membered ring. This is a familiar coordination mode for Schiff-base ligands. The second portion of the molecule contains two aluminium atoms linked by bridging oxygens. The terminal $AlMe_2$ group adopts a geometry that is structurally similar to the other $AlMe_2$ group. The central, five-coordinate aluminium atom is in a distorted trigonal-bipyramidal geometry. The equatorial bond distances are systematically shorter than the axial distances. This is exemplified in the distances for axial, Al(3)–N(3) [2.091(3) Å] compared to equatorial, Al(3)–N(4) [1.822(3) Å] atoms. The oxygens follow a similar trend [Al(3)–O(2) 1.912(3), Al(3)–O(3) 1.944(3) Å]. Closely related to **3** is the trimetallic complex (salean)AlMe$(AlMe_2)_2$ [salean = *N*,*N*′-bis(*o*-hydroxybenzyl)-1,2-diaminoethane].[8] It also contains four- and five-coordinate (trigonal bipyramidal) aluminiums bridged by oxygen atoms. In this complex the axial atoms are oxygen and form an angle of 163.0(1)° at distances of 1.982(3) and 1.959(3) Å. The differences in the N=C and N–C(Me) linkages are reflected in the N–C bond distances of 1.290(5) and 1.459(5) Å, respectively. Furthermore, the imine group appears as a singlet in the $^1$H NMR ($\delta$ 7.94) while the amine NC*H*(Me) appears as a multiplet ($\delta$ 4.14).

The use of group 13 reagents in the reduction of alkynes, alkenes and carbonyl substituents is a well known, yet still expanding area of chemistry.[9] Alkylalumination reactions generally require the intermediacy of a group 4 catalyst.[10] The catalyst acts to activate the substrate in a manner that is still being defined. That an aluminium species is being produced in **3** that can alkylate carbon–nitrogen multiple bonds in the absence of a metal catalyst is an intriguing prospect. Based upon the fact that a compound containing two five-coordinate aluminium atoms can be isolated (**2**), the third equivalent of $AlMe_3$ presumably effects the alkylation in **3**. The coordination of the first two $AlR_n$ units makes the imine linkage vulnerable to this addition. This type of reaction bears some resemblance to the alkylation of nitriles in which the first step is the formation of an organoaluminium–nitrile adduct.[11] Whether the formation of **3** is through an intra- or intermolecular alkylation remains to be determined.

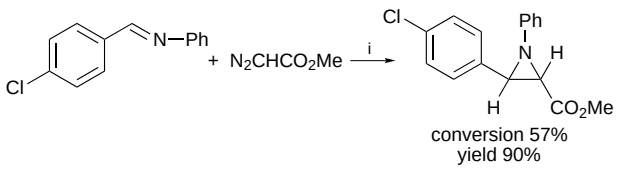
# Carbenoid transfer to imines: a new heterogeneous catalytic synthesis of aziridines

**J. Madan Mohan, B. S. Uphade, V. R. Choudhary, T. Ravindranathan and A. Sudalai***



*National Chemistry Laboratory, Pune 411 008, India*

**A heterogeneous catalytic method for the preparation of *trans*-aziridines from imines and methyl diazoacetate is described using $Rh^{III}$- and $Mn^{III}$-exchanged montmorillonite K10 clays as catalysts.**

The aziridinine ring is a versatile building block for organic synthesis, not only because the ring opening of aziridines provides a convenient entry to the stereoselective preparation of functionalized amino compounds but also because the exocyclic N-substitutent modulates the properties and reactivity of the 3-membered ring.[1] The chemistry and preparation of enantiomerically pure aziridine-2-carboxylates have been the targets of many synthetic efforts in recent years for the preparation of both α- and β-amino acids.[2] Classical methods[3] for the synthesis of aziridines are ring closure of amino alcohols, ring opening of epoxides with sodium azide and addition of α-halo ester enolates to *N*-(trimethylsilyl)imines. Although potentially a very useful method for the preparation of aziridines, the cycloaddition of carbenes to imines has not been investigated extensively. In fact very few methods have been reported for the catalytic preparation of aziridines from aromatic imines and diazo esters. These methods employ catalysts such as copper complexes[4] and methylrhenium trioxide[5] under homogeneous conditions. More recently, $BF_3{\cdot}OEt_2$-catalysed aziridination of imines with diazoacetate has been reported.[6] The other important catalytic method, *viz*. the addition of [*N*-(toluene-*p*-sulfonyl)imino]phenyliodinane (PhI=NTs) as nitrene precursor onto alkenes, has been used for the direct synthesis of aziridines using soluble $Cu^{I}$ and $Cu^{II}$ complexes.[7] However, the yields and selectivities reported are far from satisfactory. For example, Cu-catalysed addition of diazo esters to imines proceeds in low yields (15–30%) and is of limited use.[8] Further, copper triflate-catalysed carbene addition to imines proceeds to give a mixture of *cis*- and *trans*-aziridines and shows poor selectivity in terms of product distribution. Recently Aggarwal *et al*.[9] has also shown an effective asymmetric aziridination process mediated by sulfur ylides and working in a catalytic fashion.

Currently, acid catalysed organic transformations by transition metal-exchanged aluminosilicate clays is an area of considerable potential and interest due to ease of handling and workup, non-corrosiveness and low cost of clays.[10] Here we report that the $Rh^{III}$-exchanged acid activated montmorillonite clay, K10, catalyses cycloaddition reactions between methyl diazoacetate and imines to form *trans*-aziridines with good conversion and yield (Scheme 1).

Rh- and Mn-exchanged montmorillonite K10 clay catalysts were prepared by exchanging the clay with dilute solutions of $RhCl_3$ and $Mn(NO_3)_3$, respectively. For example, a mixture containing $RhCl_3$ (0.3 g) and clay (25 g) in distilled water (600 ml) was stirred vigorously at room temperature for 24 h. It was centrifuged and the clay was washed repeatedly with distilled water until the discarded filtrate was free from $Cl^-$ ions. Finally, the clay was dried at 110 °C for 12 h. A 5% Rh/C catalyst was obtained from Degussa. The 0.5 wt% $Rh/Al_2O_3$ and $Rh/SiO_2$ gel catalysts for comparison purpose were prepared using the incipient wetness impregnation technique.

**Scheme 1** *Reagents and conditions*: i, Rh-clay (10% m/m), dry benzene, 353 K, 3 h

In a typical experiment, a mixture of imine ($R^1$ = 4-$ClC_6H_4$, $R^2$ = Ph; 2.15 g, 10 mmol), methyl diazoacetate (1.2 g, 12 mmol) and Rh-clay (200 mg; 10% m/m) in dry benzene (30 ml) was heated under reflux for 5 h. The progress of the reaction was monitored by TLC. The catalyst was filtered off and the product purified by flash chromatography to afford the corresponding *trans*-aziridine† (1.63 g, 57%).

The results of aziridination of the imine ($R^1$ = 4-$ClC_6H_4$, $R^2$ = Ph) over various supported metal catalysts (Table 1) indicate that $Rh^{III}$-exchanged montmorillonite K10 clay exhibits significantly higher activity and selectivity than the $Rh/SiO_2$ and $Rh/Al_2O_3$ catalysts. However, it is to be noted that catalysts such as Cu-exchanged K10 and Rh/C failed to catalyse the reaction. Although Mn-clay also exhibited good conversion and yield in this case, it surprisingly failed to catalyse the aziridination reaction when applied to other types of imines.

Table 2 lists the results of the various imines which have been successfully aziridinated with $N_2CHCO_2Me$ catalysed by the $Rh^{III}$-clay. The yield in the process is in the range 30–75%; products other than aziridine are not formed. A novel feature of this catalytic system is that only a single isomer of the aziridine was obtained as determined by GC–MS and $^1H$ and $^{13}C$ NMR spectroscopy. The coupling constant for the aziridine ring protons for these products are in the range 3.6–3.8 Hz, which confirms that the only product is the isomer with *trans* configuration (*E*-isomer) with respect to the C–C bond. This *trans*-selective aziridination is therefore complementry to the earlier technique of Casarrubios *et al*.[6] which is *cis*-selective. A variety of aromatic imines and one aliphatic imine have undergone cycloaddition with $N_2CHCO_2Me$ over the $Rh^{III}$-clay to give aziridines in good yields and excellent selectivity. It is noteworthy that the product survives the acidic environment and does not yield side products arising out of cleavage by protonation of the aziridine ring nitrogen because of its poor

**Table 1** Aziridination of aryl imine ($R^1$ = 4-$ClC_6H_4$, $R^2$ = Ph) with $N_2CHCO_2Me$ over various catalysts[a]

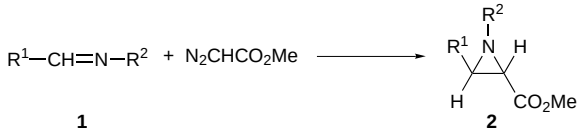
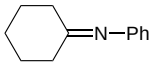
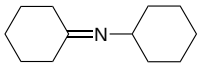
| 3 | Cu-clay | 10 | 0 |
| 4 | $Rh/SiO_2$ gel | 12 | 52 |
| 5 | $Rh/Al_2O_3$ | 12 | 40 |
| 6 | Rh/C[c] | 12 | 0 |



[a] Reaction conditions: imine (10 mmol), diazo ester (12 mmol), catalyst (10% m/m), dry benzene, reflux. [b] Isolated and purified yield. [c] Commercial catalyst from Degussa.

basicity (aromatic amine). Also this result contrasts with that using methylrhenium trioxide, which is effective only for aromatic imines.[5] The catalyst, recovered by filtration, was reused at least three times without affecting the reactivity and selectivity of the process.





In conclusion, this study was demonstrated that $Rh^{III}$-montmorillonite K10 is an efficient and reusable solid catalyst for imine aziridination using methyl diazoacetate as the carbene precursor.

# Prediction of transition state structure in protein tyrosine phosphatase catalysis using a hybrid QM/MM potential

**Jason C. Hart,[a] Neil A. Burton,[a] Ian H Hillier,*[a] Martin J. Harrison[a] and Philip Jewsbury[b]**

[a] *Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*
[b] *Zeneca Pharmaceuticals, Alderley Park, Macclesfield, Cheshire, UK SK10 4TG*

**The transition state for tyrosine phosphate hydrolysis by the enzyme protein tyrosine phosphatase (PTP1B) has been determined using a hybrid QM(PM3)/MM potential, showing that the reaction is dissociative with essentially no P–S bond formation in the transition state.**

The reversible phosphorylation of proteins is the major form of post-translational modification and is a key control mechanism in biochemistry for processes such as cell regulation.[1,2] Protein tyrosine phosphatases (PTPases) are a large family of enzymes that catalyse the hydrolysis of phosphotyrosine (pTyr) residues in specific proteins.[3,4] Structural[5] and kinetic[6] studies have provided a molecular understanding of PTPase activity. In brief, the enzyme active site is conserved for all PTPases and contains catalytic Cys (215 in PTP1B) and Asp (181 in PTP1B) residues. The former residue exists as the anion and acts as the nucleophile, the latter having the role of a general acid. The reaction involves the formation of a phosphoenzyme intermediate (with Cys 215 in PTP1B). Hydrolysis of this intermediate results in the regeneration of the active site.[4]

Two extreme mechanisms of phosphate ester hydrolysis are usually invoked, either dissociative or associative[3,7] which depend on the size of the negative charge on the phosphate group. In aqueous solution, kinetic data have led to the conclusion that phosphate monoesters hydrolyse *via* a transition state with little bond formation to the attacking nucleophile and extensive bond cleavage to the leaving group characteristic of a dissociative mechanism.[8] Retention of chiral properties rules out a true diffusable metaphosphate intermediate. At physiological pH monoesters such as pTyr exist as dianions and kinetic data, particularly heavy atom isotope measurements, have led to the general conclusion that PTPase catalysis proceeds *via* a dissociative transition state[6] similar to that observed in solution.[8] The characterisation of the transition state at a molecular level is naturally central to understanding the mode of action of PTPases and to the design of PTPase specific inhibitors.

The use of combined quantum mechanical/molecular mechanical (QM/MM) methods to model macromolecular reactivity is now well established,[9–13] and we have shown how such methods can be used to locate transition states for enzyme catalysed reactions[14] employing our hybrid QM/MM code[15] which couples the QM code GAUSSIAN94[16] with the MM code AMBER 4.0.[17] To further aid the understanding of the mode of action of PTPases we here describe a hybrid QM/MM study of the mechanism of phosphate hydrolysis by the enzyme PTP1B. We utilise the crystal structure of PTP1B (Ser-215) and a phosphotyrosine substrate[5] to study phosphoryl transfer between pTyr and the Cys residue (replacing Ser-215), involving proton transfer from Asp-181 to the Tyr leaving group. In our model, the pTyr substrate in the crystal structure was replaced by 4–methylphenyl phosphate to allow for substrate mobility. This enzyme–substrate structure was first energy minimised (using the AMBER 4.0 force field) and was then employed in a QM(PM3)/MM calculation, the QM part of the structure being shown in Fig. 1. The bulk of the enzyme was kept fixed during the modelling of the reaction, with the positions of the majority of the QM atoms, including the whole substrate, being allowed to vary. The QM link atoms, as well as the QM atoms of the protein backbone, were kept fixed. We chose to use the PM3[18] Hamiltonian due to its success in modelling studies of phosphate hydrolysis.[7]

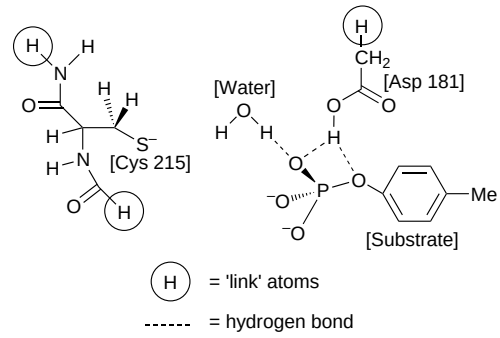

**Fig. 1** QM region of active site–substrate

We have mapped out the potential energy surface for the dissociative reaction by minimising the substrate active site structure for a range of P–O (bridge) distances (while allowing the remaining QM atoms to optimise). This led to an approximate structure of the transition state, which was subsequently refined and characterised by calculation of the harmonic frequencies. The reactant and transition state structures thus obtained are shown in Fig. 2. It is clear that the transition state is largely dissociative, with a lengthened P–O bond and effectively no increase in S–P interaction compared to the reactant structure. The calculated partial atomic charges reveal a developing negative charge on the Tyr leaving group during the course of the reaction. The formal charge on this group increases from 0.80e in the reactant to 0.92e in the transition state, 0.07e of the total increase of 0.12e being associated with the bridge oxygen. In both reactant and transition state structures the proton of Asp-181 interacts with two oxygen atoms of the substrate (Fig. 2). The effect of this developing negative charge on the leaving group is to increase the interaction with the bridge oxygen compared to that

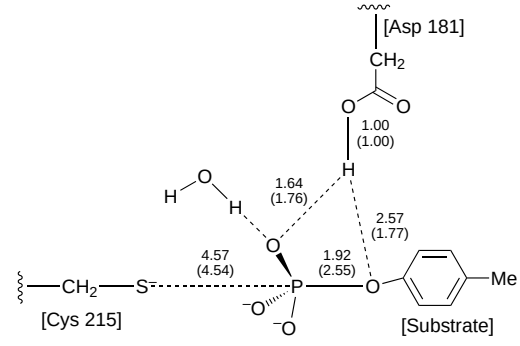

**Fig. 2** Active site–substrate geometry. Reactant structure (Å) and, in parenthesis, transition state structure.

involving the terminal oxygen. However, we do not find proton transfer from the asparate group to have occurred at the transition state. The energy barrier between the reactant and transition state structures is 27.2 kJ mol$^{-1}$. Further along the reaction pathway to the product, there is a second barrier corresponding to proton transfer to the leaving OPh group along with S–P bond formation. However, this second barrier is at lower energy than the dissociative transition state that we have identified so that the P–O bond cleavage is rate determining in line with experiment.[6]

Thus, the first theoretical prediction of the nature of the transition state for a PTP–catalysed reaction, which we have presented here where the transition state corresponds to considerable P–O bond lengthening, with little P–S bond formation, is in general agreement with the conclusions from kinetic measurements. Of particular interest is the quite flat potential energy profile in the region of the transition state with a change of only 7 kJ mol$^{-1}$ when the P–O length changes from 2.10 Å to the optimal value of 2.55 Å in the transition state (Fig. 2). This flat energy surface is also reflected in the low value of the imaginary frequency of the transition state (114*i* cm$^{-1}$). Such a flat surface suggests that there will be considerable geometric freedom in the design of suitable inhibitors of this enzymic reaction.

We thank the EPSRC for support of this research.

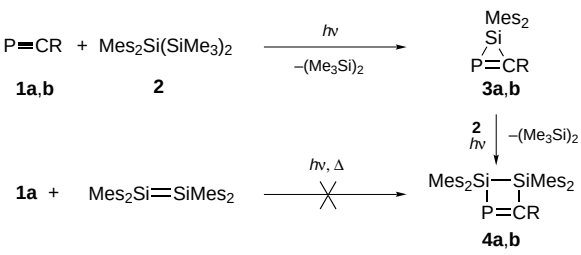
# Phosphadisilacyclobutenes by stepwise silylene additions to phosphaalkynes

**Manfred Weidenbruch,*[a] Susanne Olthoff,[a] Karl Peters[b] and Hans Georg von Schnering[b]**



[a] *Fachbereich Chemie, Universität Oldenburg, D-26111 Oldenburg, Germany*
[b] *Max-Planck-Institut für Festkörperforschung, D-70506 Stuttgart, Germany*

**The phosphaalkynes RC≡P [R = 1-adamantyl (1a) or R = 2-methylcyclohexyl (1b)] react with dimesitylsilylene, presumably by [2+1] cycloaddition followed by silylene insertion, to furnish phosphadisilacyclobutenes; the molecular structure of the adamantyl derivative was determined by X-ray crystallography.**

Since the synthesis of the first thermally stable phosphaalkyne[1] in 1981, the chemistry of this class of compounds has experienced an explosive development which is reflected in several review articles.[2] However, there are only a few examples of [2+1] cycloadditions to the P≡C triple bond and concrete evidence for [2+2] cycloadditons is still lacking. It has been shown that reaction of the silylene $R_2Si$: (R = $CMe_3$) with **1a** proceeds smoothly to furnish the phosphasilirene[3] as an oily liquid, similar to the 2*H*-phosphirenes[4] accessible by other routes and for which crystals suitable for X-ray structural analyses can only be obtained after formation of the corresponding $W(CO)_5$ complexes. A crystalline germaphosphirene has been prepared by addition of the germylene $R_2Ge$: [R = $CH(SiMe_3)_2$][5] to *tert*-butylphosphaacetylene.[6] Addition of the stannylene $R_2Sn$: [R = $CH(SiMe_3)_2$] to the same triple bond system appears to proceed by a different course since the formation of the phosphadistannacyclobutene obtained was interpreted as being more indicative of a [2+2] addition of the distannene,[7] $R_2Sn{=}SnR_2$, to the phosphaalkyne.[8] However, as can be seen from the present results, the formation of this four-membered ring system may also be explained in terms of an initial [2+1] cycloaddition and subsequent insertion of a further stannylene unit into an intermediate three-membered ring system.

Reaction of dimesitylsilylene, generated photochemically from the trisilane **2**, with the phosphaalkynes **1a,b**[9,10] afforded the phosphadisilacyclobutenes **4a** (pale yellow crystals, mp 285 °C, yield 18 %) and **4b** (yellow crystals, mp 275 °C, yield 14%) (Scheme 1). The structures of these two representatives of a new four-membered ring system were confirmed by their analytical and spectroscopic data.† Of high diagnostic value are the positions of their $^{31}P$ NMR signals, which are strongly deshielded and appear at $\delta$ 441 (**4a**) and 443 (**4b**) in the region typical of silyl-substituted phosphaalkenes.[11] In the $^{29}Si$ NMR spectra the two silicon atoms give rise to doublets with $^1J_{^{29}Si,^{31}P}$ and $^2J_{^{29}Si,^{31}P}$ couplings.

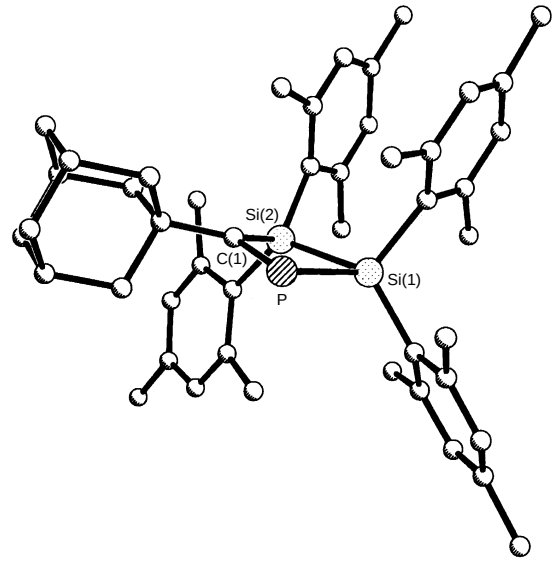
Final confirmation of the structures of these molecules was provided by an X-ray crystallographic analysis of **4a** (Fig. 1) which revealed an almost planar ring (angular sum: 359.1°).‡

**Scheme 1**

The largest endocyclic angle occurred at the carbon atom and the two smallest at the silicon atoms. In comparison to the only currently known phosphasilirene,[3] all endocyclic bond lengths are elongated to some extent, indicating the differing bonding situations in the three- and four-membered ring systems.

The different behaviour of di-*tert*-butylsilylene and dimesitylsilylene towards **1a** are assumed to be due to the larger spatial requirements of the *tert*-butyl groups which effectively shield the three-membered ring from further attack. The reactions of **1a,b** with **2** probably also proceed through the three-membered ring intermediates **3**, which undergo subsequent insertion of a second silylene molecule to furnish the four-membered ring products isolated. However, a second possibility, in which the photochemically generated silylene **2** undergoes primary dimerisation to the disilene with a Si=Si double bond and subsequent [2+2] cycloaddition with the phosphaalkyne, is also feasible. Thus, we have prepared tetramesityldisilene[12] and examined its behaviour towards **1a** under both photochemical and thermal conditions. In neither case could any reaction be detected. Hence, not only have we obtained evidence in favour of the proposed [2+1] cycloaddition to the P≡C triple bond with subsequent rapid silylene insertion into the three-membered ring, but also further illustrated the absence of unequivocally demonstrated [2+2] cycloadditions to phosphaalkynes.[2]

However, an alternative mechanism for the formation of **4a,b**, in which—according to Scheme 2—the silylene is trapped by addition to the phosphorus atoms of **1a,b** to furnish an ylide intermediate, followed by the addition of a second silylene molecule and ring closure cannot be excluded.§



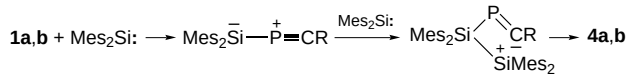


**Fig. 1** Molecular structure of **4a** in the crystal (hydrogen atoms omitted). Selected bond lengths (pm) and angles (°): C(1)–P 170.1(3), P–Si(1) 228.8(1), Si(1)–Si(2) 239.1(1), Si(2)–C(1) 190.3(3), Si(1)–P–C(1) 90.1(1), P–Si(1)–Si(2) 77.6(1), Si(1)–Si(2)–C(1) 85.5(1), P–C(1)–Si(2) 108.9(2).

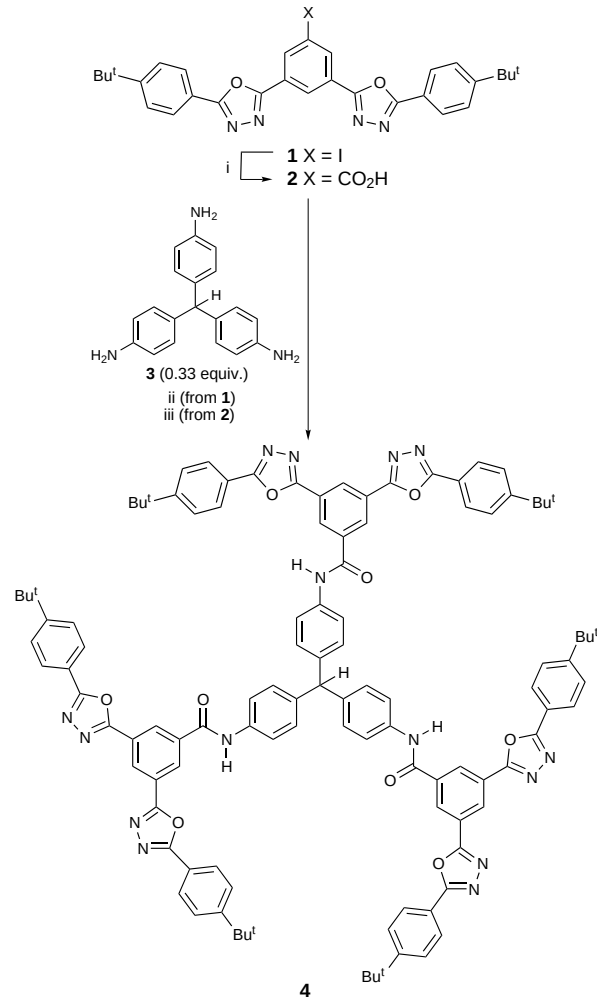
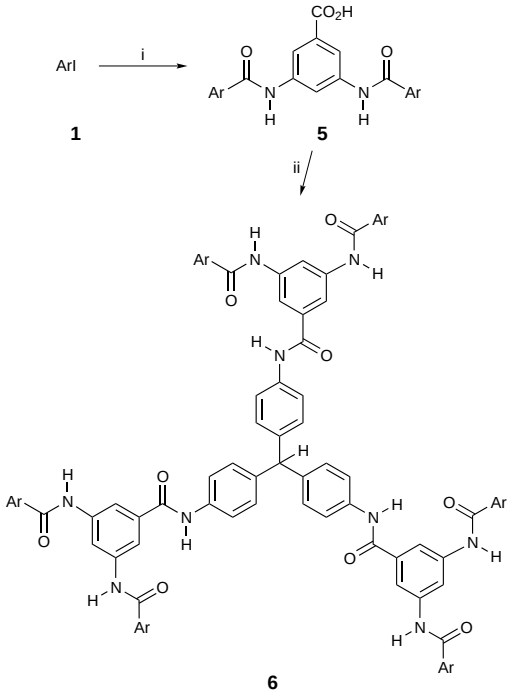
# Self-association of poly(aramide) dendrimers

**Frank Osterod and Arno Kraft***



*Department of Organic Chemistry and Macromolecular Chemistry II, Heinrich Heine University of Düsseldorf, Universitätsstr. 1, D-40225 Düsseldorf, Germany*

**Two poly(aramide) dendrimers, which possess electron-deficient 1,3,4-oxadiazole and aromatic systems linked by amide units to a triphenylmethane core, strongly self-associate in chloroform solution through hydrogen bonding.**



During the last decade, dendrimers with highly branched, spherical structures have attracted much attention.[1] They often possess unique properties, such as unusually good solubility. Linear poly(aramide)s, for example, are well-known high-performance fibre materials which owe their high tensile strength to a large degree of hydrogen bonding between aligned polymer chains; however, these polycondensates dissolve only in highly polar solvents such as concentrated sulfuric acid. In contrast, the few hitherto known dendritic or hyperbranched poly(aramide)s are soluble in DMF, DMSO and THF, yet the attempts towards their synthesis were hampered by side reactions.[2,3] We have recently embarked on a programme to synthesise dendrimers containing 1,3,4-oxadiazole systems.[4] These heterocycles are notable for their potential application as electron-transporting materials in electroluminescent devices based on organic fluorescent dyes and polymers.[5] The star-branched and dendritic derivatives with $\geqslant$3 oxadiazoles per molecule dissolve well in chlorinated and aromatic solvents, form amorphous glasses[6,7] and tend towards π-stacking in solution.[4] We now report the synthesis of oxadiazole-containing poly(aramide) dendrimers that are soluble in organic solvents such as chloroform. So far, our efforts have concentrated on structures with a triphenylmethane core, starting with triamine **3**.[8]

Palladium-catalysed carbonylations[9] form the key step in the syntheses of dendritic poly(aramide)s **4** and **6**. Branched compound **4** is thus obtained in a single step from aryl iodide **1**, **3** and carbon monoxide with *N*-methyl-2-pyrrolidone (NMP) as solvent, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as base and $PdCl_2$–$Ph_2P(m\text{-}C_6H_4SO_3Na)$[10] as catalyst (Scheme 1). The seven-component reaction furnished **4** in 45% yield after purification by column chromatography.† However, it proved very difficult to remove the last traces of the NMP residues, and we therefore sought a different method that avoided the use of a high-boiling solvent in the last step of the synthesis. Conversion of **1** into carboxylic acid **2** was accomplished by another palladium-catalysed carbonylation. In a subsequent step, acid **2** and triamine **3** were coupled with triphenyl phosphite[11] in pyridine. Carbonylation reactions were also effective for the preparation of acid **5** and had the particular advantage that no protecting groups were required. Coupling of the acid with **3** finally furnished **6** (Scheme 2).

As usually for dendrimers, solubility is mainly determined by the substitutents at the periphery (in our case, these are *tert*-butyl substituted aromatic systems) whereas the amide groups in the centre of **4** and **6** induce hydrogen-bonding interactions. In fact, the solubility of dendrimer **4** in chloroform extends to 50–60 mg $ml^{-1}$. It was at first surprising to find that **6**, which has nine amide groups, dissolves with even more ease in chloroform (over 200 mg $ml^{-1}$). This is one of the advantages of the branched dendrimer structure.[1,2] While a linear aramide structure in poly(aramide)s has a detrimental effect on solubility, the higher degree of branching in **6** counteracts the solvophobic effect of the extra amide groups. The $^1H$ NMR spectra of **4** and **6** depend strongly on concentration, temperature and solvent while lineshapes are not influenced by the NMR frequency. This rules out dynamic processes and is a strong indication of self-association.[12] The $^1H$ NMR signals of **4** in $CDCl_3$ are all broad and without fine structure. The fact that they become sharp on addition of [$^2H_6$]DMSO (15%) underlines that hydrogen-bonding is responsible for the self-association of **4**. We estimated the association constant $K_a$ of **4** in $CDCl_3$ by a dilution experiment. A decrease in concentration below $10^{-3}$ mol $dm^{-3}$ led to a significant increase in resolution of the $^1H$ NMR signals. Most chemical shifts were only slightly dependent on concentration ($\Delta\delta \leqslant 0.25$) with the exception of the NH singlet. In the concentration range investigated ($10^{-1}$ to $10^{-3}$ mol $dm^{-3}$), $\delta_{NH}$ varied from 9.91 to 9.11 and allowed $K_a$

**Scheme 1** *Reagents and conditions:* i, $LiOH{\cdot}H_2O$ (2 equiv.), $PdCl_2$ (0.03 equiv.), $Ph_2P(m\text{-}C_6H_4SO_3Na)$ (0.09 equiv.), NMP, CO, 100 °C, 1–2 d, then HCl, 79–95%; ii, $PdCl_2$ (0.03 equiv.), $Ph_2P(m\text{-}C_6H_4SO_3Na)$ (0.09 equiv.), DBU (1.2 equiv.), NMP, CO, 100 °C, 1–2 d, then HCl, 31%; iii, $P(OPh)_3$ (1.2 equiv), pyridine, 100 °C, 12 h, then HCl, 45%

**Scheme 2** *Reagents and conditions:* i, 3,5-diaminobenzoic acid (0.5 equiv.), $PdCl_2$ (0.6 equiv.), $Ph_2P(m\text{-}C_6H_4SO_3Na)$ (0.18 equiv.), DBU (1.8 equiv.), NMP, CO, 100 °C, 4 d, then HCl, 38%; ii, **3** (0.33 equiv.), $P(OPh)_3$ (1.2 equiv.), pyridine, 100 °C, 12 h, then HCl, 37%

to be estimated to 790 ± 100 $dm^3$ $mol^{-1}$ in dry chloroform at 30 °C, assuming the isodesmic model of indefinite self-association.[13] Hydrogen bonds weaken also at higher temperature: the $^1H$ NMR spectrum of a 0.005 mol $dm^{-3}$ solution of **4** in $CDCl_3$–$C_2D_2Cl_4$ (1:2) revealed sharp signals and the expected multiplicity pattern for the aromatic protons upon raising the temperature to 80 °C. Vapour-pressure osmometry (VPO) studies in chloroform at 30 °C gave evidence of an association degree ⩾4 and a number average molar mass exceeding 3500 g $mol^{-1}$ (over twice as high as expected for non-associated **4**) at concentrations ⩾0.02 mol $dm^{-3}$. At comparatively low concentrations, a significant amount of **4** is present in solution in the form of higher oligomers. Although self-association generally counteracts solubility, the branched structure of **4** successfully suppresses precipitation of the compound. Only after chromatography could a small amount of **4** be induced to crystallise from a $CH_2Cl_2$–MeOH.

Association becomes even more dominant for **6** with its nine amide groups. The $^1H$ NMR spectrum of the dendrimer in $CDCl_3$ is characterised by broad signals, and even the *tert*-butyl 'singlet' has a linewidth of $\Delta\delta \approx 0.4$ (at 0.002 mol $dm^{-3}$) at half maximum. Addition of $[^2H_6]$DMSO no longer suffices to break up all hydrogen bonds. In fact, this demands the addition of a much more polar cosolvent such as trifluoroacetic acid. The remarkably strong association is also deduced from the $^1H$ NMR spectrum of **6** in $C_2D_2Cl_4$ (0.01 mol $dm^{-3}$) at 138 °C, which still displays broadened signals for the aromatic protons and a complicated pattern for the *tert*-butyl protons between $\delta$ 0.95 and 1.50. It seems unlikely that all amide groups will be involved in hydrogen bonding because the propeller configuration of the triphenylmethane[14] core and the disordered structure of the branched periphery prevent such a fit. Nevertheless, a larger number of amide groups per dendrimer molecule enhance the probability of multiple interactions and therefore contributes to an increased association constant. In addition, the electron-deficient oxadiazole and aromatic systems also take part in aromatic–aromatic interactions, judging from the upfield $^1H$ NMR shifts of several aromatic proton signals.[15]

At first glance the molar masses of dendrimers **4** and **6** seem to be comparitively low, yet the tendency of these compounds to strongly self-associate in solution makes them behave like polymers, as is apparent by an increased viscosity and effective molar mass even in dilute solutions. Whereas polymers suffer from a lack of purification methods that makes it difficult to remedy any incorporated structural defects, dendrimers can be much more easily purified. We expect that self-associating poly(aramide) dendrimers with solubilising and electroactive functional groups at the periphery will have promising material properties, which are the subject of further investigations.

We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and Professor G. Wulff for generous support, Dr H. Luftmann (University of Münster) for MALDI-TOF MS measurements, and Ms H. Fürtges for assistance in the preparation of starting materials.

# Direct electrochemistry of horseradish peroxidase adsorbed on glassy carbon electrode from organic solutions

**Yizhu Guo and Ana R. Guadalupe***

*Department of Chemistry, PO Box 23346, University of Puerto Rico, Río Piedras Campus, San Juan, Puerto Rico 00931-3346*

**Using a 'solvent engineering' approach, the direct electrochemistry of catalytically active horseradish peroxidase (HRP) adsorbed on glassy carbon electrodes from HRP–DMSO and HRP–formamide solutions has been readily obtained in aqueous phosphate buffer (pH 7.0), with a surface formal potential of −0.365 V *vs.* Ag/AgCl and an apparent electron transfer rate constant of 0.655 $s^{-1}$.**

Study of the direct heterogeneous electron transfer of proteins and enzymes is a convenient and informative means for understanding the kinetics and thermodynamics of biological redox processes.[1] Work on direct electron transfer involving biomolecules has largely focused on relatively small proteins,[2] most notably cytochromes, microperoxidases, ferredoxins and myoglobin. Direct electron transfer between the electrode and the prosthetic group of catalytically active protein-enzymes possessing a considerably greater molar mass is prevented by exceedingly large electron hopping distances, by improper orientation of the adsorbed enzyme, or by adsorptive denaturation.[3a] Mediators or promoters are generally employed to study the electron-transfer kinetics of large proteins.[3] We report here preliminary results on the use of 'solvent engineering' for the direct electrochemistry of *catalytically active* horseradish peroxidase (HRP). 'Solvent engineering' has attracted much interest in nonaqueous enzymology in the last decade.[4] Many interesting findings and advances have been made in these areas.[5] Here we demonstrate the feasibility of this approach in bioelectrochemistry.

Amperometric peroxidase-modified electrodes have been one of the most extensively studied biosensors for the detection of hydrogen peroxide, organic hydroperoxides, phenols, aromatic amines and hazardous compounds. Many of these sensors are reported to be based on an apparent direct electron transfer between the immobilized peroxidase and the electrode surface.[6] Only one observation of the direct redox process of HRP adsorbed on electrochemically activated carbon electrodes has been claimed,[7] providing only the redox potentials in the range of −0.33 to −0.25 V *vs.* SCE. Little is known of the rate of electron transfer of HRP at electrode surfaces. Using the 'solvent engineering' approach we have readily obtained the direct electrochemistry of HRP adsorbed on glassy carbon electrodes by cyclic voltammetry.

The glassy carbon electrodes (BAS, $d$ = 1.6 mm) were polished with 0.05 μm $Al_2O_3$ and 1 micron diamond paste, respectively, sonicated in water, acetone and water successively, then dried in air at room temperature. Horseradish peroxidase solutions (2 mg $ml^{-1}$) were prepared by dissolving HRP (E.C. 1.11.1.7, 90 units $mg^{-1}$, Sigma) in pure DMSO or formamide (FA). The glassy carbon electrodes were soaked in these solutions for 15 min, then rinsed with copious amounts of phosphate buffer (pH 7.0, 20 mM) and ultrapure water. It has been demonstrated that enzymes (*e.g.* trypsin, chymotrypsin, lysozyme, ribonuclease) dissolved in pure organic solvents, such as DMSO and FA, do not inactivate irreversibly.[8] Nearly all original enzymatic activity is restored from organic solution not only upon immediate dilution with aqueous buffer but even after a 24 h incubation of the enzyme in organic solvents at 25 °C. Voltammograms were recorded with a BAS Electroanalyzer 100W/B interfaced to a 33 MHz Gateway 2000 computer. All the voltammetric experiments were performed with Ag/AgCl (3 M NaCl) reference and platinum auxiliary electrodes in 20 mM potassium phosphate buffer at pH 7.0.

Fig. 1 shows a typical cyclic voltammogram obtained for HRP adsorbed on a glassy carbon electrode from HRP–DMSO solution. The modified electrodes are quite stable, with little change in the voltammogram during cycling, as demonstrated by the first cycle and the fiftieth cycle shown in Fig. 1. The broadness of these peaks suggests an HRP adsorbate distribution[9] perhaps resulting from multiple conformations of adsorbed HRP from the organic solution or differential adsorption energies, and the full-width at half-maximum ($E_{FWHM}$) is 0.175 V. The redox potentials are in the range of −0.3 to −0.42 V with scan rate varying from 20 to 500 mV $s^{-1}$, and the surface formal potential [$E^{\circ\prime}$ = ($E_{pc}$ + $E_{pa}$)/2] was around −0.365 V. The position of the cathodic maximum is close to the value of the redox potential of the $Fe^{2+}/Fe^{3+}$ electron transfer in the active centre of peroxidase obtained by potentiometric studies (−0.3 to −0.45 V).[1c,10] The peak current $I_p$ was found to be proportional to scan rate ($v$), indicative of a surface-confined redox process. The surface coverage ($\Gamma$) was calculated to be $5.2 \times 10^{-11}$ mol $cm^{-2}$, consistent with the high intensity of the nitrogen signal in the X-ray photoelectron spectra of the modified electrodes. From the variation of $E_{pc}$ with $v$,[11] an apparent electron transfer rate constant $k_s$ was calculated to be 0.655 $s^{-1}$.

Besides DMSO, direct electrochemistry of HRP has been also observed for electrodes modified in HRP–FA solution, with $E^{\circ\prime}$ = −0.348 V, $E_{FWHM}$ = 0.190 V, $\Gamma$ = $4.4 \times 10^{-11}$

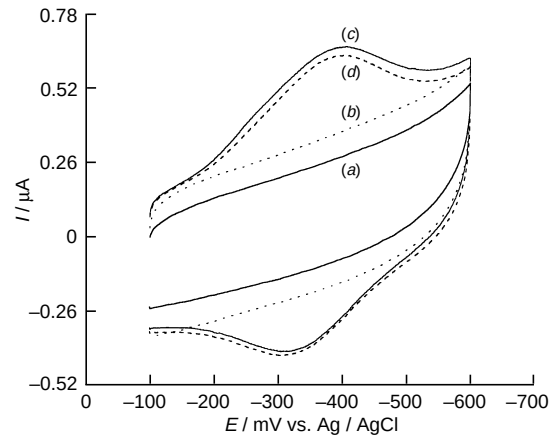

**Fig. 1** Cyclic voltammograms of a glassy carbon electrode at a scan rate of 100 mV $s^{-1}$ before and after soaking for 15 min in pure DMSO or in 2 mg $ml^{-1}$ HRP–DMSO solution: (*a*) before soaking, (*b*) after soaking in DMSO, (*c*) the first cycle after soaking in HRP–DMSO, (*d*) the fiftieth cycle after soaking in HRP–DMSO. The supporting electrolyte is 20 mM potassium phosphate buffer at pH 7.0.

mol $cm^{-2}$ and $k_s$ = 0.60 $s^{-1}$. Considering the distinctly different characters of DMSO and FA toward proteins, that is, DMSO is destructive to a protein's structural integrity[12] while FA is a solvent similar to water where there exists solvophobic interactions,[13] we might expect to observe different conformations for HRP in DMSO and in FA, and it is surprising to find that the electrochemical performance of HRP adsorbed on glassy carbon electrodes from HRP–DMSO and HRP–FA solutions is nearly the same. However, considering the reversible inactivation of dissolved enzymes in organic solvent and the complete restoration of their original catalytic activities upon dilution, these results are reasonable and expected. It is reported that a higher degree of haem exposure lowers the redox potential of a haemoprotein,[14] and there is only a few millivolt difference in the redox potentials of HRP adsorbed from HRP–DMSO and HRP–FA solutions, indicating that the restored conformation of the adsorbed enzyme upon dilution with aqueous buffer is independent of the solvent from which it was adsorbed. Furthermore, the heterogeneous electron transfer rates for HRP adsorbed on a glassy carbon electrode from organic solutions are very close to that of HRP adsorbed on a graphite electrode from aqueous solution (0.66 $s^{-1}$), which was obtained as the rate of electron transfer of the electrocatalytic reduction of $H_2O_2$ in phosphate buffer by rotating disk technique.[15] This suggests that the enzyme conformation and catalytic activity might be the same as that when the enzyme is adsorbed from aqueous solutions. As expected, these modified electrodes show catalytic activity for the reduction of hydrogen peroxide, with an onset potential at around 0.0 V and levelling off at around −0.25 V. When the peroxide inhibitor KCN was introduced into the buffer solution, the peaks of the current–voltage curve disappeared and no catalytic activity was observed after $H_2O_2$ addition. As we noticed a small direct reaction occurs between peroxide and the naked electrode and cyanide poisons the electrode, but the current on the enzyme modified electrode is much higher and the biocatalytic process is inhibited substantially by cyanide. The facts above demonstrate that the redox process of the *active* enzyme's prosthetic group has been obtained by cyclic voltammetry using 'solvent engineering'. The exact role of the organic solvents is not clear at present. Proteins dissolved in organic solvents are at least partially unfolded, resulting in a more intimate contact of the proteins with the electrode surface, a shorter electron transfer distance and a favourable orientation for the restored conformation upon rinsing with aqueous buffer. That is, one of the significant advantages of this approach is the possibility of reorganization of the conformation of adsorbed proteins on electrode surface from their organic solutions. Another possibility is to operate protein modification in protein-dissolving organic solvents, allowing inner core modification on the unfolded proteins. The latter has yet to be exploited.

In summary, we have demonstrated the feasibility of using a 'solvent engineering' approach to study the electron transfer reaction of adsorbed HRP. Applications for the direct electrochemistry of other large proteins and enzymes, and the construction of mediatorless biosensors, can be readily envisaged.

The financial support of NIH-MBRS (Grant Number S06 GM08102) is greatly appreciated.

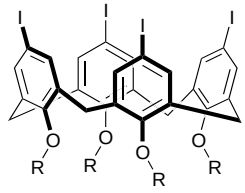
# Supramolecular intercalation of $C_{60}$ into a calixarene bilayer—a well-ordered solid-state structure dominated by van der Waals contacts

**Leonard J. Barbour, G. William Orr and Jerry L. Atwood***



*Department of Chemistry, University of Missouri-Columbia, Columbia MO 65211, USA*

**$C_{60}$ co-crystallizes with *p*-iodocalix[4]arene benzyl ether to form a layered structure in which the $C_{60}$ molecule is ordered without the presence of appreciably strong intermolecular interactions.**

There has been much interest in the supramolecular complexation of fullerenes, both in solution[1–4] and in the solid state.[5–11] Crystallographic characterization of crystals containing $C_{60}$ is often confounded by twinning[12] and orientational disorder,[9–11,13,14] the latter being mainly due to the lack of anisotropy of the molecule, and to its inability to interact strongly with other species. It is well-established that important considerations in the design of systems for molecular recognition include shape and size discrimination, as well as the exploitation of relatively weak non-covalent forces[15] (*e.g.* hydrogen bonding, π··π interactions). That these criteria are usually complementary makes the prediction of solid-state structures extremely difficult, thus forcing one to produce multicomponent materials by trial and error in order to examine the resulting structures for clues relating to their formation and stability.

Several crystal structures containing ordered $C_{60}$ molecules have been reported to date.[6,7,16,17] From these studies we are able to deduce the nature of the weak interactions which can be used to hold the molecule in place. In this context, there have been reports of interactions between six-membered aromatic rings and the electron-poor 6:5 $C_{60}$ ring fusion,[16,18] $C_5H_5$ or $C_5Me_5$ rings and the electron-rich 6:6 ring fusion,[17] $C_5$··$C_5$ interactions,[6,19] aromatic C–H··$C_6$ hydrogen-π bonds[16] and C··I interactions.[13]

We are interested in forming supramolecular complexes between fullerenes and calixarenes and have recently achieved some success in this area.[1,2] The supramolecular chemistry of calixarenes is mainly associated with a bowlic cavity which may act as a receptor site for molecular inclusion. Chemical substitution at the lower rim of calix[4]arenes invaribly results in a significant reduction in the size of the molecular cavity as the molecule adopts the so-called 'pinched-cone' conformation. However, despite the loss of the cavity, such substitution can lead to molecules with interesting solid-state packing properties relating to their shape and functionality. In an effort to gain a better understanding of some of the factors affecting the formation of stable solid-state structures, we are investigating the interaction of $C_{60}$ with a series of calix[4]arene compounds which have been modified to include both halogen and phenyl moieties. We present here the results of one such structure with a particularly interesting solid-state architecture.

**1** R = benzyl

Slow diffusion of propan-2-ol into a solution of **1** and $C_{60}$ (5:1 molar ratio) in *o*-dichlorobenzene yielded dark red crystals suitable for single-crystal X-ray diffraction analysis.† The asymmetric unit consists of one half of the calixarene molecule, which is situated on a $\bar{4}$ axis, and one quarter of a $C_{60}$ molecule which is positioned with its centre on the intersection of three mutually orthogonal two-fold rotation axes. No atoms occupy special positions in the unit cell. Although the $C_{60}$ molecule does not exhibit orientational disorder, the thermal ellipsoids of its atoms have large amplitudes parallel to its surface (Fig. 1). As shown in Fig. 2, the most striking feature of the overall structure is that $C_{60}$ molecules are intercalated into calixarene bilayers running parallel to (001). The calixarene molecule possesses $C_2$ symmetry and within each calixarene monolayer there are two distinct molecular orientations. These two orientations are rotated by 90° relative to one another and alternate like the squares on a chess board as shown in Fig. 2(*a*). The calixarene bilayer consists of two such monolayers associated with one another in a head-to-head fashion, *i.e.* where the upper rim of each calixarene molecule is one layer faces the upper rim of a calixarene molecule of the second layer across a $\bar{4}$ symmetry site. This arrangement gives rise to large intermolecular cavities which are occupied by the $C_{60}$ molecules. Fig. 2(*b*) shows a cross-section of the bilayers which are stacked along the crystallographic *c* axis with the calixarene molecules in adjacent bilayers associated with one another in a tail-to-tail arrangement. Thus the calixarene molecules are arranged in . . . a b c d a . . . columns parallel to the *c* axis.

At first glance, it would appear that the head-to-head association of the calixarenes may be facilitated by I··I interactions, while the tail-to-tail association can be attributed to π··π interactions between the benzyl moieties. However, the closest I··I approach in the structure is 4.26(2) Å. A recent survey[20] of halogen··halogen interactions, based on data from the Cambridge Crystallographic Database, suggests that symmetrical I··I distances of ⩾4.0 Å probably only correspond to van der Waals contacts which occur as a consequence of molecular packing, and thus contribute little to the energy of the crystal. Similarly, the shortest benzyl centroid··centroid dis-

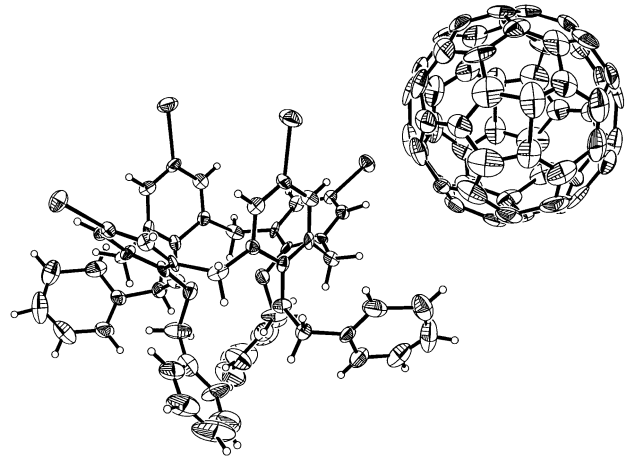


**Fig. 1** ORTEP diagram showing 30% thermal ellipsoids

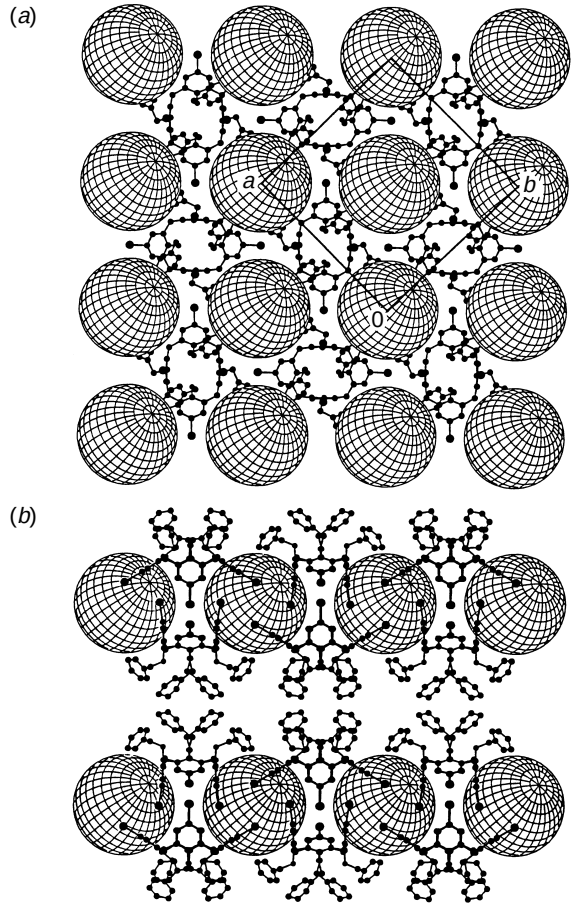

**Fig. 2** Packing diagrams (hydrogen atoms omitted) viewed along (*a*) [001], looking down the calixarene cavities and showing the $C_{60}$ molecules resting on a 2-dimensional calixarene monolyer, and (*b*) [−110], showing a cross-section of two adjacent $C_{60}$-intercalated calixarene bilayers centred at $x,y,\frac{3}{4}$, and $x,y,\frac{1}{4}$

tance of 5.28(3) Å is much too long to be attributed to an appreciably strong aromatic π··π interaction.[21]

The shortest $C_{60}$ C··I distance of 3.67(3) Å is comparable to the sum of the van der Waals radii[22] (3.68 Å) and is considerably longer than the value of 3.09 Å reported for the solvated structure $C_{60}$·$I_2$·toluene.[13] In an earlier study, $C_{60}$ C··I values of 3.29 and 3.54 Å were reported for the solvate $C_{60}$·$C_6H_6$·$CH_2I_2$,[23] implying that these interactios contribute to ordering of the $C_{60}$ molecule. Furthermore, in the present structure, the closest approach of iodine to any centroid of the fullerene rings is 3.84(4) Å. There are no calixarene aromatic centroids within 5 Å of any 6 : 5 bond of the $C_{60}$ and all fullerene ring centroids are > 3.8 Å from any calixarene atoms or ring centroids. The closest calixarene–fullerene C··C contact of 3.55 Å compares favourably with the sum of their van der Waals radii (3.54 Å). It therefore appears that the only contact between the calixarene and $C_{60}$ which may feasibly be construed as an interaction is that between an aromatic hydrogen atom (*ortho* to the iodine) of the calixarene and a carbon atom of the fullerene. This distance is 2.63(2) Å while the C–H··C angle is 168(1)°.

The closest $C_{60}$··$C_{60}$ approach is 13.46 Å within the intercalated layers and 21.18 Å between layers. The average 5 : 6 and 6 : 6 bond lengths [1.46(8) and 1.31(8) Å respectively] are in good agreement with values reported in the literature. Despite the apparent absence of any appreciable interactions between the $C_{60}$ and calixarene, it is intriguing that the structure has yielded such a well-ordered $C_{60}$ molecule.

We are grateful for funding from the National Science Foundation.

## Footnotes

† *Crystal data* for $2(C_{56}H_{44}I_4O_4)$·$C_{60}$: $M$ = 3297.62, tetragonal, $a = b$ = 19.0353(7), $c$ = 42.372(2) Å, $V$ = 15353(1) Å$^3$, space group $I\bar{4}c2$, $Z$ = 4, $D_c$ = 1.427 g cm$^{-3}$, $\mu$(Mo-Kα) = 16.71 cm$^{-1}$, $F$(000) = 6423. A dark red crystal of dimensions 0.45 × 0.25 × 0.20 mm was used. Intensity data were collected on a Siemens SMART CDD diffractometer using the omega scan mode. Data were corrected for absorption using the program SADABS which is based on the method of Blessing (ref. 24). The positions of the iodine atoms were located by the Patterson method and the structure was expanded by difference synthesis. All non-hydrogen atoms were refined anisotropically while hydrogen atoms were placed in calculated positions. A peak of 1.93 e Å$^{-3}$ in the final difference Fourier map was unaccounted for. NMR analysis of the crystals did not reveal the presence of *o*-dichlorobenzene or propan-2-ol, and the peak was thus attributed to being an artifact of the structure. Final refinement converged with $R_1$ = 0.089 for 4522 unique reflections [$I > 2\sigma(I)$, $2\theta \leqslant 46°$], 425 parameters and 12 restraints. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/471.

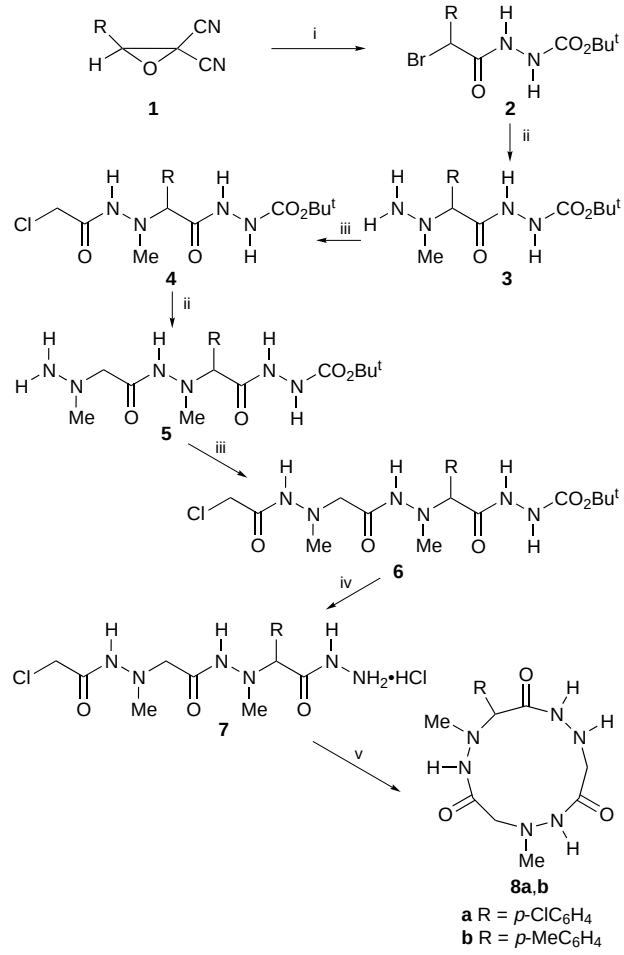
# First synthesis of cyclotrihydrazino peptides

**Sophie Carret, Michèle Baudy-Floc'h, Albert Robert and Philippe Le Grel***

*Groupe de Recherches Synthèse et Electrosynthèse Organiques Université de Rennes I, UMR CNRS 6510 Avenue du Général Leclerc, F-35042 Rennes Cédex, France*

**Synthesis of novel cyclotrihydrazino peptides using an original cyclisation method at high dilution.**

A growing number of peptides are regularly isolated from animal and human tissues. Most exhibit interesting biological effects as hormones or neuromediators. From this point of view they appear to possess high potential as therapeutic agents. However, among other reasons, their low bioavailability represents a strong limitation on their use in this field. To solve this problem peptide analogues have been synthesised and screened to produce active peptidomimetic compounds with enhanced enzyme resistance.[1] Among them, pseudo-peptides, in which the peptidic linkage is modified, are the object of great interest and have already lead to some concrete applications. For example 'Zoladex' is a powerful anticancer drug in the azapeptide class.[2]



Peptidase action is also generally lower on cyclic peptides and some, like Bottromycin, have found good use as antibiotics.[3] However, obtaining cyclic derivatives remains a problematic aspect of peptidic synthesis; yields are generally low and various factors influence the success or failure of cyclisation, including the nature and the connections of amino acid residues, solvent effects, concentration and also the type of reaction involved to induce ring closure.[4,5]

Here we report preliminary results of the synthesis of, to the best of our knowledge, the first cyclohydrazino peptides. The linear precursors were prepared using improvements to a methodology that we have already described in a previous paper.[6] To achieve the ring closure we perfected an original strategy which supplements classical methods of peptide cyclisation such as azide activation,[7] activated esters[8] or coupling reagents.[9] Scheme 1 summarizes the synthesis. Reacting *gem*-dicyano epoxides[10] **1** with $Bu^tCO_2NHNH_2{\cdot}HBr$ leads to α-halo hydrazides **2**.[11] Substitution of the halogen by methylhydrazine gives **3** which is then acylated by chloroacetyl chloride to afford **4**. Reiteration of these two steps gives **6** which includes a terminal azaglycine ester linked to an aryl hydrazinosarcosine, itself connected to an *N*-chloroacylated hydrazinosarcosine.

We took advantage of the high lability of the halogen atom in α-halo hydrazides. Indeed, we have shown that such halogens are easily displaced by nucleophiles when the reaction takes place in the presence of an additional base.[12] After elimination of the Boc function we get the polyhalo compound **7** (with undetermined HCl stoichiometry); this was then treated in high dilution in MeCN with pyridine (5 equiv.). Cyclotrihydrazino peptide **8** precipitated slowly as an amorphous powder (20% yield after purification). Compound **8** was characterized by $^1H$ and $^{13}C$ NMR spectroscopy, and its monomeric structure was established by FAB mass spectroscopy (formation of the cyclodimer had to be ruled out). Microanalysis confirmed the high purity of the compound.† At the time we undertook this work, Gani used a similar method to synthesise 1,2,5-triazepine-3,6-diones.[13]

It has been shown by X-ray and model studies that hydrazino acid residues can stabilize the folded conformation of small pseudo-peptidic patterns by hydrogen bonding.[14] The success of our synthesis of pseudo-peptide **8** may arise from such a favourable conformation bringing nearer the two reactive ends (Fig. 1).

It is worth noting that despite the high solubility of **7** and the insolubility of **8** in water, this solvent failed to allow cyclisation, possibly because competitive hydrogen bonding with water

destroys the favourable conformation for closure. This result emphasizes the crucial role played by the solvent in determining the precursor's geometry.

This preliminary work opens the way to the preparation of other original cyclopseudo-peptides of smaller or larger size, with different arrangements and various side chains. We also plan to investigate solvent effects in more detail; in particular we will examine the influence of adding ions to the reactions carried out in water.

# Photocatalytic and aerobic oxidation of saturated alkanes by a neutral luminescent *trans*-dioxoosmium(VI) complex $[OsO_2(CN)_2(dpphen)]$

**Jack Y. K. Cheng,[a] Kung-Kai Cheung,[a] Chi-Ming Che*[a] and Tai-Chu Lau[b]**

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*
[b] *Department of Biology and Chemistry, City University of Hong Kong, Tat Chee Avenue, Kowloon Tong, Hong Kong*

**A neutral *trans*-dioxoosmium(VI) complex $[OsO_2(CN)_2(dpphen)]$ (dpphen = 4,7-diphenyl-1,10-phenanthroline) is prepared and characterized by X-ray crystal analysis; the excited state is long-lived, emissive and oxidizing [$E°(Os^{VI–V})$ = 2.15 V *vs*. NHE; lifetime = 0.95 μs; quantum yield = $5 \times 10^{-4}$; $\lambda_{em}$(max.) = 650 nm]; under UV–VIS irradiation and in the presence of dioxygen, cyclohexane is oxidized to cyclohexanol and cyclohexanone with a turnover number of 16; secondary C–H bonds of propane and primary C–H bonds of *n*-hexane are also oxidized.**

The search for new metal catalysts for aerobic oxidation of saturated alkanes has continued to receive general interest.[1] One approach to this area is to develop highly oxidizing metal–oxo complexes through irradiation with UV light as represented in Scheme 1.[2,3]

**Scheme 1**

Previous studies revealed that *trans*-$[Os^{VI}(tmc)O_2]^{2+}$ (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) is capable of oxidizing a wide variety of organic substrates in acetonitrile upon UV–VIS irradiation.[2,4] However, the photoreduced product *trans*-$[Os^{II}(tmc)(MeCN)_2]^{2+}$ is stable with regard to aerobic oxidation back to the starting $[Os^{VI}(tmc)O_2]^{2+}$.[5] Herein is described a neutral *trans*-dioxoosmium(VI) complex $[OsO_2(CN)_2(dpphen)]$ **1** (dpphen = 4,7-diphenyl-1,10-phenanthroline) which can mediate photocatalytic oxidation of saturated alkanes in the presence of dioxygen.

Addition of dpphen in $CH_2Cl_2$ to a freshly prepared aqueous solution of $K_2[OsO_2(OH)_2(CN)_2]$[6] and in the presence of $NBu_4Cl$ at room temp. gave complex **1** in 85% yield.† A perspective view of the molecule is shown in Fig. 1.‡ Similarly to most octahedral *trans*-dioxoosmium(VI) complexes,[2d] the $OsO_2$ moiety is close to linear with the average Os–O distance and O=Os=O angle being 1.722(6) Å and 172.6(2)°, respectively.

Complex **1** is soluble in acetonitrile, dichloromethane and benzene. In MeCN, it shows an intense high energy absorption at $\lambda$ = 290 nm ($\varepsilon$ = 35 840 $dm^3\ mol^{-1}\ cm^{-1}$) and a shoulder at 360 (970). Compared with *trans*-$[Os^{VI}(tmc)O_2]^{2+}$, it has a much higher absorptivity in the UV region and this is attributed to the mixing of intraligand π–π* and spin-allowed $p_\pi(O^{2-})$–$d_{\pi^*}(Os^{VI})$ charge-transfer transitions.[7] In this regard, dpphen serves as an antenna for UV light. As with other *trans*-dioxoosmium(VI) complexes,[2] **1** is emissive in the solid state and in solution at room temp. Emission occurs at 635 nm with an excited state lifetime of 0.95 μs in MeCN. The $E_{0–0}$ value, estimated from the 77 K solid-state emission spectrum is 2.11 eV and the $E°(Os^{VI–V})$ by cyclic voltammetry in MeCN is 0.04 V *vs*. NHE. Using the equation, $E°(Os^{VI*–V}) = E°(Os^{VI–V}) + E_{0–0}$, the excited state is oxidizing with $E°(Os^{VI*–V})$ = 2.15 V *vs*. NHE. Upon excitation with UV–VIS light, **1** can oxidize saturated hydrocarbons such as cyclohexane, *n*-hexane, propane, adamantane and cumene. This features the first well defined metal–oxo complexes capable of oxidizing such unreactive C–H bonds. Results of photoreactions undertaken in MeCN or $CH_2Cl_2$ are summarized in Table 1. The organic products were either alcohols, ketones or aldehydes. The product yield for adamantane oxidation is low, presumably due to competitive secondary photochemical oxidation of the solvent by the excited osmium–oxo complex, the concentration of adamantane in $CH_2Cl_2$–MeCN being limited by its solubility. It is striking to find that the secondary C–H bonds of propane and primary C–H bonds of *n*-hexane could also be oxidized. Importantly, the oxidation of cyclohexane and *n*-hexane became catalytic in the presence of air. For cyclohexane oxidation, 16 turnovers were found after 12 h of reaction. The excited osmium–oxo species in this work has a significantly different reactivity from other highly oxidizing metal–oxo complexes. It is known that oxidation of adamantane by highly oxidizing Ru=O complexes takes place almost exclusively at the tertiary position.[8,9] In this work, both secondary and tertiary C–H bonds of adamantane were photochemically oxidized by **1**. Fur-

**Table 1** Photochemical oxidations of various organic substrates by **1**[a]

| Substrate | Solvent | Product(s) | Yield (%) (degassed) | Yield (%) (aerobic) |
|---|---|---|---|---|
| *n*-Hexane | MeCN (5 ml)–$CH_2Cl_2$ (2 ml) | Hexan-3-one | 26 | 160 |
| | | Hexan-2-one | 32 | 195 |
| | | Hexan-3-ol | 5 | 113 |
| | | Hexan-2-ol | 10 | 171 |
| | | Hexaldehyde } Hexan-1-ol } | 0.5 | 20 |
| Cyclohexane | MeCN (5 ml) | Cyclohexanol | 4 | 227[b] |
| | | Cyclohexanone | 35 | 225 |
| Cyclohexane | MeCN (5 ml)–$CH_2Cl_2$ (2 ml) | Cyclohexanol | 6 | 765[c] |
| | | Cyclohexanone | 30 | 800 |
| Propane | MeCN (4 ml)–propane (2 atm) | Propanone | 16.4 | |
| | | Propan-2-ol | 7.3 | |
| Cumene | $CH_2Cl_2$ (5 ml) | 2-Phenylpropan-2-ol | 115 | |
| | | Acetophenone | 77 | |
| Adamantane[d] | $CH_2Cl_2$ (8 ml)–MeCN (2 ml) | 1-Adamantanol | 10.6 | |
| | | 2-Adamantanol | 10.2 | |

[a] Complex **1** (30 mg for degassed and 10 mg for aerobic) was used with 5 ml of organic substrate; reaction time = 12 h. Yield based on **1** by GC analysis with an internal standard. [b] The yield for cyclohexanol and cyclohexanone after 2 days was 396 and 370%, respectively. [c] 2 atm $O_2$. [d] 0.2 g of adamantane used.

thermore, a small primary kinetic isotope effect ($k_H/k_D$) of *ca.* 2.2 was found for cyclohexane oxidation,which is smaller than that of 5.3 for $[Ru^{V}L(O)]^{2+}$ {HL = [2-hydroxy-2-(2-pyridyl)ethyl]bis[2-(2-pyridylethyl)]amine}.[10] The small kinetic isotopic effect and the lower tertiary C–H/secondary C–H selectivity suggests that the excited Os=O species could be regarded as a highly reactive 'ligated oxygen atom' species and Sawyer used the term 'oxene' to denote such a species.[11] A trace amount of cyclohexyl chloride was detected in the photochemical oxidation of cyclohexane in the presence of $CCl_4$.

An orange–brown solution was usually obtained after the photochemical reactions of **1** in MeCN, which slowly re-oxidized back to **1** by air. Interestingly, it gave an intense orange emission at 590 nm, the intensity of which is 20 times higher than the emission of **1** recorded under similar conditions. Our previous study revealed that $[Os^{II}I(CN)_2(X)_2L]$ complexes are highly emissive (quantum yield = 0.4–0.06) at similar energy (L = dpphen; $\lambda_{max}$/nm, X = $Me_2SO$, 625; $PPh_3$, 660).[12] We tentatively assign the photoproduct as $[Os^{II}(CN)_2(dpphen)(MeCN)_2]$. It is likely that the coordinated MeCN in $[Os^{II}(CN)_2(dpphen)(MeCN)_2]$ is more labile than in *trans*-$[Os^{II}(tmc)(MeCN)_2]^{2+}$, thus accounting the observed aerobic reoxidation of the former back to the starting *trans*-dioxoosmium(VI) complex. For the aerobic photochemical oxidations, there could be other reactive pathway(s) besides the one by the excited osmium–oxo species, since the cyclohexanone/cyclohexanol ratio for the aerobic and anaerobic oxidation of cyclohexane are different (1 : 1 *cf.* 10 : 1).

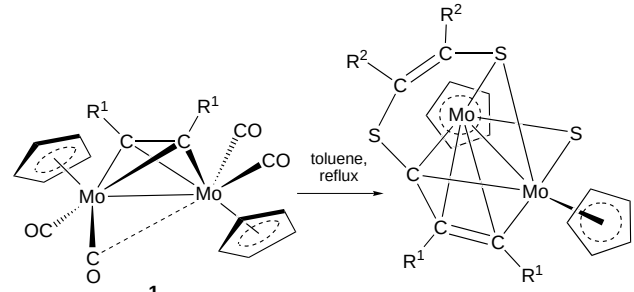
# Desulfurisation and ring opening of cyclic trithiocarbonates at a dimolybdenum centre

**Harry Adams, Matthew N. Bancroft and Michael J. Morris***

*Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*

**The dimolybdenum alkyne complexes $[Mo_2(\mu\text{-}R^1C{\equiv}CR^1)(CO)_4(\eta\text{-}C_5H_5)_2]$ ($R^1$ = $CO_2Me$, Ph) react with 1,3-dithiole-2-thiones by cleavage of the C=S bond, ring opening of the resulting carbene and coupling with the alkyne ligand; one of the products, $[Mo_2(\mu\text{-}S)(\mu\text{-}SCR^2{=}CR^2SCCR^1CR^1)(\eta\text{-}C_5H_5)_2]$ ($R^1$ = $R^2$ = $CO_2Me$), is structurally characterised.**

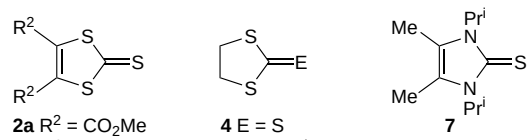
The chemistry of 1,3-dithiole-2-thiones and related sulfur heterocycles has undergone a massive expansion in the last twenty years following the observation that certain charge-transfer salts of tetrathiafulvalene (TTF) and bis(ethylenedithio)-tetrathiafulvalene (BEDT-TTF) (and their selenium analogues) exhibit conducting and superconducting properties.[1–3] The coupling of two five-membered 1,3-dithiole rings to form the central double bond is an important step in most TTF syntheses (Scheme 1), and is usually performed with $P(OEt)_3$; however yields can be variable, and the reaction often works better if X = O than if X = S, thus necessitating an extra synthetic step as the thiones are usually more easily available. Some time ago, metal carbonyls, most successfully $[Co_2(CO)_8]$, were reported to effect desulfurisation and coupling of 1,3-dithiole-2-thiones to the corresponding TTF derivatives, with moderate yields.[4] In some cases, intermediate species were observed but no organometallic products were isolated.[5] We have therefore decided to examine the chemistry of such desulfurisation reactions with the ultimate aim of discovering an efficient, widely applicable reagent to effect thione coupling.



**Scheme 1**

During our investigation of the chemistry of the alkyne complexes $[Mo_2(\mu\text{-}R^1C{\equiv}CR^1)(CO)_4(\eta\text{-}C_5H_5)_2]$ **1** ($R^1$ = H, alkyl, aryl, $CO_2Me$, *etc*.), we have shown that their reactions with thiols differ markedly from those of the parent compounds $[Mo_2(CO)_n(\eta\text{-}C_5H_5)_2]$ ($n$ = 4, 6) in that C–S bond cleavage is a common occurrence, leading to sulfido-bridged complexes.[6,7] Here we demonstrate that cleavage of the C=S bond of 1,3-dithiole-2-thiones is also possible in this system, and moreover that it leads to the construction of novel sulfur-based ligands which incorporate the alkyne bridge.

Reaction of **1** ($R^1$ = $CO_2Me$) with 1 equiv. of 4,5-bis(carbomethoxy)-1,3-dithiole-2-thione **2a** in refluxing toluene over 5.5 h resulted in the formation of a single green product, **3a**, which was isolated by chromatography in 67% yield (Scheme 2). This complex displayed no metal carbonyl absorptions in its IR spectrum, and mass spectrometry indicated incorporation of one molecule of the heterocycle into the dimolybdenum complex with retention of the alkyne ligand. Its NMR spectra† displayed equivalent $C_5H_5$ ligands and four different methyl resonances (two of them coincident in the room-temperature $^1H$ NMR spectrum). Analogous complexes **3b** ($R^2$ = SMe) and **3c** ($R^2$ = SCOPh) were formed from **1** and heterocycles **2b** and **2c** {derived from methylation or acylation of $[NEt_4]_2[Zn(dmit)_2]$ respectively[2]} in comparable yields. Ethylene trithiocarbonate **4** also reacts with **1** to produce a similar complex, formulated as $[Mo_2(\mu\text{-}S)(\mu\text{-}SCH_2CH_2SCCR^1CR^1)(\eta\text{-}C_5H_5)_2]$ **5**, showing that a saturated group linking the two sulfur atoms can be tolerated. Non-cyclic trithiocarbonates such as $(BuS)_2C{=}S$ react with **1** over a longer time period to give closely related complexes, which will be described elsewhere.[8]



The result of an X-ray crystal structure determination of **3a** is shown in Fig. 1.‡ The two molybdenum atoms, which are linked by a rather short bond of 2.5825(7) Å, are bridged virtually symmetrically by the sulfur atom S(3), which has arisen through C=S bond cleavage of the thione group. The other bridging ligand is formed by ring opening of the five-membered heterocycle and linking of the original thione carbon to the alkyne; it is bonded through the bridging sulfur atom S(1) and through carbon atoms C(11)–C(13). This latter portion bridges the two metals in an allyl-type coordination, σ-bound to Mo(2) and π-bound to Mo(1). The observation of only one $C_5H_5$ resonance in the $^1H$ NMR spectrum of **3a** at both room temperature and low temperature (218 K) implies that there is a rapid fluxional process which interchanges the σ, π coordination modes of the allyl portion of the bridging ligand.

The newly assembled ligand is formally tetraanionic, with the result that the two molybdenum atoms are both formally $Mo^{IV}$. Indeed, the molecular geometry is strongly reminiscent of that found in the quadruply bridged $Mo^{IV}$ compounds $[Mo_2(\mu\text{-}S)_2(\mu\text{-}SMe)_2(\eta\text{-}C_5H_5)_2]$[9] and $[Mo_2(\mu\text{-}S)_2(\mu\text{-}SPr^i)(\mu\text{-}PPh_2)(\eta\text{-}C_5H_5)_2]$.[10] Thus, the atoms Mo(1), Mo(2), S(1) and C(11) form a plane (maximum deviation 0.0000 Å) which within experimental error intersects at an angle of 90° with the plane formed by Mo(1), Mo(2), S(3) and C(13) (maximum deviation 0.0176 Å).

**6** E = $NPr^i$

**7**

**Scheme 2**

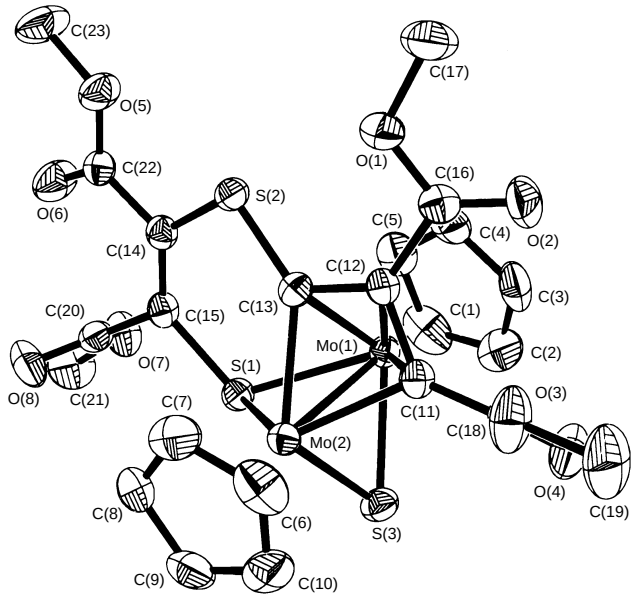

**Fig. 1** Molecular structure of complex **3a** in the crystal. Selected bond lengths (Å): Mo(1)–Mo(2) 2.5825(7), Mo(1)–S(3) 2.343(2), Mo(2)–S(3) 2.325(2), Mo(1)–S(1) 2.4594(14), Mo(2)–S(1) 2.471(2), Mo(1)–C(11) 2.176(5), Mo(1)–C(12) 2.360(5), Mo(1)–C(13) 2.223(5), Mo(2)–C(11) 2.162(5), Mo(2)–C(13) 2.200(5), C(11)–C(12) 1.416(7), C(12)–C(13) 1.415(7), C(14)–C(15) 1.349(7).

We propose that the initial step in the reaction is loss of a CO ligand and coordination of the heterocycle followed by cleavage of the C=S bond to produce the sulfido ligand and a coordinated dithiocarbene; coupling of the carbene ligand to the alkyne and ring opening by cleavage of one C–S bond would give the observed product. Dithiolium carbenes such as those derived from **2a**–**c** are pseudo-aromatic and thought to be relatively stable: they can be trapped in the reactions of $CS_2$ with activated alkynes[11] and can also be stabilised at a variety of metal centres.[12] Moreover formation of dithiocarbene ligands by desulfurisation of trithiocarbonates, including **4**, has previously been observed in reactions with iron carbonyls,[13] and an example of thioketone C=S bond cleavage at an alkoxide-ligated dimolybdenum centre leading to a bridging sulfido ligand and a terminal diarylcarbene has recently been reported.[14]

Further experiments to delineate the scope of the reaction have shown that all three sulfur atoms of the trithiocarbonate group appear to be necessary for successful product formation. Thus, neither the related 2-imino-1,3-dithiole **6** nor the tetraalkyl imidazole 2-thione **7** gave any tractable product. Changing the alkyne ligand in complex **1** also has a detrimental effect: so far only $[Mo_2(\mu\text{-}C_2Ph_2)(CO)_4(\eta\text{-}C_5H_5)_2]$ has given an analogous complex $[Mo_2(\mu\text{-}S)\{\mu\text{-}SC(CO_2Me)=C(CO_2Me)\text{-}SCCPhCPh\}(\eta\text{-}C_5H_5)_2]$ **3d** on treatment with **2a**.

Further studies on the reactivity of these novel compounds are currently in progress.

We thank the EPSRC for a studentship (M. N. B.).

# Moulding a honeycomb framework around $[Co(\eta^5\text{-}C_5H_5)_2]^+$ *via* charge-assisted C–H···O hydrogen bonds

**Dario Braga,* Alessandro Angeloni, Fabrizia Grepioni and Emilio Tagliavini**

*Dipartimento di Chimica G. Ciamician, Università di Bologna, Via Selmi 2, 40126 Bologna, Italy*

**Strong O–H···O hydrogen bonds between $[(Hta)(H_2ta)]^-$ anions derived from D,L-tartaric acid $[H_2ta]$ hold together a honeycomb superanion templated around the cation $[Co(\eta^5\text{-}C_5H_5)_2]^+$ *via* charge-assisted C–H···O hydrogen bonds.**

Organic–organometallic crystal engineering is a means to combine physical and chemical features of organic and organometallic molecules and ions in the solid state. Organic–organometallic crystals can be constructed by taking advantage of the complementary role of strong and directional O–H···O hydrogen bonds to selectively and tightly link together organic molecules, and of diffuse networks of C–H···O hydrogen bonds and anion–cation interactions to link the organic and organometallic fragments in the crystal.[1]

Along this line, we have designed, synthesized and characterized supramolecular aggregates of the paramagnetic cations $[Cr(\eta^6\text{-arene})_2]^+$ (arene = benzene and toluene) with cyclohexane-1,3-dione (CHD). The aggregation of the CHD systems in superanions is based on strong hydrogen bonds, whereas the interaction between organic fragments and organometallic complexes is based on weak C–H···O hydrogen bonds reinforced by the different polarity.[2] The participation of water oxygens in C–H···$O_{water}$ bonds has been evidenced by the structure of the hydrated $[Cr(C_6H_6)_2][CHD]\cdot 3H_2O$ and by the polar structure of the hydrated hydroxide $[Cr(C_6H_6)_2]OH\cdot 3H_2O$.[3]

Here we report that the reaction of the hydroxide $[Co(\eta^5\text{-}C_5H_5)_2]OH$ with D,L-tartaric acid $[H_2ta]$ in water (or THF) affords the novel supramolecular systems $[Co(\eta^5\text{-}C_5H_5)_2]^+[(Hta)(H_2ta)]^-$ **1** and $[Co(\eta^5\text{-}C_5H_5)_2]^+[Hta]^-\cdot H_2O$ **2** depending on the stoichiometric ratio between cobaltocenium hydroxide and tartaric acid. The hydroxide is obtained *in situ* by bubbling oxygen through a water solution of cobaltocene.† Crystals suitable for X-ray diffraction‡ are obtained by evaporation of the solvent in the air at room temp.

The cobaltocenium cation in crystalline **1** is encapsulated within an anionic organic honeycomb framework (Fig. 1) of stoichiometry [tartrate·tartaric acid]$_n$ generated by the aggregation of dimeric monoanions $[(Hta)(H_2ta)]^-$. The supramolecular monoanion $[(Hta)(H_2ta)]^-$ is formed as a consequence of the loss of one proton every two tartaric acid molecules, with the two units bonded *via* a strong –C(O)O–H···O(O)C– hydrogen bond [2.434(1) Å]. The dimers are then linked in the honeycomb framework *via* O–H···O bonds involving the two external carboxyl groups and the hydroxyl groups. The interaction between the supramolecular anionic network and the encapsulated $[Co(\eta^5\text{-}C_5H_5)_2]^+$ cations occurs *via* C–H···O hydrogen bonds[4] between the staggered cyclopentadienyl ligands of the cations and the –CO and the –OH groups of the anionic framework. Six independent C–H···O interactions are observed in the range 2.10–2.35 Å.† These values fall towards the lower limit for interactions of this type clearly indicating that the electrostatic interaction $C\text{–}H^{\delta+}\cdots O^{\delta-}$ is reinforced by the difference in charge between host and guest.[5]

The umbalance between the number of –OH and C=O acceptor sites and the number of 'conventional' donors (four –OH groups out of five participate in intramolecular –OH···O bonds) is likely to be the driving force towards aggregation around the $[Co(\eta^5\text{-}C_5H_5)_2]^+$ cations in **1**.

If the stoichiometry ratio between $[Co(\eta^5\text{-}C_5H_5)_2]OH$ and tartaric acid in the acid–base reaction is changed from 1 : 2 to 1 : 1, the hydrated crystalline salt $[Co(\eta^5\text{-}C_5H_5)_2]^+[Hta]^-\cdot H_2O$ **2** is obtained. In contrast to **1**, the $[Co(\eta^5\text{-}C_5H_5)_2]^+$ cations are in eclipsed conformation. Crystalline **2** can be described as a layered structure in which a corrugated anionic network of $[Hta]^-$ ions and water molecules alternates with layers of cobaltocenium cations (Fig. 2). The water molecules form O–H···O hydrogen-bond tetramers involving two hydroxyl groups of two neighbouring tartrate anions. As in **1**, the

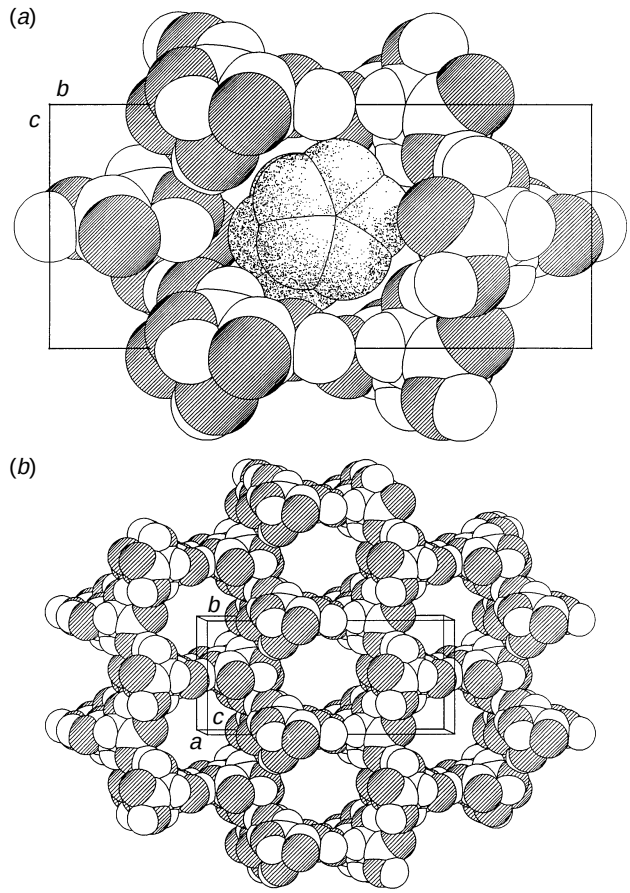

**Fig. 1** (*a*) Space-filling representation of the tartaric acid template in crystalline $[Co(\eta^5\text{-}C_5H_5)_2]^+[(Hta)(H_2ta)]^-$ **1**. (*b*) Space-filling representation of the anionic honeycomb framework formed by the $[(Hta)(H_2ta)]^-$ units, the cobaltocenium cations pile inside the channels extending along the *a*-axis. Relevant hydrogen-bonding parameters (in Å; O···O < 2.8, C–H···O < 2.5): intra, $O_{OH}\cdots Q_{CO)OH}$ 2.711, 2.638; inter, $O_{OH}\cdots Q_{CO)OH}$ 2.677; $O_{OH}\cdots Q_{OH}$ 2.776; $O^-\cdots Q_{OH}$ 2.434; $C\text{–}H_{Cp}\cdots O$ 2.396, 2.302, 2.333, 2.097, 2.354, 2.341, 2.253.† Relevant bonding parameters (in Å): mean Co–C 2.042(4); C=O 1.197(3), 1.222(3); $C{=}O_{(CO)OH}$ 1.319(2), 1.280(3); $C\text{–}O_{OH}$ 1.415(2), 1.417(2); mean C–C 1.521(6).

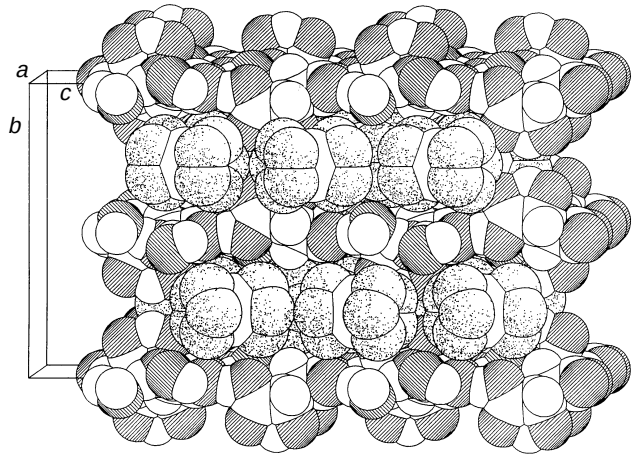

**Fig. 2** Space-filling outline of the layered structure in crystalline $[Co(\eta^5\text{-}C_5H_5)_2]^+[Hta]^-\cdot H_2O$ **2**. Relevant hydrogen bonding parameters (in Å, O···O < 2.8, C–H···O < 2.5 Å): intra $O_{OH}\cdots O_{CO/O^-}$ 2.550, 2.640; inter $O_{(CO)OH}\cdots O_W$ 2.725; $O_{OH}\cdots O_W$ 2.640, 2.784; $O^-\cdots O_{OH}$ 2.479; $C\text{–}H_{Cp}\cdots O$ 2.222, 2.338, 2.238, 2.425, 2.445. Relevant bonding parameters (in Å): mean Co–C (over the two cations) 2.016(10); mean $C_{Cp}\text{–}C_{Cp}$ 1.394(19); C=O 1.225(8), 1.220(8); $C\text{–}O_{(CO)OH}$ 1.279(8), 1.251(8); $C\text{–}O_{OH}$ 1.402(8), 1.410(8); mean C–C 1.528(14).

interaction between anion and cation is based on C–H···O hydrogen bonds (of which three in the range 2.20–2.35 Å) between the cyclopentadienyl hydrogens and the –OH and $–CO_2H$ groups. Interestingly, the two sets of C–H···O bonds in **1** and **2** stabilize, respectively, the staggered and eclipsed conformations of the organometallic cation.

With this study we have provided evidence that charge-assisted C–H···O hydrogen bonds can be used to mould O–H···O hydrogen-bond networks around organometallic cations. We have also demonstrated that it is possible to promote supramolecular aggregation of common organic acids *via* acid–base reaction with organometallic hydroxides produced *in situ*. This simple strategy opens a simple route to the preparation of a number of organic–organometallic crystalline aggregates.

Work is in progress to isolate and characterize other crystalline salts based on the utilization of chiral acids,[7] including natural amino acids, to obtain chiral organometallic crystals potentially useful for non-linear optical studies.[8]

† Powdered $[Co(\eta^5\text{-}C_5H_5)_2]$ (28 mg, 1.5 mmol) was added to 8 ml of bidistilled water at room temp. Oxygen was bubbled to completely oxidize cobaltocene into bright yellow $[Co(\eta^5\text{-}C_5H_5)_2]^+$. Powdered D,L-tartaric acid (45 mg, 3 mmol for **1**, 22.5 mg, 1.5 mmol for **2**) was then added and **1** and **2** were crystallized by evaporation at room temp. in air. The same materials can be obtained by oxidizing cobaltocene in THF at room temp. in the presence of the appropriate stoichiometric amount of solid D,L-tartaric acid. The resulting insoluble materials separate out as yellow solids, which were filtered off and dissolved in a minimum quantity of water for recrystallization. The reaction in THF very likely proceeds *via* formation of the peroxide anion $\{[Co(\eta^5\text{-}C_5H_5)_2] + O_2 \rightarrow [Co(\eta^5\text{-}C_5H_5)_2]^+ + O_2^{\cdot -}\}$ which deprotonates the acid as in the reaction between $[Cr(\eta^6\text{-}C_6H_6)_2]$ and cyclohexane-1,3-dione.[2b]

‡ *Crystal data*: $[Co(\eta^5\text{-}C_5H_5)_2]^+[(Hta)(H_2ta)]^-$ **1**: $C_{18}H_{21}CoO_{12}$, $M$ = 488.28, monoclinic, space group $P2_1/n$, $a$ = 6.589(2), $b$ = 18.210(4), $c$ = 8.208(2) Å, $\beta$ = 92.19(2)°, $U$ = 984.1(4) Å$^3$, $Z$ = 2, $D_c$ = 1.648 g cm$^{-3}$, $F(000)$ = 504, $\mu$ = 0.939 mm$^{-1}$, $\theta$ range 3.0–28°, 2606 reflections measured, 2362 of which were independent, refinement on $F^2$ for 169 parameters, $R_w$ ($F^2$, all reflections) = 0.0920, $R_1$ [1839 reflections with $I > 2\sigma(I)$] = 0.0333. Two disordered positions were found for the cyclopentadienal rings with site occupancy of 0.60 and 0.40, respectively that did not change with temperature indicating a static disorder. The two orientations correspond to two alternative sets of C–H···O interactions.

$[Co(\eta^5\text{-}C_5H_5)_2]^+[Hta]^-\cdot H_2O$ **2**: $C_{14}H_{17}CoO_7$, $M$ = 356.21, orthorhombic, space group *Pnma*, $a$ = 12.048(9), $b$ = 16.683(5), $c$ = 14.458(5) Å, $U$ = 2906(2) Å$^3$, $Z$ = 8, $D_c$ = 1.628 g cm$^{-3}$, $F(000)$ = 1472, $\mu$ = 1.214 mm$^{-1}$, $\theta$ range 3.0–28°, 3353 reflections measured, 3050 of which were independent, refinement on $F^2$ for 209 parameters, $R_w$ ($F^2$, all reflections) = 0.1778, $R_1$ [1153 reflections with $I > 2\theta(I)$] = 0.0526. Common to both compounds: graphite monochromated Mo-Kα radiation, $\lambda$ = 0.71069 Å, $T$ = 223(2) K. All non-H atoms were refined anisotropically. (O)H atoms directly located from Fourier maps and not refined. H atoms bound to C atoms were added in calculated positions. The computer programs SHELX86[6a] and SHELXL92[6b] were used for structure solution and refinement. The computer program SCHAKAL92 was used for all graphical representations.[6c] In order to evaluate the C–H···O bonds the C–H distances were normalized to the neutron derived value of 1.08 Å. CCDC 182/492.

# Dependence of metal-to-metal distances on Mo–Mo multiple bond orders; a new triple bond

**F. Albert Cotton,*[a] Lee M. Daniels,[a] Carlos A. Murillo,*[a,b] and Daren J. Timmons[a]**

[a] *Laboratory for Molecular Structure and Bonding, Department of Chemistry, Texas A&M University, College Station, TX 77843-3255, USA*

[b] *Department of Chemistry, Universidad de Costa Rica, Ciudad Universitaria, Costa Rica*

**A paddlewheel compound with a triply bonded $Mo_2^{6+}$ core is reported and used to reexamine and correct a previously reported $Mo_2^{5+}$ distance that was too long.**

The question of how the Mo–Mo distance will change when the formal Mo–Mo bond order changes in the range of three to four is not quite as simple as might naively be expected.[1] The reason is that the usual way of changing bond order also changes the average oxidation state of the metal atoms in the $Mo_2^{n+}$ core, and this in itself also affects the strength of the Mo–Mo bond. Specifically, in going through the series $Mo_2^{4+}$, $Mo_2^{5+}$, $Mo_2^{6+}$, the bonding electron configuration changes in the order $\sigma^2\pi^4\delta^2$, $\sigma^2\pi^4\delta$, $\sigma^2\pi^4$, which should progressively weaken the bond. However, in the same series, the increased charge should contract the σ and π orbitals of the metal atoms, thus also weakening the bond.† The two effects act in the same direction, so the net effect can be qualitatively predicted, namely, bond length will increase in the order $Mo_2^{4+}$, $Mo_2^{5+}$, $Mo_2^{6+}$. But by how much?

To approach the problem quantitatively, it is necessary to prepare compounds in which the core changes but the surrounding ligands do not. There has not heretofore been any such series for $Mo_2^{n+}$ although the series $[Mo_2(SO_4)_4]^{4-}$, $[Mo_2(SO_4)_4]^{3-}$, $[Mo_2(HPO_4)_4]^{2-}$ comes close.[2] The Mo–Mo distances in that case are 2.11, 2.17, 2.22 Å, respectively. The $SO_4^{2-}$ and $HPO_4^{2-}$ ligands are rather hard and would not tend to compensate very much for the effect of increasing charge, and thus the charge effect might be contributing as much (or more) than the bond order effect in this series.

One would predict that in a similar series where the ligands are much softer (more basic and/or more polarizable) the charge effect would be mitigated and the net changes would be smaller and due more to the bond order changes. We have now obtained a compound that allows us to test this prediction and correct a recently published report. This compound is $[Mo_2(hpp)_4(BF_4)_2]\cdot 4CH_2Cl_2$,‡,§ **1**$\cdot 4CH_2Cl_2$, and its structure¶ is presented in Fig. 1.

We have previously[3] prepared and structurally characterized the neutral molecule $[Mo_2(hpp)_4]$ and found the Mo–Mo bond (of order 4) to have a length of 2.067(1) Å. Thus, as shown in Table 1, the change in going from bond order 4 to bond order 3 is +0.075 Å. Similarly, earlier work in this laboratory[4] showed that with the very similar ligand, $[(p\text{-}C_6H_4Me)NC(H)N(p\text{-}C_6H_4Me)]^-$, the change in going from the neutral (quadruply bonded) compound to the +1 cation is 0.037 Å (see Table 1). Thus, the changes found on going from the $Mo_2^{4+}$ to $Mo_2^{5+}$ to $Mo_2^{6+}$ species with soft, basic ligands are only about 60% of those with the hard ligands.

However, Table 1 also shows a disturbing observation: the difference in the Mo–Mo distance in a recently reported guanidinate derivative is 0.206 Å in changing from $Mo_2^{4+}$ to $Mo_2^{5+}$.[5] Is our prediction incorrect?

A careful analysis of the supporting information provided with the structural report of the cationic guanidinate complex

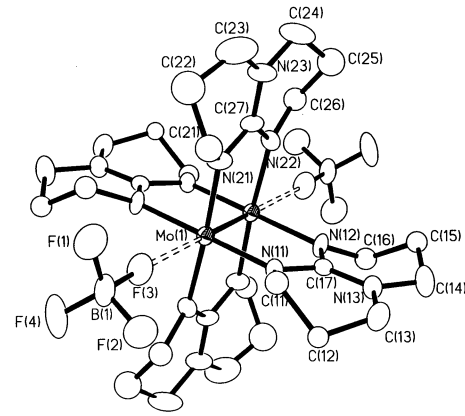

**Fig. 1** A drawing of the centrosymmetric ionic compound **1** showing the atom labelling scheme and displacement ellipsoids at the 30% probability level. The hpp ligands are conformationally disordered; only one orientation is shown. Selected bond distances (Å) are Mo(1)–Mo(1′) 2.142(2), Mo–N(11) 2.075(7), Mo(1)–N(21) 2.088(8), Mo(1′)–N(22) 2.073(8), Mo(1′)–N(12) 2.083(7), Mo(1)···F(3) 2.768(6).

**Table 1** Variations of the Mo–Mo and Mo–N distances (Å) for dimolybdenum species bridged by amidinate ligands and differences in the metal–metal distance between the corresponding cationic and neutral species

| Compound | Mo–Mo | Δ(Mo–Mo) cationic–neutral species | | Mo–N (av.) | Charge of $Mo_2^{n+}$ unit | Ref. |
|---|---|---|---|---|---|---|
| $[Mo_2(DTolF)_4]$[a] | 2.085(4) | 0.037 | | 2.17 | 4 | 4 |
| $[Mo_2(DTolF)_4]PF_6$ | 2.122(3) | | | 2.15 | 5 | 4 |
| $[Mo_2\{\mu\text{-}\eta^2\text{-}(NPh)_2CNHPh\}_4]$ | 2.0839(9) | 0.206 | 0.037 | 2.17 | 4 | 5 |
| $[Mo_2\{\mu\text{-}\eta^2\text{-}(NPh)_2CNHPh\}_4]BF_4$[b] | 2.290(1) | | | 2.14 | 5 | 5 |
| $[Mo_2\{\mu\text{-}\eta^2\text{-}(NPh)_2CNHPh\}_4]BF_4$[c] | 2.121(1) | | | 2.14 | 5 | [d] |
| $[Mo_2(hpp)_4]$ | 2.067(1) | 0.075 | | 2.16 | 4 | 3 |
| $[Mo_2(hpp)_4(BF_4)_2]$ | 2.142(2) | | | 2.08 | 6 | [d] |

[a] DTolF = N,N′-di-*p*-tolylformamidinate anion. [b] Uncorrected. [c] Corrected. [d] This work.

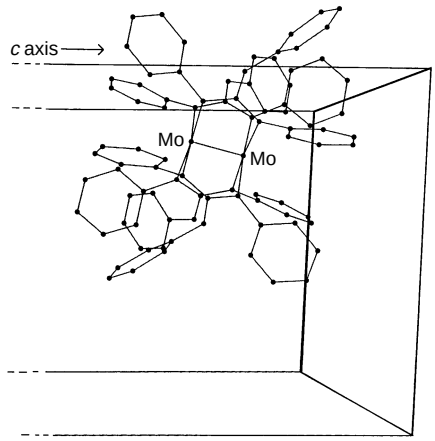

**Fig. 2** A drawing of one cation of the molecule $[Mo_2\{\mu\text{-}\eta^2\text{-}(NPh)_2CNHPh\}]BF_4$ (from ref. 5) in a box representing the unit cell, showing that the Mo–Mo unit is more or less aligned along the *c* axis

showed that the geometry of the phenyl groups in the ligands had significant distortions. In many cases the C–C distances were as long as 1.50 Å; the internal C–C–C angles varied from 115 to 125°. Furthermore, a plot of the unit cell for this compound (Fig. 2) shows that the Mo–Mo units are nearly aligned parallel to the *c* axis. Significantly, most of the long C–C bonds of the phenyl groups were more or less along the same direction. We therefore suspected that an error had been made in the input data‖ of the *c* axis used for the calculation of the bond distances and angles. Indeed, when the length of 23.573(7) Å for the *c* axis reported in the abstract given in ref. 5 is used for the calculation of the bond distances and angles, as opposed to 25.573(7) Å given in their crystallographic data and subsequently used by Bailey *et al*. for their calculations, the phenyl rings are found to be very regular. The internal bond angles vary from 119 to 121° and the C–C distances are found in the normal range 1.36–1.41 Å. Such calculation gives a Mo–Mo distance of 2.121 Å which is entirely consistent with our prediction. We are currently working on the preparation of a compound containing the $[Mo_2(hpp)_4]^+$ species which we expect to have a Mo–Mo distance similar to that of the $[Mo_2(DTolF)_4]^+$ analog.

Support from the National Science Foundation and the University of Costa Rica is gratefully appreciated.

† An equivalent explanation is that an increase in the metal charge also increases intermetal repulsions, an opposite effect to that observed for the metal-to-ligand interactions.

‡ hpp = 1,3,4,6,7,8-hexahydro-2*H*-pyrimido[1,2-a]pyrimidinate.

§ *Preparation*: Under a nitrogen atmosphere, a solution of $[Mo_2(hpp)_4]^3$ (0.74 g 1.0 mmol) in 15 ml $CH_2Cl_2$ was added to $AgBF_4^-$ (0.20 g 1.0 mmol). The reaction mixture was stirred for 30 min at room temp. and filtered. The resulting dark brown solution was carefully layered with hexanes. Within a few days, the slow diffusion of the layers afforded dark brown crystals of **1**·$4CH_2Cl_2$. Yield: 22% (based on $[Mo_2(hpp)_4]$); 44% (based on $AgBF_4$). Elemental analysis was satisfactory.

¶ *Crystal data* for **1**·$4CH_2Cl_2$: crystal dimensions 0.3 × 0.2 × 0.05 mm, $C_{32}H_{56}N_{12}B_2Cl_8F_8Mo_2$, $M$ = 1257.99, orthorhombic, space group *Pbca*, $a$ = 15.783(8), $b$ = 15.456(8), $c$ = 20.657(6) Å, $Z$ = 4, $D_c$ = 1.658 g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 0.991 mm$^{-1}$. Data were obtained at 213(2) K on a Nonius FAST diffractometer. A total of 3306 unique reflections were collected using ellipsoid-mask fitting within a $2\theta$ range of 4.72–45.1°. The structure was solved by direct methods and refined by full-matrix least squares using all 3301 reflections for 288 parameters. The hpp ligands are conformationally disordered and adjacent $CH_2$ groups deviate in opposite directions. Disordered atoms were refined isotropically. Chemically identical bonds were constrained to have identical distances. The final refinement converged to $R_1(F_o)$ = 0.081 and $wR_2(F_o^2)$ = 0.152. CCDC 186/528.

‖ Similar errors have been made before. See for example our earlier report: F. A. Cotton, L. M. Daniels, C. A. Murillo and X. Wang, *J. Am. Chem. Soc.*, 1996, **118**, 12449.

*Note added in proof*: We have been informed by the authors of ref. 5 that they concur with our discussion of the error in the bond length in their compound.

# Supramolecular assembling of the cationic complex (2,2′:6′,2″-terpyridine)methylplatinum(II) ion on α-helical poly(L-glutamic acid)

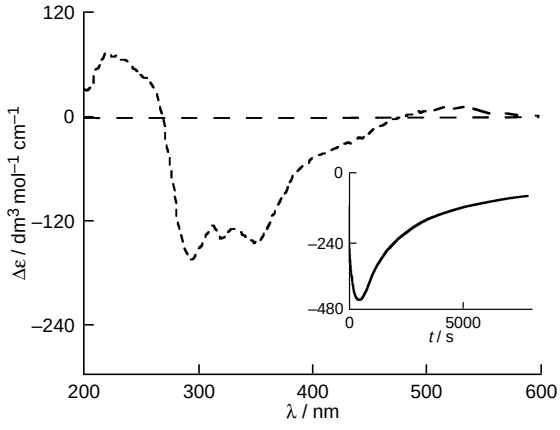
**Luigi Monsu' Scolaro,* Andrea Romeo and Antonio Terracina**

*Dipartimento di Chimica Inorganica, Chimica Analitica e Chimica Fisica, Universita' di Messina, and Istituto di Chimica dei Prodotti Naturali (ICTPN-CNR), Sezione di Messina, Messina, Italy*

**The cationic organometallic platinum(II) complex ion [Pt(terpy)Me]$^+$ aggregates on α-helical poly(L-glutamic acid) through a multistep process leading to highly organised supramolecular assemblies.**

Planar dyes, such as porphyrins and acridines, bind to helical biopolymers leading to adducts which exhibit induced circular dichroism (ICD) in the wavelength region where the bound molecules absorb light.[1–3] The biological matrix acts as a template support for the formation of short- or long-range organised assemblies of chromophores, stabilised by an interplay of electrostatic, hydrogen bonding and dispersive forces. Different types of biopolymers have been reported to behave as template systems including double-stranded DNA,[3] single-stranded DNA and RNA[4] and polypeptides.[5,6] The kinetics of the supramolecular aggregation are in general multiphasic[7] and the use of simple matrices offers a way of reducing the difficulty in assessing the mechanism of interaction. In this respect, poly(glutamic acid) is an interesting biopolymer, because the only interaction modes are electrostatic and hydrogen bonding. Furthermore, it undergoes a transition from α-helix to random-coil above pH 5[8] so that it is possible to control the structure and the nature of the resulting adduct by modulating the pH and the ionic strength.

In a previous study,[9] we reported on the strong tendency for self-aggregation of the complex ion [Pt(terpy)Me]$^+$ **1** in contrast with the well studied [Pt(terpy)(het)]$^+$ (het = 2-hydroxyethanethiolate).[10] The addition of low concentrations of nucleic acids, such as DNA[9] or single-stranded poly(rA),[11] leads to a distribution of complex **1** between its free self-aggregated form in solution and on the backbone of the DNA. The very weak ICD and resonance light-scattering (RLS)[12] signals of these adducts indicate that the aggregation on these matrices is not well structured over extended lengths.



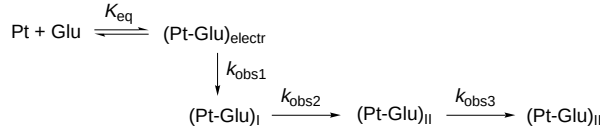


**Fig. 1** CD spectrum of the final adduct between the complex [Pt(terpy)-Me]Cl and poly(L-glutamate). The inset shows the kinetic trace recorded at 280 nm. Experimental conditions: [Pt] = $2.5 \times 10^{-5}$ M, [Glu] = $5 \times 10^{-5}$ M, pH 4.5 in 5 mM acetate buffer, $T$ = 298 K. ($k_{obs1}$ = 0.25 ± 0.03 s$^{-1}$, $k_{obs2}$ = 0.016 ± 0.002 s$^{-1}$, $k_{obs3}$ = 0.0008 ± 0.0001 s$^{-1}$, as derived from the best fitting analysis of the overall kinetic trace, see text).

Here we report a preliminary kinetic investigation of the interaction between **1** and the poly(L-glutamic acid) in the α-helical conformation. To the best of our knowledge this is the first example of a supramolecular aggregate formed by an organometallic platinum(II) complex.

On adding a solution of complex to a prethermostated solution of poly(L-glutamic acid) at pH 4.5,† the absorption spectrum shows an instantaneous and small bathochromic shift (< 2 nm) associated with a slight hypochromicity of the 313 and 331 nm bands of the complex. The spectral changes are rapidly masked by an increase in Rayleigh scattering. The time behaviour of the scattered intensity can be monitored by conventional light-scattering techniques and shows an initial rapid increase followed by slower steps. The time evolution of the process can be monitored more conveniently by CD spectroscopy (Fig. 1). On addition of the polymer, the sequence of CD spectra reveals a multiphasic process which involves the formation of at least four different species (Scheme 1), characterised by large values of $\Delta\varepsilon$ (*ca.* −180 dm$^3$ mol$^{-1}$ cm$^{-1}$ at 300 nm for the final adduct). Kinetic runs were performed at 280 nm (inset in Fig. 1) and were analysed as three coupled consecutive first-order steps. The initial CD spectral change is faster than the mixing time.

**Scheme 1**

The observed rate constants ($k_{obs1}$, $k_{obs2}$, $k_{obs3}$) exhibit a bell-shaped dependence on the concentration of the polymer (Fig. 2). The $k_{obs}$ values increase to reach a maximum corresponding to a ratio $r_f$ = 0.5 ($r_f$ = [Pt]$_o$/[poly(Glu)]$_o$). Therefore, when the concentration of the matrix is below a threshold, an increase of its concentration determines an acceleration of the rates, as a result of the increased availability of binding sites. A further increase of the concentration provokes a dispersion of the complex on the matrix and leads to a decrease in the rate. A similar concentration dependence is shown by the intensity of the ellipticity corresponding to the final adduct. In order to establish the importance of the α-helical conformation of the polymer, the dependence of the kinetic rate constants and ellipticity intensities on the pH was investigated. It has been found that these parameters exhibit, also in this case, a bell-shaped profile with the maximum centred at pH 4.5 and 4.8 for the rate and the ellipticity, respectively. An experiment performed at pH 7.0, well above the helix to coil transition, showed that the ICD spectrum is very weak and it is reversed in phase with respect to lower pH.[13]

According to the experimental findings, the following mechanism can be suggested (see Scheme 1). The first step

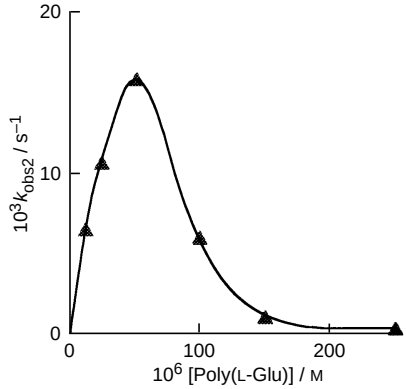

**Fig. 2** Dependence of the observed first-order rate constant ($k_{obs2}$/$s^{-1}$) for the second stage of the assembling on the concentration of poly(L-glutamate) (in molar glutamate residues). Experimental conditions: [Pt] = $2.5 \times 10^{-5}$ M, pH 4.5 in 5 mM acetate buffer, 298 K.

involves a fast electrostatic pre-equilibrium between oppositely charged species leading to a low-ordered adduct. The fairly high initial value of the ellipticity suggests the formation of dimers or higher aggregates (nucleation step). These small aggregates serve as promoters for the subsequent growth of the assembly. The following steps can be ascribed to conformational re-arrangements owing to changes in the relative orientation of the chromophores with respect to the matrix backbone or to a conformational change of the matrix itself caused by the aggregation.[14]

The reaction intermediate $(Pt–Glu)_{II}$ and the final adduct are characterised by large values of ellipticity. The value of $|\Delta\varepsilon/\varepsilon| \approx 2.3\%$ for the final adduct and resonance light scattering measurements[12] indicate the presence of extended arrays of strongly coupled chromophores forming a highly organised assembly in which the biopolymer acts as a template matrix.[5] A structural model for the supramolecular assembling can be inferred from the presence of maxima in the rate and ellipticity profiles, as shown by the glutamate concentration and pH dependences. At pH 4.5 the negative charges on the side chains are half-neutralised and, given the observed maxima at $r_f = 0.5$, a stoichiometric ratio of 1 : 1 (cationic complex to unprotonated glutamate residues) is indicated. Taking into account the translational rise of 1.5 Å for a residue in the α-helix,[15] it is possible to assume the presence of a negative charge every 3 Å. This distance is that expected for π–π stacking interactions between two terpyridine moieties.[16] Therefore, we are inclined to think that the polypeptide acts as template support to form an α-helix of chromophores, which is stabilised by electrostatic interactions with the polymer and by π–π stacking interactions between the aromatic region of the complexes.

The remarkable tendency to give supramolecular assemblies is peculiar to $[Pt(terpy)Me]^+$, as demonstrated by the fact that the closely related cation $[Pt(terpy)Cl]^+$, under the same experimental conditions, does not lead to any organised adduct. The higher hydrophobicity together with the higher extent of electron density on the metal center, in the case of the organometallic species, could be responsible for this behaviour.

The possibility of tuning the electronic and steric properties of the chromophore‡ and of the supporting biopolymer opens the way to control the molecular recognition between the interacting species.

We thank the CNR, MURST and a NATO grant #SRG 950676 for financial support. The authors are grateful to Professors Robert F. Pasternack and Raffaello Romeo for stimulating discussions.

## Footnotes

† Poly(L-glutamic acid) was obtained from Sigma as its sodium salt ($M_W \approx 13\,600$; polydispersity = 1.2). The pH of the reaction mixtures was adjusted to the desired value using 5 mM acetate buffer.

‡ The organometallic compound [Pt(Phterpy)Me]Cl (Phterpy = 4′-phenyl-2,2′ : 6′,2″-terpyridine), under the same experimental conditions, leads to ICD spectra four times less intense than those of complex **1**, as a consequence of the steric congestion brought about by the phenyl substituent on the terpyridine ring. Steric effects are crucial in determining the behaviour of the complexes [Pt(terpy)Ph]Cl and [Pt(Phterpy)Ph]Cl, where the phenyl ring is directly bound to the metal center and out of the coordination plane. These latter compounds show no detectable interaction with the polypeptide.

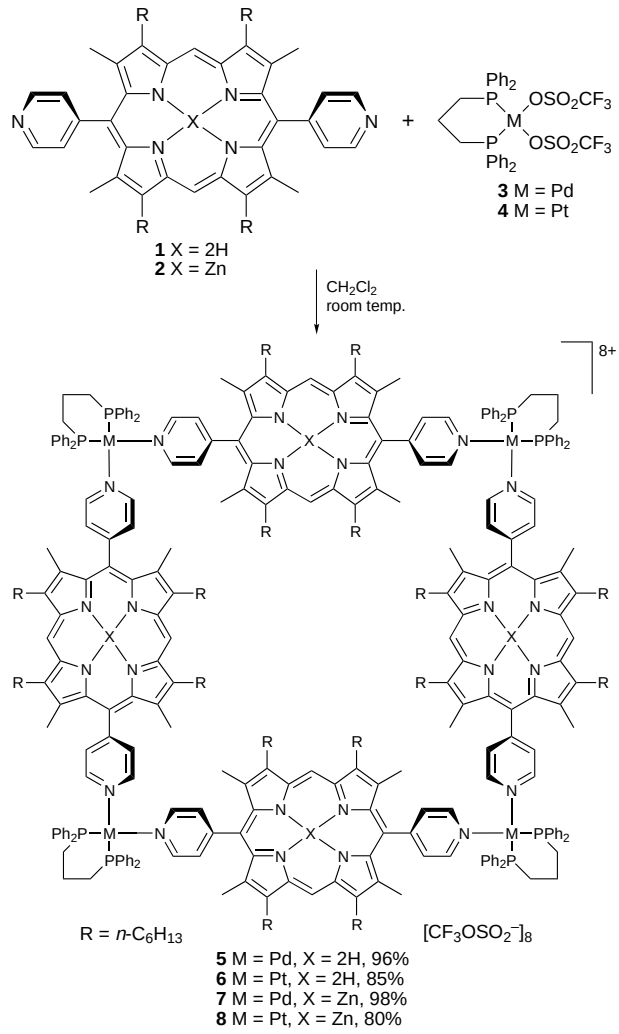
# Molecular architecture *via* coordination: self-assembly of cyclic cationic porphyrin aggregates *via* transition-metal bisphosphane auxiliaries

**Peter J. Stang,* Jun Fan and Bogdan Olenyuk**



*Department of Chemistry, The University of Utah, Salt Lake City, Utah 84112, USA*

**Self-assembly and non-covalent interactions are employed for the preparation of a new family of cationic artificial supramolecular multiporphyrin aggregates incorporating $Pd^{II}$ and $Pt^{II}$ bisphosphane complexes as auxiliaries.**

Among the variety of naturally occurring self-assembling supramolecular species the photosynthetic reaction centre[1] and light harvesting complex of purple bacteria[2] represent excellent examples of well defined multichromophore aggregates whose structure and properties and most likely function are essentially determined by the nature and positioning of their constituent components. In recent years many examples of self-assembled multiporphyrin arrays were made by employing hydrogen bonding,[3] transition-metal-mediated self-coordination,[4] self-aggregation in non-polar organic solvents[5] as well as transition-metal-directed cyclic oligomerization[6] and threading,[7] to name only a few. Combined with recent advances in the studies of directional energy transport in chromophore-labelled supramolecular assemblies,[8] they provide useful insights in the development of a completely functional artificial photosynthetic centre. An intriguing way to further extend this topic is to construct a conformationally rigid photoactive aggregate with the constituent chromophores linked together or combined with redox-active species by employing coordination to square-planar late transition-metal (namely $Pd^{II}$ or $Pt^{II}$) bisphosphanes in a *cis*-manner. Such a tetranuclear assembly will have the geometry of a square with transition metals in the corners serving as the auxiliaries. Since both the chemistry and structure of many simple examples of such molecular square complexes are currently relatively well understood,[9,10] the possible application of this type of self-assembly principle to the construction of large multiporphyrin arrays is an especially attractive task. Herein, we report the formation, characterization and absorbance characteristics of several new cationic multiporphyrin aggregates based on these concepts.

We chose to prepare porphyrin[11] **1** and its Zn complex **2** for this study owing to their relatively straightforward preparation and, most important, high solubility in common organic solvents which facilitates the self-assembly process. Interaction of the porphyrin molecule **1** with the reactive bistriflates **3** or **4**,[9d] in dichloromethane at room temperature results in the formation of the desired tetranuclear complexes **5** and **6** in excellent isolated yields (Scheme 1).† These aggregates are isolated and characterized as air-stable robust (though hygroscopic) microcrystalline solids with high decomposition points. Their NMR spectra revealed several interesting features. Both the $^1H$ and $^{13}C$ NMR spectra indicate one set of signals for the pyridine rings but two sets for the porphyrin moiety with the second set being considerably high-field shifted. The $^{31}P$ NMR of **5** and **6** however, show a single signal, supporting the formation of a single highly symmetrical entity. Compared to the starting bistriflates **3** and **4**, these $^{31}P$ signals are shifted upfield by *ca*. 10 ppm, indicative of the coordination of the nitrogen lone pair to the transition metal.‡ Taken together, these data suggest that (*i*) the porphyrin moieties in **1** are restricted in rotation around both the pyridine–porphyrin and the metal–pyridine nitrogen bonds[12] and (*ii*) the porphyrin rings are most likely coplanar with respect to each transition-metal coordination plane.§ As a consequence, each porphyrin moiety has part of the ring located 'inside' the cyclic tetranuclear assembly, which therefore is subject to the ring current effects formed by the entire large cyclic assembly as no such high-field shifts are observed for more common acyclic porphyrin aggregates and oligomers.[13] Moreover, molecular models indicate that the individual porphyrin units are coplanar and located too far apart from each other to be influenced by the ring currents of their neighbours (Fig. 1).[14]¶ These considerations along with the above discussed NMR spectroscopic data confirm the cyclic nature of aggregates **5** and **6**.

When the Zn complex of porphyrin **2** was employed under these self-assembly conditions the heterobimetallic assemblies **7** and **8** were isolated (Scheme 1). Interestingly, in the absence of the transition metal auxiliary the Zn-porphyrin **2** itself exists in solution mainly as a mixture of self-coordinated oligomers.

**Scheme 1**

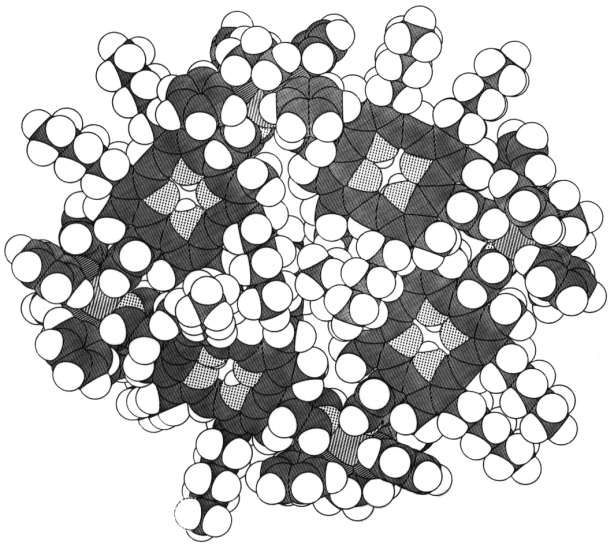


**Fig. 1** Space-filling model of tetramer **6**, derived from force-field calculations (Biosym/MSI, ESFF)

The proton signals of the pyridyl hydrogens of **2** in chloroform solution are shifted upfield and completely absent from the aromatic region of its $^1$H NMR spectrum. This large upfield shift of the pyridyl protons coordinated to the inner Zn atom of a neighbouring porphyrin moiety is indicative of their proximity to the porphyrin ring current.[4] When **3** or **4** are added to the porphyrin solution the NMR spectra indicate the coordination of pyridyl protons exclusively to $Pd^{II}$ or $Pt^{II}$, presumably due to the greater M–N bond strength compared to the Zn–N bond as well as possibly enthalpic factors which favour the formation of these cyclic tetramers more than the open-chain oligomers of the porphyrin alone.[4b] Because of this greater Pd–N, Pt–N bond strength assemblies **5**, **6** and **7**, **8** are found to be stable in a wide concentration range from $10^{-9}$ to at least $10^{-2}$ mol $dm^{-3}$. This feature makes them particularly interesting targets for spectroscopic studies in highly dilute solutions, where most of the self-coordinated Zn-containing aggregates as well as hydrogen-bonded assemblies exist in monomeric forms.[3,4] Assemblies **7** and **8** are isolated in excellent yields (Scheme 1) and are air and thermally stable. The similarity of all the NMR spectroscopic data of **7** and **8** to tetramers **5** and **6** suggests that all the above considerations regarding the solution structures **5** and **6** also apply to Zn-containing assemblies **7** and **8**.

The UV–VIS spectra of the assemblies **5** and **6** show a 8–12 nm red shift of their Soret and Q-bands as compared to **1** along with considerable decrease of their intensity. As seen, the $Pt^{II}$ tetramer **6** decreases the intensities of these absorption bands by more than a factor of two as compared to its $Pd^{II}$ counterpart **5**. Moreover, the fluorescence of the porphyrin moiety **1** is quenched to a large degree when they are assembled in tetramers **5** and **6**. The absorbance maxima in **7** and **8** are red shifted by 10–12 nm, much like in squares **5** and **6**. Interestingly, the spectra for the Zn-containing tetramers indicate an increase in the Soret and Q-band intensities, as compared to porphyrin **2** itself. Furthermore, the influence of the transition metal on the absorbance intensities seems to be reversed in **7** and **8** as compared to **5** and **6**: the $Pt^{II}$ tetramer has a higher absorbance for both the Soret and Q-bands than the $Pd^{II}$ analogue. The explanation of this phenomenon may be in the fact, that unlike porphyrin **1**, its Zn-containing counterpart largely exists in solution in the form of self-coordinated oligomers. When the auxiliary complexes of $Pd^{II}$ or $Pt^{II}$ are added, the oligomers are converted to the assemblies **7** and **8**, respectively. Since the decrease in absorbance in self-coordinated Zn-containing porphyrin oligomers as compared to free porphyrin is well documented,[4] this effect may account for the unusual spectroscopic behaviour of Zn-containing species **2** and **7**, **8**.

In conclusion, a new family of artificial cationic supramolecular multiporphyrin aggregates can be readily assembled *via* non-covalent interactions by using $Pd^{II}$ and $Pt^{II}$ bisphosphane complexes as auxiliaries. These large stable aggregates may serve as both useful models for intrasupramolecular energy transfer as well as provide useful insights for future self-assembly of photoactive supramolecular systems.

Financial support by the National Science Foundation (CHE-9529093) and University of Utah Graduate Research Fellowship to Bogdan Olenyuk are gratefully acknowledged. We also thank Johnson-Matthey for a generous loan of Pd and Pt salts.

## Footnotes

† *Preparation of aggregates* **5**–**8**: To a solution of 0.017 mmol of porphyrins **1** or **2** in 10 ml of $CH_2Cl_2$, 0.017 mmol of **3** or **4** was added and the resulting solution was stirred at room temp. from 1 h (for **5** and **7**) to 4 or 5 days (**6** and **8**, respectively). The solvent was reduced in volume to 1 ml *in vacuo* and pentane or diethyl ether were added resulting in the formation of a dark-red solids, which were collected, washed and dried *in vacuo*.

‡ Both the magnitude and the direction of the chemical shifts are comparable to those observed for the $(dppp)_2Pd^{II}$ and $(dppp)_2Pt^{II}$-based tetranuclear squares (geometry established by X-ray structural data[9d]).

§ The MM2 calculation indicates hindered rotation at room temperature. The minimum steric energy corresponds to the pyridine ring being oriented nearly perpendicularly to the porphyrin plane.

¶ ESFF force-field calculations were performed on a Biosym/MSI 95.0 package.

# Remarkable non-oxidative conversion of methane to naphthalene and benzene on Co and Fe modified Mo/HZSM-5 catalysts

**Shetian Liu, Qun Dong, Ryuichiro Ohnishi and Masaru Ichikawa***

*Catalysis Research Center, Hakkaido University, Kita-Ku, N-11, W-10, Sapporo 060, Japan*

**Remarkable production of naphthalene and benzene is found in the dehydrocondensation of methane under non-oxidative conditions on Co- and Fe-modified Mo/HZSM-5 catalysts at 973 K and 1 atm pressure of methane.**

Recently there is an increasing interest to activate methane under non-oxidative conditions and convert it to higher hydrocarbons and aromatic compounds as alternative feedstocks for the petrochemical industry.[1,2] Some supported Pt and Ru catalysts yield $C_2$–$C_5$ hydrocarbons and even benzene in the low-temperature homologation of methane[3–5] but continuous catalytic reaction does not proceed. It has been previously reported that on Mo-supported ZSM-5 zeolite catalysts, a considerable amount of benzene was produced at 973 K in 60–70% selectivity in the gas-phase products at lower methane conversion while only benzene and toluene have been observed as the aromatic products.[6,7] Nevertheless, methane conversion was drastically decreased owing to irreversible coke formation on the catalysts.

Here, we describe that Fe- and Co-modified Mo/HZSM-5 catalysts exhibit remarkable production of naphthalene and benzene as the major aromatic products together with a small amount of their derivatives such as toluene, xylene and methylnaphthalene in the dehydrocondensation of methane at 973 K and 1 atm pressure. Furthermore, it was found that the addition of cobalt and iron to Mo/HZSM-5 catalyst markedly improved the yield of naphthalene and benzene along with effective reduction of coke formation.

The Mo/HZSM-5 and Fe/Co-modified Mo/HZSM-5 catalysts were prepared by the conventional impregnation (incipient wetness) of $NH_4$ZSM-5 (Si/Al = 79, Toso Co.) with $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (Kanto Chem. Co.), $Co(NO_3)_2\cdot 6H_2O$ (Wako Pure Chem. Ind. Ltd.) or $Fe(NO_3)_3\cdot 6H_2O$ (Wako) aqueous solutions. After the impregnated samples were dried at 393 K and calcined at 773 K in air, catalytic tests were carried out under atmospheric pressure of methane in a continuous flow microreactor system equipped with a quartz tube (8 mm id) packed with 0.3 g of catalyst pellets of 20–42 mesh. After flushing with He at 973 K for 40 min, a feed gas mixture (99.99% purity, Sumitomo Seika Co.) of 98% $CH_4$ with 2% Ar as internal standard for analysis was introduced into the fixed-bed reactor at a flow rate of 7.5 ml $min^{-1}$ [space velocity = 1500 ml (g cat. h)$^{-1}$, contact time = 3.8 s] through a mass flow controller (Brooks 5850E).

Hydrocarbon products including $C_2$–$C_4$ alkanes (and/or alkenes) and condensable $C_6$–$C_{12}$ aromatics such as benzene, toluene, xylene, naphthalene and methylnaphthalenes were removed by a six-way sampling valve heating at 500 K and analyzed by on-line gas chromatography (Shimadzu GC-14A) equipped with a flame ionization detector (FID) using a 4 mm × 1 m Porapak-P column. Another GC (Shimadzu GC-8A) with a thermoconductive detector (TCD) was employed for on-line product analysis of $H_2$, Ar, CO, $CH_4$ and $CO_2$ using a 4 mm × 2 m activated carbon column. All products were identified by using GC–MS (Perkin-Elmer, Auto System GC, 910 Q-Mass).

Using an internal standard analyzing method, conversion of methane, selectivities of hydrocarbon products and coke formed on the catalyst were evaluated according to the mass balance for carbon and hydrogen. The total gas flow rate at the outlet of the reactor ($F^{\text{outlet}}$) can be calibrated by eqn. (1). The methane

$$F^{\text{inlet}} X_{\text{Ar}}^{\text{inlet}} = F^{\text{outlet}} X_{\text{Ar}}^{\text{outlet}} \tag{1}$$

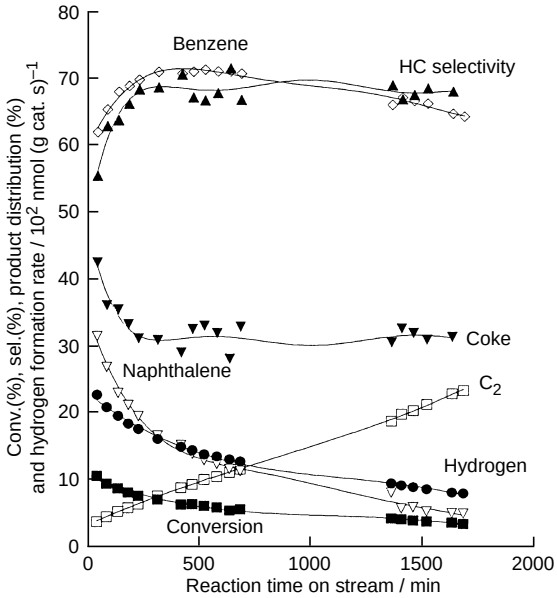
conversion (Conv.) and selectivity ($S_{\text{product}}^{\text{carbon}}$) of hydrocarbon products in gas phase on carbon base were calculated from eqns. (2) and (3). The selectivity of coke including undetected heavy

$$\begin{aligned}\text{Conv.} &= \frac{F^{\text{inlet}} X_{\text{methane}}^{\text{inlet}} - F^{\text{outlet}} X_{\text{methane}}^{\text{outlet}}}{F^{\text{inlet}} X_{\text{methane}}^{\text{inlet}}} \\ &= 1 - \frac{X_{\text{methane}}^{\text{outlet}} X_{\text{Ar}}^{\text{inlet}}}{X_{\text{methane}}^{\text{inlet}} X_{\text{Ar}}^{\text{outlet}}}\end{aligned} \tag{2}$$

$$\begin{aligned}S_{\text{product}}^{\text{carbon}} &= \frac{F^{\text{outlet}} X_{\text{product}}^{\text{outlet}} N_{\text{product}}^{\text{carbon}}}{F^{\text{inlet}} X_{\text{methane}}^{\text{inlet}} - F^{\text{outlet}} X_{\text{methane}}^{\text{outlet}}} \\ &= \frac{X_{\text{Ar}}^{\text{inlet}} X_{\text{product}}^{\text{outlet}} N_{\text{product}}^{\text{carbon}}}{X_{\text{Ar}}^{\text{outlet}} X_{\text{methane}}^{\text{inlet}} - X_{\text{Ar}}^{\text{inlet}} X_{\text{methane}}^{\text{outlet}}}\end{aligned} \tag{3}$$

aromatics, amorphous carbon and graphitic carbon on the catalysts is given by $1 - \Sigma S_{\text{product}}^{\text{carbon}}$. Here, $F$, $X$ and $N^{\text{carbon}}$ represent total gas flow rate, mole fraction and carbon number in a molecule, respectively.

The non-oxidative conversion of methane was conducted by flowing methane on the catalyst in the fixed bed at 973 K. $C_2$-hydrocarbons and aromatic compounds were continuously obtained with a considerable evolution of hydrogen on the Mo/HZSM-5 and Co/Fe-modified Mo/HZSM-5 catalysts. The major aromatic compounds produced in the reaction are benzene and naphthalene with other aromatics produced only in trace amounts. Fig. 1 shows the conversion of methane and the selectivity of hydrocarbon products such as benzene and naphthalene with time on stream of the reaction at 973 K. The selectivity of hydrocarbon products in the gas phase increases and reaches a value of 68% on carbon basis and then keeps constant, while the selectivity of coke was *ca*. 32% on the Mo/HZSM-5 catalyst. The conversion of methane decreases rapidly from 12 to 8% at the initial stage of the reaction in forming a large amount of hydrogen and CO where $MoO_3$ supported on HZSM-5 was converted to reduced Mo species and $Mo_2C$.[2,8] Methane conversion shows a moderate decrease (6–8%) upon prolonged reaction time (30 h) to give a stable selectivity of the hydrocarbon products including $C_2$–$C_4$ compounds and aromatics such as benzene and naphthalene. The thermodynamic equilibrium conversion of methane for $6CH_4 = C_6H_6 + 9H_2$ is calculated as 11.8% at 973 K and 1 atm of methane. The constant selectivity of hydrocarbon products (68%) and coke (32%) in the stationary stage of the reaction may suggest that both products are derived from a common intermediate $CH_x$ formed on the Mo/HZSM-5 catalysts. In the initial stage of the reaction, the composition of gas-phase hydrocarbons comprised 31 and 62% of naphthalene and benzene on carbon basis, respectively, and after 20 h of reaction time changed to 6 and 67% while the $C_2$ products increased to 20%. This may suggest that benzene, naphthalene and their derivatives may



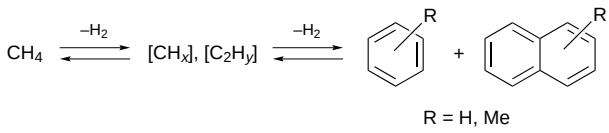


**Fig. 1** Catalytic performances of 3% Mo/HZSM-5 zeolite catalyst for methane non-oxidative dehydrocondensation reaction at 973 K. (■) Methane conversion, (▲) selectivity of hydrocarbon products, (▼) selectivity of coke, (●) formation rate of hydrogen, (◇) percentage of benzene in hydrocarbon products, (▽) percentage of naphthalene in hydrocarbon products, (□) percentage of ethane + ethene in hydrocarbon products.

consequently be produced *via* $[CH_x]$ and/or $C_2H_y$ intermediates as proposed previously[7,8] and the reaction may occur *via* Scheme 1.

**Scheme 1**

From Fig. 2 it is clear that addition of Fe, as for Co, to Mo/HZSM-5 catalysts yields a considerable enhancement of aromatic products such as naphthalene and benzene in the reaction at 973 K. It is of interest to observe that a maximum yield of benzene and naphthalene was attained in low concentrations of Fe or Co in Mo/HZSM-5 [atomic ratio *ca.* 0.2–0.4 for M/(M + Mo) (M = Fe, Co)]. 1% Co loading into 3% Mo/HZSM-5 resulted in an increase of benzene yield from 3.2 to 4.7% owing to higher conversion of methane and higher benzene selectivity in gas-phase hydrocarbon products as compared with 3% Mo/HZSM-5. On the other hand, the promotion of benzene yield upon addition of Fe to Mo/ZSM-5 is due to the suppression of coke formation from 31 to 21%, although the Fe/HZSM-5 catalyst showed preferential formation of coke (75% selectivity) in the reaction. Further addition of Fe or Co to Mo/HZSM-5 resulted in a decrease of the aromatic products owing to substantial increase of coke formation in methane conversion. The results suggest that the binary FeMo and CoMo oxide/carbides formed on the ZSM-5 support are active for the dehydrogenation of methane towards aromatics

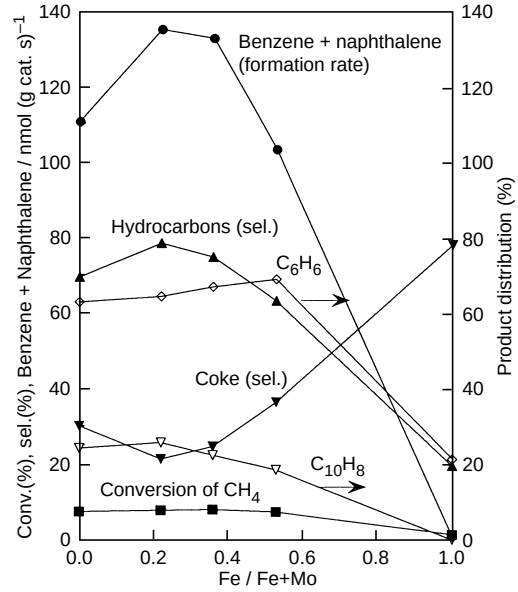

**Fig. 2** Catalytic performances of Fe-Mo/HZSM-5 zeolite catalysts for methane non-oxidative dehydrocondensation reaction at 973 K (data are taken at 160 min of the reaction time on stream). (■) Methane conversion, (▲) selectivity of hydrocarbon products, (▼) selectivity of coke, (●) formation rate of benzene and naphthalene, (◇) percentage of benzene in hydrocarbon products, (▽) percentage of naphthalene in hydrocarbon products.

such as naphthalene and benzene. In this regard, it was of interest to find that a $Fe_2(MoO_4)_3$ powdered sample prepared by coprecipitation[9] gave a remarkable evolution of hydrogen to form coke, whereas a negligible amount of hydrocarbon was produced upon admission of methane at 973 K. This implies that the FeMo binary site may highly active for the dehydrogenation of methane to promote the formation of $CH_x$ as the common species to be converted to aromatic compounds on the FeMo/HZSM-5 supported catalysts.

# A discrete cubane-like $[Cu_7Te]$ cluster: synthesis and structural characterization of $(NBu_4)_4Cu_7As_3Te_{13}$

**Chwanchin Wang and Robert C. Haushalter*†**

*NEC Research Institute, 4 Independence Way, Princeton, NJ 08540, USA*

**The structure of the $[Cu_7As_3Te_{13}]^{4-}$ anion contains a discrete cubane-like $[Cu_7Te]$ cluster which is surrounded exclusively by three $[As(Te_2)Te_2]^{3-}$ ligands and resembles the close packing of the Cu metal along the [111] direction.**

Recently, much attention has been focused on the soluble binary chalcogenides and polychalcogenides which exhibit a great deal of structural diversity due mainly to the variety of catenation and bonding modes of the chalcogen atoms.[1–5] In contrast to the large number of binary chalcogenides, comparatively few ternary chalcogenides were reported. Investigation of the ternary M–As–E (M = transition metals and main-group elements; E = S, Se) systems by using the solventothermal technique has produced several compounds.[6,7] There is a common feature in these structures, that is, a varied degree of condensation of the basic structural units, $[AsE_3]^{3-}$ (E = S and Se) through the chalcogen atoms acting as ligands toward both transition metals and main-group elements. The $[AsS_3]^{3-}$ ligand coordinated to transition-metal compounds was also reported.[8] While research has been concentrated on the sulfide and selenide systems, only one telluride compound, $(NEt_4)_4Cu_4SbTe_{12}$,[9] containing a $[Sb(Te_2)_2Te]^{3-}$ structural unit was reported. To further the investigation of the telluride systems, we have examined the Cu–As–Te system using the extractive method and report the first telluride containing a $[As(Te_2)Te_2]^{3-}$ ligand which is exclusively used as a tridentate ligand to the Cu atoms.

One gram of an alloy with a nominal composition of $K_2CuAsTe_4$, prepared from the fusion of $K_2Te$, KAs, Cu, and Te in stoichiometric proportions, was extracted by dissolving in 10 ml of ethylenediamine that had been freshly distilled from a red $K_4Sn_9$ solution. The brown extract was filtered and layered with an equal volume of a saturated solution of tetrabutylammonium bromide in ethylenediamine. After one week, $(NBu_4)_4Cu_7As_3Te_{13}$ was isolated in *ca.* 12% yield (based on Cu) as small, black elongated hexagonal-like crystals. The composition of the alloy does not seem to be crucial, as the extraction of a more Cu-rich alloy of the composition $K_2Cu_3AsTe_4$ also yielded the title compound.

The structure‡ of $(NBu_4)_4Cu_7As_3Te_{13}$ consists an unprecedented, discrete cubane-like $[Cu_7Te]$ cluster which is exclusively coordinated by three $[As(Te_2)Te_2]^{3-}$ ligands as shown in Fig. 1, **1a**. The As atom in the $[As(Te_2)Te_2]^{3-}$ ligand is bound to a $Te_2^{2-}$ and two $Te^{2-}$ ligands in a trigonal-pyramidal fashion. This ligand is observed in the title compound for the first time but is structurally quite similar to $(NBu_4)_3SbTe_4$.[10] The As–Te bond distances range from 2.561 to 2.639 Å, comparable to those of $[K(2,2,2\text{-crypt})]_2As_2Te_6$[11] and $(NEt_4)_2As_2Te_5$.[12] The Te–Te bond distances ranging from 2.720 to 2.735 Å are close to those of $(NBu_4)_3SbTe_4$[10] and $CsAs_2Te_6$,[13] in good agreement with the Te–Te covalent bond distance, 2.74 Å.[14] The three terminal Te atoms from each $[As(Te_2)Te_2]^{3-}$ ligand are bound to a rhombus-like $Cu_4$ unit with each Te atom coordinated to two Cu atoms having Cu–Te distances in the range 2.523–2.728 Å. The structure of the $[Cu_7As_3Te_{13}]^{4-}$ anion is constructed in such fashion that shows a pseudo-threefold axis running through Cu(1) and Te(13) atoms [Fig. 1, **1b**]. The most striking feature of the anion is that the inner core, which is surrounded by the three $[As(Te_2)Te_2]^{3-}$ ligands, is a cubane-like $[Cu_7Te]$ cluster [Fig. 1, **1c**]. In the $[Cu_7Te]$ cluster, there are two coordination environments of Cu atoms: Cu(1) bound to four Te atoms has a distorted tetrahedral geometry, while the rest of the Cu atoms, each bound to three Te atoms, have a nearly trigonal-planar geometry. It is somewhat surprising that, based on the charge balance, all Cu atoms bear a 1+ charge. Both tetrahedral and trigonal-planar coodination environments of $Cu^I$ ions have been previously reported.[4,9] The average Cu–Te distance [2.72(3) Å] of the $CuTe_4$ tetrahedron is

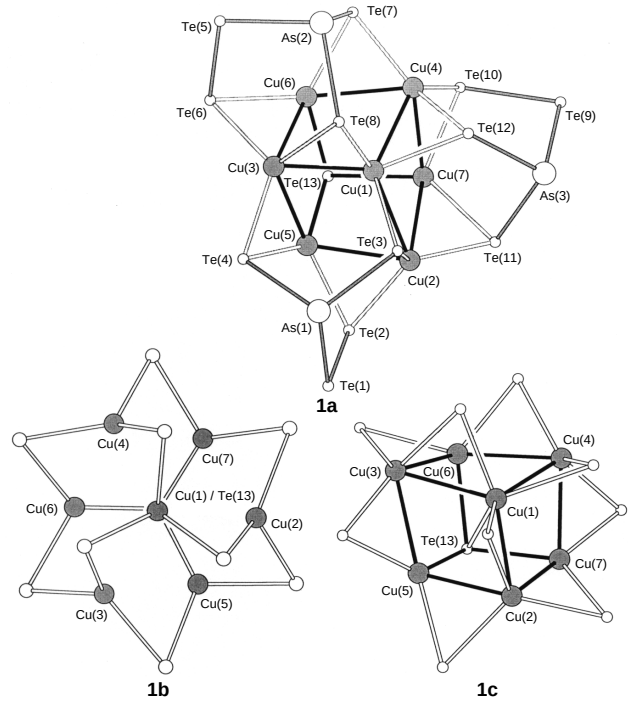

**Fig. 1** Structure of the $[Cu_7As_3Te_{13}]^{4-}$ anion **1a** which shows a pseudo-threefold axis running through Cu(1) and Te(13) atoms **1b**. Some selected bond distances (Å): Te(1)–Te(2) 2.735(3), Te(1)–As(1) 2.632(4), Te(2)–Cu(2) 2,552(4), Te(2)–Cu(5) 2.599(4), Te(3)–As(1) 2.615(4), Te(3)–Cu(2) 2.549(4), Te(3)–Cu(1) 2.685(4), Te(4)–As(1) 2.603(4), Te(4)–Cu(5) 2.534(4), Te(4)–Cu(3) 2.523(4), Te(5)–Te(6) 2.738(3), Te(5)–As(2) 2.608(4), Te(6)–Cu(3) 2.543(4), Te(6)–Cu(6) 2.614(4), Te(7)–As(2) 2.625(4), Te(7)–Cu(6) 2.542(4), Te(7)–Cu(4) 2.542(4), Te(8)–As(2) 2.602(4), Te(8)–Cu(3) 2.544(4), Te(8)–Cu(1) 2.728(5), Te(9)–Te(10) 2.720(4), Te(9)–As(3) 2.639(4), Te(10)–Cu(4) 2.560(4), Te(10)–Cu(7) 2.623(4), Te(11)–As(3) 2.619(4), Te(11)–Cu(2) 2.544(4), Te(11)–Cu(7) 2.546(4), Te(12)–As(3) 2.561(4), Te(12)–Cu(4) 2.553(4), Te(12)–Cu(1) 2.702(4), Te(13)–Cu(5) 2.501(4), Te(13)–Cu(6) 2.491(4), Te(13)–Cu(7) 2.500(4), Te(13)–Cu(1) 2.764(4), Cu(1)–Cu(2) 2.698(5), Cu(1)–Cu(3) 2.660(5), Cu(1)–Cu(4) 2.667(5), Cu(1)–Cu(5) 2.764(5), Cu(1)–Cu(6) 2.770(5), Cu(1)–Cu(7) 2.814(7), Cu(2)–Cu(5) 2.691(5), Cu(2)–Cu(7) 2.764(5), Cu(3)–Cu(5) 2.785(6), Cu(3)–Cu(6) 2.659(5), Cu(4)–Cu(6) 2.760(5), Cu(4)–Cu(7) 2.683(5). The inner core of the anion shows a cubane-like $[Cu_7Te]$ cluster in which both the Cu–Cu contacts and the Cu–Te bonds are highlighted with bold lines **1c**. Some of the atoms are omitted for clarity.

slightly longer than that [2.55(4) Å] of the trigonal planar $CuTe_3$. Another interesting feature is that the $Cu_7$ unit resembles close packing of the Cu metal along the [111] direction. The average Cu–Cu distance is 2.73(5) which is about 0.17 Å longer than that in Cu metal. The $Cu_7$ unit is then capped with a Te(13) atom at the bottom corner to complete a cube. The Te(13) atom within the cube has an umbrella-shaped coordination to a $Cu_4$ unit which shows one long [2.764(4) Å] and three short (2.491–2.501 Å) Te–Cu distances. This results in a compression of a regular cube along the body diagonal containing Cu(1) and Te(13) and, concomitantly, in the formation of two different coordination environments of Cu atoms. The cube is compressed to the extent that a bonding interaction of 2.764(4) Å develops between Cu(1) and Te(13). It is also notable that the Te atoms in the structure exhibit two [Te(1), Te(5), Te(11)], three {all the terminal Te atoms in $[As(Te_2)Te_2]^{3-}$ ligand} and four [Te(13)] coordination environments.

To our knowledge, the 23-atom anionic cluster of the title compound represents the largest ternary telluride Zintl anion that has been synthesized to-date. We and others[9] have demonstrated that both $[As(Te_2)Te_2]^{3-}$ and $[Sb(Te_2)_2Te]^{3-}$ ligands can be used as building blocks in the construction of larger Zintl anions. Our results further suggest the possibility of obtaining much larger clusters or extended structures by the use of ligands with formulae $[M(Te_2)_{3-x}Te_x]^{3-}$ (M = As, Sb; $x$ = 0–3).

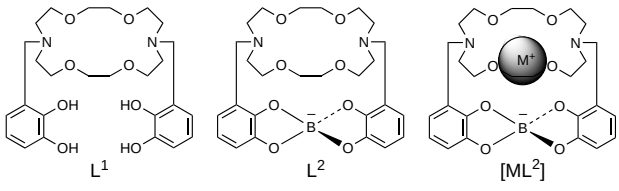
# Probing peristatic chirality of alkaline cations: NMR study of alkaline borocryptates

**Ernest Graf,[a] Roland Graff,[b] Mir Wais Hosseini,*[a] Clarisse Huguenard[c] and Francis Taulelle[c]**



[a] *Laboratoire de Chimie de Coordination Organique (URA 422 CNRS), Université Louis Pasteur, F-67000 Strasbourg, France*

**Enantiomeric differentiation of chiral borocryptates using NMR spectroscopy in a chiral liquid crystalline medium is achieved using different NMR probes localised both on the receptor and on the substrate; the observed chirality at the substrate is described as being induced by the spiroborate junction and mediated by the peristatic chirality of the cavity.**

For more than a century, chemists have been dealing with chirality which appears to be one of the most subtle aspects of chemistry.[1] On one hand, synthetic chemists use their skill to prepare compounds presenting either established[2] or new types of chirality.[3] On the other hand, physical chemists develop methods allowing measurement of chirality. Amongst such methods, NMR appears to be one of the most useful techniques.[4] In particular, NMR spectroscopy in oriented nematic phases has been shown to be a powerful method for the differentiation of enantiomers.[5]

Recently, inspired by naturally occurring antibiotics such as boromycin[6a] and aplasmomycin[6b] as well as by cryptands such as [222],[7] compound $L^1$ was designed.[8a] In the presence of a equimolar mixture of $B(OH)_3$ and MOH (M = alkali metal) in EtOH–$H_2O$, $L^1$ affords neutral binuclear complexes of the type $[ML^2]$ (Scheme 1). The binding ability of $L^2$ towards alkali-metal cations has been studied both in solution by NMR spectroscopy[8b] and in the solid state by X-ray analysis.[8c]

In dealing with chirality, the binding of boron by $L^1$ with a tetrahedral coordination geometry, affords the chiral cryptand $L^2$ (Fig. 1). The latter upon complexation with alkali-metal cations leads to chiral cryptates $[ML^2]$. The X-ray analysis of complexes with $M^+$ = $K^+$, $Rb^+$ or $Cs^+$ revealed the presence of both (*R*) and (*S*) enantiomers as a racemic mixture in the solid state.[8c] Whereas the free cryptand $L^2$ possesses an inherent chirality of the enantiomorphic type (*R* and *S*), for the labile and exchangeable complexed alkali-metal cation, the chirality is being imposed by the chiral cavity of the receptor through non-covalent interactions, and is therefore not inherent, and may be described as peristatic chirality[9] (peristasis = environment).† This type of chirality has been also recognised in a compound in which polyethyleneglycol was used to connect two catechol units.[10]

**Scheme 1**

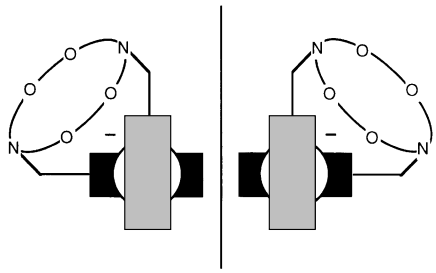

**Fig. 1** Schematic representation of chirality arising from the spiroborate junction in the borocryptand $L^2$

Enantiomeric differentiation of chiral molecules has been demonstrated using NMR spectroscopy in oriented chiral liquid crystals[5a] in particular in a poly(γ-benzyl L-glutamate) (PBLG)–$CH_2Cl_2$ (11–12% m/m) mixture[5b] forming cholesteric lyotropic mesophases.[5c]

Here, we report the extension of this method to the enantiomeric differentiation of complex molecules formed by non-covalent interactions between a receptor and a substrate.

For the chiral borocryptate $[ML^2]$, the receptor $L^2$ contains, in addition to classical $^1H$ and $^{13}C$ NMR active nuclei, both $^{10}B$ ($I$ = 3) and $^{11}B$ ($I$ = 3/2) possessing quadrupolar moments. On the other hand, the alkali-metal cations, being also NMR active, and possessing a quadrupolar moment, can also be studied by the same technique. Thus, enantiomeric differentiation in the $[ML^2]$ complexes can be studied in PBLG–$CH_2Cl_2$ (11–12% m/m), both at the level of the receptor $L^2$ and the substrate by combining the NMR data collected for the receptor part ($^{10}B$, $^{11}B$) and for the cationic substrates ($^{133}Cs$ and $^{14}N$).‡

The $^{10}B$ NMR spectrum of $[CsL^2]$ [Fig. 2(*a*)] can be deconvoluted into two sets of signals [Fig. 2(*b*), (*c*)] in 1 : 1 ratio as expected for a racemic mixture. The two distinct signals arise from each enantiomer. Whereas for one of the enantiomers [Fig. 2(*b*)], the signal was a broad singlet with a linewidth ($\Delta\nu_{1/2}$) of 51.9 Hz, the signal for the other enantiomer appeared as a sextet ($^{10}B$, $I$ = 3) with values of 221.6 and 73.3 Hz for the quadrupolar splitting ($\nu_Q$) and $\Delta n_{1/2}$, respectively [Fig. 2(*c*)].

$[CsL^2]$ was also studied by $^{11}B$ NMR. Again, the observed spectrum [Fig. 2(*d*)] could be deconvoluted into a broad signal ($\Delta\nu_{1/2}$ = 48.1) [Fig. 2(*e*)] and a triplet ($^{11}B$, $I$ = 3/2) with $\nu_Q$ = 503.2 Hz and $\Delta\nu_{1/2}$ = 48.7 Hz [Fig. 2(*f*)]. For both $^{10}B$ and $^{11}B$, the non-observation of a quadrupolar splitting for one of the enantiomers remains to be explained.

Interestingly, when investigating $[CsL^2]$ by $^{133}Cs$ NMR, the observed spectrum [Fig. 2(*g*)] was also composed of two sets of signals corresponding to two enantiomers. The spectrum could be deconvoluted into two septets ($^{133}Cs$, $I$ = 7/2), one with a small quadrupolar splitting constant ($\nu_{Q1}$ = 73.0 Hz, $\Delta\nu_{1/2}$ = 25.0 Hz) [Fig. 2(*h*)] and the other with a larger quadrupolar splitting constant ($\nu_{Q2}$ = 188.2 Hz, $\Delta\nu_{1/2}$ = 28.7 Hz) [Fig. 2(*i*)].

The binding ability of $L^2$ towards cations such as $NH_4^+$ has been previously established by an X-ray study,[11] and $NH_4L^2$ has been investigated by $^{10}B$, $^{11}B$ and $^{14}N$ NMR.

$^{10}B$ NMR observations [Fig. 3(*a*–*c*)] were similar to those obtained for $[CsL^2]$ ($\nu_{Q1}$ = 120.0 Hz, $\Delta\nu_{1/2}$ = 55.1 Hz). However, for $^{11}B$ the observed spectrum [Fig. 3(*d*)] appeared to be a superimposition of two triplets of the same intensity with

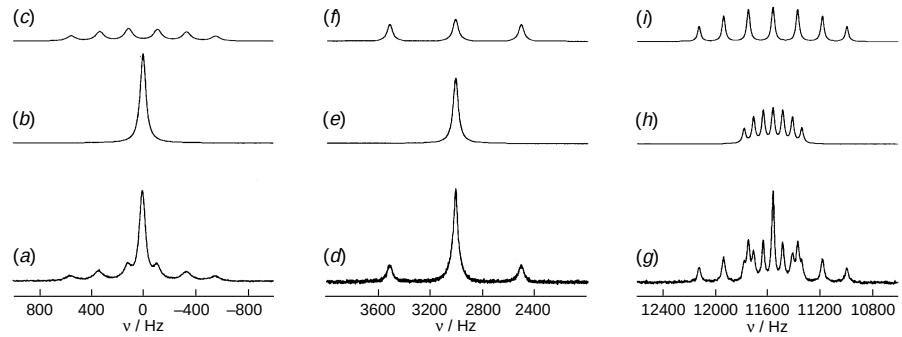

**Fig. 2** NMR spectra of [CsL²] in a chiral liquid-crystalline solvent : $^{10}$B (53.73 MHz) observed (*a*) and deconvoluted signals for both enantiomers (*b*), (*c*); $^{11}$B (160.42 MHz) observed (*d*) and deconvoluted signals for both enantiomers (*e*), (*f*); $^{133}$Cs (65.58 MHz) observed (*g*) and deconvoluted signals for both enantiomers (*h*), (*i*). $^{10}$B, $^{11}$B and $^{133}$Cs chemical shifts were referenced to $BF_3{\cdot}Et_2O$ and aqueous saturated $CsNO_3$, respectively as external references.

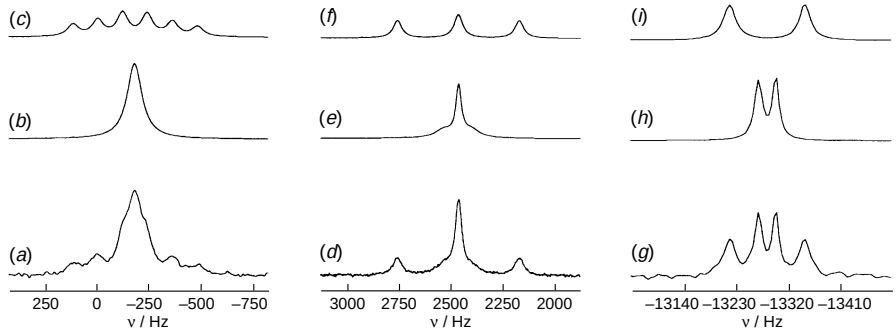

**Fig. 3** NMR spectra of [$NH_4L^2$] in chiral liquid-crystalline solvent: $^{10}$B (53.73 MHz) observed (*a*) and deconvoluted signals for both enantiomers (*b*), (*c*); $^{11}$B (160.42 MHz) observed (*d*) and deconvoluted signals for both enantiomers (*e*), (*f*); $^{14}$N (36.12 MHz) observed (*g*) and deconvoluted signals for both enantiomers (*h*), (*i*). $^{14}$N chemical shifts were referenced to neat $MeNO_2$ as external reference.

$\nu_{Q1}$ = 66.7 Hz [Fig. 3(*e*)] and $\nu_{Q2}$ = 293.2 Hz [Fig. 3(*f*)] corresponding to both enantiomers.

In $^{14}$N NMR studies, probably owing to the unsymmetrical environment around the two bridgehead nitrogen atoms leading to large quadrupolar interactions, the amino groups could not be observed. Nevertheless, the signal for the symmetrical $NH_4^+$ substrate was observed [Fig. 3(*f*)] as a superimposition of two doublets ($^{14}$N, $I$ = 1) in 1 : 1 ratio [Fig. 3(*h*), (*i*)]. Again, the two enantiomers were differentiated by large ($\nu_{Q1}$ = 128.7 Hz, $\Delta\nu_{1/2}$ = 18.0 Hz) and small ($\nu_{Q2}$ = 30.7 Hz, $\Delta\nu_{1/2}$ = 6.0 Hz) quadrupolar splitting constants.

Although not reported here, complexes formed between the cryptand L² and other cations such as $Rb^+$ and $K^+$ behaved similarly.

Enantiomeric differentiation of chiral molecules based on NMR studies in liquid-crystalline media was elegantly demonstrated by Courtieu and coworkers.[5a,b] Using different NMR probes on both the receptor and the substrate, we were able to detect, for the first time, the chirality of the ensemble, on different locations of the complex molecule. Based on our observations, we can describe the observed chirality at the cation site as induced by the spiroborate junction and mediated by the peristatic chirality of the cavity.

We thank the CNRS and the Institut Universitaire de France (IUF) for financial support.

† The adjective 'peristatic' (peristasis = environment) has been suggested at the EUCHEM Conference on Stereochemistry (Bürgenstock, May, 1966) by Professor S. D. Atkins (see ref. 11).

‡ The experiments were performed on dissolved single racemate crystals (the racemic nature was established by X-ray analysis). The deconvolution of the observed signal as two sets of signals was based on the observation of the quadrupolar splitting for one of the enantiomers which allowed abstraction of its contribution from the observed signal. The remaining signal was assigned to the other enantiomer. The ratio of the two signals was found to be 1 : 1 (±2%), as expected for a racemic mixture.

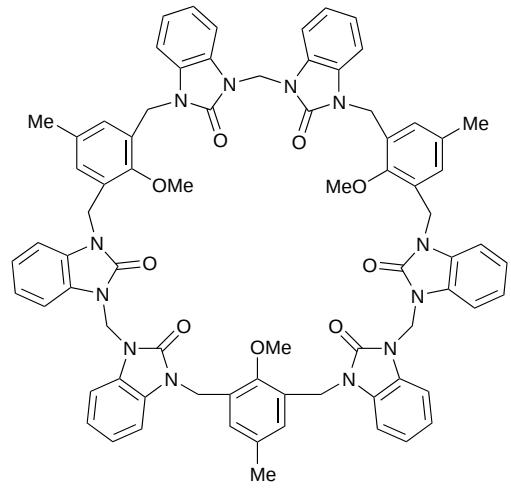
# Odd-membered higher heterocalixarene architecture featuring cage conformation. Synthesis and X-ray structure analysis of a 1 : 2 : 2 inclusion cascade complex with acetone and dichloromethane



**Jörg Trepte,[a] Mátyás Czugler,[b]† Karsten Gloe[a] and Edwin Weber*[b]**

[a] *Institut für Anorganische Chemie, Technische Universität Dresden, Mommsenstrasse 13, D-01062 Dresden, Germany*
[b] *Institut für Organische Chemie, Technische Universität Bergakademie Freiberg, Leipziger Strasse 29, D-09596 Freiberg/Sachs, Germany*

**The first crystal structure of a heterocalix[9]arene host molecule created from six benzimidazol-2-one and three *p*-methylanisole units displays guest binding *via* a cascade of interactions of the two acetone and two dichloromethane guest molecules with the host and with each other as well.**

Calixarenes and their analogues have emerged as an important topic of supramolecular chemistry.[1] In the past decade a great many structural modifications involving ring sizes and functionalization of the calixarenes have been performed and studied in terms of conformational flexibility, hollow space effects and inclusion behaviour.[2] Current directions focus on the use of calixarene frameworks as modular building blocks in order to construct higher molecular architectures.[3] Notwithstanding the great structural variety in calixarene chemistry, odd-membered higher calixarene homologues having more than eight arene subunits are very rare, to say nothing of derivatives containing heterocycles[4] instead of the conventional phenol subunits. The following study considers both items. Compared with hydrogen-bond stabilized conformations of conventional calixarene systems of the same ring size the alternate arrangement of the subunits in the new metacyclophane causes the formation of a cavity. We report the versatile synthesis of a novel heterocalix[9]arene **1** and the remarkable crystal structure of its supramolecular complex with acetone and dichloromethane, **1**·$Me_2CO$·$CH_2Cl_2$ (1 : 2 : 2). The heterocalix[9]arene host molecule **1**, in which benzimidazol-2-one moieties as heterocyclic units are involved, was obtained *via* two-step fragment condensation[4] from 2,6-bis(bromomethyl)-6-methylanisole and methylene-1,1′-bis(benzimidazol-2-one) building elements using blocking/deblocking, high dilution and template (3 equiv. $Cs_2CO_3$) techniques in dry DMF to yield 26% of **1** (mp 249–250 °C). On recrystallization from a solvent mixture of acetone and dichloromethane (1 : 1), **1** readily forms a crystalline complex composed of **1** and the two solvents in a 1 : 2 : 2 stoichiometric ratio.

An X-ray structure model‡ of the present complex in the crystal (Fig. 1) reveals typical calix-inclusion formation as one of the acetone guest molecules sits in the cavity and is visibly held fixed by a C–H··O interaction from a benzimidazolone entity.§ Steric and electrostatic matching with other neighbouring residues is also important. The second acetone molecule is bound on the perimeter *via* another C–H··O interaction, again from a benzimidazolone residue. The enhanced activity of the benzimidazolones is also shown by the cascade-like binding of the two further dichloromethane guests. These are located on the host molecular surface, kept by C–H··Cl interactions to each other and to the host in a consecutive manner. The cascade ends on a Cl··π interaction[5] with a chlorine atom to anisole ring centre distance of 3.55 Å. This anisole moiety is the only one that plays a role in the active fixing of guest molecules. As reported recently for other smaller-ring hetero-calixarene cases,[4] the side-on-side stacking of symmetry centre-related host molecules with reference to the benzimidazolone plane (interplanar distances 3.4–3.6 Å) appears repeatedly. This is also visible in the crystal packing (Fig. 2). Thus stacking of the hetero-units is an important motif, apparently contributing to crystal formation for this type of host molecule.

**1**

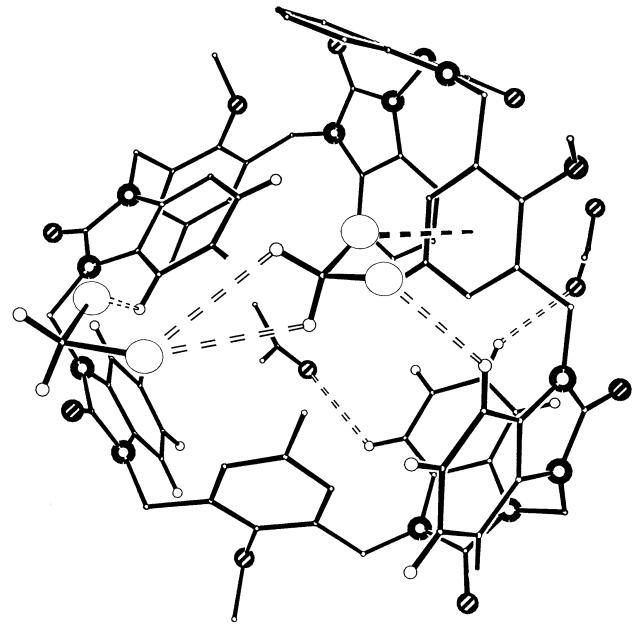


**Fig. 1** View of the **1**·acetone·dichloromethane (1 : 2 : 2) inclusion complex, with the principal cooperative interactions shown in broken lines. Only relevant hydrogen atoms are retained in the picture.

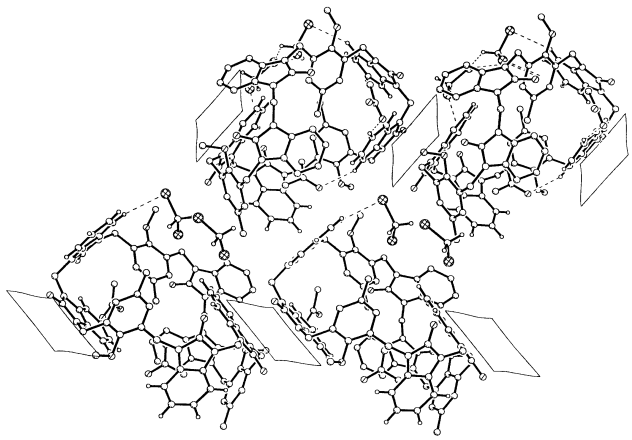

**Fig. 2** Packing in the **1**·acetone·dichloromethane (1 : 2 : 2) crystal illustrating stacking on the benzimidazolone sides (highlighted by irregular rectangles) and C–H··Cl interactions (broken lines)

We thus conclude that the unusual activity of the benzimidazol-2 one moiety renders it a particularly interesting building block for new calix frameworks, not only due to its ability to exaggerate ring dimensions and make such large rings somewhat stiffer than anisole units usually do alone, but also for its enhanced cooperativity in interactions with guest molecules.

† On leave from the Central Research Institute of Chemistry, Budapest, Hungary.

‡ *X-Ray structure analysis* of **1**·acetone·dichloromethane (1 : 2 : 2): monoclinic, $P2_1/c$ space group, $a$ = 13.127(3), $b$ = 23.977(5), $c$ = 25.526(5) Å, $\beta$ = 96.75(3)°, $Z$ = 4, total data collected (refs. 6,7) = 16 388, independent reflections = 16 098 $R_{(int)}$ = 0.179. Crystals were of poor quality, soft, air-sensitive, and could only be exposed to moderate cooling ($T$ = 203 K, they became brittle below −80 °C). The initial structure model, obtained by direct methods [SHELXS-86 (ref. 8)], was refined against 11 943 non-negative observations (using alternating conjugate gradient and full-matrix least-squares refinement on $F^2$ data) to convergence at relative poor $R$ values [final $R$ indices $I > 2\sigma(I)$: $R_1$ = 0.151, $wR_2$ = 0.395, $R$ (all data): $R_1$ = 0.289, $wR_2$ = 0.548, program SHELXL-93 (ref. 9)]. Atomic assignments in the critical regions were checked by scrutinizing $U_{iso}$ values. All non-hydrogen atoms were treated with anisotropic displacement parameters. Hydrogen atom positions were generated from geometric evidence and were kept riding on their mother atoms. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallograpic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/500.

§ The hydrogen-bonding cascade in this crystal structure is maintained in part by weak C–H··Cl interactions [C(78)–H(78)··Cl(1) = 0.94(2), 2.94(1) Å, 136(1)°; C(1e)–H(1ec)··Cl(2) = 0.98(2), 3.12(2) Å, 106(2)°; C(1e)–H(1ed)··Cl(2) = 0.98(2), 3.05(2) Å, 111(2)°] and by C(1e)–Cl(2)··X(1a) = 3.537(7) Å, 152(1)°, where X(1a) denotes a benzimidazolone ring centre. The C(49)–O(1a) = 3.07(2) Å distance is indicative of the electrostaic attraction between a benzimidazole carbon and the acetone oxygen. The long H··O distance of 2.8 Å [C(49)–H(49)··O(1a) 0.94 (2), 2.8(2) Å, 122(1)°] indicates that this is not a C–H··O interaction (ref. 10). The acetone binding also occurs *via* the benzimidazolone C–H and guest O interactions [C(69)–H(69)··O(1n) 0.96(2), 2.497 Å, 152(1)°].

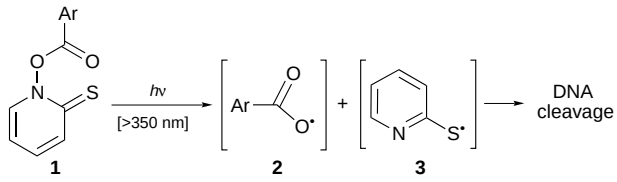
# Photochemical cleavage of duplex DNA by *N*-benzoyloxy-2-thiopyridone linked to 9-aminoacridine



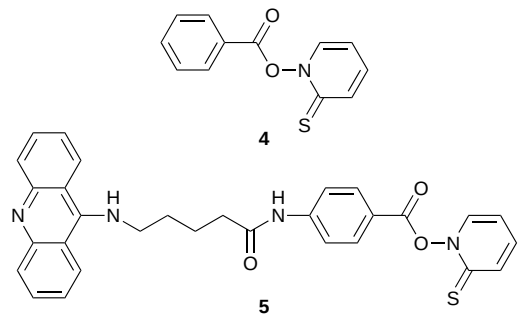
**Emmanuel A. Theodorakis,* Xin Xiang and Petra Blom**

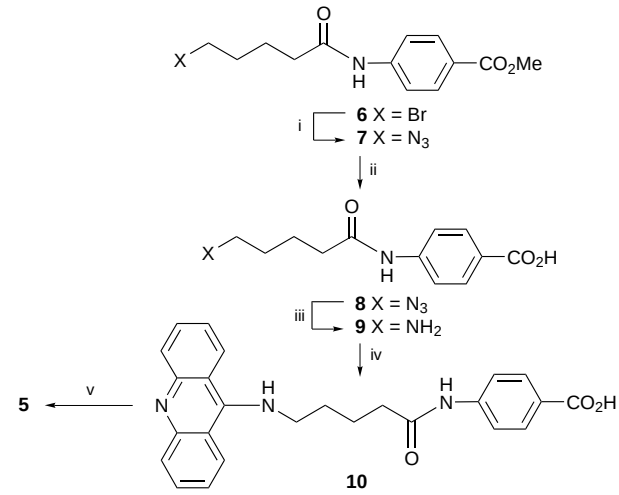
*Department of Chemistry and Biochemistry, University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093-0358, USA*

**Upon illumination *N*-aroyloxy-2-thiopyridones induce non-specific single-strand nicks in duplex DNA at micromolar concentrations.**

Synthetic reagents that cleave DNA are of great interest as tools in biochemical sciences. The design of such molecules constitutes a timely and challenging research topic and has led to the development of both sequence-specific DNA cleavers[1] and DNA footprinting reagents.[2]

Our studies are directed towards the development of conceptually new approaches to DNA cleavage, induced by photoactivation of *N*-aroyloxy-2-thiopyridone derivatives, such as **1** (Scheme 1).[3,4] To this end, we were guided by the operational advantages offered by the photoinducible DNA cleavage using the *N*-benzoyloxy-2-thiopyridone **4**.[5] These





**Scheme 1**

molecules could be ideal nucleic acid cleavers since they possess the following characteristics: a purely organic structure, facile preparation, prolonged stability in the absence of light, and well documented radical chemistry.[3] The observed nucleic acid strand scission occurs upon a simple irradiation ($\lambda$ > 350 nm), presumably *via* the generation of aroyloxyl radicals **2** and without the need of a metal or external oxidants.

Herein we describe our preliminary data on a novel family of photoactivated DNA-cleavers represented by **5**. The reagent design is based on linking a DNA photocleaving ligand to the 9-aminoacridine *via* a polymethylene chain. The aminoacridinyl group could assure high affinity for duplex DNA *via* intercalation,[6] while the thiopyridone entity could account for the DNA cleavage. Indeed, upon irradiation ($\lambda$ > 350 nm), compound **5** produces single strand breaks in duplex DNA with no intrinsic sequence selectivity.

The synthesis of compound **5** commences with bromide **6**, itself readily available by the condensation of 5-bromovaleroyl chloride with methyl *p*-amino benzoate. Azidation of **6**,

**Scheme 2** *Reagents and conditions*: i, $NaN_3$ (2.0 equiv.), 18-crown-6 (0.05 equiv.) DMF, 25 °C, 3 h, 91%; ii, KOH (2.0 equiv.), THF–$H_2O$ (1 : 1), 25 °C, 24 h, 98%; iii, 10% Pd/C (0.1 equiv.), $H_2$, MeOH, 24 h, 89%; iv, 9-chloroacridine (1.0 equiv.), PhOH, 110 °C, 1 h, 90%; v, 2-mercaptopyridine *N*-oxide (1.0 equiv.), EDC (1.0 equiv.), DMF, 25 °C, 1 h, 43%

(Scheme 2), followed by saponification of the methyl ester moiety and reduction of the azido group gave rise to amino acid **9** in 79% overall yield, through intermediates **7** and **8**. Coupling of **9** with 9-chloroacridine followed by esterification with 2-mercaptopyridine *N*-oxide using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) afforded conjugate **5** in 38% overall yield.

We further compared the visible light photolysis of **5** and **4** in the presence of supercoiled circular φX174 DNA (Fig. 1). Control experiments indicated that both light and the thiopyridone derivatives **5** or **4** are necessary for the DNA cleavage (lanes 1–3). Complete inhibition of the cleavage by glutathione (lanes 11, 12) further supports the notion that free radicals are responsible for the DNA damage. Moreover, compound **5**

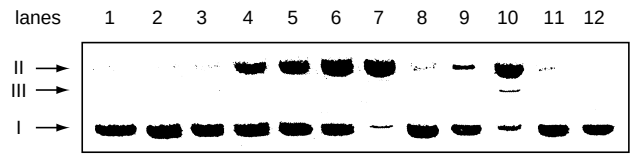


**Fig. 1** Concentration-dependent photocleavage of φX174 DNA induced by **4** and **5**. The φX174 DNA (50 μM/base pair) was incubated for 1 h at 25 °C with 4 or 5 (30 mM Tris-HCl, 20 mM NaCl), then subjected to irradiation at 4 °C (lanes 1 and 4–12) with one lamp (GE 300 W) placed at approximately 20 cm from the samples. The results were analysed on 1% agarose gel (Tris-acetate buffer) stained with ethidium bromide. Lane 1: φX174DNA (control); lane 2: DNA and 60 μM of **5** (no *h*ν); lane 3: DNA and 1 mM of **4** (no *h*ν) lanes 4–7: DNA and **5** at concentrations of 5: 5, 10, 30 and 60 μM, respectively; lanes 8–10: DNA and **4** at concentrations of **4**: 30, 60 and 1.0 mM, respectively; lane 11: DNA, 60 mM of **5**, and 3.0 mM of glutathione; lane 12: DNA, 1.0 mM of **4** and 3.0 mM of glutathione.

cleaves DNA at concentrations as low as $5 \times 10^{-6}$ M, while at $6 \times 10^{-5}$ M complete conversion of the form I to form II is observed. In comparison, derivative **4** produces similar results at $1 \times 10^{-3}$ M concentration. This substantial increase in efficiency of cleavage is attributed to the intercalating properties of 9-aminoacridine.[6]

An autoradiogram illustrating the results obtained upon irradiation of **5** in the presense of the 5′-$^{32}$P labelled 93-mer duplex DNA is shown in Fig. 2. Our data show that both **4** and **5** generate identical DNA ladders upon irradiation and the photocleavage is indisputably neither base- nor sequence-specific. Furthermore, comparison of lanes 8–12 indicate that **5** is more efficient than **4** in cleaving DNA and can accurately cut the duplex at concentrations as low as $5 \times 10^{-6}$ M. This increase in efficiency of cleavage is attributed to the presence of the 9-aminoacridinyl group. We ruled out the possibility that the 9-aminoacridinyl group enhances cleavage by altering the conformation of the DNA, since less cleavage was detected when 9-aminoacridine was added as an external intercalator (compare lines 12,13). Interestingly, the cleavage is more enhanced upon subsequent treatment with piperidine at 90 °C for 30 min without any change in sequence or base specificity (lines 7,8). Based on the above data we believe that in the case of **5** the DNA cleavage is performed by the intercalation complex and is probably mediated by aroyloxyl radicals.

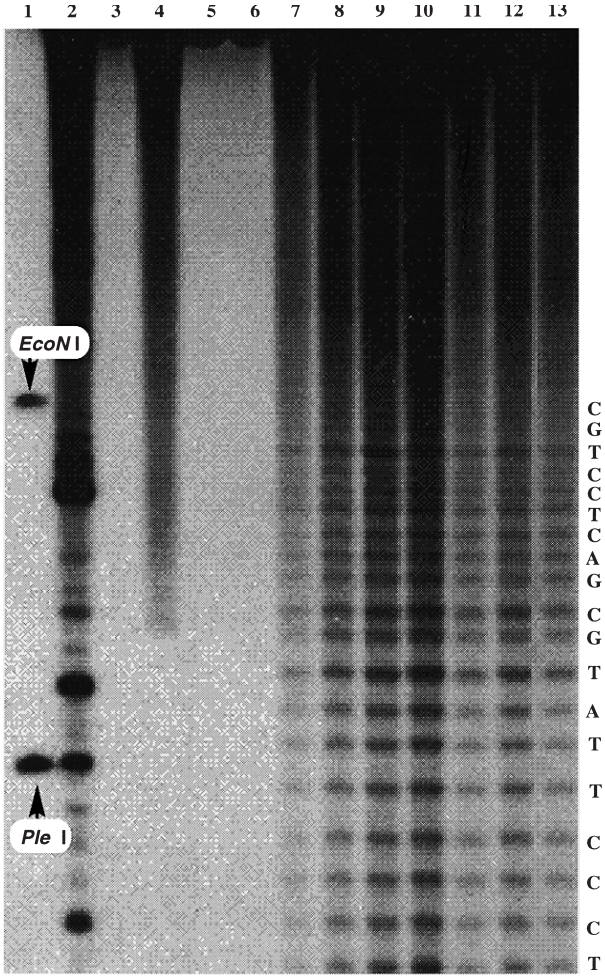

**Fig. 2** Autoradiogram of a 10% denaturing polyacrylamide gel showing photocleavage of 5′-32P end-labeled Sal I / Sph I restriction fragment of pBR322 duplex DNA (93-mer), induced by **4** and **5**. DNA was incubated for 1 h at 25 °C with compounds **4** or **5** in buffered solution (30 mM Tris-HCl, 20 mM NaCl) and then irradiated (with one GE 300 W lamp placed 20 cm from the samples) for another 2 h at 4 °C (lanes 3,4 and 7–13). The resulted solution was treated with piperidine (1 M) at 90 °C for 30 min, followed by EtOH precipitation (lanes 8–13). Lane 1: DNA cut by PIe I (14 base pairs) and EcoN I (28 base pairs); lane 2: DNase footprinting; lane 3: DNA (control); lane 4: DNA irradiated and piperidine treated without **4** or **5**; lane 5: DNA and 200 μM of **4** (no *hν*); lane 6: DNA and 60 μM of **5** (no *hν*); lane 7: DNA and 5 μM of **5** (no piperidine treatment); lanes 8–10: DNA and **5** at concentrations of **5**: 10 and 20 μM respectively; lanes 11,12: DNA and **4** at concentrations of **4**: 40 and 60 μM respectively; lane 13: DNA, **4** (60 μM) and 9-aminoacridine (30 μM).

It is evident from the above studies that the *N*-aroyloxy-2-thiopyridones **1** can induce non-specific single strand nicks in duplex DNA in a light-dependent reaction. The efficiency and/or selectivity of the cleavage could be tuned by the proper choice of the DNA recognition element. In addition the light intensity that is responsible for the photoactivation could be tuned by structurally modifying the thiopyridone core. Thus, the *N*-benzoyloxy-2-thiopyridone moiety can be used for the design of new DNA photocleaving reagents with potential use as 'photofootprinting reagents' or as 'site-directed photonucleases'. Studies across these lines are now under investigation in our laboratories.

We thank Dr T. Li and Professors Y. Tor and K. C. Nicolaou of this department for useful discussions and the Donors of The Petroleum Research Fund, administered by the American Chemical Society, for partial support of this research.

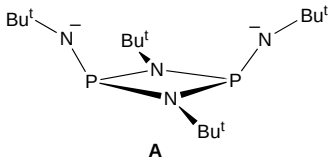
# Syntheses and single-crystal X-ray structures of $[(Bu^tNP)_2(Bu^tN)_2]MCl_2$ (M = Zr, Hf): the first transition-metal bis(alkylamido)cyclodiphosphazane complexes



**Luke Grocholl,[a] Lothar Stahl*[a] and Richard J. Staples[b]**

[a] *Department of Chemistry, University of North Dakota, Grand Forks, ND 58202-9024, USA*
[b] *Department of Chemistry and Chemical Biology, Harvard University, Cambridge, MA 02138, USA*

**The interaction of $[(Bu^tNP)\{Bu^tNLi(thf)\}_2]$ with $ZrCl_4$ and $HfCl_4$ produces the remarkably stable monomeric $[(Bu^tNP)_2(Bu^tN)_2]MCl_2$ (M = Zr, Hf) complexes.**

The organometallic chemistry of the group 4 metals is dominated by compounds of the type $(\eta\text{-}C_5H_5)_2MCl_2$ and variations thereof.[1] The ubiquity of these bent metallocenes is largely due to the cyclopentadienyl ligand's ability to stabilise large, electropositive metals sterically and electronically and to create monomeric complexes with a well defined coordination environment. Because of the success of the 'constrained-geometry catalysts', *i.e.*, hybrid complexes with a mixed $(\eta\text{-}C_5Me_4)SiMe_2NBu^t$ ligand, in the Ziegler–Natta polymerization alkenes,[2] there has in recent years been a tremendous synthetic interest in group 4 amide complexes. This research has produced a large number of early-transition-metal complexes with bi-, tri-, and tetra-dentate amide ligands.[3] Many of these new compounds are structurally interesting and some have shown outstanding reactivity.[4] Due to their small bite angles most of these chelating amides are unable to stabilize the heavier group 4 metals as monomeric complexes, however, thereby reducing potential catalytic activity.

To synthesise monomeric amide complexes of zirconium and hafnium we have used bis(*tert*-butylamido)cyclodiphosphazane, **A**, as a ligand.[5] Although these cyclic phosphorus–nitrogen molecules have been known for some time,[6] their metal chemistry is not well developed and their use as chelating bis(amide) ligands is all but unknown.[7] The obscurity of cyclodiphosphazanes is surprising, because their flexible bite angle and multidentate nature make them ideal ligands for transition- and main-group-metals alike.

**A**

The prolonged (24 h) interaction of $[(Bu^tNP)_2(Bu^tNLi{\cdot}thf)_2]$ with $MCl_4$ in hot toluene (Scheme 1) afforded $[(Bu^tNP)_2(Bu^tN)_2]MCl_2$ (M = Zr **1**, Hf **2**), in yields of *ca.* 80%.† These colourless compounds have remarkable thermal and chemical stability, being unaffected by oxygen and sulfur in hot toluene solutions even after 12 h. NMR spectral data show conclusively that the metal complexes have $C_{2v}$ symmetry in solution. Thus, for example, the $^1H$ NMR spectra of **1**(**2**) display two singlets at $\delta$ 1.41(1.40) and 1.27(1.27), for the amido and imido *tert*-butyl groups, respectively, while the $^{31}P\{^1H\}$ NMR spectra consist of only one sharp singlet at $\delta$ 101.7 and 99.9, respectively, indicative of equivalent $P^{III}$ centres.

$[(Bu^tNP)_2(Bu^tNLi{\cdot}thf)_2] + MCl_4$

toluene, 80 °C; –2 LiCl

$[(Bu^tNP)_2(Bu^tN)_2]MCl_2$

M = Zr **1**
Hf **2**

**Scheme 1**

A single-crystal X-ray analysis confirmed the solid-state structure of **1** as that shown in Fig. 1;‡ the hafnium analogue is isostructural. These compounds crystallise racemically twinned as discrete molecules in the acentric orthorhombic space group $P2_12_12_1$. The metal–chloride and metal–amide bonds define to a first approximation a pseudo-tetrahedral coordination geometry about the zirconium atom. An additional fifth, long Zr–N(1) interaction, however, reduces the molecular symmetry from $C_{2v}$ to $C_s$ in the solid state to create a highly distorted trigonal-bipyramidally coordinated zirconium atom. Alternatively the central moiety of the molecule may be described as two almost perpendicular inorganic heterocycles, consisting of phosphorus, nitrogen and zirconium atoms. Symmetry-related zirconium–nitrogen and phosphorus–nitrogen bonds are, within experimental errors, equivalent. Thus, the two zirconium–nitrogen bonds are 2.060(3) and 2.067(3) Å long, making them quite comparable to those in related compounds with monodentate

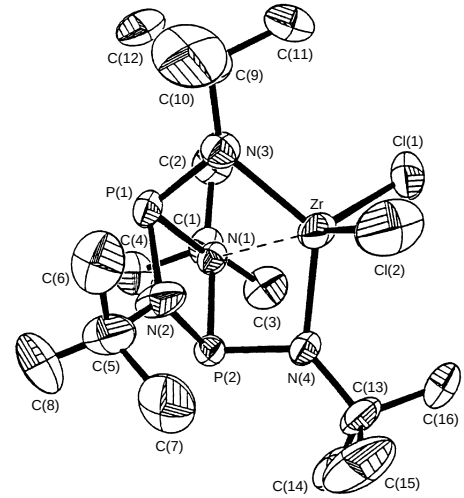


**Fig. 1** Molecular structure and labeling scheme for **1**. Selected bond distances (Å) and angles (°) not mentioned in the text: P(1)–N(1) 1.790(3), P(1)–N(2) 1.729(4), P(1)–N(3) 1.682(3), P(2)–N(1) 1.780(3), P(2)–N(2) 1.743(4), P(2)–N(4) 1.681(3), Cl(1)–Zr–Cl(2) 104.51(8), N(3)–Zr–Cl(1) 110.6(1), N(3)–Zr–Cl(2) 102.4(1), N(4)–Zr–Cl(1) 110.4(1), N(4)–Zr–Cl(2) 102.6(1). The corresponding values for **2** are: P(1)–N(1) 1.785(10), P(1)–N(2) 1.734(9), P(1)–N(3) 1.632(9), P(2)–N(1) 1.790(9), P(2)–N(2) 1.752(11), P(2)–N(4) 1.665(9), Cl(1)–Hf–Cl(2) 103.7(2), N(3)–Hf–Cl(1) 110.5(3), N(3)–Hf–Cl(2) 103.0(3), N(4)–Hf–Cl(1) 109.7(3), N(4)–Hf–Cl(2) 102.4(3).

amides.[8] The zirconium–chloride bonds, however, are shorter than those in $(\eta\text{-}C_5H_5)_2ZrCl_2$, and this may reflect the lesser steric crowding of these bonds in **1**, or perhaps a small amount of Cl to Zr π-electron donation. The slight bond asymmetry, 2.375(2) and 2.397(2) Å, is presumably the result of the ring–zirconium interaction, and it is notable that the Zr–Cl bond *trans* to the Zr–N(1) bond is the longer of the two. In keeping with the trends normally observed for isostructural zirconium and hafnium species,[1] the metal–ligand bonds in the hafnium analogue are slightly shorter than those in the zirconium complex. The hafnium compound has equidistant metal–amide bonds of 2.053(9) and 2.081(10) Å, and slightly inequivalent Hf–Cl bonds of 2.355(5) and 2.382(4) Å.

Unlike the majority of the more common chelating diamides, cyclodiphosphazane **A** can effectively envelop the central metal atom through additional bonds. This is clearly demonstrated by both the secondary N(1)–Zr donor bond of 2.398(3) Å and the extremely short non-bonding distance of 2.891(1) Å between the phosphorus atoms and the zirconium centre. Because the rigidity of the ligand prevents a closer approach between metal and phosphazane ring, it is difficult to assess the strength of this ring–metal interaction. Lone-pair donation by ring–nitrogen atoms in the related cyclophosphazenes is well documented, however, and usually forms bonds of considerable strength.[9]

Only comparatively minor structural changes are displayed by the ligand upon coordination to the metals. There is a slight puckering in the cyclodiphosphazane portion of the molecule that is also observed in the pristine ligand, resulting in a slight folding along the N(1)···N(2) line[10] The exocyclic phosphorus–nitrogen distances are significantly shorter than the endocyclic ones, a feature we believe to be due to steric factors. The trends in the P–N bond distances of N(1) and N(2) are those expected based on the differences in their coordination numbers, the four-coordinate N(1) having the longer bonds.

Like many successful ancillary ligands, cyclodiphosphazane **A** is able to impose a well defined coordination environment on its complexes. In **1** and **2**, for example, it has produced a steric pocket that is quite reminiscent of that in bent metallocenes and related compounds. The bulky *tert*-butyl substituents of the ligand form a rather wide gap in the equatorial plane of the complexes that may allow selective access of substrate molecules to the Lewis-acidic metal centres. The cyclodiphosphazane ligand subtends identical angles of 124.6(1) and 124.8(4) Å at the metal in **1** and **2**, respectively; these values are well above that of a regular tetrahedron but comparable to those found in metallocenes.

Because of their unique structural features, **1** and **2** appear to be excellent candidates for catalytic applications which demand low-coordinate, highly Lewis-acidic metal centres with well defined coordination environments and the desirable *cis*-arrangement of the chloride ligands. Whether ligand-centred reactions caused by the phosphorus and equatorial nitrogen centres compromise this reactivity, however, remains to be seen. Catalytic studies are currently under way, and they should provide insight into the reaction chemistry of the title compounds.

Found for **2**: C, 32.34; H, 6.05; N, 9.20. Calc. for $C_{16}H_{36}Cl_2HfN_4P_2$: C, 32.25; H, 6.09; N, 9.40%. Mp 201 °C. PCI MS, 597.1 $[M + H]^+$.

‡ *Crystal data*: for **1**: $C_{16}H_{36}Cl_2N_4P_2Zr$, $M_r$ = 508.55; orthorhombic, space group $P2_12_12_1$, $a$ = 9.921(2), $b$ = 15.129(3), $c$ = 16.331(4) Å, $U$ = 2451.2(8) Å$^3$, $D_c$ = 1.378 g cm$^{-3}$, $Z$ = 4, $F(000)$ = 1056. Intensity measurements were made with a Siemens SMART CCD (charge-coupled device) X-ray diffractometer equipped with an LT-2 low-temperature apparatus operating at 213 K using Mo-Kα radiation, $\lambda$ = 0.710 73 Å and $\omega$-scans of 0.3° per frame for 10 s, until a complete hemisphere was collected. A total of 9072 reflections in 1271 frames were collected in the $4° < 2\theta < 56°$ range with a final resolution of 0.84 Å. Of these reflections, 4921 were unique ($R_{int}$ = 0.0248) and observed [$I > 2\sigma(I)$] and used in the refinement. An absorption correction based on $\psi$-scans was applied to the data set, $T_{min, max}$ = 0.683, 0.962. The first 50 frames were recollected at the end of data acquisition to monitor for decay which was <1%. Cell parameters were retrieved using SMART[11] software and refined using SAINT[12] on all observed reflections. Data reduction was performed with the SAINT software which corrects for $L_p$ and decay. The absorption correction was applied using SADABS which was supplied with the program. The structure was solved in the uniquely determined space group $P2_12_12_1$ (no. 19) by using the direct methods option of the SHELX-90[13] program and refined by least-squares on $F^2$ with SHELXL-93,[14] incorporated in SHELXTL-PC V 5.03.[15] Hydrogen atom positions were calculated by geometrical methods and refined as a riding model. The refinement converged at $R_1$ = 0.0412 and $wR_2$ = 0.1017 and a final GOF = 1.016. The final difference map showed no peaks(holes) greater than 0.373(−1.039) e Å$^{-3}$.

For **2**: $C_{16}H_{36}Cl_2HfN_4P_2$, $M_r$ = 595.82; orthorhombic, space group $P2_12_12_1$, $a$ = 9.937(3), $b$ = 15.132(4), $c$ = 16.414(5) Å, $U$ = 2468(1) Å$^3$, $D_c$ = 1.603 g cm$^{-3}$, $Z$ = 4, $F(000)$ = 1184. Hardware configurations and software programs were identical to those used for **1.** A total of 6141 data were collected at 293 K in the range $4 < 2\theta < 45°$. Upon merging, $R_{int}$ = 0.0221, these yielded 3078 unique and observed [$I > 2\sigma(I)$] data which were used in the refinement. An absorption correction based on $\psi$-scans was applied, $T_{min, max}$ = 0.738, 0.942. The crystal showed no decay during the data collection. Refinement converged at $R_1$ = 0.0472, $wR_2$ = 0.1138. The largest residual electron densities in the final difference map were peaks and holes of 0.774 and −1.795 e Å$^{-3}$, respectively. # Synthesis of a new titanosilicate: an analogue of the mineral penkvilksite

**Yunling Liu, Hongbin Du, Fengqi Zhou and Wenqin Pang***

*Key Laboratory of Inorganic Synthesis and Preparative Chemistry, Department of Chemistry, Jilin University, Changchun, 130023, China*

**A new titanosilicate which is a structural analogue of the mineral penkvilksite, is obtained from $SiO_2$–$TiO_2$–$Na_2O$–$H_2O$–$(TMA)_2O$ and characterized by powder X-ray diffraction (XRD), TGA, SEM, $^{29}$Si CP MAS NMR, ion exchange and adsorption measurements.**

Titanium silicates such as TS-1,[1,2] TS-2[3] Ti-β,[4,5] *etc*., have attracted considerable research attention since they have been found to have remarkable catalytic activity and selectivity in the hydroxylation of organic compounds in the presence of dilute aqueous hydrogen peroxide. Recently, two novel titanium silicates ETS-4[6,7] and ETS-10[6–8] have been discovered, which have interesting structures and exhibited unique ion-exchange and adsorption properties. More recently, we synthesized a novel layered titanium silicate JDF-Ll[9,10] with five-coordinate titanium, which has potential in catalysis, intercalation and ion-exchange.

There are many natural titanium silicates occurring in the Earth's crust, but only a few such as pharmacosiderite[11,12] and zorite[13] could be synthesized. Penkvilksite was originally described by Bussen *et al*.,[14] as a new titanosilicate mineral, with chemical formula $Na_4Ti_2Si_8O_{22}{\cdot}5H_2O$ and space group indexed as orthorhombic or monoclinic. After the second polytype was found in nature, the orthorhombic penkvilksite was denoted penkvilksite-2O and the monoclinic penkvilksite as penkvilksite-1M.[15] Both penkvilksite-2O and penkvilksite-1M have minor substitutions of Ca, Zr, Fe and Al for Na, Ti and Si, respectively. The structure consists of $TiO_6$ octahedra and $SiO_4$ tetrahedra connected to each other to form a three-dimensional framework.

Here we report, for the first time, the synthesis of a penkvilksite-type titanium silicate. The samples were synthesized hydrothermally using tetrabutyltitanium(IV) (98%), tetramethylammonium hydroxide (TMAOH, 25%), fumed silica (99.9%), sodium hydroxide (96%) and distilled water as reactants. The chemical composition of the initial gel was $3.7SiO_2 : 5.9TiO_2 : 1.0Na_2O : 100H_2O : 0.6(TMA)_2O$. In a typical preparation, the following procedure was followed: sodium hydroxide (0.27 g) was first dissolved in distilled water (12 ml) and then $Ti(OBu^n)_4$ (5.1 g) was added slowly to the solution under vigorous stirring, to which aqueous TMAOH (2.5 ml) was added, followed by fumed silica (0.6 g). The mixture was stirred until it became homogeneous, then transferred into a Teflon-lined stainless-steel autoclave, and heated at 473 K for *ca*. 15 days. The products were recovered by filtration, washed and dried at 353 K. The sample was characterized by X-ray diffraction (Rigaku D/MAX-IIIA), thermal analysis (Perkin-Elmer, TGA-7), scanning electron microscopy (Hitachi X-650B), and $^{29}$Si CP MAS NMR (Bruker MSL-400).

The XRD pattern of the as-synthesized crystalline product is similar to that of the mineral penkvilksite, but showing different relative intensities (Fig. 1). SEM showed that the sample consisted of plate-like crystals of *ca*. 20 × 50 μm (Fig. 2).

Thermogravimetry of the product showed a total mass loss of 7.8% from 328 to 588 K. This was considered to be mainly due to the removal of waste located on the external surface and in the pores. The product is stable up to 873 K and converts into a dense phase at *ca.* 973 K, as indicated by XRD analysis.

In the $^{29}$Si CP MAS NMR study of the as-synthesized penkvilksite, three signals with chemical shifts of $\delta$ −85.2, −96.0 and −101.6 referenced to tetramethylsilane were

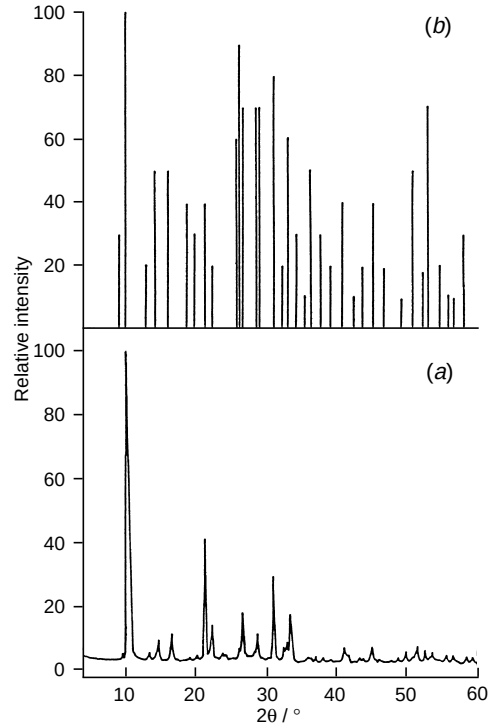

**Fig. 1.** X-Ray diffraction patterns of (*a*) as-synthesized penkvilksite and (*b*) the mineral penkvilksite

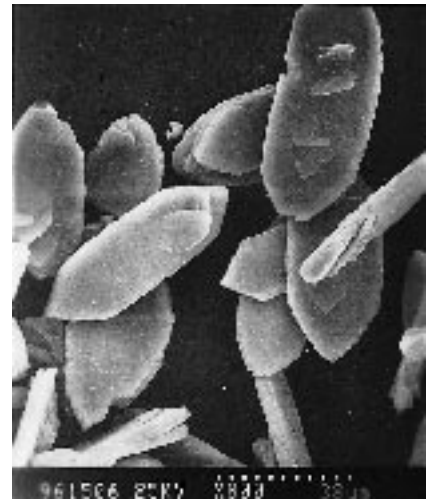

**Fig. 2.** Scanning electron micrograph of as-synthesized penkvilksite

observed. According to refs. 8 and 13, the resonance at $\delta$ −85.2 can be attributed to Si(2Si, 2Ti) and that at $\delta$ −96.0 to Si(3Si, 1Ti). These assignments are consistent with the framework connectivity of penkvilksite. The additional resonance at $\delta$ −101.6 may be due to small amount of impurities in the sample.

The ion-exchange behaviour of penkvilksite was measured in 1 M $KNO_3$ at 80 °C sitrring for 24 h. It was found that 18% of the potassium ions could be exchanged into the penkvilksite. The ion-exchange capacity of $K^+$ is 0.72 mequiv $g^{-1}$ which is lower than that of other minerals. This may be due to the short reaction time employed.

Adsorption studies were performed isothermally in a Cahn 2000 balance. Before the test, the calcined sample was dehydrated at 473 K at $10^{-3}$ Torr for 2 h, and then cooled to room temp. under vacuum. Brunauer–Emmett–Teller (BET) adsorption experiments showed type 1 adsorption behaviour and indicated that the adsorption capacity of water was 6.0 mass% at $p/p_0 = 0.2$.

In the synthesis of titanosilicate penkvilksite, we found that alkali-metal ions have an important effect on its formation. In fact, several titanosilicates were produced in $SiO_2$–$TiO_2$–$M_2O$–$H_2O$–$(TMA)_2O$ (M = $Na^+$ or $K^+$ or $Na^+ + K^+$) systems, dependent on the content of alkali-metal ions in the gel. In the presence of $K^+$, ETS-10 was readily obtained, while with $Na^+$ ions alone in the gel, penkvilksite and ETS-4 were synthesized. The former was favoured at low $Na^+$ concentration and the latter at high $Na^+$ concentration. In addition, the titanium content was also an important factor for the formation of penkvilksite. Appropriate titanium content in the gel was found to be essential in the crystallization of the pure products. Higher or lower titanium content resulted in the formation of amorphous phases or quartz impurities.

In conclusion, a titanosilicate penkvilksite analogue has been synthesized for the first time under hydrothermal conditions. Its successful synthesis provides possibilities in the synthesis of other new types of titanium silicate materials by varying various synthesis factors such as alkali-metal ions used, titanium content and templates, *etc*.

The authors would like to thank the National Natural Science Foundation of China, the Doctorial Program Foundation of the State Education Commission of China and the Key Laboratory of Inorganic Synthesis and Preparative Chemistry of Jilin University for support.

# Stereoselective synthesis of the *C*-analogue of β-D-glucopyranosyl serine

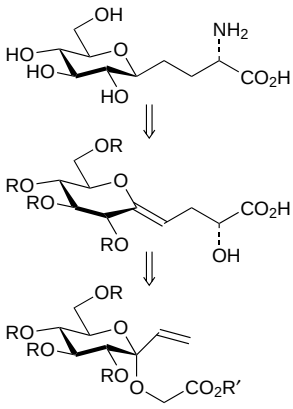
**Luigi Lay,[a] Morten Meldal,[b] Francesco Nicotra,[a] Luigi Panza*[a] and Giovanni Russo[a]**

[a] *Dipartimento di Chimica Organica e Industriale, Centro per lo Studio delle Sostanze Organiche Naturali del CNR, Università di Milano, via Venezian 21, I-20133 Milano, Italy*
[b] *Carlsberg Laboratory, Department of Chemistry, Gamle Carlsberg Vej 10, DK-2500 Valby, Copenhagen, Denmark*

**The [2,3]-Wittig sigmatropic rearrangement of an appropriate glucose derivative followed by further chemical modification afforded stereoselectively the *C*-analogue of β-D-glucopyranosyl serine.**

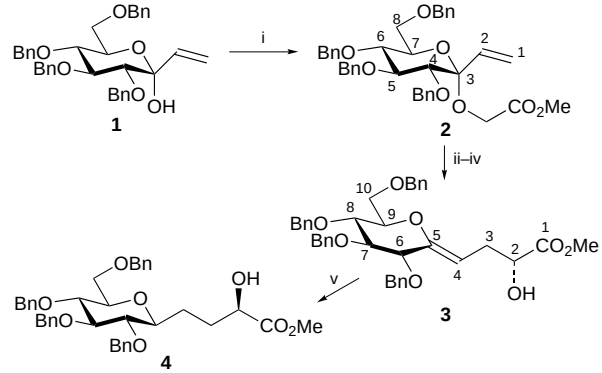
Protein glycosylation plays fundamental roles in inter- and intra-cellular recognition.[1] Thus, *N*-linked protein glycosylation is involved in protein sorting and the ability of the immune system to recognize and discriminate *O*-linked tumour associated glycoprotein antigens of malignant tissue as foreign structures has been well documented.[1] Furthermore, *O*-glycosylation of a peptide or a protein can increase their solubility and their resistance towards enzymatic degradation, can modify the conformation of the peptide backbone and modulate the biological activity. These properties have recently stimulated great interest in glycopeptides as therapeutic agents.[2]

One limitation of the use of these compounds as potential drugs is the sensitivity of the glycosidic linkage between the sugar and the peptide towards both chemical and enzymatic deglycosylation.[1] For these reasons it is of great interest to have access to stable analogues of *O*-glycosylated amino acids, such as *C*-glycosyl amino acids, in which the glycosidic oxygen atom can be substituted with a methylene group or omitted to give nor analogues. Few examples of the synthesis of *C*-glycosyl amino acids as well as their incorporation in biologically active peptides appear in the literature.[3] However, such compounds are not easily obtainable, particularly by direct carbon–carbon bond forming reactions between a sugar and an amino acid,[4] and have usually been prepared as diastereoisomeric mixtures at the α-carbon of the amino acid moiety.[3]



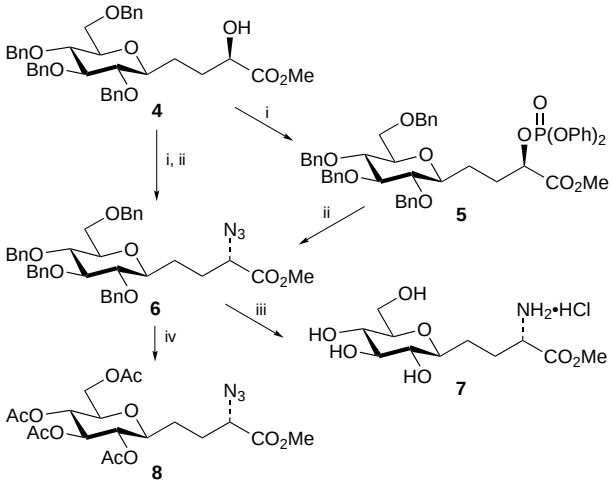
Here we describe the synthesis of the *C*-analogue of glucopyranosyl serine using a [2,3]-Wittig sigmatropic rearrangement[5] in which the chirality of the sugar induces the stereoselective formation of the amino acid moiety, according to the retrosynthetic pathway in Scheme 1.

The appropriate precursor **2**† for Wittig rearrangement was prepared in 70% yield (Scheme 2) from known compound **1**[5] by treatment with methyl glycolate (5 equiv.) and $BF_3{\cdot}Et_2O$ (1.5 equiv.) in the presence of 4 Å molecular sieves.



Since preliminary attempts to effect silyl trifluoromethanesulfonate-mediated Wittig rearrangement[6] on **2** were unsuccessful, the dianionic [2,3]-Wittig rearrangement[7] was considered. Compound **2** was then hydrolysed with 2% NaOH in MeOH. The carboxylic acid obtained was treated with excess LDA (3 equiv.) in THF at −78 °C and the reaction mixture was allowed to warm to 0 °C. The crude product was then treated wih $CH_2N_2$ in $Et_2O$–MeOH and the α-hydroxy ester **3** was isolated in 70% yield from **2** (de > 95%). The geometry of the newly formed double bond was shown to be *Z* by an NOE experiment.‡ Compound **3** was hydrogenated with freshly prepared Raney-Ni in EtOH to give **4** in 80% yield. The absolute configuration of the stereocentre at C-2 was determined converting **4** into the (*R*)- and (*S*)-MTPA esters by treatment with (*R*)- and (*S*)-MTPA chloride, respectively, in $CH_2Cl_2$–pyridine. The $^1$H NMR spectrum of the MTPA esters showed a $\Delta\delta$ value ($\delta S - \delta R$) of +0.1 ppm for the signals of the hydrogen atoms at C-3 and C-4, allowing the assigment of the absolute configuration *R* at C-2.[8]

Moreover, the chemical shift of the hydrogen atom at C-5 of **4**, which resonates at $\delta$ 3.27, suggests the presence of an equatorial substituent which was confirmed subsequently on compound **8**.



The substitution of the hydroxy group with a nitrogen was attempted using diphenylphosphoryl azide (DPPA),[9] which should have allowed the direct conversion of an α-hydroxy ester to the corresponding azide with inversion of configuration. When compound **4** was treated with DPPA (2.5 equiv.) and DBU (0.98 equiv.) in toluene at 20 °C, only the intermediate phosphate **5** was isolated in good yield (Scheme 3). Moreover, when the reaction mixture was heated, the substitution reaction with the azide was incomplete even at reflux (110 °C) and gave many byproducts. However, treatment of the phosphate with

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, $HOCH_2CO_2Me$, $BF_3{\cdot}Et_2O$, 20 °C, 70%; ii, NaOH, MeOH, room temp.; iii, LDA, THF, −78 → 0 °C; iv, $CH_2N_2$, $Et_2O$–MeOH, 70% from **2**; v, $H_2$, Raney-Ni, MeOH, 80%

**Scheme 3** *Reagents and conditions*: i, DPPA, DBU, toluene; ii, $Bu_4NN_3$, toluene; iii, $H_2$, $Pd(OH)_2$, EtOH, quant.; iv, $Ac_2O$, $Me_3SiOSO_2CF_3$, 67%

$Bu_4NN_3$ in toluene gave the desired substitution product **6** in 88% yield. The reaction conditions were then modified as follows to obtain a one-pot transformation: the phosphate ester was formed as described above, but with heating to 55 °C. Then a solution of $Bu_4NN_3$[10] (3 equiv., 0.2 M solution in toluene) was added and the mixture was stirred at the same temperature until the phosphate ester disappeared on TLC: in this way the desired azido ester **6** was obtained in 92% yield.§

Reduction of the azido group and contemporary hydrogenolysis of the benzyl ethers was carried out with $Pd(OH)_2$ in EtOH containing few drops of 5% aq. HCl to finally afford the deprotected compound **7** in an almost quantitative yield.

In order to incorporate the obtained analogue into glycopeptides using either solution or solid phase synthesis, it would be useful to maintain the azido group[11] and to change the protecting groups on the sugar moiety. The benzylated analogue **6** was thus submitted to acetolysis[12] by treatment with trimethylsilyl trifluoromethanesulfonate in $Ac_2O$ at room temp. for 40 h to give the acetylated derivative **8** in 67% yield.

The $^1$H NMR spectrum of compound **8** showed a signal at $\delta$ 3.42 due to the hydrogen atom at C-5 in which the coupling constant with the adjacent ring hydrogen at C-6 (*J* 9.5 Hz) clearly confirmed that the equatorial configuration had been obtained at position 5, corresponding to the β-anomer of the *O*-linked analogue.

The reported procedure allows a simple and stereoselective access to the *C*-linked analogue of glucopyranosyl serine which can be incorporated in synthetic peptides. As the sugar moiety is not directly involved into chemical modifications, the procedure could be, in principle, applicable to other monosaccharides. Work is in progress to extend the scope of the procedure.

Part of the present work was supported by the EU-Carenet 2 program (ERB4061PL95-0372).

**A three step stereoselective route to the fluorinated natural product (2*S*,3*S*)-4-fluorothreonine is described; the route is amenable to the preparation of (2*S*,3*S*)-4-fluoro[3-$^2$H]threonine and (2*S*,3*R*)-[4,4,4-$^2H_3$]threonine.**

4-Fluorothreonine **1** is a secondary metabolite of *Streptomyces cattleya* and is one of the few natural products that contain fluorine. The compound was first isolated[1] in 1986 in the course of studies aimed at improving thienamycin production by the organism. It was reported to be a single stereoisomer but the relative or absolute stereochemistry was not established at that time. Two syntheses of (2*S*,3*S*)-4-fluorothreonine **1** have been reported,[2] one prior[3] to its isolation from *S. cattleya*, and in each case the optical rotation values were close to that of the natural amino acid **1** ($[\alpha]_D$ −20) implying a 2*S*,3*S* absolute configuration. In our current programme[4–6] focused on evaluating the biosynthetic origin of fluoroacetate and 4-fluorothreonine in *S. cattleya* it proved necessary to confirm the absolute stereochemistry of **1**. As the two published syntheses are lengthy we have developed a new and more direct approach to (2*S*,3*S*)-4-fluorothreonine **1** which exploits Seebach's imidazolidinone methodology for the synthesis of α-amino-β-hydroxy acids.[7] This appeared attractive at the outset as a straightforward condensation between **2** and fluoroacetaldehyde should deliver the required framework. However, fluoroacetaldehyde is not readily prepared and despite several attempts we were not able to devise a suitable synthesis. The literature preparations[8] for fluoroacetaldehyde generated aqueous solutions which are inadequate for the current purpose.

