For the degradation of RhB, MB, MG, CV, and alAR, the conditions were kept identical to that of MO except that half the amount of the as-prepared AgCl–Ag nanoparticles was used. The decomposition of MR was performed in ethanol solution because of its insolublity in water.

Results and discussion

Characterization of the AgCl–Ag photocatalyst

Figure 1 presents an XRD pattern of the as-prepared AgCl–Ag nanoparticles. It clearly shows that the sample is composed of cubic AgCl (JCPDS card No. 31-1238) and metallic Ag (JCPDS card No. 87-0717). The diffraction peaks at 27.28°, 32.23°, 46.24°, 54.82°, 57.49°, and 67.46° can be

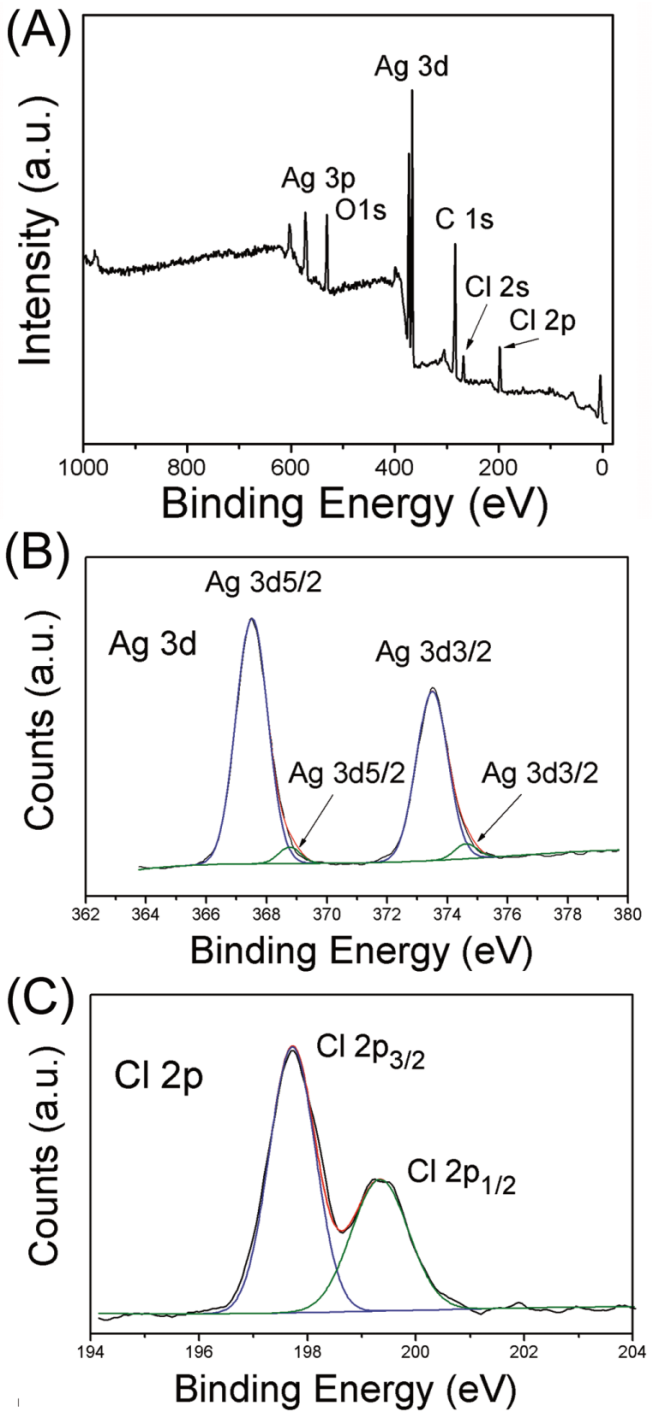
Fig. 2. X-ray photoelectron spectroscopy (XPS) spectra of the as-prepared AgCl–Ag. (A) survey, (B) Ag 3d, and (C) Cl 2p.



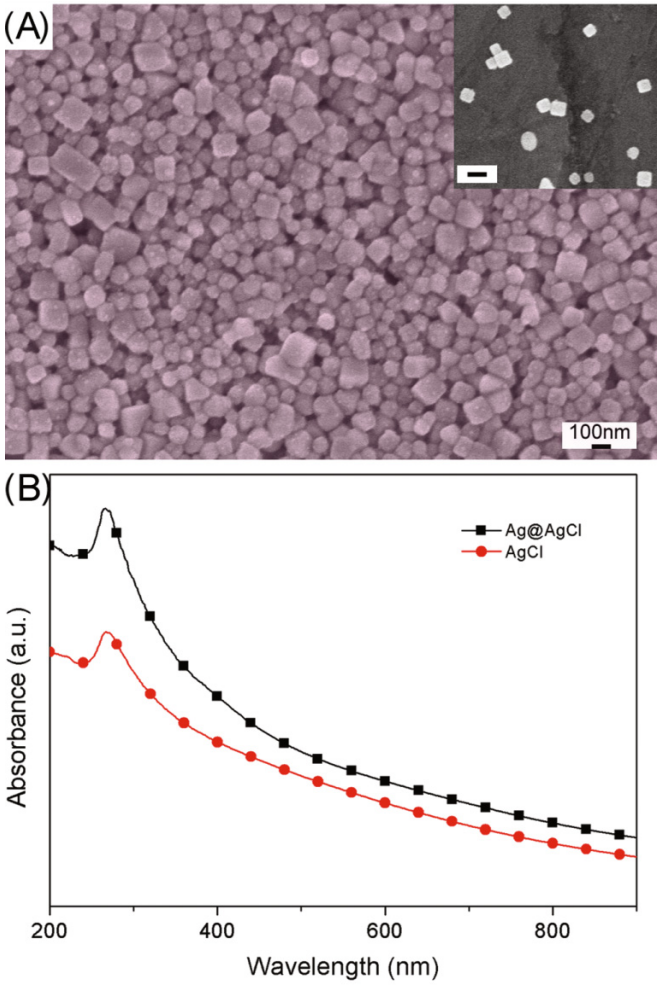


Fig. 3. (A) SEM images of AgCl–Ag. The inset at the top right corner shows the AgCl nanoparticles (scale bar is the same as for AgCl–Ag). (B) UV–vis absorbance spectra of AgCl and AgCl–Ag.

assigned to the (111), (200), (220), (311), (222), and (400) planes, respectively, of the AgCl nanoparticles. The peak at 38.07° is attributed to the diffraction of the (111) plane of metallic Ag. The elemental composition and silver content of the AgCl–Ag were further confirmed by X-ray photoelectron spectroscopy (XPS). Figure 2A reveals that Ag and Cl are the main components, and trace amounts of C and O are the adventitious hydrocarbon from the XPS instrument. As shown in Fig. 2B, the peaks at 367.5 and 373.5 eV may be assigned to the binding energy of Ag 3d 5/2 and Ag 3d 3/2 of Ag^+ in AgCl, respectively, and the peaks at 368.8 and 374.6 eV may be attributed to metallic Ag^0. The results confirmed the existence of Ag^0, and the surface ratio of metallic Ag^0 and Ag^+ is approximately 1:13. For Cl 2p, two peaks are observed at the binding energies of 197.7 and 199.3 eV.

Figure 3A shows the SEM images of as-prepared AgCl (inset) and AgCl–Ag nanoparticles. The smooth AgCl nanoparticles exhibit a cubic shape with an average edge length of 90 nm. After photochemical reduction, Ag nanoparticles are assembled on the surfaces of the parent AgCl nanocubes. The AgCl–Ag hybrid nanoparticles display convex a cubic and near-spherical shape. The UV–vis absorption spectra (Fig. 3B) of the parent AgCl and AgCl–Ag nanoparticles exhibit a similar shape, indicating that tiny Ag nanoparticles are distributed evenly on the surfaces of AgCl nanocubes. For AgCl, there is little absorption in the visible region due to its large band gaps, i.e., a direct band gap of 5.15 eV (241 nm) and an indirect band gap of 3.25 eV (382 nm).[33] The AgCl–Ag

Fig. 4. (A) The change in UV–vis spectra for the methyl orange (MO) solution with reaction time. (B) The normalized concentration of the MO as a function of reaction time in both linear (–■–) and logarithmic (–●–) scale. C_0 is the concentration of MO before irradiation; C is the concentration of MO at reaction time t.

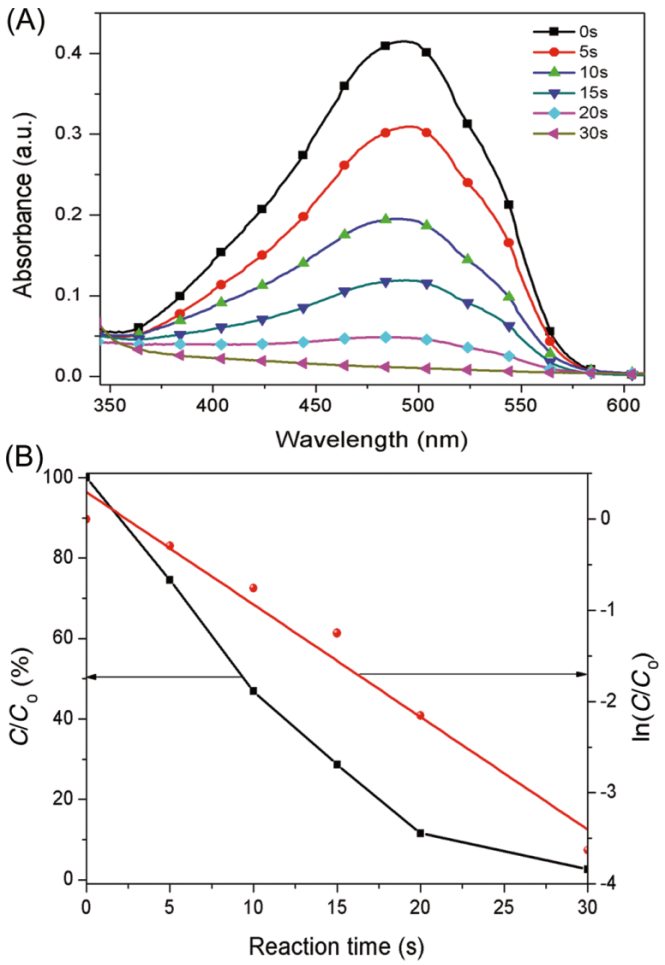

Fig. 5. Photocatalytic degradation of methyl orange (MO) for different samples under visible light irradiation, showing that AgCl–Ag-20 nanoparticles exhibits the highest performance. AgCl–Ag-20, AgCl irradiated with a 300 W Xe arc lamp for 20 min.

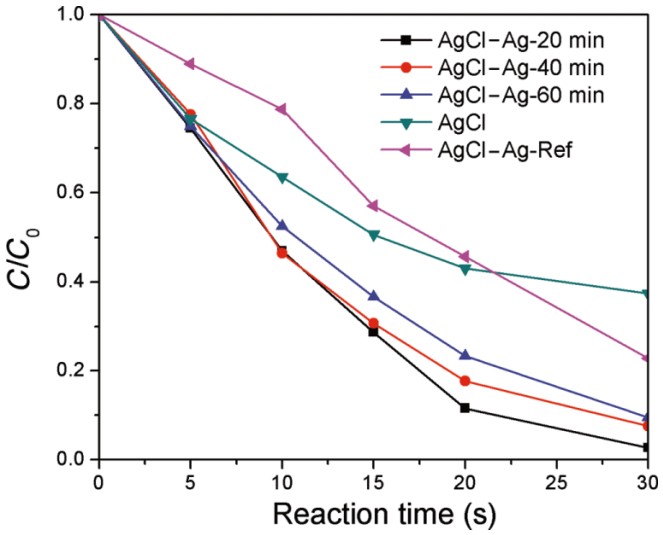

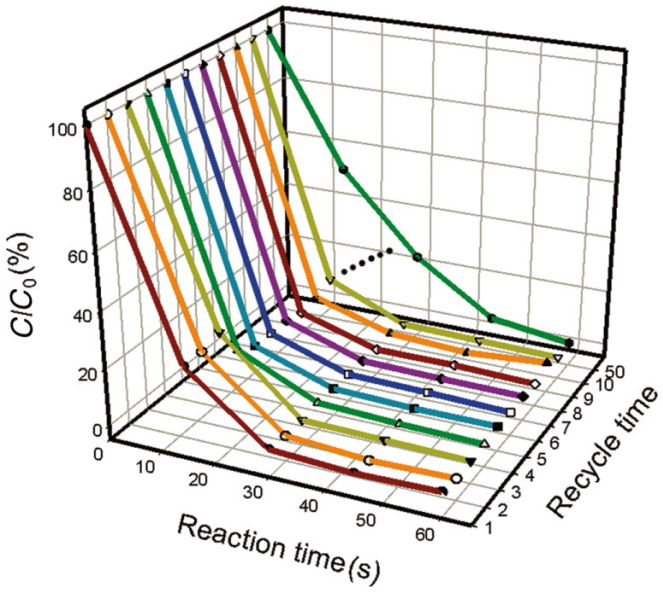

Fig. 6. The degradation curve of methyl orange (MO) solution for 50 successive reactions catalyzed with the same batch of AgCl–Ag-20 nanoparticles (as shown in Fig. 1) under visible light irradiation. AgCl–Ag-20, AgCl irradiated with a 300 W Xe arc lamp for 20 min.

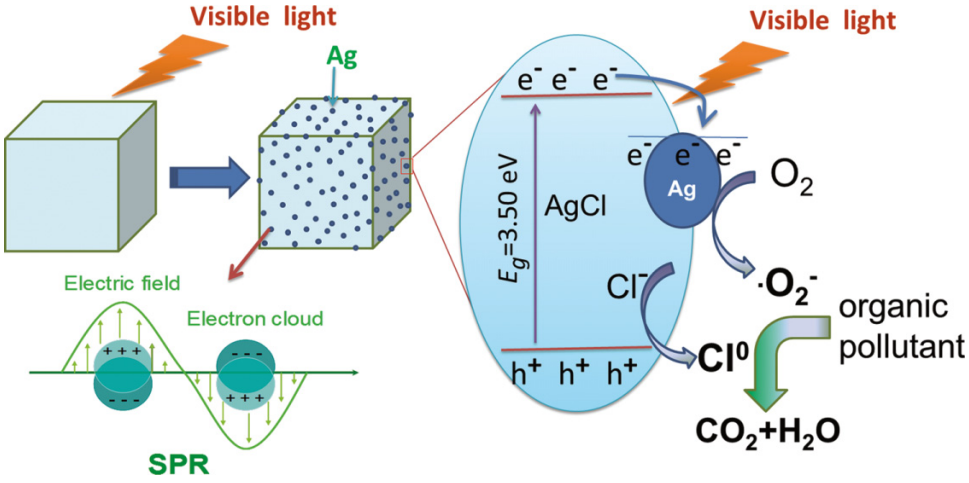


nanoparticles show a stronger absorption in the visible region than the parent AgCl owing to the SPR of the Ag species.

Photocatalytic performance of AgCl–Ag

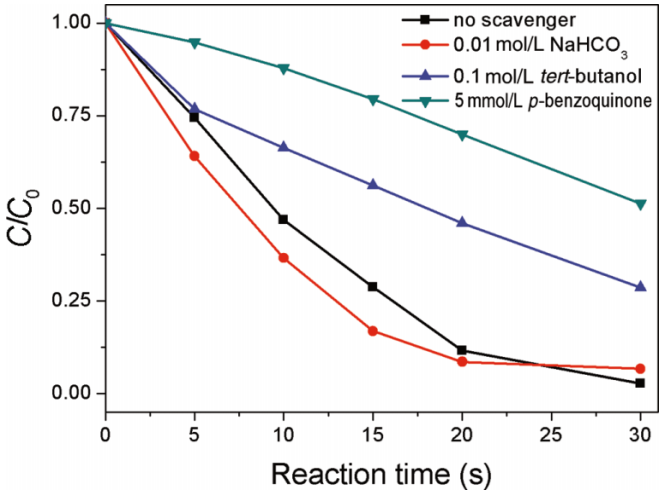
The photocatalytic performance of the as-prepared AgCl–Ag nanoparticles was evaluated by degradation of MO (5 mg L^{-1}) molecules under visible light irradiation. Figure 5A shows the evolution of the absorption spectra of methyl orange (MO) with reaction time over the AgCl–Ag-20 nanophotocatalyst. The color of the MO solution gradually changes from orange to transparent as the reaction proceeds (Supplementary data, Fig. S1), and the MO molecules rapidly decomposed within 30 s under visible light irradiation with the assistance of the AgCl–Ag nanoparticles. The blank tests in the dark with AgCl, AgCl–Ag, and under visible light without catalyst were carried out. The color of the MO solution remained unchanged, demonstrating that the AgCl–Ag nanoparticles are crucial for the degradation of the dye. Meanwhile, the effects of Ag on the photocatalytic activity were also investigated by a series of controlled experiments. As shown in Fig. 5, AgCl–Ag-20 shows the best photocatalytic performance compared with the other samples. However, AgCl–Ag-20 also shows higher activity than pure AgCl, which only degrades 63% of MO within the same time frame. The enhanced activity of AgCl–Ag may account for the synergy between the SPRs of Ag nanograins on the surface of AgCl and the polarization field from AgCl. Furthermore, the Brunauer–Emmett–Teller (BET) nitrogen adsorption analysis reveals that the specific surface area was 33.2 m^2 g^{-1}, further suggesting that the enhanced activity is not caused merely by its surface property. While excessive Ag may increase the probability of hole capture by the negative

Fig. 7. Schematic illustration of the photocatalytic reaction pathway of AgCl–Ag nanoparticles under visible light.

charge on the Ag nanoparticles, and destroy the structure of the as-achieved catalyst, this may lead to the decreased activity of the catalysts containing a high content of Ag. The function of $\ln(C/C_0)$ versus reaction time (t; Fig. 4B) exhibits a linear relationship, indicating the reaction follows pseudo-first-order kinetics. The rate constant was determined to be 0.123 s^{-1}.

In consideration of practical applications, we also tested the stability and applicability of the present hybrid nanophotocatalyst. Figure 6 shows the recycled reactions using the same batch of catalysts. The used nanophotocatalyst can still maintain high efficiency even after 50 reactions. Note that if the dye concentration was increased to 10 mg L^{-1}, the catalyst can still be reused 35 times without much decrease in activity (Supplementary data Figs. S2 and S3). Inspired by the superior stability and activity of the photocatalysts, other typical organic pollutants, such as RhB, MB, MB, CV, AR, and MR, were also selected to trigger the degradation reactions. The results demonstrate that these dyes can also be bleached steadily (Supplementary data Fig. S4), confirming the broad applicability of the as-prepared AgCl–Ag nanophotocatalysts.

Photocatalytic mechanism



Usually, semiconductor photocatalysts, e.g., TiO_2, have wide band gaps, which make them stable against corrosion in surrounding environments.[34,35] The band gap of the as-prepared AgCl nanocubes was determined to be 3.50 eV on the basis of UV–vis absorption spectrum (Supplementary data Fig. S5), which makes it a class of alternative stable photocatalysts, although visible-light excitation is difficult. The position of the conduction band (E_{CB}) of the AgCl nanocubes can be determined by the equation $E_{CB} = X - E_C - 0.5E_g$,[36] where E_C represents the energy of the free electrons on the hydrogen scale (4.5 eV), X is the electronegativity of the semiconductor, and E_g represents the band gap of the semiconductor. Thus, the E_{CB} and the position of the valence band (E_{VB}) were calculated to be −0.341 and 3.159 eV, respectively. As presented in Fig. 7A, a possible mechanism is proposed. Here, well-defined interfaces in hybrid AgCl–Ag nanoparticles may provide proper environments for enhancement of their photocatalytic performance. Ag nanoparticles can act as a sinker for photoinduced charge carriers, promoting charge separation to enhance the overall photocatalytic efficiency in contact with the parent semiconductor.[37,38] As reported by Huang and co-workers[29] and our group,[30] the interactions between the SPR of the Ag nanoparticles and the polarization field provided by the AgCl determine the photocatalytic efficiency. In the present system, photoillumination of uniform parent AgCl nanocubes results in an even distribution of Ag nanoparticles on their surfaces, and thus leads to more even charge distributions of the free electrons in Ag nanoparticles more evenly than previously reported.[29–32] In other words, regions of negative and positive charges in the Ag nanoparticles have been separated effectively, which are far from and close to the AgCl–Ag interface, respectively. The migration of photoexcited electrons away from the AgCl–Ag interfaces also prevents photoreduction of AgCl to Ag, leading to a high stability of the hybrid nanoparticles. Therefore, there is synergy between the enhanced absorption of visible light by the SPR of the Ag nanoparticles and the polarization field provided by the AgCl facilitates electron–hole separation and interfacial charge transfer. That is to say, electron and hole were delivered into the two distinct regions (Ag and AgCl region). In the Ag/solution region, photogenerated electrons can be scavenged by O_2 in the solution to form $O_2^{\bullet-}$ and other reactive oxygen species.[38–41] To confirm the roles of oxidizing species, radical and hole trapping tests weren designed to further elucidate the photocatalytic mechanism. As shown in Fig. 8, the $NaHCO_3$ scavenger for holes (h^+) and adsorbed $OH^{\bullet}$ have no significant effects on the activity of the catalyst. However, if 0.1 mol/L of *tert*-butyl alcohol for $OH^{\bullet}$ was introduced, the MO degradation rate was decreased (i.e., after reacting for 20 s, 46% MO was left in the solution.). With the addition of $O_2^{\bullet-}$ scavenger (*p*-benzoquinone), the rate of bleaching MO was depressed significantly. These results indicate that the surface-adsorbed $O_2^{\bullet-}$ and $OH^{\bullet}$ are active species in the reaction. Due to the longer life time of active e^- compared with h^+,[39] the $O_2^{\bullet-}$ and $OH^{\bullet}$ generation can be produced by the following reactions

$$O_2 + e^- \rightarrow O_2^{\bullet-}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13

Fig. 8. Photodegradation kinetics of methyl orange (MO) in AgCl–Ag water dispersion under visible light irradiation with different scavengers.

$$O_2^{\bullet -} + h^+ \rightarrow OOH^{\bullet}$$

$$OOH^{\bullet} + H^+ + e^- \rightarrow H_2O_2$$

$$H_2O_2 + e^- \rightarrow OH^{\bullet} + OH$$

Therefore, $O_2^{\bullet -}$ and $OH^{\bullet}$ radicals come from photoexcited electrons and accumulate on the silver surfaces, which is in accord with the previous discussion. Holes (h^+) play a minor role in the present reactions. The mechanism can be understood as a plasmon-induced photocatalytic reaction. Of course, further studies are still necessary to provide insight into the unraveling of the process of charge generation, transport, and the photocatalytic reaction mechanism.

Conclusion

In summary, photochemical conversion of AgCl nanocubes has been demonstrated to be a facile strategy for the preparation of highly efficient plasmonic AgCl–Ag nanophotocatalysts with strong activity, stability, and wide applicability towards the decomposition of various organic dye pollutants. MO molecules can be decomposed completely within 30 s in the presence of the as-achieved nanophotocatalyst. Furthermore, it can be reused approximately 50 times without losing activity. The possible photocatalytic reaction mechanism indicates that Ag nanoparticles play an important role in enhancing the absorption of visible light, separating electron–hole pairs and generating oxidizing species. The excellent efficiency of the plasmonic nanophotocatalyst has promise for applications in environmental remediation, clean energy creation, and solar cells.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder arising from abnormal aggregation of β-amyloid (Aβ) and progressing at different rates from person to person. There may exist endogenous compounds within the brain that play a role in inhibiting aggregation. We have devised a unique in silico screening strategy of endogenous molecules within the human brain, with special emphasis on amino acid metabolic pathways, to identify compounds with the potential to inhibit Aβ aggregation. Metabolites of tryptophan were computationally identified through this screening as potential therapeutics and were optimized via molecular modelling to determine their capacity to bind to Aβ. The most successful molecule identified was 3-hydroxyanthranilic acid (3-HAA). This endogenous molecule was then computationally explored to design novel analogues of 3-HAA with the goal of improving Aβ antiaggregant activity. These combined in silico methods of screening, identifying, and successfully "analoguing" an endogenous molecule of the brain as an AD therapeutic has yielded positive results and a novel approach to computer-aided drug design.

Key words: Alzheimer's disease, binary quantitative structure–activity relationship (QSAR), 3-hydroxyanthranilic acid (3-HAA).

Résumé : La maladie d'Alzheimer est une maladie neurodégénerative qui se pose à partir de l'agrégation anormale de la protéine β-amyloïde (Aβ) et progresse à des rythmes différent d'une personne à personne. Il peut exister des composés endogènes dans le cerveau qui peuvent jouer un rôle dans inhiber l'agrégation. Nous avons développé une stratégie de dépistage unique in silico des molécules endogènes dans le cerveau humain, avec un accent particulier sur les voies métaboliques des acides amines,d'identifier des composés ayant un potential d'inhiber l'agrégation.Les métabolites du tryptophane ont été identifiés par ce calcul de dépistage en tant qu'agents thérapeutiques potentiels et ont été optimisés par modélisation moléculaire afin déterminer leur capacité à se lier à la protéine Aβ. La molécule la plus couronnée de succès identifiés était l'acide 3-hydroxyanthranilique (3-HAA). Cette molécule endogène a ensuite été exploré de calcul pour la conception de nouveaux analogues de 3-HAA dans le but d'améliorer l'activité antiagrégant. Ces méthodes combinées de dépistage in silico, l'identification et succès en « l'analoguement » d'une molécule endogène du cerveau comme une thérapeutique d'AD a donné des résultats positive et une approche nouvelle pour la conception des médicaments assistée par ordinateur.

Mots-clés : maladie d'Alzheimer, relation quantitative structure activité (RQSA) binaire, acide 3-hydroxyanthranilique (3-HAA).

[Traduit par la Rédaction]

Introduction

Alzheimer's disease (AD) is a progressive degenerative neurological disorder in which individuals exhibit decline in cognitive awareness; currently, there is no curative or disease-modifying agent available for the treatment of AD.[1–3] Pathologically, AD is defined by the presence in the brain of two distinct misfolded protein aggregates: neurotoxic β-amyloid (Aβ) plaques and tau neurofibrillary tangles.[1] Thus, AD is thought to arise from the misfolding of Aβ, a 39–43 amino acid protein that normally occurs in a nontoxic unaggregated α-helical or random coil conformation.[4,5] The misfolding is initiated when a positively charged tetrapeptide motif within Aβ (L-histidyl-L-histidyl-L-glutamyl-L-lysine; $H_{13}HQK_{16}$ or simply HHQK) interacts with negatively charged glycosaminoglycans on the neuronal membrane surface; this begins a nucleation process whereby one misfolded Aβ triggers additional misfolding with subsequent aggregation into neurotoxic oligomers that destroy adjacent neurons.[6,7]

Although AD is a leading cause of death and disability, there are no curative drugs available for its treatment. Moreover, there is no proven molecular platform around which

drugs can be designed for the treatment of AD. Since the clinical course of AD is highly variable from person to person, we are proposing the existence of one or more endogenous molecules in the human brain that might inhibit the pathological Aβ aggregation process (i.e., an "endogenous anti-Alzheimer molecule"; EAM). For instance, if a small molecule endogenous to the human brain were to bind to the HHQK region of Aβ, it could, in principle, prevent misfolding by maintaining the protein in its nontoxic monomeric form; furthermore, such a molecule could be the starting point in the design of future therapeutics. To this end, we are proposing the novel approach of an in silico screening of molecules endogenous to the human brain to identify species that have the potential to interact with the HHQK region of Aβ. Furthermore, we wish to use the identified EAM as a platform from which to develop novel analogues to increase antiaggregant efficacy.

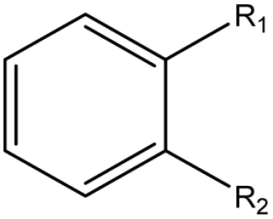
Conceptual approach

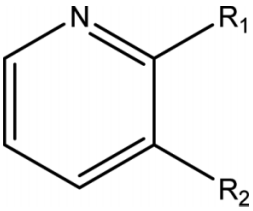
The human brain contains many molecules; a full in silico screening of all the molecules in the human brain would be inefficient. Accordingly, we initially sought a conceptual approach to enable a more efficient screening of endogenous brain molecules. To achieve this, we sought to identify other neurodegenerative disorders, similar to AD, whose neurochemical bases are understood and for which therapeutics are already available.

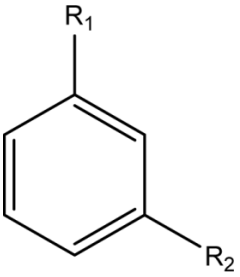
Parkinson's disease (PD) is another protein misfolding disorder; fibrils of misfolded α-synuclein are found in the Lewy bodies that are the characteristic hallmarks of the disease.[8,9] Similar to Aβ, α-synuclein normally exists in an unfolded state, but becomes toxic when it begins fibrillization and takes on the form of oligomers and protofibrils.[10] There is evidence that dopamine and its precursor, levodopa, may act to stabilize α-synuclein protofibrils, and dopamine can also inhibit fibrillization of the protein.[9] While dopamine cannot be administered directly to patients due to its inability to penetrate the blood–brain barrier, levodopa can be administered as it is capable of being transported into the brain.[8] Levodopa is metabolized into dopamine, and this will allow for dopaminergic levels to be increased using an endogenous molecule for treatment.[8] This treatment of PD involves targeting metabolites of dopamine. Therefore, an endogenous amino acid pathway provides therapeutic opportunities for the treatment of PD.

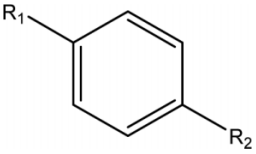
Similar to PD, AD is also a protein misfolding disorder wherein Aβ forms β-sheets in a nucleation dependent process similar to α-synuclein.[5,10] If dopamine and its metabolites may inhibit α-synuclein fibrillization, this generates the interesting hypothesis that some other amino acid based endogenous molecule may be able to act similarly in the course of AD. Consequently, we decided to selectively screen amino acid metabolic pathways in our pursuit of an endogenous anti-Alzheimer's agent; these metabolites are assumed to be able to cross the blood–brain barrier via the large neutral amino acid transporter. This in silico approach to identifying an EAM, and then developing it as a platform for "analoguing", is an approach to drug design that is both novel and cost-effective.

Computational methods









In silico methods

An endogenous library of 1451 compounds (with molecular weights less than 600) in database form was screened for potential EAMS targeting the HHQK region of Aβ; in particular, we focussed on amino acid metabolites found in the human brain. The most promising results of the in silico screen that could potentially bind to the HHQK region of Aβ were selected for gas- and solution-phase optimizations using the Chemistry at Harvard Macromolecular Mechanics (CHARMM) force field in the Molecular Operating Environment (MOE).[11,12] Optimization in MOE uses three sequential algorithms of steepest descent, conjugate gradient, and truncated Newton to find a minimum on the potential energy surface.[12] These optimizations were performed to determine the capacity of each molecule to bind to the HHQK region on different conformations of Aβ; both binding energies and number of interactions formed were considered in selecting the molecule with the most potential. The endogenous molecule that demonstrated the best capacity to bind to Aβ was selected for analoguing, with 50 analogues (Tables 1 and 2) being synthesized and tested for in vitro activity with the half maximal inhibitory concentration (IC_{50}) being calculated to perform a quantitative structure–activity relationship (QSAR) study using binary methods. The analogues were designed through the use of diverse bioisosteric substitutions, where bioisosteres are functional groups, which, although not identical, have similar physical or chemical properties that produce broadly similar biological activities for a given chemical compound.[13] In altering specific properties by these substitutions, we can evaluate the impact on biological activity, and what groups are favoured to increase activity or improve the stability of the molecule.[13,14]

For the binary QSAR, the training set was composed of 34 molecules, and the pIC_{50} (the –log of the IC_{50} value) was calculated for each compound. The molecules in the training set were selected to represent the different types of substituted compounds found in the initial 50 analogues, and covered a range of both active and inactive species (in terms of inhibiting Aβ aggregation). The binary threshold was set at –2.0 for the model, thus any compound with a pIC_{50} greater than –2.0 was considered inactive. All available descriptors in MOE were calculated initially (330+, composed of both two- and three-dimensional descriptors related to physicochemical, electronic, topologic, and geometric properties), and removed one by one to improve the predictive capacity of the model. Descriptors were removed based on their relative importance, as calculated by the software, and based on redundancy (several different descriptors described identical properties, and thus only one of each type would be necessary). The final model was composed of nine descriptors covering a variety of two- and three-dimensional properties. The descriptors used are PM3_HF (the heat of formation calculated using the PM3 Hamiltonian), SlogP_VSA5 (the log *P* (partition coefficient) in octanol–water calculated based on the accessible surface area of the molecule), SMR_VSA0, SMR_VSA1, SMR_VSA4, and SMR_VSA5 (these descriptors look at the contributions to molar refractivity based on the accessible van der Waals surface area falling within a specific range), vdw_vol (the

van der Waals volume of the molecule), vsa_don (the sum of the van der Waals surface area of the pure hydrogen bond donors), and vsurf_W2 (the hydrophilic volume of the molecule).[12] Upon statistical validation of the training set, the model was applied to the validation set of 16 molecules. As the model performed acceptably for the validation set, it was then applied to a series of 86 novel analogues developed from the original series of 50 molecules, again making use of bioisosteric substitution. Twenty-six of these analogues were synthesized to determine the accuracy of the model in predicting activity (Tables 3 and 4).

Statistical methods

The QSAR concept involves the assumption that the physical properties of a compound and its biological efficacy are related; therefore, related compounds will have similar properties.[15] QSARs involve quantitative models that are first used to relate and then predict a particular property for a series of compounds.[15] Various descriptors are calculated, and then statistical tools are applied to determine which of the descriptors are relevant to the desired property.[15] For the purposes of this study, the desired property is the IC_{50} of the compound in question is the inhibition of Aβ aggregation. The measured

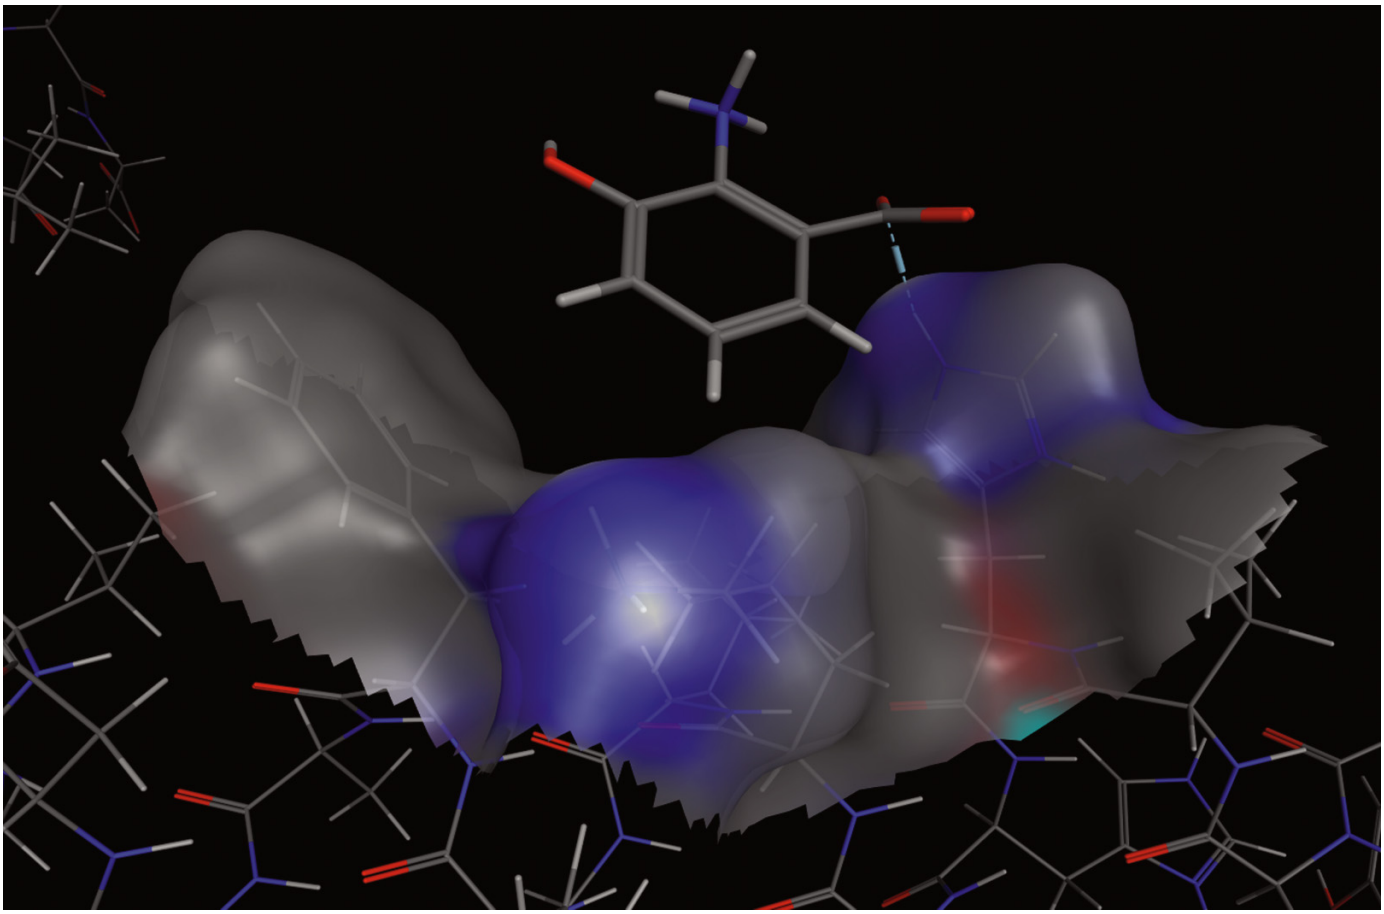
IC_{50}s of the analogues used for this QSAR were all either highly active or inactive and this precluded the use of conventional QSAR methodologies; therefore, a binary QSAR was performed. Binary QSARs are nonlinear and involve the use of probability distributions to predict activity, with relative importance of descriptors being ranked by the MOE program on how well they can predict both activity and inactivity.[12,16] The goal of a binary QSAR remains the same as other methods (to use the minimum amount of descriptors to accurately predict the activity of compounds). If too many descriptors are used, there is a risk of "overfitting" the data and losing the predictive capacity of the QSAR. A binary QSAR can only provide information on whether or not a compound is active; it cannot predict relative IC_{50} values.

With a binary QSAR, the sensitivity and selectivity of the model can be evaluated. The sensitivity is the measure of the number of correctly predicted active compounds divided by the number of compounds observed to be active. Similarly, the selectivity is the measure of the number of correctly predicted inactive compounds divided by the number of observed inactive compounds. A further statistical measure can be obtained from these results; Cohen's kappa can be used to assess the accuracy of the model, and takes into account the role of chance in accurate predictions.[17] The ideal value for Cohen's kappa is close to 1 for the best model possible.[17]

Statistical evaluations of the QSAR model were performed for the training set, validation set, and novel analogues. The total accuracy as well as the sensitivity, selectivity, and Cohen's kappa were used to determine the relevance and accuracy of the model. MOE's cross validation function was also applied to the training set model. The sensitivity, specificity, and Cohen's kappa were also calculated for the validation set and the series of novel analogues.

Fig. 1. 3-Hydroxyanthranilic acid.

Synthetic and biological methods



Chemical syntheses

All glassware was flame-dried and stored in an oven overnight at 120 °C; before use, glassware was purged with argon and allowed to cool to room temperature. All reactions were carried out under atmosphere or argon gas, and were monitored by thin-layer chromatography (TLC) analysis. Dried solvents were purchased from EMD (Canada) and all other chemicals were used as received from Sigma-Aldrich (Canada) and VWR (Canada). Flash chromatography was carried out on 44–63 μm silica gel (230–325 mesh). High-resolution mass spectrometry (HR-MS) was conducted on a BrukermicroTOF Focus orthogonal electrospray ionization time-of-flight mass spectrometer. The ^1H NMR spectra were recorded at 500 MHz.

Aβ aggregation inhibition assays

Aβ40 (>95%) was purchased from AnaSpec (USA) and was stored at −80 °C until used. Hexafluoroisopropanol (HFIP), 3-HAA, and materials for the tris(hydroxymethyl)aminomethane (Tris) buffers were obtained from Sigma-Aldrich

Fig. 2. Interaction between 3-hydroxyanthranilic acid (3-HAA) and the L-histidyl-L-histidyl-L-glutamyl-L-lysine (HHQK) region of β-amyloid (Aβ). The aromatic ring is interacting with Lys16, while the carboxylate group has formed a hydrogen bond with His13.

(USA) and were of the highest grade. All water used in the in vitro studies was micropore filtered and deionized. Aβ40 (1.0 mg) was pretreated in a 1.5 mL microfuge tube with 1 mL of HFIP and sonicated for 10 min to disassemble any preformed Aβ aggregates. The HFIP was removed with a stream of argon and the Aβ dissolved in Tris base (5.8 mL, 20 mmol/L, pH ~10). The pH was adjusted to 7.4 with concentrated HCl (~10 μL) and the solution filtered using a syringe filter (0.2 μm) before being used.

Thioflavin T aggregation assay

A thioflavin T (ThT) aggregation assay was used to quantify the attenuation of β-amyloid aggregation by small molecule antiaggregants. Aβ, in its monomeric form, is soluble in aqueous solution at physiological temperature and pH, and has an α-helical/random coil structure; during aggregation, soluble monomers undergo a structural transformation to a β-sheet conformation, thereby resulting in insoluble aggregates, or plaques, high in β-sheet content. ThT, a benzothiazole dye, has a high affinity for protein with high β-sheet content, and as such may be used to visualize Aβ aggregates. Unbound ThT has fluorescence excitation (λ_{ex}) and emission (λ_{em}) wavelengths at 430 and 342 nm, respectively; upon binding to amyloid fibrils, ThT undergoes a characteristic spectral shift (λ_{ex} = 442 nm, λ_{em} = 482 nm), which can be used to differentiate bound and unbound ThT.

Pretreated Aβ40 (40 μmol/L in 20 mmol/L Tris, pH 7.4) was diluted with an equal volume of 8 μmol/L ThT in Tris (20 mmol/L, pH 7.4, 300 mmol/L NaCl). Aliquots of Aβ/ThT (200 μL) were added to wells of a black polystyrene 96 well plate, followed by 2 μL of a compound in dimethyl sulfoxide (DMSO) (of variable concentration) or DMSO alone (controls). Incubations were performed in triplicate and contained 20 μmol/L Aβ and various concentrations of the compound in 20 mmol/L Tris, pH 7.4, 150 mmol/L NaCl, and 1% DMSO. Plates were covered with clear polystyrene lids and incubated at 37 °C in a Tecan GENios microplate reader. Fluorescence readings (λ_{ex} = 450 nm, λ_{em} = 480 nm) were taken every 15 min, after the sample was shaken at high intensity for 15 s and then allowed to settle for 10 s before each reading. Active compounds attenuated the increase in fluorescence over time that occurred in the controls.

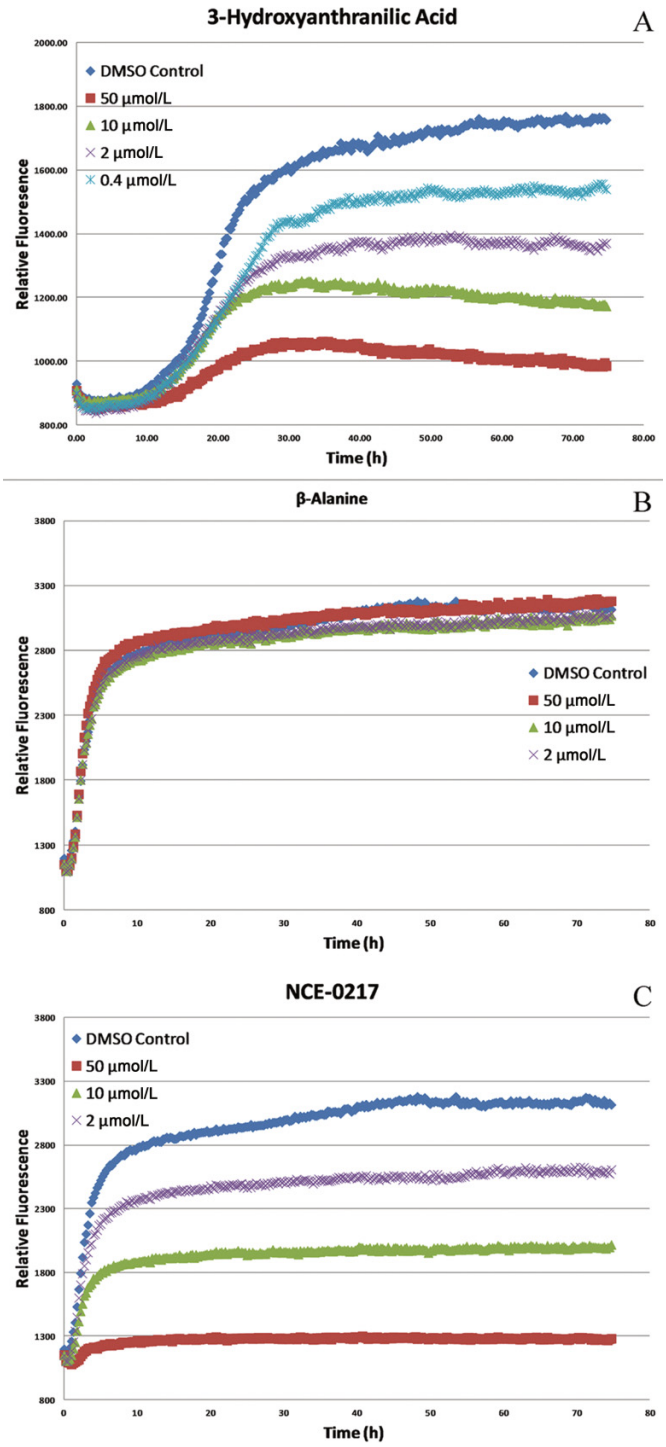
Results and discussion

Identifying an EAM

The in silico screen of endogenous small molecules of the brain led to the successful identification of several small molecules of the tryptophan metabolic pathway as potential therapeutics capable of targeting the HHQK region of Aβ. These molecules all contained features that would allow for interactions with the positively charged amino acids in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

HHQK region of Aβ: either through cation–π, ion–ion, ion–dipole, or even π–π stacking interactions (in the case of the histidine residues). In silico simulations were performed in both gas- and solution-phase environments for D- and L-tryptophan, tryptamine, and 3-hydroxyanthranilic acid (3-HAA) to determine their suitability for binding to Aβ to prevent aggregation. Of these species, 3-HAA (see Fig. 1) demonstrated favourable results for binding to the HHQK region of Aβ: This was further supported by in vitro data. Figure 2 shows one such successful binding interaction between 3-HAA and Aβ. The success of 3-HAA inhibiting Aβ aggregation in vitro relative to a compound with known activity (NCE-0217, proprietary to the Weaver group) and a compound with known inactivity (β-alanine) is demonstrated in Fig. 3.



Given the success of 3-HAA in binding to Aβ in silico, its endogenous nature, and its small size, 3-HAA presented itself as an ideal platform from which to develop novel analogues.

Expanding 3-HAA as an endogenous molecular platform

Given the successful identification of 3-HAA as an EAM, it was selected as a platform for the development of novel analogues in an attempt to improve its antiaggregant activity. Thus, 50 analogues were then prepared and tested for their IC_{50} values in inhibiting Aβ aggregation. The measured IC_{50} values were used to perform a binary QSAR study to allow for the prediction of new analogues with improved activities. Furthermore, binary QSAR methods were used for a very small data set in an approach usually reserved for high throughput screening data.

The results of the predictions of the QSAR model for the training and validation sets are given in Table 5. The final model of nine descriptors demonstrated statistical results for the training set. The total accuracy of the model when applied to the training set was 0.97, with a sensitivity of 0.92 and a selectivity of 1.00. Cross-validation of the model resulted in a total accuracy of 0.91, with 0.83 for the sensitivity and 0.95 for the specificity; these numbers indicate that the current model for the training set is valid. The Cohen's kappa value for the model is 0.93. Given the positive predictions from the model applied to the training set, it was then applied to the validation set, which was slightly less successful. For the validation set, one compound was incorrectly predicted inactive and four compounds were incorrectly predicted active, with one of them being on the borderline. Given that the model assigns values to the compounds on a scale of 0 to 1, with 0 being inactive, and 1 being active, 0.5 was selected as the point from which activity was determined: if the value was >0.5 it was active, and if the value was <0.5 it was inactive. Of the compounds incorrectly predicted active, the QSAR model assigned a value of 0.5012 to one of them, thus it is difficult to truly assign activity to this compound. Using the original activity assignments, the Cohen's kappa for the validation set was calculated as 0.23, with a sensitivity of 0.67 and a specificity of 0.77; however, if the borderline compound was assumed to be predicted inactive, Cohen's kappa jumped to 0.35. The value of Cohen's kappa is fair, but not nearly as good as that calculated for the training set. Despite somewhat of a loss in predictivity when applied to the training set, the model was used to determine the activities of 86 additional novel analogues as a better model was unlikely to be developed with the limited data available. Of the 86 new compounds, 39 were predicted to be active. To determine the efficacy of the QSAR prediction, a selection of 26 of the 86

analogues were synthesized and tested for their ability to inhibit Aβ aggregation. A mixture of active and inactive compounds were selected for the synthesis, and the results indicate that the QSAR model performed better than indicated by the validation set, but not quite as good as it performed for the training set. Of the 26 compounds, 21 had activities correctly predicted by the QSAR model (see Table 6). The sensitivity and selectivity were therefore measured as 0.75 and 0.83, respectively, with a Cohen's kappa value of 0.56. The majority of the compounds that were not correctly predicted were those with functional groups not implicated in the original 50 3-HAA analogues, which may explain the model's difficulty in predicting the activity. Overall, the binary QSAR performed quite well for predicting the activity of novel 3-HAA analogues.

Conclusions

The in silico screen of endogenous molecules of the human brain has led to the successful identification of metabolites of tryptophan as potential therapeutics for treating Alzheimer's disease. 3-HAA was the most successful in in silico simulations for binding to the HHQK region of Aβ, and thus was successfully analogued to improve binding efficacy. Furthermore, binary QSARs can be used to effectively predict compound activities for small data sets when there is a lack of range of biological activity. Despite the fact that a binary QSAR can only predict whether a compound will be active or inactive, it has still proved to be a useful tool in the development of novel analogues based on 3-HAA. The results of the QSAR also indicate that using an endogenous molecule like 3-HAA as a starting point has proved to be a viable option in the development of Aβ antiaggregants. The binary QSAR model proved itself both useful and accurate in identifying the activity of novel analogues, allowing for a more streamlined and cost-effective approach to molecular synthesis: synthesis can be focussed on molecules deemed active, and materials and time are not wasted pursuing unviable compounds. Once an adequate number of the newest series of novel analogues have been synthesized and tested for Aβ aggregation inhibition, a new QSAR model will be applied that will incorporate the newest data to improve predictivity and further aid in the

identification of molecules with antiaggregation properties that may help in treating AD in a more effective manner. In silico methods can be successfully used in an effective manner in both the identification of an EAM as a potential therapeutic and its development as a platform from which to develop novel analogues with improved activity. This methodology has not been pursued previously and represents a new, cost-effective, and convenient approach to drug design.

Abstract: Concentrations of cadmium (Cd) in extracting solutions (neutral salts) from contaminated soils are often too low to be determined by conventional flame atomic absorption spectrometry. For this reason, determination of Cd requires sensitive analytical methods free from interference problems generated by samples. In this context, vapor generation atomic absorption spectrometry (HGAAS) was combined with a high-speed self-reversal background corrector. This new approach was successfully applied after optimization of the analytical parameters to obtain a maximal absorbance signal of the volatile Cd species. The optimum condition was achieved with a 3% (*m*/*v*) $NaBH_4$ in 1.5% (*m*/*v*) NaOH reducing solution and a solution containing 0.3 mol/L HNO_3. The detection limit was 1 ng mL^{-1} under the previous conditions and the relative standard deviation was up to 5% for 10 replicate analyses of Cd at 0.2 and 1 ng mL^{-1}, reflecting a very highly sensitive and reproducible method. Moreover, the results showed that the proposed combination was an efficient method to overcome the interference problems caused by different coexisting cations, As, Al, Ca, Cu, Fe, Mg, Mn, Ni, Pb, Se and Zn, up to 10 μg mL^{-1}. The method was validated with analyses of two standard reference materials and was used for Cd determination in 0.01 mol/L $CaCl_2$ extracts from contaminated kitchen garden soils. The data were compared with those obtained by two other more conventional methods, electrothermal atomic absorption spectrometry (ETAAS) and flame atomic absorption spectrometry (FAAS). The analytical results obtained by the ETAAS and HGAAS were in a good agreement, suggesting the suitability of the method for Cd determination in 0.01 mol/L $CaCl_2$ extracting solution.

Key words: cadmium, absorption atomic spectrometry, vapor generation, high-speed self-reversal method, interference.

Résumé : Les concentrations en cadmium (Cd) dans les solutions d'extraction (sels neutres) de sols contaminés sont souvent trop faibles pour pouvoir être déterminées par spectrométrie d'absorption atomique en utilisant une simple flamme pour atomiser les éléments. La quantification de Cd à l'état de traces requière donc des méthodes d'analyses sensibles mais aussi exemptes d'interférences. Dans ce contexte, le dosage de Cd a été réalisé au moyen d'un spectromètre d'absorption atomique couplé à un générateur d'hydrure en mode continu et combiné à une méthode de correction du bruit de fond par renversement de spectre. Les conditions optimales d'utilisation de la technique ont été déterminées de manière à obtenir une sensibilité maximale. Pour des concentrations de 2,5 et 5 ng mL^{-1}, les absorbances maximales de Cd ont été obtenues en préparant une solution de $NaBH_4$ à 3 % dans une solution de soude à 1,5 % et en analysant des solutions dont la concentration en HNO_3 a été de 0,3 mol/L. Dans ces conditions, la limite de détection a été de 1 ng mL^{-1} et un coefficient de variation de 5 % a été trouvé en analysant à 10 reprises des solutions de Cd à 0,2 et 1 ng mL^{-1}, montrant ainsi une bonne sensibilité et reproductibilité de la méthode. De plus, la méthode analytique proposée s'est avérée être une méthode efficace permettant de minimiser les interférences causées par les cations As, Al, Ca, Fe, Mn, Ni, Pb, Se et Zn jusqu'à 10 μg mL^{-1}. La méthode a été validée par la détermination des concentrations en Cd dans les solutions d'extraction au $CaCl_2$ 0,01 mol/L de sols certifiés et de sols contaminés. Les données acquises avec la méthode proposées ont été comparées à celles obtenues en utilisant des méthodes d'analyses plus conventionnelles, spectrométrie absorption atomique avec atomisation électrothermique et flamme. L'ensemble des résultats obtenus a montré que la méthode proposée était sensible, reproductible et permettait de s'affranchir de certaines interférences.

Mots-clés : cadmium, spectrométrie d'absorption atomique, générateur d'hydrure, méthode par renversement de spectre, interférence.

Introduction

The human health risk of cadmium (Cd) exposure comes mainly through the environment from industry, mining, and motor vehicles. One of the particularities of this element is that it stays in the body for a long time when taken up by food, animals, and humans, even at low concentrations. Therefore, Cd is one of the most hazardous elements for human health and is of interest as a toxic pollutant even at trace levels.[1–7] For this reason, the determination of Cd at trace levels in environmental samples has been the subject of a number of recent publications.[8–12]

Interferences and matrix effects are often problematic, especially when Cd is determined using electrothermal absorption atomic spectrometry (ETAAS).[10,13–15] Consequently, new methods have been developed to minimize these interferences[10,14,16–18] and today, some of them, such as the use of a flow injection system with an on-line separation and preconcentration system combined with flame atomic absorption spectrometry (FAAS), are less prone to these interference problems.[17–19]

Less current methods that offer many advantages (speciation potentialities and no sample pretreatment before analysis) compared with ETAAS[20] consist of measuring Cd by AAS using the chemical vapor generation (CVG) technique. Cold vapor generation (CV)[21–24] and hydride generation (HG)[25–29] are the two methods used in the determination of Cd by CVGAAS. The fact that these techniques are able to form volatile hydrides offers several important advantages such as separation of the analyte from the matrix resulting in reducing matrix related interferences in comparison with ETAAS. However, the CVG technique is not totally free from interference. Indeed, strong interferences in Cd determination (such as Cu) were reported by Tsalev.[20] Even if compounds such as thiourea and L-cysteine are used to improve the tolerance of interferences, the suppression effects of the Cd signal in the presence of As, Cu, Fe, Pb, Mn, Ni, Se, Sn, and Zn concentrations in the range 0.1–10 μg mL^{-1} were highlighted.[22] Bujdoš et al.[27] observed a substantial decrease in the integrated absorbance signals in the presence of As, Cu, Fe, Ni, Sb and Pb for concentration levels ranging from 0.1 to 2 μg mL^{-1}. We therefore attempted to combine hydride generation - flame atomic absorption spectrometry (HGAAS), fitted with a 3-channel peristaltic pump, with the high-speed self-reversal (HSSR) background corrector to study the effect of potential interferents (PI) from common cations in soil solutions and other hydride-forming elements on the formation of CdH_2 and the determination of Cd. Based on the first approach of the Smith and Hieftje method,[30] this background correction system was described as an universal technique, properly working in flame and graphite furnace atomization over the entire wavelength range from 190 to 900 nm and is based on the broadening, which occurs in the resonance lines when a hollow cathode lamp is operated in a pulsed mode with a high frequency (100 Hz) at high current, up to a maximum of 600 mA.[31,32]

In the current study, the Cd lamp was operated with two different discharges, a low current value (10 mA) and then, a high current value (300 mA) to increase the emission intensity and was pulsed with a frequency of 100 Hz (HSSR-BGC). Because the high current mode measures only the background absorption, the difference between the absorption of both types of light provides accurate background compensation and measurement of the atomic absorption of the studied element.

Analytical characteristics of the proposed method (HGAAS-HSSR) were studied after the determination of the best experimental conditions and were compared with those obtained by flame atomic absorption spectrometry (FAAS) and ETAAS. This method was then applied to determine Cd in 0.01 mol/L $CaCl_2$ extracts from two reference materials (CRM BCR-483 and SRM 2710a) and contaminated kitchen garden soil samples.

Materials and methods

Instrumentation

An atomic absorption spectrometer (AA-6800, Shimadzu, Tokyo, Japan) with an ASC-6100 autosampler (Shimadzu, Tokyo, Japan) was fitted with an HVG-1 hydride vapor generator (Shimadzu, Tokyo, Japan). This continuous reagent flow system was combined with a continuous sample flow to obtain a constant output signal as soon as equilibrium was reached. A flame-in-tube quartz T-tube (170 mm length and 5 mm inner diameter) was placed in the optical axis directly over a conventional air/acetylene flame burner head equipped with T-cell tube holder and was heated. The instrumental conditions used for the determination of Cd by HGAAS in continuous flow mode were the following: pre-spray time, 60 s; integration time, 5 s; post-reaction purge time, 25 s; burner height, 14 mm; and carrier gas, argon (70 mL min^{-1} flow rate), used for stripping the solution for efficient separation of volatile species from the liquid phase. The background correction was conducted using a pulsed Cd hollow cathode lamp (Hamamatsu, Iwata, Japan) with a frequency of 100 Hz and lamp currents ranging from 8 to 100 mA and a bandwidth of 1.0 nm.

The same optical parameters were used for Cd determination by traditional FAAS. In contrast, slight modifications about the instrumental conditions were made for optimization: pre-spray time, 5 s; integration time, 3 s; post-reaction purge time, 10 s; and burner height, 7 mm.

For electrothermal atomization, the high-sensitivity GFA-EX7 (Shimadzu, Tokyo, Japan) and high-density graphite tube were used in combination with the ASC-6100 autosampler and the ASK-6100 autodiluter (Shimadzu, Tokyo, Japan). Cadmium was determined in soil extracts at 228.802 nm using a pulsed Cd hollow cathode lamp (Hamamatsu) operated in the range 8−100 mA with a bandwidth of 1.0 nm in combination with the HSSR corrector. A mixture of palladium (30 mg) and magnesium nitrate (20 mg) in 5 mL of 1.4 mol/L nitric acid was used as a chemical modifier to minimize the chloride interferences[13] produced by the extracting solutions (e.g., acid digestion and calcium chloride). The temperature program used throughout this paper is presented in Table 1.

All solutions were prepared from analytical grade reagents unless specified otherwise.

Soil sampling and pretreatment

Seven kitchen garden soils (KG1–KG7) were sampled with a hand auger up to a depth of 25 cm in a contaminated area located in the North of France. A composite sample of the ploughed layer of the soils was made starting from 5 to 10 subsamples taken randomly from the garden area. The topsoil samples were first oven-dried at 40 °C and gently crushed to pass through a 2 mm sieve and then sieved with an ultra-

centrifugal mill less than 250 μm (Retsch type ZM 200, Hann, Germany). Cadmium concentrations in the seven kitchen garden topsoil samples were in the 8.8–30.9 mg kg^{-1} dry weight (DW) range. The contamination of these garden soils was explained by the atmospheric fallout discharged by two PbZn smelters. Compared with the agricultural soils located in the same area,[33] it is important to note that the high Cd levels in kitchen garden samples can be explained by the various anthropogenic activities such as vehicular traffic, the addition of coal-burning waste or slag to improve soil texture, and the use of pesticide and fertilizers.[34]

Reagents and glassware

All solutions used throughout the study were prepared from analytical grade reagents unless specified otherwise. Double-distilled water (Carlo Erba, Val de Reuil, France) with a specific conductivity of 0.1 μS cm^{-1} was used to prepare all aqueous solutions and dilutions. Calcium chloride was analytical reagent grade from Acrōs Organics (Noisy-le-Grand, France). Standard solutions of aluminum, arsenic, cadmium, calcium, copper, iron, magnesium, manganese, lead, and zinc were prepared by dilution of 1000 μg mL^{-1} certified standard solutions in 2% HNO_3 (Chemical Products for Analysis, Association Corporation Standard Distribution called C.P.A. groupe A.C.S.D., Voisins le Bretonneux, France) and nickel and selenium solutions were prepared from standard solutions containing 1000 μg mL^{-1} of metal in 1 mol/L HNO_3 (Reagecon, Shannon, Ireland). The solution of sodium tetrahydroborate ($NaBH_4$) was prepared by dissolving the powder (Alfa Aesar, Karlsruhe, Germany) in NaOH solution (Sigma-Aldrich, Saint Quentin Fallavier, France) to obtain a 3% (*m*/*v*) $NaBH_4$ in 1.5% (*m*/*v*) NaOH reducing solution.[27] This solution was prepared daily just before use. All glassware and polypropylene material used was previously treated for 1 day in 0.5 mol/L nitric acid (J.T. Baker for metal trace analysis; Deventer, Netherlands) to leach trace elements, rinsed with double-distilled water, and stored in closed plastic bags.

Cadmium extraction procedure

Triplicate samples of each soil sample (3 g) and seven replicate samples of CRM BCR-483 (certified reference material composed of sewage–sludge-amended soil from Great Billings Sewage Farm, Northampton, UK) and SRM 2710a (standard reference material (soil) from Montana, USA) were weighed in a polypropylene tube and 30 mL of 0.01 mol/L $CaCl_2$ was added. The suspensions were shaken using a rotor disc (10 rpm) for 2 h. The extract was separated from the solid residue by centrifugation at 4530 rpm (Rotanta 460 Hettich, Tuttingen, Germany) for 20 min at room temperature. Afterwards, the solution was filtered over an acetate Millipore membrane (Millipore, 0.45 μm porosity, Minisart) and was transferred to a polypropylene container. The Cd concentrations measured in the 0.01 mol/L $CaCl_2$ extract were expressed as μg kg^{-1} DW after drying topsoil samples at 105 °C in an oven (Binder, Tuttlingen, Germany) until it reached a constant mass according to the NF ISO 11465 standard.

Statistical analyses

The Cd concentrations in 0.01 mol/L $CaCl_2$ extracts from soil samples are presented as the arithmetic mean in μg kg^{-1} with the standard deviation. The statistical significance of these mean concentrations obtained by ETAAS, FAAS, and HGAAS was determined by applying Student's *t* test. All statistical tests were performed using Statistica 6.0 (Statsoft, Tulsa, Oklahoma), and the level of significance was set at $p < 0.05$.

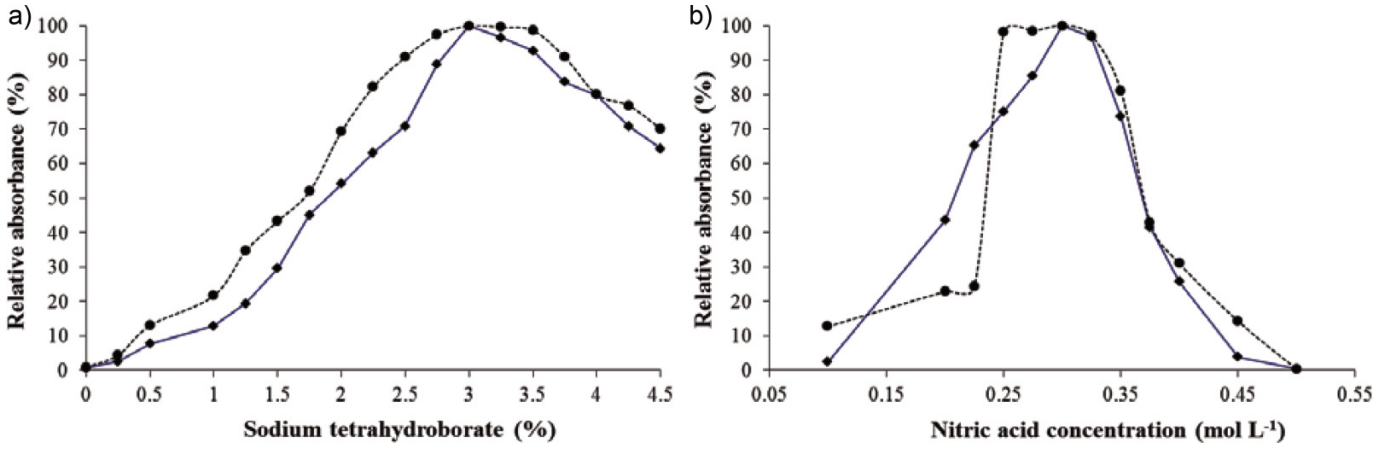
Results and discussion

Optimization of acid concentration for Cd determination by HGAAS-HSSR

Cadmium can be included in the hydride-forming elements, since it is converted to volatile species when reacted with sodium tetrahydroborate ($NaBH_4$), the most widely used compound to generate cadmium dihydride (CdH_2) using the vapor generation technique,[35] although the species are not stable.[36] Optimal conditions to produce in situ CdH_2 may be achieved using an alkaline solution containing 3% $NaBH_4$ (*m*/*v*) and 0.5% or 1.5% NaOH (*m*/*v*).[21,26] In our experiments, the best conditions were obtained with a reducing solution of $NaBH_4$ in 1.5% NaOH (Fig. 1*a*). One of the most important parameters, governing the formation of CdH_2, is the concentration of HNO_3 in the sample solution.[27,36,37] Indeed, the chemical mechanism of cadmium dihydride generation, called "nascent hydrogen," was considered by Sanz-Medel et al.[36] as the following equations:

$$Cd + 2H_3O^+ \rightarrow Cd^{2+} + 2H_2O + 2H^*$$

$$BH_4^- + 3H_2O + H^+ \rightarrow H_3BO_3 + 8H^*$$



$$8H^* + Cd^{2+} \rightarrow CdH_2 + 2H_2 + 2H^+$$

However, this mechanism was criticized by Laborda et al.[38] for Zn because neither tetrahydroborate ($E°(H_3BO_3/BH_4^-) = -0.482$ V) nor zinc ($E°(Zn^{2+}/Zn) = -0.716$ V) can reduce protons to atomic hydrogen ($E°(H^+/H) = -2.106$ V) with regard to their standard potential. The same holds true for Cd because of its lower standard potential ($E°(Cd^{2+}/Cd) = -0.403$ V). The generation of hydride can be explained by considering the hydrogenation process. Hydrides could be generated by the direct action of borane complexes or indirect action through the formation of hydroboron intermediates, which are stable in strongly acidic conditions.[39]

In this study, volumes of 70% HNO_3 ranging from 63 to 326 μL were added to 2.5 and 5 ng mL^{-1} Cd solutions. In both experiments, the maximal integrated absorbance signal was achieved with a solution containing 0.3 mol L^{-1} HNO_3

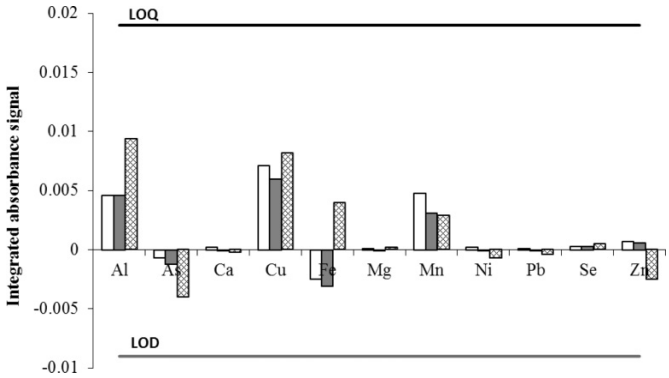
Fig. 1. Effect of HNO_3 concentration on the signal of (*a*) 2.5 (broken line) and (*b*) 5 ng mL^{-1} (solid line) sample solutions ($n = 3$).

(Fig. 1*b*). Even if the absorption signal of 2.5 ng mL^{-1} Cd reached a plateau at 0.25–0.352 mol L^{-1} concentrations, the results demonstrate that the concentration of HNO_3 strongly affects the amount of hydrogen gas generated from $NaBH_4$ and thus the formation of Cd volatile species such as CdH_2. At higher HNO_3 concentrations (>0.35 mol L^{-1}), the integrated absorbance signals decreased dramatically because of the dilution of the analyte vapour, reflecting the high production of hydrogen in these experimental concentrations. In our experiments, it is worth noting that the absorbance signals depended on the ratio BH_4^-/H^+, where H^+ was the proton in the solution after neutralization of a significant part of HNO_3 by NaOH contained in the $NaBH_4$ solution. For optimal CdH_2 formation, this ratio must be kept in very narrow range between 1.3 and 1.45. Therefore, as observed in a previous study,[27] the strong influence of the ratio BH_4^-/H^+ on the absorbance signal of CdH_2 explains the strong influence of the HNO_3 concentration to generate Cd volatile species.



Analytical performance

Under the optimal conditions described previously and using the HSSR method for background correction, absorbance (*A*) was a linear function of the Cd concentration in the range of 0.5–5 ng mL^{-1}. The correlation coefficient of the calibration curve is $r = 0.9994$ and the regression equation is $A = 0.101C - 0.021$, where *C* the concentration of Cd in ng mL^{-1}. The detection (LOD) and quantification (LOQ) limits are given by $LOD = 3\sigma/k$ and $LOQ = 10\sigma/k$, respectively, where σ is the standard deviation of 10 measurements of a reagent blank containing 0.3 mol L^{-1} HNO_3 and *k* is the slope of the calibration curve. The detection limit, found to be 1 ng mL^{-1}, is much lower than that found by FAAS (10-fold) and much higher than that obtained using ETAAS (17-fold) under similar conditions.[40] The LOQ was 3.33 ng mL^{-1}. Accordingly, it was found that the LOQ was 33.3 μg kg^{-1} with respect to the liquid:solid ratio used in the soil extraction procedure. The precision (relative standard deviation of 10 replicate analyses) was up to 5% at the 1 ng mL^{-1} Cd concentration level.

Interference studies

Under the optimized conditions, the effect of 11 coexisting cations on the generation of CdH_2 was investigated. Potential interferents (PI) included Al, As, Ca, Cu, Fe, Mg, Mn, Ni, Pb, Se, and Zn at concentrations of 1, 5, and 10 μg mL^{-1} and were first investigated without Cd in solutions and then with a 5 ng mL^{-1} Cd standard to obtain a Cd solution at a 2.5 ng mL^{-1} concentration.

Fig. 2. Integrated absorbance signal of potential interferents at 1 (white), 5 (grey), and 10 μg mL^{-1} (cross-hatched) in a solution without Cd ($n = 3$).

The integrated absorbance signals of each solution containing one PI in absence of Cd are shown in Fig. 2. Taking into consideration the regression equation, no effects from As, Ca, Mg, Ni, Pb, Se, Zn, and Fe at 1 and 5 μg mL^{-1} were observed on the integrated absorbance signal of Cd. Small effects were reported for Al, Cu, and Mn for the three concentrations (1, 5, and 10 μg mL^{-1}) and Fe at 10 μg mL^{-1}. Nevertheless, the Cd concentrations related to the integrated absorbance signal were in the LOD–LOQ range in all cases.

The effect of each of these 11 interfering cations in a Cd solution at a 2.5-ng mL^{-1} concentration level was evaluated using the optimized method. For this, we expressed the results in terms of relative absorbance, defined as the ratio of the absorbance between the solution with Cd at 2.5 ng mL^{-1} and cations and without them (Table 2). The integrated absorbance signal of this solution without any interfering cations was 0.231 (100%). The relative absorbances were in the 96%–129% range. No suppression of the integrated absorbance signal of Cd was observed from the interfering cations, as in other studies.[22,28] However, among the hydride-forming elements, we can note

Table 2. Effect of interfering cations on the relative absorbance of 2.5 ng mL^{-1} Cd.

Ion	Relative absorbance (%) [PI][a] = 1 μg mL^{-1}	[PI][a] = 5 μg mL^{-1}	[PI][a] = 10 μg mL^{-1}

that a slight underestimation of the integrated absorbance signal of Cd was obtained from As only at a high concentration (10 μg mL^{-1}). At this concentration level, competition between As and Cd with BH_4^- to form the corresponding hydride should represent a condensed-phase interference. However, regarding the results obtained in previous studies,[28,41] we cannot exclude interferences between As hydride and Cd hydride in the atomization process. Pohl and Zyrnicki[41] reported the presence of spectral interferences between As (λ = 228.812 nm) and Cd (λ = 228.802 nm) in spite of gas–liquid phase separation in the hydride generation technique. No effect of As on Cd absorbance was observed for the Cd:As concentration ratio below 2000. The improvement of the Cd absorbance in the presence of As can be explained by the background correction technique used in this study. Indeed, it was already shown that the HSSR method was a suitable method for the correction of spectral interferences between As and Cd in FAAS and ETAAS.[40] In contrast, the suppressions of the Cd signal absorbance (15%, 36%, and 63%) were observed in the presence of Cu at the three concentrations (1, 5, and 10 μg mL^{-1}, respectively). As far as we know, the cause of the signal changes has not been clearly attributed. Even at low concentration levels, Cu seems to interfere in the hydride generation reaction of Cd with $NaBH_4$. This can be explained by the formation of Cu hydride as reported by Sturgeon et al.[42] Finally, a concentration of 3.15 ng Cd mL^{-1} was measured in the mixture of Cd at 2.5 ng mL^{-1} and Fe at 10 μg mL^{-1}, reflecting a slight overestimation of the value.

Application

The proposed method was applied to the determination of Cd concentration in $CaCl_2$ extracts from two reference materials and seven contaminated soil samples. Therefore, 193 μL of HNO_3 (70%) was added to 10 mL of each $CaCl_2$ extract and the Cd values were compared with the values obtained with more conventional analytical techniques, ETAAS and FAAS (when it was possible owing to Cd concentrations lower than the detection limit, $LOD_1 = 3\sigma = 54$ μg kg^{-1} and $LOD_2 = 3\sigma/k = 301$ μg kg^{-1} in 0.01 mol/L $CaCl_2$). The results are given in Table 3.

According to the statistical tests, no significant differences were observed between the data obtained using the HGAAS and ETAAS methods. Some differences were obtained between the Cd concentrations with these two methods and those obtained with the FAAS measurements (e.g., KG1, KG3, KG4, and KG6; Table 2), reflecting that the FAAS method is not already a suitable method for the determination of Cd in 0.01 mol/L $CaCl_2$ extracting solution mainly because of the low Cd concentrations. Regarding the results obtained using ETAAS, the reliability of the proposed method is evident. On the other hand, the analytical results of the CRM BCR-483 from HGAAS and ETAAS were very close to that of the indicative value (recovery = 105%). In comparison with the results obtained by Pueyo et al.[44] using ICP–MS, better recovery was obtained (98.5%). All results showed the efficiency of the continuous sample flow combined with the continuous reagent flow system to minimize interferences. However, interference of Cu on the Cd signal absorbance was reported. Moreover, it appeared that the HSSR method was able to reduce As interference in the atomization step of its hydride up to 10 μg mL^{-1}.

Conclusion

Cadmium determination was optimized by combining vapor hydride generation atomic absorption spectrometry and high-speed self-reversal methods (HGAAS-HSSR) in terms of the concentration of NaOH in the reducing solution, gas flow rate, and concentration of HNO_3 in sample solutions. For the best conditions, the detection limit was 1 ng mL^{-1} and the relative standard deviation was up to 5% at 0.2 and 1 ng mL^{-1} Cd concentration levels, reflecting the high sensitivity and precision of this method. Furthermore, the results of Cd determination in $CaCl_2$ extracts from soil samples measured by ETAAS were in agreement with those obtained using the chemical vapor hydride generator atomic absorption spectrom-

etry combined with the high-speed self-reversal background corrector, reflecting that the HGAAS-HSSR method was suitable for low Cd concentrations in $CaCl_2$ soil extracts without any need for sample pretreatment.

Abstract: Crystal forms of polyethersulfones (PES) were investigated by using a model compound and a low molecular weight oligomer. These are amorphous as-synthesized, and can undergo solvent-induced crystallization under the appropriate conditions. The model compound, 4,4′-bis(*p*-methoxyphenoxy)diphenyl sulfone, yielded monocrystals, and its structure was solved using X-ray diffraction. Conformational disorder is present, two conformers cohabiting in 55:45 proportions. This model compound, combined to previous structural studies published in the literature, served as a basis for conformational studies of polyethersulfone. Low molecular weight polymers submitted to solvent-induced crystallization resulted in a PES crystal form different from that previously published in the literature, as shown by powder X-ray diffraction.

Key words: polyethersulfone, solvent-induced crystallization, crystal structure, polymorphism, X-ray diffraction.

Résumé : On a étudié les formes cristallines de sulfones de polyéthers (SPE) en se basant sur un composé modèle et un oligomère de faible poids moléculaire. Ces sont des produits amorphes obtenus par une synthèse-as et, dans des conditions appropriées, ils peuvent donner lieu à une cristallisation induite par un solvant. Le composé modèle, le sulfone de 4,4′-bis(*p*-méthoxyphénoxy)diphényle, peut être isolé sous la forme de monocristaux et on a déterminé sa structure par diffraction des rayons-X. On a décelé un désordre conformationnel alors que deux conformères coexistent dans des proportions de 55 : 45. Les données relatives au composé modèle combinées aux études publiées antérieurement sur les structures ont servi de base pour les études conformationnelles des sulfones de polyéthers. Les polymères de faibles poids moléculaires soumis à une cristallisation induite par un solvant ont conduit à la formation de SPE dont la forme cristalline, d'après la diffraction des rayons-X, serait différente de celles rapportées antérieurement dans la littérature.

Mots-clés : sulfone de polyéther, cristallisation induite par un solvant, structure cristalline, polymorphie, diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

Polyethersulfones, abbreviated PES, stand out among other high-performance thermoplastic polymers because of their thermal stability, amorphous morphology, and good solubility in low polarity solvents (ketones and chlorinated aromatic hydrocarbons). They are finding increasing use as membranes for a variety of applications, such as hemodialysis, water filtration, and gas separation, and are serious candidates for fuel cell membranes.

A regular polymer such as PES is rarely entirely amorphous. Blackadder et al.[1] showed that PES can undergo solvent-induced crystallization in dichloromethane under specific conditions. Upon crystallization, PES solubility markedly decreases because of the increase in interchain interactions that must be weakened before dissolution occurs.

Improving crystallization of PES could yield a better range of properties and therefore applications. On the other hand, solvent-induced crystallization has been identified as a cause for the increase in brittleness in PES upon contact with chlorinated solvents, and techniques to inhibit this crystallization could, in turn, be useful for specific applications where this crystallization issue causes problems.[2] For this, a better knowledge of the crystal phase of PES and conditions that favour its growth is needed.

The limited crystallization of regular PES and its oligomers is an exception in the world of rigid polymers. For example, polyetheretherketones (PEEKs) have a similar rigidity, but nevertheless crystallize extremely well, as reported in the literature.[3] Polythioethersulfones (PTES) and polyparaphenylenesulfone (PPS), which are also similar in chemical repeat unit and rigidity, also crystallize readily.[3] Atwood et al.[4] suggested that the combined effect of a T_g higher than that of PEEK, and a difference in the valence angle of C–S–C diarylsulfone versus C–C–C diarylketone links may explain the low PES crystallinity, whereas other authors mention the limited difference between glass transition temperature and melt temperature as the cause for the limited crystallinity observed.[5] However, this behaviour may also be related in part to the adopted crystal phase conformation. Polyethylene te-

rephtalate is usually obtained in an amorphous form, which does not crystallize easily unless submitted to annealing, stretching, or solvent-induced crystallization. It has been proposed that the key in its amorphous phase stability lies in the fact that the lowest energy conformation is not the all-trans conformation found in the crystal form and favoured by packing interactions, but a gauche conformation.[6–8] A similar origin for the limited crystallization may exist for PES.

With limited data on the PES crystalline form itself, crystal structures of model compounds become of utmost interest. Few have been studied in the literature, and the present work testifies to the difficulty in crystallizing model compounds composed of a little as two repeat units. A four-ring oligomer bearing amine terminal groups was studied by Bocelli and Rizzoli.[9] Cyclic ethersulfone oligomer crystal structures were reported by the group of Colquhoum and Williams,[3] as these yield high-quality single crystals. However, packing of these cyclic analogues is incompatible with that of polymer chains, and ring constraints may favour conformations different from those adopted in long polymeric chains. From the study of these cyclic oligomers, it was observed that face-to-face π-stacking and C–H···π interactions provided the main stabilization mechanism for crystallization.[3] Whether such interactions are at play in PES is unknown.

In recent years, our group has focussed on the design of rigid–flexible copolymers with rigid block lengths close to the thickness of a single crystalline lamellae.[10] These rigid blocks adopt the same crystal structure as the homopolymers and, because of their lower molecular weights, crystallize more readily. Furthermore, during the course of the synthesis, various low molecular weight model compounds were synthesized and attempts to crystallize them were made. The present article therefore reports the crystal structure of a new model compound, X-ray diffraction of an oligomer as well as conformational analysis, in the aim of shedding light on the crystallization of polyethersulfones for future applications.

Experimental

Synthesis and crystallization of 4,4′-bis(*p*-methoxyphenoxy)diphenyl sulfone (MPDS)

4,4′-Bis(*p*-methoxyphenoxy)diphenyl sulfone, abbreviated MDPS, was synthesized by reacting 5.085 g (20.0 mmol) of 4,4′-difluorodiphenyl sulfone, 4.967 g (40.0 mmol) of 4-methoxyphenol, and 6.08 g (44.0 mmol) of potassium carbonate in a round-bottomed flask. Thirty millilitres of dimethylacetamide (DMAc) was added to this mixture and the resulting solution was heated to 160 °C overnight under argon atmosphere. The reaction mixture was diluted with dichloromethane and washed with saturated NaCl water three times to remove DMAc and potassium carbonate. The organic layer was washed three times with distilled water and dried over MgSO4, filtered, evaporated, and dried in vacuo at 60 °C to give a white solid (MDPS). The MDPS was crystallized by solvent evaporation of the toluene/methanol solutions (3:1).

Synthesis and characterization of polyethersulfone oligomers

PPS oligomers were synthesized by chain-growth polymerization of 4-fluoro-4′-hydroxydiphenylsulfone, following the work of Yokozawa et al.,[11] which was end-capped by the addition of 4-methoxy phenol in dimethylacetamide. Methoxy end groups were deprotected by the addition of BBr_3 in CH_2Cl_2. Molecular weights of ethersulfones oligomers were determined by MALDI-TOF mass spectroscopy in positive linear mode, using a Bruker Autoflex mass spectrometer equipped with an UV laser (λ = 337 nm, 3 ns second pulse). NaCl was used as a cationizating agent in a dithranol matrix. M_n was found to be 1600 g mol^{-1} and the polydispersity index was 1.15. Oligomer crystallization was performed following the work of Blackadder et al.[1] by first dissolving the PES copolymer in dichloromethane and then lowering the temperature of the 20 wt % solutions to 5 °C for 24 h. The resulting powder was dried in air until the powder did not feel sticky any more, then introduced into a 1 mm diameter glass capillary (Charles Supper Company), and sealed using a match. X-ray diffraction diagrams were registered right away on a Bruker diffractometer equipped with a Kristalloflex 760 generator, a three-circle goniometer, and a Hi-Star area detector. The generator produced a graphite-monochromatized copper radiation (Cu Kα = 1.5418 Å) at 40 kV and 40 mA. For the MPDS model compound, the X-ray powder pattern was also calculated from the *x*, *y*, and *z* coordinates fo the resolved crystal structure using the Mercury 2.3[12] program (Cambridge Crystallographic Data Centre) and imposing a constant full-width at a half-height of 0.4°.

Single crystal determination of MPDS

A yellow crystal of MDPS having approximate dimensions of 0.16 mm × 0.15 mm × 0.07 mm was mounted on a glass fiber using Paratone N hydrocarbon oil. Measurements were made at 200(2) K on a Bruker APEX II area detector diffractometer equipped with graphite-monochromated Mo Kα radiation. Frames corresponding to an arbitrary hemisphere of data were collected using ω scans of 0.5° counted for a total of 30 seconds per frame. An orientation matrix corresponding to the cell constants listed in Table 1, along with additional details on data acquisition, was obtained from a least-squares refinement using the measured positions of 3181 centered reflections in the range $2.23° < \theta < 18.44°$. The APEX 2 program was used for cell parameter retrieval and data collection.[13]

Data were integrated using the SAINT program.[14] The data were corrected for Lorentz and polarization effects. A multiscan absorption correction was performed using the SADABS program.[15] The structure was solved and refined using SHELXS-97 and SHELXL-97.[16] All non-H atoms were refined anisotropically. Hydrogen atoms were placed at idealized positions. Neutral atom scattering factors were taken from the *International Tables for X-ray Crystallography*.[17] All calculations and drawings for this crystal structure were performed using the SHELXTL package.[18] The final model was checked either for missed symmetry or voids in the crystal structure using the PLATON software.[19,20] None was found. The crystal structure gives a satisfactory chekcif report (available in the Supplementary data).

Results and discussion

Polyethersulfone crystallinity

Experimental data on PES crystallization present in the literature is limited, to the best of our knowledge, to mainly two publications, which report X-ray diffraction of a sample crystallized at low temperature in the presence of a solvent[1] and spherulite-like structures.[21] The same crystallization

Largest diff. peak and hole (e Å^{-3})	0.229 and –0.165

procedure was applied to the low molecular weight PES blocks available in our lab, and the results are reported in Fig. 1, along with diffraction of the initial polymer as-synthesized and of the only oligomer studied from which we were able to obtain single crystals, MPDS. Whereas, as synthesized, PES oligomer samples showed only a broad peak due to scattering of the amorphous phase, small narrow peaks began to be observed after solvent treatment, although the amorphous halo was still predominant. These, however, disappeared if the sample was dried too much, indicating that solvent molecules may be included as an adduct in the crystal form, as previously proposed in the literature.[1,21]

Observed diffraction peak positions are reported in Table 2, along with those previously reported for PES by Blackadder et al,[1] and those of similar rigid–flexible polymers.[22–27] The diagram observed in the present work presents two intense diffraction spots at approximately 4.9 Å (18°) and 4.2 Å (21°). This does not match the previous report by Blackadder et al.,[1] in which the two most intense spots were positioned at 4.50 Å (19.7°) and 3.32 Å (26.9°), as reported in Table 2.

Fig. 1. X-ray diffraction powder diagrams of polyethersulfone (PES) and of a model compound, 4,4′-bis(*p*-methoxyphenoxy)diphenyl sulfone (MPDS), experimental powder spectrum (Powder) and as calculated from single crystal structure (Calcd.).

The experimental powder X-ray diffraction diagram of the MPDS model compound, as well as the diagram calculated from the single crystal structure of this compound (which is discussed in the following section) are shown in Fig. 1. As observed in the figure, experimental and calculated MPDS spectra do not match, indicating that this compound is polymorphic. The main difference lies in the relative intensity of the peak at 17.3°, the most intense for MPDS as calculated from the crystal structure, which is of much lower relative intensity in the observed spectrum, although many of the smaller intensity peaks also change in intensity below at higher diffraction angles. The main diffraction peak positions remain unchanged, within experimental error.

The strongest peaks are at similar 2θ positions for PES from this work and for MPDS, although smaller intensity peaks

Table 2. X-ray powder diffraction data for the main peaks of various rigid copolymer structures (polyetheretherketone (PEEK) peak positions calculated using unit cell dimensions proposed by Ho and Cheng[22,23]).

differ. This indicates that a similarity in structural features may occur between PES and this model compound.

Crystal structure of the MPDS model compound

The crystal structure of the MPDS model compound is reported in the present work. Atomic positions are given in Table 3, and Table 4 lists anisotropic displacement parameters. This structure is different from any of the ethersulfone model compounds reported in the literature. As depicted in Fig. 2, which also shows the numbering of the atoms, the chain exhibits conformational disorder, two different conformations appearing in the crystal packing with 55% and 45% occupancy factors at the site of a phenoxy group. This disorder is located at one of the phenyl ether groups, the rest of the structure remaining well-ordered, as if multiple conformations were possible at this specific position. Further, these two conformations are well-defined in the crystal state, as illustrated by the occurrence of similar temperature factors for the ordered and disordered parts of the molecules, as reported in Table 4. This highly unusual phenomenon points to a large conformational flexibility, and already gives insights on the possible cause for a low crystallinity of the parent PES polymer.

Geometry of the sulfonic group is comparable to that of various previously determined sulfone structures, which have been the object of a review:[28] S=O distances are short, (1.435(2) and 1.446(2) Å), corresponding to strong double bonds; the large O–S–O bond angle of 120.10(13)° is comparable to values of 116.9(8)° to 120.61(8)° for previously reported sulfones; and the C–S–C of 104.11(13)° is small for a tetrahedral angle, again as observed for other sulfones (104.11(13)°), which has been attributed to the effect of lone-pair repulsion on the sulfone group oxygen atoms.[28] Ether groups have normal geometries, with distances varying from 1.380(3) to 1.419(11) Å, with one exception, at 1.431(7) Å in one of the two disordered conformations. This may, however, be related to a slightly incorrect position of the C4 carbon atom common to both disordered conformations, as the temperature factor is larger perpendicular to the ring plane for this atom, and as an abnormally low valence C–O–C angle of 113.5(10)° is also observed, significantly lower than the average 120°–121° diaryl ether bond angle.[3,4] However, two distinct positions of this carbon atom could not be resolved, the two positions being most probably too close.

Conformational features of this structure can be described either by the dihedral angle between the two aromatic ring planes or by the two successive torsion angles C–X–C–C and C–C–X–C related to the two C–X bonds of the sulfone or ether groups. For the sulfone group, the dihedral angle is 81.0° and the torsion angles (C–S–C–C) are 87.4(3)° and 91.5(2)°, in agreement with the 90° value predicted by Koch and Moffitt[29] for maximum conjugation between aromatic rings and a sulfone group, and are also in agreement with a recent X-ray study of sulfones in which the dihedral angle between the ring plane and the sulfone plane varied from 75.3° to 86.6°.[28] A few values were found to depart from this optimal value in the literature: a value of −67°[9] and one of −102.3°[30] were observed for hydrogen-bond-forming NH_2-terminated aryl ether sulfones and an ortho-substituted nitro compound that showed steric hindrance exhibited a value of 61.2°.[28] The SO_2 plane, therefore, generally lies between the two phenyl planes in an "open-book" conformation. This conformation is also the one proposed by Tabor et al.[31] for PPS, and no evidence suggests that it should be any different for PES.

Phenoxy groups show a much larger variability in conformation than sulfone groups do. The number of aryl ethersulfone crystal structures is limited, but variations are large even within this selected group, with two main conformations having been observed: the first is analogous to the open-book conformation, although dihedral angles between aromatic rings are closer to 70° than to 90°, with successive torsion angles of 87.3° and −61.6°;[9] in the second conformation

adopted, a first ring is close to the C–O–C bridge plane and the other is almost perpendicular to this plane, with torsion angle values of 6.0° and 76.7°, 19.8° and 66.7°, or 64° and 2°.[25,32] In the crystal structure of the MPDS reported here, disorder occurs at this position, and three different sets of torsion angles were observed. None fit the open-book conformation and only one fits the second conformation previously observed, with torsion angle values of –16.1(4)° and –75.8(4)° in the nondisordered section of the molecule. In the disordered section of the molecule, the conformation adopted is either planar, with torsions angles of –0.6(9)° and 1.8(19)°, or corresponds to a new conformation with torsion angles of –28.8(9)° and –46.5(15)°. The variety of possible conformations, and the disorder observed, are in part due to a large flexibility of the phenoxy conformation, which has been established by theoretical calculations of diphenyl ether derivatives using ab initio[33,34] and semi-empirical DFT calculations.[35] An energy rotation barrier around the ether C–O bond of approximately 8 kcal/mol (1 cal = 4.184 J) was found, with a global minimum at approximately 35°, associated with a large, flat minimum

region between 30° and 95°.[33] This feature of the potential energy surface explains why, in the absence of stabilizing contacts, two different conformations are adopted with almost equal probabilities in MPDS.

The packing adopted by this molecule is presented in Fig. 3, and is clearly incompatible with that of an extended chain polymer. In the present MPDS ethersulfone model compound, as in polysulfones and poly(ethersulfones), there are no hydrogen atoms on polar atoms, and therefore no classical hydrogen bonds can form. Nevertheless, as observed previously,[28,36] soft hydrogen bonds can form between aromatic hydrogen atoms and sulfone oxygen atoms. In the present case, two short contacts are observed between the oxygen atoms of the sulfone group and the hydrogen atoms of the aromatic rings, with distances of 2.634 Å for O6···H3 and 2.651 Å for O5···H17. It is worth noting that the two S=O bond distances are significantly different, with values of 1.435(2)Å for S1–O5 and 1.446(2) Å for S1–O6, the longer distance corresponding to the weakest O···H contact. This difference in S=O bonds is therefore proposed to be the effect

Fig. 2. Single molecule of 4,4′-bis(*p*-methoxyphenoxy)diphenyl sulfone in its two observed conformers (labelled A and B), present in a 55:45 ratio. Hydrogen atoms are omitted for clarity. (*a*) Numbering of atoms. (*b*) ORTEP view with 50% probability.

of a weakening of the S=O bond due to a soft hydrogen bond interaction.

As shown in Fig. 4, for MPDS, one soft hydrogen bond is formed between the sulfonic group and a hydrogen atom of an aromatic ring bonded to both the sulfonic and the ether group, whereas a second bond is formed between the sulfonic group and a ring bonded to the ether and a methoxy end group. Although only one of the two disordered conformers is depicted in the figure for clarity, interestingly, the disordered ring is the one not interacting with the sulfone group; neither of the two disordered conformations observed showed such interactions. Therefore, it is proposed that sulfone – aromatic ring interactions are important and play a role in either stabilizing the crystal phase, if such interactions can exist in a regular close packing of polyethersulfones or, alternatively, stabilizing the amorphous phase, thereby contributing to a high energy barrier for crystallization and to a decrease in resulting crystallinity. The absence of such interactions may lead to disorder, and may therefore inhibit crystallization.

Comparison with similar rigid polymer structures

It is also interesting to compare the X-ray diffraction patterns and crystal structures of related rigid polymers, as strong similarities exist between some of these rigid polymers. Figure 5 illustrates conformations adopted in the crystal phase by a few representative rigid polymers. In poly(etherketone) (PEK) and PEEK, the aromatic ether and ketone linkages are crystallo-

graphically interchangeable, only slight variations in unit cell dimensions and relative intensity of the diffraction spots being observed.[37] These polymers are highly crystalline, surprisingly so for aromatic polymers, which are often low in crystallinity.[3] This has been attributed to the geometrical equivalence of aromatic ether and carbonyl linkages, which allows the chain to remain in a linear geometry favourable to crystallization.[37] Two crystal polymorphs are known, each having the same planar conformation and differing by the packing mode. Form I, obtained by crystallization from the melt, exhibits diffraction peaks at 3.8 and 4.8 Å and has been proposed to be monoclinic, with one chain at the center of the unit cell and another at the corner of the cell.[38] Its packing has been described as an edge-to-face phenyl packing.[39] Form II, obtained from the solution of cold crystallization, has an intense peak at 4.2 Å. Two different structures have been proposed for this form, a two-chain orthorhombic structure, also with one chain at the center and the other at the corner, but with slightly different chain organization,[38] and a one-chain or-

thorhombic structure.[39] Random etherketone copolymers are even more crystalline than regular polymers, which further illustrates the crystallographic equivalence of ether and ketone groups in this class of rigid polymers.[40]

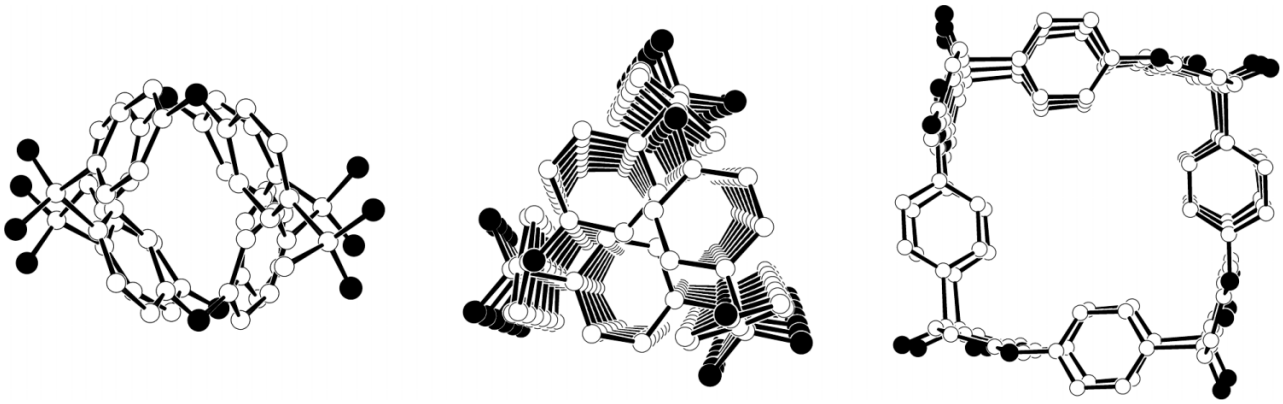
Polythioetherketone (PTEK), in which the ether group of PEK is replaced by a thioether group, also crystallizes well, in spite of the fact that thioether bond lengths and C–S–C bond angles are different from those of the ketone group.[3] Deformations occur on carbon atoms adjacent to the thioether bridge, opening up the thioether bond angle. This allows the polymer and related oligomers to remain essentially linear, and the conformation is very similar to that of PEK. This polymer is known to crystallize as two different polymorphs. Comparison of peak positions for the most intense reflections, as reported in Table 2, show strong similarity with PEK form I. Strong similarities in peak positions and relative intensities are also found between PEK form II and PTEK form II.[24,41] Form I is a body-centered monoclinic structure, whereas chains are at the corner and middle of the unit cell in the orthorhombic form II.

A third rigid polymer for which the crystal structure is known is presented in Table 2, PPS, in which the only linker between aromatic rings is a sulfone group.[27,42] Data on oligomers of PPS and proposed crystal structure show that the favoured conformation is not planar but of the open-book type, where rings are orthogonal (or nearly so) to the C–S–C plane,[42,43] as depicted in Fig. 5. This leads to a completely different chain packing and unit cell dimensions than in the case of PEK, PEEK, and PTEK. Two crystal polymorphs are also observed in this case, with peak positions bearing little similarity to those of PEK or PTEK, which can be attributed to the different chain conformation adopted.

In contrast to these rigid polymers, the crystal structure of PES has never been solved, and its repeat distance is also unknown, this polymer usually being amorphous as synthesized or even after annealing at higher temperatures in spite of its regularity, which is highly unusual. Further, when a low crystallinity is observed as synthesized, it disappears upon heating above the melt ing point.

The conformation adopted by the MPDS molecule is not all-trans nor reminiscent of a conformation leading to extended chains, as in the zig-zag conformation adopted in forms I and II of PEK and PTEK. It is also different from that of the crystal phase of PPS, which is an open-book zig-zag conformation, as shown in Fig. 5. The most interesting feature of this conformation is the fact that the open-book conformation is adopted for the sulfone group, but not for the ether groups.

As can be seen in Table 2, the diffraction diagrams of PEK, PTEK, and PPS do not match that observed in the present work for PES, the closest one being that of PPS, which exhibits three intense diffraction peaks at 16.4°, 21.1°, and 26.5°, as compared with two intense peaks at 18.0° and 21.1° for PES. PES is therefore proposed to exhibit a different crystal packing and possibly different conformation than that of related previously studied rigid polymers. Changing the carbonyl group by a sulfone group, therefore, has a more profound effect on the crystal form that by changing an ether group to a thioether group, which leads one to suspect that the change is not merely related to packing but may also relate to the conformation adopted by the chains.



Investigation of possible conformations of PES

In the absence of a repeat distance value, it is very difficult to determine without ambiguity the conformation adopted by PES in its crystal forms. In the present study, a few low-energy conformations were built and compared. These are reported at the right in Fig. 5. In all cases, helices were investigated, although pseudohelical forms cannot be excluded.

The 2_1 helix is the simplest form, conformationwise. It is similar to that of PPS, combining open-book around the sulfone group and parallel ring arrangements around the ether linkage. As reported in Table 5, torsion angles around the sulfone groups have values of 90° and 78°, and are both close to the minimum energy conformation of 90°. The ether group shows torsion angle values of 20° and –30°, close to those observed for MDPS conformation IIa (although in this conformation successive torsion angles were of the same sign, which is not the case for the 2_1 helix). This yields a zig-zag conformation reminiscent of the PPS conformation, but with bends occurring every two aromatic cycles. The chain "bends" at each sulfone group, whereas the ether groups remain in the same plane at the aromatic cycles to which they are linked. A packing similar to that of PPS would be possible with this conformation.

Various helices could be built using slight variations in the torsion angles of one of the conformations of MDPS. For example, the 3_1 helix shown in Fig. 5 is relatively compact, and its conformation angles are 90° around the sulfone group, as in the case of most crystal structures. Around the ether group, a first torsion angle of –30° is found, which is close to one value observed for MDPS conformations I and IIa However, the second torsion angle is 90°, which deviates signifi-

Fig. 6. Top view of three possible conformations of polyethersulfone (PES): 2_1, 3_1, and 4_1 helices.

cantly from values observed for model compounds, a value close to the one observed by Bocelli et al.[9] for a PES model compound, although the two successive torsion angles were not the same. The 4_1 helix was obtained from slight deviations from the torsion angles adopted by the MPDS conformation IIb and is a more "open" helix, exhibiting a void at the center. It is also close, but with opposite signs, to MDPS conformation I. This similarity, and the previously noted similarity in powder diffraction diagrams, indicates this could be the conformation adopted by the crystal structure of PES that was observed in the present work.

A top view of each of these three helices is presented in Fig. 6. The 2_1 and 3_1 helices are relatively compact, whereas a void is present at the center of the 4_1 helix. In all cases, the oxygen atoms (shown in black in this figure) lie on the outer surface of the helix. If soft hydrogen bonds between the helix and solvent molecules stabilize this crystal form, solvent molecules would be present between helices. On the other hand, as can be seen in Fig. 5, some solvent molecules could also be trapped at the middle of a 4_1 helix.

The presence of solvent molecules in the crystal structure, stabilizing the helical conformation, is in agreement with observations by Blackadder and Ghavamikia[21] that birefringent spherulitic structures and crystal-like globules can be observed in chloroform of dichloromethane, and that structures loose their birefringence and crystallinity upon drying.

Conclusion

A new crystal form for PES was observed from solvent-induced crystallization of low molecular weight PES. X-ray diffraction shows a strong similarity with X-ray diffraction patterns of the small molecule model MPDS. The crystal structure of MPDS is disordered, illustrating the relative flexibility for rotation around ether linkages, as compared with relatively more rigid sulfone bonds. For this reason, it is proposed that ether and sulfone bonds are not crystallographically interchangeable, thus destabilizing the crystal form of this polymer as compared with that of other rigid polymers, where all aryl bonding groups are crystallographically interchangeable.

Various low-energy helical forms exist for PES, and all have oxygen atoms at their outer surface with which solvent molecules can form soft hydrogen bonds to stabilize the conformation. Further, a 4_1 helix PES model built using torsion angles close to those of a MPDS conformation presents a void at the center and can therefore accommodate additional solvent molecules. Upon drying, evaporation of the solvent increases the free volume, allowing the chain to adopt other conformations and resulting in a loss of short-range order and crystallinity. It is proposed as a possible conformation for the new PES crystal form reported in the present work.

Supplementary data

Supplementary data are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v2012-066. CCDC 871798 contains the X-ray data in CIF format for this manuscript. Abstract: Presented here is a solid-state NMR investigation of the so-called "colossal expansion" material, $Ag_3Co(CN)_6$, a compound that exhibits some of the largest positive and negative thermal expansion properties reported. This study explores the ^{13}C, ^{15}N, and ^{59}Co NMR properties of this material at room temperature and at variable temperatures with the goal of probing the effects of this colossal expansion behaviour on these properties. We found that the flexible nature of the crystal framework leads to a distribution of electric field gradients, and that, oddly enough, no strong correlation is observed between the NMR parameters of $Ag_3Co(CN)_6$ and its colossal expansion nature. The ^{59}Co isotropic chemical shift increased and the ^{59}Co nuclear quadrupolar coupling constant decreased with increasing temperature, but neither of these relationships were extraordinary when compared to other octahedral Co(III) complexes. The link between the colossal expansion and the NMR properties of $Ag_3Co(CN)_6$ may be the distribution of lattice parameters and hence unusually broad features in the ^{59}Co NMR spectra. The high order of symmetry at the cobalt site resulted in a small quadrupolar coupling constant less than 1 MHz in magnitude. We also observed a $|^1J(^{107/109}Ag,^{15}N)|$ value of 96 Hz, the largest $^{107/109}Ag–^{15}N$ coupling constant reported to date.

Key words: colossal expansion material, solid-state NMR, Co-59 NMR, C-13 NMR, N-15 NMR.

Résumé : Dans ce travail, on rapporte les résultats d'une étude RMN à l'état solide du matériau dit d' « expansion colossale », $Ag_3CO(CN)_6$, un composé qui possède des propriétés d'expansion thermique positives et négatives parmi les plus grandes. Cette étude examine les propriétés RMN du ^{13}C, du ^{15}N et du ^{59}Co, à la température ambiante ainsi qu'à des températures variables, dans le but d'étudier les effets de ce comportement d'expansion colossale sur ces propriétés. On a trouvé que la nature flexible du réseau cristallin conduit à une distribution des gradients des champs électriques et que, d'une façon surprenante, il n'existe aucune corrélation forte entre les paramètres RMN du $Ag_3CO(CN)_6$ et sa nature d'expansion colossale. Le déplacement chimique isotrope du ^{59}Co augmente alors que la constante de couplage quadripolaire nucléaire du ^{59}Co diminue avec une augmentation de la température; aucune de ces relations n'est toutefois extraordinaire quand on les compare avec celles d'autres complexes octaédriques du Co(III). Le lien entre l'expansion colossale et les propriétés RMN du $Ag_3CO(CN)_6$ pourrait provenir de la distribution des paramètres de réseaux et, en conséquence, de caractéristiques anormalement larges dans les spectres RMN du ^{59}Co. Le degré de symétrie élevé au niveau du site du cobalt conduit à une constante de couplage quadripolaire faible, dont l'amplitude est inférieure à 1 Mhz. On a aussi observé une valeur $|^1J(^{107/109}Ag,^{15}N)|$ de 96 Hz, la constante de couplage la plus grande observée jusqu'à maintenant pour $^{107/109}Ag,^{15}N$.

Mots-clés : matériau d'expansion colossale, RMN à l'état solide, RMN du Co-59, RMN du C-13, RMN du N-15.

[Traduit par la Rédaction]

Introduction

In 2008, Goodwin et al.[1] reported that silver hexacyanocobaltate(III), $Ag_3Co(CN)_6$, exhibits the highest known relative positive and negative thermal crystal framework expansion. The structure of this material has been known since 1968; it arranges itself in a trigonal lattice (Fig. 1) and is comprised of alternating layers of Ag^+ and $[Co(CN)_6]^{3-}$ ions.[1,2] It crystallizes in the $P\bar{3}1m$ space group (No. 162) with (hexagonal setting) unit cell parameters $a = b = 7.030\,66(9)$ Å and $c = 7.117\,48(17)$ Å at 300 K.[1] Using variable temperature X-ray and neutron powder diffraction techniques, Goodwin et al. discovered that, with regards to the crystal unit cell, positive thermal expansion (PTE) occurs in the *a–b* plane parallel to the ion layers (i.e., $da/dT > 0$), and negative thermal expansion (NTE) occurs along the *c* axis, perpendicular to these layers (i.e., $dc/dT < 0$). The space group does not change over the temperature range studied by diffraction techniques (16–500 K), and the material decomposes at 500 K.[1] In addition to NTE, $Ag_3Co(CN)_6$ exhibits large negative linear compressibility,[3] in which the unit cell expands along the *c* axis with increasing hydrostatic pressure. Such compounds[4] that display both PTE and NTE properties simultaneously do not vary greatly in unit cell volume over broad temperature ranges, and powders of these solids could potentially be used to develop materials that resist compression in extreme

Fig. 1. Unit cell of $Ag_3Co(CN)_6$ (left), and a cobalt-centred view (right) highlighting the rotational axis of symmetry. The image was generated using previously reported diffraction data from Goodwin et al.[1] Thermal ellipsoids represent 50% electron density.

temperature and pressure conditions. However, ordered layers of such materials may also potentially be useful in highly sensitive pressure detectors.[1,3]

The diffraction studies of Goodwin et al.[1] and others,[3,5,6] including neutron total scattering and reverse Monte Carlo analyses,[6] indicate that bond flexing in the Co–CN–Ag–NC–Co chains occurs during thermal expansion/contraction of the material, and that the octahedral orientation around each Co^{3+} remains largely unaffected by temperature. The PTE/NTE in $Ag_3Co(CN)_6$ has been compared to the flexing of a piece of lattice fencing,[1] and the source of this colossal expansion behaviour has been attributed to argentophillic interactions.[7] The relative NTE coefficients were nearly a full order of magnitude larger than any previously reported values (although other NTE coefficients nearly as large have since been reported),[4] whereas the PTE coefficients are of the same order as the largest known.

