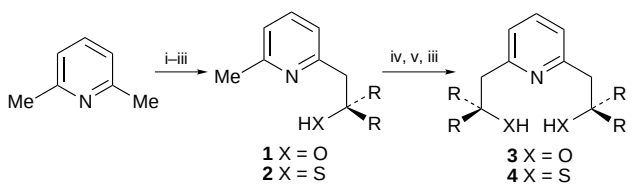
# New pyridine dithiols: synthesis and structures of complexes with acids

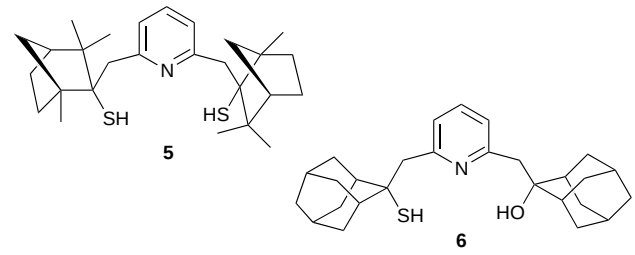
**Bartjan Koning,[a]† Ron Hulst,[a] Arjan Bouter,[a] Jan Buter,[a] Auke Meetsma[b] and Richard M. Kellogg*[a]**

[a] *Department of Organic and Molecular Inorganic Chemistry, University of Groningen, Nijenborgh 4, Groningen 9747 AG, The Netherlands*



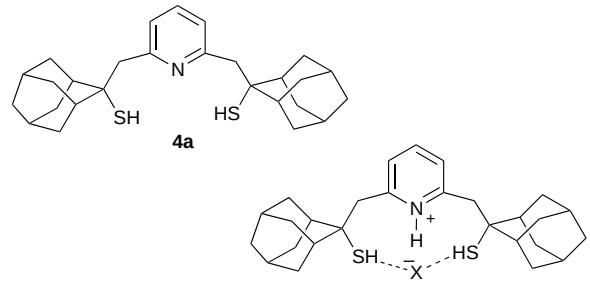
[b] *Crystal Structure Centre, University of Groningen, Nijenborgh 4, Groningen 9747 AG, The Netherlands*

**Pyridine dithiols have been synthesized by base-induced addition of 2,6-lutidine to (non-enolisable) thioketones, and have been found to encapsulate various acids.**



The addition products ('pyridine diols' **3**, Scheme 1) of 2 equiv. of ketone with 2,6-dimethylpyridine (2,6-lutidine) are tridentate ligands capable of encapsulating metal ions or acids.[1] Extensive structural variation is possible: benzophenone, fluorenone, acetone, acetophenone, adamantanone, fenchone and camphor are examples of ketones that have been used.[1d,2] Replacement of 2,6-lutidine by 2,9-dimethylphenanthroline leads to tetradentate ligands.[3] As an example of the opportunities for encapsulation of acids, we have described the crystal structure of the HCl complex of **3** whereby adamantanone was used as ketone.[3] The host organizes itself so that the acid is perfectly enclosed in a cavity wherein Cl is hydrogen bonded to the two hydroxy groups and the proton of HCl is directed towards the pyridine nitrogen.

We find that the approach of Scheme 1 can be extended to the preparation of certain 'pyridine dithiols' **4**. This method is more straightforward and efficient (overall yields 65–70%) than the multi-step synthesis of pyridine dithiols that has been reported previously and which is limited to thiols with relatively acidic α-protons.[1a–d] No products derived from addition of the carbanion to the sulfur of the thioketone have been isolated.[4] The two step addition shown leads to far better yields than either a single step approach involving direct deprotonation of 2,6-lutidine with 2 equiv. $Bu^nLi$ followed by addition of 2 equiv. thioketone or a two step, one pot approach in which the mono-adduct is not isolated. An additional advantage of this approach is that the 'single-armed' derivative **2** (or **1**) can be obtained and studied separately. The bis-lithium salt of **4a** ($–CR_2–$ = adamantane-2,2-diyl) is remarkably stable, as was confirmed by means of $^7Li$ NMR spectroscopy, and is completely converted to the dithiol only after stirring for several hours with 5 M HCl. The pyridine dithiols can be handled without special precautions except that exposure to air should be limited to prevent oxidation.



The $C_2$ symmetrical double condensation product **5** obtained from optically pure (*R*)-thiofenchone can also be prepared; the crystal structure (not shown) confirms addition from the *exo* side of thiofenchone. Thiocamphor fails to undergo addition owing to formation of the thioenolate; competitive enolate formation appears to be a limitation to the direct approach of Scheme 1 when thioketones are used. The mixed adduct **6** can be prepared by lithiation of the 'single-armed' derivative **1** followed by a quench with 1 equiv. of thioadamantanone.

**Scheme 1** *Reagents and conditions*: i, $Bu^nLi$ (1.1 equiv.), THF, −80°C; ii, −80 °C → −40 °C; iii, $R_2C{=}X$; iv, $Bu^nLi$ (1.2 equiv.), THF, −80 °C; v, −80 °C → −50 °C

The complexation behaviour of **4a** has been studied extensively; other pyridine dithiols appear to behave in a related fashion. Treatment of **4a** with 1 equiv. HCl or HBr (titrated saturated $CH_2Cl_2$ solutions) leads to the air- and moisture-stable complexes **4a**·HCl and **4a**·HBr in quantitative yields. On addition of 1 equiv. of aqueous $HNO_3$ to **4a** in $CHCl_3$ at 0 °C, **4a**·$HNO_3$ is obtained; on complexation at ambient temperature, however, the thiol groups are partly oxidized. Attempted encapsulation of phosphonic acids failed.

Complexation with $ZnCl_2$ in MeOH provides the dimer [**4a**·$ZnCl_2$·MeOH]$_2$, whereas complexation of $Zn(NO_3)_2·4H_2O$ affords a monomeric and unstable **4a**·$Zn(NO_3)_2$ complex

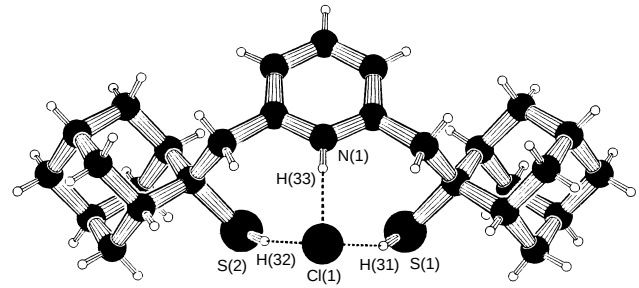


**Fig. 1** The molecular structure of **4a**·HCl. Selected distances (Å) and angles (°): H(31)–Cl 2.58(3), H(32)–Cl 2.45(5), H(33)–Cl 2.19(3), N–H(33) 0.86(3), N–Cl 3.056(2), S(1)–H(31)–Cl 162(3), S(2)–H(32)–Cl 168(3), N–H(33)–Cl 178(3).

(characterized spectroscopically), which in MeOH or MeCN is slowly converted to the **4a**·$HNO_3$ complex.‡ These structures are not shown for reasons of space.

Crystal structures of all complexes except those with HBr and $Zn(NO_3)_2$ have been determined. Those of **4a**·HCl§ (Fig. 1) and **4a**·$HNO_3$ (Fig. 2)§ are shown, and for purposes of illustration some salient features of the former are briefly mentioned.

Monomeric HCl is firmly embedded in a cavity and held in place by bonding to pyridine nitrogen and the two thiols. The free pyridine dithiol **4a** (structure not illustrated) is not preorganized in this arrangement. In the complex the thiol groups are clearly hydrogen bonded to the chloride, although the bonds are of unequal length [H(31)··Cl(1) 2.58(3), H(32)··Cl(1) 2.45(5) Å], probably as a result of crystal packing effects. The thiol groups bond from the same face (roughly a plane of symmetry in the complex) whereas in the corresponding pyridine diol complex, the hydroxy groups hydrogen bond to chloride from opposite faces (approximate $C_2$ molecular symmetry, an analogous arrangement is seen in the structure of **4a**·$HNO_3$ shown in Fig. 2).[3a] The H··Cl bond distance in **4a**·HCl is 2.19 Å, which is 0.92 Å longer than the covalent HCl bond length in the gas phase (1.27 Å).[5] A search of the Cambridge Database for pyridine··HCl complexes revealed an average bond length for the H··Cl bond distance of 2.20 Å with a deviation of 0.17 Å for 39 hits. For this screening a minimum N··H··Cl bond angle of 120° was included.

In the $^1$H NMR spectrum of **4a**·HCl (in $CDCl_3$) downfield shifts are seen at the 3- and 4-positions of the pyridine ring comparable in magnitude to those observed for the complex of 2,6-lutidine with HCl. We concluded that the NMR and bond length data are consistent with the tight ion pair (formulation **A**) rather than the covalent formulation **B**.¶

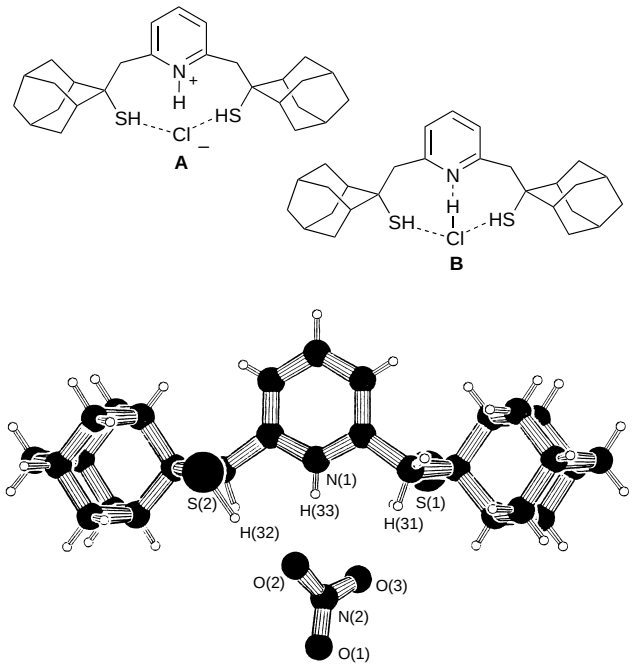

**Fig. 2** The molecular structure of **4a**·$HNO_3$. Selected distances (Å) and angles (°): H(31)–O(3) 2.21(5), H(32)–O(2) 2.26(5), H(33)–O(2) 1.92(5), H(33)–O(3) 2.58(5), H(33)–N(1) 0.87(5), N(1)–O(2) 2.762(6), S(1)–H(31)–O(3) 160(3), S(2)–H(32)–O(2) 156(3), N(1)–H(33)–O(2) 162(5), N(1)–H(33)–O(3) 143(4).

In summary, pyridine dithiols can be obtained from direct addition of 2,6-lutidine to (non-enolisable) thioketones in the presence of a strong base. These pyridine dithiols provide a well-defined cavity, perhaps even better than the pyridine diols, in which various acids are encapsulated by three point bonding. We are examining methods to transfer these complexed acids from chiral nonracemic pyridine dithiols such as **5** to suitable acceptors such as prochiral epoxides.

† B. Koning is partially supported by a grant from the Dutch National Science Foundation (NWO) administered through the Office for Chemical Research (SON).

‡ Unless otherwise mentioned, satisfactory elemental analyses and/or X-ray structure analyses were obtained for all new compounds. $^1$H NMR and infrared (IR) spectra were in accord with expectations for all compounds.

§ Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/449.

¶ Formulation **B** is mentioned because of puzzling physical properties and observations in the infrared (IR) spectra. Upon exposure of the solid to low pressure we observed that the HCl evaporates. This is not observed for other complexes, for example 2,6-lutidine·HCl. IR spectra of **4a**·HCl in KBr are complicated by the fact that the HCl absorptions are hidden under the strong adamantyl C–H bands. This led us to the study of the DCl complex. In some cases the **4a**·DCl complex shows a sharp absorption at 2211 $cm^{-1}$, which is partially masked by a broad pyridine–$D^+$ absorption in the region 2212–1850 $cm^{-1}$. The 2211 $cm^{-1}$ absorption is close to that expected for *covalent* D–Cl. For example, values of 2091 and 2090 $cm^{-1}$ for monomeric DCl in, respectively, the gas phase[6a] and in an Ar matrix[6b] are given in the recent literature. The $^1$H NMR spectra as well as the IR spectra indicate clearly that D–Cl has not exchanged with S–H (attempts to prepare the S–D derivative of **4a** have been unsuccessful owing to the failure of the S–H groups to exchange with D at a measurable rate either in free **4a** or in the D–Cl complex). The 2211 $cm^{-1}$ absorption is not observed in the D–Cl complex with 2,6-lutidine.

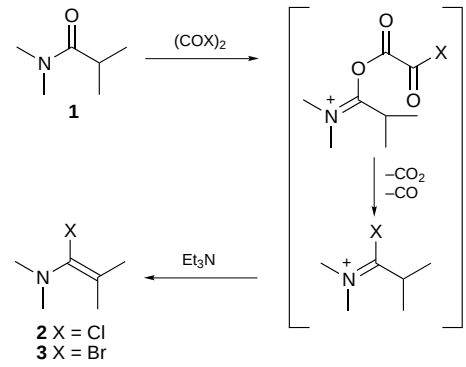
# Introduction of bromine and chlorine substituents in medium ring ethers and lactones

**Justin G. Bendall, Andrew N. Payne, Thomas E. O. Screen and Andrew B. Holmes***

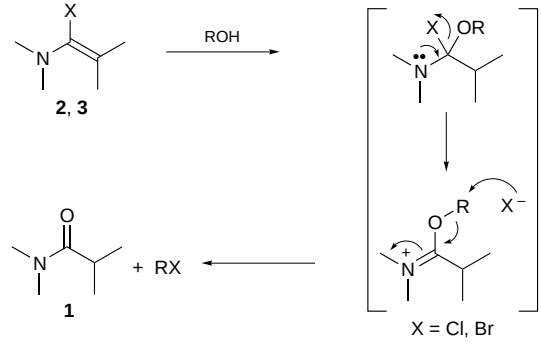
*University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*

**A convenient preparation of α-halo enamines using oxalyl halides is described together with applications of these reagents in the halogenation of β-hydroxy cyclic ethers and lactones.**



There has recently been considerable interest in the synthesis of medium ring ether marine natural prducts, and significant progress has been achieved both in ring expansion reactions and in the controlled cyclisation of acyclic precursors.[1] Of all the features present in the various *Laurencia* and related cyclic ether metabolites which have been isolated from red algae the β-halo ether substituent is probably the most challenging. In connection with our own studies towards the synthesis of medium ring marine natural products[2–4] we required a method for the stereospecific introduction of chlorine and bromine β to the ring oxygen. The most common way to achieve this so far has been displacement of hydroxy group using a phosphorus activating reagent,[5] a xanthate,[6] or a metal-mediated epoxide opening.[7] Alternatively, the halogen can be present before ring closure as in the radical cyclisations employed by Lee.[8] The β-ring oxygen can suppress nucleophilic displacement of a leaving group substantially,[9] and can potentially promote oxonium ion formation and rearrangement.[10] Here we report the use of α-halo enamine reagents to effect halide introduction by substitution reactions.

An α-halo enamine reagent was initially introduced by Speziale,[11] who prepared *N*,*N*-diethyltrichlorovinylamine and showed subsequently that it could be used to transform alcohols into alkyl chlorides with stereochemical inversion.[12] The more reactive 1-chloro-*N*,*N*,2-trimethylpropenamine **2** was later developed by Ghosez[13,14] who demonstrated conversion of carboxylic acids into acid halides.[15] We subsequently used this reagent for the first time with allylic alcohols and showed that it could be used to introduce an allylic chloro substituent into the side chain of the *cis*-maneonenes isolated from *Laurencia nidifica*.[16] Further examples have subsequently been reported by Ghosez to prepare simple alkyl halides,[17] and there are examples of steroid halogenation in the patent literature.[18] Despite having the advantage that they can be used under essentially neutral conditions these reagents have received little attention from organic chemists, possibly owing to the need to use liquid phosgene to prepare the α-chloro enamine **2**, and a subsequent bromide displacement reaction to convert **2** into the α-bromo enamine **3**.[14] In the present work, it has been found that the amide **1** reacts with oxalyl chloride or oxalyl bromide followed by treatment with triethylamine to furnish the respective α-halo enamines **2** and **3**† (Scheme 1).



The reagents **2** and **3** smoothly converted alcohols into alkyl halides in $CH_2Cl_2$ at room temperature (Scheme 2). The displacement was shown to take place with inversion of configuration as illustrated (Table 1, entry 1) for the conversion of (−)-menthol into (+)-neomenthyl halides.[17] A trace of alkene elimination product (*ca.* 5%) was also detected. This could be suppressed by performing the reactions at −78 °C.

The successful halogenation of β-hydroxy cyclic ethers was initially demonstrated (Table 1, entry 2) using 3-hydroxytetrahydrofuran. β-Hydroxy 9- and 10-membered lactones[19] were halogenated readily, and the stereochemical inversion was confirmed by comparison of the $^1$H NMR difference NOE spectra of **13** and **15**.‡ In the chloro compound **15** a large (11%) NOE was observed between the signals due to H-8 (δ 4.46, dt, *J* 9, 4, 4 Hz) and H-9 (δ 4.95–5.05, m), but no NOE was observed between the signals due to H-8 and H-9 in the alcohol **13**. The hydroxy-substituted 8-membered lactones **19**[20] and 9-membered cyclic ethers **21**[4] proved more problematical, and underwent either isobutyryl esterification or decomposition, resulting in low yields of halides. By changing the solvent to a mixture (1 : 1) of propylene oxide and $CH_2Cl_2$ the decomposition was suppressed, although the reaction rate was much slower, and the reaction was generally conducted at room temperature. Incorporation of dried 4 Å molecular sieves prevented esterification.§ The reaction was also used to prepare the (*E*)-pentenynyl bromide **25** from the alcohol **24**, which gave poor yields of bromide using other methods (Table 1, entry 8).

In summary, an exceptionally mild method of preparing the α-halo enamine reagents **2** and **3** has been described. These versatile reagents are effective in converting hydroxy compounds into the corresponding halo compounds under mild conditions, even under circumstances where rate suppression occurs due to the β-oxygen effect. Applications in the synthesis of halogenated medium ring ether natural products can be expected to follow.

## Footnotes

† Preparation of α-bromo enamine **3** from oxalyl bromide. A solution of freshly distilled *N*,*N*,2-trimethylpropionamide **1** (5.0 g, 43 mmol) in dry $CH_2Cl_2$ (10 cm³) was added dropwise over 20 min to a cooled (0 °C), mechanically stirred solution of oxalyl bromide (10.0 g, 46 mmol) in dry $CH_2Cl_2$ (10 cm³), producing mild effervescence. The mixture was stirred for 2 h and was then cooled further (−78 °C). Freshly distilled dry $Et_3N$ (7.0 cm³, 50 mmol) was added dropwise to the white paste over 10 min. The mixture was warmed to room temperature, stirred for 2 h, and then filtered and distilled under vacuum to give 1-bromo-*N*,*N*,2-trimethylpropenamine **3** as a clear, moisture-sensitive liquid (4.3 g, 55%), bp 44 °C at 10 mmHg, $\rho^{20}$ 1.20 (Found: C, 40.1; H, 7.1; N, 7.9. $C_6H_{12}BrN$ requires C, 40.5; H, 6.8; N, 7.9%); $\nu_{max}$(neat)/cm$^{-1}$ 1654, 1450, 1298, 1124, 1011, 803; $\delta_H$(400 MHz, $CDCl_3$) 1.77 (6H, s, $CMe_2$), 2.28 (6H, s, $NMe_2$); $\delta_C$(100 MHz, $CDCl_3$) 21.6 ($CMe_2$), 43.7 ($NMe_2$), 126.0 (C-2), 140.4 (C-1).

‡ All new compounds provided satisfactory spectroscopic ($^1$H and $^{13}$C NMR, IR, MS) and microanalytical or high resolution MS data.

§ Representative procedure for the preparation of the bromo compound **22**. Dried 4 Å molecular sieves (100 mg) were added to a stirred solution of the alcohol **21**[4] (17 mg, 34 μmol) in $CH_2Cl_2$ (0.3 cm³) and propylene oxide (0.3 cm³) under nitrogen, which after 10 min was cooled (−78 °C). α-Bromo enamine **3** (0.05 cm³) was added and the mixture was warmed to ambient temperature and left overnight. MeOH (0.05 cm³) was added and the mixture was chromatographed on silica gel (hexanes–diethyl ether) to give the bromide **22** (8 mg, 45%) and starting material **21** (9 mg, 54%).

¶ $[\alpha]_D$ + 73 (*c* 0.83, EtOH) [lit.,[21] +59 and +58 (*c* 1.38 and 1.44 in EtOH)]. NMR data were identical to those reported.[22]

# Mechanistic study on *meso*-hydroxyoctaethylporphyrin formation from an $Fe^{III}(oep)–H_2O_2$ complex

**Kunihiko Tajima,*[a] Kohji Tada,[b] Masato Shigematsu,[b] Kenji Kanaori,[a] Nagao Azuma[b] and Keisuke Makino[a]**

[a] *Department of Polymer Science and Engineering, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606, Japan*
[b] *Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790, Japan*

**The benzoyl ester of an iron(III) *meso*-hydroxyoctaethylporphyrin complex, containing $^{18}O$ derived from molecular oxygen, is isolated from the reaction solution of the complex $[Fe^{III}(oep)(OOH)(OH)]^-$ which is prepared by reduction of $[Fe^{II}(oep)(py)(^{18}O_2)]$ with sodium ascorbate.**

Haem enzyme–hydrogen peroxide complexes have been thought to be produced by the following two reactions: (*i*) coordination of hydrogen peroxide to the haem chromophore of enzymes, such as peroxides[1] and catalases,[2] (*ii*) one-electron reduction of the iron(II) oxygen complex of haem oxygenase[3] and P450.[4] We have reported the formation of the six coordinate $[Fe^{III}(oep)(OOH)(OH)]^-$ complex by reaction between hydrogen peroxide and $[Fe^{III}(oep)Cl]$.[5] In addition, the complex was similarly produced by reduction of the $Fe^{II}(oep)–O_2$ adduct with sodium ascorbate.[5] In the latter reaction system, the hydrogen peroxide complex was readily converted to octaethylverdohaem[6] at −30 °C. However, the possible transient intermediate species involved in the reaction pathway was still uncertain.[7] Here, the chemical reactivity of the hydrogen peroxide complex was studied by focusing upon formation of *meso*-hydroxy-oep derivatives, by means of EPR, optical absorption and product analysis using $^{18}O_2$.

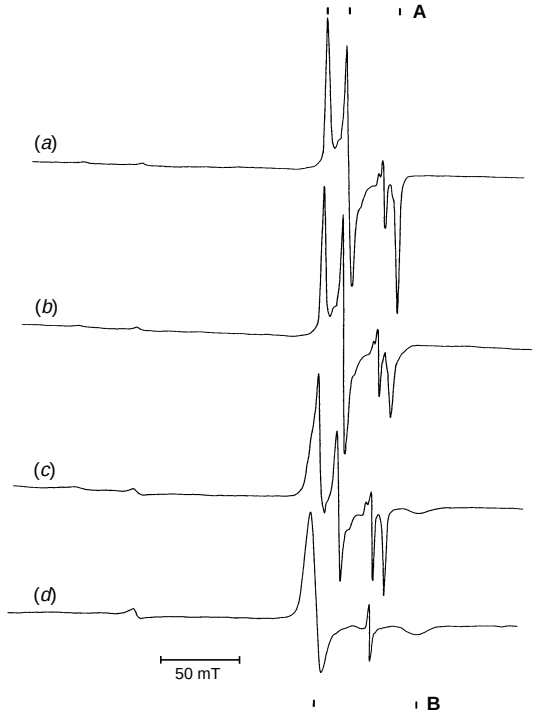

**Fig. 1** (*a*) EPR spectrum observed at 77 K for the reaction solution containing $[Fe^{III}(oep)(OH)(OOH)]^-$; (*b*) with $^{17}O_2$ (39% enrichment); (*c*) after standing a solution of (*a*) for 30 min at −50 °C, and (*d*) after 60 min at −50 °C. The signal detected in the free-spin region is ascribed to the ascorbic acid radical.

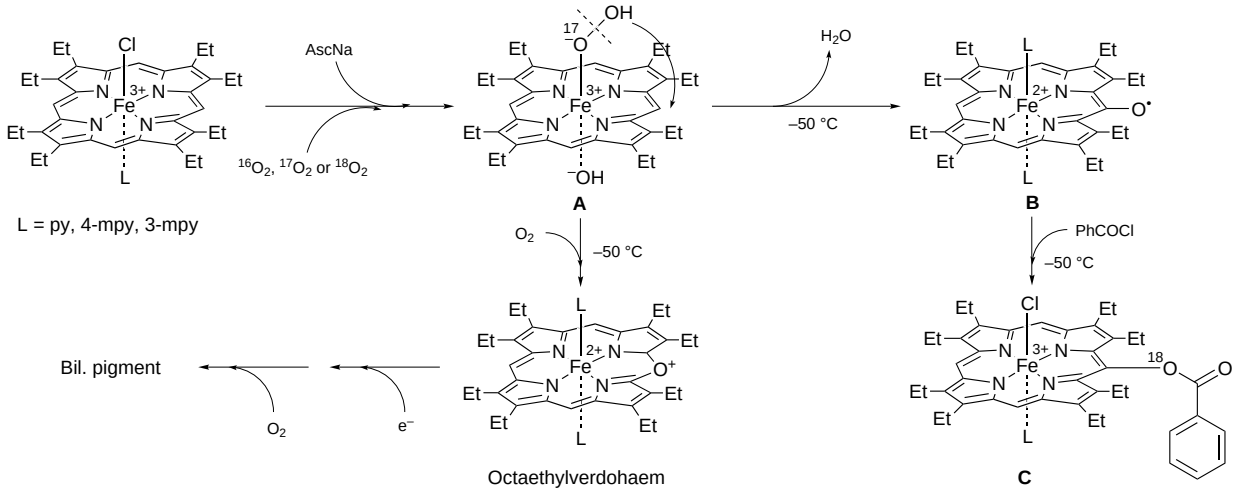
A reaction solution containing $[Fe^{III}(oep)(OOH)(OH)]^-$ was prepared in a quartz EPR tube (5.0 mm diameter), by addition of aqueous sodium ascorbate (0.5 M, 0.016 ml) to a pre-cooled (−40 °C) dmf–pyridine (py) (9 : 1) solution of $[Fe^{III}(oep)Cl]$ (1.0 mM, 0.4 ml). After 3 min of continuous oxygen bubbling in the reaction mixture, the solution was frozen at −78 °C, and the atmosphere of the sample tube was changed to nitrogen. Then the sample was immediately frozen to 77 K. EPR signals [Fig. 1(*a*)] due to an iron(III) low-spin species (**A**; $g_1$ = 2.287, $g_2$ = 2.176, $g_3$ = 1.956) were clearly recorded, and the *g*-values agreed well with previous results[5] (Table 1). Fig. 1(*b*) show that a similar EPR spectrum was successfully detected using $^{17}O_2$ (39% enrichment), with the linewidth of the $g_3$ component broadened by unresolved splitting due to $^{17}O$ ($I$ = 5/2).[8] This demonstrates the fact that the peroxide anion, ligated axially in **A**, was derived from atmospheric oxygen.



Quantitative EPR analysis was performed by means of graphic integration, using an ESPRIT ESR data analyser (JEOL). In the present case, the EPR spectrum recorded for a dmf solution of $[Cu^{II}(tpp)]$ ($S$ = 1/2) was employed as a standard to calibrate the integrated EPR signal intensity of **A**. The concentration of **A** was evaluated to be *ca*. 0.8 mM. By using the dmf solution of $[Fe^{III}(oep)Cl]$ as the standard, the total concentration of observed iron(III) high-spin species ($g$ = 6, 4.3) arising from remaining $[Fe^{III}(oep)Cl]$ and a decomposed tetrapyrrole iron complex,[8] was also estimated to be *ca*. 0.1–0.15 mM. Therefore the maximum percentage of **A** in the fresh frozen mixture was confirmed to be *ca*. 80% of the initial concentration of $[Fe^{III}(oep)Cl]$.

On standing the reaction solution at −50 °C for 30 min, new EPR signals ($g_\perp$ = 2.3, $g_\parallel$ = 1.8) began to merge with that of complex **A**, as shown in Fig. 1(*c*). After 60 min, signals due to

**Scheme 1** Possible reaction mechanisms for the formation of *meso*-hydroxy-oep *via* $[Fe^{III}(oep)(OH)(OOH)]^-$

the new species (denoted **B**; $g_\perp$ = 2.290, $g_\parallel$ = 1.805) was exclusively observed [Fig. 1(*d*)], while those of **A** completely disappeared. **A** was unstable under oxygen, and immediately changed to a green diamagnetic species (388, 493, 527 and 650 nm), after oxygen gas bubbling into the solution at −50 °C. The resulting species was isolated and identified as bis(pyridine)(octaethylverdohaem) iron(II),[9] from its NMR, and optical absorption parameters. This observation indicates that **B** is one of the intermediate species in the process of verdohaem derivative formation from **A**.

Similar EPR measurements were performed using methylated pyridine derivatives, 2-, 3-, 4-mpy, and 2,6-dmpy, in order to clarify the role of **A** in the process of verdohaem formation. Similar EPR spectra to **A** were recorded for the reaction systems composed of 3- and 4-mpy, and the observed EPR parameters agreed well to those of **A** (Table 1). Furthermore, the EPR signal of **B** was clearly detected with 3- and 4-mpy instead of py, and the observed *g*-values agreed with each other, although formation of **A** and **B** was not detected using 2-mpy or 2,6-dmpy. EPR signals of $[Fe^{III}(oep)Cl]$ completely disappeared, suggesting that the complex is reduced to the iron(II) form Fe(oep) and the formation of the oxygen complex $[Fe^{II}(oep)(O_2)]$ could be markedly suppressed. Accordingly, this provided experimental evidence that the $Fe^{II}(oep)$–$O_2$ complex is converted to **B** *via* **A** (Scheme 1).

In terms of the observed *g*-parameters, **B** is assigned as the porphyrinoxyl radical form of iron(II) *meso*-hydroxyoctaethylporphyrin (Table 1);[10] however, the origin of the oxygen atom of the hydroxy group was still debatable. MS measurements were thus performed for **B** isolated from $^{18}O_2$ (96% enrichment) as its benzoyl ester by addition of a dmf solution of benzoyl chloride (0.1 M, 0.4 ml) to a solution of **B** at −50 °C. The brownish yellow species obtained, **C** [$\lambda_{max}$ = 379, 508, 535, 636 nm ($CHCl_3$) $g$ = 6, 2 at 77 K] gave an IR band at 1740 $cm^{-1}$ due to ν(CO) of the benzoyl ester moiety. NMR was consistent for a *meso*-benzoyloxyoctaethylporphyrin iron(II) bispyridine complex.[11] MS for **C**, isolated from $^{16}O_2$ and $^{18}O_2$ atmosphere, revealed weak parent ion peaks (*m/z* 743, 745), and major fragment peaks ($M^+ - Cl^-$ at *m/z* 708, 710), respectively. In addition, a common fragment peak was detected for both samples at *m/z* 588, which corresponds to Fe(oep) after fragmentation of the chlorine and benzoyl moieties from **C**. Based on the observed *m/z* value **C** was formulated as $C_{43}H_{48}N_4{}^-(^{16}O)_2Cl$ and $C_{43}H_{48}N_4{}^-(^{16}O)(^{18}O)Cl$, respectively, indicative that the oxygen atom attached at the *meso* carbon was derived from molecular oxygen. Detectable fragment peaks due to the $^{16}O$ structure were scarcely detected in the mass spectrum of the $^{18}O$ analogue, indicating that the oxygen atoms of $H_2O$ and $OH^-$, derived from aqueous sodium ascorbate, are not the oxygen source in **C**.

Noting that **B** was produced *via* **A**, the axially ligating $OOH^-$ is regarded as the most probable oxygen source. These results are reasonably interpreted by assuming an intramolecular electrophilic addition of $OOH^-$ to the porphyrin ring resulting in the formation of the cationic form of *meso*-hydroxyporphyrin,[12] which was readily converted to **B** by loss of two protons,[10] under alkaline conditions (Scheme 1). In the process of O–O bond cleavage in **A** the formation of high-valent iron species are also postulated, however, these species are expected to be shortlived in the presence of ascorbate, and readily reduced to **B** with loss of water. Consequently, the haem $H_2O_2$ complex is the most important intermediate in the process of *meso*-oxygenation. The results described here demonstrate the role of the haem–$OOH^-$ complex in the process of haem metabolism catalysed not only by the coupled oxidation of haem,[7] but also by naturally occurring haem-oxygenases.[12]

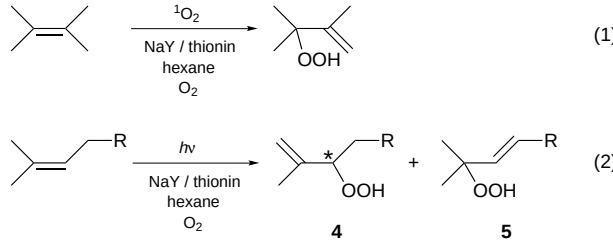
# Generation and reactivity of singlet oxygen within zeolites: remarkable control of hydroperoxidation of alkenes

**Rebecca J. Robbins and V. Ramamurthy***

*Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*

**A highly selective oxidation of alkenes included within a Y zeolite is achieved by generating singlet oxygen *via* excitation of a monomeric dye exchanged within a zeolite; conformational control brought forth by the medium is suggested to be responsible for the observed remarkable selectivity.**



One well known reaction of singlet oxygen is the hydroperoxidation of alkenes containing allylic hydrogens, often referred to as the 'ene' reaction or Schenk reaction.[1] Reaction with substrates containing several distinct allylic hydrogens produces several distinct products. Although the peroxidation *via* singlet oxygen has found much synthetic application, regio- and stereo-control are still difficult issues.[2] We show here that the interior of a zeolite offers one possible solution to this important problem. When the oxidation of alkenes **1**–**3** is conducted within the supercages of faujasite Y type zeolite a remarkable selectivity of the hydroperoxidation is observed.

Although the mechanistic details of the ene reaction are still being debated, certain trends have been identified.[3] Experiments by several groups have brought out the importance of the geometrical arrangement of the allylic hydrogens with respect to the attacking singlet oxygen during the hydroperoxide formation.[4] This suggested to us that if one succeeds in controlling the conformation of the alkene and thus the accessibility of the allylic hydrogen(s) to the reagent, singlet oxygen, one might be able to achieve selectivity in the oxidation process. We have already established that one can use zeolite as a medium to achieve conformational control on ketones that undergo Norrish type reactions.[5] With this in mind, we set out to use a similar strategy to demonstrate that zeolite can play a vital role in oxidation processes initiated by singlet oxygen. Indeed, this strategy has yielded remarkable results in terms of obtaining predominantly a single hydroperoxide from the alkenes **1**–**3** within the supramolecular assembly of alkene, thiazine dye, oxygen and zeolite.

In our system, generation of singlet oxygen entails irradiation of a thiazine dye located within the supercages of the zeolite lattice. These dyes (thionin, methylene blue and methylene green) are placed within the zeolite *via* a cation-exchange process.[6] The exchange involves dropping the zeolite (*e.g.* 600 mg unactivated NaY) in a prestirred aqueous solution of thionin (2 mg in 250 ml of water). Continuous stirring for 3 h followed by filtration and aqueous washes (or Soxhlet extraction) yields a pink zeolite. The presence of water in the zeolite has a dramatic effect on the state of aggregation of the organic dye within the zeolite cage. With coadsorbed water or in 'wet' zeolite, thionin exists as a dimer, whereas in 'dry' zeolite the organic dye exists as a monomer and as a result the zeolite turns blue.[6] It is only the monomeric form of the dye which functions as a sensitizer and generates singlet oxygen. Initial experimentation showed that in the absence of alkene, irradiation of 'dry' Na Y/thionin/oxygen generated an emission at 1268 nm corresponding to $^1O_2$. Irradiation of the dye-exchanged zeolite in the presence of 2,3-dimethylbut-2-ene, a standard alkene known to react with singlet oxygen, gave the same hydroperoxide as in the isotropic solution medium [Scheme 1, eqn. (1)].[7] This demonstrated that not only was $^1O_2$ generated in the zeolites, but that it was reactive as well.

Having established that generation of singlet oxygen within a zeolite is feasible, we tested our conformational control proposition with the alkenes **1**–**3a**–**c**. Irradiation took place in a Kimax tube containing a zeolite and alkene as a slurry in hexane. Product hydroperoxide(s) were extracted from the zeolite with tetrahydrofuran and were analysed by GC and NMR after reduction with $PPh_3$. The only products obtained are those reported. The isolated yield ranged between 65 and 75%. Products were compared and found consistent with literature reports.[8] Table 1 compares the ratio of secondary (**4**) to tertiary

**Scheme 1**

**Table 1** A comparison of the ratio of secondary to tertiary hydroperoxides in various media

| Alkene | Conditions | Secondary hydroperoxide **4** | Tertiary hydroperoxide **5** |
|---|---|---|---|
| **1** | Thionin/MeCN | 51 | 49 |
| | Rose Bengal/MeCN | 50 | 50 |
| | NaY/thionin | 72 | 28 |
| **2** | Thionin/MeCN | 40 | 60 |
| | NaY/thionin | 100 | — |
| **3a** | Thionin/MeCN | 50 | 50 |
| | Rose Bengal/MeCN | 54 | 46 |
| | LiY/thionin | 100 | — |
| | NaY/thionin | 85 | 15 |
| | RbY/thionin | 80 | 20 |
| | CsY/thionin | 66 | 34 |
| **3b** | Rose Bengal/MeCN | 56 | 44 |
| | LiY/thionin | 100 | — |
| | NaY/thionin | 100 | — |
| | RbY/thionin | 94 | 6 |
| | CsY/thionin | 92 | 8 |
| **3c** | Rose Bengal/MeCN | 52 | 48 |
| | LiY/thionin | 100 | — |
| | NaY/thionin | 100 | — |
| | RbY/thionin | 100 | — |
| | CsY/thionin | 100 | — |

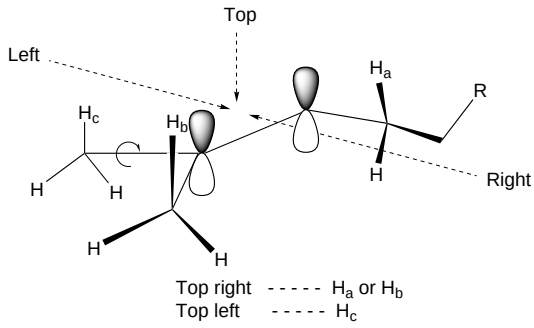


**Fig. 1**

(**5**) hydroperoxides obtained in an acetonitrile solution to that obtained in the zeolite oxidation reaction. For additional confirmation, the tertiary alcohol product of **3a** was independently synthesized as an authentic sample. Retention times and NMR of the authentic samples are consistent with the observed products. Also, the hydroperoxides generated from Rose Bengal sensitized oxidation were stirred overnight in a slurry of hexane and NaY/thionin. Both products were recovered in the same ratio as prior to zeolite treatment. These control experiments confirmed that the observed unprecedented selectivity is not an experimental artifact.

Formation of both hydroperoxides **4** and **5** in solution has been rationalized on the basis that singlet oxygen attacks the alkene from the top-right side (Fig. 1).[4] In such an approach, the transition state is stabilized by secondary interactions between the oxygen and the allylic hydrogens which are situated parallel to the π–p orbitals. As per this accepted model the methyl group on the top-left side (Fig. 1) does not participate in the oxidation process. Results within the zeolites clearly suggest that the methylene hydrogens $H_a$ of **2** and **3** (Fig. 1) are not abstracted by the singlet oxygen. While the lack of formation of **5** within zeolites is an indication that the methylene hydrogens are excluded from the reaction, selective formation of **4** does not indicate which of the two (or both) methyl groups participates in the oxidation process. Without further experiments that would distinguish between the *gem* dimethyl groups, we can only provide a tentative model for the observed selectivity.

We suggest that the R group in the alkene (Fig. 1) plays a crucial role in the type of product(s) formed. While in solution, the most favoured conformation places both the methyl and methylene hydrogens in an appropriate geometry for abstraction (Fig. 1), it is quite likely that such a conformation may not be favoured within a zeolite. In a supramolecular assembly one will have to consider the interactions that arise between the adsorbent/guest and the environment. We speculate that within a zeolite, the alkene will be adsorbed to the surface *via* cation–π interactions.[9] A rotation of the $C^3$–$C^4$ bond might result under such conditions to relieve the steric strain that develops between the bulky R group and the surface. Such a rotation will place the methylene hydrogens away from the incoming singlet oxygen (Fig. 2) and therefore no tertiary hydroperoxide would be formed. The extent of steric repulsion between the surface and the R group may depend on the distance between the group and the surface. Larger cations such as Cs ion may place the alkene slightly further from the surface and thus reduce the steric strain between the surface and the R group. Formation of small amounts of tertiary hydroperoxide **5** in the case of **3a** and **3b** is

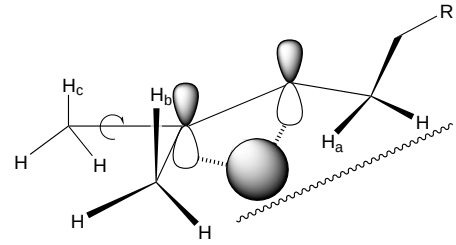

**Fig. 2**

consistent with this speculation. A comparison of the product distribution from **1** and **2** (and **3**) makes it clear that in order to achieve selectivity it is necessary to replace at least one hydrogen of the methyl group (in **1**) by a larger group such as methyl or phenyl. We recognize that the above model is only a working hypothesis and further experiments are needed to understand this unusual selectivity. The use of zeolite as a medium to achieve selective oxidation has been established and we are in the process of exploring this strategy with other alkenes. The ability to generate singlet oxygen and to achieve regioselective hydroperoxidation of alkenes within a zeolite has prompted us to consider stereoselective hydroperoxidation of alkenes with zeolite as the medium.[10]

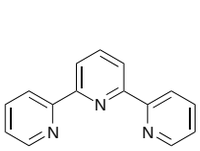
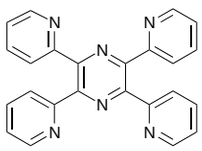
# Metallodendrimers: metal ions as supramolecular glue†

**Edwin C. Constable‡**



*Institut für Anorganische Chemie, Spitalstrasse 51, CH-4056 Basel, Switzerland*

**The coordination of appropriate organic molecules containing multiple metal-binding domains to metal ions provides a versatile alternative to carbon–carbon or carbon–heteroatom bond formation for the assembly of dendrimers.**

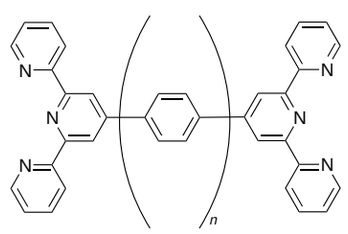


## Introduction: metallosupramolecular chemistry

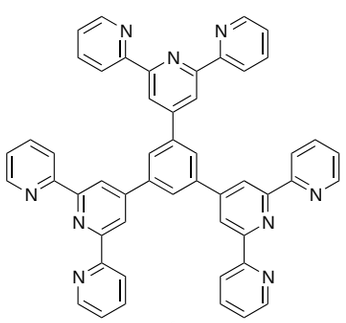
In the past two decades, dendritic molecules have developed from laboratory curiosities to components of burgeoning new technologies.[1] The majority of dendrimers are purely 'organic', with the descriptor 'organic' referring both to the chemical character of the molecular components used in the assembly and to the type of chemical reaction used in their combination. Conventionally, dendrimers are prepared with key assembly steps which involve the formation of carbon–carbon or carbon–heteroatom bonds. Although this methodology is well developed, it has a number of inherent disadvantages; whilst such bonds tend to be kinetically stable once formed, there may be significant energy barriers to their formation.

We have developed metallosupramolecular chemistry, in which the characteristic and preferred coordination numbers and geometries of metal ions are matched with the inherent bonding characteristics of polydentate ligands to control the assembly of novel supramolecular architectures.[2] A basic concept is that of a ligand domain as a metal-binding motif which may be introduced into multifunctional ligands. In our studies, we have adopted oligopyridine metal-binding domains as our favoured motif and, for reasons documented elsewhere, we have concentrated upon 2,2′:6′,2″-terpyridine **1** (tpy) domains.[3]

**1**



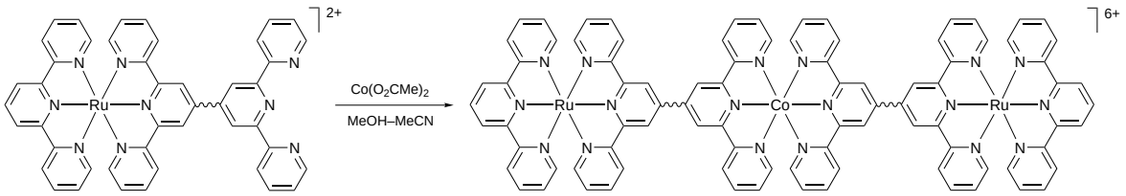
**2**



We and others[4,5] have developed metallosupramolecular approaches to dendrimers in which the key growth steps involve metal-donor atom interactions as opposed to carbon–carbon or carbon–heteroatom bond formation. This methodology is predicated on the thermodynamic and kinetic features of coordinate bond formation as opposed to conventional covalent bond formation. We describe such systems as metallodendrimers, and they may bear multiple functionality at inner generations or at the surface generation. Dendritic systems incorporating metal centres are of current interest as novel magnetic, electronic or photo-optical materials.

## Building metallodendrimers: prototype systems

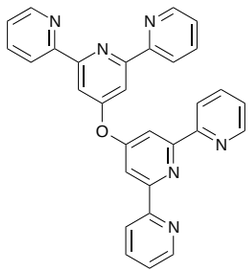
The simplest methodology relies upon the synthesis of organic molecules bearing two or more metal-binding domains, which are subsequently combined with the complementary metal components to give the desired metallodendrimers. When the tpy-based ligands are used, a six-coordinate metal centre is the appropriate complement to two tpy domains. In general, this approach leads to divergent or near-divergent syntheses. Our initial studies involved the prior synthesis of ligands containing two or more tpy metal-binding domains. Although we did not initially consider the simplest condensed bis(tpy) system, 2,3,4,5-tetra(2-pyridyl)pyrazine **2** (tppz), this, together with related pyrazine derivatives, has proved to be a useful bridging ligand[6] and we have recently embarked upon its incorporation into metallosupramolecules.[7] The first generation of ligands consisted of covalently linked tpy domains with variable length spacers **3** and the study of these compounds led to a continuing collaboration with the group of Jean-Pierre Sauvage in Strasbourg. We utilised the 'complexes as metals, complexes as ligands'[4] approach and the new ligands behaved very much as expected and gave us valuable experience in the assembly of low-nuclearity metallodendrimers.[8–11] This approach allowed the synthesis of multinuclear systems designed to give directional and spatial control over electron and/or energy transfer in components of photoconversion systems. Simple developments of the ligand syntheses lead to **4**, the progenitor of a metallosupramolecular starburst system.[11]



**3** $n = 0–4$

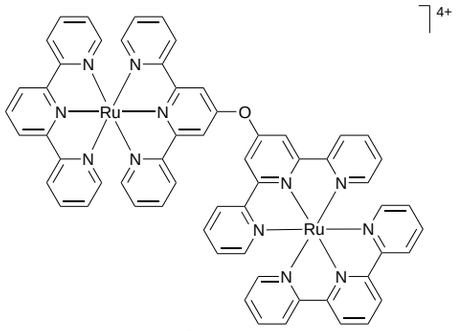
**4**

However, there were a number of inherent disadvantages with the methodology we had developed. Firstly, we were spending ever more time in ligand design and synthesis, and secondly, the routes tended to be divergent. In addressing the latter problem, we became concerned with the genesis of a convergent approach utilising labile first-row transition-metal centres in combination with kinetically inert ruthenium(II) centres (Scheme 1).[10] In the example shown, the reaction is essentially quantitative and is complete in minutes, in contrast to the formation of the corresponding triruthenium complex in lower yield after several hours at reflux. Subsequent oxidation gives a kinetically inert cobalt(III)diruthenium(II) complex. This approach partially overcame the problems associated with the



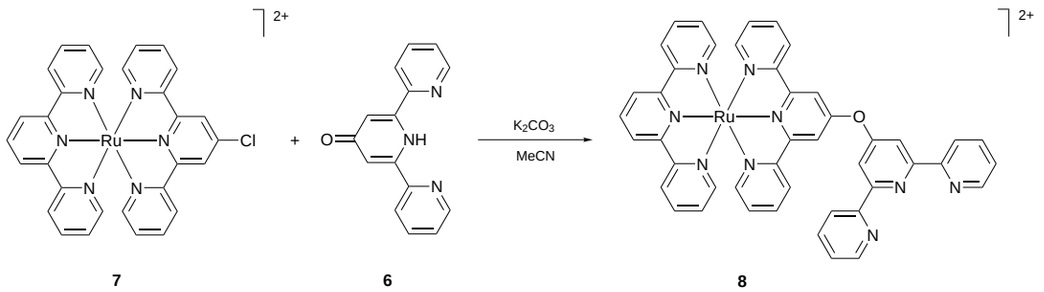
**Scheme 1**

divergent synthesis, but we were aware that many of the advantages of the metallodendritic approach would be lost if time-consuming ligand synthesis was an essential prerequisite.



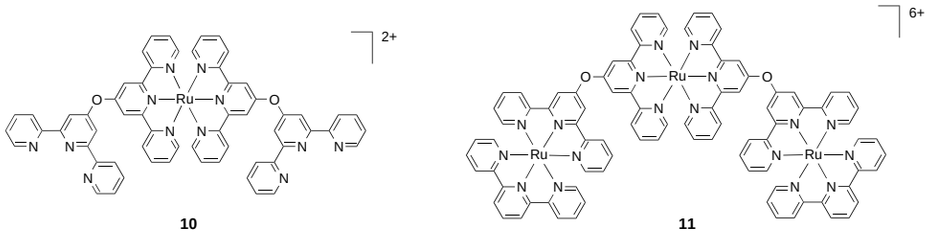
### Metal-directed reactions: *in situ* ligand synthesis

In the next phase of our work, we decided to develop *in situ* ligand assembly reactions to avoid the prior synthesis of bridging ligands. We had previously shown that the electrophilic character of 4-halopyridines was dramatically enhanced upon coordination to a transition metal[8,12] and we now extended this methodology to the *in situ* synthesis of the ether-bridged ligand **5**. The key components are the nucleophilic organic compound **6** and the electrophilic 4′-chloro-2,2′:6′,2″-terpyridine (Cltpy) complex **7** and reaction proceeds smoothly in the presence of base to give **8** in excellent yield (Scheme 2). The formation of **5** was established unambiguously by an X-ray structural determination of ligand prepared in a metal-free synthesis.[13]



**5**

We had hoped to extend the methodology to the direct formation of multinuclear complexes by the reactions of complexes of **6** with **7**; however, coordination of **6** to a metal sufficiently reduces its nucleophilicity that it does not react with **7**. However, **8** contains a non-coordinated tpy domain and so may be further reacted with appropriate metal species. Typical reactions have involved termination to yield dinuclear species **9** or the convergent assembly of trinuclear species with central iron, cobalt or ruthenium centres using the route shown in Scheme 1. It also proved to be possible to prepare **10** from the reaction of $[Ru(Cltpy)_2]^{2+}$ with **6**; this is a complex which can act as a bridging ligand.



**9**

The next question related to the formation of higher generations using this methodology. The key compound **11** could be prepared in good yield from the divergent reaction of **10** with $[Ru(Cltpy)Cl_3]$ or the convergent reaction of $[(Cltpy)Ru(\mathbf{5})]^{2+}$ with ruthenium trichloride. Analogues could be prepared using extensions of Scheme 1 with $[(Cltyp)Ru(\mathbf{5})]^{2+}$. We had hoped to react the surface Cltpy ligands with

**7** **6** **8**

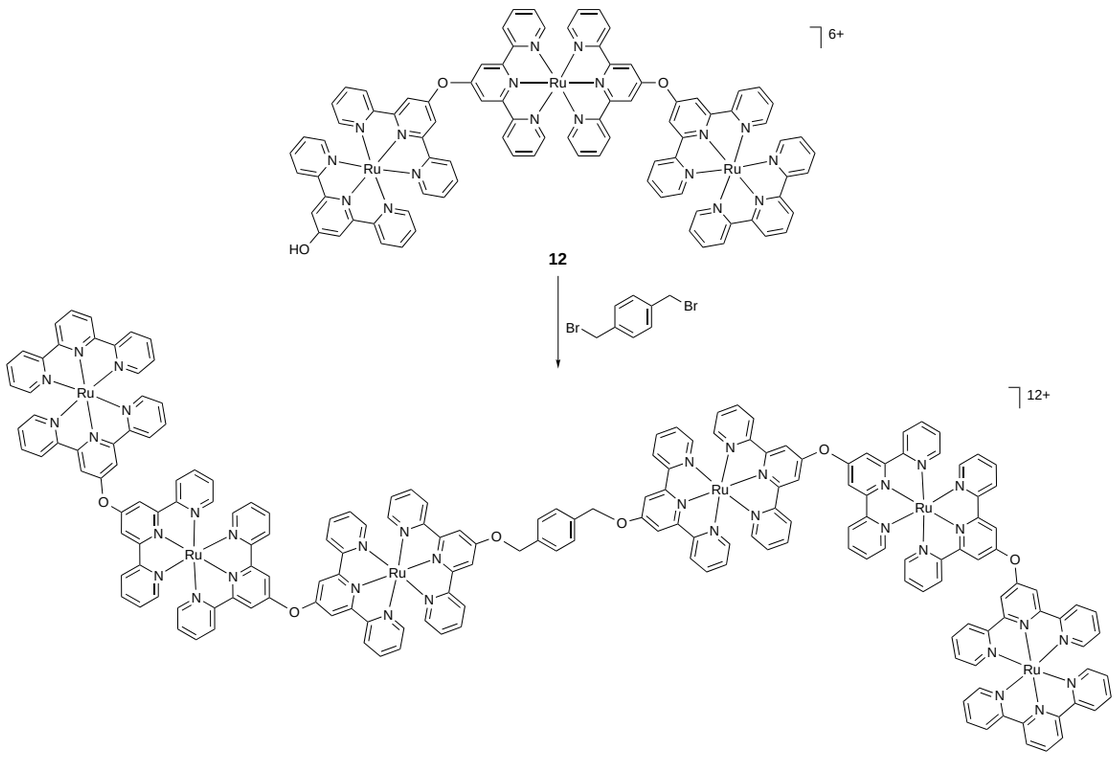
**Scheme 2**

**10** **11**

additional **6** to create new surface tpy metal-binding sites. However, it turned out that further homologation is not possible and that attack of **6** at a surface generation Cltpy is disfavoured compared to attack at inner generation ether links to give mononuclear complexes of **5** and **6** as the major products.

At this stage, we had shown that metal-directed reactions of a coordinated electrophile could be used for the formation of ether linkages within a given generation, but those new bonds were not stable under the reaction conditions required for the use of analogous reactions at later generations. Furthermore, the only control over topology and morphology came from the design of the ligand containing the multiple tpy domains.

### A second *in situ* synthesis



We noted above that complexes of **6** would not react with coordinated Cltpy electrophiles. We wondered if the use of a better electrophile might be successful and investigated the reactions of coordinated **6** with benzyl halides. In particular, we felt that the use of bis(bromomethyl)benzenes would lead to linear growth reactions. Furthermore, it was not necessary to use mononuclear complexes containing **6**, the ready accessibility of multinuclear complexes using the routes described above meant that it would be possible to incorporate building containing variable numbers and types of metal centres. This approach proved successful and a typical reaction leading to a hexanuclear species is shown in Scheme 3.[14] It is also interesting to note that this change in methodology also leads to a convergent synthesis; the hexanuclear species is formed from two trinuclear intermediates. The reaction with the electrophile occurred without any consequence for inner generation ether linkages and we could use the reaction of a coordinated electrophile with a nucleophile for the formation of one generation and the reaction of a coordinated nucleophile with an electrophile to prepare the subsequent generation.

We also noted that the convergent approach would permit us to bring more than two subunits together, and this led us to investigate the use of a 1,3,5-tris(bromomethyl)benzene centre for the assembly of three subunits. This approach was also successful and allowed the synthesis of a range of high-nuclearity species including a nonanuclear complex.[14] Finally, we considered the reaction with hexakis(bromomethyl)benzene—when the trinuclear complex **12** was used, a convergent synthesis of an octadecanuclear complex should result. Although we worried that steric interactions might prevent the reaction from proceeding to completion, we were very pleasantly surprised to find that **12** reacted smoothly with hexakis-(bromomethyl)benzene to give the desired octadecanuclear species **13**.[15]

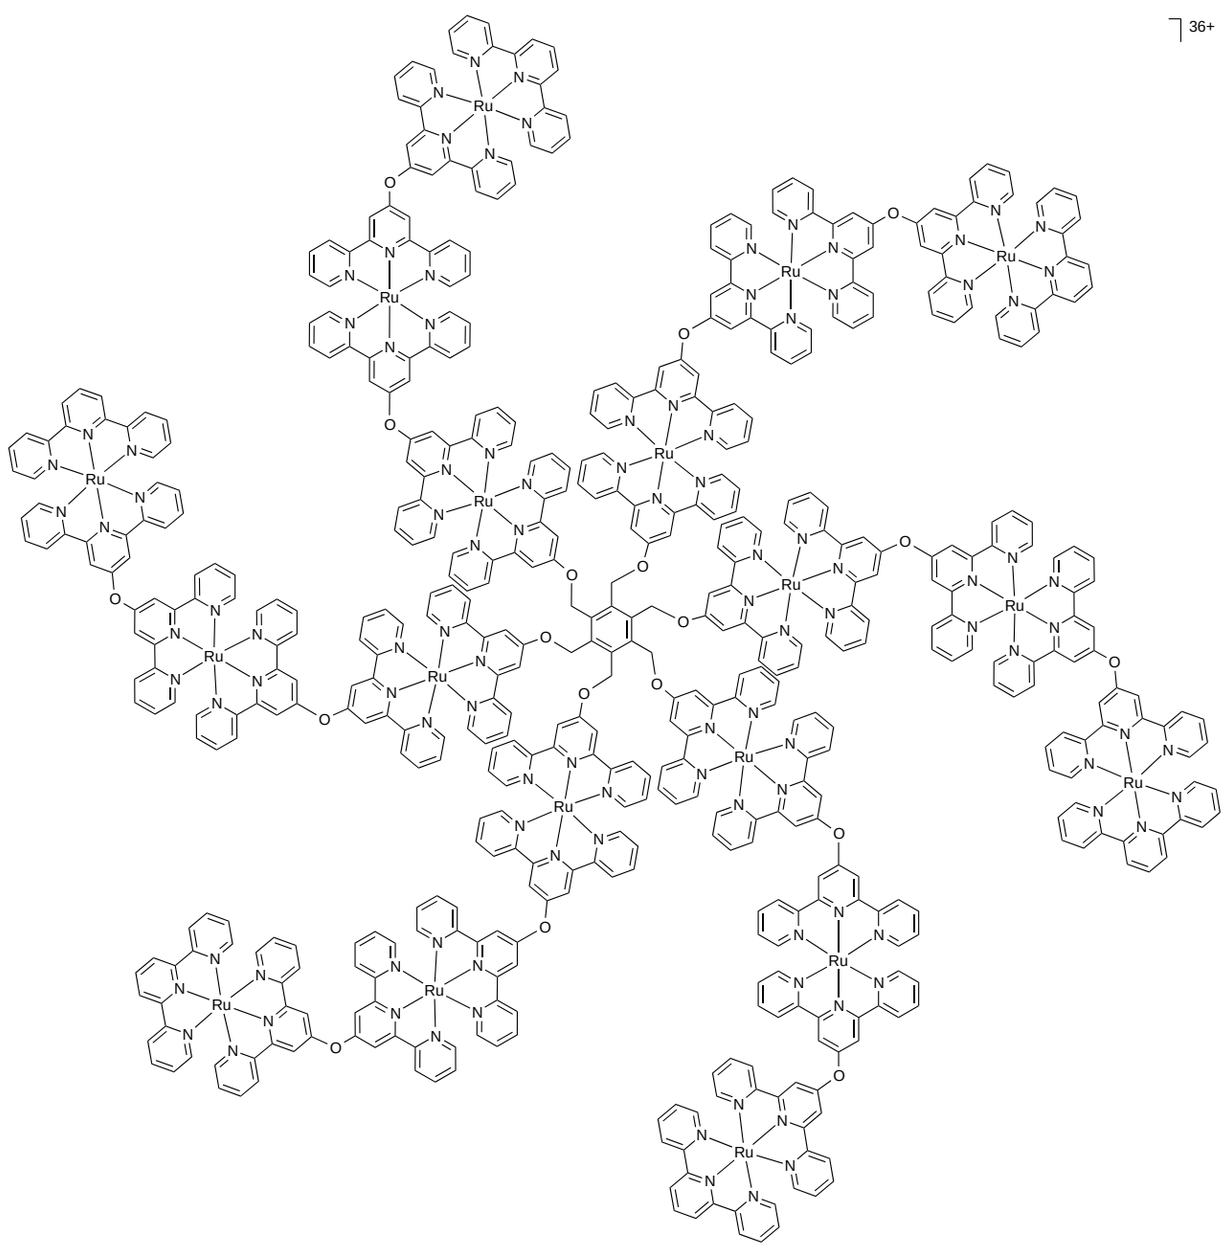
### A return to classical strategies

At this point, the use of the benzene central growth point led us to reconsider some aspects of our strategy. Although we had adopted the metallodendritic approach to circumvent kinetic barriers experienced in 'pure' organic chemistry, it now seemed that we could use high-yielding 'organic' reactions for the preparation of the central site of the dendrimer, with subsequent generations being built using the metallodendritic methodology. Preliminary experiments in collaboration with George Newkome established the viability of this hybrid approach, although we found the complexity of the organic components involved to be discouraging.[16]

We decided to adopt pentaerythrytol as a cheap and readily available starting point. The reaction of pentaerythrytol with an excess of Cltpy gave **14** with four tpy domains in excellent yield;[17] in contrast, when the pentaerythrytol was in excess, the monofunctionalised compound **15** could be isolated.[18] A related ligand **16** incorporating six tpy domains is readily prepared from dipentaerythrytol. The growth of metallodendrimers from **14** and **16** is facile; reaction with [Ru(Xtpy)$Cl_3$] gives the expected first generation tetranuclear or hexanuclear complexes in excellent yields. One of current interests lies in the incorporation of pendant functionality at the surface generation in high-nuclearity metallodendrimers and the a 40-boron first-generation *ortho*-carbaboranyl-functionalised metallodendrimer **17** is a typical example of such compounds.[17]

**Scheme 3**

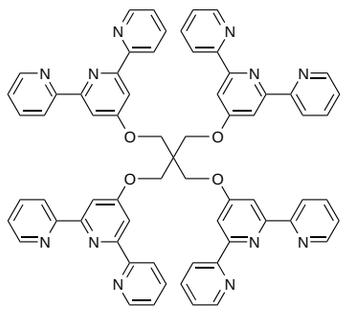
The new building block **15** now allows us to use a genuinely dendritic approach for the synthesis of metallodendrimers. The key species is **18**, which is a surface generation Xtpy functionalised species. However, in this case, the X-functionality incorporates three nucleophilic hydroxy groups. Subsequent reaction with the electrophilic complex **7** yields the expected hexadecanuclear complex.[18]



## Metallocentric dendrimers

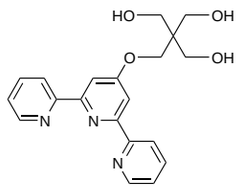
The strategies discussed above proved effective, but there were still a number of problems associated with the use of carbon-based central units. Firstly, the connectivity will be related to the three common geometries observed at carbon : linear, trigonal planar or tetrahedral and increases in connectivity can only be associated with an increase in the complexity of the central unit. Secondly, a central tetrahedral carbon centre with four identical (non-chiral) groups attached cannot function as a site for chiral initiation. In chiral dendrimers, the chirality cannot commence at a central carbon bearing four identical groups. These considerations led us to our final development to using a metal centre for dendrimer initiation.

Our rationale was quite simple and based upon a number of established features from coordination chemistry. The connectivity (coordination number) at a metal may vary from two to twelve with a wide range of coordination geometries possible. For example, four-coordinate metal centres may be square-planar or tetrahedral, in contrast, four-coordinate carbon is almost invariably tetrahedral. In addition, six-coordinate metal bonded to three didentate chelating metal-binding domains are inherently chiral, with Δ and Λ enantiomers. This point must be stressed, a metal centre bearing three identical didentate chelating ligands is inherently chiral.