The route was therefore modified as shown in Scheme 1 such that **2** was treated with fluoroacetyl chloride[9] (**WARNING**: highly toxic) to generate the resultant β-ketone **3**,† a crystalline solid. From the X-ray structure of **3** it is noteworthy that the geometry at C-5 is fully tetrahedral and that the β-carbonyl system is non-planar. This is an important feature as C-5 is rendered configurationally stable, a situation that is revealed again in the X-ray structure of the analogous defluorohydro compound **4**,‡ an intermediate in our synthesis of (2*S*,3*R*)-threonine (Fig. 1). It was not clear at the outset if the subsequent reduction of the β-carbonyls of **3** and **4** would be stereoselective and deliver the desired *threo* products, however in the event this proved to be the case. Treatment of **3** and **4** with $NaBH_4$ in MeOH generated the benzoate esters **5**§ and **6** respectively as single diastereoisomers. The benzoates **5** and **6** and not the *N*-benzoyl derivatives were the sole products, indicating a facile transacylation after carbonyl reduction. This transacylation is consistent with Seebach's observations[7b] after the direct condensation of **2** with acetaldehyde. The *allo*-diastereoisomers were not detectable by $^{13}C$, $^1H$ and $^{19}F$ (for **5** only) NMR spectroscopy of the crude reaction products, indicating that the reduction is highly stereoselective with hydride delivered exclusively to the *si* face of **3** (*re* face of **4** due to a change in assignment priorities). If the transition state conformation of **3** bears a resemblence to the ground state structure as shown in Fig. 1 then the *si* face of the carbonyl is the more exposed of the two as the *N*-benzoyl aromatic ring hinders access to the *re* face.

The benzoates **5** and **6** were subjected to hydrolysis (10 M HCl at 100 °C) and the resultant (2*S*,3*S*)-4-fluorothreonine **1**¶ and (2*S*,3*R*)-threonine **7** [identical in all respects to natural (2*S*,3*R*)-threonine] were recovered after purification on Dowex $H^+$. The *threo* relative stereochemistry of **1** was confirmed by an

**Scheme 1** *Reagents and conditions*: i, LDA, $FCH_2COCl$ (acetyl chloride for **4**), THF, −100 °C, 57%; ii, $NaBH_4$, MeOH, 20 °C, 5 min, 67%; iii, 10 M HCl, 100 °C, 72 h, 64%

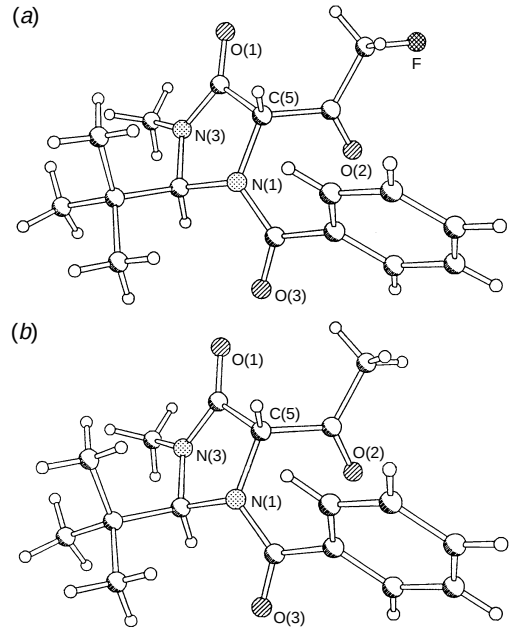

**Fig. 1** X-Ray structures of **3** (*a*) and **4** (*b*). The geometry at C-5 of the β-ketone is tetrahedral in each case.

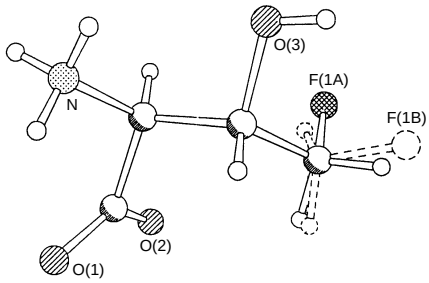

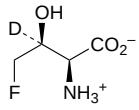

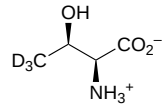

**Fig. 2** X-Ray structure of synthetic (2*S*,3*S*)-4-fluorothreonine **1**, showing two positions for the disordered $CH_2F$ group with occupancies of 66(2)% (solid) and 34(2)% (dashed)

X-ray structural study‖ (Fig. 2). The 2*S*,3*S* assignment for **1** follows from the structure of **3** where the known absolute stereochemistry of the auxiliary allows a 2*S* designation to be made at C-5 and subsequently at the α-position of the amino acid. All analytical data ($[\alpha]_D$ −20, $^{19}F$ NMR, HPLC, GC–MS of MSTFA derivative) were identical to a sample of 4-fluorothreonine **1** isolated[4] from *Streptomyces cattleya*, confirming the absolute stereochemistry of the natural product. Additionally this route to (2*S*,3*S*)-4-fluorothreonine is amenable to isotope labelling and (2*S*,3*S*)-4-fluoro[3-$^2$H]threonine **1a** was prepared by employing $NaB^2H_4$ in the reduction step. This material is being used to probe the anabolic and catabolic flux of (2*S*,3*S*)-4-fluorothreonine in *S. cattleya*.

**1a**

**7a**

The modified methodology offers an alternative route to *threo* amino acids and it displays a higher stereoselectivity to that previously described for (2*S*,3*R*)-threonine.[7b] The method has the additional advantage of using acid chlorides in place of aldehydes when the requisite aldehyde is unavailable, as in the case of fluoroacetaldehyde, or is expensive, as in the case of isotopic labelling. For example, a sample of racemic [4,4,4-$^2H_3$]threonine **7a** was prepared from [$^2H_3$]acetyl chloride, a cheaper and more highly stereoselective route to the labelled amino acid than that using [$^2H_3$]acetaldehyde with racemic imidazolidinone **2**.

We thank Dr A. S. Batsanov (University of Durham, Department of Chemistry) for help in the X-ray structural work. We are also grateful to Drs Roy Bowden, Harry Eccles and Peter Binks of BNFL for their interest in this work and to BNFL Company Research Laboratories, Springfields, for financial support.

# Designer crystals: intermolecular interactions, network structures and supramolecular synthons

**Gautam R. Desiraju**

*School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*

**Questions relating to the prediction of the crystal structure or structures of a given organic molecule may be more gainfully reversed so that retrosynthetic analysis of a target crystal network leads to the identification of molecular precursors. Crystal engineering is solid state supramolecular synthesis and supramolecular synthons, units formed by synthetic operations involving intermolecular interactions, may be used to focus efforts in such logic-driven retrosynthesis.**

## Introduction

Crystal engineering has been defined as the understanding of intermolecular interactions in the context of crystal packing and in the utilisation of such understanding in the design of new solids with desired physical and chemical properties.[1] The origins of this subject lie in the work of Gerhard Schmidt who realised, more than 25 years ago, that the systematic development of organic solid state chemistry required a proper theory of crystal packing.[2] The term 'crystal engineering' was also introduced by Schmidt in the context of solid state reactions and early papers in the subject,[3] including the first *Chemical Communications* from my research group in 1983,[4] were concerned almost exclusively with crystal engineering as a means of developing better organic reactions.

Crystal structures are mediated by intermolecular interactions and the easiest way of obtaining reliable information on these interactions is through crystallography. With the ever-increasing number of accurate X-ray and neutron diffraction analyses, a distinct change in perception occurred with regard to crystal engineering during the late eighties.[1] Instead of concentrating exclusively on topochemical reactions, structural chemists also began to conceive of organic crystals that could act as catalysts, microporous materials, frequency doublers, ferromagnets and superconductors. A particular crystal packing may also be attractive for aesthetic reasons, just as targets like cubane or dodecahedrane have been attractive molecular targets in the past. A crystal is as respectable a synthetic target as a molecule and form and function motivate current efforts in crystal design.

The awareness that a crystal is the supermolecule *par excellence* further heightened interest in crystal engineering and brought the subject into the mainstream of supramolecular chemistry.[5] Crystal engineering is recognised today as an important form of supramolecular synthesis and the full rigour of synthetic methodology and strategy may now be brought to bear in the quest for complex and general supramolecular synthetic targets in the solid state. An important consequence of these developments is the identification of a crystal as a retrosynthetic target.[6]

This article is a personal view of the development and growth of crystal engineering, seen mainly through the 25 or so *Chemical Communications* from my research group.

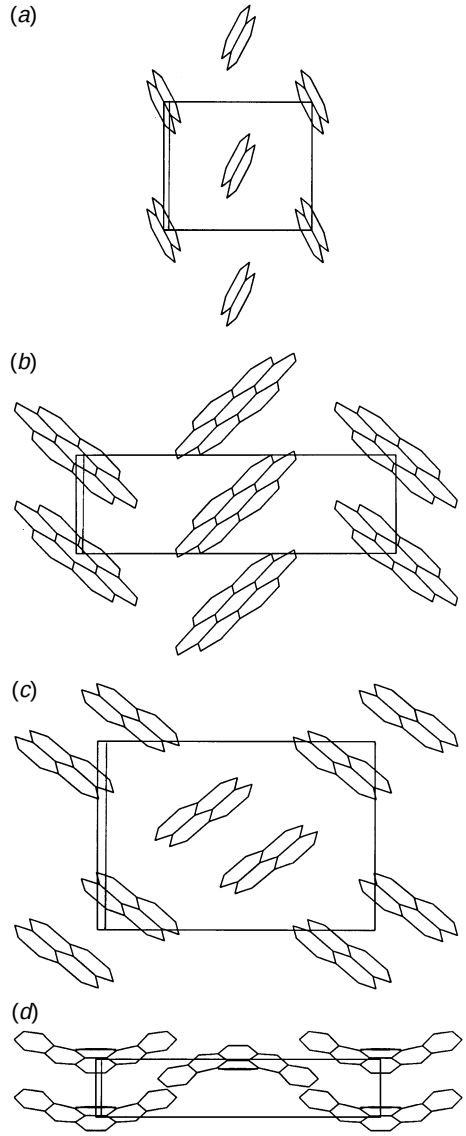
## From molecular to crystal structure

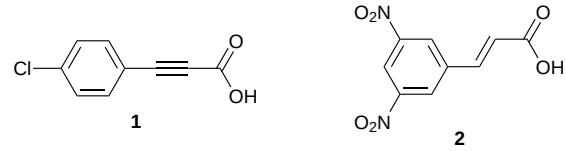
Crystals are built from molecules and the natural question that has been posed with respect to crystal engineering is, 'given the molecular structure of an organic substance, what is its crystal structure?' The molecular basis of organic chemistry makes such a question seem almost intuitive and much progress was made and is continuing to be made in seeking answers here. The first well-documented attempt in this direction is the correlation, established in 1951 by the great chemical crystallographer J. Monteath Robertson, between the molecular structures of planar fused-ring aromatic hydrocarbons and their packing type as revealed by the crystallographic short axis.[7] Robertson divided such hydrocarbons into two rather broad but fairly distinct types. He observed that disk-like molecules with an area large compared with their thickness (coronene, ovalene) tend to stack in columns and that the periodicity along this short axis, which is usually the monoclinic *b* axis, is about 4.7 Å. In the second class he included molecules which are still flat and disk-like, but of smaller area (naphthalene, anthracene) and noted that there is a tendency for such molecules to be steeply inclined to the symmetry plane and for the periodicity to be about 6.0 Å. It is remarkable that a statement of such prescience was made more than 45 years ago.

In 1988, Angelo Gavezzotti of the University of Milan and I re-examined Robertson's correlation and further amplified it.[8–10] With hindsight of knowledge on intermolecular forces, notably the ubiquitous herringbone and stacking forces, that are prevalent in all types of crystals of aromatic compounds, it was possible to divide fused aromatic hydrocarbons into four categories that are illustrated in Fig. 1: (*a*) the pure herringbone structure (naphthalene, anthracene) contains nearest-neighbour molecules which are related *only* by the inclined T-geometry and have short axes in the 5.4–8.0 Å region; (*b*) the coronene group of Roberston was designated as γ-packing and was shown to contain *both* herringbone and stacking geometries. The short axis range for this group is between 4.6–5.4 Å; (*c*) another group of structures with a monoclinic axis greater than 8.0 Å was also found to exhibit both herringbone and stacking geometries but here, molecular dimers were observed. This group is exemplified by pyrene and perylene and was designated the 'sandwich-herringbone' structure; (*d*) planar hydrocarbons do not crystallise so that *only* stacking interactions are found between nearest-neighbours, but such a possibility exists for cup-shaped molecules like tribenzopyrene. This category was designated as β-packing and it has short axes less than 4.2 Å.

With such an analysis it became possible to predict the packing pattern of any given aromatic hydrocarbon. It was recognised that the herringbone interaction (glide or screw-forming tendency) was promoted by the presence of hydrogen atoms and rim-carbon atoms, while the stacking interactions would be favoured by the presence of many internal carbon atoms in the molecular structure. Glide-stack ratios were therefore derived on the basis of empirically designated glide and stack-forming propensities for each atom in the molecular structure. Plotting these ratios against molecular surface area introduces the idea of molecular shape and with it a mapping from molecular to crystal structure. Our predictions of crystal structure from molecular structure were satisfying but even at the time we were well aware that they are accurate only because the forces in hydrocarbon crystals are isotropic.

Hydrocarbon crystals are exceptional in this regard. Most organic compounds contain heteroatoms and the intermolecular interactions in their crystals are a complex mosaic of forces of varying strengths, directionalities and distance dependence characteristics.[1] Anisotropic, long-range forces tend to dominate crystallisation preferences even as the isotropic forces contribute to the bulk of the crystal sublimation energy. These anisotropic forces are not minor irritants but conspire to render almost impossible direct and simple extrapolations from molecular to crystal structure. A functional group approach is unsuitable because the molecular recognition events during crystallisation depend on the complementarity of molecular structural features rather than on their identity. This is a fundamental problem. Suppose a general molecule to have recognition sites A, B, C, ... and so on. Then, possible recognition patterns could be found from among combinations such as A··B, B··C, A··C or from more complex patterns such as (A,C)··(B,D) or (A,B,C)··(D,E). Each favourable pattern would limit the possibilities for subsequent, subsidiary patterns, but in general the presence of even a moderate number of competitive recognition sites in a molecule, say three of four functional groups capable of hydrogen bonding, could result in a large number of crystal structures $C_1$, $C_2$, $C_3$ ... $C_n$ from a single molecular structure $M_1$. Most of these structures $C_1$–$C_n$ are not routinely realisable in the solid state because polymorphism is not a universal phenomenon. However, even in this mitigating circumstance, the prediction of the experimentally observed structure $C_m$ is not trivial.[11] Computer simulations show that structures $C_1$–$C_n$ are often closely related enthalpically and the global minimum structure is not always the one that is obtained experimentally, either because the computations are approximate or because the crystallisation process is subject to both kinetic and thermodynamic factors.





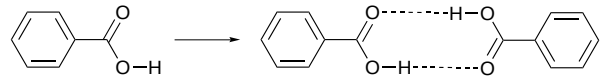


**Fig. 1** The four basic aromatic crystal packings: (*a*) naphthalene, (*b*) coronene, (*c*) pyrene, and (*d*) tribenzopyrene. The short axes are vertical in each case.

A typical manifestation of these problems is illustrated by the anomalous crystal structures of 4-chlorophenylprop-2-ynoic acid **1** and 3,5-dinitrocinnamic acid **2**. Usually it is expected that

carboxylic acids, especially those containing aromatic groups, crystallise with the dimer structure. A few acids adopt the catemer structure but such occurrences have been well-rationalised.[12] This molecular monomer → crystalline dimer transform is the basis of several recent experiments in crystal engineering and many would accept this transform as an article of faith.

However, acid **1** adopts a rare crystal structure with two symmetry independent molecules (Fig. 2).[13] In one, the carboxy group has a *syn* conformation while in the other, it is *anti*. The hydrogen bonding pattern is not quite a catemer but contains alternating molecules with the *syn* and *anti*-conformations. To compound the confusion, each hydrogen bond lies on a centre of inversion and the resulting hydrogen atom disorder does not disappear even at low temperature. In contrast, the almost identical (in molecular terms) 4-chlorocinnamic acid, adopts the 'normal' dimer structure. Again, while acid **2** (space group *C*2/*c*) forms an O–H··O dimer ring, this ring lies on the 2-fold axis rather than on the inversion centre.[14] These anomalous occurrences have been rationalised on the basis of C–H··O hydrogen bonding. In acid **2**, C–H··O hydrogen bonds are dominant and numerous and seem to be so significant that they are able to change the site symmetry of the carboxylic acid O–H··O dimer ring. In **1**, however, their absence (because of the lack of a critically large number of acidic C–H groups in the molecular structure) seems to lead to the unusual *quasi*-catemer structure. C– H··O hydrogen bonds are just one of the several secondary features that can influence, often unpredictably, crystal packing and they have been discussed extensively elsewhere.[15–17]

To summarise, a molecular functional group approach is often difficult in attempting to answer the question, 'given the

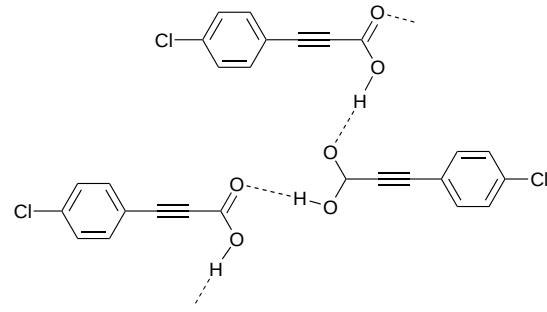

**Fig. 2**

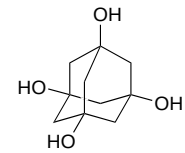
molecular structure of an organic substance, what is its crystal structure?' Of course, this question betrays the molecular basis of classical organic chemistry. Crystals are supermolecules and their structural features are best described in terms of supramolecular descriptors, that is patterns of interactions rather than in terms of molecular descriptors, that is functional groups. A one-to-one correspondence does not exist between functional groups and patterns of interactions and so questions relating to the prediction of supramolecular (crystal) structure from molecular structure (i) are difficult to answer, (ii) may have multiple answers, and (iii) may not even be the most relevant questions one might want to ask.

## The crystal as a supramolecular entity

The term 'supramolecular' signifies that which is beyond the molecule and supramolecular concepts have had the greatest influence in organic chemistry where the molecule is paramount. Supermolecules are not merely collections of molecules but they have structural features and properties that are characteristic not of the molecules themselves but of larger, more extended assemblies.[18] In keeping with this, structural chemists and crystallographers have had little difficulty in recognising an organic crystal as the ultimate example of a supermolecule.[5,19] Indeed, crystals constitute one end of the supramolecular continuum and may be viewed as 'hard' supermolecules in contrast to the 'softer' supramolecular aggregates which exist in solution. Atoms, covalent bonds and molecules have their counterparts in molecules, intermolecular interactions and supermolecules. Accordingly, it is not hard to visualise polymorphism as superisomerism and to identify structural homologous series such as benzene, naphthalene and anthracene.



If a crystal is a supermolecule, then crystal engineering is the solid state supramolecular equivalent of organic synthesis.[6] Synthesis is the distinctive feature that demarcates chemistry from the other physical sciences—*la chimie crée son objet*;[20] yet it is only in recent times that synthetic supramolecular chemistry has assumed definite contours. If studies of supramolecular systems should even be a part of chemistry, then the time-tested principles of synthesis should be found to be applicable to them. In this regard, the role of the solid state is especially relevant. Unlike solution supermolecules whose formation could often be influenced by solvent effects, the formation of stable crystal forms permits the establishment of even weak interactions which, when numerous, may affect supramolecular structure decisively. So, crystal structure as defined as a networking of intermolecular interactions is the supramolecular equivalent of molecular structure as defined as a networking of covalent bonds.

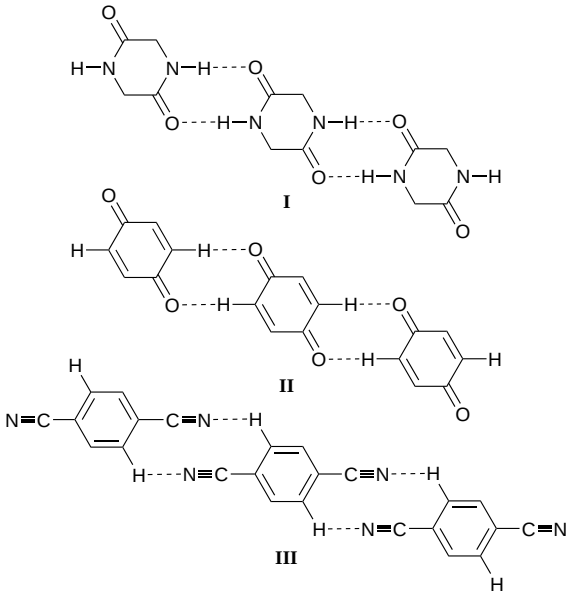
## Crystal engineering and organic synthesis

In general, any synthetic activity, in chemistry or elsewhere, may be said to possess three attributes: target identification, strategy and methodology. In loose terms, these attributes amount to knowing the job at hand, what to do, and how to do it. It is pertinent to examine the subject of crystal engineering from this standpoint.

Target identification in traditional organic synthesis consists in knowing the molecular formula of the goal molecule with all the attendant stereochemistry. Crystal engineering is supramolecular synthesis and so targets here must be defined supramolecularly, that is as networks. This is not a familiar exercise. Traditionally, structural chemists have viewed a molecular crystal as an assembly of atoms in which the distances between atoms in certain groups (molecules) are much smaller than the distances between atoms in different groups.[21] This depiction owes to Kitaigorodskii but again betrays the molecular view of organic chemistry. Even the title of Kitaigorodskii's classic *Molecular Crystals and Molecules* reflects this bias. Yet, any organic crystal may be depicted as a network with the molecules as nodes. Such a depiction, although unusual, is not completely new. In Powell's 1948 illustrations of the β hydroquinone clathrates, for example, only the network structures are shown.[22] The molecules have been reduced to points. If such an operation is carried out on the orthorhombic polymorph of benzene, the result is not far from a face-centred cubic lattice. Of course, hydrogen bonded structures lend themselves easily to a network depiction but in the end, *any* organic structure may be thus viewed.

The development of network theory to organic crystal chemistry is novel but this is hardly the case for inorganic crystal structures. Thus the logical step after depicting an organic crystal structure as a network is to search for its inorganic counterpart. Such comparisons are not just chemical curiosities but play a very important part in the development of a proper theory of crystal engineering, because one is able to draw from the very considerable literature which exists in the inorganic structural domain to choose new target networks. In this context, the structure of 1,3,5,7-tetrahydroxyadamantane **3**

**3**

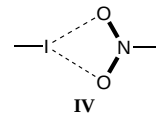


is especially interesting.[23] The crystal packing of this compound may be clearly understood only when it is simplified and reduced in terms of its hydrogen bond network. The structure is intricate and belongs to the uncommon space group *Pbcn* with molecules in both general and special positions. The structure also contains many strong O–H···O hydrogen bonds and our attempts to decipher the packing by conventional methods (plots, geometrical calculations) proved unsuccessful. As an alternative strategy, we sought to develop a structural analogy between **3** and a simple inorganic structure. Now, a hydroxy group has a supramolecular valence of two, corresponding to a pair of hydrogen bonds, one donated and the other accepted. Therefore the packing of **3** should be derivable in terms of an eight-connected net. So we simplified the structure of **3** by reducing the molecules to spheres and displaying only the hydrogen bond connections. The result is shown in Fig. 3 which is easily recognisable as a *quasi*-BCC packing. If one distinguishes between the symmetry independent molecules, one could liken this structure to CsCl or, more strictly speaking, to $Cr_2Al$.

Supramolecular synthetic methodology amounts to a knowledge of the strength and directional characteristics of the intermolecular interactions. Much has been written and said about this topic[1] and I will merely list some of the more important interactions here. Yet, as in molecular synthesis, this is the most arduous component in the synthetic exercise, requiring much knowledge and experience. In addition to the well-understood strong hydrogen bonds of the O–H···O, N–H···O and N–H···N type, weak hydrogen bonds of the C–H···O(N) and O(N)–H···π type should also be considered. A number of other weak heteroatom interactions such as N···halogen, S···S and halogen···halogen are known to have specific effects upon crystal packing, while the more exotic organometallic interactions (O–H···M, M–H···O, Au···Au) are only now beginning to be noticed.[6] A mention must be made of interactions in hydrocarbon systems. It is known for instance that phenyl groups pack with very specific geometries, leading to crystals that are characterised by high crystallinity and low solubility—the so called 'phenyl factor'.[24] In this context, it is still not clear if the C–H···π 'hydrogen bond' is an extreme case of the herringbone interaction.

The node connections in the network depiction of an organic crystal structure are of greater significance than the nodes. These connections consist of recognisable groups of inter-

molecular interactions and the term *supramolecular synthon* has been suggested in analogy to molecular synthons in organic synthesis.[6,25] Like molecular synthons, supramolecular synthons enable a focussing of synthetic strategy and allow the synthetic chemist to attack general supramolecular targets. Supramolecular synthons incorporate both chemical and geometrical aspects of molecular recognition. In principle, a given supramolecular structure contains a very large number of supramolecular synthons. However, in the most useful and significant of these, a maximum of structural information is encapsulated within the most economically-sized unit. If information is a measure of the amount of form— *Information ist das Mass einer Menge von Form*[26] the most useful synthons combine smallness with form.



Consider for instance the linear ribbon structures of piperazine-2,5-dione, 1,4-benzoquinone and 1,4-dicyanobenzene. The network depictions of each of these structures are identical. The supramolecular synthons **I**, **II** and **III** are equivalent though

they are constituted with strong (**I**) and weak hydrogen bonds (**II**, **III**) respectively. A knowledge of the piperazine-2,5-dione structure and the directional properties of C–H··O and C–H··N hydrogen bonds allows an anticipation of the benzoquinone and dicyanobenzene crystal structures. Widely different substances can have the same or similar crystal structures and in this manner, supramolecular synthons may be invoked in crystal design strategies.

## From network to molecular structures—retrosynthesis

Implicit in the supramolecular synthon approach to crystal engineering is the identification of a crystal as a retrosynthetic target. As stated above, a target is defined in terms of a network and a typical example of supramolecular retrosynthesis is now illustrated with reference to structures based on the polarisation induced iodo··nitro synthon **IV**.[27,28] Previous work showed that

there is a definite tendency for I atoms to make short, attractive contacts with nitro groups and a possible synthetic target is a linear ribbon (Fig. 4). If one alternates synthon **IV** with phenyl rings, 4-iodonitrobenzene **4** suggests itself retrosynthetically as a molecule that has few other crystallisation options. In the crystal structure of **4**, the desired ribbon pattern is obtained. The

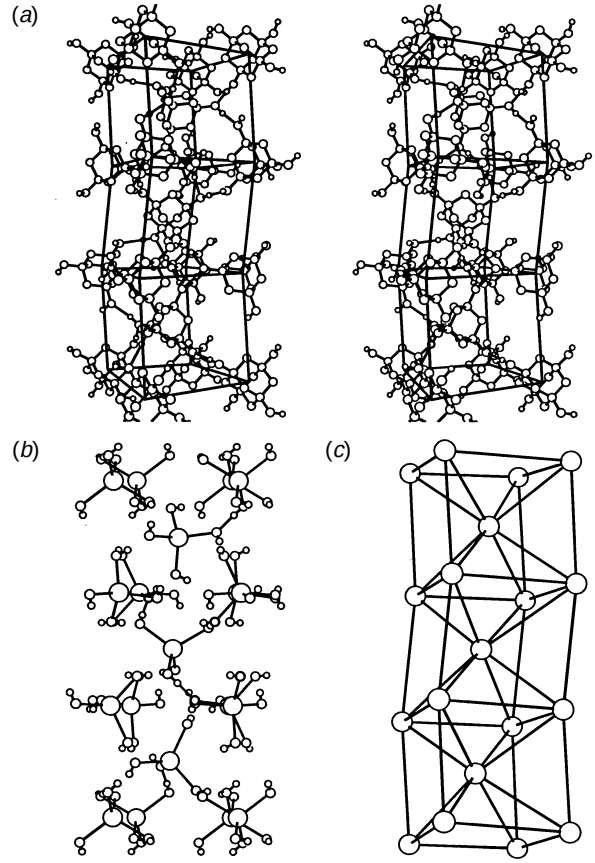


**Fig. 3** (*a*) Stereoview of the crystal structure of 1,3,5,7-tetrahydroxyadamantane **3**; (*b*) same as (*a*), with the adamantyl skeleton reduced to a sphere; (*c*) same as (*b*) with the entire molecule reduced to a sphere and hydrogen bonds shown as lines. Notice the similarity of (*c*) to the CsCl structure.

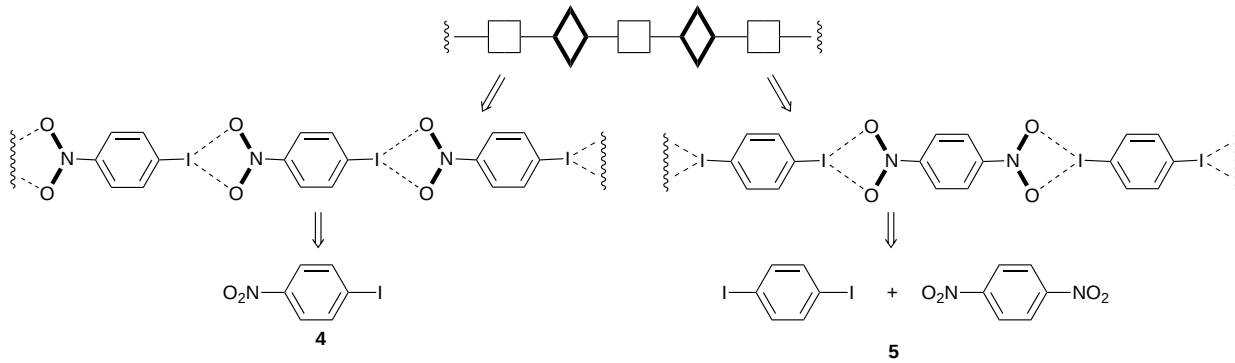

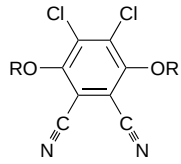

**Fig. 4**

strategy may be extended to the crystal structure of the 1:1 complex **5** of 1,4-diiodobenzene, and 1,4-dinitrobenzene where again synthon **IV** alternates, but in opposite senses, with the phenyl rings. Retrosynthetic analysis of the linear ribbon target shows that the crystal structures of compound **4** and complex **5** are equivalent. Such observations reiterate that distinct molecular structures $M_1$, $M_2$, $M_3$, ... may in general be associated with the same crystal structure $C_m$.

## The future—designer crystals

Crystal engineering is poised today at an exciting intersection of structural and supramolecular chemistry and combines scientific rigour with artistry and skill. If truly designer crystals are to become a reality, progress will become necessary in each of the three synthetic aspects: target identification, methodology and strategy.

Unlike in molecular synthesis, target identification (network designation) in crystal engineering is a non-trivial exercise. Progress in network theory and information science, coupled with technical advances in current database software such as the Cambridge Structural Database,[29] will probably become indispensable if crystal structures are to be routinely notated as networks. Consider for instance the similar networking of molecules in the 1,4-diethoxy **6** and 1,4-dihydroxy derivative **7**

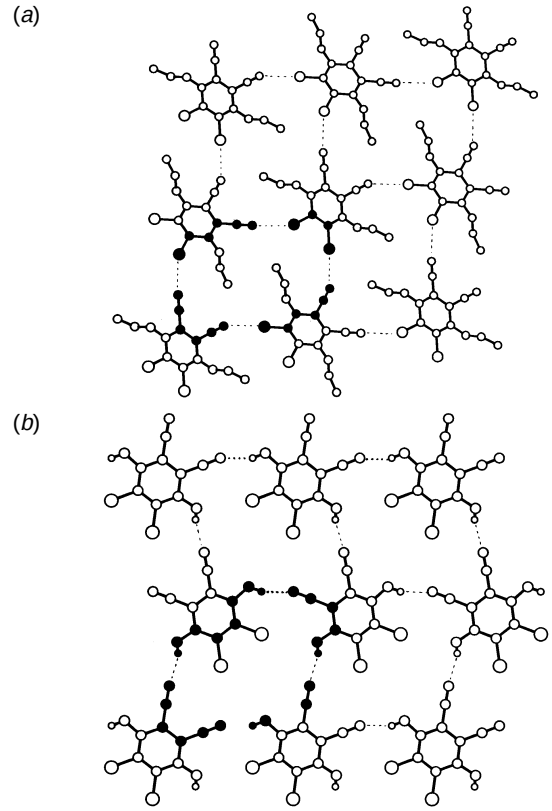
**6** R = Et
**7** R = H

of 2,3-dicyano-5,6-dichlorobenzene (Fig. 5).[30] In both cases, tetrameric loops are formed. In **6** the relevant interaction is the polarisation-induced C≡N··Cl–C, while in **7**, conventional hydrogen bonding of the C≡N··H–O type is involved. Interestingly, the O–H··O bonded tetramers in α-oxalic acid and squaric acid are topologically related to **6** and **7**. It would be desirable if comparisons such as these could be generated routinely through database protocols.

Improved supramolecular synthetic methodology will consist of obtaining more accurate and reliable information on intermolecular interactions. It is clear that a very large number of precise, low temperature X-ray structure determinations will be obtained in the future. Neutron diffraction analysis will become increasingly common as a means of studying and characterising unusual types of hydrogen bonding. We have recently collaborated with Judith Howard of the University of Durham on the neutron diffraction analysis of 2-ethynyladamantan-2-ol, which contains an O–H··π hydrogen bond and have shown that the O–H group points to the centre of the alkyne bond rather than towards one of the carbon atoms that form this bond.[31] Joint studies with Dario Braga of the University of Bologna have confirmed the existence of a number of soft hydrogen bond-like interactions: M–H··O, O–H··M, C–H··O≡C– M and the *pseudo*-agostic C–H··M.[32] How useful all these interactions will be in a general sense remains to be seen. However, it is worthwhile to note that molecular synthesis progressed greatly with an array of novel reactions and if the molecule–supermolecule analogy continues to be a reliable predictor of future events, then it is only a matter of time before the exotic interactions begin to be exploited in crystal engineering.

Another compelling need is to be able to visualise a crystal structure in its entirety, not just look at selected intermolecular interactions which have been deemed to be important. The vast majority of organic crystal structures are best considered as an interplay between the medium range, isotropic forces and the long range, anisotropic forces. Sometimes, the directional requirements of these forces act in consonance, at other times in conflict and it is hard in any given situation to predict if the isotropic or anisotropic forces will dominate. This variable and subtle interplay of intermolecular forces is both confusing and annoying. It is simplistic at best and grossly misleading at worst to try and analyse, even more so to try and design, crystal structures on the basis of only a single type of intermolecular interaction. The understanding of the interplay of intermolecular interactions is a major challenge in the practice of crystal engineering today because secondary and tertiary features often control structurally important attributes of a crystal, for example, the presence or absence of an inversion centre. Along these lines, we have been collaborating with Frank Allen of the Cambridge Crystallographic Data Centre in the use of an interaction display program, NIPMAT.[33] This program creates a pictorial matrix using the atoms in the molecular skeleton ($A_1$, $A_2$, ... $A_m$, ... $A_n$) in which the matrix element $A_mA_n$ is defined as representing the shortest intermolecular contact $A_m$··$A_n$ in the crystal. Each matrix element is shown in terms of a grey scale The shorter the contact, the greyer the square which represents that particular contact. Therefore, the plot obtained (see Fig. 6 for the NIPMAT plots of naphthalene and terephthalic acid) is a visual representation of *all* the intermolecular interactions *simultaneously*. These plots show the utter difference in packing in these two structures. In naphthalene, C··H interactions are important coupled with an overall isotropic packing. This is shown by the overall greyness of the plot. In terephthalic acid, O–H··O hydrogen bonding and C··C stacking are important and the packing is more directional. This is shown by the more black-and-white appearance of the plot.

It is in the area of new synthetic strategies that the most exciting developments may be expected. An appreciation of supramolecular synthons not only as structural units but also as



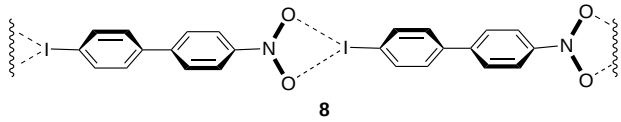


**Fig. 5** Networking of molecules in (*a*) 1,4-diethoxy-2,3-dicyano-5,6-dichlorobenzene **6** *via* C≡N··Cl interactions and (*b*) 1,4-dihydroxy- 2,3-dicyano-5,6-dichlorobenzene **7** *via* C≡N··H–O hydrogen bonds. These networks are topologically similar although the interactions are quite different.

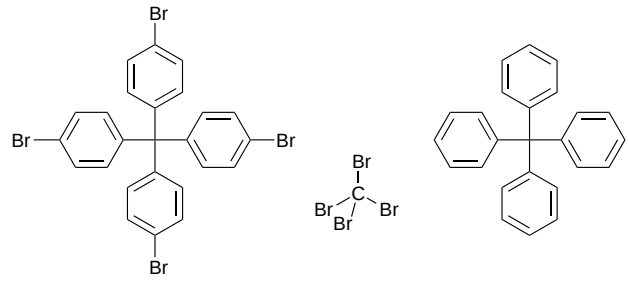
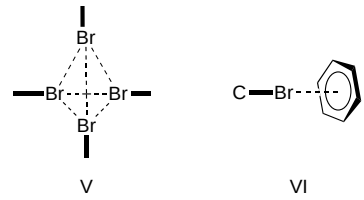


being responsible for characteristic supramolecular properties may lead to novel and unexpected solid state structures. In a recent report, we have shown that the linear ribbon structure of 4-nitro-4′-iodobiphenyl **8** may be retrosynthetically derived by



**8**

an interleaving of the iodo–nitro synthon **IV** and the twisted biphenyl molecular synthon.[34] The chiral ribbons that result pack in the non-centrosymmetric space group *Fdd2* and the crystals display moderate SHG activity (×6 urea). The term 'supramolecular chiron' has been suggested.[35] More interestingly, the calculated molecular hyperpolarisability β, of **8** is only $4.3 \times 10^{-30}$ esu. This observation hints that the crystal SHG has contributions also from the polarisation-based synthons **IV**. Many useful crystal properties are a consequence of molecular *and* supramolecular structure. It is therefore not surprising that supramolecular hyperpolarisability as manifested in synthons such as **IV** are important.

A final example demonstrates the equivalence of appropriate molecular and supramolecular synthons in crystals of tetrakis-(4-bromophenyl)methane **9** and the 1 : 1 molecular complex of $CBr_4$ **10** and tetraphenylmethane **11** (Fig. 7).[36] In **9**, a diamondoid network is formed by linking the tetraphenylmethane units with the tetrahedral supramolecular synthon **V**. Four bromine atoms are arranged in a tetrahedral fashion and the distance between any two of them is 3.91 Å. If the empty centroid in **V** is considered as a phantom 'carbon' atom, then the cluster approximates to a super-$CBr_4$ molecule.

**9** **10** **11**

V VI

One can now interchange the molecular and supramolecular synthons in the structure of **9**. The $Br_4$ clusters **V** are connected to the tetraphenyl moieties through C–Br covalent bonds. It was expected that these Ph–Br molecular synthons could be replaced with the supramolecular synthon **VI**, which is based on the Br··phenyl interaction. In other words, the replacement of **V** with $CBr_4$ accompanied by the concomitant replacement of **9** by **11** should lead to no major structural change. In practice, co-crystallisation of $CBr_4$ **10** and **11** led exclusively to the formation of a complex which is nearly isostructural with **9**. In

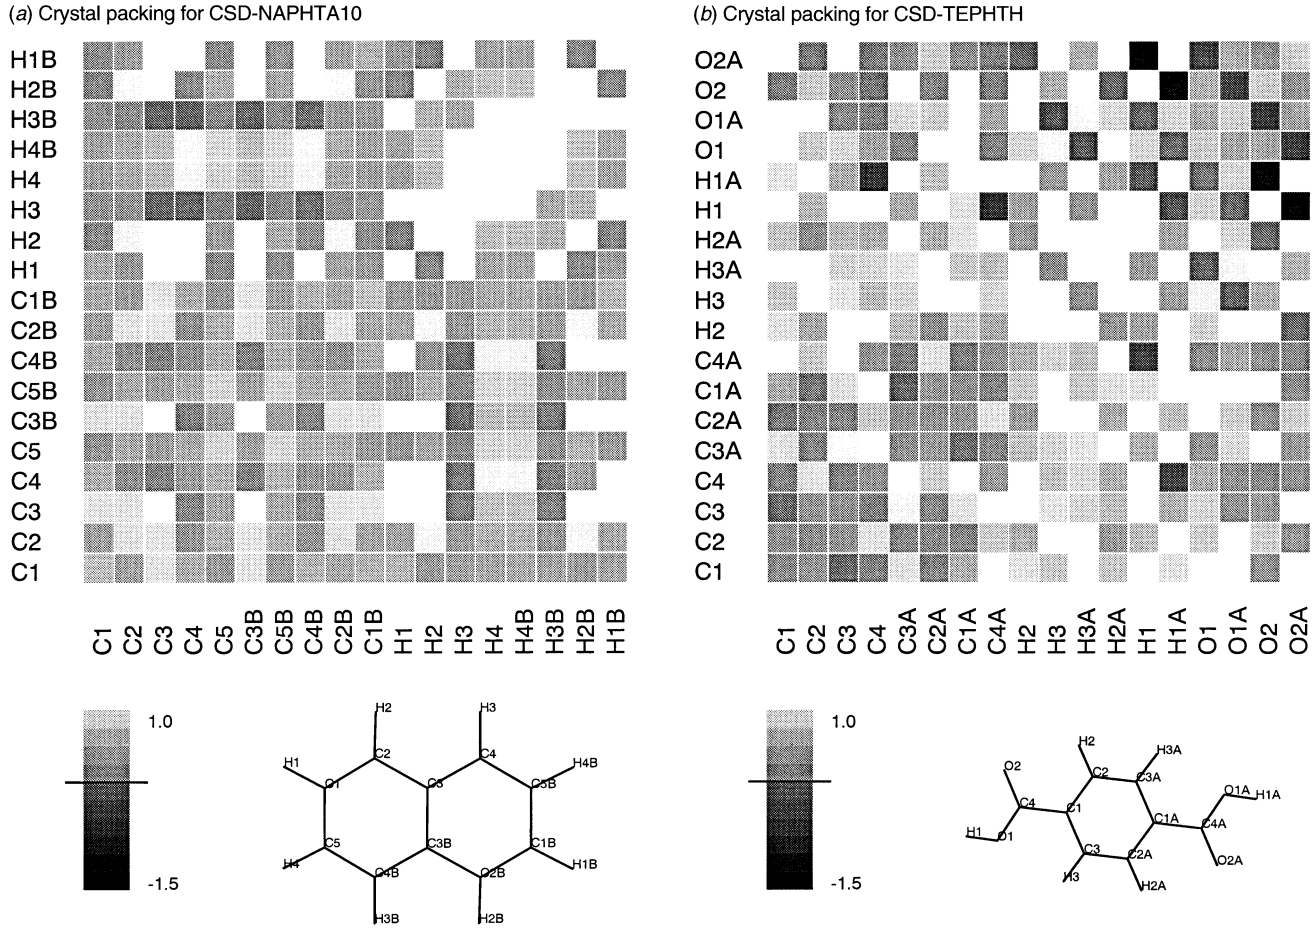


**Fig. 6** NIPMAT plots of (*a*) naphthalene (NAPHTA10) and (*b*) terephthalic acid (TEPHTH). Notice that the packing in the former is of a more isotropic nature.

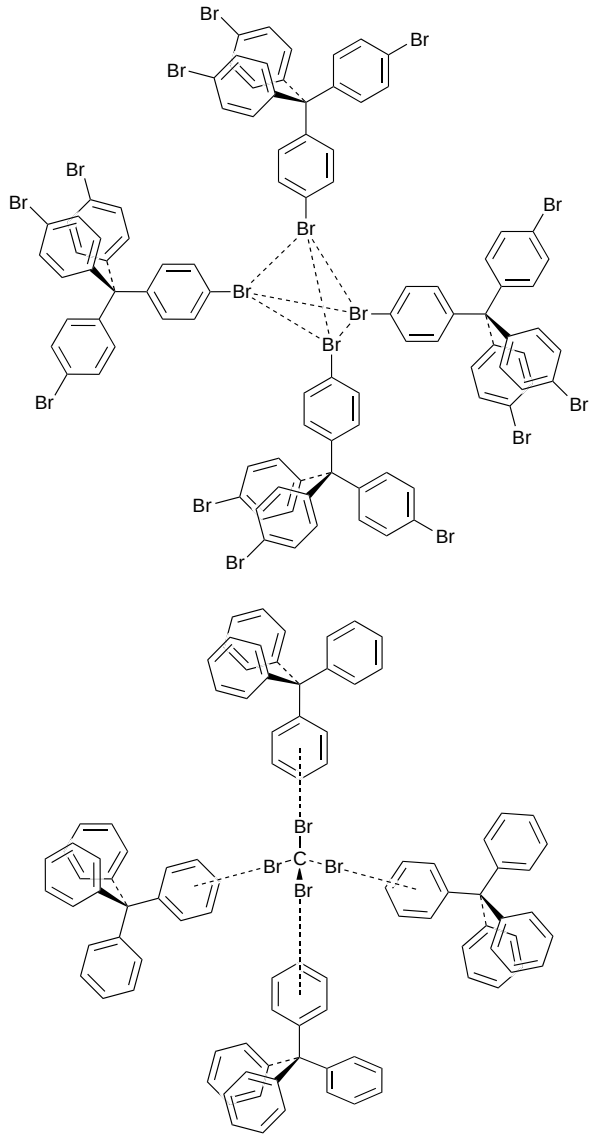

**Fig. 7**

the complex, four molecules of **11** are linked to a $CBr_4$ molecule through synthon **VI** (Br··phenyl ring centre 3.67 Å). There are no major differences in the crystal structures of **9** and the complex of **10** and **11**, and both may be simplified to distorted diamondoid networks. Although these crystal structures are formed from widely different components (**9** is a one-component crystal while the complex is a two-component crystal), they have close similarities at the supramolecular level. Most intriguingly, the distance between the bromine in the tetrahedral synthon **V** is only 12% greater than the Br··Br distance in the $CBr_4$ molecule. Observations such as this almost seem to challenge Kitaigorodskii's definition of a molecular crystal as one in which the distances between certain groups of atoms (molecules) are much smaller than the distances between atoms in different groups.[21]

## Crystallography and organic chemistry

The research described in this article is but another statement in the dialogue that has existed between X-ray crystallography and organic chemistry throughout this century.[37] This dialogue has been sometimes friendly and sometimes not, but it has always led to unexpected and fruitful developments in both subjects. Schmidt, in general, did not differentiate between these subjects when he extended the topochemical principle to organic reactions,[2] nor did say Bürgi and Dunitz when they developed the idea of structure correlation.[38] This article began with a reference to the tremendous strides in the practice of crystallography today and it has hopefully gone on to show that with the corresponding reduction of experimental burden, the endeavours of the chemical crystallographer may profitably be harnessed towards supramolecular synthesis. Crystallographers have always been confounded by technical strides in their subject and yet have always responded successfully by redefining their subject. It was J. M. Robertson who, while commenting on new methods in crystallography in the early fifties, predicted that, '*In the future, it is to be expected that the new methods will outstrip the standard degradative procedures of organic chemistry and the energies of the chemist will then be freed to concentrate on his second major problem, that of synthesis, which* ***at present*** *lie beyond the scope of crystallography*'.[39] It is with a keen sense of pleasure therefore that I draw the attention of the reader to how accurately Robertson was looking into the distant future, to a time when the subject of synthesis would come well within the ambit of X-ray crystallography.

## Acknowledgements

I thank my students, post-doctoral researchers and collaborators for their cooperation and enthusiasm. Financial support from the Department of Science and Technology, Government of India, is acknowledged. This paper is adapted from a keynote lecture delivered at the XVII Congress of the International Union of Crystallography, Seattle, in August, 1996.

**Gautam R. Desiraju was born in Madras (now Chennai) in 1952. He obtained a BSc degree from the University of Bombay in 1972 and a PhD degree from the University of Illinois at Urbana-Champaign in 1976 working with David Curtin and Iain Paul. After two years as a member of the research staff of the Eastman Kodak Company, Rochester, he returned to India where he is now a Professor of Chemistry at the University of Hyderabad. His research interests are centred in the area of structural chemistry and include crystal engineering, supramolecular chemistry, solid state reactivity and drug design.** ***Chemical Communications*** **remains one of his favourite scientific journals.**

# Fluorapatite coatings by metal organic chemical vapor deposition

**Enrico Ciliberto and Giuseppe Spoto**

*Dipartimento di Scienze Chimiche, Università di Catania, Viale A. Doria 6, Catania, 95125 Italy*

**The metal organic chemical vapor deposition technique is used for the production of fluorapatite coatings using titanium as substrate and yttrium oxide as a passive diffusion barrier.**

There has currently been tremendous interest in designing new materials to be used in repairing and reconstructing diseased or damaged parts of the human body. In this context great interest has been devoted to the study of some calcium phosphate-based materials, initially chosen for their chemical similarity to the main bone-constituting inorganic compounds,[1] whose *in vivo* behavior has been defined as bioactive.[2] Hydroxyapatite [HAP, $Ca_{10}(PO_4)_6OH_2$] and fluorapatite [FAP, $Ca_5(PO_4)_3F$] are two of the more commonly used ceramics for clinical applications. They show typical bioactive behavior *in vivo* generating direct contact between the bone and the ceramic surface with no fibrous tissue layer intervention.[3] Unfortunately though, poor mechanical properties prevent their use as load-bearing implants and considerable research has thus been directed towards the development of calcium phosphate-based coatings on high strength substrates for prosthetic applications involving complex loading arrangements.[4] In the last few years equal efforts have been made in the study and optimisation of HAP-based coatings and, more recently, FAP coatings have been produced. FAP is more stable than HAP at high temperatures[5] and has been seen to have favorable biological characteristics.[6,7]

The plasma spraying technique (PLS), first introduced by De Groot *et al*.,[8] is the most thoroughly investigated method for the production of calcium phosphate-based coatings. However, the high temperature (in the region of 10 000 K) at which the ceramic powder is maintained during the process, generates the partial decomposition of the precursor compounds. This is not easily controlled and amorphous phases are formed.[9,10] The above limitations have led to the development of new synthetic routes with the aim of increasing control of the different chemical and physical characteristics of the coatings such as stoichiometry, crystallinity, thickness and surface composition.

We report the use of metal organic chemical vapor deposition (MOCVD) as a new technique for the production of FAP coatings and as an alternative to PLS. The MOCVD technique is a widely used technique in both applicative and research fields, being based on the production of solid coatings from the chemical reactions of gaseous or vaporized metal–organic compounds.[11] Various features make this useful for the production of thick coatings on complex shaped objects. The possibility of 'chemically' and kinetically controlling the deposition process throughout its course and the scope for large-scale production[11,12] are also important aspects which make this technique extremely promising for bioceramic coating production. When compared to PLS, MOCVD allows improved control of coating characteristics as the type of nucleation and growth, the deposition rate and the final stoichiometry of the coating can be modulated.[11]

The experiments were carried out with a horizontal hot-wall reactor† using $Ca(hfa)_2$·tetraglyme (Hhfa = 1,1,1,5,5,5-hexafluoropentane-2,4-dione, tetraglyme = 2,5,8,11,14-pentaoxapentadecane) and diphenylphosphinic acid (dppa) (Aldrich) as volatile precursors. Titanium was used as the substrate (Goodfellow). To prevent deleterious effects due to the formation of an interfacial layer made up of titanium oxide, the exposed surface was modified by the application of an MOCVD-deposited diffusion barrier constituted of yttrium oxide ($Y_2O_3$).‡ For all the samples, coatings of FAP were obtained, following a double-step deposition process. The coatings made up of calcium fluoride ($CaF_2$),§ obtained after the first step, were transformed into FAP after treatment with dppa vapor. During the latter step the highest substrate temperature throughout the process was reached (550 °C). This double step made a modulation of the FAP/$CaF_2$ ratio possible by controlling the time of exposure to dppa vapor.

For all the samples X-ray diffraction (XRD)¶ patterns clearly showed the presence of polycrystalline FAP (Fig. 1) whose average crystallite size was estimated using the Scherrer formula: $t = 0.9\lambda/(B\cos\theta)$ where $t$ is the crystallite size, $\lambda$ is the X-ray wavelength, $B$ is the full width at half maximum (FWHM) and $\theta$ is the X-ray angle of incidence at the Bragg condition angle for the selected peak. This formula roughly evaluates the size of the coherent crystallite domains by considering how the decrease in size of the crystallite causes an extension of the diffracted line beyond instrumental broadening. When considering the (002) reflection an average crystallite size of *ca*. 400 Å was estimated for the coatings deposited in the reported conditions.† Surface morphology was probed by atomic force microscopy (AFM).‖ The investigation showed the presence of round particles with a diameter in the range of a few hundred nanometers. Distortion effects, induced by the tip geometry and by tip–sample interactions, that could partially alter the real particle diameters, have not been considered.[13]

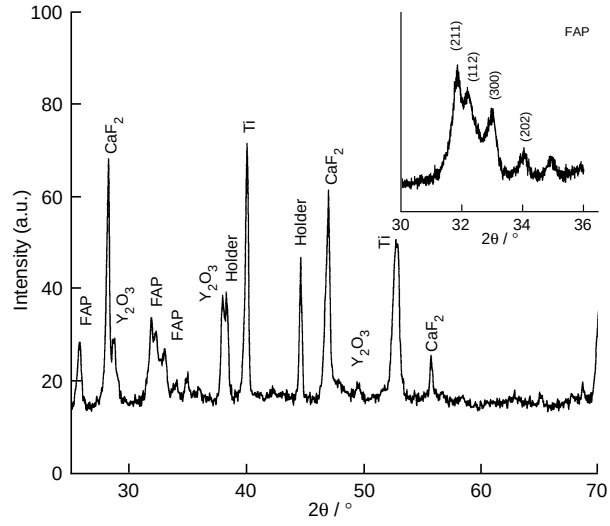

**Fig. 1** X-Ray diffraction pattern obtained from $Y_2O_3$-coated titanium after fluorapatite deposition. The spectrum obtained using Cu-Kα radiation clearly shows the presence of titanium and $Y_2O_3$ together with $CaF_2$ and FAP. Two peaks attributed to the aluminium holder are also shown. The transformation of $CaF_2$ to the crystalline FAP is a consequence of exposure to diphenylphosphinic acid vapor at 550 °C. The characteristic features of the FAP reflections included in the range $2\theta$ = 30–36° are highlighted.

This evidence, together with the XRD results, suggests that crystallites bind to form these particles.

Deposition rate, evaluated in the range of 0.5–1 μm $h^{-1}$, was estimated by examining X-ray photoelectron spectroscopy (XPS) depth profiles** after calibrating the sputter rate for the coatings using the Rutherford backscattering spectroscopy.††

The study of substrate/coating interfaces is of great relevance for problems concerning adhesion to the substrate. X-Ray photoelectron spectroscopy depth profiles were used to investigate the FAP/substrate interface when titanium was the substrate and $Y_2O_3$ was the diffusion barrier. The analyses (Fig. 2) showed the presence of an yttrium-containing layer which slowed titanium diffusion. This was a consequence of the thermodynamic stability of $Y_2O_3$ which is more stable than titanium and therefore allows a passive diffusion barrier to form for the titanium itself.[14] The relatively broad distribution of the yttrium layer and the presence of calcium, oxygen and phosphorus with only a slight decrease in concentration with depth (sputtering time) may indicate a partial substitution of the yttrium in the FAP structure. Unfortunately, no evidence for this substitution was observed in the XRD pattern.

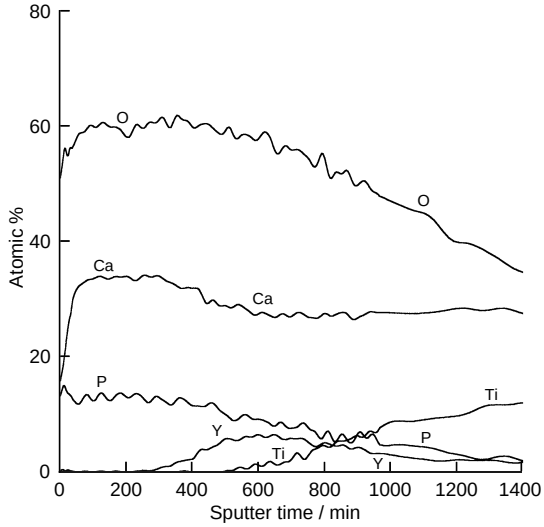

**Fig. 2** X-Ray photoelectron spectroscopy depth profile of a $Y_2O_3$-coated titanium substrate after fluorapatite deposition. Signals due to the yttrium layer appear after 200 min of $Ar^+$ sputtering, increasing in intensity up to 600 min of sputtering. Titanium diffusion towards the surface is stopped according to maximum yttrium concentration.

MOCVD is thus proposed as a new technique for the production of FAP coatings. This technique makes it possible to produce FAP coatings whose properties fit relevant properties for biomaterial coatings. In fact, the coatings are crystalline with a particle diameter in the same range as that of suitable biomaterials.[15] The use of proper diffusion barriers also reduces unwanted effects due to the formation of a brittle interface between the substrate and the coating. A positive point to be underlined is the lower temperature maintained during deposition in comparison with the temperature reached with the PLS technique.

We are now further optimizing the deposition parameters with the aim to increase the deposition rate. We are also testing various diffusion barriers in an attempt to produce coatings with increased performances.

The authors acknowledge with thanks Professors G. C. Allen, K. DeGroot, R. Langer and S. Mann for valuable discussions and interest.

† The reactor chamber was constituted by a quartz tube. During the depositions a total pressure of 10 Torr was maintained in the chamber while a continuous flux of Ar (50 ml $min^{-1}$) was used as carrier for the sublimed precursors. A temperature of 85 °C was maintained in the sublimation region of the reactor for the $Ca(hfa)_2$·tetraglyme adduct and dppa was sublimed at a temperature of 185 °C. The highest temperature reached during the experiments in in the deposition region in which the substrate to be coated was placed was 550 °C. For a detailed description of the synthetic procedure used for $Ca(hfa)_2$·tetraglyme adduct see: G. Malandrino, F. Castelli and I. L. Fragalà, *Inorg. Chim. Acta*, 1994, **224**, 203.

‡ Yttrium oxide was deposited using $[Y(dpm)_3]$ (Aldrich) as the volatile precursor maintaining the substrate to be coated at 300 °C with Ar flux (50 ml $min^{-1}$) used as carrier. The total pressure in the reactor during deposition was 10 Torr. A temperature of 165 °C was maintained in the sublimation region of the reactor during deposition.

§ The $CaF_2$ coatings were characterized by XRD and XPS; XRD spectra showed their highly crystalline nature with no preferred orientation structure. XPS confirmed the presence of Ca and F on the surface of the coatings with carbon, oxygen and silicon impurities. The atomic ratio Ca/F was *ca.* 0.5.

¶ X-Ray diffraction measurements (Ni-filtered Cu-Kα radiation) were made for the coated samples placed in aluminium sample holders, and scanned with a Philips PW1820 $\theta$–$2\theta$ goniometer. A 0.5° scatter slit and a 0.2° receiving slit were used during all the acquisitions.

‖ AFM images were recorded in air with a NanoScope III (Digital Instruments Inc.) in the constant-force mode on the as-deposited samples. The detection scheme of this instrument is based on the laser beam deflection of a microfabricated $Si_3N_4$ cantilever (spring constant 0.58 N $m^{-1}$, scan rate 8.72 Hz) with an integrated $Si_3N_4$ pyramidal tip and subsequent detection by means of a split photo diode.

** X-Ray photoelectron spectroscopy depth profiles were obtained with a PHI5600 ESCA/SAM monochromator system obtaining X-ray photoelectron spectra (Al-Kα = 1486.6 eV), anode voltage 14 kV, power setting 350 W) for the energy ranges in which the main photoemission processes for the elements of interest occur (30 second bursts of $Ar^+$ sputtering, $Ar^+$ accelerator voltage 3 kV, ion current 0.5 nA, rastered area 3 × 3 mm). The spectra were performed at a 45° takeoff angle with a pass energy of 23.58 eV for the wide scans and 5.85 eV for the narrow scans. The typical operating pressure was in the range $10^{-9}$–$10^{-10}$ Torr. The XPS spectrometer was calibrated using the Ag 3d region of an etched Ag sheet. The separation between Ag $3d_{3/2}$ (368.3 eV) and the Ag $3d_{1/2}$ was 6.00 eV. The energy resolution was 0.48 eV. The binding energy of the experimental spectra was calibrated on the basis of the most intense peak of the C 1s region at 284.5 eV.

†† Rutherford backscattering spectra were obtained using a 2 MeV $He^+$ beam (van de Graaff generator). The beam current was 8 nA and the backscattering angle was 160°.

# A new manganese cluster topology capable of yielding high-spin species: mixed-valence $[Mn_7(OH)_3Cl_3(hmp)_9]^{2+}$ with $S \geqslant 10$

**Milissa A. Bolcar,[a] Sheila M. J. Aubin,[b] Kirsten Folting,[a] David N. Hendrickson*[b] and George Christou*[a]**

**The reaction between $MnCl_2{\cdot}4H_2O$, Hhmp (Hhmp = 2-hydroxymethylpyridine) and $NEt_4MnO_4$ in MeCN gives $NEt_4[Mn_7(OH)_3Cl_3(hmp)_9]Cl[MnCl_4]$ 1; the 4 $Mn^{II}$, 3 $Mn^{III}$ cation comprises a $Mn_6$ hexagon containing a central Mn ion, and it possesses a $S \geqslant 10$ ground state.**

The study of molecules possessing unusually large spin values in their ground state is an area of intense current research.[1–6] These efforts are driven by a number of considerations, not least of which is the desire to elucidate the various factors responsible for yielding high-spin molecules. These include the topological arrangement of the paramagnetic ions, the nature (ferro- or antiferro-magnetic) of the inter-ion exchange interactions, and the presence of competing exchange interactions of comparable magnitude.[7] Further, it has recently become apparent that a relatively high ground-state spin value is one of the necessary requirements for molecules to be able to exhibit the new phenomenon of single-molecule magnetism.[1,8,9] The synthesis of new high-spin molecules is thus of interest. However, it is difficult to predict in advance for clusters what kind of topology and structure will lead to a high-spin species and even more difficult to then achieve a deliberate synthesis of such a species. We herein describe a new heptanuclear mixed-valence manganese complex with $hmp^-$ ligation (Hhmp = 2-hydroxymethylpyridine) and a new core topology for $Mn_7$ species, and show that this topology yields a high-spin ground state. Further, we show that these results suggest means whereby additional high-spin molecules might be accessed by small changes to currently available species containing a hexagon of metal ions.

Treatment of a stirred yellow slurry of $MnCl_2{\cdot}4H_2O$ (3 equiv.) and Hhmp (10 equiv.) in MeCN with solid $NEt_4MnO_4$ (2 equiv.) resulted in a dark brown solution. After 1 h, the solvent was removed *in vacuo* and the residue recrystallized twice (or more) from $CH_2Cl_2$–$Et_2O$ to give dark brown crystals of $NEt_4[Mn_7(OH)_3Cl_3(hmp)_9]Cl[MnCl_4]$ **1** in typical yields of *ca.* 40%; dried solid analyzed as $\mathbf{1}{\cdot}CH_2Cl_2{\cdot}3H_2O$.† The crystallographic sample of $\mathbf{1}{\cdot}3CH_2Cl_2$ was grown from $CH_2Cl_2$–toluene. The structure‡ of the $[Mn_7(OH)_3Cl_3(hmp)_9]^{2+}$ cation (Fig. 1) consists of a nearly planar $Mn_7$ unit comprising a central Mn(1) held within a $Mn_6$ hexagon by three $\mu_3$-$OH^-$ [O(8), O(9), O(10)] and three $\mu_3$-OR [O(29), O(53), O(77)] groups, the latter from three $hmp^-$ chelates. The remaining $hmp^-$ O atoms doubly bridge $Mn_2$ pairs of the hexagon. Three terminal $Cl^-$ ions complete peripheral ligation. Charge considerations require a 4 $Mn^{II}$, 3 $Mn^{III}$ mixed-valence description and, on the basis of $Mn^{III}$ Jahn–Teller (JT) distortions and bond valence sum calculations,[10] the $Mn^{III}$ ions are Mn(2), Mn(4) and Mn(6). The JT elongation axes contain O(29), O(53), O(77) and N(14), N(38), N(62). The cation has virtual $C_3$ symmetry. The $Cl^-$ anion is hydrogen-bonded to the $\mu_3$-$OH^-$ groups [O···Cl 3.049(16)–3.187(16) Å], but the $NEt_4^+$ and $MnCl_4^{2-}$ ions are well separated from the $Mn_7$ cation. A side view (Fig. 1) shows a Mn/O layered structure, with layers of O atoms above and below the $Mn_7$ layer, reminiscent of the hexagonal close-packed layered structure in, *e.g.* $CdI_2$.[11] The structure is different from that of other $Mn_7$ complexes, but similar to that of $[M_6NaL_{12}]^+$ (M = $Co^{II}$, $Cu^{II}$; HL = 6-methyl-2-hydroxypyridine)[12] and $[Fe_6Na(OMe)_{12}(dbm)_6]^+$ ($6Fe^{III}$; Hdbm = dibenzoylmethane),[13] where a $Na^+$ ion occupies the central position, and also $[Cu_7L_{12}]^{2+}$ ($7Cu^{II}$)[14] and $[Fe_7(OMe)_6(OPh)_6(MeCN)_{12}]^{2+}$ ($7Fe^{II}$),[15] which are homometallic.

Magnetic susceptibilities ($\chi_M$) of $\mathbf{1}{\cdot}CH_2Cl_2{\cdot}3H_2O$ have been measured in a 10.0 kG dc field and a 1.0 G ac field oscillating at 1000 Hz and corrected for the presence of the $MnCl_4^{2-}$ ($S$ = 5/2) ion, which is assumed, based on the crystal structure, to not be interacting with the $Mn_7$ cation. The dc $\chi_mT$ is essentially temperature independent at *ca.* 26.4 $cm^3$ K $mol^{-1}$ until *ca.* 100 K, and then increases to a maximum of 27.70 $cm^3$ K $mol^{-1}$ at 30.0 K and then decreases to 12.28 $cm^3$ K $mol^{-1}$ at 2.00 K. Similar values are seen for the ac $\chi_MT$ data, although it does not decrease as much at low temperatures. The data suggest a large ground-state spin value, and magnetization *vs.*

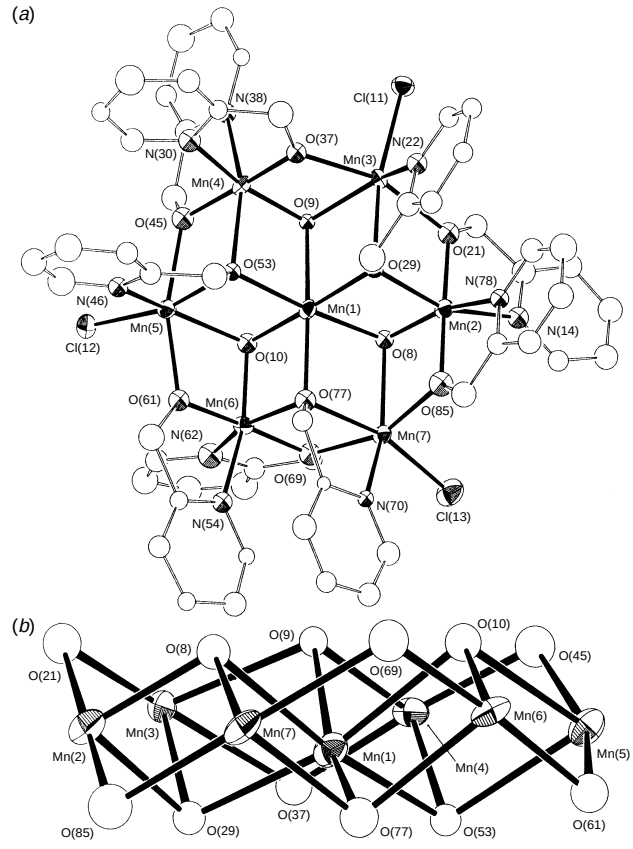

**Fig. 1** (*a*) The structure of the $[Mn_7(OH)_3Cl_3(hmp)_9]^{2+}$ cation of **1** viewed approximately along the virtual $C_2$ axis. Selected distances (Å): Mn(1)···Mn(2) 3.196(6), Mn(1)···Mn(3) 3.376(5), Mn(1)···Mn(4) 3.184(5), Mn(1)···Mn(5) 3.353(6), Mn(1)···Mn(6) 3.180(5), Mn(1)···Mn(7) 3.362(5), Mn(2)···Mn(3) 3.291(5), Mn(3)···Mn(4) 3.232(5), Mn(4)···Mn(5) 3.297(5), Mn(5)···Mn(6) 3.202(5), Mn(6)···Mn(7) 3.295(5), Mn(2)···Mn(7) 3.234(5). (*b*) A side view emphasizing the O/Mn/O layers. Displacement of Mn(1) from the $Mn_6$ least-squares plane is 0.388 Å.

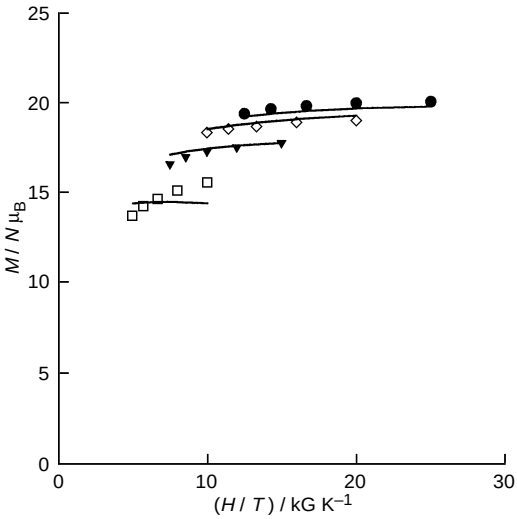

**Fig. 2** Reduced magnetization ($M/N\mu_B$) *vs.* $H/T$ data for complex **1**. The solid lines are the fit to a $S = 11$ state with $g = 1.85$ and $D = -0.15$ cm$^{-1}$.

field data were therefore collected in the 20–50 kG and 2.00–4.00 K ranges (Fig. 2). Fitting of these data, employing a spin-Hamiltonian matrix diagonalization approach, gave $S = 11$, $g = 1.85$ and $D = -0.15$ cm$^{-1}$; an equally good fit was obtained with $S = 10$, $g = 2.03$ and $D = -0.18$ cm$^{-1}$, which, however, is slightly less favored by the $g > 2$ value. Attempts to fit magnetization data measured at temperatures above *ca*. 4 K resulted in poor fits assuming only one state is populated. We conclude that in the 2–4 K range, the lowest energy state in a 20–50 kG field has $S = 11$. At temperatures above *ca*. 4 K, other states with smaller $S$ values are presumably populated and this is why the maximum in $\chi_M T$ at *ca*. 30 K falls short of the value expected for a molecule with $S = 10$ or 11; weak, intermolecular antiferromagnetic exchange interactions likely also serve to decrease the $\chi_M T$ value at low temperature. No out-of-phase ac signals were observed in the ac studies in the 2.00–50 K range.

A ground-state spin value for **1** of $S \geqslant 10$ makes this complex a new member of the small family of high-spin ($S \geqslant 8$) complexes.[1–8] With 4 $Mn^{II}$ and 3 $Mn^{III}$ ions, **1** could have ground-state values in the range $S = 2$–16. The intermediate value of $S \geqslant 10$ can be rationalized as due to competing exchange interactions of comparable magnitude.[7] The pairwise exchange interactions are of two types: $J_{io}$ and $J_{oo}$ (i = inner, o = outer), the former comprising both $J_{22}$ ($Mn^{II}$–$Mn^{II}$) and $J_{23}$ ($Mn^{II}$–$Mn^{III}$) interactions and the latter only $J_{23}$. The ground state of **1** will be dependent on the relative magnitudes of the competing $J_{io}$ and $J_{oo}$ interactions, since literature precedent indicates that $J_{22}$ and $J_{23}$ interactions are essentially always weakly antiferromagnetic and of comparable magnitude.[16] Thus, as a result of the $J_{io}$ *vs.* $J_{oo}$ competition, it is impossible for the spins in **1** to align antiparallel to each of their neighboring spins and the ground state consequently adopts an intermediate spin value, one of the highest yet observed.

The above analysis predicts that if the central Mn(1) ion of **1** were missing (or replaced by, *e.g.* $Na^+$), there would be no competing exchange interactions and the ground state would be $S = 15/2 - 6 = 3/2$. These species are currently not known and are being sought to test this prediction, but we note that $[Fe_6Na(OMe)_{12}(dbm)_6]^+$ (6 $Fe^{III}$) has an $S = 0$ ground state[13] consistent with antiparallel alignments of six $S = 5/2$ spins around the ring. Replacement of the $Na^+$ in this complex with a seventh $Fe^{III}$ or any other paramagnetic ion should give relatively high ground-state spin values as competing exchange interactions are introduced. This introduction of a seventh paramagnetic centre into preformed $M_6Na$ (or $M_6$) species may or may not prove synthetically challenging; however, challenging or not, it certainly warrants investigation since success would be extremely beneficial for the future health of the field of high-spin molecules, which is currently heavily dependent on serendipity. We also note that exactly the above kind of $Fe^{III}_7$ unit {*i.e.* $[Fe_7(\mu_3\text{-}OH)_6(\mu_2\text{-}OH)_6]^{9+}$} is a recognizable fragment within the cores of cocrystallized $[Fe_{17}O_4(OH)_{16}(heidi)_8(H_2O)_{12}](NO_3)_3/[Fe_{19}O_6(OH)_{14}(heidi)_{10}(H_2O)_{12}](NO_3)$ [heidi = $N(CH_2CO_2H)_2(CH_2CH_2OH)$] and is undoubtedly a major contributor to the *S ca.* 33/2 ground state of one of them.[2]

*Note added in proof:* the related cation $[Zn_7(hmp)_{12}]^{2+}$ has very recently been reported.[17]

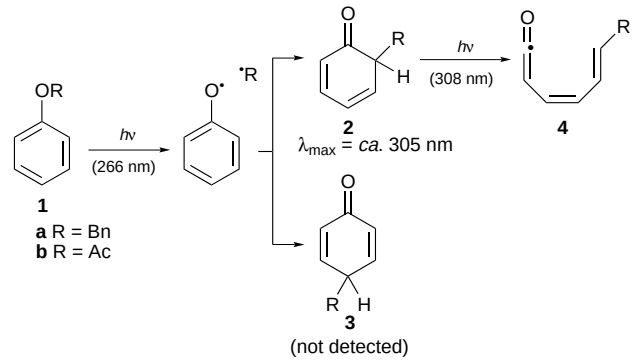
# Two-photon processes in the photo-Claisen and photo-Fries rearrangements. Direct observation of dienic ketenes generated by photolysis of transient cyclohexa-2,4-dienones

**M. Consuelo Jiménez,[a] Miguel A. Miranda,*[b] J. C. Scaiano*[b] and Rosa Tormos[a]**

[a] *Departamento de Química/Instituto de Tecnología Química UPV-CSIC, Universidad Politécnica de Valencia, Camino de Vera s/n, Apdo 22012, 46071, Valencia, Spain*
[b] *Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5*

**Using the two-laser two-colour technique it has been possible to promote two photon chemistry in the cases of benzyl phenyl ether 1a and phenyl acetate 1b; this is based on the photolysis of the transient cyclohexa-2,4-dienone intermediates 2a,b of the photo-Claisen and photo-Fries rearrangement to the dienic ketenes 4a and 4b.**



The classical Claisen and Fries rearrangements have been known for nearly 90 years.[1] Their photochemical equivalents were first reported in 1952 and 1960, respectively.[2] Since then, a considerable number of reports have appeared in connection with the synthetic as well as mechanistic aspects of both photorearrangements. Much of this work was done during the first two decades since their discovery and is summarized in several reviews.[3] A satisfactory understanding of the mechanism has been achieved by using laser flash photolysis,[4] CIDNP[4e,5] and transient Raman spectroscopy,[6] as well as studies on magnetic isotope effects and magnetic fields effects.[7]

The above contributions support the idea that photo-Claisen and photo-Fries rearrangements occur from an excited singlet state, *via* homolysis of the aryloxy–alkyl (or acyl) bond, to give radical pairs enclosed in a solvent cage. Radical recombination leads to the rearranged alkyl (or acyl) migration products, while out-of-cage hydrogen abstraction by the aryloxy radical leads to the formation of phenols. This picture has been confirmed by independent generation of the involved radicals *via* Norrish type I photoreaction of ketones in the presence of phenols, which leads to aryl ethers (or esters) plus *C*-alkyl (or *C*-acyl) phenols.[8]

Being the prototypes for geminate cage recombination/escape of relatively large radicals, both photorearrangements have attracted recent attention as model reactions to study the influence of constraining media such as cyclodextrins,[9] micelles,[10] zeolites,[11] supercritical carbon dioxide[12] and stretched low-density polyethylene films.[13]

There is some spectroscopic evidence for the involvement of non-enolized cyclohexadienones as intermediates.[4] If such transient species were actually intervening, it should be possible in principle to photolyse them at their absorption maxima using the recently developed two-laser two-colour technique.[14] If the typical photoproducts of cyclohexadienones were thus formed,[15] this could constitute an additional proof for their involvement in the photo-Claisen and photo-Fries rearrangements. Besides, this methodology could provide a direct entry to two-photon chemistry of aryl ethers and esters, which still remains to be explored.

Laser flash photolysis of deareated 5 mM solutions of benzyl phenyl ether **1a** in methylcyclohexane was carried out with a Nd-YAG laser (fourth harmonic, 266 nm, < 10 ns, ⩽ 20 mJ pulse$^{-1}$) using a 90° excitation geometry and a quartz beam diffuser in front of the sample (Scheme 1). A transient signal appeared, which was assigned to the cyclohexa-2,4-dienone **2a** by comparison with the known properties of these species.[4] In a second experiment, two-laser two-colour laser flash photolysis was employed to examine the effect of laser excitation on the above mentioned reaction intermediate. The same 266 nm laser was used as synthesis laser to generate **2a**, while a 308 nm excimer laser (HCl/Xe/Ne, 6 ns, 70 mJ pulse$^{-1}$) was used to photolyse the intermediate. The wavelength of the latter was selected to match the optical absorption of cyclohexa-2,4-dienone (maximum at *ca.* 300 nm). The synthesis laser was incident from the front face, while for the photolysis laser a 90° geometry was adopted. The most remarkable result was a permanent and irreversible bleaching of the transient signal as monitored at 295 nm (Fig. 1, insert). In the absorption spectrum obtained after photolysis of **2a**, an enhancement was observed at 260–270 nm, accompanied by a decrease at 300–320 nm. The difference spectrum displayed a well-defined maximum at 270

**Scheme 1**

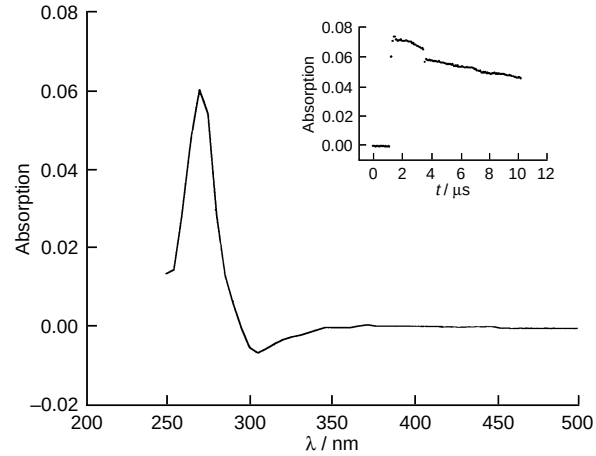


**Fig. 1** Absorption spectrum of the dienic ketene **4a** obtained from the difference between the spectra of the reaction of **1a** after and before the 308 nm laser pulse. The insert shows the bleaching of the transient signal monitored at 295 nm.

nm and a less marked emission at 305 nm (Fig. 1). Taking into account the possibility of electrocyclic ring opening in the case of **2a**, a plausible structure of the intermediate absorbing at 270 nm would be that of a dienic ketene such as **4a**. This assignment was confirmed by comparison with the spectra of similar ketenes generated by photolysis of stable 6,6-disubstituted cyclohexa-2,4-dienones.[16]

The same experiments were carried out with phenyl acetate **1b**. Flash photolysis with the 266 nm laser gave rise to a transient signal whose structure was assigned to be **2b**. When this intermediate was photolysed at 308 nm in the two-laser two-colour experiment, a sharp enhancement of the signal monitored at 330 nm was observed (Fig. 2, insert). This was somewhat surprising as, in the case of the benzyl ether **1a**, the result was bleaching of the signal. The spectrum of the new intermediate was obtained in the usual way, by examining the difference between the spectra after and before the 308 nm laser pulse. This spectrum showed a maximum at longer wavelength (330 nm) than **4a** (Fig. 2). In principle, photochemical opening of 6-acetylcyclohexa-2,4-dienone **2b** to the corresponding dienic ketene **4b** was expected to occur, by analogy with the behaviour of the 6-benzyl derivative **2a** upon photolysis at 308 nm. Transient **4b** presents an extended conjugation, owing to attachment of the acetyl group at the end of the polyunsaturated system. This would explain the position of its absorption maximum and is in agreement with the proposed structure.

In summary, using the two-laser two-colour technique it has been possible to promote two photon chemistry in the case of benzyl phenyl ether **1a** and phenyl acetate **1b**. This is based on the photolysis of the proposed cyclohexa-2,4-dienone intermediates **2a**,**b** of the photo-Claisen and photo-Fries rearrangements and involves direct detection of the electrocyclic ring opening products, the dienic ketenes **4a** and **4b**.

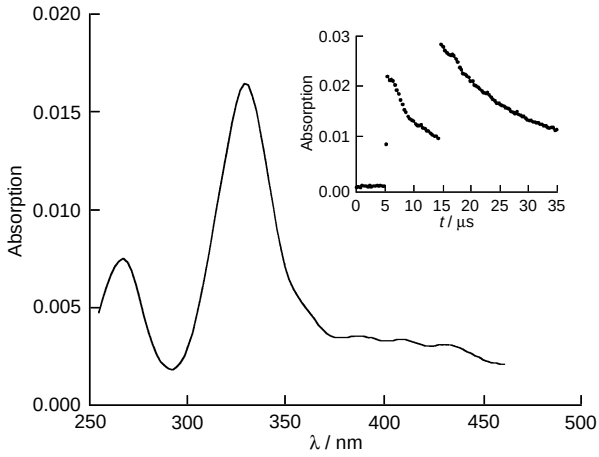

**Fig. 2** Absorption spectrum of the dienic ketene **4b** obtained from the difference between the spectra of the reaction of **1b** after and before the 308 nm laser pulse. The insert shows the jump of the transient signal monitored at 330 nm.

Financial support by the Spanish Government (fellowships to M. C. J. and R. T.) is gratefully acknowledged. We also thank Mr André Simard for skillful technical assistance.

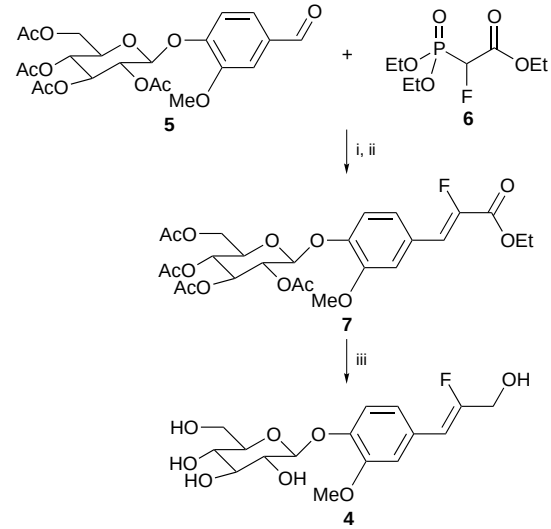
**A fluorinated analogue of coniferin (the glucoside of coniferyl alcohol) has been synthesized in three steps from vanillin tetraacetyl glucoside; bearing a fluorine atom on the β position of the propenyl side chain which is involved in the main site of coupling, it is designed as a potential inhibitor of oxidases involved in the biosynthesis of lignin, and *in vivo* experiments show a pronounced inhibition of lignin biosynthesis in poplar plantlets, with a five-fold decrease in lignin formed.**

Lignins, the second major natural biopolymer on earth after cellulose, are biosynthesized by polycondensation of cinnamyl alcohols **1a**–**c**.[1–3] The crucial step consists of an oxidative

**1a** X = Y = $R^1$ = H, $R^2$ = OMe
**b** X = Y = H, $R^1$ = $R^2$ = OMe
**c** X = Y = $R^1$ = $R^2$ = H
**2** X = F, Y = $R^1$ = H, $R^2$ = OMe
**3** X = H, Y = glucose, $R^1$ = H, $R^2$ = OMe
**4** X = F, Y = glucose, $R^1$ = H, $R^2$ = OMe

coupling of these phenols, *via* the formation of radicals[4] by a radical–radical or a radical–anion mechanism.[5,6] The enzymatic route remains unclear, since peroxidases and laccases can both, in artificial medium, catalyse the oxidation step and lead to lignin-like dehydropolymers (DHP).[7–9] To the best of our knowledge, there has been no report on specific inhibition of the polymerization step *in vivo*. Coloration tests on microcuttings, however, have shown that fluoroferulic acid is able to inhibit the activity of peroxidases.[10–12]



We herein describe the first *in vivo* inhibition of lignin biosynthesis by use of the fluorinated analogue **2** of coniferyl alcohol **1a**, the main natural precursor of lignin. A fluorine atom has been substituted for one hydrogen in the β-vinyl position. The structures of **1a** and **2** are very close, and thus we can expect similar affinities for the enzymes.[13,14] Compounds **1a** and **2** have similar redox potentials [0.11 and 0.16 V respectively](SHE),[15] as might be supposed based on the reported slightly destabilizing effect of fluorine on radical centres.[16,17] Thus no difference should be observed in the ability of the enzyme to oxidize **1a** or **2**. On the other hand, the reactivity of the radical obtained from **2** is expected to be dramatically changed, owing to the interaction between the stabilizing effect of the methoxy group on the aromatic ring[15] and the strong electron-withdrawing effect of the fluorine atom.[18]

Glucosides **3** are the natural protected forms of cinnamyl alcohols **1** and have been extensively used for radiolabelling experiments,[19,20] the glucosyl residue being cleaved *in situ* by a β-glucosidase before the polymerization step.[21–23] β-Fluoroconiferin **4** was thus designed as the stable protected form of fluoroconiferyl alcohol, the actual inhibitor.

Synthesis of **4** was easily achieved, with high yields, from the tetra-*O*-acetylglucoside of vanillin **5** (Scheme 1).[24,25] A Wadsworth–Edmons reaction with triethylfluorophosphonate **6**[26, 27] under phase transfer conditions catalysed by tris[2-(2-methoxyethoxy)ethyl]amine (TDA-1)[28] led, after isomerization of the *E/Z* mixture with bromine,[29] to pure *Z* β-fluoro α,β-unsaturated ester **7**.† The five ester groups were reduced with *in situ* generated lithium borohydride leading to pure **4**.‡

The biochemical assay was performed according to a standard test we have developed on poplar plantlets grown *in vitro* under controlled conditions.§[30] This test is based on the assimilation of the glucosides of cinnamyl alcohols which are administered to the plantlets through the growing artificial medium. Artificial substrates **3** (sample 1) and **4** (sample 2) were delivered to lignifiying zones after diffusion in the medium and crossing of the root barrier. After allowing a three week growing phase, incorporation was followed by a standard lignin analysis of the new stems: lignin was chemically degraded by thioacidolysis and residues were analysed by GC–MS and quantified by GC after silylation.¶[31,32]

After three weeks of growing, no difference was observed on the aspect of plantlets from blanks (no feeding), samples 1 (fed **3**) and 2 (fed **4**). The extent of lignification was, however,

**Scheme 1** *Reagents and conditions*: i, TDA-1, aq. $K_2CO_3$, $CH_2Cl_2$, reflux, 24 h, 91%; ii, $Br_2$ (0.05 equiv.), $CCl_4$, 4 h, 88%; iii, $NaBH_4$ (7.4 equiv.), LiCl (10 equiv.), glyme, 80 °C, 18 h, 69%

**Table 1** Thioacidolysis yields in μmol $g^{-1}$ of dried stems in main G (guaiacyl) and S (syringyl) lignin-derived monomers recovered from poplar plantlets cultured *in vitro*

| Sample | Precursor administered | G | S | S+ G | S/G |
|---|---|---|---|---|---|
| Blank | None | 21 | 10 | 31 | 0.50 |
| 1 | Coniferin | 26 | 15 | 41 | 0.58 |
| 2 | Fluoroconiferin | 4 | 3 | 7 | 0.78 |

significantly lowered in sample 2: the thioacidolysis yield (a reflection of the lignin concentration) was only 7 μmol $g^{-1}$, compared to a 31 μmol $g^{-1}$ yield for the blank and sample 1 (Table 1).

These results suggest that the designed compound fluoroconiferyl alcohol **2** acts as an inhibitor of the lignification process. As the catalytic activity of the β-glucosidase is most probably unchanged, the lignin biosynthesis must be affected at the oxidative polymerization step. Lignin precursors such as coniferyl alcohol **1a** are oxidized by any kind of oxidizing enzymes, and no specificity has yet been established. The use of labelled derivatives of **4** should allow the identification of the enzymes specifically involved in the oxidative biosynthesis of lignin.

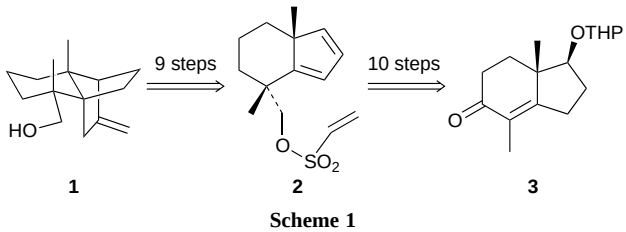
# The enantioselective total synthesis of (−)-myltaylenol

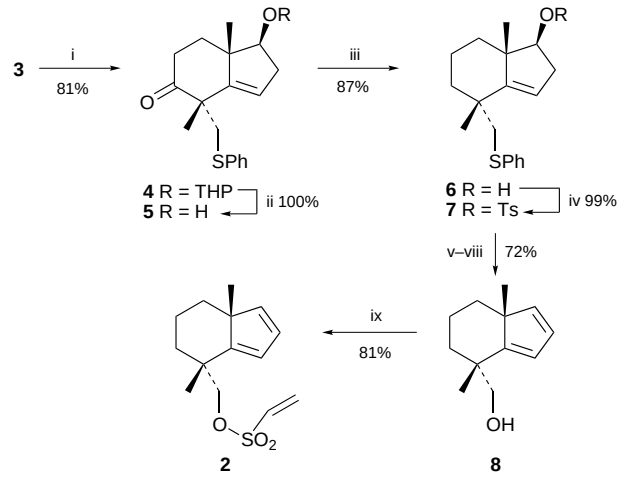
**Sven Doye, Torsten Hotopp and Ekkehard Winterfeldt***

*Institute of Organic Chemistry, University of Hannover, Schneiderberg 1b, 30167 Hannover, Germany*



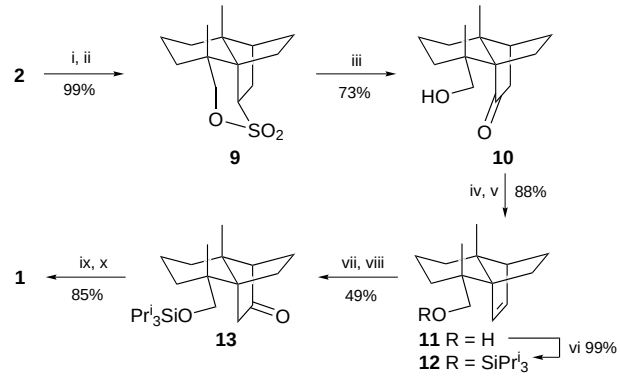
**Using an intramolecular Diels–Alder cycloaddition followed by an oxidative rupture of the connective unit as the key step, the unusual carbon framework of (−)-myltaylenol was established.**

In 1985 Matsuo[1] and his colleagues reported the isolation of the unusual sesquiterpenoid alcohol (−)-myltaylenol **1** from the liverwort *Mylia taylorii*. The compound is characterized by a novel polycyclic terpenoid framework containing three consecutive quartenary carbon atoms and although Srikrishna[2] and his group in 1994 briefly described a remarkable biomimetic transformation, which finally gave rise to the corresponding racemic desoxy compound starting from cyclogeraniol, no enantioselective approach to this type of molecule has been reported.



As retrosynthetic planning disclosed an intramolecular Diels–Alder cycloaddition employing cyclopentadiene **2** to be a potential key step and since we had in recent years gained some experience with dienes of this type, the enantioselective preparation of this compound was considered our first target.

For hydrindane derivatives of this structure the pure enantiomers of the Hajos–Wiechert ketone had been shown in our group to be an ideal starting material[3] and as the monoalkylated derivative **3** is well described in the literature[4] we employed the highly selective alkylation of this unsaturated ketone with thiophenylmethyl iodide followed by a Wolff–Kishner reduction to prepare the cyclopentenol **5**. To generate the corresponding cyclopentadiene, the tosylate **7** was formed and treated with potassium *tert*-butoxide in THF at 65 °C. Subsequent Pummerer rearrangement followed by a borohydride reduction gave rise to the primary alcohol **8**, which after treatment with ethenesulfonyl chloride was ready for the intramolecular cycloaddition. For this process and the accompanying oxidative ring fission of the sulfonate we had decided on the Metz protocol.[5] This worked nicely as far as the intramolecular cycloaddition was concerned. The oxidation employing 2-methoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane, however, which had been successfully applied by Metz and his colleagues in various instances, failed. Since the electrophilic attack has to take place next to a quarternary carbon atom we came to the conclusion that steric hindrance may be the cause for this failure. We thus treated the carbanion of **9**, generated using Bu$^s$Li, with molecular oxygen and were pleased to note the clear formation of hydroxy ketone **10**. As the yield under various conditions, however, barely exceeded 40% we investigated the relationship between the amount of Bu$^s$Li used and the yield under standard reaction conditions and noticed that a large surplus of the deprotonating species (10–11 equiv.) reliably gave a 65% yield of the hydroxy ketone. With this piece of information at hand one may speculate about the formation of *sec*-butyl hydroperoxide and its possible role as an oxidant. We hesitate, however, to discuss the mechanism of this useful process at this stage of our investigation.



Without collecting further information about this oxidation we converted the keto group into the corresponding olefin **11** in a Shapiro reaction. Since it was hoped that a very bulky protecting group on the primary alcohol would change it into a large inert moiety, thus rendering the subsequent borane addition/oxidation sequence highly regioselective, triisopropylsilyl triflate in the presence of triethylamine was used as

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, KOBu$^t$, THF, 0 °C, then $PhSCH_2I$, THF, −78 °C, 30 min; ii, HCl·EtOH, room temp., 16 h; iii, KOH, $N_2H_4$, diglycol, 200 °C, 4 h; iv, TsCl, DMAP, $CH_2Cl_2$, room temp., 16 h; v, KOBu$^t$, THF, 65 °C, 3.5 h; vi, $NaIO_4$, MeOH, 0 °C → room temp., 16 h; vii, $Ac_2O$, 100 °C, 62 h; viii, KOH, MeOH, room temp., 2 h, then $NaBH_4$, 0 °C, 30 min; ix, $ClSO_2CH{=}CH_2$, $EtNPr^i_2$, $CH_2Cl_2$, −15 °C, 1.5 h

**Scheme 3** *Reagents and conditions*: i, toluene, 111 °C, 20 h; ii, Pd/C, $H_2$, THF, room temp., 16 h; iii, Bu$^s$Li, $O_2$, THF–HMPA (7 : 1), −78 °C, 3 h; iv, $TsN_2H_3$, TsOH, EtOH, MS 3 Å, 78 °C, 2 h; v, BuLi, THF, 75 °C, 50 min; vi, $Pr^i_3SiOTf$, $NEt_3$, THF, −78 °C, 2 h; vii, $BH_3$·THF, THF, 0 °C, 24 h, then NaOH, $H_2O_2$, EtOH, 50 °C, 3 h; viii, DMSO, $(COCl)_2$,$NEt_3$, $CH_2Cl_2$, −60 °C; ix, $Ph_3PMeBr$, KOBu$^t$, benzene, room temp., 48 h; x, $Bu_4NF$, THF, room temp., 18 h

the silylating reagent. Although models indicate a remarkable regional shielding of the cyclopentene **12** the observed selectivity was less than 1.5 : 1 in favour of the desired ketone **13**.

As the chromatographic separation of the intermediate pairs of epimeric secondary alcohols did not pose any problems and the subsequent Swern oxidation gave a high yield of the corresponding ketone, we were at this stage ready to use a Wittig reaction for the introduction of the exocyclic double bond. This operation as well as the subsequent deprotection with tetrabutylammonium fluoride proceeded in very high yield and gave rise to (−)-myltaylenol **1**, which by comparison with authentic spectra kindly provided by Dr Matsuo proved to be the desired natural compound.

The kind help provided by Dr Matsuo is highly appreciated. The work described was supported by the Fonds der Chemischen Industrie, and S. Doye is grateful for a Kekulé scholarship from this institution.

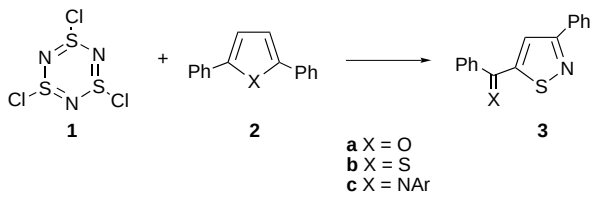
# Conversion of pyrroles into bis-1,2,5-thiadiazoles: a new route to biheterocycles

**Xiao-Guang Duan and Charles W. Rees**

*Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*

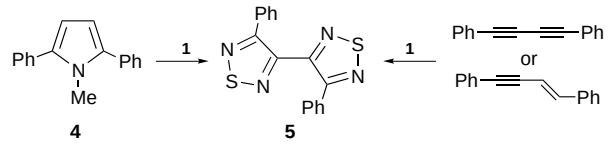
**Trithiazyl trichloride 1 converts 1-aryl-2,5-diphenylpyrroles 2c into isothiazole imines 3c, but 1-alkyl-2,5-diphenylpyrroles (*e.g.* 4) react very differently to give the bis-1,2,5-thiadiazole 5 in which two N–S–N units have been fused onto the pyrrole and the alkyl–N unit has been excised, in a new dissection of the pyrrole ring, thus providing a novel route to an aromatic biheterocycle.**

There has recently been a marked revival of interest in biheterocyclic systems (known for over a hundred years[1]) since they appear as structural subunits in many natural products and in conducting polymers like polypyrrole and polythiophene, and they have provided a wide range of finely tuned chelating ligands in coordination and organometallic chemistry.[1] The many different biheterocycles reported have been prepared by standard coupling, cyclisation and cycloaddition reactions, together with a few reactions involving the extrusion of sulfur or dinitrogen. We now describe an entirely new and unusually short route to such a system, the bis-1,2,5-thiadiazoles.



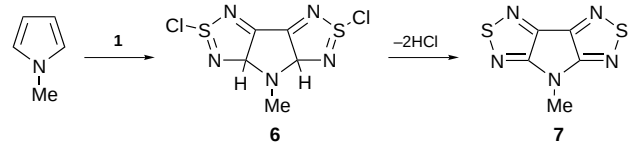
We have shown that trithiazyl trichloride **1** reacts with 2,5-diphenylfuran **2a** to give 5-benzoyl-3-phenylisothiazole **3a** regiospecifically and in high yield; 2,5-diphenylthiophene **2b** and **1** gave the same product, by formation and oxidation of the analogous thiobenzoyl compound **3b** (Scheme 1).[2] We have also shown that **1** reacts with 2,3-unsubstituted pyrroles by fusing an N–S–N unit across this bond to give pyrrolo-[1,2,5]thiadiazoles (*e.g.* **7** below), often in high yield.[3]

We now find that 1-aryl-2,5-diphenylpyrroles **2c** react with **1** in the same way as **2a** and **2b** to give the analogous products, the imines **3c**† (Scheme 1), together with the 3,4-dichloropyrroles† reflecting the high reactivity of pyrroles towards electrophilic substitution. However, when the *N*-aryl groups were replaced by alkyl groups a new and unexpected reaction was observed. Thus treatment of 1-methyl-2,5-diphenylpyrrole **4** with trimer **1** (2 equiv.) in refluxing $CCl_4$ gave a colourless crystalline solid, mp 82–83 °C, with one less carbon and with four nitrogen and two sulfur atoms in its molecular formula ($C_{16}H_{10}N_4S_2$) (45%). Assuming that the MeN unit has been lost and the remaining carbon connectivity retained, the bis-1,2,5-thiadiazole structure **5**† seemed possible. This structure was supported by all the analytical and spectroscopic data and by formation of the same product from 1,4-diphenylbuta-1,3-diyne or (*E*)-1,4-diphenylbut-1-en-3-yne with **1** under the same conditions, in similar yields (43–44%) (Scheme 2).

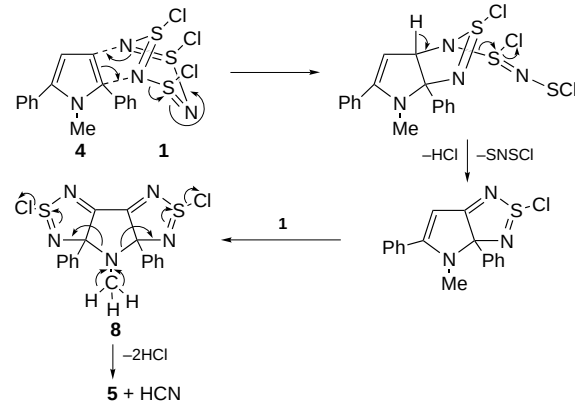


We have explained the formation of 1,2,5-thiadiazoles from such alkenes and alkynes by overall 1,3-cycloaddition of an N–S–N unit in the trimer, followed by loss of the remaining S–N–S unit as $[ClSNSCl]^+ Cl^-$ or $[SNS]^+ Cl^-$.[4] This mechanism is directly applicable to 2,3-unsubstituted pyrroles to give the observed pyrrolothiadiazoles.[3] With *N*-methylpyrrole this process can occur twice *via* an intermediate such as **6**‡ which would rapidly aromatise by elimination of HCl to give the observed product **7** (Scheme 3). The analogous intermediate, **8**,‡ from 1-methyl-2,5-diphenylpyrrole **4** cannot aromatise similarly, but it can do so by loss of two protons from the methyl group which has to be accompanied by cleavage of the *N*–C(α) pyrrole bonds (arrows in **8**) to give the very stable bis-thiadiazole **5** and HCN (Scheme 4).

With the *N*-aryl compounds, the intermediate analogous to **8** cannot aromatise by any such elimination and, if formed at all, would probably be in equilibrium with its precursors; the reaction therefore takes the different pathway described above (Scheme 1). Thus the dominant role of the *N*-substituent, and the extensive rearrangement involved in the conversion of **4** into **5**, whilst initially puzzling, appear to be mechanistically reasonable.



Hydrogen cyanide was shown to be a product of the reaction of trimer **1** with pyrrole **4** by using commercial HCN length-of-stain detector tubes.§ Blank experiments showed that this method was not sensitive to the hydrogen chloride formed in the reaction but that the monomer, NSCl, in thermal equilibrium with the trimer, did interfere if it were not efficiently condensed



**Scheme 1**

**Scheme 2**

**Scheme 3**

**Scheme 4**

out before the exit gases passed through the detector tube. Other *N*-alkyl-2,5-diphenylpyrroles reacted with **1** to give the bis-thiadiazole **5**, accompanied by 3,4-dichlorination of the pyrrole ring. The best yields of **5** were obtained from the *N*-methyl **4** and the *N*-ethyl compounds, and were improved further (to 70%) in the presence of 4 Å molecular sieves. Conversion of 1-ethyl-2,5-diphenylpyrrole into bis-thiadiazole **5** is presumably accompanied by the formation of methyl cyanide (*cf.* **8**), but certainly not HCN, and no colour change was observed in the detector tube for this reaction.

Formation of bis-1,2,5-thiadiazole **5** form *N*-alkylpyrroles and **1** represents a new dissection of the pyrrole ring and provides a novel and short route to an aromatic biheterocycle; very few bis-1,2,5-thiadiazoles have been reported,[5] and hitherto they were not readily available.

We thank Zeneca Specialties and MDL Information Systems (UK) Ltd for financial support, the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, and Dr Tai-Yuen Yue for valuable discussions.

## Footnotes and References

† All new compounds have been fully characterised by elemental analysis, spectroscopy and mass spectrometry.
‡ In **6** and **8** the sulfur–chlorine bonds are shown as covalent, but these would be partly ionised, at least, to the thiadiazolium chlorides.

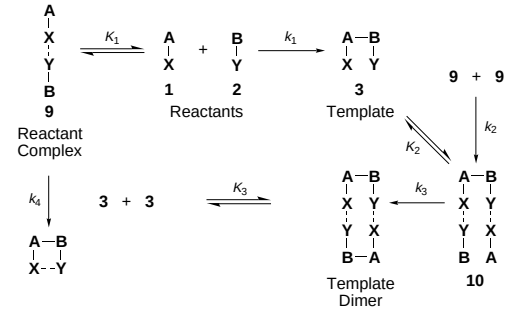
# Self-replication in a Diels–Alder reaction

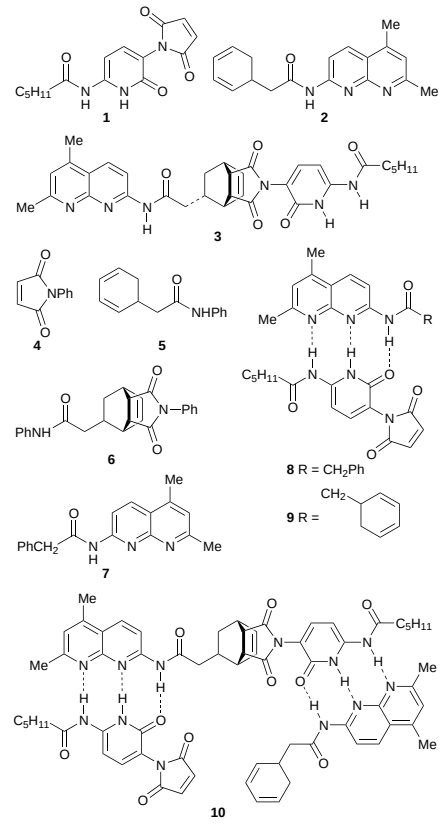
**Bing Wang and Ian O. Sutherland***



*Department of Chemistry, University of Liverpool, PO Box 147, Liverpool, UK L69 3BX*

**The Diels–Alder reaction between ene 1 and diene 2 at 23 and 40 °C shows sigmoidal characteristics for the formation of product 3 and a response to added 3 that indicates that it is an efficient catalyst for the reaction.**

Replication is an essential feature of biological systems and simple chemical analogues have been studied, usually as possible models for prebiotic replication.[1,2] The simplest example of a self-replicating system is the autocatalytic synthesis of a self-complementary molecular template (Scheme 1) and examples of such systems involving self-complementary oligonucleotides have been described[1,3] by von Kiedrowski and Orgel. Other examples which have been developed have been based upon amide formation, studied[4] by Rebek and co-workers and recently the subject[5] of a careful kinetic analysis, and anil formation studied[6] by von Kiedrowski's group. Recently Rebek has described[7] a more complex system based upon four different reactants giving two complementary templates.



Here we describe a novel self-replicating system of the type shown in Scheme 1 which is very different from the original examples inspired by consideration of prebiotic evolution. The reaction centres (**A** and **B** in Scheme 1) were selected as the ene and diene components of the classical Diels–Alder reaction because it is known[8] that the Diels–Alder reaction can be catalysed effectively by complexation of the reactants in a suitably designed ditopic host. The binding sites (**X** and **Y** in Scheme 1) were selected on the basis of work[9] by Kelly and co-workers. After careful consideration of molecular models,[10] the existing kinetic data for Diels–Alder reactions, solubility requirements and synthetic accessibility, the 6-acylamino-2-pyridone derivative **1** and the 2-acylaminonaphthyridine **2** were selected as target ene and diene systems and were synthesised by conventional procedures.

The model compounds **4** and **5** lacking the binding sites reacted very slowly in $CD_2Cl_2$ at 23 and 40 °C and the course of the reaction could be followed by $^1$H NMR spectroscopy; the product **6** is assumed to have *endo*-stereochemistry but may consist of one or both of the two possible *endo*-diastereoisomers. Reactant pairs **4** and **2** and **5** and **1** reacted together at similar rates but the pair of reactants **1** and **2** with complementary binding sites reacted relatively rapidly at both 23 and 40 °C to give product **3**, probably a mixture of *endo*-diastereoisomers, in good yield. Fig. 1, based upon integration of alkenic $^1$H NMR signals in diene **2** and product **3**, shows the rate of product formation at 40 °C; the signals of the diastereoisomers of **3** overlap and no attempt has been made to separate the diastereoisomeric reaction pathways. The sigmoidal character of the reaction curves at both temperatures indicates that an autocatalytic process of the type shown in Scheme 1 could be operating, whereas the reaction of **4** and **5** shows simple second order characteristics. The catalysis of the reaction of **1** and **2** by product **3** was confirmed by carrying out the reaction in the presence of 0.05 and 0.1 equiv. of product **3** (see Fig. 1 which shows the results); the reaction under these conditions shows initial catalysis and a loss of the induction period associated with sigmoidal character.

**Scheme 1** A simple self-replication cycle. **A** and **B** represent reacting groups attached to complementary binding sites **X** and **Y**. The full lines represent covalent attachment and the broken lines represent hydrogen bonding interactions.

The results at 40 °C were analysed in terms of the reactions and equilibria shown in Scheme 1 using a computer model† including all of the reactions and equilibria and the insertion of trial values for the rate constants and the equilibrium constants. The value of $K_1$ was found by a study of the association between pyridone **1** and the acylaminonaphthyridine **7** using an $^1$H NMR titration procedure, in which increments of **7** were added to a 0.02 M solution of **1** in $CD_2Cl_2$, and the chemical shifts of the NH protons were used in association with a simple computational procedure for finding a 'best fit' value for the association constant. The values of $K_1$ (228 mol l$^{-1}$ at 23 °C and 163 mol l$^{-1}$ at 40 °C) are consistent with some inhibition of binding (*cf.* ref. 9) between the two components of the complex **8** as a result of non-bonding interactions between the 7-methyl substituent on the naphthyridine and the alkyl group of the pyridone side-chain at position 6. These interactions, which are

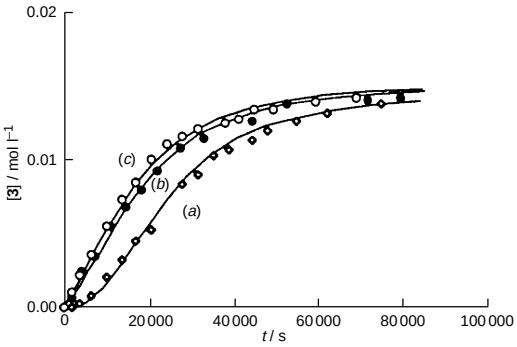


**Fig. 1** Observed and calculated reaction curves for the Diels–Alder reaction between **1** and **2** at 40 °C based upon Scheme 1: (*a*) 0%, (*b*) 5% and (*c*) 10% added template. The best fit for observed and calculated data is obtained with $k_1 = k_2 = 3.5 \times 10^{-5}$ l mol$^{-1}$ s$^{-1}$, $K_1 = 163$ l mol$^{-1}$, $K_2 = 2.66 \times 10^4$ l$^2$ mol$^{-2}$, $k_3 = 2.0 \times 10^{-3}$ s$^{-1}$, $K_3 = 2.66 \times 10^4$ l mol$^{-1}$, $k_4 = 0$ s$^{-1}$. Experimental errors in the concentrations of product **3** derived from NMR spectra are probably of the order ±0.0005 mol l$^{-1}$.

evident in molecular mechanics calculations,[10] are also expected to inhibit the dimerisation of product **3** and the formation of the templated reaction complex **10**. Accordingly a value of $K_1^2$ was assigned to the equilibrium constant $K_2$ and values of $K_3$ were chosen in the range $K_2/10$ to $10K_2$. Assignment of values to $k_4$ greater than $10^{-7}$ s$^{-1}$ did not reproduce the observed induction period for the reaction and, as expected, this reaction does not appear to make a significant contribution to the formation of product **3**. The value for $k_1$ was based initially upon the second order rate constant for the reaction of the model ene **4** and diene **5** and the reaction between complexed pairs of reactants was assumed to have a rate constant $k_2$ with the same value as $k_1$. Trial values for the first order rate constant $k_3$ for the catalysed reaction were selected in association with trial values of $K_3$. Eventually it was found that a good fit between observed and calculated reaction curves could not be obtained unless a considerably lower value than that obtained from the reaction of **4** and **5** was selected for $k_1$ and $k_2$, and the final values for rate constants and equilibrium constants are summarised below Fig. 1 which shows the comparison of observed and calculated results. It is not clear why the reaction of **4** and **5** is not a good model for the uncatalysed reaction of **1** and **2**. We note that the experimental data points have the lack of precision associated with integration of NMR signals but in spite of this the agreement between observed and calculated data is satisfactory for the reaction at 40 °C. The results at 23 °C were more difficult to analyse in the same way and satisfactory agreement between observed and calculated data has not yet been obtained, although the data does fit the simpler reaction scheme discussed below.

The calculated effective molarity of the catalysed reaction (7 mol l$^{-1}$ at 40 °C) is based upon the value of $k_3$ and the value of the bimolecular rate constant $k$ for the model reaction of **4** and **5** ($6.98 \times 10^{-5}$ mol$^{-1}$ s$^{-1}$ at 23 °C and $2.81 \times 10^{-4}$ mol$^{-1}$ l s$^{-1}$ at 40 °C) rather than the rate constant $k_1$ which cannot be measured directly, although the value of the latter suggests that this effective molarity may be an underestimate. It indicates that transition state binding by the template is reasonably efficient since it is of the same order as the effective molarity (4 mol l$^{-1}$) observed for the acceleration of a Diels–Alder reaction within a well designed cavity as reported by Sanders and co-workers.[8] It is evident from the calculations that a good sigmoidal reaction curve for the reaction in the absence of added template (see Fig. 1) requires both a moderately high effective molarity in the template catalysed reaction and a reasonably low value for the dimerisation constant $K_3$. That the Diels–Alder reaction allows this is a consequence of a transition state that resembles product but has partial bonds that are more flexible than those of the rigid bicyclic system in the product. Furthermore the template **3** holds the reactive groups of the ene **1** and diene **2** in close proximity and the intramolecular reaction in the reactant complex **9** is prevented by preference for an *endo*-transition state which requires the extended arrangement for reactants shown in **10**.

Other self-replicating systems have often been analysed[1b,3c,4] in terms of Scheme 2 involving only two reactions with a value for α of 0.5. This simple scheme with $\alpha = 0.5$ did not produce calculated reaction curves in accord with our results but more extended calculations using values for α between 0.5 and 1.0 gave a good fit for a rate law of the type shown in Scheme 2 and a value for α of 0.8 (details of calculated rate constants are given below the scheme). This value for α is based upon a value for $k_1$ equal to that computed for rate constants $k_1$ and $k_2$ in Scheme 1 and we note that the 'best fit' value for α varies as $k_1$ varies. An ideal system would have a value for α close to 1.0 which would require a value for $K_3$ much lower than that for $K_1^2$.

$$\mathbf{A} + \mathbf{B} \xrightarrow{k_1} \mathbf{C}$$

$$\mathbf{A} + \mathbf{B} + \alpha\mathbf{C} \xrightarrow{k_2} (1+\alpha)\mathbf{C}$$

Overall rate: $dC/dt = k_1[A][B] + k_2[A][B][C]^{\alpha}$

**Scheme 2** A simplified reaction scheme for a self replication cycle. **A** and **B** are the two reactants giving **C** which is a catalytic template for the reaction, and α lies between 0 and 1. A satisfactory agreement between observed and experimental data is obtained with the following values of rate constants and a value for α of 0.8: at 23 °C, $k_1 = 6.98 \times 10^{-6}$ l mol$^{-1}$ s$^{-1}$ and $k_2 = 0.133$ l$^{1.8}$ mol$^{-1.8}$ s$^{-1}$; at 40 °C, $k_1 = 3.5 \times 10^{-5}$ and $k_2 = 0.350$ l$^{1.8}$ mol$^{-1.8}$ s$^{-1}$.

The Diels–Alder reaction of **1** and **2** differs from reactions reported in other work in that reactant **2** and product **3** are chiral and that **3** can, in principle, be formed as four possible diastereoisomers. These stereochemical features, which will be discussed in the full paper, lead to diastereoisomeric reaction pathways which have not been separated in the kinetic analysis above.

We conclude that the Diels–Alder reaction with a well-defined bicyclic transition state offers a basis for efficient self-replicating systems that could be investigated for transfer of chemical information coded in terms of the regio- and stereo-selectivity[1b] of template catalysed bond formation. Other reactions with well-defined transition states which generate stereo- and regio-isomers may offer similar possibilities.

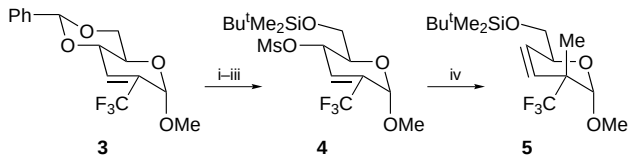
# Highly regio- and stereo-selective alkyl substitution with copper reagents for the construction of chiral trifluoromethylated quaternary carbon centres

**Shuichi Hiraoka, Takashi Yamazaki* and Tomoya Kitazume**

*Department of Bioengineering, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama 226, Japan*

**A new route for the asymmetric construction of quaternary carbon centres containing a trifluoromethyl group has been established using a highly regio- and stereo-selective $S_N2'$ reaction of organocopper and organocuprate reagents with allylic mesylates 4 and 8.**

Enhancement of biological activity in many natural product classes by the selective introduction of one, two or three fluorine atoms is a proven cornerstone strategy for medicinal and bioorganic chemists.[1] We were intrigued by the stereospecific replacement of either methyl group in the structure **1**, as found

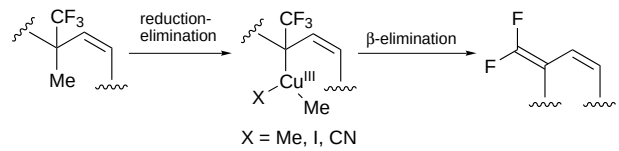


**1** $R^1 = R^2 = Me$
**2a** $R^1 = CF_3$, $R^2 = Me$
**2b** $R^1 = Me$, $R^2 = CF_3$

in Epothilone A[2] and antitumour active Shikoccidine derivatives,[3] by a trifluoromethyl moiety, which would lead to the sterically as well as electronically modified structures **2a** or **2b** with an additional asymmetric carbon centre. However, as far as we are aware, the Diels–Alder reaction of 2-(trifluoromethyl)acrylate[4] is the only reported procedure to access such a target structure, possibly due to the difficulty of alkyl substitution at a $CF_3$-attached carbon centre.[5] Although in general the $S_N2'$ reaction and 1,4-addition of cuprates are among the most efficient methods for the synthesis of quaternary centres,[6] such an approach has not yet been attempted in this context.

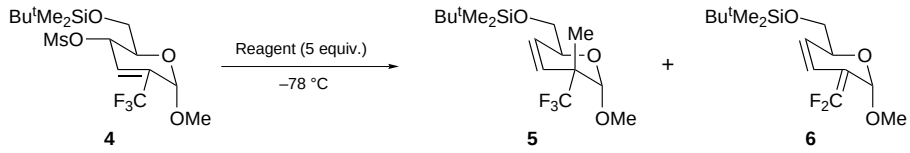
Recently we reported a novel strategy for the synthesis of optically active compounds with variously fluorinated methyl groups ($CH_{3-n}F_n$: $n$ = 1–3) *via exo*-difluoromethylene compounds synthesised from commercially available D-glucose.[7,8] Utilization of the readily accessible allylic alcohol **3** *via* $S_N2'$ reaction with copper reagents is an attractive way to create diastereoselectively a quaternary centre. An additional synthetic advantage of this approach is the possibility of controlling the alkene stereochemistry as *Z*, an outcome which is not easily obtainable otherwise. Here we describe the regio- and stereoselective alkyl substitution of allylic mesylates **4** and **8** using organocopper and organocuprate chemistry.

At the initial stages of this investigation, we chose the substrate **4** depicted in Scheme 1. To our surprise, reaction of allylic mesylate **4**, easily prepared from **3** in three steps, with



**Scheme 1** *Reagents and conditions*: i, TFA, MeOH–$H_2O$; ii, $Bu^tMe_2SiCl$, imidazole; iii, MsCl, $Et_3N$; iv, organocopper and organocuprate reagents

Gilman cuprate $Me_2CuLi$–LiI in $Et_2O$ gave the unexpected diene **6** in 98% yield, rather than either the $S_N2'$ product or the common $S_N2$ type byproduct (Table 1, entry 1). Although the desired $S_N2'$ material **5** was furnished in 35% yield after changing the solvent to THF, **6** was still the main product (54% yield, entry 2). Formation of **6** may be rationalized by the preferential Cu–F elimination because of the relatively poor reductive elimination ability of the Me ligand on the intermediary σ-copper(III) adduct (Scheme 2).† One result which supported this assumption was obtained by the addition of the electron-donating bidentate amine tetramethylethylenediamine (TMEDA) to the conditions used in entry 2: TMEDA was considered to make the ground state more stable than the corresponding transition state by analogy with HMPA,‡ and the yield of **6** was significantly increased from 54 to 92% (entry 2 *vs.* 6).



The above unfavourable pathway giving the difluorinated diene **6** was avoided by the use of cyanocuprate, known to undergo a facile reductive elimination,[9,10] resulting in complete $S_N2'$ displacement (entry 5). Moreover, it was also found that addition of $BF_3$ to the Gilman cuprate $Me_2CuLi$–LiI effectively suppressed the Cu–F elimination irrespective of the solvent (entries 3 and 4). Treatment of **4** with organocopper reagent, MeCu–LiI, yielded **5** with high stereoselectivity and complete γ-selectivity (entry 7). On the other hand, in sharp contrast to the case of the Gilman reagent, significant retardation of the reaction by $BF_3$ was observed, and this system furnished the $S_N2'$ product **5** in a disappointing 18% yield (entry 8).

It is well-known that the use of an organocopper reagent in a different solvent and/or in the presence (or absence) of ligands or Lewis acids sometimes leads to the formation of different species or equilibration mixture, and Table 1 collects the proposed reactive species in each specific conditions. Lipshutz *et al.* claimed that in $Et_2O$ solution $Me_2CuLi$ exists in the dimeric form $Me_4Cu_2Li_2$ (entry 1), while further addition of 2 equiv. of $BF_3$ affords a mixture of $Me_5Cu_3Li_2$ and MeLi–$BF_3$ (entry 3).[11] In THF, $Me_2CuLi$ forms an equilibrium mixture of MeLi, $Me_3Cu_2Li$ and $Me_4Cu_2Li_2$ (entry 2), which is converted to $Me_3Cu_2Li$ and MeLi–$BF_3$ when such a solution is treated with $BF_3$ (entry 4).[12] It should be noted that the dimeric Gilman cuprate $Me_4Cu_2Li_2$ is the reactive species leading to *exo*-difluoromethylene compounds **6** (entries 1 and 2). On the basis of chemical and NMR spectroscopic experiments, Lipshutz also proposed that MeCu–LiI was in an equilibrium with a MeLi–$BF_3$ complex and $I_2CuLi$ in the presence of $BF_3$[13] and thus, comparison of entries 7 and 8 suggests only low reactivity of MeLi–$BF_3$ in this procedure. Consequently, it is concluded that both $Me_5Cu_3Li_2$ and $Me_3Cu_2Li$ should be the 'true' reacting species giving **5** by smooth reductive elimination.

[a] 5 quiv. based on **4**. [b] Determined by $^{19}F$ NMR spectroscopy. [c] Ref. 12. [d] 10 equiv. [e] Ref. 11. [f] $BF_3$ was added at −60 °C. [g] 5 equiv. [h] Ref. 13. [i] Starting material (76%) was recovered.

Next, we performed the same reaction with a different substrate containing a $CF_3$ group at the 4-position. The requisite allylic mesylate **8** was prepared as shown in Scheme 3.

As was our expectation, treatment of **8** with cyanocuprate MeCuCNLi, the best reagent with the allylic mesylate **4**, furnished **9** again as a single stereoisomer in 96% yield. For the determination of the stereochemical course of this $S_N2'$ reaction, **9** was subjected to hydrogenation and the C-4 methyl group of thus obtained **11** was concluded to be axially oriented from NOE measurements (Scheme 3). This result is rationalized in terms of the well-accepted *anti* $S_N2'$ mechanism.[14] Deprotection of methyl glucoside **9** with $BBr_3$ and formation of the dithioacetal allowed us to readily transform **9** into the corresponding acyclic form **10** with complete retention of (*Z*) stereochemistry (11.6 Hz between H-2 and H-3).

In conclusion, a novel pathway for the highly regio- and stereo-selective $S_N2'$ reaction of allylic mesylates **4** and **8** has been realized, which forms a unique strategy for the construction of chiral quaternary carbon centres containing a trifluoromethyl group. Further application of the present reaction to mono- as well as di-fluoromethylated allylic mesylates is currently being pursued in our laboratories.

This work was financially supported by the Ministry of Education, Science, Sports and Culture of Japan [Grant-in-Aid No. 085269]. One of the authors (S. H.) is grateful for a JSPS research fellowship for young scientists.

# Lariat ethers with a novel proton-ionizable group. Synthesis and solvent extraction of alkali metal cations

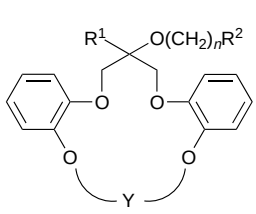
**Vincent J. Huber, Sheryl N. Ivy, Jianping Lu and Richard A. Bartsch***

*Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, USA*

**Novel lariat ethers with pendent *N*-alkyl- and *N*-aryl-sulfonyl carbamoyl groups are synthesized in two steps from *sym*-(decyl)dibenzo-16-crown-5-oxyacetic acid; for competitive solvent extraction of alkali metal cations from aqueous solutions into chloroform by these proton-ionizable lariat ethers with 'tunable' acidity, the selectivity order is $Na^+ \gg K^+$ with no detectable extraction of $Li^+$, $Rb^+$ or $Cs^+$.**

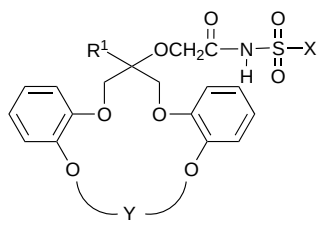
A wide variety of macrocyclic polyether compounds (crown ethers) has been developed for the complexation and separation of metal ions. Many of these crown compounds show superior binding and selectivity towards Group 1 and 2 metal cations compared to other ligands.[1–3] The binding efficiency and selectivity of crown compounds may be increased by the addition of a ligand-bearing side arm to form a lariat ether.[4] Unlike their crown ether analogues, lariat ethers possess three-dimensional cavities for the coordination of metal cations.[5] The properties of these pendent ligation sites, *i.e*. their Lewis basicity and whether they are neutral or ionizable, plays an important role in determining the metal-ion binding properties of the lariat ether.

Previously we have prepared substituted lariat ethers **1** and investigated their applications in solvent extraction and liquid membrane transport of alkali metal cations, as well as their use in polymeric membrane electrodes.[6–8] The $R^1$ substituent on the three-carbon bridge (hydrogen, alkyl, perfluoroalkyl or aryl) affects not only the lipophilicity of the lariat ether, but also the preorganization of the binding site.[9] Moreover, the ligand substituent $R^2$ can be ionizable or neutral, *e.g*. a carboxylic acid or an amide, respectively, depending on the target metal ion and the particular application of interest.[10,11] Proton-ionizable lariat ether carboxylic acids and phosphonic acid monoethyl esters are particularly effective in metal ion separation processes.[12]



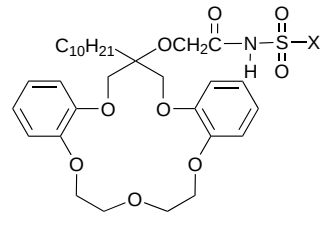
We are now investigating a novel type of proton-ionizable lariat ether in which the acidity of the pendant function is 'tunable'. In *N*-alkyl- or *N*-aryl-sulfonylcarbamoyl lariat ethers such as **2**, variation of the X group (alkyl, perfluoroalkyl or aryl) should influence the acidity of the pendent group. We now report a synthetic route to dibenzo lariat ethers **3**–**6** and the application of these novel lipophilic proton-ionizable lariat ethers in the solvent extraction of alkali metal cations.

The lariat ether **3**–**6** are prepared in two steps from the lipophilic lariat ether oxyacetic acid **7**.[13] A general procedure for the conversion of lariat ether carboxylic acid **7** into the corresponding *N*-trifluoromethylsulfonyl amide **3** is as follows: Benzene (25 ml) was added to **7** (2.00 g, 3.68 mmol) followed by oxalyl chloride (1.90 ml, 22.0 mmol). The resulting mixture was stirred at room temperature under nitrogen for 6 h then evaporated *in vacuo*. The resultant acid chloride was dissolved in dry THF (25 ml) and added to a mixture of pentane–washed potassium hydride (2.10 g, 18.4 mmol) and trifluoromethane sulfonamide (0.66 g, 4.40 mmol) in dry THF (25 ml). The mixture was stirred at room temperature for 10 h under nitrogen and then water (10 ml) was carefully added to destroy the remaining potassium hydride. The THF solution was separated from the aqueous layer and diluted with ethyl acetate (100 ml). The resulting organic solution was washed with 10% aqueous potassium carbonate (2 × 30 ml), dried over magnesium sulfate and evaporated *in vacuo*. The residue was washed with hexanes and purified by column chromatography ($Al_2O_3$, $CH_2Cl_2 \rightarrow 2\%$ MeOH–$CH_2Cl_2$) to give the potassium salt of ionized **3** as a white solid which was dissolved in $CHCl_3$ and washed with 1 M HCl (50 ml). Evaporation of the $CHCl_3$ *in vacuo* gave **3** as a white solid (2.03 g, 82% yield).† Similar procedures were utilized to prepare acetamides **4**–**6**. (For the preparation of **6**, a shorter, 1 h reaction of the lariat ether oxyacetyl chloride with the potassium sulfonamidate gave a cleaner crude product.)



A single crystal of the proton-ionizable lariat ether **3** suitable for X-ray diffraction analysis was grown and its solid-state structure determined. In the structure, the functional side arm is oriented over the polyether cavity, as noted previously for lariat ether carboxylic acid **7**.[14] Thus the presence of the geminal decyl group in **3** preorganizes the coordinating side arm for metal ion complexation.[9]

Solvent extractions of alkali metal cations from aqueous solutions into chloroform by the lariat ether carboxamides were performed.‡ Results from competitive extractions of aqueous solutions containing 20 mM (each) of the alkali metal cations with 5 mM chloroform solutions of **3**–**6** are presented in Fig. 1. Metal ion loadings at pH 11 and selectivity factors are given in Table 1.



The lariat ether oxyacetamide **3**–**6** are found to be efficient extractants with very high selectivity for $Na^+$. The maximal loading is 96–100% as calculated for the formation of 1 : 1 ionized lariat ether–metal ion complexes. Only $Na^+$ and $K^+$ are detectably extracted into the chloroform phase and the $Na^+/K^+$ selectivity is 47–49 under conditions of high loading. The similarity of extraction selectivities for the four extractants indicates that changing X does not exert an appreciable steric

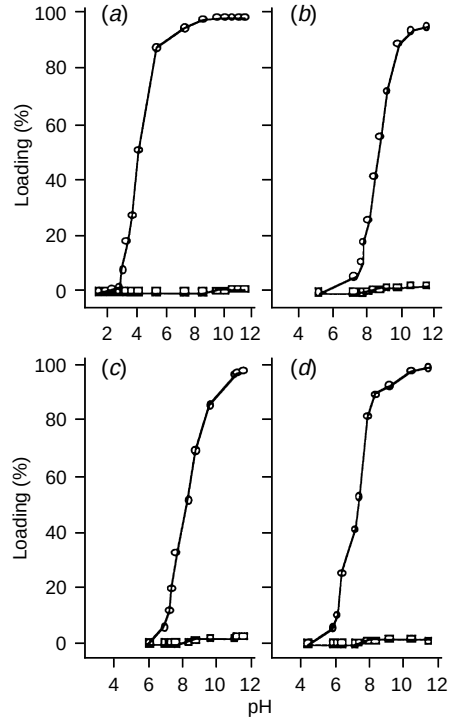

**Fig. 1** Metal loadings of the organic phase *vs.* the pH of the aqueous phase for competitive solvent extractions of 20 mM (each) solutions of alkali metal cations with 5 mM chloroform solutions of (*a*) **3**, (*b*) **4**, (*c*) **5** and (*d*) **6**, with (○) $Na^+$ and (□) $K^+$

**Table 1** Loading and selectivity factors for extraction of alkali metal cations by proton-ionizable lariat ethers **3**–**6** at pH 11[a]

| Extractant | Total loading (%) | Selectivity $Na^+/K^+$ |
|---|---|---|
| **3** | 100 | 49 |
| **4** | 96 | 47 |
| **5** | 97 | 48 |
| **6** | 100 | 49 |

[a] Concentrations of extracted $Li^+$, $Rb^+$ and $Cs^+$ were below detection limits.

effect. However, the variation of X does appreciably influence the side arm acidity. As judged from the extraction profiles, the acidities of the proton-ionizable lariat ethers decrease in the order: **3** > **6** > **4**, **5**. The efficiency with which **3** extracts $Na^+$ from acidic aqueous solutions is noteworthy.

Further investigations of metal ion separations with such 'tunable' proton-ionizable lariat ethers are in progress.

This research was supported by the Division of Chemical Sciences of the Office of Basic Energy Sciences of the U.S. Department of Energy. We thank Dr Frederick J. Brown of Zeneca Pharmaceuticals for the suggestion that *N*-alkyl- and *N*-aryl-sulfonylcarbamoyl groups be incorporated into proton-ionizable lariat ethers. We also thank Dr Carey E. Bauer of Northern Illinois University and Dr Robin D. Rogers of the University of Alabama, Tuscaloosa, for determining the X-ray crystal structure of **3**.

‡ Into a capped, metal-free, plastic 15 ml centrifuge tube was added 2.0 ml of an aqueous solution which was 20.0 mM (each) in sodium, potassium, rubidium and cesium chlorides and 20.0 mM in lithium (chloride + hydroxide). [Due to the higher acidity of **3**, some of the extracted aqueous solutions for this ligand were 20.0 mM (each) in lithium, sodium, potassium, rubidium and cesium chlorides with added HCl.] A 5.0 mM solution of the proton-ionizable lariat ether (2.0 ml) was added and the tube was shaken on a vortex mixer for 4 min and then centrifuged for 4 min to promote complete phase separation. The aqueous phase was removed with a syringe and the equilibrium pH of this aqueous phase was measured with a combination microelectrode. Of the organic phase, 1.5 ml was transferred by syringe into a new plastic centrifuge tube. After adding 3.0 ml of 0.1 M HCl, the tube was shaken on a vortex mixer for 4 min and then centrifuged for 4 min. A portion of the aqueous phase was removed with a syringe and diluted with deionized water for alkali metal cation analysis by ion chromatography.

# A new direct homolytic iodination reaction of alkanes by perfluoroalkyl iodides

**Lucia Liguori, Hans-René Bjørsvik, Anna Bravo, Francesca Fontana and Francesco Minisci***

*Dipartimento di Chimica del Politecnico, via Mancinelli 7, I-20131 Milano, Italy*

**A new method for the direct free-radical chain iodination of alkanes by perfluoroalkyl iodides is described.**

The direct free-radical iodination of alkanes by iodine, unlike the other halogens, is not feasible owing to its large positive enthalpy of hydrogen abstraction [eqn. (1)]. The rates of

hydrogen abstraction from C–H bonds [eqn. (2)] by perfluoroalkyl radicals ($R_f$·) are $>10^3$ times larger than those of the analogous hydrocarbon radicals.[1] Enthalpic (the higher energy of $R_f$–H compared to R–H bonds) and polar (the electrophilic character of $R_f$·) effects influence the rates of hydrogen abstraction. Thus, the rate of hydrogen abstraction by $C_7F_{15}$· from THF, whose α-position is particularly activated by both enthalpic and polar [eqn. (3)] factors, has been evaluated[1] at $6.1 \times 10^5$ M$^{-1}$ s$^{-1}$. On the other hand, alkyl radicals easily abstract iodine atom from $R_f$–I, as shown by the effective free-radical addition of $R_f$–I to alkenes[2] [eqns. (4) and (5)], with the polar effect playing a significant role.

Thus, the conditions of alkane iodination according to the radical chain of eqns. (6) and (7) appeared to be fulfilled.

Iodocyclohexane was obtained in 70% yield, based on $C_4F_9I$, by refluxing a solution of cyclohexane and $C_4F_9I$ in acetic acid in the presence of catalytic amounts of Bu$^t$OOH and $Fe(OAc)_3$. The reaction is explained by the radical chain of eqns. (6) and (7), initiated by a redox system [eqns. (8)–(10)] and represents a new simple, direct iodination of alkanes; we believe[3] eqn. (8) to be operating in this case, rather than eqn. (11).

In order to probe the reactivity–selectivity relationship of the reaction, an investigation was carried out with heptane, adamantane and 1-chlorohexane; heptane gave a mixture of all the iodoheptane isomers (Table 1, including a comparison with chlorination by *N*-chloroamines).

Enthalpic and steric effects contribute to the regioselectivity: the $CH_2$ groups in positions 3 and 4 have substantially the same reactivity, while the $CH_2$ in position 2 is more reactive due to steric factors and the methyl group is less reactive for enthalpic reasons. The behaviour is qualitatively similar to that for chlorination by protonated *N*-chloroamines[4] (Minisci chlorination),[5] in which the selectivity is determined by hydrogen abstraction by $R_2NH^{+\cdot}$.

The free-radical reactivity of adamantane is interesting because the selectivity of hydrogen abstraction is little affected by enthalpic factors, but it is greatly influenced by polar effects[6] (high selectivity with $R_2NH^{+\cdot}$[6] and $ArC(O)OO^{\cdot}$[7] radicals and in electron-transfer processes[8]). The yields obtained according to eqns. (6) and (7) (84.7% 1-iodo- and 15.3% 2-iodo-ada-

**Table 1** Iodination of heptane

| Iodinating agent | Iodination per hydrogen (%)[a] | | | |
|---|---|---|---|---|
| | 1-iodo | 2-iodo | 3-iodo | 4-iodo |
| $C_4F_9I$ | 1 (4.1) | 18.7 (51.0) | 11.1 (30.3) | 10.7 (14.6) |
| $Me_2NHCl^+$ | 1 | 75.8 | 39.5 | 39.0 |
| $Bu^i{}_2NCl$ | 1 | 75.3 | 26.4 | 26.1 |

[a] Figures in brackets indicate the yield of each isomer.

**Table 2** Iodination of 1-chlorohexane

| Iodinating agent | Iodination per hydrogen (%)[a] | | | | | |
|---|---|---|---|---|---|---|
| | 1-iodo | 2-iodo | 3-iodo | 4-iodo | 5-iodo | 6-iodo |
| $C_4F_9I$ | 0.2 (2.1) | 0.3 (3.5) | 1 (12.0) | 2.2 (26.7) | 4.2 (50.0) | 0.3 (5.7) |
| $Me_2NHCl^+$ | — | — | 1 | 2.9 | 10.5 | 0.2 |
| $Cl_2$ | 0.09 | 0.4 | 1 | 1.1 | 1.2 | 0.5 |

[a] Figures in brackets indicate the yield of each isomer.

mantane) confirm the expected influence of the polar effect, due to the electrophilic character of $C_4F_9^{\cdot}$, the higher stability of 1-adamantyl$^+$ with respect to its (secondary) 2-isomer[9] and the oxidation potential of adamantane ($E_{ox}$ = 2.72 V *vs*. SCE), which is lower than that of 2,3-dimethylbutane ($E_{ox}$ = 3.45 V *vs*. SCE).[8]

The iodination of 1-chlorohexane, reported in Table 2 and compared with chlorination by $Me_2NHCl^+$ and $Cl_2$, further supports our ideas about the influence of enthalpic and polar effects in hydrogen abstraction by $C_4F_9^{\cdot}$.

The σ-inductive and field effects of the chlorine atom in 1-chlorohexane are significant in the iodination, but they are lower than in chlorination by $Me_2NHCl^+$. This result suggests that the increase in hydrogen abstraction rates for $R_f^{\cdot}$ compared to the analogous hydrocarbon radicals must be mainly ascribed to the enthalpic effect (higher energy of the $R_f$–H bonds), the polar effect being a significant but minor factor.

We have recently[10] reached the same conclusion concerning the increase in addition rates of $R_f^{\cdot}$ to aromatic substrates, compared to addition of alkyl radicals, which is due mainly to the enthalpic effect, with a significant but minor polar contribution.

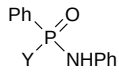
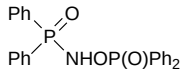
# Base induced rearrangement of *N,O*-bis(diphenylphosphinoyl)hydroxylamine: $^{18}$O-labelling evidence on how the phosphonamidic-phosphinic anhydride product is formed

**Martin J. P. Harger***

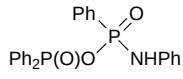


*Department of Chemistry, The University, Leicester, UK LE1 7RH*

**The $^{18}$O-labelled substrate $Ph_2P(O)NHOP(^{18}O)Ph_2$ rearranges with base (KOBu$^t$) to give $Ph(PhNH)P(O)O-P(^{18}O)Ph_2$ but not $Ph(PhNH)P(O)^{18}OP(O)Ph_2$, in accord with a concerted mechanism rather than one involving a metaphosphonimidate intermediate; $Ph(PhNH)P(^{18}O)-OP(O)Ph_2$ is also formed, but only because the substrate rapidly equilibrates with $Ph_2P(^{18}O)NHOP(O)Ph_2$ prior to rearrangement.**

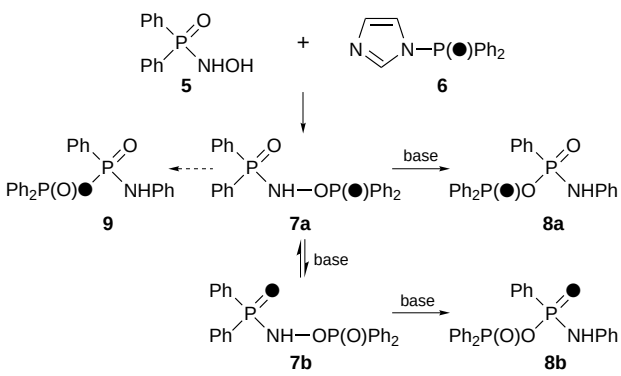


When suitably activated, *N*-phosphinoylhydroxylamines undergo base-induced reactions in which an aryl or alkyl group migrates from phosphorus to nitrogen.[1] Thus, for example, the *O*-sulfonyl compound **1** reacts readily with amines and alkoxides to give the phosphonamidic acid derivative **2** (Y = RNH or RO).[2] The *O*-phosphinoyl compound **3** is much less reactive but with *tert*-butoxide it does rearrange, giving the phosphonamidic-phosphinic mixed anhydride **4**.[3] The formation of **4** is important, adding weight to the circumstantial evidence than an analogous but short-lived phosphonamidic-sulfonic anhydride is formed initially in the rearrangement reactions of **1**.[4] Thus by studying the mechanism of the rearrangement of **3** to **4**, the more versatile and useful rearrangement reactions of **1** and related sulfonyl compounds may also be better understood.

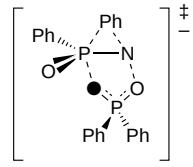


**1**

**2**

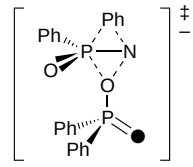


**3**



**4**

Isotopically enriched $Ph_2P(^{18}O)Cl$ was obtained from $Ph_2PCl$ (in $CH_2Cl_2$) by hydrolysis with [$^{18}$O]water (1 equiv.) followed by treatment with chlorine (slight excess). Reaction with *N*-(trimethylsilyl)imidazole then afforded the phosphinylating agent **6** (Scheme 1) and this, on stirring with *N*-(diphenylphosphinoyl)hydroxylamine **5** in $CH_2Cl_2$ (4 h at room temp.), gave the $^{18}$O-labelled substrate **7a**, mp 181–183 °C (from $CHCl_3$–diethyl ether). The mass spectrum of **7a** indicated 78% enrichment with one $^{18}$O atom [*m/z* (FAB) 434 and 436 $(M + H)^+$] and the $^{31}$P NMR spectrum [Fig. 1(*a*)] confirmed the location of the label: $\delta_P$ ($CDCl_3$; 162 MHz) 39.38 or 39.33 (both d, $J_{PP}$ 19 Hz; ratio 22 : 78; $^{18}$O-induced shift 0.048 ppm) and 29.68 (d, $J_{PP}$ 19 Hz).



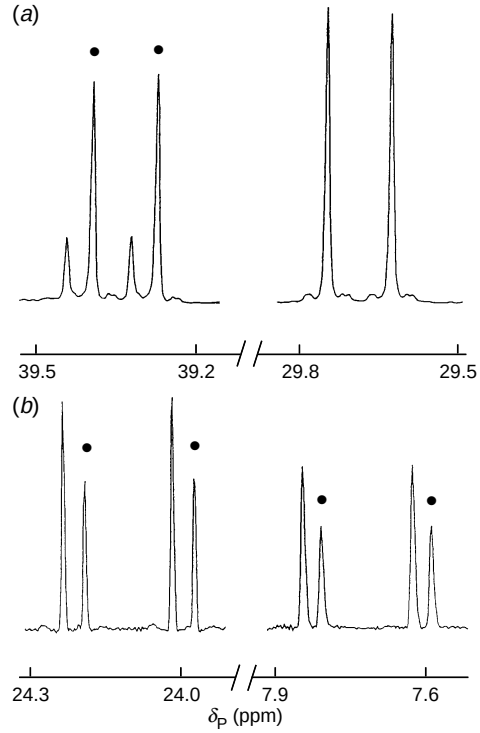
**Scheme 1**

The labelled substrate **7a** (0.07 mmol) was shaken with KOBu$^t$ (0.10 mmol) in *tert*-butyl alcohol (containing 10% $C_6D_6$ for NMR lock) (0.5 ml) and the $^{31}$P NMR spectrum of the reaction mixture was recorded. For the anhydride rearrangement product, $^{18}$O-induced high-field peaks, of equal intensity, were seen in both the phosphinoyl and phosphonamidoyl resonances [Fig. 1(*b*); *t* = 40 min]: $\delta_P$ (reaction mixture; 162 MHz) 24.12 or 24.08 (both d, $J_{PP}$ 35 Hz; $^{18}$O-induced shift 0.044 ppm) and 7.74 or 7.70 (both d, $J_{PP}$ 35 Hz; $^{18}$O-induced shift 0.037 ppm.† This might suggest structure **9** (Scheme 1), with the label located in the bridging (P–O–P) position, and a reaction mechanism in which the conjugate base of the substrate rearranges concertedly *via* a transition state such as **10**. However, the intensities of the isotope-induced high-field peaks (*ca*. 40% of the total signal) are only about half of what they should be for **9**, given the $^{18}$O-enrichment (78%) of the substrate. This points instead to an even distribution of the label between the two non-bridging (P=O) positions of the anhydride product, corresponding to an equal mixture of the structures **8a** and **8b**. Such a labelling pattern is difficult to reconcile with any reasonable rearrangement mechanism, but degradation of the product showed it to be true: reaction with methoxide gave some $Ph_2P(O)OMe$ by attack at one of the phosphorus atoms of the anhydride and some PhP(O)(NHPh)OMe by attack at the other, and these both had $^{18}$O-enrichments (40 and 37% respectively by GC–MS) equal to about half that (78%) of the substrate.

**10**

**11**

The reaction of the labelled substrate **7a** was repeated but with quenching ($CF_3CO_2H$) after just 2 min, at *ca*. 10% completion. The $^{31}$P NMR spectrum of the remaining substrate showed the $^{18}$O label to be equally shared between the P=O groups of the *O*- and *N*-phosphinoyl moieties. Apparently, under the conditions of the rearrangement, the two phosphoryl (P=O) oxygen atoms in the substrate rapidly equilibrate, *i.e.* **7a** ⇌ **7b** (Scheme 1).‡ The product resulting from the rearrangement of **7b** can only be **8b**, with the label in the phosphonamidic non-bridging position, so from **7b** we can learn nothing about the mechanism of the rearrangement. Attention must therefore be focussed on the behaviour of **7a** (half the total $^{18}$O after



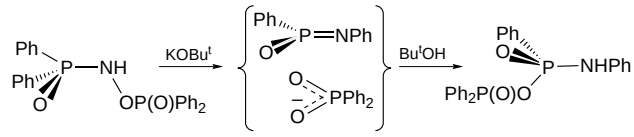


**Fig. 1** $^{31}$P NMR spectra (162 MHz; $^{1}$H decoupled) of (*a*) $^{18}$O-enriched substrate **7a** (in $CDCl_3$) and (*b*) rearrangement product **8a** + **8b** [in Bu$^t$OH–$C_6D_6$ containing KOBu$^t$]; isotope-shifted peaks (●) at high field

equilibration with **7b**). When **7a** rearranges it is a labelled phospinate group [OP($^{18}$O)$Ph_2$] that is transferred from nitrogen to phosphorus, so formation of the new O–P bond might involve the labelled or the unlabelled oxygen atom. The latter seems actually to be the case. In the $^{31}$P NMR spectrum of the rearrangement product [Fig. 1(*b*)] there are substantial high-field isotope-induced peaks for structure **8a** ($\delta_P$ 24.08; $\Delta\delta$ 0.044 ppm), derived from **7a**, and for **8b** ($\delta_P$ 7.70; $\Delta\delta$ 0.037 ppm), derived from **7b**, but not for **9**. In the case of **9** the isotope-induced shifts, due to P–$^{18}$O single bonds, would be relatively small.[5] Appropriate peaks ($\delta_P$ 24.09; $\Delta\delta$ 0.033 ppm) may just be detectable in the phosphinoyl resonance [Fig. 1(*b*)], but they are hardly significant.§ The conclusion must be that, in the rearrangement, the phosphinate group is transferred from nitrogen to phosphorus without any appreciable incorporation of the phosphoryl (P=O) oxygen atom into the new O–P bond. If the rearrangement of the conjugate base of the substrate is concerted, it must proceed *via* a transition state that resembles **11** rather than **10**.

In principle the rearrangement could be non-concerted, with a three-coordinate metaphosphonimidate intermediate, but in that case the phosphinate group would be set free and would become a fully-formed anion (Scheme 2). In the limit the two

**Scheme 2**

oxygen atoms in the anion would be equivalent and involved equally in the formation of the new O–P bond, *i.e.* **7a** would give equal amounts of **8a** and **9**. Initially, when first released from nitrogen, the oxygen atoms of the phosphinate anion might be non-equivalent, because of differences in solvation (by Bu$^t$OH) and/or association with the counterion ($K^+$), but it seems unlikely that they could remain distinct to the extent that only one of them plays any part in forming the new bond to phosphorus. We therefore feel bound to favour a concerted mechanism for the rearrangement, with a transition state resembling **11**, and also to reconsider our preference for a non-concerted mechanism in the case of sulfonyl compounds such as **1**.[6]

We thank Dr G. A. Griffith for recording NMR spectra and Professor P. M. Cullis for advice and encouragement.

## Footnotes and References

† The mixed anhydride reacts very readily with traces of water in basic media. Moisture was excluded as far as possible but some formation of the hydrolysis products $Ph_2P(O)O^-$ ($\delta_P$ 17.53 or 17.49; $^{18}$O-induced shift 0.036 ppm) and Ph(PhNH)P(O)O$^-$ ($\delta_P$ 7.05 or 7.02; $^{18}$O-induced shift 0.035 ppm) could not be avoided.

‡ The unexpected equilibration of the phosphoryl oxygen atoms (or the phosphinoyl groups) is interesting but peripheral to the present investigation.

§ The magnitude of an $^{18}$O-induced shift depends on the environment of the phosphorus atom, but the single bond (P–$^{18}$O) shift is generally in the range 0.3 to 0.7 times the double bond (P=$^{18}$O) shift (ref. 5). That being so, any appreciable amount of **9** would certainly be detectable in the presence of **8a** and **8b**. An attempt to confirm this experimentally, by treating $Ph_2P(O)^{18}O^-$ with Ph(PhNH)P(O)Cl in Bu$^t$OH, was complicated by side reactions but the phosphinoyl resonance of the mixed anhydride clearly showed a single bond shift 0.7 times the double bond shift.

# Decomplexation rate comparisons of hemicarceplexes whose single unique host bridge is changed in length and blocking power

**Juyoung Yoon and Donald J. Cram***

*Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095-1569, USA*

**Decomplexation rates of hemicarceplexes can be manipulated by changes in solvent, guest, one of four host-bridge lengths and one of four host-bridge's blocking power.**

Prior papers reported the syntheses and characterizations of hosts **1**–**6**, as well as crystal structures of **1**⊙4-$MeC_6H_4OMe$, **2**⊙$CHCl_3$, **4**⊙$PhNO_2$ and **6**⊙guests.[1–3] In five crystalline complexes of **6**, the host parts were essentially isostructural and changed only in minor ways when guests of generally similar size were involved (*e.g.* 1,4-$I_2C_6H_4$, 1,4-$Me_2C_6H_4$, $PhNO_2$, 2-$BrC_6H_4OH$ and $Me_2NCOMe$). Decomplexation rates for **7**⊙guests were generally on the human time scale only at temperatures of 100–200 °C, indicating that considerable constrictive binding must be overcome during the decomplexation process.[4,5]

**1**, A = $(CH_2)_5$; **2**, A = 1,3-$(CH_2)_2C_6H_4$; **3**, A = $(CH_2)_6$; **4**, A = 1,4-$(CH_2)_2C_6H_4$; **5**, A = 9,10-$(CH_2)_2$anthracene; **6**, A = $(CH_2)_4$; **7**, all four bridging units are 1,2-$(CH_2)_2C_6H_4$

We report here the results of a survey of decomplexation rates as a function of host structure (**1**–**5**), guest structure (4-MeO-$C_6H_4OMe$, 3-$MeOC_6H_4OMe$, 4-$MeOC_6H_4Me$ and 4-$MeC_6H_4Me$), temperature (25–120 °C) and solvent ($CDCl_3$ and $CDCl_2CDCl_2$).† Hemicarceplex **2**⊙4-$MeOC_6H_4OMe$ was selected as a standard complex, whose first order rate constants were determined by following the appearance in their $^1H$ NMR spectra of methyl proton signals for free guest in $CDCl_3$ at four temperatures (25, 35, 45 and 55 °C) and in $CDCl_2CDCl_2$ at four temperatures (90, 100, 110, 120 °C). The decomplexations exhibited good first order behaviour over several half-lives. The technique and treatment of the data are described in a prior publication as applied to decomplexation kinetics of **7**⊙guests, in which empty host was demonstrated to be the initial product.[4]‡ Table 1 records the activation parameters ($\Delta H^‡$, $\Delta S^‡$ and $\Delta G^‡_{308}$) and $t_{1/2}$ values for decomplexations of **2**⊙4-$MeOC_6H_4OMe$ in the two solvents at 35 °C.§

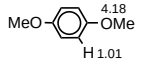
First order rate constants were also determined for decomplexations involving hosts **1**–**4** and the four disubstituted benzene guests at 35 °C in $CDCl_3$. With use of eqn. 1, $k_{relative}$

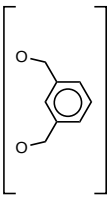
$$k_{relative} = k_{H⊙G}/k_{\mathbf{2}⊙4\text{-}MeOC_6H_4OMe} \quad (1)$$

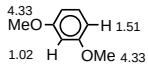
values were obtained, from which $\Delta G^‡$ values for nine complexes were calculated, and a lower limit of $\Delta G^‡$ for **5**⊙4-$MeOC_6H_4OMe$ was estimated. Table 2 provides the structures of the eleven complexes, the values of rate constants, and $\Delta G^‡_{308}$.

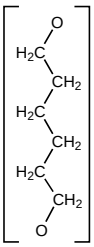
The most striking feature of the results is that the simple change of solvent from $CDCl_3$ to $CDCl_2CDCl_2$ resulted in an increase of activation free energy for decomplexation of **2**⊙4-$MeOC_6H_4OMe$ of $\Delta(\Delta G^‡_{308})$ = 4.1 kcal $mol^{-1}$. The enthalpy, $\Delta(\Delta H^‡)$ = 6.2, and entropy changes, $\Delta(T\Delta S^‡)_{308}$ = 2.1, both contribute to the change in free energy, but the enthalpy change is the larger contributor by 4.1 kcal $mol^{-1}$. The decomplexation half-life for **2**⊙4-$MeOC_6H_4OMe$ is 800 times *longer* in $CDCl_2CDCl_2$ than in $CDCl_3$. The fact that solvation plays such a large role in the transition state for decomplexation suggests that it resembles in structure the dissociated rather than the starting state of the complex. Models (Corey–Pauling–Koltun or CPK) of possible transition states show that to be significantly solvated, the guest must protrude substantially from the portal for multiple guest–solvent contacts to be made. The fact that $CDCl_2CDCl_2$ is much larger than $CDCl_3$ suggests that steric inhibition of solvation of the transition state for decomplexation is responsible for this very large effect of solvent on rate. The only other study of the effects of solvent on rates of decomplexation of hemicarceplexes involved **7**⊙$Me_2NCOMe$ (100 °C).[4] The rate constants decreased by an overall factor of about 45, and in the following order as solvent was changed: $C_6D_5Br$ > $C_6D_5Cl$ > 1,2-$(CD_3)_2C_6D_4$ > 1,4-$(CD_3)_2C_6D_4$ > $CDCl_2CDCl_2$ > $C_6D_5CD_3$. The six solvents vary considerably in their polarity and polarizability, but little in their overall size, compared to $CDCl_3$ *vs.* $CDCl_2CDCl_2$.

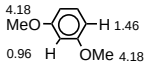
An examination of a CPK model of host **6** which contains four $O(CH_2)_4O$ bridges indicates that although the four portals are 26-membered rings, there is little chance of the substituted benzenes of this study entering or departing the inner phase of this hemicarcerand except at very high temperatures. Experimentally, **6**⊙4-$MeC_6H_4OMe$ was formed only when **6** was heated in molten guest at 170 °C for 3.5 days.[3] Decomplexation of **6**⊙$Me_2NCOMe$ required heating a solution of the complex in $Ph_2O$ at 195 °C for 5 days. We conclude that the complexations and decomplexations of **1**–**5** occur through the two 27- or 28-membered ring portals partially defined by the unique bridge.

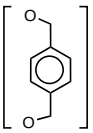


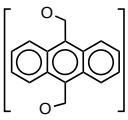












Comparisons of the activation free energies (Table 2) for decomplexations in $CDCl_3$ at 35 °C of various complexes of 4-$MeOC_6H_4OMe$ as a common guest show the effects of portal

[a] 400 MHz in $CDCl_3$ at 25 °C. [b] $\Delta G^{\ddagger}_{308} = 23.7 - RT\ln k_{relative}$.

size and blocking power of the unique bridge. For example, $\Delta G^{\ddagger}$ is 25.2 kcal mol$^{-1}$ with O(CH$_2$)$_5$O as the unique bridge, but decreases to 22.0 kcal mol$^{-1}$ with O(CH$_2$)$_6$O as the unique bridge. This decrease of 3.2 kcal mol$^{-1}$ reflects the increase of portal size by one $CH_2$ group added to the portal ring members (27 increased to 28), and corresponds to an increase in rate constant by a factor of 177. When the unique bridge is not increased in portal ring members but is decreased in blocking power by substitution of a 1,3-C$_6$H$_4$ for the internal (CH$_2$)$_3$ of the O(CH$_2$)$_5$O bridge, the $\Delta G^{\ddagger}$ value decreases by 1.5 kcal mol$^{-1}$, and the rate constant increases by a factor of 12. When the unique bridge is not changed from 28 portal ring members, but is increased in blocking power by substitution of a 1,4-C$_6$H$_4$ group for the central (CH$_2$)$_4$ moiety of O(CH$_2$)$_6$O, the $\Delta G^{\ddagger}$ value increases by 1.4 kcal mol$^{-1}$, and the rate constant decreases by a factor of 9.5. These trends correlate with the near-planarity of the 3-OCH$_2$C$_6$H$_4$CH$_2$O bridges in crystal structures of complexes containing these bridges,[6] and the near-perpendicularity of the aryl plane and the OCH$_2$··CH$_2$O plane in the crystal structure of **4**⊙C$_6$H$_5$NO$_2$.[2] When the 9,10-(OCH$_2$)$_2$-anthracenyl bridge is substituted for the O(CH$_2$)$_6$O bridge, the $\Delta G^{\ddagger}$ value increases by > 5 kcal mol$^{-1}$, and the rate constant decreases by a factor of at least 600. Model examination of **5** shows that the near perpendicularity of the two near planes of this bridge is enforced, and that the blocking ability of this bridge is greatly increased by the extension of its central ring by the two attached benzo groups. Model examination shows that in spite of this additional blocking effect, the 28-membered rings are still more available for use as portals than are the two 26-membered rings present in **5**.

Notice that independent of whether the host is **2**, **3** or **4** the increasing order of activation energy correlates with guest structural changes as follows: 4-MeOC$_6$H$_4$OMe < 4-MeC$_6$H$_4$OMe < 4-MeC$_6$H$_4$Me < 3-MeOC$_6$H$_4$OMe (see Table 2). For host **2** (27-membered ring portals), the $\Delta G^{\ddagger}$ values provide a spread of only 1.7 kcal mol$^{-1}$. For **3** (28-membered ring portals) an even lower spread of 0.8 kcal mol$^{-1}$ is observed. The more confined entryway is the more selective, as expected.

We interpret the above correlations in terms of the relative contributions of *intrinsic* and *constrictive* binding that must be overcome for decomplexation to occur.[4] The five hosts have similarly shaped cavities generally complementary to the similarly shaped guests, suggesting that the intrinsic binding energies for the complexes are close to one another. In the transition states for decomplexation, the portals of each host must become slot-shaped and complementary to the slot-shaped cross section of the departing guest. Also, by guest rotation, the Me groups must pass from occupying the hosts' axial bowls to being aligned with the equatorially disposed portals. These shape and location adaptations in the transition state must overcome constrictive binding, which should be sensitive to portal-guest complementarity, and to exposure of protruding guest parts to bulk solution.

The authors warmly thank the U.S. Public Health Service for Supporting Grant GM-12640.

† All new complexes gave elemental analyses within 0.30% of theory, and expected $^1H$ NMR and FAB (*m/z*, M + H$^+$) mass spectra.

‡ The reaction G′ + H⊙G → H⊙G′ + G, where G′ is solvent, should give first order kinetics for appearance of G. Formally, a mechanism might apply in which G′ enters H in the same transition state that G departs. When H has multiple potential entryways whose equilibrium dimensions are comparable to cross sections of G′, activation energies for guest substitution are very low, and concerted mechanisms might apply. However, $\Delta G^{\ddagger}$ values for **2**⊙4-MeOC$_6$H$_4$OMe are rather high. Molecular model examinations show that for one portal to become large enough to accommodate guest departure, the other three must decrease their apertures through many small conformational adjustments, thus becoming unavailable for simultaneous solvent entry.

§ Decomplexation kinetics were conducted on 0.5 ml samples of 2 mM solutions of complexes in degassed $CDCl_3$ or $CDCl_2CDCl_2$ in sealed $^1H$ NMR tubes in the probe of a 400 MHz spectrometer adjusted to the desired temperature (±1 °C) after the probe temperature was calibrated with HOCH$_2$CH$_2$OH (ref. 7). The $CDCl_3$ or $CDCl_2CDCl_2$ had recently been passed through a plug of neutral activated alumina. About 20–25 spectra were recorded at appropriate time intervals. The first order rate constants were calculated from the strong signals of the guest methyl groups upon decomplexation. Tables 1 and 2 record the results.

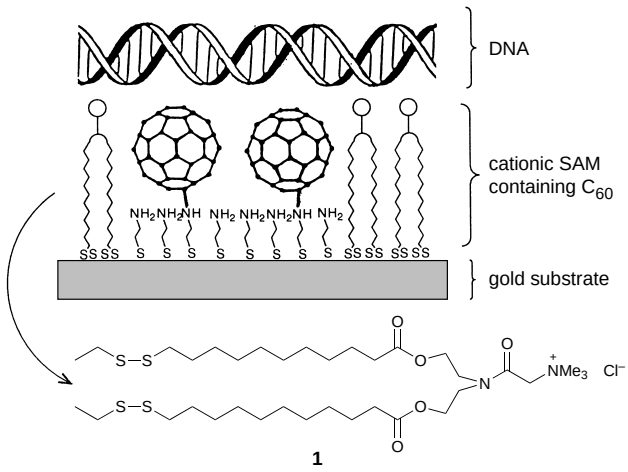
# Immobilization and cleavage of DNA at cationic, self-assembled monolayers containing $C_{60}$ on gold



**Nobuyuki Higashi,*† Takayo Inoue and Masazo Niwa***

*Department of Molecular Science & Technology, Faculty of Engineering, Doshisha University, Kyotanabe, Kyoto 610-03, Japan*

**A cationic, self-assembled monolayer on gold substrate can immobilize DNA without impairing its native structure; the site-specific photocleavage of the DNA is achieved by incorporation of [60]fullerene into the monolayer.**

The immobilization of DNA on a two-dimensional solid surface is of interest both in studies of DNA itself and in various applications. For instance, in atomic force microscopy, the DNA must be firmly affixed to a surface to minimize the effects of tip interactions during scanning.[1] Immobilization of DNA on an electrode is also used to produce biosensors.[2,3] The strategy employed in this study was to prepare, on a gold surface, a well-ordered monolayer assembly that contained cationic groups, such as quaternary ammonium salts, that would interact electrostatically with the phosphate groups of DNA. Monolayer assemblies of this type have been described previously.[4–6] Here we report immobilization of DNA on a self-assembled monolayer (SAM) of **1** and cleavage of the DNA, which is important from biological and clinical viewpoints. Recently, [60]fullerene ($C_{60}$) was found to have a G (guanine base)-selective DNA cleaving ability in the presence of visible light.[7] If $C_{60}$ could be successfully incorporated in the SAMs of **1** (Fig. 1), the immobilized DNA might be expected to cleave site-specifically.

The preparation of **1** and its adsorption property on gold substrate have been described elsewhere.[4,6] The monolayers were first formed by soaking gold mirror plates (prepared by evaporation of gold onto one side of a glass plate, 2 × 2 cm) in solutions of **1** in EtOH for 1 h. Calf thymus DNA was immobilized on the surface by soaking the SAM film in a buffer solution (50 mmol $dm^{-3}$ tris buffer, pH 7.4) of DNA (1 mg $ml^{-1}$) for 2 h. The film was then rinsed several times with the tris buffer to remove free DNA, and dried at room temperature. The reflection–absorption spectrum of this film on gold, which was measured using a multi-channel photodetector (Otsuka Electronics, MCPD–100, Japan), gave an absorption maximum at 263 nm assigned to the π–π* transition of nucleic acid bases of DNA, suggesting the binding of DNA onto the monolayer surface through electrostatic interaction. To estimate the stoichiometry of such an ion complex, the XPS spectra were measured before and after DNA binding. As a result, the phosphorous (phosphate anion in DNA) : nitrogen (ammonium group and amide bond of **1**) ratio was determined to be 2 : 1.7 (±0.3); the ammonium cation : phosphate anion ratio is thus calculated to be 1 : 1.7. This result implies that about half of the total phosphate anions of DNA contributed to the complexation with the cationic surface of **1**-SAM; in other words, half of the anions remained free.

**1**

**Fig. 1** Schematic illustration for immobilization of DNA on the cationic SAM containing $C_{60}$ on gold

Subsequently, the intercalation of Methylene Blue was examined by spectroscopic means. In aqueous solution, intercalation of Methylene Blue into DNA base pairs is known to cause both hypochromism and red shifting of the absorption maximum.[8] These observations are explained by stacking interactions of intercalated dye with base pairs in DNA and electrostatic interactions with phosphate anions of DNA, respectively.[9] In the case of the monolayer-bound DNA, the spectrum of Methylene Blue showed a 6 nm red shift of the absorption maximum. This spectral feature suggests that Methylene Blue was trapped in the monolayer-bound DNA through intercalation, although we were not able to obtain information regarding hypochromism because of difficulty in comparing the absolute absorbance of Methylene Blue before and after intercalation.

To locate $C_{60}$ close to the DNA immobilized at the monolayer surface, mixed monolayers of **1** and 2-mercaptoethylamine (cysteamine) were prepared on gold substrates. Cysteamine, which can form a SAM on gold, was employed since Caldwell *et al.*[10] described that $C_{60}$ could be bound covalently onto cysteamine-modified gold substrates. The mixed monolayer (mole fraction of **1** in the mixture, $f_1$ = 0.2) was prepared by soaking the gold plate in a 1 mmol $dm^{-3}$ EtOH solution containing **1** and cysteamine for 24 h. The monolayer-modified gold plate thus obtained was then soaked in a 1 mmol $dm^{-3}$ benzene solution of $C_{60}$ for 24 h at room temperature. The resulting substrates were thoroughly rinsed in benzene to remove residual physisorbed $C_{60}$. Incorporation of $C_{60}$ in the monolayers was confirmed by measuring the contact angle of water.‡ When the same procedure was performed on a pure **1** monolayer ($f_1$ = 1)-modified gold plate, no binding of $C_{60}$ was observed, as expected. Immobilization of DNA on the mixed monolayer-modified gold plates was carried out in the same manner as described above. To reveal the site-specificity of photocleavage, several types of DNA {salmon sperm DNA, calf thymus DNA, poly[$(dGdC)_2$] and poly[$(dAdT)_2$]} which were different in base pair composition were used. Irradiation experiments were performed under the same condition for all samples. If cleavage of DNA took place, the resultant short fragments, such as oligonucleotides and nucleotides, readily diffused into the bulk phase and were then detectable by spectroscopy.§ Fig. 2 shows UV spectra of the bulk aqueous phases from which poly[$(dGdC)_2$]-immobilized monolayer plates ($f_1$ = 0.2 and added 1) were withdrawn after 3 h irradiation. For comparison, the UV spectrum of an aqueous solution of poly[$(dGdC)_2$] itself at a concentration of 6 × $10^2$

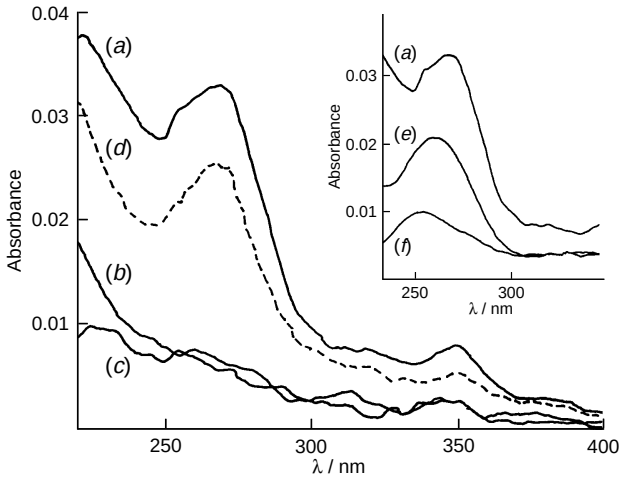


**Fig. 2** UV absorption spectra of aqueous solutions resulting from irradiation of poly[(dGdC)$_2$] monolayers under standard conditions; (*a*) $f_1$ = 0.2 monolayer; (*b*) $f_1$ = 1 monolayer; (*c*) $f_1$ = 0.2 monolayer shielded from the visible light; (*d*) aqueous solution of poly[(dGdC)$_2$] itself at a concentration of $6 \times 10^2$ ng ml$^{-1}$. Inset: spectra of aqueous solutions of DNA monolayers; (*e*) salmon sperm DNA; (*f*) calf thymus DNA, compared with (*a*) treated under the same conditions.

ng ml$^{-1}$ is included in the figure. In the case of $f_1$ = 1 without $C_{60}$, no peak was observed at around 260 nm based on the $\pi$–$\pi$* transition of nucleic acid bases. In contrast, the mixed monolayer ($f_1$ = 0.2)-bound poly[(dGdC)$_2$] gave an absorption peak at 260 nm due to cleaving although the same poly[(dGdC)$_2$] shielded from the visible light did not. These results strongly suggest that the DNA cleavage was caused by singlet oxygen[11] generated by interaction of the photoexcited $C_{60}$ group with molecular oxygen. For the mixed monolayer ($f_1$ = 0.2)-bound poly[(dAdT)$_2$], light irradiation led to no cleavage (data not shown here). Fig. 2 (inset) displays a comparison of UV spectra for different DNA samples. The absorbance at around 260 nm was found to decrease in the following order: ply[(dGdC)$_2$] > salmon sperm DNA > calf thymus DNA, which implies G-selective cleavage of DNA because this order corresponds well to the guanine content in these DNA samples.[12]

In summary, we have demonstrated that cationic SAMs can immobilize DNA without disrupting its intrinsic higher-order structure, and that site-specific cleavage of the DNA is successfully achieved by incorporation of $C_{60}$ into the SAM. A more detailed examination of the cleaved fragments is now in progress.

‡ The mixed monolayer ($f_1$ = 0.2) gave a hydrophilic surface ($\theta_{H_2O}$ = 49°) before adsorption of $C_{60}$. After soaking this mixed monolayer plate in the $C_{60}$ solution, the increased hydrophobicity of the resulting surface ($\theta_{H_2O}$ = 62°) was confirmed *via* contact angle measurements.

§ Immobilization of the DNA samples on the mixed monolayer-modified gold plates (2 × 2 cm) was first carried out, and then the plates were immersed in 2 ml tris buffer solutions (pH 7.4). After 3 h irradiation with visible light ($\lambda$ > 500 nm), UV spectra of the aqueous phases (2 ml) were measured.

# Unusual generation of methoxy groups in Barton deoxygenations of alcohols

**Caroline S. Bensasson, Sir John Cornforth,*† Ming-Hui Du and James R. Hanson***

*School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*

**Reaction of the *S*-methyl dithiocarbonate of lanosterol with excess of tributyltin deuteride and azoisobutyronitrile in benzene afforded lanosteryl methyl ether in which all hydrogen in the methoxy group originated from the organotin reagent.**

In mid-1996 C. S. B. prepared 4,4,17-trimethylandrost-5-en-17β-ol **1** from the *S*-methyl dithiocarbonate **2** in refluxing benzene with tributyltin hydride and the initiator AIBN, an unexpected product, methyl ether **3**, was formed in 28% yield. The ether was thought at the time to be a contaminant, inadvertently formed by a Williamson synthesis, of xanthate **2** which had been prepared by the usual treatment of alcohol **4** with sodium hydride, carbon disulfide and then iodomethane. However, spectra of **2** showed only slight contamination with **3**. Some months later, M. H. D. informed J. C. that an unrelated xanthate had yielded principally the analogous methoxy compound on attempted Barton deoxygenation, and that the corresponding imidazolylthiocarbamate (prepared without use of a methylating agent) gave the same methoxy compound. J. C. mentioned his view of this result to J. R. H., who recalled C. S. B.'s expermiment. We decided to investigate the matter by an experiment with lanosterol.

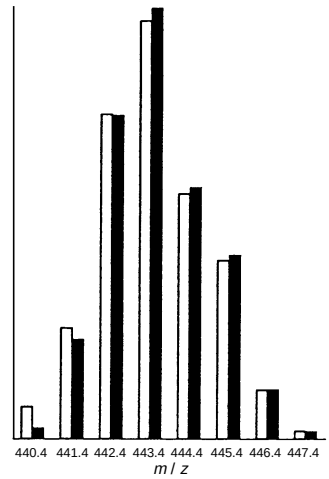
**1** X = H
**2** X = OC(=S)SMe
**3** X = OMe
**4** X = OH

**5** X = OC(=S)SMe
**6** X = OMe
**7** X = H

The lanosterol available was a commercial preparation containing the 24,25-dihydro compound. The *S*-methyl dithiocarbonate **5**, prepared by Barton and McCombie's[1] procedure, contained *ca*. 40% dihydro compound and only traces of methyl ether **6** (by $^1$H NMR spectroscopy). On reduction with tributyltin hydride (5 equiv.; initial concentration 0.17 mol dm$^{-3}$) and AIBN (0.36 equiv.) in boiling benzene for 6 h, a 42% yield of methyl ether **6**, along with deoxygenated product **7**, was formed. With tributyltin deuteride (95 atom%) the yield of **6** was 14%. The $^1$H NMR spectrum of the labelled compound at 500 MHz showed, instead of the sharp 3H singlet of **6** at $\delta$ 3.37, three signals (total 0.75H) at $\delta$ 3.33, 3.35 and 3.37. The $^2$H NMR spectrum showed that all excess deuterium was in the methoxy group and that the $CHD_2$ and $CD_3$ concentrations were about equal, as required by statistical distribution of H and D in a 1 : 3 ratio. This agrees with the total H content and corresponds to an average isotope effect ($k_H/k_D$) of *ca*. 5 for the three hydrogen transfers. The molecular ions in the EI mass spectrum were grouped in eight peaks showing minor amounts of the OMe species **6** with larger proportions of $OCH_2D$, $OCHD_2$ and $OCD_3$ species along with 24,25-dihydro analogues and $^{13}$C companions. The peak pattern was accurately matched (Fig. 1) by the distribution calculated for random substitution of 75% of the methoxy protium by deuterium (as observed by NMR spectroscopy) combined with a 70 : 30 ratio of methoxylanostadienyl ions to methoxylanostenyl ions.‡ The major peak, principally lanostadienyl trideuteromethyl ether ion, had an exact mass of 443.4210 (Calc. for $^{12}C_{31}{}^1H_{49}{}^2H_3{}^{16}O$: 443.4206). The excess of deuterium-free species indicates slight (*ca*. 0.2%) contamination of **5** with pre-existing **6**. These results demonstrate that all three hydrogen atoms in the methoxy group of the reduction product **6** originated from the tin hydride. It follows that the carbon source of this methoxy group was the –OC(=S)S– group.

Barton and co-workers[1–3] have shown that octadecyloxythiocarbonylimidazole with 2 equiv. of tributyltin hydride in boiling toluene gave the hemithioformal $C_{18}H_{37}OCH_2SSnBu_3$, and analogous by-products were also formed from various dithiocarbonates (including *S*-methyl) of cholestanol. Formation of methoxy groups has not been reported until now, although it might well have been observed and misinterpreted as we initially did. As applied to an *S*-methyl dithiocarbonate **8** the mechanism for Barton deoxygenation preferred at first by its originator[3] postulates reversible addition of tributylstannyl radical to the C=S bond (Scheme 1). The ensuing radical **9** can either undergo thermal cleavage to dithiocarbonate **10** and alkyl radical **11** leading to deoxygenated product **12** (route a), or accept a hydrogen from $Bu_3SnH$ to form **13** which is then cleaved (thermally?) to thioformate *O*-ester **14** which finally adds $Bu_3SnH$ yielding hemithioformal **15** (route b). The last step was supported by a separate experiment with *O*-ethyl thioformate which gave the hemithioformal $EtOCH_2SSnBu_3$. When later experiments[4] indicated that radicals of type **9** are thermally very unstable, a non-radical mechanism of hydride transfer was preferred for generation of **13** from **8** and presumably of **15** from **14**.

In these mechanisms both methylene hydrogens are supplied from $Bu_3SnH$ by additions, radical or non-radical, to thiocarbonyl groups. For addition of the third hydrogen no thiocarbonyl intermediate is possible. It seems necessary to postulate that



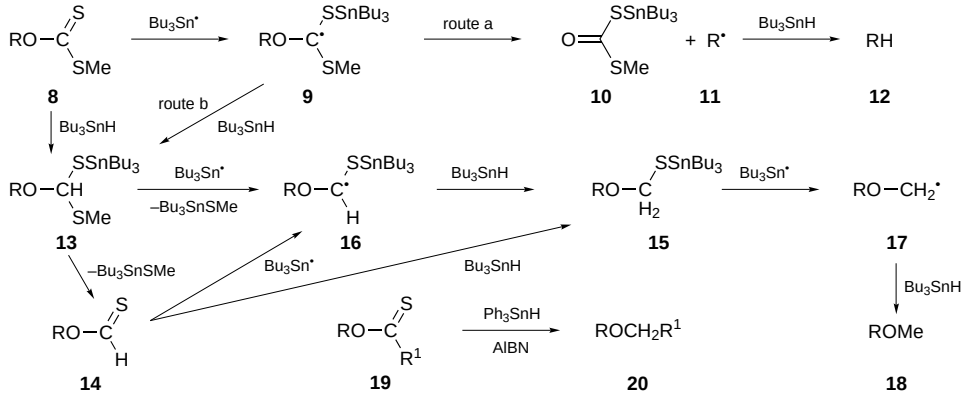


**Fig. 1** Molecular ions from deuteriated **6**: (□) measured and (■) calculated. See text for basis of calculation.

**Scheme 1**

hemithioformals **15** can generate radicals **17** either by thermolysis or (more probably, we think) by attack of $Bu_3Sn^{\cdot}$ on the sulfur atom leading to elimination of $(Bu_3Sn)_2S$. The radical product **17** then accepts its third hydrogen from $Bu_3SnH$, forming **18**. Nicolaou *et al.*§ showed[5] that thioesters **19** with triphenyltin hydride–AIBN (and in one example, less efficiently, with tributyltin hydride–AIBN) yielded ethers **20**; thioformate *O*-esters were not tried but there seems little doubt that these could yield methyl ethers. The reaction, as we also prefer, was represented as addition of $Bu_3Sn^{\cdot}$ and elimination of $(Bu_3Sn)_2S$. A similar mechanism might apply also to addition of the *second* hydrogen, attack of $Bu_3Sn^{\cdot}$ on the SMe sulfur atom of the earlier intermediate **13** leading to elimination of $Bu_3SnSMe$ and formation of the oxygen-stabilized radical **16**, which then accepts hydrogen from $Bu_3SnH$. Such a mechanism could apply to addition of the *first* hydrogen only if the initial attack of $Bu_3Sn^{\cdot}$ on **8** is at SMe instead of S=C, as Barker and Beckwith[6] suggested on the basis of experiments with $Bu_3Sn^{\cdot}$ in the absence of $Bu_3SnH$. Barton's later work[4] controverts this mechanism.

Deoxygenation to RH species by (unpromoted) $Bu_3SnH$ is favoured[1] by higher dilutions and higher temperatures: the branching to give routes a and b, whatever the mechanisms, is due to competition between a unimolecular thermolysis and a bimolecular hydrogen-transfer. Conversely, higher concentrations of $Bu_3SnH$ should favour the pathways leading to hydrogen additions. In fact an excess of $Bu_3SnH$ over the 3 equiv. theoretically required was used in all experiments where formation of ROMe was observed, and **5** with only 1.5 equiv. of $Bu_3SnD$ formed no measurable **6**. The step preceding addition of the third hydrogen is therefore the slowest.

‡ In the molecular ions the dienyl species appears to be enriched. The two heaviest fragment ions ($M-15$ containing methoxy, and methoxy-free $M-47$) show the opposite effect and their peak patterns are both matched by assuming a 55 : 45 ratio. The base peak in the spectrum is at *m*/*z* 69, indicating favoured cleavage of the dienyl species to $Me_2C{=}CHCH_2^{+\cdot}$. The observed patterns are consistent with the dienyl species being preferentially ionized, but also preferentially cleaved so as to be under-represented in the heavier fragments.

# A simple amide protecting group: synthesis of oligoamides of Nylon 6

**Gerald M. Brooke,*[a] S. Mohammed[a] and Mark C. Whiting[b]**

[a] *Chemistry Department, Science Laboratories, South Road, Durham, UK DH1 3LE*

**The 4-methoxybenzyl group (R) in amide groups NR(C=O) renders all intermediates in the synthesis of oligomers of Nylon 6 soluble in common solvents and is readily removed in boiling trifluoroacetic acid.**

Wallace Carothers described the first use of a disecondary diamine to introduce 'rubberiness' into a polyamide in an early patent—the preparation of poly(N,N'-dimethylpentamethylenesuccinamide), $\{N(Me)(CH_2)_5N(Me)(C{=}O)(CH_2)_2(C{=}O)]_n\}$;[1] the hydrogen-bonding properties due to the NH(C=O) group, which confer many of the desirable properties of Nylons, were lost from the point of view of normal use at that time, textiles. Soon afterwards, other workers investigated the use of *N*,*N*′-dialkyl derivatives of 1,6-hexamethylenediamine (alkyl = methyl, ethyl, isobutyl and benzyl) for incorporation into alkyl Nylon 6,10 polymer,[2] but very little has been published since in this area. The most noticeable physical property affected in these polymers compared with the non-alkylated materials was a marked increase in solubility in common organic solvents.

**Scheme 1** *Reagents and conditions*: i, 4-$MeOC_6H_4CHO$; ii, $NaBH_4$; iii, $Boc_2O$; iv, NaOH, the $H^+$; v, TFA, 25 °C; vi, DCC, 1-hydroxybenzotriazole; vii, EtCOCl; viii, $PrNH_2$, KCN(cat.); ix, TFA, reflux

The best science is carried out on pure compounds. Recently, the preparation of some monodisperse linear long-chain alkanes was described,[3] materials of interest for relating their properties as models to those of commercial polythene, a polydisperse substance; the folding of the molecular chains in these compounds is of particular interest.[4] The study of pure oligoamides of the Nylon family is expected to provide even more insights into the nature of the chain-folding process since both amide and alkyl folds are possible.

We have exploited the lack of inter-chain hydrogen-bonding in *N*-alkylated amides to make soluble intermediates which were purified by chromatography on silica to produce pure 'end-capped' Nylon 6 oligomers. These compounds have been made previously,[5] but their purity could not be monitored. While relatively little work has been carried out on amide protecting groups,[6] we have now discovered that the 4-methoxybenzyl group in an amide $[N(CH_2C_6H_4OMe\text{-}4)(C{=}O)]$ is an excellent protecting group, conferring solubility in common solvents† on all derivatives, and being readily removed by boiling TFA. Scheme 1 shows the initial formation of the partially protected ethyl ester of acid **1** and its final protection to give the *N*-Boc derivative **2**, the starting material for an iterative synthesis. The first protected amide linkage in **4** was formed from **3** and **1** by a method used in peptide chemistry.[7] The Boc group in **4** was removed by TFA at room temperature and the chain-doubling reaction repeated successively to give first the fully protected dimer **5** ($n$ = 2), then the tetramer **5** ($n$ = 4) *etc.* up to the hexadecamer **5** ($n$ = 16). Individual 'end-capped' amides were obtained by deprotection of the *N*-terminus in **5**, followed by propanoylation to give **6**, and conversion of the ethoxycarbonyl terminus to the propylamide derivative **7**.‡ Finally, removal of the amide protecting group gave 'end-capped' oligomers **8** ($n$ = 2, 4, 8 and 16) of Nylon 6.§ The purity of the intermediates, formed in high yielding reactions, could be monitored by HPLC and their structures confirmed by $^1H$ NMR spectroscopy. The final end-capped Nylon 6 oligomers **8** were found to be soluble in $CD_3CO_2D$ at 80 °C, which enabled the complete confirmation of their structures to be carried out by $^1H$ NMR spectroscopy at 500 MHz. Currently, we are employing similar methodology for the synthesis of oligomers of Nylon 6,6 and Nylon 4,6.

The 4-methoxybenzyl group as a protecting group on nitrogen in an amide not only renders the parent molecule more soluble (the property exploited in this work); it also removes a potentially acidic hydrogen which could be incompatible in further types of reaction. It would then assume the role of a classical protecting group, and could be introduced into a NH(C=O) bond *via* treatment with LDA–4-methoxybenzyl bromide.

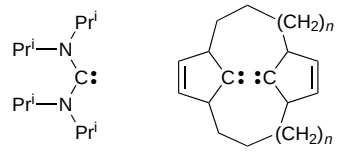
# Bis(*N*-piperidyl)carbene and its slow dimerisation to tetrakis(*N*-piperidyl)ethene

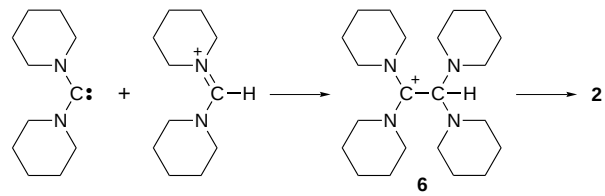


**Roger W. Alder* and Michael E. Blake**

*School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

**An unhindered bis(*sec*-amino)carbene can be generated by deprotonation of an amidinium ion with lithium diisopropylamide, and undergoes remarkably slow dimerisation to the corresponding tetraaminoethene.**

When amidinium salt **1** is treated with lithium diisopropylamide in THF at −80 °C, allowed to warm to room temperature, the THF removed and the residue dissolved in [$^2H_8$]toluene (all operations conducted under dry nitrogen), signals for two species are seen in the $^{13}C$ NMR spectrum. One of these is readily identified as the known[1] tetrakis(*N*-piperidyl)-ethene **2** ($\delta$ 25.7, 27.4, 51.6 and 134.6). The other species has lines at $\delta$ 24.8, 27.2, 53.1 and 236.8, and we assign this to bis(*N*-piperidyl)carbene **3**, on the basis of the chemical shift for the unique carbon [the central carbon in **4** absorbs at $\delta$ 255,[2] and other known[3] ylidic bis(*sec*-amino)carbene derivatives all absorb in the range $\delta$ 210–270]. All likely alternatives absorb at much lower chemical shifts (the central carbon of **1** occurs at $\delta$ 154, the carbonyl carbon in the urea absorbs at $\delta$ 171, and triaminomethane derivatives typically absorb at about $\delta$ 100). The subsequent behaviour of **2** and **3** is conveniently monitored by following the $CH_2$–N absorptions in the $^1H$ NMR spectrum, which come at $\delta$ 2.90 for **2** and $\delta$ 3.15 for **3**. Careful purification of all reagents and rigorous exclusion of air and water leads to solutions where the signals for **2** increase proportionally as those for **3** disappear (integration with respect to the residual protons in the solvent);† however, even under these conditions the reaction rate is only first order with respect to the carbene **3**. Signals for **3** persist for > 24 h in [$^2H_8$]toluene, but conversion to **2** occurs within 3 h in [$^2H_8$]THF.



Why is some dimer generated in the initial reaction with base, and why is dimerisation first order in carbene? We suggest that, during the initial reaction, carbene **3** attacks precursor **1** to generate substituted amidinium ion **6**, which is then deprotonated to give **2** (see Scheme 1). This is the reverse of the mechanism proposed by Lemal[4] to account for reactions of the tetraaminoethene derivatives studied by Wanzlick which give products apparently derived from bis(*sec*-amino)carbenes. Wanzlick[5] had proposed that there was reversible dissociation of the tetraaminoethenes, but Lemal showed that this was not the case through a crossover experiment. The subsequent slow conversion of **3** to **2** may occur by rate-limiting regeneration of low concentrations of **1** from **3** (*e.g.* by reaction with residual diisopropylamine), followed by the steps in Scheme 1. Clearly uncatalysed dimerisation of **3** is too slow to be competitive; we estimate that $\Delta G^{\ddagger} \geqslant 100$ kJ mol$^{-1}$ for this process in [$^2H_8$]toluene. Arduengo *et al.*[6] have recently reported the generation of a stable thiazol-2-ylidene and its dimer; they find that the carbene only dimerises in the presence of the thiazolium ion precursor, further supporting Scheme 1.

Why is dimerisation of **3** so sluggish? Both thermodynamic and kinetic factors must be considered. Recent calculations[7,8] and experimental results[9] with imidazol-2-ylidenes show that dimerisation of these carbenes can actually be thermodynamically unfavourable. In particular, Taton and Chen[9] have shown that intramolecular double bond formation is favourable for **5a**, but that equilibrium favours the bis-carbene for **5b**. These remarkable observations are partially due to loss of aromaticity in the tetraazafulvalene dimers and calculations predict a dissociation energy of about 200 kJ mol$^{-1}$ for the parent tetraaminoethene,[8] still much lower than for ethene itself (710 kJ mol$^{-1}$). Steric effects will reduce the dissociation energy in **2** somewhat, but the conversion of **3** to **2** is clearly favourable, and so there must be a high intrinsic barrier to the dimerisation. Hoffmann *et al.*[10] pointed out that dimerisation of singlet methylene to ethene is forbidden along the least motion pathway. They proposed a non-least motion pathway in which the sp$^2$ lone pair of one methylene approached the empty p orbital of the other. In their extended Hückel calculations, this approach led to ground state ethene without activation energy. More sophisticated theoretical calculations[11] suggest a barrier of about 170 kJ mol$^{-1}$ for this non-least motion process and moreover that it leads to an excited state of ethene. There are therefore good theoretical grounds for expecting a very significant electronic barrier in this sort of process. In addition, there could be significant steric interactions between the piperidyl rings of **3** in the non-least motion approach. We note that both rate-limiting proton transfer (as suggested above) and the uncatalysed non-least motion process are likely to involve considerable charge separation in the transition state, and so will occur faster in more polar solvents.

The persistence of the diaminocarbene **3** is very striking and it now seems that almost any bis(*sec*-amino)carbene should be observable‡ at ambient temperatures under conditions which take account of the strong basicity[12] and nucleophilicity of these species. In fact, $(Me_2N)_2C$ ($\delta_C$ 244.4) has now been generated

**Scheme 1**

using similar procedures and a study of its behaviour is currently in progress.

We thank the EPSRC for a studentship (to M. E. B.) and Professor Michael E. Denk for an exchange of information before publication.

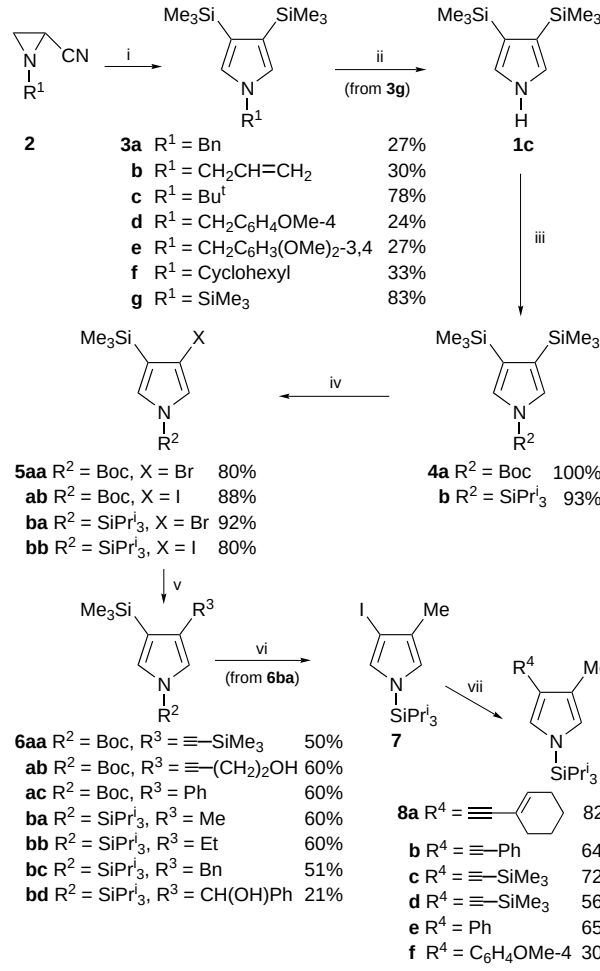
**3,4-Bis(trimethylsilyl)-1*H*-pyrrole 1c functions as a versatile building block for the construction of unsymmetrically 3,4-disubstituted pyrroles through the use of stepwise regiospecific *ipso* mono-halogenation, Sonogashira cross-coupling reactions and Suzuki cross-coupling reactions; the advantages of this strategy lie in its stepwise manner as well as in its prospect of yielding 3,4-disubstituted pyrroles with diverse substitution patterns.**

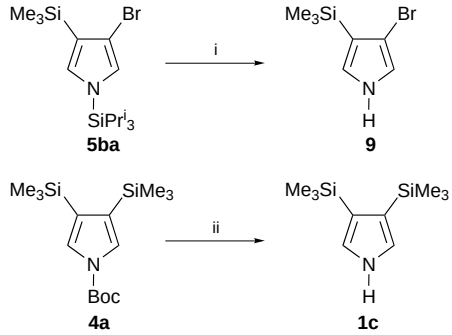
Pyrroles occur abundantly as structural units in many non-natural and natural molecules, including conducting poly(pyrroles),[1] antimitotics,[2] antitumour agents,[3] fungicides,[4] marine alkaloids[5] and porphyrins.[6] In the literature, several approaches to 3,4-disubstituted pyrroles have been recorded.[7–14] These approaches are generally not suitable for pyrroles containing elaborate substituents. With routes for the preparation of structurally diversified 3,4-disubstituted furans and thiophenes[15] from 3,4-bis(trimethylsilyl)furan **1a** and

**1a** **1b** **1c**



3,4-bis(trimethylsilyl)thiophene **1b** now at our disposal, we focused our attention on the synthesis of 3,4-disubstituted pyrroles. Herein we report our strategy for synthesizing unsymmetrically 3,4-disubstituted pyrroles utilizing 3,4-bis(trimethylsilyl)-1*H*-pyrrole **1c** as a building block.

By utilizing the [2 + 3] cycloaddition reported by La Porta *et al.*,[16] a number of *N*-protected 3,4-bis(trimethylsilyl)pyrroles were synthesized (Scheme 1) *via* thermal reactions of 2-cyanoaziridines **2**[17] with bis(trimethylsilyl)acetylene.† It is noteworthy that the preparation of **3c**, **3f** and **3g** did not require the use of sealed tubes. Amongst all the *N*-protected pyrroles prepared, only 1,3,4-tris(trimethylsilyl)pyrrole **3g** could be deprotected by a simple protodesilylation in MeOH, providing the desired molecule **1c** in good yield.



Due to the instability of **1c** as well as to the necessity for further transformation, **4a** and **4b** were synthesized by employing *tert*-butoxycarbonyl[18] and triisopropylsilyl groups[11b,c] as *N*-protecting groups. The role of a trimethylsilyl group in the *ipso*-directing substitution of aromatic compounds has been well documented.[19] In order to test the versatility of **4a** and **4b** in the realization of 3,4-disubstituted pyrroles, and the *ipso*-directing role of the trimethylsilyl groups, several halides **5** were regiospecifically prepared *via* literature procedures (Scheme 1).[20] Sonogashira reaction[21] was utilized to convert **5ab** into alkynes **6aa** and **6ab**. On the other hand, **5ab** was also successfully transformed to **6ac** by way of a Suzuki cross-coupling reaction.[22] A combined procedure involving lithiation and alkylation also converted **5ba** to **6ba**, **6bb**, **6bc** and **6bd**. In order to complete our initial plan of securing unsymmetrically 3,4-disubstituted pyrroles, **6ba** was allowed to undergo a regiospecific iodination, yielding iodide **7**. Sonogashira reaction of **7** again gave alkynes **8a**–**d**. Moreover, compounds **8e** and **8f** were also obtained from **7** *via* a Suzuki reaction pathway.

It is noteworthy that mild deprotection of **5ba** and **4a** was accomplished by using NaOMe in MeOH, affording 1*H*-pyrroles **9** and **1c**, respectively (Scheme 2).

In conclusion, making use of 3,4-bis(trimethylsilyl)-1*H*-pyrrole **1c** as a building block, an efficient and stepwise

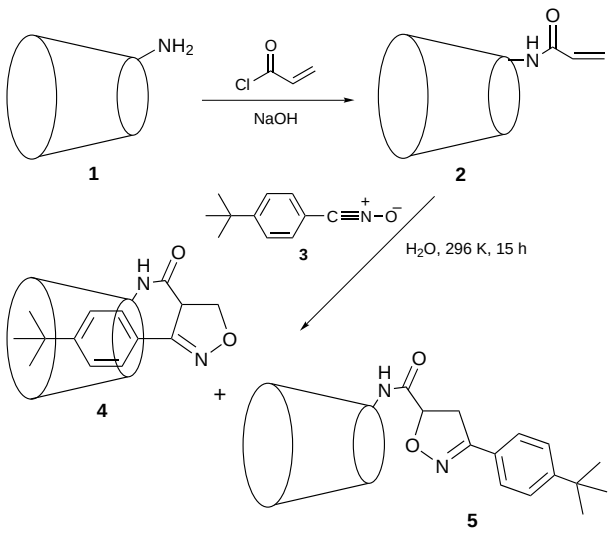
# A cyclodextrin to reverse the regioselectivity of nitrile oxide cycloaddition to a terminal alkene



**Adam G. Meyer,[a] Christopher J. Easton,*[a] Stephen F. Lincoln[b] and Gregory W. Simpson[c]**

[a] *Research School of Chemistry, Australian National University, Canberra ACT 0200, Australia*

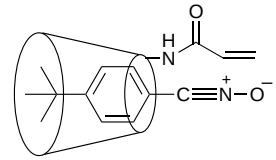
**The 1,3-dipolar cycloaddition of 4-*tert*-butylbenzonitrile oxide with 6$^A$-acrylamido-6$^A$-deoxy-β-cyclodextrin in aqueous solution favours formation of the 4-substituted isoxazoline, in contrast to the normal predominance of the 5-substituted regioisomer from reactions of monosubstituted alkenes.**

Nitrile oxide cycloaddition reactions with alkenes afford isoxazolines, which are of interest as versatile precursors of a range of 1,3-bifunctional compounds.[1] With mono- and trisubstituted alkenes the regioselectivity is usually determined by steric effects and the reactions afford almost exclusively 5- and 4,5,5-substituted isoxazolines, respectively. In order to reverse this regioselectivity, we envisaged that inclusion complexes of modified cyclodextrins[2] could be exploited. There have been reports that β-cyclodextrin affects the regioselectivity of nitrile oxide cycloadditions,[3] but it has now been demonstrated that these are in error and the cyclodextrin has no affect on the course of reaction in these examples.[4] Natural cyclodextrins have been used to accelerate Diels–Alder reactions of included guests and affect the distribution of products.[5] This occurs through self-assembly of the reactants within the cyclodextrin annulus, however our aim was to control the orientation of interaction between the reactants.

To develop this strategy, the dipolarophile was tethered to the cyclodextrin as the acrylamide **2** (Scheme 1). 4-*tert*-Butylbenzonitrile oxide **3** was selected as the dipole since alkyl-substituted aromatic compounds of this type are known to form thermodynamically stable inclusion complexes with β-cyclodextrin.[6] It was anticipated that inclusion of the hydrophobic moiety of the dipole **3** within the annulus of the modified cyclodextrin **2** would then establish the alignment for the cycloaddition (Fig. 1).

**Scheme 1**



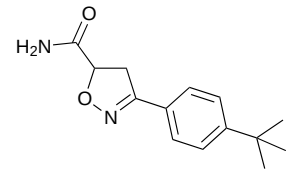


**Fig. 1** Alignment of the dipole **3** and the dipolarophile **2** in the host–guest complex

Treatment of the amino-substituted cyclodextrin **1**[7] with acryloyl chloride under basic conditions gave the acrylamide **2**.† 4-*tert*-Butylbenzaldehyde reacted with hydroxylamine, then *N*-chlorosuccinimide,[8] to give the corresponding hydroximinoyl chloride, from which the nitrile oxide **3** was generated *in situ* by reaction with triethylamine. Thus the cycloaddition involved rapidly stirring a mixture of the acrylamide **2** (0.03 mmol) and the hydroximinoyl chloride (0.12 mmol) in water (2.5 ml) at 296 K for 1 h, then adding triethylamine (0.12 mmol) and stirring that mixture for a further 15 h. After work-up, this afforded a quantitative yield of a 2.3 : 1 mixture of the isoxazolines **4** and **5**,† which were separated using HPLC (Scheme 1). The $^1$H NMR resonances due to the isoxazoline ring protons were assigned with the aid of double quantum filtered COSY experiments. When the cycloaddition reaction was repeated in DMF instead of water, the isoxazolines **4** and **5** were produced in 87% yield, as a 1 : 4 mixture.

The effect of the cyclodextrin annulus of the dipolarophile **2** was established by performing the cycloaddition of the nitrile oxide **3** with acrylamide. As expected, in either water or DMF, this reaction afforded only the 5-substituted isoxazoline **6**.†

**6**

Therefore, the production of the 4-substituted isoxazoline **4** in the reactions of the cyclodextrin derivative **2** highlights the effect of dipole **3**–dipolarophile **2** host–guest complex formation. As expected, this effect is greater in water than in DMF because the formation of cyclodextrin inclusion complexes is favoured in aqueous solutions.

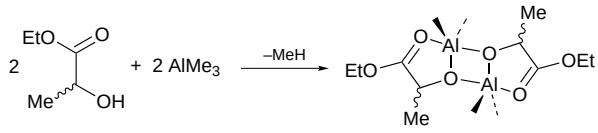
# Structure investigation of a dimethylaluminium derivative of ethyl *rac*-lactate in the solid state and solution. First evidence for stereoselective association of a dialkylaluminium *O,O′*-chelate complex

**Janusz Lewiński,* Janusz Zachara and Iwona Justyniak**



*Department of Chemistry, Warsaw University of Technology, Noakowskiego 3, PL-00-664 Warsaw, Poland*

**The reaction of $AlMe_3$ with an equimolar amount of ethyl *rac*-lactate (Helac) affords *rac*-[$Me_2Al${(*S**)-elac}]$_2$; the X-ray structure shows that the adduct is formed in a highly stereoselective manner and variable-temperature $^1H$ NMR spectra indicates that the five-coordinated complex is non-rigid in solution.**

Organoaluminium derivatives of *O,O′*-bifunctional ligands have been under investigation for many years owing to their practical and fundamental importance. For example, these compounds have been reported as organometallic intermediates in carbon–carbon bond formation reactions,[1] as precursors of catalysts in polymerisation processes[2,3] or precursors for MOCVD.[4] Although five-coordination in diorganoaluminium chelate complexes has been frequently postulated and as early as 1972 the [$R_2Al(O,O′)$]$_2$-type adduct has been reported as the first crystallographically characterised five-coordinated organoaluminium compound,[3a] there are not many examples of structurally characterised [$R_2Al(O,O′)$]$_2$-type complexes.[3a,4,5] Recently, we have described the structure characterisation of the first simple monomeric five-coordinate monoalkyaluminium chelate complex.[6] Due to the potential utility of organoaluminium derivative of *O,O′*-bifunctional ligands in organic synthesis and polymerisation processes, the investigation into the chemistry of organoaluminium chelate compounds, especially complexes bearing chiral centres,[7] has become an important challenge. The results concerning the structure of the dimethylaluminium derivative of racemic ethyl lactate are presented here as part of our studies on the structure of dialkylaluminium chelate compounds in solid state and solution. We report here that the formation of the [$R_2Al(O,O′)$]$_2$ adduct is a stereoselective reaction and show that this type of five-coordinated complex is non-rigid in solution.

The interaction of $Me_3Al$ with an equimolar amount of ethyl *rac*-lactate (Helac) results in quantitative evolution of methane and formation of *rac*-[$Me_2Al${(*S**)-elac}]$_2$ **1** (Scheme 1).†

The molecular structure of **1** has been determined by X-ray diffraction‡ and its solution structure has been characterised by $^1H$ and $^{27}Al$ NMR as well as cryoscopic molecular mass determination.§ The molecule is a dimer with two five-coordinate aluminium atoms (Fig. 1). The monomeric units are bonded *via* alkoxide oxygen atoms O(1) and O(1′) with the formation of a central four-membered ring $Al_2(\mu\text{-}O)_2$. The ethyl lactate anions form two five-membered chelate rings with aluminium, which lie approximately in one plane with a central bridging ring. The root mean square deviation of the atoms from this plane is 0.086 Å. The geometry of the aluminium atom coordination sphere can be described as a distorted trigonal bipyramid. The equatorial plane is defined by the C(6) and C(7) carbon atoms and the alkoxide oxygen. The axial positions are occupied by the O(2) oxygen atom of the carbonyl group and the alkoxide O(1′) oxygen atom of the second monomeric unit. The angle between the axial substituents is 164.74(6)°. As is shown in Fig. 1, the methyl groups bonded to the chiral C atom in the chelating ligand lie on the same side of the plane outlined by three fused heterocyclic rings, and the dimer molecule has $C_2$ symmetry. This indicates that only monomeric units of the same configuration as the chiral centre in the chelating ligand associate with each other giving exclusively (*R,R*) and (*S,S*) diastereoisomers. Thus, the formation of the dimeric five-coordinate complex **1** is a stereoselective reaction.

**Scheme 1**

It should be noted that the Al–O distances within the central $Al_2(\mu\text{–}O)_2$ ring in **1** [Al(1)–O(1) 1.848(2) Å and Al(1)–O(1′) 1.936(2) Å] differ significantly despite the fact that the same bridging oxygen atoms are bonded to the equivalent aluminium atoms. It is apparent that this results from the geometry of the dimeric five-coordinate molecules, which imposes that each bridging oxygen atom is in the equatorial position of one

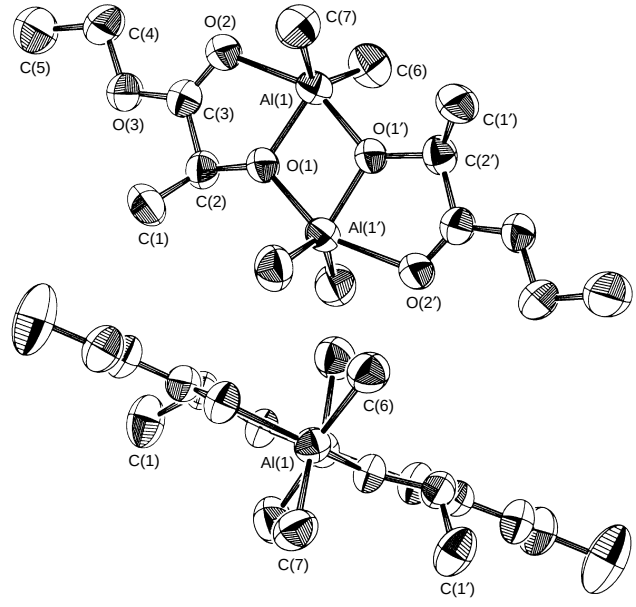


**Fig. 1** ORTEP view of the molecular structure of [$Me_2Al${(*S*)-elac}]$_2$ **1** with thermal ellipsoids drawn at 50% probability level. Bottom: view of the molecule along a mean plane formed by heterocyclic rings. Selected bond lengths (Å) and angles (°): Al(1)–O(1) 1.848(2), Al(1)–O(1′) 1.936(2), Al(1)–O(2) 2.157(2), Al(1)–C(6) 1.954(4), Al(1)–C(7) 1.956(4), O(2)–C(3) 1.224(3), O(1)–C(2) 1.405(3), O(1)–Al(1)–O(1′) 75.6(1), O(1)–Al(1)–C(6) 117.9(2), O(1)–Al(1)–C(7) 117.0(2), C(6)–Al(1)–C(7) 124.3(2), O(1)–Al(1)–O(2) 78.20(9), O(1′)–Al(1)–O(2) 153.8(1), C(3)–O(2)–Al(1) 111.4(2), C(2)–O(1)–Al(1) 122.9(2), Al(1)–O(1)–Al(1′) 104.2(1), O(1)–C(2)–C(3) 106.0(3), O(2)–C(3)–C(2) 120.4(3). Atoms labelled with a prime belong to the counterpart of dimeric units generated by two-fold axis (*y, x, −z*).

aluminium atom and in the axial position with respect to the other. Although non-equivalence of Al–O distances within the $Al_2(\mu\text{-}O)_2$ ring is usually noted in the description of structural data of compounds consisting of such a symmetrical four-centred bridging system, it is commonly interpreted as resulting from the different characters of these bridging bonds; for example, one Al–O bond is of a covalent and the other of a donor–acceptor or partial dative/covalent character.[8,9] We would like to emphasise at this point that the Al–O bonds in the $Al_2(\mu\text{-}O)_2$ ring are of the same character (σ two-centre–two-electron bonds) and the differences in the bridging Al–O bonds length are due to the different geometrical locations in the coordination sphere of the Al atoms.

The dimeric structure of **1** is retained in solution as found from a cryometric molecular mass determination in benzene. The NMR spectra of **1** are consistent with the structure found in the solid state. The $^{27}$Al NMR spectrum of **1** consists of a single resonance at $\delta$ 114 indicative of five-coordinate aluminium.[5a,10] The $^1$H NMR spectrum of **1** in $CD_2Cl_2$ solution at 20 °C displays a single resonance for the Al–$CH_3$ protons, and a doublet and quartet for the C–$CH_3$ and C–H protons, respectively, associated with the chiral centre as well as two resonances of the ester ethyl group; the methylene protons of the ethyl group are diastereotopic giving rise to an eight-line pattern. As the temperature is decreased the resonance associated with Al–$CH_3$ protons broadens (*ca.* −80 °C) and splits into two well separated resonances at −93 °C. This result can be best interpreted in terms of a dissociative process in which the Al–O chelate bond undergoes cleavage giving rise to the interchange of the chelating groups between the two aluminium centres and permitting the Al–$CH_3$ groups to become equivalent on the NMR timescale.

Additionally, we chose ethyl lactate for structure investigation in the expectation that IR spectroscopy could be a sensitive probe for detecting an equilibrium between five- and four-coordinate dimeric organoaluminium species with chelated and dangling *O,O′*-bifunctional ligand carbonyl groups. However, the IR spectrum of **1** in $CH_2Cl_2$ solution shows only one carbonyl group stretching vibration at 1690 cm$^{-1}$. The observed decrease in comparison to that in free Helac (1728 cm$^{-1}$) is consistent with the coordination of the carbonyl group to aluminium. Furthermore, the presence of the strong band of the chelate carbonyl group and lack of uncoordinated carbonyl groups bands can be interpreted in terms of dangling ligands being present at non-detectable concentrations or that intermediate species involving dangling ligands have different geometry and corresponding bands occur with non-appreciable intensities.