Cobalt-59 NMR parameters are known to be very sensitive to slight changes in structure.[8] Isotropic ^{59}Co chemical shifts fall over a range greater than 17 000 ppm, and ^{59}Co nuclear quadrupolar coupling constants can be greater than 170 MHz.[8–10] Therefore, in this study we chose to examine the temperature dependence of the solid-state ^{59}Co NMR parameters of $Ag_3Co(CN)_6$ and determine if any correlation can be made between this PTE/NTE behaviour and the magnetic shielding and electric field gradient (EFG) tensors at the ^{59}Co site. We also studied the ^{13}C and ^{15}N NMR properties of this material to further investigate the claim that the cyanide groups are entirely C-bound to the cobalt[1] and to investigate possible dynamics of the cyanide ligand.

Background and theory

For the sake of simplicity, rather than discussing magnetic shielding, we shall focus on chemical shift (CS), which is related to magnetic shielding by[11]

$$[1] \qquad \delta_{ii} = \frac{\sigma_{ref} - \sigma_{ii}}{1 - \sigma_{ref}} \approx \sigma_{ref} - \sigma_{ii}$$

$$[2] \qquad \delta_{ii} = \frac{\nu_{ii} - \nu_{ref}}{\nu_{ref}}$$

Here, σ_{ii} denotes absolute magnetic shielding tensor principal component values relative to a bare nucleus, δ_{ii} denotes chemical shift tensor principal components (typically expressed in ppm) referenced to a chosen standard, ν_{ii} is the resonant frequency of each principal component, and ν_{ref} is the isotropic resonant frequency of the reference compound. The CS interaction is typically described by a second-rank tensor in its principal axis system (PAS) and takes the form

$$[3] \qquad \begin{bmatrix} \delta_{11} & 0 & 0 \\ 0 & \delta_{22} & 0 \\ 0 & 0 & \delta_{33} \end{bmatrix}$$

where δ_{11}, δ_{22}, and δ_{33} are the principal components of the CS tensor defined such that $\delta_{11} \geq \delta_{22} \geq \delta_{33}$.[11] These principal components are, for spin $I = 1/2$ nuclei, observed at the points of discontinuity in the solid-state NMR "powder pattern" spectrum of a simple, one-site stationary powder sample in the absence of any effects other than CS anisotropy (CSA). If the crystal structure of the material is such that a threefold (or greater) axis of rotational symmetry passes through the nucleus of interest, two of the CS tensor principal components will be equivalent and oriented perpendicular to the symmetry axis, while the third component will be oriented parallel to the axis. We designate these components $\delta_\perp$ and $\delta_\parallel$, respectively. In such cases the isotropic chemical shift (δ_{iso}) is defined as $\delta_{iso} = (2\delta_\perp + \delta_\parallel)/3$ and the span is defined as $\Omega = |\delta_\perp - \delta_\parallel|$.

For nuclei with spin $I > 1/2$, the nuclear quadrupolar interaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

also affects the NMR powder pattern. The nuclear quadrupolar interaction is dependent on the EFG tensor at the quadrupolar nucleus, in this case ^{59}Co (I = 7/2). The EFG about a specific nucleus is characterized by a symmetric, traceless tensor, whose three principal components in the PAS (eq_{ii}) follow[12,13]

$$[4] \qquad |eq_{zz}| \geq |eq_{yy}| \geq |eq_{xx}|$$

Since the sum of the three principal components is zero, only two parameters are required to describe them. Typically, we consider the nuclear quadrupolar coupling constant (C_Q) and quadrupolar asymmetry parameter (η_Q), which are related to the EFG by[12,13]

$$[5] \qquad C_Q = \frac{e^2 Q q_{zz}}{h}$$

$$[6] \qquad \eta_Q = \frac{q_{xx} - q_{yy}}{q_{zz}}$$

Here, e is the elementary charge, Q is the nuclear quadrupole moment of the nucleus, and h is Planck's constant.

The full frequency width (W) of the solid-state NMR spectrum of a noninteger spin quadrupolar nucleus (I = 3/2, 5/2, 7/2, or 9/2) is related to the quadrupolar frequency ν_Q and to C_Q by[12]

$$[7] \qquad \nu_Q = \frac{3C_Q}{2I(2I-1)}$$

$$[8] \qquad W = (2I-1)\nu_Q$$

including all transitions (i.e., for I = 7/2, $m_I = +7/2 \leftrightarrow +5/2$, $m_I = +5/2 \leftrightarrow +3/2$, …, $m_I = -5/2 \leftrightarrow -7/2$, and W simplifies to $W = 6\nu_Q = (3/7)C_Q$). Generally, the span expressed in frequency units (Hz) is less than C_Q, and as such W is independent of the CSA interaction for nearly all cases, including the one studied here. If C_Q is large, it is typical to focus on the central $m_I = +1/2 \leftrightarrow -1/2$ transition, as the full width of the powder pattern, including all satellite transitions, may be too broad to observe on most NMR spectrometers.[12,14] However, if C_Q is small enough that the entire spectrum can be observed (W typically on the order of 2 MHz or less), C_Q is often obtained by measuring the full frequency width of the spectrum.

As with the CS tensor, when a threefold or greater axis of symmetry passes through the site under investigation, certain restrictions are placed on the orientation of the EFG tensor.[15–19] The largest component of the tensor (eq_{zz}) lies along the axis of symmetry, whereas the other components are equivalent and oriented perpendicular to the axis, which makes $\eta_Q = 0$. Note that if a nucleus is located in a site of perfect three-dimensional long-range tetrahedral or octahedral (or higher) symmetry, then $C_Q = 0$. Also, EFGs tend to be more sensitive to the long-range environment (within a simple point charge model, the EFG at a nucleus is inversely proportional to r^3, where r is the distance from the nucleus to the point charge), whereas CS tensors tend to be mainly sensitive to the short-range environment.[13]

Results and discussion

^{13}C and ^{15}N solid-state NMR spectroscopy

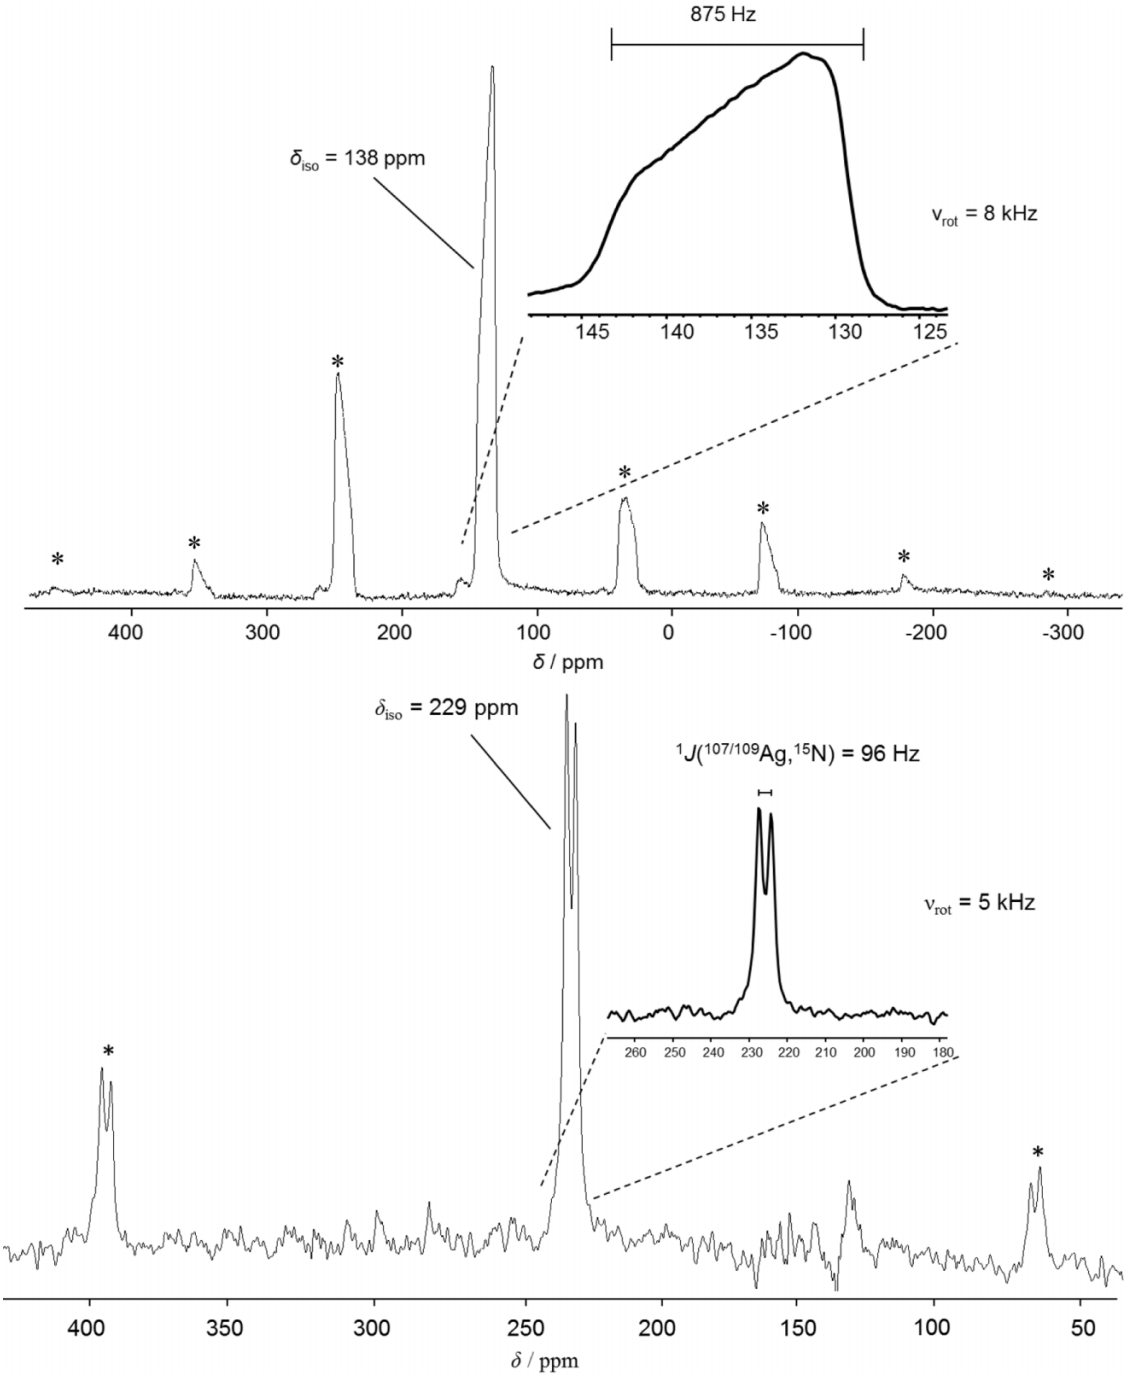

Figure 2 shows the solid-state ^{13}C and ^{15}N NMR spectra of 33% $^{13}C^{15}N$-labelled $Ag_3Co(CN)_6$ acquired with magic angle spinning (MAS) at 7.05 T. A 96 Hz splitting observed in the ^{15}N NMR spectrum is attributed to $^1J(^{107/109}Ag,^{15}N)$. ^{13}C NMR spectra demonstrate that this splitting is not due to $^1J(^{13}C,^{15}N)$ coupling (vide infra). ^{107}Ag and ^{109}Ag are both spin I = 1/2 nuclei with similar natural abundances (51.84% and 48.16%, respectively) and magnetogyric ratios (-1.089×10^7 and -1.252×10^7 rad s^{-1} T^{-1}, respectively).[20] As a result, our experimental line widths were too broad to resolve coupling to the two isotopes of silver. Thus, the observed $^1J(^{107/109}Ag,^{15}N)$ coupling is an average of the two. Nevertheless, 96 Hz is the largest value of $|^1J(^{107/109}Ag,^{15}N)|$ that has been reported to date for any material. This indicates that nitrogen is directly bonded to silver in $Ag_3Co(CN)_6$. There was no indication of splitting due to $J(^{59}Co,^{15}N)$ in the ^{15}N NMR spectrum (vide infra).

Splittings due to ^{59}Co–^{13}C spin-spin coupling were observed in the ^{13}C NMR spectra acquired with MAS, however, individual peaks were broad and poorly resolved. Nevertheless, the MAS isotropic and spinning side band line widths of ~875 Hz (see Fig. 2) and peak shapes do allow us to place an upper limit on $|^1J(^{59}Co,^{13}C)|$ of 130 Hz ($|^1J(^{59}Co,^{13}C)|$ = (875 Hz / 7) + ~10% error). This is in good agreement with the value of $^1J(^{59}Co,^{13}C)$ reported for $K_3Co(CN)_6$ dissolved in water, 126.0 Hz.[21,22] If all MAS side bands in the ^{13}C NMR spectrum are added together, the resulting line shape is symmetric (eight overlapping peaks of equal intensity). The asymmetry in each individual side band is due to the orientation dependence of the carbon-13 shielding tensor and the ^{59}Co–^{13}C spin-spin coupling tensors.[23–25] There was no indication of $J(^{107/109}Ag,^{13}C)$ coupling, which is expected to be small as it is a two-bond indirect spin-spin coupling constant. The weak-intensity peaks observed in the ^{13}C NMR spectrum (Fig. 2) are attributed to trace amounts of unreacted $K_3Co(^{13}C^{15}N)_6$. It should be noted that the spectral line widths in both the ^{15}N and ^{13}C NMR spectra were too broad to resolve $^1J(^{13}C,^{15}N)$, which is expected to be on the order of 10 Hz based on the $^1J(^{13}C,^{15}N)$ coupling within the free cyanide ion in solution as well as in several transition-metal complexes.[26,27] The observed spin-spin coupling in the spectra confirm the conclusion made by Goodwin et al.[1] based on neutron scattering data that the CN^- ions are entirely C-bound to the Co and N-bound to the Ag.[28] Furthermore, we observe no evidence of dynamic disorder of the cyanide ligand. Such disorder would result in decoupling of indirect spin-spin coupling interactions.

Room-temperature (RT) ^{59}Co NMR spectroscopy

Cobalt-59 NMR spectra were acquired at different magnetic field strengths (B_0 = 4.70, 7.05, 11.75, and 21.14 T), and as outlined as follows, the results were consistent. Stationary sample spectra were simulated using the program WSolids1.[29] Baseline corrections were applied to all MAS sample spectra. A typical ^{59}Co NMR spectrum of natural abundance $Ag_3Co(CN)_6$ obtained at 11.75 T with MAS is shown in Fig. 3. Because the cobalt nucleus is located at a site of nearly perfect octahedral symmetry, W is small

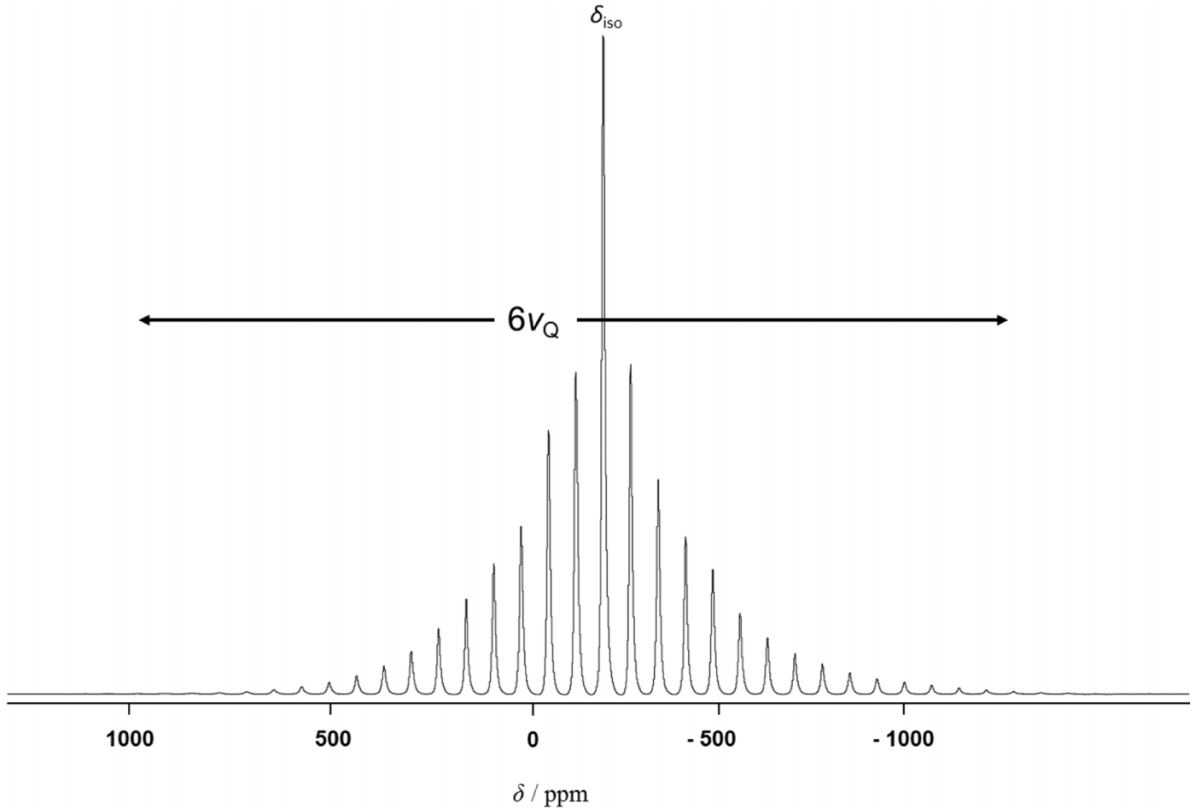
(264 kHz), a consequence of $C_Q \approx 616$ kHz. Analysis indicates that the line shapes of solid-state ^{59}Co NMR spectra are determined primarily by the magnetic shielding and first-order quadrupolar interactions. The effects of any indirect spin-spin or dipolar coupling interactions are small and not observed in the ^{59}Co NMR spectra. We also discovered that the C_Q for ^{59}Co is, in this case, small enough that we can observe the entire ^{59}Co NMR spectrum including central and satellite transitions, but large enough that W is independent of the CSA. Figure 4 highlights this conclusion. It shows the full ^{59}Co NMR spectrum for $Ag_3Co(CN)_6$ at two different magnetic field strengths with 5 kHz MAS plotted in the frequency domain. Broken lines indicate the edges of the spinning sideband manifold and that the spectral width is unaffected by field strength. By measuring the full width of the ^{59}Co NMR spectrum of $Ag_3Co(CN)_6$ at RT and 11.75 T with MAS (Fig. 3), including the satellite transitions, we are able to use eqs. [7] and [8] to obtain C_Q, which is 616 ± 37 kHz. We verified that the observed W was not an artifact of the excitation profile by stepping the transmitter offset

Fig. 3. Solid-state ^{59}Co NMR spectrum of $Ag_3Co(CN)_6$ obtained at 11.75 T (118.6 MHz) with 8 kHz MAS. Isotropic peak indicated; all others are spinning side bands. Spectrum is the result of signal averaging 54 000 transients.



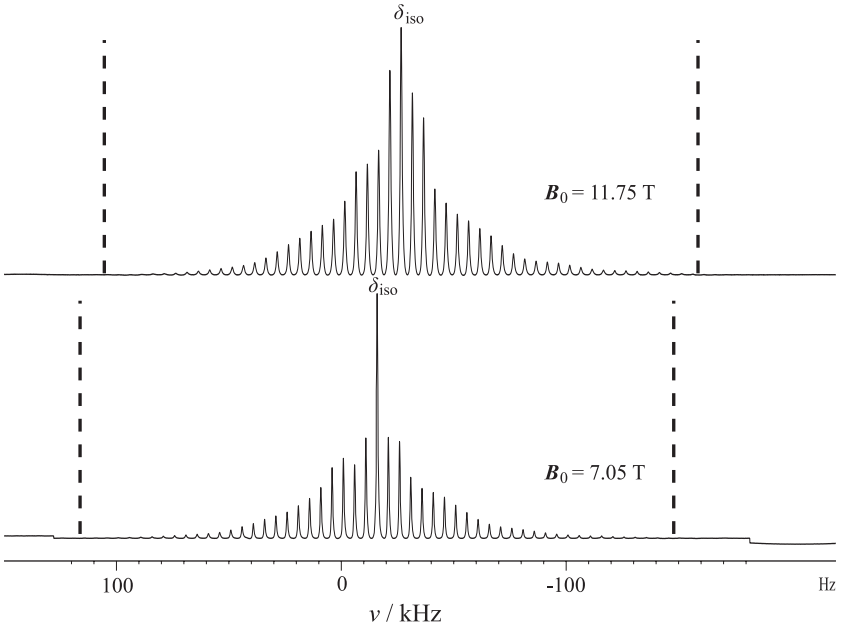


Fig. 4. Solid-state ^{59}Co NMR spectra of $Ag_3Co(CN)_6$ acquired at two different field strengths with 5 kHz MAS. Spectra are shown on the same frequency shift (Hz) scale. Full-spectrum width is indicated with broken lines in both spectra.

(vide infra). The error in C_Q was estimated on the basis of observing the entire spectrum ± one spinning sideband on each edge of the spectrum.

The measured ^{59}Co isotropic chemical shift of $Ag_3Co(CN)_6$ is –224 ± 1 ppm when spun at 8 kHz MAS (measured at 11.75 T). Note that sample heating caused by friction due to spinning causes a small increase in this value when compared with stationary spectra. See the variable-temperature (VT) NMR results for more details.

To first order, the central NMR transition ($m_I = +1/2 \leftrightarrow -1/2$) of noninteger spin quadrupolar nuclei is not perturbed by the quadrupolar interaction, and thus its line shape depends

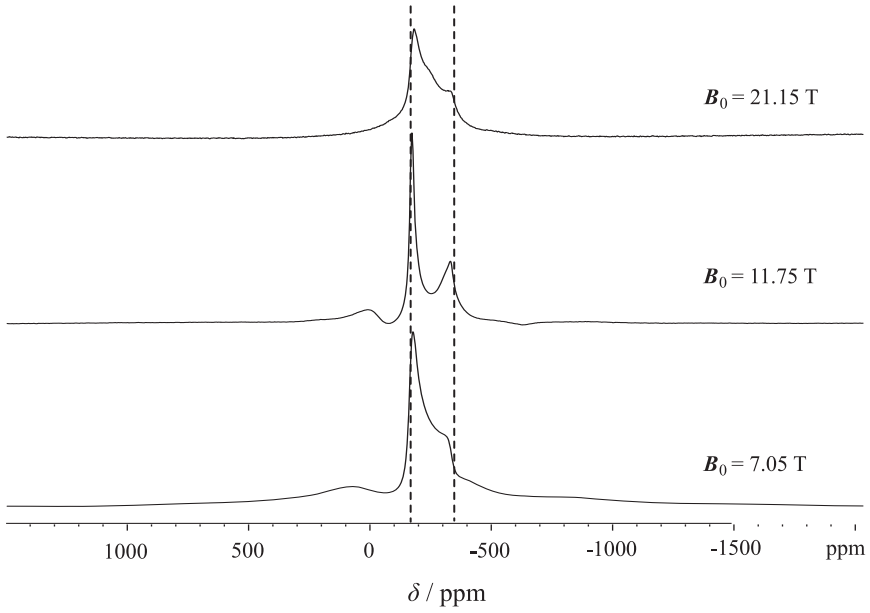
Fig. 5. Solid-state ^{59}Co NMR spectra of stationary room-temperature $Ag_3Co(CN)_6$ acquired at three different field strengths. Spectra are shown on the same chemical shift (ppm) scale. The CS tensor principal components, $\delta_\perp$ (left) and $\delta_\parallel$ (right), have been indicated with broken lines.



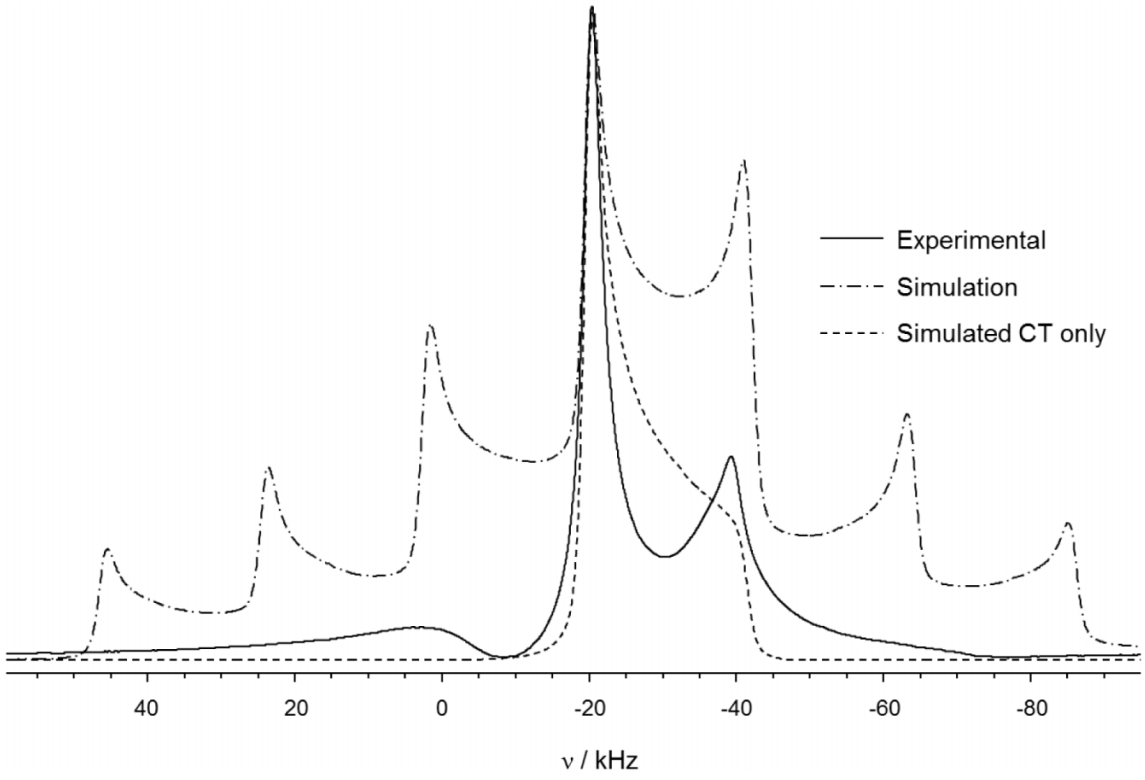


Fig. 6. Solid-state ^{59}Co NMR spectrum of stationary $Ag_3Co(CN)_6$ obtained at 11.75 T (118.6 MHz). A simulated spectrum was calculated using WSolids1 with C_Q = 616 kHz, $\delta_\perp$ = –167 ppm, and $\delta_\parallel$ = –350 ppm. The simulated central transition (CT) and full simulated spectrum have been shown separately to highlight the overlap between central and satellite transitions.

solely (in the absence of spin-spin coupling) on the magnetic shielding interaction.[12] Since C_Q is small in our case, one can ignore the second-order quadrupolar interaction when analyzing the central ^{59}Co NMR transition. Figure 5 highlights this observation and validates this assumption by showing the solid-state ^{59}Co NMR spectra of stationary $Ag_3Co(CN)_6$ at three different field strengths. The broken lines in this figure indicate the location of the two unique

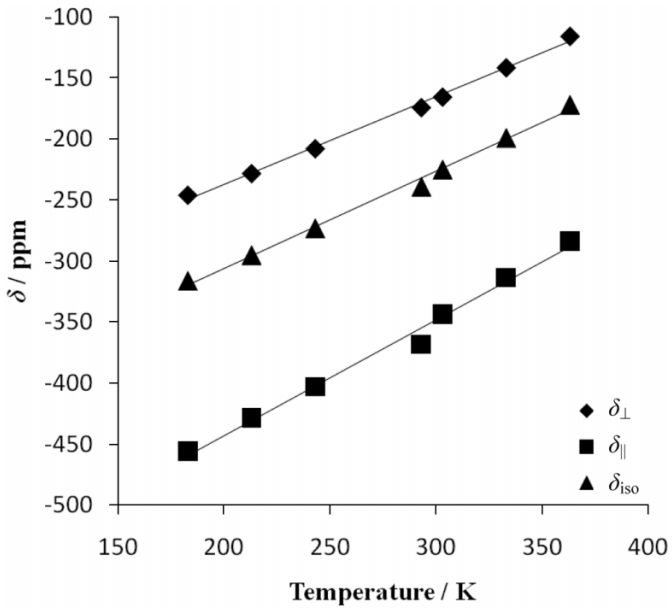
components to the CS tensor, $\delta_\perp$ and $\delta_\parallel$. One can see that the width of the central transition (in ppm) is independent of the magnetic field strength, thus proving that this transition is unaffected by the EFG interaction. From an analysis of the central transition of the ^{59}Co NMR spectrum of $Ag_3Co(CN)_6$ at 11.75 T and RT (shown in Fig. 6), it was determined that $\delta_\perp = -167 \pm 8$ ppm and $\delta_\parallel = -350 \pm 20$ ppm. Simulated spectra were calculated using the previously obtained value for C_Q of 616 kHz. Errors in CSA parameters were estimated based on this and other analyses of spectra at different field strengths. In Fig. 6, the central-transition-only simulation is shown to highlight the analysis of the cobalt CSA parameters. The full simulated spectrum is also shown; however, the experimental satellite transitions (ST) are much broader than the central transition (CT), and as such the calculated STs are not reflected in the experimental spectrum. Notice that the error in $\delta_\parallel$ is much greater than that of $\delta_\perp$. Inspection of this and other spectra at different field strengths (Figs. 5 and 6) reveals that the STs often overlap with the CT in such a way that the CT and first-order satellite transitions (ST1, $m_I = +3/2 \leftrightarrow +1/2$ and $m_I = -3/2 \leftrightarrow -1/2$) are of the same order of magnitude. This makes it particularly difficult to determine the CSA parameters accurately, as one of the ST1 transitions and the CT $\delta_\parallel$ feature are essentially coincident. The spectral line shape and broad satellite transitions will be discussed further later in this paper.

It should be noted that the pulse width and transmitter frequency used in the ^{59}Co NMR experiments had no significant effect on the observed spectra. For example, we attempted to move the transmitter to the high- and low-frequency edges of the MAS spectrum to ensure that excitation profile limitations were not causing spectral distortions. In addition, we tried shortening the pulse width (pulse power optimized for a 4 μs 90° pulse on a solution setup sample) to widen the excitation profile. Neither of these changes affected our observed spectra. Also, to ensure that we observed the entire spectrum and did not fail to observe any of the outermost side bands due to noise, 54 000 transients were signal-averaged to generate the spectrum at 11.75 T shown in Fig. 3. So, we can be confident that we have observed the entirety of the ^{59}Co NMR spectrum in all of our experiments.



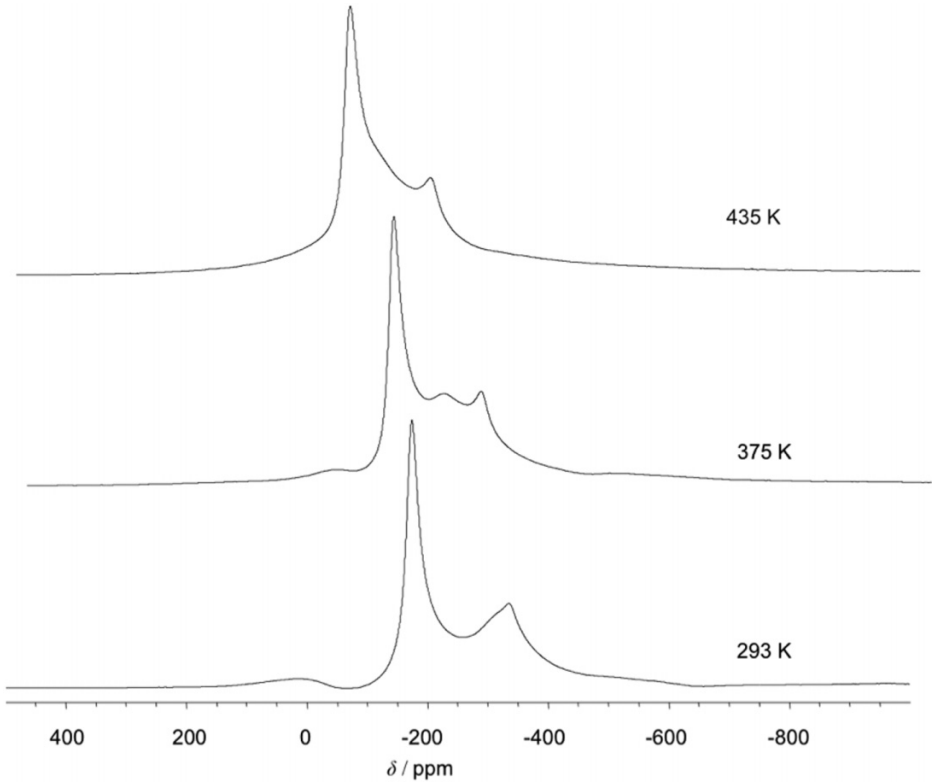
^{109}Ag NMR spectroscopy

Silver-109 NMR experiments were attempted for solid $Ag_3Co(CN)_6$ using a 7 mm rotor at 11.75 T with 5 kHz MAS. However, despite several attempts of 8–10 h each (see the Experimental section), no resonances (peaks) were observed. This is probably because the ^{109}Ag nuclei have extremely long spin-lattice relaxation times.

Variable-temperature (VT) ^{59}Co NMR spectroscopy

VT data were acquired for MAS and stationary samples at 4.70 T at temperatures ranging from 183–363 K; the results are summarized in Fig. 7. Data were also acquired at 11.75 T for stationary samples from 293–435 K. VT stationary sample spectra are presented in Fig. 8. Examination of these spectra, as well as the stationary sample spectrum shown in Fig. 6, highlights the key challenge of these ^{59}Co NMR experiments. We observe significant overlap between the CT powder pattern (which arises due to CSA) and the STs,

Fig. 7. Summary of solid-state variable-temperature (VT) ^{59}Co NMR data obtained for $Ag_3Co(CN)_6$ at 4.70 T (47.5 MHz).



which accounts for the odd shape of the CSA powder pattern. However, features in the powder patterns for the satellite transitions are very poorly defined, and we are unable to completely resolve individual sets of transitions (ST1 $m_I = +3/2 \leftrightarrow +1/2$ and $m_I = -3/2 \leftrightarrow -1/2$, ST2 $m_I = +5/2 \leftrightarrow +3/2$ and $m_I = -5/2 \leftrightarrow -3/2$, etc.). Nonetheless, the satellite transition "horns" appear to narrow for the higher-temperature spectra in Fig. 8. This is evident when one observes that the shoulder in the middle of the CT, which is in fact an ST1 horn, shifts closer to the isotropic shift at higher temperatures, as do the features at the higher-frequency end of the spectrum, which eventually are lost within the CT. This suggests that C_Q decreases slightly at higher temperatures, although the broad features prevent quantification of this decrease.

The ill-defined nature of the features in the powder pattern suggests that there is a distribution of EFG and shielding tensor parameters about the cobalt nucleus.[30] In addition, the line widths of the spectra observed for samples undergoing MAS increased with increasing magnetic field strength, with values of approximately 0.9, 1.1, and 3.0 kHz for spectra obtained at 4.70, 11.75, and 21.14 T, respectively. This suggests a distribution of ^{59}Co NMR chemical shifts as well. Both of these observations are likely a result of the material adopting a range of unit cell *a* and *c* parameters at any given temperature. This distribution in lattice parameters has been previously suggested by Goodwin et al.[1] on the basis of neutron powder diffraction results and DFT calculations, and the lattice for this material has been described as "atypically soft".[1] That is to say, there is very little difference in lattice enthalpy between unit cells of different conformations for certain *a*:*c* ratios that lie along the so-called "low enthalpy valley".[1] It is interesting to note that while this lattice parameter distribution severely broadens the solid-state ^{59}Co NMR satellite transitions, which depend on the EFG and the CS tensors, the CS tensor principal components can still be resolved from the CT line shape. Though the CT features are by no

Fig. 8. Selected solid-state variable-temperature (VT) ^{59}Co NMR spectra obtained for $Ag_3Co(CN)_6$ at 11.75 T (118.6 MHz).

means sharp, the CS tensor is still less affected by this distribution than the EFG tensor. This is reasonable given that the satellite transitions fall over a much wider frequency range than the central transition and thus any distribution that might broaden the CT will broaden the STs even more so. In other words, the satellite transitions are more sensitive to slight changes in structure than the central transition.

Although we are only able to qualitatively describe the decrease in C_Q for ^{59}Co with increasing temperature, we can quantify the temperature dependence of the chemical shift tensor components. Figure 7 reveals that these increase (i.e., shielding decreases) linearly with temperature. From a linear regression analysis of the data, the isotropic shift increases by +0.79 ± 0.03 ppm/K, whereas $\delta_\perp$ varies by +0.72 ± 0.02 ppm/K and $\delta_\parallel$ varies by +0.95 ± 0.04 ppm/K. These results seem typical for cobalt nuclei. For example, the isotropic ^{59}Co NMR shift of solid $K_3Co(CN)_6$ increases by 0.97 ppm/K,[31] and dC_Q/dT = –0.15810 kHz/K.[31–33] If the temperature dependence of the ^{59}Co quadrupolar coupling constant for $Ag_3Co(CN)_6$ is of a similar order of magnitude as the potassium salt of this anion, we are unlikely to be able to quantify it given the large error in our measurements of C_Q, caused by the poorly defined STs. Table 1 shows, for comparison, the ^{59}Co nuclear quadrupolar coupling constants for various octahedral solid materials.[31,34–36]

Some CASTEP[37–39] calculations of the ^{59}Co NMR parameters of $Ag_3Co(CN)_6$ were performed using the unit cell parameters reported in the supplementary information section of the Goodwin et al. paper.[1] Over the temperature range 183 to 363 K, calculations suggest that the isotropic ^{59}Co NMR chemical shift increases linearly with temperature by ~1.0 ppm/K while the span decreases linearly by ~1.0 ppm/K and ranges from about 320 to 150 ppm. Experimentally $d\delta_{iso}/dT$ = +0.79 ± 0.03 ppm/K and $d\Omega/dT$ = –0.23 ppm/K, with Ω ranging from 210 to 168 ppm. Qualitatively, the experimental results are reproduced by the CASTEP calculations; however, the decrease in the span with increasing temperature is overestimated. The calculated C_Q values range from ~+6 to –6 MHz from 183 to 363 K and decrease linearly with an increase in temperature, with a value of approximately –2 MHz at room temperature. While the calculated values of C_Q do not agree with experimental values, the calculations correctly indicate that the EFG at the cobalt site is decreasing with increasing temperature. The discrepancy between calculated and experimental results may at least in part be due to the neglect of thermal vibrations. Also, the calculations of C_Q may be falling short because we are dealing with a very small EFG; in this case, C_Q is less than 1 MHz, whereas values in excess of 170 MHz are known.[8–10]

Table 1. Cobalt-59 nuclear quadrupolar coupling constants for various octahedral Co compounds with errors (where reported).

Compound	C_Q (MHz)	Reference
$Ag_3Co(CN)_6$	0.616±0.037	This work

Conclusion

The observed $Ag_3Co(CN)_6$ ^{13}C and ^{15}N NMR spectra and *J*-coupling features confirm the Co–CN–Ag–NC–Co structure previously reported.[1,2] The $^1J(^{107/109}Ag,^{15}N)$ coupling of 96 Hz is the largest $^{107/109}Ag–^{15}N$ spin-spin coupling constant reported to date. The relatively small C_Q of 616 ± 37 kHz observed from the ^{59}Co NMR spectra of $Ag_3Co(CN)_6$ suggests a near-perfect octahedral environment about ^{59}Co, which also agrees with the reported structure.[1–3,7]

The ^{59}Co NMR spectra (or more specifically, the broad poorly resolved nature of the observed satellite transitions) clearly indicate the EFG at the Co nucleus is more sensitive to variations or distributions in lattice parameters than the CS parameters (expressed in Hz). This is easily justifiable given that ^{59}Co has a large nuclear quadrupole moment (Q), and any variations in eq_{zz} caused by variations in structure are magnified and reflected in C_Q.[8] Also, EFGs depend on long-range order, and CS interactions depend mainly on local environment,[13] so this suggests, as expected, that crystal structure variations that occur during colossal positive/negative expansion are not the result of severe distortions of the local $[Co(CN)_6]^{3-}$ octahedra.[1,3,5–7] The broad distribution of lattice parameters precludes an accurate characterization of C_Q as a function of temperature. Most likely, $^{107/109}Ag$ NMR parameters would be more sensitive to the colossal expansion; however, because of the low receptivity and expected long T_1 relaxation times of the silver nuclei, such experiments are not feasible.

Lastly, we conclude that while the ^{59}Co NMR parameters of $Ag_3Co(CN)_6$ vary with temperature, these variations, $d\delta_{iso}/dT = +0.79 \pm 0.03$ ppm/K, $d\delta_{\perp}/dT = +0.72 \pm 0.02$ ppm/K, $d\delta_{\parallel}/dT = +0.95 \pm 0.04$ ppm/K, and the fact that C_Q appears to decrease slightly with increasing temperature, do not seem anomalous or significantly different from the temperature dependence of the ^{59}Co NMR parameters of $K_3Co(CN)_6$.[31] Thus, we do not observe a strong correlation between the temperature dependence of these solid-state NMR parameters and the colossal expansion nature of this material. Perhaps it is the distribution of lattice parameters and resulting broad, almost featureless ^{59}Co NMR powder patterns that distinguish $Ag_3Co(CN)_6$ from other octahedral Co(III) salts and reflect its colossal expansion behaviour.

Experimental

Synthesis

All natural abundance reagents were purchased from the Sigma-Aldrich Co. Isotopically labelled $K^{13}C^{15}N$ (98%) was obtained from Cambridge Isotope Laboratories, Inc. $Ag_3Co(CN)_6$ was synthesized according to the method outlined in the literature[1,2,40] by dissolving equimolar amounts of silver nitrate and potassium hexacyanocobaltate(III) in water, boiling and mixing the resulting solutions, and filtering the resulting precipitate. This material was prepared several times. In a typical synthesis, 1.033 g of $K_3Co(CN)_6$ and 1.567 g of $AgNO_3$ were each dissolved in 15 mL of distilled water. The two solutions were mixed, and the resulting mixture was boiled and stirred for ~1 h. $Ag_3Co(CN)_6$ was obtained as a white precipitate, rinsed with cold water, and dried at about 60 °C for 17 h (yield = 1.415 g, 85%). The product was identified using X-ray powder diffraction[1] and IR spectroscopy in addition to solid-state NMR measurements.[41–43] A sample of $Ag_3Co(CN)_6$ kindly provided by Professor J. Evans[1,6,7] was also studied, and yielded identical results.

Labelled $Ag_3Co(CN)_6$ (33% $^{13}C^{15}N$) was prepared by first synthesizing $K_3Co(CN)_6$ using the methods described by Poskozim[44] and then reacting it with $AgNO_3$ as described previously. To generate the labelled compound, 33% $^{13}C^{15}N$-labelled KCN was reacted with $CoCl_2$. $K^{13}C^{15}N$ (0.284 g) and 0.561 g of natural abundance KCN were dissolved in 20 mL of distilled water and added dropwise to a 20 mL solution of 0.485 g $CoCl_2$ in distilled water. The resulting mixture was stirred while boiling for 1.5 h. Yellow $K_3Co(CN)_6$ crystals (yield = 0.661 g, 99%) were obtained and washed with 10 mL of cold ethanol. Then, 0.526 g of the labelled product and 0.788 g of silver nitrate were each dissolved in 15 mL of water. The two solutions were mixed and boiled with stirring for 1 h. A light grey precipitate was obtained and dried in an oven at about 100 °C for about 3 days (yield = 0.713 g, 86%). The products were both identified using X-ray powder diffraction[1] and IR spectroscopy in addition to solid-state NMR measurements.[41–43]

Solid-state NMR spectroscopy

Room-temperature NMR spectra were obtained at the University of Alberta, Edmonton, Alberta, at 4.70 T on a CMX Infinity 200 spectrometer, at 7.05 T on a Bruker Avance 300 spectrometer, and at 11.75 T on a Bruker Avance 500 spectrometer. Variable-temperature experiments were performed on the CMX 200 and Bruker Avance 500 systems. Experiments at 21.14 T were carried out on a Bruker Avance II 900 spectrometer at the National Ultrahigh-Field NMR Facility for Solids in Ottawa, Ontario. For nearly all ^{59}Co NMR spectra, simple one-pulse experiments were performed with pulse widths typically ranging from 2–4 μs (pulse power optimized for a 4 μs 90° pulse on a 1.0 mol/L aqueous solution of $K_3Co(CN)_6$). No differences in spectral line shapes were observed for experiments performed with different pulse widths (i.e., selective versus nonselective pulses). The T_1 relaxation time of ^{59}Co was qualitatively determined to be on the order of 100 ms, and as such recycle delays of about 0.5 s were typically used.

Room-temperature experiments including ^{13}C, ^{15}N, and ^{59}Co NMR, and VT ^{59}Co NMR studies were performed. ^{109}Ag NMR experiments were attempted for $Ag_3Co(CN)_6$ using a 7 mm rotor at 11.75 T with 5 kHz MAS. Pulse delays ranged from 1 min to 2 h; however, no ^{109}Ag NMR signal was observed. This is probably due to very long T_1 relaxation times for the silver nuclei. T_1 times for ^{13}C and ^{15}N were not determined; however, recycle delays of 10 min were necessary to observe any signal. Powder samples were subjected to both stationary and MAS conditions at rotor frequencies ranging from 4 to 15 kHz. Various rotor frequencies were used to determine the isotropic peak of each ^{13}C and ^{15}N spectrum.

^{59}Co NMR spectra were externally referenced to a 1.0 mol/L aqueous solution of $K_3Co(CN)_6$ ($\delta = 0.00$ ppm) at RT.[31] The same solution was used as a setup sample to find appropriate power levels for 90° pulses. ^{13}C NMR spectra were externally referenced to TMS by using powdered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

adamantane as a secondary reference. The $^{13}CH_2$ group isotropic peak was set to 38.56 ppm,[45] and the adamantane sample was used for the experimental setup. ^{15}N NMR spectra were referenced to the isotropic shift of neat liquid ammonia using powdered ammonium nitrate (99% ^{15}N enriched) as a secondary reference and setup sample. The $^{15}NH_4^+$ isotropic peak was set to 23.8 ppm.[46]

Errors in chemical shift measurements in spectra with MAS were estimated based on experimental line widths. Errors in CS tensor components were estimated based on the range of parameters used to calculate simulated spectra that still provided a visually acceptable fit of the experimental data. Errors in C_Q for ^{59}Co NMR spectra with MAS were estimated based on the assumption that the total width of the spectrum was observed within ± 1 spinning side bands on either edge of the spectrum.

Probe temperature calibration was attempted for the 4.70 T VT experiments using lead(II) nitrate as a standard;[47,48] however, we were unable to complete the calibration procedure. Nonetheless, a linear relationship between the ^{59}Co chemical shift parameters of $Ag_3Co(CN)_6$ was observed, and it is highly unlikely that a lack of calibration would significantly affect the slope of this curve. Rather, it is the intercept that would probably be most significantly affected, which we have not reported. Solid-state NMR spectra were simulated using WSolids1[29] version 1.20.15, a program developed by K. Eichele at the Universität Tübingen and originally created in the Wasylishen research group, that calculates spectral line shapes based on NMR parameters.

Acknowledgements

The authors wish to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Alberta for funding. Access to the 900 MHz NMR spectrometer was provided by the National Ultrahigh-Field NMR Facility for Solids in Ottawa, Ontario, a national research facility funded by the Canada Foundation for Innovation, the Ontario Innovation Trust, Recherche Québec, the National Research Council of Canada, and Bruker BioSpin and managed by the University of Ottawa (www.nmr900.ca). NSERC is acknowledged for a Major Resources Support grant. In particular, the authors wish to thank V. Terskikh at the National Ultrahigh-field NMR Facility for Solids for the acquisition of ^{59}Co NMR spectra at 21.14 T, helpful discussions, and CASTEP calculations. The authors are very grateful to Professor J. Evans[1,6,7] of the University of Durham for supplying a sample of $Ag_3Co(CN)_6$ and for helpful discussions about the lattice parameter distribution in the material. In addition, the authors thank the spectral services department at the University of Alberta, as well as T. Nakashima and the rest of R.E.W.'s Solid-State NMR research group. R.E.W. holds a Canada Research Chair in physical chemistry at the University of Alberta.

Abstract: Electrical and structural properties of mono-, di-, tri-, tetra-, and penta-fluoroanilines as candidate monomers for new conducting polymers have been investigated using hybrid density functional theory (B3LYP/6–311+G**) based methods. The effects of the number and position of the fluorine atoms on the electrical and structural properties of fluoroanilines and their radical cations have also been investigated. The values of the vibrational frequencies, charge and spin-density distributions, ionization potentials, dipole moments, electric polarizabilities, HOMO-LUMO gaps, and the NICS values of these compounds have been calculated and analyzed as well. The results showed that the double bonds in 2-fluoroaniline and 2,5-difluoroaniline are more delocalized compared with other fluoroanilines; therefore, these molecules have the most aptitude for the electropolymerization reactions. The frequency analysis showed that the electrochemical stability of 2-fluoroaniline is greater than the other fluoroanilines. Also, this molecule possesses the largest NICS value compared to the other fluoroanilines. Consequently, 2-fluoroaniline has the largest ring current and the highest conductivity among all other monomers. Based on the results obtained, 2-fluoroaniline and 2,5-difluoroaniline are the best candidate monomers among all fluoroanilines for the synthesis of corresponding conducting polymers.

Key words: fluoroanilines, conducting polymers, PANI, DFT-B3LYP.

Résumé : Faisant appel à une méthode basée sur une théorie hybride de la fonctionnelle de la densité (B3LYP/6–311+G**), on a étudié les propriétés électriques et structurales de mono-, di-, tri-, tétra- et pentafluoroanilines (PANI) comme monomères candidats pour la préparation de nouveaux polymères conducteurs. On a aussi examiné les effets du nombre et de la position des atomes de fluor sur les propriétés électriques et structurales des fluoroanilines et de leurs cations radicaux. On a calculé les valeurs des fréquences de vibration, des distributions de charge et de densité de spin, des potentiels d'ionisation, des moments dipolaires, des polarisabilités électriques et des écarts des orbitales moléculaires (OM) hautes occupes (HO) et basses vacantes (BV) et on a aussi calculé et analysé les valeurs des déplacements chimiques indépendants du noyau (DCIN) de ces composés. Les résultats montrent que les doubles liaisons de la 2-fluoroaniline et de la 2,5-difluoroaniline sont plus délocalisées que celles des autres fluoroanilines; ces molécules sont donc plus susceptibles de donner des réactions d'électropolarisation. L'analyse des fréquences a montré que la stabilité électrochimique de la
2-fluoroaniline est plus grande que celles des autres fluoroanilines. Cette molécule, par comparaison avec les autres fluoroaniline, possède aussi la valeur la plus élevée pour le déplacement chimique indépendant du noyau. En conséquence, par rapport à tous les autres monomères, la 2-fluoroaniline possède le courant de cycle le plus grand et la conductivité la plus élevée. Sur la base des résultats obtenus, parmi toutes les fluoroanilines, la 2-fluoroaniline et la 2,5-difluoroanile sont les meilleurs candidats comme monomères pour la synthèse des polymères conducteurs correspondants.

Mots-clés : fluoroanilines, polymères conducteurs (PANI), théorie de la fonctionnelle de la densité B3LYP.

[Traduit par la Rédaction]

Introduction

Electrochemical synthesis of electrically conducting organic polymers, first described in detail for polyaniline (PANI), has proven to have an important role in developing new polymeric materials with electrical properties similar to metals.[1] Electrically conducting polymers as advanced materials and the new class of "synthetic metals" have drawn great attention in the last years.[2] The reversibility of charging–discharging processes and high specific capacitance of the polymers in their oxidized states have stimulated suggestions for a variety of applications, such as rechargeable batteries, super-capacitors, electro-chromic devices, etc.[3] Also, the 2000 Nobel Prize in Chemistry recognized the discovery of conducting poly-

mers.[4,5] Conducting polymers are the most probable systems for nano-electronic applications because of the change in their optical and electrical properties in nanometric dimensions.[6–8] Polyanilines (PANIs) can produce one-dimensional morphologies, such as nano-structure polymers (nano-tube, -wire, -fiber, -filament, -rod, -composite, and -particle), and much research has been conducted on them.[9–11] Conductive polymers are materials that play important roles in nano-materials.[12] Most scientists have been interested in nano-materials because of the many applications of nano-technology in different sciences such as medicine, petrochemicals, materials, electronics, quantum computers, etc.[13–17] Nano-fibers with diameters of tens of nanometers appear to be intrinsic morphological units that were found, "naturally" formed, in the early stage of the chemical oxidative polymerization of aniline.[18] It has been known from the early years of polymer research that PANI fibrils of ~100 nm diameter can form "naturally" during electrochemical polymerization on the surface of electrodes.[19,20] Some recent research indicates that uniform PANI nano-fibers can be obtained without the need of a template, simply by controlling the electrochemical polymerization kinetics.[21–23] Conducting filaments of PANI have been prepared in the 3 nm wide hexagonal channel systems of the aluminosilicate.[24] PANIs have spectacular optical and chromic properties, which can be distinguished from other conducting electro-active polymers.[25]

Among intrinsic conducting polymers with conjugated double bonds, PANIs and their related derivatives are especially promising for commercial applications because of their easy synthesis, higher conductivity, and good environmental stability.[26,27] PANIs have been used as biosensors, gas sensors, micro actuators, data storages, polymer batteries, electronic devices, and functional membranes.[28–31] In PANIs, the mechanism of polymerization involves the formation of radical cations that react with another monomer to develop a polymeric structure (Fig. 1).[32]

PANIs have an electronic conducting mechanism that seems to be unique among other conducting polymers when doped by protonation as well as undergoing p-type doping.[33–41] PANIs may exist in a range of oxidation states; the one that can be doped to a high conducting state is called emeraldine.[42] An emeraldine salt has amine (-NH-) and imine (=N-) sites in equal proportions. The imine sites can be protonated to the bipolaron (dication) emeraldine salt form.[42] However, this form undergoes further rearrangement to form the delocalized polaron lattice, which is considered a polysemiquinone radical cation salt.[43] The structures of each stage of this process are shown in Fig. 2.[43] The conductivity of PANIs in emeraldine salt form depends on temperature as well as humidity.[44,45] In addition, the conductivity and preparation conditions[46,47] of PANIs relate to the formation of structural defects and the polymer morphology.[48] It has been reported that the conductivity of PANIs is dependent on solvent.[49] The solvent causes a change in the polymer conformation, which results in increased conductivity.[50] A recent study reports PANI salts possessing unprecedentedly high electrical conductivities of up to 1300 S/cm.[51] Although theoretical calculations have predicted that the bipolaron state is energetically more favored than that of polaron, it is widely accepted that polarons are the charge carriers that are responsible for high conductivity.[52] It has been proposed that the presence of coulombic interactions, dielectric screening, and local disorder in the PANI lattice act to stabilize the delocalized polaron state.[53,54] The proposed orthorhombic structure is shown in Fig. 3.[55–70]

Fig. 1. Mechanism of electrochemical polymerization.[42]

Computational procedures

The structures of mono-, di-, tri, and tetra-fluoroanilines and their radical cations were optimized using B3LYP/6–311+G**and UB3LYP/6–311+G** levels of theory[71,72] with the GAUSSIAN 98 package of programs.[73–75] Atomic charges were calculated using the NBO method.[76,77] The nuclear independent chemical shift (NICS)[78] and magnetic susceptibility values were calculated using GIAO/B3LYP/6–311+G** and CSGT/B3LYP/6–311+G** methods, respectively.

Results and discussion

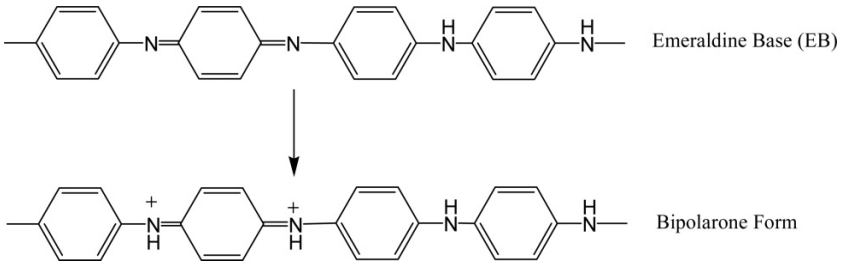
Structural analysis of fluoroanilines

The optimized structural parameters obtained at the B3LYP/6–311+G** level of theory for all fluoroanilines (as shown in Fig. 4) and UB3LYP/6–311+G** level of theory for all radical cations have been calculated and listed in Tables 1 and 2. To predict the extent of the π-conjugation character of these monomers, the *f* coefficient has been used, which is defined in eq. [1] for each aniline ring,

$$[1] \qquad f = 2R23/(R12 + R34)$$

where R23 is the length of the C_2–C_3 bond and [(R12 + R34)/2) is the average length of the C_1–C_2 and C_3–C_4 bonds in the

Fig. 2. The doping of emeraldine base with protons to form the conducting emeraldine salt form of polyaniline (a polaron lattice).[44]



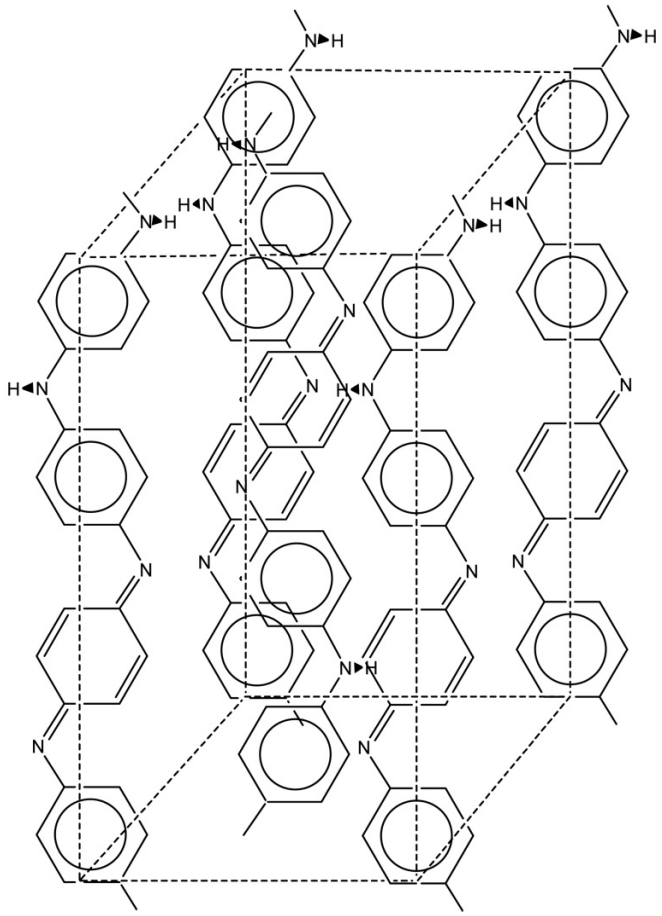


Fig. 3. Proposed EB-II orthorhombic crystal structure for the emeraldine base.

aniline ring. The value of the *f* coefficient gives a measure of the relative importance of the aromatic character (see Fig. 5, which is a polysemiquinone structure of the propagating radical cation polymer chain).

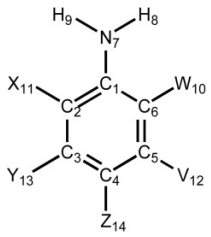
f coefficients for all fluoroanilines and their radical cations are presented in Table 1. As shown in the table, the *f* coefficient has the following trend for all neutral molecules,

$$G < B < H < P = O = J < L < I < F < C < Q < S = N = K = E < T = \text{Aniline} < R < D < M$$

As shown in the table, 2,5-difluoroaniline (G) and 2-fluoroaniline (B) have the smallest values for the *f* coefficient. Therefore, it can be suggested that the double bonds in 2,5-difluoroaniline and 2-fluoroaniline are more delocalized. Also as shown in Table 1, the radical cation monomers have smaller values of the *f* coefficient compared with other neutral monomers. Therefore, it can be suggested that the double bonds in radical cation forms are more delocalized compared with other neutral species.

Charge and spin-density distribution analysis

The electropolymerization process for each molecular radical cation is obtained from (N-C_6) linkages,[42] so it can be said that in a compound, the electropolymerization rate will be higher with greater atomic positive charge in position N . It can also be said that in a compound, the electropolymerization rate will be higher with greater atomic negative charge in position C_6. The NBO atomic charge distribution over the ring atoms of fluoroanilines and their radical cations have been calculated and presented in Table 3. As shown in this table, monomer G has the maximal negative charge on positions C_6 and the minimal negative charge on position N. This means that the electropolymerization rate of 2,5-difluoroaniline (G) can be higher compared with other molecules, in fact the initiation step of the polymerization is faster for this monomer, but the length of polymer chain may be shorter because of the large substituent effects.



From an electric charge distribution point of view, there is no significant preference for the tacticity of the fluoroaniline polymer chains, as the distributed electric charges are identical for a couple and are only slightly different for other fluoroaniline radical cations. Therefore, electric charges cannot account for any possible preferences (if any) in the tacticity of the fluoroanilines polymer chains that might be observed experimentally. The atomic charge distributions in the neutral fluoroanilines show, more or less, the same behavior as found for their radical cations. Also, it can be said that in a compound, the electropolymerization rate will be higher with greater spin density in position C_6. The spin-density distribution (Fig. 6) over the ring atoms of fluoroaniline radical cations has been calculated and presented in Table 4. As shown in this table, it is obvious that monomer G has the maximal spin density on position C_6, and it has the minimal spin density on position N as well. This means that the electropolymerization rate of 2,5-difluoroaniline can be higher compared with other molecules.

Electric dipole moments

The orientations of the polymer chains in the condensed phases are the most important parameters affecting the electric charge transport properties of polymers, so that the electrical

conductivity of a polymer chain is altered when its orientation and consequently its symmetry and non-isotropic interactions are changed. These overall interactions can be well expressed in terms of interactions between local dipole moments of monomers. The local alignment of dipole moments of monomers in solution, with respect to the orientation of the polymer chain, determines the electrochemical properties of the polymer formed on electrode surface. In addition, the orientation of monomers in the double layer of the solution in an electropolymerization cell depends on both the size and direction of the dipole moment vectors of both monomers and polymer chains.

It is necessary to study the dipole moments of these fluoroanilines to be able to predict their electropolymerization properties. The size of the dipole moment vector and its components calculated for fluoroanilines in this study are presented in Table 5. Analysis of calculated dipole moments shows that the orientation of the dipole moment vector is pointed toward the nitrogen atom for all fluoroanilines. The size and direction of the dipole moment vector depends more on the position (symmetry) of the substituent than its number.

It can also be seen in Table 5 that the dipole moments for all compounds have the following trend,

$$O > I > Q > K > J > T > P > D > E > L > C > R > F > S > G > N > M > \text{Aniline} > B > H$$

The size of the dipole moment vector for monomers O and I are greater than other compounds. Therefore, compounds O and I have a high solubility in polar solvents. These characteristics increase the efficiency of electrochemical polymerization processes of these monomers.

Ionization potentials

The first step in the electropolymerization of conducting polymers is the formation of intermediate radical cations from monomers, which can be considered as an ionization reaction[37],

$$[2] \qquad M \rightarrow M^{\cdot +} + \bar{e}$$

where M and $M^{\cdot +}$ denote monomer and its radical cation, respectively. One can see that the stability of intermediate radical cations has an important role in the electropolymerization process. Therefore, it is useful to calculate the electronic energy difference between the neutral monomer (as the initial species) and positively charged monomer (as the intermediate one). This energy difference is proportional to the ionization ootential (IP) of the monomer. Calculated values of IP for fluoroanilines based on eq. [2] are presented in Table 5. The trend of electrochemical stability of these monomers is,

$$\text{Aniline} < B < D < F < C = I < H < G < P < N < E < K < O < J < M < R < Q < L < T < S$$

Since ionization potential energies are directly proportional to the electrochemical oxidation potentials of the compounds, it can be stated that the electrochemical stability of 2-fluoroaniline (B) is greater than other fluoroanilines.

Electric polarizabilities

Values of polarizabilities of compounds containing halogen are used to interpret light scattering and intensities of vibrational Raman spectra.[5] Values for exact electrical polarizabilities as well as average polarizabilities (α_{ave}) for aniline and all fluoroanilines have been calculated and listed in Table 5. Based on this table, it can be claimed that the polarization values of these monomers are dependent on positions of fluorine atoms.

Vibrational spectra

The vibrational frequencies for all fluoroanilines were calculated using optimized structures at the B3LYP/6–311+G** level of theory. Calculated IR absorption frequencies and intensities for all fluoroanilines are presented in Table 6. To facilitate the comparison, the frequencies are divided into low-frequency (<1000 cm^{-1}) and high-frequency groups (>1000 cm^{-1}). Analysis of the frequencies listed in Table 6 suggests that thermal decomposition has the following trend,

$$G > \text{Aniline} > C > J > B > M > H > E > D = K > F > I > L > N > O = T > S > R > Q > P$$

Fig. 6. The schemes of HLG and spine-density distribution of aniline, monomer B and monomer G.

2,5-Difluoroaniline has the highest low-frequency values among all of these monomers; this means that 2,5-difluoroaniline has the largest force constant for its bending modes of vibration. Higher values of low frequencies obtained for this monomer can be regarded as a higher protection from thermal decomposition for this molecule. Also, the analysis of zero-point energy (ZPE) values for aniline and fluoroanilines shows that ZPE of 2,5-difluoroaniline is greater than for other monomers; as a result, the relative thermal stability of 2,5-difluoroaniline is higher than other monomers.

Displacements of the C_4 and H_{14} atoms (see Fig. 4) with the highest intensity vibrations in the IR spectrum of fluoroanilines have been compared in Table 7. It can be seen in this table that the displacement of the C_4 atom of monomer G is greater than for other monomers. It is important to note that the displacements are given based on the respective standard Cartesian coordinates of the molecules, which may be evidently different from each other. The displacement of the H_{14} atom of monomer G is greater than for other compounds. Furthermore, the force constant of the C_4–H_{14} bond in monomer G is greater than for other monomers. On the basis of the vibrational analysis carried out in this study, it can be predicted that the electropolymerization of the fluoroanilines can be enhanced, or even controlled, by the use of appropriate IR radiation.

Electronic properties

The energy gap between the highest occupied and the lowest unoccupied molecular orbital (HOMO and LUMO, respectively), known as the HOMO–LUMO gap or simply HLG, is a critical parameter determining molecular electrical transport properties and electric admittance (being charged under ap-

Note: The values of α_{ave} have been calculated using $\alpha_{ave} = (1/3)(\alpha_{xx}+\alpha_{yy}+\alpha_{zz})$.

plied electric filed), because it is a measure of the electron density hardness. A reasonable estimate of HLG values can be obtained from both HF and DFT calculations.[23,24] The HLG values determine the voltage produced in a photovoltaic cell as well as the electromotive force (EMF) of an electrochemical cell.[22] An increase in the chain length of a conductive polymer (or the length of the π-conjugated system) decreases the HLG values of the polymer. Therefore, it seems that HLG values of a polymer cannot be determined exactly from their monomers.[5] However, the study of HLG values of monomers may

Table 6. B3LYP/6–311+G** calculated IR absorption frequencies in cm^{-1} (intensities in km/mol) for aniline and fluoroanilines.

Note: The vibrational frequencies as well as their IR intensities are calculated with scale factors $f = 1.0100$ for low-frequency vibrations (<1000 cm^{-1}) and $f = 0.9679$ for high-frequency vibrations (>1000 cm^{-1}). Some specific vibrational modes may not be active in IR for certain compounds because of the selection rules arising from symmetrical characteristics.

Table 7. Analysis of C_4–H_{14} displacement (Å) for the most intense vibrational mode of fluoroanilines in the IR spectrum.

	C_4			H_{14}		
Molecule	Δx	Δy	Δr	Δx	Δy	Δr
Aniline	0.00	0.06	0.060	0.00	0.06	0.060
B	0.09	–0.05	0.103	0.08	0.08	0.113
C	0.07	0.06	0.092	0.10	0.03	0.104
E	0.10	0.02	0.102	0.07	0.11	0.130
G	–0.09	–0.10	0.134	0.36	–0.11	0.376
H	0.00	0.13	0.130	0.00	0.15	0.150
J	–0.11	0.07	0.130	–0.13	0.08	0.155

Note: z displacements for C_4 and H_{14} are zero for all compounds. The values of Δr have been calculated using $(\Delta r)^2 = (\Delta x)^2+(\Delta y)^2+(\Delta z)^2$.

be used to predict the comparative band gap behavior of the corresponding polymers.

The HLG values of fluoroanilines defined in Fig. 7 are calculated and listed in Table 8. It can be seen that HOMO–LUMO gap has the following trend,

$$S < D < F < P < I < \text{Aniline} = N < T < K < B < G < O < R < C < Q < H < M = E < L < J$$

where HLG values of S and D are smaller than other compounds. It can also be seen in Table 8 that the HLG value of monomer B is smaller than that of monomer G (Fig. 6); this shows that the conductivity of monomer B is greater than for monomer G. It should be noted here that HLG values are not the only parameters that determine the electric conductivity of a polymer film, the orientation and alignment of the monomers in the polymer chain are two characteristics that play an important role in the electric conductivity as well.

Nuclear independent chemical shift (NICS) analysis

The nuclear independent chemical shift (NICS) at the GIAO/B3LYP/6–311+G** and magnetic susceptibilities at the CSGT/B3LYP/6–311+G** levels of theory[78] for all fluoroanilines were calculated and are listed in Table 9. The negative values of NICS represent the magnetic shielding and electric current in cyclic compounds. NICS results showed that monomer B has the highest NICS value; this compound has the largest electrical current and the highest conductivity among all of other monomers. Based on this table, it can be claimed that the magnetic susceptibilities of these molecules increase with the number of the fluorine atoms.

Conclusion

Hybrid density functional theory (B3LYP/6–311+G**) basis set calculations have been carried out to study the structural, electric, electrochemical, and spectroscopic properties of all fluoroanilines as candidate monomers for new conducting

polymers. The values of NBO atomic charges, spin density distributions, dipole moments, ionization potentials (IPs), vibrational frequencies, NICS values, and HOMO–LUMO gaps (HLGs) have been calculated and analyzed. The results show that double bonds in 2-fluoroaniline and 2,5-difluoroaniline are more delocalized compared with other fluoroanilines. The analysis of charge and spin-density distributions showed that the electropolymerization rate of 2,5-difluoroaniline can be higher compared to other molecules. The analysis of dipole moments shows that the size and direction of the dipole moment vector is more dependent on the position of the substituent than its number. Electrochemical stability of 2-fluoroaniline is greater than other fluoroanilines. The HLG value of 2-fluoroaniline is smaller than for 2,5-difluoroaniline; this shows that probably the conductivity of 2-fluoroaniline is greater than 2,5-difluoroaniline. 2-Fluoroaniline possesses the largest NICS value; therefore this compound has the largest electrical current and most conductivity among all other monomers. Results of the present study show that 2-fluoroaniline (B) and 2,5-difluoroaniline (G) are the best candidate monomers among all fluoroanilines for the synthesis of corresponding conducting polymers. Furthermore, the synthesis feasibility and experimental measurement of these monomers are interesting subjects for study.

Abstract: In this paper, the study of various ortho and meta–substituted Sesamol derivatives is presented. The reaction enthalpies related to three antioxidant action mechanisms HAT, SET–PT, and SPLET for substituted Sesamols, have been calculated using the DFT/B3LYP method in gas phase and water. Calculated results show that electron-withdrawing substituents increase the bond dissociation enthalpy (BDE), ionization potential (IP), and electron transfer enthalpy (ETE), while electron-donating ones cause a rise in the proton dissociation enthalpy (PDE) and proton affinity (PA). In the ortho position, substituents show a larger effect on reaction enthalpies than in the meta position. In comparison with the gas phase, water attenuates the substituent effect on all reaction enthalpies. In the gas phase, BDEs are lower than PAs and IPs, i.e., HAT represents the thermodynamically preferred pathway. On the other hand, the SPLET mechanism represents the thermodynamically favored process in water. Results show that calculated enthalpies can be successfully correlated with Hammett constants (σ_m) of the substituted Sesamols. Furthermore, calculated IP and PA values for substituted Sesamols show linear dependence on the energy of the highest occupied molecular orbital (E_{HOMO}).

Key words: antioxidant, Sesamol, solvent effect, substituent effect, DFT, E_{HOMO}.

Résumé : Dans ce travail, on présente une étude de divers dérivés du Sesamol substitués dans les positions ortho et méta. Faisant appel à des calculs théoriques de la fonctionnelle de la densité au niveau B3LYP de la théorie, on a calculé les enthalpies de réactions, en phase gazeuse et en solution dans l'eau, de trois mécanismes d'action antioxydante, le transfert d'un atome d'hydrogène (TAH), le transfert d'un seul électron suivi d'un transfert de proton (TSE-TP) et une perte d'un proton suivie d'un transfert électron (PPSTE), des Sesamols substitués. Les résultats des calculs montrent que les substituants électroaffinitaires augmentent l'enthalpie de dissociation de la liaison (EDL), le potentiel d'ionisation (PI) et l'enthalpie de transfert d'électron (ETE) alors que les groupes électrodonneurs provoquent une augmentation de l'enthalpie de dissociation de la liaison (EDL) et une augmentation de l'affinité pour le proton (AP). Les effets des substituants sur les enthalpies de réaction sont plus pour les dérivés substitués en position ortho que pour ceux substitués en position méta. En phase gazeuse, les enthalpies de dissociation de la liaison (EDL) sont plus faibles que les augmentations de l'affinité pour le proton (AP) ou les potentiels d'ionisation (PI), c'est-à-dire que le transfert d'un atome d'hydrogène (TAH) correspond à la voie favorisée d'un point de vue thermodynamique. Toutefois, dans l'eau, la perte d'un proton suivie d'un transfert électron (PPSTE) est le mécanisme thermodynamiquement favorisé. Les résultats montrent qu'il est possible d'établir une corrélation entre les enthalpies calculées et les constantes d'Hammett (σ_m) des Sésamols substitués. De plus, il existe une corrélation linéaire entre les valeurs calculées des potentiels d'ionisation (PI) et des affinités pour le proton (AP) et l'énergie de l'orbitale moléculaire haute occupée (E_{OMHO}).

Mots-clés : antioxydant, Sésamol, effet de solvant, effet de substituant, théorie de la fonctionnelle de la densité, énergie de l'orbitale moléculaire haute occupée (E_{OMHO}).

Introduction

In recent years, the border between chemistry and biochemistry has become even more diffuse. The role of antioxidant has lately received much attention because they can avoid or at least significantly reduce the peroxidation of lipids by free radicals, which are related to a variety of disorders and diseases.[1–3] Antioxidants are generally supposed to protect cells against oxidative damage, resulting in health benefits, because the compounds prevent oxidation of biological molecules.[4] Sesamol is a natural organic compound that has antioxidant properties due to phenolic and benzodioxole groups in its structure.[5–10] The propagation and initiation of free radical chain reactions can be delayed or minimized by the donation of hydrogen, electron, or proton from the antioxidants. The polyphenols are more likely to scavenge free radicals at the initiation stage of lipid peroxidation and to a lesser extent at the propagation stage. Antioxidants free radicals can also react with lipid free radicals to form a stable complex compound, thereby preventing some damage. The phenolic antioxidants (ArOH) inhibit oxidation by transferring their phenolic H atom to a chain–carrying peroxyl radical ($ROO^{\bullet}$) at a rate much faster than that of chain propagation.[11] This yields an aryloxyl radical ($ArO^{\bullet}$) that it propagate peroxidation, because it is stabilized by resonance.

[1.1] $ArOH \rightarrow ArO^{\bullet} + H^{\bullet}$

[1.2] $ROO^{\bullet} + H^{\bullet} \rightarrow ROOH$

It is proposed that chain-breaking antioxidants can play their protective role via two major mechanisms.[11–13] In the first, H atom transfer (HAT) mechanism, the phenolic H atom is transferred in one step, as shown in eq. [1.1]). In the HAT mechanism, the bond dissociation enthalpy (BDE) of the phenolic O–H bond is one of the important parameters in evaluating the antioxidant action; the lower the BDE, the easier the dissociation of the phenolic O–H bond. The second mechanism, single electron transfer followed by proton transfer (SET–PT), takes place in two steps:

[2.1] $ROO^{\bullet} + ArOH \rightarrow ROO^{-} + ArOH^{+\bullet}$

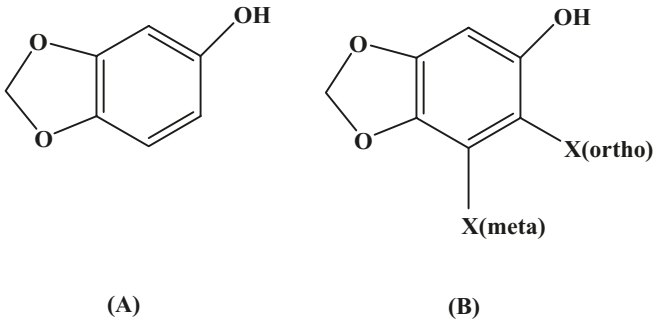
[2.2] $ArOH^{+\bullet} \rightarrow ArO^{\bullet} + H^{+}$

In the first step, a cation radical is formed (eq. [2.1]). In the second step, deprotonation of $ArOH^{+\bullet}$ occurs (eq. [2.2]), followed by the protonation of ROO^{-},

[2.3] $ROO^{-} + H^{+} \rightarrow ROOH$

Ionization potential (IP) and proton dissociation enthalpy (PDE) represent enthalpies of the SET–PT process.[14,15] In the SET–PT mechanism, the IP is the most significant parameter; the lower the IP value, the easier the electron extraction. However, low IP values favour raising electron–transfer reactivity, because they enhance the chance of generating a superoxide anion radical through the transfer of the electron directly to surrounding O_2.[11,16,17] The PDE parameter is not a limiting step in the free radical scavenging action.

Another mechanism has been discoveredthat was named sequential proton loss electron transfer (SPLET), taking place in two steps (eqs. [3.1] and [3.2]):[18–21]



[3.1] $ArOH \rightarrow ArO^{-} + H^{+}$

[3.2] $ArO^{-} + ROO^{\bullet} \rightarrow ArO^{\bullet} + ROO^{-}$

[3.3] $ROO^{-} + H^{+} \rightarrow ROOH$

The reaction enthalpy of the first step (eq. [3.1]) corresponds to the proton affinity (PA) of the phenoxide anion (ArO^{-}).[22–24] In the second step (eq. [3.2]), electron transfer from phenoxide anion to $ROO^{\bullet}$ occurs, and the phenoxy radical is formed. The reaction enthalpy of this step is denoted as electron transfer enthalpy (ETE). The second step of SPLET is the limiting step (ETE), and therefore PA is far from the best indicator to rationalize the SPLET–like free radical scavenging. From the antioxidant action viewpoint, the net result of SPLET is the same as in the two previously mentioned mechanisms, the transfer of the hydrogen atom to the free radicals. The BDE actually correlates with the global thermodynamics of the three processes. Although, reaction enthalpies (BDE, IP, PA) related to three mechanisms are of importance in evaluating the antioxidant action, other criteria, including solubility, bioavailability, and nontoxicity, must also be considered when designing an effective and safe antioxidant.[25] The biological implications and the great potential of Sesamols as antioxidant aroused our interest in elucidating its antioxidant activity by means of DFT/B3LYP calculations, which have been successfully used for a variety of antioxidants in previous studies.[26–30] Because in chemistry one often needs to compare a group of reactions differing only in the substitution, it is also important to study the effect of substituents on the reaction enthalpy. The substituent effects are among the most important concepts of structural effects influencing the chemical, physicochemical, and biochemical properties of chemical species.[31–36] In recent years, many previous experimental[22–24,37–42] and theoretical[12,22,33,43–50] investigations have been carried out on phenols and mono-substituted phenols in gas and solvent environments. Theoretical studies of the substituent effect can be utilized in the synthesis of substances with enhanced antioxidant properties. In the present paper, we investigate the effect of various substituents on reaction enthalpies related to HAT, SPLET, and SPT–ET mechanisms of Sesamol derivations. Understanding the role of different structural features and preparation of new compounds with enhanced antioxidant property is of great interest. In this paper Sesamol (Fig. 1A) is the basic structure (non–substituent), and the various substituents such as electron–withdrawing groups (EWG) and electron–donating groups (EDG) were located in ortho and meta positions on the aromatic ring of Sesamol (Fig. 1B). For Sesamol, the energy of the antioxidant action has not been studied yet. No systematic study of solvent and substituent effects on BDE, IP, and PA of substituted Sesamols have been published yet. Indeed, there are actually only a few new insights from the polyphenol–calculation community. Therefore, we have systematically investigated the substituent effect on reaction enthalpies of homolytic (HAT mechanism) and heterolytic two–step (SPLET and SET–PT) mechanisms of O–H bond cleavage for mono–substituted Sesamols in gas phase and

Fig. 1. (A) Structure of Sesamol. (B) Studied Sesamols: X=Br, Ethyl, CH=CH_2, CCH, CF_3, Me, Cl, CN, COMe, COH, COOH, F, NMe_2, NHMe, NH_2, NO_2, OMe, OH, Ph, t–Bu.

water. Correlations of calculated enthalpies with Hammett constants of substituents were investigated. So far as we know, no attempt to find a relationship between structural parameters and reaction enthalpies related to HAT, SPLET, and SET–PT mechanisms in the case of Sesamols has been made previously. This work also shows linear dependence between calculated enthalpies and the energy of the highest occupied molecular orbital (E_{HOMO}) of studied molecules in the two environments. Because SET–PT and SPLET mechanisms are of importance in solvated media, it is interesting to explore how the solvent alters the reaction enthalpies of individual steps of the two mechanisms.[18–21,33,41,70] Because Sesamol is a powerful water–soluble antioxidant, water as the main cell environment was chosen to assess the substituent effect on above mentioned enthalpies in solution phase. To shed light on the solvent effect, PCM (polarized continuum model) calculations have been performed for the molecules in water.

Computational details

The geometries of the molecules and respective radicals, radical cations, and anions were optimized using the DFT method with B3LYP functional[71–73] and the 6–31G (d, p) basis set[71,72] in the gas phase and solution phase. Single point calculations were performed using the 6–311++G (2d, 2p) basis set.[74,75] The ground–state geometries of molecules were optimized at the restricted B3LYP level, and the geometry of the radicals, radical cations, anions were optimized at the restricted B3LYP open shell (half electron) level. We estimated the change in the ROB3LYP energies of phenoxyl radicals, radical cations, and anions when the geometries were optimized at the UB3LYP and ROB3LYP levels. It was observed that the two energies differ by less than 0.09 kcal mol^{-1} (1 cal = 4.182 J). Thus, the ROB3LYP method was used for the geometry optimization of all the substituted phenoxyl radicals, radical cations, and anions. The optimized structures were confirmed to be real minima by frequency calculation. For the species having more conformers, all conformers were investigated. The conformer with the lowest electronic energy was used in this work. All reported enthalpies were zero–point (ZPE) corrected with unscaled frequencies. On the basis of the DFT optimized geometries, the partial charges were obtained using 6–31(d,p) basis set.[71,72] Solvent contribution to the total enthalpies was computed employing the PCM method.[76,77] All calculations were performed using the Gaussian 98 program package.[78] All enthalpies were calculated for 298.15 K and 1.0 atmosphere pressure (101.325 kPa).

Results and discussion

Total enthalpies of the studied species X, H(X) at temperature T are usually estimated from the expression (4),[14,42]

$$[4] \quad H(\mathrm{X}) = E_0 + \mathrm{ZPE} + \Delta H_{trans} + \Delta H_{rot} + \Delta H_{vib} + RT$$

where E_0 is the calculated total electronic energy, ZPE stands for zero–point energy, ΔH_{trans}, ΔH_{rot}, and ΔH_{vib} are the translational, rotational, and vibrational contributions to the enthalpy, respectively. Finally, RT represents PV work term and is added to convert the energy to enthalpy. From the calculated total enthalpies we have determined following quantities:

$$[5] \quad \mathrm{BDE} = H(\mathrm{ArO}^{\bullet}) + H(\mathrm{H}^{\bullet}) - H(\mathrm{ArOH})$$

$$[6] \quad \mathrm{IP} = H(\mathrm{ArOH}^{+\bullet}) + H(\mathrm{e}^{-}) - H(\mathrm{ArOH})$$

$$[7] \quad \mathrm{PDE} = H(\mathrm{ArO}^{\bullet}) + H(\mathrm{H}^{+}) - H(\mathrm{ArOH}^{+\bullet})$$

$$[8] \quad \mathrm{PA} = H(\mathrm{ArO}^{-}) + H(\mathrm{H}^{+}) - H(\mathrm{ArOH})$$

$$[9] \quad \mathrm{ETE} = H(\mathrm{ArO}^{\bullet}) + H(\mathrm{e}^{-}) - H(\mathrm{ArO}^{-})$$

The calculated gas phase enthalpy of the proton, $H(H^+)$, and electron, $H(e^-)$, is 6.197 and 3.145 kJ mol^{-1}, respectively.[79] Obtained results reveal that water causes considerable changes in the total enthalpies of molecule, radical, anion, and the radical cation of studied compounds. The enthalpy of H^+ hydration is –1090 kJ mol^{-1}.[80] It severely affects PAs and PDEs. Since the enthalpy of electron hydratation, $\Delta_{hydr}H(e^-)$, could not be found in the literature, electron hydration enthalpy computed using B3LYP/6–311++G**, $\Delta_{hydr}H(e^-)$ = –105 kJ mol^{-1}, was employed.[81] In a previous paper, Rimarèík et al. calculated H^+ and e^- solvation enthalpies in organic solvents, which were not available in the literature using PCM DFT/B3LYP/6–311++G** method as the enthalpy change in the process,[81]

$$[10] \quad \mathrm{solvent(l)} + \mathrm{H}^{+}(\mathrm{g}) \rightarrow \mathrm{solvent}^{+}(\mathrm{solv})$$

or

$$[11] \quad \mathrm{solvent(l)} + \mathrm{e}^{-}(\mathrm{g}) \rightarrow \mathrm{solvent}^{-}(\mathrm{solv})$$

where they employed the following model: a proton or electron was "attached" to one molecule of solvent. Obtained species were optimized using the PCM approach in the same solvent.[81] Potential inaccuracies related to computed solvation enthalpies will be canceled when the substituent effect is studied, as the difference in the reaction enthalpies of substituted and nonsubstituted Sesamols, i.e., in terms of ΔBDE, ΔPA, ΔETE, ΔIP, and Δ. On the other hand, BDE, PA, and IP values allow the determination of the preferred reaction pathway in the studied solvents.

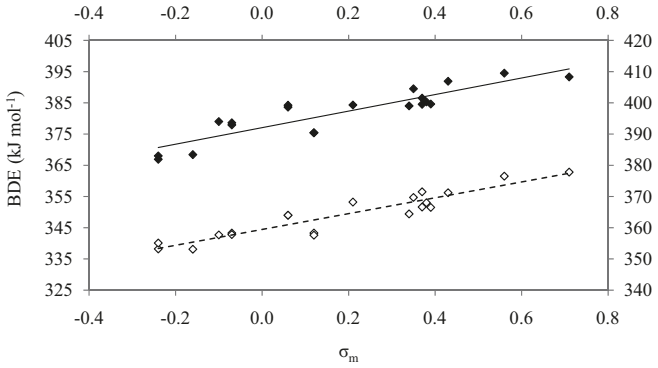
Bond dissociation enthalpies of ortho- and meta-substituted Sesamols

In gas phase

Knowledge of BDE has been accumulating substantially for the past 15–20 years owing to the development of both experimental and theoretical (quantum chemical) techniques.[38,39,41,45,47,69,70,82–94] In previous studies the solvent and substituent effects on O–H BDE values, substituted phenols have been investigated using the PCM method.[41,45,47,70,91] Fu et al.[86] and Guerra et al.[87] determined the solvation effect of water on the ΔBDE values of para-substituted phenols via PCM method, and in these studies reaction enthalpies were calculated using B3LYP method and the 6–31G* basis set. Russo et al.[57] have investigated the solvent effect on the BDE value of several phenolic antioxidants using the PCM method. Klein et al.[70] indicated that the PCM method could describe the substituent effect in very good agreement with experimental data for O–H BDE values of substituted phenols in water.[40] In this study, all conformers have been optimized, and the conformer with higher stability was used in each case. The calculated BDE for the basic structure, Sesamol, in gas phase reached 380 kJ mol^{-1}. The computed gas phase BDE and ΔBDE values, where ΔBDE = BDE(X–ArOH) – BDE(ArOH), for substituents placed in ortho and meta positions (Fig. 1B) are reported in Table 1. The O–H BDE value of the structure with NO_2 substituent in ortho and meta position were higher compared with the BDE value of Sesamol. For ortho-substituted Sesamols with NMe_2, NH_2, and NHMe the BDE values are lower compared with the Sesamol. For ortho-substituted Sesamols with halogens, the BDE values are higher than for Sesamol. For ortho-substituted Sesamols with COH, COOH, and COMe, the BDE values are higher than the BDE value of Sesamol. The O–H BDE of structure with OH substituent in ortho and meta position was lower cmopared with the BDE value of Sesamol. For meta-substituted Sesamols with NMe_2, NH_2, and NHMe, the BDE values are lower than for Sesamol. For ortho- and meta-substituted Sesamols with OMe, the BDE values are lower than the BDE value of Sesamol. The difference between the highest and lowest BDE values for ortho- and meta-substituent Sesamols were 91.4 and 32.6 kJ mol^{-1}, respectively. The obtained results can be interpreted knowing that electron–withdrawing groups in the ortho and the meta position stabilize the parent molecule and destabilize the radical; hence, they increase the O–H BDE. However, electron–donating groups in the ortho and meta positions have an opposite effect, and therefore their presence leads to a decrease in the O–H BDE.

In water



The calculated BDE for Sesamol is 360.6 kJ mol^{-1} in water phase, and that is lower than in gas phase BDE by 20 kJ mol^{-1}. The computed BDEs and ΔBDEs in water for ortho- and meta–substituted Sesamols are reported in Table 1. For ortho-substituted Sesamols with NMe_2, NH_2, and NHMe, the BDE values are 27.6, 32.6, and 41.2 kJ mol^{-1} lower than for Sesamol, respectively. For ortho-substituted Sesamols with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

halogens, the BDE values are 13 kJ mol^{-1} higher ythan for Sesamol. For meta-substituted Sesamols with halogens, the BDE values are 4.5 kJ mol^{-1} higher than the BDE value of Sesamol. For ortho- and meta-substituted Sesamols with COH, COOH, and COMe, the BDE values are ca. 25 and 9 kJ mol^{-1} higher than the BDE value of Sesamol, respectively. An inspection of the O–H BDE values appearing in Table 1 shows that in water, calculated BDE values were lower than those calculated for the gas phase. Water causes considerable changes in the enthalpies of molecules and corresponding radicals of the studied structures, but overall results reveal a weak dependence of BDE values on the solvent polarity because the enthalpy changes are similar for both thes molecule and the radical structures. In water, electron–donating substituents decrease BDE values, whereas electron–withdrawing groups increase BDE values, similar to the results found for the gas phase. The difference between the highest and lowest BDE values in the water for the ortho and meta positions were 80 and 23.5 kJ mol^{-1}, respectively. In comparison with the gas phase, the effects of various substituents, including EDG and EWG, the BDE values in the ortho and meta positions were decreased in the water phase. Therefore, we can conclude that in comparison with the gas phase, the effect of EDG–substituents and EWG–substituents on BDE in the ortho and meta positions decreases in water. Since water causes unequal stabilization–destabilization of the parent molecule and the respective radical, this could be a fundamental reason for the obtained results. Therefore, a decrease in BDEs (negative ΔBDEs) for EDG–substituted Sesamols is the combined result of the radical stabilization and the parent molecule destabilization. However, increased BDEs (positive ΔBDEs) for EWG–substituted Sesamols seem to be due to the combination of both the parent and the radical destabilization. The overall results of the calculations of O–H BDE can be summarized by the fact that EWG–substituted Sesamols with higher BDEs may exhibit weaker antioxidant activity compared with EDG-substituted Sesamols in gas phase and water. In the present study, computed results for substituted Sesamols show that substituents in ortho positions exert significantly stronger influence on O–H BDE than substituents in the meta position in gas phase and water. These results are in agreement with previous studies in the meta and ortho substituted phenols and chromans.[11,41,49,63,69]

The Hammett equation (and its extended forms) has been one of the most widely used means for the study and interpretation of organic reactions and their mechanisms. Hammett constants σ_m (for substituents in the meta position) and σ_p (for substituents in the para position) obtained from the ionization of organic acids in solutions can frequently successfully predict equilibrium and rate constants for a variety of families of reactions.[35,36] Hammett constants correlate very well with the changes in BDE in the case of anilines, phenols, or thiophenols.[39,42,83,93] DiLabio et al. found that BDE and ΔBDE values of para substituted phenols, 6-substituted-3-pyridinols, 2-substituted-5-pyrimidinols, and anilines are linearly dependent on Hammett constants σ_p.[16,88,95] Klein et al. found that BDE and ΔBDE values of para substituted and meta substituted phenols are linearly dependent on Hammett constants σ_p and σ_m.[37,48] Klein et al. have shown that BDE values of meta substituted chromans are linearly dependent on Hammett constants σ_m in the gas phase and water. BDE values

Fig. 2. Dependence of BDE on σ_m for meta-substituted Sesamols in gas phase (solid squares, solid line, bottom x-axis, left y-axis) and water (open squares, dashed line, top x-axis, right y-axis).

computed for the meta-substituted Sesamols in the gas phase and water are plotted against Hammett constants in Fig. 2.[69] The correlation coefficients in gas and water reached 0.92 and 0.93, respectively. Equations obtained from the linear regression are as follows:

$$[12] \quad \mathrm{BDE(kJmol^{-1})} = 26.5 \times \sigma_m + 380.1(\mathrm{gas})$$

$$[13] \quad \mathrm{BDE(kJmol^{-1})} = 25.4 \times \sigma_m + 360.6(\mathrm{water})$$

Linear regressions show that the DFT method describes the expected linear BDE vs. Hammett constant dependence satisfactorily. This is very important because this can be utilized in the synthesis of novel Sesamol derivatives with enhanced antioxidant properties.

Ionization potentials of ortho- and meta-substituted Sesamols

In gas phase

This paper represents the first theoretical systematic study of substituted Sesamol IP values. In previous studies the substituent effect on IPs of para- and meta-substituted phenols have been investigated in the gas phase employing the B3LYP approach.[41,47] Chandra et al. calculated IP values for substituted pyridinethiols in the gas phase.[82] In this paper, the calculated IP for the Sesamol in gas phase reached 730.5 kJ mol^{-1}. The computed gas phase IPs and ΔIP = IP(X–ArOH) – IP(ArOH) for substituents in the ortho and meta positions are reported in Table 2. In the ortho and meta positions, the highest IP values were found for strong EWG substituents (NO_2, CF_3, and CN); the lowest IPs were obtained for strong EDG substituents (NMe_2, NH_2, and NHMe). For halogens in ortho positions, the IP values are higher than for Sesamol. For ortho- and meta–substituted Sesamols with strong EDGs (NMe_2, NH_2, and NHMe) IP values are lower than for Sesamol. The decrease in IP of the molecules with the OH group in ortho and meta positions are ca. 26 and 18 kJ mol^{-1}, respectively. For ortho- and meta-substituted Sesamols with OMe, the decrease in IP reached 24 and 22 kJ mol^{-1}, respectively. The halogens in the ortho and meta positions induce 19 and 15 kJ mol^{-1} increase in IP, respectively. For ortho- and meta-substituted Sesamols with COH,

NO_2	789.9	59.4	787.9	57.4	330.8	46.4	332.1	47.6

COOH, and COMe, IP values are higher than the IP value of Sesamol. The IP values of Sesamols with the strongest electron–withdrawing NO_2 group in ortho and meta positions were higher by ca. 60 and 40 kJ mol^{-1} compared with non-substituted Sesamol, respectively. The difference between the highest and lowest IP values for the ortho and meta positions was 130 and 96 kJ mol^{-1}, respectively. As is known in organic chemistry, the EWG substituents stabilize the parent molecule and destabilize the radical and radical cation. This results in an increase in IP. However, EDG subsitutents have an opposite effect. Therefore, their presence in the molecule leads to a decrease in IP. The decrease in IP values (negative ΔIPs) of EDG–substituted Sesamols has the combined result of cation radical stabilization and parent molecule destabilization. However, the increased IP values (positive ΔIPs) of EWG–substituted Sesamols may result from the combination of both the parent and the cation radical destabilization. These results are in accordance with data published for substituent phenols.[41,47,82–85]

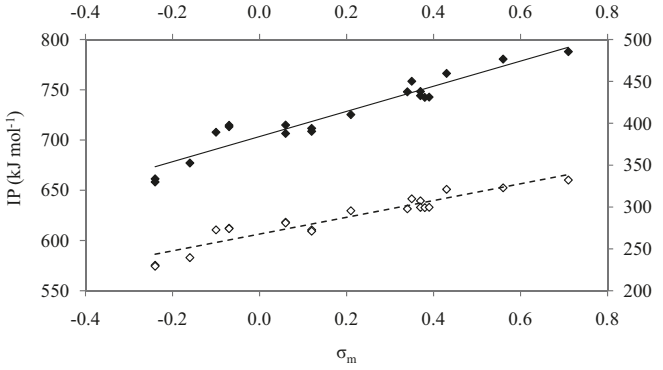
In water

The computed IPs using the above-mentioned calculated $\Delta_{hydr}H(e^-)$ value[81] in the water for molecules substituted in the meta and ortho positions are reported in Table 2. Table 2 also summarizes ΔIP values. Water causes considerable changes in the enthalpies of the molecule and cation radical of studied Sesamols. The calculated IP for Sesamol in water is lower than that in the gas phase by 284.5 kJ mol^{-1}. IP is significantly lower than that in the gas phase because of the negative enthalpy of electron hydration in water. For strong EDGs, i.e., NMe_2, NH_2, and NHMe, in ortho and meta positions, we found decreases in IP values of 50 and 40 kJ mol^{-1}, respectively. For the OH group in ortho and meta positions, the decrease in IP reached ca. 20 and 11 kJ mol^{-1}, respectively. For halogens in ortho and meta positions, the increase in IP reached 15 and 13 kJ mol^{-1}, respectively. For ortho- and meta-substituted Sesamols with strong electron–withdrawing NO_2 group, the increase in IP value was ca. 46 and 35 kJ mol^{-1}, respectively. In water, substituent-induced changes are lower than those observed in the gas phase. The EWG–substituents stabilize the parent molecule and destabilize the radical cation. On the other hand, EDG–substituents have an opposite effect. Water causes ca. 15 kJ mol^{-1} attenuation of substituent effects in terms of the narrower ΔIP range. Again, substituents in ortho positions exert stronger influence upon IP than the same substituents in meta positions. Values in Table 3 also reveal that IP values in water are considerably lower than corresponding gas phase values.

Klein et al. confirmed that there are linear relations between IPs of substituted phenols and Hammett constants σ_p and σ_m in the gas phase.[41] THe IP values computed for the meta-substituted Sesamols in the gas phase and water are plotted against Hammett constants in Fig. 3. The correlation coefficients in gas phase and water reached 0.95 and 0.94, respectively. Equations obtained from the linear regression are as follows:

$$[14] \quad IP(kJmol^{-1}) = 125.1 \times \sigma_m + 730.5(gas)$$

$$[15] \quad IP(kJmol^{-1}) = 100.1 \times \sigma_m + 284.5(water)$$



We can conclude that the DFT method describes the expected linear IP vs. Hammett constant dependence satisfactorily.

Fig. 3. Dependence of IP on σ_m for meta–substituted Sesamols in gas phase (solid squares, solid line, bottom x-axis, left y-axis) and water (open squares, dashed line, top x-axis, right y-axis).

To accelerate the discovery of novel antioxidants, considerable effort has been devoted to investigating the structure–activity relationships (SARs) for antioxidants. Furthermore, rational design strategies for antioxidants have been proposed and applied in research. It was shown that IPs determined using the DFT computational approach are sufficiently accurate to characterize the electron-donating ability of antioxidants.[96,97] The energy of the highest occupied molecular orbital (E_{HOMO}) represents an alternative parameter to assess the electron-donating ability of antioxidants. This is widely used in the antioxidant study because of the simple calculation procedure in which only the calculation for the parent molecule is required.[98,99] The E_{HOMO} is derived from DFT by employing Janak's theorem.[100] Janak's theorem states that the derivative of the total DFT energy with respect to the occupation of a given orbital is equal to the corresponding orbital energy. According to Janak's theorem, E_{HOMO} must be exactly equal to the ionization potential. Therefore, HOMO energy represents an applicable parameter for prediction of antioxidant activity[101,102] and oxidant scavenging ability[103] via SET–PT mechanism. Our results for E_{HOMO} for Sesamol in the gas phase and water are –6.15 and –6.28 eV, respectively. As a general rule, the higher the E_{HOMO}, the more active the compound is as an antioxidant.[103,104] The computed E_{HOMO} values of Sesamols in the gas phase and water are summarized in Table 3. These reveal that in the case of EWG-substituents, E_{HOMO} values become more negative, while the presence of EDG-substituents results in less negative E_{HOMO} values. Therefore, Sesamols with strong electron-donating groups are better electron donors. A previous study showed that the B3LYP/6–311+G(2d,2p) method significantly underestimates vertical gas phase ionization potentials obtained from E_{HOMO} for mono-substituted anilines, phenols, and thiophenols.[93] However, the trends in ionization potentials, in terms of ΔIPs, are described reliably. Therefore, we decided to find expected linear dependence between calculated IPs and corresponding E_{HOMO} values (Fig. 4). For meta-substituted Sesamols, correlation coefficients in gas phase and water reached 0.95 and 0.96, respectively. The obtained equations are as follows:

Fig. 4. Dependence of IP on E_{HOMO} for meta-substituted Sesamols in gas phase (solid squares, solid line, bottom x-axis, left y-axis) and water (open squares, dashed line, top x-axis, right y-axis).

[16] $$IP(kJmol^{-1}) = -103.2 \times E_{HOMO}(eV) + 77.1(gas)$$

[17] $$IP(kJmol^{-1}) = -110.4 \times E_{HOMO}(eV) - 428(water)$$

The equations enable fast IP estimations for mono-substituted Sesamols from the computed E_{HOMO} values. This can be useful in the selection of suitable candidates for the synthesis of novel Sesamol derivatives with enhanced antioxidant properties.

Proton affinities of ortho and meta substituted Sesamols

In gas phase

PA represents the reaction enthalpy of the first step in the SPLET mechanism (eq. [3.1]). PAs of substituted Sesamols have not been obtained by theoretical calculations previously.

In previous studies, the substituent effect on PAs of para- and meta-substituted phenols have been investigated by DFT using B3LYP functional in the gas phase.[22–24,41,42] Chandra et al. also calculated PA values for substituted pyridinethiols in the gas phase.[82] Calculated gas phase PA for Sesamol reached 1501.3 kJ mol^{-1}. The computed PAs and ΔPAs for the various substituents in ortho and meta positions in the gas phase are reported in Table 4. The highest values of PA for ortho and meta positions were found for NMe_2, NH_2, and NHMe groups. The lowest PA values for these positions were found for NO_2, CF_3, and CN groups. Compared with nonsubstituted Sesamol, for Sesamols with NMe_2, NH_2, and NHMe groups in ortho and meta positions, PA values are higher compared with the PA value of Sesamol. The halogens in ortho and meta positions cause a decrease in PA value. For ortho- and meta–substituted Sesamols with COH, COOH, and COMe, PAs are lower than for Sesamol. For strong electron–withdrawing NO_2 substituent in ortho and meta positions, the drops in PA reached largest values compared with the PA value of Sesamol. The differences between the highest and lowest gas phase PA values for ortho and meta substituents were 80 and 53 kJ mol^{-1}, respectively. In agreement with previous studies on substituted phenols, it can be concluded that EDG substituents increase PA, whereas EWG ones decrease PA.[22–24,42] It is known that a charged molecule is more sensitive to the effect of substituent than its neutral counterpart. EWG substituents stabilize ArO^- but destabilize the parent phenol. Electron donating groups have an opposite effect.[15,39,84,85]

In water

The present calculated PA for the Sesamol reached 56.5 kJ mol^{-1} in water. For Sesamols substituted in meta and ortho positions, computed PAs and ΔPAs in water are reported in Table 4. Water causes considerable changes in the enthalpies of anions. Calculated PA for Sesamol in water is lower than for the gas phase by 1445.5 kJ mol^{-1}. Because of the large negative enthalpy of H^+ hydration, PAs in water are significantly lower than gas phase values. Again, EWG substituents decrease PAs, whereas EDG groups increase PAs, in agreement with results for substituted phenols in water.[70] Again, strong electron–donating NMe_2, NH_2, and NHMe cause an increase in PA. For ortho- and meta–substituted Sesamols, PA values are higher in comparison with the Sesamol. The presence of OH group in ortho and meta positions results in 7 and 2.5 kJ mol^{-1} PA growth, respectively. For halogens in ortho and meta positions, the drops in PAs reached 15 and 12 kJ mol^{-1}, respectively. The largest decrease in PA occurs for Sesamol with a NO_2 group in ortho and meta positions. Differences between the highest and lowest PA values for the 3 studied positions were 50 (ortho) and 27 kJ mol^{-1} (meta). It confirms that water attenuates substituent induced changes. Klein et al. found a linear dependence between PAs of substituted phenols and Hammett constants in gas phase and water.[41,70] There is also a linear relation between PAs of substituted pyridinethiols with Hammett constants.[82] For the meta-substituted Sesamols in gas phase and water, computed PAs are plotted against Hammett constants in Fig. 5. The correlation coefficients in gas phase and water reached 0.94 and 0.95, respectively. Equations obtained from the linear regression are as follows:

$$[18] \quad PA(kJmol^{-1}) = -55.6 \times \sigma_m + 1501(gas)$$

$$[19] \quad PA(kJmol^{-1}) = -30.8 \times \sigma_m + 56.5(water)$$

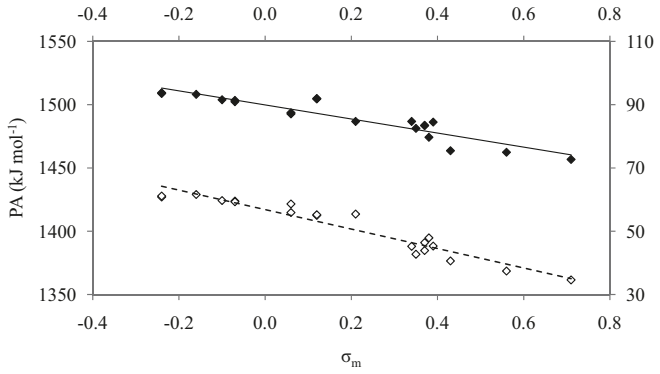
Fig. 5. Dependence of PA on σ_m for meta-substituted Sesamols in gas phase (solid squares, solid line, bottom x-axis, left y-axis) and water (open squares, dashed line, top x-axis, right y-axis).



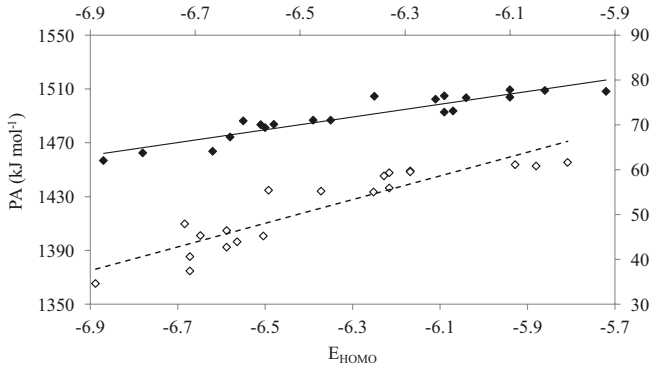


Fig. 6. Dependence of PA on E_{HOMO} for meta-substituted Sesamols in gas phase (solid squares, solid line, bottom x-axis, left y-axis) and water (open squares, dashed line, top x-axis, right y-axis).

These results show good linearity for the PA = $f(\sigma_m)$ dependences. We have also performed linear correlation of PA values with E_{HOMO} in the two environments. We also searched for expected linear dependence between calculated PAs and corresponding $-E_{HOMO}$ values (Fig. 5). Obtained dependences for substituents in meta position are shown in Fig. 6. Correlation coefficients reached 0.95 (gas phase) and 0.94 (water). The following regression linar relations were obtained:

$$[20] \quad PA(kJmol^{-1}) = 47.3 \times E_{HOMO}(eV) + 1787(gas)$$

$$[21] \quad PA(kJmol^{-1}) = 31.7 \times E_{HOMO}(eV) + 256(water)$$

The positive line slopes reflect the fact that the EDG–substituents increase PA, as well as the absolute value of E_{HOMO}. On the other hand, EWG–substituents cause a decrease in PAs and absolute E_{HOMO} values. Obtained equations may be used to predict PAs for meta–substituted Sesamols from their E_{HOMO}. We can conclude that E_{HOMO} can be employed for fast estimations of reaction enthalpies for the first step of both investigated SET–PT and SPLET mechanisms.

Proton dissociation enthalpies and electron transfer enthalpies in gas phase and water

PDE and ETE represent the reaction enthalpies of the second steps in SET–PT and SPLET mechanisms, respectively. To obtain the whole SET–PT and SPLET energetics picture, it is also important to study PDEs and ETEs and to investigate the solvent and substituent effects on these reaction enthalpies. In previous papers the substituent effect on PDEs for substituted phenols have been theoretically investigated by DFT using B3LYP functional.[12,15,41,69,105] In recent papers, the PDE and ETE values of ortho- and meta-substituted chromans have been calculated in gas and water.[69,105] There are no experimental PDEs available yet. Calculated PDEs for the Sesamol reached 1045.2 kJ mol^{-1} in the gas phase and 150.1 kJ mol^{-1} in water. The PDE of Sesamol in water is lower by 895 kJ mol^{-1}. Because of the large enthalpy of proton hydration, PDEs in water are significantly lower than gas phase values. Water also causes considerable changes in the enthalpies of radicals and radical cations of the studied structures. Computed PDE values for the substituents in ortho and meta position in the gas phase and water are reported in Table 5. The highest PDEs were found for strong EDG substituents (NMe_2, NH_2, and NHMe), whereas lowest PDEs were obtained for strong EWG substituents (NO_2, CF_3, and CN). This trend is opposite to that observed for PAs. It is known that electron–donating groups stabilize $ArOH^{+\bullet}$ but destabilize the parent structure, while electron–withdrawing groups have an opposite effect.[15,39,94] These results are in agreement with previous papers on substituted phenols and chromans.[12,15,41,44,69,105] For substituted Sesamol, ETEs were not studied previously. In the literature, only DFT/B3LYP ETEs of substituted phenols and chromans are available.[41,69,33,105] Calculated ETE values for Sesamol reached 248.3 kJ mol^{-1} in the gas phase and 330.5 kJ mol^{-1} in water. The computed ETEs values for Sesamol with substituents in ortho and meta position are compiled in Table 5. In gas phase and water, highest ETEs were found for strong EWG substituents (NO_2, CF_3, and CN). Lowest ETEs were found in the case of strong EDG substituents (NMe_2, NH_2, NHMe). This trend corroborates with that observed for BDEs and IPs. It is known that electron-withdrawing groups are favorable to stabilize ArO^-. Electron-donating groups have an opposite effect. Therefore, electron-withdrawing groups increase ETE values, while electron-donating groups decrease ETEs.[15,39,85,94,106]

Conclusions

In this article, the reaction enthalpies of the individual steps of three antioxidant action mechanisms, HAT, SET–PT, and SPLET, for various ortho- and meta-substituted Sesamols were calculated in gas phase and in water. The obtained results indicate that electron–withdrawing substituents increase the bond dissociation enthalpy (BDE), ionization potential (IP), and electron transfer enthalpy (ETE), while electron–donating substituents cause a rise in the proton dissociation enthalpy (PDE) and proton affinity (PA). Water attenuates the substituent effect on all reaction enthalpies. In the gas phase, BDEs are lower than PAs and IPs, i.e., HAT represents the thermodynamically preferred pathway. On the other hand, SPLET mechanism represents the thermodynamically favored process in water. The results show that calculated enthalpies can be successfully correlated with Hammett constants (σ_m) of the

substituted Sesamols. It has been also found that PA and IP values for substituted Sesamols can be estimated from their E_{HOMO} values. This fact may be useful for the development of new Sesamol based antioxidants.