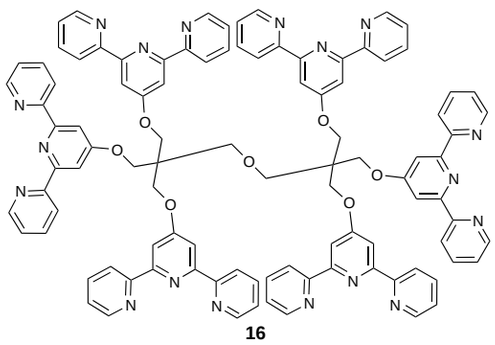


## Divergent metallocentric metallodendrimers

We initially considered a divergent approach to metallocentric systems based upon a central {M(bpy)$_3$} (bpy = 2,2′-bipyridine) unit based upon our earlier metal-directed



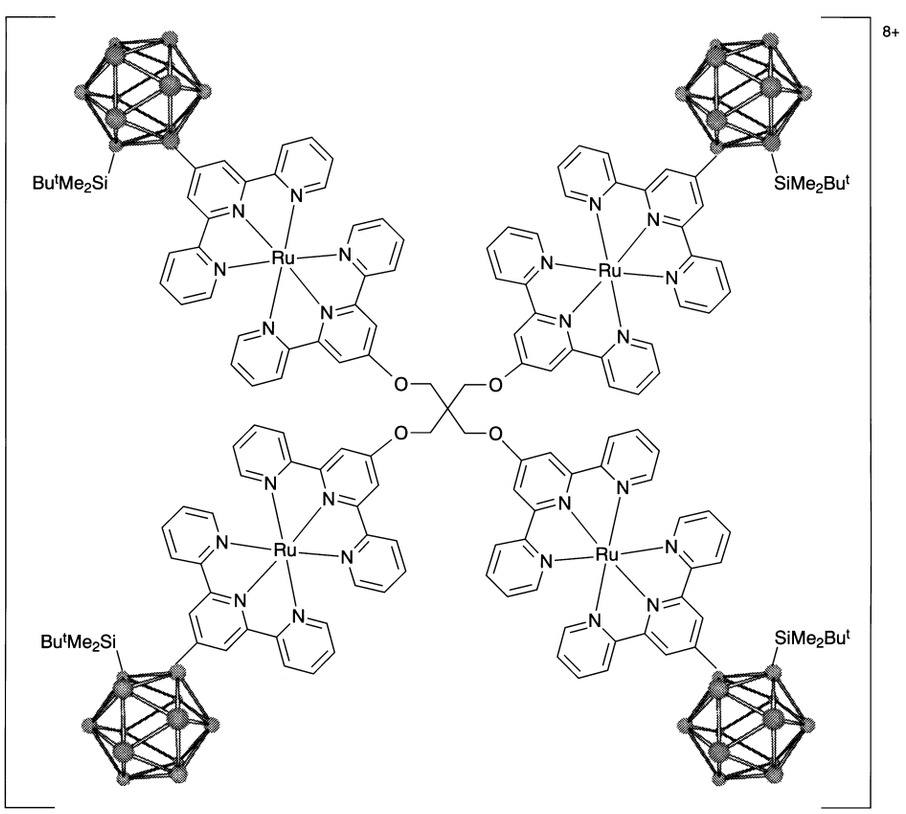
13



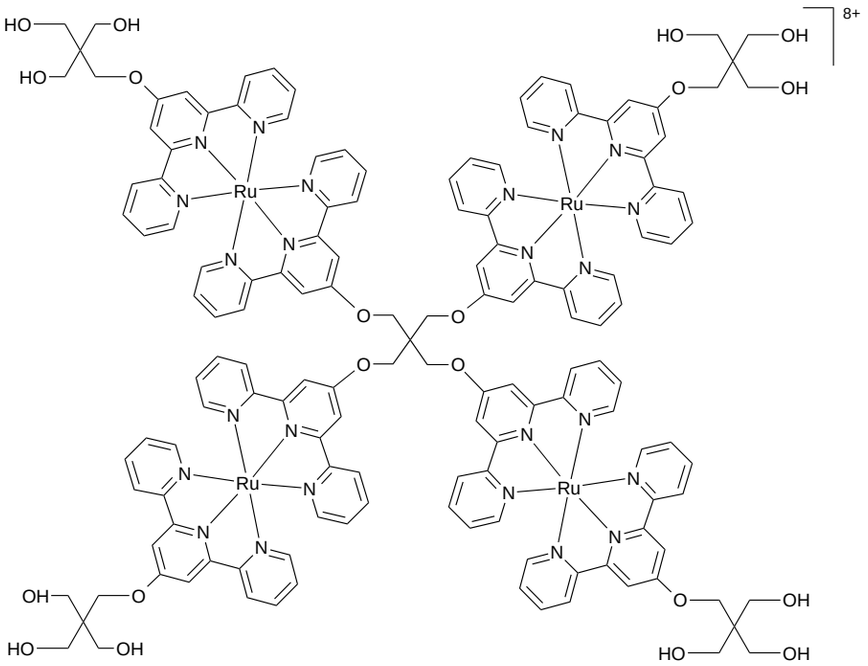
methodology. To establish the principle, we prepared $[Ru(Cl_2bpy)]^{2+}$ ($Cl_2bpy$ = 4,4′-dichloro-2,2′-bipyridine) which can, in principle, be resolved into Δ and Λ enantiomers. The coordinated halopyridine is activated towards attack by nucleophiles and the complex reacts smoothly with **6** to give a complex bearing six non-coordinated tpy domains distributed about a central, chiral, metal site. We planned the incorporation of the next generation by reaction of this species with $[Ru(tpy)Cl_3]$ (Scheme 4). This combination of chiral $\{M(bpy)_3\}$ and achiral $\{M(tpy)_2\}$ domains should avoid problems of diastereoselectivity associated with metallodendrimers based upon $\{M(bpy)_3\}$ domains alone. Unfortunately, this resulted in an inseparable mixture of compounds in which five or six sites had reacted. Clearly, steric constraints are becoming paramount in this divergent approach and we are currently designing suitable spacer groups for incorporation between the bpy and tpy domains. However, in addition to this longer term strategy, we also wondered if the steric problems might be relieved by the adoption of an alternative convergent metallocentric strategy.

**14**

**15**

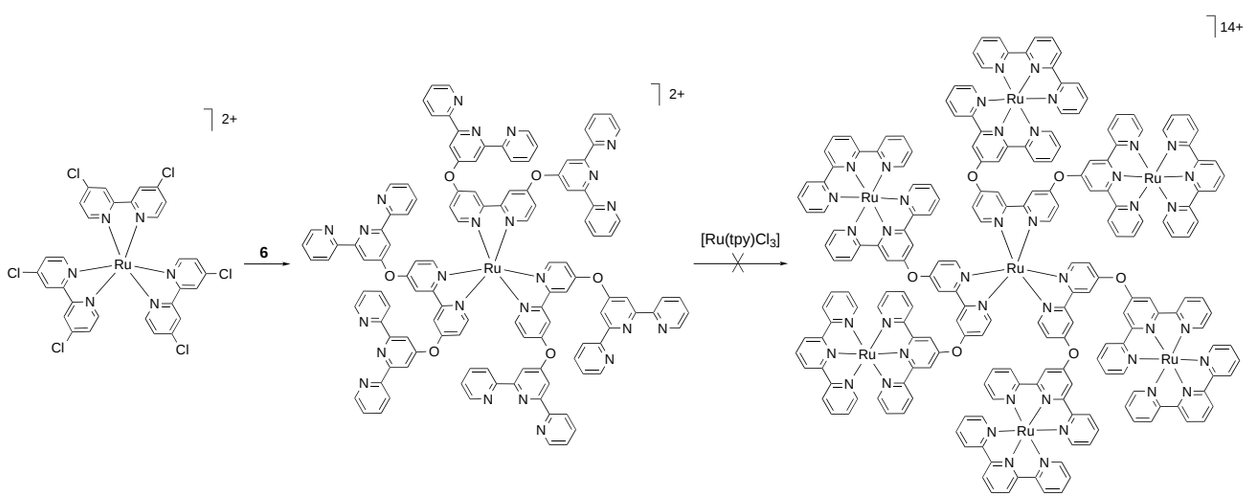


**16**

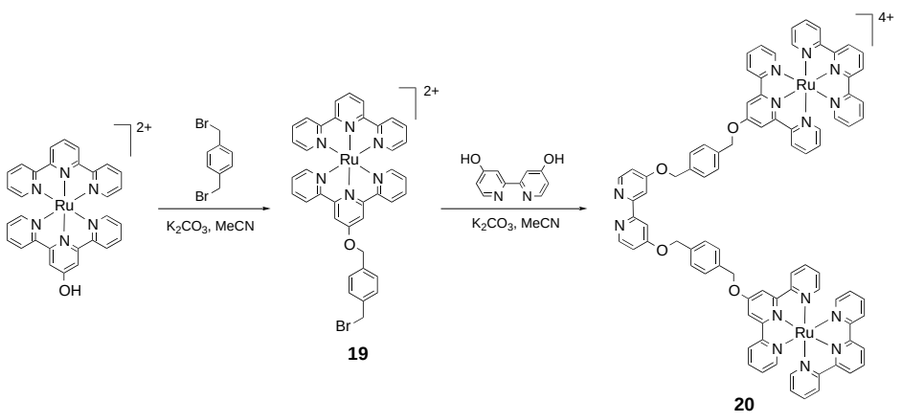


### Convergent metallocentric metallodendrimers

In our latest development, we combine many of the strategies discussed earlier. We commence by reacting a coordinated **6** ligand with an excess of a good electrophile to give a new complex **19** with an electrophilic site remote from the metal which can subsequently be reacted with a nucleophile (Scheme 5). We have selected 4,4′-dihydroxy-2,2′-bipyridine as a nucleophile which contains a didentate metal-binding domain that will eventually be used to generate a potentially chiral $\{M(bpy)_3\}$ domain. The product **20** is a dinuclear complex in which two $\{Ru(tpy)_2\}$ domains are linked by a non-coordinated bpy domain; in essence, this complex is simply a disubstituted 2,2′-bipyridine, which is expected to coordinate rapidly to labile first-row transition-metal ions such as iron(II) or cobalt(II). The reaction of the dinuclear complex **20** with either iron(II) or cobalt(II) is indeed rapid and leads to the convergent assembly of the desired heptanuclear metallocentric metallodendrimer **21** in near quantitative yield.

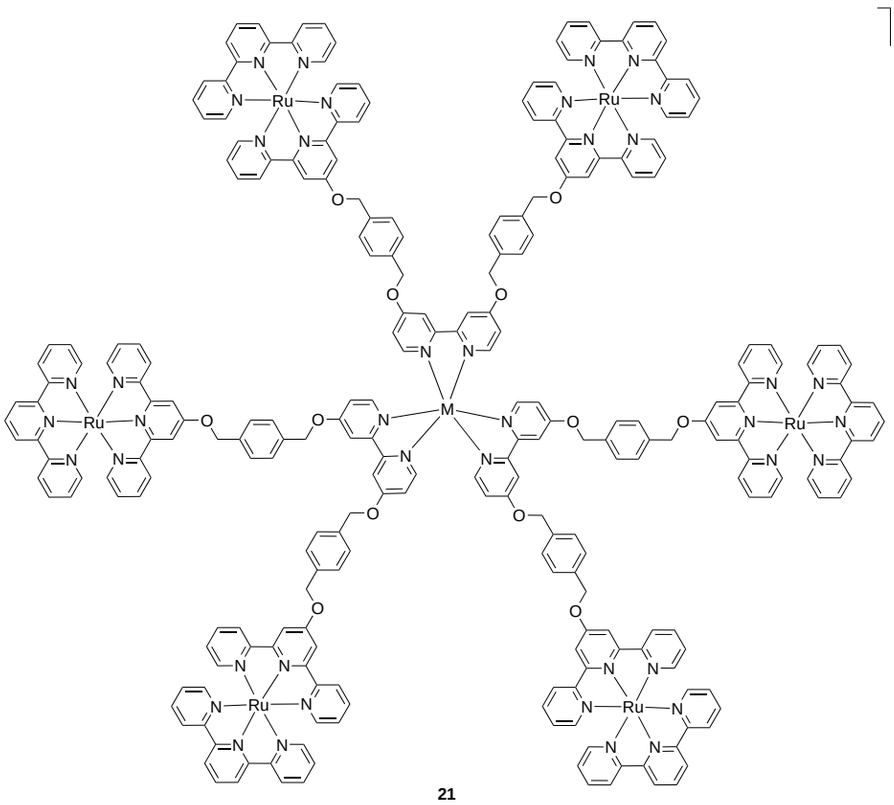


These convergent and divergent metallocentric methodologies are in many senses complementary. The divergent methodology allows the stereoretentive incorporation of predefined chirality (Δ or Λ) at the central metal site, whilst the convergent synthesis leads to a racemic mixture of the two enantiomers in the absence of chiral auxiliaries. We are presently designed a series of surface generation chiral tpy



**17**

**18**



**Scheme 4**

**19** **20**

**Scheme 5**

**21**

ligands to impose diastereoselectivity in the convergent synthesis. However, the two strategies are also fundamentally different. In the divergent case, the chiral information is propagated outwards as the dendrimer grows. In contrast, the use of chiral auxiliaries in the surface generation may allow the resolution to occur at the final stage through information transfer in an 'inwards' sense.

## Some concluding remarks

I hope that this brief overview of metallodendritic chemistry serves to emphasise some of the advantages of the methodology. The structures are attractive and the molecules themselves are tractable and may be fully characterised by the conventional techniques of the molecular chemist. Solubility is controlled by the counterions; the chloride salts are water and methanol soluble, the hexafluorophosphate salts dissolve in acetonitrile or acetone, and the tetraphenylborate salts may be dissolved in dichloromethane.

## Acknowledgements

It remains to thank the talented and hard-working coworkers who have been and are involved in this work: the initial studies of metallodendrimers were made by Dr Alex Cargill Thompson in his doctoral and post-doctoral studies and continued by Peter Harverson, who has developed the complementary electrophile–nucleophile sequences in his doctoral studies. The pentaerythrytol systems are part of the doctoral work of Dave Phillips and Marco Cattalini, with the cluster-functionalised surface generations being studied by Marco and Dr Dominique Armspach. The metallocentric systems have been studied by Pete Harverson and Dr Martin Oberholzer. The cluster-functionalisation is part of a wider collaborative project with Dr Catherine Housecroft. I should also like to thank the EPSRC, the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung, the University of Basel and Ciba-Geigy plc for support. This work is part of a continuing collaborative effort involving groups in Basel, Bologna and Strasbourg.

# γ-Radiation synthesis and characterization of polyacrylamide–silver nanocomposites

**Yingjie Zhu,[a,b] Yitai Qian,*[a,b] Xiaojun Li[c] and Manwei Zhang[c]**

[a] *Structure Research Laboratory, University of Science and Technology of China, Hefei, Anhui 230026, P. R. China*

**Polyacrylamide–silver nanocomposites with a silver particle size distribution ranging from 2 to 20 nm in a polyacrylamide matrix are synthesized by γ-irradiation at room temperature.**

Most research has concentrated on the preparation and characterization of single phase materials. More recently the field of interest has broadened to include nanocomposite materials, because of their interesting electrical and optical properties,[1] their possible commercial exploitation and their importance in providing models for understanding the physics of ultrafine particles. Among these materials, organic–inorganic nanocomposites have recently aroused much interest and attention.[2,3] This class of totally innovative materials synergize properties of both components, leading to many applications.[4]

Only a few methods have been used to prepare polymer–metal nanocomposites. Watkins and McCarthy[5] prepared nanocomposites of platinum and poly(4-methylpent-1-ene) **I** by exposing **I** to a solution of dimethyl(cyclooctadiene)platinum in supercritical fluid $CO_2$ for 4 h and subsequent reduction of platinum. Bronstein *et al*.[6] reported a method for the preparation of polymer–cobalt nanocomposites by mixing $Co_2(CO)_8$ with a polyacrylonitrile copolymer or an aromatic polyamide in dimethylformamide (dmf). $Co_2(CO)_8$ interacts with dmf giving the complex $[Co(dmf)_6]^{2+}[Co(CO)_4]_2^-$, which is converted to nanodispersed Co particles by thermolysis.

In these methods, polymerization of organic monomer and formation of nanocrystalline metal particles are performed separately, and the polymer matrix and metal nanoparticles are hybridized physically to form polymer–metal nanocomposites. Thus, metal nanoparticles are not well dispersed homogeneously in the polymer matrix. Furthermore, thermal treatment or pressure is necessary in these methods. To date, little work has been published regarding the room-temperature preparation of polymer–metal nanocomposites. Recently, we have developed the γ-radiation method to prepare ceramic–metal nanocomposites at room temperature.[7,8] Here, we report a new method for the preparation of polymer–metal nanocomposites by γ-irradiation at room temperature and atmospheric pressure. In this method, the metal salt and organic monomer are mixed homogeneously at the molecular level in the solution, and the formation of nanocrystalline metal particles and polymerization of monomer are simultaneous in solution, leading to a homogeneous dispersion of nanocrystalline metal particles in the polymer matrix.

Solutions were prepared by dissolving analytically pure $AgNO_3$ in distilled water and adding acrylamide as the monomer. Solutions were irradiated in the field of a $2.59 \times 10^{15}$ Bq $^{60}Co$ γ-ray source. After γ-irradiation, brown–red, transparent, gelatinous products were obtained. The product was dried in air, and ground to powder which was washed with distilled water and then dried. The concentration of metallic silver in the polyacrylamide matrix was determined by precipitation titration. The sample was dissolved in acetic acid–ethylene glycol (3 : 1, v/v) and nitric acid, adding $NH_4Fe(SO_4)_2$ as a precipitimetric indicator, then titrated using KSCN as a precipitant.

X-Ray powder diffraction (XRD) patterns were recorded using a $D_{max}$ $\gamma_A$ X-ray diffractometer (Japan) with graphite-monochromated Cu-Kα radiation (λ = 0.541 78 nm). TEM images were taken with a Hitachi Model H-800 transmission electron microscope.

The radiation reduction of $Ag^+$ ions by hydrated electrons produced during γ-irradiation in solution leads to the formation of metallic silver nanoparticles.[9] This process can be written in terms of eqns. (1) and (2).

$$Ag^+ + e_{eq}^- \rightarrow Ag^0 \text{ (reduction)} \quad (1)$$

$$nAg^0 \rightarrow Ag_n \text{ (aggregation)} \quad (2)$$

At the same time, polymerization of acrylamide monomer occurs in solution upon γ-irradiation.[10] Because reduction and polymerization occur simultaneously in the solution, the silver nanoparticles are dispersed homogeneously within the polyacrylamide network, which effectively prevents further growth of silver nanoparticles.

Fig. 1 shows the XRD pattern of a typical sample of a polyacrylamide–silver nanocomposite prepared by γ-irradiation of a solution containing 0.05 M $AgNO_3$ and 3.52 M acrylamide with a radiation dose of $2.7 \times 10^4$ Gy. This shows that the sample consisted of two phases, *i.e*. metallic silver, as indicated by diffraction peaks (111), (200), (220), (311), and non-crystalline polyacrylamide. The average particle size of silver is 11 nm, as estimated by the Scherrer formula. The amount of silver present as metallic species in the nanocomposite is 2.09%, as measured by precipitation titration.

A TEM micrograph of the sample prepared under the same experimental conditions as in Fig. 1 is shown in Fig. 2, from which one can see that the nanocomposite contained fine quasi-spherical metallic silver particles homogeneously dispersed and well separated in the polyacrylamide matrix. A histogram of the silver nanoparticles (Fig. 3) shows a distribution of particle sizes ranging from 2 to 20 nm. The average particle size calculated by the reported method[11] was 10.8 nm, with a standard deviation of 2.3.

In summary, γ-irradiation has been used for the first time to prepare, at room temperature, polyacrylamide–silver nanocomposites with a homogeneous dispersion of silver nanopar-

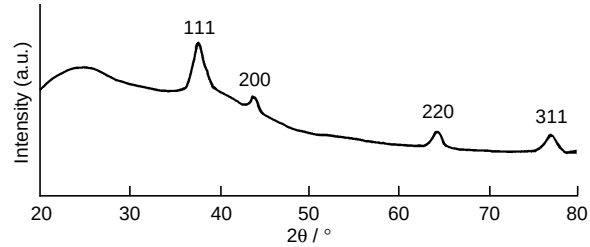

**Fig. 1** XRD pattern of the sample prepared by γ-radiation. Solution: 0.05 M $AgNO_3$–3.52 M acrylamide; radiation dose: $2.7 \times 10^4$ Gy.

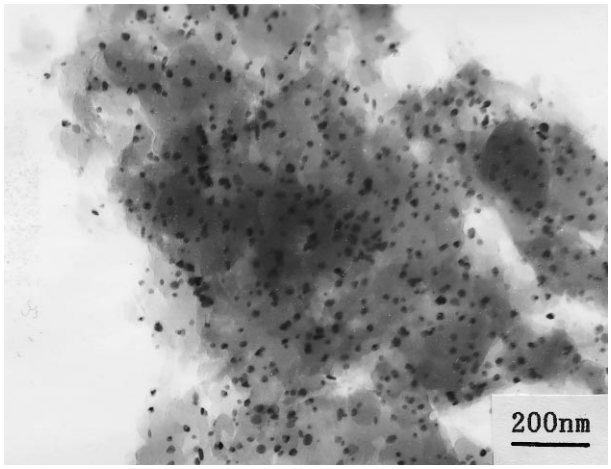

**Fig. 2** TEM micrograph of the same sample as in Fig. 1

ticles in the polyacrylamide matrix. The radiation induced reduction of metal ions and polymerization of organic monomer occurs simultaneously in solution during γ-irradiation, leading to the formation of polymer–metal nanocomposites in a single step. By appropriate control of the experimental parameters, we predict that the γ-radiation method may be extended to the preparation of a variety of polymer–metal nanocomposites as well as polymer–inorganic compound (*e.g*. polymer–metal oxide, polymer–metal sulfide, *etc*.) nanocomposites.

Financial support from a grant for a key research project in the Climbing Programme from the State Science and Technology Commission of China is gratefully acknowledged.

# A new and efficient synthesis of rosefuran. A general synthesis of furans by palladium-catalysed cycloisomerization of (*Z*)-2-en-4-yn-1-ols

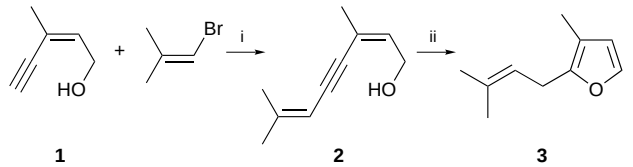
**Bartolo Gabriele and Giuseppe Salerno***

*Dipartimento di Chimica, Università della Calabria, 87030 Arcavacata di Rende, Cosenza, Italy*

**(*Z*)-3,7-Dimethylocta-2,6-dien-4-yn-1-ol, readily available from (*Z*)-3-methylpent-2-en-4-yn-1-ol, undergoes cycloisomerization in the presence of catalytic amounts of $K_2PdI_4$ to give rosefuran in high yield.**

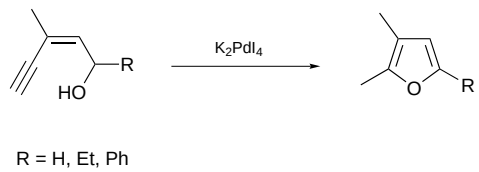
We report a new, efficient and selective synthesis of rosefuran **3**, a natural product present in the highly prized oil of rose[1] and many other natural sources.[2] The synthesis is realized in two steps with a 60% overall isolated yield, according to Scheme 1.

The key step consists of a Pd-catalysed cycloisomerization of (*Z*)-3,7-dimethylocta-2,6-dien-4-yn-1-ol **2**, readily obtainable in 78% yield from the commercially available (*Z*)-3-methylpent-2-en-4-yn-1-ol **1** *via* Pd/Cu-catalysed coupling with 1-bromo-2-methylpropene.[3] Thus, by reacting **2** (1.88 g, 12.5 mmol) under nitrogen in 5 ml of dry *N*,*N*-dimethylacetamide (DMA) at 100 °C for 24 h in the presence of $PdI_2$ (45 mg, 0.125 mmol) and KI (41.5 mg, 0.25 mmol), rosefuran **3** was obtained in 85% GLC yield. After the usual work-up, **3** was isolated by transfer distillation (1.44 g, 77%).



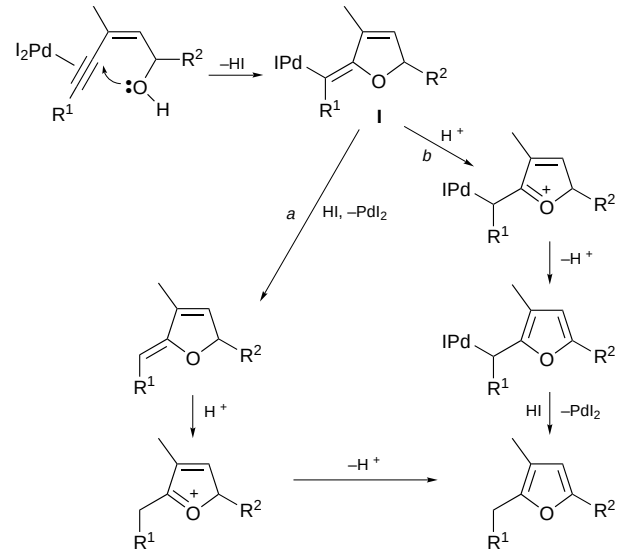
The Pd-based catalytic system here reported also works very well with substrates bearing a terminal triple bond, thus providing a general method for the synthesis of furans by cycloisomerization of (*Z*)-2-en-4-yn-1-ols (Scheme 2).

Terminal enynols are indeed much more reactive than internal ones, and were easily converted to the corresponding furans in excellent yields and with high catalytic efficiencies at 20–45 °C. For example, **1** (3.0 g, 31.2 mmol) was allowed to react under nitrogen at 20 °C† for 18 h without solvent in the presence of $PdI_2$ (22.5 mg, 0.062 mmol) and KI (20.7 mg, 0.125 mmol) to give, after transfer distillation, 2.6 g of 2,3-dimethylfuran (87%). GLC yield was higher than 92%.



The cycloisomerization process may involve an *anti-exo-dig* intramolecular nucleophilic attack of the hydroxy group to the triple bond coordinated to palladium(II)[4] with formation of a vinylpalladium intermediate **I** and HI (Scheme 3; anionic iodide ligands are omitted for simplicity). Protonolysis of **I** followed by acid-catalysed aromatization leads to the final product with regeneration of the catalytically active species (path *a*). Aromatization of **I** followed by protonolysis is another possibility, however (path *b*).

There are few other methods for synthesis of rosefuran starting from nonfuranoid substrates.[5,6] Very recently, **3** was obtained in 11% overall yield by a four-step synthesis involving a [3 + 2] nitrile oxide cycloaddition as the key step.[6g] Another approach utilized the acid-catalysed cyclization into furans of aliphatic β,γ-dihydroxy ketones, obtained by Ru-catalysed addition of allyl alcohols and alkynes followed by dihydroxylation with $OsO_4$, and afforded **3** in 23% overall yield; isorosefuran (which contains a terminal double bond) was also formed (rosefuran : isorosefuran ratio = 4).[6f] It is noteworthy that a previously reported synthesis of rosefuran starting from enynol **1** required a sequence of five steps and afforded a *ca.* 3 : 1 mixture of **3** and a β-lactone derivative; the latter had to be separated and recycled.[6e]



The Ru-catalysed cycloisomerization of (*Z*)-2-en-4-yn-1-ols has been reported, but it could only be applied to terminal enynols.[7] On the other hand, a recently proposed Pd-based catalytic system suitable for internal enynols did not work with substrates bearing a triple bond conjugated with a double bond such as **2**.[7b] The catalytic system here described, in spite of its simplicity, allows the conversion of (*Z*)-2-en-4-yn-1-ols with either internal and terminal triple bonds into the corresponding furans in high yields and with high catalytic efficiencies, and can also be applied to the synthesis of fragile biologically active furan derivatives, such as rosefuran.

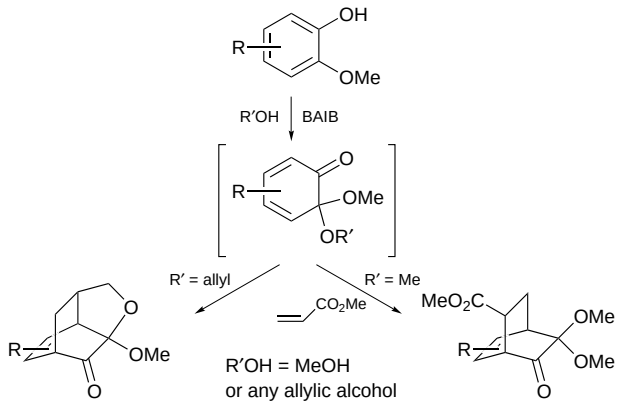
# Novel methodology for stereocontrolled synthesis of *cis*-decalins

**Puo-Yi Hsiu and Chun-Chen Liao***

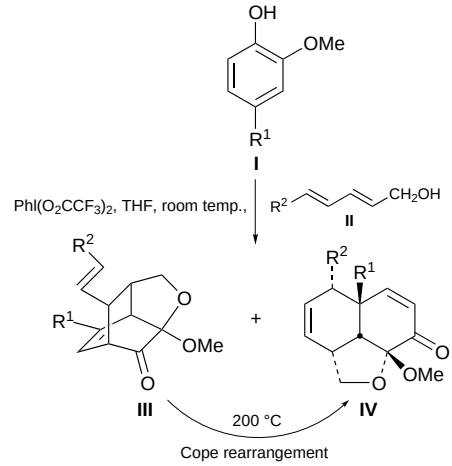
*Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043*

**Highly functionalized *cis*-decalins are stereoselectively prepared from commercially available catechol derivatives.**



A large variety of natural products of biological importance contain the decalin skeleton as an integral part of their structures.[1–3] Owing to the importance of this structural type in nature, a large number of methodologies have been developed. The Robinson annulation has been the most popular among these strategies. The requirements of modern day stereocontrolled synthesis have been the root cause of the sustained interest in this area, as reflected by the flurry of recent reports by various groups including ours.[4–11]

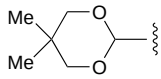
In our laboratory, a research programme towards the development of a general strategy for the synthesis of clerodane and labdane diterpenoids[2] is underway. The basic skeleton of these terpenoids is a decalin moiety with a considerable number of chiral centres. Towards this end we have recently developed a four-step methodology for the stereocontrolled synthesis of *cis*-decalins starting from commercially available catechol derivatives (Scheme 1).[11] We have already made use of this methodology in the synthesis of an alleged *cis*-clerodane diterpenoic acid.[12] We now report a more simple and efficient methodology starting from commercially available catechol derivatives and 2,4-dienols.



We have been quite successful in using masked *o*-benzoquinones, generated *in situ* from 2-methoxyphenols *via* oxidation by bis(acetoxy)iodobenzene (BAIB) or bis(trifluoroacetoxy)iodobenzene (BTIB), as dienes in inter- and intra-molecular Diels–Alder reactions.[13] The use of this type of cyclohexadienone as a dienophile has not been investigated much.[14] Since the cyclohexadienone moiety can act either as a diene or dienophile, it occurred to us that, if the allylic alcohol is replaced with a 2,4-dienol, it might give rise to *cis*-decalins **IV** and/or tricyclic compounds of the type **III** (Scheme 2).

Accordingly, we first carried out the reaction of *trans*-penta-2,4-dienol and methyl vanillate, which gave both the expected products **IIIe** and **IVe** in 1 : 1 ratio. The tricyclic compound **IIIe**, when heated to 200 °C in mesitylene, underwent Cope rearrangement smoothly. The total yield of decalin is about 60% (procedure A†). Then we extended this methodology to a variety of catechol derivatives and dienols. The ratio of **III** to **IV** depends on the substituents. The reaction conditions and results are shown in Table 1. To make the whole transformation simple, the crude Diels–Alder reaction mixtures were concentrated using a kugelrohr apparatus after the usual work-up and the residues were dissolved in mesitylene and heated to 200 °C to obtain decalins as the sole products in good yields (Table 1, procedure B‡).

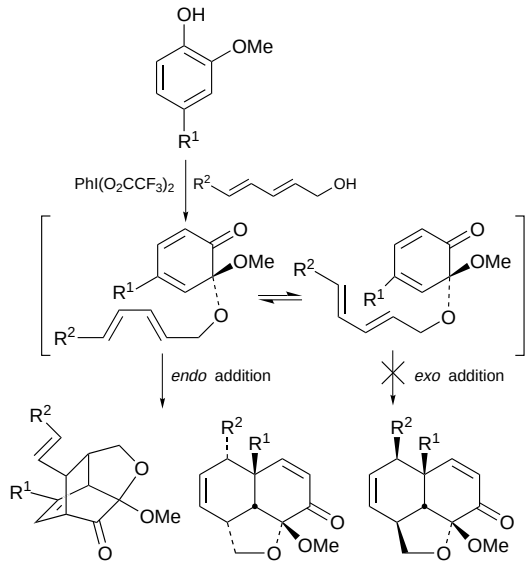
As shown in Scheme 3, the intramolecular Diels–Alder reaction can afford three products. However, we could isolate only two products **III** and **IV**. Therefore, in both modes, the cycloaddition seems to be *endo*-selective.



**Scheme 1**

**Scheme 2**

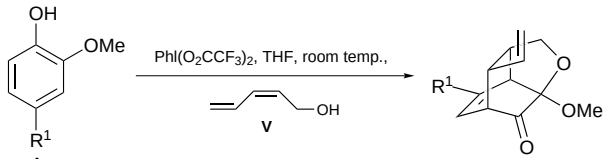
**Table 1** Preparation of *cis*-decalins



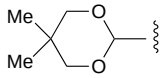
| | | Yield (%) | | Ratio | Yield of **IV** (%) | | |
|---|---|---|---|---|---|---|---|
| $R^1$ | $R^2$ | **III** | **IV** | **III : IV** | From **III** | Procedure A | Procedure B |
| Me | Me | 46 | 16 | 3 : 1 | 95 | 60 | 72 |
| | H | 40 | 20 | 2 : 1 | 93 | 57 | 62 |
| $CO_2Me$ | Me | 16 | 46 | 1 : 3 | 93 | 61 | 55 |
| | H | 31 | 31 | 1 : 1 | 92 | 60 | 50 |
|  | Me | 60 | 10 | 6 : 1 | 93 | 66 | 73 |
| | H | 57 | 19 | 3 : 1 | 100 | 76 | 60 |

When *cis*-penta-2,4-dienol **V** was employed as a dienol, only tricyclic compounds **VI** were obtained (Table 2). This may be due to the fact that the *o*-benzoquinone moiety acts more efficiently as a diene than a dienophile (Table 1). In addition to this, the equilibrium between s-*trans* and s-*cis* forms of the acyclic diene moiety should favour the s-*trans* form as a consequence of steric requirements. Predictably, these compounds did not undergo Cope rearrangement.

All the new compounds were characterized by IR, $^1$H and $^{13}$C NMR and mass spectral analysis. The stereochemistry of **IVa** was established by NOE studies, and those of other compounds **IV** were assigned by analogy with **IVa**.



In conclusion, our methodology should be among the simplest for the preparation of such highly functionalized decalins with total stereocontrol. The utilization of this methodology in the synthesis of decalin-based natural products is under active investigation in our laboratory.



We thank National Science Council (NSC) of Taiwan, R.O.C., for financial support, and Dr P. Dharma Rao for helpful discussions.

## Footnotes

† *Procedure A: Diels–Alder reaction:* To a stirred mixture of catechol derivative (10 mmol) and dienol (100 mmol) in dry THF (25 ml), a solution of bis(trifluoroacetoxy)iodobenzene (BTIB) (15 mmol) in dry THF (25 ml) was added dropwise during 10 min using a syringe pump at room temperature under nitrogen atmosphere. After 6 h stirring, solid $NaHCO_3$ (30 mmol) was added. After 10 min stirring, water (25 ml) was added and the layers were separated. The aqueous layer was extracted with ethyl acetate (3 × 25 ml). The combined organic layer was dried over anhydrous $MgSO_4$. The solvent was removed under reduced pressure on a rotavapor, followed by removal of the excess dienol using a kugelrohr apparatus. The two products **III** and **IV** were separated by column chromatography on silica gel using 15% ethyl acetate in hexane as eluent.

*Cope rearrangement*: To a solution of compound **III** (5 mmol) in mesitylene was added trimethyl orthoformate (5 mmol) and the resulting mixture was degassed with argon for 30 min. The reaction mixture was then heated for 8 h at 200 °C, cooled and the mesitylene was removed using a kugelrohr apparatus under reduced pressure to give pure product **IV** in excellent yield.

‡ *Procedure B:* The Diels–Alder reaction mixture after work-up (see Procedure A) was concentrated using a kugelrohr apparatus and the crude product mixture thus obtained was dissolved in mesitylene. To this was added 1 equiv. of trimethyl orthoformate and the resulting mixture was degassed and subjected to heating at 200 °C for 8 h. Then mesitylene was removed using a kugelrohr apparatus and the residue thus obtained was purified by column chromatography on silica gel using 15% ethyl acetate in hexane as eluent to give compound **IV** as the sole product.

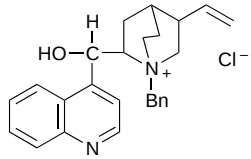
# New chiral ammonium salt hosts derived from amino acids: very efficient optical resolution of 2,2′-dihydroxy-1,1′-binaphthyl by complexation with these host compounds

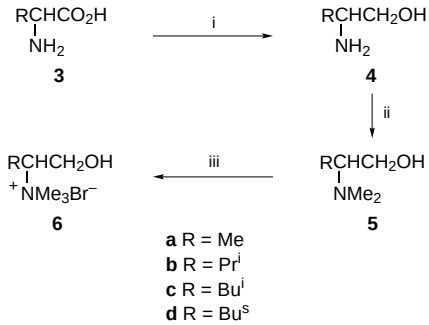
**Fumio Toda* and Kenya Tanaka**



*Department of Applied Chemistry, Faculty of Engineering, Ehime University, Matsuyama, Ehime 790, Japan*

**Chiral ammonium salt hosts are prepared from amino acids by transformation of their $NH_2$ and $CO_2H$ groups into $Me_3N^+Br^-$ and $CH_2OH$ groups, respectively, *via* three simple reaction steps; by complexation with these hosts, 2,2′-dihydroxy-1,1′-binaphthyl is resolved very efficiently.**

It has been reported that ′onium salts such as ammonium[1–5] and phosphonium salts[6] form inclusion complexes with alcohol and phenol derivatives *via* hydrogen bond formation between the counter anion of the ′onium salt host and the hydroxy group of the alcohol or phenol guest. In these inclusion complexes, molecular recognition between the host and guest occurred and separation of isomers of the guest was accomplished. When a chiral ′onium salt host is used, *rac*-guest compounds were resolved. For example, *rac*-2,2′-dihydroxy-1,1′-binaphthyl **1**



**1**

(–)-**2**

was easily resolved by complexation with *N*-benzylcinchonidinium chloride **2**, because **2** forms a 1 : 1 inclusion complex with (*R*)-(+)-**1** selectively.[4] X-Ray crystal structure analysis of the complex showed that the complex is mainly constructed *via* formation of an intermolecular hydrogen bond between $Cl^-$ of **2** and the OH group of **1**. It was also found that an intramolecular hydrogen bond between the OH group of **2** and $Cl^-$ plays an important role in forming the complex.[5] This finding suggests that a chiral compound which has $Me_3N^+X^-$ and OH groups would be a good host for resolution of *rac*-**1**. According to this idea, chiral β-hydroxy trimethylammonium bromide hosts **6a–d** were prepared from the corresponding β-amino acids **3a–d** by transformation of their $NH_2$ and $CO_2H$ groups into $Me_3N^+Br^-$ and $CH_2OH$ groups, respectively, *via* the three step reaction shown in Scheme 1.

**Scheme 1** *Reagents*: i, $LiAlH_4$; ii, $HCO_2H$, HCHO; iii, MeBr

For example, treatment of L-leucinol **4c**, prepared by $LiAlH_4$ reduction of L-leucine **3c** in 99% yield,[7] with formaldehyde and formic acid according to the reported procedure[8] gave *N*,*N*-dimethyl-L-leucinol **5c** in 98% yield. Treatment of **5c** with MeBr gave the quaternary ammonium salt host, (+)-1-hydroxymethyl-3-methylbutyl(trimethyl)ammonium bromide **6c** in 77% yield as colourless prisms.† By the same procedure, (−)-**6a**, (+)-**6b** and (+)-**6d** were prepared from L-alanine (**3a**), L-valine (**3b**) and L-isoleucine (**3d**), respectively.

When a solution of (+)-**6c** (0.5 g, 2.08 mmol) and *rac*-**1** (1.19 g, 4.16 mmol) in EtOH (6 ml) was kept at room temperature for 24 h, a 1 : 1 inclusion complex of (+)-**6c** and (+)-**1** was obtained as colourless prisms. The crude complex was recrystallised from diethyl ether to give pure complex crystals‡ and then the pure complex crystals were dissolved in a mixture of diethyl ether and water. From the diethyl ether solution, (+)-**1** (100% ee)§ was obtained (0.42 g, 70% yield). From aqueous solution, **6c** was recovered (0.43 g, 86% yield). By the same complexation experiments of *rac*-**1** with (−)-**6a**, (+)-**6b** and (+)-**6d**, (−)-**1** (100% ee, 68% yield), (+)-**1** (100% ee, 36% yield) and (−)-**1** (100% ee, 48% yield) were obtained, respectively. In all cases, host compounds were recovered in almost quantitative yield and could be reused.

In comparison to the resolution of *rac*-**1** by complexation with **2**, the present resolution with **6** of about half mole of **2** has many advantages. Since **6** can easily be prepared in large quantities from cheap L-amino acid *via* a simple three step reaction, the present resolution method is more economical than that *via* the relatively expensive **2**. Furthermore, either (+)-**1** or (−)-**1** can be obtained according to demand, as (−)-**6a** and (+)-**6d** include (−)-**1** and (+)-**6b** and (+)-**6c** include (+)-**1**.

By using the precise chiral recognition between **1** and **6** in the inclusion complex, *rac*-**6** can also be resolved by optically active **1**. For example, when a solution of *rac*-**6d** (0.34 g, 1.40 mmol), prepared from *rac*-isoleucine (*rac*-**3d**) and (−)-**1** (0.2 g, 0.69 mmol) in EtOH (3.5 ml) was kept at room temperature for 24 h, a 1 : 1 complex of (−)-**1** and (+)-**6d** was obtained, after recrystallisation from EtOH, as colourless prisms (0.28 g, 76% yield). The pure complex crystals were dissolved in a mixture of diethyl ether and water. From aqueous solution, (+)-**6d** (100% ee) was obtained (0.13 g, 76% yield). From diethyl ether solution, (−)-**1** was recovered (0.15 g, 76% yield).

We thank the Ministry of Education, Science and Culture, Japan, for a grant-in-aid for Scientific Research on Priority Areas, No. 0642105.

# Synthesis and structure of an open-framework tin phosphate, $[H_3N(CH_2)_4NH_3]_{0.5}^{2+}[Sn_4P_3O_{12}]^-$, containing intersecting channels

**Srinivasan Natarajan and Anthony K. Cheetham***

*Materials Research Laboratory, University of California, Santa Barbara, CA 93106, USA*

**A novel open-framework tin phosphate made of strictly alternating $SnO_3$ and $PO_4$ moieties contains two intersecting channels; the protonated 1,4-diaminobutane molecules are situated in one of the channels and the lone pairs of $Sn^{II}$ extend into the other, preventing access to the channel.**

The use of structure-directing agents (templates) in the synthesis of new solids exhibiting open-framework structures has gained prominence, following the seminal work at Mobil in the late 1960s and early 1970s.[1] It is now well established that for the synthesis of new micro- and meso-porous materials, an organic structure-directing agent can be used to steer the process of crystallization to form open architectures.[2–5] Not only is it possible to synthesize materials resembling naturally occurring zeolites,[6–8] but new aluminosilicate and phosphate materials with interesting structures have been synthesized and studied in great detail.[9–11] The organic moiety is normally accommodated within the cavities and channels of these open structures and, in many cases, can be removed by post-synthesis treatments such as calcination or chemical extraction (leaching). In the course of a programme[12–15] aimed at producing new open-framework structures, we have recently shown that open-framework tin phosphate compounds can be synthesized with the aid of organic structure-directing molecules.[16] We now report the synthesis and structure of a new tin phosphate with the same composition as that reported previously,[16] but synthesized in the presence of a different organic molecule: 1,4-diaminobutane rather than ethylenediamine. A new open-framework architecture is thereby created.

The title compound was synthesised from a starting tin phosphate gel containing 1,4-diaminobutane as the structure directing agent. Tin(II) oxalate (Aldrich), phosphoric acid (85 mass%, Aldrich), 1,4-diaminobutane [$H_2N(CH_2)_4NH_2$, Aldrich] and water in the ratio $SnC_2O_4 : 0.5P_2O_5 : 1.0H_2N(CH_2)_4NH_2 : 55H_2O$ were mixed and stirred until homogeneous. The mixture was sealed in a Teflon lined stainless steel autoclave (Parr, USA) and heated at 170 °C for 2 days under autogeneous pressure. The resulting product, containing a mixture of powder and colourless single crystals, was filtered and washed thoroughly with deionised water. The single crystals were separated easily by ultrasonication. The powder X-ray diffraction indicated that the product was a new material; the pattern is entirely consistent with the structure determined by single-crystal X-ray diffraction. Thermogravimetric analysis (TGA) under an oxygen atmosphere in the range from room temperature to 700 °C show only one mass loss in the region 400–475 °C. The mass loss corresponds to about 4.97% of the total mass of the sample and can be directly correlated to the decomposition of the occluded organic cation, diprotonated diaminobutane (calc. 5.3%). The powder X-ray diffraction pattern of the decomposed sample indicated the presence of another new phase.

The structure, which was solved by single-crystal X-ray diffraction,† is based on a network of strictly alternating $SnO_3$ and $PO_4$ units in which all the vertices are shared. The $SnO_3$ and $PO_4$ units form a framework with the formula $[Sn_4P_3O_{12}]^-$. Charge neutrality is achieved by the incorporation of the template in its diprotonated form; there are $0.5[H_3N(CH_2)_4NH_3]^{2+}$ ions per framework formula unit. The asymmetric unit contains 22 independent non-hydrogen atoms [Fig. 1(*a*)]: three phosphate goups are linked *via* oxygens to four tin atoms to form the building block of the framework. All the P–O distances are in the range 1.495–1.544 Å (av. 1.526 Å) and the bond angles are in the range 105.5–113.5° (av. 109.5°), which is in good agreement with those previously observed.[12–15] All the Sn atoms are three-coordinated with respect to oxygen with Sn–O distances in the range 2.075–2.206 Å (av. 2.118 Å) and the Sn–O bond angles are in the range 81.5–93.59° (av. 86.87°). These values are typical of three-coordinated Sn in the 2+ oxidation state and are in excellent agreement with other previously known tin phosphates in the literature.[16–20] The three oxygen atoms form a trigonal pyramid around the Sn with the lone pair of electrons on the Sn atoms presumably occuping the base vertex of a tetrahedron. The lone pair of electrons associated with $Sn^{II}$ opens up the possibility of using this material, or others like it, in base-catalysed reactions; zeolites and aluminophosphates are normally used for acid-catalysed processes.

The entire framework structure can be considered to be built from the networking of four-, six-, eight- and twelve-membered rings. The four- and six- (slightly distorted) membered rings are so connected as to form a one-dimensional eight-membered

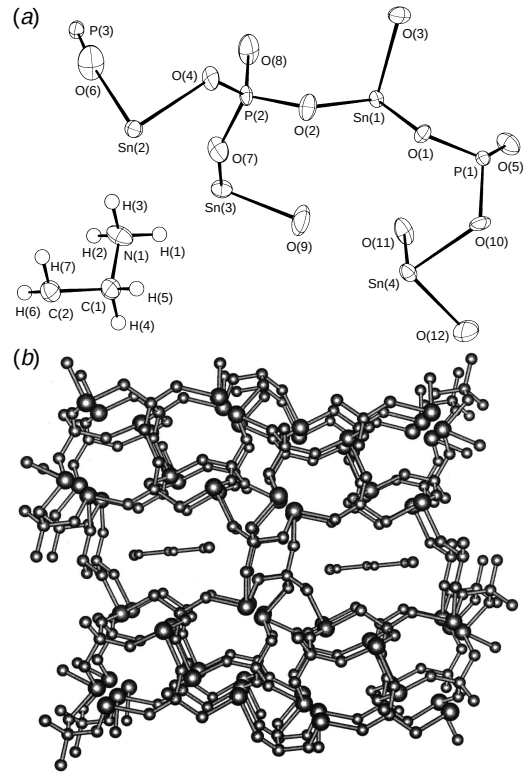

**Fig. 1** (*a*) The asymmetric unit of $[H_3N(CH_2)_4NH_3]_{0.5}^{2+}[Sn_4P_3O_{12}]^-$ and (*b*) the structure showing the uniform eight-membered channel along the *b* axis. The hydrogens on the amine molecule are not shown for clarity.

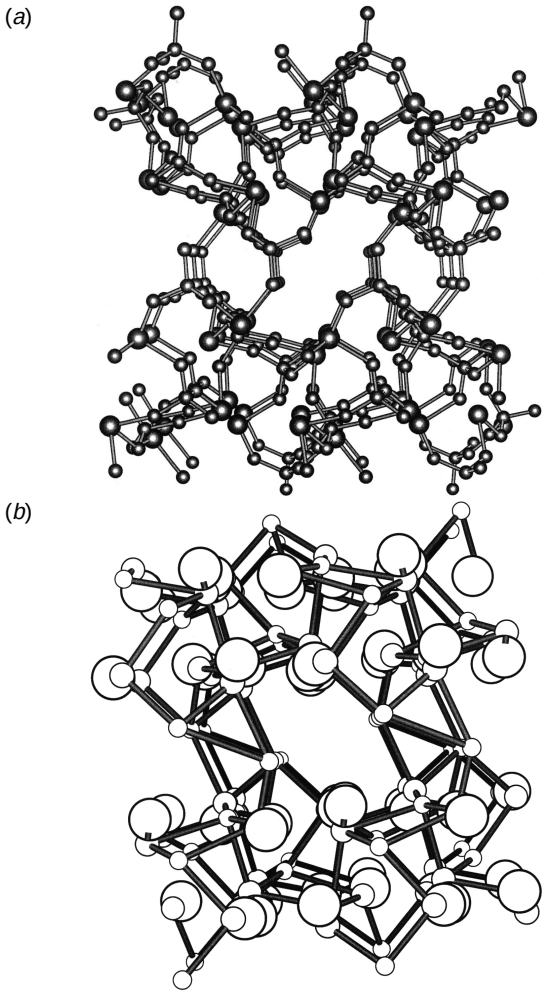

**Fig. 2** (*a*) View showing the staggered twelve-membered ring channel along the *c* axis. The amine molecule is not shown for clarity. (*b*) View showing the staggered twelve-membered ring channel along with the lone pair of electrons on the Sn atoms. The amine molecule and the oxygens are not shown.

channel along the *b* axis. The width of this channel is 9.4 × 6.2 Å. The template molecule sits in the middle of this channel [Fig. 1(*b*)]. Along the *c* direction, there is another channel delineated by twelve-membered rings. However, the twelve-membered rings are staggered and, in projection, create the appearance of a compressed eight-membered ring channel of width 9.6 × 5.1 Å [Fig. 2(*a*)]. The lone pair of electrons of the $Sn^{II}$ atoms extend into this channel and prevent access completely for any guest molecules [Fig. 2(*b*)]. The intersection of these two channels forms a cage which can be considered to be a pseudo-cube. The organic template is located at this intersection.

Presently, our efforts to remove the organic molecule by thermal methods to render the material microporous were not successful and we are pursuing softer chemical techniques (*e.g.* Soxhlet extraction) for this step. Our continuing research on tin phosphates indicates that further open-framework structures are formed under hydrothermal conditions using other structure directing agents.

The work was funded by the MRSEC program of the National Science Foundation under the award DMR 9632716.

## Footnotes

† A suitable single crystal (0.04 × 0.04 × 0.10 mm) was carefully selected under a polarizing microscope. *Crystal data* for $[H_3N(CH_2)_4NH_3]_{0.5}^{2+}[Sn_4P_3O_{12}]^-$: $M$ = 804.75(3), monoclinic, space group $P2_1/c$ (no. 14), $a$ = 10.0163(14), $b$ = 7.8878(4), $c$ = 20.1187(33) Å, β = 101.24(2)°, $U$ = 1558.84(1), $Z$ = 4, graphite-monochromated Cu-Kα radiation, λ = 1.5418 Å, $T$ = 293 K, $D_c$ = 3.428(1) g cm$^{-3}$. Data collection was performed on an Enraf-Nonius CAD4-MACH four-circle diffractometer equipped with a Rigaku rotating anode using ω–2θ scans with the width of Δω = (1.0 + 0.15tanθ)° extending 25% on each side for background measurement. The unit-cell constants were determined from 25 well centred reflections within the 2θ range 29.3–64.9°. A total of 4154 reflections were collected. These were merged to give 2955 unique data ($R_{merg}$ = 5.27) of which 2569 were considered to be observed with $I > 3\sigma(I)$. The structure was solved by direct methods using SHELX-86[21] and difference Fourier syntheses. The absorption correction was carried out using DIFABS calculation routine. Hydrogen atoms on the amine molecules were placed geometrically and held in the 'riding' mode. Final $R_F$ = 0.0414 and $R_w$ = 0.0485 (unit weights), $S$ = 1.04, were obtained for a total of 200 parameters. The final Fourier map had a minimum and maximum of −1.36 and 1.55 e Å$^{-3}$ respectively. Full-matrix least-squares structure refinement was carried out using the CRYSTALS[22] package of programs. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/440.

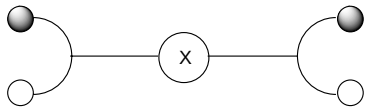
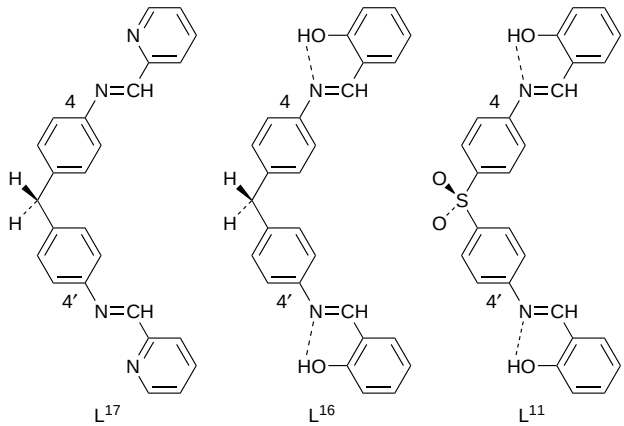
# Synthesis and structure of a dinuclear zinc(II) triple helix of an *N,N*-bis-bidentate Schiff base: new building blocks for the construction of helical structures

**Noboru Yoshida* and Kazuhiko Ichikawa**



*Laboratory of Molecular Functional Chemistry, Division of Material Science, Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060, Japan*

**The formation of a novel helical zinc(II) complex of an *N,N*-bis-bidentate Schiff base is reported; the edge-to-face and face-to-face π···π interactions play an important role in the metal-assisted self-assembling process in solution.**



Weak non-covalent interactions play an important role in the kinetics of the molecular recognition by α-cyclodextrin in aqueous solution.[1] Contrary to our expectation, enthalpic rather than entropic factors are the principal driving force to form a regioselective host–guest complex[1c–e] in which weak interactions such as London dispersion forces, dipole–dipole and CH··π interactions[2] operate. Recently, great interest has been focused on metal-assisted self-assembly of helical[3] and box-like[4] supramolecular complexes in which the stereochemical preference of a labile metal centre is exploited.[3]

Another very important aspect of self-assembly investigations has been the development of the design at ligands which induces cooperative behaviour *via* the weak interactions. From this point of view, a new type of bis-bidentate ligand has been developed (Scheme 1).[5,6]

Recently, we have focused on some semi-*N,O*-bidentate and bis-*N,O*-bidentate Schiff-base ligands which can be electronically and configurationally controlled, leading to a systematic study of the self-assembly process in solution.[7] Thus, bis-*N,N*- and bis-*N,O*-bidentate Schiff-base ligands, $L^{11}$, $L^{16}$ and $L^{17}$, have been designed (Scheme 2) to bind two separate metal ions owing to the fact that the bridging group (X = $–C_6H_4CH_2C_6H_4–$ or $–C_6H_4SO_2C_6H_4–$) prevents the metal ions from forming 1 : 1 four coordinate complexes.

**Scheme 1** X = –CONHC*H(R)$CH_2$C*H(R)NHCO– (ref. 5) or $–(CH_2)_n–$ (ref. 6*a*); ⊘ = strong donor atom, ○ = weak donor atom

**Scheme 2**

Here we report the facile synthesis of helical zinc(II) complexes utilizing weak interactions in which CH··π and π··π interactions of aromatic rings between two or three bridging groups (X = $–C_6H_4CH_2C_6H_4–$ or $–C_6H_4SO_2C_6H_4–$) having high conformational freedom may be involved in the self-assembling process.

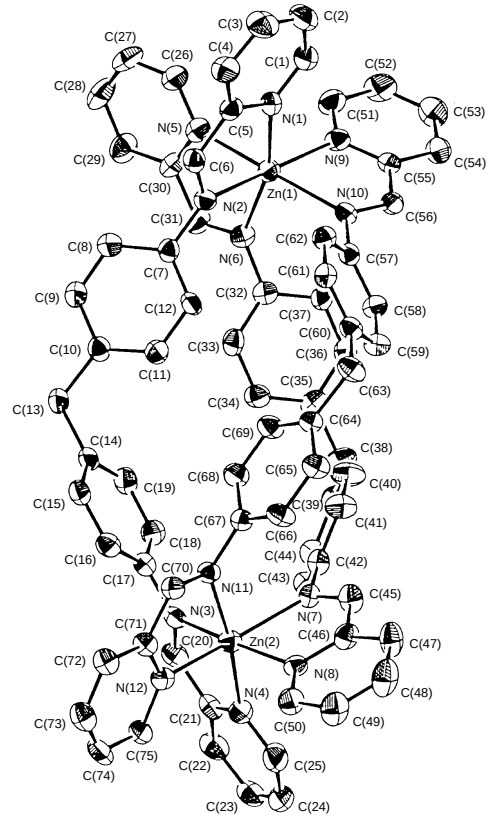


**Fig. 1** Molecular structure of the complex cation of **1**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Zn(1)–N(1) 2.158(6), Zn(1)–N(2) 2.195(5), Zn(1)–N(5) 2.186(7), Zn(1)–N(6) 2.193(6), Zn(1)–N(9) 2.154(6), Zn(1)–N(10) 2.176(6), Zn(2)–N(3) 2.174(6), Zn(2)–N(4) 2.132(7), Zn(2)–N(7) 2.247(6), Zn(2)–N(8) 2.167(6), Zn(2)–N(11) 2.200(6), Zn(2)–N(12) 2.187(6); N(1)–Zn(1)–N(2) 76.7(2), N(1)–Zn(1)–N(5) 91.3(3), N(1)–Zn(1)–N(6) 164.7(2), N(1)–Zn(1)–N(9) 98.4(2), N(1)–Zn(1)–N(10) 94.5(2), N(2)–Zn(1)–N(5) 87.6(2), N(2)–Zn(1)–N(6) 93.5(2), N(2)–Zn(1)–N(9) 173.6(2), N(2)–Zn(1)–N(10) 99.9(2), N(5)–Zn(1)–N(6) 76.5(2), N(5)–Zn(1)–N(9) 96.7(2), N(5)–Zn(1)–N(10) 171.4(2), N(6)–Zn(1)–N(9) 92.1(2), N(6)–Zn(1)–N(10) 98.7(2), N(9)–Zn(1)–N(10) 76.2(2), N(3)–Zn(2)–N(4) 77.3(3), N(3)–Zn(2)–N(7) 96.0(2), N(3)–Zn(2)–N(8) 170.1(2), N(3)–Zn(2)–N(11) 100.6(2), N(3)–Zn(2)–N(12) 97.9(2), N(4)–Zn(2)–N(7) 93.2(2), N(4)–Zn(2)–N(8) 97.1(3), N(4)–Zn(2)–N(11) 173.3(2), N(4)–Zn(2)–N(12) 98.4(2), N(7)–Zn(2)–N(8) 76.1(2), N(7)–Zn(2)–N(11) 93.4(2), N(7)–Zn(2)–N(12) 163.6(2), N(8)–Zn(2)–N(11) 85.8(2), N(8)–Zn(2)–N(12) 90.9(2), N(11)–Zn(2)–N(12) 75.4(2).

Reactions of $L^{16}$ and $L^{11}$ with $Zn(MeCO_2)_2\cdot 2H_2O$ in 1 : 1 molar ratio in hot ethanol afforded a strongly fluorescent yellow powder with many long fibres at the wall of the reaction vessel. The melting point of the formed zinc(II) complexes were > 300 °C. They were insoluble in all organic solvents. Elemental analysis indicated formation of 1 : 1 polymeric complexes. Ligand $L^{17}$ was synthesized by Schiff-base condensation[8] of bis(4-aminophenyl)methane and pyridine-2-aldehyde and reaction with $Zn(ClO_4)_2\cdot 6H_2O$ in methanol at room temp. gave a pale yellow crystalline powder (yield *ca.* 60%).† This was recrystallized from dmf–MeCN (1 : 2)–diethyl ether to give crystals of **1**·2MeCN·dmf; MeCN was indispensable for crystallization. Elemental analysis and FAB mass spectroscopy were consistent with the empirical formula of a 2 : 3 complex $[Zn_2L^{17}{}_3][ClO_4]_4\cdot$dmf·2MeCN.

The structure of **1** shown in Fig. 1‡ confirms the existence of a dinuclear triple helix. The complex contains two $Zn^{II}$ ions and three $L^{17}$ ligands. The building units, particularly the bridging groups ($-C_6H_4CH_2C_6H_4-$), are stacked face-to-face ($\pi\cdot\cdot\pi$) and edge-to-face ($CH\cdot\cdot\pi$) to each other. Formation of a helix arises from a twisting of these bridging groups. Each $Zn^{II}$ ion is six-coordinate with Zn–N(pyridyl) distances in the range 2.132(7)–2.187(6) Å and Zn–N(–CH=N) 2.174(6)–2.247(6) Å. There are three sets of bond angles N–Zn–N in the range 75.4(2)–77.3(3)°, 85.8(2)–100.6(2), and 163.6(2)–173.6(2)°, respectively. A pseudo-octahedral array of nitrogen atoms provided by three pyridylazomethine ($C_5H_4NCH=N-$) moieties are in *fac* configuration. The pyridyl nitrogen atom as a stronger donor of one ligand is situated *trans* to the weaker azomethine (–CH=N–) nitrogen atom of another ligand (Fig. 1 and Scheme 1).[8]

The new ligand system in this study is notable with regard to the synthetic advantage that the use of the C=N bond[9] allows a wide range of different supramolecular structures. This provides a basis for modelling many structural aspects and the utilization of the weak interactions in metallosupramolecular chemistry.

# Preparation and crystal structure of a new gallium phosphate $[H_3N(CH_2)_3NH_3]^{2+}[GaH(PO_4)_2]^{2-}$ from water–$Me_2SO$

**Thierry Loiseau, Fabien Serpaggi and Gérard Férey***

*Institut Lavoisier, I.R.E.M., UMR CNRS 173, Université de Versailles-Saint Quentin en Yvelines, 45, Avenue des Etats-Unis, 78035 Versailles Cedex, France*

**A novel gallium phosphate is synthesized in the presence of 1,3-diaminopropane from water–dimethyl sulfoxide ($Me_2SO$); its structure consists of twisted chains of $GaO_4$ and $PO_4$ tetrahedra separated by diprotonated 1,3-diaminopropane.**

Zeolite like materials are generally synthesized from an aqueous system under hydrothermal conditions. During the last decade, some reports[1–3] have mentioned the influence of the organic or mixed organic–water solvents on the preparation of the microporous compounds. A wide variety of alcohols (mainly glycols) has been tested for the synthesis of zeolites and also phosphate-based compounds.[4] The use of organic solvents has resulted in the discovery of new open-framework structures such as the aluminophosphates JDF-20[5] and DAF-1[6] for example, and therefore has opened the field for the investigation of new microporous compounds. Nevertheless, although some work has reported that the use of apolar organic solvents may induce the growth of large single crystals with dimensions in the size range 0.4–5.0 mm,[7] the influence of such solvents has been less studied.

We report here on the synthesis of a new gallium phosphate from organic–water mixtures in the presence of 1,3-diaminopropane as a structurant agent. With this organic template, in the purely aqueous system and depending on the pH of the reaction, the fluorinated gallium phosphates[8] ULM-3, ULM-4 and ULM-6 have been obtained. Some attempts have been performed by using mixed alcohol–water solvents (butan-1-ol, ethylene glycol) but no effect has been observed for the formation of these phases in these conditions. However, the utilization of less polar molecules like dimethyl sulfoxide ($Me_2SO$) shows significant changes for the crystallization of such compounds. This paper deals with the preparation and the crystal structure of $[H_3N(CH_2)_3NH_3]^{2+}[GaH(PO_4)_2]^{2-}$, a new gallium phosphate hydrothermally synthesized from a non-purely aqueous system in which $Me_2SO$ was used as the co-solvent.

The reagents were gallium oxyhydroxide [GaO(OH)], phosphoric acid ($H_3PO_4$, Fluka 99%), hydrofluoric acid (HF, RP Normapur 40%), dimethyl sulfoxide ($Me_2SO$, Aldrich 99.9%) and 1,3-diaminopropane (DAP, Aldrich, 99%). The starting mixture, with molar ratio 1 GaO(OH) : 1 $H_3PO_4$ : 1 HF : 1.2 DAP : 10 $Me_2SO$ : 13 $H_2O$, was placed in a Teflon-lined stainless-steel autoclave and heated at 150 °C for 24 h. The as-synthesised crystalline product was filtered off, washed with distilled water and dried at room temperature. Examination under an optical microscope indicated a powder corresponding to GaO(OH) and colourless large faceted prismatic-shaped crystals of the title compound. A suitable single crystal was easily isolated for the structure determination by X-ray diffraction.†

The structure consists of infinite macroanionic chains of empirical formula $[GaH(PO_4)_2]^{2-}$ separated by $[H_3N(CH_2)_3NH_3]^{2+}$ cations. The basic structural unit of the inorganic chain contains one Ga and two P centred tetrahedra. All of the vertices of the $GaO_4$ tetrahedron are shared with the $PO_4$ units, with Ga–O distances in the range 1.810–1.831 Å. The two inequivalent crystallographic $PO_4$ tetrahedra share two vertices with the $GaO_4$ unit (P–O 1.553–1.565 Å) and each $PO_4$ group has two terminal oxygen atoms (P–O 1.503–1.531 Å). The $GaO_4$ and $PO_4$ tetrahedra are linked in a strictly alternating manner giving rise to an infinite square-twisted chain running along [001]. This type of ribbon has previously been reported as

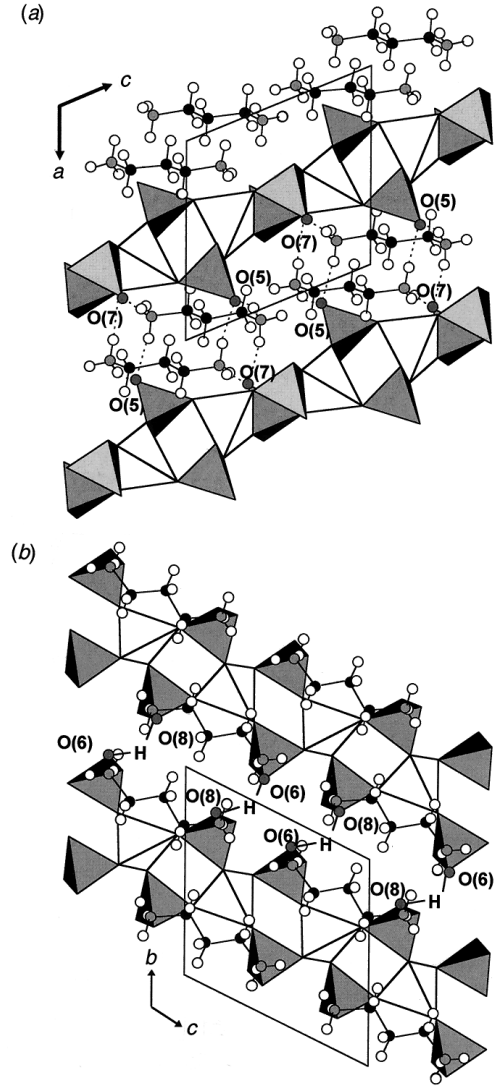

**Fig. 1** (*a*) View of the structure of $[H_3N(CH_2)_3NH_3][GaH(PO_4)_2]$ along [010] showing the hydrogen bonds (dotted lines) between the inorganic chain and the diprotonated 1,3-diaminopropane. (*b*) View of the structure along [100] showing the connection of two adjacent chains *via* hydrogen atoms between the $PO_4$ groups. For both figures, $GaO_4$ and $PO_4$ tetrahedra are indicated by white and grey shaded polyhedra, respectively. Nitrogen atoms are represented by grey circles, carbon atoms by black circles and hydrogen atoms by open circles. The terminal oxygens (with corresponding labels) of the $PO_4$ tetrahedra are indicated by grey circles at the vertices of the polyhedra.

*ts* in Smith's nomenclature.[9] Along [100], the cohesion of the structure [Fig. 1(*a*)] is ensured by strong hydrogen bonds between the hydrogen atoms of the ammonium groups of the organic molecule and one terminal oxygen atom of each $PO_4$ tetrahedron [labelled O(5) and O(7) on the figure] with the distance range $d_{N–H\cdots O}$1.868–1.923 Å. Indeed, the valence units for the corresponding oxygen atoms O(5) and O(7) are 1.45 and 1.47, respectively, instead of 2 expected for an oxygen atom. To satisfy the electroneutrality of the structure, one hydrogen atom must be added. The valence-bond analysis indicates that this hydrogen may be shared between O(6) (valence unit = 1.23) and O(8) (valence unit = 1.22) oxygen atoms from two distinct $PO_4$ tetrahedra [Fig 1(*b*)]. Moreover, the short O(6)···O(8) distance (2.444 Å) suggests the presence of positive charge between these two anions. Along [010], the cohesion of the structure is completed by hydrogen bonds between this hydrogen atom and the terminal oxygen atoms O(6) and O(8) of the $PO_4$ groups.