Further studies are required in order to determine the nature of five-coordinate $[R_2Al(O,O')]_2$ adduct formation in a highly stereoselective manner and the structural characterisation of this type of adducts derived from $AlR_3$ and racemic *O,OH* bifunctional ligands is currently in progress.

We thank Professor D. J. Stufkens (Universiteit van Amsterdam) for helpful discussion of IR spectra and the National Research Committee (Grant 3 T09A 108 12) for financial support.

† *Preparation* of **1**: ethyl *rac*-lactate (7.0 mmol) was dissolved in toluene (10 cm$^3$) and $AlMe_3$ (7.0 mmol) was added dropwise at −78 °C. After the addition was complete the reaction mixture was allowed to warm to room temp. The solvent was then removed under vacuum, leaving a white solid that was crystallised from toluene–hexane at 0 °C. The yield was essentially quantitative.

‡ *Crystal data* for **1**: $C_{14}H_{30}Al_2O_6$: tetragonal, space group $P4_12_12$ (no. 92) and $P4_32_12$ (no. 96) for (*S,S*) and (*R,R*) diastereoisomers, respectively; *D*c = 1.137 g cm$^{-3}$, $Z$ = 4, $a$ = 7.6188(7), $c$ = 35.055(6) Å, $U$ = 2034.8(4) Å$^3$, $T$ = 20 °C, Mo-K$\alpha$ radiation ($\lambda$ = 0.71073 Å), $\mu$ = 1.64 cm$^{-1}$, Siemens P3 diffractometer, $2\theta_{max}$ = 50°, $\theta$–$2\theta$ scans, 4171 reflections collected (1801 unique, $R_{int}$ = 0.0694). The structure was solved by direct methods[11] in the $P4_12_12$ space group and was refined by full-matrix least-squares on $F^2$.[12] Hydrogen atoms were included in idealised positions and refined isotropically. Refinement converged at $wR_2$ = 0.1082 for 1697 data and 112 parameters [$R_1$ = 0.0477 for 1021 unique reflections with $F_o > 4\sigma(F_o)$]. Absolute structure could not be determined reliably due to the high e.s.d. for the refined Flack $x$ parameter 0.3(4).[13] A weighting scheme $w = [\sigma^2(F_o^2) + (0.0280P)^2]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$ was used in the final stage of refinement. Residual electron density = +0.17, −0.16 e Å$^{-3}$. CCDC 182/529.

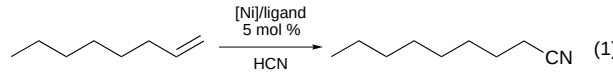
**The hydrocyanation of alk-l-enes and ω-unsaturated fatty acid esters using zerovalent nickel complexes yields the corresponding nitriles and cyanoesters, which can be useful starting materials in organic synthesis.**



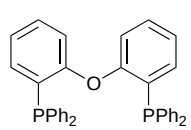
The nickel-catalysed addition of HCN to butadiene, known as the DuPont ADN Process, is the most important hydrocyanation reaction today at an industrial scale.[1] Many investigations have been made to understand its mechanism and to improve activity and selectivity.[2] A major problem still arises from the formation of inactive nickel cyanides when the zero-valent metal centre is exposed to an excess of HCN.

Recently we reported the successful application of diphosphines in the hydrocyanation of styrene.[3] These newly developed Xantphos ligands[4] have large bite angles and rigid backbones (Fig. 1). It is likely that they enhance the final reductive elimination step in the catalytic cycle by supporting a tetrahedral geometry. Dicyano nickel(II) species with a square-planar geometry affording P–Ni–P angles of about 90° are disfavoured. Moreover, the Xantphos ligands allow a large excess of HCN by providing more stable $Ni^0$ complexes compared to monodentates due to the chelate effect.

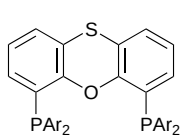
Although the first homogeneously catalysed hydrocyanation of linear alkenes was published by Arthur and Pratt[6] in 1954, only a few more examples representing this class of substrates can be found in the literature.[7] Nevertheless alkyl nitriles are valuable intermediates for the synthesis of amides, amines, carboxylic acids and esters.

Using *n*-octenes as starting materials, Keim *et al.* have found in earlier work that, irrespective of the position of the double bond, the anti-Markovnikov product 1-cyanooctane is formed with 80% regioselectivity.[8] However, in order to avoid fast deactivation of the catalyst, the monodentate phosphite ligands like $P(OC_6H_4Me\text{-}p)_3$ had to be employed in ratios (relative to Ni) > *ca*. 15 to 1. Recent efforts were made with diphosphites in the hydrocyanation of butadiene[9] and with diphosphinites in the hydrocyanation of vinylarenes.[10]

We report here the catalytic hydrocyanation of long-chain substrates having a non-conjugated double bond with $Ni^0$ complexes. This work represents the first successful hydrocyanation of alk-l-enes and ω-unsaturated fatty acid esters applying chelating diphosphines, with a ligand to metal ratio of only 1.05 [eqn. (1)].‡ These systems were shown to be stable



(1)



against an excess of HCN up to 1000 in a batch reaction. $AlCl_3$ was added to the reaction mixtures as a cocatalyst. The role of the Lewis acid is to activate the catalyst precursor when non-conjugated alkenes are used as substrates.[11]

The use of diphosphines with large bite angles induces yields that are comparable to those obtained with the commercial *ortho*-tolylphosphite system in the hydrocyanation of oct-1-ene (Table 1, entries 1–4). The hydrocyanation of dec-1-ene with the same catalysts leads to similar results. Ligands with electron-withdrawing substituents on the phosphorus atom give rise to more stable $Ni^0$ complexes, since back-donation of d electrons from the metal is favoured in this case. For that reason the Thixantphos ligand was derivatised by introducing trifluoromethyl groups at the *meta* positions in the PPh moiety (Fig. 1). Increased yields and excellent selectivities with this system clearly indicate a higher complex stability and better performance of the catalyst (Table 1, entry 4).

When dealing with monodentate phosphite ligands in hydrocyanation catalysis the Tolman angle $\theta$ is the important factor,[12] whereas with bidentate ligands the bite angle is decisive. The use of common diphosphine ligands with bite angles between 78 and 98° like dppe, dppp, dppb or binap in the hydrocyanation of styrene results in almost no conversion.[3] We observed the same behaviour in the hydrocyanation of substrates dealt with in the present communication. Best activities are obtained with bite angles around 109°.

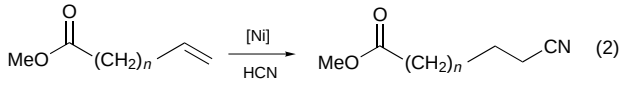
DPEphos, bite angle = 105°

Thixantphos, Ar = Ph, bite angle = 113°
$CF_3$-Thixantphos, Ar = $C_6H_3(CF_3)_2$-3,5, bite angle = 115°

**Fig. 1** Xantphos type ligands. Bite angles were calculated using molecular mechanics.† The natural bite angle is defined as the preferred chelation angle determined only by ligand backbone constraints and not by metal valence angles.[5]

**Table 1** Nickel-catalysed hydrocyanation of oct-1-ene and methyl dec-9-enoate[a]

| Entry | Ligand | Oct-1-ene | | Methyl 9-dec-1-enoate |
|---|---|---|---|---|
| | | Yield[b] (%) | Selectivity[c] (%) | yield[b] (%) |
| 1 | DPEphos | 36 | 82 | 13 |
| 2 | Thixantphos | 42 | 91 | 10 |
| 3[d] | $P(OC_6H_4Me)_3$ | 51 | 82 | 33 |
| 4 | $CF_3$-Thixantphos | 51 | 96 | 36 |



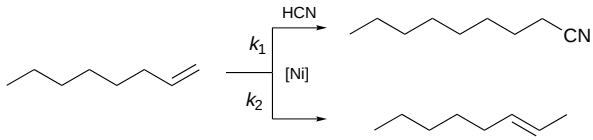
[a] *Reaction conditions*: Ni:$AlCl_3$:ligand:substrate:HCN = 1:1:1.05:20:25, 333 K, 16 h. [b] Yields are based on the substrate and were determined by temperature-controlled gas chromatography with added standard compounds. [c] Selectivity = chemical yield of nitriles / conversion (substrate). [d] Ligand to nickel ratio = 20.

**Table 2** Regioselectivity[a] towards the terminal nitriles obtained in the hydrocyanation of oct-1-ene and methyl dec-9-enoate

| Ligand | Oct-1-ene | Methyl 9-dec-1-enoate |
|---|---|---|
| DPEphos | 29 | 39 |
| Thixantphos | 84 | 75 |
| $P(OC_6H_4Me\text{-}p)_3$ | 82 | 77 |

[a] Regioselectivity is defined as the % of linear nitrile.

Hydrocyanation of functionalised alkenes leads to interesting chemical building blocks. Reaction of ω-unsaturated fatty acid esters with HCN gives the corresponding cyanoesters [eqn. (2),



(2)

$n$ = 7–11]. The substrate acid esters are readily available from natural resources.[13] To the best of our knowledge this is the first example of a catalytic hydrocyanation using this class of substrates.

For methyl dec-9-enoate the obtained yields and selectivities are similar to the unfunctionalised alkenic substrates (Table 1, entries 1–4). The presence of the ester group does not inhibit the catalytic reaction. However, with fatty acid esters containing a longer chain, such as methyl undec-10-enoate or methyl tetradec-13-enoate, the yields decrease slightly.

The Xantphos type diphosphines DPEphos and Thixantphos have almost identical electronic properties but different bite angles. Moreover, for DPEphos, the S-bridge in the backbone is missing which makes the ligand flexible. These characteristics influence the regioselectivity towards the nitrile products (Table 2). We suggest that the more rigid ligand backbones disfavour conformational changes in the metal complexes formed. With Thixantphos the observed linearity reaches 84%.

The formation of branched nitriles mainly takes place when the double bond of the starting unsaturated substrate is isomerised *via* an intermediate nickel hydride species to give an internal alkene. Usually, isomerisation and β-elimination of a thermodynamically favoured internal alkene ($k_2$) is much faster than hydrocyanation ($k_1$) (Scheme 1). Thus another approach to explain the difference in regioselectivity with DPEphos and Thixantphos is a kinetic one. The more rigid a ligand is, the more favoured is hydrocyanation ($k_1$).

**Scheme 1**

The results reported here clearly indicate the unique properties of the Xantphos type diphosphine ligands possessing large bite angles in hydrocyanation reactions. Effective nickel-catalysed hydrocyanation of long-chain unsaturated substrates can be achieved. The regioselectivity can be controlled by providing a rigid ligand backbone.

We would like to thank Professor Dr Wilhelm Keim for kindly supporting our work and Professor Dr Siegfried Warwel, H. P. Kaufmann-Institut Münster, for the donation of the fatty acid esters.

† The molecular mechanics calculations were performed on a Silicon Graphics Indigo*2* workstation using SYBYL[14] software version 6.3 and a modified TRIPOS force field with a Ni–P bond length of 2.177 Å and a P–Ni–P bending force constant of 0 kcal $mol^{-1}$ $degree^{-2}$.

§ In a typical experiment, 1 ml of a bright yellow 0.0325 mM solution of $[Ni(cod)_2]$ in toluene was added to a Schlenk tube containing a stirring bar and 1.05 equiv. of ligand. The mixture was stirred for 30 min to ensure complete formation of the catalyst precursor. Then 0.65 mmol of the substrate and 0.0325 mmol of Lewis acid ($AlCl_3$ as a stock solution) was added. The solution was then cooled to *ca*. 220 K, 30 μl of liquid HCN (0.78 mmol) was added at once and the tube was placed in a heating bath. After 16 h at 333 K, the excess of HCN was removed by a gentle stream of argon, solid particles were removed by centrifugation and the remaining solution was analysed by temperature-controlled gas chromatography.

# Phosphorus monoxide as a terminal ligand

**Marc J. A. Johnson, Aaron L. Odom and Christopher C. Cummins*†**

*Department of Chemistry, 2-227, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139-4307, USA*

**Dimethyldioxirane oxidation of phosphide PMo[N(R)Ar]$_3$ [R = C(CD$_3$)$_2$Me, Ar = C$_6$H$_3$Me$_2$-3,5] efficiently provides (OP)Mo[N(R)Ar]$_3$, a complex shown by X-ray crystallography to contain a terminal phosphorus monoxide ligand, and which reacts with dimethylzirconocene to give addition of a Zr–Me bond across the phosphoryl moiety.**

Known phosphorus monoxide complexes[1–3] are those in which PO[4–10] serves as a triply bridging ligand. These have been prepared by oxo transfer to a $P_2Ni_2W$ cluster,[1] and by hydrolysis of a $\mu_3$-P(NPr$^i_2$) functional group.[3] Recent reports of terminal phosphide ($P^{3-}$) complexes[11–15] hint at the possibility of preparing terminal PO complexes by oxygen-atom transfer to the terminal P ligand. Accordingly, dimethyldioxirane oxidation[16,17] has been found to effect the desired conversion of PMo[N(R)Ar]$_3$ **1** to (OP)Mo[N(R)Ar]$_3$ **2**. Synthetic, structural, and initial reactivity data pertaining to **2** are detailed herein.

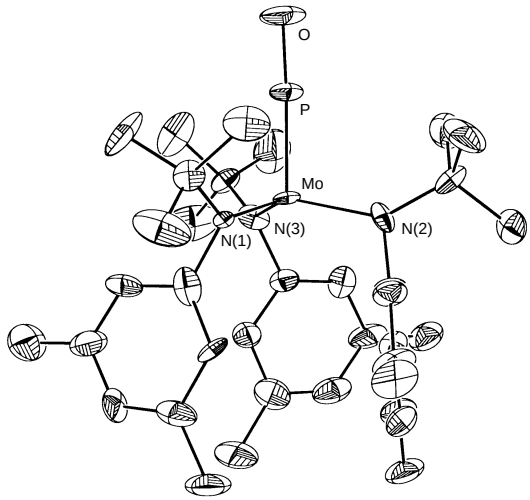
Treatment of a −78 °C gold-colored solution of **1** (1.0009 g, 1.4853 mmol) in dichloromethane (50 ml) with dimethyldioxirane (20 ml of a 0.075 M solution in acetone[18]) elicited a rapid color change to purple, the color of **2**.‡ Workup consisted of cold-filtration, precipitation of **2** by addition of acetonitrile (75 ml, pre-chilled to just above its melting point), and collection of solid **2** (73.8% yield) by filtration. Once thus obtained in pure form, solid **2** can be manipulated and maintained at 25 °C for at least *ca.* 5 days without noticeable decomposition. When dissolved in various solvents (*e.g.* benzene, diethyl ether, heptane and dichloromethane) **2** is more sensitive, undergoing gradual reversion to **1** according to $^1$H and $^{31}$P NMR spectroscopic monitoring.

Diamagnetic **2** exhibits a single $^{31}$P NMR signal at $\delta$ 269.8, shifted dramatically upfield relative to **1** but in a range typical of two-coordinate phosphorus compounds.[19] Proton NMR data for **2** are indicative of a single environment for the N(R)Ar ligands, consistent with the threefold (propellor) symmetry typical of complexes containing three N(R)Ar ligands.[20–25]

Single crystals of **2** suitable for an X-ray diffraction study§ were obtained by slow cooling to −35 °C of a diisopropyl ether solution. Molecular **2** evinces pseudo-threefold symmetry about the near-linear [177.6(8)°] Mo–P–O moiety, which is flanked by the three *tert*-butyl substituents (Fig. 1). An intriguing feature of the structure is the molybdenum–phosphorus distance *d*(MoP) = 2.079(5) Å, which is shorter by 0.04 Å than *d*(MoP) for terminal phosphide **1**.[11] Contraction of the molybdenum–phosphorus distance in this manner is explicable in terms of rehybridization at P upon addition of a terminal substituent.[26] The phosphorus–oxygen distance [1.49(2) Å] in **2** is comparable to that measured by IR diode laser spectroscopy for gaseous PO [1.476 370(15) Å)],[27,28] and to *d*(PO) values for $\mu_3$-PO complexes: 1.509(3),[3] 1.462(9) and 1.480(10).[1] Phosphoryl halide species such as $OPCl_3$ contrastingly exhibit longer phosphorus–oxygen distances, on the order of 1.54–1.58 Å,[29] while *d*(PO) for OP(C$_6$H$_{11}$)$_3$ is 1.490(2) Å.[30] Other metrical parameters pertaining to the structure of **2** are unexceptional.

Previously reported (SP)Mo[N(R)Ar]$_3$ **3**[11] was shown recently by X-ray crystallography to resemble **2** in terms of its monomeric nature and gross structural characteristics.[31] The rough similarity of **2** and **3** was used to advantage to obtain assignment of the $\nu_{PO}$ (1232 cm$^{-1}$) and $\nu_{PS}$ (782 cm$^{-1}$) IR stretching frequencies for the two complexes, by digital subtraction of solution FTIR spectra. The $\nu_{PO}$ value for **2** is similar to that reported for gaseous PO (1220.25 cm$^{-1}$), and also is comparable to values reported for $\mu_3$-PO complexes (1260, 1169 cm$^{-1}$).

Initial reactivity studies indicate that the phosphoryl phosphorus in **2** is susceptible to nucleophilic attack in a manner reminiscent of the Fischer carbene synthesis.[32] Accordingly, treatment of **2** (282.0 mg, 0.4088 mmol) with dimethylzirconocene[33] (103.3 mg, 0.4108 mmol) in benzene (7.5 ml) led to formation of [(R$^1$)(R$^2$O)P]Mo[N(R)Ar]$_3$ [**4**, R$^1$ = Me, R$^2$ = Zr(Me)($\eta$-C$_5$H$_5$)$_2$], which was isolated by crystallization



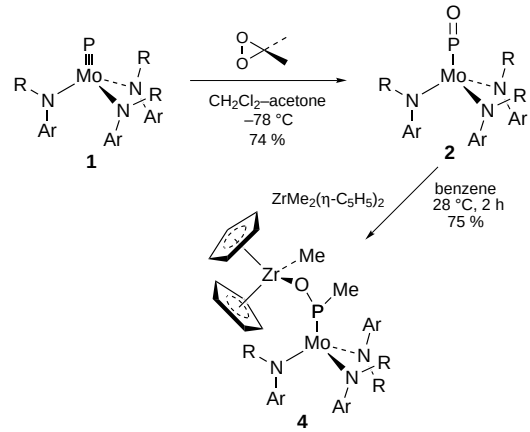


**Fig. 1** ORTEP drawing of the molecular structure of **2** with 35% probability ellipsoids. Selected bond lengths (Å) and angles (°): Mo–P 2.079(5), Mo–N(1) 1.95(2), Mo–N(2) 1.94(2), Mo–N(3) 1.994(13), P–O 1.49(2); Mo–P–O 177.6(8), P–Mo–N(1) 101.7(4), P–Mo–N(2) 101.4(5), P–Mo–N(3) 101.6(5), N(1)–Mo–N(2) 113.1(6), N(1)–Mo–N(3) 117.2(6), N(2)–Mo–N(3) 118.0(6).

**Scheme 1**

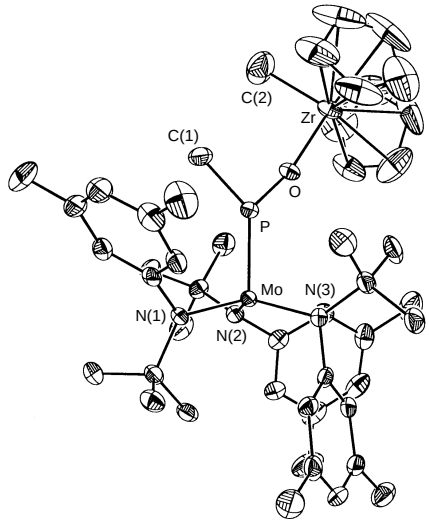

**Fig. 2** ORTEP drawing of the molecular structure of **4** with 35% probability ellipsoids. Selected bond lengths (Å) and angles (°): Mo–P 2.169(2), Mo–N(1) 1.995(5), Mo–N(2) 2.011(5), Mo–N(3) 1.993(5), P–O 1.613(5), P–C(1) 1.832(8), Zr–O 2.000(4), Zr–C(2) 2.253(11); Mo–P–O 127.7(2), Mo–P–C(1) 133.9(3), O–P–C(1) 97.6(3), Zr–O–P 163.6(3), O–Zr–C(2) 97.1(4), P–Mo–N(1) 101.6(2), P–Mo–N(2) 103.2(2), P–Mo–N(3) 101.7(2), N(1)–Mo–N(2) 109.1(2), N(1)–Mo–N(3) 112.6(2), N(2)–Mo–N(3) 125.0(2).

from a 1 : 1 diethyl ether–heptane mixture as orange–brown plates in 75.0% yield (Scheme 1). Diamagnetic **4** exhibits a single $^{31}$P NMR signal at $\delta$ 284.4 {*cf.* $\delta$ 312 for $Mo[P(C_6H_{11})_2]_4$[34]}. A reasonable oxidation state assignment for the Mo centre in **4** is +4. Proton NMR data for **4** are indicative of a single N(R)Ar ligand environment on the NMR timescale, although the solid-state structure of **4** reveals a low-symmetry conformation. A doublet ($^2J_{PH}$ 14 Hz) at $\delta$ 1.535 is attributed to the PMe moiety.

The three-coordinate phosphorus in **4** was shown by X-ray diffraction§ to be essentially planar [sum of angles = 359.2(3)°], consistent with Mo–P π bonding in the complex (Fig. 2). The observed *d*(MoP) of 2.169(2) Å is also consistent with a molybdenum–phosphorus multiple bond {*cf.* *d*(MoP) of 2.265(2) Å for $Mo[P(C_6H_{11})_2]_4$[34]}. The conformation of **4** is noteworthy in that one of the N(R)Ar ligands is oriented with its *tert*-butyl group distal from phosphorus, presenting an Ar π cloud to the methyl substituent on phosphorus. The Zr–O–P(Me)–Mo core in **4** is reminiscent of Zr–O–C(R′)–M cores in zirconoxy carbenes prepared by addition of Zr–R′ (R′ = H, alkyl) bonds across the CO unit in metal carbonyl complexes.[35]

We thank Monsanto Company for support of this work, and Michael K. Stern for helpful discussions. M. J. A. J. thanks NSERC for a predoctoral fellowship.

# Template synthesis and X-ray crystal structure of a trinuclear complex with four- and five-coordinate silver(I) centres

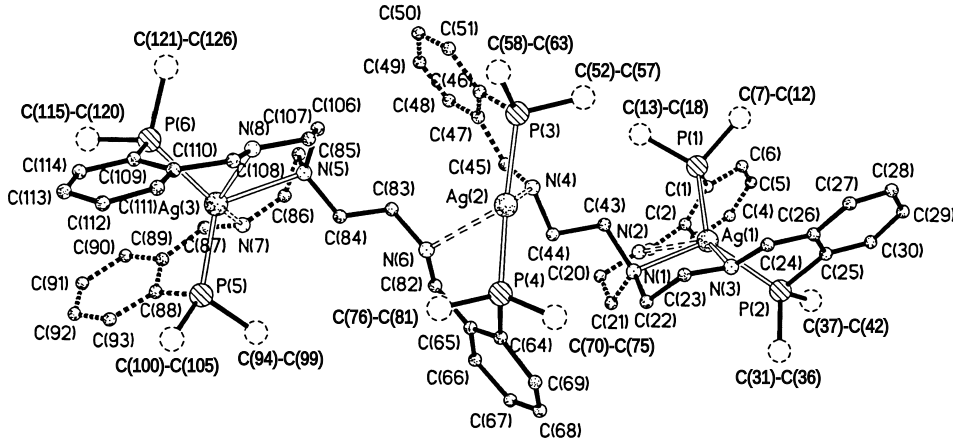
**Wai-Kwok Wong,*[a] Lilu Zhang,[a] Feng Xue[b] and Thomas C. W. Mak[b]**

[a] *Department of Chemistry,Hong Kong Baptist University, Kowloon, Hong Kong*
[b] *Department of Chemistry, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong*

**Single-crystal X-ray analysis of the trinuclear complex $[Ag_3L_2][CF_3SO_3]_3$ [L = {(*o*-$Ph_2C_6H_4$)CH = $NCH_2CH_2$}$_3$N], synthesized by interaction of $Ag(CF_3SO_3)$, $N(CH_2CH_2NH_2)_3$ and *o*-$Ph_2PC_6H_4$(CHO) in 3 : 2 : 6 molar ratio in ethanol, shows that the complex has approximate $C_2$ symmetry and is composed of a four- and two five-coordinate silver(I) centres.**

We have been interested in the preparation of diimino-, diamino- and diamido-diphosphine ligands and demonstrated that these ligands do indeed exhibit a very rich coordination chemistry.[1,2] We have extended our study to the preparation of polydentate ligands containing three or more iminophosphino groups. Herein we report the template synthesis of the heptadentate ligand {(*o*-$Ph_2PC_6H_4$)CH=$NCH_2CH_2$}$_3$N and the structure of its silver(I) complex.

Attempts to synthesize the heptadentate ligand {(*o*-$Ph_2PC_6H_4$)CH=$NCH_2CH_2$}$_3$N *via* direct condensation of $N(CH_2CH_2NH_2)_3$ with 3 equiv. of *o*-$Ph_2PC_6H_4$(CHO) were unsuccessful. However, when $Ag(CF_3SO_3)$, $N(CH_2CH_2NH_2)_3$ and *o*-$Ph_2PC_6H_4$(CHO) were allowed to react in 3 : 2 : 6 molar ratio in ethanol for 12 h at room temp., work-up gave the trinuclear silver complex $[Ag_3L_2][CF_3SO_3]_3$ **1**,† [L = {(*o*-$Ph_2PC_6H_4$)CH=$NCH_2CH_2$}$_3$N], as yellow crystals in moderate yield. Crystals of **1**·2EtOH·2$CH_2Cl_2$·$H_2O$ suitable for X-ray diffraction study‡ were grown from dichloromethane-diethyl ether–ethanol. A perspective drawing of the cation $[Ag_3L_2]^{3+}$ of **1** is shown in Fig. 1 with selected bond lengths and bond angles given in the caption. The structure analysis reveals that the trinuclear complex has approximately $C_2$ symmetry and is composed of a four- and two five-coordinated silver(I) centres. The two five-coordinate silver centres [Ag(1), Ag(3)] adopt a distorted trigonal-bipyramidal geometry with the equatorial positions occupied by two phosphino [P(1), P(2) for Ag(1); P(5), P(6) for Ag(3)] and an amino [N(1) for Ag(1), N(5) for Ag(3)] groups, and the axial positions by two imino [N(2), N(3) for Ag(1); N(7), N(8) for Ag(3)] groups of the heptadentate ligand L. Their equatorial bond angles [114.8(3), 118.8(3), 126.2(1)° summing to *ca*. 360° for Ag(1); 114.8(3), 118.7(3), 126.2(1)° summing to *ca*. 360° for Ag(3)] and axial bond angle [139.5(3)° for Ag(1); 140.2(3)° for Ag(3)] are almost identical. The Ag–P distances [Ag(1)–P(1) 2.430(5), Ag(1)–P(2) 2.429(4), Ag(3)–P(5) 2.429(5), Ag(3)–P(6) 2.440(4) Å] are normal and comparable to those of analogous silver diimino- and diamino-diphosphine complexes.[2] The Ag–amino distances [Ag(1)–N(1) 2.456(9), Ag(3)–N(5) 2.479(8) Å] are comparable to the long Ag–N distance [2.411(4) Å] in [Ag{P($C_6H_4$Me-*p*)$_3$}{$BPh_2$(pz)$_2$}] (pz = pyrazolyl).[3] The Ag–imino distances [Ag(1)–N(2) 2.580(8), Ag(1)–N(3) 2.608(9), Ag(3)–N(7) 2.661(9), Ag(3)–N(8) 2.654(7) Å] are significantly longer and comparable to the Ag–N distance [2.56(1) Å] in [Ag(Binap-$P_2N_2$)][$BF_4$] (Binap = binaphthylene).[2] The tetra-coordinated silver atom [Ag(2)] adopts a distorted tetrahedral geometry by coordinating to the two heptadentate ligands *via* pairs of imino [N(4), N(6)] and phosphino [P(3), P(4)] groups. The Ag–P distances [Ag(2)–P(3) 2.370(5); Ag(2)–P(4) 2.366(4) Å] are normal. The Ag–imino distances [Ag(2)–N(4) 2.604(9), Ag(2)–N(6), 2.643(8) Å] are comparable to those of Ag(1). The P(3)–Ag(2)–P(4) and N(4)–Ag(2)–N(6) angles are 164.8(1) and 83.1(3)°, respectively. The observed structural feature shows that the imino groups only interact weakly with the silver centres.



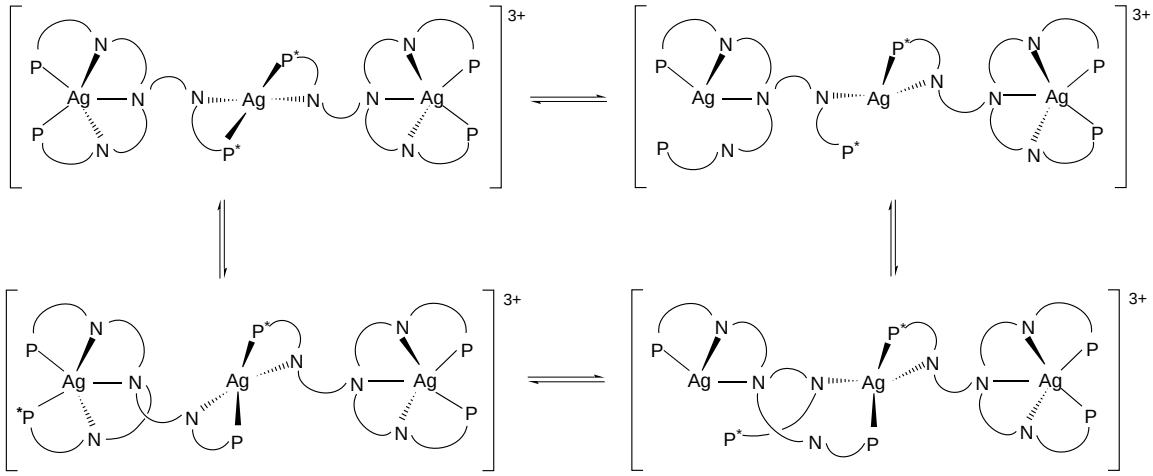


**Fig. 1** A perspective drawing of the trinuclear cation $[Ag_3L_2]^{3+}$ of compound **1**. For clarity, the hydrogen atoms are omitted and the phenyl rings of the $PPh_2$ groups are each represented by a circle with broken outline. Selected bond lengths (Å) and angles (°): Ag(1)–P(1) 2.432(5), Ag(1)–P(2) 2.435(4), Ag(1)–N(1) 2.443(9), Ag(1)–N(2) 2.580(8) , Ag(1)–N(3) 2.608(9), Ag(2)–P(3) 2.370(5), Ag(2)–P(4) 2.366(4), Ag(2)–N(4) 2.604(9), Ag(2)–N(6) 2.643(8), Ag(3)–P(5) 2.429(5), Ag(3)–P(6) 2.440(4), Ag(3)–N(5) 2.479(8), Ag(3)–N(7) 2.661(9), Ag(3)–N(8) 2.654(7), N(2)–C(19) 1.181(14), N(3)–C(24) 1.219(16), N(4)–C(45) 1.221(13), N(6)–C(82) 1.288(17), N(7)–C987) 1.294(11), N(8)–C(108) 1.154(15); P(1)–Ag(1)–P(2) 126.2(1), P(1)–Ag(1)–N(1) 114.8(3), P(2)–Ag(1)–N(1) 118.8(3), N(2)–Ag(1)–N(3) 139.5(3), P(3)–Ag(2)–P(4) 164.8(1), P(3)–Ag(2)–N(4) 73.1(3), P(3)–Ag(2)–N(6) 119.2(3), P(4)–Ag(2)–N(4) 120.1(3), P(4)–Ag(2)–N(6) 72.4(3), N(4)–Ag(2)–N(6) 83.1(3), P(5)–Ag(3)–P(6) 126.2(1), P(5)–Ag(3)–N(5) 114.8(3), P(6)–Ag(3)–N(5) 118.7(3), N(7)–Ag(3)–N(8) 140.2(3).

**Scheme 1** Proposed mechanism for the dynamic behaviour of the cation $[Ag_3L]^{3+}$

Complex **1** exhibited temperature-dependent $^{31}P\{^1H\}$ NMR spectra. At room temp. in $CD_2Cl_2$, two broad peaks centred at $\delta$ 6.5 and 10.6 appeared, which at −80 °C broadened into complex multiplets in the range $\delta$ 3.0–14.0, indicating non-equivalence of all phosphorus atoms. On the other hand, in $[^2H_7]$DMF at 120 °C the two broad peaks centred at $\delta$ 6.9 and 10.4 at 25 °C coalesced into a sharp singlet at $\delta$ 7.4, indicating that all the phosphorus atoms were equivalent. The variable-temperature $^{31}P\{^1H\}$ NMR study shows that the phosphino groups undergo facile intramolecular exchange. The observed solution dynamic behaviour can be explained by the proposed mechanism in Scheme 1 which shows that both the imino and the phosphino groups undergo rapid dissociation and association with the metal centres. The free heptadentate ligand $\{(o\text{-}Ph_2PC_6H_4)CH{=}NCH_2CH_2\}_3N$ can be liberated from **1** quantitatively by reacting **1** with an excess of KCN.

Thanks are due to the Hong Kong Baptist University and the Hong Kong Research Grants Council (HKBU 131/94P and CUHK 311/94P) for financial support.

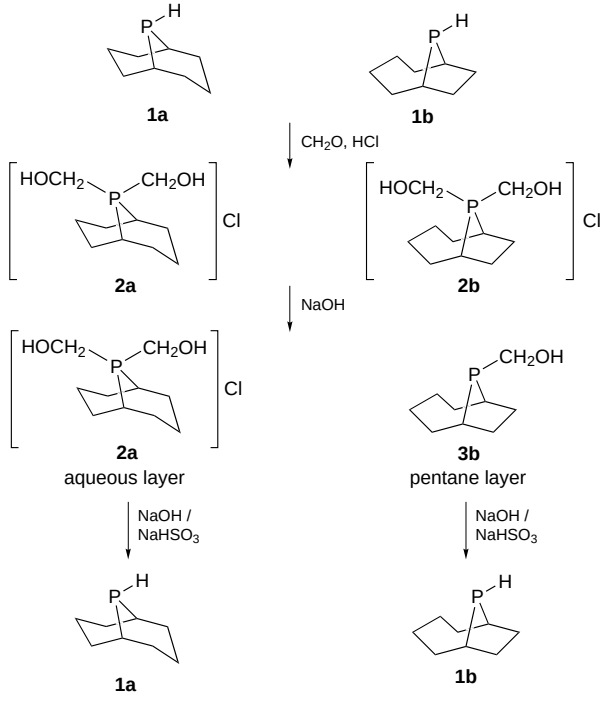
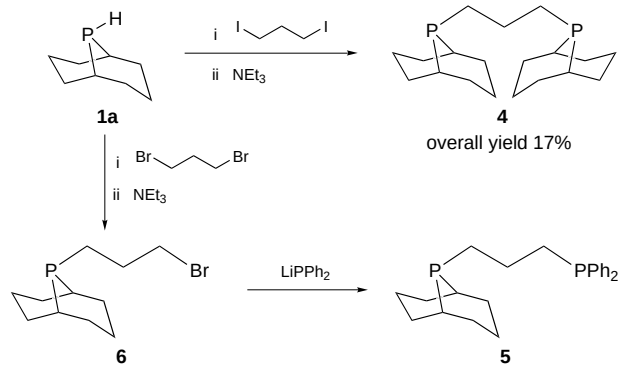
# A simple procedure for the separation of the catalytically important phosphabicyclononane isomers



**Joanne H. Downing, Victoria Gee and Paul G. Pringle***

*School of Chemistry, University of Bristol, Cantocks Close, Bristol, UK BS8 1TS*



**The isomeric [3.3.1]- and [4.2.1]-phosphabicyclononanes are readily separated by a sequence of hydrophosphination/dehydrophosphination steps; new diphosphine ligands derived from the [3.3.1] isomer are described.**

Phosphine ($PH_3$) adds to cycloocta-1,5-diene to give a mixture of the bicyclic secondary phosphines **1a** and **1b**, sometimes referred to as 'phobane'.[1,2] Tertiary phosphines made from this mixture are ligands for the cobalt-catalysed hydroformylation process[3] currently carried out on a large scale industrially.[4] Recently derivatives of **1a** and **1b** have attracted attention as ligands for hydroformylation,[5] carbonylation,[6] and asymmetric catalysis.[2,7] To date there have been no reports of the separation of the isomers **1a** and **1b** although, by exploiting the difference in reactivity between the isomers, ligands derived from the symmetrical isomer **1a** have been isolated.[2,8] Here we report an easy method for separating **1a** and **1b** and the use of pure **1a** in further ligand synthesis.

The reactions which form the basis for the separation are summarised in Scheme 1. The crystalline, air-stable phosphonium salts **2a** and **2b** are readily made from the mixture of **1a** and **1b** with $CH_2O$ in the presence of HCl. Loss of $CH_2O$ from **2a**/**b** is promoted by NaOH but we have found that one hydroxymethyl group in **2b** is much more reactive than any of the others. Thus an aqueous solution of a **2a**/**b** mixture reacted selectively with NaOH to give neutral phosphine **3b** which was then extracted into pentane to leave pure **2a** in the aqueous layer. The crystal structure of the complex *cis*-[$PtCl_2$(**3b**)$_2$] suggests that it is the hydroxymethyl group lying over the seven-membered ring that is the reactive one.[8]

**Scheme 1**

**Scheme 2** (Overall yield 50%)

Treatment of an aqueous solution of **2a** with NaOH and $NaHSO_3$ (to trap the generated $CH_2O$) gave the symmetrical secondary phosphine **1a** which was then extracted into pentane. Similarly the unsymmetrical isomer **1b** was made by treatment of a pentane solution of **3b** with aqueous NaOH and $NaHSO_3$. The separation can be carried out efficiently on a multigram scale† and both **1a** and **1b** have been isolated and fully characterised.‡

Access to **1a** has allowed us to synthesise the diphosphine derivatives **4** and **5** by the routes shown in Scheme 2; the modest overall yields reported reflect the small scale (0.1–1 g) of these preliminary reactions. Treatment of **1a** with $I(CH_2)_3I$ followed by $NEt_3$ gave **4**[5] exclusively in contrast to the mixture of isomers formed when $H_2P(CH_2)_3PH_2$ adds to cycloocta-1,5-diene. Treatment of **1a** with $Br(CH_2)_3Br$ gave the intermediate **6** which reacts with $LiPPh_2$ to give the unsymmetrical diphosphine **5**. The application of these new ligands in coordination chemistry and catalysis is in progress.

We thank EPSRC and Albright and Wilson for supporting this work.

† The separation of **1a** and **1b** was carried out as follows (under nitrogen except where specified). To a stirred solution of a crude mixture of **1a** and **1b** supplied by Albright and Wilson Ltd (77 g, *ca*. 60% **1a**/**b** by $^{31}$P NMR with the ratio of **1a** to **1b** of *ca*. 1.1 : 1) in aqueous $CH_2O$ (95 cm$^3$, 35% m/m, 1.20 mol) was added aqueous HCl (120 cm$^3$, 5 M, 0.60 mol) dropwise over 30 min. After 1 h, the volatiles were removed on a rotary evaporator in air to give a viscous white oil. In air, trituration with propan-2-ol (400 cm$^3$) gave a white solid which was filtered off, washed with cold propan-2-ol (50 cm$^3$) and diethyl ether (50 cm$^3$); the yield of salts **2a** and **2b** was 56 g which represents *ca*. 72% yield. The solid was dissolved in hot (*ca*. 60 °C) water (*ca*. 20 cm$^3$) and then when the solution had cooled to *ca*. 40 °C, acetone was added until the solution turned cloudy (*ca*. 50 cm$^3$). Then the mixture was refrigerated (0 °C) for 16 h to give crystalline **2a**/**b** in > 80% recovery. To a rapidly stirred solution of **2a**/**b** (8.5 g, 36 mmol) in water (20 cm$^3$) with a layer of pentane (35 cm$^3$), was added aqueous NaOH (16 cm$^3$, 1 M, 16 mmol) dropwise by syringe over 5 min. After a further 10 min, the pentane layer was separated and the aqueous layer washed with pentane (2 × 10

cm$^3$). To the aqueous layer, more aqueous NaOH (1 M, 1 cm$^3$) was added (to remove the final traces of **2b**) and then in a separating funnel (in air), the aqueous layer was washed with pentane (2 × 30 cm$^3$) and then separated. The aqueous layer was then deaerated, pentane (50 cm$^3$) was added, then aqueous NaOH (37.6 cm$^3$, 1 M, 37.6 mmol) added dropwise over 5 min and finally solid $NaHSO_3$ (7.8 g, 75 mmol) was added and the mixture stirred for 1 h. Then the pentane layer was separated and the aqueous layer washed with pentane (2 × 20 cm$^3$). The pentane extracts were combined, dried over $MgSO_4$, filtered and then evaporated to dryness to give a white solid **1a** (2.32 g, 87%) which was 99.5% pure **1a** (by $^{31}$P NMR).

In a separate experiment a pentane solution (*ca.* 30 cm$^3$) of **3b** (obtained as described above but from 1.78 g of **2a**/**b**, 7.5 mmol) was treated with water (20 cm$^3$) and NaOH (3.25 cm$^3$, 1 M, 3.25 mmol) followed by solid $NaHSO_3$ (3.44 g, 33 mmol) and the mixture rapidly stirred for 44 h. Then the pentane layer was separated and the aqueous layer washed with pentane (3 × 10 cm$^3$). The pentane extracts were combined, dried over $MgSO_4$, filtered and then evaporated to dryness to give a white solid **1b** (0.26 g, 55%) which was 99% pure **1b** (by $^{31}$P NMR).

‡ *Selected spectroscopic data*. **1a**: $^{31}$P NMR ($CDCl_3$, 162 MHz) $\delta$ −54.1 [$^1J$(PH) 192.1 Hz]; $^1$H ($CDCl_3$, 400 MHz) $\delta$ 3.20 [d, 1 H, $^1J$(PH) 192.1 Hz], 1.55–2.55 (br m, 14 H); $^{13}$C ($CDCl_3$, 100 MHz) $\delta$ 33.9 [d, $J$(PC) 6.1 Hz], 30.0 [d, $J$(PC) 9.2 Hz], 22.6 (s), 22.4 [d, $J$(PC) 42.7 Hz], 22.1 (s); mass spectrum (EI) $m/z$ 142 ($M^+$). **1b**: $^{31}$P NMR ($CDCl_3$, 162 MHz) $\delta$ −48.4 [$^1J$(PH) 188.1 Hz]; $^1$H ($CDCl_3$, 400 MHz) $\delta$ 2.70 [d, 1H, $^1J$(PH) 188.0 Hz], 2.59 (br s, 2 H), 2.06 (m, 2 H), 1.35–1.82 (m, 10 H). $^{13}$C ($CDCl_3$, 100 MHz) $\delta$ 37.1 [d, $J$(PC) 7.6 Hz], 35.5 [d, $J$(PC) 7.6 Hz], 35.3 [d, $J$(PC) 15.3 Hz], 25.8 [d, $J$(PC) 7.6 Hz]; mass spectrum (EI) $m/z$ 142 ($M^+$). $^{31}$P NMR data (162 MHz): **2a** ($D_2O$) $\delta$ +23.1; **2b** ($D_2O$) $\delta$ 55.4; **3a** ($CDCl_3$) $\delta$ −31.7; **3b** ($CDCl_3$) $\delta$ 4.3; **4** ($C_6D_6$) $\delta$ −37.6; **5** ($C_6D_6$) $\delta$ −38.1 (s, $PC_8H_{14}$), −17.2 (s, $PPh_2$); **6** ($C_6D_6$) $\delta$ −37.8.

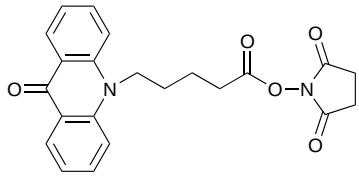
# A novel acridone derivative for the fluorescence tagging and mass spectrometric sequencing of peptides

**Thomas Faller,[a] Kathryn Hutton,[b] George Okafo,[a] Andy Gribble,[a] Patrick Camilleri*[a] and David E. Games[b]**



[a] *SmithKline Beecham Pharmaceuticals, New Frontiers Science Park, Third Avenue, Harlow, Essex, UK CM19 5AW*
[b] *University of Wales, Swansea, Singleton Park, Swansea, Wales, UK SA2 8PP*

**An acridone derivative containing an activated carboxylic group is highly reactive towards primary amine groups, and allows selective analysis either using absorbance at a wavelength of 410 nm or fluorescence at excitation and emission wavelengths of 400 and 418 nm, respectively; MS–MS analysis of peptides tagged with this reagent gives fragmentation patterns which are usually considerably more intense than background.**

Peptides tagged with a fluorescent label offer a major advantage in that they can be selectively analysed or localised even in complex biological fluids. Such derivatives have proved to be especially useful in bio- and immuno-assays. Fluorescent labels have included fluorescein, methylanthranylate, a number of cyanine dyes and succinimidyl pyrene-1-butyrate.[1–4]. These molecules can have disadvantages, such as sensitivity to light and fluorescence quenching in acidic or basic conditions. Moreover, the cyanine dyes are bulky molecules (molecular weight *ca*. 1000) which carry three to five charges at neutral pH; such properties can interfere with biological activity.

The acridone moiety is highly fluorescent and is stable to light, heat and oxidation. In earlier studies we have used 2-aminoacridone extensively in the reductive amination of monosaccharides and a variety of complex oligosaccharides.[5,6] A general and highly sensitive assay for antibody catalysis has also been demonstrated recently by using a number of acridone labelled compounds.[7]

We have now synthesised the succinimide ester **1** in three

**1**

$F^{1}VNQHLC(SO_3H)GSH^{10}LVEALYLVC(SO_3H)G^{20}ERGFFYTPKA^{30}$

**2**

steps from relatively inexpensive starting materials. Acridone was reacted with methyl 5-bromopentanoate to give methyl 9,10-dihydro-9-oxoacridine-10-pentanoate **3** (31%). Ester **3** was then hydrolysed with 10% aqueous NaOH to give the corresponding pentanoic acid **4** in (80%). Finally, to a solution of **4** and *N*-hydroxysuccinamide was added DCC to give **1** (34%) as a yellow solid (mp 181–182 °C). None of the yields mentioned have been optimised.

Compound **1** absorbs visible light at 410 nm and fluoresces intensely at excitation and emission wavelengths of 400 and 418 nm, respectively. It is neutral over the widest possible pH range and reacts rapidly with primary amines and, to a lesser extent, with phenolic hydroxy groups. To show the diversity in the use of **1** in the labelling and tracking of peptides, we have derivatised insulin chain B (oxidised) **2**, and carried out MS and enzymic digestion studies on material tagged in one or more positions. About 5 nmol of **2** were used in these experiments in 20 μl of solution. In separate experiments we have shown that a 20–50 pmol level of protein could be derivatised especially by performing the derivatisation reaction in volumes as low as 2 μl of solution. We used higher amounts for this study as it was necessary to collect derivatives of **2** for the tryptic digestion experiments which we describe later.

The extent of labelling by **1** can be controlled by its molar ratio to the peptide to be derivatised. Reactions were carried out by mixing the peptide in 10 μl of $NaHCO_3$ buffer (pH 8.5) with a solution (10 μl) of **1** in MeCN. The resulting mixture was left at room temperature for 1 h prior to analysis. For single labelling a 1:1 molar ratio is used, whereas multiple labelling is obtained in the presence of 10 molar excess of **1**. From the preliminary studies carried out on a number of peptides it appears that the ε-amino group in lysine is the first to be derivatised, followed by the amino group at the N-terminal end of the peptide and tyrosine residues. Multiple labelled peptides are easily separated and isolated by HPLC, using a reversed-phase C18 column and a mobile phase consisting of a gradient of 0.1% TFA in water and 0.1% TFA in MeCN.

Derivatisation of **2** with excess **1** yields four major products, one of which is single-tagged and the remainder of which are double tagged. We carried out LC–MS–MS analysis of triply charged parent ions using a Finnigan MAT LCQ ion trap mass spectrometer. Fig. 1 shows the total ion current for all product ions from an MS–MS experiment after derivatisation of **2** using excess **1**. Electrospray mass spectrometric and MS–MS analysis showed that peak 1 was related to **2** containing a single acridone moiety at the lysine residue in position 29. As expected this molecule elutes first as it is less hydrophobic than the double-labelled peptides. The latter peptides are again labelled at the same lysine and in addition contain a tag at the N-terminal phenylalanine (peak 2) or at a tyrosine in positions 26 (peak 3) and 16 (peak 4). It is interesting that these double labelled peptides also differ in hydrophobicity, and this may be partly due to conformational changes.

The product ion spectra from the fragmentation of the triply charged underivatised (*m/z* 1166) and double tagged **2** (*m/z*

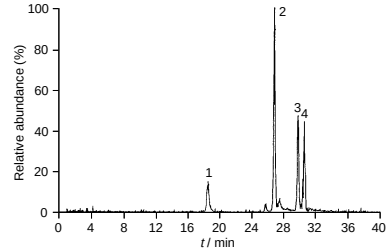


**Fig. 1** Reversed-phase HPLC–MS–MS analysis of insulin chain B derivatised with excess **1**. Detection of peaks was by monitoring total ion current for all product ions produced from triply charged parent ions. Peak 1 is related to a derivative of **2** labelled only at $^{29}$Lys, whereas peaks 2–4 are double tagged derivatives, again labelled at $^{29}$Lys and at $^{1}$Phe, $^{26}$Tyr and $^{16}$Tyr, respectively.

[a] Parent ion (single tag, peak 1).

1351) are shown in Fig. 2(*a*) and (*b*), respectively. Signals from the single and multiple tagged peptides are more intense than those from intact **2**. Product ions obtained from the fragmentation of the single tagged derivative of **2** are collected in Table 1. It is clear that besides confirming the positions of the acridone labels on **2** these data provide an abundance of sequencing information. Moreover, covalent tagging of the acridone derivative to **2** *via* a stable amide bond appears to have simplified the distribution of fragment ions compared to those obtained from **2** itself, most probably due to a decrease of the number of basic sites.

Due to the intense fluorescence of the acridone moiety we also investigated the ease of adaptation of this fluorophore as a label useful in assaying the bioactivity of an enzyme. We were especially interested to find out whether labelling hinders biological activity. For this purpose we followed the hydrolysis of single and double labelled **2** by the proteolytic enzyme trypsin. The single (peak 1) and double labelled (peak 2) insulin derivatives were isolated by HPLC and about half of the solvent was removed *in vacuo*. The volume of the remaining solution was doubled by adding 50 mM $NH_4HCO_3$ buffer (pH 7.8). Trypsin in water was added to give a derivatised peptide to enzyme ratio of 200 : 1. The hydrolysis was monitored with time

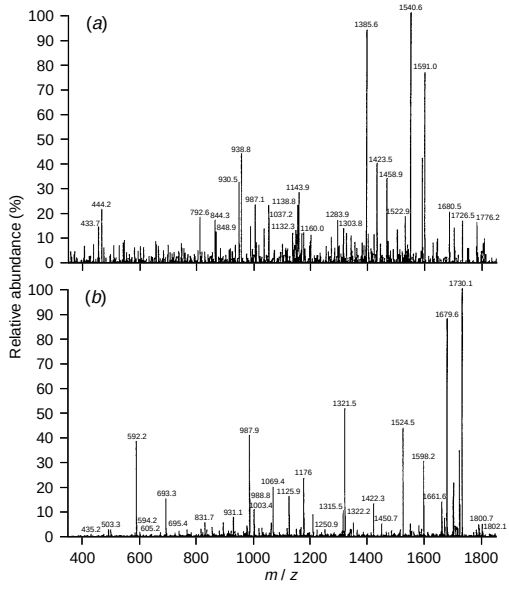

**Fig. 2** Influence of the presence of label on the product ion spectrum from the fragmentation of triply charged (*a*) original insulin chain B and (*b*) peptide labelled in positions 1 and 29

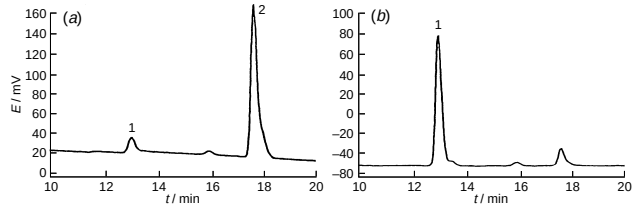

**Fig. 3** HPLC analysis of the mixture from the enzymic hydrolysis of single tagged insulin chain B. Starting material (peak 2) disappears leading to the formation of one product (peak 1) with time: (*a*) 0 and (*b*) 60 min.

by direct HPLC analysis of the reaction mixture and fluorescence detection, and was found to be complete in about 60 min.

As expected, in the case of single tagged **2** only one fluorescent product was obtained (Fig. 3). MS confirmed that the fluorescence signal was related to the peptide GFFYTPK-(tag)A (*m/z* 1206), as a result of hydrolysis at the arginine residue in position 22. The remainder of **2**, that is FVNQ...GER (*m/z* 2584), had a retention time shorter than that containing the acridone moiety, which emphasises the hydrophobic character imparted by this tag.

The tryptic digestion of double labelled **2** showed the simultaneous formation of two fluorescent signals. This confirmed that the arginine residue was located in between the two tags in the sequence. One of the signals again corresponded to the peptide GFFYTPK(tag)A. The other peptide, now with a longer retention time, corresponded to F(tag)V NQ...GER (*m/z* 2860). From these studies it is clear that derivatised lysine residues are not susceptible to tryptic digestion. However, hydrolysis on the carbonyl end of the arginine residue was not affected by this labelling procedure.

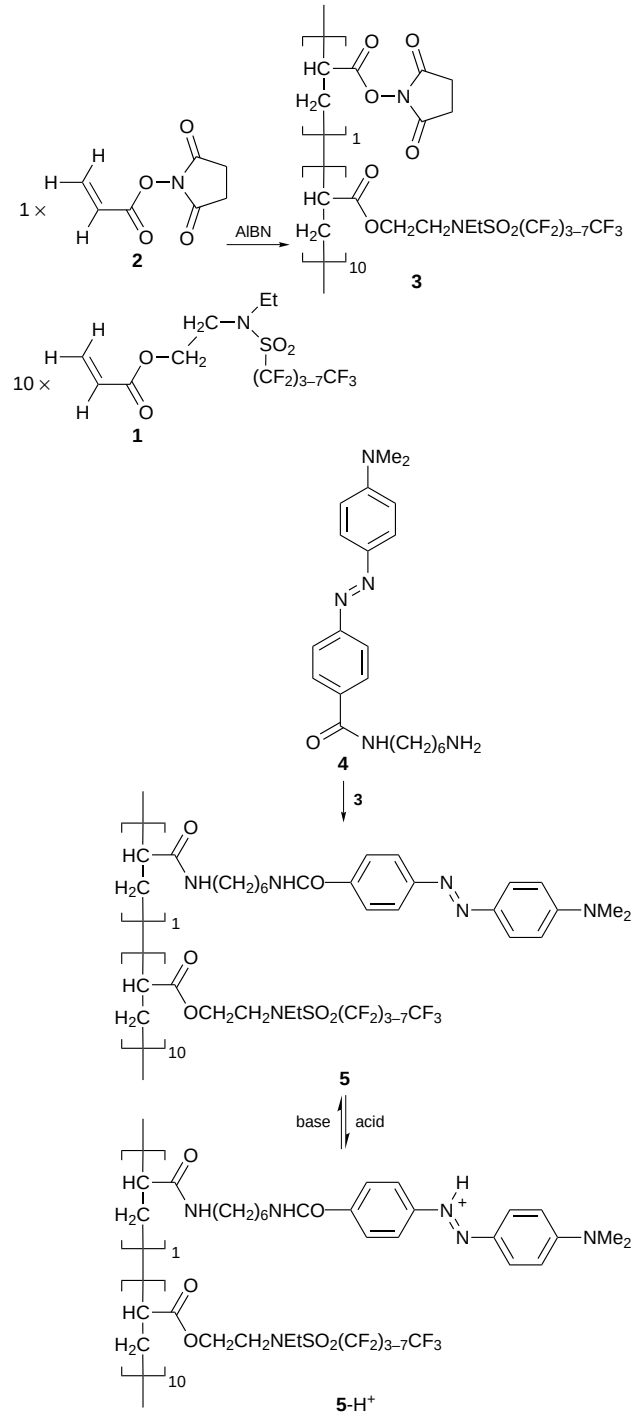
# A soluble fluorous phase polymer support

**David E. Bergbreiter* and Justine G. Franchina**

*Department of Chemistry, Texas A&M University, College Station, TX 77843-3255, USA*



**The synthesis of fluorous phase soluble fluoropolymer supports that readily covalently bind amine-containing reagents and that react with and separate from reagents in aqueous and hydrocarbon solvents is described.**

Fluorous phase chemistry is the most recent of several strategies that have been developed to facilitate separation of catalysts or reagents from products or one another.[1–5] Such separation processes are of increasing interest for environmental reasons and as a basis for the recovery, separation and processing of intermediates or products in synthetic chemistry.[2,6] As originally described by Horváth,[1] this chemistry consists of essentially three elements; a fluorocarbon solvent, a hydrocarbon solvent and a fluorous tag that renders something fluorous phase soluble. Here we describe an alternative approach to synthesis of fluorous labels. The idea was to prepare a soluble fluorocarbon polymer that has reactive sites that can be used to covalently bind reagents and to render them soluble in the fluorous phase as a polymer-bound reagent.

A soluble polymer support for fluorous phase chemistry has several requirements beyond those generally expected in a polymer support. Such a polymer should be selectively soluble in a fluorous phase as opposed to an aqueous or hydrocarbon solvent phase. It should be easy to attach or remove reagents, catalysts or ligands. Moreover, if a fluoropolymer support were to be practically useful, emulsions formed by shaking a hydrocarbon solution with the fluoropolymer in the fluorous phase should quickly and easily phase separate. Finally, a fluorous phase soluble fluoropolymer supported reagent has to react readily with species in a non-fluorocarbon aqueous or hydrocarbon phase. The preliminary experiments outlined here show that these goals can be achieved with simple fluorocarbon polymers derived from acrylic acid.

To test our ideas, we prepared a fluoropolymer-bound dye as shown in Scheme 1. The requisite fluoropolymer-bound dye is prepared in two steps. First, we prepared a fluoroacrylate–*N*-acryloyloxysuccinimide (NASI) copolymer **3**. The active ester in this copolymer was in turn used to attach an amino-containing *p*-Methyl Red derivative **4** to yield a highly coloured pH-sensitive fluoropolymer-bound dye **5**.

The copolymerization of the fluorinated acrylate **1** and the *N*-acryloyloxysuccinimide **2** was accomplished using AIBN as the initiator in *tert*-butyl alcohol. After 48 h, the copolymer precipitated. After decantation of the remaining reaction solution, any residual monomers in the fluoropolymer were removed by THF extraction. The product was characterized by IR spectroscopy (imide peaks at 1818 and 1788 $cm^{-1}$, an intense but broad carbonyl peak at 1746 $cm^{-1}$ and C–F peaks in the 1150–1250 $cm^{-1}$ region). The absence of vinyl peaks at $\delta$ 5.8–6.8 in the $^1H$ NMR spectrum of the polymer confirmed that there was no monomer in the polymeric product. The polymer's molecular weight was measured by end group titration for samples of the homopolymer of **1** and for **1**–NASI copolymers produced using 4,4′-azobis(4-cyanovaleric acid) as the initiator. These $M_n$ values were 120 345 and 107 705 Da, respectively. Viscometry was also carried out and the intrinsic viscosity of the **1**–NASI copolymer produced with AIBN initiation was 1.56 dl $g^{-1}$ in $Cl_2CFCClF_2$ at 29 °C (*K* and *a* values for this polymer are not available) (a structurally similar fluorinated polyacrylate of reasonably high molecular weight had a reported intrinsic viscosity of 0.25–0.49 dl $g^{-1}$).[7]

**Scheme 1**

Derivatization of this active ester-containing polymer with functional amines was carried out in a biphasic reaction mixture. For example, reaction of **3** with the Methyl Red derivative **4** was carried out by dissolving **3** in a fluorocarbon solvent (FC77, 3M Co., a fluorinated cyclic ether, $C_8F_{16}O$) and vigorously mixing this solution with a THF solution of the amine-containing Methyl Red derivative **4**. The yield in this reaction was high (> 90%) based on the observed complete disappearance of the broad $CH_2$ singlet of the succinimide at $\delta$ 2.9. The product copolymer **5** was isolated by simple separation of fluorocarbon phase and removal of the FC77 solvent. The product polymer's IR spectrum showed a complete loss of the active ester imide peaks (confirming the NMR results, *vide supra*) and a new amide carbonyl peak at 1638 $cm^{-1}$. The loading of Methyl Red on this polymer was estimated to be $0.075 \times 10^{-3}$ equiv. of Methyl Red per gram of polymer.

The Methyl Red-containing fluoropolymer **5** was not soluble in ordinary organic solvents (THF, alcohols, chloroform, DMSO, toluene) but **5** like **3**, was soluble in fluorinated solvents such as FC77 or $PhCF_3$.[8,9] Solutions of **5** or **5**-$H^+$ in FC77 were immiscible with water and organic solvents. Separation of this fluoropolymer-bound dye from these solvents appeared visually to be quantitative. A more quantitative estimate of > 99.9% of **5** being retained in the fluorous phase was obtained by UV–visible spectroscopy of the THF or water layer, which showed no Methyl Red present in this second phase.

Shaking solutions of **5** in FC77 with THF produces emulsions that separate within 10 min. In the case of mixtures of **5**–FC77 and water, the emulsion of **5**-$H^+$–FC77 and water required up to 60 min to separate on standing.

Reaction of the fluoropolymer-bound Methyl Red with aqueous HCl or with HCl that had been added to an immiscible THF phase led to an immediate protonation of the fluoropolymer-bound dye as evidenced by the instantaneous change in the fluorous phase colour from yellow to red. Similarly, addition of a base to the THF or water solution produced a change back to yellow. Bases like NaOH–$H_2O$ or $Et_3N$ in THF were equally effective.

Another advantage of this fluorocarbon polymer support is that the so-called 'Teflon pony-tails' are well insulated from the reacting group. However, it is worth noting that this alone is not sufficient to make ionic chemistry in a fluorous phase equivalent to that in an aqueous phase. Equilibration of **5** in FC77 with buffer solutions of varying pH and with THF solutions of **4** show that **5** is a weaker base than **4**. We estimate that the p$K_a$ of the fluorous phase Methyl Red **5** is between 1.0 and 1.5 based on the colour change for fluorocarbon solutions of **5** equilibrated with aqueous buffer solutions. This greater than one hundred-fold decrease in the acidity of **4** on covalent binding to **3** is most likely due to decreased solvation of the cation in the fluorous phase.

In summary, vinyl fluoropolymers copolymerize with other vinyl monomers that contain reactive groups to form starting materials for synthesis of polymer-supported reagents that will be fluorous phase soluble. The product polymer-supported species can easily be separated from organic or aqueous solutions but still have excellent reactivity as judged by the fast protonation/deprotonation experiments described here. Continuing work will explore other fluoropolymer supports and exploit this reactivity in catalytic chemistry.

Support of this work by the National Science Foundation (CHE-9222717) and the Robert A. Welch Foundation is gratefully acknowledged. We are also indebted to Drs D. W. Zhu and N. L. Franchina of 3M for supplying us with the necessary monomer and fluorocarbon solvents.

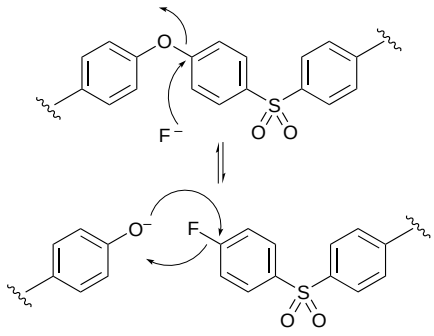
# Ring-closing depolymerisation of aromatic polyethers



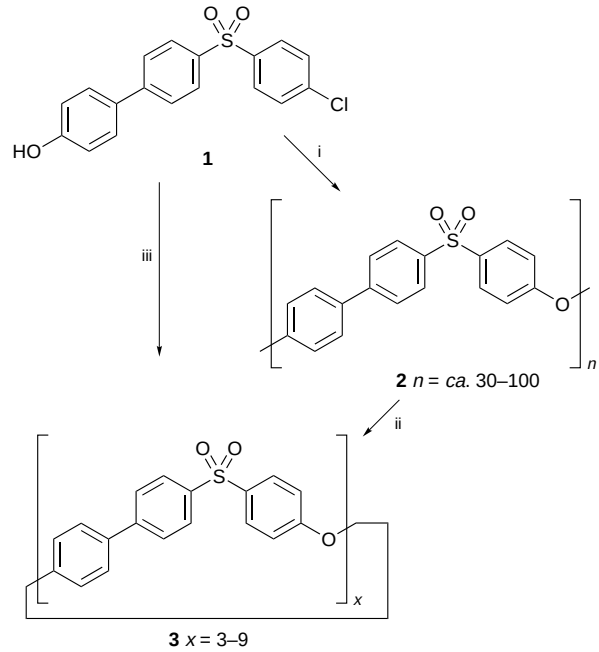
**Abderrazak Ben-Haida,[a] Ian Baxter,[b] Howard M. Colquhoun,*[a]† Philip Hodge,*[a]‡ Franz H. Kohnke[a]§ and David J. Williams*[b]**

[a] *Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*
[b] *Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY*

**Equilibration of aromatic poly(ether sulfone)s and poly(ether ketone)s under conditions of fluoride-catalysed ether exchange leads, at low polymer concentrations in dipolar aprotic solvents, to efficient ring-closing depolymerisation.**

Ring-opening polymerisation of macrocyclic aromatic ether ketones and ether sulfones offers a potentially valuable route to high-performance aromatic polymers,[1–3] and such chemistry has recently become the focus of significant research activity.[4] Advantages of this approach, in the production of composite structures for example, include the very much lower initial viscosities of macrocyclic oligomers relative to the corresponding high molecular weight polymers, the complete absence of by-products, and the fact that ring-opening polymerisations of strain-free macrocycles are largely entropy-driven and thermally neutral.

The synthesis and ring-opening polymerisation of macrocyclic aromatic ethers was first reported in 1989,[1] but the key reaction which would enable recycling of such materials (ring-closing depolymerisation)[5] has not so far been demonstrated. Aromatic poly(ether sulfone)s and poly(ether ketone)s do however undergo catalytic transetherification at high temperatures in the presence of strong but kinetically labile nucleophiles such as fluoride ion,[6] and the existence of this process (Scheme 1) strongly suggests a potential mechanism for polymer–macrocycle interconversion.



**Scheme 1**

We now report that efficient ring-closing depolymerisation of the aromatic poly(ether sulfone) **2** ($M_w$ = 29 000, $M_n$ = 8500 Da) can be achieved in dimethylacetamide (DMA) solution at 0.03 M monomer-equivalent concentration and at a temperature of 150 °C, using CsF (0.02 M) as catalyst (Scheme 2). Under these conditions the broad GPC peak associated with the starting polymer disappears over the course of about 12 h, and is progressively replaced by a series of sharp peaks representing macrocyclic oligomers in the approximate molecular weight range $M_w$ = 800–4000 (Fig. 1). It should be noted that the macrocylic oligomers are present (as is often the case for condensation polymers) at a low level even in the starting polymer **2**. Indeed, when polycondensation of monomer **1** is carried out under high-dilution conditions these same macrocyles, identified by FAB-MS, come to represent the major fraction of the product (Scheme 2).

After equilibration of polymer **2** for 48 h in the presence of CsF there is no further change in the molar mass distribution, and the oligomers can be recovered in *ca*. 95% yield by precipitation in aqueous MeOH. Elemental analysis for fluorine (after repeated extraction with water to remove residual inorganics) reveals only very low levels of fluoride ion incorporation (*ca*. one fluorine for every thirty polymer repeat units) consistent with the formation of mainly cyclic species. Peak positions in the GPC and HPLC chromatograms of the depolymerised product are superimposable on those of the macrocyclic oligomers formed by polycondensation of monomer **1**. Moreover, FAB mass spectra of the products from macrocyclisation of **1** and from depolymerisation of **2** show an identical series of parent ions associated exclusively with cyclic species, from cyclotrimer ($[M + H]^+$ 925) to cycloheptamer ($[M + H]^+$ 2158).

The cyclic trimer, tetramer, pentamer and hexamer were isolated from the products of depolymerisation by column chromatography (silica gel; $ClHC{=}CCl_2$ : $CH_2Cl_2$ : EtOAc, 64 : 33 : 3) and were characterised by FAB mass spectrometry, $^1H$ and $^{13}C$ NMR spectroscopy, GPC, HPLC and DSC. Their well-resolved $^1H$ NMR spectra confirm that, as expected for pure cyclic oligomers, only three AA′BB′ systems are present in the aromatic region. Resonances assigned to protons *ortho* to the biphenyl linkage show significant variations of chemical shift as a function of ring-size, and are for example shifted upfield by *ca*. 0.1 ppm in the cyclic trimer **3** ($x$ = 3), relative to the higher ring sizes. Crystals of **3** ($x$ = 3) suitable for X-ray

**Scheme 2** *Reagents and conditions*: i, $K_2CO_3$, $PhSO_2Ph$, 280 °C; ii, CsF, DMA, 150 °C; iii, $K_2CO_3$, DMA, 150 °C

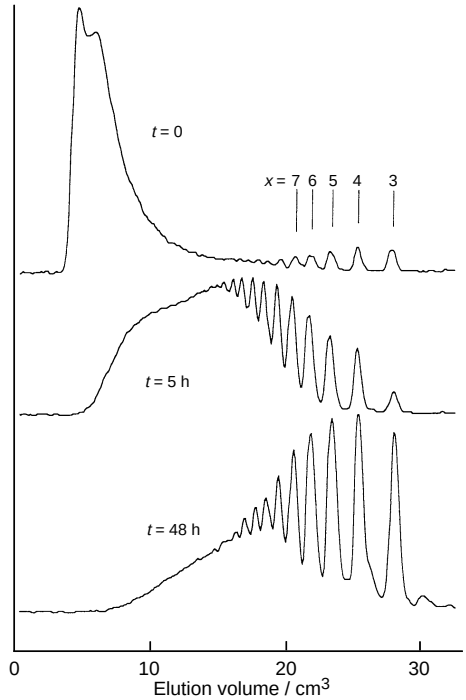


**Fig. 1** Gel permeation chromatograms (eluent $CHCl_3$) showing progressive ring-closing depolymerisation of polymer **2** and formation of the macrocyclic oligomers $[OArArSO_2Ar]_x$ (Ar = 1,4-phenylene)

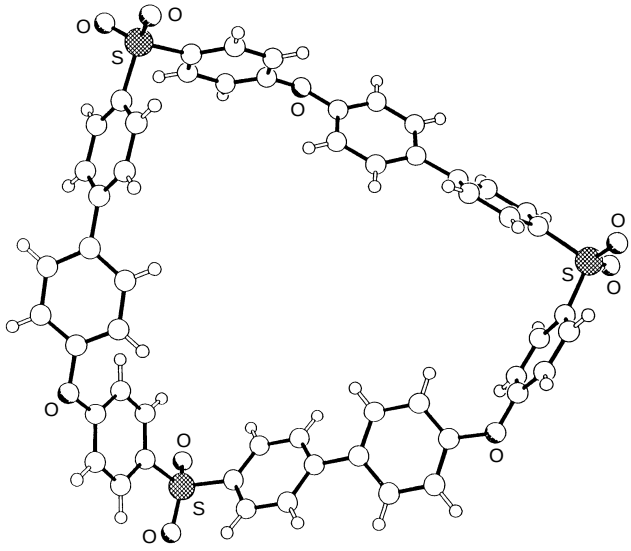
analysis, were isolated from $CHCl_3$. These melted sharply at 475 °C, but higher cyclic oligomers decomposed above 500 °C without melting. The structure of **3** ($x$ = 3), determined by single-crystal X-ray diffraction,¶ is shown in Fig. 2. There is evidence for a slight degree of ring-strain in this macrocycle, in that all three C–S–C bond angles (101.6 ± 0.1°) are compressed by about 3.3° from their normal open-chain value of 104.9°. The biphenyl unit, which frequently adopts a coplanar conformation as a consequence of crystal packing and symmetry considerations,[7] here takes up a conformation close to its isolated



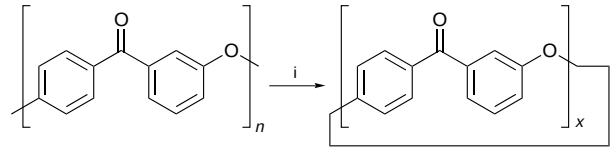


**Fig. 2** Molecular geometry of the cyclic trimer **3** ($x$ = 3) (the solvating molecule of $CHCl_3$, which partly fills the molecular cavity, has been omitted for clarity)

**4** $x$ = 2–11

**Scheme 3** *Reagents and conditions*: i, CsF, DMA, 155 °C

minimum-energy position,[8] with inter-ring torsion angles for the three independent biphenyl residues in the range 34–38°.

Ring-closing depolymerisation appears to be a quite general reaction for activated aromatic polyethers. The poly(ether ketone) **4** (Scheme 3), for example,[9] is cleaved to form macrocyclic species under very similar conditions and on much the same timescale as polymer **2**. Analysis of the product mixture by GPC, HPLC and FAB-MS demonstrates formation of macrocyclic ether ketone oligomers up to at least the cycloundecamer, and lower oligomers from cyclic dimer to cyclic hexamer have been isolated in pure form by column chromatography.

The potential of ring-closing depolymerisation chemistry for recycling (in every sense!) high-performance aromatic polyethers has thus been demonstrated for the first time. The possibility that non-equilibrium conditions might circumvent the current requirement for very low polymer concentrations in such reactions is now under investigation.

We wish to thank the Royal Society and the EPSRC for financial support of this research.

**Novel aromatic silylboranes involving trigonally bonded boron display absorption and fluorescence emission in the visible range due to the Si–B bond; these results are supported by MNDO calculations.**

We have recently described the synthesis and characterisation of novel organosilylboranes (compounds **1**–**3**) possessing a dimesitylboryl moiety linked to a triarylsilyl group.[1]

**1** $R^1 = R^2 = H$
**2** $R^1 = Me$, $R^2 = H$
**3** $R^1 = H$, $R^2 = NMe_2$

mes = mesityl

Surprisingly, these reasonably stable silylboranes strongly absorb in the visible region as evidenced by their yellow or yellow–green colour. Meanwhile, it has been pointed out by others[2] that a toluene solution of a bis(amino)silylene–tris(pentafluorophenyl)borane adduct exhibits a deep yellow colour. This Lewis adduct slowly isomerizes into a new silylborane possessing a trigonally bonded boron, but no information was given concerning the origin of the coloration of this compound. Here we report our preliminary results demonstrating the close connection between the electronic absorption and fluorescence emission properties of silylboranes and the presence of the Si–B bond.

The UV spectra of organosilylboranes **1**–**3** and two reference compounds, $Ph_3SiMe$ **4** and $(mes)_2BPh$ **5** in a non-polar solvent, are shown in Fig. 1. Compounds **1**–**3** display a broad absorption band around 400 nm which is independent of the concentration. This band does not appear in phenylsilanes and phenylboranes which usually present $\lambda_{max}$ at appreciably shorter wavelengths.[3,4] Thus, the UV spectra of both reference compounds **4** and **5** in *n*-hexane (insert of Fig. 1) only exhibit absorption bands around 270 and 320 nm, respectively, and the spectrum of an equimolar mixture of these two compounds roughly corresponds to the sum of the spectra of each component. Therefore, the new band peaking in the visible range for derivatives **1**–**3** is due to the presence of the Si–B bond.

Interestingly, this long-wavelength absorption shifts from 397 nm for **2** to 405 nm for **1**. This bathochromic effect might be connected to a stronger interaction between boron and silicon in **1**. For **3**, a marked bathochromic effect is revealed ($\lambda_{max}$ = 409 nm), anticipating a much larger interaction between Si and B: the presence of the dimethylamino group probably augments the electron-donating ability of the silyl group to boron. This is consistent with the strong electron-acceptor ability of the dimesitylboryl group which was reported to behave in an analogous manner to a nitrile one.[5] Likely, these electronic factors might contribute to increase the electron density on the Si–B link and therefore the strength of this bond. The UV absorption spectra of compounds **1**–**3** are weakly sensitive to the polarity of the solvent, suggesting that their ground state does not exhibit a significant charge-transfer character.

The fluorescence emission of compounds **1**–**3** is characterised with a low fluorescence quantum yield ($\Phi_f$ *ca.* $5 \times 10^{-3}$ for **1**) indicating efficient non-radiative deactivation pathways for the singlet excited state. Upon excitation at 300 nm, **1**–**3** display two fluorescence emission bands ($\lambda_{max}$ *ca.* 340 and 480 nm) and only one (*ca.* 480 nm) upon excitation at 400 nm. On the other hand, the two reference compounds **4** and **5** present an emission band at 320 and 370 nm respectively, when excited at 300 nm. Addition of their spectra results in a broad band around 350 nm, which roughly matches the position of the high energy band observed for organosilylboranes **1**–**3** when excited at the same wavelength. Therefore, the second emission band at 480 nm can be attributed to the Si–B chromophore. Moreover, excitation spectra recorded in the 480 nm region indicate that an efficient intramolecular energy transfer occurs from aromatics to the Si–B bond.

The fluorescence emission spectra of **1** in solvents of increasing polarity are shown in Fig. 2.

In contrast to the UV absorption, the fluorescence emission of compounds **1**–**3** is very sensitive to the polarity of the solvent (Table 1). Thus, a marked solvatochromic effect is found for compound **1,** even stronger for **3**, as the values of $\lambda_{max}$ shift from

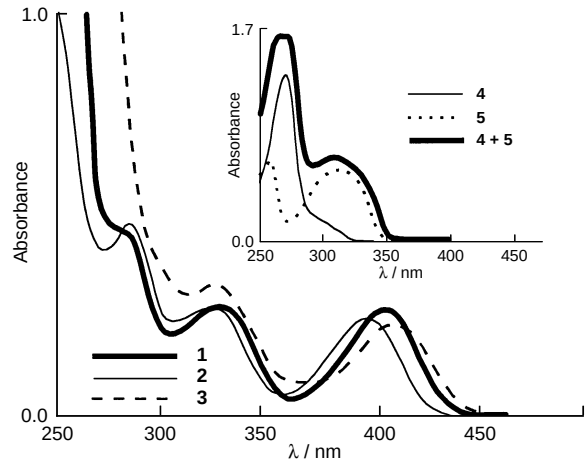

**Fig. 1** Electronic absorption spectra of organosilylboranes **1**–**3** in *n*-hexane, room temp., conc. $5.8 \times 10^{-5}$ (**1**), $6.4 \times 10^{-5}$ (**2**) and $8.4 \times 10^{-5}$ M (**3**). Insert: spectra of the reference compounds in *n*-hexane, room temp., conc. $7.7 \times 10^{-5}$ (**4**), $8.4 \times 10^{-5}$ (**5**) and $4.1 \times 10^{-5}$ M for each component of the mixture **4** + **5**.

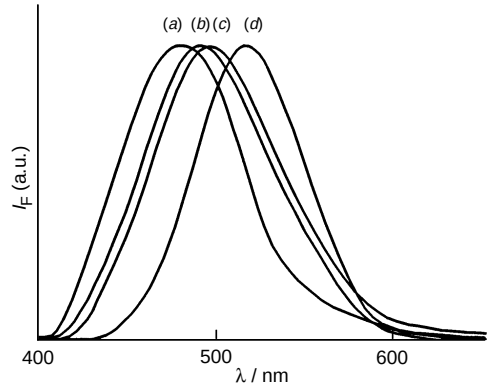

**Fig. 2** Emission fluorescence spectra of **1** in various solvent ($\lambda_{exc}$ = 400 nm): *n*-hexane (*a*); diethyl ether (*b*); chloroform (*c*); acetonitrile (*d*)

480 nm in *n*-hexane to 640 nm in acetonitrile. From the relationship[6] between the variation of $\nu_{max}$, the polarity factor $\Delta f$, and the radius of the solvent cavity $\rho$ (estimated from space-filling molecular models), it is possible to estimate the dipole moment $\Delta\mu$ in the excited state (on the assumption that $\mu \approx 0$ in the ground state).[7–9] The calculated values are relatively high as they range from 11.3 D (**1**) to 19.5 D (**3**), pointing out the large charge-transfer character of the fluorescent excited singlet state.

To rationalise the photoelectronic properties of silylboranes **1**–**3**, MNDO/CI (single excitations and single and double excitations CI) calculations[10] based on 10 occupied and 10 unoccupied MOs around the Fermi level have been performed on **1**, **4** and **5,** using the AMPAC program.[11] In reference compounds **4** and **5**, theoretical singlet absorption wavelengths $\lambda$ and relative oscillator strengths *f* (**4**: $\lambda$ = 225 nm, *f ca.* 1.5; **5**: $\lambda$ = 260 nm, *f ca.* 0.25; $\lambda$ = 230 nm, *f ca.* 0.5) appear to be in good semi-quantitative agreement with the experimental spectra shown in the insert of Fig.1, although the theoretical wavelengths are systematically blue-shifted by *ca*. 50 nm with respect to the experimental ones. Similar determinations performed on **1** reveal three singlet absorptions: 357 (0.08), 296 (0.08) and 233 nm (1.03) which are in good agreement with the experimental spectrum (Fig. 1) within the 50 nm blue-shift range. Analysis of the relevant wavefunctions shows that (*i*) in **4**, the 225 nm transition corresponds to a $\pi$–$\pi^*$ excitation involving the aromatic rings, the positively charged silicon atom being unchanged by this transition; (*ii*) in compound **5**, the 260 and 230 nm transitions are associated with a significant electronic transfer from the phenyl and mesityl groups to the boron atom (slightly positively charged in the ground singlet state); and (*iii*) in **1**, the first band (357 nm) corresponds to a noticeable charge transfer from silicon to boron atom, the second one (296 nm) to a transfer from mesityl groups to boron atom and the third one (233 nm) to a $\pi$–$\pi^*$ excitation in the aromatic rings with a slight electronic depletion on silicon atom. Analogous studies using the MNDO/d method,[12] which take into account Si d atomic orbitals, do not qualitatively change these results.

**Table 1** Maxima of the fluorescence emission bands of compounds **1** and **3** *vs.* polarity of the solvent ($\lambda_{exc}$ = 400 nm, room temp.)

| | | λ/nm | |
|---|---|---|---|
| Solvent | $\Delta f^a$ | **1** | **3** |
| Cyclohexane | 0.09 | 480 | 480 |
| Benzene | 0.10 | 480 | 525 |
| Diethyl ether | 0.25 | 492 | 560 |
| Chloroform | 0.25 | 495 | 580 |
| Acetonitrile | 0.39 | 515 | 640 |

[a] $\Delta f = f - \frac{1}{2}f'$; $f = (\varepsilon - 1)/(2\varepsilon + 1)$; $f' = (n^2 - 1)/(2n^2 + 1)$.

To examine the role of the solvent polarity on the emission spectrum of **1**, calculations have also been performed on UV absorption and emission transitions with a continuum solvation model, the COSMO approach,[13] coupled to the MNDO/CI method. It turns out that the theoretical absorption spectrum of **1** is unaltered by the presence of a polar solvent, even a very high polar one like acetonitrile. Conversely, calculation indicates a bathochromic shift on the emission spectrum. This result is in excellent accord with the experimental findings.

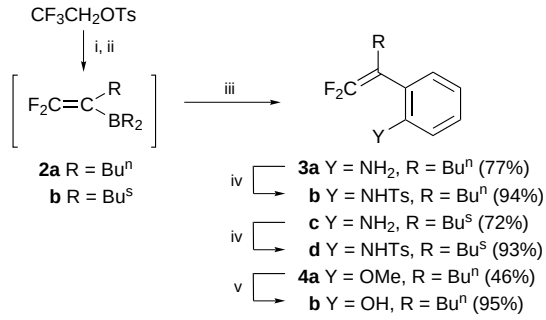
# 5-*endo*-Trigonal cyclization of *o*-substituted *gem*-difluorostyrenes: syntheses of 2-fluorinated indoles, benzo[*b*]furans and benzo[*b*]thiophenes

**Junji Ichikawa,*† Yukinori Wada, Tatsuo Okauchi and Toru Minami***

*Department of Applied Chemistry, Kyushu Institute of Technology, Sensui-cho, Tobata, Kitakyushu 804, Japan*

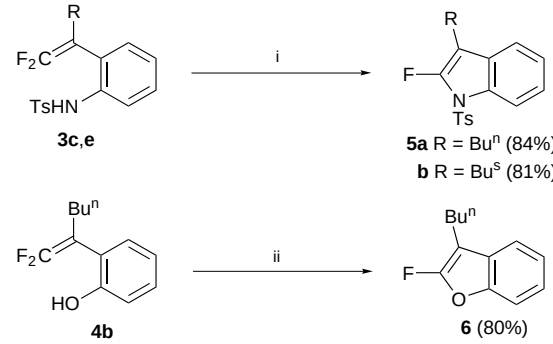


**β,β-Difluorostyrenes bearing tosylamido, hydroxy or methylsulfinyl groups at the *o*-position undergo intramolecular substitution of the nitrogen, oxygen or sulfur with loss of fluorine *via* a 5-*endo*-trigonal process leading to 2-fluorinated heterocyclic systems in high yields.**

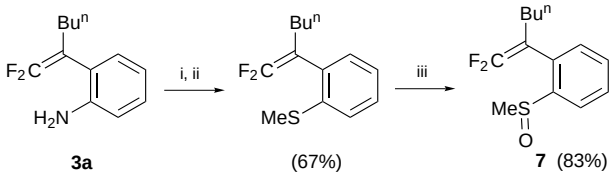
*gem*-Difluoroalkenes possess remarkable reactivity toward nucleophilic substitution for their fluorine atoms *via* addition–elimination processes.[1] This reactivity is due to (i) the electrophilic activation of the carbon–carbon double bond by the two fluorines and (ii) the leaving-group ability of the fluoride ion. This chemical reactivity renders these alkenes valuable as synthetic building blocks[2] as well as mechanism-based enzyme inhibitors.[3] We have recently reported the reactions of 2,2-difluorovinyl ketones with external nucleophiles leading to facile syntheses of α,β-unsaturated ketones,[4] α-oxo ketene derivatives[5] and 3- or 5-fluoropyrazoles.[6] Our interest in the further application of *gem*-difluoroalkene chemistry led us to explore an intramolecular version of such vinylic fluorine substitution reactions. Here we report the construction of ring-fluorinated heterocyclic systems starting from *o*-substituted β,β-difluorostyrenes.[7]

β,β-Difluorostyrenes **1** bearing nucleophilic *ortho* nitrogen, oxygen or sulfur heteroatoms were designed as substrates for the intramolecular substitution. We sought to effect the 5-*endo*-trigonal ring closure of **1** to afford 5-membered 2-fluoro heterocycles despite this cyclization being disfavoured in Baldwin's rules.[8] Among 5-*endo*-trigonal cyclizations, such nucleophile-driven ring closures have only rarely been observed in synthetic chemistry,[9] in contrast with electrophile-driven[10]‡ and radical-initiated ring closures.[11] We expected that the unique properties of *gem*-difluoroalkenes could make a nucleophilic approach feasible. Specifically, we thought that (i) the highly polarized difluorovinylidene alkenic bond displays significant single bond character ($^{13}$C NMR: *ca.* $\delta$ 150 and 90 for $CF_2$=C) and would allow initial ring formation, and (ii) the successive elimination of fluoride ion could suppress the reverse ring opening. Such a process would provide an efficient access to 2-fluorinated indoles, benzo[*b*]furans, and benzo[*b*]-thiophenes, of which synthetic methods are quite limited in spite of the potential uses of 2-fluoro heterocycles as components of agrochemicals, pharmaceuticals and dyestuffs.[12] On the basis of these considerations, we investigated the cyclization of **1**.

The starting materials were easily prepared as outlined in Scheme 1 by using the one-pot sequence which we have previously developed for the preparation of *gem*-difluorostyrenes.[13] The coupling reactions of 2,2-difluorovinylboranes **2a** and **2b** (generated *in situ* from 2,2,2-trifluoroethyl toluene-*p*-sulfonate) with *N*-butylmagnesio-*o*-iodoaniline were effected in the presence of CuI with palladium catalysis to prepare *o*-amino-β,β-difluorostyrenes **3a** and **3c** as precursors of 2-fluoroindoles. *o*-Hydroxy-β,β-difluorostyrene **4b**, a precursor of 2-fluorobenzo[*b*]furan, was similarly obtained by the coupling of **2a** with *o*-iodoanisole, followed by demethylation with $BBr_3$.



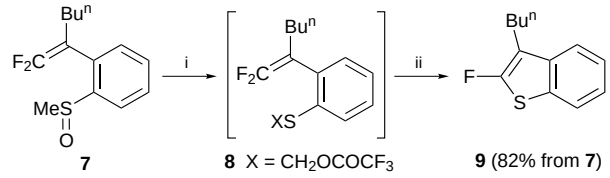
The attempted cyclization of **3a** by treatment with 1.2 equiv. of Bu$^n$Li failed, while treatment of toluene-*p*-sulfonamide **3b** with 1.2 equiv. of NaH in DMF successfully promoted the



**Scheme 1** *Reagents and conditions*: i, Bu$^n$Li (2.1 equiv.), THF, −78 °C, 0.5 h; ii, $BR_3$ (1.1 equiv.), THF, −78 °C, 1 h then room temp., 3 h; iii, ArI (0.9 equiv.), CuI (1.0 equiv.), $Pd_2(dba)_3$·$CHCl_3$ (0.02 equiv.), $PPh_3$ (0.08 equiv.), THF–HMPA (4 : 1), room temp. 1 h; iv, TsCl (1.1 equiv.), pyridine, 0 °C to room temp., 11 h; v, $BBr_3$ (1.1 equiv.), $CH_2Cl_2$, −15 °C to room temp., 2 h

'disfavoured' 5-*endo*-trigonal cyclization to afford 2-fluoroindole **5a** in 84% yield (Scheme 2).[14]§ Successful ring closure did not necessitate the use of high-dilution conditions, and proceeded smoothly even in the case of the starting styrene **3d** which bore a secondary alkyl group at the α-position. Moreover, when the hydroxystyrene **4b** was treated under similar conditions, 5-*endo*-trigonal cyclization of the corresponding alkoxide occurred leading to 2-fluorobenzo[*b*]furan **6** in 80% yield (Scheme 2).[15]¶

As a further example of the cyclization we next tried the intramolecular substitution utilizing a sulfur nucleophile. For the purposes of generating a thiolate moiety, the methlysulfinyl group was selected as an *ortho* substituent of β,β-difluorostyrene. The Pummerer rearrangement of *o*-methylsulfinyl-β,β-difluorostyrene **7** followed by solvolysis would allow the cyclization *via* the unisolated intermediate, hemiacetal trifluoroacetate **8**.[16] Thus, **7** was readily derived from **3a** *via* diazotization as depicted in Scheme 3. Successive treatment of **7** with (i) trifluoroacetic anhydride and $Et_3N$ and (ii) $K_2CO_3$ in MeOH provided 2-fluorobenzo[*b*]thiophene **9** in 82% yield as expected (Scheme 4).[17]‖



**Scheme 2** *Reagents and conditions*: i, NaH (1.2 equiv.), DMF, 80 °C, 7 h; ii, NaH (1.2 equiv.), DMF, 0 to 60 °C, 2 h

**3a** (67%) **7** (83%)

**Scheme 3** *Reagents and conditions*: i, $CF_3CO_2H$ (2 equiv.), $Me_2CHCH_2CH_2ONO$ (2 equiv.), MeCN, 0 °C, 0.5 h; ii, aq. NaSMe (3 equiv.), MeCN, 0 °C to room temp., 1.5 h; iii, aq. $TiCl_3$ (2 equiv.), aq. $H_2O_2$ (3 equiv.), MeOH–$H_2O$, room temp., 2 h

**7** **8** X = $CH_2OCOCF_3$ **9** (82% from **7**)

**Scheme 4** *Reagents and conditions*: i, $(CF_3CO)_2O$ (3 equiv.), $Et_3N$ (3 equiv.), $CH_2Cl_2$, 0 °C, 0.5 h; ii, $K_2CO_3$ (6 equiv.), MeOH, 0 °C to reflux, 2 h

In conclusion, nucleophilic addition–elimination reactions with the β,β-difluorovinylidene moiety allows normally 'disfavoured' 5-*endo*-trigonal cyclizations to occur. This cyclization process affords ring-fluorinated indoles, benzo[*b*]furans, and benzo[*b*]thiophenes in high yields. These 'anti-Baldwin' results indicate that some of the unique reactivity of *gem*-difluoroalkenes may be derived from a partial single bond character of the alkene.

We gratefully acknowledge financial support for this research in the form of a grant from the Ministry of Education, Science, Sports, and Culture, Japan (Grant-in-Aid for Scientific Research No. 09640641), and Central Glass Co. Ltd. to J. I. We also thank the Center for Instrumental Analysis KIT for the measurement of analytical data.

‡ Electrophile-driven cyclizations refer to ring closure initiated by the coordination of the double bond in a substrate to an external electrophile such as $I_2$ and PhSeCl. Strictly speaking, this type of cyclization does not seem likely to be an exception to Baldwin's rules.

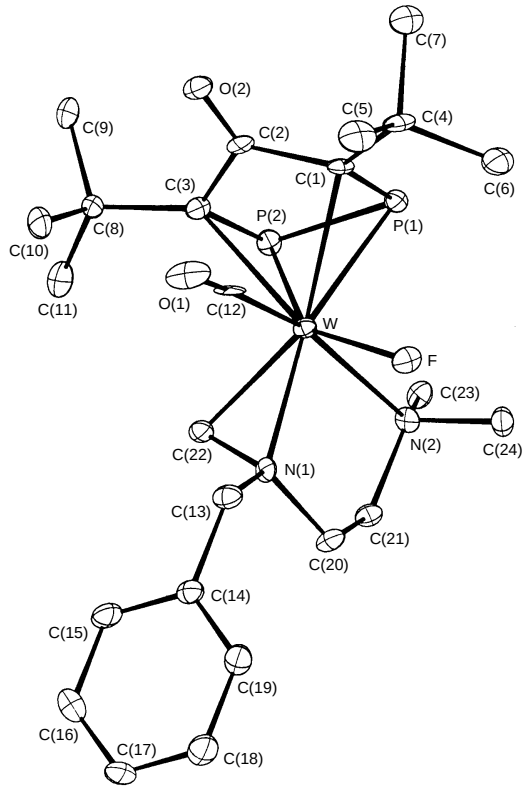
**An unusual series of reactions involving an intermediate 4e $\eta^2$-phosphaalkyne tungsten complex is described.**

There is current interest in the coordination chemistry of phosphaalkynes, RC≡P, and transition-metal compounds containing phosphorus analogues of unsaturated ring systems such as 1,2- and 1,3-diphosphacyclobutadiene, 1,2- and 1,2,4- di- and tri-phosphacyclopentadienyl, and most recently 1,3,5-triphosphabenzene, which can all be derived from the parent phosphaalkyne.[1–3]

The number of examples of phosphaalkynes acting as $\eta^2$-(4e) ligands to transition-metal centres is very limited and to date none have been structurally characterised owing to their ready further reaction to afford 1,3-diphosphacyclobutadiene complexes.[4] In order to extend the range of such complexes we have now synthesised the $Bu^tC{\equiv}P$ analogue of the recently described[5] structurally related $\eta^2$-(4e) nitrile complex $[WF(C_6H_4CH_2NMeCH_2CH_2NMe_2)(CO)(\eta^2\text{-}N{\equiv}CC_6F_5)]$. Although NMR spectroscopic evidence† (P≡C, $\delta_P$ 452.4, $\delta_C$ 315.2; $^1J_{PC}$ 117.7, $^1J_{PW}$ 82.0 Hz) fully confirmed[4] the expected formation of the green $\eta^2$-(4e) phosphaalkyne complex $[WF(C_6H_4CH_2NMeCH_2CH_2NMe_2)(CO)(\eta^2\text{-}P{\equiv}CBu^t)]$ **2**, when $[WF(C_6H_4CH_2NMeCH_2CH_2NMe_2)(CO)_3]$ **1**,[6] was treated with $Bu^tC{\equiv}P$ for 3 h in toluene at room temp. it proved impossible to isolate it in crystalline form. A facile further reaction of **2** with $Bu^tC{\equiv}P$ (5 equiv. at 90 °C for 2 h in toluene in a closed system) affords the novel red complex $[WF\{CH_2N(CH_2Ph)CH_2CH_2NMe_2\}(CO)\{\eta^4\text{-}PCBu^t(CO)CBu^tP\}]$ **3**, (30% yield), containing an $\eta^4$-ligated 3,4-diphosphacyclopentadieneone and a three-membered $NCH_2W$ ring system. Complex **3** has been structurally characterised by spectroscopic data‡ and by a single-crystal X-ray diffraction study§ (Fig. 1). The reactivity of **2** contrasts with the behaviour of the analogous $\eta^2$-(4e) nitrile complex which does not undergo coupling reactions and whose chemistry is dominated by ready dissociation of the nitrile ligand.



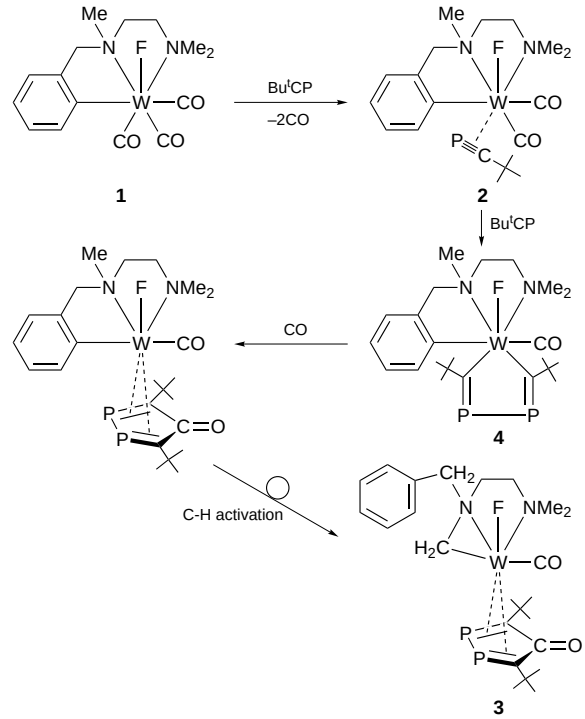


**Fig. 1** Molecular structure of **3**. Selected bond lengths (Å) and angles (°): W–P(1) 2.504(2), W–P(2) 2.490(2), W–C(1) 2.412(7), W–C(3) 2.443(8), W–C(12) 1.992(9), W–C(22) 2.169(9), W–F 1.997(4), W–N(1) 2.175(6), W–N(2) 2.408(6), P(1)–P(2) 2.173(3), P(1)–C(1) 1.740(8), P(2)–C(3) 1.769(8), O(1)–C(12) 1.158(10), O(2)–C(2) 1.233(9), N(1)–C(22) 1.441(10), C(1)–P(1)–P(2) 94.6(3), C(3)–C(2)–C(1) 109.4(6), C(3)–P(2)–P(1) 93.8(3).

**Scheme 1**

We believe that **3** results either from CO insertion into an intermediate $\eta^4$-ligated 1,2-diphosphacyclobutadiene complex formed from **2** and $Bu^tC{\equiv}P$, or alternatively into the five-membered tungstadiphosphacyclopentadiene ring of complex **4**, followed by reductive elimination (Scheme 1). No such intermediates could be detected spectroscopically, however we showed previously[7] that carbonyl insertion and reductive elimination occurs in the closely related tungsten(II) alkoxide. Presumably the bulky $\eta^4$-ligated 3,4-diphosphacyclopentadieneone ring system generated from **2** causes crowding at the metal centre, and subsequent relief of steric strain results in the formation of **3** *via* (*i*) C–H activation of the uncoordinated $NCH_3$ group to generate the $NCH_2W$ ring system and (*ii*) hydrogen transfer to the metallated $C_6H_4$ fragment.

Previously we described (*i*) CO coupling of two phosphaalkynes to give rhodium(I) complexes of the six membered ring system RhPCORCRP, (R = $Bu^t$, adamantyl),[8] and (*ii*) carbonylation of coordinated phosphaalkynes to give phosphinidene $[Bu^t(CO)P]$ complexes,[9,10] however the formation of the 3,4-diphosphacyclopentadienone ring in **3** is unprecedented, although Cowley and coworkers[11] have structurally characterised the isomeric diphosphatricyclo[1.2.0.$0^{2,5}$]pentane ring system. Likewise, reports of C–H activation of an N–Me group are also rare in organometallic systems. A recent report by van Koten *et al.*[12] described the stereoselective C–H activation of an N–Me group in the tantalum complex $[TaCl_2(CH_2Ph)_2\{C_6H_4(Me)NMe\text{-}2\}]$, in which the key step proceeds by a σ-bond metathesis which also involves the relief of steric strain.

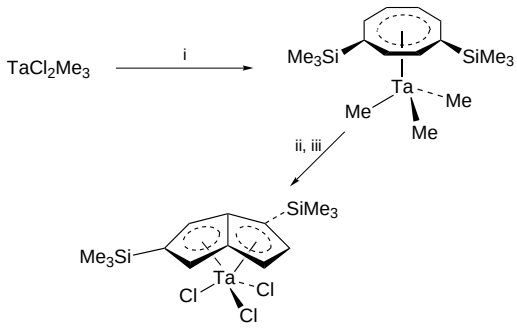
# The first mononuclear η⁸-coordinated pentalene complex: synthesis and molecular structure of [Ta{η⁸-$C_8H_4(SiMe_3)_2$-1,4}$Cl_3$]

**Qasim A. Abbasali, F. Geoffrey N. Cloke,* Peter B. Hitchcock and Stephen C. P. Joseph**

*The Chemistry Laboratory, School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*



**Treatment of [$TaCl_2Me_3$] with $Li_2$(cot″) (cot″ = 1,4-bis(trimethylsilyl)cyclooctatetraene] affords [Ta(η-cot″)$Me_3$], which reacts with [$NHPr^i_2Et$]Cl in dichloromethane to yield the complex [Ta{η⁸-$C_8H_4(SiMe_3)_2$-1,4}$Cl_3$]; X-ray crystallography shows the latter to contain a pentalene ligand bound through all eight carbons to a single tantalum centre.**

Transition-metal complexes derived from pentalene, or its dianion, are somewhat rare, and presently known examples fall into two categories: (*a*) binuclear systems which contain the planar pentalene dianion *e.g.* [$M_2$(η⁵,η⁵-$C_8H_6$)$_2$] (M = Co, Ni),[1] [(η³-$C_3H_5$)Ni(η⁵,η⁵-$C_8H_6$)Ni(η³-$C_3H_5$)][2] and [(η⁵-$C_5Me_5$)M(η⁵,η⁵-$C_8H_6$)M(η⁵-$C_5Me_5$)] (M = Fe, Co, Ni);[3] (*b*) binuclear systems in which two metal carbonyl fragments are bound to the five-membered rings of a folded pentalene ring system, formed by *in situ* elimination of dihydrogen from a cyclooctatetraene ligand, *e.g.* [{Ru($MMe_3$)(CO)$_2$)}$_2$(η⁵,η⁵-$C_8H_6$)] (M = Si, Ge), [$Ru_3$(CO)$_8$(η⁵,η⁵-$C_8H_6$)] and [$Ru_3$(CO)$_8${η⁵,η⁵-$C_8H_4(SiMe_3)_2$-1,4}].[4]

Recently, we have been exploring the chemistry of group 4 metal complexes incorporating the cot″ ligand [cot″ = 1,4-bis(trimethylsilyl)cyclooctatetraene] and were interested in extending this work to the group 5 elements.[5] Here we report the surprising conversion of an η⁸-cot″ ligand into an η⁸-pentalene ligand on a single tantalum centre.

Attempts to prepare a complex of the type [Ta(η-cot″)$Cl_3$] starting from $TaCl_5$, as an entry into mono-cot″ tantalum chemistry, were uniformly unsuccessful, persistently producing brown intractable solids. As an alternative starting material, dark purple [Ta(η-cot″)$Me_3$] **1** was prepared from the reaction between $Li_2$(cot″) and [$TaCl_2Me_3$] in hexane at −78 °C (Scheme 1) in 70% yield,† in an analogous fashion to that described by Schrock and coworkers for the synthesis of [Ta(η-cot)$Me_3$].[6] The $^1$H and $^{13}$C{$^1$H} NMR spectra of **1** show the typical resonances for a planar η⁸-cot″ ring and the Ta–Me groups.‡

In an attempt to prepare [Ta(η-cot″)$Cl_3$], the complex [Ta(η-cot″)$Me_3$] was treated with 3 equiv. of [$NHPr^i_2Et$]Cl in $CH_2Cl_2$; however, after work up air-sensitive red needles of the pentalene complex [Ta{η⁸-$C_8H_4(SiMe_3)_2$-1,4}$Cl_3$] **2** (Scheme 1) were obtained in 10% yield.§

**Scheme 1** i, $Li_2$[(cot″)(thf)$_x$], *n*-pentane; ii, 3 [$NHPr^i_2Et$]Cl, $CH_2Cl_2$; iii, vacuum sublimation ($10^{-5}$ mbar, 140 °C)

The $^1$H NMR spectrum of **2** exhibits four downfield signals ($\delta$ 6.51–5.32) attributable to four distinct ring proton environments and two upfield singlets ($\delta$ 0.4 and 0.3) assignable to two distinct trimethylsilyl groups. The $^{13}$C{$^1$H} NMR spectrum shows ten resonances, eight of which are at low field and as such can be attributed to the carbon ring framework, whilst those carbons associated with the trimethylsilyl substituents are identified by two singlets at $\delta$ −0.2 and −0.7.¶

Single crystals of **2**, suitable for X-ray diffraction studies,‖ were grown by vapour-phase diffusion in an evacuated sealed tube at 160 °C. The molecular structure of **2**, as shown in Fig. 1, shows the complex to contain the first example of a pentalene ligand η⁸-coordinated to a single metal centre. The pentalene ring in **2** is folded about the bridgehead [C(2)–C(6)] bond, with a fold angle of 33°; in the metal–metal bonded binuclear complex [{Ru($GeMe_3$)(CO)$_2$}$_2$(η⁵,η⁵-$C_8H_6$)] the fold angle is 9°.[7] The tantalum–ring carbon distances of **2** range from 2.182(13), for the bridgehead carbons to 2.583(13) Å for the 'wingtip' carbons, and may be compared to the tantalum–ring carbon distances in [Ta(cot″)$Me_3$] **1** which lie between 2.424(6) and 2.488(5) Å.[8] The pentalene ring C–C bond lengths in **2** range from 1.36(2) [C(7)–C(8)] to 1.48(2) [C(1)–C(2)] Å with a bridgehead [C(2)–C(6)] bond length of 1.47(2) Å. In the planar pentalene ring system found in [(η⁵-$C_5Me_5$)Fe(η⁵,η⁵-$C_8H_6$)Fe(η⁵-$C_5Me_5$)], the ring C–C distances lie between 1.464(5) (for the bridgehead) and 1.408(5) Å. For the folded (9°) ligand in [{Ru($GeMe_3$)(CO)$_2$}$_2$(η⁵,η⁵-$C_8H_6$)],[6] the ring C–C distances range from 1.32(5) to 1.51(4) with a bridgehead C–C distance of 1.43(5) Å. The Ta–Cl bond lengths in **2** range from 2.362(3) to 2.386(3) Å and can be compared to the Ta–Cl

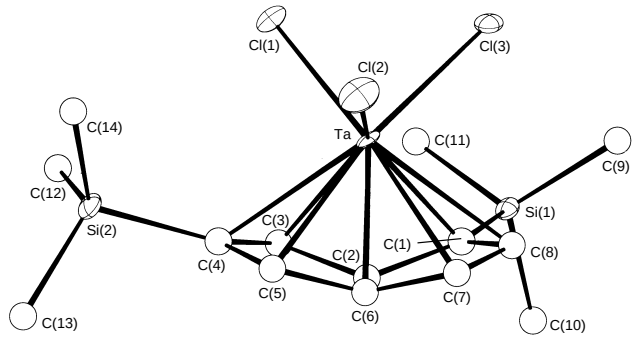


**Fig. 1** CAMERON[12] representation of the crystal structure of **2**. Selected bond lengths (Å) and angles (°): Ta–C(1) 2.351(12), Ta–C(2) 2.182(13), Ta–C(3) 2.358(12), Ta–C(4) 2.583(12), Ta–C(5) 2.469 (13), Ta–C(6) 2.217(12), Ta–C(7) 2.488(13), Ta–C(8) 2.539(13), Ta–Cl(1) 2.362(3), Ta–Cl(2) 2.374(4), Ta–Cl(3) 2.386 (3), C(1)–C(2) 1.48(2), C(2)–C(6) 1.47(2), C(2)–C(3) 1.40(2), C(3)–C(4) 1.43(2), C(4)–C(5) 1.41(2), C(5)–C(6) 1.43(2), C(6)–C(7) 1.43(2), C(7)–C(8) 1.36(2), C(8)–C(1) 1.45(2); C(1)–C(2)–C(3) 129.8(11), C(2)–C(3)–C(4) 109.7(11), C(4)–C(5)–C(6) 108.9(12), C(7)–C(6)–C(2) 108.2(10), C(8)–C(7)–C(6) 107.8 (11), C(8)–C(1)–C(2) 104.0 (10), C(3)–C(2)–C(6) 106.8(11), C(6)–C(2)–C(1) 106.7(10), C(5)–C(4)–C(3) 107.8 (11), C(7)–C(6)–C(5) 133.8(12), C(5)–C(6)–C(2) 106.7(11), C(1)–C(8)–C(1) 113.0(11).

distance of 2.387(11) Å in [Ta($\eta^5$-$C_5Me_5$)$Me_2Cl_2$].[9] Further comparisons are difficult due to the lack of other, related compounds.

Attempts are currently underway to study the mechanism of this reaction and to improve the yield of **2**; the latter promises to be a versatile precursor to monopentalene tantalum chemistry.

We thank the EPSRC and BP Chemicals for CASE Studentships (to Q. A. A. and S. C. P. J.), Dr A. G. Avent for the NMR studies and Dr A. Abdul-Sada for mass spectral analysis.

# One- and two-dimensional organic–inorganic composite solids constructed from molybdenum oxide clusters and chains linked through {M(2,2′-bpy)}$^{2+}$ fragments (M = Co, Ni, Cu)

**Pamela J. Zapf,[a] Christopher J. Warren,[b] Robert C. Haushalter[b] and Jon Zubieta*[a]**

[a] *Department of Chemistry, Syracuse University, Syracuse, NY 13244, USA*
[b] *NEC Research Institute, 4 Independence Way, Princeton, NJ 08540, USA*

**Hydrothermal reactions of $Na_2MoO_4·2H_2O$ and $MoO_3$ with $MCl_2·xH_2O$ (M = Co, Ni, Cu) and 2,2′-bipyridine yield one- and two-dimensional solids, characterized by molybdenum oxide monomers, clusters and chains linked by {M(2,2′-bpy)}$^{2+}$ groups and represented by the formulae $[M(bpy)_x(H_2O)_yMo_nO_{3n+1}]$ ($n$ = 2, M = Cu, $x$ = 1, $y$ = 0; $n$ = 3, M = Co, $x$ = 1, $y$ = 0; $n$ = 4, M = Ni, $x$ = 2, $y$ = 0).**

Metal oxide-based solids have provoked significant contemporary interest by virtue of their applications to areas as diverse as catalysis, sorption, molecular electronics, energy storage, optical materials and ceramics.[1,2] While the rational synthesis of new solids possessing unique structures and properties remains a challenge,[3] the structure-directing properties of organic components have been successfully exploited in the synthesis of metastable composite materials which retain the structural characteristics of the starting materials.[4,5] These organic constituents are most commonly present in the roles of tethers between metal sites, a mode adopted by 4,4′-bipyridine and related ligand types,[6] of charge-compensating cations such as organoammonium units,[7] or of ligands covalently linked to the inorganic backbone of the solid.[8] We recently demonstrated an additional type of composite material based on amine-ligated transition- or post-transition-metal cation complexes intercalated between mixed-valence vanadium oxide layers.[9] This observation suggested that appropriate transition-metal coordination compounds could also be incorporated directly into the covalent backbone of the solid either as peripheral metal/organic components or as complex bridging ligands. This expectation has been realized in the preparation and characterization of the one-dimensional solids $[Ni(2,2′\text{-bpy})_2Mo_4O_{13}]$ **1** and $[Cu(2,2′\text{-bpy})Mo_2O_7]$ **2** and the two-dimensional phase $[Co(2,2′\text{-bpy})Mo_3O_{10}]$ **3**.

Compounds **1**–**3** were prepared from mixtures of $Na_2MoO_4·2H_2O$, $MoO_3$, $MCl_2·xH_2O$, and 2,2′-bpy, heated to 160 °C for 72–120 h.† The IR spectra of **1**–**3** exhibit strong bands in the range 910–970 cm$^{-1}$ attributed to $\upsilon$(Mo=O), and a series of bands characteristic of 2,2′-bpy in the range 1100–1600 cm$^{-1}$.

The structure of $[Ni(2,2′\text{-bpy})_2Mo_4O_{13}]$ **1** (Fig. 1) is constructed from the common β-molybdate clusters $[Mo_8O_{26}]^{4-}$, linked through $\{Ni(bpy)_2O_2\}^{2+}$ octahedra into a one-dimensional ribbon. The molybdenum core consists of edge-sharing $\{MoO_6\}$ octahedra in the compact β-molybdate geometry.[10] Two adjacent molybdenum sites on either side of the cluster engage in corner-sharing interactions through bridging oxo-groups to a $\{NiN_4O_2\}$ octahedron, such that each $\{Mo_8O_{26}\}^{4-}$ cluster is linked through four $\{NiN_4O_2\}$ octahedra to the two neighboring clusters of the ribbon. The nickel site is defined by four nitrogen donors from two 2,2′-bpy ligands and *cis*-oxo groups from two adjacent molybdenum clusters.

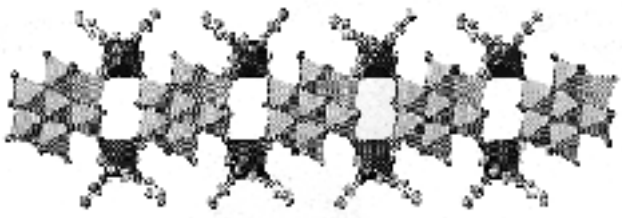

**Fig. 1** A polyhedral representation of the one-dimensional structure of **1**. The lighter polyhedra represent the molybdenum sites and the darker the nickel octahedra. The carbon atoms of the bipyridyl ligands are shown as light spheres. Selected bond lengths (Å): Ni–N, 2.053(7), 2.058(7), 2.060(6), 2.072(7); Ni–O, 2.056(6), 2.090(5).

Examination of the structure of **1** would suggest that further condensation of molybdenum oligomers into one-dimensional molybdenum oxide motifs should be feasible. As illustrated in Fig. 2, the structure of $[Cu(2,2′\text{-bpy})Mo_2O_7]$ **2** consists of a buckled one-dimensional molybdenum oxide chain linked to peripheral $\{CuN_2O_4\}$ octahedra. The $\{Mo_2O_7\}$ chain is constructed from edge-sharing $\{MoO_6\}$ octahedra and $\{MoO_5\}$ square pyramids. Each molybdenum octahedron shares common edges with a neighboring molybdenum octahedron, a

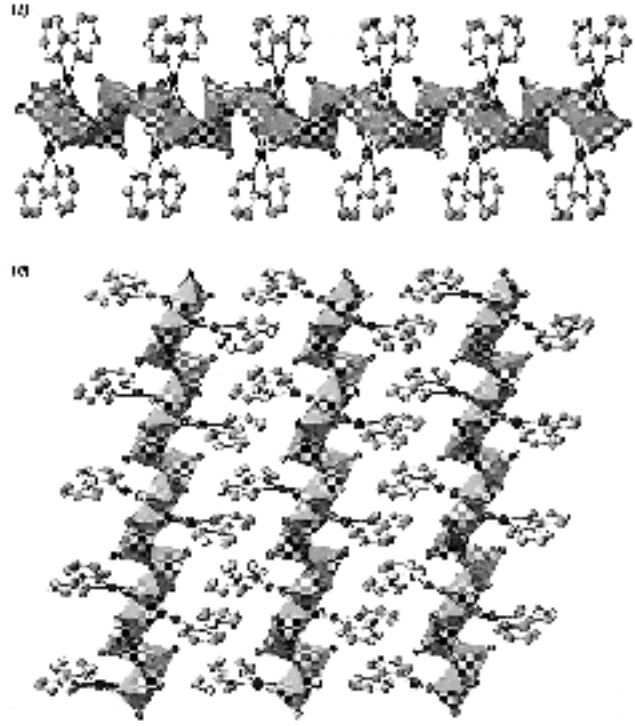

**Fig. 2** (*a*) A view of the one-dimensional structure of **2**. The molybdenum sites are represented as polyhedra, while the Cu centers are shown as dark spheres. (*b*) The packing of adjacent one-dimensional strands, showing the stacking of bipyridyl rings from adjacent chains. Selected bond lengths (Å): Cu(1)–N, 2.011(14), 2.003(14); Cu(1)–O, 1.989(11), 1.995(10), 2.355(11), 2;405(10); Cu(2)–N, 1.974(14), 1.976(14); Cu(2)–O, 1.995(11), 1.997(11), 2.355(11), 2.360(11). The longer Cu–axial oxygen bonds have been omitted for clarity.

molybdenum square pyramid, and two copper octahedra, and a common corner with one square-pyramidal unit. One square-pyramidal site engages in edge-sharing with an adjacent square pyramid and a molybdenum octahedron and displays corner-sharing with a second molybdenum octahedron and two $\{CuN_2O_4\}$ octahedra, while the second $\{MoO_5\}$ site exhibits edge-sharing to a square-pyramidal and an octahedral molybdenum site and corner-sharing to a $\{MoO_6\}$ site and a $\{CuN_2O_4\}$ octahedron. Consequently, each $\{CuN_2O_4\}$ unit links to four molybdenum polyhedra of the chain, sharing four vertices in two edge and two corner interactions with the molybdenum sites. The folding of the molybdenum chain reflects the incorporation of the $\{CuN_2O_4\}$ units through four-point, two-edge attachments and illustrates the role of the $M^{2+}$ site in defining chain geometry.

Since one-dimensional molybdenum oxide chains are a recurring theme in oxide structural chemistry,[16,17] the incorporation of appropriate metal–ligand subunits should allow bridging into higher dimensional solids. The structure of $[Co(2,2'\text{-bpy})Mo_3O_{10}]$ **3** (Fig. 3) illustrates this point. The structure consists of one-dimensional molybdenum oxide chains, constructed of molybdenum tetrahedra, octahedra and square pyramids, linked through $\{CoN_2O_4\}$ octahedra into a two-dimensional covalent network. The oxide chain itself results from the edge-sharing of $\{MoO_6\}$ octahedra and $\{MoO_5\}$ square pyramids. The $\{MoO_4\}$ tetrahedra link to the chain through a single corner-sharing interaction, but bridge two $\{CoN_2O_4\}$ octahedra through two additional corner-sharing linkages. Each Co site is defined by the nitrogen donors of the bpy ligand and four oxygen donors from three $\{MoO_4\}$ groups and one $\{MoO_6\}$ octahedron. The overall structure may be described as folded chains of edge-sharing molybdenum polyhedra linked through double chains of alternating $\{CoN_2O_4\}$ octahedra and $\{MoO_4\}$ tetrahedra into a two-dimensional network.

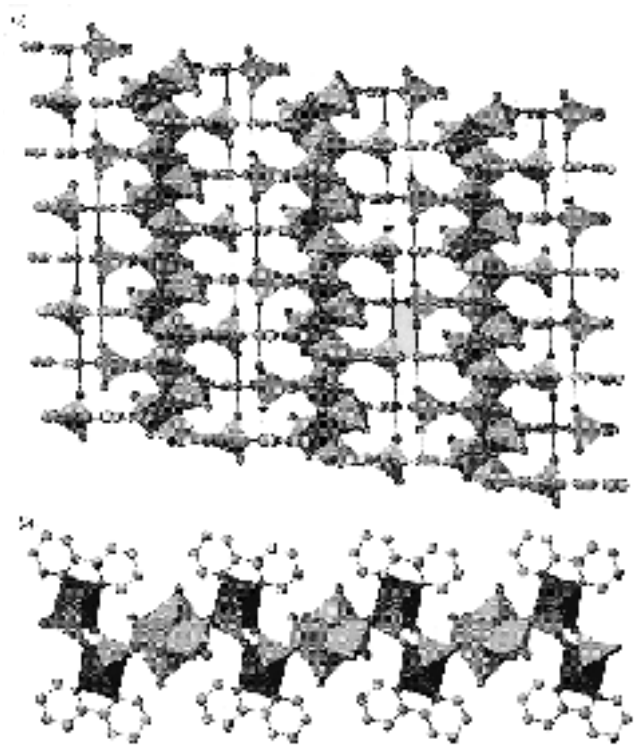

**Fig. 3** (*a*) A view of the two-dimensional structure of **3** parallel to the crystallographic *c* axis. The molybdenum sites are represented as polyhedra, while the cobalt sites are illustrated as larger darkened spheres. (*b*) A view down the *a* axis showing the linking of molybdenum polyhedral chains through $\{(MoO_4)_2[Co(bipy)]_2\}$ units in parallel chains. Selected bond lengths (Å): Co–N, 2.082(9), 2.105(9); Co–O, 2.092(8), 2.094(8) ×2, 2.119(7).

Molybdenum oxides have received considerable attention for their catalytic properties in organic oxidations[13,14] and for their intercalation properties.[15,16] Recent studies[11,12] have focused on structural modification and design of metal oxides through the introduction of organic components as templates, charge-compensating cations, tethers, or covalently linked network constituents. Another approach to composite metal oxide/organic solids is that illustrated in the preparation of **1**–**3**, which employs metal–organic ligand fragments as covalent linkers to metal oxide components of various nuclearities or dimensionalities. A curious feature of these initial investigations is the range of structural types which evolve from the introduction of $\{M'(bpy)_n\}^{2+}$ units as the divalent d-block element is varied. A degree of primitive synthetic design appears inherent in the systematic variation of the divalent metal, the diamine ligand, and the hydrothermal conditions employed.

This work was supported by NSF grant CHE9617232.

**A new method to compare the oxygen buffering capacity (OBC) of catalysts shows that Ce–Tb mixed oxide presents an exceptional capability for attenuating fast oscillations of oxygen partial pressure.**

Ceria has been for years one of the components of catalytic automobile exhaust converters (TWC). The capacity and the rate of response to buffer the oscillations of the oxygen partial pressure in the waste gases are recognised among its key properties.[1] However, improvements in such features are currently demanded for designing better catalytic cartridges for cleaner cars.[2,3]

The present paper reports on a simple technique to compare the oxygen buffering capacity (OBC) of catalysts. We illustrate the working principle of this new method with results given by four samples: $CeO_2$, Rh (3 mass%)/$CeO_2$, Rh (3 mass%)/$SiO_2$, and a Ce–Tb mixed oxide (20 mol% Tb), hereafter referred to as CT-80/20.

The results reported here show that the performance of CT-80/20 is much better than that of the other studied systems. We highlight the overlying properties of CT-80/20 in the following conditions: (*a*) at low temperature, with the catalyst starting to work effectively from 473 K, (*b*) over a very broad range, including temperatures higher than 873 K, (*c*) in the absence of noble metal, CT-80/20 being superior to the two Rh-containing tested catalysts, and (*d*) following severe ageing and sintering treatments. The new method described herein was useful to reveal and discriminate the advantages of CT-80/20, giving in a single test valuable information both of the capacity and rate of response of the samples as oxygen buffers.

The ceria and silica supports were high surface area samples, with 100 and 180 $m^2\ g^{-1}$ BET surface area, respectively. Rhodium was dispersed in both cases by conventional impregnation from aqueous nitrate solutions. The metal dispersion obtained in both cases by HREM is higher than 70%. The Ce–Tb mixed oxide was prepared by precipitation with ammonia from a solution of the nitrates. The terbium-modified ceria was obtained by calcination at 873 K, showing fluorite-like structure and a BET surface area of 45 $m^2\ g^{-1}$. The pretreatment for $CeO_2$ and CT-80/20 samples consisted of oxidation at 873 K in a flow of $O_2$(5%)–He, followed by slow cooling to 293 K. The rhodium-containing samples were first reduced in hydrogen at 623 K, flowed with helium from 623 up to 673 K, cooled in helium to 293 K, and reoxidized in a flow of $O_2$(5%)–He up to 373 K. After these pretreatments, the gas flow, in each case, is turned to He, and the temperature is tuned to the value selected for carrying out the test.

The experimental method consists of injecting 0.25 ml $O_2$(5%)–He pulses, at 10 s intervals, over the 60 ml $min^{-1}$ inert gas stream. The $O_2$ content at the outlet of the reactor is measured with a thermal conductivity (TC) detector. The $O_2$ content is the result of the balance of the oxygen injected, consumed and released by the sample.

The amount of catalyst used in the experiments was 200 mg. We focus the comparative study of the four catalyst samples at 673 K, this rather low value being relevant because of the particular interest of improving the TWC efficiency during the cold start period of operation of motor vehicles.[2,3]

If the sample does not have any oxygen buffer capacity at the selected operating conditions, we detect oscillations in the TC signal with a maximum height of 0.75 mV. This is found for pure ceria, as shown in Fig. 1(*a*). A blank test without sample leads to a pattern of oscillations coincident with that shown in Fig. 1(*a*).

Conversely, Fig. 1(*b*) clearly illustrates how the Rh/$CeO_2$ catalyst attenuates the oscillations of the oxygen partial pressure induced by the pulses. Those injected during the first minute are partially consumed increasing the oxidation level of the sample and making it active for buffering; after this the catalyst reaches a steady response to the oxygen pressure oscillations. When the injections cease after 8 min the sample gradually returns to its initial equilibrium state in the flowing He carrier. The efficiency of a sample as an oxygen buffer can be accounted by the attenuation factor, defined as the ratios of the steady-state amplitude of the oscillations in the absence of sample (0.75 mV) and in its presence. For Rh/$CeO_2$ the attenuation factor is 2.1.

The Rh/$SiO_2$ sample is tested as a representative case of a catalyst in which it is assumed that the support does not have the

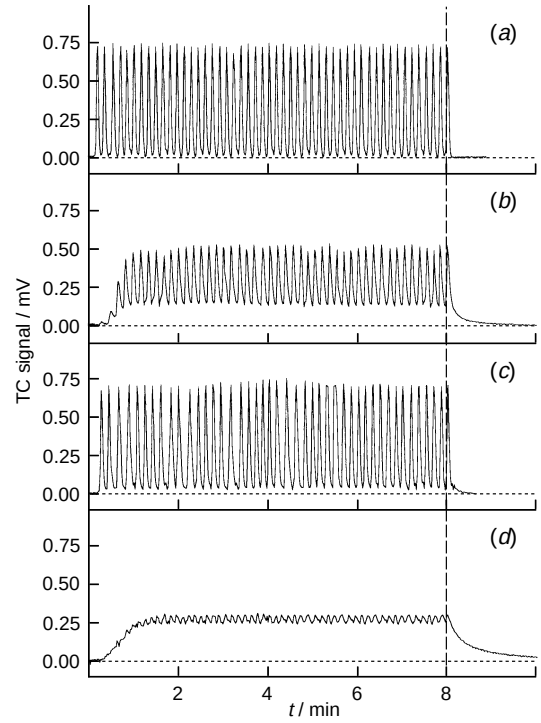

**Fig. 1** TC signals for OBC experiments carried out at 673 K on: (*a*) $CeO_2$, (*b*) Rh/$CeO_2$, (*c*) Rh/$SiO_2$ and (*d*) CT-80/20. The dotted vertical line corresponds to the time at which we stopped the injection of pulses.

ability to contribute to the OBC. In this case, Fig. 1(*c*), the oxygen signal oscillations show only a tiny level of attenuation, with an attenuation factor of 1.06. Such an effect must be attributed to the influence of the oxygen partial pressure on its chemisorption–desorption on the oxidised rhodium.

The above experiments [Fig. 1(*a*)–(*c*)] allow one to conclude that the OBC of the $Rh/CeO_2$ catalyst is not the result of the simple overlap of Rh and $CeO_2$ buffering capacities, and that a synergetic effect must be invoked to understand its behaviour. This observation is in agreement with the well known existence of singular metal-support interactions for noble metals supported on ceria,[1,4–8] thus giving credence to the reliability of the experimental technique.

Fig. 1(*d*) shows the behaviour of the Ce–Tb mixed oxide, CT-80/20. This catalyst gradually varies its oxidation level retaining part of the oxygen injected in the starting pulses. After this, the CT-80/20 oxide reaches a state in which its oxygen buffering ability is extremely high. The attenuation factor of the oxygen pressure oscillations in this case is 10.8. This behaviour is related to the ability of the mixed oxide to rapidly change its composition in response to the pulses. It is through these changes that CT-80/20 can attenuate the $O_2$ pressure oscillations, undergoing oxidation when the atmosphere is rich in oxygen and reduction when the $O_2$ partial pressure in the flowing gas is low.

The performance of CT-80/20 was also outstanding when the temperature was changed within very broad limits. This can be checked by analysing the results of a similar pulse experiment carried out at a linear heating rate of 20 K $min^{-1}$, from 323 up to 873 K. In this way rapid collection of OBC data was possible. Fig. 2 shows the temperature range in which the catalyst does not have the ability to attenuate pulses ($T$ < 473 K). From 473 to 573 K the attenuation of the pulses rapidly increases while from 573 to 873 K the attenuation factor remains high and almost constant.

The very high rate of response of the CT-80/20 mixed oxide in the whole temperature range in which the oxygen pressure oscillations attenuation is effective is remarkable. Because of experimental constraints the frequency of the pulses, 0.1 Hz, could not be increased; however, it is not far from the typical frequency of such oscillations in real TWC converters, of the order of 1 Hz.[2,3]

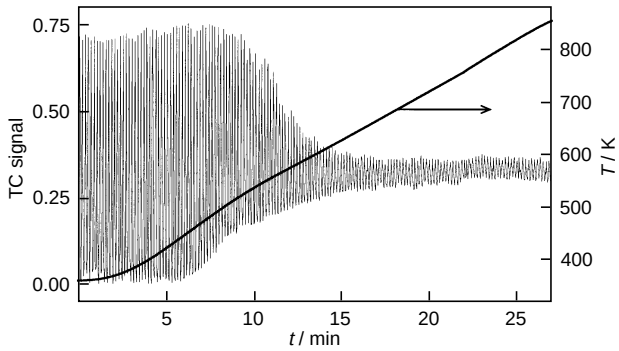

**Fig. 2** TC signal for an OBC experiment on CT-80/20, at a heating rate of 20 K $min^{-1}$

Some other available results show that the performance of CT-80/20 is maintained for low surface area samples (8 $m^2$ $g^{-1}$), obtained by ageing the starting mixed oxide for 2 h at 1123 K in a flow of He. In this case the attenuation factor of the oxygen pulses remains > 8. This result suggests the participation of oxygen from the bulk in the buffering mechanism. The lack of a proportional dependence between the OBC of CT-80/20 and the surface area of the sample is a very valuable feature for catalysts like TWCs which must operate under high temperature conditions for prolonged periods, thus potentially contributing to extension of its useful lifetime.[8]

One additional comment is that, like pure ceria, the buffering abilities of pure terbia are very different from those for the terbia modified cerium oxide, CT-80/20. The mixed oxide presents a much better performance than those of its individual components.

The details of the experimental conditions used in these tests have been adapted to obtain a good discrimination among the essayed samples. However, it would be possible to change some of the experimental settings, such as loop volume, amount of sample, inert gas flow rate, *etc.*, to obtain a good level of discrimination for other catalysts or temperature testing conditions.

In conclusion, we have proposed a new method to compare, in a fast and simple way, the OBCs of catalysts. Using this method we find that the modification of pure ceria by addition of 20 mol% of terbia increases dramatically its capability for attenuating fast oscillations of the oxygen partial pressure. This makes the terbia-modified cerium oxide CT-80/20, which shows superior properties over $Rh/CeO_2$, a potential candidate for inclusion in improved TWC formulations.

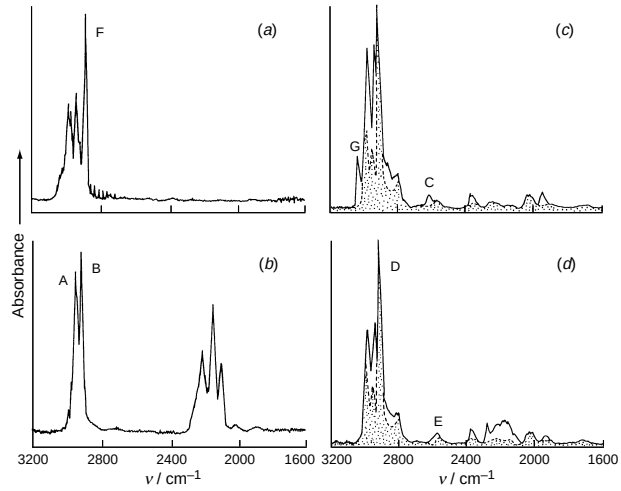
**The IR spectra of normal and specifically deuteriated [$CH_3CH_2TiCl_3$] show that coordination by $Me_2PCH_2CH_2PMe_2$ (dmpe) results in an unusually low stretching frequency for one of the β-C–H bonds in the ethyltitanium fragment; the results are analysed for their relevance to the bonding in the β-agostic unit in the light of quantum chemical calculations.**

Despite their potential significance,[1] so-called agostic interactions can be tormentingly difficult to pin down in transition-metal alkyls. Whilst the presence of M···H–C interactions (M = metal) may often be inferred from a distorted M–alkyl geometry, the true degree and nature of the effect are hard to ascertain. Diffraction with X-rays, if not with neutrons, and NMR and (particularly) vibrational spectroscopies have failed in most cases to afford clearcut results.

Vibrational studies of the coordinated alkyl group have mostly been impaired by the lack of any definitive analysis aimed at establishing the true natures of the various transitions. In principle, the C–H stretching modes should be a highly sensitive index to the bonding and geometry of the alkyl group: in practice, coupling with, or masking by, other modes, and notably $2 \times \delta_{asym}(CH_3)$, tends to cloud the picture. In an extensive study of small organic molecules, partial deuteriation has been exploited to decouple C–H stretching fundamentals from other modes.[2] The 'isolated' C–H stretching modes [$\nu^{is}$(CH)] thus identified provide an unusual insight into conformational, stereoelectronic and bonding effects, and prove to be an extremely sensitive measure of C–H bond strength. As part of a comprehensive, systematic enquiry into the nature of β-agostic interactions in transition-metal alkyls,[3] we have investigated the IR spectra of the base-free molecule [$EtTiCl_3$] **1** and its adduct **2** with $Me_2PCH_2CH_2PMe_2$ (dmpe), each incorporating either normal $CH_3CH_2$ or specifically deuteriated $CHD_2CD_2$ groups. Complex **2** has been deliberately chosen in view of its seminal rôle in relation to notions about β-agostic interactions, X-ray diffraction having identified a $TiCH_2CH_3$ fragment with a curiously tight TiCC angle (86°).[4]

The low volatility and thermal instability of [$EtTiCl_3$] poses serious problems in the measurement and interpretation of the IR spectrum of the molecule in the gas phase. Notwithstanding these complications, we have obtained and assigned spectra for several isotopomers. The IR spectrum of the gaseous [$CH_3CH_2TiCl_3$] molecule, **1**, [Fig. 1(*a*)] shows all the C–H stretching fundamentals to occur in the 'normal' region, *i.e.* 2800–3100 $cm^{-1}$. The spectrum of the $CHD_2CD_2$ isotopomer, **1**-$h_1$, [Fig. 1(*b*)] shows just two proximal bands attributable to $\nu^{is}$(CH) modes and corresponding to conformers with the unique C–H bond disposed either out of or within the mirror plane of the $C_s$-symmetric molecule [C–H″ 2953 (A) or C–H′ 2927 $cm^{-1}$ (B), respectively; Fig. 1(*b*), Scheme 1]. The spectra bear a close resemblance to those reported for [($\eta$-$C_5H_5$)$TiCl_2Et$][5] and clearly imply a normal or anagostic structure for **1**, in keeping with the findings of an electron diffraction study.[3]

By contrast, the IR spectrum of solid [$CH_3CH_2TiCl_3$(dmpe)] [Fig. 1(*c*)] exhibits, in addition to bands in the region 2800–3100 $cm^{-1}$, a broad absorption centred at 2615 $cm^{-1}$ (C). The spectrum of the $CHD_2CD_2$ isotopomer **2**-$h_1$ [Fig. 1(*d*), Scheme 1] resembles that of **1**-$h_1$ in containing just two features identifiable with $\nu^{is}$(CH) modes, but with frequencies of 2933 (D) and 2585 $cm^{-1}$ (E) for the out-of-plane (C–H″) and in-plane



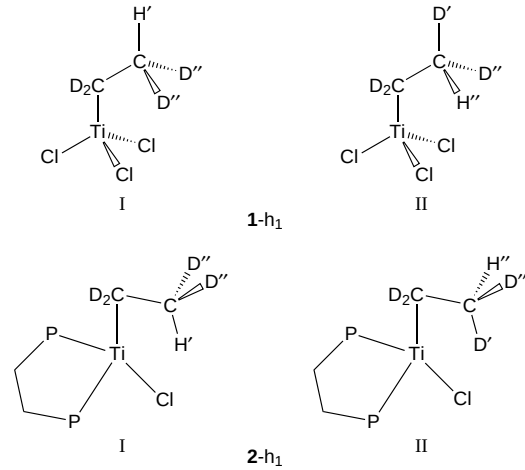


**Fig. 1** IR spectra of **1** (*a*), **1**-$h_1$ (*b*), **2** (*c*), and **2**-$h_1$ (*d*) in the region corresponding to C–H(D) stretching vibrations. In (*c*) and (*d*) the spectrum of [$TiCl_4$(dmpe)] has been overlaid (stippled) to aid identification of the internal modes of the ethyl moiety.

**Scheme 1**

[a] Scale factors: $[EtTiCl_3]$, methyl, CH″ 0.951, CH′ 0.968; methylene, 0.971; $[EtTiCl_3(H_2PCH_2CH_2PH_2)]$, methyl, CH″ 0.930, CH′ 0.917; methylene, 0.953. The very small differences between the two CH″ bonds in both the methyl and methylene groups have been ignored. Calculated $\nu$(CD) values have been multiplied by 1.011 to offset anharmonicity. [b] Conformers specified by I and II as in Scheme 1. [c] Frequency used for scaling the DFT force field. [d] Likely to be affected by Fermi resonance. [e] These descriptions are approximate. [f] ol signifies overlay by features arising from the dmpe ligand.

(C–H′) modes, respectively; the separation between them is an order of magnitude greater than that found for **1**-$h_1$. These observations point unmistakably to the presence of two chemically distinct types of C–H bond attached to the β-carbon atom of the ethyl ligand in **2** [*viz*. two terminal (C–H″) and one agostic (C–H′)]. For the C–H′ bond in **2**-$h_1$, $\nu^{is}$(CH) thus has a frequency comparable with those reported for the normal (coupled) $\nu$(CH) modes in other β-agostic complexes.[3] To our knowledge, the $\nu^{is}$(CH) frequency of 2585 $cm^{-1}$ in **2**-$h_1$ is the first to be determined in a complex whose β-agostic structure has been verified by diffraction methods. It is remarkable for being some 200 $cm^{-1}$ lower than that of any $\nu^{is}$(CH) reported hitherto (*cf*. 2799 $cm^{-1}$ in $NMe_3$ where the C–H bonds are weakened through interaction with the antiperiplanar lone pair[2]).

Drawing on the empirical equations developed elsewhere[2,6] leads from the values of $\nu^{is}$(CH) displayed by **2**-$h_1$ to the following estimates of spectroscopic bond length ($r_0$ in pm) and adiabatic bond dissociation enthalpy ($D_0$ in kJ $mol^{-1}$): $r_0$(C–H″) = 109.8, $D_0$(C–H″) = 410; $r_0$(C–H′) = 113.4, $D_0$(C–H′) = 280. At face value, therefore, the results imply that, as the β-$CH_3$ unit of the ethyl group approaches the Ti centre, the in-plane C–H′ bond suffers an appreciable weakening, being 3.6 pm longer and having a dissociation enthalpy 130 kJ $mol^{-1}$ smaller than its out-of-plane (C–H″) counterparts.† However, there is no suggestion of significant chemical activation of the C–H′ bond, nor of any significant degree of alkene hydride character to the ethyl unit on the evidence of $^2H$ NMR measurements on samples of **2** in the presence of $D_2$, $CD_4$ and $C_2D_4$.

There is a second noteworthy feature of the IR spectra. Coordination of $[EtTiCl_3]$ by dmpe results also in a significant increase in the frequencies of the $\nu$(CH) modes associated with the methylene portion of the ethyl ligand [from 2878 (F), 2933 $cm^{-1}$ in **1** to 2933, 3028 $cm^{-1}$ (G) in **2**]. A concomitant widening of the HCH angle can be inferred from the increase in the ratio $\nu_{as}/\nu_s$ for the $C_\alpha H_2$ unit. Complexation thus appears to give a methylene group with C–H bonds roughly 1.3 pm shorter and 20 kJ $mol^{-1}$ stronger than those in base-free $[EtTiCl_3]$.[7] Simultaneously the methylene $^{13}C$ resonance of the solution species undergoes a substantial low-frequency shift, while $^1J$(CH) increases from 134.3 to 147.3 Hz.[1,3]

The interpretation of the IR spectra has been underpinned by density functional theory (DFT) calculations on $[EtTiCl_3]$ and the model compound $[EtTiCl_3(H_2PCH_2CH_2PH_2)]$ **2a**. Since optimisation yields equilibrium structures in good agreement with those determined experimentally for **1** and **2**,[3,4] replacement of the methyl groups in dmpe by hydrogen appears to have very little effect on the overall structure of the complex. Accordingly, the calculated (harmonic) frequencies of the EtTi group of **2a** may reasonably be expected, with due allowance for scaling, to approximate those determined by experiment for **2**. The results listed in Table 1 for the $\nu$(CH) and $\nu$(CD) modes of **1**, **2**, and **2a** bear out this expectation. Inspection of the calculated force field shows the normal mode characterising the $C_\beta$–H′ stretching vibration to consist exclusively of a rectilinear motion almost perpendicular to the Ti–H directrix. Computational evidence indicates that the Ti–$C_\alpha$ bonding electrons are delocalised over both $C_\alpha$ and $C_\beta$ atoms as well as over their appended H atoms, and that reduction of the TiCC valence angle allows the establishment of covalent bonding between Ti and $C_\beta$, and to a lesser extent, one of its H atoms.[3] The spectroscopic evidence is fully consistent with such a model.

† Against these quantitative estimates certain caveats need to be entered. Firstly, the empirical correlations between $\nu^{is}$(CH) and (*i*) bond length and (*ii*) bond enthalpy are founded on the assumptions of a C–H potential well whose curvature varies in a linear manner with the C–H distance and well depth, respectively. These conditions are likely to be met only for C–H bonds which are very similar in nature, with but small deviations from a 'norm'. Secondly, a low $\nu^{is}$(CH) frequency increases the likelihood of coupling of this mode, *e.g.* with the symmetric $\nu$(CD) mode of the terminal $CHD_2$ group (at *ca.* 2120 $cm^{-1}$), and so putting its vibrational isolation at risk.

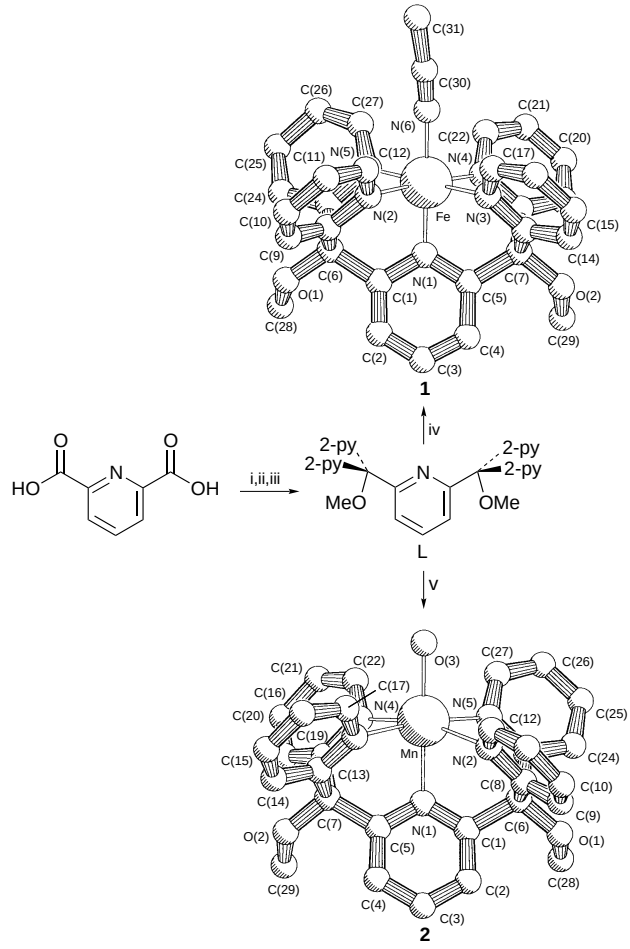
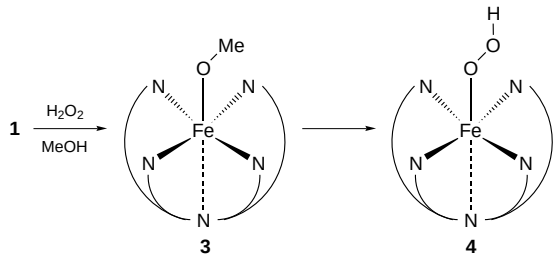
**A novel pentadentate ligand L is capable of stabilising $Fe^{II}$ and $Mn^{II}$ centres, the first of which gives a transient iron hydroperoxide species upon treatment with hydrogen peroxide.**

Mononuclear iron and manganese centres are common in oxygenases and the synthesis of low molecular mass complexes that show structural and functional similarities to natural systems is of great current interest.[1,2] An approach to novel biomimetic catalysts for selective oxygenations is based on the design of multidentate ligands that can accommodate low-valent iron[1,2] or manganese[1,3] and are capable of stabilising intermediates in the oxygenation cycles. We wish to present a unique ligand L with a fivefold pyridine donor set which is particularly effective for this purpose. This is demonstrated by the synthesis and structural characterisation of the corresponding iron $[FeL(MeCN)][ClO_4]_2$ **1** and manganese $[MnL(H_2O)][ClO_4]_2$ **2** complexes.



Ligand L was prepared in a three step procedure, from pyridine-2,6-dicarboxylic acid (Scheme 1). Treatment with $SOCl_2$ was followed by reaction of the acid chloride with 6 equiv. of 2-pyridyllithium. The resulting 2,6-bis[hydroxybis(2-pyridyl)methyl]pyridine was methylated to afford L.

Complexation of L with $Fe(ClO_4)_2 \cdot 6H_2O$ in MeCN–$CH_3OH$ (1 : 1) gave **1** in 86% yield. Red–brown crystals were obtained by slow diffusion of ethyl acetate into the product solution. Complex **1** is a low-spin iron(II) complex as deduced from its diamagnetic $^1H$ NMR spectrum‡ and absence of EPR signals. Furthermore in acetonitrile the complex has an absorption maximum at 425 nm. Cyclic voltammetry of **1** in acetonitrile shows reversible oxidation at 1.21 V *vs*. SCE corresponding to the $Fe^{III}$–$Fe^{II}$ couple.



The crystal structure of **1** shows a six-coordinate $Fe^{II}$ centre surrounded by nitrogen atoms from four equatorial and one apical pyridine moieties.§ The second apical position is occupied by an acetonitrile molecule. The four equatorial pyridine rings are not positioned perpendicular to the basal plane but are folded outwards to provide a cleft-type of arrangement. The Fe–N bond lengths to N(1), N(4), N(5) and N(6) of 1.93–2.00 Å are characteristic for a low-spin $Fe^{II}$ centre.[4–6] The Fe–N(2) and Fe–N(3) bond lengths of 2.08 Å are long for a low-spin iron(II) complex, which is probably due to the fact that the cleft formed by the four equatorial pyridine rings is slightly too large to accommodate a low-spin $Fe^{II}$ with equal Fe–N distances.

Treatment of **1** in methanol with an excess (100 equiv.) of hydrogen peroxide at 25 °C (Scheme 2) causes the appearance of a blue species ($\lambda_{max}$ = 592 nm) with a half-life of 3 h.

The nature of this intermediate was examined by electrospray ionisation mass spectrometry (nozzle = 70 V). The results show that immediately after addition of $H_2O_2$ a prominent ion, with a peak cluster at *m/z* 661 is formed which can be formulated as $\{[FeL(OCH_3)](ClO_4)\}^+$ **3**.¶ This indicates initial oxidation of iron(II) complex **1** to an iron(III) species. In the course of the reaction with hydrogen peroxide an ion with *m/z* 663 is formed at the expense of **3** which corresponds to $\{[FeL(OOH)](ClO_4)\}^+$ **4**.

**Scheme 1** Synthesis of L, complexes **1** and **2** and X-ray crystal structures of the cations of **1** and **2**. Hydrogens have been omitted for clarity. *Reagents and conditions*: i, $SOCl_2$, reflux, 4 h; ii, $Bu^nLi$, 2-bromopyridine, thf; iii, NaH,MeI, thf; iv, $Fe(ClO_4)_2 \cdot 6H_2O$, MeCN, MeOH; v, $Mn(ClO_4)_2 \cdot 6H_2O$, MeCN. Selected interatomic distances (Å): for **2**: Fe–N(1) 1.927(8), Fe–N(2) 2.078(8), Fe–N(3) 2.076(9), Fe–N(4) 1.995(9), Fe–N(5) 1.957(8), Fe–N(6) 1.952(8). For **3**: Mn–O(3) 2.100(3), Mn–N(1) 2.223(3), Mn–N(2) 2.297(3), Mn–N(3) 2.248(3), Mn–N(4) 2.230(3), Mn–N(5) 2.214(3).

**Scheme 2** Formation of the blue iron(II) hydroperoxide complex **4**

The assignment of the blue species as a hydroperoxide complex **4** is furthermore based on similar spectroscopic data as reported recently for an iron(III) hydroperoxide intermediate.[5,6] It is also corroborated by the results from EPR measurements at 77 K which exhibit *g* values at 2.15, 2.13 and 1.98 indicative of a low-spin iron(III) species.[2,5–7] Based on the available coordination site and the pentadentate nature of L an end-on hydroperoxide structure for **4** is proposed.

Preliminary investigations show that complex **1** is catalytically active in the oxidation of alkanols. For example, treatment of benzyl alcohol in acetone with 100 equiv. of $H_2O_2$ in the presence of **1** gave a clean and fast conversion to benzaldehyde (65 equiv. with respect to **1** within 0.5 h).‖

Treatment of a solution of L in acetonitrile with $Mn(ClO_4)_2{\cdot}6H_2O$ followed by vapour diffusion of diethyl ether resulted in greyish crystals of $[MnL(H_2O)][ClO_4]_2$ **2** (35% yield). Complex **2** shows no absorptions in the visible spectrum which points to a high-spin manganese(II) complex.[3,8]

Electrospray ionisation mass spectrometry (nozzle = 70 V) affords prominent peaks at *m/z* 265, 629, corresponding to the ions $[MnL]^{2+}$ and $\{[MnL](ClO_4)\}^+$, respectively. The crystal structure of **2** exhibits similar features as found for **1** including six-coordination of manganese with four pyridines in the equatorial positions.§ In contrast to complex **1**, one apical position is occupied by a water molecule, which donates two hydrogen bonds to the two independent $ClO_4^-$ anions. The Mn–N bond lengths of 2.21–2.30 Å are typical for the Mn–N(pyridyl) distances observed in six-coordinated manganese(II) complexes.[3,8] The Mn–O distance is 2.10 Å.

In conclusion, a new pentadentate ligand L has been designed. The pentadentate nature of L is evident from the structures of **1** and **2** leaving a sixth coordination site free to accommodate weakly bonded ligands such as acetonitrile and water. This ligand is effective in the formation of iron(II) and manganese(II) complexes and capable of stabilising a transient hydroperoxide species. Catalytic oxidation experiments with these new complexes are in progress.

We gratefully acknowledge stimulating discussions with Professor L. Que, Jr. and we thank M. Jeronimus-Stratingh for the ES–MS measurements. This work was supported in part (A. L. S.) by the Netherlands Foundation of Chemical Research (SON) with financial aid from the Netherlands Organisation for Scientific Research (NWO) and in part (R. M. La C.) by IOP catalysis.

‡ $^1$H NMR (200 MHz, $CD_3CN$, 25 °C): $\delta$ 2.11 (m, 3 H, MeCN), 4.04 (s, 6 H, $OCH_3$), 8.01 (m, 15 H, py), 9.94 (m, 4 H, py).

§ *Crystal data*: for **2**, $C_{31}H_{28}Cl_2FeN_6O_{10}$, $M_r$ = 771.35, red–brown, block-shaped crystal (0.2 × 0.2 × 0.1 mm), monoclinic, space group $P2_1$ (no. 4), $a$ = 9.751(2), $b$ = 19.326(5), $c$ = 9.7986(17) Å, $\beta$ = 101.427(17)°, $U$ = 1809.9(7) Å$^3$, $Z$ = 2, $D_c$ = 1.415 g cm$^{-3}$, $F(000)$ = 792, $\mu$(Mo-K$\alpha$) = 6.3 cm$^{-1}$, 3495 reflections measured, 3293 independent, ($1.05 < \theta < 25.00°$, $\omega$ scan, $T$ = 150 K, Mo-K$\alpha$ radiation, graphite monochromator, $\lambda$ = 0.71073 Å) on an Enraf-Nonius CAD4 Turbo diffractometer on rotating anode. Data were corrected for $L_p$ effects and for linear decay of 3% of the reference reflections, but not for absorption. The structure was solved by automated Patterson methods (DIRDIF96). Refinement on $F^2$ was carried out by full-matrix least-squares techniques (SHELXL-96); no observance criterion was applied during refinement. Electron density in a disordered solvent area (164 Å$^3$, 47.9 e per asymmetric unit) was taken into account in the refinement *via* PLATON/SQUEEZE. Where relevant, data cited above are given without disordered solvent contribution. Hydrogen atoms were included in the refinement on calculated positions riding on their carrier atoms. Refinements of a racemic twin model resulted in slightly lower $wR_2$ values and a component ratio of 0.84(10) : 0.16. Refinements converged at a final $wR_2$ value of 0.1674, $R_1$ = 0.0669 [for 2282 reflections with $F_\sigma > 4\sigma(F_\sigma)$], $S$ = 0.985, for 455 parameters. A final difference Fourier showed no residual density outside −0.76 and 0.59 e Å$^{-3}$.

For **3**, $C_{29}H_{27}Cl_2MnN_5O_{11}$, $M_r$ = 747.40, greyish, block-shaped crystal (0.4 × 0.2 × 0.1 mm), monoclinic, space group $P2_1/c$ (no. 14), $a$ = 12.5605(12), $b$ = 12.8173(12), $c$ = 19.3461(17) Å, $\beta$ = 93.360(8)°, $U$ = 3109.2(5) Å$^3$, $Z$ = 4, $D_c$ = 1.597 g cm$^{-3}$, $F(000)$ = 1532, $\mu$(Mo-K$\alpha$) = 6.7 cm$^{-1}$, 8433 reflections measured, 7119 independent, ($1.06 < \theta < 27.50°$). Data collection and handling were performed as described for compound **2**. The reference reflections displayed a linear decay of 2%. The structure was solved by automated Patterson methods (SHELXS-86). The water hydrogen atoms were located on a Fourier map and subsequently included in the refinement. Refinement converged at a final $wR_2$ value of 0.1331, $R_1$ = 0.0564 [for 4676 reflections with $F_\sigma > 4\sigma(F_\sigma)$], $S$ = 1.021, for 462 parameters. A final difference Fourier showed no residual density outside −0.66 and 0.50 e Å$^{-3}$. CCDC 182/491.

¶ A related iron(III) methoxy species was observed by ES–MS for $[FeL'(MeCN)](ClO_4)_2]$ [L′ = *N*,*N*-bis(2-pyridylmethyl)-*N*-bis(2-pyridyl)-methylamine] and the crystal structure of the corresponding methoxy complex was recently solved; manuscript is in preparation.

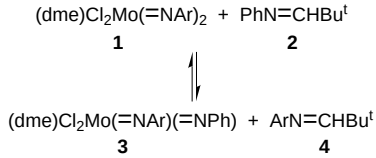
# Azaheteroalkene metathesis: reaction of imines with molybdenum(VI) bis(imide) complexes

**Gidget K. Cantrell and Tara Y. Meyer***



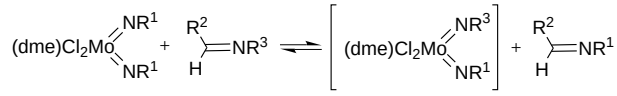
*Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA*

**Bis(imide) complexes (dme)$Cl_2$Mo(=NR)$_2$ (R = $Bu^t$, $C_6H_3Pr^i_2$-2,6) and ($Bu^tO$)$_2$Mo(=NAr)$_2$ (Ar = $C_6H_3Pr^i_2$-2,6) undergo imide/imine metathesis with PhN=CH($Bu^t$) or ($Pr^n$)N=CHPh.**

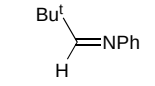
Transition-metal-mediated reactions offer many potential advantages over traditional approaches to carbon–heteroatom bond formation including selectivity, mild reaction conditions, varied functional group tolerances, and increased reaction rates. A promising strategy for the development of these coupling reactions involves the extension of metal–alkylidene-mediated alkene metathesis, which is used extensively in polymer synthesis and increasingly in the preparation of natural products,[1–3] to heteroalkenes. We are particularly interested in carbon–nitrogen bond formation through metal–imide-mediated imine metathesis.

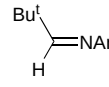
Reports of catalytic metathesis of azaheteroalkenes are rare and no system of general utility has been described.[4,5] Carbodiimides have been metathesized by $Cl_4Mo$=NR[6] and isocyanates by [(η-$C_5H_4$Me)Mo(=NR)$_2$]$_2$.[7] Only one example exists, however, of the metathesis of the less activated, but more versatile imine substrates. The early transition-metal imide complex, (η-$C_5H_5$)$_2$Zr(=$NBu^t$)(thf), reacted with *N*-phenylimines to give diazametallacycles that underwent further metathetical exchange with external imines, presumably *via* imide intermediates.[8,9] Although this reagent is an imine metathesis catalyst, it suffers from significant limitations, the reaction is inhibited by high imine concentrations and the reagent is reported to undergo a competing dimerization that deactivates it towards further reaction. Herein, we identify a class of metal complexes that exhibit the key step of catalytic imine metathesis, imide/imine metathesis, without such substrate inhibition or terminal dimer formation.

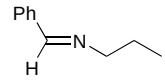
Treatment of (dme)$Cl_2$Mo(=NAr)$_2$[10] (Ar = $C_6H_3Pr^i_2$-2,6) **1**, with 0.8 equiv. of *tert*-butylanil **2**† in $C_6D_6$ at 100 °C produced metathesis product **4** over the course of several days as observed by $^1$H NMR spectroscopy (Scheme 1). After 18 days the ratio of **2** to **4** was *ca.* 1 : 1.‡ When the reaction was repeated with 12 equiv. of imine **2** to 1 equiv. of bis(imide) **1**, the reaction proceeded much more rapidly, producing 1.4 equiv. of imine **4** after 8 days at 85 °C.§ Inversion of the stoichiometry, 9 equiv. of **1** to 1 equiv. of imine **2**, slowed the reaction to the degree that only a trace of product imine **4** was observed after 8 days at 85 °C. Unambiguous identification of product imine **4** was achieved by comparison of the $^1$H NMR spectrum with that of an authentic sample and by GC–MS analysis of the reaction mixture. Increasing the temperature results in a concomitant increase in rate; the optimum reaction conditions have not yet been determined.

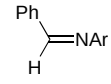


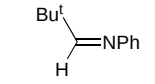
**Scheme 1**

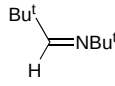


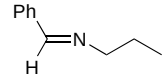


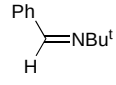


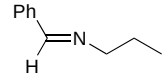


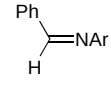


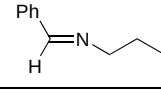












These reactions proceeded cleanly. No evidence for precoordination or for metallacyclic intermediates was observed by $^1$H NMR spectroscopy for any of the stoichiometric combinations;¶ nor were alkenes detected. Competing intermolecular imide/imide metathesis,[11] which in these systems equilibrates all bis(imide) complexes, prevented isolation and complete characterization of the mixed imide product (dme)$Cl_2$Mo(=NAr)(=NPh) **3**. $^1$H NMR resonances associated with **3** were, however, identified in the reaction mixture by comparison with those from a spectrum of an authentic sample.‖,**

Imide/imine metathesis is remarkably general for this class of bis(imides). The reaction proceeds despite changes in substrate imine, imide-nitrogen substituent, or ancillary ligand (Table 1). Specifically, imides **1** and (dme)$Cl_2$Mo(=$NBu^t$)$_2$, **5**,[10] react with imine **2**. Imides **1**, **5**, and ($Bu^tO$)$_2$Mo(=NAr)$_2$, **6**,[12] also react with *N*-propylbenzaldimine **8**, to give the expected exchange products. Only the sterically crowded (ArO)$_2$Mo(=NAr)$_2$, **7**, is unreactive.†† The fact that imide/imine metathesis occurs in all but one of the examples investigated to date suggests that these catalysts can be 'tuned' by varying the ancillary ligands.

One goal of this work was to identify a catalyst that does not undergo significant termination reactions. Compelling evidence for a lack of such termination reactions in the systems we have described can be found by examining the $^1$H NMR spectra; no significant amount of any species other than those described above was present. Specifically, we did not observe any stable

**Table 1**. Imide/imine metathesis

| Bis(imide) | | Substrate imine | | Product imine[a] |
|---|---|---|---|---|
| (dme)$Cl_2$Mo(=NAr)$_2$ | **1** |  | **2** |  |
| | |  | **8** |  |
| (dme)$Cl_2$Mo(=$NBu^t$)$_2$ | **5** |  | **2** |  |
| | |  | **8** |  |
| ($Bu^tO$)$_2$Mo(=NAr)$_2$ | **6** |  | **8** |  |
| (ArO)$_2$Mo(=NAr)$_2$ | **7** |  | **8** | No reaction |

[a] Characterized by $^1$H NMR spectroscopy and/or GC–MS analysis.

imide-bridged dimers, a particular concern since similar dimer formation limited the utility of $(\eta\text{-}C_5H_4Me)_2Zr(=NBu^t)(thf)$ as an imine metathesis catalyst.[8,9] Previous workers, who have examined these molybdenum bis(imide) complexes for other applications, have also found them to be primarily monomeric in solution. In a particularly relevant and elegant study, Gibson and coworkers observed intermolecular imide/imide exchange of $(Bu^tO)_2Mo(=NBu^t)_2$ with $(Bu^tO)_2Mo(=NAr)_2$.[11] Although the most likely mechanism for exchange would involve an imide-bridged dimer, no spectral evidence for a significant concentration of this intermediate could be found. Also germane is the observation by Chisholm *et al.* that an analogous bis(imide) dimer $[(Bu^tO)_2Mo(=NPh)(\mu\text{-}NPh)]_2$,[13] characterized by X-ray crystallography, exhibited a monomeric solution molecular mass.[14] Based on our data and these reports we can conclude that, although imide-bridged dimers are likely to be present in our reaction mixture, they do not represent a termination step for imide/imine metathesis.

Although these preliminary studies do not provide a complete picture of the metathesis, the data do provide some insights into the mechanism. It is clear, for example, that the imine products do not arise from a pathway involving initial decomposition of the metal imide. In control experiments, catalysts **1** and **5** were observed to be stable for weeks at 100 °C in $C_6D_6$. Moreover, integration of imide $^1$H NMR resonances *vs.* an internal standard showed that there was very little diversion of metal–imide complexes to insoluble or unidentified species.

We also do not believe that the reaction we are observing is water catalyzed. No acceleration was observed when trace water was added to the reaction mixture, nor was the reaction retarded when the reaction mixture was pre-dried for 3 days over molecular sieves before it was decanted and combined with bis(imide) complex **1**.

Like many of the alkylidene catalysts, the bis(imide) catalysts described herein do not exhibit precoordinated nor metallacyclic intermediates in their reaction with unsaturated substrates.[1c] Further studies are required to ascertain if, in fact, the metathesis proceeds through a [2 + 2] mechanism as would be expected by analogy to alkene metathesis systems. These studies are currently being pursued.

In summary, we have identified the first potential catalysts for imine metathesis. These bis(imide) catalysts undergo a general metathesis with imines without termination by dimer formation.

* E-mail: tmeyer+@pitt.edu

† Imines were prepared by condensation of the parent aldehyde and amine in benzene over molecular sieves, followed by purification by vacuum distillation. The procedure was analogous to that described for imine preparation by S. R. Sandler, and W. Karo, in *Organic Functional Group Preparations*, Academic Press, New York, 1986, vol. II, p. 302.

‡ The ratio of products reported reflects the equilibrium reached after complete metathesis of the first and partial metathesis of the second imide reactive site.

§ *Typical NMR experiment*: reaction of $(dme)Cl_2Mo(NAr)_2$ **1** and $PhN{=}CH(Bu^t)$ **2**. Complex **1** (0.005 g, 0.008 mmol, 1 equiv.) was dissolved in *ca.* 0.5 ml $C_6D_6$ in an NMR tube equipped with a Teflon stopcock. Hexamethylbenzene in $C_6D_6$ and imine **2** (*ca.* 12 equiv.) were added. The sample was maintained for 24 h at room temp. to verify the stoichiometry and stability of the reaction mixture. The sample was heated and maintained at 85 °C for 18 d. The progress of the reaction was monitored by $^1$H NMR spectroscopy. $^1$H NMR ($C_6D_6$) of $ArN{=}CH(Bu^t)$ (unisolated) $\delta$ 7.25 (s, 1, C*H*$Bu^t$), 3.05 (spt, 2, C*H*$Me_2$, $J_{CH}$ 6.7 Hz), 1.17 (d, 12, CH*Me*$_2$, $J_{CH}$ 6.6 Hz), 1.07 (s, 9, $Bu^t$); mass spectrum (EI) *m/z* 245 ($M^+$), 188 ($M^+ - Bu^t$). $^1$H NMR ($C_6D_6$) $(dme)Cl_2Mo(NAr)(NPh)$ (unisolated) $\delta$ 4.40 (spt, 2, C*H*$Me_2$, $J_{CH}$ 7.1 Hz), 1.30 (d, 12, CH*Me*$_2$, $J_{CH}$ 6.8 Hz). Phenyl and aryl resonances could not be definitively assigned owing to the complexity of the spectrum in this region.

¶ The diazametallacycle, if present, exists only in trace amounts since the total imine concentration (substrate + product) remains nearly constant throughout the reaction.

‖ Compound **3** was independently prepared by the reaction of bis(imide) **1** with phenyl isocyanate.

** $(dme)Cl_2Mo(=NPh)_2$ should be present as well, arising from metathesis of both imido groups and, also, from intermolecular imide/imide metathesis. The complexity of the phenyl region of the spectrum precludes the assignment of resonances for this species.

†† $(ArO)_2Mo(NAr)_2$ was prepared by analogy to $(Bu^tO)_2Mo(NAr)_2$ by reaction of $(dme)Cl_2Mo(NAr)_2$ with 2 equiv. of LiOAr. $^1$H NMR ($C_6D_6$) $\delta$ 6.87–7.08 (m, 12, aryl), 3.82 (spt, 4, C*H*$Me_2$, $J_{CH}$ 6.8 Hz), 3.48 (spt, 4, C*H*$Me_2$, $J_{CH}$ 6.8 Hz), 1.25 (d, 24, CH*Me*$_2$, $J_{CH}$ 6.8 Hz), 1.00 (d, 24, CH*Me*$_2$, $J_{CH}$ 6.8 Hz); $^{13}$C NMR ($C_6D_6$) $\delta$ 160.7 ($C_{ipso}$, OAr), 154.4 ($C_{ipso}$, NAr), 143.6, 138.2, 127.6, 124.3, 123.9, 123.1 (aryl), 29.4 (C*H*$Me_2$, OAr), 28.0 (C*H*$Me_2$, NAr), 24.5 (CH*Me*$_2$, OAr), 24.2 (CH*Me*$_2$, NAr). Anal. Calc. for $C_{48}H_{68}N_2O_2Mo$: C, 71.87; H, 8.56; N, 3.50. Found: C, 71.91; H, 8.74; N, 3.50%.

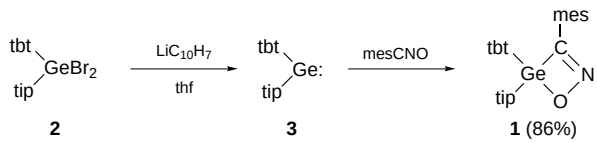
# First oxazagermete: synthesis, structure and thermal cycloreversion into a germanone

**Tsuyoshi Matsumoto, Norihiro Tokitoh and Renji Okazaki***

*Department of Chemistry, Graduate School of Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan*

**A novel four-membered ring compound, 1,2,4-oxazagermete, is obtained by the reaction of diarylgermylene tbt(tip)Ge: with mesitonitrile oxide; its thermolysis generates germanone tbt(tip)Ge=O as evidenced by trapping reactions with dimethylbutadiene and ethanol.**



Small-ring compounds containing a group 14 element have been of current interest because of their intriguing structural properties and potential utility as precursors of reactive intermediates taking advantage of their ring strain. Since many such small-ring compounds are highly reactive under ambient conditions, some stabilization is often necessary for their isolation, for example, the use of a very bulky substituent.[1]

Here we report the synthesis of kinetically stabilized 1,2,4-oxazagermete **1**, a novel four-membered ring compound containing germanium, by an efficient steric protecting group, 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl (tbt).[2] There have been several reports on 1,2-oxazetes. They were observed as reactive intermediates in the thermal and photochemical reactions of α,β-unsaturated nitro compounds or in the reaction of vinyl radicals and NO,[3] and some oxazetes having bulky substituents have been isolated although their molecular structures were not established.[4] In contrast, there has been no report so far on the heavier group 14 element analogue of an 1,2-oxazete.

Oxazagermete **1** was synthesized as stable colourless crystals in 87% by the reaction of diarylgermylene tbt(tip)Ge: **3** (tip = 2,4,6-triisopropylphenyl), generated from dibromogermane **2** and lithium naphthalenide in thf,[5] with mesitonitrile oxide (Scheme 1). This represents the first synthesis of an oxazagermete as well as the first isolation of a [1 + 3]-cycloaddition reaction product of a germylene with 1,3-dipolar reagents.[6]

Oxazagermete **1** showed characteristic spectral data.† The C=N bond stretching was observed at 1612 $cm^{-1}$ in the IR spectrum, which is similar to those reported for 1,2-oxazetes.[4] In the $^{13}C$ NMR spectrum, a singlet peak was observed at $\delta$ 174.8 assignable to the carbon in the four-membered ring, which is more shielded than that of an oxazete owing to the more electropositive Ge atom on the carbon.[4c]

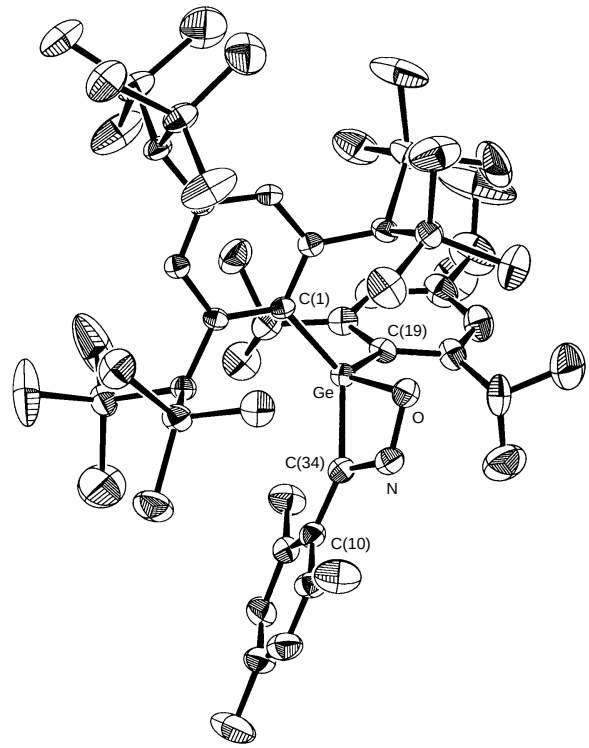
The molecular structure of **1** has been determined by X-ray crystallographic analysis and an ORTEP drawing is shown in Fig. 1.‡ The bond angle C(34)–Ge–O considerably shrinks from that of normal $sp^3$ configuration to 68.7(2)°, suggesting the large ring strain of the four-membered ring, which is also reflected on the long Ge–O bond length [1.872(4) Å] compared with that of a typical Ge–O single bond (1.75–1.85 Å).[7] The four-membered ring of **1** is perfectly planar with the sum of the bond angles being 360°.

**Scheme 1**

Thermolysis of **1** was carried out in the expectation that it would dissociate into a germanium–oxygen double-bond species (germanone) tbt(tip)Ge=O **4** and mesitonitrile, since an 1,2-oxazete is known to undergo thermal cycloreversion into the corresponding ketone and nitrile.[3,4] The chemistry of germanones has not been fully disclosed yet, although they have been a fascinating subject of considerable attention in recent years.[1b,8]

When a [$^2H_6$]benzene solution of **1** and 2,3-dimethylbuta-1,3-diene in a sealed NMR tube was heated at 120 °C for 12 h, the starting materials were consumed completely ($^1H$ NMR) to afford **5**–**7** and mesitonitrile (Scheme 2).§ Formation of compounds **5**–**7** and an almost quantitative yield of mesitonitrile clearly indicates the generation of intermediary germanone **4**, since we previously reported the formation of **7** from germanone **4** generated from by the reaction of germylene **3** with tribenzylamine *N*-oxide.[8]

Compounds **6** and **7** are most likely produced from germanone **4** *via* intramolecular cyclization,[9] while the formation of compound **5** is reasonably explained in terms of an ene



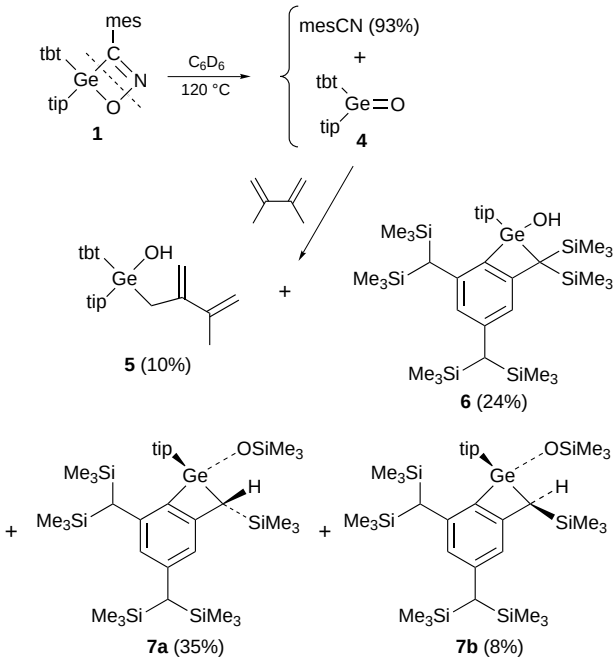


**Fig. 1** ORTEP drawing of oxazagermete **1** with thermal ellipsoid plots (30% probability). Selected bond lengths (Å) and angles (°): Ge–O 1.872(4), Ge–C(1) 1.968(6), Ge–C(19) 1.974(6), Ge–C(34) 2.001(6), C(34)–N 1.291(9), N–O 1.418(8), C(10)–C(34) 1.459(10); C(1)–Ge–O 105.9(2), C(1)–Ge–C(19) 114.9(2), C(1)–Ge–C(34) 123.0(3), C(19)–Ge–O 112.9(3), C(19)–Ge–C(34) 119.1(3), O–Ge–C(34) 68.7(2), Ge–O–N 92.7(3), O–N–C(34) 107.6(5), Ge–C(34)–N 91.1(5), Ge–C(34)–C(10) 146.2(5), N–C(34)–C(10) 122.7(6).

**Scheme 2**

reaction of germanone **4** with the butadiene. In the cases of chalcogen double-bond species, tbt(tip)Ge=X (X = S, Se, Te), the corresponding [4 + 2] cycloadducts were obtained in the reactions with dienes.[2] The reason for this difference is not clear at present.

The total yield of the silyl-migrated compounds **7a** and **7b** is higher than that of the hydrogen-migrated compound **6**, which is probably due to the higher affinity of silicon for oxygen. The product ratio of **7a** to **7b** is considered to be kinetically determined since no isomerization from **7a** to **7b** is observed even at 180 °C.

The generation of germanone **4** was also confirmed by the thermal reaction of **1** in benzene (at 120 °C, in a sealed tube) in the presence of ethanol, in which ethoxy(hydroxy)germane tbt(tip)Ge(OH)(OEt) **8**, an ethanol adduct of **4**, was obtained in 82%. This finding indicates that the intermolecular reaction with ethanol was faster than the intramolecular silyl or hydrogen migration mentioned above. It was also confirmed by thermolysis (120 °C) of a [$^2H_6$]benzene solution of oxazagermete **1** in the presence of 0.3 equiv of ethanol while being monitored by $^1$H NMR. In the initial stage, the ethanol adduct **8** was observed exclusively, and, after consumption of ethanol, the rearrangement reaction to **6**, **7a** and **7b** occurred.

In summary, we have succeeded in the isolation and crystallographic analysis of the first 1,2,4-oxazagermete **1**, which undergoes thermal cycloreversion into mesitonitrile and germanone tbt(tip)Ge=O.

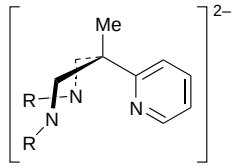
# Highly selective trimerisation of MeNC by a novel titanium imido complex containing a tridentate dianionic ligand

**Alexander J. Blake,[a] Philip E. Collier,[a] Lutz H. Gade,*[b] Mary McPartlin,[c] Philip Mountford,*[a] Martin Schubart[b] and Ian J. Scowen[c]**



[a] *Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD*
[b] *Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany*
[c] *School of Applied Chemistry, University of North London, Holloway Road, London, UK N7 8DB*

**A new type of imido compound [Ti(NBu$^t$)L(py)] 1 containing a tripodal dianionic ligand is reported which effects the remarkably selective trimerisation of MeNC; the crystal structures of 1 and [TiL{N(Me)N(Bu$^t$)($C_4H_3N_2$Me)}] 2 are described [L = MeC(2-$C_5H_4N$)($CH_2NSiMe_3$)$_2$].**

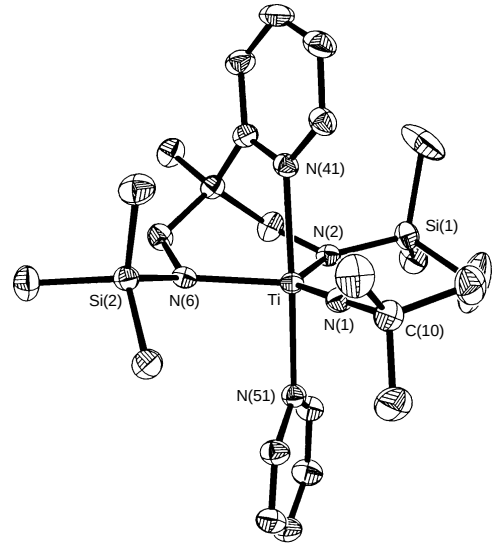
Transition-metal imido complexes are relevant to industrially important processes such as acrylonitrile synthesis and ring-opening metathesis polymerisation, and also to biological processes such as nitrogen fixation.[1] Highly reactive transition-metal imido transients, in particular, have demonstrated a rich chemistry including cycloaddition reactions, catalytic hydroammination and C–H bond activation.[1b] Imido complexes that have reactive {M=NR} functionalities but yet are sufficiently kinetically stable to be isolated are extremely rare. Cognisant of the very successful use of the trianionic triamidoamine ligands [($RNCH_2CH_2$)$_3$N]$^{3-}$ **A** in developing groups 5–7 metal–ligand multiple bond chemistry,[2] we wished to explore the potential of the dianionic tripodal ligands [MeC(2-$C_5H_4N$)($CH_2NR$)$_2$]$^{2-}$ **B**.

**A**

**B**

The ligand system **B** is related to **A**, but features several important differences. Firstly, the pyridyl nitrogen donor function in **B** is only relatively weakly coordinating (compared to amide donor groups in **A**) and this 'arm' can potentially dissociate[3] from the metal centre during reactions to open up a larger reactive site. Furthermore, **B** is only a dianionic ligand and thus allows access to neutral metal–ligand multiply bonded complexes of the group 4 metals. Here, we report the synthesis of a novel titanium imido complex containing a tridentate ligand of the type **B**, along with an example of its reactivity.

Reaction of the previously described complex [Ti(NBu$^t$)Cl$_2$(py)$_3$][4] with the dilithiated diamidopyridine ligand [Li$_2$L]$_2$[5] in benzene followed by standard work-up afforded [Ti(NBu$^t$)L(py)] **1** in good yield [L = MeC(2-$C_5H_4N$)($CH_2NSiMe_3$)$_2$]. The X-ray structure of **1** is shown in Fig. 1† and is consistent with the solution $^1$H and $^{13}$C NMR data.‡ Compound **1** comprises an approximately trigonal-bipyramidal titanium centre with the *tert*-butylimide and the amide donor groups of the diamidopyridine ligand occupying the equatorial sites. The pyridyl-N atom of the diamidopyridine ligand lies in one of the apical sites and a pyridine ligand completes the coordination sphere. Compound **1** is the first fully characterised example of a terminal titanium imido complex supported by an amido ligand, although complexes of the type [Ti(NR)(NHR)$_2$] (R = SiBu$^t_3$) have been proposed as reactive



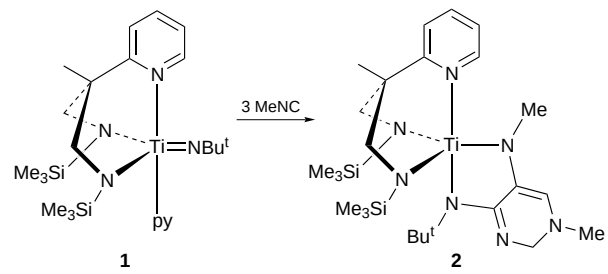


**Fig. 1** Molecular structure of [Ti(NBu$^t$)L(py)] **1**. Hydrogen atoms are omitted for clarity and thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°): Ti–N(1) 1.724(2), Ti–N(2) 2.025(2), Ti–N(6) 1.983(2), Ti–N(41) 2.203(2), Ti–N(51) 2.278(2); Ti–N(1)–C(10) 175.10(17), N(1)–Ti–N(2) 130.09(9), N(1)–Ti–N(6) 115.84(9), N(2)–Ti–N(6) 113.33(8), N(41)–Ti–N(51) 165.83(7).

transients.[6] The Ti=NBu$^t$ bond length of 1.724(2) Å lies at the long end of the range of known titanium–*tert*-butylimido bond lengths.[1b] The pyridine molecule is substantially less tightly bound [Ti–N(51) 2.278(2) Å] than the pyridyl fragment [Ti–N(41) 2.203(2) Å] of the diamidopyridine ligand and is readily lost in reactions of **1**.

Preliminary reactivity studies of [Ti(NBu$^t$)L(py)] **1** with a range of unsaturated substrates have indicated that this complex possesses a very reactive Ti=NBu$^t$ linkage. By way of example, we describe here the novel reaction of **1** with methyl isocyanide. Thus compound **1** reacts with 3 mol equiv. of MeNC at room temp. to yield a single product [TiL{N(Me)N(Bu$^t$)($C_4H_3N_2$Me)}] **2** (Scheme 1). On titration of **1** with

**1** **2**

**Scheme 1**

MeNC in $C_6D_6$, $^1$H NMR spectroscopy indicated complete cooperativity in the trimerisation (*vide infra*) of the isocyanide molecules as no intermediates were observed.

The solid-state structure of **2** was established unambiguously by X-ray crystallography (Fig. 2) which revealed a central five-coordinate Ti atom with a distorted trigonal-bipyramidal arrangement of N-donor atoms. The apical positions are occupied by the pyridyl [Ti–N(41) 2.282(2) Å] and *tert*-butyl amide fragment N-donor atoms. The Ti=NBu$^t$ linkage of **1** has clearly undergone C–N and C–C coupling (with concomitant C–H bond migration) with three molecules of MeNC to form a coordinated 3-methyl-5,6-diamino-2,3-dihydropyrimidine derivative. The type of reaction giving rise to **2** is unprecendented in group 4 imido chemistry. Reactions of later transition-metal imido complexes with aryl isocyanides have very recently been described[7] but pyrimidine-type rings were not formed.

In conclusion, we have shown that the type of trifunctional amido-supported imido complex described can generate novel chemistry. The instantaneous formation of **2** and the absence of detectable intermediates precludes the proposal of a mechanistic pathway at this stage, but such studies will be included in further investigations into this new type of metal-mediated isocyanide cyclisation. Further preliminary results in these laboratories indicate that compounds analogous to **1** can be formed for other tridenate diamidoamines and transition metals, and work is in progress to establish the overall scope of this chemistry.

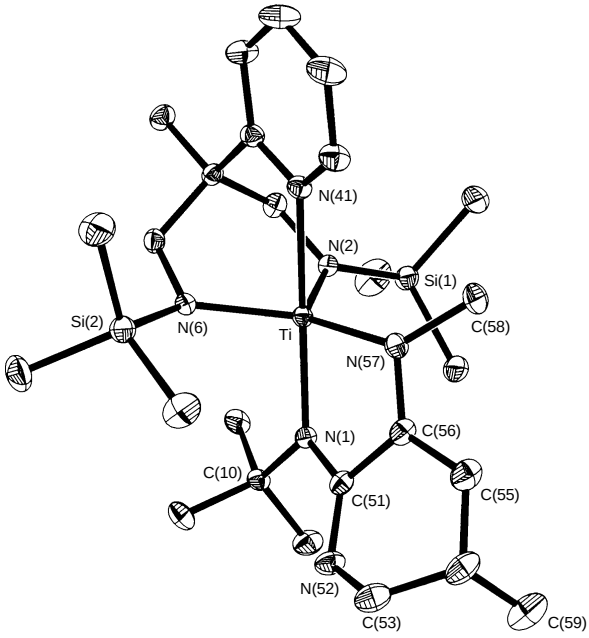

**Fig. 2** Molecular structure of [TiL{N(Me)N(Bu$^t$)($C_4H_3N_2$Me)}] **2**. Hydrogen atoms are omitted for clarity and thermal ellipsoids are drawn at the 20% probability level. Selected bond lengths (Å) and angles (°): Ti–N(1) 2.034(2), Ti–N(2) 1.890(2), Ti–N(6) 1.936(2), Ti–N(41) 2.282(2), Ti–N(57) 1.965(2), N(1)–C(51) 1.379(3), C(51)–N(52) 1.299(4), N(52)–C(53) 1.457(4), C(53)–N(54) 1.448(4), N(54)–C(55) 1.414(4), C(55)–C(56) 1.349(4), C(51)–C(56) 1.484(4); N(1)–Ti–N(1)–N(2) 109.87(9), N(1)–Ti–N(6) 98.66(9), N(2)–Ti–N(6) 108.53(10), N(1)–Ti–N(41) 163.94(9).

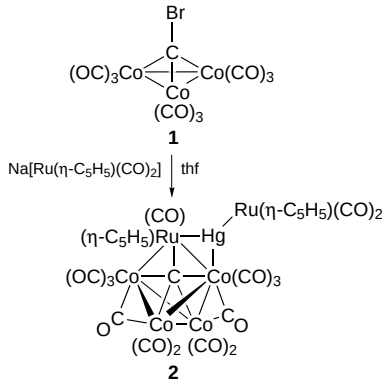
# Synthesis and structural characterization of a tetrahedral sp³ carbide cluster compound



**Yoshiaki Takahashi, Munetaka Akita* and Yoshihiko Moro-oka***

*Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226, Japan*

**Treatment of the ($\mu_3$-halomethylidyne)tricobalt cluster compound ($\mu_3$-X–C)$Co_3(CO)_6L_3$ with Na[Ru($\eta$-$C_5H_5$)$(CO)_2$] produces the heptanuclear ($\mu_5$-C)($\eta$-$C_5H_5$)$_2Ru_2Co_4Hg(CO)_{13}$ 2 [X = Br; $L_3$ = $(CO)_3$] and tetranuclear carbide cluster compound ($\eta$-$C_5H_5$)$(CO)_2Ru(\mu_4$-C)$Co_3(CO)_6$(tdpm) 4 [X = Cl; $L_3$ = $CH(PPh_2)_3$ (tdpm)], *via* substitution of $\mu_3$-X–C; the latter complex 4 is the first example of a structurally characterized tetrahedral sp³ carbide cluster compound.**

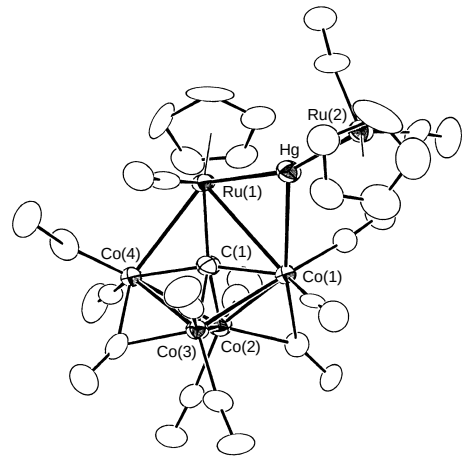
Transition-metal carbide cluster compounds have been studied extensively over twenty years as model compounds for a carbide species adsorbed on a metal surface.[1,2] Previous studies have revealed various aspects of such a species as a pivotal intermediate in catalytic transformations of hydrocarbons and carbon monoxide (*e.g.* conversion to $CH_x$ species through H-addition).[3] However, the carbido carbon atoms in the previous examples are partly or completely encapsulated in a metal array such as butterfly and octahedral structures.[1] To the best of our knowledge, no example of a structurally characterized carbide cluster compound with an sp³-hybridized carbido carbon atom has been reported so far,[4,5] although it would be the most probable structure that an organic chemist expects. Our research interest has been focused on synthetic study toward polymetallic compounds with a simple carbon linkage such as permetallated ethane, ethene and ethyne,[6] and herein we report the synthesis of the first structurally characterized example of a tetrahedral sp³ carbide cluster compound, a permetallated methane.

The synthetic method that we have employed is nucleophilic substitution of the classical ($\mu_3$-halomethylidyne)tricobalt cluster derivatives, ($\mu_3$-X–C)$Co_3(CO)_6L_3$,[7] by a metal anion.[5a,8] When the ($\mu_3$-bromomethylidyne)nonacarbonyl derivative, ($\mu_3$-Br–C)$Co_3(CO)_9$ **1** [X = Br; $L_3$ = $(CO)_3$] was treated with the ruthenate, Na[Ru($\eta$-$C_5H_5$)$(CO)_2$], in thf, a heptanuclear carbide cluster compound ($\mu_5$-C)($\eta$-$C_5H_5$)$_2Ru_2Co_4Hg(CO)_{13}$ **2** was obtained in low yield (*ca.* 10%) by way of replacement of Br and addition of metal fragments (Scheme 1).† The molecular structure determined by X-ray crystallography (Fig. 1) contains a carbido carbon atom which is encapsulated in the pentanuclear

**Scheme 1**

$RuCo_4$ wingtip-bridged butterfly structure.‡ Interaction of one of the two Ru–Co edges with the [HgRu($\eta$-$C_5H_5$)$(CO)_2$]$^+$ fragment, which is isolobal with $H^+$, causes slight elongation of the Ru(1)–Co(1) bond [2.937(2) Å; *cf.* Ru(1)–Co(4) 2.837(3) Å] owing to a three-center–two-electron interaction. Judging from the Co(1)–C(1)–Co(4) [165.0(10)°] and $M_{ax}$–C(1)–$M_{eq}$ angles [82–99°: $M_{ax}$ = Co(1), Co(4)], the coordination structure of the central carbido carbon atom can be described as distorted trigonal bipyramidal with a Ru(1)–Co(2)–Co(3) equatorial plane. This type of ($\mu_5$-C)$M_5$ structure has several precedents.[8] The mechanism of formation of **2** should involve initial nucleophilic substitution of **1** with the ruthenate giving a tetrahedral carbide intermediate, which picks up $Co(CO)_n$ and [HgRu($\eta$-$C_5H_5$)$(CO)_2$]$^+$ fragments present in a reaction mixture§ to form the electron-precise species **2** with 76 cluster valence electrons (the wingtip-bridged butterfly $RuCo_4$ core). The formation of **2** suggests susceptibility of the $\mu_3$-CBr moiety in **1** toward nucleophilic substitution, and similar reactions affording encapsulated carbide cluster compounds have already been reported.[9]

In order to prevent the tricobalt unit from fragmentation and cluster core expansion, the three cobalt atoms were linked together by a tripodal ligand, tris(diphenylphosphino)methane (tdpm). Treatment of the $\mu_3$-chloromethylidyne cluster supported by tdpm, ($\mu_3$-Cl–C)$Co_3(CO)_6$(tdpm) **3** [X = Cl; $L_3$ = tdpm],¶ with Na[Ru($\eta$-$C_5H_5$)$(CO)_2$] in thf gave the brown complex **4** (5–10%) along with the $\mu_3$-methylidyne complex, ($\mu_3$-H–C)$Co_3(CO)_6$(tdpm) **5**, after chromatographic separation (Scheme 2).† A $^1$H NMR spectrum of **4** containing a $\eta$-$C_5H_5$ signal ($\delta$ 5.81) in addition to signals from tdpm [$\delta$ 5.77 (1 H, q, $J_{PH}$ 6.1 Hz, $P_3CH$), 6.7–7.3 (30 H, m, $Ph_6$)] is consistent with



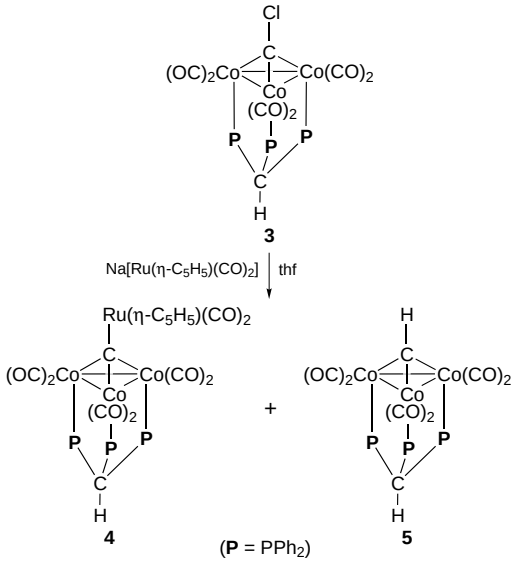


**Fig. 1** Molecular structure of **2** drawn at the 30% probability level. Important bond lengths (Å) and angles (°): C(1)–Ru(1) 1.97(2), C(1)–Co(1) 1.86(2), C(1)–Co(2) 1.95(2), C(1)–Co(3) 1.93(2), C(1)–Co(4) 1.87(2), Ru(1)–C(1)–Co(1) 99.6(7), Ru(1)–C(1)–Co(2) 139.1(9), Ru(1)–C(1)–Co(3) 142.2(9), Ru(1)–C(1)–Co(4) 95.4(7), Co(1)–C(1)–Co(2) 82.7(6), Co(1)–C(1)–Co(3) 86.6(6), Co(1)–C(1)–Co(4) 165.0(10), Co(2)–C(1)–Co(3) 78.6(6), Co(2)–C(1)–Co(4) 85.4(6), Co(3)–C(1)–Co(4) 82.1(6).

**Scheme 2**

the expected structure, $(\eta\text{-}C_5H_5)(CO)_2Ru(\mu_4\text{-}C)Co_3(CO)_6(tdpm)$, which is supported by the single $^{31}P$ NMR resonance ($\delta$ 39.0) and established by X-ray crystallography (Fig. 2).‡ The central carbido carbon atom [C(1)] is bonded to the distal Ru atom and the basal $Co_3$ triangle through σ bonds [C(1)–Ru 2.122(8) Å, C(1)–Co 1.887–1.924(9) Å]. Although the Ru–C(1)–Co [129.2–132.9(5)°] and Co–C(1)–Co angles [80.4–81.6(3)°] deviate from the ideal tetrahedral angle (109.4°) owing to the fact that the Co atoms are linked together by metal–metal bonds, the hybridization of the central carbido carbon atom is found to be close to $sp^3$. Thus the tetranuclear complex **4** has been characterized as a tetrahedral $sp^3$ carbide cluster compound, a permetallated methane. The formation of the $\mu_3$-CH compound **5** suggests participation of a radical mechanism initiated by electron transfer from the ruthenate to **3**. Coupling of the resulting radical species, $\cdot(\mu_3\text{-}C)Co_3(CO)_6(tdpm)$ and $\cdot Ru(\eta\text{-}C_5H_5)(CO)_2$, would furnish **4**, but H-abstraction from the reaction medium may give rise to **5**.

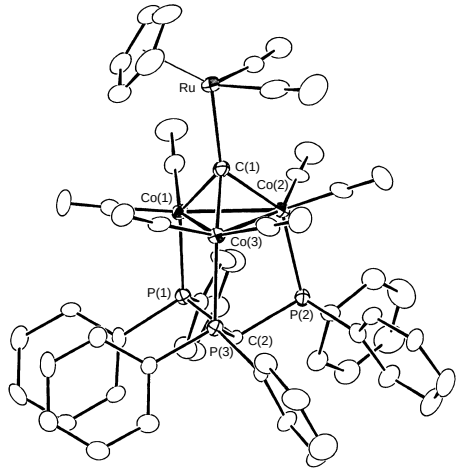

**Fig. 2** Molecular structure of **4** drawn at the 30% probability level. Important bond lengths (Å) and angles (°): C(1)–Ru 2.122(8), C(1)–Co(1) 1.887(9), C(1)–Co(2) 1.924(8), C(1)–Co(3) 1.912(9), Ru–C(1)–Co(1) 129.2(4), Ru–C(1)–Co(2) 132.9(5), Ru–C(1)–Co(3) 132.2(5), Co(1)–C(1)–Co(2) 80.9(3), Co(2)–C(1)–Co(3) 80.4(3), Co(3)–C(1)–Co(1) 81.6(3).

In conclusion, the present study has revealed the versatility of the synthetic method for carbide cluster compounds *via* nucleophilic displacement of halogenomethylidyne clusters with metalates, and the first example of a structurally characterized tetrahedral $sp^3$ carbide cluster has been prepared successfully by this method.

This work was supported by grants from the Ministry of Education, Science, Sports and Culture of the Japanese Government.

**Secondary ammonium salts of trimesic acid form robust interdigitated lamellar structures which are sustained by a combination of strong hydrogen bonds in two dimensions and hydrophobic interactions in the third dimension.**

Various types of lamellar, bilayer and monolayer architectures have been investigated for applications in membranes, mesogens, surfactants and Langmuir–Blodgett (LB) films.[1] A better understanding of the structural details of these systems and their relationship to specific chemical processes and functions requires structural information from the crystalline state. Rational design of such organized molecular assemblies in the solid state is also a fundamental and contemporary problem of crystal engineering[2,3] and the use of hydrogen bonds to impart dimensional control over network structures is now well established.[4] We report herein a novel two-dimensional hydrogen bonded motif which forms lamellar crystal structures because of strong hydrogen bonds between complementary organic cations and anions. Furthermore, the entire three-dimensional molecular arrangement is predictable with reasonable accuracy as a consequence of hydrophobic interactions between interdigitated alkyl or aryl groups in the third dimension.

Partially or fully deprotonated salts of 1,3,5-benzenetricarboxylic acid (trimesic acid, $H_3TMA$) invariably react with amines to afford salts with flat hydrogen-bonded sheet structures.[5] These rigid hydrogen-bonding patterns are robust and the presence of ammonium cations in the sheet makes such structures ideal for designing interdigitated supramolecular lamellar structures since long-chain alkyl groups can be substituted at the ammonium moiety. Scheme 1 depicts various possible layered structures that one might design using secondary alkylammonium salts of $HTMA^{2-}$. The series of dialkylammonium salts, $[NHPr_2]_2[HTMA]$ **1**, $[NH(C_6H_{13})_2]_2[HTMA]$ **2**, $[NH(C_8H_{17})_2]_2[HTMA]$ **3** and $[NH(C_{10}H_{21})_2]_2[HTMA]$ **4**, were synthesized by slow addition of 2 equiv. of the appropriate amine to 1 equiv. of $H_3TMA$ in MeOH and, in order to prevent precipitation of non-stoichiometric products, refluxing for 2 h. Quantitative yields of the colourless solids **1**–**4** were obtained by slow evaporation of MeOH. Crystals of **1** and **2**–**4** suitable for single-crystal X-ray crystallography were obtained from butan-1-ol and MeOH, respectively (**1**, mp > 300 °C; **2**, mp 243 °C; **3**, mp 248 °C; **4**, mp 265 °C).

**Scheme 1**

The crystal structures† of **1**–**4** exhibit identical two-dimensional hydrogen-bonding networks stabilized by $N^+–H\cdots O^-$ and $O–H\cdots O^-$ hydrogen bonds as shown in Fig. 1. Table 1 is a compilation of hydrogen bond lengths of **1**–**4** and indicates that the relevant hydrogen bond lengths are almost identical. The ammonium protons in the sheet are engaged in a robust hydrogen-bonding network and are arranged in alternating columns (Fig. 1). The hydrophobic alkyl substituents of the ammonium cations project above and below the sheet and the space between the protruding columns of alkyl groups facilitates interdigitation or close-packing of the adjacent layers (Fig. 2). The geometrical arrangement of the cations in the layer is

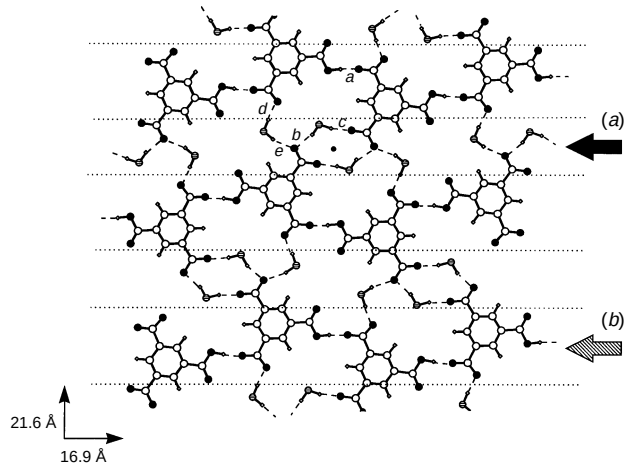

**Fig. 1** The two-dimensional hydrogen bonding network observed in **1**–**4**. Five different hydrogen bonds are marked (shown as dashed lines, *a*–*e*, Table 1). The alkyl substituents of the ammonium cations are omitted for clarity. N and O atoms are shown as hatched and filled circles, respectively. The dotted lines are marked on the sheet to show the alternating columns of alkyl subsituents. (*a*) Substituents of the ammonium cation project perpendicular to this plane; (*b*) space suitable for interdigitation of alkyl groups from neighbouring layers.

**Table 1** Hydrogen bonding distances (Å) in the two-dimensional layers of **1**–**5**

| | O···O | N···O | | | |
|---|---|---|---|---|---|
| | *a* | *b* | *c* | *d* | *e* |
| **1** | 2.540(6) | 2.773(8) | 2.732(6) | 2.887(8) | 2.654(8) |
| **2** | 2.511(10) | 2.765(12) | 2.728(11) | 2.834(12) | 2.635(15) |
| **3** | 2.543(4) | 2.772(5) | 2.701(4) | 2.829(4) | 2.654(4) |
| **4** | 2.524(12) | 2.766(13) | 2.696(11) | 2.818(13) | 2.690(13) |
| **5**[a] | 2.567(7) | 2.751(8) | 2.709(8) | 2.809(8) | 2.687(7) |
| | | 2.777(8) | 2.769(7) | | |

[a] **5** crystallizes in a non-centrosymmetric space group ($P2_1$). Consequently, unlike **1**–**4**, there is no crystallographic inversion center across *b* and *c*.

critical and controls the stacking in the third direction. The interlayer separations of **1**–**4** are *ca*. 7.0, 10.3, 12.4, 14.6 Å, respectively, and are directly related to the alkyl chain lengths and the interdigitation of the alkyl groups that facilitates close packing. There is a recognizable tilt in the octyl and decyl chains of **3** and **4** with respect to the surface of the sheet (77.2, 73.9°), especially when compared to that seen for the propyl and hexyl groups in **1** and **2**, respectively (87.4, 89.0°). Such an observation is to be expected.[6] The dimensions of the repeating unit of the plane are *ca*. 16.9 × 21.6 Å in all five compounds, but only correspond to unit-cell parameters, *i.e*. the *bc* plane, in **3**–**5**.

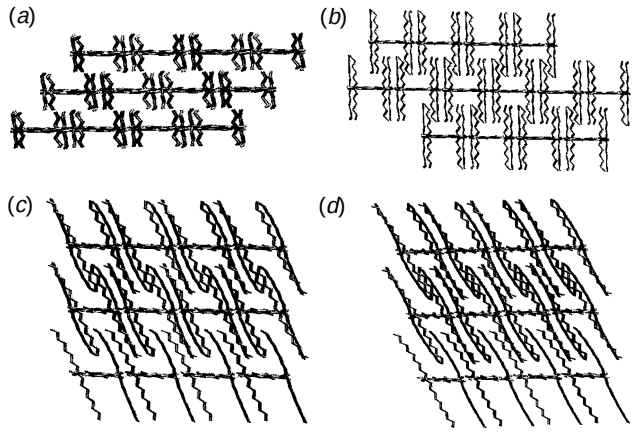

**Fig. 2** Perspective views of the supramolecular laminates **1**–**4** [(*a*)–(*d*)]. Note that interdigitation and tilt of the alkyl groups occurs as the chain length increases.

We have also been able to synthesize a mixed-cation supramolecular laminate of $HTMA^{2-}$ with *N*,*N*-dibenyzlammonium and *N*,*N*-dipropylammonium, **5** [Scheme 1(*b*)].[6] **5** is a doubly deprotonated salt and the asymmetric unit contains four $HTMA^{2-}$ anions, six *N*,*N*-dibenzylammonium cations, two *N*,*N*-dipropylammonium cations and one molecule of MeOH. The crystal structure reveals an interdigitated supramolecular laminate architecture with alternating layers of different composition (Fig. 3). The hydrogen-bonding pattern of layer A, a mixed-cation supramolecular laminate, is similar to **1**–**4** (Fig. 1, Table 1). However, layer B, which contains dibenzylammonium cations, has a slightly different hydrogen-bonding pattern as the MeOH molecule is also involved in the hydrogen-bonding scheme. This observation suggests that a wide range of new supramolecular laminates is at hand, possibly with interesting properties such as liquid crystallinity and the ability to intercalate guest molecules.[7]

In conclusion, **1**–**5** serve as good examples of rationally designed solids and should be of help for the general study and understanding of laminate packing arrangements. The results reported herein further suggest that the complex problem of controlling three-dimensional architecture in solids can successfully be reduced to a simple one-dimensional problem by using the strategy of choosing a suitably substituted rigid two-dimensional layer as a starting point.[4]

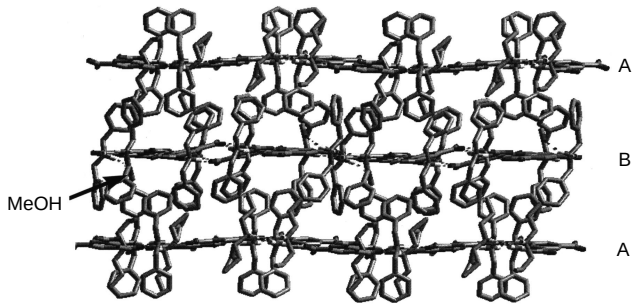

**Fig. 3** The interdigitated mixed supramolecular laminate structure of **5**. Layer A contains *N*,*N*-dibenzylammonium and *N*,*N*-dipropylammonium cations. Layer B contains dibenzylammonium cations only. Note that MeOH is involved in the hydrogen bonding in layer B.

We acknowledge the generous financial support of the NSERC and ESTAC (Canada) in the form of research grants.

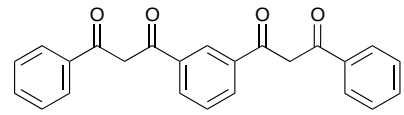
# Bis(β-diketonate) ligands for the synthesis of bimetallic complexes of $Ti^{III}$, $V^{III}$, $Mn^{III}$ and $Fe^{III}$ with a triple-helix structure



**Vincent A. Grillo, Elisa J. Seddon, Craig M. Grant, Guillem Aromí, John C. Bollinger, Kirsten Folting and George Christou***

*Department of Chemistry and the Molecular Structure Center, Indiana University, Bloomington, IN 47405-4001, USA*

**Addition of the bis(β-diketone) ligand L [L = 1,3-bis(3-phenyl-3-oxopropanoyl)benzene] to a suitable source of $M^{III}$ ions (M = Ti, V, Mn, Fe) in a L : M = 3 : 2 ratio gives the dinuclear products $[M_2L_3]$, which have a triple-helical structure.**

The use of oligopyridyl, oligo-2,2′-bipyridyl and related ligands in transition-metal chemistry has been receiving a great deal of attention in recent years.[1–7] Their products with mononuclear metal ions have displayed a variety of fascinating structures such as double[1,2,4,8] or triple helices,[1,2,3,6,9] and 'cylindrical',[10] 'capped'[11] or 'circular'[12] architectures. As such, these ligands have been amongst the central players in the supramolecular chemistry field.

Bis(β-diketonate) ligands offer similar potential for the preparation of supramolecular assemblies, and we herein report the initial use of the ligand L for the synthesis of bimetallic complexes of formula $[M_2L_3]$ (M = $Ti^{III}$, $V^{III}$, $Mn^{III}$, $Fe^{III}$) with a triple-helix structure. Ligand L† was prepared from a Claisen condensation employing dimethyl isophthalate and acetophenone in the presence of NaH, a method related to that in the early literature of bis(β-diketonates).[13] Addition of L to a convenient source of $M^{III}$ [$MCl_3(thf)_3$[14] (M = Ti, V), $Mn(O_2CMe)_2{\cdot}4H_2O$/$NBu^n_4MnO_4$, $Fe(ClO_4)_2{\cdot}6H_2O$/air] in dmf or $CH_2Cl_2$ gave dark coloured solutions from which could be isolated crystalline $[M_2L_3]$ (M = Ti **1**, V **2**, Mn **3**, Fe **4**) in 30–70% yields, followed by recrystallisation from dmf–MeOH (**1**–**3**) or thf–$Me_2CO$ (**4**).‡ Complexes **1**–**4** are isostructural§ (Fig. 1) and consist of two six-coordinate $M^{III}$ ions chelated and bridged by three $L^{2-}$ groups. The M···M separations are very similar [7.222(2) **1**, 7.224(2) **2**, 7.350(2) **3**, 7.262(4) Å **4**] and the molecules are in a triple-helix conformation, as emphasized by the view along the M···M vector (Fig. 2). The average ligand twist angles (defined as the angles between the two M–M–C(methine) planes for each ligand) are 42.8 **1**, 44.0 **2**, 47.4 **3** and 40.8° **4**. The structural parameters show only the small differences expected from varying the $M^{III}$ ion and the presence in **3** of a Jahn–Teller axial elongation along the O(3)–Mn(1)–O(35) and O(8)–Mn(2)–O(40) axes. The metal geometries are essentially octahedral. The series could undoubtedly be extended to other $M^{III}$ ions (*e.g.*, $Cr^{III}$, $Co^{III}$) and this is currently being explored. The triple-helix structures of **1**–**4** with the ligand $L^{2-}$ are new additions to the relatively small but growing family of dinuclear metal complexes with a triple-helix structure, hitherto with ligands other than β-diketonates.[2,3,6,9,15–17]

L

Detailed characterisation of **1**–**4** by a variety of spectroscopic and physical methods is in progress. Preliminary electrochemical studies by cyclic voltammetry in dmf confirm that the two $M^{III}$ ions are interacting. The 'richest' CV scans belong to **1** and **2** which show very similar electrochemical behaviour (Fig. 3). Both exhibit two pairs of closely spaced reversible reductions: −1.076, −1.212 V ($\Delta E$ = 0.136 V) and −1.720,

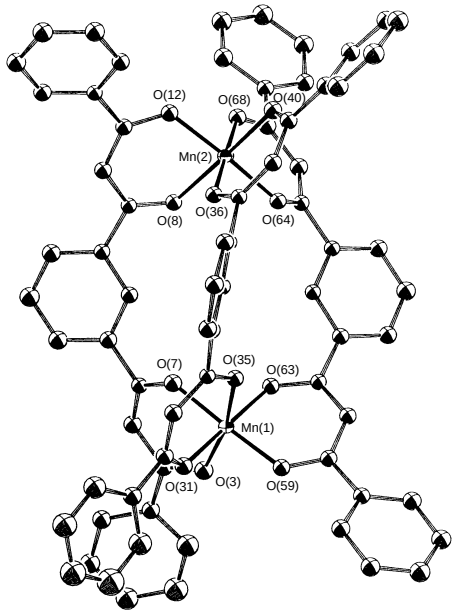


**Fig. 1** The structure of $[Mn_2L_3]$ **3**; complexes **1**, **2** and **4** are isostructural

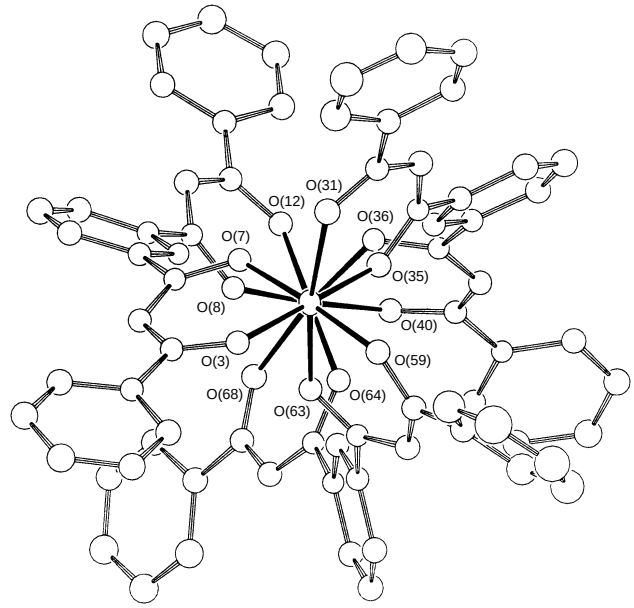

**Fig. 2** A view down the Mn···Mn vector of **3** emphasizing the triple-helical conformation of the molecule

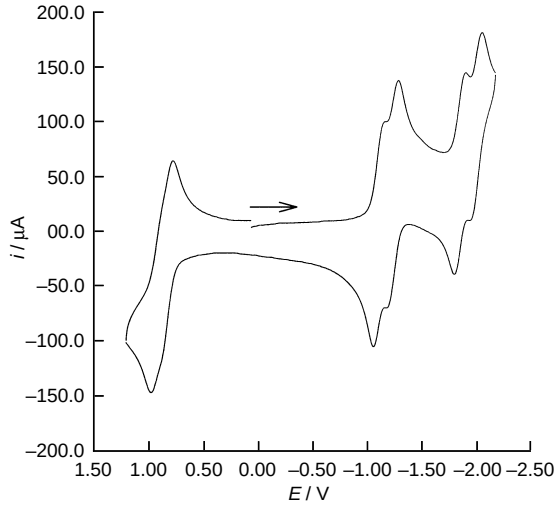

**Fig. 3** Cyclic voltammogram at 100 mV $s^{-1}$ for complex **2** in dmf at a glassy carbon electrode and with $NBu^n_4PF_6$ as supporting electrolyte

−1.900 V ($\Delta E$ = 0.180 V) for **1** and −1.104, −1.240 V ($\Delta E$ = 0.136 V) and −1.840, −2.000 V ($\Delta E$ = 0.160 V) for **2** *vs.* SCE. In addition, for both complexes, there is a less well resolved pair of oxidation processes: +0.016, +0.092 V for **1** ($\Delta E$ = 0.076 V) and +0.808, +0.884 V for **2** ($\Delta E$ = 0.080 V). The large $\Delta E$ values are indicative of intramolecular interactions between the two $M^{III}$ ions. Complex **4** shows only a single pair of reversible reductions, at −0.460 and −0.584 V. Complex **3** shows a broad, quasi-reversible reduction process at −0.018 V ($E_{pc} - E_{pa}$ = 0.520 V), with an additional irreversible oxidation at approximately +1.238 V. For all four species, additional reductions are observed at < −2.0 V. The redox behaviour of **1**–**4** is related to that of the corresponding mononuclear $M(dbm)_3$ (dbm = anion of dibenzoylmethane), which exhibit single redox processes at similar processes to **1**–**4**. Variable-temperature magnetic susceptibility studies on **1**–**4** are currently in progress to quantitate the strength of intramolecular interactions within these molecules.