Acknowledgement

I would like to thank my colleagues for their valuable discussions on the computational matters.

A short formal total synthesis of (±)-hirsutic acid

Guillaume Revol, Christian Fuchs, and Samir Z. Zard

Abstract: A short formal total synthesis of (±)-hirsutic acid is described using a Claisen rearrangement and a radical cascade as the key steps. The radical sequence involves an intermolecular addition of a radical derived from a xanthate followed by a cyclization and transfer of the xanthate group.

Key words: hirsutic acid, complicatic acid, triquinanes, Claisen rearrangement, radical cyclization, xanthates.

Résumé : Une synthèse totale formelle courte de l'acide (±)-hirsutique est décrite, employant comme étapes-clés un réarrangement de Claisen et une cascade radicalaire. La séquence radicalaire implique une addition intermoléculaire d'un radical issu d'un xanthate, suivie d'une cyclisation, puis du transfert du groupe xanthate.

Mots-clés : acide hirsutique, acide complicatique, triquinanes, réarrangement de Claisen, cyclisation radicalaire, xanthates.

Introduction

(+)-Hirsutic acid **1** (Fig. 1) was isolated in 1947 from a fungus (*Stereum hirsutum*), but its structure was only determined 20 years later.[1,2] It belongs to the family of linear triquinanes and is closely related to (+)-complicatic acid **2**, a secondary metabolite from the fungus *Stereum complicatum*, which also produces hirsutic acid.[3] The biogenetic precursor for both compounds is presumably (+)-hirsutene (**3**), a linear triquinane isolated from a basidiomycete, *Coriolis consors*.[4] While a few of these natural products exhibit interesting biological acivities, it is mostly the intricate structure of hirsutic acid and its congeners that has attracted the attention of synthetic organic chemists over four decades. Thus, no less than nine total and formal syntheses of hirsutic acid have been reported so far.[5–13]

Apart from constructing the triquinane skeleton of hirsutic acid **1**, there is the challenge of controlling the stereochemistry of seven chiral centers, including the tertiary carboxylic acid at C-11. This complicates significantly the synthetic planning in comparison with hirsutene **3** where this carbon is not chiral and simply bears a *geminal* dimethyl group. In contemplating simpler routes to hirsutic acid, we envisaged the possibility of using the chirality at C-11 to install the remaining six chiral centers. Our retrosynthetic analysis is outlined in Scheme 1.

Intermediate tricyclic enone **4** is a key precursor in several of the published syntheses. It can be converted into complicatic acid in four steps and into hirsutic acid in five steps as was initially demonstrated by Matsumoto and co-workers[6] in 1971. We envisaged obtaining this compound by a radical addition–cyclization of *S*-acetyl xanthate **6** on monocyclic enone **5**. This enone could, in principle, be obtained through a Claisen rearrangement starting from allylic alcohol **7**, itself derived from the simple and commercially available ketoester **8**.

Indeed, allylic alcohol **7** had already been prepared by Kato et al.,[14] both as racemate and as optically pure material. The synthesis of the racemic modification is displayed in Scheme 2. Treatment of ketoester **8** with methyl iodide and potassium carbonate accomplished the desired methylation to give compound **9** in near quantitative yield. The unsaturation could be introduced using Saegusa's conditions[15] applied on the corresponding enol silyl ether **10**. Unfortunately, enone **11** was obtained in a variable overall yield ranging from 12% to 51%. Nevertheless, this was sufficient to confirm the selectivity of the reduction step leading to allylic alcohol **7**.

Using Luche conditions,[16] the reduction at –40 °C furnished an 80:20 mixture of allylic alcohol **7** and completely reduced alcohol **12**, respectively, in 65% combined yield. Both the yield and the selectivity could be increased by lowering the reaction temperature to –78 °C (Scheme 2). Furthermore, we later found that enone **11** could be obtained more reliably and in much better yield by oxidation of ketone **9** with an excess of 2-iodoxybenzoic acid (IBX), according to the procedure described by Nicolaou et al.[17]

The conversion of alcohol **7** into enone intermediate **5** relied on a Claisen rearrangement.[18] After a number of mostly unsuccessful attempts, we finally found that heating a mixture of alcohol **7**, *n*-butyl vinyl ether, and a catalytic amount of mercuric acetate to 200 °C in a microwave oven for 2 h furnished the desired aldehyde **14** in 48%–60% yield.[19] This compound was rapidly treated with isopropenylmagnesium bromide in THF at 0 °C to furnish carbinol **15** in a yield ranging between 52% and 70%. Oxidation with manganese dioxide in refluxing dichloroethane (DCE) afforded enone **5**, whereas acetylation gave acetate **16** in 58% and 63% yield, respectively (Scheme 3).

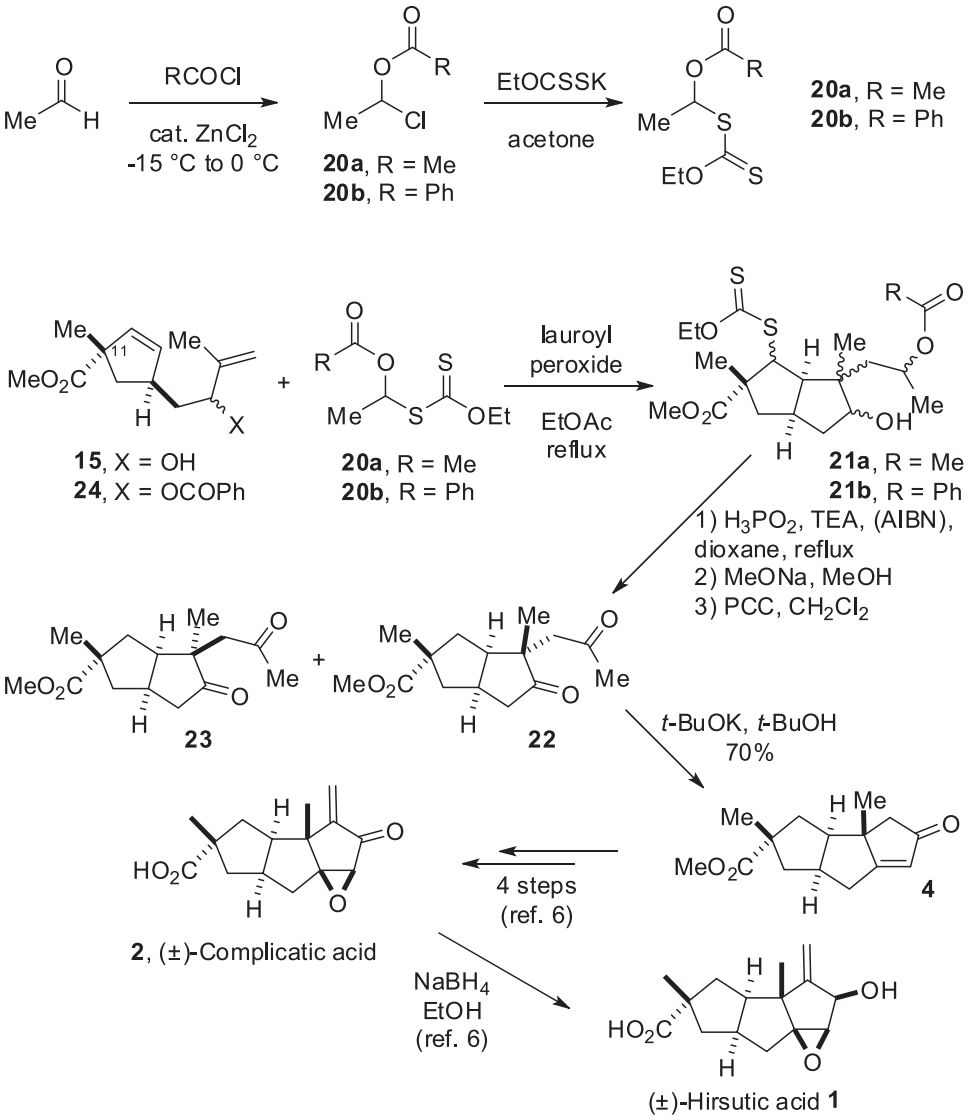
Scheme 4. Key radical cascade.



We were now in a position to examine the key radical cascade based on xanthate chemistry.[20] The anticipated sequence of intermolecular radical addition – cyclization is outlined in Scheme 4. In analogy with previous work,[21] the acetyl radical generated from *S*-acetyl xanthate **6** should add to the enone in **5**, and the resulting adduct radical **17a** should undergo ring closure and transfer of the xanthate group to finally give bicyclic structure **19** via intermediate radical **18a**. We hoped that the smaller methyl group would occupy the more congested endo face, resulting in the correct relative stereochemistry found in hirsutic acid, in preference to the alternative conformation shown as **17b**, which would lead to the epimeric cyclized radical **18b**. Reductive removal of the xanthate group and base-induced Robinson-type annelation would deliver ultimately tricyclic enone **4**, thus completing the formal synthesis of both complicatic and hirsutic acids.

Unfortunately, our attempts to add *S*-acetyl xanthate **6** to enone **5** met with failure. This contrasts with the successful addition of *S*-butanoyl xanthate to an enone we achieved a few years ago.[21] We also failed to accomplish an addition of *S*-acetyl xanthate **6** to allyl acetate **16**. *S*-Acyl xanthates are rather labile substances: a small quantity of a nucleophilic impurity can cause complete decomposition by an ionic chain process.[20a] This lability is more pronounced in the smaller members of the family.

Faced with these unexpected setbacks, we slightly modified our approach by replacing the *S*-acetyl xanthate **6** with acetoxy xanthate **20a**. This xanthate is readily prepared by displacement of chloride from 1-acetoxy-1-chloroethane, a known compound[22] obtained by reaction of acetaldehyde with acetyl chloride in the presence of catalytic zinc chloride (Scheme 5). However, the addition of xanthate **20a** to enone **5** again surprisingly gave a complex mixture from which the desired bicyclic structure could not be isolated. In contrast, the reaction with allylic alcohol **15** proceeded as expected to furnish bicyclic derivative **21**, as a complex mixture of diastereoisomers **21a**, which were not further purified. Reductive elimination of the xanthate with triethylammonium hypophosphite,[23] saponification of the acetate group with sodium methylate, and oxidation of both alcohol groups with pyridinium chlorochromate (PCC) gave a 1:4 mixture of two epimeric diketones (**22** and **23**) in 42% overall yield from alcohol **15**. Unfortunately, the major epimer had the wrong relative stereochemistry. The ratio of the two epimers **22** and **23** could be improved to 1:2 by using xanthate **20b**, where the acetate group was replaced with the bulkier benzoate. The overall yield of the epimeric mixture of **22** and **23** for the four steps from allylic alcohol **15** remained roughly the same (24%–41%).

Both bicyclic diketones are known compounds, and the correct epimer **22** has indeed been converted into hirsutic acid by base-induced cyclisation into Matsumoto's intermediate

Scheme 5. Final steps in the formal synthesis of (±)-hirsutic acid.

4.[6] This completes a short, formal total synthesis of both (±)-complicatic acid and (±)-hirsutic acid. While the key radical cascade finally succeeded, it is still very far from perfect. The crude model for the ring closure displayed in Scheme 4 clearly does not reflect reality. The cyclization leads to what appears as the slightly more congested and unwanted isomer. More effort is therefore needed to establish the best combination of xanthate and allylic alcohol **15** or a derivative thereof that ultimately leads to the greatest ratio in favour of the desired epimer **22**. Some progress was made using benzoate **20b**, and this could perhaps be improved further. Placing a bulky group on the allylic alcohol in **15** could also be used to modify the stereoselectivity. Indeed, a preliminary small-scale experiment using benzoate **24** in combination with xanthate **20b** resulted in an approximately 2:3 ratio of the desired[22] over the undesired, [23] but this has to be confirmed on a larger scale, and this would also provide a reliable value for the yield. Nevertheless, despite these various shortcomings, the present route to hirsutic acid is significantly shorter than most of the earlier syntheses. More generally, it illustrates the potential of xanthate chemistry for the construction of polyquinanes through the combination of the radical process with the powerful Claisen rearrangement. Finally, this synthesis could be easily made enantioselective since allylic alcohol **7** has already been prepared in enantiopure form by Kato et al.[14] The methylation of ketoester **8** could also be performed in an enantioselective manner by the use of a chiral base or through the use of chiral imines or hydrazones, allowing the control of the absolute stereochemistry at the very beginning of the synthesis.

Abstract: Several C-1 homologues of pancratistatin and 7-deoxypancratistatin were synthesized by a phenanthrene–phenathridone oxidative recyclization strategy. The key steps involved the enzymatic dihydroxylation of bromobenzene, addition of an aryl alane to an epoxyaziridine, an intramolecular aziridine opening on silica gel in solid phase, and the above-mentioned recylization strategy. Experimental and spectral data are reported for all new compounds. All synthesized C-1 homologues of pancratistatin and 7-deoxypancratistatin were evaluated for antiproliferative activity in a panel of human cancer cell lines. As expected, the 7-hydroxy compounds were found to be more potent and the activity of the C-1 benzoxymethyl analogue exceeded that of narciclasine, which was used as a positive control.

Key words: C-1 homologues of pancratistatin, amaryllidaceae alkaloids, anticancer activities, intramolecular aziridine opening, solid-phase silica catalysis.

Résumé : On a réalisé la synthèse de plusieurs homologues en C-1 de la pancratistatine et de la 7-désoxypencratistatine en faisant appel à une stratégie de recyclisation oxydante phenantrène–phénathridone. Les étapes clés impliquent la dihydroxylation du bromobenzène, l'addition d'une arylalane à une époxyaziridine, une ouverture intramoléculaire d'aziridine sur gel de silice en phase solide et la stratégie de recyclisation mentionnée plus haut. Les données expérimentales et spectrales sont rapportées pour tous les nouveaux produits. Tous les homologues en C-1 de la pancratistatine et de la 7-désoxypencratistatine ont été évalués pour leur activité à contrer la prolifération dans un éventail de lignées de cellules cancéreuses humaines. Tel que prévu, les composés 7-hydroxy sont les plus puissants alors que l'activité de l'analogue C-1 benzoxyméthyle est supérieure à celle de la narciclasine qui a été utilisée comme contrôle positif.

Mots-clés : analogues en C-1 de la pancratistatine, alcaloïdes des amaryllidacées, activité anticancéreuse, ouverture intramoléculaire d'aziridine, catalyse par le gel de silice en phase solide.

[Traduit par la Rédaction]

Introduction

Pancratistatin (**1**), narciclasine (**2**), and other Amaryllidaceae constituents, Fig. 1, continue to attract attention on account of their promising anticancer properties. Since the isolation of pancratistatin in 1984 by Pettit et al.[1] and its preliminary evaluation as a potent antitumor agent, many creative syntheses of **1** and its congeners have been reported.[2] The activity concerning the total synthesis of these constituents continues unabated to the present day.[3] More recently, however, the studies of these natural products have shifted toward the investigation of unnatural derivatives that would offer the potential of better bioavailability than the rather insoluble natural products. In the last two decades, many reports have appeared describing the synthesis and evaluation of truncated derivatives from the groups of Pettit,[4] McNulty,[5] Kornienko,[6] Chapleur,[7] Alonso,[8] Marion,[9] Banwell,[10] and Gonzalez.[11] Truncated derivatives of the core of these constituents as well as various heteroatom analogues have been reported and some of these compounds displayed various levels of biological activity, usually of lower potency than the natural products. The only exceptions were compounds that contained a large lipophilic fragment in position C-1. The first example of such an analogue was the benzoate ester of the C-1 hydroxyl of pancratistatin, prepared and tested by Pettit et al.,[4c] which displayed nanomolar activity. Later, a library of C-1 nitrogenated derivatives prepared by Marion et al.[9] showed the highest activity with substituents such as benzamide.

Scheme 1.

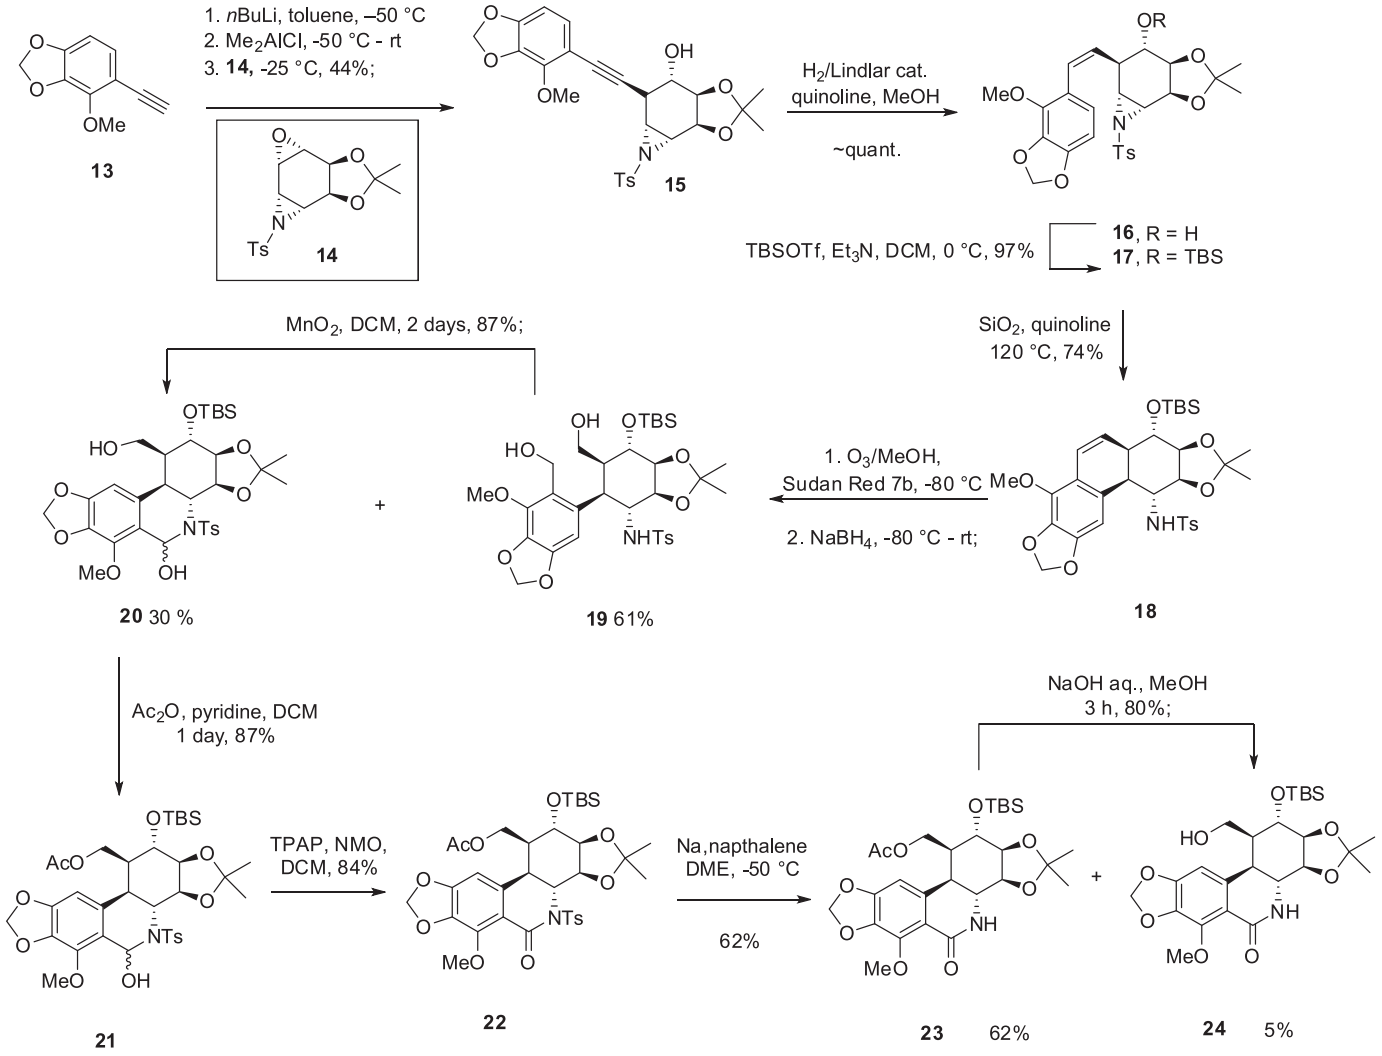
In our group, we have been investigating various truncated derivatives of pancratistatin, and 7-deoxypancratistatin,[12] as well as derivatives with variations of functionality at the aromatic core,[13] including an indole mimic of 7-deoxypancratistatin.[14] More recently, and inspired by Pettit's report of the C-1 benzoate ester,[4c] we investigated carbon homologues of 7-deoxypancratistatin at position C-1 and found that the hydroxymethyl and acetoxymethyl derivatives (**5** and **6**, respectively) were reasonably active.[3a] 7-Deoxypancratistatin is far less active than pancratistatin as it lacks the 7-OH functionality and we reasoned that the C-1 homologues of **1** might approach the activity of the natural products. Indeed, this was shown to be the case and homologues **7** and **8** showed nanomolar activities in preliminary screening.[15] In this paper, we report the full details of the synthesis of these compounds, the synthesis of the C-1 benzoxymethyl analogue, as well as the complete details of the biological evaluation in several cell lines.

Results and discussion

The strategy for the synthesis of C-1 homologues followed the previously disclosed approach in which a C-1 aldehyde possessing the full pancratistatin core is generated by the oxidative cleavage–recyclization in a phenanthrene–phenanthridol transformation.[16] To adjust this protocol to the synthesis of the pancratistatin core, the hydroxy aldehyde **10**, prepared from piperonal by a known method,[17] was chosen as the starting material.

As shown in Scheme 1, compound **10** was methylated to **11**[18] and converted via the Corey–Fuchs reaction to acetylene **13**.

The alane generated from **13** was reacted with epoxyaziridine **14**,[19] which was prepared in five steps from bromobenzene via enzymatic dihydroxylation, the Yamada aziridination protocol, dehalogenation, and epoxidation. Addition of the epoxyaziridine **14** to the alane gave acetylene **15**, which was subjected to reduction conditions. The best results for selective alkyne–alkene reduction were obtained using a short time for the hydrogenation (1–1.5 h) under Lindlar's conditions with 1 atm (1 atm = 101.325 kPa) of hydrogen to provide the *cis*-olefin **16**. Different catalysts and conditions led to significant over-reduction of **15**. The intramolecular aziridine opening was accomplished by heating the *tert*-butyldimethylsilyl triflate (TBS)-protected ether **17** adsorbed on silica gel according to a solid-phase protocol developed in our laboratory for an aziridine opening of this type.[14–16] It is worth mentioning that the addition of 10% *w*/*w* quinoline to the substrate during the solid-phase cyclization helps to suppress the decomposition of material and improves the yield of this reaction from 45% to 74%, probably because of the decreased acidity of the silica gel.



The product of the silica-catalyzed cyclization, phenanthrene **18**, was subjected to several different sets of oxidative protocols. The originally disclosed conditions,[16] which included OsO_4/$NaIO_4$-promoted oxidation–recyclization, did not lead to the desired product. This was probably the result of an increased steric hindrance by the methoxy group in the environment of the double bond (this interaction was absent in the cyclization of the precursor to 7-deoxypancratistatin). Instead, a different protocol was developed, which included selective ozonolysis of the double bond in the presence of azo dye Sudan Red 7B to help prevent oxidation of the electron-rich aromatic ring. Reductive workup of the ozonide with sodium borohydride led to a mixture of diol **19** and hemiaminal **20**. The former compound was subjected to selective oxidation of the benzylic alcohol by MnO_2, generating the intermediate aldehyde, which, after in situ cyclization, produced compound **20**.

The primary alcohol in **20** was selectively acetylated by stirring with acetic anhydride in pyridine–dichloromethane. Several different oxidation conditions were attempted to transform the hemiaminal moiety to the phenathridone amide, including pyridinium dichromate (PDC), pyridinium chlorochromate (PCC), *o*-iodoxybenzoic acid (IBX), Dess–Martin, and tetrapropylammonium perruthenate / *N*-methylmorpholine-*N*-oxide (TPAP/NMO). Of these, only the latter conditions led to the desired product; all other conditions led to the decomposition of the starting material. Detosylation with Na/naphthalene in 1,2-dimethoxyethane (DME) provided compound **23** with traces of alcohol **24** (Scheme 2).

The O-demethylation of **23** was performed by freshly fused LiCl in dry dimethylformamide (DMF).[20] Alternative

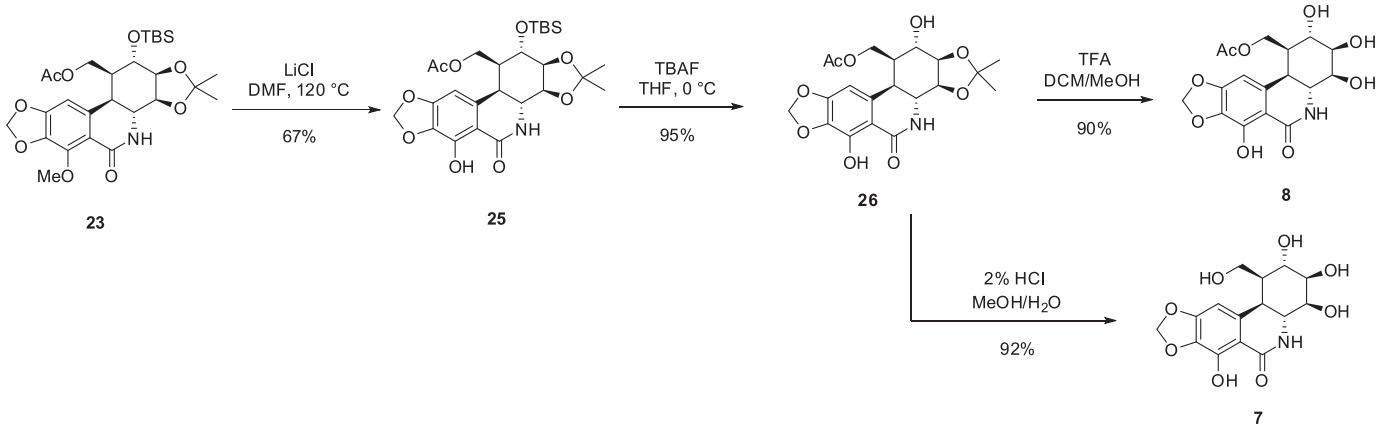
Scheme 2.

protocols of demethylation such as BBr_3[21] or sodium dodecathiolate[22] did not lead to product. In the first case, overdeprotection of the acetonide and the methylenedioxo groups was observed. In the second case, the reaction did not proceed at all. Desilylation led to compound **25**, which can be selectively deprotected to provide either acetoxymethyl derivative **8** or hydroxymethyl analogue **7** (Scheme 3).

To provide access to the benzoate derivative **9**, a point of diversion in synthesis was chosen to be compound **23**, which possesses all the required functionality and is prone to basic hydrolysis. Benzoylation of alcohol **24** provided access to compound **27**, which was subjected to the deprotection protocol to furnish the C-1 benzoxymethyl derivative **9** (Scheme 4).



Evaluation of biological activities

The hydroxymethyl, acetoxymethyl, and benzoxymethyl analogues (**7**, **8**, and **9**, respectively), together with their 7-deoxy counterparts (**5** and **6**), were evaluated in a small panel of cancer cell lines diversely representing several types of human malignancy (Table 1). As expected, the 7-hydroxy compounds were found to be more potent, again underscoring the beneficial effect of the 7-hydroxy substituent. For example, both **7** and **8** were about 10 times more potent than their 7-deoxy analogues (**5** and **6**) against the prostate DU-145 cells, and this 10-fold difference in activity is similar to that between **1** and **3**.[2a,13b] In addition, the double-digit nanomolar potency of the acetoxymethyl analogue (**8**) is noteworthy and it approaches that of narciclasine, which was used as a reference compound. The most encouraging activity was found, however, with the benzoxymethyl compound (**9**). It is three to five times more potent than narciclasine against the pancreatic BXPC-3 and prostate DU-145 cancer cells, while showing a similar magnitude of effect toward the other two cell lines used. This finding is consistent with the previous observations of the beneficial effects imparted by large hydrophobic C-1 substituents as was reported by Pettit et al.[4c] for the C1-benzoate derivative of pancratistatin. The benzoate moiety could be part of the cytotoxic pharmacophore or it could merely assist the parent hydroxyl compound in cell penetration and then undergo intracellular hydrolytic removal to its hydroxy analogue (**7**). Further studies are required to provide a satisfactory answer to this important question.

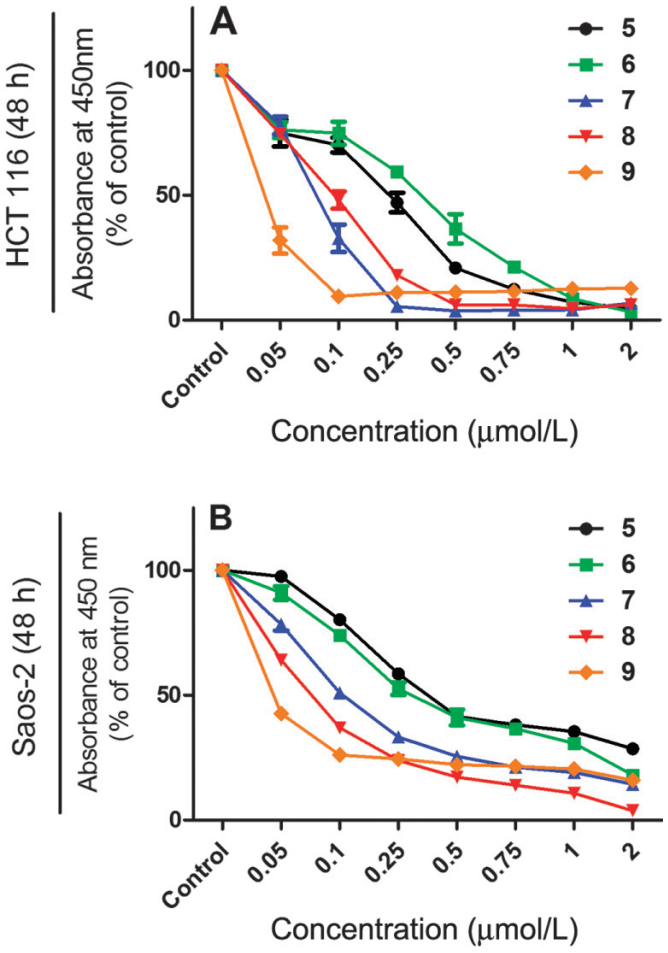
Scheme 3.

Scheme 4.

As pancratistatin was previously found to be effective in selectively producing cytotoxicity in an array of cancers, we additionally evaluated the activity of **5**–**9** in the colorectal cancer cell line HCT 116 and in the osteosarcoma cell line Saos-2 with the water soluble tetrazolium salt (WST-1)-based colorimetric assay for cell viability. After 48 h of treatment, all of these pancratistatin analogues decreased cell viability in a dose-dependent manner. The benzoate ester analogue (**9**) demonstrated the greatest anticancer activity at lower concentrations and had half-maximal inhibitory concentration (IC_{50}) values below 0.05 μmol/L after 48 h in both HCT 116 and Saos-2 cells (Figs. 2A and 2B, respectively); however, its effectiveness plateaus at 0.1 μmol/L, after which **7** becomes more effective against HCT 116 cells and **8** becomes more effective against Saos-2 cells.

The effect of pancratistatin analogues on cellular viability of colorectal cancer and osteosarcoma cells was determined by the WST-1-based colorimetric assay. HCT 116 and Saos-2 cells (Figs. 2A and 2B, respectively) were treated with pancratistatin analogues for 48 h and the WST-1 reagent was used to quantify cell viability. Absorbance was read at 450 nm and expressed as a percentage of the control (Me_2SO). Values are expressed as the mean ± SD from quadruplicates of three independent experiments.

Conclusions



Three new C-1 homologues of pancratistatin have been synthesized and tested in various cancer cell lines. The results were compared with the two previously tested C-1 homologues of 7-deoxypancratistatin. The newly synthesized C-1 homologues manifested nanomolar antiproliferative activities against a panel of human cancer cell lines similar to the parent natural products. The benzoxymethyl compound (**9**), however, exhibited the most encouraging activity, which was three to five times more potent than that of narciclasine against the pancreatic BXPC-3 and prostate DU-145 cancer cells. The various C-1 analogues screened in this study have very high cytoxicity at low concentrations in a variety of aggressive cancer cells. We observed remarkable enhancement of cytotoxicity in compounds containing the hydroxyl group at C-7 and the benzoate ester at C-1 in human colorectal cancer and osteosarcoma. These novel analogues may hold the potential to be very effective anticancer therapeutic agents.

Table 1. Activity of C-1 analogues with narciclasine as a standard (IC_{50}, μmol/L).

Cancer type	Cell line	Structure narciclasine **2**	**5**	**6**	**7**	**8**	**9**
Pancreatic	BxPC-3	0.05±0.01	0.77±0.01	0.34±0.05	0.22±0.01	0.07±0.01	0.01±0.00

Note: The half-maximal inhibitory concentration (IC_{50}) is the concentration required to reduce the viability of cells by 50%, after 48 h of treatment with indicated compounds, relative to the dimethyl sulfoxide (DMSO) control; ±standard deviation (SD) from two independent experiments, each performed in four replicates, determined by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay.

Fig. 2. Pancratistatin analogues cause cytotoxicity in cancer cells in a dose-dependent manner.

Experimental section

General

Reactions were carried out under inert atmosphere in oven-dried glassware unless stated otherwise. LiCl was fused under vacuum immediately before use. Solvents were distilled: CH_2Cl_2, DMF, *i*-Pr_2NEt, and pyridine from CaH_2, MeOH from magnesium methoxide, tetrahydrofuran (THF) and DME from Na/benzophenone, toluene from Na, and quinoline from Zn. Qualitative thin-layer chromatography (TLC) was done with precoated silica gel aluminum sheets (EMD silica gel 60 F_{254}) with detection by UV or by spraying with a cerium ammonium molybdate (CAM) solution (5 g of $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$, 1 g of $Ce(SO_4)_2$, and 100 mL of 10% H_2SO_4) or a 0.5% aqueous $KMnO_4$ solution followed by heating. Melting points are uncorrected. Flash chromatography was performed using silica gel SiliaFlash P60 from Silicycle (40–66 μm). Optical rotation was measured in a 1 dm cell at 20–25 °C and 589 nm with a concentration (*c*) in g/100 mL. IR spectra were recorded in KBr pellets or as a thin film. ^1H and ^{13}C NMR spectra were recorded at 300 or 600 MHz and 75 or 150 MHz, respectively, and were calibrated on the solvent residual peak or tetramethylsilane (TMS) signal ($CDCl_3$, 7.28 ppm; DMSO-d_6, 2.51 ppm); the chemical shifts are reported in ppm. Copies of ^1H and ^{13}C NMR spectra for compounds **7**–**9**, **12**, **13**, and **15**–**29**) are available in the Supplementary data.

4-Methoxy-1,3-benzodioxole-5-carbaldehyde (11)

Dimethyl sulfate (22.7 mL, 240 mmol) was added to a mixture of K_2CO_3 (55.2 g, 400 mmol) and phenol **10** (made from piperonal by literature procedure;[17] 33.2 g, 200 mmol) in acetone (260 mL). The reaction was stirred under reflux until consumption of the starting material was observed (TLC, approximately 4 h). Then the reaction mixture was cooled and inorganic salts were removed by filtration and rinsed with acetone (2 × 100 mL). The solution was evaporated, redissolved in CH_2Cl_2, and washed sequentially with a 10% solution of NaOH, water, and saturated solution of NaCl. The organic solution was then dried over anhydrous Na_2SO_4 and evaporated to obtain compound **11** (30.2 g, 84%) as pale brown crystals, which was used without further purification; mp 102–104 °C (EtOH) (lit.[18] mp 103–105 °C (EtOH)). R_f = 0.65 (hexanes/EtOAc, 9:1). ^1H NMR ($CDCl_3$, 300 MHz) δ: 10.24 (s, 1H), 7.49 (d, *J* = 8.3 Hz, 1H), 6.62 (d, *J* = 8.3 Hz, 1H), 6.05 (s, 2H), 4.14 (s, 3H).

5-(2,2-Dibromovinyl)-4-methoxy-1,3-benzodioxole (12)

Triphenylphosphine (64.0 g, 244 mmol) in CH_2Cl_2 (100 mL) was added dropwise to a stirring solution of CBr_4 (40.5 g, 122 mmol) in CH_2Cl_2 (150 mL) at 0 °C (ice bath). After 15 min of stirring, a solution of aldehyde (**11**; 11.0 g,

For personal use only.

61.0 mmol) in CH_2Cl_2 (50 mL) was added dropwise. Upon completion, the reaction was reduced in volume to 100 mL and slowly poured into vigorously stirred hexanes (1400 mL). The mixture was then filtered through a short plug of silica, washed with a mixture of hexanes/EtOAc (10:1, 200 mL), and evaporated. Subjection of this material to flash column chromatography (eluent hexanes/EtOAc, 9:1) and concentration of the relevant fractions gave **12** (16.11 g, 78.6%) as a white solid; mp 38–40 °C (pentane). R_f = 0.9 (hexanes/EtOAc, 9:1). IR (KBr, cm^{-1}) ν: 3448, 2981, 2948, 2934, 2900, 2876, 2838, 2770, 1625, 1605, 1471, 1427, 1384, 1350, 1265, 1213, 1126, 1072, 1045, 979, 960, 939, 929, 848, 829, 788, 767, 729, 644. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.49 (s, 1H), 7.24 (d, J = 8.3 Hz, 1H), 6.57 (d, J = 8.3 Hz, 1H), 5.96 (s, 2H), 4.02 (s, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 149.7, 141.1, 136.1, 132.3, 122.5, 121.4, 102.3, 101.2, 89.0, 59.9. MS (+EI) m/z (%): 338 ([^{81}Br + ^{81}Br, M]$^+$, 49), 336 ([^{81}Br + ^{79}Br, M]$^+$, 100), 334 ([^{79}Br + ^{79}Br, M$^+$], 51), 242 (55), 240 (57), 176 (53), 175 (42), 131 (29). HR-MS (+EI) calcd for $C_{10}H_8Br_2O_3$: 333.8820; found: 333.8845. Anal. calcd for $C_{10}H_8Br_2O_3$: C 35.75, H 2.40; found: C 35.99, H 2.41.

5-Ethynyl-4-methoxy-1,3-benzodioxole (13)

To a solution of **12** (19.38 g, 57.68 mmol) in THF (350 mL) was added a solution of *n*-BuLi (52.9 mL, 2.5 mol/L, and 130 mmol) at –78 °C. After 20 min of stirring at –78 °C, the reaction mixture was warmed to room temperature over a period of 2 h. A saturated solution of NH_4Cl (40 mL) was poured into the reaction mixture, which was later extracted by CH_2Cl_2 (3 × 50 mL). The combined organic phases were dried over Na_2SO_4, filtered, and evaporated. The crude compound was purified by flash chromatography (hexanes/EtOAc 2:1) and white crystals of acetylene **13** were obtained (8.5 g, 81.7%); mp 77–78 °C (pentane). R_f = 0.9 (hexanes/EtOAc, 2:1). IR (KBr, cm^{-1}) ν: 3278, 3254, 3000, 2945, 2901, 2846, 2794, 2097 (weak), 1620, 1600, 1469, 1433, 1336, 1267, 1229, 1077, 1043, 979, 950, 930, 797. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.01 (d, J = 7.9 Hz, 1H), 6.50 (d, J = 8.29 Hz, 1H), 5.98 (s, 2H), 4.11 (s, 3H), 3.20 (s, 1H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 150.1, 144.8, 136.2, 128.0, 108.1, 102.9, 101.3, 79.9, 79.4, 60.0. MS (+EI) m/z (%): 176 ([M]$^+$, 100), 175 (29), 131 (16), 53 (18). HR-MS (+EI) calcd for $C_{10}H_8O_3$: 176.0473; found: 176.0475. Anal. calcd for $C_{10}H_8O_3$: C 68.18, H 4.58; found: C 68.27, H 4.55.

(3a*S*,4*R*,5*R*,6*R*,7*S*,7a*R*)-6-[(4-Methoxy-1,3-benzodioxol-5-yl)ethynyl]-2,2-dimethyl-8-[(4-methylphenyl)sulfonyl] hexahydro-4,5-epimino-1,3-benzodioxol-7-ol (15)

To a solution of alkyne **13** (1.580 g, 8.95 mmol) in toluene (30 mL) at –50 °C, *n*-BuLi (3.80 mL, 2.35 mol/L, and 8.95 mmol) was added dropwise. After 15 min of stirring, Me_2AlCl (9.0 mL, 1.0 mol/L, and 8.95 mmol) was added dropwise. The reaction mixture was warmed to 0 °C within 1 h and stirred for an additional 40 min at 0 °C. The reaction mixture was allowed to warm to room temperature and stirred for 40 min. The reaction mixture was cooled to –30 °C and a solution of epoxide **14** (1.510 g, 4.47 mmol) in toluene (20 mL) was added dropwise. The reaction mixture was stirred for 1 h and was allowed to warm to room temperature overnight. The reaction mixture was cooled to 0 °C by ice bath and quenched with 1 N HCl (1 mL), followed by ice-cold water (1 mL) and 1 N HCl (2 mL). The reaction mixture was filtered through a plug of Celite and extracted with EtOAc (3 × 20 mL). The combined organic phases were dried over Na_2SO_4, filtered, and evaporated. The crude product was purified by column chromatography (gradient hexanes/EtOAc 5:1 to 3:1) to give the product as colourless oil (1.02 g, 44%). Repetition of this procedure on a 4.12 g scale of **13** provided **15** in a 38% yield. $[\alpha]_D^{24}$ +78.4 (*c* 1.0, $CHCl_3$). R_f = 0.3 (hexanes/EtOAc, 2:1). IR (film, cm^{-1}) ν: 3482, 3093, 2986, 2935, 2900, 1620, 1599, 1470, 1434, 1404, 1383, 1332, 1307, 1260, 1225, 1186, 1183, 1071, 985. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.83 (d, J = 8.3 Hz, 2H), 7.39 (d, J = 8.3 Hz, 2H), 6.88 (d, J = 8.1 Hz, 1H), 6.47 (d, J = 8.3 Hz, 1H), 5.96 (s, 2H), 4.48 (d, J = 6.2 Hz, 1H), 4.19 (t, J = 5.7 Hz, 1H), 4.06 (s, 3H), 3.98–3.95 (m, 1H), 3.44–3.41 (m, 1H), 3.26 (d, J = 6.8 Hz, 1H), 3.24 (dd, J = 5.0, 2.1 Hz, 1H), 3.08 (d, J = 8.7 Hz, 1H), 2.48 (s, 3H), 1.51 (s, 3H), 1.34 (s, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 149.7, 145.4, 144.4, 136.3, 134.1, 130.1, 127.9, 127.2, 110.1, 108.8, 102.8, 101.3, 87.6, 80.5, 75.5, 70.3, 69.0, 60.0, 42.3, 40.2, 31.9, 27.3, 25.1, 21.7. Cell culture

The human non-small cell lung cancer line, NCI-H460 (American Type Culture Collection (ATCC) No. HTB-177), and human pancreatic adenocarcinoma cancer cell line, BxPC-3 (ATCC No. CRL-1687,) were cultured in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS) (GIBCO BRL Carlsbad, California), 100 mg/L penicillin G, and 100 mg/L streptomycin (Cellgro, Manassas, Virginia). Human prostate carcinoma cells, DU-145 (ATCC No. HTB-81), were cultured in Dulbecco's modified Eagle's medium (Cellgro) supplemented with 10% FBS, 100 mg/L penicillin G, and 100 mg/L streptomycin. Human mammary carcinoma cells, MCF-7 (ATCC No. HTB-22), were cultured using Dulbecco's modified Eagle's medium supplemented with 10% FBS, 100 mg/L penicillin G, 100 mg/L streptomycin, 1.0 mmol/L GlutaMAX, and 1.0 mmol/L sodium pyruvate (Gibco).

MTT assay

To evaluate the cytotoxic effects of the C-1 homologues of pancratistatin, mitochondrial dehydrogenase activities were measured. Briefly, BxPC-3, NCI-H460, DU-145, and MCF-7 lines were assessed by seeding 4×10^3 cells/well into microplates. The cells were grown for 24 h before treatment at concentrations ranging from 0.001 to 10 μmol/L and incubated for 48 h. MTT reagent (5 mg/mL, MP Biomedical, Solon, Ohio) was added to each well and incubated further for 2 h. The resulting formazan crystals were dissolved in DMSO and the optical density (OD) was determined at a wavelength of 490 nm. The experiments were repeated at least twice for each compound per cell line. Cells treated with 0.1% DMSO and narciclasine were used as negative and positive controls, respectively.

Cell culture

The human colorectal cancer cell line HCT 116 (ATCC, Cat. No. CCL-247, Manassas, Virginia) was grown and cultured with McCoy's mMedium 5a (Gibco BRL, VWR, Mississauga, Ontario) supplemented with 2 mmol/L L-glutamine, 10% FBS, and 10 mg/mL gentamicin (Gibco BRL, VWR). A human osterosarcoma cell line, Saos-2 (ATCC, Cat. No. HTB-85, Manassas, Virginia), was grown in McCoy's 5A mMedium Modified (Sigma-Aldrich Canada, Mississauga, Ontario) supplemented with 15% (*v*/*v*) FBS (Thermo Scientific, Waltham, Massachusetts) and 10 mg/mL gentamicin (Gibco BRL, VWR). All cells were grown at 37 °C and 5% CO_2.

WST-1 assay for cell viability

The WST-1-based colorimetric assay was conducted as per the manufacturer's protocol (Roche Applied Science, Indianapolis, Indiana) to determine cell viability as a function of active cell metabolism. Ninty-six well, clear bottom tissue culture plates were seeded with approximately 2.0×10^3 HCT 116 cells/well or 6.0×10^3 Saos-2 cells/well, and treated with various compounds at the indicated concentrations and durations. Following treatment, the WST-1 reagent was added to each well and incubated for 4 h at 37 °C. Absorbance readings were taken at 450 nm on a Wallac Victor^3 1420 multilabel counter (PerkinElmer, Woodbridge, Ontario) and were expressed as percentages of the solvent control group (Me_2SO).

Supplementary data

Supplementary data (copies of ^1H and ^{13}C NMR spectra for compounds **7**–**9**, **12**, **13**, and **15**–**29**) are available with the article through the journal Web site at http://nrcresearchpress.com/doi/suppl/10.1139/v2012-073.

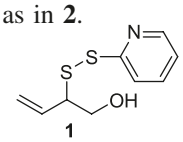
2-(Selenocyanatomethyl)-2-propenol — A convenient synthon for ligation via the deselenative allylic rearrangement of allyl selenosulfides: preparation, functional group compatibility, and application

David Lachkar, Caroline Boudet, Xavier Guinchard, and David Crich

Abstract: The preparation and reactions of 2-(selenocyanatomethyl)-2-propenol are described and reveal the compatibility of the allylic selenocyanate group with a range of mild oxidizing and Lewis acidic conditions. 2-(Selenocyanatomethyl)-2-propenol and its derivatives are employed in the functionalization of simple and amino acid derived thiols in methanolic solution at room temperature to give 2-(hydroxymethyl)allyl sulfides in good to excellent yield.

Key words: selenocyanates, selenosulfides, selenosulfoxides, ligation.

Résumé : Nous décrivons la préparation et les réactions de dérivatisation du 2-(sélénocyanatométhyl)-prop-2-énol, montrant ainsi la compatibilité fonctionnelle du groupement sélénocyanate allylique envers les réactions en conditions oxydantes et en présence d'acides de Lewis. Cet alcool et ses dérivés fonctionnalisés ont été engagés dans des réactions de fonctionnalisation de thiols à température ambiante dans des conditions douces pour conduire à des sulfures de 2-(hydroxyméthyl)allyle avec de bons rendements.



Mots-clés : sélénocyanates, sélénosulfures, sélénosulfoxydes, ligature.

Introduction

Organoselenium chemistry is a major component of the organic chemist's toolbox,[1] and the organoselenocyanates are some of the most readily available and versatile of the chalcogenide-based reagents. For our part, we have developed the use of allylic seleno Bunte salts and allylic selenocyanates as convenient precursors to the allyl selenosulfides, substrates for dechalcogenative rearrangement to allyl alkyl sulfides (Scheme 1),[2] and as our contribution to the burgeoning field[3] of chemical ligation. In continuation of this program we required a minimal hydroxyl-substituted allylic selenocyanate to serve as a handle for introduction of the allylic selenocyanate group into a range substrates. We report here on the synthesis of 2-(selenocyanatomethyl)allyl alcohol for this purpose, on functional group compatibility of the selenocyanate moiety, and on its incorporation into various substrates.

In earlier work on the desulfurative allylic rearrangement of allyl alkyl disulfides, we developed 2-(2-pyridyldithio)-3-propenol (**1**) or its analogs as precursors to the necessary allyl alkyl disulfides,[2b,4] but were foiled in many of our attempts to derivatize the hydroxyl group by the relative sensitivity of the allylic disulfide functionality.[5] For this reason, we turned to the allylic selenocyanates[6] with the expectation of greater stability to a number of derivatization reactions.[2b] To avoid possible problems arising from facile 1,3-sigmatropic rearrangement of disymmetric allylic selenocyanates, we targeted systems in which such rearrangements would have a degenerate nature, namely, those based on methallyl selenocyanate substituted at the 2 postion as in **2**.

1

2

We focused on 2-(selenocyanatomethyl)-3-propenol (**6**), as the smallest possible alcohol derived from methallyl selenocyanate. To this end, *p*-methoxybenzyl alcohol was alkylated with methallyl chloride to give the ether[7] **3**, which was converted with sulfuryl chloride into the known[8] methallyl chloride **4** in 29% yield (Scheme 2). Reaction with potassium

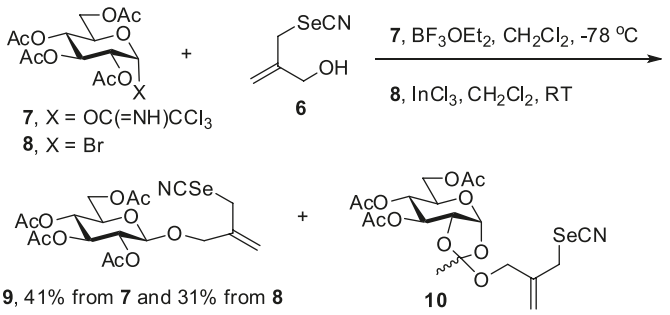
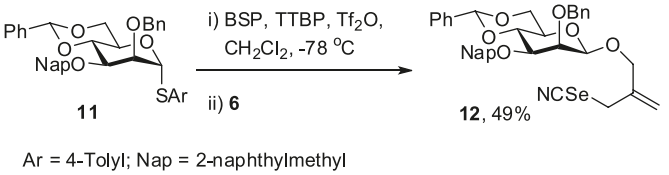
Scheme 2. Preparation of 2-(selenocyanatomethyl)-3-propenol.



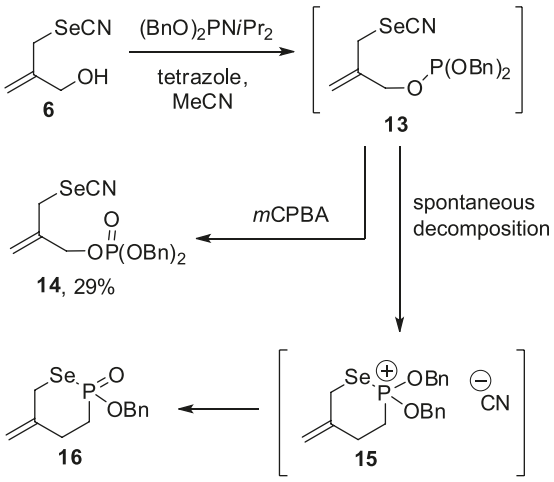
selenocyanate in DMF then afforded the selenocyanate **5** in 81% yield. Exposure to 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in wet dichloromethane finally gave the desired alcohol **6** in 74% yield and demonstrated the stability of the allylic selenocyanate functionality to the mild oxidative conditions used for removal of the *p*-methoxybenzyl ether (Scheme 2).

With **6** in hand we turned to its application as a glycosyl acceptor. Activation of tetraacetyl-α-glucopyranosyl trichloroacetimidate[9] (**7**) in the presence of **6** with BF_3 etherate afforded the desired β-glycoside **9** in 41% yield (Scheme 3) typically accompanied by the orthoester products **10**. Orthoesters of this general type are typical byproducts in neighboring group participation directed glycosylation reactions and are particularly problematic when the acceptor is a primary alcohol.[10] When acetobromoglucose **8** was employed as donor and indium trichloride[11] as promotor the glycoside **9** was obtained in 31% yield, but attempts at activation of **8** with more typical silver-based reagents resulted only in the formation of decomposition products. While the yields from these glycosylations are only moderate, they are nevertheless instructive as they demonstrate the stability of the allylic selenocyanate functionality toward selected Lewis acidic conditions.



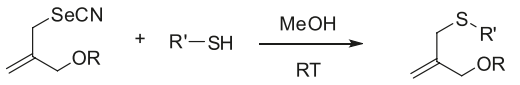
In a second glycosylation reaction, donor **11** was coupled to **6** using the 1-benzenesulfinylpiperidine (BSP) / trifluoromethanesulfonic anhydride conditions[12] in the presence of the hindered base 2,4,6-tri-*tert*-butylpyrimidine (TTBP)[13] (Scheme 4). Glycoside **12** was obtained as a single isomer in 49% yield.

Encouraged by these results, we investigated the compatibility of **6** with typical conditions for phosphitylation such as would be necessary for incorporation into nucleotides.[14] Thus, **6** was allowed to react with dibenzyl *N*,*N*-di(isopropyl)phosphoramidite in the presence of tetrazole as promoter, to give a presumed intermediate phosphite **13**, followed by exposure to *m*-CPBA as oxidant (Scheme 5). Unfortunately, complex reaction mixtures were obtained under all reaction conditions investigated from which the anticipated phosphate **14** could only be isolated in modest yield. A cyclic byproduct **16** was obtained in varying quantities from all reaction mixtures and affords a possible explanation for the complexity: Arbuzov-type reaction initiated by intramolecular attack of the first formed phosphite on the electron-deficient selenocyanate.

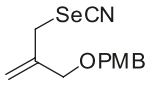


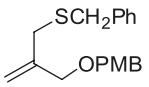
Scheme 3. Formation of 2-(selenocyanatomethyl)allyl tetraacetyl-α-D-glucopyranoside (**9**).

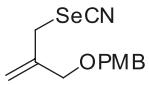
Scheme 4. Formation of 2-(selenocyanatomethyl)allyl β-D-mannopyranoside (**12**).

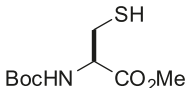


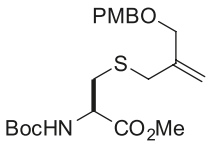
Scheme 5. Reaction of **6** with a phosphoramidite.

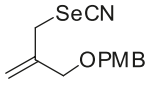


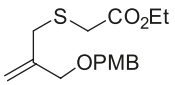


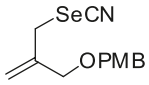


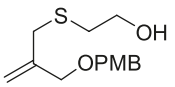


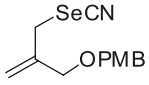


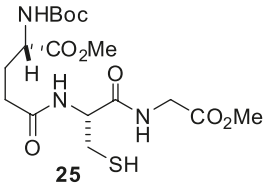


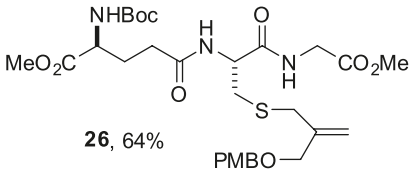


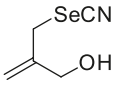


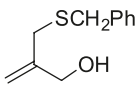


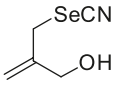


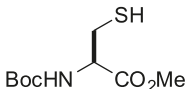


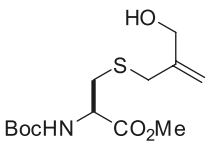


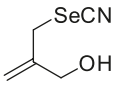


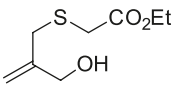


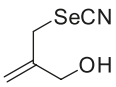


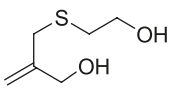












Finally, attention was turned to the ligation reaction. Thus, selenocyanates **5**, **6**, **9**, and **12** were allowed to react with a variety of aliphatic thiols in methanol at room temperature under an argon atmosphere. After stirring overnight, and filtration to remove precipitated selenium, chromatography on silica gel afforded the coupled products with the yields set out in Table 1.

In an attempt to probe the mechanism of the ligation reaction, we monitored the reaction of selenocyanate **6** with benzylmercaptan in deuteriomethanol at room temperature by ^1H and ^{77}Se NMR spectroscopy (Figs. 1 and 2). In the ^1H NMR spectrum a slight upfield shift of the signals attributed to **6** is observed on addition of the thiol, followed by the formation of a set of new signals assigned to the intermediate selenosulfide. This substance is then transformed rapidly and cleanly into the final product (**18**). The kinetics of the reaction are such

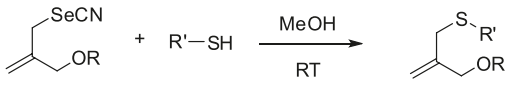


Table 1. Ligation of **6** and its derivatives with assorted thiols.

Table 1 (*concluded*).

Entry	Substrate	Thiol	Product, yield
10	 **6**	 **25**	 **31**, 80%
11	 **9**	 **25**	 **32**, 61%
12	 **12**	 **25**	 **33**, 63%
13	 **12**	 **19**	 **34**, 57%

that the onset of the formation of **18** is seen before the complete conversion of **6** to the selenosulfide intermediate. A set of minor signals attributable neither to the selenosulfide nor to the final product, and which are lost by the end of the reaction, may represent the selenosulfoxide intermediate, a functional group that to date has not been described in the literature. To probe this possibility further, we turned to ^{77}Se NMR spectroscopy. The rapid transformation of **6** to the selenosulfide is clearly seen, with its disappearance later as the reaction proceeds to completion. A minor unidentified signal is formed over the course of the reaction at δ 500 but, as this signal persists at the end of the reaction, it cannot be the selenosulfoxide intermediate and must represent a minor selenium-containing byproduct. Unfortunately, selenosulfoxides, like their thiosulfoxide cousins,[2] must retain their status as hypothetical reaction intermediates for the present.

In conclusion, 2-(selenocyanatomethyl)-3-propenol (**6**) is a readily prepared functionalized allylic selenocyanate whose alcohol moiety may be derivatized by glycosylation under standard conditions without detriment to the selenium functionality. Attempted derivation of **6** as a phosphite ester was, however, mostly unsatisfactory because of the apparent incompatibility of the selenocyanate group with a strong intramolecular nucleophile. Alcohol **6** itself and its derivatives react with a variety of thiols in methanolic solution at room temperature to give the corresponding mixed dialkyl sulfides with the corresponding loss of selenium. Finally, compatibility of the selenocyanate functionality with oxidative removal of a *p*-methoxybenzyl ether and Lewis and (or) Brønsted acidic conditions of glycosylation reactions has been demonstrated.

ternal solvent signal. ^{77}Se NMR chemical shifts are given in ppm with respect to dimethylselenide with the aid of referencing to the internal solvent signal. Multiplicities are given as follows: s (singlet), br s (broad singlet), d (doublet), t (triplet), q (quadruplet), dd (doublet of doublet), dt (doublet of triplet), and m (multiplet). Coupling constants (*J*) are given in Hz. Infrared spectra were recorded on a PerkinElmer FT-IR instrument and the data are reported in reciprocal centimetres (cm^{-1}). Mass spectra were recorded on a Micromass LCT (ESI). Reactions were performed using oven-dried $MgSO_4$ glassware under an atmosphere of dry argon. TLC plates (Merck 60 F_{254} aluminum sheets) were visualized by UV and (or) spraying with vanillin (1%) + sulfuric acid (5%) in EtOH followed by heating. THF and CH_2Cl_2 were dried by standing over molecular sieves under argon. Unless otherwise noted, all reagent-grade chemicals and solvents were obtained from commercial suppliers and were used as received. Specific rotations are expressed in deg cm^3 g^{-1} dm^{-1} and *c* is expressed in g/100 cm^3.

2-(Chloromethyl)allyl *p*-methoxybenzyl ether (4)

p-Methoxybenzyl methallyl ether (**3**)[7] (9.2 mmol, 1.77 g) in CH_2Cl_2 (100 mL) was treated with $LiClO_4$ (1.8 mmol, 0.2 g) and pyridine (11. mmol, 0.89 mL) and cooled to –78 °C before SO_2Cl_2 (11.0 mmol, 0.89 mL) was added. After 1 h at 0 °C, the reaction mixture was quenched with saturated aqueous $NaHCO_3$, extracted with CH_2Cl_2, and washed with brine. The combined organic layers were dried over $MgSO_4$, filtered, and evaporated in vacuo. The crude product was purified by chromatography over silica gel (eluent, MTBE/Hept 5:95) to give **4** (0.60 g, 29%) whose spectral data correspond to those reported in the literature.[8]

2-(Selenocyanatomethyl)allyl *p*-methoxybenzyl ether (5)

KSeCN (11.8 mmol, 1.7 g) was added to a solution of **4** (5.9 mmol, 1.34 g) in DMF (24 mL) and the solution was stirred at 40 °C for 3 h. Water was added and the solution was extracted twice with MTBE. The combined organic layers were dried over $MgSO_4$, filtered and evaporated in vacuo. The crude product was purified by chromatography on silica gel (eluent, AcOEt/Hept 1:3) to give **5** (1.41 g, 81%) as a yellow oil. IR (neat, cm^{-1}): 817, 921, 1031, 1077, 1174, 1246, 1302, 1514, 1610, 2148, 2836. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 3.78 (s, 2H), 3.83 (s, 3H), 4.12 (s, 2H), 4.46 (s, 2H), 5.27 (s, 1H), 5.33 (s, 1H), 6.91 (d, J = 8.2 Hz, 2H), 7.28 (d, J = 7.9 Hz, 2H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 31.9 (CH_2), 55.4 (CH_3), 70.8 (CH_2), 72.3 (CH_2), 102.4 (CN), 114.1 (2 CH), 118.6 (CH_2),[3] 129.7 (2 CH), 129.8 (Cq), 140.5 (Cq), 159.6 (Cq). HRMS (ESI) calcd for $C_{13}H_{19}N_2O_2Se$: 315.0606; found: 315.0634 $[M + NH_4]^+$.

2-(Selenocyanatomethyl)prop-2-en-1-ol (6)

Water (330 μL) and DDQ (1.1 mmol, 230 mg) were added to a solution of **10** (0.68 mmol, 200 mg) in CH_2Cl_2 (6.6 mL) and the resulting solution was stirred for 3 h. It was quenched with an aqueous saturated solution of $NaHCO_3$, extracted with CH_2Cl_2, and washed with brine. The combined organic layers were dried over $MgSO_4$, filtered, and evaporated in vacuo. The crude product was purified by chromatography on silica gel (eluent, AcOEt/Hept 1:1) to give **6** (87.6 mg, 74%) as a yellow oil. IR (neat, cm^{-1}): 727, 915, 1022, 1054, 1197, 1366, 1426, 1646, 1738, 2150, 2923, 3394. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.6–2.8 (br s, OH), 3.79 (s, 2H), 4.25 (s, 2H), 5.26 (s, 1H), 5.27 (s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 31.5 (CH_2), 63.9 (CH_2), 102.6 (CN), 117.1 (CH_2), 142.8 (Cq). ^{77}Se NMR (95.4 MHz, $CDCl_3$) δ: 251.8. HRMS (ESI) calcd for C_5H_6NOSe: 176.9693; found: 175.9606 $[M - H]^-$.

2-(Selenocyanatomethyl)allyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (9)

***From trichloroacetimidate* 7**

A solution of **6** (0.28 mmol, 50 mg) in CH_2Cl_2 (1 mL) and 4 Å molecular sieves was stirred 30 min at room temperature and then cooled at –78 °C. $BF_3.OEt_2$ (0.16 mmol, 20 μL) and **7** (0.71 mmol, 350 mg) were added and the solution was stirred at 0 °C for 2 h 30 min. The reaction mixture was then quenched with NEt_3, filtered, and evaporated in vacuo. The crude product was purified by chromatography on silica gel (eluent, AcOEt/Hept 1:1) to give **9** (58.3 mg, 41%) as a colorless oil.

***From bromide* 8**

Compound **6** (0.28 mmol, 50 mg) was added to CH_2Cl_2 (2 mL) and 4 Å molecular sieves. The solution was stirred for 30 min at room temperature and the donor **8** was added (0.381 mmol, 140 mg). $InCl_3$ (0.14 mmol, 31.4 mg) was then added and the solution was stirred for 3 days at room temperature. The reaction mixture was diluted in CH_2Cl_2 and filtered through a Celite pad. The filtrate was evaporated in vacuo and the crude product was purified by chromatography on silica gel (eluent, AcOEt/Hept 1:1) to give **14** (45.1 mg, 31%) as a colorless oil. $[\alpha]_D^{25}$ –15.4 (*c* 0.54, $CHCl_3$). IR (neat, cm^{-1}): 697, 907, 1367, 1431, 1744, 2153, 2940. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.98 (s, 3H), 2.00 (s, 3H), 2.03 (s, 3H), 2.07 (s, 3H), 3.64–3.77 (m, 3H), 4.13–4.23 (m, 3H), 4.41 (d, J = 12.3 Hz, 1H), 4.53 (d, J = 7.9 Hz), 4.98 (dd, J = 7.9, 9.7 Hz, 1H), 5.06 (t, J = 9.7 Hz, 1H), 5.18 (t, J = 9.5 Hz, 1H), 5.23 (s, 1H), 5.29 (s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 20.6 (2 CH_3), 20.7 (CH_3), 20.8 (CH_3), 31.3 (CH_2), 61.8 (CH_2), 68.3 (CH), 71.2 (CH), 72.0 (CH), 72.7 (CH), 69.9 (CH_2), 100.0 (CH), 101.6 (CN), 119.1 (CH_2), 139.3 (Cq), 169.3 (CO), 169.4 (CO), 170.2 (CO), 170.6 (CO). ^{77}Se NMR (95.4 MHz, $CDCl_3$) δ: 248.0. HRMS (ESI) calcd for $C_{19}H_{29}N_2O_{10}Se$: 525.0982; found: 525.1033 $[M + NH_4]^+$.

4-Methylphenyl 2-*O*-benzyl-4,6-*O*-benzylidene-3-*O*-(2-naphthalenylmethyl)-α-D-thiomannopyranoside (11)

A mixture of (4-methylphenyl) 4,6-*O*-benzylidene-β-D-thiomannopyranoside (2.4 mmol, 900 mg) and *n*-Bu_2SnO (2.9 mmol, 722 mg), in dry toluene (25 mL), was refluxed overnight. The resulting solution was cooled at room temperature and then concentrated under reduced pressure. The residue was dissolved in dry DMF (10 mL) and then CsF (4.8 mmol, 730 mg) and NAPBr (3.6 mmol, 780 mg) were added. The resulting mixture was stirred 6 h at room temperature, diluted with CH_2Cl_2, and filtered through Celite. The filtrate was concentrated under reduced pressure. The residue was dissolved in dry DMF (10 mL), cooled at 0 °C, and NaH (4.8 mmol, 231 mg) was added. After 10 min of stirring, BnBr (4.8 mmol, 570 μL) was added. The resulting mixture was stirred overnight at room temperature, quenched with an aqueous saturated $NaHCO_3$ solution, and extracted twice with CH_2Cl_2. The combined organic layer was brine, dried ($MgSO_4$), and concentrated under reduced pressure. The crude product was purified by chromatography on silica gel (eluent, 10% *t*-BuOMe

in heptane) to give 4-methylphenyl 2-*O*-benzyl-4,6-*O*-benzylidene-3-*O*-(2-naphthalenylmethyl)-α-D-thiomannopyranoside (**11**, 1.32 g, 91%) as a clear viscous oil. $[\alpha]^{22}_D$ +102.2 (*c* 1.0, $CHCl_3$). ^1H NMR (500 MHz, $CDCl_3$) δ: 2.32 (s, 3H), 3.89 (t, *J* = 10.0 Hz, 1H), 4.02–4.07 (m, 2H), 4.23 (dd, *J* = 10.0 Hz, *J* = 4.5 Hz, 1H), 4.26–4.37 (m, 2H), 4.72 (d, *J* = 13.5 Hz, 1H), 4.75 (d, *J* = 13.5 Hz, 1H), 4.81 (d, *J* = 12.5 Hz, 1H), 4.94 (d, *J* = 12.5 Hz, 1H), 5.44 (s, 1H), 5.64 (s, 1H), 7.08 (d, *J* = 7.5 Hz, 2H), 7.29–7.48 (m, 10H), 7.52–7.55 (m, 2H), 7.70–7.73 (m, 1H), 7.78–7.83 (m, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 65.4, 68.5, 72.9, 73.0, 76.2, 77.8, 79.0, 87.3, 101.5, 125.6, 125.8, 126.0, 126.1, 126.1, 126.2, 127.6, 127.8, 127.9, 128.0, 128.1, 128.4, 128.8, 129.8, 129.9, 132.2, 132.9, 133.6, 135.8, 137.6, 137.7, 137.9. HRMS (ESI) calcd for $C_{38}H_{36}O_5S$: 622.2627; found: 622.2641 $[M + NH_4]^+$.

2-(Selenocyanatomethyl)allyl 2-*O*-benzyl-4,6-*O*-benzylidene-3-*O*-(2-naphthylmethyl)-β-D-mannopyranoside (12)

A stirred solution of thioglycoside **11** (0.54 mmol, 330 mg), TTBP (1.0 mmol, 248 mg), BSP (0.6 mmol, 119 mg) in CH_2Cl_2 (10 mL) was cooled to –78 °C and treated with Tf_2O (0.6 mmol, 96 μL). The resulting solution was stirred for 1 h before addition of a solution of **6** (0.63 mmol, 110 mg) in CH_2Cl_2 (2 mL). After stirring for 1 h at –78 °C, the reaction mixture was quenched with saturated aqueous $NaHCO_3$, warmed to room temperature and extracted twice with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$, filtered, and evaporated in vacuo and the residue was purified by chromatography on silica gel (eluent, XXXX 1:4) to give **12** (172 mg, 49%) as a colorless oil. $[\alpha]_D^{23}$ –31.2 (*c* 0.92, $CHCl_3$). IR (neat, cm^{-1}): 1086, 1377, 1454, 2149, 2874, 3047. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.34–3.42 (m, 1H), 3.60–3.75 (m, 3H), 3.94–4.02 (m, 2H), 4.2 (d, *J* = 12.5 Hz, 1H), 4.29 (t, *J* = 9.6 Hz, 1H), 4.34–4.38 (m, 1H), 4.51 (s, 2H), 4.81–4.86 (m, 1H), 4.90–5.02 (m, 3H), 5.28 (s, 1H), 5.33 (s, 1H), 5.69 (s, 1H), 7.31–7.90 (m, 17H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 31.7, 67.9, 68.7, 70.3, 72.8, 75.1, 76.2, 78.1, 78.8, 101.4, 101.8, 119.2, 125.8, 126.1, 126.3, 126.6, 127.9, 128.1, 128.3, 128.4, 128.8, 129.1, 133.2, 133.4, 135.9, 137.7, 138.5, 139.8. ^{77}Se NMR (95.4 MHz, $CDCl_3$) δ: 247.4. HRMS (ESI) calcd for $C_{36}H_{39}N_2O_6Se$: 675.1968; found: 675.1996 $[M + NH_4]^+$.

Dibenzyl 2-(selenocyanatomethyl)allyl phosphate (14)

A stirred solution of **6** (0.28 mmol, 50 mg) in CH_3CN (2.64 mL) was cooled to 0 °C and treated with 1*H*-tetrazole (0.77 mmol, 53.6 mg). Dibenzyl-*N*,*N*-diisopropyl phosphoramidite (0.57 mmol, 187 μL) was then added and the resulting solution was stirred for 1 h. *m*-CPBA (0.99 mmol, 171 mg) was then added and, after 10 min, the reaction mixture was quenched with water. The solution was extracted with CH_2Cl_2 and the combined organic layers were dried over $MgSO_4$, filtered, and evaporated in vacuo. The crude product was purified by chromatography on silica gel (eluent, AcOEt/Hept 1:1) to give **14** (35.5 mg, 29%) as a colorless oil. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.56 (s, 2H), 4.52 (s, 1H), 4.53 (s, 1H), 4.99–5.09 (m, 4H), 5.20 (s, 1H), 5.27 (s, 1H), 7.32–7.35 (m, 8H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 31.1, 67.7, 67.8, 69.8, 69.9, 120.5, 128.3, 128.9, 129.0, 129.7. ^{31}P NMR (75.5 MHz, $CDCl_3$) δ: –0.43. HRMS (ESI) calcd for $C_{19}H_{24}N_2O_4P^{77}Se$: 455.0633; Found: 455.0643 $[M + NH_4]^+$.

2-(Benzyloxy)-5-methylene-1,3,2-oxaselenaphosphinane 2-oxide (16)

This compound, a colorless oil, was obtained in varying amounts from different preparations of **14**. IR (neat, cm^{-1}): 672, 697, 741, 789, 976, 1008, 1261, 1456. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.30–3.38 (m, 1H), 3.54–3.60 (m, 1H), 4.68–4.78 (m, 2H), 5.11–5.22 (m, 4H), 7.32–7.44 (m, 5H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 24.9, 68.9, 74.6, 74.7, 117.8, 128.4, 128.9, 135.5, 136.9. ^{31}P NMR (75.5 MHz, $CDCl_3$) δ: 8.07. ^{77}Se NMR (95.4 MHz, $CDCl_3$) δ: 208.8; 213.7. HRMS (ESI) calcd for $C_{11}H_{14}O_3PSe$: 304.9846; found: 304.9933 $[M + H]^+$.

General procedure for ligation

To freshly prepared selenocyanate **5** or **6** (1 mmol) in degassed MeOH (10 mL) under an argon atmosphere was added a solution of thiol (1.2 mmol) in MeOH (5 mL). The reaction mixture was stirred at room temperature overnight and filtered through a Celite pad, which was further rinsed with MeOH. The solvent was evaporated to dryness and the residue was purified by column chromatography.

2-(Benzylthiomethyl)allyl *p*-methoxybenzyl ether (18)

Prepared according to the general procedure, by reaction of **5** (1.01 mmol, 300 mg) with benzylmercaptan **17** (1.21 mmol, 143 μL), affording **18** (241 mg, 76%) as a colorless oil. IR (neat, cm^{-1}): 702, 819, 910, 1034, 1087, 1302, 1453, 1512, 1612, 2835. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.11 (s, 2H), 3.63 (s, 2H), 3.80 (s, 3H), 4.07 (s, 2H), 4.43 (s, 2H), 5.05 (s, 1H), 5.19 (s, 1H), 6.86–6.90 (m, 2H), 7.24–7.30 (m, 7H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 34.3 (CH_2), 35.6 (CH_2), 55.5 (CH_3), 71.1 (CH_2), 72.1 (CH_2), 114.0 (2 CH), 115.1 (CH_2), 127.1, 128.7, 129.3 (5 CH), 129.5, 129.6 (2 CH), 130.5 (Cq), 138.4 (Cq), 141.9 (Cq), 159.4 (Cq). HRMS (ESI) calcd for $C_{19}H_{26}NO_2S$: 332.1679; found: 332.1670 $[M + NH_4]^+$.

N-(*tert*-Butoxycarbonyl) *S*-(*p*-methoxybenzyloxymethyl)allyl L-cysteine methyl ester (20)

Prepared according to the general procedure, by reaction of **5** (1.01 mmol, 300 mg) with the L-cysteine derivative **19** (1.26 mmol, 209 μL), affording **20** (356 mg, 83%) as a colorless oil. $[\alpha]_D^{25}$ +8.5 (*c* 0.66, $CHCl_3$). IR (neat, cm^{-1}): 819, 915, 1034, 1246, 1366, 1513, 1613, 1713, 1746, 2976, 3359. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.45 (s, 9H), 2.78–2.93 (m, 2H), 3.16–3.26 (m, 2H), 3.75 (3H, CH_3), 3.80 (3H, CH_3), 4.05 (s, 2H), 4.44 (s, 2H, CH_2), 4.51–4.54 (br s, 1H), 5.08 (s, 1H), 5.18 (s, 1H), 5.29–5.34 (br s, 1H), 6.88 (d, *J* = 8.5 Hz, 2H), 7.26 (d, *J* = 8.7 Hz, 2H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 14.2 (CH_3), 28.5 (3 CH_3), 33.6 (CH_2), 35.4 (CH_2), 52.7 (CH), 55.5 (CH_3), 70.6 (CH_2), 72.1 (CH_2), 114.0 (2 CH), 115.9 (CH_2), 129.6 (2 CH), 130.4 (Cq), 141.6 (Cq), 159.4 (Cq), 171.8 (CO). HRMS (ESI) calcd for $C_{21}H_{34}N_2O_6S$: 425.1872; found: 426.1928 $[M + NH_4]^+$.

Ethyl 2-(*p*-methoxybenzyloxymethyl)allylthioacetate (22)

Prepared according to the general procedure, by reaction of **5** (0.17 mmol, 50 mg) with ethyl thioglycolate (**21**, 0.20 mmol, 24.4 mg), affording **22** (48.3 mg, 92%) as a colorless oil. IR (neat, cm^{-1}): 818, 911, 1034, 1090, 1171, 1246, 1512, 1609, 1724, 2936. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.30 (t, *J* = 7.0 Hz, 3H), 3.15 (s, 2H), 3.35 (s, 2H), 3.83 (s, 3H), 4.09 (s, 2H), 4.20 (q, *J* = 7.1 Hz, 2H), 4.46 (s, 2H), 5.13 (s, 1H), 5.23 (s, 1H), 6.90 (d, *J* = 8.6 Hz, 2H), 7.29 (d, *J* = 8.2 Hz, 2H). ^{13}C NMR (75.5 MHz,

For personal use only.

$CDCl_3$) δ: = 32.2, 34.9, 41.5, 55.3, 61.3, 61.7, 71.9, 113.8, 115.9, 129.1, 129.4, 130.3, 140.8, 159.2, 170.4. HRMS (ESI) calcd for $C_{16}H_{26}NO_4S$: 328.1577; found: 328.1557 $[M + NH_4]^+$.

_p_-Methoxybenzyl 2-(2-hydroxyethyl)thiomethyl ether (24)

Prepared according to the general procedure, by reaction of **5** (0.14 mmol, 40 mg) with 2-mercaptoethanol (**23**, 0.16 mmol, 13.0 mg), affording **24** (23.1 mg, 57%) as a colorless oil. IR (neat, cm^{-1}): 712, 760, 818, 915, 1033, 1066, 1173, 1301, 1511, 1612, 1647, 2835, 2912, 3399. ^1H NMR (500 MHz, $CDCl_3$) δ: 2.68 (t, J = 5.8 Hz, 2H), 3.25 (s, 2H), 3.72 (t, J = 5.8 Hz, 2H), 3.83 (s, 3H), 4.10 (s, 2H), 4.47 (s, 2H), 5.01 (s, 1H), 5.13 (s, 1H), 6.91 (d, J = 8.5 Hz, 2H), 7.29 (d, J = 8.2 Hz, 2H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 34.2, 34.3, 35.3, 60.1, 70.6, 71.9, 113.8, 115.4, 129.4, 144.8, 156.3. HRMS (ESI) calcd for $C_{14}H_{20}O_3S$: 268.1133; found: 269.1215 $[M + H]^+$.

_N_-(*tert*-Butoxycarbonyl) _S_-(_p_-methoxybenzyloxymethyl)allyl glutathione dimethyl ester (26)

Prepared according to the general procedure, by reaction of **5** (0.10 mmol, 30 mg) with the glutathione derivative **25** (0.12 mmol, 59.7 mg), affording **26** (40.6 mg, 64%) as a colorless oil. $[\alpha]_D^{25}$ +0.5 (_c_ 0.98, $CHCl_3$). IR (neat, cm^{-1}): 735, 1031, 1169, 1207, 1246, 1512, 1646, 1706, 1742, 2952, 3301. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.45 (s, 9H), 1.98 (m, 1H), 2.15 (m, 1H), 2.87 (m, 2H), 3.29 (s, 2H), 3.75 (s, 3H), 3.76 (s, 3H), 3.82 (s, 3H), 4.07 (s, 2H), 4.14 (s, 2H), 4.45 (s, 1H), 5.21 (m, 1H), 5.37 (m, 1H), 6.89 (d, J = 8.5 Hz, 2H), 7.28 (d, J = 8.5 Hz, 2H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 28.3 (3 CH_3), 28.7 (CH_2), 32.9 (CH_2), 34.9 (CH_2), 41.3 (CH_2), 52.4, 55.3, 70.7 (CH_2), 71.9 (CH_2), 113.8, 116.2 (2 CH), 129.5 (2 CH), 141.5 (Cq), 154.2 (Cq), 155.5 (Cq), 170.1 (Cq), 172.2 (Cq), 173.0 (Cq). HRMS (ESI) calcd for $C_{29}H_{44}N_3O_{10}S$: 626.2669; found: 626.2769 $[M + H]^+$.

2-(Benzylthiomethyl)prop-2-en-1-ol (27)

Prepared according to the general procedure, by reaction of **6** (0.57 mmol, 100 mg) with benzyl mercaptan **17** (0.68 mmol, 80 μL), affording **27** (94.5 mg, 86%) as a colorless oil. IR (neat, cm^{-1}): 756, 907, 1028, 1232, 1453, 1494, 2916, 3347. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.06 (s, 2H), 3.58 (s, 2H), 4.15 (s, 2H), 4.92 (s, 1H), 5.12 (s, 1H), 7.17–7.27 (m, 5H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 34.2 (CH_2), 35.4 (CH_2), 64.6 (CH_2), 113.7 (CH_2), 127.1, 128.6, 129.2 (5 CH), 138.1 (Cq), 144.2 (Cq). HRMS (ESI) calcd for $C_{11}H_{18}NOS$: 212.1104; found: 211.0785 $[M + NH_4]^+$.

_N_-(*tert*-Butoxycarbonyl) _S_-(hydroxymethyl)allyl L-cysteine methyl ester (28)

Prepared according to the general procedure, by reaction of **6** (0.57 mmol, 100 mg) with the L-cysteine derivative **19** (0.68 mmol, 160.4 mg), affording **28** (90.3 mg, 52%) as a colorless oil. $[\alpha]_D^{26}$ +8.5 (_c_ 0.55, $CHCl_3$). IR (neat, cm^{-1}): 913, 1055, 1217, 1367, 1437, 1513, 1698, 2978, 3374. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.42 (s, 9H), 2.00 (s, 2H), 3.20 (s, 2H), 3.73 (s, 3H), 4.11–4.22 (m, 2H), 4.49–4.54 (br s, 1H), 5.01 (s, 1H), 5.16 (s, 1H) 5.26–5.31 (br s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 14.3 (CH_3), 28.5 (3 CH_3), 34.1(CH_2), 35.4 (CH_2), 52.8 (CH), 64.1 (CH_2), 114.2 (CH_2), 144.3 (Cq), 171.8 (CO). HRMS (ESI) calcd for $C_{13}H_{27}N_2O_5S$: 328.1635; found: 328.1184 $[M + NH_4]^+$.

Ethyl 2-(hydroxybenzyloxymethyl)allylthioacetate (29)

Prepared according to the general procedure, by reaction of **6** (0.57 mmol, 100 mg) with ethyl thioglycolate **21** (0.68 mmol, 75 μL), affording **29** (61.8 mg, 57%) as a colorless oil. IR (neat, cm^{-1}): 757, 908, 1125, 1155, 1271, 1367, 1410, 1650, 1725, 2982, 3428. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.24 (t, J = 7.1 Hz, 3H), 2.16 (br s, 1H), 3.11(s, 2H), 3.28 (s, 2H), 4.05–4.17 (m, 4H), 5.10 (s, 1H), 5.16 (s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 14.3, 21.2, 32.4, 35.1, 60.6, 61.6, 64.2, 114.6, 143.5, 170.7. HRMS (ESI) calcd for $C_8H_{18}NO_3S$: 208.1002; found: 213.0549 $[M + NH_4]^+$.

2-(2-Hydroxyethylthiomethyl)prop-2-en-1-ol (30)

Prepared according to the general procedure, by reaction of **6** (0.13 mmol, 22 mg) with 2-mercaptoethanol **23** (0.14 mmol, 10.7 mg), affording **30** (16.8 mg, 91%) as a colorless oil. IR (neat, cm^{-1}): 695, 820, 1062, 1104, 1254, 1314, 1520, 1605, 3420. ^1H NMR (500 MHz, MeOD) δ: 2.70 (t, J = 6.0 Hz, 2H), 3.27 (s, 2H), 3.75 (t, J = 5.9 Hz, 2H), 4.26 (s, 2H), 5.07 (s, 1H), 5.18 (s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 34.1, 34.3, 60.3, 64.3, 114.1, 145.6.

_N_-(*tert*-Butoxycarbonyl) _S_-(hydroxymethyl)allyl glutathione dimethyl ester (31)

Prepared according to the general procedure, by reaction of **6** (0.28 mmol, 50 mg) with the glutathione derivative **25** (0.35 mmol, 154.7 mg), affording **31** (115.1 mg, 80%) as a colorless oil. $[\alpha]_D^{24}$ +2.4 (_c_ 0.92, $CHCl_3$). IR (neat, cm^{-1}): 733, 1028, 1052, 1207, 1365, 1435, 1516, 1645, 1688, 1742, 2980, 3293. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.44 (s, 9H), 1.98 (m, 1H), 2.18 (m, 1H), 2.38 (m, 2H), 2.88 (m, 1H), 2.93 (m, 2H), 3.33 (dd, J = 13.7 Hz, J = 20.2 Hz, 2H), 3.76 (s, 6H), 4.23 (s, 2H), 4.40 (s large, 1H), 4.68 (q, J = 6.9 Hz, 1H), 5.15 (s, 1H), 5.22 (s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 25.6 (CH_2), 28.5 (3 CH_3), 32.3 (CH_2), 34.4 (CH_2), 41.3 (CH_2), 52.4 (2 CH_3), 53.0 (CH), 64.0 (CH), 68.0 (CH_2), 80.3 (Cq), 114.3 (CH_2), 144.40 (Cq), 155.70 (NH–C=O), 169.95 ((C=O)O–Me), 170.13 ((C=O)NH), 172.47 (C=O), 172.93 (C=O). HRMS (ESI) calcd for $C_{21}H_{36}N_3O_9S$: 506.2094; found: 506.2159 $[M + H]^+$.

_N_-(*tert*-Butoxycarbonyl) _S_-[(2,3,4,6-tetra-_O_-acetyl-β-D-glucopyranosyl)methyl]allyl glutathione dimethyl ester (32)

Prepared according to the general procedure, by reaction of the glucose derivative **9** (0.04 mmol, 21.7 mg) with the glutathione derivative **25** (0.05 mmol, 23.3 mg) in CH_3CN, affording **32** (21.9 mg, 61%) as a colorless oil. $[\alpha]_D^{25}$ –5.6 (_c_ 0.82, $CHCl_3$). IR (neat, cm^{-1}): 910, 1040, 1167, 1367, 1437, 1518, 1660, 1747, 2932, 2953, 3313. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.43 (s, 9H), 2.00 (s, 3H), 2.03 (s, 3H), 2.05 (s, 3H), 2.10 (s, 3H), 2.31–2.41 (m, 2H), 2.75–2.89 (m, 2H), 3.22 (s, 2H), 3.75 (s, 3H), 3.76 (s, 3H), 4.05 (m, 2H), 4.17–4.19 (m, 1H), 4.21–4.26 (m, 1H), 4.33–4.42 (m, 2H), 4.54–4.63 (m, 2H), 4.98–5.14 (m, 2H), 5.14–5.26 (m, 3H), 5.29–5.36 (m, 1H), 6.72–6.82 (br s, 1H), 7.01–7.08 (br s, 1H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 20.8, 20.9, 21.0, 28.5, 29.9, 32.3, 32.8, 34.8, 41.5, 52.5, 52.6, 52.7, 52.9, 62.1, 68.7, 70.2, 71.5, 72.0, 73.0, 100.1, 116.8, 140.3, 169.6, 170.1, 170.5, 170.7, 172.3, 173.0. HRMS (ESI) calcd for $C_{35}H_{57}N_4O_{18}S$: 853.3383; found: 853.3362 $[M + NH_4]^+$.

_N_-(*tert*-Butoxycarbonyl) _S_-[(2-_O_-benzyl-4,6-_O_-benzylidene-3-_O_-(2-naphthylmethyl)-β-D-mannopyranosyl)methyl]allyl glutathione dimethyl ester (33)

Prepared according to the general procedure, by reaction of the mannose derivative **12** (0.18 mmol, 120 mg) with the glutathione derivative **25** (0.24 mmol, 105 mg), affording **33** (113 mg, 63%) as a colorless oil. $[\alpha]_D^{26}$ –13.4 (*c* 1.40, $CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.43 (s, 9H), 1.86–2.00 (br s, 1H), 2.04 (s, 2H), 2.10–2.25 (br s, 1H), 2.28–2.38 (m, 1H), 2.76–2.92 (m, 2H), 3.23 (s, 1H), 3.63–3.68 (m, 1H), 3.72 (s, 6H), 3.88–4.03 (m, 4H), 4.06–4.17 (m, 2H), 4.24 (t, J = 9.6 Hz, 1H), 4.28–4.43 (m, 2H), 4.44–4.65 (m, 3H), 4.76–4.82 (m, 2H), 4.89–5.00 (m, 1H), 4.83–5.05 (m, 1H), 5.15–5.21 (m, 2H), 5.27–5.34 (br s, 1H), 5.65 (s, 1H), 6.69–6.81(br s, 1H), 6.97–7.07 (br s, 1H), 7.21–7.93 (m, 17H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 14.4, 28.5, 32.4, 35.0, 41.5, 52.6, 60.6, 67.9, 68.7, 70.5, 72.5, 75.1, 76.0, 78.0, 78.8, 101.7, 116.4, 125.8, 126.0, 126.2, 126.3, 126.5, 127.9, 128.1, 128.3, 128.4, 128.9, 129.1, 133.1, 133.4, 135.9, 137.9, 138.5, 140.6, 170.1, 170.8, 172.3, 173.0.

_N_-(*tert*-Butoxycarbonyl) _S_-[(2-_O_-benzyl-4,6-_O_-benzylidene-3-_O_-(2-naphthylmethyl)-β-D-mannopyranosyl)methyl]allyl L-cysteine methyl ester (34)

Prepared according to the general procedure, by reaction of the mannose derivative **12** (0.18 mmol, 127 mg) with the L-cysteine derivative **19** (0.23 mmol, 51.3 mg), affording **34** (79.6 mg, 57%) as a colorless oil. $[\alpha]_D^{20}$ –20.1 (*c* 0.45, $CHCl_3$). IR (neat, cm^{-1}): 698, 730, 817, 857, 908, 1049, 1165, 1368, 1453, 1496, 1602, 1709, 2872, 2924. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.44 (s, 9H), 2.76–2.92 (m, 2H), 3.17 (s, 1H), 3.26–3.37 (m, 1H), 3.60–3.65 (m, 1H), 3.92–3.95 (m, 2H), 4.03–4.12 (m, 1H), 4.18–4.34 (m, 2H), 4.39–4.51 (m, 2H), 4.68–4.84 (q, J = 10.5 Hz, 2H), 4.87 (d, J = 12.3 Hz, 1H), 4.99 (d, J = 12. 3 Hz, 1H), 5.08 (s, 1H), 5.16 (s, 1H), 5.39 (br s, 1H), 5.63 (s, 1H), 7.24–7.81 (m, 17H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 28.5, 29.9, 33.2, 35.2, 67.8, 68.8, 70.3, 72.5, 75.0, 75.9, 78.0, 78.8, 101.5, 101.7, 116.2, 125.8, 126.0, 126.2, 126.3, 126.4, 127.8, 128.1, 128.2, 128.4, 128.8, 129.1, 133.1, 133.4, 135.9, 137.8, 138.5, 140.5. HRMS (ESI) calcd for $C_{43}H_{53}N_2O_{10}S$: 789.3415; found: 789.3381 $[M + NH_4]^+$.

Monitoring of the reaction of 6 with benzylmercaptan by ^{1}H and ^{77}Se NMR spectroscopy

The reaction of **6** (0.23 mmol, 40 mg) with benzyl mercaptan (0.27 mmol, 34 mg) in CD_3OD (1 mL) was monitored by NMR spectroscopy through an iterative sequence of ^{1}H spectra (64 scans, 500 MHz, 300 K), ^{77}Se NMR spectra (64 scans, 95 MHz, 300 K), and DEPT ^{77}Se spectra (32 scans, 95 MHz, 300 K). Acquisition parameters for F1: size, 32 768 points; spectral width, 47 619 Hz).

Acknowledgments

We thank J.-F. Gallard and S. Picard, Institut de Chimie des Substances Naturelles (ICSN), for help with the recording of ^{77}Se NMR spectra and for the gift of **11**, respectively.

A versatile method for the synthesis of γ-pyrones

Garrison E. Beye, Athanasios Karagiannis, Alieh Kazemeini, and Dale E. Ward

Abstract: A versatile three-step procedure to annulate a γ-pyrone onto a methylene ketone was developed involving (*i*) aldol reaction with a dithiolane-protected β-ketoaldehyde, (*ii*) oxidation of the aldol adduct to a β-diketone, and (*iii*) treatment of the resulting dithiolane-protected 1,3,5-trione with 2-iodoxybenzoic acid (IBX) and trifluoromethanesulfonic acid (triflic acid; TfOH) in acetonitrile at ambient temperature to give the corresponding γ-pyrone. Cyclization proceeded with IBX alone, but significantly improved yields were obtained with added acid, particularly triflic acid. A dithiolane was more effective than a dithiane or acyclic dithioacetal protecting group. The method was amenable to the preparation of a variety of substituted γ-pyrones simply by altering the initial aldol reactants. Overall yields of 50%–60% were obtained in six examples. The method was applied to prepare a key fragment for the total synthesis of baconipyrones A and C and siphonarin B.

Key words: γ-pyrone synthesis, 2-iodoxybenzoic acid (IBX), 1,3-dione, dithiolane, siphonariid polypropionates.

Résumé : On a développé une méthode versatile, en trois étapes, qui permet de réaliser l'annellation d'une γ-pyrone sur une méthylène cétone et qui implique les étapes suivantes : (*i*) une réaction aldolique impliquant un β-cétoaldéhyde protégé par un dithiolane; (*ii*) l'oxydation de l'adduit aldolique en β-dicétone et (*iii*) le traitement de la 1,3,5-trione protégée par un groupe dithiolane qui en résulte par de l'acide 2-iodoxybenzoïque (IBX) et de l'acide trifluorométhanesulfonique (acide triflique, TfOH), dans de l'acétonitrile, à la température ambiante, pour conduire à la formation de la γ-pyrone correspondante. La cyclisation se produit même si on utilise l'acide IBX seul, mais les rendements sont de beaucoup améliorés en présence d'un acide additionnel, tel l'acide triflique. Le groupe dithiolane est beaucoup plus efficace qu'un dithiane ou un dithioacétal acyclique comme groupe protecteur. La méthode peut être utilisée pour la préparation d'une variété de γ-pyrones substituées; il suffit de modifier les réactifs aldoliques utilisés. On a obtenu des rendements allant de 50 % à 60 % dans les six exemples étudiés. La méthode a été appliquée à la préparation de fragments clés dans la synthèse totale des baconipyrones A et C et de la siphonarine B.

Mots-clés : synthèse de γ-pyrone, acide 2-iodoxybenzoïque (IBX), 1,3-dione, dithiolane, polypropionates de siphonariides.

Introduction

A γ-pyrone motif in polypropionate natural products imbues these privileged structures with a range of biological properties.[1] In recent years, there has been a resurgence of interest in the synthesis of γ-pyrone-containing natural products and in the formation of the γ-pyrone moiety.[2,3] The synthesis of γ-pyrones can be accomplished through a variety of methods, but many of these methods lack generality.[4,5] The most common approach involves dehydrative cyclization of 1,3,5-triketones, classically achieved by treatment with strong protic acids.[4] Such harsh conditions are generally not appropriate for the synthesis of complex natural products, and in recent years a variety of alternative reagents to achieve this transformation have been reported, including PPh_3/CCl_4,[6] dimethyl sulfoxide (DMSO)/$(COCl)_2$ (Swern reagent),[6] Amberlyst with P_2O_5 on Celite,[7] sterically hindered diarylammonium sulfonates,[8] and $C_6F_5SO_3H$/heptane.[9] Although the most popular of these methods, PPh_3/CCl_4,[6] has been featured in several natural product syntheses,[3,10] failed applications have also been reported.[7] Cyclizations of masked derivatives of 1,3,5-triketones (e.g., ethylene ketals,[11] enol ethers,[12] silyl enol ethers,[13] enamines,[14] and 5-hydroxy-1,3-cyclohexanediones[15]) to produce γ-pyrones also have been reported. Despite the work thus far, the scope and limitations of the available methods have not been systematically investigated especially with respect to the nature and number of substituents. To the best of our knowledge, there are no methods capable of annulating a γ-pyrone onto a ketone that allows flexibility in the substitution pattern. Herein, we report the synthesis and cyclization of dithiolane-protected 1,3,5-triketones to afford γ-pyrones with a high degree of synthetic versatility.

Results and discussion

In the context of our synthetic studies on the polypropionates from *Siphonaria zelandica*,[16,17] we envisioned the synthesis of the key γ-pyrone fragment (**2**) by functional group

Scheme 1. Synthetic strategy for γ-pyrone synthesis.

Scheme 2. Synthesis of γ-pyrones.

manipulation on **3**, obtained via cyclization of the 1,3,5-triketone intermediate **7** (Scheme 1). The latter would be accessed from readily available ethyl ketone **1**[16,18] through a simple three-step procedure: aldol reaction with dithioacetal aldehyde **4a**[16] followed by oxidation of the resulting adduct **5** to dione **6** and then hydrolysis of the dithioacetal protecting group. This strategy would provide significant flexibility in terms of the timing of installation of the γ-pyrone as the sequence might be delayed or interrupted in response to unforeseen synthetic challenges.

The planned sequence for introduction of the γ-pyrone was tested using 3-pentanone (**8a**) as a model ketone (Scheme 2). Addition of aldehyde **4a**[16] to the lithium diisopropylamide (LDA)-generated lithium enolate of **8a** gave a mixture of aldol diastereomers **9a** in 86% yield. Surprisingly, treatment of **9a** with 2-iodoxybenzoic acid (IBX)[19] in hot (80 °C) acetonitrile according to More and Finney's[20] procedure gave the known[6,21] γ-pyrone **11a** as the only isolable compound in ~30% yield. Despite extensive experimentation, the yield of this process could not be improved; *retro*-aldol was suspected as a significant decomposition pathway. Considering that oxidation of the alcohol in **9a** must occur prior to cyclization, an alternative oxidation protocol (i.e., IBX in DMSO at room temperature) was employed to arrive at diketone **10a**. Subjecting **10a** to IBX oxidation in hot acetonitrile gave a dramatically improved yield of **11a** (Table 1, entry 1) compared with the reaction of **9a** under the same conditions.

A series of experiments was performed to further optimize the formation of **11a** from **10a** (Table 1). Increasing the amount of IBX to 1.5 equiv gave a moderate improvement in the yield that was unchanged using 2 equiv (Table 1, entries 2 and 3). Changing the solvent[20] proved deleterious (Table 1, entries 4 and 5). The addition of water to facilitate hydrolysis of the dithioacetal attenuated the reaction significantly (Table 1, entry 6). The dithiane **9f** and diethyl thioacetal **9g** were prepared by aldol reactions of **8a** with aldehydes **4c** and **4d**, respectively. Oxidation of **9f** with IBX in DMSO under the same conditions that proved successful with **9a**, gave pyrone **11a** (46%), trione **12**[6,22] (15%), and dione **10f** (20%). Despite extensive experimentation, the yield of **11a** from the oxidation

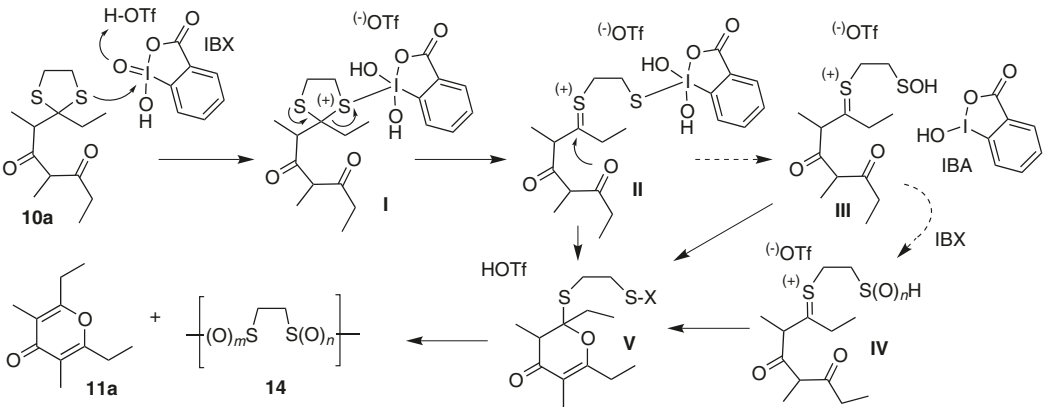
[c]Reaction without IBX.
[d]No reaction.
[e]Room temperature (rt, ~21 °C).



of **9f** could not be significantly improved. It is noteworthy that subjecting triketone **12** to IBX gave little, if any, pyrone **11a**. However, subjecting **10f** to IBX in hot acetonitrile gave **11a**, albeit in poor yield (Table 1, entry 7). Treatment of **9g** with IBX in DMSO at room temperature also produced **11a** (44%) and **12** (20%), along with the dihydropyran **13** (14%) but without evidence of the desired diketone. Having established conditions for the transformation of **10a** into pyrone **11a** in reasonable yield (Table 1, entries 2 and 3), oxidations of diones **10b**–**10d**, prepared analogously to **10a**, were attempted (Table 1, entries 7–10). Unfortunately, only modest yields of the corresponding pyrones **11b**–**11d** were obtained; thus, additional optimization studies were conducted.

The hydrolysis of dithioacetals by treatment with IBX in DMSO is well-known, with dithianes and acyclic dithioacetals being much more susceptible than dithiolanes.[23,24] The fate of the dithiane moiety under these oxidative conditions is likely 1,2-dithiolan-1,1-dioxide[25] and we could identify this compound in the ^{1}H NMR spectra of the crude products from IBX oxidations of **9f** in DMSO and of **10f** in hot acetonitrile. However, the byproduct(s) of oxidative hydrolysis of dithiolanes and in IBX-mediated formation of **11a** from **10a** (or **9a**) is (are) uncertain. Speculating that acidic byproducts were plausible (vide infra), the effect of an added acid on the reaction of **10a** with IBX was investigated (Table 2). A small improvement in yield of **11a** was observed on addition of a catalytic amount of *p*-TsOH·H_2O (Table 2, entry 1), but near quantitative conversion was observed with stoichiometric amounts (Table 2, entry 2). Reaction of **10a** with *p*-TsOH in the absence of IBX returned starting material (Table 2, entry 3), confirming the crucial role of IBX in the transformation. Reaction of **10f** with IBX gave a markedly higher yield of **11a** in the presence of *p*-TsOH (1 equiv) (Table 2, entry 4; cf. Table 1, entry 7); however, these conditions gave more modest improvements with **10b** and **10d** (Table 2, entries 5 and 6; cf. Table 1, entries 8 and 10).

The effect of acid additives was further explored with the recalcitrant **10d** (Table 2, entries 6–17). The yield of pyrone **11d** increased with increasing acidity of the additive (Table 2, entries 6–9) and the highest conversion was obtained with trifluoromethanesulfonic acid (triflic acid; TfOH) (1 equiv; Table 2, entry 9). Conversions improved with increasing amounts of triflic acid up to 1 equiv (Table 2, entries 10–12), but there was little reaction in the absence of IBX (Table 2, entry 13). Although pyrone formation does not occur at room temperature with IBX alone (heterogeneous mixture), the conversion of **10d** to **11d** was complete within ~13 h with added triflic acid (homogeneous mixture) (Table 2, entries 14–17). Subjecting diketones **10a**–**10e** to these optimized conditions and monitoring the reaction progress by thin layer chromatography (TLC) gave the corresponding pyrones **11a**–**11e** in good to excellent yields (Table 2, entries 18–22).

A plausible mechanism for the formation of pyrone **11a** from diketone **10a** is illustrated in Scheme 3. In analogy with previous proposals,[23,24] we suggest that one of the dithiolane sulfur atoms becomes associated with IBX (i.e., **I**), a process that would be facilitated by acid, and assistance from the neighboring sulfur atom leads to the fragmented sulfonium ion **II**. In the case of dithianes, it was proposed that the analogous sulfonium ion is attacked by the iodoxy oxygen ultimately leading to deprotected ketone.[23] With the much less reactive dithiolanes and in the presence of acid (i.e., giving a less nucleophilic OH versus $O^{(-)}$ on IBX), we suggest that **II** might rearrange to **III** (and iodosobenzoic acid (IBA)) that could be

Scheme 3. Plausible mechanism for γ-pyrone formation.

Scheme 4.

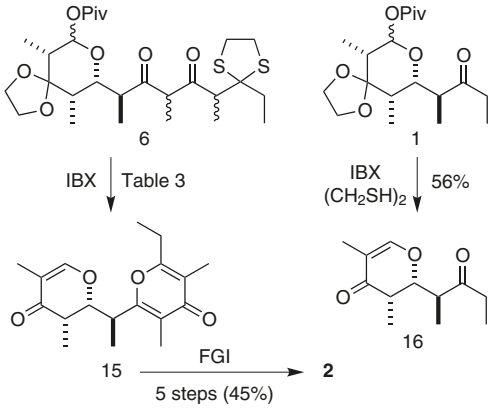


Table 3. Optimization of 2-iodoxybenzoic acid (IBX)-mediated transformation of **6** to γ-pyrone **15**.

Entry	Acid (equiv)	Temp. (°C)	Time (h)	Yield (%)[a]
1	None	80	24	41
2[b]	None	80	24	48
3	*p*-TsOH (1)	80	24	60[c]
4	*p*-TsOH (1)	rt[d]	72	63
5	CF_3SO_3H (1)	rt[d]	16	81

Note: Reaction of **6** (~0.1–0.2 mmol, 0.04 mol/L) with IBX (2 equiv) in acetonitrile.

[d]Room temperature (rt, ~21 °C).

further oxidized by IBX (e.g., to **IV**). In any event, the sulfonium ions **II**–**IV** are poised to cyclize by attack of the δ-carbonyl group, ultimately leading to the pyrone **11a** after elimination of the sulfide group. Presumably, the cyclization occurs via the keto tautomers of the diketones **10** as the intramolecular hydrogen bond in the enol tautomers would prevent ring closure. Thus, another possible beneficial effect of added acid is accelerated keto–enol tautomerism. Interestingly, **10a**, the diketone easiest to cyclize, is predominantly in the keto form, whereas **10b**–**10e** are almost exclusively in the enol form (by ^{1}H NMR in $CDCl_3$). Because we were unable to detect signals in the ^{1}H NMR spectra of the crude product (or by monitoring reactions conducted in CD_3CN) that would correspond to the methylene groups originating from the dithiolane, the formation of a polymeric material is suggested (e.g., **14**).

Towards the total synthesis of siphonariid polypropionates, this methodology was applied to the synthesis of the key γ-pyrone fragment (**2**; Scheme 1).[16] Aldol reaction of the readily available ketone **1** with aldehyde **4a** followed by oxidation of the resulting adducts **5** gave diketone **6** in excellent yield.[16] Reactions of **6** with IBX under a variety of conditions were investigated (Scheme 4 and Table 3). Using the method initially successful with **10a** (cf. Table 1, entry 3) resulted in the formation of **15**[16] as the only isolable pyrone-containing product in moderate yield (Table 3, entry 1). The yield of **15** could not be improved by modifying the procedure (i.e., with variations in reaction time, temperature, stoichiometry, IBX addition rate, concentration, etc.). Although these conditions resulted in the formation of the desired pyrone, elimination of the pivaloate and hydrolysis of the ketal in **6** occurred concomitantly. The latter transformations were presumed to be acid-mediated and the acidity of IBX was suspected.[26] However, ketone **1** was inert to IBX (and its reduced congeners IBA and *o*-iodobenzoic acid) under these reaction conditions. Interestingly, the addition of ethanedithiol (0.1 equiv) to a reaction of **1** and IBX (1 equiv) in acetonitrile at 80 °C gave the dihydropyrone **16** in 56% yield. This result suggested that IBX-mediated cyclization of diketones **10** might produce acidic compounds by oxidation of the dithiolane byproducts and prompted a study of the effect of acid additives on the reaction (Table 2). Indeed, the addition of *p*-TsOH·H_2O (1 equiv) to the reaction of **6** with IBX at 80 °C improved the yield of **15** but also produced ~20% of an unwanted diastereomer (Table 3, entry 3); however, prolonged reaction at room temperature suppressed the isomerization (Table 3, entry 4). Finally, the reaction of **6** with IBX and triflic acid at room temperature gave **15** in excellent yield (Table 3, entry 5). Straightforward functional group transformations on **15** produced **2**, a key fragment in the total syntheses of baconipyrones A and C and siphonarin B.[16]

Conclusion

A simple three-step procedure to annulate a γ-pyrone onto a methylene ketone was developed involving (*i*) aldol reaction with

a dithiolane-protected β-ketoaldehyde, (*ii*) oxidation of the aldol adduct to a β-diketone, and (*iii*) treatment of the resulting dithiolane-protected 1,3,5-trione with 2-iodoxybenzoic acid (IBX) and triflic acid in acetonitrile at ambient temperature. Despite the lower reactivity of dithiolanes towards IBX, cyclization of the dithiolane-protected 1,3,5-trione was much more effective than the corresponding dithiane or *S*,*S*-diethyl acetal protecting groups. In contrast to other approaches, the method provides easy access to a variety of substituted γ-pyrones simply by changing the ketone and (or) aldehyde components. Dithiolane-protected β-ketoaldehydes are readily prepared on gram scale from commerically available β-ketoesters. The synthetic utility of the method was demonstrated through the synthesis of a key intermediate used in the total synthesis of several natural products.

