c at the different studied temperatures were determined from the product of the Langmuir equation parameters $Q°$ and b.[24] The plot of $\log K_c$ vs $1/T$ is a straight line as shown in Fig. 9 The values of $\Delta H°$, $\Delta S°$, and $\Delta G°$ are evaluated and tabulated in Table 3. The values of free energy decrease (from –2.9 to –15.5 kJ/mol for Cs(I) and from –9.7 to –14.6 kJ/mol for Co(II)) with an increase in temperature, indicating that the process is favorable at higher temperatures. The negative value of $\Delta G°$ indicates that the adsorption behavior of Cs(I) and Co(II) ions is spontaneous, with a high preference of metal ion adsorption in prepared graphite. The changes of energy for physical adsorption are up to –1.123 kJ/mol and those for chemical adsorption are up to –22.71 kJ/mol.[25] From Table 3, the magnitude of adsorption $\Delta G°$, ranging from –2.9 to –15.5 kJ/mol for Cs(I) and from –9.7 to –14.6 kJ/mol for Co(II), suggests that the adsorption can be considered as a chemical adsorption. However, the positive values of $\Delta H°$ and $\Delta S°$ indicate that the adsorption is spontaneous and endothermic.

Conclusions

On the thermal annealing of polyacrylamide gel, nanostructured carbon particles were synthesed. The structure and composition were investigated by XRD and FT-IR, which confirmed the existence of functional groups on the nanostructured graphite surfaces. The prepared material has promising applications in the treatment of the aqueous environment for heavy metals such as Cs(I) and Co(II) because of its low cost, high capacity, ease of production, and rapid uptake rate. The adsorption of Cs(I) and Co(II) on the prepared powder was investigated by batch technique. For the pH range 2–12, the adsorption of Cs(I) remains almost constant, whereas the adsorption of Co(II) is low at low pH and increases rapidly at pH > 8 as it hydrolyzes and starts to precipitate. Equilibrium isotherms were studied using the Freundlich and Langmuir isotherm models to assess the maximum adsorption capacities of both metal ions and the equilibrium adsorptions. The maximum adsorption capacity of Cs (I) was found to be greater than that of Co(II).

Abstract: The sequential complexations of the hydrophilic and hydrophobic end groups of benzethonium chloride by cucurbit[7]uril (CB[7]) in aqueous solution have been investigated using ^{1}H NMR spectroscopy and electrospray ionization mass spectrometry. The initial binding is to the benzyldimethylammonium group, with a stability constant of $(8.7 \pm 3.1) \times 10^7$ $(mol/L)^{-1}$. This binding constant and the complexation-induced upfield shifts of the benzyl guest protons are similar to those values observed with other cationic guests containing benzyl moieties. This equilibrium is followed by the binding of a second equivalent of the host to the hydrophobic 2-(2,4,4-trimethylpentyl) group, with a stability constant of $(4.0 \pm 1.9) \times 10^3$ $(mol/L)^{-1}$. The relatively strong binding of this uncharged hydrophobic end of the guest molecule is consistent with the inclusion of eight heavy (nonhydrogen) atoms within the inner cavity of CB[7], with its low polarizability. The packing coefficient for the 2-(2,4,4-trimethylpentyl) group with the inner cavity is calculated to be 61%, close to Rebek's ideal value of 55%.

Key words: cucurbit[7]uril (CB[7]), benzethonium, host–guest complex, hydrophobic, hydrophilic.

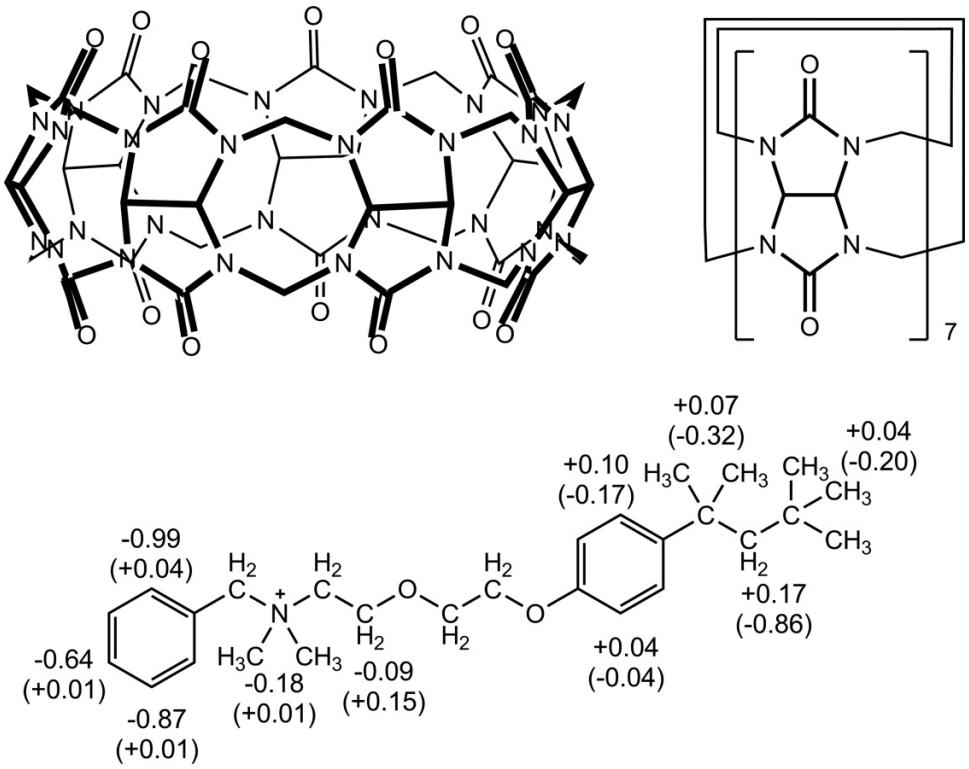
Résumé : Faisant appel à la spectroscopie RMN du ^{1}H et à la spectrométrie de masse avec ionisation par électronébulisation, on a étudié les complexations séquentielles des groupes terminaux hydrophiles et hydrophobes du chlorure de benzéthonium par une solution aqueuse de cucurbit[7]urile. La fixation initiale se fait au niveau du groupe benzyldiméthylammonium, avec une constante de stabilité de $(8{,}7 \pm 3{,}1) \times 10^7$ $(mol/L)^{-1}$. Ces constantes de fixation ainsi que les déplacements chimiques vers les hauts champs, induits par la complexation, des protons benzyles invités sont semblables aux valeurs qui ont été observées avec d'autres invités cationiques contenant des portions benzyliques. Cet équilibre est suivi par la fixation d'un deuxième équivalent de l'invité par le groupe hydrophobe 2-(2,4,4-triméthylpentyl), avec une constante de stabilité de $(4{,}0 \pm 1{,}9) \times 10^3$ $(mol/L)^{-1}$. Cette fixation relativement forte de la portion hydrophobe non chargée de la molécule hôte est en accord avec l'inclusion de huit atomes lourds (qui ne sont pas des atomes d'hydrogène) dans la cavité intérieure du CB[7] de faible polarisabilité. On a calculé que le coefficient de compactage du groupe 2-(2,4,4-triméthylpentyle) à l'intérieur de la cavité est de 61 %, très près de la valeur idéale de 55 % de Rebek.