# First identification by EPR spectra of lanthanum(II) organometallic intermediates (and $E_{\frac{1}{2}}$ for $La^{3+} \rightarrow La^{2+}$) in the C–O bond activation of dimethoxyethane†

**M. Cristina Cassani,[a] Michael F. Lappert*[a] and Franco Laschi[b]**

[a] *The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ*
[b] *Universita' di Siena, Dipartimento di Chimica, Siena, Italy I-53100*

**The reaction of [La(Cp″)$_3$] with K in dimethoxyethane (dme) at ambient temperature leads to the formation of lanthanocene(III) methoxides *via* persistent paramagnetic lanthanum(II) intermediates that are characterised by EPR spectroscopy and tentatively assigned to [K(dme)$_x$]-[La(Cp″)$_3$] and [La(Cp″)$_2$(dme)$_y$] [Cp″ = η$^5$-C$_5$H$_3$(SiMe$_3$)$_2$-1,3]; the cyclic voltammogram of [La(Cp″)$_3$] in thf is also reported, $E_{\frac{1}{2}}^{red}$ = −2.8 V.**

Recently we showed that the reaction of [Ln(Cp″)$_3$] [Ln = Ce or Nd, Cp″ = η$^5$-C$_5$H$_3$(SiMe$_3$)$_2$-1,3] with K in dimethoxyethane (dme) gave the lanthanocene(III) methoxide [{Ln(Cp″)$_2$(μ-OMe)(}$_2$].[1] It was postulated that a Ln$^{II}$ complex was a plausible transient intermediate involved in the C–O bond cleavage.

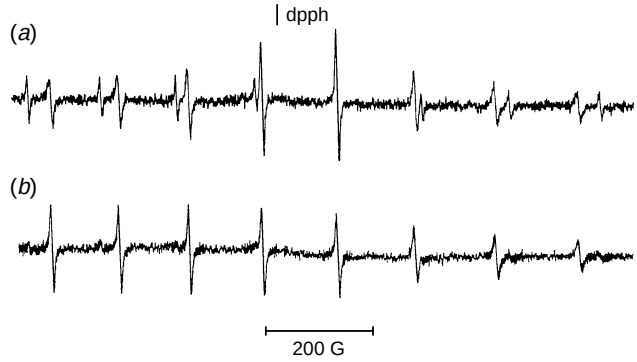
We now report that treatment of [La(Cp″)$_3$] **1** with a K mirror in dme led to the immediate formation of a dark royal blue solution **2** from which a white crystalline mixture was obtained. The latter contained K(Cp″), [{La(Cp″)$_2$(μ-OMe)}$_2$] **3**, and an as yet unidentified polynuclear lanthanum methoxide **4**, Scheme 1.‡

The particularly striking feature of this reaction is that the blue solution **2** was paramagnetic and its EPR spectrum revealed it to contain two lanthanum(II) complexes.§ Fig. 1(*a*) shows the ambient-temperature EPR spectrum which consisted of two sets **A** and **B** of well resolved $S$ = 1/2 metal-centred octuplets with **A** : **B** *ca.* 1.5 : 1. In each of **A** and **B**, the height of the EPR lines progressively decreased from their centre while concomitantly their peak separation increased from left to right. Each of the **A** and **B** sets arises from the hyperfine coupling of the unpaired electron with the $^{139}$La nucleus (99.91% natural abundance, $\mu_1$ = +2.776, $I$ = 7/2), with $g_{\mathbf{A}}$ = 1.972(8), $a_{\mathbf{A}}$($^{139}$La) = 134.0(5) G and $g_{\mathbf{B}}$ = 1.970(8), $a_{\mathbf{B}}$($^{139}$La) = 145.0(5) G. These hyperfine couplings are of similar magnitude but intermediate between (*i*) the calculated value of 186 G (using spin-polarised unrestricted Hartree–Fock wavefunctions),[2a] and (*ii*) that measured (*ca.* 50 G at 20 K) for a La$^{2+}$ defect in a CaF$_2$ lattice; this being, as far as we are aware, the only prior experimental literature value.[3] These data strongly contrasted with those from the EPR spectrum of (*i*) [La$^{3+}$@C$_{82}^{3-}$] which consists of eight extremely narrow ($\Delta H$ = 0.125 G) equally spaced [$a$($^{139}$La) = 1.25 G] lines of equal height centred at $g$ = 2.0010 (1,1,2,2-tetrachloroethane, 293 K);[2a–d] and (*ii*) [LaI$_2$(bipy)$_2$(dme)] [$a$($^{139}$La) = 7.4 G, $g$ = 2.0031 (dme, 293 K)], [LaI$_2$(bipy)$_2$(thf)$_2$] [$a$($^{139}$La) = 5.9 G, $g$ = 2.0009 (thf, 293 K)] or [LaI$_2$(bipy)(dme)$_2$] [$a$($^{139}$La) = 7.0 G, $g$ = 2.0015 (thf, 293 K)] containing one radical anion ligand (bipy = 2,2-bipyridyl)[4] and underline the significant La orbital character of the actual isotropic spectral pattern.

The EPR spectra recorded at the melting point (200–220 K) of the glassy blue solution **2**, exhibited the isotropic spectral features of **A**, that of **B** being undetected up to 275 K. Fig. 1(*b*) shows the EPR spectrum at 275 K. Upon gradually increasing the temperature, the signals due to **B** started appearing and their intensity steadily increased until at 330 K, **B** became the major species. This behaviour was reversed upon cooling. We conclude that in **2**, **A** and **B** represent distinct species in thermal equilibrium, and a plausible interpretation is that the EPR signals **A** and **B** be assigned to the lanthanum(II) species [K(dme)$_x$][La(Cp″)$_3$] and [La(Cp″)$_2$(dme)$_y$], respectively.

Similar features to those described above for the [La(Cp″)$_3$]–K system in dme were observed for those in thf, except that no reaction product involving solvent fragmentation was observed; K(Cp″) was isolated. The EPR spectral data for the thf system showed two octuplets at 295 K (**A** : **B**, *ca.* 4 : 1): $g_{\mathbf{A}}$ = 1.969(8), $a_{\mathbf{A}}$($^{139}$La) = 136.0(8) G and $g_{\mathbf{B}}$ = 1.971(8), $a_{\mathbf{B}}$($^{139}$La) = 146.0(8) G.

In order to investigate the reduction of [La(Cp″)$_3$] in an alternative fashion, and to obtain a value for the La$^{3+}$–La$^{2+}$ reduction potential, the electrochemical reduction of [La(Cp″)$_3$] was examined. The cyclic voltammogram of [La(Cp″)$_3$] in thf at a vitreous carbon electrode is shown in Fig. 2. The reduction potential $E_{\frac{1}{2}}$ (La$^{3+}$ → La$^{2+}$) was found to be −2.8 V and the process was reversible. The cited $E_{\frac{1}{2}}$ value is relative to the Fc$^+$–Fc couple, ferrocene (Fc) being used as the internal standard.



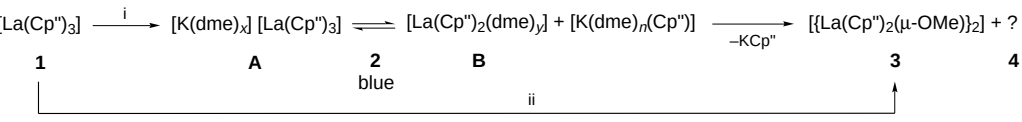


**Fig. 1** EPR spectrum of solution **2** in dme at (*a*) 295 and (*b*) 275 K

**Scheme 1** *Reagents and conditions*: i, K mirror, dme, 3 h at −40 °C and then 45 h at 25 °C; ii, MeOH, toluene, 2 h −40 °C. The yield of crystalline **3** (not optimised) was 46% (i) or 50% (ii).

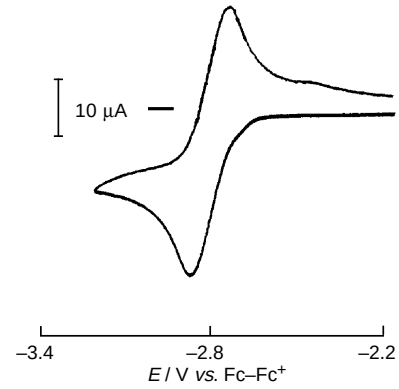

**Fig. 2** Cyclic voltammogram of **1** in thf with 0.2 mol $dm^{-3}$ $[NBu_4][PF_6]$ as supporting electrolyte at a vitreous carbon working electrode; scan rate 50 mV $s^{-1}$, 25 °C

By using the NMR-accessible, diamagnetic $La^{III}$ ($f^0$), it was further shown that in the reduction of $[La(Cp'')_3]$ in dme by K, the nature of the final product (like that of the intermediate **A** and **B**) was temperature dependent. When the reduction was initiated at −40 °C, the $^1H$ NMR spectrum in $C_6D_6$ of the eventually isolated crystalline white solid showed signals attributed not only to K(Cp″) and $[\{La(Cp'')_2(\mu\text{-}OMe)\}_2]$,‡¶ but also to another species (or mixture) **4** comprising a doublet at $\delta$ 6.99 and a singlet at $\delta$ 3.47 having *ca.* 10% of the intensity of the corresponding signals in **3**. Repeating the same reaction at ambient temperature, integration showed that the relative abundance of **4** : **3** was *ca.* 1 : 1. A similar trend was observed in the $^{13}C$ NMR spectra. Homonuclear decoupling and NOE experiments confirmed that the $^1H$ NMR spectral doublet at $\delta$ 6.99 and singlet at $\delta$ 3.47 be attributed to a second bis(cyclopentadienyl)lanthanum(III) methoxide (the expected triplet for the Cp″ and singlet for the $SiMe_3$ protons of **4** overlapped with those of **3**); from their relative intensity it is estimated that **4** has three $Cp''^-$ ligands for each $OMe^-$. One possible molecular formula, consistent with a $La^{3+}$ oxidation state, is $[La_6(Cp'')_{12}(OMe)_4O]$.

From equimolar portions of $[La(Cp'')_3]$ and methanol, a similar mixture of **3** and **4** was obtained and their relative proportions showed a comparable temperature dependence. Evans *et al.* have previously demonstrated that the reaction of $[Y(\eta\text{-}C_5H_5)_2Cl(thf)]$ with KOMe gave the polynuclear organo-yttrium methoxide oxide $[\{Y(\eta\text{-}C_5H_5)_2(\mu\text{-}OMe)\}_2\{Y(\eta\text{-}C_5H_5)_2\}(\mu_3\text{-}O)]^-$.[5]

Among organolanthanide compounds, stable +2 oxidation state complexes were unambiguously established only for those of Yb ($f^{14}$), Eu($f^7$) and Sm($f^6$), although claims have been made for $Ce^{II}$[6] and $Nd^{II}$.[7] The present results provide definitive evidence for thermally stable organolanthanide(II) complexes, which being oxophilic and powerful reducing agents are able to cleave the C–O bond of dme at ambient temperature (as previously postulated for related Ce and Nd systems).[1]

We thank Drs S. K. Ibrahim and C. J. Pickett for the cyclic voltammetric data, Dr A. G. Avent for the NOE experiment, the European Union for the provision of a Marie Curie Fellowship for M. C. C. and EPSRC for other support.

## Footnotes and References

† No reprints available.

‡ *General experimental procedure*: **1** was added to a K mirror in dme at −40 °C. The colour changed immediately to dark blue and after 3 h the mixture was warmed to room temp. and then stirred for 45 h. After filtration, the filtrate was concentrated to a small volume and cooled at −30 °C to give a white crystalline mixture (desolvated by heating for 5 h at 70–80 °C/$10^{-2}$ mmHg). Alternatively, after filtration the solvent was evaporated *in vacuo* and pentane added: a thermolabile, dark green, insoluble product separated from the colourless solution. The nature of the exceedingly air- and moisture-sensitive green product is currently under investigation, while the colourless solution contained K(Cp″), **3** and **4**. After complete removal of coordinated dme the lanthanum(III) methoxides were separated from the K(Cp″) by extraction with toluene.

§ EPR data were taken on an ER 200-D Bruker spectrometer operating at X-band (9.43 GHz); UV–VIS (dme, 298 k): $\lambda_{max}$ 578.9, 689.8(sh) nm.

¶ *Spectroscopic and analytical data*: K(Cp″) was identified by elemental analysis and by comparing its NMR spectra with those of a separately prepared compound (from HCp″ + KH in thf). The EIMS spectra of the crystalline lanthanum methoxide mixture, obtained either from the reduction in dme or from the protolytic reaction with methanol did not show the dinuclear molecular ion $M^+$ at $m/z$ = 1178 but the following principal fragments were observed: $m/z$ 1147 $[M - OCH_3]^+$, 1133, 1115, 967 $[M - Cp'']^+$, 953, 939, 921, 729 and 557 $[La(Cp'')_2]^+$. $^1H$ NMR ($C_6D_6$, 293 K) of **3**: $\delta$ 7.08 (t, $^4J$ 1.8 Hz), 6.96 (d, $^4J$ 1.8 Hz), 3.53 (s), 0.39 (s). DEPT $^{13}C$ NMR ($C_6D_6$, 293 K) of **3**: cyclopentadienyl region partially obscured by solvent, $\delta$ 130.0 (CH), 125.6 (CH), 54.2 ($OCH_3$), 1.3 ($SiCH_3$). IR (Nujol): 3069m, 3042m, 1316m, 1246s, 1208m, 1176w, 1078s, 1051s, 922s, 834vs br, 773s, 751s br, 689s, 640s, 625s $cm^{-1}$.

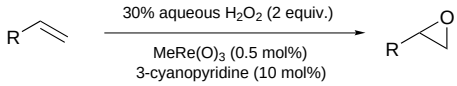
# A simple and efficient method for epoxidation of terminal alkenes

**Christophe Copéret, Hans Adolfsson and K. Barry Sharpless***

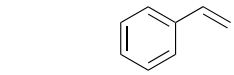


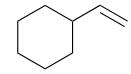
*Department of Chemistry, The Scripps Research Institute, 10550 N. Torrey Pines Road, La Jolla, California 92037, USA*

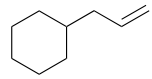
**The use of a catalytic amount of 3-cyanopyridine in the methyltrioxorhenium catalysed epoxidation of terminal alkenes with aqueous hydrogen peroxide speeds turnover, which results in the formation of many functionalized epoxides in high yields.**

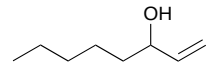
Despite numerous literature precedents, the epoxidation of terminal alkenes remains a challenge in organic synthesis.[1] While screening for other examples of ligand accelerated catalysis (LAC),[2] our group has recently discovered that pyridine enhances the rate of the methyltrioxorhenium (MTO)-catalysed epoxidation of alkenes, while also tempering the Lewis acidity of the metal centre and thereby protecting the epoxide from destruction.[3] This method gives high yields of epoxides for di-, tri- and tetra-substituted alkenes; however, the epoxidation of terminal alkenes requires prolonged reaction times (3–5 days) and the conversion rarely exceeds 60–80%. Therefore, we decided to investigate the epoxidation of styrene, which is both a terminal alkene and the progenitor of a sensitive epoxide. The intention was to probe the relationship between the basicity of various pyridine ligands and their effectiveness.† We found that while basic pyridines (pyridine, 4-*tert*-butyl- and 4-methoxy-pyridine) protected the epoxide from ring opening, they also diminished the catalyst lifetime. On the other hand, less basic pyridines, and especially the ones bearing electron-withdrawing substituents in the meta position, *e.g.* 3-cyano-pyridine, 3-fluoropyridine, methyl nicotinate and even nicotinic acid, allowed high conversions (90–100%), but provided little or no protection for the epoxide. As a result mixtures of benzaldehyde, benzoic acid, styrene diol and only trace amounts of styrene oxide were obtained.

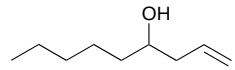
With these two facts in hand, epoxidation with a mixture of the two types of pyridines was attempted. Thus, treatment of a mixture of styrene (20 mmol), pyridine (2 mmol), 3-cyanopyridine (2 mmol) and MTO (0.1 mmol) in $CH_2Cl_2$ (14 ml) with 30% aqueous $H_2O_2$ (4 ml, 40 mmol) at room temperature gave, after 17 h, a 76% yield of styrene oxide along with 10% recovered styrene according to GC analysis. Using 2.5 ml instead of 14 ml of $CH_2Cl_2$—increasing the concentration from 1.2 to 5.0 M—allowed a better conversion (97–99%) in a shorter time (6 h) and gave an 89–92% yield of styrene oxide.‡ Other combinations of pyridines were less effective and presence of the parent pyridine was essential for the protection of the epoxide. In fact, even under the best conditions, benzaldehyde (0–0.5%), benzoic acid (0–1%) and styrene diol (2–3%) were always detected.

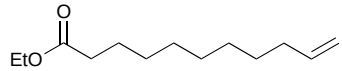


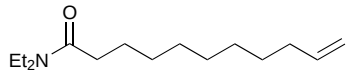


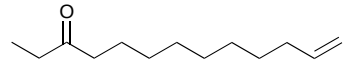




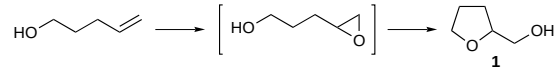








The other terminal alkenes in Table 1 give epoxides which are much less acid sensitive and their epoxidation did not require the use of a mixture of pyridines [eqn. (1)].§



(1)

3-Cyanopyridine proved to be the optimal ligand in these cases.¶ A representative procedure for the epoxidation of such terminal alkenes is as follows: a mixture of dec-1-ene (28.0 g, 200 mmol), 3-cyanopyridine (2.08 g, 20 mmol) and MTO (249 mg, 1 mmol) in $CH_2Cl_2$ (120 ml) was treated with 40 ml of 30% aqueous $H_2O_2$ (400 mmol) and stirred for 17 h at 24 °C.‖ The biphasic reaction mixture was then treated with crushed ice (20 g) and a catalytic amount of $MnO_2$ (25 mg) and stirred until

**Table 1** MTO-catalysed epoxidations of terminal alkenes with hydrogen peroxide in the presence of 3-cyanopyridine[a]

| Entry | Alkene | Yield (%)[b,c] | *t*/h |

| 14 |  | 96 | 24 |

[a] Reaction conditions: Alkene (1 equiv.), MTO (0.5 mol%), 3-cyanopyridine (10 mol%), 30% $H_2O_2$ (aq.) (2 equiv.) in $CH_2Cl_2$. Alkene concentration: 1.3 M. See footnote §. [b] Conversions are > 99%. [c] Isolated yield. [d] A mixture of 3-cyanopyridine and pyridine (10 mol% of each) was employed. Alkene concentration: 4 M. [e] The epoxides were formed as a 1 : 1 mixture of diastereomers. [f] The initially formed epoxy alcohol cyclized completely to the tetrahydrofurfuryl alcohol **1**, which was isolated in 97% yield.

**1**

oxygen evolution ceased (1 h). Following phase separation, the water layer was extracted with $CH_2Cl_2$, the combined organic layers were dried over $Na_2SO_4$ and concentrated to an oil. Hexane was added to this crude product, and the resulting white precipitate was removed by filtration.** The filtrate was concentrated, and the crude colourless oil was distilled to yield 31.4 g of decene oxide (94% yield, 96.5% purity).††

This method is general and quite independent of the steric bulk at the α-position of the alkene (entries 3 and 4). Moreover, the presence of alcohol functionalities did not significantly affect the yield of epoxidation (entries 6–8) or its diastereoselectivity (entries 7 and 8).‡‡ However, the bis(homoallylic) alcohol (entry 9) gave only the furan **1** in high yields, but the epoxide is isolated in excellent yield if the hydroxy group is protected (entry 10). Other remote functionalities (amides, chlorides, esters and ketones) are also compatible with this epoxidation method (entries 11–14), and it is noteworthy that in the epoxidation of the ω-alkenone (entry 14) the possible Baeyer–Villiger products were not detected (*i.e.* < 1%) based on NMR spectroscopy of the crude reaction mixture.[4]

In summary, a remarkable, albeit poorly understood, beneficial effect of 3-cyanopyridine on MTO-catalysed epoxidations of terminal alkenes has been established. For this challenging class of substrates, this method of epoxidation could prove to be one of the most convenient because (i) it shows good functional group compatibility (wide scope), (ii) it is mild (*i.e.* neutral conditions, room temperature), (iii) it uses a readily available, safe and environmentally friendly oxidizing agent (30% aqueous $H_2O_2$), and (iv) it is easy to perform on the scales common (1 to 200 mmol) in the laboratory (no tedious work-up, no by-products). We are currently investigating ways to increase turnover numbers as well as trying to understand the special nature of the 3-cyanopyridine ligand.

We are grateful to the National Institutes of Health (GM 28384), the National Science Foundation (CHE 9521152), the W. M. Keck Foundation, and the Skaggs Institute for Chemical Biology for financial support. H. A. and C. C. are also grateful to the Swedish Natural Science Research Council and the Association des Amis des Sciences for post-doctoral fellowships, respectively. We also want to thank Drs Wallace Pringle, Yuji Tokunaga and Andrei Yudin for helpful discussions.

## Footnotes and References

† Studies on the effect of various pyridine ligands (substituent effect) for the MTO–pyridine derivatives system are still underway.

‡ Longer reaction time did not increase conversion, and favoured formation of the by-products.

§ All compounds were isolated and characterized by standard techniques. All reactions proceeded to > 99% conversion unless otherwise noted.

¶ In the absence of 3-cyanopyridine, the reaction was slower and showed evidence of catalyst deactivation (*i.e.* only 93% conversion after 40 h). Anhydrous $H_2O_2$—reaction in *tert*-butyl alcohol— resulted in lower yields and prolonged reaction times, see ref. 1(*b*) and especially W. A. Herrmann, R. W. Fischer, M. U. Rauch and W. Scherer *J. Mol. Catal.*, 1994, **86**, 243.

‖ The reaction is slightly exothermic, and should be kept around 24 °C with a water bath.

** It is worth pointing out that 90–100% of the 3-cyanopyridine is consumed by the end of the reaction, and the white precipitate formed was identified as 3-cyanopyridine *N*-oxide. Monitoring the reaction with NMR spectroscopy showed that its formation became significant only late in the reaction, when the amount of alkene remaining was close to the amount of 3-cyanopyridine. For oxidations of amines using MTO, see Z. Zhu and J. H. Espenson, *J. Org. Chem.*, 1995, **60**, 1326; R. W. Murray; K. Iyanar, J. Chen and J. T. Wearing, *Tetrahedron Lett.*, 1996, **37**, 805; A. Goti and L. Nannelli, *Tetrahedron Lett.*, 1996, **37**, 6025; S. Yamazaki, *Bull. Soc. Chem. Jpn.*, 1997, **70**, 877.

†† This yield does not take into account the purity of the starting material; Aldrich dec-1-ene is 94% pure.

‡‡ No or little diastereoselectivity is usually observed in the MTO-catalysed epoxidation of allylic and homoallylic alcohols (W. Adam and C. M. Mitchell, *Angew. Chem., Int. Ed. Engl.*, 1996, **35**, 533; T. R. Boehlow and C. D. Spilling, *Tetrahedron Lett.*, 1996, **37**, 2717). This is in sharp contrast to some other transition metal-catalysed epoxidation reactions, see K. B. Sharpless and T. R. Verhoeven, *Aldrichim. Acta*, 1979, **12**, 63.

1 Terminal alkenes are much less reactive, and only few reactions give good conversion. (*a*) For seminal papers and some recent advances in epoxidation of alkenes other than the MTO-catalysed ones, see G. Berti, F. Bottari, B. Macchia and F. # Graphite as an effective catalyst for Friedel–Crafts acylation

**Mitsuo Kodomari,* Yoshitada Suzuki and Kouji Yoshida**

*Department of Industrial Chemistry, Faculty of Engineering, Shibaura Institute of Technology, Shibaura, Minato-ku, Tokyo 108, Japan*

**Graphite is found to promote Friedel–Crafts acylation of aromatic compounds such as anisole, toluene and *o*-xylene with acyl halides to give the corresponding acylated products in high yields.**

Friedel–Crafts acylation of aromatic compounds is one of the most important syntheses of aryl ketones. In contrast to Friedel–Crafts alkylation, which proceeds readily in the presence of catalytic amounts of Lewis acid, acylation requires more than one equivalent, *e.g.* of $AlCl_3$. This is due to the complexation of $AlCl_3$ by the ketone product. The catalyst used cannot easily be recovered and recycled; therefore, a large amount of toxic waste is generated. In order to solve this problem, some catalytic Friedel–Crafts acylations have recently been developed. $Ln(OTf)_3$–$LiClO_4$,[1] $TiCl(OTf)_3$–TfOH [2] and $ReBr(CO)_5$[3] have been reported as catalysts for Friedel–Crafts acylation. In addition, the use of inorganic solid supported reagents[4] or solid acids[5] as catalysts, resulting in higher selectivity, easier work-up and environmentally safe reactions, has been reported. For instance, HZSM-5 zeolite has been reported to promote the liquid-phase acylation of anisole with carboxylic acid.[5b] However, it has limitations with regard to generality and efficiency. Recently, it has also shown that alumina promotes the acylation of reactive aromatics such as anisole and

[a] ArH (2 mmol), benzoyl bromide (3 mmol), graphite (1 g) and benzene (5 ml). [b] Yields were determined by the internal standard method *via* GLC. [c] Addition of sodium carbonate (6 mmol). [d] Solvent: toluene (5 ml). [e] Solvent: *o*-xylene (5 ml).

thiophene with carboxylic acid in the presence of trifluoroacetic anhydride.[6] During the course of our studies aimed at developing supported reagents as catalysts for Friedel–Crafts reaction,[7] we found that graphite, without any treatment, promotes the Friedel–Crafts acylation of aromatic compounds with acyl halides to afford the corresponding acylated products in high yields.

Graphite was shown to have a remarkably high activity for the acylation of active aromatic compounds such as anisoles and polymethylbenzenes with acyl halide to give the corresponding acylated compounds in high yields, without any of the environmental disadvantages of using toxic homogeneous reagents such as $AlCl_3$. In a typical experiment, graphite† was added to a mixture of anisole (2 mmol) and benzoyl bromide (3 mmol) in benzene. The mixture was heated under reflux for 8 h. Graphite was removed by filtration, and the filtrate was washed with aqueous sodium hydrogen carbonate, to remove the excess benzoyl bromide, and concentrated under reduced pressure. The crude product was chromatographed on silica gel to afford *p*-methoxybenzophenone (80%). The products obtained were analysed by GLC, IR and NMR spectroscopy. The amount of graphite used relative to benzoyl bromide was between 0.5 and 2 g. The optimum yield of *p*-methoxybenzophenone was obtained with 1 g of graphite, whereas 2 g gave a slightly lower yield. When a large amount of graphite was used, the yields were decreased due to absorption of an appreciable amount of the product and starting material on the graphite. Empirical testing of five inorganic solids revealed that graphite was most effective in promoting the reaction. MS-5A, though less effective than graphite, was also effective, whereas active charcoal, silica gel and alumina were entirely ineffective (see Table 1). Alkanoyl and cycloalkanecarbonyl chlorides could be used as acylating reagents in the reactions, and the corresponding acylated products were obtained in good yield (Table 2). The reaction of anisole with isobutyl chloride and with cyclohexanecarbonyl chloride gave isopropyl 4-methoxyphenyl ketone and cyclohexyl 4-methoxyphenyl ketone, respectively, in high yields. However, the acylation of anisole with acetyl chloride gave *p*-methylacetophenone in low yield. This is probably due to evaporation (low boiling point of acetyl chloride). Benzoylation of several anisoles and polymethylbenzenes with benzoyl bromide in the presence of graphite was carried out and the results are summarised in Table 3. Anisole, veratrole and α-methoxynaphthalene reacted with benzoyl bromide to give the corresponding benzoylated products in high yields. In the present reactions, benzoyl bromide was a better acylating reagent than benzoyl chloride. For example, anisole reacted with benzoyl bromide to afford *p*-methoxybenzophenone in 89% yield, whereas a 50% yield was obtained in the reaction with benzoyl chloride under the same conditions; the yield was improved to 85% when the reaction was carried out at 120 °C in chlorobenzene. These graphite-promoted acylations proceeded even after addition of sodium carbonate, which traps hydrogen bromide generated during the reaction, although the rate of the reaction was slower than that in the reaction without sodium carbonate (Table 3, run 2). Polymethylbenzenes such as mesitylene, 1,2,3,5-tetramethylbenzene and pentamethylbenzene gave the corresponding benzoylated products in high yields. However, benzoylation of toluene and *o*-xylene was very slow in refluxing benzene, giving methylbenzophenone (a mixture of *o*- and *p*-isomers) and 3,4-dimethylbenzophenone in low yield, respectively; the yields were improved when the reaction was performed using toluene and *o*-xylene as both substrate and solvent. Benzene was hardly benzoylated under similar conditions. The reaction of benzene with benzoyl bromide was heated to reflux for 24 h to give benzophenone in 20% yield.

Further understanding of the catalysis by graphite and the application of graphite to other synthetic reactions are now under investigation.

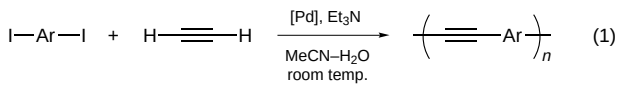
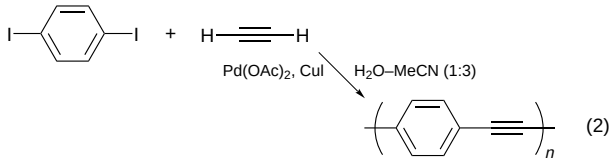
# Palladium catalysed polymerization of aryl diodides with acetylene gas in aqueous medium: a novel synthesis of areneethynylene polymers and oligomers



**Chao-Jun Li,*[a] William T. Slaven IV,[a] Vijay T. John[b] and Sukanta Banerjee[b]**

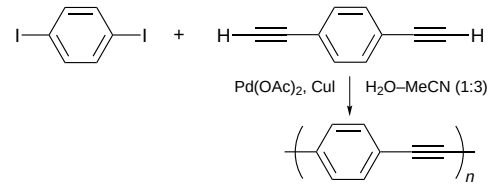
[a] *Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*
[b] *Department of Chemical Engineering, Tulane University, New Orleans, LA 70118, USA*

**Palladium catalysed copolymerization of aryl iodides with acetylene gas in an aqueous medium provides areneethynylene polymers and oligomers.**



Poly(areneethynylene) is an important class of conjugated polymer exhibiting properties such as photoluminescence,[1] electronic conductivity and nonlinear optics.[2] These polymers also exhibit exceptionally high quantum yields of fluorescence in comparison to other conjugated polymers.[3] Such properties render the polymers potentially useful for applications in constructing light emitting diodes (polymer LEDs)[4] and fluorescence sensors.[5] Previously, areneethynylene polymers and oligomers have been synthesized by the polymerization of aryl dihalides with aryl diacetylenes (requiring multistep syntheses) through Sonogashira coupling.[6] The reaction also requires the use of triethylamine as solvent and refluxing conditions.

As part of our continuing interest in synthesizing areneethynylene-type polymers and oligomers,[7] we required a simple and practical method for ready access to these materials. Conceptually, a convenient and economical way of generating these polymers is *via* the copolymerization of aryl dihalides with acetylene gas. During our studies of aqueous organic reactions,[8] we became interested in synthesizing poly(areneethynylene)s *via* polymerization of aryl halides with acetylene gas in aqueous medium [eqn. (1)].

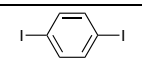


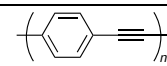
(1)

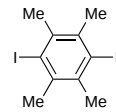
To ensure that the reactants were soluble, a mixture of water–MeCN was used as the reaction solvent. The average molecular weights ($M_w$ and $M_n$) of the polymer were characterized by gel permeation chromatography (GPC) using polystyrene as standard and THF as the eluent. Thus, 1,4-diiodobenzene was stirred with acetylene gas in a mixture of MeCN and water (3 : 1) in the presence of a catalytic amount of palladium acetate and cuprous iodide, together with 3 equiv. of triethylamine at room temperature. After three days, a dark brown polymeric solid was generated quantitatively [eqn. (2)]. The polymer thus

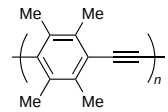
(2)

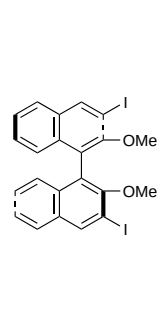
generated had very low solubility in common solvents, *e.g.* THF, benzene, $CH_2Cl_2$. We were unable to determine the molecular weight of this insoluble polymer. However, the molecular weights of the soluble fraction indicate oligomers with $M_n$ = 828 and $M_w$ = 4326. The polymer generated through this method appears very similar to those prepared by the polymerization of aryl dihalides with aryl diacetylenes [eqn. (3)]. The effectiveness of this preliminary investigation led us

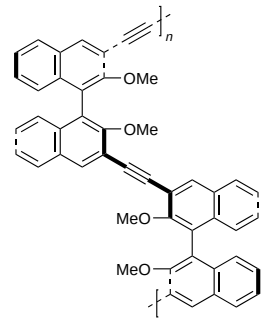












(3)

investigate the preparation of other areneethynylene polymers and oligomers by this convenient method. The results are listed in Table 1.[9]

The polymerization of 1,4-diiodo-2,3,5,6-tetramethylbenzene and acetylene gas generated a polymer (yield 51%) which is slightly more soluble in THF than the phenylethynylene polymer. GPC measurement of the soluble portion showed $M_n$ = 1185 and $M_w$ = 3495. Polymerization of 4,4′-diiodobiphenyl and acetylene gas again generated an insoluble polymer. The soluble, low molecular weight portion

**Table 1** Data for areneethynylene polymers and oligomers[a]

| Entry | Diiodoarene | Polymer (oligomer) | Reaction conditions[b] | $M_n$ | $M_w$ |
|---|---|---|---|---|---|
| |  |  | A | 828 | 4326 |
| |  |  | B | 504 | 1291 |
| |  |  | B | 1185 | 3495 |
| |  |  | C | 1250 | 3180 |

[a] All reactions were carried out at room temperature under an atmosphere of acetylene gas. $M_n$ and $M_w$ distributions are based only on the soluble portion of the polymerized material. [b] Reaction conditions: A = $Pd(OAc)_2$ (5%), $PPh_3$ (10%), CuI (5%), $Et_3N$ (5 equiv.), 3 days, in MeCN–$H_2O$ (3 : 1); B = $Pd(OAc)_2$ (5%), $PPh_3$ (10%), CuI (5%), $Et_3N$ (5 equiv.), 3 days in THF–$H_2O$ (3 : 1); C = Pd(OAc) (5%), P(*m*-$PhSO_3Na)_3$ (10%), CuI (5%), $Et_3N$ (5 equiv.), 5 days, in THF–MeCN–$H_2O$ (1 : 1 : 2).

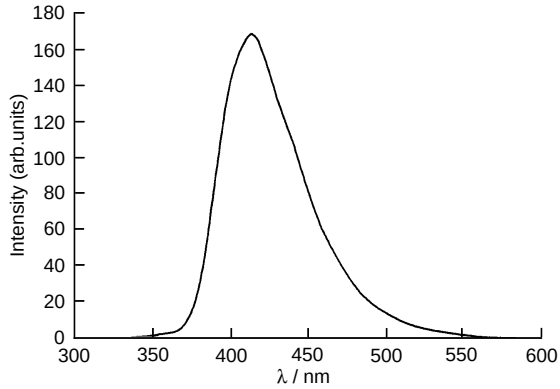


**Fig. 1** Fluorescence of the binaphthyl polymer in THF (excitation wavelength = 324 nm)

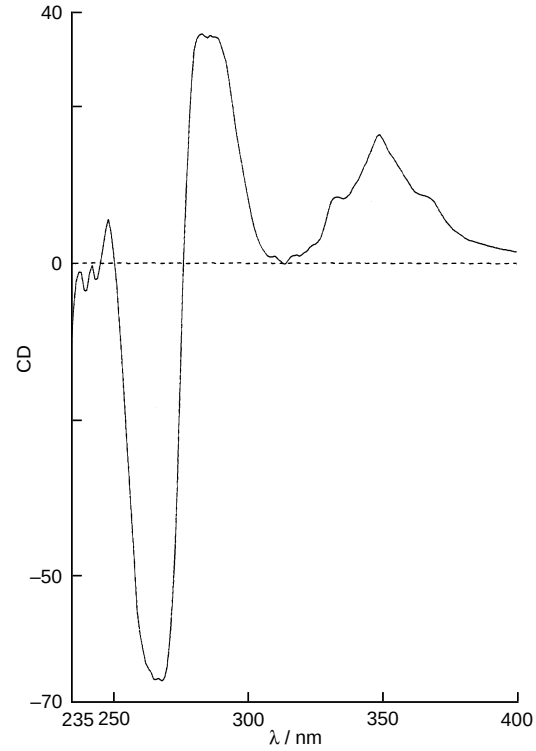

**Fig. 2** Circular dichroism spectrum of the binaphthyl polymer

showed $M_n$ = 504 and $M_w$ = 1291. On the other hand, polymerization of 3,3′-diiodo-2,2′-dimethoxy-1,1′-binaphthyl and acetylene gas generated a polymer (yield 48%) which is soluble in a variety of common organic solvents (*e.g.* THF, $CH_2Cl_2$, $CHCl_3$). Characterization showed $M_n$ = 1250 and $M_w$ = 3180, which are similar to those of the corresponding polymer that was prepared *via* the palladium-catalysed Stille reaction[10] by a modified procedure of Cummins[11] using bis(tributylstannyl)acetylene in refluxing 1,4-dioxane ($M_n$ = 1860 and $M_w$ = 3200). The polymer shows a strong fluorescence, which suggests the potential for LED applications. The fluorescence spectrum of the polymer (Fig. 1) shows an emission maxima of 435 nm when excited at 324 nm. Both $^1H$ and $^{13}C$ NMR showed significant broadening of all the corresponding peaks. The circular dichroism (CD) spectrum of the polymer in chloroform (Fig. 2) shows a negative Cotton effect at λ = 245 nm and a positive effect at λ = 277 nm. Attempts to obtain information about the endgroups of the oligomers *via* MALDI MS were not successful. Further evaluation of the method for synthesis of areneethynylene polymers and oligomers as well as the characterization of the polymers and oligomers is in progress.

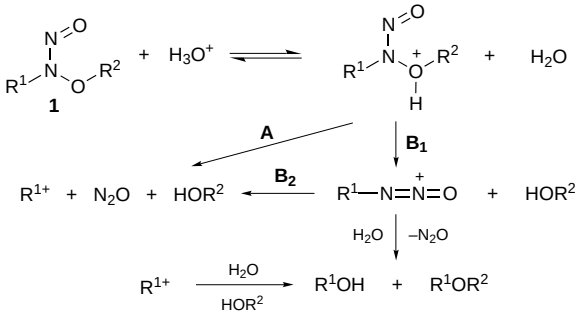
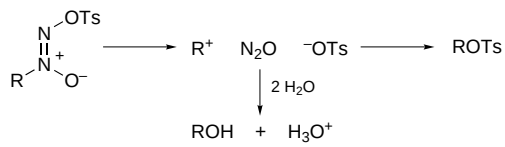
# Isotopic labelling studies of the deaminative fragmentation of *N*-nitrosohydroxylamines and related compounds by kinetics, millimetre-wave spectroscopy and $^{17}O$ NMR spectroscopy

**Johanna Haider, M. N. Stuart Hill, Iain D. Menneer, Howard Maskill* and John G. Smith**



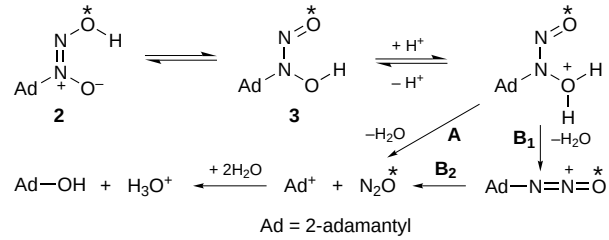
*Department of Chemistry, Bedson Building, University of Newcastle upon Tyne, Newcastle upon Tyne, UK NE1 7RU*

**Nitrous oxide enriched with $^{18}O$ has been identified by millimetre-wave spectroscopy from the acid-induced hydrolysis of $N^1$-(2-adamantyl)-$N^2$-[$^{18}O$]hydroxydiazen-1-ium $N^1$-oxide 2 which, along with $^{17}O$ NMR studies and an α-deuterium kinetic isotope effect of $k_H/k_D$ = 0.98 (±0.02) for *N*-nitroso-*N*-(2-[2-$^2$H]adamantyl)-*O*-benzylhydroxylamine 4, confirms (i) that nitrous oxide is liberated in these reactions, and (ii) that the fragmentations in these reactions are step-wise and not concerted.**

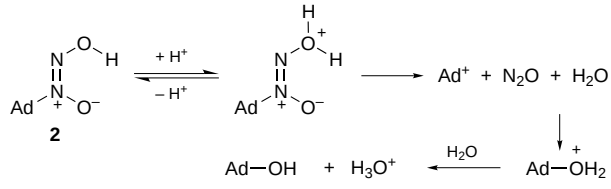


A decade ago, the biological importance of nitric oxide (NO) was first recognised,[1] and this led to the search for compounds capable of releasing NO under mild physiological conditions. Promising first results were reported for some rather complex *N*-nitrosohydroxylamine derivatives,[2] whereas simpler analogues were shown to undergo a new deamination type of reaction.[3] Since related *N*-nitrosamines are known to be carcinogenic,[4] and deamination reactions involve highly reactive electrophilic intermediates with mutagenic potential, the borderline between the possibly benevolent homolytic reaction and the almost certainly hazardous heterolytic alternative from *N*-nitrosohydroxylamines required exploration, and both mechanisms need better characterization.

The mechanism we proposed for the acid-induced deamination type of solvolysis of *N*-nitroso-*N*,*O*-dialkylhydroxylamines **1** is shown in Scheme 1.[3] Our earlier results did not allow us to distinguish between the concerted fragmentation (path A) and the step-wise alternative (path B). We had previously established, however, that the related fragmentation of alkylazoxy arenesulfonates, shown in Scheme 2 for azoxy tosylates, is concerted.[5] $N^1$-(2-Adamantyl)-$N^2$-hydroxydiazene-1-ium $N^1$-oxide **2**, the product of nitrosation of *N*-(2-adamantyl)hydroxylamine, also undergoes acid-induced hydrolysis with kinetic features very similar indeed to those of several *N*-nitroso-*N*,*O*-dialkylhydroxylamines.[3] Consequently, a mechanism involving isomerization of **2** into its *N*-nitroso isomer **3** followed by protonation and fragmentation was proposed, and is shown in Scheme 3. In this mechanism also, the fragmentation could be concerted (path A) or step-wise (path B). Additionally, however, the direct mechanism from **2** shown in Scheme 4 in which the other oxygen departs as part of the nucleofuge appeared a viable alternative, especially in view of the above-mentioned fragmentation of alkylazoxy tosylates (Scheme 2). We now report that, by a combination of isotopic studies and spectroscopic methods, we have been able to distinguish between the concerted and step-wise alternatives for compounds **1**, and between the mechanisms of Schemes 3 and 4 for $N^1$-(2-adamantyl)-$N^2$-hydroxydiazene-1-ium $N^1$-oxide **2**.

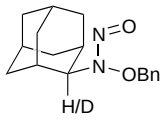


Compound **2** was prepared by reaction of *N*-(2-adamantyl)-hydroxylamine with aqueous nitrous acid enriched with $^{17}O$ following a procedure established by Dahn,[6] and the labelled atom, marked with an asterisk in Scheme 3, was confirmed by $^{17}O$ NMR spectroscopy [$\delta_O$ 198 (relative to $^{17}OH_2$), the other oxygen giving a signal at $\delta_O$ 334].[3]† The $^{17}O$ NMR spectrum of the adamantan-2-ol ($\delta_O$ = 30), isolated from acid-induced hydrolysis of this labelled substrate, was then recorded and shown to be identical to a sample of natural abundance adamantan-2-ol,‡ *i.e.* none of the $^{17}O$ in the substrate ended up in the adamantanol. Since appreciable quantities of the ether R–O–R′ are formed from the hydrolysis of the *N*-nitroso-*N*,*O*-dialkylhydroxylamines **1**, we are confident that the water molecule which departs as nucleofuge from **2** (or from **3**–whichever is involved) would be trapped to some extent by the 2-adamantyl cation. We concluded on the basis of this admittedly negative evidence that the isotopically labelled oxygen departs entirely as nitrous oxide according to the mechanism in Scheme 3. To obtain positive evidence, we also

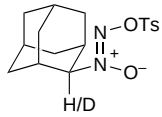


**Scheme 1**

**Scheme 2**



**Scheme 3**



**Scheme 4**

prepared compound **2** specifically enriched with $^{18}O$ at the oxygen marked with an asterisk in Scheme 3. The acid-induced hydrolysis was then carried out for more than eight half-lives at 65 °C, and the evolved gas was flushed through by a stream of nitrogen, dried by a potassium hydroxide tower, and trapped at liquid nitrogen temperature. It was then transferred *via* normal vacuum line procedures to a millimetre-wave spectrometer and part of its rotational spectrum was recorded.[7] In addition to the band at 125 614 MHz due to the $J$ 5 ← 4 rotational transition in the $N_2O$ containing $^{16}O$, we also observed the band at 71 155 MHz corresponding to the $J$ 3 ← 2 transition of the $N_2O$ molecule containing $^{18}O$; both frequencies are in excellent agreement with values calculated from literature data.[8] This result corroborates the $^{17}O$ NMR result described above, and together they are compatible with the mechanism of Scheme 3 and rule out that in Scheme 4.

We also prepared *N*-nitroso-*N*-(2-adamantyl)-*O*-benzylhydroxylamine **4** specifically labelled with deuterium at C-2 of the

**4**

**5**

**6a** R = 2-adamantyl
**b** R = H

**7a** R = H
**b** R = 2-adamantyl

**8**

adamantyl system, and measured the α-deuterium kinetic isotope effect (KIE). Results of $k_H/k_D$ = 1.09–1.13 for the α-deuterium KIE for solvolysis of 2-adamantylazoxy tosylate **5** were part of the evidence that cleavage of the C–N bond is involved in the rate-limiting transition state for the solvolysis of **5** (Scheme 2).[5] Similar results would be expected for **4** if the mechanism follows path A in Scheme 1 (or if the reaction is step-wise with step $B_2$ rate limiting). The step-wise mechanism with the initial step $B_1$ rate limiting would be expected to have an α-deuterium KIE of approximately unity since only minor perturbations of the α-C–H vibrations are expected in the formation of the transition structure from the reactant molecule. Reactions were measured at two temperatures and two acid concentrations as shown in Table 1, and results of $k_H/k_D$ = 0.98 (±0.02) were obtained; these are compatible only with the stepwise mechanism and rate-limiting departure of the nucleofuge.

The protonated form of **2** in Scheme 4 is clearly analogous to **5** in that both have good nucleofuges, $H_2O$ and $TsO^-$ respectively, bonded to the terminal nitrogen of the azoxy group. Stepwise fragmentation of **5** and of the protonated form of **2** would involve **6a** as an intermediate. In a theoretical investigation, however, we have already shown that **6b** exists only as a transition structure in the gas-phase isomerization of **7a** into **8**,[9] and that no bonded structure corresponding to **6a** is expected to exist. So, whereas **5** avoids formation of **6a** by a concerted fragmentation, we have now shown that formation of **6a** from **2** in acidic solution is avoided by rearrangement and a step-wise route involving **7b** (Scheme 3, path B).

**Table 1** Rate constants and α-deuterium kinetic isotope effects for the acid-induced hydrolysis of *N*-nitroso-*N*-(2-adamantyl)-*O*-benzylhydroxylamine[a]

| Compound | $T$/°C | $[HClO_4]$/mol dm$^{-3}$ | $k/10^{-3}$ s$^{-1}$ | $k_H/k_D$ |
|---|---|---|---|---|
| **4**-H | 34.68 | 0.10 | 1.14 | |
| **4**-D | 34.68 | 0.10 | 1.16 | 0.98 |
| **4**-H | 44.67 | 0.10 | 2.90 | |
| **4**-D | 44.67 | 0.10 | 2.92 | 0.99 |
| **4**-H | 44.68 | 0.50 | 4.86 | |
| **4**-D | 44.68 | 0.50 | 5.04 | 0.96 |

[a] Reaction rates were measured by our normal UV spectrophotometric method which has already been described (refs. 3, 5). Simultaneous reactions were monitored for about three half-lives with two cells containing the protium compound and two cells containing the deuterium analogue in the same thermostatted four-cell block. Identical solvolytic media were used for H and D compounds in one four-cell experiment, and the ionic strength in all reactions was 1.0 mol dm$^{-3}$ ($NaClO_4$). The rate constant for a given compound was reproducible to within 1%, and standard deviations on individual rate constants were always less than 1%. The maximum error in $k_H/k_D$ is estimated to be 0.02.

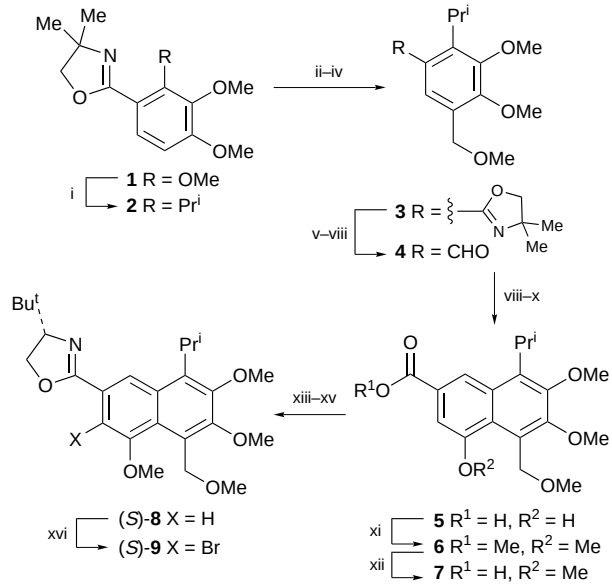
# The synthesis of (*S*)-(+)-gossypol *via* an asymmetric Ullmann coupling

**A. I. Meyers* and Jeffrey J. Willemsen**

*Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523-1872, USA*



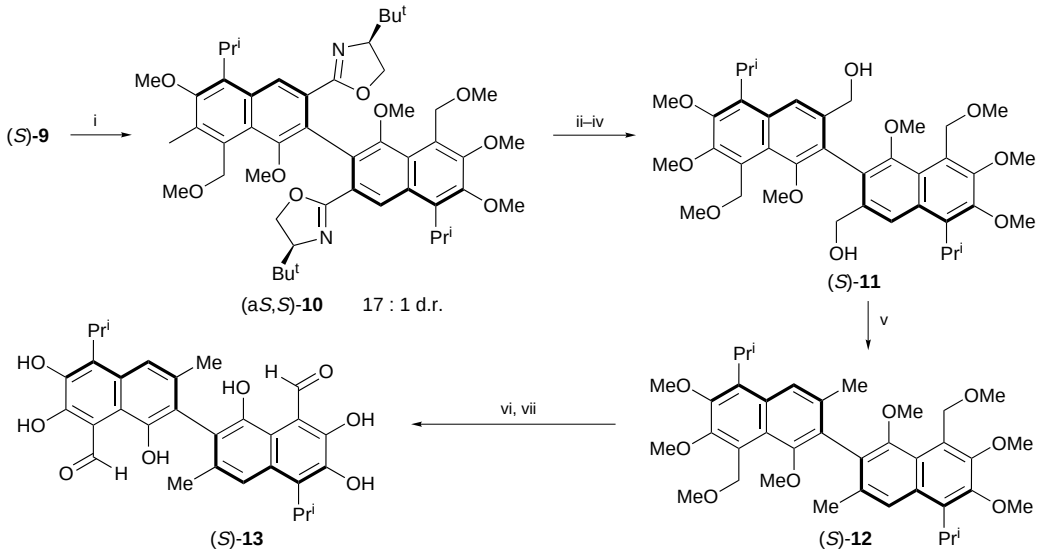
**The first asymmetric total synthesis of (*S*)-(+)-gossypol is described using chiral oxazolines as the naphthyl substituent in a highly diastereoselective aryl–aryl coupling.**

In 1886, racemic gossypol **13** was isolated[1] from cotton seeds and its structure elucidated in 1938 by Adams.[2] It is known to be active as an oral anti-spermatogenic agent[3] and has recently been tested on male subjects in China.[4] Additionally, (*R*)-gossypol was shown to be ten times more effective than its *S* antipode against tumour cells[5] and also showed inhibitory activity against HIV type 1.[6] The *S* antipode, on the other hand, has exhibited activity against herpes simplex virus,[7] and influenza[8] and parainfluenza virus.[7] The *S* enantiomer also induces DNA strand breaks in human leukocytes.[9]

Synthetic efforts to reach this axially chiral system have thus far only led to racemic gossypol, along with various analogues in the search for further biological activity.[10] The synthetic routes to gossypol feature mainly phenolic oxidative coupling, although in one instance an organolithium–$CoBr_2$ oxidative coupling was reported to proceed in poor (25%) yield.[10*c*]

Our approach to gossypol in enantiomerically pure form (either *R* or *S*) was based upon our earlier reports on asymmetric Ullmann couplings of 2-phenyl[11] or several naphthyl oxazolines.[12,13] In these earlier studies we showed that biaryl atropisomers could be accessed in high enantiomeric purity by either a thermodynamically controlled reaction[11] or a kinetically controlled process.[12,13] Due to the ample *ortho* substitution present in gossypol, restricted rotation about the symmetrically structural aryl–aryl bond showed relatively stable axially chiral enantiomers and indeed both have been isolated from natural sources.[14,15]

From the rich chemistry that has been developed[16] for the oxazoline moiety, both chiral and achiral, we felt this was a further opportunity to highlight a number of different reactions exhibited by the oxazolines. The route to (*S*)-**13** was initiated by transforming 2,3,4-trimethoxybenzene into the oxazoline **1** and displacing the 2-methoxy with isopropylmagnesium bromide as described previously (Scheme 1).[13] However, the route to gossypol required a pentasubstituted benzene **3** and, unlike the previous report, its preparation was not a trivial matter. We found that **2** could be metallated with ethoxyvinyllithium–HMPA[17] followed by addition of DMF to afford the intermediate formyl derivative. Reduction of the latter with $LiAlH_4$ and conversion to the methyl ether gave the tetrasubstituted phenyl oxazoline **3**. The oxazoline was removed, as described in previous studies,[16] to furnish the tetrasubstituted benzaldehyde **4** in 89% yield from **2**. A Stobbe condensation[18] followed by cyclization ($Ac_2O$–AcOH) and hydrolysis afforded the properly substituted naphthoic acid **5**. Our previous report on a model system[13] lacked the crucial substituent at C-5 in the naphthalene moiety. The naphthoic acid **5** was transformed, *via* its methyl ester **6**, to the tetramethoxynaphthoic acid **7** in 34% overall yield from starting oxazoline **1**. Conversion of **7** to the chiral oxazoline **8**[16*c*]† was performed with (*S*)-(+)-*tert*-leucinol[19] and then brominated in good yield to the bromonaphthalene **9**. This now represented the completely substituted precursor to gossypol and was subjected to the asymmetric Ullmann conditions. Heating a 40% solution of **9** in freshly distilled DMF and activated copper[20] (2 equiv.) at reflux for 1 h gave the



**Scheme 1** *Reagents and conditions*: i, $Pr^iMgCl$, 96%; ii, EtOCH=CHLi, DMF; iii, $LiAlH_4$; iv, NaH, MeI, 72% over 3 steps; v, $MeOSO_2CF_3$; vi, $NaBH_4$; vii, $H_2O^+$, 89% from **2**; viii, NaH, dimethyl succinate; ix, AcOH, $Ac_2O$; x, KOH, 59% over 3 steps; xi, $K_2CO_3$, $Me_2SO_4$, 97%; xii, KOH, 98%; xiii, $(COCl)_2$; xiv, (*S*)-*tert*-leucine; xv, $SOCl_2$, 87% over 3 steps; xvi, $Br_2$, AcOH, 74%

binaphthyl system **10**‡ in 80% yield (Scheme 2) as a 17 : 1 diastereoisomeric mixture (NMR; *tert*-butyl singlets integrated between $\delta$ 0.50–0.55, ± 1% after several determinations). This is in contrast to the earlier report[13] where only a 11 : 1 diastereomeric ratio was obtained using a model system. After chromatography, the pure (a*S*,*S*)-**10** was relieved of its chiral auxiliary using previously described procedures[16*c*] to afford the diol (*S*)-**11**, which was immediately reduced to the requisite dimethyl derivative (*S*)-**12**.§ The *S* configuration assigned to **12** is based upon the previous transition state models[11,12] and had to await confirmation when gossypol was reached, since its X-ray structure and chiroptical properties have been reported.[21] The final approach to (*S*)-gossypol was accomplished by cleaving all eight methyl ethers with $BBr_3$ in $CH_2Cl_2$ at −78 °C for 24 h and immediatley transforming the polyhydroxy system to the bis(formyl) derivative using Swern conditions. The product (*S*)-**13**, reached in 9% overall yield from **1**, showed all The properties¶ for gossypol described in the literature[22,23] and was reached in only six steps from the bromonaphthyl oxazoline **9**. The enantiomeric purity of synthetic gossypol, as prepared above, was assessed as 99.2 : 0.8 by preparing the Schiff base from (*S*)-phenylalanine methyl ester and comparing it to racemic gossypol.[15]‖

Although the *S* enantiomer is known to be inactive as a male fertility agent,[3] simply carrying out the above syntheses using (*R*)-(−)-*tert*-leucinol would give the other gossypol antipode.

# Chiral linear assembly of amino acid bridged dimeric porphyrin hosts

**Hai-yang Liu,[a] Jin-wang Huang,[a] Xuan Tian,[b] Xiang-dong Jiao,[a] Guo-tian Luo,[a] and Liang-nian Ji*[a]**

[a] *Department of Chemistry, Zhongshan University, Guangzhou 510275, China*
[b] *National Laboratory of Applied Organic Chemistry, Lanzhou University, Lanzhou 730000, China*

**Chiral linear zinc porphyrin arrays are constructed from amino acid bridged zinc porphyrin dimers and ethylenediamine *via* self-assembly in $CHCl_3$; the induced CD sign and shape of the array are different from that of the porphyrin subunit.**

In photosynthesis, plant cells utilize arrays of up to three hundred porphyrin molecules (chlorophyll) for light capture.[1] These porphyrin chromophores are fixed spatially and orientationally by the skeleton material of the cells. The design and synthesis of artifical molecular systems aimed at mimicking the structure and/or function of photosynthetic centres has attracted much recent interest.[2] In order to construct large porphyrin arrays, a 'building block' strategy has been developed.[3] It was considered that unidimensional porphyrin arrays were particularly well-adapted to accommodate multistep electron-transfer (ET) reactions, eventually leading to long-lived and spatially-remote charge separation states. Each module consists of a porphyrin covalently attached to a chelate and transition metals have been used for making these one-dimensional multicomponent molecular systems.[4] We have synthesized a number of amino acid bridged chiral zinc porphyrin dimers *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$,[5] and here we report a facile approach to the construction of chiral linear zinc porphyrin arrays from these zinc porphyrin dimers and a bidentate ligand (ethylenediamine) in $CHCl_3$. Our 'module–linker' strategy for making one-dimensional porphyrin arrays is illustrated in Fig. 1.

*o,o*-$C_2$-AA-$C_2$-$(TPP_2)Zn_2$

R = H (AA = Gly)
R = Me (AA = Ala)
R = CH(OH)Me (AA = Thr)
R = Bn (AA = Phe)

UV–VIS spectra of metal-free porphyrin dimers *o,o*-$C_2$-AA-$C_2$-$(TPP)_2$ exhibited the usual free base porphyrin bands and the $\lambda_{max}$ values were close to those of tetraphenylporphyrin. However, Q band red-shifting (*ca.* 10–15 nm) occurred for zinc

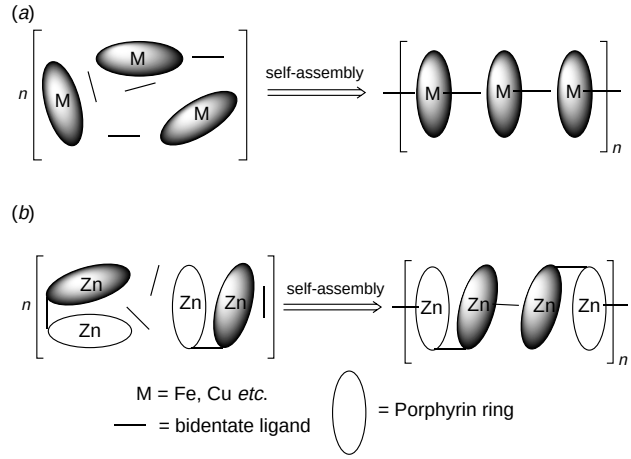

**Fig. 1** 'Module–linker' strategy used to assemble one-dimensional porphyrin arrays. The basic module is metalloporphrin monomer (*a*) or zinc porphyrin dimer (*b*) and the linker is a suitable linear bidentate ligand.

porphyrin dimers *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ (Table 1). As the π–π interaction between two porphyrin chromophores is enhanced by metallaton,[6] the red shift indicated π–π attraction made the two zinc porphyrins adopt a head to tail arrangement in the dimer and an intramolecular exciton coupling interaction[7] existed between the two zinc porphyrins.

Split induced circular dichroism (ICD) at the soret absorption band was observed for chiral amino acid (Ala, Thr, Phe) bridged zinc porphyrin dimers *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ and the L- and D-amino acid bridged zinc porphyrin dimers constituted pairs of enantiomers (Fig. 2). No significant ICD was observed for the corresponding free base porphyrin dimers. This strongly suggested that the ICD of these complexes was correlated to the chiral π–π stacking of the zinc porphyrins in the dimers. Namely, the observed ICD was caused by chiral exciton coupling interactions.[8]

Molecular orientation in porphyrin-based aggregates can be conveniently monitored by CD spectroscopy.[9] Here CD titration methods were used to detect the formation of the chiral porphyrin array. The ICD spectra of chiral zinc porphyrin dimers *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ is dramatically reduced upon the addition of propylamine; this suggests that the coordination of propylamine to *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ blocked much of

**Table 1** Electronic absorption spectrum data of *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ (in $CHCl_3$, room temp.)

| | UV–VIS $\lambda_{max}$/nm | | |
|---|---|---|---|
| Zinc porphyrin | Soret | Q | |
| (TPP)Zn[a] | 418.3 | 547.1 | 583.9 |
| *o,o*-$C_2$-Gly-$C_2$-$(TPP)_2Zn_2$ | 418.5 | 557.1 | 599.3 |
| *o,o*-$C_2$-Ala-$C_2$-$(TPP)_2Zn_2$ | 419.9 | 556.1 | 598.1 |
| *o,o*-$C_2$-Thr-$C_2$-$(TPP)_2Zn_2$ | 421.9 | 554.9 | 594.5 |
| *o,o*-$C_2$-Phe-$C_2$-$(TPP)_2Zn_2$ | 420.1 | 553.3 | 595.3 |

[a] This work.

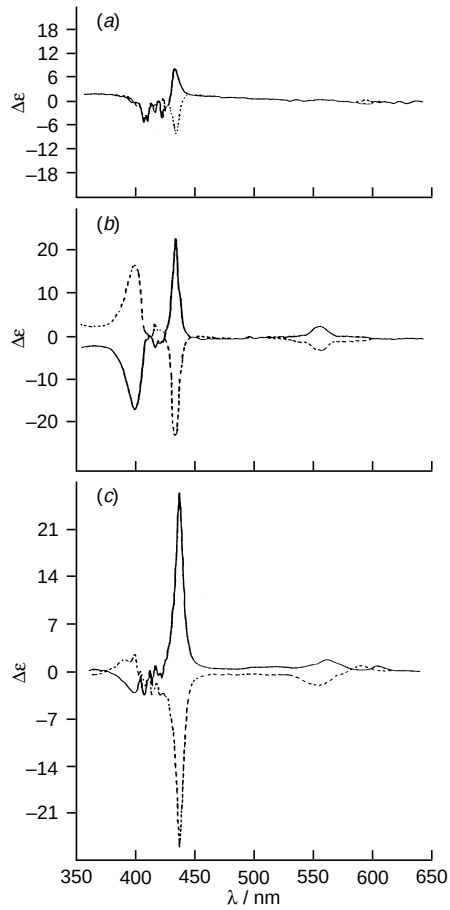

**Fig. 2** CD spectra of *o,o*-$C_2$-(L-AA)-$C_2$-$(TPP)_2Zn_2$ (——) and *o,o*-$C_2$-(D-AA)-$C_2$-$(TPP)_2Zn_2$ (- - -) in $CHCl_3$ at room temperature: (*a*) *o,o*-$C_2$-Ala-$C_2$-$(TPP)_2Zn_2$, (*b*) *o,o*-$C_2$-(Thr)-$C_2$-$(TPP)_2Zn_2$ and (*c*) *o,o*-$C_2$-Phe-$C_2$-$(TPP)_2Zn_2$

the exciton interaction.[6] The change in the ICD spectra of the system might also be due to changes in dimer conformation arising from coordination of the metal of the porphyrin, for coordination of the metal by a ligand reduces the magnitude of the π–π interaction in metalloporphyrins and generally leads to disaggregation.[10] When bidentate ligand ethylenediamine was added to a solution of *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$, however, this was not the case (Fig. 3). At the first stage of the addition (ethylenediamine : zinc porphyrin ≤ *ca.* 1 : 1), the CD sign at *ca.* 436 nm was gradually reversed with increasing ethylenediamine. With further addition of ethylenediamine, the ellipticities gradually decreased, and finally disappeared when a large excess of ethylenediamine was added. Surprisingly, when a diamine having a long connecting chain, such as 1,10-diaminodecane, was added to the solution of *o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$, the ICD of the system gradually reduced and finally disappeared. No reversed ICD was observed at any [1,10-diaminodecane] : [zinc porphyrin] molar ratio. We suggest that the reversed ICD of ethylenediamine–*o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ complexes is due to the formation of relatively rigid chiral linear porphyrin arrays [Fig. 1(*b*)], since reversed ICD should have been observed for the 1,10-diaminodecane–*o,o*-$C_2$-AA-$C_2$-$(TPP)_2Zn_2$ complex if it were due to the formation of the species with the bidentate ligand binding inside the cavity of the zinc porphyrin dimer. The CD ethylenediamine titration experiments revealed that the chiral linear zinc porphyrin array [Fig. 1(*b*)] reached a maximum concentration when [ethylenediamine] : [zinc porphyrin] was *ca.* 1 : 1. At higher ethylenediamine content, this bidentate ligand would act as a monodentate ligand and would result in the dissociation of the arrays.

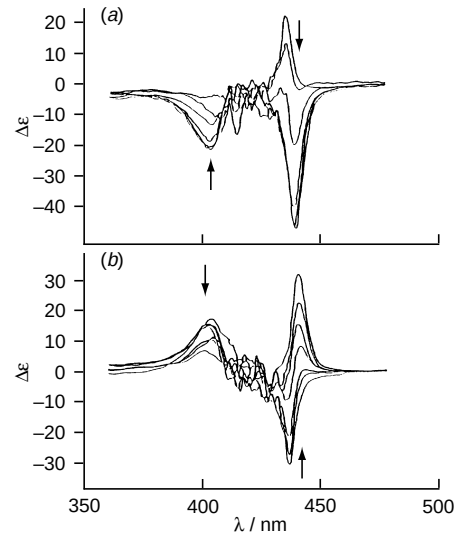

**Fig. 3** Changes in the CD spectra upon addition of ethylenediamine to a solution of *o,o*-$C_2$-Thr-$C_2$-$(TPP)_2Zn_2$ (in $CHCl_3$ at room temp., [ethylenediamine] : [zinc porphyrin] ≤ 1 : 1); (*a*) *o,o*-$C_2$(L-Thr)-$C_2$-$(TPP)_2$ and (*b*) *o,o*-$C_2$-(D-THr)-$C_2$-$(TPP)_2Zn_2$

In conclusion, we have demonstrated that chiral linear zinc porphyrin arrays can easily be built with amino acid bridged zinc porphyrin dimer and the bidentate ligand ethylenediamine in solution *via* a 'module–linker' self-assembling strategy. The present study should also be helpful for the investigation of ICD of porphyrins.[8]

# Ferrocene-containing liquid-crystalline dendrimers: a novel family of mesomorphic macromolecules

**Robert Deschenaux,*[a] Elisabeth Serrano[a] and Anne-Marie Levelut[b]**

[a] *Institut de Chimie, Université de Neuchâtel, Av. de Bellevaux 51, 2000 Neuchâtel, Switzerland*

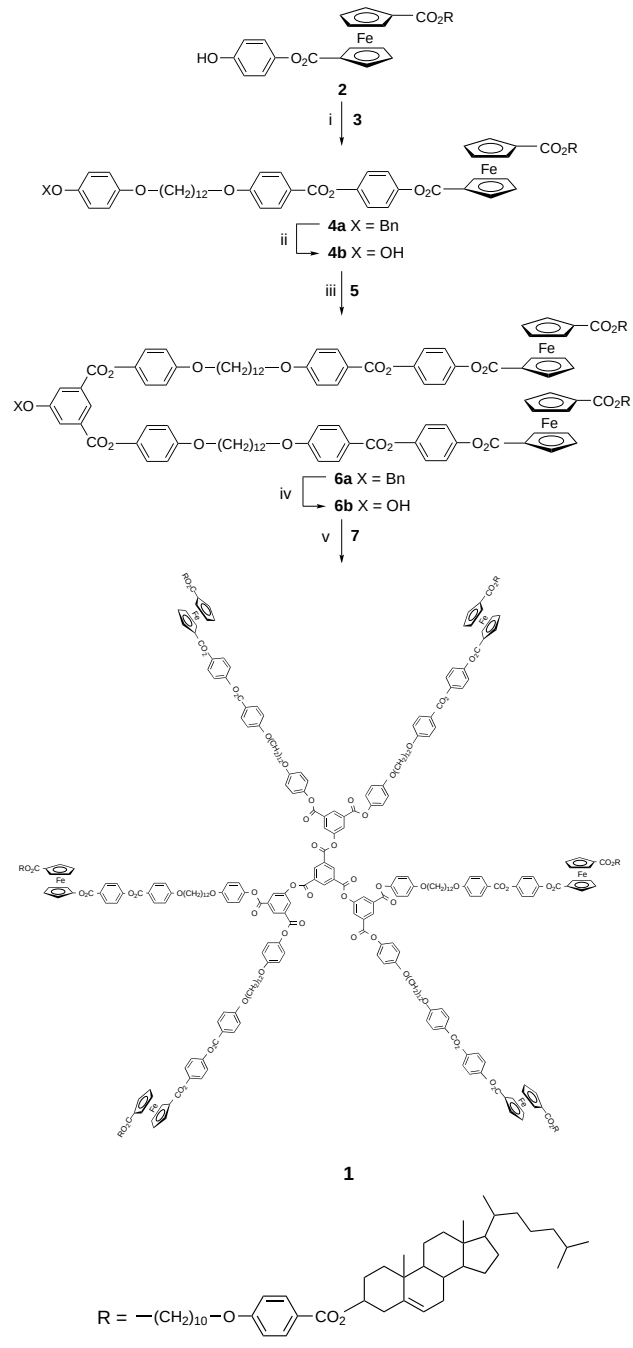
**The synthesis and liquid-crystalline properties of a first-generation dendritic core substituted with six mesomorphic ferrocene units are reported; the investigated compound exhibited a broad enantiotropic smectic A phase (polarized optical microscopy, DSC, and XRD studies) and good thermal stability (thermogravimetry).**



Increasing interest is currently accorded to the design and synthesis of dendrimers.[1] The possibility of creating new materials, characterized by a well defined and aesthetic macromolecular structure, displaying unique properties (such as catalysis,[2] encapsulation,[3] chiroptical activity[4] and redox activity[5]) strongly motivated these studies.

Liquid-crystalline dendrimers have been recently reported. An $AB_2$ rod-like mesogenic monomer was used to synthesize dendrimers up to the fourth generation.[6] Nematic and smectic phases were observed for these materials. First-[7] and second-generation[8] polysiloxane dendrimers were functionalized by mesogenic moieties, and showed smectic A or smectic C phases. Metal complexes were prepared from various metal ions and first- or second-generation ethyleneimine dendrimers and a hexagonal columnar phase was identified for a $Cu^{II}$ complex.[9] These novel structures form a most interesting class of anisotropic materials from a fundamental and practical viewpoint: the structural features of such compounds should lead to important basic information for a better understanding of the structure–mesomorphic properties relationship for liquid-crystalline macromolecules and, ultimately, could be exploited for elaborating new liquid-crystalline devices. To our knowledge, organometallic-type liquid-crystalline dendrimers have not been reported.

To further explore the capability of mesogenic ferrocene derivatives to act as mesomorphic building blocks for the construction of liquid-crystalline macromolecules,[10] we extended our interest to ferrocene-containing thermotropic dendrimers. This communication describes the synthesis and mesomorphic properties of the ferrocene-containing thermotropic dendrimer **1**, which represents the first organometallic-type liquid-crystalline dendrimer.

A first-generation dendrimer was selected to explore the thermal and liquid-crystalline behavior of such a new structure. A ferrocene-based cholesterol framework was used as a mesomorphic promoter owing to the high liquid-crystalline tendency of cholesterol derivatives: recently, we reported the first fullerene[60]-containing thermotropic liquid crystal obtained by derivatizing the $C_{60}$ core with a twin-cholesterol derivative.[11]

The synthesis of **1** is outlined in Scheme 1. Condensation of ferrocene derivative **2**† with 4-(4′-benzyloxyphenoxy)-dodecyloxybenzoic acid chloride **3**† gave the protected ferrocene-containing unramified sub-unit **4a**. Deprotection of the latter species under standard conditions gave the phenol derivative **4b**, which was subsequently reacted with 5-benzyloxyisophthaloyl dichloride **5**† to furnish the protected ferrocene-containing ramified branch **6a**. Removal of the benzyl protecting group under standard conditions led to the phenol intermediate **6b**. Finally, treatment of **6b** with 1,3,5-ben-

**Scheme 1** *Reagents and conditions*: i, 4-(4′-Benzyloxyphenoxy)-dodecyloxybenzoic acid chloride **3**, $Et_3N$, $CH_2Cl_2$, reflux, overnight, 96%; ii, $H_2$, Pd/C, $CH_2Cl_2$–EtOH, room temp., overnight, 96%; iii, 5-Benzyloxyisophthaloyl dichloride **5**, $Et_3N$, $CH_2Cl_2$, reflux, overnight, 73%; iv, $H_2$, Pd/C, $CH_2Cl_2$–EtOH, room temp., 2 d, 63%; v, 1,3,5-benzenetricarbonyl trichloride **7**, $Et_3N$, $CH_2Cl_2$, reflux, 24 h, 86%.

zenetricarbonyl trichloride **7** gave the targeted ferrocene-containing dendrimer **1** as an orange solid. The latter species was purified by column chromatography (silica gel, eluent: $CH_2Cl_2$–acetone–heptane 10 : 0.5 : 2 v/v/v) and crystallization ($CH_2Cl_2$–heptane). Its structure and purity were confirmed by $^1$H NMR spectroscopy and elemental analysis.‡

The thermal and liquid-crystalline properties of **1** were investigated by a combination of differential scanning calorimetry (DSC), polarized optical microscopy (POM), and X-ray diffraction studies.§

A glass transition temperature ($T_g$) was detected by DSC (second heating run) at 47 °C (onset transition) followed by an endotherm at 150 °C (peak transition, $\Delta H$ = 69.6 kJ mol$^{-1}$).

POM examinations clearly revealed the formation of a liquid-crystalline phase between $T_g$ and the endothermic peak. The latter corresponded to the clearing point. Slow cooling of the sample from the isotropic liquid into the mesophase gave rise to a focal conic texture and homeotropic areas. From these observations, the mesophase was identified as an enantiotropic smectic A phase.

The nature of the liquid-crystalline phase was clearly and unambiguously established from X-ray data. Firstly, diffraction patterns typical of disordered smectic phases, characterized by a sharp diffraction peak at the low-angle region (a second-order diffraction peak was observed in some cases) and a diffuse peak at the wide-angle region, were obtained. The layered structure was retained below $T_g$. The *d*-layer spacing was found to be 40.7 Å at room temperature and 41.3 Å at 86 °C (the sample was heated to the isotropic liquid, cooled to room temperature, and re-heated to the desired temperature). Secondly, a sample was oriented by mechanical shearing on mica close to the clearing point, and was analysed at room temperature. A diffraction pattern typical of a smectic phase, consisting of aligned equidistant sharp spots at small angles and of two diffuse arcs at wide angles, was obtained. The sharp spots are aligned along the shearing direction (meridian) and the points of highest intensity in the diffuse arcs are located in the equatorial plane. Therefore the director is parallel to the shearing direction and perpendicular to the layer planes. The mesophase is actually smectic A.

Finally, compound **1** showed good thermal stability as confirmed by thermogravimetry (10 °C min$^{-1}$, under $N_2$), which indicated that no decomposition occurred up to *ca*. 250 °C. Mass losses of 1, 5 and 10% were detected at 258, 281 and 322 °C, respectively.

The above results demonstrate that ferrocene-containing liquid-crystalline dendrimers represent a valuable family of mesomorphic macromolecules, showing a pronounced liquid-crystalline tendency and good thermal stability. Furthermore, ferrocenyl functionalized dendrimers have emerged as an interesting class of electro-active macromolecules.[5a,b] The presence of the ferrocene unit in mesomorphic dendrimers is particularly attractive with potential for elaborating dendrimer-based switchable molecular units: we have recently shown that electron transfer can be used to generate mesomorphism in the ferrocene–ferrocenium redox system.[13]

# Spontaneous oxidation of $C_{60}Ph_5X$ (X = H, Cl) to a benzo[*b*]furanyl[60]fullerene

**Anthony G. Avent, Paul R. Birkett, Adam D. Darwish, Harold W. Kroto, Roger Taylor* and David R. M. Walton**

*The Chemistry Laboratory, CPES School, University of Sussex, Brighton, UK BN1 9QJ*

**On exposure to air, both $C_{60}Ph_5H$ and $C_{60}Ph_5Cl$ spontaneously oxidise with elimination of the hydrogen or chlorine attached to the cage and the *ortho* hydrogen of the adjacent phenyl group, giving a benzo[*b*]furanyl[60]fullerene; a second oxygen is located in the pentagon that is surrounded by phenyl groups.**

Various fused five-membered heterocyclic derivatives of fullerenes, each prepared by [3 + 2] cycloaddition reactions, have been described. The parent heterocyclic rings (or derivatives thereof) are pyrrole,[1] pyrazole,[2] triazole,[3] isoxazole,[4] oxazole,[5] isothiazole,[6] disilolane,[7] azirine[8] and furan;[9] a bis(fullerene) derivative of furan has also been described.[10] We now report the formation of a benzo[*b*]furan derivative (Fig. 1) *via* an entirely different route, involving spontaneous oxidation.

Pure $C_{60}Ph_5H$ was prepared as described previously.[11] A sample which had been in air for *ca*. one year was found to have changed colour from bright red to orange–brown. A minor component (*ca*. 10%), soluble only in acetone, contained C=O and OH groups (IR) but could not be identified further. Analysis of the remainder by HPLC (4.6 mm × 25 cm Cosmosil Buckyprep column, 1 : 1 toluene–hexane eluent at 0.25 ml $min^{-1}$) showed it to consist of two new compounds of 1060 and 1136 amu (respective retention times 46.8 and 35.8 min *cf*. 29.7 min for $C_{60}Ph_5H$). The 1060 amu species (*ca*. 30%) is unsymmetrical $C_{60}Ph_4O_2$, which fragments during EI mass spectrometry to $C_{60}Ph_n$ ($n$ = 0–4) and $C_{58}Ph_n$ ($n$ = 0–4) species, the latter arising from 2 × CO loss.[12] The structure of the 1136 amu species (*ca*. 60%) is described below, but it can also be produced by an alternative and more rapid route, involving easier purification. In this, a benzene solution of $C_{60}Ph_5Cl$ (87 mg) was exposed to sunlight for two weeks, whence all of the reagent was consumed. Chromatography ($SiO_2$, $CCl_4$) of a $CCl_4$ solution of the product gave a small quantity of orange material. Elution with toluene produced the orange–red 1136 amu species ($R_f$ = 0.57, 30 mg, 34%, needles from $CCl_4$). An OH-containing product co-eluted with a small amount of this, and there was a considerable amount of unidentified residue on the column which was removed with $CH_2Cl_2$–MeOH (9 : 1).

The EI mass spectrum (Fig. 2) of the 1136 amu species showed reproducible fragmentation involving successive loss of 16 and 14 amu species. The 16 amu fragment is clearly

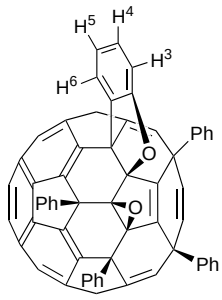

**Fig. 1** The proposed structure of $C_{60}Ph_4C_6H_4O_2$; the second oxygen probably forms an epoxide across one bond of the central pentagon, thereby introducing the required asymmetry

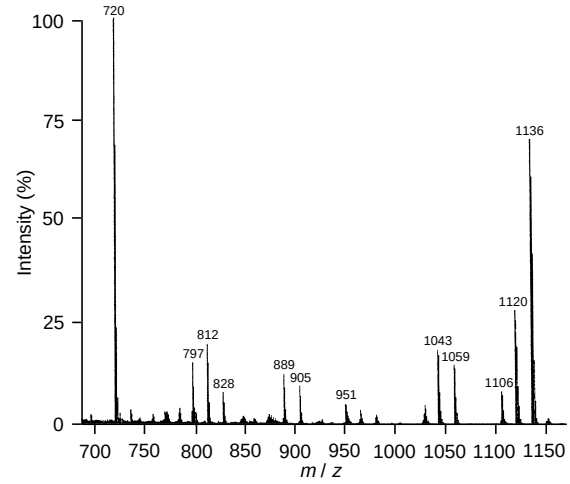

**Fig. 2** EI mass spectrum (70 eV) for $C_{60}Ph_4C_6H_4O_2$

oxygen; the 14 amu loss was shown by $^1$H NMR analysis not to be due to a methylene species. There remained the possibility that in the structure two hydrogens had been replaced by an oxygen bridge either between two *ortho* positions of adjacent phenyl groups, or between one *ortho* position and the hydrogen on the cage (in the derivation from $C_{60}Ph_5H$). The latter conjecture was proven by the $^1$H NMR spectrum (Fig. 3) with 2D-COSY analysis, and by $^{13}$C NMR spectroscopy. (In the derivation from $C_{60}Ph_5Cl$, the second oxygen replaces one *ortho* hydrogen and the chlorine on the cage.)

The *ortho*, *meta* and *para* hydrogens of four of the phenyl rings (designated A, B, C, and D) are indicated on the spectrum (Fig. 3). The spread of resonances between the positions of the rings is greater, the more downfield the signal for the *ortho*-hydrogen as noted previously for phenylated fullerenes. There

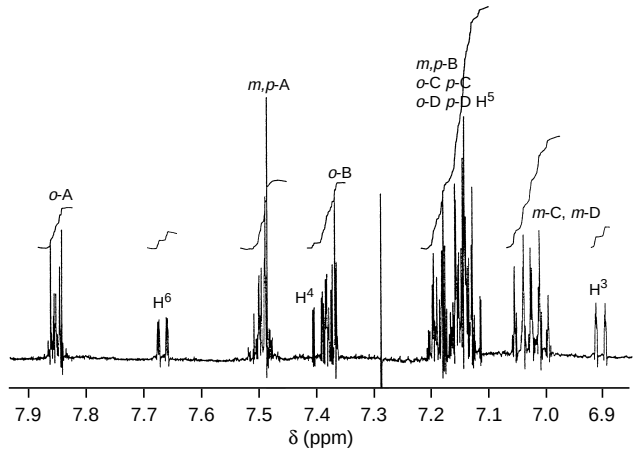

**Fig. 3** $^1$H NMR spectrum for $C_{60}Ph_4C_6H_4O_2$

are only four hydrogens present in the fifth ring and these appear at $\delta$ 7.66 (dd, *J* 7.5 and 1.3 Hz), 7.40 (dd, *J* 7.75 and 1.15 Hz), 7.12 (dd, *J* 7.40 and 1.0 Hz) and 6.90 (dt, *J* 8.12 and 0.8 Hz). These peaks are assigned (2D-COSY) to $H^6$, $H^4$, $H^5$ and $H^3$ respectively; the most downfield resonance is attributed to $H^6$, *cf.* the spectrum of 2-methylanisole.[13] Since the structure is unsymmetrical, it is probable that the remaining oxygen forms an epoxide across one of the double bonds in the pentagon at the epicentre of the phenyl groups, thereby reducing strain in this ring. One might *a priori* then expect to observe the attachment of a second oxygen across the remaining double bond in this pentagon, but this will be unfavourable due to p-orbital repulsions arising from the adjacent oxygens. This conjecture is not discounted by the indication that diepoxide formation occurs across the 1,2- and 3,4-positions of a six-membered ring (in an iridium derivative)[14] because here the greater ring size places the oxygens substantially further apart.

The 2D analysis shows that the 1,4 relationship of the four phenyl groups is D→A→C→B, but the positions relative to the epoxide in the pentagonal ring of the cage are uncertain.

The proposed structure requires that eight resonances be observed in the $sp^3$ region of the $^{13}C$ NMR spectrum. These are found at $\delta_C$ 55.86, 55.87, 58.77, 58.80, 60.24, 74.98, 81.30,and 94.49 (all 1 C). The latter two resonances can be assigned to the epoxide carbons, since reported $\delta$ values for fullerene epoxides are $\delta$ 90.18 for $C_{60}O$,[15] and 85.78 (5,6-isomer) and 92.42, 90.99 (1,2-isomer) for $C_{70}O$;[16] the resonance at $\delta$ 74.98 probably refers to the other cage carbon that bears oxygen, and that at $\delta$ 60.24 to the carbon bearing the unique aryl group. The remaining four resonances occur as two pairs, consistent with the structure.

The structure requires 52 peaks in the $sp^2$ region and these are found (all 1 C except for indicated coincidences) at $\delta_C$ 152.81, 151.44, 150.86, 150.00, 148.94, 148.92, 148.89 (2 C), 148.86, 148.73, 148.68, 148.66, 148.59, 148.53, 148.45, 148.41, 148.33, 148.27, 147.97, 147.86 (3 C), 147.81, 147.80, 147.68, 147.67, 147.60, 147.58, 145.27, 144.83, 144.75, 144.66, 144.60, 144.47, 144.46, 144.44, 144.16, 144.13, 144.09, 144.03, 143.96, 143.90, 143.86, 143.77, 143.74, 143.69, 143.62, 143.44, 143.33, 143.29, 142.63, 142.42. It requires eight pairs of resonances of 2 C intensity due to the *ortho* and *meta* carbons of the four phenyl rings, and these (confirmed by proton decoupling) occur at $\delta_C$ 129.40, 129.08, 128.92, 128.51, 128.33, 128.22, 128.18 and 128.15. The fourteen remaining 1 C resonances for the other carbons of the aryl rings occur at $\delta_C$ 157.91 (*C*–O, *cf.* 159.8 for the *ipso* carbon in anisole[17]), 138.50, 138.36, 137.25, 136.73, 130.57, 128.46, 127.74, 127.71, 127.63, 125.84, 124.59, 122.47 and 110.76.

The mechanism involved in the reactions is unclear, but a rationale can be provided for the formation of the benzo[*b*]fullerene from $C_{60}Ph_5H$. The facile light-catalysed oxidation of hydrofullerenes to fullerenols[18] is a typical alkane oxidation to alkanol which proceeds *via* intermediate formation of a hydroperoxide followed by disproportionation with a second alkane molecule. For $C_{60}Ph_5H$, this disproportionation will be sterically hindered by the adjacent phenyl groups, whereas elimination of water between the hydroperoxide and the *ortho* hydrogen of the adjacent phenyl group is sterically favourable (and also reduces steric interactions between the phenyl groups). Consistent with this explanation is the fact that preformed $C_{60}Ph_5OH$ does not form the benzo[*b*]furan derivative on standing.[19] The epoxidation of one of the double bonds in the second pentagon is a typical fullerene reaction, which may here proceed *via* intermediate formation of an endoperoxide by a standard [2 + 4] cycloaddition involving singlet oxygen (readily produced by fullerenes) as dienophile.[20]

The mechanism for the formation of the same product from the chloro precursor is presently obscure, and we plan to investigate the effect of substituents in the aryl rings upon the reaction rate, in order to clarify the mechanism.

We thank the Royal Society and the EPSRC for support.

**Hollow nanotubes of zirconia as well as of yttria-stabilized zirconia are successfully prepared by first coating the carbon nanotubes appropriately with the oxidic material and then burning off the carbon of the template.**

Preparation of hollow nanotubes of ceramic metal oxides is an important and challenging problem. Hollow nanotubes of silica have been recently prepared by the hydrolysis of tetraethylorthosilicate (TEOS) in a mixture of ethanol, ammonia, water and tartaric acid.[1] We were able to prepare silica nanotubes by calcining acid-treated carbon nanotubes coated with TEOS and then oxidizing the carbon at higher temperatures. The silica comprising the nanotubes was however amorphous. We considered that it would be most rewarding if we could prepare hollow nanotubes of important ceramic oxides. Here we report the first successful preparation of hollow nanotubes of both zirconia and yttria-stabilized zirconia through the use of carbon nanotubes as templates.

The procedure employed by us for preparing zirconia nanotubes is as follows. In a typical preparation, 200 mg of multi-walled carbon nanotubes (prepared by the arc evaporation of graphite[2] and subjected to heat treatment at 973 K in air for 20 min to remove other forms of carbon[3]) were refluxed in nitric acid (16 M) for 12 h to create acidic sites on the surface.[4,5] The acid-treated carbon nanotubes were reacted with 2 ml of $Zr(OPr^n)_4$ in an argon atmosphere, sonicated for 2 min and the mixture was stored in a desiccator for 48 h. The product was then washed with dilute HF (48%) followed by dry methanol, to remove the excess alkoxide, followed by drying at 373 K and calcination at 723 K in air for 12 h. This procedure yielded zirconia-coated carbon nanotubes. Fig. 1(*a*) shows a typical scanning electron microscope (SEM) image of carbon nanotubes coated with $ZrO_2$ in this manner. A transmission electron microscope (TEM) image of a zirconia-coated nanotube is shown in Fig. 1(*c*). The $ZrO_2$-coated carbon nanotubes were heated at 973 K in air for 48 h to oxidize the carbon. Thermogravimetry indicated that the carbon is oxidized around 973 K. By this means, we could obtain pure zirconia nanotubes as revealed in the SEM and TEM images of Fig. 2(*a*) and (*b*), respectively. The tube diameter is generally *ca*. 40 nm and the wall thickness is *ca.* 6 nm. The hollow nature of the nanotubes is clearly indicated by the TEM image. Electron and X-ray diffraction patterns showed the material to be composed of a 50 : 50 mixture of monoclinic and tetragonal phases. Heating to

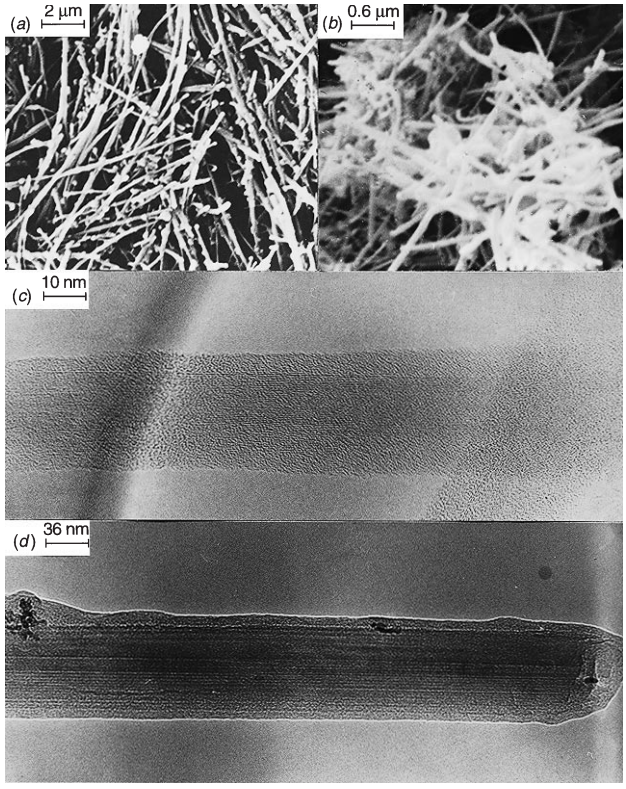

**Fig. 1** (*a*) SEM image of zirconia-coated carbon nanotubes, (*b*) SEM image of carbon nanotubes coated with stabilized zirconia, (*c*) TEM image of a zirconia-coated carbon nanotube and (*d*) TEM image of a carbon nanotube coated with stabilized zirconia

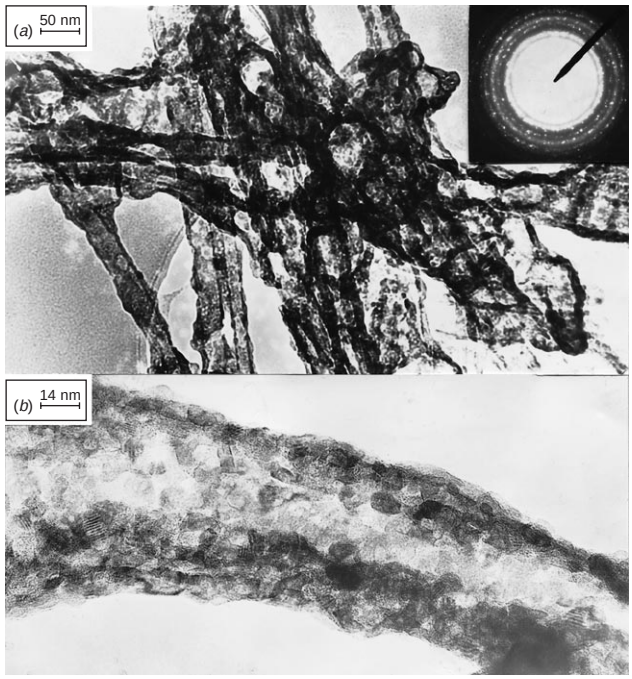

**Fig. 3** TEM images showing hollow nanotubes of stabilized zirconia. The electron diffraction pattern is shown in the inset.

high temperatures to obtain monophasic nanotubes resulted in the collapse of the nanotubes, because of the first-order nature of the monoclinic–tetragonal transformation.[6] Since this would not be a problem with stabilized zirconia, we proceeded to prepare the nanotubes of yttria-stabilized zirconia (0.92 $ZrO_2$–0.08 $Y_2O_3$) by a similar procedure.

In order to prepare the nanotubes of yttria-stabilized zirconia, 1.5 g of $ZrOCl_2 \cdot 8H_2O$ was dissolved in 10 ml of distilled water, to which 3 ml of a solution of 0.1 g of $Y_2O_3$ in 16 M $HNO_3$ was added. After cooling the solution to 273 K, the pH of solution was adjusted to 9 by the addition of ammonia, to obtain a gel. The gel was washed thoroughly with distilled water and dissolved in $HNO_3$ (1 M). 300 mg of acid-treated carbon nanotubes were stirred with this solution for 24 h. The solvent was slowly evaporated in a hot air oven, the product dried at 373 K for 12 h and then calcined at 723 K in air for 12 h. This procedure yielded carbon nanotubes coated with stabilized zirconia. Thermogravimetry showed that the carbon in the coated tubes is oxidized completely around 970 K in air.

A typical SEM image of carbon nanotubes coated with stabilized zirconia is shown in Fig. 1(*b*) and a TEM image of one such nanotube is shown in Fig. 1(*d*). We have found it desirable to treat the nanotubes coated with stabilized zirconia with ethylene glycol followed by dilute $HNO_3$, before burning off the carbon, in order to stabilize the tubular structure of stabilized zirconia. After oxidizing the carbon at 973 K, we obtained hollow nanotubes of stabilized zirconia. The TEM images in Fig. 3 show the outer diameter to vary between 40 and 50 nm, and the wall thickness to be *ca.* 6 nm. The image in Fig. 3(*b*) shows the lattice fringes of the oxide in some regions. The hollow nature of the nanotubes is also revealed in the images. The electron diffraction and X-ray diffraction patterns showed the material to possess the known cubic structure of stabilized zirconia ($a$ = 5.1164 Å). We believe that such hollow ceramic nanotubes may have several applications. We are now in the process of preparing such ceramic nanotubes starting with single-walled carbon nanotubes.

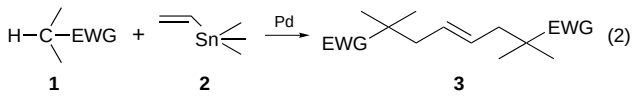
# Palladium catalysed alkylative dimerization between pronucleophiles and vinyltins

**Itaru Nakamura, Naofumi Tsukada, Mohammad Al-Masum and Yoshinori Yamamoto***

*Department of Chemistry, Graduate School of Science, and Research Center for Organic Resources and Materials Chemistry, Institute for Chemical Reaction Science, Tohoku University, Sendai 980-77, Japan*

**In the presence of catalytic amounts of $Pd_2(dba)_3$·$CHCl_3$ and dppb, the reaction of pronucleophiles 1 with vinyltins 2 gives the corresponding alkylative dimerization products of the vinyl group, 1,4-disubstituted butene derivatives 3, in good to high yields.**

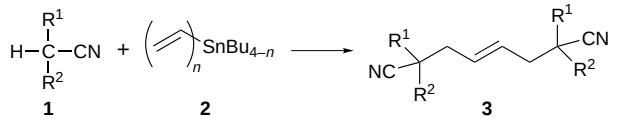


Palladium catalysed addition of carbon pronucleophiles to unactivated C–C double bonds is becoming an important new procedure for C–C bond formation[1–4] [eqn. (1)]. It has been

(1)

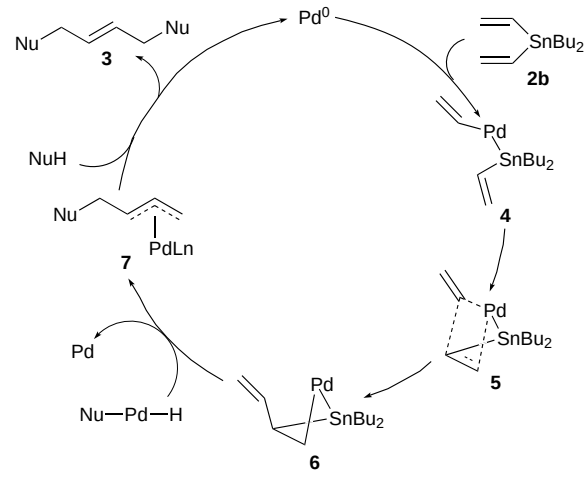
reported that allenes,[2] dienes[3] and enynes[4] can be used as the unactivated olefinic compounds for the pronucleophile addition.

However, until now, it was not known that simple alkenes undergo this type of addition in the presence of palladium catalysts. During this investigation, we have found that the palladium catalysed reaction of vinyltins **2** with certain pronucleophiles **1** gives the corresponding alkylative dimerization products of the vinyl group, 1,4-disubstituted butene derivatives **3** [eqn. (2)].



(2)

The results are summarized in the Table 1. The reaction of ethyl 2-phenyl-2-cyanoacetate **1a** (1 equiv.) with vinyltributyltin **2a** (1 equiv.) in the presence of $Pd_2(dba)_3$·$CHCl_3$ (10 mol%) dppb (20 mol%) in THF at room temperature gave the alkylative dimerization product **3a** in 51% yield (entry 1). Very interestingly, the yield of **3a** increased to 81% using divinyldibutyltin **2b** instead of **2a** (entry 2). The reaction of **1a** (1 equiv.) with **2a** (2 equiv.) produced **3a** in 51% yield, indicating that the increase of the yield in the reaction with **2b** was not due to the presence of two vinyl groups in **2b**. The reaction of **1a** with tetravinyltin **2c** afforded **3a** in 78% yield (entry 3), pointing out that the presence of two vinyl groups in the reagent molecule is enough to enhance the chemical yield. The reaction of phenylmalononitrile **1b** with **2b** produced **3b** in 89% yield (entry 4). To investigate the influence of electronic effect of phenyl substituents upon the product yield, the *para*-substituted arylcyanoacetates **1c**, **1d** and **1e** were treated with **2b** and the corresponding alkylative dimerization products **3c**, **3d** and **3e** were obtained in 75, 71 and 65% yield, respectively (entries 5–7). Therefore, electronic effects did not exert a significant influence upon the product yield. The reaction of isopropylmalononitrile **1f** with **2b** gave **3f** in 43% (entry 8). The *trans* stereochemistry of the products **3** was determined unambiguously by comparison with authentic samples prepared independently.[5] No *cis*-isomers were detected in all reactions. Other pronucleophiles, such as malononitrile, diethyl malonate and diethyl phenylmalonate, did not react with vinyltins **2**. The alkylative dimerization took place with other catalysts such as $Pd(PPh_3)_4$ and $Pd(dba)_2$, but the use of $Pd_2(dba)_3$·$CHCl_3$ gave the best result. The reaction did not proceed at all with $PdCl_2(PPh_3)_2$, $Pd(OAc)_2$, and $Pt(PPh_3)_4$ as catalyst.



The reaction of **1a** with **2b** is representative. A mixture of $Pd_2(dba)_3$·$CHCl_3$ (51.7 mg, 0.05 mmol), dppb (42.6 mg, 0.1 mmol), ethyl 2-phenyl-2-cyanoacetate **1a** (0.09 ml, 0.52 mmol) and divinyldibutyltin **2b** (0.13 ml, 0.51 mmol) in dry THF (3 ml) was stirred under an argon atmosphere at room temperature for 2 days. The reaction was monitored by TLC analysis, and the

**Table 1** Palladium catalysed alkylative dimerization of vinyltins[a]

| Entry | Pronucleophile | | | Vinyltin | | Product | Isolated yield (%) |
|---|---|---|---|---|---|---|---|
| | | $R^1$ | $R^2$ | | *n* | | |
| 1 | **1a** | Ph | $CO_2Et$ | **2a** | 1 | **3a** | 51 |
| 2 | **1a** | Ph | $CO_2Et$ | **2b** | 2 | **3a** | 81 |
| 3 | **1a** | Ph | $CO_2Et$ | **2c** | 4 | **3a** | 78 |
| 4 | **1b** | Ph | CN | **2b** | 2 | **3b** | 89 |

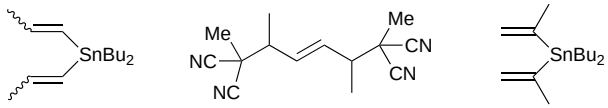
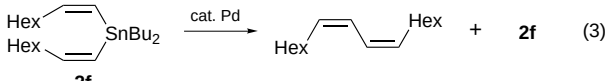
| 8 | **1f** | $Pr^i$ | CN | **2b** | 2 | **3f** | 43 |

[a] The reaction of **1** (0.5 mmol) with **2** (0.5 mmol) was carried out in the presence of $Pd_2(dba)_3$·$CHCl_3$ (10 mol%) and dppb (20 mol%) in THF at room temperature.



**Scheme 1**

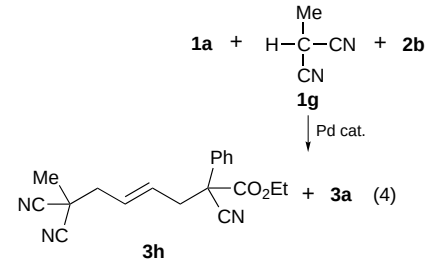
starting materials disappeared after 2 days. The reaction mixture was purified by silica gel flash column chromatography using hexane–ethyl acetate (10 : 1) as eluent, giving the alkylative dimerization product **3a** (88.5 mg, 0.21 mmol) in 81% yield.



A plausible mechanism for this unprecedented alkylative dimerization reaction is shown in Scheme 1, although it is speculative. The oxidative insertion of $Pd^0$ into the carbon–tin bond of **2b** would produce the vinylpalladium intermediate **4**. The intramolecular carbopalladation to the double bond of a vinyl group would afford the allyltin–palladium complex **6** *via* **5**. It is known that the palladium catalysed reaction of allyltin with certain pronucleophiles (NuH) gives the corresponding allylation product ($CH_2$=$CHCH_2$Nu).[6] Accordingly, it is probable that **6** would react with pronucleophiles to give the π-allylpalladium complex **7**. The Trost–Tsuji type reaction of **7** with pronucleophiles (NuH) would give the butene derivatives **3**.

In order to gain an insight into the mechanism for the alkylative dimerization, the reaction of dibutyldiprop-1-enyltin **2d** with methylmalononitrile **1g** was carried out under similar

**2d** **3g** **2e**



conditions as above. The alkylative dimerization product **3g** was obtained as a mixture of diastereoisomers in only 10% yield; the ratio of the diastereomers was not determined. Furthermore, the reaction of dibutyldi(1-methylethenyl)tin **2e** with **1a** did not proceed at all and the starting materials were recovered. Perhaps the carbopalladation step becomes sluggish in the reaction of **2d** (the similar step for **2b** is shown in Scheme 1, from **4** to **6**) because of the steric effect of a β-methyl subsituent, and an α-methyl substituent would stop the carbopalladation step completely, as was observed in the reaction of **2e**. Dibutyldi(*cis*-oct-1-enyl)tin **2f**, which was synthesized in our laboratory by the method reported recently,[7] was treated with $Pd_2(dba)_3$·CHCl (10 mol%) and dppb (20 mol%) in dry THF at room temperature for 1 day, and *cis,cis*-hexadeca-7,9-diene **8** was obtained in 23% yield along with recovered **2f** [eqn. (3)]. This result clearly indicates that the

**2f** 23% 14%

oxidative insertion of $Pd^0$ into the carbon–tin bond of **2f** takes place readily, although it is not clear at present how the stereoselective dimerization of the *cis*-octenyl group proceeds under the reaction conditions.[8] Although the reaction of **8** with pronucleophiles was not investigated, the reaction of certain dienes, such as buta-1,3-diene and 2-methylbuta-1,3-diene, with pronucleophiles (**1a** and **1g**) under the same reaction conditions as above gave only mono-adducts in high yields:[9] no traces of the double addition products **3** were found. This result clearly indicated that the palladium catalysed reaction of vinyltins with pronucleophiles does not form dienes as intermediates.

Finally, the reaction of **2b** in the presence of two different kinds of pronucleophiles was carried out in order to ascertain whether a second pronucleophile (Nu'H) can participate at the stage from **7** to **3** [eqn. (4)]. A mixture of **1g** (0.5 mmol), **2b** (1.0

**3h**

mmol), $Pd_2(dba)_3$·$CHCl_3$ (0.1 mmol) and dppb (0.2 mmol) in dry THF was stirred at room temperature for 30 min and then the second pronucleophile **1a** (0.5 mmol) was added. The mixture was stirred for 2 days. The cross-coupling product **3h** was obtained in 5% yield along with **3a** (50%). Since the reactivity of **1g** is lower than **1a**, the homo-coupling product **3a** was afforded as the major product. There is still room for improvement in order to produce a synthetically useful cross-coupling procedure, but the experimental results suggests that the process shown in **7**→**3** would intervene in the alkylative dimerization.

Although further investigation is needed to establish the mechanism for this unprecedented reaction, the coupling is useful for the synthesis of functionalized but-2-ene derivatives.

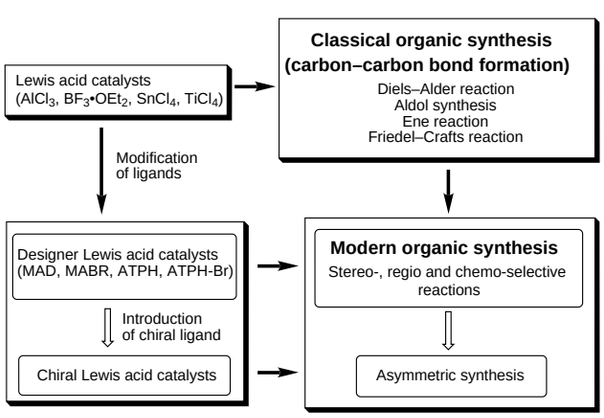
FEATURE ARTICLE

# Designer Lewis acid catalysts—bulky aluminium reagents for selective organic synthesis

**Susumu Saito and Hisashi Yamamoto***



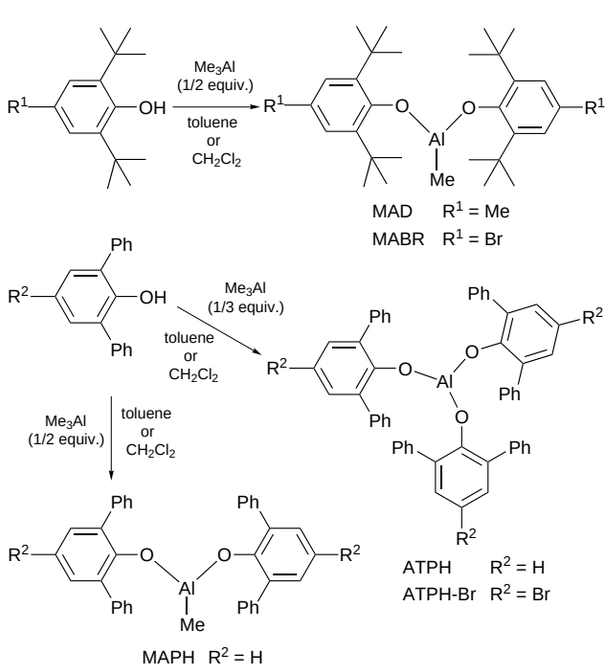
*Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-01, Japan*

**Sterically hindered aluminium aryloxides have been developed as designer Lewis acid catalysts for stereo-, regio- and chemo-selective carbon–carbon bond-forming reactions. Compared with classical Lewis acids, these aluminium reagents coordinate strongly with various oxygen-containing substrates, and this coordination is affected by the steric environment of their ligands. The carbonyl groups of the bound substrates are either electronically activated or sterically deactivated depending on the aluminium reagent used and the type of reaction. Designer chiral catalysts based on the structure of these bulky aluminium reagents have also been examined.**

## Introduction

Lewis acid-promoted carbon–carbon bond-forming reactions are some of the most important processes in organic synthesis. Traditionally, the Friedel–Crafts reaction,[1] the ene reaction,[2] the Diels–Alder reaction[3] and the Mukaiyama aldol synthesis[4] are catalysed by ordinary Lewis acids such as $AlCl_3$, $TiCl_4$, $BF_3$, and $SnCl_4$. These classical Lewis acids activate a wide variety of functional groups and the reactions usually proceed efficiently but with relatively low stereo-, regio- and chemoselectivities. The relatively simple design of ligands for these Lewis acids leads to monomeric Lewis acids in organic solvent and consequently to high Lewis acidity and reactivity. Furthermore, upon coordination with designed ligand(s), the well designed Lewis acid exhibits new selectivity (Scheme 1).

Several bulky aluminium reagents can be prepared from sterically hindered phenols. Most aluminium reagents in solution exist as dimeric, trimeric, or higher oligomeric structures.[5] In contrast, methylaluminium bis(2,6-di-*tert*-butyl-4-methylphenoxide) (MAD)[6] and aluminium tris(2,6-diphenylphenoxide) (ATPH)[7] are monomeric in organic solvents. The Lewis acidity of these reagents decreases with the coordination of more electron-donating aryloxides, but this can be compensated for by loosening of the aggregation. Compared with classical Lewis acids, the steric effect of our aluminium reagents also plays an important role in selective organic synthesis, which is the subject of this article.



**Scheme 1**

## Preparation of various aluminium phenoxides

MAD, ATPH, methylaluminium bis(4-bromo-2,6-di-*tert*-butylphenoxide) (MABR)[8] and methylaluminium bis(2,6-diphenylphenoxide) (MAPH)[9] are readily prepared by treatment of $Me_3Al$ with a corresponding amount of the phenol in toluene (or in $CH_2Cl_2$) at room temperature for 0.5–1 h with rigorous exclusion of air and moisture. These reagents can be used without further purification for all of the reactions described here. The reactivity of a phenol toward $Me_3Al$ largely depends on the steric limitations of the phenol. For example, treatment of 3 equiv. of 2,6-di-*tert*-butyl-4-methylphenol with $Me_3Al$ in $CH_2Cl_2$ at room temperature under argon results in the generation of bis(phenoxide) MAD together with the unreacted phenol. In contrast, 3 equiv. of 2,6-diphenylphenol react completely with 1 equiv. of $Me_3Al$ to produce the tris(phenoxide) ATPH (Scheme 2).

## Structural features of ATPH

The X-ray crystal structure of the *N*,*N*-dimethylformamide (DMF)–ATPH complex[7] disclosed that the three arene rings of ATPH form a propeller-like arrangement around the aluminium centre, and hence ATPH has a cavity with $C_3$ symmetry. By contrast, the X-ray crystal structure of the benzaldehyde–ATPH complex shows that the cavity surrounds the carbonyl substrate upon complexation with slight distortion from $C_3$ symmetry. A

**Scheme 2**

particularly notable structural feature of these aluminium–carbonyl complexes is the Al–O–C angles and Al–O distances (Fig. 1), which clarify that the size and the shape of the cavity changes flexibly depending on the substrates. According to these models, the cavity should be able to differentiate between carbonyl substrates, which, when accepted into the cavity, should exhibit unprecedented reactivity under the steric and electronic environment of the arene rings. $^1$H NMR analysis of the crotonaldehyde–ATPH complex (300 MHz, $CD_2Cl_2$) revealed that the original chemical shifts of the aldehydic proton ($H_a$) at $\delta$ 9.50, and the α- and β-carbon protons ($H_b$ and $H_c$) at $\delta$ 6.13 and 6.89, were significantly shifted upfield to $\delta$ 6.21, 4.92 and 6.40, respectively. The largest $\Delta\delta$ value of $H_a$ of 3.29 suggests that the carbonyl is effectively shielded by the arene rings of the cavity. This observation is in contrast to the resonance frequencies of the crotonaldehyde–$Et_2AlCl$ complex at −60 °C ($H_a$: $\delta$ 9.32; $H_b$: $\delta$ 6.65; $H_c$: $\delta$ 7.84), and those of crotonaldehyde complexes with other ordinary Lewis acids.[10]

**Molecular recognition with bulky aluminium reagents**

The monomeric aluminium phenoxides have sufficient Lewis acidity and thus bind with polar functionalities. The complexation is heavily dependent on the structural features of these functional groups. Thus, functional groups on the outside of a molecule bind to bulky aluminium reagents rather tightly, while functional groups on the inside of a molecule will not form stable complexes. In other words, the steric bulk of aluminium reagents appears to play a crucial role in discriminating between structurally or electronically similar substrates.

*Discrimination of two different ethers*

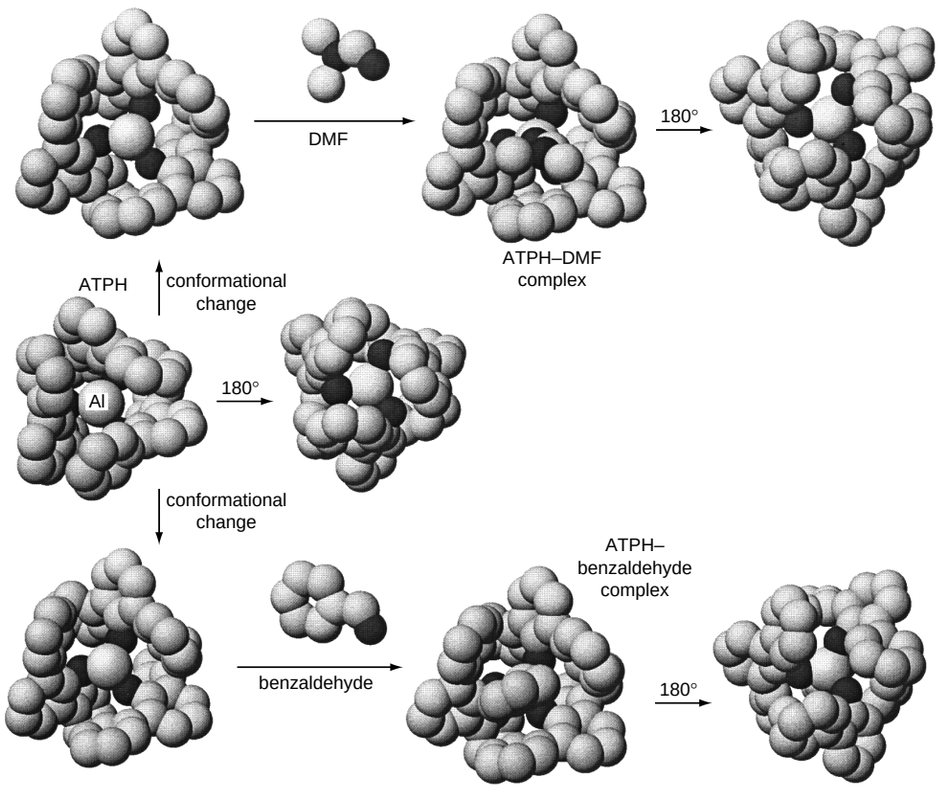
The 125 MHz $^{13}$C NMR spectrum of a mixture of 1 equiv. each of MAD, methyl 3-phenylpropyl ether **1**, and ethyl 3-phenylpropyl ether **2** in $CDCl_3$ (0.4 M solution) at −50 °C (Scheme 3) showed that the original signal of methyl ether **1** at $\delta$ 58.7 shifted downfield to $\delta$ 60.1, whereas the signal of the α-methylene carbon of ethyl ether **2** remained unchanged. This unusual selectivity could not be observed with other Lewis acids as shown below. This method could be extended to the use of a polymeric aluminium aryloxide in complexation chromatography: heteroatom-containing solutes can be separated by complexation with a stationary, insolubilized organoaluminium polymer.[11]

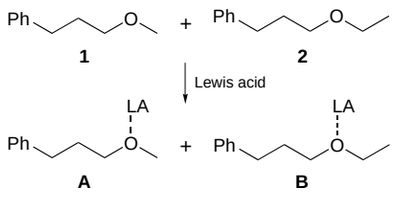
*Discrimination of two different ketones*

Selective reduction of more hindered or electronically less polarizable ketones can be accomplished using MAD as a selective stabilizer of the carbonyls of less hindered or electronically more polarizable ketones.[12] Treatment of 1.0 equiv. each of acetophenone **3** and pivalophenone **4** in $CH_2Cl_2$ with 1.0 equiv of MAD at −78 °C, followed by subsequent addition of diisobutylaluminium hydride (DIBAL-H) at this temperature yielded alcohols **5** and **6** in a ratio of 1 : 10 (Scheme 4). Selective coordination of MAD with **3** was observed by $^{13}$C NMR spectroscopy. These results suggest that the tight binding of MAD with sterically less congested **3** inhibited the attack of DIBAL-H at the carbonyl of **3**.

*Discrimination of two different esters*

Discrimination between two different ester carbonyls can be similarly achieved with MAD.[13] For example, reaction of *tert*-butyl methyl fumarate **7** with 1.1 equiv. of MAD in $CH_2Cl_2$ at −78 °C gave organoaluminium–fumarate complex **8** exclusively (Scheme 5), the structure of which was rigorously established by low-temperature $^{13}$C NMR spectroscopy. Diels–Alder reaction of complex **8** with cyclopentadiene at −78 °C in





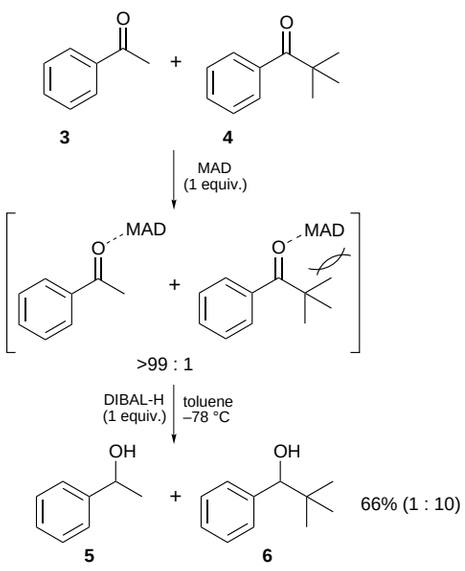


**Fig. 1** Schematic complexation processes of DMF and benzaldehyde with ATPH, and the X-ray crystal structures of the ATPH–DMF and ATPH–benzaldehyde complexes. The protons are omitted for clarity. Front side view [looking down the O($sp^2$)–Al bond] and back side view [180° rotation from the front side view around the axis perpendicular to the O($sp^2$)–Al bond] are shown. Selected distances (Å) and angles (°): ATPH–DMF: Al–O($sp^3$)–C 135.6(8), Al–O($sp^2$)–C 138.1(3), Al–O($sp^3$) 1.711(3), Al–O($sp^2$) 1.795. ATPH-benzaldehyde: Al–O($sp^3$)–C 149.6(5), 136.1(5) and 144.1(5), Al–O($sp^2$)–C 135.7(9), Al–O($sp^3$) 1.694(3), 1.728(5) and 1.709(5), Al–O($sp^2$) 1.856(5).

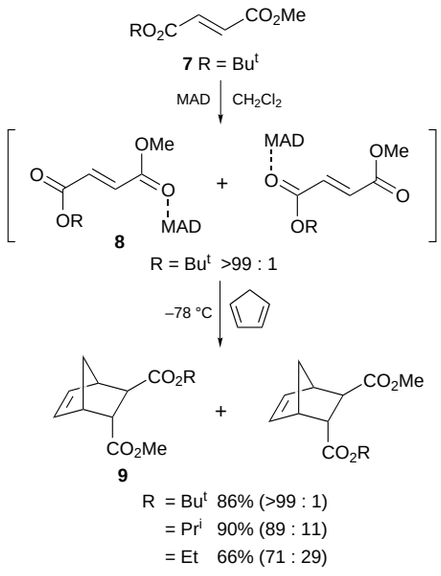
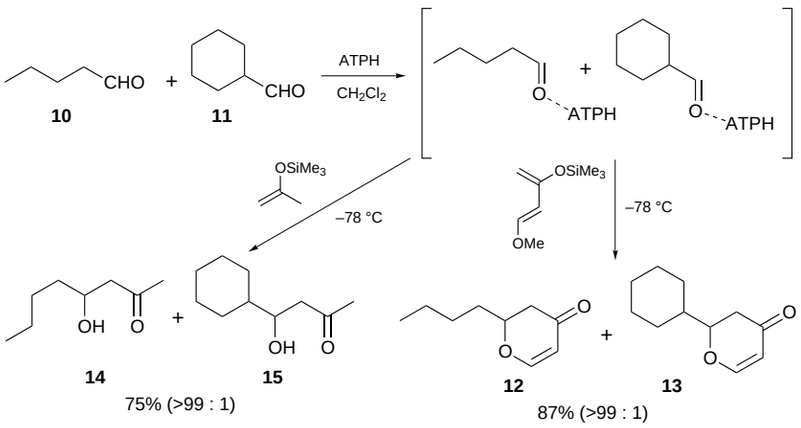
toluene gave, after 1 h, cycloadduct **9**, predominantly with *endo* orientation of the methoxycarbonyl group. Thus, the methyl ester coordinated with the aluminium reagent gave us high *endo*-selectivity of the Diels–Alder reaction. Even methyl and isopropyl or methyl and ethyl can be fairly well discriminated with MAD.

| Lewis acid | **A** : **B** |
|---|---|
| MAD | >99:1 |
| $Bu^i_3Al$ | 4 : 1 |
| $SnCl_4$ | 2 : 1 (ether : Lewis acid = 2:1) |
| $BF_3{\bullet}OEt_2$ | no complexation |
| $BEt_3$ | 5 : 3 |

**Scheme 3**



**Scheme 4**



*Discrimination of two different aldehydes*

ATPH can discriminate between structurally similar aldehydes, thereby facilitating the selective functionalization of the less hindered aldehyde carbonyl.[14] Treatment of an equimolar mixture of valeraldehyde **10** and cyclohexanecarboxaldehyde **11** with 1.1 equiv. of ATPH in $CH_2Cl_2$ at −78 °C, followed by addition of Danishefsky's diene at this temperature, gave hetero-Diels–Alder adducts **12** and **13** in a ratio of >99 : 1 (Scheme 6). It should be noted that only the complexed aldehyde could react with the diene. The reaction gave relatively low chemoselectivity with other typical Lewis acids: [**12** : **13** ratios: $(Pr^iO)_2TiCl_2$ = 6.2 : 1; $Me_3Al$ = 5 : 1; MAD = 3.7 : 1; $TiCl_4$ = 2 : 1; $BF_3{\cdot}OEt_2$ = 1.3 : 1; MAPH = 1 : 3.4]. This fact emphasizes that the cavity of ATPH plays an important role in differentiating between the reactivities of the two different aldehydes. In a similar manner, the aldol reaction of a mixture of **10** and **11** was effected equally well with ATPH to furnish 4-hydroxyoctan-2-one **14** without **15**.

Obviously, the coordinated aldehyde is electronically activated but sterically deactivated with bulky aluminium reagents. The selective functionalization of more sterically hindered aldehydes was accomplished by the combined use of MAPH and alkyllithiums (RLi; R = $Bu^n$ or Ph) (Scheme 7).[15] In this system, MAPH acted as a carbonyl protector of a less hindered aldehyde such as **10**, and therefore the carbanions preferentially

**Scheme 5**

**Scheme 6**

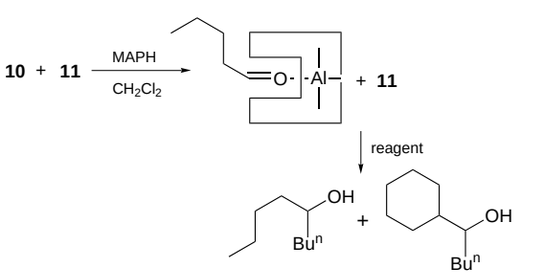
react with more hindered carbonyl groups. It should be noted that alkyllithium reagents could react with aldehydes in the absence of the aluminium reagent.

**Bulky aluminium reagents for selective organic syntheses**

So far we have discussed the discriminating abilities of aluminium reagents. In this section, we will focus on the reactions promoted with bulky aluminium reagents which could not be achieved with ordinary Lewis acid catalysts.

*Conjugate addition to α,β-unsaturated carbonyl compounds*

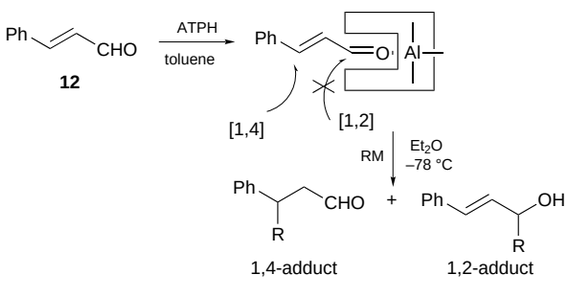
Organocuprates are the most widely used reagents for Michael addition to α,β-unsaturated ketones, one of the most powerful and important carbon–carbon bond-forming reactions. ATPH can be used as a carbonyl protector upon complexation, which facilitates 1,4-addition to even α,β-unsaturated aldehydes,[10] for which 1,4-addition is virtually unexplored. Complexation of cinnamaldehyde **12** with 1.1 equiv. of ATPH in $CH_2Cl_2$ at −78 °C, followed by subsequent addition of 1.5 equiv. of *n*-butylmagnesium bromide ($Bu^nMgBr$), gave the 1,4-addition product preferentially (Scheme 8). The alkylation of **12** with MAD and $Bu^nMgBr$ gave unsatisfactory results (95%; 1,4 : 1,2 adduct ratio = 7 : 93). The combination of MAPH with the same butylating agent gave an equal mixture of 1,4- and 1,2-adducts (98%; ratio = 49 : 51). Replacing organomagnesium reagents with organo-calcium, -strontium and -barium reagents enhanced 1,4-selectivity. One of the advantages of this method over organocopper-mediated conjugate addition is the availability of lithium alkynides and thermally unstable lithium carbenoids as Michael donors. With alkynides, raising the reaction temperature after the Michael addition triggered cyclopropanation to give a sole diastereoisomer (Scheme 9).



Application of this system to α,β-unsaturated ketones gave even more general and pronounced 1,4-selectivity ( > 99 : 1).[16] In this case, various alkyllithiums can be used as Michael donors, and this ATPH–RLi system enables the introduction of perfluoroalkyl or perfluoroaryl substituents at the β-positions of carbonyl functions (Scheme 10).[17]

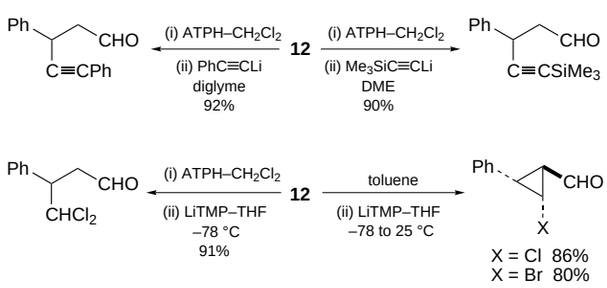
Several ketone lithium enolates and the dianions of β-dicarbonyl substrates similarly undergo highly selective 1,4-addition to various α-enones. Thus, tandem inter- and intramolecular Michael addition using the enolates of α,β-unsaturated ketones as Michael donors[18] was achieved successfully: treatment of **13**–ATPH complex in toluene with a THF solution of the benzylideneacetone lithium enolate at −78 °C, followed by refluxing for 13 h, gave stereochemically homogeneous annulation product **14** in 50% yield ( > 84% de) (Scheme 11).

Michael addition of the dianions derived from β-dicarbonyl compounds facilitated another annulation: Michael addition of a dianion, followed by intramolecular aldol condensation.[19] Complexation of ATPH with *trans*-chalcone **15** in $CH_2Cl_2$ at −78 °C, followed by treatment with the dianion of methyl acetoacetate gave, after quenching with aq. HCl, bicyclic product **16** in high yield (Scheme 12). This system can also be used for elaboration of the bicyclo[3.5.1]undecane ring system in **17**, which can be found in the backbones of terpenoids[20] and the taxol family.[21]



The exceedingly bulky aluminium reagent aluminium tris(2,6-di-*tert*-butyl-4-methylphenoxide) (ATD)[22] was superior to ATPH or MAD as a carbonyl protector in ynones.[23] Initial complexation of oct-3-yn-2-one **18** in toluene with ATD and subsequent addition of a hexane solution of $Bu^nLi$ at −78 °C generated 1,4-adduct **19** in 92% yield together with a small amount of the 1,2-adduct (Scheme 13).

Selective 1,6-addition of alkyllithiums to aromatic carbonyl substrates such as benzaldehyde or acetophenone was achieved with ATPH to give cyclohexadienyl compounds **20** and **21**, respectively (Scheme 14).[24] According to the molecular structure of the benzaldehyde–ATPH complex (Fig. 2), it is



| | |
|---|---|

**Scheme 14**

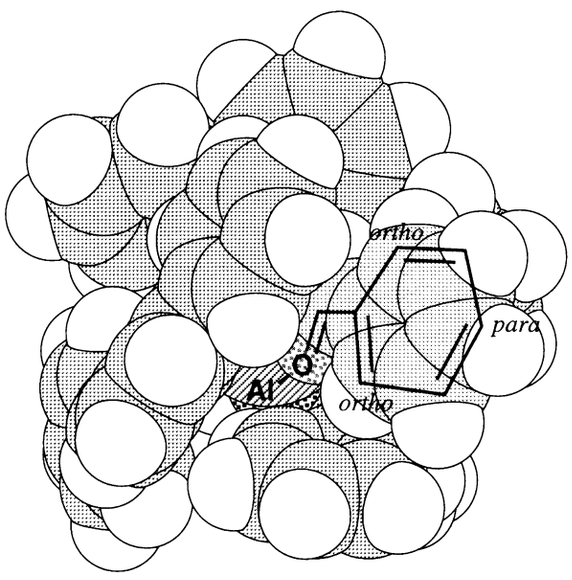

**Fig. 2** X-Ray crystal structure (space-filling model) of the ATPH–benzaldehyde complex, which shows the more facile nucleophilic attack at the *para*-position

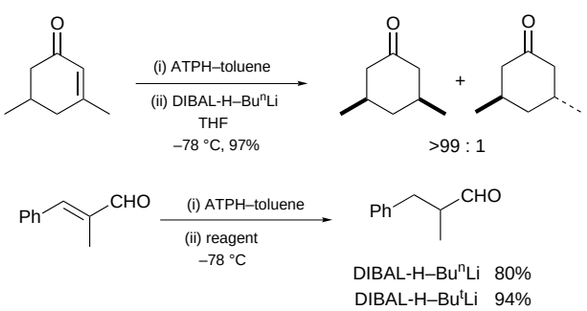
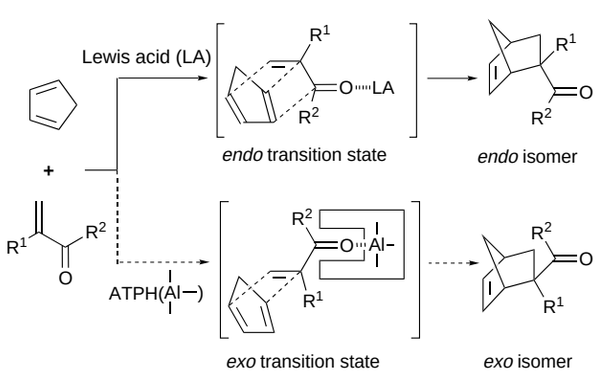


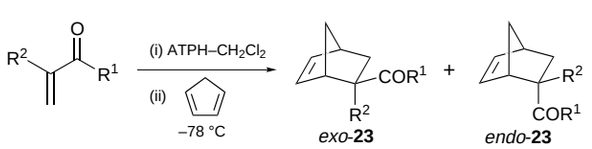
obvious that the *para* position of benzaldehyde is deshielded by the three arene rings, which effectively block the *ortho* position and the carbonyl carbon from nucleophilic attack.

Efficient conjugate reduction of several α,β-unsaturated carbonyl substrates was similarly realized by the combined use of ATPH and diisobutylaluminium hydride–butyllithium 'ate' complex (DIBAL-H–BunLi) as a reducing agent (Scheme 15).[25] Diisobutylaluminium hydride–*tert*-butyllithium (DIBAL-H-ButLi) was more effective for the 1,4-reduction of α,β-unsaturated aldehydes.



*exo-Selective Diels–Alder reaction*

One characteristic stereochemical feature of the Diels–Alder reaction is *endo* selectivity. The origin of the *endo* preference in Diels–Alder reactions can be ascribed to 'secondary orbital interactions'. If the carbonyl functions of dienophilic α,β-unsaturated carbonyl substrates are effectively shielded by complexation with ATPH, secondary interaction is decreased, thereby disfavouring the hitherto preferred *endo* transition state (Scheme 16).



As expected, precomplexation of α,β-unsaturated ketone **22a** with ATPH in $CH_2Cl_2$ at −78 °C, followed by cyclization with cyclopentadiene, resulted in stereochemical reversal to furnish *exo*-**23a** as a major product (Scheme 17). Similarly, the Diels–Alder reaction with other dienophiles **22b,c** complexed with ATPH exhibited *exo* selectivity.[26]

**Scheme 15**

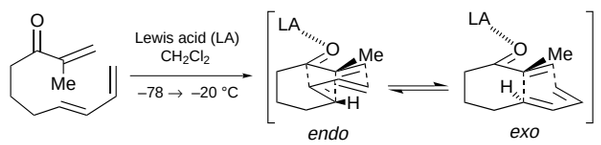
**Scheme 16**

**22a** $R^1$ = Ph, $R^2$ = H **a** 81% (73:27)
**b** $R^1$ = Ph, $R^2$ = Me **b** 81% (96:4)
**c** $R^1$ = $R^2$ = Me **c** 87% (87:13)

**Scheme 17**

This concept was extended intramolecularly to give *trans*-fused stereoisomer **25**, while an ordinary aluminium reagent gave *cis*-isomer **24** *via* an *endo* transition state (Scheme 18).

*Stereoselective and asymmetric Claisen rearrangement*

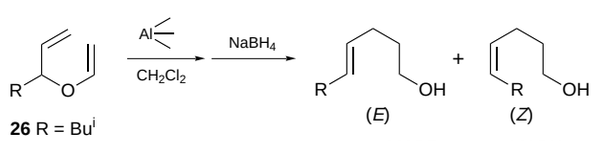


Claisen rearrangement[27] is accelerated significantly with bulky aluminium reagents. With MABR, the rearrangement of 1-substitutedprop-2-enyl vinyl ether derivatives **26**–**28** takes place in a few seconds even at −78 °C to give the (*Z*)-alk-4-enols after reduction with $NaBH_4$ (Scheme 19). When MABR is replaced by MAPH, (*E*)-isomers are formed preferentially.[28] This stereochemical reversal observed with MABR and MAPH can be accounted for by the two possible chair-like transition state structures *ax*-**29** and *eq*-**29**, respectively,[28,29] which are suggested by the absolute configuration of the double bonds and the allylic carbons of the produced aldehydes (Scheme 20).

Optically pure aluminium reagent (*R*)-**30** was synthesized from 1 equiv. each of (*R*)-(+)-3,3′-bis(triarylsilyl)-1,1′-bi-2-naphthol and $Me_3Al$,[30] based on the structure of MAPH. Chiral (*R*)-**30** is an excellent promoter for the asymmetric Claisen rearrangement of allyl vinyl ethers **31** or **32** which possess bulky substituents such as trialkylsilyl or trialkylgermyl groups,[31] but is totally ineffective for sterically less hindered substrates (Scheme 21).

Claisen rearrangement is considered to proceed *via* a six-membered transition state.[27,32] The preferential conformation of the reactant in the transition state might be due to the shape and the size of the cavity of ATPH. This hypothesis can be verified by treatment of 1-butylprop-2-enyl vinyl ether **33** with ATPH at 0 °C to give isomeric rearrangement products (*E*)- and (*Z*)-**34** in 87% yield in a ratio of 16 : 1 (Scheme 22). MAPH-mediated rearrangement of **33** gave fairly good stereoselectivity [(*E*)-**34** : (*Z*)-**34** = 5 : 1].

The effect of the electron-withdrawing group of the ATPH ligands on stereoselectivity and acceleration of the rearrangement was also investigated.[33] The rearrangement of **33** with ATPH-Br proceeded with prominent stereoselectivity [−78 °C, 13 h; (*E*)-**34** : (*Z*)-**34** = > 200 : 1], which suggests that both the cavity and the high Lewis acidity are responsible for the high degree of stereocontrol. The rearrangement of (*E*)-**35** and (*Z*)-**35** with various aluminium reagents indicates that the reaction rate was significantly enhanced with ATPH-Br to give **36** almost quantitatively (Scheme 23).



The catalytic Claisen rearrangement of 1,1-dimethyl-3-phenylprop-2-enyl vinyl ether **37** was achieved with 5–10 mol% of ATPH-Br by taking advantage of its high Lewis acidity

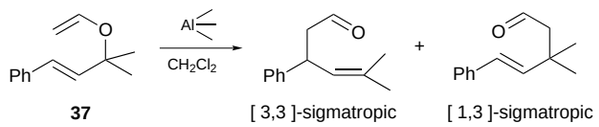
**Scheme 23**

(Scheme 24). MABR was entirely ineffective for the catalytic rearrangement.

Based on the structure of ATPH, an optically active catalyst, aluminium tris[(*R*)-1-(1-naphthyl)-3-phenyl-2-naphthoxide] [(*R*)-ATBN], was synthesized, and was subjected to the asymmetric Claisen rearrangement of (*E*)-**35** and **38**–**40** to give the corresponding aldehydes in moderate enantioselectivities (> 60% ee) (Scheme 25). In contrast, the more elaborated (*R*)-ATBN analogue, aluminium tris[(*R*)-1-(1-naphthyl)-3-(*p*-fluorophenyl)-2-naphthoxide] [(*R*)-ATBN-F], generated products with up to 92% ee. Taking in account the decomposition of (*E*)-**35** which took precedence over the rearrangement with (*R*)-**30**, adequate design of Lewis acid catalysts was proven to be important for the stereoselective and asymmetric Claisen rearrangement.

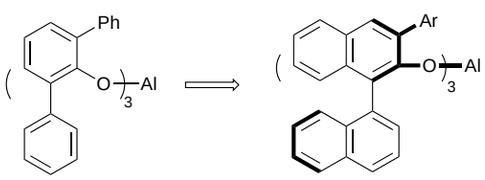


*Selective alkylation at the α-carbon of unsymmetrical ketones*

An unsymmetrical dialkyl ketone can form two regioisomeric enolates upon deprotonation under either kinetic or thermodynamic control. Ideal conditions for the kinetic control of less-substituted enolate formation are those in which deprotonation is irreversible using lithium diisopropylamide (LDA). On the other hand, at equilibrium, the more substituted enolate is the dominant species with moderate selectivity. A hitherto unknown method, *i.e.* the kinetically controlled generation of the more substituted enolate, was realized by the combined use of ATPH and LDA.[34]

Precomplexation of ATPH with 2-methylcyclohexanone **41** at −78 °C in toluene was followed by treatment with LDA in THF, and the mixture was stirred for 1 h (Scheme 26). Subsequent treatment with methyl trifluoromethanesulfonate (MeOTf) furnished 2,2-dimethylcyclohexanone **43** and 2,6-dimethylcyclohexanone **42** in an isolated yield of 53% in a ratio of 32 : 1. Similarly, highly regiocontrolled alkylation of unsymmetrical **44** and **46** with octyl trifluoromethanesulfonate ($C_8H_{17}OTf$) was achieved to give **45** and **47**, respectively (> 99 : 1) (Scheme 27). Replacing ATPH with MAD resulted in a lack of regioselectivity (**42** : **43** = *ca* 1 : 1).

Using *tert*-butyldimethylsilyl trifluoromethanesulfonate ($Bu^tMe_2SiOTf$) in place of alkyl trifluoromethanesulfonates in the present alkylation system produced silyoxybutylated product **48** as a result of THF ring-opening, where alkylation similarly occurred at the more hindered α-carbon of unsymmetrical ketone **41** (Scheme 28).[35]



Generation of the kinetically deprotonated more substituted enolate can be explained in terms of the effect of ATPH on the inherent coordination preference of unsymmetrical ketones. Most likely, the bulky aluminium reagent ATPH prefers coordination with one of the lone pairs *anti* to the more hindered α-carbon of the unsymmetrical ketones. As a consequence, the aluminium reagent surrounds the less hindered site of the carbonyl group, thus obstructing the trajectory of the nucleophilic attack of LDA (Fig. 3).

## Conclusion

The designer Lewis acids described here show several unique characteristics. In particular, these designer Lewis acids can (i) discriminate between structurally and electronically similar oxygen functionalities, (ii) protect the carbonyl groups of α,β-unsaturated carbonyl compounds from nucleophiles (this observation was extended to selective 1,4- and 1,6-additions, as well as new annulation processes), (iii) promote stereoselective Claisen rearrangement, and the chiral catalysts lead to an asymmetric rearrangement, (iv) selectively coordinate with unsymmetrical carbonyl compounds to generate more substituted enolates. The designer Lewis acid catalysts described here are only a few examples of what is possible. Thus, the search for a new and practical designer Lewis acid still remains a challenge in selective organic synthesis.

## Acknowledgments

We are indebted to our co-workers whose names appear in the references. In particular, we gratefully acknowledge the contribution of Professor Keiji Maruoka, who has since moved to Hokkaido University. We appreciate the support of Mr T. Inohara of the Ono Pharmaceutical Company for performing the single crystal X-ray analysis of the benzaldehyde–ATPH complex, and acknowledge the finacial support of the Ministry of Education, Science, and Culture of Japan.

**Susumu Saito, born in 1969, was educated at the Department of Applied Chemistry, Nagoya University, between 1991 and 1995 under the supervision of Professor H. Yamamoto. He has been a Research Associate in organic chemistry at the Graduate School of Engineering, Nagoya University, since 1995.**

**Professor Hisashi Yamamoto received his bachelor's degree from Kyoto University in 1967 under Professor H. Nozaki, and he attended Harvard University for his PhD studies under the direction of Professor E. J. Corey. His first academic position was as Instructor and then Lecturer at Kyoto University, and in 1977 he became Associate Professor of chemistry at the University of Hawaii. In 1980, he became an Associate Professor at Nagoya University and became Professor there in 1983. He was recipient of the Chemical Society of Japan Award in 1995.**

**The new mononuclear complex [(DEAS-bpy)Re(CO)$_3$(BPP)]$^+$ is prepared {DEAS-bpy = 4,4′-bis[*p*-(diethylamino)-α-styryl]-2,2′-bipyridine, BPP = 1,10-bis(4-pyridyl)-3,8-dimethyl-1,3,5,7,9-decapentaene} in which electrochemical and photophysical properties clearly indicate the presence of a long-lived charge-separated excited state at room temperature upon light excitation.**

Photoinduced charge separation is a pivotal process in natural photosynthesis. Archetypal examples of artificial systems include porphyrin triads and polypyridyl complexes of d$^6$ transition-metal complexes.[1–10] The rhenium(I) tricarbonyl complexes appear particularly interesting not only for their photophysical properties, but also because it is quite easy to synthesize species containing two different ligands connected to the same *fac*-Re$^I$(CO)$_3$ core.

We have now prepared the new mononuclear *fac*-[(DEAS-bpy)Re(CO)$_3$(BPP)]CF$_3$SO$_3$ complex **2** starting from *fac*-[(DEAS-bpy)Re(CO)$_3$Cl],[11] **1**, by introducing the electron-

[(DEAS-bpy)Re(CO)$_3$(BPP)]$^+$ **2**

acceptor BPP ligand in the axial position.† The simultaneous coordination of BPP and DEAS-bpy on the same metal center gives rise to a very interesting donor–acceptor complex, which forms a long-lived charge-separated state upon light excitation.

Table 1 collects the electrochemical, absorption, and luminescence data of **1** and **2**, and of the free DEAS-bpy and BPP ligands. Electrochemical characterization of complex **2** indicates that the first reduction process occurs at −0.88 V. This process can be assigned to BPP reduction by comparison with the reduction potentials of the two free DEAS-bpy and BPP ligands. The first oxidation process observed for complex **2** (+0.75 V) is bielectronic and irreversible, indicating that this process involves DEAS-bpy amine oxidation as indeed found in the free DEAS-bpy ligand (bielectronic irreversible wave at +0.66 V). On the other hand, it is known that the coordinated bpy unit is oxidized only at very high potential ($E$ > 2 V),[13] and oxidation of the free ligand BPP features a monoelectronic process at +1.00 V.

Fig. 1 illustrates absorption and emission spectra of complexes **1** and **2**. The photophysical properties of **2** in a rigid matrix at 77 K are very similar to those shown by **1**. Indeed, the two complexes show emission spectra almost identical in position and shape, and with similar lifetime values (Table 1). As in **1** the 77 K emission is known to originate from a DEAS-

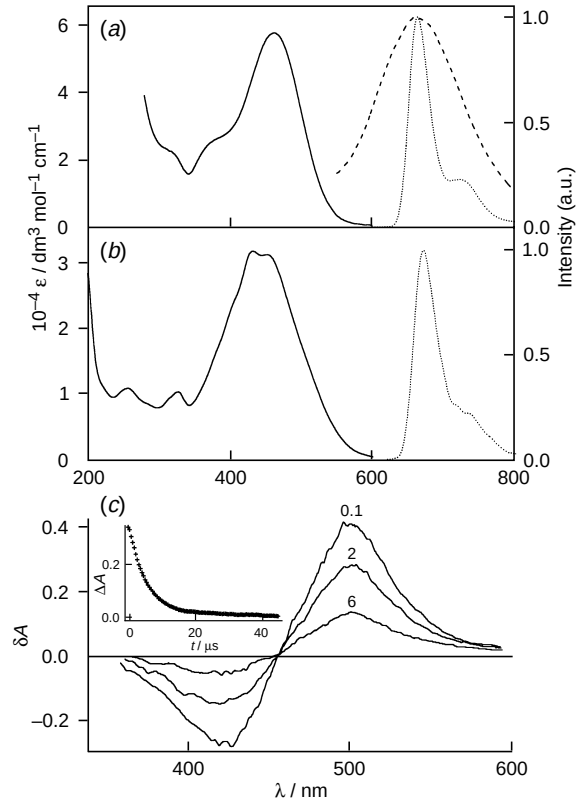

**Fig. 1** Absorption spectrum (——), and uncorrected luminescence spectra at room temp. (- - - -) and at 77 K (dotted line) for complexes **1** (*a*) and **2** (*b*); solvents are DMF at room temperature and DMF–$CH_2Cl_2$ (9 : 1 v/v) at 77 K for **1**; for complex **2** acetonitrile and methanol–ethanol (4 : 1 v/v) were used at 293 and 77 K, respectively. (*c*) Transient absorption spectra at room temp. in deaerated acetonitrile solution for **2**. $\lambda_{exc}$ 355 nm. The spectra were acquired with a delay of 0.1, 2 or 6 μs after the pulse, and a width of 0.5 μs. Inset: decay of the transient signal, monitored at 510 nm.

bpy ligand centered (LC) phosphorescence emission, the same should hold also for **2**. The photophysical properties at room temp. in fluid solution are, on the contrary, completely different. Complex **1** features an emission band again due to a DEAS-bpy LC phosphorescence emission, whereas **2** does not show any luminescence emission.‡

Further experiments at room temp. showed that in **2** a transient species is formed following laser flash excitation in deaerated acetonitrile (Fig. 1). An absorption band with $\lambda_{max}$ *ca.* 520 nm is observed arising from the new transient species formed, together with the bleaching of the ground-state absorption around 430 nm. The kinetic of the back reaction to the ground state was followed both at 510 nm (decay of the transient species) and at 430 nm (ground state recovery), obtaining in both cases a good first-order fit, with the same kinetic constant within experimental error ($k = 0.23 \times 10^6$ s$^{-1}$). No sign of decomposition was observed.

In an additional experiment, absorption of the triplet state of the free BPP ligand was measured populating it by energy transfer using anthracene as the triplet donor. The spectrum measured 2 μs after the excitation pulse features a single absorption band at 640 nm. This excludes that the transient spectrum observed in complex **2** may arise from triplet energy transfer to the BPP subunit.

The photophysical behavior of complex **2** can be rationalized by considering the energy position of the relevant states that can be reached after light excitation.

At room temp., the energy of the DEAS-bpy LC phosphorescence can be taken from the 77 K emission (corresponding to $E = 1.83$ eV), by considering that the energy of a LC state is essentially temperature independent. Electrochemical data (Table 1) indicate that the simultaneous presence of DEAS-bpy and BPP modules, which are both electroactive units, gives rise to a redox-separated state, corresponding to BPP reduction and DEAS-bpy oxidation, with $E = 0.88 + 0.75 = 1.63$ eV. Given the relative energy position of these two states, at room temp., **2** is not emissive because of the presence of this redox-separated state as the lowest excited state, thus deactivating the LC state. The transient observed for complex **2** in laser flash experiments is assigned to this redox-separated species.

At 77 K, complex **2** features emission from the lowest-lying LC state, as the level corresponding to the charge-separated state moves to higher energy. Indeed it is known that in rigid media, charge-separated states are normally trapped in a non-equilibrium condition, so that their energy content is higher with respect to the room temp. situation.[14]

The simultaneous coordination of the bidentate DEAS-bpy and the monodentate BPP ligands to a *fac*-$Re^I(CO)_3$ center leads to a donor–acceptor complex which at room temp. gives rise to a 4.3 μs charge-separated state upon light excitation. It is worth noting that this charge-separated state is noticeably long-lived compared to those observed in other donor–acceptor complexes in homogeneous solution.[4,5,9,10] The slowness of the intramolecular back-electron-transfer reaction to the ground state can be justified by considering that its energy content (1.63 eV) places it in the so called 'Marcus inverted region'.[15]

† Complex **2** has been prepared by reacting **1** with $AgCF_3SO_3$ followed by subsequent addition of the BPP ligand. The deep-red crude product was then purified by chromatography and recrystallization. Elemental analysis, IR, NMR, and $FAB^+$ spectra were performed with satisfactory results.

‡ Note that, whereas MLCT states are usually important to determine the spectroscopic properties of $Re^I(CO)_3$ complexes, in **1** and **2** the behavior is dominated by LC states.

# Reduction of $Ge(Cl)C_6H_3mes_2$-2,6 to give the cyclotrigermenyl radical $(GeC_6H_3mes_2\text{-}2,6)_3^{\cdot}$ and the trigermenyl anion salt $K(GeC_6H_3mes_2\text{-}2,6)_3$

**Marilyn M. Olmstead, Lihung Pu, Richard S. Simons and Philip P. Power***

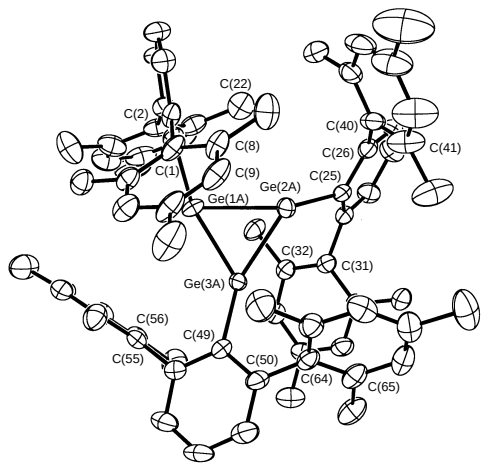
*Department of Chemistry, University of California, Davis, California 95616, USA*

**Treatment of $Ge(Cl)C_6H_3mes_2$-2,6 1 with 1 equiv. of $KC_8$ furnishes the new cyclotrigermenyl radical $(GeC_6H_3mes_2\text{-}2,6)_3^{\cdot}$, 2) which is characterized by EPR and X-ray crystallography; reduction with a further equivalent of $KC_8$ gives the new trigermenyl allyl anion analogue $K(GeC_6H_3mes_2\text{-}2,6)_3$ which has an open $Ge_3$ framework with a wide Ge–Ge–Ge angle of 159.19(10)° at the central Ge and a Ge–Ge distance of 2.422(2) Å.**

Recent reports have shown that sterically crowding ligands with terphenyl substituents can stabilize coordination and bonding not readily observed with other ligands. Prominent examples include low-coordinate metal thiolates such as the monomeric $Fe(SC_6H_3mes_2\text{-}2,6)_2$[1] (mes = $C_6H_2Me_3$-2,4,6), the formally aromatic cyclotrigallane $M_3(GaC_6H_3mes_2\text{-}2,6)_3$ (M = Na[2a] or K[2b]), or the germylyne complex $(\eta^5\text{-}C_5H_5)(CO)_2MoGeC_6H_3mes_2$-2,6 featuring a MoGe triple bond.[3] The synthesis of the latter species by the reaction of $Na[Mo(\eta^5\text{-}C_5H_5)(CO)_3]$[4] with $Ge(Cl)C_6H_3mes_2$-2,6, **1**,[5] has prompted further investigation of the chemistry of the $Ge(Cl)C_6H_3mes_2$-2,6 species. Here, its reduction to form either the neutral radical $(GeC_6H_3mes_2\text{-}2,6)_3^{\cdot}$, which has a three-membered $Ge_3$ ring, or the salt $K(GeC_6H_3mes_2\text{-}2,6)_3$, with an open $Ge_3$ core structure, is described.

Treatment of $Ge(Cl)C_6H_3mes_2$-2,6, **1**,[5] with slightly less than 1 equiv. of $KC_8$[6] affords the radical $(GeC_6H_3mes_2\text{-}2,6)_3^{\cdot}$ **2**, as dark blue crystals in moderate yield.† In a similar manner, the addition of excess $KC_8$ (2 equiv. per germanium) gives the anionic trigermanium species $(GeC_6H_3mes_2\text{-}2,6)_3^-$ as its potassium salt $K(GeC_6H_3mes_2\text{-}2,6)$, **3**, which was isolated as dark green crystals.

The structures of both **2** and **3** have been determined by X-ray crystallography.‡ The data for **2** showed that it crystallizes as crystallographically independent trimeric units which feature a cyclic triangular arrangement of three germaniums (Fig. 1) in which the average Ge–Ge distance is 2.35(7) Å. Unfortunately, the structure displayed disorder problems involving the important core atoms, which adopt a number of slightly different positions such that several plausible $Ge_3$ triangular arrays are possible which leave the organic ligand atoms unmoved. Nonetheless, the structure could be refined to an overall residual ($R_1$) value of 0.064. The presence of a disordered core unit is consistent with the formulation of **2** as a substituted cyclogermenyl radical (*i.e.* a germanium analogue of a cyclopropenyl radical). In valence bond terms, the ring in such a species is expected to involve a double bond between two members with the unpaired electron located on the remaining atom. Thus, three orientations (**A**, **B**, **C**) may be written since each germanium bears the same $C_6H_3mes_2$-2,6 substituent.



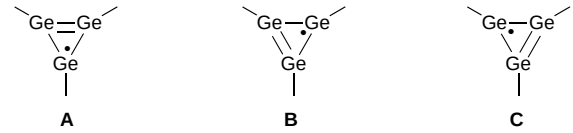


**Fig. 1** Crystal strucutre of **2** featuring one possible arrangmeent of the $Ge_3$ core. The average Ge–Ge distance is 2.35(7) Å.

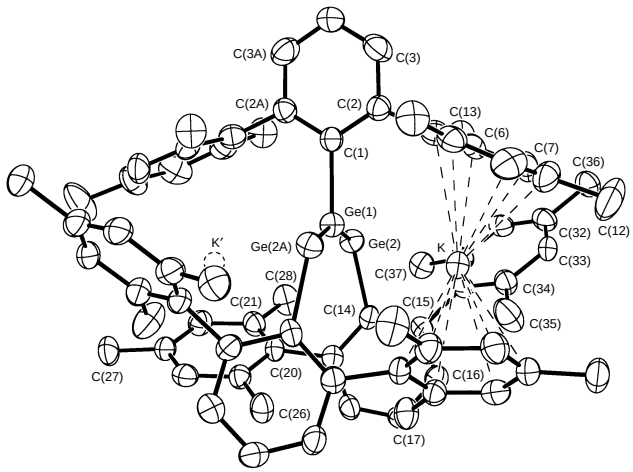
The EPR spectrum of **2** in hexane solution at room temp. displays a major signal with $g$ = 2.0069 and has a hyperfine coupling to a single $^{73}Ge$ ($I$ = 9/2, 7.8% natural abundance) nucleus. The relative intensity of the hyperfine lines in the EPR spectrum is consistent with the location of the unpaired electron on one germanium atom. The π-molecular orbital picture of the ring features a molecular orbital of a symmetry occupied by a pair of electrons and the doubly degenerate e antibonding level occupied by the unpaired electron. The relatively low hyperfine coupling, a ($^{73}Ge$) = 16 G, is consistent with the location of the unpaired electron in an orbital of π-symmetry indicating planar or near-planar geometry at the germanium center.

Treatment of **1** with 2 equiv. of $KC_8$[6] affords the anionic species **3** (Fig. 2) as its potassium salt. Apparently, the addition of a further electron to **2** results in the opening of the $Ge_3$ ring to afford a trigermenyl analogue of the allyl anion (Scheme 1).

The structure of **3** is characterized by a two-fold rotation axis of symmetry along the C(1)–Ge(1) axis implying planar geometry at Ge(1). The torsion angle between the C(1) ring and the coordination plane at Ge(1) is 81.2°. The potassium countercation is complexed in a π fashion by the C(5) (K–centroid 2.68 Å) and C(20) (K–centroid 2.84 Å) mesityl rings and occupies the two possible coordination sites with equal probability (*i.e.* 50% occupancy of each site). The complexing mesityl rings form a bent sandwich structure at the $K^+$ ion which also interacts very closely with a methyl group [$K^+\cdots C(35)$ 2.81Å] from the C(29) methyl ring. The $K^+\cdots\pi$-interactions are at the lower end of the range previously observed [*cf.* K–C range 3.142(5)–3.253(4) Å and K–centroid of 2.87 Å in (pmdeta)(thf)$KCPh_3$;[7] K–C 3.167(2)–3.288(2) Å in {(pmdeta)$KCH_2Ph_\infty$}.[8]]. The $Ge_3$ array is characterized by a wide Ge(2)–Ge(1)–Ge(2a) angle of 159.19(10) Å and a Ge(1)–Ge(2) distance of 2.422(2) Å. The Ge(1)–C(1) and Ge(2)–C(14) distances are 2.048(14) and 2.022(10) Å. In addition, the Ge(1)–Ge(2)–C(14) angle is



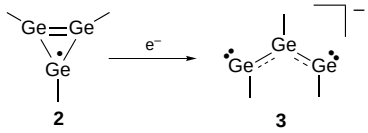


**Fig. 2** Crystal structure of **3**. The 50% $K^+$ occupancy of each site is indicated by displaying only one set of $K^+$ mesityl interactions. Some important bond distances (Å) and angles (°) are: Ge(1)–Ge(2) 2.422(2), Ge(2)–Ge(1)–Ge(2A) 159.19(10), Ge(1)–Ge(2)–C(14) 111.3(3). Further data are given in the text.

**Scheme 1**

111.3(3)° and there is a torsion angle of 20.6° in the C(14)–Ge(2)···Ge(2a)–C(14a) array. These geometrical features are consistent with the description of the $(GeC_6H_3mes_2\text{-}2,6)_3^-$ ion as an allyl anion analogue in which the (*Z*-oriented) lone pairs of the two outer germaniums behave as phantom ligands.

In many respects the structures of **2** and **3** complement that of the recently reported cyclotrigermenium cation $[GeSiBu^t_3]_3^+$ **4**[9] which has a formally aromatic 2π-electron system with an average Ge–Ge bond distance of 2.326(4) Å, *cf*. Ge–Ge double bond distance of 2.239(4) Å in the $Ge_3$ ring species *c*-$[\{GeSiBu^t_3\}_2\{Ge(SiBu^t_3)_2\}]$.[10] The addition of a further electron may afford a neutral cyclotrigermenyl radical species exemplified by **2**, which contains an unpaired electron in a doubly degenerate antibonding π orbital. The average Ge–Ge bond length observed in **2** is 2.327(12) Å which is very similar to that in **4** and *ca*. 0.1 Å shorter than a normal Ge–Ge single bond, 2.44 Å.[11] However, the large standard deviations in the structural parameters of **2**, as well as the different type of substituent, make such a comparison of limited value. Further reduction of **2** affords **3**. Presumably, the addition of a second electron to **2** results in sufficient destabilization of the structure to effect its rearrangement to give **3**. In MO terms the HOMO in the open structure is non-bonding rather than antibonding as it would be if the ring structure were retained. The average Ge–Ge bond length in **3** is *ca*. 0.1 Å longer than that seen in **4**. It is probable that the increased interelectronic repulsion owing to the negative charge, coupled with the 20.6° torsion angle between the planes at Ge(2) and Ge(2a), contributes to the lengthening of the Ge–Ge bonds which are only marginally shorter than a normal Ge–Ge single bond.[11] Further investigation of the chemical and spectroscopic properties of **2** and **3** and their tin analogues is in progress.

We thank the National Science Foundation and the Donors of the Petroleum Fund administered by the American Chemical Society for generous financial support.

† All manipulations were carried out under anaerobic and anhydrous conditions. The compound $Ge(Cl)C_6H_3mes_2$-2,6,[5] which exists as Ge–Ge bonded dimer in the solid, and $KC_8$ [6] were synthesized as described in the literature.

**2**·0.5thf. To a well stirred solution of **1** (0.42 g, 1.0 mmol) in thf (15 ml) was added $KC_8$ (0.135 g, 0.85 mmol) *via* a solids-addition tube. The solution which was initially yellow became a very dark red, almost black, color. After 3 h all the $KC_8$ appeared to have been consumed, whereupon the volatile materials were removed under reduced pressure. The black residue was extracted with hexane (2×20 ml) and the solution was filtered through Celite. The volume was reduced to *ca*. 20 ml and the solution was placed in a −20 °C freezer for 4 days to afford a mixture of a minor amount of microcrystalline orange crystals (*i.e.* **1**) together with large dark blue, almost black, crystals which could be easily separated by suspending the microcrystals in the solution and decanting rapidly with a cannula to afford X-ray quality crystals of **2**·thf [mp > 100 °C (decomp.)]. Yield 0.13 g, 28.5%. The thf in **2**·0.5thf may be removed by prolonged (12 h) pumping at 0.01 mmHg.

**3**·$0.5C_6H_{14}$, $LiC_6H_3mes_2$-2,6[12] (1.2 g, 3.73 mmol) was added *via* a solids-addition funnel to $GeCl_2$·dioxane (0.86 g, 3.73 mmol) in thf (30 ml) and stirred for 3 h. $KC_8$ (1.01 g, 7.4 mmol) was then added *via* a solids-addition funnel and the mixture was stirred for a further 2 h. The volatile materials were then removed under reduced pressure and the residue was extracted with 30 ml of hexane–toluene (4 : 1). The solution was filtered through Celite and concentrated to *ca*. 20 ml. Storage of 2 days in a −20 °C freezer afforded the product **3** as dark green crystals. Yield 0.35 g, 0.29 mmol, 23.5%. Mp 180–2 °C, $^1$H NMR($C_7D_8$) $\delta$ 2.02 (s, 24H, *o*-$CH_3$), 2.03 (s, 12H, *o*-$CH_3$), 2.21 (s, 6H, *p*-$CH_3$), 2.26 (s, 12H, *p*-$CH_3$), 6.63 (s, 8H, *m*-mes), 6.767 (d, 6H, $J_{HH}$ 6.9 Hz), 6.84 (s, 4H, m-mes), 7.08 (t, 3H, $J_{HH}$ 7.0 Hz), *p*-$C_6H_3$). $^{13}$C{$^1$H} NMR ($C_6D_6$) $\delta$ 21.16, 22.69 (*o*-$CH_3$), 22.89, 23.19 (*p*-$CH_3$), 135.02, 135.82, 130.45, 137.96, 138.55, 139.14, 139.62, 141.18, 142.19, 143.23, 143.91, 145.55, 145.85 (aryl). UV–VIS ($\lambda_{max}$, ε: 266 nm, $\varepsilon$ = 7000 $dm^3\ mol^{-1}\ cm^{-1}$).

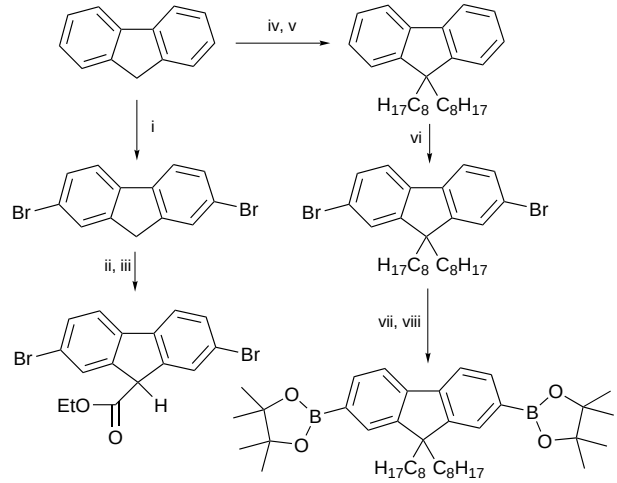
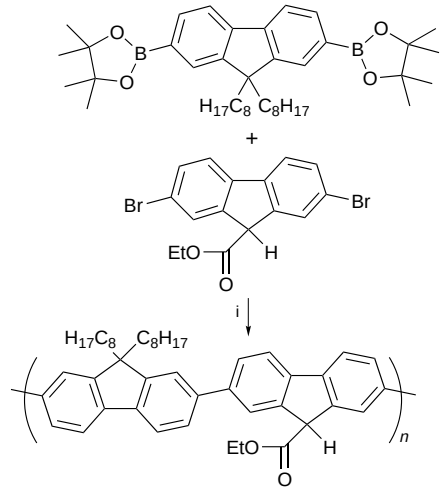
# Novel base-dopable poly(2,7-fluorenylene) derivatives



**Maxime Ranger and Mario Leclerc***

*Département de Chimie, Université de Montréal, Montréal, Québec, Canada H3C 3J7*

**A novel acidic poly(fluorenylene) derivative has been synthesized which, upon base-doping, shows electrical conductivities of $10^{-6}$–$10^{-5}$ S cm$^{-1}$; this new doping method for conjugated polymers opens the way to the preparation of air-stable n-type conducting polymers.**



Conjugated polymers, such as poly(acetylene)s, poly(pyrrole)s, poly(thiophene)s, *etc.*, can undergo redox processes (partial oxidation or reduction) which create mobile charge carriers (radical cations, dications or their negative analogs) and lead to high electrical conductivities.[1] These reversible redox reactions (also called doping reactions) modify the electronic structure of the conjugated polymers and are also accompanied by colour changes (electrochromism). Another major development in the field of conducting polymers appeared with the possibility of creating positive charge carriers through the protonation of basic conjugated polymers. For instance, poly(aniline)s can exhibit an insulating-to-conducting transition through a simple protonation of the imine moieties (without any external redox process).[2] Once again, this doping reaction induces colour changes which are related to the formation of the charge carriers. Conversely, acidic conjugated polymers could be base-dopable and this approach should lead to negative charge carriers which could be particularly interesting for the development of electron-injecting electrodes in light-emitting or electrochemical devices. Along these lines, interesting work on poly(2-hydroxy-1,4-phenylene) was recently published by Pei *et al.*,[3] where delocalization of negative charges on the side chains onto the conjugated main chain led to conductivities of 5 $\times$ $10^{-9}$ S cm$^{-1}$. However, it could be more interesting to create charge carriers directly on the backbone and for this purpose, 9-monosubstituted poly(2,7-fluorenylene)s are certainly promising candidates. Indeed, fluorenes bearing a cyano or an ester group at the 9-position exhibit relatively low p$K_a$ (8–10) values in organic solvents, which can be rationalized by the fact that the deprotonation reaction induces the aromatization of the inner ring.[4] Therefore, we report here the first synthesis of a well-defined acidic poly(2,7-fluorenylene) derivative and the characterization of its electrical and optical properties upon base-doping.

As shown in Scheme 1, ethyl 2,7-dibromofluorene-9-carboxylate was easily synthesized in two steps from fluorene. Recently, Pei and Yang[5] reported the nickel-catalysed reduction with metallic zinc of 2,7-dibromo 9,9-disubstituted fluorenes to yield well-defined 9,9-disubstituted poly(2,7-fluorenylene)s, but first attempts with this method were found to be inefficient in the case of acidic 2,7-dibromofluorene-9-carboxylates. The oxidative synthesis of fluorene-9-carboxylates, following the method reported by Yoshino and co-workers,[6] gave only highly cross-linked polymers. Finally, as reported for the synthesis of well-defined processable poly(*p*-phenylene)s,[7] it has been found that palladium-catalysed Suzuki couplings between 2,7-dibromofluorene-9-carboxylates and fluorene derivatives bearing diboronic moieties lead to well-defined poly(2,7-fluorenylene) derivatives. For this purpose, as also described in Scheme 1, 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene was synthesized, in good yield, in three steps from fluorene. This synthetic procedure could not be applied to 2,7-dibromofluorene-9-carboxylate because of the use of organolithium compounds in the preparation of the boron derivatives. All monomers were characterized by NMR spectroscopy and mass spectrometry and complete details of their synthesis will be published in a forthcoming publication. As shown in Scheme 2, this method yields a well-defined alternating copolymer where 50% of the repeat units can be base-doped. Nevertheless, this alternating structure can indeed be useful since it has been shown that fully protonated polyanilines are less conducting than 50% acid-doped polyanilines.[8]

**Scheme 1** *Reagents and conditions*: i, $CuBr_2$, $Al_2O_3$, $CCl_4$, reflux, 5 h, 97%; ii, LDA (2.1 equiv.), THF, −78 °C; iii, $ClCO_2Et$ (1 equiv.), 92% over two steps; iv, Bu$^n$Li (2 equiv.), THF, −78 °C; v, $C_8H_{17}Br$ (3 equiv.), 99% over two steps; vi, $Br_2$ (2 equiv.), $FeCl_3$ (2 mol%), $CHCl_3$, O→25 °C, 24 h, 99%; vii, Bu$^n$Li (2.1 equiv.), THF, −78 °C; viii, 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (2.5 equiv.), 65% over two steps

The synthesis of this alternated poly(2,7-fluorenylene) derivative gives a pale yellow polymer, completely soluble in THF

**Scheme 2** *Reagents and conditions*: i, $[(PPh_3)_4]Pd$ (2 mol%), PhMe–$Na_2CO_3$ (2 M aq.), Ar, reflux, 48 h, 65%

and $CHCl_3$. On the basis of size exclusion chromatography measurements performed in THF, and using a calibration curve obtained with monodispersed polystyrene standards, this polymer has a weight-average molecular weight of 8000 and a polydispersity index of 1.4. This class of materials should show some acidic properties. Indeed, fluorene-9-carboxylate has a $pK_a$ of around 10 in a mixture of DMSO–$H_2O$ (90 : 10 v/v), the deprotonated form giving an absorption maximum around 400 nm.[4] Accordingly, the corresponding neutral polymer exhibits an absorption maximum at 376 nm in THF while a new broad absorption band appears around 430 nm in the presence of potassium *tert*-butoxide. Consequently, this base-doping of the polymer induces a yellow-to-orange colour change. This phenomenon is reversible and, upon protonation, the polymer recovers its initial colour.

Four-probe electrical measurements on dried pressed pellets of the base-doped polymer revealed conductivities of $10^{-6}$–$10^{-5}$ S cm$^{-1}$. This electrical conductivity is excellent for an n-doped polymer considering that the conducting state has been obtained from a simple deprotonation reaction and that all measurements have been carried out in air. Moreover, it is worth noting that poly(fluorenylene)s are not particularly good conducting materials (probably due to weak interchain interactions); for instance, oxidized poly(fluorenylene) derivatives show electrical conductivities of $10^{-3}$ S cm$^{-1}$[6,9] whereas neutral poly(fluorenylene) derivatives show conductivities lower than $10^{-9}$ S cm$^{-1}$. However, these promising results obtained with a base-dopable poly(fluorenylene) derivative opens a new route for the preparation of n-doped conducting polymers. It is believed that the synthesis of cyano-monosubstituted poly(fluorenylene)s could lead to more conducting materials since, as reported for the monomers, the deprotonated form of fluorene-9-carboxylate may involve a partial localisation of the negative charge on the enolate form of the ester group, which is impossible with a cyano substituent.[4] Moreover, 9-cyanofluorene is more acidic than the carboxylate derivatives. Finally, the preparation of double-stranded, fully soluble poly(fluoreneacene)s, as developed by Scherf and Müllen,[10] bearing strong electron-withdrawing substituents could also lead to conducting, base-doped polymers.

This work was supported by research grants from the Natural Sciences and Engineering Research Council (NSERC) of Canada. The authors acknowledge D. Rondeau for his help in the synthesis of some monomers and C. Mellon and Professor L. Breau for much helpful advice.

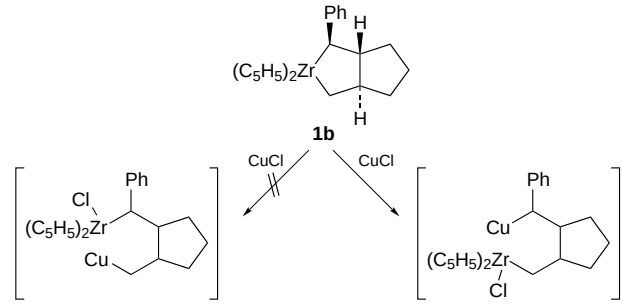
# Highly regio- and diastereo-selective carbon–carbon bond formation reaction of unsymmetrical zirconacyclopentanes using copper salt

**Tamotsu Takahashi,* Yasushi Nishihara, Ryuichiro Hara, Shouquan Huo and Martin Kotora**

*Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University, Kita-ku, Sapporo 060, Japan*

**Reaction of unsymmetrical zirconacyclopentanes with allyl chloride or benzoyl chloride in the presence of copper chloride gave allylated or benzoylated products with high regio- and diastereo-selectivities.**

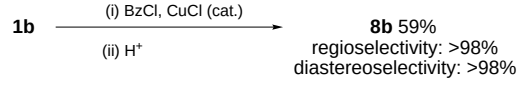
Regio- and stereo-selective reactions are attractive and useful for organic synthesis. Recently we reported the unprecedented highly regioselective transmetalation of zirconacyclopentanes such as **1a** with EtMgBr to afford Grignard compound **2a**.[1] It is known that zirconacyclopentane **1a** is prepared by the reaction of $(C_5H_5)_2Zr(CH_2{=}CH_2)$,[2] which is generated from $(C_5H_5)_2ZrCl_2$, 2 equiv. of EtMgBr and β-methylstyrene with high stereo- and regio-selectivity.[3] However, further reaction of **1a**, for example with allyl chloride by transmetalation from zirconium to magnesium, gave a mixture of two diastereomers **3a** and **4a** in a ratio of almost 1 : 2 (Scheme 1). Here we report the regio- and diastereo-selective C–C bond formation reactions of unsymmetrical zirconacyclopentanes.



**Scheme 1**

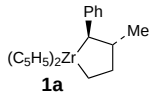
Unsymmetrical zirconacyclopentanes **1a**–**d** were prepared by the reaction of β-methylstyrene with $(C_5H_5)_2ZrEt_2$[1,3] or by the reaction of dienes[3] or trienes[4] with $(C_5H_5)_2ZrBu_2$ (the Negishi reagent).[5] The unsymmetrical zirconacyclopentanes have two different Zr–C bonds. One of the most attractive aspects of these species is the regioselective C–C bond formation reactions of these two different Zr–C bonds. Reaction of zirconacyclopentane **1a** with allyl chloride in the presence of a stoichiometric amount of copper(I) chloride gave product **3a** in 64% yield as the sole product. The C–C bond formation reaction selectively proceeded at the carbon which had a phenyl substituent. The formation of the regioisomer was not observed (regioselectivity > 98%). More interestingly, the $^{13}C$ NMR spectrum of **3a** showed that the only one diastereoisomer was formed. This is in sharp contrast to the case with EtMgBr.

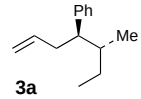
The stereochemistry of the product **3a** was determined by comparison of the $^{13}C$ NMR spectrum of its hydrogenation product with those of the two diastereomers **5** and **6** which were prepared as authentic samples. The $^{13}C$ NMR spectrum of the hydrogenation product of **3a** was identical to that of **5**. This result clearly indicated that this type of copper mediated C–C bond formation reaction of **1a** with allyl chloride gave diastereomerically pure product **3a** and no formation of its stereoisomer **4a** was observed. The stereochemistry between the Ph and Me substituents was maintained during this allylation reaction of **1a**.

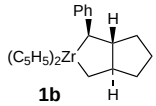


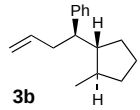
Unsymmetrical bicyclic zirconacyclopentane **1b** also showed the same selectivity for the copper catalysed allylation reaction as shown in Table 1. Allylation product **3b** was obtained in 94% yield after hydrolysis. Iodinolysis instead of hydrolysis afforded **7b** in 90% yield. The allylation selectively occurred at the carbon which had a phenyl substituent. In the reaction of **1b** with BzCl the regioselectivity was very high ( > 98%). The first step of this reaction is a transmetalation reaction from zirconium to copper as reported.[6–10] This suggests that this step is highly regioselective. The more sterically hindered carbon attached to zirconium is transferred to copper (Scheme 2) due to the repulsion between cyclopentadienyl ligands and the substituent. Even a methyl group at the β-position has a remarkable effect on the regioselectivity, as shown in the case of **1c** and **1d**. Allylation product **3c** and benzoylation product **8d** were obtained with > 98% regioselectivity.

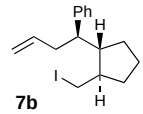
**Scheme 2**

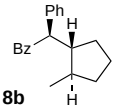


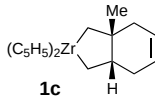


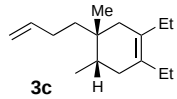


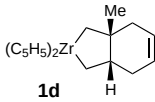


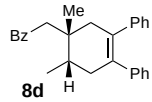












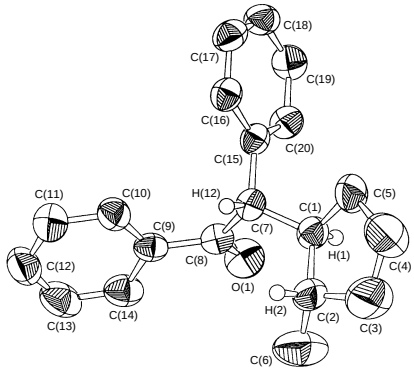
When **1b** reacted with allyl chloride or benzoyl chloride (Scheme 3), only one diastereomer was obtained as observed in the case of **1a**. The stereochemistry of the product **8b** was determined by X-ray analysis as shown in Fig. 1. It clearly showed that the stereochemistry of **1b** was also maintained during the reactions. There are two possible paths to explain this stereochemistry (Scheme 4). One is a retention-retention path for the transmetalation step and the C–C bond formation step. The other is an inversion-inversion path. The former path is more likely, although the mechanism is not clear yet.

**Scheme 3**

**Table 1** Regio- and diastereo-selective carbon–carbon bond formation reactions of unsymmetrical zirconacyclopentanes[a]

| Zircona-cyclopentane | Chloride | *t*/h | *T*/°C | Product | Yield (%)[b] | Regio-selectivity | Diastereo-selectivity |
|---|---|---|---|---|---|---|---|
|  **1a** |  | 1 | 0 |  **3a** | 64[c] (48) | >98 | >98 |
|  **1b** |  | 6 | 0 |  **3b** | 94 (83) | >98 | >98 |
| |  | 6 | 0 |  **7b** | 90 (78) | >98 | >98 |
| | BzCl | 1 | 0 |  **8b** | 59 (49) | >98 | >98 |
|  **1c** |  | 1 | 0 |  **3c** | 74 (58) | >98 | *d* |
|  **1d** | BzCl | 1 | 0 |  **8d** | 70 (59) | >98 | *d* |

[a] Catalytic amount (0.1 equiv.) of CuCl was used. [b] Yields were determined by GC. Isolated yields are shown in parentheses. [c] One equivalent of CuCl was used. [d] Product was diasteromerically pure.



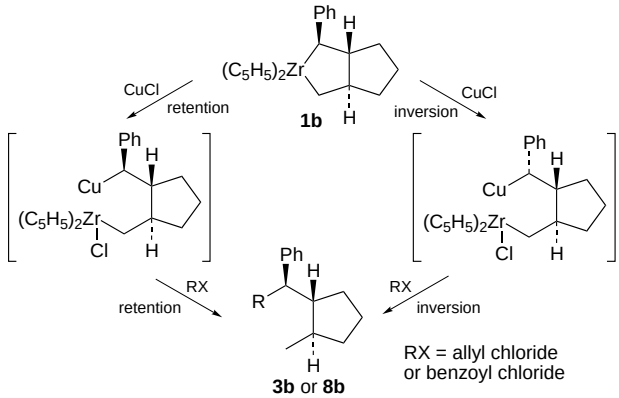


**Fig. 1** ORTEP Drawing of **8b**

**Scheme 4**

Further investigations on the selective C–C bond formation characteristics of zirconacycles are in progress.

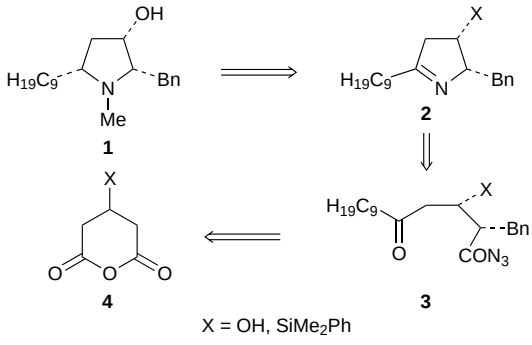
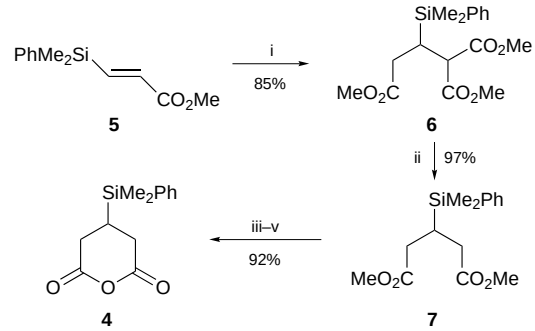
# A silicon controlled total synthesis of the antifungal agent (+)-preussin

**Rekha Verma and Sunil K. Ghosh***



*Bio-Organic Division, Bhabha Atomic Research Centre, Trombay, Mumbai 400 085, India*

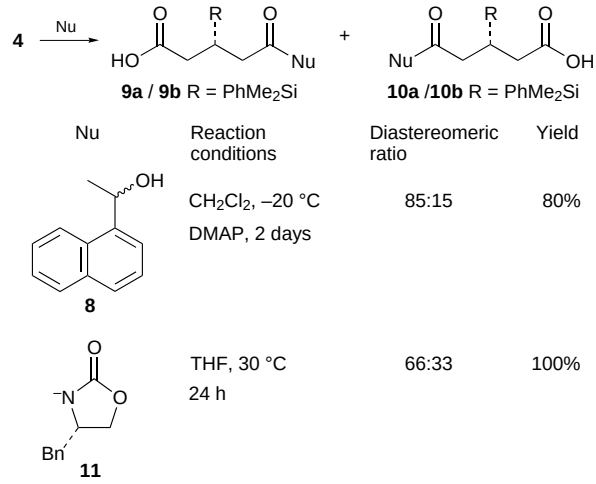
**A stereoselective total synthesis of (+)-preussin has been achieved from a *meso* anhydride featuring a dimethyl(phenyl)silyl group as a masked hydroxy group which also restricts elimination reactions, stereodirects hydrogenation and ester enolate alkylation, and facilitates Curtius reaction.**



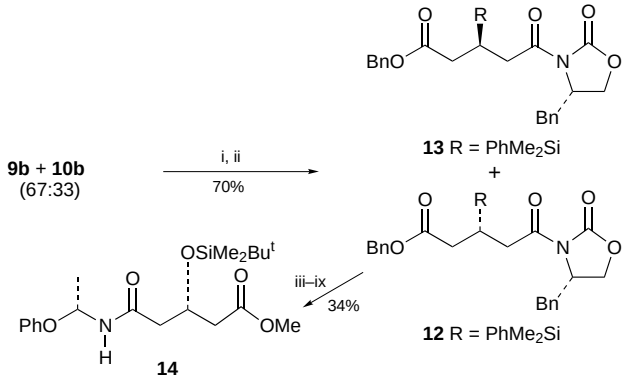
(+)-Preussin, (2*S*,3*S*,5*R*)-1-methyl-5-nonyl-2-benzylpyrrolidin-3-ol (also known as L-657,398), **1** was isolated from the fermentation broths of *Aspergillus ochraceus* ATCC 22947 and *Preussia sp.*[1] This structurally novel pyrrolidine alkaloid has broader spectrum antifungal activity against both filamentous fungi and yeasts than the structurally related antibiotic anisomycin. The first total synthesis of (+)-preussin was reported by Pak and Lee[2] taking D-glucose as a substrate. Four more syntheses have been published subsequently using (*S*)-phenylalanine[3] and its enantiomer[4] as starting materials.

A simple retrosynthetic analysis could be postulated for (+)-preussin **1** from *meso* anhydride **4**[5] *via* $\Delta^1$-pyrroline **2** as shown in Scheme 1 (X = OH). However, as pointed out by Livinghouse,[3a] an intermediate like **2** is unstable due to the ease of elimination of the protected or unprotected OH group to provide a pyrrole derivative. Therefore, a substitute for this group is desirable which would resist elimination, could be stereospecifically converted to a hydroxy group when desired, could possibly stereodirect both saturation of the $\Delta^1$-pyrroline system and introduction of the benzyl group, and possibly facilitate the Curtius reaction of **3**. Considering all these requirements, we envisaged that a dimethyl(phenyl)silyl ($PhMe_2Si$) group would be an ideal substitute. It is known to be a poor leaving group and, as shown by Fleming,[6] it can be stereospecifically converted to a hydroxy group with retention of configuration. They have further shown that β-silyl ester enolate alkylations occur with high *anti* stereoselectivity.[7] Moreover, we have found that a β-silicon group facilitates the Curtius reaction of acyl azides‡ in close analogy to silicon directed Bayer–Villiger oxidation of β-silyl ketones.[8]

The starting *meso* anhydride **4** could easily be obtained in a few steps from β-silyl acrylate **5**[9] *via* the triester **6** and Fleming's *meso* diester **7**[10] as depicted in Scheme 2. When **4** was opened up with (±)-naphthylethanol **8**, it was expected to show good diastereocontrol, as observed by Fleming and Ghosh[11] for the opening up of a 3,4-bis-silyl substituted *meso* adipic anhydride. However, we obtained an inseparable 85 : 15

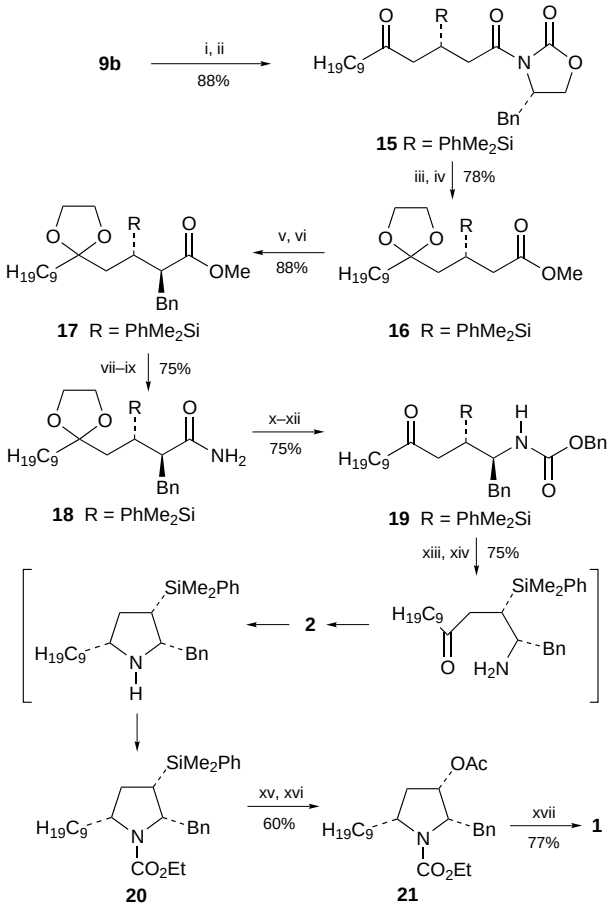


**Scheme 1**



**Scheme 2** *Reagents and conditions*: i, NaOMe, dimethyl malonate, room temp., 48 h; ii, NaCl, DMSO, $H_2O$, heat, 2.5 h; iii, KOH, MeOH, $H_2O$, room temp., 48 h; iv, dil. HCl; v, $Ac_2O$, reflux, 2.5 h

mixture of diastereoisomeric acids **9a** and **10a** (stereochemistry not determined) (Scheme 3) in 80% yield. In a related study, Theisen and Heathcock[5a] have also observed that 3-alkyl substituted glutaric anhydrides show poor diastereocontrol with increasing size of the alkyl groups. Alternatively, we opened up the anhydride with the lithium anion of the Evans' auxiliary[12] **11** which quantitatively provided a mixture of diastereoisomeric acids **9b** and **10b** in a ratio of *ca.* 67 : 33 (analysed as their methyl esters by NMR spectroscopy). To the best of our knowledge, this forms the first example of the desymmetrization of a *meso* anhydride using an anion of a chiral imide. Although the selectivity was low, the benzyl esters **12** and **13**‡ of these acids were easily separable by chromatography. The absolute stereochemistry of the major acid **9b** was established by converting it to a known derivative **14**[5b] following the reactions depicted in Scheme 4.



The major acid **9b** was converted to the ketone **15** in 60% yield (88% based on recovered **9b**) (Scheme 5), which was quantitatively protected[13] as the acetal and the auxiliary was removed[12] to provide the homochiral methyl ester **16** in 78% yield.§ We could recover the auxiliary in 78% yield (> 99% considering the wrong attack on the auxiliary) without any loss

**Scheme 3**

**Scheme 4** *Reagents and conditions*: i, $Et_3N$, PivCl, −78 to 0 °C, 1 h; ii, BnOH, DMAP, room temp., 24 h; iii, chromatographic removal of **13**; iv, $H_2$, 10% Pd–C; room temp., 24 h; v, KBr, NaOAc, AcOOH, room temp., 24 h; vi, (*S*)-phenylethylamine, DCC, DMAP, room temp., 24 h; vii, LiOOH, THF, 0 °C, 40 min; viii, $CH_2N_2$; ix, $Bu^tMe_2SiCl$, DMF, imidazole, room temp., 15 h

**Scheme 5** *Reagents and conditions*: i, $Et_3N$, PivCl, −78 to 0 °C, 1 h; ii, $C_9H_{19}MgBr$, −25 °C, 48 h; iii, 1,2-bis(trimethylsilyloxy)ethane, $Me_3SiOSO_2CF_3$, −20 °C, 48 h; iv, MgOMeBr, THF, 30 °C, 18 h; v, LiTMP, THF–DMPU, −78 °C, 1 h; vi, BnBr, −78 to −10 °C, 60 h; vii, KOH, MeOH, $H_2O$, 80 °C, 32 h; viii, $Im_2CO$, room temp., 30 min; ix, liq. $NH_3$; x, $Pb(OAc)_4$, BnOH, DMF, 100 °C, 15 h; xi, TsOH, acetone, $H_2O$, reflux, 2.5 h; xii, chromatographic removal of minor diastereoisomer; xiii, $H_2$, 10% Pd–C, EtOH, AcOH, 7 h; xiv, EtOCOCl, $Et_3N$, 0 °C, 15 h; xv, KBr, NaOAc, AcOOH, room temp., 20 h; xvi, $Ac_2O$, DMAP, $CH_2Cl_2$, room temp., 20 h; xvii, $LiAlH_4$, THF, room temp., 24 h

of optical purity. The ester enolate *C*-benzylation took place with high *anti* selectivity[7] (*anti*:*syn* = 93:7) to give ester **17** which was resistant to hydrazinolysis. This ester was hydrolysed, converted to primary amide **18** *via* its acid imidazolide and was subjected to modified Curtius reaction conditions[14] which smoothly† provided the expected benzyloxycarbonyl protected amine in good yield. The acetal protection was subsequently removed to give the ketone **19** in overall 75% yield from **17**. At this stage we could easily separate the unwanted minor diastereoisomer by chromatography. The ketone **19** was subjected to hydrogenolysis whereupon removal of the benzyloxycarbonyl group took place. The generated amino group condensed intramolecularly with the carbonyl group spontaneously to provide the $\Delta^1$-pyrroline **2** (X = $PhMe_2Si$) which was *in situ* hydrogenated with hydrogens coming from the least hindered surface, *i.e*. away from the silicon and benzyl groups, to provide the pyrrolidine derivative with all three substituents having *cis* stereochemistry. Subsequently, the NH group was protected as ethoxycarbonyl derivative **20** and the silyl group in the molecule was converted to a hydroxy group[6] and then to its acetate **21**.¶ Lithium aluminium hydride reduction of this acetate provided (+)-preussin **1** in 77% yield. Since we started with the homochiral methyl ester **16,** and the synthetic sequence does not cause any epimerisation, the enatiomeric purity of (+)-preussin should undoubtedly be very high (>99%). This was confirmed from its specific rotation value ($[\alpha]_D^{25}$ + 31.1, *c* 1, $CHCl_3$) and spectral data.[2] The overall yield of (+)-preussin from the homochiral ester **16** was 17.2%.

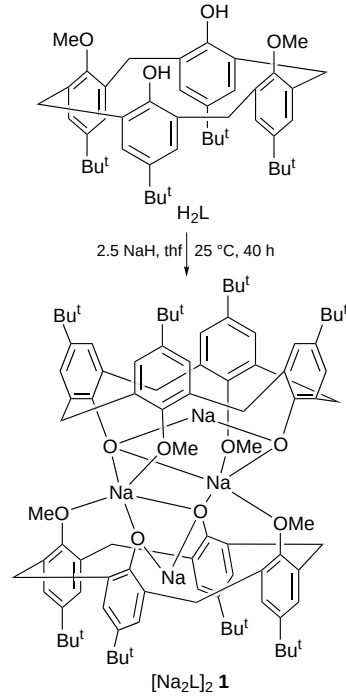
# *exo*-Binding of $Na^+$ between two fused calix[4]arenes and *endo* binding of $Na^+$ within the calix[4]arene cones in the disodium salt of 1,3-dimethyl ether *p-tert*-butylcalix[4]arene

**Stuart R. Dubberley, Alexander J. Blake and Philip Mountford***

*Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD*

**Reaction of 1,3-dimethyl ether *p-tert*-butylcalix[4]arene ($H_2L$) with sodium hydride in tetrahydrofuran affords the dimeric metallocalixarene species $[Na_2L]_2$ which possesses a novel structure in which the $Na^+$ ions are coordinated in two very different environments.**



The study of calixarenes (and their derivatives) as receptor molecules *via endo*-binding of substrates within their cavities is a very active area of current research.[1] Furthermore, calixarenes can also act as polydentate O-donor ligands to main-group and transition-metal centres forming mononuclear[2] and fused binuclear[3] derivatives. O-Derivatised calixarenes with pendant arms containing Lewis-basic amide, ester, or polyether functionalities have also been widely studied for their ion-binding properties.[1b,c] In contrast, the simple O-alkylated calix[4]arenes have received very little attention and only a handful of metallo derivatives have been reported; these include mononuclear organometallic zirconium,[4] zinc,[3a] aluminium and gallium[5] derivatives of 1,3-dimethyl ether *p-tert*-butylcalix[4]arene ($H_2L$) and an $Na^+$ complex of tetramethyl ether *p-tert*-butylcalix[4]arene with the metal cation bonded in an *exo* fashion (with respect to the cavity of the cone) to the four ethereal oxygen atoms.[6]

Recent spectroscopic and structural studies have shown that complexation of alkali-metal cations within the calix[4]arene cavity involves cation–π interactions.[7] Furthermore, O-coordination of a transition metal at the lower rim of mononuclear *p-tert*-butylcalix[4]arenes can also allow for alkali-metal binding within the cavity.[2f] Binuclear derivatives wtih metals bridging the lower rims of two fused calixarene ligands may bind organic substrates within the divergent cavities.[3b,c] Here we show that simple metallation of 1,3-dimethyl ether *p-tert*-butylcalix[4]arene affords a lipophilic binuclear structure with both *exo* binding of $Na^+$ between the fused calixarene units and *endo* binding of $Na^+$ within the two calixarene cones.

A tetrahydrofuran (thf) solution of 1,3-dimethyl ether *p-tert*-butylcalix[4]arene ($H_2L$)[8] and sodium hydride (2.5 equiv.) was stirred at room temp. for 40 h (Scheme 1). Filtration and concentration afforded colourless crystals of the poly(thf) solvate of $[Na_2L]_2$ **1** suitable for X-ray diffraction analysis (*vide infra*). These crystals very readily lose thf; the total yield of pure base-free **1** on removal of all residual thf was 70%. The molecular structure of $[Na_2L]_2$ **1** is shown in Fig. 1.† Molecules of **1** lie on crystallographic twofold axes; the thf molecules of crystallisation (not shown) exhibit no unusual contacts to the $Na^+$ ions or calix[4]arene ligand and occupy lattice interstitial sites.

Molecules of $[Na_2L]_2$ **1** comprise two doubly deprotonated 1,3-dimethyl ether *p-tert*-butylcalix[4]arene dianions fused at the lower rim by two bridging sodium cations [Na(2) and Na(2A)], each of which possesses an approximately trigonal-bipyramidal coordination geometry. Each bridging sodium is coordinated to two ethereal O-donors and to three phenolate anionic O-donors, with three of the oxygen atoms belonging to one $L^{2-}$ unit and the remainder to the other. The second pair of sodium cations [Na(1) and Na(1A)] are situated *endo* to the lower rim within the calixarene cone. Na(1) is tightly bonded to the two mutually opposite phenolate O-donors [namely O(2) and O(4)] and has bonding[9] contacts to all four phenol ring *ipso* (with respect to oxygen) carbons at < *ca.* 2.9 Å [range 2.792(3)–2.900(5) Å]. There are further Na···C(arene) π-contacts in the range 2.918(6)–3.056(6) Å to the two arene rings bearing O(1) and O(3) (Fig. 1). The former ring appears to be $\eta^3$-bonded (the *m* and *p*-carbons are not strongly bound) to Na(1) while the latter has effectively $\eta^5$-coordination (the *p*-carbon is significantly less closely bound). The Na(1)···ring centroid distances for the two coordinated rings are 2.76 [for that supporting O(1)] and 2.65 Å. The normals to the least-squares planes of the two coordinated rings form an angle of 3.8°, whereas the non-coordinated rings are somewhat flattened with an angle of 75.1° between the normals to their planes. The four sodium ions and the oxygen donor atoms O(2), O(4), O(2A) and O(4A) in **1** comprise an unusual short, twisted ladder structure which may be viewed as an $Na_4O_4$ cubane that has been opened up along two of the Na···O vectors![10a] Furthermore, **1** is a rare example of a structurally characterised, base-free sodium phenoxide.[10b,c] A search of the Cambridge Structural Database showed that the individual Na–O and Na···C distances in **1** lie within the ranges previously observed for non-calixarene systems.

The structure of $[Na_2L]_2$ is unusual in calixarene metal complex chemistry since it exhibits simultaneous bonding of

**Scheme 1**

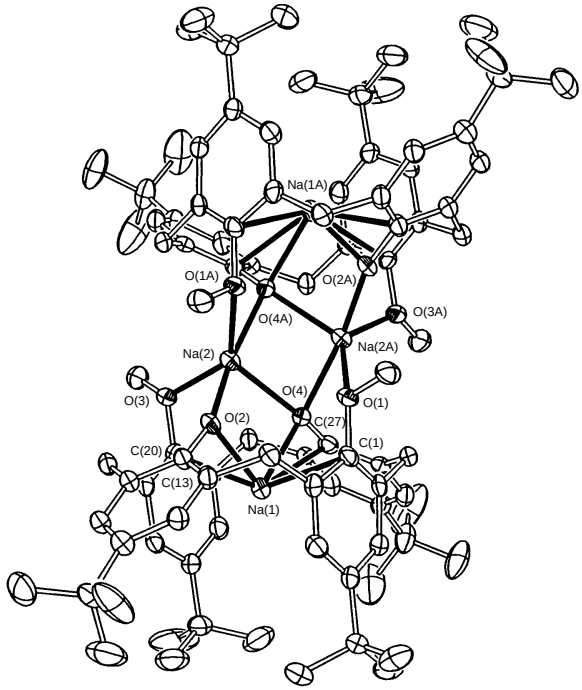


**Fig. 1** Molecular structure of $[Na_2L]_2$ **1**. Hydrogen atoms and thf molecules of crystallisation omitted for clarity, principal bonds to the sodium ions are shown in black and thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths (Å) and angles (°): Na(1)–C(1) 2.792(3), Na(1)–C(13) 2.800(6), Na(1)–C(20) 2.900(5), Na(1)–C(27) 2.797(5), Na(1)–O(2) 2.281(4), Na(1)–O(4) 2.283(4), Na(2)–O(1A) 2.538(4), Na(2)–O(2) 2.129(4), Na(2)–O(3) 2.343(4), Na(2)–O(4) 2.376(4), Na(2)–O(4A) 2.259(4); O(2)–N(2)–O(4A) 163.32(17), O(2)–Na(2)–O(1A) 90.84(15), O(2)–Na(2)–O(3) 89.86(15), O(2)–Na(2)–O(4) 88.55(15), O(1A)–Na(2)–O(3) 138.53(15), O(1A)–Na(2)–O(4) 127.84(14), O(3)–Na(2)–O(4) 93.63(15). Atoms denoted A are related to their counterparts by the symmetry operator: $1 - x, y, 3/2 - z$.

two pairs of otherwise Lewis-base free sodium ions in both possible coordination modes, namely between the fused calixarene units and also within the cones. It is also the first example of a fused dicalix[4]arene bridged by alkali (or alkaline earth) metals; only transition-metal- or post-transition-metal-fused dicalix[4]arenes have been reported previously.[2c–e] A fused derivative of the tetraanion of *p-tert*-butylcalix[4]arene featuring three bridging Zn or Zn(tmeda) units with *endo* ZnEt groups has very recently been described.[3a] Other examples of calix[4]arenes having an *endo* coordinated metal ion have also generally featured additional ligation by Lewis-base donors or other substituents.[2f,7b] In addition, Floriani has recently suggested that coordination of a transition metal to the lower rim O-donors can provide a general strategy for binding alkali-metal ions inside the calix[4]arene cavity.[2f] The homoleptic structure of **1** demonstrates that straightforward encapsulation of sodium ions within the cavity is achieved in a simple one-pot system without the need for transition-metal complexation or additional Lewis-base ligands. The structure of **1** also confirms that cation binding by deprotonated calix[4]arenes within the cone involves a substantial degree of metal–oxygen binding in addition to metal–π-ring interactions.

Preliminary experiments have indicated that $[Na_2L]_2$ is a precursor to new group 2 and early transition-metal complexes *via* sodium halide elimination reactions. We are currently studying the synthesis and structures of other base-free, group 1 and group 2 homoleptic derivatives of 1,3-dialkyl ether *p-tert*-butylcalix[4]arenes, and of *p-tert*-butylcalix[4]arene itself, to explore the relative importance of the metal–phenolate and metal–π-ring interactions.

This work was supported by grants from the EPSRC, Leverhulme Trust and Royal Society (to P. M.). We also thank the EPSRC for a studentship (to S. R. D.) and the provision of a diffractometer and Dr M. G. Davidson (University of Durham) and Professor V. C. Gibson (Imperial College, London) for sharing their results with us prior to publication (see pages 1605 and 1607 of this issue).

† *Crystal data* for $[Na_2L]_2 \cdot 6thf$: $C_{84}H_{116}Na_4O_8 \cdot 6C_4H_8O$, $M$ = 1778.43, monoclinic, space group $C2/c$, $a$ = 18.606(5), $b$ = 30.461(10), $c$ = 20.228(5) Å, $\beta$ = 99.22(3)°, $U$ = 11316(6) Å$^3$, $Z$ = 4, $D_c$ = 1.044 g cm$^{-3}$, $F(000)$ = 3872, $T$ = 150 K, Mo-Kα radiation, $5.7 \leqslant 2\theta \leqslant 47.1°$. The structure was solved by direct methods (SHELXS-96[11a]) and 591 parameters were refined (SHELXL-96[11b]) on $F^2$ for 8351 data to give final conventional $R_1$ = 0.1097 [for data with $F_o > 4\sigma(F_o)$] and $wR_2$ = 0.3436 (all data). Notes on the refinement: phenyl rings were restrained to have local $C_{2v}$ symmetry and to be coplanar with their 1- and 4-substituent atoms. The fully occupied thf solvate molecules were refined with local $C_2$ symmetry. H atoms were included in geometrically calculated positions or located from Fourier difference syntheses; H atoms for partially occupied thf solvates were not included. All full-site occupancy, non-H atoms were refined anisotropically with extensive rigid bond restraints applied to the $U^{ij}$ components. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/469.

# Can alkali-metal ions influence the coordination and reactivity of calix[4]arenes at transition-metal centres?†

**Vernon C. Gibson,*[a] Carl Redshaw,[a] William Clegg[b] and Mark R. J. Elsegood[b]**

[a] *Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY*
[b] *Department of Chemistry, University of Newcastle, Newcastle upon Tyne, UK NE1 7RU*

**Novel chromium and molybdenum calix[4]arene complexes are described in which the calixarene coordination is constrained by alkali-metal ion interactions with the phenoxide units; in the chromium example, an unprecedented calixarene C–H bond activation is found.**

There is currently much interest in the synthesis and characterisation of new metallocalixarenes.[1–6] The simplest of the calixarenes, the calix[4]arene system, usually binds in tetradentate fashion and retains its cone-like appearance.[1–9] In recent examples, however, it has been found that the calix[4]arene is capable of adopting alternative conformations in binding at metal centres, for example a partially flattened cone arrangement identified in aluminium[10] and zinc compounds[11] and an alkali-metal-constrained elliptical conformation in which the calixarene oxygens occupy mutually *cis* and *trans* sites in an octahedral geometry.[2] There has also been a report of an elliptical calixarene arrangement in the absence of alkali-metal ions;[8] it is thus unclear whether it is the transition metal or the alkali-metal ions that exert the more substantial influence on calix[4]arene conformation. Here, we describe two unusual structures that contain alkali-metal ions within elliptical calixarene ligands; in one case an unprecedented C–H bond activation of the calixarene ligand results, providing the first indication that highly reactive metal centres may arise from these constrained geometry ligand–metal environments.

Treatment of $[Mo(NAr)(CHCMe_2Ph)(O_3SCF_3)_2(dme)]$ (Ar = $C_6H_3Me_2$-2,6) with 1 equiv. of $K_4L$ ($H_4L$ = *p-tert*-butylcalix[4]arene) in tetrahydrofuran (thf) affords, after work-up, orange prisms of $[Mo(NAr)(L)K_2(NCMe)_3O]_2$ **1**‡ in 70% yield. Crystals of **1** suitable for an X-ray determination§ were grown from acetonitrile at room temp. The asymmetric unit comprises one half of a dimeric molecule and two non-coordinated molecules of acetonitrile. The molecular structure is shown in Fig. 1 and selected bond lengths are given in the caption. The molecule is a centrosymmetric dimer in which each molybdenum atom possesses a pseudo-octahedral geometry. The calixarene 'cones' are distorted in such a way that two opposing phenoxide rings are drawn together by π interactions with potassium atom K(1) which is also bonded to the oxygens of the remaining two phenoxide units. One of the latter two rings is also involved in a π interaction with a bridging potassium atom, K(2), which forms part of a ladder motif. The Mo–O(5) bond distance within this motif, at 1.752(2) Å, is consistent with substantial multiple bond character.[12] The origin of the ladder oxygen atoms is most likely the thf solvent since the reaction and subsequent work-up were conducted under rigorous air- and moisture-free conditions.

In extending our investigations to chromium, $[Cr(NBu^t)_2Cl_2]$ was reacted with 2 equiv. of $LiOBu^t$ in thf to generate $[Cr(NBu^t)_2(OBu^t)_2]$ which was then treated *in situ* with 2 equiv. of $H_4L$. This led after work-up to the formation of large green needles of **2** in 60% yield. Crystals suitable for an X-ray determination§ were grown from acetonitrile solution at room temp.; they incorporate four uncoordinated molecules of acetonitrile per molecule of the complex. The molecular structure is shown in Fig. 2; selected bond lengths and angles are given in the caption. All of the *tert*-butylimido and *tert*-butoxide ligands of the starting chromium species are sacrificed, as *tert*-butylamine and *tert*-butyl alcohol, respectively, and two calix[4]arene units are coordinated to the chromium centre. One possesses a similar coordination geometry to that observed in **1** with the exception that the smaller lithium ion interacts with just one of the arene rings and the interaction is strongest with the *ipso* and *ortho* ring carbons [Li···C(*ipso*) 2.599(10) Å, Li···C(*ortho*) 2.716(10), 2.797(10) Å]. A remarkable feature of the complex is the joining of this calixarene to a second calixarene unit *via* an ether [O(1)] linkage. This formally arises from the activation of a bridging methylene C–H bond of the second calixarene, to our knowledge the first time such reactivity has been observed in a metallocalixarene complex. The resultant ether oxygen atom is then bonded to an axial coordination site in the chromium complex.