Experimental

General methods

Anhydrous solvents were distilled under argon atmosphere as follows: tetrahydrofuran (THF) from benzophenone sodium ketyl and DMSO from CaH_2 at reduced pressure (stored over 4 Å molecular sieves). All experiments involving air- and (or) moisture-sensitive compounds were conducted in an oven-dried round-bottom flask capped with a rubber septum, and attached via a needle and connecting tubing to an argon manifold equipped with a mercury bubbler (~5 mm positive pressure of argon). Low-temperature baths were ice/water (0 °C) and CO_2(s)/acetone (–78 °C). Unless otherwise noted, reaction temperatures refer to that of the bath. Concentration refers to the removal of volatiles at water aspirator pressure on a rotary evaporator. Preparative TLC (PTLC) was carried out on glass plates (20 × 20 cm^2) precoated (0.25 mm) with silica gel 60 F_{254}. Materials were detected by visualization under an UV lamp (254 nm) and (or) by treating a 1 cm vertical strip removed from the plate with a solution of phosphomolybdic acid (5%) containing a trace of ceric sulfate in aqueous sulfuric acid (5% v/v) followed by charring on a hot plate. Flash column chromatography (FCC) was performed according to Still et al.[27] with silica gel 60 (40–63 μm). All mixed solvent eluents are reported as v/v solutions. Unless otherwise noted, all reported compounds were homogeneous by TLC and by ^{1}H NMR.

Spectral data

High-resolution mass spectra (HR-MS) and low-resolution mass spectra (LR-MS) were obtained on a double-focusing high-resolution spectrometer; only partial data are reported. Electron impact (EI) ionization was accomplished at 70 eV. IR spectra were recorded on a Fourier transform interferometer using a diffuse reflectance cell (i.e., diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy); only diagnostic and (or) intense peaks are reported. Unless otherwise noted, NMR spectra were measured in $CDCl_3$ solution at 500 MHz for ^{1}H and 125 MHz for ^{13}C. Signals due to the solvent (^{13}C NMR) or residual protonated solvent (^{1}H NMR) served as the internal standard: $CDCl_3$ (7.26 δ_H, 77.23 δ_C); C_6D_6 (7.16 δ_H, 128.39 δ_C); and $(CD_3)_2SO$ (2.50 δ_H, 39.52 δ_C). The ^{1}H NMR chemical shifts and coupling constants were determined assuming first-order behavior. Multiplicity is indicated by one or more of the following: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), br (broad), and ap (apparent); lists of coupling constants (*J*) correspond to the order of the multiplicity assignment. Coupling constants (*J*) are reported to the nearest 0.5 Hz (i.e., ±0.25 Hz as consistent with the digital resolution ~0.2 Hz/point). The ^{1}H NMR assignments were made based on chemical shift and multiplicity and were confirmed by homonuclear decoupling and (or) two-dimensional correlation experiments (gradient correlation spectroscopy (gCOSY), gradient heteronuclear single quantum coherence (gHSQC), and gradient heteronuclear multiple bond coherence (gHMBC)).[28] The ^{13}C NMR assignments were made on the basis of chemical shift and multiplicity[29] (as determined by ^{13}C-DEPT (distortionless enhancement by polarization transfer) or gHSQC) and were confirmed by two-dimensional ^{1}H/^{13}C correlation experiments (gHSQC and (or) gHMBC).[28] ^{1}H and ^{13}C NMR spectra for all reported compounds can be found in the Supplementary data.

Materials

The following compounds and reagents were prepared as described previously: **1**, **4a**, **6**, and **15**;[16] IBX[30]; and ethyl 2-methyl-3-oxopentanoate.[31] Aldehyde **4b** was prepared from ethyl acetoacetate according to Rama Rao et al.[32] except IBX (88% yield) was used in the final step instead of pyridinium dichromate (PDC; 65% yield). *i*-Pr_2NH was freshly distilled under argon atmosphere from CaH_2. All other reagents were commercially available and, unless otherwise noted, were used as received.

General procedure for $LiAlH_4$ reduction of esters

A solution of ester (typically 40–60 mmol) in THF (~0.5 mol/L) was added dropwise via syringe to a stirred suspension of lithium aluminum hydride (1.2 equiv) in THF (~0.5 mol/L) at 0 °C under Ar. The mixture was allowed to warm to ambient temperature and the reaction progress was monitored by TLC until the ester was consumed (~1–2 h). The mixture was cooled to 0 °C and water (*n* mL for *n* g of lithium aluminum hydride) was added slowly. (Caution: H_2 evolution.) To the vigorously stirred suspension, 15% aq NaOH (*n* mL) and water (3*n* mL) were added dropwise sequentially. The initially gray suspension turned white over 1 h. The mixture was filtered through Celite washing with ethyl acetate. The combined filtrate and washings were dried over Na_2SO_4 and concentrated to give the product.

General procedure for IBX oxidation of primary alcohols

IBX (1.5 equiv) was added to a stirred solution of alcohol (typically 20–30 mmol) in anhydrous DMSO (~0.5 mol/L) at room temperature. When TLC analysis indicated complete consumption of alcohol (~2 h), the mixture was diluted with ethyl acetate and washed sequentially with saturated aq $NaHCO_3$, water, and brine, dried over Na_2SO_4, and concentrated to give the crude aldehyde.

*2-(2-Methyl-1,3-dithiolan-2-yl)acetaldehyde (***4b***)*

IBX oxidation of 2-(2-methyl-1,3-dithiolan-2-yl)ethanol[32] (3.69 g, 22.5 mmol) according to the general procedure followed by fractionation of the crude product by FCC (10% ethyl acetate in hexane) gave the title compound (3.21 g, 88%). IR ν_{max} (cm^{-1}): 1721. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 9.78 (1H, br s, HC-1), 3.46–3.32 (4H, m, H_2C-4, H_2C-5′),

2.97 (2H, br s, HC-3), 1.85 (3H, s, H_3C-1″). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 200.7 (d, C-1), 61.3 (s, C-2), 56.7 (t, C-2), 40.6 (t × 2, C-4, C-5′), 33.7 (q, C-1″). LR-MS (EI) *m*/*z* (relative intensity): 162 ($[M]^+$, 77), 146 (6), 134 (12), 119 (100), 87 (11), 74 (45), 58 (95). HR-MS *m*/*z* calcd for $C_6H1_0OS_2$: 162.0173; found: 162.0169 (EI). Spectral data were in accord with those previously reported.[32]

Preparation of aldehyde 4c from ethyl 2-methyl-3-oxopentanoate

Ethyl 2-(2-ethyl-1,3-dithian-2-yl)propanoate

$F_3B{\cdot}OEt_2$ (6.2 mL, 6.9 g, 49 mmol) was added to a stirred solution of ethyl 2-methyl-3-oxopentanoate (7.0 g, 45 mmol) and 1,2-dithioethane (4.8 mL, 5.4 g, 47 mmol) in CH_2Cl_2 (64 mL) at room temperature under Ar. After 30 min (reaction complete by TLC analysis), the mixture was diluted with diethyl ether (300 mL) and saturated aq $NaHCO_3$ (200 mL) was added with vigorous stirring. (Caution: effervescence.) After 30 min, the organic layer was washed sequentially with water and brine, dried over Na_2SO_4, concentrated, and fractionated by FCC (15% ethyl acetate in hexane) to give the title compound as a pale yellow oil (9.5 g, 86%). IR ν_{max} (cm^{-1}): 1734. ^1H NMR (500 MHz, $CDCl_3$) δ: 4.22–4.09 (2H, m, H_2CO), 3.40 (1H, q, *J* = 7 Hz, HC-2), 3.12 (1H, ddd, *J* = 3, 11.5, 14.5 Hz, HC-4), 2.93 (1H, ddd, *J* = 3, 11.5, 14.5 Hz, HC-6), 2.71–2.66 (2H, m, HC-4, HC-6), 2.19 (1H, dq, *J* = 7.5, 15 Hz, HC-1″), 2.05–1.99 (1H, m, HC-5′), 1.89–1.78 (2H, m, HC-1″, HC-5′), 1.31 (3H, d, *J* = 7 Hz, H_3C-3), 1.27 (3H, t, *J* = 7 Hz, H_3CCH_2), 1.10 (3H, t, *J* = 7.5 Hz, H_3C-2″). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 173.5 (s, C-1), 60.6 (t, CH_2O), 55.6 (s, C-2), 46.3 (d, C-2), 27.9 (t, C-1″), 26.2 (t, C-4), 26.1 (t, C-6), 24.8 (t, C-5′), 14.4 (q, H_3CCH_2), 13.7 (q, C-3), 9.4 (q, C-2″). LR-MS (EI) *m*/*z* (relative intensity): 248 ($[M]^+$, 20), 219 (13), 147 (100), 128 (20), 100 (7), 68 (10). HR-MS *m*/*z* calcd for $C_{11}H_{20}O_2S_2$: 248.0905; found: 248.0904 (EI).

2-(2-Ethyl-1,3-dithian-2-yl)propan-1-ol

$LiAlH_4$ reduction of the above ethyl 2-(2-ethyl-1,3-dithian-2-yl)propanoate (5.5 g, 22 mmol) according to the general procedure followed by fractionation of the crude product by FCC (20% ethyl acetate in hexane) to give the title compound (4.0 g, 89%). IR ν_{max} (cm^{-1}): 3419. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.96 (1H, ddd, *J* = 5.5, 6,11.5 Hz, HC-1), 3.73 (1H, ddd, *J* = 5.5, 6.5, 11.5 Hz, HC-1), 2.89–2.72 (4H, m, H_2C-4, H_2C-6), 2.40 (1H, dd, *J* = 6, 6.5 Hz, HO), 2.25–2/17 (1H, m, HC-2), 2.11 (1H, dq, *J* = 7.5, 15 Hz, HC-1″), 1.97–1.87 (3H, m, HC-1″, H_2C-5′), 1.11 (3H, d, *J* = 7 Hz, H_3C-3), 1.03 (3H, t, *J* = 7.5 Hz, H_3C-2″). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 65.5 (t, C-1), 57.8 (s, C-2), 41.1 (d, C-2), 28.8 (t, C-1″), 25.9 (t, C-4), 25.8 (t, C-6), 25.3 (t, C-5′), 12.8 (q, C-3), 9.4 (q, C-2″). Preparation of aldehyde 4d from ethyl acetoacetate

Ethyl 3,3-bis(ethylthio)-2-methylpentanoate

Freshly distilled $TiCl_4$ (0.90 mL, 8.2 mmol) was added via syringe to a stirred solution of ethyl acetoacetate (1.30 g, 8.2 mmol) and ethanethiol (1.6 mL, 21 mmol) at 0 °C under Ar. After 1 h, the ice bath was removed and, after 24 h, the reaction was quenched by the addition of ice cold saturated aq $NaHCO_3$. The mixture was diluted with diethyl ether, washed sequentially with ice cold sat aq $NaHCO_3$ and brine, dried over Na_2SO_4, concentrated, and fractionated by FCC (5% ethyl acetate in hexane) to give the title compound (440 mg, 20%). IR ν_{max} (cm^{-1}): 1735. ^1H NMR (500 MHz, $CDCl_3$) δ: 4.14–4.03 (2H, m, H_2CO), 2.90 (1H, q, *J* = 7 Hz, HC-2), 2.72–2.48 (4H, m, H_2CS × 2), 2.00–1.83 (2H, m, H_2C-4), 1.26 (3H, d, *J* = 7 Hz, H_3CC-2), 1.22 (3H, t, *J* = 7 Hz, H_3CCO), 1.15 (3H, t, *J* = 7.5 Hz, H_3CCS), 1.14 (3H, t, *J* = 7.5 Hz, H_3CCS), 1.01 (3H, t, *J* = 7.5 Hz, H_3C-5). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 173.4 (s, C-1), 65.9 (s, C-3), 60.5 (t, CH_2O), 48.3 (d, C-2), 30.5 (t, C-4), 23.83 (t, CH_2S), 23.77 (q, CH_2S), 14.3 (q, CH_3CO), 14.2 (q, CH_3C-2), 13.9 (q, CH_3CS), 13.7 (q, CH_3CS), 9.8. LR-MS (EI) *m*/*z* (relative intensity): 264 ($[M]^+$, 1), 203 (53), 157 (33), 129 (100), 101 (8), 67 (17). HR-MS *m*/*z* calcd for $C_{12}H_{24}O_2S_2$: 264.1218; found: 264.1216 (EI).

3,3-Bis(ethylthio)-2-methylpentan-1-ol

$LiAlH_4$ reduction of the ethyl 3,3-bis(ethylthio)-2-methylpentanoate (454 mg, 1.70 mmol) according to the general procedure followed by fractionation of the crude product by FCC (20% ethyl acetate in hexane) gave the title compound (367 mg, 97%). IR ν_{max} (cm^{-1}): 3356. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.88 (1H, br d, *J* = 11 Hz, HC-1), 3.68 (1H, br d, *J* = 11 Hz, HC-1), 2.67–2.60 (4H, m, H_2CS × 2), 2.40 (1H, br s, HO), 2.10–2.03 (1H, m, HC-2), 1.89–1.77 (2H, m, H_2C-4), 1.22 (3H, t, *J* = 7.5 Hz, H_3CCS), 1.21 (3H, t, *J* = 7.5 Hz, H_3CCS), 1.14 (3H, d, *J* = 7 Hz, H_3CC-2), 1.02 (3H, t, *J* = 7.5 Hz, H_3C-5). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 67.8 (s, C-3), 65.7 (t, C-1), 43.8 (d, C-2), 30.6 (t, C-4), 24.1 (t, CH_2S), 24.0 (t, CH_2S), 14.7 (q, CH_3CS), 14.4 (q, CH_3CS), 13.7 (q, CH_3C-2), 9.6 (q, C-5). LR-MS (EI) *m*/*z* (relative intensity): 222 ($[M]^+$, 1), 163 (5), 161 (100), 131 (38), 103 (31). HR-MS *m*/*z* calcd for $C_{10}H_{22}OS_2$: 222.1112; found: 222.1120 (EI).

*3,3-Bis(ethylthio)-2-methylpentanal (***4d***)*

IBX oxidation of the 3,3-bis(ethylthio)-2-methylpentan-1-ol (1.52 g, 7.4 mmol) according to the general procedure followed by fractionation of the crude product by FCC (10% ethyl acetate in hexane) gave the title compound (1.24 g, 83%). IR ν_{max} (cm^{-1}): 1720. ^1H NMR (500 MHz, $CDCl_3$) δ: 9.97 (1H, d, *J* = 2 Hz, HC-1), 2.70–2.60 (5H, m, HC-2, H_2CS × 2), 1.90–1.80 (2H, m, H_2C-4), 1.23 (3H, t, *J* = 7.5 Hz, H_3CCS), 1.22 (3H, d, *J* = 7 Hz, H_3CC-2,), 1.21 (3H, t, *J* = 7.5 Hz, H_3CCS), 1.03 (3H, t, *J* = 7.5 Hz, H_3C-5).

^{13}C NMR (125 MHz, $CDCl_3$) δ: 203.3 (d, C-1), 65.4 (s, C-3), 54.0 (d, C-2), 30.8 (t, C-4), 23.7 (t, CH_2S), 23.5 (t, CH_2S), 14.05 (q, CH_3CS), 14.03 (q, CH_3CS), 10.6 (q, CH_3C-2), 9.6 (q, C-5). LR-MS (EI) *m/z* (relative intensity): 220 ($[M]^+$, 3), 159 (100), 131 (83), 101 (30), 84 (24), 69 (60). HR-MS *m/z* calcd for $C_{10}H_{20}OS_2$: 220.0956; found: 220.0953 (EI).

General procedure for aldol reaction

A solution of *n*-BuLi in hexane (1.2 equiv) was added dropwise via syringe to a stirred solution of freshly distilled diisopropylamine (1.25 equiv) in THF (~0.2 mol/L) at 0 °C under argon. After 15 min, the mixture was cooled to –78 °C and the ketone (1.2 equiv) was added dropwise via syringe. After 30 min, a solution of aldehyde (typically 2–10 mmol) in THF (~0.3 mol/L, 1.0 equiv) was added via syringe. After 15 min, the reaction was quenched by the addition of saturated aq $NaHCO_3$. The reaction mixture was diluted with ethyl acetate, washed sequentially with saturated aq $NaHCO_3$ and brine, dried over Na_2SO_4, and concentrated to give the crude aldol product.

***6-(2-Ethyl-1,3-dithiolan-2-yl)-5-hydroxy-4-methylheptan-3-one* (9a)**

Following the general procedure, aldol reaction of 3-pentanone (0.17 g, 2.0 mmol) with **4a** (316 mg, 1.66 mmol) and fractionation of the crude product by FCC (30% ethyl acetate in hexane) gave the title compound as a 48:42:10 mixture of diastereomers (393 mg, 86%). IR ν_{max} (cm^{-1}): 3480, 1707. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 4.50–4.42 (0.9H, m, HC-5), 4.26 (0.1H, br d, J = 8.5 Hz, HC-5), 3.86 (0.1H, br s, HO), 3.27 (4H, br s, H_2C-4, H_2C-5′), 3.19 (0.48H, br s, HO), 3.16 (0.42H, br s, HO), 2.77–2.65 (1H, m, HC-4), 2.60–2.40 (2H, m, H_2C-2), 2.22–1.80 (3H, m, H_2C-1″, HC-6), 1.20 (1.5H, d, J = 7 Hz, H_3CC-4), 1.14 (0.3H, d, J = 7 Hz, H_3CC-4), 1.13–0.99 (6H, m, H_3C-2″, H_3C-7), 0.97 (1.3H, d, J = 7 Hz, H_3CC-4). ^{13}C NMR (125 MHz, $CDCl_3$; two major isomers only) δ: 215.4 (s), 214.6 (s), 77.9 (s), 77.6 (s), 74.5 (d), 72.8 (d), 51.6 (d), 49.7 (d), 43.4 (d), 41.9 (d), 40.24 (t), 40.19 (t), 39.75 (t), 39.67 (t), 37.0 (t), 36.8 (t), 36.6 (t), 35.2 (t), 14.1 (q), 13.9 (q), 11.6 (q), 11.1 (q), 10.9 (q), 10.8 (q), 7.9 (q), 7.7 (q). LR-MS (EI) *m/z* (relative intensity): 276 ($[M]^+$, 1), 229 (1), 190 (1), 161 (2), 133 (100). HR-MS *m/z* calcd for $C_{13}H_{24}O_2S_2$: 276.1208; found: 276.1218 (EI).

***6-(2-Ethyl-1,3-dithiolan-2-yl)-5-hydroxyheptan-3-one* (9b)**

Following the general procedure, aldol reaction of butanone (1.2 mL, 0.99 g, 14 mmol) with **4a** (2.00 g, 10.5 mmol) and fractionation of the crude product by FCC (25% ethyl acetate in hexane) gave the title compound as a 7:1 mixture of diastereomers (2.05 g, 80%). IR ν_{max} (cm^{-1}): 3477, 1710. ^{1}H NMR (500 MHz, $CDCl_3$; major isomer only) δ: 4.78 (1H, m, HC-5), 3.25 (1H, d, J = 2 Hz, HO), 3.24–3.19 (4H, m, H_2C-4, H_2C-5′), 2.67 (1H, dd, J = 9, 16 Hz, HC-4), 2.51–2.42 (2H, m, H_2C-1), 2.32 (1H, dd, J = 4, 16 Hz, HC-4), 2.05–1.95 (2H, m, H_2C-1″), 1.98 (1H, br q, J = 7 Hz, HC-6), 1.05 (3H, d, J = 7 Hz, H_3C-7), 1.01 (6H, ap t, J = 7 Hz, H_3C-1, H_3C-2″). ^{13}C NMR (125 MHz, $CDCl_3$;) δ: 210.9 (s, C-3), 77.6 (d, C-2), 68.4 (s, C-5), 48.6 (t, C-4), 45.7 (d, C-6), 40.1 (t, C-4), 39.6 (t, C-5′), 36.8 (t, C-1″ or C-2), 36.1 (t, C-1″ or C-2), 11.0 (q, C-2″ or C-7), 10.7 (q, C-2″ or C-7), 7.7 (q, C-1). Following the general procedure, aldol reaction of 3-pentanone (0.12 mL, 0.10 g, 1.1 mmol) with **4d** (192 mg, 0.871 mmol) and fractionation of the crude product by FCC (20% ethyl acetate in hexane) gave the title compound as a 3:1 mixture of diastereomers (265 mg, 99%). IR ν_{max} (cm^{-1}): 3436, 1715. ^{1}H NMR (500 MHz, C_6D_6) δ: 4.50 (0.75H, br d, J = 9 Hz, HC-5), 4.45 (0.25H, dd, J = 1.5, 9.5 Hz, HC-5), 3.70 (0.25H, d, J = 2 Hz, HO), 3.66 (0.75H, d, J = 2 Hz, HO), 2.72–2.50 (4H, m, HC-2, HC-4, HCS × 2), 2.41–2.12 (3H, m, HC-2, HCS × 2), 2.10–1.95 (1H, m, HC-6), 1.85–1.64 (2H, m, H_2C-8), 1.23 (0.75H, d, J = 7 Hz), 1.18 (0.75H, d, J = 7 Hz), 1.10* (2.25H, d, J = 7 Hz), 1.09 (2.25H, t, J = 7 Hz), 1.04 (0.75H, t, J = 7 Hz), 1.02–0.88 (6H, m), 0.82 (2.25H, d, J = 7 Hz). ^{13}C NMR (125 MHz, C_6D_6; *major isomer) δ: 213.4* (s, C-3), 213.2 (s, C-3), 74.1* (d, C-5), 72.2 (d, C-5), 69.5 (d, C-7), 69.1* (s, C-7), 51.5 (d, C-4), 49.6* (d, C-4), 43.7 (d, C-6), 42.0* (d, C-6), 37.4* (t, C-2), 35.9 (t, C-2), 30.6* (t × 2, C-8), 25.1* (t, CH_2S), 23.7* (t, CH_2S), 15.1 (q, CH_3C-4), 14.5 (q, CH_3CS), 14.4* (q, CH_3CS), 14.23* (q, CH_3CS), 14.20 (q, CH_3CS), 13.9* (q, CH_3C-4), 10.09 (q), 9.51* (q), 9.48 (q), 9.37* (q), 8.16* (q), 8.13 (q). LR-MS (EI) *m/z* (relative intensity): 306 (1), 245 (10), 227 (13), 159 (10), 131 (100), 115 (20), 73 (10). HR-MS *m/z* calcd for $C_{15}H_{30}O_2S_2$: 306.1687; found: 306.1692 (EI).

General procedure for IBX oxidation of aldol adducts

IBX (2 equiv) was added to a stirred solution of the aldol (typically 0.2–0.5 mmol) in DMSO (~0.04 mol/L at ambient temperature. When TLC analysis indicated the consumption of aldol (~24 h), the mixture diluted with ethyl acetate, washed sequentially with saturated $NaHCO_3$, water and brine, dried over Na_2SO_4, and concentrated to give the crude product.

*2-(2-Ethyl-1,3-dithiolan-2-yl)-4-methylheptane-3,5-dione (***10a***)*

Following the general procedure, IBX oxidation of **9a** (393 mg, 1.42 mmol) and fractionation of the crude product by FCC (20% ethyl acetate in hexane) gave the title compound (326 mg, 83%). IR ν_{max} (cm^{-1}): 3400, 1722, 1699, 1574. ^{1}H NMR (500 MHz, $CDCl_3$; a 30:35:35 mixture of enol and two keto (a and b) tautomers, respectively) δ: 16.84 (0.3H, s, HO enol), 3.96 (0.35H, q, J = 7 Hz, HC-4 keto a), 3.88 (0.35H, q, J = 7 Hz, HC-4 keto b), 3.39 (0.35H, q, HC-2 keto a or b), 3.35 (0.35H, q, HC-2 keto a or b), 3.30 (0.3H, q, HC-2 enol), 3.25–3.10 (4H, m, H_2C-4, H_2C-5′), 2.58–2.40 (2H, m, H_2C-6), 2.11–1.83 (2H, m, H_2C-1″), 1.86 (0.9H, s, H_3CC-4 enol), 1.38 (0.9H, d, J = 7 Hz, H_3C-1 enol), 1.33–1.27 (4.2H, m, H_3C-1, H_3CC-4 keto), 1.15–0.97 (6H, m, H_3C-2″, H_3C-7 enol and keto). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 208.9 (s), 208.7 (s), 208.1 (s), 207.5 (s), 196.4 (s), 192.8 (s), 103.9 (s), 75.4 (s), 74.0 (s), 62.4 (d), 61.5 (d), 56.7 (d), 56.5 (d), 47.5 (d), 41.0 (t), 40.40 (t), 40.38 (t), 40.23 (t), 40.21 (t), 40.13 (t), 39.69 (t), 35.6 (t), 34.7 (t), 34.2 (t), 32.5 (t), 32.4 (t), 30.0 (t), 15.8, 15.6 (q), 15.4 (q), 13.2 (q × 2), 12.4 (q), 10.7 (q), 10.31 (q), 10.29 (q), 9.3 (q), 7.8 (q), 7.7 (q). LR-MS (EI) *m/z* (relative intensity): 274 ([M]$^+$, 3), 245 (2), 189 (1), 159 (10), 133 (100), 113 (6), 57 (26). HR-MS *m/z* calcd for $C_{13}H_{22}O_2S_2$: 274.1061; found: 274.1060 (EI).

*6-(2-Ethyl-1,3-dithiolan-2-yl)heptane-3,5-dione (***10b***)*

Distilled DMSO (0.069 mL, 76 mg, 0.97 mmol) was added to a stirred solution of oxalyl chloride (0.050 mL, 74 mg, 0.58 mmol) in CH_2Cl_2 (5.8 mL) at –78 °C under Ar. After 15 min, a solution of **9b** (101 mg, 0.386 mmol) in CH_2Cl_2 (1 mL) was added dropwise via syringe over 10 min. After 1 h, *i*-Pr_2EtN (0.54 mL, 3.1 mmol) was added to the reaction mixture and the reaction was allowed to warm to 0 °C. The mixture was diluted with ethyl acetate and washed sequentially with saturated aq NH_4Cl, saturated aq $NaHCO_3$ and brine, dried over Na_2SO_4, concentrated, and fractionated by FCC (25% ethyl acetate in hexane) to give the title compound (80 mg, 80%). IR ν_{max} (cm^{-1}): 3408, 1718, 1699, 1599. ^{1}H NMR (500 MHz, $CDCl_3$; >10:1 enol form) δ: 15.49 (1H, s, OH), 5.62 (1H, s, HC-4), 3.20–2.90 (4H, m, H_2C-4, H_2C-5′), 2.87 (1H, q, J = 7 Hz, HC-2), 2.32 (2H, ap q, J = 7.5 Hz, H_2C-6), 2.10 (1H, dq, J = 7, 15 Hz, HC-1″), 1.94 (1H, dq, J = 7, 15 Hz, HC-1″), 1.42 (3H, d, J = 7 Hz, H_3C-1), 1.13 (3H, t, J = 7.5 Hz, H_3C-7), 1.10 (3H, t, J = 7 Hz, H_3C-2″). ^{13}C NMR (125 MHz, $CDCl_3$; >10:1 enol form) δ: 196.7 (s, C-3), 194.4 (s, C-5), 99.3 (d, C-4), 74.8 (s, C-2), 53.3 (d, C-2), 41.0 (d, C-4), 40.1 (d, C-5′), 35.9 (d, C-1″), 31.3 (s, C-6), 16.4 (d, C-1), 10.8 (d, C-2″), 9.9 (d, C-7). HR-MS *m/z* calcd for $C_{12}H_{20}O_2S_2$; 260.0905; found: 260.0905 (EI).

3-Methyl-1-(2-methyl-1,3-dithiolan-2-yl)hexane-2,4-dione (10e)

Following the general procedure, IBX oxidation of **9e** (955 mg, 3.85 mmol) and fractionation of the crude product by FCC (25% ethyl acetate in hexane) gave the title compound (880 mg, 92%). IR ν_{max} (cm^{-1}): 3404, 1726, 1699. ^1H NMR (500 MHz, $CDCl_3$; 2.7:1 mixture of keto and enol tautomers) δ: 16.38 (1H, s, HO enol), 3.71 (1H, q, J = 7 Hz, HC-4 keto), 3.39–3.24 (4H, m, H_2C-4, H_2C-5′ keto/enol), 3.25 (1H, d, J = 17 Hz, HC-6 keto), 3.19 (1H, d, J = 17 Hz, HC-6 keto), 3.16 (1H, s, HC-6 enol), 2.61–2.42 (2H, m, H_2C-2 keto/enol), 1.91 (3H, s, H_3C-1″ enol), 1.860 (3H, s, H_3CC-4 enol), 1.856 (3H, s, H_3C-1″ keto), 1.32 (3H, d, J = 7 Hz, H_3CC-4 keto), 1.14 (3H, t, J = 7.5 Hz, H_3C-1 enol), 1.05 (3H, t, J = 7.5 Hz, H_3C-1 keto). ^{13}C NMR (500 MHz, $CDCl_3$) δ: 207.7 (s, C-3 keto), 204.3 (s, C-5 keto), 195.0 (s, C-3 enol), 188.4 (s, C-5 enol), 105.1 (s, C-4 enol), 64.0 (s, C-2 enol), 62.0 (s, C-2 keto), 61.4 (t, C-4 keto), 56.4 (d, C-6 keto), 50.6 (d, C-6 enol), 39.88 (t, C-4 enol), 39.86 (t, C-4 keto), 39.7 (t × 2, C-5′ keto/enol), 35.0 (t, C-2 keto), 32.7 (q, C-1″ enol), 32.0 (q, C-1″ keto), 29.7 (t, C-2 enol), 12.8 (q, C-4 keto), 12.7 (q, C-4 enol), 9.4 (q, C-1 enol), 7.8 (q, C-1 keto). LR-MS (EI) m/z (relative intensity): 246 ($[M]^+$, 13), 145 (6), 133 (11), 119 (100), 101 (7), 57 (37). HR-MS m/z calcd for $C_{11}H_{18}O_2S_2$: 246.0748; found: 246.0710 (EI).

6-(2-Ethyl-1,3-dithian-2-yl)-4-methylheptane-3,5-dione (10f)

Following the general procedure, IBX oxidation of **9f** (96 mg, 0.33 mmol) and fractionation of the crude product by FCC (50% ethyl acetate in hexane) gave **11a** (27 mg, 46%), **12**[6,22] (10 mg, 15%), and the title diketone (19 mg, 20%). IR ν_{max} (cm^{-1}): 3394, 1724, 1696, 1625. ^1H NMR (500 MHz, $(CD_3)_2SO$; a 1.3:1 mixture of diastereomers along with ~5% of the enol form) δ: 17.03 (0.05H, s, HO enol), 4.17–4.09 (1H, m, HC-4), 3.87 (0.41H, q, J = 7 Hz, HC-6), 3.72 (0.54H, q, J = 7 Hz, HC-6), 3.16–2.40 (6H, m, H_2C-4, H_2C-5′, H_2C-6), 2.06–1.62 (4H, m, H_2C-2, H_2C-1″), 1.23 (1.25H, d, J = 7 Hz), 1.17 (1.65H, d, J = 7 Hz), 1.12 (1.25H, d, J = 7 Hz), 1.10 (1.65H, d, J = 7 Hz), 1.01 (1.25H, t, J = 7 Hz), 0.99 (1.65H, t, J = 7 Hz), 0.94 (1.65H, t, J = 7 Hz), 0.90 (1.25H, t, J = 7 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 210.6, 210.2, 209.2, 209.0, 64.9, 62.7, 56.1, 56.0, 50.45, 50.39, 34.5, 33.9, 28.5, 28.3, 27.0, 26.9, 26.3, 24.90, 24.86, 14.4, 14.2, 13.7, 12.9, 9.5, 9.4, 7.93, 7.86. LR-MS (EI) m/z (relative intensity): 288 ($[M]^+$, 21), 213 (1), 181 (9), 175 (41), 149 (10), 147 (100). HR-MS m/z calcd for $C_{14}H_{24}O_2S_2$: 288.1218; found: 288.1224 (EI).

General procedure for pyrone formation

IBX (2 equiv) was added to a stirred solution of diketone (~0.2 mmol) in acetonitrile (5 mL, ~0.04 mol/L) at ambient temperature. CF_3SO_3H (1 equiv) or p-TsOH·H_2O (1 equiv) (or no acid) was added. The mixture was heated at the temperature indicated in Tables 1–3. After the indicated time, the mixture was diluted with ethyl acetate, washed with saturated aq $NaHCO_3$ and brine, dried over Na_2SO_4, concentrated, and fractionated by FCC (60%–80% ethyl acetate in hexane) to give the product.

2,6-Diethyl-3,5-dimethyl-4H-pyran-4-one (11a)

^1H NMR (500 MHz, $CDCl_3$) δ: 2.57 (4H, q, J = 7.5 Hz, H_2C × 2), 1.92 (6H, s, H_3CC × 2), 1.19 (6H, t, J = 7.5 Hz, H_3CCH_2 × 2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 180.1 (s, C-4), 164.5 (s × 2, C-2, C-6), 118.0 (s × 2, C-3, C-5), 25.0 (t × 2, CH_2), 11.5 (q × 2, CH_3CH_2), 9.6 (q × 2, CH_3C). Abstract: The synthesis of the pharmaceutical (*R*)-tolterodine is reported using lithiation/borylation–protodeboronation of a homoallyl carbamate as the key step. This step was tested with two permutations: an electron-neutral aryl Li-carbamate reacting with an electron-rich boronic ester and an electron-rich aryl Li-carbamate reacting with an electron-neutral boronic ester. It was found that the latter arrangement was considerably better than the former. Further improvements were achieved using magnesium bromide in methanol leading to a process that gave high yield and high enantioselectivity in the lithiation/borylation reaction. The key step was used in an efficient synthesis of (*R*)-tolterodine in a total of eight steps in a 30% overall yield and 90% ee.

Key words: asymmetric synthesis, boronic esters, *gem*-diarylalkyl, lithiation/borylation reaction, tolterodine.

Résumé : La synthèse du médicament : la (*R*)-toltérodine a été réalisé suivant une étape clé de lithiation/borylation-protodéboronation d'un carbamate homoallilyque. Deux permutations ont été évalué. Premièrement un carbamate d'aryle et de lithuim éléctronqiuement neutre réagissant sur un estre boronique riche en électron et deuxièmement un carbamate d'aryle et de lithium riche en électron réagissant sur un ester boronique électroniquement neutre. Cette dernière s'est révélée être la meilleure. D'autres améliorations ont été obtenues : notament en utilisant le bromure de magnésium en solution dans le méthanol. Cette méthodologie donne un rendement et une énantiosélectivité élevé pour la réaction de lithiation/borylation. L'étape clé permet de réaliser une synthèse éfficace de la (*R*)-toltérodine en huit étapes avec un rendement global de 30% et un ee de 90%.

Mots-clés : synthèse asymétrique, esters boroniques, *gem*-diarylalkyle, réaction de lithiation/borylation, toltérodine.

Introduction

The enantioselective synthesis of pharmaceuticals and biologically active natural products is a major theme for synthetic chemists. In particular, the formation of chiral *gem*-diarylalkyl compounds, a motif that is present in many therapeutically important molecules, is especially challenging owing to the lack of nearby functional groups that might be enlisted to enable the formation of C–C bonds.[1] Examples of these compounds include (*R*)-tolterodine (**1**, Detrol), (+)-sertraline (**2**, Zoloft), and (+)-indatraline (**3**) (Fig. 1).

(*R*)-Tolterodine (**1**) is a potent competitive muscarine receptor antagonist for the treatment of urinary incontinence and other symptoms related to an overactive bladder,[2] a compound that has achieved blockbuster status ($1.21 billion in sales in 2008[3]). Because of its importance and challenging *gem*-diarylalkyl stereocenter, it has become a popular target for asymmetric synthesis. Whereas the original route relied on optical resolution to separate (*R*)-tolterodine from the racemate,[4] initial asymmetric routes used chiral auxiliaries[5] or asymmetric Me-CBS (Corey–Bakshi–Shibata) reduction[6] to introduce the stereogenic center. More recently, asymmetric strategies have utilized transition-metal-catalyzed processes including hydrogenation,[7] hydroformylation,[8] or arylboration.[9]

Recently, we reported the highly enantioselective syntheses of (+)-sertraline (**2**) and (+)-indatraline (**3**) using a lithiation/borylation[10]–protodeboronation[11] strategy (Scheme 1). (+)-Sertraline (**2**), a potent competitive selective serotonin reuptake inhibitor (SSRI), is a commonly prescribed therapeutic for the treatment of depression and other anxiety-related disorders and has also achieved blockbuster status[12] ($3.36 billion in sales in 2004[13]). The related molecule, (+)-indatraline (**3**), is a potent psychoactive compound that acts as a monoamine reuptake inhibitor[14] and has the potential to be used in maintenance therapy to treat cocaine abuse.[15] A lithiation/borylation reaction and subsequent protodeboronation gave access to both **2** and **3** in high yield and excellent enantioselectivity. In contrast with other substrates devoid of the alkene function, for homoallylic carbamate **4** it was found necessary to add a crown ether or to carry out a solvent exchange to $CHCl_3$ to achieve 1,2-metalate rearrangement of the intermediate ate complex.[11b] The requirement for such unusual conditions has made us probe this type of rearrangement further with a view to applying it in the asymmetric synthesis of (*R*)-tolterodine. Once again, we found that modifications of

the improved conditions for this class of substrates were required to promote 1,2-metallate rearrangement, but this did ultimately enable us to complete a successful synthesis of (*R*)-tolterodine using our lithiation/borylation–protodeboronation strategy.

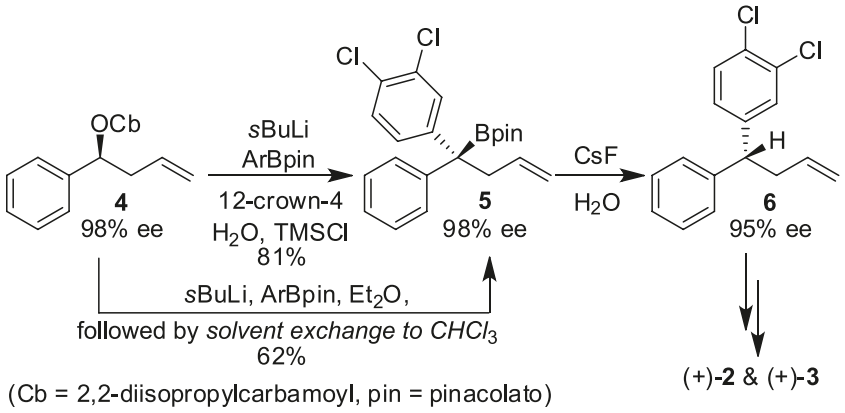
Results and discussion

Encouraged by the results for the synthesis of (+)-sertraline and (+)-indatraline, we applied a similar strategy for the synthesis of (*R*)-tolterodine (**1**). The retrosynthetic analysis for **1** (Scheme 2) involves, as a key step, the lithiation/borylation of benzylic carbamate **4** with boronic ester **7** to form **8**. Subsequent protodeboronation of tertiary boronic ester **8** would lead to olefin **9**. Both the lithiation/borylation[10] and protodeboronation[11] have been found to be highly stereoselective, occurring with retention of the stereochemistry. Functional group manipulation of the key intermediate **9** would then provide (*R*)-tolterodine (**1**).

However, attempts to realize this in practice were not straightforward: when we carried out the lithiation/borylation of carbamate **4** with boronic ester **7**, using 12-crown-4, trimethylsilyl chloride (TMSCl), and H_2O as additives, no product was formed (Scheme 3). A solvent switch after ate complex formation from diethyl ether to $CHCl_3$ gave only trace amounts of tertiary boronic ester **8**. Both sets of conditions had been successfully employed in the synthesis of sertraline; the only difference here was the use of 2-methoxy-5-methylphenyl boronic ester in place of 3,4-dichlorophenyl boronic ester. Monitoring the reaction by ^{11}B NMR revealed that an intermediate boron–ate complex (**A**) formed (~5 ppm), but instead of a 1,2-migration to the product, ate complex **A** decomposed over time returning some starting material.

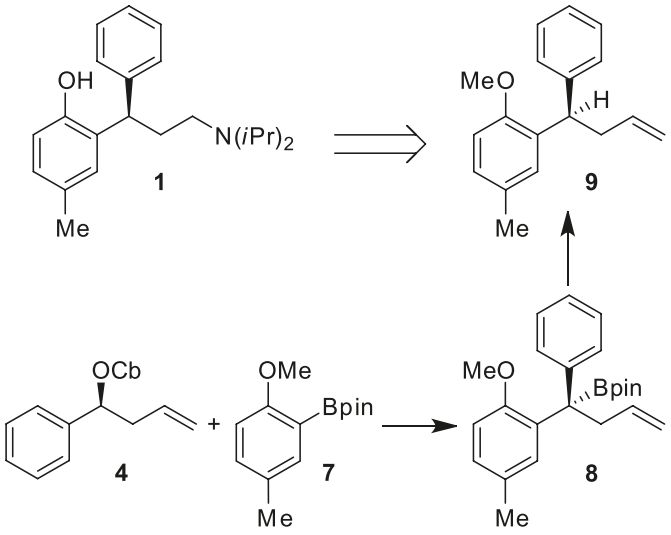
Previous experiments in the syntheses of **2** and **3** revealed that the double bond can interfere in the lithiation/borylation process, presumably by formation of a Li–π complex, as the saturated compound underwent smooth lithiation/borylation under standard conditions (either (*i*) no additives were required, simply warming to room temperature (RT) or (*ii*) the addition of $MgBr_2$/MeOH prior to warming to RT).[11b] To determine whether the problem was related to the double bond, propylcarbamate **10** was tested in the lithiation/borylation reaction with pinacol boronic ester **7** (Scheme 4). The formation of a boron–ate complex was confirmed by ^{11}B NMR, but again no product could be isolated. We believed that the extra steric hindrance of the aryl boronic ester (bearing an ortho substituent) was perhaps responsible for the low reactivity. We therefore investigated the use of the less-hindered neopentyl boronic ester **12**, instead of the pinacol boronic ester **7**, under the same reaction conditions. Utilizing carbamate **10** and neopentyl boronic ester **12** in the lithiation/borylation reaction gave tertiary boronic ester **13** in 62% isolated yield after column chromatography. To our delight, lithiation/borylation of homoallylic carbamate **4** (99% enantiomeric excess (ee)) and neopentyl boronic ester **12** gave tertiary boronic ester **14** in good yield and high enantioselectivity (Table 1, entry 1). This showed that the presence of the double bond was not interfering in the reaction. However, attempts to improve both yield and enantioselectivity by the addition of additives after ate complex formation were not successful (Table 1, entries 2–8).

We therefore considered an alternative protocol. Instead of using carbamate **4** with 2-methoxy-5-methylphenyl boronic ester we decided to switch the two aryl groups. In other words, we considered the possibility of the reaction of homoallylic carbamate **18** with phenyl boronic ester in a lithiation/borylation reaction. Although the two ate complexes have similar steric properties, we believed that the presence of the *ortho*-methoxy group might assist in the expulsion of the carbamate, thereby promoting the 1,2-metallate rearrangement.



Homoallylic carbamate **18** was synthesized in a three-step sequence starting from the commercially available aldehyde **15** (Scheme 5). The phenolic hydroxyl group was protected as the methyl ether to give aldehyde **16**. Subsequent, Brown-mediated asymmetric allylation using (+)-B-allyl (diisopinocampheyl)borane ((+)-Ipc_2Ball) gave alcohol **17** in 92% ee,[16] which was followed by carbamoylation furnishing the desired carbamate in 97% yield and 92% ee.

The lithiation/borylation reaction between racemic homoallylic carbamate **18** and phenyl pinacol boronic ester **19** now proceeded well to give tertiary boronic ester **8** in 40% yield (Table 2, entry 1). In contrast with our earlier work, the reaction gave only a poor yield when neopentyl boronic ester **20** was used (Table 2, entry 2). Therefore, an optimization of the lithiation/borylation reaction of carbamate **18** with phenyl pinacol boronic ester **19** was carried out. Better results were obtained with the Lewis acidic additives TMSCl or $MgBr_2$ in anhydrous MeOH (Table 2, entries 6 and 8). The optimum conditions/additives of the lithiation/borylation reaction ($MgBr_2$/MeOH; Table 2, entry 8) were applied to the enantioenriched carbamate **18** and we were pleased to find that the reaction proceeded with 98% es (Scheme 6). Hence, we used these optimized conditions to complete the synthesis of (*R*)-tolterodine.



Interestingly, when we reinvestigated the lithiation/borylation reaction as applied in the synthesis of sertraline, the reaction with an electron-rich aryl group associated with carbamate **4** and an electron-deficient aryl group (3,4-$Cl_2C_6H_4$) on boronic ester **21** worked much better than having an electron-deficient aryl group associated with carbamate **22** and an electron-rich aryl group on boronic ester **19** (Scheme 7). This suggests that this arrangement of electronic substitution of the aryl rings is likely to be general.

With the lithiation/borylation problem solved, we focused on the next step: protodeboronation of tertiary boronic ester **8**.

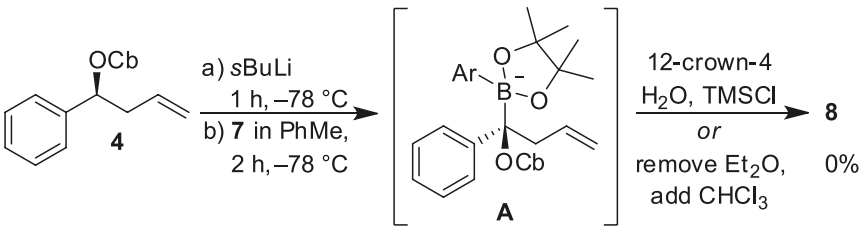
Scheme 1. Enantioselective syntheses of (+)-sertraline (**2**) and (+)-indatraline (**3**) using a lithiation/borylation–protodeboronation strategy.

Scheme 2. Retrosynthetic scheme for the synthesis of (*R*)-tolterodine (**1**).

Unfortunately, our standard procedure for the protodeboronation of diarylalkyl boronic esters (1.5 equiv CsF, 2.5 equiv H_2O, 1,4-dioxane)[11] proceeded very sluggishly and it took 48 h at 80 °C until full conversion of **8** was achieved. This is probably due to the electron-rich aryl ring, which makes deboronation more difficult. In the case of protodeboronation of aryldialkyl boronic esters, we also found that CsF/H_2O was very slow, but that tetrabutylammonium fluoride trihydrate (TBAF·3H2O) was considerably superior.[11a] Using these previously reported conditions (1.5 equiv TBAF·3H_2O, toluene), tertiary boronic ester **8** was smoothly protodeboronated at ambient temperature within 90 min in excellent yield and enantioselectivity to give key intermediate **9** (Scheme 6).

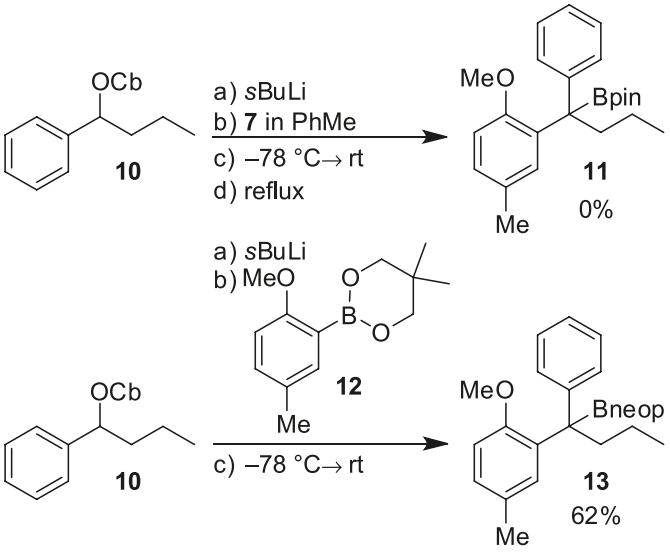
The remaining synthesis was completed in a three-step sequence (Scheme 6). The double bond in olefin **9** was successfully cleaved by a Lemieux–Johnson oxidation,[17] with in situ generated osmium tetroxide, to the corresponding aldehyde **23**. Subsequent reductive amination with diisopropylamine and sodium triacetoxyborohydride gave the protected tolterodine precursor **24** in a good yield. Finally, removal of the methyl group by acidic hydrolysis resulted in the formation of (*R*)-tolterodine (**1**) in an excellent yield. The *R* configuration was confirmed by comparison of the optical rotations, $[\alpha]_D^{20}$ +28.0 (*c* 0.50, MeOH) for **1** with that reported in the literature ($[\alpha]_D^{20}$ +32.5 (*c* 0.89, MeOH)).[7e] Thus, using our lithiation/borylation–protodeboronation methodology as a key step, (*R*)-tolterodine was synthesized through an eight-step sequence in an overall yield of 30%.

Conclusion



In conclusion, lithiation/borylation and subsequent protodeboronation has been used in the generation of *gem*-diarylalkyl stereocenters in both high yield and high enantioselectivity. More importantly, we have found that the optimum arrangement of groups is to have an electron-rich aryl group associated with the carbamate to promote the 1,2-metallate rearrangement, otherwise, reversion to starting materials tends to dominate. This methodology has been applied to a highly enantioselective synthesis of (*R*)-tolterodine.

Experimental



Reaction mixtures were stirred magnetically. Air- and moisture-sensitive reactions were carried out in flame-dried glassware under argon atmosphere using standard Schlenk manifold technique. All required fine chemicals were purchased from Acros Organics, Alfa Aesar, Inochem-Frontier Scientific, or Sigma-Aldrich and used as received unless otherwise mentioned. Anhydrous solvents were prepared using anhydrous solvent drying columns.[18] Microwave reactions were carried out in a Biotage Initiator EXP EU microwave synthesizer. Analytical thinlayer chromatography (TLC) was performed on aluminum-backed silica plates (Merck, silica gel 60 F_{254}, 0.25 mm). Compounds were visualized by exposure to UV light or by staining the plates with a 5% solution of phosphomolybdic acid ($H_3PMo_{12}O_{40}$) in EtOH followed by heating. Flash column chromatography was performed on silica gel (Sigma-Aldrich, silica gel 60, 40–63 μm). ^{1}H NMR spectra were recorded in $CDCl_3$ at 400 or 500 MHz on a Joel ECP 400, a Varian 400, or a Varian 500 Fourier transform (FT) spectrometer. Chemical shifts (δ_H) are quoted in parts per million (ppm) and referred to $CHCl_3$ (7.27 ppm). ^{1}H NMR coupling constants are reported in hertz and refer to apparent multiplicities. Data are reported as follows: chemical shift, multiplicity (s = singlet, br s = broad singlet, d = doublet,

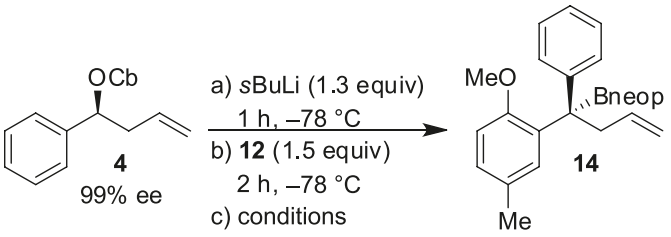

Scheme 4. Lithiation/borylation of carbamate **10**, pinacol boronic ester **7**, and neopentyl boronic ester **12**.

t = triplet, m = multiplet, dd = doublet of doublet, etc.), coupling constant, integration, and assignment. ^{13}C NMR spectra were recorded at 101 or 126 MHz on a Jeol ECP 400, a Varian 400, or a Varian 500 instrument. Chemical shifts (δ_C) are quoted in ppm and referenced to $CHCl_3$ (77.0 ppm). ^{11}B NMR spectra were measured using quartz NMR tubes at 96 or 128 MHz on a Jeol Lambda 300, a Joel ECP (Eclipse) 300, or a Varian 400 with complete proton decoupling using $BF_3{\cdot}Et_2O$ (0.0 ppm) as an external standard. Mass spectra were recorded by the University of Bristol, School of Chemistry departmental mass spectrometry service using chemical ionization (CI) or electrospray ionization (ESI) techniques for low- and high-resolution mass spectra (LR-MS and HR-MS, respectively). All IR spectra were recorded on the neat compounds using a PerkinElmer Spectrum One FT-IR spectrometer. Optical rotations were obtained using a Bellingham + Stanley Ltd. ADP220 polarimeter. Melting points were measured with a Reichert hot stage apparatus and are uncorrected. Chiral HPLC separations were performed on an Agilent 1100 Series HPLC unit equipped with a UV–vis diode array detector using a Daicel Chiralpak IB column (4.6 × 250 mm^2, 5 μm) fitted with a guard (4 × 10 mm^2). (Chiral HPLC traces and ^1H and ^{13}C NMR spectra can be found in the Supplementary data).

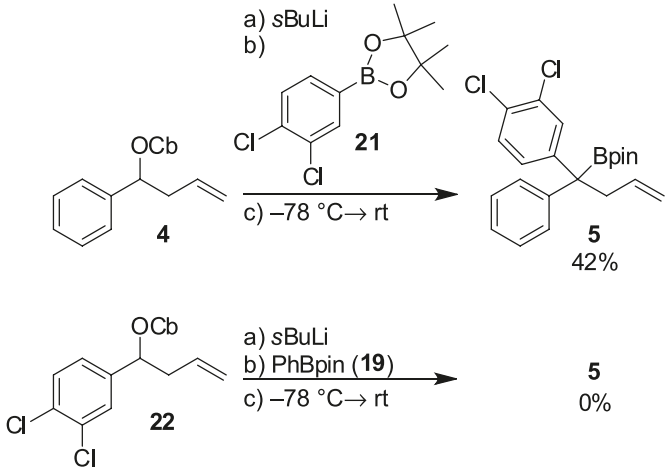
1-Phenylbutyl diisopropylcarbamate (10)

To a suspension of sodium hydride (60% dispersion in mineral oil, 300 mg, 7.50 mmol, 1.5 equiv) in anhydrous tetrahydrofuran (THF; 20 mL), 1-phenylbutan-1-ol (751 mg, 5.00 mmol, 1.0 equiv) was added dropwise and the mixture was stirred for 75 min at RT. A solution of *N*,*N*-diisopropylcarbamoyl chloride (982 mg, 6.00 mmol, 1.2 equiv) in anhydrous THF (5.0 mL) was added and the reaction mixture was heated under reflux for 44 h. The solvent was removed in vacuo and the residue was portioned between water and diethyl ether. The phases were separated and the aqueous layer was re-extracted with diethyl ether. The combined organic layers were dried over anhydrous $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was subjected to flash chromatography (SiO_2, pentane/EtOAc, 6:1) to obtain carbamate **10** (1.13 g, 4.07 mmol, 81%) as a colourless oil. TLC (pentane/EtOAc, 6:1): 0.46. IR (neat, cm^{-1}) ν_{max}: 2962, 1687. ^1H NMR (400 MHz, $CDCl_3$, ppm) δ_H: 7.37–7.29 (m, 4H, H_{Ar}), 7.29–7.23 (m, 1H, H_{Ar}), 5.71 (t, J = 6.9 Hz, 1H, CHOCb), 4.04 (br m, 1H, $CH(CH_3)_2$), 3.84 (br m, 1H, $CH(CH_3)_2$), 1.94 (m, 1H, $CHHCHO$), 1.76 (m, 1H, $CHHCHO$), 1.44–1.27 (m, 2H, CH_2CH_3), 1.22 (br m, 12H, $CH(CH_3)_2$), 0.92 (t, J = 7.4 Hz, 3H, CH_2CH_3). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ_C: 155.1 (NCO), 141.8 (C), 128.2 (CH), 127.3 (CH), 126.5 (CH), 76.4 (CHOCb), 46.1 (br, $CH(CH_3)_2$), 39.0 (CH_2CHO), 21.4 (br, $CH(CH_3)_2$), 18.9 (CH_2CH_3), 13.9 (CH_2CH_3). MS *m/z* (%) (CI^+): 278 ($[M + H]^+$, 77), 236 (11), 218 (10), 146 ($[CbOH + H]^+$, 100), 133 ($[Ph(CH_2)_4]^+$, 57), 128 (16), 102 (12), 91 ($[PhCH_2]^+$, 30). HR-MS (CI^+) calcd for $C_{17}H_{28}NO_2$ $[M + H]^+$: 278.2120; found: 278.2116.



2-(1-(2-Methoxy-5-methylphenyl)-1-phenylbutyl)-5,5-dimethyl-1,3,2-dioxaborinane (13)

1-Phenylbutyl diisopropylcarbamate (**10**; 139 mg, 0.50 mmol, 1.0 equiv) was dissolved in anhydrous diethyl ether (1.5 mL) and chilled to −78 °C. *s*-BuLi (500 μL, 1.3 mol/L solution in cyclohexane/hexane, 98:2, 0.65 mmol, 1.3 equiv) was added dropwise and the mixture was stirred at this temperature for 1 h. A solution of neopentyl ester **12** (176 mg, 0.75 mmol, 1.5 equiv) in anhydrous diethyl ether (0.5 mL)

Scheme 6. Synthesis of (*R*)-tolterodine (**1**).

Scheme 7. Lithiation/borylation of carbamates **4** and **22**.

was added dropwise and the mixture was stirred for 2 h at −78 °C. The cooling bath was removed and stirring was continued at RT overnight (15 h). The reaction mixture was cooled to 0 °C and 1 mol/L KH_2PO_4(aq) (2.0 mL) was added slowly. After stirring for 10 min at RT, the phases were separated and the aqueous phase was extracted with diethyl ether. The combined organic phases were dried over anhydrous $MgSO_4$, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography (SiO_2, pentane/EtOAc, 30:1) to give tertiary boronic ester **13** (114 mg, 0.31 mmol, 62% or 92% based on recovered starting material (BRSM)) as a colourless oil, which crystallized upon standing to white cubes; mp 86–87 °C (pentane/EtOAc). TLC (pentane/EtOAc, 30:1): 0.22. IR (neat, cm^{-1}) ν_{max}: 2955, 2873, 1494, 1244. ^1H NMR (400 MHz, $CDCl_3$, ppm) δ_H: 7.42–7.38 (m, 2H, H_{Ar}), 7.28–7.23 (m, 2H, H_{Ar}), 7.16–7.11 (m, 1H, H_{Ar}), 6.97 (ddd, J = 8.2, 2.2, 0.6 Hz, 1H, H_{Ar}), 6.82–6.79 (m, 2H, H_{Ar}), 3.85 (s, 3H, OCH_3), 3.53 (s, 4H, OCH_2), 2.25–2.17 (m, 1H, C*H*HCH_2), 2.19 (s, 3H, $C_{Ar}CH_3$), 2.02–1.93 (m, 1H, CH*H*CH_2), 1.31–1.21 (m, 1H, C*H*HCH_3), 0.87–0.78 (m, 4H, CH_2CH_3, CH*H*CH_3), 0.65 (s, 6H, CH_3). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ_C: 154.9 (C), 144.0 (C), 136.3 (C), 130.9 (CH), 129.4 (CH), 129.3 (C), 127.2 (CH), 126.7 (CH), 124.5 (CH), 110.4 (CH), 72.3 (OCH_2), 56.1 (OCH_3), 34.8 (CH_2CH_2), 31.6 ($C(CH_3)_2$), 21.5 (CH_3), 20.8 ($C_{Ar}CH_3$), 17.9 (CH_2CH_3), 14.8 (CH_2CH_3). ^{11}B NMR (96 MHz, $CDCl_3$, ppm) δ_B: 27.9 (br s). Abstract: We herein report biomimetic syntheses of 6-substituted salicylates from the cross metathesis of 2,2-dimethyl-6-vinyl-1,3-dioxin-4-one with homoallylic alcohols, oxidation, and aromatization of the intermediate enone–dioxinones. Of particular note is the use of the catalyst 1,4-diazabicyclo[2.2.2]octane in the microwave thermolytic ketene generation and trapping, cyclization, and dehydration reaction sequence.

Key words: salicylates, biomimetic synthesis, dioxinone, polyketide synthesis.

Résumé : Dans ce travail, on rapporte les synthèses biomimétiques de salicylates substitués en position-6, par le biais d'une réaction de métathèse croisée de la 2,2-diméthyl-6-vinyl-1,3-dioxin-4-one avec des alcools homoallyliques, suivie d'une oxydation et d'une aromatisation de l'intermédiaire énone–dixoinones. Il est important de noter l'utilisation du 1,4-diazabicyclo[2.2.2]octane comme catalyseur dans la génération thermolytique du cétène, de son piégeage, de sa cyclisation et de sa déshydrogénation dans la séquence réactionnelle.

Mots-clés : salicylates, synthèse biomimétique, dioxinone, synthèse d'un polycétide.

[Traduit par la Rédaction]

Introduction

Salicylates have long been applied in medicine, fragrances, flavorings, and cosmetics. Simple examples include acetyl salicylic acid and methyl salicylate (oil of wintergreen).[1] 6-Substituted salicylates also occur widely in natural products, which show a wide variety of activities. These include macrocyclic salicylates such as salicylihalamide A and B;[2] apicularen A;[3] and marinomycins A–D,[4] which show anticancer activity (the latter class also displaying antibacterial activity); the fungal metabolite CJ-12 950,[5] which has the potential to treat hypercholesterolemia and hyperlipidemia; long-chain salicylic acids such as anacardic acid and derivatives that are antibiotics and antioxidants;[6] and the diacetylenic natural product frutescin.[7]

The most common syntheses of salicylates are via modification of salicylic acid (itself available from the Kolbe–Schmitt reaction)[8] by esterification or through modification via classical aromatic chemistry. De novo syntheses of these systems are less common but include methods such as oxidative cyclization,[9,10] cycloaromatization of conjugated polyenynes,[11] Diels–Alder reactions,[12] titanium(IV) chloride mediated [3 + 3] additions,[13] and domino "Michael–retro-Michael–Wittig" reactions.[14]

Previously reported biomimetic syntheses of salicylates have involved the synthesis of polycarbonyl precursors via partially reduced pyrones **2**[15] or by addition reactions to β-ketoaldehydes **4** (Scheme 1).[16] In the first case, substrates were limited to those that could be selectively reduced (i.e., not 6-phenacyl-4-hydroxy-2-pyrone), and in the second case a *tert*-butyl ester was necessary to prevent self-condensation of sodioformylacetone.

Inspired by the polyketide biosynthesis for aromatic natural products and the related biomimetic synthesis studies by Harris and Harris,[17] we sought to extend our work on the synthesis of resorcylates from diketodioxinones,[18] to the synthesis of 6-substituted salicylates. We reasoned that salicylates **7** would be available by intramolecular aldol condensation of diketo esters **8**, synthesized by ketene generation and trapping from dioxinone **9**, itself available through cross metathesis of dioxinone **10** and enone **11** (Scheme 2).

Herein, we report the concise synthesis of 6-substituted salicylates using dioxinones as stable precursors without the requirement for protecting groups or harsh reaction conditions.

Results and discussion

Vinyl dioxinone **10** was prepared by the procedure of Gebauer and Blechert[19] from *tert*-butyl 5-chloro-3-oxopentanoate[20] in a 72% yield over two steps. The homoallylic alcohols **14a**–**14k** were synthesized in 82%–94% yields by reaction of allylmagnesium bromide with the corresponding aldehydes.[21] Oxidation of homoallylic alcohol **14a** with pyridinium chlorochromate (PCC)[22] gave the enone **11** in a 64% yield, but attempted cross metathesis of **11** with vinyl dioxinone **10** using the Grubbs–Hoveyda II catalyst **12** was unsuccessful and only gave rise to the enedione **13** in a poor yield. In contrast, cross metathesis of homoallylic alcohol **14a** with vinyl dioxinone **10** gave dioxinone **15a** in an 81% yield (Scheme 3).[23]

Subsequently, we examined the oxidation of the cross metathesis product **15a** to give enone–dioxinone **16a** (Table 1). Our initial attempts involving pyridinium chlorochromate and manganese dioxide were unsuccessful with unreacted starting material being recovered (Table 1, entries 1 and 2). Modified Oppenauer oxidation[24] was of limited use owing to contamination of the product with the hydrogen acceptor 2,4-dinitrobenzaldehyde. Swern conditions gave an intractable mixture of products possibly because of chlorination as has been observed for aryl vinyl ketones.[25]

In contrast to these failures, oxidations with hypervalent iodine reagents were more useful. While oxidation with iodoxybenzoic acid (IBX) in dimethyl sulfoxide (DMSO)[26] resulted in overoxidation, reaction in ethyl acetate[27] gave

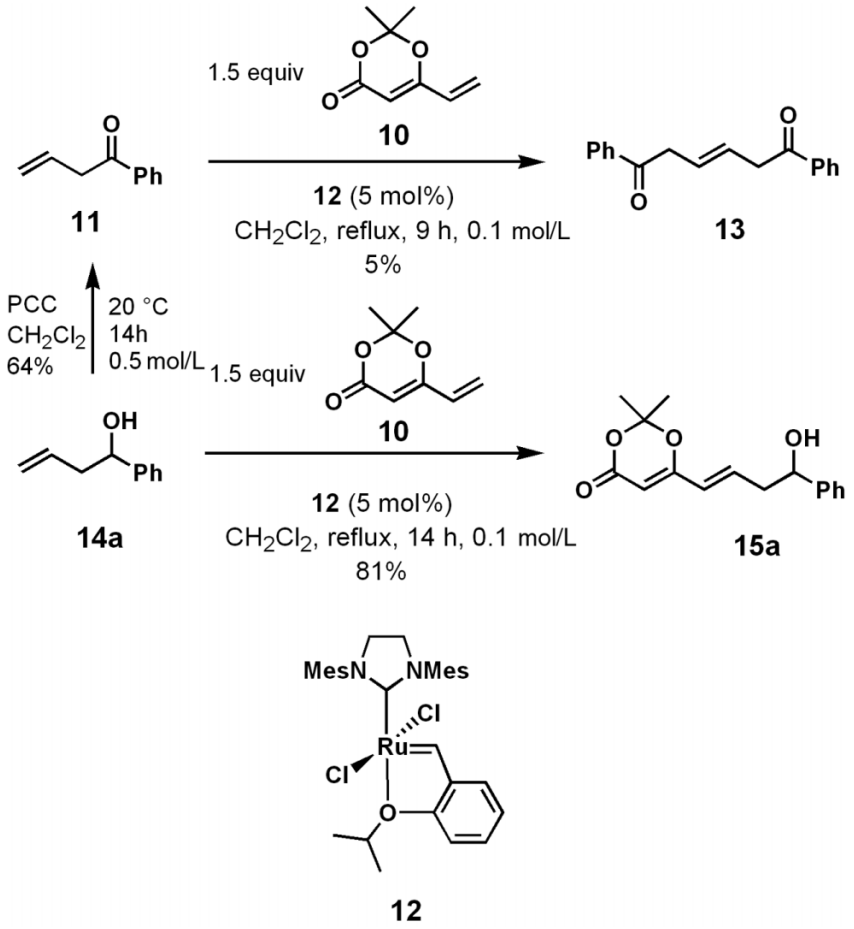
Scheme 3. Cross metathesis reactions of vinyl dioxinone **10**.



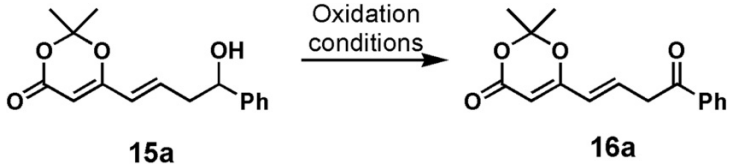


Table 1. Conditions for the oxidation of **15a**.

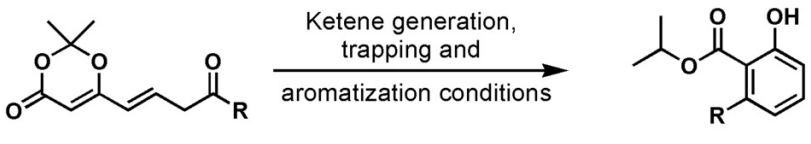

Entry	Oxidation conditions	Yield of **16a** (%)
1	PCC, CH_2Cl_2, 20 °C	0
2	MnO_2, CH_2Cl_2, 20 °C	0
3	IBX, EtOAc, 80 °C	67
4	DMP, CH_2Cl_2, 20 °C	40
5	DMP, CH_2Cl_2, 0 °C	77

Note: PCC, pyridinium chlorochromate; IBX, iodoxybenzoic acid; DMP, Dess–Martin periodinane.

enone–dioxinone **16a** in a 67% yield (Table 1, entry 3). Dess–Martin periodinane (DMP)[28] was found to be most efficient and oxidation at 0 °C gave enone **16a** in a 77% yield (Table 1, entries 4 and 5).

Reflux of a toluene solution of dioxinone **16a** and in situ trapping of the resultant ketene with 2-propanol gave the salicylate **17a** in a 53% yield (Table 2, entry 1). When heating of **16a** was carried out under microwave conditions, ketene generation and trapping was complete within 45 min (as observed by ^{1}H NMR spectroscopy), and heating of the intermediate for a further 8 h to effect aromatization gave salicylate **17a** in a 14% yield (Table 2, entry 2).[29] It was found that the microwave reaction of **16a** in the presence of 1,4-diazabicyclo [2.2.2]octane (DABCO) was more rapid and gave salicylate **17a** in a 55% yield after 1.5 h (Table 2, entry 3). Excess DABCO was not required for the acceleration (Table 2, entry

4) and prolonged heating failed to give any further conversion (Table 2, entry 5). The mechanism of rate enhancing action by DABCO is yet to be determined, though alkene (trans to cis) isomerization is a possibility.[30]

As has been shown previously, reaction of diketodioxinones with triethylamine smoothly gave the corresponding benzodioxinones.[31] In contrast, we have now found that the reaction of enone–dioxinone **16a** with triethylamine, Hünig's base, 5 mol/L hydrochloric acid, or ammonium acetate resulted only in decomposition and the arene **18** was not formed. No reaction was observed with acetic acid (Fig. 1).

The optimized reaction conditions for the cross metathesis, oxidation, and aromatization were applied to synthesize a range of salicylates **17a**–**17i** in good yields (Scheme 4). Efficient cross metathesis in some cases required the use of an increased amount (10 mol %) of catalyst **12** to achieve an acceptable yield. In these cases, some self-metathesis of vinyl dioxinone **10** was observed (<10%). The homoallylic alcohol **15k** failed to undergo cross metathesis, presumably because of coordination of the pyridine nitrogen to ruthenium, resulting in catalyst deactivation.

In all cases, aromatization proceeded in good yield except in one instance (**16j** → **17j**). In this example, steric hindrance presumably suppressed the initial intramolecular aldol reaction. Notably, the nature of the para substituent on the aryl unit (R) had little effect with both electron-donating groups (**16e**) and electron-withdrawing groups (**16b**) undergoing aromatization with comparable efficiency.

Conclusion

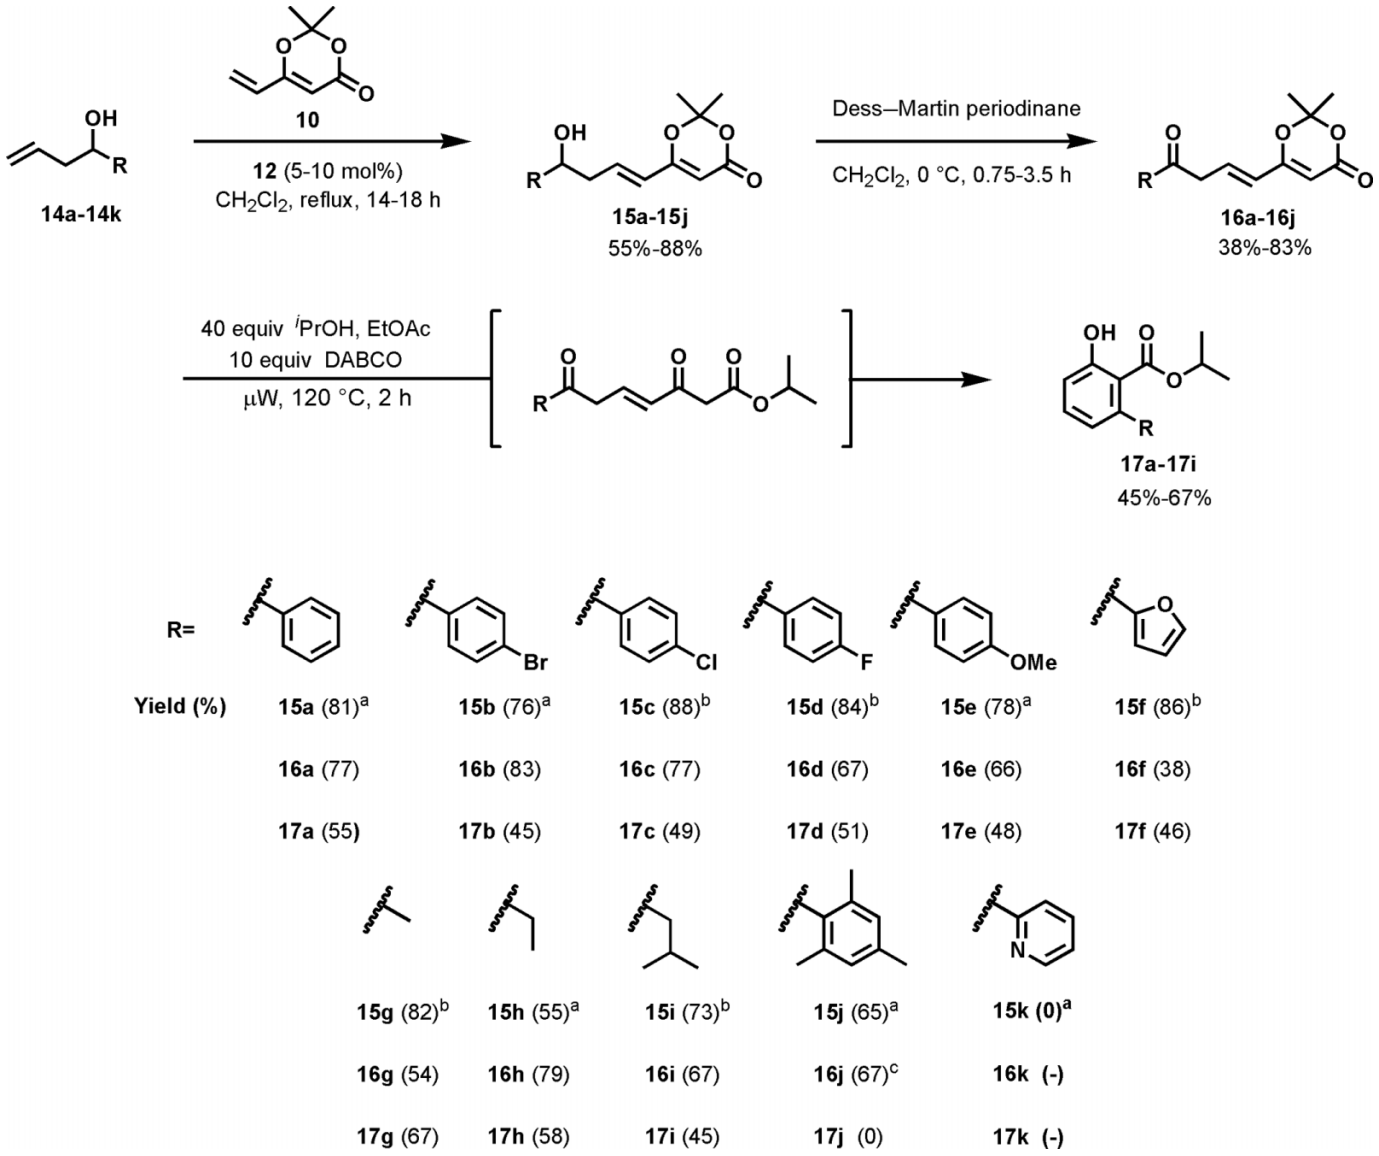
A range of isopropyl 6-aryl and 6-alkyl salicylate esters were prepared from the vinyl dioxinone **10** by cross metathesis with the homoallylic alcohols **14a**–**14i**, Dess–Martin periodinane (DMP) oxidation, and aromatization via generation and trapping of enedione–ketenes. The methodology is a mild and convenient process for the preparation of salicylates with these substitution patterns. Further aspects of this methodology will be reported in due course. ^{1}H and ^{13}C NMR spectra for all new compounds can be found in the Supplementary data.

Experimental

General methods

All reactions were carried out in oven-dried glassware under N_2, using commercially supplied solvents and reagents unless otherwise stated. CH_2Cl_2 was redistilled from CaH_2. Flash chromatography was carried out on silica gel (eluents are given in parentheses). Analytical TLC was performed on precoated silica gel F_{254} aluminum plates with visualization under UV light and by staining with acidic vanillin or acidic potassium permanganate solutions. Melting points were determined using a hot-stage microscope and are uncorrected. ^{1}H and ^{13}C NMR spectra were, respectively, recorded at 400 and 101 MHz with the solvent used in each case specified and spectra referenced to residual solvent peaks. Elemental analysis was carried out by the London Metropolitan elemental analysis service.

With the exception of commercially available pent-4-en-2ol (**14g**) the homoallylic alcohols **14a**,[32] **14b**,[33] **14c**,[34] **14d**,[34] **14e**,[32] **14f**,[32] **14h**,[35] **14i**,[35] **14j**,[32] and **14k**,[36] were prepared as described in the literature from the corresponding aldehydes by reaction with allylmagnesium bromide.[21]



General procedure A for cross metathesis of homoallylic alcohols 14a–14k

Catalyst **12** (5–10 mol %) was added with stirring to vinyl dioxinone **10** (1.5–2 equiv) and homoallylic alcohol (**14a**–**14k**, 0.1 mol/L) in CH_2Cl_2 at reflux and heating was continued for

Scheme 4. Synthesis of 6-aryl and 6-alkyl salicylates.

14–18 h. The mixture was rotary evaporated and chromatographed to give the corresponding dioxinone (**15a**–**15j**).

General procedure B for oxidation of dioxinones 15a–15j

DMP (1.4 equiv) was added with stirring to dioxinone (**15a**–**15j**, 0.1 mol/L) in CH_2Cl_2 at 0 °C and stirring continued at this temperature for 0.75–3.5 h. The mixture was chromatographed eluting with Et_2O, and the fractions containing product were rotary evaporated. Chromatography of the residue gave the enone–dioxinone (**16a**–**16j**).

General procedure C for aromatization of enone–dioxinones 16a–16j

Molecular sieves (100 mg per 0.1 mmol **16a**–**16j**), DABCO (10 equiv), *i*-PrOH (40 equiv), and enone-dioxinone (**16a**–**16j**) in EtOAc (0.02 mol/L) were placed in a 10 mL microwave vial and microwave heated at 120 °C for 2 h. The resulting mixture was filtered and rotary evaporated. The residue was taken up in EtOAc (10 mL) and washed with 1 mol/L aqueous HCl. The aqueous layer was extracted further with EtOAc (2 × 10 mL), and the combined organic layers were dried ($MgSO_4$), rotary evaporated, and chromatographed to give the salicylates **17a**–**17i**.

*(***E***)-6-(4-Hydroxy-4-phenylbut-1-enyl)-2,2-dimethyl-4*H*-1,3-dioxin-4-one (*15a*)*

According to general procedure A, reaction of alcohol **14a** (210 mg, 1.42 mmol) and dioxinone **10** (328 mg, 2.13 mmol) with catalyst **12** (45 mg, 0.071 mmol) for 14 h and chromatography (hexanes–Et_2O, 7:3 to 1:1) gave dioxinone **15a** (315 mg, 81%) as a brown oil. IR (thin film, cm^{-1}): 3422, 1703, 1649, 1589, 1389, 1373, 1273, 1252, 1200, 1018, 967, 903, 757, 700. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.40–7.32 (m, 5H), 6.64–6.55 (m, 1H), 6.02–5.95 (m, 1H), 5.25 (s, 1H), 4.84 (dd, J = 7.8, 4.9 Hz, 1H), 2.70–2.60 (m, 2H), 2.27 (br s, 1H), 1.70 (s, 6H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 162.9,

HR-MS (CI) *m/z* calcd for $C_{16}H_{16}ClO_3$: 291.0788 [M + H]$^+$; found: 291.0786. Anal. calcd for $C_{16}H_{15}ClO_3$: C 66.10, H 5.20; found: C 65.98, H 5.24.

***Isopropyl 4′-fluoro-3-hydroxybiphenyl-2-carboxylate* (17d)**

According to general procedure C, aromatization of enone–dioxinone **16d** (35 mg, 0.21 mmol) and chromatography (hexanes–Et_2O, 19:1) gave salicylate **17d** (17 mg, 51%) as a colorless solid; mp 85–87 °C (Et_2O–pentane). IR (thin film, cm^{-1}): 1650, 1606, 1513, 1445, 1367, 1280, 1227, 1213, 1177, 1093, 842, 815. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 11.01 (s, 1H), 7.40 (t, *J* = 7.8 Hz, 1H), 7.22–7.16 (m, 2H), 7.10–7.03 (m, 2H), 7.01 (dd, *J* = 8.3, 1.5 Hz, 1H), 6.74 (dd, *J* = 7.6, 1.2 Hz, 1H), 4.98 (spt, *J* = 6.3 Hz, 1H), 0.91 (d, *J* = 6.4 Hz, 6H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 170.3, 161.7, 143.8, 139.2 133.4, 129.8, 122.5, 116.9, 114.5, 114.3, 112.5, 69.3, 21.0. MS (CI) *m/z*: 275 [M + H]$^+$. HR-MS (CI) *m/z* calcd for $C_{16}H_{16}FO_3$: 275.1083 [M + H]$^+$; found: 275.1081. Anal. calcd for $C_{16}H_{15}FO_3$: C 70.06, H 5.51; found: C 70.00, H 5.60.

***Isopropyl 3-hydroxy-4′-methoxybiphenyl-2-carboxylate* (17e)**

According to general procedure C, aromatization of enone–dioxinone **16e** (37 mg, 0.12 mmol) and chromatography (hexanes–Et_2O, 100:0 to 19:1) gave salicylate **17e** (17 mg, 48%) as a yellow solid; mp 42–45 °C (Et_2O). IR (thin film, cm^{-1}): 1655, 1602, 1515, 1446, 1369, 1271, 1243, 1218, 1175, 1094, 1034, 807. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 10.86 (s, 1H), 7.38 (t, *J* = 7.8 Hz, 1H), 7.18–7.11 (m, 2H), 6.98 (dd, *J* = 8.3, 1.0 Hz, 1H), 6.94–6.87 (m, 2H), 6.77 (dd, *J* = 7.3, 1.0 Hz, 1H), 4.97 (spt, *J* = 6.3 Hz, 1H), 3.86 (s, 3H), 0.91 (d, *J* = 6.4 Hz, 6H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 170.5, 161.4, 158.7, 144.6, 135.7, 133.3, 129.4, 122.6, 116.3, 113.0, 112.8, 69.1, 55.4, 21.1. MS (CI) *m/z*: 304 [M + H_2O]$^+$, 287 [M + H]$^+$. HR-MS (CI) *m/z* calcd for $C_{17}H_{19}O_4$: 287.1283 [M + H]$^+$; found: 287.1275. Anal. calcd for $C_{17}H_{18}O_4$: C 71.31, H 6.34; found: C 68.02, H 6.55.

***Isopropyl 2-(furan-2-yl)-6-hydroxybenzoate* (17f)**

According to general procedure C, aromatization of enone–dioxinone **16f** (30 mg, 0.12 mmol) and chromatography (hexanes–Et_2O, 100:0 to 19:1) gave salicylate **17f** (13 mg, 46%) as a colorless oil. IR (thin film, cm^{-1}): 1664, 1606, 1572, 1453, 1374, 1275, 1222, 1178, 1103. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 10.67 (s, 1H), 7.47 (d, *J* = 1.0 Hz, 1H), 7.40 (t, *J* = 7.8 Hz, 1H), 7.03 (dd, *J* = 8.3, 1.0 Hz, 1H), 6.95 (dd, *J* = 7.3, 1.0 Hz, 1H), 6.47 (dd, *J* = 3.4, 2.0 Hz, 1H), 6.40 (d, *J* = 2.9 Hz, 1H), 5.13 (spt, *J* = 6.3 Hz, 1H), 1.12 (d, *J* = 6.4 Hz, 6H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 170.0, 161.2, 154.2, 141.7, 133.5, 132.8, 122.3, 118.0, 112.7, 111.1, 107.1, 69.3, 21.5. MS (CI) *m/z*: 247 [M + H]$^+$. HR-MS (CI) *m/z* calcd for $C_{14}H_{15}O_4$: 247.0970 [M + H]$^+$; found: 247.0972.

***Isopropyl 2-hydroxy-6-methylbenzoate* (17g)**

According to general procedure C, aromatization of enone–dioxinone **16g** (73 mg, 0.348 mmol) and chromatography (pentane–Et_2O, 100:0 to 98:2) gave salicylate **17g** (45 mg, 67%) as a colorless oil. IR (thin film, cm^{-1}): 1727, 1650, 1606, 1580, 1459, 1439, 1365, 1291, 1251, 1212, 1165, 1100, 1078, 1034, 965, 911, 863, 806, 756, 702. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 11.43 (s, 1H), 7.27 (t, *J* = 7.8 Hz, 1H), 6.84 (d, *J* = 8.3 Hz, 1H), 6.71 (d, *J* = 7.3 Hz, 1H), 5.34 (spt, *J* = 6.2 Hz, 1H), 2.56 (s, 3H), 1.43 (d, *J* = 6.4 Hz, 6H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 171.2, 162.8, 141.3, 133.9, 122.9, 115.6, 112.7, 69.7, 24.2, 22.0. MS (ESI) *m/z*: 212 [M + H_2O]$^+$, 195 [M + H]$^+$. Anal. calcd for $C_{11}H_{14}O_3$: C 68.02, H 7.27; found: C 67.87, H 7.21.

***Isopropyl 2-hydroxy-6-ethylbenzoate* (17h)**

According to general procedure C, aromatization of enone-dioxinone **16h** (76 mg, 0.339 mmol) and chromatography (pentane–Et_2O, 100:0 to 19:1) gave salicylate **17h** (41 mg, 58%) as a colorless oil. IR (thin film, cm^{-1}): 1727, 1654, 1606, 1577, 1447, 1363, 1308, 1295, 1245, 1207, 1167, 1102, 931, 908, 816. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 11.33 (s, 1H), 7.30 (t, *J* = 8.1 Hz, 1H), 6.85 (dd, *J* = 8.3, 1.5 Hz, 1H), 6.74 (d, *J* = 7.3 Hz, 1H), 5.36 (spt, *J* = 6.3 Hz, 1H), 2.96 (q, *J* = 7.3 Hz, 2H), 1.43 (d, *J* = 6.4 Hz, 6H), 1.23 (t, *J* = 7.3 Hz, 3H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 171.0, 162.6, 147.4, 134.1, 121.7, 115.6, 112.2, 69.7, 29.6, 21.8, 16.5. MS (ESI) *m/z*: 231 [M + Na]$^+$, 209 [M + H]$^+$. Anal. calcd for $C_{12}H_{16}O_3$: C 69.21, H 7.74; found: C 69.18, H 7.64.

***Isopropyl 2-hydroxy-6-isobutylbenzoate* (17i)**

According to general procedure C, aromatization of enone–dioxinone **16i** (78 mg, 0.310 mmol) and chromatography (pentane–Et_2O, 100:0 to 19:1) gave salicylate **17i** (31 mg, 45%) as a colorless oil. IR (thin film, cm^{-1}): 1651, 1606, 1577, 1478, 1363, 1308, 1294, 1250, 1229, 1202, 1164, 1097, 1062, 911, 833, 803, 763, 709. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 11.35 (s, 1H), 7.28 (t, *J* = 7.8 Hz, 1H), 6.86 (dd, *J* = 8.3, 1.5 Hz, 1H), 6.66 (dd, *J* = 7.6, 1.2 Hz, 1H), 5.37 (spt, *J* = 6.3 Hz, 1H), 2.82 (d, *J* = 7.3 Hz, 2H), 1.76–1.91 (m, 1H), 1.43 (d, *J* = 6.4 Hz, 6H), 0.89 (d, *J* = 6.4 Hz, 6H). ^{13}C NMR (101 MHz, $CDCl_3$, ppm) δ: 171.2, 162.8, 144.5, 133.5, 123.7, 115.8, 112.5, 69.6, 45.5, 30.0, 22.5, 21.8. MS (ESI) *m/z*: 259 [M + Na]$^+$, 237 [M + H]$^+$. Anal. calcd for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 71.08, H 8.45.

Synthesis of hydrazine and azapeptide derivatives by alkylation of carbazates and semicarbazones

Yesica Garcia-Ramos, Caroline Proulx, and William D. Lubell

Abstract: Hydrazine and azapeptide analogs were synthesized effectively by alkylation of alkylidene carbazates and semicarbazones. In comparisons of benzylidene, benzhydrylidene, and fluorenylidene *tert*-butyl carbazates in alkylations using bases of different pK_b character, superior conversion was obtained using the fluorenone derivative. Mild alkylation conditions were found employing Et_4NOH as base and used to convert fluorenylidene *tert*-butyl carbazate into 13 different protected hydrazines. Moreover, racemization was avoided during alkylation of fluorenylidene semicarbazide in the synthesis of aza-propargylglycinylphenylalanine *tert*-butyl ester, the protecting groups from which could be selectively removed.

Key words: carbazate, tetraethylammonium hydroxide, semicarbazone, alkylation, fluorenone hydrazine.

Résumé : L'alkylation de carbazates et de semicarbazones d'alkylidène permet de réaliser efficacement la synthèse d'analogues hydrazino- et aza- de peptides. Des comparaisons des réactions d'alkylation des *tert*-butyl carbazates de benzylidène, de benzhydrylidène et de fluorénylidène en présence de bases de pK_b divers ont permis de montrer que les meilleures conversions sont obtenues avec le dérivé de la fluorénone. Des conditions d'alkylation douces, faisant appel à Et_4NOH comme base, ont été utilisées pour transformer le *tert*-butyl carbazate de fluorénylidène en 13 hydrazines protégées différentes. De plus, il a été possible d'éviter la racémisation au cours de l'alkylation du fluorénylidènesemicarbazide dans la synthèse de l'ester *tert*-butylique de l'aza-propargylglycinylphénylalanine à partir duquel les groupes protecteurs peuvent être enlevés d'une façon sélective.

Mots-clés : carbazate, hydroxyde de tétraéthylammonium, semicarbazone, alkylation, hydrazone de la fluorénone.

Introduction

Hydrazine derivatives are employed as pesticides and drugs for treating depression, Parkinson disease, and tuberculosis.[1,2] Substituted hydrazine analogs have also been used as building blocks for heterocycle and azapeptide synthesis.[3,4] The latter peptidomimetics have evoked particular interest for studying biologically active peptides because of their potential for rigidifying conformation, increasing metabolic stability, and improving bioavailability.[5,6]

Hydrazine synthesis has, however, remained a challenge owing to the inherent difficulty in differentiating the adjacent nitrogen atoms. Different ways have been described for functionalizing hydrazine selectively. For example, monoalkylation of hydrazine, usually in excess, has been achieved using different alkyl halides, albeit mixtures may ensue from multiple alkylation.[7,8] Alternatively, alkyl hydrazines have been synthesized by hydrogenation and by hydride reduction of their corresponding hydrazones.[9–11] Issues of overalkylation have been addressed by employing carbazates in reductive amination protocols,[4] as well as by reactions with reactive alkyl halides; however, *N*′,*N*′-dialkylcarbazate has been observed as a side product from the latter process and removed by chromatography.[12,13] Combinations of protecting groups have also been employed in attempts to enhance reactivity and selectivity in the alkylation of hydrazine. For example, *N*-*tert*-butyloxycarbonyl- and *N*-benzyloxycarbonyl-aminophthalimides were shown to be sufficiently reactive acid partners in protocols featuring alkylations with alcohols using the Mitsunobu reaction.[14] Although a variety of alkylations of such carbamatophthalimides were successful, attempts to employ ureidophthalimides in similar Mitsunobu conditions as well as in reactions with alkyl halides and potassium *tert*-butoxide as base returned mostly starting material.[15] Considering alkylation of such aza-glycine amide derivatives is a key step for the diversity-oriented synthesis of azapeptide and azadiketopiperazine derivatives, semicarbazones were subsequently explored and shown to undergo alkylation effectively using alkyl halides and relatively strong bases.[15,16] Conditions have also been developed for the alkylation of *tert*-butylisopropylidene carbazate;[17] in particular, 77%–93% yields were obtained in reactions with a set of six primary alkyl bromides using potassium hydroxide under phase-transfer conditions, albeit at 80 °C.[18] In addition, a set of five *tert*-butyl arylidene and cyclohexylidene carba-

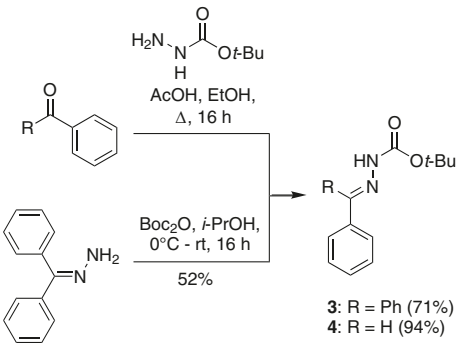
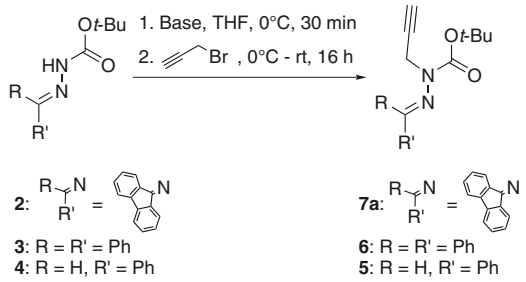
zates were alkylated with allyl and benzyl bromides, respectively, in a >85% yield using cesium carbonate in the absence of solvent with ball milling at 30 Hz.[19]



The introduction, alkylation, and deprotection of semicarbazone-protected aza-glycine residues has given rise to the submonomer synthesis of azapeptides.[16] For the key alkylation reaction, aza-glycine has been protected with benzylidene and diphenylmethylidene hydrazones, respectively, on solid support and in solution, to achieve chemoselective deprotonation employing KO-*t*-Bu and *tert*-butyliminotri (pyrrolidino)-phosphorane (BTPP) as base.[15] In the alkylation of the azadipeptide ester, aza-Gly-Phe-O-*t*-Bu, racemization was, however, detected owing to the competitive removal of the ester α proton. The influence of the hydrazone structure in the alkylation of aza-glycine analogs has thus been examined in pursuit of a means for avoiding racemization without sacrificing yield by employment of milder basic conditions. In early studies, electron-withdrawing groups were considered for favoring deprotonation by anion stabilization; however, their inductive effects had modest influence at best during alkylation. Inspired by the application of fluorenyl imines in the alkylation of glycine esters,[20] the resonance stabilization of the 14 π-electron fluorenyl anion (Fig. 1) has now been explored for favoring deprotonation of the semicarbazone and compared with reactions of the benzylidene and diphenylmethylidene counterparts. The application of this strategy has led to effective means for selective hydrazine alkylation under mild conditions and ambient temperature, as well as a racemization-free method for assembling azadipeptide building blocks for azapeptide synthesis.

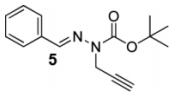
Results and discussion

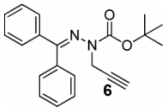


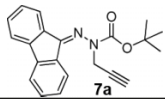
Fluorenylidene *tert*-butyl carbazate (**2**) was made by acylation of fluorenone hydrazone (**1**),[21] using di-*tert*-butyl dicarbonate (Scheme 1). On the other hand, diphenylmethylidene and benzylidene carbazates (**3** and **4**) were synthesized effectively from the condensation of benzophenone and benzaldehyde, respectively, with *tert*-butyl carbazate in ethanol (Scheme 2).[22]

With carbazates **2**–**4** in hand, alkylation was studied using propargyl bromide (150 mol %) and different bases (150 mol %), with the pK_a of the conjugate acids varying from 19 to 10.7

Scheme 2. Synthesis of carbazates **3** and **4**.







Scheme 3. Propargylation of alkylidene carbazates **2**–**4**.

(Scheme 3 and Table 1).[23–28] Conversion was analyzed by ^{1}H NMR spectroscopy. Complete alkylation was consistently observed using all three carbazates and *tert*-butoxide as strong base, and no reaction occurred with triethylamine as the weakest base. Significant differences in reactivity were observed employing 2-*tert*-butyl-1,1,3,3-tetramethylguanidine and hydroxide ion as base. Using such bases, fluorenylidene *tert*-butyl carbazate (**2**) gave superior conversion in comparison with carbazates **3** and **4**. In particular, complete conversion was achieved in the alkylation of **2** employing the 10% tetraethylammonium hydroxide in H_2O (Table 1, entry 5). For comparison, 10% sodium hydroxide in H_2O was also employed in the alkylations of carbazates **2**–**4** with propargyl bromide (150 mol%). Although a slight improvement in conversion to diphenylketamine carbazate (**6**) was observed using **3** and aqueous NaOH, yields of carbazates **5**–**7** were superior with aqueous tetraethylammonium hydroxide, albeit nearly identical in the alkylation of **2** with both forms of the aqueous hydroxide ion. The scope of the alkylation of **2** was thus examined employing aqueous tetraethylammonium hydroxide.

To examine the scope of the alkylation reaction employing Et_4NOH (150 mol %) as base, **2** (100 mol %) was treated with different alkylating agents (150 mol %) in tetrahydrofuran (THF) at 0 °C and the reactions were allowed to warm to room temperature over 16 h (Table 2). Yields varied with the electronic and steric natures of the electrophile. For example, reactive alkyl halides (Table 2, entries 1–9) gave 62%–89% yields of isolated carbazates **7a**–**7i**. On the other hand, the reaction with bulky alkyl halides isopropyliodide and 1-bromoethylbenzene required microwave irradiation (50–60 °C) to give alkyl branched carbazates **7j** and **7k** in 55% and 61% yields, respectively. Relative to the ethyl and butyl counterparts, the longer alkyl chain of 1-iodooctane

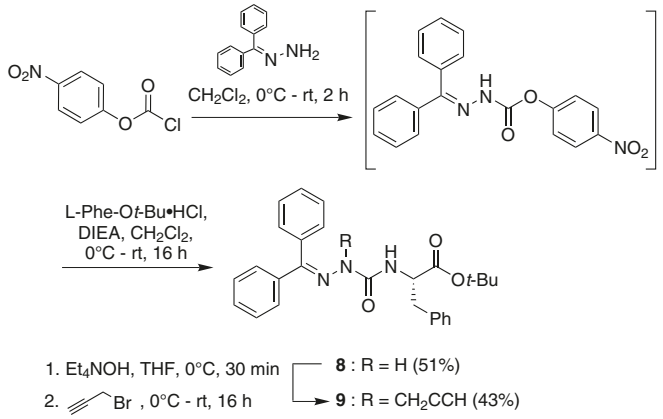
reduced the yield of carbazate **7l** to a 60% yield. Attempts to perform Michael reactions using *tert*-butyl acrylate, acrylamide, and dimethylvinyl phosphonate provided only recovered starting material, perhaps because of competitive retro-Michael reactions. On the contrary, phenylvinylsulfone reacted with **2** to furnish carbazate **7m** in a 56% yield.

The synthesis and alkylation of aza-Gly-Phe-O-*t*-Bu dipeptides **8** and **11** were subsequently explored using propargyl bromide and tetraethylammonium hydroxide to examine effects on yield and racemization. Benzhydrylidene **8** was synthesized by activation of benzophenone hydrazone with *p*-nitrophenyl chloroformate and coupling to L-phenylalanine *tert*-butyl ester (Scheme 4).[29] From the alkylation of **8** with propargyl bromide using KO-*t*-Bu (130 mol %) as base, aza-propargylglycine **9** was produced as a racemic mixture, as ascertained by supercritical fluid chromatography (SFC) analysis on a Chiralpak AD-H column. Removal of the Phe α proton was considered to compete with semicarbazone deprotonation during alkylation of **8** using KO-*t*-Bu as a relatively strong base. Alkylation of **8** was next performed with the weaker base Et_4NOH and gave **9** without racemization, albeit in a 43% yield.



Fluorenylidene aza-glycinyl-phenylalanine *tert*-butyl ester (**11**) was synthesized by treatment of L- and D,L-phenylalanine *tert*-butyl ester with phosgene to prepare the corresponding isocyanate, which was reacted with fluorenone hydrazone (**1**, Scheme 5).[30] Azadipeptide **11** was alkylated as described above using Et_4NOH and furnished aza-propargylglycine **12** without racemization in a 92% yield.

After alkylation, fluorenylidene aza-propargylglycinyl-D,L-phenylalanine *tert*-butyl ester (D,L-**12**) was selectively converted to amino ester **13** and semicarbazone acid **14** by respective treatments with $NH_2OH{\cdot}HCl$ in pyridine at 60 °C

for 12 h, and anhydrous acid. In the latter reaction, *tert*-butyl ester removal was accomplished more efficiently with HCl gas in CH_2Cl_2 than 1:1 TFA/CH_2Cl_2 (Scheme 6).

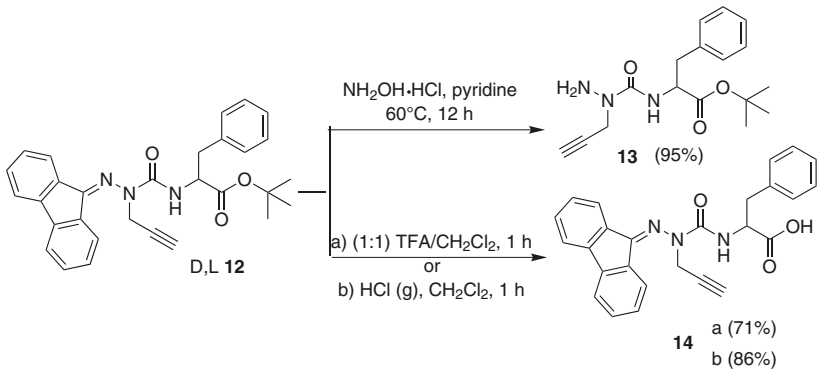
In summary, milder conditions for the alkylation of semicarbazones have been achieved by employing fluorenone derivatives. Tetraethylammonium hydroxide proved an efficient base for the alkylation of fluorenylidene carbazate **2** with diverse alkyl halides at ambient temperature. Moreover, racemization was avoided and a high yield was achieved in the alkylation of the fluorenylidene azadipeptide **11**. In addition, the orthogonal semicarbazone and carboxylate functions of aza-propargylglycine **12** were selectively removed. In light of the potential for subsequent employment of the alkyl derivatives in the synthesis of hydrazines, heterocycles, and longer azapeptide sequences, this method may find valuable applications in medicinal chemistry and peptide science.

Experimental section

General method

Unless specified otherwise, fluorenone hydrazone (**1**), *tert*-butyl 3-diphenylmethylene carbazate (**3**), and *tert*-butyl 3-benzylidene carbazate (**4**) were prepared according to the literature protocols.[21,22] Alkyl halides were purchased from Sigma-Aldrich and filtered through a small plug of silica gel prior to use. Anhydrous solvents (THF and dichloromethane (DCM)) were obtained by passage through a solvent filtration system (GlassContour, Irvine, California). Flash chromatography[31] was on 230–400 mesh silica gel, and thin-layer chromatography was performed on silica gel 60 F_{254} plates from Merck. Melting points were determined on a Gallankamp apparatus. Specific rotations ($[\alpha]_D$ values) were calculated from optical rotations measured at 20 °C in $CHCl_3$ at the specified concentrations (*c* in g/100 mL) using a 1 dm cell (*l*) on a PerkinElmer Polarimeter 341, using the general formula $[\alpha]_D^{20} = (100\alpha)/(lc\alpha)$. Accurate mass measurements were performed on an (LC–MS) instrument from Agilent technologies in positive electrospray ionization (ESI) mode at the Université de Montréal Mass Spectrometry facility. Sodium adducts, $[M + Na]^+$, were used for empirical formula confirmation. ^1H and ^{13}C NMR spectra were measured in $CDCl_3$ (7.26 and 77.36 ppm, respectively), coupling constant (*J*) values were measured in hertz (Hz), and chemical shift values in parts per million (ppm). IR spectra were recorded neat on an ATR Bruker apparatus.