Mots-clés : cucurbit[7]urile, benzéthonium, complexe hôte–invité, hydrophobe, hydrophile.

[Traduit par la Rédaction]

Introduction

The cucurbit[*n*]urils (CB[*n*], $n = 5–8, 10$) are a family of macrocyclic host molecules comprised of *n* glycoluril units bridged by 2*n* methylene groups.[1–4] While the CB[6] member was first prepared over 100 years ago,[5] it has been in the last decade, since the methods for preparing the other members of the family were first reported,[6,7] that investigations into the applications of CB[*n*] as host molecules have significantly increased.[4] Guest molecules may bind to the CB[*n*] hosts by means of ion–dipole, dipole–dipole, and dipole–quadrupole interactions, as well as the hydrophobic effect. The largest stability constants have been observed between CB[7] (Fig. 1), the most soluble member of the family, and cationic guests based on ferrocene,[8–11] adamantyl,[12,13] or bicyclo[2.2.2] octane groups.[12,13] These ultrahigh affinity guests form CB[7] complexes with stabilities that rival that of the avidin–biotin complex in nature, and this feature has been applied to the binding of ultrahigh affinity labeled proteins to CB[*n*]-coated beads.[14] The cucurbiturils have been found to be relatively nontoxic,[15–18] and there have been a diverse set of guests of biological and medicinal interest investigated with CB[7], including proteins,[19] anticancer agents,[20,21] vitamins,[22] and fungicides.[23] The ability to solubilize more hydrophobic guests in aqueous solution,[24] as well as to significantly modulate the pK_a values of acidic guests,[25,26] have led to the applications of CB[7] in drug delivery,[24,26] stability,[27,28] and controlled release.[29]



Benzethonium chloride (Fig. 1) is a synthetic quaternary ammonium compound used primarily as an antifungal preservative.[30] It also has moderate antiseptic and anti-infective properties, making it useful as a disinfectant and a viable

Fig. 1. Structure of cucurbit[7]uril (CB[7], top) and the benzethonium cation (bottom). The ^{1}H NMR limiting chemical shift change, $\Delta\delta_{lim}$, values are shown for the guest proton resonances upon formation of the host–guest complex between the benzethonium cation and CB[7]. The top numbers represent the shifts associated with the first host binding event and the bottom numbers in brackets represent shifts associated with the second binding event. The shifts of some of the guest protons were obscured by the proton resonances of CB[7] and the solvent, and therefore could not be measured.

alternative to alcohol-based hand sanitizers. It was recently determined in a cell-based small molecule screen that benzethonium is selectively toxic to human pharyngeal cancer cells, but not to normal human or mouse cells.[31] When it is desirable to isolate organisms from solutions containing antimicrobial agents, such as benzethonium chloride, nonionic detergents, or phospholipids, which trap the antimicrobial agents within micelles, are commonly employed. These molecules, however, can also be lethal to the microorganisms. Macrocyclic host molecules, such as β-cyclodextrin, have been shown to be effective as an alternative to detergents for neutralizing quaternary ammonium compounds such as benzethonium chloride.[32] The cyclodextrins generally bind to cationic guests with binding constants considerably smaller than determined for the cucurbiturils, owing to weaker ion–dipole interactions between the positive charge(s) on the guest and the portal functional groups (hydroxyls on cyclodextrins versus ureido carbonyls on cucurbiturils). A recent example is the superior binding of CB[7] to a series of local anaesthetics[33] compared with β-cyclodextrin or the *p*-sulfonated calix[4]arene.[34] The CB[7] host, therefore, should be more efficient at neutralizing the antimicrobial effects of the benzethonium cation than either β-cyclodextrin or nonionic detergents.

The benzethonium cation possesses a hydrophilic cationic benzyldimethylammonium fragment on one end and a hydrophobic 2-(2,4,4-trimethylpentyl)-substituted phenyl group on the other end, with a diethyleneglycol unit in the centre. This would allow for the binding of two cucurbit[7]uril host molecules using different noncovalent interactions to stabilize the host–guest interactions. We have observed a similar phenomenon with coenzyme B_{12}, where the first CB[7] bound to the protonated α-axial 5,6-dimethylbenzimidazole base, which had dissociated from the Co(III) centre ($K_{CB[7]}$ = (3.02 ± 0.35) × 10^6 (mol/L)$^{-1}$).[22] This was followed by a second weaker binding to the neutral β-axial 5′-deoxyadenosyl ligand ($K_{CB[7]}$ = (1.1 ± 0.2) × 10^3 (mol/L)$^{-1}$) without its detachment from the Co(III) centre. The three orders of magnitude difference in the binding constants allowed for the two processes to be observed separately in the ^{1}H NMR spectrum.