The remainder of the second calixarene unit is bonded to the metal centre through two phenoxide linkages whose oxygen atoms are hydrogen bonded to atoms O(5) and O(6), which in turn are coordinated to a lithium atom bound to O(3). The net result is the encapsulation of an octahedral chromium(III) centre by two fused calix[4]arene rings. While it is not possible to establish with any degree of certainty the mechanism of C–H bond activation in **2**, it is possible that it may be a consequence of the constrained calixarene coordination geometry which leads to severe bending at the axial oxygens O(1) and O(3) [120.0(3), 112.6(3)°, respectively]. Future studies will be directed towards probing the influence of the constrained

‡ Satisfactory elemental analyses have been obtained. *Selected spectroscopic data* for **1**: $^1$H NMR ($CDCl_3$, 500 MHz, 298 K) $\delta$ 7.00 −6.65 (overlapping m, 22 H, aryl), 4.42 (d, 4 H, $^3J_{HH}$ 13.8 Hz, $CH_2$), 4.31 (d, 4 H, $^3J_{HH}$ 14.3 Hz, $CH_2$), 3.27 (d, 4 H, $^3J_{HH}$ 14.5 Hz, $CH_2$), 3.07 (d, 4 H, $^3J_{HH}$ 14.0 Hz, $CH_2$), 2.37 (s, 12 H, $CH_3$Ar), 1.31 (m, 18 H, MeCN), 1.19 − 1.11 (overlapping m, 72 H, [$(CH_3)_3$C]). $^{13}$C{$^1$H} NMR ($CDCl_3$, 100.6 MHz, 298 K) $\delta$ 165.5, 164.2, 162.7, 154.1 (4 × s, *ipso*-aryl), 140.2, 138.7, 138.2, 134.8, 134.3, 134.1, 133.8, 132.2, 131.1, 130.9, 130.6, 128.2, 127.2, 124.1, 123.8, 123.6, 123.1, 122.9, 122.8, 122.5, 36.2 (Ar$CH_2$Ar), 35.4 (Ar$CH_2$Ar), 32.0 [C($CH_3$)$_3$], 31.9 [C($CH_3$)$_3$], 31.8 [C($CH_3$)$_3$], 31.7 [C($CH_3$)$_3$], 28.0, 22.5, 18.5 ($C_6H_3Me_2$-2,6) [quaternary $(CH_3)_3C$ not observed]. $^1$H NMR spectra of **2** are broad and uninformative; the X-band EPR spectrum (solid, 298 K) is complex comprising broad low-field features centred at $g$ = 3.35 and several weaker features out to $g$ = 1.19.

§ *Crystal data*: **1**·4MeCN: $C_{116}H_{140}K_4Mo_2N_8O_{10}$·4$CH_3CN$, $M$ = 2318.9, monoclinic, space group $P2_1/n$, $a$ = 20.2461(12), $b$ = 12.0202(7), $c$ = 27.1727(15) Å, $\beta$ = 110.700(2)°, $U$ = 6185.9(6) Å$^3$, $Z$ = 2, $D_c$ = 1.245 g cm$^{-3}$, $\mu$ = 0.40 mm$^{-1}$ (Mo-K$\alpha$, $\lambda$ = 0.710 73 Å), $T$ = 160 K. 37 557 reflections were measured on a Siemens SMART CCD area-detector diffractometer and corrected semiempirically for absorption (transmission 0.761–0.917), yielding 13 952 unique data ($2\theta_{max}$ = 55.0°, $R_{int}$ = 0.0479). The structure was determined by direct methods and refined by $F^2$ for all data, with anisotropic displacement parameters, and riding isotropic H atoms. Final $R_w$ = $\{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ = 0.1135 for all data, conventional $R$ = 0.0571 on $F$ values of 11 481 reflections with $F_o^2 > 2\sigma(F_o^2)$; goodness of fit = 1.232 on $F^2$ values for 715 refined parameters. All final difference map features were within ± 0.5 e Å$^{-3}$.

**2**·4MeCN: $C_{92}H_{111}CrLi_2N_2O_8$·4$CH_3CN$, $M$ = 1602.9, monoclinic, space group $P2_1/c$, $a$ = 17.5630(7), $b$ = 46.3196(18), $c$ = 13.0311(5) Å, $\beta$ = 108.796(2)°, $U$ = 10 035.6(7) Å$^3$, $Z$ = 4, $D_c$ = 1.061 g cm$^{-3}$, $\mu$ = 0.17 mm$^{-1}$ (Mo-K$\alpha$, $\lambda$ = 0.710 73 Å), $T$ = 160 K. Experimental and computational methods were as for **1**, with 47 608 measured data, transmission 0.448–0.962, 13 090 unique data ($2\theta_{max}$ = 45.0°, $R_{int}$ = 0.0681), disorder in some Bu$^t$ groups modelled with restraints, $R_w$ = 0.2646 for all data, $R$ = 0.0873 for 9667 data having $F_o^2 > 2\sigma(F_o^2)$; goodness of fit = 1.067 for 1136 refined parameters and 306 restraints, extremes of difference map +1.29 and −0.39 e Å$^{-3}$. The hydroxyl hydrogens were located in a difference map and freely refined. Programs: Siemens SMART (control), SAINT (integration) and SHELXTL, and local programs. CCDC 182/537.

# Synthesis and X-ray structures of tetralithium derivatives of *tert*-butylcalix[4]arene containing unique Li–O cores based on a square-pyramidal geometry

**Matthew G. Davidson,* Judith A. K. Howard, Sarah Lamb and Christian W. Lehmann**

*University of Durham, Department of Chemistry, Science Laboratories, Durham, UK DH1 3LE*

**Tetralithiation of *tert*-butylcalix[4]arene in the presence of hmpa (hexamethylphosphoramide) results in the isolation of either a monomeric complex in which LiOH is incorporated into an $Li_5O_5$ core based on an isolated square pyramid of Li atoms, or a dimeric LiOH-free species containing an $Li_8O_8$ core in which the same structural motif is maintained by edge-sharing of two square pyramids of Li atoms.**

Both underivatised and partially O-alkylated calixarenes have attracted much attention as phenolic ligands for both transition and p-block metals. The flexible orientation of the coordinating phenolic oxygen atoms, coupled with the potential for multi-metallations has recently led to reports of some fascinating and unique structures.[1,2] Although the interaction of alkali metals with neutral lower-rim-modified calixarenes is well known,[1] the isolation and characterisation of homometallic phenoxy-bound alkali-metal derivatives of calixarenes is restricted to only one Cs-[3] and one Na-containing[4] example. Floriani *et al*. have very recently reported the syntheses and X-ray structures of some mixed alkali-metal–transition metal–calixarene complexes[5] although in these cases solvation of the alkali metal is exclusively in the cavity of the calixarene. In the light of these considerations and also in view of the unusual structural chemistry that has recently been found to result from multilithiations of organic molecules[6] we felt it was timely to consider the simple metallation of calixarenes with s-block metals. We herein report our preliminary results concerning the simple reaction of $Bu^nLi$ with *tert*-butylcalix[4]arene $H_4L$ (below) which has resulted in the isolation and X-ray structural characterisation of two related tetralithiated calixarenes.

$H_4L$

Reaction of $H_4L$ in toluene solution with 4 equiv. of $Bu^nLi$ in the presence of an excess of hexamethylphosphoramide hmpa (used as received, without pre-drying, *vide infra*) resulted in the formation of a fine white precipitate suspended in a pale yellow solution. Dissolution of this solid by warming to 100 °C and then cooling to room temp. afforded a crop of colourless, air-sensitive crystals. Preliminary characterisation by IR (in particular a strong sharp O–H stretch at 3612 $cm^{-1}$) and $^1H$ NMR spectroscopies, and then an X-ray crystal structure† revealed the isolated product to be $Li_4L{\cdot}LiOH{\cdot}4hmpa$ **1**. In the solid state (Fig. 1) the molecule lies on a crystallographic twofold axis. The four coplanar Li atoms which formally metallate the calixarene lie below the plane defined by the O atoms of the calixarene's lower rim. Each of the Li atoms is coordinated to a neutral hmpa molecule. Together, the four hmpa ligands create a lower rim cavity of similar dimensions to that defined by the four aryl groups of the calixarene on the opposite side of the macrocycle, which itself retains a normal cone configuration. In spite of their similar proportions the two cavities are electronically very different. The bottom of the upper cavity is anionic ($O^-$ lined) while the lower one is cationic ($Li^+$ lined) in nature, which facilitates the complementary binding of a $Li^+$ cation [Li(3) bound to all four phenolic oxygen atoms] and an $OH^-$ anion [O(99), $\mu_4$-bridged to the four coplanar Li atoms]. An additional feature of the structure of **1** is that both the normal upper rim cavity and the novel lower rim cavity (defined by the hmpa ligands) act as hosts for guest toluene molecules (not shown in the figure), emphasising their similar dimensions. Thus overall, the structure of **1** may be viewed as resulting from the incorporation of LiOH into a $Li_4L$ moiety; Li(3)···O(99) [2.25(1) Å] is longer than other Li–O bonds within the core of **1** [1.92(1)–2.089(4) Å] though an interaction between the two is still probable.

The incorporation of LiOH and $Li_2O$ into organolithium compounds, whether deliberately or serendipitously, has been reported before,[7] and in order to probe the source of the LiOH unexpectedly incorporated into **1**, and to obtain an LiOH free complex, similar reactions were carried out using a freshly dried (over activated 13X molecular sieve) sample of hmpa. Analysis of the resulting crystalline solid, again ultimately by X-ray crystallography,† revealed the composition of complex **2** to be $(Li_4L{\cdot}2hmpa)_2$. In the solid state **2** is dimeric, is free from LiOH, and has only two rather than four hmpa molecules per calixarene (Fig. 2). The crystallographic asymmetric unit consists of two independent but geometrically and chemically similar $Li_4O_4$ 'monomeric' units which then give centrosymmetric 'dimeric' aggregates. Within the $Li_8O_8$ core there are

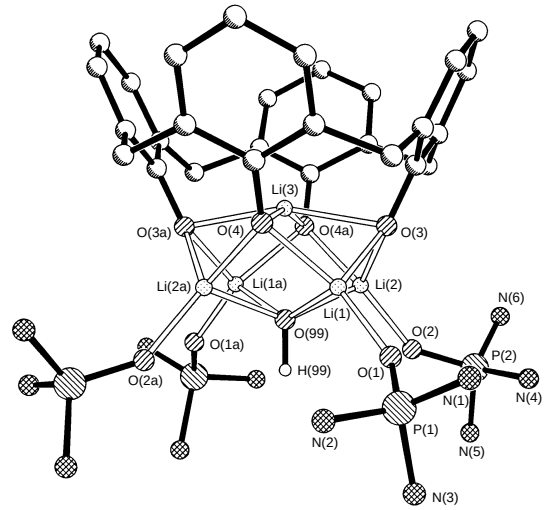

**Fig. 1** Molecular structure of **1**; for clarity, all hydrogen atoms, calixarene Bu$^t$ groups, hmpa methyl groups and lattice solvent are omitted

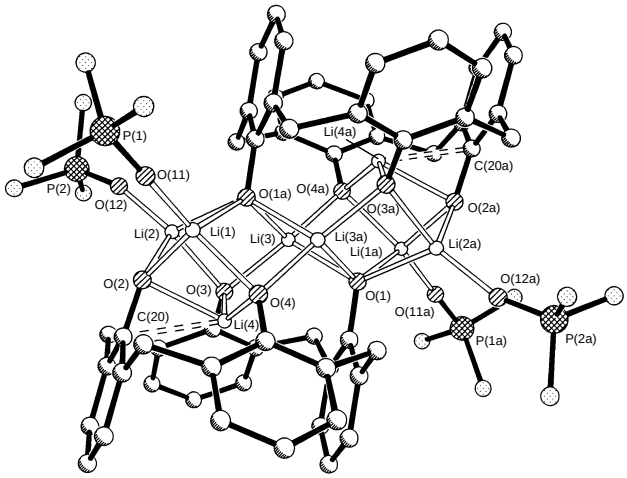

**Fig. 2** Molecular structure of **2** (only one of two crystallographically independent but chemically similar molecules is shown). For clarity, all hydrogen atoms, calixarene Bu$^t$ groups, hmpa methyl groups and lattice solvent are omitted.

three distinct lithium environments: two Li atoms [Li(1) and Li(2)] are complexed by hmpa and retain a similar environment to that found for the four coplanar Li atoms of **1**; Li(3) is uncomplexed by hmpa and bridges the two calixarenes; and Li(4) lies within the calixarene cavity. One oxygen atom [O(1)] fulfils the $\mu_4$-capping role played by O(99) in **2**, resulting in a distortion of the original cone conformation of the calixarene. Thus, Li(4) is bound to only three O atoms which prompts an interaction with the $\pi$-system of one of the calixarene aryl groups [Li(4)–C(20) 2.31(1) Å]. The distance between O(1) and Li(4a) ( > 2.8 Å) is considerably longer than the corresponding Li···O separation found in **1**. Other Li–O distances within the core of **2** [1.91(1)–2.11(1) Å] are comparable to those found in **1**. Thus, despite being free of LiOH, in **2** the same general structural features are present as in **1**: a $Li^+$ cation lies in the O lined cavity of the calixarene and an $O^-$ anion caps four Li atoms. The $^1$H NMR spectrum of **2** suggests that the complex retains a distorted cone configuration in solution: three resonances assigned to Bu$^t$ groups (relative integrals 2 : 1 : 1) and three corresponding Ar–H resonances are observed, which is consistent with the asymmetry of the calixarene seen in the solid state, and contrasts with the equivalence of Bu$^t$ groups (and Ar–H protons) in the $^1$H NMR spectrum of **1**.

In the light of the structures of **1** and **2**, one can envisage the latter as being suited to act as a carrier for inorganic salts by binding the ion-separated components of the salt in two complementary cavities, resulting in a complex for which **1** is a model. In contrast to the work described by Floriani,[5] in which the shape of the calixarene cavity was modified using Nb or Ta in order to accommodate alkali-metal cations, the structures of **1** and **2** suggest that significant deviation from the normal cone configuration is unnecessary in order to bind lithium within the cavity.

Although **2** can be reproducibly prepared using dried hmpa, the synthesis of **1** has not to date been reproduced, even though spectroscopic evidence suggests that its crystal structure is representative of the bulk product obtained. The source of LiOH incorporated in **1** remains an open question. Although the use of 'wet' hmpa is consistent with the product obtained, it is possible that LiOH present in the sample of Bu$^n$Li used,[7c] or contamination from another source was responsible. We are currently investigating the incorporation, by controlled and reproducible means, of s-block metal salts (including LiOH) into lithiated calixarene derivatives.

Also of note in these structures are the geometries of the $Li_5O_5$ and $Li_8O_8$ cores of **2** and **3**. Both are best viewed as derived from a square-pyramidal structural motif (Fig. 3). In **2**

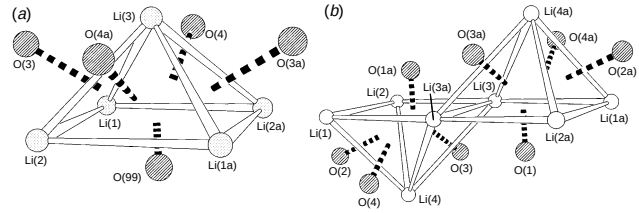

**Fig. 3** Li–O cores of (*a*) **1** and (*b*) **2**; connections between lithium atoms are not intended to imply bonding interactions

all five faces of an isolated square pyramid of lithium atoms are capped by oxygen atoms [four $\mu_3$ and one $\mu_4$, Fig. 3(*a*)]. In **2**, the same motif persists, though here two square pyramids of lithium share one edge and the inner triangular face of each is uncapped leaving the eight oxygen atoms to cap the other eight faces [six $\mu_3$ and two $\mu_4$, Fig. 3(*a*)]. To our knowledge, these are the first observations of such a structural motif in organolithium chemistry, though pentanuclear organolithium species of any geometry are extremely rare.[8] The arrangement of a square plane of lithium atoms capped by a $\mu_4$ oxygen atom is, however, reminiscent of an isolated fragment of the polymeric layered structure of LiOMe.[9]

We thank Durham (University Scholarship for S. L), The Royal Society (Leverhulme Trust Senior Research Fellowship for J. A. K. H.), and Dr P. Mountford (Nottingham) for communication of unpublished results.

# Gene sensor using ferrocenyl oligonucleotide

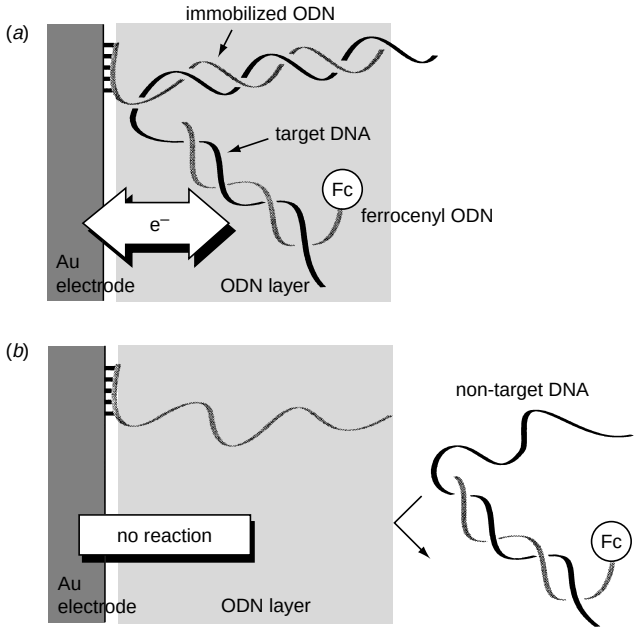
**Toshihiro Ihara,*† Masamichi Nakayama, Mitsuru Murata, Koji Nakano and Mizuo Maeda***

*Department of Chemical Science and Technology, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812-81, Japan*

**An electrochemical gene sensing system has been developed using a redox-active ferrocene-modified oligonucleotide and an oligonucleotide anchored on a gold electrode, both of which formed a sandwich-type ternary complex with the target DNA to give a redox current.**

Radioactive isotopes (RI) such as $^{32}P$ are widely used as labels of DNA because of their high detection sensitivity. However, due to their hazardous nature and short shelf life, the development of an alternative detection system that is convenient and practical without relying on RI is eagerly hoped for. We have proposed electrochemical methods as the alternative[1–3] and proved their potential using a high performance liquid chromatography–electrochemical detector system.[4] Recently, several systems for electrochemical detection of DNA have been reported.[5–11] Here we describe a novel electrochemical technique for gene detection in which a sandwich-type complex from an oligodeoxynucleotide (ODN) immobilized on a gold electrode, the target DNA and a ferrocenyl ODN is formed to give a response (Fig. 1).

All ODNs used in this study were prepared on a fully automated DNA synthesizer (Parmacia, Gene Assembler Plus). The ferrocenyl ODN (**T12Fc**) was synthesized by the coupling of amino-terminated ODN with an activated ester of ferrocenecarboxylic acid according to our previous report.[1,4] A 16-mer ODN (**e16S**) which has five successive phosphorothioate units on its 5′-terminus was synthesized using Beaucage's reagent.[12]



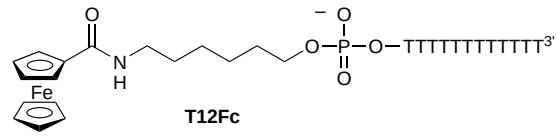


**Fig. 1** Schematic illustration of the electrochemical gene sensing system based on the formation of complementary sandwich-type complex. (*a*) Target DNA combines the ferrocenyl ODN with the ODN on electrode. Oxidation current due to the concentrated ferrocenyl units should reflect the concentration of the target. (*b*) Ferrocenyl units are not concentrated onto the electrode using non-target DNA.

**e16** 5′TTTTTTCTCATACATG3′
**t19** 5′CATGTATAAAAAAAAAAAA3′
**m19** 5′CATCTATAAAAAAAAAAAA3′
**c19** 5′TTCCGCGAAAAAAAAAAAA3′

**T12Fc**

s = phosphorothioate linkage

The ODN was anchored on the gold electrode *via* chemisorption[13,14] in the following manner: a 10 μl droplet of a 50 μM aqueous solution of **e16S** (containing 100 mM KCl) was cast on well-polished gold disk electrodes (1.6 mm diameter, BAS). The electrodes were then washed with 100 mM KCl solution and stored at 5 °C before use.

Cyclic voltammetric (CV) measurements using a ferrocyanide/ferricyanide redox couple were carried out in order to confirm the ODN modification on the electrode.[13] While the electrode treated with **e16**, which does not have any sulfur atoms, gave the same voltammogram as the bare electrode, the peak current obtained for the **e16S**-modified electrode was significantly suppressed, indicating that the redox couple was excluded from the electrode surface due to electrostatic repulsion between the anionic redox species and the ODN polyanion anchored on the electrode. Heat-treatment of the **e16S**-modified electrode at 80 °C for 30 min in water made no difference to the voltammogram produced. It is likely that the multi-point anchoring of the DNA *via* the phosphorothioate moieties will give stable immobilization of DNA on the gold electrode. This method should be useful for fixation of synthetic DNA onto electrodes.

The electrode modified with **e16S** was immersed in a 50 μM aqueous solution of an equimolar mixture of **T12Fc** and **t19** [**T12Fc**–**t19**, the target containing 100 mM KCl, 5 mM Tris-HCl (pH 8.0)] for 24 h at 5 °C. The electrode was then rinsed with 100 mM KCl at 5 °C. In CV measurements in 100 mM KCl, the modified electrode gave reversible redox waves showing a peak separation of 50 mV. We estimated the amount of the bound probe (**T12Fc**) to be 22–55 pmol $cm^{-2}$ by integration of the charge under the anodic peak. Fig. 2 shows differential pulse voltammograms (DPVs) for the modified electrode. A significant anodic peak due to oxidation of the ferrocene moiety was observed for the electrode treated with the target DNA. On the other hand, only a slight peak was observed for the **e16S**-modified electrode which was treated similarly with a mixture of **T12Fc** and **m19** (**T12Fc**–**m19**, mismatch control) and **T12Fc** and **c19** (**T12Fc**–**c19**, control, data not shown).

The peak potential ($E_p$) of the DPV was +620 mV (*vs.* Ag/AgCl), which means the redox potential ($E_{1/2}$) of the ferrocenyl unit of **T12Fc** on the electrode was +645 mV [$E_{1/2} = E_p + (\Delta E/2)$]. This value is exceedingly positive compared with that in bulk solution; CV measurements of aqueous **T12Fc** showed a

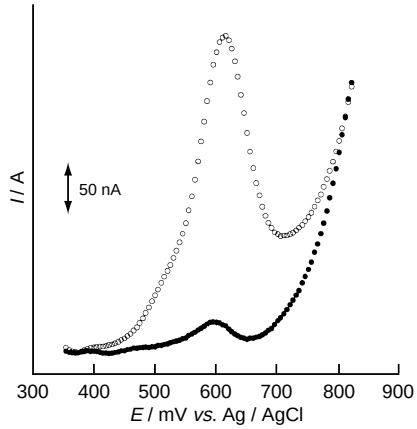

**Fig. 2** Differential pulse voltammograms of the ODN modified electrode treated with (○) **T12Fc–t19** (target) and (●) **T12Fc–m19** (mismatch control). The ODN electrode was sensitive only for the target **t19**. Electrodes: Pt plate, Ag/AgCl; pulse period: 200 ms; scan rate: 25 mV $s^{-1}$; pulse amplitude: 50 mV; pulse width: 50 ms, *T*: 5 °C.

redox potential of *ca.* +430 mV.[1] A similar positive shift was observed in Letsinger's study,[15] in which the ferrocenyl mononucleotide was confined on the electrode surface using sulfur (thiol group)–gold chemisorption.

While the peak for the target sample (**T12Fc–t19**) did not change at all after rinsing the electrode with 100 mM KCl at 5 and 10 °C, similar treatment at 20 °C reduced the peak current appreciably to *ca*. 25%, providing a comparable peak with those obtained for the control samples. On the other hand, the small peaks observed for the control sample (**T12Fc–c19**) and for the mismatch control sample (**T12Fc–m19**) scarcely changed after similar treatment at 20 °C. These results indicate that the binding of the target sample was temperature sensitive. That is, the target was recognized by means of complementary base-pairing with the ODN immobilized on the electrode. On the other hand, the slight current observed in the control and mismatch samples should be ascribed to the non-specific binding of **T12Fc–c19** and –**m19** to the ODN. Thus the detecting device proposed here should be a basis for a simple and highly selective sensing system. Optimization of the measurement conditions such as temperature, salt concentration and/or coexisting non-specific binding blocker (mRNA or sonicated calf thymus DNA) should be made to improve the sensitivity of this system. The electrode's durability also needs to be studied before practical application of this technique to gene diagnosis.

# Unexpectedly selective ligand binding within the cavity of a cyclic metalloporphyrin dimer

**R. Stephen Wylie, Esther G. Levy and Jeremy K. M. Sanders***

*Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*

**4-Substituted pyridines of an appropriate size show a remarkable preference for binding inside the cavity of a cofacial butadiyne-linked zinc porphyrin dimer; the origin of the effect is not entirely clear but may be related to solvent release or favourable host–guest contacts**

We report here that the binding of a pyridine ligand to a zinc porphyrin dimer can occur selectively on the inner face of a cavity rather than on the more accessible but otherwise apparently equivalent outer face.

Previous work in this laboratory had demonstrated that pyridine binds to monomers such as $ZnL^1$ and dimers such as $Zn_2L^2$ with essentially the same microscopic binding constant in $CH_2Cl_2$ solution;[1,2] each individual zinc porphyrin can form only a 1:1 complex with amines. For larger oligomers such as trimers, which have spacious cavities, we interpreted the results to indicate that binding of successive pyridines to different porphyrin subunits was independent and statistical; we also concluded that binding on the inside and outside occurred randomly and to the same extent. However, the small cavity associated with dimer $Zn_2L^2$ does not allow for the same independence of inner binding: ligation of a 4-substituted pyridine to the inner face of one porphyrin might tend to inhibit binding to the internal face of the other. We therefore expected that a careful study of the binding of pyridines to $Zn_2L^2$ [eqns. (1) and (2)] would demonstrate negative cooperativity: $K_1$

$$Zn_2L^2 + X \overset{K_1}{\rightleftharpoons} Zn_2L^2{\cdot}X \quad (1)$$

$$Zn_2L^2{\cdot}X + X \overset{K_2}{\rightleftharpoons} Zn_2L^2{\cdot}2X \quad (2)$$

should be twice as large as for binding to $ZnL^1$ ($K_{mon}$) due to the presence of two binding sites, each with the possibility of inner and outer binding, while $K_2$ should be less than half the size as inner binding of the second ligand would be hindered. The results for spectrophotometric titrations in toluene solution were very different from those expected. Pyridine itself has a $K_1/K_{mon}$ value (Table 1) of 3.2, which differs from the expected value of 2.0 by slightly more than the experimental error. The discrepancy is larger for 4-methylpyridine (4-Mepy), while the first 4-*tert*-butylpyridine (4-Bu$^t$py) binds some 50 times more strongly to the dimer than to the monomer.

**Table 1** Equilibrium constants (dm$^3$ mol$^{-1}$) for binding of ligands X to $ZnL^1$ and $Zn_2L^{2a}$ (X = $NC_5H_4R$)

| R | $Zn_2L^2$ ($K_1$) | $ZnL^2$ ($K_2$) | $ZnL^1$ ($K_{mon}$) | $K_1/K_{mon}$ | $K_2/K_{mon}$ |
|---|---|---|---|---|---|
| H | $1.6 \times 10^4$ | $2.9 \times 10^3$ | $5.0 \times 10^3$ | 3.2 | 0.6 |
| 4-Me | $6.2 \times 10^4$ | $1.1 \times 10^4$ | $1.1 \times 10^4$ | 5.6 | 1.0 |
| 4-Bu$^t$ | $7.3 \times 10^5$ | $3.0 \times 10^4$ | $1.4 \times 10^4$ | *ca.* 50 | 2.1 |

[a] In toluene at 25 °C using electronic spectroscopy;[2] estimated uncertainties 7–10%.

To rigorously exclude the possibility of problems that can easily arise from the analysis of multiple binding equilibria, the free-base dimer $H_4L^2$ was partially metallated, and the singly metallated $Zn(H_2L^2)$ species was isolated by chromatography. Now only a single ligand can be bound, and data analysis is simpler. Table 2 summarises the results for a wider range of ligands, the *f* value ( = $K_{dim}/K_{mon}$) giving a direct comparison of binding strength. The trends are similar to those seen for the doubly metallated host, the maximum effect of 25-fold being for *R* = 4-Bu$^t$ in toluene. Preferential binding is not restricted to alkyl substituents, as is apparent in the results for 4-hydroxymethylpyridine. Only when the substituent is so large that the ligand cannot comfortably fit inside the cavity is the *f* value less than 1. Similar trends were seen for titrations in dichloromethane (Table 2, results in italics), although the absolute size of the effect is smaller, and now pyridine itself is bound less well by the dimer than by the monomer.†

The larger *f* values for some ligands imply that binding occurs preferentially to one face of the porphyrin, presumably the intracavity one. One explanation for these results might be that molecules of solvent toluene are more strongly associated with the dimer cavity than with the open faces of the monomer,[3] and that binding of an appropriately sized ligand within the cavity would then lead to entropically favourable solvent release. Where one ligand releases more than one solvent molecule this can lead to entropy-driven binding.[4] However there is no

[a] In toluene at 25 °C using electronic spectroscopy; [2] estimated uncertainties 7–10%. [b] In $CH_2Cl_2$ at 25 °C. [c] Y = *trans*-(4-Pyridyl)ethenyl.

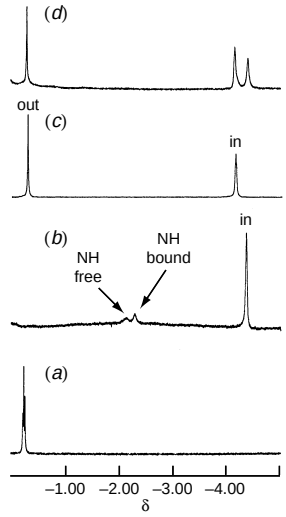

**Fig. 1** Partial 400 MHz $^1$H NMR spectra at −60 °C in [$^2H_8$]toluene of (*a*) $ZnL^1$ in the presence of 0.5 equiv. 4-Bu$^t$py, indicating that three complexes are formed (Fig. 2); (*b*) $Zn_2(H_2L^2)$ in the presence of 0.5 equiv. 4-Bu$^t$py, demonstrating exclusively inside cavity binding; (*c*) $Zn_2L^2{\cdot}2$(4-Bu$^t$py), showing inside and outside binding; and (*d*) $Zn_2L^2$ in the presence of 1.0 equiv. 4-Bu$^t$py showing the co-existence of 1 : 1 and 1 : 2 complexes

evidence for such an effect in this system: Van't Hoff plots (25–55 °C) for 4-Bu$^t$py binding in the temperature range 25–55 °C give very similar values for $-T\Delta S$ [24 kJ mol$^{-1}$ at 298 K for $ZnL^1$ and 23 kJ mol$^{-1}$ for $Zn(H_2L^2)$] in toluene. The major difference in driving force is in $-\Delta H$, which is 47 kJ mol$^{-1}$ for $ZnL^1$ and 54 kJ mol$^{-1}$ for $Zn(H_2L^2)$. Solvent-dependent binding within cavities has been reported in many other systems, but these can be usually be rationalised in terms of optimising host–guest or disrupting host–solvent interactions.[5]

To prove that preferential binding occurs within the cavity we turned to $^1$H NMR spectroscopy at a temperature low enough to ensure slow ligand exchange; the large ring current associated with the porphyrin π system leads to particularly marked shielding of ligands sandwiched inside the cavity of a dimer.[1, 2] At – 60 °C in [$^2H_8$]toluene, the Bu$^t$ resonance in the complex of 4-Bu$^t$py with $ZnL^1$ appears as three very close singlets at $\delta$ –0.2 [Fig. 1(*a*)], a shift of 1.2 ppm on binding; the three signals result from the slow exchange between three isomeric complexes (Fig. 2).[6] By contrast, when 0.5 equiv. 4-Bu$^t$py are added to $Zn(H_2L^2)$ at −60 °C in [$^2H_8$]toluene, a single Bu$^t$ resonance due to the complex of 4-Bu$^t$py appears at $\delta$ −4.3 [Fig. 1(*b*)], a binding shift of 5.3 ppm that is consistent only with the ligand being bound within the cavity as shown in Fig. 3(*a*); no externally bound ligand is seen. It is notable that the NH resonances of the free-base porphyrin are sensitive to the presence of the ligand within the cavity, shifting from $\delta$ −2.1 to −2.3 upon ligation of the other porphyrin unit. The $^1$H NMR spectrum of the $ZnL^2{\cdot}2$(4-Bu$^t$py) complex [Fig. 1(*c*)] contains

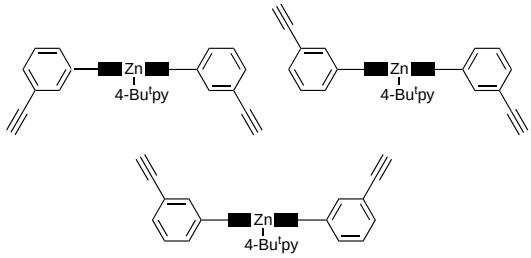

**Fig. 2** Three isomeric forms of the complexes of 4-Bu$^t$py with $ZnL^1$. The *trans*-atropisomer complex is statistically twice as abundant as either of the individual *cis*-atropisomer complexes.

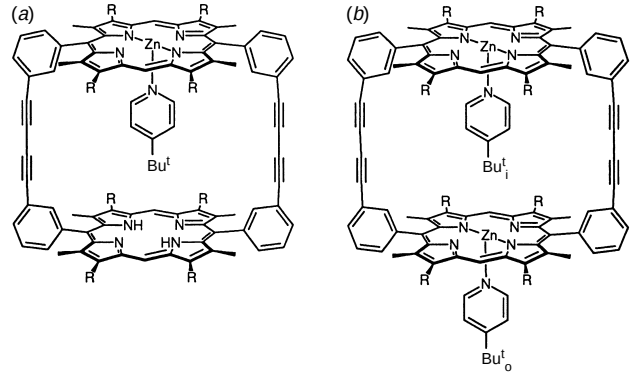

**Fig. 3** Geometries of (*a*) $Zn(H_2L^2){\cdot}$4-Bu$^t$py and (*b*) $Zn_2L^2{\cdot}2$(4-Bu$^t$-py)

two signals in a 1 : 1 intensity ratio and with shifts that show one ligand bound inside and one outside the cavity [Fig. 3(*b*)], while a deficiency of the ligand yields a mixture of the 1 : 2 complex with the inside-only 1 : 1 complex [Fig. 1(*d*)]. The results described here show that cavity effects can have unpredictable influences on the strength and position of binding. The dependence of the first binding constant on ligand size may reflect a direct van der Waals enthalpic contribution from ligand contact with the non-binding porphyrin,‡ but this explanation seems hard to reconcile with the similarity of effect between $Zn(H_2L^2)$ and $Zn_2L^2$, and between polar and non-polar substituents on the ligand. It seems more likely that the effect is an unpredictable outcome of the delicate changes in host and guest solvation that occur on complex formation. The corresponding cyclic porphyrin trimer in toluene displays small but measurable preferences for binding some ligands within its cavity, and this may influence the rate of host-catalysed reactions within the cavity. Details will be reported elsewhere.

We thank Dr Nick Bampos for the methyl ester analogue of $Zn(H_2L^2)$, NSERC Canada (R. S. W.), the Cambridge Commonwealth Trust and New Zealand Vice-Chancellors' Committee (E. G. L.) for financial support, and the EPSRC Mass Spectrometry Service for FAB spectra.

† Control experiments with the toluene-insoluble methyl ester analogues of $ZnL^1$ and $Zn(H_2L^2)$ (R = $CH_2CH_2CO_2Me$) in dichloromethane show no significant difference in binding behaviour, ruling out effects due to interaction with the long alkyl side-chains.

§ The small but probably real increase of $K_2$ for $Zn_2L^2$ with ligand size may reflect subtle geometry changes in the second porphyrin as the first ligand binds within the cavity and contacts the second porphyrin.

**Nitromethane reacts *via* a diastereoselective double Michael addition with electrophilic alkenes activated by cyano and methoxycarbonyl groups [$XC_6H_4CH{=}C(CN)CO_2Me$] in the presence of catalytic amounts of piperidine under solvent-free conditions coupled with focused microwave irradiation to afford new, highly functionalized cyclohexenes; no cyclopropane formation is observed.**

Organic synthesis in dry media coupled with microwave irradiation is currently a matter of increasing interest.[1–3] Microwave-assisted organic reactions in the presence or absence of solvents have recently been reviewed.[4] In the course of our studies related to the catalytic effect of piperidine towards condensations[5–7] under microwave irradiation (MWI), we report a novel reaction of nitromethane **1** with some electrophilic alkenes **2a–g**,† which leads to highly functionalized cyclohexenes **3a–g**‡ and/or **4a–g**‡ after demethoxycarbonylation of **3** (Scheme 1). Nitroalkanes and electrophilic alkenes are known to give cyclopropanes, although in the case of nitromethane, the yields are rather poor.[8–10]

The simple mixture of **1** and **2**, without solvent in the presence of adjusted amounts of piperidine, afforded **3** or **4** at room temperature (for example **3a** was obtained in 60% yield after 98 h, with 12 mol% piperidine with respect to the alkene) or in a few minutes under focused microwave irradiation in a Synthewave 402 Prolabo[11] at 90 °C (monitored temperature[12]) (see Tables 1 and 2). The reaction is highly diastereoselective: only two isomers were detected in the crude product by $^1H$ NMR spectroscopy. The relative configuration of the major isomer has been established by X-ray analysis (Fig. 1).[13] However, the relative configuration of the minor isomer has not yet been established.

In order to check the effect of the focused microwave irradiation, we performed the following experiments for the

[a] Pure isolated product after column chromatography on silica gel (eluent $CH_2Cl_2$) and then crystallization from diethyl ether.

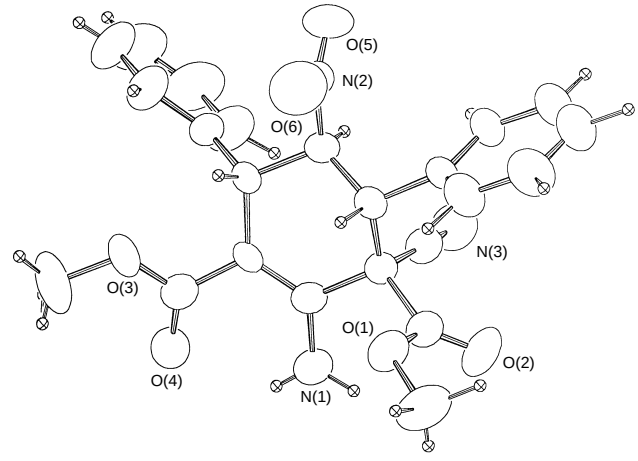

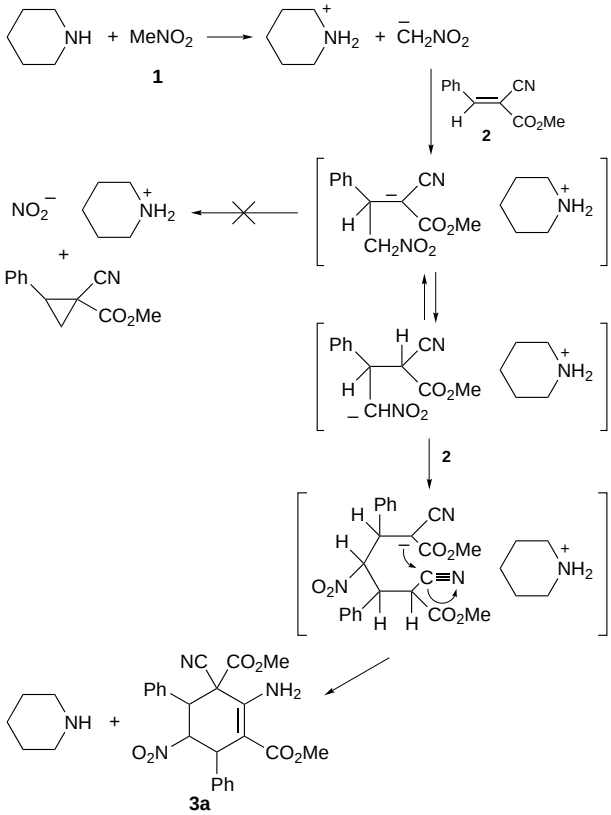

**Fig. 1** ORTEP diagram of **3a**

**Scheme 2**

synthesis of **3a**. (i) The reaction mixture was irradiated at 750 W in a domestic oven (Philips M602) for the same time (11 min, 97 °C measured at the end), and gave 5% of **3a** (estimated by $^1$H NMR spectroscopy). (ii) The same reaction mixture was placed in an oil bath at 90 °C for the same time (11 min), but the reaction only went to 60% completion; the low yield of **3a** (27%) is due to competition from the Michael monoadduct. After 20 min this yield remained unchanged.

Cyclohexene formation can be explained by the mechanism presented in Scheme 2. After a double Michael addition, the ring closure occurs *via* nucleophilic attack on the nitrile group by the carbanion and regeneration of piperidine in a catalytic cycle. A stoichiometric amount of piperidine promotes the demethoxycarbonylation of **3** to **4** by a mechanism already described by Carrié.[14]

This cyclohexene synthesis, previously unreported in the literature, is a simple, clean, economical and environmentally benign process which can be performed either at room temperature over a rather long reaction time or under focused microwave irradiation in a short time with better yields.

The extension of this reaction to other electrophilic alkenes (dicyano and cyano amide) is under investigation.

† *Typical procedure*: A mixture of alkene (5 mmol), nitromethane (0.18 g, 3 mmol) and piperidine (20 μl, 0.2 mmol for **3a** and 250 μl, 2.5 mmol for **4a**) was placed in a quartz tube (diameter 37 mm) and introduced into a Synthewave 402 Prolabo microwave reactor (2.45 GHz) fitted with a rotational system, adjustable power within the range 20–300 W and a wave guide (monomode $T_{01}$) (ref. 11). Microwave irradiation was carried out at 90 °C (ref. 12) (obtained after 3 min and then maintained for 8 min). Other irradiation times are given in Tables 1 and 2. The mixture was cooled to room temperature and the crude residue was characterized by $^1$H NMR spectroscopy. Pure product was isolated after chromatography on silica gel (eluent $CH_2Cl_2$) and slow crystallization from diethyl ether.

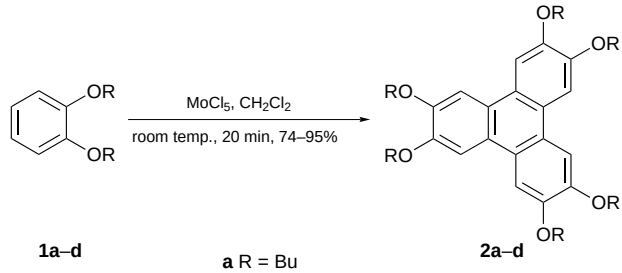
# Oxidative trimerization of *o*-dialkoxybenzenes to hexaalkoxytriphenylenes: molybdenum(v) chloride as a novel reagent

**Sandeep Kumar* and M. Manickam**

*Centre for Liquid Crystal Research, P.O. Box 1329, Jalahalli, Bangalore 560 013, India*

**Symmetrically substituted hexaalkoxytriphenylenes are obtained from *o*-dialkoxybenzenes by oxidative trimerization with $MoCl_5$ in high yields; oxidative coupling of a 3,3′,4,4′-tetraalkoxybiphenyl and 1,2-dialkoxybenzenes yields unsymmetrically substituted derivatives of triphenylene and a direct coupling of a 3,3′,4,4′-tetraalkoxybiphenyl with alkoxyphenol produces the monofunctionalized triphenylenes.**

Hexasubstituted triphenylenes are the most widely synthesized and studied discotic mesogens.[1] Recently, these materials have been discussed as potential candidates for opto-electronic devices.[2,3] Several research groups are currently working on the synthesis of symmetrical, unsymmetrical and functionalized triphenylene discotic liquid crystals.[4–9] Here we report the synthesis of a variety of triphenylene derivatives using a novel reagent, molybdenum(v) chloride.



Synthesis of hexamethoxytriphenylene has been achieved previously by oxidative trimerisation of 1,2-dimethoxybenzene (veratrol) in $H_2SO_4$ using chloranil or iron chloride as oxidant.[10] The trimerization involves three consecutive Scholl reactions but surprisingly under normal Scholl conditions using aluminium chloride and nitrobenzene this does not work well.[10e] Triphenylene derivatives show mesomorphism only when the six peripheral alkoxy chains have a minimum of four carbon atoms, *i.e.* butoxy chains. The trimerization using chloranil is limited to the preparation of hexamethoxytriphenylene only and with higher homologues like 1,2-dihexyloxybenzene it gives only a poor yield of hexahexyloxytriphenylene with many side products.[4g] To prepare these long chain derivatives, the methyl groups of hexamethoxytriphenylene are dealkylated by $BBr_3$ or HBr and the resultant hexaphenol is realkylated with the appropriate alkyl halide to give different hexaalkoxytriphenylene discotics.

Hexamethoxytriphenylene can also be prepared by the cyclic anodic trimerization of dimethoxybenzene and, using a chemical or electrochemical reductive work-up, a moderate yield of the product can be obtained.[11] The method is not limited to dimethoxybenzene but can be extended to other dialkoxybenzenes to form directly hexaalkoxytriphenylene discotics, but this slow reaction is only applicable on a very small scale and, thus, limited in its use.

The use of $FeCl_3$ as oxidant was further explored by the Ringsdorf group, which reported the synthesis of hexahexyloxytriphenylene by the trimerization of 1,2-dihexyloxybenzene in 70% $H_2SO_4$ at 80 °C using iron chloride in 20% yield.[12] A further modification to this process was implemented by the Boden group, who used only a catalytic amount of $H_2SO_4$ (0.3%) in $CH_2Cl_2$ and reported yields of 55–86% for different alkoxytriphenylenes.[4g] Coupling of a tetraalkoxybiphenyl with the appropriate dialkoxybenzene under the same conditions gives unsymmetrical hexaalkoxytriphenylenes in 45–77% yield.[4f]

Well-defined synthesis of unsymmetrical and low degree substituted triphenylenes has been reported recently using organometallic chemistry and $FeCl_3$.[7,8] These sophisticated methods are useful for the preparation of low degree substituted triphenylenes but difficult to apply for a large scale production.

We have discovered that molybdenum(v) chloride is a novel reagent for the oxidative trimerization of 1,2-dialkoxybenzenes to hexaalkoxytriphenylenes in high yield. The reaction occurs under very mild conditions with or without acid catalyst and in a very short time at room temperature (Scheme 1). In a typical reaction, $MoCl_5$ (1.4 g, 0.0051 mol) was added to a solution of 1,2-dibutoxybenzene (1.1 g, 0.005 mol) in 10 ml of dry $CH_2Cl_2$. The reaction mixture was stirred at room temperature for 20 min under anhydrous conditions. It was then poured over cold MeOH (15 ml), diluted with water (20 ml) and extracted with hexane (4 × 20 ml). The combined extracts were washed with water and brine, dried over anhydrous sodium sulfate, the solvent was removed under vacuum and the crude product was purified by column chromatography over silica gel, yielding 1.04 g (95%) of hexabutoxytriphenylene. The product was characterized by its spectral data, phase behaviour and a direct comparison with an authentic sample. Yields of different hexaalkoxytriphenylenes are given in Table 1. As $MoCl_5$ is a 2 $e^-$ oxidant, only *ca.* 1 equiv. of the reagent is required to

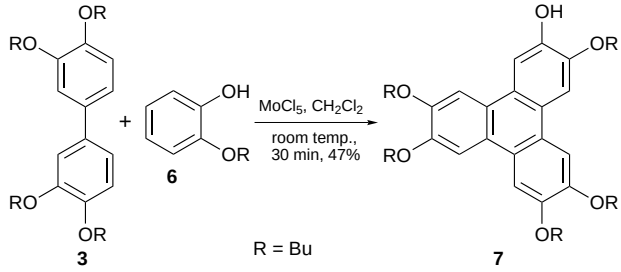
| **3** + **6** | 0.2 | **7** | 47 |



perform the reaction. The best yields of hexaalkoxytriphenylenes were obtained without using any acid and gave better yields than any of the known methods. We have also observed that on increasing the amount of $H_2SO_4$, partial dealkylation of hexaalkoxytriphenylenes occurs and variable amounts of monohydroxypentaalkoxytriphenylene can be isolated (Table 1). The work-up of the reaction is very simple; in most cases, on pouring the reaction mixture over MeOH, a white precipitate forms which can be filtered and recrystallized. Otherwise, addition of water followed by extraction with hexane gives a colourless product.

Synthesis of unsymmetrical and monofunctionalized triphenylenes was achieved by coupling a 3,3′,4,4′-tetraalkoxybiphenyl and appropriate 1,2-dialkoxybenzenes (Scheme 2) under similar reaction conditions. Thus, when 3,3′,4,4′-tetrabutoxybiphenyl **3**, prepared by classical Ullman coupling of dialkoxymonoiodobenzene, was coupled with 2-butoxyanisole **4**, 2-methoxy-3,6,7,10,11-butoxytriphenylene **5** was formed in 90% yield. Symmetrical and nonsymmetrical trimers of 1,2-dialkoxybenzenes were the two side products in this reaction.

**Scheme 2**

Monofunctionalized triphenylene, an extremely important precursor for the synthesis of discotic dimers, oligomers and polymers, can be prepared by direct coupling of a 3,3′,4,4′-tetraalkoxybiphenyl and monoalkoxyphenol. Thus, oxidative coupling of 3,3′,4,4′-tetrabutoxybiphenyl **3** and 2-butoxyphenol **6** using $MoCl_5$ under similar reaction conditions yielded 2-hydroxy-3,6,7,10,11-butoxytriphenylene **7** in 47% yield (Scheme 3).

**Scheme 3**

The potential of this new reagent is currently under investigation for the synthesis of different symmetrical, unsymmetrical and functionalized triphenylenes. The effects of different solvents, acids and concentrations are also under investigation and the results will be published in due course.

We are very grateful to Professor S. Chandrasekhar and Professor H. Ringsdorf for many helpful discussions.

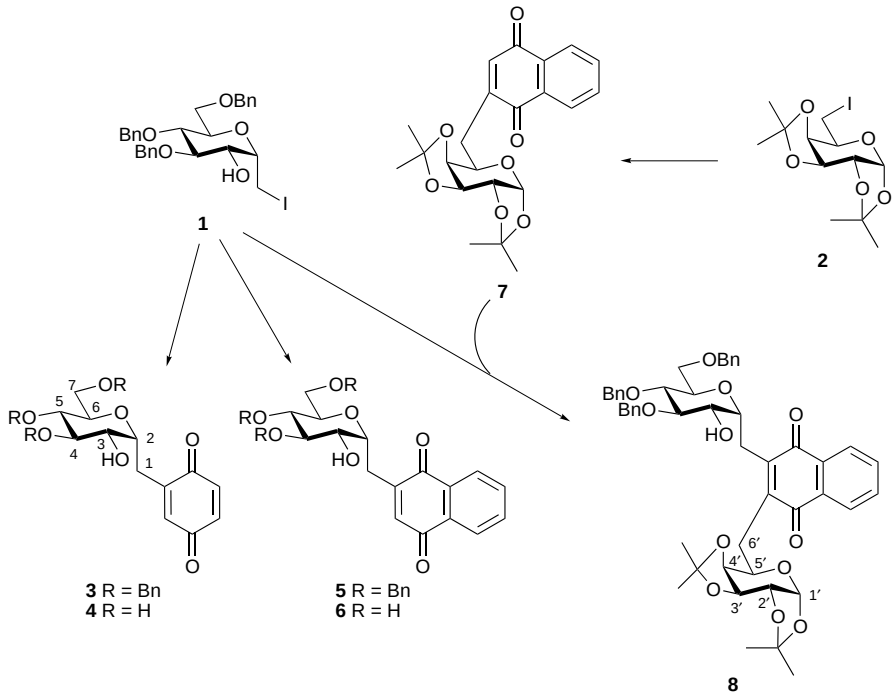
# *C*-Glucosyl quinones and related spacer-connected *C*-disaccharide

**Laura Cipolla,[a] Marco Guerrini,[b] Francesco Nicotra,*[a]† Giangiacomo Torri[b] and Elena Vismara*[c]**

[a] *Dipartimento di Chimica Organica e Industriale, Università degli Studi di Milano, Via Venezian 21, 20133 Milano, Italy*
[b] *Istituto di Chimica e Biochimica 'Giuliana Ronzoni', V. G. Colombo 81, 20133 Milano, Italy*
[c] *Dipartimento di Chimica, Politecnico di Milano, Via Mancinelli 7, 20131 Milano, Italy*

***C*-Glycosyl radicals obtained from iodide 1 react with benzo- and naphtho-quinone to afford, after deprotection, *C*-glycosyl quinones 4 and 6 which inhibit yeast α-glucosidase; employing a naphthoquinone linked to the non-reducing end of a sugar 7, a spacer-connected *C*-disaccharide 8 is obtained.**



There is a growing interest in *C*-glycosides and *C*-disaccharides as potential inhibitors and regulators of carbohydrate processing enzymes and as stable mimics of saccharidic structures involved in recognition phenomena.[1] In this context, particular attention has been devoted to molecules that interfere in the biosynthesis of N-linked glycoproteins, so inhibiting pathologic processes such as HIV replication,[2] or tumour growth and metastasis formation.[3] The biosynthesis of N-linked glycoproteins involves a common asparagine-linked oligosaccharide intermediate which undergoes a trimming process, the first two trimming enzymes being α-glucosidases (I and II).[4] As a consequence α-glucoside mimics, among them α-*C*-glucosides, are potential inhibitors of N-linked glycoprotein biosynthesis.

**Scheme 1**

Many α-*C*-glucosides have been synthesised, among them aryl *C*-glucosides, in which the aromatic group is directly linked to the anomeric centre of the sugar.[5] Molecules of this kind, with quinones (especially flavonoids) directly linked to the anomeric centre of the sugar, are found in nature and are believed to form stable complexes with DNA. On the other hand, the presence of a naphthoquinone aglycon in *O*- and *S*-glycosides is responsible for antitumour[6] and antifungal[7] activity, and irreversible glycosidase inhibition.[8]

To mimic natural α-*O*-glucosides, and at the same time to produce a stable *C*-glycosidic linkage between the sugar and a quinone, we decided to synthesise α-*C*-glucosidic compounds in which the quinone is linked to the anomeric carbon through a methylene bridge. In the light of the fact that the conversion of this methylenic carbon into a nucleophile often gives rise to undesired elimination reactions or epimerization, we decided to use a radical approach. Quinones were in fact extensively studied as radical scavengers both from a mechanistic and a synthetic point of view.[9] In this context we decided to investigate the substitution by *C*-glycosyl radicals derived from

**Scheme 2**

*C*-glycosyl iodides and diazonium tetrafluoroborate according to Scheme 1. As this kind of quinone substitution is governed by enthalpic and, to a minor extent, steric effects, a radical at a methylenic carbon linked to the anomeric centre of a sugar appeared to be an attractive reagent.

An α-*C*-glucosyl radical can be obtained from the corresponding iodide provided that the hydroxy group at C-2 is not benzylated,[10] otherwise an abstraction of the benzylic hydrogen occurs with formation of the more stable benzyl radical. We synthesised (3,4,6-tri-*O*-benzyl-α-D-glucopyranosyl)iodomethane **2**, which lacks the benzyl protecting group at C-2, exploiting a vinylation–electrophilic cyclisation procedure[11] using 2,3,5-tri-*O*-benzyl-D-arabinose **1**.

In a typical experimental procedure (Scheme 2), a solution of 4-nitrobenzenediazonium tetrafluoroborate (2 mmol) in degassed DMSO (7 ml) was added dropwise to a solution of **1** (1 mmol), the quinone (1 mmol) and powdered $FeSO_4 \cdot 7H_2O$ (2 mmol) in degassed DMSO (15 ml). The solution was stirred until the evolution of nitrogen ceased. Usual work-up and chromatography afforded **3** {oil, $[\alpha]_D$ + 31.3 (*c* 1, $CHCl_3$)}‡ or **5** {oil, $[\alpha]_D$ + 47.6 (*c* 1, $CHCl_3$)}§ in 30–35% yield (80–85% yield based on converted **1**), and unreacted **1** was resubmitted to the reaction. Catalytic hydrogenation of **3** and **5** (Pd/C in EtOH) afforded **4** {oil, $[\alpha]_D$ − 9.7 (*c* 1, MeOH)} and **6** {mp 108–109 °C; $[\alpha]_D$ + 86.5 (*c* 1, acetone)}, respectively, in quantitative yield.

The biological activities of **4** and **6** as inhibitors of yeast α-glucosidase were tested according with the procedure reported by Wong.[12] Compound **4** is a poor competitive inhibitor ($K_i$ = 2.9 mM) but interestingly the presence of a further aromatic ring in **6** strongly enhances the inhibitory activity ($K_i$ = 0.17 mM).

The radical generated from **1** was also trapped (50% yield) by the sugar-substituted naphthoquinone **7**¶ (obtained from **2** *via* the procedure above). This reaction provided the naphthoquinone-connected *C*-disaccharide **8** {oil, [α] + 39.2 (*c* 1, $CHCl_3$); *m/z* 846}‖ in which two sugars are permanently linked through a naphthoquinone spacer. Recently, different saccharides connected with aliphatic[13] and aromatic[14] spacers have been synthesised to mimic biologically active natural oligosaccharides; this is the first example in which two saccharides are permanently connected *via* C–C linkages to a quinone spacer.

We gratefully thank MURST and CNR for financial support.

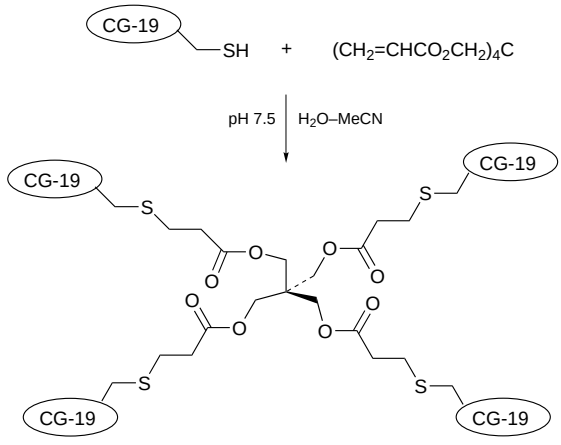
# Synthesis of a symmetric branched peptide. Assembly of a cyclic peptide on a small tetraacetate template

**Chuan-Fa Liu and James P. Tam***



*Department of Microbiology and Immunology, Vanderbilt University, A5119 Medical Center North, Nashville, TN 37232-2363, USA*

**A method for the synthesis of a symmetric peptide dendrimer (MW 8685.0) by assembling four copies of an unprotected Cys-containing cyclic peptide *via* Michael addition onto a small organic template, pentaerythritol tetraacrylate, is described.**

Branched peptides in which peptides radiate from a central core are emerging as a new class of artificial proteins with many potential applications.[1–3] Notable examples include the cascade peptide dendrimers found in the design of Multiple Antigenic Peptides (MAPs), in which the core structures are peptidyl templates organized by geometric branching of a bivalent lysine,[2] and TASP, which contains a preorganized, linear lysyl peptide template.[3–5] More recently, small, rigid organic compounds,[6] such as cavitands[7] and Kemp's triacid,[8] have also been exploited as templates for branched peptides. These templates have the advantages that they are readily obtainable and form branched peptides that have pseudo-symmetry. We have report the use of a readily available small organic molecule, pentaerythritol tetraacrylate (PETA), as the tempalte to prepare a symmetrical branched peptide containing four copies of a large cyclic peptide *via* Michael addition of a cysteinyl thiol (Scheme 1).

Together with branched peptide design, efficient methods to accomplish their synthesis are also required. Thus, recent advances in the development of ligation methods using unprotected peptides as building blocks have greatly facilitated their preparation.[9–13] These methods are mainly dependent on either thiol or weak base–aldehyde chemistry.[2] Our scheme for synthesizing symmetric peptide dendrimers involves Michael addition of a cysteinyl thiol to the double bond of the acrylate moiety of PETA. In practice, a two-fold excess (8 equiv.) of peptide with respect to the tetravalent PETA† was found to be adequate to drive the reaction to completion in 45 min, even at a relatively dilute concentration of peptide (1–2 mM). The reaction was performed in $H_2O$ at pH 8 with MeCN (50%) as a cosolvent to increase the solubility of PETA. However, the assembly reaction could also be carried out in 4–6 M guanidine hydrochloride solutions with comparable reaction rates. The only detectable side reaction was the disulfide formation of CG-19, and which could be minimized when a trialkyl phosphine was present in the reaction medium.[12] In 15 min, > 80% of the four-branch peptide dendrimer was formed, together with < 15% of the two- and three-branch intermediates, as monitored by HPLC (Fig. 1). Both the three-branch and four-branch products were isolated from HPLC and analysed by MALDI-TOF MS, which gave expected mass units for both products: 6604.0 (calc. 6602.0) for three branch and 8685.7 (calc. 8685.0) for four-branch (Fig. 1). The tetravalent peptide dendrimer was stable at both acidic and basic pH, and no decomposed product was found after 24 h treatment at pH 2 or 8 as monitored by HPLC.

An advantage of our synthetic scheme is the regioselectivity of Michael addition by a thiol to the acrylate moiety in the presence of other amine nucleophiles. This selectivity permits the use of unprotected, cyclic peptide as the building block for the assemblage on the PETA template. Furthermore, such cyclic peptides with a pendant cysteinyl thiol side chain can be readily synthesized through the intramolecular orthogonal coupling methods developed recently in our laboratory.[16,17] the cyclic peptide CG-19, which is rich in amino side chains, is derived from the sequence of the V3 loop of the gp 120 protein of HIV-1 (III-B). The linear, unprotected peptide precursor was prepared by solid phase synthesis through Boc-benzyl chemistry on a thioester resin.[15] HF cleavage gave the unprotected peptide with an $N^{\alpha}$-Cys(Npys) and a thiocarboxylic acid at the C-terminus with all other side chains unprotected. Cyclization was achieved *in situ* immediately after HF cleavage in which the C-terminal CO–SH reacted with the N-terminal H-Cys(NPys) residue,

CG-19 = cyclo(CysAlaLysArgIleGlnArgGlyProGlyArgAlaPheValTheIleGly)

**Scheme 1**

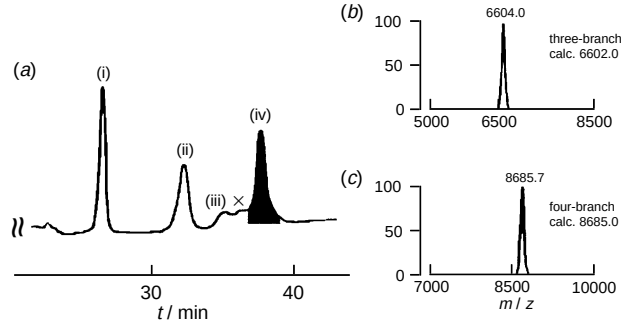


**Fig. 1** (*a*) HPLC monitoring of the Michael reaction of the thiol cyclic peptide CG-19 with PETA after 15 min. (*b*) MALDI MS of the 3-branch peptide dendrimer. (*c*) MALDI MS of the four-branch peptide dendrimer. Peaks are (i) cyclic peptide CG-19, (ii) cyclic peptide CG-9 disulfide, (iii) three-branch, (iv) four-branch (x = two-branch). HPLC analyses were run on a Shimadzu system with a Vydac analytical column (0.46 × 25 cm, $C_{18}$ reverse phase) at a flow rate of 1.5 ml $min^{-1}$, with UV detection at 225 nm and a linear gradient from 20 to 65% buffer B in buffer A in 45 min. Buffer A = $H_2O$ (0.045% TFA); Buffer B = 60% MeCN in $H_2O$ (0.04% TFA).

leading to the formation of an internal Gly–Cys peptide through proximity-driven acyl migration.[15] After purification, a cyclic peptide building block with unambiguous structure and composition was obtained for the subsequent assemblage on PETA. Michael addition of a thiol to the maleimido group has been extensively used for peptide–protein conjugates.[9] However, the hydrolysis of the maleimide at basic pH is a well recognized disadvantage.[9b] Thus, the use of PETA, which forms a more stable and non-maleimide product, is a significant advantage.

The method presented here provides a straightforward and practical approach to preparing branched peptide dendrimers that would be useful for the preparation of specific antibodies as well as for the development of synthetic vaccines. We anticipate that other types of artifical proteins might also be synthesized using this method.

# Rhodium-catalysed arylation of aldehydes with arylstannanes

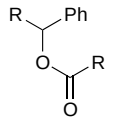
**Shuichi Oi,* Mitsutoshi Moro and Yoshio Inoue**

*Department of Materials Chemistry, Graduate School of Engineering, Tohoku University, Sendai 980-77, Japan*

**Aryltrimethylstannanes react with aldehydes in the presence of a catalytic amount of a cationic rhodium complex, [Rh(cod)(MeCN)$_2$]BF$_4$, affording the corresponding arylated secondary alcohols in good yields.**

The addition of organometallic reagents to aldehydes has been the general method for the synthesis of secondary alcohols. Among these reagents, organolithium and organomagnesium (Grignard reagent) compounds are recognized to be the most versatile. However, limitations to their use arise from the very nature of the reagents, namely, their extraordinary reactivity as nucleophiles and bases. This feature often gives rise to undesired reactions in the synthesis of multifunctional compounds such as natural products. In order to realize chemoselective addition to aldehydes, various organometallic reagents have been investigated. Nozaki and Hiyama[1] and Kishi[2] reported the addition of organochromium compounds to aldehydes in the presence of a nickel catalyst. Although this reaction is highly chemoselective and displays wide compatibility with the functional groups in both reaction partners, a large excess (200–1600 mol%) of chromium salt is required. The allylation of aldehydes with allylstannanes promoted by a Lewis acid is one of the most promising reactions and has been applied successfully in organic systhesis.[3] Recently, this allylation was reported to be also catalysed by transition metal complexes such as those of rhodium,[4] palladium and platinum.[5] There is, however, no report on the addition of other organostannanes to aldehydes except 1-carboranylstannane,[6] a very special agent. We wish to report here a novel, highly chemoselective arylation reaction of aldehydes with arylstannanes catalysed by a cationic rhodium complex [eqn. (1)].

The general procedure is as follows. A mixture of 1.2 mmol of arylstannane **1**, 1.0 mmol of aldehyde **2** and 0.02 mmol of [Rh(cod)(MeCN)$_2$]BF$_4$ (cod = cycloocta-1,5-diene) in 1 ml of dried THF was stirred at 60 °C for an appropriate period of time under $N_2$ atmosphere in a sealed Schlenk tube. The reaction was monitored by TLC. The reaction was quenched by adding a small amount of water and then stirred for 1 h. After the solvent was removed *in vacuo*, the product was isolated by silica gel column chromatography.



The results are summarized in Table 1. The arylation of benzaldehyde with trimethylphenylstannane proceeded smoothly in the presence of 2 mol% cationic rhodium complex [Rh(cod)(MeCN)$_2$]BF$_4$, affording diphenylmethanol in 85% isolated yield (entry 1). NMR examination of the reaction mixture prior to quenching the reaction by adding water indicated the formation of the corresponding stannyl ether. Therefore, the hydrolysis of the stannyl ether must take place during the work-up. Addition of phosphine ligands such as $PPh_3$ to [Rh(cod)(MeCN)$_2$]BF$_4$ inhibited the reaction. Neutral rhodium complexes such as RhCl($PPh_3$)$_3$ and [RhCl(cod)]$_2$ did not promote the reaction, nor did the traditional Lewis acids like $TiCl_4$ and $BF_3{\cdot}OEt_2$. The employment of tributylphenylstannane and tetraphenylstannane instead of trimethylphenylstannane gave diphenylmethanol in lower chemical yields of 65 and 17%, respectively (entries 2 and 3). The reaction of *p*-fluorophenyltrimethylstannane and *p*-methoxyphenyltrimethylstannane with benzaldehyde proceeded smoothly, affording the corresponding diarylmethanols in good

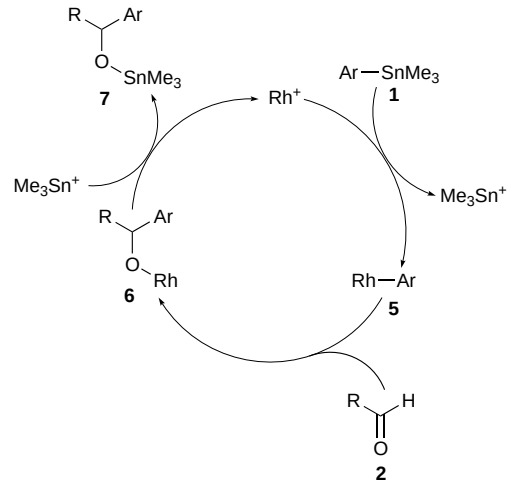
[a] A mixture of **1** (1.2 mmol), **2** (1.0 mmol) and [Rh(cod)(MeCN)$_2$]BF$_4$ (0.02 mmol) in THF (1 ml) was stirred under $N_2$ atmosphere. [b] Isolated yield based on **2**. Values in parentheses were determined by GC. [c] Ester **4a** (28%) was formed concomitantly. [d] Ester **4b** (36%) was formed concomitantly. [e] Ester **4c** (8%) was formed concomitantly.

yields (entries 4 and 5). The reaction of trimethylphenylstannane with substituted benzaldehydes and furfural also proceeded smoothly, affording the corresponding diarylmethanol in good to excellent yields (entries 6 to 12). It is noted that the reaction was highly chemoselective, since other electrophilic functional groups in **2** such as the acetyl, methoxycarbonyl and nitro groups remained intact (entries 9, 10 and 11). The reactions of trimethylphenylstannane with aliphatic aldehydes, *i.e.* hexanal, cyclohexanecarboxaldehyde and trimethylacetaldehyde, afforded the corresponding alcohols in lower yields of 34, 40 and 54%, respectively (entries 13 to 15). In these cases, esters **4a**, **4b** and **4c** were formed as by-products



**4a** R = $C_5H_{11}$
**b** R = c-$C_6H_{11}$
**c** R = $Bu^t$

in 28 (0.14 mmol), 36 (0.18 mmol) and 8% (0.04 mmol) yield, respectively. On the contrary, the reactions of trimethylphenylstannane with ketones, *i.e.* acetophenone and heptan-2-one, did not take place at all under similar conditions. The reaction with cyclohexanone proceeded sluggishly, affording the corresponding alcohol in 29% yield (entry 16). To ensure the chemoselectivity of the reaction toward aldehyde and ketone, a competitive reaction of benzaldehyde (1 mmol) and cyclohexanone (1 mmol) with trimethylphenylstannane (1 mmol) was carried out at 60 °C for 5 h. The yield of diphenylmethanol was 79% and that of 1-phenylcyclohexanol was only 4%, indicating that the addition of trimethylphenylstannane to benzaldehyde occurred preferentially.

To gain information on the reaction mechanism, the reactivity of $[Rh(cod)(MeCN)_2]BF_4$ toward benzaldehyde was studied. However, the cationic rhodium complex did not show any indication of a reaction with an equimolar amount of benzaldehyde in THF. The interaction of the rhodium complex with trimethylphenylstannane **1a** was then investigated. When 0.1 mmol of $[Rh(cod)(MeCN)_2]BF_4$ was treated with 1.0 equiv. of **1a** in 5.0 ml of THF at 25 °C for 20 h followed by quenching the reaction with water, the stannane **1a** was consumed completely, affording benzene (44% yield) and a trace amount of biphenyl. On quenching the reaction with $D_2O$ instead of $H_2O$, the benzene formed was not deuteriated. On the other hand, 78% of the yielded benzene (62% yield) was deuteriated on carrying out the reaction in the presence of 1.0 mmol of $D_2O$. A control experiment confirmed that the stannane **1a** was inert to water. These results indicate the generation of a water-labile species from $[Rh(cod)(MeCN)_2]BF_4$ and the stannane **1a**, which we attribute to an unstable phenylrhodium species that should decompose rapidly to give benzene. Actually, the reaction of $[Rh(cod)(MeCN)_2]BF_4$ with 1.0 equiv. of **1a** in the presence of 2.0 equiv. of styrene gave *trans*-stilbene in 49% yield, which would be formed by a Heck-type reaction between the phenylrhodium species and the styrene.[7] We tried in vain to detect a peak corresponding to the species by $^1H$ and $^{13}C$ NMR measurement of the reaction performed in $[^2H_8]THF$. There are several reports on the transmetallation between transition metals and arylstannanes to give arylmetal species as are shown in the Stille coupling reaction.[8] It was also reported that a phenylrhodium complex, $RhPh(CO)(PPh_3)_2$, thermally decomposes into benzene,biphenyl and benzophenone.[9]

The presumed reaction pathway for the novel arylation reaction of aldehydes **2** with arylstannanes **1** is shown in

**Scheme 1**

Scheme 1. The transmetallation of the cationic rhodium complex with **1** would produce the arylrhodium intermediate **5**. Then, addition of **5** to an aldehyde would occur to afford a rhodium alkoxide complex **6**, which would afford the stannyl ether **7**. The presence of $PPh_3$ inhibited the reaction. This observation is in accord with that reported by Hegedus where alkyl- and aryl-rhodium(I) phosphine complexes prepared on the action of Grignard or organolithium reagents on the corresponding chlororhodium(I) complexes are unreactive to benzaldehyde.[10] Thus a phosphine-free phenylrhodium species is responsible for this reaction. The mechanism for the formation of the ester **4** would involve the insertion of another aldehyde **2** into the Rh–O bond of **6**. A similar mechanism was proposed by Slough in the Tishchenko-type disproportionation of aldehydes catalysed by rhodium complexes.[11]

The reaction reported herein represents a new method for highly chemoselective arylation of aldehydes with aryltrimethylstannanes under neutral conditions using a catalytic amount of a cationic rhodium complex. Further work is now in progress to investigate the full scope of this reaction.

# Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$ shows minor groove AT selectivity with oligonucleotides

**Emma M. Proudfoot,[a] Joel P. Mackay,[b] Robert S. Vagg,[a] Kymberley A. Vickery,[a] Peter A. Williams[c] and Peter Karuso*[a]**

[a] *School of Chemistry, Macquarie University, NSW, 2109, Australia*
[b] *School of Biochemistry, University of Sydney, NSW, 2006, Australia*
[c] *Department of Chemistry, University of Western Sydney, Nepean, NSW, 2747, Australia*

**NMR studies show that the ternary octahedral Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$ cation binds with AT selectivity in the minor groove of [d(CGCGATCGCG)$_2$] and [d(ATATCGATAT)$_2$] duplexes through a non-intercalative interaction.**

The design of metal complexes for sequence-specific DNA-binding has attracted much attention recently,[1,2] and elucidation of the structural aspects of such binding is clearly a crucial step in the design process. Some measure of controversy exists over the general mode of interaction with DNA of complexes based on the ligand phen (1,10-phenanthroline). For example, on the basis of $^1$H NMR data, one study concluded that Δ-[Ru(phen)$_3$]$^{2+}$ binds intercalatively in the major groove of the [(GTGCAC)$_2$] duplex, while its Λ-isomer surface binds in the minor groove.[3] In contrast, a like study indicated minor groove non-intercalative binding for both Δ and Λ forms.[4] Furthermore, other studies employing a variety of experimental techniques and nucleotides arrive at different and often contradictory conclusions regarding the mode of binding of this complex.[5–7] Recent publications[4,8,9] have indicated that a similar debate exists over the binding site preferences of Δ- and Λ-[Ru(phen)$_2$(dppz)]$^{2+}$.

The interactions of potential intercalators with oligonucleotides may be probed using ternary complex compounds based on the [Ru(*R***R**-picchxnMe$_2$)(bidentate)]$^{2+}$ cation template.[2] In such complexes the tetradentate ligand *R***R**-picchxnMe$_2$ [(1*R**,2*R**)-*N*,*N*′-dimethyl-*N*,*N*′-di(2-picolyl)-1,2-diaminocyclohexane][10] determines the chirality of the cation and its overall shape, with the bidentate ligand serving as the putative intercalator.[2] In contrast to [Ru(bidentate)$_3$]$^{2+}$, ternary complexes of this type avoid complications due to averaging between the three possible bound states. Here we report the synthesis and preliminary NMR studies on the binding of the chiral Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$ complex cation† (Fig. 1) to the self-complementary duplexes [d(CGCGATCGCG)$_2$] and [d(ATATCGATAT)$_2$]. The study is the first to allow a rigorous evaluation of sequence and groove selectivities for metalloprobes based on a single phen ligand.

Titration of the metal complex into a solution of duplex [d(CGCGATCGCG)$_2$], monitored by one-dimensional $^1$H NMR spectroscopy at 313 K (Fig. 2), shows considerable upfield shifts of all phen resonances ($-1.23 \geqslant \Delta\delta \geqslant -0.29$ ppm), consistent with significant shielding by the duplex. In contrast, the pyridyl and aliphatic protons of the picchxnMe$_2$ ligand are only slightly affected ($< \pm 0.2$ ppm). This titration also provides evidence for preferential binding at the central AT sequence of the oligonucleotide. At a 1 : 1 complex–duplex ratio, the A5H2 peak is observed to shift 0.29 ppm upfield, while each of the other DNA base protons move marginally downfield ($\leqslant 0.09$ ppm). The A5H2 upfield shift is consistent with the findings of a recent NMR study using the same oligonucleotide sequence and the Δ- and Λ-[Ru(phen)$_3$]$^{2+}$ complex enantiomers.[4]

While chemical shift changes alone are insufficient to deduce the nature of the binding interaction (for example, the AH2 proton has been noted for its sensitivity to the binding of small molecules in both the major and minor grooves[3]), our one-dimensional titration data are indicative of minor groove binding to the AT site. 2D NOESY spectra, recorded at both 303 and 273 K (1 : 1 complex–duplex ratio), provide evidence to support this conclusion. First, three NOE cross peaks are observed between A5H2 (which points into the minor groove) and the metal complex protons H3, H7 and H8 (Fig. 3). Secondly, both T6CH$_3$ and A5H8, which point directly towards the major groove and show a number of intramolecular NOEs, display no cross peaks with the protons of the cation. Thirdly, there is no measureable disruption in the intensities of the sequential H1′–H6/H8 NOE signals in the complex–duplex adduct, indicating that the regular B-form DNA helical structure is retained.[4]

In total, 25 intermolecular NOE signals have been unambiguously assigned at 303 K, all supporting a single binding site model for the ruthenium complex at the central AT sequence, and involving a non-intercalative minor groove binding mode. The NOESY spectrum recorded at 273 K reveals a number of weak intermolecular NOE signals involving cation protons and

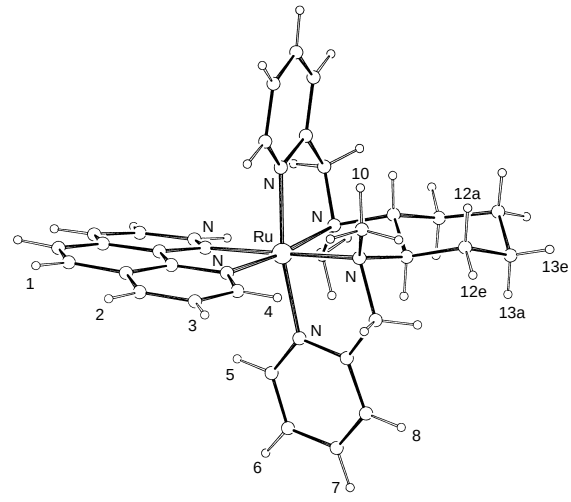

**Fig. 1** The structure of the Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$ cation. The proton numbering system used in the text is indicated. The Δ absolute configuration of the cation was confirmed by NMR spectroscopy of the complex. In a compensated ROESY spectrum[12] ($\tau_m$ = 50 ms, 4 kHz spinlock), using the H13a–H13e cross peak intensity as a calibration (1.78 Å), the average distances for H10–H12a (2.64 Å) and H10–H12e (3.24 Å) were measured according to the formula $r_{ij}/r_{kl} = [\sigma_{kl}/\sigma_{ij}]^{1/6}$. (Due to differences in $\tau_c$ for individual protons, an error of 15% can be expected (ref. 13). These distances correspond well to those of the computed model of the Δ-isomer shown [H10$_{(av)}$–H12a = 2.75 Å; H10$_{(av)}$–H12e = 3.35 Å], but not to those of the Λ-isomer [H10$_{(av)}$–H12a = 3.89 Å; H10$_{(av)}$–H12e = 2.94 Å).

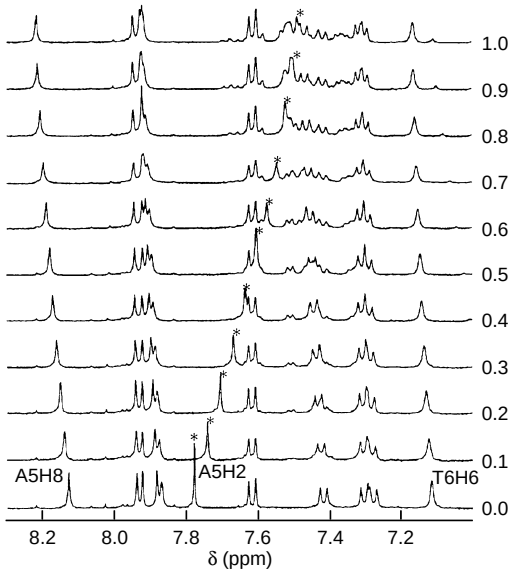

**Fig. 2** One-dimensional $^1$H NMR spectra of the nucleobase protons of [d(CGCGATCGCG)$_2$] at varying cation–duplex ratios (0.0–1.0) (313 K). Note that the resonances of A5H2 and A5H8 shift considerably with complex addition while the others are little affected.

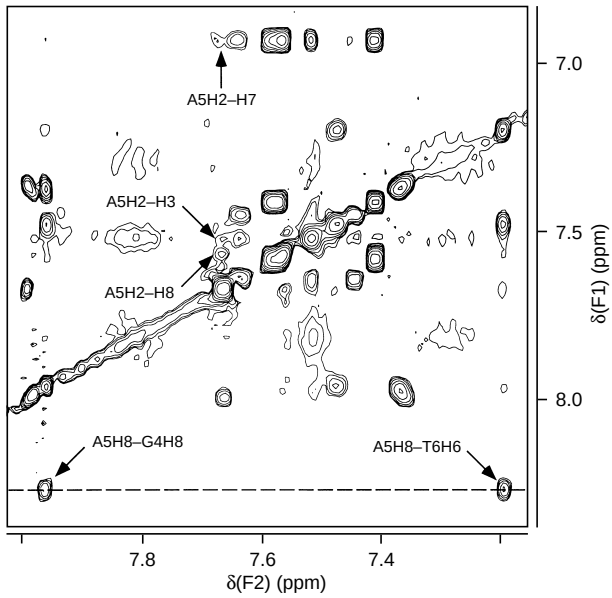

**Fig. 3** A $^1$H NOESY spectrum of the Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$–[d(CGCGATCGCG)$_2$] adduct (1 : 1 ratio, 273 K) showing NOE cross peaks involving the complex protons H3, H7 and H8 and the A5H2 proton in the minor groove. The broken line indicates the positions at which any A5H8–complex cross peaks would be observed if present. These studies were carried out using Bruker AMX600/DMX600 and Varian XL400 NMR spectrometers ([oligonucleotide] = 1.25 mM in 100% $D_2O$ containing 10 mM $NaH_2PO_4$, 10 mM NaCl, 0.01% $NaN_3$, uncorrected pD 7.00). Proton assignments were made using DQF-COSY, TOCSY ($\tau_m$ = 80 ms) and NOESY ($\tau_m$ = 400 ms) spectra. Assignments for the free oligonucleotide were consistent with published data (ref. 14).

those on C1 and G10, suggesting that a secondary weaker binding mode exists at lower temperatures. This may involve aromatic stacking, which could occur at the termini of the duplex. None of these NOE signals are observed at 303 K, and there are no significant chemical shift changes for the C1H6 and G10H8 protons ($\Delta\delta \leqslant 0.01$ ppm), indicating that this interaction is weak.

A similar titration of the cation with a [d(ATATCGATAT)$_2$] duplex[11] was carried out at 298 K. On addition of the complex an immediate broadening of the A7H2, A7H8 and T4CH$_3$ resonances occurs, and at a 1 : 1 ratio significant broadening extends throughout the spectrum. 2D TOCSY and NOESY spectra at 313 K (1 : 1 complex–duplex ratio, $\tau_m$ = 400 ms) allowed the assignment of all resonances for the cation and nucleotide base, H1′, H2′, and H2″ protons (the A3-, A7- and A9-H2 resonances were not assignable due to severe line broadening even at higher temperatures). Ten weak intermolecular NOE cross peaks were observed, predominantly between the pyridyl protons of the cation and H1′ sugar protons of the T4, C5, A7, T8, A9 and T10 nucleobases. No NOE cross peaks were observed involving the major groove AH8 or TCH$_3$ protons. These results are consistent with binding occurring in the minor groove at the several AT sites available in this duplex. Thus it is clear that the preferential AT binding observed with the [d(CGCGATCGCG)$_2$] sequence is not due simply to the higher stability of the central part of that oligonucleotide, a potential problem with short DNA duplex sequences.

In conclusion, we have shown that Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$ binds preferentially to AT sequences in duplex oligonucleotides, the predominant molecular binding component being the phen ligand. A range of chemical shift, line broadening and NOE evidence has been used to demonstrate that binding occurs non-intercalatively in the minor groove, thereby contributing significantly to the debate regarding the role of the phen ligand as a DNA-binding epitope. The present work provides a firm basis from which to evaluate the DNA binding properties of other ternary complexes incorporating known intercalating bidentate ligands and based on the [Ru(*R***R**-picchxnMe$_2$)(bidentate)]$^{2+}$ template.[2]

This research was supported by the Australian Research Council through an ARC large grant (to R. S. V., P. K. and P. A. W.), an ARC Mechanism C grant (to P. K. and others) for the purchase of the Bruker DMX600 600 MHz NMR spectrometer, and an ARC Research Fellowship (to J. P. M.). Δ-*cis*-α-[Ru(*RR*-picchxnMe$_2$)(phen)]$^{2+}$ was synthesised by K. Vickery. We gratefully acknowledge G. Ball and K. Tonkin for assistance with NMR measurements and W. Kett for assistance with HPLC.

# Surface plasmon resonance analysis of glycopeptide antibiotic activity at a model membrane surface

**Matthew A. Cooper, Dudley H. Williams* and Younghoon R. Cho**

*Cambridge Centre for Molecular Recognition, Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

**Affinity constants of glycopeptide antibiotics for peptides anchored in a lipid monolayer measured by surface plasmon resonance show a correlation with *in vitro* antimicrobial activity.**

The vancomycin group of glycopeptide antibiotics is active against a wide range of Gram-positive bacteria, particularly many *staphylococci* and *enterococci* responsible for post-surgical infections. Unfortunately resistance to vancomycin is now widespread,[1] and the accompanying increase in the number of deaths from bacterial infections has given new urgency to the search for novel antibiotics. The activity of the glycopeptide antibiotics arises from their ability to bind mucopeptide precursors terminating in the sequence –Lys-D-Ala-D-Ala (–KAA).[2,3] We have shown previously that with the exception of the teicoplanins, glycopeptide antibiotics dimerise in aqueous solution[4] and that dimerisation plays an important role in their biological activity.[5,6] We have employed sodium dodecyl sulfate micelles as model membranes to study the binding interactions between antibiotic and peptide ligands anchored to the lipid surface.[7,8] The small size of the micelles allows NMR analysis of antibiotic–ligand–micelle aggregates, but their high radius of curvature and surfactant properties make them a poor membrane model.

Biacore AB have recently commercialised a hydrophobic association chip for use in their surface plasmon resonance (SPR) instruments, which consists of a self assembled monolayer of alkanethiol on a gold film. Vesicles spontaneously absorb onto the alkane surface to form a supported lipid monolayer[9] which chemically and physically resembles the surface of a cell membrane. The phenomenon of surface plasmon resonance can then be exploited to study interactions with lipophilic ligands inserted into the monolayer. Changes in the measured refractive index at the interface, given in response units, are proportional to the amount of material in the immediate vicinity of the sensor surface.[10] Buffered solutions of an analyte are passed over the surface and the affinity of the binding event can be calculated from analysis of the resultant binding curve.

A phosphate buffered solution of phosphatidylcholine vesicles (0.5 mM) formed by extrusion through a 50 nm polycarbonate filter[11] was loaded on the chip at low flow rate (2 μl $min^{-1}$) immediately after an injection of octyl glucoside, a non-ionic detergent used to clean the alkanethiol surface (Fig. 1). Sodium hydroxide (10 mM) was then injected at high flow rate (to remove any multilamellar structures) which resulted in a stable baseline. Complete coverage of the chip surface with lipid was confirmed by the lack of non-specific binding of bovine serum albumin, which binds strongly to the hydrophobic self assembled monolayer alone. *N*-α-Docosanoyl-ε-acetyl-Lys-D-Ala-D-Ala (Doc-KAA) was then inserted into the lipid monolayer by direct injection across the surface as a dilute solution (data not shown). Antibiotics possessing some variation in measured binding affinities to di-*N*-acetyl-Lys-D-Ala-D-Ala (Ac-KAA) in free solution, but varying more in their propensity to dimerise (Table 1), were then exposed to the ligand–lipid monolayer (Fig. 2). Affinity constants were

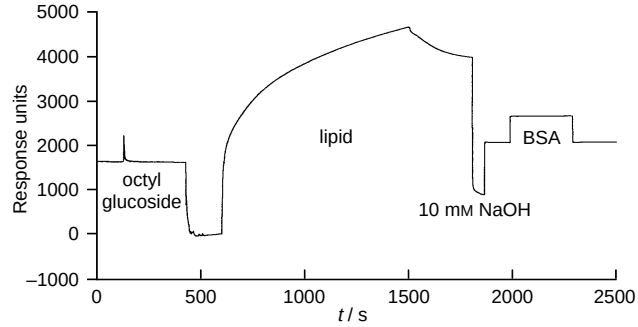

**Fig. 1** Loading of the chip with phosphatidylcholine vesicles formed by extrusion. (Note that dramatic changes in the measured response at the point of injection are due to bulk refractive index shifts between buffer and the injected solution.)

**Table 1** Minimum inhibitory concentrations, affinity constants ($K_A$) for Ac-KAA and Doc-KAA and dimerisation constants ($K_{dim}$) for various antibiotics

| Antibiotic | MIC[a] for *B. Subtilis*/ μg $ml^{-1}$ | $K_{dim}$/ $M^{-1}$[b] | $K_A/M^{-1}$[c] | |
|---|---|---|---|---|
| | | | Ac-KAA | Doc-KAA |
| $TA_3$-1 | 4 | — | $1.2 \times 10^6$ | $4.9 \times 10^5$ |
| Vancomycin | 0.25 | 700 | $2.4 \times 10^6$ | $1.4 \times 10^6$ |
| Ristocetin A | 1 | 300 | $5.9 \times 10^5$ | $6.3 \times 10^6$ |
| Eremomycin | 0.03 | $4.0 \times 10^5$ | $3.0 \times 10^4$ | $1.7 \times 10^7$ |
| CE | 0.03 | $1.6 \times 10^4$ | $1.0 \times 10^6$ | $2.1 \times 10^7$ |
| BCE | 0.008 | $2.0 \times 10^5$ | $5.9 \times 10^5$ | $1.4 \times 10^7$ |
| Teicoplanin | 0.5 | — | $1.6 \times 10^6$ | $1.0 \times 10^7$ |

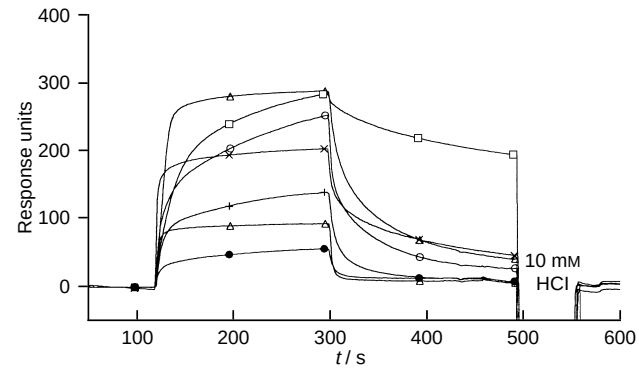

**Fig. 2** Binding of glycopeptide antibiotics at 2 μM to a Doc-KAA–lipid monolayer and removal of bound antibiotic with 10 mM HCl; (△ (ristocetin A, (□) BCE, (○) CE, (×) teicoplanin, (+) eremomycin, (△) $TA_3$-1 and (●) vancomycin

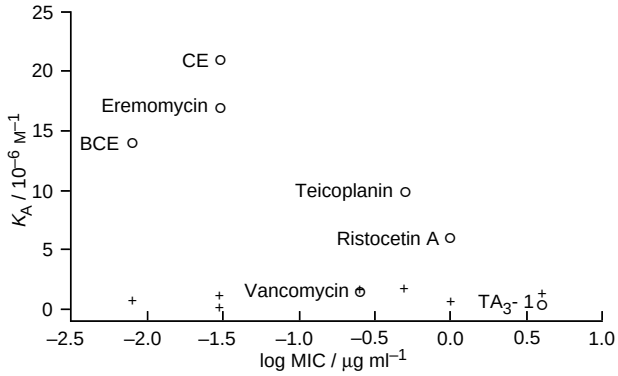

**Fig. 3** Correlation between surface affinity constants (○) of glycopeptide antibiotics to mucopeptide analogues and MIC values against *B. Subtilis*. Solution affinity constants (+) do not correlate with MIC values.

determined by Scatchard analysis of the equilibrium response levels at varying concentrations (kinetic analysis will be discussed in a full paper). Data from a flow cell containing the ligand–lipid monolayer were subtracted from data from a control flow cell containing lipid only. This control negates changes in the SPR signal due to unbound antibiotic in solution.

Affinity constants of antibiotics for Doc-KAA at the membrane-like surface determined by SPR showed a much better correlation with antimicrobial activity[12] than those measured to Ac-KAA[13–16] in solution by UV difference spectroscopy (Table 1, Fig. 3). Eremomycin, for example, has a low affinity constant to Ac-KAA in solution, but nevertheless has a low minimum inhibitory concentration (MIC) value (Table 1). This is because eremomycin dimerises strongly and is able to bind cooperatively[7] to a pair of ligands anchored to the surface. The initial binding of ligand to one half of the dimer is intermolecular, whereas binding to the other half of the dimer at the surface is effectively intramolecular and results in an affinity constant over 500-fold greater than that in solution (Table 1). In contrast the antibiotic $TA_3$-1, which has a high affinity for peptide in solution but is not known to dimerise,[16] has a relatively high MIC value. In this case there is no cooperative benefit to be gained from templated binding at a surface (Table 1) as the antibiotic can only bind as monomer. In general, strongly dimerising antibiotics[17] such as eremomycin and chloroeremomycin (CE, or LY264826)[18] have enhanced affinities for Doc-KAA at the surface, and weakly dimerising antibiotics such as ristocetin A[4] have correspondingly weaker enhancements. Teicoplanin is exceptional as it does not dimerise, yet has a higher affinity constant at the surface than in free solution. This is because teicoplanin possesses a $C_{11}$ acyl chain which functions as a membrane anchor to localise the antibiotic at the surface.[7] Binding to peptide in this case is cooperative as the antibiotic and peptide are attached to the same template and this event is effectively intramolecular as is the case with the dimerising antibiotics. Biphenylchloroeremomycin (BCE, or LY307599),[19] a semisynthetic derivative of CE that dimerises strongly and possesses a biphenyl substituent which can function as a membrane anchor,[8] also binds tightly to Doc-KAA at the surface. In accord with the hypothesis that dimerisation and membrane anchoring promote antibiotic activity, it has been shown that these features make the antagonism of antibiotic action by externally added Ac-KAA *in vitro* much more difficult.[6]

We have shown that SPR is well suited for the analysis of binding interactions at a model membrane surface and that the calculated binding affinities at the surface are more relevant to *in vitro* activity than corresponding values determined in free solution. We have shown that cooperativity in the binding of glycopeptides to bacterial cell wall analogues is promoted by dimerisation and membrane anchoring of the antibiotic. The joint operation of these two locating devices is crucial for the activity of semisynthetic antibiotics against vancomycin-resistant bacteria.[8,20]

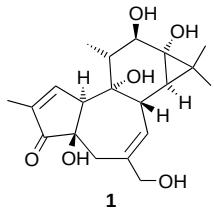
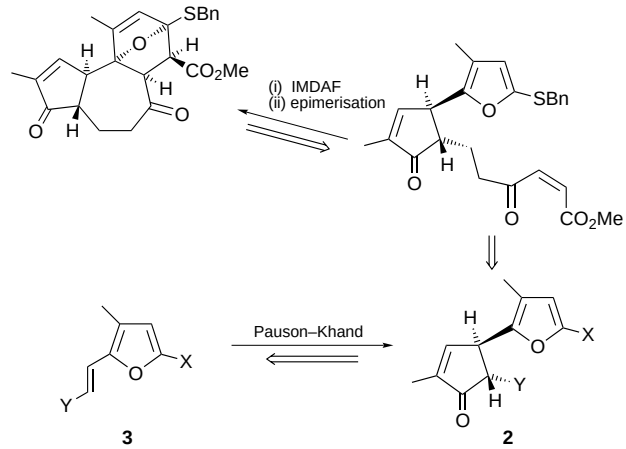
# Unexpected regiocontrol in the Pauson–Khand reaction due to 2-furyl substitution of the alkene component



**Laurence M. Harwood*[a] and Lucía San Andrés Tejera[b]†**

[a] *Department of Chemistry, University of Reading, Whiteknights, Reading, UK RG6 6AD*
[b] *Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QY*

**2-Vinylfuran derivatives undergo regiocontrolled Pauson–Khand reaction, in which the furan exerts the dominant directing influence, to furnish 5-(2-furyl)cyclopent-2-enones, overwhelming the strong directing effects of a homoallylic thioether and appearing to inhibit intramolecular reaction in which bridging constraints are in opposition to the directing influence of the 2-furyl substituent.**

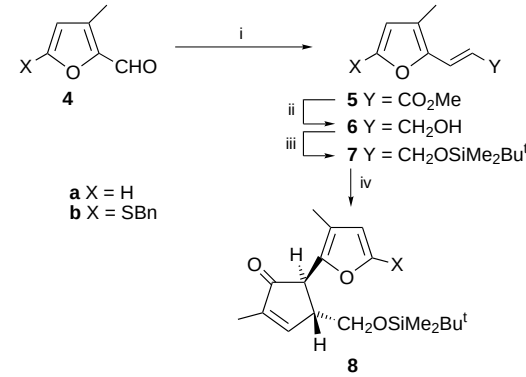


For sheer efficiency in construction of cyclopent-2-enones there is surely no match for the Pauson–Khand reaction, which links three components in a single process to furnish products in which the substitution pattern is often highly controlled and predictable.[1] Enantiocontrolled variants have been reported[2] and mild conditions developed in which amine oxides accelerate reaction.[3] The 2-methylcyclopent-2-enone motif is a recurrent sub–unit in many families of terpenoid natural products, such as the tiglianes,[4] and the Pauson–Khand reaction has proven its worth for synthetic approaches to such systems.[1]

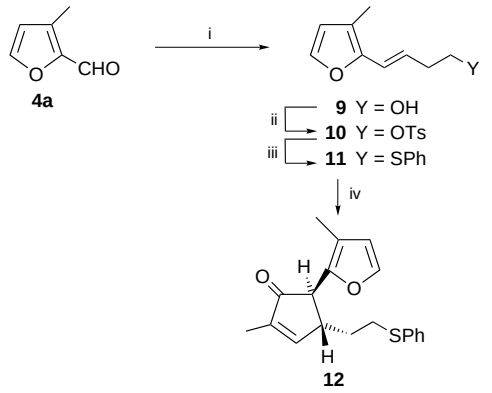
In the course of our work towards the total synthesis of phorbol **1** and analogues, *via* an approach in which the lynchpin is the high pressure mediated intramolecular furan Diels–Alder reaction,[5] we required a flexible means of access to a range of 5–substituted 4-(2-furyl)-2-methylcyclopent-2-one intermediates of general structure **2**. We envisaged such structures might be accessible *via* Pauson–Khand reaction of the corresponding *(E)*-(2-furyl)prop–2–enyl derivatives **3** with μ-propynehexacarbonyldicobalt. Mechanistic considerations and literature precedent[6] made us hopeful of achieving the desired arrangement of the propyne-derived methyl substituent but we recognised the potential for regiochemical ambiguity of alkene incorporation during cyclisation (Scheme 1).

**1**

To investigate the outcome, substrates **7a**,**b** were prepared from the corresponding furan-2-carbaldehydes **4** by stereoselective Wittig olefination, reduction of the resultant esters **5** to the alcohols **6** and protection as the *tert*-butyldimethylsilyl ethers **7**.‡ Optimised Pauson–Khand reaction conditions [μ-propynehexacarbonyldicobalt (2 equiv.), $CH_2Cl_2$–MeOH (100 : 1), reflux, 10 days] led to a single cyclopentenone in both cases (**8a**: 67%, **8b**: 41%) uncontaminated by any diene side products (Scheme 2), in marked contrast to previous observations.[7] Attempts to accelerate reaction by addition of amine oxides to the reaction mixture had a detrimental effect. Unfortunately, analysis of NOE difference spectra and couplings in the two-dimensional $^1$H NMR spectra of the products



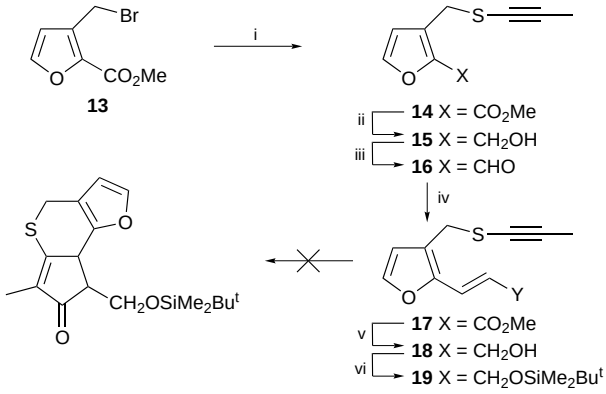
**Scheme 1**



clearly showed that the undesired C-4/C-5 substitution had been selectively obtained in both cases.§

Reports that a homoallylic thioether on the alkene component accelerates and exerts good regiocontrol on its participation in the Pauson–Khand reaction[8] led us to synthesise **11** in an attempt to obtain the desired substitution pattern. This was achieved *via* reaction of **4a** with the ylide derived from 3-hydroxypropyl(triphenyl)phosphonium bromide to furnish **9**, followed by tosylation to form **10** and displacement with sodium phenylthiolate, giving the required substrate **11** (Scheme 3). Pauson–Khand reaction under previously optimised conditions again led to a single cycloadduct **12** (43%)§ in which the furyl group had apparently overwhelmed the directing influence of the homoallylic thioether to furnish the undesired regioisomer once more.

An attempt to force the regiocontrol led us to consider an intramolecular Pauson–Khand cyclisation; tethering the alkene



**Scheme 2** *Reagents and conditions*: i, $Ph_3P{=}CHCO_2Me$, $CH_2Cl_2$, reflux (**a** 74%, **b** 45%); ii, $Bu^i_2AlH$ (2 equiv.), toluene, −78 °C (**a** 93%, **b** 78%); iii, $Bu^tMe_2SiCl$, $Et_3N$, DMAP (cat.), $CH_2Cl_2$, 0 °C → room temp. (**a** 92%, **b** 78%); iv, $(HC{\equiv}CMe)Co_2(CO)_6$, $CH_2Cl_2$–MeOH (100 : 1), reflux, 10 days (**a** 67%, **b** 41%)

**Scheme 3** *Reagents and conditions*: i, $Ph_3P{=}CHCH_2CH_2O^-$ $Li^+$, THF, −78 °C → room temp., 58%; ii, TsCl, pyridine, 0 °C → room temp., 88%; iii, $PhS^-$ $Na^+$, THF, reflux, 57%; iv, $(HC{\equiv}CMe)Co_2(CO)_6$ (2 equiv.), $CH_2Cl_2$–MeOH (95 : 5), reflux, 10 days, 43%

and alkyne by a thioether which could be hydrogenolysed subsequent to directed cyclopentenylation. Methyl 3-methyl-2-furoate was converted *via* furylic bromination to **13**,[9] halide displacement with lithium propyne-1-thiolate to give **14** and two step conversion to furnish 3-(prop-1-ynylthiomethyl)furan-2-carbaldehyde **16** (Scheme 4). Subsequent elaboration as before gave the intramolecular Pauson–Khand reaction precursor **19** in three steps. However, despite extensive efforts, no conditions could be found which resulted in the isolation of any cyclopentenone, despite the fact that thioether bridges have been used successfully to direct such reactions in prop-2-ynylic systems.[10] From this we conclude that the influence of the 2-furyl substituent attached to the alkene plays a strong role in directing the Pauson–Khand cycloaddition to the extent that, in situations where regiochemical choice is not possible, reaction appears to be disfavoured.

**Scheme 4** *Reagents and conditions*: i, $Me{\equiv}CS^-Li^+$, $Et_2O$, −70 °C → room temp., 85%; ii, $NaBH_4$ (excess), EtOH, room temp., 79%; iii, $MnO_2$/C, $CH_2Cl_2$, room temp., 73%; iv, $Ph_3P{=}CHCO_2Me$, $CH_2Cl_2$, reflux, 87%; v, $Bu^i_2AlH$ (2 equiv.), toluene −70 °C, quant.; vi, $Bu^tMe_2SiCl$, $Et_3N$, DMAP (cat.), $CH_2Cl_2$, room temp., 98%

In conclusion, we present evidence that, for the intermolecular Pauson–Khand reaction, the presence of a 2-furyl substituent on the alkene component substrate exerts a powerful regiodirecting effect causing the furan unit to appear at C-5 of the resultant cyclopent-2-enone. Although rendering this approach inappropriate for our initial specific need, this unexpected regiocontrol has more general synthetic potential.

We thank the Gobierno Autònomo de Canarias, Spain, for a postdoctoral fellowship (to L. S. A. T.) and Dr W. J. Kerr of the Department of Pure and Applied Chemistry, University of Strathclyde, for valuable discussions.

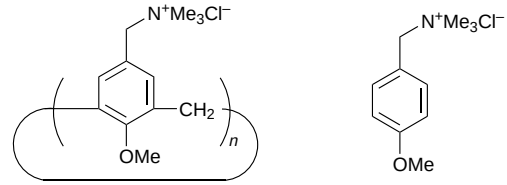
# Water-soluble calixarenes as new inverse phase-transfer catalysts. Nucleophilic substitution of alkyl and arylalkyl halides in aqueous media

**Shoichi Shimizu,* Katsuyuki Kito, Yasuyuki Sasaki and Choichiro Hirai**



*Department of Industrial Chemistry, College of Industrial Technology, Nihon University, Narashino, Chiba 275, Japan*

**The water-soluble calix[*n*]arenes $\mathbf{1}_n$ (*n* = 4, 6 and 8) containing trimethylammoniomethyl groups act as efficient inverse phase-transfer catalysts in the nucleophilic substitution reaction of alkyl and arylalkyl halides with nucleophiles in water.**

Inverse phase-transfer catalysts facilitate reactions between two immiscible reactants *via* the transport of an organic substrate into an aqueous solution of a second reactant where reactions take place.[1,2] The use of inverse phase-transfer catalysis (IPTC) has two major advantages over that of normal phase-transfer catalysis (PTC): (i) the aqueous catalyst solution is easily separated and recycled, and (ii) no other organic solvent is necessary if organic reactants are liquid at the reaction temperature. However, in sharp contrast to the case of normal PTC, the understanding, development and applications of this method for conducting organic reactions have not expanded yet to the extent that it deserves. This is mainly due to the fact that only a limited number of inverse phase-transfer agents are known, *e.g.* cyclodextrins (CDs) and their derivatives, water-soluble metal complexes and pyridine *N*-oxides.[2]

We now report that water-soluble calix[n]arenes $\mathbf{1}_n$ (*n* = 4, 6 and 8) containing trimethylammoniomethyl groups can catalyse the nucleophilic substitution of alkyl and arylalkyl halides with simple nucleophiles in water, demonstrating the first example of the application of water-soluble calixarenes to organic reactions as efficient inverse phase-transfer catalysts.

During the past fifteen years, calixarenes have received increasing attention due to their utilization in supramolecular chemistry.[3] Some functionalized calixarenes have been developed as new phase-transfer agents for normal PTC reactions.[4] We thought that water-soluble calixarenes would serve as a new class of inverse phase-transfer catalysts *via* their ability to form inclusion complexes. In this work we have prepared the water-soluble calixarenes $\mathbf{1}_n$ (*n* = 4, 6 and 8)† and examined their catalytic ability using nucleophilic substitution reactions in water [eqn. (1)].‡ The results are summarized in Table 1.

$\mathbf{1}_n$ (*n* = 4, 6, 8) **2**

[a] Conditions: catalyst (0.5 mol%), substrate (4.6 mmol), nucleophile (10 mmol), water (5 ml), stirring speed 1300 rpm. In the reaction of 2-(bromomethyl)naphthalene, dipropyl ether (1 ml) was used (entries 18–22). [b] Based on substrate. Refers to GC yield (entries 1–7 and 11–17) or isolated yield (entries 8–10 and 18–22). [c] Catalyst: 3.0 mol% used. [d] Catalyst: 0.05 mol% used. [e] By-product: benzyl alcohol (8%).

Treatment of 1-bromooctane with NaCN in water for 6 h at 100 °C afforded 1-cyanooctane in 6% yield with 86% recovery of the starting material (entry 1). However, when we carried out the same reaction in the presence of the calixarene **1$_6$** (0.5 mol%), the yield of 1-cyanooctane increased to 83% (entry 5). To evaluate the ability of **1$_6$**, we examined the reactions with a conventional inverse phase-transfer catalyst, β-CD, and found that the calixarene **1$_6$** is more efficient than β-CD by a factor of 5.5 for cyanide substitution on 1-bromooctane, and 2.3 and 6.9 for benzyl bromide and 2-(bromomethyl)naphthalene, respectively (entries 13 and 21). Noteworthily, the use of as little as 0.05 mol% of **1$_6$** is sufficient, showing its remarkable catalytic activity (entry 14).

CDs function as inverse phase-transfer catalysts in aqueous–organic two-phase reactions of alkyl halides with nucleophiles owing to their ability to form host–guest complexes.[5–7] The water-soluble calixarenes may behave similarly to CDs, since they also have the ability to include organic guest molecules in their cavity. No acceleration effect is observed when (*p*-methoxybenzyl)trimethylammonium chloride **2** is added to the reaction mixture as a monomeric counterpart of **1$_6$** (entry 2). The distribution of **1$_6$** into the organic phase was negligible,§ indicating that the reaction catalysed by **1$_6$** takes place predominantly in the aqueous phase.

The efficiency of the calixarenes **1$_n$** varied depending on the size and/or shape of the substrate molecules. For example, no difference in the catalytic activities of **1$_n$** is detected in the reaction of benzyl bromide (**1$_4$** ≈ **1$_6$** ≈ **1$_8$**). On the other hand, their activities increase in the order of **1$_4$** < **1$_6$** ≈ **1$_8$** for 1-bromooctane and in the order of **1$_4$** ≤ **1$_6$** < **1$_8$** for 2-(bromomethyl)naphthalene. The size of the cavity of **1$_4$** is large enough for benzyl bromide, but **1$_8$** is required for bulkier 2-(bromomethyl)naphthalene. This result is consistently supported by the fact that *p*-sulfonatocalixarenes are capable of molecular recognition on the basis of the hole-size selectivity in an aqueous system.[8]

In conclusion, we have shown here that IPTC by water-soluble calixarenes **1$_n$** provides a simple and effective means for conducting nucleophilic substitution reactions of activated and unactivated organic halides, in which they exhibit much higher activity than CDs. This is the first example of the use of water-soluble calixarenes in organic reactions as inverse phase-transfer catalysts.

We thank Takashi Suzuki and Naoyuki Shinoda for their experimental assistance. The present work was partially supported by a General Individual Research Grant for 1995 from Nihon University.

† The water-soluble calix[*n*]arenes **1$_n$**·*n*H$_2$O (*n* = 4, 6 and 8) were prepared following literature methods (ref. 9) and identified by IR and NMR spectroscopy as well as elemental analysis.

‡ General procedure for the nucleophilic substitution reactions is as follows. A mixture of substrate (4.6 mmol), nucleophilic reagent (10 mmol), a catalytic amount (0.5 mol%) of **1$_n$**·*n*H$_2$O and water (5 ml) was heated to 60 or 100 °C and stirred with a magnetic stirring bar. The resulting mixture was extracted with $CHCl_3$. After the usual work-up, the crude product was purified by preparative GPC and its isolated yield was determined. For the reactions of 1-bromooctane and benzyl bromide with NaCN, the yield of product was determined by GC analysis of a mixture of $Et_2O$ extracts and an internal standard.

§ A mixture of **1$_6$**·6H$_2$O (0.157 g, 0.106 mmol) and water (25 ml) was extracted with $Et_2O$ (5 × 50 ml). The combined organic layer was dried over anhydrous $Na_2SO_4$, and concentrated under reduced pressure. No extract was detected by measurement of weight.

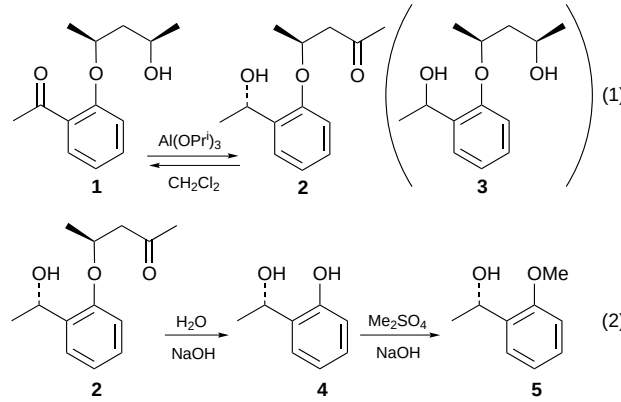
# Reliable chiral transfer through thermodynamic equilibrium of the intramolecular Meerwein–Ponndorf–Verley reduction and Oppenauer oxidation

**Morifumi Fujita,*† Yoshihiro Takarada, Takashi Sugimura and Akira Tai***

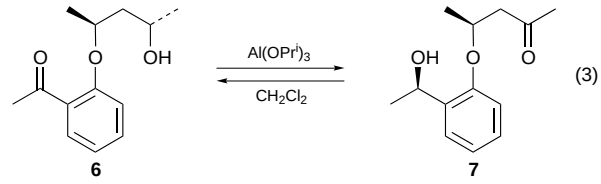
*Faculty of Science, Himeji Institute of Technology, Kanaji, Kamigori, Ako-gun, Hyogo 678-12, Japan*



**Forward and reverse hydride transfer with rigorous diastereodifferentiation is attained using intramolecular Meerwein–Ponndorf–Verley reduction and Oppenauer oxidation of a 2-acetylphenyl ether containing an optically active 3-hydroxy-1-methylbutyl group.**

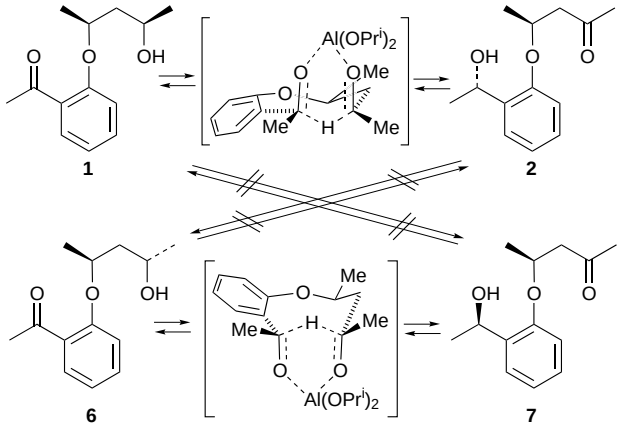
Meerwein–Ponndorf–Verley (MPV) reductions and Oppenauer oxidations have been revealed to proceed *via* reversible hydride transfer between carbonyl groups and alcohols.[1] Recently, intramolecular MPV reductions have been reported to proceed with high stereodifferentiation.[2–5] Reversible stereodifferentiating reactions, however, have the risk of lowering the stereochemical purity as well as chemical yield of products due to the reverse step, which does not always restore the formed product to the same stereoisomer as the initial reactant. Previous intramolecular stereocontrolled MPV reductions have succeeded as a result of the reaction being driven to completion under kinetic control.[2–5] In contrast, under thermodynamic equilibrium, both the forward and reverse steps must proceed with complete stereodifferentiation in order to prevent any decrease in optical purity of the reactant from the reverse step. Such stereodifferentiation reactions under thermodynamic equilibrium, however, have not yet been described for the intramolecular MPV–Oppenauer reaction.

We now report that the intramolecular hydride transfer of 2-acetylphenyl ether containing an optically active 3-hydroxy-1-methylbutyl group (**1**) proceeds with rigorous stereodifferentiation under thermodynamic equilibrium. The optically active 3-hydroxy-1-methylbutyl moiety acts as both the chiral auxiliary and hydride donor, and can easily be removed from the product **2** by alkaline hydrolysis as a result of the oxidation of the alcohol moiety to a ketone. Thus the multi-functional nature and simple structure of the optically active 3-hydroxy-1-methylbutyl moiety[4,6] provide an opportunity to construct a simple and reliable system for intramolecular chiral transfer *via* thermodynamic equilibration of the MPV–Oppenauer reaction.



Evaluation of hydrogenation enthalpy data[1,7] for the conversion of ketones to the corresponding alcohols revealed that acetophenone is favorable to some extent as a hydride acceptor of intramolecular hydride transfer from the alcohol moiety, on the basis of the estimation that the enthalpy change ($\Delta H$) for reduction of acetophenone by propan-2-ol is $-3$ kJ mol$^{-1}$, from which the quilibrium constant ($K_{calc}$) is calculated to be 3.0 at 313 K. The reactant, (1′*S*,3′*R*)-2-(3′-hydroxy-1′-methylbutoxy)acetophenone **1**, was prepared in 66% yield *via* the Mitsunobu reaction[8] of (2*R*,4*R*)-pentane-2,4-diol with 2′-hydroxyacetophenone. The epimer of **1**, (1′*S*,3′*S*-)-2-(3′-hydroxy-1′-methylbutoxy)acetophenone **6**, was also obtained by inversion of the alcohol moiety of **1** in 78% yield *via* the Mitsunobu reaction of **1** with benzoic acid followed by hydrolysis.

Treatment of **1** with $Al(OPr^i)_3$ (2.0 equiv.) in $CH_2Cl_2$ at reflux for 20 h caused the intramolecular hydride transfer from the alcohol to the aromatic ketone to yield **2** as a single isomer in 68% yield [eqn. (1)]. It should be noted that no diol **3**, produced by intermolecular hydride transfer from isopropoxide or **1**, was obtained. The remaining 32% was recovered as the reactant **1**, with no epimer **6**.‡ The product **2** was readily hydrolysed under alkaline conditions to give 1-(2-hydroxyphenyl)ethanol **4**, which was isolated after conversion to 1-(2-methoxyphenyl)ethanol **5** [eqn. (2)]. From the negative



optical rotation of **5**, the absolute configuration of the α-position of **2** was determined to be *S*.[9]§

When **6** was treated with $Al(OPr^i)_3$ (2.0 equiv.) in $CH_2Cl_2$ at reflux for 20 h, the other diastereoisomer **7** was obtained at 67% yield [eqn. (3)] with the recovery of the reactant **6** in 33% yield.

These results indicate that the stereogenic centre at the hydroxy group, but at the ether, is responsible for that of the newly formed chiral centre.

The ratio of **1**:**2** remained constant at 1:2 and the epimerisation of **1** to **6** was also not observed even after extending the reaction period to 4 days. Increasing the quantity of $Al(OPr^i)_3$ to 4 equiv. also resulted in the same product distribution of **1**:**2**. The constant product ratio of **1**:**2** (1:2) which is independent of the reaction time and the amount of $Al(OPr^i)_3$ indicates that the intramolecular hydride transfer between **1** and **2** reaches an equilibrium with the equilibrium constant $K = 2.0$ The recovery of the initial reactant without empimerisation under the thermodynamic equilibrium implies the complete stereodifferentiation of the reverse step. Such rigorous stereodifferentiation in the reverse step as well as in the forward step may be a consequence of the restricted orientation of the carbonyl group and the alcohol in the transition state of

**Scheme 1**

the intramolecular MPV–Oppenauer reaction (Scheme 1). Preferential intramolecular coordination to aluminium also ensures from no formation of **3** generated by intermolecular MPV reduction is observed. Thus, the intramolecular hydride transfer proceeds without mixing the equilibrium between **1** and **2** with that between **6** and **7**.

In conclusion, a rigorous diastereodifferentiating hydride transfer has been achieved under a thermodynamic equilibrium, resulting from both the forward and reverse steps of the equilibrium proceeding diastereospecifically.

# Versatile synthesis of *myo*-inositol phospholipid precursors

**Simon J. A. Grove,[a] Ian H. Gilbert,[a] Andrew B. Holmes,*[a,b] Gavin F. Painter[a,b] and Malcolm L. Hill[c]**

[a] *Cambridge Centre for Molecular Recognition, Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

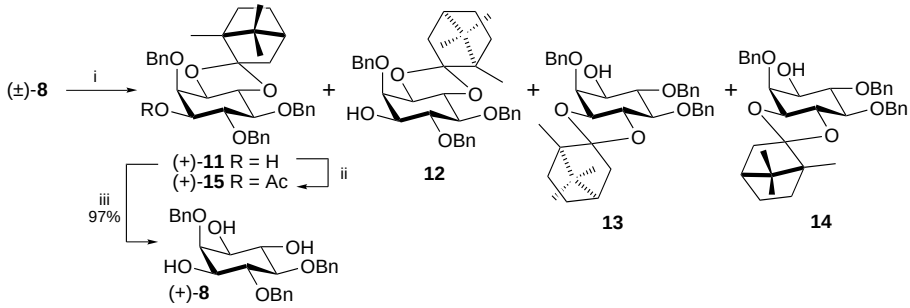
**Homochiral *myo*-inositol derivatives 16 and 20 and their corresponding enantiomers possessing either the natural or unnatural ring stereochemistry for inositol phospholipids are synthesised from *myo*-inositol derivatives 8 and 9 respectively using camphor dimethyl acetals in a resolution–protection sequence.**

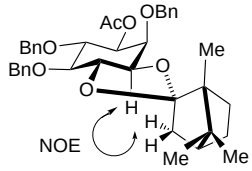
The biological importance of various inositol phosphates and inositol phospholipids in cell signal transduction and related processes is well documented.[1] In most cases these compounds are not readily available in any quantity from natural sources owing to their low cellular concentrations.[2] Consequently their synthesis[3] has received extensive attention in recent years. Despite this effort many inositol derivatives are still not readily available, owing in part to the lack of availability of suitably protected homochiral *myo*-inositol derivatives.[4] Here we present concise routes to differentially protected ring enantiomers of *myo*-inositol compounds which are suitable starting materials for the synthesis of *myo*-inositol phospholipids.

**Scheme 1** *Reagents and conditions*: i, NaH, *p*-$MeOC_6H_4CH_2Cl$ (PMBCl), DMF, 0 °C to room temp.; ii, NaH, BnBr, DMF, 0 °C to room temp.; iii, DIBAL-H (2.5 equiv.), $CH_2Cl_2$–hexanes, 0 °C to room temp.; iv, NaH, allyl bromide, DMF, 0 °C to room temp.; v, $Ac_2O$, DMAP, pyridine, room temp.; vi, HCl, MeOH, reflux.



The readily available triol **1**[5] was chemoselectively *p*-methoxybenzylated[6] to give the diol **2** which was then benzylated to afford the fully protected derivative **3** (Scheme 1).† A regioselective DIBAL-H reduction[7,8] of the orthoformate **3** furnished the liberated alcohol **4** as a single isomer in high yield, the structure of which was confirmed by NMR experiments performed on the acetate **5**. Benzylation or allylation of the alcohol **4** afforded the required intermediates **6** and **7**, respectively. Acidic hydrolysis resulted in the simultaneous cleavage of the acetal and *p*-methoxybenzyl ether groups to give the racemic triols **8**[9] and **9** in overall yields of 58 and 56%, respectively, from the triol **1**.

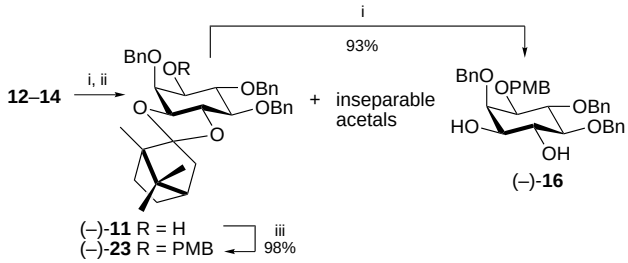
Treatment[4] of **8** with (1*R*)-(+)-camphor dimethyl acetal **10** afforded a diastereoisomeric mixture of acetals **11**–**14** (Scheme 2). This procedure allowed simultaneous protection–resolution of (±)-**8**.



From this mixture the acetal (+)-**11** was isolated by flash chromatography in a yield of 31%, and the remaining acetals were obtained in a combined yield of 59%. The stereochemistry of the acetal (+)-**11** was determined by chemical correlation and NMR experiments. Mild acid hydrolysis (MeOH–AcCl) afforded the triol (+)-**8**,[10,11] which corresponds to the unnatural ring configuration for inositol phospholipids.

Acetylation of the hydroxy group of (+)-**11** gave the acetate (+)-**15** for which a positive NOE was observed between the signal due to the D-1-inositol ring proton and that of the camphor 3′-$H_{endo}$ methylene proton in the $^1H$ NMR spectrum. Since no enhancement of the methyl resonances was observed upon irradiation of the D-1-inositol ring proton, the stereochemistry of **15** was assigned as 1D-1-*O*-*endo*-6-*O*-*exo* (Fig. 1).

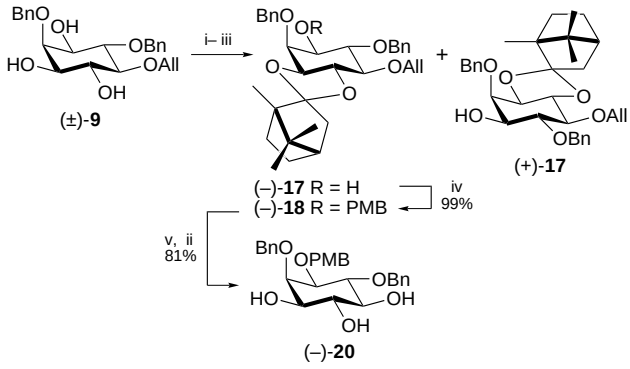
The chromatographically inseparable mixture of acetals enriched in **13** and **14** is also a source of (−)-**11** (Scheme 3).



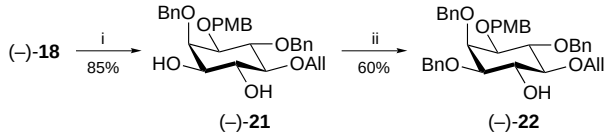
**Scheme 2** *Reagents and conditions*: i, (+)-**10** (2.3 equiv.), TsOH (cat.), $CH_2Cl_2$, reflux; ii, $Ac_2O$, DMAP, pyridine, room temp.; iii, AcCl, $CH_2Cl_2$–MeOH (2 : 1)

(+)-**15**

**Fig. 1** Assignment of relative stereochemistry of the acetal (+)-**15** by NOE measurement



**Scheme 3** *Reagents and conditions*: i, AcCl, $CH_2Cl_2$–MeOH (2:1); ii, (−)-**10**, TsOH, $CH_2Cl_2$, reflux; iii, NaH, PMBCl, DMF



Hydrolysis of the mixture, followed by reacetalisation with the *enantiomeric* camphor dimethyl acetal (−)-**10** afforded after purification (−)-**11** in 40% yield (25% from racemic **8**). *p*-Methoxybenzylation of (−)-**11** gave the PMB ether (−)-**23** which yielded the diol (−)-**16**[10] on mild acidic hydrolysis. The diol (−)-**16** contains a suitable functional group array for elaboration to PtdIns(3,4)$P_2$.

In a similar protection–resolution sequence using the 5-allyloxy-1,3,4-triol **9**, the enantiomeric acetals (−)-**17** and (+)-**17** were obtained in 27 and 24% yield, respectively, (Scheme 4). *p*-Methoxybenzylation of the 1-hydroxy group of (−)-**17** gave (−)-**18**. Cleavage of the 5-allyloxy and 3,4-acetal groups gave (−)-**20**.[11] The triol **20** is a suitable precursor for elaboration to PtdIns(3,4,5)$P_3$.

Finally, mild acidic hydrolysis of the 3,4-acetal (−)-**18** afforded the diol (−)-**21** (Scheme 5). Monobenzylation of the 3-hydroxy group using Gigg's procedure[12] (dibutytin oxide, $Bu_4NBr$ and BnBr) furnished the 4-alcohol (−)-**22** in 60% yield. Cleavage of the 5-allyloxy ether would then lead to a suitable precursor for the preparation of PtdIns(4,5)$P_2$.

**Scheme 4** *Reagents and conditions*: i, (−)-**10**, TsOH, $CH_2Cl_2$, reflux, then separate; ii, AcCl, $CH_2Cl_2$–MeOH (2:1); iii, (+)-**10**, TsOH, $CH_2Cl_2$, reflux; iv, NaH, PMBCl, DMF; v, $(Ph_3P)_3RhCl$, DABCO, EtOH–toluene–$H_2O$ (7:3:1), reflux

**Scheme 5** *Reagents and conditions*: i, AcCl, $CH_2Cl_2$–MeOH (2:1); ii, $Bu_2SnO$, $Bu_4NBr$, BnBr, MeCN, reflux

In conclusion, the combination of a *meso* starting material, high yielding protection–deprotection sequences and especially a combined resolution–protection strategy, involving the camphor acetals **10**, provides ready access to a number of *myo*-inositol phospholipid precursors. In the accompanying communication we describe the reduction of this concept to practice.

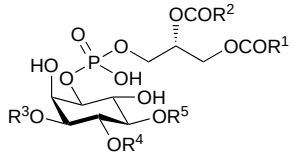
# Synthesis of dipalmitoyl phosphatidylinositol 3,4-bis(phosphate) and 3,4,5-tris(phosphate) and their enantiomers

**Simon J. A. Grove,[a] Andrew B. Holmes,*[a,b] Gavin F. Painter,[a,b] Phillip T. Hawkins[c] and Leonard R. Stephens[c]**



[a] *Cambridge Centre for Molecular Recognition, Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

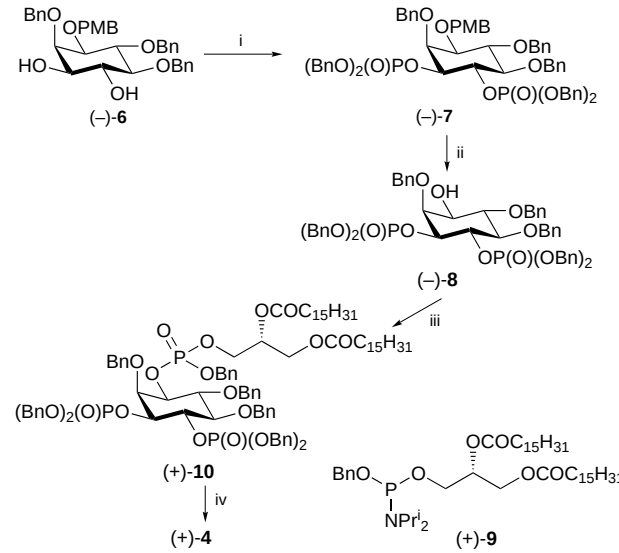
[b] *Melville Laboratory for Polymer Synthesis, Department of Chemistry, University of Cambridge, Pembroke Street, Cambridge, UK CB2 3RA*

[c] *Babraham Institute, Department of Signalling, Inositide Laboratory, Cambridge, UK CB2 4AT*

**The dipalmitoyl derivatives 4 and 5 of 3-phosphorylated *myo*-inositol phospholipids 2 and 3 and their enantiomers are synthesised from homochiral *myo*-inositol precursors 6 and 11; they serve as biological probes for cell signal transduction.**

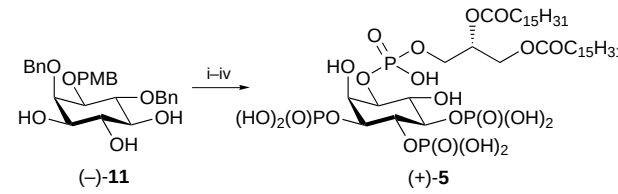
The group of *myo*-inositol phospholipids PtdIns(3)P **1**, PtdIns(3,4)$P_2$ **2** and PtdIns(3,4,5)$P_3$ **3** are believed to have a role in the mechanisms by which cell surface receptors for antigens,

**1** $R^1 = C_{19}H_{31}$, $R^2 = C_{17}H_{35}$, $R^3 = P(O)(OH)_2$, $R^4 = R^5 = H$
**2** $R^1 = C_{19}H_{31}$, $R^2 = C_{17}H_{35}$, $R^3 = R^4 = P(O)(OH)_2$, $R^5 = H$
**3** $R^1 = C_{19}H_{31}$, $R^2 = C_{17}H_{35}$, $R^3 = R^4 = R^5 = P(O)(OH)_2$
**4** $R^1 = R^2 = C_{15}H_{31}$, $R^3 = R^4 = P(O)(OH)_2$, $R^5 = H$
**5** $R^1 = R^2 = C_{15}H_{31}$, $R^3 = R^4 = R^5 = P(O)(OH)_2$



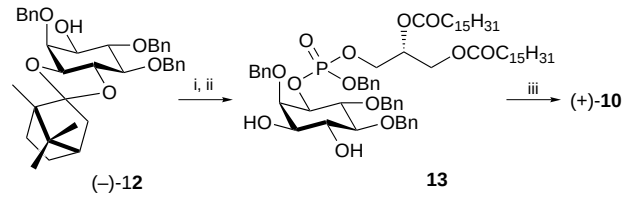
inflammatory stimuli and growth factors control a variety of cellular functions.[1–3] These lipids appear to be resistant to hydrolysis by phosphatidyl inositol-specific phospholipase C (PI-PLC),[4] implying an independent cell signalling pathway from that already established for PtdIns(4,5)$P_2$.[5] In order to probe the function of the phospholipids **2** and **3** in signal transduction we proposed to synthesise the functionally similar dipalmitoyl derivatives **4** and **5** and their enantiomers for use in biological assays. The synthetic work presented here utilises differentially protected homochiral *myo*-inositol derivatives **6** and **11** which were obtained efficiently from *myo*-inositol orthoformate.[6]

Dipalmitoyl PtdIns(3,4)$P_2$ **4** was prepared from (−)-**6** in four synthetic steps with an overall yield of 72% (Scheme 1). The 3,4-bisphosphorylated derivative (−)-**7** was prepared *via* phosphitylation of (−)-**6** with bis(benzyloxy)(*N*,*N*-diisopropylamino)phosphine[7] and 1*H*-tetrazole followed by *in situ* oxidation with MCPBA. After removal of the *p*-methoxybenzyl ether with ceric ammonium nitrate the 1-hydroxy group was coupled with the phosphoramidite (+)-**9**.[8,9] *In situ* oxidation of the phosphorus(III) species afforded the fully protected phospholipid (+)-**10**. Reductive debenzylation was readily effected using the conditions reported[10] by Kozikowski *et al.*, furnishing dipalmitoyl PtdIns(3,4)$P_2$ (+)-**4**.†



Elaboration of the antipodal diol (+)-**6** *via* the same reaction sequence as shown in Scheme 1 and coupling with (−)-**9**,‡ afforded (−)-4,† the enantiomer of dipalmitoyl PtdIns(3,4)$P_2$.

The use of similar reagents and reaction conditions as outlined for the synthesis of (+)-**4** afforded dipalmitoyl PtdIns(3,4,5)$P_3$ (+)-**5**† in 70% yield from the 3,4,5-triol (−)-**11** (Scheme 2). Similarly (−)-**5**† was synthesised from (+)-**11** and (−)-**9** by the route used in Scheme 2.



An alternative synthesis of dipalmitoyl PtdIns(3,4)$P_2$ (+)-**4** was also carried out from the 3,4-protected alcohol (−)-**12** (Scheme 3).[6] The alcohol was coupled directly with the

**Scheme 1** *Reagents and conditions*: $(BnO)_2PNPr^i_2$, 1*H*-tetrazole, $CH_2Cl_2$, then MCPBA; ii, $(NH_4)_2Ce(NO_3)_6$, MeCN–$H_2O$ (4:1); iii, (+)-**9**, 1*H*-tetrazole, $CH_2Cl_2$, then MCPBA; iv, $Pd(OH)_2$–C, $H_2$ (60 psi), $Bu^tOH$

**Scheme 2** *Reagents and conditions*: i, $(BnO)_2PNPr^i_2$, 1*H*-tetrazole, $CH_2Cl_2$, then MCPBA; ii, $(NH_4)_2Ce(NO_3)_6$, MeCN–$H_2O$ (4:1); iii, (+)-**9**, 1*H*-tetrazole, $CH_2Cl_2$, then MCPBA; iv, $Pd(OH)_2$–C, $H_2$ (60 psi), $Bu^tOH$

**Scheme 3** *Reagents and conditions*: i, (+)-**9**, 1*H*-tetrazole, $CH_2Cl_2$, then MCPBA; ii, AcCl, MeOH–$CH_2Cl_2$ (1:1); iii, $Pd(OH)_2$–C, $H_2$ (60 psi), $Bu^tOH$

phosphoramidite (+)-**9**, and the product was then cleaved at the 3,4-acetal with acid (AcCl–MeOH) to afford the 3,4-diol **13**. Phosphitylation of the free hydroxy groups with bis(benzyloxy)(*N*,*N*-diisopropylamino)phosphine and 1*H*-tetrazole, followed by *in situ* oxidation with MCPBA, afforded the common fully protected phospholipid (+)-**10**. This route required two fewer steps than the original procedure, as the *p*-methoxybenzyl protection and deprotection at the D-1-hydroxy are not required. The overall yield is slightly better than that of the original procedure.

In summary we have demonstrated a general synthesis of 3-phosphorylated *myo*-inositol phospholipids **4** and **5** from the homochiral precursors **6** and **11** which also allows the synthesis of enantiomeric derivatives containing the unnatural stereochemistry. These materials play an important rôle in evaluating the activation of protein kinase B.[11]

We thank the EPSRC and BBSRC for financial support and provision of the Swansea Mass Spectrometry Service, Glaxo-Wellcome for a CASE studentship (to S. J. A. G.), Drs D. R. Marshall and M. L. Hill for their interest in this work and Dr A. P. Kozikowski for experimental details of debenzylation procedures.

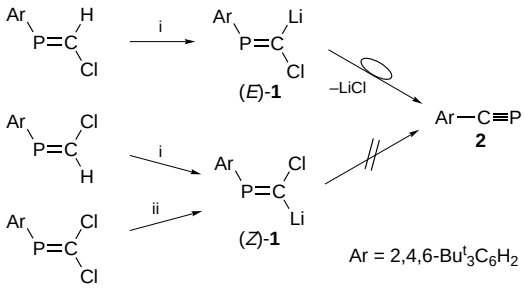
# Formation of 6,8-di-*tert*-butyl-3,4-dihydro-4,4-dimethyl-1-phosphanaphthalene by the reaction of 2,2-dibromo-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethene with butyllithium

**Shigekazu Ito,† Kozo Toyota and Masaaki Yoshifuji***

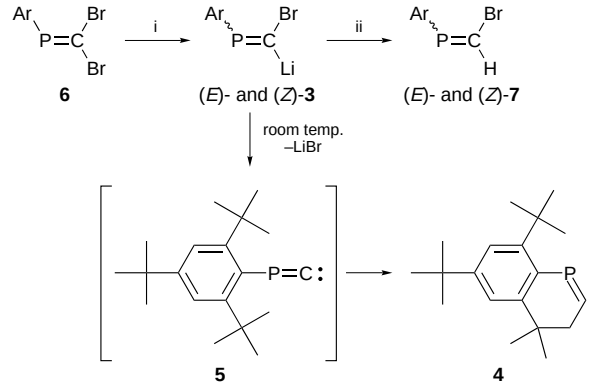
*Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-77, Japan*

**Sterically crowded 1-bromo-2-(2,4,6-tri-*tert*-butylphenyl)-2-phosphaethenyllithium gave 6,8-di-*tert*-butyl-3,4-dihydro-4,4-dimethyl-1-phosphanaphthalene by intramolecular insertion of an intermediary phosphinidene carbene species into one of the C–H bonds of the two *o*-*tert*-butyl groups.**



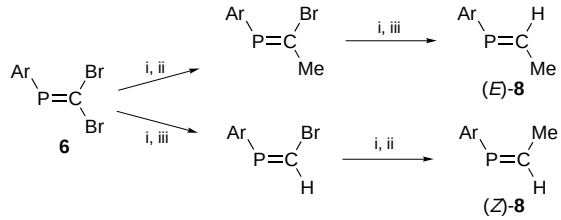
Compounds containing multiple bonds of heavier main group elements such as phosphorus are of current interest.[1] The 2,4,6-tri- *tert*-butylphenyl group (hereafter abbreviated to Ar) is one of the typical and powerful bulky protecting groups for such bonds and by utilizing this substituent we have prepared various types of low coordinated tervalent phosphorus compounds such as diphosphenes[2] and phosphacumulenes.[3]

Recently, we and others have reported on the conversion of (*E*)-1-chloro-2-(2,4,6-tri-*tert*-butylphenyl)-2-phosphaethenyllithium [(*E*)-**1**] to 2-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethyne **2** (Scheme 1),[4] as well as on the synthetic application of (*E*)- and (*Z*)-**1** as a building block having a phosphorus–carbon double bond.[5,6] Although formation and some reactions of the bromo analogue **3** have been described in the literature,[6,7] C–H insertion reactions involving the phosphinidene carbenoid have not been reported. We report here the formation of 6,8-di-*tert*-butyl-3,4-dihydro-4,4-dimethyl-1-phosphanaphthalene **4** *via* (2,4,6-tri-*tert*-butylphenyl)phosphinidene carbene **5**.

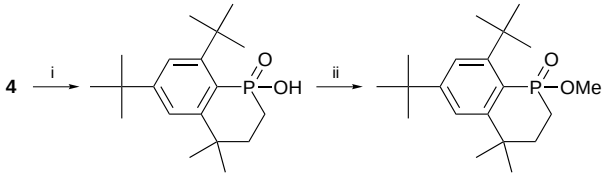


2,2-Dibromo-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethene[6,8] **6** was allowed to react with butyllithium in THF at −78 °C to give 1-bromo-2-(2,4,6-tri-*tert*-butylphenyl)-2-phosphaethenyllithium **3**.[8] Quenching of the resulting solution of **3** with MeOH at −78 °C gave (*E*)- and (*Z*)-2-bromo-1-phosphaethenes **7** in 2 and 58% yields, respectively, after column chromatographic treatment (Scheme 2). In a separate experiment, $^{31}$P NMR spectroscopy of the resulting solution at 210 K showed the formation of (*E*)- and (*Z*)-phosphaethenyllithiums in a 1 : 5 peak ratio [(*E*)-**3** : $\delta_P$ ([$^2H_8$]THF) 369.7; (*Z*)-**3** : $\delta_P$ 254.6].‡

When the mixed solution of (*E*)- and (*Z*)-**3** was warmed to room temperature, it turned violet, and the 3,4-dihydro-1-phosphanaphthalene derivative **4** was obtained in 17% yield after work up with silica-gel column chromatography.§ The formation of **4** is explicable by intramolecular insertion of an intermediary phosphinidene carbene **5** into one of the C–H bonds of the two *o*-*tert*-butyl groups, although attempts to trap the carbene with cyclohexene and tetracyanoethene failed. An analogous intramolecular C–H insertion reaction of alkylidene carbenoid has been reported by Köbrich in the reaction of 1-chloro-2,7-dimethylocta-1,6-diene with butyllithium to give 1-methyl-3-isobutenylcyclopent-1-ene.[9] Compound **4** was also obtained from the chloro congener (*Z*)-**1** in $Et_2O$ in a very low yield (1%), probably because of accompanying complicated reactions, although no formation of **4** was detected from (*Z*)-**1** in THF under similar conditions. In contrast to (*E*)-**1**, which gave the phosphaethyne **2** but not **4** as mentioned above, the 1-bromo-2-phosphaethenyllithium **3** did not afford **2**. These facts may indicate that the carbene **5** is smoothly generated from the bromo derivative **3**, because of the better leaving ability of bromide ion, to give **4** in a better yield, compared to either (*Z*)-**1** or (*E*)-**1**. Nevertheless, these results do not mean that phosphinidene carbenes should not isomerise to phosphaethynes. Competitive formation of phosphaethynes may accompany intra- and/or inter-molecular C–H insertion reactions if phosphinidene carbenes bear substituents which retard intramolecular C–H insertion reaction, since theoretical investigation (at the MP4/6-31G** level) has shown that the linear HPC and HCP isomers represent the transition state and the energy minimum, respectively, on the energy surface of the singlet ground state.[10]¶



The UV spectrum of **4** was compared with those of 1-phosphapropenes (*E*)- and (*Z*)-**8**, which were prepared by the method shown in Scheme 3.‖ Although the three compounds exhibit absorption maxima at a similar wavelength of *ca.* 300 nm, the molar absorption coefficient of the dihydrophosphanaphthalene **4** is about ten times larger than those of (*E*)- and (*Z*)-**8**.§ This fact probably indicates that the phosphorus–carbon double bond in **4** is nearly coplanar with the aromatic ring (Ar) while the double bond systems in (*E*)- and (*Z*)-**8** are not coplanar with the Ar ring. In fact, X-ray crystallographic analysis of (*E*)- and (*Z*)-2-phenyl-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethenes, the phenyl analogues of



**Scheme 1** *Reagents and conditions*: i, Bu$^t$Li or Bu$^s$Li, THF, −78 °C; ii, Bu$^n$Li, THF, −78 °C

**Scheme 2** *Reagents and conditions*: i, Bu$^n$Li, THF, −78 °C; ii, MeOH, −78 °C

**Scheme 3** *Reagents and conditions*: i, Bu$^n$Li, THF, −78 °C; ii, MeI, −78 °C; iii, MeOH, –78 °C

**Scheme 4** *Reagents and conditions*: i, 1 M HCl aq., $Et_2O$–EtOH (5 : 1), air, room temp.; ii, $CH_2N_2$, $Et_2O$, room temp.

(*E*)- and (*Z*)-**8**, shows that the phosphorus–carbon double bonds for those are nearly perpendicular to the aromatic rings of the Ar groups to avoid steric congestion.[11] Attempted X-ray analyses of **4**, however, have been unsuccessful because of difficulties in obtaining a suitable single crystal.

When compound **4** was allowed to react with hydrochloric acid in $Et_2O$–EtOH, phosphinic acid **9** was obtained in 30% yield (Scheme 4),§ indicating that there is enough room around the phosphorus atom for the approach of water or oxygen.†† However, attempted reaction of **4** with $M(CO)_5$(thf) (M = Cr, W) in THF at room temperature resulted in the decomposition of **4**, which may indicate that the end-on coordination site in **4** is blocked by the *o*-*tert*-butyl groups. Furthermore, attempted reaction of **4** with either $PtCl_2(PPh_3)_2$ and $N_2H_4{\cdot}H_2O$ at 60 °C for side-on coordination or $Cr(CO)_6$ in refluxing dioxane for π-complex formation was not successful and resulted in the decomposition of **4**.

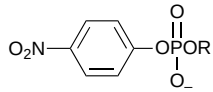
# Extraordinary acceleration of phosphodiester hydrolyses by thorium cations

**Robert A. Moss,* Jing Zhang and Kathryn Bracken**

*Department of Chemistry, Rutgers University, New Brunswick, New Jersey 08903, USA*

**$Th^{IV}$ cations in aqueous Brij micelles strongly promote the hydrolyses of several phosphodiester substrates; in the case of bis(*p*-nitrophenyl)phosphate 1, the observed rate constant (0.028 $s^{-1}$) represents an acceleration of *ca* 2.8 billion.**

Much attention is deservedly focused on the remarkable acceleration of phosphodiester hydrolyses educed by lanthanide (Ln) cations.[1] Acting as Lewis acids, they bind the substrate's P–$O^-$ and mitigate its negative charge, while simultaneously furnishing a metal-bound hydroxide nucleophile to attack the phosphodiester's phosphoryl group. Both Lewis acid strength and the acidity of the cation's water of hydration increase with increasing positive charge density, so that $Ce^{IV}$, the only lanthanide with a readily accessible +4 oxidation state, is of particular interest for the mediated hydrolysis of *e.g.* DNA.[2] Indeed, an excess of a 2 : 1 palmitate–$Ce^{IV}$ complex in aqueous Brij micelles at pH 7 and 37 °C cleaves the model phosphodiester substrate, bis(*p*-nitrophenyl)phosphate **1**, (BNPP), with



**1** (BNPP)

$k = 2.6 \times 10^{-2}$ $s^{-1}$,[3] representing a record enhancement of *ca.* $2 \times 10^9$ relative to the uncatalysed reaction at 25 °C.[1h]

Similarly, we examined hydrolyses mediated by the actinide uranyl cation.[4] Uranium offers a +6 oxidation state, but exists in water as $UO_2^{2+}$, which is less reactive than $Ce^{IV}$; *e.g.* $k = 9.5 \times 10^{-6}$ $s^{-1}$ for hydrolysis of BNPP by excess $UO_2^{2+}$–*N*-hexadecyl-*N*,*N*′,*N*′,- trimethylethylenediamine (HTMED, pH 4.9, 37 °C).[4] Although this is equivalent to a rate enhancement of at least $8.6 \times 10^5$ relative to the uncatalysed reaction, $UO_2^{2+}$ is inferior to $Ce^{IV}$ by a kinetic factor of *ca.* 1100 in the cleavage of BNPP.

The actinide thorium, however, affords a stable +4 oxidation state in aqueous solution with multiple coordinated water molecules.[5] The 'hard acid' $Th^{4+}$ readily coordinates with oxygen ligands (including phosphates),[5] so that we anticipate nonoxidative,[6] hydrolytic potency toward phosphodiesters. Indeed, $Th^{4+}$ accelerates the hydrolysis of plasmid DNA and nucleotides at pH 4 or 5, with rate constants approaching those of $Ce^{IV}$.[6]

In order to quantitatively evaluate $Th^{4+}$ relative to $UO_2^{2+}$ and various Ln promoters of phosphodiester cleavage, we have now determined the reactivity of $Th^{4+}$ toward BNPP and additional substrates **2**–**4**. We are pleased to report conditions under which

**2** R = $CH_2CH(OH)Me$
**3** R = $C_{16}H_{33}$
**4** R = Et

the reactivity of $Th^{4+}$ far exceeds that of $UO_2^{2+}$, is comparable to that of $Ce^{IV}$, and surpasses that of other metal cations.

Substrates **1**–**4** were hydrolysed readily in the presence of aqueous $Th(NO_3)_4$. Optimal conditions (see below) comprised 2 mM Brij-35, 10 mM HEPES buffer, pH 6.0 (10 mM KCl, 37 °C). We employed a 20-fold excess of $Th^{4+}$ (1 mM) over substrate (0.05 mM). Kinetics were followed spectrophotometrically, monitoring the disappearance of the substrate's *p*-nitrophenyl moiety (290 nm) and the concomitant appearance of *p*-nitrophenol (317 nm). Reactions were observed for more than eight half-lives and pseudo-first order rate constants were obtained as the means of triplicate runs with $r > 0.997$ and reproducibilities within ±5%.

Rate constants appear in Table 1, where $k$ for BNPP hydrolysis, 0.028 $s^{-1}$, represents an acceleration of *ca.* 2.8 *billion* relative to the uncatalysed reaction at pH 7,[1h] whilst the entry for the intramolecularly assisted cleavage of RNA model **2**, $k = 0.013$ $s^{-1}$, is *ca.* $3.9 \times 10^5$ greater than in the absence of metal cations at pH 7.[1a] These enhancements appear to be the largest reported to date for Ln or actinide cations with these commonly employed model substrates. We note, however, that the 20-fold excess of $Th^{4+}$ is necessary; $k_{obs}$ slows markedly as $[Th^{4+}]$ : [BNPP] is reduced below 15 : 1 at pH 6. Control experiments also reveal inhibition of the hydrolysis by (added) inorganic phosphate.

The hydrolysis of BNPP was examined in detail: pH was varied from 3.5–7.0 in water, aqueous HEPES buffer, or HEPES–micellar Brij; added ligands included *N*-octyl-D-glucamine.[3] In HEPES– Brij, $k_{obs}$ increased steadily from $9.3 \times 10^{-4}$ $s^{-1}$ at pH 3.5 to a maximum of $2.8 \times 10^{-2}$ $s^{-1}$ at pH 6.0, before declining slightly at pH 6.5 or 7.0. Above pH 7, precipitation of OH-bridged Th oligomers[5] was observed. A similar pH dependence was seen in water, with $k_{obs} = 5.2 \times 10^{-3}$ $s^{-1}$ at pH 3.5 and $2.2 \times 10^{-2}$ $s^{-1}$ at pH 6.0 (maximum). The $pK_a$ for water bound to $Th^{4+}$ varies from 2.4 to 5.0, depending on the exact conditions;[7] a recent report[6] gives $pK_{a1} = 3.89$ and $pK_{a2} = 4.20$. These data are consistent with our observation of a reactivity maximum around pH 6.

The $Th^{4+}$-mediated hydrolysis of BNPP occurs with release of both *p*-nitrophenyl groups. Kinetic experiments under the conditions of Table 1 reveal that $Th^{4+}$ hydrolysis of the presumptive intermediate, *p*-nitrophenylphosphate, is twice as fast ($k = 5.5 \times 10^{-2}$ $s^{-1}$) as that of BNPP. The reported rate constants therefore describe the hydrolysis of the first *p*-nitrophenyl group of BNPP, which is the rate-limiting step.

Brij micelles enhance the $Th^{4+}$ reactivity: $k_{obs}$ increases steadily at pH 6 in HEPES buffer from $5.5 \times 10^{-3}$ $s^{-1}$ in the absence of Brij, to a maximum of $2.8 \times 10^{-2}$ $s^{-1}$ at 2.0 mM Brij. Not only does micellar Brij potentiate the reactivity of $Th^{4+}$ (presumably by binding substrate molecules and cations), but its oxygen atoms appear to solubilize the $Th^{4+}$ cations or oligomers

**Table 1** Kinetics of $Th^{4+}$ mediated hydrolyses[a]

| Substrate | $k_{obs}/10^{-4}$ $s^{-1}$ |
|---|---|
| **1** | 282[b] |
| **2** | 132 |
| **3** | 11.9 |
| **4** | 8.54 |

[a] At pH 6.0, 37 °C; other conditions are detailed in the text. Rate constants are reported as means of three runs with $r > 0.997$ and reproducibilities within ±5%. [b] Both *p*-nitrophenyl groups were cleaved.

above pH 5. Brij-35 has been previously used to stabilize metal cation catalysts for phosphodiester hydrolysis.[4,8]

In contrast to $Ce^{IV}$, which requires both a complexing ligand and micellar Brij to remain in solution above pH 4–5, $Th^{IV}$ is stabilized by Brij alone; added ligands merely sap its reactivity. For example, $k_{obs} = 2.8 \times 10^{-2}$ s$^{-1}$ ($Th^{4+}$–BNPP in aqueous Brij at pH 6) is reduced to $1.4 \times 10^{-3}$ s$^{-1}$ upon the addition of 1 equiv. of *N*-octyl-D-glucamine, a ligand useful in the stabilization of $Ce^{IV}$.[3]

$Th^{4+}$ is much more reactive than $UO_2^{2+}$ toward substrates **1** or **2**. The rate constants of Table 1 can be compared with *k*(pH 4.9) = $9.5 \times 10^{-6}$ s$^{-1}$ for **1** ($UO_2^{2+}$–HTMED) or $2.2 \times 10^{-4}$ s$^{-1}$ ($UO_2^{2+}$) for **2**.† Using BNPP hydrolysis as a reactivity measure, $Th^{4+}$ is comparable to $Ce^{IV}$–palmitate in Brij ($k = 2.6 \times 10^{-2}$, pH 7),[3] but more reactive than $Eu^{3+}$ ($k = 1.7 \times 10^{-4}$ s$^{-1}$, pH 7, 50 °C),[1e,f] or various $Eu^{3+}$ complexes (2.0–6.7 $\times$ $10^{-4}$ s$^{-1}$, pH 7–7.4, 25–50 °C),[1f,9] $La^{3+}$ ($1.4 \times 10^{-7}$ s$^{-1}$)[1g] or $La^{3+}$–$H_2O_2$ ($4.8 \times 10^{-3}$ s$^{-1}$, both at pH 7, 25 °C),[1g] 1 : 1 $La^{3+}$–$Fe^{3+}$ ($2.8 \times 10^{-4}$ s$^{-1}$, pH 7, 50 °C),[10] or binuclear azamacrocyclic complexes of $Eu^{3+}$ ($1.4 \times 10^{-3}$ s$^{-1}$, pH 7, 50 °C) or $Pr^{3+}$ ($8.4 \times 10^{-4}$ s$^{-1}$, pH 7, 50 °C).[11]

It is clear from these comparisons that $Th^{IV}$ and $Ce^{IV}$ are the most reactive actinide or lanthanide cations yet reported for the acceleration of BNPP hydrolysis. A similar conclusion follows from the reactivity of $Th^{IV}$ toward substrate **2**. Indeed, $Th^{IV}$ and $Ce^{IV}$ appear to be more reactive toward BNPP or **2**[1c] than any other metal cations thus far described, including (complexes of) cobalt[12] and copper.[13]

Toward long-chain phosphodiester substrate **3**, comicellized with 2 mM Brij-35 (critical micelle concentration, 0.06–0.09 mM[8a]), excess $Th^{4+}$ affords $k_{obs} = 1.2 \times 10^{-3}$ s$^{-1}$. Comparisons are lacking except for $UO_2^{2+}$–HTMED where $k_{obs} = 1.1 \times 10^{-4}$ s$^{-1}$.[4] Perhaps a fairer comparison of $Th^{4+}$–Brij *vs.* $UO_2^{2+}$–HTMED is with the short-chain substrate **4**, where $Th^{4+}$ (Table 1) manifests a 500-fold rate advantage over $UO_2^{2+}$ ($k = 1.7 \times 10^{-6}$ s$^{-1}$).‡

In conclusion, $Th^{IV}$ cations are an extraordinarily reactive, readily employed promoter of the hydrolysis of a variety of model phosphodiester substrates. We are continuing to probe their application to challenging problems in this area.

We are grateful to the U.S. Army Research Office for financial support.

## Footnotes and References

† No attempt is made in the kinetic comparisons to correct for differing conditions or cation–substrate ratios. Rather, the maximum rate constants available in the literature are compared to those of $Th^{4+}$.

‡ The minimal rate advantage for $Th^{4+}$ cleavage of micellized substrate **3**, relative to nonmicellar analogue **4**, contrasts with rate enhancements of 50–70 previously observed with $Eu^{3+}$ or $UO_2^{2+}$ toward aggregated substrates (refs. 4, 14). The differing behaviour may be due to the Brij comicelles employed with $Th^{4+}$.

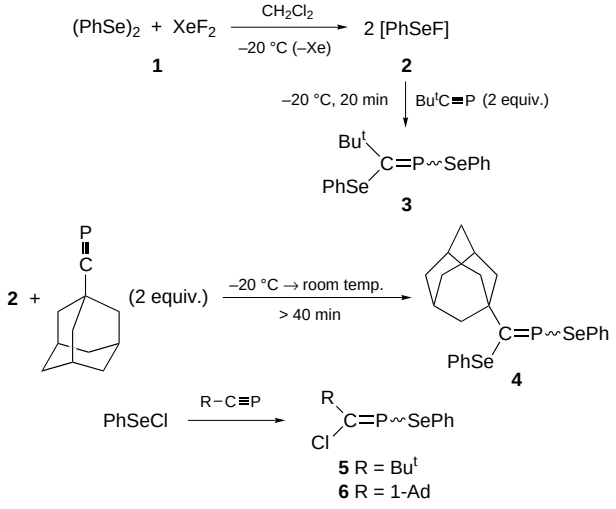
# Reaction of phosphaacetylenes Bu$^t$C≡P and 1-AdC≡P with $(PhSe)_2$–$XeF_2$: first examples of vicinal bis-selenenylation (at P and C) to form novel phosphaalkenes

**Kenneth K. Laali,*[a] Wolfgang Fiedler[a,b] and Manfred Regitz[b]**



[a] *Department of Chemistry, Kent State University, Kent, OH 44242, USA*
[b] *Fachberich Chemie, Universität Kaiserslautern, Erwin-Schrödinger-Strasse, D-67663 Germany*

***tert*-Butyl- and 1-adamantyl-phosphaacetylenes (2 equiv.) react with $(PhSe)_2$–$XeF_2$ (→ 2 PhSeF) to give novel phosphaalkenes by vicinal bis-phenylselenenylation (at P and C), in contrast to acetylenes which undergo fluoroselenenylation.**

Whereas PhSeCl and PhSeBr are commercially available sources of selenenic electrophiles, PhSeF is too labile to be isolated. It was recently reported[1] that the system $(PhSe)_2$–$XeF_2$ **1** acts as an *in situ* source of PhSeF **2**, whose reaction with selected alkenes led to fluoroselenenylation (predominantly *E* alkenes). Subsequently, **1** was shown to be an efficient vicinal fluoroselenenylation reagent for alkynes.[2,3] The preferred *E* configuration of the alkene product (*trans* stereochemistry) may be traced to the intermediacy of the phenylselenirenium cation, a stable salt of which has been characterized.[4] In addition to **1**, PhSeBr·AgF in $CH_2Cl_2$ under sonication and PhSeCl·AgF in MeCN also serve as *in situ* sources of PhSeF for fluoroselenenylation of alkenes, alkynes and α-diazo ketones (α-diazo esters).[5]

In relation to our previous and ongoing studies of electrophilic chemistry of phosphaalkynes, ionization of phosphirenes (→ phosphirenylium cation) and electrophilic reactivity of the tetraphosphacubane skeleton,[6–9] we became interested in possible fluoroselenenylation of RC≡P, anticipating that, based on previous results on addition of protic and Lewis superacids,[6] 'PhSe$^+$' would attack at the P≡C carbon.

Under the conditions where **2** is expected to be present *via* system **1**,[2,3] Bu$^t$CP (2 equiv.) was added to the reaction mixture under argon in dry $CH_2Cl_2$ at −20 °C (rapid Xe loss) (Scheme 1); $^{31}$P NMR monitoring of the reaction mixture indicated that following 20 min at −20 °C, only traces of Bu$^t$CP remained unreacted. The solvent was removed *in vacuo* (room temp.), the residue was taken up in $CDCl_3$ and subjected to multinuclear NMR analysis (Fig. 1). The major product ( > 90% based on $^{31}$P NMR integral ratios)† gives rise to a phosphorus resonance at $\delta$ 351.9 with a one-bond P/Se coupling of 319.1 Hz and a two-

**Scheme 1**

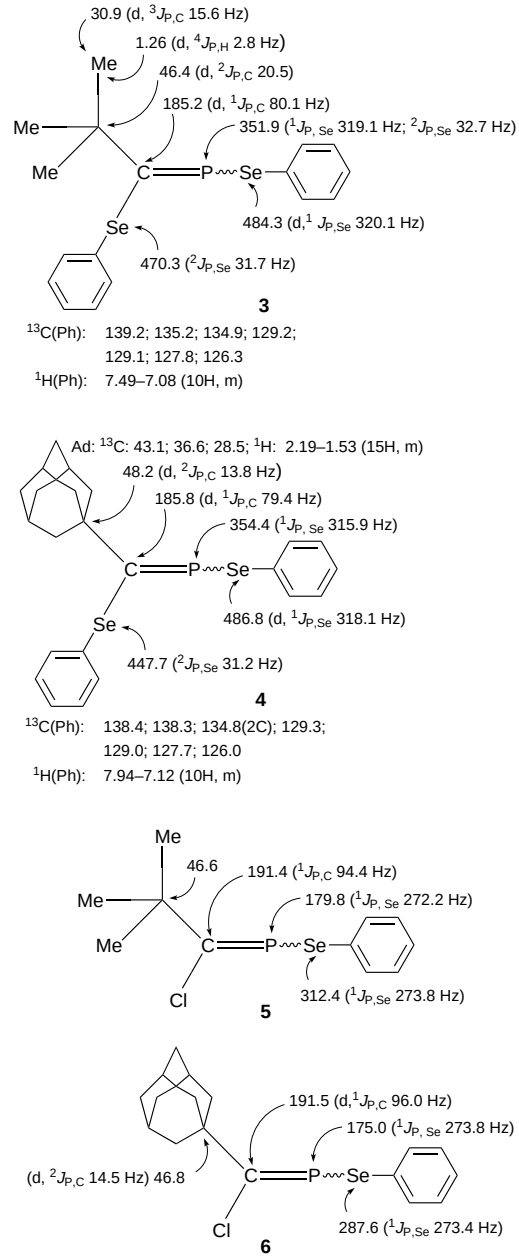


**Fig. 1** Multinuclear NMR data for **3**, **4**, **5** and **6**

bond P/Se coupling of 32.7 Hz. In the $^{77}$Se NMR spectrum, there are two resonances (1 : 1 ratio), one for the P–SePh moiety at $\delta$ 484.3 (one-bond P/Se coupling 320 Hz) and the other for C–SePh at $\delta$ 470.3 with a two-bond P/Se coupling of 31.7 Hz, supporting vicinal bis-selenenylation (→ **3**). Presence of an intact C=P moiety is apparant in the $^{13}$C NMR spectrum *via* a distinct doublet at $\delta$ 185.2 with a one-bond P/C coupling of 80.1 Hz typical of phosphaalkenes.[10] Both *tert*-butyl carbon resonances (at $\delta$ 46.4 and 30.9) appear as doublets due to phosphorus coupling. The SePh ring carbon resonances give rise to eight resonances between $\delta$ 139.2–126.3.

Phosphaalkene **3** has a limited life-time at room temp., and prolonged reaction times gave a complex mixture, as did attempted isolation. Additional proof of the structure came from the EI-MS spectrum of a freshly prepared sample, showing the $M^+$ at *m/z* 412 with the appropriate isotope pattern for two Se atoms.

Attempted Se-ethylation with one and two equivalents of EtOTf, to selectively form the derived mono- and di-selenonium cation salts,[3,11] led to complex mixtures ($^{31}$P NMR), probably by competing C=P ethylation.

Reaction of system **1** with the more sterically crowded 1-AdC≡P was slower. After the initial addition at −20 °C, the reaction was allowed to warm to room temperature under stirring. Following an additional 40 min stirring at room temp., **4** was formed (*ca*. 75% based on $^{31}$P NMR integrals; with *ca*. 25% of 1-AdC≡P remaining unreacted). Multinuclear NMR data on **4** (Fig. 1) fully agree with the suggested structure. The more shielded nature of the selenium centre (at C) in the more sterically crowded **4** as compared to **3** is noteworthy.

In the absence of $XeF_2$, vicinal bis-phenylselenenylation still occurs, albeit at a much slower rate. Thus $(PhSe)_2$ reacted slowly with Bu$^t$C≡P (1 equiv.) in dry $CH_2Cl_2$: $^{31}$P NMR monitoring showed that the initial product is **3**, but its slow formation and increase over time is accompanied by extensive decomposition at room temp. Similar observations were made in experiments where only *ca.* 0.1 equiv. of $XeF_2$ was used. Thus although fluoroselenenylation is not the final outcome, the presence of 1 equiv. of $XeF_2$ is needed. The presence of 2 equiv. of RC≡P is also required, since addition of 1 equiv. of Bu$^t$C≡P to **1** under similar conditions led only to traces of **3**. The need for a 1 : 1 PhSeF–RC≡P stoichiometry (as oppossed to 1 : 0.5) coupled to the absence of the additional equivalent of RC≡P in the $^{31}$P NMR is remarkable; it is tentatively rationalized by initial bis-fluoroselenenylation followed by 'elimination' (transfer fluorination of RC≡P and rapid polymerization of the resulting difluorophosphaalkene), somewhat similar to fluoroselenenylation of monosubstituted alkynes with *N*-phenylselenophthalimide–$Et_3N$–3HF forming vinylic diselenated compounds by HF loss.[12]

For comparison, we examined the reactions of Bu$^t$C≡P and 1-AdC≡P with PhSeCl (1 equiv.) in $CH_2Cl_2$ (Scheme 1). Dropwise addition of a solution of PhSeCl ($CH_2Cl_2$) to a cold solution of Bu$^t$C≡P ($CH_2Cl_2$) at dry ice–acetone temperature (over 30 min) followed by slow warming to room temp. and removal of solvent *in vacuo* gave the chloroselenenylation product **5** (70–80% in independent reactions). Under comparable conditions, chloroselenenylation of 1-AdC≡P was slower (→ **6**; *ca*. 60%). These reactions demonstrate that 'PhSe$^+$' attacks at phosphorus, not carbon.‡ Whereas the phosphorus and carbon environments in the phosphaalkene unit and the one-bond P/Se couplings are very similar for **5** and **6**, the selenium chemical shifts vary by almost 25 ppm. Observation of minor amounts of $(PhSe)_2$ ($\delta_{^{77}Se}$ 460.8) in both cases suggests possible intervention by a radical process.§

The observed bis-selenenylations with the $(PhSe)_2$–$XeF_2$ system points to a different addition mechanism for 'PhSeF' compared to PhSeCl towards the P≡C triple bond. Moreover, although PhSeCl effects chloroselenenylation, its regiochemistry is opposite to protonation and Lewis acid complexation reactions of RC≡P.[6]

The stereochemistry in **3** and **4** has not been unambiguously established, but the magnitude of $^2J_{C,P}$ is a good indicator of a synperiplanar relationship between the R group and the lone-pair at phosphorus (*syn* addition).[10,13]

We thank Dr S. Hollenstein for conducting some duplicate experiments. This material is based upon work supported by the US Army Research Office under grant number 35222-CH-II.

# Synthesis and conformation of 3′-*O*,4′-*C*-methyleneribonucleosides, novel bicyclic nucleoside analogues for 2′,5′-linked oligonucleotide modification

**Satoshi Obika, Ken-ichiro Morio, Daishu Nanbu and Takeshi Imanishi***

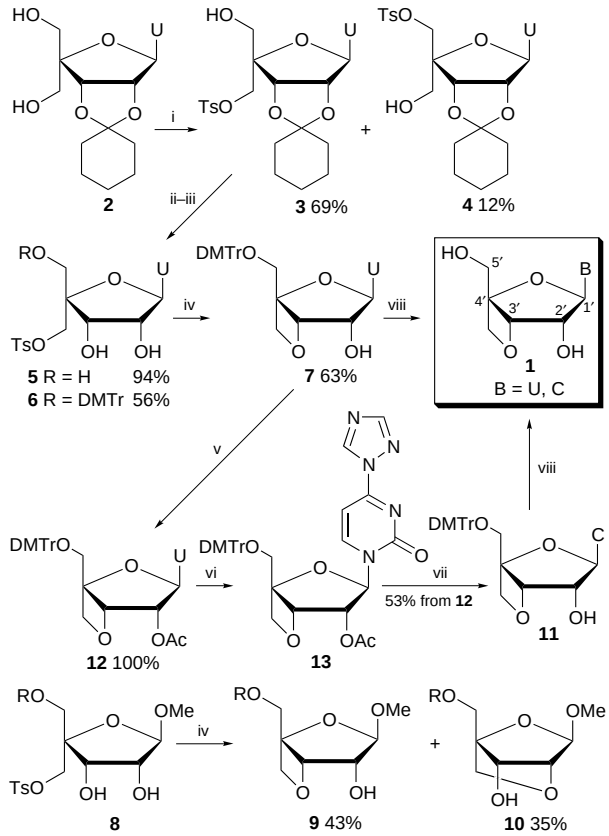
*Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565, Japan*

**Novel bicyclic nucleoside analogues 3′-*O*,4′-*C*-methyleneribonucleosides 1 are conveniently prepared starting from uridine; the sugar puckering of 1 is found to be nearly in the *S*-conformation by means of PM3 calculations and $^1$H NMR studies.**

Non-genetic 2′,5′-linked oligonucleotides have been attracting much attention since the syntheses and properties of oligonucleotides with 2′,5′-linkages were reported in 1992.[1–3] Using NMR studies[4] and molecular modeling,[5] it was suggested that oligoribonucleotides containing 2′,5′-linkages (2′,5′-RNA) preferentially adopted the C2′-*endo* conformation (*S*-conformation), while 2′,5′-linked oligodeoxyribonucleotides (2′,5′-DNA) existed mainly with C3′-*endo* sugar puckering (*N*-conformation). Interestingly, these results are the opposite of what is observed with the corresponding 'genetic' 3′,5′-RNA and -DNA. There have been some reports concerning successful application of 2′,5′-linked oligonucleotides to antisense uses.[6–9] On the other hand, 2-5A (2′,5′-oligoadenylate 5′-triphosphate) is known to be formed in interferon-treated cells and to have antiviral activity with the aid of 2-5A dependent ribonuclease (RNase L),[10] and intensive studies on various 2-5A analogues have been reported.[11]

We have designed a bicyclic nucleoside analogue, 3′-*O*,4′-*C*-methyleneribonucleoside **1**,[12] which is a promising precursor for both novel types of therapeutic nucleoside derivatives and 2′,5′-linked oligonucleotide analogues. The sugar moiety in **1** consists of a 2,6-dioxabicyclo[3.2.0]heptane ring system, with the tetrahydrofuran part conformationally restricted by the fused oxetane ring. Here we describe a convenient first synthesis of **1** (B = U and C), and also discuss its conformation.

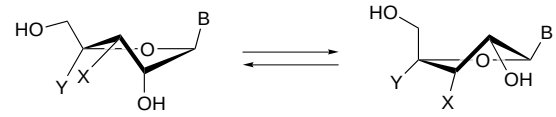
The synthetic route to the target molecule **1** (B = U) is shown in Scheme 1. A selective toluene-*p*-sulfonylation of the diastereotopic hydroxymethyl groups in 2′,3′-*O*-cyclohexylidene-4′-hydroxymethyluridine[13,14] **2** afforded monotosylate **3** (69%) along with its isomer **4** (12%). The stereochemistry at C4′ in **3** was confirmed by means of NOE measurements. Acidic hydrolysis of **3** gave triol **5** (94%) and then selective protection of the primary hydroxy group in **5** with a 4,4′-dimethoxytrityl (DMTr) group in the usual manner afforded **6** (56%).



Oxetane ring formation from **6** was accomplished on treatment with a large excess of sodium hexamethyldisilazide in THF at room temperature, yielding the desired product **7**† (63%). The exclusive oxetane ring formation is attributable to the predominant *S*-conformation of the starting material **6**,‡ in which only the 3′-OH is thought to be located near the 4′-methylene carbon centre; the 2′-OH is too far away to attack the 4′-methylene carbon. In fact, 1′-methoxy congener **8**, which should exist mainly in the *N*-conformation due to the anomeric effect,‡ gives a *ca.* 1:1 mixture of 2′-*O*,4′-*C*-methylene derivative **9** and 3′-*O*,4′-*C*-methylene derivative **10** under the same conditions.[15]

Transformation of **7** into the cytidine derivative **11** by exchange of nucleobase was also undertaken as shown in Scheme 1. After 2′-*O*-acetylation of **7**, treatment of **12** with 1,2,4-triazole and 4-chlorophenyl phosphorodichloridate in pyridine[16] gave **13**, which was then subjected to ammonolysis to give **11**† (overall 53% yield from **7**). Acid catalysed detritylation of **7** and **11** gave the corresponding 2′,5′-diol compounds **1** (B = U)† and **1** (B = C)† quantitatively.

In general, the sugar moiety in natural and modified nucleosides exists in an equilibrium between *N*- and *S*-conformations. The conformation of nucleoside analogues in solution is easily obtainable from coupling constants between the ribose ring protons in the $^1$H NMR spectrum.[17] The simplest equation for calculation of percentage of *S* conformation is shown in eqn. (1). The calculation results for the obtained nucleoside



$$S(\%) = 100 \times (J_{1'2'} - 1)/6.9 \qquad (1)$$

analogues are summarized in Table 1, and show that all of the 3′-*O*,4-*C*-methyleneribonucleoside analogues have very large *S* values. A PM3 calculation[18]§ also indicates that an *S*-conformation (C1′-*exo*-C2′-*endo*) is the most stable conformation for the ribose ring in **1** (Fig. 1). It is very interesting and noteworthy that the oxetane ring fused nucleoside deriva-

# Ruthenium(II) ammine centres as efficient electron donor groups for quadratic non-linear optics

**Benjamin J. Coe,*[a] Jonathan P. Essex-Lopresti,[a] James A. Harris,[a] Stephan Houbrechts[a] and André Persoons[b,c]**

[a] *Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL*

**Ruthenium(II) complex salts *trans*-$[Ru(NH_3)_4(L^D)(L^A)][PF_6]_3$ ($L^D$ = an N-donor ligand, $L^A$ = a 4,4′-bipyridinium ligand) exhibit large, tunable static first hyperpolarizabilities $\beta_0$ which are associated with intense, visible metal-to-ligand charge-transfer excitations.**

Organic materials possessing non-linear optical (NLO) properties are the focus of much current research activity directed towards applications in advanced electronics systems.[1] Within this field, transition-metal organometallic and coordination complexes have attracted limited attention,[2] but their great potential as novel NLO materials is yet to be fully explored.

Solution measurements of hyperpolarizability coefficients allow the correlation of NLO properties with molecular structure. This facilitates the rational design and synthesis of efficient NLO chromophores which may subsequently be incorporated into active materials. Extensive data concerning the first (quadratic) hyperpolarizability $\beta$ is now available for purely organic compounds,[1] but corresponding information for metal complexes is scarce.[2] This situation is gradually being rectified and $\beta$ values have been determined for selected complexes including bimetallic sesquifulvalenes,[3] Schiff-base derivatives,[4] and σ-acetylides.[5]

Recent reports show that ruthenium mixed-valence,[6] 2,2′-bipyridine (bipy),[7] and σ-acetylide[8] complexes can possess large $\beta$ values, although two-photon excited luminescence may explain these results for the bipy complexes.[9] Ruthenium(II) ammine complexes are promising candidates as high $\beta$ molecules due to the strong π-donor ability of the $d^6$ metal centres.[10] Such complexes are structurally versatile, and their readily accessible $Ru^{III/II}$ redox couples may permit reversible, molecular-level modulation of NLO properties.

A series of complex salts *trans*-$[Ru^{II}(NH_3)_4(L^D)(L^A)][PF_6]_3$ [Fig. 1; $L^D$ = $NH_3$, $L^A$ = *N*-methyl-4,4′-bipyridinium ($MeQ^+$) **1**, *N*-phenyl-4,4′-bipyridinium ($PhQ^+$) **2** or *N*-(2,4-dinitrophenyl)-4,4′-bipyridinium ($DNPhQ^+$) **3**; $L^D$ = 1-methylimidazole (mim), $L^A$ = $MeQ^+$ **4** or $PhQ^+$ **5**; $L^D$ = 4-dimethylaminopyridine (dmap), $L^A$ = $MeQ^+$ **6** or $PhQ^+$ **7**] have been synthesized by using established coordination chemistry based on $[Ru^{II}(NH_3)_5(H_2O)][PF_6]_2$ or *trans*-$[Ru^{II}Cl(NH_3)_4(SO_2)]Cl$;[11,12] **1**, **4** and **6** are known,[11,13] but the other salts are new. [$PhQ^+$]Cl and [$DNPhQ^+$]Cl were synthesized by using a modification of a literature report for *N*,*N*′-diphenyl-4,4′-bipyridinium dichloride.[14] All of the compounds have been fully characterized by using various techniques including UV–VIS spectroscopy and cyclic voltammetry,† and the first molecular hyperpolarizabilities $\beta$ of the complex salts have been determined *via* the hyper-Rayleigh scattering (HRS) technique.[15]

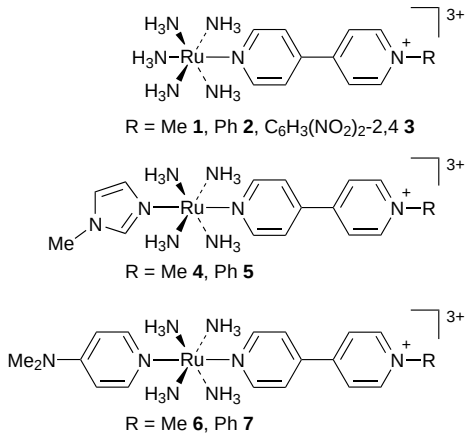

**Fig. 1** Structures of the complex cations in **1**–**7**

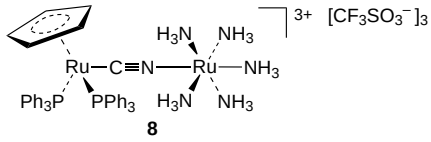
A common spectroscopic feature of low-valent ruthenium complexes of π-acceptor ligands are low-energy metal-to-ligand charge-transfer (MLCT) absorptions, the energies of which are governed by the electron-donor ability of the ruthenium centre and the ligand electron-acceptor capacity.[16] The exploitation of MLCT excited states as a basis for large $\beta$ values has often been suggested,[2] but only very recently demonstrated.[8] The $MeQ^+$ ligand is a particularly effective π acceptor due to conjugation between the pyridyl rings.[17]



The complex salts show intense, broad $d_\pi(Ru^{II}) \rightarrow \pi^*(L^A)$ MLCT bands in the visible region (Table 1). For a given $L^D$, the MLCT energies decrease in the order $L^A$ = $MeQ^+$ > $PhQ^+$ > $DNPhQ^+$, with a red-shift of 70 nm going from **1** to **3**. This is because the electron acceptor strength of the ligand increases as the conjugation pathlength is extended. In keeping with this, the potentials for ligand-based reduction obtained *via* cyclic voltammetry (Table 1) show that the lowest unoccupied molecular orbital energy of $PhQ^+$ is lower than that of $MeQ^+$ by 140–160 mV. With $L^A$ fixed, the MLCT energies decrease in the order $L^D$ = $NH_3$ > mim > dmap, with a red-shift of 30 nm going from **2** to **7** reflecting the increasing basicity of $L^D$. The reversible $Ru^{III/II}$ oxidation waves are at constant potential, showing that the energy of the metal-based highest occupied molecular orbital is unaffected by the ligand changes. The MLCT bands are highly solvatochromic, with the maximum for **6** occurring at 604 nm in $MeNO_2$ and at 706 nm in HMPA. Such behaviour, which often accompanies large $\beta$ values in organic compounds,[18] confirms that the MLCT excitations are the primary contributors to $\beta$ in these complexes.

The HRS setup and the method for derivation of $\beta$ were as described in a recent report.[19] All samples were passed through a 0.45 mm filter, and were checked for fluorescence which can interfere with the HRS signal.[9,20] The $\beta$ values obtained are extremely large (Table 1), and similar to those reported for ruthenium organometallics.[8] A much smaller HRS $\beta_{1064}$ value of $78 \times 10^{-30}$ esu was found for the mixed-valence salt **8** (Fig. 2) in which the $\{Ru^{III}(NH_3)_5\}^{3+}$ centre acts as an electron acceptor.[9] Since salts **1**–**7** absorb in the region of the second harmonic at 532 nm (Table 1), their $\beta$ values are resonantly

**Table 1** Electrochemical, UV–VIS and non-linear optical data in acetonitrile for the salts *trans*-$[Ru(NH_3)_4(L^D)(L^A)][PF_6]_3$

[a] Measured in solution 0.1 M in $[NBu^n_4]PF_6$ at a Pt bead working electrode with a scan rate of 200 mV s$^{-1}$ (ferrocene internal reference $E_{1/2}$ = 0.40 V, $\Delta E_p$ = 65 mV). [b] Extinction at 532 nm as a percentage of that at the MLCT maximum. [c] $\beta_{1064}$ is the uncorrected first hyperpolarizability measured by using a 1064 nm Nd:YAG laser fundamental; $\beta_0$ is the static hyperpolarizability estimated by using the two-level model.[22] A relative error of ±15% is estimated for $\beta$ values. The quoted cgs units (esu) are converted into SI units (C$^3$ m$^3$ J$^{-2}$) by dividing by a factor of $2.693 \times 10^{20}$. [d] $E_{pa}$ for an irreversible oxidation process. [e] $E_{pc}$ for an irreversible reduction process. [f] Ref.13.

**8**

**Fig. 2** Structure of the diruthenium salt **8**

enhanced, to the greatest extent for **1** and to the least extent for **3**. Correlations between $\beta$ and the intramolecular charge-transfer (ICT) energy have been found for dipolar organics in which a single ICT absorption dominates $\beta$.[21] In similar fashion, $\beta$ for these complexes clearly increases as the MLCT band shifts to lower energy. This trend is evident despite the concomitant decreasing extent of resonance enhancement.

Static first hyperpolarizabilities $\beta_0$, which provide an estimate of the intrinsic molecular hyperpolarizability with resonance effects removed, were obtained by application of the two-level model.[22] The $\beta_0$ values are very large and are in excess of those for most NLO-active molecules. By way of contrast, the organic dye Brilliant Green has an ICT maximum at 632 nm and a $\beta_0$ value of $97 \times 10^{-30}$ esu derived from HRS in 5% MeOH–1,4-dioxane at 1064 nm.[23] A broad inverse correlation between $\beta_0$ and the MLCT energy is observed for **1**–**7**.

In conclusion, we have demonstrated that readily synthesized and structurally versatile ruthenium coordination complexes can exhibit very large $\beta$ and $\beta_0$ values which are associated with low-energy MLCT excitations. The MLCT energy is readily tuned by ligand modifications, which will allow the maximization of $\beta_0$ and the establishment of further structure–property correlations for this novel class of NLO molecules.

Support from The Royal Society, from the Belgian National Fund for Scientific Research (G.2103.93 and 9.0011.92), the Belgian government (IUAP-16) and the University of Leuven (GOA/1/95) is acknowledged. S. H. is a Research Assistant of the Belgian National Fund for Scientific Research. Johnson Matthey plc are thanked for a loan of ruthenium trichloride.

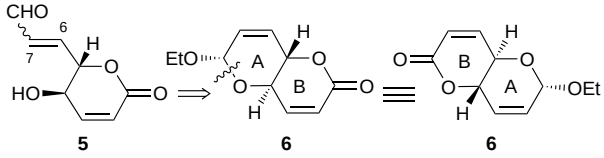
# A novel entry to naturally occurring 5-alkenyl α,β-unsaturated δ-lactones from D-glucose: syntheses of (+)-acetylphomalactone and (+)-asperlin

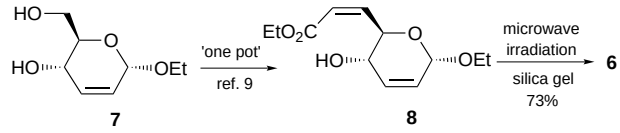
**Ana M. Gómez,* Beatriz López de Uralde, Serafín Valverde and J. Cristóbal López*†**

*Instituto de Química Orgánica General (CSIC), Juan de la Cierva 3, 28006 Madrid, Spain*



**A bicyclic pyranosidic glycoside 6, readily obtained from D-glucose, has been used as the key intermediate in enantioselective syntheses of (+)-acetylphomalactone and (+)-asperlin, in which the configuration at C-5 corresponds to that of the hexopyranosides in the L-sugar series.**

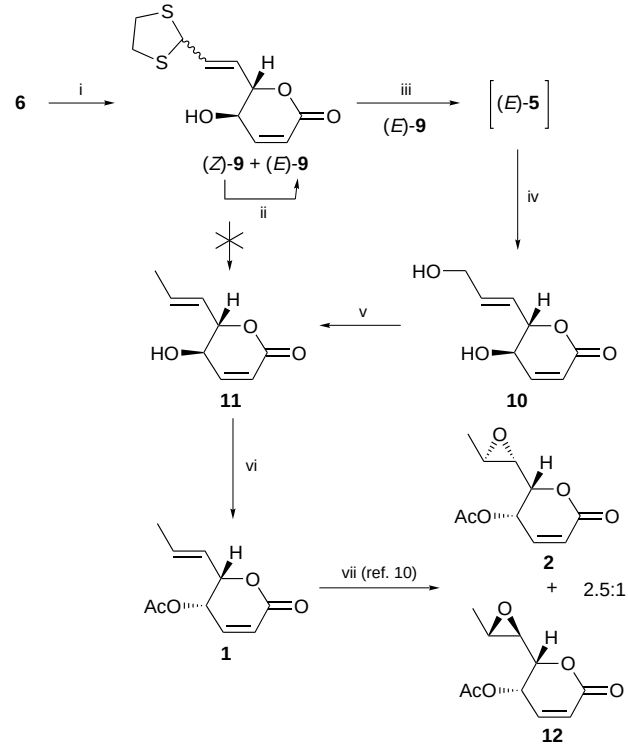
Naturally occurring 5-substituted α,β-unsaturated δ-lactones, *e.g.* **1**–**4**, represent an important class of products with a diverse range of biological activity.[1] They have been reported to be plant growth inhibitors, insect antifeedants and antifungal and antitumour agents.[1] They are widely distributed and have been isolated from both plants and fungi. Acetylphomalactone **1**[2] and asperlin **2**[3] are prominent members of this family. (+)-Acetylphomalactone **1** is an antimicrobial metabolite isolated from *Aspergillus caespitous*,[2] and (+)-Asperlin **2** was isolated from *Aspergillus nidulans* and possesses antitumour and antibacterial activity.[3] Among the more relevant structural characteristics of this family are: (i) the absolute configuration at C-5, and (ii) the presence of a chain at C-5, which normally presents a $\Delta^{6,7}$ unsaturation or an epoxide derived therefrom.[1] The design of a general, enantioselective approach to this family of lactones from currently available carbohydrates (D- series) is not obvious because the absolute configuration at C-5 correlates with that of a hexopyranoside of the L-series. Accordingly, D-sugars have been used in syntheses of unnatural isomers of asperlin **2**[4,5]‡ and anamarine **3**[6] as well as synthetic precursors for *ent*-olguine **4**.[7] Herein we report the first general approach to this family of lactones, starting from D-glucose, and its application to the syntheses of acetylphomalactone **1** and asperlin **2**.



**1** **2** **3** **4**

Our strategy (Scheme 1) is based on the recognition that D-glucose-derived bicyclic glycoside **6** can be viewed as a 5-alkenyl α,β-unsaturated δ-lactone. Chemoselective cleavage of ring A on **6** leads to lactone **5**, which already fulfils the above-mentioned structural requirements.

**5** **6** **6**



**Scheme 1**

**7** **8**

**Scheme 2**

Additionally, the feasibility of this approach greatly benefits from the facile preparation of **6** from readily available Ferrier's diol **7**[8] (Scheme 2). Thus, compound **7** is efficiently transformed, *via* a one pot operation, into hydroxy ester **8**,[9] and microwave-induced lactonization of the latter on silica gel gives rise to glycoside lactone **6** in fairly good yield (73%).§ The glycosidic moiety on **6** can be unravelled under acid catalysis in the presence of ethanedithiol to furnish a *ca.* 2 : 1 mixture of 5-alquenil lactones (*E*)-**9** and (*Z*)-**9**, which upon further treatment leads to (*E*)-**9** as a single isomer (83% overall) (Scheme 3). At this stage, direct desulfurization of (*E*)-**9** to yield **11** was attempted under a variety of conditions,¶ although in our hands this transformation still remains elusive. A less direct route to **11** was then designed which involves deprotection of

**Scheme 3** *Reagents and conditions*: i, $HSCH_2CH_2SH$, $BF_3{\cdot}OEt_2$, $CH_2Cl_2$, −20 °C; ii, $BF_3{\cdot}OEt_2$, $CH_2Cl_2$, 0 °C, 83% from **6**; iii, $CaCO_3$, MeI, MeCN–$H_2O$ (8 : 2), 60 °C; iv, $BH_3{\cdot}Me_2S$, THF, 0 °C, 66% from (*E*)-**9**; v, *N*-(phenylseleno)phthalimide, $PBu_3$, $CH_2Cl_2$, −20 °C, then $Bu_3SnH$, AIBN, PhMe, 80 °C, 41% from **10**; vi, $PPh_3$, AcOH, diisopropyl azodicarboxylate, THF, room temp., 61%; vii, MCPBA, $CH_2Cl_2$, 4 days, room temp.

the dithiane group followed by reduction of the resulting aldehyde function in **5**‖ to furnish diol **10** (66% overall). Sequential phenylselenation–tin mediated deselenation of the latter yielded **11** (41% overall). One additional isomer with a $\Delta^{7,8}$ unsaturation, resulting from the reduction of the allylic radical at C-6, was also observed (*ca*. 3.5 : 1 ratio). Mitsunobu inversion of **11** with acetic acid at C-4 led to **1**** (61%), which upon epoxidation gave raise to asperlin **2**,** along with its 6*R*,7*S*-diastereoisomer.[10]

In summary, we have developed an efficient synthetic approach to naturally occurring 5-alkyl and 5-alkenyl α,β-unsaturated δ-lactones[1] using D-glucose as the starting material. The approach illustrates the usefulness of bicyclic D-glycoside **6** as a key intermediate for biologically active lactones in which C-5 correlates with that of a hexopyranoside of the L-series. Further studies along this line for the preparation of other lactones are under way.

**Two new ferrocene receptors bind to a series of neutral carboxylic acid guests *via* hydrogen bonding interactions; complexation induces a significant change in the electronic properties of the proximate ferrocene units, as evidenced by the recognition of these neutral guests by cyclic voltammetry.**

Supramolecular compounds that undergo a change in their redox properties upon complexation are relevant to the development of molecular sensing and switching devices.[1] So far, research in this area has focused almost exclusively on redox-active receptor molecules that bind and sense either cations[2] or anions.[3] However, although the chemistry of neutral molecule recognition is well-developed,[1,4] there are only a few reports of systems where the binding of neutral guest molecules in solution has been followed electrochemically.[5,6] The recent interest in hydrogen bonded supramolecular systems containing metal centres,[7] combined with evidence that hydrogen bonding contributes to the magnitude of redox potentials in metalloproteins,[8] suggest that effective electrochemical sensing of neutral molecules, *via* hydrogen bonding interactions, is within reach. Here we report two new receptor compounds containing ferrocene units and give preliminary results on their interaction with a range of neutral carboxylic acids.

Two simple redox-active ferrocene compounds **1** and **2**, containing a mono- and bis-amido pyridine moiety respectively, have been synthesised in good yield from the reaction of either chlorocarbonylferrocene or 1,1′-bis(chlorocarbonyl)ferrocene with 2-aminopicoline in $CH_2Cl_2$ in the presence of base.

Complex formation between receptors **1** and **2** and a series of monocarboxylic acids **3a**–**c** and a dicarboxylic acid, glutaric acid **4**, is evidenced by changes to the $^1$H NMR spectra of **1** and **2** in $CDCl_3$. For each receptor, the addition of excess substrate causes marked shifts in the signals corresponding to the amide and cyclopentadienyl protons. A complex of 1 : 1 stoichiometry between **2** and **4** is revealed by monitoring the downfield shift for the $H_a$ proton of **2** ([**2**] ≈ 1 mM) upon addition of aliquots of **4** (Fig. 1).† The large shift of *ca*. 1.9 ppm is strong evidence for a hydrogen bonding interaction.[7a,10]

Titrations of **1** and **2** (1 mM, $CDCl_3$) with monoacids **3a**–**c** give complexes of 1 : 1 and 1 : 2 (Fc : acid) stoichiometry respectively, whereas a titration of **1** with diacid **4** proceeds *via* a dimeric complex of 2 : 1 (Fc : acid) stoichiometry to give a 1 : 1 complex upon the addition of excess guest. In agreement with the solution studies, an X-ray structure of a crystal grown by slow evaporation of a $CDCl_3$–$Et_2O$ solution of **1** and excess **4** reveals a hydrogen bonded dimer (Fig. 2), consisting of two linked complexes of 1 : 1 stoichiometry [N(1)–H(1)–O(3) distance 2.92 Å, N(1)–H(1)–O(3) angle 166°; O(2)–H(2)–N(2) 2.65 Å, 171°; O(5)–H(5)–O(4) 2.63 Å, 167°].‡

This X-ray structure and the NMR studies suggest that the complex between **2** and **4** is likely to consist of an intermolecular four-point binding interaction, in which the guest is bridged between the two cyclopentadienyl rings. A similar geometry has been found by Hamilton[10] for related complexes between neutral terephthalate bis-amidopyridine derivatives and dicarboxylic acids.

Cyclic voltammetry studies in $CH_2Cl_2$ (1 mM) reveal that substrate complexation can be detected electrochemically (Table 1). The addition of excess monoacid (**3a**–**c**) to **1** causes small negative shifts ($\Delta E°$ = −20 to −25 mV) in the reversible redox wave of the receptor, whereas for receptor **2** the magnitude of the shift is approximately twice that amount ($\Delta E°$ = −55 to −60 mV). This indicates that the number of hydrogen bonds is approximately proportional to the shift in the redox potential. The shift of −20 mV found for **1** in the presence of excess **4** therefore denotes a 1 : 1 complex, which is in agreement with the NMR and X-ray studies. However, the significantly larger shift of −85 mV found for **2** with diacid **4** is likely to be a result of the effect of four strong hydrogen bonds, combined with the unique geometry of the complex. In this conformation the guest is bridged across the ferrocene unit, much closer to the redox-active iron centre.

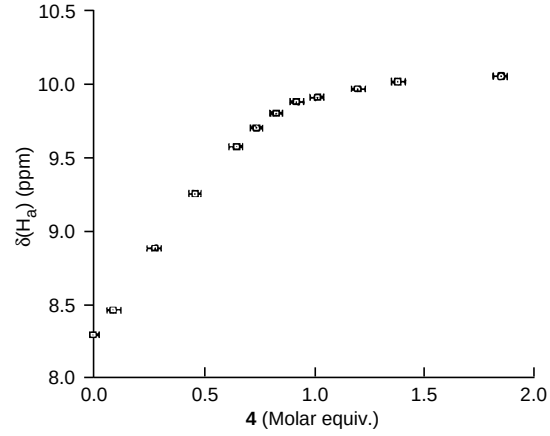

**Fig. 1** $^1$H NMR shift value of the $H_a$ proton of **2** in $CDCl_3$ as a function of molar equivalents of glutaric acid **4**

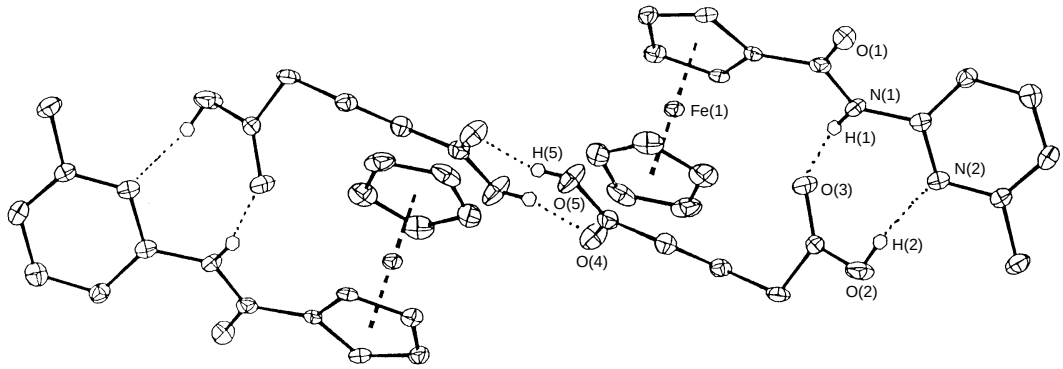

**Fig. 2** Crystal structure of [**1**·**4**]$_2$ (the dotted lines indicate strong hydrogen bonds between the two species and also between a pair of acid molecules

**Table 1** Electrochemical data[a] for compounds **1** and **2** in $CH_2Cl_2$ in the absence and presence of neutral guest substrates **3a**–**c** and **4**

| | | $\Delta E°$/V[c] | | | |
|---|---|---|---|---|---|
| Compound[b] | $E°$/V | **3a** | **3b** | **3c** | **4** |
| **1** | +0.24 | −20 | −20 | −25 | −20 |
| **2** | +0.44 | −60 | −55 | −55 | −85 |

[a] Cyclic voltammograms were carried out at a scan rate of 200 mV s$^{-1}$ in $CH_2Cl_2$ containing tetrabutylammonium perchlorate (TBAP) as supporting electrolyte (0.1 M), ferrocene as internal reference (*ca.* 1 mM) and the appropriate ferrocene receptor (1 mM) at room temp. The following electrode system was used: Pt wire working electrode, Pt wire counter electrode and Ag wire pseudo-reference electrode. [b] Redox potentials ($E°$) were referenced to ferrocene as an internal standard where $E° = 0.5 (E°_{pa} - E°_{pc})$. The confidence limit is ±10 mV. For each voltammogram, the reversibility of the redox wave matched that of the ferrocene internal reference ($\Delta E°_p$ = 70–100 mV). [c] The cathodic shift (mV) of the reversible redox couple of **1** or **2** upon addition of excess substrate.

In all cases, negative shifts in the redox waves of **1** and **2** are observed, which indicates that complexation increases the electron density at the iron centre. This is most likely a result of complexation delivering more electron density to the amide nitrogen. However, an attempt to monitor the change in the amide carbonyl stretch of 2 ($\nu_{C=O}$ 1668 cm$^{-1}$, KBr disc) using IR spectroscopy was hampered because of overlap by the carboxylic acid peaks of each guest. At any rate, there is no evidence of shifts being induced by protonation of the pyridine units, which would be the case if binding is of the zwitterionic form; addition of H$^+$ leads to large positive shifts in the redox waves of **1** and **2**.[9]

The $\Delta E°$ values reflect the difference in substrate binding strength between the two redox states of each complex.[11] In this case, the negative shifts indicate that each guest is bound more strongly once the ferrocene unit is oxidised. Such a trend is consistent with a positive charge on the ferrocene unit increasing the acidity of the amide N–H bond of the receptor.[12] However, recent quantitative studies on related systems[7b] show that the strength of hydrogen bonding may in fact increase or decrease upon the introduction of a postive charge at an adjacent metal centre. The direction and magnitude of this change appears to be strongly dependent upon the type of donor–acceptor system and the degree of conjugation between the metal centre and the binding site.

As far as we are aware, this system represents the most significant change in the redox properties of a supramolecular receptor compound that is induced by the complexation of a *neutral* guest. In other examples, the effect has either been smaller,[5] or has involved systems in which the guest, and not the host, is redox-active.[6] Studies are currently underway to fully explain the nature of this redox response in these and other related systems.

We thank the University of Exeter for the award of a University Research Studentship (J. D. C.) and the EC Erasmus Scheme.

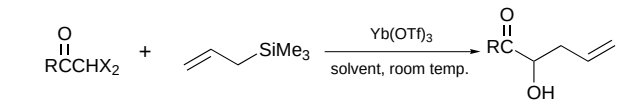
# $Yb(OTf)_3$ catalysed allylation of the hydrates of α-keto aldehydes and glyoxylates with allylsilane

**Yang Yang, Mingwen Wang and Dong Wang***

*Institute of Chemistry, Chinese Academy of Sciences, Beijing 100080, P. R. China*

**$Yb(OTf)_3$ catalysed allylation reactions of the hydrates of α-keto aldehydes and glyoxylates with allyltrimethylsilane at room temperature give α-keto and α-ester homoallylic alcohols in good yield.**



Recently, lanthanide trifluoromethanesulfonates [lanthanide triflates, $Ln(OTf)_3$] have attracted attention[1] because of their catalytic ability in various Lewis acid promoted carbon–carbon bond forming reactions, including Diels–Alder reactions,[2] Michael reactions[3] and allylation reactions of carbonyl compounds by allyl metals, for example allyltributylstannane and tetraallylgermane.[4] Kobayashi[5] also reported the $Ln(OTf)_3$ catalysed reaction of enol silyl ethers with carbonyl compounds (Mukaiyama aldol reaction) in aqueous media. Among the Lewis acid promoted C–C bond forming reactions, the allylation of carbonyl compounds with allylsilanes (Sakurai reaction,[6] Scheme 1) is one of the most important reactions in organic synthesis. However, stoichiometric amounts of Lewis acid must be employed due to the low nucleophilicity of allylsilane and the tight binding of the produced homoallylic alkoxide to the Lewis acid. The reaction can be performed using sub-stoichiometric amounts of silylating reagent [$Me_3SiOTf$, $Me_3SiI$ and $Me_3SiB(OTf)_4$],[7] while the $Ln(OTf)_3$ catalysed Sakurai reaction was not realized until quite recently.[8] Compared with typical Lewis acids such as $TiCl_4$, $SnCl_4$, $BF_3$ and $AlCl_3$, $Ln(OTf)_3$ possesses stronger Lewis acidity, and is water soluble or water-tolerant, air-stable and easy to handle, not requiring anhydrous treatment. On the basis of the tolerance of $Ln(OTf)_3$ to active protons, we examined the ytterbium trifluoromethanesulfonate [$Yb(OTf)_3$] catalysed allylation of α-keto aldehydes hydrates **2**–**4** and glyoxylate hydrates **5** and **6** with allyltrimethylsilane **1**. We also explored the extent of asymmetric induction in the allylation reactions of chiral glyoxylate hydrate **6** in the presence of catalyst $Yb(OTf)_3$.

**Scheme 1**

Oxidation of the substituted acetophenones with selenium dioxide gave the corresponding hydrates **2**–**4**, while the (−)-menthyl glyoxylate monohydrate **6** was prepared according to Kornblum's method,[9] starting from (−)-menthol. The allylation reactions (Scheme 2) were carried out following a standard procedure. To a solution of the hydrate (0.25 mmol) and $Yb(OTf)_3$ (0.025 mmol) in 2 ml of $CH_2Cl_2$, allyltrimethylsilane (0.3 mmol) was added, followed by stirring for a given time (Table 1) at room temperature. The reaction mixture was worked up with brine and extracted with $Et_2O$. The crude product was purified by flash chromatography. The experimental results are listed in Table 1.

Compounds with α-keto and α-ester homoallylic alcohol moieties have been used as precursors for a number of biologically active natural products such as antibiotics.[10] Among the procedures currently available for the preparation of these compounds, allylation of α-keto aldehydes and glyoxylates using allyltrimethylsilane promoted by Lewis acids is a convenient method. However, the α-keto aldehyde and glyoxylates are often moisture sensitive and easily hydrated and polymerized. In practice, although the hydrates are more stable to air and moisutre, it is necessary to transform them to the corresponding α-keto aldehydes and glyoxylates before carrying out the Lewis acid promoted reaction, in order to avoid interaction between the Lewis acid and the hydroxy group. Under conventional Lewis acid conditions, hydroxy

groups in the substrates need to be protected. In contrast, the results (entries 1–5) obtained here show that the catalytic capability of $Yb(OTf)_3$ appears not to be affected by hydroxy groups on the substrate, including the phenoxy group in **3**. The reactions proceeded smoothly with a catalytic amount of $Yb(OTf)_3$ (10 mol%), giving α-keto homoallylic alcohols **9**–**11** and α-ester homoallylic alcohols **12** and **13** in good yields (65–83%). The various substrates exhibited different reactivity, the glyoxylate hydrates **5** and **6** being more reactive than the α-keto aldehyde hydrates **2**–**4** (*cf.* entry 7 *vs.* entries 2 and 3). The solvents used strongly influenced the reaction rate, which is fast in $CH_2Cl_2$ but slow in 1,4-dioxane. For the hydrates **3** and **4**, MeCN is the solvent of choice becasue of the low solubility of the hydrates in $CH_2Cl_2$ and 1,4-dioxane. On reducing the reaction temperature to 0 °C, the reaction slowed down noticeably (*cf.* entry 5 *vs.* entry 6). While the aldehyde hydrates can be considered as equivalent to an aldehyde carbonyl function in these catalytic allylation reactions, the aldehyde carbonyl groups themselves are more reactive (entries 11 and 12 *vs.* entries 4 and 1). On the other hand, if the corresponding acetals **14** and **15** were used, $Yb(OTf)_3$ catalysed allylation with

**1** did not proceed at all, even in the presence of 20 mol% of catalyst.

When chiral glyoxylate hydrate **6** was employed, catalytic diastereoselective allylation occurred. The diastereoselectivity (de) of the reactions was low to moderate (5–30%), determined by the ratio of absorptions of diastereomeric protons in the $^1H$ NMR spectrum of the product **13**. The absolute configuration of the newly formed stereogenic centre was deduced through comparison with an authentic compound.[11] The de of the product strongly depended on the solvents used, with moderate de (30%) obtained in 1,4-dioxane, and rather poor de in $CH_2Cl_2$ and MeCN. Reducing the reaction temperature to 0 °C did not improve the de (entry 6). It is interesting to note that if (−)-allyldimethyl[(1*R*,2*S*,3*R*)-menthoxy]silane **16** was used, the de (*cf.* entry 5 *vs.* entry 9) increased noticeably (from 5 to 20%), but with 1,4-dioxane as the reaction solvent the absolute configuration of the new stereogenic centre was reversed. All these results indicated that the chiral group on the silicon participated in the stereocontrol of the allylation reaction. This is different from the conventional Lewis acid ($TiCl_4$, $AlCl_3$ and $BF_3$) promoted allylation of **6** with **16**, where the chiral group on the silicon did not affect the de of the product **13** to any significant extent.[11]

To our knowledge, these results are the first example of $Ln(OTf)_3$ catalysed allylation of aldehydes bearing unprotected hydroxy groups with allylsilane. $Ln(OTf)_3$ is therefore a novel mild catalyst for allylation with allylsilanes which is tolerant to substrates with active protons. It is expected that this $Ln(OTf)_3$ catalysed allylation reaction should also be effective in aqueous media.

We gratefully acknowledge financial support by the National Natural Science Foundation of China and the National Laboratory of Elemento-Organic Chemistry in Nankai University of China, and thank Professor T. H. Chan for helpful discussions.

# Preparation and X-ray crystallographic characterisation of the trititanate $[Ti_3O(\mu\text{-}OPr^i)_3(OPr^i)_4\{Me_2C(O)CH{=}C(O)CH_2C(O)Me_2\}]$, a reaction product of $[Ti(OPr^i)_4]$ and propan-2-one

**James V. Barkley, Jason C. Cannadine, Ian Hannaford, Marjorie M. Harding, Alexander Steiner, John Tallon and Robin Whyman***

*Department of Chemistry, University of Liverpool, PO Box 147, Liverpool, UK L69 7ZD*

**Reaction of $Ti(OPr^i)_4$ with propan-2-one, under initially anhydrous conditions, yields a colourless moisture-sensitive crystalline product which is structurally identified as the trinuclear oxoalkoxide $[Ti_3O\{\mu\text{-}OPr^i)_3(OPr^i)_4\{Me_2C(O)CH{=}C(O)CH_2C(O)Me_2\}]$ containing a coordinated $C_9$ ligand derived from the condensation of propan-2-one.**

There is considerable current interest in the identification and structural characterisation of titanium(IV) polyoxoalkoxides of the general formula $[Ti_xO_y(OR)_{4x-2y}]$ (where the value of $y/x$ is defined as the degree of condensation) which comprise intermediates in the condensation process between molecular $Ti(OR)_4$ entities and bulk $TiO_2$.[1] At present several structurally characterised titanium(IV) polyoxoalkoxides are known, with $y/x$ values in the range 0.57–1.33, as exemplified by $[Ti_{16}O_{16}(OEt)_{32}]$ and $[Ti_7O_4(OEt)_{20}]$. The lowest degree of polycondensation ($y/x$ = 0.33) to be found in these types of complexes is represented by a single example of a recently structurally characterised trinuclear oxoalkoxide $[Ti_3O(OMe)(OPr^i)_9]$, obtained from the reaction of $[Ti(OPr^i)_4]$ with water and methanol in isopropyl alcohol solution.[1] Titanium alkoxides are themselves widely used as catalysts for esterification, transesterification, and condensation reactions, and cross-linking of ester-containing resins and epoxides.[2] The reaction mechanisms involved in many of these transformations remain somewhat obscure although they are commonly interpreted in terms of the intermediacy of simple mononuclear titanium alkoxide complexes.[3,4]

Since the production of condensed titanium(IV) polyoxoalkoxides generally involves the controlled hydrolysis of the parent alkoxides, we reasoned that the ready ability of aldehydes and ketones to undergo condensation reactions of the aldol type,[4] with the co-production of water, might (*i*) facilitate such hydrolyses with a high degree of control and (*ii*) lead to the possible isolation and detection of coordinated intermediate fragments of aldol coupling. Consistent with this idea we have found that mixing $[Ti(OPr^i)_4]$ with freshly distilled dry propan-2-one and allowing to stand at room temp. under an atmosphere of dry dinitrogen leads to the deposition of a highly moisture-sensitive colourless crystalline product from a yellow solution.† X-Ray crystallographic analysis has shown this to represent the second example of a presumed family of low-nuclearity titanium polyoxoalkoxides based on a $Ti_3O_{11}$ core, which is formulated as

$[Ti_3O(\mu\text{-}OPr^i)_3(OPr^i)_4\{Me_2C(O)CH{=}C(O)CH_2C(O)Me_2\}]$ **1**

The molecular structure of **1**‡ (Fig. 1) contains a trinuclear $Ti_3O$ core supported by three doubly bridging [O(4), O(4a), O(4b)] and four monodentate isopropoxide groups. Three of the latter [O(5), O(5a), O(5b)] are located on one side of the $Ti_3$-triangular face within which the $\mu_3$-oxygen atom O(3) is situated, and the fourth $OPr^i$ group O(2″) is on the other side together with the tridentate $C_9$ ligand, which is the enolate form of a trimeric condensation product of propan-2-one, 2,6-dimethylhept-3-en-2,4,6-triol. The 2,6-oxygen atoms [O(2), O(2′)] of the enolate ligand are each coordinated in a monodentate manner to separate titanium atoms, while the central four-coordinate oxygen atom O(1) occupies a triply bridging position within interaction distance of all three titanium atoms, yielding a central $Ti_3O_{11}$ core which corresponds to the central arrangement of three distorted face sharing octahedra found in $[Ti_3O(OMe)(OPr^i)_9]$ (where a methoxide ligand provides the second $\mu_3$-O unit).