The authors are grateful to Professor M. Leblanc (Université du Maine) for the X-ray data collection and Rhône-Poulenc for financial support.

† *Crystal data* for $[H_3N(CH_2)_3NH_3][GaH(PO_4)_2]$: triclinic space group $P\bar{1}$ (no. 2); $a$ = 8.325(1), $b$ = 8.633(1), $c$ = 8.903(1) Å, $\alpha$ = 111.725(5), $\beta$ = 107.559(6), $\gamma$ = 98.394(6)°, $U$ = 542.2(1) Å$^3$, $Z$ = 2, $M_r$ = 336.82, $D_c$ = 2.06 g cm$^{-3}$, crystal dimensions: 0.152 × 0.0684 × 0.912 mm, $\mu$(Mo-K$\alpha$) = 28.63 cm$^{-1}$, $\lambda$ = 0.710 69 Å, X-rays monochromatised by graphite. The data were collected on a Siemens AED-2 four-circle diffractometer in the range $2\theta \leqslant 80°$. A total of 5255 reflections with $I \geqslant 2\sigma(I)$ was considered for the refinement. The data were corrected for Lorentz-polarisation and absorption effects. The structure was solved by direct methods analysis (SHELXS-86): one gallium and two phosphorus atoms were first located and all the remaining atoms except the isolated hydrogen atoms between the $PO_4$ groups were revealed from the difference Fourier map. The Fourier map analysis indicated three electron density residues around the two nitrogen atoms corresponding to the ammonium groups. Refinement (147 variables) was performed by full-matrix least-squares analysis (SHELXL-93): the reliability factors converged to $R$ = 0.032, $wR_2$ = 0.091. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/445.

**Thymine functionalised poly(norbornene)s are synthesised *via* living ring-opening metathesis polymerisation using the ruthenium initiator {$RuCl_2(CHPh)[P(C_6H_{11})_3]_2$}.**

In recent years there has been rapid progress in the controlled assembly of polymers *via* living chain-growth polymerisation. Some of the most dramatic advances have occurred in ring-opening metathesis polymerisation (ROMP),[1] where well-defined transition metal initiators allow control over many aspects of the polymer assembly, including its molecular weight and molecular weight distribution,[2] alkene backbone configuration[3] and tacticity.[4] An important recent addition to the armoury of initiators is the ruthenium system introduced by Grubbs,[5] which has been shown to give the widest tolerance yet of key functionalities, including aldehydes, primary amines and most significantly the Brønsted acid groups OH and $CO_2H$. Thus, it is now possible to address the controlled synthesis of highly functionalised polymers incorporating features of complex biological macromolecules. In a previous report[6] we described the synthesis of polymers derived from amino ester-containing monomers, and the synthesis of polymers from carbohydrate derived monomers has also been disclosed.[7–9] Here, we report the application of ring-opening metathesis polymerisation to the synthesis of nucleotide base functionalised poly(norbornene)s, synthetic macromolecules that may be viewed as a first step *en route* to all-carbon backbone analogues of deoxyribonucleic acid (DNA).

The nucleotide base-substituted monomer **4** was prepared according to Scheme 1. Treatment of himic anhydride **1** with excess ethylenediamine in refluxing toluene gave monoamine **2**‡ in 30% yield. Coupling of amine **2** with thymineacetic acid[10] **3** was achieved using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC, water-soluble carbodiimide) as the coupling agent in DMF and gave monomer **4** as a white solid in 74% yield. The *exo*-isomer of **4** can be obtained by a closely related series of transformations with the exception that it is necessary to protect one end of the ethylenediamine with a triphenylmethyl group prior to its reaction with *exo*-norborn-5-ene-2,3-dicarboxylic anhydride and subsequently to remove the protecting group with trifluoroacetic acid.

Direct evidence that ring-opening occurs in a controlled manner is provided by $^1$H NMR spectroscopy and MALDI-TOF mass spectrometry. Fig. 1 shows the crude $^1$H NMR spectrum obtained after treatment of {$RuCl_2(CHPh)[P(C_6H_{11})_3]_2$} with 3 equiv. of **4** in [$^2H_8$)]THF in a sealed NMR tube for 90 min. The resonance at δ 20.35 corresponds to the carbene hydrogen of the initiator, while the nearby doublet of doublets resonance at δ 19.09 may be attributed to the carbene hydrogen arising from ring-opening of the first monomer unit, with couplings to the β-hydrogen and the remaining ruthenium-bound tricyclohexylphosphine ligand. Upon standing for several hours this resonance broadens as more monomer is incorporated. In a separate experiment, 3 equiv. of *exo*-**4** were added to the initiator, the mixture stirred for 24 h, and then terminated by addition of ethyl vinyl ether. The MALDI-TOF spectrum of the resultant product [Fig. 2(*a*)] confirms that multiple insertions have occurred to give a narrow molecular weight distribution product ($M_n$ 2340, $M_w$ 2500, $M_w/M_n$ = 1.07).§ The most intense signals are due to protonated oligomers {$[M + H]^+$} with observable minor signals due to sodium {$[M + Na]^+$} and potassium {$[M + K]^+$} salts. The mass of each oligomer confirms the repeat unit (372.38 amu) and the presence of benzylidene and methylidene end-groups arising from the ruthenium initiator and the ethyl vinyl ether terminating agent respectively. The observed $M_n$ is higher than $M_n$(calc) (1221)

**Scheme 1** *Reagents and conditions*: i, $H_2NCH_2CH_2NH_2$ (6 equiv.), toluene, heat; ii, EDC, DMF

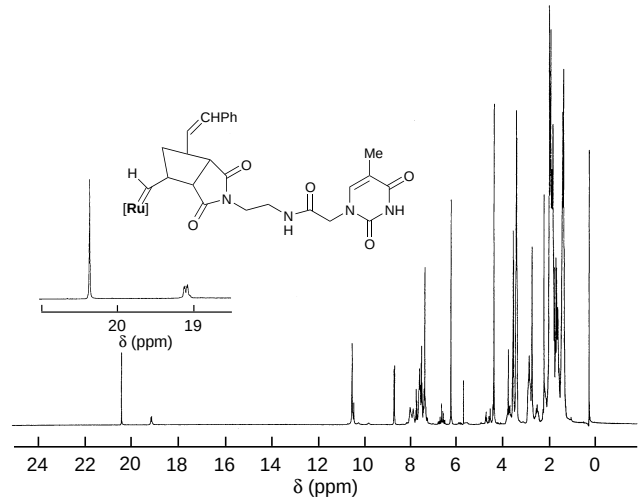

**Fig. 1** 250 MHz $^1$H NMR spectrum ([$^2H_8$]THF) of the products arising from treatment of {$RuCl_2(CHPh)[P(C_6H_{11})_3]_2$} with **4** (2 equiv.); [Ru] = [$RuCl_2(PCy_3)$]

due to the faster rate of propagation *versus* initiation for this monomer–initiator combination.

The MALDI-TOF spectrum of the product mixture prior to the addition of terminating agent is shown in Fig. 2(*b*). In this experiment, which employed indoleacetic acid as the matrix, the oligomers were detected as their sodium salts. The most intense signals are attributable to chains bearing benzylidene and oxo (aldehyde) end-groups, the latter arising from a termination reaction with molecular oxygen.¶ This reaction bears close similarity to that established for well-defined molybdenum initiators.[11] However, unlike the molybdenum system, in which the resultant aldehyde end-capped polymer reacts further with the propagating molybdenum alkylidene species to give a product of twice the anticipated molecular weight, in the case of ruthenium the aldehyde end-groups are tolerated by the ruthenium carbene and thus no further reaction occurs. Interestingly, in the ruthenium-initiated system, signals are also present (indicated by arrows) that correspond to ($n$ − 1) protonated chains that remain attached to the propagating ruthenium centres, *i.e.* $[RuCl_2(PCy_3)]$. The presence of $[M + Na]^+$ and $[M + K]^+$ signals for these species explains the greater multiplicity of signals in Fig. 2(*b*).

Overall, these observations provide direct evidence for a controlled polymerisation of nucleotide base-substituted monomers, and afford insight into a key termination reaction in the ruthenium system. In future publications, extensions of this work to other nucleotide base polymers and copolymers will be described.

‡ All new compounds gave satisfactory analytical and spectroscopic data.

§ Measured on a Kratos Analytical Kompact MALDI IV spectrometer in linear positive ion mode, accelerating voltage 20 kV, electron multiplier detector. The data presented are a running average of 250 laser shots over the sample position. It should be noted that MALDI-MS has been shown in certain cases to observe components of lower mass preferentially (ref. 12). This results in *M*w being lowered to a greater extent than *M*n, consequently affording a lower molecular weight distribution than the true value. The detector response is also known to affect the measured polymer weight distribution (ref. 13).

¶ Solutions of the ruthenium initiator are known to be sensitive to dioxygen. The reaction observed here occurs upon preparation of the sample slides under non-anaerobic conditions.

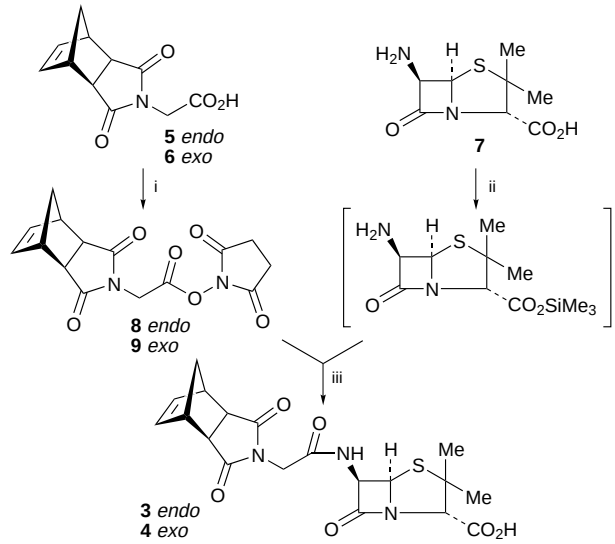
**Penicillin functionalised poly(norbornene)s are synthesised *via* living ring-opening metathesis polymerisation using the ruthenium initiator {$RuCl_2(CHPh)[P(C_6H_{11})_3]_2$}.**

There is currently much interest in the synthesis of new polymeric structures possessing unusual functionalities and/or molecular architectures. One of the most versatile approaches to the preparation of such polymers is the ring-opening metathesis polymerisation (ROMP) of strained ring systems, especially norbornenes, using well defined polymerisation initiators based upon molybdenum,[1] *e.g.* **1a**–**c**, or ruthenium,[2] *e.g.* **2**, as illustrated in Scheme 1. This process allows the preparation of polymers *via* a living polymerisation which gives excellent control of the molecular weight and polydispersity, and facilitates the synthesis of more complex polymer architectures such as block copolymers. The molybdenum based initiators **1a**–**c** also allow the alkene geometry within the polymer to be controlled, whilst ruthenium based initiator **2** is tolerant of a wide range of functional groups.

In recent reports, we have described the use of ROMP initiators **1a**–**c** and **2** to prepare polymers derived from amino acids[3] and from nucleic acid bases,[4] respectively. The synthesis of carbohydrate derived polymers has also been reported.[5]



Here, we show how this methodology may be used to prepare polymers incorporating penicillin units. Penicillin was chosen as an archetypal, biologically active peptide, which is also susceptible to decomposition under a wide range of reaction conditions.[6] Thus the preparation of polymers incorporating this group would demonstrate both the ability to prepare polymers with potential biological activity, and illustrate the compatibility of the methodology with even the most sensitive of functional groups. Polymers derived from penicillin or other biologically active peptides have a number of potential applications: high molecular weight polymers may be suitable for the preparation of slow release capsules or bandages for the treatment of surface wounds, whilst low molecular weight oligomers may be able to deliver multiple copies of a drug to its site of action simultaneously, thus helping to circumvent problems of drug resistance. It should also be possible to prepare chromatography columns from polymers of this type, and to utilise these in isolating the biological receptors.

**Scheme 1**

The synthesis of the desired monomers **3** and **4**‡ was achieved as shown in Scheme 2, the preparation of *endo* and *exo* glycine derivatives **5** and **6** having been previously reported.[7] All attempts to couple activated derivatives (preformed acid chloride or *N*-hydroxysuccinimide ester) of acids **5** and **6** directly to (+)-6-aminopenicillanic acid (6-APA) **7** were unsuccessful, resulting in extensive decomposition of the penicillin ring. Eventually, we found that monomers **3** and **4** could be prepared by treatment of 6-APA first with bis-(trimethylsilyl)acetamide to protect the acid functionality,[8] followed, without isolation of the ester, by coupling with the *N*-hydroxysuccinimide esters **8** and **9**, and aqueous workup. Samples of monomers **3** and **4** prepared in this way contained silyl alcohol and/or silyl ether by-products which could not be removed without extensive decomposition, but were suitable for use in subsequent polymerisation reactions. So far, our polymerisation studies have focused on the *exo* derivative **4** which we have found to polymerise in a more controlled fashion than its *endo* isomer **3**.

Addition of initiator **2** to a stirred solution of **4** (10 equiv.) in acetone afforded a magenta solution which within a few minutes turned light brown and precipitated a beige solid. This suspension was stirred at room temperature for 22 h. The polymerisation was then terminated by addition of ethyl vinyl ether (50 μl) and the resultant solid collected and dried *in vacuo* for 2 h. It proved possible to follow the reaction of the closely related but more soluble silyl ester derivative of **4** by NMR spectroscopy in $CDCl_3$. The 270 MHz $^1H$ NMR spectrum of a sample containing the ruthenium initiator and 10 equiv. of $Me_3Si$-**4**, recorded a few minutes after mixing, is shown in Fig. 1. The sharp singlet resonance at δ 19.9 is attributable to the carbene hydrogen of unconsumed initiator, while the broadened resonance closeby is due to the carbene hydrogens of the [Ru]

**Scheme 2** *Reagents and conditions*: i, DCC, *N*-hydroxysuccinimide; ii, $MeC(OSiMe_3)=NSiMe_3$; iii, $H_2O$

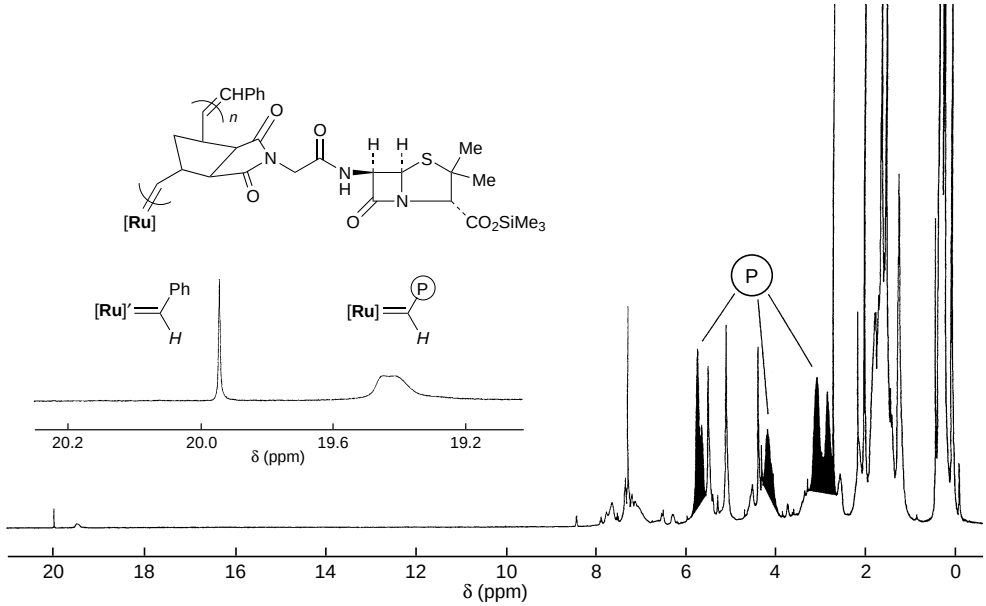


**Fig. 1** 270 MHz $^1$H NMR spectrum ([$^2$H]chloroform) of the products arising from treatment of $\{RuCl_2(CHPh)[P(C_6H_{11})_3]_2\}$ with ($Me_3Si$-**4**) (10 equiv.); [Ru] = $[RuCl_2(PCy_3)]$, [Ru]′ = $[RuCl_2(PCy_3)_2]$

end-groups of the propagating polymer chains. The shaded resonances in the region δ 2–6 are attributable to protons attached to the hydrocarbon backbone of the ring-opened products. In the olefinic region (*ca.* δ 5.5–6.0) there are two principal resonances (shaded); the more intense signal is tentatively assigned to the vinylene hydrogens of the *trans* polymer, consistent with the predominantly *trans* products arising from polymerisations of other closely related glycine-functionalised monomers with this ruthenium initiator (typically 80–90% *trans*[9]).

An infrared spectrum on the isolated polymer shows that the penicillin ring system survives intact during the polymerisations; a characteristic high frequency absorption at 1770 $cm^{-1}$ is observed for the β-lactam carbonyl. Attempts to further characterise the polymers by GPC were frustrated due to their insolubility in standard GPC solvents, and abnormal elution from the column when DMF was used as the GPC solvent. An approximate value for the number average molecular weight ($M_n$) could, however, be obtained from the $^1$H NMR spectrum of living poly($Me_3Si$-**4**); integration of the chain-end ruthenium carbene hydrogen resonance *versus* the olefinic hydrogens of the polymer backbone gave an approximate value for $M_n$ of 11800, corresponding to *ca.* 24 repeat units.§ To date, unlike for thymine-functionalised poly(norbornene)s,[4] it has not proved possible to obtain good quality MALDI-TOF mass spectra on these polymers. Electrospray mass spectrometry on the other hand does give some, if limited, information on the molecular weight distributions of the resultant polymers. The negative ion electrospray mass spectrum in DMF–MeCN–$H_2O$ of a polymer prepared from 10 equiv. of *exo*-monomer **4** and ruthenium initiator **2** shows molecular ion or fragment (loss of $CO_2$) peaks attributable to polymer chains containing 8–17 monomer units. The corresponding positive ion spectrum shows a series of fragment peaks attributable to consecutive loss of penicillin residues from the polymer chains. Thus, in addition to providing information on the molecular weights of the polymer chains, the mass spectra also provide corroborative evidence that the β-lactam ring survives intact.

In conclusion, we have shown that ROMP methodology using well-defined ruthenium initiators is compatible with the penicillin ring system. Our work on the synthesis of biomimetic polymers using ROMP methodology is continuing, and further results will be presented in due course.

The authors thank the EPSRC (Innovative Polymer Synthesis Initiative) for financial support, and Novartis Pharmaceuticals and the EPSRC for a studentship to M. R. G. Mass spectra were acquired by the EPSRC mass spectrometry service at the University of Wales, Swansea, and GPC analyses in DMF were carried out by the EPSRC service at RAPRA. The staff of these services are thanked for their efforts.

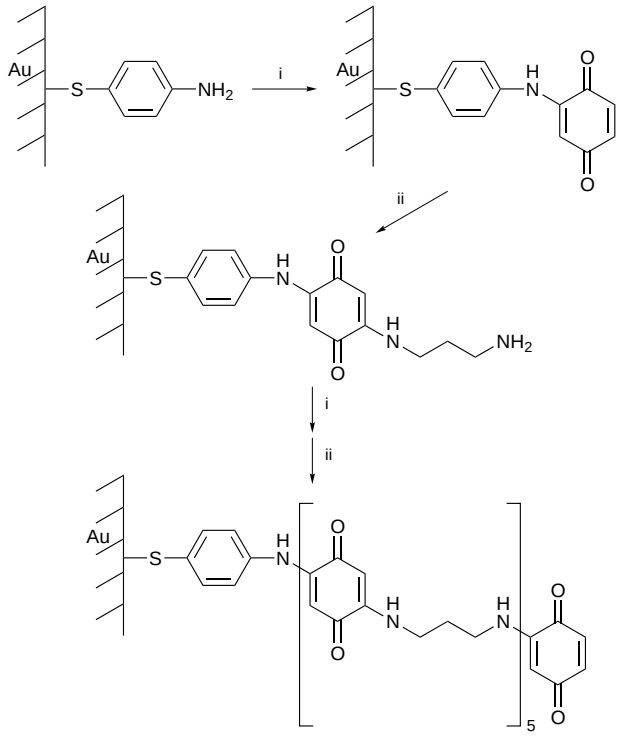
# Polyaminoquinone self-assembled films on electrodes: synthesis of all-organic molecular wires by solution phase epitaxy

**Jukka Lukkari,* Kari Kleemola, Minna Meretoja and Jouko Kankare**



*Department of Chemistry, University of Turku, FIN-20014 Turku, Finland*

**Redox active molecular wires consisting of successive benzoquinone and diamino moieties are formed on a gold surface using repetitive self-assembly and solution epitaxy.**

Quinones constitute an interesting group of electroactive compounds which take part in several biologically important oxidation–reduction processes. The electrochemistry of quinones has been extensively studied and their complex redox mechanisms considered in detail.[1a,2] The reactivity of quinones towards nitrogen addition is also well known.[1b] The reaction of 1,4-benzoquinone with an amine is kinetically facile and proceeds, in the presence of an oxidant, *via* successive addition of amines predominantly at the 2,5-positions. Nitrogen addition lowers the redox potential of quinone and, therefore, unreacted benzoquinone can serve as an oxidant in the process. Several aliphatic diaminoquinones have been prepared and their spectral and electrochemical properties studied.[3,4]

Berlin and co-workers have employed 1,4-amino addition, using aromatic diamines, to prepare aminoquinone polymers.[1c] These polymers are obtained as dark powders, which are insoluble in most solvents, rendering their purification and study difficult. They were, however, found to possess semiconducting properties, which makes them interesting candidates for molecular wires and other devices in molecular electronics.[5] In order to avoid problems in the synthesis and purification of aminoquinone oligomers we have utilised repetitive self-assembly onto a solid substrate in order to grow aminoquinone molecular wires by solution epitaxy. The process involves successive immobilisation of quinones and diamines on a suitable primed electrode surface (Scheme 1), as originally suggested by Katz and Schmidt.[6] We have chosen *p*-mercaptoaniline for surface priming because it has been shown to form well ordered monolayers on Au(111).[7]

The sequential formation of polyaminoquinone on the surface of a polycrystalline gold electrode was followed by cyclic voltammetry (Fig. 1).† The gold electrode primed with the monolayer of *p*-mercaptoaniline exhibits no electroactivity in the potential range studied. After the immobilisation of the

**Scheme 1** *Reagents and conditions*: i, benzoquinone (0.5 M), MeCN–phosphate buffer (pH 7.2) (1 : 1), 3 h; ii, 1,3-diaminopropane in EtOH (30% v/v), 40 min

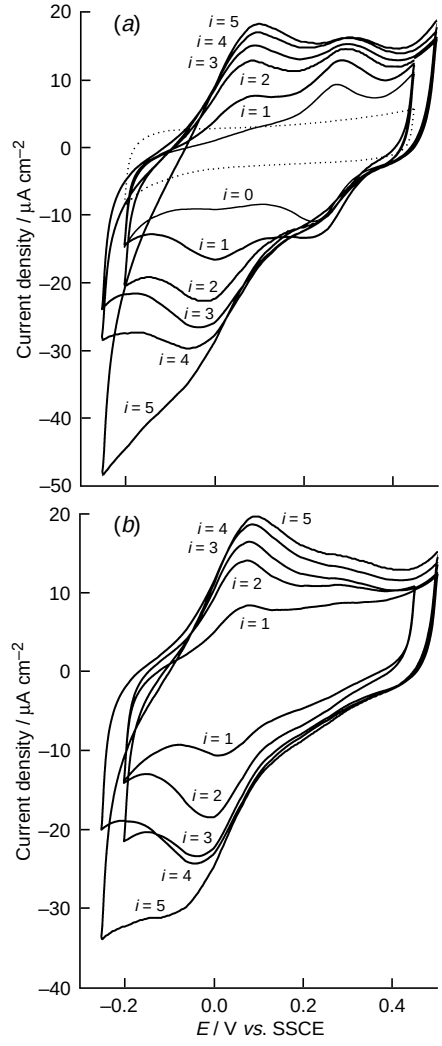


**Fig. 1** Cyclic voltammograms of (*a*) quinone terminated Au–SPhNH–$(Q–A)_i$–Q, and (*b*) amino terminated Au–SPhNH–$(Q–A)_i$ electrodes in 0.5 M $HClO_4$ at 100 mV $s^{-1}$. Dotted curve is Au–$SPhNH_2$ electrode.

first quinone the peaks due to the oxidation and reduction of amino substituted quinone appear at +0.26 V *vs.* sodium saturated calomel electrode (SSCE). The redox potential shifts 58 mV decade$^{-1}$ to the cathodic direction in the pH range from 0 to 8, showing the ($2H^+$, $2e^-$) nature of the reaction. The surface density of aminoquinone was calculated from the charge under the oxidation wave. Using the real surface area of the electrode, determined by oxidation of the bare gold electrode in 0.5 M $H_2SO_4$ up to the Burshtein minimum, a surface density of $1.75 \times 10^{-11}$ mol cm$^{-2}$ was obtained.[8] This is somewhat lower than reported for naphthoquinone or benzoquinone monolayer electrodes with aliphatic amino thiol primer.[6,9] The width of the voltammetric peak is 86 mV, which is much larger than the theoretically expected value of 90.6/*n* mV.

Fig. 1(*a*) and (*b*) shows the voltammograms of the successively formed quinone and amino terminated surfaces, respectively. Qualitatively the trend is very clear. The peaks due to monoaminoquinone in the Au–SPhNH–Q electrode (Q = benzoquinone) disappear after treating the electrode with 1,3-diaminopropane (A). Instead, a pair of peaks appears at 0.045 V *vs*. SSCE indicating the formation of a Au–SPhNH–Q–A electrode. A small residual peak can be seen at +0.26 V, which shows that the conversion is not complete, and the charge under this peak corresponds to *ca.* 12% of the total charge. After further reaction with benzoquinone the peak originating from monoaminoquinone reappears. It disappears after treatment with 1,3-diaminopropane with a concomitant increase in the peak attributable to diaminoquinone. These observations indicate the formation of Au–SPhNH–Q–A–Q and Au–SPhNH–Q–A–Q–A surfaces, respectively. It is noteworthy that the amount of the residual monoaminoquinone does not increase in the last step. The same process can be repeated with the same observed voltammetric behaviour, so that the final curves in Fig. 1(*a*) and (*b*) correspond to Au–SPhNH–(Q–A)$_5$–Q and Au–SPhNH–(Q–A)$_5$ electrode surfaces, respectively.

The quantitative determination of the charges under the waves in the cyclic voltammograms is complicated due to the large width of the waves. We chose to fit the data to the sum of two reversible surface waves, with separate linear baselines.[10]

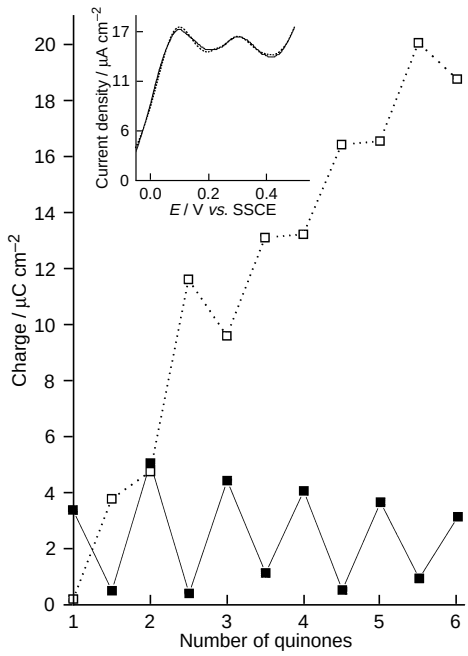

**Fig. 2** Charges calculated from oxidation peaks in Fig. 1; monoaminoquinone (■) and diaminoquinone (□). Inset shows the fit (dashed line) to the curve with $i = 4$ in Fig. 1(*a*) (solid line).

The results of such analysis are shown in Fig. 2, where the half-integer values on the *x*-axis refer to amino terminated surfaces. The inset shows an example of fitting results and demonstrates the reasonably good success of the simple model used. The charge due to the monoaminoquinone oscillates between *ca*. zero and 4 μC cm$^{-2}$, with very little damping. On the other hand, the charge due to diaminoquinones increases upon amine addition but stays more or less constant during the addition of quinone to the chain. This kind of behaviour is exactly what is expected for the sequential formation of polyaminoquinone chains on the electrode surface. Other charge integration procedures used all produced qualitatively the same result, *i.e*. a saw-tooth curve for the monoaminoquinone and a staircase curve for the diaminoquinone.

We have demonstrated the feasibility of building long aminoquinone chains on a solid substrate by repetitive self-assembly. The approach is very flexible and using only commercially available quinones and diamines it is possible to create, with minimal synthetic work, a large variety of structures with different properties. Preliminary results show that Au–SPhNH–(Q–A)$_5$–Q electrode retains *ca*. 70% of its total electroactivity after 40 days when stored in water under ambient atmosphere. The data in Fig. 2 show that the conversion efficiency is not markedly decreased with increasing number of quinone units. This implies that the reactivity of the chains, as a function of length, is not a limiting factor for attainable aminoquinone chain lengths. On the other hand, peak separations and widths increase with increasing chain length. These effects can be attributed to non-equal positions of the quinones within the chain and to the intra-chain interactions between the quinone redox centres. A detailed study of the structure, electrochemical and spectroelectrochemical properties of mono- and poly-aminoquinone modified electrodes, with aliphatic and aromatic diamines, is underway in our laboratory and will be reported in forthcoming papers.

# Stable isotope labelling studies on the biosynthesis of pinguisane-type sesquiterpenes in axenic cultures of *Aneura pinguis*

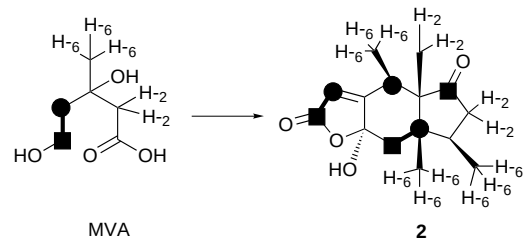
**Hiroyuki Tazaki,*[a] Hiroshi Soutome,[a] Takeshi Iwasaki,[a] Kensuke Nabeta[a] and Duilio Arigoni[b]**

[a] *Department of Bioresource Chemistry, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, 080 Japan*
[b] *Laboratorium fur Organische Chemie, ETH-Z, 8092 Zurich, Switzerland*

**$^2$H and $^{13}$C NMR analyses of 6α-hydroxy-3-oxopinguis-5(10)-ene-11,6-olide produced by axcenic cultures of the liverwort *Aneura pinguis* in the presence of $^2$H- and $^{13}$C-labelled mevalonates clarify the biosynthesis of pinguisane-type sesquiterpenes from FPP *via* a 1,2-hydride shift, two 1,2-methyl shifts, a cleavage of the main FPP chain and then recyclization.**

Pinguisone **1**[1] and its biosynthetically related compounds have been isolated from many Metzgeriales and Jungermanniale liverworts.[2] They are biosynthetically interesting since the biogenesis of their structures is difficult to explain simply in terms of the isoprene rule. This led us to investigate the structures and biosynthesis of pinguisane-type sesquiterpenes. In previous work, we isolated three new pinguisane-type sesquiterpenes as co-occurring compounds[3] and proposed a biosynthetic pathway to **1** in an axenic culture of gametophytes of *Aneura pinguis* by feeding [2-$^{13}$C]acetate.[4] As a probe of the biosynthetic pathway of pinguisane-type sesquiterpenes, we administered labelled mevalonates ([4,5-$^{13}C_2$]-, [5-$^{13}$C]-, [2-$^2H_2$]- and [6-$^2H_3$]-MVA) to the cultured gametophyte of *A. pinguis*. The results revised the previous route.[4] Here we propose the most plausible biosynthetic pathway to form the pinguisane skeleton.

**1** **2** **12**



[4,5-$^{13}C_2$]-, [5-$^{13}$C]-, [2-$^2H_2$]- and [6-$^2H_3$]-MVA were prepared by procedures reported previously.[5] Axenic cultures of gametophyte of *A. pinguis* were grown in Gamborg B5 medium,[6] to which were fed 10.0 mmol of potassium MVA, under continuous light at 20 °C. 6α-Hydroxy-3-oxopinguis-5(10)-ene-11,6-olide **2** was the main sesquiterpene isolated from axenic cultures of *A. pinguis*. Compound **2** was biosynthesized from [4,5-$^{13}C_2$]-, [5-$^{13}$C]-, [2-$^2H_2$]- and [6-$^2H_3$]-MVA and isolated by HPLC as described previously.[3] Deviations in the levels of $^2$H and $^{13}$C enrichment (1.50–9.45 atom% excess) were observed among the differently labelled MVAs but may have been caused by variations in the incubation periods. Analysis of the resulting $^2$H and $^{13}$C labelled **2** (and its methyl ester) clearly showed the incorporation patterns illustrated in Fig. 1.

The presumed locations of $^2$H at the C-12, C-13 and C-15 positions in **2**, originating from C-6 of MVA, and at the C-2 and C-14 positions in **2**, originating from C-2 of MVA, were confirmed by feeding [2-$^2H_2$]- and [6-$^2H_3$]-MVA. Deuterium incorporation in the methyl groups at the C-12 and C-15 positions shows that these originate from the C-6 of MVA and provided evidence for 1,2-methyl migrations from C-9 to C-8 and C-5 to C-4 in the formation of the pinguisane skeleton. On the other hand, feeding [2-$^2H_2$]-MVA revealed that, in contrast to previous route,[4] the methyl group at the C-14 originates from the C-2 of MVA.

In the $^{13}$C NMR spectrum of **2** incorporating [4,5-$^{13}C_2$]-MVA, $^{13}$C–$^{13}$C coupling was observed between C-7 and C-8 ($J_{C\text{-}7,C\text{-}8}$ = 35.4 Hz), and between C-10 and C-11 ($J_{C\text{-}10,C\text{-}11}$ = 64.7 Hz). The enhanced singlets at C-3 ($\delta_C$ 217.3, 1.47 atom% excess) and C-4 ($\delta_C$ 32.2, 2.27 atom% excess) originate from C-5 and C-4 of MVA, respectively. The presumed location of $^{13}$C at the C-3 position in **2**, originating from C-5 of MVA, was confirmed by feeding [5-$^{13}$C]-MVA. These results indicated that a cleavage of the C-9–C-10 bond of FPP took place in the formation of pinguisane skeleton.

On the basis of these data, the biosynthetic pathway shown in Fig. 2 is proposed for the pinguisane-type sesquiterpenes of axenic cultures of *A. pinguis.* A postulated cyclized cation (**3**) may be formed *via* the formation of a C-6–C-11 bond from FPP without elimination of diphosphate. Cation **3** is converted to diphosphate **4** with the migration of a 1,2-methyl and a 1,2-hydride shift. Formation of the C-3–C-10 bond in **4** with the elimination of diphosphate gives the bicyclic cation **5**. Rupture of the C-9–C-10 bond of **4** and recyclization to form a cyclopentane ring in **5** gives the indane cation **6** which is further converted to the pinguisane skeleton by a 1,2-methyl shift. An alternative sequence, *i.e.* FPP → cation **13** → **5**, is excluded by the following reasons. The formation of **13** implies an unprecedented *cis*-addition to the isopropylidene double bond. The migration of the H-ligand in **13** would leave the positive charge on a forbidden bridgehead position. Furthermore, the migration of a 1,2-hydride shift from C-9 to C-8 in **13** would be predicted to result in the wrong stereochemistry for the secondary methyl group in the cyclopentane ring.

Recently, compound **11** has been isolated from the liverwort *Dicranolejeunea yoshinagana* (Hatt.) Mizut.[7] Compound **11** is most probably a biogenetic byproduct of a pinguisane-type sesquiterpene formed from cation **6** by a 1,2-vinyl shift. On the other hand, β-monocyclonerolidol **7** isolated from *Ptychanthus striatus* (Lehm. st Lindenb) Nees[8] which co-occurrs with striatene **8** and ptychanolide **12**, and the oxygenated sesquiterpene ricinocarpin A **9** from *Ricinocarpus natans*[9] is postulated to be derived from cation **3**. Similarly, striatene **8** may be also derived from the cyclohexene diphosphate **4**. In addition,

MVA **2**

**Fig.1** $^2$H and $^{13}$C labelling of **2**

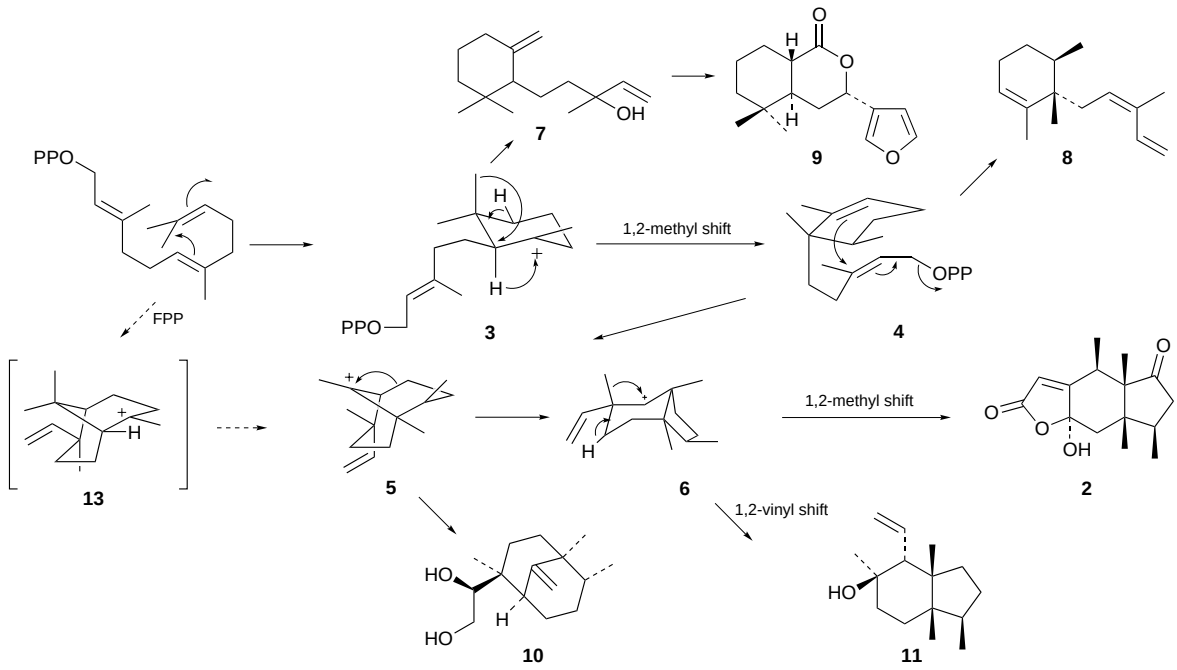


**Fig. 2** Proposed biosynthetic pathway of pinguisane type and related sesquiterpenes

trifarienol A **10** isolated from *Cheilolejeanea trifaria* is postulated to be formed from cation **5**. Thus, the biosynthetic pathway illustrated in Fig. 2 seems to be widely occurring in liverworts which produce not only pinguisane-type sesquiterpene but also three other skeletal sesquiterpenes represented by **7**, **8** and **10**.

While the pathway shown in Fig. 2 satisfies the results of labelling studies, the sequence of steps involved need to be proven by enzymatic studies.

This research was supported financially by the Agricultural Chemical Research Foundation of the Japan Society for Bioscience, Biotechnology and Agrochemistry, the Suhara Memorial Foundation, and a Grand-in-aid for Scientific Research from the Ministry of Education, Science and Culture, Japan.

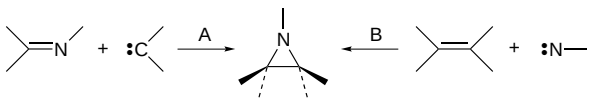
# Crystal structure of an imine–$SnCl_4$ complex. The intermediate in catalytic aziridination reactions

**Kaare G. Rasmussen, Rita G. Hazell and Karl Anker Jørgensen***

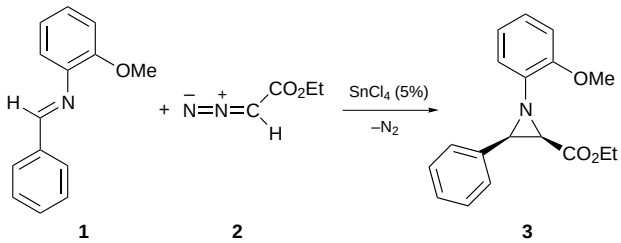
*Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark*

**An imine–$SnCl_4$ complex, which is an intermediate in Lewis acid catalysed aziridination reactions, is isolated and characterised by X-ray diffraction; the structure and catalytic properties of the complex are discussed.**



The metal-catalysed aziridination reaction is a new area of organic transformation. Two new catalytic aziridination reactions have been presented within the last few years; one is the metal-catalysed addition of a carbene fragment to an imine (Scheme 1, route A),[1] the other is the addition of a nitrene fragment to an alkene (Scheme 1, route B).[2]

The formation of aziridines from imines and ethyl diazoacetate (EDA) as the carbene-donor fragment (Scheme 1, route A) can take place by two different reaction paths, either by the formation of a metal–carbene, formed by reaction of the metal with EDA with elimination of $N_2$, then reaction with the imine giving an ylide as the intermediate,[1a,c] or by activation of the imine by the metal—a Lewis acid—followed by a nucleophilic attack by EDA followed by elimination of $N_2$.[1d,f,h,i]



In an attempt to develop a selective aziridination of imines we have turned our attention to potentially bidentate substrates. Here we present the isolation and characterisation of the intermediate in the Lewis acid catalysed aziridination using $SnCl_4$ as the catalyst. This imine–$SnCl_4$ intermediate gives important information about the reaction course for the Lewis acid catalysed aziridination of imines using EDA as the carbene fragment donor.

Reaction of *N*-benzylidine-*o*-anisidine **1** with EDA **2** in the presence of $SnCl_4$ as the catalyst (5 mol%) gives the *cis*-aziridine **3** selectively in reasonable yields (Scheme 2).† In the absence of $SnCl_4$ no reaction takes place.

Choosing imine **1** as the substrate was an attempt to utilise the nitrogen and oxygen lone-pair electrons to give bidentate coordination to the metal. $^{13}C$ NMR spectroscopic investigations of **1** and $SnCl_4$ in $CDCl_3$ shows a 1:1 complex **4** in solution. The major changes in the $^{13}C$ NMR chemical shifts of **4**, relative to **1**, are (data in brackets are for **1**): δ 168.6 (161.3), 135.2 (131.2), 131.9 (126.6), 131.2 (128.8), 129.5 (128.6), 113.1 (111.4), 58.1 (55.8). It appears from the $^{13}C$ NMR data that some of the major changes are in the shifts of the imine and methoxy carbon atoms, from δ 161.3 to 168.6 and from δ 55.8 to 58.1, respectively, by coordination to $SnCl_4$.

**Scheme 1**

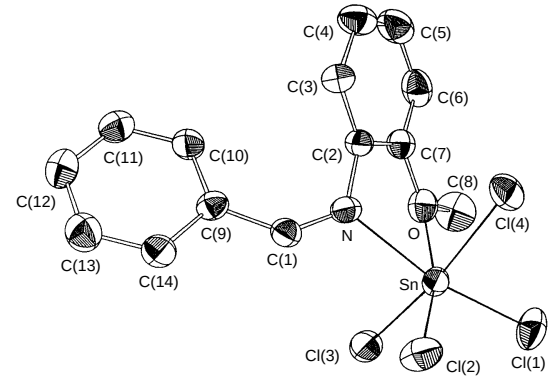
**1** **2** **3**

**Scheme 2**

Complex **4** was prepared by the addition of $SnCl_4$ (23.4 mg, 0.20 mmol) to a solution of imine **1** (35.7 mg, 0.20 mmol) in 0.7 ml $CDCl_3$ under Ar. When pale yellow crystals formed the solvent was decanted off to give **4** (50.5 mg, 54%) [mp = 166–72 °C (decomp.)]. The structure of **4**, determined by X-ray diffraction, is depicted in Fig. 1.‡

The structure of **4** consists of the imine **1** coordinated to $SnCl_4$ by the nitrogen and oxygen atoms giving a nearly octahedral geometry at the metal. The X-ray structure shows several interesting structural features, the most remarkable being is the change of geometry of **1**, which in **4** has a *cis*-geometry. The structure of **1** in solution ($CDCl_3$) has been studied by $^1H$ NMR spectroscopy. A NOEDIF spectrum gives a coupling between the hydrogen atom of the imine and the *ortho*-hydrogen atom in the *o*-anisidine substituent of −3%, showing that **1** is *trans* in solution. The imine **1** isomerises thus by coordination to $SnCl_4$.[3] A mechanism for the *trans* to *cis* isomerisation of **1** by reaction with $SnCl_4$ is proposed in Scheme 3. The first step is a nucleophilic attack of the imine at $SnCl_4$, giving a zwitterion intermediate **I**. The imine part in the zwitterion now has a C–N bond with single bond character which allows rotation, resulting in the *cis* isomer found in **4**. The reason for this isomerisation is probably steric repulsion between the *C*-phenyl substituent and one of the equatorial chlorides. This steric repulsion has been confirmed by modelling of the *trans* isomer of **1** coordinated to $SnCl_4$.

The structural data for **4** presented in Fig. 1 show that the Sn–N and Sn–O bond lengths are 2.222(5) and 2.370(4) Å, respectively, of which the former is similar to the same bond length in the only complex characterised having tin bound to four chlorides and a nitrogen and an oxygen atom.[4] The imine C(1)=N bond in **4** [1.285(8) Å] is not affected by the coordination to $SnCl_4$ and is similar to other imines charac-



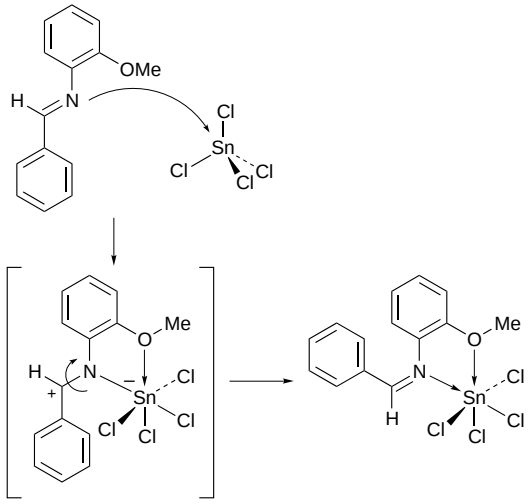


**Fig. 1** Molecular structure of **4**. C–H hydrogen atoms are not shown. Selected distances (Å) and angles (°) for **4**: Sn–N 2.222(5), Sn–O 2.370(4), Sn–Cl(1) 2.356(2), Sn–Cl(2) 2.351(2), Sn–Cl(3) 2.372(2), Sn–Cl(4) 2.385(2), N–C(1) 1.285(8), N–C(2) 1.439(7), C(7)–O 1.389(7), O–C(8) 1.439(7), N–Sn–O 68.3(2), Sn–N–C(1) 119.9(4), Sn–N–C(2) 112.8(4), N–C(1)–C(9) 136.0(6), N–C(1)–C(9)–C(10) 8(1), C(1)–N–C(2)–C(3) 47.3(9).

**I** **4**

**Scheme 3**

terised.§ The angle between the C(1)–C(9)–C(10)–C(14) and N–C(2)–C(3)–C(7) planes is 48°, which is due to steric repulsion between the two aromatic substituents at the imine.

The 1 : 1.2 reaction between complex **4** and EDA gives the aziridine **3**. However, the isolated yield of **3** is relatively low, caused by the decomposition of the aziridine by $SnCl_4$. Furthermore, we have tried to perform the catalytic reaction of the imine **1** with EDA in the presence of chiral ligands, especially chiral diamines, under various reaction conditions, but racemic **3** was formed. Based on the X-ray structure of **4** and the assumption that the chiral ligand replaces the two equatorial chlorides in **4** modelling studies account for the missing enantioselectivity in aziridination reactions by suggesting that the chiral ligand does not discriminate between the two faces of the imine.

Further work is in progress to understand the catalytic properties of **4** and to develop selective reactions based on this approach.

## Footnotes

† *Reaction conditions:* imine 1 (1.0 mmol) was added to a 5 ml Schlenk flask which was evacuated and filled twice with Ar. $CH_2Cl_2$ (4 ml) was added, followed by $SnCl_4$ or **4** (0.05 mmol). The solution was cooled to −15 °C before the addition of EDA **2** (1.3 mmol). When the evolution of $N_2$ ceased the reaction mixture was poured onto ice and the resulting aqueous phase was extracted with $CH_2Cl_2$ (3 ml). The organic phase was washed with 5% aq. $NaHCO_3$ and brine and dried with $Na_2SO_4$. The crude product was then purified by flash chromatography on silica gel using 5% EtOAc–light petroleum as eluent to give the pure aziridine **3**; $\delta_H$ 0.95 (t, *J* 7.2, 3H), 3.09 (d, *J* 6.5, 1H), 3.59 (d, *J* 6.5, 1H), 3.82 (s, 3H), 3.93–4.12 (m, 2H), 6.85–6.89 (m, 2H), 6.94–7.03 (m, 2H), 7.28–7.36 (m, 3H) and 7.54–7.57 (m 2H); $\delta_C$ 13.9, 45.9, 47.6, 55.4, 60.8, 111.0, 119.8, 120.6, 123.9, 127.6, 127.8, 127.9, 134.8, 140.8, 152.1 and 168.1; *m/z* 297.133 ($C_{18}H_{19}NO_3$ requires 297.133, 19%), 252 (13) and 224 (100).

‡ *Crystallographic data* for **4**: $C_{14}H_{13}NOCl_4Sn$, monoclinic, space group *C*2/*c*, *a* = 30.9076(1), *b* = 7.6820(1), *c* = 16.3239(1) Å, β = 119.773(1)°, *V* = 3443.07(7) Å$^3$, *Z* = 8; 4361 independent reflections measured at 298 K on a Siemens SMART CCD diffractometer; Mo-Kα; 2750 reflections with $I > 3\sigma(I)$ and 191 variables yields $R = 0.038$, $R_w = 0.052$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/457.

§ A search in the CCDA data file gave for a series of very similar imines an average C=N bond length of 1.28 Å.

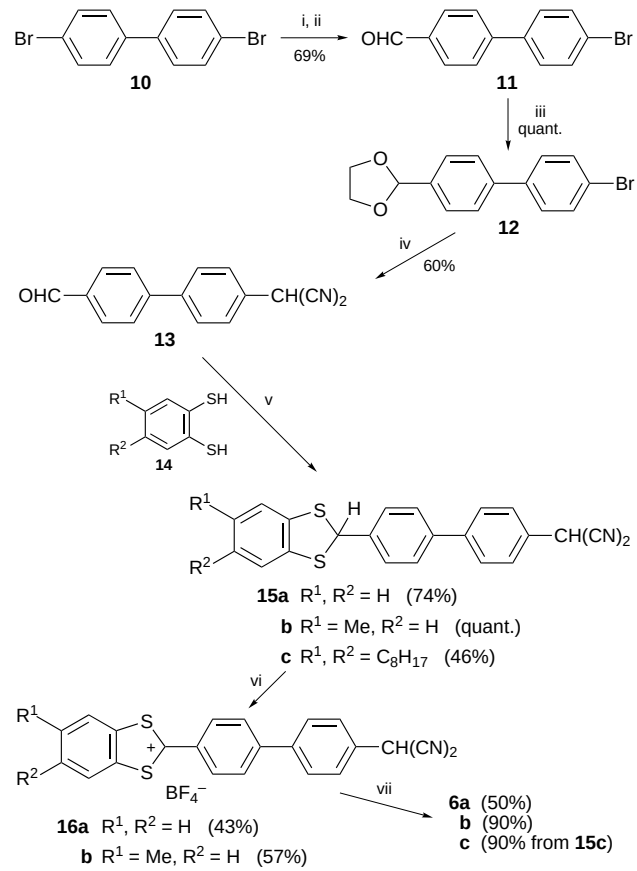
# Push-pull type of diphenoquinoid chromophores as novel near-infrared dyes

**Shinobu Inoue, Yoshio Aso and Tetsuo Otsubo***

*Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Kagamiyama 1-4-1, Higashi-Hiroshima 739, Japan*



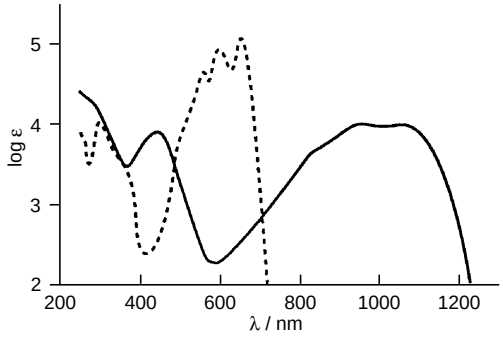
**Novel push-pull diphenoquinoid chromophores, in which one of the terminal positions carries a strong donor group, benzo-1,3-dithiol-2-ylidene, and the other a strong acceptor group, dicyanomethylene, are synthesized and show a strong absorption in the near-infrared region.**

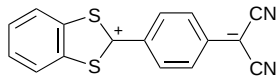
The search for highly-coloured organic compounds has attracted current attention in terms of advanced optoelectronic materials, such as near-infrared dyes and nonlinear optics.[1,2] Push-pull types of conjugated π-electronic systems provide an entry to highly-coloured chromophores.[3] Such compounds containing a quinoid ring are especially interesting, because the push-pull stabilization can be promoted by the aromatization of the ring. Some time ago, Gompper *et al.* reported the quinoid compound **1** and benzo-fused derivative **2**, in which one of the terminal positions carries a strong donor group, 1,3-dithiol-2-ylidene, and the other a strong acceptor group, dicyanomethylene.[4] These compounds showed a strong intramolecular charge-transfer absorption band in the visible region (*vide infra*). The 1,4-naphthoquinoid analogue **3** and the 9,10-anthraquinoid one **4** were also prepared, but their absorption bands showed rather hypsochromic shifts.[4,5] The extensively conjugated diphenoquinoid systems **5** and **6**, so far unknown, are expected to show a bathochromic shift of the absorption band and serve as a receptor for near-infrared light. Here we report the synthesis and spectroscopic properties of the benzo derivatives **6a**–**c**.

Although the Gompper method, involving reaction of dicyanomethylbenzene **7** with 2-methylthio-1,3-dithiolium methanesulfonate **8**, is very convenient and useful for the preparation of the benzoquinoid system,[4] attempted syntheses of the diphenoquinoid compounds **5** and **6** by the same method using 4-dicyanomethylbiphenyl **9** were unsuccessful. Alternatively, we synthesized **6a**–**c** by another route starting with 4,4′-dibromobiphenyl **10** as shown in Scheme 1: one of the functional groups of **10** was converted *via* lithiation to a formyl group, and then the other one to a dicyanomethyl group by the Takahashi reaction.[6] The intermediate **13** thus obtained was reacted with benzenedithiol **14** in the presence of a catalytic amount of toluene-*p*-sulfonic acid to give the dithioacetal **15**, which was then dehydrogenated *via* the carbonium salt **16** to the desired compound **6**.[7] All the reactions proceeded in reasonable to excellent yields.†

The benzoquinoid compounds **1** and **2** are blue in $CH_2Cl_2$ solution, and their electronic absorption spectra show a strong

**Scheme 1** *Reagents and conditions*: i, Bu$^n$Li, $Et_2O$, −15 °C, 0.5 h; ii, DMF, −78 °C to room temp., 1 h; iii, $HOCH_2CH_2OH$, TsOH, benzene, reflux, 1 h; iv, $NaCH(CN)_2$, $Pd(PPh_3)_4$, THF, reflux, 4 h; v, TsOH, benzene, reflux, 1 h; vi, $Ph_3CBF_4$, $CH_2Cl_2$–MeCN, 60 °C, 3 h; vii, $Et_3N$, MeCN, room temp., 2 h





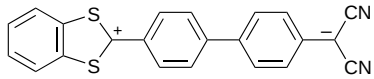


**Fig. 1** Electronic spectra of **2** (- - -) and **6a** (——) in $CH_2Cl_2$

colour-determining band with fine structure in the region of 550–650 nm. The band shows very little solvent shift. On the other hand, the diphenoquinoids **6a–c** look green–black in the solid state but are faint yellow in solution, and their electronic spectra have a characteristic broad band in the near-infrared region as well as a second band at around 450 nm. Fig. 1 demonstrates the specific spectral features of **2** and **6a**, and Table 1 summarizes the electronic absorption maxima and nitrile vibrational absorptions of **1**, **2** and **6a–c**. Interestingly, the absorption bands of **6**, unlike those of **1** and **2**, show large negative solvatochromism with increasing solvent polarity: for example, $\lambda_{max}$ of **6a** is 957 and 1045 nm in $CH_2Cl_2$, 934 nm in PhCN, and 790 nm in $Me_2SO$.

It is reasonable to assume that the push-pull quinoid systems **2** and **6** exist as a resonance hybrid with the zwitterionic forms **17** and **18**, respectively. Infrared spectra provide definite

**17**

**18**

information on these resonance structures: the nitrile vibrational absorption of **2** appears at a much lower frequency (2195 $cm^{-1}$) than that of TCNQ (2226 $cm^{-1}$). This indicates a considerable contribution by the ionic form **17**. The absorptions of **6a–c** are further shifted (2174–2180 $cm^{-1}$) and comparable to those of lithium phenyldicyanomethanide (2178 $cm^{-1}$) and sodium phenyldicyanomethanide (2188 $cm^{-1}$). This indicates that the diphenoquinoid system **6** predominantly exists as the ionic form **18**, consistent compatible with the large negative solvatochromism. The predominance of the ionic form **18** must presumably be promoted by the benefit of gaining double aromaticity.

The present results clearly demonstrate that the diphenoquinoid compounds **6a–c** are an interesting push-pull system with highly polar character and a new type of dyes strongly absorbing near-infrared light.

**Table 1** $\lambda_{max}$ and $\nu_{CN}$ of quinoid compounds **1**, **2** and **6**

| Compound | $\lambda_{max}$/nm[a] | $\nu_{CN}$/$cm^{-1}$ [b] |
|---|---|---|
| **1** | 551(4.46), 592(4.78), 644(4.89) | 2191 |
| **2** | 548(4.68), 589(4.93), 641(4.97) | 2195 |
| **6a** | 957(3.71), 1045(3.91) | 2174 |
| **6b** | 962(4.41), 1042(4.42) | 2180 |
| **6c** | 963(4.46), 1031(sh, 4.25) | 2180 |

[a] Measured in $CH_2Cl_2$. [b] Measured on a KBr disk.

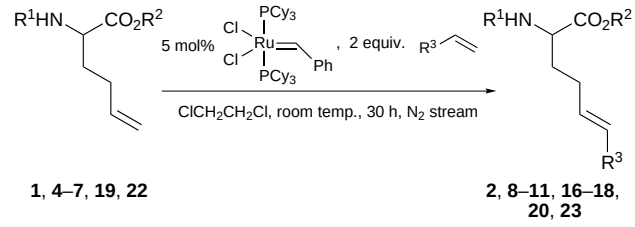
# Cross metathesis of the amino acid homoallylglycine

**Susan E. Gibson (née Thomas),* Vernon C. Gibson and Stephen P. Keen**

*Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*



**Reaction of various protected forms of the amino acid homoallylglycine with aryl- and alkyl-substituted alkenes in the presence of 5 mol% $Cl_2(PCy_3)_2Ru$=CHPh gives cross metathesis products in acceptable synthetic yield (43–66%).**

The development of olefin metathesis, until recently a reaction applied mainly in bulk chemical production and polymer synthesis, into a reaction of general use in fine organic chemical synthesis continues to gain momentum. Seminal studies earlier this decade[1] led to the ring closing metathesis reaction (RCM) being used in several successful pioneering organic syntheses,[2] and the number of applications of this reaction in the past year suggests that it is now accepted as a useful synthetic tool.[3] The entropically more challenging but equally promising cross metathesis reaction has received much less attention from synthetic chemists and has been the subject of a mere handful of reports to date: early studies involved styrenes[4] and acrylonitrile[5] and very recently successful reactions using allylsilanes,[6] polymer-bound amino alcohols[7] and allyl stannanes[8] have been reported. Styrene cross metathesis has been applied recently to the elaboration of allylboration products[9] and β-lactams.[10]

In view of their biological role and myriad applications, it is not surprising that amino acids and their protected derivatives are attracting considerable attention as metathesis substrates. Initially they were ROMPed into polymers[11] and there now appears to be phrenetic interest in the use of amino acid derived substrates in RCM reactions.[12] In view of the level of activity in this area and the increasing interest in cross metathesis, we report here the first examples of cross metathesis reactions involving (protected) amino acids.

Homoallylglycine (Hag) was prepared by alkylation of diethyl acetamidomalonate with 4-bromobut-1-ene, ester loss and hydrolysis,[13] and subsequent amide hydrolysis. Standard protection procedures were then employed to generate the various protected forms of Hag discussed below.

Initially BocHagOMe **1**[14] was reacted with 2 equiv. of styrene in the presence of the ruthenium metathesis catalyst $Cl_2(PCy_3)_2Ru$=CHPh[15] using a variety of solvents, temperatures, reaction times, catalyst loadings and BocHagOMe concentrations. The yields of the cross metathesis product **2** were also measured from a reaction performed in a glove box under nitrogen, and from reactions carried out using Schlenk line techniques under both a static pressure and a steady stream of both nitrogen and argon. Interestingly there was no advantage to working in the glove box or under argon and, more significantly, changing the nitrogen atmosphere from a static pressure (*ca*. 1 atm) to a steady stream across the reaction mixture led to a 30% yield enhancement. The optimum conditions for the cross metathesis reaction between **1** and styrene were found to involve stirring a 0.25 M solution of BocHagOMe **1** in dichloroethane with 2 equiv. of styrene and 5 mol% of $Cl_2(PCy_3)_2Ru$=CHPh at room temperature with a steady stream of nitrogen blowing across the top of the reaction mixture for 30 h. These conditions gave a 52% isolated yield of the novel amino acid **2**† (based on BocHagOMe **1**) and a 40% yield of the BocHagOMe self metathesis product **3** (also based on **1**) (Table 1, entry 1).

In order to assess the merits of various protecting groups in the cross metathesis reaction, PhthHagOMe **4**, AcHagOMe **5**, BocHagOBn **6**[14] and BocHagOBu$^t$ **7**[16] were synthesised and reacted with styrene under the conditions described above. The

**Table 1** Cross metathesis of homoallylglycine derivatives with styrene, hex-1-ene and oct-1-ene[a]

| Entry | Substrate | Alkene R1 | Alkene R2 | Alkene R3 | Cross metathesis product[b] | Isolated yield (%)[c] | Self metathesis product[d] | Isolated yield (%)[e] |
|---|---|---|---|---|---|---|---|---|
| 1 | **1** | Boc | Me | Ph | **2** | 52 | **3** | 40 |
| 2 | **4** | Phth | Me | Ph | **8** | 55 | **12** | 35 |
| 3 | **5** | Ac | Me | Ph | **9** | 43 | **13** | 48 |
| 4 | **6** | Boc | Bn | Ph | **10** | 53 | **14** | 44 |
| 5 | **7** | Boc | Bu$^t$ | Ph | **11** | 55 | **15** | 45 |
| 6 | **1** | Boc | Me | Bu | **16** | 55 | **3** | 43 |
| 7 | **1** | Boc | Me | Hex | **17** | 66 | **3** | 28 |
| 8 | **7** | Boc | Bu$^t$ | Hex | **18** | 63 | **15** | 28 |
| 9 | **19** | Fmoc | Me | Hex | **20** | 58 | **21** | 25 |
| 10 | **22** | Fmoc | H | Hex | **23** | 58[d] | **24** | 18 |

[a] The experimental procedure for the conversion of **1** to **17** (entry 7) is typical: A nitrogen-saturated solution of **1** (0.121 g, 0.50 mmol) and oct-1-ene (0.156 cm$^3$, 1.00 mmol) in dichloroethane (2 cm$^3$) was added *via* a cannula to solid $Cl_2(PCy_3)_2Ru$=CHPh (0.021 g, 0.0235 mmol). The resulting purple solution was stirred under a steady stream of nitrogen for 30 h at room temperature. The dichloroethane was subsequently replaced with diethyl ether (*ca*. 50 cm$^3$) and the mixture stirred for 16 h under air to effect decomposition of the catalyst. Removal of the diethyl ether *in vacuo* and flash chromatography [$SiO_2$; light petroleum (40–60 °C)–diethyl ether, 1 : 0–5 : 1–1 : 2 gradient elution] gave the cross metathesis product **17** (0.108 g, 66%) and the self metathesis product **3** (0.032 g, 28%) as microanalytically pure colourless oils. [b] $R^3$ = Ph, *trans* : *cis* ≥ 10 : 1; $R^3$ = alkyl, *trans* : *cis ca.* 4 : 1. [c] Based on amino acid substrate. [d] Amino acid self metathesis product; alkene self metathesis products were also observed. [e] Product contaminated with 6% starting material.

yields of the cross metathesis products **2**, **8**–**11** and the self metathesis products **3**, **12**–**15** indicated that, with the exception of AcHagOMe **5**, the course of the reaction is independent of the nature of the protecting groups (Table 1, entries 1–5).

In order to determine whether the cross metathesis of Hag may be used to introduce alkyl groups into the amino acid side chain, BocHagOMe **1** and BocHagOBu$^t$ **7** were reacted with hex-1-ene and oct-1-ene (Table 1, entries 6–8). Comparison of the yields of the cross metathesis products **16**–**18** with entries 1 and 5 reveals that whilst the yields obtained for styrene and the relatively volatile hex-1-ene are essentially equivalent, use of the less volatile oct-1-ene gives significantly higher yields of cross metathesis product than styrene. Reaction of FmocHagOMe **19** with oct-1-ene also gave an acceptable yield of the cross metathesis product **20** together with some self metathesis product **21** (Table 1, entry 9) indicating that the commonly used Fmoc protecting group is compatible with these cross metathesis conditions.

Finally, in view of the importance of FmocXaaOH components in solid phase peptide synthesis, a cross metathesis reaction between FmocHagOH **22** and oct-1-ene was examined. This gave the cross metathesis product **23** (and the self-metathesis product **24**) in good yield (Table 1, entry 10) thus demonstrating that an unprotected carboxylic acid may be used in cross metathesis reactions.

We gratefully acknowledge the EPSRC for a studentship (S. P. K.).