While the cationic benzylammonium fragment is known to bind strongly to CB[7],[35,36] there have been few studies of the binding of branched hydrocarbon groups to this host molecule. Florea and Nau[37] recently reported that CB[6] is capable of binding a range of hydrocarbons in aqueous solution, with host–guest stability constants of up to 10^6 (mol/L)$^{-1}$ (isobutene and cyclopentane). The binding of the hydrocarbons to CB[7] was investigated using a competitive fluorescent dye displacement technique, as the low solubility of CB[6] in pure water prevents the use of NMR spectroscopy. Nau et al.[38] also carried out a detailed analysis of the role of the hydrophobic effect in the complexation of neutral molecules to CB[*n*] hosts, and this has shown that CB[6] and CB[7] possess cavity sizes (inner cavity volumes of 142 and 242 Å^3, respectively) that allow for the inclusion of guests with up to seven and 12 heavy atoms,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

respectively. The largest binding constants for CB[7] with both neutral and cationic guests are observed with those containing adamantyl (nine heavy atoms) or ferrocenyl (11 heavy atom) groups. Nau and co-workers[37,38] have shown that these findings are in line with the empirical determination of Mecozzi and Rebek[39] that the optimal host–guest stability is found when the guest occupies 55% ± 9% of the interior cavity volume of the host.

The 2-(2,4,4,-trimethylpentyl) group on the benzethonium cation has eight heavy atoms and would be therefore expected to displace the 7–8 waters located in the CB[7] cavity and bind reasonably strongly using the hydrophobic effect. In this study, we used electrospray ionization mass spectrometry (ESI-MS) and ^{1}H NMR spectroscopy to investigate the relative complexations of the CB[7] host molecule to the hydrophilic and hydrophobic ends of the benzethonium cation in aqueous solution.

Experimental section

Materials

Cucurbit[7]uril was prepared and characterized by the method of Day et al.[7] Benzethonium chloride and benzyltrimethylammonium bromide (Sigma-Aldrich) were used as received.

Methods

The ESI mass spectrum was recorded on a QStar XL TOF instrument and the ^{1}H NMR spectra were obtained using Bruker Avance AM 400 and 500 MHz instruments. The 1:1 host–guest stability constant ($K^1_{CB[7]}$) was determined by a ^{1}H NMR competitive binding experiment in D_2O (50 mmol/L NaOAc buffer, pD 4.7), using the protocol of Isaacs and co-workers,[40] with the benzyltrimethylammonium cation as the competitor guest ($K_{CB[7]} = (2.5 \pm 0.6) \times 10^8$ (mol/L)$^{-1}$).[36] The 2:1 host–guest binding constant ($K^2_{CB[7]}$) was determined by a ^{1}H NMR titration in which the ratio of the bound to total guest (determined by integrations of proton resonances) as a function of [CB[7]] was fit to a 1:1 binding isotherm. Molecular modelling of the structures of the host–guest complex was performed using Chem3D software (CambridgeSoft) with MM2 energy minimizations.

Results and discussion

Host–guest complexation

ESI-MS measurements

The high-resolution electrospray ionization mass spectrum (ESI-MS) of an aqueous solution of the benzethonium cation in the presence of a fivefold excess of CB[7] reveals peaks with m/z = 1574.6675 and 1380.0013. The former peak corresponds to the 1:1 [CB[7]·benzethonium]$^+$ complex (calculated m/z = 1574.6645 for $C_{69}H_{84}N_{29}O_{16}^+$) and the second peak corresponds to the 2:1 [CB[7]·benzethonium·CB[7]·Na]$^{2+}$ complex (calculated m/z = 1379.9987 for $C_{111}H_{126}N_{57}O_{30}Na^{2+}$).

NMR measurements

^{1}H NMR spectroscopy has proven to be a very useful method for determining the portion(s) of guest molecules that are located within the hydrophobic cavity as opposed to being positioned adjacent to the polar carbony-lined portals of the cucurbiturils. An upfield shift in a resonance of the guest proton upon complexation by CB[7] ($\Delta\delta_{lim} = \delta_{bound} - \delta_{free}$) is indicative of its position within the cavity, whereas a downfield shift indicates that the guest proton is located outside, near one of the portals. A ^{1}H NMR titration of the benzethonium cation by CB[7] is shown in Fig. 2. The complexation-induced chemical shift changes for the guest proton resonances indicate two sequential binding processes by CB[7] host molecules. The first process is the binding of the more hydrophilic end of the molecule, over the benzyldimethylammonium group (protons H_j, H_k, H_l, and H_m; Fig. 2). This is followed by the complexation of the more hydrophobic end, containing the 2-(2,4,4-trimethylpentyl) substituent on the aromatic ring (protons H_a, H_b, and H_c; Fig. 2). The slight downfield shifts in the H_f, H_g, and H_h protons of the central linker indicate that this portion of the molecule is not complexed by the CB[7] host. The limiting chemical shift changes ($\Delta\delta_{lim}$) are given in Fig. 1 for the two binding processes. A gas-phase energy minimization calculation (MM2) for the structure of the 2:1 host–guest complex between CB[7] and the benzethonium cation, which is consistent with the complexation-induced chemical shift changes, is shown in Fig. 3.