The space group symmetry $R\bar{3}$ m in the crystal structure of **1** implies a molecular $C_{3v}$ symmetry. Fig. 2 illustrates the resulting disorder at the $C_9$-ligand face to the $Ti_3$ triangle, which is generated by a crystallographic threefold axis and three associated mirror planes. Therefore both terminally arranged $Me_2CO$ units [O(2), C(3), C(4), C(5) and O(2)′, C(3′), C(4′), C(5′)] of the enolate ligand and the monodentate isopropoxide ligand [O(2″), C(3″), C(4″), C(5″)] occupy crystallographically identical positions. Beyond it the methyl groups are split over two positions. In the central ligand unit [–CH=C(O)–$CH_2$–] the oxygen atom O(1) is located on a fully occupied site (3 m), while C(1) in α position is symmetrically distributed over three and C(2) in β position over six sites, resulting in crystallographically identical positions for the $sp^2$ hybridised alkenic centre C(2) and the $sp^3$ hybridised methylene centre C(2′). However owing to the crystal symmetry, both central ligand bonds C(1)=C(2) [1.320(9) Å] and C(1)–C(2′) [1.620(9) Å] are

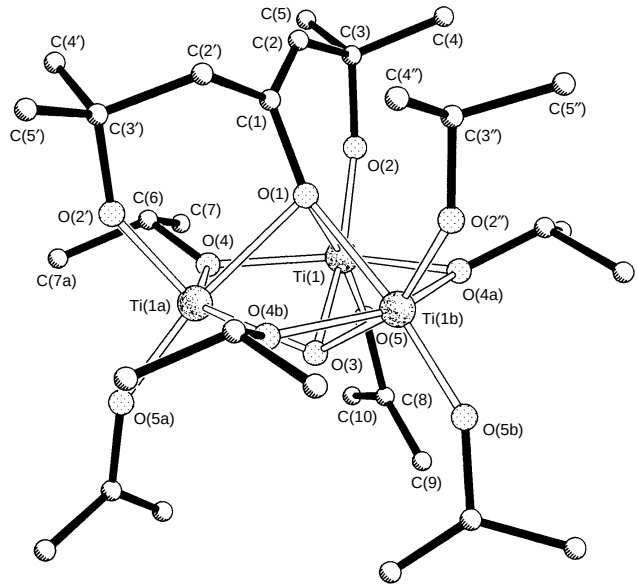

**Fig. 1** Molecular structure of **1**. Selected interatomic distances (Å) and angles (°): Ti(1)···Ti(1a) 2.962(2), Ti(1)–O(1) 2.205(4), Ti(1)–O(2) 1.803(3), Ti(1)–O(3) 1.969(4), Ti(1)–O(4) 2.024(3), Ti(1)–O(5) 1.780(4), O(1)–C(1) 1.47(2), C(1)–C(2) 1.32(2), C(1)–C(2′) 1.62(2), C(2)–C(3) 1.56(2), O(2)–C(3) 1.43(2); C(2)–C(1)–C(2′) 125(1), C(1)–C(2)–C(3) 111(1), C(1)–C(2′)–C(3′) 131(1).

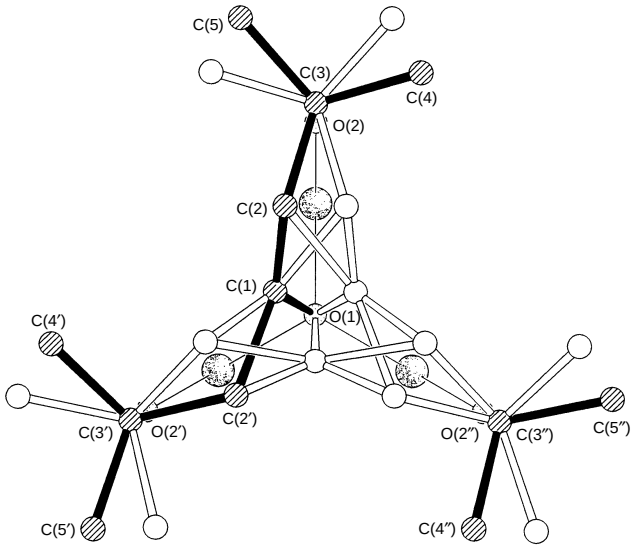

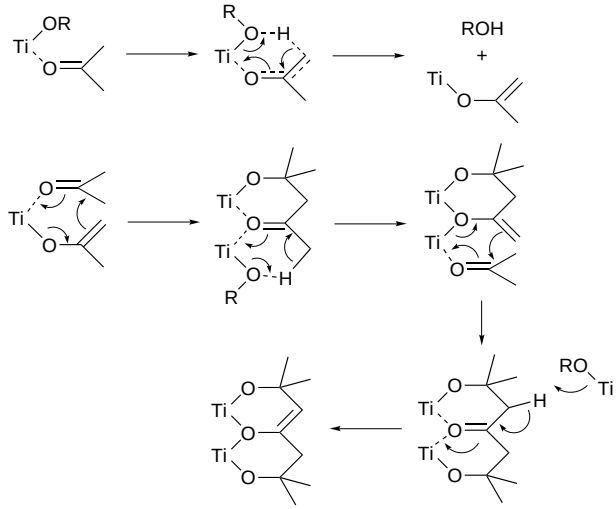

**Fig. 2** $C_9$-ligand face of $Ti_3$ unit illustrating the disorder along the crystallographic threefold axis. The six remaining $OPr^i$ ligands have been omitted for clarity.

chemically as well as crystallographically non-equivalent, because each one is generated by a different symmetry operation [relative to C(1)].

The very closely related structures of **1** and $[Ti_3O(OMe)(OPr^i)_9]$, where formally the tridentate $C_9$-ligand is substituted by one methoxide and two isopropoxide ligands illustrates a highly flexible ligand behaviour on a more or less rigid $Ti_3O_{11}$ core, which then can act as a template in the formation of the $C_9$-triolate ligand by a co-condensation reaction of three enolate moieties derived from propan-2-one.

Consistent with the structural observations relating to the identification and characterisation of the coordinated $C_9$ triolate ligand, GC–MS analysis of the mother-liquors from which the crystals were isolated confirms the presence of the common aldol condensation products of propan-2-one, namely, 4-methylpent-3-en-2-one (mesityl oxide) and 2,6-dimethylhepta-2,5-dien-4-one (phorone), together with propan-2-one and isopropyl alcohol. In addition, $^1$H NMR spectra of the reaction solutions show the appearance of new resonances at $\delta$ 1.87 and 6.09 which may be attributed to the presence of phorone and/or mesityl oxide and $\delta$ 3.56 which is consistent with the presence of hydroxyl protons present in, for example, diacetone alcohol. In view of the mild reaction conditions used in the preparative work, it is not unlikely that initially formed hydroxylated products of condensation are also present in the reacting solution but are dehydrated to, for example, mesityl oxide, within the injection ports of the gas chromatograph.

**Scheme 1**

The mechanism by which this unprecedented reaction product is formed is at present unclear. Notwithstanding an equilibrium constant (in water) of $2.5 \times 10^{-6}$ for the enolisation of propan-2-one[5] it seems most likely that the initial step in the reaction the involvement of coordination of propanone in the enolate form to the titanium centre, followed by the titanium alkoxide promoted oligomerisation reaction, as indicated in Scheme 1.§ Such reactions may prove, contrary to conventional wisdom,[3,4] the involvement of polynuclear rather than mononuclear reaction intermediates. Finally, it should be noted that the isolation and characterisation of **1** may also be of relevance to processes occurring during the initial stages of formation of polyketones.

The authors wish to thank Tioxide Specialties Ltd for supply of tetraisopropyltitanate, Mr J. Ridland (Tioxide) for helpful discussions, ICI Chemicals and Polymers Ltd for support (to J. C. C.) and Mr A. Mills (Liverpool) for the measurement of mass spectra.

† *Preparative details*: Mixtures of dried, freshly distilled propan-2-one and $[Ti(OPr^i)_4]$ in molar ratios ranging between 1 : 1 and 10 : 1 were allowed to stand under an atmosphere of dinitrogen. The solutions were initially colourless, became yellow over several hours following which large irregular three-dimensional colourless crystals deposited on standing for 2–3 days. These crystals continued to grow in needle-like columns if the solutions were allowed to stand for several weeks. The mother-liquors were decanted from the crystals which were washed several times with dry propan-2-one and subsequently dried under vacuum.

*Selected data for* **1**: IR(Nujol mull): $\nu$(C=C) of unsaturated coordinated triolate ligand, 1656 cm$^{-1}$. FABMS (3-noba): *m/z* 685 $[M^+ - 59\ (OPr^i)]$, 627 $[M^+ - 117\ (OPr^i + OC_3H_6)]$, 385 $[Ti_2(OPr^i)_2(C_9H_{15}O_3)]$ and 343 $[Ti_2(OH)(OPr^i)(C_9H_{15}O_3)]$, isotopic simulations consistent with these fragments, together with several sequences of higher masses at repeat intervals of 80 mass units which presumably correspond to the formation of poly-$TiO_2$ cluster ions within the mass spectrometer.

‡ *Crystal data* for **1**: $C_{30}H_{64}O_{11}Ti_3$, $M_w$ = 744.51, rhombohedral, space group $R\bar{3}m$, $a$ = 17.894(3), $c$ = 21.021(4) Å, $U$ = 5829(2) Å$^3$, $Z$ = 6, $\lambda$ = 0.71073 Å, $T$ = 153(2) K, $D_c$ = 1.273 Mg m$^{-3}$, $\mu$(Mo-K$\alpha$) = 0.651 mm$^{-1}$. Data were collected on a Rigaku AFC6S diffractometer using a crystal of dimensions 0.25 × 0.20 × 0.75 mm. Of a total of 2480 reflections ($2\theta_{max}$ = 50°), 1271 were independent ($R_{int}$ = 0.028). The structure was solved by direct methods (SHELXS-86) and refined by full-matrix least squares on $F^2$ using all data to final values of $R_1$ = 0.051 [$F > 4\sigma F$ (1014 reflections)], $wR_2$ = 0.139 (all data) (SHELXS-93). Largest features in the final difference map, 0.618 and −0.325 e Å$^{-3}$. All non-hydrogen positions have been refined anisotropically. Hydrogen positions have been set geometrically. In addition to the disorder of the $C_9$-ligand face at the central $Ti_3$ unit, which is described in the text, isopropoxide ligands at the opposite face of the metal plane are disordered and could be refined on two positions. No restraints have been applied at all in final refinement cycles. Refinements in the lower symmetry space groups $R\bar{3}$ and $R32$, respectively, gave either twinning or occupancy factors of 50% and led to higher $R$ factors in connection with considerable correlation between higher symmetry dependent parameters. CCDC 182/544.

# Synthesis, characterisation and reactivity of novel bis(tosyl)imidoruthenium(VI) porphyrin complexes; X-ray crystal structure of a tosylamidoruthenium(IV) porphyrin

**Sze-Man Au,[a] Wai-Hong Fung,[a] Ming-Chuan Cheng,[a] Chi-Ming Che*[a] and Shie-Ming Peng†[b]**

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*
[b] *Department of Chemistry, National Taiwan University, Taipei, Taiwan*

**Bis(tosyl)imidoruthenium(VI) porphyrin complexes are prepared and characterised by spectroscopic means; [$Ru^{VI}$(tpp)$(NTs)_2$] can undergo imido group transfer reactions with alkenes to afford aziridines, as well as C–H bond oxidation of benzyl alcohol to give benzaldehyde; a tosylamido ruthenium(IV) complex is also isolated and characterised by X-ray diffraction.**

The transition metal catalysed aziridination of alkenes by PhINTs provides direct access to aziridines from alkenes. This reaction can be performed selectively and, in some cases, high enantioselectivity can be attained.[1–3] However, the mechanism of the reaction remains elusive, it becomes difficult to improve the catalysis in a rational manner. Although both the metal–imido species [M=NTs] and the Lewis-acid PhINTs adduct [M–N(Ts)(IPh)] have been proposed to be the reactive intermediates, neither has been isolated or spectroscopically characterised.[1] Reports on imidoruthenium complexes remain sparse, notable examples include [$Ru^{VI}$(tpp)$(NBu^t)$O],[4] *trans*-[$Ru^{IV}(NBu^t)_2(PMe_3)_4$][5] and [$Ru^{II}{\equiv}NC_6H_2Bu^t_3$-2,4,6)($\eta^6$-*p*-cymene)],[6] but none of them are known for imido group transfer reactions with alkenes. Indeed, there are few reports in the literature concerning alkene aziridination reactions using a well characterised metal–imido complex.[7] Herein we describe the synthesis, spectroscopic characterisation and reactivities of the bis(tosyl)imidoruthenium(VI) porphyrin complexes [$Ru^{VI}$(tpp)$(NTs)_2$] **1** and [$Ru^{VI}$(oep)$(NTs)_2$] **2** (tpp = dianion of 5,10,15,20-tetraphenylporphyrin, oep = dianion of 2,3,7,8,12,13,17,18-octaethylporphyrin, Ts = tosyl).

Complexes **1** and **2** were prepared by the treatment of the corresponding [$Ru^{II}$(por)(CO)(MeOH)] complexes[8] (por = dianion of porphyrin, 0.2 mmol) with PhINTs[9] (0.6 mmol) in dried $CH_2Cl_2$ (20 ml) for 5 min at room temp. under an inert atmosphere. Removal of the solvent followed by washing with MeOH afforded the desired products as red–violet solids. The complexes were further purified by chromatography on a short neutral alumina column with $CH_2Cl_2$ as the eluent (overall yield 60%†).

The imidoruthenium(VI) complexes **1** and **2** are stable in the solid state at −20 °C for days, whereas in purified $CH_2Cl_2$ the compounds can be kept for hours at room temp. without significant decomposition. Their UV–VIS absorption spectra highly resemble those of structurally related dioxoruthenium(VI) porphyrin complexes[10,11] (Fig. 1). The IR spectra of **1** and **2** exhibit intense $\nu_{as}$(Ru=NTs) stretching absorptions at 914 and 900 $cm^{-1}$ respectively, which are at lower wavenumbers than the $\nu_{as}$(Os=NTs) absorption at 924 $cm^{-1}$ found in [$Os^{VI}$(tpp)$(p\text{-}NC_6H_4NO_2)_2$].[12] It is important to note that the oxidation state markers for **1** and **2** appear at 1016 and 1018 $cm^{-1}$ respectively, which is in accordance with the formulation of the ruthenium(VI) oxidation state.[10a,11] The diamagnetic behaviour of the complexes, together with the above findings, strongly suggest a terminal $d^2$ metal–imido system. $^1$H NMR spectra reveal that **1** and **2** possess pseudo $D_{4h}$ symmetry, and the aromatic protons of the Ts groups (H′ and H″) appear as doublets at $\delta$ 6.45 and 4.87. The pyrrolic protons for **1** ($\delta$ 8.82) appear at higher field than that for [$Ru^{VI}$(tpp)$O_2$] ($\delta$ 9.1),[10] this coincides with the fact that the (tosyl)imido ligand is a stronger $\pi$ donor than the oxo ligand.[12]

At room temp., **1** reacts readily with alkenes to give aziridines in good yields (Table 1). With the addition of pyrazole (Hpz), apart from aziridines [$Ru^{IV}$(tpp)(NHTs)(pz)] **3** (NHTs = tosylamido) was also isolated and characterised.‡ The UV–VIS and IR absorption spectra of **3** (oxidation marker band at 1012 $cm^{-1}$) are very similar to those observed for [$Ru^{IV}$(tpp-$(OMe)_3$-3,4,5)$(NPh_2)_2$][tpp-$(OMe)_3$-3,4,5 = dianion of *meso*-tetrakis(3,4,5-trimethoxyphenyl)porphyrin].[13] Together with the magnetic susceptibility measurement [$\mu_{eff}$ = 3.20 $\mu_B$ (300 K), Evans method], the formulation as ruthenium(IV) with two unpaired electrons in the ground state is confirmed. The

[a] Isolated yield based on the amount of [$Ru^{VI}$(tpp)$(NTs)_2$].

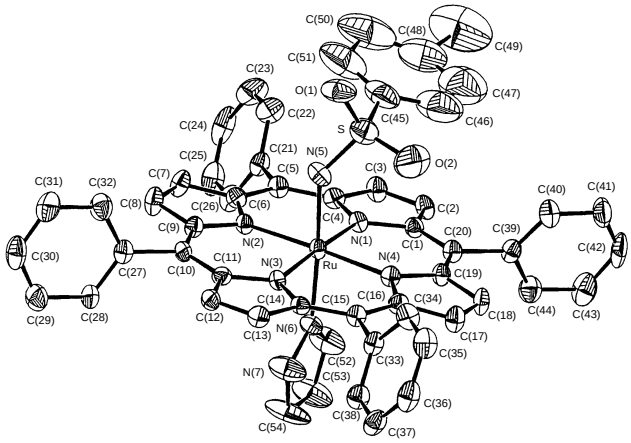

**Fig. 2** A perspective view of **3** with atom labelling scheme. Selected bond distances (Å) and angles (°): Ru–N(5) 2.025(11), Ru–N(6) 2.111(11), Ru–N(1) 2.041(8), Ru–N(2) 2.032(9), Ru–N(3) 2.033(8), Ru–N(4) 2.037(9); N(5)–Ru–N(6) 176.2(4), Ru–N(5)–S 136.4(7).

structure of **3** has been established by X-ray crystal analysis.‡ As shown in Fig. 2, the Ru–N(5) bond distance of 2.025(11) Å is comparable to the $Ru^{IV}$–N(amide) distances of 1.987–2.044(5) Å found in $[Ru^{IV}(chbae)(PPh_3)(py)]$ [chbae = 1,2-bis(3,5-dichloro-2-hydroxybenzamido)ethane tetraanion].[14] The Ru–N(5)–S(1) bond angle of 136.4(7)° is not unexpected for a coordinated amide ligand since a similar value of 138.4(6)° has been reported for $[Ru^{II}(Et_2dtc)(PPh_3)_2(CO)(NHSO_2C_6H_2Pr^i_3\text{-}2,4,6)]$ ($Et_2dtc$ = *N*,*N*'-diethyldithiocarbamate).[15]

The UV–VIS spectral trace for the reaction of **1** with excess styrene in $CH_2Cl_2$ containing pyrazole (2% m/m) exhibited clean isosbestic points [Fig. 1(*b*)]. The reactions of **1** with alkenes followed the second-order rate law, rate = $k_2[Ru^{VI}][alkene]$. The second-order rate constants $k_2$ measured at 298 K are $(9.7 \pm 0.3) \times 10^{-3}$ and $(1.1 \pm 0.1) \times 10^{-3}$ dm$^3$ mol$^{-1}$ s$^{-1}$for styrene and norbornene, respectively. The activation parameters for the styrene aziridination by **1** were determined to be $\Delta H^{\ddagger} = 4.7 \pm 0.1$ kcal mol$^{-1}$ and $\Delta S^{\ddagger} = -52.4 \pm 0.2$ cal K$^{-1}$ mol$^{-1}$ (1 cal = 4.184J). The negative value of $\Delta S^{\ddagger}$ is consistent with an associative mechanism. For the aziridination of various *para*-substituted styrenes (*p*-OMe, -Me, -F, -Cl, -$CF_3$) by **1**, the $k_2$ values were found to span a narrow range. The log $k_{rel}$ [$k_{rel} = k_2$(*p*-substituted styrene)/$k_2$(styrene)] values correlate linearly with the $\sigma^+$ values with a small magnitude of $\rho^+ = -1.1$ ($R = 0.98$); this indicates a minor development of positive charge in the transition state.

Stoichiometric oxidation of benzyl alcohol by **1** in dichloromethane containing pyrazole (2% m/m) gave benzaldehyde and tosyl amine quantitatively (Table 1), and **3** was formed as the product of the reduction of the imidoruthenium(VI) complex. The observed rate law for the reaction of benzyl alcohol with **1** was found to be: rate = $k_2[Ru^{VI}][PhCH_2OH]$, with the second-order rate constant of $(3.6 \pm 0.1) \times 10^{-1}$ dm$^3$ mol$^{-1}$ s$^{-1}$ at 298 K. It is noteworthy that a large primary kinetic isotope effect was observed using $PhCD_2OH$ ($k_H/k_D = 7.4$) indicating that the reaction should proceed *via* a hydrogen atom abstraction pathway.

We acknowledge support from The University of Hong Kong and the Hong Kong Research Grants Council.

# $[(p\text{-}Pr^iC_6H_4Me)_4Ru_4Mo_4O_{16}]$: an amphiphilic organoruthenium oxomolybdenum cluster presenting a unique framework geometry

**Georg Süss-Fink,* Laurent Plasseraud, Vincent Ferrand and Helen Stoeckli-Evans**

*Institut de Chimie, Université de Neuchâtel, CH-2000 Neuchâtel, Switzerland*

**The amphiphilic title compound, easily accessible from (*p*-cymene)ruthenium dichloride dimer and sodium molybdate in aqueous solution, presents an unprecedented $Ru_4Mo_4O_{12}$ framework comprising a central $Mo_4O_4$ cube with four folded ORuO flaps resembling the sails of a windmill.**

The past two decades have witnessed a steadily growing interest in molecules containing both organometallic groups and oxometallic entities,[1] particularly since they provide molecular models for heterogeneous catalysts derived from organometallic complexes adsorbed at metal oxide surfaces.[2] Organometallic metaloxo clusters contain soft as well as hard metal centers, and hydrophobic as well as hydrophilic ligands. Since the discovery of the first species of this type, $[(C_5H_5)TiPW_{11}O_{39}]^{4-}$ in 1978,[3] this field has been pioneered mainly by the groups of Klemperer,[4] Isobe,[5] and Finke.[6] The combination of low- and high-valent transition metals and the amphiphilic character predispose these molecules also as homogeneous catalysts for oxidation reactions; the catalytic potential of these compounds has been reviewed recently.[7]

**1**

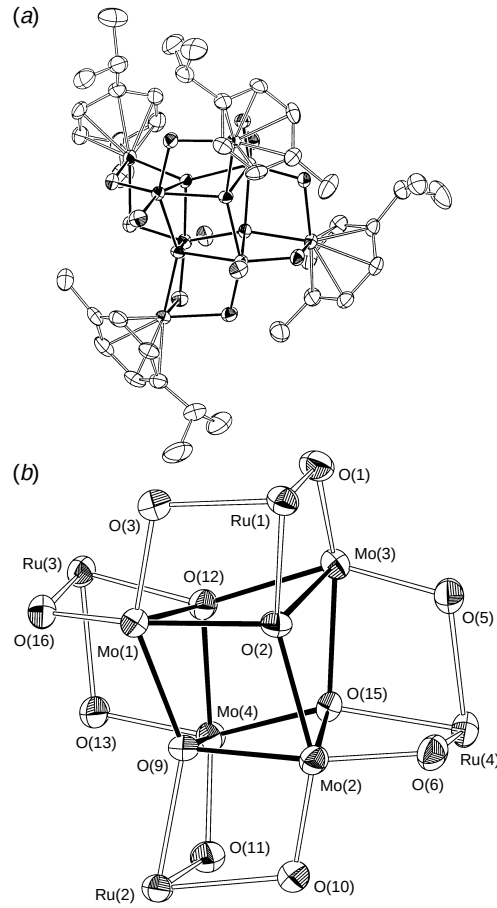
Here, we report the synthesis and structure of $[(p\text{-}Pr^iC_6H_4Me)_4Ru_4Mo_4O_{16}]$ **1**, a neutral organoruthenium oxomolybdenum cluster which presents an unprecedented geometry of the $Ru_4Mo_4O_{12}$ framework. Compound **1** is easily accessible from (*p*-cymene)ruthenium dichloride dimer and sodium molybdate in aqueous solution (Scheme 1).† Orange crystals of correct elemental composition are obtained by crystallization from dichloromethane–toluene. Compound **1** is amphiphilic, that is to say sparingly soluble in both water and aromatic hydrocarbons, and well soluble in polar organic solvents such as dichloromethane or methanol.

$$2\ [(p\text{-}Pr^iC_6H_4Me)_2Ru_2Cl_4] + 4\ Na_2MoO_4 \downarrow [(p\text{-}Pr^iC_6H_4Me)_4Ru_4Mo_4O_{16}] + 8\ NaCl$$

**Scheme 1**

The FAB mass spectrum of **1** shows the molecular ion at *m/z* 1581 presenting the expected $Ru_4Mo_4$ isotope pattern. In the $^1H$ NMR spectrum ($CD_2Cl_2$) of **1**, the four *p*-cymene ligands give rise to only one set of signals at $\delta$ 1.39 (d, 6, *J* 7 Hz), 2.27 (s, 3), 2.97 (spt, 1, *J* 7 Hz), 5.30 (d, 2, *J* 6 Hz) and 5.37 (d, 2, *J* 6 Hz), showing all ruthenium positions to be equivalent. In the IR spectrum (KBr) of **1**, the Mo=O stretching vibrations are observed at 921s and 874m $cm^{-1}$, while the Mo–O–Ru stretches are assigned to the absorptions at 785s, 739s, 642m and 602s $cm^{-1}$.

Single-crystal X-ray structure analysis§ of $\mathbf{1}\cdot 2C_6H_5Me$ (orange, rod-like crystals) revealed the molecule to contain a unique $Ru_4Mo_4O_{12}$ framework which can be described as a central $Mo_4O_4$ cube with four folded ORuO flaps resembling the sails of a windmill. The distortion [Mo(2)–O(2)–Mo(1) 106.04(12)°, O(12)–Mo(1)–O(2) 71.37(10)°] with respect to



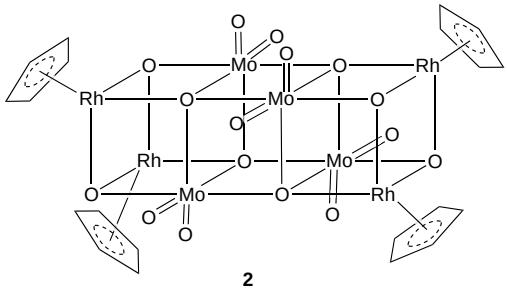


**Fig. 1** ORTEP[11] representation of the molecular structure of **1**. (*a*) Complete molecule, hydrogen atoms and two toluene molecules (in the crystal) omitted for clarity. (*b*) $Ru_4Mo_4O_{12}$ framework with labelling scheme. Selected bond distances and angles (°): Mo(1)–O(2) 2.122(3), Mo(1)–O(3) 1.804(3), Mo(1)–O(7) 1.706(3), Mo(1)–O(9) 2.073(3), Mo(1)–O(12) 2.365(3), Mo(1)–O(16) 1.798(3). Ru(1)–O(1) 2.088(3), Ru(1)–O(2) 2.089(3), Ru(1)–O(3) 2.094(3); O(12)–Mo(1)–O(9) 72.20(11), Mo(3)–O(12)–Mo(1) 105.31(11), O(7)–Mo(1)–O(16) 103.93(2). Ru(2)–O(9)–Mo(1) 145.40(2), O(10)–Ru(2)–O(11) 80.53(12).

the idealized cubic representation is due to the geometry of the oxygen atoms of the central cube which is more tetrahedral than octahedral (Fig. 1). Eight of the twelve framework oxygen atoms are doubly bridging, while four are quadruply bridging. Each ruthenium atom is coordinated to an $\eta^6$-*p*-cymene ligand [Ru(1)–$C_6$ ring centroid 1.627 Å], and each molybdenum atom carries a terminal oxo ligand [Mo(1)–O(7) 1.706(3) Å].

The cluster $[(C_5Me_5)_4Rh_4Mo_4O_{16}]$ **2**, reported by Isobe and coworkers,[5a] which is isoelectronic to **1**, has a completely different structure: the $Rh_4Mo_4O_{12}$ framework forms a triple cube which is more closed than the open windmill-like structure of **1**. As a consequence, each molybdenum atom carries two terminal oxo ligands, and four of the eight framework oxygen atoms are triply bridging, while the other four are quadruply bridging.

**2**

Another $Mo_4O_{16}$ unit, found in the solid phase $Cs_3Mo_4P_3O_{16}$, also contains a central $Mo_4O_{16}$ cube; however, the framework geometry is completely different: the $Mo_4O_{16}$ core must be considered as four $MoO_6$ octahedra each sharing three edges with three $MoO_6$ units giving an array with tetrahedral symmetry.[7]

Interestingly, with ruthenium the reaction seems to work only for the *p*-cymene derivative. Up to now it has not been possible to isolate the benzene and hexamethylbenzene analogues of **1**.

This work was supported by the Fonds National Suisse de la Recherche Scientifique (grant 20-46592.96). A generous loan of ruthenium trichloride hydrate from the Johnson Matthey Technology Centre is gratefully acknowledged.

† *Synthesis* of **1**: A suspension of $[(p\text{-}Pr^iC_6H_4Me)_2Ru_2Cl_4]$ (200 mg, $3.27 \times 10^{-4}$ mol) in 20 cm$^3$ of water was added dropwise to an aqueous solution (10 cm$^3$) of $Na_2MoO_4 \cdot 2H_2O$ (790 mg, $3.3 \times 10^{-3}$ mol). The mixture was stirred for 4 h at 25 °C. After evaporation of the water, the product was extracted with $CH_2Cl_2$ (20 cm$^3$) and crystallized from dichloromethane–toluene (1 : 1) to give, after drying *in vacuo*, analytically pure orange crystals (155 mg, 60%).

§ *Crystal structure data* for **1**: $C_{40}H_{56}Mo_4O_{16}Ru_4 \cdot 2C_7H_8$ (including two molecules of toluene per cluster), triclinic, space group, $P\bar{1}$, $a$ = 13.846(2), $b$ = 15.210(2), $c$ = 16.1038(14) Å, $\alpha$ = 88.124(11), $\beta$ = 78.938(10), $\gamma$ = 65.471(11)°, $U$ = 3023.7(6) Å$^3$, $Z$ = 2, $D_c$ = 1.939 g cm$^{-3}$, $T$ = 223 K, $\mu$(Mo-K$\alpha$) = 1.66 mm$^{-1}$. The data were measured using a Stoe-Siemens AED2 four-circle diffractometer with graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). 11234 independent reflexions were measured by $\omega$–$2\theta$ scans in the range $2.0 < \theta < 25.5°$; 9939 were considered observed [$I > 2\,\sigma(I)$]. The structure was solved by Patterson and Fourier techniques using the program SHELXS-86[8] and refined by full-matrix least squares on $F^2$, using SHELXL-93.[9] Hydrogen atoms were included in calculated positions and treated as riding atoms using SHELXL-93 default parameters. An empirical absorption correction was applied using DIFABS[10] (transmission factors min., max. 0.722, 1.174). Refinement converged at $R_1$ = 0.0337 and $wR_2$ = 0.0757 (observed data). # A sulfur nitrogen triple, double and single bond in one ligand: synthesis and structure of $[Co\{N{\equiv}SF_2{-}N{=}S(O)F_2\}_4][AsF_6]_2{\cdot}SO_2$

**Reinhard Hoppenheit, Enno Lork, Jan Petersen and Rüdiger Mews***

*Institut für Anorganische und Physikalische Chemie der Universität Bremen, Leobener Strasse NW2, Postfach 330440, D-28334 Bremen, Germany*

**$NSF_2NS(O)F_2$ reacts quantitatively with $[Co(SO_2)_n][AsF_6]_2$ to give $[Co\{N{\equiv}SF_2{-}N{=}S(O)F_2\}_4][AsF_6]_2{\cdot}SO_2$; X-ray structure analysis confirms the presence of a triple, double and single bond in the same ligand.**

Sulfur nitrogen fluorine chemistry is one of the most fascinating fields in inorganic chemistry. Due to the possibilities of sulfur possessing different oxidation states and coordination numbers, forming single, double and triple bonds and being incorporated into acyclic and cyclic systems, an almost unprecedented variety of combination possibilities has been experimentally verified.[1] Although a large number of compounds have been reported, structural investigations on them are relatively rare. SN bond distances determined by electron diffraction on molecules in the gas phase range from 141.4 pm for $N{\equiv}SF_3$[2] to 169.8 pm in $SF_5{-}NF_2$[3] and in the solid state from 137–138 pm in coordination compounds of $NSF_3$ {*e.g.* $[M(NSF_3)_4(FAsF_5)_2]$,[4] $[Re(CO)_5(NSF_3)]^{+}$[5]} to 164–166 pm in $RSO_2{-}NR'_2$[6] and 169 pm in $SF_5N{=}CR_2$,[7] respectively, from X-ray structure determinations. The bond distances are dependent on the coordination number (hybridization) of sulfur and nitrogen[8] and on the oxidation state of sulfur. For $N{\equiv}SF_2{-}N{=}S(O)F_2$[9] the simple valence bond description suggests the presence of a triple, single and double bond between N and tetracoordinated $S^{VI}$ centres. Coordination of this ligand to the 'naked' $Co^{2+}$ centre[10] in pink $[Co(SO_2)_n][AsF_6]_2$[11] gives deep blue $[Co\{NSF_2NS(O)F_2\}_4][AsF_6]_2{\cdot}SO_2$ in quantitative yield.†

$$[Co(SO_2)_n][AsF_6]_2 \;+\; NSF_2NS(O)F_2\ (\text{excess}) \quad (\mathbf{1})$$

$$\downarrow$$

$$[Co\{NSF_2NS(O)F_2\}_4][AsF_6]_2{\bullet}SO_2 \quad (\mathbf{2})$$

At ambient temperature $SO_2$ is readily removed from **2** under dynamic vacuum. The structure of the cation of compound **2** is shown in Fig. 1.‡ The central $Co^{2+}$ is surrounded by a regular tetrahedron [N–Co–N 108.0(2)–110.4(2)°] the Co–N distances being in the range 195.4(4)–197.4(5) pm. The bond distances in the ligand justify the description as containing an NS triple, single and double bond between isocoordinated N and S centres in the same ligand.

$$[Co\{N \overset{138.9\ pm}{\equiv} SF_2 \overset{158.8\ pm}{-} N \overset{149.9\ pm}{=} S(O)F_2\}_4]^{2+}$$

So far, bond lengths for NS triple bonds have been documented only for coordination compounds of $NSF_3$[4,5] and $NSF_2NMe_2$[5] and lie in the range 137–139 pm, Exchange of one fluorine in $NSF_3$ by other substituents has little effect on the N≡S bond length. From 170 structure determinations of organic $-\overset{\|}{S}=$ N–systems reported in the CCDC an average of 154.4 pm for the NS double bond is found, while for $-\overset{\|}{S}-$N= single bonds

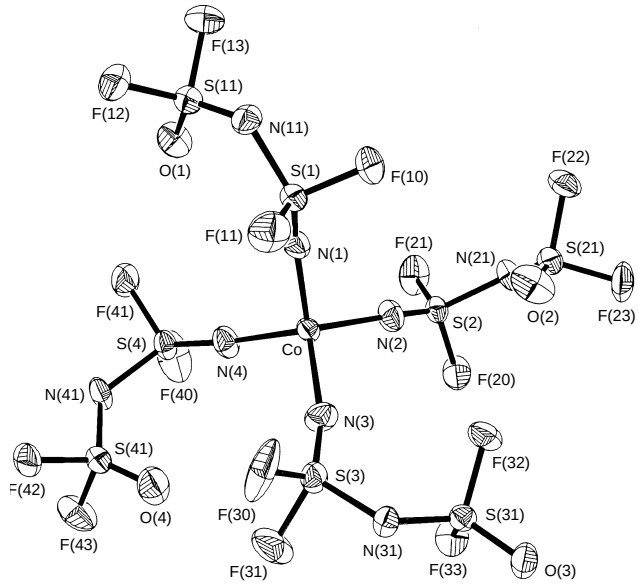

**Fig. 1** Structure of the cation of **2** with selected bond distances (pm) and angles (°): Co–N 195.4(4)–197.4(5) (av. 196.9), $N^1{\equiv}S^1$ 138.3(4)–139.3(5) (138.9), $S^1{-}F^1$ 151.8(4) 153.1(4) (152.5), $S^1{-}N^2$ 157.6(4)–159.5(4) (158.8), $N^2{=}S^2$ 149.4(4)–150.6(5) (149.9), $S^2{-}O$ 137.3(4)–138.8(4) (138.2), $S^2{-}F^2$ 149.0(4)–151.6(4) (151.0), $N^1{-}Co{-}N^2$ 108.0(2)–110.5(2) (109.5), Co–$N^1{\equiv}S^1$ 159.6(3)–171.6(3) (166.4), $N^1{\equiv}S^1{-}N^2$ 123.6(3)–127.1(3) (125.2), $S^1{-}N^2{=}S^2$ 121.4(3)–125.7(3) (123.5). $S^1$=S(1), S(2), S(3), S(4); $S^2$=S(11), S(21), S(31), S(41); $N^1$=N(1), N(2), N(3), N(4); $N^2$=N(11), N(21), N(31),N(41); $F^1$=F(10), F(11), F(20), F(21), F(30), F(31), F(40), F(41); $F^2$=F(12), F(13), F(22), F(23), F(32), F(33), F(42), F(43); O=O(1), O(2) O(3), O(4).

(334 examples) an average of 160.5 pm is reported.[12] The average N=S and N–S bond distances in **2** are significantly shorter than this as a result of orbital contraction owing to the highly electronegative substituents in our ligand system.

In the non-coordinating $SO_2$ molecule of **2** [S(10)–O(11) 138.4(5) pm, S(10)–O(12) 141.2(5) pm, O–S–O 119.9(4)°] the O–S–O angle is identical to that of $SO_2$ in the gas phase (O–S–O 119.3°, S–O 143.3 pm).[13] The difference in the S–O bond lengths in **2** is due to the differing thermal motions of the sulfur and both of the oxygen atoms, which may also be the cause of the shortened S–O bonds in **2** compared to free $SO_2$.

Support of the FNK (University of Bremen) and the Fonds der Chemischen Industrie is gratefully acknowledged.

# Porous clay heterostructures (PCH) as acid catalysts

**Anne Galarneau, Anis Barodawalla and Thomas J. Pinnavaia***

*Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, MI 48824, USA*

**Porous clay heterostructures formed by surfactant assembly of open framework silica in the galleries of a smectite clay represent a new family of solid acid catalysts, as evidenced by the selective dehydration of 2-methylbut-3-yn-2-ol to 2-methylbut-3-yn-1-ene.**

Pillared interlayered clays have been extensively studied as promising solid-state alternatives to traditional acid catalysts, such as aluminium trichloride, sulfuric acid and hydrofluoric acid.[1,2] We recently reported a new type of clay intercalate with high surface area and a structural porosity substantially larger than pillared clays. These new derivatives, which we call porous clay heterostructures (PCH) are formed by surfactant-directed assembly of open-framework silica in the galleries of smectite clays with high charge density.[3] In contrast to microporous pillared clays with pore sizes typically below 10 Å, PCH materials exhibit regular porosity in the supermicropore to small mesopore range (15–25 Å).

PCH synthesis makes use of the micellar ordering of silicate species and surfactants in a manner not unlike the supramolecular ordering processes for mesoporous MCM-41 molecular sieves.[4,5] However, as shown in Fig. 1, PCH assembly differs from MCM-41 chemistry insofar as framework organization occurs in the restricted two-dimensional gallery region of the clay rather than in the three-dimensional bulk phase. Because PCH design combines the open framework structure of the gallery silica with the chemistry of the clay layer, new properties for selective heterogeneous catalysis may be anticipated. Using the dehydration of 2-methylbut-3-yn-2-ol (MBOH) as a probe reaction, we demonstrate in the present work the acid catalytic activity of PCH materials relative to alumina-pillared clays and related catalysts.

Cetyltrimethylammonium (CTMA) exchange cations and decylamine were used as co-surfactants to form a PCH with fluorohectorite as the clay host. Synthetic lithium fluorohectorite (Li-FH) with the unit cell composition $Li_{1.12}$-$[Li_{1.12}Mg_{4.88}](Si_8O_{20})F_4{\cdot}xH_2O$ (Corning, Inc.) was allowed to react at 50 °C with 0.3 M aqueous $[(C_{16}H_{33})NMe_3]Br$ in twofold excess of the clay cation exchange capacity. After a reaction time of 24 h, the product was washed with ethanol and water to remove the excess surfactant and air dried. The clay then was added to the decylamine in the molar ratio CTMA-FH : decylamine = 1 : 20, and the resulting suspension was stirred for 30 min. Sufficient tetraethylorthosilicate (TEOS) was added to achieve a final molar ratio of CTMA-FH : decylamine : TEOS = 1 : 20 : 150. After a reaction time of 4 h at room temp., the reaction product was recovered by centrifugation, air-dried and calcined at the desired temperature for 4 h using a temperature ramp rate of 2 °C $min^{-1}$. The calcined products were denoted FH-PCH-X where X is the calcination temperature in °C. Chemical analyses indicated the presence of 10.4 moles of gallery Si per fluorohectorite $O_{20}F_4$ unit cell.

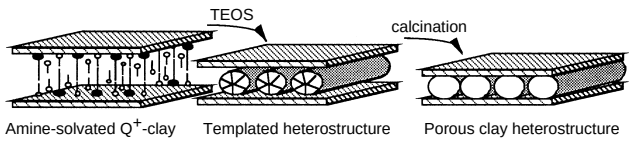

**Fig. 1** Schematic illustration of porous clay heterostructure (PCH) formation through surfactant-directed assembly of open framework silica in the galleries of a layered silicate co-intercalated by a quaternary ammonium ion surfactant (filled head groups) and a neutral amine co-surfactant (open head groups)

Table 1 provides the basal spacings, BET surface areas, and Horvath–Kowazoe pore sizes for FH-PCH samples calcined in the range 300–550 °C. Three orders of 00*l* X-ray reflection are observed in accord with a lamellar structure. Although the basal spacing decreases from 38.1 to 33.5 Å with increasing temperature, there is a general increase in the BET surface areas to a maximum value of 790 $m^2\ g^{-1}$ at 500 °C where the removal of gallery surfactant ( < 1 mass% C) and the dehydroxylation of the gallery silica become more complete. The lamellar structure is retained even at 700 °C, but the basal spacing begins to decrease more rapidly at this temperature. At 800 °C the PCH structure degrades substantially with the formation of quartz as a decomposition product. Clearly, the thermal stability of the PCH structure degrades substantially with the formation of quartz as a decomposition product. Clearly, the thermal stability of the PCH structure is sufficient to conduct a wide range of acid catalyzed conversions.

Table 1 also includes the results for the catalytic conversion of MBOH over calcined FH-PCH samples. This probe reaction is sensitive to the presence of acid-base sites on the catalyst surface.[6] Acidic sites result in the dehydration of MBOH to 2-methylbut-3-yn-1-ene (MByne), whereas basic sites cause cleavage to acetone and acetylene. As indicated by the high selectivity to MByne, particularly for FH-PCH-350, the surfaces of FH-PCH contain mainly acidic sites. In contrast, pristine $Li^+$ fluorohectorite is highly basic, affording primarily acetone and acetylene as reaction products. Thus, the intercalation of surfactant-assembled silica and the subsequent calcination of the heterostructure imparts acidic surface functionality.

The results given in Table 1 further show that FH-PCH-350 is a much more active acid catalyst than either mesoporous MCM-41 silica or microporous alumina pillared fluorohectorite (APF-350). The latter intercalate is an especially active alkylation catalyst among pillared clays.[7] The reactivity of FH-PCH-350 even approaches that of K-10 montmorillonite, a commercially available acid-restructured clay. This latter material, however, lacks framework porosity and is incapable of shape selective catalysis.

The FH-PCH materials reported here are hybrid structures of the smectite clay fluorohectorite, which is basic, and weakly acidic MCM-41 silica (*cf.* Table 1). Some Brønsted acidity is expected for PCH materials, however, because the initial gallery cations (*i.e.* $Li^+$) are replaced first by surfactant cations and then by protons upon destruction of the surfactant through calcination. Also, fluorohectorite is known[8] to undergo hydrolysis of lattice fluorine at temperatures above 250 °C. Proton dissociation from the resulting hydroxyl groups also can contribute to Brønsted acidity. In addition, the silicate layers of fluorohectorite can undergo local restructuring upon calcination at elevated temperatures, giving rise to Lewis-acid sites in the gallery region.[8]

**Table 1** Physical and acid catalytic properties of calcined FH-PCH derivatives and related solids

| Sample | $d_{001}$/Å | Surface area/ $m^2\ g^{-1}$ | HK pore size/Å | MBOH conv. (%) | MBOH product selectivity[a] | | |
|---|---|---|---|---|---|---|---|
| | | | | | Basic[b] | | Acidic MByne |
| | | | | | Acetylene | Acetone | |
| FH-PCH-300 | 38.1 | 575 | 18.9 | 47.0 | 0 | 0 | 100 |
| FH-PCH-350 | 38.7 | 555 | 19.6 | 52.7 | 0 | 0.1 | 99.9 |
| FH-PCH-450 | 37.1 | 630 | 22.3 | 32.9 | 0.2 | 0.2 | 99.6 |
| FH-PCH-500 | 35.3 | 790 | 22.6 | 23.6 | 0.4 | 0.8 | 98.9 |
| FH-PCH-550 | 33.5 | 750 | 21.7 | 19.0 | 2.9 | 3.4 | 93.8 |
| Li-FH | 10.5 | 50 | 0 | 5.0 | 36.2 | 46.5 | 17.3 |
| K-10[c] | — | 250 | 0 | 67.9 | 0 | 0.1 | 99.9 |
| APF-350[d] | 18.9 | 214 | < 10 | 16.4 | 3.6 | 3.6 | 92.9 |
| MCM-41[e] | — | 1100 | 22.0 | 11.0 | 8.0 | 7.0 | 85.0 |

[a] Reactions of MBOH were carried out over 150 mg quantities of catalyst at 180 °C in a packed-bed reactor linked to an on-line Perkin-Elmer 8500 gas chromatograph equipped with FID detection and a packed column of 3% SP-1500 on Carbopack B. The catalysts were activated at 200 °C for 2 h prior to testing under a helium flow of 20 ml $min^{-1}$. MBOH in the gas phase (0.35 mmol $h^{-1}$) was diluted to 2.5% in helium. [b] Basic active sites afford acetone and actylene as reaction products, whereas acid sites afford exclusively MByne. [c] A commercial acid-treated clay (Aldrich) calcined at 350 °C. [d] Alumina-pillared fluorohectorite, prepared according to ref. 8 and calcined at 350 °C. [e] Mesoporous silica molecular sieve assembled from cetyltrimethylammonium bromide according to ref. 4 and calcined at 350 °C.

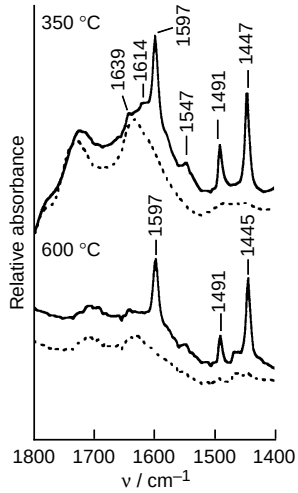

**Fig. 2** IR spectra of pyridine chemisorbed at 150 °C on FH-PCH samples calcined at 350 and 600 °C (solid lines). The dashed lines are spectra for the pristine FH-PCH samples prior to pyridine adsorption.

FTIR spectra for pyridine chemisorbed at 150 °C on FH-PCH-350 and -600 provide insights into the nature of the acid sites in PCH materials (Fig. 2). The C–C ring stretching frequencies near 1445 and 1547 $cm^{-1}$ are diagnostic of the bonding of pyridine to Lewis and Brønsted sites,[9] respectively. The relative intensities of these bands are very similar to those observed for APF. This similarity in acid functionality is somewhat surprising, because the Lewis acidity of alumina pillared clays normally is associated with the presence of coordinatively unsaturated sites on the alumina pillars. FH-PCH, however, contains no aluminium.

To better understand the origin of the observed acidity for FH-PCH materials and the relationship of the acidity to APF, we carried out $^{19}F$ and $^{29}Si$ MAS NMR studies for materials calcined to 550 °C. $^{19}F$ NMR showed that the fluorine sites associated with the negatively charged octahedral triads of the silicate layers ($\delta$ −16) diminish to *ca*. 25% of the initial intensity when calcined at 350 °C. This latter result is in accord with the previously observed hydrolysis chemistry of fluorohectorite (APF-350).[8] Also, $^{29}Si$ MAS NMR showed that the silicate layers in FH-PCH are locally restructured in a manner analogous to APF-350. Upon layer restructuring at calcination temperatures up to 350 °C, the $Q^3$ resonance of the clay broadens and shifts progressively from $\delta$ −93.3 to −96.6 signifying an increase in the Si–O–Si bond angle of the tetrahedral sheet. The $Q^3$ ($\delta$ −103) and $Q^4$ ($\delta$ −110) resonances of the assembled gallery silica, however, are not affected by calcination over this temperature range. Inversion and grafting of the clay tetrahedral sheet to the gallery silica, as evidenced by a new resonance at $\delta$ −99.7, does not occur until the FH-PCH is calcined in the range 450–550 °C. Such local restructuring of the silicate layer also occurs for APF over the same temperature range.

On the basis of the above FTIR and MAS NMR results we conclude that FH-PCH-350 and APF-350 share the same type of acid functionality and layered structural features. The important difference, of course, is that FH-PCH-350 is a surfactant-assembled supermicroporous to mesoporous intercalate, whereas APF-350 is exclusively a microporous pillared derivative. The enhanced access to the framework gallery sites in FH-PCH-350 most likely contributes greatly to the superior catalytic activity of this intercalate.

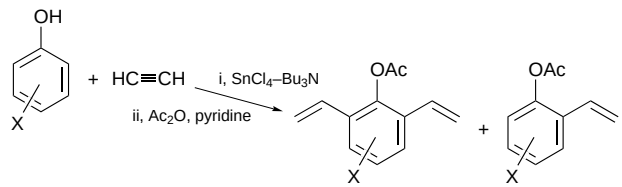
# 2,6-Divinylation of phenols with ethyne



**Masahiko Yamaguchi,*[a] Mieko Arisawa,[b] Yoshiyuki Kido[a] and Masahiro Hirama[b]**

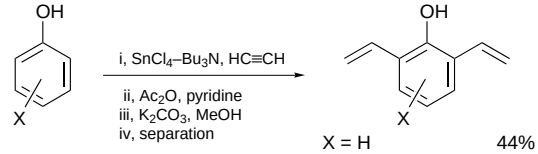
[a] *Faculty of Pharmaceutical Sciences, Tohoku University, Aoba, Sendai 980-77, Japan*
[b] *Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-77, Japan*

**Phenols are 2,6-divinylated by treatment with ethyne at 100 °C in chlorobenzene in the presence of $SnCl_4$–$Bu_3N$, the divinylation occurring predominantly to exclusively with phenol, alkylphenols and alkoxyphenols; an appropriate amount of the tin reagent and the correct reaction temperature are essential for the divinylation.**

Divinylbenzenes are an important class of chemicals possessing two reactive sites. They are popular cross-linking agents in polymer chemistry. Alternating copolymers have been synthesized by bis-addition reactions to divinylbenzenes, and use of the Heck reaction, amine addition reaction and olefin metathesis have been reported.[1] The Diels–Alder reaction of divinylbenzenes is a convenient method for the synthesis of polycyclic aromatic compounds.[2] In spite of their significance in polymer and organic synthesis, studies have been limited to the three isomers of divinylbenzene,[3] and very few functionalized derivatives are known. This is due to the lack of a straightforward method for their preparation, since the direct substitution of aromatic C–H bonds with C–CH=$CH_2$ groups has proved extremely problematic.[4] Divinylbenzenes have been synthesized by stepwise transformations from benzene *via* diethylbenzene, dihalobenzene, diformylbenzene *etc*.[5] Functionalized divinylbenzenes can be accessed only by multi-step syntheses if these methods are employed. Previously, we reported the direct *ortho*-vinylation of phenols with ethyne.[6] Described here is the direct 2,6-divinylation of phenols (Scheme 1). Two vinyl groups are introduced to the benzene nucleus at *meta*-positions in one step.

Ethyne was bubbled into a chlorobenzene solution of $SnCl_4$–$Bu_3N$ (5 equiv.) at −50 °C.† $SnCl_4$–$Bu_3N$ (2 equiv.) and *p-tert*-butylphenol (1 equiv.) were added, and the mixture was heated at 100 °C for 30–60 min. The reaction was quenched with 2 M NaOH and EtOH at reflux. After acetylation, 4-*tert*-butyl-2,6-divinylphenyl acetate and 4-(*tert*-butyl-2-vinylphenyl acetate were obtained in 71% combined yield in a ratio of 5 : 1 (by NMR spectroscopy). The divinylphenols were acetylated before isolation for the purpose of stabilization. When the reaction was conducted at 60 °C, monovinylphenol predominated. Serious decomposition took place at chlorobenzene reflux temperature (132 °C). Other aromatic solvents with high boiling points, such as toluene, *o*-xylene and 1,2-dichlorobenzene, could also be used. Treatment of isolated *o*-vinylphenol with ethyne under these conditions resulted in decomposition. Analogous to the monovinylation reaction of phenols,[6] the divinylation probably involves formation of alkynyltin and phenoxytin followed by the carbostannylation reaction between these species. The alkaline quench (2 M NaOH–EtOH at reflux) is essential for the effective protonation of the carbostannylated intermediate. The amount of tin reagent (5 + 2 equiv.) is also critical to obtain the divinylphenol predominantly. When it was changed, for example, to 2 + 2, 2 + 5, 5 + 5 or 5 + 0 equiv., 1 : 1 mixtures of monovinylated and divinylated products were formed. Employing a large excess of reagnet (12 + 0 equiv.) resulted in the monovinylation reaction dominating in a ratio of 6 : 1. The reaction mechanism of the divinylation therefore appears to be rather complex.

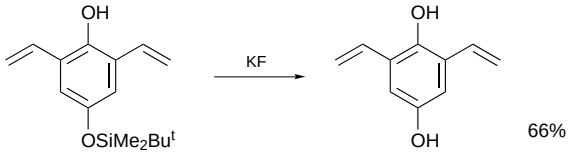
**Scheme 1**



Several *para*- and *meta*-substituted phenols and phenol itself were treated with ethyne under the above conditions, and the results are summarized in Table 1. The reaction can be carried out on a 1 g scale. Alkoxy and alkyl derivatives gave divinylphenol predominantly or exclusively. *p*-Pivaloxyphenol and *p*-phenylphenol gave comparable amounts of monovinyl and divinyl derivatives. The divinylation is facilitated by electron-donating substitutents on the aromatic ring. Styrenes with oxygen functionalities at the *ortho*- and/or *para*-positions are known to be extremely sensitive to acids.[7] It is therefore notable that the present vinylation reaction can be applied to *m*-methoxyphenol and *m*-silyloxyphenols. Even 3,5-bis(silyloxy)phenol is divinylated giving a protected 2,6-divinylbenzene-1,3,5-triol. In order to avoid desilylation, the reactions of silyloxyphenols were quenched with either $K_2CO_3$ in MeOH or $K_2CO_3$ in THF–water at room temperature. The latter conditions were employed in the divinylation of *m*-silyloxyphenols. Alcohol addition to the reactive olefin took place when the protonation was conducted in the presence of MeOH.

Mixtures of di- and mono-vinylphenyl acetate were treated with $K_2CO_3$ in MeOH at room temperature to give 2,6-divinylphenol and 2-vinylphenol, which were readily separable by silica gel chromatography. Thus, divinylphenols are obtained from phenol, alkylphenols and alkoxyphenols in overall yields ranging from 40 to 60% (Scheme 2). The treatment of 4-(*tert*-butyldimethylsilyloxy)phenol with KF in MeOH gave 2,6-di-

**Table 1** 2,6-Divinylation of phenols with ethyne[a]



| X | Yield (%) | Divinyl : Monovinyl |
|---|---|---|
| H | 66 | 5 : 1 |

† Typical experimental procedure: Ethyne was bubbled into chlorobenzene (170 ml) at −50 °C for 1 h. Bubbling was stopped, and $SnCl_4$ (5.9 ml, 50 mmol) and $Bu_3N$ (11.9 ml, 50 mmol) were added. The mixture was stirred at room temperature for 1 h under an argon atmosphere, and *p*-methoxyphenol (1.24 g, 10 mmol) in chlorobenzene (30 ml), $SnCl_4$ (2.3 ml, 20 mmol) and $Bu_3N$ (4.8 ml, 20 mmol) were added successively. After heated at 100 °C for 1 h, 2 M NaOH (400 ml) and ethanol (150 ml) were added, and heating was continued for another 2 h at 100 °C. The mixture was cooled, and acidified with 2 M HCl. The organic materials were extracted with diethyl ether, washed with brine, dried over $MgSO_4$ and filtered. After removal of the diethyl ether under reduced pressure, pyridine (8.1 ml) and acetic anhydride (4.7 ml) were added to the resulted chlorobenzene solution, and the products were acetylated by stirring at room temperature for 12 h. An aqueous work-up followed by flash chromatography (hexane–ethyl acetate 100 : 1) over silica gel gave 4-methoxy-2,6-divinylphenyl acetate (1.49 g, 77%), containing *ca.* 5% of 4-methoxy-2-vinylphenyl acetate as indicated by $^1$H NMR spectroscopy.

**The synthesis, characterization and rapid hydrolysis of *trans*-[Ir(CO)Me$L_2$] (L = a water-soluble phosphine) to *trans*-[Ir(CO)(OH)$L_2$] and $CH_4$ are reported.**

There have been increasing reports on use of water-soluble organometallic complexes as catalysts for hydroformylation and hydrogenation of alkenes.[1,2] Such catalytic reactions involve, of necessity, formation of metal alkyls. Several alkyl complexes of $Cr^{III}$, $Co^{III}$ and $Pt^{III}$ have been studied in aqueous solution[2,3] with both homolytic and heterolytic decomposition pathways identified. However, alkyl complexes of lower valent organometallic centres have not been reported. In this manuscript we report the synthesis of the sodium and potassium salts of *trans*-[Ir(CO)Me(tppms)$_2$] [tppms = $PPh_2$(*m*-$C_6H_4SO_3^-$)], the attempted synthesis of *trans*-[Ir(CO)Me(tppts)$_2$] [tppts = P(*m*-$C_6H_4SO_3Na)_3$] and the rapid hydrolysis of the Ir–Me bond in water.

The methyl complexes of tppms were prepared by ligand exchange on *trans*-[Ir(CO)Me($PPh_3$)$_2$] [eqn. (1)].[4]†

$$trans\text{-}[Ir(CO)Me(PPh_3)_2] + 2tppms \xrightarrow{thf} trans\text{-}[Ir(CO)Me(tppms)_2](\downarrow) + 2PPh_3 \quad (1)$$

Both the $Na^+$ and $K^+$ salts precipitate from thf. The characterization data shown in Table 1 confirm the formulation as do the microanalytical data.‡

Dissolving *trans*-[Ir(CO)Me(tppmsNa)$_2$] in $H_2O$ (or $D_2O$) results in *trans*-[Ir(CO)(OH)(tppmsNa)$_2$][5] and $CH_4$ in seconds. The *trans*-[Ir(CO)(OH)(tppmsNa)$_2$] was indicated by the $^{31}P$ resonance at $\delta$ 28.4(s)[5] and the $CH_4$ by a sharp singlet at $\delta$ −0.07(s) in the $^1H$ NMR. No other resonances were observed in the $^{31}P$ or the $^1H$ NMR to higher field than $\delta$ 6.0. The NMR tube was opened and an IR spectrum recorded ($\nu_{CO}$ = 1953 $cm^{-1}$). To complete characterization of the iridium product the water was removed by vacuum and the residue dissolved in $(CD_3)_2SO$ and combined with 10 mg of *trans*-[Ir(CO)($CH_3$)(tppmsNa)$_2$] for NMR characterization. The $^1H$ and $^{31}P$ NMR spectra clearly showed equal quantities of *trans*-[Ir(CO)(OH)(tppmsNa)$_2$] {$^{31}P$ NMR [$(CD_3)_2SO$]}, $\delta$ 26.9(s); $^1H$ NMR [$(CD_3)_2SO$], $\delta$ 0.2 (t, $J_{PH}$ 6.5 Hz) and the methyl complex. Thus a rapid hydrolysis of the iridium–methyl bond occurred in water [eqn. (2), L = tppmsNa].

$$trans\text{-}[Ir(CO)MeL_2] + H_2O \rightarrow trans\text{-}[Ir(CO)(OH)L_2] + CH_4 \quad (2)$$

The reaction was sufficiently rapid that the methyl complex could not be observed in $H_2O$ by NMR.

Attempts to prepare *trans*-[Ir(CO)Me(tppts)$_2$] by biphasic exchange of tppts for $PPh_3$ always resulted in formation of *trans*-[Ir(CO)(OH)(tppts)$_2$]§ in a similar hydrolysis reaction.

The very rapid hydrolysis of iridium methyl complexes provides a caution for increasing use of water-soluble organometallic compounds as catalysts. Such hydrolyses, coupled with facile water–gas shift reactions, offer different mechanistic possibilities for organometallic complexes in water.

The authors are grateful to the Department of Energy, ER 13775, for support of this research.

**Table 1** IR and NMR characterization data for iridium complexes

| Complex | $\nu_{CO}$ ($Me_2SO$) | $\delta_P$ [$(CD_3)_2SO$] | $\delta_H$ [$(CD_3)_2SO$] ($J_{PH}$/Hz) |
|---|---|---|---|
| *trans*-[Ir(CO)Me($PPh_3$)$_2$] | 1935 | 31.2 | −0.4(t) (8.5) |
| *trans*-[Ir(CO)Me(tppmsK)$_2$] | 1937 | 31.5 | −0.4(t) (8.9) |
| *trans*-[Ir(CO)Me(tppmsNa)$_2$] | 1937 | 31.6 | −0.4(t) (8.5) |
| *trans*-[Ir(CO)(OH)(tppmsNa)$_2$] | 1953 | 26.9 | 0.2(t) (6.5) |

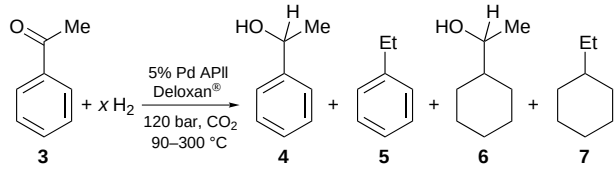
# Continuous hydrogenation of organic compounds in supercritical fluids

**Martin G. Hitzler and Martyn Poliakoff***

*Department of Chemistry, University of Nottingham, Nottingham, UK NG7 2RD*

**A small flow reactor (5 ml volume) is used for continuous hydrogenation in supercritical $CO_2$ or propane with polysiloxane-supported noble metal catalysts; a wide range of organic functionalities can be hydrogenated with good throughput (up to 1200 ml $h^{-1}$ in favourable cases) and the various parameters (temperature, pressure, concentration of $H_2$, *etc.*) can be controlled *independently* to optimise the selectivity for a particular product.**

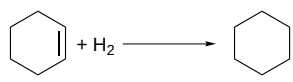
Hydrogenation of organic compounds is a process of major chemical importance. Gaseous $H_2$ is an inexpensive and versatile reagent for hydrogenation but it can often be difficult to use in practice. Laboratory-scale hydrogenation is usually slow because $H_2$ is sparingly soluble in common solvents. By contrast, supercritical fluids are completely miscible[1] with $H_2$, but it is only recently that this miscibility has been exploited[2–9] for hydrogenation and related reactions, mostly as batch reactions in sealed autoclaves. However, the gas-like nature of supercritical fluids makes them particularly suitable for continuous flow reactors. For any reaction, a flow reactor can be smaller than the corresponding batch reactor needed to generate a comparable amount of product. This reduction in size is particularly attractive for supercritical fluid systems because it reduces both the cost and the safety problems of high pressure equipment. There is a very brief report[10] of an industrial supercritical hydrogenation process with a 250-fold reduction in the volume of the reactor, and more recently small-scale reactors have been used to hydrogenate fats and fatty esters in near-critical or supercritical $CO_2$ ($scCO_2$) and propane (scPropane).[11,12]



Here, we describe the use of a flow reactor system† for a wide range of continuous hydrogenation reactions. Although the reactor is larger than our previous flow reactors for the photochemical synthesis of organometallic dihydrogen compounds,[13] the entire apparatus can still be accommodated within a standard fume cupboard. The hydrogenation of cyclohexene **1** to cyclohexane **2** was used to establish the performance of the reactor. The reaction was extremely rapid in $scCO_2$ [$T_c$ = 31.1 °C, $P_c$ = 73.8 bar (10 bar = 1 MPa)] or scPropane ($T_c$ = 96.8 °C, $P_c$ = 42.6 bar) and could be initiated without any external heating of the reactor. Table 1 shows that the overall rate of conversion is extremely high, with up to 20 ml (0.2 mol) per minute of **1** hydrogenated in a reactor (5 ml volume) containing only 4 ml of catalyst.

The role of the supercritical fluid is almost certainly more complex than merely enhancing the concentration of $H_2$. The fluid reduces viscosity and increases diffusion rates compared to the liquid phase, so that transport to and from the catalyst surface is no longer a limiting factor. At flow rates > 1.5 ml $min^{-1}$ of substrate, we have measured temperatures > 300 °C in the catalyst bed, higher even than the critical temperature of cyclohexene itself ($T_c$ = 287.3 °C, $P_c$ = 43.4 bar). Indeed, at high throughput, we have found that once the temperature of the reactor has stabilised, only a very small flow of $scCO_2$ is required to sustain the reaction; the mixture is predominantly cyclohexene and $H_2$, which measurements in our laboratory have shown to be completely miscible under these conditions.‡ Experiments with a commercially significant derivative of cyclohexene indicate that hydrogenation in $scCO_2$ is more selective than the gas phase reaction and is quicker than the liquid phase, requiring *ca*. 35 times less catalyst.

The particular advantage of supercritical fluids is the ability to control conditions with great precision and, hence, to manipulate the selectivity of reactions. Thus, the hydrogenation of acetophenone **3** can lead to at least four possible products **4**–**7** (Scheme 1).



When the reactor is operated with $scCO_2$ at 90 °C, there is almost quantitative conversion of **3** to **4**. As the amount of $H_2$ and the temperature of the reactor are raised, there is a controllable shift towards the more hydrogenated products so that, by 300 °C, **7** is the major product (see Fig. 1).

However, the presence of a single phase within the reactor means that the various parameters (temperature, pressure, concentration of $H_2$, *etc.*) can be adjusted *independently*. Thus, reducing the ratio of $H_2$ : **3** from 4 : 1 to 2 : 1 (at $T$ = 200 °C and

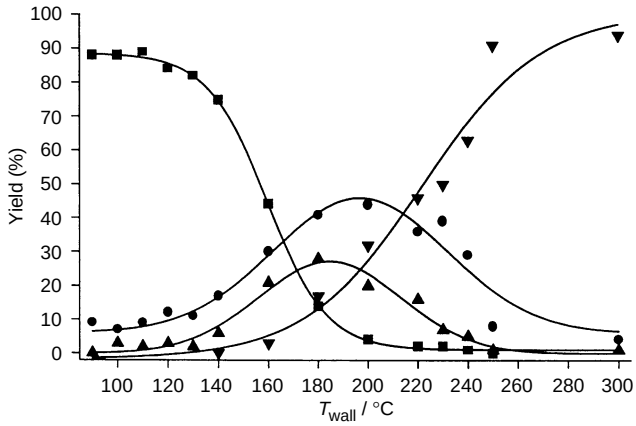

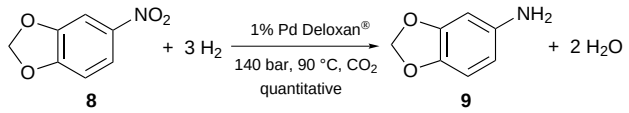

**Fig. 1** Dependence of product distribution on reactor wall temperature for the hydrogenation of acetophenone **3** in $scCO_2$ with 5% Pd APII Deloxan® catalyst: (■) **4**, (●) **5**, (▲) **6** and (▼) **7**. Reactions were run with flow rates of 0.5 ml $min^{-1}$ **3**, 1.0 ml $min^{-1}$ gaseous $CO_2$, and a ratio of $H_2$:**3** increasing from 2:1 to 6:1 at higher temperatures. The total pressure was held at 120 bar throughout. Product analysis by $^1H$ NMR spectroscopy ($CDCl_3$).

$p$ = 120 bar) increases the yield of **5** from 44 to 69% at the expense of **7**, or reducing the total pressure (at $T$ = 240 °C and with *constant* $H_2$:**3** = 4:1) from 120 to 40 bar (*i.e.* to the near-critical region) reduces the degree of hydrogenation, changing the ratio of products **5**:**7** from 1:2 to 2:1, presumably by reducing the residence time. Thus, without changing catalyst, one can tune conditions to maximise the yield of a particular product, and the reactor is then sufficiently stable to maintain those conditions.

The reactor is primarily designed to operate with reactants and products which are liquids at ambient temperature but it can also be used to hydrogenate solids, dissolved in an inert organic solvent. For example, 1,2-(methylenedioxy)-4-nitrobenzene§ **8** (mp 146–148 °C) was hydrogenated quantitatively to **9** in $scCO_2$ by pumping it through the reactor (*ca*. 8 g $h^{-1}$) in MeOH–THF (2:1 v/v) (Scheme 2).

**Scheme 2**

The flow reactor can be used to hydrogenate a substantial range of other organic functional groups. Epoxides, oximes, nitriles, alcohols and aromatic and aliphatic aldehydes and ketones have been successfully hydrogenated, most with conversions comparable to those described above and several with better selectivity than in non-supercritical hydrogenation. Most significantly, we have shown that compounds can be hydrogenated continuously on a relatively large scale using reactors of very small volume. Thus supercritical fluids can transform hydrogenation with gaseous $H_2$ into a viable, rapid and highly controllable laboratory technique for organic chemistry on a large preparative scale. At the same time, only modest scale-up will be required to generate compounds in quantities appropriate to the industrial production of some pharmaceuticals and fine chemicals.

† The substrate, supercritical fluid and $H_2$ are brought together in a heated mixer, passed through the reactor containing the catalyst, and then expanded to separate the product from the fluid and excess $H_2$. The reactor is assembled from commercially available units: $scCO_2$ and scPropane pump PM101, $H_2$ compressor CU105 and Expansion Module PE103 (all from NWA GmbH, Lörrach, Germany), a high pressure mixer (Medimix) and a Gilson 305 pump (for the organic substrate). **Safety note**: Flow reactors have a comparatively small volume under pressure. Nevertheless, equipment with the appropriate pressure and temperature rating should always be used for high pressure experiments.

‡ Although previous reports have shown that hydrogenation catalysts can be rather short-lived under supercritical conditions (ref. 11), we have found that the Deloxan® catalysts (S. Wieland and P. Panster, *Catalysis of Organic Reactions*, Marcel Dekker, New York, 1995, p. 383) have survived several hours under these harsh conditions and can even be used successfully up to 400 °C.

§ The hydrogenation of nitrobenzene itself over a 5% Pt APII Deloxan® catalyst in scPropane is particularly striking, with conversion of *ca*. 25% of the starting material to $NH_3$ and cyclohexane, a reaction which requires addition of no less than seven $H_2$ molecules to each molecule of nitrobenzene within a residence time of $< 5$ min in the reactor (200 °C, 80 bar). By contrast, a 1% Pd APII Deloxan® catalyst gives aniline in 100% yield under similar conditions.

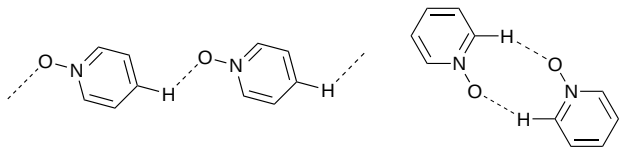
# Supramolecular networks *via* pyridine *N*-oxide CH···O hydrogen bonding in the crystal structures of 2,2′-dithiobis(pyridine *N*-oxide) and its complexes with 1,2,4,5-tetracyanobenzene and pyromellitic dianhydride

**Satish G. Bodige, Robin D. Rogers and Silas C. Blackstock***



*Department of Chemistry, The University of Alabama, Tuscaloosa, Alabama 35487-0336, USA*

**CH··O hydrogen bonding in crystals of 2,2′-dithiobis(pyridine *N*-oxide) (DTPO) supports network formation.**

Crystal packing depends critically upon molecular geometry and directional intermolecular forces. Conventional hydrogen bonding (X–H··Y; X, Y = N or O) has been extensively employed to command supramolecular network formation in organic solids.[1,2] By comparison, the construction of networks *via* weak CH···O hydrogen bonding[3] is much less advanced, despite the widespread importance of these interactions.[4] Here, we present a set of new supramolecular networks constructed from pyridine *N*-oxide (PO) CH···O hydrogen bonds in the crystal structures of 2,2′-dithiobis(pyridine *N*-oxide) (DTPO) and its complexes with tetracyanobenzene (TCNB) and pyromellitic dianhydride (PMDA).

Precedence for PO self association *via* hydrogen bonding can be found in the Cambridge Structure Database (CSD).[5]† Both chain propagating (**X**) and chain termination (**Y**) modes of CH···O bonding occur, the former being much more common

than the latter. For DTPO, self-association in at least two dimensions *via* CH···O interactions should be possible if the conformational preference of aryl disulfides (twisted orientation of aryl rings) survives in the solid. Thus, we have investigated the CH···O network formation ability of DTPO in the solid state.

Crystals of DTPO **1** [mp 205 °C (decomp.)] were grown from nitromethane and analysed by X-ray diffraction.‡ The crystal structure is a three-dimensional CH···O bonded racemic supernetwork in which each DTPO molecule participates in eight (four unique) CH···O hydrogen bonds (see Fig. 1). By virtue of the disulfide conformational preference for a 90° C–S–S–C twist angle,[6] the DTPO molecule is axially dissymmetric. Both DTPO enantiomers are present in crystal **1**. We refer to the lattice as a supernetwork because it is composed of two interpenetrated three-dimensional homochiral DTPO networks which associate *via* two (of eight) CH···O hydrogen bonds per DTPO molecule.

The open network character of the homochiral fragments of **1** suggested that guest inclusion in a DTPO lattice might be possible. To test this possibility, DTPO was crystallized in the presence of electron-deficient additives TCNB and PMDA.[7]

Light yellow crystals of $(DTPO)_2TCNB(H_2O)_4$ **2** [mp 250 °C (decomp.)] were obtained from nitromethane,‡ Homochiral networks are not observed in **2**, but guest inclusion is observed. In this cocrystal, DTPO molecules self-assemble *via* **X** and **Y** mode CH···O bonding to yield a ladder host array clathrated by TCNB guests, as shown in Fig. 2. The ladder cavity dimensions are 8.4 × 6.5 Å, and the cavity contains π-stacked DTPO dimer donor and TCNB acceptor moieties with an inter-plane distance of *ca*. 3.25 Å, indicative of an attractive donor–acceptor (DA) interaction.[8] Two unique water molecules (not shown) also appear in the lattice between ladders and hydrogen bond to each other and to the DTPO oxygens of the ladder host. These water molecules fill space between the DTPO superstructures and, by OH···O hydrogen-bonding, effectively cross-link adjacent DTPO ladders which orient parallel to each other in the lattice.

In the presence of PMDA in MeCN, DTPO forms dark yellow plates of $(DTPO)_2PMDA$ **3** [mp 220 °C (decomp.)].‡ The crystal structure is shown in Fig. 3. The DTPO host network of **3** closely resembles that of **2**, yielding guest-occupied DTPO

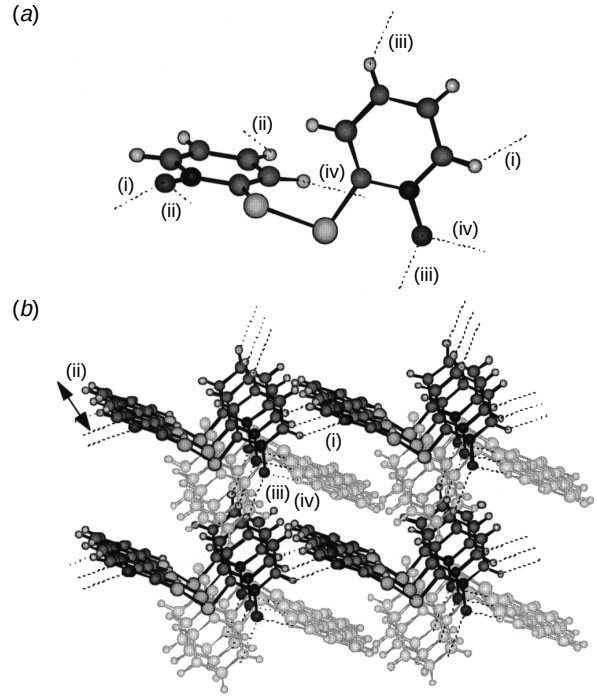


**Fig. 1** CH···O hydrogen bonding at DTPO in crystal **1**: (*a*) single DTPO molecule and (*b*) enantiomer-shaded racemic network; [H···O (Å), C(H)···O (Å), CH···O (°)]: (i) 2.36(2), 3.113(2), 137(2); (ii) 2.35(3), 3.170(3), 143(2); (iii) 2.41(2), 3.179(2), 146(2); (iv) 2.44(2), 3.346(2), 157(2)

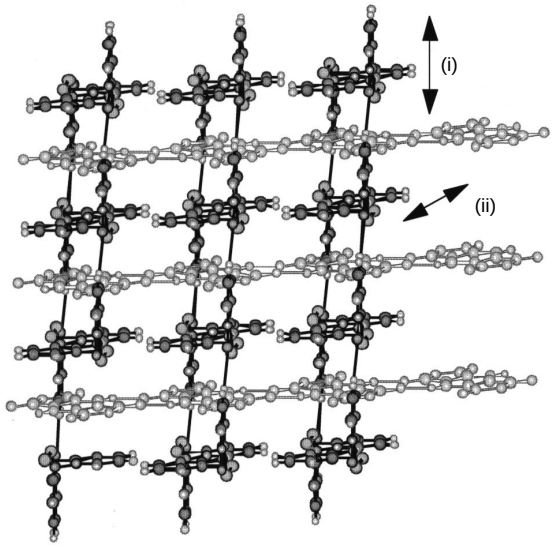

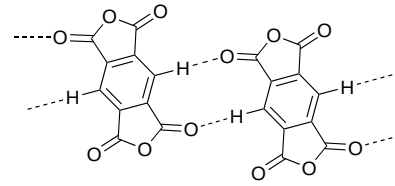

**Fig. 3** DTPO ladder host networks (dark) threaded by PMDA stands (light) in crystal **3**: [H···O (Å), C(H)···O (Å), CH···O (°)]: DTPO (i) 2.32(3), 3.130(3), 145(2); DTPO (ii) 2.35(3), 3.220(3), 172(3); PMDA 2.36(3), 3.257(3), 164(2)

ladders. An added feature of **3** is guest self-association. PMDA forms 10-membered rings as CH···O hydrogen bonded dimers,[9] giving PMDA tapes which thread the ladder host cavities to form a two-dimensional host–guest array with a novel supramolecular polypseudorotaxane architecture.[10] The plane-to-plane distance between DTPO and PMDA rings is *ca*. 3.3 Å. Adjacent DTPO ladders on different threads associate *via* a third (interladder) CH···O hydrogen bond‖ between DTPOs to complete three-dimensional ordering of the lattice. From a crystal engineering perspective, **3** is a novel solid in which three distinct supramolecular bonding schemes cooperate to effect three-dimensional molecular organization in the two-component solid.

In summary, the above structures illustrate the propensity of the pyridine *N*-oxide units of DTPO to form networks *via* CH···O bonding in the solid state. Knowledge of such interactions is important to crystal engineering with the POs whose strong molecular dipole makes them attractive substrates for optical or electronic materials preparation. Structures **2** and **3** display an interplay of CH···O and π DA interactions, culminating in three-dimensional host–guest arrays.

We acknowledge the NSF and donors of the Petroleum Research Foundation, administered by the ACS, for support and L. M. Rogers for technical assistance.

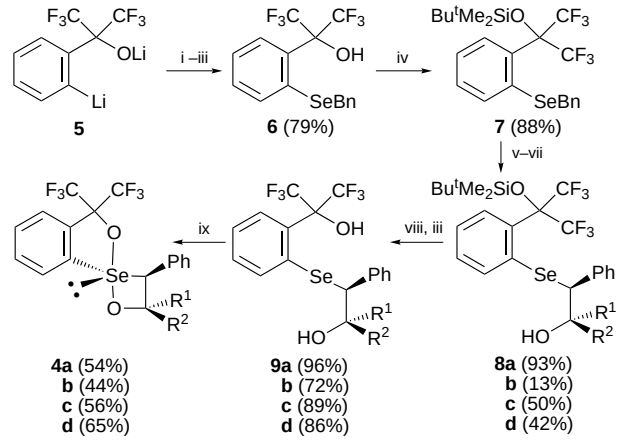
# Novel reactivity of tetracoordinate 1,2λ⁴-oxaselenetanes: oxirane formation reaction with retention of configuration

**Fumihiko Ohno, Takayuki Kawashima*† and Renji Okazaki***

*Department of Chemistry, Graduate School of Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan*

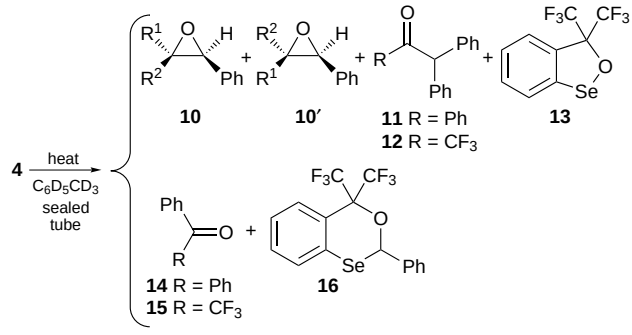


**Stable tetracoordinate 3-phenyl-1,2λ⁴-oxaselenetanes give the corresponding oxiranes upon thermolysis; in sharp contrast to Corey–Chaykovsky type reactions, oxirane formation proceeds with retention of configuration, and the reaction can be recognised as a new type of carbon–oxygen ligand coupling reaction of λ⁴-selenanes.**

The reactions of carbonyl compounds with phosphorus ylides (Wittig reaction) afford alkenes *via* 1,2λ⁵-oxaphosphetanes,[1] while those with group 16 element (S, Se, Te) ylides (Corey–Chaykovsky type reaction) give oxiranes.[2] The latter type of oxirane formation reaction has been proposed to involve the formation of an *anti*-betaine followed by a back side attack of an oxido anion on the β-carbon.[2,3] In the course of our study on oxetanes bearing a highly coordinate main group element at the position adjacent to the oxygen atom,[4] we have reported the syntheses and isolations of tetra- and penta-coordinate 1,2-oxathietanes **1** and **2**, and the oxirane formation reaction with

retention of configuration in the thermolysis of **2**.[5] This stereochemistry suggests another possible mechanism for the Corey–Chaykovsky reaction, *i.e.* the formation and carbon–oxygen ligand coupling reaction[6] of intermediary highly coordinate 1,2-oxathietanes, which prompted us to examine the reactivity of such a species on changing the central atom from sulfur to a heavier chalcogen. Although no oxirane formation was observed in the thermolysis of the first tetracoordinate 1,2λ⁴-oxaselenetanes **3** having no substituent at the 3-position,[7] 3-phenyl derivatives were expected to give the corresponding oxiranes in view of the reactivity of the sulfur analogues. We now report on the first example of oxirane formation from tetracoordinate 1,2λ⁴-oxaselenetanes and the stereochemistry of the reaction.

Tetracoordinate 3-phenyl-1,2-oxaselenetanes **4**‡ were synthesised from **5**[8] by the same method as that for the synthesis of sulfur analogues **1** (Scheme 1).[5]§ The $^{19}F$ and $^{1}H$ NMR spectra of the crude reaction mixtures showed the signals due to the diastereoisomers of **4** in which the phenyl group was *cis* to the lone pair. However, the *cis* isomers were less stable toward hydrolysis than **4** and gradually decomposed in the course of purification. All compounds **4** were stable colourless plates at room temperature in the air. The relative stereochemistry between the 3- and 4-positions of **4c** and **4d** was determined by differential NOE experiments; an NOE between the methine

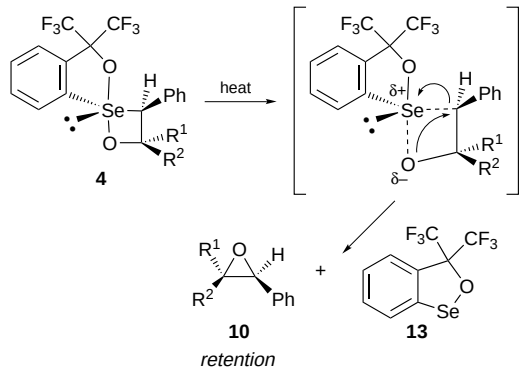


**Scheme 1** *Reagents and conditions*: i, Se, THF, 0 °C, then 25 °C, 12 h; ii, BnBr, 0 °C, then 25 °C, 2 h; iii, aq. $NH_4Cl$; iv, $Bu^tMe_2SiOSO_2CF_3$, $Et_3N$, $CH_2Cl_2$, 0 °C, then 40 °C, 1 d; v, LDA (2 equiv.), THF, −78 °C, 20 min; vi, $R^1R^2C{=}O$, THF, −78 °C, 30 min; vii, flash column chromatography (for **8c** and **8d**); viii, $Bu^n_4NF$ (2 equiv.), THF, 0 °C, 30 min; ix, $Et_3N$ (2 equiv.), $Br_2$ (1 equiv.), $CCl_4$, 0 °C, then 25 °C, 4 h.

proton of the 3-carbon and the *ortho*-protons of the phenyl group of the 4-carbon was observed for **4c** but not for **4d**.

The results of thermolysis ($C_6D_5CD_3$, in a degassed sealed tube) of **4** are summarised in Scheme 2 and Table 1. Although the yield of oxirane **10a** from the 3,4,4-triphenyl derivative **4a** was low because of concomitant phenyl-migrated ketone formation, **4b** gave oxirane **10b** almost quantitatively. Furthermore, thermolysis of **4c** and **4d** afforded the corresponding oxirane stereospecifically in high yield with retention of the relative stereochemistry of the starting oxaselenetanes, although a small amount (2%) of an inverted product was obtained from **4c**.

These results indicate that the stereochemistry of the oxirane formation from 1,2-oxaselenetanes **4** is the reverse of that



**Scheme 2**

**Scheme 3**

expected from the back side attack of the oxido anion, and hence the reaction can be recognised as a carbon–oxygen ligand coupling reaction of λ⁴-selenanes (Scheme 3). In the thermolysis of **4**, migration of the phenyl group on the 4-carbon¶ and deprotonation from the 3-position by the oxido anion can be considered to be sterically inhibited by the phenyl group on the 3-position, which is absent in **3**. Moreover, it can be assumed that the phenyl group on the 3-carbon assists the Se–C bond cleavage by stabilising the anionic character of the 3-carbon induced in the transition state.

In the case of the sulfur analogues **1**,[5a,b] oxirane formation was observed to a minor extent, with fragmentation back to the starting ketone or isomerisation *via* a 1,3-proton shift being the major decomposition pathways; this made it difficult to elucidate the reaction mechanism although oxirane formation from **1** with retention of configuration was observed.[9] In sharp contrast, in the reaction of **4c** and **4d**, yields of oxirane were almost quantitative and the stereochemistry exhibited 96 and 100% retention of configuration, respectively. The present results and the stereochemistry of the thermolysis of **2**[5c] strongly suggest that such a concerted oxirane formation from highly coordinate oxachalcogenetanes generally proceeds regardless of the central atom or its coordination number.‖

This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Area (No. 09239101) (T. K.) from the Ministry of Education, Science, Sports and Culture, Japan. F. ‡ *Selected data* for **4c**: colourless plates (hexane–$Et_2O$); mp 192.4–194.0 °C (decomp.); $^1H$ NMR ($CDCl_3$, 500 MHz): δ 6.21 (s, 1 H, SeC*H*Ph), 7.32–7.41 (m, 3 H), 7.44–7.51 (m, 3 H), 7.54 (d, $^3J$ 7.6, 4 H), 7.64–7.68 (m, 2 H), 7.75–7.81 (m, 1 H), 8.57 (d, $^3J$ 7.9, 1 H); $^{77}Se$ NMR ($CDCl_3$, 95 MHz): δ 792.9 (q, $^4J_{SeF}$ 27). Calc. for $C_{24}H_{15}F_9O_2Se$: C, 49.25; H, 2.58. Found: C, 49.25; H, 2.64%.

For **4d**: colourless plates (hexane–$Et_2O$); mp 149.0–150.5 °C (decomp.); $^1H$ NMR ($CDCl_3$, 500 MHz): δ 6.46 (s, 1 H, SeC*H*Ph), 6.85 (d, $^3J$ 7.4, 2 H), 7.16–7.32 (m, 8 H), 7.74–7.79 (m, 2 H), 7.85–7.90 (m, 1 H), 8.57 (d, $^3J$ 8.0, 1 H); $^{77}Se$ NMR ($CDCl_3$, 51.5 MHz): δ 781.0 (s). Calc. for $C_{24}H_{15}F_9O_2Se$: C, 49.25; H, 2.58. Found: C, 49.39; H, 2.70%. Satisfactory $^{13}C$ and $^{19}F$ NMR spectra were obtained for both **4c** and **4d**.

§ In the synthesis of **8b**, other products formed by an electrophilic reaction of hexafluoroacetone at the *para*-position of the benzyl group were obtained.

¶ The phenyl migration in **4c** and **4d** was additionally retarded by the electronic effect of the adjacent trifluoromethyl group.

‖ Although the stereochemistry of the oxirane formation from 4,4-diaryl-3-phenyl derivatives has not been elucidated, it is unlikely that the trifluoromethyl group at the 4-position changed its stereochemistry completely, because the electron-withdrawing group of the position can electronically stabilise both the ground state and the transition state.

# The crystal packing of bis(2,2′-dipyridylamido)cobalt(II), $Co(dpa)_2$, is stabilized by C–H···N bonds: are there any real precedents?

**F. Albert Cotton,*[a] Lee M. Daniels,[a] Glenn T. Jordan IV[a] and Carlos A. Murillo*[a,b]**

[a] *Laboratory for Molecular Structure and Bonding, Department of Chemistry, Texas A&M University, College Station, TX 77843-3255, USA*

[b] *Department of Chemistry, University of Costa Rica, Ciudad Universitaria, Costa Rica*

**A crystallographic study of $Co(dpa)_2$ reveals that the pseudo-tetrahedral molecules stack together to form a one-dimensional ribbon with the molecules linked together through significant C–H···N interactions; the C···N separation is 3.41(3) Å and the angle at the hydrogen atom is 177(2)°.**

While studying the varied behavior of 2,2′-dipyridylamine, Hdpa, and its anion $dpa^-$, in cobalt complexes[1] we prepared† and structurally characterized‡ the pseudo-tetrahedral complex $Co(dpa)_2$, shown in Fig. 1. The two dpa anions are related by a crystallographic twofold axis and each is nearly planar; the dihedral angle between the two pyridyl rings within the ligand is only 3.6°. This feature is similar to that found for the copper analog.[2]

An analysis of the packing of the molecules in the crystal (Fig. 2) shows a prominent characteristic: the molecules stack in a way that gives an extended array with relatively short C(6)–H(6)···N(2B) contacts. The distances obtained from the X-ray diffraction studies are C(6)–H(6) 0.97(3) Å, H(6)···N(2B) 2.44(3) Å and C(6)···N(2B) 3.41(3) Å; the angle at the hydrogen atom is 177(2)°.

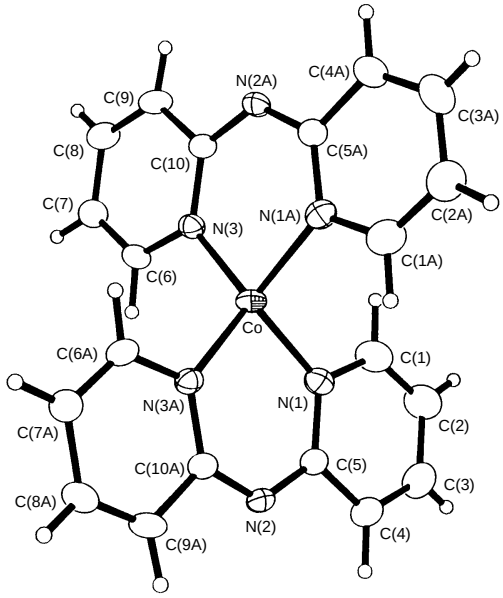

**Fig. 1** Molecular structure of $Co(dpa)_2$. Selected bond lengths (Å) and angles (°): Co–N(1) 1.972(2), Co–N(3) 1.963(2), N(1)–C(1) 1.364(4), N(1)–C(5) 1.367(4), N(2)–C(5) 1.346(4), N(2)–C(10A) 1.344(4), N(3)–C(6) 1.378(4), N(3)–C(10) 1.371(4); N(3)–Co–N(1) 120.66(9), N(3A)–Co–N(1) 94.5(1), C(10A)–N(2)–C(5) 128.2(2).

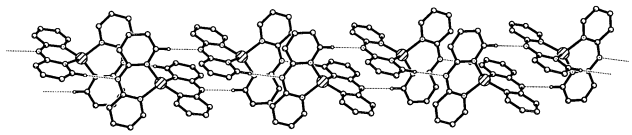

**Fig. 2** Packing diagram of $Co(dpa)_2$ viewed along the *a* axis showing the C–H···N bonds; C···N 3.41(3) Å, C–H 0.97(3) Å, N···H 2.44(3) Å, C–H···N 177(2)°

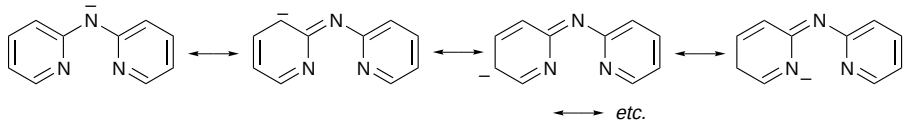

The questions that immediately arise are: how do these distances compare to those in other compounds with C–H···N interactions, and is it 'truly' a hydrogen bond? A superficial check of the literature quickly gives several references to 'C–H···N hydrogen bonds'.[3] However, as one starts to dig into the references to find the 'real examples' they are not easily found. Taylor and Kennard[4] give a few references to such bonds based on neutron diffraction studies. They assumed that C–H···N distances between 2.522 and 2.721 Å were indicative of hydrogen bonding. In their data, C–H···N angles varied from 157.3° to as low as 124.6°. Another system, which contains 1,3,5,7-tetrabromoadamantane, hexamethylenetetramine and $CBr_4$[5] is said to have a C–H···N bond when the C···N distance is 3.77 Å and the angle at the H atom is 151°.

Of course, the importance of hydrogen bonding is unquestionable in many aspects of chemistry,[6] particularly for so-called crystal engineering. As a result of the excitement in this field, the distinction between a simple classical van der Waals interaction and a hydrogen bond is being continuously blurred. A 'hydrogen bond' is regarded as 'any cohesive interaction X–H···Y, where H carries a positive and Y a negative (partial or full) charge',[7] where the angle at H can be anything > 90°, and consequently a 'very distorted geometry cannot be regarded as anomalous'.[8]

This type of very loose working definition has led to the proliferation of very questionable claims of 'hydrogen bonds' such as C–H···O in compounds where the C···O distance is 3.60 Å and the angle at H is 136°[9] or C···O of 3.82 Å and an angle of 154°.[10] Another recent example is the suggestion of 'intermolecular C–H···C interactions' in a complex which has a C···C distance of 3.83 Å and an angle at the H atom of 159°.[11]

It is clear that the field is getting muddier and muddier as the definition of a hydrogen bond is relaxed. What is not clear is why it is justified to continue to publish communications regarding this topic. We strongly disagree with the newer and more relaxed definitions that do not distinguish between a 'hydrogen bond' and what is nothing more than a classical van der Waals interaction.

In $Co(dpa)_2$, the linearity of the C–H···N moiety and the short N···H distance of 2.44 Å are possibly an indication of a relatively important hydrogen bonding interaction, especially when one takes into account that the C–H distance, as determined by X-ray crystallography, is roughly 0.10 Å shorter than the actual distance to the proton that would be determined by neutron diffraction.[12] Consequently, the probable N···H distance is about 2.33 Å. This value is among the shortest of the C–H···Y, Y = N or O distances.[13] A similar N···H interaction is also present in $Cu(dpa)_2$; the distance obtained from an X-ray crystallographic study is 2.52 Å. The reason why a short and possibly real C–H···N hydrogen occurs in $Co(dpa)_2$ is that the N atom doubtless bears a considerable amount of negative charge.

**Scheme 1**

From a valence bond resonance point of view, it appears that distribution of the negative charge on the dpa$^-$ ion away from the N atom from which the proton has been removed is not likely to be very complete, as shown in Scheme 1.

In the case of $Co(dpa)_2$ we believe that it is justified to invoke the existence of a C–H···N hydrogen bond. The sum of the van der Waals radii of H and N (1.2 + 1.5 = 2.7 Å) is significantly longer than the distance found (2.41 Å). Moreover, the C–H···N unit is very nearly linear. In most, if not all, of the previously claimed examples of C–H···N 'hydrogen bonds' the contact is little (or no) different from that expected for an ordinary, classical van der Waals contact and the angles at the H atom are well below (often far below) 180°. While the literature contains numerous allusions to C–H···N 'hydrogen bonds' there seems little if any reason to accept this description. Or, to invoke the parable of the emperor's new clothes, the question of why many people seem to find the emperor well dressed despite any persuasive evidence that he isn't naked, arises. In the packing of molecules containing both C–H bonds and N atoms, there seems to us to be no reason whatever to refer to perfectly normal van der Waals contacts between the two as 'hydrogen bonds'.

Support from the National Science Foundation and the University of Costa Rica is gratefully appreciated.

† In a 100 ml round-bottom flask, 0.963 g (5.62 mmol) of Hdpa was dissolved in 30 ml of toluene. The solution was cooled to −78 °C and 4.1 ml of 1.4 M MeLi was added. The solution immediately turned milky white. The reaction mixture was warmed to near room temp. upon which 0.344 g (2.64 mmol) of anhydrous $CoCl_2$ was added from a solid addition tube. After several min of stirring, 20 ml of thf was added forming a dark red–brown solution. The reaction was stirred overnight at room temp. The majority of the product precipitates from solution as an orange powder. It was collected by filtration, washed twice with small amounts of thf, and dried under vacuum to yield 0.700 g (66.4%) of $Co(dpa)_2$. Crystals were obtained from work-up of the filtrate. The filtrate was evaporated to dryness and then dissolved in 25 ml of toluene to give a deep red-wine solution. This solution was filtered through Celite and layered with 40 ml of hexanes. Red crystals (0.0395 g, 3.75%) grew after two weeks of diffusion. IR (KBr, cm$^{-1}$): 3051w, 1609s, 1533s, 1440vs, 1250m, 1241m, 1146s, 1111w, 1095w, 1045w, 1006s, 894m, 849m, 786m, 767s, 733m, 726m, 656w, 553w. UV–VIS ($CH_2Cl_2$): $\lambda$ = 390, 355, 342 nm.

‡ *Crystal data* for $Co(dpa)_2$: crystal dimensions 0.18 × 0.15 × 0.13 mm, $C_{20}H_{16}CoN_6$, $M$ = 399.32, monoclinic, space group $I2/a$, $a$ = 12.325(1), $b$ = 10.689(5), $c$ = 14.229(1) Å, $\beta$ = 107.94(1)°, $U$ = 1783.4(9) Å$^3$, $Z$ = 4, $D_c$ = 1.487 g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 0.980 mm$^{-1}$. Data were obtained at 213(2) K on a Nonius FAST diffractometer. A total of 1164 unique reflections were collected using ellipsoid-mask fitting within a $2\theta$ range of 45.06°. The structure was solved by the Patterson method and refined by full-matrix least squares on $F^2$. All hydrogens were located from Fourier difference maps and their positional and thermal parameters were refined. The final refinement converged to $R_1$ = 0.038 and $wR_2$ = 0.079 (for 1164 data and 155 parameters). CCDC 182/500.

# *In situ* ligand synthesis and construction of an unprecedented three-dimensional array with silver(I): a new approach to inorganic crystal engineering

**Alexander J. Blake, Neil R. Champness,* Simon S. M. Chung, Wan-Sheung Li and Martin Schröder***

*Department of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD*

**Reaction of 1,2-*trans*-(4-pyridyl)ethene with $AgBF_4$ results in the formation of a three-dimensional network based upon a cyclobutane-linked tetrapyridyl ligand, 1,2,3,4-tetrakis(4-pyridyl)cyclobutane, linked by $Ag^I$ ions; the *in situ* formation of the ligand represents a potential new direction for inorganic crystal engineering.**

Inorganic supramolecular chemistry and the construction of polymeric arrays is an area of great current interest.[1–5] The design of different network topologies *via* ligand design and the use of different transition-metal coordination numbers has resulted in a wide variety of structural motifs.[1–5] More subtle effects on network topology such as anion control[4] and the use of the π–π stacking have received growing attention.[5] During our research into polymeric arrays formed by silver(I) complexes of bipyridyl ligands we have observed a common structural motif of linear chains of alternating Ag ions and linking ligands.[2,4–6] In complexes where the ligand has significant π–π stacking ability, adjacent chains may tend to adopt an arrangement to maximise both π–π stacking and Ag–Ag interactions (Fig. 1).[4–6] However, the reaction of $AgBF_4$ with 1,2-*trans*-(4-pyridyl)ethene revealed an unexpected *in situ* cyclisation to yield the ligand 1,2,3,4-tetrakis(4- pyridyl)cyclobutane which is incorporated within a three-dimensional metal–complex polymeric array.

A crystalline sample from the reaction of $AgBF_4$ and 1,2-*trans*-(4-pyridyl)ethene was prepared in MeCN and $CH_2Cl_2$ in the presence of light. Colourless blocks, suitable for single-crystal X-ray analysis were grown following diffusion of the two solvents over the period of *ca.* one month.†

An X-ray structural determination‡ revealed that the ligand had undergone a [2 + 2] cyclisation to form a tetrapyridyl-substituted cyclobutane ring (Fig. 2). The complex exists as a three-dimensional cationic polymer in which each $Ag^I$ centre is coordinated in a tetrahedral geometry to four pyridyl groups [Ag–N 2.302(4), 2.360(4) Å] each from different 1,2,3,4-tetrakis(4-pyridyl)cyclobutane ligands. The lattice grows so that channels are generated which accommodate the $BF_4^-$ counter anions and MeCN solvent molecules (Fig. 3). These channels are intriguing in that the silver–pyridyl–cyclobutane–pyridyl–silver chain forms a helix which winds around the channel. The handedness of these helices alternates along adjacent channels providing the lattice with no overall chirality. Somewhat suprisingly and unusually for such three-dimensional networks, the lattice fills space efficiently without requiring inter-penetration of independent lattices. We believe that this non-interpenetrating lattice with helical channels is a previously unobserved network topology.

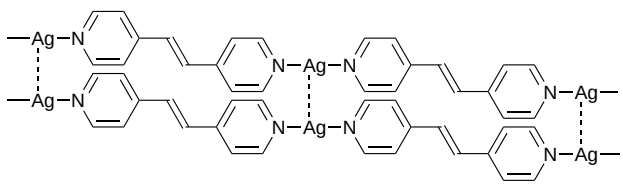

**Fig. 1** The common structural motif of linear chains observed for silver(I) bipyridyl complexes allowing Ag···Ag contacts and π–π interactions

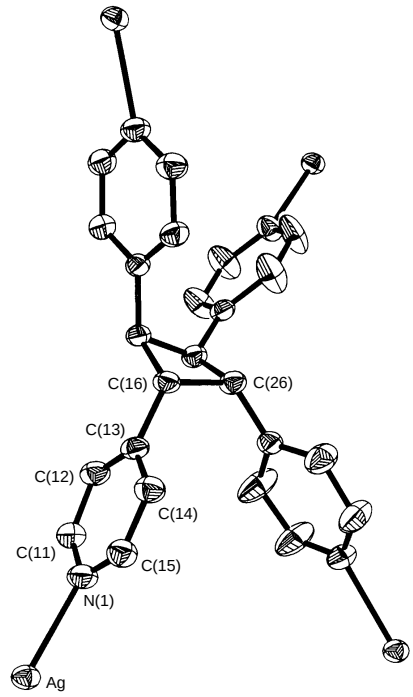

**Fig. 2** View of the structure of 1,2,3,4-tetrakis(4-pyridyl)cyclobutane with $Ag^I$ coordinated to each pyridyl group

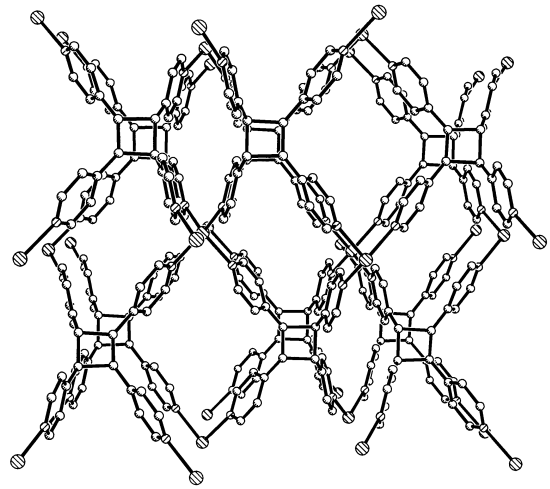

**Fig. 3** View of the polymeric array formed by [Ag{1,2,3,4-tetrakis(4-pyridyl)cyclobutane}]$^+$ illustrating the channels formed

Dimerisation of substituted alkenes is most commonly achieved by UV photolysis.[7,8] Interestingly, UV photolytic dimerisation of 1,2-*trans*-(4-pyridyl)ethene in MeOH or $C_6H_6$ affords two isomers of the ligand, but cyclisation does not occur in the absence of a UV source.[8] Furthermore, 1,2-*trans*-(4-pyridyl)ethene does not dimerise in the solid state, and this has been attributed to an unfavourable arrangement of the ligands within the crystalline lattice.[8] Interestingly, the reaction reported herein produces only a single isomer of the tetrapyridyl ligand (confirmed by NMR studies of the bulk product) consistent with the reaction proceeding in the solid state as outlined by Schmidt *et al.*,[7] and contrary to the reported UV photolytic dimerisation of 1,2-*trans*-(4-pyridyl)ethene in solution which would be expected to give two isomers of the cyclised ligand.[8] Significantly, no dimerisation product was observed in the reaction of $Ag^I$ with 1,2-*trans*-(4-pyridyl)ethene in the absence of light. This indicates a key role of the $Ag^I$ ions in the light-induced dimerisation process, but does not confirm whether the ligand cyclisation occurs in the solid state or in solution.

In conclusion, the reaction of $Ag^I$ with 1,2-*trans*-(4-pyridyl)-ethene represents the first example of the formation of an inorganic three-dimensional lattice *via* the *in situ* generation of a ligand, and the first structurally characterised network incorporating 1,2,3,4-tetrakis(4-pyridyl)cyclobutane. We are currently probing the mechanism of cyclodimerisation reactions and the wider applications of this approach to inorganic crystal engineering.

We thank the Nuffield Foundation (to S. S. M. C.) and EPSRC for funding.

† *Experimental*: {[Ag(1,2,3,4-tetrakis(4-pyridyl)cyclobutane]$BF_4$}$_\infty$. A solution of $AgBF_4$ (50 mg, 0.26 mmol) in MeCN (10 cm$^3$) was layered over a solution of 1,2-*trans*-(4-pyridyl)ethene (bpe) (95 mg, 0.52 mmol) in $CH_2Cl_2$ (10 cm$^3$). The two layers were allowed to diffuse and colourless block crystals were grown over a period of *ca.* one month. The sample was exposed to daylight throughout the experiment. Yield (63 mg, 44%). Satisfactory spectroscopic and analytical data were obtained.

‡ *Crystal data* for {[Ag(1,2,3,4-tetrakis(4-pyridyl)cyclobutane]$BF_4$·3MeCN}$_\infty$: $C_{30}H_{29}AgBF_4N_7$, $M$ = 682.28, orthorhombic, space group *Fddd* (no. 70), $a$ = 10.292(2), $b$ = 29.887(6), $c$ = 38.593(8) Å, $U$ = 11871(4) Å$^3$, $T$ = 150 K, $Z$ = 16, $F$(000) = 5536, $D_c$ = 1.527 g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 0.738 mm$^{-1}$. Colourless crystal (0.48 × 0.36 × 0.36 mm). Stoe Stadi-4 four-circle diffractometer, graphite-monochromated Mo-K$\alpha$ radiation, $\omega$–2$\theta$ scans, data collection range ($\theta_{max}$ = 25.0°). An absorption correction based upon $\psi$-scans was applied to the data ($T_{min}$ 0.645, $T_{max}$ 0.768), 2631 unique reflections, of which 2220 had $F_o > 4\sigma(F_o)$, were used in all calculations. The structure was solved using direct methods[9] and all non-H atoms were located using subsequent difference-Fourier methods.[10] The $BF_4^-$ counter anion was found to be disordered into two equally occupied sites. The two carbon atoms of one acetonitrile solvent molecule were found to be disordered over two equally occupied sites. Hydrogen atoms were placed in calculated positions and were allowed to ride on their parent atoms. All atoms except H, F, B and the disordered carbon atoms of a MeCN solvent molecule were refined with anisotropic thermal parameters. The weighting scheme {$w^{-1} = [\sigma^2(F_o^2) + (0.0756P)^2 + 175.39P]$, $P = [\max(F_o^2,0) + (2F_c^2)/3]$ was adopted. At final convergence[10] $R_1$ [$I > 2\sigma(I)$] = 0.054 $wR_2$ (all data) = 0.147 for 195 parameters, $S$ = 1.041, $(\Delta/\sigma)_{max}$ = −0.002, $\Delta\rho_{max}$ = 0.598 e Å$^{-3}$. # Magnetically induced optical bi-stability of the molecular nanomagnet $Mn_{12}O_{12}(OOCMe)_{16}(H_2O)_4$ in an organic glass

**Myles R. Cheesman,[a] Vasili S. Oganesyan,[a] Roberta Sessoli,[b] Dante Gatteschi[b] and Andrew J. Thomson*[a]**

[a] *School of Chemical Sciences, University of East Anglia, Norwich, Norfolk, UK NR4 7TJ*
[b] *Department of Chemistry, University of Firenze, Firenze, Italy 50144*

**The magnetic hysteresis of the mixed-valence manganese cluster, $Mn_{12}O_{12}(OOCMe)_{16}(H_2O)_4$, ($Mn_{12}$),[1] a molecular superparamagnet,[2] can be optically detected in a dilute, frozen organic glass below the blocking temperature of 3.8 K by magnetic circular dichroism spectroscopy.**

The manganese ions of $Mn_{12}$ form a mixed valence cluster of overall tetragonal symmetry $S_4$, with four inner manganese(IV) ions each of spin $S = 3/2$, surrounded by eight manganese(III) ions of spin $S = 2$ (Fig. 1). Exchange interactions within the cluster result in a total cluster spin of $S = 10$. Anisotropy of uniaxial symmetry, due to the cluster crystalline field, separates the spins into a ladder of energy levels with $M_S = \pm 10$ being lowest in energy, about 60 K below the highest level with $M_S = 0$.[3,4] Thus the spins encounter a thermal barrier to re-orientation at ultra-low temperature and relaxation between sublevels $+S$ and $-S$ is extremely slow.[5,6] Consequently, at low temperatures, hysteresis is observed in the susceptibility as the magnetic field is cycled. Remarkably, hysteresis loops observed with single crystals of $Mn_{12}$, oriented with the unique molecular axis ($Z$) parallel to an applied field, show distinct stepped features at magnetic fields where the energies of different collective spin states of the manganese cluster coincide. This is interpreted as quantum mechanical tunnelling (QMT) of the electron spins through the thermal barrier.[5,6]

Although the absorption spectrum between 400 and 850 nm of an optically clear, organic glass of $Mn_{12}$ is almost featureless, the magnetic circular dichroism (MCD) spectrum[7] shows a series of broad bands of positive and negative signs, Fig. 1. At 1.7 K after application of a polarising field of ±5 T a circular dichroism signal remains at zero magnetic field with an intensity of 30% of the signal at magnetic saturation. The sign of this signal depends on the direction of the polarising magnetic field. Hence the MCD signal reports the previous magnetic history of the sample.

Measurement of the magnetic field dependence of the MCD intensity at a given wavelength at a temperatures below and above the blocking temperature of 3.8 K (Fig. 2) shows a marked hysteresis on cycling the field at 1.7 K but no hysteresis at 4.2 K. It is, at first sight, surprising that significant polarisation remains at zero field since there is no molecular orientation in the glass.

In the case of $Mn_{12}$ the optical selection rules for the cluster electronic states are $\Delta S = 0$ and $\Delta L = +1$ or $-1$ for the absorption of right or left circularly polarised light. It is expected that, in the wavelength region 400–800 nm, single-ion intra-d shell transitions will be present, arising from $^5E_g \rightarrow {}^5T_{2g}$ of $Mn^{III}$ and $^4A_{2g} \rightarrow {}^4T_{1g}$ and $^4T_{2g}$ of $Mn^{IV}$, under $O_h$, although the possibility of oxide to $Mn^{IV}$ charge transfer transitions cannot be excluded.[8,9] Exchange coupling of the $Mn^{III}$ and $Mn^{IV}$ imparts an overall cluster spin to these states. The orbital moments of the excited states dictate the selection rule $\Delta L = \pm 1$. Optical transitions arising from the ground-state spin manifolds $M_S = -S$ and $M_s = +S$ give rise to oppositely circularly polarised transitions whose intensity depends on the population differences between the $\pm S$ levels. Absorption of circularly polarised light requires that the optical transitions being excited have non-zero electric dipole components perpendicular to one another and to the applied field.[10] Hence $Mn_{12}$ cluster subpopulations with particular orientations will be selectively detected if either the Zeeman splitting is highly

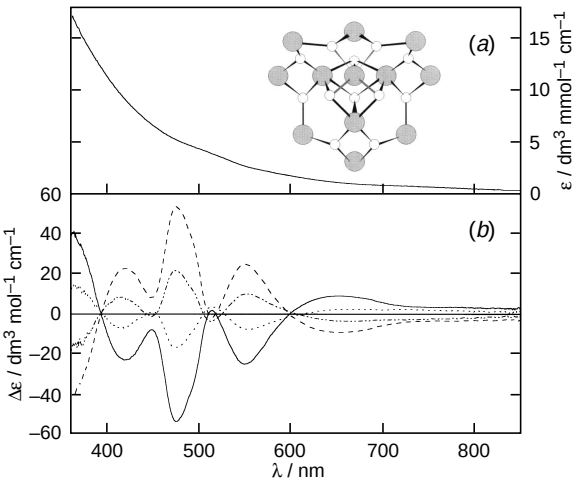

**Fig. 1** (*a*) Absorption spectrum of $Mn_{12}$ at room temperature; (*b*) MCD spectra of $Mn_{12}$ in a frozen organic glass (dmf–MeCN) at 1.70 K and magnetic fields of 5 T (——) followed by reduction of field to zero (·····) and then application of a field of − 5 T (– – –) followed by zero field (–·–·–). MCD spectra are measured as the differential absorption of left and right circularly polarised light, ($\Delta\varepsilon = \varepsilon_L - \varepsilon_R$), by applying a uniform magnetic field parallel to the direction of the light beam.[7]

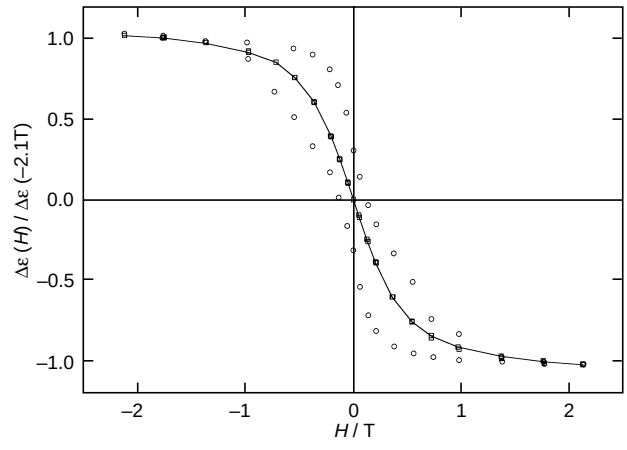

**Fig. 2** MCD magnetisation measured between −2.1 and +2.1 T at 474 nm and at temperatures of (□) 4.2. and (○) 1.70 K of a frozen glass of $Mn_{12}$: upper line, field swept from −2.1 to +2.1 T; lower line, field swept from +2.1 to −2.1 T. Each point was determined by changing the magnetic field to a new value in steps of 0.1–0.2 T and allowing the MCD signal to become static, a period of 20–30 s. No further change in the MCD signal was observed over a period of several minutes. The solid line is the simulated curve for a multi-step Orbach process with orientational averaging.

anisotropic or the optical transitions are strongly polarised. The field dependences of the MCD intensities, at temperatures above the blocking temperature, are sensitive to the linear polarisation of optical transitions, that is, whether they are polarised *XY* and *XZ* (or *YZ*).[11] The MCD magnetisation at 550 nm can be fit well to the case of a purely *XY* polarised transition whereas that of 475 nm component corresponds to an equal mixture of *XY* and *XZ* (or *YZ*) polarisation (data not shown). Thus MCD hysteresis can be detected *via* an optical transition which has mixed polarisation presumably because of the high *g*-value anisotropy, $g_{//} = 40$, $g_{\perp} = 0$, within the $M_S = \pm 10$ pair of ground levels.

Attempts have been made to simulate the MCD and susceptibility hysteresis curves using a model in which relaxation takes place between two potential wells *via* a multi-step Orbach process. In this model the system is excited from one spin level to the next, until it reaches the top of the anisotropy barrier, followed by decay to the bottom of the other well.[12] A phonon density distribution curve was used resulting in a single-parameter model giving a simulation of the effective rate which depends only on the spin–lattice relaxation rate. The simulation reproduces the overall form of the susceptibility curves, including the fields at which the polarisation falls to zero at three different temperatures, and the MCD curves at 4.2 K (Fig. 2). However, it fails to account adequately for the MCD hysteresis seen at 1.7 K. This is probably due to the importance of QMT effects at lower temperatures.[5,6,13–16]

In conclusion, we have shown that the MCD spectra of $Mn_{12}$ allow ground-state hysteresis effects to be measured even in randomly oriented molecular arrays. The MCD method offers a rapid method of surveying molecular paramagnets with potentially interesting properties. The shape of the curves suggests the need to include quantum tunnelling effects before the MCD hysteresis behaviour can be fully understood. But the feature of most significance reported here is that the resultant solutions are optically bi-stable and the effects can be induced or erased by application of a magnetic field. These properties suggest means of storing information in molecular magnetic devices with potential applications as quantum computers. Optical methods of addressing such molecules have the advantage of sensitivity and high speed combined with narrow band widths.

# The first crystal structure determination of biphosphole–transition-metal complex: crystal structure of square-planer *meso*-[Pd(3,3′,4,4′-tetramethyl-1,1′-diphenyl-2,2′-biphosphole)$_2$][$BF_4$]$_2$

**Takahiko Kojima, Kaoru Saeki, Kazuhiro Ono, Masaaki Ohba and Yoshihisa Matsuda***

*Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-Ku, Fukuoka 812-81, Japan*

**The first X-ray crystal structure determination of a biphosphole–transition-metal complex is reported; the square-planar palladium(II) complex has unique intramolecular π–π interaction between phenyl groups on chiral phosphorus atoms of two biphosphole ligands.**

Chelating phosphine ligands have contributed to the consstuction of a fertile background for organometallic chemistry and organometallic catalysis such as hydroformylation, hydrogenation, *etc*. Among these chelating phosphine ligands, we have focused on ligands in which the phosphorus atom is involved in conjugated π systems such as phosphorins (phosphabenzenes) and phospholes (phosphapyrroles) that have been synthesized by Mathey and coworkers.[1] These ligands are expected to give the metal center some intriguing properties which are different from those of usual tertiary phosphine–metal complexes. Therefore, we started our project to develop P-containing macrocyclic π-conjugation systems including phosphorus porphyrins and to investigate the properties and reactivity of those transition-metal complexes in low valence states. This is in sharp contrast to the fact that higher valent and hard metal ions are favored in metalloporphyrins.

As for transition-metal–phosphole complexes, only monodentate phosphole complexes have been synthesized and characterized.[2] However, there are no reports on metal complexes containing chelating phosphole ligands. Here, as an initial attempt toward the goal mentioned above, we describe the synthesis and characterization of a novel Pd complex containing a chelating biphosphole ligand, 3,3′,4,4′-tetramethyl-1,1′-diphenyl-2,2′-biphosphole (bidmpp).[3]

[Pd(bidmpp)$_2$][$BF_4$]$_2$ **1** was synthesized in moderate yield *via* ligand substitution between [Pd(MeCN)$_4$][$BF_4$]$_2$ and bidmpp in $CH_2Cl_2$.†

X-Ray crystallography of **1** showed a structure with an inversion center at palladium (Fig. 1);‡ the square-planar $Pd^{II}$ ion being surrounded by four phosphorus atoms [Fig. 1(*b*)]. The Pd–P bond lengths were all 2.343(3) Å and the bite angle of bidmpp [P(1)–Pd–P(2)] was 84.5(1)°, both of which were comparable to those found in homoleptic [Pd(dppe)$_2$]$^{2+}$ [dppe = 1,2-bis(diphenylphosphino)ethane].[4] The geometry around the phosphorus atoms of bidmpp was distorted tetrahedral [C(1)–P(1)–C(4) 92.4(6)°, Pd–P(1)–C(1) 133.1(4)°, C(13)–P(2)–C(16) 92.3(6)° and Pd–P(2)–C(16) 129.5(4)°]. The configuration of the chiral phosphorus atoms of bidmpp in **1** was (*S*),(*S*),(*R*),(*R*), for P(1), P(2), P(1*), P(2*), respectively; the structure determined by X-ray analysis was a *meso* form. The chirality of conformation of both chelate rings were λ for the (*S*,*S*)-bidmpp and δ for the counterpart. Owing to the steric hindrance of the methyl groups on the phosphole rings, bidmpp is compelled to be chiral and the conformation is rigid. As observed in the crystal structure, the interatomic distance between the two nearest methyl groups [C(6) and C(17)] was 3.87 Å and the dihedral angle between two phosphole rings was 126.6° so as to avoid repulsion. In this configuration, phenyl rings on the same side of the Pd coordination plane were cofacial as shown in Fig. 1(*b*) and exhibited an intramolecular π–π interaction [C(12)··C(20*) 3.41 Å, C(11)··C(21*) 3.65 Å]. This type of π–π interaction has not been reported previously even in similar complexes such as [Pd(dppe)$_2$]$^{2+}$ or [Ni(3,3′,4,4′-tetramethyl-1,1′-diphenyl-2,2′,5,5′-tetrahydro-2,2′-biphosphole)$_2$]$^{2+}$.[4,5]

$^1$H and $^{31}$P NMR studies revealed the existence of two species, *meso*- and *rac*-**1** (Fig. 2). In the $^1$H NMR spectrum in $CD_2Cl_2$, peaks assigned to methyl protons were observed at δ 2.22 (d, *J* 1 Hz) and 1.94 for *meso*-**1** and δ 2.36 (d, *J* 1 Hz) and 1.78 for *rac*-**1**. Even when the crystals of **1** were dissolved into

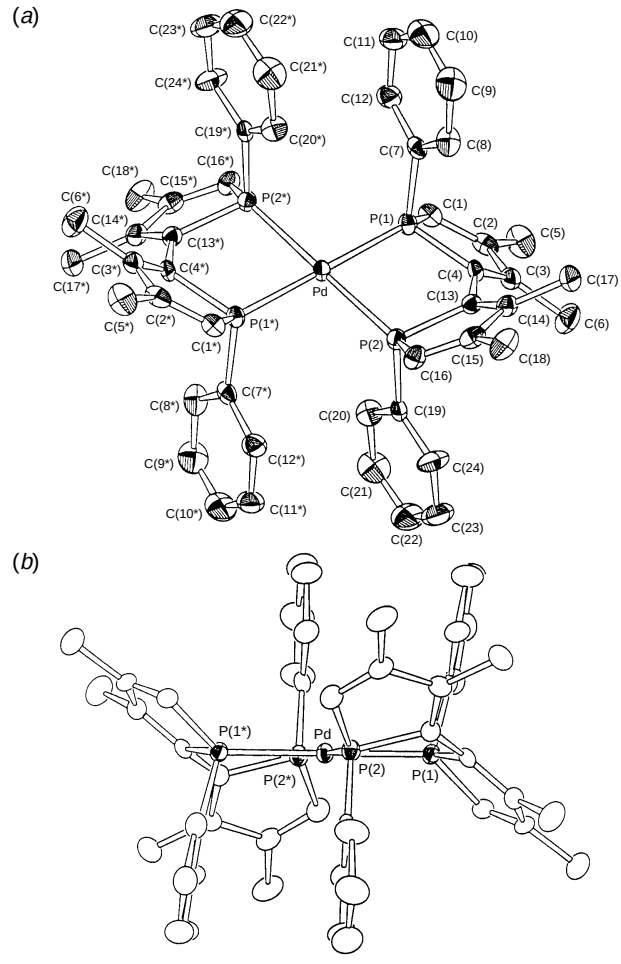

**Fig. 1** An ORTEP drawing of the dication of **1** (*a*) and a side view (*b*) with thermal ellipsoids at 30% probability level. Selected bond lengths (Å) and angles (°): Pd–P(1) 2.343(3), Pd–P(2) 2.343(3), P(1)–C(1) 1.78(1); P(1)–C(4) 1.79(1), P(1)–C(7) 1.82(1), C(1)–C(2) 1.34(2), C(2)–C(3) 1.49(2), C(3)–C(4) 1.34(2), C(2)–C(5) 1.49(2), C(3)–C(6) 1.50(2), C(4)–C(13) 1.46(2), P(1)–Pd–P(2) 84.5(2), P(1)–Pd–P(2*) 95.5(1), C(1)–P(1)–C(4) 92.4(6), C(1)–C(2)–C(3) 114(1), C(2)–C(3)–C(4) 113(1), C(3)–C(4)–C(5) 113(1), P(1)–C(4)–C(3) 109.8(9).

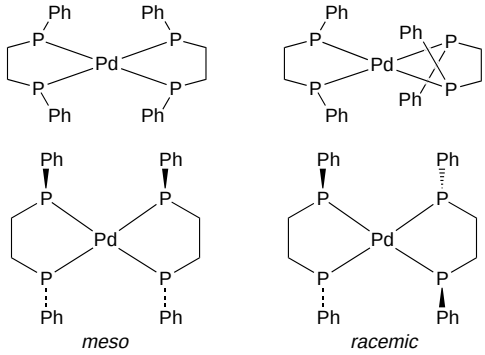

**Fig. 2** Possible isomers for $[Pd(bidmpp)_2]^{2+}$

$CD_2Cl_2$, two sets of peaks were observed, suggesting interconversion between the *meso* and *rac* forms. We distinguished them by their different solubility in $CHCl_3$ or $CH_2Cl_2$; the solubility of *meso*-**1** was much lower than that of *rac*-**1**. The ring proton signal of free bidmpp was observed at $\delta$ 6.41 as a multiplet in $CD_2Cl_2$ whereas those of the Pd-bound bidmpp showed downfield shifts from that of free bidmpp to overlap with phenyl proton resonances at $\delta$ *ca.* 7.3 and 7.7 for *meso*- and *rac*-**1**, respectively. We could detect the ring proton resonances by $^1$H–$^1$H COSY to observe cross peaks due to long-range coupling with methyl protons, however we were unable to determine the exact chemical shifts and the coupling constants because of overlap.

The $^{31}$P NMR spectrum of **1** in $CD_2Cl_2$ showed two singlets at $\delta$ 34.5 for *rac*-**1** and at $\delta$ 37.3 for *meso*-**1**. The assignments were made by comparing the integration of peaks in the $^{31}$P NMR spectrum with that in the $^1$H NMR spectrum. Both of the resonances were downfield shifted from free bidmpp ($\delta$ 17.6). Combined with the observation in $^1$H NMR spectroscopy, the bidmpp binds to the Pd center predominantly through σ-donation as observed in other tertiary phosphine complexes. The coordination shift of **1** in the $^{31}$P NMR spectrum is 17–20 ppm, which is much smaller than that of homoleptic $[Pd(dppe)_2]Cl_2$ in $CDCl_3$ ($\Delta\delta$ = 68.1 ppm).[6] Therefore, it is suggested that π-back bonding from the Pd center contributes to some extent to stabilize **1**, concomitant with σ-donation to the metal center.[2b]

We appreciate Professor F. Mathey (Ecole Polytechnique, France) for his helpful suggestion to synthesize bidmpp.

† $[Pd(bidmpp)_2[BF_4]_2$ **1** was synthesized as follows: To a suspension of $[Pd(MeCN)_4][BF_4]_2$ (0.25 mmol) in $CH_2Cl_2$ (12 ml), was added a solution of bidmpp (200 mg, 0.53 mmol) in $CH_2Cl_2$ (3 ml) to give a reddish orange solution within 5 min. The solution was stirred for 30 min at room temp. and filtered through a Celite column. After removing the solvent, the residue was dissovled into a small volume of $CH_2Cl_2$ and then poured into hexane with stirring to obtain a reddish orange powder of **1** in 71% yield. Calc. for $C_{48}H_{48}B_2F_8P_4Pd$: C, 56.04; H, 4.70. Found: C, 55.67; H, 4.74%. FABMS: 941.2 ($[M - BF_4]^+$).

‡ A single crystal of **1** was obtained by recrystalization from $CH_2Cl_2$. *Crystal data*: $C_{48}H_{48}B_2F_8P_4Pd$, $M$ = 1028.81, orange prismatic (0.20 × 0.20 × 0.20 mm), trigonal, space group $R\bar{3}$, $a = b$ = 31.21(3), $c$ = 14.41(2) Å, $U$ = 12154(13) Å$^3$, $Z$ = 9, $D_c$ = 1.265 g cm$^{-3}$, $\mu$(Mo-Kα) = 5.19 cm$^{-1}$, $R$ = 0.055, $wR_2$ = 0.086 for 2492 refrections with $I > 3\sigma(I)$. Structural refinements and calculations were performed using the teXsan crystallographic software package. The structure was solved by direct methods and all non-hydrogen atoms were refined anisotropically. All hydrogen atoms were located at calculated positions but not refined. We could not determine the solvent molecules ($CH_2Cl_2$) of crystallization due to their partial dissipation and severe disorder; a differential Fourier map showed the $CH_2Cl_2$ molecules located at a special position on a threefold axis. # Towards golf ball shaped reagents: dendrimer fixed concave pyridines

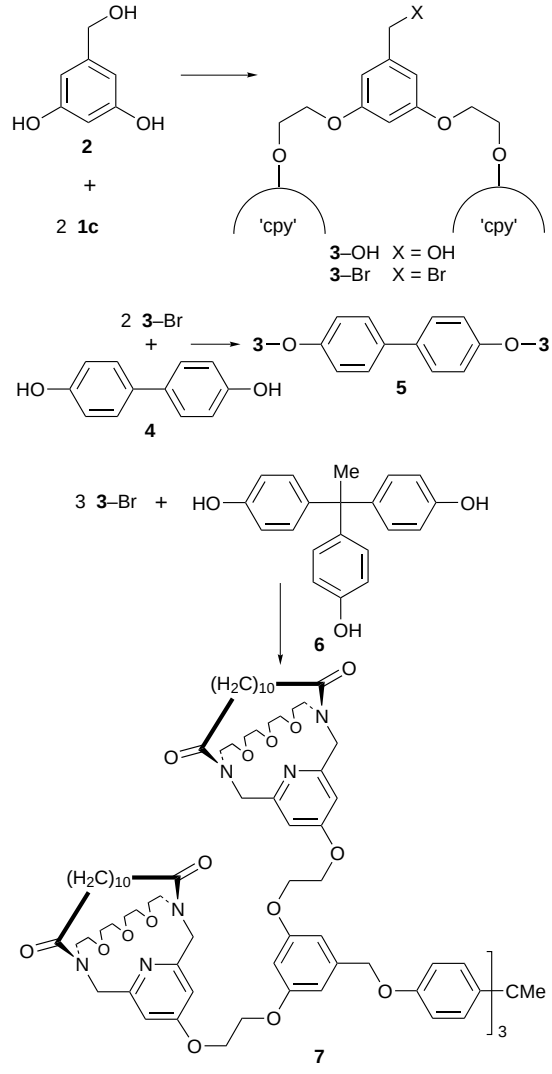
**Torsten Marquardt and Ulrich Lüning***

*Institut für Organische Chemie der Christian-Albrechts-Universität zu Kiel, Olshausenstraße 40, D-24098 Kiel, Germany*

**Two first generation dendrimers 5 and 7 carrying four and six concave pyridines on their surface have been synthesized by convergent synthesis; they have been applied as catalysts in selective acylations, and 7 can be separated from smaller molecules by nanofiltration.**

According to the concept of concave reagents,[1] a variety of bimacrocyclic concave acids and bases such as pyridines **1**, 1,10-phenanthrolines, carboxylic acids, sulfinic acids and bridged calixarenes have been synthesized by incorporation of an appropriate functional group into a concave environment.[2] The concave reagents have been investigated in a variety of model reactions and increases in selectivity by the use of these reagents have been achieved. As the synthesis is rather tedious and the recovery of these concave reagents has not yet been solved satisfactorily, larger scale application has not been realized up to now. The recovery problem can be avoided by using polymeric reagents.

**1a** R = Me
**b** R = $CH_2CH_2OH$
**c** R = $CH_2CH_2I$
**d** R = $CH_2CH_2$–Merrifield polymer
**e** R = $CH_2CH_2$–poly(vinylbenzyl chloride)



Here we describe the synthesis of the first generation of dendrimer fixed concave pyridines **1**. The fixation of a concave pyridine **1b** to a Merrifield polymer resin giving **1d** has been described.[3] Because of the insolubility of this functionalized resin, **1d** could only be used as a heterogeneous reagent or catalyst. Soluble polymers combine the advantages of common soluble reagents with attributes of solid phase reagents. Soluble polymers can be separated from the reaction products by ultrafiltration. In the case of linear polymers the problem of reptation through the semipermeable membrane must be overcome. It should be avoided by the use of soluble branched polymers.

These reflections consequently lead to dendrimer-fixed concave pyridines. Dendrimers are highly branched macromolecules with well-defined structures[4] which are rather easy to characterize because they possess a single molecular weight. We chose the poly(aryl alkyl ether) dendrimers developed by Frechet and Hawker[5] as the main frame, which are synthesized by a convergent route. The concave pyridine **1c** was fixed on the dendritic structure *via* its convex back side by a spacer.

In contrast to the polymers **1d** and **1e**, the fractional coverage of the dendrimers functionalized by concave pyridines (**5** and **7**) is 100% (83 wt%) [Merrifield polymer **1d**: 9% (20 wt%); linear soluble polymer **1e**: 29% (60 wt%)]. This guarantees the absence of other functional groups on the surface, and optimizes these fixed concave pyridines **5** and **7** for applications.[6]

The products **5** and **7**† were synthesised according to Scheme 1 and characterized by $^1$H NMR spectroscopy. Because of the large number of aliphatic protons in the side chains of the concave pyridines, the important portion of the spectra is between 4.5–8.5 ppm and contains the absorbtions of the aromatic and benzylic protons. The ratio between the aromatic pyridine protons and the aromatic phenyl protons, as well as the ratio between the aromatic (6.5–7.5 ppm) and benzylic protons (4.5–5.4 ppm), was diagnostic. These results and the $^{13}$C NMR spectra elucidated the structures of **5** and **7**.

The functionalized dendrimers **5** and **7** showed the same behaviour as the analogous unfixed concave pyridines **1a**, **1b** and **1c**. Three different amide conformers could be observed in the $^1$H NMR spectra of **5** and **7**, in the same ratio as it had been observed in solutions of the unfixed concave pyridines **1a**, **1b** and **1c**.[8] Because the dendrimer-fixed concave pyridines **5** and

**Scheme 1**

**Table 1** Selectivity increase in the base-catalysed acylation of primary, secondary and tertiary alcohols with diphenylketene[a]

| Catalyst | Selectivity | | |
|---|---|---|---|
| | EtOH | $Pr^iOH$ | $Bu^tOH$ |
| Pyridine | 4.7 | 1 | 0 |
| Lutidine | 7.1 | 1 | 0 |
| **1a** | 12.0 | 1 | 0 |
| **1e** | 9.5 | 1 | 0 |
| **1d** | 7.4 | 1 | 0 |
| **5** | 11.6 | 1 | 0 |
| **7** | 11.4 | 1 | 0 |

[a] Conditions have been described previously (ref. 6).

**7** showed the same conformer ratio, it might be expected that the selectivity increase in the model reaction would also be the same. This assumption was checked in the base catalysed acylation of primary, secondary and tertiary alcohols with diphenylketene in an intermolecular competition reaction.[6] As Table 1 shows, the selectivity increase was the same as found for the unfixed concave bases, such as **1a**, but better than the increase produced by the use of concave pyridines fixed on linear polymers **1e**, and much better than that produced by the use of concave pyridines fixed on the Merrifield polymer resin **1d**.

With **5** and **7**, the first two dendrimers loaded with concave reagents with molecular weights of 2557 (**5**) and 3863 (**7**), respectively, have been synthesized. Compound **7** is large enough to be filtered off by nanofiltration. Retention and permeation have been checked gravimetrically. It can be recovered in good yield (70–90%) from a $CH_2Cl_2$ solution using a nanofiltration membrane. Therefore dendrimer-fixed concave pyridines can be recycled from batch reaction mixtures by nanofiltration. For a continuous process, however, the retention needs to be optimized. This should be possible with higher generations of dendrimer-fixed concave pyridines. In these higher generations the coverage of the surface by concave reagents will increase, finally reaching an overall geometry which resembles a golf ball.

We thank Dr M. Felder and Dr U. Kragl at the Forschungszentrum Jülich for carrying out the nanofiltration experiments.

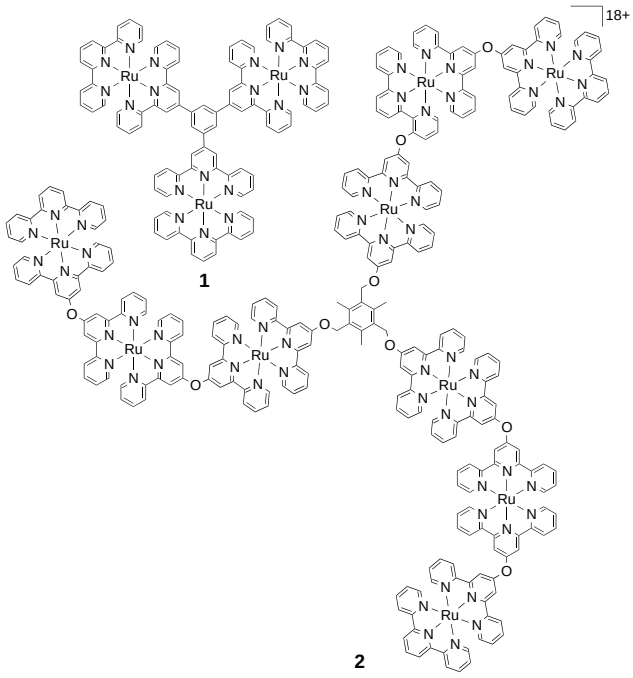
# Adsorption of ruthenadendrimers to silica–titania surfaces studied by optical waveguide lightmode spectroscopy (OWLS)



**Edwin C. Constable,[a] Peter Harverson[a] and Jeremy J. Ramsden*[b]**

[a] *Department of Inorganic Chemistry, University of Basel, Spitalstrasse 56, 4056 Basel, Switzerland*
[b] *Department of Biophysical Chemistry, University of Basel, Klingelbergstrasse 70, 4056 Basel, Switzerland*

**Kinetic analysis of the assembly of metallodendrimers at silica–titania surfaces shows that the deposition mode strongly depends on the bulk concentration.**

Metallodendrimers are potentially key components for future generations of ultraminiature computing, sensing and photoconversion devices. We are developing a methodology for the incorporation of metallodendrimers into nanostructured composites that relies on the assembly of mono- or multi-layers on substrate surfaces in contact with solutions of the desired component. Here we describe the use of optical waveguide lightmode spectroscopy (OWLS) for studying the assembly of surface layers of metallodendrimers on smooth silica–titania.

Our initial studies were made on the rigid triruthenium complex **1**[1] and the more flexible nonaruthenium compound **2**.[2] The measurements are based on the observation that the modes of an unclad waveguide shift their energies in response to

changes in the waveguide environment.[3,4] Planar optical waveguides are particularly convenient for probing surface deposition processes[4,5] not only because of their well defined geometry, but also because they can be fabricated from a wide variety of different materials. The mode spectrum can be very conveniently and accurately measured using a grating coupler.[6] In order to maximize the sensitivity of the measurements,[6] we used thin waveguides supporting only the zeroth order transverse magnetic (TM) and transverse electric (TE) modes. Measurement of the mode energies, expressed as effective refractive indices *N*, enabled the two optogeometric parameters characterizing the deposited layer, thickness $d_A$ and refractive index $n_A$, to be determined.[4,6] From these the surface density (Gibbs excess) $\Gamma$ in molecules per unit area can be calculated from:[4]

$$\Gamma = d_A(n_A - n_C)/(\mathrm{d}n/\mathrm{d}c) \quad (1)$$

where $n_C$ is the refractive index of the covering medium (in our case, acetonitrile), and d*n*/d*c* is the refractive index increment of the compound, determined using a Rayleigh interferometer (1.45 and 0.49 dm$^3$ mol$^{-1}$ for **1** and **2**, respectively). As substrates for adsorption, we used Si(Ti)$O_2$ planar optical waveguides. They were fabricated by oxidatively sputtering a Si/Ti target onto an optical glass support into which a shallow (*ca*. 10 nm) grating coupler (grating constant $\Lambda$ = 833.3 nm) had been photolithographically etched. Their surface composition was $Si_{0.76}Ti_{0.24}O_2$, measured using X-ray photoelectron spectroscopy, and their mean roughness was 0.12 ± 0.05 nm, measured using atomic force microscopy. A cylindrical cuvette (diameter = 9 mm) was sealed to the grating region of the waveguide using a 'Kalrez' o-ring and the mode spectrum measured at 632.8 nm. The baseline spectrum was recorded with pure acetonitrile (Baker spectroscopic grade) flowing through the cuvette. Flow was then switched to a solution (concentration $c_b$) of **1** or **2** in acetonitrile, while continuing to measure the mode spectrum. After an adsorption plateau appeared to have been attained, flow was switched back to pure acetonitrile. Desorption was negligible, except for the deposition of **2** at the largest bulk concentration tested (0.2 mM).

Transport to the surface is *via* convective diffusion and hence governed by a law of the type:

$$\mathrm{d}\Gamma/\mathrm{d}t = Dc_b/\delta \quad (2)$$

where $\delta$ is the thickness of the diffusion boundary layer[7] (*ca*. 80 μm in our experiments[8]), and *D* the diffusivity of the molecules in acetonitrile (estimated from the dimensions of the molecule as $8 \times 10^{-6}$ cm$^2$ s$^{-1}$).

Fig. 1 shows representative measurements of $\Gamma$ *vs. t*. The initial deposition rates d$\Gamma$/d*t* are much lower than predicted by eqn. (2), implying that energy barrier and/or orientational

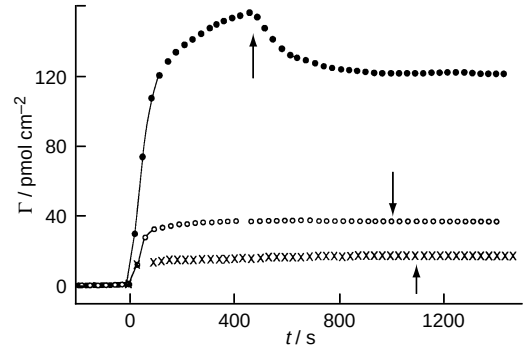


**Fig. 1** Representative experimental data: (×) **1**, $c_b$ = 4 μM; (○) **2**, $c_b$ = 2 μM; (●) **2**, $c_b$ = 200 μM. Bulk flow was switched to the ruthenadendrimer solution at $t$ = 0. The arrows denote when the flow reverted to pure buffer.

factors result in not every adsorption attempt being successful. Furthermore, the rate of deposition decreases with time, but since there is no desorption, this cannot be due to the establishment of an equilibrium, but rather to the progressive blockage of the adsorbing surface as molecules adsorb. Hence eqn. (2) must be modified to take these effects into account.

We do this by considering a layer of solution just above the plane of adsorption. Let the concentration of metallodendrimers in this plane be $c_1$. The rate of deposition is, per unit area $S$ of surface, $Sk_ac_1\phi$. The chemical rate constant $k_a$ is to a first approximation proportional to the product $\kappa\exp(-E_a)$, where $\kappa$ is the probability that the incoming molecule arrives in an orientation permitting incorporation into the surface adlayer, and $E_a$ is the energy barrier (electrostatic, *etc*.) hindering adsorption. $\phi$ is the fraction of the surface available for adsorption. Since the molecules are deposited at random onto a continuum, the dependence of $\phi$ on $\theta$, the fraction of the surface occupied ($\theta = \Gamma a$, $a$ being the area occupied per molecule) is not straightforword.[9,10] Analysis of the geometry of deposition, using the concept of exclusion zones, leads to the expression:[9]

$$\phi = \frac{(1-\tilde{\theta})^3}{1-0.812\tilde{\theta}+0.2336\tilde{\theta}^2+0.0845\tilde{\theta}^3}. \qquad (3)$$

Here $\tilde{\theta} = \theta/\theta_J$; $\theta_J$ (*ca*. 0.55 for disk-shaped objects[9]) is the jamming coverage, at which no spaces large enough to accept a further molecule exist on the surface.

Diffusion from the bulk to the layer above the surface follows the usual Fick–Smoluchowski kinetics, and hence

$$(V/S)(dc_1/dt) = (c_b - c_1)D/\delta - k_ac_1\phi \qquad (4)$$

where $V$ is unit volume. By letting the left hand side go to zero, an expression for $c_1$ is obtained, which is used to obtain a corrected rate law:

$$d\Gamma/dt = c_b/[\delta/D + 1/(k_a\phi)] \qquad (5)$$

This equation was fitted to the experimental data transformed by numerical differentiation into $d\Gamma/dt$ *vs*. $\Gamma$ plots, with $a$ and $k_a$ as free parameters. The results are given in Table 1. Also shown in the extreme right hand column is the product of the apparent plateau value of $\Gamma$ read off the experimental curves and the fitted $a$: the agreement with the expected jamming coverage $\theta_J$ of 0.55 is satisfactory. This is itself a strong indication that the random sequential adsorption (RSA) model[9,10] applies; further evidence is that eqn. (5), with $\phi$ given by eqn. (3), fitted all the transformed curves (except for compound **2** at $c_b$ = 20 nM, for which the $\Gamma$ *vs. t* plot consisted of two linear portions). There was no evidence for surface diffusion of the adsorbed molecules (which leads to $d\Gamma/dt$ decreasing linearly with $\Gamma$).[11]

**Table 1** Parameters derived from fitting eqn. (5) to the experimental data

| | $c_b$/μM | $a$/nm² | $k_a$/cm s$^{-1}$ | $\Gamma_\infty{}^a$/ pmol cm$^{-2}$ | $a\Gamma_\infty{}^b$ |
|---|---|---|---|---|---|
| **1** | 0.4 | 5.7 | $2.1 \times 10^{-3}$ | 16 | 0.61 |
| | 4 | 6.0 | $2.0 \times 10^{-3}$ | 17 | 0.56 |
| | 40 | 5.7 | $2.0 \times 10^{-3}$ | 17 | 0.58 |
| **2** | 0.02 | —[c] | $1.6 \times 10^{-4}$ [c] | 35 | —[c] |
| | 0.2 | 2.3 | $1.4 \times 10^{-1}$ [d] | 42 | 0.58 |
| | 2 | 2.4 | $7.0 \times 10^{-3}$ | 40 | 0.58 |
| | 20 | 1.8 | $2.0 \times 10^{-4}$ | 55 | 0.59 |
| | 200 | 0.51 | $4.3 \times 10^{-5}$ | 42 | 0.51 |

[a] The value of $\Gamma$ at saturation, estimated from the experimental curves. [b] *i.e.* $\theta_J$ (*cf.* the theoretial value of 0.55 for spheres/disks[9]). [c] Could not be determined since eqn. (5) did not fit the data. $\Gamma(t)$ consisted of two linear portions, with slope 3.2 fmol cm$^{-2}$ s$^{-1}$ initially, up to $\Gamma$ = 27 pmol cm$^{-2}$, *i.e.* $\theta \approx 0.4$, assuming $a \approx 2.4$ nm², and 0.3 fmol cm$^{-2}$ s$^{-1}$ thereafter, with no indication of exclusion effects. The given value of $k_a$ was obtained by dividing the initial rate by $c_b$. [d] Preceded by a linear portion up to $\Gamma$ = 34 pmol cm$^{-2}$ yielding $k_a = 4.6 \times 10^{-4}$ cm s$^{-1}$.

Compound **1** followed pure random sequential adsorption kinetics. The parameters were almost invariant with $c_b$ and consistent with the molecule lying flat on the surface.

Compound **2** behaved in a more complicated way, which differed qualitatively over the concentration range investigated. Since the molecule can adsorb to the surface in various conformations, the parameter $a$ must be interpreted as an average area. Surprisingly, even though **2** is much bigger than **1**, the area it occupies is much smaller. We interpret this as the molecule attaching itself to the surface with only one of its arms. At the highest bulk concentration (0.2 mM), the adsorption shows a qualitatively different pattern: the amounts adsorbed are much higher, and unlike the layers assembled from lower $c_b$, they desorb to a significant degree. This appears to indicate the formation of a second layer only weakly attached to the first and hence removable upon dilution of the cover solution, an inference supported by the mean thicknesses $d_A$ *ca*. 0.5 nm for $c_b \leqslant 20$ μM and 2.2 nm for $c_b \geqslant 0.2$ mM ('mean thickness' refers to the mean distance of the optically densest portion of the molecule from the adsorbing surface). The very small fitted $a$ for $c_b$ = 0.2 mM partly reflects the formation of the second layer, but it is in fact much less than half the value given by the lower $c_b$, and hence indicates that the molecules pack into a much more compact conformation within the layer. We propose that this is achieved *via* lateral interpenetration of the dendrimers: the RSA theory as developed hitherto[9,10,12] only considers smooth geometrical objects such as spheres, ellipsoids, *etc*.

These results demonstrate the primordial importance of bulk concentration in directing the self-assembly of complex molecules at surfaces.

# (*cis*)-5,10,15,20-Tetrakis[2-(arylurea)phenyl]porphyrins: novel neutral ligands for remarkably selective and exceptionally strong chloride anion complexation in $(CD_3)_2SO$

**Raymond C. Jagessar and Dennis H. Burns***

*Department of Chemistry, Wichita State University Wichita, Kansas 67260-0051, USA*

**Urea appended free-base porphyrins 2–4 bind strongly ($K$ > $10^5$ dm$^3$ mol$^{-1}$) to spherical $Cl^-$ in $(CD_3)_2SO$ and exhibit significant binding selectivity since they complex with $Cl^-$ to a much greater extent ($10^3$–$10^2$ : 1) than with the trigonal $NO_3^-$ and tetrahedral $H_2PO_4^-$ anions.**

The importance of anion binding and transport in chemical and biochemical processes has been the impetus for the design and fabrication of supramolecular anion receptors.[1] We have begun a project to prepare neutral anion receptors that exhibit selective anion binding, ultimately for the development of sensors and transport mimics that function in an aqueous environment. Here, we report the synthesis (Scheme 1) of our initial receptors **2**–**7**, superstructured porphyrins functionalized with urea moieties. Owing to the different pocket size and orientation of urea groups on the porphyrin scaffolding, it was anticipated that **2**–**4** would exhibit different aptitudes and selectivities for anion complexation than those seen with the previously prepared urea appended receptors.[2–6] Furthermore, the addition of electronegative substituents (Cl, F) to the *para* position of the phenyl rings of **3** and **4**, as well as the porphyrin's ability to bind metals in its core, allow for the moderation of the strength and selectivity of anion binding for the supramolecule.

**Scheme 1**: *Reagents and conditions*: i, *p*-$RC_6H_4NCO$, $CHCl_3$, room temp.; R = H (**2**, **5**, **8**), Cl (**3, 6, 9**) or F (**4**, **7**, **10**)

These receptors are the first example of a class of neutral, free-base porphyrins† able to act as very selective anion receptors, with **2**–**4** binding $Cl^-$ greater than 1000 : 1 compared to $NO_3^-$ or 280 : 1 compared to $H_2PO_4^-$ (*vide infra*) ($Cl^-$ receptors are biologically relevant, for $Cl^-$ ion channels are involved in the facilitated exchange of $Cl^-$ for $HCO_3^-$ anions in erythrocytes, and, when not functioning properly, have been implicated in the genetic disease cystic fibrosis[7]). For comparison, the expanded porphyrin receptors can bind anions only when protonated, and thus exhibit modest anion selectivity due to nondirectional coulombic interactions[3] (for example, sapphyrin binds $H_2PO_4^-$ and $F^-$ ions with similar binding constants in methanol[1f]). Cobaltocene and ferrocene appended porphyrins have recently been reported.[8] The former is another example of a positively charged anion receptor, whereas the neutral ferrocene appended porphyrins do not bind anions unless metallated; both systems show little anion selectivity (no better than 4 : 1 binding selectivity between halides, nitrate and sulfate ions).

Porphyrins **2**–**4** were synthesized (Scheme 1) by the addition of 4 equiv. of the requisite isocyanate (**8**–**10**) to the *cis* isomer of $H_2TAPP$[9,10] **1** in $CHCl_3$ at room temp. and were obtained in yields of 70–85% after purification by silica-gel column chromatography and subsequent recrystallization from $CH_2Cl_2$–$C_6H_{14}$. The Zn complexes **5**–**7** were synthesized by stirring the free-base ligands with excess $Zn(OAc)_2{\cdot}2H_2O$ in $CH_2Cl_2$–MeOH (2 : 1, v/v) and were obtained in 90–95% yield. The model tetraphenylporphyrin was prepared using standard literature procedure.[11] The $^1$H NMR spectra of **2**–**4** recorded in $(CD_3)_2SO$ at ambient temperature revealed a singlet resonance for the β-pyrrole protons, indicative of the *cis* conformation of the molecules. In all cases, the urea NH protons were observed as two broad singlets, the one at high field presumably due to those in close proximity to the porphyrin ring, resulting from the shielding effect of the macrocycle. The proposed structures **2**–**4** were corroborated by HRFABMS.

UV–VIS spectral anion titration revealed anion binding through perturbation of the Soret and visible bands of **2**–**4** when the anions $Cl^-$, $NO_3^-$ and $H_2PO_4^-$ were added as their $NBu_4^+$ salts. Addition of $NO_3^-$ and $Cl^-$ anions produced a hypsochromic shift with concomitant decrease in intensity of the Soret band after the addition of 1 equiv. of anion. Further addition of anion resulted in an increase in intensity (Fig. 1). Titration of porphyrins **2**–**4** with $H_2PO_4^-$ produced a hypsochromic shift of the Soret band followed by a bathochromic shift and an increase in absorbance with the addition of >1 equiv. of anion. Furthermore, with porphyrins **3** and **4**, a broadened Soret band with the appearance of a shoulder was observed (Fig. 1). Changes in the Soret band combined with shifts of the porphyrin NH protons (*vide infra*) upon titration with the anions strongly suggests that the anions were bound within the porphyrin–urea pocket.

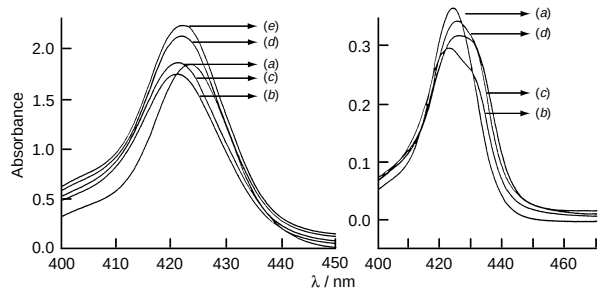

**Fig. 1** UV–VIS spectra of porphyrins **3** and **4** demonstrating the change in the Soret bands upon titration with anions in $CH_2Cl_2$. (Left) porphyrin **4** titrated with $NBu_4Cl$ in mol equiv.: (*a*) 0, (*b*) 1, (*c*) 2, (*d*) 5, (*e*) 10. (Right) porphyrin **3** titrated with $NBu_4H_2PO_4$ in mol equiv.: (*a*) 0, (*b*) 1, (*c*) 2, (*d*) 10.

Quantification of the association constants of neutral hosts **2**–**4** was accomplished by following the titrations of the anions by $^1$H NMR in the strongly solvating solvent $(CD_3)_2SO$. In all cases, proton shifts were observed for the receptor porphyrin-phenyl, β-pyrrole, porphyrin NH, and urea-phenyl protons. Larger shifts were observed for the urea NH protons, with the downfield urea proton the most perturbed. The larger shift of the urea NH proton was indicative of its essential role in the anion recognition process.[2,4] The association constants of **2**–**4** in $(CD_3)_2SO$ determined from their binding curves (Fig. 2) for the complexation of $Cl^-$ ion were calculated[12] to be $> 10^5$ dm$^3$ mol$^{-1}$ (Table 1),[13] so it was impossible to judge any selectivity in binding that might be occurring for these anions between the different porphyrins. However, binding constants for $Cl^- > 10^5$ dm$^3$ mol$^{-1}$ are significantly larger than those that have been previously reported for urea functionalized anion receptors.[1–6] The very strong binding of $Cl^-$ ion allowed the mole ratio method[14] to be used in the determination of the binding stoichiometry, which was found to be 1 : 1 for the three porphyrins.

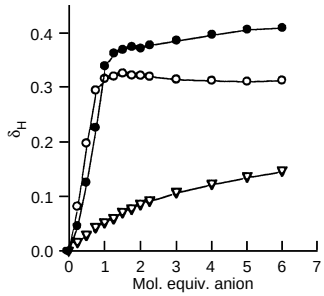

**Fig. 2** Binding curves for porphyrin **4** and $Cl^-$ (○), $H_2PO_4^-$ (●) and $NO_3^-$ (▽) ions in $(CD_3)_2SO$

The association constants of **2**–**4** in $(CD_3)_2SO$ for the binding of $H_2PO_4^-$ ion were 400, 300, and 1400 dm$^3$ mol$^{-1}$ (Table 1), respectively. Thus, there seemed to be some small selectivity between the *p*-fluorophenylurea porphyrin **4** and the other two porphyrins in their affinity for $H_2PO_4^-$. Presumably, the very electronegative *p*-F substituent produced a large enough increase in the acidity of the urea protons to strengthen their hydrogen bonding with the anion electrostatic field. Both Job's method of continuous variations[14] and the mole ratio method,[14] determined by UV–VIS spectrophotometry, showed the stoichiometry of binding was 1 : 1. The binding affinity of **2**–**4** for $NO_3^-$ was even weaker (Table 1).‡ The noteworthy selectivity in the binding of $Cl^-$ with **2**–**4** was presumably due to a less complementary fit of the trigonal $NO_3^-$ or tetrahedral $H_2PO_4^-$ than that of spherical $Cl^-$ within the urea binding pocket of the free-base porphyrins. Under analogous titration conditions, tetraphenylporphyrin exhibited negligible perturbation in its $^1$H NMR and UV–VIS spectra, indicating the changes observed with ligands **2**–**4** were truly caused by anion binding.

**Table 1** Binding constants ($K$/dm$^3$ mol$^{-1}$) for porphyrins **2**–**4** and $Cl^-$, $NO_3^-$ and $H_2PO_4^-$ anions in $(CD_3)_2SO$

| Porphyrin | $Cl^-$ | $NO_3^-$ | $H_2PO_4^-$ |
|---|---|---|---|
| **2** | $> 10^5$ | 90 | 400 |
| **3** | $> 10^5$ | 60 | 300 |
| **4** | $> 10^5$ | 55 | 1400 |

Future investigations will examine solvent systems where the association constants of **2**–**4** for the complexation of $Cl^-$ and other spherical anions are of the proper magnitude (*i.e.* $< 10^5$)[13] to allow for an accurate determination of their binding constants, and therefore the determination of possible selectivity trends with the different porphyrins. Future experiments will also examine if metallated receptors **5**–**7** will bind anions with the same selectivity trends as those observed with the free-base porphyrins.

We thank Dr Todd Williams for obtaining the FAB mass spectra. This research was supported by the National Science Foundation (EPS-9550487).

† Neutral *meso*-octaethylporphyrinogens have been shown to bind selectively to $F^-$ in $CD_2Cl_2$.[1a] However, the lack of macrocyclic aromaticity (*i.e.*, little useful UV–VIS, fluorescence, or electrochemical information) makes this system less attractive for sensor development.

‡ Although the complexation stoichiometries for porphyrins **2**–**4** and $NO_3^-$ have yet to determined by Job's method,[14] the calculated errors for the binding constants were small only when a 1 : 1 binding isotherm was utilized.

# Radical cage effects. Effect of radical mass and bond energies on cage recombination efficiencies for photochemical cage pair intermediates of $[Mo_2(CO)_6[(\eta^5\text{-}C_5H_4CH_2CH_2OSiMe_3)_2]$, $[Mo_2(CO)_6(\eta^5\text{-}C_5H_4Me)]$ and $[W_2(CO)_6(\eta^5\text{-}C_5H_4Me)]$

**Britt E. Lindfors, Jonathan L. Male, Katharine J. Covert and David R. Tyler***

*Department of Chemistry, University of Oregon, Eugene, Oregon 97403-1253, USA*

**The cage recombination efficiency of the $[(\eta^5\text{-}C_5H_4Me)(CO)_3W\cdot, \cdot W(CO)_3(\eta^5\text{-}C_5H_4Me)]$ radical cage pair in hydrocarbon solvent systems is higher than that of the analogous, but less massive, $[(\eta^5\text{-}C_5H_4Me)(CO)_3Mo\cdot, \cdot Mo(CO)_3(\eta^5\text{-}C_5H_4Me)]$ cage pair; the difference is shown to be attributable not to differences in the radical masses but to differences in the metal–metal bond energies or in the spin–orbit coupling.**

Radical cage effects[1–4] have an enormous impact on chemical reactivity in solution and they are necessary to explain some of the most fundamental physical reaction phenomena.[5–7] Despite the recognition that cage effects can be important, virtually nothing systematic or quantitative is known about how changes in radical mass affect the cage effect.‡ In a prior study, we showed that the cage effect for the photogenerated $[(\eta^5\text{-}C_5H_4Me)(CO)_3Mo\cdot, \cdot Mo(CO)_3(\eta^5\text{-}C_5\text{-}H_4Me)]$ radical pair was smaller than that for the similarly sized but more massive W analogue, $[(\eta^5\text{-}C_5H_4Me)(CO)_3W\cdot, \cdot W(CO)_3(\eta^5\text{-}C_5H_4Me)]$.[8] As tempting as it was to attribute the difference to a change in the mass of the radical fragments, the difference may instead be attributable to differences in the M–M bond energies or to differences in spin–orbit coupling.‡ In order to separate changes caused by differences in radical mass from changes caused by bond energies or spin orbit coupling, we synthesized and studied **1**.

**1**

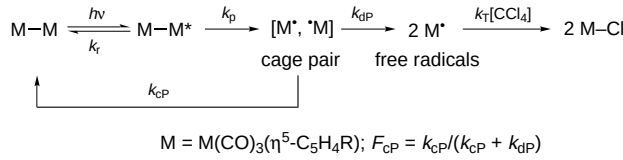
This molecule was chosen because its constituent radicals have about the same mass (361.3) as the $W(CO)_3(\eta^5\text{-}C_5H_4Me)$ radicals (347.0), yet it has a Mo–Mo bond. A comparison of **1** with $[Mo_2(CO)_6(\eta^5\text{-}C_5H_4Me)_2]$ **2** (259.1 for the radical) will therefore allow us to eliminate the influence of different M–M bond energies. Here we report the results of our comparison of the cage effects in the $[(\eta^5\text{-}C_5H_4Me)(CO)_3M\cdot, \cdot M(CO)_3(\eta^5\text{-}C_5H_4Me)]$ (M = Mo, R = Me, $CH_2CH_2OSiMe_3$; M = W, R = Me) radical cage pairs.

Compound **1** was synthesized by the route shown in Scheme 1.§

$[Mo_2(CO)_6(\eta^5\text{-}C_5H_4CH_2CH_2OH)_2]$

↓ i, $Bu^nLi$, –80 °C, thf; ii, $Me_3SiCl$, –80 °C, thf

$[Mo_2(CO)_6(\eta^5\text{-}C_5H_4CH_2CH_2OSiMe_3)_2]$



**Scheme 1**

The electronic spectra of **1** and **2** are virtually identical, a feature that suggests the Mo–Mo bond is not significantly perturbed by the changes in the side-chain and that therefore the Mo–Mo bond energies are essentially the same in each molecule.¶,‖

As previously reported,[8] the cage effect is measured by analyzing the quantum yields for disappearance of the dimer as a function of viscosity when the dimers are irradiated in the presence of a radical trap.** The radical trap used in these experiments was $CCl_4$ [eqn. (1), Scheme 2].[8]

$$[M_2(\eta^5\text{-}C_5H_4R)_2(CO)_6] \xrightarrow[CCl_4,\ \text{hexane–paraffin oil}]{h\nu\ (540\ \text{nm})} 2[M(\eta^5\text{-}C_5H_4R)(CO)_3Cl] \quad (1)$$

There is no back-reaction of the free radicals under the reaction conditions because the concentration of $CCl_4$ (2 M) is high enough to trap every free radical.†† The quantum yields for eqn. (1) were measured in hexane solution, and paraffin oil was used to increase the viscosity. (Paraffin oil was used to increase the viscosity since it is a straight-chain hydrocarbon; thus, we sought to avoid preferential solvation in the hexane solvent.[8]) Fig. 1 shows the quantum yields for the reactions of the two Mo dimers and $[W_2(CO)_6(\eta^5\text{-}C_5H_4Me)_2]$ **3** with $CCl_4$ as a function of viscosity.

M = $M(CO)_3(\eta^5\text{-}C_5H_4R)$; $F_{cP} = k_{cP}/(k_{cP} + k_{dP})$

**Scheme 2** Reaction scheme for metal–metal bond photolysis

Plots of the cage effect ($F_{cP}$) *vs*. viscosity for the three dimers are shown in Fig. 2. Note that at any viscosity, the cage effects increase in the order $Mo(CO)_3(\eta^5\text{-}C_5H_4Me) \approx Mo(CO)_3(\eta^5\text{-}C_5H_4CH_2CH_2OSiMe_3) << W(CO)_3(\eta^5\text{-}C_5H_4Me)$. The large difference in $F_{cP}$ between the $[(\eta^5\text{-}C_5H_4Me)(CO)_3W\cdot,$

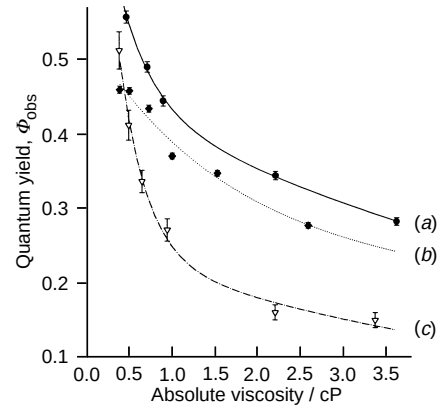


**Fig. 1** Plot of $\Phi_{obs}$ *vs*. viscosity for the photochemical reactions ($\lambda$ = 540 nm) of **1** (*a*), **2** (*b*) and **3** (*c*) with $CCl_4$ (2 M) in hexane–paraffin oil at 23 ± 1 °C. All error bars represent ±1$\sigma$.

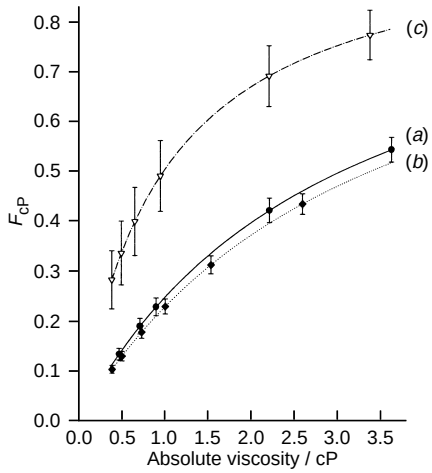

**Fig. 2** Plot of $F_{cP}$ *vs*. viscosity for **1** (*a*), **2** (*b*) and **3** (*c*) at 23 ± 1 °C in hexane–paraffin oil solutions. All error bars represent ±1$\sigma$.

·W(CO)$_3$($\eta^5$-C$_5$H$_4$Me)] and [($\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OSiMe$_3$)(CO)$_3$Mo·, ·Mo(CO)$_3$($\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OSiMe$_3$)] cage pairs (which have about the same mass) and the similarity in the cage effects for the Mo(CO)$_3$($\eta^5$-C$_5$H$_4$Me) and Mo(CO)$_3$($\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OSiMe$_3$) cage pairs shows that a mass effect is not responsible for the difference reported earlier between [($\eta^5$-C$_5$H$_4$Me)(CO)$_3$Mo·, ·Mo(CO)$_3$($\eta^5$-C$_5$H$_4$Me)] and [($\eta^5$-C$_5$H$_4$Me)(CO)$_3$W·, ·W(CO)$_3$($\eta^5$-C$_5$H$_4$Me)]. The difference may be attributed to several factors. One possible factor is the smaller difference between the bond dissociation energy and the photochemical excitation energy for **2** compared to **3**.‡ The excess photonic energy for Mo may lead to an increase in translational energy in the photogenerated radicals and a consequent decrease in the cage effect. Alternatively, the larger cage effect for the W radical pair may reflect the increased driving force (and consequently lower activation barrier) for the recombination of the two W radicals compared to the Mo radicals. A third explanation is the increase in spin–orbit coupling for W compared to Mo. The increase will facilitate intersystem crossing, which may be important if there is a spin barrier to recombination of the cage pair.

It might be argued that the difference in cage effects between the W(CO)$_3$($\eta^5$-C$_5$H$_4$Me) and Mo(CO)$_3$($\eta^5$-C$_5$H$_4$MeCH$_2$-CH$_2$OSiMe$_3$) radical pairs depicted in Fig. 2 is attributable to a size effect.‡‡ This alternative explanation is unlikely for two reasons. First, in his mathematical description of the cage effect,[3] Noyes predicted that sterically larger radicals will have larger cage effects than smaller radical cage pairs. Second, our experiments with the $\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OSiR$_3$ (R = Pr$^n$, Pr$^i$, *n*-C$_6$H$_{13}$) analogues of compound **1** show that, as the R group gets bigger, the cage effect increases.[11] Thus, our experiments confirm Noyes's prediction that bigger cage pairs will have larger cage effects. It is concluded therefore that the difference in cage effects between the W(CO)$_3$($\eta^5$-C$_5$H$_4$Me) and Mo(CO)$_3$($\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OSiMe$_3$) radical pairs is not attributable to a size effect.

Two fundamental conclusions result from this study. First, the effects of radical mass on the cage effect are not nearly as pronounced as suggested by the previously reported data for the [($\eta^5$-C$_5$H$_4$Me)(CO)$_3$Mo·, ·Mo(CO)$_3$($\eta^5$-C$_5$H$_4$Me)] and [($\eta^5$-C$_5$H$_4$Me)(CO)$_3$W·, ·W(CO)$_3$($\eta^5$-C$_5$H$_4$Me)] cage pairs. Secondly, differences in bond energies may influence the cage effect, and it is important therefore to always compare systems with similar bond energies. We are continuing to investigate molecular parameters that influence the magnitude of the cage effect.

† Some incidental data are available, but no systematic studies have been done. See ref. 2(*a*), p. 174.

‡ $D_{W-W}$ ≈ 56 kcal mol$^{-1}$; $D_{Mo-Mo}$ ≈ 32 kcal mol$^{-1}$ [9] $h\nu$ = 52 kcal mol$^{-1}$.

§ The molecule was synthesized under nitrogen as follows: To a −80 °C (dry ice/acetone) solution of [Mo$_2$(CO)$_6$($\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OH)$_2$] in thf was added 2.2 equiv. of Bu$^n$Li dropwise over 20 min. After 1 h of reaction time, a brick-red solid was allowed to settle. The supernatant was removed with a cannula and the solid was washed twice with thf at −80 °C (20 ml). Tetrahydrofuran (25 ml) was again added and the mixture was cooled to −80 °C. To the mixture was added 2 equiv. of Me$_3$SiCl. The reaction was allowed to proceed until the solution became clear and deep burgundy. After removal of thf *in vacuo*, hexanes were added and the resulting cloudy burgundy solution was filtered through a fine frit. The product was eluted with hexanes through a short, basic alumina column prior to crystallization from hexanes.

¶ The molecule has an intense band at 393 nm ($\varepsilon$ ≈ 20 000 dm$^3$ mol$^{-1}$ cm$^{-1}$), assigned to the σ→σ* transition, and a weaker band at 512 ($\varepsilon$ ≈ 2000), assigned to a $d_\pi$→σ* transition.

‖ By having a –CH$_2$CH$_2$– spacer, we also sought to minimize the difference in the electronic structures of the molecules. For an example of a similar strategy, see ref. 10.

** The cage effect is denoted by $F_{cP}$ and is defined as the ratio of the rate constant for cage recombination to the sum of the rate constants for all cage processes. The procedure for obtaining $F_{cP}$ is to plot $1/\Phi_{obs}$ *vs*. viscosity. The plots are linear with a *y* intercept equal to $1/\Phi_{pair}$, the quantum yield for the formation of the cage pair species. This value of $\Phi_{pair}$ is then used in the equation $1/\Phi_{obs} = [1/\Phi_{pair}][1 + k_{cP}/k_{dP}]$, and the value of $F_{cP}$ is calculated by rewriting $k_{cP}/k_{dP}$. Complete details are found in ref. 8 and 11. The $\Phi_{pair}$ values were: 0.51 ± 0.01 (**2**), 0.61 ± 0.02 (**1**), 0.58 ± 0.09 (**3**).

†† The quantum yields increased with increasing concentration of $CCl_4$ up to *ca*. 0.1 M, at which point saturation was achieved.

‡‡ The static molecular volumes of W(CO)$_3$($\eta^5$-C$_5$H$_4$Me) and Mo(CO)$_3$($\eta^5$-C$_5$H$_4$CH$_2$CH$_2$OSiMe$_3$) were calculated as 107 and 185 Å$^3$, respectively, by using the computer program Steric (written by B. Craig Taverner, Department of Chemistry, Witwatersrand, Private Bag 3, WITS 2050, Johannesburg, South Africa).

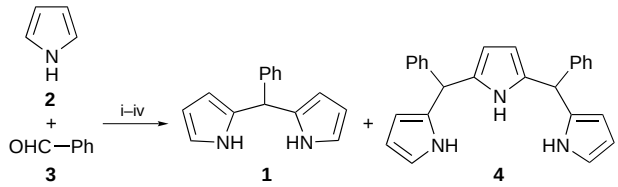
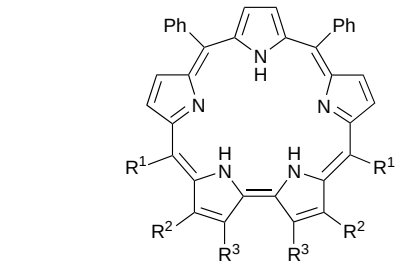
# 5,10-Diphenyltripyrrane, a useful building block for the synthesis of *meso*-phenyl substituted expanded macrocycles

**Christian Brückner, Ethan D. Sternberg, Ross W. Boyle and David Dolphin***



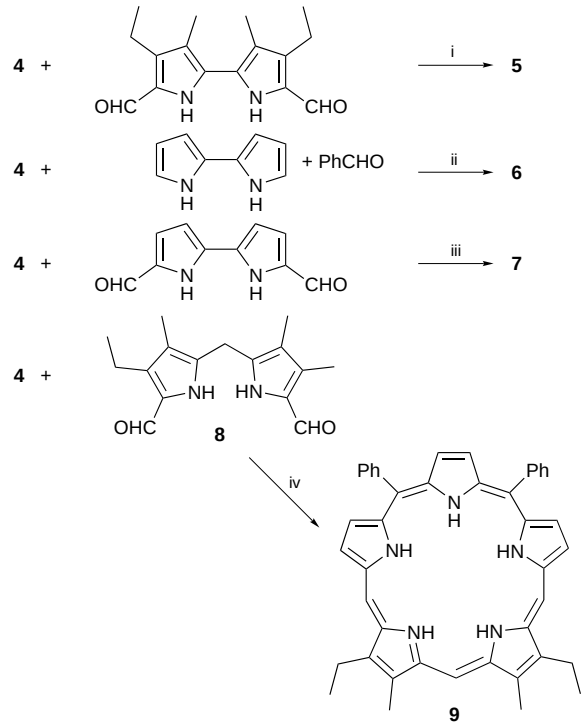
*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC, V6T 1Z1, Canada*

**Pyrrole and benzaldehyde were condensed under acidic conditions to produce a mixture of 5-phenyldipyrromethane and 5,10-diphenyltripyrrane; the tripyrrane was utilized in syntheses of *meso*-phenylsapphyrins, *meso*-diphenylpentaphyrin and *meso*-hexaphenylhexaphyrin.**



Expanded porphyrins[1] are a diverse class of pyrrolic compounds containing a larger macrocycle than that found in porphyrins. They are being utilized in fields such as photodynamic therapy (PDT),[2] neutral substrate binding, anion recognition[3] and annulene research.[4] Although β-unsubstituted *meso*-aryl substituted porphyrins are very prominent in the synthetic porphyrin field,[5] they are rarely found in expanded porphyrins.[6–8] This, perhaps, reflects the lack of a suitable building block as well as the reduced stability of some of these systems, as will be outlined below.

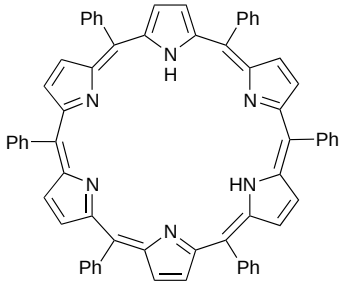
We report here the improved preparation of 5-phenyldipyrromethane, itself an important building block for *meso*-phenylporphyrinoids,[8] the one-step synthesis of the novel building block 5,10-diphenyltripyrrane and its use in 3 + 2- and 3 + 3-type syntheses to yield three *meso*-phenyl substituted sapphyrins varying in their β-substituents, a partially β-substituted pentaphyrin and a fully β-unsubstituted *meso*-hexaphenylhexaphyrin.



5-Phenyldipyrromethane **1** was synthesized by condensing excess pyrrole **2** and benzaldehyde **3** in the presence of an acid according to the procedures of Lee and Lindsey[9] or Carrel,[10] with the exception that generally 50% lower benzaldehyde to pyrrole ratios were used and, most importantly, work-up procedures were altered. The crude oils resulting from the condensation were, after pre-purification by column chromatography, transferred into a sublimation apparatus and heated under high vacuum (Scheme 1). Under these conditions, **1** sublimed as a white crystalline material of analytical purity. The reaction could be scaled up to provide up to 15 g (*ca.* 50% yield) of **1** per run. The residue left in the bottom of the sublimation apparatus hardened, upon cooling, into a red–orange glass. Analysis of this glass proved that it contained *ca.* 95% 5,10-diphenyltripyrrane **4**.† Lee and Lindsey[9] and Vigmond *et al.*[11] have previously reported the occurrence of a small amount of an unstable tailing component which, based on $^1$H NMR spectroscopy, was provisionally assigned structure **4**. In subsequent work, Lee and co-workers synthesized this tripyrrane in a multi-step procedure and utilized it in the formation of heteroporphyrins.[11] Tripyrrane **4** was obtained by us in yields ranging typically from 10–20%, and, even when ground into a powder, is stable in the solid form but could not, in our hands,

**Scheme 1** *Reagents and conditions*: i, pyrrole, PhCHO (1 : 10) (neat), TFA (5%), 1 h, under $N_2$, or pyrrole, PhCHO (1 : 8), PhMe, reflux, TsOH (cat.), under $N_2$; ii, evaporation of solvents *in vacuo*; iii, flash chromatography (silica gel, $CH_2Cl_2$); iv, sublimation at 130 °C at 1 torr, initial heating: 1 °C $min^{-1}$

**5** $R^1$ = H, $R^2$ = Et, $R^3$ = Me
**6** $R^1$ = Ph, $R^2$ = $R^3$ = H
**7** $R^1$ = $R^2$ = $R^3$ = H



**Scheme 2** *Reagents and conditions*: i, abs. EtOH (1 mM), $O_2$ bubble, TsOH (4 equiv.); evaporation of solvents *in vacuo*; column chromatography (neutral alumina, activity I, 2.5% MeOH–$CH_2Cl_2$); ii, $CH_2Cl_2$, under $N_2$, $BF_3{\cdot}Et_2O$ (cat.), 1 h; chloranil, reflux, 30 min; evaporation of solvents *in vacuo*; column chromatography (neutral alumina, activity I, 2.5% MeOH–$CH_2Cl_2$); preparative TLC (alumina, 1 : 1 $CH_2Cl_2$–$CCl_4$); iii, abs. EtOH (1 mM), $O_2$ bubble, TsOH (4 equiv.); evaporation of solvents *in vacuo*; trituration with $CHCl_3$; preparative TLC (silica gel, 0.5% MeOH–$CH_2Cl_2$); iv, $CH_2Cl_2$, TFA (cat.), 48 h, room temp., neutralisation with $Et_3N$, then an additional 36 h; column chromatography (neutral alumina, 1–3% MeOH–$Ch_2Cl_2$); then preparative TLC (silica gel, $CH_2Cl_2$–20% EtOAc–1% $Et_3N$)

be further purified without retrieving it as an unstable oil. We attribute this, in part, to the presence of three stereoisomers in **4**. This route to tripyrrane **4** is comparatively simple given that the syntheses of β-alkyltripyrranes generally involve many reaction steps from starting materials which are not commercially available, unlike pyrrole and benzaldehyde. It is anticipated that the ease of preparation of **4** will encourage its use as a synthetic building block.

With the novel 5,10-diphenyltripyrrane **4** in hand, we had the opportunity to prepare *meso*-diphenyl substituted sapphyrins **5** and **7**‡ and, in a four-component Rothemund-type condensation, *meso*-tetraphenylsapphyrin **6** (Scheme 2). Recently, Sessler *et al.* published the synthesis of **5** *via* a multi-component condensation under Lindsey-type conditions[6] and Chmielewski *et al.* published the isolation of sapphyrin **6** as a side-product from a Rothemund synthesis of tetraphenylporphyrin.[7] Both procedures, however, produce the particular sapphyrins in low yields (*ca.* 10 and 1.1%, respectively) and both require extensive chromatographic work-up. The syntheses presented here using the preformed tripyrrolic precursor are short, produce up to 39% yield in the final sapphyrin condensation (for **5**) and, due to the absence of any other porphyrinic by-products, require only minimal chromatographic work-up. The inversion of one pyrrolic unit in **7** upon protonation–deprotonation as observable by NMR spectroscopy is analogous to that described before for **6**.[7] The *meso*-positions flanking the 'flipping' pyrrolic unit do not participate in this inversion.

A TFA catalysed 3 + 2-type condensation of tripyrrane **4** and dipyrromethane **8** in the presence of nitrogen, followed by treatment with base and then by chromatography, produced the orange *meso*-diphenyltetra-β-alkyl pentaphyrin **9** in 13% yield (Scheme 2). The pentaphyrin was characterized by 1H NMR spectroscopy, mass spectrometry and UV-VIS spectroscopy.§ Its optical properties are similar to those of previously reported β-alkyl pentaphyrins.[13] The strongly solvent-dependent $^1$H NMR spectrum can be rationalized in terms of inversions of pyrrolic units similar to those observed in sapphyrins. However, unlike the stable β-alkyl pentaphyrins, this macrocycle exhibited poor stability even in the solid state and decomposed when exposed to air, with a half-live of several days. It remains to be seen whether the macrocycle can be stabilized by metal complexation.[14]

On the other hand, a 3 + 3-type condensation reaction employing **4** and benzaldehyde **3** furnished, after oxidation with chloranil and chromatography, a blue product which could be identified by its mass and UV-VIS spectra as the *meso*-hexaphenylhexaphyrin **10**.¶ Its $^1$H NMR was complex and

**10**

largely depended on pH and the nature of the solvent. This may reflect its non-static conformation. Such flexibility of the macrocycle has also been observed for β-alkyl hexaphyrins. Further studies of this macrocycle were hampered by its instability.

The above examples prove the synthetic utility of **4**. It also emerges that the *meso*-phenyl substituted versions of the larger expanded macrocycles pentaphyrin and hexaphyrin exhibit a significantly decreased stability when compared with their β-alkyl analogues. This stability trend has been observed before,[8] and, if this is a general trend, may limit the extent to which *meso*-phenyl substituted analogues of other known expanded macrocycles can be made.

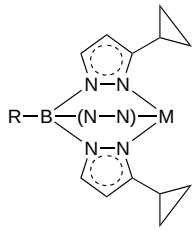
# Formation of a tetrahedral $Tl_4$ cluster directed by a novel homoscorpionate ligand



**Arnold L. Rheingold, Louise M. Liable-Sands and Swiatoslaw Trofimenko**

*Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716, USA*

**The thallium complex of a novel ligand, hydrotris(3-cyclopropylpyrazol-1-yl)borate, forms a stable tetramer, $[Tl(Tp^{Cpr})]_4$, containing a perfect tetrahedron of Tl atoms, with each Tl in an octahedral environment.**

The formation of Tl···Tl bonds, or strong interactions between two Tl atoms, has been found or postulated in a number of thallium(I) compounds, although the exact nature of such bonding remained enigmatic.[1] Most of these examples featured two Tl atoms bridged by one, two, or three ligands enforcing a certain proximity between them, and leading to a Tl···Tl interaction. For instance, a Tl–Tl distance of 3.69 Å was found in a complex structure, containing a triangle consisting of two Tl atoms (further bonded to manganese carbonyl moieties) bridged by a $Mn(CO)_2$ link.[2] The Tl···Tl relationship was considered one of bonding interaction, being only 0.29 Å longer than the metal–metal distance in elemental Tl.[3] Other examples have also been reported,[4] and cited in a review devoted to this subject.[1] Some insight into the nature of the Tl–Tl interaction was elicited from an unbridged species, the quasi-dimer of $[Tl\{C_5(CH_2Ph)_5\}]$, formed about an inversion center, where the Tl···Tl distance is 3.63 Å.[5] It was proposed that bonding interaction results from the mixing of empty p levels into filled s combinations, with the desideratum expressed that 'further work is needed in finding more structures to develop a better understanding of this fascinating problem'.[1] Since that time, other examples appeared,[6] including a fairly unstable tetrameric cluster of the monoalkylthallium compound $[Tl\{C(SiMe_3)\}]_4$, containing Tl in a tetrahedral environment, within a distorted structure.[7] Earlier, similar group 13 analogue structures such as $[In\{C(SiMe_3)_3\}]_4$,[8] and $[Ga\{C(SiMe_3)_3\}]_4$,[9] containing tetrahedra of In and Ga, respectively, have been reported.

In the course of fine-tuning the coordinative behavior of homoscorpionate [hydrotris(pyrazol-1-yl)borate] ligands through modification of their 3-R substituents,[10] we had synthesized hydrotris(3-cyclopropylpyrazol-1-yl)borate ($Tp^{Cpr}$), isolated it as the stable, high-melting Tl salt,† and determined its structure by X-ray crystallography.‡

$[Tl(Tp^{Cpr})]$ R = H, M = Tl

–(N–N)– represents the third, hidden, 3-(cyclopropyl)pz

To our surprise, this thallium salt, $[Tl(Tp^{Cpr})]$, revealed a highly symmetrical tetrameric structure, containing a perfect tetrahedron of four Tl atoms, each capped by the three nitrogens of a $Tp^{Cpr}$ ligand, thus placing each Tl in an octahedral coordination environment, an unprecedented structure involving $Tl^{I}$–$Tl^{I}$ bonding. Previously, all structures of Tl salts of homoscorpionate ligands, including $[Tl(Tp^{But})]$,[11] $[Tl(Tp^{But,Me})]$,[12] $[Tl(Tp^{But2})]$,[13] $[Tl(Tp^{Menth})]$,[14] $[Tl(Tp^{Mementh})]$,[14] [Tl{tris(1,4-dihydroindeno[1,2-*c*]pyrazol-1-yl)borato}],[15] $[Tl(Tp^{Ant})]$,[16] [Tl{hydrotris(7-*tert*-butylindazol-2-yl)borate}][$Tl(Tp^{3Bo,7Me})$][17] and [Tl{HB(3,5-[*p*-$C_6H_4$-$But]_2pz)_3$}]],[18] [Tl{HB[pz$(CF_3)_2$-3,5]}]],[19] and $[Tl(Tp^{Tol})]$,[20] which have been determined by X-ray crystallography, are monomeric or in one case dimeric. In all these cases, Tl is coordinated to the three nitrogen atoms of the ligand, usually with retention of the ligand $C_{3v}$ symmetry, except for the very hindered $Tp^{But2}$ and $Tp^{Ant}$ derivatives which were distorted. The Tl–N bond lengths ranged from 2.50 to 2.68 Å, and the N–Tl–N angles from 76 to 78° with the exception of the distorted $Tp^{Ant}$, where the angle was 66°. The only thing resembling a Tl···Tl interaction was noted in the case of $[Tl(Tp^{Tol})]$, the structure of which showed two molecules in a face-to-face conformation, akin to that found in $[Tl\{C_5(CH_2Ph)_5\}]$, with the Tl atoms 3.86 Å apart. However, in contrast to $[Tl\{C_5(CH_2Ph)_5\}]$, which had a *trans*-bent geometry, the $[Tl(Tp^{Tol})]$ 'dimer' was not bent, but had a collinear B–Tl–Tl–B sequence.

The structure of $[Tl(Tp^{Cpr})]_4$ has the $Tl_4$ tetrahedron as its core (Fig. 1) with each Tl capped by a $Tp^{Cpr}$ ligand, and all Tl–Tl bonds equal at 3.6468(4) Å, with the Tl–Tl–Tl angles the expected 60°. Each $Tp^{Cpr}$ ligand is rotated by about 30° about its threefold axis with respect to a staggered relationship to the triangle of Tl atoms below. The crystals are face-centered cubic, and the unit cell consists of four discrete crystallographically perfect tetrameric tetrahedral thallium clusters (Fig. 2). The Tl–N bonds are 2.532(3) Å, which is close to the short end of the reported values, while the N–Tl–N angles are 76.58(12)°, and thus in the typical range for $[Tl(Tp^{x})]$ complexes. All the

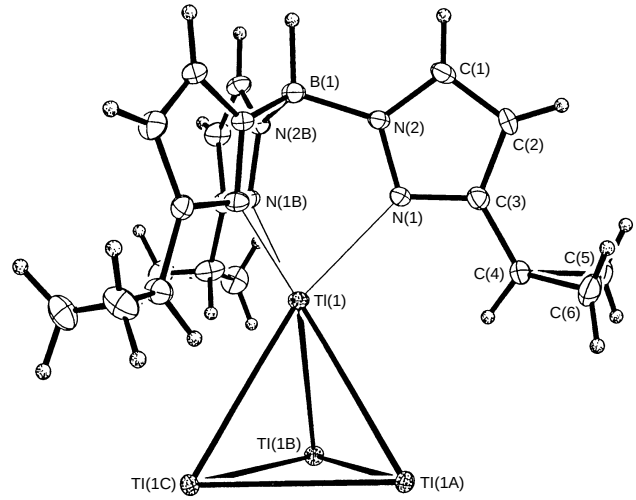


**Fig. 1** ORTEP diagram of $[Tl(Tp^{Cpr})]_4$ showing atom labelling scheme. Thermal ellipsoids at 30% probability. Hydrogen atoms and three of the $Tp^{Cpr}$ ligands have been omitted for clarity. Selected distances (Å) and angles (°): Tl(1)–Tl(2) 3.647; Tl(1)–N(1), 2.532; Tl(1)–Tl(2)–Tl(3) 60.0, N(1)–Tl(1)–N(2) 123.2.

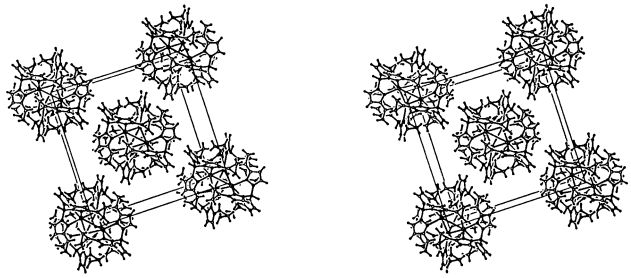

**Fig. 2** Stereoview of the unit cell showing discrete tetrameric tetrahedral thallium clusters

cyclopropyl groups are turned in such a way that only the tertiary hydrogen is pointed at the metal.

The reason why the $Tl_4$ cluster is formed with $Tp^{Cpr}$ but not with any of the other $Tp^x$ ligands cannot be simply a steric one, in the sense that the cyclopropyl group is smaller than any of the 3-R substituents in $[Tl(Tp^x)]$ complexes whose structures are known. We have determined the structure of [Tl(Tp)], the least hindered Tl homoscorpionate, with 3-R = H, and found only unassociated monomers in the crystal with the nearest Tl–Tl distance 4.8 Å, and thus definitely out of bonding range.[21] Since there is no steric hindrance to prevent formation of the $Tl_4$ cluster, what seems to be missing is an additional driving force for its formation, supplied by the 3-cyclopropyl substituent. Moreover, structures of the closely related $[Tl(Tp^x)]$ compounds with 3-R = $Pr^i$ or 3-R = *c*-$C_4H_9$ have also been determined and, again, found to be simple monomers.[21]

Looking at the space-filling model of the structure of $[Tl(Tp^{Cpr})]_4$, we see that the cyclopropyl groups from one ligand cross over past the Tl atom to which the ligand is bonded, and protrude over an adjacent Tl atom, creating an intimately interlocking network of 'rabbet joints', which involves all four ligands over the tetrahedral array of Tl atoms. This resembles somewhat the intermeshing of the R groups of $Tp^R$ ligands in octahedral $[M(Tp^R)_2]$ complexes, and makes the whole structure appear spherical (Fig. 2). However, in $[Tl(Tp^{Cpr})]_4$ each $Tp^{Cpr}$ ligand interlocks with three others, thus generating a rather rigid structure, with little rotational freedom for the cyclopropyl groups, or for twisting of the pz groups. It is this unstrained fit of all the components within $[Tl(Tp^{Cpr})]_4$ that seems to be the driving force for the formation of this supramolecular structure and, possibly, for the lowering of surface energy (cluster *vs*. four monomeric units) during crystallization of the monomeric species present in solution. The reported results are obviously unrelated to cases where individual Tp ligands are capping a corner in preformed metallic clusters, as for instance in $[Fe_4S_4]^{2+}$,[22] or in $[VFe_3S_4]^{2+}$.[23]

We have to conclude that the specific nature of the 3-R substituents in homoscorpionate ligands can exert a very subtle, and yet dominant, influence on their coordination chemistry, not always predictable *a priori*.[24]

† *Synthesis*: 3-cyclopropylpyrazole was synthesized in 58% yield from methyl cyclopropyl ketone by the method used for making 3-isopropylpyrazole.[25] Bp 122–124 °C (2.8 Torr.) $^1$H NMR: $\delta$ 12.45 (s, 1 H, NH), 7.46 (s, 1 H, H-5), 5.93 (d, 1 H, H-4), 1.97 (spt, 1 H, tertiary H), 0.93 (dt, 2 H, cyclopropyl) and 0.74 (dt, 2 H, cyclopropyl). $^{13}$C NMR: $\delta$ 7.89, 101.1, 134.0, 150.6 (the fifth peak is hidden under the $\delta$ 7.9 peak). Calc. for $C_6H_8N_2$: C, 66.7; H 7.41; N 25.9. Found: C, 66.9; H, 7.51; N, 25.7%.

$[Tl(Tp^{Cpr})]$ was prepared by heating 3-cyclopropylpyrazole with $KBH_4$ (3.6 : 1 mole ratio) until the theoretical amount of hydrogen was evolved. After distilling out excess 3-cyclopropylpyrazole *in vacuo*, the residue was dissolved in thf and converted to the Tl salt in 77% yield, by treatment with aqueous $TlNO_3$. Mp 144–146 °C. IR: BH 2438 cm$^{-1}$. $^1$H NMR: $\delta$ 7.50 (d,1 H, H-5), 5.74 (d, 1 H, H-4), 2.04 (m, 1 H, tertiary H), 0.93 (m, 2 H, cyclopropyl), 0.566 (m, 2 H, cyclopropyl). $^{13}$C NMR: $\delta$ 8.1, 9.0, 99.7, 135.9, 155.8. Calc. for $C_{18}H_{22}BN_6Tl$: C, 40.2; H, 4.10; N, 15.6. Found: C, 40.1; H, 4.18; N, 15.4%. $CDCl_3$ was used as NMR solvent in all cases. Molecular mass determination by the Signer method in chloroform gave a value of 556 (monomer 537).[26]

‡ *Crystal data* for $[Tl(Tp^{Cpr})]_4$: $C_{72}H_{88}B_4N_{24}Tl_4$: $M_w$ = 537.60, cubic, $F23$, $a$ = 20.5104(2) Å, $U$ = 8628.2(2) Å$^3$, $Z$ = 4, $T$ = 173(2), $D_c$ = 1.655 g cm$^{-1}$, $\mu$ = 75.00 cm$^{-1}$, $R(F)$ = 0.0217 and $R(wF^2)$ = 0.0627 for 1708 observed independent reflections ($3 \leqslant 2\theta \leqslant 56°$). CCDC 182/545.

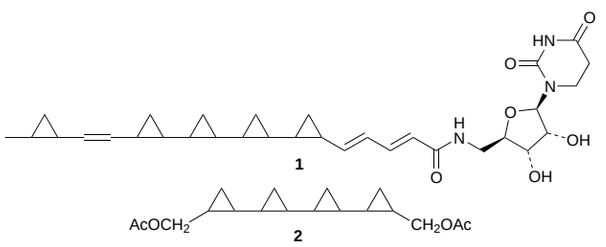
# Assembly of the antifungal agent FR-900848 and the CETP inhibitor U-106305: studies on remarkable multicyclopropane natural products†

**Anthony G. M. Barrett,*[a] Wendel W. Doubleday,[b] Dieter Hamprecht,[a] Krista Kasdorf,[a] Gary J. Tustin,[a] Andrew J. P. White[a] and David J. Williams[a]**

[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*
[b] *Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523, USA*



**The full structural elucidation of FR-900848, an antifungal pentacyclopropane nucleoside natural product from *Streptoverticillum fervens*, is reported. A series of model compounds are prepared using multiple asymmetric Simmons–Smith cyclopropanation reactions. Comparisons of spectroscopic data of synthetic 1,2-dicyclopropylethene, quatercyclopropane-2,2‴-dimethanol and 2-methylcyclopropanecarbaldehyde derivatives of defined absolute stereochemistry with FR-900848 and its degradation products are used to unequivocally establish the absolute stereochemistry of the natural product.**

**A $C_2$-symmetric quatercyclopropane-2,2‴-dimethanol is converted by a sequence of desymmetrisation, selective monocyclopropanation of a 5-(quatercyclopropyl)penta-2,4-dien-1-ol derivative, deoxygenation and Horner–Emmons homologation into the fatty acid side chain of FR-900848. Coupling of this carboxylic acid with 5′-amino-5′-deoxy-5,6-dihydrouridine gives synthetic FR-900848. The unusual helical structure of FR-900848 is discussed and compared with U-106305, a cholesteryl ester transfer protein inhibitor from the fermentation broth of *Streptomyces* sp. UC 11136. The full structure and stereochemistry of U-106305 is established by total synthesis using a bi-directional strategy closely following the route to FR-900848.**

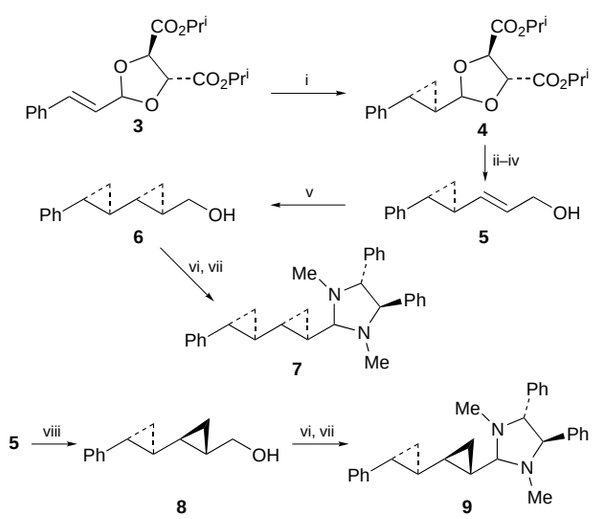
## Introduction

There is very considerable alarm amongst the medical profession regarding fungal disease. Dermatophyte infections such as tinea pedis and candidiasis, although rarely fatal, are common and widespread throughout the world.[1] There are other fungal diseases that are far darker in reputation and significance. Pathogens such as *Candida albicans*, *Cryptococcus neoformans*, *Pneumocystis carinii* and *Aspergillus fumigatus* are the cause of considerable morbidity and mortality in immunocompromised patients. Current therapies for the treatment of serious systemic fungal infection are deficient. There is need for novel therapies for serious fungal disease and for the management of the legions of topical fungal infections. In consequence several pharmaceutical companies world-wide are seeking to develop superior fungicidal agents. Owing to evolutionary pressures of microbial antagonism, fermentation broths are rich sources of novel anti-infective agents, and natural product chemistry continues to play a major role in antibiotic discovery.

In 1990 Yoshida *et al*. in the Fujisawa laboratories in Tsukuba reported the partial structural elucidation of a remarkable natural product.[2]‡ Fractionation of the fermentation broth from *Streptoverticillium fervens* and extensive chromatography led to the isolation of a structurally unique nucleoside. The structure of the new isolate was established by extensive NMR spectroscopy and partial degradation. That the compound was a 5′-amino-5′-deoxy-5,6-dihydrouridine derivative was unusual but not especially exciting. However, the fact that FR-900848 **1**,

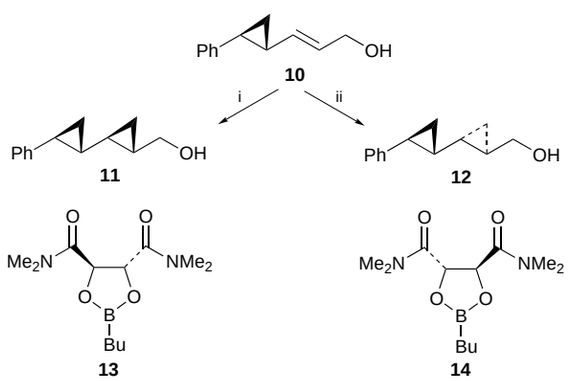
the unassuming Fujisawa file number for the new natural product, possessed an unusual fatty acid side chain was most noteworthy. This $C_{23}$ fatty acid residue is endowed with five cyclopropanes, four of which are contiguous. Although the initial degradation studies at Fujisawa determined the constitution of the molecule,[2] there remained eleven elements of ambiguity in the structure: the geometry of $\Delta^{18}$, the stereochemistry of the isolated cyclopropane and the stereochemistry of the quatercyclopropane unit. Tanaka and co-workers, however, did establish[3] that the central quatercyclopropane unit **2**, obtained by ozonolysis with a sodium borohydride work-up and acetylation, was $C_2$-symmetric. This partial structural assignment followed from the simplicity of the $^1$H NMR spectrum and the presence of only seven lines in the $^{13}$C NMR spectrum. In addition, the $[\alpha]_D$ for diester **2** was consistent with a $C_2$-structure rather than *meso* stereochemistry.

FR-900848 **1** shows potent, selective activity against filamentous fungi such as *Aspergillus niger*, *Mucor rouxianus*, *Aureobasidium pullulans*, various *Trichophyton* sp., *etc*. In contrast it is essentially inactive against non-filamentous fungi such as *Candida albicans* and Gram-positive and -negative bacteria. It shows activity *in vivo* and is not appreciably toxic.[2,4] Thus FR-900848 **1** represents a significant new lead for the design of nucleoside antifungal agents active against the major human pathogen *Aspergillus fumigatus*. It is certain that the fatty acid side chain of FR-900848 **1** is considerably conformationally restricted. The influence of this fact on bioactivity and mode of antifungal action is as yet undefined. The biosynthetic origin of FR-900848 **1** is not yet clear nor is it obvious as to what evolutionary advantage there is in endowing a fatty acid with five cyclopropane ring systems with the attendant strain energy of about 130 kcal mol$^{-1}$. Finally, FR-900848 **1** provides an intriguing model upon which to design a new class of materials: stereoregular poly(cyclopropene). Such compounds may well have unique and useful physical properties. All these factors underscore the potential importance of synthetic chemistry on FR-900848 **1** and related multicyclopropane arrays.



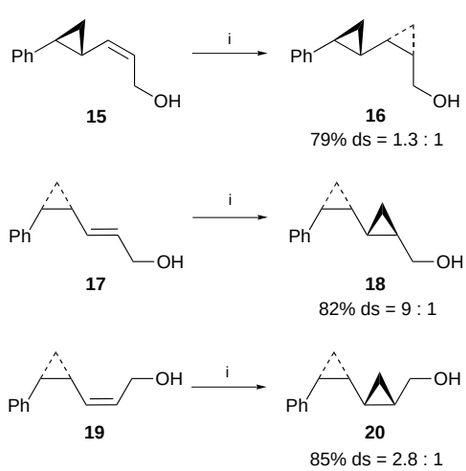
## Stereoselective synthesis of bicyclopropanes

There is an extensive literature on the synthesis and reactions of bicyclopropane arrays. For example, Buchert and Reissig[5] have reported the synthesis of highly substituted bicyclopropanes. In addition, Nijveldt and Vos have carried out an X-ray crystallographic study of bicyclopropane.[6] Prior to the discovery of FR-900848 **1**, little attention was paid to issues of stereochemistry in bicyclopropane chemistry. Recently, ourselves[7–9] and the Zercher[10,11] and Armstrong[12] groups have independently reported stereoselective methods for the preparation of bicyclopropane systems relevant to the total synthesis of FR-900848 **1**. All of these approaches have applied known asymmetric Simmons–Smith reactions to control all four stereocentres in the assembly of 2,2′-disubstituted bicyclopropanes.



We have prepared both the *syn*- and *anti*-bicyclopropanes **6** and **8** stereoselectively using both Yamamoto[13,14] and Fujisawa[15] asymmetric cyclopropanation chemistry (Scheme 1). Thus Yamamoto cyclopropanation of the chiral acetal **3** gave cyclopropane **4**[13] as a single diastereoisomer following chromatographic purification. Subsequent acid hydrolysis, Horner–Emmons homologation and DIBAL-H reduction gave the enantiomerically pure allylic alcohol **5**. Reaction of alcohol **5** with diethylzinc and diiodomethane in the presence of L-(+)-diethyl tartrate or D-(−)-diethyl tartrate according to the Fujisawa protocol,[15] respectively gave the *syn*- and *anti*-bicyclopropane derivatives **6** (ds 6 : 1) and **8** (ds 6 : 1). Thus, *syn*- or *anti*-bicyclopropanes can be prepared *via* reagent control. In contrast, treatment of alcohol **5** with diethylzinc and diiodomethane with the absence of tartrate esters gave both bicyclopropanes **6** and **8** (*ca.* 1 : 1) in 82% yield. It is clear from these observations that the prexisting cyclopropane ring in alkene **5** has little influence on the stereochemistry of the second cyclopropanation reaction. Zercher has observed similar low stereoselectivity in the cyclopropanation of racemic alkene **5**.[10] The structures of the bicyclopropanes **6** and **8** were unambiguously established by oxidation and conversion[16,17] into the imidazolidines **7** and **9** respectively and an X-ray crystal structure analysis[7] of isomer **7**.

Zercher has utilised the excellent Charette asymmetric cyclopropanation reaction[18,19] for the highly stereoselective preparation of both *syn*- and *anti*-bicyclopropanemethanol derivatives.[10] These studies are exemplified by the chemistry in Scheme 2. Thus the allylic alcohol **10** was respectively converted into the bicyclopropanes **11** (67%) and **12** (72%) using the tartramide additives **13** and **14** to control absolute stereochemistry (ds > 12 : 1). In addition, the Zercher group has used double Charette asymmetric cyclopropanation chemistry and sulfur ylide methodologies to elaborate various bicyclopropanes with the *cis-trans*- and *cis-cis*-ring stereochemistries.[10,11] During these studies this group noted, in some cases, that the prexisting cyclopropane ring dramatically influenced the stereochemistry of the second cyclopropanation reaction. For example, this is underscored by the high *anti*-selectivity in the cyclopropanation of alkene **17** to provide bicyclopropane **18**, in contrast to the lower stereoselectivities observed on the cyclopropanation of alkenes **15** and **19** (Scheme 3). In general in these systems, except when substrate and reagent stereochemical biases are mismatched, Simmons–Smith cyclopropanation in the presence of the Charette additives **13** and **14** proceeds with good to excellent stereoselectivity. It is probable that the diastereoselectivity in the conversion of alkene **17** into the bicyclopropane **18** has its origin in steric approach control and the minimization of allylic 1,3-strain.[20] The use of the Charette chemistry[18,19] will feature repeatedly in this article and there is no doubt that the method represents a significant advance in enantioselective synthesis.



We have shown that 2,4-dienols **21** react with diethylzinc and diiodomethane in 1,2-dichloroethane at −20 °C to generate the corresponding racemic bicyclopropane derivatives **23** and **24** in good yield (68–80%) and with good diastereoselectivity (5 : 1 to > 95 : 5) favouring the *anti*-isomers **23** (Scheme 4).[8] It is reasonable to speculate that the reaction involves the intermediacy of the monocyclopropane **22** and stereoelectronic control of the second cyclopropanation step (see Fig. 1). In this analysis, overlap of the most electron-rich cyclopropane σ-bond

(bond a, not bond b) with the alkene π-system should enhance its nucleophilicity and favour *anti*-delivery of the zinc carbenoid electrophile.

Armstrong has used both Yamamoto cyclopropanation[13] and allylsilane chemistry in the elaboration of a *syn*-bicyclopropane **30** (Scheme 5).[12] Thus sequential reaction of the acetal **26** with allylsilane in the presence of titanium(IV) chloride, ozone and triethylamine gave the enal **28**. Condensation with L-(+)-diisopropyl tartrate gave the corresponding acetal **29** and this was further cyclopropanated to produce the bicyclopropane **30** (65%, > 90% de). We have also used a double Yamamoto cyclopropanation strategy to produce a *syn*-bicyclopropane (Scheme 6).[9,21] Noyori acetalisation[22] of muconaldehyde[23] **31** or, alternatively, the Stille coupling[24] of vinyl iodide **35** with the vinyl stannane **36** gave the dienyl diacetal **32**. In turn, both alkenes **35** and **36** were prepared[21] from prop-2-ynyl alcohol *via* radical hydrostannylation, PCC oxidation and Noyori acetalisation.[22] Cyclopropanation of diene **32** according to the Yamamoto adaptation of the Simmons–Smith reaction[13] provided dicyclopropane **33** in good overall yield (56% from dial **31**) and essentially as a single diastereoisomer. A single crystal X-ray structure determination of bicyclopropane **33** was used to establish the relative and absolute stereochemistry of the four new chiral centres present in the molecule.[9] It is clear from this result that diene double cyclopropanation provides a simple

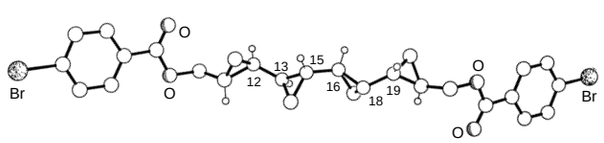
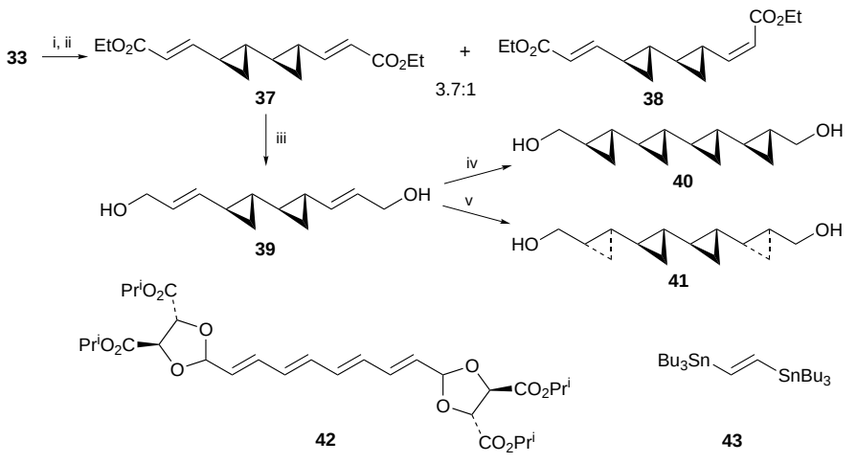
entry to *syn*-bicyclopropane systems. Clearly, following the Yamamoto mechanistic model, each Lewis basic acetal oxygen should independently direct the Simmons–Smith zinc carbenoid to one face of the adjacent alkene.

## Stereoselective syntheses of quatercyclopropanes and the stereochemical elucidation of FR-900848 1

We have explored three strategies for the stereoselective construction of quatercyclopropane arrays: (i) a double Yamamoto cyclopropanation followed by a double Charette cyclopropanation,[9,25] (ii) a double Charette cyclopropanation followed by a second double Charette cyclopropanation,[26] and (iii) a tetraene tetracyclopropanation reaction.[21] In the first approach (Scheme 7), acid catalysed hydrolysis of the diacetal **33** gave the corresponding dialdehyde, which was directly homologated using a double Wittig reaction to provide a mixture of the *E*,*E*-diester **37** and the *E*,*Z*-diester **38** (3.7 : 1). DIBAL-H reduction of pure diester **37** gave the corresponding diol **39** in high yield (91%). Pre-mixing of diol **39** with dioxaborolane **14** followed by treatment with preformed bis(iodomethyl)zinc gave quatercyclopropane **40** (94%), essentially as a single diastereoisomer. Likewise, use of dioxaborolane **13** gave the quatercyclopropane **41** (100%). It was apparent from $^1H$ and $^{13}C$ NMR data that the quatercyclopropanes **40** and **41** were two different $C_2$-symmetric isomers, and we rigourously established structures by an X-ray crystallographic study[25] of the bis(4-bromobenzoate) ester derived from **40** (Fig. 2). Interestingly, the four cyclopropyl units that form the backbone of the molecule are arranged helically.

