Pulse studies of the interaction of  $CH_4$  and  $NiO/Al_2O_3$  catalysts at 500°C indicate that  $CH_4$  adsorption on reduced nickel sites is a key step for  $CH_4$  oxidative conversion. On an oxygen-rich surface,  $CH_4$  conversion is low and the selectivity of  $CO_2$  is higher than that of CO. With the consumption of surface oxygen, CO selectivity increases while the  $CO_2$  selectivity falls. The conversion of  $CH_4$  is small at 500°C when a pulse of  $CH_4/O_2$  ( $CH_4: O_2 = 2: 1$ ) is introduced to the partially reduced catalyst, indicating that  $CH_4$  and  $O_2$  adsorption are competitive steps and the adsorption of  $O_2$  is more favorable than  $CH_4$  adsorption

Keywords: pulse reaction; NiO/Al<sub>2</sub>O<sub>3</sub> catalysts; methane activation

#### 1. Introduction

During the last decade or so, a considerable amount of efforts have been devoted to the conversion of methane to transportable and/or value added products [1–4]. Besides the well-known methane oxidative coupling process, partial oxidation of methane to syngas has recently been found to be promising. High selectivities to CO and H<sub>2</sub> with excellent methane conversion have been reported over a number of supported transition metal catalysts, particularly the Ni catalysts [4–8].

The activation of methane on Ni single-crystal surfaces and model thin films of NiO had been studied by a number of researchers, using techniques such as molecular beam [9], Auger electron spectroscopy [10,11], and theoretical calculations [12]. However, for practical supported nickel catalysts, the  $\mathrm{CH_4/O_2}$  to syngas reaction was investigated mainly using continuous flow microreactor systems. Data concerning activity and selectivity of the catalysts were obtained, but a very limited

<sup>&</sup>lt;sup>1</sup> To whom correspondence should be addressed.

amount of information about the interaction of methane with the catalysts is made available. Moreover, Lunsford and coworkers [13] found that during the catalytic oxidation of  $CH_4$  to syngas over  $Ni/Yb_2O_3$  catalysts in the continuous flow reaction system and at high space velocities, the exothermic reaction gave rise to large temperature gradation, resulting in the generation of hot spots. The temperature of the hot spots would be as much as 300°C higher than the temperature measured by thermocouple. Because of this hot spot problem, data obtained by Choudhary et al. [5–7] are considered to be questionable [13]. In a pulse microreactor, the reactant gas is introduced in pulses, and because the amount of reactant introduced is small each time, hot spots are not generated and reliable data can be obtained. In this paper, we studied the activation of methane over  $NiO/Al_2O_3$  catalysts using the pulse method. Some useful information about  $CH_4$  activation was obtained. The mechanism of  $CH_4$  interaction with NiO is discussed.

### 2. Experimental

Catalyst preparation. The NiO/Al<sub>2</sub>O<sub>3</sub> catalyst (with 10 wt% of nickel) was prepared by impregnating Al<sub>2</sub>O<sub>3</sub> powder with nickel nitrate (BDH, A.R. grade) solution. The paste generated was dried at 110°C and annealed at 400°C for decomposition. After being pressed and crushed, the material was sieved to a grain size of 20–40 mesh before being calcined at 800°C in air for 4 h.

Pulse reaction system. The reaction was carried out using a pulse microreactor. A schematic diagram of the system is shown in fig. 1. The reactor was made of stainless-steel tube with 4 mm i.d. For each study, 50 mg of NiO/Al<sub>2</sub>O<sub>3</sub> catalyst

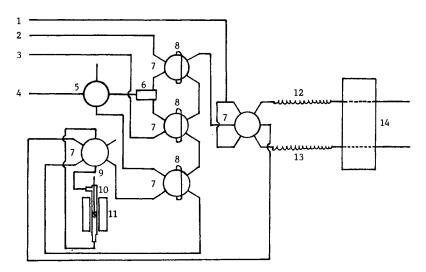

Fig. 1. Schematic diagram of the pulse microreactor system: (1) helium, (2) methane, (3) oxygen, (4) hydrogen, (5) four-way valve, (6) gas mixing tube, (7) six-way valves, (8) sampling tubes, (9) thermocouple, (10) reactor, (11) temperature programmed oven, (12) 5A zeolite column, (13) Porapak Q, (14) thermal conductivity detector.

was used. The pulse volumes of  $CH_4$ ,  $O_2$ ,  $H_2$  and  $CH_4/O_2$  were 1.11, 0.44, 1.03 and 1.03 ml respectively. During the reaction, helium was used as carrier gas and its flow rate was 17 ml/min. At 500°C, in the absence of the catalyst  $NiO/Al_2O_3$  or in the presence of the support material  $Al_2O_3$ , the blank runs showed no activity whatsoever under the reaction conditions mentioned in this paper.