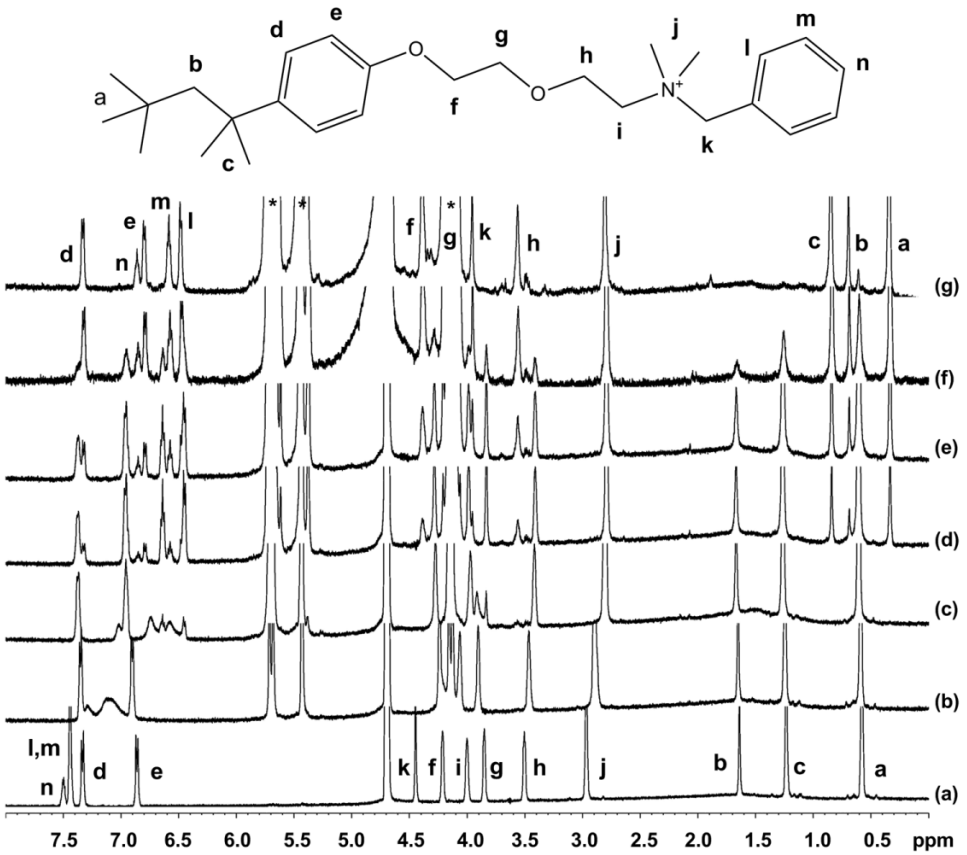
Binding of the hydrophilic moiety

The addition of 1 equiv of CB[7] to a solution of the benzethonium guest results in the complexation of the benzyldimethylammonium end of the molecule bearing the positive charge. The limiting chemical shift changes for the aromatic and methylene protons are upfield and are of comparable magnitude to other cationic guest molecules with benzyl end groups, such as the benzylammonium,[41] benzyltrimethylammonium,[36] benzylcholine,[42] and *N*-benzyl-1-(1-naphthyl)ethylammonium[35] cations (Fig. 4). The magnitudes of the $\Delta\delta_{lim}$ values suggest that the complexation places the benzyl group within the cavity with the quaternary nitrogen centre placed near the oxygens of the ureido carbonyl groups on the portals.

Complexation at the first binding site is mainly driven by ion–dipole interactions between the cationic ammonium group of the benzethonium cation and the polar portals of CB[7]. This binding site is also stabilized by the hydrophobic effect, which results from the terminal phenyl group of benzethonium being encapsulated by the hydrophobic cavity of CB[7]. As a result of these two effects working in tandem, CB[7] is able to form a very stable complex with the benzethonium cation. In the case of tightly bound host–guest complexes ($K_{CB[7]} > 10^4$ (mol/L)$^{-1}$), the binding constant cannot be determined by fitting a binding curve from a ^{1}H NMR titration with host and guest concentration in the millimolar range. The plot of $\Delta\delta_{obs}$ for the aromatic proton resonances as a function of [CB[7]]/[benzethonium] is linear until a 1:1 ratio (Fig. 5), and as such it was not possible to accurately determine the first binding constant by fitting this data. Instead, the binding constant was determined by a competition study with a known competitor, using the protocol of Isaacs and co-workers.[40] The host–guest stability constant for the CB[7] complex with the benzethonium cation was determined to be $K^1_{CB[7]} = (8.7 \pm 3.1) \times 10^7$ (mol/L)$^{-1}$ using the benzyltrimethylammonium cation (Fig. 4*b*, $K_{CB[7]} = (2.5 \pm 0.6) \times 10^8$ (mol/L)$^{-1}$)[36] as the competititor guest.

The stability constant for the 1:1 host–guest complex between CB[7] and the benzethonium cation may be compared with other cationic guests containing benzylammonium moieties (Fig. 4).

Fig. 2. ^{1}H NMR (400 MHz) titration of the benzethonium cation (1.00 mmol/L) by cucurbit[7]uril (CB[7], *) in D_2O: (*a*) 0.00 equiv CB[7], (*b*) 0.42 equiv CB[7], (*c*) 0.99 equiv CB[7], (*d*) 1.39 equiv CB[7], (*e*) 1.61 equiv CB[7], (*f*) 2.10 equiv CB[7], and (*g*) 3.52 equiv CB[7].



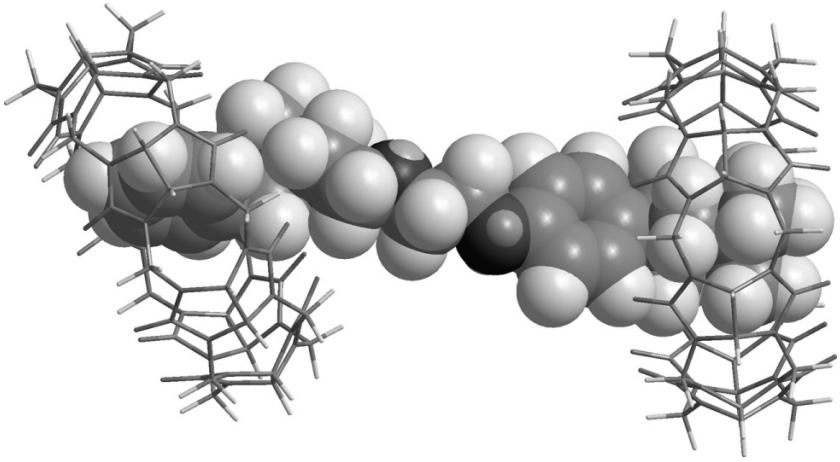


Fig. 3. A gas-phase energy-minimization (MM2) calculation of the structure of the 2:1 host–guest [CB[7]·benzethonium·CB[7]]$^+$ complex. CB[7], cucurbit[7]uril.