^1H and ^{13}C NMR spectra for compounds **2**, **5**, **6**, **7a**–**7n**, and **8**–**12** and SFC traces for compounds **9** and **12** can be found in the Supplementary data.



tert-*Butyl 3-fluorenylidene carbazate (2)*

A solution of fluorenone hydrazone (250 mg, 1.28 mmol, 1 equiv) in THF (10 mL) was treated with pyridine (103 μL, 1.28 mmol, 1 equiv) and 4-dimethylaminopyridine (DMAP; 16 mg, 0.13 mmol, 0.2 equiv), cooled with an ice bath, and treated slowly with di-*tert*-butyl dicarbonate (419 mg, 1.92 mmol, 1.5 equiv). The ice bath was removed and the reaction mixture was allowed to warm to room temperature. After 16 h, CH_2Cl_2 (50 mL) was added to the mixture, which was extracted three times with H_2O, dried with $MgSO_4$, filtered, and evaporated under vacuum. The residue was purified by silica gel flash chromatography (100% CH_2Cl_2). Evaporation of the collected fractions gave a yellow solid (193.7 mg, 51% yield); mp 109.8–111 °C. R_f 0.32 (8:2 hexane/EtOAc). IR (neat, cm^{-1}) ν_{max}: 2997, 2968, 1729, 1707, 1507, 1230, 1150, 768. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.85 (s, 1H), 7.94 (d, J = 7.5 Hz, 1H), 7.79 (dt, J = 7.7, 0.9 Hz, 1H), 7.74 (dt, J = 7.5, 0.9 Hz, 1H), 7.61 (dt, J = 7.4, 0.9 Hz, 1H), 7.47 (td, J = 7.6, 1.0 Hz, 1H), 7.37 (hd, J = 3.9, 1.2 Hz, 2H), 7.31 (td, J = 7.5, 1.1 Hz, 1H), 1.61 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 153.1, 142.7, 139.4, 137.4, 131.3, 130.2, 130.1, 128.6, 128.2, 125.6, 122.7, 121.2, 119.9, 82.7, 28.6. tert-*Butyl* N-*(propargyl)benzylidene carbazate (5)*

tert-Butyl 3-benzylidene carbazate (**4**; 52.9 mg, 0.24 mmol, 1 equiv) was dissolved in 1 mL of anhydrous THF at 0 °C, treated with potassium *tert*-butoxide (39 mg, 0.34 mmol, 1.5 equiv) for 30 min, followed by propargyl bromide (51 μL, 0.34 mmol, 1.5 equiv). The ice bath was removed and the mixture was allowed to warm to room temperature. After stirring for 16 h, CH_2Cl_2 was added to the mixture, which was then extracted twice with H_2O, dried with $MgSO_4$, and evaporated. The residue was purified by flash chromatography using 1:9 EtOAc/hexane as the solvent system. Evaporation of the collected fractions gave carbazate **5** as an oil (27.1 mg, 44% yield). R_f 0.42 (8:2 hexane/EtOAc). IR (neat, cm^{-1}) ν_{max}:

tert-*Butyl* N-*(propargyl)benzhydrylidene carbazate (6)*

Employing the procedure used to make carbazate **5**, *tert*-butyl 3-diphenylmethylene carbazate (**3**; 54.7 mg, 0.18 mmol, 1 equiv) was reacted with potassium *tert*-butoxide (28.4 mg, 0.26 mmol, 1.5 equiv) and propargyl bromide (38 μL, 0.26 mmol, 1.5 equiv.), and the product was purified by flash chromatography using 5:95 EtOAc/hexane as the solvent system to afford carbazate **6** as an oil (35.9 mg, 63% yield). R_f 0.64 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 3290, 3059, 2976, 1693, 1366, 1237, 1150, 694. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.61 (m, 2H), 7.44 (m, 3H), 7.37 (m, 5H), 4.40 (d, J = 1.9 Hz, 2H, CH_2), 2.28 (t, J = 2.5 Hz, 1H), 1.25 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 173.3, 152.0, 138.2, 135.9, 131.0, 129.6, 129.4, 129.1, 128.4, 128.2, 81.6, 79.6, 72.5, 40.8, 28.3. HR-MS (LC-ESI) m/z calcd for $C_{21}H_{22}N_2O_2Na$ $(M + Na)^+$: 357.1574; found: 357.1562.

tert-*Butyl* N-*(propargyl)fluorenylidene carbazate (7a)*

tert-Butyl 3-fluorenylidene carbazate (**2**; 51.4 mg, 0.17 mmol, 1 equiv) was dissolved in 1 mL of anhydrous THF at 0 °C, treated with 10% tetraethylammonium hydroxide in H_2O (384 μL, 0.27 mmol, 1.5 equiv), stirred for 30 min, and treated with propargyl bromide (39 μL, 0.27 mmol, 1.5 equiv). The ice bath was removed, and the mixture was allowed to warm to room temperature, stirred for 16 h, treated with CH_2Cl_2, extracted twice with H_2O, dried with $MgSO_4$, filtered, and evaporated. The residue was purified by flash chromatography using 5:95 EtOAc/hexane as the solvent system. Evaporation of the collected fractions gave carbazate **7a** as a yellow solid (50.2 mg, 87% yield); mp 139.7–140.0 °C. R_f 0.61 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 3314, 1685, 1357, 1339, 1243, 1153, 1140, 738. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.93 (m, 2H), 7.60 (dd, J = 12.8, 7.5 Hz, 2H), 7.44 (t, J = 7.5 Hz, 2H), 7.29 (dt, J = 17.2, 7.5 Hz, 2H), 4.59 (d, J = 2.2, 2H), 2.24 (t, J = 2.2 Hz, 1H), 1.39 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.9, 152.6, 143.1, 141.6, 136.8, 132.4, 131.9, 131.8, 128.6, 128.5, 128.3, 123.7, 120.3, 120.0, 82.6, 79.7, 72.1, 41.6, 28.4. HR-MS (LC-ESI) m/z calcd for $C_{21}H_{20}N_2O_2Na$ $(M + Na)^+$: 355.1417; found: 355.1399.

tert-*Butyl* N-*(methyl)fluorenylidene carbazate (7b)*

Employing the procedure to make carbazate **7a**, carbazate **2** (52.6 mg, 0.18 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (395 μL, 0.27 mmol, 1.5 equiv) and iodomethane (17 μL, 0.27 mmol, 1.5 equiv), and the product was purified by flash chromatography using 5:95 EtOAc/hexane as the solvent system. Carbazate **7b** was obtained as a yellow solid (46.6 mg, 85% yield); mp 66–67.8 °C. R_f 0.61 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2998, 2970, 1685, 1366, 1130, 736. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.91 (d, J = 7.3 Hz, 1H), 7.87 (d, J = 7.4, 1H), 7.61 (dd, J = 14.2, 7.4 Hz, 2H), 7.44 (tq, J = 7.5, 1.2 Hz, 2H), 7.30 (m, 2H), 3.42 (s, 3H), 1.41 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.4, 153.5, 142.6, 141.2, 136.6, 132.0, 131.4, 131.1, 128.3, 128.2, 127.8, 123.1, 120.0, 119.7, 81.4, 38.4, 28.2. HR-MS (LC-ESI) m/z calcd. for $C_{19}H_{20}N_2O_2Na$ $(M + Na)^+$: 331.1417; found: 331.1408.

tert-*Butyl* N-*(ethyl)fluorenylidene carbazate (7c)*

Employing the procedure to make carbazate **7a**, carbazate **2** (52.9 mg, 0.18 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (397 μL, 0.27 mmol, 1.5 equiv) and iodoethane (22 μL, 0.27 mmol, 1.5 equiv), and the product was purified by flash chromatography using 5:95 EtOAc/hexane as the solvent system. Carbazate **7c** was obtained as a yellow solid (47.6 mg, 82% yield); mp 150.8–153.7 °C. R_f 0.57 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2972, 2925, 1681, 1448, 1363, 1276, 1164, 738. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.92 (d, J = 7.5 Hz, 1H), 7.88 (d, J = 7.3, 1H), 7.61 (dd, J = 13, 7.4 Hz, 2H), 7.43 (t, J = 7.4 Hz, 2H), 7.33–7.25 (m, 2H), 3.9 (q, J = 7.1 Hz, 2H), 1.38 (s, 9H), 1.3 (t, J = 7.1 Hz, 3H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 152.7, 142.9, 141.4, 137.0, 132.1, 131.7, 131.6, 128.5, 128.4, 128.0, 123.3, 120.2, 119.9, 81.5, 46.5, 28.5, 13.8. HR-MS (LC-ESI) m/z calcd for $C_{20}H_{23}N_2O_2$ $(M + H)^+$: 323.1754; found: 323.1764.

tert-*Butyl* N-(n-*butyl)fluorenylidene carbazate (7d)*

Employing the procedure to make carbazate **7a**, **2** (60.6 mg, 0.21 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (455 μL, 0.31 mmol, 1.5 equiv) and 1-iodobutane (35 μL, 0.31 mmol, 1.5 equiv), and the product was purified by flash chromatography using 1:9 EtOAc/hexane

as the solvent system. Carbazate **7d** was obtained as a yellow solid (45.7 mg, 62% yield); mp 80–82 °C. R_f 0.6 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2921, 2876, 1682, 1446, 1364, 1245, 1145, 736. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.90 (m, 2H), 7.61 (dd, J = 13.3, 7.4 Hz, 2H), 7.43 (t, J = 7.3 Hz, 2H), 7.33–7.26 (m, 2H), 3.87 (t, J = 7.3 Hz, 2H), 1.69 (m, 2H), 1.43–1.38 (m, 11H), 0.94 (td, J = 7.3, 2 Hz, 3H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.9, 152.9, 142.9, 141.4, 137.1, 132.1, 131.8, 131.6, 128.5, 128.0, 123.4, 120.2, 119.9, 81.6, 51.8, 31.1, 28.5, 20.5, 14.1. HR-MS (LC-ESI) *m/z* calcd for $C_{22}H_{27}N_2O_2$ $(M + H)^+$: 351.2067; found: 351.2077.

tert-*Butyl* N-*(benzyl)fluorenylidene carbazate (7e)*

Employing the procedure to make carbazate **7a**, **2** (200 mg, 0.68 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (1.5 mL, 1.02 mmol, 1.5 equiv) and benzyl bromide (122 μL, 1.02 mmol, 1.5 equiv), and the product was purified by flash chromatography using 1:9 EtOAc/hexane as the solvent system. Carbazate **7e** was obtained as a yellow solid (232.3 mg, 89% yield); mp 106.7–109.1 °C. R_f 0.47 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2980, 2918, 1685, 1321, 1242, 1148, 730. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.90 (d, J = 7 Hz, 1H), 7.79 (d, J = 7.1, 1H), 7.59 (dd, J = 10.9, 7.7 Hz, 2H), 7.42 (m, 4H), 7.30 (t, J = 7.3, 3H), 7.23 (m, 2H), 5.05 (s, 2H), 1.37 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.4, 152.9, 142.9, 141.4, 138.5, 137.1, 132.1, 131.8, 131.6, 128.6, 128.48, 128.46, 128.45, 128.1, 127.5, 123.4, 120.2, 119.9, 82.1, 56.3, 28.5. HR-MS (LC-ESI) *m/z* calcd for $C_{25}H_{24}N_2O_2Na$ $(M + Na)^+$: 407.173; found: 407.1725.

tert-*Butyl* N-*(cinnamyl)fluorenylidene carbazate (7f)*

Employing the procedure to make carbazate **7a**, carbazate **2** (50 mg, 0.17 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (376 μL, 0.26 mmol, 1.5 equiv) and cinnamyl bromide (52 mg, 0.26 mmol, 1.5 equiv), and the product was purified by flash chromatography using 1:9 EtOAc/hexane as the solvent system. Carbazate **7f** was obtained as an oil (53.4 mg, 77% yield). R_f 0.4 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2973, 2928, 1687, 1448, 1366, 1226, 1142, 729. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.90 (m, 2H), 7.60 (dd, J = 15.8, 7.5 Hz, 2H), 7.42 (hd, J = 3.8, 1 Hz, 2H), 7.37–7.2 (m, 7H), 6.64 (d, J = 15.8 Hz, 1H), 6.40 (dt, J = 15.8, 6.4 Hz, 1H), 4.61 (dd, J = 6.3, 1 Hz, 2H), 1.40 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.4, 152.4, 142.4, 140.9, 136.6, 136.4, 132.4, 131.7, 131.2, 131.1, 128.2, 128.0, 127.9, 127.6, 127.2, 126.2, 124.8, 122.9, 119.7, 119.4, 81.4, 53.8, 28.0. HR-MS (LC-ESI) *m/z* calcd for $C_{27}H_{26}N_2O_2Na$ $(M + Na)^+$: 433.1886; found: 433.1885.

tert-*Butyl* N-*(allyl)fluorenylidene carbazate (7g)*

Employing the procedure to make carbazate **7a**, carbazate **2** (50 mg, 0.17 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (376 μL, 0.25 mmol, 1.5 equiv) and allyl iodide (24 μL, 0.25 mmol, 1.5 equiv), and the product was purified by flash chromatography using 1:9 EtOAc/hexane as the solvent system. Carbazate **7g** was obtained as a yellow solid (47.3 mg, 83% yield); mp 109.2–111.4 °C. R_f 0.47 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2956, 2921, 2852, 1676, 1374, 1251, 1142, 738. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.90 (d, J = 7.6 Hz, 1H), 7.88 (d, 1H), 7.61 (dd, J = 14.9, 7.5 Hz, 2H), 7.43 (td, J = 7.5, 1.0 Hz, 2H), 7.29 (m, 2H), 6.01 (m, 1H), 5.30 (dq, J = 17.1, 1.5 Hz, 1H), 5.16 (dq, J = 10.3, 1.2 Hz, 1H), 4.46 (d, J = 6 Hz, 2H), 1.39 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 165.4, 152.9, 142.9, 141.4, 138.5, 137.1, 132.1, 131.8, 131.6, 128.6, 128.5, 128.1, 127.5, 123.4, 120.2, 119.9, 82.1, 56.3, 28.5. HR-MS (LC-ESI) *m/z* calcd for $C_{21}H_{22}N_2O_2Na$ $(M + Na)^+$: 357.1573; found: 357.1558.

tert-*Butyl* N-*(cyanomethyl)fluorenylidene carbazate (7h)*

Employing the procedure to make carbazate **7a**, **2** (52.8 mg, 0.18 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (396 μL, 0.27 mmol, 1.5 equiv) and iodoacetonitrile (20 μL, 0.27 mmol, 1.5 equiv), and the product was purified by flash chromatography using 1:9 EtOAc/hexane as the solvent system. Carbazate **7h** was obtained as a yellow solid (42.7 mg, 71% yield); mp 165–168 °C. R_f 0.32 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2980, 2187, 1715, 1595, 1345, 1313, 1235, 1144, 726. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.88 (m, 1H), 7.81 (m, 1H), 7.60 (m, 2H), 7.46 (m, 2H), 7.30 (m, 2H), 4.67 (m, 2H), 1.40 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 167.4, 152.3, 143.3, 141.6, 136.4, 132.9, 132.3, 131.7, 128.7, 128.6, 128.2, 123.8, 120.5, 120.1, 116.0, 84.2, 40.4, 28.3. HR-MS (LC-ESI) *m/z* calcd for $C_{20}H_{20}N_3O_2$ $(M + H)^+$: 334.1550; found: 334.1566.

tert-*Butyl* N-*(tert-butylacetyl)fluorenylidene carbazate (7i)*

Employing the procedure to make carbazate **7a**, carbazate **2** (50 mg, 0.17 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (368 μL, 0.25 mmol, 1.5 equiv) and *tert*-butyl bromoacetate (38 μL, 0.25 mmol, 1.5 equiv), and the product was purified by flash chromatography using 1:9 EtOAc/hexane as the solvent system. Carbazate **7i** was obtained as a yellow solid (50.6 mg, 73% yield); mp 135.5–136.7 °C. R_f 0.39 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2978, 2929, 1745, 1692, 1365, 1224, 1147, 752. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.86 (d, J = 7.5 Hz, 2H), 7.61 (d, J = 7.5 Hz, 1H), 7.58 (d, J = 7.6 Hz, 1H), 7.42 (td, J = 7.6 Hz, 2H), 7.28 (m, 2H), 4.46 (s, 2H), 1.47 (s, 18H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 168.8, 153.0, 142.9, 141.5, 137.1, 132.1, 131.9, 131.6, 128.8, 128.4, 128.3, 123.5, 120.1, 119.9, 82.4, 82.0, 54.7, 28.4. HR-MS (LC-ESI) *m/z* calcd for $C_{24}H_{29}N_2O_4$ $(M + H)^+$: 409.2122; found: 409.2104.

tert-*Butyl* N-*(isopropyl)fluorenylidene carbazate (7j)*

Employing the procedure to make carbazate **7a**, carbazate **2** (51.9 mg, 0.18 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (383 μL, 0.26 mmol, 1.5 equiv) and isopropyl iodide (26 μL, 0.26 mmol, 1.5 equiv), and stirred at 50 °C under microwave irradiation in a 300 MW Biotage apparatus on the high absorption level with automated temperature monitoring for 12 h. The product was purified by flash chromatography using 5:95 EtOAc/hexane as the solvent system. Carbazate **7j** was obtained as a yellow solid (32.4 mg, 55% yield); mp 119.7–120.8 °C. R_f 0.75 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2965, 2919, 2850, 1683, 1302, 1088, 737. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.92 (d, J = 7.5 Hz, 1H), 7.87 (d, J = 7.5, 1H), 7.60 (dd, J = 12.6, 7.5 Hz, 2H), 7.41 (m, 2H), 7.30 (t, J = 7.5 Hz, 1H), 7.24 (t, J = 7.3 Hz, 1H), 4.71 (q, J = 6.6 Hz, 1H), 1.34 (s, 15H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 166.5, 152.2, 143.0, 141.4, 137.2, 132.0, 131.9, 131.5, 128.5, 128.4, 128.0, 123.4, 120.2, 119.9, 81.4, 51.5,

Benzhydrylidene aza-glycinyl-L-phenylalanine* tert-*butyl ester (8)

In a flame-dried round-bottom flask, at 0 °C, a solution of 4-nitrophenylchloroformate (1.12 g, 5.58 mmol, 1.1 equiv) in dry CH_2Cl_2 (40 mL) was treated dropwise by cannula with a 0 °C solution of benzophenone hydrazone (1 g, 5.07 mmol, 1 equiv) in dry CH_2Cl_2 (40 mL). The ice bath was removed and the reaction mixture was allowed to warm to room temperature. After stirring for 1 h, the mixture was cooled to 0 °C, and treated dropwise by cannula with a premixed 0 °C solution of L-Phe-O-*t*-Bu·HCl (1.44 g, 5.60 mmol, 1.1 equiv) and *N*, *N*-diisopropylethylamine (DIEA; 1.80 mL, 10.14 mmol, 2 equiv) in CH_2Cl_2 (13 mL). The ice bath was removed. The reaction mixture was allowed to warm to room temperature and stirred for 16 h. The volatiles were evaporated and the residue was purified on a column of silica gel using flash chromatography with 30% diethyl ether in petroleum ether as the solvent system. Ester **8** was obtained as an oil (1.15 g, 51% yield). $[\alpha]_D^{20}$ 14.2 (*c* 1.02, $CHCl_3$). R_f 0.21 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 2974, 2931, 1662, 1590, 1515, 1333, 1109, 692. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.08 (d, J = 9.2 Hz, 1H), 7.24–7.67 (m, 15H), 6.80–6.91 (m, 1H), 4.77–4.82 (m, 1H), 3.17–3.30 (m, 2H), 1.48 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 170.5, 162.9, 154.7, 148.4, 136.4, 135.8, 131.2, 129.5, 129.4, 129.2, 128.2, 128.0, 127.0, 126.9, 126.7, 125.7, 115.2, 81.9, 53.6, 38.3, 27.6. HR-MS (LC-ESI) *m/z* calcd for $C_{27}H_{29}N_3O_3Na$ (M + Na)$^+$: 466.2101; found: 466.2082.

Benzhydrylidene aza-propargylglycinyl-L-phenylalanine* tert-*butyl ester (9)

Employing the procedure to make carbazate **7a**, **8** (50 mg, 0.11 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (243 μL, 0.16 mmol, 1.5 equiv) and propargyl bromide (25 μL, 0.16 mmol, 1.5 equiv), and the product was purified by flash chromatography eluting with 1:9 EtOAc/hexane. Ester **9** was obtained as a white oil (21.1 mg, 43% yield). $[\alpha]_D^{20}$ −1.8 (*c* 1.24, $CHCl_3$). R_f 0.33 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 3227, 2967, 2920, 1734, 1671, 1505, 1150, 694. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.45 (m, 6H), 7.36 (m, 4H), 7.27 (m, 5H), 7.08 (d, J = 8.2 Hz, 1H), 4.77 (m, 1H), 4.21 (dd, J = 17.9, 2.4 Hz, 1H), 3.91 (dd, J = 17.9, 2.4 Hz, 1H), 3.20 (d, J = 5.9 Hz, 2H), 2.08 (t, J = 2.4 Hz, 1H), 1.43 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 171.1, 158.3, 158.0, 138.8, 136.8, 135.8, 130.3, 130.0, 129.5, 129.0, 128.9, 128.7, 128.4, 127.1, 82.2, 79.0, 72.2, 55.3, 38.8, 35.4, 28.3. HR-MS (LC-ESI) *m/z* calcd for $C_{30}H_{31}N_3O_3Na$ (M + Na)$^+$: 504.2258; found: 504.2234. The degree of racemization (enantiomeric excess, 98.9%) was determined by SFC analysis on a chiral stationary phase (Chiralcel AD-H 25 cm, 15% *i*-PrOH, 3 mL/min, 35 °C, 150 bar (1 bar = 100 kPa), t_r (major): 3.33 min, t_r (minor): 5.29 min).

Fluorenylidene aza-glycinyl-L-phenylalanine* tert-*butyl ester (11)

In a flame-dried flask under N_2, L-Phe-O-*t*-Bu·HCl (500 mg, 1.95 mmol, 1 equiv) was suspended in CH_2Cl_2 (8 mL), treated with pyridine (629 μL, 7.8 mmol, 4 equiv), cooled to 0 °C for 15 min, and treated with a 20% solution of phosgene in toluene (1.45 mL, 2.93 mmol, 1.5 equiv). (Caution: Phosgene is extremely toxic and should be employed in a well-ventilated hood.) After stirring for 2 h at 0 °C, the mixture was washed twice with ice cold 0.5 mol/L HCl. The combined aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

fractions were extracted with cold CH_2Cl_2. The combined organic phases were washed with ice cold NaCl, dried with $MgSO_4$, filtered, and evaporated. The resulting isocyanate **10** was obtained as an oil (375.7 mg, 74% yield), which was used directly in the next reaction without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.33 (m, 3H), 7.26 (m, 2H), 4.16 (dd, J = 5.0, 7.5 Hz, 1H), 3.14 (dd, J = 4.8, 13.8 Hz, 1H), 3.04 (dd, J = 7.5, 13.7 Hz, 1H), 1.50 (s, 9H). Under inert atmosphere, to fluorenone hydrazone (195 mg, 1 mmol, 1 equiv) in CH_2Cl_2 (8 mL) containing molecular sieves at 0 °C, DIEA (174 μL, 1 mmol, 1 equiv) was added. The mixture was stirred for 15 min and treated with a solution of isocyanate **10** (375.7 mg, 1.5 mmol, 1.5 equiv) in CH_2Cl_2 (2 mL). The ice bath was removed. The reaction was allowed to warm to room temperature, stirred for 16 h, and evaporated. The residue was purified by flash chromatography eluting with 2:8 EtOAc/hexane. Azadipeptide **11** was isolated as a yellow solid (261.5 mg, 54% yield); mp 65.6–67.6 °C. R_f 0.18 (8:2 hexane/EtOAc). $[\alpha]_D^{20}$ 25.9 (c 1.04, $CHCl_3$). IR (thin film, cm^{-1}) ν: 2966, 2919, 1673, 1508, 1149, 1115, 1077, 727. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.73 (s, 1H), 7.87 (d, J = 7.7 Hz, 1H), 7.76 (d, J = 7.5 Hz, 1H), 7.67 (dd, J = 17.0, 7.5 Hz, 2H), 7.49 (td, J = 7.5, 0.7 Hz, 1H), 7.40 (m, 2H), 7.36–7.28 (m, 6H), 7.03 (d, J = 8.2 Hz, 1H), 4.85 (m, 1H), 3.25 (m, 2H), 1.47 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 171.0, 155.4, 143.7, 142.5, 139.5, 137.2, 136.6, 131.2, 130.2, 130.1, 130.0, 128.8, 128.4, 128.3, 127.3, 125.7, 121.8, 121.2, 120.0, 82.6, 54.4, 39.1, 28.3. HR-MS (LC-ESI) m/z calcd for $C_{27}H_{27}N_3O_3Na$ $(M + Na)^+$: 464.1945; found: 464.1943.

Fluorenylidene aza-glycinyl-D,L-phenylalanine tert-*butyl ester (D,L-11)*

D,L-**11** was synthesized employing the same procedure described for **11** using D,L-Phe-O-*t*-Bu·HCl and was obtained as a yellow solid (236.2 mg, 54% yield).

Fluorenylidene aza-propargylglycinyl-L-phenylalanine tert-*butyl ester (12)*

Using the procedure to make carbazate **7a**, ester **11** (50 mg, 0.11 mmol, 1 equiv) was reacted with 10% tetraethylammonium hydroxide in H_2O (250 μL, 0.17 mmol, 1.5 equiv) and propargyl bromide (33 μL, 0.22 mmol, 1.5 equiv), and the product was purified by flash chromatography eluting with 1:9 EtOAc/hexane. Ester **12** was obtained as a yellow solid (42 mg, 83% yield); mp 82.5–85.4 °C. $[\alpha]_D^{20}$ –50.8 (c 1.04, $CHCl_3$). R_f 0.3 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 3208, 2958, 2921, 2854, 1750, 1742, 1674, 1497, 1217, 1144, 736. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.93 (d, J = 7.6 Hz, 1H), 7.83 (d, J = 7.5 Hz, 1H), 7.65 (d, J = 7.4 Hz, 1H), 7.60 (d, J = 7.5 Hz, 1H), 7.47 (m, 2H), 7.31 (m, 2H), 7.21 (s, 5H), 6.54 (d, J = 7.9 Hz, 1H), 4.80 (m, 1H), 4.68 (dd, J = 17.4, 2.3 Hz, 1H), 4.54 (dd, J = 17.4, 2.3 Hz, 1H), 3.18 (m, 2H), 2.21 (t, J = 2.3 Hz, 1H), 1.40 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 170.8, 164.2, 158.4, 143.6, 141.6, 136.8, 136.6, 133.0, 132.1, 130.1, 129.8, 129.0, 128.8, 128.6, 127.1, 123.6, 120.7, 120.2, 82.3, 79.1, 72.6, 55.1, 40.5, 38.9, 28.3. HR-MS (LC-ESI) m/z calcd for $C_{30}H_{29}N_3O_3Na$ $(M + Na)^+$: 502.2101; found: 502.2079. The degree of racemization (enantiomeric excess, 99.8%) was determined by SFC analysis on a chiral stationary phase (Chiralcel AD-H 25 cm, 15% *i*-PrOH, 3 mL/min, 35 °C, 150 bar, t_r (major): 8.26 min, t_r (minor): 21.32 min).

Aza-propargylglycinyl-D,L-phenylalanine tert-*butyl ester (13)*

Fluorenylidene aza-propargylglycinyl-D,L-phenylalanine *tert*-butyl ester (D,L-**12**; 54.4 mg, 0.11 mmol, 1 equiv) was treated with a solution of NH_2OH·HCl (28 mg, 0.44 mmol, 4 equiv) in pyridine (12 mL) at 60 °C for 12 h. The volatiles were evaporated and the residue was purified by flash chromatography eluting with 4:6 EtOAc/hexane. Ester **13** was obtained as a white oil (34.3 mg, 95% yield). R_f 0.1 (8:2 hexane/EtOAc). IR (thin film, cm^{-1}) ν: 3285, 2982, 2936, 1726, 1658, 1498, 1368, 1152. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.31–7.20 (m, 5H), 6.91 (d, J = 8.3 Hz, 1H), 4.64 (m, 1H), 4.40 (dd, J = 2.4, 17.5 Hz, 1H), 4.31 (dd, J = 2.4, 17.5 Hz, 1H), 3.72 (s, 2H), 3.09 (m, 2H), 2.30 (t, J = 2.4 Hz, 1H), 1.41 (s, 9H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 170.7, 157.1, 136.0, 128.9, 127.6, 126.1, 81.1, 77.3, 72.7, 53.9, 39.0, 38.0, 27.3. HR-MS (LC-ESI) m/z calcd for $C_{17}H_{23}N_3O_3Na$ $(M + Na)^+$: 340.1632; found: 340.1620.

Fluorenylidene aza-propargylglycinyl-D,L-phenylalanine acid (14)

tert-Butyl ester D,L-**12** (48.6 mg, 0.1 mmol, 1 equiv) in dry CH_2Cl_2 (10 mL) was treated with bubbles of HCl for 1 h. The volatiles were evaporated and the residue was purified by flash chromatography eluting with 1:20 MeOH/CH_2Cl_2. Acid **14** was obtained as a yellow solid (37 mg, 86% yield): decomposition was observed after 98.1 °C. R_f 0.2 (9:1 CH_2Cl_2/MeOH). IR (thin film, cm^{-1}) ν: 3265, 1709, 1663, 1506, 1447, 1314, 1230, 1154, 1083, 931, 730. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.49 (s, 1H), 7.85 (d, J = 7.6 Hz, 1H), 7.75 (d, J = 6.9 Hz, 1H), 7.59 (dd, J = 7.4, 13.1 Hz, 2H), 7.44 (t, J = 6.7 Hz, 2H), 7.27 (m, 2H), 7.16 (m, 5H), 6.45 (d, J = 5.6 Hz, 1H), 4.83 (m, 1H), 4.55 (m, 2H), 3.22 (m, 2H), 2.19 (m, 1H). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 163.8, 158.1, 142.6, 140.6, 135.5, 135.2, 132.1, 131.3, 128.8, 128.6, 128.1, 127.9, 127.8, 127.6, 126.3, 122.7, 119.7, 119.2, 77.8, 71.9, 39.6, 36.8. HR-MS (LC-ESI) m/z calcd for $C_{26}H_{21}N_3O_3Na$ $(M + Na)^+$: 446.1475; found: 446.1481.

Abstract: Two series of cross-conjugated 1,3,5,7-octatetraynes (**1a**–**1l** and **6a**–**6d**) have been synthesized. UV–vis spectroscopic analysis shows that pendent groups connected to the cross-conjugated skeleton have little effect on the λ_{max} energies, irrespective of whether the groups are electron withdrawing or donating. A number of the isolated products readily give crystals suitable for X-ray crystallography, and the solid-state structural properties of five derivatives (**1k**, **1l**, **6a**, **6c**, and **6d**) have been examined by X-ray crystallographic analysis. Parallel packing of the polyynes in the solid state indicates that four of the five samples are potentially suitable for topochemical polymerization, based on solid-state packing parameters θ, *R*, and *d*. Attempts to effect a solid-state reaction have been explored through UV–vis and γ-ray irradiation as well as thermal heating. The course of these reactions was monitored by differential scanning calorimetry (DSC) analysis, as well as UV–vis and solid-state ^{13}C NMR spectroscopy (for **1d**, **1j**, **1k**, and **6d**), which offered evidence of polymer formation from these reactions. Structural determination of the product(s), however, remains elusive.

Key words: polytriacetylenes, polyynes, solid-state NMR spectroscopy, tetraynes, topochemical polymerization.

Résumé : On a réalisé la synthèse de deux séries de 1,3,5,7-octatétraynes à conjugaisons croisées (**1a**–**1l** et **6a**–**6d**). L'analyse de leurs spectres UV–visible montre que les groupes pendants attachés au squelette à conjugaison croisée n'ont que peu d'effet sur les énergies des λ_{max}, que les groupes attachés soient électroaffinitaires ou électrorépulsifs. Un certain nombre de produits isolés fournissent des cristaux susceptibles d'être soumis à une diffraction par des rayons-X; on a ainsi pu déterminer les propriétés structurales de cinq dérivés (**1k**, **1l**, **6a**, **6c** et **6d**) par une analyse des données cristallographiques par cette méthode. L'entassement parallèle des polyynes à l'état solide indique que quatre des cinq échantillons pourraient éventuellement être susceptibles de donner lieu à une polymérisation topochimique si on se base sur leurs paramètres d'empilement θ, *R* et *d*. On a exploré la possibilité de réaliser des réactions à l'état solide par des irradiations UV–visible et par des rayons γ ainsi que par un chauffage thermique. On a suivi le cours de ces réactions par le biais d'une analyse par calorimétrie à balayage différentiel (CBD) ainsi que par les spectroscopies UV–visible et RMN du ^{13}C à l'état solide (pour les composés **1d**, **1j**, **1k** et **6d**) qui fournissent des données suggérant qu'il y a formation de polymères au cours de ces réactions. La détermination des structures de ces produits demeure toutefois incertaine.

Mots-clés : polytriacétylènes, polyynes, spectroscopie RMN à l'état solide, tétraynes, polymérisation topochimique.

[Traduit par la Rédaction]

Introduction

During the past couple of decades, solid-state polymerization of polyynes has been the subject of considerable exploration in the quest for conjugated organic materials with qualities suitable for applications in nanoscience, nonlinear optics, organic electronics, supramolecular chemistry, and sensing.[1–8] Solid-state polymerization of polyynes is an attractive route to such materials because it can provide large and nearly defect-free polymer crystals, as well as materials with unique solution-state properties.[9–11] The topochemical polymerization of a "diacetylene" (diyne) monomer into a polydiacetylene polymer was first reported by Wegner[12] in 1969. In the intervening years, the breadth of this general process has been studied and expanded. These investigations have documented quite clearly that the solid-state packing of the polyyne precursor in the crystalline state is crucial to formation of the desired polymer.[13–16] In polyyne crystals, molecules must move cooperatively during the reaction process to arrive at the ordered structure of the polymeric product

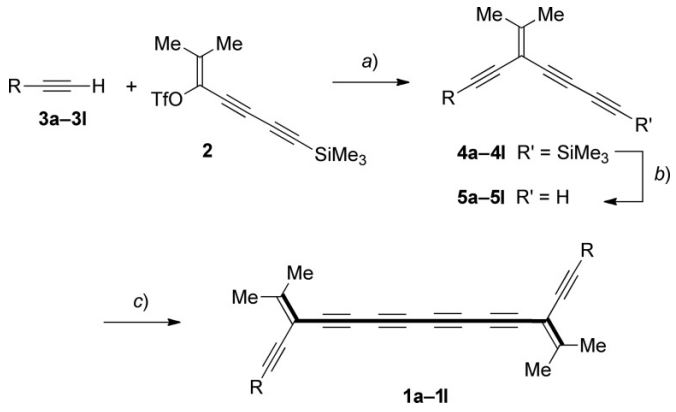
(*d*) Ladder polymer formation via two sequential 1,4-additions.



(i.e., a phase transition). When the solid-state arrangement of the polyyne precursors offers a reaction pathway with minimal translational energy, a topochemical reaction is possible when initiated by, for example, heat, UV light, pressure, or γ-ray radiation. Such reactions are common for diynes and selectively form the polydiacetylene product. For longer polyyne precursors, however, multiple reaction possibilities exist, as schematically shown in Fig. 1 for tetraynes. Thus, while polyyne precursors offer a tantalizing opportunity to form highly conjugated polymer products,[15,17,18] the various modes of reactivity present a number of challenges, including the realization of the single crystals with optimal packing parameters, dictating one particular reaction pathway to the exclusion of another, and characterization of the often insoluble reaction product(s).

Efforts to effect polymerization of polyynes beyond the length of a diyne have been relatively rare, although several examples are described for the polymerization of triynes,[19]

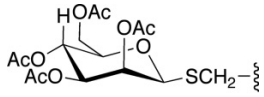
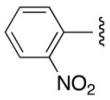
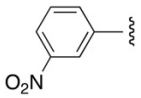
pentaynes,[20] and hexaynes.[21] There has been slightly more work done in the area of tetraynes,[22] likely because of the fact that tetraynes are both easy to synthesize and relatively stable under ambient conditions.[23] In considering the topochemical polymerization of tetraynes, several pathways must be considered, as outlined in Fig. 1. In each case, packing parameters based on the orientation of neighbouring molecules stacked parallel in the solid state govern reactivity patterns that might be energetically accessible. The packing parameters are defined as (*i*) the stacking or translational distance of the monomers in the parallel stack (*d*), (*ii*) the angle formed between the polyyne and the stacking axis (the "tilt angle"; θ), and (*iii*) the distance between the reacting carbon atoms in neighbouring molecules of the stack (*R*).[13,15] For example, 1,8-addition for a tetrayne gives a polytetraacetylene product (Fig. 1*a*), whereas 1,6-addition forms a polytriacetylene[24] product (Fig. 1*b*). A variety of reaction pathways are possible that would result in polydiacetylene formation via a formal 1,4-addition pattern, such as those in Figs. 1*c* and 1*d*, which afford interesting cross-conjugated polymers.[25] It is noteworthy that topochemical polymerization can also lead to polydiacetylene "ladder polymers" through two sequential 1,4-polymerization events (Fig. 1*d*).[17b] As part of an ongoing interest in the structural and electronic properties of cross-conjugated enyne systems,[25a,26] we serendipitously discovered that a large number of cross-conjugated tetrayne products crystallize with the polyynes stacked in parallel, with packing parameters potentially suitable for topochemical polymerization. Thus, we report herein on the synthesis and study of two series of tetraynes, the spectroscopic characterization of these compounds, our efforts to polymerize these polyynes, and difficulties encountered in the characterization of the product(s) of these solid-state reactions.

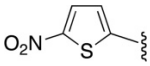
Synthesis

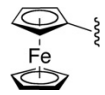
Notably, the synthesis of the cross-conjugated tetrayne series **1a**–**1l** is achieved in three efficient steps, as described in Scheme 1 and summarized in Table 1.[27] First, Pd-catalyzed Sonogashira cross coupling[28] of the known vinyl triflate **2**[29] with various terminal acetylenes (**3a**–**3l**) gave enynes **4a**–**4l**. These reactions generally proceeded smoothly at room temperature (rt) and were complete within 2 h. Isolated yields of triynes **4a**–**4l** were good to excellent, and, with the exception of **4a** (an oil), triynes **4** are isolated as stable solids. Protodesilylation of **4a**–**4l** then provided the terminal alkynes **5a**–**5l**, which were carried on directly, following workup, to the oxidative homocoupling step using Cu-mediated Hay conditions.[30] The homocoupling reactions were typically complete in ~0.5 h at rt using either acetone or a mixture of acetone/CH_2Cl_2 (1:1) as solvent. Isolated yields for **1a**–**1l** ranged from excellent to poor, depending primarily on the stability of the resulting product. Nitroaryl functionalized tetraynes **1e**–**1g** had particularly poor stability, even at low temperature and in solution. This resulted in drastically reduced isolated yields for **1e** and **1f**, whereas **1g** was insufficiently stable for isolation. While *n*-butyl- and cyano-substituted tetraynes **1a** and **1h**, respectively, were also relatively unstable at room temperature, yields were nevertheless reasonable and the products could be handled without significant decomposition if kept in solution.











Next, our investigations of α,ω-polyynes[31] led to the formation of the dibromoolefinic analog of tetrayne **1c**, namely **6a** (Scheme 2). Compound **6a** was isolated as a crystalline solid with interesting solid-state packing based on X-ray analysis (vide infra). This suggested a second class of octatetraynes that might be explored for their solid-state behaviour. Tetraynes **6a**–**6d** were easily synthesized starting from commercially available acid chlorides **7a**–**7d** as shown in Scheme 2 and summarized in Table 2. In the first step, a Friedel–Crafts acylation reaction of **7a**–**7d** with 1,4-bis-trimethylsilyl-1,3-butadiyne (**8**) in the presence of $AlCl_3$ afforded the intermediate ketones **9a**–**9d**, after quenching of the reaction and aqueous workup.[32] The crude ketones were then converted directly to dibromoolefins **10a**–**10d** via the Ramirez olefination reaction.[33] Isolated yields were good to excellent over the two steps, and **10a**–**10d** were obtained as stable crystalline solids. With diyne precursors **10a**–**10d** in hand, desilylation using K_2CO_3/MeOH gave the terminal alkynes, which were carried on directly to Hay[30] homocoupling in CH_2Cl_2. The desired products (**6a**–**6d**) were isolated pure in good to moderate yields by either column chromatography or recrystallization from hexanes.

^{13}C-labelling of compound 6d

It is well-established that solid-state ^{13}C NMR spectroscopy can provide invaluable structural information concerning the products of topochemical polymerization reactions.[34] With this in mind, the synthesis of tetrayne **6d** enriched with ^{13}C atoms was undertaken (Scheme 3). The synthesis began with the known dibromoolefin **11**,[35] which incorporated ~34% ^{13}C at position C(1) (indicated with an *). The reaction of the dibromoolefin **11** with excess lithium diisopropylamide (LDA) at low temperature effected elimination, and the resulting lithiated diyne product was trapped via the reaction with Me_3SiCl to give differentially silylated diyne **12**.[36] Following a similar reaction sequence as outlined in Scheme 2, diyne **12** was then converted into ketone **13** via a Friedel–Crafts acylation with **7d**, and the ketone was carried on directly to a standard dibromoolefination reaction affording dibromoolefin **14** in a reasonable yield (35%) over the two steps. The presence of the triisopropylsilyl group in **14** necessitated the use of

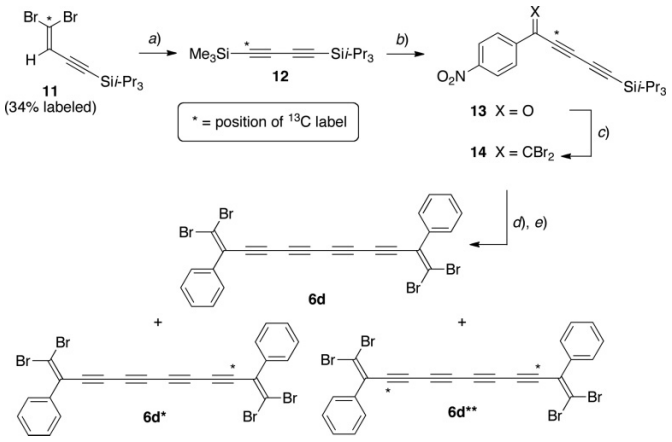
tetrabutylammonium fluoride (TBAF) to effect desilylation, and the thus formed terminal diyne was then subjected to oxidative homocoupling under Hay conditions. As a result of the partial labelling, three isotopomers were formed from the homocoupling reaction, including compound **6d** (no labelled carbon), **6d*** (one labelled carbon), and **6d**** (two labelled carbons). As expected, however, the ^{13}C NMR spectrum of this mixture is identical to that of the unlabelled compound **6d**, except for the enhanced signal of the C(1) carbon of the octayne chain and the associated ^{13}C–^{13}C coupling (vide infra).

Solution-state ^{13}C NMR spectroscopic characterization



Solution-state ^{13}C NMR spectroscopy of compounds **1a**–**1l** shows that the α carbons of the isopropylidene backbone (Me_2C=C<) are easily identified because they are quite deshielded, resonating in the range of 160–165 ppm.[37] Electron-withdrawing aryl groups result in a downfield shift of this signal, such that the resonances of **1d** (4-NO_2–C_6H_4–), **1e** (2-NO_2–C_6H_4–), **1f** (3-NO_2–C_6H_4–), and **1h** (4-NC–C_6H_4–) are found at 163.9, 165.0, 163.4, and 163.6 ppm, respectively. Conversely, electron-donating groups result in a slight upfield shift of this carbon resonance, as with derivatives **1j** (4-NMe_2–

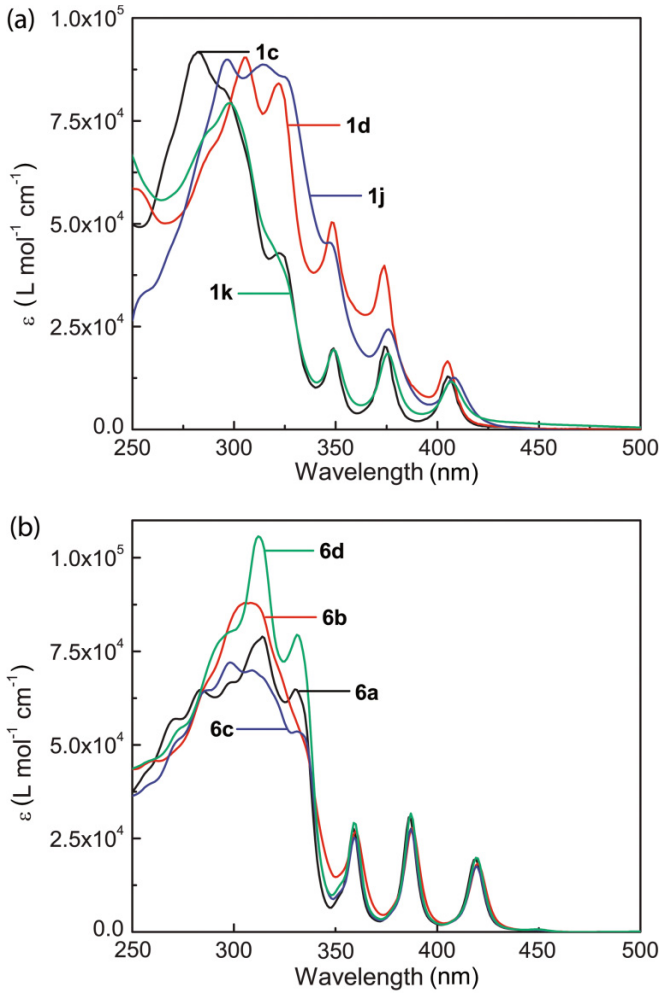
C_6H_4–) and **1k** (ferrocenyl) at 159.5 and 159.9 ppm, respectively. The analogous carbons for tetraynes **6a**–**6d**, terminated with a dibromovinyl group (Br_2C=C<), are found at much lower chemical shift values, a result of the heavy atom effect, typically in the range of ~100 ppm based on published studies using ^{13}C labelling.[38] This places the resonance in the region of the alkyne carbon signals and complicates unambiguous assignment for **6a**–**6d**. Empirically, however, signals observed for **6a**–**6d** (and **10a**–**10d**) in the range of 102–108 ppm are consistent with this assignment. Conversely, the β-alkylidene carbons (Me_2C=C<) for isopropylidene compounds such **1a**–**1l** are typically found in the range of 99–100 ppm,[37] and thus they are also difficult to conclusively discern from the alkyne carbon resonances. For compounds **6d** and **14**, the β-alkylidene carbon (Br_2C=C<) can be identified at 127.6 and 128.3 ppm, respectively, as a result of the large one-bond coupling ($^1J(^{13}C, ^{13}C)$ = 98 Hz) in each case to the ^{13}C-labelled carbon at C(1). This compares to one-bond $^1J(^{13}C, ^{13}C)$ values of 34.6, 67.6, and 171.5 Hz for ethane, ethylene, and acetylene, respectively.[39]

Generally, the resonances of carbons C(3) and C(4) of an octatetrayne moiety (–C(1)≡C(2)–C(3)≡C(4)–C≡C–C≡C–) are found upfield relative to those of C(1) and C(2).[35,40,41] In the case of **1a**–**1l**, this places C(3) and C(4) at either ~64 or 68 ppm, regardless of the substitution pattern. The adjacent carbons C(1) and C(2), on the other hand, resonate in the range of 74–77 ppm. A similar pattern is found for **6a**–**6d**, where labelling of **6d*/6d**** provides an opportunity to identify each specific carbon within this tetrayne series. The labelled carbon C(1) for **6d*/6d**** is observed at 75.6 ppm, and the large coupling with C(2) at δ 82.7 ($^1J(^{13}C, ^{13}C)$ = 187 Hz) sets this carbon resonance. Coupling between C(1) and C(3) at 71.4 ppm is also clearly observed with $^2J(^{13}C, ^{13}C)$ = 32 Hz, and C(4) is thus identified as the remaining resonance at 64.9 ppm.

Solution-state UV–vis spectroscopic characterization

Highest occupied and lowest unoccupied molecular orbital (HOMO–LUMO) transitions for **1a**–**1l** and **6a**–**6d** should result from the longest linearly conjugated segment of these molecules (the ene–tetrayne–ene group highlighted in bold, Schemes 1 and 2).[27] In **1a**–**1l**, there is a progression of three absorptions at approximately 350, 375, and 405 nm (Fig. 2*a*). The various pendent functional groups have a negligible effect on the energy of these transitions as a result of the cross-conjugated framework.[25–27,42] The most distinguishing effect based on structure is observed for derivatives with strong electron withdrawing and donating substituents, **1d** and **1j**, respectively, where an enhancement in molar absorptivity is observed in comparison with other derivatives. For the organometallic member of the series (**1k**), a weak, broad peak at 450 nm is attributed to the absorption characteristic of the ferrocenyl groups.

All members of the second series of tetraynes **6a**–**6d** also display three peaks in the low-energy region of the spectra at ~359, 387, and 419 nm (Fig. 2*b*). In addition, all four compounds have similar molar absorptivity values (ε). Thus, for **6a**–**6d**, as observed for **1a**–**1l**, varying the pendent substituents does not appreciably influence the wavelength of maximum absorption (λ_{max}) values.



Solid-state properties and attempted topochemical polymerization

Looking at the kinetic and thermal stability of cross-conjugated tetraynes **1a**–**1l** and **6a**–**6d**, derivatives with 4-nitrophenyl (**1d**), 4-*N*,*N*-dimethylaminophenyl (**1j**), ferrocenyl (**1k**), and triisopropylsilyl (**1l**) substituents show sufficient stability for detailed study, as do all four compounds **6a**–**6d**. As described in the following sections, our studies to date

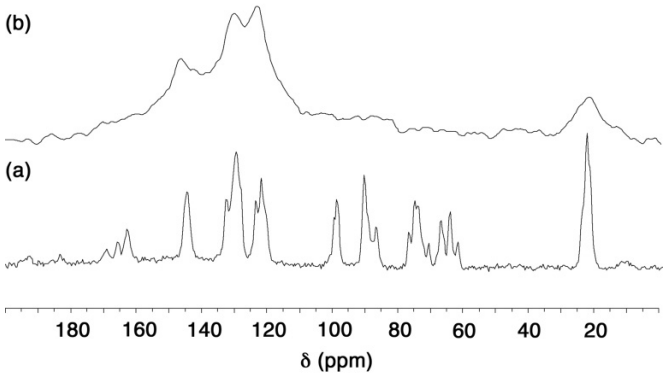

Fig. 2. Electronic absorption spectra (ε, L mol^{-1} cm^{-1}) for (*a*) **1c**, **1d**, **1j**, and **1k** in $CHCl_3$ and (*b*) **6a**–**6d** in THF.

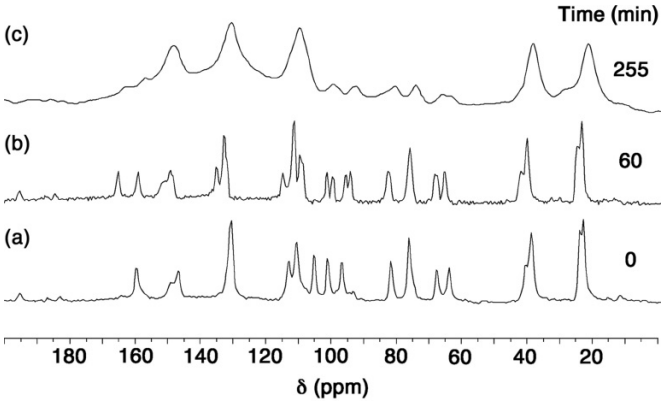
include differential scanning calorimetry (DSC) analysis for all eight of these compounds, X-ray crystallographic analysis of **1k**, **1l**, **6a**, **6c**, and **6d**, and solid-state ^{13}C NMR spectroscopic analysis of **1d**, **1j**, **1k**, and **6d** during attempts to effect topochemical polymerization.

Last but not least, it is useful to point out several common threads from this study, as a prelude to the specific discussions that follow. Many reports for the solid-state reaction of polyynes have underscored the fact that the most important criteria for effective topochemical polymerization are the solid-state packing parameters θ, *R*, and *d* as summarized in Fig. 1. Supplemented with DSC analysis, this information offers, a priori, a guide for the selection of crystalline candidates for further study. It will become clear in the following sections, however, that a combination of suitable packing parameters and "sharp" DSC traces are only a part of the story for polymerization of tetraynes. As the solid-state ^{13}C NMR spectroscopic studies eventually demonstrate, each "promising prospect" for thermal polymerization to a defined product results in only ambiguous evidence of the nature of the product, regardless of how "optimal" the packing parameters.

Fig. 3. Solid-state ^{13}C NMR spectra for **1d** recorded (*a*) before heating and (*b*) after heating at 120 °C for 2 h and then 160 °C for 1 h.



Tetrayne 1d

The DSC profile of **1d** shows a relatively broad and featureless Gaussian-shaped peak at 193 °C (see the Supplementary data), which suggests that the polymerization probably occurs in a random, nonregioselective manner. This premise has been examined by solid-state ^{13}C NMR spectroscopy. The spectrum of pristine **1d** (Fig. 3*a*) shows moderate resolution, and major signals for the sp and sp^2 carbons in the region of 64–100 ppm are reasonably consistent with solution-state ^{13}C NMR data. In addition to the expected resonances, however, several unidentified peaks are observed, likely the result of nonequivalent carbon atoms in the solid state (from a structure where C_2 symmetry has been lost). The same is true for the resonance of the external vinylidene carbon (Me_2C=C), which is observed at 164 ppm in addition to two additional signals at a similar chemical shift. After heating the sample of **1d** at 120 °C for 2 h, the resulting ^{13}C NMR spectrum is identical to that of the original, indicating that polymerization had not occurred at this temperature. Subsequent heating at 160 °C for 1 h, on the other hand, gives a black solid. The spectrum of this product shows that the characteristic resonances for interior tetrayne carbons at 64–67 ppm are completely gone after heating (Fig. 3*b*). While in agreement with a polymerized product, the loss of acetylenic signals coincides with the appearance of several broadened resonances in the region of 100–160 ppm, presumably the result of sp^2 carbons of olefinic and aryl moieties. In addition, the resonances of the methyl groups are also broadened significantly to a range of 15–30 ppm. The transition to broad featureless resonances, along with the absence of signals from sp carbon atoms, suggests that a random and nonregioselective polymerization occurs for this sample upon heating.

Tetrayne 1j

The DSC trace of **1j** shows a sharp exotherm at 165 °C (see the Supplementary data), suggesting that a solid-state reaction may be more regioselective than that observed for **1d**. In the absence of crystallographic data, the reaction has been explored by solid-state ^{13}C NMR spectroscopy. The spectrum of **1j** at room temperature (Fig. 4*a*) shows reasonable resolution when compared to the solution-state ^{13}C NMR spectrum. All eight unique sp and sp^2 carbons of the cross-conjugated enyne skeleton are clearly observed at 65, 68, 77, 82, 98, 102, 106,

Fig. 4. Solid-state ^{13}C NMR spectra for **1j** recorded (*a*) before heating (time = 0), (*b*) after heating at 100 °C for 60 min, and (*c*) after heating at 100 °C for 255 min.

and 160 ppm, while the two methyl carbons of the isopropylidene moiety are also distinct at 23 and 25 ppm. Finally, the *N*,*N*-dimethylanilino carbons are observed at 40 ppm. After heating at 100 °C for 1 h, the crystalline sample turns dark brown, and the ^{13}C NMR spectrum shows several distinct differences with fair resolution (Fig. 4*b*). The most significant changes upon heating are (*i*) the emergence of two nonequivalent vinylidene peaks at 159 and 165 ppm, (*ii*) splitting of the signal at 130 ppm, and (*iii*) several additional resonances in the range of 90–110 ppm. The characteristic resonances of the carbons of the polyyne fragment have approximately the same chemical shift values (in the region of 60–85 ppm), but they are broadened. Additional heating at 100 °C for ~3 h yields a black solid, the spectrum of which shows severely broadened signals, centred at 20, 40, 110, 130, and 150 ppm (Fig. 4*c*), although many of the major features observed in the initial spectrum after 60 min (Fig. 4*b*) are still distinguishable. In combination, these spectra suggest that polymerization may proceed in a regioselective manner, since distinct chemical shifts are still observed for the product (i.e., Fig. 4*c*). Several points deserve further discussion. If the reaction occurs via 1,6-addition, C_2 symmetry of the starting tetrayne would be destroyed while generating a polytriacetylene (PTA) product. The upfield signals at 60–70 ppm are not, however, consistent with the presence of a diyne group of a PTA. Alternatively, reaction via 1,8-addition would afford a polytetraacetylene product (Fig. 1*a*), and resonances in the ranges of 60–70 ppm could be consistent with the formation of an unsymmetrical triyne moiety.[43] Unfortunately, without crystallographic data of the starting material or product, more definitive conclusions are difficult to draw.

Tetrayne 1k

For ferrocenyl-substituted **1k**, an exotherm is found at ~187 °C in the DSC analysis, and a shoulder peak is also noticeable at slightly lower temperature (165 °C; see the Supplementary data). Compound **1k** is remarkably crystalline, and orange-brown translucent needle-shaped crystals of **1k** suitable for X-ray crystallography are obtained easily by diffusion of methanol into an Et_2O solution at –4 °C. The solid-state structure shows that the 16-carbon C_{2v} symmetrical enyne skeleton is virtually planar with a maximum deviation of 0.056(3) Å from a least-squares plane (Fig. 5). All triple bonds are comparable to other reported tetraynes (Table 3).[13] The carbons of the tetrayne framework show a gradual curvature with bond angles deviating from 180° by less than 4° in all cases (Table 4). The plane of the cyclopentadienyl ligand for the ferrocene group is, nevertheless, twisted out of the enyne plane by an angle of ~31°.

The most notable feature of the solid-state structure of **1k** is the parallel stacking of tetrayne moieties, suggesting the possibility of a topochemical polymerization. In the solid-state packing of **1k**, molecules show a tilt angle (θ) of 30° and the translational distance (*d*) is 7.4 Å. There are two potential modes for 1,6-polymerization, with $R_{1,6} = R_{3,8} = 3.7$ Å. Thus, these features correspond quite well with the optimal parameters of θ = 28°, $R_{1,6} < 4$ Å, and $d = 7.4$ Å for topochemical polymerization in a 1,6-addition manner.

With a viable crystal seemingly in hand for effecting 1,6-polymerization, several approaches have been explored. Polymerization via UV irradiation (monochromic 280 nm for 12 h) fails to induce polymerization, and crystals show a diffraction pattern identical to the original tetrayne sample. Likewise, γ-ray irradiation (^{60}Co, 54 ± 3 krad/h for 2 weeks) also fails to initiate polymerization. Attempts to induce a thermal reaction show that when heated to 150 °C for 30 min, crystals of **1k** transform into a black solid, suggesting that topochemical polymerization of **1k** can be effected through heating. The resulting solid is, however, amorphous rather than crystalline, as established by X-ray crystallographic analysis.

UV–vis spectroscopy was used to analyze the thermal polymerization of **1k** in a solid film cast onto a quartz plate. Three characteristic absorptions are observed for **1k** at 354, 381, and 414 nm, and these absorptions are redshifted by 5–7 nm for **1k** versus those measured in $CHCl_3$ (Fig. 6). After heating the sample open to air at 150 °C for 5 min, the UV–vis spectrum clearly shows loss of the low-energy absorptions ascribed to the ene–tetrayne–ene moiety, and these signals are replaced by a broad featureless peak at 400–550 nm. Disappointingly, the lack of specific fine structure in the spectrum of the product offers little hint as to the structure(s) resulting from polymerization.

Following the results of the UV–vis study, thermally initiated polymerization of a crystalline sample of **1k** was explored by heating to 150 °C under air. Attempts to analyze the polymerization product by solution-state ^1H and ^{13}C NMR spectroscopy did not, however, afford meaningful spectra because the sample is not soluble in typical organic solvents. Finally, the thermal polymerization for **1k** was monitored by solid-state ^{13}C NMR spectroscopy, while the sample was heated at 150 °C, and spectra were acquired over a period of 5 h (Fig. 7). The solid-state spectrum of the pristine tetrayne **1k** shows excellent resolution in comparison with the solution-state spectrum, and all unique sp and sp^2 carbons of the conjugated skeleton are clearly identified. As the sample is heated, the spectra show gradual peak broadening that increases with heating time. After heating the sample for 300 min, the spectrum is dominated by three broad signals centered at approximately 30, 75, and 142 ppm. The most intense, at δ 75 ppm, seemingly derives from the carbons of the ferrocenyl group (the isotropic ^{13}C chemical shift for solid ferrocene is 70 ppm[44]), and this broad signal engulfs the

region where polyyne signals are expected, making any particular assignments impossible. The signal at the highest chemical shift is very broad, spanning from 120–160 ppm, and probably results from sp^2 carbons of the vinylidene carbons and olefinic carbons formed during polymerization, or both. A background signal from the probe is also expected to contribute signal to this region. Thus, in comparison with **1j**, there is little clear evidence that **1k** polymerizes through a regioselective process, i.e., 1,6-addition, as suggested by its crystallographic analysis.

Tetrayne 1l

DSC analysis of crystalline **1l** shows a well-defined melting point at 103–104 °C, which is then followed by decomposition of the sample at 145 °C (see the Supplementary data). Yellow single crystals of tetrayne **1l** are obtained by diffusion of MeOH into a CH_2Cl_2 solution at –20 °C. Surprisingly, two different polymorphs of **1l** could be obtained from seemingly identical crystallization conditions. In addition, there appears to be no way to direct which polymorph will result for a given crystallization attempt. Both solid-state structures adopt geo-

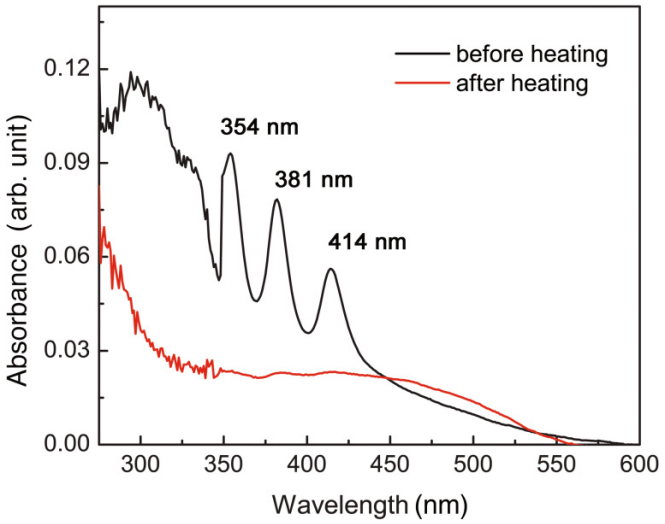
Fig. 6. Solid-state UV–vis spectra for **1k** before and after heating the thin-film sample to 150 °C for 5 min.



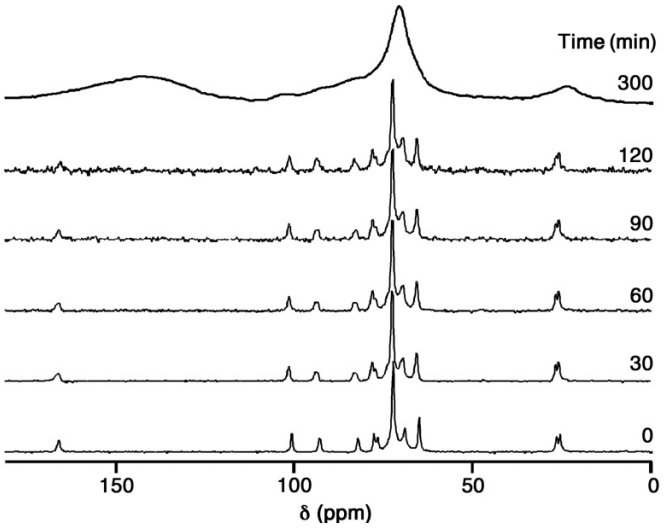


Fig. 7. Solid-state ^{13}C NMR spectra for **1k** recorded before and after heating at 150 °C for the times shown.

metrically similar s-trans orientations with respect to the octatetrayndiyl moiety (as shown in Fig. 8).[27] For one structure, molecules are aligned in parallel stacks, such that topochemical polymerization might be possible (this structure is shown in Fig. 8). The π framework of **1l** in this polymorph is virtually planar, with a maximum deviation of 0.02 Å from a least-squares plane for the 16 carbons of the conjugated skeletons. Triple bonds are unremarkable and comparable to other reported polyynes of this length (Table 3).[13,45] The eight tetrayne carbons show only a slight curvature with bond angles deviating from linear by less than 3° in all cases (Table 4).

Crystal packing analysis of tetrayne **1l** shows that the individual molecules are aligned in a parallel fashion that is predicted to favour the 1,6-addition polymerization (Fig. 8). The packing parameters of θ = 28° and d = 7.7 Å correspond quite well to those required for 1,6-polymerization, while two close contacts are also in a favourable range, $R_{1,6}$ = 3.7 Å and $R_{3,8}$ = 3.6 Å.

In spite of the favourable packing parameters observed for **1l**, all efforts to effect the thermal polymerization of single crystals for this tetrayne have been unsuccessful. Heating a sample of **1l** at 90 °C (i.e., just below the melting point) for 8 h gives a sample that is slightly darkened to yield an opaque solid that is no longer crystalline as documented by the absence of an X-ray diffraction pattern. Other methods to initiate the polymerization have also been explored, including monochromatic UV irradiation (280 nm for 24 h) and γ-irradiation (54 ± 3 krad/h for 2 weeks). In both cases, darkened yellow-orange single crystals are produced. X-ray analysis of these crystals, however, reveals exactly the same diffraction pattern as found for pristine **1l**, and there appears to be little change in the solid beyond a possible reaction at the outer surface of the crystal. Thus, there is so far no efficient way to trigger a solid-state polymerization in single crystals of **1l**.

Tetrayne 6a

DSC analysis of tetrayne derivative **6a** shows a sharp, narrow exotherm at 192 °C, which is consistent with the possibility of a reasonably well-defined topochemical polymerization (see the Supplementary data). Compound **6a** affords crystals for X-ray crystallography from a mixture of hexanes and CH_2Cl_2. The solid-state structure (Fig. 9 and Tables 3 and 4) shows that neighbouring molecules align in stacks as centrosymmetric dimeric pairs, thus giving an alternating A–B–A–B pattern. This is most easily identified in Fig. 9 by the different twist angles of the phenyl rings, which rotate out of the planar enyne framework by ~56° and 43°. The C–C≡C angles of **6a** deviate slightly from linearity, but by no more than about 3° (Table 4), whereas the torsion angle generated from vinyl groups (C10–C9···C11–C12) is ~3°.

Analysis of the solid-state packing parameters shows that the tetrayne groups of neighbouring molecules are aligned with θ = 42°, $R_{1,4}$ = $R_{3,6}$ = $R_{5,8}$ = 3.4 Å, and d = 5.1 Å. Thus, whereas 1,6-polymerization is not possible ($R_{1,6}$ = 4.3 Å), the observed packing values are quite close to the optimal values for 1,4-polymerization (θ = 45°, $R_{1,4}$ < 4 Å, and d = 5.1 Å). Combined with the intense and sharp exotherm in the DSC measurement, it seems possible that compound **6a** might undergo a 1,4-topochemical polymerization reaction. Because of our focus on 1,6-polymerization processes, however, further studies on **6a** have not yet been conducted.

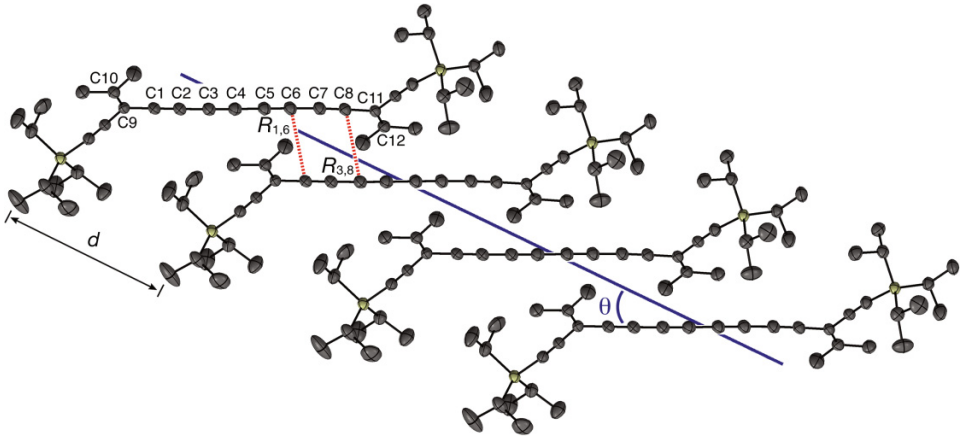
Tetrayne 6b

The DSC spectrum of tetrayne **6b** shows a sharp endotherm at ~176 °C, immediately followed by a broad exotherm at 179 °C (see the Supplementary data). No melting point is, however, observed in a capillary melting point analysis. Thus, it is not clear if the initial endotherm observed by DSC is a phase transition or a true melting point. In any case, this behaviour suggests that product analysis from a thermal solid-state reaction would not be straightforward, so no further analysis of this compound has been pursued.

Tetrayne 6c

Compound **6c** shows an apparent melting point of 168–170 °C in a capillary melting point analysis, and the sample slowly darkens as the temperature is increased. DSC analysis,

Fig. 8. ORTEP drawing (50% probability level) of **1l** showing a segment of crystal packing. Geometry parameters: θ = 28°, $R_{1,6}$ = 3.7 Å, $R_{3,8}$ = 3.6 Å, and d = 7.7 Å. (Note: The numbering of the carbon chain corresponds to the structural characterization listed in Tables 3 and 4, whereas the numbering for $R_{1,6}$ and $R_{3,8}$ refers to reactivity patterns from Fig. 1.)



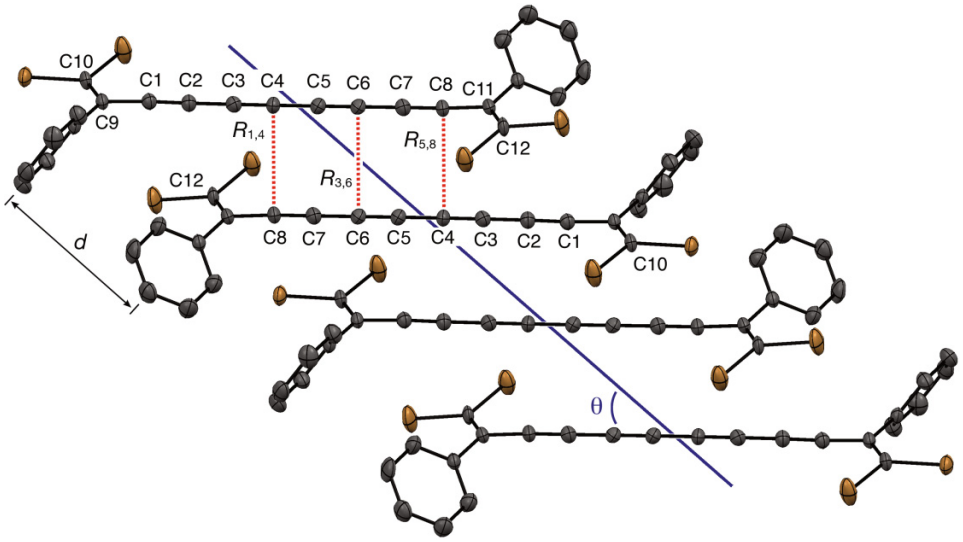


Fig. 9. ORTEP drawing (50% probability level) of **6a** showing a segment of the crystal packing. Geometry parameters: θ = 42°, $R_{1,4}$ = 3.4 Å, $R_{3,6}$ = 3.4 Å, $R_{5,8}$ = 3.4 Å, and d = 5.1 Å. (Note: The numbering of the carbon chain corresponds to the structural characterization listed in Tables 3 and 4, whereas the numbering for $R_{1,4}$, $R_{3,6}$, and $R_{5,8}$ refers to reactivity patterns from Fig. 1.)

on the other hand, shows an initial broad, weak exotherm with an onset at about 190 °C, and a second, sharp exotherm that initiates at about 230 °C, with a maximum at 233 °C (see the Supplementary data).

X-ray quality crystals of **6c** were obtained via the diffusion of hexanes into a solution of **6c** in hexanes/CH_2Cl_2 at –4 °C. The solid-state structure of **6c** (Fig. 10 and Tables 3 and 4) reveals that the terminal acetylene angles C(5)–C(1)–C(2) are the most distorted at 175.9(3)°. The enyne framework of the centrosymmetric structure is completely planar, whereas the aryl rings twist significantly from this plane by 65°. Analysis of the crystal packing shows that neighbouring molecules of compound **6c** are aligned in a parallel fashion, and the packing parameters for **6c** are similar to that observed for **6a**, with θ = 38°, $R_{1,4}$ = 3.8 Å, $R_{3,6}$ = 3.7 Å, $R_{5,8}$ = 3.8 Å, and d = 5.9 Å. Thus, packing parameters are suboptimal for either 1,4- or 1,6-polymerization, and thermal analysis of this compound has not been further explored.

Tetrayne 6d

DSC analysis of the nitro-derivative **6d** shows a very sharp exotherm at 191 °C (T_{onset} = 189 °C and T_{max} = 191 °C, see the Supplementary data). **Warning:** An explosion occurred at approximately 190 °C when heating a small quantity of compound **6d** (60 mg) in a capped tightly packed solid-state NMR rotor. When handling any polyyne, one should always take the appropriate safety precautions when the sample is heated above room temperature. This is particularly true if the sample is a terminal polyyne, where precautions should be taken at all temperatures.

Single crystals of **6d** for analysis by X-ray crystallography were obtained via the evaporation of a $CDCl_3$ or $CHCl_3$

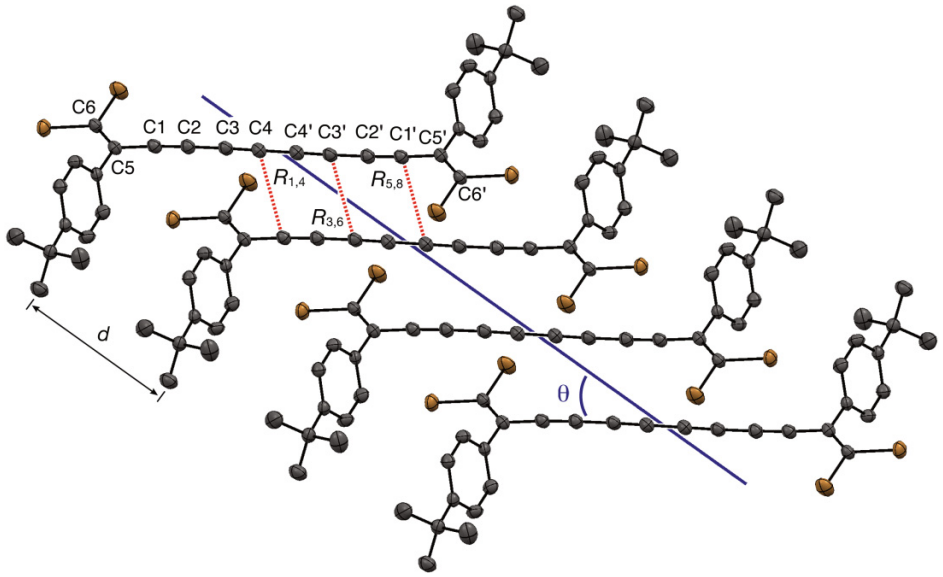
Fig. 10. ORTEP drawing (50% probability level) of **6c** showing a segment of the crystal packing. Geometry parameters: θ = 38°, $R_{1,4}$ = 3.8 Å, $R_{3,6}$ = 3.7 Å, $R_{5,8}$ = 3.8 Å, and d = 5.9 Å. (Note: The numbering of the carbon chain corresponds to the structural characterization listed in Tables 3 and 4, whereas the numbering for $R_{1,4}$, $R_{3,6}$, and $R_{5,8}$ refers to reactivity patterns from Fig. 1.)



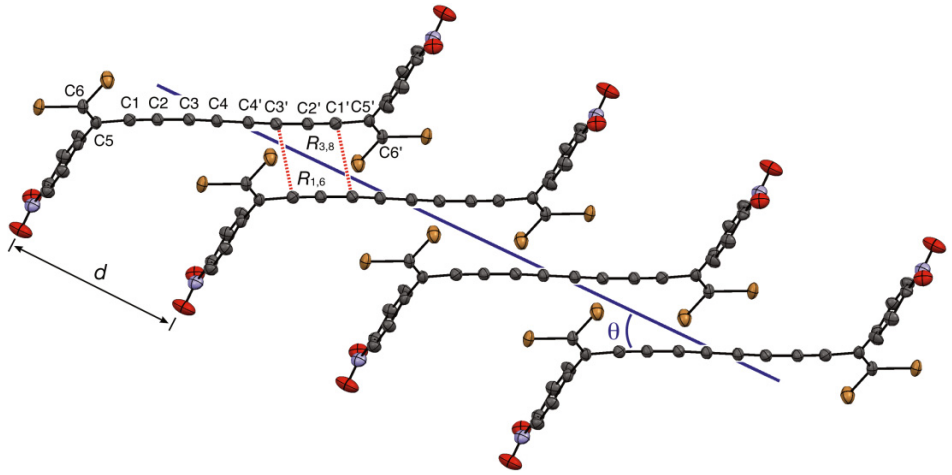


Fig. 11. ORTEP drawing (50% probability level) of **6d** showing a segment of crystal packing. Geometry parameters: θ = 29°, $R_{1,6}$ = 3.5 Å, $R_{3,8}$ = 3.5 Å, and d = 7.5 Å. (Note: The numbering of the carbon chain corresponds to the structural characterization listed in Tables 3 and 4, whereas the numbering for $R_{1,6}$ and $R_{3,8}$ refers to reactivity patterns from Fig. 1.)

solution at −4 °C (Fig. 11). As with **6a** and **6c** (Table 4), the terminal C(5)–C(1)–C(2) bond angle of **6d** is the most distorted from linearity at 174.3(4)°, and the centrosymmetric enyne framework is planar. Molecules of compound **6d** are packed in parallel stacks, and the distance separating reactive atoms of adjacent molecules is $R_{1,6}$ = $R_{3,8}$ = 3.5 Å. The translational distance (d) is 7.5 Å, with a packing angle (θ) of 29°. These values are thus ideal for a 1,6-topochemical polymerization.

The UV–vis absorption spectrum of compound **6d** has been measured in the solid state (Fig. 12) for a thin film produced by casting a solution of compound **6d** in CH_2Cl_2 onto a quartz slide and allowing the solvent to evaporate. The UV–vis spectrum of the film shows absorbance values of 368, 400, and 434 nm, which are somewhat red-shifted from those for the sample in solution (359, 384, and 419 nm in THF). As the thin film is then heated at 170 °C under an argon atmosphere for 17 h, UV–vis absorption spectra have been examined at various time intervals (Fig. 12). After heating for 1 h, the intensity of the three low-energy absorbances decreases, and λ_{max} values are slightly blue-shifted to 365, 397, and 430 nm. After heating for 5 h, only two distinct signals remain in the low-energy region at ~393 and 424 nm, and these two signals finally merge into one broad signal after heating for a total of 17 h. Rather surprisingly, this analysis implies that the conjugated ene–tetrayne–ene framework is transformed into a *less conjugated* product, rather than one with extended conjugation as would be expected upon formation of a polytriacetylene product (Fig. 13).

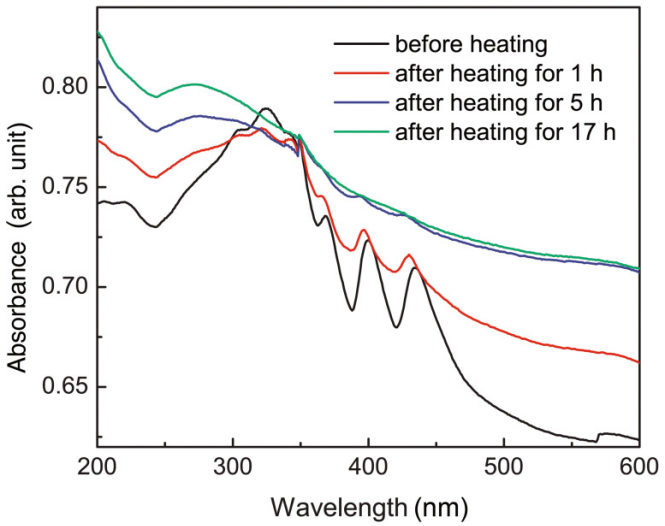
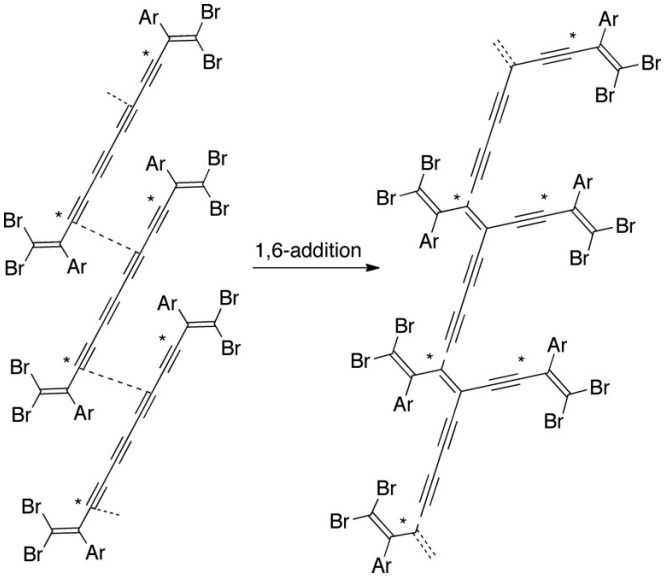
Fig. 12. Solid-state UV–vis spectra for compound **6d** before and after heating at 170 °C for the times given.





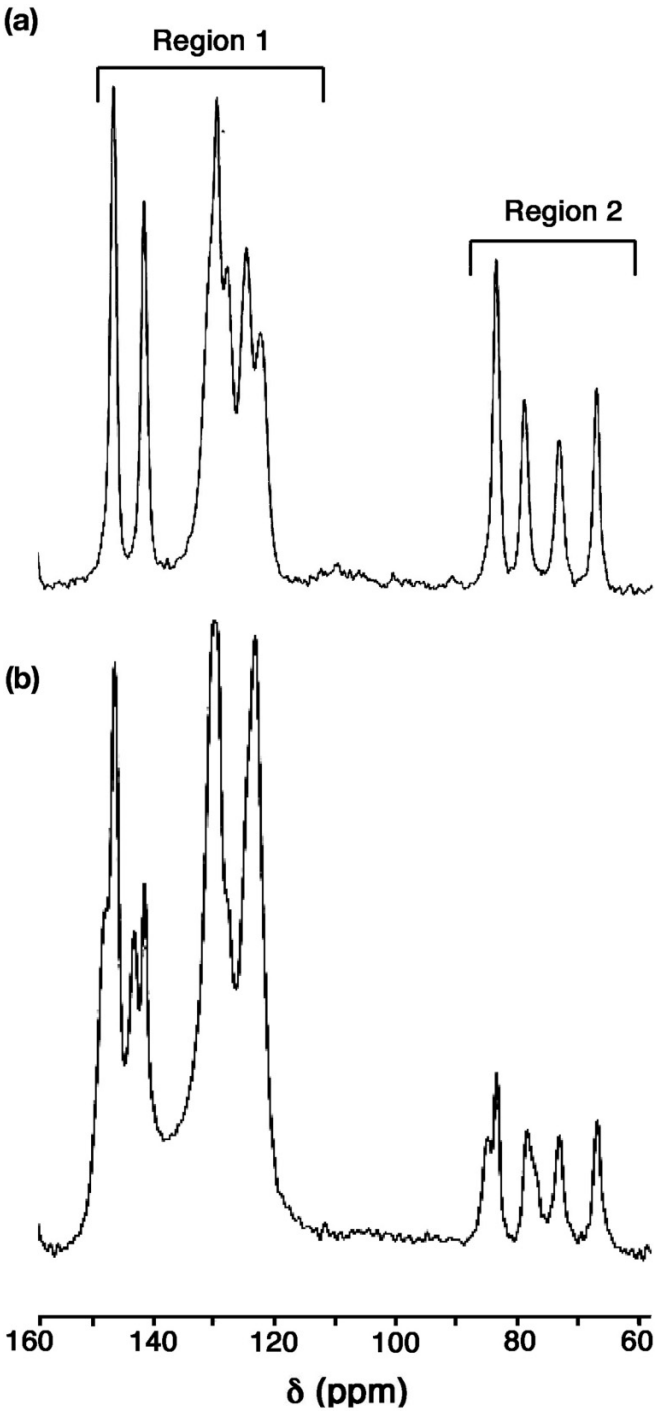


Fig. 13. Idealized structure resulting from 1,6-polymerization of **6d** or labelled **6d/6d*/6d**** (* indicates ^{13}C atoms).

Thermal polymerization of **6d** has been explored by heating a crystalline sample to 170 °C under argon (see the previous warning for compound **6d**). Attempts to analyze the resulting sample by solution-state ^{1}H and ^{13}C NMR spectroscopy show that the resulting polymer is insoluble, and useful spectra could not be obtained. Solid-state ^{13}C NMR spectroscopy has therefore been used to explore the thermal transformation of **6d** (Fig. 14). In the pristine sample, four aromatic and two alkenyl signals are observed in region 1 (Fig. 14, 120–150 ppm). These resonances are found at similar chemical shifts as in solution, except for the α-vinyl signal ($Br_2C{=}C<$), which appears downfield from its solution value of 107.5 ppm. The alkynyl peaks appear in region 2 (Fig. 14, 60–90 ppm), and chemical shifts for the four distinct signals (67, 73, 79, and 84 ppm) correlate well with those found in the solution-state

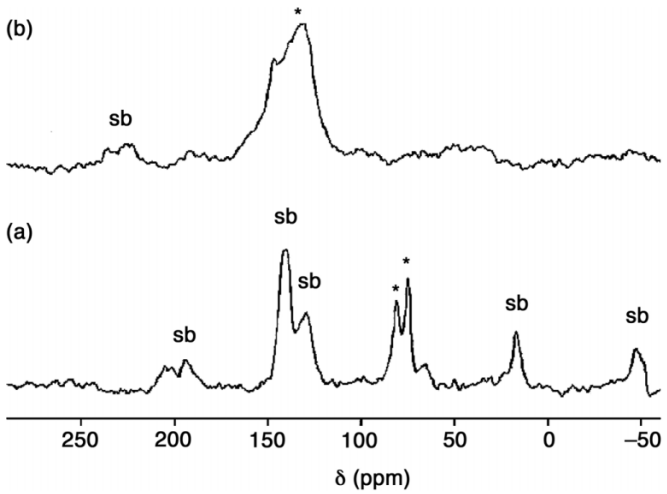

Fig. 14. Solid-state ^{13}C NMR spectra of compound **6d** (*a*) before heating and (*b*) after heating at 170 °C for 6 h under argon.

spectrum at 64.8, 71.2, 75.9, and 82.6 ppm. After heating the solid at 170 °C under an Ar atmosphere for 6 h, both downfield signals in region 1 (Fig. 14, 142 and 147 ppm) appear to split into two signals, while the remaining two signals in region 1 broaden somewhat. Signals in region 2 follow a similar pattern, where two signals (79 and 84 ppm) seemingly split and those at 67 and 73 ppm broaden slightly. Furthermore, the intensity of all alkyne signals in region 2 decreases noticeably

Fig. 15. Solid-state ^{13}C NMR spectra for compound **6d/6d*/6d****. (*a*) Before heating. (*b*) After heating (sb, spinning side band; *, labelled ^{13}C signal). Spectra were acquired at 11.75 T (125 MHz for ^{13}C) using CP/MAS and a spinning frequency of 8 kHz. Spectra acquired at various spinning frequencies (not shown) confirmed that the peaks in the 100–150 ppm region in (*a*) arise primarily from spinning sidebands.

relative to those in region 1. The spectral changes in regions 1 and 2 for the spectrum acquired after heating suggest a loss of molecular symmetry, which is evidence for polymerization as shown for the idealized transformation outlined in Fig. 13. Unfortunately, it is once again not clear if the reaction proceeds via a 1,6-addition process as suggested by X-ray crystallographic analysis or via an alternative pathway.

Crystals of partially labelled tetrayne sample **6d/6d*/6d**** could be obtained, but unfortunately only on a small scale, giving a total sample amount of ~1 mg. X-ray crystallography has established that the solid-state geometric packing of this sample is identical to that of unlabelled **6d**. A solid-state ^{13}C NMR spectrum of **6d/6d*/6d**** was acquired at 11.75 T (125 MHz for ^{13}C) using cross-polarization/magic-angle spinning (CP/MAS) and a spinning frequency of 8 kHz (Fig. 15). In the pristine sample, two strong signals are observed at 75.4 and 81.5 ppm owing to the presence of ^{13}C labelling. This is surprising given that the solid-state structure of **6d** is expected to be centrosymmetric based on the crystallographic analysis, and only a single resonance for the labelled carbon is observed in solution (75.6 ppm; see the Supplementary data). The origin of the second signal is, at present, unexplained. Unfortunately, spinning side bands are also quite intense. After heating the sample holder containing compound **6d/6d*/6d**** at 170 °C under Ar for 3 days, the resulting spectrum shows the enhanced ^{13}C signals at ~130 and 142 ppm, characteristic of sp^2-hybridized carbon atoms. At first sight, this result is inconsistent with the analysis of unlabelled **6d** for which alkyne signals are still observed after heating (Fig. 14). It is likely, however, that the extended heating time for **6d/6d*/6d**** at 170 °C (3 days) versus that of **6d** (6 h) results in additional and nonselective reactions, ultimately giving a material composed primarily of sp^2-hybridized carbon. Thus, compound **6d/6d*/6d**** may undergo a 1,6-topochemical polymerization, but the structure of the final product, frustratingly, remains unsolved.

Conclusions

We have described the synthesis of functionalized, cross-conjugated tetraynes. UV–vis spectroscopic analysis shows that the electronic characteristics of the tetrayne moiety dominate the lower energy absorption region, and the side groups, either electron-donating or electron-withdrawing, have only a marginal influence on the absorption energy of the central tetrayne chromophore. The solid-state structural properties of five derivatives have been examined by X-ray crystallographic analysis. Examination of the crystal structures with an eye toward inducing solid-state reactions shows that the packing parameters (θ, *R*, and *d*) for all but **6c** fall within a range suitable for topochemical polymerization, and the values for three (**1k**, **1l**, and **6d**) are quite close to the values ideal for a 1,6-polymerization. To our knowledge, this is the first series of structurally similar tetraynes that shows a consistent packing motif conducive to topochemical polymerization. In addition to X-ray crystallography, DSC analysis also supports the prospect of a viable polymerization reaction toward a defined product in many cases. Thus, the polymerization of tetraynes has been explored using thermal, photochemical, and (or) γ-irradiation for initiation. Furthermore, the thermally induced solid-state reaction of **1d**, **1j**, **1k**, and **6d** has been studied in more detail via solid-state ^{13}C NMR spectroscopy. In all cases, however, it has been frustratingly difficult to ascertain the structure of the product, often owing to broadening of the observed resonances in the ^{13}C spectra, presumably because of a regiorandom polymerization reaction.

Our inability to effect clean polymerization of these crystallized samples is the most significant outcome of this study. A survey of reports for topochemical polymerization of diynes shows that there is typically a good correlation between packing parameters and successful polymerization to a polydiacetylene product. Combined with reports of successful polymerization of polyynes as described in the Introduction, this leads to the naïve assumption that the controlled polymerization of polyynes might also be predicted based on solid-state packing. But the story is not so simple, and it is now quite obvious to conclude that the successful polymerization of tetraynes is far more complex than a simple analysis of solid-state packing parameters θ, *R*, and *d*.

Experimental section

Irradiation with ^{60}Co

Single crystals of either **4k** or **4l** were placed into a glass vial and subjected to the irradiation from a ^{60}Co source (~54 ± 3 krad/h, previously located at the Chemistry Department, University of Alberta, Edmonton, Alberta) for 2 weeks at room temperature. After irradiation, the colours of the crystals became slightly darker and the crystals were re-examined by X-ray single crystal diffraction analysis.

X-ray crystallographic data

Data for 1k

Single crystals of **1k** were obtained via the diffusion of methanol into an Et_2O solution at –4 °C. Formula $C_{40}H_{30}Fe_2$, fw = 622.34; monoclinic crystal system, space group $P2_1/c$ (No. 14); a = 18.075(3) Å, b = 7.4082(11) Å, c = 11.7293(16) Å; β = 103.751(3)°; V = 1525.6(4) Å^3; Z = 2; $\rho_{(calcd.)}$ = 1.355 g cm^{-3}; $2\theta_{max}$ = 52.80°; μ = 0.978 mm^{-1};

$T = -80$ °C; total data collected = 7305. Final $R_1(F) = 0.0562$ (1455 observed reflections with $F_o^2 \geq 2\sigma(F_o^2)$); $wR_2(F^2) = 0.0901$ for 212 variables, 3133 unique reflections, and 0 restraints; residual electron density = 0.326 and −0.327 e Å^{-3}. CCDC 862755.

Data for 1l

Single crystals of **1l** were obtained via the diffusion of MeOH into a CH_2Cl_2 solution at –20 °C (as reported in ref. 27). Formula $C_{38}H_{54}Si_2$, fw = 566.99; monoclinic crystal system, space group $P2_1/c$ (No. 14); a = 13.5571(8) Å, b = 7.7132(5) Å, c = 35.616(2) Å; β = 96.5990(10)°; V = 3699.7(4) Å^3; Z = 4; $\rho_{(calcd.)}$ = 1.018 g cm^{-3}; $2\theta_{max}$ = 51.50°; μ = 0.118 mm^{-1}; $T = -80$ °C; total data collected = 19122. Final $R_1(F) = 0.0472$ (4842 observed reflections with $F_o^2 \geq 2\sigma(F_o^2)$); $wR_2(F^2) = 0.1366$ for 365 variables, 7039 unique reflections, and 0 restraints; residual electron density = 0.389 and −0.235 e Å^{-3}. CCDC HOZSAQ.

Data for 6a

Single crystals of **6a** were obtained via the diffusion of hexanes into a solution of hexanes/CH_2Cl_2 at −4 °C. Formula $C_{24}H_{10}Br_4$, fw = 617.96; triclinic crystal system, space group $P\bar{1}$ (No. 2); a = 9.4512(7) Å, b = 10.1187(7) Å, c = 11.6133(8) Å; α = 96.0941(13)°, β = 92.5663(13)°, γ = 103.4569(13)°; V = 1071.25(13) Å^3; Z = 2; $\rho_{(calcd.)}$ = 1.916 g cm^{-3}; $2\theta_{max}$ = 52.76°; μ = 7.521 mm^{-1}; $T = -80$ °C; total data collected = 7878. R_1 = 0.0368 (3413 observed reflections with $F_o^2 \geq 2\sigma(F_o^2)$); wR_2 = 0.0930 for 253 variables, 4356 unique reflections, and 0 restraints; residual electron density = 1.164 and −0.586 e Å^{-3}. CCDC 862756.

Data for 6c

Single crystals of **6c** were obtained via the diffusion of hexanes into a solution of hexanes/CH_2Cl_2 at −4 °C. Formula $C_{32}H_{26}Br_4$, fw = 730.17; triclinic crystal system, space group $P\bar{1}$ (No. 2); a = 5.8968(7) Å, b = 11.1037(14) Å, c = 11.9247(15) Å; α = 69.2510(17)°, β = 78.1507(18)°, γ = 86.0880(19)°; V = 714.58(15) Å^3; Z = 1; $\rho_{(calcd.)}$ = 1.697 g cm^{-3}; $2\theta_{max}$ = 52.74°; μ = 5.651 mm^{-1}; $T = -80$ °C; total data collected = 5606. R_1 = 0.0342 (2418 observed reflections with $F_o^2 \geq 2\sigma(F_o^2)$); wR_2 = 0.0905 for 163 variables, 2911 unique reflections, and 0 restraints; residual electron density = 0.618 and −0.492 e Å^{-3}. CCDC 862758.

Data for 6d

Single crystals of **6c** were obtained via the evaporation of a $CDCl_3$ solution at −4 °C. Formula $C_{24}H_8Br_4N_2O_4$, fw = 707.96; orthorhombic crystal system, space group *Pbcn* (No. 60); a = 7.5156(7) Å, b = 14.8934(14) Å, c = 21.328(2) Å; V = 2387.3(4) Å^3; Z = 4; $\rho_{(calcd.)}$ = 1.970 g cm^{-3}; $2\theta_{max}$ = 52.82°; μ = 6.777 mm^{-1}; $T = -80$ °C; total data collected = 14313. R_1 = 0.0322 (1968 observed reflections with $F_o^2 \geq 2\sigma(F_o^2)$); wR_2 = 0.0825 for 154 variables, 2461 unique reflections, and 0 restraints; residual electron density = 1.129 and −0.406 e Å^{-3}. CCDC 862757.

Synthetic and spectroscopic details

General experimental details

Column chromatography: silica gel 60 (230–400 mesh) from General Intermediates of Canada. Thin-layer chromatography (TLC): aluminium sheet coated with silica gel F_{254} from Whatman; visualization by UV light or $KMnO_4$ stain. Melting point: Fisher-Johns or Gallenkamp apparatus; uncorrected. UV–vis spectra: Varian Cary 400 at rt; λ in nm (ε in L mol^{-1} cm^{-1}). IR spectra (cm^{-1}): Nicolet Magna-IR 750 (neat) or Nic-Plan IR microscope (solids). ^{1}H and ^{13}C solution-state NMR: Varian 300, 400, 500, or 600 and Bruker AM-300 instruments, at rt in $CDCl_3$; solvent peaks (7.24 ppm for ^{1}H and 77.0 ppm for ^{13}C) as reference. For simplicity, the coupling constants of the aryl protons have been reported as pseudo-first-order, even though they are AA′BB′ second-order spin systems; coupling constants are reported as observed. ^{13}C solid-state NMR: CMX Infinity 200 as well as Bruker Avance 300 and 500 spectrometers operating at 50, 75, and 125 MHz, respectively, for ^{13}C. Samples were packed in 4 mm outside diameter (o.d.) MAS rotors spinning at frequencies ranging from 5 to 12 kHz. All spectra were acquired with cross polarization using contact times of 1.0–6.0 ms, ^{1}H 90° pulses of 2.5–4.0 μs, and recycle delays of 3.0–10.0 s. To improve decoupling efficiency, the two-pulse phase modulated (TPPM) sequence of Griffin and co-workers[46] was used. Spectra were referenced to tetramethylsilane (TMS; δ = 0) by setting the high-frequency peak of adamantine to 38.56 ppm.[47] EI-MS (*m*/*z*): Kratos MS 50 instrument. ESI-MS (*m*/*z*): Micromass Zabspec oaTOF or PE Biosystems Mariner TOF instruments. Elemental analyses were performed by the Microanalytical Service, Department of Chemistry, University of Alberta.

General methods

Reagents and solvents were purchased reagent grade and used without further purification. Compounds **2**,[29] **3b**,[48] **3g**,[49] **3k**,[50] **10a**–**10c**,[31] and **11**[35] were prepared based on literature precedent. Anhydrous $MgSO_4$ was used as the drying agent after aqueous workup. Evaporation and concentration in vacuo was done at H_2O-aspirator pressure. All reactions were performed in standard glassware under an inert atmosphere of Ar or N_2. A positive pressure of Ar or N_2 was essential to the success of all Pd-catalyzed reactions. Deoxygenation of solvents was accomplished by vigorously bubbling Ar or N_2 through the solution at rt for ~30 min. Brine refers to a saturated aqueous solution of NaCl. Flash chromatography was conducted on silica gel using the eluent system defined in the individual experimental procedures.

For mass spectrometric analyses, low-resolution data are provided in cases when M^+ is not the base peak; otherwise, only high-resolution data are provided. The samples for ESI mass spectrometry were typically dissolved in $ClCH_2CH_2Cl$ and made use of a 3:1 MeOH/toluene mixture as the carrier solvent.

DSC measurements were measured on a PerkinElmer Pyris 1 DSC instrument. Melting points from DSC analysis are reported as the peak maxima, and in cases when the sample decomposed, the onset temperature of the decomposition exothermic peak is reported, as well as the exothermic maxima corresponding to the decomposition.

Formation of the Hay catalyst was conducted as follows: CuI (50 mg) and tetramethylethylenediamine (TMEDA, 75 mg) were added to CH_2Cl_2 (2 mL) and stirred until homogeneous; this solution was prepared fresh for each reaction. Wet THF/MeOH refers to the use of THF and MeOH that have not been previously dried by distillation, i.e., the solvent is

used "straight out of the bottle" and is assumed to contain a small amount of water.

General procedure A — Desilylation procedure

To the appropriate trimethylsilyl polyyne in wet THF/MeOH (1:1, 20 mL) was added K_2CO_3 (~20 mg), and the resulting mixture was stirred at rt until TLC indicated the starting material had been consumed (~2 h). Ether (50 mL) and saturated aq NH_4Cl (50 mL) were added, the organic phase separated, washed with saturated aq NH_4Cl (2 × 50 mL), dried over $MgSO_4$, and filtered. The solvent was then reduced to ~1 mL via rotary evaporation, taking care to ensure that the product remained in solution during the concentration process. The resulting solution was carried on to the next step.

General procedure B — Palladium-catalyzed cross-coupling procedure

The appropriate alkyne **3** was added to a solution of vinyl triflate **2** in THF (20 mL) and the resulting mixture deoxygenated. $PdCl_2(PPh_3)_2$ (~0.05 equiv) and *i*-Pr_2NH were sequentially added, the solution was stirred for 5 min, CuI (~0.15 equiv) was added, and the solution was stirred under conditions described in the individual procedures, typically until TLC analysis no longer showed the presence of either **2** or **3**. Ether (40 mL) and H_2O (30 mL) were then added, the organic phase separated, washed with saturated aq NH_4Cl (2 × 50 mL), dried over $MgSO_4$, filtered, and the filtrate concentrated in vacuo. Flash column chromatography and (or) precipitation from MeOH gave the desired enyne oligomer.

General procedure C — Copper-catalyzed oxidative acetylenic-coupling procedure

The terminal acetylene from general procedure A was added to acetone (10 mL), acetone/CH_2Cl_2 (1:1, 10 mL), or CH_2Cl_2 (60 mL). A solution of Hay catalyst mixture (1 mL) was then added. The mixture was stirred at rt under air until TLC analysis no longer showed the deprotected polyyne (generally less than 0.5 h). The reaction solution was concentrated in vacuo to ~5 mL and diethyl ether (50 mL) was added. The ethereal solution was consecutively washed with a 10% HCl solution (25 mL), saturated aq $NaHCO_3$ (25 mL), and brine (25 mL), dried, and the solvent removed. Flash column chromatography and (or) precipitation from MeOH gave the product **1** or **6**.

Compound **1a**

Compound **4a** (66 mg, 0.26 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 1 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1a** (45 mg, 94%) as a brown oil that slowly decomposed over a period of hours to days when stored neat. R_f = 0.78 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 302 (57 800), 320 (41 700), 348 (17 100), 374 (18 800), 405 (11 800). IR ($CHCl_3$, cast, cm^{-1}): 2958, 2932, 2872, 2193, 2125, 1959, 1587. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.33 (t, J = 6.6 Hz, 4H), 2.02 (s, 6H), 2.01 (s, 6H), 1.54–1.36 (m, 8H), 0.90 (t, J = 7.2 Hz, 6H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 159.7, 100.5, 94.2, 75.7, 75.8, 75.5, 67.7, 64.0, 30.8, 23.1, 23.0, 22.0, 19.2, 13.6. EI HR-MS calcd for $C_{28}H_{30}$ (M^+): 366.2347; found: 366.2349.

Compound **1b**

Compound **4b** (20 mg, 0.035 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 0.5 h as described in general procedure C. Flash chromatography (hexane / ethyl acetate, 1:5) afforded **1b** (16 mg, 91%) as a brown solid; mp 57–62 °C. R_f = 0.62 (hexane / ethyl acetate, 1:5). IR (CH_2Cl_2, cast, cm^{-1}): 2934, 2193, 1750, 1587, 1433. ^1H NMR (600 MHz, $CDCl_3$) δ: 5.51 (d, J = 3.5 Hz, 2H), 5.28 (t, J = 10.1 Hz, 2H), 5.09 (dd, J = 10.1 Hz, J = 3.5 Hz, 2H), 5.02 (s, 2H), 4.29 (dd, J = 12.3 Hz, J = 5.7 Hz, 2H), 4.13 (dd, J = 12.3 Hz, J = 2.4 Hz, 2H), 3.73 (d, J = 17.0 Hz, 4H), 3.71 (m, 2H), 3.43 (d, J = 17.0 Hz, 4H), 2.16 (s, 6H), 2.07 (s, 12 H), 2.04 (s, 12H), 1.97 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 170.7, 170.1, 170.0, 169.7, 162.3, 99.7, 87.6, 80.9, 76.9, 76.4, 75.1, 72.1, 70.2, 69.6, 68.1, 65.8, 62.6, 31.8, 29.3, 23.4, 23.2, 20.80, 20.75, 20.66, 20.6. ESI-MS m/z (MeOH): 1029.3 ([M + Na]$^+$).

Compound **1c**

Compound **4c** (68 mg, 0.24 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 0.5 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1c** (32 mg, 66%) as a yellow waxy solid. R_f = 0.61 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 282 (91 200), 296 (82 100), 322 (41 900), 349 (18 600), 374 (19 900), 405 (11 800). IR (μscope, cm^{-1}): 3057, 2930, 2906, 2194, 2127, 1598, 1583, 1490, 1443. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.46–7.42 (m, 4H), 7.32–7.28 (m, 6H), 2.13 (s, 6H), 2.12 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 161.5, 131.5, 128.5, 128.4, 122.9, 100.4, 92.9, 84.4, 76.4, 75.0, 67.9, 64.1, 23.4, 23.3. EI HR-MS calcd for $C_{32}H_{22}$ (M^+): 406.1722; found: 406.1728.

Compound **1d**

Compound **4d** (88 mg, 0.27 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 0.5 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1d** (64 mg, 95%) as a yellow solid; mp > 115 °C (dec). R_f = 0.57 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 287 (66 700), 306 (90 400), 323 (83 700), 349 (50 200), 374 (39 800), 405 (15 900). IR (μscope, cm^{-1}): 3104, 2932, 2847, 2198, 2128, 1594, 1520, 1491, 1432, 1343. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.17 (d, J = 8.8 Hz, 4H), 7.57 (d, J = 8.8 Hz, 4H), 2.149 (s, 6H), 2.146 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 163.9, 147.1, 132.1, 129.7, 123.6, 99.9, 90.8, 89.5, 76.7, 74.2, 68.1, 63.9, 23.54, 23.47. EI HR-MS calcd for $C_{32}H_{20}N_2O_4$ (M^+): 496.1423; found: 496.1425. DSC: decomposition 172 °C (onset), 193 °C (peak).

Compound **1e**

Compound **4e** (53 mg, 0.16 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 2 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1e** (11 mg, 27%) as a yellow waxy semisolid that

slowly decomposed over a period of hours to days. R_f = 0.28 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 283 (72 300), 304 (63 000), 323 (52 600), 349 (28 500), 374 (27 000), 405 (14 700). IR (μscope, cm^{-1}): 2927, 2200, 1608, 1567, 1528, 1479, 1438, 1336. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.06 (dd, J = 8.0, 1.2 Hz, 2H), 7.66 (dd, J = 8.0, 1.6 Hz, 2H), 7.57 (td, J = 8.0, 1.2 Hz, 2H), 7.44 (td, J = 8.0, 1.6 Hz, 2H), 2.22 (s, 6H), 2.15 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 165.0, 149.0, 134.7, 132.9, 128.7, 124.7, 118.5, 100.1, 92.2, 88.0, 76.6, 74.3, 68.0, 64.0, 23.6, 23.5. EI HR-MS calcd for $C_{32}H_{20}N_2O_4$ (M^+): 496.1423; found: 496.1419.

***Compound* 1f**

Compound **4f** (77 mg, 0.24 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 0.5 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1f** (23 mg, 39%) as a yellow waxy semisolid that slowly decomposed over a period of hours to days. R_f = 0.4 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 280 (98 100), 299 (87 500), 320 (54 200), 348 (20 100), 374 (21 400), 405 (13 300). IR (CH_2Cl_2, cast, cm^{-1}): 3087, 2197, 1536, 1346. ^1H NMR (300 MHz, $CDCl_3$) δ: 8.28–8.27 (m, 2H), 8.17–8.13 (m, 2H), 7.75–7.72 (m, 2H), 7.49 (t, J = 8.1 Hz, 2H), 2.152 (s, 6H), 2.146 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 163.4, 148.2, 137.1, 129.4, 126.3, 124.8, 123.1, 99.9, 90.2, 86.9, 74.3, 68.1, 64.0, 23.6, 23.5 (one coincident peak not observed). EI HR-MS calcd for $C_{32}H_{20}N_2O_4$ (M^+): 496.1423; found: 496.1409.

***Compound* 1h**

Compound **4h** (40 mg, 0.13 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone (10 mL) in the presence of Hay catalyst (1 mL) and air for 0.5 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1h** (22 mg, 74%) as a yellow waxy semisolid that slowly decomposed over a period of hours to days when stored neat. R_f = 0.63 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 300 (104 400), 323 (69 600), 348 (17 600), 374 (17 700), 405 (9 700). IR (CH_2Cl_2, cast, cm^{-1}): 2228, 2194, 2126, 1959, 1603, 1450, 1432. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.59 (d, J = 8.4 Hz, 4H), 7.51 (d, J = 8.4 Hz, 4H), 2.14 (s, 12H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 163.6, 132.1, 132.0, 127.8, 118.5, 111.8, 100.0, 91.1, 88.7, 76.7, 74.3, 68.1, 64.0, 23.6, 23.5. EI HR-MS calcd for $C_{34}H_{20}N_2$ (M^+): 456.1627; found: 456.1629.

***Compound* 1i**

Compound **4i** (93 mg, 0.26 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and homocoupled in acetone/CH_2Cl_2 (1:1; 10 mL) in the presence of Hay catalyst (1 mL) and air for 0.5 h as described in general procedure C. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **1i** (63 mg, 85%) as a yellow solid; mp > 110 °C (dec). R_f = 0.21 (hexane/CH_2Cl_2, 2:1). UV–vis ($CHCl_3$) λ_{max} (ε): 288 (104 300), 322 (49 000), 349 (17 600), 375 (20 100), 406 (12 200). ence of $PdCl_2(PPh_3)_2$ (3 mg, 0.004 mmol), diisopropylamine (2 mL), and CuI (1.5 mg, 0.0079 mmol) for 1 h as described in general procedure B. Flash chromatography (hexane / ethyl acetate, 3:1) afforded **4b** (37 mg, 65%) as a colourless solid vide infra; mp 54–57 °C. R_f = 0.33 (hexane / ethyl acetate, 3:1). IR (μscope, cm^{-1}): 2961, 2916, 2849, 2199, 2098, 1744, 1592, 1433. ^1H NMR (600 MHz, $CDCl_3$) δ: 5.51 (d, J = 3.5 Hz, 1H), 5.28 (t, J = 10.0 Hz, 1H), 5.09 (dd, J = 10.0 Hz, J = 3.6 Hz, 1H), 5.02 (s, 1H), 4.29 (dd, J = 10.0 Hz, J = 0.6 Hz, 1H), 4.13 (dd, J = 10.0 Hz, J = 0.2 Hz, 1H), 3.72 (d, J = 16.7 Hz, 1H), 3.70 (m, 1H), 3.42 (d, J = 16.7 Hz, 1H), 2.16 (s, 3H), 2.07 (s, 3H), 2.05 (s, 3H), 2.023 (s, 3H), 2.020 (s, 3H), 1.96 (s, 3H), 0.18 (s, 9H). ^{13}C NMR (75 MHz, CD_2Cl_2, APT) δ: 170.8, 170.4, 170.2, 169.9, 160.4, 99.9, 91.6, 87.8, 87.5, 81.3, 79.8, 77.1, 76.3, 74.0, 72.3, 70.5, 66.0, 62.7, 30.1, 23.2, 23.0, 20.9, 20.7, 19.6, −0.4 (one coincident peak not observed). ESI HR-MS calcd for $C_{28}H_{36}O_9NaSSi$ ($[M + Na]^+$): 599.1742; found: 599.1740.

***Compound* 4c**

Trimethylphenylethynylsilane (60 mg, 0.34 mmol) was desilylated with K_2CO_3 in THF/MeOH (1:1) as per general procedure A to give **3c**, which was cross-coupled with triflate **2** (109 mg, 0.336 mmol) in degassed THF (20 mL) in the presence of $PdCl_2(PPh_3)_2$ (12 mg, 0.017 mmol), diisopropylamine (2 mL), and CuI (6 mg, 0.03 mmol) for 50 min as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **4c** (90 mg, 96%) as a colourless solid; mp 71–72 °C. R_f = 0.63 (hexane/CH_2Cl_2, 2:1). IR (CH_2Cl_2, cast, cm^{-1}): 2960, 2904, 2199, 2094, 1594, 1489. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.45–7.42 (m, 2H), 7.31–7.27 (m, 3H), 2.10 (s, 3H), 2.09 (s, 3H), 0.20 (s, 9H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 158.8, 131.4, 128.25, 128.19, 123.1, 100.5, 92.1, 90.9, 88.0, 85.0, 76.0, 73.8, 23.00, 23.06, −0.4. EI MS m/z (rel. intensity): 276.1 (M^+, 100), 261.1 ($[M - Me]^+$, 88). EI HR-MS calcd for $C_{19}H_{20}Si$ (M^+): 276.1334; found: 276.1334.

***Compound* 4d**

Trimethyl(4-nitrophenylethynyl)silane (75 mg, 0.34 mmol) was desilylated with K_2CO_3 in THF/MeOH (1:1) as described in general procedure A to give **3d**, which was cross-coupled with triflate **2** (109 mg, 0.336 mmol) in degassed THF (20 mL) in the presence of $PdCl_2(PPh_3)_2$ (12 mg, 0.017 mmol), diisopropylamine (2 mL), and CuI (6 mg, 0.03 mmol) for 50 min as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 1:1) afforded **4d** (97 mg, 90%) as a yellow solid; mp 94–95 °C. R_f = 0.40 (hexane/CH_2Cl_2, 1:1). IR ($CHCl_3$, cast, cm^{-1}): 2960, 2199, 2095, 1595, 1519, 1491, 1433, 1342. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.15 (d, J = 8.9 Hz, 2H), 7.54 (d, J = 8.9 Hz, 2H), 2.11 (s, 6H), 0.19 (s, 9H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 161.2, 146.9, 132.0, 129.9, 123.5, 100.1, 91.5, 90.3, 90.2, 87.6, 76.6, 72.8, 23.22, 23.19, −0.5. EI MS m/z (rel. intensity): 321.1 (M^+, 100), 306.1 ($[M - Me]^+$, 58). EI HR-MS calcd for $C_{19}H_{19}NO_2Si$ (M^+): 321.1185; found: 321.1180. Anal. calcd for $C_{19}H_{19}NO_2Si$: C 70.99, H 5.96; found: C 70.88, H 5.96.

***Compound* 4e**

Trimethyl(2-nitrophenylethynyl)silane (75 mg, 0.34 mmol) was desilylated with K_2CO_3 in THF/MeOH (1:1) as described in general procedure A to give **3e**, which was cross-coupled with triflate **2** (109 mg, 0.336 mmol) in degassed THF (20 mL) in the presence of $PdCl_2(PPh_3)_2$ (12 mg, 0.017 mmol), diisopropylamine (2 mL), and CuI (6 mg, 0.032 mmol) for 2 h as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 1:1) afforded **4e** (95 mg, 87%) as a yellow solid; mp 93–94 °C. R_f = 0.45 (hexane/CH_2Cl_2, 1:1). IR (CH_2Cl_2, cast, cm^{-1}): 2960, 2199, 2094, 1607, 1526, 1480, 1438, 1343. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.02 (dd, J = 8.3, 1.2 Hz, 1H), 7.62 (dd, J = 7.8, 1.5 Hz, 1H), 7.54 (dt, J = 7.5, 1.3 Hz, 1H), 7.41 (dt, J = 8.3, 1.5 Hz, 1H), 2.17 (s, 3H), 2.11 (s, 3H), 0.19 (s, 9H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 162.4, 148.9, 134.6, 132.8, 128.5, 124.6, 118.6, 100.2, 93.0, 91.2, 87.9, 87.3, 76.3, 73.1, 23.3, 23.2, −0.4. EI MS m/z (rel. intensity): 321.1 (M^+, 35), 73.0 (Me_3Si^+, 100). EI HR-MS calcd for $C_{19}H_{19}NO_2Si$ (M^+): 321.1185; found: 321.1182. propylamine (2 mL), and CuI (3 mg, 0.02 mmol) for 1.5 h as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 1:1) afforded **4h** (52 mg, 80%) as a yellow solid; mp 60–62 °C. R_f = 0.48 (hexane/CH_2Cl_2, 1:1). IR (CH_2Cl_2, cast, cm^{-1}): 2960, 2904, 2229, 2199, 2095, 1604, 1499, 1433. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.59 (d, J = 8.6 Hz, 2H), 7.50 (d, J = 8.6 Hz, 2H), 2.11 (s, 6H), 0.20 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 160.9, 132.0, 131.9, 128.1, 118.5, 111.6, 100.2, 91.5, 90.4, 89.5, 87.7, 73.0, 23.3, –0.4 (two coincident peaks not observed). EI MS *m/z* (rel. intensity): 301.1 (M^+, 93), 286.1 ([M – Me]$^+$, 100). EI HR-MS calcd for $C_{20}H_{19}NSi$ (M^+): 301.1287; found: 301.1292.