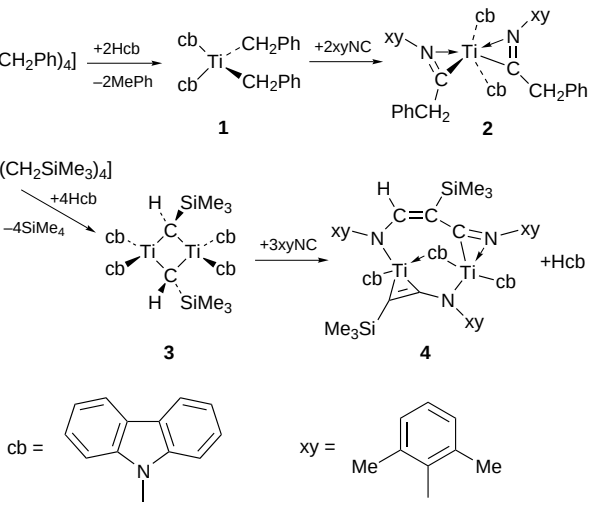
# Alkyl and alkylidene derivatives of titanium supported by carbazole ligation

**Patrick N. Riley, Phillip E. Fanwick and Ian P. Rothwell***



*1393 Brown Building, Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393, USA*

**The bis(benzyl) $[(cb)_2Ti(CH_2Ph)_2]$ 1 and alkylidene bridged dimer $[(cb)_2Ti(\mu\text{-}CHSiMe_3)_2Ti(cb)_2]$ 3 are formed by adding carbazole (Hcb) to the tetraalkyls $[TiR_4]$ (R = $CH_2Ph$, $CH_2SiMe_3$); the reaction of 1 and 3 with 2,6-dimethylphenyl isocyanide leads to organometallic products containing new carbon–carbon bonds.**

There has recently been considerable research interest in the organometallic chemistry of the group 4 metals associated with amido ligation.[1–3] In this context we communicate here our studies of some organotitanium chemistry of the carbazole ligand, an amido group predicted to be a weaker π donor than dialkylamido ligands.[4]

The addition of carbazole (2 equiv.) to hydrocarbon solutions of $[Ti(CH_2Ph)_4]$[5] lead to the bis(benzyl) compound **1** in moderate yield (Scheme 1). The spectroscopic data† on **1** indicate that the benzyl ligands are $\eta^1$-bound.[6] Solutions of **1** react with 2 equiv. of 2,6-dimethylphenyl isocyanide (xyNC) to produce the bis($\eta^2$-iminoacyl) complex **2**. The iminoacyl carbon chemical shift of δ 246.9 in the $^{13}C$ NMR spectrum indicates $\eta^2$-C,N binding and this is confirmed by the solid-state molecular structure of **2** (Fig. 1).[7] The coordination geometry and iminoacyl parameters in **2** are similar to those found in other group 4 metal bis($\eta^2$-iminoacyl) compounds,[7,8] the only significant difference being the non-parallel orientation of the iminoacyl units in **2**.

The reaction of the more bulky alkyl substrate $[Ti(CH_2SiMe_3)_4]$[9] with carbazole is slow (as monitored by $^1H$ NMR) at ambient temperatures. At 100 °C the reaction produces a sparingly soluble product identified (Fig. 2) as the alkylidene bridged dimer $[(cb)_2Ti(\mu\text{-}CHSiMe_3)_2Ti(cb)_2]$ **3**. In the $^1H$ NMR spectrum of **3** a singlet at δ 14.75 can be assigned to the alkylidene proton. The structural parameters for the 1,3-dimetallacyclobutane unit in **3** are similar to those found in related molecules and in particular the methylidene bridged $[\{(C_6H_{11})_2N\}_2Ti(\mu\text{-}CH_2)_2Ti\{N(C_6H_{11})_2\}_2]$.[2] Treatment of **3** with xyNC (> 3 equiv.) slowly ($^1H$ NMR) produces a single organometallic species **4** and 1 equiv. of free carbazole. The molecular structure of **4** (Fig. 3) shows it to be dinuclear, containing a total of three isocyanides within two distinct bridging units. Two terminal and one non-symmetrically bridged carbazole ligand are also present. The structural parameters lead us to propose the structure for **4** shown in Scheme 1. Although the exact sequence of events leading to **4** is presently unknown, reasonable elementary steps for its formation can be proposed. One of the bridging units in **4** [N(6)–C(7)–C(8)] is best described as an amidoalkyne ligand. Identical

ligands have been formed by addition of xyNC to trimethylsilylmethylidyne bridges in 1,3-dimetallacyclobutadiene derivatives of Nb or Ta.[4] The unit may have originated *via* initial α-hydrogen abstraction to produce an alkylidyne intermediate or by hydrogen abstraction from an initially formed iminoacyl. In both cases the hydrogen abstraction takes place by a carbazole ligand. The other bridging unit corresponds to the insertion of 2 equiv. of isocyanide into an alkylidene bridge combined with a 1,2-hydrogen shift. The transfer of adjacent hydrogen to iminoacyl carbon atoms has precedence.[7]

An interesting feature of the molecular structure of **4** concerns the distances within the iminoacyl component. Specifically the Ti–N(5) and Ti–C(4) distances lead to a value of −0.3 Å for the parameter [*d*(Ti–N)−*d*(Ti–C)].[7] This value combined with the long C(4)–N(5) distance are consistent with the much debated amido-carbene resonance picture.[10]

We thank the National Science Foundation (Grant CHE-9321906) for financial support of this research.

Of the 5056 unique reflections collected (5.32 ⩽ 2θ ⩽ 52.64°) with Mo-Kα radiation (λ = 0.710 73 Å), the 5056 with $I > 3\sigma(I)$ were used in the final least-squares refinement to yield $R$ = 0.036 and $R_W$ = 0.041.

For **4** at 233 K: $C_{71}H_{68}N_6Si_2Ti_2$, $M$ = 1157.35, monoclinic, space group $P2_1/n$ (no. 14), $a$ = 12.788(2), $b$ = 33.329(5), $c$ = 14.616(3) Å, β = 96.76(2)°, $U$ = 6186(3) Å$^3$, $D_c$ = 1.242 g cm$^{-3}$, $Z$ = 4. Of the 8122 unique reflections collected (5.26 ⩽ 2θ ⩽ 113.70°) with Cu-Kα radiation (λ = 1.541 84 Å), the 8122 with $F_o^2 > 2\sigma(F_o^2)$ were used in the final least-squares refinement to yield $R(F_o)$ = 0.074 and $R_W(F_o^2)$ = 0.184. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/447.

# An *ab initio* study of the aggregation of LAuX molecules and $[LAuL]^+[XAuX]^-$ ions

**Pekka Pyykkö,*[a] Wolfgang Schneider,[b] Andreas Bauer,[b] Angela Bayler[b] and Hubert Schmidbaur*[b]**

[a] *Department of Chemistry, University of Helsinki, P.O.B. 55 (A. I. Virtasen aukio 1), FIN-00014 Helsinki, Finland*

**Pseudopotential *ab initio* calculations on dimers and tetramers of formula $\{[(H_3P)_2Au]^+[AuCl_2]^-\}_n$ ($n$ = 1, 2) which are the products of a ligand distribution of systems $(H_3PAuCl)_{2n}$, show that the different experimentally observed structures are actually energetically quite comparable.**

Many neutral gold(I) complexes of the type LAuX (L = neutral donor, X = anionic ligand) undergo facile ligand scrambling: NMR data on solution equilibria,[1,2] and solid-state structural data (*e.g.* L = $C_5H_5N$, X = halide;[3] L = $C_4H_8Se$, X = I;[4] L = $PMe_2Ph$, X = $GeCl_3$;[5] L = $Ph_2C{=}NH$, X = Cl, Br[6]), suggest that the energy differences associated with the ligand exchange according to eqn. (1) are very small, but there are no calculations to support this assumption.

$$2\ LAuX \rightleftharpoons (L_2Au)^+ + (AuX_2)^- \qquad (1)$$

It appears that solvation of the species in solution and aggregation of the components in the crystal play an important role in determining the equilibria.

When examining the details of the supramolecular chemistry of representative examples in the solid state, very unexpected modes of aggregation have been discovered[5] including non-standard ion sequences following the pattern [−++−] or [+−−+], instead of [+−+−], for tetramers of the formula $[LAuX]_4 = \{[L_2Au]^+[AuX_2]^-\}_2$.

In order to analyse the effects governing the aggregation modes, both Hartree–Fock (HF) and second-order Møller–Plesset (MP2) calculations (Table 1) were performed for di- and tetra-nuclear species of this type, and the previous $(H_3P)AuCl$ model, using GAUSSIAN 94 and either 11 or 19 valence-electron (11- or 19-VE) pseudopotentials.[7] We have pointed out earlier the importance of correlation and relativistic effects[8–10] for the underlying $Au^I\cdots Au^I$ interactions.[11] The use of a $PH_3$ group to model the structures with higher $PR_3$ groups was found to be acceptable,[12] although this approach at the semiempirical level has been criticised.[13] At *ab initio* MP2 level, $PMe_3$ gives the same interaction depth, but larger $R_e$,[14] as $PH_3$.

The dihedral angles (P–Au–Au–Cl, Cl–Au–Au–Cl or P–Au–Au–P) were fixed at 90° in the dimers $(\mathbf{1})_2$, **2** and linear tetramers **3**, **4**, **6** (Fig. 1 and Table 2). The $Au_4$ geometry in cyclic tetramers **5** $[(\mathbf{5a})_2]$, was assumed to be rectangular with a parallel arrangement of all PAuP and ClAuCl axes. The Au···Au distance, $R_{intra}$, established for the dimers was kept constant in the tetramers. The 19-VE geometries of the monomers **1**, **2a** and **2b** (Table 1) were adopted for the 11-VE calculations.

**Table 1** Optimized monomer properties at the 19-VE MP2 level. Distances in pm, energies in $E_h$ ($E_h$ = 4.35975 × $10^{-18}$ J)

| System | Au–P/pm | Au–Cl/pm | P–H/pm | Au–P–H/° | $-E$ |
|---|---|---|---|---|---|
| $(H_3P)AuCl$ **1** | 224.3 | 226.3 | 141.3 | 117.42 | 158.47013 |
| | | | | | 56.69561[a] |

| [+−+−], **6** | 294.2 | 313.7 | −11.4 | 11 VE |

[a] 1 cal = 4.184 J.

The energies and gold··gold distances obtained for the di- and tetra-meric systems are summarized in Table 2. The former were calculated starting from the monomeric units (**1**, **2a**, **2b**), complemented by their interaction energies as obtained by subtracting the value for monomers (dimers) from those of the dimer (tetramer), including a counterpoise correction.

In all three linear tetramers a short $R_{inter}$ Au···Au contact is observed. The shortest distance is found for the [+−−+] system followed by [−++−] and finally [+−+−]. A similar result is observed experimentally for the compound $[(Me_2PhP)_2Au^+$-$Au(GeCl_3)_2^-]$ {sequence [+−−+]} which indeed shows the shortest Au···Au contact between the two anions. This result is clearly at variance with Coulomb's law. However, focussing on the natural bond orbital (NBO) populations of the Au atoms, it is easier to understand the insensitivity of the total energy to the ionic arrangement. All gold atoms of $AuCl_2^-$ have charges between 0.53320 and 0.57567 (0.60541 in the monomeric $AuCl_2^-$, **2b**, and 0.56730 in the dimer [+−], **2**), and those in cations between 0.473 59 and 0.494 71 {0.442 63 in the monomeric $Au(PH_3)^+$, **1a**, and 0.47359 in the dimer [+−], **2**}. The Mulliken Au populations vary more and are in the ranges 0.26500–0.39708 and −0.02241–0.13594 for anions and cations, respectively.

It should be mentioned that the $R_{intra}$ values of the dimers were kept constant in every tetramer, and therefore the geometries obtained may not be the absolute minima on the energy surfaces. We have also not attempted a full-crystal simulation, and it should finally be noted that a short Au···Au contact does not necessarily correlate with the lowest energy. The main point is that all curves in Fig. 2 are evidence for attractive interactions and that the distances in Tables 2 and 3 are comparable.

The cyclic tetramer shows a larger $R_{inter}$ distance probably due to the steric repulsion between the hydrogen and the chlorine atoms, which come very close together in the parallel arrangement of the individual units. Nevertheless this oligomer has the lowest energy as compared to the linear-chain tetramers. The optimum arrangement for two dipoles [+−] and the occurrence of one additional Au···Au interaction between dimers may be the reasons for this preference.

In conclusion, we have found that the molecular and ionic dimers of the type $[(H_3P)AuCl]_2$ and $[(H_3P)_2Au^+AuCl_2^-]$ are closely comparable in energy. This is made plausible by the close similarity of the gold atom NBO charges in the anion, cation and neutral monomer.

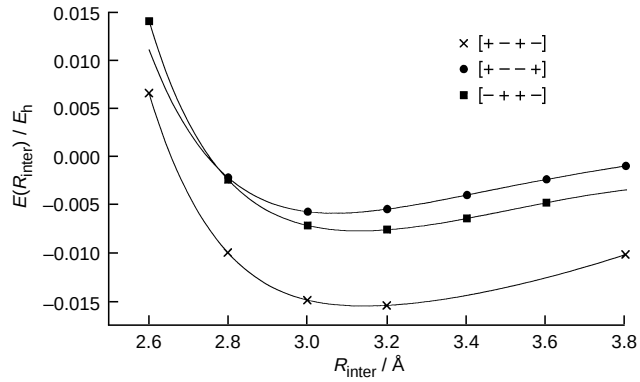

**Fig. 2** Calculated bond energies for the intermolecular gold···gold contacts in the linear-chain tetramers using the 11 VE pseudopotential at MP2 level

**Table 3** $R_{intra}$ and $R_{inter}$ distances of some experimentally known compounds

| Compound | $R_{intra}$/pm | $R_{inter}$/pm |
|---|---|---|
| (py)AuCl, type **3** and **5**[3b] | 324.9(3) | 341.6(4) |
| (py)AuBr, type **6**, infinite chain[3a] | 330.2(2) | 356.3(2) |
| (py)AuBr, type **3**[3a] | 324.6(1) | 349.6(2) |
| (py)AuI, type **3**[3b] | 299.0(1) | 329.1(1) |
| $[(Me_2PhP)_2Au]^+[Au(GeCl_3)_2]^-$, type **4**[5] | 297.9 av. | 288.1(1) |
| $[(Ph_2CNH)_2Au]^+[AuCl_2]^-$, type **5**, Z-shaped[6] | 319.44(5) | 360.4(1) |

The calculations were carried out on DEC Alpha stations at Helsinki. We thank DAAD for travel scholarships and Dr Fernando Mendizabal for discussions. P. Pyykkö is Research Professor of The Academy of Finland.

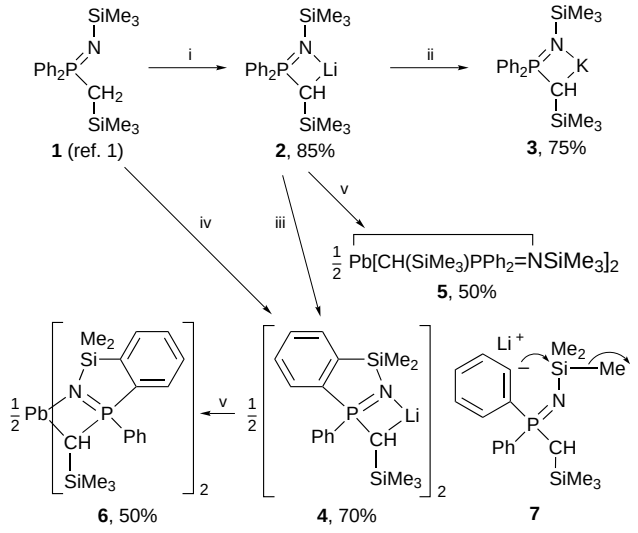
# Novel (silylimino)diarylphosphoranyl(trimethylsilyl)methyl-*C*,*N* ligands $[CH(SiMe_3)PPh_2{=}NSiMe_3]^-$ ($[LL']^-$) and $[CH(SiMe_3)\{Ph(1,2\text{-}C_6H_4)P{=}NSiMe_2\}]^-$ ($[LL'']^-$) and the structures of $[Li(LL'')]_2$ and $[Pb(LL')_2]$†



**Peter B. Hitchcock, Michael F. Lappert* and Zhong-Xia Wang**

*The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ*

**Metal complexes containing the ligands $[CH(SiMe_3)PPh_2{=}NSiMe_3]^-$ {≡$[LL']^-$} and $[CH(SiMe_3)\{Ph(1,2\text{-}C_6H_4)P{=}NSiMe_2\}]^-$ {≡$[LL'']^-$} are reported [from, as initial precursor, $CH_2(SiMe_3)PPh_2{=}NSiMe_3$]: Li(LL′), K(LL′), $[Li(LL'')]_2$ 4, Pb(LL′)$_2$ 5 and Pb(LL″)$_2$; mass and multinuclear NMR spectra and single-crystal X-ray diffraction data for 4 (a fused tricyclic complex having a central LiNLiN ring) and 5 are presented.**

We report the synthesis and characterisation of five lithium, potassium and lead(II) homoleptic derivatives of two novel *C*,*N*-centred (iminophosphoranyl)methyl ligands, including the X-ray structures of two of them.

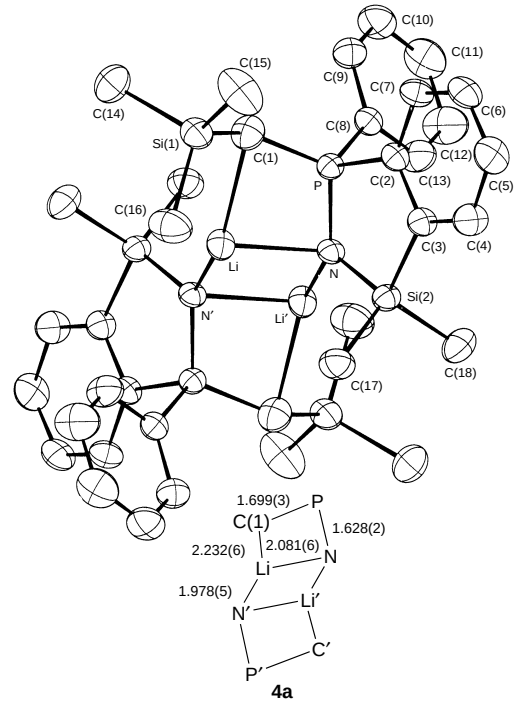
Treatment of the phosphinimine $CH_2(SiMe_3)PPh_2{=}NSiMe_3$ **1**[1] with LiBu$^n$ yielded (Scheme 1, step i) colourless $[Li\{CH(SiMe_3)PPh_2{=}NSiMe_3\}]_2$ {≡$[Li(LL')]_2$} **2**, which with KOBu$^t$ in hexane afforded (Scheme 1, step ii) the insoluble, pale yellow K(LL′) **3**, which was soluble in thf or pyridine. Reacting **2** with LiBu$^n$ gave (Scheme 1, step iii) the colourless *ortho*-silylated product $[Li(CH(SiMe_3)\{Ph(1,2\text{-}C_6H_4)P{=}NSiMe_2\})]_2$ {=$[Li(LL'')]_2$} **4**, which was also accessible (Scheme 1, step iv) from **1** and 1.2 equiv. of LiBu$^n$. The product obtained (Scheme 1, step v) from $PbCl_2$ and either **2** or **4** was the yellow Pb(LL′)$_2$ **5** or the colourless Pb(LL″)$_2$ **6**. The yields shown in Scheme 1 refer to isolated, pure, crystalline (or for **3**, powder) **2**–**6**.

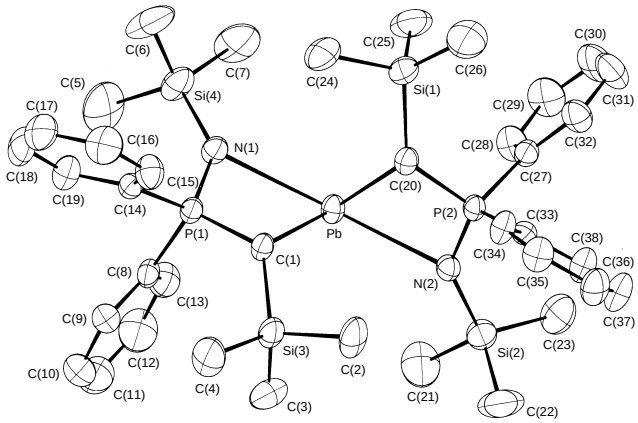
**Scheme 1** Synthesis of (silylimino)diarylphosphoranyl(trimethylsilyl)methyl-*C*,*N*]metal complexes **2**–**6**. *Reagents and conditions*: i, LiBu$^n$, hexane, −20 °C to room temp., 3 h; ii, KOBu$^t$, hexane, room temp., 3 h; iii, LiBu$^n$, hexane, reflux, 4 h; iv, 1.2 equiv. LiBu$^n$, hexane, −20 °C to room temp., 5 d; v, 1/2 $PbCl_2$, $Et_2O$, −45 to *ca*. 20 °C.

The conversion of **2** to **4** (Scheme 1, step iii) probably proceeded *via* an *ortho*-lithiated intermediate, followed by an intramolecular displacement of Me$^-$ at silicon by the aromatic anion, as shown in **7**. In a separate experiment (Scheme 1, step iv) it was shown that the transformation **2** to **4** was effected catalytically using 0.2 mol excess of LiBu$^n$.

Each of the compounds **2**–**6** (except **3**), were hydrocarbon-soluble, gave satisfactory microanalytical, as well as $^1$H, $^{13}$C{$^1$H}, $^{31}$P{$^1$H}, $^7$Li{$^1$H} (**2** and **4**) and $^{207}$Pb{$^1$H} (**5** and **6**) NMR‡ and EI mass spectra {which showed as the highest ion $[M - Li \text{ (or K)} + 1]^+$ (*ca*. 30% for **2** or **3**), $[M - Li]^+$ (58% for **4**) and $M^+$ (1% for **5** and 5% for **6**)} (thf = $OC_4H_8$, M = the mononuclear molecular ion). Single-crystal X-ray diffraction data§ established the molecular structures of **4** (Fig. 1), **5** (Fig. 2) and **6**; the structure of **6** will be presented in the full paper.

Noteworthy features of the NMR spectra‡ include the demonstration of (*i*) long-range phosphorus–silylmethyl coupling in the $^{13}$C{$^1$H} NMR spectrum of **2**, $^3J(^{13}C–^{31}P)$ 3.5, 4.6





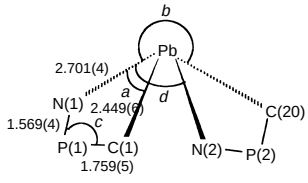


**Fig. 1** The molecular structure of crystalline complex **4**. Selected bond lengths (Å) (see also **4a**) and angles (°): N–Li–C(1) 80.1(2), N–Li–N′ 103.8(2), N′–Li–C(1) 135.0(3), N–P–C(1) 113.18(14), P–N–Li 86.2(2), P–N–Li′ 126.4(2), P–C(1)–Li 79.9(2), Li–N-Li′ 76.2(2).

Hz for the two $SiMe_3$ groups; (*ii*) separate (axial and equatorial) Si–Me $^1$H signals due to the endocyclic $SiMe_2$ group in **4** and **6**; and (*iii*) $^2J(^{31}P–^{207}Pb)$ and $^2J(^{207}Pb–^{31}P)$ in **5** and **6**.

The structures of crystalline $[Li\{CH_2PMe_2{=}NSiMe_3\}]_4$ **8** and $[Li\{CMe_2PPr^i_2{=}NSiMe_3\}]_2$ **9** have the lithium atoms bridged by carbon.[2] It is surprising, therefore, that the dinuclear crystalline **4** (Fig. 1) has the imido nitrogen atoms bridging the lithium atoms, the skeletal structure being ladder-shaped, **4a**. The central LiNLi′N′ ring is planar, with the angle at N narrower [76.2(2)°] than that at Li, 103.8(2)°. The terminal LiNPC rings are puckered, Li lying 0.26 Å out of the NPC plane. The bond angles at the three-coordinate Li range from 80.1(2) [N–Li–C(1)] to 135.0(3)° [N′–Li–C(1)], the sum of the angles at Li being *ca*. 319°. The six bond angles at N (av. 108°) vary from 76.2(2) to 129.6(2)° [Si(2)–N–Li]. The Li–N and Li–C bond lengths are unexceptional,[3] while the Li···P contact of 2.556(5) Å is similar to the 2.56 (av.), 2.58 (av.) or 2.520(9) Å found in $[\{Li(thf)_2\}_2\{PhPCH_2CH_2PPh\}]$,[4] $[\{Li(tmen)\}_2$-$C_6H_4(PPh)_2$-1,2$\}]$,[5] or $Li(thf)_2[\{N(SiMe_3)\}_2PPh_2]$,[6] respectively [tmen = $(Me_2NCH_2)_2$]. The average Li–N and Li–C distances are 2.03 (**8**) and 1.928 (**9**), and 2.39 (**8**) and 2.27 (**9**), respectively.[2] The X-ray structure of $[Li\{2\text{-}C_6H_4PPh_2{=}NSi$-$Me_3\}_2Li(OEt)_2]$ is available.[7]

Crystalline **5** is mononuclear, Fig. 2. The four-coordinate lead has a stereochemically active lone pair of electrons. The phosphorus approximates to its having tetrahedral geometry. A simplified bonding pattern is shown in **5a**. The P–N bond length of 1.569(4) Å indicates a double bond, while the mean endocyclic P–C distance of 1.757(6) Å is slightly shorter than usual for a $P^V$–C single bond. The average Pb–N distance of 2.678 Å is much longer than in anionic nitrogen-centred lead(II) compounds, *e.g.*, 2.24(2) Å in $Pb[N(SiMe_3)_2]_2$,[8] or 2.465 Å (av.) in $Pb[\{N(SiMe_3)\}_2PPh_2]_2$,[9] while the mean Pb–C($sp^3$) bond length of 2.448 Å in **5** may be compared with the Pb–C($sp^2$) distance of 2.336 Å in $Pb[C_6H_2(CF_3)_3$-2,4,6$]_2$.[10]

**5a** [*a*, 62.52(14); *b*, 107.6(2); *c*, 107.2(2); *d*, 167.27(11)°]

**Fig. 2** The molecular structure of crystalline complex **5**. Selected bond lengths (Å) and angles (°) (see also **5a**): Pb–C(20) 2.447(5), Pb–N(2) 2.654(4), P(2)–C(20) 1.756(5), P(2)–N(2) 1.569(4); C(20)–Pb–C(1) 88.2(2), C(20)–Pb–N(2) 63.6(2), C(1)–Pb–N(2) 106.69(14), C(20)–Pb–N(1) 107.6(2), N(2)–Pb–N(1) 167.27(11), N(2)–P(2)–C(20) 108.1(2).

The new ligands $[LL']^-$ and $[LL'']^-$ should have an extensive coordination chemistry. Using Li(LL′) **2** or Li(LL″) **4**, we have made *inter alia* $Sn(LL')_2$, $Sn(LL'')_2$, $[Sn(LL')]_2$, $Pb(LL'')_2$ and $[Fe(LL')_3]$, as well as some analogues of Li, K, $Sn^{II}$, $Fe^{II}$ and $Co^{II}$.

We thank the Chinese Government and the British Council for the award of a studentship to Z.-X. W. and the EPSRC for other support.

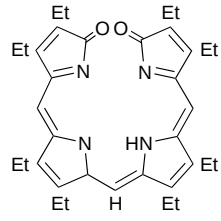
# Axial ligation modulates the electron distribution in helical cobalt complexes derived from octaethylbilindione

**Saeed Attar, Andrew Ozarowski, Pamela M. Van Calcar, Krzysztof Winkler† and Alan L. Balch***

*Department of Chemistry, University of California, Davis, California 95616, USA*



**Addition of pyridine to the four-coordinate cobalt(II) complex, $[Co^{II}(oebOx)]I_3$, which shows an EPR spectrum with well resolved Co hyperfine coupling, converts the complex into one with $Co^{III}$/ligand radical structure and an EPR spectrum with $g_z$ = 1.98, and $g_{xy}$ = 2.02 and no cobalt hyperfine coupling.**

Biliverdin 1Xa, **1a**, a product of haem catabolism, has been recently reported to have two interesting physiological activities: antioxidant activity and anti-HIV activity.[1] In order to understand the molecular bases for these activities, we have undertaken the study of redox behaviour of biliverdin analogues and their metal complexes. Octaethylbilindione, **1b**, a symmetrically substituted version of biliverdin 1Xa, forms a series of helical metal complexes with cobalt, nickel and copper in which the electronic structure indicates a significant contribution from a ligand-based free radical.[2–7] Upon treatment with an oxidant (*e.g.* diiodine) **1b** undergoes a facile two-electron oxidation to form **2** which has been isolated in a protonated form.[8] Recently we have shown that the cobalt complex of **1b**, Co(**1b**), undergoes a series of reversible, one-electron redox reactions as shown in eqn. (1).[9] Two members of this series, [Co(**1b**)] **3** and $[Co(C_{35}H_{43}N_4O_2)]^+$ **4**$^+$, have been isolated and thoroughly characterized. The electronic structure of four-coordinate **3** has been described in terms of contributions from both the $Co^{III}$/$oeb^{3-}$ and $Co^{II}$/$oeb^{\cdot 2-}$ forms, where $oeb^{\cdot 2-}$ is the radical obtained by one-electron oxidation of $oeb^{3-}$.[4] Complex **4**$^+$ has been isolated as the triiodide salt. In the solid state the Co–$I_3$ distance is long (2.818 Å) and has been interpreted in terms of an ion-paired structure.[9] The structural and magnetic properties of [**4**$^+$]$I_3$ indicate that it is a cobalt(II) complex of the two-electron oxidized ligand **2**, *i.e.* it is $[Co^{II}(oebOx)]I_3$.[9] Here we demonstrate that the electronic structure of [**4**$^+$] is altered by the addition of axial pyridine ligands.

**1a** A = C = methyl
B = vinyl
D = propionate

**1b** A = B = C = D = ethyl
($H_3$oeb)

**2** (HoebOx)

$$[Co(\mathbf{1b})]^{2-} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Co(\mathbf{1b})]^{-} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Co(\mathbf{1b})]\ \mathbf{3} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Co(\mathbf{1b})]^{+}\ \mathbf{4} \quad (1)$$

The EPR spectrum of [**4**$^+$]$I_3$, like other cobalt(II) complexes, is sensitive to its environment. At 77 K it shows a rhombic pattern that can be fit with $g_1$ = 2.42, $g_2$ = 2.23 and $g_3$ = 2.01 but hyperfine coupling from cobalt was not resolved.[9] However, in dichloromethane–methanol at 77 K the spectrum shown in Fig. 1(*a*) is obtained. The parallel portion of the spectrum is clearly resolved with $g_z$ = 2.013 and $A_z$ = 89.3 × $10^{-4}$ $cm^{-1}$. The perpendicular region is more difficult to interpret because of the dependence of linewidth on both orientation and the quantum number $M_I$. However, $g_x$ and $g_y$ are estimated at 2.29 with $A_x$ *ca.* 16 × $10^{-4}$ $cm^{-1}$ and $A_y$ *ca.* 35 × $10^{-4}$ $cm^{-1}$. This spectrum is indicative of the formulation of the complex as $[Co^{II}(oebOx)]I_3$. Addition of pyridine to a sample of [**4**$^+$]$I_3$ in MeOH–$CH_2Cl_2$ results in the formation of $[(py)_2Co^{III}(oeb\cdot)]I_3$, [**5**$^+$]$I_3$, as shown by a marked alteration in the EPR spectrum. The resulting spectrum for a solution frozen at 77 K is shown in Fig. 1(*b*). The new spectrum shows a sharp, slightly anisotropic signal ($g_{x,y}$ = 1.996, $g_z$ = 2.018) near the free electron *g* value. The cobalt hyperfine interaction is also lost. These alterations in the EPR spectrum suggest that a significant rearrangement of the electronic structure of the complex [**4**$^+$]$I_3$ occurs when axial pyridine ligands are present and that the pyridine adduct behaves as if it contains a ligand-based free radical.

Deep purple prisms of [**5**$^+$]$I_3$ may be isolated by dissolving a sample of [**4**$^+$]$I_3$ in pyridine and allowing the solution to stand. The structure of [**5**$^+$]$I_3$ has been determined by X-ray crystallography.‡ A view of the cation, which has crystallographic $C_2$ symmetry with the rotation axis passing through the cobalt ion and the unique methine carbon atom, is shown in Fig. 2. The cobalt ion is six-coordinate with bonds to the nitrogen atoms of two axial pyridine ligands and the four nitrogen atoms of the helical tetrapyrrole ligand. The Co–N bond distances [Co–N(1) 1.950(5), Co–N(2) 1.956(4) and Co–N(3) 1.997(5) Å] are indicative of the presence of a $Co^{III}$ centre in the complex.[10] The Co–N distances [1.916(7), 1.910(7), 1.926(7) and 1.898(7) Å] in [**4**$^+$]$I_3$ are slightly shorter than the equatorial Co–N distances in [**5**$^+$]$I_3$.[9] However, the pattern of Co–N distances seen for [**5**$^+$]$I_3$ is similar to those of low-spin cobalt(III) porphyrin complexes such as $[Co^{III}(ttp)(Him)_2]^+$ (where Him is imidazole

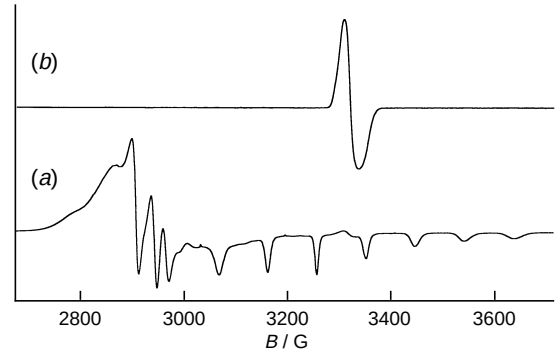


**Fig. 1** EPR spectra of frozen solutions at 77 K of (*a*) $[Co^{II}(oebOx)]I_3$ in $CH_2Cl_2$–MeOH and (*b*) $[Co^{III}(oebO\cdot)(py)_2]I_3$ {obtained by adding py to a $CH_2Cl_2$–MeOH solution of $[Co^{II}(oebOx)]I_3$}

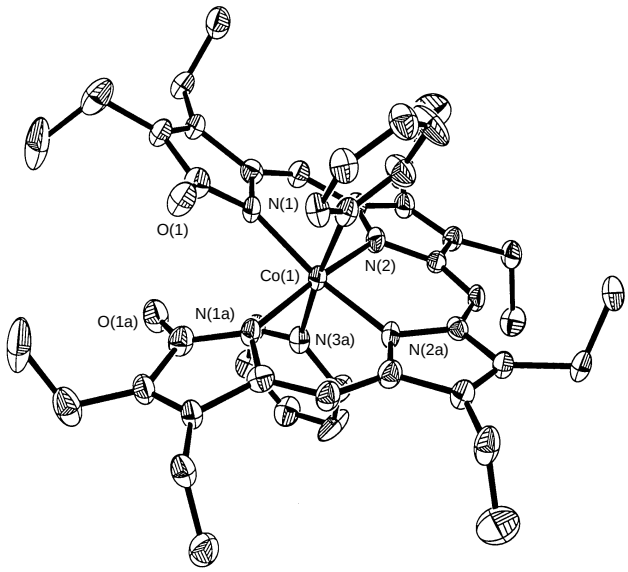

**Fig. 2** A perspective view of $[Co(oebO\cdot)py)_2]^+$ with 50% thermal contours for all atoms. Selected bond lengths (Å) and angles (°): Co–N(1) 1.950(5), Co–N(2) 1.956(4), Co–N(3) 1.997(5), C(1)–O 1.216(7); N(1)–Co–N(2) 89.8(2), N(1)–Co–N(3) 85.6(2), N(1)–Co–N(1a) 91.3(3), N(2)–Co–N(3) 94.6(2), N(2)–Co–N(2a) 92.0(3), N(2)–Co–N(1a) 167.2(2), N(3)–Co–N(3a), 174.5(3).

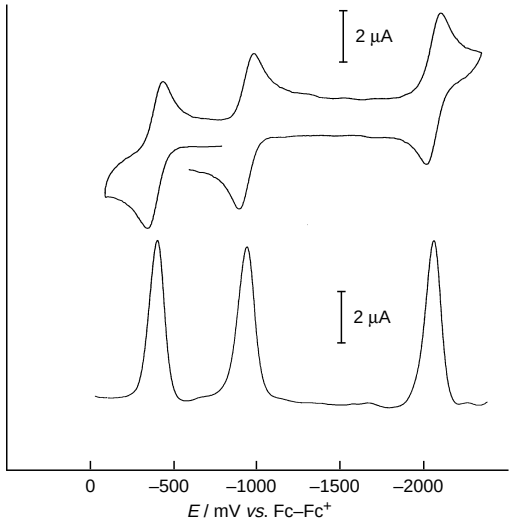

**Fig. 3** Cyclic voltammogram and differential pulse voltammogram of Co(oeb) (1.6 mM) in pyridine solution with 0.1 M $NBu^n_4ClO_4$ as supporting electrolyte

and ttp is the dianion of tetraphenylporphyrin) which has a Co–$N_{(axial)}$ distance of 1.93(2) Å and an average Co–$N_{eq}$ distance of 1.98(2) Å.[11] In marked contrast, the axial Co–N distances are longer than the in-plane Co–N distances for cobalt(II) porphyrins. For example in $[Co^{II}(oep)(3Me\text{-}py)_2]$ the axial Co–N distance is 2.386(2) Å while the in-plane Co–N distances average 1.992 Å.[12]

$[\mathbf{5}^+]I_3$ dissolves readily in dichloromethane solution to produce a purple solution with $\lambda_{max}$/nm ($\varepsilon$/dm$^3$ mol$^{-1}$ cm$^{-1}$): 290 (46 900), 360 (32 400), 628 (9900). The magnetic moment of a dichloromethane solution of the complex $[\mathbf{5}^+]I_3$ is 2.0(2) $\mu_B$.

Electrochemical studies show that in pyridine solution a four-membered electron transfer series exists for this family of cobalt complexes. Fig. 3 shows cyclic voltammetric and Osteryoung square-wave voltammetric data for Co(oeb) in pyridine solution. One reversible oxidation [at −388 mV with $\Delta E_p$ = 64(2) mV and $w_{1/2}$ = 112(2) mV] and two reversible reductions [at −924 mV with $\Delta E_p$ = 66(2) mV and $w_{1/2}$ = 118(2) mV and at −2046 mV with $\Delta E_p$ = 66(2) mV and $w_{1/2}$ = 112(2) mV] are observed. The reversible nature of these processes suggests that the axial ligation of cobalt does not change during the redox process and previous work has demonstrated spectral changes for Co(oeb) in pyridine as compared to dichloromethane solution that are indicative of axial ligation by pyridine.

The alteration in internal oxidation states in $[Co^{II}(oebOx)]I_3$, $[\mathbf{4}^+]I_3$, and $[Co^{III}(oeb\cdot)(py)_2]I_3$, $[\mathbf{5}^+]I_3$, has some parallels in the valence tautomerization observed for other transition-metal complexes. For example the oxidation of $Ni^{II}$(porphyrin) is known to yield either $[Ni^{III}(porphyrin)]^+$ or $[Ni^{II}(porphyrin\ radical)]^+$.[13] Cobalt complexes of dioxolene ligands also experience valence tautomerization, $Co^{III}$(bipy)(semiquinone)(catecholate)/$Co^{II}$(bipy)(semiquinone).[14] In all these complexes the redox potentials of the ligands and the metal centres are close in energy so that the electron distribution between these components is markedly effected by environmental effects, which in the present case involve the availability of axial ligands.

We thank the National Institutes of Health (Grant GM26226) for financial support.

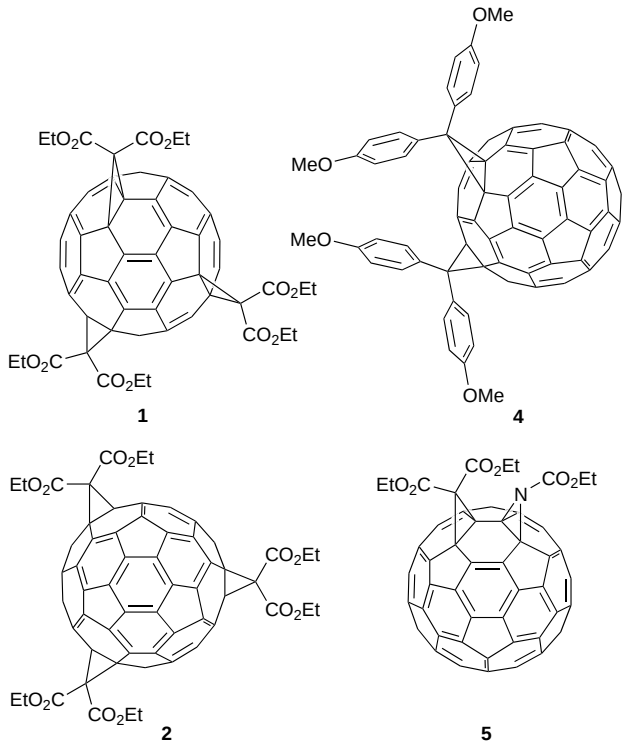
# Enantiomeric separation of [60]fullerene derivatives with an inherent chiral addition pattern

**Birgit Gross,[a] Volker Schurig,*[a] Iris Lamparth,[b] Andrea Herzog,[b] Francis Djojo[b] and Andreas Hirsch*[b]**

[a] *Institut für Organische Chemie, Auf der Morgenstelle 18, 72076 Tübingen, Germany*
[b] *Institut für Organische Chemie, Henkestr. 42, 91054 Erlangen, Germany*



**Enantiomeric separation of bis-, tris- and hexakis-adducts of [60]fullerene with achiral addends and an inherent chiral addition pattern is achieved by HPLC using a chiral Whelk-O1 phase.**

Investigations on chiral fullerene derivatives is a topic attracting increasing interest.[1] Recently there has been a lot of effort directed towards the synthesis and characterization of various chiral [60]fullerene adducts. If the addends themselves are achiral, chirality is still possible due to the nature of the addition pattern. In these cases the fullerene based π-systems themselves are chiral, and the chiroptical properties are due to an asymmetric fullerene chromophore.

We recently reported the synthesis and characterization of several regioisomeric bis- and tris-adducts of [60]fullerene with both identical and different addends, *e.g.* diethoxycarbonylmethylene $C(CO_2Et)_2$, dianisylmethylene $C(anisyl)_2$ and ethoxycarbonylnitrene $NCO_2Et$.[2,3] Some of these isomers are chiral due to their addition pattern and they were isolated and characterised as racemates. In order to isolate single enantiomers[4,5,6] of chiral fullerene derivatives two different approaches can be considered: (1) enantioselective synthesis of enantiomerically enriched or pure products, which has been demonstrated, *e.g.* with asymmetric bisosmylation[4] and enantioselective addition of malonates[5] and (2) enantiomeric separation by means of preparative chromatography (HPLC) on a chiral stationary phase.

Chiral Whelk-O1 HPLC columns are well suited to the separation of enantiomers with either π-acidic or π-basic groups. Welch *et al.* were the first to resolve enantiomeric monoadducts of [60]fullerene on a Whelk-O1 column.[7] [76]Fullerene monoadducts[8] as well as a [70]fullerene monoadduct[9] were also successfully separated using this chiral stationary phase. Recently, a malonate bisadduct of [60]fullerene was resolved into its enantiomers.[5]

Here we report the enantiomeric separation of several racemic bis-, tris- and hexakis-adducts of [60]fullerene by chiral HPLC using a (*R*,*R*)-Whelk-O1 column† and we show the circular dichroism spectra of the single enantiomers. The HPLC separation of the enantiomers of the $C_3$-symmetric trisadduct **1** (*f*C)-I,eI,eII[11,12] and (*f*A)-I,eI,eII with an *e*,*e*,*e*-addition pattern and of the $D_3$-symmetric trisadduct **2** (*f*C)-I,III*,III* and (*f*A)-I,III*,III* with a *trans*-3, *trans*-3, *trans*-3 addition pattern represents the first resolution of racemic fullerene trisadducts. A chiral $C_1$-symmetrical hexakisadduct $C_{66}(CO_2Et)_{12}$ **3** of unknown structure, which is a side product in the synthesis of the corresponding $T_h$-symmetrical hexakisadduct,[13] is the first example of the separation of a racemic hexakisadduct of [60]fullerene. Successful chromatographic resolution was also achieved with the enantiomers of bisadduct **4** (*f*C)-I,III and (*f*A)-I,III as well as **5** (*f*C)-I,II and (*f*A)-I,II. The chromatogram of the enantiomeric separation of **3** is shown in Fig. 1. Several solvent compositions were tested for the five racemic derivatives. Usually fullerene adducts are only sparingly soluble in solvents like MeCN, MeOH or water. Therefore all the fullerene separations described in the literature so far are carried out in the normal phase mode, using toluene or solvent mixtures with *e.g.* either hexane or $CH_2Cl_2$. The bisadducts **4** and **5** are very soluble in toluene and hexane or heptane mixtures. Trisadducts **1** and **2** as well as the hexakisadduct **3** were separated using a reversed phase mode. Whereas with MeOH only broad peaks leading to poor resolution were observed, the use of MeCN–

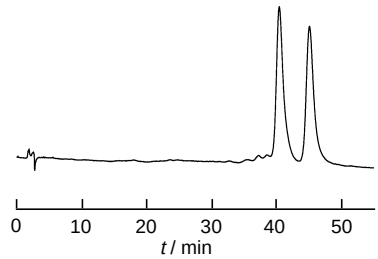


**Fig. 1** Chromatogram of the enantiomer separation of **3** on Whelk-O1 Eluent: MeCN–$H_2O$, 75:25; flow rate: 0.8 ml $min^{-1}$; UV detection: 254 nm.

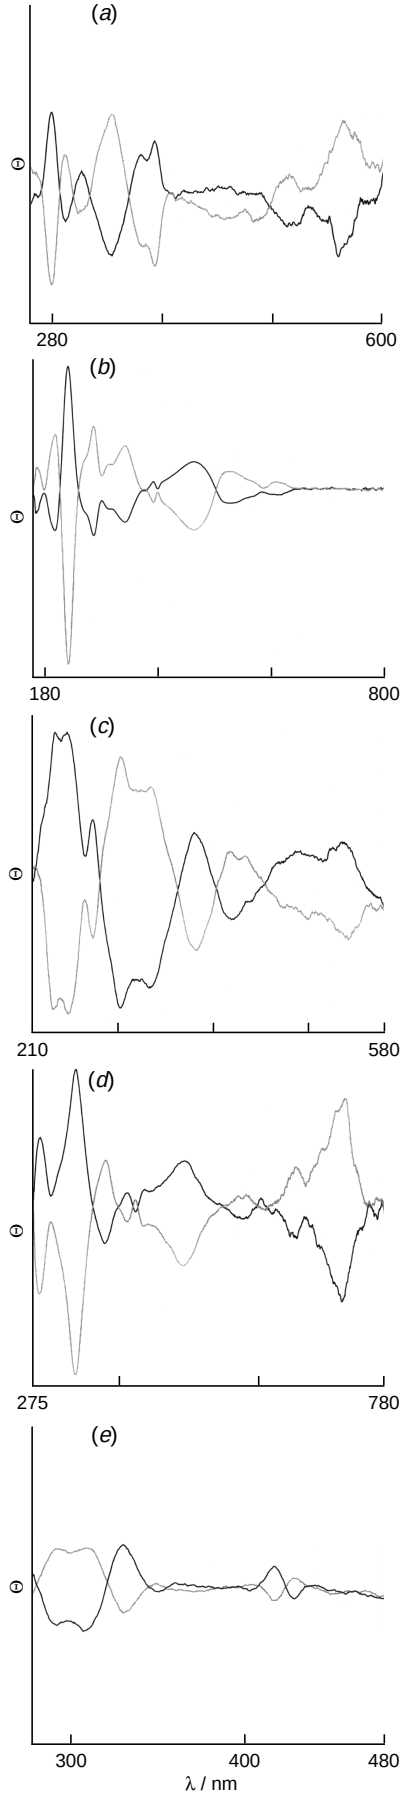

**Fig. 2** Circular dichroism spectra of the enantiomers **1**–**5**: (*a*) **1**, (*b*) **2**, (*c*) **3**, (*d*) **4** and (*e*) **5**. — First eluted enantiomer. **—** Second eluted enantiomer.

water mixtures guaranteed a good separation into the corresponding enantiomers **1**–**3** with chiral separation factors α in the range 1.04–1.12. The best separation was achieved with the hexakisadduct **3** showing a resolution $R_s$ = 2.37. In pure toluene the resolution for the bisadducts **4** and **5** was very poor. Increasing percentages of hexane or heptane lead to an improvement of the α- and $R_s$-values. As these adducts are less soluble in hexane or heptane, a higher percentage of these solvents in toluene leads to bad peak shapes and no further improvement in separation.

After separation of the enantiomers of **1**–**5** on a semipreparative scale CD spectra were recorded (Fig. 2),‡ which are comparable to those reported for other fullerene adducts.[4–10] Since in our case chirality arises exclusively from the addition pattern on the carbon cluster itself, the CD originates from the chiral functionalized fullerene chromophore. Each derivative gives rise to mirror image CD curves for the enantiomers (Fig. 2).

We thank the BMBF, the Fonds der Chemischen Industrie and the Hoechst AG for financial support. We thank R. Süssmuth for recording the CD spectra and C. Welch for a gift of a Whelk-O1 column.

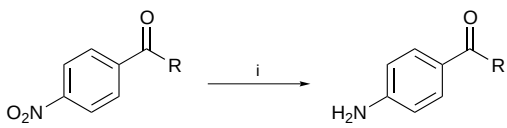
# Chemoselective transfer hydrogenation of nitroarenes, aldehydes and ketones with propan-2-ol catalysed by Ni-stabilized zirconia

**T. T. Upadhya, S. P. Katdare, D. P. Sabde, Veda Ramaswamy and A. Sudalai***



*National Chemical Laboratory, Pune-411 008, India*

**Nickel-stabilized zirconia ($Zr_{0.8}Ni_{0.2}O_2$), a reusable, solid catalyst, efficiently catalyses the chemoselective reduction of nitroarenes, aldehydes and ketones using propan-2-ol and KOH, in the liquid phase, exhibiting the reactivity order $NO_2 \gg C{=}O > C{-}X \gg C{=}C$.**

The chemoselective reduction of organic compounds is synthetically important, both in the laboratory and in industry. In comparison with catalytic reduction using molecular hydrogen,[1] transfer reduction using hydrogen donors, *viz.* propan-2-ol, has real and potential advantages because neither hydrogen containment nor a pressure vessel is required. Moreover, the transfer hydrogenation method could offer enhanced selectivity in the reduction process. A wide variety of homogeneous and heterogeneous catalytic systems in combination with different hydrogen donors have been employed to selectively reduce most major functional groups attached to aliphatic and aromatic structures.[2] Chemoselective reduction of the functional groups can be achieved by classical Meerwein–Ponndorf–Verley reductions. However, the use of aluminium isopropoxide in stoichiometric amounts and under drastic reaction conditions often leads to undesired side reactions.[3] Recently, transfer hydrogenation of ketones using homogeneous complexes of Cu, Fe, Rh, Ru, Ir, Pd and Ni with propan-2-ol has been reported.[4] However, it has been observed that controlling the reduction rates is difficult with these active catalysts.[5] On the other hand, the use of heterogeneous catalysts offers several advantages over the homogeneous systems such as ease of recovery, recycling and enhanced stability. Raney Ni catalyst has also been extensively used in combination with hydrazine hydrate or propan-2-ol as a hydrogen source for reductions. However, Raney Ni is pyrophoric and does not show any selectivity towards functional groups such as C–X, C=O and $NO_2$, reducing all of them simultaneously. Further it has been observed that the use of Raney Ni for the reduction of aromatic ketones leads to hydrogenolysis of alcohols quite easily at the benzylic position.[6]

Considerable efforts have been devoted in use of zirconium oxide, which is known to be a bifunctional catalyst, either as a single oxide or in a mixed metal oxide, for application in organic synthesis as is evident from the literature.[7] Here, we report the potential application of nickel-stabilized zirconia as an active, heterogeneous catalyst for chemoselective reduction of nitro and carbonyl functions under transfer hydrogenation conditions in the liquid phase using propan-2-ol (Scheme 1).

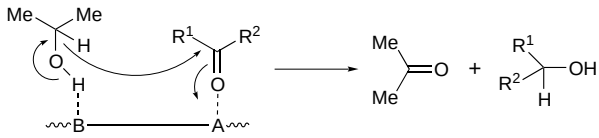
Zirconia samples stabilized by Cr, Mn, Fe, Co or Ni were prepared by the procedure reported from our laboratory.[8] In particular, $Zr_{0.8}Ni_{0.2}O_2$ was prepared by treating an aqueous solution of zirconyl nitrate and nickel nitrate (molar ratio 80 : 20) with tetramethylammonium hydroxide (25% aqueous solution) as a precipitating agent under vigorous stirring until a pH of 8.0 was achieved. The resultant hydroxide precipitate was washed with deionised water, acetone and dried at 110 °C for 24 h and was subsequently heated to 500 °C under a programmed heating rate of 2 °C $min^{-1}$ and then calcined for 8 h. It was then characterized by powder X-ray diffraction, FTIR, surface area determination by the BET method, X-ray fluorescence (XRF), temperature programmed reduction (TPR) and cyclic voltammetry (CV) techniques.

**Scheme 1** *Reagents and conditions:* i, $Zr_{0.8}Ni_{0.2}O_2$ (cat.), $Pr^iOH$, KOH, reflux, 3 h

The XRD profiles of nickel-stabilized zirconia shows the formation of a cubic (fluorite) phase The FTIR spectrum in the framework region shows a broad band at *ca.* 480 $cm^{-1}$ characteristic of the cubic phase of $ZrO_2$.[9] Scanning electron microscopy indicates the presence of uniform particles with sizes ranging between 0.5 and 1.0 μm. The surface area of the sample as determined by the BET method† was 96 $m^2\ g^{-1}$. The chemical composition determined by XRF[10] was 79.97 mol% Zr and 20.03 mol% Ni. TPR[11] shows a single peak at *ca.* 417 °C which can be attributed to a single step reduction of $Ni^{2+}$ to $Ni^0$. The cyclic voltammogram of nickel-stabilized zirconia shows a reversible system ($E_{pa}$ + 0.32 V, $E_{pc}$ = 0.40 V *vs.* SCE with $E_{1/2}$ = 0.04 V). This electrochemical behaviour is attributed to the $Ni^{2+}$–$Ni^0$ redox cycle indicating that Ni in the solid matrix of zirconia undergoes a facile two-electron transfer process.[12]

The selective and rapid reduction of nitro compounds is an interesting area of research, particularly when other potentially reducible moieties are present in the molecule.[13] The results of the reduction of nitrobenzene to aniline over various catalysts are presented in Table 1 which shows that nickel-stabilized zirconia exhibits significantly higher activity and selectivity than pure $ZrO_2$, $Ni(O_2CMe)_2$ or Raney Ni. In the absence of either catalyst or KOH, no reaction took place. In a typical reaction procedure, a mixture of nitrobenzene (1 g, 0.0081 mol), KOH pellets (0.045 g, 0.0008 mol) and $Zr_{0.8}Ni_{0.2}O_2$ (10% *m/m*)

**Table 1** Transfer hydrogenation of nitrobenzene to aniline with propan-2-ol over different catalysts[a]



| | | | Yield[b] | |
|---|---|---|---|---|
| Entry | Catalyst | Surface area/ $m^2\ g^{-1}$ | Aniline (mass%) | Unreacted nitrobenzene (mass%) |
| 1 | No catalyst/No KOH | — | 0 | 100 |

[a] *Reaction conditions:* substrate (8 mmol), KOH pellets (8 mmol) and $Zr_{0.8}Ni_{0.2}O_2$ catalyst (10% *m/m*) in propan-2-ol (15 ml); reflux for 3–6 h. [b] Products were characterized by IR, $^1$H, $^{13}$C NMR and MS. [c] Isolated yield after chromatographic purification, the remainder is essentially unreacted starting material. [d] Diphenylmethane is obtained with Raney Ni.[6] [e] Yield with Raney Ni.[6]

**Scheme 2**

in propan-2-ol (15 ml) was refluxed for 3–5 h. The progress of the reaction was monitored by TLC, the catalyst was then filtered off and the product purified by flash chromatography to afford aniline (96% yield).

As summarized in Table 2, in refluxing propan-2-ol (82 °C), the present catalytic system efficiently reduces both nitroarenes and carbonyl compounds in excellent yields. Both aromatic and aliphatic aldehydes and ketones are reduced to the corresponding alcohols. It is remarkable that both C–Br and C–Cl bonds are not reduced and are stable under the reaction conditions (Table 2: entries 2, 7, 13 and 14). Another notable feature of this catalytic system is that both 4-nitroacetophenone and 4-nitrobenzophenone undergo chemoselective reduction to 4-aminoacetophenone and 4-aminobenzophenone, respectively, in high yields without reduction of the carbonyl function. Further, cinnamaldehyde is reduced chemoselectively to cinnamyl alcohol without reducing C=C. The present catalytic system did not reduce functional groups such as $CO_2H$, CN, $CO_2R$, *etc.*, under the present experimental conditions. The catalyst was easily recovered by filtration, and could be reused three times for the reduction of nitrobenzene without affecting the activity or selectivity of the process. The XRD pattern of the used catalyst shows no structural deterioration.

Mechanically, stabilization of zirconia by nickel does not alter its bifunctional behaviour.[7] Propan-2-ol is adsorbed on the basic site (B) and the ketone on the adjacent acidic site (A); the $Ni^{2+}$ on the surface promotes dehydrogenation of propan-2-ol by KOH, and is reduced to the active $Ni^0$ species as evident from CV measurements and finally the hydrogen is transferred as hydride as shown in Scheme 2. It appears that the active $Ni^0$ species, formed instantaneously during the reaction, is responsible for the catalytic reduction.

In conclusion, incorporation of Ni into the bulk structure of $ZrO_2$, not only stabilizes $ZrO_2$ in its cubic (fluorite) form but also moderates the reactivity of Ni in the stabilized zirconia enabling chemoselective functional group reduction.

S. P. K. thanks CSIR (New Delhi) for the award of Senior Research Fellowship and T. T. U. and D. P. S. are grateful to the Director, NCL for providing facilities. Special thanks are given to Dr S. G. Hegde and Dr A. V. Ramaswamy for fruitful discussions.

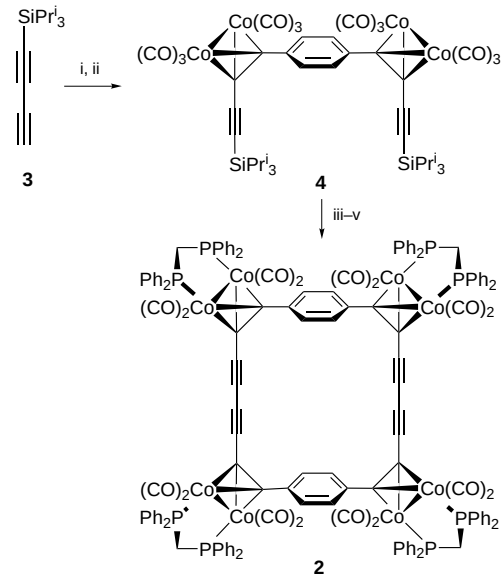
# Cyclophyne chemistry: synthesis and study of an octacobalt complex of [8.8]paracyclophaneoctayne

**Michael M. Haley* and Brandi L. Langsdorf**

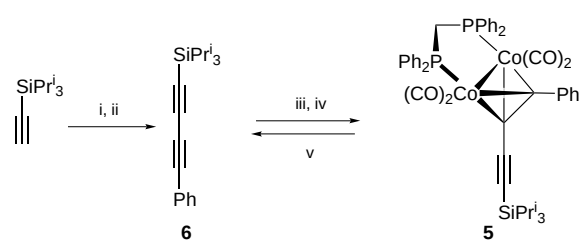
*Department of Chemistry, University of Oregon, Eugene, Oregon 97403, USA*

**Use of a palladium/cobalt/copper alkyne reaction strategy provides the cobalt-stabilized complex of a highly strained cyclophane.**

The recent discovery of the fullerenes[1] and related carbon nanotubes[2] has prompted a flurry of activity directed toward the synthesis and study of curved, fully conjugated π-systems.[3] In a similar regard, there have been numerous attempts to prepare related belt-shaped molecules possessing conjugated π-electron circuits; the various belt- and hoop-shaped compounds studied include cyclacenes,[4] [*n*]cyclocarbons,[5] cyclic paraphenylenes[6] and others.[7] Recently, two groups reported the successful preparation of fully conjugated, belt-shaped compounds. Oda and co-workers produced cyclic paraphenylacetylenes containing six and eight subunits.[8] Herges and co-workers isolated a 'picotube' based on four anthracene units.[9] Our recent work on polyacetylenic macrocycles[10] spurred an interest in systems possessing the cyclic π-orbital motif. We report herein our work toward the synthesis of [8.8]paracyclophaneoctayne **1**, a cyclophane-cyclocarbon hybrid nicknamed a cyclophyne.[11]



**1**



An octacobalt complex such as **2** was envisioned for the immediate precursor to the target macrocycle as: (*i*) the carbon skeleton could be assembled quickly and efficiently using known methodology, and (*ii*) the alkyne C≡C–C angles in this type of (μ-acetylene)dicobalt hexacarbonyl complex are reduced to *ca.* 140°, thus allowing the complex to participate in reactions that might be difficult or otherwise impossible for the rigid, unbound molecule to undergo. The synthesis of **2** is depicted in Scheme 1. Palladium-catalysed alkynylation of 1,4-diiodobenzene with excess triisopropylsilylbutadiyne **3**[12] furnished a pale yellow tetrayne, which in turn reacted with 2 equiv. of octacarbonyldicobalt to provide the sterically favoured tetracobalt complex **4**.† Attempted desilylation with tetrabutylammonium fluoride led to complete decomposition of **4**. Ligand exchange[5a] with bis(diphenylphosphino)methane (dppm) afforded a bridged complex (85% yield) stable to fluoride ion; desilylation now proceeded in high yield ( > 95%). Eglinton coupling[13] of the terminal acetylenes provided fine, deep maroon crystals of **2**† in 47% yield. Spectroscopic data supported formation of the strain-free dimeric structure.

In their work with the hexacobalt complex of [18]cyclocarbon, Diederich *et al.* were unable to free $C_{18}$ of the protecting groups by mild oxidation.[5a,14] With this problem in mind, we prepared model complex **5**† (Scheme 2) in order to investigate various methods to remove the cobalts. Of the numerous reagents and conditions explored, only oxidation by molecular iodine was found to regenerate butadiyne **6** cleanly and in excellent yield.

Application of the iodine-promoted decomplexation method to **2** provided dppm as the sole organic-soluble component along with a copious amount of insoluble material. Analysis of an aliquot of the crude reaction mixture by $^1$H NMR showed a broad signal at δ 7.6 attributable to the phosphine ligand; no other aromatic peaks were observed. Although disappointing, this result is not wholly unexpected. A survey of the current literature reveals that, despite significant efforts on the part of several research groups, systems containing contiguous, bent triynes and higher polyynes have proven elusive.[5] Only strained monoyne[8,15] and diyne[16] derivatives are known. The cyclocarbons represent the ultimate bent polyyne macrocycles; $C_{18}$ is predicted to exhibit C≡C–C bond angles near 160°, leading to a strain energy of around 72 kcal mol$^{-1}$.[5b] Cyclophyne **1** should be similarly strained as the triple bond angles are calculated to

**Scheme 1** *Reagents and conditions*: i, 1,4-diiodobenzene, $Pd(PPh_3)_2Cl_2$, CuI, $Et_3N$, 73%; ii, $Co_2(CO)_8$, $Et_2O$, 66%; iii, dppm, toluene, 85%; iv, $Bu_4NF$, THF, > 95%; v, $Cu(OAc)_2{\cdot}H_2O$, py, 47%

**Scheme 2** *Reagents and conditions*: i, $CBr_4$, $PPh_3$, $CH_2Cl_2$, 85%; ii, phenylacetylene, CuCl, $NH_2OH{\cdot}HCl$, $PrNH_2$, MeOH, $H_2O$, 82%; iii, $Co_2(CO)_8$, $Et_2O$, 76%; iv, dppm, toluene, 87%; v, $I_2$, THF, 85%

be between 161.7 and 163.6°.[17] Whether the failure to prepare these two classes of macrocycles is due to the extreme reactivity of the distorted polyyne moiety or to the lack of a viable synthetic route is not certain. Thus isolation and characterization of smaller bent hexatriyne- and octatetrayne-containing systems should help answer these questions. To this end, we are currently studying dehydrobenzoannulenes possessing higher polyynes distorted on one or more edge.[18] These results will be reported in due course.

We acknowledge the donors of The Petroleum Research Fund, administered by the American Chemical Society, and the University of Oregon for generous support of this research.

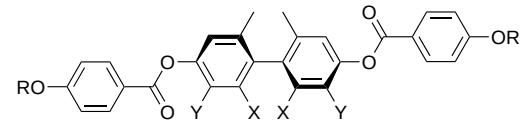
# Enhanced polar ordering in ferroelectric liquid crystals induced by atropisomeric dopants

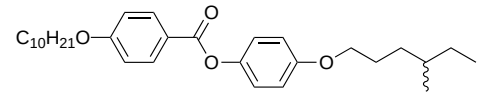
**Despina Vizitiu, Brian J. Halden and Robert P. Lemieux***

*Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6*



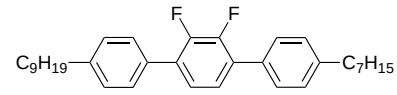
**The spontaneous polarization of a $S_C$* liquid crystal phase induced by atropisomeric dopants with large transverse molecular dipoles exhibits a very strong dependence on the nature of the $S_C$ liquid crystal host.**

A ferroelectric smectic C* liquid crystal phase possesses a permanent dipole moment, the spontaneous polarization ($P_S$), which is a macroscopic manifestation of molecular chirality.[1] The dependence of $P_S$ on the molecular structure of the chiral component(s) of a $S_C$* phase has received considerable attention over the past 15 years as it relates directly to the performance optimization of FLC light valves and displays.[2–4] In general, ferroelectric liquid crystals suitable for display applications are induced $S_C$* phases obtained by mixing a chiral dopant with high polarization power ($\delta_P$) in a $S_C$ liquid crystal host mixture with low viscosity and broad temperature range. The polarization power is a measure of the propensity of a chiral dopant to induce a spontaneous polarization in a $S_C$ host as expressed by eqn. (1), in which $P_o$ is the reduced polarization of the FLC and $x_d$ is the dopant mole fraction.[5]† In most cases, the polarization power of a chiral dopant is independent of the nature of the $S_C$ host. However, Stegemeyer has reported several examples of chiral dopants with rigid chiral cores that exhibit a dependence of $\delta_P$ on the nature of the $S_C$ host; these compounds are referred to as Type II dopants.[6]



$$\delta_p = \left(\frac{dP_o(x_d)}{dx_d}\right)_{x_d \to 0} \quad (1)$$

Recently, we reported the induction of a $S_C$* phase by the atropisomeric dopant (−)-**1**, which exhibited a pronounced Type II host dependence in the $S_C$ liquid crystal hosts PhBz and NCB76 (Fig. 1).[7] We proposed that polar ordering of (−)-**1** in the $S_C$ lattice originates from a small asymmetric bias in the rotation of the biphenyl core about the ester C–O bonds, which we estimated by AM1 calculations on the model compound 3-methyl-5-nitrophenyl benzoate at 0.4 kcal mol$^{-1}$ (1 cal = 4.184 J). We have extended this conformational analysis to other phenyl benzoate derivatives as model compounds, and found that shifting the symmetry-breaking $NO_2$ group to the *ortho*-position with respect to the ester group raises the rotational bias about the ester C–O bond to 1.1 kcal mol$^{-1}$. In order to test the validity of this conformational analysis in predicting the relative polar ordering of atropisomeric dopants, and to further investigate the generality of Type II behaviour in these systems, we have synthesized the dopant (−)-**2** in optically pure form and measured its polarization power in the $S_C$ hosts PhBz,[8] NCB76 (E. Merck) and DFT.[9]



The precursor **5** was synthesized in racemic form starting with the known benzidine **3**,[10] as shown in Scheme 1, and resolved by chiral stationary phase HPLC using a Daicel Chiralcel OJ column to give the (−) enantiomer in optically pure form.‡ The latter was esterified under mild conditions using DCC/DMAP to give the diester (−)-**2**, which showed no liquid crystalline behaviour by differential scanning calorimetry. Compound (−)-**2** was doped in the $S_C$ hosts PhBz, DFT and NCB76 at four different concentrations in the range $0.01 < x_d < 0.05$. Each mixture was introduced into polyimide-coated ITO glass cells with a 4 μm gap, and aligned by slow cooling from isotropic liquid to the $S_C$* phase at $T–T_{AC} = -5$ °C. Spontaneous polarization and tilt angle (θ) values were measured as a function of $x_d$ by the triangular wave method using a Displaytech APT II polarization testbed (100 Hz, 6 V μm$^{-1}$).[11] At $x_d = 0.03$, the dopant (−)-**2** gave a $P_S$ value of −2.5 nC cm$^{-2}$ (θ = 9.5°) in NCB76, and a $P_S$ value of −1.7 nC cm$^{-2}$ (θ = 10.5°) in DFT. In these two hosts, a plot of $P_o$ *vs.* $x_d$ gave a good linear fit, from which $\delta_P$ values were

NCB76; phase sequence:
Cr 66 ($S_G$ 55) $S_C$ 73 $S_A$ 117 N 125 I

**Fig. 1**

**Scheme 1** *Reagents and conditions*: i, $NaNO_2$, HCl, 5 °C; ii, 10% $H_2SO_4$, reflux; iii, $Fe(NO_3)_3 \cdot 9H_2O$, EtOH, reflux; iv, chiral stationary phase HPLC resolution, semiprep Daicel Chiralcel OJ column, hexanes–EtOH 9 : 1, 3 ml min$^{-1}$; v, 4-nonyloxybenzoic acid, DCC, DMAP, $CH_2Cl_2$, 25 °C

obtained (Fig. 2).† In the host PhBz, $P_S$ was too low to be measured at $x_d$ = 0.05; an upper limit value for $\delta_P$ was estimated based on the instrument detection limit (0.3 nC cm$^{-2}$) and an observed tilt angle of 10° at $T$–$T_{AC}$ = −5 °C. These results are presented in Table 1, including previously unreported data for dopant (−)-**1** in DFT, and correlated with dielectric anisotropy values ($\Delta\varepsilon = \varepsilon_{\parallel} - \varepsilon_{\perp}$) measured in the nematic phase for structurally analogous mesogens.§ The $\Delta\varepsilon$ values are consistent with the increase in transverse dipole moment of the mesogens in the order PhBz < DFT < NCB76.