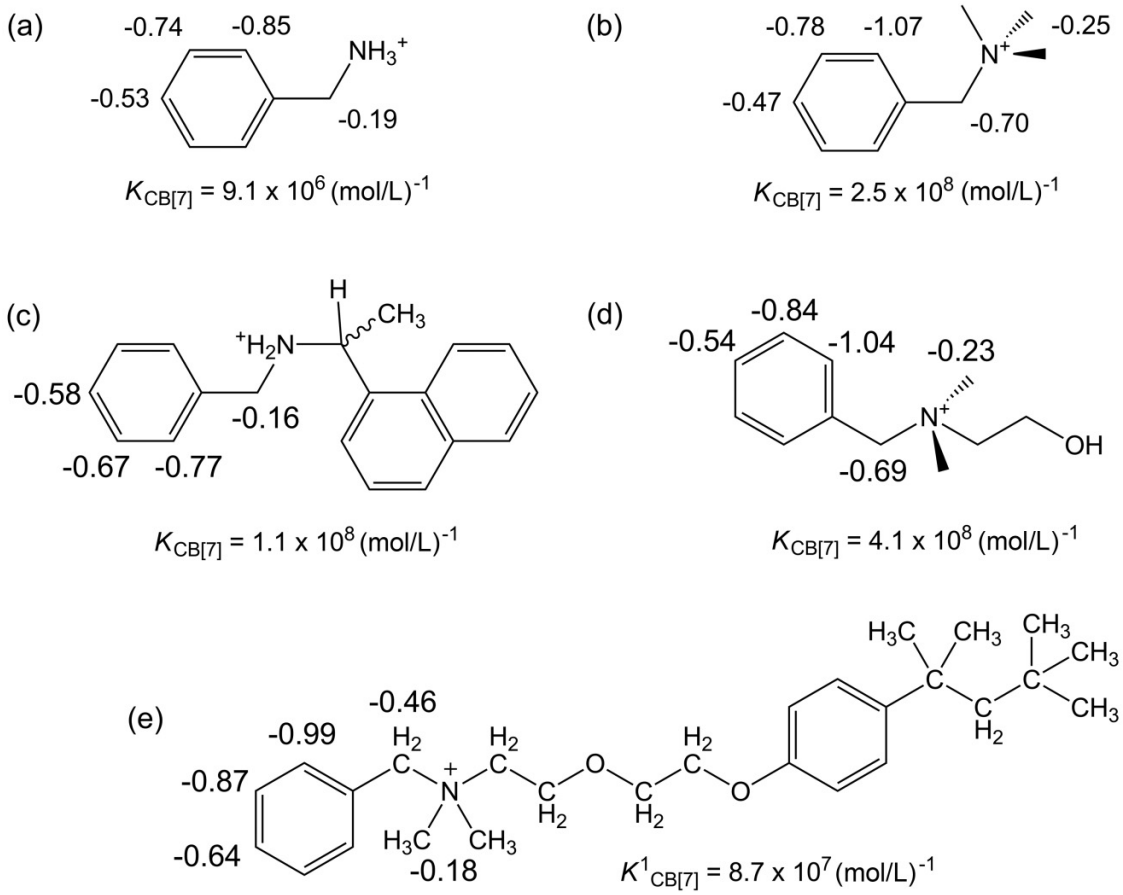

The value for benzethonium is within the range of 10^7–10^8 (mol/L)$^{-1}$ reported for this series of guests.[35,36,41,42] The more hydrophobic benzyltrialkylammonium cations tend to form a more stable complex with CB[7] than the benzylammonium cations. In addition, the values of $\Delta\delta_{lim}$ (Fig. 4) suggest a deeper inclusion of the benzyltrialkylammonium cations compared with the benzylammonium cations.

Binding of the hydrophobic moiety

The addition of further cucurbit[7]uril beyond 1 equiv to the benzethonium guest results in a second weaker binding interaction with the more hydrophobic end of the molecule, the 2-(2,4,4-trimethylpentyl) substituent on the phenyl ring. The most notable changes in the ^{1}H NMR spectra of the host–guest mixtures (Fig. 2) are the upfield shifts of the alkyl protons of