Compound 4i

(4-Bromophenylethynyl)trimethylsilane (101 mg, 0.399 mmol) was desilylated with K_2CO_3 in THF/MeOH (1:1) as described in general procedure A to give **3i**, which was cross-coupled with triflate **2** (130 mg, 0.401 mmol) in degassed THF (20 mL) in the presence of $PdCl_2(PPh_3)_2$ (14 mg, 0.020 mmol), diisopropylamine (2 mL), and CuI (7 mg, 0.04 mmol) for 2 h as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 1:1) afforded **4i** (112 mg, 79%) as a colourless waxy solid. R_f = 0.80 (hexane/CH_2Cl_2, 1:1). IR ($CHCl_3$, cast, cm^{-1}): 2959, 2198, 2094, 1484, 1421. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.42 (d, J = 8.4 Hz, 2H), 7.28 (d, J = 8.4 Hz, 2H), 2.08 (s, 6H), 0.20 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 159.3, 132.8, 131.5, 122.5, 122.0, 100.4, 91.1, 91.0, 87.9, 86.2, 76.2, 73.5, 23.1, 23.0, –0.4. EI HR-MS calcd for $C_{19}H_{19}{}^{81}BrSi$ (M^+): 356.0419; found: 356.0419.

Compound 4j

N,*N*-Dimethyl(4-trimethylsilylethynylphenyl)amine (109 mg, 0.501 mmol) was desilylated with K_2CO_3 in THF/MeOH (1:1) as described in general procedure A to give **3j**, which was cross-coupled with triflate **2** (162 mg, 0.501 mmol) in degassed THF (20 mL) in the presence of $PdCl_2(PPh_3)_2$ (18 mg, 0.026 mmol), diisopropylamine (2 mL), and CuI (9 mg, 0.05 mmol) for 1.5 h as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **4j** (133 mg, 83%) as a yellow solid; mp 82–83 °C. R_f = 0.50 (hexane/CH_2Cl_2, 2:1). IR ($CHCl_3$, cast, cm^{-1}): 2959, 2902, 2200, 2094, 1609, 1521, 1481, 1445. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.30 (d, J = 8.8 Hz, 2H), 6.60 (d, J = 8.8 Hz, 2H), 2.96 (s, 6H), 2.09 (s, 3H), 2.07 (s, 3H), 0.22 (s, 9H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 156.9, 150.0, 132.5, 111.7, 109.8, 100.9, 93.3, 90.5, 88.2, 82.9, 75.6, 74.4, 40.1, 22.9, 22.8, –0.4. EI HR-MS calcd for $C_{21}H_{25}NSi$ (M^+): 319.1756; found: 319.1750. Anal. calcd for $C_{21}H_{25}NSi$: C 78.94, H 7.89, N 4.38; found: C 78.70, H 8.04, N 4.47.

Compound 4k

Ethynylferrocene **3k** (76 mg, 0.36 mmol) was cross-coupled with triflate **2** (117 mg, 0.362 mmol) in degassed THF (20 mL) in the presence of $PdCl_2(PPh_3)_2$ (13 mg, 0.018 mmol), diisopropylamine (2 mL), and CuI (7 mg, 0.04 mmol) for 2 h as described in general procedure B. Flash chromatography (hexane/CH_2Cl_2, 2:1) afforded **4k** (78 mg, 56%) as a yellow solid; mp 84–85 °C. R_f = 0.82 (hexane/CH_2Cl_2, 2:1). IR (μscope, cm^{-1}): 3099, 2964, 2908, 2214, 2191, 2091, 1593, 1426, 1410. ^1H NMR (600 MHz, $CDCl_3$) δ: 4.42 (t, J = 1.8 Hz, 2H), 4.21 (s, 5H), 4.19 (t, J = 1.8 Hz, 2H), 2.06 (s, 3H), 2.05 (s, 3H), 0.19 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$, APT) δ: 157.6, 100.9, 91.1, 90.7, 88.1, 81.2, 74.2, 71.4, 70.0, 68.8, 65.1, 23.1, 22.9, –0.3 (one coincident peak not observed). EI HR-MS calcd for $C_{23}H_{24}FeSi$ (M^+): 384.0997; found: 384.1001.

Compound 6a

Compound **10a** (62.5 mg, 0.164 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and the resulting product was subjected to a homocoupling reaction in CH_2Cl_2 (60 mL) in the presence of Hay catalyst (1 mL) and air as described in general procedure C. Flash chromatography (hexanes/CH_2Cl_2, 7:1) gave **6a** (38.0 mg, 75%) as a yellow crystalline solid; mp 185 °C (dec). R_f = 0.46 (hexanes/CH_2Cl_2, 7:1). UV–vis (THF) λ_{max} (ε): 299 (66 600), 314 (78 600), 330 (64 700), 359 (27 600), 386 (30 600), 419 (19 500). IR ($CHCl_3$, cast, cm^{-1}): 3010, 2192, 1524, 1488. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.36 (s). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 136.6, 129.5, 129.1, 128.7, 128.5, 105.3, 81.9, 76.5, 70.9, 64.9. EI MS *m/z* (rel. intensity): 617.7 (M^+, 80), 298.1 ([M – 4Br]$^+$, 100). HR-MS calcd for $C_{24}H_{10}{}^{79}Br_2{}^{81}Br_2$ (M^+): 617.7475; found: 617.7488. Anal. calcd for $C_{24}H_{10}Br_4$: C 46.66, H 1.63; found: C 46.35, H 1.46. DSC: decomposition 191 °C (onset), 192 °C (peak).

Compound 6b

Compound **10b** (582 mg, 1.42 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and the resulting product was subjected to a homocoupling reaction in CH_2Cl_2 (60 mL) in the presence of Hay catalyst (1 mL) and air as described in general procedure C. Flash chromatography (hexanes/CH_2Cl_2, 3:1) gave **6b** (223 mg, 46%) as a yellow-green solid; mp 168–170 °C. R_f = 0.41 (hexanes/CH_2Cl_2, 3:1). UV–vis (THF) λ_{max} (ε): 296 (80 200, sh), 308 (93 100), 331 (59 200, sh), 360 (26 900), 388 (27 800), 420 (18 300). IR ($CHCl_3$, cast, cm^{-1}): 2924, 2190, 1605, 1505, 1252. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.32 (d, J = 9.0 Hz, 4H), 6.88 (d, J = 9.0 Hz, 4H), 3.81 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$, APT) δ: 156.0, 123.0, 129.1, 128.8, 114.0, 104.2, 81.7, 70.9, 65.0, 55.3 (one signal coincident or not observed). EI HR-MS calcd for $C_{26}H_{14}{}^{79}Br_2{}^{81}Br_2O_2$ (M^+): 677.7686; found: 677.7697. Anal. calcd for $C_{26}H_{14}Br_4O_2$: C 46.06, H 2.08; found: C 45.87, H 1.93. DSC: mp 176 °C; decomposition 176 °C (onset), 179 °C (peak).

Compound 6c

Compound **10c** (401 mg, 0.914 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and the resulting product was subjected to a homocoupling reaction in CH_2Cl_2 (60 mL) in the presence of Hay catalyst (1 mL) and air as described in general procedure C. Flash chromatography (hexanes/CH_2Cl_2, 7:1) gave **6c** (265 mg, 80%) as a yellow crystalline solid; mp 168–179 °C (dec). R_f = 0.52 (hexanes/CH_2Cl_2, 7:1). UV–vis (THF) λ_{max} (ε): 299 (72 100), 309 (70 500), 331 (55 100), 359 (25 200), 387 (27 600), 419 (17 500). IR ($CHCl_3$, cast, cm^{-1}): 2963, 2182, 1531. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.38 (d, J = 8.7 Hz, 4H), 8.7 (d, J = 8.7 Hz, 4H), 1.30 (s, 18H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 152.3, 133.5, 129.4, 128.2, 125.6, 104.6, 81.8, 77.3, 70.9, 65.0, 34.9, 31.3. EI HR-MS calcd for $C_{32}H_{26}{}^{79}Br_2{}^{81}Br_2$ (M^+): 729.8727; found: 729.8750. DSC: decomposition initial onset ~200 °C; 229 °C (onset), 233 °C (peak).

***Compound* 6d**

Compound **10d** (1.10 g, 2.58 mmol) was desilylated with K_2CO_3 in MeOH/THF (1:1) as described in general procedure A, and the resulting product was subjected to a homocoupling reaction in CH_2Cl_2 (60 mL) in the presence of Hay catalyst (1 mL) and air as described in general procedure C. Flash chromatography (hexanes/CH_2Cl_2, 1:1) gave **6d** (469 mg, 51%) as a yellow crystalline solid; mp > 190 °C (dec). R_f = 0.4 (hexanes/CH_2Cl_2, 1:1). UV–vis (THF) λ_{max} (ε): 296 (80 200), 312 (106 200), 331 (80 000), 359 (29 200), 387 (31 700), 419 (19 900). IR ($CHCl_3$, cast, cm^{-1}): 3104, 2188, 2114, 1517, 1346. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.24 (d, J = 9.2 Hz, 4H), 7.57 (d, J = 9.2 Hz, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 147.8, 142.5, 129.6, 127.4, 123.8, 107.5, 82.6, 75.4, 71.2, 64.8. EI MS *m/z* (rel. intensity): 707.7 (M^+, 23), 388.0 ([M – 4Br]$^+$, 6). HR-MS calcd for $C_{24}H_8{}^{79}Br_2{}^{81}Br_2N_2O_4$: 707.7177 ($M^+$); found: 707.7217. Anal. calcd for $C_{24}H_8Br_4N_2O_4$: C 40.72, H 1.14, N 3.96; found: C 40.94, H 1.10, N 3.80. DSC: decomposition 189 °C (onset), 191 °C (peak).

***Compound* 10d**

Under an inert atmosphere of nitrogen, 4-nitrobenzoyl chloride (2.45 g, 13.2 mmol) and bis(trimethylsilyl)butadiyne (**8**; 2.30 g, 11.8 mmol) were dissolved in CH_2Cl_2 (100 mL) and the temperature of the solution lowered to –20 °C. $AlCl_3$ (2.4 g, 18.0 mmol) was added slowly over ~1 min, the cooling bath removed, and the reaction mixture allowed to warm to rt over ~3 h. The reaction was carefully quenched by the addition of the reaction mixture to 10% HCl (50 mL) in ice (50 mL). (Caution: This step is exothermic and can cause the CH_2Cl_2 to boil!) Et_2O (70 mL) was added, the organic layer separated, washed with saturated aq $NaHCO_3$ (2 × 20 mL) and brine (2 × 20 mL), dried over $MgSO_4$, and the solvent removed in vacuo. The resulting product **9d** was carried on to the next step without further purification.

CBr_4 (3.15 g, 9.50 mmol) and PPh_3 (5.00 g, 19.1 mmol) were added to CH_2Cl_2 (100 mL) at 0 °C and the solution stirred for ~5 min at rt until the mixture turned orange. The ketone **9d**, dissolved in CH_2Cl_2 (~5 mL), was added in one portion. The reaction was allowed to warm to rt and monitored by TLC analysis until the ketone was no longer observed (~1 h). When the reaction was judged complete, the solvent was reduced to ~5 mL, hexanes (50 mL) were added, the inhomogeneous mixture filtered through a plug of Celite layered on top of silica gel, and the resulting filtrate was concentrated in vacuo. This process can be repeated a second time if necessary to remove phosphine/phosphonium byproducts. Column chromatography (silica gel, hexanes/CH_2Cl_2, 1:1) gave **10d** (2.54 g, 51%) as a cream-coloured powder; mp 80–83 °C. R_f = 0.60 (hexanes/CH_2Cl_2, 1:1). IR ($CHCl_3$, cast film, cm^{-1}): 2960, 2096, 1595, 1523. ^1H NMR (300 MHz, $CDCl_3$) δ: 8.22 (d, J = 8.7 Hz, 2H), 7.58 (d, J = 8.7 Hz, 2H), 0.19 (s, 9H). ^{13}C NMR (125 MHz, $CDCl_3$, APT) δ: 147.7, 143.4, 129.7, 128.1, 123.8, 104.8, 96.7, 86.8, 83.2, 73.8, –0.6. EI MS *m/z* (rel. intensity): 426.9 (M^+, 28), 411.9 ([M – CH_3]$^+$, 100). HR-MS calcd for $C_{15}H_{13}NO_2Si^{79}Br^{81}Br$ (M^+): 426.9062; found: 426.9064. Anal. calcd for $C_{15}H_{13}NO_2SiBr_2$: C 42.18, H 3.07, N 3.28; found: C 42.30, H 2.81, N 3.16.

***Compound* 11**

$^{13}CBr_4$ (287 mg, 0.865 mmol), CBr_4 (431 mg, 1.30 mmol), and PPh_3 (1.14 g, 4.33 mmol) were added to CH_2Cl_2 (15 mL) at 0 °C and the solution stirred for ~5 min at rt until the mixture turned bright orange. Triisopropylsilylpropargylaldehyde (501 mg, 2.38 mmol) dissolved in CH_2Cl_2 (~2 mL) was added in one portion. The reaction was allowed to warm to rt and monitored by TLC analysis until the ketone was no longer observed (~1 h). When the reaction was judged complete, the solvent was reduced to ~5 mL, hexanes (25 mL) were added, the inhomogeneous mixture filtered through a plug of Celite layered on top of silica gel, and the resulting filtrate concentrated in vacuo. This process can be repeated a second time if necessary to remove phosphine/phosphonium byproducts. Column chromatography gave **11** (638 mg, 73%) with ~34% labelling. Spectral data are consistent with those previously reported, see ref. 35. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.59 (d, J = 1.5 Hz, 1H), 1.08 (s, 21H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 120.0 (d, ^1J = 360 Hz), 102.9 (C*, s and d, ^1J = 360 Hz), 102.5 (s), 100.8 (d, ^3J = 25 Hz), 18.6, 11.1.

***Compound* 12**

To a solution of compound **11** (638 mg, 1.74 mmol) in Et_2O (2 mL) at –78 °C was added via cannula a solution of LDA (formed from BuLi (2.5 mol/L in hexanes, 2.1 mL, 5.3 mmol) and diisopropylamine (0.73 mL, 0.53 mg, 5.23 mmol) in Et_2O (17 mL)) at –78 °C, and the resulting solution was stirred for 2 h at –78 °C. To this mixture was added dropwise Me_3SiCl (0.33 mL, 0.28 mg, 2.61 mmol). The reaction was allowed to warm to rt and stirred overnight. Et_2O (10 mL) and saturated aq NH_4Cl (10 mL) were added. The organic phase was separated, washed with brine (2 × 10 mL), and dried over $MgSO_4$. Solvent removal and purification by column chromatography (silica gel, hexanes) afforded **12** (325 mg, 67%) as a colourless oil. R_f = 0.67 (hexanes), which was carried on to the next step without further purification.

***Compound* 14**

Under an inert atmosphere of nitrogen, 4-nitrobenzoyl chloride (239 mg, 1.29 mmol) and compound **12** (321 mg, 1.15 mmol) were dissolved in CH_2Cl_2 (12 mL) and the temperature of the solution lowered to –20 °C. $AlCl_3$ (230 mg, 1.72 mmol) was added slowly over ~1 min, the cooling bath removed, and the reaction mixture allowed to warm to rt over ~3 h. The reaction was carefully quenched by the addition of the reaction mixture to 10% HCl (25 mL) in ice (25 mL). (Caution: This step is exothermic and can cause the CH_2Cl_2 to boil!) Et_2O (50 mL) was added, the organic layer separated, washed with saturated aq $NaHCO_3$ (2 × 20 mL) and brine (2 × 20 mL), dried over $MgSO_4$, and the solvent removed in vacuo to give ketone **13** as a colourless oil. The ketone **13** was carried on to the next step without further purification.

CBr_4 (764 mg, 2.30 mmol) and PPh_3 (1.21 g, 4.61 mmol) were added to CH_2Cl_2 (12 mL) at 0 °C and the solution stirred for ~5 min at rt until the mixture turned bright orange. Ketone **13**, dissolved in CH_2Cl_2 (~2 mL), was added in one portion. The reaction was allowed to warm to rt and monitored by TLC analysis until the ketone was no longer observed (~1 h). When the reaction was judged complete, the solvent was reduced to ~5 mL, hexanes (50 mL) were added, and the inhomogeneous mixture filtered through a plug of Celite layered on top of silica gel. The resulting filtrate was concentrated in vacuo to give compound **14** (206 mg, 35%) as a colourless oil.

^{13}C NMR (125 MHz, $CDCl_3$) δ: 147.7, 143.5, 129.7, 128.3 (d, J = 98 Hz), 123.8, 104.5, 94.3, 88.5 (d, J = 18 Hz), 83.6 (d, J = 202 Hz), 72.7 (C*, m), 18.5, 11.2.

Compounds* 6d/6d*/6d*

To compound **14** (206 mg, 0.403 mmol) in THF (6 mL) was added TBAF (1.0 mol/L in THF, 0.52 mL, 0.52 mmol). The solution was stirred at rt until TLC analysis showed complete conversion to the terminal alkyne. Et_2O and saturated aq NH_4Cl were added, the organic phase was separated, washed with saturated aq NH_4Cl (2 × 10 mL) and brine (10 mL), and then dried over $MgSO_4$. The solution was concentrated to 1–2 mL via rotary evaporation and diluted with CH_2Cl_2 (6 mL). Hay catalyst (1 mL) was added and the reaction continued as described in general procedure C to give a mixture of isotopomers **6d/6d*/6d**** (59.7 mg, 42%). Spectral data were consistent with those of **6d**. ^{13}C NMR (125 MHz, $CDCl_3$) δ: 147.9, 142.7, 129.7, 127.6 (d, J = 98 Hz), 124.0, 107.6, 82.7 (d, J = 187 Hz), 75.6 (C*, m), 71.4 (d, J = 32 Hz), 64.9.

Supplementary data

MINIREVIEW / MINISYNTHÈSE

Mesoporous silica and organosilica materials — Review of their synthesis and organic functionalization

Tewodros Asefa and Zhimin Tao

Abstract: Mesoporous silica and organosilica materials are a class of nanostructured materials that have porous structures with tunable nanometer pores, large surface areas, high pore volumes, and, in some cases, well-ordered mesostructures. Furthermore, in the case of mesoporous organosilicas, the materials possess various types of organic functional groups. This review highlights the different synthetic methods developed for mesoporous silica and organosilica nanomaterials. The review also discusses the various synthetic strategies used to functionalize the surfaces of mesoporous silica materials and produce highly functionalized mesoporous materials. Rational design and synthetic methods developed to place judiciously chosen one or more than one type of functional group(s) on the surfaces of mesoporous silica materials and generate monofunctional and multifunctional mesoporous silica materials are also introduced. These organic functionalization methods have made possible the synthesis of organically functionalized mesoporous silicas and mesoporous organosilicas with various interesting properties and many potential applications in different areas, ranging from catalysis to drug delivery and biosensing.

Key words: mesoporous silica, mesoporous organosilica, nanoporous material, organic functionalization, nanomaterial.

Résumé : Les silices mésoporeuses et les matériaux organosiliciés forment une classe de matériaux nanostructurés possédant des structures poreuses dont les pores de l'ordre du nanomètre sont ajustables, volumes élevés de pores et, dans certains cas, des nanostructures bien organisées. De plus, dans le cas des produits organosiliciés mésoporeux, les matériaux peuvent porter divers types de groupes fonctionnels organiques. Cette revue permet de mettre en relief les diverses méthodes de synthèse développées pour les silices mésoporeuses et pour les nanomatériaux organosiliciés. Cette revue discute aussi des diverses stratégies de synthèse utilisées pour fonctionnaliser les surfaces des matériaux siliciés mésoporeux et pour produire des matériaux mésoporeux hautement fonctionnalisés. On introduit aussi des méthodes de conception et de synthèse rationnelles développées pour introduire à des endroits choisis d'une façon judicieuse un ou plusieurs types de groupes fonctionnels sur les surfaces de matériaux siliciés mésoporeux et pour générer des matériaux siliciés mésoporeux monofonctionnels et multifonctionnels. Ces méthodes de fonctionnalisation organiques rendent possibles les synthèses de silices et de matériaux organosiliciés mésoporeux organiquement fonctionnalisées possédant diverses propriétés intéressantes et plusieurs possibilités d'applications dans divers domaines, allant de la catalyse à l'administration de médicaments et à la biodétection.

Mots-clés : silice mésoporeuse, organosilice mésoporeuse, matériau nanoporeux, fonctionnalisation organique, nanomatériel.

Introduction

Over the last two decades, a variety of nanomaterials with unique physical and chemical properties has been reported.[1–6] This includes mesoporous silica materials, which are a class of nanoporous materials with uniform cylindrical mesochannel and tunable nanosize pores, large surface areas per unit mass, and sometimes controllable particle sizes and shapes. Because of the extensive research advances made in materials chemistry in the last two decades,[7–9] mesoporous silica materials that possess not only a diverse range of structural features but also different functional groups on their easily

modifiable external or internal surfaces can now be easily synthesized.[10,11] The fact that mesoporous silica materials can be synthesized with different particle sizes, morphology, and mesoporosity, as well as different functional groups, allows these materials to have different tunable physical and chemical properties. This, in turn, enables mesoporous silica materials to have many potential applications, such as delivery vehicles for pharmaceutical and biological molecules, host materials for bioimaging or biocatalytic agents, and platform materials for sensory or catalytic moieties.[12–17] At the same time, the possible toxicities of these engineered nanoparticles on humans and the environment have become a concern; thus, many toxicity studies of different nanomaterials are being broadly assessed by many researchers.[18–21] Considering the promising applications of mesoporous silica materials in a variety of areas such as nanomedicine or catalysis, it has also become essential to obtain as much information as possible regarding their structure–property relationships so that they may be well utilized for catalysis and biological, medical, and other applications. Such studies are being conducted in different laboratories worldwide.

In this review, we first briefly highlight the history of the various synthetic methods developed for mesoporous silica and organic-functionalized mesoporous silica materials. The different synthetic mechanisms proposed for mesoporous silica materials by different research groups are then summarized. These mechanisms help our understanding of how various mesoporous silica materials with different structural features form and how their particle sizes, shapes, and pore structures can be controlled. Finally, chemical routes utilized for surface modification of mesoporous silica materials or to produce a diverse range of multifunctional mesoporous silica nanomaterials are discussed.

Syntheses and structural properties of various mesoporous silica materials

Synthetic mechanism

According to the International Union of Pure and Applied Chemistry (IUPAC), mesopores are defined as pores with sizes in the range of 2–50 nm. The first report on the synthesis of mesoporous materials, e.g., MCM-41 (Mobil Crystalline Materials), in the early 1990s was a milestone in materials chemistry.[22,23] These materials have significantly larger pores than molecular sieves and zeolites. Their smaller pore sizes are actually what causes the latter to have limited applications. Thus, these new reports on the syntheses of mesoporous materials with larger pores than molecular sieves and zeolites invigorated a wave of research interest on the synthesis of other mesoporous materials with different ordered structures and pore sizes.

The general approach to synthesis of mesoporous silica materials involves "soft-templating", which is actually the same as the method used to make traditional molecular sieve and zeolite materials. However, there are some key differences between the two, i.e., between the synthetic methods used for making the two classes of porous materials (mesoporous silicas versus molecular sieves and (or) zeolites). Traditional molecular sieve and zeolite materials are typically synthesized through hydrothermal reactions between aluminosilicate gels and quaternary organic compounds having short alkyl chains, such as tetrapropylammonium or tetrabutylammonium ions.[24–26] While these organic groups serve as templating agents, they only allow the formation of micropores, i.e., pores with diameters < 2 nm according to IUPAC.

In one of the first groundbreaking works in the early 1990s, Kato and co-workers[28] developed a convenient method for synthesizing mesoporous silicas by using polysilicate kanemite ($NaHSi_2O_5{\cdot}3H_2O$) as the silica precursor and alkyltrimethylammonium chlorides, which have a much bigger size than tetrapropylammonium or tetrabutylammonium ions, as the structure-directing or templating agents. Moreover, by changing the length of the alkyl chains, the authors showed that the layered kanemite could be intercalated with different guest molecules and, most importantly, could be made to have tunable pore sizes ranging from 2 to 4 nm in diameter. Although this demonstrated one of the first syntheses of mesoporous materials with tunable pore sizes, the experiment did not result in materials with an extensive array of ordered mesoporous structures. This was the case until the reports on the synthesis of MCM-41 by Kresge and co-workers.[22,23]

In major groundbreaking works, also in the early 1990s, Kresge and co-workers[22,23] reported the synthesis of MCM-41 and the concomitant syntheses of MCM-48 and -50 mesoporous silicas (the M41S family of mesoporous materials). These were among the first series of mesoporous materials with not only mesoscopic pores but also well-ordered mesoporous structures to be documented in the literature. These reports also paved a new avenue to a vast number of the other ordered mesoporous materials reported subsequently. The M41S family of mesoporous materials was synthesized from the hydrolysis and condensation of silica precursors around ordered arrays of surfactant micelle templates, followed by the removal of the templates by calcination or solvent extraction. The synthetic method, sometimes called soft-templating, allowed the formation of different types of mesoporous silica materials having regular arrays of uniform cylindrical channel pores as a result of the spontaneous self-assembly of surfactant species, such as the cationic surfactant cetyltrimethylammonium ion (i.e., $C_{16}H_{33}(CH_3)_3N^+$), in aqueous solution into a regular array of cylindrical micelle aggregates or templates. Furthermore, the synthesis enabled mesoporous silica materials with different pore sizes to form simply by using surfactants with different alkyl chain lengths or by adding auxiliary hydrocarbons (e.g., alkylated benzene) into the reaction mixture to swell the micelles. Furthermore, the shapes of the regular arrays of surfactant micelles as well as the resulting mesoprous silica materials were easily changed from hexagonal to cubic by increasing the molar ratio of surfactant-to-silica precursor in the solutions.

To explain how the highly ordered structures in the M41S family of mesoporous materials formed, Kresge and co-workers[22,23] proposed a mechanism known as liquid crystal templating (LCT) (Fig. 1*a*). Acoording to the authors, the process involves the following four steps: (1) surfactant micelles form in the aqueous solution and assemble into cylindrical micelles; (2) the cylindrical micelles are stacked into a regular array of liquid crystalline structures; (3) anionic silicates form in the solution from the silica sources such as tetraethyl orthosilicate (TEOS) and then adsorb onto the

positively charged surfaces of liquid crystalline surfactant micelles; and (4) the removal of the surfactant templates either by calcination or by solvent extraction results in the mesoporous silicas. In an alternative pathway described by the same authors, step 3 was considered to take place at the same time as steps 1 and 2.[22,23] As the steps in this LCT process vary upon changing reaction conditions, such as by changing the ionic strength in the solution, the anionic charges on the silicate species and the surfactant concentrations in the solution, or by adding co-surfactants, the structures of the final mesoporous materials can also change accordingly.[22,23]

Interestingly, mesoporous silicas were also shown to form at very low concentrations of silicate and surfactant in strongly basic solutions, conditions under which liquid crystalline phases should not form according to the surfactant–water phase diagrams.[29] Thus, based on these observations, Davis and co-workers[31] proposed an alternative mechanism called cooperative self-assembly for the synthesis of MCM-41. This consisted of the following three synthetic steps: (1) the surfactant micelles form in such a way that the cationic head groups of the surfactant would be in contact with the surrounding solvent molecules; (2) negatively charged silicates, which form from silica precursors under basic conditions, aggregate on the periphery of surfactant micelles via Coulombic attraction, producing a layer of silicate species; and (3) the silicate–surfactant complexes spontaneously form hexagonally ordered mesostructures as the condensation of silicates with the surfactant molecules takes place. This model suggested that charge matching between cationic surfactants and anionic silicates could play an important role for the self-assembly of silicate–surfactant complexes into ordered arrays.[32] However, this proposition was still not able to explain why the ordered packing structures of surfactant–silicate complexes changed as the surfactant-to-silicate ratio was altered.

Using ^{14}N nuclear magnetic resonance (NMR) spectroscopy, Steel et al.[33] investigated surfactant mesophases during the formation of highly ordered mesostructured materials and proposed a so-called "puckering layer" model, in which silicate species were first formed and then directed by surfactant templates into layered structures. These layered structures were further wrinkled into hexagonal channels as the silicate species aggregated around the surfactant micelle templates. Around the same time as this proposition was made, Stucky and co-workers[29] reported the synthesis of MCM-41 materials at different temperatures and with different reaction times. The authors investigated the structures and compositions of the mesoporous materials using X-ray diffraction and ^{29}Si magic-angle spinning (MAS) solid-state NMR spectroscopy. Based on the results, they provided an explanation for how the ordered mesoporous structures in the mesoporous silicas were formed, which is illustrated in Fig. 1*b*. Their proposed model included the following processes: (1) oligomeric silica polyanions (denoted as I^-) outcompete monovalent silicates to bind with cationic head groups of surfactants (denoted as S^+); (2) charge density matching at the interface between the silicate anions and the surfactant cations takes place, forming surfactant–silicate complexes (S^+I^-), which lead to thermodynamically favored lamellar configurations in the early stages of the reaction; (3) as polymerization of the silicates continues, two oppositely facing lamellar layers with the same charge, which tend to repel apart, result in the reduction of charge density of the anionic silicates while, at the same time, augmenting the head group area of the surfactant assembly; and (4) to match the reduced charge density and keep the silicate-to-surfactant ratio constant, the hexagonal mesophases shape up. This cooperative mechanism provided a good explanation for the precipitated mesophases from dilute surfactant and silicate solutions, and also predicted the possible formation of cubic mesostructures under some specific reaction conditions.

Huo et al.[34,35] extended the model proposed by Stucky and co-workers[29] so that it would be generic enough to explain the formation of various other mesostructured nanomaterials (besides mesoporous silica), those having inorganic–organic interfaces, and those synthesized from reactants containing different charges. For instance, this model managed to explain the formation of a variety of mesostructured metal oxides at low pH from inorganic compounds that are more acidic than silicic acid. Furthermore, the model was applied to different mesophases, where S^-I^+-type assembly was possible by simply varying the $[H^+]$ in solutions and where the charge density between the cationic inorganic species (I^+) and the anionic surfactant templates (S^-) was matched. Furthermore, the model could also be applied to systems containing positively charged surfactant S^+ and inorganic moieties I^+ (or negatively charged S^- and I^-).[34,35] In this case, the formation of the mesophases and their structures could be controlled as long as the mediated counterions X^- (or X^+ in the case of S^- and I^-) were properly chosen. In cases where a cationic surfactant and an inorganic compound were used, X^- (X^- = halide ions, e.g., Cl^- or Br^- ions) first bound to the cationic head groups of surfactants and formed (X^-S^+)-type double layers.[34,35] This left the outer negatively charged surface to bind to the positively charged inorganic species (I^+); the resulting aggregate generated a sandwich-like triple-layered ($I^+X^-S^+$) structure. Likewise, ($I^-X^+S^-$) self-assembly was formulated for reactions containing I^-, S^-, and X^+ (X^+ = alkali metal ions, e.g., Na^+ or K^+).[34,35] Both $I^+X^-S^+$- and $I^-X^+S^-$-type self-assembled structures were found to be stable, versatile, and lead to a diverse range of mesophases as well as self-assembled surfactant-templated mesostructured materials. The removal of the surfactant templates from these as-made mesostructured materials by calcination or solvent extraction then resulted in different types of mesoporous materials. Thus, this model provided a theoretical foundation and an experimental guidance for phase-controlled synthesis of a variety of mesoporous silica materials.

Shortly after this proposal, the Pinnavaia group[36,37] demonstrated a synthetic route to mesoporous silicas using neutral surfactants (S^0) (e.g., primary amines and polyethylene oxides, PEO) as templates with inorganic silica precursors (I^0) (e.g., TEOS). In this case, the surfactant monomers first formed rod- or worm-like neutral micelles in aqueous solution, which were bound to hydrolyzed silica sources via hydrogen bonding (S^0I^0). This was followed by the condensation of silanol groups of the hydrolyzed silicate species and their assembly with the surfactant micelles into the hexagonal mesostructured materials. With the addition of a co-solvent (for example, ethanol or methanol) in the reaction solutions to enhance the solubility of the neutral surfactant molecules,

Fig. 1. (*a*) Proposed liquid crystal templating (LCT) mechanism for MCM-41 formation via two possible pathways (indicated as 1 and 2) as stated in the text.[22,23] (From Beck et al. 1992, reproduced (adapted) with permission of J. Am. Chem. Soc., Vol. 114, p 10834, © 1992 American Chemical Society). (*b*) Illustration to demonstrate the phase shift of surfactant–silicate aggregates from lamellar to hexagonal form.[29] (From Monnier et al. 1993, reproduced (adapted) with permission of Science, Vol. 261, p 1299, © 1993 The American Association for the Advancement of Science). nonionic molecules also self-assembled into hexagonal-type mesoporous silicas, denoted as the HMS or MSU series.[36,37] These materials had larger pores and thicker pore walls, but short-range-ordered hexagonal structures compared with that of MCM-41. This is because a much weaker interaction, i.e., hydrogen bonding between the neutral surfactant molecules and the silica precursors, is involved in HMS or MSU synthesis, whereas stronger interaction, i.e., electrostatic forces between charged ion pairs, is involved in MCM-41 synthesis.[36,37] Moreover, the residual alcohols, either used as a co-solvent or produced in the reaction when the TEOS underwent hydrolysis, were believed to destruct the liquid crystalline structures originally formed when the nonionic surfactants were added, thereby leading to a less-ordered mesostructure.[36]

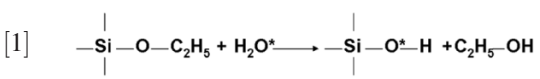
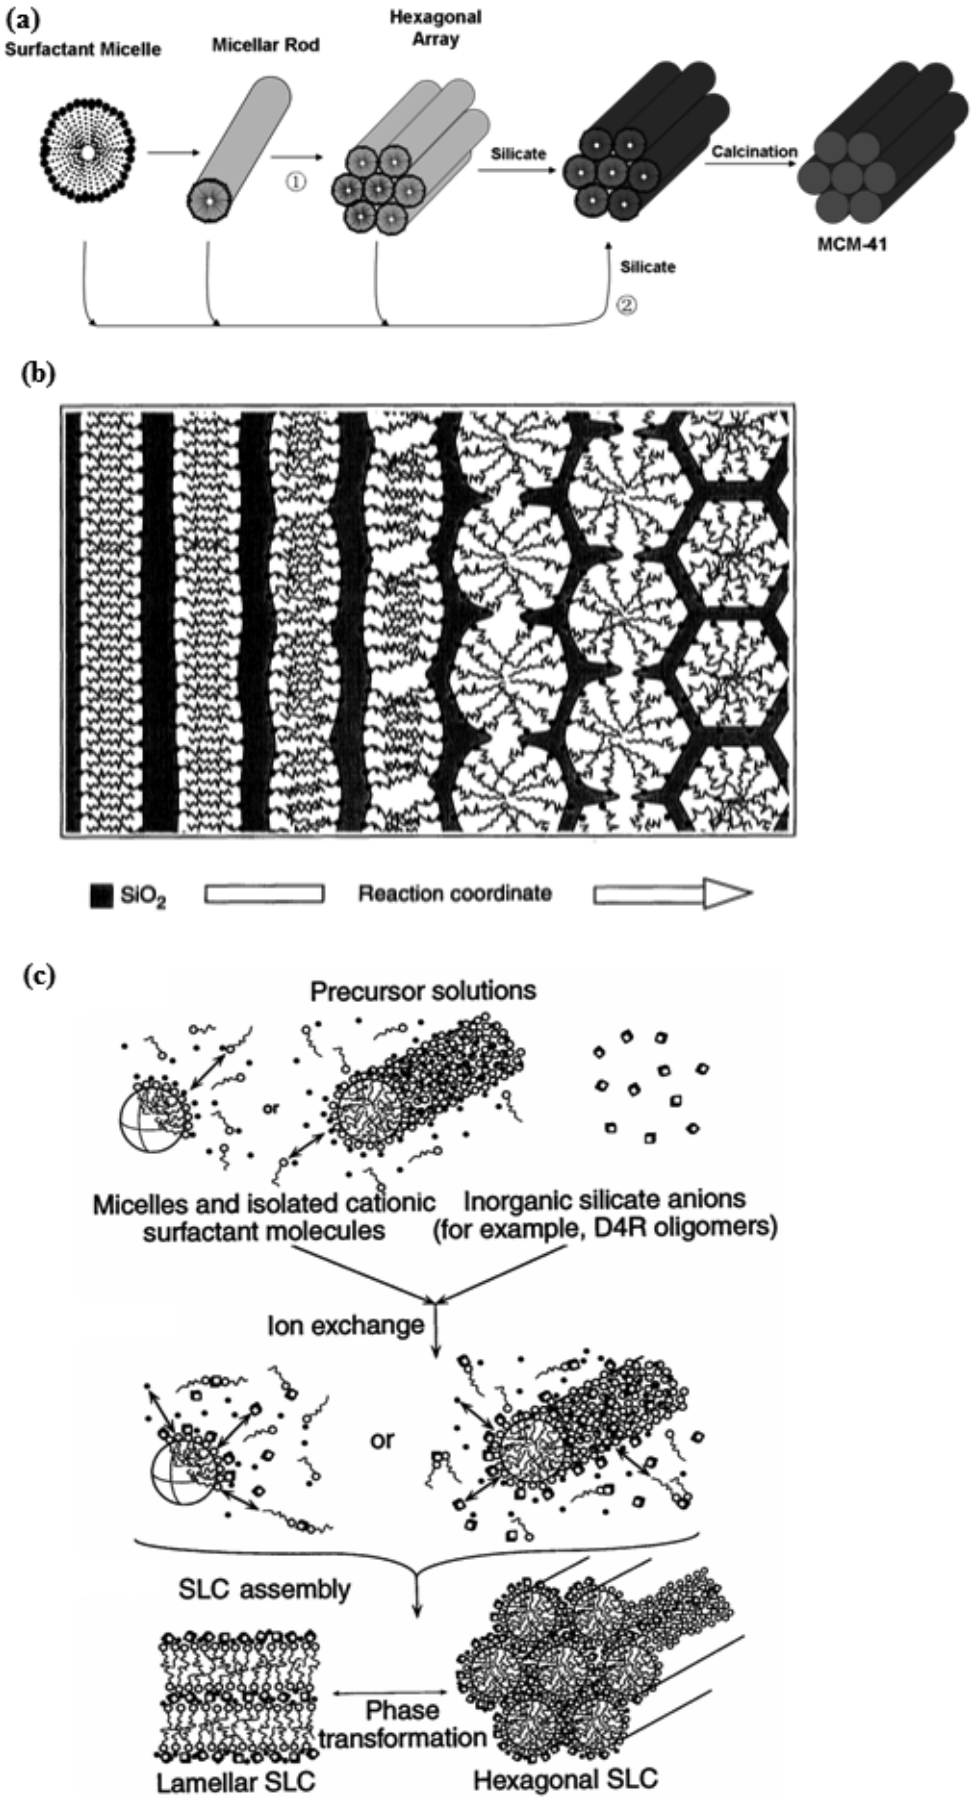
With these research reports on nonionic surfactant template synthesis of mesoporous materials in place, the LCT mechanism proposed previously was revisited by the Goltner group[38–40] to describe the synthesis of mesoporous silicas (pore diameter = 3 nm) in reactions where neutral surfactants in relatively high concentrations were used. The formation of a homogenous lyotropic liquid crystal (LLC) phase was detected even before the addition of silica precursors. These ordered liquid crystalline mesophases were believed to then serve as templates for directing the condensation of inorganic silicates. The big similarity between the phase diagrams of the surfactant / silica precursor / water system at high surfactant concentration and the surfactant/water system without silica precursors further supported the formation of organic mesophases independent of the inorganic silicate species.[38–40]



By incorporating the "ion exchange" concept adopted in the work reported by Inagaki et al.,[41] Chmelka and co-workers[30,42] proposed a silicatropic liquid crystal (SLC) model to further explain how mesoporous silicas were formed under low concentrations of ion pairs of organic and inorganic species. Based on neutron scattering data and various NMR spectra, the authors explained how mesophases with ordered arrays were self-assembled as follows: (1) An equilibrated solution of organic surfactant contained the individual molecules as well as various micelles with different geometries, whereas silicates in extremely basic condition were oligomerized to form polyanionic charged species. (2) Immediately after the silica precursors and surfactants were mixed, ion exchange took place between surfactant anions and negatively charged silicates to form organic–inorganic complexes in which the double-four-ring silicate oligomers (cubic octamer) were preferentially formed. (3) The silicate species in diluted surfactant solutions were coordinated with the isotropic micelles, forming an ordered surfactant–silicate array, shaping an SLC mesophase.[30,42] This model underscored the existence of micelle aggregates with certain geometries in solutions containing surfactant and silica precursors and the presence of cooperative organization of surfactant–silicate moieties into ordered arrays of mesostructures. This proposed mechanism was also what has finally become the generally accepted mechanism for the direct synthesis of mesoporous silica materials with different pore sizes and shapes.

Synthetic condition and structural determination



The combination of the "sol-gel" process and supramolecular self-assembly under hydrothermal conditions is what has been widely adopted as the synthetic method towards various mesoporous silica materials. In the process, silica precursors such as TEOS are dissolved into an aqueous solution containing surfactant. The silica precursors then undergo hydrolysis and condensation to form a solution called *sol*, which contains oligomeric and polymeric silicate species. In the presence of surfactant and their aggregates (or micelles), the hydrolysis and condensation reactions of silica precursors lead to the formation of organic–inorganic (i.e., surfactant–silicate) species that become increasingly polymerized and form a *gel* as the reactions proceed. The self-assembled surfactant–silicate material (or the *gel*) ultimately precipitates out of the solution. The solution is then filtered, and the solid materials are washed and treated by calcination or solvent extraction to remove the surfactant-templating agents and to produce the mesoporous silica materials.

The experimental variables, such as pH, reaction temperature, type of surfactant or silica source, etc., employed during the supramolecular self-assembly of the mesostructured materials can affect how the sol-gel reactions and self-assembly processes take place, and thereby what structural features of the final mesoporous silica materials will have.[7–9] Thus, the selection of an appropriate silica precursor and surfactant is vital for mesoporous silicas with the desired structural features to form. Furthermore, as temperature and pH affect the rates of hydrolysis and condensation of silica precursors and the dynamic self-assembly process in which the silica precursors aggregate with the surfactant micelles, these variables should be optimized to obtain mesoporous silicas with suitable or optimized structures for various applications. For example, TEOS, which is one of the most commonly used silica precursors, undergoes hydrolysis and polymerization as illustrated in eqs. [1]–[3] with variable reaction rates in solutions at different pHs.

Condensation

[2] 

or

[3] 

Brinker and Scherer[43,44] suggested that the hydrolysis of silica precursors and silicate intermediates occurs with the oxygen atoms from water molecules (asterisked in eq. [1] initiating nucleophilic attack on silicon atoms of the silica precursors or intermediates, regardless of what the pH of the solution is. Subsequently, the condensation reaction, which produces alcohol (eq. [2]) or water (eq. [3]) as the byproduct, takes place to produce dimers, linear or cyclic silicate trimers, and tetramers that grow into a cross-linked network of silicate structures.[43,44] The rate of the hydrolysis reaction decreases as the length of the silicate species increases,[9] since the alkyloxide groups on longer silicate chains are worse leaving groups owing to their reduced ability to donate electrons as well as their increased steric hindrance for nucleophilic attack.[43,44]

The rate of hydrolysis or condensation of silica precursors during the synthesis of mesoporous materials strongly depends on the pH of the solution. For example, under basic conditions, hydrolysis of silica precursors is accelerated, since OH^-, which is a good electron-providing group with a small size, can attack effectively the silicon atoms of the silica precursors. However, when pH > 8, the condensation rate decreases and even becomes reversible. As a result, penta- or hexa-coordinated silicate intermediates are transiently produced or, conversely, highly cross-linked silicates are unable to form in such strongly alkaline solution.[7,43] Under acidic conditions, the silanol groups on the silica oligomers are easily protonated, making the silicon atoms become more electrophilic. Simultaneously, the counterions (X^-), such as F^-, Cl^-, or Br^-, from the acidic catalysts or surfactant act as the nucleophiles to attack the silicon atoms.[43,44] This results in the rapture of Si–O bonds and the formation of Si–X bonds that can be more easily hydrolyzed. The silicate species with protonated silanols then fuse together or with other silicate species having neutral silanols, leading to polymerization.[43] In this process, the stronger X^--bonded surfactants catalyze the condensation reaction and often result in faster polymerization.[45] At pH < 2, the rate of condensation becomes higher at lower pH; whereas at 2 < pH < 8, condensation becomes quicker at higher pH.[7] At pH 2 (i.e., the isoelectronic point or pI of silica), the rate of condensation becomes the slowest because of the zero net charge carried by silicon atoms. Under this condition, silicates undergo the slowest hydrolysis because of the limited amount of available protons or hydroxyl ions on them. However, once hydrolyzed, the silica precursors produce either positively and negatively charged silicate species that lead to faster condensation. For this reason, neutral solutions were once thought inappropriate for synthesis of mesoporous silicas with ordered structures.[9]

As mentioned previously, the synthesis of MCM-41[22,23] is possible with surfactants at concentrations below the critical micelle concentration (CMC). However, it is well-known that surfactants at such low concentrations cannot form micelles or mesophases. Furthermore, the hydrolysis and condensation of silica precursors such as TEOS without surfactants only lead to the formation of amorphous silica. Thus, combining these facts and observations, it was concluded that the surfactant-directed condensation of silica at the micelle–silicate interface must be responsible for the formation of mesostructured or mesoporous silica materials.[46]

To explain this further, a packing parameter (p) of an effective surfactant ion pair, first defined by Israelachvili,[47] was introduced by Stucky and co-workers[29,48] as a structural variable to analyze the geometry of surfactant–silicate mesophases and the phase transformation of mesostructures under various conditions. The packing parameter is given by the equation $p = v/a_0 l_c$, where v is the molecular volume, a_0 is the head-group area with minimum energy at the hydrophobic–hydrophilic interface, and l_c is the maximum length of the hydrophobic chain. As the value of p increases, the ordered mesostructures change from hexagonal, cubic, and lamellar aggregates to their reverse counterparts because of the changes in the physicochemical properties of the solutions; i.e., changes in either the surfactant (changes in its v, a_0, or l_c) or the reaction conditions (e.g., pH, temperature, and type of solvent used in the reaction).[49]

Surfactants employed in the synthesis of mesoporous silica materials can be cationic, nonionic, and to a lesser extent, anionic. Regardless of the type of surfactant used for the synthesis of mesoporous silicas, once the concentration of surfactant reaches the surfactant's CMC value, the surfactant molecules in aqueous media assemble into micelles with centripetal (hydrophobic) tails and centrifugal (hydrophilic) heads, forming a system with the lowest interfacial energy. Surfactants with low CMC values were generally found to be suitable for the synthesis of mesoporous silicas with highly ordered structures.[50] Similarly, for a given surfactant, any reaction variable including pH, temperature, a co-solvent, or an electrolyte that can lower the surfactant's CMC often lead to mesoporous silicas with well-ordered structures. Given the fact that the pI of silica is 2.0, silica is negatively charged under most pH values. Thus, cationic surfactants, which were originally used in mesoporous silica materials syntheses,[22,23,29,31,33–35] especially those with quaternary ammonium head groups and long alkyl chains, are more suitable for synthesis of mesoporous silicas because of their stable positively charged head groups independent of the pH of the solution and their comparatively low CMC values.

Huo et al.[48] reported the formation of different types of mesophases and mesoporous silica materials when cationic surfactants with different sizes were used in the synthesis. Under similar alkaline solutions containing a mixture of TEOS and different alkyltrimethylammonium ($C_nH_{2n+1}(CH_3)_3N^+$) surfactants, the authors described the formation of hexagonal MCM-41 when n = 10–18, but lamellar MCM-50 when $n \geq 20$. Given $p = v/a_0 l_c$ and the fixed a_0 value of the surfactant, the ratio between v and l_c remained nearly unchanged for $C_nH_{2n+1}(CH_3)_3N^+$ when n = 10–18. This ratio further increased as the value of v was kept constant and the value of l_c became smaller owing to the coiled hydrocarbon chain when $n \geq 20$.[48] The change in mesophase and the structure of the materials from MCM-50 to MCM-41 was also demonstrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13

by inserting hydroxyl groups into the surfactant molecules. The hydroxyl groups enhanced the hydrophilicity of the head groups of the surfactant, and thereby reduced their effective head group area a_0 and their p values.[48] Furthermore, upon changing the methyl groups of the cationic surfactant (i.e., $C_nH_{2n+1}(C_2H_5)_3N^+$) to ethyl groups or upon changing the solution from basic to acidic, the value of p generally became smaller. This can be accompanied by the formation of cubic SBA-1 (Santa-Barbara Amorphous-1) material for $n \leq 18$ and hexagonal SBA-3 for $n \geq 20$.

Gemini surfactants, a class of amphiphilic molecules encompassing two traditional surfactants connected by a spacer via covalent bonds (e.g., $[C_nH_{2n+1}(CH_3)_2N^+–(CH_2)_s–N^+(CH_3)_2C_mH_{2m+1}]\cdot 2Br^-$ or $C_{n–s–m}$, in a simplified notation), were also employed as templating agents for the synthesis of mesoporous silicas.[51,52] Gemini surfactants generally have lower CMC values and higher surface activity compared with either one of the single-chain surfactants in them. If the length of the spacer (s) in the gemini surfactant remains unchanged while either one of the two alkyl chains gets longer (i.e., either n or m increases), the the $C_{n–s–m}$ gemini surfactant becomes more like a mono-quaternary ammonium surfactant and, most importantly, its CMC value decreases exponentially. Furthermore, for gemini surfactants with $n = m = 12$ or 16, the CMC value of the surfactant gradually reaches the highest value as the value of s is increased from 1 to 5, but then the CMC value dramatically declines when $s = 6–16$.[53] The spacer between the two head groups of the individual surfactant chains was also found to play an important role on the shape of the micelles and the rate of their formation.[54–56] For example, the shorter spacers resulted in the formation of aggregates with less curvature and a faster rate of formation of the micelles. Thus, by changing n and m as well as s of the gemini surfactants, not only different micelles can be prepared but also mesoporous silicas with different structures and tunable pore sizes can be synthesized. For instance, when $C_{16–s–16}$-type surfactants with $s = 2$ or 3, $s = 8$, and $s = 12$ were used as templating agents, lamellar-type MCM-50, hexagonal MCM-41, and cubic MCM-48 mesoporous silicas, respectively, were obtained.[51,52] When $C_{n–s–1}$ was used as the surfactant, SBA-2 mesoporous silica with a three-dimensional hexagonal cage structure formed.[48,51,52]

As briefly mentioned, neutral surfactants were also employed as templating agents to synthesize mesoporous silicas. In particular, the work by the Pinnavaia group[36,37] on the synthesis of various mesoporous silica materials at neutral pH using different neutral surfactants is worth mentioning. Specifically, primary amines or PEO-based surfactants were used and self-assembled with TEOS via hydrogen bonding at ambient temperatures, producing ordered mesoporous silicas. When the neutral surfactants were composed of $C_8–C_{18}$ alkyl chains containing primary amines, hexagonal mesoporous silicas with correspondingly increasing micro- or mesopore sizes (1.6–3.1 nm) depending on the size of the alkyl chains were obtained.[36] Interestingly, the mesoporous silicas produced with these neutral surfactant-templating agents had smaller pores and thicker pore walls compared with those synthesized using cationic surfactants with similar alkyl chain lengths as templates.[36] When alkyl chains containing PEO groups, $C_nH_{2n+1}O(CH_2CH_2O)_iH$, with $n = 11–15$ and $i = 9–30$, were used as templating agents, various mesoporous silica materials called the MSU series were formed. When the value of i changed from 9 to 30, the materials' pore sizes generally increased from 2.5 to 4.8 nm and their surface areas decreased from 1010 to 525 m^2/g.[37] Furthermore, substituting the C_6H_{13} with a phenyl group (that is, using alkyl chains with shorter lengths but with the same total number of carbon atoms) led to the formation of a material called MSU-2 mesoporous silica having a reduced pore size and surface area.

The other most commonly and successfully utilized neutral surfactants for the synthesis of mesoporous silica materials are a class of block copolymers called Pluronics. A Pluronic surfactant composed of polyethylene oxide – polypropylene oxide (PEO–PPO) block copolymers was among the first of these types of surfactants to have been used for the synthesis of mesoporous silica, specifically mesoporous silica called MSU-3 having large pores (5.8 nm) and high surface area (1190 m^2/g).[37] However, although these MSU-type mesoporous silicas had mesoporous structures and high surface areas, their mesoporous structures were not well-ordered, as evidenced by their disordered pore structures in their TEM images and the broad peaks in their X-ray diffraction (XRD) patterns. By optimizing the reaction temperatures to 25–65 °C,[57] by switching to gemini-type or sorbitan ester derivatives,[58,59] or by replacing the inorganic silica precursors with water-soluble silicates,[60] some improvements in their structures were made and MSU-X mesoporous silicas with worm-hole mesostructures and, most importantly, some short-range-ordered structures were obtained.[58,61] It is also worth mentioning that these MSU-X mesoporous silicas exhibited high (hydro)thermal stability owing to the high degree of silica cross-linkages in their structures.[58,61]

In a groundbreaking work, Zhao et al.[62,63] demonstrated the use of Pluronics multiblock copolymers of high molecular weights as templating agents in aqueous acidic solutions (pH < 1) to produce SBA-type mesoporous silicas with highly ordered mesostructures and tunable large pores. In their syntheses, different poly(alkylene oxide) (PAO) triblock copolymers, also known as Pluronic triblock copolymers, (e.g., poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide), i.e., PEO–PPO–PEO, or $EO_n–PO_l–EO_m$), were mixed with TEOS at low temperatures of 35–80 °C and aged for a few days.[62] By changing the synthetic conditions, SBA-type mesoporous silicas with various pore sizes and wall thicknesses were produced. When the surfactant had a low EO:PO ratio, the as-made mesoporous materials had hexagonally ordered mesoporous structures, which were named SBA mesoporous silica materials. The most notable member of this family of materials is hexagonally ordered SBA-15 mesoporous silica, which has typical pore sizes in the range of 3–10 nm depending on the specific synthetic conditions used to make it. It is worth noting that the pore sizes, as well as wall thicknesses, of SBA-15 are bigger than those of hexagonally ordered MCM-41. Increasing the surfactant-to-TEOS ratio in the reaction mixture resulted in the formation of lamellar structure, whereas increasing the EO:PO ratio led to the formation of cubic-shaped mesoporous silica called SBA-16.[62]

When triblock copolymers were replaced by star-shaped diblock copolymers, the synthesis led to the formation of cubic-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

ordered mesostructures, usually having a higher surface area (>1000 m^2/g) and a smaller pore size (3.0–4.5 nm) compared with those obtained with Pluronics.[63] Furthermore, whereas shorter EO segments on the Pluronics surfactants favored the formation of lamellar-shaped aggregates, the longer ones led to the formation of cubic-ordered mesostructured materials called SBA-11. The cubic-ordered mesostructured materials were also produced when neutral surfactants with shorter alkyl chains such as $C_{16}H_{33}$ were used as templating agents. Their longer alkyl chain counterparts such as $C_{18}H_{37}$, however, favored the formation of a 3D hexagonally ordered mesoporous silica material called SBA-12.[63]

During the formation of SBA-X type mesoporous silicas with these nonionic PAO surfactants under acidic solutions (with pH < 2), electrostatic- and hydrogen-bonding interactions were suggested to be the prominent types of interactions occurring between the nonionic PAOs and the silica precursors in solutions. During the self-assembly process, the counterions X^- (e.g., halide, NO_3^-, or SO_4^{2-}) from the acid added into the solution to lower the pH bound to the positively charged silicate species in the periphery, and they subsequently attracted the protonated PEO sections of the surfactant molecules.[64–66] This then led to the formation of $(S^0H^+)(X^-I^+)$-type self-assembled structures, and ultimately materials such as SBA-15 mesoporous silica.

This proposed mechanism for formation of mesoporous silica using nonionic Pluronic surfactants was supported by solid-state NMR spectroscopy and XRD data. Besides the well-ordered mesoporous structures, gas adsorption measurement of the SBA-type material further revealed that there were some small disordered pores (diameter < 3.4 nm) between the large pores.[67] The formations of these complementary micro- and (or) meso-pores were suggested to be formed as a result of the insertion of the hydrophilic PEO chains into the silicate network during the very early stage of the supramolecular self-assembly of the material.[65,67] These sidewall pores exhibited a high thermal stability and also contributed to the total surface area of the material,[67] potentially serving as a host for guest molecules and some catalytic groups.

Later, by using various neutral triblock copolymers in acidic media, the Zhao group synthesized many new types of mesoporous silicas with a variety of shapes, named FDU-type mesoporous silicas.[9] The list includes caged cubic-ordered mesoporous silicas with large pore sizes (up to 12 nm) called FDU-1,[68] 3D bicontinuous gyroid-shaped mesoporous silicas with narrow pore size distributions (4.5–9.5 nm in pore diameter) called FDU-5,[69] and cagelike face-centered cubic-ordered mesoporous materials with large pore mouths (4–9 nm in pore diameter) called FDU-12.[70]

The fact that $(S^+X^-I^+)$, (S^+I^-), and $(S^0H^+)(X^-I^+)$ types of interactions between cationic or neutral surfactants and inorganic silica sources led to mesoporous silicas made researchers become curious about whether anionic surfactants could also be utilized as templating agents for the synthesis of mesoporous silicas via (S^-I^+) or $(S^-X^+I^-)$ types of interaction. Common anionic surfactants include those containing long hydrocarbon chains with terminal sulfate, sulfonate, phosphate, and carboxylate groups and whose pK_a values are generally >2 (or the pI of silica).

To examine the feasibility of the use of anionic surfactants in supramolecular self-assembly of mesostructured materials, it is essential to understand the possible interactions in the system used for the synthesis. On the one hand, for reaction media where pH << pK_a of the anionic surfactant, the anionic surfactants remain barely dissociated and barely soluble in aqueous solutions, making the interactions owing to charge matching between surfactants and silica precursors almost impossible. Therefore, acidic conditions are not usually suitable for the preparation of mesoporous silicas with anionic surfactants via the (S^-I^+) route. On the other hand, under basic conditions with pH ≥ pK_a of the anionic surfactant, condensation of silica precursors leads to negatively charged silicate networks that repel the anionic surfactants. Thus, a counterion X^+ has to be involved for an $(S^-X^+I^-)$ type of interaction to occur and for mesoporous silica to form under basic conditions.

These hypotheses were first tested by the Dai group,[71,72] which successfully synthesized bridged inorganic–organic nanocomposite materials using anionic sodium dodecyl sulfate (SDS) as the surfactant and 3-aminopropyltriethoxysilane (APTES) as the silica precursor in the presence of coordination compounds containing the metal cations Cd^{2+}, Zn^{2+}, or Ni^{2+}. The Coulombic force between the anionic surfactant and the cationic metal compounds and the strong coordination bonds formed between the metal ions and the amine groups in APTES led to the self-assembly of such a system into different types of mesophases, depending on the type of metal used and the mole ratio of the substances used for the synthesis.[72] Similarly, the Tatsumi group[73,74] reported the synthesis of mesoporous silicas using anionic surfactants as templating agents. Specifically, the authors used 3-aminopropyltrimethoxysilane (APS) or *N*-trimethoxysilylpropyl-*N*,*N*,*N*-trimethylammonium chloride (TMAPS) as the co-structure-directing agent (CSDA) to form $S^-X^+I^-$ types of self-assembled structures or anionic-surfactant-templated mesoporous silicas (AMSs). During the synthesis, the alkoxysilyl portion of APS or TMAPS was integrated with the alkoxysilyl portion of a typical silica source (e.g., TEOS) to produce the silica network. The protonated amino groups of APS (i.e., protonated $X(H)^+$ species, which were produced when their $pK_b \geq 14 - pH$) or when the positively charged quaternary ammonium ions of TMAPS made electrostatic interactions between the silicate ions and the anionic surfactants (e.g., *N*-acyl amino acids or long alkylsulfates) possible. This finally led to the formation of as-synthesized AMS materials. Furthermore, by changing the type of anionic surfactant and its mole composition, AMS materials with different mesostructures, ranging from hexagonal- and cubic-ordered 3D materials called AMS-1 and AMS-2, respectively, to double-diamond-shaped bicontinuous cubic-ordered AMSs called AMS-10 were produced.[74–77] It is worth noting that, compared with mesoporous silicas synthesized by using cationic or neutral surfactants, AMS generally possessed smaller surface areas (typically in the range of 387–963 m^2/g).

Neutral chiral molecules (e.g., *N*-acyl-L-alanine or *N*-acyl-D-alanine) can also be used as templating agents for making mesoporous silicas. Interestingly, such templating agents form mesoporous materials that are chiral. Che et al.[78] synthesized chiral mesoporous silicas with helically twisted rod-like morphologies of 130–180 nm in diameter and 1–6 μm in length. The material had uniform hexagonally ordered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

mesochannels with an average pore diameter of 2.2 nm.[78] Moreover, by using APS as the CSDA, instead of TMAPS, the ratio of left-handed to right-handed structures in the resulting material was altered from 65:35 to 75:25. These novel mesoporous silica materials with a chiral mesoporous structure were further used successfully to direct the growth of chiral metal nanowires inside their channel pores.[78] Thus, besides their interesting structures, the resulting chiral mesostructured materials may also find potential applications in chiral catalysis and enantioseparation.[79]

Efforts towards the synthesis of mesoporous silicas by using unconventional molecules or nonsurfactant systems as templating agents were made by Wei and co-workers.[80–84] The authors attempted and successfully synthesized various mesoporous silica materials by using carbohydrates, such as glucose or maltose, or hydroxyl carboxylates, such as citric acid or tartaric acid, as pore-forming agents.[80–84] In their typical synthetic procedure, they mixed the organic SDAs to interact with the inorganic silica precursors at ambient temperatures and under mild pH (~6 or slightly higher).[80–84] After extraction of the organic groups from the final solid materials, they obtained MCM-41-like materials with tubular mesopores, high surface areas (~1000 m^2/g), and large pore volumes (~1.0 cm^3/g). Furthermore, they showed that the pore sizes in the materials were reasonably monodisperse (2–6 nm in diameter) and tunable by changing the concentration of the organic templates[80–84] or, to a lesser extent, by changing the type and molecular size of the templates.[80]

The mechanism leading to the formation of the mesophases and mesoporous silica materials with nonsurfactant templates was proposed to be similar to those obtained with surfactant (nonionic) templates.[36,37] Hydrogen-bonding interactions between the nonsurfactant molecules and the silica precursors were again considered to play significant roles in their self-assembly into mesostructured materials.[80,83] Other interactions were also considered to be possible depending on the composition of the reaction mixture. For instance, when TEOS and tartaric acid were used with metal chlorides such as NaCl, $MgCl_2$, and $AlCl_3$, the metal ions were coordinated with the carboxylate groups in tartaric acid, forming metal-modified structure-templating complexes. These complexes then interacted with the inorganic silica species and underwent self-assembly.[84] In this process, the larger metal ions were found to promote the formation of enlarged aggregates, in the order of $Al^{3+} > Mg^{2+} > Na^{+}$.[84]

It is worth noting at this point that the synthesis of porous silicas using nonsurfactant templates was actually attempted in 1997, when Mann and co-workers[85] reported the synthesis of macroporous MCM-41 fibers (~500 nm pore width) with an extended length scale porous structure using a thread of multicellular filaments from soil bacteria as templates. In the synthesis, bacterial filaments were used not only as the templating agents but also as an alignment axis for silica growth as well as as pore-swelling agents.

It is important to mention here that all these nonsurfactant self-assembly routes to mesoporous silicas are considered to be more environmentally friendly compared with traditional surfactant self-assembly syntheses, as the former utilize greener organic or natural and (or) biological molecules as templates. However, although they have large surface areas and pore sizes, the mesoporous silica materials resulting from nonsurfactant self-assembly routes do not have highly tunable porous structures because of the limitation of the templating agents.

The other unconventional materials or molecules that have been successfully used as structure-directing agents or templates for the synthesis of mesoporous silica materials include ionic liquids. Room-temperature ionic liquids (RTILs) are a group of organic salts that remain liquid over a wide range of temperatures and that possess negligible vapor pressures and high ionic strengths. With regard to the use of ionic liquids as templates, the first report can be dated back to as early as the year 2000, where the Dai group[86] reported the synthesis of porous silica aerogels using RTILs as SDAs for silicate species produced by hydrolysis and condensation. In the report by Dai et al.,[86] formic acid, tetramethylorthosilicate (TMOS) and 1-ethyl-3-methylimidazolium bis[(trifluoromethyl)sulfonyl]amide were mixed and self-assembled under mild conditions. The removal of the RTILs from the materials with acetonitrile under reflux resulted in a homogeneous silica aerogel, without further supercritical drying. Later on, alkylated imidazolium-based ionic liquids were employed as templates to synthesize MCM-41-like hexagonal mesoporous silicas and organic–inorganic hybrid mesoporous nanocomposite materials.[87,88] This approach offered a new avenue for the synthesis of mesoporous silicas with highly ordered structures by using RTILs as SDAs.

The low volatility and high thermal stability of RTILs renders the RTILs' unique properties and advantageous features as templating agents for the synthesis of mesoporous silicas compared with other organic SDAs. For example, at 40 °C, the long-chain RTIL,1-alkyl-3-methylimidazolium chloride (i.e., $[C_n\text{min}]^+Cl^-$, where n = No. of carbon atoms in the alkyl chain; for example, $n = 16$), interacted with TMOS in the presence of acidic catalysts and produced ordered lamellar supermicroporous silica, with an interlayer spacing of ~2.7 nm and a slit pore diameter of ~1.3 nm.[89] However, unlike conventional surfactant templates, changing the alkyl chain length of the RTIL from $n = 14$ to $n = 18$ did not result in any change in the microstructures of the materials, leaving the pore diameters to vary only between 1.2 and 1.5 nm. Despite this drawback, at an elevated reaction temperature of 90 °C (40 °C < melting point of $[C_n\text{min}]^+Cl^-$, $n = 14–18 < 90$ °C), the pore structure became wormhole-like with a bigger pore size of ~2.7 nm.[90] Moreover, the synthesis using short-chain $[C_4\text{min}]^+BF_4^-$ or 1-butyl-3-methylimidazolium-tetrafluoroborate led to the formation of highly ordered mesoporous silicas that had bicontinuous wormhole-like mesopores of ~2.5 nm in diameter and ~2.5–3.1 nm in wall thickness.[91]

The self-assembly mechanism for $[C_n\text{min}]^+X^-$-templated synthesis of mesoporous silicas (here X^- stands for generic counterion, usually containing atoms of high electronegativity) involves interactions between X^- with silanol groups of silica precursors via hydrogen bonding on one side and π–π stacking between neighboring imidazole rings on the other side.[91] By using this mechanism, the effect of temperature on the structures of the mesoporous silica materials formed using the RTIL as the SDA can be explained. At elevated temperatures (or temperatures higher than the melting point of the RTIL), the fluidity of the RTIL molecules increases,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13
For personal use only.

promoting molecular movement and altering their spatial aggregation to different micro- or meso-structures.

Besides acidic solutions, RTILs were also successfully used in basic solutions to produce mesoporous silicas. The Lin group used basic solutions for the self-assembly of $[C_n\text{min}]^+Br^-$ (n = 14, 16, or 18) with TEOS at 80 °C.[92] They obtained mesoporous silicas with pore sizes of 2.7–3.3 nm and with various morphologies ranging from spherical/ellipsoid to rodlike as the carbon number in the RTILs' alkyl chains increased and the intermolecular stacking between $[C_n\text{min}]^+$s subsequently strengthened.

The advantages of employing RTILs as templating agents to synthesize mesoporous silicas include their application as SDAs over a broad range of reaction temperatures as many of them remain liquid and stable under wide temperature ranges. It was also shown that some RTILs in the resulting mesostructured materials could render the materials with interesting properties, including inherent germicidal and antibacterial properties.[92]

Molecules such as folic acid have also been successfully used as templating agents for synthesis of mesoporous silica materials. For example, the self-assembly of folic acids and TEOS was recently shown to produce hexagonally ordered mesoporous materials with pore sizes of 2.5–3.0 nm, very large surface areas of up to 1155 m^2/g, and chiral mesostructures.[88] The materials were also shown to load many benzyl ring-containing anticancer drugs (e.g., doxorubicin) through π–π stacking between the drug and the mesoporous materials (specifically because of the pterin moiety of their folic acid groups).[93] Furthermore, because of their chiral properties, these mesoporous materials can be expected to find potential applications in chiral separation or asymmetric catalysis. Similar chiral-mesostructured silica materials were also obtained by using small chiral amino acid molecules, such as *N*-acyl-L-alanine or *N*-acyl-D-alanine, as templating agents, as indicated in the previous sections.[78]

Despite the different synthetic mechanisms proposed for mesoporous materials and the various synthetic routes used to make them, it is generally accepted that the interactions between templating agents and silica precursors play an essential role in the formation of highly ordered mesoporous silicas. Furthermore, the reaction times and temperatures influence how the organic templates aggregate and assemble with silicate species. This, in turn, determines the types of mesoporous silica materials the synthesis ultimately results in. For example, in surfactant-templated synthesis of mesoporous silicas, the addition of co-solvent could affect the shape and size of surfactant micelles and thus the dimension of the mesopores, depending on the polarity of the additives and the ionic strength of the solution. In general, in aqueous media, polar additives tend to fill up the gaps between the hydrophilic tails of the micelles, which leads to increased micelle volume but decreased micelle curvature. Nonpolar co-solvents, on the other hand, occupy the hydrophobic center and enlarge the sizes of the micelles.[9,51,62,63] For example, 1,3,5-trimethylbenzene has been commonly used as a swelling agent in the synthesis of SBA-type mesoporous silicas with bigger pores.[62,63] Besides increasing the pore diameters of the mesoporous materials, such additives can also affect the formation of the mesostructured silica materials. Generally, additives that induce more surfactant–silicate interactions tend to form more stable and organized silicate structures, and vice versa. In addition, elegant synthetic methods, sometimes called morphosynthesis, which were applied first by the Ozin group and a few other research groups, allowed fine tuning of the morphologies of mesoporous silica materials or produced mesoporous silicas with interesting structures and shapes, akin to the silica-based materials synthesized by organisms.[1,3]

Irrespective of the synthetic methods and the types of SDAs used, after the synthesis of the as-made mesostructured silica materials, all the surfactant templates have to be removed to generate the pores within the materials. This is typically performed either by solvent extraction or by high-temperature calcination.

The solvent-extraction method involves stirring the self-assembled silica–surfactant material in a solvent to wash off the surfactant, organic molecules, or ions from the material. As such, this method does not degrade the surfactant or the organic templates. Therefore, the extracted surfactant or templating agents can be recycled and reused, if necessary. Furthermore, this method results in mesoporous silicas with large densities of the surface hydroxyl groups, which can assist the materials during its functionalization with various guest molecules (see next section for more detail). However, this method has some disadvantages as well. Most notably, this method often results in incomplete removal of the organic templates, which sometimes causes detrimental effects, especially when the mesoporous silicas are applied in biological systems.

The second method, i.e., calcination, involves heating the as-made surfactant containing mesostructured silica material at high temperature (typically above 350 °C) in air or oxygen to remove the surfactant templates in the form of CO_2 and H_2O. This method enables the complete removal of the organic templates from the materials; therefore, this method is highly recommended, especially when as-synthesized mesostructured materials possess strong interactions between their surfactant templates and silica networks or when the final mesoporous silica materials are required to be completely free of organic templates, for example, for biological applications. However, compared with solvent extraction, calcination of mesostructured materials renders some disadvantages as well. In particular, calcination results in mesoporous silicas with lower densities of the surface silanol groups. Furthermore, calcination sometimes results in the partial collapse of the ordered structures or the mesochannel pores in the mesoporous silicas. By optimizing the calcination conditions, such as by using relatively low heating temperatures and short calcination times, some of these problems could be minimized.

Functionalization of mesoporous silicas

Functionalization strategies

Generally, functionalization of nanomaterials often enables the materials to obtain applications in many different areas. For instance, organic functionalization of nanomaterials allows the nanomaterials to have increased adsorption capacity and improved release profiles to guest (drug) molecules. Functional groups on nanomaterials can also serve as ligands to strongly bind to organometallic complexes and to catalytic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13

groups and then form nanomaterial-supported heterogeneous nanocatalysts.

The functionalization of mesoporous silicas typically involves the introduction of organic functional groups into the materials by using organosilanes. The process results in functional groups on the external, internal, or both surfaces of the mesoporous silica material. In some cases, the functional groups can also be within the framework of the mesoporous silica materials. To achieve organic functionalization of mesoporous silica materials, three basic synthetic strategies can be employed generally: (*i*) stepwise (post-grafting) synthesis, (*ii*) one-pot (co-condensation) synthesis, and (*iii*) self-assembly synthesis with bridging organosilanes into periodic mesoporous organosilica (PMO)-type materials.

Post-grafting synthetic method for functionalized mesoporous silicas

The post-grafting synthetic method to functionalized mesoporous silicas is comprised generally of two steps, i.e., synthesis of as-made mesostructured silica materials, followed by a post-synthetic modification of their surfaces with organosilanes. For example, Liu and co-workers[94] synthesized mercaptopropyl-functionalized MCM-41 mesoporous silica by treating calcined MCM-41 mesoporous silica, with a surface area of 900 m^2/g and an average mesopore size of ~5.5 nm, with tris(methoxy)mercaptopropylsilane (TMMPS) in chloroform. The mesoporous structure of the material was found to remain intact after surface modification of the MCM-41 by the mercaptopropyl groups. Because of its mercaptopropyl groups, this surface-modified material showed significantly improved binding affinity and higher adsorption capacity towards heavy metal ions such as Hg^{2+}.[94] This clearly exemplifies the benefits of the functionalization of mesoporous silicas with organic functional groups.

The post-grafting synthetic method for functionalized mesoporous silica materials has advantages and disadvantages. Its advantages include (*i*) it enables the introduction of functional groups to as-made mesoporous silica without causing the mesostructure and mesoporosity of the material to degrade; (*ii*) it can be used for selective functionalization of the inner or outer surface of the mesoporous silica by sequential organosilane grafting procedures, i.e., grafting the outer surface of the surfactant-containing mesostructured silica with one type of organic group, followed by extraction of the surfactant templates to empty the pores, and finally grafting the second functional group onto the inner pore surfaces of the mesoporous silica; and (*iii*) it involves a simple procedure to effectively functionalize the surfaces of mesoporous silicas with organic or other functional groups. Among its disadvantages, its inability to produce homogeneous distribution of the functional groups throughout the channel pores of the mesoporous materials is the most notable one.

The degree of functionalization of mesoporous silica can be affected by how the parent mesoporous silica is synthesized. For example, if the as-made mesoporous silica is prepared by calcination rather than solvent extraction, the material will have less silanol groups and thus lower ability to react with organosilanes (such as 3-mercaptopropyltriethoxysilane), resulting in less density of the organic functional groups (e.g., mercaptopropyl groups) in the mesoporous material.[94] The conditions and reagents employed during the grafting of the organosilanes onto the mesoporous silica, such as pH, temperature, reaction time, and the organosilane and the solvent used, can also affect the density of the grafted organic groups in the final material. Our group,[95] for example, found that the density of grafted organic groups on mesoporous silica can vary depending on the type of solvent (e.g., ethanol versus toluene) and the reaction time employed during the grafting synthesis. While the grafting of 3-aminopropyltrimethoxysilane onto mesoporous silicas in toluene produced higher densities of the organoamine groups in the materials, the corresponding grafting in ethanol led to significantly less density of the organoamine groups that were spatially distributed in the materials. Interestingly, the two materials exhibited different properties in catalysis, i.e., the material with less density of the organoamine (or basic catalytic) groups catalyzed the Henry reaction much more efficiently than the one with more organoamine (or basic catalytic) groups.[95] This result shows that the polarity and relative permittivity of the solvents can play important roles during the grafting of organic groups on mesoprous silicas and affect the distribution of the grafted organic groups and the physicochemical properties of the resulting organic-functionalized mesoporous silicas.[96] Similarly, temperature or ionic strength can affect the rates of reactions between the organosilanes and the silanol groups on the mesoporous silica and, consequently, some of the properties of the resulting organic-functionalized mesoporous silicas.

It is worth mentioning that the density and distribution of the functional groups formed on mesoporous silica can also rely on the physical properties of the as-made mesoporous silica, such as its morphology, pore size, and surface area. For instance, the surface coverage of organoammonium groups on the SBA-15-type mesoporous silica was found to be about three times denser than that on MCM-41-type mesoporous silica after the two parent materials were stirred with the quaternary ammonium-containing organosilanes under the same conditions and for the same period of time.[18]

In another interesting novel approach, the Jaroniec group[97] reported the post-synthetic functionalization of template-containing materials directly, which allowed the substitution of the surfactant templates in the as-synthesized mesostructured silicas with organic functional groups from the organosilanes. In this method, the reactive organosilanes with desired functional ligands replaced the surfactant templates in as-synthesized materials, producing stable surface-functionalized mesoporous silicas with surface areas up to 800 m^2/g and pore widths up to 4.9 nm in a relatively short reaction time (8–10 h).[97] Besides allowing the functionalization of mesoporous silicas with organic functional groups, this method removes the surfactant templates without the need of additional calcination or solvent-extraction steps. Furthermore, this method does not compromise the mesostructures of the material. Moreover, it does not degrade the surfactant, making it potentially recycleable and reuseable, as necessary.

Co-condensation synthetic method for functionalized mesoporous silicas

The co-condensation or one-pot synthetic method for functionalized mesoporous silicas involves the co-assembly of the

Fig. 2. (*a*) Organic functionalization of mesoporous silicas by hydrophilic (R_1) or hydrophobic (R_2) organic groups, where R represents a normal alkyl chain.[10] (From Trewyn et al. 2007, reproduced (adapted) with permission of Acc. Chem. Res., Vol. 40, p 846, © 2007 American Chemical Society. (*b*) Synthetic procedure of periodic mesoporous organosilicas (PMOs) under basic conditions, with some common organic bridging groups used to prepare the PMOs.[109] (From Hatton et al. 2005, reproduced (adapted) with permission of Acc. Chem. Res., Vol. 38, p 305, © 2005 American Chemical Society.

silica precursors (including organosilanes) with the SDAs in one pot. As a result, the organic-functionalized mesoporous silicas are produced directly in one step, and the organic functional groups are incorporated into the mesoporous material while the mesostructured material forms. Using this synthetic method, for example, mesoporous silicas functionalized with alkyl, aryl, allyl, vinyl, amino, and epoxy groups were successfully synthesized.[98–101]

During co-condensation synthesis, the kind of organosilanes added to undergo co-assembly with the silica precursor (e.g., TEOS) and the kind of templating agents used in the reaction can determine what types of mesophases, template–silicate aggregates, and organic-functionalized mesoporous silica materials form. For instance, the Lin group[102–104] reported the synthesis of organic-functionalized mesoporous silicas with controlled morphology simply by varying the mole proportion of the organoalkoxysilane used in the reaction mixture during the co-condensation synthesis. The authors specifically demonstrated the synthesis of monofunctional mesoporous silicas by using organosilanes containing 3-[2-(aminoethylamino)ethylamino]propyl (AEP) or 3-cyanopropyl (CP) groups.[102] The authors also showed that the syntheses could yield bifunctional mesoporous silicas by co-condensation of the two organosilanes in the same reaction mixture, along with the silica precursor and the surfactant-templating agent. Interestingly, as the mole ratio of the two organosilanes was varied, the structures of the resulting organic-functionalized mesoporous silicas changed. For example, as the relative amount of organosilane containing AEP over that containing CP was increased, the shape of the bifunctionalized mesoporous silicas changed from rod- to sphere-shaped. Furthermore, an increase in the composition of AEP augmented the pore size of the final mesoporous material, possibly because of the hydrophilic nature of the AEP groups.[102]

The type of organic groups in the organosilanes can also affect the rate of the co-condensation reaction and the density of the organic groups in the final organic-functionalized mesoporous silica material. This was demonstrated, for example, with co-condensation synthesis of organic-functionalized mesoporous materials using TEOS and a variety of organoalkoxysilanes containing amine, isocyanate, nitrile, or vinyl groups in the presence of cetyltrimethylammonium bromide (CTAB) surfactant.[103] The syntheses resulted in various functionalized mesoporous silicas, which were found to have some differences in the surface coverage of the organic groups.[103] In comparison with the organoalkoxysilanes with a hydrophilic moiety (e.g., primary amines), those with hydrophobic functional groups (e.g., isocyanate, nitrile, or vinyl groups) were more effectively condensed and incorporated in the functionalized materials in higher density. On the other hand, organosilanes containing more hydrophilic organic groups produced bigger organic-functionalized mesoporous silicas in a nanoarray geometry with increased curvature. These differences were explained by the authors as follows. Having a similar size of siloxane head group, the organoalkoxysilanes encompassing hydrophobic tails gave rise to reduced curvature in the self-assembled micelles and thus significantly smaller particle size of the organic-functionalized mesoporous silica compared with a pristine MCM-41 material synthesized from TEOS under the same conditions. Nonetheless, regardless of being hydrophilic or hydrophobic, when the organic groups in the organosilanes were longer, the organic-functionalized mesoporous silicas had bigger mesopore diameters.[103]

The density of the functional groups in organic-functionalized mesoporous silicas obtained by the co-condensation synthetic method was also found to depend on how strongly the terminal groups in the organosilanes interacted with the cationic surfactant ions and their counterions. Thus, the organosilanes used in co-condensation should be more carefully chosen in order not to compromise the self-assembly process, and thereby the structures of the organic-functionalized mesoporous materials. Organosilanes containing thiolate, carboxylate, or sulfonate groups exchange with the Br^- ions of CTAB, and thus interact with surfactant ions forming the micelle–silica aggregates. However, the strength of these interactions varied, causing a decrease in the degree of interaction and stability of the corresponding micelle–silica aggregates in the order of sulfonate > carboxylate > thiolate.[104] This, in turn, led to organic-functionalized mesoporous silicas with different densities of the organic functional groups. Based on these results, the following mechanism was proposed to explain how the organosilanes affected the degree of functionalization of the mesoporous materials during co-condensation (Fig. 2*a*).[10,103,104] In an aqueous basic solution containing cationic surfactant and silica precursors, the organosilanes interacted with the micelle–silicate complexes through two possible processes: (*i*) electrostatic interaction between negatively charged silicate moieties and positively charged head groups of the cationic surfactant and (*ii*) condensation or co-condensation between the hydrolyzed organosilicate or silicate species that were derived from the organosilanes or silica sources (such as TEOS), respectively. During these processes, organosilanes with hydrophobic tail groups exhibited a tendency to insert their functional groups into the gaps between surfactant micelles. As a result of this, hydrophobic organosilanes stabilized the mesophases better, accelerated their condensation with any silica precursor present, and produced organic-functionalized mesoporous silicas with more ordered and intact structural features. In contrast, organosilanes with hydrophilic tail groups exhibited a tendency to weaken the micelle–silica aggregates, underwent less condensation with silica precursors, and undermined the structural integrity of the resulting materials. In either case (i.e., organosilanes with hydrophobic or hydrophilic tails), at the end of the synthesis and solvent extraction of the templating agents, functionalized

mesoporous silicas with organic functional groups exposed on the inner and outer surfaces of the mesoporous material were formed.

Generally, compared with the post-grafting synthetic method, co-condensation synthesis offers a more convenient route for the modification of mesoporous silicas with rather homogenous distribution of functional groups. It is also worth including that, apart from their roles as functional surface modifiers, organosilanes adopted in co-condensation synthesis can influence the physical properties of the organic-functionalized mesoporous materials, such as their size, morphology, and mesoporosity.

Self-assembly of bridging organosilanes to periodic mesoporous organosilicas

Another more popular synthetic route to organic-functionalized mesoporous silicas employs a different class of organosilanes rather than the ones mentioned previously. These organosilanes, which are called bridging organoalkoxysilanes, have a general formula of $(RO)_3Si–R'–Si(OR)_3$ (where R = alkyl and R′ = alkyl or alkenyl). The method of their self-assembly into mesoporous materials was independently and almost simultaneously developed by three research groups, led by Ozin, Inagaki, and Stein.[105–107] In a typical synthesis, these organosilanes by themselves or in combination with silica precursors self-assemble in the presence of surfactant templates and generate the organic-functionalized mesoporous materials, called PMOs.[105–107] Specifically, the bridging organosilane and cationic surfactant are mixed into slightly alkaline solutions, stirred, and aged for hours or days. The solution is then filtered, and the surfactant templates from the recovered solid material are subsequently removed by solvent extraction to produce the PMO material.[105–107] The resulting materials (i.e., PMOs) constitute a new class of organic–inorganic hybrid mesoporous silicas with highly ordered mesoporous structures, and most importantly, with organic functional groups (R′) covalently bonded via non-hydrolyzable Si–C bonds among two or more than two siloxane groups on the walls of the mesoporous materials (Fig. 2*b*).[108–110] It is worth emphasizing that the R′ functional moieties introduced into the framework of mesoporous materials with these organosilanes become a part of the framework of the final functionalized mesoporous material.

Like the structures of organic-functionalized mesoporous silica synthesized from the co-condensation of terminal organosilanes, those of the PMOs depend on the synthetic conditions as well as the types of surfactant and SDAs employed during their synthesis. For instance, when 1,2-bis(trimethoxysilyl)ethane (BTME, $(H_3CO)_3Si–CH_2–CH_2–Si(OCH_3)_3$) was self-assembled with octadecyltrimethylammonium chloride (ODTMA, $C_{18}H_{37}N(CH_3)_3Cl$) surfactant, 2D-hexagonal PMOs containing bridging ethane groups with a surface area of ~750 m^2/g and a pore size of ~3.1 nm were formed.[106] Increasing the concentration of surfactant and the alkalinity of the solution during the synthesis resulted in 3D-hexagonal PMOs, possessing a surface area of ~1170 m^2/g and a pore size of ~2.7 nm.[106] The presence of the bridging organic groups (ethane groups in this case) and their density in the PMO materials can be reliably determined by using solid-state ^{13}C and ^{29}Si NMR spectroscopy.[105,106] For PMOs containing reactive groups such as ethylene (–Si–CH=CH–Si–), the presence of the functional groups (ethylene) can also be verified by using specific reactions, in which the bridging organic groups can undergo the reactions. For example, the bromination reaction can be applied to ethylene–PMO as bromination of the ethylene groups converts the sp^2-hybridized carbon atoms of the ethylene–PMO into sp^3-hybridized carbon atoms. This can easily be probed by methods such as ^{13}C solid-state NMR spectroscopy, indirectly allowing the determination of the presence of ethylene groups in the original PMO.[105]

Besides hexagonal-ordered mesostructures, PMOs with other structures can also be made by following other procedures that were employed to synthesize different types of mesoporous silicas and terminal-organic-functionalized mesoporous materials. In addition to 2-D and 3-D hexagonally ordered mesoporous silicas, the self-assembly of $(C_2H_5CO)_3Si–R'–Si(OC_2H_5)_3$, in which R′ = $–CH_2–CH_2–$ or –CH=CH–, with CTAB can produce wormlike PMOs with uniform mesochannels (pore size = 2.2–2.4 nm and surface area > 1200 m^2/g) and thicker pore walls compared with the synthesized MCM-41.[107]

Recently, a new strategy to synthesize PMOs using the self-assembly of organosilanes and block copolymers in the presence of reactive organic precursors was reported by the Jaroniec group.[111] In a typical synthesis, reactive precursors (e.g., *N*-hydroxyurea) were added into the solution containing PEO–PPO–PEO as the soft template, followed by addition of bridged organosilane (1,2-bis(triethoxysilyl)ethane or BTES). Acidic ethanol solution was used to extract the templates in as-prepared samples, producing PMOs with an ethane–silica framework with reactive organic functionalities in the hydrophilic realm of the well-orderd mesostructure.[111]

Owing to the presence of organic groups in their framework, PMOs exhibit improved hydrothermal stability and enhanced hydrophobicity, compared with regular mesoporous silicas.[107] PMOs are also unique compared with terminal-functionalized mesoporous silicas that can be produced by either postsynthetic grafting or co-condensation method. The most important difference between the two types of materials is that the organic functional groups in PMOs are part and parcel of the material's framework compared with those of the latter. This can, in turn, result in a different electron density and chemical microenvironment in the framework of the mesoporous materials, rendering PMOs distinct physicochemical properties. Furthermore, unlike those in terminal-organic-functionalized mesoporous silicas, the R′ groups are part of the mesoporous framework in PMOs; thus, changes in the type of the organic groups can significantly modify the physical as well as the mechanical properties, besides the chemical properties, of the materials.

Conclusion

Mesoporous silica and organosilica materials can be synthesized with different structures and physiochemical properties such as high surface areas, pore volumes and tunable nanosize pores. In this review, the various methods used to synthesize different types of mesoporous silica and organosilica materials are described. The synthetic methods developed for introducing organic functional groups into mesoporous

silicas to further tune the materials' properties have also been included. The different mechanisms to illustrate how mesostructured materials form have been summarized. The advantages and disadvantages of the different types of organic functionalization methods have been discussed. Their organically modifiable surfaces allow mesoporous materials to be versatile for various applications. Their unique properties, such as high surface area, nanometer pores, and easily modifiable surfaces, lead to many different potential applications for these materials in many areas, including catalysis, drug delivery, molecular adsorption, and organic separations. Typical examples where these functionalized mesoporous materials have been successfully utilized in catalysis, drug delivery, or chiral separation have been mentioned in different sections.

REVIEW / SYNTHÈSE

Recent advances in the synthesis of colloidal nanowires

Anton Repko and Ludovico Cademartiri

Abstract: We review critically the advances in the synthesis of colloidal nanowires that have occurred over the past three years, with a focus on those that produced very thin (or "ultrathin") nanowires (~2–3 nm in diameter or less). We discuss the importance of these ultrathin nanowires, especially in light of the emerging evidence of their topological properties and their potential similarities with polymers.

Key words: nanowires, ultrathin, polymers, topology, synthesis, colloidal.

Résumé : On fait une revue critique des améliorations aux méthodes de synthèse des nanofils colloïdaux qui ont été proposées au cours des trois dernières années, en particuliers pour celles qui conduisent à la production de nanofils très fins (ou ultrafins) (de diamètres d'environ 2 à 3 nm de diamètre ou moins). On discute de l'importance de ces nanofils ultrafins, particulièrement à la lumière de données qui émergent relativement à leurs propriétés topologiques et leurs similarités potentielles avec les polymères.

Mots-clés : nanofils, ultrafin, polymères, topologie, synthèse, colloïdal.

[Traduit par la Rédaction]

Why should we care about nanowires?

Nanowires can be defined summarily as solids the size of whose atomic lattice is in the nanoscale along two out of three dimensions.[3–12] They can be made in a variety of phases and compositions: ceramics,[13] semiconductors,[14] metals,[15–17] polymers,[18] and glasses.[19] They can be crystalline[13] or amorphous.[19] They can be colloidally stable[15–17] or supported on surfaces.[13]

There is no widespread consensus on what range of aspect ratios characterize a nanowire. Typically, the properties of nanowires depend very weakly on their aspect ratio: most of the physical properties arising from the extension of the atomic lattice along one axis (e.g., polarization of photoluminescence[20]) are already evident at relatively small aspect ratios (~2–10). Large aspect ratios (e.g., 10^2 or more) are desired for interconnects (the length of a nanowire determines how far two places (e.g., electrodes) can be connected by it), or for the integration at a higher density of devices (i.e., a higher level of integration can be envisioned if multiple devices could be embedded on one nanowire).[21] On the other hand, nanowires with very large aspect ratios are difficult to make, integrate in planar devices (they tend to flex), and keep dispersed in solution (they are very prone to bundling).

Why should we care then about nanowires? Their morphology is attractive, for example, for any application that requires

This article is part of a Special Issue dedicated to Professor Geoffrey Ozin. Reactions capable of producing very thin (2–3 nm or less) and colloidally stable filaments of inorganic materials are, as we will argue in the following pages, one of the most interesting developments in the field of nanochemistry over the past few years. I was directly involved with the discovery of one of these syntheses while in the Ozin lab.[1] Since I had the privilege of being invited to contribute this manuscript to this Festschrift for Geoff Ozin's 70th birthday, I feel it is appropriate to dedicate this contribution to Geoff in light of his contributions to chemistry but also of his invaluable mentorship. Geoff was a demanding advisor, an unfailing supporter, a tireless teacher, and an inexhaustible (and sometimes exhausting) source of enthusiasm, drive, and inspiration. I have always felt, as his student, that being overwhelmed was a much better fate than being underwhelmed. As Ph.D. programs suffer from the epidemic lack of enthusiasm that is so convincingly demonstrated by the popularity of Ph.D. Comics,[2] one realizes that there really is no substitute for the kind of energy Geoff provides. Happy Birthday Geoff, and may you keep inspiring young scientists for many more years. I'll never cease to be amazed! Mazel tov! L.C.

Fig. 1. "Weird" wires: Results of a simulation of the structures of Al and Pb wires of decreasing diameter. As illustrated, noncrystalline structures dominated by the surface effects emerge as the diameter is reduced. (From Gülseren et al. 1998, reproduced (adapted) with permission of Phys. Rev. Lett., Vol. 80, p 3776, © 1998 American Physical Society.)

both large surface areas and contiguity of the atomic lattice (characteristics they share with mesoporous materials, their structural "negative"). In the case of batteries,[22–24] the one-dimensional geometry allows nanowires to have a large surface area in contact with the electrolyte and to accommodate the large volume swings associated with Li intercalation.[23] In the case of solar cells, the shape of nanowires can be harnessed to improve the absorption of light into the material.[13,25,26] In the case of piezoelectric transducers, the one-dimensional geometry allows for more efficient transduction.[27,28] In all these applications, nanowires are grown from flat substrates to preserve a solid connection with what is typically a planar device.

The case for the importance of colloidal nanowires would seem less clear. Their integration on planar devices requires their placement with nanoscale precision and their precisely controlled bonding to the substrate, both of which are challenges to this day.[29] Their directed self-assembly in controlled architectures, while interesting from a biomimetic perspective, is more troublesome than for nanostructures with smaller aspect ratios,[30,31] e.g., high aspect ratio nanowires are difficult to stabilize as colloids.

Nonetheless, we argue that there are at least two arguments that can justify an interest in colloidal nanowires.

1. The potential utility of nanowires is typically assessed by first considering the intrinsic physical properties (e.g., electrical conductivity) of the phase they are made of (e.g., Si, GaAs, or ZnO), and then how a one-dimensional morphology can affect the characteristics (e.g., quantum confinement) and applicability of those properties. A different perspective is to first consider their morphology and the properties that it bestows on the nanowires: one-dimensional morphologies are capable, in principle, of unique topological properties (e.g., entanglement and reptation) that elude bulk and approximately isotropic inorganic crystals. Many of the functions of polymers are based on their topological properties (e.g., glues and rubbers). The application of these functions has always been constrained by the physical and chemical limitations of the typically organic composition of polymers. From this perspective, it is plausible to speculate that bringing topological properties to the inorganic world of crystalline nanowires could introduce new capabilities of technological significance.
2. Recent years have seen the development of reliable synthetic strategies for the synthesis of colloidally stable spherical clusters, especially of metals.[32–40] These structures are monodisperse and possess atomic structures that are often quite different from those shown by the bulk phase with the same composition. There is convincing theoretical and experimental evidence that metal nanowires could also show (when reduced to diameters of only a few atoms) atomic structures that are quite different from those of the bulk phase (Fig. 1) and possessing different properties.[41–53] These properties could be studied more easily and made to be much more applicable if these wires could be made on a larger scale and in a colloidally stable state.

Both of these arguments require the synthesis of especially thin nanowires. In an attempt to classify this search for ever thinner nanowires, the vague term "ultrathin" is commonly applied to nanowires that are ~2–3 nm in diameter or less.[7]

Topological properties in nanowires

Two aspects that determine the topological properties of one-dimensional objects are (*i*) the ratio between their contour length (*L*), i.e., the length of the object along the path of their "backbone", and their persistence length (*p*) and (*ii*) the dynamics of the conformation of the object or, in other words, the extent by which the persistence length is determined by dynamic fluctuations in the conformation.[54] The persistence length[55] is the minimum distance that separates two points on

a path whose tangents to the path are, on a time average over thermal fluctuations, uncorrelated with each other. Linear polymers are straight molecules with a coiled conformation in solution. They coil because the C–C bonds that form their backbone can rotate around their axis owing to Brownian motion at room temperature. Therefore, the conformation of polymers is typically dynamic: its persistence length is almost entirely determined by its variations in time. When searching for topological properties in other objects (e.g., nanowires), one should look for large *L*/*p* ratios and spontaneous deformations at room temperature. In the case of nanowires, these requirements translate, to a first approximation, into long lengths and very small diameters. The persistence length of a solid cylinder can be estimated from its diameter (*d*) and from the Young's modulus (*Y*) of its atomic structure by using the formula

$$[1] \qquad p = \frac{\pi d^4 Y}{64 k_B T}$$

where k_B is Boltzmann's constant and T is the absolute temperature. (The formula can be derived by noticing that $p = B/k_BT$, where B is the bending stiffness, which is expressed as $B = IY$, where I is the moment of inertia of the cross section of the object. In the case of a cylindrical rod, $I = \pi d^4/64$. For details, see the treatment by Landau and Lifshitz,[55] by Harris and Hearst,[56] and the summary of Hatami-Marbini and Mofrad.[57]) If we take this formula at face value, any solid of respectable strength (e.g., 10 GPa, the modulus of wood) would need to be extraordinarily thin (<17 Å) to exhibit a persistence length of less than a micrometer, and its length would have to be of millimetres or centimetres to obtain the kind of *L*/*p* ratios that would lead to noticeable topological properties. However, this equation should be applied with caution to solids of near-molecular dimensions, since their deformation might occur by mechanisms that can be substantially different (e.g., not elastic) from those found in bulk solids.

Recent reports of topological properties and transformations in nanowires

Equation [1] seems to suggest that the topological properties of polymers should never be exhibited by crystalline solids. Nonetheless, recent work by the Ozin and Winnik laboratories[58] demonstrates that ultrathin nanowires of a crystalline material (Bi_2S_3) can show a wormlike conformation (analogous to that of semiflexible polymers) and *L*/*p* ratios of ~10^4 (analogous to those of the longest synthetic polymers). The data reported was from static light scattering and electron microscopy, and it was therefore impossible to conclude from them that the persistence length of those wires originated exclusively from thermal fluctuations of their conformation. Nonetheless, there are strong hints that at least part of the observed persistence length is a result of dynamic changes in the conformation: (*i*) the nanowires conformed over distances much larger than the persistence length to flat surfaces without breaking, (*ii*) the changes in direction of the nanowires observed under transmission electron microscopy (TEM) were smooth and not sharp as twinning would predict, and (*iii*) a dilute solution of nanowires injected in a dilute (micromolar) solution of cross-linker (a molecule bearing two amine groups) would lead to the formation of flexible and dense microfibers composed of cross-linked nanowires.[59]

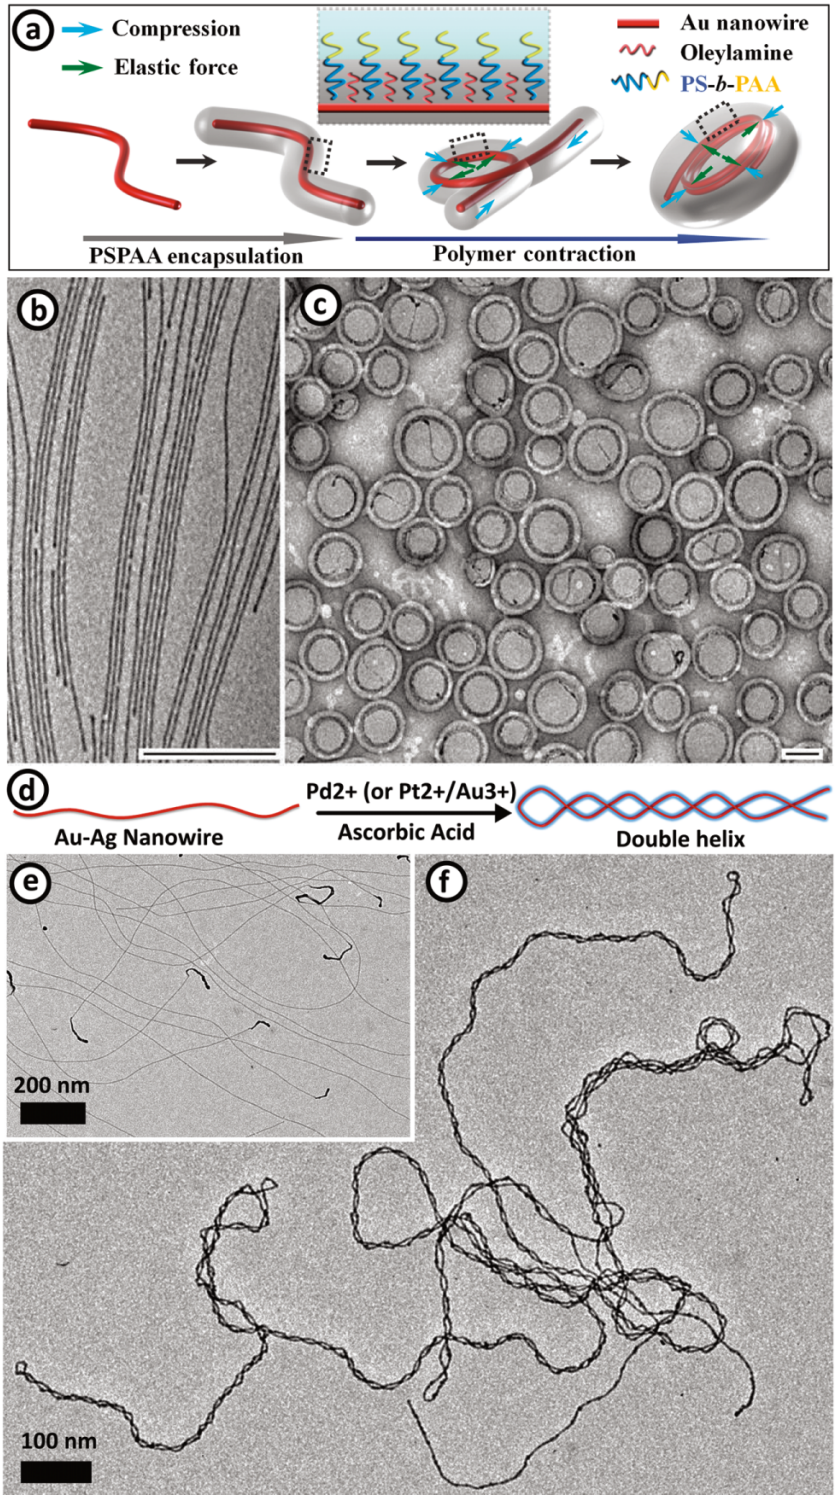
Recently, the groups of B. Xing and H. Chen[60] demonstrated how 2 nm thick Au nanowires can be forced to coil into tight springs (radius of ~25–50 nm) by encapsulation in block copolymer micelles (Fig. 2).[60] Remarkably, the nanowires coiled without snapping or breaking and without penetrating the soft interface of the micelle. In another remarkable topological transformation in nanowires, Chen's group[61] showed how straight ultrathin Ag–Au alloy nanowires would coil into double helices as a third metal was deposited on their surface (Fig. 2).

Therefore, much work needs to be done to understand (*i*) the extent by which inorganic crystals can replicate the properties of polymers and (*ii*) if and how this combination of properties would be of technological interest. But the results are encouraging!

The scope of this review

Early work on the synthesis of ultrathin nanowires was covered to a good extent in a previous review.[7] This review will attempt to identify and elucidate emergent patterns in the syntheses of colloidal ultrathin nanowires by focusing on developments over the past three years that we consider to be conceptually novel. Despite the fairly large number of new reports of ultrathin nanowires, most of the experimental work in this area of research is still phenomenological: mechanisms are often postulated, but they are rarely supported by sufficient evidence. Therefore, we found it very difficult to discern patterns.

In these few pages, (*i*) we critically review the recent literature, (*ii*) we attempt to find heuristic guidelines for the synthesis of ultrathin nanowires, and (*iii*) we highlight the new strategies that have been developed. Please note that some of the approaches that we discuss do not report nanowires, but they are based on concepts that we believe could be used to make ultrathin nanowires.



General strategies for the synthesis of colloidal nanowires

The strategies for the synthesis of nanowires have not changed substantially and are distinguished by the approach they use to break the symmetry of the growth process (Fig. 3).

Controlling the spatial distribution of precursors

When a crystal grows in solution, from gas, and from melt, the precursors are uniformly distributed and will collide with its facets in a way that is typically proportional to their surface area. Therefore, crystal growth is usually approximately isotropic and the growth rates of different crystal facets are largely dependent on their chemical potential. The crystal habit can be controlled by managing the spatial distribution of the precursor or, in often equivalent terms, the exposure of the crystal to the precursor. At a macroscopic scale, this approach is the essential principle of operation of Czochralski crystallization, in which the crystal is slowly pulled out of the melt, and of Bridgman crystallization, in which the crystal gradually fills the container it occupies (Fig. 3).[62] At the nanoscale, the exposure of the crystal to the precursor is often controlled by templates that can be either "hard" or "soft". Nanowires (or

other shaped crystals) can be nucleated and grown a la Bridgman in a hard template that provides a rigidly confined anisotropic environment (e.g., zeolites,[63–67] alumina membranes,[68] periodic mesoporous materials,[69–71] and carbon nanotubes[72]): as the facets of the nanostructure contact the hard surface of the template, they become inaccessible to the precursor and they stop growing (Fig. 3). The nanoscale dimensions of nanowires enable new approaches to templating that are fundamentally distinct from those employed in bulk crystallization: nanowires can be formed by using a hard template in the form of a "precursor" crystal (Fig. 3). A molecular reagent reacts with the precursor crystal and, through a chemical process (e.g., galvanic replacement,[73–75] ion exchange,[76,77] oxidation and diffusion,[78] or hydrolysis and condensation[19,79]), transforms its composition and often its shape; the composition and the shape of the precursor crystal is a determining factor in the composition and the shape of the product. In the case of soft templates, the exposure to the precursor is typically controlled

by steric hindrance. Nanowires are typically grown in solution in the presence of ligands that bind to their surface.[1,80–94] The ligands modulate the surface energy of the growing facets, but might also modulate the accessibility of the facets to incoming precursors (Fig. 3). Another form of soft templating is provided by nanoscale liquid droplets (typically of a low melting metal, e.g., Bi).[89,95,96] These droplets act as localized "nanoreactors" in which the "active" precursor that adds to the crystal is formed.[97] These metal droplets can be patterned on surfaces to create nanowire arrays or can spontaneously form in solution and attach to the growing ends of nanorods and nanowires (Fig. 3). The attachment of these droplets can break the symmetry of highly symmetric atomic lattices (e.g., it has allowed the formation of colloidal nanorods from cubic phases like PbSe).[98] This approach can be used for growing ultrathin nanowires, as recently demonstrated for 4 nm thick In_2O_3 nanowires.[99]

Controlling the chemical potential of the growing facets

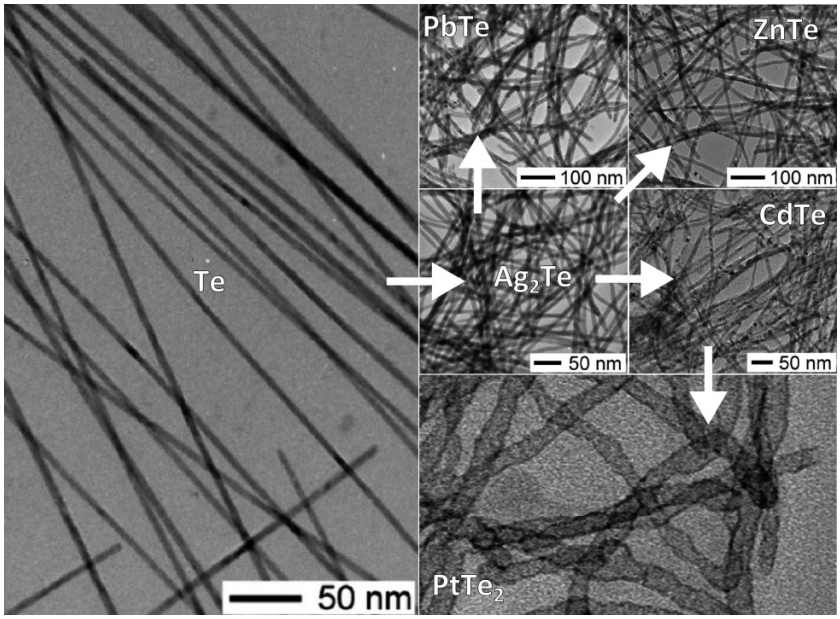
The natural habit of a crystal is largely determined by the chemical potential of its facets (see, for example, the work of Gibbs,[100] Wulff,[101] Cerf,[102] and von Laue[103]). In principle, any control over the chemical potential of the facets would offer some control over the shape and the crystallographic orientation of the crystal. The chemical potential of a growing surface is typically controlled by binding a labile ligand to it. As the ligand binds, the chemical potential of the surface is reduced. (Chemical etching works in a similar way by removing parts of the surface that have a higher chemical potential.) This approach is especially suitable for the specific conditions that are used in the synthesis of colloidal nanomaterials. In these syntheses, the nuclei are typically formed in large quantities and are entirely immersed in a solution that is homogeneously populated by precursor. Therefore, a ligand dissolved in the solution can control equally the growth of all particles growing in it. The binding of ligands to surfaces can reduce their rate of growth by sterically impeding the adsorption of precursor to them (as discussed previously) and (or) by reducing their chemical potential (Fig. 3). Therefore, ligands can limit (but almost never halt) the natural tendency of the lattice to grow along a specific crystallographic direction. For example, we are not aware of Bi_2S_3 nanowires that are elongated along an axis different from [001][83,104–107] (Bi_2S_3 has a strongly anisotropic unit cell consisting of Bi_2S_3 "ribbons" stretching along the *c* axis of the unit cell). This incomplete control on the crystal orientation is a distinctive limitation of current wet chemistry approaches to the growth of nanowires or nanorods. It seems to indicate that the effect of ligands on the surface energy of the crystals is not sufficiently strong and that their binding is not sufficiently selective of specific crystal facets. Nonetheless, ligands that form strong bonds with the surface of crystals are typically considered inefficient in the growth of nanocrystals as they can prevent them from forming (e.g., this hypothesis is consistent with our experience in trying to grow PbS nanocrystals from a trioctylphosphine sulfide precursor).

Controlling the aggregation of preformed crystals

"Classical" crystallization is defined by the time-averaged addition of molecular, ionic, or atomic species to the growing surface of a nucleus or a crystal. In the classical approaches to crystallization (e.g., Czochralski or Bridgman), only one nucleus (i.e., the "seed") is provided, nucleation is eliminated, and the growth proceeds from the melt or from atomic or molecular precursors in the vapour phase. Colloid science deals instead with the simultaneous nucleation and growth of large ensembles of crystals.[108] In these conditions, crystals display the tendency to grow also (and sometimes exclusively) by processes of aggregation.[109] These processes typically lead to polycrystalline solids but can also be controlled to form large single crystals by the crystallographically oriented coupling of separate crystals (Fig. 3).[110–114] Aggregation that is not crystallographically oriented can still result in the formation of a single crystal if the size of the crystal is sufficiently small that a structural rearrangement is energetically favourable.[115] It is interesting to note that aggregation processes can be quite different from the adsorption, surface diffusion, and desorption processes involved in the addition of molecular, atomic, or ionic precursors. For example, the process of aggregation between nanoscale seeds can be guided at a long range and facilitated by the presence of electric or magnetic dipoles.[94,116] (In ionic solids like NaCl, the electrostatic interaction typically plays a role only at a very short range. The most stable facets of NaCl are (100), which appear to be electrically neutral at all distances much larger than the Na–Cl bond length. In nanocrystals, however, the whole solid can possess a dipole that can act, compatibly with screening, at much larger distances.)