In NCB76 and DFT, the dopant (−)-**2** shows a much higher polarization power than (−)-**1**, which is consistent with the increase in rotational bias about the ester C–O bond predicted by the AM1 calculations. Furthermore, (−)-**2** exhibits a very strong dependence of $\delta_P$ on the nature of the $S_C$ host. To the best of our knowledge, the > 15-fold enhancement in polarization power shown by (−)-**2** as a function of the $S_C$ host is the largest thus far reported for a Type II dopant. For each dopant, a correlation exists between the polarization power and the dielectric anisotropy of the $S_C$ host, which suggests that the Type II dependence observed in this case arises from enhanced coupling of the dopant with the $S_C$ lattice *via* transverse dipole–dipole interactions. This coupling mechanism is likely to induce polar ordering of the $S_C$ host and cause an asymmetric distortion of the achiral $S_C$ lattice that further enhances rotational ordering of the atropisomeric core. We plan to continue testing the validity of this model through the design and characterization of new series of atropisomeric dopants analogous to **1** and **2**.

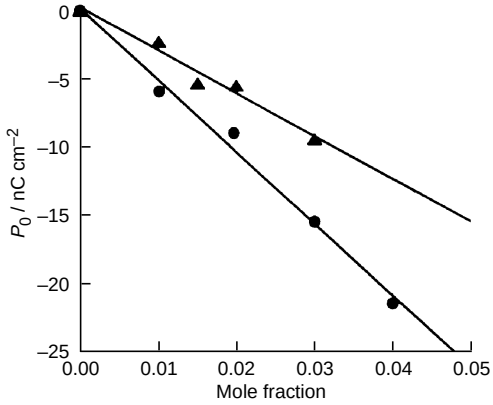

**Fig. 2** Reduced polarization $P_o$ as a function of mole fraction for the dopant (−)-**2** in the $S_C$ hosts NCB76 (circles) and DFT (triangles) at $T$–$T_{AC}$ = −5 °C

**Table 1** Polarization power values for dopants (−)-**1** and (−)-**2** in the $S_C$ hosts NCB76, DFT and PhBz

| | | $\delta_P$/nC cm$^{-2}$ [a] | | | |
|---|---|---|---|---|---|
| Host | $\Delta\varepsilon$ [b] | (−)-**1** | sign | (−)-**2** | sign |
| NCB76 | −4.7 | 170 [c] | + | 523 | − |
| DFT | −1.7 | 63 [d] | + | 312 | − |
| PhBz | −0.35 | < 20 | − | < 34 | − |

[a] Measured at $T$–$T_{AC}$ = −5 °C. [b] Dielectric anisotropy values measured in the nematic phase for the structural analogues 4-(4′-pentylbiphenyl-4-yl)-1-propylcyclohexanecarbonitrile, 2′,3′-difluoro-4,4″-dipropyl-*p*-terphenyl,[12] and 4-hexyloxyphenyl 4-decyloxybenzoate.[13] [c] From ref. 7. [d] This value was extrapolated from a single $P_o$ measurement at $x_d$ = 0.04.

We are grateful to the Natural Sciences and Engineering Research Council of Canada for financial support of this work, and to Professor H. Stegemeyer for a generous gift of NCB76.

## Footnotes

* E-mail: lemieux@chem.queensu.ca

† The reduced polarization is intrinsic to the chiral component(s) of the $S_C$* phase at a fixed temperature difference below the $S_C$*–$S_A$* phase transition ($T$–$T_{AC}$), and is related to the spontaneous polarization ($P_S$) and tilt angle ($\theta$) of the $S_C$* phase by the equation:

$$P_o = P_S/\sin\theta$$

‡ All new compounds gave satisfactory spectral data ($^1$H, $^{13}$C NMR and mass spectra) and combustion analyses.

§ Dielectric anisotropy values for PhBz, DFT, NCB76 are currently unavailable.

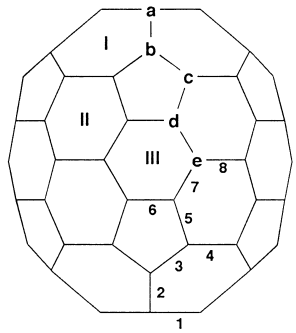
# Triruthenium cluster complexes of $C_{70}$. Synthesis and structural characterization of $\{Ru_3(CO)_9\}_x(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{70})]$ ($x$ = 1, 2)

**Hsiu-Fu Hsu, Scott R. Wilson and John R. Shapley***

*School of Chemical Sciences, University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA*

**The interaction of $C_{70}$ and $[Ru_3(CO)_{12}]$ provides $[Ru_3(CO)_9(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{70})]$, in which the $Ru_3$ triangle is coordinated to only one of the three possible six-membered ring types; analogous double-addition products are isolated and one structurally characterized.**

The prolate ellipsoidal fullerene $D_{5h}$-$C_{70}$ displays a striking variety of structural features, with five types of carbon atoms, eight types of C–C bonds, two types of five-membered rings, and three types of six-membered rings (Scheme 1). Theoretical as well as structural studies of $C_{70}$ are in agreement that bond types 2 and 4 near the poles are the shortest in the molecule, whereas the equatorial belt bonds of type 8 are the longest.[1] Within the six-membered rings, bond distance alternation is marked in type I rings, moderate in type II rings, and non-existent in type III rings; the equatorial type III rings have been characterized as 'aromatic'.[2]



Additions to $C_{70}$ occur primarily at the 'double' bonds of types 2 and 4, with addition at the more pyramidalized bond 2 generally favoured.[3–7] We were interested in the possible ligating characteristics of six-membered ring types I–III toward an arene-complexing fragment, in particular, $Ru_3(CO)_9$.[8] Recently, the coordination of this group to $C_{60}$ has been described.[9] Here we report the preparation and structure of the first hexahapto complex of $C_{70}$, $[Ru_3(CO)_9(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{70})]$ **1**, in which the $Ru_3$ triangle is bonded to a six-membered ring of type I. In addition, we have prepared and separated the expected three isomers of the double substitution product, $[\{Ru_3(CO)_9\}_2C_{70}]$ **2** and have determined the structure of one isomer.

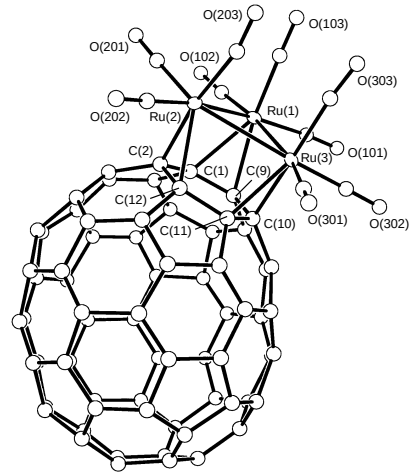
Heating a mixture of $C_{70}$ and $[Ru_3(CO)_{12}]$ in *n*-hexane for several days produces little visible change, since the fullerene is poorly soluble and a precipitate is present throughout. However, extraction of the precipitate with carbon disulfide followed by preparative thin-layer chromatography on silica provides a new compound in addition to recovered $C_{70}$. Compound **1** was crystallized from carbon disulfide by slow infusion of benzene. The results of a single-crystal X-ray diffraction study of **1**·$CS_2$ revealed two inequivalent molecules (A and B) in the unit cell; the structure of molecule A is illustrated in Fig. 1.†

The triruthenium unit is coordinated to one of the type I rings, with one Ru bonded to a type 4 C–C bond and the other two Ru atoms bonded to type 2 C–C bonds. However, each Ru–$C_2$ interaction shows one longer and one shorter Ru–C distance, which alternate around the ring, consistent with a slight twist of the $Ru_3$ triangle with respect to the $C_6$ ring. The Ru–C distances average 2.24, 2.27 Å in A and 2.23, 2.32 Å in B, and the twist angles are 2 and 4° in A and B, respectively. Accompanying the twist between the two attached rings is a threefold twist of each $Ru(CO)_3$ moiety that positions each axial carbonyl at an angle to the axis perpendicular to the $Ru_3$ plane; these angles average 10° in A and 12° in B. These structural features were also seen in $[Ru_3(CO)_9(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{60})]$ **3**[9] as well as in $[Ru_3(CO)_9(\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_6H_6)]$ **4**,[8] and they were attributed to packing forces acting on a relatively flat potential for small angles of rotation around the $Ru_3$–$C_6$ axis. The two different sets of structural parameters observed for molecules A and B of **1** provide direct support for this idea. Overall, the local structures for **1** and **3** are closely comparable.

The Ru–Ru bond distances in **1** [2.894(5), 2.918(3), 2.836(3) Å in A and 2.861(4), 2.875(4), 2.869(3) Å in B] are on average slightly longer than those in $[Ru_3(CO)_{12}]$ [2.855(1) Å].[10] Although the e.s.d.s are large, the C–C bond distances of the coordinated six-membered ring seem to show short–long alternation, with averages 1.39, 1.49 Å for A and 1.40, 1.48 Å for B. The average C–C bond lengths for the different types of bond in the unsubstituted halves of the $C_{70}$ ligands in molecules A and B of **1** show the same patterns seen in previous $C_{70}$ structure analyses.[1,6,7]

The coordination of the $Ru_3$ triangle to a six-membered ring of type I is in conformity with the positions of other single-metal addends as mentioned above. This result suggests that the formation of **1** may be a kinetically controlled reaction, in which coordination of the first metal atom at a type 2 bond determines

**Scheme 1**



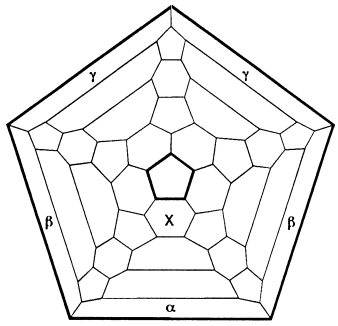


**Fig. 1** A perspective view of **1** (molecule A), showing part of the atom labelling scheme. Selected bond lengths (Å): Ru(1)–Ru(2) 2.894(5), Ru(2)–Ru(3) 2.918(3), Ru(1)–Ru(3) 2.836(3), Ru(1)–C(1) 2.33(2), Ru(1)–C(9) 2.25(2), Ru(2)–C(2) 2.21(2), Ru(2)–C(12) 2.26(2), Ru(3)–C(10) 2.24(2), Ru(3)–C(11) 2.27(2), C(1)–C(2) 1.48(3), C(1)–C(9) 1.37(3), C(2)–C(12) 1.45(3), C(9)–C(10) 1.51(3), C(10)–C(11) 1.36(3), C(11)–C(12) 1.48(3).

the coordination sites of the remaining two metal atoms. On the other hand, these sites are already the most pyramidal in the molecule, and they require relatively little further distortion to coordinate favourably to the $Ru_3$ framework, by comparison of bond angles at coordinated *vs.* uncoordinated carbons. In contrast the type III rings, which have been characterized as aromatic on the basis of their essentially equivalent C–C distances, are actually slightly concave (carbons e,e are *ca.* 0.1 Å below the plane of the four d carbons[7]), so that coordination of one of these rings to a metal triangle would involve considerable distortion of the $C_{70}$ framework. However, since good evidence for the addition of radical moieties in the equatorial region has been presented,[11] the possible coordination of ring types II and III with more reactive reagents or in the formation of higher addition products remains to be explored.

**Scheme 2**

The addition of a second $Ru_3$ unit to the $C_{70}$ ligand in **1** could result in three disubstituted isomers, as shown in Scheme 2, assuming the second unit is added to the same type of six-membered ring in the opposite polar region. Indeed, increasing the ratio of $[Ru_3(CO)_{12}]$ to $C_{70}$ under the same reaction conditions produces three new products, **2α**, **2β**, and **2γ**, which can be separated by preparative thin-layer chromatography ($CS_2/SiO_2$). The new compounds **2α**, **2β**, and **2γ** (isolated ratio 2 : 3 : 1) are formulated as disubstituted derivatives $C_{70}[Ru_3(CO)_9]_2$ on the basis of molecular ion multiplets seen by FABMS spectroscopy. All three isomers have two IR ($\nu_{CO}$) bands at 2074 and 2046 $cm^{-1}$, and the only difference among them is the position of the third peak at 2010, 2013 and 2012 $cm^{-1}$ for **2α**, **2β**, and **2γ**, respectively. These IR spectra are almost identical to that of **1**, which suggests the same bonding mode is adopted for both $Ru_3$ units as in **1**. Single crystals of isomer **2β** suitable for X-ray diffraction study were obtained from carbon disulfide by slow diffusion of methanol; a structural diagram of **2β** is shown in Fig. 2.‡ The two $Ru_3$ units are each bonded to type I six-membered rings in a fashion analogous to **1**, and their relative positions conform to the idealized $C_2$ symmetry of isomer **2β**. Attempts to characterize the structures of the other two double addition products, presumably $C_{2v}$-**2α** and $C_2$-**2γ**, are underway.

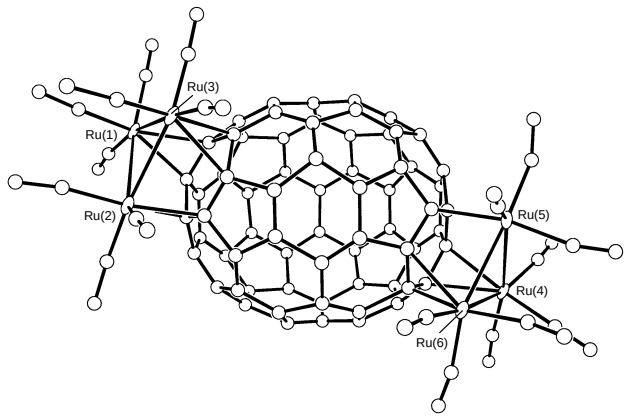

**Fig. 2** A perspective view of **2β**, showing part of the atom labelling scheme. Selected bond lengths (Å): Ru(1)–Ru(2) 2.911(3), Ru(2)–Ru(3) 2.889(3), Ru(1)–Ru(3) 2.855(3), Ru(4)–Ru(5) 2.877(3), Ru(5)–Ru(6) 2.878(3), Ru(6)–Ru(4) 2.866(3).

# Fluorous-phase soluble rhodium complexes: X-ray structure of [RhCl(CO)(P($C_2H_4C_6F_{13}$)$_3$)$_2$]

**John Fawcett,[a] Eric G. Hope,*[a] Raymond D. W. Kemmitt,[a] Danny R. Paige,[a] David R. Russell,[a] Alison M. Stuart,[a] David J. Cole-Hamilton[b] and Marc J. Payne[b]**

[a] *Department of Chemistry, University of Leicester, Leicester, UK LE1 7RH*
[b] *School of Chemistry, University of St. Andrews, St. Andrews, Fife, UK KY16 9ST*

**Rhodium(I) complexes of the ligands P($CH_2CH_2C_6F_{13}$)$_3$ and P($C_6H_4C_6F_{13}$-4)$_3$, which can be compared to their perprotio analogues, maintain their structures in fluorous solvents.**

Following the first report of the alternative approach to two-phase catalysis called the 'fluorous biphase system' (FBS)[1] this methodology has been employed in a number of organic reactions,[2] and catalytically in the epoxidation of alkenes.[3] In short, the FBS approach involves derivatising inorganic or organic reagents with long perfluorinated aliphatic 'ponytails' which renders these reagents soluble in a perfluorocarbon phase allowing the facile separation of these reagents, after catalysis, from the substrate/product dissolved in an organic solvent. The approach is attracting significant interest since it should allow the facile separation of catalyst from reactants and products using simple liquid/liquid separation techniques and benign, non-toxic, reusable perfluorocarbon solvents for industrial scale homogeneous catalysis. However, although it has been shown that catalyst separation is readily achieved under FBS regimes,[1–3] the exact nature and the influence of the highly electron-withdrawing fluorous ponytails on these fluorous-soluble catalysts has not been established. Since (*i*) phosphorus(III) ligands have found wide application in homogeneous catalysis, (*ii*) the first FBS report outlined the use of an uncharacterised rhodium–phosphine catalyst[1] and (*iii*) we have a long-standing interest in fluorinated phosphorus(III) ligands,[4] we have been investigating the coordination chemistry of a series of derivatised phosphine ligands and here report the synthesis and characterisation of some rhodium(I) complexes and the first structural characterisation of a fluorous-phase soluble metal complex.

The reaction of either of the tris-derivatised fluorous-phase soluble ligands P($CH_2CH_2C_6F_{13}$)$_3$ or P($C_6H_4C_6F_{13}$-4)$_3$[5] with [{RhCl(CO)$_2$}$_2$] yields the complexes [RhCl(CO)$L_2$], in high yields, as slightly air-sensitive yellow solids. Despite the unusually high molecular masses of these complexes, they have been characterised by standard techniques.† The influence of the $C_6F_{13}$ units can be probed by a comparison of the $\nu$(CO) and $^1J$(RhP) data with that for the analogous triethyl- and triphenylphosphine complexes {$\nu$(CO): [RhCl(CO)(P$Et_3$)$_2$] 1953 cm$^{-1}$, [RhCl(CO)(P$Ph_3$)$_2$] 1961 cm$^{-1}$; $^1J$(RhP): [RhCl(CO)(P$Et_3$)$_2$] 116 Hz, [RhCl(CO)(P$Ph_3$)$_2$] 124 Hz}.[6] In both cases, although the $^1J$(RhP) values are very similar, $\nu$(CO) is significantly higher as a result of introducing the fluorous ponytails, suggesting that the electron-withdrawing capacity of the ponytails is removing electron density from the metal centres.

Crystals of [RhCl(CO){P($CH_2CH_2C_6F_{13}$)$_3$}$_2$], suitable for crystallographic characterisation, have been obtained by slow evaporation from perfluoro-1,3-dimethylcyclohexane solution (Fig. 1).‡ The $^1$H, $^{19}$F and $^{31}$P{$^1$H} NMR, IR and mass spectra of **1a** and **1b** are entirely consistent with this structure.† The metal coordination geometry is very similar to that obtained for a range of *trans*-square-planar complexes, [RhCl(CO)$L_2$] (L = monodentate phosphine) Rh–$P_{mean}$ 2.328 Å, Rh–$Cl_{mean}$ 2.386 Å, Rh–$C_{mean}$ 1.803 Å.[7] For **1a**, the Rh–P and Rh–Cl bond distances are shorter than these calculated mean values, but are not the shortest metal–ligand distances seen for this class of complex and are very similar to those reported for trisalkyl phosphine ligands, *e.g.* [RhCl(CO)(P$Me_3$)$_2$] (Rh–P 2.307, 2.310 Å; Rh–Cl 2.354 Å).[8] Although there are no unusual angles at phosphorus, there are two types of fluorinated tails. Two pairs on each phosphorus spiral, in a similar fashion to that observed for fully fluorinated hydrocarbons, above and below the Cl–Rh–CO axis in nearly planar 'rugby-post' arrangements. These sets of rugby-posts stack on top of each other in adjacent unit cells. The third, unique, ponytail on each phosphorus does not spiral but kinks, in the same direction, either above or below the Cl–Rh–CO axis into the space in the unit cell between adjacent sets of rugby-posts pointing, generally, away from any other fluorous part of the molecule.

We were interested to establish whether these complexes dissolve, without reaction, in fluorous solvents and have investigated the first coordination sphere at the metal centre in the solid-state and in fluorous solution by rhodium K-edge

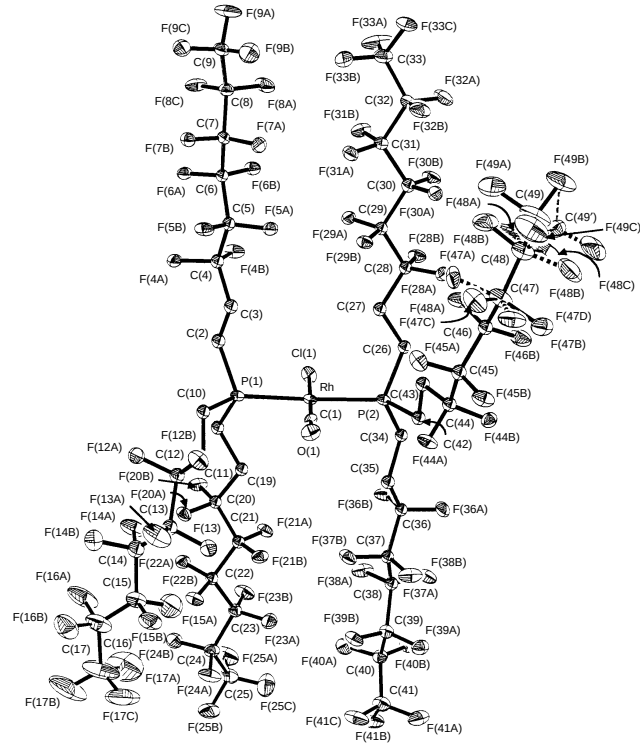

**Fig. 1** Molecular structure of **1a**. Selected interatomic distances (Å) and angles (°): Rh–P(1) 2.300(2), Rh–P(2) 2.304(2), Rh–Cl 2.356(2), Rh–C(1) 1.807(5), C(1)–O(1) 1.152(6), P(1)–C(2) 1.835(6), P(1)–C(10) 1.833(5), P(1)–C(18) 1.830(5), P(2)–C(26) 1.829(5), P(2)–C(34) 1.834(6), P(2)–C(42) 1.844(5), av. **Table 1** Metal-centred interatomic distances for **1a**[a]

| | X-Ray | Solid-state EXAFS[b] | | Solution EXAFS[c] | |
|---|---|---|---|---|---|
| | *d*/Å | *d*/Å | $2\sigma^2$/Å[d] | *d*/Å | $2\sigma^2$/Å[d] |
| Rh–P | 2.300(2), 2.304(2) | 2.300(1) | 0.005(1) | 2.301(2) | 0.010(1) |
| Rh–Cl | 2.356(2) | 2.360(9) | 0.016(1) | — | — |
| Rh–C | 1.807(5) | 1.787(4) | 0.004(1) | 1.792(6) | 0.008(1) |
| Rh···O | 2.959 | 2.929(6) | 0.016(1) | 2.912(5) | 0.013(1) |
| C–O | 1.152(6) | 1.142 | — | 1.120 | — |

[a] Standard deviation in parentheses. [b] Transmission EXAFS data collected on station 9 : 2 using a Si(220) monochromator for **1a** diluted with boron nitride and held between Sellotape strips. Note that the systematic errors in bond distances arising from the data collection and analysis procedures are *ca*. ±0.02 Å for the first coordination shells and *ca*. ±0.04 Å for subsequent shells. Fit index = $\Sigma_i[\chi^T \circledcirc \chi^E)k_i^3]^2$ = 0.380. $R$ = $[\int(\chi^T \circledcirc \chi^E)k^3 dk / \int\chi^E k^3 dk]$ = 23.0% [c] Transmission EXAFS data for a *ca*. 0.013 mol dm$^{\circledcirc 3}$ solution of **1a** in perfluoro-1,3-dimethylcyclohexane in a flattened FEP (perfluoroethylene–propylene copolymer) tube.[10] The poorer data quality did not allow for the distinction between the Rh–P and Rh–Cl shells. The fit given here is for a single shell of 3 P atoms. Fit index = $\Sigma_i[(\chi^T \circledcirc \chi^E)k_i^3]^2$ = 0.580. $R$ = $[\int(\chi^T \circledcirc \chi^E)k^3 dk / \int\chi^E k^3 dk]$ = 22.6%. [d] Debye–Waller factor.

EXAFS (Table 1). The data, analysed by standard procedures,[9,10] clearly indicate that these complexes dissolve without reaction in fluorous solvents and that the active sites of fluorous soluble metal catalysts could be probed in this way; the active sites of hydrocarbon soluble metal catalysts have been probed, under catalytic conditions, by EXAFS.[9] Further work on the coordination chemistry of these, and related, ligands and the catalytic activity of these metal complexes under the FBS regime is underway.

We would like to thank the EPSRC (D. R. P., A. M. S. and M. J. P.), the Royal Society (E. G. H.) and BP Chemicals Ltd (D. R. P. and M. J. P.) for financial support. We would also like to thank Dr M. Jones (BP Chemicals Ltd.) for helpful discussions, Dr I. Horváth for the gift of some $P(C_2H_4C_6F_{13})_3$ (D. J. C. H. and M. J. P.), the Director of the Daresbury laboratory for the provision of facilities and the EPSRC for the provision of low-temperature crystallographic facilities.

‡ *Crystal data* for **1a**: $C_{49}H_{24}ClF_{78}OP_2Rh$, *M* = 2310.98, triclinic, space group $P\bar{1}$, *a* = 11.205(9), *b* = 15.062(4), *c* = 22.506(5) Å, $\alpha$ = 84.70(2), $\beta$ = 86.23(4), $\gamma$ = 79.93(2)°, *U* = 3719(3) Å$^3$, *Z* = 2, $D_c$ = 2.064 Mg m$^{\circledcirc 3}$, *F*(000) = 2240, $\mu$(Mo-K$\alpha$) = 0.815 mm$^{\circledcirc 1}$, crystal dimensions 0.71 $\circledcirc$ 0.40 $\circledcirc$ 0.12 mm. Accurate unit-cell dimensions were determined by least-squares refinement of 37 centred reflections with 2.53 < $\theta$ < 12.5°. Data were measured on a Siemens P4 diffractometer at 150 K with Mo-K$\alpha$ radiation using $\omega$-scans. 15 371 reflections were measured with $\theta$ < 25° and $\circledcirc$ 1 ◀ *h* ◀ 12, $\circledcirc$ 17 ◀ *k* ◀ 17, $\circledcirc$ 26 ◀ *l* ◀ 26. The reflections were corrected for Lorentz and polarisation effects and merged to give 11 855 independent reflections ($R_{int}$ = 0.0188). An analytical absorption correction was applied to the data ($T_{max}$, $T_{min}$ = 0.88, 0.65, respectively). The structure was solved by direct methods using the program SHELXTL-PC. The terminal atoms of one of the chains were found to be disordered with the atoms having 60 : 40 occupancy over two sites. All hydrogen atoms were included in calculated positions (C–H 0.96 Å) with isotropic displacement parameters set to 1.2 $U_{eq}$ of the bonded C atom. The first six carbon atoms of each chain were refined with isotropic displacement parameters and all other atoms were refined with anisotropic thermal parameters. Final cycles of refinement with full-matrix least squares on $F^2$ gave $R_1$ = 0.0560, $wR_2$ = 0.1287. The maximum and minimum residual electron densities in the final $\Delta F$ map were 1.686 and $\circledcirc$ 0.571 e Å$^{\circledcirc 3}$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallograpic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/459.

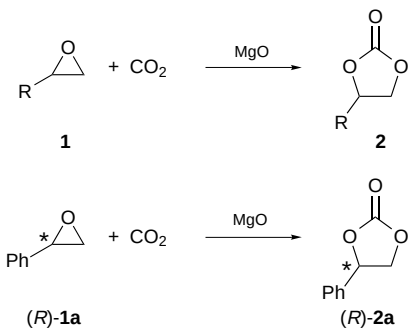
# Magnesium oxide-catalysed reaction of carbon dioxide with an epoxide with retention of stereochemistry

**Takashi Yano,[a] Hideo Matsui,[a] Takahiro Koike,[a] Hiroyasu Ishiguro,[a] Hisashi Fujihara,[b] Masakuni Yoshihara*[a] and Toshihisa Maeshima[a]**



[a] *Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Kowakae, Higashi-Osaka 577, Japan*
[b] *Environmental Science Research Institute, Kinki University, Kowakae, Higashi-Osaka 577, Japan*

**Magnesium oxide is an efficient catalyst for the cycloaddition of carbon dioxide to epoxides under mild conditions; the reaction of carbon dioxide with (*R*)-styrene oxide in the presence of magnesium oxide gives (*R*)-phenyl carbonate in 97% ee with retention of stereochemistry.**

Carbon dioxide fixation has recently received much attention owing to environmental concerns and the reaction of carbon dioxide with epoxides has been of interest as a useful catalytic fixation method.[1]

The synthesis of organic compounds using metal oxides as catalysts is also of considerable current interest. For example, magnesium oxide possesses both acid and base surface sites, and many of the catalytic applications of magnesium oxide are based on the principle of acid–base catalysis. Several reports on the adsorption of carbon dioxide on the surface of magnesium oxide prompted us to develop a new method for its fixation using the metal oxide,[2] although magnesium oxide has not been used as a catalyst for the conversion of carbon dioxide. We have now found that the reaction of carbon dioxide with epoxide is promoted by the addition of magnesium oxide as a catalyst under atmospheric pressure. Here we present a novel method for the fixation of carbon dioxide by metal oxide together with the stereochemistry of the carboxylation of epoxide with carbon dioxide in the presence of magnesium oxide.

Preliminary carboxylation studies were carried out using styrene oxide **1a** as a model compound (Scheme 1). A typical experimental procedure for the carboxylation of epoxide with carbon dioxide is as follows. Magnesium oxide (0.4 g) was added to a solution of epoxide **1a** (10 mmol) in *N*,*N*-dimethylformamide (DMF, 3 ml) in a pressure bottle under a $CO_2$ atmosphere.† The mixture was heated at 135 °C for 12 h and then filtered. The magnesium oxide was washed with acetone and the filtrates were combined. The solvents were removed under reduced pressure and the crude product was chromatographed on silica gel to give the corresponding cyclic carbonate **2a**. The product was analysed by NMR, IR and MS spectroscopy and microanalysis and the results are shown in Table 1.

**Scheme 1**

The reaction of **1a** with carbon dioxide in the presence of uncalcined magnesium oxide led to the formation of phenyl carbonate **2a** in 47% yield (Table 1, entry 1). Magnesium oxide was found to be effective in the carboxylation of epoxide with carbon dioxide. An analogous result was obtained by using the calcined magnesium oxide at 300 °C (entry 2). When calcined magnesium oxide at 400 °C was used for the reaction, the yield of the carbonate **2a** was somewhat increased (entry 3). The carbon dioxide incorporation into the epoxide ring was further examined for a few epoxides (Table 1, entries 4 and 5). The aliphatic terminal epoxides afforded the corresponding cyclic carbonates in good yields. This is, to the best of our knowledge, the first example of the activation of carbon dioxide using magnesium oxide.

The yield of the carbonate **2a** in the reaction of **1a** with carbon dioxide was increased by increasing amount of magnesium oxide (Fig. 1).‡ On the other hand, the carbon dioxide pressure had no effect on the yield of the carbonate **2a**, as shown in Fig. 2, although it has been reported that the epoxide–$CO_2$ reaction required a high pressure of carbon dioxide.[1]

**Table 1** MgO catalysed carboxylation of epoxides **1** with $CO_2$[a]

| Entry | Epoxide **1** | R | Calcination temp./°C[b] | Yield of **2** (%) |
|---|---|---|---|---|
| 1 | **a** | Ph | —[c] | 47 |
| 2 | **a** | Ph | 300 | 49 |
| 3 | **a** | Ph | 400 | 60 |
| 4 | **b** | Me | 400 | 41 |
| 5 | **c** | Et | 400 | 72 |

[a] Reaction conditions: MgO (0.4 g), $CO_2$ pressure 20 kg cm$^{-2}$, epoxide (10 mmol), DMF (3 ml), 135 °C, 12 h. [b] MgO was calcined for 3 h. [c] Uncalcined MgO.

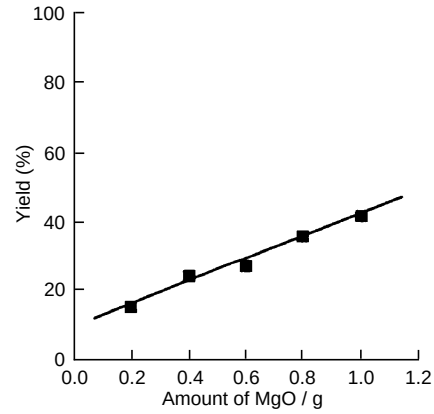


**Fig. 1** Relationship between the yield of phenyl carbonate **2a** and the amount of MgO. The reaction was carried out with epoxide **1a** (5 mmol) in the presence of MgO in DMF (2 ml) under $CO_2$ (20 kg cm$^{-2}$) at 135 °C for 4 h.

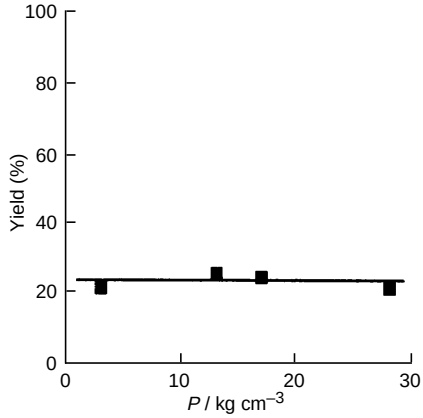
Interestingly, magnesium oxide controlled the stereochemistry of the epoxide, *i.e*. treatment of a chiral epoxide, (*R*)-**1a**, with carbon dioxide in the presence of magnesium oxide gave (*R*)-(⍯)-phenyl carbonate, (*R*)-**2a**, in 63% chemical yield with 99% ee (Scheme 1).§ The absolute configuration of this compound was *R*, as deduced from (*R*)-(⍯)-1-phenylethane-1,2-diol which was obtained from the hydrolysis of (*R*)-**2a** with 1 M NaOH.¶ Thus the carboxylation proceeded with retention of the epoxide configuration. We thus propose the following mechanism (Scheme 2). Carbon dioxide and the epoxide are adsorbed on MgO to form the complex **3** and then the carboxylate anion of **3** attacks the *β*-carbon atom of the epoxide to generate the oxy anion of **4**, which subsequently attacks the carbonyl group of **4** to afford the cyclic carbonate **2**.



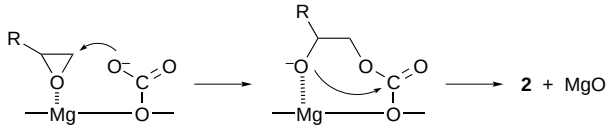


**Fig. 2** Relationship between the yield of phenyl carbonate **2a** and the pressure of $CO_2$. The reaction was carried out with epoxide **1a** (5 mmol) in the presence of MgO (0.4 g) in DMF (2 ml) under $CO_2$ at 135 °C for 4 h.

**A novel charge-transfer complex, $[4\text{-DMSP}]_4[NH_2Me_2]_2HSiFeMo_{11}O_{40}\cdot 3H_2O$ 1 {4-[DMSP]I = 4[*p*-(dimethylamino)styryl]pyridine methiodide} prepared and crystallized in a non-centrosymmetric (space group *P*1) structure, exhibits second harmonic generation (SHG) of 1064 nm radiation with an efficiency 1.2 times that of $KH_2PO_4$ under the same conditions.**

Non-linear optical (NLO) materials have attracted great interest in recent years, for their wide range of applications in laser technology, telecommunications, data storage and optical switches.[1–6] Most investigations, so far, have concentrated on inorganic crystals, organometallic compounds, organic molecules and polymers with delocalized $\pi$-electron systems.[7–15] It is known that there are three main factors influencing the magnitude of second harmonic generation, namely, (*a*) the presence of electron donor and acceptor groups in the molecule, (*b*) the nature and relative position of the groups and their ability to promote charge-transfer transitions between them and (*c*) extension of the conjugated path through which electrons are transferred under the influence of electric fields.

According to the concepts of 'molecular self-organization' and 'molecular engineering', we have designed and synthesized a new type of charge-transfer compound. We chose a hemicyanine dye as the organic cation, which contains electron donor and acceptor groups and possesses large SHG efficiency.[16,17] Since SHG is only observed in acentric materials, a simple way to meet this condition is to use molecules that can crystallize in accentric space groups. We selected Keggin structure heteropolyanions $XM_{12}O_{40}$ (X = P, Si; M = Mo, W) as electron acceptors, as $XO_4$ in the polyanions has $T_d$ symmetry and readily accepts electrons.[18] By using this method, a non-centrosymmetric molecular material is obtained when [4-DMSP]I and $[NBu_4]_4KH_2SiFeMo_{11}O_{40}$ are reacted. The procedure of design of such NLO molecular materials can be expressed by eqn. (1).

$$[\text{donor}\text{–}\pi\text{–acceptor}]^{+}{}_n[\text{polyanion}]^{n\ominus} \underset{h\nu_2}{\overset{h\nu_1}{\rightleftharpoons}} [\text{donor}\text{–}\pi\text{–acceptor}]^{1+\delta}{}_n[\text{polyanion}]^{n(1+\delta)\ominus} \quad (1)$$

In this work, we synthesized the charge-transfer salt $[4\text{-DMSP}]_4[NH_2Me_2]_2HSiFeMo_{11}\cdot 3H_2O$ **1**, and determined its SHG and crystal structure.

The determination of the second harmonic intensity of powdered samples (Kurtz powder test) was made relative to that of powdered $KH_2PO_4$. A pulse Q-switched Nd : YAG laser with a pulse (width 60 ps, repetition 1 Hz) of energy 1 mJ at a wavelength of 1064 nm was used to generate an SHG signal from the sample. The backward scattered SHG light was collected using a spherical concave mirror and passed through a filter which transmits only 532 nm radiation. Boxcar gate sampling was used to provide data points averaged over ten pulses and the mean of ten of these points provided the quoted values of relative harmonic intensity for second harmonic generation.

The electronic spectra of **1** [4-DMSP]I and $[NBu_4]_4KH_2SiFeMo_{11}O_{40}$ (*ca.* $1 \times 10^{-3}$ M) are shown in Fig. 1. Neither the cation $4\text{-DMSP}^+$ nor $[NBu_4]_4KH_2SiFeMo_{11}O_{40}$ show any absorption in the range 600–1100 nm. However, **1** shows a broad absorption in this range, and a weak absorption at *ca.* 1000 nm, which suggests the presence of a strong charge-transfer interaction between the polyanion and the organic cation and explains the source of second harmonic generation.

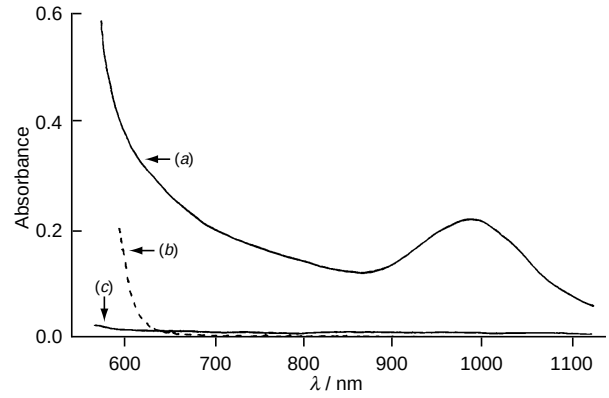

**Fig. 1** Comparison of the electronic spectra of [4-DMSP]I, $[NBu_4]_4KH_2SiFeMo_{11}O_{40}$ and **1** in dmf; (*a*) **1**, (*b*) [4-DMSP]I, (*c*) $[NBu_4]_4KH_2SiFeMo_{11}O_{40}$. All spectra were obtained for $1 \times 10^{-3}$ M solutions at 15 °C.

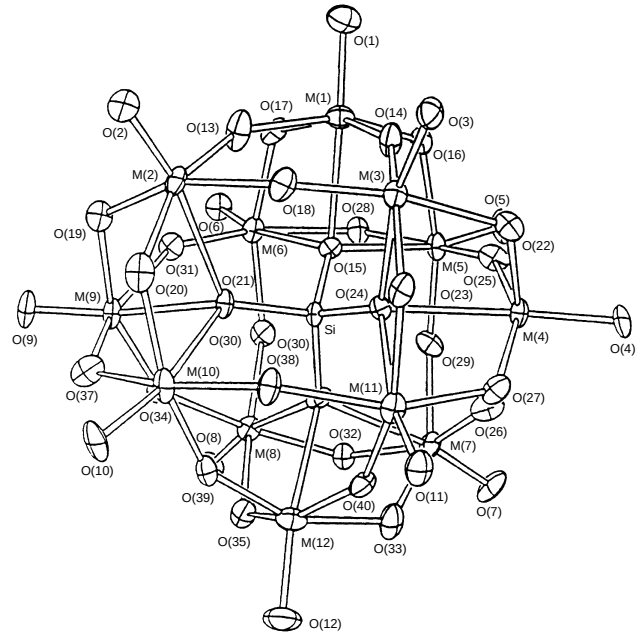

**Fig. 2** ORTEP of the polyoxoanion $[SiFeMo_{11}O_{40}]^{7-}$, showing 30% thermal elipsoids; M represents Fe or Mo (SOF = 11/12 for Mo and 1/12 for Fe at each M atom). Average bond distances (Å) for the polyoxoanion: Si–$O_a$ (central) 1.612(3), M–$O_a$ 2.357(3), M–$O_t$ (terminal) 1.673(3), M–$O_b$ (bridging) 1.871(3).

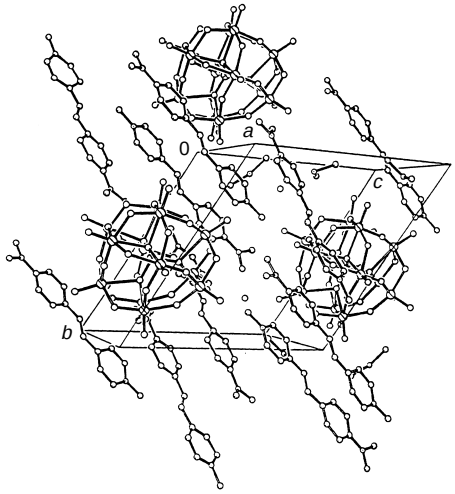

**Fig. 3** Crystal packing of **1** viewed down the *a* axis

The X-ray crystal structure analysis indicates that **1** crystallizes in the space group $P\bar{1}$, and the molecular structure is shown in Fig. 2, with the molecule packing diagram shown in Fig. 3. The shortest contacts between the polyanion and organic cation are C(16)···O(4) 3.056(3) Å and C(49)···O(5) 2.963(3) Å, respectively, indicating the presence of strong hydrogen bonding. This means that there is an interaction between the polyanion and the organic substrate, leading to partial charge transfer.

A significant new result from the work is that the design and synthesis of a new type of charge-transfer salt from the view point of molecular engineering has led to a material which possesses a larger SHG than $KH_2PO_4$ and is the most efficient than that we have ever reported.[19] However, the SHG is lower than that reported for some transition-metal complexes.[20] The above result shows that a new system showing non-linear optical properties is found and we expect enhanced properties if the polyoxometalates are mixed valence species.[21]

We thank Associate Professor Z.-G. Cai for the SHG measurement. Our thanks are also given to the State Science and Technology Commision and the National Nature Science Foundation of China.

## Footnotes

† Complex **1** was prepared by reacting 139.4 mg (0.5 mmol) of $[NBu_4]_4KH_2SiFeMo_{11}O_{40}$[22] dissolved in 20 ml of acetonitrile with 915.6 mg (2.5 mmol) of [4-DMSP]I. A suitable red prism crystal obtained from dmf was investigated by single-crystal X-ray diffraction.

‡ *Crystal data* for $C_{68}H_{97}FeMo_{11}N_{10}O_{43}Si$, triclinic, space group $P\bar{1}$, $a$ = 13.647(3), $b$ = 14.877(2), $c$ = 15.279(2) Å, $\alpha$ = 105.53(1), $\beta$ = 108.71(2), $\gamma$ = 111.35(2)°, $U$ = 2462.7(6) Å$^3$, $Z$ = 1. A red prismatic crystal with dimensions of 0.32 × 0.28 × 0.22 mm was mounted on a glass fibre. The intensities were collected at 291 K on a Siemens P4 four-circle diffractometer with monochromated Mo-K$\alpha$ ($\lambda$ = 0.710 73 Å) radiation using the $\theta$–2$\theta$ scan mode with a variable scan speed 5.0–50.0° min$^{-1}$ in $\omega$. The data were corrected for Lorentz and polarization effects during data reduction using XSCANS. The structure was solved by direct methods and refined on $F^2$ by full-matrix least-squares methods using SHELXTL (version 5.0). The two $NH_2Me_2^+$ ions are disordered [site occupancy factor (SOF) is 1/2 for N(10), C(68) and N(11), C(69), C(70), respectively]. In the polyanion structure, the positions of Fe and Mo atom can not be indentified; M represents Fe or Mo (SOF = 11/12 for Mo, and 1/12 for Fe at each M atom). All the non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were placed in caculated positions (C–H 0.96 Å) assigned fixed isotropic thermal parameters at 1.2 times the equivalent isotropic $U$ of the atoms to which they are attached (1.5 times for the methyl groups) and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factor calculations. Structure solution and refinement based on 12 255 reflections and 1234 parameters gave $R_1$ = 0.0667. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/465.

# Conversion of alkenes and alcohols to azides over zeolite-supported sodium azide

**R. Sreekumar,*[a] R. Padmakumar[b] and P. Rugmini[b]**

[a] *Department of Physiology, University of Wisconsin, Madison, USA*
[b] *Department of Chemistry and Biochemistry, University of Nebraska, Lincoln, USA*

**Zeolite-supported sodium azide reagents are versatile catalysts for the conversion of various alkenes and alcohols to the corresponding azides in good yield under mild conditions.**

Azides are important precursors of nitrenes or amino compounds and belong to a large family of 1,3-dipoles which undergo cycloaddition to alkenes.[1] While aromatic azides can be obtained by a variety of methods, aliphatic azides are mainly prepared by substitution of alkyl halides, diazo transfer to aliphatic amines or additions to alkenes.[2] In recent years there have been several reports on the use of zeolites for selective organic transformations leading to the synthesis of various fine chemicals.[3–5] Here we report a convenient heterogeneous catalytic methodology for the conversion of alkenes and alcohols to the corresponding azides over zeolite-supported sodium azide reagents (Table 1).

The alkenes and alcohols were purchased from Aldrich and Fluka Chemical Co. and the zeolites (Y-Zeolite, EMT, ZSM-5 and Zeolite beta) were synthesized according to the reported procedure.[6] The Na-zeolites thus obtained were converted to H-zeolites by treatment with aqueous $NH_4Cl$ followed by filtration and activation at 450 °C for 12 h.

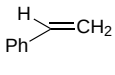
Zeolite-supported sodium azide reagents were prepared by dissolving $NaN_3$ (1 mmol) in 5 ml of deionized water in a 15 ml flask. About 0.75 g of Zeolite were then added and the mixture was stirred for 3 h at room temperature. The mixture was then filtered and washed several times with deionized water. Prior to use the zeolite supported reagents were further dried at 65 °C (5 Torr) for 2 h in a current of air.

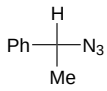
The loading amount of $NaN_3$ (*A* wt%) and the amount of residual water (*B* wt%) on a zeolite supported reagent were defined as shown in eqns. (1) and (2), where *z* is the weight

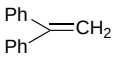
$$A = 100\ \{z / [z+(1-\alpha/100)y]\} \quad (1)$$

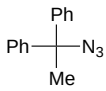
$$B = 100\{[W - W_o - z(1 - \alpha/100)y]/(W - W_o)\} \quad (2)$$

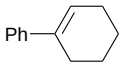
of $NaN_3$ supported, *y* is the weight of zeolite used, $\alpha$ is the wt% of physisorbed water in the zeolite, $W_o$ is the mass of the flask used for the preparation of the zeolite supported reagent and *W* is the mass of the flask containing the zeolite supported reagent after drying at 65 °C (5 Torr) for 2 h. The value of $\alpha$ was determined by thermogravimetric analysis of the zeolite-supported reagent in the temperature range of 30–250 °C. The zeolite supported reagent used for the present study contained 8 wt% loading of $NaN_3$ and 15 wt% of residual water. Zeolites consist of small uniform pores or channels and the exterior surface area of zeolite is only 0.5–2.0% of the total surface area.[7] Hence most of the supported $NaN_3$ seems to be finely dispersed inside the pores or channels of zeolite and interacts with water molecules or hydroxy groups on the surface of the zeolite. The role of the small amount of water associated with supported reagents and its reactivity has been discussed by Ando *et al.*[7] Probably the water molecules, as well as the hydroxy groups on the zeolite surface, coordinate to the dispersed $NaN_3$ to loosen the ion-pairing of $[Na^+\cdots N_3^-]$, leading to the enhancement in nucleophilicity of the azide anion.

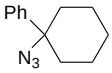


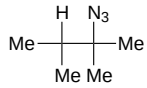


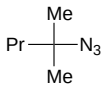


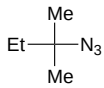


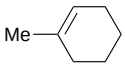


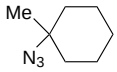


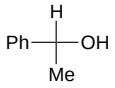


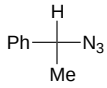


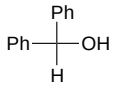


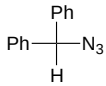


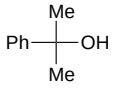


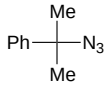


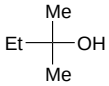


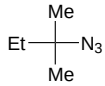


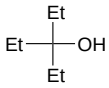


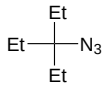












Azide ions ($N_3^-$) have strong and characteristic IR bands in the region of 2100 $cm^{-1}$ arising from the asymmetric stretching mode while the solid $NaN_3$ has a diagnostic absorption at 2130 $cm^{-1}$.[8] A 25 wt% $NaN_3$ supported zeolite reagent shows a new peak at 2065 $cm^{-1}$ in addition to the parent peak at 2130 $cm^{-1}$, whereas 8 wt% loaded samples have an absorption peak at only 2065 $cm^{-1}$ (Nujol mull). After zeolite-supported reagents (1 g) were treated with styrene (1 mmol) in the different solvents listed in Table 2 (10 ml) at 70 °C for 2 h, the supported reagents were analysed immediately by IR spectroscopy. It was found that the intensity of the peak at 2065 $cm^{-1}$ decreased dramatically compared with the peak at 2130 $cm^{-1}$ in 25 wt% $NaN_3$ supported zeolite reagents. In the case of 8 wt% loaded samples, the intensity of 2065 $cm^{-1}$ peak was very low. These results indicate that the azide ions showing the lower frequency peak of 2065 $cm^{-1}$ are much more reactive for the conversion of alkenes and alcohols to the corresponding azides than the azide ions which appeared at 2130 $cm^{-1}$. Hence, we speculate that the finely dispersed form of $NaN_3$ shows absorption at 2065 $cm^{-1}$ and the coagulated $NaN_3$ crystals exhibit absorption at 2130 $cm^{-1}$. Under the same reaction conditions, the low loading (8 wt%) samples show higher reactivity for the conversion of styrene to 1-azido-1-phenylethane (84%) compared to a 25 wt% loaded samples (42%). Hence in further studies 8 wt% $NaN_3$ supported zeolite reagents were used.

Initially the reactions were carried out in a flow reactor as reported elsewhere.[5] The styrene (1 mmol) dissolved in dry cyclohexane (20 ml) was introduced at the top of the reactor by means of an infusion pump (flow rate 20 ml $h^{-1}$). The liquid products were collected in a water-cooled receiver and the removal of cyclohexane did not furnish any product. The zeolite was removed from the reactor and extracted with 50 ml of methanol. Analysis of the methanol extract by GC (Hewlett Packard, 5890 Series II, gas chromatograph with a flame ionization detector, capillary column : OV-1, 25 m) showed only 29% conversion of styrene to 1-azido-1-phenylethane.

The experiments were then carried out in a magnetically stirred Teflon-lined autoclave equipped with a temperature controller. Styrene (1 mmol) dissolved in 10 ml of dry cyclohexane was added to a suspended mixture of HY-zeolite-supported $NaN_3$ (1 g) in cyclohexane (15 ml) and the mixture was stirred at 70 °C for 2 h under nitrogen atmosphere, after which it was filtered. The cyclohexane filtrate did not contain any dissolved matter. The product was extracted from the pores of the zeolite by washing with methanol (3 × 50 ml). Removal of methanol and further purification of the crude material by flash chromatography using an alumina column and $CH_2Cl_2$ as eluent furnished 84% of the corresponding azide. The recovered zeolite could be reused after $NaN_3$ treatment and activation.

Even in a heterogeneous reaction system where the zeolite supported $NaN_3$, a reactant and a solvent were mixed, the polarity of the solvent influenced the reaction rate to a significant extent. The extent of conversion of styrene and 1-phenylethanol to the corresponding azide in different solvents over HY-zeolite and HEMT supported reagents at 70 °C for 2 h was found to be in the order of cyclohexane > $C_6H_6$ > $CHCl_3$ > MeCN, and the results are summarized in Table 2. This could

be attributed to the stronger adsorbtion of solvent on the zeolite surface affecting (weakening) its acidic properties.

In order to compare homogeneous reagent systems with the zeolite-supported reagent system, styrene dissolved in aqueous methanol was treated with $NaN_3$ and unsupported HY-zeolite at 70 °C for 2 h and furnished 1-azido-1-phenylethane in low yield (14%); in the case of 1-phenylethanol the yield of the corresponding azide was only 12%. In a control experiment, triphenylmethanol (1 mmol), a molecule which cannot enter the pores of HZSM-5 due to its large size, was dissolved in 10 ml of dry cyclohexane and added to a suspention of zeolite-supported $NaN_3$ (1 g) in dry cyclohexane (15 ml). The reaction

| $C_6H_6$ | 69 (73) | 76 (67) |
| $CHCl_3$ | 42 (34) | 39 (30) |
| MeCN | 9 (5) | 11 (7) |

[a] $T$ = 70 °C, $t$ = 2h. [b] Yield of isolated pure product. [c] Yield of azide from 1-phenylethanol in parentheses.

mixture was stirred for 2 h at 70 °C and afforded the corresponding azide in 5% yield, while over HY-zeolite (a large pore zeolite)-supported reagent the yield of the azide was 68%. This result indicates that in zeolite-supported $NaN_3$ reagents most of the $NaN_3$ is located inside the pores, not on the outside surface of the zeolites. Silica gel and alumina mediated addition of $HN_3$ to alkenes has been studied in the past and attempts to add $HN_3$ to diphenylethene in the presence of a strong acid, such as sulfuric acid, led to considerable decomposition due to the susceptability of the resulting azide to protonation and Schmidt rearrangement.[9] The observed efficient performance of HY-zeolite may be attributed to its large pore openings (0.74 nm) and three dimensional channel system and the comparitively low yields of the desired products over HZSM-5 may be due to its small pore opening (0.56 nm).[7] Zeolite-supported sodium azide, when mediating the conversion of alkenes to the corresponding azides, furnished only the Markovnikoff product.

In summary, we have established a facile heterogeneous catalytic method for the conversion of alkenes and alcohols to the corresponding azides. The positive features of these inexpensive zeolites include stability, ease of handling, lack of corrosiveness and other environmental hazards and ease of separation of the product and regeneration of the catalyst.

R. S. thanks Professor C. N. Pillai, IIT, Madras and Professor J. Weitkamp, University of Stuttgart, Germany, for providing the facilities for the synthesis of zeolites.

# Fluorescent diaza crown ether sensitive to complexation, conformation and microenvironment

**Greg E. Collins* and Ling-Siu Choi**

*Naval Research Laboratory Chemistry Division, Code 6116 Washington DC 20375-5342, USA*

**A newly synthesized diaza crown ether, BPDC, demonstrates sensitivity to solvent polarity, microviscosity and metal complexation with spectroscopic changes in monomer and excimer fluorescence.**

In order to address the sensing challenges presented by complex, real-world matrices, we are designing new molecules tailored with fluorescent sidearms sensitive to the complexation, molecular conformation and microenvironment of the sensing molecule. Specifically, our interest is in the development of a metal sensing probe operable in ship bilge water, a matrix that contains heavy-metal ions in a complex and variable environment of surfactants, oils, and other contaminants. To study the nature of metal complexation in these environments, we synthesized a new, sensor molecule, *N*,*N*-bis(1-pyrenecarbonyl)-7,16-diaza 18-crown-6 (BPDC), designed to signal the sensitive complexation of heavy-metal ions, as well as respond spectroscopically to changes in its microenvironment. While bis-pyrene linked probes have been previously used for monitoring microviscosity,[1] metal ion concentration,[2] and organics,[3] this communication describes the response to all three of these variables together in a single probe.

BPDC

The vibronic fine structure of pyrene fluorescence is very sensitive to solvent polarity changes with changes in the ratio of $I_1/I_3$.[4] According to their protic or aprotic nature, solvents were classified into two, linear polarity scales by BPDC. Comparison of the $I_1/I_3$ ratios and Dimroth's $E_T$ values are shown in Fig. 1. The $E_T$ scale is an excellent measure of solvent polarity generated from the intramolecular charge-transfer band of Reichardt's dye.[5]

The ability of BPDC to form an intramolecular excimer provides additional insight into the conformation and microviscosity experienced by this sensor molecule. The intensity of excimer fluorescence, $I_e$, is correlated with the probability that an excited pyrene moiety can rotate to a position of close, parallel molecular contact with an unexcited pyrene neighbour prior to its own electronic, excited singlet state decay (as monomer fluorescence, $I_{monomer}$).[6] This probability is dependent on both (*i*) the conformation of the molecule in the solvent, a feature that is strongly linked to the solvent's relative permittivity $\varepsilon$, and (*ii*) the viscosity, $\gamma$, of the medium. A plot of the relative monomer emission, $I_m$ [$I_m = I_{monomer}/(I_{monomer}{}^{+}I_e)$], from BPDC *vs*. the product $\varepsilon\gamma$ for various protic and aprotic solvents is shown in Fig. 2. With the exception of *n*-hexane and *n*-heptane, the possibility of intermolecular excimer formation was precluded by sequential dilution of BPDC until no changes were evident in $I_m$.

Examining the aprotic solvents in Fig. 2, as the solvent changes from *n*-heptane to $CHCl_3$ [(*a*)–(*f*)] there is only a minor change in the viscosity. This indicates that it is the increase in relative permittivity which is primarily responsible for the increase in monomer emission. BPDC has very low solubility in solvents of low relative permittivity, *n*-hexane and *n*-heptane, owing to poor solvation of the crown ether backbone. Aggregation of BPDC could explain the smaller $I_m$ values apparent in these solvents. As the relative permittivity of the solvent increases, the solvent sheath formed about the crown ether backbone forces apart the two pyrene moieties. For solvents with $\varepsilon > 7$, both the crown ether backbone and pyrene linkages are effectively solvated and BPDC adopts a similar conformation with $I_m$ *ca.* 0.7.

For protic solvents, as the solvents progress from methanol to pentanol [Fig. 2(*i*)–(*m*)], the increase in viscosity causes the

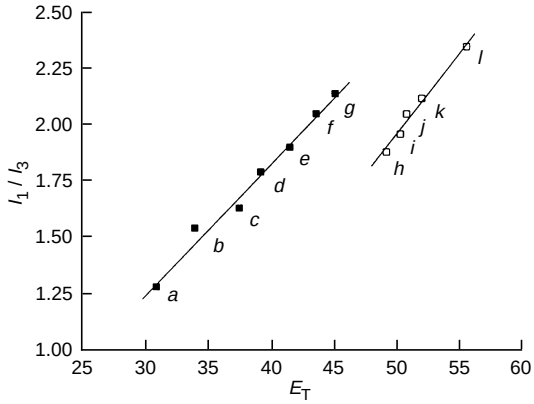

**Fig. 1** Plot of the intensity ratio $I_1/I_3$ from the emission of BPDC *vs*. Dimroth's $E_T$ values in various aprotic (■) and protic (□) solvents. Solvent: (*a*) *n*-hexane, (*b*) toluene, (*c*) THF, (*d*) $CHCl_3$, (*e*) $CH_2Cl_2$, (*f*) DMF, (*g*) $Me_2SO$, (*h*) *n*-pentanol, (*i*) *n*-butanol, (*j*) *n*-propanol, (*k*) ethanol, (*l*) methanol; [BPDC] = 2.9 μM.

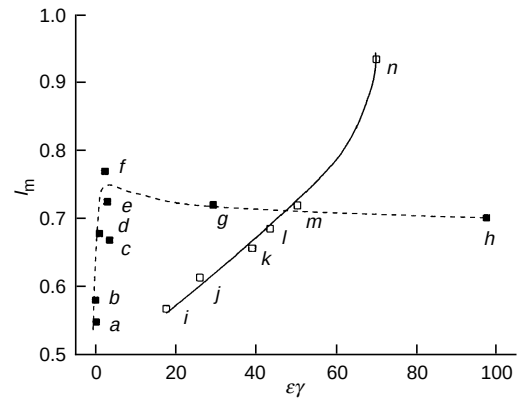

**Fig. 2** Plot of the relative monomer emission, $I_m$, from BPDC *vs*. the product of the relative permittivity ($\varepsilon$) and the viscosity ($\gamma$). Aprotic solvents (■): (*a*) *n*-heptane (*b*) *n*-hexane, (*c*) $CH_2Cl_2$, (*d*) toluene, (*e*) THF, (*f*) $CHCl_3$, (*g*) DMF, (*h*) $Me_2SO$; protic solvents (□): (*i*) methanol, (*j*) ethanol, (*k*) *n*-propanol, (*l*) *n*-butanol, (*m*) *n*-pentanol, (*n*) water; [BPDC] = 2.9 μM.

monomer emission to increase owing to a reduction in mobility of the pyrene appendages as well as an improvement in solvation of the pyrene groups. Water, because of its extremely high relative permittivity and hydrogen-bonding ability, leads to the highest monomer emission for BPDC. This result is in contrast to the majority of bis-pyrene molecules studied previously, which exhibit significant intramolecular excimer formation in water due to the hydrophobic interaction of the two pyrene appendages.[7,8] For BPDC, water is apparently so effective at stabilizing the crown ether backbone that the pyrene moieties are effectively isolated from one another due to hydrophobic repulsion.

In order to monitor the influence of metal complexation on the conformation of BPDC the $I_1/I_3$ ratio and $I_m$ parameters were additionally studied. From Fig. 3 it is evident that as [$Cu^{II}$] increases, there is a strong quenching of the emission due to a paramagnetic effect of the complexed metal ion.[9] It is interesting to note from the inset chart that both $I_1/I_3$ and $I_m$ decrease linearly with the increase in [$Cu^{II}$]. Fig. 2 indicates that

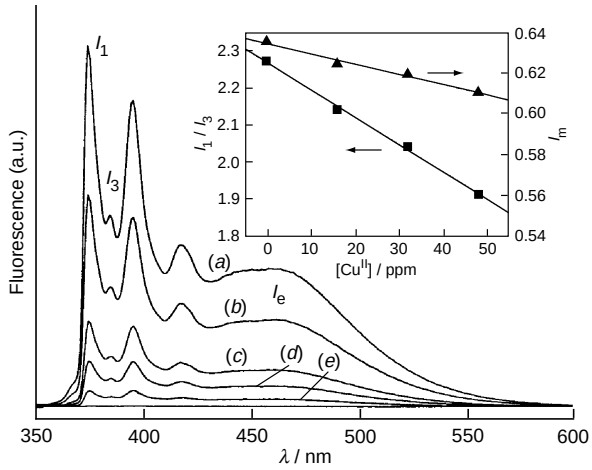

**Fig. 3** Fluorescence spectra recorded for BPDC in ethanol at different $CuCl_2$ concentrations. The inset chart graphs the change in $I_1/I_3$ and $I_m$ with the addition of $Cu^{II}$ metal ions in solution. [$CuCl_2$] in ppm = (*a*) 0, (*b*) 16, (*c*) 32, (*d*) 48, (*e*) 64, (*f*) 128; [BPDC] = 2.9 $\mu$M.

the two pyrene moieties of BPDC are preferentially oriented to one side of the crown ether backbone when dissolved in ethanol. As expected, complexation of a $Cu^{II}$ metal ion does not compete for binding on this side of the compound, but, instead, binds to the exposed, crown ether side. Distortion of the diaza crown ether binding sites for binding of the metal ion results in the two pyrene moieties being brought in closer proximity to each other, increasing intramolecular excimer formation. Similarly, the decrease seen in $I_1/I_3$ is indicative of the more non-polar environment encountered by the molecule due to the enhanced association of the two pyrene appendages on one side of the diaza crown ether.

In conclusion, the present study demonstrates that the introduction of bis-pyrene appendages to a metal complexing agent can be an important tool for understanding the complexation, conformation and microenvironment of the sensing molecule.

The authors gratefully acknowledge John H. Callahan and Mona Shahgholi for the mass spectroscopic identification of compound BPDC, and the Office of Naval Research for partial funding support of this study.

# A superoctahedral complex derived from a polyoxometalate: the hexakis(arylimido)hexamolybdate anion $[Mo_6(NAr)_6O_{13}H]^{2\ominus}$

**Joseph B. Strong,[a] Brian S. Haggerty,[b] Arnold L. Rheingold[b] and Eric A. Maatta*[a]**

[a] *Department of Chemistry, Kansas State University, Manhattan, Kansas 66506, USA*
[b] *Department of Chemistry, University of Delaware, Newark, Delaware 19716, USA*

**Reaction of $[Mo_6O_{19}]^{2\ominus}$ with an excess of 2,6-diisopropylphenyl isocyanate (ArNCO) affords the title anion in which the hexamolybdate framework serves as an octahedral nexus for six terminal arylimido ligands.**

The rich diversity of structure and function afforded by various polyoxometalate clusters[1] is evidenced by their relevance in areas ranging from catalysis to chemotherapy to molecular magnetism.[2] In many instances, the global symmetry of a polyoxometalate ion conforms to that present within its core: for example, the idealized $T_d$ symmetry of the Keggin phosphomolybdate $[Mo_{12}O_{40}P]^{3\ominus}$ mirrors that of its encapsulated tetrahedral $[PO_4]^{3\ominus}$ unit, while the idealized $O_h$ symmetry of the Lindquist hexamolybdate $[Mo_6O_{19}]^{2\ominus}$ reflects the octahedral environment surrounding its central $[O]^{2\ominus}$ core. We were intrigued by the prospect of exploiting the radiating $O_h$ symmetry of the hexamolybdate by using this anion as a nexus for the construction of a superoctahedral derivative. Although multiple functionalization of polyoxometalates has been achieved in the preparations of various organoimido derivatives of $[Mo_6O_{19}]^{2\ominus}$,[3] and in the highly functionalized *p*-tolylimido complex $[Mo_{10}(NC_6H_4Me\text{-}p)_{12}O_{18}(py)_2]$,[4] a complete derivatization which maintained the global symmetry of the polyoxometalate parent had not been realized. Here we establish that the hexamolybdate ion can serve as an octahedrally directing template for the incorporation of six terminal arylimido ligands along the Cartesian axes of its framework.