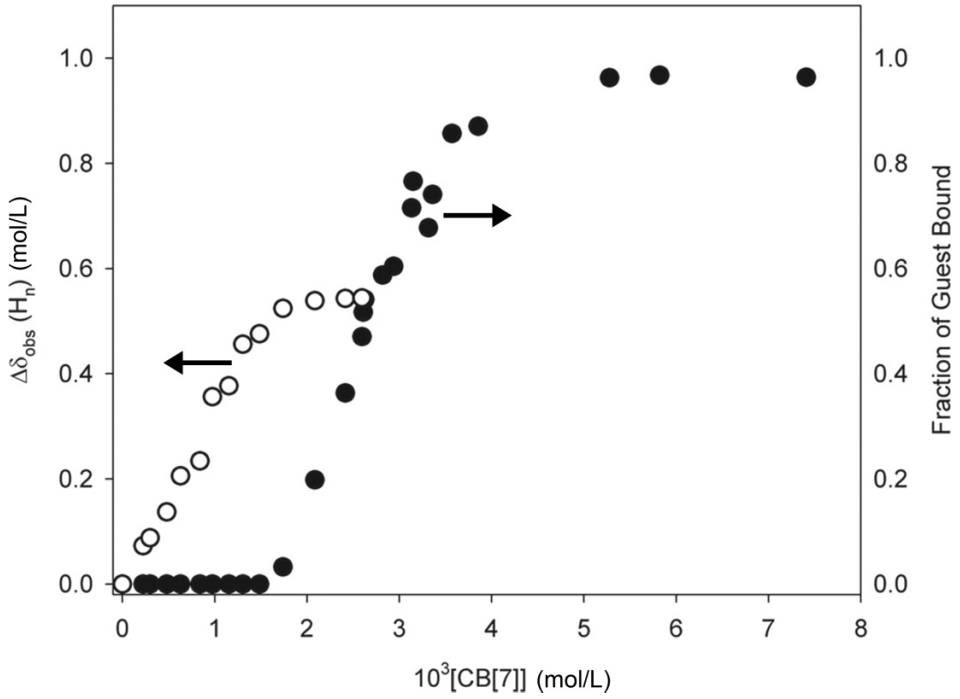
Fig. 4. The cucurbit[7]uril (CB[7]) complexation-induced limiting chemical shift changes ($\Delta\delta_{lim}$, ppm) for cationic guests containing benzylammonium and related binding sites: (*a*) benzylammonium,[41] (*b*) benzyltrimethylammonium,[36] (*c*) *N*-benzyl-1-(1-naphthyl) ethylammonium,[35] (*d*) benzylcholine,[42] and (*e*) benzethonium. The stability constants ($K_{CB[7]}$) for the 1:1 host–guest complexes with CB[7] are indicated below the guest.



this substituent, with slow exchange behaviour (separate resonances for the free and bound guest protons) on the NMR timescale. The largest shift is found for the methylene protons (H_b), with $\Delta\delta_{lim} = -0.86$ ppm, while the methyl protons shift upfield to a smaller extent (−0.20 and −0.32 ppm for methyl protons, H_a and H_c, respectively). The stability constant for the binding of the second CB[7] to this hydrophobic region was determined to be $K^2_{CB[7]} = (4.0 \pm 1.9) \times 10^3$ (mol/L)$^{-1}$ by integrating the methyl proton resonances associated with the free and bound benzethonium cations. Recently, Yu et al.[43] reported that the benzyl(dimethyl)hexadecylammonium cation formed both 1:1 (encapsulating the benzyl group) and 2:1 (second CB[7] complexes the hexadecyl chain) host–guest complexes with CB[7], with stability constants of 1.88×10^8 and 4.8×10^4 (mol/L)$^{-1}$, respectively.

The value for complexing the hydrophobic 2-(2,4,4-trimethylpentyl) portion of the benzethonium cation, with eight heavy atoms, is comparable in magnitude to those we determined previously for butan-2-one (3.1×10^3 (mol/L)$^{-1}$)[44] and 3,3-dimethylbutan-2-one (6.74×10^3 (mol/L)$^{-1}$),[44] which have five and nine heavy atoms, respectively. Nau et al.[38] recently analyzed the properties of the inner cavity of cucurbiturils and determined that the cavity of cucurbiturils, including CB[7], have a very low polarizability and are capable of tightly binding hydrophobic groups of a certain size, specified by either the number of heavy (nonhydrogen) atoms or by the molar volume. In the case of CB[7], the highest reported affinities for neutral guests are adamantylcarboxylic acid (3.2×10^5 (mol/L)$^{-1}$)[40] and hydroxymethylferrocene (3.2×10^6 (mol/L)$^{-1}$),[8] which have 9 and 11 heavy atoms, respectively, in the adamantyl and ferrocenyl fragments. The capacity of the CB[7] cavity appears to be 12 heavy atoms, as we have reported that the 2-aminopyridinium cation, bound to CB[7] in a 1:2 host–guest complex, can undergo a photodimerization[45] to yield a product whose volume is 151 Å^3 (the packing coefficient (PC) = 62%),[37] with all of the guest but the two amino substituents within the inner cavity. Mecozzi and Rebek,[39] based on host–guest binding in capsules, calculated that the optimum PC, obtained by dividing the volume of the guest by the volume of the cavity of the host, is 55% ± 9%, with the remaining void space necessary to retain some vibrational, rotational, and translational degrees of freedom of the guest, along with vibrational degrees of freedom for the host, to maximize entropy. Host–guest complexes with lower or higher PC values were associated with lower stability constants in solution. Nau et al.[38] considered Mecozzi and Rebek's[39] principle of 55% packing coefficient ideal in host–guest complexes. The "expanded" cavity volume of CB[7], which includes the "bond dipole regions" near the

For personal use only.

portals, was calculated to be 279 Å^3, compared with the "inner" cavity volume of 242 Å^3.[37] The latter is considered to be the more appropriate cavity volume when it comes to binding hydrophobic guests.

With the benzethonium guest, the uncharged hydrophobic 2-(2,4,4-trimethylpentyl) substituent has eight heavy atoms and the upfield shifts of all of the protons within this substituent suggests that the inner cavity can accommodate them. The molar volume of 2,2,4-trimethylpentane was calculated to be 147 Å^3,[46] and using the inner cavity volume of CB[7], results in a packing coefficient of 61%, close to Mecozzi and Rebek's[39] ideal value of 55%. This accounts for the relatively strong binding of this neutral moiety on the benzethonium guest.