Selective etching and size reduction

Another approach to the control of shape in crystals focuses on establishing selective dissolution, rather than selective deposition. In some instances, the dissolution occurs in a post-processing step (as commonly done to etch trenches in silicon wafers), whereas, in other cases, it occurs at the same time as the growth process (Fig. 3). This approach is especially well-developed for metallic structures, where controlled etching has been used to form highly controlled and monodisperse prismatic structures.[117,118]



Advances in the recent literature

Interesting new approaches to these strategies have been demonstrated in the past three years. We categorize these works in terms of the strategy that they developed or introduced.

Chemical transformations of nanowire "precursors"

The chemical transformation of precursor or template nanostructures by ion-exchange or galvanic replacement can serve not only as means to obtain nanostructures with different compositions. In the case of ion exchange, the transformation of the atomic structure can lead to changes in the shape and size of the nanostructures. In many cases, especially for very thin and long nanostructures, the structural strains can be so large that the objects are broken apart in smaller isotropic objects.[119] Nonetheless, the ion exchange can induce topotactic structural transformations that minimize the strain to the existing atomic structure. For example, amine-coated 1.4 nm $CdCl_2$ lamelles could be smoothly converted into CdSe lamelles.[120]

Fig. 4. Chemical transformations of Te nanowires. The transformation of Te to Ag_2Te occurs via topotactic transformation and preserves the nanostructure morphology. Conversions to CdTe, ZnTe, and PbTe also preserve the one-dimensional morphology. Conversion of CdTe nanowires to $PtTe_2$ is instead accompanied by a large volume change, which is accommodated by the nanostructure by changing its morphology to that of a nanotube. (From Moon et al. 2010, reproduced (adapted) with permission of ACS Nano, Vol. 4, pp 2309–2319, © 2010 American Chemical Society.)

In the case of galvanic replacement, however, dissolution and deposition occur in different places. This spatial separation can lead to predictable and useful changes in the shape of the template structure[73] or to a collapse of the structure. For example, the surface of cubic Ag nanoparticles (50 nm) can be partially doped with Au and subsequently etched by $Fe(NO_3)_3$. Dealloying leads to the migration of Au atoms and to the formation of nanoframes with 10 nm thick edges.[121] Alternatively, Ag nanocubes with truncated corners (80 nm) separated the Ag dissolution on (111) from Au deposition on (100), so that the subsequent etching of Ag led to nanoboxes with holes at the corners. Therefore, while the dealloying approach avoids the spatial separation of dissolution and deposition, it still transforms the morphology of the template structure. Selenium and tellurium nanowires appear to be promising candidates and can be prepared, for example, by hydrothermal reduction in the presence of poly(vinylpyrrolidone) (PVP).[122,123] Tellurium nanowires, especially, have been used recently as templates for the preparation of Pd, Pt,[123] PdPt, PdAu,[124] and tellurides of Ag, Cd, Zn, Pb, Pt,[77] and Bi.[125] Oxide nanowires can also undergo ion exchange; for example, $Cd(OH)_2$ (4 nm) to CdSe[126] and $K_2Ti_8O_{17}$ (7 nm) to (Sr, Ba, and Pb)TiO_3.[127]

Complete galvanic transformation of Te nanowires (7 nm) into Pd or Pt nanowires or nanotubes can be achieved in ethylene glycol at 50 °C (2 h).[123] $PdCl_2$ (10 mmol/L), H_2PtCl_6 (5 mmol/L), or $[PtCl_2(NH_3)_2]$ were used in twofold excess to the Te in the nanowires (2.5 mmol/L). The authors state that the increased viscosity of ethylene glycol reduced the reaction rate, which, in turn, prevented the formation of large nanoparticles. Pd^{2+} or Pt^{2+} precursors led to a relatively small contraction in volume and preserved the continuous nanowire morphology. However, Pt^{4+} yielded a larger volume contraction, which, in turn, led to a morphological change of nanowires into nanotubes with 2 nm walls and 5.2 nm diameter. This work shows how the valence of the precursor can be used to reduce the size of a nanostructure, without necessarily compromising its dimensionality.

The reaction of Te nanowires with $AgNO_3$ led to Ag_2Te nanowires and subsequent ion exchanges were used to transform them into CdTe, ZnTe, PbTe, and $PtTe_2$ nanostructures (Fig. 4).[77] While the first step (Te → Ag_2Te) was associated with a large (twofold) volume increase, the conversion of the Te lattice into the Ag_2Te lattice was topotactic despite the large change in symmetry (from trigonal to monoclinic) and helped to retain the crystal habit and the single-crystalline nature of the nanostructure. To achieve further ion exchange against otherwise unfavourable thermodynamic conditions (i.e., Ag_2Te is expected to have a very low solubility product, since $K_{SP}(Ag_2Se) = 10^{-54}$),[128] the authors used tributylphoshine as a selective complexing reagent for silver. The transition from the Ag_2Te lattice to the (Cd, Zn, and Pb)Te lattices did not involve a large volume change (<20%), so the single-crystalline structure was retained. Further transformation to $PtTe_2$ was instead accompanied by a 46% volume contraction and led to polycrystalline nanotubes with 1–2 nm wall thickness. Thus, in a similar way as electrochemical potentials are used for the thermodynamic description of galvanic replacement, the viability of ion exchange in inorganic nanomaterials can be estimated from the corresponding solubility products. Still, an otherwise thermodynamically unfavourable reaction can be made favourable by selectively solvating specific ions by ligation.

"Defect" templating

Another "style" of templating, with great potential for the reduction of feature sizes, uses defects as nucleation centers (Fig. 5). This approach is based on one of the most common aspects of heterogeneous nucleation and crystal growth (i.e., crystal defects) that was previously used and controlled to yield nanostructures on flat surfaces.[129] Colloidal nanostructures can display well-defined defects in their atomic structure.[3,117] These predictable defects can emerge on the surface of the colloid, where they will exhibit a higher chemical potential than the surrounding surface. This localized increase in chemical potential can act as a "template" that directs the

Fig. 6. Schematic of polymer-based templating of ultrathin silica and organosilica nanowires: (*a*) and (*b*) the polymer backbone undergoes atom transfer radical polymerization (ATRP) to form a polymer brush whose brushes are populated by silanes, (*b*) and (*c*) further polymerization allows the growth of a hydrophilic outer shell, (*c*) and (*d*) hydrolysis and condensation of the silane inner shell produces a water-dispersible organosilica nanowire, and (*d*) and (*e*) calcination at 700 °C leads to ultrathin pure silica nanowires. nucleation and deposition of another material. The underlying colloid can then be dissolved to yield ultrathin nanostructures.

Ag decahedrons (size = 50 nm) entirely delimited by (111) facets joined by twinning boundaries at the edges were used as templates for deposition of Au. The Au deposited preferentially on the twin boundaries. Subsequent etching of silver resulted in nanoframes of 3 nm thickness.[75] Au deposition was obtained by reducing $HAuCl_4$ with ascorbic acid, whereas the galvanic replacement was suppressed by maintaining a high pH (8–9). (Higher pH led to a coverage of the (111) facets.) The thickness of the beams composing the frames (3–4.5 nm) and their overall size (40–50 nm) could be somewhat tuned by the amount of Au (Au:Ag = 3%–10%): a reduction of the thickness of the edges to 1.6 nm (at 1% Au) led to a loss of the integrity of the frames. While the reaction required a certain fine-tuning of the reaction conditions and the choice of an unusual template, we believe that this work illustrates a concept that could be explored for the fabrication of other ultrathin nanostructures, such as nanowires. The higher chemical potential of defects can, in principle, be employed for the deposition of most crystals.

Polymer templating

Müller and co-workers[19] at the University of Bayreuth demonstrated a very elegant example of bottom-up nanowire design (Fig. 6). They took a polymer backbone as a template and grewside chains decorated by silanes on it (by atom transfer radical polymerization (ATRP)). The side chains were further extended with hydrophilic monomers. The hydrolysis and condensation of the silanes within the inner shell formed an organosilica network in the shape of a nanowire. The hydrophilic outer shell provided these hybrid nanowires with dispersibility in water. The hybrid nanowires exhibited a glass transition at $T < -45$ °C and they decomposed above 200 °C. Above 530 °C they yielded pure silica nanowires, following a weight loss of 96.5%. A calcination of the nanowires at 700 °C produced dense silica nanowires.[19] This bottom-up approach could precisely control the thickness (9–21 nm) and length (140–300 nm) of the nanowires by driving polymerizations to a designed degree. Müller and co-workers[79] extended this work by demonstrating the formation of silica nanotubes by incorporating a nonhydrolyzable innermost shell in the polymer brush. This method could be quite broadly applicable to sol–gel precursors and should be amenable to the fabrication of ultrathin structures. However, it is limited by the underlying polymer chemistry (e.g., the length of the nanowire and their polydispersity will depend on how large and monodisperse a polymer can be polymerized) and its compatibility with the sol–gel chemistry. Additional challenges could be found in maintaining the structural integrity of the nanowires upon the large mass loss occurring during calcination. Nonetheless, the possibility of translating the control of structure given by polymer chemistry to the design and synthesis of ultrathin inorganic structures is tantalizing. Furthermore, it is conceivable that the oxide nanowires obtained with this method could be further transformed into a multitude of other compositions by appropriate chemical transformations (e.g., reduction and sulfidation).[130]

Other ultrathin nanowires might grow by polymer templating. For example, the successful synthesis of 1.8 nm Au nanowires capped by oleylamine reported by the Xia group[17] and others,[15,16,131] appears to be templated by the formation, reduction, and assembly of a one-dimensional AuCl–oleylamine complex.[17]

Carbon nanotube templating

Hard templating in zeolites[63–67] or periodic mesoporous oxides[69–71] is a proven method for producing nanowires of precise diameters. However, it is difficult to extract, isolate, and colloidally stabilize the nanowires embedded in them. Furthermore, these approaches do not lend themselves well to scale-up. These issues might not be so severe if carbon nanotubes (CNTs) are chosen as templates. CNTs can be produced in fairly large quantities and are somewhat dispersible in a few solvents. They can encapsulate the nanowire within them, providing it with protection against degradation and agglomeration.

Deposition of Eu (under 10^{-6} Torr (1 Torr = 133.3224 Pa) and 500–600 °C) into double-walled CNTs led to ultrathin (one to four atoms across) metal nanowires that were resistant to oxidation and ultrasonication (Fig. 7).[72] Eu–Eu spacing was larger than in bulk metal by 7%–18%. The authors claim that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by MCGILL UNIVERSITY on 02/02/13

a similar procedure also worked for producing analogous nanowires from Sm, Sr, and Yb. While CNT templating seems to be a promising way to obtain nanowires of reactive metals and to enable fundamental studies on the physics of ultrathin nanowires, it might remain severely limited as a synthetic approach by the relatively limited colloidal stability of CNTs.

Ligand-controlled growth of atomically thin nanowires

Some of the most remarkable findings of the past three years in the formation of ultrathin nanowires demonstrated the formation of colloidally stable one-dimensional structures held together by single bonds.

The Ritter group[132] at Harvard University obtained colloidally stable and atomically thin nanowires of Pd^{3+} and $Pd^{2.5+}$ by a clever use of molecular inorganic chemistry. The nanowires were fairly long (~0.5 μm) and showed semiconducting (Pd^{3+}) or metallic ($Pd^{2.5+}$) conductivity. The nanowires were dispersible in CH_2Cl_2 and coordinated by acetate (or hexanoate) and benzo[*h*]quinolinyl and accompanied by F^- or BF_4^- anions. However, their crystals were not stable above –35 °C. (These Pd nanowires remind us of the AuCl–oleylamine polymer used to form Au nanowires.[17]) While the approach by the Ritter group[132] is elegant and apparently effective, it might not be widely applicable to other metals.

In a procedurally simpler, but mechanistically mysterious example, Liu and Yang[133] grew atomically thin (0.4 nm) anatase (TiO_2) nanowires from $Ti(OBu)_4$ in the presence of oleic acid and oleylamine at 180 °C. While the nanowires did not exceed 25 nm in length, this work is remarkable in that it displays the possibility of creating nanowires with a truly monodisperse section by fairly traditional ligand-based approaches and without the use of a hard template. We and others have previously argued on several occasions about the importance of pursuing the synthesis of perfectly monodisperse colloids.[29,134–138] We have attempted to achieve this objective in our research and not quite succeeded yet. These colloidal nanowires do represent one of the very few cases where this objective has been accomplished successfully with nanowires, with ceramics, and by using a fairly conventional strategy.

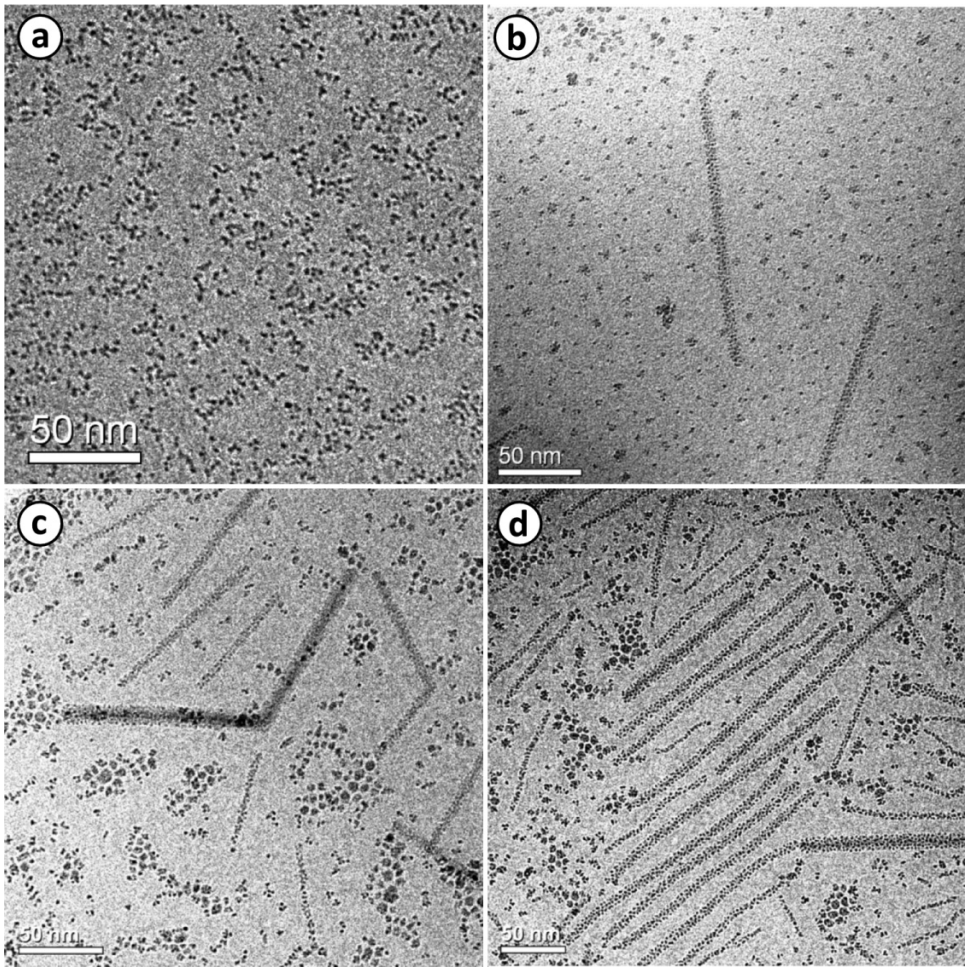
Much longer (~μm) but somewhat thicker (1.8 nm) nanowires of EuOF were obtained instead by decomposition of $Eu(CF_3COO)_3$ in the presence of oleic acid and oleylamine at 310 °C.[139] ZnS ultrathin (~2.0 nm) nanowires were obtained by decomposing a single source precursor ($Zn(S_2CN\text{-}n\text{-}Bu_2)_2$) in the presence of dodecylamine and triphenylphosphine.[87] In a previous example, ultrathin ZnS nanowires (1.2 nm in diameter) were obtained by reacting a *S*-oleylamine solution with a Zn^{2+}–oleylamine precursor in the presence of dodecanethiol.[86]

Growth in aqueous solutions

Interesting cases have also been reported in which well-known chemistry, investigated in a novel way, has led to ultrathin nanowires.

For example, the slow evaporation of ammonia at 60 °C from an aqueous $[Cd(NH_3)_4]^{2+}$ solution led to the growth of $Cd(OH)_2$ nanowires (4 nm × ~100 nm) on SiO_2 spheres (300 nm)[126] from which they can be detached later by exposure to ultrasounds. The authors postulated that the colloids of silica provided a large and negatively charged surface area that would promote the growth of nanowires of the positively charged cadmium hydroxide. This approach does not use organic ligands; presumably, the nanowires are stabilized by electrostatic repulsion. Somewhat similarly, ultrathin $W_{18}O_{49}$ nanowires were obtained when WCl_6 was dissolved in ethanol and treated in an autoclave at 180 °C. During this process, the chloride undergoes hydrolysis and forms bundles of <2 nm nanowires.[140] The hydrothermal treatment of molybdenic acid in water–dodecanethiol at neutral pH led to single-walled MoO_3 nanotubes with diameters of 6 nm.[141] The authors indicate that the reduction by dodecanethiol could be responsible for straining the individual MoO_3 layers (α-MoO_3 is known for its layered orthorombic structure) into tubes. It is possible that nanowires of other materials can be prepared by analogous approaches, but they have so far escaped our attention.

Oriented attachment



Oriented attachment is usually proposed when there is a transformation of nanocrystals into nanowires. "Oriented" typically implies that two identical facets (e.g., (111)) on two separate crystals attach, leading to the seamless welding of the two crystals. Temporary electric dipoles (quite often present in growing ionic crystals, depending on the composition of a facet[94]) are often invoked to justify the occurrence of this phenomenon, which is otherwise thought to be exceedingly rare owing to the geometric requirements of the collision. However, in some cases, we should be careful at suggesting electric dipoles for at least two reasons: (*i*) magic-sized clusters[142] (CdSe) typically possess high symmetries that are often not compatible with electric dipoles (fluctuating adhesion or dissociation of atoms could, nonetheless, lead to temporary dipoles by temporarily breaking this symmetry) or (*ii*) metallic particles, e.g., 2–3 nm Au, Pd, and Pt,[143] which cannot create permanent dipoles (this limitation is valid if the particle is indeed metallic and has conduction or freely moving electrons (Au clusters can be semiconducting)). Nonetheless, the ligands attached to the particles could bear charge and form dipoles and control aggregation.[116,144,145]

Furthermore, it is interesting to note how the size of the particles involved in the attachment can somewhat relieve the requirements of orientation. As shown in recent in situ high-resolution (HR)-TEM studies by the Alivisatos group,[115] the nonoriented attachment of small nuclei can result in a structural rearrangement to form a single crystal.

Cryo-TEM was quite remarkably and convincingly put to use to show the prearrangement of nanoparticles prior to fusion. The self-assembly and fusion of goethite (iron oxide) nanoparticles was demonstrated during aging in water at 80 °C for several days (Fig. 8).[112] The rodlike aggregates had a shape similar to that of the final goethite nanorods (even twinned rods were present). This observation, together with the aligned fringes in cryo-HR-TEM, suggested a crystallographic alignment of nanoparticles in rodlike aggregates before their final fusion occurred.

The recent work of the Ozin laboratory[58] further demonstrated that end-to-end attachment can be an effective mechanism in producing nanowires with large aspect ratios. Bi_2S_3 nanowires (1.6 nm wide) were grown in solution by reacting a slurry of bismuth citrate in oleylamine with a sulfur–oleylamine solution at 100 °C.[1] The nanowires can grow for hours without changing diameter and yet would elongate in the same time frame from a few nanometers to hundreds of micrometers. Static

light scattering determined that their conformation was worm-like (analogous to that of many semiflexible polymers) and characterized by a persistence length of 17.5 nm. The knowledge of these structural parameters allowed for the development of a kinetic model for the growth of these nanowires that explained how, while the yield of the reaction increased logarithmically with time, the number of nanowires in the solution decreased by two orders of magnitude over 2 h of growth. The model included a process of epitaxial addition to the ends of the nanowires and an end-to-end coupling of separate nanowires. The coupling process had a rate constant comparable to that of the chain coupling observed in many step-growth polymerizations. Nonetheless, the nanowires appear to be polycrystalline by X-ray diffraction.

Conclusion

In the past three years, the efforts in the synthesis and characterization of ultrathin colloidal nanowires have (*i*) yielded a multitude of new compositions, especially for metals, (*ii*) progressed our understanding of their growth, and (*iii*) produced some remarkable observations of their properties.[132,146–148] We could summarize the take away messages as follows.

Ultrathin colloidal nanowires can be produced by a number of approaches

Ligand-controlled precipitation or reduction, hydrothermal synthesis, condensation of polymer brushes, vapour–liquid–solid growth, solution–liquid–solid growth, oriented attachment, chemical transformation, and size reduction of precursor nanostructures are all viable approaches that are, in different measures, displaying flexibility in terms of the compositions they can obtain. Despite the number of approaches that are available, none of them display chemical flexibility, clear potential for scalability, and atomic-level control of the structure. Much work remains to be done.

Amine-terminated ligands are featured in a majority of the syntheses

Is this just a result of the popularity of oleylamine in academic nanochemistry laboratories or is there some more substantial aspect to it? Is the impurity of the commercially available oleylamine to be credited for these results? It would not be the first time that impurities in a ligand obtained with "technical" purity have determined the role of the ligand in nanocrystal synthesis.[149–152]

In-depth studies of the kinetics and thermodynamics of crystal nucleation and growth are sorely needed in this area

Much of the development of syntheses of these systems, especially for ligand-based approaches, still depends on serendipity and (or) screening of a broad spectrum of conditions and reagents. To this day, we have a lack of predictive power in this area (a trait that is shared to an extent with the wider field of nanocrystal synthesis). This issue seems to be dictated, among other things (e.g., purity of reagents, as discussed previously), by a substantial lack of experimental data (e.g., surface energies, binding constants, dissociation energies, and solubility constants) on which to build a quantitative and predictive framework for nanowire synthesis. When theoretical predictions exist, they are often difficult to validate quantitatively.[153] The exquisite control that crystal growers have achieved on the growth of single crystal silicon resulted from an equally exquisite knowledge of the thermodynamic variables involved in the process. Unless a similar quantitative framework is established, we believe that this area of nanochemistry is bound to be stunted in its development and in its ability to translate into real world application. A partial solution for this problem, at least for ultrathin morphologies, might be offered by approaches such as those demonstrated, for example, by Müller and co-workers[19,79] and Ritter and coworkers,[132] that build the nanowire from the bottom up as a molecular construct. In these approaches, the morphology of the structure is "hard-wired" in the molecular structure that acts as a precursor.

Topological properties are starting to emerge as a powerfully distinctive aspect of ultrathin nanowires

The increasing availability of ultrathin nanowires is resulting in the first observations of topological transformations.[59–61] The increasing quality of the materials is permitting sophisticated studies on the structure and conformation of these wires in solution.[58] The next few years should give the first definitive answers to the fundamental questions that we mentioned in the introduction (Why should we care about nanowires?): Can the topological properties of polymers be observed (and used) in colloidal inorganic crystals of near molecular dimensions? Can colloidal nanowires be produced with the atomic structures predicted by theory at near-molecular dimensions? More pragmatically, what are we going to do with these extremely interesting materials between crystals and polymers?

Acknowledgments

We thank Iowa State University for start-up funding. A.R. acknowledges the support of the Grant Agency of the Czech Republic under project No. P108/10/1250 and the Long-Term Research Plan MSM0021620857 of the Ministry of Education of the Czech Republic.

Abstract: We report an inexpensive method using solvent-swollen poly(methyl methacrylate) as a sacrificial template for mesoporous titanium oxide thin films with tunable meso/nano morphology. The conversion efficiency reaches 4.2% despite using a solid-state electrolyte, which circumvents the longevity issues of liquid electrolytes. The cells show a large short-circuit photocurrent density of 7.98 mA, open-circuit voltage of 0.78 V, and maximum conversion efficiency of 4.2% under air-mass 1.5 global illumination. At higher titania precursor ratios, nanodisk particles are formed that increase light scattering and double the efficiency over our previous reports. The tunability of the semiconductor morphology and all solid-state nature of the cells makes the method a viable alternative to existing solar cell technology.

Key words: polymer templating, TiO_2 thin film, dye-sensitized solar cell, poly(methylmethacrylate), nanodisk.

Résumé : On a mis au point une méthode peu coûteuse de préparation de films minces d'oxyde de titane mésoporeux avec une morphologie ajustable méso/nano qui fait appel à l'utilisation de poly(méthacrylate de méthyle) gonflé par un solvant comme matrice sacrifiée. L'efficacité de la conversion atteint 4,2 % même si on utilise un électrolyte à l'état solide pour contourner les problèmes de longévité des électrolytes liquides. Les cellules permettent de déceler une densité élevée (7,98 mA) de photocourant de court-circuit, un voltage de circuit ouvert de 0,78 V et une efficacité de conversion de 4,2 % sous une illumination globale de 1,5 de la masse d'air. À des rapports plus élevés de blanc de titane, il se forme des particules nanodisques qui augmentent la diffusion de la lumière et dont l'efficacité est égale au double de ce qui avait été rapporté antérieurement. La possibilité de modifier la morphologie du semiconducteur et la nature d'état complètement solide des cellules fait que cette méthode est une alternative viable à la technologie des cellules solaires existantes.

Mots-clés : matrice de polymère, film mince d'oxyde de titane, cellule solaire sensibilité par un colorant, poly(méthacrylate de méthyle), nanodisque.

[Traduit par la Rédaction]

Introduction

Since O'Regan and Gratzel's[1–5] significant breakthrough in 1991, extensive studies have been devoted to the development of dye-sensitized solar cells (DSSCs). The cells have the potential to replace conventional silicon-based solar cells due to their lower cost. They also employ, however, liquid electrolyte usually in the form of an I^-/I_3^- redox couple dissolved in an organic solvent such as acetonitrile. This configuration causes long-term practical problems including flammability, reduced stability, and evaporation and (or) leakage of electrolyte. Recent efforts have led to the development of solid-state electrolytes using room-temperature ionic liquids or iodide-containing polymers to achieve photovoltaic performance comparable to the record of 11% for liquid-electrolyte-based DSSCs.[6–8]

TiO_2 semiconductor thin-film anodes serve as the electron carrier and require sensitization by an adsorbed dye that can be excited in the visible region. While most research has focused on the nature of the dye,[9–11] electrolyte, and redox couple,[12–14] it is becoming evident that the TiO_2 morphology is equally important to determining cell properties.[15–18] Unlike the high-vacuum chemical vapor deposition (CVD) or solvothermal method,[9,19,20] the polymer templating of inorganic materials approach is facile, inexpensive, and not substrate-specific.[21–23] There have been several reports where the TiO_2 thin-film anode of DSSCs was prepared by polymer templating.[16,24,25] Caruso and co-workers[16] reported the synthesis of mesoporous TiO_2 beads with hexadecylamine as a template to achieve high-performance DSSCs of 7.20% with liquid electrolyte. Wang et al.[24] developed a method based on octadecylamine as a structure directing agent for a single-layer TiO_2 nanostructure. Their maximum conversion efficiency was 1.5%, comparatively low with respect to DSSCs but a solid-state electrolyte was used.

Although polymer swelling by organic solvents is a common phenomenon, combining this swelling with templating

effects has occurred only in recent years.[18,23,26–29] Caruso's group[27] first reported the use of agarose gels to template high-crystalline macroporous metal oxide monoliths.[28] Our group had independently been employing polymer templates to achieve a variety of titania morphologies including monoliths,[27,28] networks,[29] beads,[16,17] and thin films.[18,23] The advantage of this method is that the resultant morphology can, to some degree, be controlled through the choice of polymer, its concentration, degree of swelling, and (or) cross-linking. Studies on optimizing the swollen polymer templating method for DSSCs, however, are limited. Indeed, the detailed mechanisms were not investigated regarding the synthetic procedures and conditions.

The photoanode of DSSCs is the side from which light enters the cell, where the light traverses from the conductive working electrode towards the sensitized semiconductor layer. Multilayer TiO_2 thin films with increasing particle size and porosity from the bottom layer to the top layer leads to ~23%–48% higher conversion efficiency than the typical nonporous single layers of nanoparticles.[25,30–32] Stathatos et al.[32] reported the synergistic effect with two distinct nanoparticle layers that increased the efficiency from 4.8% to 6.9%.[29] In theory, the enhancement is due to light scattering (i.e., Mie, Rayleigh, and Raman scattering) by the top layer, which enhances the absorption of red light by the surface layer and, in turn, light harvesting.[31] Previous studies have created a DSSC multilayer photoanode with a submicrometer size Al_2O_3 and SiO_2 top layer to light scatter and facilitate light energy capture by the 400 nm particle size TiO_2 bottom layer.[31] Cao and co-workers[33–35] developed hierarchically structured ZnO aggregates 100–400 nm in size to provide both large surface area and efficient light scattering. They achieved an impressive enhancement of DSSC conversion efficiency from 2.4% to 5.4% compared with conventional ZnO nanoparticle thin films.[33–35] These light-scattering layers based on TiO_2 and ZnO lead to higher open-circuit voltage (V_{oc}),[30,32] short-circuit current density (J_{sc}),[15,25] or both.[33–36]

Herein, we describe an inexpensive one-step method to synthesize a double-layer porous anatase thin film using methyl ethyl ketone (MEK) swollen poly(methyl methacrylate) (PMMA) as a sacrificial structure directing agent. The ratio of nanodisks to nanospheres in the composite film scales with titanium precursor concentration. The nanodisks, coupled with an improved solid-state electrolyte and sensitizing dye, lead to a much higher J_{sc} and conversion efficiency over our previous reports.

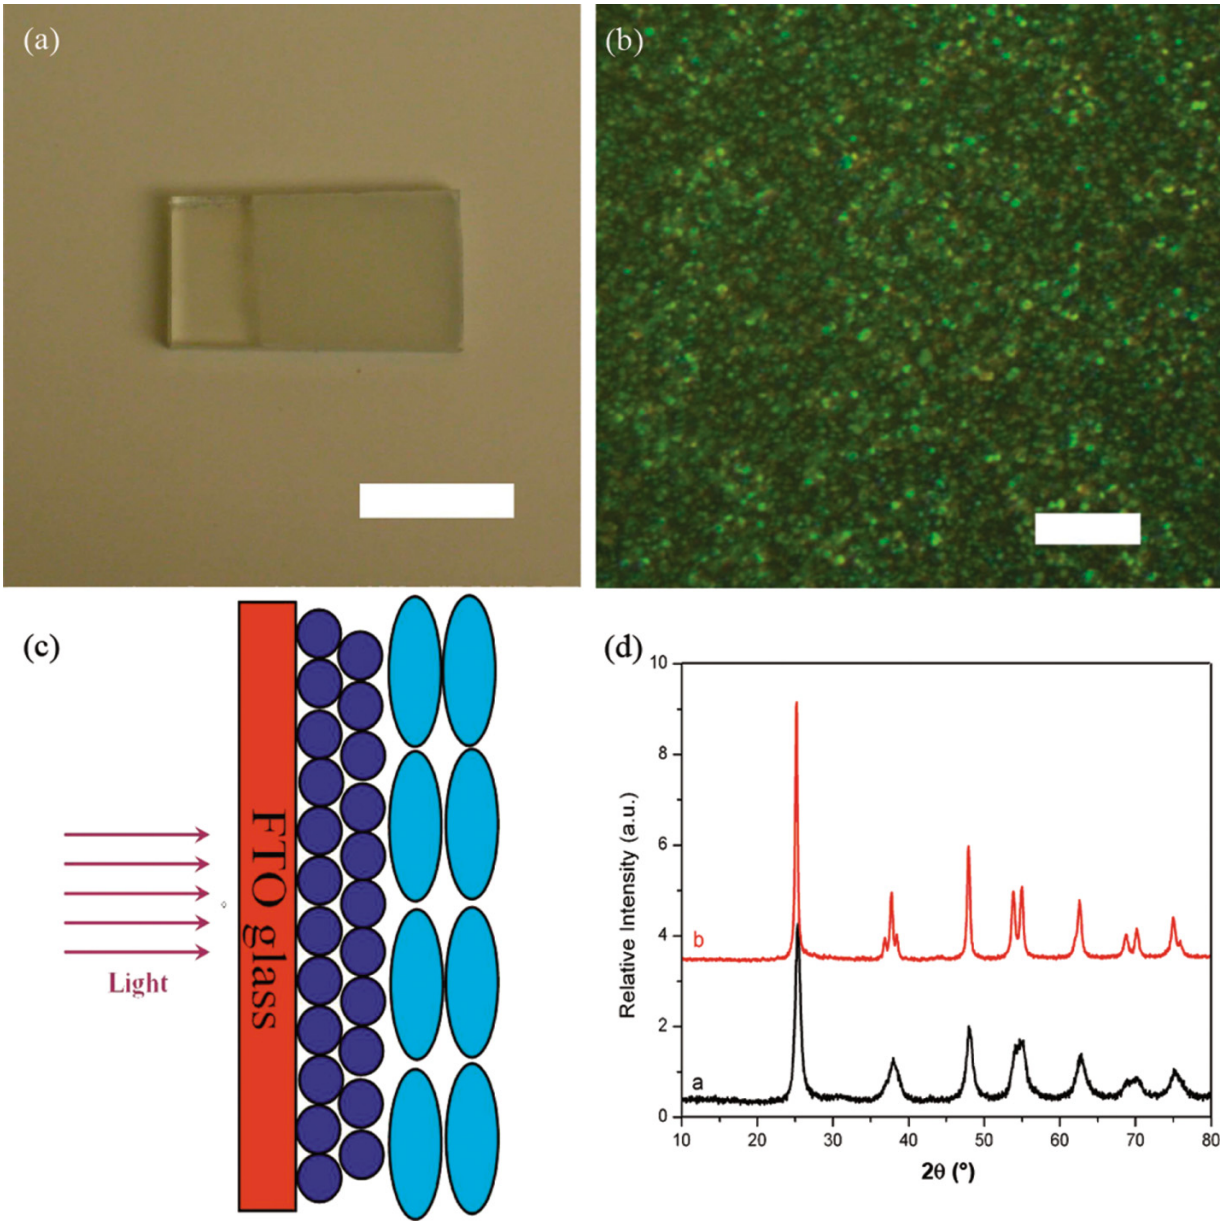
Experimental

Materials

Titanium *n*-butoxide (Alfa Aesar) and PMMA (MW 350 000, Sigma-Aldrich) were used as-purchased. MEK (Acros Organics) was used as solvent. 4,4′-Dicarboxylate-2.2′-dipyridyl (98%, Alfa-Aesar), ruthenium(III) chloride hydrate (35%–40% Ru, Acros), and ammonium thiocyanate (≥98%, Fisher Scientific) were used as received to synthesize the N3 dye according to literature methods.[37] The polymer electrolyte components were also used as-purchased without further modification: LiI (MP Biomedicals), I_2 (>99.9%, Alfa-Aesar), poly(ethylene oxide) (PEO, MW 5 000 000, Polysciences, Inc.).

Preparation of TiO_2 thin film

PMMA was first stirred in 20 mL MEK at a concentration of 10% (*w*/*v*). After stirring at 40 °C for 4–8 h, the PMMA was completely dissolved and a clear transparent solution was formed. Titanium *n*-butoxide (4%, 6%, or 8% (*w*/*v*)) was then introduced quickly and the solution sealed with parafilm and stirred at room temperature for 2–4 h. The yellow transparent solution was spin-coated on F-doped SnO_2 (FTO) glass (Hartford Glass Co.) that had been first cleaned with ethanol and deionized water and sonicated and dried under an N_2 stream. The thin film was heated in a tube furnace to 450 °C at a rate of 1 °C/min, then annealed for 2 h. Annealing removed the PMMA and resulted in the final double-layer pure-phase anatase thin-film anode. Sonication of the thin film in deionized water removed the top layer, leaving only the transparent bottom layer on the substrate.



Fabrication of solar cells

The N3 dye was used to sensitize the TiO_2 electrode by immersing the created thin film in a 0.5 mmol/L dye solution in absolute ethanol for at least 48 h. The film was then rinsed with ethanol and dried thoroughly. The electrolyte solution was prepared using reported methods[38] with slight modification: 0.01 mol/L LiI, 1 mmol/L I_2, 6 mmol/L PEO, and 0.011 mmol/L (0.0220 g) TiO_2 (Degussa P25) dissolved in 25 mL acetonitrile. The electrolyte solution was cast dropwise on the film at a temperature of 70 °C using a hot plate. The electrolyte deposition was repeated several times and the thin film became dark red in color. Finally, another FTO glass plate sputter-coated with gold was placed on top of the surface with no applied pressure. This sandwich configuration was compressed with alligator clips to facilitate penetration of the electrolyte into the TiO_2 nanostructure. The edge area of the solar cell was then sealed with epoxy to avoid contact of the electrolyte with air, thus ensuring long-term stability. Photovoltaic performance and characterization were carried out 6 h after preparation of the cell.

Instrumentation

Scanning electron micrographs (SEMs) were collected on a Hitachi S-2700 SEM. Samples for powder X-ray diffraction (PXRD) were obtained by manually removing material from the FTO glass using a razor blade. A Rigaku Americas Miniflex Plus diffractometer was scanned from 10° to 80° (2θ) at a scan rate of 2° (2θ) per minute and with a 0.04° step size, under Cu Kα radiation (λ = 1.5418 Å). The solid-state DSSCs (SDSSCs) were illuminated using a calibrated Xe lamp (660 W, Leviton Manufacturing Co.). Current–voltage (*I*–*V*) measurements were carried out with a CHI 440 electrochemical workstation. UV–vis spectroscopic studies were performed with a Hewlett-Packard Model 8452A spectrophotometer. Tapping-mode atomic force microscope (AFM) images were collected with a PicoLE SPM instrument (Molecular Imaging Inc.) to acquire the bottom layer morphology. Thermogravimetric analysis (TGA) was performed using a TA Instruments 2050 TGA by heating from 25 to 800 °C in air at a rate of 15 °C/min. Fourier transform infrared (FTIR) spectroscopy of the materials was collected on a PerkinElmer Spectrum One spectrophotometer with KBr pellets. ^{1}H NMR spectra were collected with a Varian Oxford 600 MHz

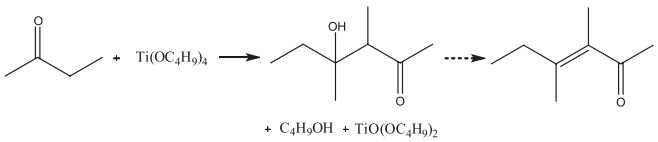
spectrometer by dissolving the sample in 700 μL of deuterated chloroform with tetramethylsilane as internal standard.

Results and discussion



The optimum concentration of PMMA in MEK was determined to be 10% (*w*/*v*). Lower ratios did not give rise to a nanodisk morphology, which facilitates light scattering (vide infra). Ratios higher than 15% resulted in overly viscous mixtures and inhomogeneous films after spin coating as well as cracks after annealing. The PXRD pattern of both top and bottom-layer thin films after annealing at 450 °C for 2 h indicated pure-phase anatase (Fig. 1*d*). This form of titania has been shown to have better photoelectrochemical properties than rutile.[4] The FTIR and TGA traces of the titania before dye sensitization and pure PMMA clearly demonstrate that the annealing removed almost all of the original polymer (Figs. 2*a* and 2*b*). The ~10% decrease in mass in the TGA of the calcined sample is likely due to physisorbed water up to 100 °C and the remainder is trace amounts of PMMA in the porous thin film. The FTIR of titania after calcination further indicates only a negligible amount of organics in the calcined thin film, with the disapearence of bands at ~3000 and ~1750 cm^{-1}, characteristic of C–H and C=O bands, respectively. Two weak broad bands located at 3500 and 700 cm^{-1} are possibly due to O–H from physisorbed water and Ti–O stretching, respectively.[39]

Fig. 2. FTIR (top) and TGA curves (bottom) in the range of 25 to 800 °C for (*a*) pure PMMA powder and (*b*) powder removed from a thin film prepared from 8% (*m*/*v*) titanium precursor and 10% (*w*/*v*) poly(methyl methacrylate) (PMMA) in methyl ethyl ketone (MEK) followed by annealing at 450 °C for 2 h.

Scheme 1. Self-condensation of 2-butanone via titanium *n*-butoxide into 5-methyl-4-hepten-3-one, 1-butanol, and titanoxane.

A possible mode of formation of the pure anatase phase thin film is self-condensation of 2-butanone (Scheme 1). Yatluk et al.[40] reacted titanium alkoxide with carbonyl compounds to form titanoxane, while MEK self-condensed into 3,4-dimethyl-3-hexene-2-one. Titanoxane is known to crystallize into anatase or rutile by annealing under air.[41,42] This pathway would explain the observed colour change of solution, from colourless to yellow after introducing the titanium precursor into 2-butanone, with the intensity increasing with stirring time. ^{1}H NMR (Supplementary data Figs. S1–S3) of neat titanium *n*-butoxide and MEK solution after introduction of the titanium precursor also support an aldol condensation reaction. Although the products provided small intergrated peak areas due to the MEK solvent as well as ketone precursor, the bands (δ 0.82, m, 2H; δ 1.10, m, 2H; δ 2.25, m, 3H; and δ 2.47, m, 3H) are characteristic of the self-condensed product of either β-hydroxycarbonyl or dehydrated self-condensed ketone. The pure titanium precursor (δ 0.92, m, 3H; δ 1.22, m, 2H; δ 1.39, m, 2H; and δ 1.52, m, 2H) have no replicate peaks in the condensation product but provide comparable intergrated area, indicating the completeness of the reaction. In addition, spin coating neat titanium precursor in an attempt to obtain a TiO_2 thin film was unsuccessful; instead amorphous organic residues were present after calcination.

Optical images and micrographs of the thin film after sintering (Figs. 1*a* and 1*b*) indicate that the surface is homogeneous and crack-free over the long range (2 cm × 1 cm). Most calcined nanoparticle TiO_2 thin films in the literature lack such long-range homogeneity and often have cracks.[43] The as-synthesized TiO_2 thin films consist of a bilayer structure (Fig. 1*c*), with the top layer characterized by SEM and the bottom layer by tapping mode AFM after sonication. SEM images of porous thin films made from 10% (*w*/*v*) PMMA and 4%, 6%, 8% (*w*/*v*) titania precursor are shown in Fig. 3. The top layer is composed of nanosphere particles and is likely responsible for enhancing the light scattering effect. The films from all percentages of titanium *n*-butoxide have the identical underlayer. A cross-sectional SEM image indicates that the thickness of thin film is ~7 μm. Though slightly thinner than the conventional P25 deposition method, this thickness is within the optimized range shown for liquid-based DSSCs cells.[1,37]

A nanodisk morphology is observed for the samples using higher concentrations of titania precursor (6%, Fig. 3*b*; and 8%, Fig. 3*c*). This new morphology not observed before for DSSCs is in a higher concentration for the 8% sample. The nanodisks all show a similar thickness of ~50 nm and a round shape with an average diameter of ~500 nm. The nanosphere morphology, however, is still present and mixed with the nanodisks. Although the percentage of nanodisks increases with Ti *n*-butoxide concentration, the nanosphere particle size shows little change, with an average size of ~150 nm. One possible explanation for this new type of nanodisk morphology is that our system uses swollen PMMA with limited interior channels or pores for the growth of the metal oxide. Higher concentrations of titania precursor lead to a more complete filling and replica of the original channel space of the swollen PMMA. This pathway would also account for the lack of nanodisk formation in our previously reported experiments with 2%–8% PMMA, which gave only nanospheres because of the larger swollen volume.

The nanodisks likely possess distinct optical properties from typical nanospheres. Specifically, increased light scattering is possible, which would lead to enhanced photoelectrochemical performance.[31,32] UV–vis spectra of the three mentioned calcined TiO_2 thin films before dye loading are shown in Fig. 4. The energy difference between the TiO_2 valence and conduction bands is well-known to lie between 3.0 and 3.3 eV,

Fig. 3. SEM images of the top TiO_2 layer synthesized by 10% (*w*/*v*) poly(methyl methacrylate) (PMMA) and (*a*) 4% (*w*/*v*) titanium *n*-butoxide, (*b*) 6% (*w*/*v*) titanium *n*-butoxide, (*c*) 8% (*w*/*v*) titanium *n*-butoxide in methyl ethyl ketone (MEK; scale bar: 1 μm). The inset of (*c*) is a closer side image of a nanodisk (scale bar, 500 nm).

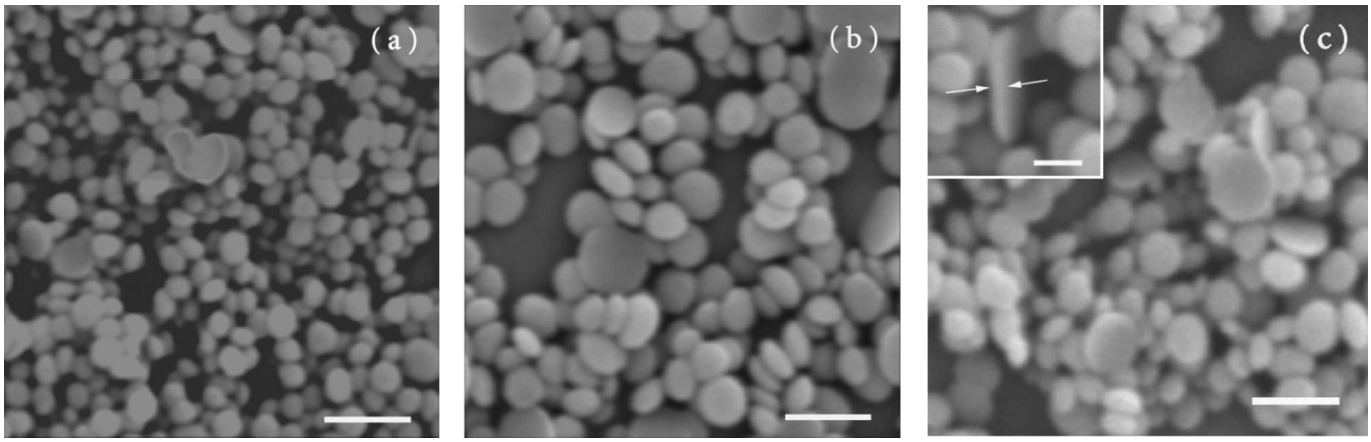

Fig. 4. UV–vis spectra of TiO_2 thin films synthesized by 10% (*w*/*v*) poly(methyl methacrylate) (PMMA) and the shown percentage (*w*/*v*) of titanium *n*-butoxide in methyl ethyl ketone (MEK). The spectrum for bare glass is shown for comparison.

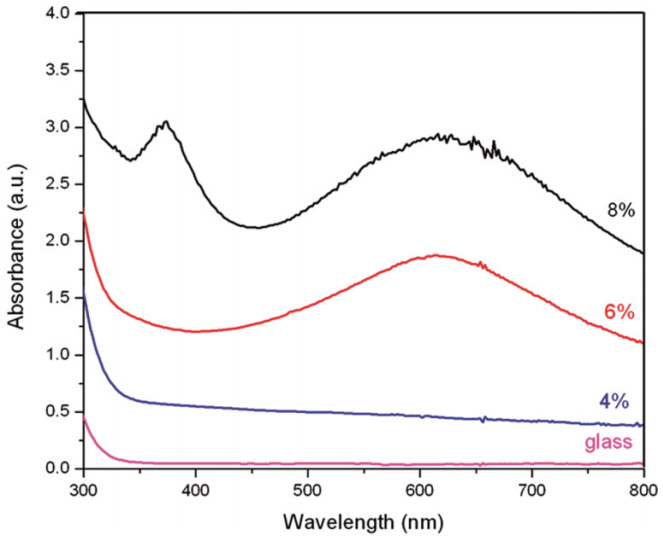

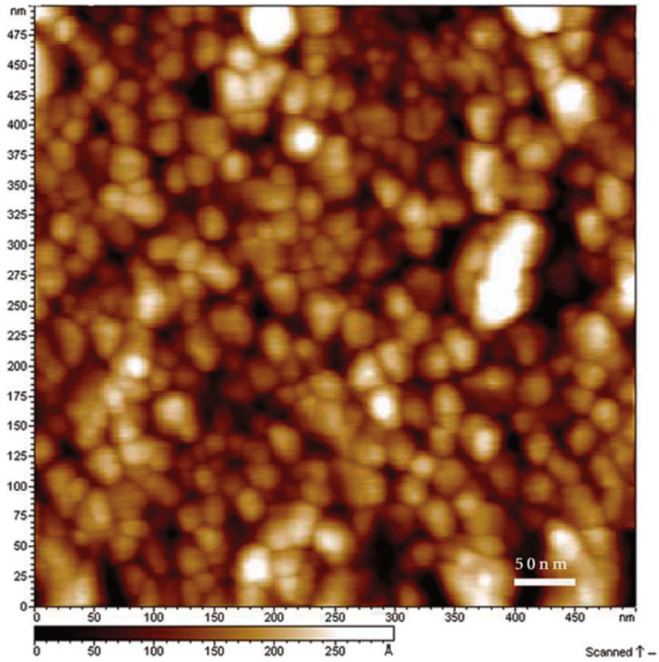

Fig. 5. Tapping-mode atomic force microscope (AFM) image of the bottom layer of the porous TiO_2 thin film from 8% Ti-butoxide (scale bar, 50 nm).

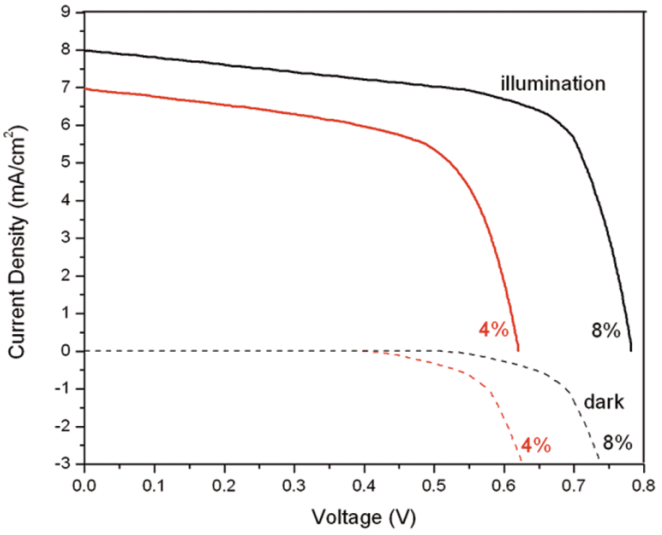

corresponding to a wavelength range of 375–400 nm. Therefore, no absorption occurs in the visible region above 400 nm and dye sensitization is required. Increased absorption is observed in the 500–750 nm wavelength range as the titanium *n*-butoxide concentration is increased. Ferber and Luther used Mie theory to account for the light-scattering ability of the top layer of bilayer DSSCs.[43] The surface particles enhance the photon scattering mainly in the 500–750 nm region. Nanodisk scattering increases the light path length within the top layer, thus enhancing light adsorption and contributing to the higher photocurrent density.[43] The stronger light-scattering effect of nanodisks has already been studied for WO_3, where the absorption profile from 400 to 500 nm is enhanced over that of a WO_3 nanosphere thin film. Moreover, ultrathin WO_3 nanodisks extend the absorption to the near-IR region of 500–780 nm.[44,45] Therefore, it is reasonable to ascribe our increased TiO_2 thin film red light absorption to the presence of the nanodisk morphology and its scattering effect. The absorption band occurring from 350 to 400 nm at 8% Ti *n*-butoxide is due to an interband transition, as discussed earlier.[46]

The bottom nanostructure layer was analyzed by tapping-mode AFM (Fig. 5). The top layer was first removed by sonication in deionized water, leaving only the transparent bottom layer on the substrate. The bottom layer image indicates an average nanoparticle size of ~20 nm. The average sizes of the nanoparticles in the top and bottom layers as determined by the Scherrer eq. ($0.9\lambda/(\beta \cos \theta)$, where λ is the X-ray wavelength, β is the peak width at half height, and θ is the Bragg angle) of the strongest PXRD peak (Fig. 1*d*, red and

Fig. 6. Photocurrent density–voltage curves for the TiO_2 thin film (solid lines) prepared from 4% (*w*/*v*) and 8% (*w*/*v*) Ti *n*-butoxide, sensitized by N3 dye and coated with a polymer electrolyte composed of poly(ethylene oxide) (PEO), TiO_2 (Degussa P25), LiI, and I_2 under 100 W/cm^2 (AM 1.5 illumination). Dark conditions (broken lines) are also shown for comparison.

black, respectively) were 145.2 and 22.0 nm, respectively. Both the top and bottom layers are therefore crystalline, with the calculated particle size matching well with the observed particle size (Figs. 3 and 5). The nanocrystalline TiO_2 bottom layer with ~20 nm particle size increases the surface area up to 1000-fold over that of the top layer, for greater adsorption of dye.[4,43] The more compact array of the underlayer serves to also minimize contact of the electrolyte with the anode conductive glass. This separation likely retards the back transfer of electrons, which is known to be the main pathway for electron–hole recombination and low conversion efficiency of DSSCs.[14,47,48]

Considering the higher ratio of nanodisks and increased homogeneity, the optimized sample from 10% PMMA and 8% titanium *n*-butoxide was tested for *I*–*V* measurements and a sample with 4% titanium *n*-butoxide was tested for comparison (Fig. 6). Under an illumination of AM 1.5 (100 mW/cm^2), the nanodisk cell from 8% titanium precursor exhibits V_{oc} = 0.78 V, J_{sc} = 7.98 mA/cm^2, a fill factor of 67.2%, and the overall light-to-electricity efficiency reaches 4.2%. The corresponding cell from 4% titania, however, reaches V_{oc} = 0.62 V, J_{sc} = 6.99 mA/cm^2, a fill factor of 61.9%, and an overall conversion efficiency of only 2.7%. The cell with the higher ratio titanium precusor exhibits 25% higher open-circuit voltage performance, likely because of the longer electron residence time in the larger distinct particle sizes, further increasing the Fermi level of the photoelectrode semiconductor. The higher V_{oc} is also likely due to the larger particle size and higher crystallinity, which are known to limit electron–hole recombination. Usually, electron trapping would also occur and lower the current density. It seems the better light-harvesting ability of our nanodisk morphology overcomes this disadvantage, for a slightly enhanced current. The improved current density might be also ascribed to the higher adsorption of dye owing to a more homogeneous structure and pore space versus that of the thin film made from 4% titanium precursor.

Our previous report used a lower ratio of 8% PMMA and 6% Ti *n*-butoxide, a *meso*-tetra(4-carboxyphenyl)porphyrin dye and electrolyte containing polyethylene glycol, KI, and I_2 without P25 inorganic nanoparticle filler (Table 1).[18] The *I*–*V* curve for the present report shows an increase in J_{sc} from 3.02 to 7.98 mA/cm^2, but a decrease of V_{oc} from 1.18 to 0.78 V. The increase in current density is likely due to several factors (*i*) the nanodisk morphology leads to more effective light scattering, thereby enhancing light harvesting and limiting the back transfer of electrons; (*ii*) the P25 TiO_2 nanoparticles reduce the crystallinity of the PEO electrolyte for a more effective charge transport;[38] (*iii*) the N3 dye has a stronger absorption ability in the 350–650 nm region, with absorbance greater than 0.5 in 0.5 mmol/L ethanol solution. The latter two points are also backed up by the current improvement from 4% titanium precursor compared with our previous cells. Our previous *meso*-tetra(4-carboxyphenyl)porphyrin dye has weaker absorption from 350 to 500 nm. Therefore, the N3 dye also contributes to this effective optimization for light-harvesting efficiency by an SDSSC.[30,37,48]

The open-circuit voltage arises from the difference between the Fermi level of the TiO_2 semiconductor and the electrolyte redox potential. The lower V_{oc} for the current data is likely due to the smaller particle size of the top layer, which is ~150 nm compared with ~500 nm in our earlier report.[18] The closer match of the two layers for the current report likely increases the lifetime of charge carriers and raises the Fermi level.[32] Despite the relatively slight decrease in V_{oc}, J_{sc} significantly increases from 3.02 to 7.98 mA/cm^2. This enhancement was achieved by the optimization of the film morphology, particle size, and improvement in the dye and electrolyte, greatly increasing light-to-electricity conversion efficiency.

Conclusion

A simple swollen polymer method has been developed to fabricate an inexpensive large-area SDSSC with a new record efficiency of 4.2%. This test was carried out under a large sensitizing area (2 cm^2) and only requires the commercially available solid-state polymer PEO to achieve efficient photovoltaic performance. The rare nanodisk morphology of the TiO_2 thin films contributes to high scattering of low-energy visible light for enhancing light absorption and photovoltaic performance. The fabrication method is low cost and far more reliable and tunable than the conventional P25 backblading method. We are currently working on further optimizing the porosity and thus performance of the thin films through the choice and concentration of both inorganic precursor and polymer.

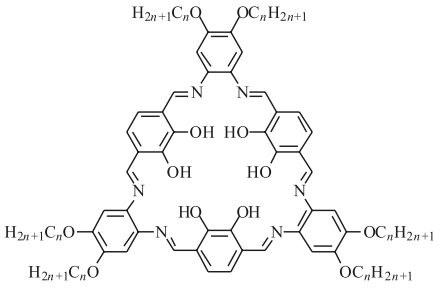
Abstract: Schiff-base macrocycles **1**, which have a crown ether-like interior, form ionic nematic lyotropic liquid crystals in various organic solvents when functionalized with long alkoxy substituents and complexed to diverse ammonium and alkali metal salts. From X-ray diffraction and transmission electron microscopy studies, and by comparison with the organization of macrocycles functionalized with shorter chains, these macrocycles assemble into lyotropic liquid crystals where the macrocycles are stacked and the cation is included in their interiors.

Key words: macrocycle, supramolecular, liquid crystal, Schiff base, lyotropic.

Résumé : Les macrocycles **1**, formés à partir de bases de Schiff, qui comportent une partie intérieure semblable à un éther couronne et qui ont été fonctionnalisés avec des substituants à longues chaînes alkoxy, forment des cristaux liquides lyotropes nématiques et ioniques dans divers solvants organiques et ils se complexent à divers sels d'ammonium et de métaux alcalins. Sur la base d'études par diffraction des rayons-X et de microscopie de transmission d'électron ainsi que par comparaisons avec l'organisation de macrocycles fonctionnalisés avec des chaînes plus courtes, on a pu observer que ces macrocycles s'assemblent en cristaux liquides lyotropes dans lesquels les macrocycles sont empilés et le cation est inclus à l'intérieur.

Mots-clés : macrocycle, supramoléculaire, cristal liquide, base de Schiff, lyotrope.



[Traduit par la Rédaction]

Introduction

Liquid crystals (LCs) play an important role in a variety of applications, notably temperature sensors[1–4] and displays.[5–8] These applications utilize thermotropic LCs, which form a temperature-dependent liquid crystalline phase between the crystalline state and the isotropic melt. A large number of organic and inorganic substances have been investigated that exhibit thermotropic liquid crystallinity.[9–13]

Lyotropic LCs, on the other hand, form liquid crystalline phases in solution where the molecules organize into micelles, nematic LCs, hexagonal LCs, and other phases.[14] Typically, lyotropic LCs can be prepared in water with amphiphilic molecules (surfactants) that have a polar headgroup and a hydrophobic tail.[15–19] Soaps, for example, form lyotropic LCs in water. Numerous compounds that exhibit lyotropic mesomorphism have been found to have good anisotropic ionic conductivities.[20] G-quartets are known to assemble into rigid rods in aqueous solution that organize into lyotropic LC phases.[21] However, lyotropic LCs detected in organic solvents are rare, but are promising as an organizational method for constructing supramolecular materials.[22–25]

Here we report novel lyotropic LCs formed by complexes between macrocycles **1c–1e** (and mixtures) and various ammonium or alkali metal salts. These species form LCs in chloroform, toluene, and chlorobenzene. Based on an amphiphilic ionic columnar structure, these mesogens represent an unusual motif for observing liquid crystallinity. These new LC phases may serve as templates for constructing ion-conducting lyotropic phases or new mesoporous materials formed in non-aqueous solvent.

Fig. 1. Polarized optical micrographs of chloroform solutions of NH_4BF_4 with macrocycles (*a*) **1e**, (*b*) **1d**, and (*c* and *d*) **1c** (1:1 ratio of **1**–NH_4^+) show typical textures observed for the liquid crystal (LC) samples under crossed polarizers. Samples were viewed at room temperature between a slide and a cover slip as the solvent evaporated from samples that were approximately 10 wt % macrocycle **1**.

Experimental

General procedures

All reagents were used as received unless otherwise stated. Ammonium tetrafluoroborate, lithium tetrafluoroborate, sodium tetrafluorobroate, and sodium tetraphenylborate were obtained from Sigma-Aldrich. Chlorobenzene, HPLC grade chloroform, and toluene were obtained from Fisher Scientific. The syntheses of Schiff base macrocycles **1c**–**1e** were carried out according to literature procedures.[26]

Equipment

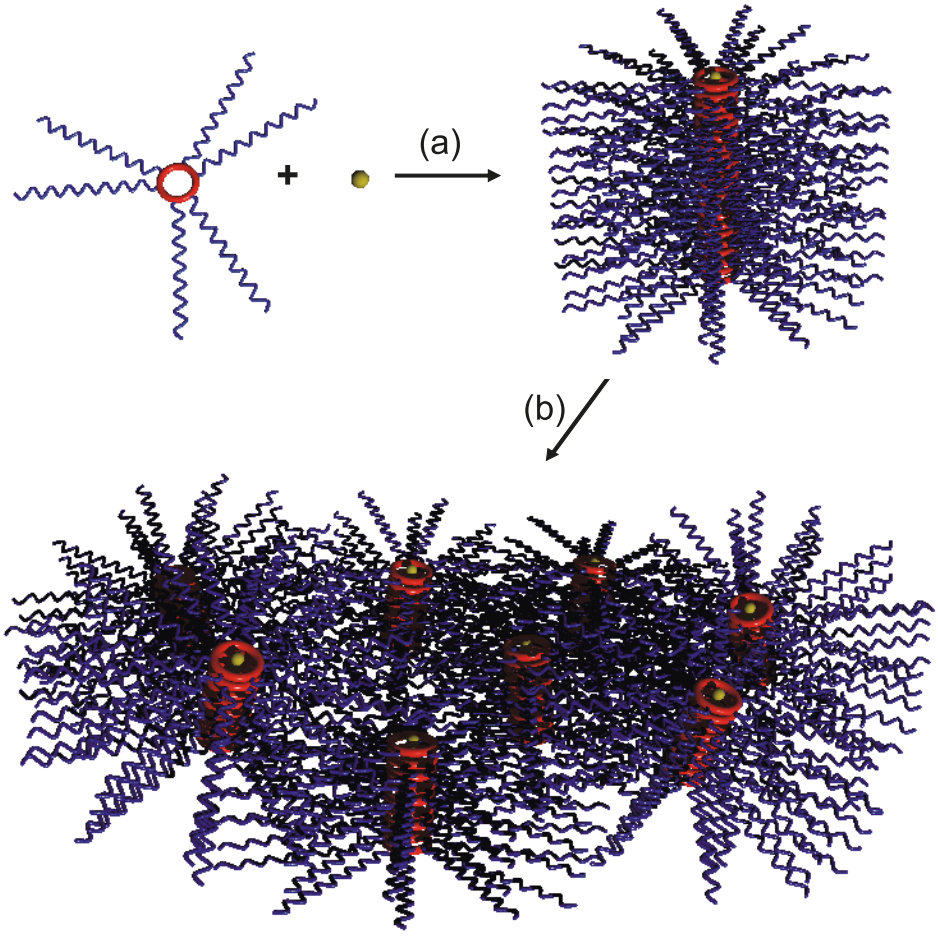
Polarizing optical microscopy (POM) studies were performed with an Olympus BX41 microscope equipped with a digital camera. The textures were identified by comparison with literature references and the book *Textures of liquid crystals*.[27] We have not been able to find a good example of the "mesh" texture as shown in Figs. 1*c* and 1*d*, but we believe it is also from the nematic phase. X-ray diffraction (XRD) data of the solution samples were obtained on a D8 Discover X-ray diffractometer equipped with GADDS, in which chloroform solutions at a concentration of approximately 40 wt % macrocycle were contained in sealed 0.2 mm thin-walled special glass capillary tubes manufactured by Charles Supper. Powder X-ray diffraction (PXRD) data were recorded on a D8 Advance powder X-ray diffractometer by drop-casting the sample solutions onto silicon plates. IR spectra were obtained neat with a Thermo Nicolet 6700 FT-IR equipped with ATR.

General sample preparation of lyotropic LCs for POM imaging

The Schiff base macrocycle (i.e., **1c**–**1e**) (1.5 mg) was dissolved in chloroform (1 mL) and was mixed with an excess amount of ammonium or alkali metal salt (50 mg) for ~5 s to give a dark red solution. The solution was allowed to stand for 5 min before the removal of the excess salts by filtration through a short pad (5–10 mm) of cellulose (Kimwipe). The dark red solution was then concentrated through evaporation before drop-casting onto the microscope glass slides for viewing under POM to observe the liquid crystalline textures. We observed lyotropic liquid crystallinity at about 15 wt % macrocycle in samples that were prepared on a larger scale. The optical micrographs obtained under crossed polarizers were persistent over a broad concentration range.

Results and discussion

Ion-induced lyotropic liquid crystallinity from Schiff base macrocycles 1c–1e



We previously reported a series of conjugated triangular [3+3] Schiff base macrocycles (**1**) having two peripheral alkoxy substituents on each phenylenediimine unit.[26] The macrocycles with butyloxy and hexyloxy side chains (macrocycles **1a** and **1b**) self-assemble into hierarchically organized nanofibers upon the addition of alkali metal or ammonium salts,[28] with the cations situated in the center of a column of macrocycles. This polycationic macrocycle assembly is charge balanced by counteranions located outside of the columnar aggregates.

As macrocycles **1a**–**1e** have the same symmetry (D_{3h}) as the well-known family of thermotropic mesogens, hexaalkoxytriphenylenes,[29,30] we explored whether macrocycles **1** could form thermotropic liquid crystalline phases. Our attempts to impart liquid crystallinity upon macrocycles **1** simply by introducing long alkyl chains led to substances with reduced melting points, but no liquid crystallinity.[26]

Chloroform solutions of macrocycle **1e** failed to show any birefringence, even when concentrated. However, when chloroform solutions of macrocycle **1e** with NH_4BF_4 (1:1) were viewed under crossed polarizers with a POM, to our surprise, we observed a texture characteristic of a nematic LC (Fig. 1*a*). The lyotropic mesomorphism was apparent at a concentration of approximately 10 wt % and higher. In the LC phase, the samples were relatively viscous but fluid.

Based on our results with the shorter chain analogues (macrocycles **1a** and **1b**),[31] we postulate that upon the addition of NH_4BF_4, macrocycle **1e** stacks and binds the cation in its interior, forming a polyelectrolyte. This is supported by ^{1}H NMR data; when NH_4BF_4 was added to macrocycle **1e**, we observed substantial line broadening and shifting as observed with macrocycle **1b**.[32–34] Electrospray ionization mass spectrometry (ESI-MS) of macrocycle **1e** with NH_4BF_4 showed the molecular ion as the dominant peak, but also displayed peaks corresponding to oligomers (dimers and trimers). In addition, elemental analysis of the aggregates indicated that their composition was about three macrocycles to four ammonium salts (a ratio of 1:1.3 macrocycle **1e**–NH_4BF_4). In the case of macrocycles **1a** and **1b**, the assemblies subsequently organize into insoluble fibers through electrostatic interactions.[28] With longer chains present in macrocycle **1e**, however, the macrocycles are more soluble and instead form a lyotropic LC in solution. Unlike macrocycles **1a** and **1b** with shorter alkoxy chains that allow the columnar aggregates to pack into nanofibers, long dodecyloxy chains on macrocycle **1e** render the columnar aggregates more soluble (Fig. 2). The macrocycles retain the one-dimensional ion-induced columnar assembly and organize with some long-range orientational order in terms of the alignment of the columns.

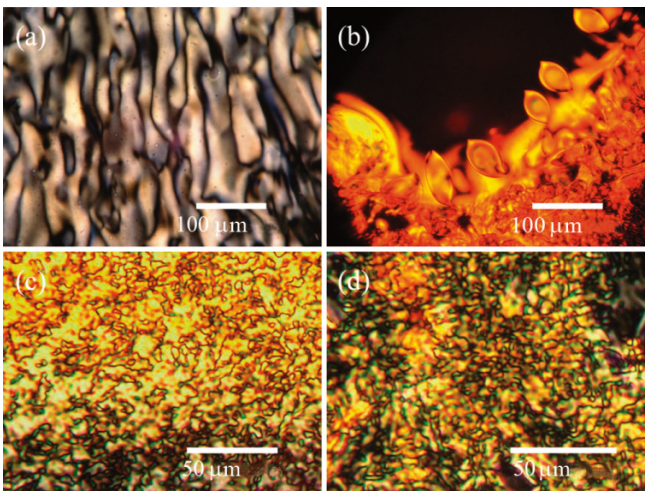


Fig. 2. Model for the ion-induced assembly leading to the formation of lyotropic liquid crystals (LCs). (*a*) In solvent, macrocycles **1c**–**1e** combine with cations (yellow spheres) to form a 1-D polymeric structure where the macrocycles are bridged by the cations. (*b*) Upon concentration, these 1-D assemblies organize into a nematic LC phase where they retain orientational order. The counteranions have been omitted for clarity.

Addition of NH_4BF_4 to macrocycles **1c** and **1d**, having octyloxy and decyloxy chains, respectively, also gave birefringent chloroform solutions. The optical micrograph of macrocycle **1d** with NH_4BF_4 displays a texture (Fig. 1*b*) that is similar to that observed for macrocycle **1e** and characteristic of a nematic mesophase. Macrocycle **1c**, however, showed textures in chloroform possibly corresponding to both smectic and nematic mesophases, as shown in Figs. 1*c* and 1*d*. One texture, which may be of a smectic phase, was observed around the outer area of the sample droplet, whereas the nematic phase occurred at the center (it is possible that both textures correspond to the nematic phase). The columnar aggregates formed from macrocycles **1** appended with octyloxy substituents (i.e., macrocycle **1c**) appear to retain higher orientational and positional order than those of macrocycles **1d** and **1e**, represented by the smectic mesogenic texture. From these experiments, the transition between nanofibers and LCs occurs between hexyloxy and octyloxy substituents for the macrocycles.

To investigate the scope of mesophase formation in this system, we varied the ions and the solvent. When macrocycle **1e** was combined with $LiBF_4$ or $NaBF_4$ in chloroform, nematic mesophases were identified by POM (Figs. 3*a* and 3*b*). In

Fig. 3. Polarized optical micrographs of macrocycle **1e** observed under crossed polarizers at room temperature. (*a*) $LiBF_4$ in chloroform, (*b*) $NaBF_4$ in chloroform, (*c*) NH_4BF_4 in toluene, and (*d*) NH_4BF_4 in chlorobenzene.

addition, macrocycle **1e** was mixed with NH_4BPh_4 to observe the effect of counteranions on the morphology of the LC phase. Surprisingly, even with the bulky BPh_4^- anion, liquid crystallinity was observed. Furthermore, we prepared macrocycle **1e** with NH_4BF_4 in different solvents, namely toluene and chlorobenzene (Figs. 3*c* and 3*d*). Once again, nematic mesophases were imaged by POM and the textures are similar to the one prepared in chloroform. These results show that the lyotropic mesomorphism is robust and can be observed with diverse cations, anions, and organic solvents.

Whereas XRD is a crucial method for phase identification of thermotropic LCs, it is much more problematic with lyotropic LCs, where the low concentration and greater disorder leads to very weak X-ray scattering. Efforts to obtain XRD from solutions of NH_4^+ complexes of macrocycles **1c**–**1e** in chloroform (where they are liquid crystalline) have been a challenge owing to insufficient diffraction. However, after numerous attempts of varying the concentration of the chloroform solution of macrocycle **1c** with NH_4BF_4, a diffraction pattern with sufficient signal intensity was obtained at a concentration of approximately 40 wt % macrocycle **1c** (Fig. 4*a*). The integration of the XRD pattern shows a broad diffraction peak centered near 3.7° 2θ. To obtain diffraction patterns with higher intensity, we undertook XRD studies of the films prepared from the dried LC samples.[35] Although these are not the lyotropic LCs themselves, XRD of the films should give an indication of the order present in the sample prior to drying. XRD patterns of dried samples of macrocycles **1c**–**1e** with NH_4BF_4 all displayed one intense broad diffraction peak with d spacing of approximately 24.8, 25.4, and 26.9 Å, respectively (Fig. 4*b*). Since the dried film of macrocycle **1c** with NH_4BF_4 has a diffraction peak with 2θ very close to that of the liquid sample, we believe that the films have a similar structure to the lyotropic LC from which they were formed. From rough modelling of a hypothetical columnar assembly (Supplementary data Fig. S1), this diffraction peak corresponds quite well to the expected interstack separation rather than intermolecular separation within the stack. As well, the increase in the d spacing with increasing chain length agrees with this interpretation. The absence of additional diffraction peaks is also consistent with a poorly organized structure, as expected for a nematic LC. XRD of films prepared from the LC phases of macrocycle **1e** with $LiBF_4$ and $NaBF_4$ in chloroform was also measured for comparison with the diffraction pattern of the NH_4BF_4 sample. All three XRD patterns have a diffraction peak at 26.9 Å d spacing (Fig. 4*c*), supporting the assignment of this peak as owing to interstack organization, since this is not expected to show a metal dependence. The patterns for the $LiBF_4$ and NH_4BF_4 show only one peak and are virtually identical. Interestingly, additional peaks are observed in the XRD pattern of the $NaBF_4$ sample, indicating that the columnar aggregates are more ordered with the incorporation of Na^+. Quite possibly, the additional ordering is only present upon solidification. We have no explanation for this discrepancy, but perhaps the Na^+ interacts with the interior of the macrocycles in a different way that facilitates improved order.

As the ESI-MS and NMR data suggested that the macrocycles aggregate in solution with the presence of salts, we investigated their supramolecular assembly in the solid state by transmission electron microscopy (TEM). Figure 5 shows the morphology of a dried sample of macrocycle **1c** with

Fig. 4. (*a*) Left: X-ray diffraction (XRD) pattern of macrocycle **1c** with NH_4BF_4 in chloroform (approximately 40 wt %). Right: Integration of the outlined area. Dried XRD patterns of (*b*) macrocycles **1c**–**1e** with NH_4BF_4 and (*c*) macrocycle **1e** with NH_4BF_4, LiBF4, and $NaBF_4$.

NH_4BF_4. Fibers with diameters of approximately 25 nm and lengths of hundreds of nanometers were observed. This phenomenon is attributed to the macrocycles forming one-dimensional polyelectrolytes with the cations binding to the interior and the counteranions of the salts surrounding on the outside, which further organize into nanofibers through electrostatic interactions. This self-assembly is identical to that of the shorter chain analogues (macrocycles **1a** and **1b**),[28] despite the formation of lyotropic LCs for macrocycles **1c**–**1e**. However, the fibers of macrocycle **1c** with NH_4BF_4 are narrower and shorter than those prepared from the shorter chain analogues (macrocycles **1a** and **1b**).

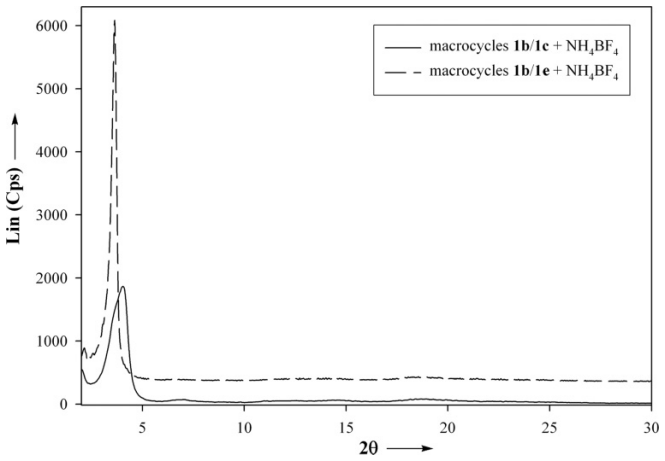
Ion-induced lyotropic liquid crystallinity from the mixtures of Schiff base macrocycles 1b/1c and 1b/1e



As noted, addition of alkali metal or ammonium salts to macrocycle **1** functionalized with short and long alkoxy substituents leads to the formation of nanofibers and lyotropic LCs, respectively. We were interested to know what would happen if the two types of macrocycles were combined in the presence of salts in solution. We performed the investigation by observing a chloroform solution of macrocycles **1b** and **1c** (1:1 mixture) that was combined with excess NH_4BF_4.[36] The solution sample displayed an oily streak LC texture when viewed by POM as shown in Fig. 6*a*. The texture observed for the mixture is different than that obtained from macrocycle **1c** alone with the ammonium salt. It is noteworthy that a helical texture was observed in segments of the LC (Fig. 6*b*). The occurrence of these textures was unexpected, and the difference in texture suggests that the incorporation of macrocycle **1b** led to different packing behavior among the polyelectrolytes when compared with that of macrocycle **1c** alone with NH_4BF_4. Moreover, the optical micrographs of the chloroform solution containing a 1:1 mixture of macrocycles **1b** and **1e** with NH_4BF_4 (Figs. 6*c* and 6*d*) also display different textures than the solution sample with macrocycle **1e** alone. Surprisingly, a fingerprintlike texture (Fig. 6*d*) could be seen in the early stage of the observation after transferring the chloroform sample onto the microscope glass slide, but the lines slowly merged together and eventually disappeared because of the flow of the LC.

We further examined the dried samples of the NH_4^+ complexed mixtures by TEM. The images (Figs. 7*a* and 7*b*) reveal that the morphology of macrocycles **1b** and **1c** with NH_4BF_4 resemble the morphology observed for the sample with macrocycle **1c** alone (Fig. 5). On the other hand, for the sample of the NH_4^+ complex of macrocycles **1b** and **1e**, two textures, fingerprintlike and nanofibrous, could be seen under TEM (Figs. 7*c* and 7*d*). As illustrated in Fig. 7*c*, the spacing between the black lines of the fingerprintlike region is 207 ± 42 nm (based on a count of 75). Figure 7*d* shows that the fibers have diameters of approximately 90 nm and lengths of hundreds of nanometers. The morphological studies of the dried mixtures support the formation of columnar assemblies from the addition of NH_4BF_4 to a mixture of two macrocycles.

The mixture of macrocycles **1b** and **1c** with NH_4BF_4 was further analyzed by ESI-MS. A mass-to-charge ratio corresponding to one macrocycle **1b** and one macrocycle **1c** with NH_4^+ was detected, along with the signals of the NH_4^+-complexed homodimers of the respective macrocycles. The same ESI-MS features were observed from the sample of macrocycles **1b** and **1e** combined with NH_4BF_4. This data supports co-aggregation of the two macrocycles in the electrostatic assembly rather than phase separation.

Fig. 8. X-ray diffraction (XRD) patterns of the dried mixtures of macrocycles **1b/1c** and macrocycles **1b/1e** with NH_4BF_4.

XRD investigations were undertaken on the chloroform solutions of the NH_4^+ complexed mixtures. Despite repeated efforts, we were unable to obtain satisfactory data on the solutions, even when concentrated. Instead, we performed the XRD analyses on dried samples of the mixtures to gain stronger diffraction signals (Fig. 8). The XRD patterns of both dried mixtures only show one intense peak at low angle with d spacing of approximately 21.9 and 24.4 Å for the NH_4^+ complexes of macrocycles **1b** with **1c** and **1e**, respectively. The d spacing of each mixture, which reflects the distance of the interstack separation, is expected to be larger than that of the macrocycle with shorter substituents and smaller than that of the longer alkoxy chain component because each mixture originates from macrocycles **1b** with **1c** or **1e**. The PXRD data agree with this postulation, in which the values of the mixtures lie between the measured d spacing of macrocycles **1b** (20.2 Å), **1c** (24.8 Å), or **1e** (26.9 Å) alone with NH_4BF_4.

Conclusion

In summary, we have discovered unusual lyotropic LCs that form in nonpolar organic solvents such as chloroform, toluene, and chlorobenzene. We postulate that these mesogens are formed by ion-induced columnar assemblies of a Schiff base macrocycle–cation complex, where they have a charged interior surrounded by hydrophobic alkyl substituents. The polyelectrolytic columns retain a degree of orientational ordering in solution, leading to lyotropic mesomorphism. This ion-induced assembly is reminiscent of the organization observed in self-assembled G quartets with alkali metals,[22] but, to the best of our knowledge, is unprecedented in macrocycle chemistry. Electrostatic self-assembly of macrocycles into lyotropic mesogens may be a useful design principle for constructing organized materials that can function as ion-conducting materials or as templates for nanostructures (for example, after cross-linking of polymerizable substituents on the macrocycles). We are now pursuing these directions.

Abstract: We report a simple method to pattern wetting properties on thin films of periodic mesoporous organosilica (PMO). A hydrophobic methane PMO thin film was covered by masks and exposed to oxygen plasma to make the unmasked area hydrophilic. The wettability patterns could be revealed only when the films were immersed in water or exposed to moisture. We expect that our method would extend the utility of PMO to such areas as sensing and information security.

Key words: wetting, plasma, mesoporous materials, thin film.

Résumé : On a mis au point une méthode simple de déterminer les propriétés de mouillage de films minces d'organosilice mésoporeux périodique (OMP). Un film mince d'OMP de méthane hydrophobe a été recouvert de masques et exposé à un plasma d'oxygène pour produire des surfaces hydrophiles non masquées. Les patrons de mouillage ne peuvent être mis en évidence que lorsque les films sont immergés dans l'eau ou exposés à de l'humidité. On a bon espoir que cette méthode permettra d'étendre la plage d'utilité des OMP aux domaines de la détection et de la sécurité de l'information.

Mots-clés : capacité de mouillage, plasma, matériaux mésoporeux, film mince.

[Traduit par la Rédaction]

Introduction

Spatially patterned porous materials combine the characteristics of a pattern, such as shape and dimensions, with the characteristics of a porous material, such as high surface area and large pore volume, to deliver functions that promise applications in sensors, catalysis, photonics, displays, microfluidics, and electronics.[1–6] Patterns of ordered mesoporous materials have been produced using self-assembled monolayers (SAMs),[2,7,8] photolithography,[4] micromolding in capillary,[1,6] direct writing,[5] ink-jet printing,[5] and scanning electrochemical microscopy.[9] These patterns are produced either by selectively generating materials in the patterned area or by selectively removing materials from the nonpatterned area. In other words, they are distinguished by the physical presence or absence of materials. Here, we report a method to create patterns of different wettability on thin films of mesoporous organosilica. This method creates patterns of properties, in contrast to patterns of materials. These patterns only reveal themselves when the films are immersed in water or exposed to moisture. We expect our method could lead to applications in sensing and information security and also could provide a convenient platform for fundamental studies in wetting dynamics and nanofluidics.

Experimental

Materials

Bis(triethoxysilyl)methane was purchased from Gelest. Cetyltrimethylammonium chloride (CTACl) 25 wt % solution in water was purchased from Sigma-Aldrich. Reagents were used as received.

Synthesis of methane periodic mesoporous organosilica (PMO) thin films

The synthesis was performed according to a previous report.[10] Briefly, bis(triethoxysilyl)methane was added into a solution of CTACl, HCl, water, and ethanol with moderate stirring. The molar ratio of the reactants was

Fig. 1. Scheme of the patterning experiments. (*a*) Methane periodic mesoporous organosilica thin film and an O-shaped mask. (*b*) Plasma treatment. (*c*) The resulting patterned thin film after plasma treatment is optically indistinguishable from the original film. (*d*) The pattern revealed by adding water droplets on the film or by exposing the film to water vapor.

Si/CTACl/HCl/H_2O/EtOH = 1:0.15:0.0002:19.1:15. The solution was aged for 70–90 min. These as-deposited thin films were heated at 150 °C for 2 h (ramping 1 °C / min) and then at 500 °C for 2 h (ramping 1 °C / min) under continuous nitrogen flow.

Patterning by plasma treatment

Stencil masks were cut out of 90 μm thick plastic films (PET) using a VersaLaser cutting system. Metallic letters were ordered from Gemini Sign Letters. Stencil masks or metallic letters were placed directly on top of the thin film as masks. Plasma exposure was performed under oxygen atmosphere for 20–40 s on a FEMTO plasma system from Diener Electronics.

Characterizations

Low-angle X-ray diffraction (XRD) was performed on a Scintag XDS2000 diffractometer using Cu Kα radiation operated at 40 kV and 30 mA. Transmission electron microscopy (TEM) was performed on JEOL 2100 TEM with an accelerating voltage of 200 kV. Ellipsometry data were collected on a Woollam spectroscopic ellipsometer over a wavelength range of 500–900 nm. Photos and videos were taken on a Canon EOS Rebel T2i model.

Results and discussion

The material we choose is methane periodic mesoporous organosilica (PMO). PMO, invented in 1999, is a class of mesoporous materials with organosiliceous pore walls that have one organic bridging group covalently bonded to two or more silicon atoms.[11–13] These bridging organic groups impart unique chemical, biological, optical, and dielectric properties to PMO and distinguish PMO from its pure siliceous counterpart.[14,15] We use methane PMO, with a –CH_2– bridge, as an archetype to demonstrate our patterning technique because, at a temperature higher than 400 °C, the transformation of bridging –CH_2– groups into terminal –CH_3 groups hydrophobizes the surface of the pore wall[10,16,17] and exposes the terminal methyl groups for subsequent plasma treatment. Another PMO that can be similarly hydrophobized is three-ring PMO; in contrast, ethane and ethene PMO do not possess this ability.[10]

We chose plasma treatment as the way to generate patterns. Plasma treatment with the aid of a preformed mask was shown to be a fast (on the order of minutes) and clean (liquid-free) method to create patterns of SAMs on a flat surface at length scales from sub-100 nm to centimetres.[18] We have previously extended this technique to three-dimensional (3D) porous siliceous inverse-opal structures by iterating silanization and shadow-masked oxygen plasma to produce spatial patterns of surface chemistry within the pores.[19,20] The slow propagation of plasma oxidation fronts in porous structures enables patterning by masking only the top surfaces of the structures.[18–20] In this report, we use oxygen plasma to convert terminal methyl groups into silanol groups in thermally treated methane PMO. This conversion switches the hydrophobic pore wall to a hydrophilic one, and enables us to create patterns of different wettability in one single material (Fig. 1).

We produced thin films of methane PMO by spin-coating, followed by thermal treatment at 500 °C to remove surfactants and to initiate self-hydrophobization.[10,17] The mesostructure of methane PMO was confirmed by low-angle XRD and TEM (Figs. 2 and 3). The decrease in d spacing (from 4.2 to 3.2 nm) and the increase in diffraction intensity after thermal treatment are due to anisotropic shrinkage in the out-of-plane direction[21] and increased electron density contrast.[22] Both wormlike[23] and two-dimensional (2D) hexagonally ordered porous channels were observed in TEM.

We then patterned thin films in oxygen plasma treatment with preformed masks placed directly on their top surfaces. Masks were made out of metal, plastic, or glass. A flat smooth surface is required to provide a conformal contact with the underlying thin films. The plasma treatment did not alter the visible appearance of methane PMO thin films (Fig. 4). As a specific example, the O-shaped pattern was revealed when a water droplet was placed on the surface of the film or when the film was exposed to water vapor. The refractive index of the thermally treated thin film was 1.26 ± 0.01 at 633 nm (repeated wetting by water could increase the refractive index up to 1.30 ± 0.02 at 633 nm). Vapor condensation inside mesopores was studied previously in the context of the application of PMOs as low-dielectric constant materials in semiconductor microproces-

sors.[10] This vapor condensation increased the effective refractive index of the hydrophilic regions of the pores to the range of 1.4–1.5,[10] providing enough contrast in refractive indices to make the pattern visible to the naked eye. The principle behind this vapor-phase response is different from most of the current sensing methods that exploit properties imparted by the physisorbed molecules on the porous surface[23] and could lead to further design of novel vapor sensors.

The versatility of our technique is illustrated in the gallery of wetting patterns (Fig. 5). The top two rows show that

successive addition of water gradually diminished the unwetted area and changed the shape of the pattern from a star to a circle as the result of a balance of surface tensions (glass substrates are used for optimum visual effect). The first image on the third row shows that the star-shaped pattern was visible when the whole thin film was covered with water (silicon wafer as the substrate). This visual contrast under water demonstrates that liquid water did not fill the mesopores in the hydrophobic regions. The star-shaped pattern and the letters "GAO" were made from positive masks (metallic letters), whereas the smiley face and the Canadian flag were made from negative masks (plastic sheets with patterned areas removed by laser cutting).

We also observed that an increase in the duration of plasma treatment increased the wettability of a pattern (Supplementary data, movies 1–3). The vertical line and the horizontal line in movies 1–3 (Supplementary data) were exposed to plasma for 20 and 40 s, respectively. Placing a droplet at the area where the two lines cross revealed that water wet the horizontal lines (more hydrophilic) faster than the vertical lines (less hydrophilic) (Supplementary data, movie 1). Excess water was removed by the capillary action from the tip of a glass pipette (inside diameter ~1 mm) (Supplementary data, movie 2). Water added at the end of the lines spontaneously transferred to the center because the curvature of a water droplet at the center was larger than the curvature of a water droplet at the end and, consequently, the Laplace pressure was smaller at the center than that at the end (Supplementary data, movie 3). The transportation of water seems to occur inside the mesoporous thin films rather than along the surface of the thin film because no visible bulge exists along the line of water transportation. We further used these wetting phenomena in an interesting demonstration of hiding and revealing the pattern of a smiley face (Supplementary data, movie 4). Detailed analysis in quantifying the hydrophilicity after plasma treatment and further exploration on liquid transport phenomena are ongoing in our lab.

Conclusion

In conclusion, we have demonstrated that plasma treatment of thermally processed thin films of methane PMO is a fast and clean method to create patterns of wettability. These patterns can only be revealed when exposed to water or moisture. We also demonstrated a few interesting phenomena of wetting dynamics. Our technique may provide a way to study some fundamental aspects of wetting dynamics, such as fluid transport in the presence of a gradient of wettability and the complex geometry of wettability patterns, as well as some applications of this selective wetting phenomenon, such as hiding, revealing, and transforming shapes (and hence information), in sensing and information security.

Abstract: Herein, we present a comparative study of thermo- and environmentally responsive TiO_2/SiO_2 one-dimensional photonic crystals (Bragg stacks) fabricated by different deposition methods and fabrication schemes, featuring various multilayer nanomorphologies. These include dense multilayer systems processed by physical vapor deposition and wet-chemistry protocols, as well as porous systems, namely, nanoparticle-based optical filters exhibiting textural porosity, and evaporation-induced self-assembled mesoporous Bragg stacks exhibiting predominantly structural porosity, as well as hybrid structures comprising both dense and porous layers. We investigate the spectral shift of the photonic stop band for the different Bragg stack nanomorphologies induced by the humidity-enhanced thermo-optic effect in a temperature range from 15 to 60 °C. We also demonstrate the response and recovery kinetics of the multilayer systems during external changes in ambient humidity. Notably, the choice of fabrication method plays a significant role in the thermal and humidity response of the system. Taking advantage of different material nanomorphologies we can tune the thermal shift of the photonic stop band in the range 0.2–32.9 nm for the Bragg stacks at ambient relative humidity. In addition, we can design dense multilayer systems nonresponsive to humidity and achieve time responses of the porous systems to external changes in humidity ranging from about 1 to 3 s.

Key words: thermoresponsive photonic crystal, Bragg stack, thermo-optic effect, humidity.

Résumé : Dans ce travail, on rapporte les résultats d'une étude comparative de cristaux photoniques monodimensionnels (empilements de Bragg) de TiO_2/SiO_2 à réponses thermiques et environnementales préparés par diverses méthodes de déposition et de schémas de fabrications caractérisées par diverses nanomorphologies multicouches. Celles-ci incluent des systèmes multicouches denses obtenus par des dépôts de vapeurs physiques et des protocoles de chimiques humides ainsi que des systèmes poreux, particulièrement, des filtres optiques à base de nanoparticules présentant une texture poreuse des empilements de Bragg mésoporeux auto-assemblés par évaporation induite comportant principalement une structure poreuse ainsi que des structures hybrides comportant des couches denses et d'autres poreuses. On a étudié le déplacement spectral du filtre coupe bande photonique des nanomorphologies des différents empilements de Bragg induit par l'effet thermo-optique rehaussé par l'humidité sur la plage de température allant de 15 à 60 °C. On a déterminé les cinétiques de réponse et de récupération des systèmes multicouches lors de changements externes dans l'humidité ambiante. On a particulièrement noté que la méthode de choix pour la fabrication joue un rôle significatif dans la réponse du système à la chaleur et à l'humidité. Tirant avantage des nanomorphologies des divers matériaux, il est possible d'ajuster le déplacement thermique du filtre coupe bande photonique pour la plage allant de 0,2 à 32,9 nm des empilements de Bragg dans l'humidité relative ambiante. De plus, il est possible de développer des systèmes multicouches qui ne réagissent pas à l'humidité et qui peuvent atteindre des temps de réponse allant de 1 à 3 s pour des systèmes poreux soumis à un changement d'humidité.

Mots-clés : cristal photonique à réponse thermique, empilement de Bragg, effet thermo-optique, humidité.

Introduction

The development of periodic dielectric nanostructures, i.e., photonic crystals (PCs), with tailored optical and built-in chemical properties has recently been brought to fruition by the materials science and photonics communities.[1,2] The photonic stop band, a characteristic region of high reflectivity in the optical spectrum manifesting itself in "structural color", provides ample possibilities for the design of tunable optical systems.[3] A variety of stop-band tuning mechanisms along with promising synthetic routes towards the fabrication of stimuli-responsive PCs have been reported.[4] Widespread interest in the production of tunable photonic nanostructures is due to potential applications in fields as diverse as sensor design,[5] micro-optics,[6] optofluidics,[7] medical diagnostics,[8] color displays,[9] food and water quality control,[10] and many others. One of the proposed photonic stop-band tuning scenarios employs materials featuring responsiveness to an external *temperature* change, such as hydrogels,[11,12] microgels,[13] polyglycidol – polystyrene core – shell particles,[14] magnetic fluids,[15] liquid-crystal elastomers,[16] or $BaTiO_3$[17] through the thermo-optic effect (TOE).[18] The principle of thermo-optic spectral tuning is based on the thermo-optic coefficient (TOC), namely, the dependence of the refractive index (n) on temperature (T) and, hence, dn/dT, owing to both changes of the dielectric function and thermal expansion/contraction. Thermo-optic photonic stop-band tuning has already been successfully demonstrated in microring resonators,[19] thermo-optic switches,[18] and wavelength-division multiplexing.[20,21] Substantial interest has arisen from the thermo-optic tuning realized with one-dimensional systems, i.e., periodic multilayer structures with a modulation of the dielectric constant in one direction, such as thermally tunable multilayer optical filters,[22] and monolithic microcavities[23] deposited by complex physical vapor deposition (PVD) methods. Interestingly, owing to the recent progress in synthetic chemistry, sputtered and evaporated PCs may be complemented by lower cost and easier to fabricate analogues (sol–gel processed one-dimensional PCs, also called Bragg stacks (BSs)) without a significant loss in the optical quality.[24,25] Although one of the main problems in the fabrication of sol–gel coatings in general and of multilayers in particular is the stress induced during heat treatment of the layers leading to defects and cracks in the films, an ample amount of recent publications successfully dealt with the optimization of the fabrication routes to achieve better optical and mechanical quality films and BSs.[26] In contrast to the PVD-deposited PCs, synthetic BSs offer a plethora of modification possibilities towards enhancing or modifying their environmental response, for example, by varying the nanomorphology (denoted further as "morphology") of the individual layers, i.e., the texture, porosity, curvature, size, and shape of the particles or monoliths constituting the layers.[27,28] While the influence of the BSs' morphology on the stop-band tuning of wet-chemistry synthesized TiO_2/SiO_2 BSs induced by chemical stimuli has already been examined,[29–33] a comprehensive study of the interrelation between morphology and shift in *thermoresponsive* sol–gel processed BSs has not yet been performed.

Recently, we demonstrated the thermal tunability of nanoparticle-based TiO_2/SiO_2 BSs fabricated by a spin-coating method.[34] It was shown that the shift of the stop band due to the thermo-optic effect in the constituent materials in such systems is amplified in the presence of ambient humidity: The observed enhancement of the shift is due to adsorption of water molecules into the interparticle voids in the layers, causing an increase in the effective refractive index (RI) of the layers. Therefore, one can introduce an *effective* thermo-optic effect including both thermal and humidity influences on the effective RI. Furthermore, we simulated the influence of the layer thickness, refractive index, and thermo-optic coefficient on the thermal response of various BS architectures to work out design criteria for optimizing the thermal tuning performance of the BSs.[35]

The general goal of our present study is to rationally design photonic crystals that are tunable by both the inherent thermo-optic effect of the constitutent materials and by concurrent temperature-dependent adsorption of humidity into the multilayer system. As the latter is highly sensitive to the porosity of the layers, this aspect of the layer morphology will be central to our experimental focus. In this manuscript, we demonstrate the influence of the morphology of the constituent layers on the thermal tuning properties of various one-dimensional TiO_2/SiO_2 BSs. We show that the layer morphology is one of the key factors to be taken into account when designing tailor-made thermally tunable BSs. Towards this end, the BSs were fabricated by different sol–gel synthesis schemes, ranging from nonporous wet-chemistry-processed nanostructures to porous systems, that is, nanoparticle-based optical filters exhibiting textural porosity, and evaporation-induced self-assembled mesoporous Bragg stacks exhibiting predominantly structural porosity, as well as hybrid structures comprising both dense and porous layers. The thermo-optic response of these systems is interpreted and rationalized by comparison with the thermal response of a nonporous, PVD-derived optical filter. We also present a comparative study of the response and recovery times of the proposed structures and demonstrate that the fabrication method can serve as a design criterion for producing tailor-made photonic crystals with desired thermal response under ambient conditions.

Experimental

Materials

Tetraethyl orthotitanate (TEOT, 99%) and tetraethyl orthosilicate (TEOS, 99%) were purchased from Merck (Darmstadt, Germany); ethanol (99%), *n*-butanol (99%), colloidal silica LUDOX SM-30 (30 wt % in H_2O), and Pluronic F127 and P123 were purchased from Sigma-Aldrich (Dorset, UK); HNO_3 (0.1 mol/L) was purchased from Acros Organics (Geel, Belgium); and HCl (0.1 mol/L, 2 mol/L, 37%) was obtained from Biesterfeld (Hamburg, Germany).

Titania nanoparticle (NP) suspension was prepared as described elsewhere.[34] Particle size distribution of the precursor TiO_2 and SiO_2 suspensions was analyzed using dynamic light-scattering photocorrelation spectroscopy (Malvern Nano ZS Zetasizer) at 20 °C. Silica sol for TiO_2-NP/SiO_2-sol and TiO_2-sol/SiO_2-sol BSs was prepared by mixing TEOS, ethanol, and HCl in a ratio of 1:10:1 and 2:10:2, respectively, and subsequent ageing for 12 h. Titania sol (0.1 mol/L) for TiO_2-sol/SiO_2-sol BSs was prepared by mixing TEOT (0.228 g) in ethanol (10 mL) with subsequent ageing until the desired optical quality of spin-coated thin films was reached. To synthesize the mesoporous silica sol (meso-SiO_2), TEOS

(3.12 g) was diluted in ethanol (19 mL) with the subsequent addition of surfactant Pluronic F127 (1.5 g), HCl (0.15 g, 2 mol/L), and H_2O (1.35 mL). The mixture was stirred for 5 min until it became translucent and was subsequently aged for 1 h. To prepare the mesoporous titania sol (meso-TiO_2), TEOT (2.1 g) was diluted in *n*-butanol (7.4 mL) with Pluronic P123 (0.65 g) and HCl (1.35 mL, 37%). The solution was stirred vigorously for 5 min and afterwards aged for at least 1 h. All suspensions were filtered prior to use (Acrodisc, GHP, 13 mm, 0.2 μm). The anatase modification of the TiO_2 powder calcined at 350 °C for 1 h was confirmed by X-ray diffraction (Bruker D8 Discover).

Bragg stack fabrication

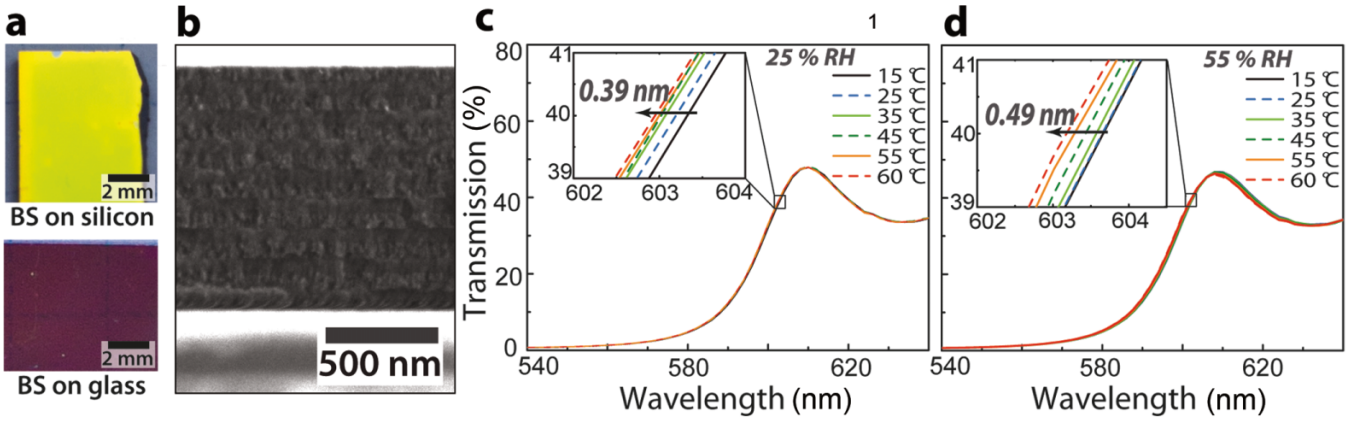
Evaporated dense TiO_2/SiO_2 BSs

The dense TiO_{2-x}/SiO_{2-x} multilayers were deposited in a Pfeiffer Vacuum Classic 500 evaporation system in vacuum ($<2 \times 10^{-6}$ mbar; 1 bar = 100 kPa) onto soda-lime glass substrates at room temperature starting from the TiO_{2-x} layer. The TiO_{2-x} layers were evaporated by using an electron gun. The SiO_{2-x} layers were evaporated by using resistive heating of SiO_2 contained in a molybdenum boat. The deposition rate for both materials was approximately 0.2 nm s^{-1}, which was monitored, as well as the layer thicknesses, in situ by a quartz crystal microbalance (QCM). The alternation of the layers was achieved by shuttering the flux of the corresponding layer. The oxygen content in the multilayers was reduced because of deposition in vacuum; therefore, further annealing in an oxygen atmosphere for 1 h at 450 °C was performed to recover the stoichiometry and optical properties of the multilayers.

TiO_2/SiO_2 BSs based on sol–gel fabrication methods

We obtained TiO_2-sol/SiO_2-sol BSs by sequential spin-coating of silica sol (3000 rpm, 1500 rpm s^{-1}) and titania sol without calcination. For the titania sol (0.1 mol/L), we performed triple spin-coating (4000 rpm, 2000 rpm s^{-1}) until the necessary film thickness was achieved. Nanoparticle-based (NP-based) BSs were prepared by spin-coating as described elsewhere.[34] TiO_2-NP/SiO_2-sol BSs were prepared by sequential spin-coating of a titania NP suspension (3000 rpm, 1500 rpm s^{-1}) and silica sol (3000 rpm, 1500 rpm s^{-1}) with subsequent calcination of the films at 200 °C for 15 min. Similarly, TiO_2-sol/meso-SiO_2 BSs were fabricated by spin-coating mesoporous silica (2500 rpm, 2000 rpm s^{-1}) and titania sol (0.05 mol/L, 3000 rpm, 2000 rpm s^{-1}). Mesoporosity was generally achieved by taking advantage of the evaporation-induced self-assembly (EISA) method and through subsequently removing the surfactant via calcination of the films at 400 °C for 15 min. Meso-TiO_2 /meso-SiO_2 were obtained by spin-coating mesoporous titania (5000 rpm, 2000 rpm s^{-1}) and mesoporous silica (5000 rpm, 2000 rpm s^{-1}). The single thin film thickness and refractive index were characterized by spectroscopic ellipsometry, performed on a Woollam M200D variable angle ellipsometer in the entire spectral range of 190–1000 nm at angles of incidence of 65°, 70°, and 75°. To calculate the porosity of the layers the Lorentz–Lorenz equation was used, for which the RIs of the single films were measured first with void pores and then with the pores filled with toluene. Scanning electron microscopy (SEM, JEOL JSM-6500F operating at an accelerating voltage of 2–5 kV) was used to examine the morphology of the BSs' cross sections and flat surfaces.

Thermo-optic and humidity response characterization



To obtain transmission spectra of the BSs in the range of 400–800 nm we used a monochromator (Cornerstone260 1/4 m) with a high-pressure arc lamp as a light source and a 10×10 mm^2 calibrated silicon detector connected to a digital lock-in amplifier (Merlin).[34] The temperature of the BS was varied by two Peltier elements and the PT100 temperature sensor was attached to the other side of the BS above the optical axis. Peltier elements and the temperature sensor were connected to a remote-controlled source meter (Keithley). The heating and cooling of the Peltier elements were regulated by a proportional integral derivative (PID) controller. The measured deviation of the temperature during the measurement was less than 0.1 °C. For each temperature the sample was equilibrated for 60 s. The measurements in N_2 atmosphere (to mimic 0% relative humidity) were performed in a cryostat with two windows, in which the samples of interest were kept for 24 h prior to the measurements.

For the response and recovery time characterization we changed the relative humidity (RH) of the environment (20%) by introducing water vapor onto the sample surface. The tubing with the nitrogen stream carrying the water vapor was mounted above the surface of the BS. The measured RH of the vapor was 65%. Additionally, the valve located on the tubing allowed the instant turning off of the vapor stream. In a typical experiment, the BS was fixed under an optical microscope such that the measurement spot could be constantly monitored. Time-dependent spectroscopy was performed with a fiber optic spectrometer (Ocean Optics USB2000+) integrated with an optical light microscope (Leica DM2500 M).

Results and discussion

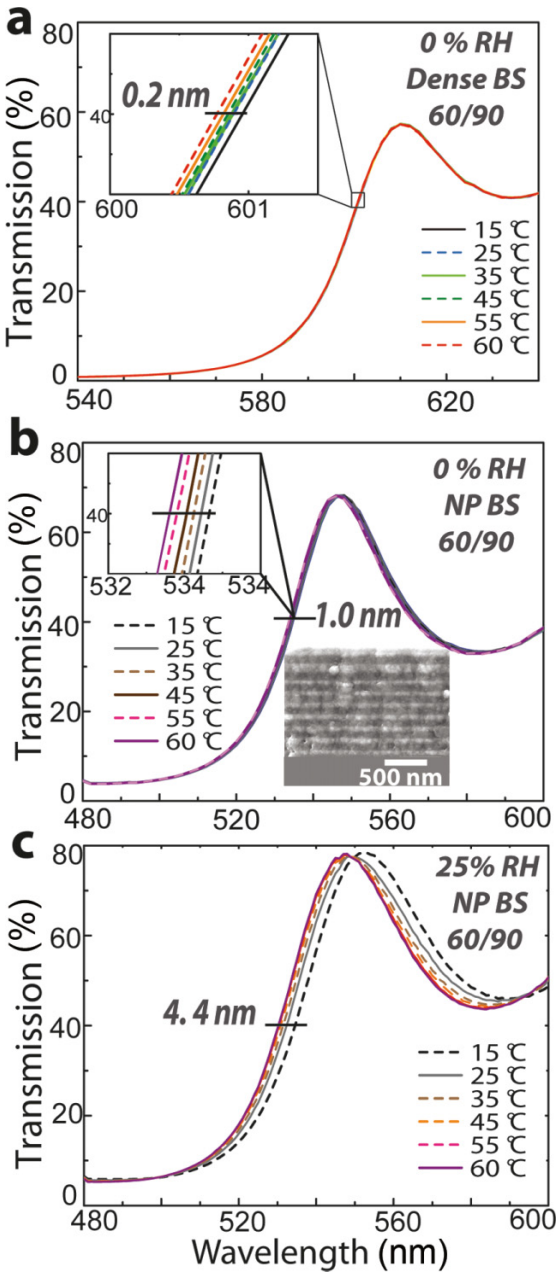
Photonic multilayer systems fabricated by PVD feature inherently dense oxide layers (Fig. 1) and can therefore be taken as a nonporous reference system for our comparative study of the thermo-optic tuning behavior. Evaporated TiO_2/SiO_2 multilayers have been extensively examined as all-dielectric optical filters for passive optical elements[36,37] and therefore represent an excellent "classical" platform for the comparison with BSs obtained by wet-chemistry methods. Photographs of the evaporated BS samples, deposited under the same conditions, are shown in Fig. 1*a*: The top image presents a BS on a Si wafer, captured at an angle of ≈45° with respect to the normal to the BS's surface, and the bottom image shows a BS on a glass substrate, captured normal to the BS's surface. As can be seen in Fig. 1*a*, such BSs are almost defectless, however, their optical properties, including RI and absorption properties, are highly dependent on the deposition method and annealing conditions.[38] The cross-sectional SEM image in Fig. 1*b* depicts a BS composed of 8.5 bilayers (BLs) of 60 nm TiO_2 ($n \approx 2.41$) and 90 nm SiO_2 ($n \approx 1.55$). The maximum transmission of the BS annealed in air at 450 °C for 1 h to annihilate oxygen vacancies is around 50%. It is known that films deposited by PVD show a columnar microstructure with intercolumnar voids leading to inhomogeneities and roughness.[36,39] Nevertheless, the high RIs obtained for electron beam (e-beam) evaporated TiO_2 and thermally evaporated SiO_2 by spectroscopic ellipsometry are testament to their overall low porosity. Note, however, that the RI of SiO_2 may likewise be rationalized by the presence of residual substoichiometric oxide species (SiO_{2-x}) in the film. The impact of

Fig. 1. (*a*) Photographs of the electron beam (e-beam) evaporated TiO_2 (60 nm) and thermally evaporated SiO_2 (90 nm) 8.5 bilayer (BL) Bragg stack (BS) (starting from the first TiO_2 layer) deposited on a Si wafer (top image: captured at an angle) and on a glass substrate (bottom image: captured normal to the BS surface). The scale bar is 2 mm. (*b*) The cross-sectional SEM image of the evaporated BS from 1*a* (bottom). The scale bar is 500 nm. (*c*) Transmission spectra of the BS shown in 1*a* (bottom) featuring a blue shift of the stop band of ≈0.39 nm in a temperature range of 15 to 60 °C at 25% relative humidity (RH). (*d*) Transmission spectra of the same BS as in 1*c* demonstrating a slightly larger blue shift of the stop band (≈0.49 nm) in a temperature range of 15 to 60 °C at 55% RH.

textural porosity on the thermo-optic response of the BS can be derived from the dependence of the optical shift on the environmental humidity as seen in Figs. 1*c* and 1*d*. Clearly, the magnitude of the thermal shift at 55% RH (0.49 nm) is higher than at 25% RH (0.39 nm) upon an increase in temperature from 15 to 60 °C, which can be rationalized by the effective TOC enhanced by the penetration of ambient humidity into the textural pores of the BS.