In addition, the quatercyclopropane **40** was prepared from mucondiol using two sequential double Charette cyclopropanation reactions.[26] Since this strategy was crucial in our total synthesis of FR-900848 **1**,[26] discussion of this approach is





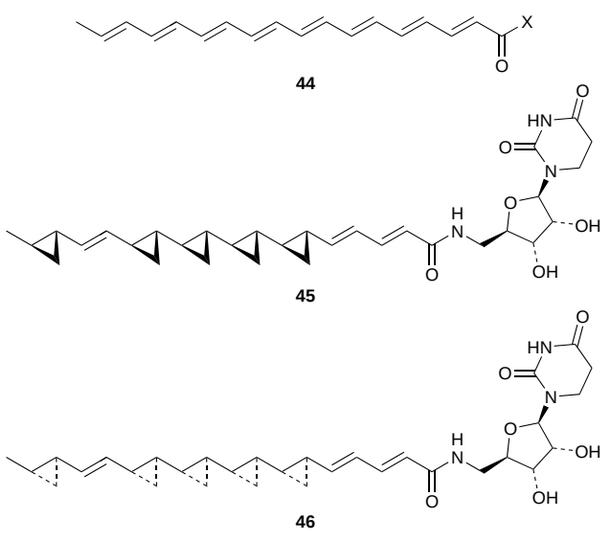


**Fig. 2** The molecular structure of the bis(4-bromobenzoate) ester of diol **40** showing the absolute stereochemistry

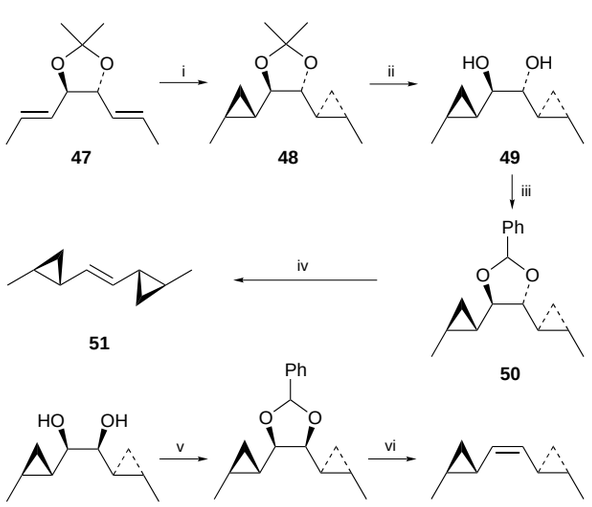
**Scheme 7** *Reagents and conditions*: i, TsOH, THF–$H_2O$, 55 °C; ii, $Ph_3P{=}CHCO_2Et$, $CH_2Cl_2$, 61% from **33**; iii, DIBAL-H, $CH_2Cl_2$, −78 °C, 91%; iv, **14**, $Zn(CH_2I)_2$, $CH_2Cl_2$, 0 °C to room temp. 94%; v, **13**, $Zn(CH_2I)_2$, $CH_2Cl_2$, 0 °C to room temp., 100%

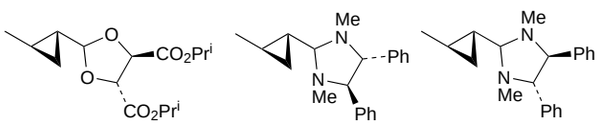
delayed until the next section. Finally, we have briefly examined the preparation of a quatercyclopropane using the direct tetracyclopropanation of a tetraene. Thus tetraene **42** was prepared from the iodoalkene **35** and alkene **43** using a sequence of Stille coupling,[24] iododestannylation and a second Stille coupling. Although reaction of tetraene **42** with diiodomethane and diethylzinc gave a quatercyclopropane, the stereochemical identity of this substance has yet to be established.



In our structural elucidation of FR-900848 **1** our planning was driven by speculation as to the biosynthetic origin of the natural product.[27] We considered that since the carbon count of **1** is odd at $C_{23}$, it is likely that all the cyclopropanes are introduced late from a polyenoic acid precusor. This precusor may be derived *via* a mixed acetate/propanoate biosynthetic origin and be already $C_{23}$ or, more likely, the precusor may be the $C_{18}$-polyene **44** in which the five cyclopropanes are

introduced from a $C_1$ source such as *S*-adenosyl methionine. If the $C_{18}$-polyene **44** is indeed a key biosynthetic intermediate then the geometry is most likely to be all *trans* since $\Delta^{2,4}$ are unequivocally *trans*. If these suppositions are true, FR-900848 **1** should be represented by either **45** or **46** since each enzymatic cyclopropanation should retain the alkene geometry and show the same absolute stereochemical bias. In addition, the geometry of $\Delta^{18}$ should be *trans* following the same biosynthetic speculation. In consequence of these considerations we sought to prepare model cyclopropane systems including quatercyclopropanes **40** and **41** to establish the sterochemistry of FR-900848 by correlation with key fragments from degradation. Falck[28] has also speculated as to the biosynthetic origin of the natural product and undertaken the synthesis of polycyclopropanated compounds as precursors to FR-900848 **1**.

Finally, Upjohn scientists have very recently reported on the isolation and biosynthesis of U-106305, a natural product related to FR-900848 **1**.[29] This substance has been shown to be biosynthetically derived from both acetate and methionine, but more of this later.

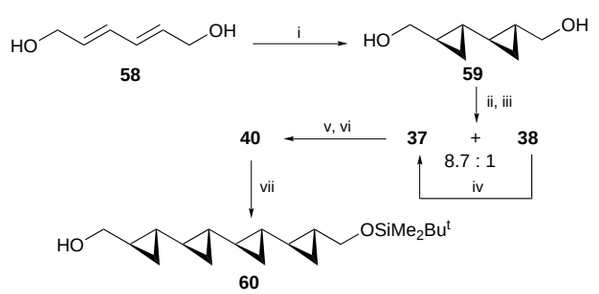


The isolated alkene unit of FR-900848 **1** was established to be *trans* by the following experiments (Scheme 8).[30–32] Double Simmons–Smith cyclopropanation of alkene **47** proceeded with excellent diastereoselectivity to provide only a single $C_2$-symmetric dicyclopropane **48** (89%). Sequential acid-mediated deprotection (63%) and condensation with benzaldehyde (64%) gave the benzylidene derivative **50**. Subsequent C-2 lithiation (1,3-dioxolane numbering) resulted in Whitham elimination[33] to provide the geometrically pure *E*-alkene **51** (60%). Alternatively, diol **52** was prepared from diol **49** *via* Swern oxidation[34] and sodium borohydride reduction. Whitham elimination of the derived acetal **53** gave the corresponding geometrically pure *Z*-alkene **54**. Comparison of the $^1H$ NMR

**Scheme 8** *Reagents and conditions*: i, $Et_2Zn$, $CH_2I_2$, $ClCH_2CH_2Cl$, −20 °C, 89%; ii, TsOH (cat), THF–$H_2O$ (5 : 1), 70 °C, 63%; iii, PhCHO, $H_2SO_4$ (cat), PhMe, 111 °C, 64%; iv, BuLi, pentane, 60%; v, PhCHO, camphorsulfonic acid, 96%; vi, BuLi, pentane

spectra of alkenes **51** and **54** with FR-900848 **1** was consistent with the assignment of the natural $\Delta^{18}$ geometry as *trans*. Clearly this stereochemical assignment is fragile unless the structures of the acetals **50** and **53** are secure. This insurance was underwritten by single crystal X-ray crystal structures[30,31] for both 3,5-dinitrobenzoate diesters derived from diols **49** and **52**.

The stereochemistry of the quatercyclopropane unit of FR-900848 **1** was determined[25,32] by comparison of the acetates prepared from the model diols **40** and **41** with the corresponding degradation product **2**[3] derived from the natural product. We were delighted to observe that quatercyclopropane **2** was identical in all respects, including the absolute stereochemistry, with the diacetate from diol **40**. Finally, two imidazolidine derivatives **56** and **57** were prepared from crotonaldehyde *via* acetal **55** using Yamamoto asymmetric cyclopropanation,[13,14]

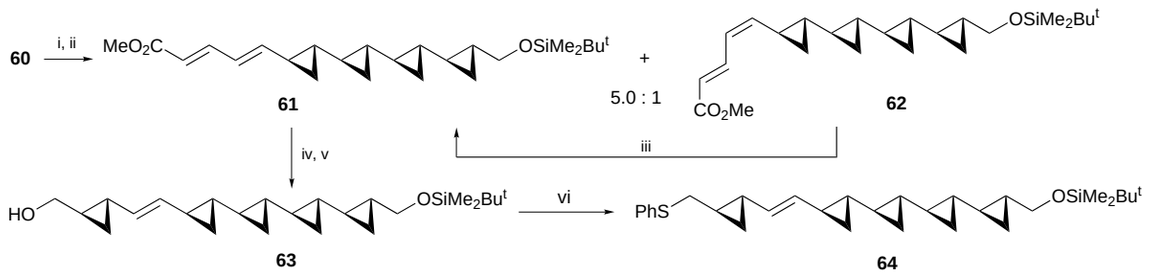


**55** **56** **57**

acid catalysed hydrolysis and condensation with the corresponding chiral diamines.[17] Ozonolysis of an authentic sample of FR-900848 **1** and subsequent reaction with (1*R*,2*R*)-*N*,*N*′-dimethyl-1,2-diphenylethanediamine gave an imidazolidene derivative which was identical with the synthetic adduct **56**. All these facts are consistent with the assignment of structure **45** to FR-900848.

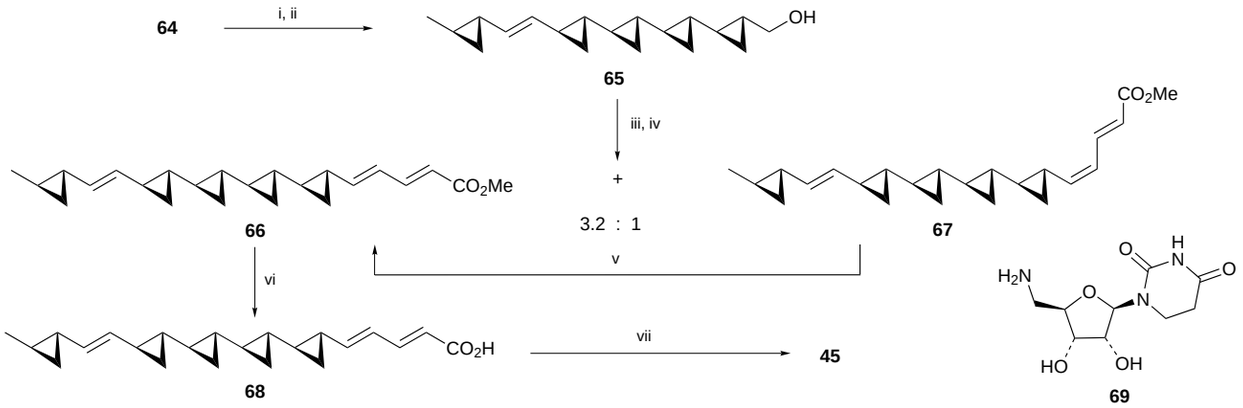
### Total synthesis of FR-900848 45

We have recently reported the total synthesis of FR-900848 **45** using a sequence of Charette cyclopropanation reactions (Schemes 9, 10 and 11).[26] Mucondiol **58** was bicyclopropanated in the presence of the chiral auxillary **14**[18] to provide bicyclopropane **59** (89%) predominately as a single enantiomer (Scheme 9). PCC oxidation and subsequent direct homologation without purification of the intermediate dialdehyde provided a separable mixture of *E*,*E*-diester **37** and the *E*,*Z*-isomer **38** (8.7 : 1, 67% from **59**). The unwanted diester **38** was smoothly converted into diester **37** using $LiTi(OPr^i)_4(SPh)$, a reagent introduced by Hunter[35] for the *Z* to *E* isomerisation of α,β-unsaturated esters. DIBAL-H reduction of diester **37** (94%) and bicyclopropanation of the resultant diol under Charette conditions[18] provided diol **40** (93%), predominately as a single diastereoisomer. Subsequent mono-*tert*-butyldimethylsilylation, oxidation and Horner–Emmons homologation gave esters **61** and **62** (Scheme 10). Again, Hunter isomerisation[35] was crucial in converting the undesired isomer **62** into additional *E*,*E*-ester **61**. Finally, DIBAL-H reduction of *E*,*E*-ester **61** (91%) followed by a third Charette asymmetric cyclopropanation[19] gave the pentacyclopropane alcohol **63** in high yield (90%). Very recently, Charette has reported related monocyclopropanation reactions on related dienols.[36]



**Scheme 9** *Reagents and conditions*: i, **14**, $Et_2Zn$, $CH_2I_2$, $CH_2Cl_2$, 0 to 25 °C, 89%; ii, pyridinium chlorochromate, NaOAc, silica, $CH_2Cl_2$, 0 to 25 °C; iii, $Ph_3P{=}CHCO_2Et$, $CH_2Cl_2$, 67% from **59**; iv, PhSH, BuLi, $Ti(OPr^i)_4$, THF, 0 to 25 °C, 50%; v, DIBAL-H, $CH_2Cl_2$, −78 °C, 94%; vi, **14**, $Et_2Zn$, DME, $CH_2I_2$, $CH_2Cl_2$, −15 to 25 °C, 93%; vii, NaH, $Bu^tMe_2SiCl$, THF, 44%

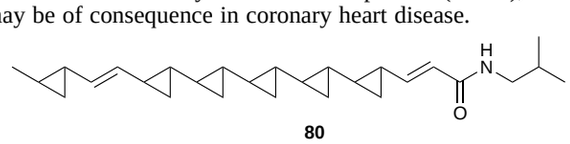
In general we have been significantly frustrated in our attempts to effect substitution reactions on multiple cyclopropanemethanol derivatives *via* hydroxy activation and displacement. Although such approaches usually lead to extensive degradation, reaction of alcohol **63** with *N*-(phenylsulfenyl) succinimide and tributylphosphine[37] cleanly gave the sulfide **64** (89%). Treatment of sulfide **64** with Raney nickel followed by ammonium fluoride gave alcohol **65** without significant alkene hydrogenation or cyclopropane degradation (Scheme 11). Finally, PCC oxidation of alcohol **65**, Horner–Emmons homologation (with Hunter isomerisation[35] of the unwanted *E*,*Z*-ester **67**), potassium trimethylsilanolate[38] mediated hydrolysis and bis(2-oxo-3-oxazolidinyl)phosphinic chloride (BOP-Cl)[39] mediated coupling with the nucleoside amine **69**[40] gave FR-900848 **45**. Much to our delight the synthetic material was identical with an authentic sample of the natural product.



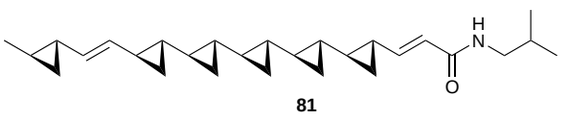
Falck *et al.* have also reported a total synthesis of FR-900848 **45** which elegantly underscores the value of Horeau amplification of absolute stereochemical purity (Scheme 12).[41] The vinylstannane **70** was converted into the corresponding cyclopropane **71** using Charette cyclopropanation[19] and protection. Tin to lithium to copper exchange and oxygenation gave the corresponding bicyclopropane **72**. This in turn was converted *via* the carboxylic acid **73**, Barton bromodecarboxylation[42] and a second dimerization reaction to reveal the quatercyclopropane **75**. These two oxidative dimerization reactions were accompanied by an enhancement in enantiomeric purity from 88–90% ee to > 99% ee in a process that is a variant of the Horeau amplification principle.[43] The diether **75** was converted into FR-900848 **45** using *inter alia* a Julia–Peterson olefination reaction, Horner–Emmons homologation and acylation *via* *p*-nitrophenyl ester activation.

### Total synthesis and structural elucidation of U-106305 80

In late 1995 Kuo *et al.* at Upjohn reported the isolation of U-106305 **80** from the fermentation broth of *Streptomyces* sp. UC 11136.[29] The authors determined that all the cyclopropanes are *trans*-disubstituted and that both alkenes are *E*, but the full structure was not determined. Their statement that 'U-106305 represents a structural class of compounds not

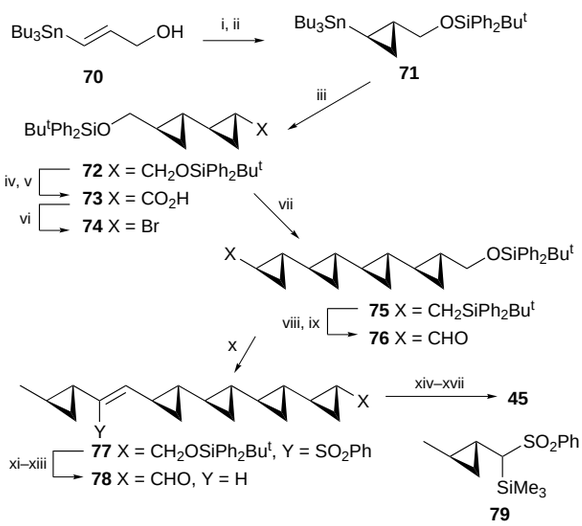


**Scheme 10** *Reagents and conditions*: i, pyridinium chlorochromate, NaOAc, silica, $CH_2Cl_2$, 0 to 25 °C; ii, (*E*)-$MeO_2CCH{=}CHCH_2P(O)(OMe)_2$, NaH, THF, 0 to 25 °C, 71% from **60**; iii, PhSH, BuLi, $Ti(OPr^i)_4$, THF, 0 to 25 °C, 63%; iv, DIBAL-H, $CH_2Cl_2$, −78 °C, 91%; v, **14**, $Et_2Zn$, DME, $CH_2I_2$, $CH_2Cl_2$, −40 °C, 90%; vi, *N*-(phenylsulfenyl)succinimide, $Bu_3P$, PhH, 89%



**Scheme 11** *Reagents and conditions*: i, Raney Ni, EtOH, −40 °C; ii, $NH_4F$, EtOH, 65 °C, 49% from **64**; iii, pyridinium chlorochromate, NaOAc, silica, $CH_2Cl_2$, 0 to 25 °C; iv, (*E*)-$MeO_2CCH{=}CHCH_2P(O)(OMe)_2$, NaH, THF, 0 to 25 °C, 63% from **65**; v, PhSH, BuLi, $Ti(OPr^i)_4$, THF, 0 to 25 °C, 51%; vi, $KOSiMe_3$, $CH_2Cl_2$, 85%; vii, **69**, BOP-Cl, $Et_3N$, DMA, 69%

previously reported from microbial fermentations' is inaccurate and both FR-900848 **45** and U-106305 **80** are clearly very closely related. It is therefore reasonable to speculate that U-106305 **80** has the same stereochemistry as **81**. It should be noted that U-106305 **80** is also biologically active. It is an inhibitor of cholesteryl ester transfer protein (CETP), which may be of consequence in coronary heart disease.

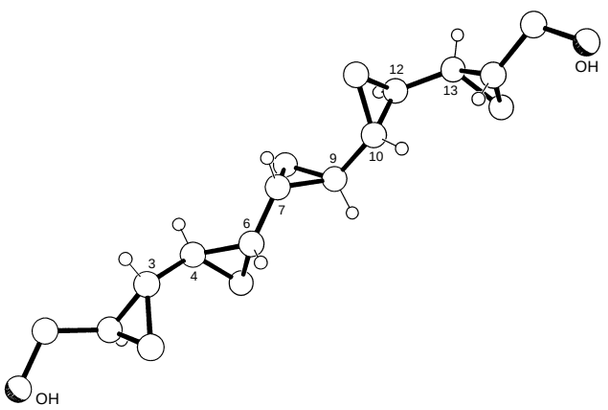


**80**

**81**

We have synthesized U-106305 **81** using a bi-directional approach to assemble the $C_2$-symmetrical quinquecyclopropane unit **87** using methodology as for FR-900848 **45** (Scheme 13).[44] Charette cyclopropanation[19] of diol **82** gave **83** in 89% ee. Dess–Martin oxidation[45] and Wittig olefination gave the diene diester **84**. Much to our delight, fractional recrystallization of **84** was especially efficient in enriching the material in the required enantiomer. Thus recrystallizaton from $Et_2O$–hexanes gave first racemic material and subsequently enantiomerically pure *E,E*-diester **84**. The structures for both the enantiomerically pure diester **84** and the corresponding racemic modification were confirmed by X-ray crystallography.[46] Diester **84** was converted onto the corresponding tercyclopropane and subsequently the quinquecyclopropane **87** using two sequential double Charette cyclopropanation reactions.[19] The structure of the near-helical quinquecyclopropane **87** was confirmed by X-ray analysis[44] and is shown in Fig. 3. This substance was

**Scheme 12** *Reagents and conditions*: i, **14**, $Et_2Zn$, $CH_2I_2$, $CH_2Cl_2$, 23 °C, 98%; ii, $Bu^tPh_2SiCl$, imidazole, DMF, 23 °C, 88%; iii, $Bu^sLi$, THF, −40 °C, then $[ICuPBu_3]_4$, −78 °C, then $O_2$, −78 °C, 73%; iv, $Bu_4NF$, THF, 23 °C, 72%; v, $RuCl_3$, $NaIO_4$, $CCl_4$, MeCN, $H_2O$, 23 °C, 91%; vi, *N*-hydroxypyridine-2-thione, DCC, DMAP, $BrCCl_3$, 23 °C; hν, 0 °C, 77%; vii, $Bu^tLi$, THF, −78 °C, then $[ICuPBu_3]_4$, −78 °C, then $O_2$, −78 °C, 75%; viii, $Bu_4NF$, THF, 23 °C, 72%; ix, $Pr_4NRuO_4$, NMO, 4 Å molecular sieves, $CH_2Cl_2$, 23 °C, 91%; x, **79**, BuLi, THF, −78 °C, 65%; xi, Li, naphthalene, THF, −78 °C, 70%; xii, $Bu_4NF$, THF, 23 °C, 95%; xiii, $Pr_4NRuO_4$, NMO, 4 Å molecular sieves, $CH_2Cl_2$, 23 °C, 91%; xiv, (*E*)-$EtO_2C$-$CH{=}CHCH_2P(O)(OEt)_2$, $LiN(SiMe_3)_2$, THF, −78 °C, 89%; xv, LiOH, MeOH, $H_2O$, 23 °C, 90%; xvi, 4-nitrophenol, DCC, DMAP, $CH_2Cl_2$, 23 °C, 73%; xvii, **69**, DMF, 23 °C, 76%



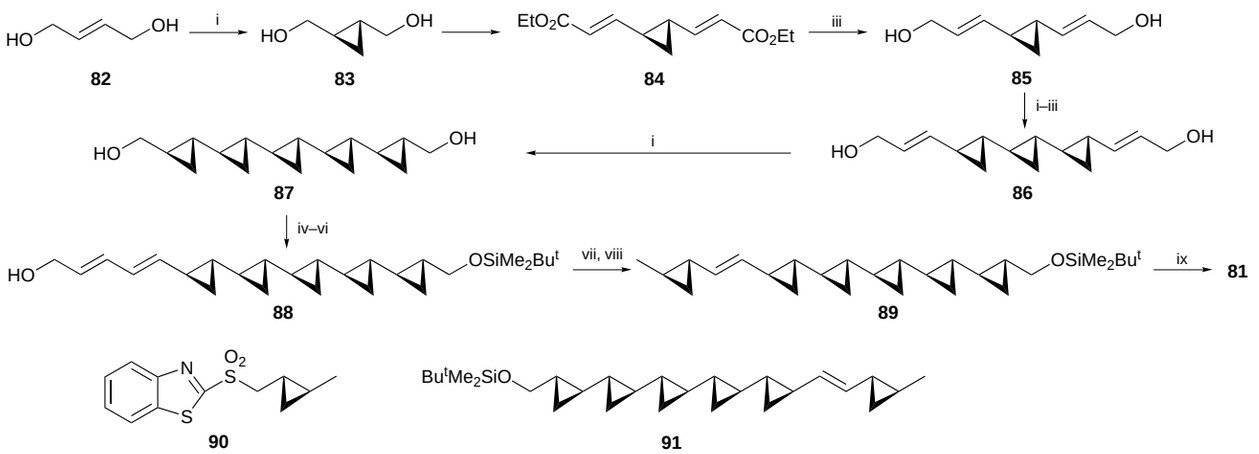


**Fig. 3** The molecular structure of the quinquecyclopropanedimethanol **87** showing the absolute stereochemistry

converted into U-106305 **81** using essentially the same strategy as in our synthesis of FR-900848 **45**. The synthetic material was identical in all respects with an authentic sample of U-106305. All these results clearly established the full structure and stereochemistry of U-106305 **81**. Charette and Lebel have also recently reported[47] a total synthesis of the antipode of U-106305 **81** using a bidirectional strategy that is closely related to our work. The synthesis differs in the later stages in the use of a Julia–Lythgo coupling[48] reaction to link the quinquecyclopropane and monocyclopropane units. The use of sulfone **90** provided the corresponding alkene **91** with 4 : 1 *E* : *Z* geometric selectivity.

## Future directions

Much remains to be done on the chemistry and biology of multiple cyclopropane arrays. It is clear from the Upjohn work that the biological effects mediated by multiple cyclopropane

**Scheme 13** *Reagents and conditions*: i, **14**, 4 Å molecular sieves, $Zn(CH_2I)_2$·DME, $CH_2Cl_2$, −40 to 25 °C, 83–91%; ii, Dess–Martin periodinane, pyridine, $CH_2Cl_2$ or DMSO, 25 °C, then $PPh_3$, *ca*. 10 °C, then $Ph_3P{=}CHCO_2Et$, 75–81%; iii, DIBAL-H, $CH_2Cl_2$, hexanes, −78 °C, 96–97%; iv, $Bu^tMe_2SiCl$, imidazole, $CH_2Cl_2$, 25 °C, 75% (calc.) at 78% conversion; v, Dess–Martin periodinane, pyridine, DMSO, 25 °C, then $PPh_3$, 25 °C, then $(E)$-$(MeO)_2P(O)CH_2CH{=}CHCO_2Me$, NaH, DBU, 25 °C, 88%; vi, DIBAL-H, $CH_2Cl_2$, hexanes, −78 °C, 95%; vii, **14**, 4 Å molecular sieves, $Zn(CH_2I)_2$·DME, $CH_2Cl_2$, −50 °C → −25 °C, 72%; viii, *N*-(phenylsulfenyl)succinimide, $PBu_3$, $C_6H_6$, 25 °C, 91%, then Raney nickel, THF, 25 °C, 44%; ix, $Bu_4NF$, THF, 25 °C, then DMSO, pyridine, 25 °C, Dess–Martin periodinane, 25 °C; then $PPh_3$, *ca*. 15 °C; then $Cl^-Ph_3P^+CH_2CONHCH_2Pr^i$, DBU, 25 °C, 91%

fatty amides should be much more general than anti-infective. Further aspects of the synthesis, reactions and properties of cyclopropene oligomers will be reported in due course.

## Acknowledgements

Dedicated to Professor Dieter Seebach on the occasion of his 60th Birthday, 31 October 1997.

We thank Glaxo Group Research Ltd. for the most generous endowment (to A. G. M. B.), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, the Engineering and Physical Sciences Research Council, the U.S. Department of Education under the Graduate Assistance in Areas of National Need Program, the Overseas Research Students Program for fellowship support (to K. K.), the National Institutes of Health (AI-22252) for support when this work started in the U.S.A., the European Commission for a TMR Research Training Grant (to D. H.), the Fujisawa Pharmaceutical Company Ltd. for generous donations of samples of FR-900848 **1** and key spectroscopic data, Pharmacia & Upjohn, Inc. for a sample of U-106305 **80**, ChemGenics Pharmaceutical Inc. for support of our research on antifungal agents and G. D. Searle & Company for generous unrestricted support.

**Tony Barrett's research interests are concerned with the development of organic and organometallic methodology, the total synthesis of bioactive natural products, asymmetric synthesis and catalysis, polymer supported synthesis, and ligand design and coordination chemistry. He obtained his BSc and PhD degrees at Imperial College and was then appointed as Lecturer in that institute. In 1983 he was appointed a full professor of Chemistry at Northwestern University in Evanston, Illinois, USA and in 1990 he moved to Colorado State University. After nearly ten years research in the USA, he returned to his *alma mater*, Imperial College, as Glaxo Professor of Organic Chemistry, Director of the Wolfson Centre for Organic Chemistry in Medical Science and Head of the Organic Section. Professor Barrett has received several awards for his contributions to research including the 1980 Meldola Medal, the 1982 Harrison Medal, the 1986 Corday–Morgan Medal and the 1994 Tilden Lectureship from the Royal Society of Chemistry, a 1986 Arthur C. Cope Scholar Award from the American Chemical Society, a 1987 Teacher-Scholar Award from the Camille and Henry Dreyfus Foundation and a 1989 Fellowship from the Japan Society for the Promotion of Science.**

**Wendel Doubleday obtained his BS degree at Ursinus College in 1982 and his PhD degree with Professor Ted Cohen at the University of Pittsburgh (1991), and subsequently carried out postdoctoral work with Tony Barrett in Colorado State University. He is currently employed by Ligand Pharmaceuticals Inc. in San Diego, California.**

**Dieter Hamprecht studied chemistry at Würzburg and Munich. He obtained his diploma in 1992 and his PhD degree in 1995 with Professor Wolfgang Steglich at the University of Munich. Currently he is employed by SmithKline Beecham in Harlow, UK.**

**Krista Kasdorf obtained her BS degree at North Carolina State University in 1990. After working for a year at Research Triangle Institute she began her graduate studies at Colorado State University and in 1995 obtained her PhD degree at Imperial College. She is currently carrying out postdoctoral work with Professor Dennis Liotta in Emory University, Atlanta, Georgia.**

**Gary Tustin obtained his BSc degree at Warwick University in 1989 and his PhD degree with Sue Gibson at Imperial College (1992), and subsequently carried out postdoctoral work with Tony Barrett both at Colorado State University and Imperial College.**

**Andrew White obtained both his BSc (1990) and PhD degrees (1994 with Bill Grifith) at Imperial College, where he remains carrying out postdoctoral work with David Williams.**

**David Williams' principal research interests are in the area of supramolecular chemistry and the interpretation of the rôle non-covalent interactions play in determining short and long range molecular structure. He took his first degree in Physics and obtained a PhD in crystallography at Imperial College, where he has held the posts of Lecturer and Reader, and is currently Professor of Structural Chemistry in the Organic Section.**

# Large variation of rates for platination of phosphorothioate-containing oligonucleotides: end effects and counter ion influence

**Johan Kjellström and Sofi K. C. Elmroth***

*Inorganic Chemistry 1, Chemical Center, Lund University, PO Box 124, S-221 00 Lund, Sweden*

**The rate of site-specific platination of short oligonucleotides can be varied up to 500 times by a change of the bulk composition and the molecular environment surrounding the binding site.**

Interactions between metal complexes and DNA are influenced by several factors. Some are related to the coordination environment and kinetic characteristics of the metal complex, others to the electrostatic and structural properties of the polymeric DNA. Improving our understanding of the mechanism for metal ion–DNA interactions is important, since DNA is believed to be the major target for many metal-based antitumour drugs.[1] In the case of biologically relevant intermediates of antitumour active *cis*-platinum complexes, several observations indicate that the location of their primary monofunctional adducts with DNA is likely to be controlled by kinetic rather than thermodynamic factors.[1–6] The aim of the present study was to further elucidate how general parameters such as location and molecular environment of a particular binding site as well as bulk composition may be utilized to obtain maximum kinetic separation between different types of adducts. The influence on reactivity originating from variations in the molecular structure surrounding the binding site was investigated by a comparison of the reactivity of $d(T_8p(S)T_8)$ with that of $d(Tp(S)T_{15})$ and d(Tp(S)T). Incorporation of a single phosphorothioate binding site has previously been shown to result in specific platination of the sulfur donor, both in the presence and absence of the naturally preferred G-N7 binding site.[2,3,7–9] The influence of bulk composition on the rate of platination of the oligonucleotides with *cis*-$[Pt(NH_3)(NH_2C_6H_{11})Cl(OH_2)]^+$ **1**, was studied at constant pH 4.2 by a variation of the concentration of inert monovalent bulk cations in the interval 1.5 mM–0.50 M. As previously discussed, the use of the monoaqua complex **1** simplifies the reaction mechanism to that of direct substitution of the labile $H_2O$ ligand by the nucleophilic sulfur atom of the phosphorothioate containing oligonucleotides.[3]

The cationic monoaqua complex **1** is a weak acid with p$K_a$ 6.4 ± 0.2, and its reactivity towards phosphorothioates has previously been shown to decrease with increasing bulk pH in the range 5–8.[3] This decrease in reactivity was rationalized in terms of an increase in concentration of the less reactive monohydroxo complex, *cis*-$[Pt(NH_3)(NH_2C_6H_{11})Cl(OH)]$ **2**. Such decrease has been observed also for other model systems for interactions of mono-aquated platinum complexes with DNA.[10,11] The use of binding sites located on a negatively charged oligonucleotide makes the mechanistic interpretation of rate variations as a function of pH more complicated in the present systems than in the case of reactions between small molecules, however. The non-selective electrostatic attraction of cations onto the surface of the polymer that can be expected to take place here,[12–14] implies that not only cationic reactants but also oxonium ions may accumulate in its vicinity.[15–17] In a situation where the distribution between **1** and **2** is sensitive towards small variations of pH, it may thus be possible that an observed difference in reactivity between adduct formation on the polymer and the corresponding reaction in absence of surrounding bases could, at least partially, be the result of a local pH change. The present study made at pH 4.2 minimizes such contributions since at this pH the equilibrium distribution between **1** and **2** is affected to a negligible extent by local changes of the oxonium ion concentration. The use of a diluted buffer allowed for pH control during the reaction with a minimum of interference from competitive reactions with buffer anions.[18]† The reactions of **1** with the oligonucleotides were studied under pseudo-first-order conditions with $Pt^{II}$ in *ca.* 10-fold excess compared to the concentration of oligomers by use of HPLC. The kinetic parameters were evaluated at 298 K from the time-dependent changes in integrated HPLC peak areas of unplatinated and platinated oligonucleotides, respectively (Supplementary data, Fig. S1).‡ Both the decay of reactants and formation of products were well described by single exponentials (Supplementary data, Fig. S2). The observed pseudo-first-order rate constants, $k_{obs}$, were linearly dependent on the total concentration of $Pt^{II}$ (Supplementary data, Table S1, and Fig. S3).

As shown in Fig. 1, the apparent second-order rate constants, $k_{2,app}$,§ for platination of the oligonucleotides exhibit a common trend for $[Na^+, K^+] \leqslant 0.3$ M with a monotonous increase in reactivity as a function of decreasing bulk cation concentration. In addition, a relative reactivity order of $k_{2,app}(d(T_8p(S)T_8)) > k_{2,app}(d(Tp(S)T_{15})) > k_{2,app}(d(Tp(S)T))$ is maintained throughout the whole concentration range investigated. There are striking differences in reactivity behaviour, however. First of all, the limiting rate constants obtained for $[Na^+, K^+] > 0.3$ M are significantly different for the three types of DNA: 5.7 ± 1.5, 0.87 ± 0.15 and 0.43 ± 0.05 $dm^3\ mol^{-1}\ s^{-1}$ for $d(T_8p(S)T_8)$, $d(Tp(S)T_{15})$ and d(Tp(S)T), respectively. Secondly, the response to decreasing salt concentration exhibits different characteristics with an increase in reactivity that is most pronounced, both in absolute and relative terms, for platination of $d(T_8p(S)T_8)$. The maximum second-order rate constant for the latter reaction was determined as 200 ± 40 $dm^3\ mol^{-1}\ s^{-1}$ at the lowest salt concentration investigated, $[Na^+, K^+]$ = 1.5 mM. At this concentration of bulk cations the rate constant for

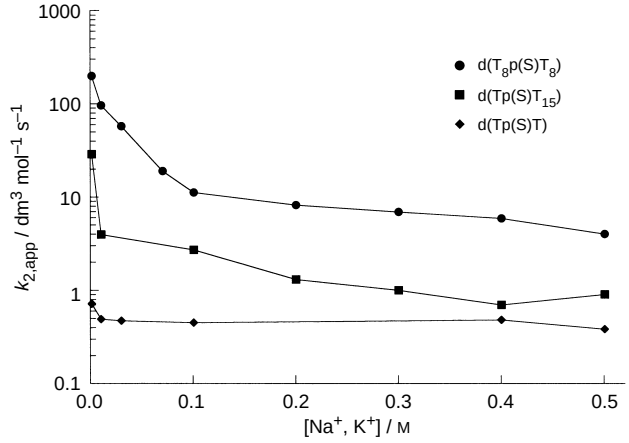

**Fig. 1** Semilogarithmic plot of the apparent second-order rate constant *vs.* the concentration of monovalent bulk cations for reaction of **1** with (●) $d(T_8p(S)T_8)$, (■) $d(Tp(S)T_{15})$ and (◆) d(Tp(S)T), at pH 4.2 and 25 °C

platination of d(Tp(S)$T_{15}$) was found to be 30 ± 10 $dm^3\ mol^{-1}\ s^{-1}$. With respect to the rate of platination of d(Tp(S)T), $k_{2,app}$ = 1.0 ± 0.5 $dm^3\ mol^{-1}\ s^{-1}$ at [$Na^+$, $K^+$] = 1.5 mM, these rate constants thus represent a 200- and 30-fold rate increase for d($T_8$p(S)$T_8$) and d(Tp(S)$T_{15}$), respectively.

These results clearly demonstrate that bulk conditions as well as the molecular environment of the phosphorothioate binding site have a large influence on the rate of platination also of short single-stranded oligonucleotides which lack the typical polyelectrolyte behaviour of extended DNA.[14,19–21] It is noteworthy, that although the absolute value of the rate constants may be changed by orders of magnitude by a variation of the concentration of monovalent cations in the bulk, such a variation does not affect the relative reactivity order for formation of the different types of adducts. Surprisingly, the rate of platination of d(Tp(S)$T_{15}$) exhibits reaction characteristics intermediate between those of d($T_8$p(S)$T_8$) and d(Tp(S)T). This observation suggests that association of the cationic metal complex with the polymer prior to adduct formation is of importance for the reaction mechanism also for platination of the end position where the polyelectrolyte effect can be expected to be reduced to a minimum.[19–21] The present study, in which pH effects can be excluded from contributing to the rate increase, indicates that rate accelerations similar to those observed for freely diffusing species[17] may be obtained also for reactions where the rate determining step involves formation of a covalent bond with donor atoms located on the charged phosphodiester backbone of the DNA. These findings thus give strong support for a previously suggested reaction mechanism for platination of oligonucleotides comprising preassociation of metal complex onto the oligomer followed by rapid diffusion along the contour length of the polymer to the kinetically preferred binding site.[3] In addition to the impact of this mechanism on biological systems, awareness of its large influence on reactivity, as exemplified here by a maximum variation of the platination rate between d($T_8$p(S)$T_8$) and d(Tp(S)T) by a factor of *ca.* 500, should also be of importance for antisense strategies using for example cross-linking reagents, as well as for synthetic chemistry.

Financial support from the Swedish Cancer Foundation (grant 961699, S. K. C. E.) is gratefully acknowledged. We also thank Ms Emma Svensson for preliminary experimental studies of the d(Tp(S)$T_{15}$) system and Mrs Bodil Eliasson for valuable technical assistance.

# C–H··π interactions in ethynylbenzenes: the crystal structures of ethynylbenzene and 1,3,5-triethynylbenzene, and a redetermination of the structure of 1,4-diethynylbenzene

**Hans-Christoph Weiss,[a] Dieter Bläser,[a] Roland Boese,*[a] Brandon M. Doughan[b] and Michael M. Haley[b]**

[a] *Institut für Anorganische Chemie, Universität Essen, Universitätsstrasse 3-5, D-45117 Essen, Germany*
[b] *Department of Chemistry, University of Oregon, Eugene, Oregon 97403, USA*

**The crystal structures of 1,4-diethynylbenzene 1 and 1,3,5-triethynylbenzene 2 show similar packing principles with CH··π (triple bond)-zigzag networks; surprisingly, the packing motif of ethynylbenzene 3 is quite different.**

Recent work has shown that the π-electrons of a C≡C triple bond can act as a hydrogen bond acceptor.[1–6] In addition to the usual donor substituents, such as hydroxy and amino groups, it was shown that carbon-bonded hydrogen atoms can also display donor properties. Terminal alkynes represent one of the best CH··π hydrogen bond donors due to the acidity of the alkynyl hydrogen atom.[7] This functional group has the advantage of providing simultaneously donor and acceptor properties for CH··π hydrogen bridges. Whereas the expected geometry for this type of intermolecular interaction is T-shaped,[8] as in acetylene,[9] this idealized motif with a CH··π angle of (180 ± 10°) is rarely found in the solid state. We report herein the comparison of the CH··π interactions in the three title ethynylated aromatics.

Although already known,[10] the structure of 1,4-diethynylbenzene **1** was redetermined under the same conditions as for 1,3,5-triethynylbenzene **2** and ethynylbenzene **3** for a better comparison and higher accuracy (mainly for the positions of the hydrogen atoms).† In the solid state **1** has a layer structure; the arrangement within the layers is shown in Fig. 1.

The molecules are connected by CH··π hydrogen bridges in a zigzag pattern along a mirror glide plane similar to that known for other compounds with terminal ethynyl groups, *e.g.* DL-prop-2-ynylglycine,[7] but-3-ynoic acid[11] and 1,4-diethynylcubane.[12] Each molecule is fixed by four hydrogen bridges and the geometrical data indicate ideal conditions for relatively strong CH··X hydrogen bonds (Table 1). Between the layers there exist no herringbone interactions as in benzene, and only a staggering of the coplanar rings can be observed (plane–plane distance 353 pm). The CH··M contacts (M is the centre of the triple bond) are among the shortest contacts found in the Cambridge Structural Database.[13] The molecules are tilted by 25.0° to the 100 plane. Thus the major attractive forces which contribute to the lattice energy are the hydrogen bridges to the triple bonds, which form a two-dimensional network.

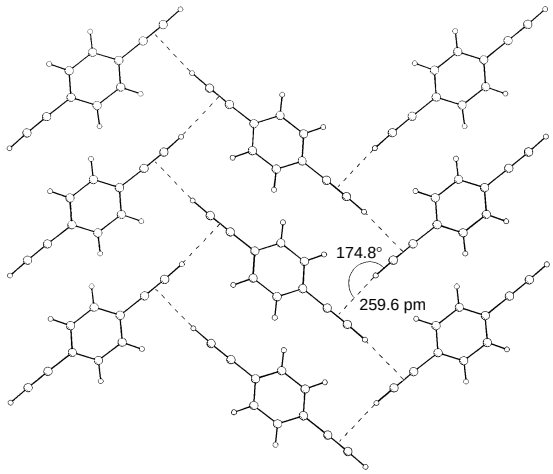

**Fig. 1** Section of the layer structure of **1** in the 100 direction

**Table 1** CH··π distances and angles for **1**–**3**

| Compound | Bond geometry[b] | H··M[a] distance/pm | CH··M[a] angle/° |
|---|---|---|---|
| **1** | trip | 259.6 | 174.8 |
| **2** | trip | 268.1 | 165.7 |
| | trip | 272.3 | 147.3 |
| | trip | 281.4 | 140.1 |
| **3** | ring | 260.2 | 143.6 |
| | ring | 268.3 | 160.5 |
| | trip | 257.7 | 174.3 |

[a] M = centre of the π-system. The positions of the hydrogen atoms were normalized to a C–H distance of 108 pm. [b] Ring = bond to π-system of the phenyl group; trip = bond to π-system of the triple bond.

A similar packing principle can be observed in the crystal structure of **2**; however, because of the different molecular geometry the packing is more complex and can be described as a folded layer structure. The main attractive forces between the molecules of **2** are also hydrogen bond bridges from the ethynyl hydrogen atoms to the π-electrons of the triple bonds. Each molecule acts three times as an acceptor and as a donor, making six contacts per molecule with three distinct distances (Fig. 2). The connections of each molecule to its environment, however, are not symmetrical: the first ethynyl group acts only as a donor, the second acts as a donor and an acceptor and the third acts as a donor and a double acceptor. All of the contacts are rather short and the angles $C_{ethynyl}H··M$ lie between 140 and 180° and compare well with those in **1**.

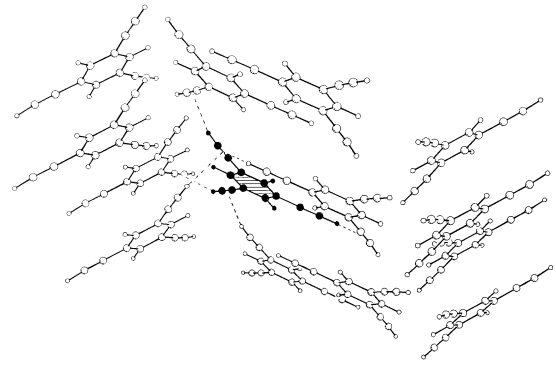

**Fig. 2** Folded layers of **2**; one highlighted molecule shows the six hydrogen bridges

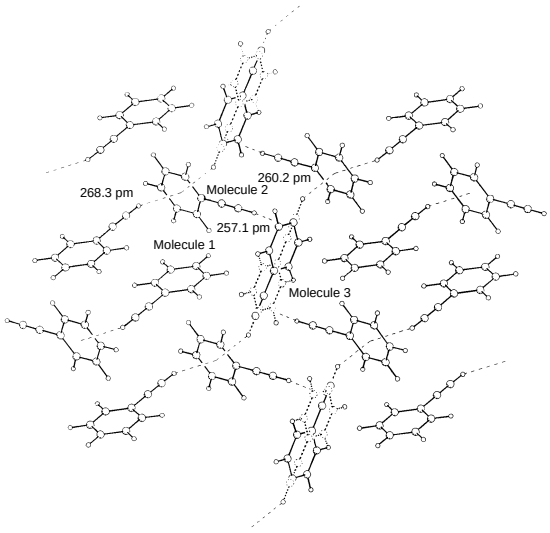

**Fig. 3** Packing of **3**; molecule 3 is disordered (additional dotted molecule)

Surprisingly, the parent ethynylated benzene derivative **3** exhibits a very different packing in the crystal lattice. Five molecules are found in the unit cell (space group $P\bar{1}$) with two and a half in the asymmetric unit; consequently the half molecule is disordered. One of the ethynyl hydrogen atoms points to a triple bond and the other two point to the π-systems of two surrounding phenyl rings.

In contrast to **1** and **2** the molecules in **3** show benzene-type edge-to- face interactions.[14,15] The angles between the planes of the rings lie between 80 and 90°, and the shortest CH···M contact is 282.2 pm (276.4 pm for benzene[14]). The crystal structure of **3** represents a compromise between the herringbone packing of benzene and the coplanar stacking, as found for **1**, with $CH\cdot\cdot\pi_{trip}$ interactions. The respective intermolecular distances and angles for **1**–**3** are summarized in Table 1.

Comparison of the physical properties of molecules **1**–**3** and benzene (Table 2) sheds light on the stability of the compromise packing of **3**. The melting point of **3** is abnormally low—over 50 °C lower than that of benzene. The calculated densities of the solids show a similar tendency: **1** and **2** have significantly higher densities than **3**. For **3** one would expect a higher density than for benzene, as its molecular mass is between those of benzene and **1**; however, the densities are approximately the same. These data clearly indicate that the lattice energy of **3** must be substantially less and that the compromise packing is not as efficient as that of benzene or of **1** and **2**.

**Table 2** Melting points and calculated densities[a] for **1**–**3** in the solid state

| Compound | mp/°C | $\rho_{calc}$/Mg m$^{-3}$ |
|---|---|---|
| Benzene[b] | 5.5[c] | 1.094 |
| **1** | 96.5[d] | 1.202 |
| **2** | 103–104[e] | 1.178 |
| **3** | −44.8[c] | 1.100 |

# Efficient panchromatic sensitization of nanocrystalline $TiO_2$ films by a black dye based on a trithiocyanato–ruthenium complex

**Md. K. Nazeeruddin, P. Péchy and M. Grätzel***

*Institute of Photonics and Interfaces, Swiss Federal Institute of Technology, CH-1015 Lausanne, Switzerland*

**A black trithiocyanato–ruthenium(II) terpyridyl complex where the terpyridyl ligand is substituted by three carboxyl groups in 4,4′,4″-positions achieves very efficient panchromatic sensitization of nanocrystalline $TiO_2$ solar cells over the whole visible range extending into the near-IR region up to 920 nm.**

Dye-sensitized nanocrystalline $TiO_2$ solar cells are presently under intensive investigation.[1–3] So far, the best performing charge transfer sensitizer employed for such an application is a *cis*-dithiocyanato bis(4,4′-dicarboxy-2,2′-bipyridine)ruthenium(II) complex,[4] yielding solar to electric power conversion efficiency of 10% under standard AM 1.5 condition. To improve further the efficiency of such systems, an enhanced spectral response of the sensitizer in the red and near-IR region is required. The present study reports the synthesis and characterization of a new class of trithiocyanato–ruthenium(II) terpyridyl complex. Substitution of the terpyridyl ligand by three carboxyl groups in 4,4′,4″-positions yields a black dye displaying very efficient panchromatic sensitization over the whole visible range extending into the near-IR region up to 920 nm.

The oxidation of 4,4′,4″-trimethyl-2,2′:6′,2″-terpyridine[5,6] (0.32 g, 1.16 mmol) was carried out in sulfuric acid (4 ml), with chromium trioxide (1.05 g, 10.5 mmol) at 75 °C, yielding 4,4′,4″-tricarboxy-2,2′:6′,2″-terpyridine (0.15 g, 41%).†

4,4′,4″-Tricarboxy-2,2′:6′,2″-terpyridine (127 mg) was esterified by refluxing in methanol (15 ml) and sulfuric acid (70 mg) for 3 days. The white crystals were filtered, washed with methanol and diethyl ether successively, yielding 4,4′,4″-trimethoxycarbonyl-2,2′:6′,2″-terpyridine L (102 mg, 72%).‡

The $[RuLCl_3]$ complex was synthesized by adding a solution of 4,4′,4″-trimethoxycarbonyl-2,2′:6′,2″-terpyridine (40 mg), in dichloromethane (20 ml), to a solution of hydrated ruthenium trichloride (26 mg) in ethanol (30 ml). The reaction mixture was refluxed for 2 h and the solution was concentrated to 20 ml. The precipitated complex was collected and washed thoroughly with ethanol to remove any unreacted ruthenium trichloride (yield 48 mg, 79%).§

The complex $[NHEt_3][RuL(NCS)_3]$ **1** was obtained by refluxing $[RuLCl_3]$ (48 mg) and ammonium thiocyanate (100 mg) in dmf–water for 3.5 h at 120 °C, in the dark under an argon atmosphere. The ester groups of the terpyridine ligand were hydrolysed by further refluxing for 15 h in the presence of triethylamine (6 ml). The isolated solid was recrystallised from methanol–diethyl ether (yield 39 mg, 69%).¶

The UV–VIS absorption spectrum of **1** in ethanol shows an intense metal-to-ligand charge transfer band at 620 nm [Fig. 1(*a*)], with a molar absorption coefficient of 6500 $dm^3\ mol^{-1}\ cm^{-1}$. Bands at 291 and 329 nm with a distinct shoulder at 340 nm are assigned to the intraligand π–π* transition of the 4,4′,4″-tricarboxy-2,2′:6′,2″-terpyridine ligand. The interesting feature of complex **1** is the red-shifted MLCT absorption band in the visible region compared to the $[Ru(tpy)_2]^{2+}$ (tpy = 2,2′:6′,2″-terpyridine) family.[7] The three thiocyanato anionic ligands stabilize the excited states by electron donation to Ru causing a red shift in the MLCT bands. The electrochemical data of **1** suggest that the red shift in the MLCT is due to the decrease in the π* level of the 4,4′,4″-tricarboxy-2,2′:6′,2″-terpyridine ligand and an increase in the energy of the $t_{2g}$ metal orbital.

The MLCT and the π–π* bands of **1** were displaced to higher energy (590 nm) upon deprotonation of the carboxyl groups, which could be due to increase in the energy of the π* orbital of the 4,4′,4″-tricarboxy-2,2′:6′,2″-terpyridine ligand. When excited within the MLCT absorption band, **1** in ethanol solution at 298 K, exhibits a luminescence (measured as described in ref. 4) consisting of a single band with a maximum at 950 nm [Fig. 1(*b*)] and a lifetime of 18 ± 5 ns.

The cyclic voltammogram of **1** measured in dmf containing 0.1 M $[NBu_4][CF_3SO_3]$ shows one quasireversible wave at 0.6 V (*vs.* Ag/AgCl), which is attributed to the $[Ru^{II/III}L(NCS)_3]$ redox couple. In the negative potential range two irreversible waves at −1.1 and −1.2 V (*vs.* Ag/AgCl) are observed which are assigned to ligand reduction. A monolayer of complex **1** was adsorbed from a $2 \times 10^{-4}$ M solution in ethanol, containing 40 mM sodium taurodeoxycholate, as a co-adsorbent, onto a 12 nm thick nanocrystalline $TiO_2$ (anatase) film prepared on conducting glass as previously described.[4] The black film exhibited striking performance when tested in a photovoltaic cell in

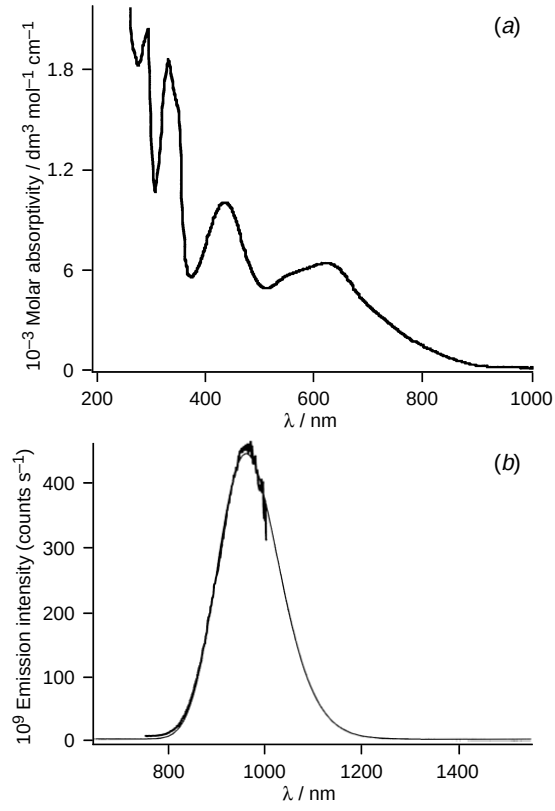

**Fig. 1** (*a*) Absorption spectrum of complex **1** in ethanol solution and (*b*) emission spectrum in ethanol solution at room temperature. The smoother curve corresponds to a Gaussian fit (instrument limit is 1000 nm).

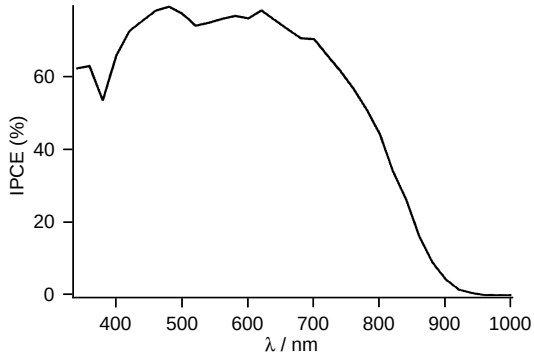

**Fig. 2** Photocurrent action spectrum obtained with a nanocrystalline $TiO_2$ film supported onto a conducting glass sheet and derivatized with complex **1**. The incident photon to current conversion efficiency is plotted as a function of wavelength. A sandwich type cell configuration was used to measure this spectrum.

conjunction with a redox electrolyte such as 0.9 M LiI and 0.1 M $LiI_3$ in propylene carbonate.

Fig. 2 shows the photocurrent action spectrum of such a cell where the incident photon to current conversion efficiency (IPCE) is plotted as a function of wavelength. Experimental details are described elsewhere.[4] The broad feature appears covering the entire visible spectrum and extending into the near-IR region up to 920 nm, the IPCE value in the plateau region being *ca.* 80%. Taking the light losses in the conducting glass into account the efficiency of electric current generation is practically 100% over a broad wavelength range extending from 400 to 700 nm. The overlap integral of this curve with the standard global AM 1.5 solar emission spectrum yields a photocurrent density of 20 mA $cm^{-2}$ and the first results obtained with these cells in the sun have confirmed these expectations. The discovery of this new black dye exhibiting enhanced light harvesting in the red and near-IR region opens up the way to improve significantly the overall efficiency of nanocrystalline photovoltaic devices.

This work was supported by grants from the Swiss Federal Institute for Energy (OFEN) and the Institut für Angewandte Photovoltaik (INAP, Germany). R. Humphrey-Baker assisted with the fluorescence work.

# Homogeneous modeling of ammoxidation chemistry: nitrile formation using a soluble analogue of $MoO_3$

**Thomas R. Mohs, Yuhua Du, Bruce Plashko and Eric A. Maatta***

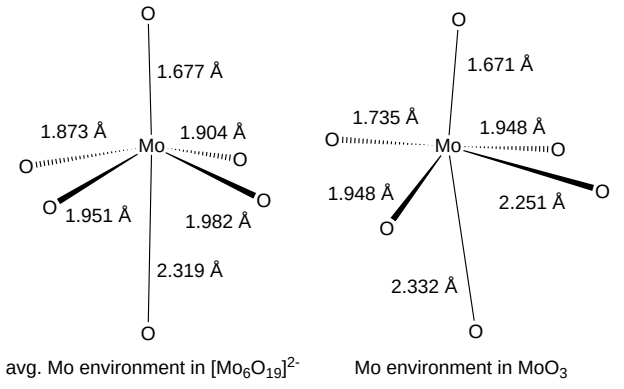
*Department of Chemistry, Kansas State University, Manhattan, Kansas 66506, USA*

**The reaction of the soluble $MoO_3$ analogue $[Mo_6O_{19}]^{2-}$ with $Ph_3P{=}NCH_2Ph$ replicates key features of heterogeneous ammoxidation chemistry by producing moderate yields of PhC≡N through the proposed intermediacy of the benzylimido hexamolybdate complex $[Mo_6O_{18}(NCH_2Ph)]^{2-}$.**

The SOHIO/BP process for the heterogeneous oxidation of propene by $O_2$ in the presence of ammonia to yield acrylonitrile (*i.e.*, the 'ammoxidation' of propene) constitutes the largest volume example of an allylic oxidation in commercial practice.[1] A minimalistic representation of this remarkable transformation is provided in Scheme 1. It is now well established that the bismuth oxide component of the catalyst serves to abstract a hydrogen atom from propene, affording an allyl radical;[2] subsequent C–N bond formation and redox events occur at sites within the $MoO_3$ component.[3] Drawing on the extensive studies of Grasselli and Burrington,[4] key nitrogenous surface species proposed to be involved in this chemistry include imido {Mo≡NH}, allylamido {Mo=NHCH$_2$CH=CH$_2$}, allylimido {Mo≡NCH$_2$CH=CH$_2$}, and allylideneamido {Mo=N=CHCH=CH$_2$} fragments. Several groups have reproduced aspects of the proposed transformations in studies of various mononuclear systems.[5–7]

**Scheme 1**

In order to further refine these homogenous analogues of proposed ammoxidation events we sought to transfer this chemistry into a coordination environment which more closely resembles that provided by bulk $MoO_3$. As shown in Fig. 1, the soluble hexamolybdate cluster $[Mo_6O_{19}]^{2-}$ possesses an $MoO_6$ coordination sphere[8] which is conspicuously similar to that within $MoO_3$.[9] Realizing that a large number of organoimido-substituted hexamolybdates recently have been accessed through reactions of $[Mo_6O_{19}]^{2-}$ with various imido delivery reagents,[10] this structural correspondence suggested to us that allylimido- and benzylimido-hexamolybdates would provide the closest approximation yet available of purported ammoxidation surface species. We now report that the reaction of $[Mo_6O_{19}]^{2-}$ with the benzylimido delivery reagent $Ph_3P{=}NCH_2Ph$ affords benzonitrile in moderate yield (37%) thus replicating essential features of heterogeneous ammoxidation chemistry through the proposed intermediacy of an unstable benzylimido hexamolybdate system $[NBu_4]_2[Mo_6O_{18}(NCH_2Ph)]$, **1**.



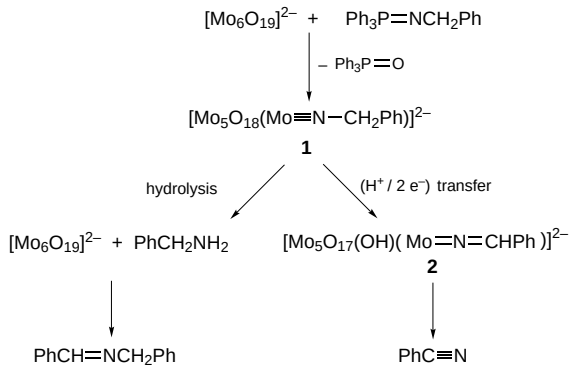


**Fig. 1** Comparison of the Mo environments in $[Mo_6O_{19}]^{2-}$[8] and in $MoO_3$[9]

The addition of 1.47 mmol of $Ph_3P{=}NCH_2Ph$ to an equimolar amount of $[NBu_4]_2[Mo_6O_{19}]$ in 30 ml MeCN at room temp. produces a brown coloration within 1 min of mixing. After this solution was heated at 82 °C under $N_2$ for 72 h, analysis by GC–MS techniques revealed the presence of benzonitrile (0.54 mmol, 37%) and *N*-benzylidenebenzylamine (0.25 mmol, 34%) along with quantitative production of triphenylphosphine oxide. Using an identical protocol, the thermolysis of $Ph_3P{=}NCH_2Ph$ in the absence of hexamolybdate produced only a trace of benzonitrile (0.009 mmol, 0.6%) and a modest amount of triphenylphosphine oxide (0.17 mmol, 11.7%); importantly, the latter product signals the presence of residual water in the acetonitrile solvent. $^1$H NMR monitoring throughout the reaction between $Ph_3P{=}NCH_2Ph$ and $[Mo_6O_{19}]^{2-}$ provided only broad and uninformative spectra, inferring the presence of paramagnetic species. In confirmation, aliquots withdrawn from the reaction solution were analyzed by EPR spectroscopy as frozen glasses and gave spectra identical to that published for the brown trianion $[Mo_6O_{19}]^{3-}$.[11]

In order to test whether $PhCH{=}NCH_2Ph$ is an intermediate in the formation of benzonitrile, a MeCN solution containing equimolar quantities of the imine and the hexamolybdate was treated and analyzed as above. No reaction occurred, suggesting that the imine is formed on a reaction pathway different from that leading to benzonitrile. Benzyl amine was suspected as the imine precursor since various polyoxometalates are known to effect this transformation.[12] Accordingly, the reaction of 1.47 mmol amounts of $PhCH_2NH_2$ and $[Mo_6O_{19}]^{2-}$ in MeCN was performed as described above and produced a brown solution immediately; subsequent GC–MS analysis revealed the production of $PhCH{=}NCH_2Ph$ (0.37 mmol, 46%) and only minor amounts of PhCN (0.029 mmol, 1.8%). It is important to note that the 0.25 mmol of $PhCH{=}NCH_2Ph$ produced in the reaction between $Ph_3P{=}NCH_2Ph$ and $[Mo_6O_{19}]^{2-}$ requires far more benzyl amine (0.50 mmol) than can be accounted for by hydrolytic decomposition of $Ph_3P{=}NCH_2Ph$ alone (0.17 mmol); this discrepancy can be accommodated by the reasonable assumption that the reaction between $Ph_3P{=}NCH_2Ph$ and $[Mo_6O_{19}]^{2-}$ affords an intermediate which is more sensitive than $Ph_3P{=}NCH_2Ph$ toward hydrolytic release of $PhCH_2NH_2$.

Since an initial redox reaction between $Ph_3P{=}CH_2Ph$ and the hexamolybdate is unlikely,† and given the demonstrations of forming complexes $[Mo_6O_{18}(NR)]^{2-}$ in reactions between the hexamolybdate and $Ph_3P{=}NR$ reagents,[10a,d] we propose that our observations are best accommodated by formation of an unstable benzylimido hexamolybdate $[Mo_6O_{18}(NCH_2Ph)]^{2-}$, **1**, which undergoes two modes of decomposition. In accord with observations on related d$^0$ benzylimido[13,14] (and allylimido[6]) complexes, **1** should be extremely moisture sensitive

**Scheme 2** Proposed decomposition pathways for **1**

and its hydrolysis (to produce benzyl amine and hexamolybdate) will initiate the reaction sequence leading to $PhCH{=}NCH_2Ph$ (Scheme 1).

The conversion $\{[Ph–CH_2–N]^{2-} \rightarrow Ph–C{\equiv}N\}$ requires the formal export of 2 $H^+$ and 4 $e^-$. Precedent suggests that the $\alpha$-$CH_2$ hydrogens within **1** should be acidic[6,13,14] while the oxo sites within **1** will display enhanced basicity[10*b*,*g*] as a result of the effective electron donation provided by the benzylimido ligand. These combined attributes suggest that the decomposition of **1** to produce benzonitrile is triggered by initial $H^+$ migration, probably in a pairwise[10*g*] fashion; an accompanying 2 $e^-$ reduction of its hexamolybdate cage will produce a reduced benzylideneamido dianion **2** (Scheme 2).[6,13] While further reduction of **2** is improbable, several species in the reaction solution should be capable of oxidizing **2** {the most potent of which is $[Mo_6O_{19}]^{2-}$}. Such an oxidation would increase the acidity of the remaining methine hydrogen atom, facilitating a second $H^+$–2 $e^-$ transfer process, allowing the release of benzonitrile. Efforts are underway to isolate complexes analogous to **1** and **2**.

We thank the Office of Basic Energy Sciences, Department of Energy (USA) for support of this work.

# Supramolecular control of the photochemistry of stilbenes by cyclodextrins

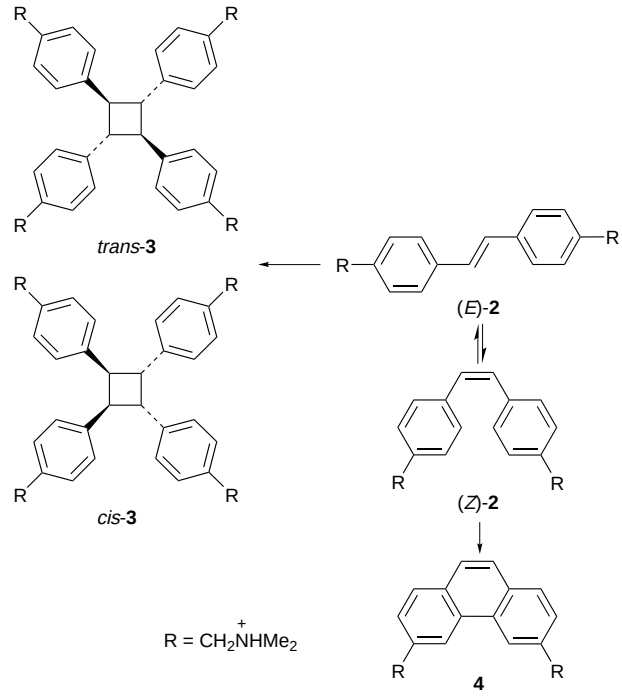
**Wolfgang Herrmann, Susanne Wehrle and Gerhard Wenz***

*Polymer-Institut der Universität Karlsruhe (TH), Hertzstrasse 16, D-76187 Karlsruhe, Germany*

**Upon UV irradiation in the presence of β-cyclodextrin, (*E*)-4,4′-bis(dimethylammoniomethyl)stilbene is transformed to the (*Z*)-isomer, but in the presence of γ-cyclodextrin only the [2 + 2]-cycloaddition products are obtained; the products are a molecular imprint of the cavity of the cyclodextrin.**

Supramolecular assemblies are formed by the self organisation of complementary molecules, *e.g.* host and guest molecules.[1] They may show a high degree of short range order which allows chemical reactions to be performed with high specificity. Photochemical reactions can be especially well-controlled by supramolecular assembly of the reactive molecules as the close vicinity of the molecules makes the selective transformation of highly energetic intermediates possible.[2] Processes like energy[3] or electron transfer,[4] dimerisations[5–7] and polymerisations[8] have been successfully performed in organised media.[9] Here we report on the control of the photochemistry of stilbenes by inclusion in cyclodextrins.

**1a** *n* = 6
**b** *n* = 7
**c** in = *8*



Cyclodextrins **1a**–**c** are torus shaped cyclic oligomers of glucose. They provide a hydrophobic cavity for the inclusion of hydrophobic guest molecules in aqueous solution.[10] The formation of ternary inclusion compounds of one cyclodextrin ring and two guests facilitates bimolecular reactions between the two guests:[11,12] the cyclodextrin ring acts like a molecular reaction vessel. Thus the photo-dimerisation of two anthracene,[13] acenaphthylene[14] or coumarin molecules[15] is accelerated by inclusion in **1c**. In contrast, the inclusion of stilbenes in **1b** leads to the prevention of the photo-dimerisation, as only one guest molecule is included.[16,17] Here the host **1b** seems to exert a shielding effect on the guest. We report on the influence of the ring size of a cyclodextrin on the photochemistry of the stilbene (*E*)-**2**. It is well suited for such investigations because of its high solubility in water.

The stilbene derivative[18] (*E*)-**2** was synthesised from 4,4-dimethylstilbene by bromination of the methyl groups and subsequent substitution with dimethylamine. UV irradiation† of an aqueous solution of [(*E*)-**2** afforded a mixture of products, mainly the (*Z*)-isomer (*Z*)-**2**, small amounts of the educt (*E*)-**2**, the tetraphenyl cyclobutanes *trans*-**3** and *cis*-**3** and phenanthrene **4**, as expected for stilbenes (Table 1 and Scheme 1).[19] The distribution of the products is dependent on the irradiation time (Fig. 1): the amount of the photo-stable products **3** and **4** increased with longer irradiation time.

**Table 1** Distribution of products after the irradiation of (*E*)-**2** in aqueous solution with UV light ($\lambda$ 312 nm) in the presence of cyclodextrins

| | | Content (%) | | | | |
|---|---|---|---|---|---|---|
| Cyclodextrin | *t*/h | (*E*)-**2** | (*Z*)-**2** | *trans*-**3** | *cis*-**3** | **4** |
| none | 24 | 10 | 62 | 7 | 2 | 19 |
| **1a** | 24 | 20 | 60 | 0 | 0 | 20 |
| **1b** | 24 | 16 | 83 | 0 | 0 | 1 |
| **1c** | 72 | 0 | 0 | 79 | 19 | 2 |

In the presence of hosts **1a** or **1b** the photo-dimerisation leading to cyclobutanes was totally restrained. Obviously, the stilbene moieties were shielded from each other by the formation of 1 : 1 inclusion compounds with **1a** or **1b**. Furthermore, inclusion in **1b** almost totally prevented the formation of phenanthrene **4**. Stilbenes **2** included in **1b** only show reversible photo-isomerisation with almost no side reactions. Consequently, **1b**–**2** is well suited for photo-switchable devices. In the presence of the larger host **1c**, the photo-dimerisation was found to be strongly favoured. After long irradiation times, high yields (up to 98%) of the cyclobutanes **3** were found (Table 1). For shorter times the (*Z*)-isomer (*Z*)-**2** of the educt appeared in the product mixture as an intermediate. Moreover, the presence of **1c** led to an increase of the rate of consumption of **2e**, *e.g.* after 1 h the product mixture contained 24% (44%) of (*E*)-**2** in the presence

**Scheme 1**

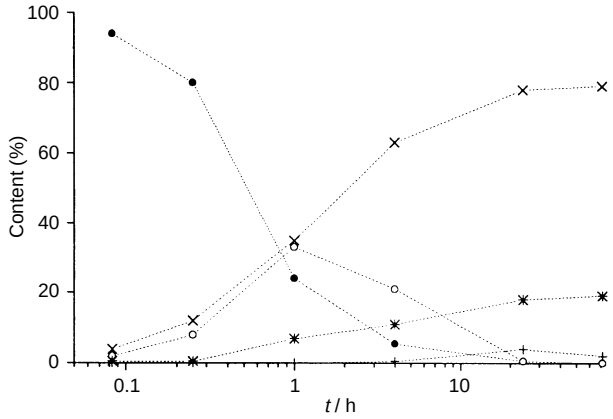


**Fig. 1** The time dependence of the product distribution after irradiation of (*E*)-**2** in the presence of **1c**: (●) (*E*)-**2**, (○) (*Z*)-**2**, (×) *trans*-**3**, (∗) *cis*-**3** and (+)-**4**

**Table 2** Thermodynamic parameters for the inclusion of the guests in cyclodextrins as determined by microcalorimetric titration (1 cal = 4.184 J)

| | $K_s$/ dm³ mol | $-\Delta G°_m'$/ kcal mol$^{-1}$ | $-\Delta H°_m'$/ kcal mol$^{-1}$ | $T\Delta S°_m'$/ kcal mol$^{-1}$ |
|---|---|---|---|---|
| **1a**–(*E*)-**2** | 1520 ± 50 | 4.3 | 6.4 ± 0.1 | −2.1 |
| **1a**–(*Z*)-**2** | 360 ± 110 | 3.5 | 1.9 ± 1.5 | 1.6 |
| **1b**–(*E*)-**2** | 705 ± 20 | 3.9 | 2.7 ± 0.1 | 1.2 |
| **1b**–(*Z*)-**2** | 540 ± 220 | 3.7 | 9.7 ± 8.4 | −6.0 |
| **1c**–(*E*)-**2** | 385 ± 10 | 3.5 | 1.1 ± 0.3 | 2.4 |
| **1c**–[(*E*)-**2**]$_2$ | 2730 ± 60 | 4.7 | 7.2 ± 0.1 | −2.5 |
| **1c**–*trans*-**3** | 18 000 ± 6600 | 5.8 | 7.1 ± 1.2 | −1.3 |
| **1c**–*cis*-**3** | 520 ± 700 | 3.7 | −5.4 ± 11.0 | 9.1 |

(absence) of host **1c**. The selective formation of cyclobutanes **3** upon addition of **1c** was attributed to the preceding formation of the ternary inclusion compound **1c**–**2**$_2$. The close proximity of the two included stilbenes should strongly favour the [2 + 2] addition.

To confirm this assumption we investigated‡ the formation of inclusion compounds of stilbenes **2** by microcalorimetric titration.[20] Indeed, host **1c** includes two molecules of **2**. The binding constant for the formation of **1c**–**2**$_2$ is relatively high compared to the literature values for other guest molecules (Table 2).[21] In contrast, we observed the formation of 1 : 1 inclusion compounds of **2** in hosts **1a** and **1b**. For the smallest host **1a**, the inclusion enthalpy is strongly negative for (*E*)-**2**, accompanied by a loss of entropy which is typical for a rather tight axial inclusion compounds **1a**–(*E*)-**2**.[22] On the other hand, the formation of inclusion compound **1b**–(*E*)-**2** has a low enthalpy gain but also some entropy gain. These findings are attributed to the formation of a loose complex as guest (*E*)-**2** is too slim to completely fill the cavity of **1b**. Turro drew the same conclusion from fluorescence lifetime measurements.[23] In contrast, isomer (*Z*)-**2** is tightly bound by **1b**, presumably in a non-axial arrangement, as Ramamurthy has postulated.[17]

Consequently, the photo-dimerisation of stilbenes **2** is hindered by a 1 : 1 inclusion in hosts **1a** and **1b** but enhanced by an 1 : 2 inclusion in host **1c**. An excited stilbene in **1c**–[(*E*)-**2**]$_2$ can react rapidly with its neighbour. Furthermore, we found that dimerisation products **3**, especially *trans*-**3**, form stable 1 : 1 inclusion compounds with **1c**. The inclusion of *trans*-**3** is accompanied by an enthalpy gain and an entropy loss, typical of a tight fit between host and guest. Consequently, in the presence of hosts **1b** and **1c** the formation of the photo-product with the highest affinity towards the host was favoured most. The main photo-product is therefore a molecular imprint (replica) of the host.[24] The principle might be further exploited for the targeted photochemical synthesis of other molecules. The photo-chemical synthesis of poly(rotaxane)s is the subject of our current research.

We thank the Deutsche Forschungsgemeinschaft (project We 1092/2-1) and Wacker-Chemie, Burghausen, for supporting this work.

## Footnotes and References

† A solution of (*E*)-**2**·(HCl)$_2$ (0.01 mol dm$^{-3}$; 10 cm³) was irradiated with UV light (λ 312 nm, source type D89008, 6 W, Bioblock Scientific, Illkirch Cedex, France) for 0.08, 0.25, 1.00, 5.00, 24.00 and 72 h. Afterwards, the solution was brought to pH 10 by addition of NaOH (2 mol dm$^{-3}$) and **2**–**4** were extracted with $CHCl_3$. The product distribution was determined by integration of the $^1$H NMR signals of the crude product in $CDCl_3$. *Selected data* for (*E*)-**2** $\delta_H$ ($CDCl_3$, 400 MHz) 2.26 (s, 12 H, $CH_3$), 3.44 (s, 4 H, $CH_2$), 7.10 (s, 2 H, =CH), 7.30 (d, *J* 8.4, 4 H, ArH), 7.47 (d, *J* 7.9, 4 H, ArH). For (*Z*)-**2**: $\delta_H$ 2.23 (s, 12 H, $CH_3$), 3.37 (s, 4 H, $CH_2$), 6.56 (s, 2 H, =CH), 7.15 (d, *J* 8.0, 4 H, ArH), 7.21 (d, *J* 8.0, 4 H, ArH). For *trans*-**3**: $\delta_H$ ($CDCl_3$, 400 MHz) 2.17 (s, 24 H, $CH_3$), 3.30 (s, 8 H), 4.42 (s, 4 H, CH), 7.04 (s, 16 H, ArH). For *cis*-**3**: $\delta_H$ ($CDCl_3$, 400 MHz) 2.26 (s, 24 H, $CH_3$), 3.40 (s, 8 H, $CH_2$), 3.63 (s, 4 H, CH), 7.23 (s, 16 H, ArH). For **4**: $\delta_H$ ($CDCl_3$, 400 MHz) 2.32 (s, 12 H, $CH_3$), 3.69 (s, 4 H, $CH_2$), 7.57 (d, *J* 7.9, 2 H, ArH), 7.70 (s, 2 H, ArH), 7.84 (d, *J* 7.9, 2 H, ArH), 8.62 (s, 2 H, ArH).

‡ The microcalorimetric titrations were carried out using a Microcal Omega Titration Calorimeter, MicroCal Inc., Northampton Massachusetts. A solution of cyclodextrin (0.002 mol dm$^{-3}$; 1.336 cm³) was titrated with 20 portions of guest (0.045 mol dm$^{-3}$; 5 μl) ammonium acetate buffer (pH 5.7; 0.1 mol dm$^{-3}$) at 25 °C. The interaction heat data were fitted to models for either 1 : 1 or stepwise 1 : 2 inclusion processes by the program Origin ITC, MicroCal Inc. The binding constants and enthalpies were obtained as fitting parameters. We could not isolate pure (*Z*)-**2**. Thus we used a mixture of (*Z*)-**2** (64%) and (*E*)-**2** (36%) for the inclusion experiment and the data were fitted to the model 'two sets of sites' of the program package Origin ITC. This procedure was also applied for the mixture of *trans*-**3** (79%) and *cis*-**3** (21%).

**Iron(III) complexes with a 3N/3S chromophore reproduce a mixed N/S heterocyclic ligand environment, metal–ligand bond lengths, and low-spin state ($S$ = 1/2) characteristic of the hydrolytic metalloenzyme nitrile hydratase; $Fe^{III}N_2S_2Cl$ species possesses a quantum mechanically admixed $S$ = 3/2, 5/2 state and able to form low-spin solvent adducts, possible analogues of the substrate-bound form of the enzyme.**

Iron–thiolate metal centers have until recently been considered mainly in the context of Fe–S cluster assemblies of metalloproteins and in relation to their role in electron-transfer processes. One of the emerging new non-redox functions of biological iron–thiolate centers is that associated with their Lewis-base activity in catalyzing hydration–dehydration reactions of organic substrates.[1,2] Even though most of these transformations are catalyzed by the metalloenzymes containing Fe–S clusters in their active site, *e.g.*, aconitase, certain others apparently lack cluster units. Another example of a metalloenzyme with an iron–thiolate active site that is not redox active and does not belong to the heme or Fe–S cluster families is bacterial nitrile hydratase, which catalyzes the conversion of nitriles to corresponding amides. Combined physicochemical results[3] provide solid evidence for the presence of a low-spin ($S$ = 1/2) $Fe^{III}N_3S_2$ chromophore with a sixth coordination site occupied by a water molecule or hydroxide ion, which is probably replaced by acetonitrile in the catalytic cycle. Synthetic iron(III) complexes with mixed N/S donor sets, common in coordination chemistry, can be useful models of the protein active site. However, there are only few examples[4] of such species owing to the often facile oxidation of thiolate ligand by $Fe^{III}$. Studying synthetic models of blue copper proteins, tetracoordinate bis-chelate copper(II)–thiolato complexes of Schiff-base ligands notorious for the same type of redox instability, we found[5] that the presence of the potentially supplementary coordinating group in the ligand structure leads to the stabilization of the higher metal oxidation states.

Following this strategy, we report novel stable iron(III) complexes **1** and **2** with a 3N/3S chromophore simulating the N/S ligand environment of the nitrile hydratase active site and some of its spectroscopic properties. Complex **3** contains a potentially labile terminal chloride ligand which may be substituted by solvent molecules involving acetonitrile. Possibilities for the ligand modifications in **1**–**3** provide an entry to an extended series of $Fe^{III}$–N/S complexes which might provide insight into intimate structural and electronic features of general interest and those relevant to the active site of metalloenzyme.

Reaction of the ligands $H_2L$ [*N*,*N*′-bis(5-mercapto-3-methyl-1-phenylpyrazol-4-ylmethylene)ethylenediamine] and HL [5-mercapto-1-phenyl-3-methyl-4-ylmethylene(8-amino)-quinoline] with $Fe(ClO_4)_3nH_2O$ or $FeCl_3{\cdot}6H_2O$ in ethanol affords in good yields complexes **1**–**3**.[6] The X-ray molecular structure§ of **1** is shown in Fig. 1 The iron center is octahedrally

**1** X = $FeCl_4^-$
**2** X = $ClO_4^-$
**3**

coordinated by the two azomethine, and two quinoline nitrogens and two thiolate sulfur atoms in *cis*-positions [S(1)–Fe–S(2) 95.15(8)°]. Three metal–ligand angles [S(1)–Fe–N(2) 175.1(2), S(2)–Fe–N(6) 173.2(2), N(1)–Fe–N(5) 176.5(2)°] are close to 180°, thus indicating a tendency for a cubic symmetry ligand arrangement. Iron–sulfur bond lengths, Fe(1)–S(1) 2.227(2) and Fe(1)–S(2) 2.230(2) Å, are similar to that reported for nitrile hydratase (2.21 Å from EXAFS data[3e] for a pH 7.3 form) and *ca*. 0.07 Å shorter than for a high-spin $FeN_2S_3$ complex.[4e] Iron–nitrogen bond lengths in **1**, Fe–$N_{av}$ 1.99 Å, are also identical to those in the enzyme.

The EPR spectra of **I** recorded in frozen $CHCl_3$ and dimethylformamide solutions display a very large signal at $g \approx$

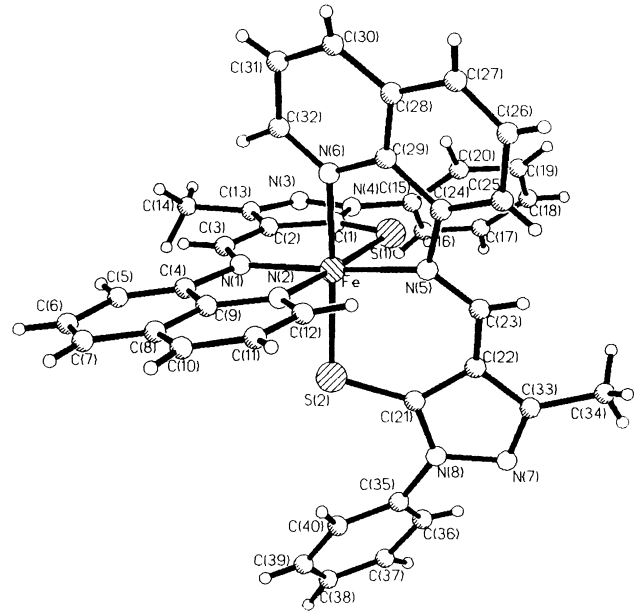

**Fig. 1** Molecular structure of **1**. Selected bond lengths (Å) and angles (°): Fe–S(1) 2.227(2), Fe–S(2) 2.230(2), Fe–N(1) 1.969(5), Fe–N(2) 2.005(6), Fe–N(5) 1.980(5), Fe–N(6) 2.004(6); S(1)–Fe–S(2) 95.15(8), S(1)–Fe–N(2) 175.1(2), S(1)–Fe–N(1) 99.7(2), S(1)–Fe–N(5) 81.5(2), S(2)–Fe–N(6) 173.2(2), N(1)–Fe–N(5) 176.5(2).

2, superimposed on which is a rhombic spectrum with the components $g$ = 2.19, 2.12 and 1.98, typical of a low-spin ($S$ = 1/2) iron(III) complex. Given a high-spin ($S$ = 5/2) nature of the anionic residue $FeCl_4^-$, low-spin features can be attributed to the $[FeL_2]^+$ species. Consistent with this assignment, complex **2** displays no broad component at $g$ = 2 but only a well resolved low-spin spectrum with $g$ = 2.193, 2.130 and 1.986.

Magnetic susceptibility measurements in the solid state reveal a low-spin ($S$ = 1/2) iron species **2** with $\mu_{eff}$ = 1.95 $\mu_B$, independent of temperature (77–300 K). Magnetic moments of **1**, containing $FeCl_4^-$ as a counter anion, are also temperature independent, 6.17 $\mu_B$ (per 2Fe) (4.44 $\mu_B$ per 1 Fe), which agrees well with presence of the contribution from the high-spin ($S$ = 5/2) center ($\mu_{eff}$ = 5.95 $\mu_B$).

The Mössbauer spectrum of **2** shows a symmetrical doublet with the following isomer shift and quadrupole splitting parameters at 77(300) K: $\delta$ = 0.15 (0.11) mm s$^{-1}$ (relative to Fe metal), $\Delta E_Q$ = 2.01 (1.99) mm s$^{-1}$. This situation corresponds to the $S$ = 1/2 iron complexes with an unpaired electron localized on the $d_{xy}$ orbital. Low values of the isomer shift indicate strong metal–ligand π interactions.[7a] For **1**, in addition to a similar doublet, $\delta$ = 0.25 (0.15) mm s$^{-1}$, $\Delta E_Q$ = 1.98 (2.08) mm s$^{-1}$ at 77(300) K there is another doublet with fairly small quadrupole splitting and isomer shift, $\delta$ = 0.29 (0.23) mm s$^{-1}$, $\Delta E_Q$ = 0.33(0.26) mm s$^{-1}$ which is typical for four-coordinate high-spin ($S$ = 5/2) iron(III) complexes and can be unequivocally assigned to the $FeCl_4^-$ anion.[7b]

Electronic spectra of **1** and **2** in $CHCl_3$ contain two bands in the IR region: $\lambda_{max}$/nm ($\varepsilon$/dm$^3$ mol$^{-1}$ cm$^{-1}$) 750 (600), 1005 (1410) (**1**) and 750 (535), 995 (1250) (**2**). Compared to nitrile hydratase [$\lambda_{max}$ = 715 nm ($\varepsilon$ = 1100 dm$^3$ mol$^{-1}$ cm$^{-1}$) at pH 7.3 and $\lambda_{max}$ = 690 ($\varepsilon$ = 1300) at pH 9], the 750 nm band may correspond to that observed in the enzyme and attributed to the Fe–S LMCT absorptions (with some contribution from an Fe–N chromophore) on the basis of a recent resonance-Raman study.[3d]

With respect to a specific low-spin nature of both substrate-free and bound nitrile hydratase, a significance of the particular ligand field strength may be to allow ligand substitution reactions to occur appropriately (at the early steps of nitrile binding) and also to activate a nitrile bond. To follow this line, we synthesized **3**, the complex with a potentially labile terminal ligand. Hydrolytic properties of the $Fe^{III}N_2S_2Cl$ species are implicated by the early results of Murray *et al.*,[4b] who failed to isolate a sulfur analogue of [Fe$^{III}$(salen)Cl] but only the complex with a partly hydrolyzed Schiff-base ligand, *N*-[(2-aminoethyl)thio]salicylideneamine. In contrast to the low-spin species **1** and high-spin [Fe$^{III}$(salen)Cl],[8] the magnetic moment of **3** in the solid state, $\mu_{eff}$ = 4.45 $\mu_B$ (300 K), indicates the less common intermediate-spin ($S$ = 3/2) state. This value drops to 3.84 $\mu_B$ at 77 K. The temperature dependence of the magnetic susceptibility for **3** suggests a contribution from the quantum mechanically admixtured $S$ = 5/2 spin state.[9] Consistently, the Mössbauer spectra of **3** display a single symmetrical doublet with similar parameters at 77(300) K: $\delta$ = 0.31(0.23) mm s$^{-1}$, $\Delta E_Q$ = 2.68 mm s$^{-1}$, typical of the mixed $S$ = 3/2, 5/2 state iron porphyrin complexes and also detected for $S$ = 3/2 iron species.[9b,10] In frozen solutions of **3**, we observed a low-spin species with spectral patterns similar to that for **2** in dmf ($g$ = 2.191, 2.159, 1.981), pyridine–DMF (1 : 1) ($g$ = 2.169, 1.979) and $CHCl_3$ ($g$ = 2.193, 2.162, 1.988) whereas in MeCN there is a low-spin spectrum ($g$ = 2.190, 2.161, 1.985) superimposed on the very broad signal. This result may be explained by formation of either a six-coordinate solvent adduct **3**·solv or a chloride-dissociated species with two axial solvent molecules.¶ The terminal ligand substitution reaction with a concomitant ground spin-state alteration are well established in porphyrin systems, although they usually occur with N-donor type ligands or strongly coordinating solvents.[9c] Complex **3** may be a suitable starting point to pursue an ultimate goal of nitrile hydrolysis[11] given the opportunities of ligand modifications, *e.g.*, conversion to corresponding aminothiol, variation of the bridging group and incorporation of the nitrile functionality into the ligand framework.

We are grateful to the Russian Fund of Fundamental Research (Grant No. 97-03-33479a) for a partial support of this work.

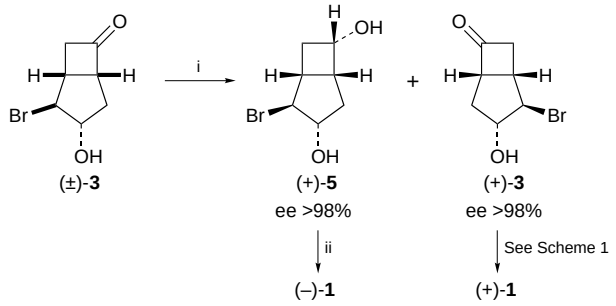
[d] *Max Planck-Gesellschaft Zur Förderung der Wissenschaften e.v., University of Rostock, D-18055 Rostock, Germany*

**The hydrogenation of alkenes 7a–g using a chiral rhodium catalyst 6 (based on a bicyclo[3.2.0]heptane framework) takes place to give the phenylalanine derivatives 8a–g with remarkably high stereoselectivity (59–92% ee).**



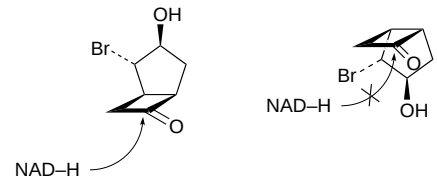
The relatively inflexible, angular shape of the bicyclo[3.2.0]heptane ring system means those substituents on the concave (*endo*) face of the molecule are positioned close together in space. Molecular modelling studies suggested that the hydroxy groups in bicyclo[3.2.0]heptan-3-*endo*, 6-*endo*-diol would be positioned in such a way that derivitization to form bis(diarylphosphinyl) groups may provide a novel chiral ligand for organorhodium-catalysed hydrogenation reactions.[1]

Optically pure diol **1** may be prepared from (−)-bicyclo[3.2.0]hept-2-en-6-one[2] **2** by the route described in Scheme 1. Thus, formation of the bromohydrin[3] **3**, hydrodebromination (furnishing **4**) and stereocontrolled reduction by delivery of hydride ion from the more exposed *exo*-face afforded the diol **1** in 50% overall yield.

**Scheme 1** *Reagents and conditions*: i, *N*-Bromosuccinimide, acetone, $H_2O$, 6 h, 80%; ii, $Bu_3SnH$, AIBN, toluene, heat, 82%; iii, $NaBH_4$, MeOH, −78 °C, 76%

However, since both enantiomers of the diol **1** were required as intermediates to the chiral ligands it seemed more sensible to perform a kinetic resolution further along the synthetic sequence. Kinetic resolution of the racemic alcohols **1** and **4** using lipase-catalysed acylation reactions were unsuccessful. The bromohydrin (±)-**3** was resolved by employing *Pseudomonas fluorescens* lipase in vinyl acetate[4] but a more satisfactory

**Scheme 2** *Reagents and conditions*: i, Yeast, $H_2O$, 6 h, 100% crude yield; ii, $Bu_3SnH$, AIBN, toluene, heat, 86%



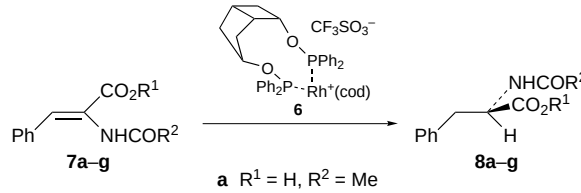


**Fig. 1** Delivery of hydride to **3**

and efficient biocatalytic method utilised a yeast-catalysed highly enantio- and stereo-selective reduction of racemic ketone **3** (Scheme 2).

It is noteworthy that reduction takes place to give only the (6*S*)-bromodiol **5**, unlike the corresponding non-enantioselective bioreduction on the parent compound **2** which gave (1*S*,5*R*,6*S*)-bicyclo[3.2.0]hept-2-en-6-*endo*-ol and (1*R*,5*S*,6*S*)-bicyclo[3.2.0]hept-2-en-6-*exo*-ol in almost equal quantities.[5] Presumably delivery of the hydride ion from the concave face of (+)-**3** is prohibited by unfavourable steric interactions within the active site of the dehydrogenase (Fig. 1).

The diol (−)-**1** was converted into the rhodium complex **6** using standard methodology, and this complex was used to catalyse the asymmetric hydrogenation of compounds **7a–g** to afford the (*R*)-phenylalanine derivatives **8a–g** in excellent yield and moderate to good enantiomeric excess (Table 1). Indeed,

**Table 1** Asymmetric hydrogenation of some enamide esters, **7a–g**

[a] Estimation by HPLC using a Chirasil-Val column.

**Table 2** Asymmetric hydrogenation of enamide ester **7a**

| *T*/°C | Volume of solvent/ml | Enantiomeric excess of product (%) |
|---|---|---|
| 25 | 15 | 81 |
| 12 | 15 | 83.5 |
| 2 | 15 | 87.5 |
| 25 | 10 | 88 |
| 25 | 5 | 91.5 |
| 2 | 5 | 92.5 |

given the subtlety of the chirality of the bicyclo[3.2.0]heptane framework, the observed level of enantioselectivity is surprisingly high. The reaction rates were perfectly satisfactory (the reaction was completed in 2–10 min) using 1 mmol substrate and 0.01 mmol catalyst in MeOH (15 ml) under an atmosphere of hydrogen. Using similar conditions, itaconic acid was reduced to (2*S*)-methylsuccinate in quantitative yield and 80.5% ee.

The reaction conditions for the asymmetric reduction of substrate **7a** were investigated further. Lowering the temperature of the reaction and increasing the concentration of the reactants both proved to be beneficial, with a satisfactory 92.5% ee for product **8a** being obtained at low temperature and high concentration (Table 2).† The concentration effect may be explained by the effect on the rate of delivery of hydrogen to the catalyst, which will be slower in the reactions using small amounts of solvent. Thus, in the more concentrated solution the catalyst may experience a lower 'effective' hydrogen concentration.[6]

We thank the BBSRC for a Fellowship (to U. V.) and a CASE award (to M. J. G.), Chiroscience, and EPSRC and the University of Exeter for studentships (to J. M. and G. W.) and Donna Blackmond for enlightening discussions.

† Experimental procedure for the asymmetric hydrogenation of compound **7a**. A mixture of complex **6** (8 mg, 0.01 mmol) and α-acetamidocinnamic acid **7a** (205 mg, 1 mmol) was cooled (2 °C) under a nitrogen atmosphere. Dry, degassed MeOH (5 ml) was added to the mixture, which was stirred vigorously. The flask was evacuated, filled with hydrogen and stirred for 10 min. A 0.5 ml aliquot was removed from the reaction vessel and treated with $Me_3SiCHN_2$ (2.0 M solution in hexane) in order to convert the acid to the methyl ester. The solvent was evaporated and the residue was treated with diethyl ether; filtration and evaporation gave a crude residue (21 mg). The enantiomeric excess of the product **8a** was determined to be 92.5% by chiral gas chromatography, using a Chirasil-Val-III column.

# $[\{Mo^{VI}_8V^{IV}_4O_{36}(V^{V}O_4)(V^{IV}O)_2\}_n]^{7n-}$: capped α-Keggin fragments linked to a chain

**Achim Müller,* Michael Koop, Peter Schiffels and Hartmut Bögge**

*Fakultät für Chemie der Universität, D-33501 Bielefeld, Germany*

**The synthesis and single-crystal X-ray structure analysis of the unusual Mo/V polyoxometalate compound $Na_{0.5}K_{6.5}[Mo^{VI}_8V^{IV}_4O_{36}(V^{V}O_4)(V^{IV}O)_2]\cdot12.5H_2O$ which contains capped α-Keggin fragments linked to a chain is reported; this chain is an interesting object for magnetochemists and can be considered to consist of an assembly of electron storage units.**

Despite their ability to act as ligands, polyoxometalate clusters are generally reported as discrete entities, for instance as Keggin type anions or their derivatives.[1,2] Very few examples are known where polymers are built up (like chains) for instance by linking anionic polyoxometalate ligands with transition-metal centres[3–5] as in the case of $[\{(Co^{II}(H_2O)_4)_2(H_2W_{12}O_{42})\}_n]^{6n-}$. Only one compound has been reported in which a derivative of a lacunary $\{W_{11}\}$ type species (that means with an integrated low-valent metal atom) was linked to a chain,[6] but until now, no corresponding compound has been isolated in which chains are built up by a classical polyanion containing metal centres from only group 5 and 6. Here we report the synthesis and single-crystal X-ray structure analysis of the blue–violet mixed valent polyoxometalate compound $Na_{0.5}K_{6.5}[Mo^{VI}_8V^{IV}_4O_{36}(V^{V}O_4)(V^{IV}O)_2]\cdot12.5\ H_2O$ **1** containing capped, reduced α-Keggin type fragments which are linked to a chain.

Compound **1** was prepared by heating a solution of $VOCl_2$ (10 mmol), $Na_2MoO_4\cdot2H_2O$ (20 mmol) and KCl (93.9 mmol) in 60 ml degassed water (pH 6.2) for 5 days at 45–50 °C in an argon atmosphere. Blue–violet crystals of **1** which precipitated from the solution at 45 °C (46% yield based on Mo) were filtered and characterized by a single-crystal X-ray structure analysis (including bond valence sum calculations),† vibrational spectra‡ and redox titrations for the determination of the number of $V^{IV}$ centres. Compound **1** rapidly decomposes in solution in the presence of air, whereby a yellow colour is observed.

The crystal structure of **1** shows the abundance of chains built up by '*trans*-vanadium' capped α-Keggin type $\{Mo^{VI}_8V^{IV}_4O_{36}(V^{V}O_4)(V^{IV}O)_2\}$ units [Fig. 1(*a*)]. These are structurally similar to the two $\{Mo_8V_7O_{42}\}$ units which build up the discrete $[Mo^{VI}_{16}V^{IV}_{12}V^{V}_2O_{84}]^{14-}$ anion.[7] The structure of the basic (anionic) unit of **1** [Fig. 1(*b*)] can be described as follows: four $Mo^{VI}$ centres of an α-Keggin type $[Mo^{VI}_{12}O_{36}(V^{V}O_4)]^{3-}$ species are replaced by $V^{IV}$ centres resulting in a 'layered' type structure formed by the different metal atoms. The corresponding three layers are spanned by one $\{V_5\}$ set and two $\{Mo_4\}$ type sets, the latter being separated by 4.8 Å [Fig. 1(*a*)]. The $V^{IV}\cdots V^{V}$ distance between atoms within each layer is 5.1 Å and *ca.* 11 Å between layers in adjoining units. Therefore the compound is interesting for the study of exchange interactions by the magnetochemist. The rhombicuboctahedron spanned by 24 $\mu_3$-O atoms of the Keggin unit is capped at two parallel (100) planes by 2 $\{V^{IV}O\}$ [V(3)] groups (for details of the relevant topology see ref. 8). If all of the six equivalent planes were capped, a unit with a similar structure to the $\{V_{12}O_{36}(VO_4)(VO)_6\}$ type species[9] would result. Whereas the $Mo^{VI}$ and $V^{IV}$ centres Mo(1), Mo(2) and V(1) have, as expected, rather regular octahedral coordination environments, the two V(3) centres [Fig. 1(*b*)] possess a highly distorted octahedral coordination environment, bordering on the distorted trigonal-prismatic geometry described for the above mentioned discrete $[Mo^{VI}_{16}V^{IV}_{12}V^{V}_2O_{84}]^{14-}$ anion.[7] The Keggin fragments are linked by V(3)–O(11)$_2$–V(3) bridges forming chains along the *c* axis [V(3)–O(11) 1.88(1) Å; separation of adjacent V(3) centres 2.81(1) Å].

The formation of **1** is facilitated by the direct use of a solution containing $VO^{2+}$ ions. The relevant reaction using $V^{V}$ centres under similar reaction conditions at pH 4–6.5 yields the discrete $[Mo^{VI}_6V^{V}_2O_{26}(H_2O)_{16}]^{6-}$ anion.[10,11] In a previous investigation of the $V^{IV}/Mo^{VI}$ system[12,13] it was erroneously proposed that such solutions with relative concentration $Mo^{VI}/V^{IV} = 2$ yielded the salts $K_4H_2[V_2Mo_4O_{19}]\cdot9H_2O$ at pH 4.5 and $K_2H_4[V_2Mo_4O_{19}]$ at pH 3, whereby the authors assumed that these would contain Lindquist type anions. One can envisage the formation of the obtained chains *via* the initial formation of highly nucleophilic species such as $\{Mo^{VI}_8V_4{}^{IV}O_{36}(V^{V}O_4)\}^{11-}$ {whose structure may be analogous to the discrete $[Mo^{VI}_8V^{V}_4O_{40}(VO_4)]^{7-}$ anions[14]} and the subsequent interception of these by the $VO^{2+}$ nucleophiles present in solution. This deliberation corresponds to our general procedure to generate growth of species by increasing their negative charge and consequently their nucleophilicity, a procedure which facilitates the generation of increasingly larger molecular systems. In the

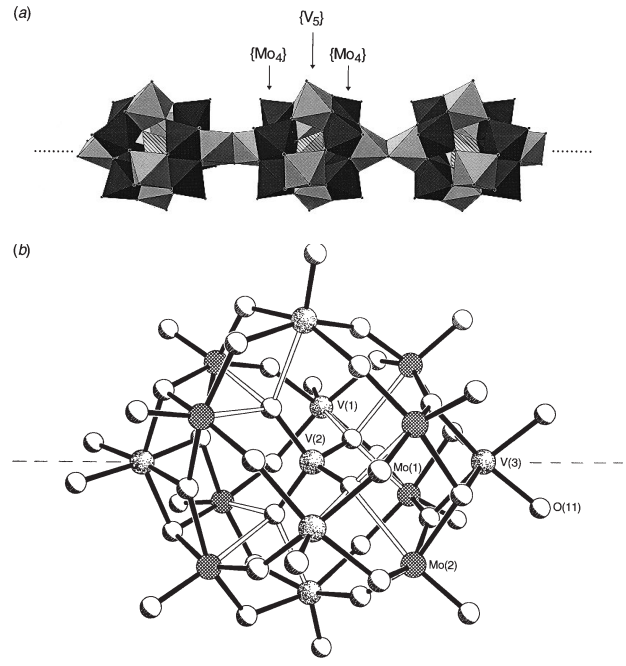

**Fig. 1** The structure of the polymeric anion in crystals of **1**: (*a*) polyhedral representation (darker polyhedra represent $Mo^{VI}O_6$ octahedra, hatched ones the $V^{V}O_4$ tetrahedra). The $Mo^{VI}$ and $V^{IV}$ atoms of the relevant polyhedra span $\{Mo^{VI}_4\}$ and $\{V^{IV}_4\}$ layers. (*b*) Ball-and-stick representation of the capped α-Keggin type unit with stoichiometry $\{Mo^{VI}_8V^{IV}_4O_{36}(V^{V}O_4)(V^{IV}O)_2\}$; V atoms dotted, Mo atoms cross hatched; V(2)–O 1.71(1) Å, V(3)–O(11) 1.88(1) Å, V(3)···V(3) 2.81(1) Å; O(11)–V(3)–O(11) 83.0(5)°.

present case, the increased nucleophilicity results from the simple replacement of metal centres with a high oxidation state ($Mo^{VI}$) by those with a lower one ($V^{IV}$). Groups containing the $V^{IV}$ centres are directly added to the reaction medium which is in contrast to an earlier investigation[15] where a solution containing $Mo^{VI}$ and $V^{V}$ centres was treated with a reducing agent, thus resulting in the reduction of the $V^{V}$, but also some of the $Mo^{VI}$. Additionally, it is important to note that in the present case, linking *via* $V^{IV}$–O–$V^{IV}$ bonds is preferred to linking *via* $Mo^{VI}$–O–$Mo^{VI}$ bonds as a consequence of the expected higher basicity of the O atom in M–O bonds containing M centres in lower oxidation states.

We thank Dr S. Dillinger, T. Heitkamp, K. Janiak and E. Krickemeyer for earlier contributions to the work and the Deutsche Forschungsgemeinschaft as well as the Fonds der Chemischen Industrie for their financial support.

† *Crystal data* for **1**: $H_{25}K_{6.5}Mo_8Na_{0.5}O_{54.5}V_7$, $M$ = 2286.95 g mol$^{-1}$, tetragonal, space group $I4/m$, $a$ = 14.941(2), $c$ = 22.124(5) Å, $U$ = 4938.8(15) Å$^3$, $D_c$ = 3.076 g cm$^{-3}$, $\mu$(Mo-Kα) = 3.89 mm$^{-1}$, $Z$ = 4, $T$ = 198 K, $R$ = 0.052 for 1428 reflections with $I_0 \geqslant 2\sigma(I_0)$, crystal dimensions: 0.1 × 0.1 × 0.2 mm; Siemens R3m/V diffractometer (Mo-Kα, graphite monochromator). A total of 2503 reflections were collected ($4 < 2\theta < 50°$). The structure was solved by direct methods[16] and refined[16] by full-matrix least-squares techniques. In the asymmetric unit two under-occupied sodium positions were found each at a distance of *ca*. 1.8 Å from two (also underoccupied) potassium positions. The occupancy factors of the disordered atoms were refined in agreement with the above given formula. $\Psi$-scan reflections for an empirical absorption correction were collected. As the absorption correction showed no significant effect, however, the uncorrected data were used in the final refinement process. The bond valence sum calculations indicate, as expected, the presence of only $Mo^{VI}$ and $V^{IV}$ centres in the shell, as well as one central $V^{V}$ atom. CCDC 182/547.

# Phenol/phenolate-dependent on/off switching of the luminescence of 4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacenes

**Thomas Gareis,[a] Christian Huber,[b] Otto S. Wolfbeis*[b]† and Joerg Daub*[a]‡**

[a] *Institut für Organische Chemie der Universität Regensburg, Universitaetsstraße 31, D-93040 Regensburg, Germany*
[b] *Institut für Analytische Chemie, Chemo- and Biosensorik, Universitaetsstraße 31, D-93040 Regensburg, Germany*

**Boradiazaindacenes 1 and 2 bearing phenolic subunits show deprotonation/protonation dependent fluorescence off/on-switching; the lack of emission of the phenolate forms is attributed to photoinduced electron transfer (PET) between the phenolate and indacene subunits.**

There is still considerable need for novel molecular probes for fluorescent analysis and materials science chemistry. Difluoroboryldipyrromethene complexes are of high interest as fluorophores due to their favourable photophysical and opto-electronic properties.[1] Whilst the work on their syntheses,[2] photophysical properties[3] and application as fluorophoric probes is well established, their potential for sensing by optoelectronic switching has been only partially explored. Previously, we have demonstrated that reversible redox activation of boradiazaindacenes gives rise to efficient electrochemically generated luminescence[4,5a] (ECL). By using a non-fluorescent dimethylaminophenyl derivative, it could be shown that strong emission occurs on protonation.[5] The present study is directed towards shifting the on/off switching of luminescence to higher pH. Therefore, the phenol/phenolate couples **1** and **2** have been investigated.

**1** $R^1$ = OH, $R^2$ = H
**2** $R^1$ = OH, $R^2$ = $Bu^t$
**3** $R^1$ = $R^2$ = H

We synthesized the phenolic dyes **1** and **2**[4] according to previously applied procedure.[2] Owing to the presence of methyl groups at positions C-1 and C-7, the phenyl and boraindacene systems are twisted and conjugatively uncoupled. This follows from an X-ray analysis[5a] of a structurally similar compound and from the high-field NMR chemical shift of the methyl protons.[4] Both **1** and **2** are therefore representatives of orthogonal fluorophor–receptor systems.[6] A phenolate is formed by deprotonation, which may exhibit a PET-like quenching mechanism.[7]

The preliminary objective was to study the emissive properties of the phenol/phenolate equilibrium in organic solvents using an organic base for deprotonation. To avoid intermolecular charge transfer quenching, which is often observed in the presence of tertiary amines,[8] we used pyridine as the proton acceptor.

Fig. 1 shows the fluorescence titrations of **1** dissolved in $CHCl_3$ by successive addition of pyridine. The fluorescence signals of **1** and **2** significantly decrease, whereas the wavelength of emission remains unchanged. Reprotonation by addition of trifluoroacetic acid restores fluorescence. Switching between the fluorescent on/off states can be repeated without decomposition or formation of precipitates. To prove that the observed decrease in fluorescence intensity is due to the phenolic properties of **1** and **2**, the same titration experiments were performed with 8-phenylboradiazaindacene **3**.[2c] No base-dependent response could be observed. By fluorescence titration experiments in a MeOH–$H_2O$ mixture[9] (1 : 1), the p$K_a$ value of compound **1** was determined to be 10.4 ± 0.5 (see Fig. 2) which indicates the decoupling of the subunits.

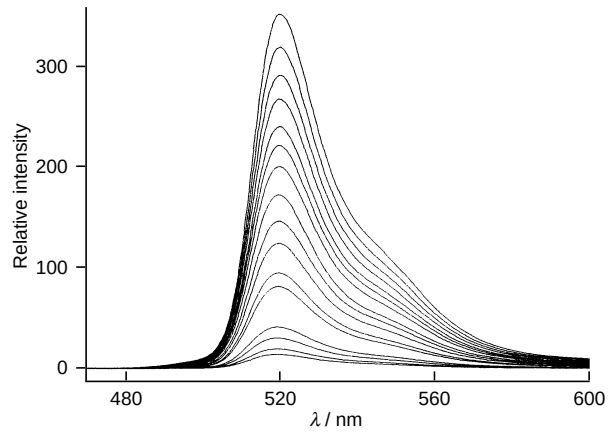

**Fig. 1** Decrease of fluorescence intensity during tiration of **1** on successive addition of pyridine (2.7 ml of dye; $2.1 \times 10^{-5}$ mol $l^{-1}$ in $CHCl_3$, excitation at 500 nm, end concentration of pyridine: $3.2 \times 10^{-1}$ mol $l^{-1}$)

The determination of p$K_a$ values for **2** failed due to its poor solubility in the aqueous solvent mixture. Compounds **1** and **2** also have been embedded into a hydrogel matrix, according to a previously published procedure,[9] with the aim of obtaining a material for use in sensors. Membranes were tested in a home-

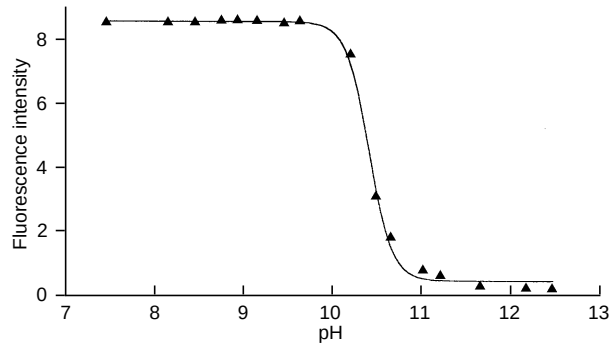

**Fig. 2** Fluorescence intensity–pH profiles of **1** (p$K_a$ 10.4) in a MeOH–$H_2O$ (1 : 1): (▲) measured values, (—) sigmoidal fit; ionic strength of 150 mmol $l^{-1}$ (NaCl) (dye concentration: $2 \times 10^{-6}$ mol $l^{-1}$; $I_{NaCl}$ = 150 mmol $l^{-1}$; $\lambda_{ex}$ = 490 nm; $\lambda_{em}$ = 506 nm)

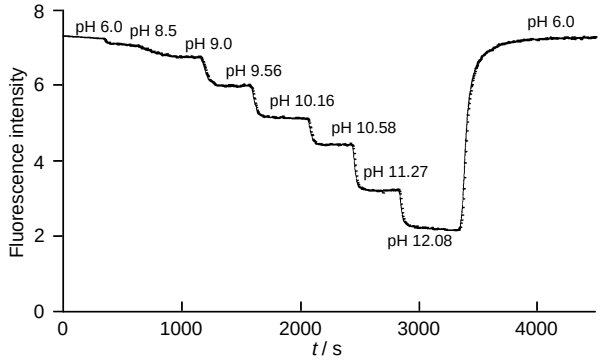

**Fig. 3** Relative signal change, response time and reversibility of **1** incorporated in a hydrogel matrix on exposure to a flow of buffers. The pH values are inserted in the graph. Ionic strength is kept constant at 150 mmol $l^{-1}$ (NaCl); concentration: 39 mmol per kg of matrix.

made flow-through cell with respect to the response of various pH values. To minimize effects of ionic strength, sodium chloride (150 mmol $l^{-1}$) was added. Again, the base form is only weakly fluorescent due to electron transfer from the phenolate group (the receptor) to the indacene fluorophore. The excitation/emission maxima of the membrane for **1** and **2** are at 504/515 nm and 502/508 nm, respectively. However, excitation was performed at 500 nm in order to minimize straylight. Fig. 3 shows the response behaviour and reversibility characteristics of **1** embedded in the matrix. The response times were faster (2 to 3 min) when going to lower pH than in the reverse direction (5 to 8 min).

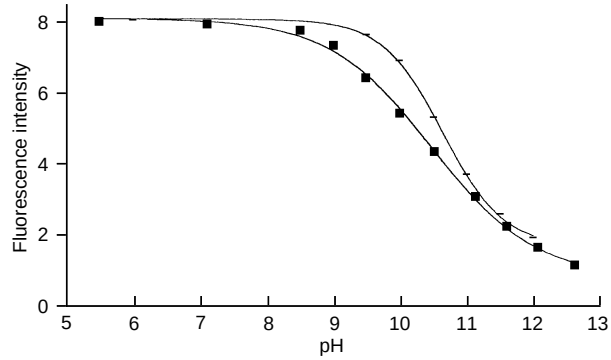

**Fig. 4** pH titration plot of **1** and **2** incorporated in a hydrogel matrix: (■) **1** (p$K_a$ 10.4) and (—) **2** (p$K_a$ 10.8)

The pH titration curves of sensors **1** and **2** exhibit the typical sigmoidal shape and are depicted in Fig. 4. The p$K_a$ values of the two membranes are 10.4 and 10.8, respectively.

# Synthesis and structure of $KIn(en)_2SnTe_4 \cdot 1.5en$ containing a mixed-metal one-dimensional chain

**Chwanchin Wang and Robert C. Haushalter*†**

*NEC Research Institute, 4 Independence Way, Princeton, NJ 08540, USA*

**The linkage of a coordination compound, *cis*-$[In(en)_2Te_2]$, and a Zintl anion, $[SnTe_4]$, into a one-dimensional chain by sharing Te atoms is observed for the first time in the title compound.**

Two decades ago, attempts to synthesize the low-dimensional transition-metal chalcogenide complexes that incorporated $[ME_4]^{n-}$ (M = transition or post-transition metal; E = S, Se) ligands and ethylenediamine (en) were conducted mainly to study the varied degree of the coordinating ability of the ligands and how these ligands affected the overall structure.[1,2] Based on these studies, it was proposed that these chalcogenide complexes might have low-dimensional structures. Recently, several ternary transition and post-transition metal sulfides and selenides, using, for example, $[As_xE_y]^{n-}$ (E = S, Se) as ligands in the construction of low-dimensional structures, were successfully synthesized, by using solventothermal synthesis, and structurally characterized.[3–5] The non-traditional solventothermal technique has been shown to be an efficient synthetic technique to obtain new materials with unusual structures which are not accessible by using more common synthetic methods. While the research has been mostly concentrated on the ternary sulfides and selenides, the ternary telluride systems are relatively unexplored. In the telluride system, an early study showed that the one-dimensional chain structures can also be built up by the incorporation of the $[ATe_4]^{4-}$ (A = Ge, Sn) building blocks in $K_2HgSnTe_4$, $(NEt_4)_2HgSnTe_4$ and $(PPh_4)InGeTe_4$.[6] The structures of these ternary tellurides are substitutional variants of the one-dimensonal chain compound $NaInTe_2$.[7] During our investigation of the ternary In–Sn–Te system using solventothermal synthesis in ethylenediamine, we have discovered a new compound, $KIn(en)_2SnTe_4 \cdot 1.5en$, which also uses $[SnTe_4]^{4-}$ as a building block to construct a new one-dimensional chain structure.

The telluride $KIn(en)_2SnTe_4 \cdot 1.5en$ was synthesized by mixing 0.3 g of $K_2Te$, SnTe, $In_2Te_3$ and Te in a mole ratio of 1 : 2 : 0.5 : 1.5 with 1 ml of ethylenediamine in an evacuated Pyrex tube (*ca.* 10 ml). The reaction tubes were heated to

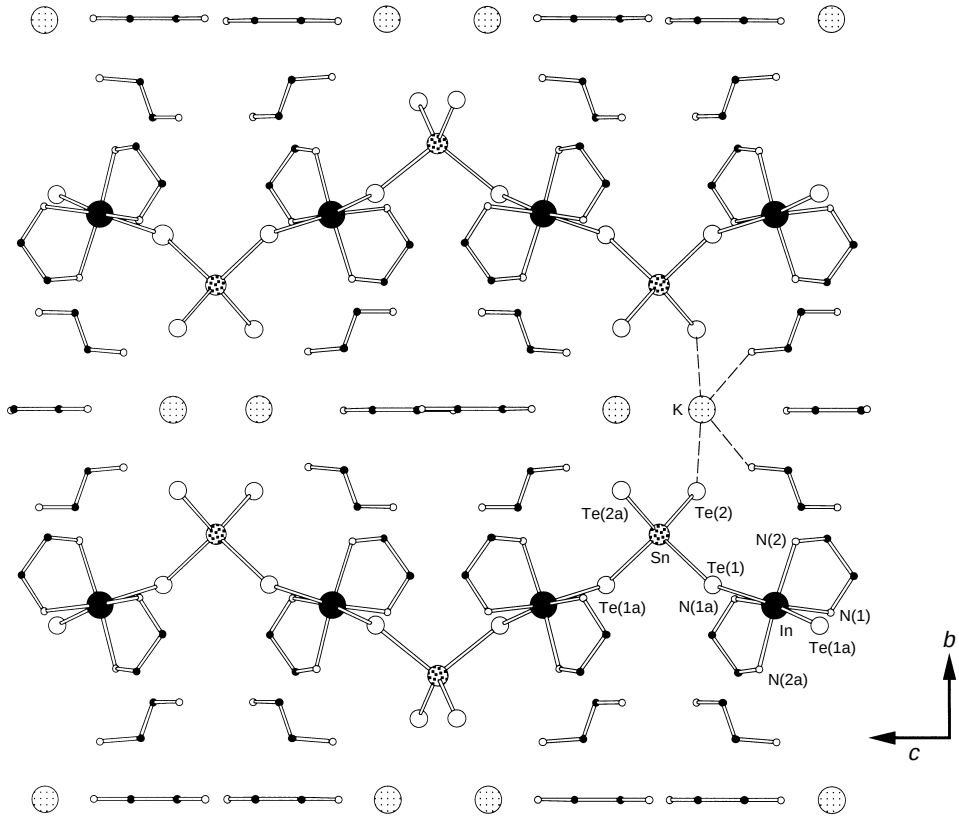

**Fig. 1** One-dimensional chain structure of the $[In(en)_2SnTe_4]^{1-}$ anion approximately projected onto the *bc* plane. The anionic chain consists of a corner-sharing of alternating *cis*-$[In(en)_2Te_2]$ octahedra and $[SnTe_4]$ tetrahedra. The close contacts between the K and both Te and N atoms are shown as dashed lines. Some selected bond distances (Å) and angles (°): Sn–Te(1)/Te(1a), 2.766(2), Sn–Te(2)/Te(2a), 2.691(2), In–Te(1)/Te(1a), 2.827(2), In–N(1)/N(1a), 2.35(1), In–N(2)/N(2a), 2.28(2), Te(1)–Sn–Te(1a), 104.89(9), Te(1)–Sn–Te(2), 110.64(5), Te(1)–Sn–Te(2a), 107.60(5), Te(2)–Sn–Te(2a), 115.0(1), Sn–Te(1)–In, 109.07(5), Te(1)–In–Te(1a), 85.32(7), Te(1)–In–N(1a), 94.2(4), Te(1)–In–N(1), 171.3(4), N(1)–In–N(1a), 87.6(7), N(1)–In–N(2), 75.5(5), N(1)–In–N(2a), 86.2(5), N(2)–In–N(2a), 154.6(8).

150 °C for 12 h and maintained at 150 °C for 3 days followed by cooling to room temp. at a rate of 10 °C $h^{-1}$. Dark red, cube-like crystals of $KIn(en)_2SnTe_4 \cdot 1.5en$ were isolated and separated from by-products in *ca*. 60% yield. Energy dispersive X-ray analysis on selected crystals gave an approximate ratio of 1 : 1 : 1 : 4.3 for K, In, Sn and Te atoms. $KIn(en)_2SnTe_4 \cdot 1.5en$ can also be successfully synthesized by using the extraction method on an alloy with an exact composition of $KInSnTe_4$, prepared from the fusion of KIn, Sn and Te in stoichiometric proportions. One gram of the alloy was extracted by dissolving it in 10 ml of ethylenediamine. After three weeks, $KIn(en)_2SnTe_4 \cdot 1.5en$ was obtained in the container which contained the $KInSnTe_4$ sludge, and the product of the red–brown extract turned out to be only $KInTe_2 \cdot 2en$.[8] These results also demonstrate one of the advantages of solventothermal synthesis in that it can accelerate the reaction toward the product formation.

While $(PPh_4)InGeTe_4$[6] adopts a one-dimensional chain structure which is composed of alternating $[InTe_4]$ and $[GeTe_4]$ tetrahedra, the structure‡ of $KIn(en)_2SnTe_4 \cdot 1.5en$, which is not isostructural with $(PPh_4)InGeTe_4$, is also built up from a one-dimensional chain with alternating $[In(en)_2Te_2]$ octahedra and $[SnTe_4]$ tetrahedra instead (Fig. 1). In the structure of $KIn(en)_2SnTe_4 \cdot 1.5en$, the In atom lies a twofold axis and is coordinated by two ethylenediamine and two Te atoms forming a distorted *cis*-$[In(en)_2Te_2]$ octahedron. The In–Te distances [2.827(2) Å] are comparable to those of the one-dimensional chain compound, $Na_5In_2Te_6$, (2.706–2.853 Å),[9] and are significantly longer than those in $(PPh_4)InGeTe_4$ [2.686(2) Å].[6] In the *cis*-$[In(en)_2Te_2]$ octahedron, the *trans* In–N(2) distances are slightly shorter than the *cis* In–N(1) distances, but neither is very different from those observed in the nitrogen-ligated complexes.[10] The Sn atom lies on a twofold axis and is bound to four Te atoms, forming a slightly distorted $[SnTe_4]$ tetrahedron which shares two Te atoms with the neighboring *cis*-$[In(en)_2Te_2]$ octahedra. The terminal Sn–Te bond distances [2.691(2) Å] are slightly shorter than those of the shared ones [2.766(2) Å] and are close to those observed in dimeric species, $(NMe_4)_4Sn_2Te_6$[11] and $Cs_4Sn_2Te_7$.[12] The *cis*-$[In(en)_2Te_2]$ octahedra and $[SnTe_4]$ tetrahedra then share two Te corners in the construction of the unusual one-dimensional $[In(en)_2SnTe_4]^-$ chain propagating along the *c* axis. There is only one crystallographically unique $K^+$ ion, located near the Te(2) atoms, that has close contact with four terminal Te(2) atoms (3.90–4.00 Å) and two N atoms [2.70(3) Å] from the ethylenediamine. A similar strong interaction between the K and the N atoms has been observed in $(PPh_4)_2[K_2Au_4Te_4(en)_4]$[13] and $K_6In_2Te_6 \cdot 4en$.[14] In Fig. 1, the unbound ethylenediamines are located in a large cavity (*ca*. 12 Å diameter across the $K^+$ ions), created by the surrounding $K^+$ ions, *cis*-$[In(en)_2Te_2]$ octahedra and $[SnTe_4]$ tetrahedra. Although the X-ray crystallography can not discern the difference between In and Sn atoms, the assignment of each atom in a specific position can be empirically confirmed by the use of bond valence sum calculations.[15] The bond valence sum calculation for $In^{3+}$ and $Sn^{4+}$ ions in $KIn(en)_2SnTe_4 \cdot 1.5en$, based on the structure mentioned above, results in the respective sums of 3.16 and 4.09.[16] When the In and Sn atoms are exchanged, the results are 3.62 and 3.53 for $In^{3+}$ and $Sn^{4+}$ ions, respectively. Thus, the results obtained from the bond valence sum calculation favor the assignment of the *cis*-$[In^{3+}(en)_2Te_2]$ octahedron and the $[Sn^{4+}Te_4]$ tetrahedron.

$KIn(en)_2SnTe_4 \cdot 1.5en$ represents the first example using both a Zintl anion, $[SnTe_4]$, and a coordination compound, *cis*-$[In(en)_2Te_2]$, in the construction of a one-dimensional chain compound. Recently, a similar strategy using the *cis*-octahedral units, incorporated with either tetrahedral or octahedral units, in the formation of the heteroatomic one-dimensional chain structures was reported in transition-metal hydroxo-complexes.[17] The investigation on the post-transition metal systems, based on this strategy, may lead to the discovery of new materials with unusual structures and properties.

‡ *Crystal data* for $KIn(en)_2SnTe_4 \cdot 1.5en$: orthorhombic, space group *Cmca* (no. 64), $a$ = 26.069(8), $b$ = 15.278(4), $c$ = 14.972(4) Å, $U$ = 5962(2) $Å^3$, $Z$ = 8, $D_c$ = 2.432 g $cm^{-3}$, $\mu$(Mo-K$\alpha$) = 56.04 $cm^{-1}$. 2922 unique reflections were collected at 273 K of which 1601 had $I \geqslant 3\sigma(I)$. An empirical absorption correction was applied. The structure was solved by direct methods and refined by the teXsan crystallographic software package of Molecular Structure Corporation to a final $R$ = 0.044 ($R_w$ = 0.060). All K, In, Sn and Te atoms were refined anisotropically. The carbon and nitrogen atoms of two ethylenediamines were refined isotropically while those of the third ethylenediamine, located on special positions, were fixed. The hydrogen atoms were calculated but not refined. Although the isotropic thermal parameter of $K^+$ ion is about four times larger than those of Te atoms, the refinement of a disordered model for splitting the $K^+$ ion was unsuccessful. However, the occupancy factor of the $K^+$ ion was refined and is close to unity. CCDC 182/540.

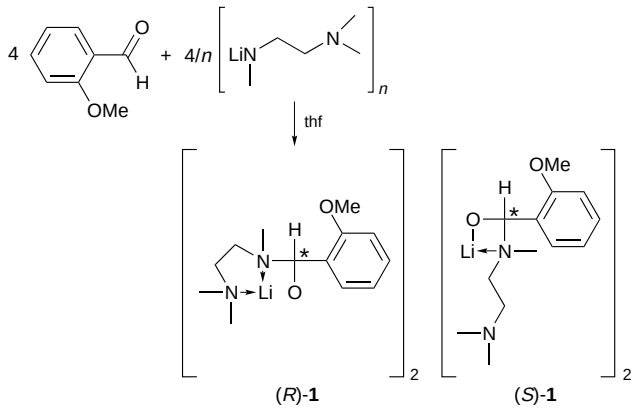
# Synthesis and novel structure of the first crystallographically characterised chiral α-amino lithium alkoxide



**John E. Davies, Paul R. Raithby, Ronald Snaith and Andrew E. H. Wheatley***

*Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

**Lithium *N,N,N′*-trimethylethylenediamide, LiN(Me)$(CH_2)_2$NMe$_2$, reacts with *o*-anisaldehyde, *o*-MeOC$_6$H$_4$CHO, to afford a chiral α-amino lithium alkoxide 1, which in the solid state is a racemic tetramer with an 'open' pseudo-cubane core; the extent to which the *N,N,N′*-trimethylethylenediamido moieties internally solvate the Li centres varies with the chirality of the protected aldehyde groups.**

Directed metallations of aromatic systems have been the subject of intensive research.[1] In particular, various carbonyl-derived directing groups have been applied to the problem of regiospecifically metallating arylaldehydes.[2] It has been reported that *in situ* protection of benzaldehyde derivatives[2,3] and heterocyclic arylaldehydes[4] *via* reaction with lithium dialkylamides, so giving α-amino lithium alkoxides, can be followed by ring lithiation, affording a convenient one-pot route to *ortho*-substituted arylaldehydes. Typically, a lithium dialkylamide is reacted with 1 equiv. of arylaldehyde (see, *e.g.* Scheme 1), yielding the corresponding chiral α-amino lithium alkoxide which is capable not only of protecting the formyl functionality but also of directing subsequent lithiation, in the presence of excess Bu$^n$Li, to the *o*-ring position. It is surprising that the nature of chiral lithiated intermediates in general has gone largely unexplored, with only a few examples of solution studies,[5] solid-state structures[5a,b] and theoretical investigations reported.[6] It is this scarcity of data which prompted us to investigate chiral α-amino lithium alkoxides, in order to establish precisely how the Lewis-base N-centres of the added amino moieties might stabilise the metal centres and, thereby, how subsequent lithiation might be directed.

We report here the isolation and structural characterisation of the first lithium α-amino alkoxide, **1**. It is obtained by the 1 : 1 reaction of *o*-anisaldehyde with *in situ* generated lithium *N,N,N′*-trimethylethylenediamide in thf† at −78 °C (Scheme 1). Warming affords a yellow solution, the storage of which at room temp. for 24 h yields colourless crystals of **1**. X-Ray crystallography‡ shows that in the solid state **1** is a novel tetramer based on an 'open' pseudo-cubane core (Fig. 1). The molecule sits on a crystallographic twofold axis which passes through the Li(1)O(2)Li(1A)O(2A) and Li(2)O(4)Li(2A)O(4A) planes of the cube. The Li centres each demonstrate fourfold coordination, although the fashion in which this is achieved is linked to the chirality of the protected aldehyde carbon. The observed exclusion of thf from the product is due to intramolecular stabilisation of the metal centres. This could occur *via* coordination by the α-N- or the δ-N-centres, or by both. Although there are several examples of intact $(LiO)_4$ pseudo-cubanes demonstrating intramonomer N-stabilisation[5a,b,10,11] of the metal centres, including two diastereomeric aggregates,[5a,b] it is nevertheless intriguing that in **1** the amino moieties are mono- or bis-chelating depending upon whether they are associated with (*S*)- or (*R*)-ligands, respectively. Opening of one end of the pseudo-cubane, which results from bis-chelation by the (*R*)-ligands, necessarily incurs significant variations in core Li–O bond lengths. Viewing the tetramer as an aggregate in which a dimeric pair of (*R*)-ligands lie next to a dimeric pair of (*S*)-ligands (Fig. 1, right to left), the inter-dimer Li–O distances vary between 1.909(8) Å [Li(2)–O(2)] and 1.852(8) Å [Li(1A)–O(4)]. The four-membered $(LiO)_2$ ring which is associated with dimerisation of the two (*S*)-ligands and constitutes the closed face of the pseudo-cubane, is likewise composed of two Li–O bond types. Those between the two (*S*)-monomers [*e.g.* Li(1)–O(2) 1.903(8) Å] are rather shorter than those present in the

**Scheme 1**

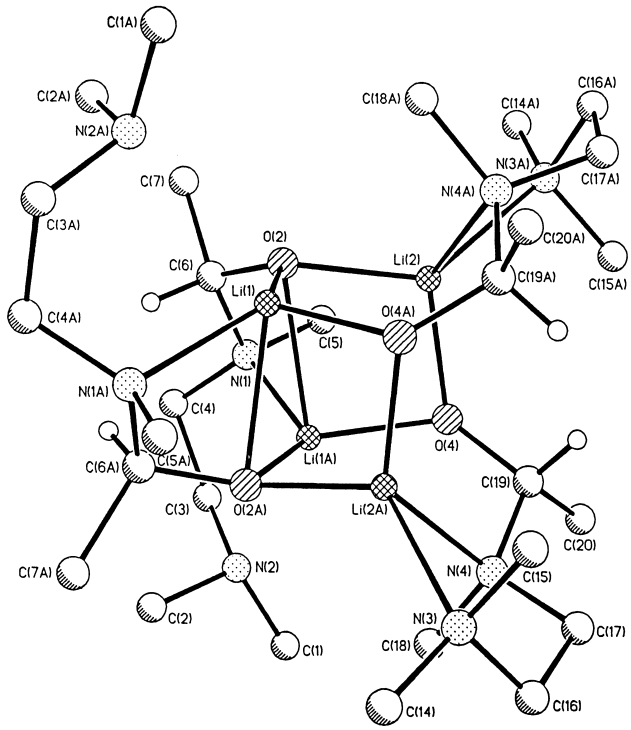


**Fig. 1** Structure of the $(LiO)_4$ 'open' pseudo-cubane core of **1**; hydrogen atoms (except the protected aldehyde hydrogens) have been omitted for clarity and only the *ipso*-carbon atoms of the aromatic rings are shown. The symmetry operation which relates original atoms to their 'A' equivalents is $1 - x, y, \frac{1}{2} - z$.

four-membered chelate rings [*e.g.* Li(1A)O(2)C(6)N(1), Li(1A)–O(2) 2.303(8) Å] which result from mono-chelation of the α-amino moieties and which demonstrate *anti*-geometrical isomerism about the C–N bond. At 2.101(8) Å, the Li(1A)–N(1) distance is consistent with distances found in related mono-chelates.[5a,b,10] The two (*R*)-ligands behave in a bis-chelating fashion with both α- and δ-N-centres stabilising the metal centres. Concomitantly, two eclipsed intramonomer Li–O bonds in the pseudo-cubane core have cleaved [*i.e.* Li(2)···O(4A)]. The result is that instead of each (*R*)-ligand incorporating a four-membered Li–O–C–N chelate ring, both (*R*)-ligands combine with two intact edges of the open pseudo-cubane, yielding an eight-membered $(Li–O–C–N)_2$ ring in a boat conformation, in which geometrical isomerism about the C–N bonds is once again of the *anti*-form. The intact Li–O bonds [Li(2)–O(4)], at only 1.872(8) Å, are rather shorter than those in the (presumably) strained four-membered mono-chelate rings associated with the (*S*)-isomers. While the α-N–Li [Li(2)–N(4A)] distance, at 2.118(8) Å, is essentially unchanged from the analogous interactions in the mono-chelated (*S*)-ligands, the δ-N–Li [Li(2)–N(3A)] bond length is somewhat longer, at 2.365(8) Å.

At 2.723(8) Å, the non-bonded Li(2)···O(4A) distance is relatively short compared with that of 3.14 Å in [PhOLi·thf]$_4$·PhOH, the only other known example of an 'open' $(LiO)_4$ pseudo-cubane.[12] However, unlike **1** this tetramer demonstrates opening of only one cubane bond, a phenomenon brought about by the inclusion of a non-lithiated phenol molecule whose hydroxyl group bridges one cubane edge. More extensive fragmentation, as seen in **1**, has been recorded in a lithium halide. Here, however, the fracture of intraaggregate bonds results from polymerisation,[13] $(LiBr·thf)_\infty$ representing the only previous example of an 'open' pseudo-cubane in which, as for **1**, two eclipsed Li–X bonds are absent.

Multinuclear NMR studies suggest the solution behaviour of **1** to be of a complicated nature. Firstly, $^7$Li NMR spectroscopy does not show two lithium environments in a 1 : 1 ratio. This suggests that the (*R*)- and (*S*)-monomers do not retain their solid-state differences in solution and that, therefore, either the tetramer is fluxional or it deaggregates. In fact, cryoscopy in benzene§ suggests that a monomer/dimer equilibrium is dominant in non-polar solution. Accordingly $^7$Li NMR spectroscopy shows two major features in a 3.8 : 1 ratio at ambient temperature in [$^2H_6$]benzene ($\delta$ −0.35, −0.47). Variable-temperature $^7$Li NMR spectroscopy in [$^2H_8$]toluene allows us to assign these as dimer and monomer respectively. The room-temp. spectrum shows peaks at $\delta$ −0.42 and −0.55 which are comparable to those observed in [$^2H_6$]benzene. However, at 193 K the high-field signal is absent, the low-field one having moved to $\delta$ −0.26.†

$^1$H NMR spectroscopy in [$^2H_6$]benzene at 298 K also reflects the complex behaviour of **1** in solution, showing as it does a dominant protected aldehyde signal at $\delta$ 6.48 along with five much smaller satellites in the range $\delta$ 6.12–6.01, all of which correlate with the protected aldehyde carbon centre at $\delta$ 88.60 (by HMQC spectroscopy).[14] Solution studies of **1** are on-going.

We thank the UK EPSRC (A. E. H. W.) and The Royal Society (J. E. D., P. R. R.) for financial support.

† Bu$^n$Li (1.88 ml, 1.6 M in hexanes, 3.0 mmol) was added to *N*,*N*,*N*′-trimethylethylenediamine (0.38 ml, 3.0 mmol) in thf (4 ml) at −78 °C under $N_2$. After stirring for 10 min, *o*-anisaldehyde (0.36 ml, 3.0 mmol) was added and the resultant colourless solution was stirred for a further 10 min at −78 °C. Warming to room temp. gave a white suspension, which afforded a yellow solution on gentle heating. Storage at room temp. for one day afforded colourless, rectangular crystals of **1**, mp, 160–161 °C, yield, 82%. $^1$H NMR (500.13 MHz, 298 K, $C_6D_6$), $\delta$ 8.14 (d, 1 H, Ar), 7.18 (d, 1 H, Ar), 7.14 (dd, 1 H, Ar), 6.78 (dd, 1 H, Ar), 6.48–6.01 [m, 1 H ArC(*H*)(O)$NR_2$], 3.72–3.31 (m, 3 H, $OCH_3$), 2.75–2.69, 2.32 (m, 2 H, $CH_2$), 2.68–2.21 (m, 3 H, $NCH_3$), 2.53–2.49 (m, 2 H, $CH_2$), 2.41–1.92 [m, 6 H, N′$(CH_3)_2$].$^{13}$C NMR (100.61 MHz, 298 K, $C_6D_6$), $\delta$ 157.03, 135.83, 130.61, 126.83, 119.91, 110.01 (Ar), 88.60 [Ar*C*(H)(O)$NR_2$], 59.02 ($CH_2$), 54.86 ($OCH_3$), 52.13 ($CH_2$), 46.66–45.54 [m, N′$(CH_3)_2$], 36.87–34.73 (m, $NCH_3$). $^7$Li NMR (155.51 MHz, 298 K, $C_6D_6$, ref. PhLi $\delta$ 0) $\delta$ −0.35 (s, 3.8 Li), −0.47 (s, 1 Li); (298 K, $C_6D_5CD_3$, ref. PhLi $\delta$ 0) $\delta$ −0.42 (s, 3.5 Li), −0.55 (s, 1 Li); (273 K) $\delta$ − 0.38 (s, 4.9 Li), −0.50 (s, 1 Li); (248 K) $\delta$ − 0.33 (s); (223 K) $\delta$ −0.29 (s); (193 K) $\delta$ −0.26 (s).

‡ *Crystal data* for **1**: $C_{52}H_{84}Li_4N_8O_8$, monoclinic, space group *C*2/*c*, $a$ = 21.795(6), $b$ = 12.828(4), $c$ = 20.754(7) Å, $\beta$ = 105.19(2)°, $M_r$ = 977.03, $Z$ = 4, $D_c$ = 1.159 Mg m$^{-3}$, $\mu$(Mo-Kα) = 0.077 mm$^{-1}$, $F$(000) = 2112. Data were collected by the $\omega$–2$\theta$ scan method on a Rigaku AFC5R four-circle diffractometer at 150(2) K using the 'oil drop mounting technique'.[7] Graphite-monochromated Mo-Kα radiation ($\lambda$ = 0.710 69 Å) was used in the range 5.12 < 2$\theta$ < 39.96°, ±$h$, ±$k$, +$l$; 2707 reflections of which 2604 were independent ($R_{int}$ = 0.0335) and used in all calculations. The structure was solved using direct methods[8] and subsequent Fourier-difference syntheses and refined[9] by full-matrix least squares on $F^2$ with anisotropic thermal parameters for all non-hydrogen atoms except Li. H-atoms were placed in geometrically idealised positions and refined using a riding model or as rigid methyl groups. Final $R(F)$ = 0.0536 for 2595 reflections with [$I > 2\sigma(I)$], $wR(F^2)$ = 0.1412 for all data; 316 parameters; goodness of fit = 1.045. Maximum peak and hole in final Fourier difference map 0.172 and −0.186 e Å$^{-3}$ respectively. CCDC 182/548.

§ Cryoscopy on **1** in benzene suggests that the average aggregation state varies from 1.3 to 1.5 (±0.1) in the concentration range 0.006–0.016 M (1.4–3.9 mg ml$^{-1}$). NMR spectroscopy used *ca.* 2 mg ml$^{-1}$ samples.

# Cuprophilicity? a rare example of a ligand-unsupported $Cu^{I}$–$Cu^{I}$ interaction

**Ulrich Siemeling,* Udo Vorfeld, Beate Neumann and Hans-Georg Stammler**

*Fakultät für Chemie, Universität Bielefeld, Universitätssraße 25, D-33615 Bielefeld, Germany*

**The reaction of 1,1′-bis(2-pyridyl)octamethylferrocene (L) with $[Cu(NCMe)_4]BF_4$ in $CH_2Cl_2$ affords $[CuL][CuCl_2]$, the structure of which is determined by a single-crystal X-ray diffraction study; this reveals a remarkably short ligand-unsupported $Cu^{I}$–$Cu^{I}$ contact of 281.0(2) pm.**

Attractive interactions between formally closed-shell metal centres ($s^2$ of $d^{10}$) are well documented.[1] The body of evidence is especially large in the case of gold(I). Here, the term 'aurophilicity' has been coined to describe this special kind of metal–metal bonding interaction,[2] which can be as strong as 11 kcal $mol^{-1}$ (1 cal = 4.184 J).[3] The question whether a similar metallophilicity[4] exists for the other two coinage metals, copper and silver, is still a matter of controversy. For example, the presence of such $d^{10}$–$d^{10}$ bonding interactions has been disputed on theoretical grounds for the dinuclear complexes $[M(MeC_6H_4NCHNC_6H_4Me)]_2$ in spite of short metal–metal distances [247.7(2)/270.5(1) pm for M = Cu/Ag], which were therefore attributed to the ligand architecture.[5] A most instructive case is that of the trinuclear copper complex $[Cu(MeC_6H_4N_5C_6H_4Me)]_3$, the metal centres of which have an average distance of only 235 pm.[6] The existence of a bonding interaction between them has both been supported[7] and refuted[8] at various levels of theory.

Metallophilic effects are easily blurred by the effects exerted by a bridging ligand architecture, and hence examples of ligand-unsupported metal–metal interactions are of great importance in this discussion. They are, however, notoriously scarce for silver[9] and especially for copper.[10] The first example of a copper complex exhibiting such an interaction appears to be the trinuclear species $[CuL']_3$ {HL′ = 2-[3(5)-pyrazolyl]pyridine}, which crystallises as a dimer showing two close metal–metal contacts between the two associated trinuclear units in the absence of any supportive bridging ligation [*d*(Cu–Cu) = 290.5(3) pm].[10]

We have obtained a species with an even shorter ligand-unsupported $Cu^{I}$–$Cu^{I}$ contact from the reaction of 1,1′-bis(2-pyridyl)octamethylferrocene[11] (L) with $[Cu(NCMe)_4]BF_4$ in dichloromethane, which yielded $[CuL][CuCl_2]$ **1**.† This species contains two copper(I) ions in an almost linear dicoordinate environment as shown by a single-crystal X-ray diffraction study (Figs. 1 and 2).‡ Whereas the $[CuCl_2]^-$ anion is very well known,[12] few structurally characterised examples of a copper(I) ion coordinated by just two N donors have been described to date.[13] The majority of the work published in this area was stimulated by the notion that complexes containing coordinatively unsaturated copper(I) ions and nitrogen heterocyclic ligands are of interest as possible models for deoxyhemocyanin.[14] An important feature of the structure of **1** is the short distance between the two copper centres of only 281.0(2) pm. The coordination axes of the anion and the cation, which are both slightly bent [N(1)–Cu(1)–N(2) 171.4(6), Cl(1)–Cu(2)–Cl(2) 176.9(3)°], are approximately perpendicular to each other [torsion angles: N(1)–Cu(1)–Cu(2)–Cl(1) 85.5, N(2)–Cu(1)–Cu(2)–Cl(2) 89.4°] (Fig. 3). There are no appreciable secondary interactions between the nitrogen-coordinated copper centre and the chlorine atoms of the anion, since both Cu–Cl distances [Cu(1)–Cl(1) 337, Cu(1)–Cl(2) 358 pm] are considerably larger than the sum of the van der Waals radii of Cu (140 pm) and Cl (175 pm).[15] There is no indication for intermolecular interactions of the Cl-coordinated Cu centre, its shortest intermolecular contact (Cu–C 398 pm) being that to the methyl group attached to C(1) of a neighbouring $[CuL]^+$ unit.

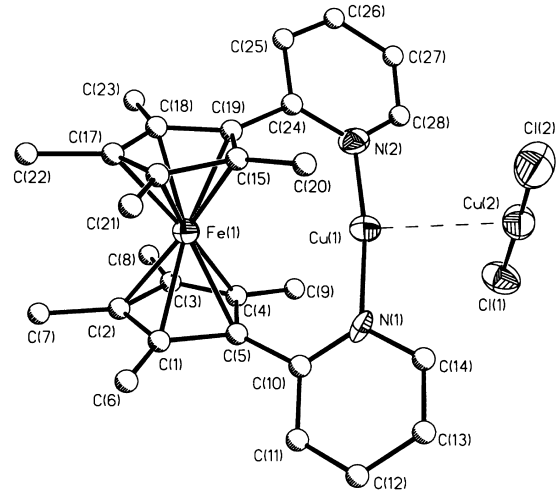

**Fig. 1** Molecular structure of **1**. Selected bond lengths (pm) and angles (°): Cu(1)–N(1) 195(2), Cu(1)–N(2) 190(2), Cu(2)–Cl(1) 212.3(7), Cu(2)–Cl(2) 206.6(7); N(1)–Cu(1)–Cu(2) 94.9(4), N(2)–Cu(1)–Cu(2) 93.6(5), Cl(1)–Cu(2)–Cu(1) 84.9(2), Cl(2)–Cu(2)–Cu(1) 93.2.

It has been noted in the chemistry of gold(I) that metallophilic energy minima can be rather shallow.[16] The same is assumed to be true for copper(I), so that crystal packing forces[17] may very well overrule weak cuprophilic interactions. In comparison, this appears to be the case for $[Cu(C_5H_2NMe_3\text{-}2,4,6)][CuCl_2]$,[13b,e] whose $Cu^{I}$–$Cu^{I}$ distance of 361.1(2) pm is *ca.* 80 pm longer than that in **1**, although the coordination parameters of the respective $Cu^{I}$ centres are quite similar for both complexes. Closer inspection reveals that the packing of the $[Cu(C_5H_2NMe_3\text{-}2,4,6)]^+$ units in the crystal, which involves stacking of

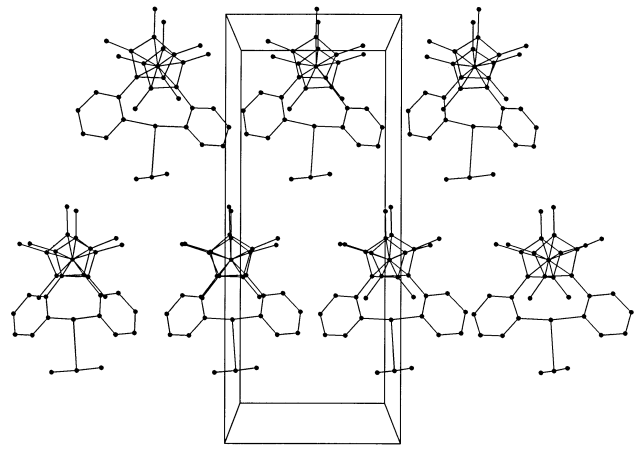

**Fig. 2** Packing diagram of **1** (viewed down the *c* axis of the unit cell)

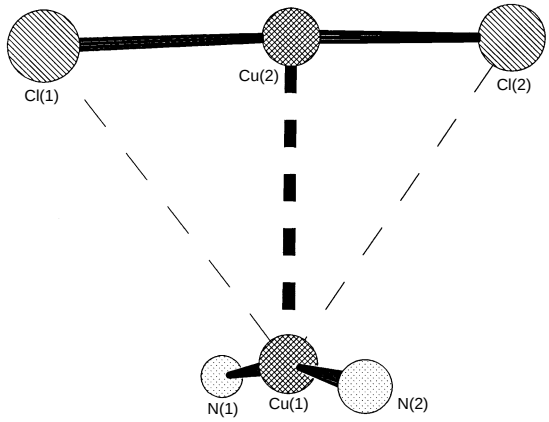

**Fig. 3** View of the coordination spheres of the copper centres in **1**

neighbouring collidine ligands with a closest inter-ring distance of 348 pm,§ prohibits a closer approach of the copper centres.

In summary, we have synthesised a rare example of a complex which exhibits a remarkably short ligand-unsupported $Cu^{I}$–$Cu^{I}$ contact, reflecting an interaction between the two formally closed-shell metal centres that may be due to a cuprophilic interaction between them.

We acknowledge financial support by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the University of Bielefeld. U. S. thanks Professor P. Pyykkö for making refs. 1(*a*) and 16 available to him prior to publication. We thank one of the referees for helpful comments.

† *Preparation*: a solution of L (362 mg, 0.80 mmol) in dichloromethane (5 $cm^3$) was added at ambient temperature to a solution of $[Cu(NCMe)_4]BF_4$ (126 mg, 0.40 mmol) in $CH_2Cl_2$ (10 $cm^3$) with vigorous stirring. After 12 h volatile components were removed *in vacuo* leaving a viscous, brown–red oil, which was dissolved in a minimal amount of $CH_2Cl_2$. Vapour-phase diffusion of *n*-pentane into this solution afforded **1** {66 mg, 43% with respect to $[Cu(NCMe)_4]BF_4$} as red crystals (decomp. *ca.* 160 °C), which are insoluble in hydrocarbons and diethyl ether, very soluble in dichloromethane and moderately soluble in $CHCl_3$. The solvent obviously participated in the reaction, since it was the only source of Cl present. The reaction proved to be irreproducible. *Selected spectroscopic data*: FABMS *m*/*z* 515 ($[CuL]^+$, 100%), 453 ($[HL]^+$, 67%). $^1$H NMR ($CDCl_3$): $\delta$ 1.64, 1.86 (2 s, 24 H, Me), 7.25, 7.40, 7.74, 9.42 (4 br. s, 8 H, aromatic H). $^{13}C\{^1H\}$ NMR ($CDCl_3$) $\delta$ 9.7, 12.0 (Me), 80.2, 82.6, 85.6 (cyclopentadienyl ring C), 122.5, 127.7, 137.7, 151.9 (pyridyl CH), 158.7 (q pyridyl C).

‡ *Crystal data*: $C_{28}H_{32}Cl_2Cu_2FeN_2$, $M_r$ = 650.39; orthorhombic, space group $Pna2_1$, $a$ = 21.238(4), $b$ = 8.773(1), $c$ = 14.257(1) Å, $U$ = 2656.4(6) Å$^3$, $Z$ = 4, $D_c$ = 1.626 g cm$^{-3}$; $F$(000) = 1328, $\mu$(Mo-K$\alpha$) = 2.347 mm$^{-1}$, $\lambda$ = 0.71073 Å, $T$ = 173(2) K, crystal size 0.30 × 0.10 × 0.10 mm. A total of 2423 reflections all of which were unique were collected with a Siemens P2(1) four-circle diffractometer using ω scans with 1.92 < $\theta$ < 25.04°. The structure was solved by direct methods and developed routinely. Full-matrix least-squares refinement with 184 parameters was based on $F^2$. Hydrogen atoms were considered in calculated positions. Carbon atoms were refined isotropically and all other atoms anisotropically. The refinement converged at $R_1$ = 0.0688 and $wR_2$ = 0.1029 [for 1186 reflections with $I > 2\sigma(I)$] {$w = [\sigma^2(F_o^2) + (0.0319P)^2]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$}; final GOF = 1.039. The final difference map showed no peak > 0.6 and no hole < −0.5 e Å$^{-3}$. Programs used were Siemens SHELXTL plus and SHELXL-93. CCDC 182/531.

# What are the reacting species in the oxidation of bisulfite by hydrogen peroxide in water clusters?

**Mark A. Vincent, Ian H. Hillier* and Ian J. Palmer**

*Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*

***Ab initio* calculations suggest that in the oxidation of $HSO_3^-$ to sulfuric acid by $H_2O_2$ under acid conditions, $SO_2$ and not $HSO_3^-$, is the reacting species, a result relevant to modelling the formation of acid rain.**

One of the most studied of the multiphase reactions in the troposphere is the oxidation of $SO_2$ to sulfuric acid in water droplets by oxidants such as $H_2O_2$.[1,2] The elucidation of the mechanism of this reaction is naturally central to modelling the formation of acid rain. It is usual to invoke the involvement of the bisulfite anion, $HSO_3^-$, in proposed reaction mechanisms.[3,4] However, the actual mechanism by which the proposed intermediate, the peroxymonosulfite ion, is produced, is unclear. Indeed many $S^{IV}$ species have been proposed to be involved along the reaction pathway.[3,4]

To provide further insight into this reaction we have studied the mechanism by employing high level *ab initio* electronic structure calculations. These were carried out using a 6-311+g** basis[5–7] and included electron correlation at the B3LYP level[8] *via* the Gaussian 94 suite of programs.[9] Two possible transition states for the reacting $H_2O_2$ and $HOSO_2^-$ species, leading to the proposed intermediate peroxymonosulfite ion,[3,4] have been determined. One of the transition states included two explicit water molecules and the other included no solvent (Fig. 1). A similar direct participation of additional water molecules has been invoked in the calculation of the reaction of $SO_3$ with $H_2O$ to form $H_2SO_4$.[10]

A common feature of both of these calculated transition states are the two very long S–O bond lengths (2.75–2.87 Å), and two others (1.47–1.48 Å) close to the value in $SO_2$ itself (1.46 Å). In addition, in both transition structures there is a well developed hydroxide group. Furthermore, if the unsolvated transition state is located without the $SO_2$ being present, the structure changes very little, and involves proton transfer between $HO^-$ and $H_2O_2$. Thus both transition states essentially correspond to the dissociation of the bisulfite ion to $SO_2$. However, it would be expected that in acid solution the developing negative charge on the OH group would be neutralized at an early stage to yield free $SO_2$.

Indeed there is evidence that in the absence of $H_2O_2$ protonation of aqueous bisulfite can lead to the formation of $SO_2$. NMR studies of aqueous bisulfite[11] have demonstrated exchange of the oxygen atoms associated with the sulfur atom, suggesting ease of formation of $SO_2$. Computationally we have previously found from *ab initio* calculations[12] that protonation of the OH oxygen atom of $HOSO_2^-$, in a small water cluster, also leads to the formation of $SO_2$ with little or no barrier, again suggesting the direct involvement of $SO_2$. This latter result is supported by the experimental[11] evidence that exchange of oxygen in the bisulfite ion is first order in both $H_3O^+$ and $HOSO_2^-$.

These results, both experimental and theoretical, suggest that under acid conditions the reacting species in water droplets containing bisulfite is probably $SO_2$. In view of this we have modelled the subsequent reaction of sulfur dioxide and $H_2O_2$. The corresponding transition state for the reaction leading to peroxymonosulfurous acid, and involving two explicit water molecules was located, and is shown in Fig. 2. This structure

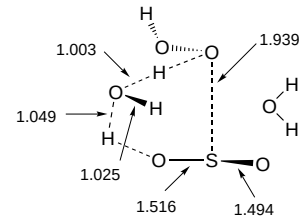

**Fig. 2** Transition state for the reaction of $SO_2$ and $H_2O_2$ involving two water molecules (bond lengths in Å)

involves somewhat greater perturbation of the $SO_2$ moiety than in the corresponding reaction of $HOSO_2^-$ (Fig. 1), with a well developed $H_3O^+$ entity acting as a proton shuttle between $H_2O_2$ and $SO_2$. Both this structure and the corresponding transition state for the reaction of $HOSO_2^-$ with $H_2O_2$ involve a six-membered ring, which is probably less strained than the cyclic transition state for the reaction without explicit solvation. When this structure is further solvated using a continuum approach[13] the barrier from the hydrogen bonded reactants is calculated to be 12.3 kcal mol$^{-1}$ (1 cal = 4.184 J). This value is somewhat larger than the experimental barrier[4] of 8.8 kcal mol$^{-1}$, for the formation of the peroxymonosulfite ion from $H_2O_2$ and $HOSO_2^-$ in acid solution.

There are thus compelling reasons to believe that the reactive species involved in the formation of acid rain, from bisulfite and hydrogen peroxide in acid solution, is $SO_2$.

We thank EPSRC for support of this research.

# Intercalation of decamethylferrocenium cations in bimetallic oxalate-bridged two-dimensional magnets

**Miguel Clemente-León, Eugenio Coronado,* José-Ramón Galán-Mascarós and Carlos J. Gómez-García**

*Dpto. de Química Inorgánica. Univ. Valencia. Dr. Moliner 50, 46100 Burjasot, Spain*

**The structure and magnetic properties of novel hybrid molecule-based magnets formed by combination of two magnetically active sublattices, the bimetallic oxalato-bridged honeycomb net $[Mn^{II}M^{III}(ox)_3]$ ($M^{II}$ = Mn, Fe, Co, Cr, Ni, Cu; $M^{III}$ = Cr, Fe) and the organometallic cation decamethylferrocenium, are reported.**

Much interest has been shown in oxalate complexes in the search for new molecule-based magnets since the discovery at the beginning of the nineties of new polymeric bimetallic phases of variable dimensionality.[1] Especially interesting are the two-dimensional bimetallic phases $A[M^{II}M^{III}(ox)_3]$ ($M^{II}$ = Mn, Fe, Co, Cr, Ni, Cu; $M^{III}$ = Cr, Fe) because they behave as ferro-,[2] ferri-[3] or canted antiferro-magnets[4] with critical temperatures ranging from 5 up to 44 K. Their structure[5] consists of extended oxalate-bridged layers of the two metal atoms separated by $A^+$, an electronically 'innocent' counter ion of the type $[XR_4]^+$ (X = N, P; R = Ph, $Pr^n$, $Bu^n$), which may act as a template controlling the formation of the net structure and thus determining the interlayer separation.[4b] The change of this cation to an electroactive one could create new hybrid molecular materials with interesting properties or combinations of properties, depending on the nature of the cation and the possible interactions with the magnetic network. Very recently we reported an example of such hybrid materials: the $[TTF]_4\{M^{II}(H_2O)_2[M^{III}(ox)_3]_2\}\cdot nH_2O$ family,[6] in which the cation is the organic π-donor molecule tetrathiafulvalene (TTF), although instead of the extended two-dimensional network, a molecular layer of oxalato-bridged bimetallic trimeric clusters is formed.

Here we show that it is possible to combine the layered bimetallic oxalate complexes with the magnetically interesting organometallic cation $[Fe(Cp^*)_2]^+$ ($Cp^*$ = decamethylferrocenium), which has spin $S = 1/2$. It is to be noticed that other salts formed by decamethylmetallocenium cations and two-dimensional molecule-based magnets have been very recently reported, but the structure of these materials is unknown.[7]

The new family of organometallic–inorganic magnetic compounds has the formula $[Fe(Cp^*)_2][M^{II}M^{III}(ox)_3]$ ($M^{II}$ = Mn, Fe, Co, Ni, Cu, Zn; $M^{III}$ = Cr, Fe). They were obtained by the one-pot reaction of the tris(oxalato) complex $[M^{III}(ox)_3]^{3-}$ with the divalent metal ion $M^{II}$ and $[Fe(Cp^*)_2]^+$ cations in water. Crystals of good quality were obtained by diffusion, and the crystal structure was solved for the $Fe^{III}Mn^{II}$ derivative. The structure† consists of anionic layers of the well known honeycomb bimetallic oxalato-bridged network with decamethylferrocenium cations intercalated in between [Fig. 1(*a*)]. The bimetallic layers are eclipsed by each other creating hexagonal channels running along the *c* axis. The organometallic cations exhibit a staggered configuration (symmetry $D_{5d}$). They are ordered within the interlayer space. In fact, they are located at the center of the hexagonal channels forming a pseudo-hexagonal arrangement. These cations are tilted with respect to the layer by an angle of 32.6° (angle defined by the fivefold symmetry axis of the cation with the normal to the bimetallic plane) in such a way that the two pentamethylcyclopentadienyl molecules of each $[Fe(Cp^*)_2]^+$ cation are pointing towards the center of the hexagons of two adjacent layers [Fig. 1(*b*)]. The interlayer separation is 9.213 Å, similar to that found in previous compounds of two-dimensional phases,[5,4b] and there is no evidence of hydrogen-bond interactions between the cations and the layers (the minimum H···O distance is 2.584 Å). A distinctive feature of this structure with respect to the other structurally known two-dimensional phases is that now the cation does not penetrate into the honeycomb net (the minimum distance of the cation to this plane is 0.88 Å; distance from the mean plane defined by the metals to the closest hydrogen from a methyl group). A second difference deals with the stacking of the bimetallic layers. Thus, in contrast with the $[XR_4]^+$ derivatives, all the layers are of the same type so that the metals of one layer lie directly over those in the next layer.‡

All these compounds are magnets exhibiting spontaneous magnetization below $T_c$ and hysteresis loops. As in the $[XR_4]^+$ derivatives, the compounds of the $Cr^{III}M^{II}$ series behave as ferromagnets§ which have ferromagnetic interactions between $Cr^{III}$ and $M^{II}$ ions through the oxalate group, while in the $Fe^{III}M^{II}$ series this coupling is antiferromagnetic giving rise to ferrimagnets (for $M^{II}$ = Fe, Co) or canted antiferromagnets (for $Mn^{II}$ = Mn). We have performed ac susceptibility measure-

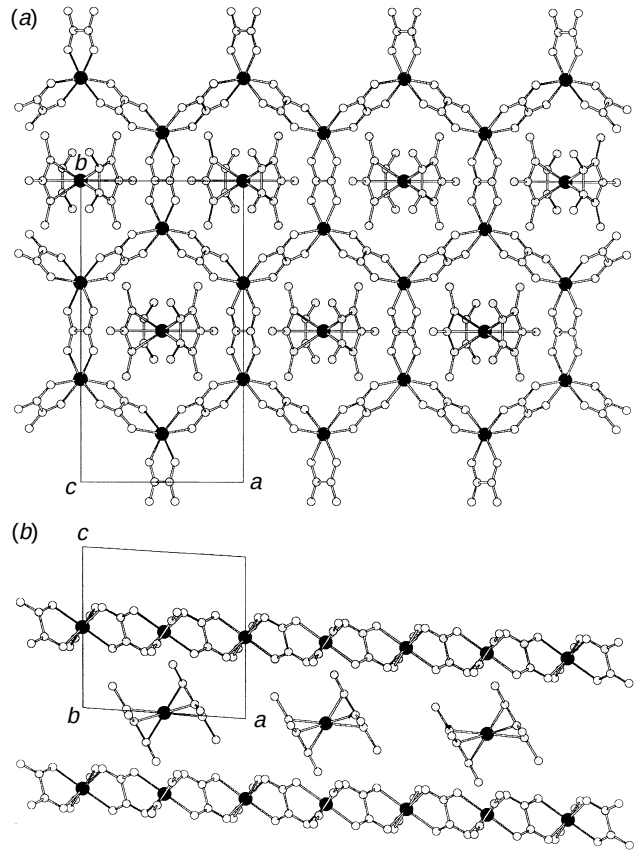

**Fig. 1** View of the structure in the *ab* plane showing the honeycomb magnetic layers (*a*) and in the *ac* plane (*b*)

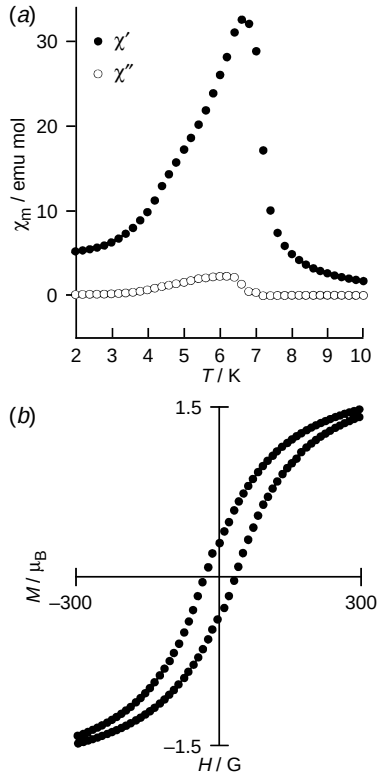

**Fig. 2** Magnetic properties of the $Cr^{III}Cu^{II}$ derivative: (*a*) ac susceptibility *vs.* temperature showing the out-of-phase signal ($\chi''$); (*b*) hysteresis loop at 5 K

ments in order to obtain accurate values of $T_c$. These data show a sharp peak in both the in-phase and the out-of-phase susceptibility signals at $t_c$ (Fig. 2). The relevant magnetic parameters (critical temperatures and coercive fields for the Cr–M ferromagnets and critical temperatures for the Fe–M ferrimagnets) are summarized in Table 1 and compared to those reported for the $[XR_4]^+$ derivatives. As we can see, the $[Fe(Cp^*)_2]^+$ salt of the $Fe^{III}Co^{II}$ derivative has no precedent among the $[XR_4]^+$ salts. This material undergoes ferrimagnetic ordering at $T_c$ = 19.5 K. As far as the magnetic ordering is concerned what becomes apparent from the above magnetic results is that the paramagnetic $[Fe(Cp^*)_2]^+$ cations are not

**Table 1** The series of compounds $[Fe(Cp^*)_2][M^{II}M^{III}(ox)_3]$. Critical temperatures and coercive fields (at 5 K) for $Cr^{III}M^{II}$ and critical temperatures for $Fe^{III}M^{II}$. Comparison with the $[XR_4]4^+$ salts

| | $T_c$/K | | $H_{coerc}$/G | |
|---|---|---|---|---|
| $M^{III}M^{II}$ | $[Fe(Cp^*)_2]^+$ | $[XR_4]^+$ | $[Fe(Cp^*)_2]^+$ | $[XR_4]^+$ |
| CrMn | 5.3 | 6 | 10 | 20 |
| CrFe | 13.0 | 12 | 320 | 320 |
| CrCo | 9.0 | 10 | 50 | 80 |
| CrNi | 14.5 | 14 | 250 | 160 |
| CrCu | 7.0 | 7 | 30 | 30 |
| FeMn | 28.4 | 25–29 | | |
| FeFe | 43.3 | 33–48 | | |
| FeCo | 19.5 | — | | |

directly involved in the long-range magnetic ordering, which is essentially controlled by the bimetallic layers. Thus, $T_c$ values are found to be roughly the same as those observed in the $[XR_4]^+$ derivatives. On the other hand, the coercive fields are also very similar. These results indicate that the two magnetic sublattices essentially behave independently, without a significant cation–layer electronic interaction, in agreement with the structural features. Unusual magnetic effects may arise from the coexistence of these two magnetic sublattices. For example, in the ordered state the magnetic layers are expected to polarize the spins of the metallocene layer and therefore a Zeeman splitting of the $S$ = 1/2 spins of the paramagnetic cations may be observed. Complete physical characterization of these and other molecular magnetic multilayers that can be obtained using the same methodology is now in progress.

# First synthesis of mesostructured thiogermanates

**Michael Fröba* and Nadine Oberender**

*Institute of Inorganic and Applied Chemistry, University of Hamburg, Martin-Luther-King-Platz 6, 20146 Hamburg, Germany*

**Two mesostructured thiogermanates are prepared and characterized by powder XRD, TEM and TG–DTA.**

Since the first synthesis of mesoporous M41S phases in 1992[1] numerous systems of mesoporous metal oxides have been reported.[2] The range of possible applications of mesoporous systems is broadened by the use of sulfides instead of oxides. Porous semiconductors are of interest owing to their special electronic and optical properties, such as luminescence. In the area of microporous sulfides promising results have already been achieved,[3] but there were only a few attempts to prepare mesostructure metal sulfides.[4–6]

In the present work we report the synthesis of different mesostructured thiogermanates dependent on pH, temperature and reaction time. We used amorphous germanium sulfide as the inorganic source and cetyltrimethylammonium bromide as the supramolecular template. The reactions were carried out under hydrothermal conditions.

There is a minimum temperature and, at lower temperatures, a minimum reaction time necessary to obtain mesostructured organic/inorganic composites (Fig. 1).

The powder diffraction pattern of the thiogermanates prepared at various pH values differ. Samples prepared at low pH (product 1) show generally one or two reflections with relatively low intensities indicating a lower crystallinity [Fig. 2(*a*)]. High pH values (product 2) lead to products with multiple, more intense reflections [Fig. 2(*b*)]. Both mesostructured thiogermanates have a lamellar structure whereas product 1 shows a higher degree of condensation between the inorganic building units.

In both cases all reflections can be indexed as 00*l* reflections whereas product 1 shows a larger *d* spacing (3.2 nm) for the 001 reflection than the corresponding *d* value of product 2 (2.8 nm).

For product 2 the TEM shows an ordered lamellar structure (Fig. 3). The distance between the layers is *ca.* 2.7 nm. In contrast product 1 is more disordered.

The results of thermochemical measurements also show significant differences between the two products. Fig. 4(*a*) and (*b*) show TG and DTA results of products 1 and 2, respectively. The former has a more simple mechanism of decomposition with three steps of mass loss whereas the latter shows a more complex course with at least five steps.

Calculations result in a much lower molar mass of *ca.* 230 for product 1 in contrast to 600 for product 2. These results suggest a much higher content of template in product 2 which is obvious because the degree of condensation is relatively low. At high pH charge-matching interactions between the surfactant cations

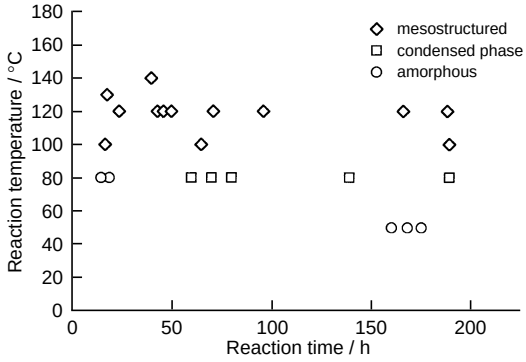

**Fig. 1** Correlation between reaction time, temperature and the products obtained

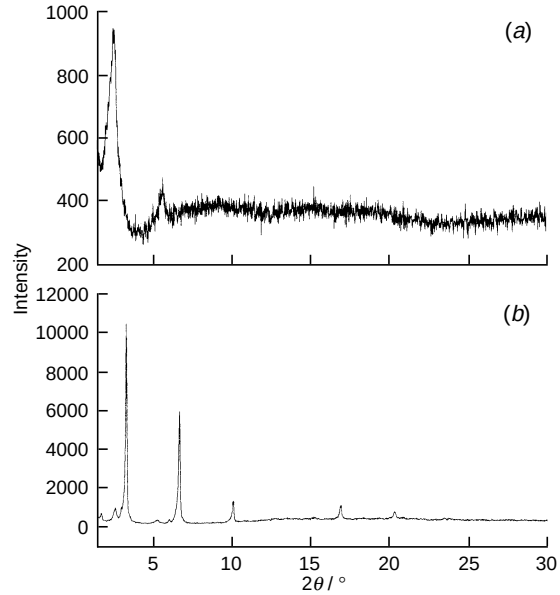

**Fig 2** X-Ray powder diffraction patterns of the mesostructured products 1 (*a*) and 2 (*b*)

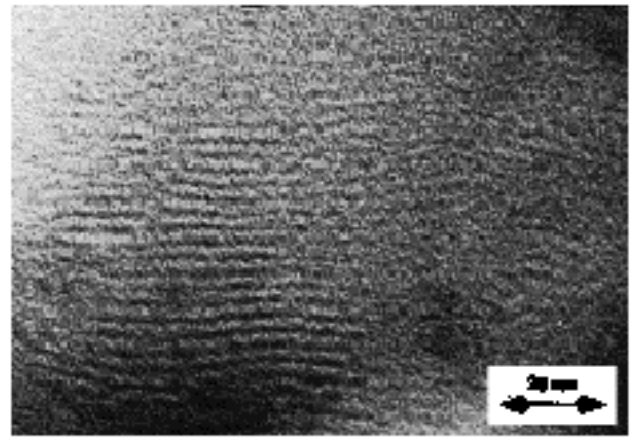

**Fig 3** Transmission electron micrograph of the mesostructured product 2

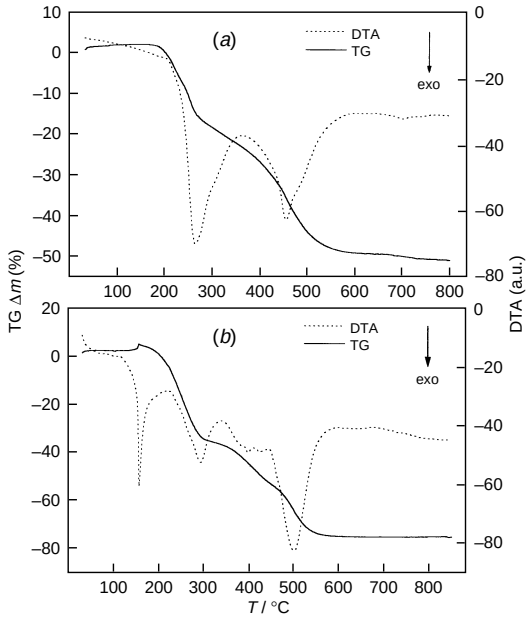

**Fig. 4** TG–DTA measurements of the mesostructured products 1 (*a*) and 2 (*b*) (atmosphere: oxygen, heating rate = 5 K $min^{-1}$)

and the smaller thiogermanate anions lead to a more crystalline saltlike structure [Fig. 2(*b*)] in order to attain electrical neutrality. At low pH additional condensation reactions take place and there is less charge per $Ge_xS_y$ as the units get larger. Elementary analysis data give the same results.

In conclusion, we were able to mesostructure thiogermanates and demonstrated the basic correlations between reaction time, temperature, pH and the corresponding structures of the products.

We thank Olaf Muth for carrying out the TEM measurements. Financial support by the University of Hamburg, the Swiss Federal Energy Office and the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

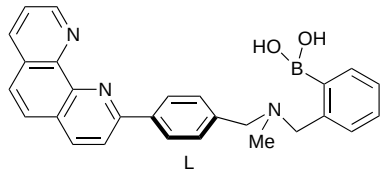
# Fluorescent sensing of uronic acids based on a cooperative action of boronic acid and metal chelate

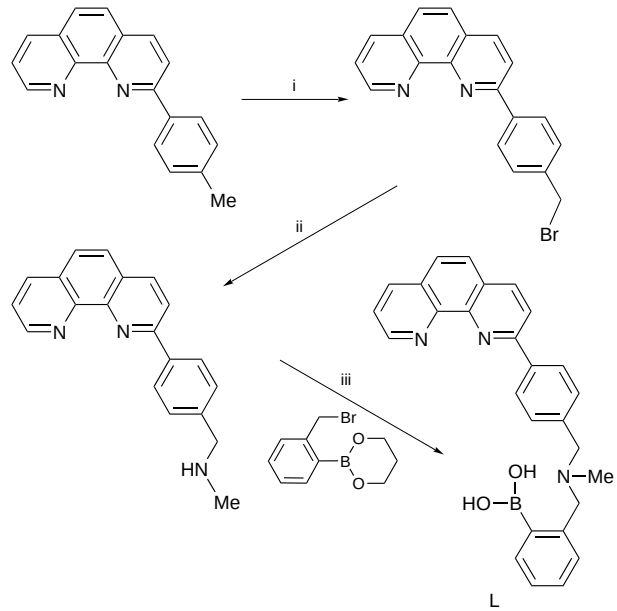


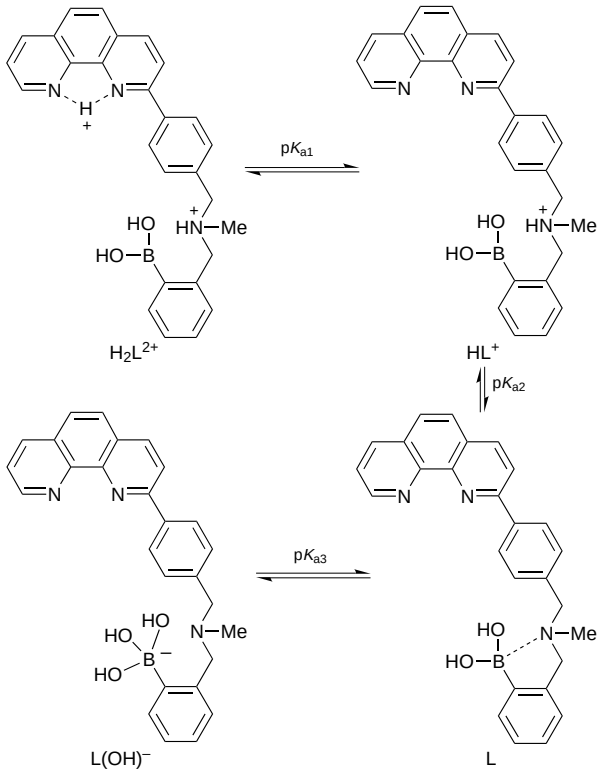
**Masayuki Takeuchi, Masashi Yamamoto and Seiji Shinkai***

*Department of Chemical Science & Technology, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan*

**A new fluorescent molecular sensor for uronic acids is designed, which features two-point interactions of boronic acid–diol complexation and zinc(II)–carboxylate coordination.**

Saccharides are nature's conveyors of energy and play many crucial roles in metabolic cycles. Uronic acids are known to appear in the oxidation process of monosaccharides or in the biosynthetic process of L-ascorbic acid. The quantitative analysis of uronic acids has so far been accomplished by classical colorimetic methods such as naphthoresorcine–HCl[1] and carbazole–$H_2SO_4$.[2] Obviously, it seems very important to develop a new analytical method which is useful under physiological conditions and in addition, shows high selectivity and sensitivity towards uronic acids in the presence of concomitant neutral saccaharides. We have recently demonstrated the usefulness of the boronic acid function as a saccharide receptor in a saccharide recognition system.[3] Judging from the structure of uronic acids, molecular design including both a boronic acid moiety for diol binding and a metal chelate moiety for carboxylate binding within a molecule should lead to an excellent uronic acid receptor. To achieve high sensitivity it is desirable to combine this system with the concept of a photoinduced electron-transfer (PET) sensor.[4,5] We previously designed compound L′ which selectively binds 1,2- and 4,6-diols of glucose with two boronic acids and reports the binding event by a fluorescence change in the PET mechanism.[6] Here, we have rationally designed a molecular sensor L for uronic acids in which one boronic acid group in L′ is replaced by a metal chelation site. We have found that the zinc(II) complex of this new molecular sensor selectively responds to uronic acids in neutral aqueous solution.





The synthesis of L was achieved from 2-(*p*-tolyl)-1,10-phenanthroline[7] by the route outlined in Scheme 1. The product (mp 166–169 °C) was identified by IR and $^1$H NMR spectroscopic evidence and elemental analysis.

Since the water solubility of L was not good, we used a mixed medium of water–MeOH (1 : 2 v/v) to avoid self-aggregation. The absorption maximum of L shifted from 301 to 290 nm upon a pH change from 2.0 to 7.5 with a tight isosbestic point (at 294 nm). This change corresponds to deprotonation of the chromophoric 1,10-phenanthroline moiety (p$K_{a1}$ 4.4, Scheme 2). The absorption spectra did not change further at higher pH. Using 294 nm as the excitation wavelength we measured the fluorescence spectra. Fig. 1 shows plots of the fluorescence intensity ($\lambda_{max}$ at 375 nm) *vs.* pH. In the absence of saccharide, the fluorescence intensity increase at pH 2–6 corresponds to deprotonation of the 1,10-phenanthroline moiety, which again gives p$K_{a1}$ 4.4. The fluorescence intensity decrease starting from pH 5.5 and pH 10 corresponds to deprotonation of the tertiary amine (p$K_{a2}$) and $OH^-$ adduct formation with the boronic acid group (p$K_{a3}$), respectively. Because of the overlap of the dissociation groups the p$K_{a2}$ could be only approximately estimated to be *ca.* 7, whereas the p$K_{a3}$ could not be determined accurately. In the presence of saccharide ([D-fructose] = 100 mmol dm$^{-3}$, Fig. 1), the fluorescence intensity is increased at pH 6–11. This is due to the B–N interaction intensified by complexation of saccharide with the boronic acid group.[6] The association constants ($K_{ass}$) in the absence of $Zn^{II}$ were estimated from plots of the fluorescence intensity against the saccharide concentration. The results are summarized in Table 1.

Addition of $Zn^{II}$ [added as $Zn(NO_3)_2 \cdot 6H_2O$] decreased the absorbance in the UV region of the absorption spectrum and the visible region of the fluorescence spectrum and the final spectra were very similar to those of $H_2L^{2+}$. The results suggest that $Zn^{II}$ is primarily associated with the phenanthroline moiety. Since the spectral changes were saturated at [$Zn^{II}$]/[L] = 4.0, we fixed the ratio to this value and then added saccharides. The fluorescence intensity increased with increasing saccharide concentration and was saturated at high concentration. From the

**Scheme 1** *Reagents and conditions* [yields]: i, NBS, AIBN, $CCl_4$, reflux; ii, $MeNH_2$, $CCl_4$ [30%, calculated from 2-(*p*-tolyl)-1,10-phenanthroline]; iii, $K_2CO_3$, MeCN, reflux [40%]

**Scheme 2**

analysis of the plots the $K_{ass}$ values in the presence of $Zn^{II}$ were determined and are summarized in Table 1.

Examination of Table 1 reveals that as expected,[6] D-fructose gives the largest $K_{ass}$ with L in the absence of $Zn^{II}$. On the other hand, uronic acids are scarcely bound to L (except D-galacturonic acid with $K_{ass}$ = 80 dm$^3$ mol$^{-1}$). In contrast, the $K_{ass}$ values for three uronic acids are remarkably improved in the presence of $Zn^{II}$ whereas those for three neutral monosaccharides are scarcely affected. The difference clearly supports the view that uronic acids are bound to $[Zn^{II}L]^{2+}$ by a cooperative action of boronic acid–diol complexation and zinc(II)–carboxylate coordination.

It is known that when saccharides interact with the receptor at two points to form a cyclic structure, the resultant complexes become CD-active.[6,8] In fact, D-glucuronic acid and D-galacturonic acid with large $K_{ass}$ values gave CD-active

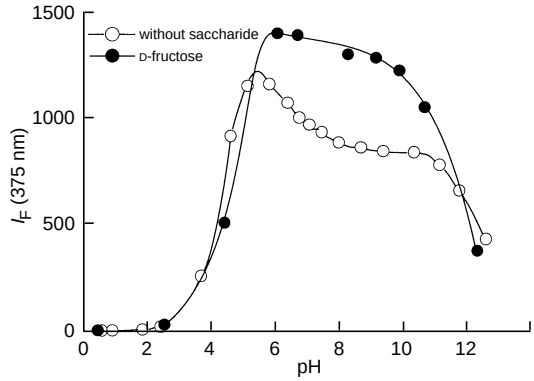


**Fig. 1** Fluorescence intensity *vs.* pH profile of L ($1.00 \times 10^{-5}$ mol dm$^{-3}$); 25 °C [D-fructose] = 0 or 100 mmol dm$^{-3}$, $\lambda_{ex}$ = 294 nm

**Table 1** Association constants (log $K_{ass}$)[a] for saccharides with L and $[Zn^{II}L]^{2+}$

| | Log $K_{ass}$ ($I_{max}/I_0$) | |
|---|---|---|
| Saccharide | L | $[Zn^{II}L]^{2+}$ |
| D-Glucuronic acid | —[b] | 3.4 (2.11) |
| D-Galacturonic acid | 1.9 (1.15) | 3.1 (3.69) |
| Sialic acid (*N*-Acetylneuraminic acid) | —[b] | 2.3 (1.83) |
| D-Glucose | —[b] | —[b] |
| D-Galactose | 1.7 (1.12) | 1.3 (1.50) |
| D-Fructose | 2.5 (1.33) | 2.4 (1.90) |

[a] pH = 8.0 (5.0 mmol dm$^{-3}$ MOPS buffer), water–MeOH (1 : 2 v/v). [b] Too small to determine (log $K_{ass}$ < 1).

complexes with $[Zn^{II}L]^{2+}$: $\lambda_{max}$ and $[\theta]$ = 305 nm and $4.0 \times 10^3$ ° cm$^{-2}$ dmol$^{-1}$ for D-glucuronic acid and 282 nm and $28.0 \times 10^3$ ° cm$^{-2}$ dmol$^{-1}$ for D-galacturonic acid. Job plots using the CD intensity provided a maximum at $[ZnL^{2+}]/([ZnL^{2+}] + [\text{uronic acid}]) = 0.50$, indicating that the stoichiometry of these complexes is 1 : 1.

In conclusion, the present study demonstrates a new saccharide receptor for uronic acids, which features two-point interactions of boronic acid–diol complexation and zinc(II)–carboxylate coordination. The receptor can discriminate well between uronic acids and neutral monosaccharides and the binding event can be sensitively read out by a fluorescence change. We believe that this is a new molecular design concept utilizing the cooperative action of boronic acid and the metal chelate. Further applications are continuing in this laboratory.

# The first double oxidative addition of $CH_2Cl_2$ to a metal complex: facile synthesis of $[Ru(CH_2)Cl_2\{P(C_6H_{11})_3\}_2]$

**Montserrat Oliván and Kenneth G. Caulton***

*Department of Chemistry, Indiana University, Bloomington, IN 47405-4001, USA*

**$[Ru(H)_2(H_2)_2L_2]$ [L = $P(C_6H_{11})_3$] serves as a formal source of zerovalent '$RuL_2$', and undergoes unprecedented oxidative addition of both C–Cl bonds of $CH_2Cl_2$ to a single metal center, providing a convenient synthesis of the alkene metathesis catalyst $[Ru(CH_2)Cl_2L_2]$.**

Ruthenium carbenes of the form $[Ru(CRR')Cl_2L_2]$ (L = phosphine) play a central role in alkene metathesis methodology in organic chemistry. The original form[1] of the ruthenium catalyst has now been simplified,[2] but access to carbene complexes remains less than rational: α-elimination from an alkyl complex or use of a diazoalkane reagent are the primary synthetic methodologies.

$$L_nM + X_2CRR' \rightarrow L_n(X)_2M{=}CRR' \qquad (1)$$

*gem*-Dihalogeno compounds are formally attractive as a source of a carbene ligand [eqn. (1)], but converting this idea into reality has been elusive. Eqn. (1) makes clear that $L_nM$ must be a 14-valence electron species, or its equivalent, and the scarcity of such species accounts for the rarity of eqn. (1). Eqn. (1) might be expected to proceed stepwise, with an X–M–CRR'X intermediate, and indeed, there are numerous examples of halogenomethyl ligands that have been formed from $CX_2RR'$.[3] However, a double oxidation addition of an $R_2CX_2$ $sp^3$ carbon is unprecedented. Set against this background, we report here the first oxidative addition of both C–Cl bonds of a *gem*-dihalide to a single metal center, where all constituents of $R_2CX_2$ become attached to a single metal in the product,[4] and an example where this occurs in high yield to produce the simplest of ruthenium alkene metathesis catalysts, $[Ru(CH_2)Cl_2L_2]$, with L = $P(C_6H_{11})_3$.

Reaction† of $[Ru(H)_2(H_2)_2L_2]$ [L = $P(C_6H_{11})_3$] with $CH_2Cl_2$ in pentane or benzene under argon occurs over 3 h at 25 °C (1 : 4 mol ratio) or 15 min at 60 °C (1 : 1.5 mole ratio) to give the known molecule $[RuCl_2(CH_2)L_2]$,[2b] characterized by $^1H$, $^{13}C$ and $^{31}P$ NMR spectroscopies. The $^1H$ NMR signal of the carbene ligand is the most unique spectroscopic feature, appearing at $\delta$ 19.4. If the reaction is carried out with $CD_2Cl_2$, $[RuCl_2(CD_2)L_2]$ is the only isotopomer produced ($^1H$ and $^2H$ NMR assay),‡ showing that there is no scrambling of the metal- and carbon-derived hydrogen. This reaction is remarkable because it involves a four-electron reduction of $CH_2Cl_2$ (to $Cl^-$ and what is formally $CH_2^{2-}$). It thus depends upon $[Ru(H)_2(H_2)_2L_2]$ being a formal source of uncharged $RuL_2$ (*i.e.* zerovalent Ru), by virtue of reductive elimination of hydride from $Ru^{II}$, as $H_2$. When this reaction is repeated in a closed NMR tube, we see ($^{31}P\{^1H\}$ NMR) no growth and decay of any intermediate. Since there is no evidence for production of $CH_3Cl$ or $CH_4$, this reaction is an unprecedented oxidative addition of both C–Cl bonds of $CH_2Cl_2$ to a single metal center. This reaction proceeds more slowly in an NMR tube under 1 atm argon, than in a well agitated, round-bottom flask with a considerable head-space, a fact we attribute to the accumulation of $H_2$, which shifts eqn. (2) to the left and thus decreases the amount of unsaturated $[Ru(H)_2(H_2)L_2]$, which is apparently the necessary reaction partner for $CH_2Cl_2$.[5]

$$[Ru(H)_2(H_2)_2L_2] \leftrightharpoons [Ru(H)_2(H_2)L_2] + H_2 \qquad (2)$$

This idea of competitive inhibition by $H_2$ is supported by the fact that, if $[Ru(H)_2(H_2)_2L_2]$ is stirred with $CH_2Cl_2$ (1 : 4) at 25 °C under 1 atm $H_2$ in pentane, there is no reaction over 3 h. The reaction is thus not outer-sphere electron transfer from $[Ru(H)_2(H_2)_2L_2]$, and a 16-electron complex is the reactive species.

Since $[RuH_3ClL_2]$[6] is also produced in < 15% yield in this reaction, we considered that HCl {which we independently verified could convert $[Ru(H)_2(H_2)_2L_2]$ to $[RuH_3(Cl)L_2]$} might participate in the reaction which forms the carbene complex. However, when the reaction of $[Ru(H)_2(H_2)_2L_2]$ with $CH_2Cl_2$ is executed in the presence of $NEt_3$ (1 : 4 : 2 mole ratio), the carbene product and yield are unchanged, as is (qualitatively) the rate. No $[NHEt_3]Cl$ precipitates. This gives support for the idea that $H_2$ is the fate of all metal-bound H, that $[RuH_3(Cl)L_2]$ is produced in a side reaction, and that a 'ClRuCH$_2$Cl' species mediates the reaction. However, any such species must react further to give carbene product faster than it reacts with $NEt_3$, to quaternize the amine (giving 'ClRuCH$_2$-$NEt_3^+$' and $Cl^-$); chloromethyl ligands readily react with nucleophiles.[3a]

The idea of multiple oxidative addition to $[Ru(H)_2(H_2)_2L_2]$, and the idea that facile multiple losses of $H_2$ from this molecule permits it to serve as a formal equivalent of zerovalent '$RuL_2$' deserves further exploration.

† $[RuCl_2(=CH_2)\{P(C_6H_{11})_3\}_2]$ (method A): To a suspension of $[RuH_2(H_2)_2\{P(C_6H_{11})_3\}_2]$[7] (100 mg, 0.15 mmol) in pentane (7 ml) was added $CH_2Cl_2$ (38 μl, 0.60 mmol) *via* a syringe. The resulting suspension was stirred at room temp. for 3 h. During this time, the suspension changed from white to brown–red. The red solid obtained by filtration was washed with pentane and dried *in vacuo*. Yield: 70 mg (63%). Alternatively (method B), the reaction could be carried out heating at 60 °C for 15 min, starting from $[RuH_2(H_2)_2\{P(C_6H_{11})_3\}_2]$ (100 mg, 0.15 mmol) and $CH_2Cl_2$ (14.4 μl, 0.22 mmol) in pentane (5 ml). Yield: 75 mg (67%). All the spectroscopic data are consistent with those reported previously.[2b] When the crude suspension was dried *in vacuo* and dissolved in $C_6D_6$, $^1H$ and $^{31}P$ NMR show the presence of $[RuH_3Cl\{P(C_6H_{11})_3\}_2]$,[6] in addition to $[RuCl_2(=CH_2)\{P(C_6H_{11})_3\}_2]$, in a yield of < 15%. This was shown independently to be formed by the action of $H_2$ on $[Ru(CH_2)Cl_2\{P(C_6H_{11})_3\}_2]$.

‡ $[RuCl_2(=CD_2)\{P(C_6H_{11})_3\}_2]$: this compound was prepared analogously as described for $[RuCl_2(=CH_2)\{P(C_6H_{11})_3\}_2]$ (method A) by starting from $[RuH_2(H_2)_2\{P(C_6H_{11})_3\}_2]$ (50 mg, 0.075 mmol) and $CD_2Cl_2$ (19 μl, 0.30 mmol). $^2H$ NMR (61 MHz, $C_6H_6$): $\delta$ 19.40 (s, Ru=$CD_2$).

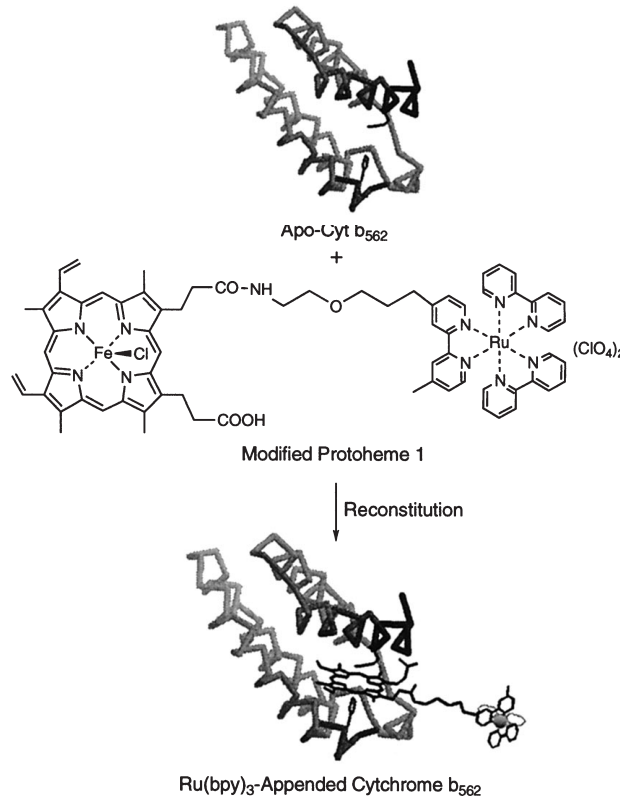
# Photocontrol of the redox state of ruthenium–tris(bipyridine)-appended cytochrome $b_{562}$

**Itaru Hamachi,*[a] Shigeaki Tanaka,[a] Shinya Tsukiji,[a] Seiji Shinkai,[a] Masafumi Shimizu[b] and Teruyuki Nagamune[b]**

[a] *Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, Hakozaki Fukuoka 812-81 Japan*

[b] *Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku 113 Japan*



**Ruthenium–tris(bipyridine)-appended heme is successfully reconstituted with apo-cytochrome $b_{562}$ (Cyt-$b_{562}$); the redox state of the active site in the resultant semisynthetic Cyt-$b_{562}$ can be switched by visible light irradiation.**

Photocontrol of naturally occurring enzymes/proteins activity is one of the attractive targets in the recent protein engineering.[1] For the redox-active enzymes or proteins, it seems promising to modulate the redox state of the active site of the enzymes by photoelectron injection or abstraction.[2] We recently demonstrated that the dioxygen binding activity of myoglobin was successfully photoregulated by the covalent attachment of a ruthenium polypyridine complex to the heme site.[3] This approach is so convenient that it is desirable to establish the generality of our proposed method. In addition to myoglobin, we therefore applied the reconstitution method to another hemoprotein, cytochrome $b_{562}$, an electron-transporting hemoprotein, which possesses one protoheme in its active site.[4]

The soluble Cyt-$b_{562}$ was obtained and purified from *Escherichia coli* (strain TB-1 harboring pNS207 plasmid)[5] except that Cyt-$b_{562}$ was released from periplasmic space by treatment with chloroform.[6] The apoprotein was prepared at 4 °C using the butanone extraction method.[7] A synthetic heme **1** bearing ruthenium tris(2,2′-bipyridine) dissolved in dimethyl sulfoxide was added dropwise to the resultant apo-Cyt-$b_{562}$ solution (50% aqueous $Me_2SO$). After incubation at 4 °C for 1 h, the mixture was purified by gel-column chromatography [Sephadex G-50, 50 mM phosphate buffer (pH 7.0) eluent] to obtain a red solution. The UV–VIS spectrum of this solution showed a sharp absorption at 419 nm due to the Soret band and a weak band at 530 nm due to the Q band of the heme cofactor. Upon reduction with $Na_2S_2O_4$, the absorption maxima shifted to 427, 531 and 561 nm. These absorption maxima are identical to those of the oxidized $Fe^{III}$ and reduced $Fe^{II}$ state of native Cyt-$b_{562}$.[4] These results indicate that the synthetic heme **1** was successfully incorporated into the heme crevice of apo-Cyt-$b_{562}$ [Ru(bpy)$_3$–Cyt-$b_{562}$, Scheme 1].

Steady-state emission of Ru(bpy)$_3$ (emission at 610 nm, excitation at 450 nm) in an intermolecular mixture of Ru(bpy)$_3$ and native Cyt-$b_{562}$ was only slightly lowered (0.8-fold intensity), compared to that of the Ru(bpy)$_3$ itself. On the other hand, the emission intensity of Ru(bpy)$_3$ in Ru(bpy)$_3$–Cyt-$b_{562}$ was found to be markedly weaker than that of an intermolecular mixture (0.013-fold). This suggests that the intramolecular electron transfer quenching of the excited $Ru^{II}$ state by the heme in Ru(bpy)$_3$–Cyt-$b_{562}$ occurs more efficiently than in the intermolecular system under the present experimental conditions (protein concentration 0.3–10 μM).

Fig. 1 shows the absorption spectral change of Ru(bpy)$_3$–Cyt-$b_{562}$ during visible light irradiation (using a high-pressure Hg lamp, cut-off at $\lambda < 450$ nm) in the presence of *N*,*N*-dimethylaminobenzoate (NNDB), a sacrificial donor.[8] The absorbances at 419 and 530 nm gradually decrease and those at 430, 538 and 580 nm grow with six isosbestic points at 420, 444, 518, 538, 550 and 569 nm. These spectral changes clearly reveal the photoreduction of the oxidized Cyt-$b_{562}$ to the reduced form. The inset of Fig. 1 compares the photoreduction efficiency of Ru(bpy)$_3$–Cyt-$b_{562}$ to that for the intermolecular reaction system [*i.e.* a simple mixture of Ru(bpy)$_3$, native Cyt-$b_{562}$ (1 : 1 molar ratio) and NNDB]. Apparently, the intermolecular reaction proceeds very slowly. The initial reaction rate of the intramolecular Ru(bpy)$_3$–Cyt-$b_{562}$ (0.05 μM min$^{-1}$) is 28 times greater than the value of the intermolecular control experiment (0.0018 μM min$^{-1}$). The quantum yield ($\Phi$) of this photoreduction was determined to be 1.4–8.2 $\times$ $10^{-4}$ at protein concentrations of 0.7–7.6 μM. The activation efficiency is more than 10 times greater than that of the intermolecular system ($\Phi$ = 0.1–0.3 $\times$ $10^{-4}$).† This difference is in good agreement with the above-mentioned emission quenching efficiency; photoreduction does not take place in the absence of NNDB. The visible light on–off experiment showed that the visible light is essential for the reduction of the active center of Ru(bpy)$_3$–Cyt-

**Scheme 1** Reconstitution of ruthenium–tris(bipyridine)-appended heme to apo-cytochrome $b_{562}$

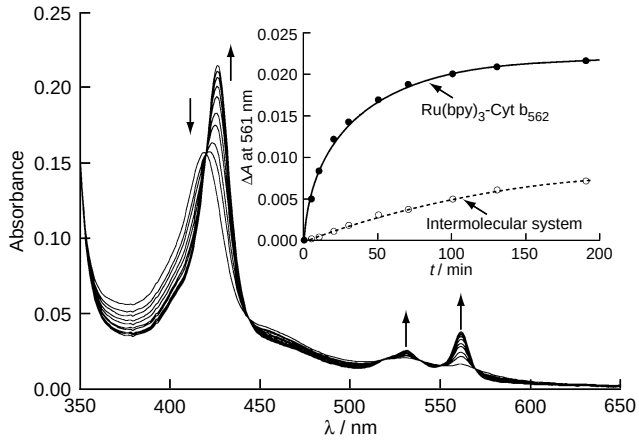


**Fig. 1** Absorption spectral changes of $Ru(bpy)_3$–Cyt-$b_{562}$ upon steady-state photoirradiation (wavelength cut-off below 450 nm, high-pressure Hg lamp) under anaerobic conditions: 1.5 μM $Ru(bpy)_3$–Cyt-$b_{562}$ and 10 mM NNDB in phosphate buffer (50 mM, pH 7.0) at 25 °C. The inset shows the time course of the photogeneration of red-Cyt-$b_{562}$ in the intramolecular [$Ru(bpy)_3$–Cyt-$b_{562}$] reaction system (——) and the intermolecular reaction system [$Ru(bpy)_3$ + native Cyt-$b_{562}$] (- - -).

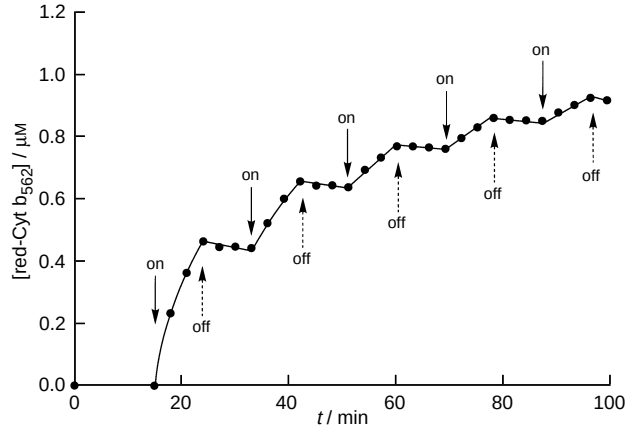

**Fig. 2** The light on–off experiment for $Ru(bpy)_3$–Cyt-$b_{562}$. The solid and dashed arrows indicate switching on and off, respectively: 1.5 μM $Ru(bpy)_3$–Cyt-$b_{562}$, 10 mM NNDB in phosphate buffer (50 mM, pH 7.0) at 25 °C.

$b_{562}$ in the present system. As shown in Fig. 2, the reduced form of $Ru(bpy)_3$–Cyt-$b_{562}$ is not generated in the absence of visible light. The reduction smoothly started upon light irradiation and completely stopped when the light was turned off. This process can be repeated by turning the light on and off.

Next, we conducted the tandem photoreduction of cytochromec (Cyt-c) using the semisynthetic $Ru(bpy)_3$–Cyt-$b_{562}$. When a mixed solution of Cyt-c and $Ru(bpy)_3$–Cyt-$b_{562}$ (5 : 1 mol : mol) was irradiated by visible light in the presence of NNDB, reduced Cyt-c was smoothly formed and $Ru(bpy)_3$-Cyt-$b_{562}$ catalytically cycled (turnover frequency = 0.33 $h^{-1}$) this reaction. We found that the present system was 3.5 times more efficient than the conventional intermolecular reaction [*i.e.* Cyt-c : Cyt-$b_{562}$ : $Ru(bpy)_3$ = 5 : 1 : 1].‡

In conclusion, with the aim of preparation of artificial photoenzymes, we successfully expanded the feasibility of the reconstitution method of the photosensitizer-appended cofactor to a hemoprotein other than myoglobin. It is suggested that the present semisynthetic $Ru(bpy)_3$–Cyt-$b_{562}$ has an interesting potential to regulate the activity of other proteins by photocoupling reactions. The detailed photocatalytic properties of $Ru(bpy)_3$–Cyt-$b_{562}$ are now being actively studied in our laboratory.

We are grateful to Professor S. Sligar for his kind gift of the TB-1 cells harboring the pNS207 plasmid. We thank Mr Hideki Horiuchi for his skilful preparation of a specially designed UV–VIS cell.

# Intramolecular migration of $[Pt(dien)]^{2+}$ (dien = 1,5-diamino-3-azapentane) from sulfur to imidazole-$N^1$ in histidylmethionine (his-metH)

**Christian D. W. Fröhling and William S. Sheldrick***

*Lehrstuhl für Analytische Chemie, Ruhr-Universität Bochum, D-44780 Bochum, Germany*

**HPLC and NMR investigations of the kinetics of competitive binding by neighbouring side chains in his-metH demonstrate that at pH > 6 initial S coordination is followed by slow isomerization to an imidazole-$N^1$ bound complex through a dinuclear intermediate $[\{Pt(dien)\}_2$(his-metH-1κ$N^1$:2κ$S$)$]^{4+}$**

Pt binding by sulfur-containing bioligands such as L-methionine (Hmet) is believed to be responsible for the concentration-dependent nephrotoxicity of the widely used antitumor agent cisplatin, *cis*-$[PtCl_2(NH_3)_2]$.[1] Recent reports[2,3] of the replacement of a thioether S by guanine-$N^7$ in the square-planar coordination sphere of the model fragment $[Pt(dien)]^{2+}$ have also nourished the concept of a drug reservoir mechanism in which initial protein binding may provide a route to DNA platination.[4] Interestingly, whereas 5′-GMP selectively displaces Hmet in $[Pt(dien)(Hmet\text{-}\kappa S)]^{2+}$, no reaction is observed[3] between the likewise imidazole-containing amino acid L-histidine (Hhis) and this complex, even after 3 days. In contrast to this finding, we now report HPLC and NMR evidence for his-$N^1$ replacement of S-bound met, when both are neighbouring peptide residues.

Equimolar 0.8mM solutions of the three model dipeptides his-metH, met-hisH and *cyclo*-his-met with $[Pt(dien)(H_2O)]^{2+}$ in the range 3 < pH < 11 were incubated at 313 K for 14 days, after which the reaction products were separated by reversed-phase HPLC in the presence of 0.1% (v/v) pentafluoropropionic acid as an ion-pairing agent.[5,6] The distribution diagrams presented for the $[Pt(dien)(H_2O)]^{2+}$/his-metH system in Figs. 1–3 were calculated using peak areas of the separated species at the detection wavelength of 220nm and individual molar absorbance coefficients obtained from a least-squares fit for the chromatographic data collected over the full pH range. Products were characterized by FAB mass spectrometry and multinuclear ($^1$H,$^{195}$Pt) NMR spectroscopy.† Methionine κ$S$ coordination leads to a pronounced downfield shift for the thioether δ-$CH_3$ protons from $\delta$ 2.12 in the free dipeptide (pH* = 6.9) to $\delta$ 2.53 in $[Pt(dien)(his\text{-}metH\text{-}\kappa S)]^{2+}$ **1**, the dominant Pt complex in acid solution. At pH > 6.1, the $N^1$-bound complex, $[Pt(dien)(his\text{-}metH\text{-}\kappa N^1)]^{2+}$ **2**, provides the major species; **2** is characterized by its lack of a δ-$CH_3$ downfield shift, the equivalence of its $^3J(^1H\text{–}^{195}Pt)$ values (19 Hz) for the imidazole $H^2$ and $H^5$ resonances and its typical $^{195}$Pt NMR chemical shift (δ −2861) for a square-planar $N_4$ coordination sphere.[7] In contrast to Hhis itself with an $N^3/N^1$ binding ratio of 1.5 for $[Pt(dien)]^{2+}$ at pH* = 6.5,[8] the κ$N^3$ complex appears to play a minor role for his-metH in neutral aqueous solution, as is also the case for met-hisH and *cyclo*-his-met. These latter dipeptides exhibit respective crossover pH values of 5.9 and 3.8 for the change in their preferred binding mode from κ$S$ to κ$N^1$. Inspection of Fig. 1 indicates that a dinuclear complex $[\{Pt(dien)\}_2(his\text{-}metH\text{-}1\kappa N^1:2\kappa S)]^{4+}$ **3**, characterized by its FABMS base peak and two $^{195}$Pt resonances, reaches its maximum concentration at the crossover pH value and a similar state of affairs was established for met-hisH and *cyclo*-his-met.

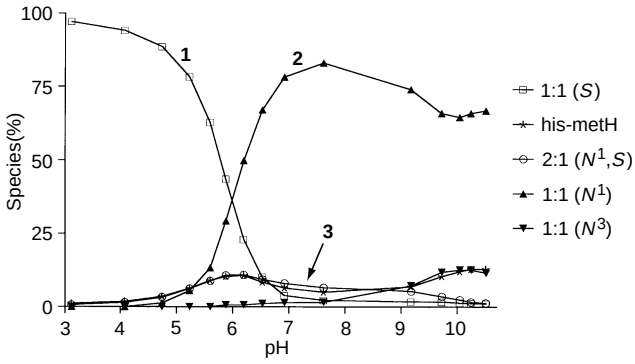

**Fig. 1** Species distribution for the 1 : 1 $[Pt(dien)(H_2O)]^{2+}$–his-metH reaction system as determined by HPLC for the range pH 3.0–10.5 ($T$ = 313 K, $t_{reaction}$ = 14 d). Two minor species are omitted for clarity.

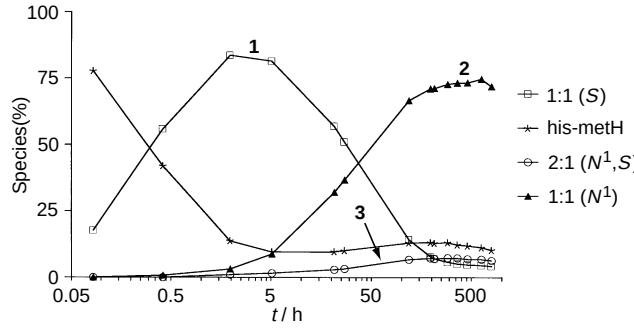

**Fig. 2** Time-course of the 1 : 1 reaction between $[Pt(dien)(H_2O)]^{2+}$ and his-metH at pH = 9.4 as monitored by reversed-phase HPLC ($T$ = 313 K). A minor species is omitted for clarity.

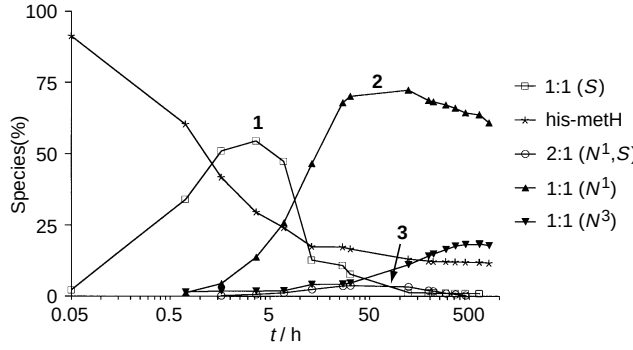
Time-dependent HPLC studies of the $[Pt(dien)(H_2O)]^{2+}$–his-metH reaction system at 313 K (Figs. 2 and 3) demonstrate that, as expected,[2–4,9] the kinetically favoured S-bound complex **1** is formed rapidly and reaches a maximum concentration within 2–3 h. At the pH values considered (6.5, 9.4), **1** then slowly isomerizes to the thermodynamically preferred κ$N^1$ complex **2** over a period of 500 h (Scheme 1). In Fig. 2, the dinuclear complex **3** appears in chromatograms together with **2** for the



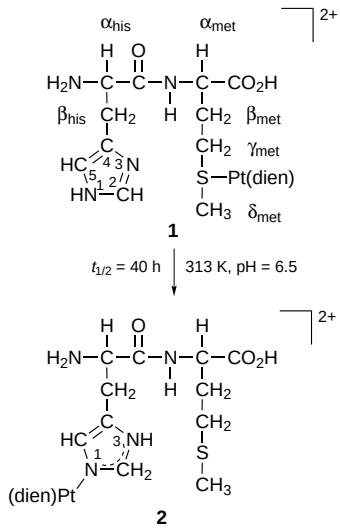


**Fig. 3** Time-course of the 1 : 1 reaction between $[Pt(dien)(H_2O)]^{2+}$ and his-metH at pH = 9.4 as monitored by reversed-phase HPLC ($T$ = 313 K). A minor species is omitted for clarity.