#### 3. Results and discussion

By introducing pulses of CH<sub>4</sub> to the catalyst bed at 500°C, we monitored the activity and selectivity of

- (I) freshly prepared NiO/Al<sub>2</sub>O<sub>3</sub> catalyst;
- (II) NiO/Al<sub>2</sub>O<sub>3</sub> catalyst partially reduced by one pulse of H<sub>2</sub> (1.03 ml) at 500°C;
- (III) NiO/Al<sub>2</sub>O<sub>3</sub> catalyst treated with CH<sub>4</sub>/O<sub>2</sub> (CH<sub>4</sub>: O<sub>2</sub> = 2:1, pressure = 1 atm, flow rate = 54 ml/g s) for 10 min at 700°C.

In case I, the CH<sub>4</sub> conversion during the first pulse of CH<sub>4</sub> was extremely small, implying that the surface of the catalyst was not active (fig. 2a). However,

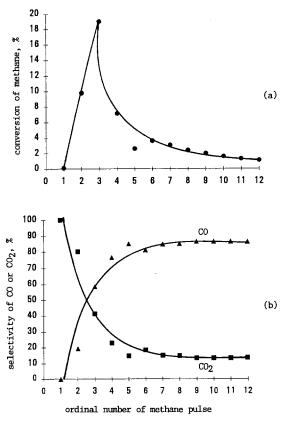

Fig. 2. The relationship between (a) CH<sub>4</sub> conversion and (b) selectivity of CO or CO<sub>2</sub> and ordinal number of CH<sub>4</sub> pulsing over freshly prepared NiO/Al<sub>2</sub>O<sub>3</sub> catalyst at 500°C.

during the second pulse,  $CH_4$  conversion was obviously higher with  $CO_2$  as the main product (figs. 2a and 2b).  $CH_4$  conversion was highest (ca. 19%) at the third pulse of  $CH_4$ . Further exposure of the catalyst to pulses of  $CH_4$  resulted in the decline of  $CH_4$  conversion and  $CO_2$  selectivity, with the CO selectivity being observed to increase. After the sixth pulse, the conversion of  $CH_4$  was 3.5% and it declined to 1% at the twelfth pulse.  $CO_2$  selectivity was 100% initially and, after the fourth pulse, dropped to about 23% while the CO selectivity respectively increased from 0 to 77%.

In case II, the catalyst was partially reduced by one time of H<sub>2</sub> pulsing at 500°C. The conversion of CH<sub>4</sub> was highest (ca. 26%) at the first pulse of CH<sub>4</sub>. Further exposure of the catalyst to pulses of CH<sub>4</sub> resulted in the decline of CH<sub>4</sub> conversion and CO<sub>2</sub> selectivity with the CO selectivity being observed to increase (fig. 3).

In case III, the catalyst was treated with  $CH_4/O_2$ .  $CH_4$  conversion was ca. 25% at the first and second pulse and then declined gradually afterwards (fig. 4a).  $CO_2$  selectivity was higher than CO initially and as the number of pulses increased,  $CO_2$  selectivity dropped while CO selectivity rose (fig. 4b).

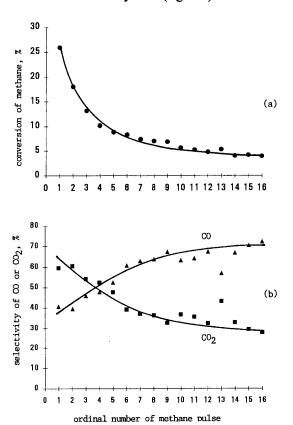

Fig. 3. The relationship between (a) CH<sub>4</sub> conversion and (b) selectivity of CO or CO<sub>2</sub> and ordinal number of CH<sub>4</sub> pulsing over NiO/Al<sub>2</sub>O<sub>3</sub> catalyst reduced by one time of pulsing H<sub>2</sub> at 500°C.

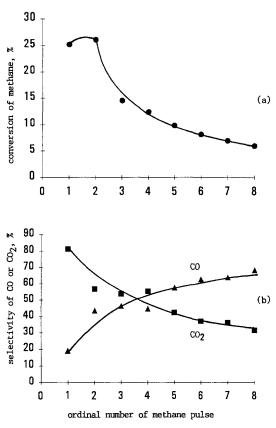

Fig. 4. The relationship between (a) CH<sub>4</sub> conversion and (b) selectivity of CO or CO<sub>2</sub> and ordinal number of CH<sub>4</sub> pulsing at 500°C over NiO/Al<sub>2</sub>O<sub>3</sub> catalyst after pretreatment in CH<sub>4</sub> + O<sub>2</sub> (CH<sub>4</sub> : O<sub>2</sub> = 2 : 1) at 700°C.

Fig. 5 shows that, when a mixture of CH<sub>4</sub> and O<sub>2</sub> (CH<sub>4</sub>/O<sub>2</sub> = 2/1) was pulsed to a NiO/Al<sub>2</sub>O<sub>3</sub> catalyst which had been treated with CH<sub>4</sub>/O<sub>2</sub> (CH<sub>4</sub>/O<sub>2</sub> = 2/1, pressure = 1 atm, flow rate = 54 ml/g s) for 10 min at 700°C, the conversion of CH<sub>4</sub> at 500°C stayed at around 1% and the CO<sub>2</sub> selectivity was 100% at every pulse of CH<sub>4</sub>/O<sub>2</sub>.