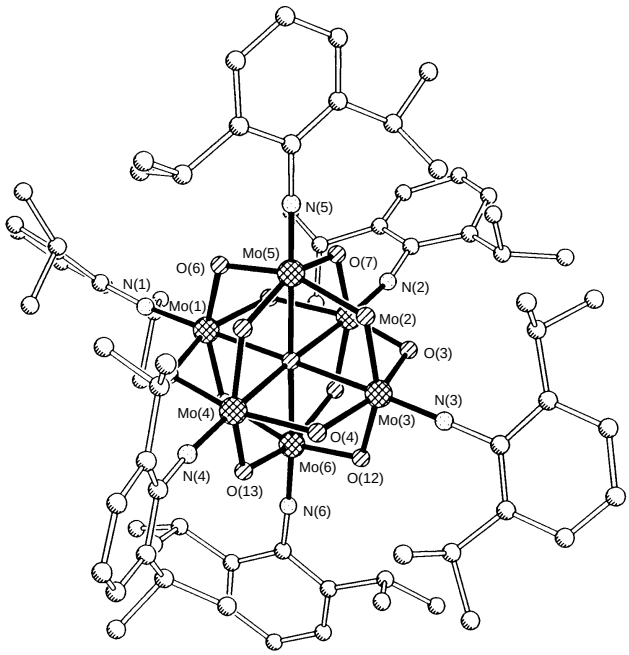

**Fig. 1** Structure of the $[Mo_6(NAr)_6O_{13}H]^{2\ominus}$ anion of **1**. Selected bond lengths (Å) and angles (°): Mo(1)–N(1) 1.725(10), Mo(2)–N(2) 1.737(14), Mo(3)–N(3) 1.742(11), Mo(4)–N(4) 1.727(14), Mo(5)–N(5) 1.755(10), Mo(6)–N(6) 1.734(10), Mo(1)–N(1)–C(6) 172.7(9), Mo(2)–N(2)–C(18) 170.5(9), Mo(3)–N(3)–C(30) 176.6(10), Mo(4)–N(4)–C(42) 171.0(10), Mo(5)–N(5)–C(54) 175.0(12), Mo(6)–N(6)–C(66) 176.4(12).

Reaction of $[NBu_4]_2[Mo_6O_{19}]$ with a twenty-fold molar excess of 2,6-diisopropylphenyl isocyanate (ArNCO) in refluxing pyridine for three weeks occurs with the evolution of $CO_2$ and the development of a dark orange–red solution. After removal of volatiles under vacuum and washing the residue with ether (in which some of the product dissolves), a red solid was obtained. Fractional crystallization ($CH_2Cl_2$–$Et_2O$) led to the initial separation of crystalline $[NBu_4]_2[Mo_6O_{14}(NAr)_5]$;[3a] the remaining mother-liquor was concentrated and additional ether vapour was admitted causing the growth of dark red crystals of $[NBu_4][Mo_6(NAr)_6O_{13}H]$ **1**, as the monoetherate in *ca.* 20% yield.† At room temperature, a single arylimido environment is seen in the $^1$H NMR spectrum of the complex. The incorporation of a proton into the hexamolybdate framework of **1** is without precedent among complexes derived from the $[Mo_6O_{19}]^{2\ominus}$ system and testifies to the greatly enhanced electron donation provided by the arylimido ligand set. Although no $^1$H NMR resonance for the bound proton was observed in either $CD_3CN$ or $CDCl_3$ solution, a band at 3550 $cm^{\ominus 1}$ in the IR spectrum of **1** corroborates its presence; the most likely source of the proton is through reaction with adventitious water. The IR spectrum is devoid of bands assignable as $\nu$(Mo≡O) in the 900–1000 $cm^{\ominus 1}$ region, containing only a single medium intensity absorption at 995 $cm^{\ominus 1}$, which may be associated with the Mo≡NAr units.

The molecular structure of the $[Mo_6(NAr)_6O_{13}H]^{2\ominus}$ anion as determined by single-crystal X-ray diffraction is shown in Fig. 1.‡ Six terminal arylimido ligands radiate from the octahedral $Mo_6$ core; the distance between opposed *para*-aryl carbon atoms averages 1.634 nm. The six Mo–N bond lengths span the range 1.725(10)–1.755(10) Å, and the associated Mo–N–C angles are all essentially linear [170.5(9)–176.6(10)°]. Comparison of the metrical data for the $\{Mo_6O_{13}\}$ core within **1** to that within the $[Mo_6O_{19}]^{2\ominus}$ parent reveals little perturbation as a result of the introduction of the six arylimido ligands: in **1**, the distances from the central O(1) atom to the surrounding set of six Mo atoms average 2.313(9) Å, while in the hexamolybdate the corresponding average is 2.319(4) Å.[5] Similarly, the Mo–O distances involving the $\mu$-O atoms of **1** span the range 1.903(7)–2.019(8) Å, while in $[Mo_6O_{19}]^{2\ominus}$ analogous bond lengths range from 1.855(4) to 2.005(4) Å. Scrutiny of the metrical parameters of **1** reveals no evidence for the localization of the proton; most likely, it is disordered over the twelve $\mu$-O atoms in the solid state.

We propose that in solution the proton undergoes rapid exchange throughout the set of $\mu$-O atoms, thus accounting for both its non-observance and the equivalence of the six arylimido ligand environments in the $^1$H NMR spectrum of **1**. A possible low-energy pathway for such a proton exchange can be visualized in the alternate view of the anion structure provided in Fig. 2, in which the isopropyl methyl groups have been omitted for clarity. Each particular $\mu$-O atom can be seen to be have four nearest-neighbour oxygen atoms which, in combination, define two trigonal faces of the superoctahedron. These $O_b\cdots O_b$ separations within the anion average 2.70 Å, a value

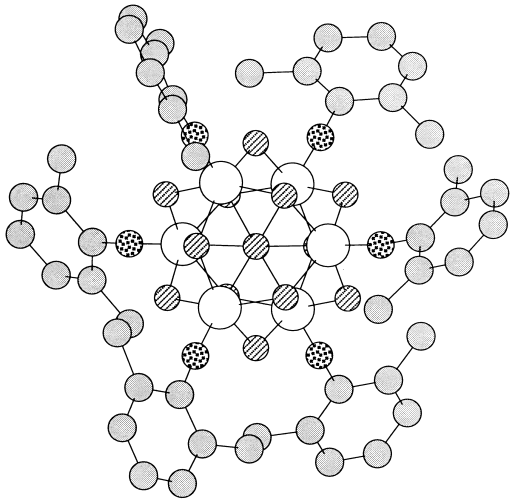

**Fig. 2** Alternate view of the $[Mo_6(NAr)_6O_{13}H]^{\ominus}$ anion emphasizing the $\{Mo_6O_{13}\}$ core

which is reminiscent of the corresponding 2.76 Å separation within ice[6] and which can enable facile proton migration *via* O–H···O interchanges.

If the superoctahedral derivatization of the hexamolybdate described herein can be replicated with organoimido ligands whose substituents bear appropriate remote functionality,[3c,7] then we can anticipate the designed construction of extended three-dimensional networks of tunable porosity; such systems are currently being explored.

We thank the Office of Basic Energy Sciences, Department of Energy (USA) for support of this work.

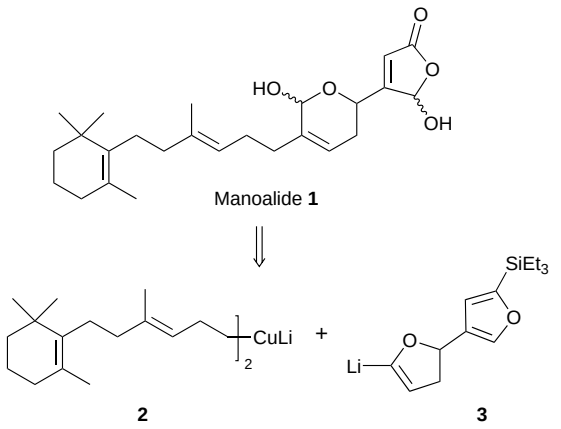
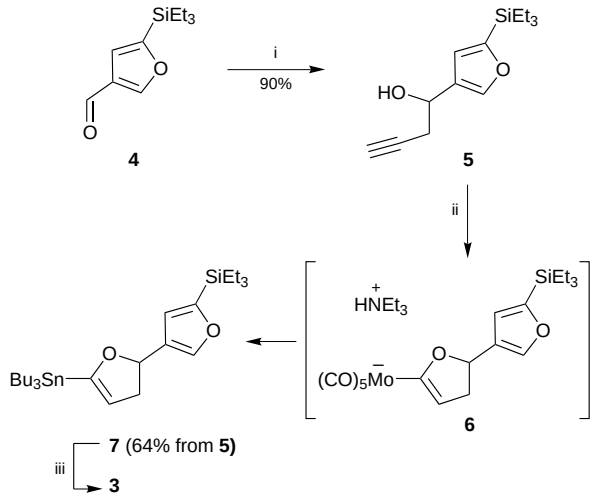
# Synthesis of manoalide using a 1,2-metallate rearrangement



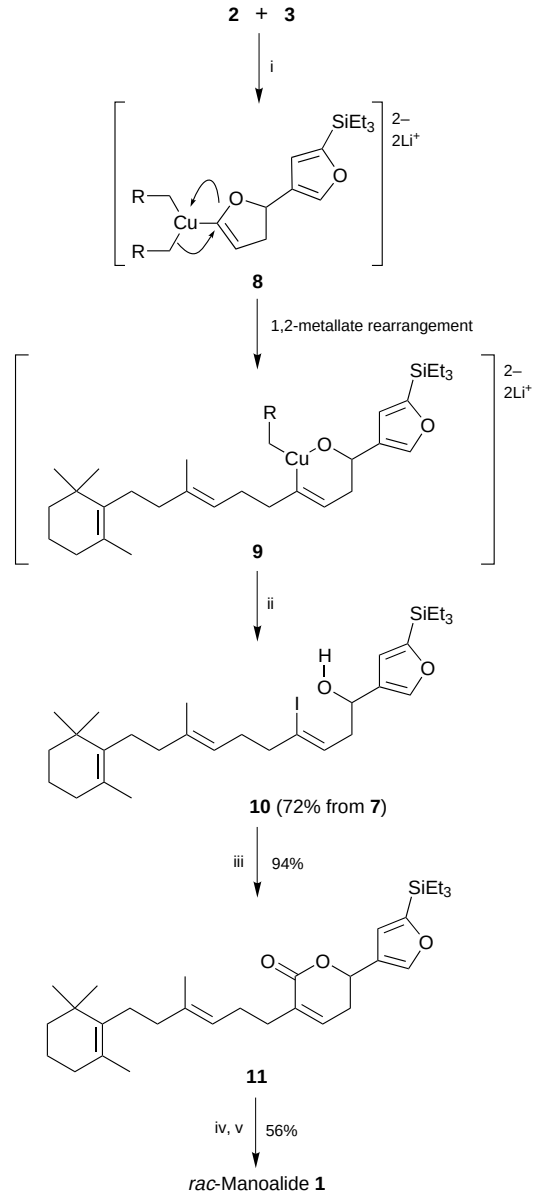
**Agnès Pommier and Philip J. Kocieński***

*Department of Chemistry, University of Glasgow, Glasgow, UK G12 8QQ*



**Manoalide, a marine antiinflammatory sesterterpenoid, has been synthesised using a 1,2-metallate rearrangement of a higher order cuprate and a $Pd^0$-catalysed carbonylation of an iodo alkene to generate the central dihydropyranone ring.**

Manoalide **1** is a sesterterpenoid metabolite isolated from the Pacific sponge *Luffariella variablis*.[1] As a potent inhibitor of phospholipase $A_2$, it has been evaluated in phase II clinical trials for the treatment of psoriasis.[2] We now report a short synthesis of racemic manoalide from the homocuprate **2** and lithiated dihydrofuran **3** (Scheme 1) which features the use of a 1,2-metallate rearrangement of a higher order cuprate and a $Pd^0$-catalysed carbonylation of an iodo alkene to generate the central dihydropyranone ring.



The lithiated dihydrofuran **3** was prepared as shown in Scheme 2. Addition of prop-2-ynylmagnesium bromide to 5-triethylsilyl-3-furaldehyde **4**† gave the homoprop-2-ynylic alcohol **5** in 90% yield. The Fischer carbene complex generated by electrophilic cyclisation of **5** with $(CO)_5Mo{\cdot}NEt_3$‡ was converted *in situ* to the alkenylstannane **7** in the presence of $Bu_3SnOTf$ according to the procedure of McDonald *et al.*[3] (64% overall from **5**). Transmetallation of the alkenylstannane to the desired alkenyllithium **3** was plagued by competing metallation at the 2-position of the furan ring and success was only achieved after a protracted study of the reaction conditions. Clean transmetallation was eventually accomplished with $Bu^sLi$

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, prop-2-ynylmagnesium bromide, $Et_2O$, ② 40 °C → room temp.; ii, $(CO)_5Mo{\cdot}NEt_3$, $Bu_3SnOTf$, $Et_2O$–$Et_3N$, room temp., 48 h; iii, $Bu^sLi$, $Et_2O$–pentane, ② 60 °C, 20 min

**Scheme 3** *Reagents and conditions*: i, add a solution of **3** in $Et_2O$–pentane to a solution of **2** in $Et_2O$–$Me_2S$ (1 : 1) at ② 40 °C; ii, $I_2$ (4 equiv.), ② 30 °C; iii, $Pd(PPh_3)_4$, $Pr^i_2NEt$, THF–MeOH, CO (2 atm), 60 °C, 24 h; iv, DIBAL-H, $CH_2Cl_2$, ② 80 °C; v, $O_2$, h$\nu$, rose bengal, MeOH, ② 80 °C

in a diethyl ether–pentane mixture at ② 60 °C for 20 min and the lithium reagent **3** used immediately in the next step.

The key step in our synthesis involved a 1,2-metallate rearrangement[4] of the higher order cuprate **8** derived from addition of alkenyllithium **3** to the lower order homocuprate **2**§ which occurred with clean inversion of configuration to give the alkenylcuprate **9** (Scheme 3). Attempts to carboxylate **9** with $CO_2$ in the presence of triethyl phosphite[5]—a ploy which had been successful in our synthesis of the related terpenoid luffariolide E[6,7]—failed to give any of the desired lactone **11**. We therefore quenched the alkenylcuprate **9** with iodine at ② 30 °C to give iodo alkene **10** in 72% overall yield from **7**, and then introduced the remaining carbon (94% yield) by $Pd^0$-catalysed carbonylation using a modification of conditions previously described by Heck.[8] Finally, reduction of the lactone to the lactol with DIBAL-H (94%) and photooxidation of the silylfuran (60%)[9] gave manoalide, identical by high field NMR spectroscopy ($^1H$ and $^{13}C$) and mass spectrometry with a sample prepared previously and correlated with the natural product.[10]

The synthesis of racemic manoalide reported herein was accomplished in a total of 12 steps (4% overall) from commercially available *β*-ionone and 3-furaldehyde. The discovery of conditions for transmetallating stannyldihydrofuran **6** without competing metallation of the furan was a crucial advance. Another tactical advance was the iodination of the metallate rearrangement product **10** which provided a clean, efficient and highly stereoselective route to the (*Z*)-iodo alkene **11**, itself a useful precursor to a wide range of trisubstitued alkenes. The overall yield of our synthesis compares favourably with previous syntheses.[10–14]

We thank the EPSRC for financial support, Dr Michael Garst for NMR spectra of authentic manoalide and Rhonan Ford for technical advice.

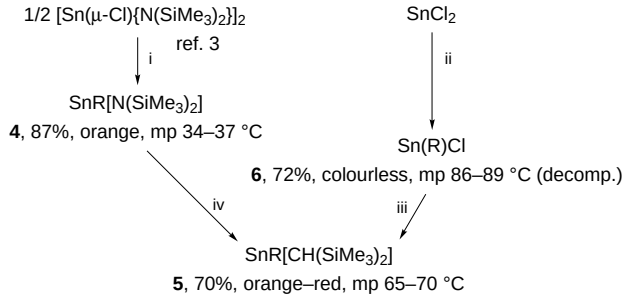
# The novel, chelating C, N-bidentate 2,6-bis(dimethylamino)phenyl ligand ($R^{②}$), showing ambidentate N,N′-character in $M(R)_2$ (M = Ge, Sn, Pb) and Sn(R)X [X = $N(SiMe_3)_2$, $CH(SiMe_3)_2$, Cl]†

**Christian Drost, Peter B. Hitchcock, Michael F. Lappert* and Luc J.-M. Pierssens**

*The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ*



**Treatment of $MCl_2$ or $[Sn(\mu\text{-}Cl)\{N(SiMe_3)_2\}]_2$ with $[Li(\mu\text{-}R)]_3$ [R = $C_6H_3(NMe_2)_2$-2,6] under mild conditions and in appropriate stoichiometry affords $MR_2$ (M = Ge 1, Sn 2, Pb 3) or Sn(R)X [X = $N(SiMe_3)_2$ 4, Cl 6], while 4 or 6 with $LiCH(SiMe_3)_2$ give $SnR[CH(SiMe_3)_2]$ 5; compounds 1–6 are characterised by their multinuclear NMR and MS spectra and 1–3 by X-ray crystal structures.**

We draw attention to the chelating, C,N-bidentate, monoanionic terminal ligand $^{②}C_6H_3(NMe_2)_2$-2,6 ($R^{②}$) having ambidentate N,N′-character which promises to find a useful role in organometallic chemistry. It was previously known only as the lithium complex $[Li(\mu\text{-}R)]_3$ in which $R^{②}$ was C,N-chelating and N′-bridging.[1] The ligand $R^{②}$ differs from the well established $^{②}C_6H_3(CH_2NMe_2)_2$-2,6, which is tripodal, as in $Sn[C_6H_3(CH_2NMe_2)_2$-2,6]X (X = Cl, $C_6H_4Me$-4).[2]

At this time, we report the synthesis and characterisation of (*i*) the monomeric homoleptic 2,6-bis(dimethylamino)phenylmetal(II) heavy group 14 metal carbene analogues $MR_2$ (M = Ge **1**, Sn **2**, Pb **3**), (*ii*) the first monomeric heteroleptic aryltin(II) amide and alkyl $SnR[N(SiMe_3)_2]$ **4** and $SnR[CH(SiMe_3)_2]$ **5** and (*iii*) Sn(R)Cl **6**.

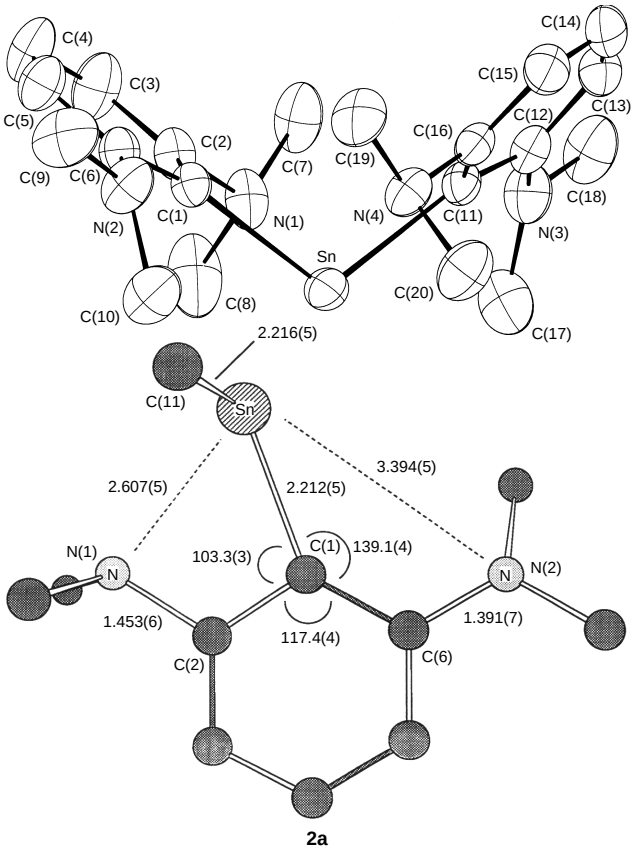
The yellow, crystalline complexes **1** (65%, mp 142–145 °C), **2** (90%, mp 85–90 °C) and **3** (70%, mp 126–130 °C [decomp.]) were prepared from $[Li(\mu\text{-}R)]_3$[1] and $MCl_2$ in appropriate stoichiometry at *ca*. 25 °C in diethyl ether for **2** and **3**, but preferably in tetrahydrofuran (thf) for **1**. An alternative procedure, from 2 RH + $Sn[N(SiMe_3)_2]$, proved unsuccessful; despite the fact that aromatic stannation using this tin(II) amide and $C_6H_4[N(SiMe_3)H]_2$-2,6 had readily yielded $Sn_3[\{1,3\text{-}(Me_3Si)N\}_2C_6H_3$-2]$_2$.[3]

The syntheses, in good yields and under mild conditions, of compounds **4**–**6** are illustrated in Scheme 1. Treatment of 1/3$[Li(\mu\text{-}R)]_3$ and 1/2$[Sn(\mu\text{-}Cl)\{N(SiMe_3)_2\}]_2$[4] or $SnCl_2$ afforded the colourless, crystalline **6** or the orange **4**, (Scheme 1, steps i or ii). From either **4** or **6** and 1/3 $[Li(\mu\text{-}R)]_3$, the orange–red **5** was obtained, (Scheme 1, steps iii or iv). Pure, crystalline compounds **4** and **5** were isolated after vacuum distillation.

**Scheme 1** Synthesis of the heteroleptic aryltin(II) complexes **4**–**6** [R = $C_6H_3(NMe_2)_2$-2,6]. *Reagents and conditions*: i, LiR, hexane, 0 °C, 12 h; ii, LiR, $Et_2O$, 0 °C, crystallisation from $Et_2O$–hexane; iii, LiR + $SnCl_2$, $Et_2O$, 25 °C, 12 h, (*in situ*) $LiCH(SiMe_3)_2$, hexane; iv, $LiCH(SiMe_3)_2$, hexane, 0 °C, 12 h, $Et_2O$.

Each of the hydrocarbon-soluble compounds **1**–**6** gave satisfactory microanalytical, as well as $^1H$, $^{13}C\{^1H\}$, $^{29}Si\{^1H\}$ (**4**, **5**), $^{119}Sn\{^1H\}$ (**2**, **4**–**6**) and $^{207}Pb\{^1H\}$ (**3**) NMR‡ and EI (70 eV) mass spectra (each giving, as the highest *m/z* peak,the parent monomeric molecular ion in significant intensity: from 8% for **4** to 35% for **2**). Additionally, single-crystal X-ray diffraction data established the molecular structures of the isomorphous, isostructural complexes **1**, **2** (Fig. 1) and **3**;§ the structures of **1** and **3** will be discussed in the full paper.

The $^1H$ NMR spectra of each of the homoleptic complexes $MR_2$ **1**–**3** in $C_6D_6$ (**1**, **3**) or [$^2H_8$]toluene (**2**)‡ showed singlets for both the $NMe_2$ and the 3,5-aromatic protons at 298 K, but for **2** each split into two separate signals at 178 K. This indicates that at the higher temperature there is a rapid exchange process involving 2-$Me_2N\cdots M \rightleftharpoons$ 6-$Me_2N\cdots M$ exchange; while at the lower temperature, the spectra are consistent with the solid-state structures,§ having each ligand $R^{②}$ bonded in a bidentate chelating fashion, with one of the $NMe_2$ groups being non-bonding. This analysis is supported by the $^{119}Sn$ NMR spectra for **2**.‡ Thus, the magnitude of the $^{119}Sn\{^1H\}$ chemical shift in PhMe–$C_6D_6$, $\delta$ 442.2 at 298 K (similarly, $\delta$ $^{207}Pb\{^1H\}$ 3919 in **3**) reflects a higher than two-coordinate metal(II) environment,[5] and moreover was similar to the CP MAS value of $\delta$ 492. The $^{119}Sn\{^1H\}$ NMR spectral chemical shifts in the heteroleptic complexes Sn(R)X **4**–**6** ($\delta$ 422 **4**, 758 **5** and 380 **6**) are consistent with their having three-coordinate tin(II), being intermediate between the values for the homoleptic $SnR_2$ **2** and $SnX_2$ [X = $N(SiMe_3)_2$, $\delta$ 776; X = $CH(SiMe_3)_2$, $\delta$ 2310 at 373 K[6*a*] (or 2315 at 375 K[6*b*]) for $Sn[CH(SiMe_3)_2]_2$ in [$^2H_8$]toluene and $\delta$ 725, 745 by CP MAS for the dimer[6*b*]]. The $^1H$ NMR solution spectra of **4**–**6**‡ also showed single $NMe_2$ and identical 3- and 5-aromatic proton environments at 298 K; low-temperature data are not yet to hand for **1** or **3**–**6**. The low-temperature $^1H$ NMR solution spectra of both **2** (containing the C,N-chelating $R^{②}$) and $Sn[C_6H_3(CH_2NMe_2)_2$-2,6]Cl[2] (having the C,N,N′-tripodal ligand) were consistent with their solid-state structures, but at higher temperatures each showed fluxional behaviour.



Complex $SnR[N(SiMe_3)_2]$ **4** is similar to the three-coordinate tin(II) compound $Sn[C(SiMe_3)_2C_5H_4N$-2][$N(SiMe_3)_2$],[5] both with respect to its yellow colour and $^{119}Sn\{^1H\}$ chemical shift, $\delta$ 319; while $\delta$ [$^{119}Sn\{^1H\}$] for the four-coordinate $SnR_2$ **2** is at a higher frequency than for the similarly coordinated tin(II) complexes $Sn[C(SiMe_3)_2C_5H_4N$-2]$_2$ ($\delta$ 139),[5] $Sn[C_6H_3(CH_2NMe_2)_2$-2,6]X (X = Cl, $\delta$ 155.6; X = $C_6H_4Me$-4, $\delta$ 209.5),[2] or $Sn(C_{10}H_6NMe_2$-8)$_2$ ($\delta$ 150.9 at ② 80 °C).[7]

The aryltin(II) chloride **6** was reasonably thermally stable, but in solution it slowly deposited metallic tin. Its stability is attributed to its three-coordinate nature, as in $Sn[C(SiMe_3)_2C_5H_4N$-2]Cl;[5] attempts to make $Sn[CH(SiMe_3)_2]Cl$ from $Sn[CH(SiMe_3)_2]_2$ + $SnCl_2$ afforded $Sn[CH(SiMe_3)_2]_2Cl_2$ + Sn.[8] However, **6** was clearly less robust than the four-coordinate tin(II) complex $Sn[C_6H_3(CH_2NMe_2)_2$-2,6]Cl.[2]

Crystalline $SnR_2$ **2**, illustrated in Fig. 1 and **2a**, is a mononuclear, four-coordinate tin(II) complex, the shortest Sn···Sn separation being 6.7 Å.§ The C(1)–Sn–C(11) angle of 105.6(2)° is typical of two-coordinate $SnX_2$ complexes, *e.g.* 103.6(1)° in $Sn(C_6H_2Bu^t_3\text{-}2,4,6)_2$,[9] but significantly different from those in the four-coordinate tin(II) complexes $Sn[C(SiMe_3)_2C_5H_4N\text{-}2]_2$ [125.0(2)°][5] or $Sn(C_{10}H_6NMe_2\text{-}8)_2$ [93.8(5)°];[7] the nature of the chelate bite-angle is clearly a major factor. The coordinating $NMe_2$ groups, one from each ligand, are arranged in a transoid fashion around the distorted trigonal-pyramidal tin centre, assuming that a lone pair of electrons occupies an equatorial site. The three CNC angles at each of the coordinating N atoms [N(1), N(4)] range from 108.9(5) to 114.1(5)° (av. 111.1°), while those at the more remote N atoms [N(2), N(3)] vary from 115.5(5) to 120.1(6)° (av. 117.7°), thus approximating to $sp^3$ and $sp^2$ N environments, respectively. The Sn···N(1) and Sn···N(4) distances (av. 2.64 Å) may be compared with an average of 2.42 Å in $Sn[C(SiMe_3)_2C_5H_4N\text{-}2]_2$[5] or 2.56 Å in $Sn[C_6H_3(CH_2NMe_2)(CH_2NMe_2)\text{-}2,6]_2Cl$.[2] To ensure optimal Sn···N(1) [or N(4)] donation, the Sn–C(1) and Sn–C(11) bonds are strongly tilted towards N(1) and N(4); hence, the C(2)–C(1)–Sn and C(16)–C(11)–Sn angles (av. 104.0°) and C(6)–C(1)–Sn and C(12)–C(11)–Sn (av. 138.2°) are severely distorted from $sp^2$ values.

The Sn–C(1) and Sn–C(11) bond lengths (av. 2.214 Å) are similar to the Sn–$C_{aryl}$ bond lengths in $Sn(C_6H_2Bu^t_3\text{-}2,4,6)_2$ [av. 2.261(4) Å][9] and $Sn[C_6H_2(CF_3)_3\text{-}2,4,6]_2$ [av. 2.281(5) Å],[10] the latter having significant Sn···F contacts with each of the 2- and 6-$CF_3$ groups.

The average Li–C and Li–N(N′) bond distances in $[Li(\mu\text{-}R)]_3$ are rather similar, 2.17 and 2.12 Å, respectively,[1] whereas in **2** the Sn–C bonds are considerably (*ca*. 20%) shorter than the chelating Sn–N distances.

**2a**

**Fig. 1** CAMERON representation of the molecular structure of $Sn[C_6H_3(NMe_2)_2\text{-}2,6]_2$ **2**. Selected bond lengths (Å) and angles (°) (see also **2a**): Sn···N(1) 2.607(5), Sn···N(4) 2.669(5); C(1)–Sn–C(11) 105.6(2), Sn–C(11)–C(16) 104.7(3), Sn–C(11)–C(12) 137.4(4).

The data here presented, together with experiments in progress, including the formation of a thermally stable tin-centred radical and cation $^{\cdot}SnR_3$ and $[SnR_2\{CH(SiMe_3)_2\}]BPh_4$, respectively, and the borane adduct $SnR_2(BH_3)$, encourage us to regard this ligand as having considerable potential.

We thank the European Commission for fellowships for C. D. (category 30) and L. J.-M. P. (cat. 20), Mr J. Keates and Dr G. A. Lawless for the CP MAS spectra and Dr A. Abdul-Sada for the MS spectral data and the EPSRC for other support.

# Insertion of arylsulfonylnitrene fragments into Pd–Pd bonds. Crystallographic characterization of the novel $[Pd_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}NSO_2C_6H_4NO_2\text{-}2)]$ A-frame adduct

**Gábor Besenyei,* László Párkányi, Isabella Foch, László I. Simándi† and Alajos Kálmán**

*Central Research Institute for Chemistry, Hungarian Academy of Sciences, H-1525 Budapest, P.O. Box 17, Hungary*

**The dimeric palladium complex $[Pd_2Cl_2(\mu\text{-dppm})_2]$ reacts with arylsulfonyl azides affording novel arylsulfonylnitrene-bridged dinuclear A-frame complexes, $[Pd_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}NSO_2Ar)]$.**

We have reported earlier that palladium complexes catalyse the carbonylation of sulfonamide derivatives such as salts of *N*-chloroarylsulfonamides, arylsulfonyliodoimines and arylsulfonylselenylimines with CO to the corresponding arylsulfonyl isocyanates.[1] These reactions are of potential interest in the phosgene-free synthesis of arylsulfonylurea type herbicides. Although the mechanisms of these reactions are not known, it is reasonable to assume that arylsulfonylnitrene intermediates may be involved as isocyanate precursors reacting with CO in the coordination sphere of the palladium catalyst. Mononuclear arylsulfonylnitrene complexes have been isolated from reactions of complexes of Mo and W with various sources of the $ArSO_2N$ fragment and obtained *via* oxidation of the coordinated $ArSO_2NH$ moiety.[2,3] The arylsulfonamide ligand has also been observed in complexes of Pt, Ru and Os.[4–6]

To our knowledge no palladium complexes containing the arylsulfonylnitrene ligand have thus far been synthesised and characterised although Lee and Trogler have reported on a palladium complex bearing phenylnitrene ligands that span over two palladium centres.[7] We now report the first examples of dimeric palladium complexes in which the arysulfonylnitrene ligand occupies a bridging position.

We have observed that the dimeric palladium complex $[Pd_2Cl_2(\mu\text{-dppm})_2]$ [**1**, dppm = bis(diphenylphosphino)methane] reacts readily with arylsulfonyl azides **2** at room temp. in $CH_2Cl_2$ [eqn. (1)], affording the novel A-frame type palladium

$$[Pd_2Cl_2(\mu\text{-dppm})_2] + ArSO_2N_3 \longrightarrow [Pd_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}NSO_2Ar)] + N_2 \quad (1)$$

**1** **2** **3**

**a** Ar = 4-$MeC_6H_4$
**b** Ar = Ph
**c** Ar = 2-$NO_2C_6H_4$
**d** Ar = 2-Naphthyl

complexes **3** with the $ArSO_2N$ ligand in an apical position. The reaction is accompanied with characteristic changes in the UV–VIS spectrum and the evolution of *ca*. 0.95 mol $N_2$ per mol Pd complex, as demonstrated by gas volumetric measurements. In a typical experiment the reacting solution contained 0.2 mmol of **1** and 0.3 mmol of **2**, and the expected volume of $N_2$ was released in *ca*. 2 h. Evaporation and precipitation with MeOH afforded the products in better than 90% yield.

According to X-ray structure analysis, **3c** has an extended boat conformation of the eight-membered Pd–P–C ring (Fig. 1),‡ which is typical for A-frame adducts.[8–11] Remarkably, the coordination geometry of the bridging nitrogen is almost planar [$\Sigma\phi(N)$ = 356.2°; the N atom is located only 0.204 Å above the Pd(1)Pd(2)S plane]. An analogous feature has been observed for the complex $[Ir_2(CO)_2(dppm)_2(\mu\text{-NPh})]$.[12] The short S–N(1) bond distance (1.544 Å) is indicative of $d_\pi$–$p_\pi$ interaction, shifting electron density from the bridging nitrogen to the sulfonyl group. The contribution of resonance structures with negatively charged sulfonyl oxygen atoms is in line with the low values recorded for the $\nu_{as}(SO_2)$ bands (1240–1252 $cm^{-1}$). Although the S–N(1) bond has a pronounced double bond character, rotation around this axis should be considered feasible.

$^1H$ and $^{31}P$ NMR chemical shifts and coupling constants of **3a–d**, diagnostic for the dppm ligand in A-frame complexes, fall within a very narrow interval, supporting the close structural similarity of these complexes (Table 1). The observed splitting patterns in the $^1H$ NMR spectra and the singlets observed for the P nuclei show the equivalence of the diphosphine ligands.[8,9] The nature of the Ar group exerts only a negligible influence on the NMR parameters. We have found that complexes **3** are inert

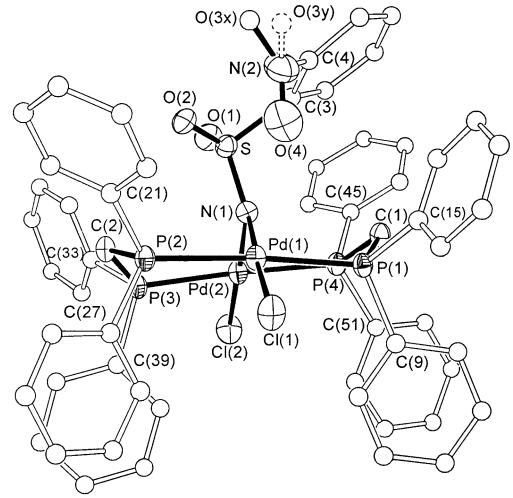

**Fig. 1** The molecular structure of $[Pd_2Cl_2(\mu\text{-dppm})_2(\mu\text{-}NSO_2C_6H_4NO_2\text{-}2)]$, **3c**. toward CO. Exposure of **3a** and **3c** in $CH_2Cl_2$ to 30 bar CO at 20 °C for 18 h did not afford any products derived from the sulfonylnitrene moieties. This is in agreement with the observation of Ge and Sharp,[13] who demonstrated that CO is inserted into the Rh–N bond of $[Rh_2(CO)_2(dppm)_2(\mu\text{-NR})]$ only if R is not a strongly electron-withdrawing group. Similar factors may be responsible for the lack of reactivity of compounds **3**.

Although arylsulfonylnitrene complexes are probably involved in the carbonylation of sulfonamide derivatives, complexes **3** as model intermediates are too stable for reaction with CO, but very convenient for structural characterisation.

Work is in progress to further explore synthetic routes leading to palladium sulfonylnitrene complexes and their role in catalytic N-carbonylations.

We thank the Hungarian Research Fund (OTKA) for financial support (Grants T-16213 and B-033).

‡ *Crystal data* for **3c**: $C_{56}H_{48}Cl_2N_2O_4P_4Pd_2S{\cdot}CHCl_3$, orange plate, 0.45 × 0.30 × 0.08 mm, monoclinic, space group $P2_1/n$, $a$ = 12.827(1), $b$ = 19.622(1), $c$ = 23.149(6) Å, β = 98.74(2)°, $U$ = 5758.7(16) Å$^3$, $Z$ = 4, $D_c$ = 1.582 Mg m$^{-3}$, μ = 1.051 mm$^{-1}$. Data were collected at 293 K on an Enraf-Nonius CAD4 four-circle diffractometer using graphite-monochromated Mo-Kα radiation. Reflections were collected in the range 2.44 ⩽ θ ⩽ 29.46° and 15935 independent reflections were used in the structure analysis. A semi-empirical (ψ-scan) absorption correction has been applied to the data. The structure was solved by the heavy-atom method and refined against all $F^2$ data (SHELXL-93)[14] to $R_1$ = 0.0490 [for 12251 $F^2 > 2\sigma(F^2)$]; $wR_2$ = 0.1555 and goodness of fit = 0.978 for all 15935 $F^2$, 731 parameters; all non-hydrogen atoms anisotropic except the minor disorder component of O(3) and three Cl atoms of out of nine disordered positions of the solvent. The highest peak of 1.254 e Å$^{-3}$ in the final difference map is located in the vicinity of the Pd(1) atom. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Unusually long open times, determined by planar bilayer conductances studies, for a synthetic tris(macrocycle) that functions as a transmembrane channel in a phospholipid bilayer

**Ernesto Abel, Eric S. Meadows, Iwao Suzuki, Takashi Jin and George W. Gokel***

*Bioorganic Chemistry Program and Department of Molecular Biology and Pharmacology, Washington University School of Medicine, 660 South Euclid Avenue, Campus Box 8103, St. Louis, MO 63110 USA*

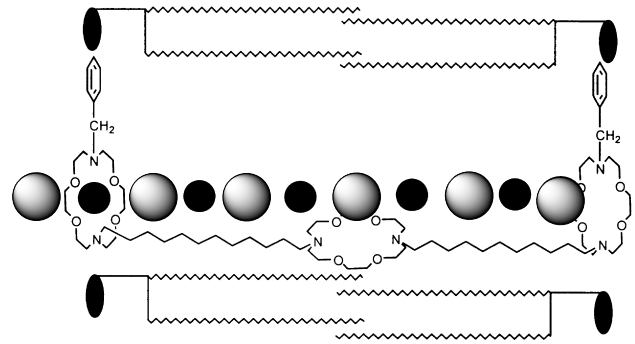
**Two tris(macrocycle)s are shown by bilayer clamp studies to function as cation channels in a phospholipid bilayer; one of the pair of closely related compounds shows unusually long open times compared either to the other tris(macrocycle) or to natural channel-forming proteins.**

The transport of sodium, potassium, and calcium cations *in vivo* is accomplished almost exclusively with the aid of proteins believed to have multiple transmembrane spans. Many of the structural features of natural cation-conducting channels have been inferred from biophysical and molecular biological studies.[1] The critical importance to biology of protein channel compounds and the fact that the chemical details of channel function remain obscure has fostered the design, synthesis, and study of several model channel systems. We have recently reviewed this area.[2] Our own cation channel model system was designed to possess macrocyclic polyethers that function both as head groups and as entry portals for cations. The original design used flexible *n*-dodecyl chains to connect the head-groups to a third macrocycle that was intended to function as a 'relay' unit, midway between the two.[3] The headgroups were attached on each distal side to a second 12-carbon chain that was expected to interact with the phospholipid bilayer in which it was embedded and to stabilize the extended conformation. The fact that alkyl-substituted crowns can serve as head groups for the formation of micelles[4] and stable vesicles[5] comports with our design. Based on the accumulated experimental evidence,[3] we believe that the benzyl channel (**1**, shown) adopts the conformation illustrated in Fig. 1.

We have prepared several channel model compounds in this class in which the distal macrocycles are substituted by aralkyl residues. Such residues include benzyl (**1**), methoxybenzyl[6] (**2**) and indolylmethyl.[7] We have previously shown that these structures conduct $Na^+$ through a phospholipid bilayer using a dynamic NMR method previously described.[8] We now show that these compounds exhibit cation transport behaviour typical of, if somewhat less effective than, that of transmembrane protein channels. These results were obtained by using a patch clamp amplifier and a bilayer headstage (planar bilayer conductance or pbc method). The black lipid bilayer membrane† is formed over a pinhole in a Teflon disk separating two compartments containing salt solutions. Bilayer formation is detected by a sudden drop in conductance. A continuous series of 10 mV, square-wave pulses (train pulse) is applied to the membrane to monitor its capacitance. A $10^{-6}$ M channel solution (in $CF_3CH_2OH$) was added and the solution was stirred for 1–10 min. A holding potential (see Figs. 2 and 3)was then applied and the channel responses were recorded.‡ The data shown in Fig. 2 (applied potential +100 mV) are typical for compound **2** but they represent only a small fraction of the data collected.

The recordings show the ion flux, usually for a single channel. The baseline corresponds to periods in which there is no observed cation flux. When a flat-topped peak is observed, it indicates that ions (presumably $Na^+$) are flowing. If each channel passes ions by the same mechanism, then a fixed peak height will be observed corresponding to whether the system is open or closed. When more than one channel is open simultaneously, similar flat-topped peaks will be observed but these will have an amplitude multiplied by an integer corresponding to the number of channels open. Well behaved, one- and two-channel opening behaviour is apparent in the traces shown in Fig. 2.

Similar, albeit somewhat noisier, data were obtained for **1** and are shown in Fig. 3(*a*). The traces shown are selected from and typical of approximately 100× the amount of data shown for **1**. Plotting current amplitude of single transitions *vs*. holding voltage for this system gives a straight line with $R > 0.98$ for 11



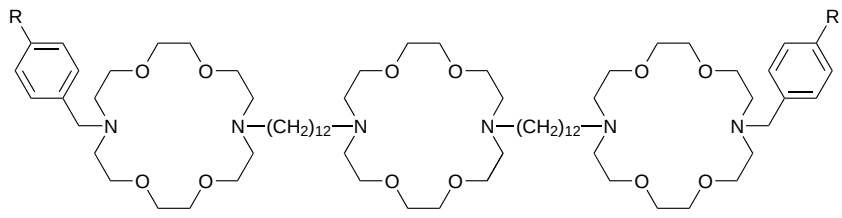


**Fig. 1** Conformation of **1** in a phospholipid bilayer inferred from experimental evidence. Sodium (larger spheres) and water are shown schematically only to indicate their presumed presence.

**1** R = H, **2** R = OMe

points. The linear relationship between current amplitude and applied voltage for benzyl channel **1** shows that it obeys Ohm's law and that there are no voltage-gated phenomena. The slope of the curve gives the channel's conductance. For **1**, it was determined to be 12.8 pS for a 0.1 M NaCl solution. We note that although the overall behaviour of **1** and **2** are similar to that observed for a typical, natural sodium channel, the magnitude of ion flux [12.8 pS for **2** (100 mM $Na^+$)] is less than the *ca*. 18 pS typically observed for the transmembrane proteins.[9] This channel is thus remarkably active for such a low molecular mass system. The methoxybenzyl channel (**2**) appears by $^{23}Na$ NMR studies to be about half as effective as the gramicidin channel,[10] a dimeric peptide, which also exhibits a lower flux than do proteins.

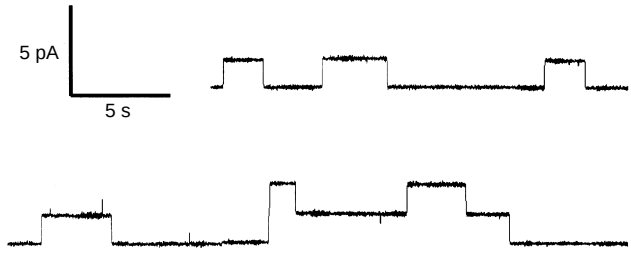

**Fig. 2** Bilayer clamp traces for methoxybenzyl channel (**2**) recorded at +100 mV

Traces are shown in Fig. 3 for **1** and **2** (additional data) on the same scale as each other and as in Fig. 2. Data were recorded at 120 mV for **1** and at 80 mV for **2**. These differences in holding voltage are expected to change the amplitude but not to have a significant effect on channel open times. Benzyl channel, **1**, opens and closes on a timescale of a few seconds typical of many proteins [Fig. 3(*a*)]. As in the methoxybenzyl case, integral amplitudes are observed for the square peaks. Compound **1** shows peaks indicating both longer and shorter opening times but none of the traces thus far obtained indicate that any channel remains open for more than *ca*. 5 s. As apparent in Fig. 2, **2** also shows 'typical' opening and closing behaviour much of the time. During the course of recording, however, several of the data segments showed behaviour that stood in striking contrast to this 'typical' behaviour. Specifically, **2** showed peaks indicating that single channels remained open for more than 30 s [Fig. 3(*b*)]. These remarkably long open times for **2** have been observed at several different applied potentials

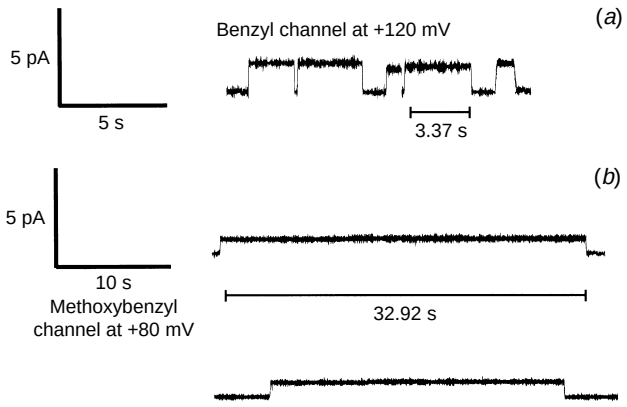

**Fig. 3** Comparison of observed open times for the benzyl channel (**1**) and methoxybenzyl channel (**2**)

in the range ±80–120 mV. Thus, this unusual behaviour does not appear to correlate with potential differences or polarity.

Channel structures **1** and **2** have a molecular mass of *ca*. 1300 and an extended length of > 30 Å. It seems remarkable that changing a hydrogen to a methoxy group at the distal ends of this system could so dramatically alter the cation transport behaviour. We are currently attempting to clarify the cause of this behaviour and to determine if other terminal groups can lifewise affect cation transport so dramatically.

We thank the NIH for a grant (GM 36262) that supported this work.

† Bilayers were prepared by the 'painting method' using L-α-lecithin (a soybean lipid mixture containing 20% phosphatidylcholine, remainder unspecified). The bilayers (capacitance ≥100 pF) were allowed to stabilize for ≥1 h prior to adding the transporter (2–40 pmol). After addition of the ionophore, the mixture was stirred for *ca*. 10 min and then the membrane was allowed to equilibrate for *ca*. 5 min. Recordings were obtained during *ca*. 9 h for the benzyl channel (membrane stable) and *ca*. 3 h for the methoxybenzyl channel ( > 100-fold the amount shown). Each experiment was repeated a minimum of three times.

‡ Single channel signals were detected and recorded using a Warner Instruments PC-505 Patch Clamp Amplifier equipped with a bilayer headstage (50 GΩ), a Digidata 1200A A/D converter, and the computer based data acquisition software Axoscope (v. 1.1.1). The holding voltage was changed manually to obtain channel responses at different voltages. Single-channel current amplitude and standard deviations were determined using Axoscope and/or pCLAMP6.

§ 'Unmodified $Na^+$ channels activated by batrachotoxin have a dominant conductance of 18 ± 2 pS in 100 mM $Na^+$.[9]

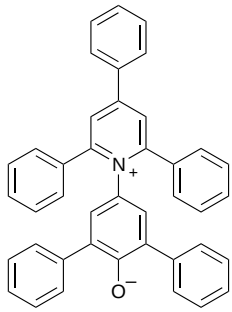
# Reichardt's dye as a probe for surface polarity of chemically and thermally treated silicas



**Stewart J. Tavener, James H. Clark,* Gary W. Gray, Paul A. Heath and Duncan J. Macquarrie**

*Department of Chemistry, University of York, Heslington, York, UK YO1 5DD*

**The polarity of surfaces may be conveniently estimated by measuring the energy of the π → π* transition of adsorbed Reichardt's dye.**

Surface polarity strongly affects the ability of material surfaces to adsorb compounds, which may in turn affect many useful properties of solids including catalytic activity. In heterogeneous catalysis, the reaction occurs either at the catalyst surface, inside pores, or in the slow moving liquid film at the surface (Nernst layer). The adsorption of substrates and the desorption of products are important steps in heterogeneous catalytic processes and are often rate limiting.[1] In certain cases, such as supported phase-transfer catalysts, the compatability of the surface with the reactant phases is critical.[2] However, measuremants of surface polarity are not easy and are rarely used in practice.

Reichardt's dye (**I**) is a useful indicator of solvent polarity.[3]

**I**

It is strongly solvatochromic, and shows a range of energies for its π → π* absorption band from 147 kJ mol$^{-1}$ (810 nm) in diphenyl ether to 264 kJ mol$^{-1}$ (453 nm) in water. Solvent polarity is measured simply by recording the energy of the π → π* transition in kJ mol$^{-1}$. This may be normalised to avoid non-SI units [eqn. (1)].

$$E_T^N = \frac{E_{T(solvent)} - E_{T(TMS)}}{E_{T(water)} - E_{T(TMS)}} \quad (1)$$

Reichardt's dye immobilised on silica gel has recently been reported as being a sensitive optical chemical sensor, giving significant shifts in $\lambda_{max}$ when the liquid environment of the sensor was changed, although these shifts were smaller than those seen for the free dye in solution.[4] Reichardt's dye doped organic polymers have been used as optical sensors for humidity, gaseous ammonia, and for polar additives in hydrocarbon blends.[5]

Some attempts have been made to measure solvatochromic parameters for the surfaces of inorganic oxides, but these investigations have usually involved the study of the solid in contact with a mobile liquid phase.[6] Silica samples studied as a suspension in 1,2-dichloroethane were found to have an $E_T^N$ value of 0.798 to 0.842,[7] and were also found to have extremely high polarities as measured by the UV adsorption maximum of adsorbed 4-nitroanisole.[8] Reichardt's dye has been used to demonstrate that dry alumina surfaces have a greater polarity than bulk water.[9]

We now wish to report that Reichardt's dye will also act as a convenient probe for the polarity of surfaces of chemically and thermally treated silica surfaces. A solution of the dye (in dichloromethane) is simply added to the the material under study, the solvent removed on a rotory evaporator and the material dried on a vacuum line for 10 min, after which no residual dichloromethane could be detected on the material by DRIFTS. Care must be taken to avoid overloading the surface with dye, as dimerisation is known to occur in solution at higher concentrations: the amount of dye added was therefore restricted to 1 μmol g$^{-1}$ (*ca.* 2 nmol m$^{-2}$).[9] The choice of solvent used to download the dye is critical: alcohols and ketones will react with or bind strongly to surface hydroxy groups on silica surfaces,[10] and the dye is insufficiently soluble in apolar solvents such as aliphatic hydrocarbons. THF also proved troublesome as high peroxide concentrations caused bleaching of the dye. Dichloromethane was found to be the most suitable solvent by virtue of its high volatility and chemical stability. The π → π* transition energy of the adsorbed dye is measured by diffuse reflectance UV–VIS spectrophotometry, although the polarity may be estimated by eye: very polar surfaces such as untreated silicas are red, ranging through purple and blue for organosilicas, to green for non-polar surfaces such as macroporous polystyrene. The values for $E_T^N$ presented here are calculated using a modified version of eqn. (1), using $E_{T(surface)}$ instead of $E_{T(solvent)}$.

The dye may not be used in strongly acidic environments as the oxygen centre becomes protonated, preventing the solvatochromic transition.[11] Residual adsorded HCl prevents sensible values from being obtained for the surface polarities of silicas treated with chlorosilanes.

A range of thermally treated silicas were prepared by heating commercial mesoporous silicas (Kieselgel 60 and Kieselgel 100, *ex Merck*) for 20 h at the desired temperature under a flowing nitrogen atmosphere before being treated with the dye solution. Thermal dehydration of silica gel is known to have a

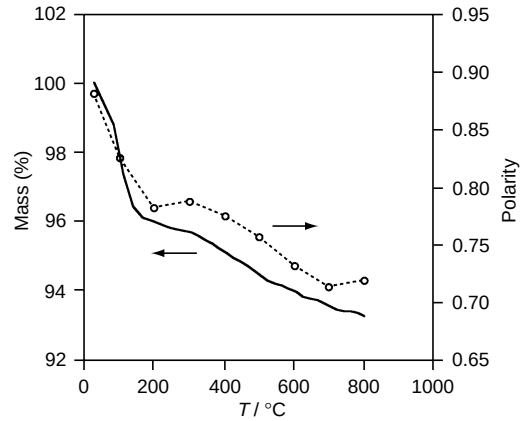


**Fig. 1** Thermogravimetric analysis and the effect of thermal treatment on the polarity ($E_T^N$) of Kieselgel 60 silica

large effect on surface chemistry of the silica, but comparatively little effect on its surface area: heating silica to 810 °C will decrease the surface area by only 25%, but will decrease the concentration of surface hydroxy groups by 80%.[12] Thermal treatment of both silicas was found to have a marked effect on its polarity, with the $E_T^N$ value reflecting thermogravimetric analysis data (Fig. 1). Initial heating causes a rapid loss of mass as loose, physisorbed water is removed from the surface, and a decrease in polarity as the adsorbed dye is no longer in a wet 'supported water' environment, but now sees a hydrogen-bonded network of surface silanols.[10] Further heating will remove some of these silanols, producing isolated polar groups whose polarity is not mediated by hydrogen bonding, this is reflected in the slight increase in polarity observed in the 300–400 °C region for both silicas. As the temperature is raised to 700 °C, more surface hydroxy groups react, eliminating water and producing more and more siloxane bridges (Fig. 2). Both

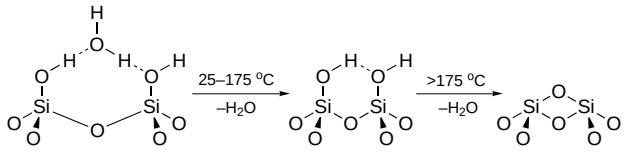

**Fig. 2** Thermal dehydration of a silica surface

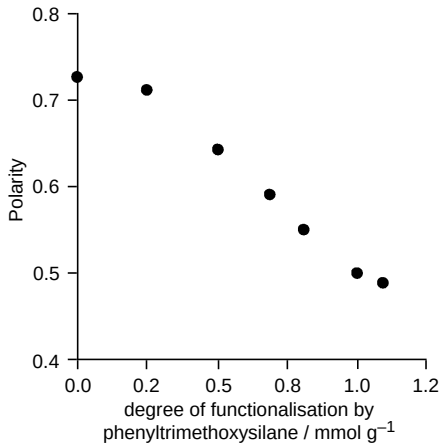

**Fig. 3** Effect of the degree of functionalisation on the polarity ($E_T^N$) of silicas treated with phenyltrimethoxysilane

**Table 1** Polarities of a range of organically modified silicas

| Material[a] | Degree of functionalisation[b]/ mmol g$^{-1}$ | $\lambda_{max}$/nm | $E_T^N$ | $\Delta E_T^N$/ mmol$^{-1}$ g |
|---|---|---|---|---|

| Silica–(CH$_2$)$_3$N[d] | 0.97 | 611 | 0.497 | −0.485 |
| Polystyrene[e] | — | 752 | 0.225 | — |

[a] Prepared by reaction with the appropriate organosilane, unless otherwise stated. [b] Measured by C, N elemental microanalysis. [c] Kieselgel 100, untreated. [d] Imidazole functionalised silica; for preparation method see ref. 14. [e] Amberlite XAD4 macroporous polystyrene.

silicas show an increase in polarity on heating beyond 700 °C. The cause of this is not clear but may be due to a low energy restructuring of the gel matrix, although no energy changes could be detected by differential scanning calorimetry. The temperature is lower than the quartz–tridymite phase change for crystalline silicas, which occurs at 870 °C.[10]

Silicas chemically modified by reaction with organosilane reagents such as phenyltrimethoxysilane show a reverse linear correlation between degree of functionalisation and polarity as measured by the $E_T^N$ values (Fig. 3). For these materials the dye is exposed to greasy non-polar organic functions as well as fewer polar surface hydroxy groups, compared with the unmodified silica. The measured polarities of a range of organically modified silicas at specific degrees of functionalisation are given in Table 1. There was no observable change in the IR spectra of the various materials after absorption of the dye, although it should be noted that the dye is present in quantities approximately 1000 times smaller than those of the surface bound organic groups, and is below the limits of detectability by IR.

Although all of the organic groups studied reduce the polarity of silica, they do so by different degrees. The decrease in polarity per mmol of organic groups per gram of silica ($\Delta E_T^N$) increases in the order: cyanoethyl < aminopropyl < imidazole < phenyl < chloropropyl < trimethylsiloxyl which is broadly in agreement with the $E_T^N$ values found for comparable compounds in the liquid phase: TMS = 0.000, benzene = 0.111, 1-chlorobutane = 0.191, *n*-butylamine = 0.213, propionitrile = 0.401, water = 1.00.[13]

Adsorption of Reichardt's dye on chemically and thermally treated silicas is an easy and rapid method for reliably determining the polarity of surfaces. This method should prove to be a valuble technique in the study of adsoption and desorption in liquid/solid catalytic systems.

We thank the EPSRC clean technology unit for a ROPA award (to S. J. T.), the Royal Academy of Engineering/EPSRC for a Fellowship (to J. H. C.) and the Royal Society for a fellowship (to D. J. M.).

# Isolation and structural characterisation of $[\{(Me_3Si)_2NMg[\mu\text{-}OC(H)Ph_2]\cdot(O{=}CPh_2)\}_2]$, an intermediate in the β-hydride transfer reaction between an alkyl(amido)magnesium and benzophenone

**Kenneth W. Henderson,* John F. Allan and Alan R. Kennedy**

*Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL*

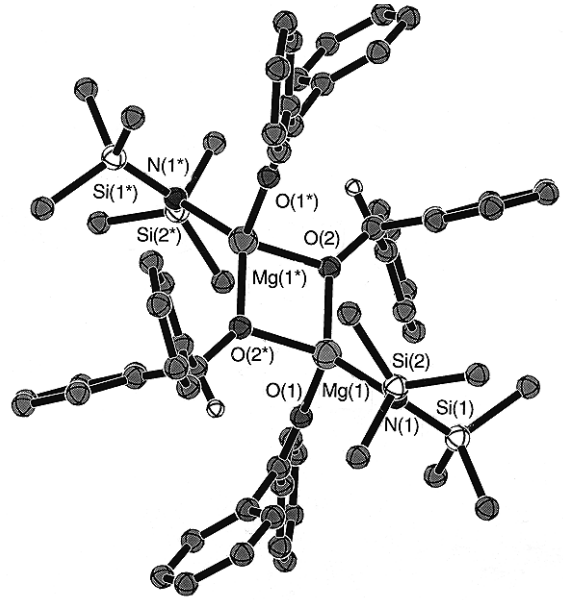
**The *in situ* reaction of $Bu_2Mg$ with 2 mol. equiv. of $(Me_3Si)_2NH$ followed by addition of $Ph_2CO$ yields the heteroleptic amide/alkoxide complex $[\{(Me_3Si)_2NMg[\mu\text{-}OC(H)Ph_2]\cdot(O{=}CPh_2)\}_2]$ 1, whereas reaction of purified $[\{(Me_3Si)_2N\}_2Mg]$ 2 with $Ph_2CO$ results in formation of the solvate $[\{(Me_3Si)_2N\}_2Mg\cdot(O{=}CPh_2)_2]$ 3, the difference being due to incomplete amination of the bis(alkyl)magnesium compound resulting in β-hydride transfer to the ketone, which is the first example of this type of transformation using an alkyl(amido)magnesium reagent.**

While Hauser bases[1] ($R_2NMgX$) and bis(amido)magnesium compounds[2] $[(R_2N)_2Mg]$ have been in the literature for some time, very little is known regarding their use as reagents to perform organic transformations. Magnesium amides are more thermally stable and less reactive than the widely used lithium amides ($R_2NLi$), leading to selectivity variations between these reagents.[3]

We are interested in studying selective deprotonation reactions between magnesium amide bases and ketones carrying an α-hydrogen, to yield magnesium enolates.[3b,4] With this in mind we decided to prepare a pre-enolisation complex[5] of a magnesium amide, for use as a model intermediate in the enolisation reaction. This involved reacting $Bu_2Mg$† (5 mmol) with hexamethyldisilazane, hmds, (10 mmol) in 10 ml of hexane for 3 h at 25 °C, followed by the addition of the non-enolisable ketone benzophenone (5 mmol).[6] It was expected that a simple ketone solvated bis(amido)magnesium complex would be produced, which could then be used for further analysis. To our surprise the only isolable product from the reaction was the crystalline compound $[\{(Me_3Si)_2NMg[\mu\text{-}OC(H)Ph_2]\cdot(O{=}CPh_2)\}_2]$ **1**.

The identity of **1** was confirmed by $^1H$ NMR analysis,‡ and its crystal structure was determined by an X-ray study (Fig. 1).§ Clearly, benzophenone had been reduced and the solvated, secondary alkoxide was obtained. The origin of the hydride was then investigated. A reaction was carried out in $C_6D_6$ to determine if the hydride was derived from the solvent; however, **1** was produced without deuterium incorporation. To exclude the possibility of moisture contamination as the hydride source, a reaction was conducted under strictly hydrophobic conditions, using triply distilled amine and sublimed $Ph_2CO$, again **1** was obtained. Our next avenue of inquiry proved to be more successful. Pure, crystalline $[\{(Me_3Si)_2N\}_2Mg]$ **2** was prepared by refluxing $Bu_2Mg$ (20 mmol) and hmds (40 mmol) in 20 ml of heptane for 3 h and on cooling to approximately 40 °C, large, colourless, crystalline blocks of **2** were deposited from solution.¶ The solid was isolated by filtration and stored in an argon-filled glove box. This procedure is high yielding and much simpler than the recently reported electrochemical synthesis.[3b] Reaction of the pure bis(amide) (5 mmol) with benzophenone (10 mmol) in 5 ml of hexane gave a clear yellow solution, which yielded needle crystals of the solvated bis(amide) $[\{(Me_3Si)_2N\}_2Mg\cdot(O{=}CPh_2)_2]$ **3**, on standing at room temperature. Hence, the explanation for the preparation of **1** must lie in performing the amination reaction followed by solvation *in situ*.

To investigate the amination process, a reaction between $Bu_2Mg$ and hmds was performed in $C_6D_6$ at 25 °C. A $^1H$ NMR spectrum of the solution after 3 h showed that alkyl peaks were still evident. This indicates that amination ceases or at least slows, at the alkyl(amido) state $[(Me_3Si)_2NMgBu]$[7] at this temperature. Using this information it is possible to propose a pathway for reduction of the ketone *via* β-hydride transfer from the alkyl(amido)magnesium intermediate (Scheme 1).[8]



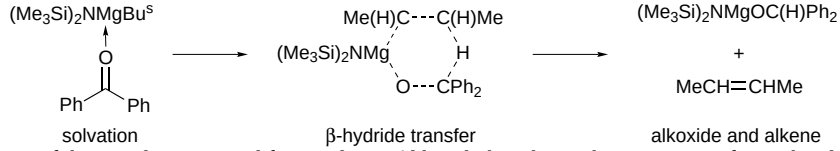


**Fig. 1** Crystal structure of **1** with hydrogen atoms (except the alkoxide H) omitted for clarity. Starred atoms are related by the symmetry operation 1-*x*, -*y*, -*z*. Key bond lengths (Å) and angles (°): Mg(1)–N(1) 2.019(3), Mg(1)–O(1) 2.046(3), Mg(1)–O(2) 1.967(2), Mg(1)–O(2*) 1,991(2); O(2)–Mg(1)–O(2*) 82.9(1), O(2)–Mg(1)–N(1) 127.0(1), O(1)–Mg(1)–O(2) 109.1(1), O(1)–Mg(1)–O(2*) 98.1(1), O(2*)–Mg(1)–N(1) 129.5(1).

**Scheme 1**. The aggregation state of the complex is ignored for simplicity. Although the scheme shows reaction of a *sec*-butyl function, a similar reaction will occur with an *n*-butyl producing but-1-ene.

To test the feasibility of this route [$(Me_3Si)_2NMgBu^S$] was prepared and isolated as a pure compound[9] and reacted with benzophenone. The solid produced from this reaction was identified as **1**. It therefore appears that the origin of the hydride is indeed from the alkyl group attached to magnesium and that this is still present due to incomplete amination of the bis(alkyl)magnesium.

Complex **1** may be regarded as an intermediate in the reduction reaction of a ketone to an alcohol, *i.e.* prior to hydrolysis. To our knowledge, this is the only example of a magnesium alkoxide prepared *via* reduction to be structurally characterised. Although a wealth of information is available on the preparation of alcohols using metal reagents, the exact nature of the reacting species is still unclear. We also believe that this is the first report of the use of an alkyl(amido)magnesium compound as a hydride transfer reagent.[10] An alternative reaction possible between the alkyl(amido)magnesium and the ketone is alkylation, to give a tertiary alcohol (after hydrolysis). This is the preferred reaction mode between [$MeMgNR_2$] ($NR_2$ = $NPr^i_2$, $NPh_2$ or $NC_5H_8Me_2$) and the cyclic ketones 4-*tert*-butylcyclohexanone and 2,2,6,6-tetramethyl-4-*tert*-butylcyclohexanone.[11] The combined steric bulk of the alkyl anion and the phenyl groups of the ketone appear to negate this possibility in our system.

Turning to the structure of **1** a dimeric arrangement utilising bridging alkoxide anions is found. Each metal bonds terminally to one amide anion and tetracoordination is completed by carbonyl solvation from a benzophenone unit. Each magnesium adopts a distorted tetrahedral environment, with angles ranging from 82.9(1)° for O(2)–Mg(1)–O(2*) to 129.5(1)° for O(2*)–Mg(1)–N(1). Although the structural motif of a dimer is not unusual for magnesium,[12] the constitution of **1** is novel. Heteroleptic magnesium compounds where the metal is attached to two different anions are rare,[13] and surprisingly **1** is the first homometallic amide/alkoxide magnesium compound to be structurally characterised.[14]

Also noteworthy in **1** is the bis solvation by benzophenone. In this system **1** is prepared preferentially over further reduction by [$(Me_3Si)_2NMgBu$]. A maximum conversion of ketone to alcohol is therefore 50% due to deactivation of the coordinated $Ph_2CO$. Strong solvation of the highly Lewis-acidic magnesium centre by the carbonyl may disfavour the dissociation necessary for further reduction to take place.

The work reported herein illustrates the merit in isolating pure organometallic reagents before further reaction, as opposed to performing *in situ* transformations. We are currently studying the chemoselective properties of alkyl(amido)magnesium compounds and their use as asymmetric induction reagents.