To put the humidity-enhanced thermo-optic response of the PVD-derived BS into perspective, we compare it with the response of solution-processed, spin-coated BSs with the same average layer thicknesses (the thickness of spin-coated BSs can deviate about 10%–20% on average) and number of bilayers (8.5), but composed of TiO_2 and SiO_2 NP layers. An intrinsic property of the NP-based BSs is textural porosity (porosity arising from interparticle voids in the film). With the measured NP size distributions (6–10 nm for SiO_2 and 8–20 nm for TiO_2 NPs) one can obtain films with 10% and 25% porosity for SiO_2 and TiO_2, respectively.[34] First, we investigated the thermo-optic response of the PVD-derived and porous NP-based BSs decoupled from the influence of ambient humidity. Consequently, in this experiment one can derive the shift of the stop band caused solely by the impact of the TOE. Figures 2*a* and 2*b* highlight the thermo-optic response of the samples kept in a nitrogen atmosphere for 24 h prior to the experiment. Clearly, the evaporated BS shows a small shift of 0.2 nm upon heating from 15 to 60 °C, whereas the NP-based BS shows a fairly linear thermo-optic response of 1.0 nm, which is in agreement with the theoretical value of the thermo-optic shift in this temperature range based on the TOCs reported for titania and silica, respectively.[34] We assume that the smaller shift observed for the evaporated BS is due to the TOCs of the layer materials being slightly different from the literature values for TiO_2[40] (1.77×10^{-4} K^{-1}) and SiO_2[41] (1×10^{-5} K^{-1}) owing to the presence of substoichiometric oxide species (TiO_{2-x} and SiO_{2-x}) in the multilayer.

To demonstrate the humidity-enhanced thermal tunability of the NP-based BS, we performed similar measurements in ambient humidity (25% RH). One can discern a humidity-amplified blue shift of 4.4 nm owing to the effective TOE, which is about four times larger than in N_2 atmosphere (Fig. 2*c*). This observation suggests a significant difference in the porosity of the solution-processed and thermally evaporated BSs. Specifically, the higher textural porosity of the NP-based BS renders it more accessible to water, thus leading to a more pronounced humidity enhancement of the thermal shift.



Having discussed two model systems with different porosities and, hence, thermal response behavior, it is instructive to explore alternative, yet solution-based routes to low-porosity BS architectures that can "mimic" the low-response thermo-optic behavior of evaporated BSs. In Figs. 3*a*, 3*d*, and 3*g*, we demonstrate the tuning properties of a BS fabricated by alternate spin-coating of titania and silica sols. As can be inferred from the SEM image (Fig. 3*a*), the 4 BL TiO_2-sol/SiO_2-sol BS apparently has a rather dense morphology. Low porosity of the layers is also confirmed by the thermal tuning behavior presented in Fig. 3*d* at ambient humidity. Notably, the shift of the stop band is only 0.8 nm upon heating from 15 to 60 °C. Evidently, the magnitude of the effective thermal shift of the TiO_2-sol/SiO_2-sol BS is only slightly larger than the one of the PVD-derived BS at 25% RH (0.39 nm, Fig. 1*c*). The low RI and at the same time the low response to temperature changes may be in part due to organic residues within the sol–gel based structure rendering the BS more hydrophobic, as no calcination was done after film deposition (see the Experimental section).

In contrast, a much higher thermal response is observed for hybrid systems in which one of the layers is kept dense, while the other possesses textural or structural porosity, as is the case for NP-based and mesoporous layers, respectively (Figs. 3*b* and 3*c*, respectively). As can be seen from Figs. 3*e* and 3*f*, both systems exhibit a significant response to heating under ambient conditions. The blue shift of a TiO_2-NP/SiO_2-sol is 8.9 nm for the blue and 20.0 nm for the red edge of the stop band, and the responses of TiO_2-sol/meso-SiO_2 BSs are 32.0 and

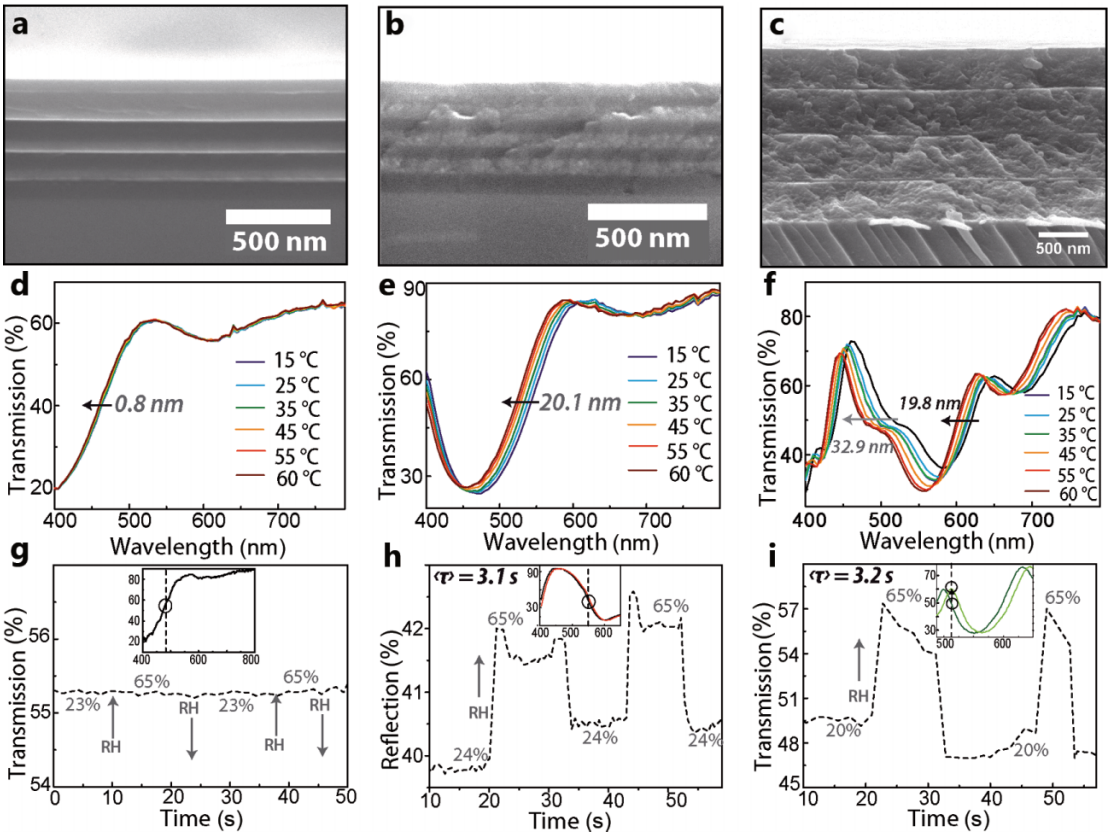
Fig. 2. (*a*) Transmission spectra of the evaporated Bragg stack (BS) shown in Fig. 1*a* (bottom) demonstrating a small blue shift of the stop band of ≈0.2 nm upon heating from 15 to 60 °C in N_2 atmosphere. (*b*) Transmission spectra of the nanoparticle (NP)-based TiO_2/SiO_2 8.5 bilayer (BL) BS featuring a blue shift of the stop band of ≈1.0 nm upon heating from 15 to 60 °C in N_2 atmosphere. The inset shows the cross-sectional SEM image of the corresponding BS. The scale bar is 500 nm. (*c*) Transmission spectra of the BS from Fig. 2*b* recorded under ambient conditions (25% RH) in the *T* range of 15 to 60 °C. (From Pavlichenko et al.[34] 2012, reproduced with permission of J. Phys. Chem. C, Vol. 116, pp 298–305, © 2012 American Chemical Society. RH, relative humidity.

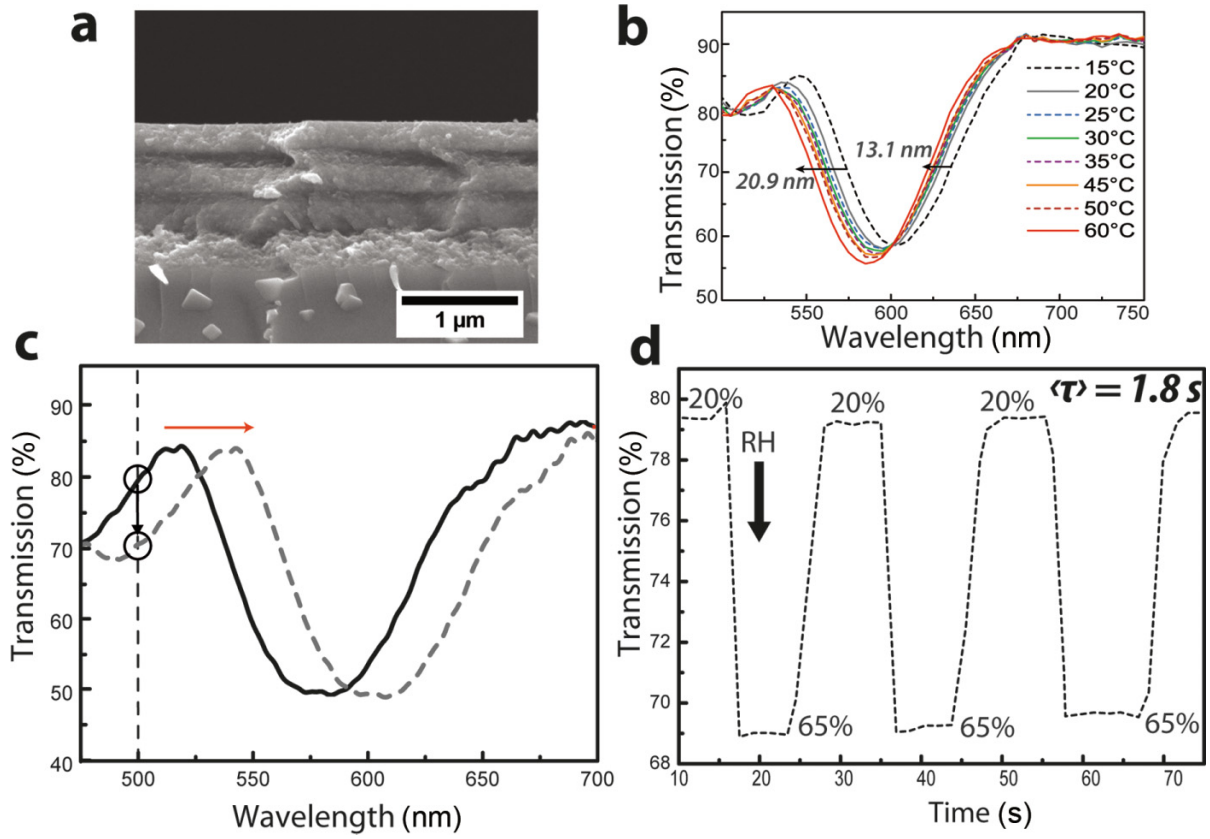


19.8 nm for the blue and red edges of the stop band, respectively. The shifting behavior of both systems is in good agreement with previous predictions relating the relative changes of the blue and red edges of the stop band to the RI changes taking place primarily in one type of layer in the bilayer system:[27,35] (*i*) The larger magnitude of the shift for the red edge of the stop band in the TiO_2-NP/SiO_2-sol system suggests that the high RI material TiO_2 undergoes the dominant RI changes; hence, we conclude that the water mainly adsorbs in the porous TiO_2–NP layers rather than in the dense SiO_2-sol ones. (*ii*) The transmission of the stop band is higher at higher *T*, indicative of a gradual lowering of the RI contrast of the layers with increasing *T*, suggesting that upon heating water desorbs mainly from the TiO_2 layers, thus reducing their RI and, hence, the overall RI contrast. These phenomena illustrate the predominant influence of TiO_2 on the thermal response. On the contrary, the change of the stop band for the TiO_2-sol/meso-SiO_2 BS is larger at the red edge and the transmission is lower at higher temperatures, highlighting the dominant influence of porous SiO_2 rather than dense TiO_2, as water seems to condense primarily into the silica layers.

Next, we compared the tuning properties of the porous hybrid systems with their nonhybrid analogues, in which both layers are comprised of either NPs or mesoporous materials, namely, with the TiO_2-NP/SiO_2-NP BS (Fig. 2*c*) and a meso-TiO_2/meso-SiO_2 3 BL BS (Fig. 4*a*). The thermal shift (20.1 nm for the red edge of the stop band) of the hybrid TiO_2-NP/SiO_2-sol BS in the *T* range between 15 and 60 °C at 30% RH is larger than for the nonhybrid TiO_2-NP/SiO_2-NP system (4.4 nm at 25% RH and 16.4 nm at 45% RH). The higher response of the hybrid system compared with the TiO_2-NP/SiO_2-NP stack may be due to more restricted moisture diffusion into the latter owing to the larger number of BLs, rendering the multilayer system more compact and less accessible to moisture. Along similar lines, for the TiO_2-sol/meso-SiO_2 BS the thermal shifts between 15 and 60 °C (32.0 and 19.8 nm for the blue and red edges, respectively) are larger than the 20.9 nm (blue edge) and 13.1 nm (red edge) shifts for the meso-TiO_2/meso-SiO_2 BS shown in Fig. 4*b*. The observed behavior may be rationalized by the differences in layer thicknesses and hence the relative impact of the more porous layers on the adsorption behavior: higher porosity films of SiO_2 were obtained with the triblock copolymer F127 used as a template (Fig. 5*a*), resulting in nanometer-sized channels (~10 nm) organized into two-dimensional (2D) hexagonal domains parallel to the substrate, as also observed previously.[42] In contrast, P123-templated TiO_2 (Fig. 5*b*) forms pores with an average size of 5 nm,[43] which is about half the size of the SiO_2 pores. Therefore, the larger porosity of SiO_2 together with the larger layer thickness of the SiO_2 layers in the sol–meso BS compared to the meso–meso BS is the most likely rationale for the larger thermal response observed for the sol–meso BS. Other factors may be fluctuations in ambient humidity, the mutual influence of adjacent layers (of higher and lower porosity) and their pore sizes and texture on the confinement and transport of moisture within the multilayer,[26,28] as well as other phenomena such as pore blocking at the interfaces and capillary and surface wettability effects that are naturally augmented in complex nanomorphologies.

To analyze the kinetics of the environmental response (i.e., separated from the pure thermo-optic response) and the possible impact of the layer morphology on the response time, we investigated the behavior of the multilayer systems with respect to changes in ambient humidity, while keeping the temperature constant. Time-resolved measurements were car-

(*g*) and (*i*) Time-resolved transmission and (*h*) reflection changes in response to the change in RH from ≈20% to 65%; $<\tau>$ is the response time. The inset graphs show the reflection and transmission spectra of the BS demonstrating the change in transmission at (*g*) 480 nm and (*i*) 512 nm, and reflection at (*h*) 550 nm corresponding to the RH change from ≈20% to 65%. RI, refractive index; BL, bilayer; BS, Bragg stack; NP, nanoparticle; meso, mesoporous; RH, relative humidity.



ried out by detecting changes in the reflection/transmission spectrum occurring during the instantaneous change in RH of the environment, from ≈20% to 65%. The change in reflection/transmission was monitored at fixed wavelengths. Note that only the initial shifts right after the RH increase or decrease were recorded, while subsequent slower processes, e.g., owing to diffusion of humidity within the multilayer stacks, were neglected. Therefore, the response times only reflect the principal accessibility of the outer surfaces of the multilayer system.

Comparison of the response times (given as $<\tau>$) to humidity changes for the two dense systems (TiO_2-sol/SiO_2-sol and PVD-derived BS) shows a peculiar difference: The dense sol-based BS shows a complete lack of response to humidity change (Fig. 3*g*), whereas the response of its classical evaporated counterpart occurs promptly (1.3 s), albeit being associated with only a minor shift of 0.5 nm. The absence of response to the transient humidity changes for the sol–sol BS may be due to the larger hydrophobicity of the noncalcined layers and concomitant slow diffusion of water within the multilayer system. The porous systems with similar layer morphologies show rather fast response times, $<\tau>$, which are around 1.5–2 s for the NP–NP BS as reported earlier[35] and ≈1.8 s for the meso–meso BS (Figs. 4*c* and 4*d*). The response times of the hybrid BSs are somewhat larger than those of the NP–NP, meso–meso, and dense PVD-BSs: The $<\tau>$ are around 3 s for both multilayer systems (Figs. 3*h* and 3*i*). Although there is no clear trend discernible, fast response times may be triggered by (*i*) low accessibility of the layers to ambient humidity as seen for the PVD-BS, presumably resulting in surface rather than bulk condensation of water, and (*ii*) fast percolation of water within the porous layers as in the meso–meso BS. The *overall* shifts induced right after the humidity change are a testament to both the porosity and the connectivity of the water percolation pathways within the multilayer systems: The magnitude of the red shift increases in the order dense/sol (≈0 nm) < dense/PVD (≈0.5 nm) < sol–NP (≈5 nm) < NP–NP (≈8 nm) < sol–meso (≈12 nm) < meso–meso (≈25 nm), thus reflecting the increasingly porous and interconnected layer morphologies along this series, which is consistent with the observations made previously. The somewhat lower and more sluggish humidity-induced shifts observed for the hybrid

systems compared with their thermal response can be rationalized by the fact that the dense layer is mediating the humidity response of the system, thus preventing fast penetration of moisture into the multilayer. In terms of BS design criteria, an optimally fast and strong effective thermo-optic response can be seen in porous multilayer systems with the same morphologies, such as fully NP-based or meso BSs.

Conclusion

We have studied the influence of the nanomorphology on the effective, i.e., humidity-enhanced thermo-optic response of different TiO_2/SiO_2 BSs: PVD-derived and sol–gel BSs both show relatively small blue shifts of 0.39 and 0.80 nm, respectively, upon heating of the system from 15 to 60 °C at ambient relative humidity. This similarity in the optical response suggests low textural porosity in both systems, thus rendering the solution-processed sol–gel multilayer an excellent substitute for the classical low-response optical filters deposited by PVD. Alternatively, we have shown that a low thermo-optic response (1 nm as compared with 4.4 nm at 25% RH) even for porous architectures can be realized by excluding ambient humidity, equivalent to encapsulation of the system. Analysis of the effective thermo-optic response of hybrid systems composed of both dense and porous layers as well as that of an all-meso BS reveals large optical shifts attributable to a higher degree of textural porosity and accessibility of the system compared with the dense PVD and sol-based counterparts. Furthermore, the impact of morphology on the response and recovery times of the proposed systems to abrupt changes in humidity from ≈20% to 65% was studied. The fastest kinetics were observed for systems with the same layer morphologies (1.3 s for the evaporated, 1.5–2.0 s for the nanoparticle-based and 1.8 s for the meso BS), whereas the response of the hybrid sol–NP (3.1 s) and sol–meso (3.2 s) systems takes somewhat longer. Low or even complete insensitivity towards humidity was observed for PVD- and sol-derived BSs owing to their low degree of textural porosity, combined with larger hydrophobicity of the noncalcined layers in the sol–sol configuration. These observations point to a substantial tunability of the overall thermo-optic response as well as the response kinetics through the choice of the fabrication method and, thus, the resulting morphology of the layers. As a perspective, the multilayers presented in this study lend themselves well as general model systems with precisely controlled porosities and types of curvatures, which can translate the adsorption of arbitrary fluids under ambient conditions into a visibly perceptible optical readout.

Abstract: DFT/B3LYP calculations are used to analyse the occurrence of reverse isotope shift ratios (ISR) in H/D substitution of the free-base tetrapyrroles, in situations where the frequency ratio ν_H/ν_D is less than 1. The reverse ISR effect is found to be most evident in the out-of-plane bending modes (b_{2g} and b_{3u} symmetry) involving some N–H motion for the four molecules studied, viz., porphine (H_2P), tetraaza-porphine (H_2TAP), tetrabenzo-porphine (H_2TBP), and phthalocyanine (H_2Pc). It was analysed by following the evolution of the normal mode frequencies with incremental variation of the H atom masses from 1 to 2 amu. This method allows direct, unambiguous mode correlations to be established between the light and the heavy isotopologues. When the NH(D) motion is predominant, the H to D frequency evolution decreases in a continuous manner for a particular normal mode. In the case of two modes of the same symmetry and whose frequencies are similar, their frequency evolutions could cross, depending on the extent of NH(D) motion involved in them. The evolution diagrams may show avoided crossings of various extents, which thereby reflects the degree of the NH(D) motion in the modes. The reverse ISR effect is directly correlated to these avoided crossings. Because the isotope shifts are quite small (<10 cm^{-1}) and occur in the congested 1500–500 cm^{-1} spectral region, high-resolution methods yielding narrow line transitions are required for experimental analysis. The matrix isolation technique is particularly well suited for this work and is proposed for use in a search for this effect.

Key words: vibrational spectroscopy, porphyrins, DFT calculations, matrix-isolation.

Résumé : Des calculs DFT basés sur la fonctionnelle B3LYP ont été menés sur des molécules tétrapyrroliques afin d'analyser le cas de rapports de déplacements isotopiques (RDI) inverses reliés à la substitution H/D dans les bases libres, c'est-à-dire le cas de rapports de fréquences ν_H/ν_D inférieurs à 1. Ces rapports RDI inverses apparaissent clairement dans les modes de pliage hors plan (symétries b_{2g} et b_{3u}) impliquant un mouvement N–H pour les quatre molécules étudiées : porphine (H_2P), tétraazaporphine (H_2TAP), tétrabenzoporphine (H_2TBP) et phthalocyanine (H_2Pc). Les RDI inverses ont été analysés en suivant l'évolution des fréquences des modes normaux lors d'une augmentation continue de 1 à 2 amu de la masse de l'atome d'hydrogène. Cette méthode permet d'établir de façon directe et non ambiguë les corrélations entre les fréquences des deux isotopologues. Lorsque le mouvement N-H(D) est prédominant dans un mode donné, l'évolution de la fréquence de H à D diminue continûment. Lorsque deux modes de même symétrie ont des fréquences voisines, leurs évolutions en fréquence de H à D peuvent se croiser, selon le degré d'implication du mouvement N-H(D) dans les deux modes considérés. Les diagrammes d'évolutions correspondants peuvent alors montrer des croisements évités plus ou moins prononcés, reflétant ainsi le poids du mouvement N-H(D) dans les modes impliqués. L'effet de RDI inversé est directement corrélé à ces croisements évités. Les déplacements isotopiques sont assez faibles (<10 cm^{-1}) et ont lieu dans une région spectrale très dense (1500–500 cm^{-1}). C'est pourquoi, il est nécessaire d'utiliser des méthodes spectroscopiques à haute résolution permettant l'observation de transitions en bandes fines pour une analyse expérimentale. La technique d'isolation en matrice est particulièrement bien adaptée et elle est proposée pour la recherche expérimentale de cet effet.

Mots-clés : spectroscopie vibrationnelle, porphyrines, calculs DFT, isolation en matrice.

The time one of us (JMcC) spent as a graduate student in Geff Ozin's group was the beginning of an enriching, life-long career in research and education. In particular, the use of group theoretical quantum chemistry and the matrix-isolation techniques, all of which are used in this contribution, were first encountered in the Ozin lab. Accordingly, it is with pleasure and gratitude that the present article is dedicated to Geff.

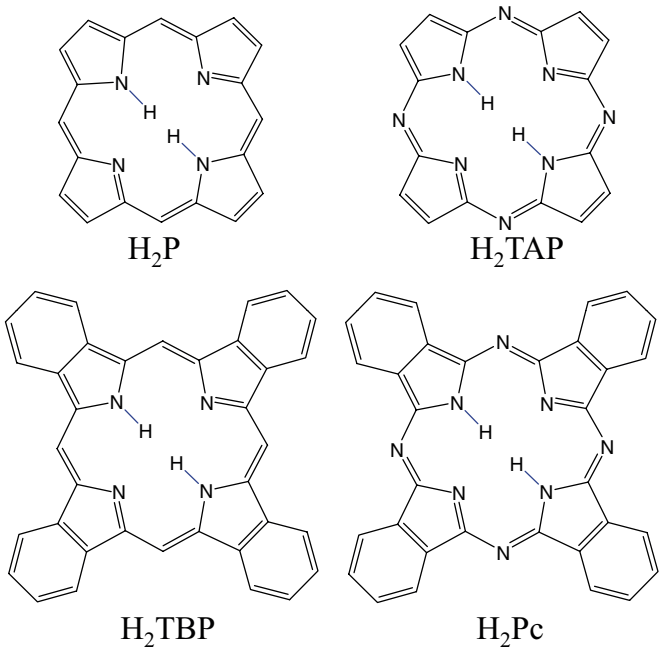
Introduction

The tautomerism exhibited by the free-base tetrapyrroles, in which the two inner hydrogen atoms migrate between opposite pairs of the four central nitrogen atoms, has been studied with a wide variety of both experimental[1] and theoretical[2] means. Of the methods applied, vibrational spectroscopy is a direct means of probing the mechanism underlying the tautomerism, since the N–H stretch and in-plane bending modes have been proposed to be involved. In spectroscopic work, isotope substitution[3] is a well-known tool in achieving a reliable vibrational analysis, with substitution of hydrogen (H) by deuterium (D) by far the most utilized method, as it produces the largest frequency shifts[4] because of the approximate factor of two[5] difference in the masses of the isotopes. Arising from the inverse relationship between the mode frequency, ν, and the mass of the H-atom isotope, m, given by the expression,



$$[1] \qquad \nu = \frac{1}{2\pi}\sqrt{\frac{k}{m}}$$

in which k is the force constant, the heavier isotope is thereby expected to occur at lower values. This behaviour assists greatly in making mode assignments in experimental spectra. Moreover, for the free-base tetrapyrroles, H/D substitution of the two inner hydrogens is particularly appealing as the D_{2h} molecular symmetry is conserved, allowing direct comparisons between the two isotopologues.

However, in a recent combined IR/Raman and high-level density functional theory (DFT) study[6] of free-base phthalocyanine (H_2Pc), we observed quite peculiar behaviour upon H/D substitution, whereby the frequency of one particular mode of the deuterium isotopologue was found to be higher than that of hydrogen. The mode in question is the IR-active out-of-plane bending vibration observed in Ar matrices at 722.7 cm^{-1} for H_2Pc, but which shifts up to 729.9 cm^{-1} in D_2Pc. The observed isotope shift ratio (ISR) of 0.990, determined as the ν_H/ν_D ratio, was very well reproduced in the theoretical DFT results. To probe whether this unusual reversed ISR (<1) effect is a peculiarity of Pc, we have extended the theoretical work in the present study to cover the 3 most closely related free-base tetrapyrroles, namely porphine (P), tetraaza-porphine (TAP), and tetrabenzo-porphine (TBP). The structures of all four molecules are provided in Fig. 1, revealing the strong similarities of these very important materials, often called the "colours of life".[7]

A theoretical prediction of the occurrence of a reversed isotope shift ratio (ISR < 1) was made several years ago by Li and Zgierski in their work on developing a local mode description of the vibrations in the porphines for both free-base and metallo-porphines.[8] Their vibrational analysis was based on a valence force field and conducted with the Wilson-GF matrix method.[9] However, as will be shown later, the upward shifts in the heavier isotope were much larger than what we have seen with the force fields generated in the present quantum chemical method. The earlier work[8] only considered in-plane vibrations, i.e., the N–H stretches and in-plane bending modes, but as we have found experimentally[6], the most easily identifiable instance of the reversed ISR effect in the phthalocyanines involved an out-of-plane N–H bending

Fig. 1. Structures of the 4 closely related free-base tetrapyrrole molecules, namely porphine (H_2P), tetraaza-porphine (H_2TAP), tetrabenzo-porphine (H_2TBP) and phthalocyanine (H_2Pc), whose vibrational frequency shifts upon H/D isotope substitution have been studied by the DFT method. The bond lengths and bond angles found in the DFT/B3LYP geometry optimisations are provided in Table 2 for the four molecules. With the present method, all are found to have high (D_{2h}) symmetry.

motion. A more recent DFT calculation of free-base phthalocyanine by Liu et al. also found a reverse ISR.[10] While these authors did not present an analysis of the origins of this effect, they did comment that for the mode concerned, the direction of the H atom motions was opposite to that of the D atoms.

A group theoretical analysis of the four free-base tetrapyrroles, all belonging to the D_{2h} point group, provides the symmetry types and numbers of the normal vibrational modes of the molecules being studied. The results of such an analysis, in which the z-axis is aligned with the two central N–H bonds, are collected in Table 1.[11] As expected, the numbers of modes in the two tetra-aryl molecules (tetrabenzo-porphine and phthalocyanine) are much larger because of the increase in the number of atoms, N. For the purposes of illustration, the material presented herein will concentrate on the smaller parent molecules porphine and tetraaza-porphine. However, in all four molecules the symmetry types of the 6 modes involving N–H motion are the same and can be compared with the complete normal vibrational modes in Table 1.

The main goal then is to establish the correlations between similar NH and ND modes and to rationalize the observed and calculated frequency shifts. Calculating normal mode frequencies with incremental (artificial) variation of the masses of H from 1 to 2 allows these correlations to be established. When the NH(D) motion is predominant, the H to D evolution in the normal mode frequency will decrease in a continuous manner. In the case of two modes of the same symmetry and whose

#Modes	108	96	180	168			

Note: The values in parenthesis are the numbers of atoms in each of the molecules. On the right-hand side, the symmetries of the six possible N–H motions are provided for an analysis conducted with the *z*-axis co-linear with the two central N–H bonds. The abbreviations STR, IPB, and OPB represent the N–H stretching, in-plane bending, and out-of-plane bending modes, respectively.

frequencies are similar, their frequency evolutions could cross, depending on the extent of NH(D) motion involved in them. The evolution diagrams will thus show avoided crossings of various extents, which thereby reveal the degree of the NH(D) motion in the modes. If both normal modes involve similar atomic motions, including the NH(D) one, they will be distorted around the mass of H corresponding to the crossing, to avoid it. This is similar to the well-known characteristic of avoided crossing found in potential energy surfaces for electronic states with the same spatial symmetry.[12] It allows an analysis of the underlying mode interactions. In the present paper, the instances of ISR < 1 are especially focussed on.

Methods

DFT was utilized with the 6–311G++(2d,2p) basis set for both geometry optimization and the calculation of the vibrational frequencies. The B3LYP functional is currently the most effective for calculating ground-state molecular vibrational frequencies, and when used with a large basis set, generates accurate IR intensities. Moreover, as demonstrated in our previous study of both zinc and free-base phthalocyanine, the Raman intensities are also reliable.[6] Another advantage of this method is that it runs efficiently on multiprocessor computers. The present calculations were conducted with the Gaussian-03 suite of programmes[13] running, as described elsewhere[6], on a Linux workstation with two quad-core processors. All the calculated vibrational frequencies presented in this work are, unless stated otherwise, unscaled values obtained within the harmonic approximation.

Because of the un-intuitive nature of the effect being analysed, the approach taken in calculating the vibrational frequencies involves increasing the masses between H and D incrementally, in steps of 0.05 amu, so that the evolution of the modes from the light to the heavy isotopologue can be followed in a near-continuous manner. This is the approach we utilized in our previous phthalocyanine work.[6] Recently, this method has been applied successfully by Wright and coworkers in their work on re-numbering the vibrational modes of benzene and its monosubstituted derivatives.[14] The task in the present analysis is to track the mass dependence of the normal modes to see where they cross, but more importantly, it is to identify where curve-avoidance occurs and analyse the underlying mode coupling that produce ISR values less than 1. In doing this, we exploit the high symmetries found in the optimized geometries of the free-base tetrapyrroles. Accordingly, this analysis is done on normal modes of a given symmetry type with a particular focus on those modes involving the N–H vibrations. As mentioned earlier, there are only 3 types of N–H motions, but 6 distinct symmetries are involved. Thus, the reducible representation (Γ) for motion involving ONLY the two inner H-atoms (iH) can be shown to be $\Gamma_{iH} =$ 6 –2 0 0 0 0 2 2. Application of the reduction formula to Γ_{iH} gives the symmetries of the N–H vibrations as $1a_g$, $1b_{2g}$, $1b_{3g}$, $1b_{1u}$, $1b_{2u}$, and $1b_{3u}$. These 6 modes as listed in Table 1 for the 4 free-base molecules considered.

To analyse details of the atomic motions producing the reverse isotope substitution ratios (ISR < 1), we have extracted the contributions of the internal coordinates to the normal modes. The internal mode contributions to a specific normal mode are expressed as percentages, which were generated directly in the Gaussian-03 package.[15] The calculation of the "% Internal modes" involves a projection of the normal modes onto the displacement vectors that define the redundant internal coordinates. Only the most important terms are given, with the default being all modes greater than 0.1, with the cut-off being reduced until the total of 0.9 is reached. This is implemented with the "freq=internal" command in the input file.

Results

The optimized geometries obtained with the DFT/B3LYP method and the 6–311G++(2d,2p) basis set for the 4 free-base tetrapyrrole molecules studied are shown in Fig. 1. Complete listings of the geometric parameters for the free-base tetrapyrroles, porphine (H_2P), tetraaza-porphine (H_2TAP), tetrabenzo-porphine (H_2TBP), and phthalocyanine (H_2Pc) are provided in Table 2. In all cases, high (D_{2h}) symmetry was preserved in the geometry optimisations, and no imaginary

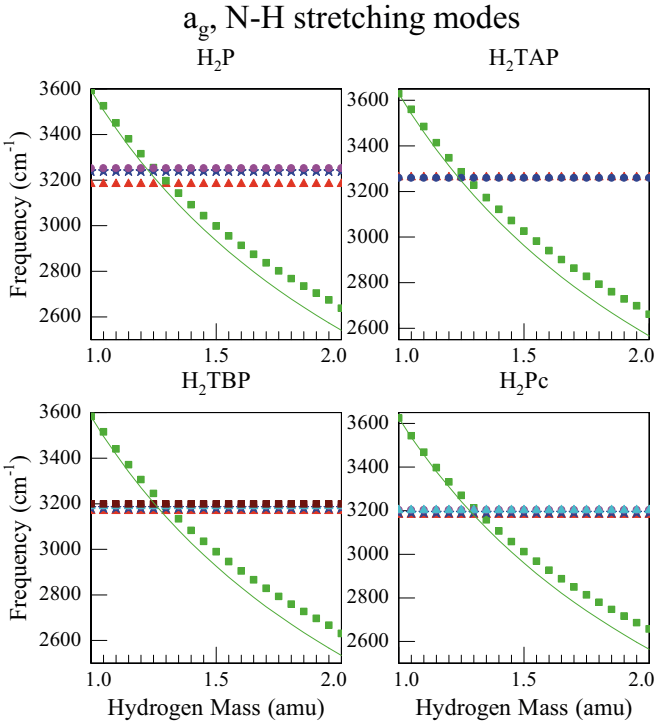
Note: The atom labelling follows standard notation used in our previous work on H_2Pc.[6]

low frequencies were found. These results indicate that the planar geometry is the most stable in all 4 cases.

In the present H/D isotope substitution study, we focus on the vibrations involving N–H motion of which there are 3 types. As indicated in Table 1, the N–H stretching (STR) modes are the a_g and b_{1u} symmetries corresponding to the Raman-active symmetric and IR-active asymmetric vibrations, respectively. The N–H in-plane bending (IPB) modes are of b_{3g} and b_{2u} symmetry, arising from the in-phase and out-of-phase bending motions, which are Raman-active and IR-active, respectively. The N–H out-of-plane bending (OPB) modes are of b_{2g} and b_{3u} symmetry, the Raman-active in-phase and IR-active out-of-phase modes, respectively. The behaviour of each of these 3 N–H modes will now be analysed on the basis of the 6 possible symmetries that they possess.

From the summary of the group theory results presented in Table 1, one might expect that the H/D isotope dependence of the N–H OPB motion would be the easiest to follow. For instance, in H_2TAP the OPB mode is 1 of only 8 (b_{2g}) normal modes, while the N–H stretch should be the most difficult, being 1 of 17 (a_g) modes. In H_2TBP, this stretching mode is 1 of 31 modes. However, as we have found experimentally for H_2Pc, identifying the OP bending in H/D substitution is far from obvious when the frequency of some modes *increase* in D_2Pc![6] The contrasting behaviour of these modes arises, as will be elaborated later, for two reasons. The first is that the N–H stretch modes occur at high frequencies, energetically distinct from all other modes except for the C-H stretching modes, while the IPB and OPB modes occur in congested regions where multiple mode crossings occur. The second reason is that the internal N–H stretching modes are very well localized on the N–H bonds. In contrast, avoided crossings occur in the IP and OP bending motions, rendering mode attributions in the deuterium isotopologue difficult.



N–H stretching (a_g and b_{1u}) modes

The frequencies of the N–H stretching modes are shown in Figs. 2 and 3 for the 4 free-base tetrapyrrole molecules studied, as a function of incrementally increasing the H-atom mass from 1 to 2 amu. Taking porphine (H_2P) as an example, shown on the upper left in Fig. 2, the Raman-active (but weak) a_g N–H stretching mode crosses directly over three C-H stretching modes and continues to decrease monotonically from 3593.5 cm^{-1} in H_2P to 2638.3 cm^{-1} in D_2P. This corresponds to a shift of 955.2 cm^{-1} and a ν_H/ν_D (ISR) ratio of 1.362. This is close to the expected value of approximately $\sqrt{2}$ for H/D isotopic substitution of a normal mode involving nearly pure N–H motion.[16] The solid curve in Fig. 2 shows the theoretical mass dependence ($1/\sqrt{m_H}$) given by eq. [1]. It is evident that the agreement between the DFT predicted data and this theoretical dependence is good.

The mass dependence of the (strong) IR-active b_{1u} mode, shown on the upper left in Fig. 3, exhibits a similar pattern with the N–H stretch at 3552.3 cm^{-1} in H_2P, crossing over three C-H stretches as the masses of the central hydrogens are increased. The N-D mode has a frequency of 2611.9 cm^{-1}, which gives a ν_H/ν_D ratio of 1.360. As illustrated in Fig. 3, this pattern is observed for the 3 other molecules studied. H_2TAP is the simplest system having the least amount of C-H modes, just 2 in number. In contrast, the tetra-aryl molecules, H_2TBP and H_2Pc, have numerous C-H modes. However in all cases,

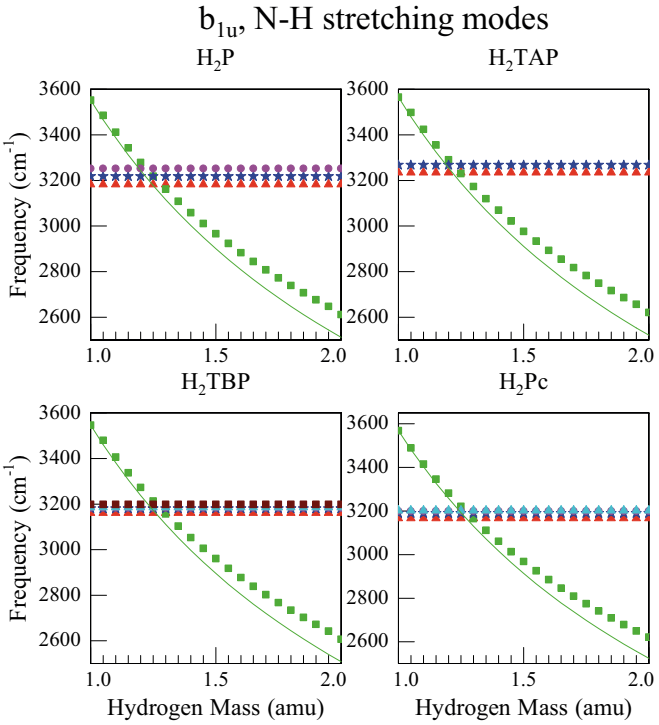
Fig. 2. Dependence of the vibrational frequencies of the Raman-active N–H stretch (a_g symmetry) normal modes of the 4 (D_{2h}) free-base tetrapyrrole molecules with H/D isotope substitution of the two inner hydrogens. The values shown are harmonic results calculated by increasing the H mass from 1 to 2 in increments of 0.05 amu. The solid trace provides the predicted inverse dependence of the frequency on the square root of the mass, indicating close agreement with the calculated values. The frequencies of the C-H stretching modes are completely unaffected by the H/D isotope substitution of the two inner hydrogens.



direct crossings of the normal modes occur indicating the absence of coupling between N–H(D) stretching modes and C-H stretching modes.

The frequencies of the N–H stretching modes of H_2P, H_2TAP, H_2TBP, and H_2Pc are collected in the upper section of Table 3 for the light and heavy isotopologues. The ISR (ν_H/ν_D) values calculated from these frequencies are listed for the two (a_g and b_{1u}) symmetries involved. From the values provided in Table 3, it is clear that the ISR values span a small range, from 1.364 for the a_g mode of phthalocyanine (Pc) to 1.360 for the b_{1u} mode of porphine (P). It is evident that for both symmetries, presented in Figs. 2 and 3, respectively, the N–H stretching mode passes directly through the C-H stretching modes in all four molecules without any interaction amongst these high-frequency modes. An examination of the C-H stretching modes reveals that the changes in their frequencies, after being crossed by the N–H modes, are extremely small. In all cases, except TBP where it is 0.04 cm^{-1}, these changes are in the third decimal place. With this small magnitude, these shifts are less than the uncertainty of the method and are not considered significant.

An analysis of the internal modes reveals the small deviation of the calculated ISR values (1.36) from $\sqrt{2}$ arises from the involvement of the pyrrole ring deformation that accompanies the N–H stretching motion for kinematic reasons. No other internal motions are involved in these nearly pure NH(D) stretching modes. See the upper panels of Tables 4 and 5 for details of the % internal N–H motions of these modes in the smaller tetrapyrroles, TAP and porphine, respectively.

Fig. 3. Similar to Fig. 2 except for the IR-active b_{1u} symmetry normal modes.

OPB (b_{3u} and b_{2g}) modes

b_{3u} N–H bending modes

The mass dependences of the b_{3u} OPB modes of P, TAP, TBP, and Pc are shown in the 4 panels of Fig. 4. In the frequency range 800–550 cm^{-1} presented in these plots, all 4 molecules show the same number of normal modes, and the mass dependence is clearly not simple in any of them.[17] Most conspicuous is the pronounced avoided crossing that occurs between two modes in the central section of the P and TAP plots. In both cases a normal mode that starts out strongly mass dependent, and is an N–H OPB motion, becomes mass independent and evolves into a mode that involves large amplitude C-H OPBs. This is clearly not a correct mode attribution of the light to the heavy isotopologues. To help analyse the complex behaviour exhibited, the theoretical mass dependence given by eq. [1] is overlaid as a solid trace in Fig. 4. This curve, in contrast with the previous ones generated for the a_g and b_{1u} modes, was calculated from the lowest frequency D_2 mode, because the N–H OPB motion is manifested more strongly in the heavier isotopologues of these molecules than in the lighter ones (corresponding to a less congested spectral region for b_{3u} modes). The internal mode analysis provided in Table 4 for TAP shows the contribution in D_2TAP as 72%, while it is only 53% in H_2TAP. Table 5 reveals a similar pattern for the b_{3u} mode of porphine.

Note: All frequencies are unscaled DFT results given in cm^{-1}. The isotope shift ratios (ISR) are calculated as $\nu H/\nu D$, i.e., the hydrogen frequency divided by the deuterium value. ISR values significantly less than one are highlighted as they are indicative of strongly avoided crossings.

*No curve crossings occur between these two modes in TAP. The values chosen for inclusion were selected on the basis of the similarities of their motion with the three other tetrapyrrole molecules.

From the match shown for P in the upper left panel of Fig. 4, between the calculated data and the simple $1/\sqrt{m_H}$ mass-dependence, it is clear that the frequency of the "pure" N–H OP mode decreases from 739.9 cm^{-1} in H_2P to 541.8 cm^{-1} in D_2P. The resulting ν_H/ν_Dratio is 1.366, quite close to the expected value of $\sqrt{2}$. This mode crosses a pure C-H OPB with a frequency of 709.5 cm^{-1}, which is H-atom mass-independent and is thereby not affected by the N–H isotopic substitution. In contrast, it produces an avoided crossing with another C-H OPB mode, which has an initial value of 651.4 cm^{-1} in H_2P but increases to 657.9 cm^{-1} in D_2P. A clear consequence of the avoided crossing is that this mode shifts up in frequency by 6.53 cm^{-1} and produces an ISR value (ν_H/ν_D ratio) considerably less than unity — the value is 0.9901. As indicted in Table 3, similar behaviour is exhibited by this mode in all 4 molecules. The most extreme situation is found for TAP, which has an ISR value of 0.9882.

Figure 5 shows a vector diagram for the atomic motions involved in the modes of TAP that exhibits the most pronounced reversed ISR effect. From the motions presented, the association of the 760.8 cm^{-1} mode with the 547.7 cm^{-1} mode is unquestionable. Thus as illustrated, the vector diagrams for the N–H OPB motions of H_2TAP and D_2TAP are indistinguishable for these two frequencies. However, a consequence of these mode assignments is that the mode at 656.7 cm^{-1} must be correlated with that at 664.5 cm^{-1}, an upward shift of 7.82 cm^{-1} in D_2TAP. This correlation is supported by the very similar C-H OPB motions illustrated for both isotopologues on the bottom of Fig. 5. However, on closer scrutiny of these two diagrams it can be seen that the direction of the N–H bending motion with respect to the molecule is reversed in the N-D mode. This change in the motion of the light and heavy isotopologues is found to be a characteristic of all the modes exhibiting the large reverse ISR, which involve strongly avoided mode crossings.

Reverse ISRs are observed to be larger in cases with more pronounced avoided crossings, i.e., with stronger coupling, W, between the modes. The reversal of the directions of the H-atom motions in the light and heavy species can be seen as a direct consequence of perturbation theory in first order. In the simplified case of two coupled modes, one mode, ν_H, involving large H motion and the other, ν_N, involving little H motion as is the case for when the H→D progression is very flat except in the region of the crossing, the result of perturbation theory will give new modes ν'_N with $|\nu'_N\rangle = |\nu_N\rangle + W/(E_{nN} - E_{nH})|\nu_H\rangle$. The reason for the reversed directions can be understood as follows. Since the sign of the matrix element W ($= \langle\nu_H|W|\nu_N\rangle$) does not change from H to D, but it does change for the energy term, i.e., $(E_{nN} - E_{nH}) < 0$ for H, whereas $(E_{nN} - E_{nH}) > 0$ for D, this means that the motion of $H(|m_H\rangle)$ appears with opposite signs in the description of $|\nu_N\rangle$ in the hydrogenated and the deuterated species, i.e., reversal of directions. This "reversal" is larger and more obvious when the coupling W strength is greater.

Table 4. Contributions of the N–H internal modes to the normal modes involving crossings, or avoided crossings of TAP.

b_{2g} N–H bending modes

The H/D isotope dependences of the Raman-active b_{2g} N–H OPB modes of porphine and TAP are, as shown in the upper panels of Fig. 6, relatively straightforward, exhibiting a continuous mode evolution from the light to the heavy isotopologue. As indicated in Table 3, they exhibit an ISR of 1.33 and follow the simple mass dependence shown by the smooth curve in Fig. 6. In contrast, TBP and Pc are both complicated by the existence of an additional mode that is crossed by the N–H b_{2g} OPB mode at different locations.

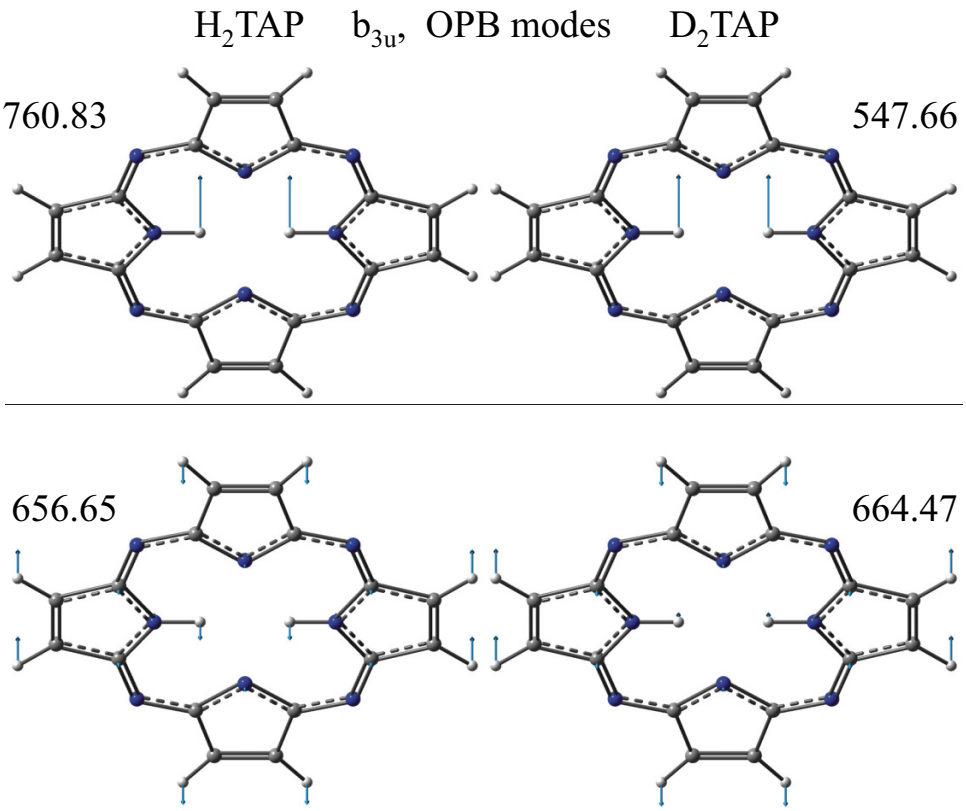
Fig. 4. Mass dependence of the IR-active b_{3u} symmetry normal modes for the OPB vibrations. In contrast to the high frequency modes, strong coupling occurs between the N–H OPB modes and especially the C-H OPB modes. This is indicated by the large avoided crossing that is clearly evident in the top two panels where P and TAP results are shown. A strong correlation exists between the N–H OPB modes of the light and heavy isotopologues, as indicated by the theoretical mass dependence of the frequency. However, the frequency of the C-H OPB mode "crossed" by the N–H mode *increases* in the deuterated molecule, leading to reversed isotope shift ratios (ISR < 1).

Again, the mass dependence curve is very instructive in identifying the correct mode evolution. As listed in Table 3, the 711.7 cm^{-1} mode of H_2TBP correlates with the 520.1 cm^{-1} mode of D_2TBP, giving an ISR value of 1.368; a similar value is present for phthalocyanine. However, the curve avoidance that is now present produces ISR values significantly less than 1 in both cases for the modes crossed. Table 3 lists these as 0.991 and 0.989 for TBP and Pc, respectively.

IPB (b_{2u} and b_{3g}) modes

Summaries of the isotope dependences of the b_{2u} and b_{3g} N–H IPB modes are provided in Figs. 7 and 8, respectively. The mass dependences of these modes are evidently not simple but are quite similar for all 4 molecules. It is clear that these IPB modes do not show a mass dependence that is as strong as ($m_H^{-1/2}$), shown by the smooth line. Instead, several modes appear to have a weak, near-linear dependence on mass. The slope of the ($m_H^{-1/2}$) law is never approached, whatever the isotopologue. This effect is due to an extreme dilution of NH IP motions in many modes of the same symmetry. Modes exhibiting the highest absolute slope at $m_H = 1$ or 2 correspond in fact to the modes involving the highest % of NH or ND IP motion, respectively. This is verified in Tables 4 and 5, where the b_{2u} and b_{3g} modes exhibiting the highest % are reported for TAP and P, respectively.

b_{2u} N–H bending modes



Some mode crossings do occur for the b_{2u} N–H IPB motion, and because of the similarity of the behaviour in the mid-frequency region for all 4 molecules, the modes in the 850–1070 cm^{-1} range have been chosen for inclusion in Table 3.

The IR-active b_{2u} modes of porphine and TAP are quite similar, showing a diluted effect upon isotopic substitution of the inner hydrogens. As listed in Table 3, the mode at 1003.5 cm^{-1} in H_2P, involving an N–H IPB, drops down to 882.8 cm^{-1} in D_2P. This shift corresponds to a ν_H/ν_D ratio of only 1.137, a value much less than $\sqrt{2}$. This mode shows a weak avoided crossing with the one at 967.2 cm^{-1}, a pyrrole ring stretching mode. This avoided crossing has the effect of increasing the frequency of the pyrrole ring stretching mode in D_2P by a small amount to 967.4 cm^{-1} and generating a ν_H/ν_D ratio of 0.9997. While the 0.27 cm^{-1} shift in frequency for the pyrrole mode is small, similar values are exhibited by all the tetrapyrroles, except Pc where it is yet smaller, 0.06 cm^{-1}. The significance of these ISR values is hard to ascertain because while they are consistently less than 1, they are very close to it. It is worth noting however that for the pure C-H stretching a_g and b_{1u} modes crossed over by the N–H(D) mode (see Figs. 2 and 3), the ISR values are much closer to 1. In the present IPB b_{2u} mode, vector diagrams indicate that there is some N–H character in the pyrrole ring stretch, so the small ISR values are deemed significant.

While not included in the global ISR summary provided in Table 3, it is evident in Fig. 7 that mode crossings do occur in the lower frequency range, but the crossing regions vary from molecule to molecule. Thus direct crossings are exhibited by P and Pc, while avoided crossings are present in TAP and TBP. Information on the avoided crossing in the former is provided in Table 4, where the 776.5 cm^{-1} mode of H_2TAP decreases to 726.4 cm^{-1} for D_2TAP with a small ISR value of 1.069. However, this then produces a frequency increase in the interacting mode at 748.9 cm^{-1} that moves up to 754.0 cm^{-1} in D_2TAP and has an ISR significantly less than 1, with a value of 0.9932. Porphine does not exhibit this behaviour, so a corresponding value is not given in Table 5.

In the higher frequency region, only P and TBP exhibit avoided crossings and detailed information on the behaviour of porphine is presented in Table 5. It is evident there that a reverse ISR is present with an upward frequency shift of 16 cm^{-1}, producing an ISR value of 0.9866. Thus the highest frequency N–H IPB mode at 1260.6 cm^{-1} correlates with the 1120.3 cm^{-1} mode of D_2P, yielding a diminished ISR of 1.125. A consequence of this attribution is that the H_2P mode at 1179.3 cm^{-1} must be associated with the 1195.3 cm^{-1} mode of D_2P. An upward shift of 108 cm^{-1} was previously highlighted by Li et al. for a b_{2u} symmetry asymmetric deformation, δ_{as}(NH), mode.[8] However, this earlier correlation involved modes at 986 and 1094 cm^{-1}, which do not correspond to the present ones at 1179 and 1195 cm^{-1}.

Fig. 5. Vector diagrams showing the very similar atomic motions involved in the pure N–H OPB motion of TAP for the hydrogenated and deuterated molecules, top left and right, respectively. In the bottom, the motions in the C-H mode involved in the avoided crossing with the N–H OPB are shown. The 656/664 cm^{-1} mode correlations of the two istopomers are clearly correct. However, on closer scrutiny it is evident that the direction of the small N–H motion, which this mode possesses, is reversed in the H and D molecules. This behavior is exhibited in all the modes involved in the avoided crossings.

b_{3g} IPB N–H modes

The Raman-active b_{3g} modes presented in Fig. 8 exhibit similar behaviour to the IR-active b_{2u} modes, but the mass dependence is even more diluted. This dilution effect is extreme in the case of the larger molecules TBP and Pc, where every mode, except one at 1140 cm^{-1}, shows a slight mass dependence. As a result, most of the modes are parallel, which mitigates against curve crossings. In contrast, the behaviour in P and TAP is more well-defined with two modes at around 810 and 1020 cm^{-1}, clearly mass independent, while the remainder all show some mass dependence.

Taking porphine as an example, the most "pure" N–H IPB mode (listed in Table 5 as 26.4%) has a frequency of 1264.1 cm^{-1}, a value that decreases to 1184.6 cm^{-1} as the mass is increased from 1 to 2 amu. As quoted in Table 3, this correlation produces a ν_H/ν_D ratio of 1.067, and the aforementioned mode exhibits an avoided crossing with the one at 1213.1 cm^{-1} involving C-H IPBs. It thereby generates a small increase in the frequency in the heavy isotopologue. This increase is listed in Table 3 as 1.22 cm^{-1}, and when compared with TBP, consistent ISR values of 0.999 are obtained. No curve crossings occur between these two modes in TAP. The TAP values chosen for inclusion in Table 3 were selected on the basis of the similarities of their motion with the 3 other tetrapyrrole molecules.

Discussion

To examine the occurrence of the reversed ISRs, the so-called product rule presented by Wilson et al. on isotope shifts in high-symmetry molecules will now be considered.[9] The general form of the product rule for isotopic substitution is given (Ref. 9, p. 248) as:

$$[2]\qquad \frac{\omega_1'\omega_2'\ldots\omega_n'}{\omega_1\omega_2\ldots\omega_n} = \left[\left(\frac{\mu_\alpha'}{\mu_\alpha}\right)^a\left(\frac{\mu_\beta'}{\mu_\beta}\right)^b\ldots\left(\frac{M'}{M}\right)^t\left(\frac{I_x'}{I_x}\right)^{r_x}\left(\frac{I_y'}{I_y}\right)^{r_y}\left(\frac{I_z'}{I_z}\right)^{r_z}\right]^{1/2}$$

Equation [2] pertains to all the vibrational frequencies $\omega_1\omega_2\ldots\omega_n$ of a single symmetry species for the light molecule, while $\omega_1'\omega_2'\ldots\omega_n'$ are the corresponding values of the heavy isotopologue. In eq. [2] the exponents *a, b,*. . . relate to the atoms being substituted, while the values of *t*, r_x, r_y, and r_z are the translation and rotation representations, respectively. μ, *M*, and *I* are the reduced mass, the total molecular mass, and the moments of inertia, respectively. Appendix A presents the equations specific to the 6 vibrational modes sensitive to H/D substitution of the two inner H-atoms for D_{2h} symmetry. A comparison of the numerical values arising from the DFT calculations done on H_2TAP/D_2TAP with the theoretical values predicted by the specific equations in Appendix A is provided in Table 6.

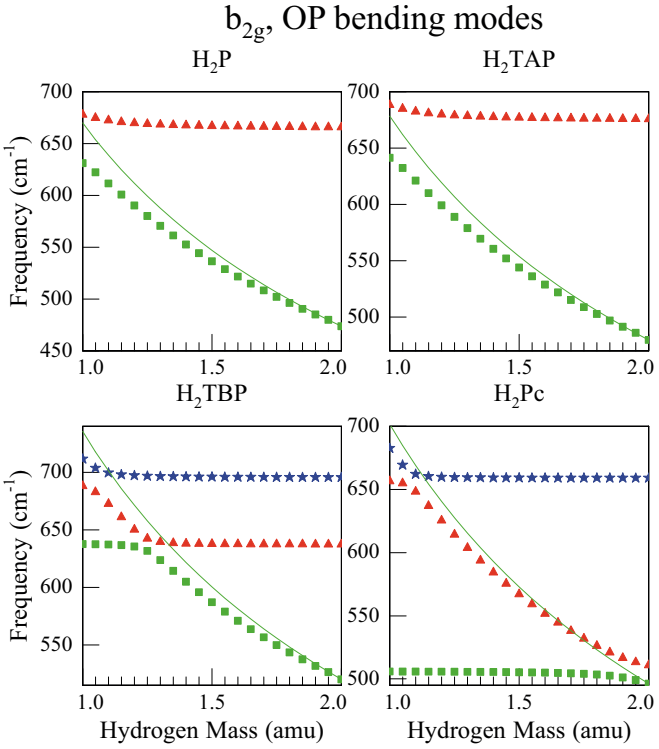
Fig. 6. Similar to Fig. 4 except for the Raman-active b_{2g} symmetry N–H OPB modes. Particularly simple behaviour is exhibited in the smaller molecules P and TAP, as indicated by the close agreement with the solid curve showing the theoretical mass dependence.



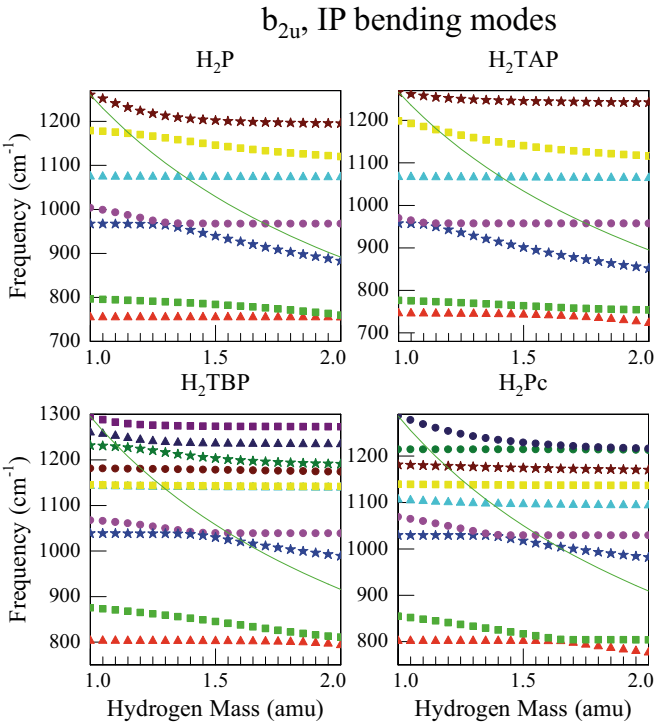


Fig. 7. Mass dependence of the IR-active b_{2u} symmetry for the N–H IPB modes. Particularly evident is the large number of modes and the fact that they nearly all show a dependence on mass. This reveals immediately that the N–H bending vibration is diluted over many modes, none of which can show the expected mass dependence of a pure mode indicated by the smooth curve.

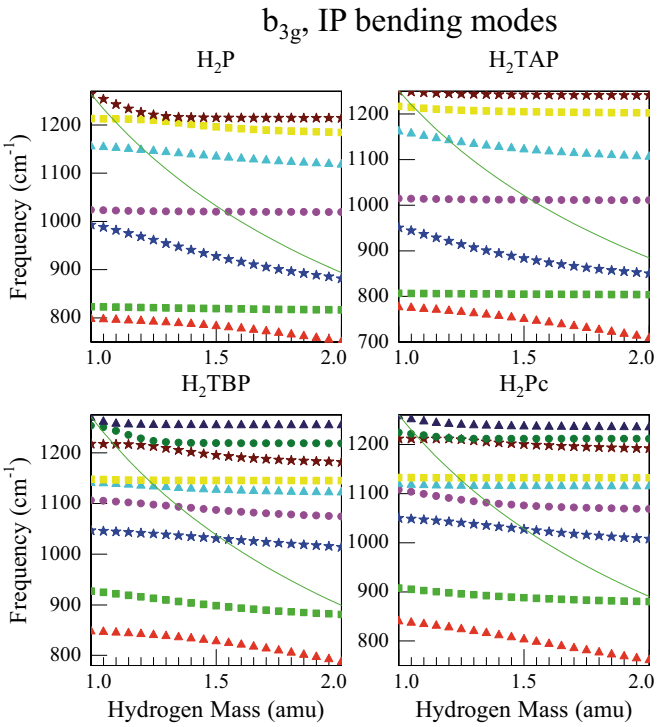
As indicated by the values given in Table 6, the product rule unfortunately does not reveal the reversed ISR effect very clearly. However, the deviations between the calculated DFT values and those predicted by eq. [2] are largest for the IPB and OPB modes. These deviations, shown on the right-hand column in Table 6, are greater than the N–H stretch (STR) modes and the two modes where no H/D dependence is (correctly) predicted. The reason for this inability to highlight the reversed ISR is because eq. [2] involves *all* the modes of the same symmetry. This means that the normal modes with avoided crossings (reversed ISRs) are "compensated" by other regular modes. Despite this shortcoming, the product rule indicates the accuracy of the DFT results, as the deviations between calculation and theory are very small indeed.



Comparison with other calculations

In the detailed theoretical study carried out by Li and Zgierski on developing a force field for free-base porphine, upward frequency shifts were proposed for the b_{1g} and b_{2u} IPB modes upon deuteration.[8] However, the previous study dealt only with the in-plane vibrations, namely the N–H stretching and IPB modes. Because of the use of a different axis system (see Note 11) in the current and previous works, b_{1g} symmetry of Li et al.[8] corresponds to our b_{3g} mode, while the b_{2u} modes are the same in both studies. In Scheme I of Ref. 8, these workers proposed a large increase in the frequency of two modes upon H/D isotopic substitution, both of which involved IPB. Specifically, they proposed that the b_{1g} N–H IPB mode crosses with the a pyrrole half-ring stretch mode, which had the effect of shifting the frequency of the pyrrole mode up by 56 cm^{-1}, from 976 cm^{-1} in H_2P to 1032 cm^{-1} in D_2P. The other mode that showed this effect was a b_{2u} mode, in which the asymmetric N–H IPB vibrations and the pyrrole ring stretch cross. This caused the pyrrole stretch to shift up in energy by 108 cm^{-1}, from 986 cm^{-1} to 1094 cm^{-1}. It is not evident why the OPB modes were not analysed for this effect in the earlier study; it may have been due to their interest in the role of the N–H stretch and IPB vibrations in the tautomerism of free-base porphine.[8]

As indicated in the upper left panels in Figs. 7 and 8, reverse isotope shifts of this magnitude are not exhibited by porphine in the b_{3g} and b_{2u} IPB modes, respectively. Evidently there are significant differences between Li's results[8] and the findings of the present DFT method. The earlier work identified only two instances of this increased frequency, both of which are much larger than what we find. These differences may arise for a number of reasons. Their calculations were carried out with the GF matrix method and a valence force field. While their method was paramaterised to give a good match with experimental data, it is likely the valence force field is not capable of accounting for all the interactions present in molecules of this size. Complete sets of force constants are of course available from quantum chemical calculations, and the use of high level DFT calculations are currently the most powerful for predicting the ground-state vibrational frequencies of large polyatomic molecules. Based on the favourable findings of our previous DFT results on ZnPc and H_2Pc and the matrix-IR spectra[6] of these

Fig. 8. Similar to Fig. 7 except for the Raman-active b_{3g} symmetry N–H IPB modes.

molecules, we are confident that the present results are a more accurate reflection of the extent of the up-shifted frequencies.

Li et al. identified the NH(D) IPB b_{2u} modes at 1223 (825) cm^{-1}, corresponding to 1261 (883) cm^{-1} in our calculations.[8] These modes exhibit, as listed in Table 5, the highest % of NH(D) IPB motion. A mode which also involves non-negligible NH bending motions was identified at 986 cm^{-1} (ν_{44a}) in the previous work and corresponds to the mode at 1003 cm^{-1} in the present work (14.8% N–H IPB in Table 5). This mode is found to correlate with the mode at 883 cm^{-1} in the deuterated species, i.e., the mode involving the highest % N-D IPB motion. In the discussed case, the entries in Table 5 show that modes at 1261 and 1003 cm^{-1} in the H species correlate with modes at 1120 and 883 cm^{-1}, with a decrease of the N-"H" IPB % in the higher frequency mode and an increase of the N-"H" IPB % in the lower frequency one, explaining the earlier result. It must be mentioned that the b_{2u} mode at 1094 cm^{-1} highlighted by Li et al.[8] in the correlations for the D species, corresponds to a mode at 1076 cm^{-1} in our calculation; this mode does not involve N-D IPB motion. The discrepancies between the earlier results from Li et al. and the present results on b_{3g} modes of porphine are similarly explained. The curves of Fig. 7 and 8 show clearly the correlations between H and D species and are summarized in Table 5. Because of a strong mixing of various atomic motions in the b_{3g} and b_{2u} modes for the frequency range of interest, a slightly different description of normal modes can have important consequences in their assignments, as highlighted by the example in this last discussion.

Comparison with experiments

The results of the current calculations can be compared with experimental isotope substitution work, but because the mass-related shifts are quite small in the congested 1500–500 cm^{-1} spectral range, high-resolution methods yielding narrow line transitions are required for analysis. The matrix-isolation technique is particularly well suited for this work. Currently however, only a very limited number of tetrapyrroles have been examined in this way. One system that has been examined already is our recent work on the phthalocyanines, from which the current investigation has emerged.[6] The other is the earlier study of Radziszewski et al., who used matrix-IR spectroscopy to look at deuteration effects in free-base porphine.[18] To compare the present theoretical results on porphine with the experimental matrix work,[19] the simulated DFT IR absorption spectra of H_2P and D_2P are shown scaled by a factor of 0.98 in Fig. 9 on the same spectral range as shown in Fig. 12 of the Radziszewski et al.[18] paper. The agreement between the two studies is very good, which testifies to the strength of the current method in predicting not only the IR absorption frequencies of the tetrapyrroles but also their intensities.

In agreement with Radziszewski et al.[18], the mode of H_2P, which was observed at 731 cm^{-1} and attributed to OPB, is predicted at 739.9 cm^{-1} (scaled by 0.98, 725.1 cm^{-1}) in the present calculations. However, their comment that this motion will be distributed over several fundamental modes of D_2P is not borne out by our calculations. As Fig. 10 shows (and listed in Table 3), the N-D OPB mode is well defined and is located at 541.8 cm^{-1} (scaled by 0.98, 530.9 cm^{-1}) in a sparse region of the IR spectrum. Moreover, it is actually much stronger than the corresponding H_2P OPB, so it should be easily identified. While Radziszewski et al. did not present any spectra for this lower frequency region in this early work[18], they did show a strong band around 540 cm^{-1} in Fig. 1 for D_2P in a more recent work.[20] Confusingly, this band is not listed under the D_2P (d_2) column in their Table 1 of Ref. 20, but instead a strong band at 540 cm^{-1} is listed for H_2P in the (d_0) column. From the actual H_2P (d_0) and D_2P (d_2) spectra shown in Fig. 1 of Ref. 20, we conclude that the 540 cm^{-1} band is the OPB of D_2P. Contrary to the expectation of Radziszewski et al.,[18] the frequency of this mode is indicative of an ISR value of a "pure" N–H vibration. This result is entirely consistent with the results of the current DFT calculations. Clearly, it is not a diluted motion, distributed over many bands as Radziszewski et al. stated in their 1989 paper.[18]

The reason this OPB vibration is not diluted over several modes is evident in Fig. 4. As indicated in that plot, its mass dependence is limited to just two modes, both of which exhibit the inverse dependence on the root of mass. This simple behaviour is entirely attributable to the small number (10) of b_{3u} symmetry modes listed in Table 1 for the OPB of free-base porphine. Essentially identical behaviour is predicted for TAP, while Fig. 4 predicts the OPB will only be slightly more complex in H_2TBP and H_2Pc because of the crossing of a single, lower frequency mode.

A key aspect of the current work is the upward shift in the frequencies of specific modes (highlighted in Table 3) in the heavier isotopologue upon H/D substitution. As indicated in that table, the most pronounced instance of this effect in free-base porphine is expected in the OPB mode, where the 651.4 cm^{-1} mode shifts up to 657.9 cm^{-1}. This region is highlighted in Fig. 10 on an expanded intensity scale. This region was presented in the more recent paper by Radziszewski

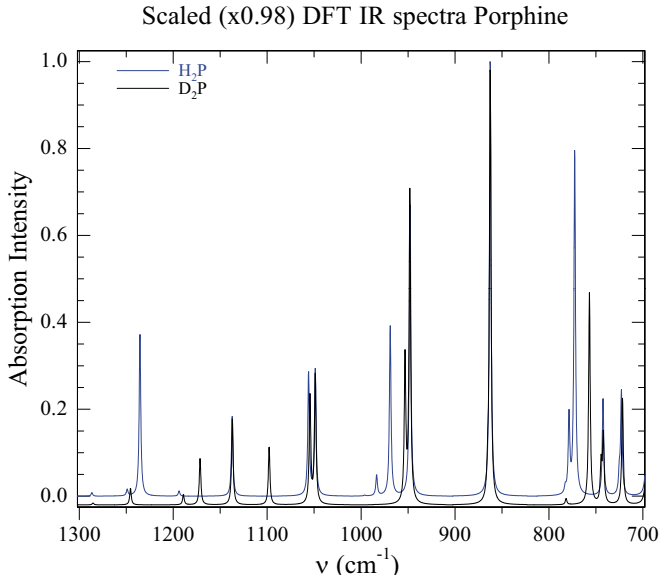
Note: All the normal modes are given even those (b_{1g} and a_u symmetries) where no isotope (H/D) dependence is expected upon substitution of the two inner H-atoms (see Table 1).

Fig. 9. Low-resolution (fwhm = 4 cm^{-1}) plots of the IR absorption spectra generated by the DFT/B3LYP method for the vibrational modes of H_2P and D_2P. The spectral range and format has been selected for direct comparison with the matrix-IR absorption data published by Radziszewski et al.[18] As indicated, the predicted values are scaled by a factor of 0.98 throughout.



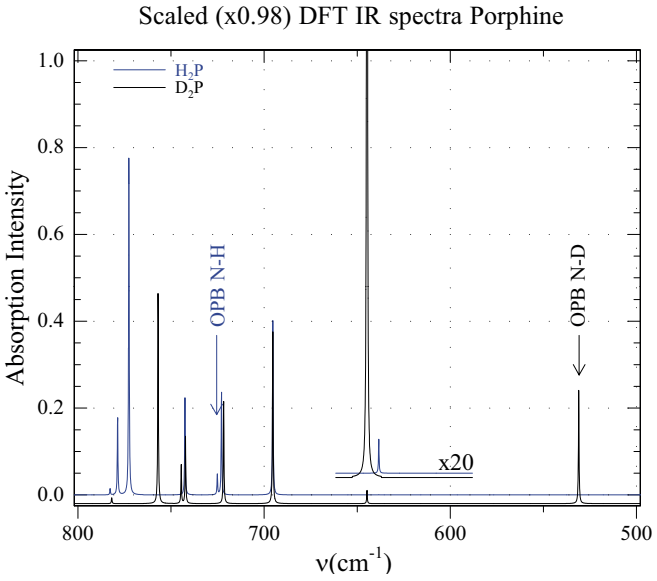


Fig. 10. High-resolution (fwhm = 0.2 cm^{-1}) plots of the IR absorption spectra generated by the DFT/B3LYP method for H_2P and D_2P. The spectral range presented is the region where the large isotope shift on the OPB is predicted. This range was presented in the latest matrix-IR absorption data published by Radziszewski et al.[20], but the band at 540 cm^{-1} in the D_2P spectrum was not attributed to the OPB mode of D_2P.

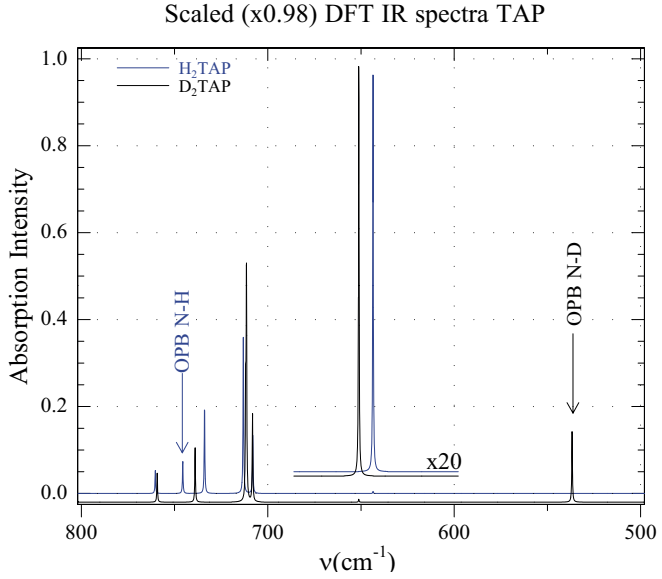
et al. but was not analysed or discussed in the text of the article.[20] In any case, the ISR effect will not be immediately evident in the recorded spectra, because while the D_2P mode at 657.9 cm^{-1} has significant intensity (4.3 km/mol), that of the related H_2P mode at 651.34 $cm^{-1}$is very weak (0.08 km/mol). In the experimental spectrum of the heavier isotope, this ISR effect will present an "unknown" peak in the spectrum not easily connected with H_2P. However, using the matrix-isolation technique, which has high sensitivity, it should be possible to observe the ISR effect in porphine as already done in phthalocyanine.[6]



Future work on the reverse ISR effect

While the reverse ISR effect will not be immediately evident in porphine, the situation is much more favourable for its identification in TAP. Figure 11 presents the low-frequency spectral region of interest. Once again the OPB of this molecule shows the expected mass dependence of the N–H OPBs, as indicated by the labelled arrows. Fortuitously, in this case the intensities of the reversed ISR (0.988) modes are of comparable magnitude in the two isotopologues. These two bands are shown with expanded intensities in the centre of Fig. 11. On the basis of the present DFT calculations, TAP is the system of choice for a matrix-isolation study of this reverse ISR effect, because it produces the largest effect, the H_2TAP and D_2TAP modes are equally strong and they occur in a sparse region of the IR spectrum. To the best of our knowledge this study has not yet been attempted.

Conclusions

The results of the present DFT calculations of H/D substitution on the free-base tetrapyrroles can be summarized as follows. The

Fig. 11. High-resolution (fwhm = 0.2 cm^{-1}) plots of the IR absorption spectra generated by the DFT/B3LYP method for H_2TAP and D_2TAP. The spectra range and format has been selected for examination of the region where the large isotope shift on the OPB mode is predicted to occur.

high-frequency, N—H bond stretching modes are well localized and direct crossings occur with the C-H stretching modes. As these internal modes involve very different motions that are localized on specific bonds, no intermode coupling occurs, yielding the expected values for the isotope shift ratios.

The lower-frequency N–H OPB motions are not distributed over several normal modes principally because the b_{2g} and b_{3u} modes are not numerous. As a result, these modes involve well-defined OPB motions in both the N–H and the N–D bonds. For the smaller tetrapyrroles (P and TAP) no crossings occur for the b_{2g} symmetry Raman-active modes. In the larger molecules, crossings occur but the b_{2g} modes of Pc and TBP still involve localized N–H motions, as illustrated by the similarity with the simple mass-dependence curves. Due to a single mode crossing that occurs in both Pc and TBP, frequency increases do occur in the heavier isotopologue, but because of the involvement of only two modes, instances of reversed ISR can be easily identified in the mass-dependent calculations.

The IR-active b_{3u} OPB modes are slightly more numerous than their b_{2g} Raman counterparts and exhibit more complex behaviour. For all 4 molecules, the N–H OPB mode is crossed by two modes. Clear differences exist between the crossings of these two modes. One is not (or is only very weakly) coupled with the N–H OP bend and passes directly through, while the other mode is strongly coupled and produces a large avoided crossing. A consequence of the strong coupling in the latter case is that the frequency in the heavier isotopologue increases significantly yielding reversed ISR values.

More complicated behaviour is observed for the N–H IPB modes than the OPB modes just described because of the larger number of modes with b_{2u} and b_{3g} symmetries. As a result, the N–H motions are dispersed over many normal modes. Accordingly, the decrease in the NH frequencies is much less than the $m_H^{-1/2}$ mass dependence due to the dilution of this motion over several modes. No normal mode can be identified as "the" NH or ND IPB mode, since the percentages of NH(D) motion are always below 30%. Another consequence of this is that most of the modes are nearly parallel, which reduces the extent of modes crossings. Crossings appear in a congested spectral region, where a mode exists involving no NH(D) motion. This is the case in the region 1000 cm^{-1} in all molecules. In all instances, the crossing is direct and the modes are clearly not strongly coupled. For the b_{3g} modes couplings occur for some molecules in the high-frequency (1200 cm^{-1}) range but produce only weak avoided crossings. The best examples of this are present in porphine and TBP. This coupling does not occur in TAP and only weakly in Pc.

The b_{3u} and b_{2g} OPB modes provide the most clear-cut examples of the effect of avoided crossings. Thus, some of these modes have no effect on each other showing simple, direct crossing without intermode coupling, whereas large avoided crossings are observed in other cases, implying mode frequencies in the same spectral range. Reverse ISR values are obtained in these last cases of large avoided crossings, i.e., crossing between strongly coupled modes involving same atomic motions. This leads to a mixture of these motions, which depend very strongly on minor molecular effects such as the mass of the H atom on the vibration. In all the situations of reverse ISR effect, the vector diagrams of the atomic motions reveal a reversal of the directions of the N–H and N-D movements between the light and heavy isotopologue, explaining how ISR < 1 can arise.

Based on predictions made in the present work and the previously identified instance in which an ISR has already been observed in matrix-IR spectra[6] of the phthalocyanines, it would appear that TAP is the ideal system to make a definitive experimental study of this effect through observation of OPB modes.

(11) In our previous vibrational analysis of the phthalocyanines (Ref. 4) the *z*-axis was chosen perpendicular to the plane of the molecules H_2Pc and D_2Pc. This was done to allow the modes of these D_{2h} species to be directly correlated with those of D_{4h}, ZnPc. Use, in the present work, of the axes system in which the *z*-axis is aligned with the two N–H bonds has the effect of interchanging the 1 and 3 subscripts of the irreducible representations.

(16) The theoretically predicted ν_H/ν_D ratio depends on the reduced mass of the normal mode under consideration. It will be close to, but slightly less than $\sqrt{2}$ in the case of a pure X-H(D) vibration, where X is the mass of the entire molecule minus 1(2). Since the mass of the H-atom is 1.0078250 amu and the D atom is 2.0141018 amu, the limiting (with X of infinite mass) predicted ν_H/ν_D ratio is $\sqrt{1.9985} = 1.41367$.
(17) This finding may seem inconsistent with the group theory analysis presented in Table 1, but the additional modes of TBP and Pc are located at frequencies both above and below the range shown in the figure. The least number of modes are indeed present in the smaller molecules P and TAP.

Appendix A

The values of the numbers *t*, r_x, r_y, and r_z in eq. [2] can be read directly from the character table of the point group, while the exponents *a, b*. . . must be determined by group theoretical methods for the atoms concerned. For the D_{2h} molecule free-base tetraazaporphine (H_2TAP) H/D substitution will produce the reducible representation (Γ_{iH}) for the motion involving ONLY the two inner H-atoms

$$\Gamma_{iH} = 6 \quad -2 \quad 0 \quad 0 \quad 0 \quad 0 \quad 2 \quad 2$$

which gives $1a_g$, $1b_{2g}$, $1b_{3g}$, $1b_{1u}$, $1b_{2u}$, and $1b_{3u}$. Thus, the value for exponent *a* is 1 in the case of H/D substitution for all six symmetries. Moreover, as *only* H-atoms are being substituted, the reduced mass term μ'_α/μ_α in eq. [2] becomes m_H/m_D.

Substitution of these values in eq. [2] thereby provides the following expressions for the isotopic shifts of the 6 modes affected by substitution of the two inner hydrogen atoms.

a_g [17]:
$$\frac{\omega'_8\omega'_{17}\ldots\omega'_{69}\omega'_{72}}{\omega_8\omega_{17}\ldots\omega_{69}\omega_{72}} = \left[\left(\frac{m_H}{m_D}\right)^1\right]^{1/2}$$

b_{2g} [8]:
$$\frac{\omega'_5\omega'_{11}\ldots\omega'_{31}\omega'_{39}}{\omega_5\omega_{13}\ldots\omega_{32}\omega_{35}} = \left[\left(\frac{m_H}{m_D}\right)^1\left(\frac{I_Y^{D2}}{I_Y^{H2}}\right)^1\right]^{1/2}$$

b_{3g} [16]:
$$\frac{\omega'_9\omega'_{13}\ldots\omega'_{64}\omega'_{68}}{\omega_9\omega_{12}\ldots\omega_{64}\omega_{68}} = \left[\left(\frac{m_H}{m_D}\right)^1\left(\frac{I_x^{D2}}{I_x^{H2}}\right)^1\right]^{1/2}$$

b_{1u} [16]:
$$\frac{\omega'_{14}\omega'_{23}\ldots\omega'_{66}\omega'_{71}}{\omega_{11}\omega_{19}\ldots\omega_{66}\omega_{71}} = \left[\left(\frac{m_H}{m_D}\right)^1\left(\frac{M^{D2}}{M^{H2}}\right)^1\right]^{1/2}$$

b_{2u} [16]:
$$\frac{\omega'_9\omega'_{13}\ldots\omega'_{64}\omega'_{68}}{\omega_9\omega_{12}\ldots\omega_{64}\omega_{68}} = \left[\left(\frac{m_H}{m_D}\right)^1\left(\frac{M^{D2}}{M^{H2}}\right)^1\right]^{1/2}$$

b_{3u} [9]:
$$\frac{\omega'_1\omega'_3\ldots\omega'_{27}\omega'_{33}}{\omega_1\omega_3\ldots\omega_{26}\omega_{34}} = \left[\left(\frac{m_H}{m_D}\right)^1\left(\frac{M^{D2}}{M^{H2}}\right)^1\right]^{1/2}$$

In these equations the mode numbering, ω_n, is that generated by the DFT calculation, which also provides the moments of inertia for the two isotopologues. m_H and m_D are the atomic masses of hydrogen and deuterium, respectively, while M^{D2} and M^{H2} are the molecular masses of D_2TAP and H_2TAP, respectively. The outcome of this analysis is compared with DFT results in Table 6.

TRIBUTE

Tak-Hang (Bill) Chan was born on 28 June 1941 in Hong Kong. He developed an interest in chemistry during his high school years very much because of the inspiring teaching of his chemistry teacher, K.T. Cheung, of Pui Ching Middle School in Hong Kong. After finishing high school, he applied to Canadian universities and was admitted to the University of Ottawa. Even though his family did not have the financial resources to support his education in Canada, they scraped up enough money to get him the airfare to Canada in 1958. In his first year of study, he worked as a dishwasher on the weekends to pay for his tuition and living expenses. In the summer of 1959, he started his first summer job as a gardener. The work was short-lived, but his employer gave him the nickname Bill, which he has continued to use.

He transferred to the University of Toronto (U of T) where he completed his undergraduate education while continuing to work part time. At U of T, he came under the influence of George Wright (organometallic chemistry) and Adrian Brook (organosilicon chemistry), leading to a later research interest in those areas. In the summers of 1961 and 1962, he worked as a summer research student in the laboratory of Morris Kates with the National Research Council of Canada (NRC) in Ottawa, Ontario. At that time, chemistry at U of T was very much physical science (mathematics, physics, and chemistry) in emphasis. The work in the Kates' lab exposed him to biochemistry and, together, they published two papers on lipid chemistry. After completion of his undergraduate degree in 1962, he was accepted into the graduate program at Princeton University, Princeton, New Jersey. However, before he went to the United States, he applied for and was granted landed immigrant status in Canada.

At Princeton University, Bill did his Ph.D. thesis under the supervision of Richard Hill, a true scholar/teacher. The thesis research allowed him to appreciate the wonderful world of natural products and the challenge of stereochemistry. By 1965, he was ready to finish his Ph.D. thesis. This was also the year that Robert Woodward, together with Roald Hoffmann, electrified the chemical world with the publication of a series of papers on the role of orbital symmetry on chemical reactions. In spite of other tempting offers, he decided to work for a year as a postdoctoral fellow in Woodward's laboratory on the total synthesis of vitamin B_{12}. It was a tremendous experience, not only in learning from the great master, but also to meet other bright young chemists, especially the contingent from Canada, including Pierre Deslongchamps, Larry Weiler, Chiu Ming Wong, and David Dolphin.

Bill Chan joined the chemistry department of McGill University, Montreal, Quebec, in 1966 and began his independent research career. During his McGill career, Bill served as Chair of the Chemistry Department (1985–1991), Dean of Science (1991–1999), and Vice Principal (Academic) (1994–1999). In 2000, he was named the Tomlinson Professor of Chemistry, a chair that he held until his retirement in 2005. Bill now serves the Department in the well-deserved capacity of Professor Emeritus. In 1979, he was the first Western scientist to bring modern chemistry to China in the post-Cultural Revolution era, and had an enormous impact on Chinese chemistry.

In the first phase of his research, Chan made pioneering contributions to the use of organosilicon reagents for organic synthesis. He and his co-workers developed the use of β-functionalized silanes for alkene synthesis (T.H. Chan. *Acc. Chem. Res.* 1977, **10**: 442–448). This led to a general synthesis of allenes, allene oxides, and bridgehead alkenes. Following that, he examined the regioselectivity and stereochemistry of electrophilic substitution of vinylsilanes. Together with Ian Fleming of the University of Cambridge, Cambridge, UK, he published an important review (T.H. Chan and I. Fleming. *Synthesis*. 1979. 761–786), which has served as the key review in the use of organosilicon compounds for organic synthesis. Chan then developed the use of enol silyl ethers for synthesis. An important contribution was the use of 1,3-bis(trimethylsiloxy)-1-methoxy-1,3-butadiene as a dianion equivalent of methyl acetoacetate. This synthon is often referred to in the chemical literature as "Chan's diene" and is used in many synthetic applications including a novel cycloaromatization reaction (P. Brownbridge, T.H. Chan, M. Brook, and G.J. Kang. *Can. J. Chem.* 1983. **61**: 688). In the course of his study on enol silyl ether chemistry, a new rearrangement reaction was discovered (S.D. Lee, T.H. Chan, and K.S. Kwon. *Tetrahedron Lett*. 1984. **25**: 3399) and is now known as the Chan Rearrangement. The reaction has been used in the syntheses of several complex natural products including boromycin, taxol, and diazonamide A. Another focus of his in organosilicon chemistry involved the study of α-silylcarbanions, which have been used for enantioselective (T.H. Chan and P. Pellon. *J. Am. Chem. Soc.* 1989. **111**: 8737–8738) and regioselective synthesis (T.H. Chan, K. Koumaglo, R. Horvath, D. Wang, Z.Y. Wei, G.L. Yi, and J.S. Li. 1988. *Silicon chemistry*. Ellis Horwood Ltd., New York. Chapter 5).

From 1990 onward, Chan began the second phase of his research career. He has played a leadership role in the development of green chemistry research in Canada. Green chemistry is the effort to develop new chemical reactions and processes that are benign to the environment. The field is relatively young and the term "green chemistry" was first coined in the 1990s. In 1991, he published his first research paper on a new organometallic reaction in aqueous media together with his graduate student, C.J. Li (C.J. Li and T.H. Chan. *Tetrahedron Lett.* 1991. **32**: 7017–7020). Before this study, organometallic-type reactions were usually carried out in organic solvent under anhydrous conditions. Chan was able to demonstrate that a number of organometallic-type reactions can be carried out in aqueous media (T.H. Chan, C.J. Li, M.C. Lee, and Z.Y. Wei. *Can. J. Chem.* 1994. **72**: 1181–1192). In particular, the indium-mediated reaction has found extensive applications in organic synthesis, especially for carbohydrates, as this eliminates the need for protecting group chemistry.

Chan has also contributed to the understanding of the mechanisms of these reactions in aqueous media (T.H. Chan and Y. Yang. *J. Am. Chem. Soc.* 1999*.* 141: 3228–3229; W. Miao, L.W. Chung, Y.-D. Wu, and T.H. Chan. *J. Am. Chem. Soc.* 2004. **126**: 13326–13334). Chan then followed the study in aqueous media to the investigation of organometallic reactions in ionic liquids, including the use of indium, tin, zinc, and magnesium (M.C. Law, K.Y. Wong, T.H. Chan. *Chem. Commun.* 2006. 2457–2459).

As a result of the study on ionic liquids, he and his group proposed a novel liquid-phase strategy for organic synthesis by using ionic tags as a soluble support (W. Miao and T.H. Chan. *Acc. Chem. Res.* 2006. **39**: 897–908). The homogeneous reaction is usually carried out in a relatively polar solvent. After the reaction, the ion-tagged species is easily separated from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

the other reagents by precipitation with a less polar solvent. The ion-tagged species can function in the role of a catalyst, as a reagent, or as the substrate in the synthesis of small molecules or bio-oligomers. He demonstrated the success of this approach in the synthesis of peptides, oligosaccharides, and nucleotides in collaboration with Masad Damha of McGill University (R.A. Donga, M. Hassler, T.H. Chan, and M.J. Damha. *Nucleosides, Nucleotides and Nucleic Acids.* 2007. **26**(10–12): 1287–1293).

In 1997, Chan and Li published the monograph *Organic Reactions in Aqueous Media*, and this was the first book on the subject and was recognized as the definitive reference in the field. In 2007, a second edition, *Comprehensive Organic Reactions in Aqueous Media*, was published to bring up-to-date the development in this important and rapidly expanding area of research.

In addition to his research contributions, Chan is also dedicated to the teaching of green chemistry to students. In 2000, he developed and taught the first undergraduate course on green chemistry offered in a Canadian university. He has championed green chemistry teaching by sharing his experience in teaching this course with colleagues in Canada and internationally. A number of Canadian universities now offer green chemistry as part of their curriculum. In 2002, Chan became the founding coordinator of the Canadian Green Chemistry Network, linking more than 50 researchers from over 20 Canadian universities and research institutes with the mission to promote green chemistry research and education in Canada, as well as to foster international collaboration. This network serves as part of the international networks affiliated with the Green Chemistry Institute of the American Chemical Society. Green chemistry is now a thriving area of research in several Canadian universities including Queen's University, Kingston, Ontario, Saint Mary's University, Halifax, Nova Scotia, University of Ottawa, McGill University, and Université de Montréal. Bill Chan has been cited as "le «père» de la chimie verte au Canada" (see *Le magazine de l'Université de Sherbrooke.* Vol. 1, No. 1).

Chan has contributed to research in medicinal/pharmaceutical chemistry. This had started as an interest in natural products chemistry with a synthesis of specionin, which may be of interest in controlling the spruce budworm problem in Canada (A.K. Mohammad-Ali, T.H. Chan, A.W. Thomas, B. Jewett, and G.M. Strunz. *Can. J. Chem.* 1994. **72**: 2137–2143). This was followed by the enantioselective synthesis of epigallocatechin-3-gallate (EGCG), the active polyphenol component from green tea (L. Li and T.H. Chan. *Org. Lett.* 2001. **3**: 739–741). In collaboration with Q.P. Dou of the Karmanos Cancer Center of Wayne State University, Detroit, Michigan, an extensive program on the development of green tea polyphenols and analogs as anticancer agents has been developed. This has led to a novel pro-drug of the green tea polyphenol (–)-epigallocatechin-3-gallate as a potential anticancer agent. (K.R. Landis-Piwowar, C. Huo, D. Chen, V. Milacic, G. Shi, T.H. Chan, and Q.P. Dou. *Cancer Res.* 2007. **67**: 4303–4310). The compound was found to be active in animal models against breast cancer and androgen-independent prostate cancer. Several patents on green tea polyphenols have been filed worldwide and some have been granted.

Another ongoing project is in collaboration with Larry M.C. Chow of the Hong Kong Polytechnic University to discover novel flavonoid dimers for overcoming multidrug resistance in cancer chemotherapy. Treatment of cancer patients with chemotherapeutic drugs often leads to the emergence of tumors with a multidrug-resistant (MDR) phenotype, which constitutes a major obstacle for cancer chemotherapy. Three major ATP-binding cassette (ABC) family members, ABCB1, ABCC1, and BCRP, are responsible for the majority of efflux-based MDR. Chan and his collaborators have developed potent modulators for all three types of transporters with safety and selectivity (K.F. Chan, Y. Zhao, B.A. Burkett, I.L. Wong, L.M. Chow, and T.H. Chan. *J. Med. Chem.* 2006. **49**: 6742–6759; I.L. Wong, K.F. Chan, K.H. Tsang, C.Y. Lam, Y. Zhao, T.H. Chan, L.M. Chow. *J. Med. Chem.* 2009. **52**: 5311–5322; K.F. Chan, I.L.K. Wong, B.A. Burkett, Y. Zhao, C.S.W. Yan, J.W.Y. Kan, K.H. Tsang, C.Y. Lam, T. Chow, T.H. Chan, and L.M.C. Chow. *Prog. Nutr.* 2010. **12**: 51–57). Several patents on these novel flavonoid dimers have been filed and development is expected to continue.

Bill Chan has received numerous awards including the Merck Sharpe & Dohme Award (1982), the Canada Council's Senior Killam Fellowship (1983–1985), and the R.U. Lemieux Award of the Canadian Society of Chemistry (1993). He was also named Fellow of the Royal Society of Canada in 1993. Now we are privileged to have this special issue of the *Canadian Journal of Chemistry* dedicated to him, to celebrate his outstanding contributions to scientific research, to science education, and his service to the broad scientific community in Canada and worldwide.

Tak-Hang (Bill) Chan est né le 28 juin 1941 à Hong Kong. Il manifeste de l'intérêt pour la chimie au cours de ses études secondaires, en grande partie grâce aux talents d'enseignement de son professeur de chimie, K.T. Cheung, à l'école intermédiaire Pui Ching (Hong Kong). À la fin de ses études secondaires, il fait des demandes auprès d'universités canadiennes et est admis à l'Université d'Ottawa. Même si sa famille ne dispose pas des ressources financières nécessaires pour soutenir son éducation au Canada, elle rassemble à grand-peine suffisamment d'argent pour payer son billet d'avion, en 1958. Au cours de sa première année d'études, il travaille la fin de semaine comme plongeur de vaisselle pour payer ses frais de scolarité et de subsistance. Au cours de l'été 1959, il obtient son premier emploi d'été comme jardinier. Ce travail est de courte durée, mais son employeur le surnomme Bill, surnom qu'il utilise encore aujourd'hui.

Il quitte l'Université d'Ottawa pour l'Université de Toronto où il termine ses études de premier cycle tout en occupant un emploi à temps partiel. Là-bas, il se retrouve sous l'influence de George Wright (chimie organométallique) et d'Adrian Brook (chimie des composés d'organosilicium), ce qui le mènera plus tard à s'intéresser à ces deux domaines de recherche. Au cours des étés 1961 et 1962, il travaille comme étudiant d'été au laboratoire de Morris Kates pour le Conseil national de recherches du Canada (CNRC) à Ottawa (Ontario). À cette époque, on considère la chimie surtout comme une science physique (mathématiques, physique et chimie) à l'Université de Toronto. Les travaux effectués au laboratoire de Kates l'exposent à la biochimie et ensemble, ils publient deux articles sur la lipochimie. Après l'obtention de son diplôme de premier cycle en 1962, il est accepté au programme d'études supérieures à l'Université de Princeton au New Jersey. Toutefois, avant de se rendre aux États-Unis, il fait une demande de statut d'immigrant admis au Canada, qu'il obtient.

À l'Université de Princeton, Bill rédige sa thèse de doctorat sous la direction de Richard Hill, un véritable professeur érudit. Cette thèse de recherche lui permet de comprendre le monde merveilleux des produits naturels et le défi que représente la stéréochimie. En 1965, il termine sa thèse de doctorat. C'est également l'année où Robert Woodward et Roald Hoffmann exaltent le monde de la chimie par la publication d'une série d'articles sur le rôle de la symétrie orbitale dans les réactions chimiques. Malgré d'autres offres alléchantes, Bill décide de travailler pendant un an à titre de boursier postdoctoral au laboratoire de Robert Woodward sur la synthèse totale de la vitamine B_{12}. Cette expérience est extraordinaire, non seulement pour apprendre au contact du grand maître, mais aussi pour faire la rencontre d'autres jeunes chimistes brillants, en particulier le contingent canadien composé notamment de Pierre Deslongchamps, de Larry Weiler, de Chiu Ming Wong et de David Dolphin.

Bill Chan se joint au Département de chimie de l'Université McGill de Montréal (Québec) en 1966 et commence sa carrière de chercheur indépendant. Au cours de sa carrière à McGill, il s'acquitte des fonctions de directeur du Département de chimie (1985–1991), de doyen des sciences (1991–1999) et de vice-recteur à l'enseignement (1994–1999). En 2000, il est nommé Professeur Tomlinson de chimie, une chaire qu'il dirige jusqu'au moment de sa retraite, en 2005. Maintenant, Bill offre ses services au Département à titre de professeur émérite, titre qu'il a bien mérité. En 1979, il est le premier scientifique occidental à introduire la chimie moderne en Chine dans l'ère de l'après-révolution culturelle, et il a une influence énorme sur la chimie en Chine.

Dans la première phase de ses travaux de recherche, Bill apporte des contributions d'avant-garde à l'utilisation de réactifs d'organosilicium dans la synthèse organique. Avec ses collègues, il intègre l'utilisation de silanes β-fonctionnalisés dans la synthèse des alcènes (T.H. Chan. *Acc. Chem. Res.* 1977, **10**: 442–448). Cette intégration conduit à une synthèse générale d'allènes, d'oxydes d'allène et d'alcènes en tête de pont. Par la suite, il examine la régiosélectivité et la stéréochimie de la substitution électrophile des vinylsilanes. En collaboration avec Ian Fleming de l'Université de Cambridge (Royaume-Uni), il publie un article de synthèse important (T.H. Chan et I. Fleming. *Synthesis*. 1979. 761–786) qui sert de synthèse clé dans l'utilisation de composés d'organosilicium pour la synthèse organique. Bill met ensuite au point l'utilisation des éthers d'énols silylés pour la synthèse. L'une de ses contributions importantes est l'utilisation du 1,3-bis(triméthylsiloxy)-1-méthoxy-1,3-butadiène comme équivalent dianion de l'acétoacétate de méthyle. Dans la documentation relative à la chimie, on appelle souvent ce synthon le « diène de Chan », que l'on utilise dans de nombreuses applications synthétiques, dont une réaction de cycloaromatisation originale (P. Brownbridge, T.H. Chan, M. Brook et G.J. Kang. *Can. J. Chem.* 1983. **61**: 688). Au cours de ses travaux sur la chimie des éthers d'énols silylés, il découvre une nouvelle réaction de réarrangement (S.D. Lee, T.H. Chan et K.S. Kwon. *Tetrahedron Lett.* 1984. **25**: 3399) que l'on nomme désormais le réarrangement de Chan. Cette réaction est utilisée dans la synthèse de plusieurs produits naturels complexes, dont celle de la boromycine, du paclitaxel et du diazonamide A. Un autre volet de ses travaux en chimie des organosiliciums est l'étude des α-silylcarbanions, utilisés dans la synthèse énantiosélective (T.H. Chan et P. Pellon. *J. Am. Chem. Soc.* 1989. **111**: 8737–8738) et régiosélective (T.H. Chan, K. Koumaglo, R. Horvath, D. Wang, Z.Y. Wei, G.L. Yi et J.S. Li. 1988. *Silicon chemistry*. Ellis Horwood Ltd., New York. Chapitre 5).

À partir de 1990, Bill Chan amorce la seconde phase de sa carrière de chercheur. Il joue un rôle de chef de file dans le développement de la recherche en chimie verte au Canada. La chimie verte consiste à s'efforcer de mettre au point des réactions et des procédés chimiques originaux qui ne nuisent pas à l'environnement. Ce domaine est relativement jeune et l'expression « chimie verte » a été inventée dans les années 1990. En 1991, il publie avec C.J. Li, son étudiant diplômé, son premier article sur une nouvelle réaction organométallique en milieu aqueux (C.J. Li et T.H. Chan. *Tetrahedron Lett.* 1991. **32**: 7017–7020). Avant la réalisation de ces travaux, on effectuait généralement les réactions de type organométallique dans un solvant organique, sous des conditions anhydres. Bill parvient à démontrer que plusieurs réactions de type organométallique peuvent se produire en milieu aqueux (T.H. Chan, C.J. Li, M.C. Lee et Z.Y. Wei. *Can. J. Chem.* 1994. **72**: 1181–1192). Notamment, on découvre de vastes applications de la réaction médiée par l'indium en synthèse organique, surtout pour les hydrates de carbone, car elle permet d'éliminer le recours à des groupes protecteurs.

Bill Chan contribue également à la compréhension des mécanismes de ces réactions en milieu aqueux (T.H. Chan et Y. Yang. *J. Am. Chem. Soc.* 1999. 141: 3228–3229; W. Miao,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Renmin University of China on 09/02/12
For personal use only.

L.W. Chung, Y.-D. Wu et T.H. Chan. *J. Am. Chem. Soc.* 2004. **126**: 13326–13334). Par la suite, il se sert de ses travaux en milieu aqueux pour étudier les réactions organométalliques dans des liquides ioniques, en utilisant notamment l'indium, l'étain, le zinc et le magnésium (M.C. Law, K.Y. Wong, T.H. Chan. *Chem. Commun.* 2006. 2457–2459).

Les travaux menés sur les liquides ioniques donnent lieu à la proposition, par Bill et son équipe de recherche, d'une stratégie en phase liquide originale pour la synthèse organique en utilisant des étiquettes ioniques (*ionic tags*) comme support soluble (W. Miao et T.H. Chan. *Acc. Chem. Res.* 2006. **39**: 897–908). La réaction homogène s'effectue habituellement dans un solvant relativement polaire. Après la réaction, l'espèce marquée d'un ion (*ion-tagged species*) est facilement séparée des autres réactifs par précipitation avec un solvant moins polaire. Elle peut jouer le rôle de catalyseur, de réactif, ou de substrat dans la synthèse de petites molécules ou de bio-oligomères. Bill met en évidence le succès de cette méthode en synthétisant des peptides, des oligosaccharides et des nucléotides, en collaboration avec Masad Damha de l'Université McGill (R.A. Donga, M. Hassler, T.H. Chan et M.J. Damha. Nucleosides, Nucleotides and Nucleic Acids. 2007. **26**(10–12): 1287–1293).

En 1997, Bill et C. J. Li publient la monographie *Organic Reactions in Aqueous Media*. Il s'agit du premier ouvrage abordant ce sujet et on le reconnaît comme étant « la » référence du domaine. En 2007, une deuxième édition de l'ouvrage *Comprehensive Organic Reactions in Aqueous Media* est publiée pour mettre à jour les découvertes qui se font dans ce domaine de recherche important et qui connaît une expansion fulgurante.

Outre ses contributions à la recherche, Bill se consacre également à l'enseignement de la chimie verte. En 2000, il met sur pied et donne le premier cours de premier cycle de chimie verte offert dans une université canadienne. Il se fait le défenseur de l'enseignement de la chimie verte en partageant son expérience en enseignement de ce cours avec des collègues au Canada et à l'échelle internationale. Plusieurs universités canadiennes offrent maintenant la chimie verte dans leur programme d'études. En 2002, Bill devient le coordonnateur fondateur du Réseau canadien de chimie verte, qui réunit plus de 50 chercheurs provenant d'une vingtaine d'universités et d'instituts de recherche canadiens, et dont la mission est de promouvoir la recherche et l'éducation en chimie verte au Canada et d'encourager la collaboration internationale. Ce réseau fait partie des réseaux internationaux affiliés au Green Chemistry Institute de l'American Chemical Society. La chimie verte est maintenant un domaine de recherche florissant au sein de plusieurs universités canadiennes dont l'Université Queen's à Kingston (Ontario), l'Université Saint Mary's à Halifax (Nouvelle-Écosse), l'Université d'Ottawa, l'Université McGill et l'Université de Montréal. Bill Chan est cité comme étant « le "père" de la chimie verte au Canada » (voir le magazine de l'Université de Sherbrooke *UdeS*, vol. 1, no 1).

Bill Chan contribue également à la recherche en chimie pharmaceutique. Le point de départ est un intérêt pour la chimie des produits naturels et la synthèse de la spécionine, une molécule qui pourrait s'avérer intéressante dans la lutte contre le problème de la tordeuse des bourgeons de l'épinette au Canada (A.K. Mohammad-Ali, T.H. Chan, A.W. Thomas, B. Jewett et G.M. Strunz. *Can. J. Chem.* 1994. **72**: 2137–2143). Par la suite, il met au point la synthèse énantiosélective de l'épigallocatéchine-3-gallate (EGCG), le polyphénol actif présent dans le thé vert (L. Li et T.H. Chan. *Org. Lett.* 2001. **3**: 739–741). En collaboration avec Q.P. Dou du Karmanos Cancer Center de l'Université d'État Wayne à Détroit (Michigan), il met sur pied un vaste programme sur la mise au point d'agents anticancéreux en utilisant des polyphénols du thé vert et des analogues. Ce programme mène à la création du promédicament polyphénol (–)-épigallocatéchine-3-gallate du thé vert comme agent anticancéreux potentiel (K.R. Landis-Piwowar, C. Huo, D. Chen, V. Milacic, G. Shi, T.H. Chan et Q.P. Dou. *Cancer Res.* 2007. **67**: 4303–4310). Chez les modèles animaux, ce composé se révèle actif contre le cancer du sein et celui de la prostate androgéno-indépendant. Plusieurs demandes de brevets relatifs aux polyphénols de thé vert ont été déposées dans le monde entier et certains ont été accordés.

Un autre projet en cours, en collaboration avec Larry M.C. Chow de l'Université polytechnique de Hong Kong, consiste à trouver de nouveaux dimères de flavonoïdes pour vaincre la multirésistance aux médicaments en chimiothérapie anticancéreuse. Le traitement des patients cancéreux par des produits chimiothérapeutiques mène souvent à l'apparition de tumeurs qui présentent un phénotype de multirésistance aux médicaments (MRM), ce qui constitue un obstacle majeur à la chimiothérapie anticancéreuse. Trois principaux membres de la famille des cassettes de liaison à l'ATP (ABC, pour *ATP-binding cassette*), à savoir ABCB1, ABCC1 et BCRP, sont responsables de la majorité des MRM par efflux. Chan et ses collaborateurs mettent au point des modulateurs puissants pour ces trois types de transporteurs qui sont sûrs et sélectifs (K.F. Chan, Y. Zhao, B.A. Burkett, I.L. Wong, L.M. Chow et T.H. Chan. *J. Med. Chem.* 2006. **49**: 6742–6759; I.L. Wong, K.F. Chan, K.H. Tsang, C.Y. Lam, Y. Zhao, T.H. Chan et L.M. Chow. *J. Med. Chem.* 2009. **52**: 5311–5322; K.F. Chan, I.L.K. Wong, B.A. Burkett, Y. Zhao, C.S.W. Yan, J.W.Y. Kan, K.H. Tsang, C.Y. Lam, T. Chow, T.H. Chan et L.M.C. Chow. *Prog. Nutr.* 2010. **12**: 51–57). Plusieurs brevets sur ces dimères de flavonoïdes sont déposés et des développements en ce sens devraient se poursuivre.

Bill Chan reçoit de nombreuses récompenses dont le prix Merck Sharpe & Dohme (1982), la bourse de perfectionnement en recherche Killam du Conseil des Arts du Canada (1983–1985) et le prix R.U. Lemieux de la Société canadienne de chimie (1993). Il est également nommé membre de la Société royale du Canada en 1993. Nous avons maintenant le privilège de lui consacrer ce numéro spécial de la *Revue canadienne de chimie* pour célébrer ses contributions remarquables à la recherche et à l'éducation scientifiques et son dévouement à l'ensemble de la communauté scientifique au Canada et dans le monde entier.