A freshly prepared NiO/Al<sub>2</sub>O<sub>3</sub> catalyst would have a surface composed of oxide. Initial CH<sub>4</sub> pulsing at 500°C showed little activation but CH<sub>4</sub> conversion definitely increased in the second and third pulsing (fig. 2). This may be because initial interaction between methane and the surface is that between CH<sub>4</sub>(g) and NiO(s). The process is possible but slow at 500°C. Since no CO and H<sub>2</sub> were detected at the first pulse of methane, initial Ni sites were mainly generated by total oxidation of methane. Once reduced sites are generated, CH<sub>4</sub> adsorption and dissociation become feasible, resulting in higher CH<sub>4</sub> conversion. This shows that reduced nickel sites have higher ability for CH<sub>4</sub> activation than nickel oxide sites. CH<sub>4</sub> conversion increased as the reduced nickel sites increased with the ordinal number of CH<sub>4</sub> pulses. However, as the surface is further reduced, it is deprived of

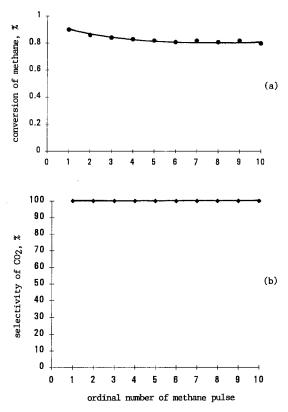

Fig. 5. The relationship between (a) CH<sub>4</sub> conversion and (b) selectivity of CO<sub>2</sub> and ordinal number of CH<sub>4</sub>/O<sub>2</sub>(2/1) pulsing at 500°C over the NiO/Al<sub>2</sub>O<sub>3</sub> catalyst after pretreatment in CH<sub>4</sub> + O<sub>2</sub> (CH<sub>4</sub>: O<sub>2</sub> = 2:1) at 700°C.

oxygen and  $CH_4$  conversion reached a maximum and declined afterward. After the initial pulse of methane, CO and  $H_2$  were generated, implying reduced Ni sites could be further generated by total as well as partial oxidation of methane. When  $NiO/Al_2O_3$  was first partially reduced by one pulse of  $H_2$ , the conversion of  $CH_4$  was at its highest during the first pulse of  $CH_4$  (fig. 3). This is because enough amount of reduced nickel sites was already generated by the pulse of hydrogen before the first pulse of  $CH_4$  was introduced. It has been shown that methane adsorbs dissociatively on Ni(100) [10,11], Ni(111) [9,10,12] and Ni(110) surfaces [10]. Campbell et al. showed that the reaction probability of methane on NiO films was significantly lower than that observed on the clean Ni(100) surface [11]. These results are consistent with our data over the  $NiO/Al_2O_3$  catalyst.

After the NiO/Al<sub>2</sub>O<sub>3</sub> catalyst was treated with  $CH_4/O_2$  at 700°C,  $CH_4$  conversion at 500°C reached 25% at the first pulse of  $CH_4$  (fig. 4), indicating that some reduced nickel sites were generated in the  $CH_4/O_2$  to syngas process at 700°C. This is consistent with the XPS and XRPD results obtained by Lunsford and coworkers [14].

At 500°C, CH<sub>4</sub>/O<sub>2</sub> mixture reacted poorly with the reduced catalyst (fig. 5), indicating that the adsorptions of O<sub>2</sub> and CH<sub>4</sub> on the reduced sites were competitive processes. As O<sub>2</sub> chemisorption occurs more readily than CH<sub>4</sub> chemisorption, the surface is reoxidized, rendering the chemisorption of CH<sub>4</sub> unfavorable and resulting in poor CH<sub>4</sub> conversion.

In all cases, CO<sub>2</sub> formation was more favorable than CO initially and as the surface was deprived of oxygen, CO<sub>2</sub> selectivity decreased and CO selectivity increased. Based on the above observations, we propose the following mechanism for the interaction between CH<sub>4</sub> and NiO/Al<sub>2</sub>O<sub>3</sub> at 500°C:

$$2NiO + \frac{1}{2}CH_4(g) \rightarrow 2Ni + \frac{1}{2}CO_2(g) + H_2O(g)$$
 (1)

$$Ni + CH4(g) \rightarrow CHx(s) + (4 - x)H(s)$$
 (2)

$$CH_x(s) \to C(s) + xH(s)$$
 (3)

$$H(s) + H(s) \rightarrow H_2(g) + 2Ni \tag{4}$$

$$C(s) + NiO \rightarrow Ni + CO(s)$$
 (5)

$$CO(s) + NiO \rightarrow CO_2(s) + Ni$$
 (6)

$$CO(s) \rightarrow Ni + CO(g)$$
 (7)

$$CO_2(s) \rightarrow Ni + CO_2(g)$$
 (8)

$$2H(s) + NiO \rightarrow H_2O(g) + Ni.$$
 (9)

Comparing with step 2, step 1 is very difficult. After the initial generation of Ni sites in step 1, the activation of  $CH_4$  occurs mainly according to step 2 and the generation of CO,  $CO_2$  and  $H_2$  follows the steps similar to those proposed by Hickman et al. [8] over Pt and Rh monoliths.