The demonstration that the neutral 2-(2,4,4-trimethyl)pentyl moiety of the benzethonium cation forms a stable host–guest interaction with CB[7], by virtue of hydrophobic effect, may be applied to other hydrophobic guests of biological and medicinal interest, to increase their aqueous solubility and contribute to controlled release applications. We are presently investigating the binding of CB[7] to other guests bearing hydrophobic groups of similar molar volumes (e.g., the antimicrobial and potential antitumour agent alexidine) to evaluate the relationship between the nature of the guest binding sites and the stability and properties of the host–guest complexes. The observance of slow exchange behaviour in the ^{1}H NMR spectra of the benzethonium cation in the presence of CB[7] suggests that the kinetics of dissociation of the CB[7] from both the hydrophilic and hydrophobic ends of the cation should be investigated in view of potential controlled release applications.

At present, quaternary ammonium antimicrobial agents, such as benzethonium chloride, may be removed or have their activity neutralized by the applications of nonionic micelle-forming detergents or complexing agents, such as cyclodextrins. The CB[7] is an attractive alternative as it forms very stable host–guest complexes at lower host to benzethonium ratios than used with cyclodextrins or detergents, by virtue of stronger ion–dipole interactions between the guest (benzylammonium group) and the polar portals. In addition, CB[7] has been demonstrated to be relatively nontoxic to cells and bacteria,[15–18] which is a problem with some neutralizing detergents. The complexations of quaternary ammonium biocides by cyclodextrins have been shown to have a wide range of effects on their antimicrobial activity, from total inhibition or a reduction in activity to a significant increase in activity, depending on the nature of the cyclodextrins and the biocides, and their relative concentrations.[47] Further investigations of the effects of CB[7] and other cucurbit[*n*]urils on the antimicrobial activity of these quaternary ammonium agents, including benzethonium chloride, as well as the kinetics of the controlled release of these guests will be necessary to adjudicate their applicability as inactivating or activating hosts.

Conclusion

The benzethonium cation is capable of forming sequential 1:1 and 2:1 host–guest complexes with CB[7] in aqueous solution. The initial binding of the benzyldimethylammonium end of the guest is facilitated by ion–dipole interactions with the polar portals, as well as hydrophobic interactions of the aromatic ring in the CB[7] cavity. The second, weaker binding process involves the complexation of the other end of the host, which involves encapsulation of the hydrophobic 2-(2,4,4-trimethylpentyl) group in the host cavity. A calculation of the packing coefficient, using the inner cavity volume of CB[7] gives a value of 61%, and

accounts for the reasonable binding stability, given that the only driving force for the host–guest complexation on this end of the guest molecule is the hydrophobic effect.

Abstract: The performance of a photocatalytic reaction is mainly determined by the quality of the photocatalyst. For real applications, significantly enhancing the stability and activity of the photocatalysts still remains a challenge for materials scientists and chemists. In this paper, we have achieved a highly efficient plasmonic AgCl–Ag nanophotocatalyst via photochemical conversion of AgCl nanocubes. Compared with reported photocatalysts, the as-achieved nanophotocatalyst exhibits superior activity, long-term stability, and wide applicability in the decomposition of organic dye pollutants. For example, only 30 s is needed to bleach methyl orange molecules assisted by AgCl–Ag nanoparticles. Furthermore, the catalyst can be reused up to 50 times without significant loss of activity. A possible mechanism was discussed and the specified photocatalytic reactions verified that both $O_2^{\bullet-}$ and $OH^{\bullet}$ radicals were the main active species in decomposing pollutants. The excellent performance of the present photocatalyst suggests promising applications in environmental remediation, clean energy creation, and solar cells.

Key words: pasmonic photocatalyst, silver chloride, visible light photocatalysis, organic pollutant.

Résumé : La performance d'une réaction photocatalytique est déterminée principalement par la qualité du photocatalyseur. Pour des applications réelles, l'augmentation significative de la stabilité et de l'activité du photocatalyseur reste le défi à surmonter pour les scientifiques et les chimistes. Dans ce travail, on a préparé un nanophotocatalyseur AgCl–Ag plasmonique très efficace en procédant à une conversion photochimique de nanocubes de AgCl. Par comparaison avec les photocatalyseurs rapportés antérieurement, le nanophotocatalyseur tel que préparé présente une activité supérieure, une stabilité à long terme et une large plage de domaines d'application dans la décomposition des colorants organiques polluants. Par exemple, à l'aide de nanoparticules de AgCl–Ag, il suffit de 30 s pour blanchir des molécules de méthylorange. De plus, le catalyseur peut être réutilisé jusqu'à 50 fois sans perte significative d'activité. On discute d'un mécanisme potentiel pour cette réaction et, faisant appel à des radicaux $O_2^{\bullet-}$ et $OH^{\bullet}$, il a été possible de vérifier que les réactions photocatalytiques spécifiées sont bien les espèces catalytiques principales dans la décomposition des polluants. L'excellente performance de ce photocatalyseur suggère qu'il devrait posséder des applications prometteuses dans la dépollution environnementale, la création d'énergie propre et dans les cellules solaires.

Mots-clés : photocatalyseur plasmonique, chlorure d'argent, photocatalyseur à la lumière visible, polluant organique.

Introduction

Since the discovery of photocatalytic splitting of water to produce hydrogen on TiO_2 electrodes,[1] photocatalysis has attracted much attention as a promising green approach for utilizing solar energy to solve energy and environmental issues. Great progress has been made in the fields of new energy generation,[2–4] conversion of carbon dioxide into valuable chemicals,[5–7] environmental purification,[8,9] solar cells,[10] and water disinfection.[11,12] Nowadays, the development of visible light driven photocatalysts has become one of the most important topics in this area. The strategies to create visible-light response photocatalysts can be classified into two categories. One is to narrow the band gap of TiO_2 by doping external elements, i.e., metals or nonmetals,[13–16] and engineering microstructures of titanate.[17] The other is to explore complex oxide visible photocatalysts, such as Ag_3PO_4,[18] $InTaO_4$,[2] $BiFeO_3$,[19,20] Bi_2WO_6,[21,22] and $PbBi_2Nb_2O_9$.[23] For real