# Pheromones: synthesis and bioactivity†

**Kenji Mori**

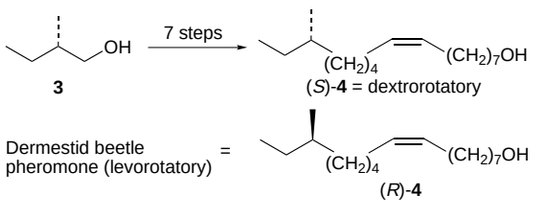
*Department of Chemistry, Science University of Tokyo, Kagurazaka 1-3, Shinjuku-ku, Tokyo 162, Japan*

**Pheromones play an important role in chemical communication among organisms. Various chiral and non-racemic pheromones have been identified since the late 1960s. Their enantioselective syntheses were achieved so as to establish the absolute configuration of the naturally occurring pheromones and also to clarify the relationship between absolute configuration and the bioactivity of the chiral pheromones.**

**Four recent examples of pheromone synthesis are given. The enantiomers of sordidin 14, the banana weevil pheromone, have been synthesized starting from (*S*)-propylene oxide. (−)-*exo*-Isobrevicomin 17 and its (−)-*endo*-isomer 21, the components of the volatiles of the mountain pine beetle, have been synthesized by employing the Sharpless asymmetric dihydroxylation and lipase-catalysed acetylation as the key reactions. The enantiomers of (*Z*)-hexadeca-7,15-dien-4-olide 24, the sex pheromone of the yellowish elongate chafer, have been synthesized *via* lipase-catalysed resolution. Lurlene 27, the pheromone of the green flagellate *Chlamydomonas allensworthii*, has been synthesized by employing a phenyl sulfone coupling reaction as the key reaction.**

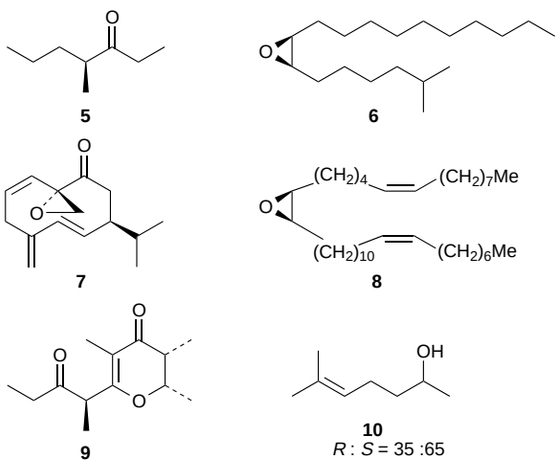
**The relationships between absolute configuration and bioactivity are diverse. For example, neither the (*R*)- nor the (*S*)-enantiomer of sulcatol 10, the aggregation pheromone of the ambrosia beetle *Gnathotrichus sulcatus*, is bioactive, but when combined to give an enantiomeric mixture they become active. In the case of olean 46, the olive fruit fly pheromone, (*R*)-46 is active for the males, while (*S*)-46 is active for the females.**

## Introduction

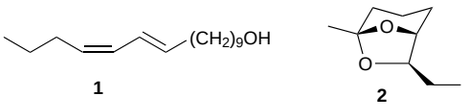


Pheromone chemistry began in 1959 when Butenandt established the structure **1** of bombykol, the sex pheromone of the silkworm moth (*Bombyx mori*). Subsequently in late 1960s a number of chiral pheromones were identified, as exemplified by *exo*-brevicomin **2**, the aggregation pheromone of the western pine beetle (*Dendroctonus brevicomis*). The absolute configuration of a chiral and non-racemic pheromone must be studied to elucidate the stereostructure of the naturally occurring material and also to clarify the relationship between stereochemistry and pheromone activity.

Mori demonstrated in 1973 that the naturally occurring and levorotatory dermestid beetle pheromone was (*R*)-**4** by converting the commercially available (*S*)-**3** to the dextrorotatory (*S*)-**4** (Scheme 1).[1,2] This work was the first successful identification of the absolute configuration of an insect pheromone by its enantioselective synthesis.



In 1974 three independent groups synthesized both the enantiomers of three different insect pheromones. Riley *et al*. synthesized the enantiomers of the alarm pheromone of the leaf-cutting ant (*Atta texana*), and found the (*S*)-isomer **5** to be about 400 times more active than the (*R*)-isomer.[3] The enantiomers of disparlure, the gypsy moth (*Lymantria dispar*) pheromone, were synthesized by Marumo's group, and they examined the electroantennographical (EAG) and behavioural responses of the male gypsy moth to the enantiomers.[4] (7*R*,8*S*)-(+)-Disparlure **6** was the most effective, (±)-**6** came second, while the (7*S*,8*R*)-(−)-isomer inhibited the activity of (+)-**6**.[4] Mori synthesized both the enantiomers of *exo*-brevicomin by starting from the enantiomers of tartaric acid.[5] Only (+)-*exo*-brevicomin **2** was bioactive against the western pine beetle.[6] The discovery that the absolute configuration of pheromones was of the utmost importance to the expression of their bioactivities accelerated stereochemical studies on insect pheromones.

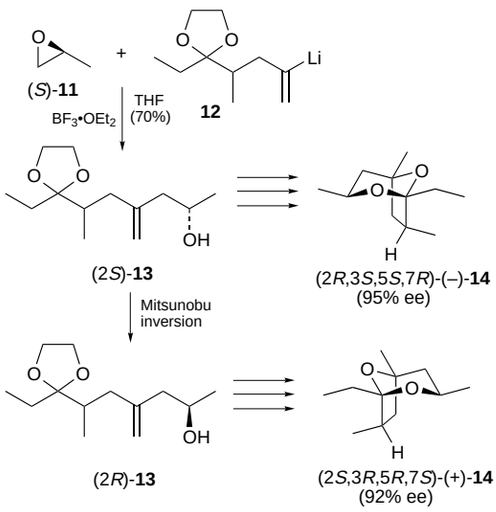


Synthesis of pheromone enantiomers can solve the stereochemical problems in pheromone chemistry, if proper methods are available for the discrimination of the enantiomers. Limited availability of the naturally occurring chiral pheromones makes it difficult to determine their absolute configuration by conventional means, especially because most of the pheromones are volatile liquids. A synthetic sample of a pheromone with known absolute configuration is useful as a reference material to assign the absolute configuration of the naturally occurring one. Accordingly, one must compare the synthetic sample with the natural pheromone by physical and/or biological methods.

The classical and accepted method for the assignment of absolute configuration is the comparison of the specific rotation of an unknown sample with that of the reference. The magnitude of the specific rotation, however, varies very much according to

**Scheme 1**

the structure of the pheromone. The largest $[\alpha]_D$ value observed among insect pheromones was $[\alpha]_D^{24}$ −547 (hexane) in the case of periplanone A **7**, the American cockroach pheromone,[7] and the smallest was $[\alpha]_D$ 0 in the case of the nymph recognition pheromone **8** of the cockroach, *Nauphoeta cinerea*.[8] Therefore, in the case of the latter, an attempt to measure the specific rotation of the natural product does not provide useful information as to its absolute configuration. If a chiral pheromone has carbonyl chromophores such as in the case of stegobinone **9**, the drugstore beetle pheromone, its CD spectrum provides useful information.[9]



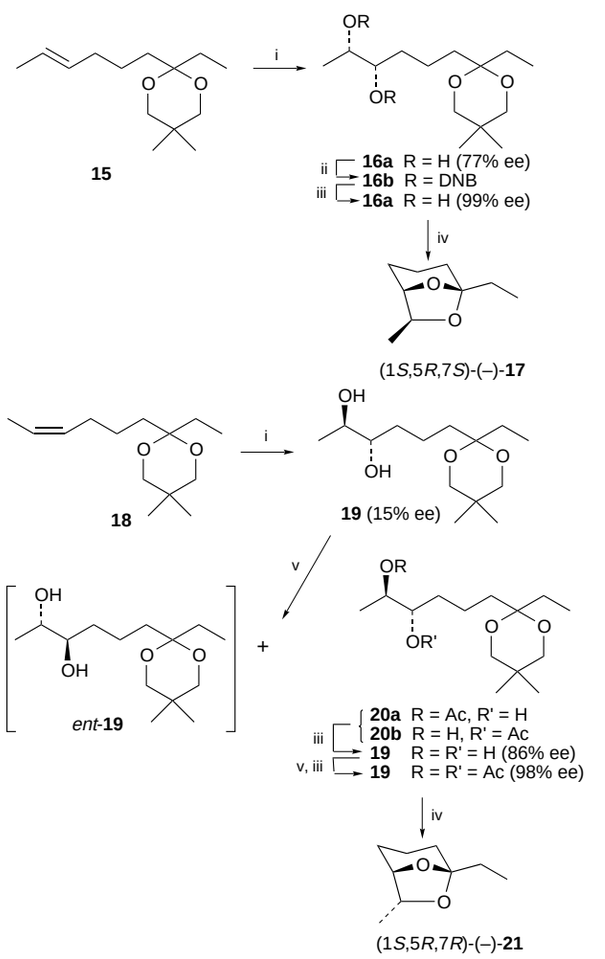
Determination of the absolute configuration and estimation of the enantiomeric composition of a chiral pheromone are possible by NMR spectroscopic methods, if a sufficient amount of the sample is available to measure the spectrum in the presence of a chiral shift reagent and/or after derivatization with a chiral derivatizing reagent. The enantiomeric purity of sulcatol **10**, the male-produced aggregation pheromone of the ambrosia beetle *Gnathotrichus sulcatus*, was determined as 30% ee [(*S*)-(+) > (*R*)-(−)] by the NMR method.[10]

HPLC with cellulose-based chiral stationary phases or GC with cyclodextrin-based chiral stationary phases are two popular methods for determination of the absolute configuration of pheromones.[11] Even with achiral stationary phases, HPLC and GC are useful for analysing chiral pheromones after derivatization with a chiral derivatizing reagent. Cyclodextrin-based GC columns are particularly useful, and almost all of the recent results on stereochemical studies of pheromones have been obtained using them.[11,12]

## Synthesis of the enantiomers of sordidin

Aspects of pheromone synthesis have been reviewed.[13–16] In particular two of them deal with enantioselective synthesis of pheromones.[15,16] Enantioselective synthesis of a chiral and non-racemic pheromone can be executed by one of the following three methods: (i) derivation from a known chiral and non-racemic building block, (ii) use of chemical or enzymatic asymmetric reactions, and (iii) use of chemical or enzymatic enantiomer separation (*i.e.* resolution) at a certain stage of the synthesis. Four recent examples from our group will be given here.

The enantiomers of sordidin **14**, the male-produced aggregation pheromone of the banana weevil (*Cosmopolites sordidus*),[17] were synthesized as summarized in Scheme 2.[18] (*S*)-Propylene oxide **11** was employed as the chiral building block. Cleavage of **11** with the alkenyllithium **12** in the presence of boron trifluoride–diethyl ether yielded the homoallylic alcohol (2*S*)-**13**. This was converted to (−)-sordidin **14**. Mitsunobu inversion of (2*S*)-**13** afforded (2*R*)-**13**, which furnished (+)-sordidin **14**. The enantiomers of **14** were compared with the natural pheromone by GC analysis (Cyclodex B® column), and (+)-**14** coincided with the natural product. The absolute configuration of natural sordidin was therefore determined as 1*S*,3*R*,5*R*,7*S*.[18]



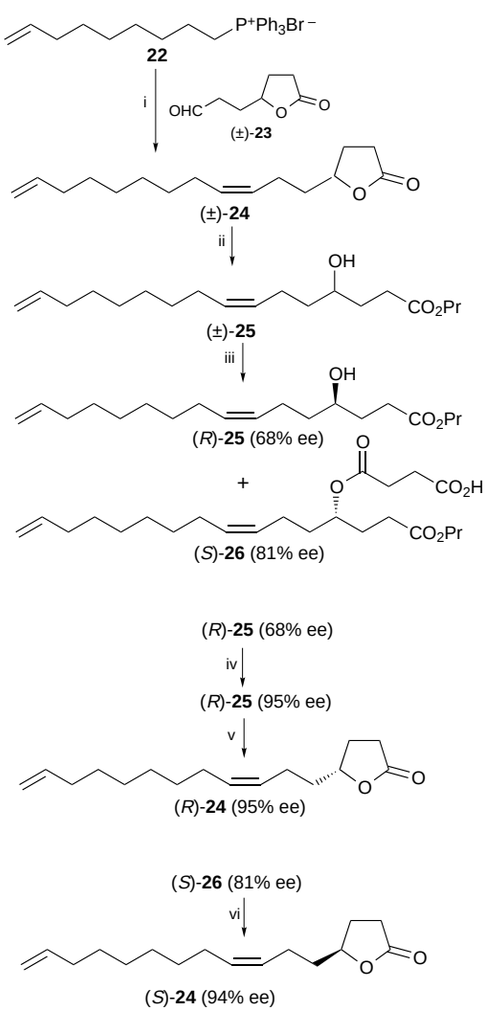
**Scheme 2**

## Synthesis of (−)-*exo*- and (−)-*endo*-isobrevicomins

Both the *exo*- and *endo*-isomers of isobrevicomin **17** and **21** were isolated in 1996 by Francke *et al*. as the components of the volatiles obtained from male mountain pine beetles (*Dendroctonus ponderosae*).[19] They synthesized (1*S*,5*R*,7*S*)-(−)-**17** by starting from (+)-tartaric acid, and the natural **17** was found to be (1*S*,5*R*,7*S*)-**17** of at least 90% ee by GC analysis.[19]

The naturally occurring *endo*-isobrevicomin may share the same (1*S*,5*R*)-6,8-dioxabicyclo[3.2.1]octane skeleton as depicted for **21**, but it needed to be proved. We therefore synthesized both (1*S*,5*R*,7*S*)-**17** and (1*S*,5*R*,7*R*)-**21** as summarized in Scheme 3.[20] Sharpless asymmetric dihydroxylation of **15** with AD-mix-α® gave the diol **16a** (77% ee). This was purified *via* the crystalline *bis*- 3,5-dinitrobenzoate **16b** to give pure **16a** (99% ee), which furnished (1*S*,5*R*,7*S*)-**17** by acid treatment. Similar dihydroxylation of **18** with AD-mix-α® afforded the diol **19** of 15% ee. The diol **19** was then purified by lipase-catalysed asymmetric acetylation. Treatment of **19** (15%

**Scheme 3** *Reagents*: i, AD-mix-α®, $MeSO_2NH_2$, $Bu^tOH$, $H_2O$ (94% for both **16a** and **19**); ii, 3,5-dinitrobenzoyl chloride (DNBCl), $C_5H_5N$, $CH_2Cl_2$, then recrystallization (59%); iii, $K_2CO_3$, MeOH [92% for **16a** (99% ee); 53% for **19** (86% ee) based on **19** (15% ee); 77% for **19** (98% ee) based on **19** (86% ee); iv, dil. HCl (64%); v, $CH_2$=CHOAc, immobilized lipase PS (Amano), $Bu^tOMe$, then chromatographic separation of *ent*-**19** and **20a**,**b**



ee) with vinyl acetate and immobilized lipase PS (Amano) gave a mixture of *ent*-**19** and **20a**,**b** which could be separated by chromatography. Deacetylation of **20a**,**b** to give **19** (86% ee) was followed by the second enzymatic enrichment of the enantiomeric purity to give **19** of 98% ee. Acid treatment of **19** (98% ee) furnished (−)-*endo*-isobrevicomin **21**. Gas chromatographic comparison of (−)-**21** with the naturally occurring *endo*-isobrevicomin established its absolute configuration.

### Synthesis of the enantiomers of (*Z*)-hexadeca-7,15-dien-4-olide

(*R*,*Z*)-Hexadeca-7,15-dien-4-olide **24** is the female-produced sex pheromone of the yellowish elongate chafer (*Heptophylla picea*).[21] The absolute configuration of the natural pheromone was assigned as *R* by the conversion of (*S*)-malic acid to (*R*)-**24**, which was identical with the natural product.[21]

We became interested in synthesizing both the enantiomers and the racemate of **24** so as to clarify the stereochemistry–bioactivity relationship. Because (±)-**24** had to be prepared for its biological evaluation, its optical resolution was considered to be the most convenient way to prepare both the enantiomers of **24**. The synthesis is summarized in Scheme 4.[22] The Wittig reagent prepared from **22** reacted with the aldehyde (±)-**23** under the Bestmann conditions to give (±)-lactone **24**, ($Z:E$ = 96.5 : 3.5). Enzymatic methods were employed for the optical resolution of (±)-**24**. The lactone (±)-**24** was first converted to the hydroxy ester (±)-**25**, which was treated with succinic anhydride in the presence of lipase PS (Amano) to give (*R*)-**25** (68% ee) and (*S*)-**26** (81% ee). The mixture was readily separable by chromatography. Treatment of (*R*)-**25** (68% ee) with pig pancreatic lipase (PPL) in diethyl ether converted (*R*)-**25** (68% ee) to a mixture of (*R*)-**25** (95% ee) and (*S*)-**24** (30% ee), which was separated by chromatography. Subsequent treatment of the hydroxy ester (*R*)-**25** (95% ee) with Amberlyst-15 yielded the (*R*)-lactone **24**, (95% ee). For the preparation of the non-natural (*S*)-lactone (**24**), the (*S*)-succinoyl ester **26**, (81% ee) was submitted to enzymatic lactonization catalysed by lipase OF-360 (Meito) to give the enantiomerically enriched (*S*)-**24** (94% ee). In the present case, asymmetric catalysis of lipases was useful for the preparation of both the enantiomers of **24**. Biotransformations catalysed by enzymes and microorganisms are frequently employed in pheromone synthesis.[15,23]

Bioassay of our synthetic samples revealed both (*R*)-**24** and (±)-**24** to be bioactive. This means that (*S*)-**24** is not inhibitory.

**Scheme 4** *Reagents*: i, $NaN(SiMe_3)_2$, THF (66%); ii, KOH, $H_2O$, then PrBr, DMF(91%); iii, succinic anhydride, lipase PS (Amano), $Pr^i{}_2O$ [56% of (*R*)-**25** and 41% of (*S*)-**26**]; iv, PPL, $Et_2O$ (74%); v, Amberlyst-15, hexane (89%); vi, lipase OF-360 (Meito), 0.3 M phosphate buffer (pH = 7) (52%)

### Synthesis of lurlene

The sex pheromone produced by the female gametes of *Chlamydomonas allensworthii* was isolated, named as lurlene, and identified as **27** by Starr, Jaenicke and Marner in 1995.[24,25] Lurlene **27** attracts the male gametes at a concentration as low as $10^{-12}$ M.[24] Our first synthesis of **27** was achieved by employing the palladium-catalysed Stille coupling between the stannane **28** and the allylic acetate **29** as the key step (Scheme 5).[26] The coupling reaction, however, brought about the partial isomerization of the (*E*) double bond at C-12 to give a mixture of **30** and its (12*Z*)-isomer in a ratio of 2 : 1.[26] This mixture could not be separated, and therefore was processed to give the final product as a bioactive mixture of lurlene **27** and its (12*Z*)-isomer.

Our second synthesis of lurlene **27** utilized the sulfone coupling reaction, and afforded the final product as pure (12*E*)-lurlene **27**.[27] The crucial steps of the second synthesis are also shown in Scheme 5. The isoprenoidal side-chain part **31** was synthesized from (*E*,*E*)-farnesol, converted to the corresponding dianion, and alkylated with the aromatic part **32** to give the phenyl sulfone **33**. Palladium-catalysed reductive desulfonylation[28] of **33** gave the pure aglycone part **34**, which was converted to lurlene **27** *via* **30**.

The pheromones of organisms other than insects are now under active investigation.

### Stereochemistry–bioactivity relationships among insect pheromones

The most notable advance in pheromone science in the last two decades is the recognition of the importance of chirality in pheromone perception. Fig. 1 summarizes the stereochemistry–pheromone activity relationships. The relationships are divided into ten categories as detailed below.

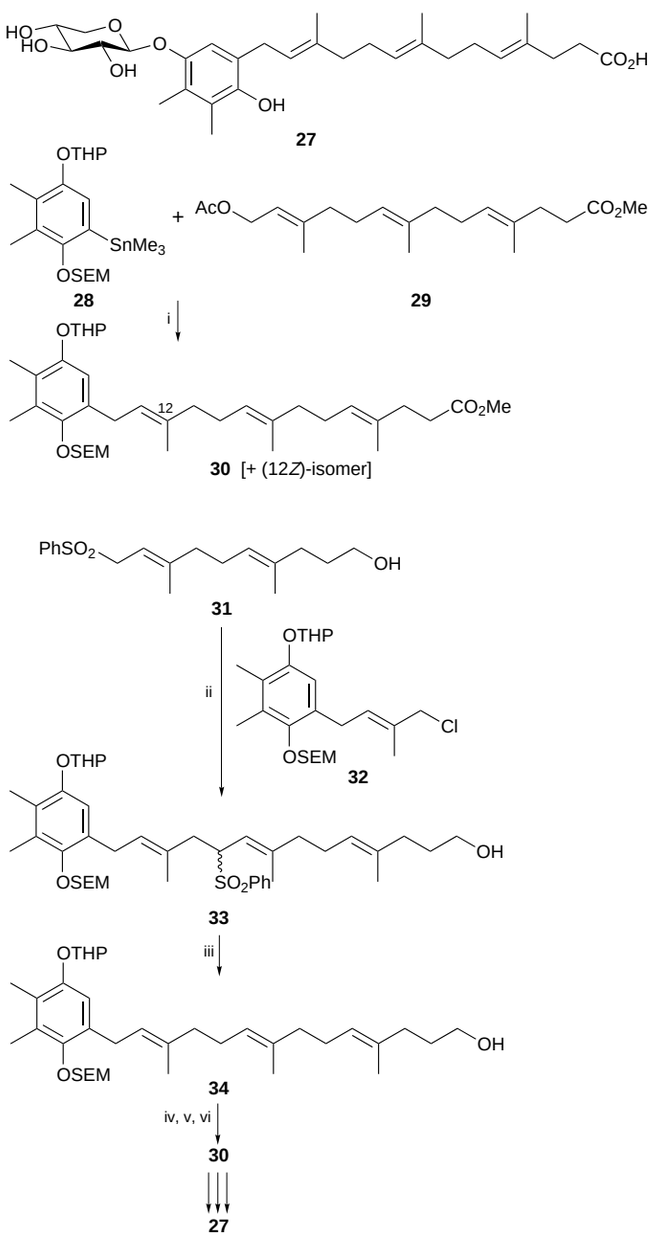
#### (*a*) *Only a single enantiomer is bioactive, and its opposite enantiomer does not inhibit the action of the pheromone*

This is the most common relationship, and the majority (about 60%) of the chiral pheromones belong to this category. Other bioregulators such as hormones generally belong to this category. Many people therefore believed that this relationship must be the only reasonable one. As we shall see later, there are many other cases.

Only the (1*R*,5*S*,7*R*)-isomer of *exo*-brevicomin (**2**) is bioactive.[6] (3*S*,4*R*)-Faranal **35** is the bioactive enantiomer of the trail following pheromone of the pharaoh's ant.[29]

(*b*) *Only one enantiomer is bioactive, and its opposite enantiomer inhibits the action of the pheromone*

Disparlure (7*R*,8*S*)-**6** is the first studied pheromone which belongs to this group.[4] Under field conditions, males of the gypsy moth (*Lymantria dispar*) and males of the nun moth (*Lymantria monacha*) responded to (7*R*,8*S*)-**6**. However, the addition of (7*S*,8*R*)-**6** significantly suppressed response by *L. dispar*, while (7*S*,8*R*)-**6** did not show such an effect on the response of *L. monacha*.[30]



Japonilure (*R*)-**36** is the female-produced sex pheromone of the Japanese beetle.[31] The bioactive enantiomer is (*R*)-(+)-**36**, while (*S*)-**36** strongly inhibits the action of (*R*)-**36**. Accordingly, (+)-**36** of 99% ee was about 2/3 as active as the pure (*R*)-**36**, that of 90% ee was about 1/3 as active as (*R*)-**36**, that of 80% ee was about 1/5 as active as (*R*)-**36**, and both (+)-**36** of 60% ee and (±)-**36** were inactive.[31]

For the practical use of pheromones belonging to this category, one must synthesize highly pure enantiomers in order to ensure trap capture of the insects. Enantiomerically pure commercial products are now available in the cases of disparlure **6** and japonilure **36**.

(*c*) *Only one enantiomer is bioactive, and its diastereomer inhibits the action of the pheromone*

Sericornin (4*S*,6*S*,7*S*)-**37** is the female-produced sex pheromone of the cigarette beetle. Bioactivity of the stereoisomers of **37** was studied by Mori *et al.* in the course of developing practical pheromone traps.[32] Only (4*S*,6*S*,7*S*)-**37** was bioactive, and its (4*S*,6*S*,7*R*)-isomer was inhibitory against the action of (4*S*,6*S*,7*S*)-**37**. Accordingly, the commercial pheromone lure must be manufactured without contamination with the (4*S*,6*S*,7*R*)-isomer.

Stegobinone (2*S*,3*R*,1′*R*)-**9** is one of the two components of the female-produced sex pheromone of the drugstore beetle. It has been shown that the addition of (2*S*,3*R*,1′*S*)-epistegobinone

**Scheme 5** *Reagents*: i, 0.05 equiv. bis(dibenzylideneacetone)palladium(0) [$Pd(dba)_2$], 3 equiv. LiCl, DMF (98%, $E : Z = 2 : 1$); ii, 2 equiv. BuLi, THF, HMPA (62%); iii, 0.1 equiv. $PdCl_2$[1,3-bis(diphenylphosphino)propane] [$PdCl_2(dppp)$], 3 equiv. $LiBEt_3H$, THF (93%); iv, Dess–Martin periodinane; v, $NaClO_2$, $NaH_2PO_4$, DMSO, MeCN, $H_2O$; vi, $CH_2N_2$, $Et_2O$ (73% based on **34**)

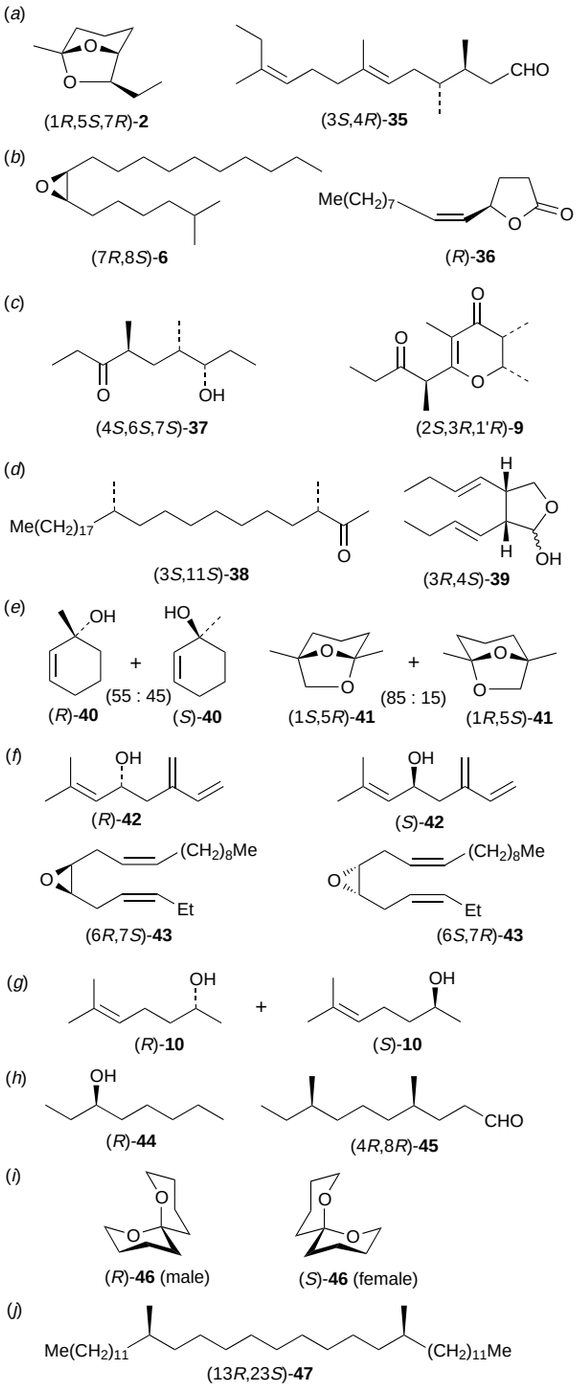


**Fig. 1** Relationships between stereochemistry and bioactivity of insect pheromones. The names of the insects which release the pheromones **2**, **6**, **9** and **35**–**47** are listed below: (*a*) **2** (*exo*-brevicomin), western pine beetle *Dendroctonus brevicomis*; **35** (faranal), pharaoh's ant *Monomorium pharaonis*; (*b*) **6** (disparlure), gypsy moth *Lymantria dispar*; **36** (japonilure), Japanese beetle *Popillia japonica*; (*c*) **37** (serricornin), cigarette beetle *Lasioderma serricorne*; **9** (stegobinone), drugstore beetle *Stegobium paniceum*; (*d*) **38**, German cockroach *Blattella germanica*; **39**, spined citrus bug *Biprorulus bibax*; (*e*) **40**, Douglas-fir beetle *Dendroctonus pseudotsugae*; **41** (frontalin), southern pine beetle *Dendroctonus frontalis*; (*f*) **42** (ipsdienol), (*R*)-isomer: bark beetles *Ips calligraphus* and *I. avulsus*; (*S*)-isomer: California five spined ips *I. paraconfusus*; (*R*) and (*S*)-isomers: pine engraver *Ips pini*; **43**, (6*R*,7*S*)-isomer; geometrid moth *Colotois pennaria*; (6*S*,7*R*)-isomer: geometrid moth *Erannis defoliaria*; (*g*) **10** (sulcatol), ambrosia beetle *Gnathotrichus sulcatus*; (*h*) **44**, ant *Myrmica scabrinodis*; **45** (tribolure), red-flour beetle *Tribolium castaneum*; (*i*) **46** (olean), olive fruit fly *Bactrocera oleae*; (*j*) **47**, tsetse fly *Glossina pallidipes*.

to **9** significantly reduces the response of the male drugstore beetles to the pheromone.[33]

*(d) The natural pheromone is a single enantiomer, while its antipode or diastereomer is also active*

Male German cockroaches do not discriminate among the four stereoisomers of the female-produced sex pheromone, although the natural product is (3*S*,11*S*)-**38**.[34]

The male spined citrus bug produces (3*R*,4*S*)-**39** as an aggregation pheromone. The opposite (3*S*,4*R*)-enantiomer of the pheromone is also bioactive, indicating that the insect does not discriminate between the enantiomers.[35]

*(e) The natural pheromone is an enantiomeric mixture, and both the enantiomers are separately active*

Female Douglas-fir beetles produce a 55 : 45 mixture of (*R*)- and (*S*)-**40** as a component of their aggregation pheromone. The combined effect of the enantiomers of **40** was additive, rather than synergistic, and both the enantiomers are required for maximum response.[36]

Male southern pine beetles produce an 85 : 15 mixture of (1*S*,5*R*)-frontalin **41** and its (1*R*,5*S*)-isomer.[37] In laboratory and field bioassays, the response of the beetles was significantly greater to the mixture of (1*S*,5*R*)-**41** and α-pinene than to (1*R*,5*S*)-**41** and α-pinene, although both were active. Both the enantiomers of **41** stimulated the same olfactory cells, suggesting that each cell has at least two types of enantioselective receptors.[37]

*(f) The different enantiomers or diastereomers are used by different species*

(*S*)-Ipsdienol **42** is the pheromone component of the California five spined ips (*Ips paraconfusus*), while other bark beetles *I. calligraphus* and *I. avulsus* respond to (*R*)-**42**.[38] Further detailed study was reported on variation of the enantiomeric purity of **42** in the bark beetle *I. pini*.[39]

Chirality of pheromones is important for discrimination between two species of the winter-flying geometrid moths in Middle Europe. Thus (6*R*,7*S*)-**43** is the pheromone of *Colotois pennaria*, while *Erannis defoliaria* uses (6*S*,7*R*)-**43** as its pheromone.[40]

*(g) Both the enantiomers are required for bioactivity*

Sulcatol **10** is the male-produced aggregation pheromone of the ambrosia beetle *Gnathotrichus sulcatus*. Neither (*R*)-**10** nor (*S*)-**10** was bioactive. But when combined to give a racemic mixture, the synthetic **10** was more active than the natural pheromone, which was a mixture of (*R*)-**10** and (*S*)-**10** in a ratio of 35 : 65.[41]

*(h) One enantiomer is more active than the other stereoisomer(s), but an enantiomeric or a diastereomeric mixture is more active than the most active enantiomer alone*

In the case of the trail following pheromone **44** of the ant *Myrmica scabrinodis*, the naturally occurring mixture of (*R*)-**44** and (*S*)-**44** (*R* : *S* = 9 : 1) was more attractive than pure (*R*)-**44** or (±)-**44**, while (*S*)-**44** was inactive.[42]

Tribolure (4*R*,8*R*)-**45** is the male-produced aggregation pheromone of the red-flour beetle *Tribolium castaneum*. Suzuki *et al*. found (4*R*,8*R*)-**45** to be as active as the natural pheromone, while a mixture of (4*R*,8*R*)-**45** and its (4*R*,8*S*)-isomer in a ratio of 8 : 2 was about ten times more active than (4*R*,8*R*)-**45** alone.[43]

*(i) One enantiomer is active on male insects, while the other is active on females*

Olean **46** is the female-produced sex pheromone of the olive fruit fly. Its (*R*)-isomer was active on the males, while the

(*S*)-isomer was active on the females.[44] The natural olean was racemic.[44]

### (*j*) *Only the* meso-*isomer is active*

In the case of the tsetse fly sex pheromones, *meso*-alkanes seem to be bioactive. Thus (13*R*,23*S*)-**47** was active as the sex-stimulant pheromone of the female tsetse fly, *Glossina pallidipes*, while neither (13*R*,23*R*)-**47** nor (13*S*,23*S*)-**47** was bioactive.[45]

## Conclusion

The progress of synthetic organic chemistry in this last quarter of the 20th century is manifested by the fact that we can now synthesize the pure enantiomers of a pheromone with even higher enantiomeric purity than that of the naturally occurring one. This has been made possible by the development of various methods of both asymmetric synthesis and stereochemical analysis. We can now determine the absolute configuration of a natural pheromone and investigate the stereochemistry–bio-activity relationships on the basis of highly enantioselective synthesis of the pheromones.

Chemists and biologists are able to unveil the remarkable biodiversity in the stereochemical aspects of pheromone perception. Insects use chirality to enrich their communication systems. The next task for biochemists and molecular biologists is to clarify the biochemical mechanisms which make the diversity possible.

Finally, from the standpoint of practical applications, one must not forget that the stereoisomers of pheromones can be inhibitors of the pheromone action.

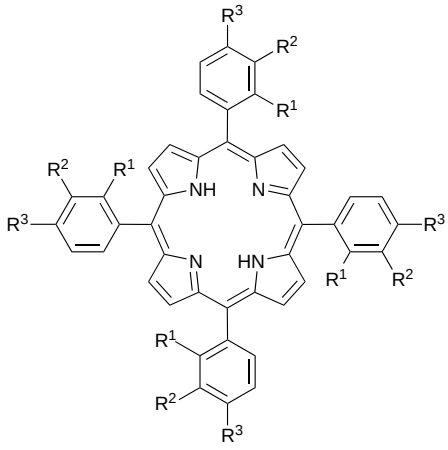
# Non-resonant third-order optical non-linearity of porphyrin derivatives



**K. Kandasamy,[a] Shankar J. Shetty,[b] P. N. Puntambekar,[a] T. S. Srivastava,[b] T. Kundu[a] and Bhanu P. Singh*[a]**

[a] *Department of Physics, Indian Institute of Technology, Bombay-400 076, India*
[b] *Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India*

**Non-resonant second molecular hyperpolarisabilities ($\gamma$) of tetraphenylporphyrin ($H_2$tpp) and five substituted derivatives are measured by the *Z*-scan technique at 784 nm; the relationship between the various structures and their corresponding molecular hyperpolarisabilities is explained on the basis of electronic interaction between the external substituents and the porphyrin core.**

The non-linear optical properties of π-conjugated organic molecules[1,2] have been the subject of intense scientific research owing to their potential applications in photonic technology. Porphyrin derivatives are attractive owing to their large polarisable π-electron system. Further, these hold the promise of vast improvement in their optical non-linearities by way of molecular engineering. This requires an understanding of the structure–non-linearity relationship. Such an understanding is still in its infancy and more systematic studies are needed. With this motivation, we have undertaken the investigation of the effect of external substituents in porphyrin structures on their second molecular hyperpolarisabilities using the *Z*-scan technique.

Six porphyrin structures (Fig. 1) having external substitution of ester and methoxy groups at systematically varying positions of the phenyl ring have been synthesised using standard procedures.[3–5] Substituents were chosen such that their electron donating/accepting capacity varies. The third-order non-linear optical susceptibilities of $10^{-4}$ M solutions of these compounds in toluene were measured using the *Z*-scan[6] technique. A self-mode-locked Ti : sapphire laser, generating 60 fs transform limited pulses at 784 nm, was employed for these experiments. The laser beam was focused to a spot size of 25 μm using an 8 cm focal length lens and the 1 mm sample cell was scanned through its focal region. The experimental set-up was standardised by toluene. Its measured $\chi^{(3)}(-\omega,\omega,-\omega,\omega)$ value ($4.55 \times 10^{-13}$ esu) is in excellent agreement with the earlier reported value of $4.76 \times 10^{-13}$ esu obtained by the optical Kerr effect.[7] The intensity levels in *Z*-scans of various samples varied in the range of 0.8–33.0 kW to contain the phase variation below π radians. For the measurement of non-resonant non-linearities, an excitation wavelength of 784 nm is chosen far away from the B (*ca*. 419 nm) and Q (*ca*. 615 nm) absorption bands of the porphyrins.

**1** $R^1$ = H, $R^2$ = H, $R^3$ = H
**2** $R^1$ = $OCH_2CO_2Et$, $R^2$ = H, $R^3$ = H
**3** $R^1$ = H, $R^2$ = $OCH_2CO_2Et$, $R^3$ = H
**4** $R^1$ = H, $R^2$ = H, $R^3$ = $OCH_2CO_2Et$
**5** $R^1$ = H, $R^2$ = $OCH_2CO_2Et$, $R^3$ = $OCH_2CO_2Et$
**6** $R^1$ = H, $R^2$ = OMe, $R^3$ = $OCH_2CO_2Et$

**Fig. 1** Structures of porphyrins used in this study. 5,10,15,20-Tetraphenylporphyrin **1**, 5,10,15,20-tetrakis[2-(carboethoxymethyleneoxy)phenyl]porphyrin **2**, 5,10,15,20-tetrakis[3-(carboethoxymethyleneoxy)phenyl]porphyrin **3**, 5,10,15,20-tetrakis[4-(carboethoxymethyleneoxy)phenyl]porphyrin **4**, 5,10,15,20-tetrakis[3,4-bis(carboethoxymethyleneoxy)-phenyl]porphyrin **5**, 5,10,15,20-tetrakis[2-(carboethoxymethyleneoxy)-phenyl]porphyrin **6**.

A typical closed-aperture *Z*-scan for **2** is shown in Fig. 2. In all samples, it exhibits a pre-focal maximum followed by a post-focal minimum. This indicates a negative non-linear index of refraction. No transmittance variations in any of the open-aperture *Z*-scans are observed. This suggests that the measured non-linearities are predominantly refractive and non-resonant. Third-order non-linear susceptibilities $\chi^{(3)}$ for the solutions and the solvent were obtained by fitting the experimental *Z*-scan data to the expressions for the closed-aperture transmittance given in ref. 6. For a dilute solution of non-interacting particles, the second hyperpolarisability ($\gamma$) of the solute in a pairwise additive model,[8] is given by eqn. (1).

$$\gamma = \frac{\chi^{(3)}_{\text{soln}} - \chi^{(3)}_{\text{solvent}}}{L^4 N_{\text{solute}}} \quad (1)$$

where $N_{\text{solute}}$ is the number density of solute, $L = (n^2 + 2)/3$ is the local-field factor[9] and $n$ is the refractive index of the medium. The $\chi^{(3)}_{\text{soln}}$ was found to vary linearly with concentration

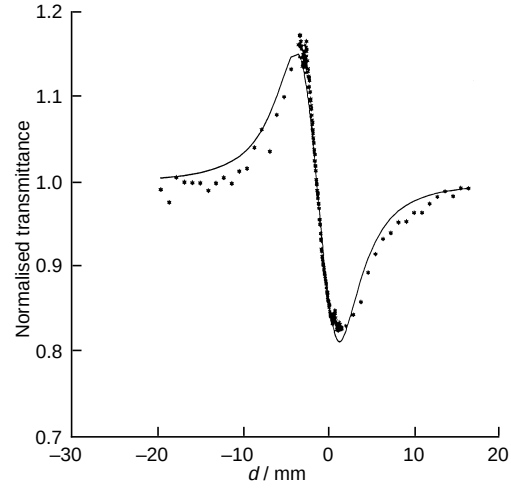


**Fig. 2** Closed-aperture *Z*-scan trace of **2** in neutral conditions at 784 nm. The solid line represents the theoretical fit to eqn. (1).

for all the porphyrin derivatives. This justifies the applicability of pairwise additive model.

Table 1 shows the measured second molecular hyperpolarisabilities for six porphyrin derivatives. The influence of external substitution on the γ values is clearly evident. A very large enhancement of γ (nearly six times that of $H_2$tpp) is seen for **2** having ester groups at *ortho* positions. The external substituents can influence the γ values by perturbing the charge density in the porphyrin core. As a preliminary attempt to explain the systematics of the observed variation of γ with structural modification, the correlation was sought with the Hammett constant σ, a measure of substituents electron-donating/accepting capacity. The net Hammett constant[10] is given by

$$\sigma = Ca_r\sigma_r + a_i\sigma_i \quad (2)$$

where $a_r$ and $a_i$ represent the relative contributions of resonant and inductive effects, and $C = 0.075$ for the *meta* position and unity otherwise. The values of the resonant ($\sigma_r$) and inductive ($\sigma_i$) parts of the Hammett constant for ester and methoxy groups are $\sigma_r = -0.4$, $\sigma_i = 0.33$ and $\sigma_r = -0.45$, $\sigma_i = 0.34$, respectively.

A linear relation between γ and σ is observed considering a 70% inductive and 30% resonant contribution. The inductive effect is expected to dominate as all these molecules in their free-base form have $D_{2h}$ symmetry, since the porphine core and the phenyl ring are perpendicular to each other. Compound **2** has not been included in this correlation as the Hammett constant cannot be defined for substituents at the *ortho* positions. It is seen from Table 1 that a more positive value of σ results in reduced hyperpolarisability. The positive sign of σ indicates electron withdrawal from the core to the substituents. This leads to a decrease of the core electron density and hence a reduction of the hyperpolarisability.

To substantiate the above, the pH environment of porphyrin molecules was changed by adding a drop of trifluoroacetic acid to the samples. In the acidic environment, the symmetry changes from $D_{2h}$ to $D_{4h}$ owing to the formation of the dication[11] and a dramatic increase of the second hyperpolarisability was observed. A linear relation between γ and σ was observed when assuming a 70% resonant and 30% inductive effect. The resonant contribution is expected to dominate the interaction between the porphyrin core and the substituent, as for the $D_{4h}$ symmetry, the core and the phenyl ring are almost parallel.[12] The calculated Hammett constants along with the observed hyperpolarisabilities are listed in Table 1. The negative sign of the Hammett constant implies an increase of the electron density in the core owing to electron donation by the substituents. It can be seen from Table 1 that the second molecular hyperpolarisability increases with increasing negative value of the Hammett constant. Thus, the observed trend of γ with the variation of substituent site is again consistent with our argument. The enhancement in the γ value of $H_2$tpp in an acidic environment over a neutral one may be attributed to increased π-electron delocalisation in the planar molecule, which is reflected in the red shift (*ca*. 20 nm) of the HOMO–LUMO gap in the absorption spectrum.

**Table 1** Values of γ for six porphyrin derivatives in neutral and acidic environments. From repeated measurements and stability of the laser, the measurement tolerance is estimated to be ±2%

| | Neutral | | Acidic | |
|---|---|---|---|---|
| | $10^{30}$ γ/esu | σ | $10^{30}$ γ/esu | σ |
| **2** | −48.2 | — | −273.5 | — |
| **1** | −8.5 | 0.0 | −20.7 | 0.0 |
| **4** | −6.7 | 0.11 | −31.0 | −0.18 |
| **3** | −6.5 | 0.22 | −17.1 | 0.08 |
| **5** | −6.3 | 0.33 | −25.7 | −0.10 |
| **6** | −6.2 | 0.34 | −25.4 | −0.10 |

The important finding of this study is the massive enhancement of the non-linearity (*ca*. six times that of neutral $H_2$tpp) in **2** having substituents at *ortho* positions. An even larger non-linearity of this molecule (*ca*. 36 times that of neutral $H_2$tpp) is observed in an acidic environment. This high non-resonant non-linearity is large enough for practical non-linear optical devices.

In view of the arguments presented above, large enhancement of γ in **2** should arise due to (*i*) enhanced charge density in the core and (*ii*) increased π-electron delocalization.

Both of these effects will operate when the phenyl ring is not perpendicular to the core. The strong interaction between the β-pyrrole hydrogen and oxygen of the ester substituents at *ortho* positions may lead to increased planarity between the core and the phenyl ring.[13] The degree of planarity will depend upon the relative strength of the interaction between the β-pyrrole hydrogen and oxygen and steric hindrance due to the substituents. Substitution at *ortho* positions is expected to lead to more effective electron donation owing to its shear proximity to the core. In acidic conditions, further increased planarity in **2** will lead to still larger enhancement of the non-linearity for the above reasons.

In conclusion, non-linear properties of porphyrins can be vastly improved by external substitution of strong electron-donor groups at *ortho* positions of the planar porphyrin molecule. Further work to understand the origin of this enhancement at the microscopic level is in progress. However, this preliminary study provides some guidelines for molecular engineering.

We thank the Department of Science and Technology for financial support. Professor T. S. Srivastava would like to thank the All India Council of Technical Education for financial support.

# Synthesis and structure of [Sb{(Pr$^i$N)$_2$CNHPr$^i$}{(Pr$^i$N)$_2$CNPr$^i$}]; a distorted trigonal-bipyramidal antimony(III) complex with a helical hydrogen-bond network

**1,2,3-Triisopropylguanidine [(Pr$^i$NH)$_2$C=NPr$^i$], reacts with antimony tris(dimethylamide) [Sb(NMe$_2$)$_3$] to provide [Sb{(Pr$^i$N)$_2$CNHPr$^i$}{(Pr$^i$N)$_2$CNPr$^i$}] 1, a heavily distorted trigonal-bipyramidal complex in which the Sb is chelated by a [C(NPr$^i$)$_3$]$^{2-}$ dianion and a [(Pr$^i$N)$_2$CNHPr$^i$]$^-$ monoanion; in the solid state the complexes form helices by N–H···N hydrogen bonding of the single proton.**

Our recent interest in trisubstituted guanidines and their anions as ligands has led to the characterisation of a number of new complexes which have demonstrated the flexibility of this new ligand system in both chelating and bridging coordination modes.[1–4] The ligands also exhibit a marked ability to stabilise higher oxidation states in transition-metal complexes.[4] The ability of the system to coordinate as a neutral ($H_2L$), monoanionic ($HL^-$) or dianionic ($L^{2-}$) ligand, and the presence of ionisable protons on the former two, adds to its flexibility. Hydrogen bonding plays an important role in much of the chemistry of guanidines and molecules containing the guanidine unit such as the nucleic acid base guanine, and we have thus become interested in the hydrogen-bonding properties of metal coordinated guanidines containing residual protons. Here we report a complex containing a single hydrogen which is formed by chelation of a trivalent metal by two trisubstituted guanidines, one a monoanion and the other a dianion, thus providing an N–H hydrogen-bond donor on one ligand and a imine nitrogen hydrogen-bond acceptor on the other.

Treatment of 1,2,3-triisopropylguanidine with 1 mol. equiv. of [Sb(NMe$_2$)$_3$][5] in toluene solution provides a yellow solution. Reduction of this solution to dryness in vacuum and dissolution of the residue in warm hexane followed by filtration, concentration and cooling provided highly air-sensitive crystals of [Sb{(Pr$^i$N)$_2$CNHPr$^i$}{(Pr$^i$N)$_2$CNPr$^i$}] **1** in 10% yield.† The presence of both the anion $HL^-$ and dianion $L^{2-}$ is confirmed by the $^1$H NMR spectrum of **1** which shows that there are five independent isopropyl groups in the ratio 1 : 1 : 1 : 1 : 2, consistent with free rotation only about the uncoordinated C–NHPr$^i$ bond of the $HL^-$ ligand whilst the C=NPr$^i$ bond of the $L^{2-}$ remains static. The formation of **1**, which retains an N–H hydrogen despite the presence of sufficient metallating agent in the reaction mixture to remove all such hydrogens, is worthy of note and may be a result of preferential crystallisation of the hydrogen-bonded partially metallated species, *vide infra*, and explain its low yield. Unfortunately, the extreme air sensitivity of **1** prevented the recording of any IR spectra.

Crystals of **1** are chiral with space group $P3_121$ or $P3_221$ and a low-temperature X-ray crystallographic study‡ shows that there are two independent, but chemically equivalent, molecules in the unit cell which differ only marginally in the conformations of their isopropyl groups and in their bond lengths and angles. One molecule lies on a twofold rotational axis relating the two ligands (Fig. 1), whilst the other (molecule 2, not shown) lacks this axis. The complex consists of [Sb{(Pr$^i$N)$_2$CNHPr$^i$}{(Pr$^i$N)$_2$CNPr$^i$}] molecules in which each Sb$^{III}$ centre is formally chelated by a monoanion $HL^-$ and a dianion $L^{2-}$ ligand. The molecular structure of **1** is consistent with the ten-electron count of the Sb centre and can best be described as a heavily distorted trigonal-bipyramidal $N_4Sb$ molecule with the fifth coordination site being occupied by the lone pair. In both independent molecules the Sb$^{III}$ centres are asymmetrically coordinated by the two guanidine ligands [*e.g.* Sb(1)–N(11) 2.227(6) Å, Sb(1)–N(13) 2.069(6) Å]. This pattern of bond lengths is consistent with the description of the structure as distorted trigonal bipyramidal since in this geometry each ligand would be coordinated to an axial and an equatorial position. The nature of the distortion can be appreciated if it is considered that in this structure trigonal-bipyramidal geometry requires the chelating angle at the metal (N–Sb–N) to be 90°, whilst in **1** far more acute angles at Sb are found as a consequence of the geometric constraints arising from the chelation by the rigid guanidine ligands [*e.g.* N(11)–Sb(1)–N(13) 62.0(2)°]. The result of this is that the N–Sb–N angle between the axial N centres is distorted from the 180° [to

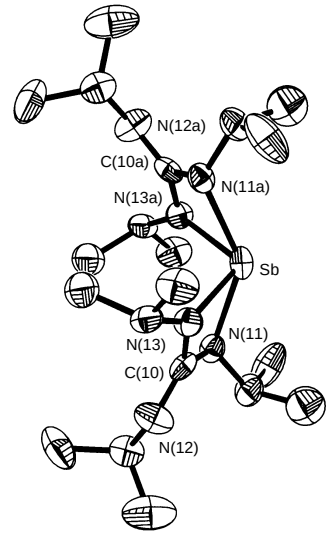

**Fig. 1** Molecular structure of **1**. Hydrogen atoms have been omitted for clarity. **Fig. 2** Stereoview showing the association of molecules of **1** *via* N–H···N hydrogen bonds into helices. Symmetry transformations used to generate equivalent atoms a, *x–y*, *–y*, *–z* + 1/3.

140.3(3)° for N(11)–Sb(1)–N(11a)] and that for the equatorial N centres is distorted from the 120° [to 104.5(3)° for N(13)–Sb(1)–N(13a)] required for ideal trigonal-bipyramidal geometry. The distorted trigonal-bipyramidal geometries of the $Sb^{III}$ centres of **1** are very similar to those observed for the central metal atom in the $[\{(Me_2N)_2Sb(NC_6H_{11})_2\}_2Sb]^-$ monoanion,[6] which is the only other structurally characterised unit containing an $Sb^{III}$ centre four-coordinated by nitrogen ligands.

Although the ligands in each molecule of **1** must formally be a monoanion and a dianion to provide the necessary trianionic ligand set for the $Sb^{III}$ centre, in the crystal they cannot be distinguished in this way since each of the uncoordinated $NPr^i$ groups is involved in hydrogen bonding to an adjacent molecule with an N···N distance of 3.184(12) Å and N–H···N angle of 160°. As a consequence of the alignment of these groups, which is dictated directly by the distorted trigonal-bipyramidal geometry present in the molecular units of **1**, the resulting hydrogen-bonded H···L–Sb–L–H···L–Sb–L–H··· chains form left-handed helices through the crystal studied with three molecules of **1** per 360° turn (Fig. 2). It is probable that other crystals have the opposite chirality and hence right-handed chirality. Helical association of monomer units has been identified in a few polymeric phosphido and amido lithium complexes[7] and packing of molecules of $[Ru_3(CO)_9\{\mu\text{-}NCH(SiMe_3)_2\}(\mu\text{-}N(C_6H_2Pr^i_3\text{-}2,4,6)_2]$ exclusively into β helices occurs in the solid state.[8] However, helical packing or association of molecules is extremely rare in transition and main group metal compounds and, to our knowledge, the helical hydrogen-bonded association found in **1** is unprecedented for any metallo-organic complex.

† 1,2,3-Triisopropylguanidine (0.928 g, 5.0 mmol) was dissolved in toluene (10 $cm^3$) and 2.6 $cm^3$ of a 1.93 M solution of $[Sb(NMe_2)_3]$ in toluene (1.275 g, 5.02 mmol) was added by syringe under argon. Over a period of 2 h the solution became yellow and the solvent was then removed *in vacuo*. The residue was dissolved in warm hexane (25 $cm^3$) and filtered through Celite to give a clear yellow solution. The volume was reduced to *ca*. 5 $cm^3$ and the resulting microcrystalline precipitate redissolved by warming. Gradual cooling in a water bath over two days provided X-ray quality crystals of **1** (*ca*. 10%). (Found: C, 48.2; H, 8.81; N, 16.4. $C_{20}H_{43}N_6Sb$ requires C, 49.1; H, 8.80; N, 17.1%). $^1$H NMR (250 MHz) in [$^2H_6$]benzene: δ 0.7–1.6 [m, 36 H, $CH(CH_3)_2$], 3.34 [br, 2 H, $CH(CH_3)_2$/NH], 3.72 [spt, 2 H, $CH(CH_3)_2$], 4.12 [spt, 1 H, $CH(CH_3)_2$], 4.35 [spt, 1 H, $CH(CH_3)_2$], 4.83 [spt, 1 H, $CH(CH_3)_2$].

‡ *Crystal data* for **1**: $C_{20}H_{43}N_6Sb$, $M_w$ = 489.35, trigonal, space group $P3_221$, $a$ = 17.356(2), $b$ = 17.356(2), $c$ = 21.919(4) Å, $U$ = 5718(2) $Å^3$, $Z$ = 9, λ = 0.710 73 Å, $D_c$ = 1.279 Mg $m^{-3}$, μ(Mo-Kα) = 1.101 $mm^{-1}$. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated crystal[8] of dimensions 0.2 × 0.2 × 0.2 mm using the θ–ω method ($4.04 \leqslant \theta \leqslant 22.73°$). Of a total of 6438 reflections collected, 4985 ($R_{int}$ 0.026) were independent. The crystal studied was intimately twinned, giving a diffraction pattern approximating to 6/*mmm* ($D_{6h}$) symmetry. Twin refinement in space group $P3_221$ with [1$\bar{1}$0] as the twin axis gave 56.46(9)% as the contribution of the major component and 0.03(3) as the Flack *x*-parameter, indicating that both twins have the same correct absolute structure. No conclusons may be drawn about the chirality of the other crystals in the batch. The structure was solved by Patterson methods, and refined by full-matrix least squares on $F^2$ to final values of $R_1$ = 0.027 [for 4985 data with $F > 4\sigma(F)$] and $wR_2$ = 0.070 (all data) [$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR_2 = \{[\Sigma w(F_o^2 - F_c^2)]^2/\Sigma wF_o^4\}^{0.5}$, $w = 1/[\sigma^2(F_o^2) + (0.040P)^2 + 4.26P]$, $P = (F_o^2 + 2F_c^2)/3$].[10] Largest difference between peak and hole in the final difference map, 0.42, −0.38 e $Å^{-3}$. The hydrogen-bonded N–H hydrogens were placed in calculated positions and allowed to ride between their respective nitrogen atoms with a site occupancy of 0.5. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Dehalogenation of organic halides by flash vacuum pyrolysis over magnesium: a versatile synthetic method

**R. Alan Aitken,*[a] Philip K. G. Hodgson,[b] Adebayo O. Oyewale[a] and (in part) John J. Morrison[a]**

[a] *School of Chemistry, University of St. Andrews, North Haugh, St. Andrews, Fife, UK KY16 9ST*

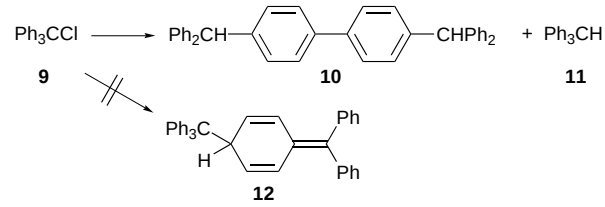
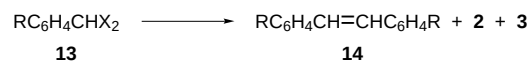
**Flash vacuum pyrolysis over magnesium at 600 °C results in efficient dehalogenation of a variety of organic halides and provides a preparatively useful method for C–C bond formation and other reactions.**

Pyrolytic processes in organic chemistry normally involve either fragmentation or rearrangement. The thermal generation of species such as radicals or carbenes may be followed by dimerisation but their high reactivity frequently leads to other competing processes. In order to develop a general method for C–C bond formation in the gas phase we decided to examine the pyrolysis of organic halides over solid magnesium. There has been little previous work on gas phase pyrolysis over solid reagents but pyrolysis over solid bases has been used effectively by Denis and co-workers.[1] Dehydrofluorination of alicyclic precursors over iron or nickel has been used to obtain fluorinated aromatics,[2] and pyrolysis of hexachlorocyclopentadiene over iron results in C–C bond formation to give perchlorofulvalene.[3] The few studies using other metals have all involved the generation of highly reactive species for spectroscopic detection. Thus, benzocyclobutadiene was first generated by flash vacuum pyrolysis (FVP) of diiodobenzocyclobutene over zinc at 230 °C[4] and can alternatively be formed by FVP of α,α,α′α′-tetrabromo-*o*-xylene over magnesium at 440–470 °C,[5] while FVP of $PXCl_3$ (X = O, S) over silver at 880 °C leads to generation of the reactive $P^{III}$ species, Cl–P=X[6] and FVP of trichloroacetyl chloride over zinc at 420 °C gives dichloroketene.[7] We report here that FVP of organic halides over freshly resublimed magnesium at 600 °C provides a versatile and preparatively useful method for C–C bond formation.



Initial experiments using benzyl chloride established that for maximum activity the magnesium had to be used in the range 500–700 °C and was best prepared by freshly subliming the metal over the surface of glass wool.† FVP of benzyl chloride through the system at 600 °C gave a liquid in the cold-trap which proved to be toluene (16%) and a solid at the furance exit which was essentially pure bibenzyl (58%). By using excess benzyl chloride it was established that approximately 20% of the magnesium used was available for reaction assuming conversion to $MgCl_2$. The method was equally effective for a range of substituted benzyl chlorides and bromides (Table 1)

giving the bibenzyls **2** and toluenes **3** in good to excellent combined yield. The bibenzyls were readily obtained in pure form by a single recrystallisation of the solids from the furnace exit and this represents a gas-phase alternative to the Wurtz coupling. The somewhat unexpected formation of the reduction products was a general observation in these studies and presumably results from sacrificial carbonisation of the substrate. For 2-halobenzyl halides, further dehalogenation to give dihydrophenanthrene **4** and phenanthrene **5** was observed as a minor process. The result for 2-methylbenzyl bromide shows a clear distinction from pyrolysis without magnesium which results in 1,4-loss of HBr and cyclisation of the resulting *o*-xylylene to give benzocyclobutene as the major product.[9] Reaction of 1,2-bis(halomethyl)benzene derivatives results in efficient formation of the benzocyclobutenes and this was used to obtain the 3- and 4-fluoro compounds **7** directly from **6** as



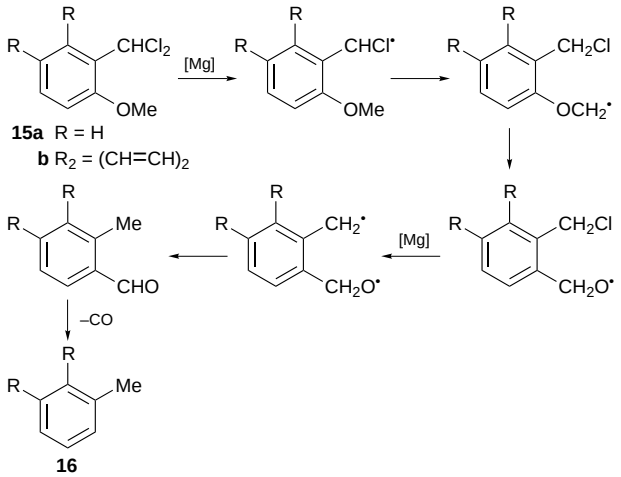
compared to the literature method which takes three steps for this transformation.[10] Bromo- and chloro-diphenylmethane behaved similarly giving tetraphenylethane (60–70%) and diphenylmethane (20%), apparently derived respectively from dimerisation and reduction of the corresponding radical. It was therefore of great interest to investigate trityl chloride **9** in view

of the long-standing controversy over the structure of the trityl radical dimer.[11] The products were **10** (46%) and triphenylmethane **11** (39%) with none of the non-benzenoid dimer **12** formed from dimerisation of $Ph_3C^{\cdot}$ in solution. The conditions used have obviously favoured *p–p* dimerisation of the reactive intermediate involved followed by two 1,5-hydrogen shifts to give the stable aromatic product. It is interesting to note that this is also the product formed from photochemical dimerisation of the trityl cation in solution.[12]

The method it also effective in coupling benzylidene chlorides **13** to give the corresponding stilbenes **14** in moderate

yield (Table 1), together with the reduction products **2** and **3**. Convenient direct access to polycyclic aromatic systems is also possible as illustrated by conversion of 2-chlorobenzylidene dichloride into phenanthrene (47%) and 1,3-bis(dibromomethyl)benzene into pyrene (54%) and this method should be amenable to formation of specifically substituted products. An unexpected result was obtained for the 2-methoxy compounds **15a, b** where the main products **16**, formed in 60 and 51% yields, respectively, seem likely to result from the sequence shown in Scheme 1 involving two intramolecular hydrogen atom transfers between the adjacent groups and decarbonyla-

tion. This is in contrast to the pyrolysis of these substrates without magnesium which gives benzofurans by a carbene route.[13]



In order to gain further insight into the nature of the intermediates involved, we examined the reactivity of some aliphatic halides. Neopentyl bromide was of particular interest since the products formed from generation of both neopentyl radical and the carbene, neopentylidene, under very similar conditions have been described.[14] The products obtained over magnesium, 2-methylbut-2-ene (43%) and 2-methylbut-1-ene (33%) together with a trace of 2-methylpropene, indicate that neither the free gas-phase radical (2-methylpropene : 2-methylbut-1-ene, 1.2 : 1) nor the carbene (1,1-dimethylcyclopropane as main product) are involved. Where dehydrohalogenation is possible it usually occurs, as shown by the high yielding synthesis of 2,3-dimethylbuta-1,3-diene (84%) from the inexpensive precursor 2,3-dichloro-2,3-dimethylbutane, but C–C bond formation is also possible as shown by formation of cyclopropane (60%) from 1,3-dibromopropane. For longer α,ω-dihalides an intramolecular hydrogen transfer occurs and this is optimal for 1,6-dibromohexane resulting in the remarkably efficient formation of hex-1-ene (72%) by loss of $Br_2$. Further evidence against the involvement of free gas-phase radicals was provided by reaction of 6-bromohex-1-ene which gave mainly cyclohexene (50%) and isomeric hexadienes (23%) with no major products derived from cyclopentylmethyl radical.[15] It appears that the reactions may proceed by way of surface-adsorbed organomagnesium species.‡

Whatever the nature of the intermediates involved, this method appears to allow a range of synthetically useful transformations and further applications to organic halides and halides of other main group elements will be reported shortly.

We thank British Petroleum Research International Limited for a Research Studentship (A. O. O.) and The Royal Society for a Warren Research Fellowship (R. A. A.).

† *Pyrolysis procedure.* Using the normal apparatus for FVP described previously (ref. 8), magnesium turnings (1–2 g) were placed between two plugs of glass wool in the centre of the pyrolysis tube. The system was connected up as normal except that a stopper was used in place of the inlet tube, and the evacuated pyrolysis tube was briefly heated to 650–700 °C until the magnesium melted and sublimed evenly over the surface of the glass wool. Careful observation at this stage revealed an initial vigorous reaction on the wool, interpreted as the formation of magnesium silicide, but this was subsequently covered by magnesium and does not play a significant part in the reactions. The furnace was then cooled to the pyrolysis temperature, usually 600 °C, the pump was isolated and the system cautiously refilled with dry nitrogen to atmospheric pressure. The stopper was then removed, the inlet tube containing the substrate (5–10 mmol) attached (*CAUTION*: admission of air at this stage may lead to an explosion), and the pyrolysis continued as normal. After the pyrolysis was complete, the products were removed from the cold trap and analysed using the normal methods. The used pyrolysis tube was disposed of by cautiously placing it in a bath of 2 M HCl behind a safety shield (*CAUTION*: this results in a vigorous reaction accompanied by explosive ignition of the pyrophoric gases evolved. This is thought to be due to low molecular weight silanes formed by hydrolysis of the magnesium silicide).

‡ For comparison, FVP of each substrate was examined without magnesium at 600 °C and this led to formation of the previously reported (refs. 9, 13) dehydrohalogenation products for **1** (R = 2-Me), **6**, **13** (R = 2-Me) and **15** and to recovery of unchanged starting material in all other cases.

**A new photoactive bis-anthracenyl crown undergoes a reversible photocyclisation to form a cryptand, with the efficiency of the forward reaction and the rate of the thermal reverse reaction strongly affected by the presence of cation substrates.**

Photoresponsive molecular devices are of current interest due to their relevance to semiochemistry, substrate transport and sensor technology.[1] A number of supramolecular systems incorporating the photoactive anthracene moiety have previously been studied,[1f,2] including iono-photoswitches, where light is used to affect the ion binding properties of a system.[3] Here we report a new bis-9-anthracenyl crown ether **1** (Scheme 1) and give preliminary results on its unusual spectroscopic properties and photoreactivity in the absence and presence of guest substrates.

Compound **1** can be synthesised from diaza-18-crown-6 *via* two different routes; either directly from the reaction with 9-bromoethyloxyanthracene[4] or with 9-anthracenyloxyacetyl chloride,‡ followed by reduction using a method described previously.[5] An X-ray crystallographic study fully confirms the structure of **1** with the two pendant arms *trans* to one another.[6]

Complex formation with $H^+$, $Na^+$, $K^+$, $Cs^+$ and $Rb^+$ is evidenced by changes to the $^1H$ NMR spectrum of **1** (300 MHz) in $CDCl_3$–$CD_3OD$ (1 : 1; 0.04 M). Addition of aliquots of Group 1 cations to **1** confirms the 1 : 1 stoichiometry of each complex, which can, in principle, adopt either a *cis* or *trans* geometry (Fig. 1). The observation of only one set of signals throughout each titration indicates that cation exchange between free ligand and complex, as well as any interconversion between the two isomers, is fast on the NMR timescale.