**Scheme 1** Isomerization **1** → **2**

first time after 2 h and exhibit a distribution curve with a time-dependence similar to that of the $N^1$-bound complex. Contrastingly, **2** reaches a maximum concentration after *ca*. 30 h at pH 9.4 (Fig. 3) and can no longer be detected after 500 h. In accordance with the findings of Sadler and coworkers,[3] we also confirmed[10] that the individual amino acid Hhis plays only a minor role in Pt binding when $[Pt(dien)(H_2O)]^{2+}$ is also allowed to react with an equimolar solution of Hmet and Hhis for 14 days at 313 K in the range $3 < pH < 11$. The S-bound complex $[Pt(dien)(Hmet\text{-}\kappa S)]^{2+}$ is present over the whole experimental range and exhibits a crossover pH (as dominant species) of 8.3 to a second N(amino)-bound Hmet complex. A two-step intramolecular route involving the dinuclear intermediate product **3**, which would contrast to a normal five-coordinate intermediate, can be discussed for the isomerization of **1** to **2**. Initial coordination of the kinetically favoured thioether S in **1** is the first step and blocks this binding site for further reactions. Subsequently a second $Pt(dien)^{2+}$ fragment is bound to the thermodynamically preferred imidazole-$N^1$ and the dinuclear complex **3** is formed. For an equimolar ratio of Pt to ligand, this complex dissociates to the mononuclear species **2** by cleavage of the less stable Pt–S bond (Fig. 3). This final step is favoured by the associated reduction in cation charge from +4 to +2. At the higher pH value (9.4), the required dinuclear intermediate **3** can no longer be detected after completion of the conversion **1** → **2**. In contrast, no intermediate could be established for the intramolecular migration of $Pt(dien)^{2+}$ from S to guanine-$N^7$ in S-guanosyl-L-homocysteine.[2,11] This isomerization is more rapid ($t_{\frac{1}{2}}$ = 10 h at 295 K, pH < 6.5) than for the conversion **1** → **2**, which exhibits a half-life ($t_{\frac{1}{2}}$ *ca.* 40 h at 313K, pH = 6.5) more comparable with that reported for the reaction of $[Pt(dien)(Hmet\text{-}\kappa S)]^{2+}$ with 5′-GMP ($t_{\frac{1}{2}}$ = 167 h at 300 K, pH* = 7.0).[3] Under pseudo-first-order conditions, the formation of the dinuclear complex **3** exhibits a reaction rate of $1 \times 10^{-4}$ $s^{-1}$, which is nearly an order of magnitude slower than that for **1** ($k = 9 \times 10^{-4}$ $s^{-1}$) but similar to the rate constant of **2** ($k = 8 \times 10^{-5}$ $s^{-1}$). Such values are, of course, not directly comparable with intramolecular competition conditions (1 : 1), because of pronounced changes in the final product distribution. The observed acceleration in formation of **2** at pH 9.4 (Fig. 3) could be due to faster coordination of a second $Pt(dien)^{2+}$ fragment to the now non-protonated imidazole ring. Temporary formation of **3** is then followed by disappearance of this dinuclear complex which is not thermodynamically stable under these conditions.

The present investigation provides evidence for intramolecular Pt migration from a kinetically favoured met residue to a thermodynamically preferred his side chain in peptides. Although the conversion is relatively slow, it should be remembered that Pt has an *in vivo* half-life of several days after administration of cisplatin.[12] The presence of spatially neighbouring his residues could, therefore, influence the reactivity of met-bound Pt in DNA-binding proteins and should be considered in discussions on the mechanism of action of Pt anticancer drugs.

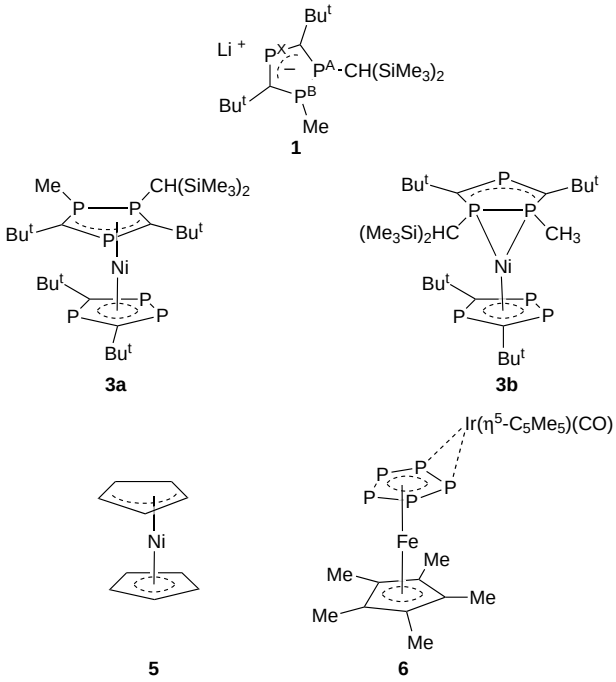
# Remarkable 'edge' ligation of a triphosphacyclopentenyl ring system. Synthesis, crystal and molecular structure of $[Ni(\eta^5\text{-}P_3C_2Bu^t_2)\{\eta^2\text{-}P_3C_2Bu^t_2CH(SiMe_3)_2Me\}]$



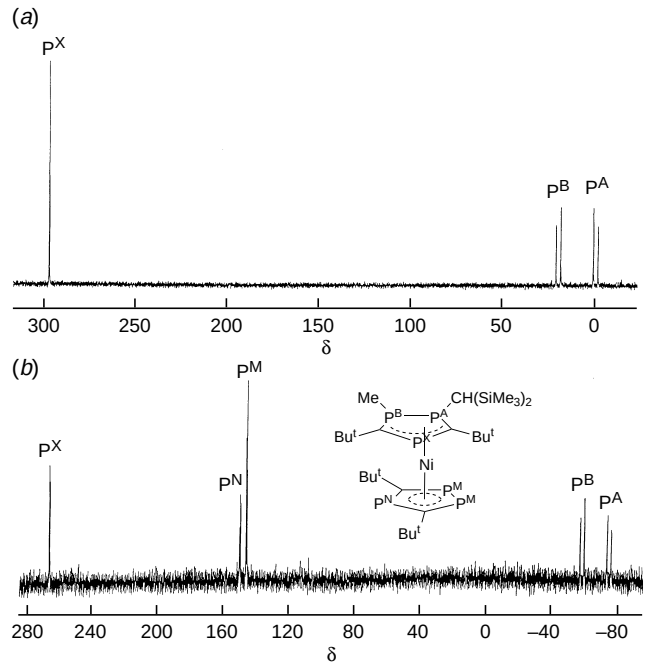
**Vinicius Caliman, Peter B. Hitchcock and John F. Nixon***

*School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*

**In the nickel(II) complex $[Ni(\eta^5\text{-}P_3C_2Bu^t_2)(\eta^2\text{-}P_3C_2Bu^t_2CH(SiMe_3)_2Me)]$ the triphosphacyclopentenyl ring $P_3C_2Bu^t_2CH(SiMe_3)_2Me$ is unexpectedly coordinated to the metal exclusively *via* the two adjacent saturated ring phosphorus atoms, rather than *via* the 2-phosphaallyl fragment.**

Very recently[1] we reported the synthesis of the lithium triphosphacyclopentenyl salt $LiP_3C_2Bu^t_2RR'$ **1** [R = $(Me_3Si)_2$CH, R′ = Me] by treatment of the 1,2,4-triphosphole $P_3C_2Bu^t_2R$ **2**[2] with LiMe. The $^{31}P\{^1H\}$ NMR spectrum of **1** can be readily interpreted[1] in terms of the $\eta^3$-2-phosphaallylic structure [Fig. 1(*a*)]. Although several ligation modes of the triphosphacyclopentenyl ring anion in **1** towards transition metals can be envisaged, it was anticipated that $\eta^3$-ligation *via* the 2-phosphaallyl fragment would be most likely in complexes of nickel(II) halides, however, unexpectedly a completely different type of ligation of the ring to the metal centre occurs as discussed below.

Treatment of $Li[P_3C_2Bu^t_2CH(SiMe_3)_2Me]$ with 1 equiv. of $NiBr_2$ in diethyl ether at −78 °C affords a dark green solution which on further treatment with 1 equiv. of $Li[P_3C_2Bu^t_2]$ affords the purple complex $[Ni(\eta^5\text{-}P_3C_2Bu^t_2)\{P_3C_2Bu^t_2CH(SiMe_3)_2Me\}]$ **3**. Scheme 1 shows the likely steps of the synthesis of **3** *via* the postulated intermediate complex **4** which could not be isolated on account of its air- and moisture-sensitivity. Complex **3** was obtained in 45% yield after chromatography and was fully characterised by mass spectrometry, $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopy.† Its structure, which was confirmed by a single-crystal X-ray diffraction study,‡ surprisingly proved not to involve the expected $\eta^5:\eta^3$ ligation of the two five-membered ring systems which is well known for the related cyclopentadienyl cyclopentenyl nickel(II) complex $[Ni(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_5H_7)]$ **5**.



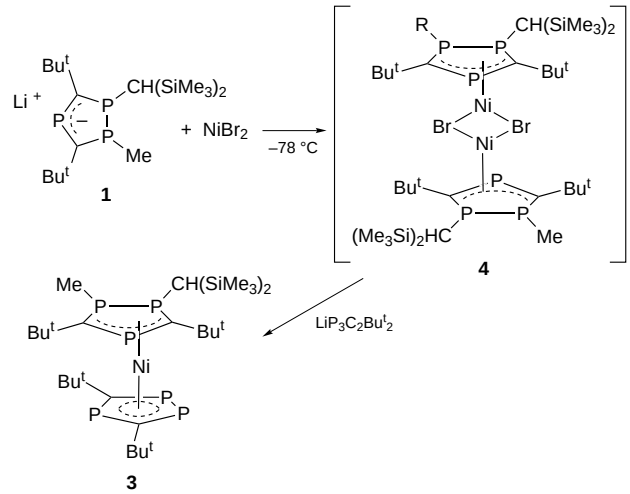


**Fig. 1** $^{31}P\{^1H\}$ NMR spectra of (*a*) **1** and (*b*) **3**

**Scheme 1**

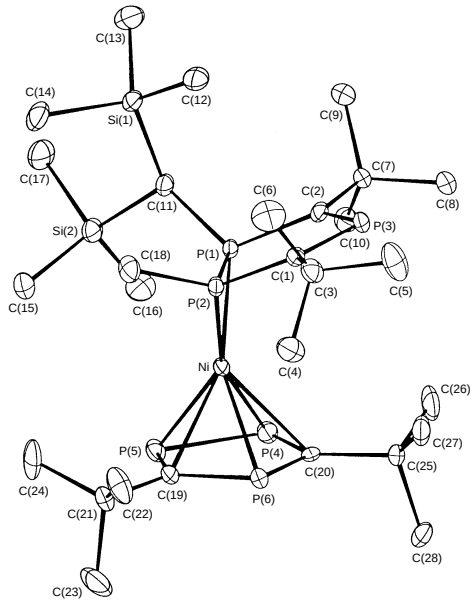

**Fig. 2** Molecular structure of **3** with atomic numbering scheme

The $^{31}P\{^{1}H\}$ NMR spectrum of **3** [Fig. 1(*b*)] exhibits a pattern of lines expected for an $[ABM_2NX]$ spin system. The $\eta^5$-$P_3C_2Bu^t_2$ ring gives rise to signals corresponding to $P^M$ and $P^N$ ($\delta$ 145.8 and 149.7, respectively) with the expected magnitude of the $^2J_{PP}$ coupling constant for this type of aromatic ring system.[3–6] The pattern of lines observed for the $P_3C_2Bu^t_2CH(SiMe_3)_2Me$ ring in **3** is similar to that exhibited for the free anion in **1**; the $P^A$ and $P^B$ resonances of the two $sp^3$-hydridised phosphorus showing characteristic high-field resonances ($\delta$ $P^A$ −74.5; $\delta$ $P^B$ −58.3) with a typically large one bond $^1J_{P^AP^B}$ coupling constants (251.3 Hz), whereas $P^X$ exhibits a typical chemical shift for an $sp^2$-hybridised phosphorus ($\delta$ $P^X$ 266.2), suggesting structure **3a**.

A single-crystal X-ray diffraction study on **3** unexpectedly revealed the remarkable molecular structure **3b** (Fig. 2), in which the 2-phosphaallylic fragment of the $P_3C_2Bu^t_2CH(SiMe_3)_2Me$ ring is not involved in bonding to the nickel, which is in fact solely ligated *via* the P(1) and P(2) lone pair electrons of the two saturated phosphorus centres. The two rings in **3** are both planar, with a dihedral angle of 18°, and structural data are summarised in Fig. 3. The $\eta^5$-ligated $P_3C_2Bu^t_2$ ring exhibits bond lengths and angles very similar to several related transition-metal complexes containing this triphospholyl anion.[3–6] The triphosphacyclopentenyl ring $P_3C_2Bu^t_2CH(SiMe_3)_2Me$ in **3** is attached to the $Ni^{II}$ *via* two P–Ni single bonds [P(1)–Ni 2.201(2), P(2)–Ni 2.155(2) Å] and the P(1)–Ni–P(2) bond angle is 58.64(5)°. The intracyclic bond lengths in the triphosphacyclopentenyl ring clearly confirm the partial double bond character expected for the two P–C bonds of the uncoordinated 2-phosphaallylic system [P(3)–C(1) 1.728(5), P(3)–C(2) 1.723(5) Å].

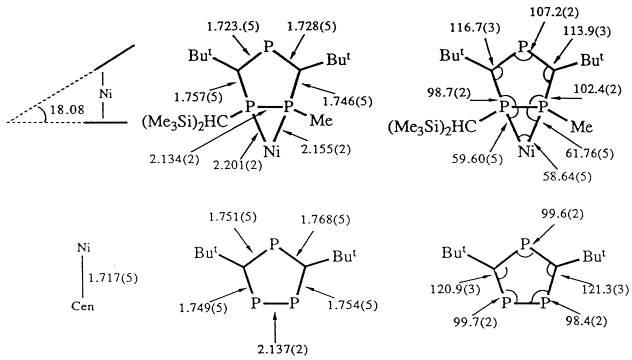

**Fig. 3** Important structural features from **3a**. Distances in (Å) and angles in (°).

To our knowledge, the bonding exhibited by the triphosphacyclopentenyl ring in **3** is unprecedented. Scherer and coworkers[7] recently reported the synthesis and molecular structure of the complex $[(\eta^5\text{-}C_5Me_5)Fe(\mu\text{-}\eta^5:\eta^2\text{-}P_5)Ir(\eta^5\text{-}C_5Me_5)(CO)]$ **6**, in which there is a $\eta^2$-'edge' coordination of the 16-electron $[Ir(CO)(\eta^5\text{-}C_5Me_5)]$ fragment to two adjacent phosphorus atoms in the pentaphospholyl ring. However, the $\eta^2$-coordination of the $P_5$ ring in **6** is completely different to that described for complex **3** above, since it involves an unsaturated P–P ring linkage. It is therefore 'alkene-like' in its ligating mode towards the $Ir^I$ centre, whereas in **3** the two saturated $sp^3$-hybridised phosphorus atoms must presumably utilise their lone pair electrons in bonding to $Ni^{II}$. These bonding differences are clearly reflected in the very different P–P bond lengths observed within the $\eta^5$-$P_5:\eta^2$-$P_5$ and $\eta^2$-$P_3C_2Bu^t_2CH(SiMe_3)_2Me$ rings in **3** and **6**. There is a significant lengthening (*ca.* 0.2 Å) of the P–P distance in **6** [P(1)–P(2) 2.359(2) Å], compared with that of the parent complex $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}P_5)]$,[7] whereas no such elongation results on $\eta^2$-coordination of the $P_3C_2Bu^t_2CH(SiMe_3)_2Me$ ring in **3**, and a normal P(1)–P(2) single bond distances [2.134(2) Å] is observed.

We thank CNPq (Brazil) for a studentship (for V. C.) and EPSRC for their continuing support for phosphaalkyne chemistry at Sussex.

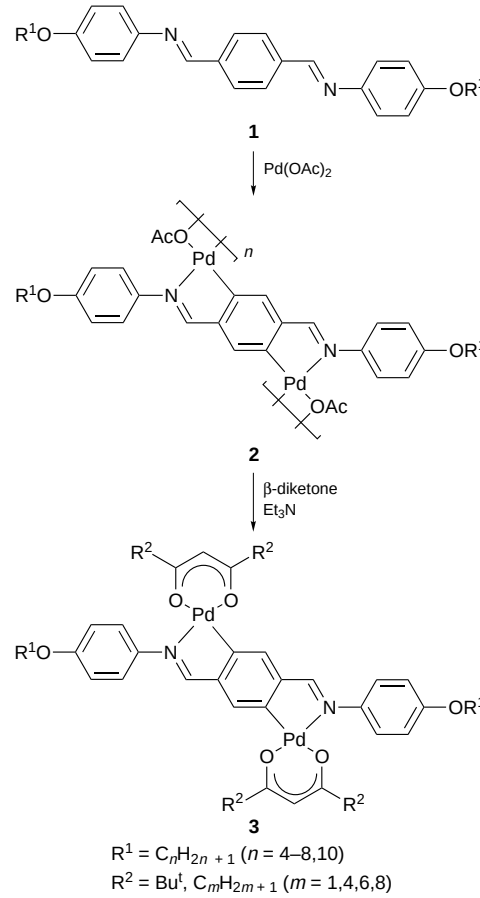
# Di-cyclopalladated Schiff's base liquid crystals: novel metallomesogens

**Donocadh P. Lydon and Jonathan P. Rourke***

*Department of Chemistry, Warwick University, Coventry, UK CV4 7AL*

**The double cyclopalladation of di-Schiff's bases and subsequent reaction with a β-diketone yields novel metallomesogens containing a dimetallated organometallic core: these compounds show nematic phases, and the use of simple alkyl substituted diketones has a very dramatic effect on both the melting and clearing points, bringing them down substantially.**



There is currently much interest in the synthesis of metal-containing liquid crystals (metallomesogens) due to the perceived advantages of combining the properties of liquid crystal systems with those of transition metals. The area has been well-reviewed recently,[1,2] with excellent new work appearing constantly.[3–7] Cyclopalladated compounds have proved to be a particularly fertile area of research, with many different examples from many different groups.[7–14]

Most recently, our own work has focused on the role of the co-ligand in a given mesogenic core.[14] Here we report the synthesis, characterisation and mesogenic behaviour of novel complexes that contain two metals cyclometallated to the central core. Although one co-ordination complex containing two metals has previously been reported[15] and two families of dimeric mesogens have been extensively investigated,[5,8,16–28] our new compounds represent the first examples of calamitic organometallic mesogens whose core contains two metals.

The synthesis of the new mesogens **3** is summarised in Scheme 1.† The complexes are based on a di-Schiff's base core[14] with two palladiums cyclometallated in a *trans* fashion to this core. The co-ligands on the palladium are diketonate derivatives. All the new compounds were analysed by $^1$H NMR spectroscopy and microanalysis.‡ Thus, compounds with alkyl chains of between four and ten carbons on the di-Schiff's base core were synthesised with a simple acetylacetonate co-ligand. In addition, with one Schiff's base core ($n$ = 8), the alkyl chain on the diketonate was systematically varied (R′ = Me, Bu, hexyl, octyl and Bu$^t$).

The thermal behaviour of the diketonate complexes **3** is detailed in Table 1 and summarised in Figs. 1 and 2. Thus nematic phases (identified on the basis of optical texture) were exhibited by all but three of the complexes. Confirmation of the mesomorphism was obtained by differential scanning calorimetry (DSC) measurements where possible (decomposition of some of the compounds obscured some of the transitions).

The simple acetylacetonate complexes (Fig. 1) exhibit nematic phases at relatively high temperatures (in most cases greater than 200 °C) and the transition from the nematic to the isotropic liquid was often accompanied by extensive decomposition. As one would expect, the melting and clearing points are brought down in temperature by the use of longer chains on the Schiff's base unit (*i.e.* increasing *n*). However, a more dramatic reduction in both the melting and clearing points (some 80 K) can be achieved by using short chain length alkyl diketones (Fig. 2). This effect is most marked for the $m$ = 4 case, *i.e.* R′ = Bu, where the mesophase is observed well below the decomposition point of the compound. In contrast, when Bu$^t$ groups are attached to the diketonate core, a high melting point is observed with no mesophase, even on rapid cooling. One way of viewing this behaviour is to consider the freely moving alkyl chains on the diketonate groups as disrupting the crystal

**Scheme 1**

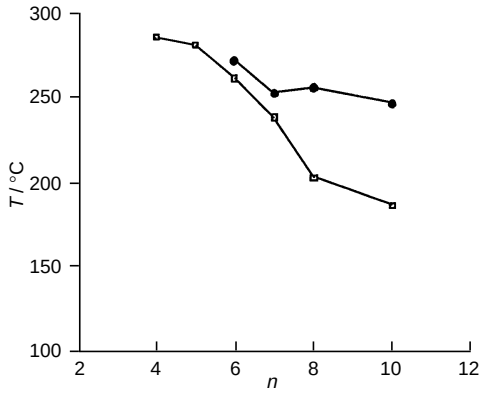

**Fig. 1** Phase behaviour of compounds **3** as a function of *n*; (□) K → N and (●) N → I

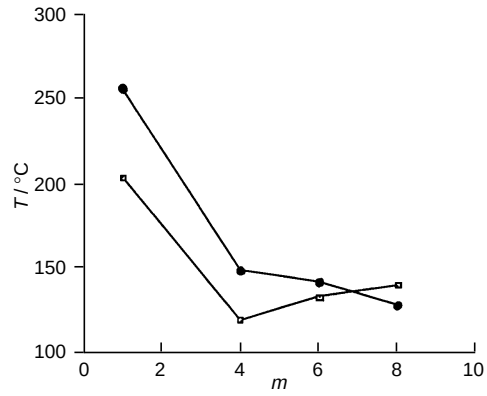

**Fig. 2** Phase behaviour of compounds **3** as a function of *m*; (□) K → N, I and (●) N → I

packing of the molecules and thus reducing the melting point. The Bu$^t$ group is a compact group that cannot move freely, and will not disrupt the packing forces, hence its much higher melting point.

It is perhaps surprising that compounds **3** show any mesogenic behaviour at all: others have suggested that at least four aromatic rings would be necessary to promote mesogenic behaviour in molecules with large metal groups pendant to the central core.[30,31] Here we have only three aromatic rings, and two pendant metal groups. If, however, we consider the core of the molecule to be the central benzene ring, the two cyclometallated units and the two diketonate groups with the alkoxyphenyl groups being the pendant moieties, we encounter a similar problem. Thus it appears that it would be best to consider all of the central Schiff's base unit, with both the alkoxyphenyl and Pd–diketonate groups, as the mesogenic core of the molecule.

In conclusion, we have synthesised a totally new family of metallomesogens with two metal groups in a *trans* fashion about the central ring, and are now working on the *cis* compounds, where both cyclopalladated groups are on the same side of the ring.

We thank the University of Warwick for financial support (D. P. L.), and Johnson-Matthey for the loan of chemicals.

† Palladium acetate (0.150 g, 6.70 × $10^{-4}$ mol) was added to a solution of **1** (*n* = 10) (0.200 g, 3.35 × $10^{-4}$ mol) in acetic acid (200 ml) at 60 °C and stirred (24 h). The solvent was removed, and the product **2** (*n* = 10) used without further purification.

Compound **2** (*n* = 10) (0.180 g, 2.00 × $10^{-4}$ mol) and sodium acetylacetonate (0.073 g, 6.00 × $10^{-4}$ mol, 1.5 equiv.) were suspended in acetone (200 ml) and stirred (24 h). The solvent was removed and the crude product extracted with $CHCl_3$. The product was further purified by chromatography on silica (eluent: $CHCl_3$): yield 0.154 g (77%).

‡ *Selected data* for **3** (*n* = 10, R′ = Me) (all others are similar): $\delta_H$ 8.13 (2 H, s, imine), 7.56 (2 H, s, central ring), 7.39 (4 H, AA′XX′, aromatic), 6.88 (4 H, AA′XX′, aromatic), 5.34 (2 H, s, central acac), 3.99 (4 H, t, $^3J$ 6.5, $OCH_2$), 2.07 (6 H, s, acac Me), 1.89 (6 H, s, acac Me), 1.40 (28 H, m, chain), 0.89 (6 H, t, $^3J$ 6.5 chain $CH_3$). Good elemental analysis data were obtained for all compounds. Evidence for the *trans* arrangement of the palladium atoms about the central ring comes from preliminary single crystal X-ray studies (ref. 29).

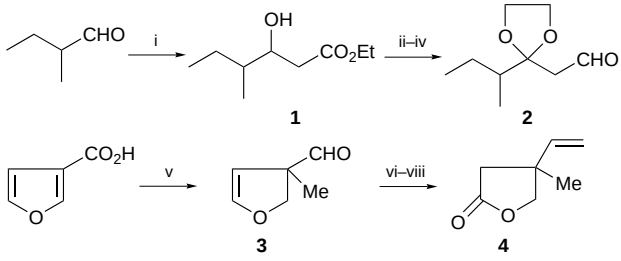
# First total synthesis of (±)-hyperolactone A

**Daisuke Ichinari,[a] Toshihiko Ueki,[a] Kazuo Yoshihara[b] and Takamasa Kinoshita*[a]**

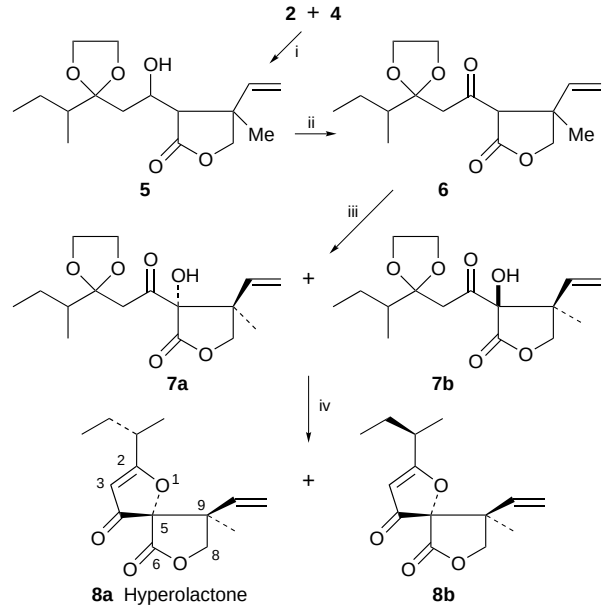
[a] *Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558, Japan*
[b] *Suntory Institute for Bioorganic Research, Shimamoto-cho, Osaka 618, Japan*

**The first total synthesis of (±)-hyperolactone A, isolated from *Hypericum chinense* L., is accomplished from 3-furoic acid and 2-methylbutanal.**



Hyperolactone A[1] is a unique spiro compound isolated from *Hypericum chinense* L., which has a 2-alkyl-9-methyl-9-vinyl-1,7-dioxaspiro[4,4]non-2-ene-4,6-dione skeleton, and is thus an interesting compound as a target for synthesis. The structure[1a] was deduced by spectroscopic experiments, chemical transformations and X-ray crystallography. We describe herein the first total synthesis of (±)-hyperolactone A **8a** by condensation of two fragments, aldehyde **2** and lactone **4**.

The aldol reaction of the lithium enolate of lactone **4**, derived from 3-furoic acid, with the aldehyde **2**, derived from 2-methylbutanal (Scheme 1), afforded **5**† in 81% yield (Scheme 2). The crude alcohol **5** was oxidized to furnish **6** (a mixture of four diastereoisomers‡) by the Swern method in 92% yield. Attempted oxidation of **6** with $MoO_5$·pyridine·HMPA (MoOPH)[3] was unsuccessful, giving the undesired **7b** only in 18% yield, while with Davis reagent[4] a separable isomeric mixture of **7a** and **7b**§ was obtained in 57% yield in a ratio of 2 : 3. A NOE was observed between the 9-methyl group and the OH for the minor isomer **7a**, but not for the major isomer.



On treatment of **7a** with 3 M HCl in boiling THF to remove the ketal protecting group (which strongly resisted hydrolysis), a mixture of the final product **8a** and its isomer **8b** was obtained in 85% yield in a ratio of 1 : 1, which was separated to give (±)-hyperolactone **8a**¶ as an oil.

The advantages of this strategy are that it is short and efficient, and provides a one-step construction of the spirolactone by acid catalysis *via* deprotection, cyclization and elimination.

We are grateful to Professor M. Tada (Tokyo University of Agriculture and Technology) for kindly providing a reference spectra of Hyperolactone A and for useful comments.

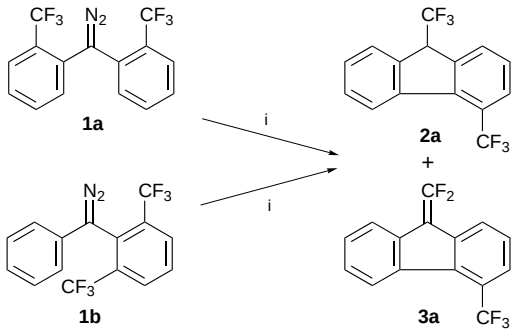
# Flash vacuum pyrolysis of trifluoromethylated diphenyldiazomethanes. Role of trifluoromethyl group in the arylcarbene rearrangement

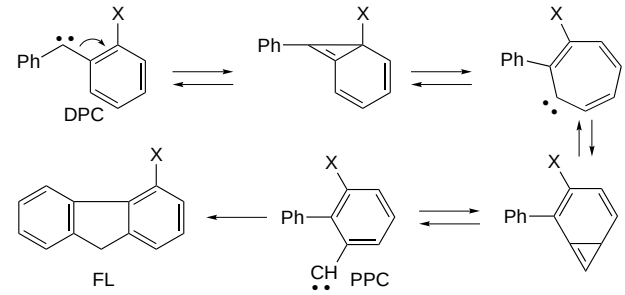
**Hideo Tomioka* and Kohji Taketsuji**

*Chemistry Department for Materials, Faculty of Engineering, Mie University, Tsu, Mie 514, Japan*



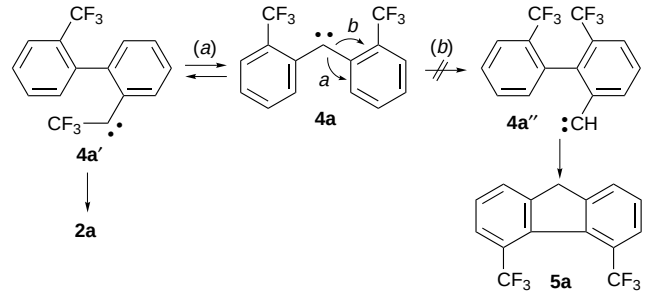
**Flash vacuum pyrolysis (350 °C/10$^{-4}$ Torr) of the title diazo compounds gives trifluoromethylated fluorenes, indicating that the C–F bonds are completely unreactive toward carbene even in the gas phase at high temperatures.**

Fluorinated molecules often display unique reactivity relative to their nonfluorinated analogues and have been the object of considerable interest for many years.[1] This is also true in the field of carbene chemistry.[2,3] The fluoro group is especially interesting in carbene chemistry because it can play key roles either intramolecularly or intermolecularly. On the other hand, C–F bonds are known to be almost the only type of bond unreactive toward carbenic centres. In spite of these unique characteristics, the influence of aryl $CF_3$ groups on the reactivity of arylcarbenes has been poorly characterized.[4] In this regard, we have examined the effect of $CF_3$ groups on the rearrangement of diarylcarbenes in the gas phase. The study not only reveals that $CF_3$ groups show a profound influence on the selectivity of the rearrangement, but also confirms that the C–F bond is completely unreactive toward carbenes, even in the gas phase at high temperature.



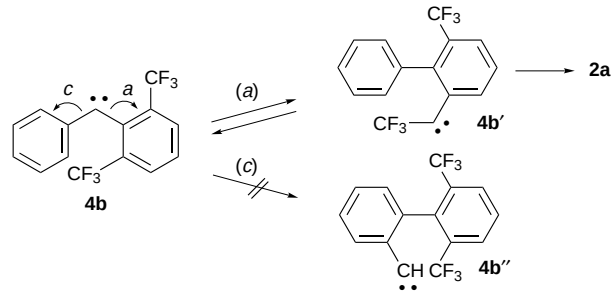
Flash vacuum pyrolysis (FVP)[5] of bis(2-trifluoromethylphenyl)diazomethane **1a**† at 350 °C/10$^{-4}$ Torr gave two fluorene derivatives **2a** (38%)‡ and **3a** (8%)‡ as volatile products (Scheme 1). Control experiments showed that FVP of **2a** under similar conditions gave **3a**, suggesting that **3a** can be produced by a secondary reaction of **2a** as a result of HF elimination.

It is well-documented that arylcarbenes undergo repeated rearrangement in the gas phase, where a divalent carbon is transmitted through a benzene ring to a position that is accessible for intramolecular reactions. Diphenylcarbene (DPC), for instance, rearranges to produce 2-phenylphenylcarbene (PPC), where the carbene centre is trapped by the 2-phenyl ring to form fluorene (FL) Scheme 2.



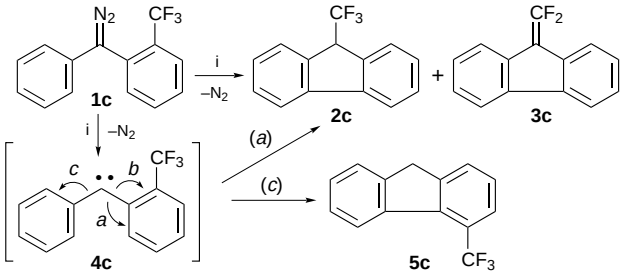
According to the mechanism, carbene **4a** generated from **1a** can undergo ring-expansion in two directions, one [path (*a*)] away from the $CF_3$ group and the other [path (*b*)] toward the substituent (Scheme 3). The former will produce carbene **4a′**, a precursor to **2a**, while the latter should generate **4a″** which should produce **5a**. Exclusive formation of **2a** suggests that the rearrangement of **4a** is highly selective with respect to the substituent. The fact that neither 1,2-F migration nor C–F bond insertion was observed indicates, on the other hand, that the C–F bond is unreactive toward carbenic centres even in the gas phase at this high temperature.

**Scheme 1** *Reagents and conditions*: i, 350 °C/10$^{-4}$ Torr



**Scheme 2**

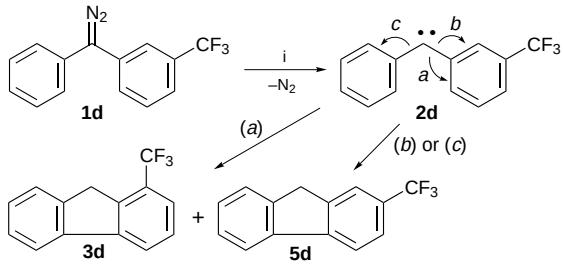
**Scheme 3**



FVP of 2,6-bistrifluoromethylphenyl(phenyl)diazomethane **1b**,† a positional isomer of **1a**, under similar conditions gave essentially the same result, thus affording the same products, **2a** (48%) and **3a** (9%), in similar yields (Scheme 1). The results, although initially puzzling, can also be understood in terms of the carbene rearrangement (Scheme 4). Since the two rings in **4b** bear different substituents, regioselectivities in terms of ring arise in this case [*i.e.* path (*a*) and (*c*)], while there is no selection with respect to the ring substituents [*i.e.* Scheme 3, path (*a*) = path (*b*)]. The ring-expansion toward the substituted ring [path (*a*)] can generate carbene **4b′** responsible for the observed

**Scheme 4**

products, while the another movement [path (*c*)] should produce carbene **4b″**, which is not responsible for the product. The exclusive formation of **2a** might then indicate that the selectivity with respective to the rings is also very high in this case. It may be, however, that since the $CF_3$ group has been shown to be unreactive even under these conditions, the carbene **4b″** has no intramolecular reaction channels and hence regenerates **4b** which eventually produces **2a**.



In order to check this possibility, we generated carbenes **4c** where the *ortho* C–H bonds are available for the carbenes from both types of rearrangement, *i.e.* **4c′** and **4c″**. FVP of **1c**† produced **2c**‡ (32%) and **3c**‡ (27%) again as the main products and only a very small amount of **5c**‡ (1%) was detected. The result shows that path (*a*) rearrangement is favoured over path (*c*), although not exclusively (Scheme 5).

**Scheme 5** *Reagents and conditions*: i, 350 °C/$10^{-4}$ Torr

Both types of regioselectivity are completely lost when the $CF_3$ group is introduced at the 3-position of diphenylcarbene. Thus, FVP of **1d**† afforded **2d**‡ (33%) and **5d**‡ (35%) in comparable yields (Scheme 6). Formation of **2d** is explicable in terms of type (*a*) rearrangement while **5d** might be produced by either type (*b*) or (*c*) rearrangement.

The regioselectivities of the rearrangement of diarylcarbenes carrying different substituents on the aryl rings can be interpreted in terms of a simple frontier MO analysis.[6] Thus, the occupied σ-orbital of carbene can interact with the LUMO of the aromatic ring in the ipso-position, while the vacant p orbital can interact with the aromatic HOMO in the *ortho*-position. The two interactions are synergetic. The σ-LUMO interaction is favoured by low-lying LUMOs possessing large coefficients in the *ipso* position and the p-HOMOs interactions is favoured by high-energy HOMOs with large coefficients in the *ortho*-positions. Phenyl(4-pyridyl)carbene, for instance, undergoes exclusive rearrangement involving the pyridine ring, since the pyridine LUMO has a large coefficient at positions 2 and 4. On the other hand, the rearrangement of phenyl(3-pyridyl)carbene does not involve the pyridine ring, since the LUMO coefficient at the 3-position is very small. Essentially the same explanation can be applied to the selectivities observed for the present system. Thus, a $CF_3$ group will lower the LUMO energy of the benzene ring, and trifluoromethylbenzene has large coefficients at positions 2 and 4. A high preference for the 2-trifluoromethylated phenyl ring will result in carbenes **4a**–**c**, while the regioselectivity is lost in **4d** where the LUMO coefficient of the aromatic ring in the *ipso*-position is small, and hence the p-HOMO interaction becomes competitive.

**Scheme 6** *Reagents and conditions*: i, 350 °C/$10^{-4}$ Torr

Regioselectivities with respect to the ring substituent are not well characterized. In the case of *ortho*-substituted phenylnitrenes, the nitrene nitrogen movement away from the substituent is preferred but is not exclusive and depends on other factors such as the nature of the reaction partner and electronic effects.[7] On the other hand, this issue has been examined extensively only for tolylcarbenes in the carbene rearrangement, where the methyl group is acting as a trap.[7,8] The 'away' selectivity is slightly favoured in this case. However, this again depends on the other factors such as the reaction conditions and precursors.[8]

Finally we wish to emphasize here that the present results reveal that trifluoromethylated diphenylcarbenes can be regarded as synthetically useful intermediates for trifluoromethylated fluorene derivatives which are otherwise not easily obtained. The method is specially advantageous since the $CF_3$ group is intact during the reaction, and its position in the resulting fluorene is predictable based on the regioselectivities shown above.

The authors are grateful to the Ministry of Education, Science and Culture of Japan for support of this work. We also thank Professor Curt Wentrup of the University of Queensland for helpful discussions.

## Footnotes and References

† All diazomethanes except **1b** employed in this study were prepared by the conventional hydrazonation–oxidation procedure and obtained as unstable red oils. 2,6-Bistrifluoromethylphenyl(phenyl)diazomethane **1b** was prepared by treating the corresponding *N*-nitrosocarbamate with KOBu$^t$.

# Strong exciton coupling and circularly polarised luminescence in rigid complexes of chiral macrocyclic tetranaphthylamides

**Rachel S. Dickins,[a] Judith A. K. Howard,[a] Janet M. Moloney,[a] David Parker,*[a] Robert D. Peacock[b] and Giuliano Siligardi[c]**

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

[c] *Department of Pharmacy, King's College London, Manresa Road, London, UK SW3 6LX*

**Strong exciton coupling occurs between adjacent pairs of naphthyl chromophores in the chiral sodium and europium complexes of $L^1$; in the constitutionally isomeric complexes of $L^2$, intramolecular excimer formation is observed and both sets of Eu complexes give a well defined, metal-based circularly polarised emission.**

Recently we have been examining the luminescence behaviour of lanthanide complexes of N-substituted octadentate ligands derived from 1,4,7,10-tetraazacyclododecane (cyclen).[1–4] The chiral europium and terbium complexes of $L^3$ are conformationally rigid and stereochemically homogeneous in solution on the timescale of the metal-centred luminescence (*i.e.* ms), and the remote chiral centre at carbon in the N-substituent determines both the configuration of the macrocyclic ring and the helicity of the array of N-substituents.[1] With this model complex in mind, we have prepared the corresponding enantiomeric pairs of 1- and 2-naphthyl substituted ligands, $L^1$ and $L^2$ and their Eu complexes. A particular motivation for this work has been the consideration that strong exciton coupling between proximate chromophores may be a necessary condition in seeking the efficient population of the enantiomeric ($\pi$–$\pi^*$) excited states of these lanthanide complexes.

Reaction of (*S*)- or (*R*)-*N*-2-chloroethanoyl-1-(1′-naphthyl)-ethylamine with 1,4,7,10-tetraazacyclododecane (dmf, $K_2CO_3$, 60 °C) afforded the ligands (*S*)- or (*R*)-$L^1$ (mp 195 °C). The constitutionally isomeric ligand, $L^2$, based on 1-(2′-naphthyl)ethylamine was prepared analogously (mp 182 °C). Aqueous solutions of $[H_2L^2]^{2+}$, as the trifluoroacetate salt, gave rise to a structureless band in the emission spectrum at 400 nm whose intensity was independent of concentration in the range $10^{-4}$–$10^{-6}$ mol dm$^{-3}$. This band was not observed in MeOH or MeCN, so that intramolecular excimer formation[4] may be favoured by a particularly strong hydrophobic interaction involving expulsion of hydrogen-bonded water molecules from the solvated protonated ligand. In MeOH, the enantiomers of ligand $L^2$ gave mirror-image CD spectra. No exciton coupling features were observed for the CD bands at 280 and 310 nm, which were attributed to $^1L_a$ and $^1L_{1b}$ 2-naphthyl $\pi$–$\pi^*$ transitions.[5] In the far-UV region, the apparent bisignate CD spectrum was assigned to naphthyl $^1B_b$ (225 nm) and $^1C_b$ (210 nm) transitions, rather than exciton coupling.[5]† No sign of exciton coupling was evident from the mirror image CD spectra (MeOH) for the enantiomers of $L^1$, at room temp. (Fig. 1). The CD band at *ca.* 280 nm ($^1L_a$ $\pi$–$\pi^*$) appeared to mask the $^1L_b$ 1-naphthyl transition at 305 nm.[5] However, at −86 °C, a bisignate profile with crossover at 222 nm was observed for the free ligand (*R*)-$L^1$ and similar exciton coupling was observed at room temp. in the presence of 2 equiv. of $Na^+$, $K^+$, $Ca^{2+}$. The intensity of the bisignate profile was enhanced on lowering the temperature. Such behaviour is consistent with coupling of the electric dipole transition moments along the long axis of the naphthyl chromophores, and with positive chirality.

The crystal structure (Fig. 2) of the sodium complex of $L^1$‡ at 150 K revealed a twisted square-antiprismatic eight-coordinate geometry about the sodium ion [mean Na–O = 2.46(3) Å, Na–N = 2.72(4) Å, twist angle 28° from prismatic geometry]. All four naphthyl rings are steeply inclined to the $O_4$ coordination plane (angles ranging from 81 to 103°) and are in a near orthogonal relationship to each other. Given that the amplitude of exciton coupling is maximal when the dihedral angle between the two chromophores is *ca.* 70°, and tends to zero as the angle approaches 0 or 180°,[8] this arrangement of the naphthyl groups is consistent with the observed exciton

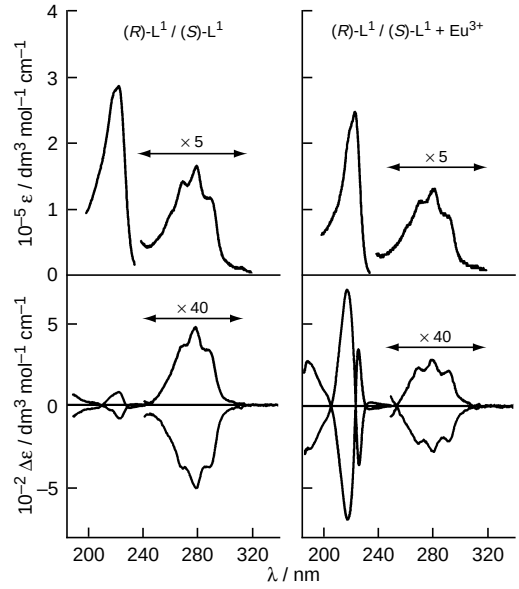

**Fig. 1** CD spectra of the enantiomers of $L^1$ and $[EuL^1][CF_3SO_3]_3$ in MeOH [293 K; (*R*)-enantiomer is upper trace] showing the bisignate profile in the metal complex associated with exciton coupling of the 1-naphthyl $^1B_b$ bands

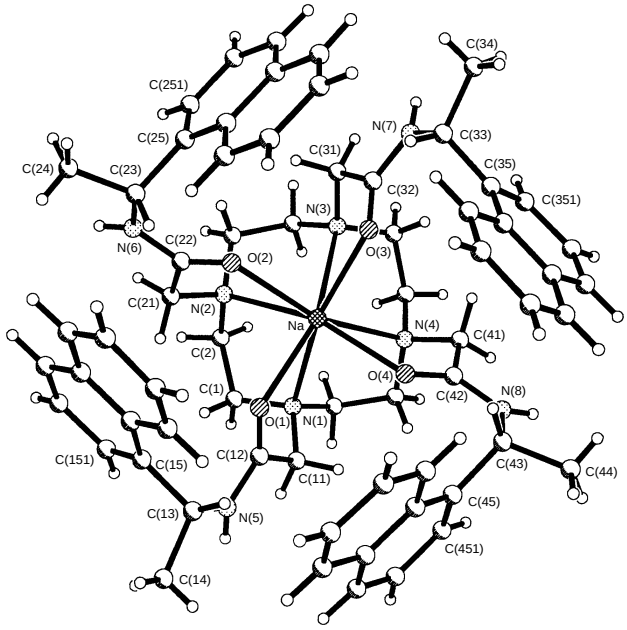

**Fig. 2** Structure of the complex $[NaL^1]CF_3CO_2$ in the crystal, showing the octadentate and twisted square-antiprismatic coordination about sodium

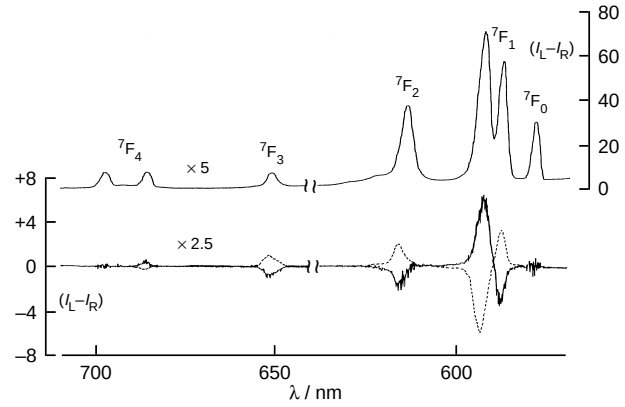

**Fig. 3** Total luminescence ($I_L + I_R$) and circularly polarised luminescence spectra ($I_L - I_R$) of $[Eu\{(R)\text{-}L^1\}]^{3+}$ (solid line) and $[Eu\{(S)\text{-}L^1\}]^{3+}$ (dashed line) [$\lambda_{exc}$ = 395 nm (Xe lamp), 293 K, MeOH, $2 \times 10^{-3}$ mol dm$^{-3}$]

coupling: for $[Na\{(R)\text{-}L^1\}]^+$: $\Delta\lambda$ = 10 nm; $g_{abs}$ (219) = $-2.2 \times 10^{-3}$, $g_{abs}$ (229) = $+1.4 \times 10^{-3}$. Methanolic solutions of (*S*)-L$^1$ in the presence of 2 equiv. of NaCl, NaOAc or $Na_2HPO_4$ gave rise to mirror-image CD spectra, with a bisignate profile typical of negative chirality, and independent of the anion.

Solution NMR studies in $CD_3OD$ of the Eu complexes of L$^1$ and L$^2$, indicated the presence of a single $C_4$-symmetric complex, that showed no evidence for exchange broadening in the range 200–320 K (400 MHz). With $[EuL^2]^{3+}$, there was no evidence for exciton coupling in the solution CD spectrum, and in the fluorescence emission spectrum, an excimer band was evident at 400 nm (40% of the monomer emission intensity) only if water was present. In 100% MeOH, no excimer was discerned, resembling the behaviour shown by the protonated ligand. Formation of an excimer requires the co-planarity of the two aryl groups and their close juxtaposition (3.5 Å): the absence of observed exciton coupling is consistent with this behaviour as the average interchromophoric dihedral angle must be near 0°. In the isomeric complex, [Eu L$^1$]$^{3+}$, the situation is reversed: no distinct excimer band was observed in the emission spectrum irrespective of the presence of water , and in the CD spectrum (Fig. 1) of $\{(R)\text{-}L^1\}[Eu]^{3+}$, positive chirality was exhibited with a bisignate profile associated with strong exciton coupling for which $g_{abs}$ (219) = $-6 \times 10^{-3}$ and $g_{abs}$ (229) = $+3 \times 10^{-3}$. Excimer emission between proximate naphthyl chromphores has been reported previously, *e.g.* in poly(1-naphthylmethylglutamate),[6] and in poly(1-naphthyl-Ala) no evidence for excimer formation was found whereas in the isomer, poly(2-naphthyl-Ala), a weak excimer emission was observed in degassed dmf solutions.[7]

Although these europium complexes are only weakly emissive in their metal-based luminescence spectra following sensitised excitation *via* the naphthyl antenna {[EuL$^1$]: $\lambda_{exc}$ = 280 nm, $\tau H_2O$ = 0.53, $\tau D_2O$ = 2.7 ms; [EuL$^2$]: $\tau H_2O$ = 0.55, $\tau D_2O$ = 2.1 ms} primarily because of competitive photoinduced charge transfer from the excited naphthyl singlet to the $Eu^{3+}$ ion,[15,16] both gave rise to well defined circularly polarised luminescence (CPL) spectra following excitation into the charge-transfer transition at 390 nm. The unpolarised luminescence is characteristic of Eu in a $C_4$ environment and the strength of the $^5D_0$–$^7F_0$ transition implies a large axial perturbation. The $^5D_0$–$^7F_0$ transition at 580 nm showed no CPL, but for the allowed transitions associated with a change in magnetic dipole, *e.g.* $^5D_0$–$^7F_1$, strong CPL was clearly observed (Fig. 3). For $\{(R)\text{-}L^1\}[Eu]$, the $g_{em}$ factors are −0.12(A) and +0.18(E) for $\Delta J$ = 1, −0.1 for $\Delta J$ = 2 (only the E is observed), −0.3 for $\Delta J$ = 3 and −0.11 and 0 for $\Delta J$ = 4. The enantiomeric Eu complexes gave rise to enantiomeric CPL spectra, and CPL spectra from $[EuL^2]^{3+}$ were very similar.

In summary, the Eu complex of L$^1$ gives rise to strong exciton coupling between adjacent pairs of naphthyl chromophores. In the isomeric 2-substituted Eu complex of L$^2$, the naphthyl chromophores are aligned almost parallel and excimer formation occurs.

We thank EPSRC, the BBSRC the National Chiroptical Service (King's, London) and the University of Durham for support.

† Such assignments were confirmed by variable-temperature studies and by the appearance of true exciton coupling (negative chirality with a crossover at *ca*. 225 nm), on addition of 2 equiv. of KCl to (*R*)-L$^2$ (at room temperature) or $CaCl_2$ (revealed at −86 °C). In these latter two cases, the intensities of both bands of the bisignate profile increased as the temperature was lowered. No such behaviour was observed with the free ligand L$^2$.

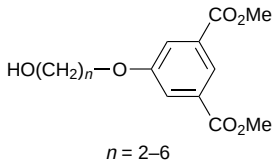
# Synthesis, structure and cyclics content of hyperbranched polyesters



**W. James Feast, Angela J. Keeney, Alan M. Kenwright and David Parker**

*IRC in Polymer Science & Technology, University of Durham, Durham, UK DH1 3LE*

**Dimethyl 5-(hydroxyalkoxy)isophthalates undergo step growth condensation polymerisation to produce hyperbranched polymers with a degree of branching lower than statistically expected and with a high proportion of cyclic structures.**

The step-growth condensation polymerisation of $AB_x$ type monomers was described in a theoretical treatment by Flory, who predicted the formation of polydisperse polymers containing branched and linear segments.[1] It is often assumed that steric constraints preclude intramolecular reactions such as cyclisation, the absence of which is believed to be necessary for continued growth.[2,3]

Previously we have reported the single-step melt condensation polymerisation of dimethyl 5-(2-hydroxyethoxy)isophthalate.[4] As part of this continuing programme into the synthesis and properties of $AB_x$ hyperbranched polymers we have studied the step growth polymerisation of a series of dimethyl 5-(hydroxyalkoxy)isophthalates.

These $AB_2$ monomers underwent step growth polymerisation, eliminating methanol, on heating between 210 and 240 °C in a stream of dry nitrogen and in the presence of a transesterification catalyst which has found previous application in the commercial synthesis of linear polyesters. It utilises a combination of manganese(II) acetate and antimony trioxide, with triphenyl phosphate as a suppressant of thermal degradation.[5] The resulting $AB_2$ polyesters, unlike their linear analogues, were highly soluble in common organic solvents such as $CHCl_3$ and THF which allowed the determination of polystyrene equivalent molecular weights by size exclusion chromatography.

Variation of the alkylene chain length ($n$ = 2 to 6) had a marked effect upon the polymerisation characteristics. When $n$ = 2 both the molecular weight and polydispersity ($M_w/M_n$) of the polymer increased with increasing reaction time up to a weight average molecular weight of 107 000 and $M_w/M_n$ values of 15 after 24 h. This continuous increase in $M_w/M_n$ was as expected from Flory's predictions and has been observed in other hyperbranched systems.[6] However, on increasing the alkylene chain length ($n$ = 3 to 6) this steady increase in molecular weight and polydispersity with reaction conversion was no longer observed. The molecular weight in these instances was found to increase until a maximum was reached, after which it remained constant and no further growth was apparent. This phenomenon is consistent with deactivation or loss of the A functionality. Furthermore an 'odd/even effect' was observed, with alkylene chain lengths of 2, 4 and 6 methylene units yielding higher molecular weights than the corresponding 3 and 5 methylene chain polymers.

Copolymerisation of the $AB_2$ monomer, where $n$ = 2, with potential $B_2$ (dimethyl isophthalate) and $B_3$ (trimethyl benzene-1,3,5-tricarboxylate) core molecules afforded a method of molecular weight control for these systems. Increasing the core to monomer ratio resulted in a decrease in molecular weight and a narrowing of the polydispersity. In principle, an $AB_2$ condensation polymerisation can give rise to branched linear or terminal units (Fig. 1). A measure of the relative proportions of these structural units, the degree of branching (DB), is defined in eqn. (1), where $N_x$ is the number of type x units in the structure.

$$\mathrm{DB} = \frac{N_b + N_t}{N_b + N_l + N_t} \quad (1)$$

Quantitative $^{13}C$ NMR spectra of the polymers with $n$ = 2 at elevated temperature reveals fine structure attributable to the different types of repeat units in the polymers. These may be assigned to branched, linear and terminal contributions on the basis of their line-widths; the branched species are expected to be the least mobile and hence have the wider line-width, whilst the more mobile terminal species will have the narrower linewidth. Analysis of the $^{13}C$ NMR signals from the ester carbons (Fig. 2) gave a degree of branching of *ca* 0.5 which was independent of molecular weight. Analysis of the aromatic carbons in the structure confirm this DB. Purely statistical polymerisation would give a value of 0.66.

MALDI-TOF mass spectrometry (2,5-dihydroxybenzoic acid matrix + KCl, Kratos Kompact MALDI IV, linear mode) of polymers where $n$ = 2 or 3 showed a series of peaks corresponding to degrees of polymerisation in the range 3 to 16 (Figs. 3 and 4, for $n$ = 2). Ions were observed as their $[M + K]^+$ species. For low molecular weight polymers the main ion series corresponds to oligomers resulting from 3 to 16 simple condensation steps where the mass of an oligomer of $n$ units is [$n \times$ (monomer mass) $-$ ($n - 1$) $\times$ (mass of MeOH)]. A minor

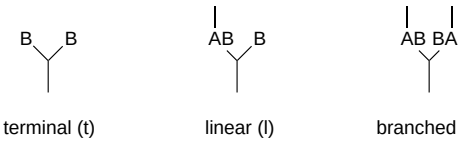


**Fig. 1** Structural sub-units of an $AB_2$ hyperbranched polymer

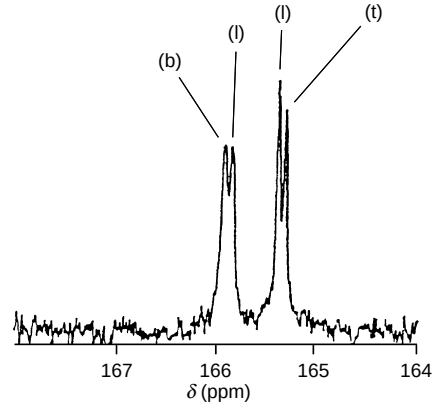

**Fig. 2** $^{13}C$ NMR peak assignments for ester carbonyls

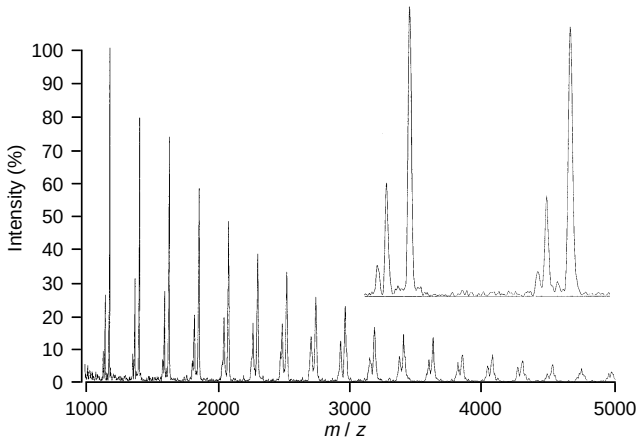

**Fig. 3** MALDI-TOF spectrum. Inset: region *m/z* 1340–1680

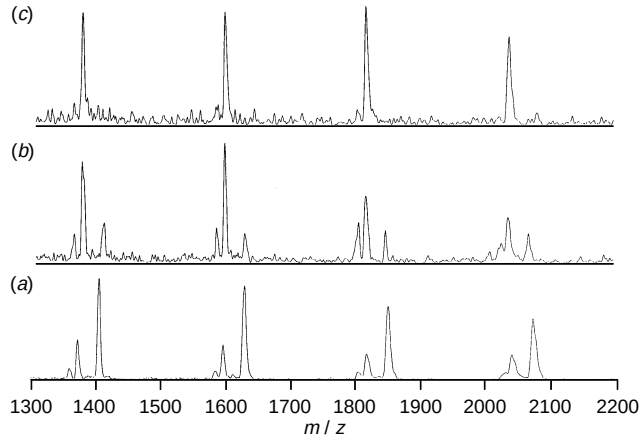

**Fig. 4** MALDI-TOF spectra for varying reaction times: (*a*) 1, (*b*) 2 and (*c*) 24 h

series of peaks is observed 32 mass units behind the main series. This is attributed to the loss of a further single methanol moiety to form a cyclic polymer. An alternative interpretation of this series would be hydrolysis of a single methyl ester unit; if this is occurring it seems reasonable to expect that, particularly for high mass species, more than one of the many methyl ester units in each molecule would undergo the reaction, but there is no evidence for the extra methanol losses required. The relative proportion of the cyclic oligomers increases with increasing oligomer size. For higher molecular weight polymers produced at longer reaction times *only* cyclic oligomers are observed. In the case of the $AB_2/B_x$ copolymers ($n = 2$, $x = 2$ or 3) two series of ions are observed attributable to polymer incorporating a core molecule and cyclic oligomers but no simple non-cyclic $AB_2$ oligomers. Cyclic structures predominate at low core to monomer ratios, whereas core terminated oligomers are more abundant at high core ratios.

This work clearly established that in $AB_2$ step growth polymerisations the outcome cannot be predicted by simple generalisations but is a sensitive function of monomer structure, reactions conditions and duration. In particular cyclisation, which can be growth terminating, occurs readily in the systems described here and becomes easier as the monomers become larger and more flexible. This observation is not unexpected but appears to have been overlooked previously.

We thank the Engineering and Physical Sciences Research Council for support through the IRC Special Grant and a Studentship (A. J. K.).

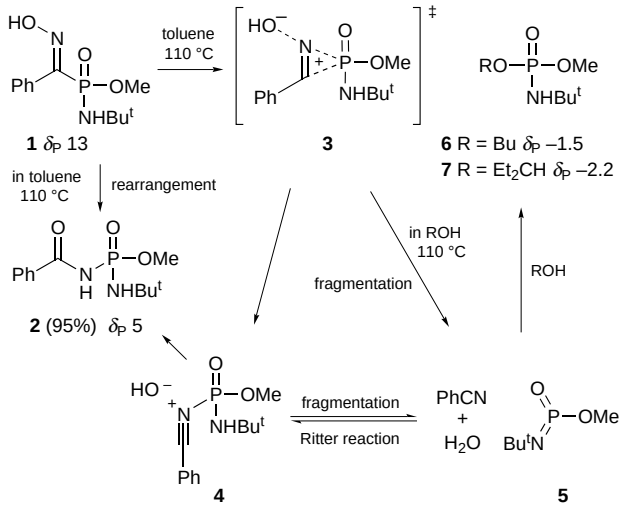
# Unusual solvent-dependent behaviour of hydroxyiminophosphonamidates in the Beckmann reactions: choice between rearrangement or fragmentation to metaphosphonamidate species



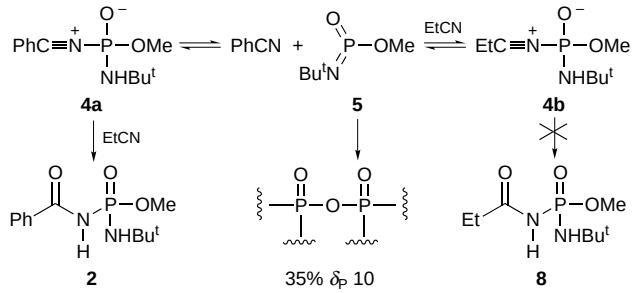
**Jan Kehler† and Eli Breuer***

*Department of Pharmaceutical Chemistry, The School of Pharmacy, The Hebrew University of Jerusalem, PO Box 12065, Jerusalem, 91120, Israel*

**Methyl α-hydroxyiminobenzyl-*N*-*tert*-butylphosphonamidate undergoes Beckmann rearrangement (BR) when heated in toluene, but fragmentation (*via* metaphosphonamidate) to a phosphoramidate and PhCN when heated in BuOH, supporting the assumption of a common intermediate for the BR and the Beckmann fragmentation; polar solvents retard the rearrangement.**

Recently it was reported from our laboratory that α-hydroxyiminobenzylphosphonamidates (*e.g.* **1**) rearrange easily ($t_{1/2}$ 92 min) in boiling toluene to *N*-benzoylphosphorodiamidates (*e.g.* **2**, Scheme 1).[1] Here we report that the behaviour of methyl *N*-*tert*-butyl α-hydroxyiminobenzylphosphonamidate **1** changes dramatically with a change in the solvent. While in aprotic solvents it undergoes cleanly Beckmann rearrangement (BR) to methyl *N*-benzoyl-*N*′-*tert*-butylphosphorodiamidate **2**, in alcohols it undergoes fragmentation to PhCN and a (mixed) dialkyl *N*-substituted phosphoramidate (*e.g.* **6** or **7**).

Although the mechanism of the Beckmann reactions is still not completely understood, according to the generally accepted view,[2] the BR and the Beckmann fragmentation reactions both involve the intermediacy of a nitrilium species (analogous to **4a**) formed by the concerted migration of the group *anti* to the departing hydroxy *via* a transition state such as **3**. Very recently it was calculated[3] that the first event in the classical BR is most likely protonation of the nitrogen, followed by a rate-determining 1,2 proton migration to the oxygen. Another result in this recent paper was the prediction of catalysis by solvents such as water, formaldehyde or formic acid, which were shown to play an important role in the transition state of the rate determining step. Once formed, the nitrilium species can undergo water addition to form the BR product or it can fragment in what is called the abnormal BR (considered a side reaction) to a nitrile and a carbocation or, as in our case, a metaphosphate species such as **5**. In the classical BR it has not been possible to control the ratio of rearrangement to fragmentation, however, it was found that the electronic properties of the migrating group played a crucial role. Thus, it was found that migrating groups capable of forming stable carbocations favour fragmentation.‡ The overall mechanistic picture is complicated by the fact that the nitrile and the electrophilic species can recombine in a Ritter reaction, reforming the nitrilium ion. Application of these mechanistic considerations to the Beckmann reaction of an α-hydroxyiminobenzylphosphonamidate is shown in Scheme 1.



**Scheme 1**

Nitrilium species such as **4a** have been postulated as reversibly forming intermediates when metaphosphates were generated in MeCN.[4] Therefore, **4a** is conceivably a metaphosphonamidate (**5**) precursor. One of the commonly accepted diagnostic tests for metaphosphate-like species as reactive intermediates is the absence of any steric effect in the phosphorylation of hindered alcohols as compared to primary ones.[5] Consequently, in order to further investigate the present Beckmann fragmentation, we studied the thermal behaviour of methyl *N*-*tert*-butyl-α-hydroxyiminobenzylphosphonamidate **1** as a representative of this type of compounds in alcohols (butan-1-ol and pentan-3-ol) capable of trapping metaphosphates. The two alcohols were chosen as media for the thermal reactions of **1** for two reasons: (i) the closeness of their boiling points to that of toluene§ should allow easy comparison of reaction rates and (ii) their differing steric effects should shed light as to the nature of the reaction intermediates.[6] Monitoring by $^{31}$P NMR spectroscopy of a 0.18 M butan-1-ol solution of **1** kept at 110 °C revealed the relatively slow ($t_{1/2}$ 1829 min; first order kinetics) development of one new product ($\delta_P$ −1.5), along with concurrent consumption of the starting material ($\delta_P$ 13), in a clean reaction. The product was isolated and identified as butyl methyl *N*-*tert*-butylphosphoramidate **6**.¶ Similarly, heating a solution of **1** in pentan-3-ol at 110 °C gave methyl 1-ethylpropyl *N*-*tert*-butylphosphoramidate **7** ($\delta_P$ −2.5).‖ In addition, the presence of PhCN in both reaction mixtures was demonstrated by GC–MS and HPLC. Carrying out the reaction in a 1 : 1 (v/v) mixture of butan-1-ol and toluene gave the same result. When **1** was heated in a 1 : 1 (mol/mol) mixture of butan-1-ol and pentan-3-ol the formation of the two products **6** and **7** in 65 : 35 ratio was observed by $^{31}$P NMR spectroscopy.

The formation of the two phosphorodiamidates **6** and **7** in a 65 : 35 ratio in the thermolysis in the butan-1-ol–pentan-3-ol mixture is consistent with the formation of a reactive metaphosphonamidate intermediate **5** which is trapped by two alcohols with different steric requirements in an almost non-selective manner. If the alcohols were involved in the rate determining step of the reaction the ratio between the rates of formation of products should reflect the steric effects of the two alcohols[6] and therefore, the ratio of yields for **6** and **7** should be about 40 : 1.

Further considering the possible intermediacy of metaphosphate–nitrile addition species in the thermolytic reactions

of **1**, we reasoned that if species **4a** were involved, then carrying out the reaction in the presence of a large excess of another nitrile (*e.g.* EtCN) would cause the two nitriles to compete and lead to **4b** (Scheme 2), which in turn would give methyl *N*-propionyl-*N′*-*tert*-butylphosphorodiamidate. However, when **1** was heated in EtCN at 110 °C, it reacted ($t_{1/2}$ 225 min) to give two types of product only: (i) **2** (65%) by BR, and (ii) products (35%) having a group of signals at around $\delta_P$ −10,[7] consistent with oligomeric P–O–P type species; no methyl *N*-*tert*-butyl-*N′*-propionylposphorodiamidate was formed. In contrast, heating **1** in DMF at 100 °C, gave **2** cleanly in a slow ($t_{1/2}$ 5500 min) BR.

**Scheme 2**

Our system is unique in a number of ways. (i) In contrast to the normal BR, both the rearrangement and the fragmentation occur without acid catalysis. This makes it possible to isolate and to study the influence of further environmental and structural variations on the reactions and on the choice between them. (ii) In contrast to the predictions in ref. 3, in our case the BR is *retarded* by polar, basic solvents (DMF or EtCN) in comparison to toluene. This can be rationalized by assuming ground state stabilization of **1** by strong hydrogen bonding. In fact, **1** has a significantly lower solubility in toluene. Along with suppressing the rearrangement, the polar solvents DMF and alcohol (and to some extent EtCN) promote dissociation of intermediate **4a** by solvating the incipient metaphosphonamidate **5**, which can subsequently be trapped by the alcohols. The absence of steric effects observed in the reactions in alcohols is consistent with the formation of a reactive intermediate trapped nonselectively by alcohols of differing steric requirements. In EtCN the solvent forms an addition compound, thus stabilizing the metaphosphonamidate intermediate which polymerizes in the absence of an efficient trap, in addition to considerable proportion of the normal rearrangement product. (iii) The reactions described here proceed without acid catalysis, presumably because of the high migratory aptitude of the phosporus moiety. This seems to be a new manifestation of the 'β-effect' namely the ability of phosphorus functionalities to stabilize an electron deficient centre situated in β-relationship.[8]

In conclusion, our results show a new aspect of acylphosphonate and oxyiminophosphonate chemistry.[9] The versatility of this class of molecules, the countless ways they can be modified and the different types of reactions they can undergo so readily make them a focus of continuing interest and a source of models uniquely suitable for mechanistic studies.

Finally, our results seem to support the assumption that both the BR and the fragmentation proceed *via* a common intermediate. To the best of our knowledge, such a dramatic change in the reactions' course resulting from changing the solvent is unprecedented in this area.

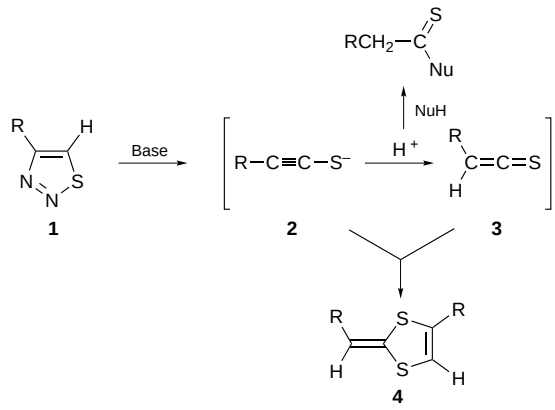
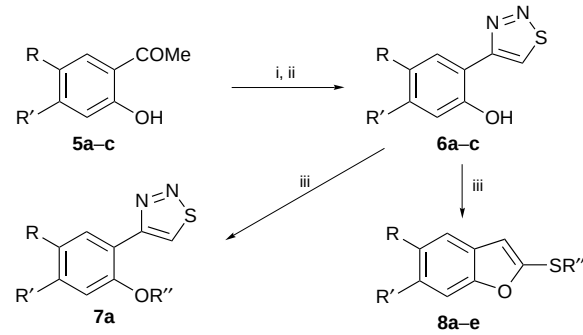
# A general synthesis of benzofuran-2-thiolates *via* intramolecular addition of phenolates to alkynethiolates

**Bart D'hooge, Stefan Smeets, Suzanne Toppet and Wim Dehaen***



*Department of Chemistry, University of Leuven, Celestijnenlaan 200F, B-3001 Leuven (Heverlee), Belgium*

**4-(*ortho*-Hydroxyaryl)-1,2,3-thiadiazoles can be transformed into benzofuran-2-thiolates *via* an intramolecular cyclization.**

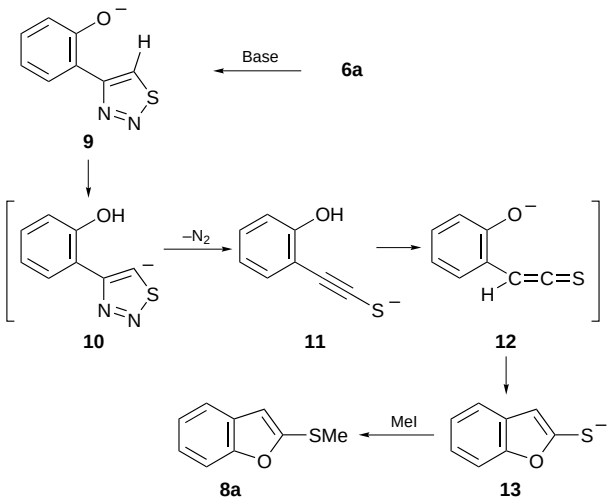


1,2,3-Thiadiazoles **1**, unsubstituted at the 5-position, are cleanly decomposed into alkynethiolates **2** under the influence of strong bases such as organolithium reagents, sodamide, sodium hydride and potassium *tert*-butoxide.[1] These alkynethiolates are interesting reagents which have been alkylated and acylated at sulfur, and converted with nucleophiles into derivatives of the thioketenes **3** which result from protonation at carbon of **2**.[1,2] Another possibility is the combination of alkynethiolate **2** with thioketene **3** to give a dithiafulvene **4**. The dimer **4**[2] will be formed in protic solvents or when no efficient nucleophile is present to trap the thioketene **3** (Scheme 1).

The method of Hurd and Mori[3] gives access to 5-unsubstituted 1,2,3-thiadiazoles **1**, and consists of reacting methyl ketones successively with ethyl carbazate (or tosylhydrazide) and thionyl chloride. This procedure was used to obtain 4-(orthohydroxyaryl)-1,2,3-thiadiazoles **6a**–**c** from the acetophenones **5a**–**c** in 37–74% overall yield.[4] We wanted to use the alkylation of phenol **6a** as a means to attach the 1,2,3-thiadiazole group to other molecules.[5] However, the thiadiazole **6a** proved to be susceptible to relatively weak bases, such as potassium carbonate, and in the presence of alkylating agents the unexpected thioethers **8a**–**c** were formed in high yields instead of the *O*-alkylated thiadiazoles **7**. Only with the very reactive methyl iodide is some *O*-alkylated product **7a** formed. The formation of **7a** can be suppressed by adding the alkylating agent after the decomposition is completed. (Scheme 2, Table 1).

The mechanism of this unusual reaction was elucidated by following the decomposition of **6a** by $^1$H NMR (400 MHz) spectroscopy. Thus, a solution of compound **6a** in $CD_3CN$ was treated with aqueous tetrabutylammonium hydroxide at room temperature. Initially, the phenolate **9** was present as indicated by the disappearance of the phenolic OH at $\delta_H$ 9.69 (as compared to the spectrum without base) and the downfield shift of the thiadiazole 5-H from $\delta_H$ 9.20 to 9.76. In addition, the

**Scheme 1**



**Scheme 2** *Reagents and conditions*: i, $EtO_2CNHNH_2$; ii, $SOCl_2$; iii, base, R″X, acetone, reflux

phenyl protons at the 3, 4 and 5 positions moved upfield by 0.42, 0.34 and 0.64 ppm, respectively, whereas the 6-H was little affected ($\Delta\delta$ +0.17 ppm). Slow nitrogen evolution was observed, and after a period of 21 h the $^1$H NMR spectrum corresponded to a 1 : 1 mixture of compounds **9** and **13**. The 5-H of the 1,2,3-thiadiazole ring of **9** was partially deuterated under these conditions, proving the intermediacy of the 1,2,3-thiadiazol-5-yl anion **10**. After 93 h the reaction was completed and the NMR spectrum showed a clean absorption pattern of benzofuran-2-thiolate[7] with $\delta_H$ 5.98 (3-H), 6.81, 6.90 (5-H and 6-H) and 7.06 (4-H and 7-H), with no detectable impurities present. When the same reaction was followed by NMR spectroscopy in [$^2H_6$]DMSO, the alkynethiolate **11** (48%) was observed after 15 min, together with the phenolate **9** (35%) and benzofuran **13** (17%). Compound **11** showed peaks in the $^{13}$C NMR spectrum at $\delta$ 71.8 (d) and 101.2 (s) for the alkyne carbons (respectively $\beta$ and $\alpha$ to sulfur). After 3 h the phenolate **9** had disappeared and the spectrum showed a 1 : 1 mixture of **11** and **13**. The $^{13}$C NMR spectrum of thiolate **13** had peaks at 173.9 (d, $^2J_{CH}$ 9 Hz) and 99.1 (d, $^1J_{CH}$ 173 Hz) for the C-2 and C-3 carbons of the benzofuran, respectively. After one week, the transformation to benzofuranthiolate **13** was complete and the reaction could be treated with methyl iodide to give an immediate and quantitative reaction, affording the sulfide **8a**. From this it follows that an alternative pathway where, in the first step, the alkynethiolate **11** is alkylated, followed by

**Table 1** Products and yields from the reactions of **6a**–**c** with base and alkylating agents

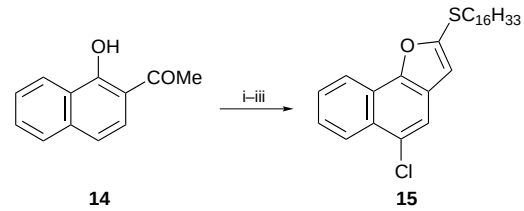

**Scheme 3**

intramolecular phenolate addition,[8] can be excluded (Scheme 3).

It is most unusual that a weak base such as phenolate would be capable of abstracting the 5-thiadiazole hydrogen. We found that the decomposition reaction to alkynethiolate **2** also occurs, although at a much slower rate (several days), when equal amounts of phenol and 4-phenyl-1,2,3-thiadiazole **1** are reacted in refluxing acetone in the presence of equivalent amounts of potassium carbonate and benzyl chloride. There is no observable reaction when only **1**, potassium carbonate and benzyl chloride are present, proving the intermediacy of the phenolate anion. Here, the major products are the known[2] dimeric dithiafulvalene **4** and benzyl phenyl ether. It is interesting to note that no dimers have been detected in the reactions starting from **6a**–**c**. Apparently, intramolecular phenolate addition is much more effective than the intermolecular dimerization process.

The generality of the reaction was investigated by reacting the 2,4-dihydroxyphenyl- and 2,5-dihydroxyphenyl-thiadiazoles **6b** and **6c** with hexadecyl bromide under the same reaction conditions. In the presence of one equivalent of alkylating agent, only the *S*-monoalkylated products **8d** and **8e**, respectively, were formed in fair to excellent yields (Scheme 1, Table 1). The chloronaphthofuran **15** was produced following a

**Scheme 4** *Reagents and conditions*: i, $EtO_2CNHNH_2$; ii, $SOCl_2$; iii, $K_2CO_3$, $C_{16}H_{33}Br$, acetone, reflux

similar strategy from 2-acetyl-1-naphthol **14**. The chlorine was introduced on the electron rich naphthol at the stage of the Hurd–Mori reaction (Scheme 4).[3]

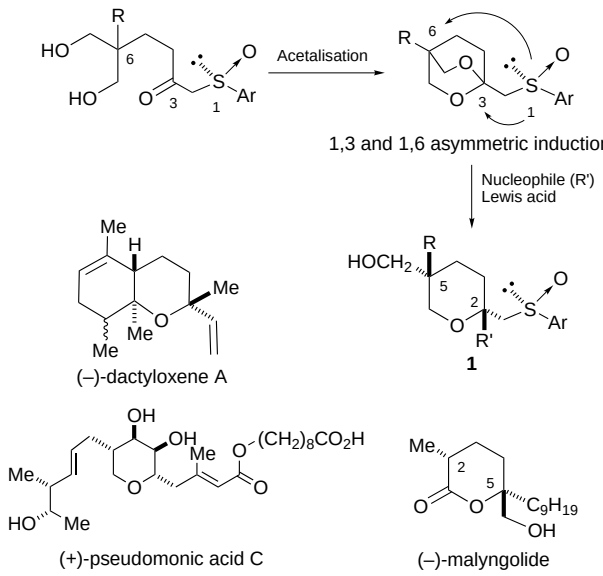
# Stereoselective synthesis of a chiral synthon, 2,2,5-trisubstituted tetrahydropyran, based on simultaneous 1,3- and 1,6-asymmetric induction *via* nucleophilic acetal cleavage reaction of the bicyclic acetal: a total synthesis of (−)-malyngolide



**Naoyoshi Maezaki,[a] Yûki Matsumori,[a] Takeshi Shogaki,[a] Motohiro Soejima,[a] Tetsuaki Tanaka,[a] Hirofumi Ohishi[b] and Chuzo Iwata*[a]**

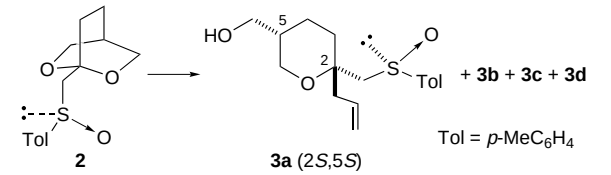
[a] *Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565, Japan*
[b] *Osaka University of Pharmaceutical Sciences, 4-20-1 Nasahara, Takatsuki, Osaka 569-11, Japan*

**A chiral 2,2,5-trisubstituted tetrahydropyran is synthesised efficiently *via* facial and group selective nucleophilic acetal cleavage reaction of a bicyclic acetal, wherein simultaneous 1,3- and 1,6-asymmetric induction from a sulfinyl chirality is accomplished with high diastereoselectivity; this chiral synthon is successfully applied to a total synthesis of (−)-malyngolide.**

The development of a methodology for remote asymmetric induction is one of the most challenging problems in organic synthesis.[1,2] In addition, the simultaneous installation of chiral centres separated by more than two carbons is a very difficult task. We have previously reported a novel asymmetric desymmetrisation of a prochiral 1,3-diol *via* diastereoselective acetal cleavage reaction.[2] The results prompted us to develop a methodology for simultaneous 1,3- and 1,6-asymmetric induction *via* a nucleophilic acetal cleavage reaction,[3] wherein a chiral sulfinyl group controls both the diastereotopic C–O bond cleavage and diastereofacial nucleophilic addition, thereby yielding chiral 2,2,5-trisubstituted tetrahydropyrans with two chiral centres at the $C_2$ and $C_5$ positions (Scheme 1).† The resulting tetrahydropyran derivative **1** is considered as a useful chiral synthon for various natural products, *i.e.* (−)-dactyloxene A,[4] (+)-pseudomonic acid C[5] and (−)-malyngolide.[6]

Here we describe a novel method of synthesising 2,2,5-trisubstituted tetrahydropyran based on simultaneous 1,3- and 1,6-asymmetric induction with high diastereoselectivity *via* group and facial selective nucleophilic acetal cleavage reactions and apply this chiral synthon to a total synthesis of (−)-malyngolide.

**Scheme 1**



Upon treatment with a mixture of the bicyclic acetal **2**[2] and allyltrimethylsilane with $TiCl_4$, nucleophilic acetal cleavage reaction took place at −78 °C to produce allylated alcohol **3a** along with the three diastereomeric isomers **3b–d**‡ (67 : 10 : 17 : 6) (Table 1). Selectivity was increased by lowering the reaction temperature; $CH_2Cl_2$ was the most suitable solvent. The best result was obtained when $TiCl_4$ (5 equiv.) was added to a mixture of substrate and allyltrimethylsilane (10 equiv.) in $CH_2Cl_2$ at −100 °C. In this case, the ratio of **3a** and its three other isomers was 84 : 6 : 7 : 3.

The absolute configuration of the major product **3a** was inferred from the relative configuration determined by single crystal X-ray analysis of the p-nitrobenzoate§ and the known absolute configuration of the sulfoxide.¶

The reaction was rationalised as follows: $TiCl_4$ coordinates between the sulfinyl oxygen and one of the acetal oxygens to form the chelation intermediates **A** or **B**, in which the bulky tolyl group located at equatorial position (Fig. 1). The intermediate **A** is more favourable than **B**, since the electropositive sulfur atom is located between electronegative oxygens and is *anti* to the bulky 7-methylene group in the intermediate **A**.[7] The C–O bond coordinated by $TiCl_4$ is weakened or cleaved to produce transition state **C** or tight ion pair intermediate **D**, respectively. Allyltrimethylsilane reacts with the bicyclic acetal from the backside of the breaking C–O bond *via* an $S_N2$-type substitution (transition state **C**) or an $S_N1$-like mechanism (intermediate **D**)[8] to give the (2*S*,5*S*)-isomer **3a** diastereoselectively as a potential multifunctional chiral synthon.

We planned to apply this chiral synthon to the synthesis of a marine antibiotic, (−)-malyngolide.[6] Although various synthe-

(97%); iv, $PdCl_2(PhCN)_2$, benzene, 80 °C (60%, 90% based on recovery of material); v, $O_3$, MeOH, −78 °C then $NaBH_4$, room temp. (93%); vi, MOMCl, $Pr^i_2NEt$, $CH_2Cl_2$, room temp. (77%)

ses of malyngolide have been reported,[9] most of synthetic routes lack stereocontrol at the $C_2$ methyl group. A few methods overcome this problem by constructing the two chiralities one by one.[9a,c,e,f] After the nucleophilic acetal cleavage reaction of **2**, the major diastereomeric isomer **3a**, which possesses three appropriately installed side-chains for the synthesis of (−)-malyngolide, was isolated as a mesylate **4** (73% yield from **2**). After reduction of the mesylate moiety with Super Hydride®, a catalytic amount of $PdCl_2(PhCN)_2$ was used to isomerise the allyl group to a prop-1-enyl group.[10] Ozonisation was followed by a reductive work-up, and protection as a methoxymethyl (MOM) ether was undertaken to yield **5** (Scheme 2).

The *p*-tolylsulfinyl group was converted into the alcohol **6** *via* Pummerer rearrangement followed by reduction with $LiBH_4$. After Dess–Martin oxidation,[11] eight carbon elongation at the hindered position was successfully accomplished with a Wittig reagent followed by hydrogenation of the olefin to produce compound **7** in good yield. Finally, the tetrahydropyran ring was oxidised to the δ-lactone with $RuO_4$, and the MOM ether was removed with $Me_3SiBr$ to give (−)-malyngolide without epimerisation at the methyl group (Scheme 3). The spectroscopic data and specific rotation [$[\alpha]_D$ −12.5 ($CHCl_3$)] were consistent with the reported data [$[\alpha]_D$ −13.0 ($CHCl_3$)].[6]

**Scheme 3** *Reagents and conditions*: i, $Ac_2O$, AcONa, 130 °C (90%; 2 : 1 diastereomeric ratio); ii, $LiBH_4$, THF, room temp. (97%); iii, Dess–Martin periodinate, $CH_2Cl_2$, 0 °C (88%); iv, $Ph_3P^+(C_8H_{17})Br^-$, KHMDS, THF, 0 °C (94%); v, $H_2$, 10% Pd–C, MeOH, room temp. (86%); vi, $RuCl_3{\cdot}3H_2O$, $NaIO_4$, $CCl_4$–MeCN–$H_2O$ (57%, 80% based on recovery of material); vii, $Me_3SiBr$, $CH_2Cl_2$, −30 °C (85%)

In summary, we have synthesised 2,2,5-trisubstituted tetrahydropyran **1** as a multifunctional chiral synthon based on facial and group selective acetal cleavage reactions, in which highly diastereoselective 1,3- and 1,6-asymmetric induction was observed. The utility of this chiral synthon was demonstrated by its application to the total synthesis of (−)-malyngolide.

† Relative and absolute configurations at the $C_2$ and the $C_5$ positions in the chiral synthon **1** can be controlled by the sulfinyl chirality. Furthermore, inversion of the stereochemistry at the $C_2$ position in **1** (R′ = allyl) is also possible, since both allyl and sulfinyl groups can be converted into variety of functional groups.

‡ The absolute configurations of **3b**–**d** were determined as (2*S*,5*R*), (2*R*,5*S*), and (2*R*,5*R*), respectively. Structural determination of these compounds will be reported elsewhere.

§ The X-ray crystal structure of compound **3a** confirms the relative configuration at $C_2$ and $C_5$ although the quality of the data is not adequate for publication. These assignments are supported by the conversion of **3a** into (−)-malyngolide.

¶ The absolute configuration of the sulfoxide moiety in **3a** was based on the optical rotation of the known methyl *p*-tolyl sulfoxide (ref. 12), from which **3a** was derived (ref. 2). Since all synthetic intermediates after introduction of the sulfinyl group (including **2** and **3a**) possess positve optical rotations, their absolute configurations on sulfur are assumed to be retained during the transformations [by the empirical rule (ref. 13)].

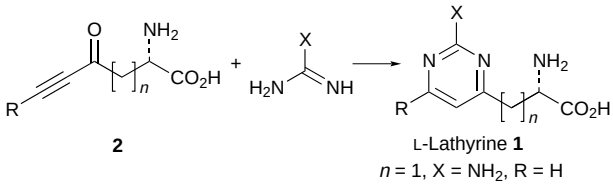
# A versatile approach to pyrimidin-4-yl substituted α-amino acids from alkynyl ketones; the total synthesis of L-lathyrine

**Robert M. Adlington, Jack E. Baldwin,* David Catterick and Gareth J. Pritchard**

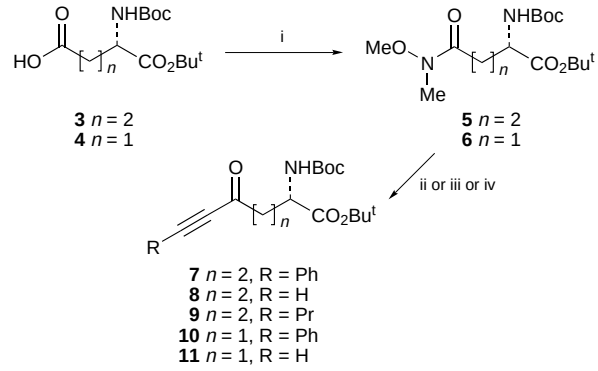
*The Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY*



**A range of pyrimidin-4-yl substituted α-amino acids has been synthesised by the reaction of amidines with α-amino acid alkynyl ketones.**

The stereoselective synthesis of α-amino acids is an active field of research.[1] In particular heterocyclic substituted non-proteinogenic amino acids show a diverse range of biological activities. Examples of these include azatyrosine,[2] mimosine,[3] lathyrine **1**[4,5] and discadenine.[6] In view of the wide range of biological activities shown we wished to develop a versatile route to these types of compounds, which may also be applicable to parallel and/or combinatorial syntheses, thus providing families of related compounds.

Our initial target was to introduce alkynyl ketones as a versatile reactive group for the construction of heterocycles into the side chain of α-amino acids. Alkynyl ketones have been used in the synthesis of a range of heterocyclic systems[7] and very recently have been condensed with amidines to give pyrimidines.[8] As our approach offered the possibility of three different groups on the heterocyclic ring, one of which being an α-amino acid, a large range of structurally related families should be readily accessible (Scheme 1).

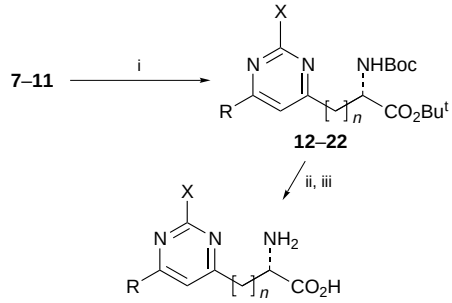


Glutamic acid and aspartic acid were considered as suitable precursors to **2**, where the side chain acid could be activated and reacted with a lithium acetylide. The activation chosen was the 'Weinreb' amide, which has been used to synthesise aryl ketone amino acids.[9,10] Thus α-*tert*-butyl *N*-*tert*-butoxycarbonyl-glutamate **3** was prepared following a five step procedure from L-glutamic acid,[11,12] which was then converted to the amide **5** by reaction of *N*,*O*-dimethylhydroxylamine *via* a mixed anhydride in satisfactory yield.[10] Subsequent reaction of the amide **5** with a five-fold excess of lithium phenylacetylide, ethynylmagnesium bromide or lithium propylacetylide at −78 °C in THF afforded the ethynyl ketones **7**, **8** and **9** in good yields (Scheme 2).

Trial cyclocondensations between **8** and benzamidine hydrochloride showed that optimal conditions for the formation of the desired pyrimidinyl substituted amino acid **12** were stirring an MeCN or EtOAc solution of the ethynyl ketone with benzamidine hydrochloride and solid $Na_2CO_3$ with a catalytic amount of water at reflux. Acetylenic ketones **7**, **8** and **9** containing aryl, hydrogen and alkyl functionalities respectively then underwent a series of cyclocondensations with a range of hetero, aryl, alkyl and hydrogen functionalised amidines to generate the pyrimidines **12**–**19** (Scheme 3 and Table 1). The enantiomeric purity of these compounds was determined by conversion of their N-deprotected forms (Boc deprotection carried out by azeotropic distillation with $TsOH·H_2O$–PhMe) to both (*R*)- and (*S*)-Mosher's amides and proved to be greater than 98% ee.[13]

**2** L-Lathyrine **1**
$n$ = 1, X = $NH_2$, R = H

**Scheme 1**



**3** $n$ = 2
**4** $n$ = 1
**5** $n$ = 2
**6** $n$ = 1
**7** $n$ = 2, R = Ph
**8** $n$ = 2, R = H
**9** $n$ = 2, R = Pr
**10** $n$ = 1, R = Ph
**11** $n$ = 1, R = H

**Scheme 2** *Reagents and conditions*: i, NMM,Bu$^i$OCOCl, THF, −15 °C; HN(OMe)Me·HCl, $NEt_3$, DMF, 74% (**5**), 76% (**6**); ii, PhCCLi (5 equiv.), THF, −78 °C, 79% (**7**), 62% (**10**); iii, HCCMgBr (5 equiv.), $Et_2O$, −78 °C, 61% (**8**), 78% (**11**); iv, PrCCLi (5 equiv.), THF, −78 °C, 95% (**9**)

Thus from a key precursor **5** a large family of diverse structures can be built up incorporating hydrogen, alkyl, aryl and hetero functionality. The amidine used allows control at the 2 position of the resulting pyrimidine whilst the choice of acetylide controls the 6 position.

To allow further variation in the substitution at the pyrimidine 4 position, the chemistry was expanded to L-aspartic acid. The α-*tert*-butyl *N*-*tert*-butoxycarbonylaspartate **4** was prepared and converted to the 'Weinreb' amide **6** as previously for **5**. The acetylenic ketones **10** and **11** were then formed by reaction of **6** with a five-fold excess of ethynylmagnesium bromide or lithium phenylacetylide respectively (Scheme 2). The ketones **10** and **11** underwent high yielding condensations to produce **20**, **21** and **22** (Scheme 3 and Table 1). Investigation

of the enantiomeric purity of these pyrimidines by Mosher's amide formation showed up to 5% racemisation when the cyclocondensations were carried out at reflux temperatures; however, this was reduced by carrying out the condensations at 40 °C affording enantiomeric purity greater than 98% ee.

One compound of note is pyrimidine **17**, which is a homologue of the naturally occurring amino acid L-lathyrine.[4] The condensation of **8** with guanidine to give **17** had, however, given a disappointingly low yield. In order to attempt the synthesis of L-lathyrine itself as well as other analogues and to further diversify the functionality at the pyrimidine 2 position it was decided to undertake nucleophilic aromatic substitutions of suitable leaving groups. It was expected that the existing thiomethyl functionality, derived from cyclisations of ethynyl ketones with 2-methyl-2-thiopseudourea, if oxidised to the corresponding sulfone, would be susceptible to substitution by nucleophiles.[14] Reaction of the pyrimidines **16**, **18**, **20** and **22** with 2 equiv. of MCPBA resulted in the corresponding sulfones **23**–**26**. Substitution of the methylsulfonyl group using liquid ammonia was then possible. Good yields of the corresponding pyrimidines **27**–**29** were thus achieved, **29** being protected L-lathyrine. When 1 M NaOH was used in the substitution reaction with **23**, followed by mild acidic work up ($KH_2PO_4$–$H_2O$) and purification by ion-exchange chromatography, pyrimidone **45** was obtained in 71% yield (Scheme 4 and Table 2).

| **29** | 1 | H | $NH_2$ | 93 |

Deprotection of the protected pyrimidin-4-yl amino acids was achieved by dissolution in TFA–anisole. The free amino acids **30**–**32**, **34**–**38**, **40**–**47** and **1** were obtained by ion-exchange chromatography as solids in high yields (90–100%). A lower yield was observed for the deprotection/purification of **33** due to the low solubility of its TFA salt and **39** was preferentially isolated as its TFA salt (Schemes 3 and 4). The optical rotation of **1** (synthetic L-lathyrine) had a value of $[\alpha]_D^{21}$ −55.4 (*c* 1.2, $H_2O$), consistent with that reported for the naturally occurring amino acid [lit.,[5] −55.9 (*c* 1.2, $H_2O$)].

In conclusion we have developed a versatile approach, applicable to parallel synthesis, to a family of pyrimidin-4-yl substituted α-amino acids, the chemistry allowing diversification by control of the 2, 4 and 6 positions of the pyrimidine. This route allows the total synthesis of non-proteinogenic amino acids in approximately 20% overall yield from aspartic or glutamic acids. Further routes to other families of natural product derivatives will be reported in due course.

We thank the EPSRC for a studentship to D. C. and the EPSRC mass spectrometry service (Swansea) for high resolution mass spectra.

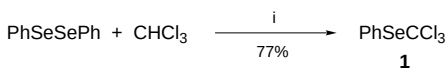
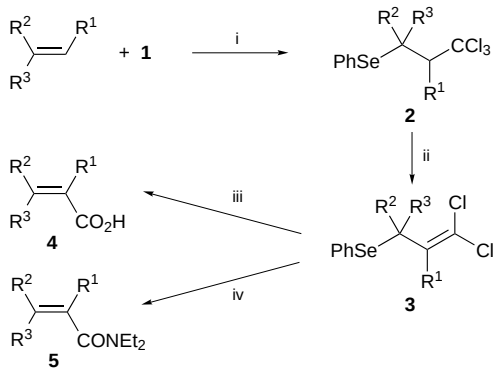
# The free-radical addition of phenyl trichloromethyl selenide to alkenes: a new method for the regioselective carboxylation of alkenes

**Thomas G. Back* and Kazimierz Minksztym**



*Department of Chemistry, University of Calgary, Calgary, AB, Canada, T2N 1N4*

**The free-radical addition of phenyl trichloromethyl selenide to alkenes affords 2-phenylseleno-1-trichloromethylalkanes, which can be converted into α,β-unsaturated carboxylic acids or amides by base-promoted dehydrochlorination, followed by [2,3]sigmatropic rearrangement of the corresponding selenoxides in the presence of water or diethylamine, respectively.**



Free-radical 1,2-additions of selenium compounds of general structure PhSeX to alkenes and alkynes[1] provide a synthetically useful means for introducing the versatile phenylseleno group, as well as an additional functionality [*e.g.* X = $SO_2Ar$,[2] SePh,[3] C(=O)R,[4] SC(=O)Ph,[5] and $CHZ_2$,[6] where Z is an electron-withdrawing group] into the substrates. Free-radical additions of perhaloalkanes such as bromotrichloromethane are also well known.[7] Moreover, PhSe group transfers to alkyl radicals occur with rates comparable to those of bromine atom transfers,[8] suggesting that phenyl trichloromethyl selenide **1**[9] should undergo free-radical additions similar to those of bromotrichloromethane. We now report the novel photo-initiated or thermally initiated radical additions of **1** to alkenes, followed by some illustrative further transformations of the trichloromethyl and phenylseleno moieties that permit the overall conversion of the alkene into the corresponding α,β-unsaturated carboxylic acid (or amide), as shown in Scheme 1. Other methods for the carboxylation of alkenes generally require the presence of activating substituents to permit deprotonation of the alkene, or an existing functionality (*e.g.* halide, stannane) that provides a site for metallation, followed by reaction with carbon dioxide or

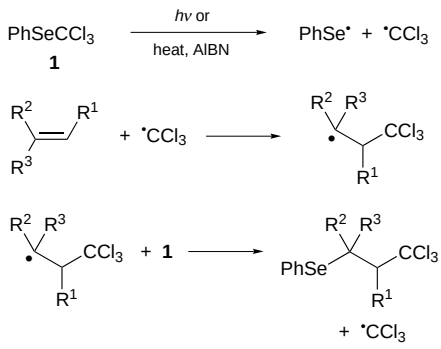
**Table 1** Addition of **1** to alkenes[a]

| Alkene | Product | Yield (%) | *t*/h |
|---|---|---|---|
|  |  **2a** | 88 | 12 |
| | | 62[b] | 60 |
| | | 78[c] | 25 |
|  |  **2b** | 75 | 13 |
|  |  **2c** | 81 | 5 |
|  |  **2d** | 65 | 13 |
|  |  **2e** | 69 | 12 |
|  |  **2f** | 60[d] | 19 |
|  | **2f** | 54[e] | 12 |
|  |  **2g** | 43 | 17 |
|  |  **2h** | 63[f] | 24 |
|  |  **2i** | 87 | 19 |

[a] All reactions were performed neat using photo-initiation and 5 equiv. of the alkene unless otherwise noted; isolated yields are reported. [b] Only 1.5 equiv. of the alkene was used. [c] Performed in benzene at 80 °C with 10 mol% of AIBN. [d] The diastereomeric ratio was 3.8 : 1, as determined by NMR integration. [e] The diastereomeric ratio was 4.2 : 1, as determined by NMR integration. [f] The *cis* : *trans* ratio was 1 : 1.8, as determined by NMR integration.

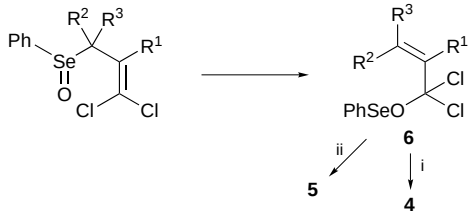
one of its synthetic equivalents.[10] The present method permits the use of unactivated olefins.

Selenide **1** was conveniently prepared by a new method from the base-catalysed reaction of diphenyl diselenide with $CHCl_3$ (Scheme 2). Thus, a mixture of the diselenide, a catalytic amount of Adogen 464® (methyltrialkylammonium chloride), 50% aqueous NaOH and $CHCl_3$ was stirred for 9 h at 15–20 °C, while air was bubbled through the reaction mixture to recycle the byproduct selenolate ($PhSe^-$). The product was isolated in 77% yield by flash chromatography.



The free-radical 1,2-addition of **1** to various alkenes to give **2** was then effected as shown in Scheme 3 and Table 1. Monosubstituted alkenes afforded adducts **2a**–**e** with only traces ( < 5%) of their corresponding regioisomers, as indicated by NMR analysis. Both *cis*- and *trans*-dec-5-ene produced **2f** as the same *ca*. 4 : 1 mixture of diastereomers. Cyclohexene furnished a mixture of *cis* and *trans*-adducts **2h** in a ratio of 1 : 1.8. Thus, the additions are highly regioselective, but only moderately stereoselective. β-Pinene underwent ring-opening during the addition to afford the rearranged 1,6-adduct **2i**. In general, the reactions were performed by irradiation of the reaction mixture, either neat or in benzene solution, containing an excess (usually five-fold) of the alkene with a 300 W incandescent lamp. The use of a smaller excess of the alkene resulted in lower yields and required longer reaction times. The reaction was also performed in the case of **2a** in benzene at 80 °C in the presence of 10 mol% of the radical initiator AIBN. These results suggest a free-radical chain process in which cleavage of the Se–$CCl_3$ bond initiates the reaction, followed by addition of the trichloromethyl radical to the less substituted alkenic atom, and finally transfer of the PhSe group from **1** to the resulting 2-alkyl radical (Scheme 4).

Several of the adducts **2** were then transformed into allylic selenides **3** by dehydrochlorination with $KOBu^t$ in THF at −30 °C (except for **3f**, which required 6 h at 10 °C), and finally into α,β-unsaturated carboxylic acids **4** by oxidation and *in situ* [2,3]sigmatropic rearrangement (Scheme 3) of the resulting selenoxides.[11] Products **4a**, **4b** and **4f** were obtained as the *E*-isomers with high stereoselectivity. When $Et_2NH$ was present during the latter step, the corresponding diethylamides were obtained instead. These results are shown in Table 2. Presumably, the sigmatropic rearrangement produces **6** initially, which then hydrolyses to the carboxylic acid **4** (Scheme 5). On the other hand, **6** reacts preferentially by aminolysis in the presence of diethylamine to afford the amide **5** instead of **4** after aqueous workup.



All new compounds reported here gave IR, $^1H$ NMR, $^{13}C$ NMR and low and high resolution mass spectra consistent with their structures.

These results demonstrate that the free-radical additions of readily available selenide **1** to alkenes occur efficiently and with high regioselectivity. Moreover, when the above process was used in conjunction with base-promoted dehydrochlorination and [2,3]sigmatropic rearrangement of the corresponding selenoxides, a novel method for the overall regioselective carboxylation of alkenes was achieved.

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support.

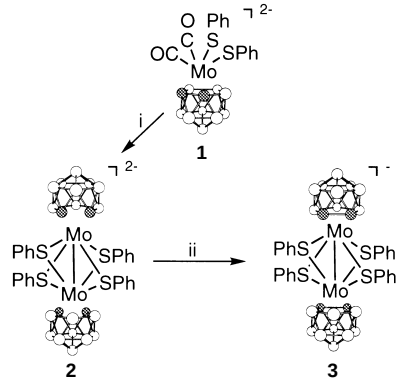
# First tetrathiolate-bridged dinuclear molybdacarbaboranes: scission and formation of the C–C cluster bond during oxidation processes

**Jae-Hak Kim, Mouad Lamrani, Jeong-Wook Hwang and Youngkyu Do***

*Department of Chemistry and Center for Molecular Science, Korea Advanced Institute of Science and Technology, Taejon 305-701, Korea*



**Unprecedented tetrathiolate-bridged dinuclear ionic molybdacarbaboranes $[(C_2B_9H_{11})Mo(SPh)_2]_2^{n-}$ ($n$ = 2, 1) are prepared by successive oxidation of $[(C_2B_9H_{11})Mo^{II}(CO)_2(SPh)_2]^{2-}$ with diphenyl disulfide and iodosylbenzene: X-ray crystal structure determinations and NMR studies show unusual scission and reformation of the C–C carbaborane cage bond.**

We have recently demonstrated that the dicarbabollide anion [*nido*-7,8-$C_2B_9H_{11}]^{2-}$ is useful in synthesizing high oxidation state molybdenum oxo complexes.[1] In particular, the mononuclear thiolatomolybdacarbaborane $[(C_2B_9H_{11})Mo(CO)_2(SPh)_2]^{2-}$ **1**[1] coupled with iodosylbenzene as an oxygen-transfer agent was proven a convenient system in deriving oxometals, raising a possibility of using anion **1** as a synthon in preparing high oxidation state molybdenum thiolate complexes. To pursue this matter, the versatile oxidation reactivity of the synthon **1** has been exploited, leading to the first observation of tetrathiolate-bridged dinuclear molybdacarbaboranes $[(C_2B_9H_{11})Mo(\mu\text{-}SPh)_2]_2^{n-}$ ($n$ = 2 **2**, $n$ = 1 **3**) involving unusual scission and formation of the C–C bond of the unsubstituted carbaborane cage during oxidation processes.

Oxidation of a red solution of 0.5 mmol $[N(PPh_3)_2]_2$ **1** in 30 ml of MeCN with excess diphenyl disulfide (0.7 mmol) under refluxing for 24 h causes gradual precipitation of yellow product $[N(PPh_3)_2]_2$ **2**† (Scheme 1, path i) in 41% yield upon recrystallization from dmf–$Et_2O$. The dianionic **2** can be further oxidized to mixed-valence monoanionic **3** using PhIO [Scheme 1, path ii): treatment of a dmf solution (30 ml) of 0.1 mmol $[N(PPh_3]_2]_2$ **2** with six fold excess of PhIO at 100 °C for 24 h, filtration and addition of $Et_2O$ to the concentrated filtrate gave rise to a black precipitate. Recrystallization from dmf–$Et_2O$ yielded analytically† pure black crystalline $[N(PPh_3)_2]$ **3** in a yield of 74%. The use of $Br_2$ instead of PhIO also affords the monoanionic **3** in 66% yield.

The structures‡ of **2** (Fig. 1) and **3** (Fig. 2) are seen to be based on discrete dimers oriented about a crystallographic inversion center. In both compounds, four bridging thiolate groups are arranged such that two planar MoSMoS rhombi are perpendicular to each other, the MoS(1)Mo′S(1′) plane bisects the cage C···C vector and the overall symmetry lacks a mirror plane. The observation of two well resolved singlets at $\delta$ 3.63 and 3.92 for carbaboranyl protons in the $^1$H NMR spectrum of diamagnetic **2** in $(CD_3)_2SO$ at 23 °C is consistent with the expected magnetic inequivalency of two carboranyl CH protons. For **3**, similar observation was hampered by its paramagnetism ($\mu$ = 1.70 $\mu_B$). It is interesting to note that at elevated temperature **2** becomes fluxional and two carboranyl CH proton signals coalesce at 93 °C, suggesting that the free energy of activation associated with the fluxional motion of **2** is 74.2 kJ mol$^{-1}$ which is comparable to those of other thiolate bridged dimers $[Fe_2(CO)_6(\mu\text{-}SBu^t)_2]_2$[2] (77 kJ mol$^{-1}$) and $[W_2O_2Cl_4(\mu\text{-}Cl)(\mu\text{-}SBu^i)_2]^-$[3] (75 kJ mol$^{-1}$) where inversion[4] at the three-coordinate bridging sulfur atoms is operative.

The $C_2B_9Mo$ cage geometry in **2** is derived by the scission[5] of the C(1)–C(2) cage bond [C(1)···C(2), 2.55(6) Å] with concomitant movement of B(6) toward the molybdenum atom. The absence of the coupling peaks of carboranyl CH protons in the $^1$H–$^1$H COSY NMR spectra of **2** is in good agreement with the X-ray structure. On the other hand, the $C_2B_9Mo$ cage geometry in **3** is dictated by the formation of the C(1)–C(2) cage bond [1.65(2) Å]. The scission and the formation of the unsubstituted carbaborane C–C bond upon successive oxidation

**Scheme 1** Synthesis of $[N(PPh_3)_2]_2[(C_2B_9H_{11})Mo(SPh)_2]_2$ and $[N(PPh_3)_2][(C_2B_9H_{11})Mo(SPh)_2]_2$. *Reagents*: i, PhSSPh ; ii, 6PhIO.

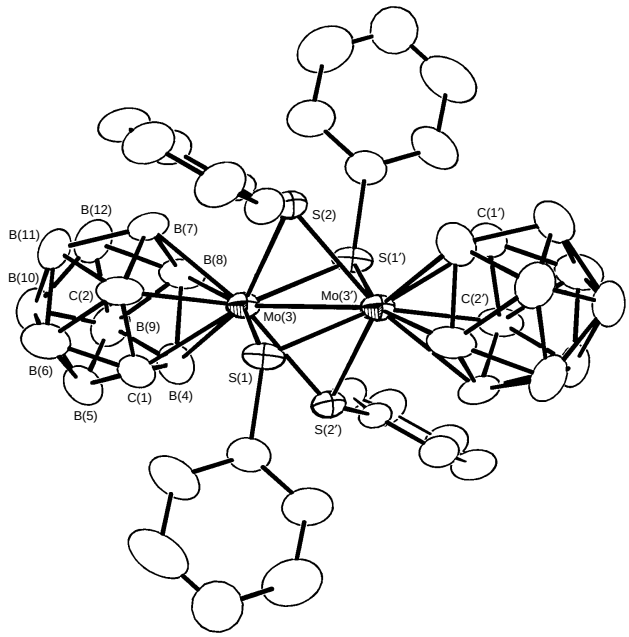

**Fig. 2** ORTEP drawing of the $[(C_2B_9H_{11})Mo(SPh)_2]_2^-$ monoanion. Selected bond distances (Å) and angles (°): Mo(3)–Mo(3′) 2.725(2), C(1)–C(2) 1.65(2), Mo(3)–C(1) 2.311(10), Mo(3)–C(2) 2.336(10), Mo(3)–B(4) 2.391(11), Mo(3)–B(6) 3.680, Mo(3)–B(7) 2.394(12), Mo(3)–B(8) 2.452(14), Mo(3)–S(1) 2.453(3), Mo(3)–S(1′) 2.485(3); C(1)–Mo(3)–C(2) 41.7(4), S(1)–Mo(3)–S(1′) 113.01(8), S(1)–Mo(3)–Mo(3′) 57.06(7).

processes, which constitutes the first example of its kind, are quite fascinating since it has often been surmised[5] that the presence of bulky and electron rich exo-cluster substituents at the cage carbon atoms induces the breaking of the C–C cage bond. It is interesting that the two-electron reduction of $[PtW(CO)_2(PEt_3)_2\{\eta^6\text{-}C_2B_9H_8(CH_2C_6H_4Me\text{-}4)Me_2\}]$,[6] where the carbaborane C atoms are both substituted, causes the $WC_2B_9$ framework change from open to closed geometry with an exopolyhedral B(3)–Pt σ–bond formation ($[PtW(\mu\text{-}H)\{\mu\text{-}\sigma,\eta^5\text{-}C_2B_9H_7(CH_2C_6H_4Me\text{-}4)Me_2\}(CO)_2(PMe_3)(PEt_3)_2]$). In our case, **2** was oxidized by a one-electron process and no rearrangement of the complex backbone has occurred. Additionally, the **2** and **3** are intriguing since no mixed metallacarbaboranes with bridged thiolate ligands have yet been reported in spite of the observation that the thiolate group bridging ligands have been previously shown to provide stable di- and poly-nuclear molybdenum compounds.[7–12]

The *closo* $MoC_2B_9$ icosahedal framework in the oxidized derivative **3** suggests that the $C_2B_9H_{11}$ cages in **3** behave as *nido* dianionic ligands. Therefore, the observed paramagnetism is consistent with the expected mixed $Mo^{III}Mo^{IV}$ valence for **3**. The closely interrelating features of the deltahedron nature[13] of the $MoC_2B_9$ cages and the oxidation states of the metal centers in **2** remain to be clarified. The straightforward availability of these stable compounds from the dicarbabollide and thiolate ligands may make similar classes of compounds accessible for further investigations, such as connecting the two carbon cage atoms by various bridging aliphatic groups [-$(CH_2)_n$-; $n$ = 3, 4] and in particular, tungsten homologue insertion reactions. We are currently investigating this possibility along with the XPS, electrochemical and electronic spectral studies on anions **2** and **3** to clarify the effects of electronic densities in these types of systems.

Support of this work by the Korea Science and Engineering Foundation is gratefully acknowledged.

Reflection data were collected on an Enraf-Nonius CAD4TSB diffractometer with graphite-monochromated Mo-Kα radition at 293 K. Accurate cell parameters and orientation matrices for **2** and **3** were determined from the least-square fit of 25 accurately centered reflections in the range of $20.48 \leqslant 2\theta \leqslant 28.64$ and $16.63 \leqslant 2\theta \leqslant 26.67$, respectively. All data were collected with the $\omega$–$2\theta$ scan mode and corrected for $L_p$ effects. ψ-Scan absorption correction was applied. The structure compounds was solved by Patterson's heavy-atom methods (SHELXS-86).[14] Non-hydrogen atoms were refined by full-matrix least-square techniques (SHELXL-93)[15] with anisotropic displacement parameters. The phenyl rings were refined as rigid groups with fixed bond lengths ($d_{CC}$ = 1.390 Å) and angles (120.0°). Phenyl hydrogen and carbaboranyl hydrogen atoms, except for two hydrogens bonded to carbon atoms of carbaboranyl groups in $[N(PPh_3)_2]_2$ **2**, were placed at their geometrically calculated positions ($d_{CH}$ = 0.930 Å for phenyl and $d_{BH}$ = 1.100 Å for carbaboranyl) and refined riding on the corresponding carbon atoms with isotropic thermal parameters [$U$ = 1.2 $U(C_{phenyl})$ and 1.2 $U(B_{carbaboranyl})$]. CCDC 182/552.

# Preparation and characterisation of a dithiadiazolyline complex: X-ray crystal structure of $[Pd_2\{\mu\text{-SNC(Ph)N(H)S-}S,S'\}(dppe)_2][BF_4]_2\cdot 3CDCl_3$

**Arthur J. Banister,[a] Judith A. K. Howard,[a] Iain May[a] and Jeremy M. Rawson*[b]**

[b] *Department of Chemistry, The University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

**While the protonated dithiadiazolyl compound, PhCNSSNH 1 is unknown, oxidation of $[Pd(dppe)_2]$ with $[PhCNSSN]_2$ yields the monometallic complex [Pd{SNC(Ph)NS-*S*,*S*′}(dppe)] 2 which can be oxidized with $[NO][BF_4]$ in the presence of moisture to yield the dimetallic complex $[Pd_2\{\mu\text{-SNC(Ph)N(H)S-}S,S'\}(dppe)_2][BF_4]_2$ 3 which contains coordinated 1; the X-ray crystal structure of 3 is reported as its solvate $3\cdot 3CDCl_3$.**

Previously we have reported a series of dithiadiazolyl metal complexes[1–6] containing one, two or three metal centres. In the monometallic compounds, the dithiadiazolyl ligand ring-opens at the S–S bond and chelates the metal, *e.g.* $[Pt\{SNC(Ph)NS\text{-}S,S'\}(PPh_3)_2]$, whereas in the di- and tri-metallic complexes the dithiadiazolyl ligand bridges two metal centres, *e.g.* as in $[Ni_2(\eta\text{-}C_5H_5)_2\{\mu\text{-SNC(Ph)NS-}S,S'\}]$ and $[Pt_3\{\mu\text{-SNC(Ph)NS-}S,S'\}_2(PPh_3)_4]$. The versatility of this ligand is exemplified by the number of electrons which it can utilise for metal bonding; two to three electrons in the chelate mode and five or six electrons in the μ,μ-bridging mode. Recent NMR and IR studies (coupled with the absence of an EPR signal)[7,8] on the related complex $[Fe_2(CO)_6\{\mu\text{-SNC(Ph)NS-}S,S'\}]$ indicated that this complex had been protonated on the ring N and should be more correctly formulated as $[Fe_2(CO)_6\{\mu\text{-SNC(Ph)N(H)S-}S,S'\}]$. The free ligand, PhCNSSNH **1**, itself is unknown and we have been intrigued by the possibility of forming other complexes containing this species. We now report the synthesis of the first monometallic palladium dithiadiazolyl compound, [Pd{SNC(Ph)NS-*S*,*S*′}(dppe)] **2** in which the monometallic structure is stabilised through the presence of the chelating diphosphine dppe, and describe its reaction with $[NO][BF_4]$, in the presence of adventitious moisture, to yield the dimetallic palladium dithiadiazolyline complex, $[Pd_2\{\mu\text{-SNC(Ph)N(H)S-}S,S'\}(dppe)_2][BF_4]_2$ **3**.

Oxidative addition[3] of $(PhCNSSN)_2$ to $[M(PPh_3)_4]$ (M = Pt, Pd) yielded the trimetallic complexes, $[M_3\{\mu\text{-SNC(Ph)NS-}S,S'\}_2(PPh_3)_4]$. When M = Pt, this was shown to proceed *via* the monometallic complex $[M\{SNC(Ph)NS\text{-}S,S'\}(PPh_3)_2]$, but the analogous Pd complex could not be detected. We have now found that the chelating phosphine, dppe [1,2-bis(diphenylphosphino)ethane] stabilises the monometallic Pd complex and [Pd{SNC(Ph)NS-*S*,*S*′}(dppe)] **2** can be prepared† in excellent yield by direct reaction of $(PhCNSSN)_2$ with freshly prepared $[Pd(dppe)_2]$. The unpaired electron in **2** occupies an antibonding orbital based on the metalloheterocyclic framework, of the same symmetry[5] as $[Pt\{\mu\text{-SNC(Ph)NS}\}(PPh_3)_2]$ and the solution EPR spectrum of **2** (Fig. 1) exhibits hyperfine coupling to two equivalent N and two equivalent P nuclei, plus satellites for the low-abundance $^{105}Pd$ isotope (22%, $I$ = 5/2).

The antibonding character of the singly occupied molecular orbital,[5] and the electron-rich (16/17e$^-$) nature of the metal centre, indicated that one-electron oxidation of **2** should be facile. Preliminary electrochemical investigations on **2** showed three irreversible oxidations with half-wave potentials at −0.10, +0.30 and +1.12 V (referenced to the SSCE). Chemical oxidation‡ of **2** with 1 equiv. of $[NO][BF_4]$ in acetonitrile produced two products, by $^{31}P$ NMR, of which the major product [two doublets at $\delta$ 56.6 and $\delta$ 52.9 ($J_{PP}$ 28 Hz)] fortuitously crystallised from $CDCl_3$ and was found to be the dithiadiazolyline complex, $[Pd_2\{\mu\text{-SNC(Ph)N(H)S-}S,S'\}(dppe)_2][BF_4]_2$ **3**. Protonation at the heterocyclic nitrogen due to reaction with moisture renders the phosphorus environments inequivalent, resulting in a pair of doublets in the $^{31}P$ NMR

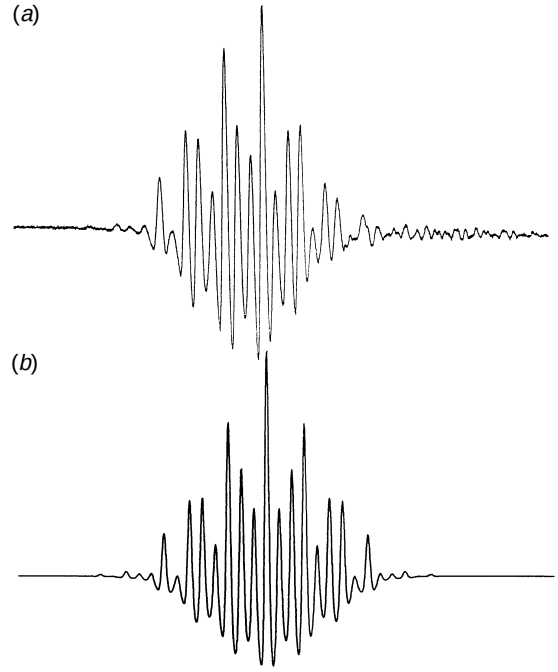

**Fig. 1** Solution EPR spectra of **2** in $CH_2Cl_2$ at room temp; (*a*) experimental, (*b*) simulation; $g$ = 2.031, $a_N$ = 5.7 G, $a_P$ = 3.8 G, $a_{Pd}$ = 37.2 G, $\Delta B_{PP}$ = 1.0 G

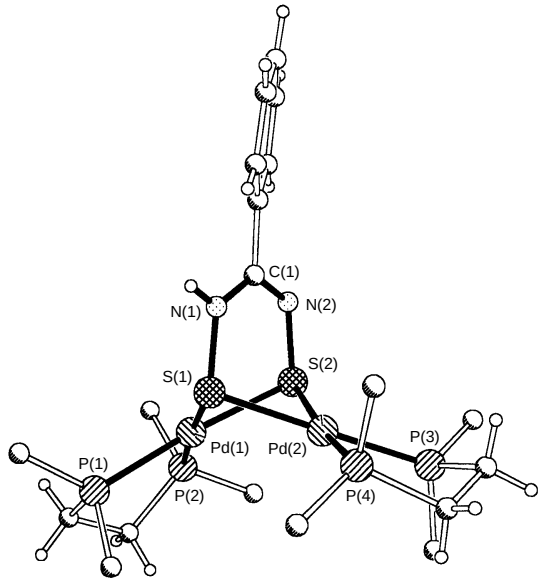

**Fig. 2** Structure of the dication in **3** (phosphine phenyl C atoms not bonded to P are removed for clarity). Further selected bond lengths (Å): Pd(1)–P(1) 2.305(2), Pd(1)–P(2) 2.283(2), Pd(2)–P(3) 2.283(2), Pd(2)–P(4) 2.297(2), Pd(1)–S(1) 2.351(2), Pd(1)–S(2) 2.352(2), Pd(2)–S(1) 2.354(2), Pd(2)–S(2) 2.384(2), N(1)–S(1) 1.690(6), N(2)–S(2) 1.683(6).

spectrum. The mass spectrum (FAB) shows a molecular ion peak at *m/z* 1191.6 consistent with ring-protonation {$[Pd_2\{\mu$-SNC(Ph)N(H)S-*S*,*S*′}$(dppe)_2]^{2+}$ has a formula mass of 1191.8}. Compound **3** gave satisfactory microanalytical data, an N–H absorption in the IR (3205 $cm^{-1}$) and was EPR inactive. The minor product, observed as a singlet at $\delta$ 59.6 in the $^{31}P$ NMR, has not been characterised.

The structure§ of the salt **3** was determined by X-ray crystallography and was found to crystallise as a $CDCl_3$ solvate, **3**·3$CDCl_3$. The structure of the dication in **3** is shown in Fig. 2. It consists of two approximately square-planar Pd atoms bridged by the two sulfur atoms of a protonated dithiadiazolyl ligand, with each Pd chelated by a dppe ligand. The bidentate nature of both $P_2$ and $S_2$ donor sets induces SPdS and PPdP bond angles to be less than the idealised 90° and the strain is accommodated by the Pd atoms which sit approximately 0.1 Å above the $P_2S_2$ mean plane. The Pd···Pd contact [3.0687(8) Å] is longer than the sum of the metallic radii (2.76 Å) and is unsurprising since no Pd–Pd bond is necessary to satisfy the bonding requirements of either metal (see below). Within the heterocyclic ring, the S–S bond is formally broken to accommodate the two metal ions [*cf.* 3.106(2) in **3** and 2.089(5) Å in the free ligand[9] $(PhC\overline{NSSN})_2$]. This ring-opening is accompanied by marked increases in the bond angles at C and N {128.8(7), 129.3(5) and 125.7(5)° at C(1), N(1) and N(2), respectively, *cf.* 121 and 116° for the free ligand $(PhC\overline{NSSN})_2$}. Although the location of the N–H proton could not be unambiguously determined from the X-ray data, an analysis of the heterocyclic bond lengths and angles clearly supports a more localised structure with protonation at N(1); within **3** the bond angle at N(1) is notably larger than that at N(2) and the C(1)–N(1) bond length is marginally (3 esds) longer than C(1)–N(2). In addition, the close approach of one of the $BF_4^-$ counter ions to N(1) [N(1)···F(21) at 2.82 Å] can be rationalised in terms of an N–H···F hydrogen bond.

The combined crystallographic and spectroscopic evidence, clearly support the presence of a protonated dithiadiazolyl ligand. Electronically, the protonated dithiadiazolyl ligand acts as a six-electron donor, each sulfur forming a σ bond to one Pd and a dative bond to the second Pd. Thus each Pd formally has a 16-electron configuration (ten valence electrons, four from the chelating phosphine, three from the dithiadiazolyline ligand, less one to accommodate the doubly positive charge on the ion) which is consistent with the observed square-planar geometry.

These results provide the first example of a monometallic Pd dithiadiazolyl complex (**2**) and also provide conclusive spectroscopic and structural evidence for the existence of dithiadiazolyline complexes. Compound **3** provides the first experimental evidence for a dimetallic intermediate in the formation of the trimetallic Pt and Pd complexes from the corresponding monometallic dithiadiazolyl derivatives. The exact source of protonation of the dithiadiazolyl ligand in **3** is presently unclear, although it is evident that the presence of adventitious moisture, as in the synthesis of $[Fe_2(CO)_6\{\mu$-SNC(Ph)NS-*S*,*S*$\}]$ could also play a role here. The $^{31}P$ NMR spectrum clearly indicates the protonation occurs readily at an early stage in the reaction and not during the slow recrystallisation process.

We would like to thank the EPSRC for a studentship (I. M.) and Dr R. C. B. Copley for able assistance with crystallographic data collection and Mr J. N. B. Smith for further characterisation of compound **3**.

# Three procedures of reversible dissolution/deposition of gold using halogen-containing organic systems

**Yukimichi Nakao**

*National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba, Ibaraki 305, Japan*

**Gold is reversibly and repeatedly dissolved and deposited under restricted conditions in a solution consisting of an elemental halogen, a halide and acetonitrile by a procedure involving one of three physical operations: addition of methanol, cooling, or evaporation to dryness.**

Most organic and inorganic substances are 'physically' dissolved in aqueous or organic media, and hence are often recovered from solution by means of physical operations such as (*i*) addition of non-solvent, (*ii*) cooling, or (*iii*) evaporation (to concentrated solutions or dryness), which results in deposition.[1,2] On the other hand, metals are 'chemically' dissolved as metal ions. Therefore, it has been believed that an appropriate reductive treatment is necessarily required to recover them in the metallic state.

We reported new organic solvent systems consisting of an elemental halogen ($X_2$), a halide ($X^-$), and an organic solvent (organic–X systems, X = Cl, Br, I), which dissolve a number of metals including noble metals.[3] It is found that metallic gold is deposited in solutions of some organic–X systems, which are previously saturated with gold, not by chemical treatment but by each of the physical operations (*i*)–(*iii*), and that gold is dissolved in solutions obtained from the resulting supernatants or residues. UV–VIS spectroscopy confirmed that such reversible dissolution/deposition of gold is, in most cases, a chemical process based on the following disproportionation equilibrium.[4]

$$3Au^+ \rightleftharpoons 2Au + Au^{3+} \quad (1)$$

Shifts to right and left in this equilibrium correspond to the deposition and dissolution of gold, respectively.

Three typical procedures of repeated dissolution/deposition of gold involving each of the operations were carried out in selected organic–X systems containing acetonitrile (AN). Dissolution of gold was performed using an excess amount of gold wire of 0.2 mm diameter under refluxing, and deposition of

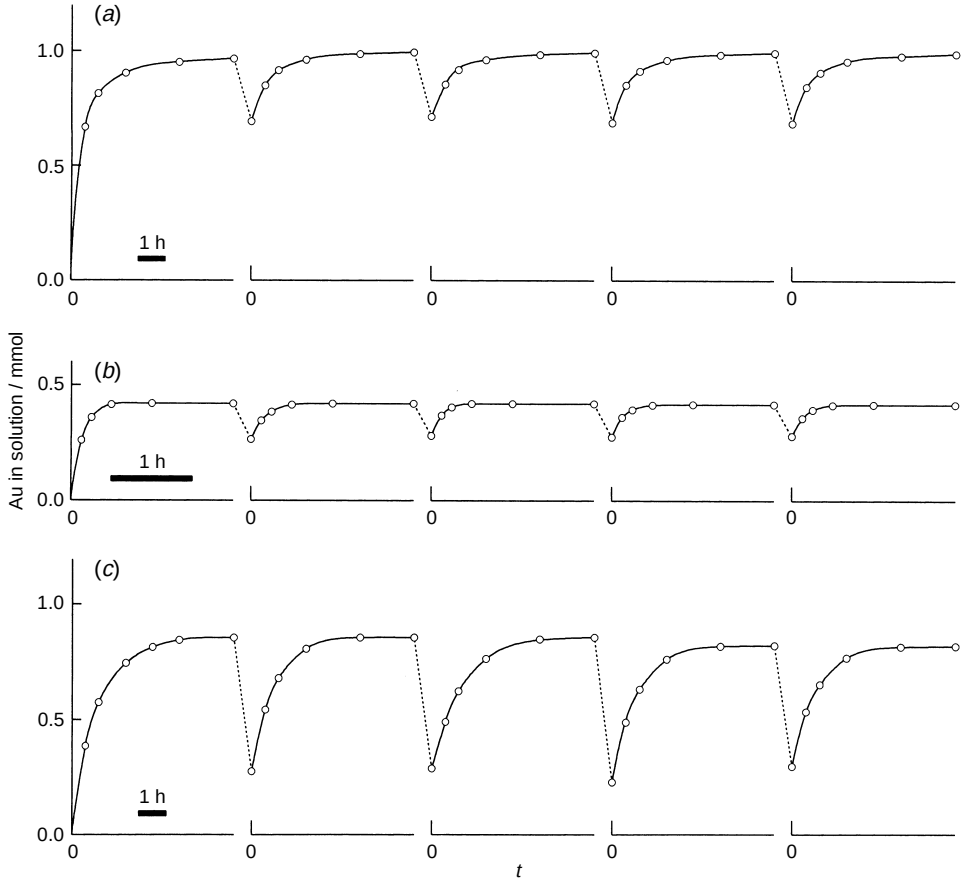

**Fig. 1** Time-course of gold content in the solutions during repeated dissolution/deposition of gold using (*a*) $Br_2$ (0.5 mmol)–[$NEt_4$]Br (1 mmol)–AN (2 g), (*b*) $I_2$ (1 mmol)–[$NEt_4$]I (1 mmol)–AN (10 g) and (*c*) $I_2$ (0.5 mmol)–NaI (1 mmol)–AN (2 g): dissolution of gold was carried out under refluxing at 82 °C. Each of the gold-saturated solutions was treated by (*a*) adding methanol (8 g), heating at 60 °C for 2 h, the supernatant was evaporated to dryness, and the residue was redissolved in An (2 g), (*b*) cooling to 20 °C and allowing to stand overnight or (*c*) evaporating to dryness, and the residue was redissolved in AN (2 g). The broken lines correspond to reduction in gold content in the solutions upon deposition of gold.

gold was carried out by adding methanol to the solution, cooling it, or evaporation to dryness. Amounts of gold in the solutions were determined by weighing the residual gold wire and the deposited gold. The contents of Au species in the solutions were evaluated by UV–VIS spectra which were measured using thin liquid films (8 or 200 μm thickness) on the basis of the characteristic bands of each species: $[AuBr_2]^-$ (192, 200, 212 nm), $[AuBr_4]^-$ (256, 395 nm), $[AuI_2]^-$ (217 nm) and $[AuI_4]^-$ (510, 670 nm).

First, deposition of gold was caused by adding methanol to gold-saturated solutions from organic–X systems in which the ratio $X_2/X^-$ was near to 0.5. The supernatant was then evaporated to dryness to give a residue, which was redissolved in AN, and the resulting solution, after separation from the deposited gold, was used for the next dissolution of gold. Fig. 1(*a*) shows a procedure of repeated dissolution/deposition of gold involving addition of methanol using an organic–Br system consisting of $Br_2$ (0.5 mmol), $[NEt_4]Br$ (1 mmol), and AN (2 g). The following equilibrium is proposed on the basis of UV–VIS spectra of the solutions before and after dissolution of gold.

$$3[NEt_4][AuBr_2] \rightleftharpoons 2Au + [NEt_4][AuBr_4] + 2[NEt_4]Br \quad (2)$$

A similar dissolution/deposition of gold occurred in gold saturated solutions of either organic–Cl systems or organic–I systems. In the latter, another equilibrium as given below seems to be involved, since the $Au^{3+}$ species was not detected.

$$2[NEt_4][AuI_2] \rightleftharpoons 2Au + [NEt_4]I_3 + [NEt_4]I \quad (3)$$

Although the methanol is apparently likely to act as non-solvent, it would actually shift the disproportionation equilibrium to the right as well as water.[4]

Second, as recently reported,[5] gold is deposited by cooling gold-saturated solutions of organic–I systems in which the $I_2/I^-$ ratio was $> 0.5$. Such deposition of gold was not observed in the solutions of either organic–Cl or organic–Br systems. The supernatants could be used for further dissolution of gold at elevated temperatures. Fig. 1(*b*) illustrates a procedure of repeated dissolution/deposition of gold using a system consisting of $I_2$ (1 mmol), $[NEt_4]I$ (1 mmol), and AN (10 g), which involves alternating heating and cooling. The following equilibrium has already been proposed for this process.[5]

$$3[NEt_4][AuI_2] + 2I_2 \rightleftharpoons 2Au + [NEt_4][AuI_4] + 2[NEt_4]I_3 \quad (4)$$

Third, gold was deposited in solutions from certain organic–I systems by concentrating the solution. It was reported that, when the ratio $I_2/I^-$ is 0.5 and the cation of the iodide is $[NEt_4]^+$, evaporation of the gold-saturated solution gives an $Au^+$ complex, $[NEt_4][AuI_2]$.[5] On the contrary, when the cation was an alkali-metal ion or an alkaline-earth metal ion, gold was deposited as the solution was concentrated by evaporation. After AN was completely removed, the resulting tarry residue was redissolved in AN, and the solution to be used again for dissolution of gold was separated from the deposited gold as quickly as possible. Fig. 1(*c*) shows a procedure using a system consisting of $I_2$ (0.5 mmol). NaI (1 mmol), and AN (2 g), involving deposition of gold by evaporation. In this case, the $Au^{3+}$ species, $[AuI_4]^-$, was confirmed to be formed with deposition of gold. Thus, the equilibrium for this process would be as follows.

$$3Na[AuI_2] \rightleftharpoons 2Au + Na[AuI_4] + 2NaI \quad (5)$$

Dissolution/deposition of gold in the procedures stated above were all reversible and the efficiency of dissolution of gold was maintained constant throughout although a definite amount of gold still remained dissolved in the solution after deposition of gold. These procedures can be expected to be applied to a completely closed gold-recovering process which is very useful for the extraction of gold from ores and wastes of electronics industries. The gold thus recovered should also be of higher purity.

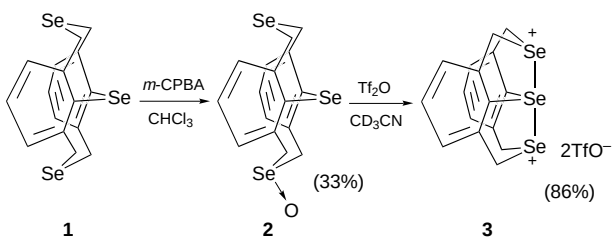
# First molecular and electronic structure determination of the dicationic salt of 1,11-(methanoselenomethano)-5*H*,7*H*-dibenzo[*b*,*g*][1.5]diselenocin by X-ray crystallographic analysis and *ab initio* calculation

**Tsukasa Nakahodo, Ohgi Takahashi, Ernst Horn and Naomichi Furukawa***

*Tsukuba Advanced Research Alliance Center, Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

**The X-ray crystallographic analysis of the dication salt of 1,11-(methanoselenomethano)-5*H*,7*H*-dibenzo[*b*,*g*][1,5]-diselenocin shows that the dication has a selenium atom in a trigonal-bipyramidal bonding environment; an *ab initio* calculation carried out for the dication revealed that the positive charge is exclusively carried by the three selenium atoms.**

Recently, we have reported the synthesis of a selenium-bridged diselenametacyclophane, 1,11-(methanoselenomethano)-5*H*,7*H*-dibenzo[*b*,*g*][1,5]diselenocin **1** and the isolation of its dicationic salt. We also reported the interconvertible redox structural changes resulting from the multicenter chalcogenide interaction between **1** and its dicationic salt as observed by NMR spectra.[1] However, until recently we could not obtain any structural data of the dicationic salt, because of the difficulty of obtaining suitable single crystals. After several recrystallization attempts using different counter anions, we obtained suitable crystals for a detailed X-ray structural analysis, and thus the structure of the dication was determined. Furthermore, the electronic structure of the dication was elucidated by an *ab initio* molecular orbital calculation.



It is of particular interest that a conformational change of the selenoxide **2** occurred in the reaction of **2** with trifluoromethanesulfonic anhydride and triflic anhydride [$(CF_3SO_2)_2O$, $Tf_2O$]; *i.e.*, treatment of **2** with $Tf_2O$ (1 equiv.) in anhydrous $CHCl_3$ under an Ar atmosphere at room temp. resulted in the formation of the dicationic salt **3** (86%) (Scheme 1).†

The crystal structure of dicationic salt **3** was determined by single-crystal X-ray crystallographic analysis (Fig. 1).‡

The X-ray analysis clearly reveals that in the solid state the conformation of **3** is a distorted boat–boat form fixed by the three-center transannular bond between the three selenium atoms.

Although, normally in case of **1** and **2** the chair conformer has been shown to be more stable and rigid than the boat conformer.[1,2] The respective Se···Se distances, 2.645(2) and 2.556(2) Å for Se(1)···Se(2) and Se(2)···Se(3), are longer than the normal Se–Se single bond (2.34 Å) found in diselenides.[3] The Se(1)–Se(2)–Se(3) bond angle of 170.21 (6)° is almost linear, and the $C_{eq}$–Se(2)–$C_{eq}$ bond angle is 95.6(4)°. Thus, the bonding configuration about the seleniun atom is a distorted trigonal-bipyramidal structure with two apical Se–Se bonds, two equatorial Se–C bonds, and the lone-pair electrons occupying the third equatorial position. These structural features are consistent with a selenurane structure.[4]

In order to understand the electronic structure of the dication, we carried out an *ab initio* RHF calculation using the 3-21G(*) basis set.[5] The geometry was optimized with a $C_2$ symmetry constraint, and the optimized $C_2$ structure which is shown in Fig. 2 was confirmed to be a true minimum by a vibrational analysis. The calculated structure is in reasonably agreement with the X-ray determined structure.

**Scheme 1**

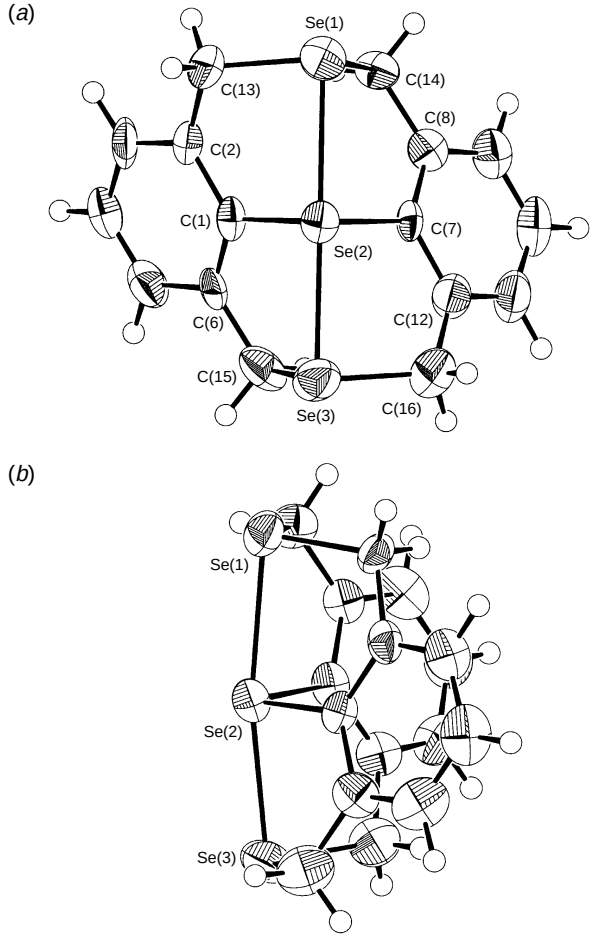


**Fig. 1** Crystal structure of dication **3**. (*a*) View from above. (*b*) Side-on view. For clarity, triflate anions are omitted. Selected bond lengths (Å) and angles (°) (X-ray): Se(1)–Se(2) 2.645(2), Se(2)–Se(3) 2.556(2), Se(1)–C(13) 1.96(1), Se(2)–C(1) 1.93(1), Se(2)–C(7) 1.962(10), Se(3)–C(15) 1.93(1), C(1)–C(2) 1.42(1), C(1)–C(6) 1.39(1), C(2)–C(13) 1.49(2), C(6)–C(15) 1.51(2); Se(1)–Se(2)–Se(3) 170.21(6), C(1)–Se(2)–C(7) 95.6(4), Se(1)–Se(2)–C(1) 86.5(3), Se(3)–Se(2)–C(1) 86.8(3), Se(2)–C(1)–C(2) 119.5(8), Se(2)–C(1)–C(6) 119.9(8), C(2)–C(1)–C(6) 120(1), C(1)–C(2)–C(13) 121.5(10), C(1)–C(6)–C(15) 122(1), Ce(1)–C(13)–C(2) 113.0(8), Se(3)–C(15)–C(6) 112.0(9).

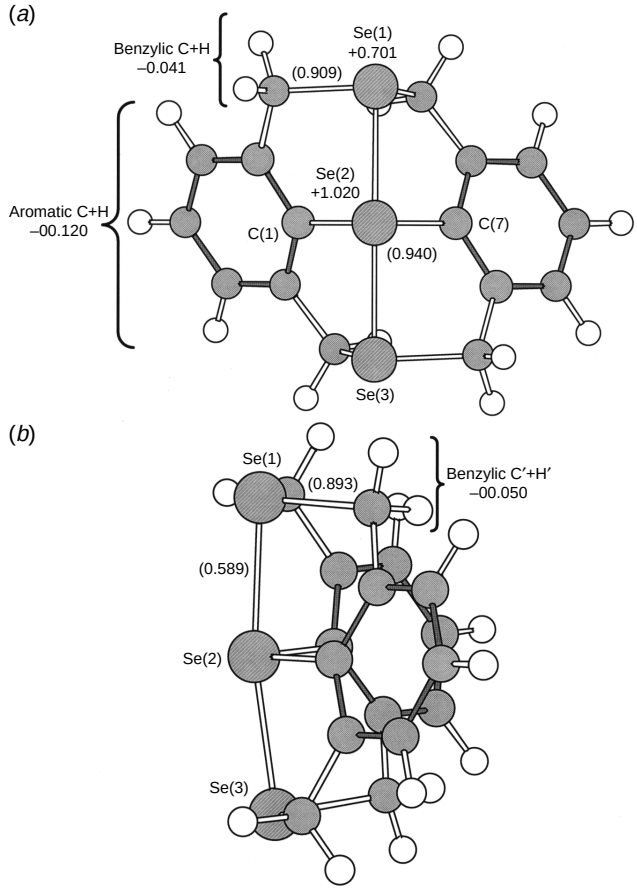

**Fig. 2** The RHF/3-21G(*) optimized structure ($C_2$) of the dication. (*a*) View from above. (*b*) Side-on view. Charge distribution and bond orders (in parentheses) are also shown. Selected bond lengths (Å) and angles (°): Se(1)–Se(2) 2.537, Se(2)–C(1) 1.931; Se(1)–Se(2)–Se(3) 170.2, C(1)–Se(2)–C(7) 98.0, Se(1)–Se(2)–C(1) 86.8, Se(3)–Se(2)–C(1) 86.8.

The charge distribution obtained by natural population analysis (NPA)[6] is shown in Fig. 2. The charge on the central Se atom is +1.020 and those of the apical Se atoms are +0.701, which indicates that the +2 charge is exclusively carried by the three Se atoms. It is surprising that the positive charge is not delocalized onto the benzene rings at all; the rings are slightly negatively charged. The Mulliken bond order of the Se–Se bonds was calculated to be 0.589, while that of the equatorial Se–C bonds was 0.940. The central Se atom carries a more positive charge than the two apical Se atoms, indicating that the two apical Se–Se bonds are highly polarized as in the neutral hypervalent molecules having a three-center-four-electron (3c–4e) bond. The 4d orbital population of the central Se atom is 0.039, which is small and comparable with those of the apical Se atoms (0.026). Thus, the 4d orbitals of the central Se atom are not significantly involved in the 3c–4e bond which is in accordance with the current view of hypervalent molecules.[7] In the 3c–4e model by Rundle[8] and Musher[9] the HOMO (−16.1 eV) and LUMO (−6.4 eV) correspond to the non-bonding and antibonding orbitals respectively, though the HOMO is largely delocalized onto the benzene rings as a result of an interaction between the Se–Se–Se non-bonding orbital and the HOMOs of the benzene rings.

Although the counter ions were not included in the *ab initio* calculation, the calculated structure is in good agreement with the X-ray structure. We think that the electrostatic factor is dominant in the dication–counter ions interaction. It should be noted that the positive charge is exclusively carried by the three Se atoms in the absence of the counter ions; a further accumulation of the positive charge induced by the counter ions is not expected.

We also calculated the two-center dication (boat–chair form). The optimized structure ($C_s$ symmetry) is 27.6 kcal mol$^{-1}$ (1 cal = 4.184 J) higher in energy than the three-center dication; the $Se^+$–$Se^+$ bond length were calculated to be 2.329 Å. The large energy gap between the two-center (boat–chair) and three-center (boat–boat) dications confirms that the dication always assumes a boat–boat form regardless of the environment in which it exists.

In summary, the hypervalent bonding structure of the dication salt of 1,11-(methanoselenomethano)-5*H*,7*H*-dibenzo[*b*,*g*][1,5]diselenocin **1** has been revealed by X-ray crystallographic analysis and *ab initio* calculation. Moreover, it has been shown that the positive charge is exclusively carried by the three Se atoms.

Further studies on related compounds are currently in progress.

# Synthesis and characterization of ordered organo–silica–surfactant mesophases with functionalized MCM-41-type architecture

**Christabel E. Fowler, Sandra L. Burkett and Stephen Mann***

*School of Chemistry, University of Bath, Bath, UK BA2 7AY*

**Ordered organo–silica–surfactant mesophases containing covalently linked functionalized moieties are prepared with MCM-41-type architectures by template-directed co-condensation of tetraethoxysilane and organotrialkoxysilanes $(RO)_3Si–R'$ [R = Me, Et; R′ = $(CH_2)_3SH$, $(CH_2)_3NH_2$, $(CH_2)_3OCH_2CH(O)CH_2$, $(CH_2)_3NCHNCH_2CH_2$ or $CH_2CHCH_2$].**

The synthesis of ordered mesoporous silica materials, MCM-41 (hexagonal symmetry) and MCM-48 (cubic symmetry), and related transition-metal oxide analogues, is a burgeoning field of materials chemistry (for recent reviews see refs. 1–4). Tailoring of these materials for specific applications requires both structural and compositional control. This can be achieved by chemical modification of the reaction constituents or *via* post-synthesis activation of the mesostructured product. In a recent paper,[5] we described a new route to the synthesis of MCM-41-type hybrid mesophases containing covalently linked phenyl or *n*-octyl groups. The basis of this approach was to couple the use of supramolecular surfactant templates with co-condensation reactions involving siloxane (tetraethoxysilane, TEOS) and organosiloxane precursors. TEOS was used as the primary silica source and as a reagent for the formation of fully saturated $Q^4$ linkages which are required to maintain structural integrity in the organo–silica–surfactant mesophase. Here we extend this approach to the direct synthesis of more complex organo–MCM-41-type materials containing covalently linked chemically reactive groups. We show that organosiloxanes containing thiol, amine, epoxide, imidazole or allyl functionalities can be incorporated into ordered hybrid mesophases by cooperative assembly of silicate and organosilicate species at the cationic headgroups of rod-like surfactant micelles.

Organo–silica–surfactant mesophases with MCM-41-type architectures were synthesized at room temp. from alkaline mixtures containing varying molar ratios of TEOS and a functionalized organotrialkoxysilane in the presence of the surfactant, hexadecyltrimethylammonium bromide ($C_{16}$TMABr) (molar composition = 0.12 $C_{16}$TMABr : 0.50 NaOH : 1.0 total siloxane : 130 $H_2O$).† The following functionalized organotrialkoxysilanes $(RO)_3Si–R'$ were used; 3-sulfanylpropyltrimethoxysilane [TTMS, R′ = $(CH_2)_3SH$], 3-aminopropyltriethoxysilane [ATES, R′ = $(CH_2)_3NH_2$], 3-(2,3-epoxypropoxy)propyltrimethoxysilane [EPTMS, R′ = $(CH_2)_3OCH_2CH(O)CH_2$], 3-imidazoletriethoxysilane [IMTES, R′ = $(CH_2)_3NCHNCH_2CH_2$], allyltrimethoxysilane (ALTMS, R′ = $CH_2CHCH_2$). Experiments with ATES and IMTES were repeated using a neutral surfactant, *n*-dodecylamine.[6] In each case, an acidic solvent extraction technique[7] was used to prepare functionalized mesoporous silicas by removal of the surfactant from the as-synthesized materials.

Small-angle X-ray powder diffraction (XRD) (Table 1) and transmission electron microscopy (Fig. 1) indicated that the as-synthesized materials were single phases with mesoscopic order. Samples were generally prepared with 20 mol% of the functionalized organotrialkoxysilane in the initial synthesis composition and gave a series of higher-order XRD peaks which were indexed to organo–silica–surfactant hexagonal mesophases with unit-cell parameters between 40 and 45 Å ($a = 2d_{100}/\sqrt{3}$). Materials prepared using $C_{16}$TMABr were more ordered than those synthesized in the presence of *n*-dodecylamine. Removal of the surfactant by acid extraction gave ordered organo-functionalized mesoporous silicas for the materials derivatized with amino and thiol moieties (Table 1). In each case, contractions in the lattice parameter and loss of the higher order reflections were observed. For the EPTMS, ALTMS and IMTES samples, surfactant extraction appeared to significantly disrupt the ordered mesostructure of the as-synthesized material.

The extent of organotrialkoxysilane incorporation into the mesostructured materials, and the local structure of the organosilica walls were determined by $^{29}$Si MAS NMR of the as-synthesized and post-synthesized materials. Distinct resonances were observed for the siloxane [$Q^n$ = $Si(OSi)_n(OH)_{4-n}$, $n$ = 2–4] and organosiloxane [$T^m$ = $RSi(OSi)_m(OH)_{3-m}$, $m$ = 1–3) units (Table 2). The data indicate that increasing amounts of the organo-functionalized moieties are condensed into the wall structures with increasing mol% in the synthesis composition, but that the yield of incorporation was often low (Table 2). The relative amounts of ($Q^4$ + $T^3$), ($Q^3$ + $T^2$) and ($Q^2$ + $T^1$) species were essentially constant and equal to the respective $Q^4$, $Q^3$ and $Q^2$ contents of a sample prepared from 100 mol% TEOS sample (data not shown), suggesting that the organosiloxane species are distributed uniformly throughout the silica network.

The nature of the organic functional groups incorporated into the ordered mesostructured silica framework was investigated by $^{13}$C CP MAS NMR. The data qualitatively indicated that functional groups such as amine, imidazole, allyl and thiol could be incorporated without significant modification after surfactant extraction (NMR data: ATES, $\delta$ 10.0, 21.3, 43.0; ALTES, $\delta$ 19.8, 115.3, 131.7; IMTES, $\delta$ 9.0, 20.0, 37.1, 45.6, 50.4, 159.3; TTMS, $\delta$ 11.2, 23.0, 41.4). In contrast, the epoxide moiety underwent a ring-opening reaction during the synthesis procedure. Under the highly alkaline conditions employed, the epoxide ring was transformed into a diol terminal group

**Table 1** XRD data for organo–silica–surfactant mesophases

| | XRD *d*-spacings/Å | | | |
|---|---|---|---|---|

[a] Samples prepared using *n*-dodecylamine surfactant. [b] Data from surfactant-extracted samples.

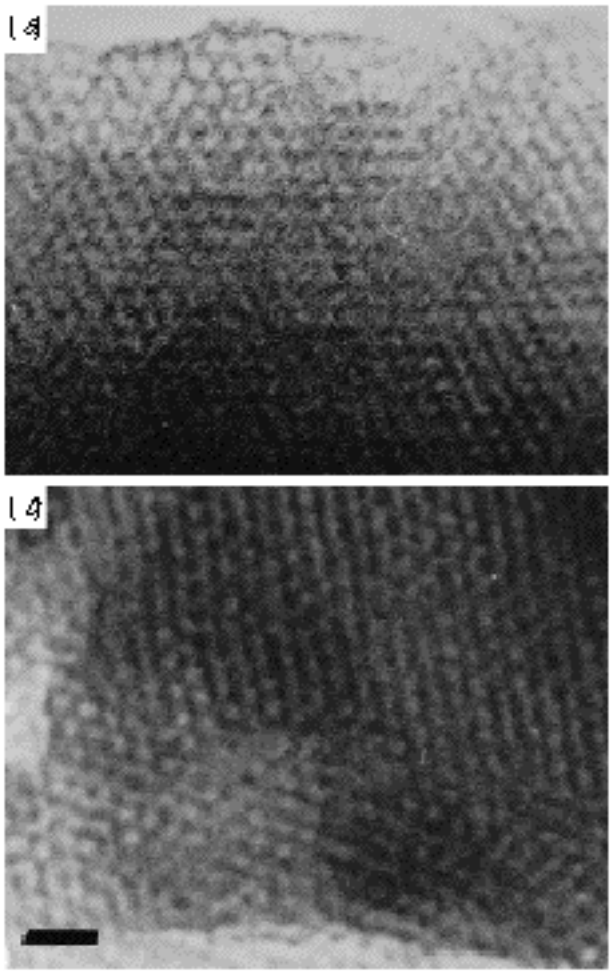

**Fig. 1** TEM micrographs of functionalized organo–silica–surfactant ordered mesophases containing covalently linked (*a*) amino and (*b*) thiol moieties; scale bar = 8 nm in both micrographs

(indicated by the broadening of the two resonances at $\delta$ 67 and 73 in the NMR spectrum of the as-synthesised material). The presence of hydrochloric acid in the surfactant extraction procedure led to further reaction and substitution of the beta hydroxyl group by chloride (NMR data: $\delta$ 46.8, 64.2).

Our results indicate that functionalized organotrialkoxysilanes can be covalently linked into ordered silica mesophases by co-condensation reactions in the presence of surfactant templates. Several different functional groups have been incorporated, suggesting that with appropriate modifications in the synthesis protocol, a wide range of ordered hybrid inorganic–organic frameworks could be prepared by this approach. A vinyl-functionalized MCM-41 has been reported recently.[8] The chemical reactivity of some of these materials is currently under investigation.

The authors would like to thank Dr David C. Apperley at the University of Durham, UK, for the solid-state NMR data, Christine G. Göltner and Ingrid Zenke at the Max Planck Institute of Colloids and Interfaces, Teltow, Germany, for small-angle XRD data, and the EPSRC and University of Bath for financial support.

† In a typical preparation (20 mol% EPTMS), 0.40 g of $C_{16}$TMABr (Aldrich) was dissolved in 5.00 g of 1.0 mol dm$^{-3}$ NaOH and 17.55 g of distilled, deionized $H_2O$. 1.51 g of TEOS (Aldrich) and 0.43 g of EPTMS were added and the solution was stirred for 24 h at room temp. The solid product was filtered, washed with $H_2O$ and dried for 10 h at 100 °C *in vacuo*. ATES, EPTMS, IMTES and TTMS were obtained from Aldrich and ALTMS was obtained from Apollo Sci. Ltd. All compounds were used as received. Extraction of the surfactant was performed by stirring a suspension of the solid product (0.99 g dm$^{-3}$) in 1.0 mol dm$^{-3}$ HCl in EtOH at 75 °C for 24 h. The extracted material was filtered, washed with EtOH and dried for 10 h at 100 °C *in vacuo*. Extraction of the *n*-dodecylamine surfactant was carried out by stirring a suspension of the solid product (0.99 g dm$^{-3}$) in EtOH at 75 °C for 24 h. The extracted material was filtered, washed with EtOH and dried for 10 h at 100 °C *in vacuo*.

# Luminescent gold(I) supermolecules with trithiocyanuric acid. Crystal structure, spectroscopic and photophysical properties

**Biing-Chiau Tzeng,[a] Chi-Ming Che*[a] and Shie-Ming Peng[b]**

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*
[b] *Department of Chemistry, Natonal Taiwan University, Taipei, Taiwan*

**The first example of an ordered array of $Au_6$ clusters with trithiocyanuric acid, $[(LAu)(AuPPhMe_2)_2]_2$ ($H_3L$ = trithiocyanuric acid), is prepared and characterized by X-ray crystallography; it has a two-dimensional structure *via* intermolecular $Au^I \cdots Au^I$ interactions and possesses photoluminescence properties; the ability of trithiocyanuric acid to act as a bridging ligand for molecular assembly of two-dimensional polymeric solids is demonstrated.**

Molecular materials composed of discrete metal clusters arranged in extended structures are useful model systems for understanding surface chemistry and catalysis, but the synthesis of such materials is usually serendipitous. Herein we show that $Au^I \cdots Au^I$ interactions can provide a driving force for self-assembly of such molecular solids,[1–6] as well as the first example of an ordered array of $Au_6$ clusters arranged in a two-dimensional structure *via* intermolecular $Au^I \cdots Au^I$ interactions. While examples of one-dimensional gold(I) chains are not uncommon in the literature,[1a,2b,4–6] gold(I) solids with two-dimensional structures are rare.[1b]

Complexes $L(AuPPh_3)_3$ **1** and $L(AuPPhMe_2)_3$ **2** were prepared by treating $AuCl(PPh_3)$ and $AuCl(PPhMe_2)$ respectively with a methanolic solution of $H_3L$ ($H_3L$ = trithiocyanuric acid) and NaOMe. Slow diffusion of diethyl ether into a $CH_2Cl_2$–MeOH solution of complex **2** gave $[(LAu)(AuPPhMe_2)_2]_2$ **3** with low solubility.†

Complexes **1** and **3** have been characterized by X-ray crystallography. The structure of complex **1** features a triazine with three bent S–Au–$PPh_3$ appendages pointing away from each other. This is similar to that of the reported $[\{CSAu(PPh_3)\}_6]$ supermolecule,[2c] whereas there is no intermolecular close contact of the gold(I) atoms in both complexes. Presumably, this is due to the steric hindrance provided by the $AuPPh_3^+$ units.

A perspective view of complex **3** and its extended two-dimensional structure are shown in Figs. 1 and 2, respectively. Complex **3** is a hexanuclear gold(I) supermolecule with a crystallographic centre of inversion at the centre of the 12-membered ring metallocycle. Four gold(I) centres are arranged in the form of a parallelogram with $Au^I \cdots Au^I$ distances of 2.964(2) and 2.987(2) Å, and a long transannular $Au^I \cdots Au^I$ separation of 3.347(3) Å. A similar arrangement of $Au_4$ has been found in $[\{Au_2(C_6H_4S_2\text{-}1,2)(PEt_3)\}_2]$[2d] and $[Au_4(\mu\text{-}S_2C_6H_3Me)_2(PEt_3)_2]$.[7] Notably, there is an intermolecular $Au^I \cdots Au^I$ close contact of 3.130(2) Å resulting in a novel two-dimensional structure with the $Au_6$ supermolecule as the repeating unit. One recent novel example is $[L'(AuCl)_4]_\infty$ [L′ = 1,4,8,11-tetrakis(diphenylphosphinomethyl)-1,4,8,11-tetraazacyclotetradecane].[1b] The intermolecular $Au^I \cdots Au^I$ separation in complex **3** is comparable to related values in one- and two-dimensional gold(I) solids such as 3.104(1) Å in $[L'(AuCl)_4]_\infty$,[1b] 3.174(1) Å in $[Au_2(C{\equiv}CPh)_2(\mu\text{-}C{\equiv}NBu^t{}_2C_6H_2N{\equiv}C]_\infty$[5a] and 3.200(1) Å in $[Au_2(p\text{-}tc)_2(dpppn)]_\infty$ [*p*-tc = *p*-thiocresol; dpppn = 1,5-bis(diphenylphosphino)pentane].[6b] Another important structural feature is coordination of $Au(PPhMe_2)^+$ units to one of the nitrogen atoms in each of the triazine rings, which is isolobal to a proton. A reaction scheme which rationalizes the formation of the $Au_6$ supermolecule is shown in Scheme 1.

Recently, the gold(I) complexes of two tridentate bridging ligands, 1,3,5-tris(diphenylphosphino)benzene[4b] and

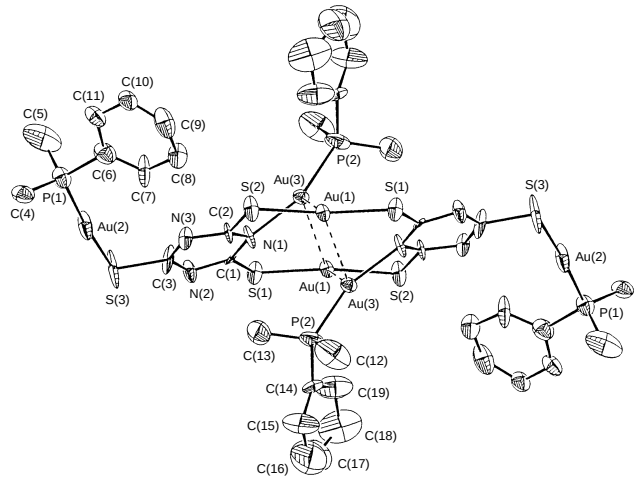

**Fig. 1** A perspective view of complex **3** (bond lengths in Å, angles in °): Au(1)···Au(3) 2.987(2), Au(1)···Au(3) 2.964(2), Au(3)···Au(3) 3.347(3), Au(1)–S(1) 2.279(9), Au(1)–S(2) 2.280(9), Au(2)–P(1) 2.234(10), Au(2)–S(3) 2.310(10), Au(3)–P(2) 2.210(11), Au(3)–N(1) 2.094(22); S(1)–Au(1)–S(2) 168.1(3), S(3)–Au(2)–P(1) 174.7(5), P(2)–Au(3)–N(1) 160.4(7)

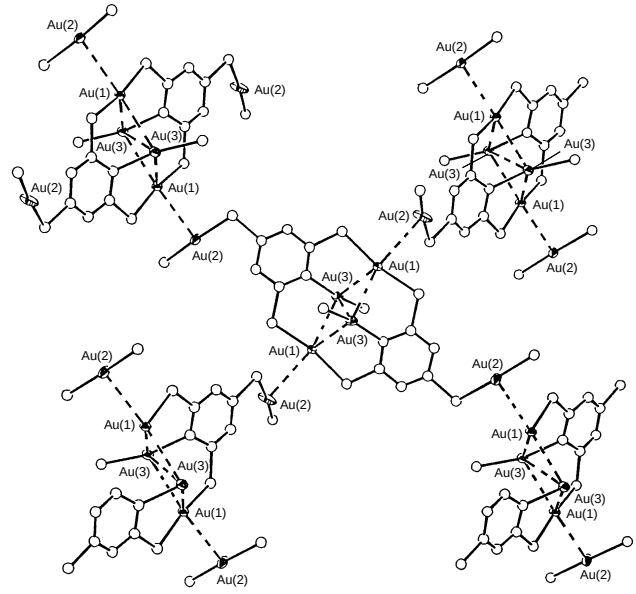

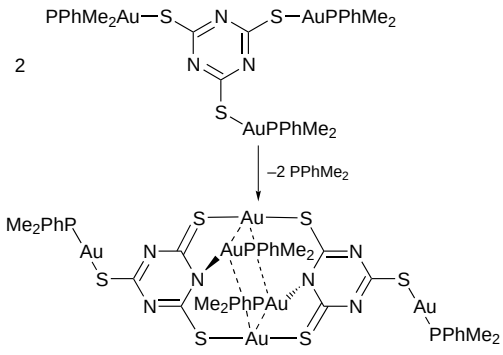

**Fig. 2** An extended two-dimensional structure of complex **3** with intermolecular Au···Au distances of 3.130(2) Å (the phenyl and methyl groups are omitted for clarity)

**Scheme 1**

$[C_6H_3(C{\equiv}C)_3]^{3-}$ [5b] are shown to form interesting one-dimensional polymeric solids *via* $Au^{I}\cdots Au^{I}$ interactions. Here, the trithiocyanuric acid demonstrates its ability to act as a bridging ligand for molecular assembly of two-dimensional polymeric solids.

The absorption spectra of complexes **1** and **2** measured in $CH_2Cl_2$ are very similar. As shown in Fig. 3 (insert), both complexes exhibit an intense absorption band at *ca*. 295 nm ($\varepsilon_{max}$ = 51 320 and 45 650 $dm^3\ mol^{-1}\ cm^{-1}$ for complexes **1** and **2**, respectively). However, complex **3** shows intense absorption at 320 nm ($\varepsilon_{max}$ = 44 870). This red shift in transition energy is not uncommon in $d^{10}$–$d^{10}$ systems and hence the 320 nm band in complex **3** is assigned to the $5d(d_{\sigma^*}) \rightarrow 6p(_{\sigma})$ tansition modified by $Au^{I}\cdots Au^{I}$ interactions.[8] As with most gold(I) complexes, complexes **1**–**3** are emissive both in solution and in the solid state, showing a broad emission at *ca*. 520–530 nm with long lifetimes (0.37, 0.34, 0.34 μs in degassed $CH_2Cl_2$; 3.7, 10.4, 11.6 μs in the solid state for complexes **1**, **2**, and **3**, respectively) upon photoexcitation at 300–400 nm (shown in Fig. 3), and these emissions are assigned to the $S \rightarrow Au$ excitation.[9]

This work highlights the application of $Au^{I}\cdots Au^{I}$ interactions as well as the judicious choice for bridging ligands in the formation of a two-dimensional array of luminescent metal clusters.

# Solvothermal synthesis of $[Mn(en)_3]_2[Mn_4(en)_9(SbSe_4)_4]\cdot 2H_2O$: the first example of a selenoantimonate(v) acting as a ligand in a transition-metal complex

**Wolfgang Bensch,* Christian Näther and Michael Schur**

*Institut für Anorganische Chemie, Universität Kiel, Olshausenstr. 40, D-24098-Kiel, Germany*

**Reaction of elemental manganese, antimony and selenium under mild solvothermal conditions yields the complex anion $[Mn_4(en)_9(SbSe_4)_4]^{4-}$, the first example of a transition-metal complex with $SbSe_4^{3-}$ anions acting as ligands; the anions are coordinated in a terminal position as well as a bridging ligand.**

During recent years an increasing interest in new chalcogenide framework structures has been observed owing to their promising combination of 'zeotype' structures with new properties.[1] Application of mild solvothermal processes has led to a wealth of novel chalcogenides extending from unique thiometallate clusters to three-dimensional frameworks.[2,3] A special interest is focussed onto the combination of main-group and transition-metal chalcogenides, especially with respect to the incorporation of the latter into the 'open' frameworks of thio-germanates, -stannates or -antimonates.[4,5] Under mild solvothermal conditions we obtained new thioantimonate framework types,[6,7] thioantimonate polysulfides[8] and manganese-containing $Sb_xS_y$ frameworks.[9] Despite the expected new and unusual electronic properties the chemistry of the heavier chalcogenides is less developed. It is well documented that in aqueous solutions seleno- and telluro-metalates[3] undergo hydrolysis reactions and consequently non-aqueous reaction media are preferred for their syntheses. Nevertheless, the reaction of elemental antimony, selenium and manganese in an aqueous amine solution with addition of ethylenediamine (en) yielded the remarkable transition-metal complex $[Mn(en)_3]_2[Mn_4(en)_9(SbSe_4)_4]$.† The use of pure metals in the synthesis has attracted some attention in recent years including the insertion of transition metals into R–X bonds of alkyl- or phosphoryl-halogens[10] or the donor solvent mediated reaction of metals with sulfur to give polysulfido complexes.[11] The observation that the $SbSe_4^{3-}$ ligands in the title compound are formed using the elements as starting materials raises the question about the mechanism involved.

The crystal structure‡ of the title compound consists of isolated $Mn(en)_3^{2+}$ cations and the $[Mn_4(en)_9(SbSe_4)_4]^{4-}$ anions are probably stabilized by the large $Mn(en)_3^{2+}$ ions [Fig. 1(*a*) and (*b*)]. The anion is built up from two $SbSe_4$–$Mn(en)_2$–$SbSe_4$–$Mn(en)_2$ subunits, connected *via* a bridging ethylenediamine ligand, which is located around a center of inversion. The subunits contain two crystallographically independent manganese centers in distorted octahedral coordinations. The two different $SbSe_4^{3-}$ groups exhibit different binding modes. The $Se(1)_{br}$ (br = bridging) center of the $Sb(1)Se_4^{3-}$ unit joins the Mn(1) and Mn(2) atoms. Each Mn is chelated by two en ligands. The coordination sphere of Mn(2) is completed by $Se(5)_t$ (t = terminal) of the terminal $Sb(2)Se_4^{3-}$ ligand, leading to a *cis*-configuration of the distorted octahedral environment [Fig. 1(*a*)]. The Mn(1) centers are bridged by an en ligand, and therefore the Mn(1) is coordinated by five N atoms and one Se center.

The Sb–Se distances for both $SbSe_4^{3-}$ anions are in good agreement with those found in isolated $SbSe_4^{3-}$ anions[12,13] with the exception that $Sb(1)–Se(1)_{br}$ is elongated by *ca*. 0.04 Å. As expected the $Mn(2)–Se(5)_t$ distance of 2.673(2) Å is shorter than to the bridging $Se(1)_{br}$ atom. The Mn–Se distances to $Se(1)_{br}$ amount to 2.825(2) Å for Mn(1) and to 2.757(2) Å for Mn(2), a significant difference of 0.068(2) Å. This might be due to intramolecular hydrogen bonding between the $Se(2)_t$ center of the $Sb(1)Se_4^{3-}$ anion and an amino hydrogen of a chelate ligand bound to Mn(2). The Se(2)···H distance of 2.614(5) Å is significantly shorter than the sum of their van der Waals radii and the Se···H–N angle of 176.1(2)° is indicative of a hydrogen bond. There is an additional hydrogen bond between one amino hydrogen of a chelate ligand and the oxygen of a water molecule which is located in holes of the structure (Fig. 2). The O···H bond length is 2.39(2) Å and the O···H–N angle is 151.4(3)°.

The title compound is the first structurally characterized example of a transition-metal complex containing $SbSe_4^{3-}$ anions as ligands. Chalcogeno–antimonates(III) often crystallize as extended frameworks[14–16] whereas chalcogeno–antimonates(v) form isolated anions[12,13] or dense structures.[17,18] The

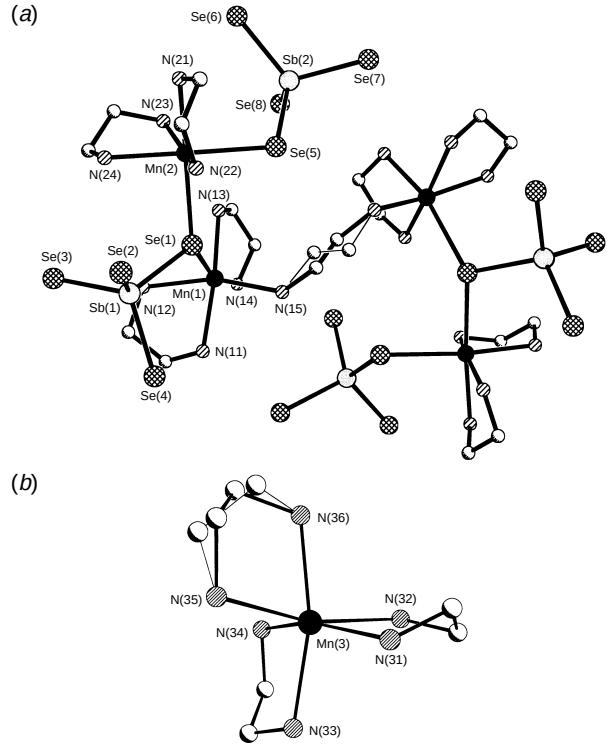

**Fig. 1** Crystal structure of $[Mn(en)_3]_2[Mn_4(en)_9Sb_4Se_{16}]$: (*a*) view of the anion $[Mn_4(en)_9Sb_4Se_{16}]^{2-}$ with numbering. Selected bond lengths (Å) and angles (°): Sb(1)–Se(2) 2.4550(8) Sb(1)–Se(4) 2.4690(7), Sb(1)–Se(3) 2.4713(8), Sb(1)–Se(1) 2.5111(7), Sb(2)–Se(8) 2.4439(10), Sb(2)–Se(6) 2.4738(8), Sb(2)–Se(7) 2.4787(8), Sb(2)–Se(5) 2.4812(8), Se(1)–Mn(2) 2.7573(11), Se(1)–Mn(1) 2.8251(12), Se(5)–Mn(2) 2.6728(12); Mn(2)–Se(1)–Mn(1) 128.32(4), Sb(2)–Se(5)–Mn(2) 110.88(3), Se(5)–Mn(2)–Se(1) 88.04(3); (*b*) note the disorder of one chelate ligand in the cation; hydrogen atoms are omitted for clarity

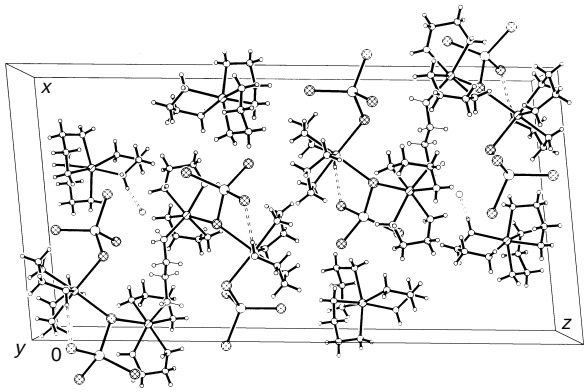

**Fig. 2** Packing of the molecules with view along the *b*-axis. For clarity, the disordered atoms of the ligands are omitted; hydrogen bonds are shown as broken lines.

combination of thio- and seleno-arsenates(III) with transition metals resulted in the preparation of a still growing number of low-dimensional structures.[19] However, the only examples of chalcogenopnictide(V) acting as ligands are $AsS_4^{3-}$ groups in nickel complexes as established by spectroscopical methods, but no structural data were reported.[20] It is noted that thiometallates of transition metals can be used as ligands.[21,22]

The complex anion in the crystal structure of the title compound may be regarded as a precursor for polymeric structures. Further studies are under way in order to enlarge the degree of condensation and to prepare extended structures.

† *Synthesis*: The title compound was obtained by reacting stochiometric amounts of elemental manganese, antimony and selenium in an aqueous solution of 70 vol% ethylamine and 20 vol% ethylenediamine (en) (yield: *ca*. 95% based on Mn). The probe was heated to 130 °C for 6 days in a Teflon-lined steel vessel under autogenous pressure. The crystalline product was filtered, washed with dry ethanol and stored under vacuum. The crystals are dark red, moisture-sensitive prisms up to 5 mm long with excellent cleavage perpendicular to the needle axis. The compound could not be prepared in aqueous en solutions, whereas syntheses carried out in amine solutions without addition of en led to the rapid formation of $Sb_2Se_3$.

‡ *Crystal structure determination*: $[Mn(en)_3]_2[Mn_4(en)_9(SbSe_4)_4]\cdot 2H_2O$, $M$ = 3017.6 monoclinic, space group $P2/n$ (no. 13), $a$ = 16.519(2), $b$ = 8.248(1), $c$ = 32.599(3) Å, $\beta$ = 95.76(1)°, $U$ = 4419.1(9) Å$^3$, $T$ = 295 K, $Z$ = 2, STOE AED-II four-circle diffractometer (Mo-K$\alpha$ radiation, $\lambda$ = 0.7107 Å), $\mu$ = 8.664 mm$^{-1}$. 11 518 reflections collected in the range $3 \leqslant 2\theta \leqslant 53°$, 9180 unique reflections. Face-indexed absorption correction; structure solution with SHELXS-86; structure refinement against $F^2$ using SHELXL-93. 398 parameters, $R$ for 5968 reflections with $I > 2\sigma(I)$ = 0.0359, $wR_2$ for all 9180 data = 0.0990, GOF 1.013. Residual electron density: 1.525, −1.088 e Å$^{-3}$. The heavy atoms were refined anisotropically. The hydrogen atoms were positioned with idealized geometry and refined with individual isotropic displacement parameters using a riding model. The highest difference peak in the Fourier map according to a composition of $[Mn(en)_3]_2[Mn_4(en)_9(SbSe_4)_4]$ is located in the small cavity between the bridging and the terminal $SbSe_4$ ligands. It was assumed that this peak is due to incorporated solvent water molecules which was confirmed by IR spectroscopy showing a broad absorption band between 3600 and 3000 cm$^{-1}$. In space group $P2/n$ the two carbons of the bridging en ligand are around a center of inversion and hence they are disordered. This disorder is not observed in the non-centrosymmetric space group $Pn$. However, the detailed analysis of the refinements in $Pn$ and $P2/n$ clearly revealed the centrosymmetric arrangement of the remaining part of the structure. CCDC 182/557.

# SSZ-42: the first high-silica large pore zeolite with an undulating, one-dimensional channel system

**C. Y. Chen,[a] L. W. Finger,[b] R. C. Medrud,[a] P. A. Crozier,[c] I. Y. Chan,[a] T. V. Harris[a] and S. I. Zones*[a]**

[a] *Chevron Research & Technology Co., Richmond, CA 94802, USA*
[b] *Carnegie Institution of Washington, Geophysical Laboratory, Washington, D.C. 20015, USA*
[c] *Center for Solid State Science, Arizona State University, Tempe, AZ 85287, USA*

**The framework topology of the novel zeolite SSZ-42 is determined from single crystal data (15 × 15 × 35 μm) and refined from powder diffraction data; the crystalline architecture is characterized by an undulating, one-dimensional 12-membered ring channel system.**

In this report we describe the structure of a novel zeolite designated as SSZ-42. The zeolite is synthesized using *N*-benzyl-1,4-diazabicyclo[2.2.2]octane cation as the template molecule.[1] In one synthesis batch we were fortunate to find single crystals of uniform size (15 × 15 × 35 μm) which were optically of very high quality, and which extinguished uniformly under crossed polarizers.

The framework arrangement of SSZ-42 was solved from single-crystal data collected with a CCD camera in the applications laboratory of Siemens Energy and Automation, Inc. in Madison, WI, using a crystal that still contained the occluded template molecules. Although the measurable intensity was obtained on only about half of the available reflections in a three-dimensional set of data and most of those reflections were weak, the data from this very small SSZ-42 crystal were sufficient to locate the framework atoms by using direct methods in SHELXTL (version 5.03) to generate a very good trial model, but not precise enough to get good bond distances. The crystal system is monoclinic. The symmetry of the silica framework can be described in space group *C*2/*m*. There are four topologically distinct T-atoms and 10 O-atoms.

Full powder patterns for both as-synthesized and calcined samples (crystal size 1–2 μm) were collected at high-resolution beamline X7A of the National Synchrotron Light Source, Brookhaven National Laboratory.† The calcined sample used for the powder diffraction was prepared by heating the calcined material at 350 °C for several hours in a glass capillary under vacuum, to remove as much of the adsorbed species as possible, and then sealing. The unit-cell parameters from the powder data are shown in Table 1. The framework atom parameters from the single-crystal data were used as a starting model to refine the powder data from the calcined sample, which contains only the framework atoms. Convergence was accomplished without difficulty using the program GSAS.[2] Difference electron density slices through the channel cross-section show no residual electron density. The refinement led to residuals of $wR_p$ = 0.066, and $R_p$ = 0.050 and $R_{Bragg}$ = 0.061 with $\chi^2$ = 1.02. The Rietveld difference plot in Fig. 1 shows that the observed and calculated powder patterns of the calcined sample agree very well.

**Table 1** Unit-cell parameters for SSZ-42

| Sample | As-synthesized | Calcined |
|---|---|---|
| *a*/Å | 18.6309(9) | 18.4991(2) |
| *b*/Å | 13.3359(1) | 13.4078(1) |
| *c*/Å | 7.61731(3) | 7.57548(2) |
| *β*/° | 102.017(1) | 101.471(1) |
| *V*/Å$^3$ | 1851.12(1) | 1841.49(2) |

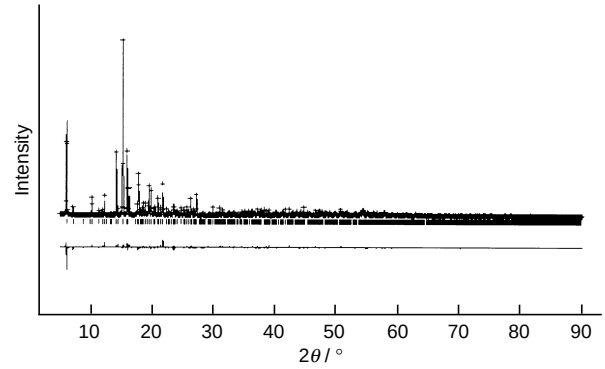

**Fig. 1** Results of Rietveld refinement of a calcined SSZ-42 sample

The framework structure, viewed along the 12-MR channel (Fig. 2), is characterized by an undulating, one-dimensional channel system with pores comprised of 12 T-atoms. The framework density is 17.4 T/1000 Å$^3$. The pore diameter at the narrowest point in the *XZ* projection is 6.4 Å. The cage at the widest point is *ca.* 10 Å. As shown by the *XZ* projection in Fig. 3, the channel exhibits 'side pockets' which are reminiscent of those in SSZ-33[3] and Beta[4] zeolites formed by the intersection of channels. In SSZ-42, however, there are no intersecting channels. In the perpendicular projection (*YZ*) there are no undulations and the pore diameter is 6.7 Å. It is apparent that the 12-membered ring is considerably distorted, giving the smaller than expected pore size.

The powder diffraction data from the as-synthesized sample displays considerable electron density in the channel. The template molecule must be disordered for the space group *C*2/*m*. Elemental analysis indicates two template molecules per unit cell. A possible location for the template molecule was generated by molecular modelling in the Insight computational environment (see Fig. 3).[5] The template molecule spans the

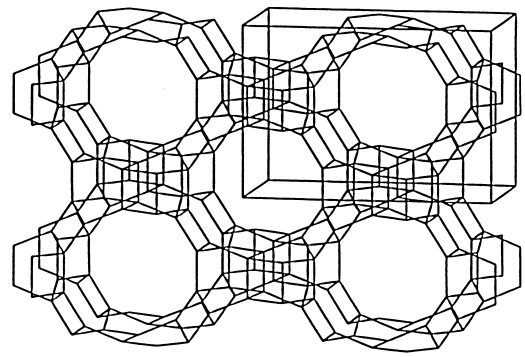

**Fig. 2** The SSZ-42 framework viewed along [001]

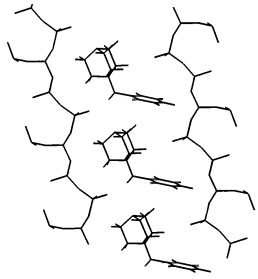

**Fig. 3** *XZ* projection of the SSZ-42 framework showing minimized location of template molecules

volume from one side pocket diagonally to the next. The details of further structure refinement based on the as-synthesized synchrotron powder XRD pattern will be discussed at a later date.[6] The atomic coordinates and selected bond distances and angles for the calcined form are listed in Tables 2 and 3, respectively. This structure does confirm once again the effective use of organocations as 'guest molecules' in developing the 'host' molecular sieve architecture.

Fig. 4 shows the experimental and simulated high-resolution electron micrograph (HREM) viewed along the [001] projection of SSZ-42. The experimental image is a spatially averaged image obtained with the low-dose method of Pan and Crozier.[7] Initial analysis of the circumference of the main channel led us to the preliminary proposal of a 10-MR channel system but we were unable to come up with a structure that would yield a good

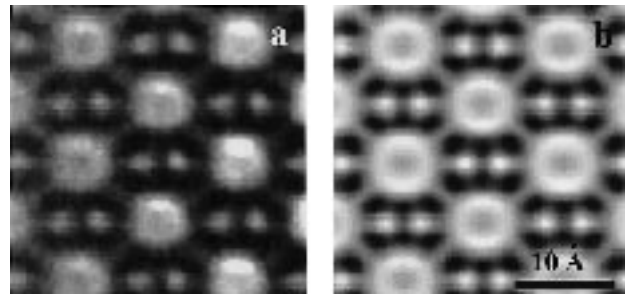

**Fig. 4** (*a*) Spatially averaged experimental HREM image from [001] projection of SSZ-42 acquired with a JEOL 4000 EX operating at 400 kV. The image (showing point-to-point resolution of 2.2 Å) was recorded from a wedge-shaped crystal resulting in a gradation of the image intensity from left to right. (*b*) Simulated image of proposed SSZ-42 structure in the [001] projection. The image was calculated using multi-slice techniques for a crystal 40 Å in thickness and the objective lens set to Scherzer defocus (−490 Å).

fit between the simulated image and the experimental image. However, if we use the atomic coordinates derived from the XRD data we obtain an excellent match between the simulated and experimental HREM data [see Fig. 4(*b*)]. In this case, the unusual geometry causes the 12-MR to appear as a 10-MR ring in [001] projection. However, the comparison between the experimental and simulated images is clearly a stringent test of the accuracy of the proposed structure model.

The existence of large pores was also experimentally confirmed by the adsorption of a series of molecules with varying dimensions. $N_2$, *n*-hexane, 2,2-dimethylbutane and cyclohexane have a high adsorption capacity of *ca.* 0.20 ml $g^{-1}$ in SSZ-42, which is closer to the adsorption data obtained in SSZ-33 and Beta, both possessing intersecting 10/12- or 12/12-MR channels. Based on these adsorption data, one could easily come to the incorrect conclusion that the framework architecture of this new material consists of an intersecting 10/12- or 12/12-MR channel system. In fact, the large adsorption capacity of SSZ-42 is due to large cages rather than to an intersecting channel system. The high adsorption capacity is exceptional for a large pore zeolite with a one-dimensional channel system.[6]

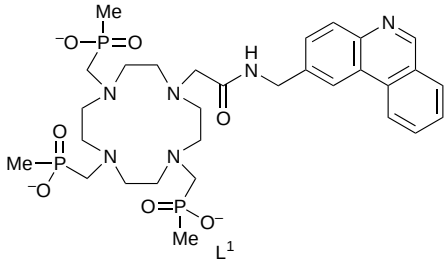
# Luminescent chemosensors for pH, halide and hydroxide ions based on kinetically stable, macrocyclic europium–phenanthridinium conjugates†



**David Parker,* Kanthi Senanayake and J. A. Gareth Williams**

*Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

**The neutral europium complex [EuL$^1$] shows a pH dependent luminescence enhancement of over 500, while in the *N*-methylated analogue the metal-based luminescence is selectively quenched by chloride and (above pH 10) by hydroxide anions.**

Chemically robust, single-component luminescent sensors are needed not only for the analysis of the ionic composition of cells[1] but also in monitoring aqueous systems in the environment or during industrial processes. Fluorescent sensors have been devised for determining intracellular concentrations of species such as $Ca^{2+}$,[2] $Zn^{2+}$,[3] $H^+$ [4] and $Cl^-$.[5] Recently, the long-lived (ms range) luminescence of lanthanide complexes has been exploited in various bioassays with time-gating, permitting easy distinction from the shorter-lived (sub-μs) background fluorescence present in most biological systems.[6] Several of these sensors operate by ion-promoted suppression of photo-induced electron transfer (PET) from the ion receptor to the proximate lumophore. Examples include pH sensors incorporating a $Ru(bpy)_3^{2+}$ reporter (in $H_2O$–MeOH)[7] and a pentadentate terpyridyl ligand bearing aminomethyl substituents which in water forms a weak 1 : 1 complex with Tb.[8] The lanthanide luminescence is 'switched on' following amine protonation and luminescence enhancements of up to 16 were reported. The PET sensor principle is not the only means of allowing changes in ionic concentrations to be signalled: modulation of the spectral properties of the chromophore ($\varepsilon$, $\lambda_{abs}$) can be equally effective.

Following our recent work on the synthesis,[9] stereochemical analysis[10] and physicochemical properties[11] of kinetically stable macrocyclic lanthanide complexes in aqueous media, we have now prepared the charge-neutral europium complex of ligand L$^1$. Monoamide triphosphinate derivatives of

L$^1$

1,4,7,10-tetraazacyclododecane (cyclen) have been shown to form one predominant diastereomer in water following lanthanide binding[10] with partial hydration of the firmly bound lanthanide[12] ($\beta_{ML} \geqslant 10^{19}$). The phenanthridine chromophore was chosen because of its favourable absorption characteristics for excitation in biological media, its ease of N-alkylation allowing the study of halide induced quenching[5] of the derived phenanthridinium ion and because in its protonated or alkylated forms the phenanthridine moiety should serve as an effective 'antenna' for europium sensitisation minimising the ligand-to-metal charge-transfer process that often limits the overall luminescence efficiency of europium complexes in solution.[10]

Cyanation of 2-bromophenanthridine[13] (CuCN, dmf, 170 °C) followed by reduction with $BH_3$·thf afforded the aminomethyl derivative in 79% overall yield. Coupling with chloroacetic acid (EDC, HOBt, $CH_2Cl_2$) gave the corresponding α-haloamide (96%) which was used to monoalkylate the molybdenum-tricarbonyl complex of cyclen using established methodology.[9] Subsequent phosphinoxymethylation [$MeP(OEt)_2$, thf, $(CH_2O)_n$, 4 Å series] followed by base hydrolysis gave the octadentate ligand L$^1$ [$\delta_P$ (pD 6): 40.3] and reaction with $Eu(NO_3)_3$ in water followed by purification by alumina chromatography gave the neutral complex [EuL$^1$] [$\delta_P$ (pD 5.5): 101.1, 88.9, 70.3 with ⩾90% of this diastereoisomer]. Quaternisation of the phenanthridine N in [EuL$^1$] proceeded cleanly (MeI, MeCN, 40 °C), with the europium ion serving as a suitable protecting group for the ligand heteroatoms.

At pH 1.5 and 7, [EuL$^1$] possessed one bound water molecule ($\tau_{H_2O}$ = 0.71 ms, $\tau_{D_2O}$ = 1.92 ms). The phenanthridyl absorption and fluorescence excitation spectra were pH dependent and shifted to longer wavelength upon protonation with $CF_3CO_2H$. With excitation of the phenanthridyl antenna at 370 nm, luminescence from the Eu ion was 'switched on' following protonation (Figs. 1 and 2). The overall luminescence enhancement factor was at least 500 as can be seen by comparing the metal emission intensity at 594 nm ($\Delta J$ = 1) as a function of pH (Fig. 2). Indeed excitation at 380 nm (pH 7.4) gave rise to no measurable europium emission and acidification 'turns on' the red Eu europium luminescence, thereby creating a genuine pH switch. The p$K_a$ of [EuL$^1$] was calculated to be 4.45(8), and the same value was obtained from an analysis of the pH dependence of phenanthridyl fluorescence intensity ($\lambda_{em}$ = 405 nm, $\lambda_{exc}$ = 320 nm). Absolute quantum yields [relative to $Ru(bpy)_3^{2+}$, $\phi$ = 0.028][18] were measured for [EuL$^1$] (0.011 in $H_2O$, 0.034 in $D_2O$) and [Eu(HL$^1$)]$^+$ (0.030 in $H_2O$), and were independent of excitation wavelength above 300 nm. The PET process operative in this system evidently contributes little to the measured metal-based luminescence enhancement factors which are ascribed to the pH dependence ($\lambda_{abs}$, $\varepsilon$) of the sensitising antenna chromophore, (Fig. 1). Consistent with this analysis was the luminescence enhancement factor measured

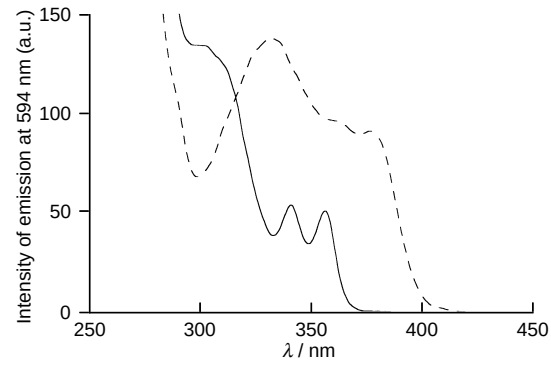


**Fig. 1** Metal luminescence excitation spectra ($\lambda_{em}$ = 594 nm, delay 0.1 ms) at pH 6.8 (solid line) and 1.5 (dashed)

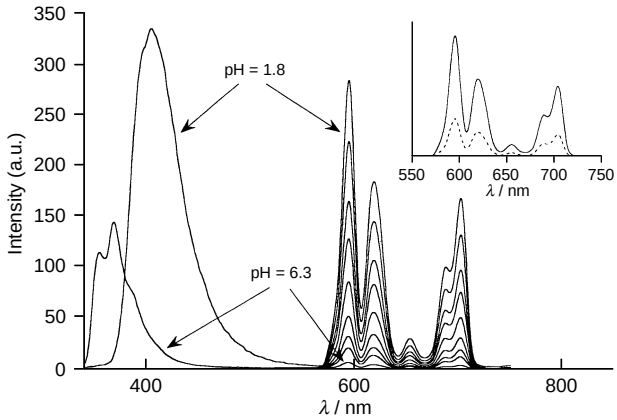

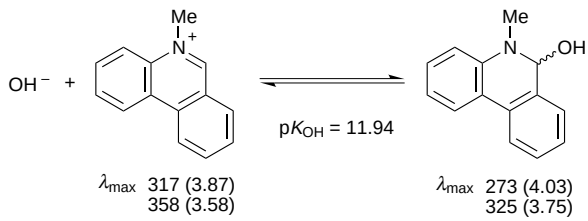

**Fig. 2** Effect of pH on phenanthridinium fluorescence (excitation at 320 nm) and on the intensity of europium luminescence ($\lambda_{exc}$ 370 nm, delay 0.1 ms, pH 1.88 to 6.33, $I$ = 0.1 M $NMe_4ClO_4$; spectra were acquired using a Perkin-Elmer LS 50B spectrofluorimeter). Insert shows the effect following excitation at the isosbestic point (solid line pH 1.8, dotted 6.3), where the difference in intensity reflects differences in the excited state behaviour only.

following excitation at the isosbestic point (315 nm): an enhancement of 3 was also seen (Fig. 2, insert).

N-Alkylated quinolinium and phenanthridinium ions possess a fluorescence which is quenched selectively by halide ions.[5] In complex [Eu(NMe)L1] [at pH 6.8, $\tau_{H_2O}$ = 0.73 ms, $\phi$ = 0.014 (as iodide salt with $\lambda_{exc}$ = 320 or 360 nm)], the europium luminescence was also quenched by addition of $Cl^-$, $Br^-$ or $I^-$ ions and an effective dissociation constant for $Cl^-$ binding of 45 mM was calculated. The observed luminescence quenching by $Cl^-$ was independent of pH (in the range 1.5–9), and was unaffected by the presence of added phosphate (5 mM), citrate (1 mM), lactate (5 mM) or bicarbonate (30 mM) auguring well for the development of such a sensory system for intracellular $Cl^-$ (typically 55–80 mM).

*N*-Methylphenanthridinium ions reversibly add hydroxide at the 6-position forming a pseudo-base (Scheme 1) and the equilibrium constant for the parent system is 11.94.[14] The concomitant change in the spectral characteristics of the aromatic chromophore (*e.g.* band at 358 nm disappears on adduct formation) suggested that the europium luminescence would be sensitive to the presence of $OH^-$ ions above pH 10. Addition of KOH to **1** caused a steep decrease in the sensitised europium luminescence, (Fig. 3), ($\lambda_{exc}$ = 360 nm, quenching factor ⩾200) and an effective binding constant of 12.2 (0.1) ($I$ = 0.1 M $NMe_4ClO_4$) was calculated in reasonable agreement with that measured for the parent system. Such behaviour, involving reversible C–O bond formation, constitutes an unusual method of assaying anionic species in solution, and has been observed previously in the quenching of N-methylacridinium fluorescence by $OH^-$, following attack at the 9-position.[14]

In summary, the europium complexes described constitute attractive new sensory systems for pH and for halide and hydroxide anions. Given the ease of modification of the heteroaromatic chromophore (and parallel quinolinium systems with p*K*as of *ca*. 5.8 have been recently prepared)[15] the facility of changing the Ln ion to Yb for near IR emission,[16] and the good selectivity of the halide sensor, practicable sensors for intracellular signalling based on such lanthanide probes (*e.g.* measuring the time-resolved emission intensity at 594 or 616 nm) may be expected. Furthermore the *N*-alkylphenanthridyl moieties are known to form relatively stable adducts with DNA and given that emissive enantiopure tetraamide complexes of Eu and Tb have been defined recently,[17,18] luminescent chiral lanthanide probes for DNA may also be feasible.

**Scheme 1**

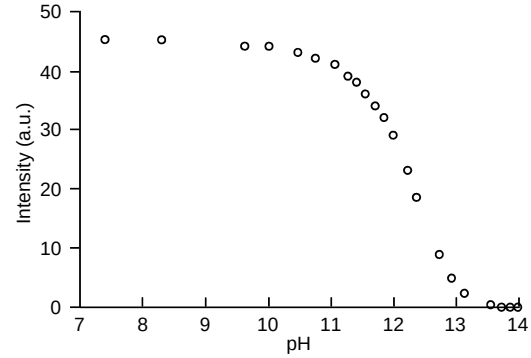

**Fig. 3** Effect of hydroxide ions on the intensity of the europium luminescence ($\lambda_{exc}$ = 380 nm, $\lambda_{em}$ = 594 nm, delay 0.1 ms; $I$ = 0.1 M $NMe_4ClO_4$)

We thank the EPSRC and BBSRC for grant support.

# The role of back-bonding in the determination of classical *vs*. non-classical bonding in $EH_3^+$ and $EH_5^+$ minimum structures for E = C, Si and Ge

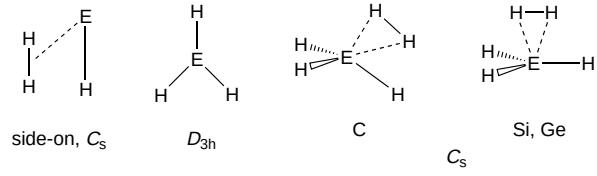
**Emma del Río, María I. Menéndez, Ramón López and Tomás L. Sordo***

*Departamento de Química Física y Analítica, Facultad de Química, Universidad de Oviedo, C/Julián Clavería, 8. 33006 Oviedo, Principado de Asturias, Spain*

**A rationalization of bonding in $EH_3^+$ and $EH_5^+$ classical and non-classical most stable minimum structures is proposed for E = C, Si and Ge by means of a back-bonding interaction which when present is clearly displayed by a configuration analysis and explains the lack of bridged hydrogens in the corresponding structure.**

Very recently there has been a strong interest in the study of the species $EH_3^+$ and $EH_5^+$ for E = C, Si and Ge.[1–8] For $CH_3^+$ high level computations have rendered no side-on $HC^+\cdots H_2$ complex the classical $D_{3h}$ symmetric structure being the most favored energetically. In contrast, for $SiH_3^+$ and $GeH_3^+$ two different minimum structures have been found: one of $D_{3h}$ symmetry and the other, a non-classical side-on complex, of $C_s$ symmetry.[1] On the other hand, for the $EH_5^+$ systems, the global minimum structures are non-classical $C_s$ structures characterized by a three-center–two-electron bond having a five-coordinate central atom and bridged hydrogens. No classical five-coordinate minimum structure have been found for these $EH_5^+$ systems.[2–8] It has been argued that this is so because the energy required to break the H–H bond is not compensated by the two newly formed E–H bonds[7] in contrast with the classical $EH_3^+$ structures where the $H_2$ cleavage seems to be adequately compensated.

In this work we propose a rationalization of bonding in the title $EH_3^+$ and $EH_5^+$ systems by using the back-bonding concept which when present is clearly displayed by a configuration analysis.



All structures were optimized at the Becke3LYP DTF level[9] with the standard 6-311++G(2d,2p) basis set using the Gaussian 94 program.[10] The nature of the stationary points was further characterized by frequency calculations which also gave the zero-point vibrational energy (ZPVE) correction. This theory level has previously proved to be adequate to study some of the title systems.[1] DFT wavefunctions were analyzed by means of a theoretical method developed by Fukui's group[11] using the ANACAL program.[12] This method is based on the expansion of the MOs of a complex system in terms of those of its fragments, and configuration analysis. This type of analysis has proved useful for understanding the chemical features of complex formation from chemically interacting systems.

Table 1 collects the Becke3LYP/6-311++G(2d,2p) total energies and ZPVE of the $EH_3^+$ and $EH_5^+$ (E = C, Si and Ge) minimum structures studied in this work: the classical $D_{3h}$ minimum structures of $CH_3^+$, $SiH_3^+$ and $GeH_3^+$, the side-on $C_s$ structures of $SiH_3^+$ and $GeH_3^+$, and the global minimum structures of $C_s$ symmetry of $CH_5^+$, $SiH_5^+$ and $GeH_5^+$. For $SiH_3^+$ and $GeH_3^+$ the $D_{3h}$ structures are the most stable ones by 28.4 and 11.1 kcal mol$^{-1}$, respectively (27.1 and 10.0 kcal mol$^{-1}$ when ZPVE is included).

Table 2 presents the most important changes in the electronic population of the Kohn–Sham MOs of $EH_3^+$ and $EH_5^+$ minimum structures. Table 3 displays the coefficients of the most important electronic configurations of fragments in the minimum structures studied in this work.

We see from Table 2 that in the $EH_3^+$ structures of $D_{3h}$ symmetry the HOMOs of both fragments and the NHOMO of the $EH^+$ fragment lose electronic population and the LUMO and the NLUMO of the $EH^+$ cationic fragment and the LUMO of $H_2$ become appreciably populated. Table 3 shows that this

electronic rearrangement is caused by two different interactions between the fragments: a charge transfer from the HOMO of $H_2$ to the LUMO or NLUMO of the $EH^+$ moiety, and a back-donation from the HOMO of the cationic fragment to the LUMO of $H_2$. In the side-on structures of $SiH_3^+$ and $GeH_3^+$ the spatial disposition of the fragments is compatible only with an interaction of dihydrogen with the vacant orbitals of $EH_3^+$. In effect, Table 2 shows that the LUMO or NLUMO of the $EH^+$ cationic fragment gain electronic population whereas the HOMO of $H_2$ becomes less populated. We see in Table 3 that this redistribution of electrons is due to an HOMO($H_2$)–LUMO ($SiH^+$) or HOMO($H_2$)–NLUMO ($GeH^+$) interaction. These are then donor–acceptor complexes between the dihydrogen ligand (donor) and $EH^+$ as already reported.[1] The reason why there is no side-on structure in the case of $CH_3^+$ is that the LUMOs of $CH^+$ are more stable (−0.55 eV) than the HOMO of $H_2$ (−0.43 eV). As a consequence, in a hypothetical side-on structure of $CH_3^+$ a very strong charge transfer would take place from $H_2$ to $CH^+$ in a first phase. The depopulation of the HOMO of $H_2$ produced by this charge transfer would cause an important elongation of the H–H bond and a stabilization of the LUMO of dihydrogen which would allow the interaction of $H_2$ with the HOMO of $CH^+$ through back-bonding and the formation of the $D_{3h}$ structure.

For the $EH_5^+$ systems the most stable structures have $C_s$ symmetry with the $H_2$ unit bound sideways to the $EH_3^+$ fragment. However, there is a significant difference between $CH_5^+$ and $SiH_5^+$ and $GeH_5^+$. In $SiH_5^+$ and $GeH_5^+$ the $H_2$ unit preserves its entity only slightly perturbed by the interaction with the $EH_3^+$ fragment whereas in $CH_5^+$ the $H_2$ unit presents a considerably elongated bond (see Table 2). This difference can be understood in terms of the electronic configurations of the fragments (see Table 3). In effect, for $SiH_5^+$ and $GeH_5^+$ the wavefunction is a mixture mainly of the zero configuration and the monotransference from the HOMO of $H_2$ to the LUMO of $EH_3^+$ whereas for $CH_5^+$ the wavefunction includes in addition the ditransference from the HOMO of $H_2$ to the LUMO of $EH_3^+$ and a small contribution from the cross transference from the HOMO of $H_2$ to the LUMO of $CH_3^+$, and from the HOMO of $CH_3^+$ to the LUMO of $H_2$. Accordingly, we see in Table 2 that the LUMO of the $EH_3^+$ fragment is considerably more populated and its HOMO loses more electronic density, and the HOMO of $H_2$ loses more electronic population and its LUMO becomes more populated in the case of $CH_5^+$ than in the other two cases. This can be explained again as a consequence of the fact that the LUMO of $CH_3^+$ (−0.49 eV) is more stable than the HOMO of $H_2$. This determines a very strong charge transference from the $H_2$ fragment to $CH_3^+$ which causes the elongation of the H–H bond making possible even a back donation from the HOMO of $CH_3^+$ to the LUMO of $H_2$. As a consequence, while in $SiH_5^+$ and $GeH_5^+$ the $H_2$ fragment interacts only with the $p_z$ orbital of the central atom whose three $sp^2$ hybrids form three E–H bonds, in $CH_5^+$ two of the $sp^2$ hybrids of the central atom form two C–H bonds and the NHOMO of the $CH_5^+$ is a linear combination of the third $sp^2$ hybrid, the 1s atomic orbital (AO) of the two H atoms of the $H_2$ moiety and the 1s AO of the remaining H atom. This difference is clearly appreciated in the geometry of the $EH_5^+$ systems. In the case of E = Si, Ge the $H_2$ fragment is symmetrically situated in front of the $p_z$ AO of the central atom parallel to the $sp^2$ plane whereas in $CH_5^+$ the $H_2$ fragment is placed between one of the $sp^2$ hybrids and the $p_z$ AO of C, the remaining H atom being displaced from the linear direction along the hybrid AO.

The authors are grateful to Professor Agustí Lledós for helpful comments and suggestions, and to DGICYT for financial support (PB94-1314-C03-01). E. del R. also thanks to the DGICYT (Spain) for a grant.

# Aminopropylated MCMs as base catalysts: a comparison with aminopropylated silica

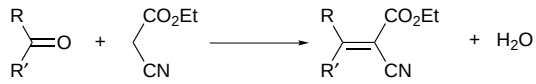
**Duncan J. Macquarrie* and Dominic B. Jackson**

*Department of Chemistry, University of York, Heslington, York, UK YO1 5DD*

**Aminopropyl-functionalised MCMs, prepared *via* a one-pot method, are found to be effective base catalysts for the Knoevenagel reaction, with significant improvements in terms of turnover number and solvent dependence to the ostensibly similar aminopropylsilica.**

We, and others, recently reported a simple one-pot method for the preparation of surface-modified monodisperse MCM-type silica.[1,2] This method can be used to prepare organically modified materials in high yield, which have very high surface areas (650–1600 $m^2\ g^{-1}$) and are functionalised with a variety of organic groups. The pore size distribution of these materials is very narrow and in the mesoporous region (1.8–3.9 nm). Such properties would make these materials potentially very interesting as novel catalysts. We have recently reported that aminopropylated silica is an effective base catalyst, which is limited in its usefulness by an unusual solvent dependency, and which is poisoned by amide formation at the $NH_2$ groups.[3] We now wish to report our findings on aminopropylated MCMs, materials which display considerable differences in catalytic activity to the apparently similar aminopropylsilicas.

The aminopropylated MCMs were prepared according to known methods.[1] Three catalysts were prepared, whose structural and compositional characteristics are shown in Table 1. The ability to increase loading of these materials by changing the ratio of the two silanes [aminopropyl(trimethoxy)silane and tetraethoxysilane] used in their preparation makes this methodology more flexible than the post-modification of silica, where maximum loadings are in the region of 1 mmol $g^{-1}$. The surface area and pore size distributions are as expected for such materials, and their surface polarity, as measured using adsorption of Reichardts dye[4] is significantly higher than that of the corresponding silica-derived materials, and approaches that of underivatised silica [$E_N^T$ ($SiO_2$) = 0.89–0.96, depending on drying conditions. Similar values are obtained for unmodified MCMs]. This difference can be ascribed to the larger amount of exposed, unfunctionalised surface in the case of the MCM materials, and, in agreement with this, the 2.5 mmol $g^{-1}$ loading catalyst has a value lower than that of the 1.2 mmol $g^{-1}$ material. Such a difference might be expected to lead to different solvent dependency in reactions catalysed by the MCMs compared to the silica-derived catalysts, owing to different partitioning of reactants between the catalyst surface and the bulk solution.



The catalysts were then evaluated in a series of reactions. Reactions used were the Knoevenagel condensation of aldehydes and ketones with ethyl cyanoacetate, a model reaction which has been studied in some detail.[3,5,6,7] The CH acid and the ketone (20 mmol of each) were added to a suspension of the catalyst (0.25 g) in the appropriate solvent (25 ml) at reflux. All reactions were run with continuous removal of water. Reactions were followed by GC using *n*-dodecane as internal standard, and products were isolated using conventional techniques. Results are shown in Table 2. Yields are generally high and compare favourable well with those in the literature.[3,5,6,8] As

can be seen, the overall reactivity bears some similarity to that of aminopropylated silica.[3,5] Aldehydes and ketones both react with ethyl cyanoacetate, chosen as a carbon acid of moderate activity and synthetic utility. Surprisingly, benzaldehyde reacts extremely sluggishly with the MCM catalysts, despite being a facile substrate with both the silica-derived catalysts and with homogeneous amines such as piperidine. Otherwise, the relative reactivity of ketones is typical of both aminopropyl-modified silica and of most homogeneous systems. For reactions of ketones, the rates of reaction in cyclohexane, the optimum solvent for the silica variant, are typically 20–30% slower with the catalysts described here. However, as will be discussed later, the MCM-type catalysts are less restricted by solvent than their amorphous silica equivalents. Immediately obvious is the generally increased turnover numbers (TONs), although the reactivity and TON of acetophenone is disappointingly low. This, coupled with the remarkably low activity of benzaldehyde, may suggest that the reduced electrophilicity of the aromatic carbonyl, relative to the aliphatic, plays an unusually significant role in reactions catalysed by these materials.

Other points of interest are that the small pore (1.8 nm) catalyst **3** gives a poor conversion compared to the larger pore analogue **1**. However, it is interesting to note that the rate of reaction caused by both catalysts is essentially identical, the difference being that **1** remains active for longer. Increasing the loading from 1.2 mmol $g^{-1}$ to 2.5 mmol $g^{-1}$ causes a corresponding increase in reaction rate. Such an increase in loading is readily achieved by altering the ratio of silanes in the preparation of the MCM catalysts, but is not possible with the post-functionalisation of silica, where 1.0 mmol $g^{-1}$ is the maximum loading achievable. In connection with TON, the mode of catalyst deactivation also differs between the two catalyst types. For the silica catalysts, there is clear evidence for a slow, irreversible formation of surface-bound amide groups, arising from the reaction of the surface-bound primary amine and the ester of the ethyl cyanoacetate [Fig. 1(*a*)]. In the case of the MCM catalysts, recovered spent catalyst does not display bands for nitrile or amide groups, but rather indicates the presence of some adsorbed organics [Fig. 1(*b*)]. The identity of the species responsible is currently the subject of investigation.

A further point of divergence between the two types of catalyst is their behaviour in different solvents. Whereas the silica-based catalyst has a very limited range of solvents in