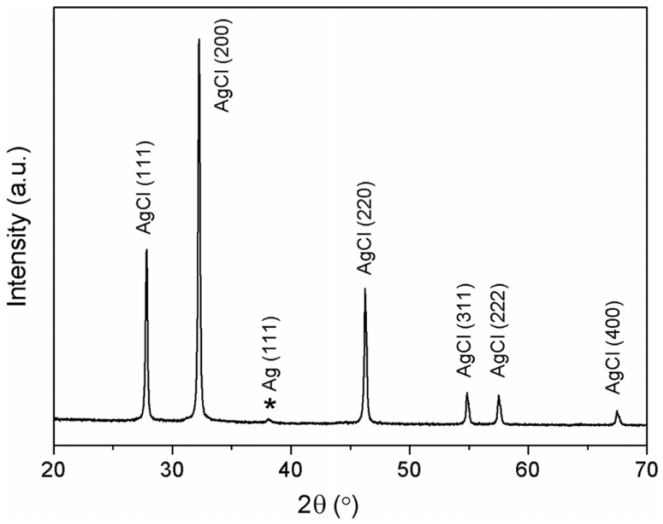
applications, significantly enhancing the stability and activity of the photocatalysts still remains a challenge to materials scientists and chemists.

Nanoparticles of noble metals, i.e., Au and Ag with surface plasmon resonance (SPR) effects, exhibit high absorption efficiency in the visible region, making them an ideal class of light absorber materials in the photocatalysis field.[24,25] Doping TiO_2 with Au (or Ag) has been demonstrated to greatly enhance the photoactivity of TiO_2 by reducing the recombination rate of the photogenerated charge carriers.[24,26–28] The absorption edges of TiO_2 were only extended to approximately 420 nm, leading to most of the solar spectrum being unable to drive these photocatalysts.

Silver halides decorated with Ag or Au represent a class of promising plasmonic photocatalysts because they not only exhibit high absorption coefficients in the visible region owing to the contribution of SPR, but also show enhanced photocatalytic performance.[29–31] For example, Ag@AgCl (or AgBr) photocatalysts have been prepared[29,32] through ion-exchange reactions followed by the UV conversion of some Ag^+ to Ag^0 on the surfaces of the parent crystallites. The microscale and irregular shapes of the obtained catalysts result in reduced surface areas, unclear interfaces, and thus reduced catalytic performance compared with nanoparticles. Therefore, creating photocatalysts with high activity, long-term stability, and wide applicability is of paramount importance and highly desirable.

Herein, we have developed a simple photochemical conversion of AgCl nanocubes to fabricate a class of long-term stable hybrid plasmonic AgCl–Ag nanoparticles with superior activity towards the decomposition of organic pollutants, i.e., methyl orange (MO), rhodamine B (RhB), methylene blue (MB), malachite green (MG), crystal violet (CV), alizarin red (AR), and methyl red (MR). MO molecules can be rapidly decomposed within 30 s under visible light irradiation with the assistance of the AgCl–Ag nanoparticles. The catalyst can be recycled up to 50 times without losing activity. These features mean the as-achieved nanophotocatalysts have good prospects in water disinfection and environmental remediation.



Experimental

Preparation of catalysts

AgCl nanocubes were synthesized by a simple polyol precipitation process.[30] In a typical procedure, 10 mL of ethylene glycol (EG, Sinopharm Chemical Reagent Co., Ltd) was placed in a 50 mL flask and heated at 60 °C under magnetic stirring at 350 rpm. Then poly(vinyl pyrrolidone) (PVP, 54 mg, Sinopharm Chemical Reagent Co., Ltd) and NaCl (22 mg, AR, Sinopharm Chemical Reagent Co., Ltd) were added. After they were dissolved completely, a 1 mL EG solution of $AgNO_3$ (52 mg/mL, Sinopharm Chemical Reagent Co., Ltd) was rapidly injected to this mixture. The mixture was maintained at 60 °C for 30 min, resulting in a milky dispersion containing AgCl nanoparticles. The sample was rinsed with deionized water several times and collected via centrifugation.

The as-prepared AgCl nanoparticles can be easily dispersed in 10 mL deionized water. The water dispersion of AgCl was irradiated with a 300 W Xe arc lamp equipped with an UV cutoff filter for different times, i.e., 0, 20, 40, and 60 min (corresponding samples were denoted as AgCl, AgCl–Ag-20, AgCl–Ag-40, AgCl–Ag-60, respectively). The color of the resulting dispersion changed from milky to grayish purple, indicating metallic silver nanoparticles were produced on the surfaces of AgCl. The synthesis of the referred catalyst (AgCl–Ag-ref) is described in the Supplementary data.

Fig. 1. X-ray diffraction (XRD) pattern of the as-prepared AgCl–Ag nanoparticles.

Characterization

The crystalline phases of the products were analyzed by X-ray diffraction (XRD, Philips X'Pert with Cu Kα radiation (λ = 0.154 18 nm). The morphology and size of the AgCl–Ag nanoparticles were observed by an S-4800 field emission scanning electron microscope (SEM; Hitachi, Japan). The optical absorption spectra were measured on a UV–vis spectrometer (Specord 205, Analytik Jena) over a range of 200 to 900 nm.

Evaluation of photocatalytic performance

In a typical reaction, a 10 mL water dispersion of the as-prepared AgCl–Ag nanoparticles was transferred to an aqueous solution of MO (10 mL, 10 mg L^{-1}). The mixture was stored in the dark for 60 min with magnetic stirring to reach the adsorption–desorption equilibrium of MO molecules on the surface of the nanoparticles. The reaction was then started under a 300 W Xe arc lamp (PLS-SXE300/300UV) equipped with a UV cutoff filter as the visible light source (λ ≥ 400 nm). The degradation rate of MO was measured by UV–vis spectroscopy at different times. After the reaction was completed, centrifuging the solution enables the AgCl–Ag nanoparticles to be collected to catalyze new reactions.