Previous crystallographic studies on Group 1 complexes of a closely related diaza-crown ether derivative[7] suggest that a *cis* orientation is favoured for larger ions, with the cation situated

**Scheme 1**

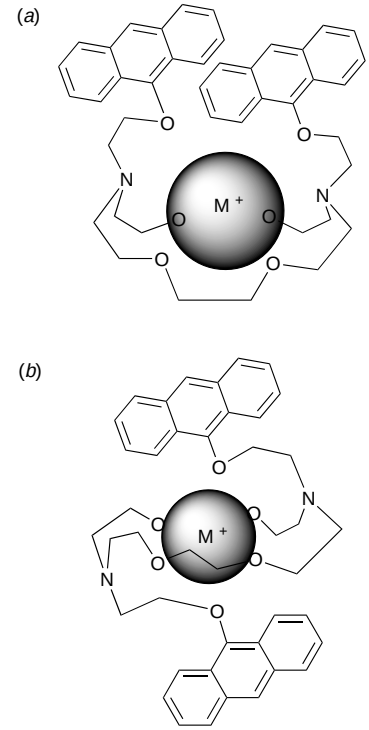

**Fig. 1** The complex **1** : $M^+$ with the anthracenyl groups depicted (*a*) *cis* and (*b*) *trans* to one another

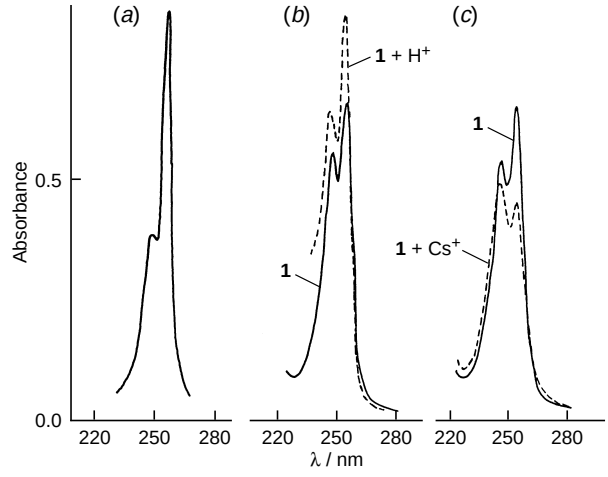

**Fig. 2** UV spectra in $CH_3OH$ (conc *ca.* $5 \times 10^{-5}$ M, room temp.) of (*a*) 1-(9-anthryloxy)-3,6,9-trioxadecane, as the monochromophoric reference compound; (*b*) compound **1** (—); **1** + $CF_3COOH$ (*ca.* $10^{-2}$ M) (----); (*c*) compound **1** (—); **1** + $CsClO_4$ (*ca.* $10^{-2}$ M) (----)

above the plane or the ring [Fig. 1(*a*)], whereas a *trans* orientation is prefered for complexes of smaller ions, with the cation symmetrically located in the plane of the macrocycle [Fig. 1(*b*)]. For this system, the addition of either $Rb^+$ or $Cs^+$ to **1** produce NMR spectra markedly different from those found with other guests. In particular, large upfield shifts for all five anthracene signals are observed upon the addition of $Rb^+$ and $Cs^+$ (and to a lesser extent with $K^+$) which is indicative of a strong π-π interaction.[8] Such an interaction is consistent with the *cis* conformation being favoured as the size of the guest increases.

Previous UV studies on bis-anthracenes have shown that the shape of the second electronic transition band ($^1$Bb) is characteristic of the mutual interaction between the two aromatic (A) rings: For an isolated A ring [Fig. 2(*a*)], the 256 nm component largely predominates; conversely the 248 nm component intensity increases as a function of the degree of interring interaction.[3b] The UV spectrum of **1** [Fig. 2(*b*) and (*c*), solid line] in MeOH is thus indicative of a mixture of *cis* and *trans* isomers. Addition of excess $CF_3CO_2H$ [Fig. 2(*b*), dotted line] induces a slight increase of the 256 nm component intensity, in keeping with an increase of the *trans*/*cis* ratio. With $Cs^+$ in excess, however, the intensity of the 248 nm band increases [Fig. 2(*c*), dotted line] which points to an increase of the *cis*/*trans* ratio. Similar results were obtained with $K^+$ and $Rb^+$ but no significant spectral modifications were displayed with $Na^+$.

The fluorescence emission spectrum of **1** is complex; it consists of a structured part (monomer emission) and a non-structured red-shifted band originating in exciplex (amine–anthracene) and excimer (anthracene–anthracene) species (Fig. 3). In the presence of a large excess of $CF_3CO_2H$, a strong increase of the fluorescence intensity and a clear decrease of the long wavelength contribution are observed. Among the metal cations investigated, $Cs^+$ gives the highest excimer/monomer ratio (Fig. 3), presumably because the 1:1 complex *cis* conformation, favoured in the ground state, displays the best geometry for excimer formation.

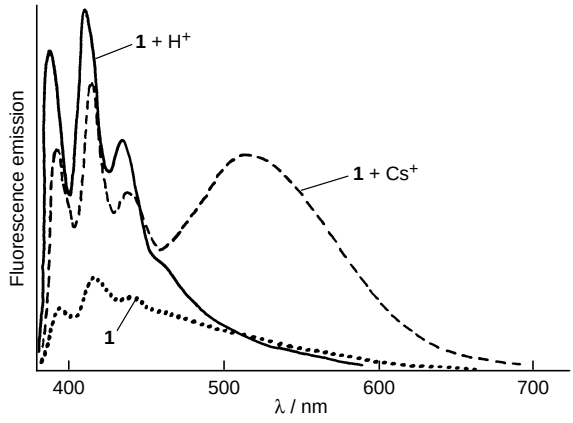

**Fig. 3** Corrected fluorescence spectra (conc. *ca.* $5 \times 10^{-5}$ M, $\lambda_{exc}$ = 380 nm, room temp.) in degassed MeOH and fluorescence quantum yield ($\phi_F$) of: **1** free ligand (●●●●) $\phi_F$: 0.04; **1** + $CF_3COOH$ (*ca.* $10^{-2}$ M) (—) $\phi_F$: 0.16; **1** + $CsClO_4$ (*ca.* $10^{-2}$ M) (----) $\phi_F$: 0.145. For comparison, 1-(9-anthryloxy)-3,6,9-trioxadecane has $\phi_F$: 0.29.

**Table 1** Intramolecular photocylcoaddition quantum yields ($\phi_R$) for the formation of **2** from **1** (*ca.* $5 \times 10^{-5}$ M) in the absence and in the presence of an excess of cations (*ca.* $10^{-2}$ M) in degassed MeOH (366 nm) and thermal dissociation rate constants for the reverse process at 25 °C

| System | $\Phi_R$ (366 nm) | $k_{diss}/10^{-6}$ s$^{-1}$ | $t_{1/2}$/h |
|---|---|---|---|
| **1** | 0.10 | 5 | 38 |
| **1** + $CF_3CO_2H$ | 0.03 | 1.2 | 160 |
| **1** + $CsClO_4$ | 0.04 | 0.3 | 638 |

On irradiation of a methanol solution of **1** (*ca.* $5 \times 10^{-5}$ M) at 366 nm, the photocycloadduct **2** is formed as evidenced by the disappearance of the $^1$La UV absorption (300–400 nm) and the emergence of a new absorption (270–290 nm) characteristic of an *o*-xylene system. The reaction efficiency for this process ($\Phi_R$ = 0.10) is much greater than those found for analogous processes with more sterically hindered systems.[3b] Cryptand **2** reverts back to the crown **1** in the dark with a half life of 38 h. Preliminary photocyclisation studies have been carried out in the presence of $H^+$ and $Cs^+$ (*ca.* 1000-fold excess) with the relevant data displayed in Table 1. The closing and opening rates clearly depend upon the type of guest present; significantly, $Cs^+$ retards the rate of both the forward and reverse processes. It is likely that this substrate dependency is a result of increased steric hindrance for the forward process and an increased stabilisation of the cryptand geometry for the reverse process, as a consequence of the cation being enclosed within the cryptand cavity.

This is the first example of a molecular system that, upon the action of an external trigger, can switch *reversibly* between a crown and cryptand.[9] Preliminary studies indicate that the photocyclisation quantum yields and the rates of the thermal reverse reactions are clearly influenced by the nature of the bound substrate. Detailed studies of the cation binding ability of both **1** and **2** and also the transient kinetic analysis and electrochemical properties of **1** are currently underway.

We thank the CNRS, la Région Aquitaine and the University of Exeter for financial support and J. Lauret, M. Gotta and Tran Thanh Hung Linh for technical assistance.

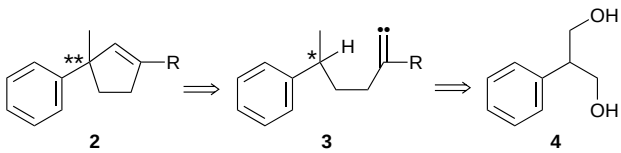
# New asymmetric construction of the benzylic quaternary stereogenic centre: an enantiocontrolled access to (−)-α-cuparenone

**Takamitsu Kosaka, Toshikazu Bando and Kozo Shishido***

*Institute for Medicinal Resources, University of Tokushima, Sho-machi 1, Tokushima 770, Japan*

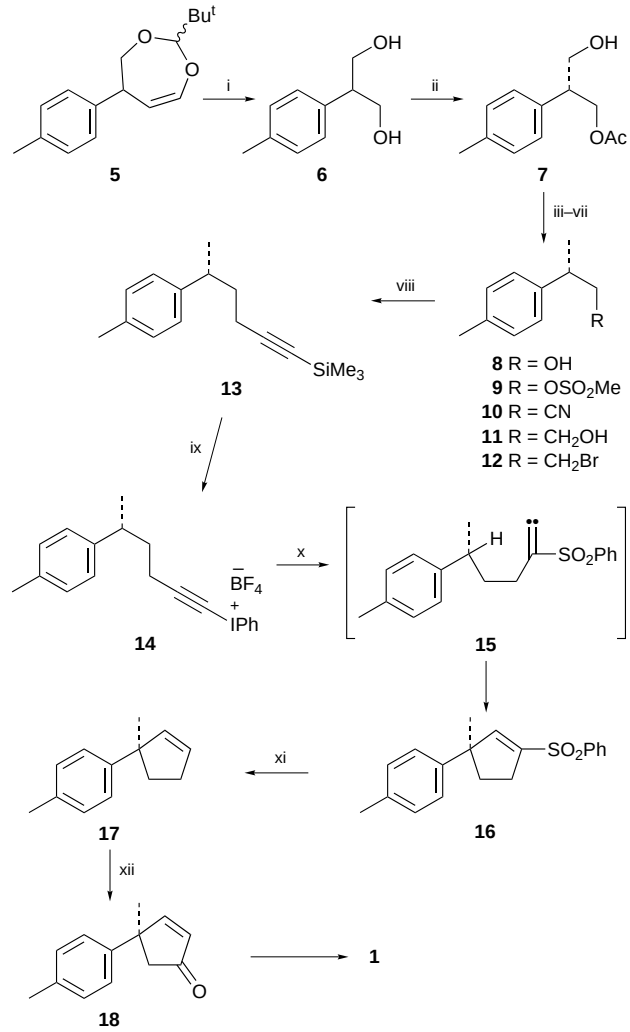
**An efficient and enantiocontrolled formal total synthesis of (−)-α-cuparenone has been accomplished by employing a new asymmetric construction methodology for formation of the benzylic quaternary stereogenic centre.**



Development of the methodology for assembling an asymmetric quaternary stereogenic centre has been a challenging and important target in organic synthesis.[1] Particularly, construction of benzylic quaternary centres has become of special interest[2] since it is involved in many biologically significant molecules. Here we present a new and efficient strategy for the asymmetric construction of the benzylic quaternary carbon centre by illustrating an enantiocontrolled formal total synthesis of (−)-α-cuparenone **1**.[3] Our basic strategy is shown in Scheme 1.

**1**

We envisaged that a pivotal construction of the benzylic quaternary carbon in **2** might be realized by employing the diastereoselective [1,5] C–H insertion reaction of alkylidene carbene **3**,[4] in which the benzylic tertiary asymmetric centre should be generated *via* a lipase-mediated asymmetric acetylation[5] of the prochiral diol **4**. It is well known that the C–H insertion reaction proceeds with complete retention of configuration.[4b,c]



Treatment of 2-*tert*-butyl-4,5-dihydro-5-(4-methylphenyl)-1,3-dioxepine **5**,[6a] prepared by the Heck reaction[6] between 4-methyliodobenzene and 2-*tert*-butyl-4,7-dihydro-1,3-dioxepine,[7] under ozonolytic cleavage conditions followed by reductive workup with $NaBH_4$ provided the prochiral 1,3-diol **6** in 84% yield (Scheme 2). It should be noted that the procedure is efficient and superior to the conventional method.[8] With the prochiral diol in hand, we examined the optimum conditions for asymmetric acetylation using some lipases.[9] Of these, porcine pancreatic lipase (PPL)-catalysed transesterification in diethyl ether using vinyl acetate as an acetyl donor at room temperature proved to be the best choice and (*R*)-monoacetate **7**, $[\alpha]_D$ + 15.6 (*c* 1.28, $CHCl_3$) {lit.,[9] for the (*S*)-isomer; $[\alpha]_D$ − 16.2 (*c* 1.20, $CHCl_3$)}, was obtained in 84% yield. The enantiomeric excess was 99% as determined by $^1H$ NMR analysis of its MTPA ester derivative. Removal of the hydroxy moiety in **7** by tosylation and subsequent reduction with $NaBH_4$ in $Me_2SO$[9] furnished the alcohol **8**, which was mesylated to give **9** in 88% yield from **7**. Sequential cyanation, DIBAL-H reduction–acidic workup, and further reduction with $NaBH_4$ gave one-carbon elongated alcohol **11** in 75% overall yield. Reaction of the bromide **12**, prepared from **11** by a standard method, with lithium trimethylsilylacetylide produced the alkynylsilane **13** in 69% yield.

**2** **3** **4**

**Scheme 1**

The stage was now set to explore the crucial construction of the quaternary stereogenic centre *via* the [1,5] C–H insertion reaction of the alklidene carbene. For this purpose, we intended to use the procedure developed by Ochiai,[4d,e,g] since the product obtained by this method is vinyl sulfone, which would be

**5** **6** **7** **8** R = OH, **9** R = $OSO_2Me$, **10** R = CN, **11** R = $CH_2OH$, **12** R = $CH_2Br$, **13** **14** **15** **16** **17** **18** **1**

**Scheme 2** *Reagents and conditions*: i, $O_3$ then $NaBH_4$, $CH_2Cl_2$, −78 to 0 °C, 84%; ii, vinyl acetate, PPL, $Et_2O$, room temp., 84%; iii, TsCl, $Et_3N$, DMAP, $CH_2Cl_2$, room temp., then $NaBH_4$, $Me_2SO$, 60 °C, 73%; iv, MsCl, $Pr^i_2NEt$, $CH_2Cl_2$, room temp., 88%; v, KCN, 18-crown-6, $Me_2SO$, 60 °C, 90%; vi, DIBAL-H, hexane–$CH_2Cl_2$ (1 : 1), −78 °C then 1 M HCl, $NaBH_4$, MeOH, 75%; vii, $Ph_3P$, $CBr_4$, $CH_2Cl_2$, −40 °C, 94%; viii, $Bu^nLi$, HC≡$CSiMe_3$, THF, HMPA, −78–0 °C, 69%; ix, $(PhIO)_n$, $BF_3$·$OEt_2$, $CH_2Cl_2$, 0 °C; x, $PhSO_2Na$, $H_2O$, 0 °C, 83% for 2 steps; xi, Na–Hg (5%), MeOH, sonication, room temp., 70%; xii, PDC, $Bu^tOOH$, Celite, benzene, 10 °C–room temp., 72%

convenient for further transformations. Thus, treatment of **13** with iodosylbenzene in the presence of boron trifluoride–diethyl ether in $CH_2Cl_2$ at 0 °C followed by treatment with aqueous sodium tetrafluoroborate provided the iodonium tetrafluoroborate **14**, which was immediately exposed to aqueous sodium benzenesulfinate at 0 °C to give the cyclized vinyl sulfone **16**,† *via* the alkylidene carbene intermediate **15**, in 83% overall yield from **13** as the sole product. The absolute configuration at the newly-generated quaternary centre was deduced to be *R*, which was confirmed by the following conversion. Removal of the benzenesulfonyl moiety in **16** using Na–Hg under sonication[10] afforded **17** in 70% yield. Finally, oxidation of the allylic methylene in **17** with pyridinium dichromate (PDC) in the presence of *tert*-butylhydroperoxide and Celite[11] produced the enone **18**, whose $^1$H NMR data and optical rotation, $[\alpha]_D$ + 101 (*c* 1.28, EtOH) {lit.[3a] $[\alpha]_D$ + 114 (*c* 1.36, EtOH)}, were identical with those reported. Since the compound **18** has already been converted into (−)-α-cuparenone **1** by a two-step sequence,[3a] the present synthesis constitutes a formal total synthesis of **1**.

In summary, we have developed an efficient and unprecedented methodology for assembling benzylic quaternary stereogenic centres and demonstrated the formal total synthesis of (−)-α-cuparenone as an application of the procedure.

We are grateful to Professor Masahito Ochiai and Mr Takuya Sueda, University of Tokushima, for valuable discussions.

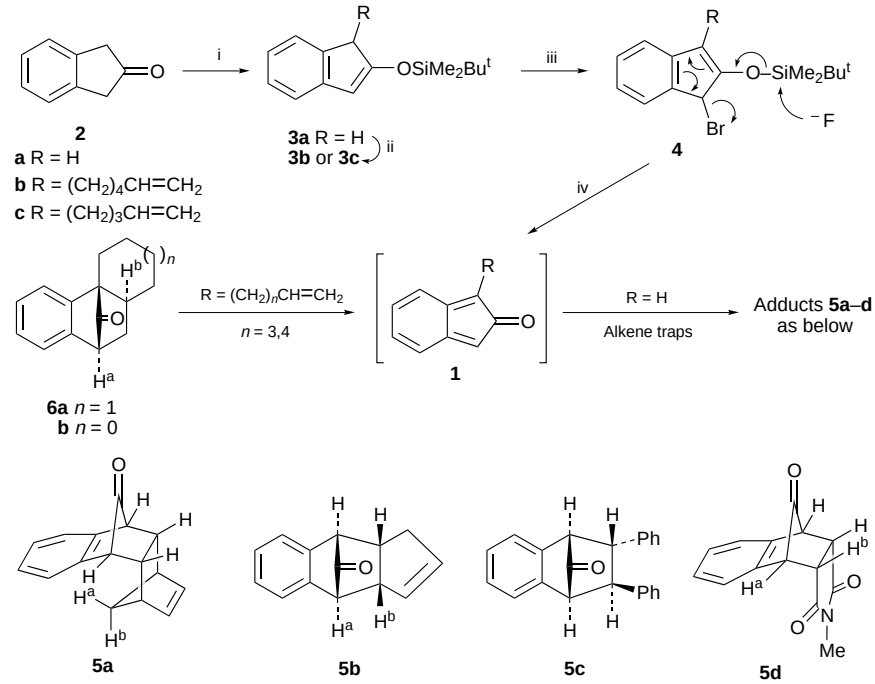
# Generation and inter- and intra-molecular trapping of isoindenones (inden-2-ones)

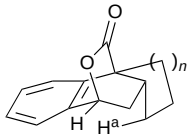
**David W. Jones* and Tracie C. L. M. Ryder**

*School of Chemistry, The University, Leeds, UK LS2 9JT*

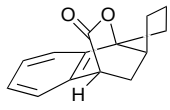


**Inden-2-one and some simple derivatives are smoothly generated by reaction of caesium fluoride with 1-bromo-2-*tert*-butyldimethylsilyloxyindenes and they can be efficiently trapped in both intra- and inter-molecular additions; the intramolecular additions proceed with *exo*-addition of the tether, in contrast to the intermolecular additions and intramolecular additions to 2-benzopyran-3-ones.**

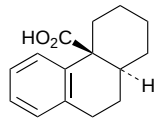
Isoindenones (inden-2-ones) are of interest as derivatives of two very reactive dienes, *o*-quinodimethane and cyclopentadienone; resonance involving the oxyallyl structure is also a possibility (Scheme 1).



**Scheme 1**



From the MO point of view the HOMO–LUMO energy gap is expected to be particularly small for isoindenones as it is for cyclobutadienes and other antiaromatic species.[1] We have shown that 1,3-diphenylinden-2-one is readily generated by dissociation of its dimer,[2] and that it is efficiently trapped by a range of alkenes in Diels–Alder reactions.[2,3] We further showed that the potentially more synthetically useful parent system (Scheme 1) could be generated from 1,3-dibromoindan-2-one by reaction with copper powder or sodium iodide, but generation/trapping was inefficient (8% yield of adduct with cyclopentadiene using copper powder in boiling benzene).[4] We now describe an efficient method of generating and trapping simple inden-2-ones **1** (Scheme 2). Commercially available indan-2-one **2** was converted into enol silyl ether **3a** (64%). This could be alkylated to give either **3b** or **3c** in 61 and 75% yield, respectively. With *N*-bromosuccinimide in refluxing $CCl_4$ and irradiation with a sun lamp (500 W), **3b** and **3c** gave **4b** (75%) and **4c** (71%) respectively. Slow addition of **4b** (syringe pump) to a refluxing mixture of MeCN and CsF gave the adduct **6a** in good yield (66%).† The adduct showed a characteristic high frequency carbonyl stretch at 1778 $cm^{-1}$. In the $^1H$ NMR spectrum a shielded resonance such as that found for related *endo*-2-benzopyran-3-one adducts like **7** (*n* = 1 or 2) was absent.[5] A similar adduct **6b** was obtained in 73% yield† from **4c** but again the NMR spectrum showed the absence of a shielded proton. Since modelling[6] suggested a very similar location of the proton $H^a$ with respect to the aromatic ring in the (hypothetical) *endo*-chain adducts from the isoindenones and the known *endo*-chain adducts of the 2-benzopyran-3-ones,[5] an *exo*-chain addition to the isoindenones seemed likely. The assignment was reinforced by Baeyer–Villiger oxidation of **6b** to **8** (79% yield) which also failed to show a shielded proton, although if **8** were an *endo*-chain adduct the location of $H^a$ with respect to the aromatic ring would be very similar to that in **7** (*n* = 1). Finally the stereochemistry of **6a** was confirmed by



**Scheme 2** *Reagents and conditions*: i, LDA (1.4 equiv.), THF, −78 °C, 10 min; then $Bu^tMe_2SiCl$ (1 equiv.), −78 °C, 10 min, then HMPA, −78 °C, 15 min, allowed to warm to 20 °C; ii, BuLi (1 equiv.), THF, 0 °C, 10 min, then iodo-alkene (1.7 equiv.), HMPA (1 ml $g^{-1}$ of base) added, allowed to warm to 20 °C and stirred for 10 min; iii, NBS, $CCl_4$, AIBN, reflux, sun lamp (500 W), 2 h; iv, CsF (2 equiv.), MeCN, reflux, bromo compound added in MeCN (10 ml mg) *via* syringe pump, 4 h

**14**

modified Haller–Bauer cleavage[7] to give the *trans* acid **9** (62%), mp 164.5–167 °C (lit.,[8] mp 162 °C: the *cis* acid has mp 143 °C). Accordingly, and in contrast to the IMDA additions to 2-benzopyran-3-ones, the inden-2-one additions proceed with clean *exo*-selectivity.

The synthetic utility of products of type **6a** is illustrated by the foregoing cleavage of **6a** to **9** and photodecarbonylation of **6a** in the presence of oxygen; **6a** in benzene saturated with oxygen was irradiated through silica with a MP 125 W mercury lamp with slow passage of oxygen through the solution to give the hydroxy ketone **10** (70% yield). This probably arises *via* the expected *o*-quinodimethane **11** and the *endo* peroxide **12** in the manner indicated by the arrows in **12**. An alternative mechanism for the decomposition of related peroxides involves homolytic cleavage of the O–O bond.[9] Such a route is also possible for our example.

This route to inden-2-ones appears general as it can be applied to the parent compound **1a** (Scheme 2). Allylic bromination of **3a** gave **4a** (62%) which, upon reaction with CsF in the presence of norbornadiene (10 equiv.), gave the *endo* norbornadiene adduct **5a** (68% yield). The related norbornene adduct was obtained in a similar way (43% yield), as was the cyclopentadiene adduct **5b** (49% yield). Trapping with *trans*-stilbene was less satisfactory, giving **5c** in 8% yield. Trapping with *N*-methylmaleimide gave only 22% yield of **5d**, although here there is a problem isolating the adduct from a considerable amount of polymeric material derived from the dienophile, which streaked extensively upon chromatography.

In view of the *exo*-chain addition observed for the intramolecular reactions, the exclusive *endo*-addition† in the intermolecular reactions is noteworthy. Evidence for the *endo* configuration of the intermolecular adducts includes the value of the vicinal coupling constant $J_{HaHb}$ (see structures **5b** and **5d**, Scheme 2). This is *ca*. 4 Hz, as expected for an *endo*-adduct ($\phi_{ab}$ *ca*. 40°) rather than < 0.5 Hz expected for an *exo*-adduct ($\phi_{ab}$ *ca*. 80°). Additional evidence is provided by the strong shielding of *endo*-disposed groups, *e.g.* $H^a$ in the norbornadiene adduct **5a** resonates at δ −0.64 and $H^b$ at δ +0.47. In the corresponding norbornene adduct, $H^a$ and $H^b$ appear at δ −0.72 and +0.34, respectively. In the *N*-methylmaleimide adduct **5d** the NMe resonance is shielded (δ 2.2) in comparison with the methyl in *N*-methylmaleimide (δ 3.07). The contrasting stereochemistry of the intra- and inter-molecular additions is presumably due to conformational factors in the connecting chain. Work on this question is continuing.

In the absence of a trap, **1** (R = H) gives the dimer **13**† of a formal $\pi^4s^+\pi^4s$ addition. The parent isoindenone therefore dimerises in the same way as its diphenyl derivative. As in that case[2] a biradical intermediate like **14** is likely to be involved in forming this orbital symmetry forbidden product.

In summary, we have provided an efficient way of generating simple inden-2-ones and trapping them both intra- and intermolecularly. In addition to their theoretical interest, these molecules are useful intermediates in making benzonorbornenones and hence products like **9** and **10**. Regioselective Haller–Bauer-like cleavage,[7] in combination with the clean *exo*-selective addition of the tether observed in the IMDA additions, is clearly of potential use in the synthesis of diterpenoids like pisiferic acid which have the *trans*-BC ring junction.[10]

† For the intramolecular additions the TLC and 300 MHz $^1$H NMR spectra of the crude reaction products failed to reveal any *endo* addition product. Similarly, the adduct fraction obtained by chromatography indicated a single adduct in both cases. The intermolecular additions proceeded somewhat less cleanly and the presence of some 5–10% of *exo*-adduct cannot be excluded. In the preparation of **5a** without the use of slow addition (syringe pump), the spectra of the crude product clearly showed the presence of the dimer **13**.

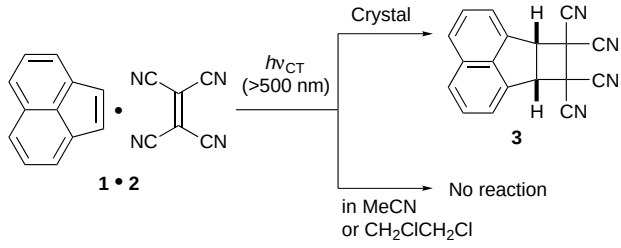
# Exclusive production of a cycloadduct from selective excitation of the charge-transfer complex between acenaphthylene and tetracyanoethylene in the crystalline state in contrast to failure of reaction in solution

**Naoki Haga,*[a] Hiroyuki Nakajima,[a] Hiroaki Takayanagi[a] and Katsumi Tokumaru[b]**

[a] *School of Pharmaceutical Sciences, Kitasato University, Minato-ku, Tokyo 108, Japan*
[b] *University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

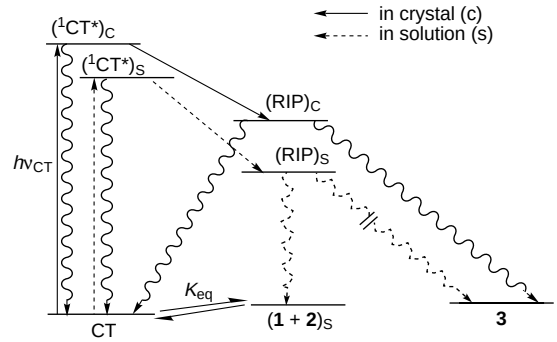
**Selective excitation of the charge-transfer complex between acenaphthylene and tetracyanoethylene in the crystalline state exclusively affords a 1:1 [2 + 2] cycloadduct, in contrast to the excitation in solution, which gives no product.**

Many electron donors and acceptors give charge-transfer (CT) complexes in solution and in the solid state, and their behaviour on photochemical irradiation has been investigated.[1,2] We now report that irradiation with light of wavelength longer than 500 nm of the crystalline CT complex between acenaphthylene **1** and tetracyanoethylene **2** affords a 1 : 1 [2 + 2] cycloadduct **3** of **1** and **2** as the sole product, whereas excitation in solution does not induce any reaction. To the best of our knowledge, this is the first observation of excitation of a CT complex leading to reaction in the crystal but not in solution.



Mixing **1** and **2** in organic solvents immediately produces a tan–brown colour due to formation of their CT complex (with an absorption extending to 700 nm) in equilibrium with **1** and **2**. Evaporation of the solvent from an equimolar mixture of **1** and **2** in ethyl acetate affords crystals of a 1 : 1 CT complex **1·2** as tan–brown cubes (satisfactory elemental analysis, mp 103.0–105.0 °C, orthorhombic, space group $P2_1/n$).

X-Ray crystallographic diffraction of **1·2** indicates that molecules of **1** and **2** are stacked alternately with a distance of 4.0 Å between the **1** and **2** planes, with a dihedral angle of 0.8°. The alkenic parts of **1** and **2** are aligned with interatomic distances of 3.3–3.9 Å and a torsion angle of 62.2°.



On irradiation of crystalline **1·2** with light of wavelength longer than 500 nm at 20 °C, where neither **1** nor **2** was excited, **3** was isolated in a 80% yield (based on consumed **1**) as the sole product (Scheme 1).† The quantum yield for formation of **3** was *ca.* 4 (±1) × $10^{-3}$ under irradiation with 546.1 nm monochromatic light.[3]‡

In contrast, irradiation of an equimolar (0.1 M) mixture of **1** and **2** in MeCN or dichloroethane with light of > 500 nm did not result in any reaction; however, irradiation with light of > 400 nm to excite **1** led to formation of **3** in low yield accompanied by larger amounts of the dimer of **1**.

A tan–brown fine powder prepared by pulverizing an equimolar mixture of **1** and **2** was irradiated with light of > 500 nm to give *ca.* 5% of **3** with larger amounts of the dimer of **1**. Formation of the dimer of **1** reflects the presence of two molecules of **1** in close proximity in the fine powder, whereas in the crystal the nearest two molecules of **1** are separated by more than 6 Å.

**Scheme 1**

**Scheme 2**

Excitation of the CT complex can induce electron-transfer from **1** to **2**. The standard free energy change for this process,[4] $\Delta G^0$, is estimated to be −132 kJ $mol^{-1}$ in MeCN.§

On excitation of the CT complex, the initially produced Frank–Condon excited CT state will rapidly change to a relaxed state or radical ion pair (RIP). In solution, the RIP is solvated and, therefore, much more stabilized than in the absence of solvents. The lack of reaction resulting from the CT excitation in solution indicates that the excited CT state and/or the RIP undergo facile deactivation and/or backward electron-transfer preceeding to charge separation in solution.[5] On the other hand, production of the cycloadduct from excitation of the CT complex crystal suggests that the fixed positions of **1** and **2**, separated by 3–4 Å in both the excited CT state and the resultant RIP in the crystal, might retard the deactivation and backward electron-transfer and enable them to undergo cycloaddition. Moreover, the absence of solvent molecules precludes stabilization of the RIP; therefore, this will also retard backward electron-transfer and enable the RIP to undergo cycloaddition (Scheme 2).

Finally it should be noted that the present results provide for the possibility of exclusive production of a cycloadduct *via* selective excitation of a crystalline CT complex when the proper conditions are met. Furthermore, the remarkable contrast in reactivity between the crystalline state and solution on CT excitation seems to indicate the important role of solvents for stabilization of the RIP. Full details of this present result will be published elsewhere.

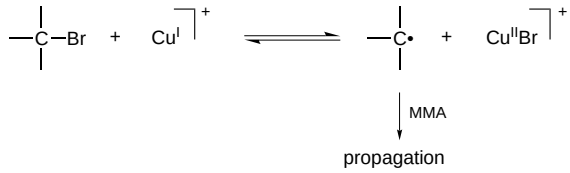
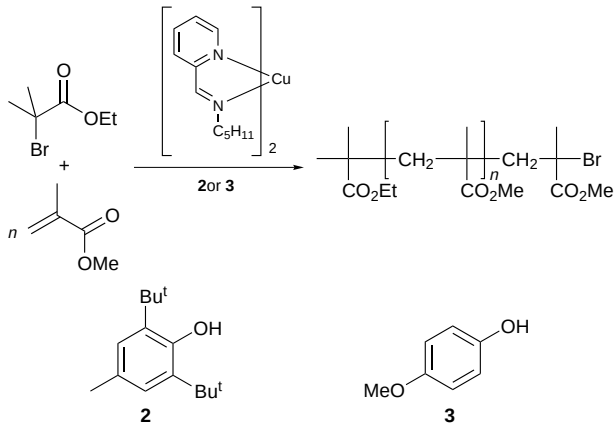
# Atom transfer radical polymerisation (ATRP) of methyl methacrylate in the presence of radical inhibitors



**D. M. Haddleton,* A. J. Clark, M. C. Crossman, D. J. Duncalf, A. M. Heming, S. R. Morsley and A. J. Shooter**

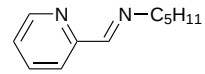
*Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL*



**Atom transfer radical polymerisation of methyl methacrylate mediated by copper(I) bromide, alkyl bromides and *N*-pentyl-2-pyridylmethanimine has been shown to be enhanced by the addition of substituted phenols, traditionally used as radical inhibitors.**

Atom transfer radical polymerisation has emerged as an efficacious method for the living polymerisation of vinyl monomers.[1–8] The ATRP process involves the combination of an alkyl halide and a low valent metal complex, *e.g.* $Cu^{I}Br$–bipyridine,[1–3] $Ru^{II}Cl_2(PPh_3)_2$,[4] $Ni^{II}[C_6H_3(CH_2NMe_2)_2$-2,6]Br,[7] which is capable of being oxidised to the $n + 1$ state by addition of a halogen atom. The mechanism proposed by both Matyjaszewski *et al.*[1] and ourselves[9] involves abstraction of the halogen atom from the propagating polymer to give a carbon-based radical and a new metal halide with the metal in the $n$ +1 oxidation state, *e.g.* $Cu^{II}$. Propagation is then proposed to be *via* free radical attack of the polymer radical on a monomer as in normal free radical polymerisation. Termination is prevented by the reverse abstraction of halogen atom from the metal halide to give a new polymeric alkyl halide (Scheme 1).

Polymerisation of methyl methacrylate in the presence of copper(I), ruthenium(II) and nickel(II) salts gives polymers with stereochemistry similar to that from normal free radical polymerisation.[2,4,7] All three metal-based catalysts have also been reported to lead to polymerisation which is completely inhibited by free radical inhibitor, *e.g.* galvinoxyl. The reactivity ratios for the copolymerisation of butyl and methyl methacrylate have also been shown to be entirely consistent with free radical propagation.[10] Thus all evidence presented to date is consistent with free radical propagation where the halogen atom is abstracted from the growing polymer chain. The objective of the present work was to investigate how robust ATRP is towards various functional groups. Surprisingly, we have found that phenolic free radical inhibitors enhance ATRP as opposed to suppressing polymerisation, as would have been expected for a free radical polymerisation or indeed an anionic polymerisation.



**Scheme 1**

**Scheme 2**

Atom transfer radical polymerisation of methyl methacrylate (MMA) was carried out with ethyl 2-methyl-2-bromopropionate as initiator in conjunction with *N*-pentyl-2-pyridylmethanimine **1** and copper(I) bromide in xylene solution at

**1**

90 °C (Scheme 2) in the presence of 2,6-di-*tert*-butyl-4-methylphenol **2** or 4-methoxyphenol **3**, or in the absence of phenol, as a control reaction. Both **2** and **3** are commonly added to commercial monomers to prevent polymerisation on transport and storage. Although phenolic inhibitors are more effective in the presence of oxygen they still inhibit radical reactions *via* transfer of a phenolic hydrogen atom in the absence of oxygen.[11] Polymerisation of methyl methacrylate in the presence of an equimolar amount of **2** with respect to initiator leads to poly(methyl methacrylate) with a polydispersity index (PDI) of 1.21 after 240 min (Table 1). Increasing the amount of **2** ([**2**] : [initiator] = 10 : 1) again leads to polymer with narrow PDI with *M*n increasing linearly with converstion (Fig. 1), as would be expected for a living polymerisation. Indeed this increase in the amount of **2** results in an acceleration in the rate of polymerisation so that 74.6% conversion is achieved in 240 min as opposed to 56.8% with stochiometric equivalents of initiator and **2**. The same is observed when **2** is replaced with **3**. Fig. 2 shows the increase in

**Table 1** Polymerisation of methyl methacrylate *via* ATRP

| Phenol[a] | [Phenol] : [initiator] | *t*/min | Conversion (%)[b] | *M*n (SEC) | PDI (SEC) |
|---|---|---|---|---|---|
| **2** | 1 | 240 | 56.8 | 7460 | 1.21 |
| **2** | 10 | 30 | 25.1 | 3700 | 1.18 |
| **2** | 10 | 60 | 34.8 | 4320 | 1.21 |
| **2** | 10 | 120 | 52.4 | 5710 | 1.22 |
| **2** | 10 | 180 | 61.2 | 6560 | 1.23 |
| **2** | 10 | 240 | 74.6 | 7970 | 1.21 |
| **3** | 1 | 240 | 54.4 | 7010 | 1.23 |
| **3** | 10 | 30 | 31.0 | 4120 | 1.18 |
| **3** | 10 | 60 | 35.7 | 4690 | 1.25 |
| **3** | 10 | 120 | 51.5 | 6460 | 1.22 |
| **3** | 10 | 180 | 61.3 | 7240 | 1.25 |
| **3** | 10 | 240 | 74.0 | 8970 | 1.25 |
| None | — | 240 | 54.0 | 6790 | 1.21 |

[a] All reactions carried out with [MMA] : [initiator] : [**1**] : [CuBr] = 100 : 1 : 3 : 1, under nitrogen at 90 °C at 37 mass% in degassed xylene solution. [b] From gravimetry.

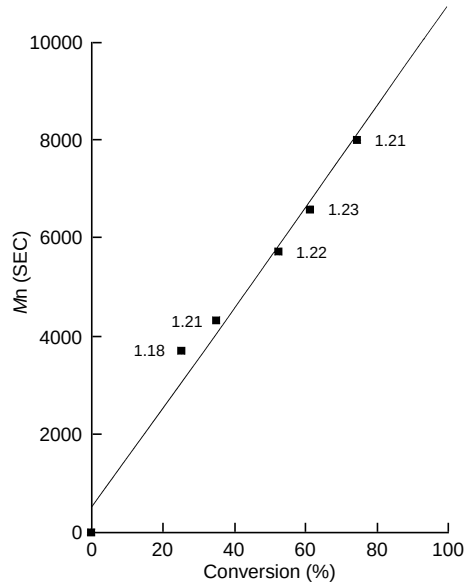


**Fig. 1** Plot showing how *M*n from SEC increases with conversion for ATRP of MMA in the presence of **2** in a ten-fold excess with respect to initiator. SEC carried out in THF at 1 ml min$^{-1}$ with calibration against poly(methyl methacrylate) narrow molecular weight standards. Polydispersity index (PDI) is given for each point.

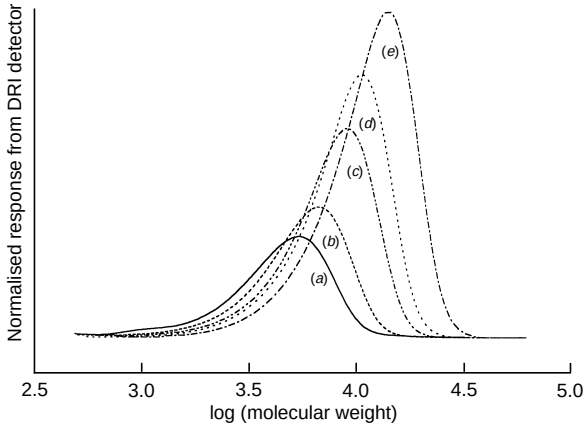

**Fig. 2** SEC traces for ATRP of MMA in the presence of **3** in a ten-fold excess with respect to initiator. The area beneath each trace has been normalised for conversion where conversion at 240 min is 74%: (*a*) 30 min, PDI = 1.18; (*b*) 60 min, PDI = 1.25, (*c*) 120 min, PDI = 1.22; (*d*) 180 min, PDI = 1.25; (*e*) 240 min, PDI = 1.25.

molecular weight with conversion (time) with a ten-fold excess of **3** with respect to initiator, as observed by size exclusion chromatography (SEC).

Fig. 3 shows the results of following the polymerisation by automated dilatometry, collecting one data point every 20 s over 8 h, in the presence and absence of a stochiometric equivalent of **3** with respect to initiator. The final rate of polymerisation is similar in both the presence and absence of **3**. Both are fairly constant between 60 and 180 min prior to showing a decrease in $k_p$[Pol*], the gradient of the graph (where Pol* is the active polymerisation centre). However, in the absence of **3** an induction period is present of *ca.* 60 min as observed by an increase in $k_p$[Pol*]; an induction period has previously been observed in ATRP of MMA using Ni$^{II}$ catalyst.[7] The induction period is removed by **3**, accounting for the increase in yield in the presence of substituted phenols.

Atom transfer radical polymerisation of MMA with bis(*N*-pentyl-2-pyridylmethanimine)copper(I) is enhanced by

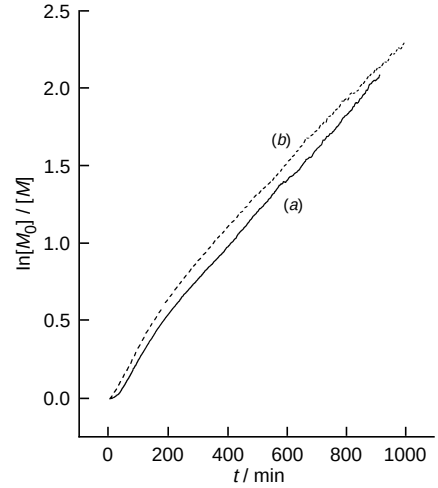

**Fig. 3** First order plots from automated dilatometry for the ATRP of MMA (*a*) in the absence of added phenol, and (*b*) with an equimolar amount of **3** with respect to initiator

substituted phenolic radical inhibitors. This indicates that propagation does not take place *via* a carbon-centred free radical. It is more likely that the copper(I) coordinates to the bromide, weakening the carbon–bromine bond and allowing single electron nucleophilic attack on monomer resulting in the transfer of a bromine atom in a concerted fashion. The active copper(I) species is not a simple four coordinate *pseudo*-tetrahedral compound as might have been expected. It appears that the active catalyst is formed during the initial stages of the reaction. Formation of the active species is accelerated by phenolic compounds. The role of the phenol is currently under investigation in our laboratory. In summary, ATRP does not take place *via* a normal free radical mechanism and the living polymerisation is enhanced by the addition of certain substituted phenols in excess relative to the amount of initiator.

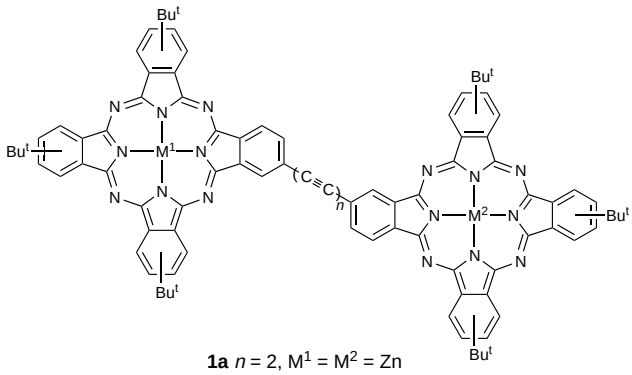
# Homo- and hetero-dimetallic ethynyl- and butadiynyl-bridged bisphthalocyaninato complexes

**Eva María Maya, Purificación Vázquez and Tomás Torres***

*Departamento de Química Orgánica (C-I), Facultad de Ciencias, Universidad Autónoma de Madrid, 28049-Madrid, Spain*



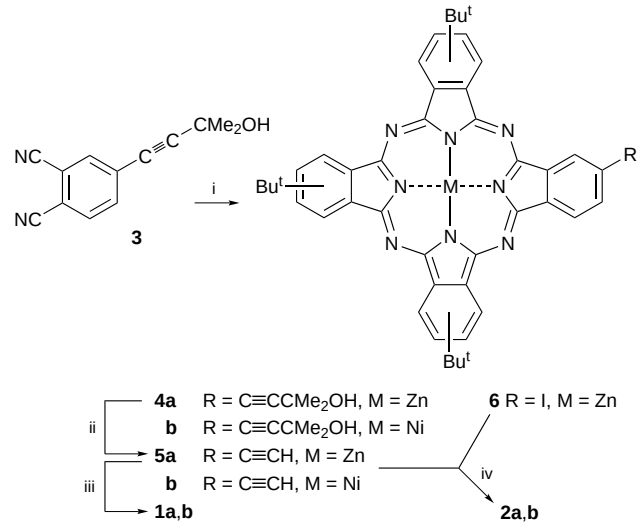
**A new type of phthalocyanine-based chromophore system having two metallophthalocyanine rings bound together through ethynyl linkages has been synthesized.**

Much effort has been expended in recent years to exploit electronic- and photonic-based cooperation between individual subunits of porphyrins.[1] However, despite the great interest of the related phthalocyanine (Pc) chromophore,[2] for example as a building block for the construction of new molecular materials, the effort devoted to preparing multiphthalocyanine arrays has not been as large. The main reason could be the difficulty of preparing unsymmetric Pcs,[3] necessary for a stepwise approach to building more complex Pc systems,[4] and in the purification of Pcs[2] in comparison with porphyrins. Non-conjugated binuclear Pcs, in which the two Pc nuclei are covalently bound *via* various kinds of linkage, have been reported.[5] However, to date very few examples of systems having phthalocyanine-to-phthalocyanine conjugated connections, namely planar binuclear phthalocyanines, have been described.[6]

Ethyne and oligoethyne bridges between chromophores have been recognized as ideal linkages, enabling unusually high excitonic and electron coupling between chromophore centres.[7] Recently, symmetric[8] and unsymmetric[9] Pcs having ethynyl functions have been described, but to the best of our knowledge the ethynyl linkage has not been used hitherto to assemble phthalocyanine systems with extended conjugation.

We are presently concentrating on the synthesis of Pcs and related compounds for nonlinear optics (NLO).[10] In this regard, the preparation of multiphthalocyanine arrays with extended conjugation represents an important goal.[10b]

Here the well-known metal-mediated cross- and homo-coupling methodology is applied for the first time to the preparation of homo- and hetero-dimetallic ethynyl- and butadiynyl-bridged bis(phthalocyaninato)zinc and nickel complexes **1a**,**b** and **2a**,**b**.



**1a** $n$ = 2, M$^1$ = M$^2$ = Zn
**b** $n$ = 2, M$^1$ = M$^2$ = Ni
**2a** $n$ = 1, M$^1$ = M$^2$ = Zn
**b** $n$ = 1, M$^1$ = Zn, M$^2$ = Ni

4-Iodophthalonitrile[11] was reacted with commercially available 2-methylbut-3-yn-2-ol in the presence of bis[triphenylphosphine]palladium(II) dichloride and copper(I) iodide[11,12] to yield aryl alcohol **3**. The mixed condensation of this phthalonitrile with an excess of 4-*tert*-butylphthalonitrile in the presence of the corresponding metal(II) chloride afforded the corresponding zinc and nickel complexes **4a**,**b**† in moderate yield, as a statistical mixture of isomers in each case (Scheme 1). The protecting group was then removed by treatment with sodium hydroxide in toluene[12] to give ethynyl derivatives **5a**,**b**†‡ in good yields. Similarly, compound **6**†‡ was obtained by statistical mixed condensation of 4-iodophthalonitrile with 4-*tert*-butylphthalonitrile and zinc chloride, in low yield (*ca*. 20%) after chromatographic purification.

Oxidative homocoupling[11] of terminal alkynes **5a**,**b** in the presence of copper(II) acetate monohydrate in a mixture of dry pyridine and dry methanol led, after purification by chromatography on silica gel, to the homonuclear dimetallic complexes **1a**,**b**† in *ca*. 50% yield.

Cross-coupling of alkynes **5a**,**b** with monoiodophthalocyanine **6** in freshly distilled and deaerated piperidine, in the presence of a catalyst formed *in situ* by the addition of tris(dibenzylideneacetone)dipalladium(0) [$Pd_2(dba)_3$] and triphenylarsine[1a,13] afforded the corresponding homonuclear and heterodimetallic butadiynyl-bridged bis(phthalocyaninato) complexes **2a**,**b**† in *ca*. 40% yield, after chromatographic purification. The same cross-coupling was accomplished in lower yield and with longer reaction times (12 h) by using the catalytic system $Pd(PPh_3)_2Cl_2$ and CuI[8] in freshly distilled and deaerated $NEt_3$ as solvent.

Fig. 1 shows the electronic absorption spectrum of butadiynyl-bridged bis(phthalocyaninato)zinc complex **1a**. The optical features of this new chromophoric system differ remarkably from that of the unsymmetric parent compound **5a**. The Soret (B) transition of **1a** occurring in the blue region of the spectra span wavelength ranges of 300–450 nm, similar to that

**Scheme 1** *Reagents and conditions*: i, 4-*tert*-butylphthalonitrile (3 equiv.), dimethylaminoethanol, reflux, $MCl_2$ (M = Zn, Ni); ii, toluene, NaOH; iii, $CuOAc{\cdot}H_2O$, 5% MeOH–pyridine, 55–60 °C, 90 min; iv, $Pd_2(dba)_3$, $As(Ph_3)_3$, piperidine, 35 °C, 4 h

of compound **5a** (maximum at 350 nm). However, while ethynyl compound **5a** exhibits only one Q-band at 684 nm, typical of metalated Pcs, dimer **1a** shows a splitting of this Q-band as well as a remarkable broadening and redshift of this transition, most probably resulting from the extended π-conjugation.§ Thus in compound **1a** two intense bands appear at 675 and 709 nm, respectively. In addition, at higher concentrations, a shoulder centred at *ca*. 770 nm is observed which extends to *ca*. 820 nm.¶

Fig. 2 shows the UV–VIS spectra of ethynylbis(phthalocyaninato)-zinc and -nickel complexes **2a**,**b**. The spectrum of **2a** is quite similar to that of **1a**, with the absorption maximum of the B-band slightly shifted to the blue (maximum at 344 nm), whereas the absorption maxima of the Q-bands appear slightly redshifted at 678 and 710 nm. In this case a broad band centred at 770 nm is also observed. The heterodimetallic compound **2b** shows only one intense absorption of the Q-band zone at 678 nm, with a shoulder at 713 nm.

The absorption coefficients of the Q-bands in **1** and **2** decrease, with regard to the mononuclear species **5**, due to increasing conjugation. The spectra are essentially unchanged down to $5 \times 10^{-7}$ M. Compounds **1a**,**b** and **2a**,**b** show no sign of intermolecular aggregation in $CHCl_3$ at concentrations below $5 \times 10^{-5}$ M. At higher concentrations, however, intermolecular aggregation takes place in some cases.

The degree of intramolecular aggregation in solution and the extent of electronic coupling between the two halves of the binuclear molecules in unsymmetrically substituted derivatives are under investigation.[15]

This series of alkynyl-bridged bis(phthalocyaninato)metal compounds **1** and **2** represent a basis set of supramolecular chromophore systems for studying electron and excitation transfer processes. On the other hand, the stepwise synthetic procedure described will allow the preparation of systems with distinct central metals and different kinds of substituents, for example donor and acceptor, in each one of the Pc subunits for NLO purposes.[10*b*]

† Elemental analysis and spectral data [FAB-MS, $^1$H NMR ($CDCl_3$), IR (KBr) and UV–VIS ($CHCl_3$)] for compounds **1**–**6** were consistent with assigned structures.

*Selected data* (for UV–VIS see Figs. 1 and 2) for **1a**: *m/z* 1539 (M + H$^+$); $\delta_H$ 9.5–7.2 (br signals, arom-H), 1.6 [br signals, C(CH$_3$)$_3$]. For **1b**: *m/z* 1525 (M + H$^+$); $\delta_H$ 9.4–7.1 (br signals, arom-H), 1.6 [br signals, C(CH$_3$)$_3$]. For **2a**: *m/z* 1514 (M + H$^+$); $\delta_H$ 9.4–7.0 (br signals, arom-H), 1.6 [br signals, C(CH$_3$)$_3$]. For **2b**: *m/z* 1507 (M + H$^+$); $\delta_H$ 9.5–7.2 (br signals, arom-H), 1.6 [br signals, C(CH$_3$)$_3$]. For **3**: *m/z* 211 (M + H$^+$); $\delta_H$ 4.0 (OH), 1.4 (CH$_3$); $\delta_C$ 115.2 (CN), 101.4 (C≡C), 30.0 (CH$_3$). For **4a**: *m/z* 826 (M + H$^+$); $\delta_H$ 8.4–7.2 (br signals, arom-H), 4.0 (OH), 1.6 [br signals, C(CH$_3$)$_3$], 1.4 (CH$_3$). For **4b**: *m/z* 820 (M + H$^+$); $\delta_H$ 8.2–7.3 (br signals, arom-H), 4.0 (OH), 1.6 [br signals, C(CH$_3$)$_3$], 1.4 (CH$_3$). For **5a**: *m/z* 768 (M + H$^+$); $\delta_H$ 9.0–7.5 (br signals, arom-H), 3.4 (C≡CH), 1.6 [br signals, C(CH$_3$)$_3$]; $\nu_{max}$/cm$^{-1}$ 3295, 2103 (C≡C–H). For **5b**: *m/z* 762 (M + H$^+$); $\delta_H$ 9.0–7.6 (br signals, arom-H), 3.4 (C≡CH), 1.6 [br signals, C(CH$_3$)$_3$]; $\nu_{max}$/cm$^{-1}$ 3295, 2103 (C≡C–H). For **6**: *m/z* 870 (M + H$^+$).

‡ Tri-*tert*-butylethynyl- (**5a**) and tri-*tert*-butyliodo-phthalocyanine (**6**) have been recently prepared following a different procedure (ref. 9).

§ Taking into account that compounds **1** and **2** are definitely a mixture of structural isomers, it could be considered that a higher ratio of one or more of these isomers might be the reason of the splitting of the Q-bands observed in the UV–VIS spectra (ref. 14). However, the magnitude of the splitting, the kind of substituents involved, the lack of splitting in the starting materials **5** and **6** (which are also mixtures of isomers) and preliminary results obtained for other symmetrically substituted dimers (ref. 15), suggest that the observed splitting is due, to a major degree, to the extended π-conjugation of the system.

¶ Similarly to **1a**, compound **1b** shows a broad absorption between 550 and 850 nm, with the only clear maximum at 670 nm. The Q-band of the parent compound **5b** appears at 673 nm.

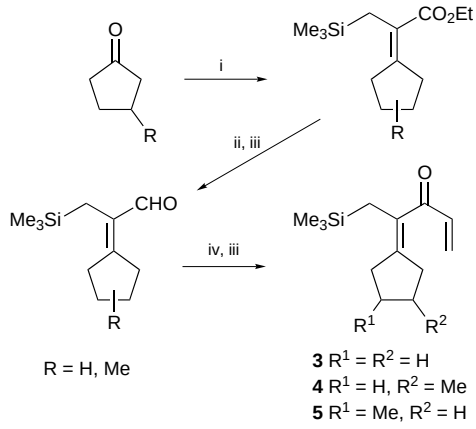
# Iron(III)-induced tandem Nazarov cyclization–rearrangement of α-(trimethylsilylmethyl)divinyl ketone. Synthesis of the bicyclo[4.3.0]nonane ring system *via* spiro[4.4]nonane

**Chiaki Kuroda,* Hiroshi Sumiya, Atsushi Murase and Akira Koito**

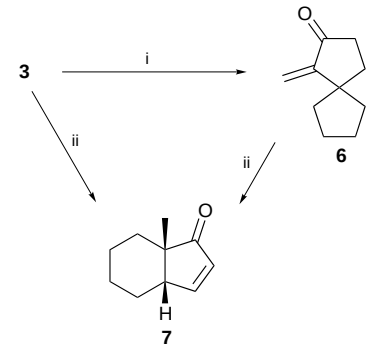
*Department of Chemistry, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171, Japan*



**6-Methylbicyclo[4.3.0]non-8-en-7-one was synthesized by $FeCl_3$-induced tandem Nazarov cyclization–rearrangement of 4-cyclopentylidene-5-trimethylsilylpent-1-en-3-one, *via* 7-methyl-1-methylenespiro[4.4]nonan-2-one as intermediate.**

Construction of various carbocyclic ring systems is fundamental chemistry in the synthesis of terpenoids and related compounds.[1] Allylsilanes have been developed as useful intermediates for this purpose.[2] We are studying the synthesis of carbocycles[3] and lactones,[4] basic structures of terpenoids,[5] utilizing intramolecular cyclization of β-(ethoxycarbonyl)-allylsilane. Recently we reported that Nazarov cyclization of α-(trimethylsilylmethyl)divinyl ketone derivatives **1**, derived from β-(ethoxycarbonyl)allylsilane attached to a six-membered ring, gives spiro[4.5]decanes **2** (Scheme 1).[6,7] Here we report that the α-(trimethylsilylmethyl)divinyl ketone attached to a five-membered ring undergoes tandem Nazarov cyclization–skeletal rearrangement to yield the bicyclo[4.3.0]nonane ring.[8]

**Scheme 1**



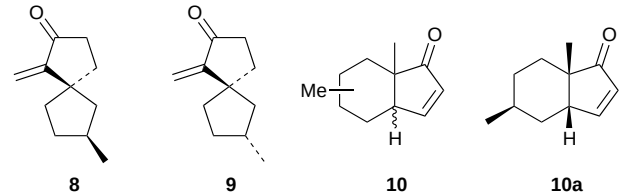
Synthesis of the cyclization precursors, α-(trimethylsilylmethyl)divinyl ketone **3**, was executed from cyclopentanone in five steps according to Scheme 2.[6] Similarly, **4** and **5** were prepared from 3-methylcyclopentanone and were separated by column chromatography.

**Scheme 2** *Reagents and conditions*: i, $(EtO)_2POCH(CO_2Et)CH_2SiMe_3$, NaH, DME, room temp.; ii, $LiAlH_4$, $Et_2O$, 0 °C; iii, $MnO_2$, $CH_2Cl_2$, room temp.; iv, $CH_2$=CHMgBr, THF, 0 °C

The Nazarov cyclization of **3** was carried out by treatment with $FeCl_3$ (2.5 equiv.) in $CH_2Cl_2$ at 0 °C† for 4 h, giving spiro[4.4]nonane **6**‡ in 56% yield. However, when **3** was subjected to the same treatment at room temperature§ for 24 h, compound **7** [9]¶ was obtained as the sole product in 62% yield. Treatment of **6** under the same reaction conditions (room temp., 24 h)§ gave **7** in 60% yield. From this result, along with the observation of behaviour on TLC, it was suggested that **7** was formed from **3** *via* **6** as intermediate (Scheme 3).

A further study of the stereochemistry of this Nazarov cyclization and subsequent skeletal rearrangement was made using methyl derivatives **4** and **5** as substrates. First, **4** and **5** were treated with $FeCl_3$ at 0 °C,† giving two isomers of spiro[4.4]nonanes¶ **8** and **9** as inseparable mixtures. The ratios of the two isomers were **8** : **9** = 4 : 1 from **4**, and 1 : 1 from **5**. The tandem Nazarov cyclization–rearrangement reaction was next examined and the results are summarized in Table 1. The rearranged product **10** consisted of five isomers **10a–e** as inseparable mixtures. Although the exact structures of each isomer could not be determined, the major isomer **10a** was shown to have the illustrated structure by $^1$H NMR spectroscopy. It was confirmed here again that the bicyclo-[4.3.0]nonene is formed *via* spiro[4.4]nonane. Thus both direct treatment of **4** (entry 1) and treatment of spiro compounds obtained from **4** (entry 3) afforded **10** in similar ratios. Compound **5** showed parallel results (entries 2 and 4). Different ratios of the isomers were obtained when the reaction

**Scheme 3** *Reagents and conditions*: i, $FeCl_3$, $CH_2Cl_2$, −30 to 0 °C, 4 h; ii, $FeCl_3$, $CH_2Cl_2$, −30 °C to room temp., 24 h



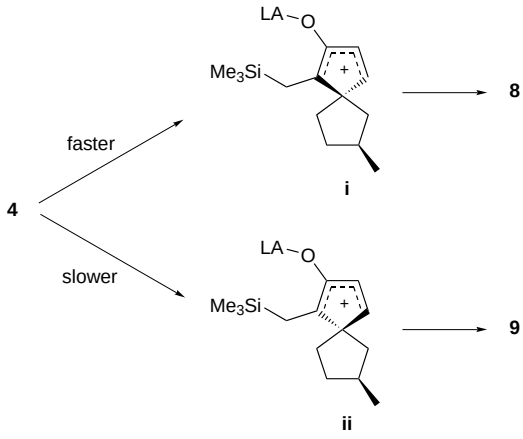


**Table 1** Nazarov cyclization–rearrangement of **4** and **5**[a]

| Entry | Substrate | Temp. | *t*/h | Yield (%) | Ratio of isomers[b] **10a : 10b : 10c : 10d : 10e** |
|---|---|---|---|---|---|
| 1 | **4** | room temp.[e] | 25 | 64 | 72 : 12 : 5 : 3 : 8 |
| 2 | **5** | room temp.[e] | 26 | 65 | 46 : 32 : 10 : 6 : 6 |
| 3 | **8** + **9** (4 : 1)[c] | room temp.[e] | 49 | 67 | 69 : 13 : 5 : 4 : 9 |
| 4 | **8** + **9** (1 : 1)[d] | room temp.[e] | 53 | 63 | 42 : 25 : 10 : 11 : 12 |
| 5 | **5** | room temp.[f] | 25 | 67 | 13 : 13 : 9 : 26 : 39 |

[a] The reactions were carried out in $CH_2Cl_2$ with $FeCl_3$ (2.5 equiv.). [b] **10a**: δ 5.90 (dd, *J* 2.5, 6 Hz) and 6.70 (dd, *J* 2, 6 Hz); **10b**: δ 5.88 (dd, *J* 2.5, 6 Hz) and 6.65 (dd, *J* 2, 6 Hz); **10c**: δ 5.84 (dd, *J* 1.5, 6 Hz) and 6.85 (dd, *J* 3, 6 Hz); **10d**: δ 5.81 (br d, *J* 5.5 Hz) and 6.96 (br d, *J* 5.5 Hz); **10e**: δ 5.80 (br d, *J* 5.5 Hz) and 6.95 (br d, *J* 5.5 Hz) (in $C_6D_6$). [c] Obtained from **4**; see text. [d] Obtained from **5**; see text. [e] The reagents were added at −30 °C and then the mixture was slowly warmed to room temp. over period of 7 h, which is included in the reaction time. [f] The reagents were added at −30 °C and the cooling bath was immediately removed.

**Scheme 4**

temperature was raised immediately after addition of the reagent (entry 5).

In contrast, this type of skeletal rearrangement did not proceed when analogous spiro[4.5]decanes **2** (R = H, Me, and Bu$^t$)[6] were subjected to the same treatment. Accordingly, the rearrangement is considered to be limited to the strained spiro five-five membered ring system.

The stereochemistry of the Nazarov cyclization of **4** and **5** can be explained by steric interaction between the methyl group and the vinyl group, but not the trimethylsilylmethyl group (Scheme 4). Thus intermediate **i** derived from **4** is favoured over **ii**, in which the methyl group and the vinyl group are on the same side of the cyclopentane ring, while the distance between these two groups gives non-stereoselectivity for **5**.

Although the reaction mechanism of the rearrangement (*e.g.* **6** to **7**) is not clear, it can be deduced that **10a** is produced from **8** with *ca.* 90% selectivity. Similarly, **10b** must be the major product from **9**.

In conclusion, a new entry to bicyclo[4.3.0]nonane carbon framework was established *via* a tandem Nazarov cyclization–skeletal rearrangement of α-(trimethylsilylmethyl)divinyl ketone. Synthesis of the bicyclo[4.3.0]nonane ring system from a compound having a five-membered ring is one of the classical methods.[1] However, this new entry from cyclopentanone is different, since (i) the newly-formed ring is still five-membered, and (ii) the original five-membered ring becomes a six-membered ring.[10] We have previously reported a synthesis of the bicyclo[4.3.0]nonane ring system using β-(ethoxycarbonyl)allylsilane.[3] Thus the same carbon framework can be synthesized from β-(ethoxycarbonyl)allylsilane by two independent strategies.

We thank Dr M. M. Ito and Dr T. Niitsu, Soka University, for the measurements of mass spectra.

## Footnotes

† The reagents were added at −30 °C and the reaction mixture was slowly warmed to 0 °C.

# Air oxidation of supercritical phase isobutane to *tert*-butyl alcohol

**Li Fan,* Yuri Nakayama and Kaoru Fujimoto**

*Department of Applied Chemistry, School of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo, 113, Japan*

***tert*-2-Butyl alcohol can be synthesized efficiently on $SiO_2$–$TiO_2$ or Pd–C catalyst if air is directly introduced to the supercritical-phase isobutane.**

As the initial material in methyl *tert*-butyl ether (MTBE) production and methyl methacrylate (MMA) synthesis where MTBE is high-octane-number gasoline additive and MMA is a resin material, *tert*-butyl alcohol (TBA) is of increasing importance.[1,2] On the other hand, TBA can be used to produce isobutene *via* a dehydration reaction. Commercially, production of isobutene from isobutane *via* direct dehydrogenation needs high reaction temperatures (500–600 °C) and a catalyst which is deactivated quickly. Here we report a new synthesis of TBA where air is used directly as oxidant to convert isobutane to TBA. This synthesis can be conducted efficiently if isobutane is in the supercritical phase on selected catalysts.

Wide attention has recently been devoted to supercritical fluid applications in catalytic systems, both in homogeneous and heterogeneous systems, such as the Fischer–Tropsch reaction, alkylation and carbon dioxide conversion.[3–6] However, organic oxidation in the supercritical phase has hardly been studied until now, especially when air is used directly as oxidant. It is also of theoretic interest to pursue the reaction behaviour of oxygen species such as peroxide in supercritical fluid. It is expected that high solubility, high diffusion capacity—especially the cluster structure formed around solute molecules—and the special ionization effects of the supercritical fluid might exert a strong influence on the reaction mechanism.

Listed in Table 1 are the reaction performance data for two catalysts and a non-catalytic case, in the supercritical, gas and liquid phases.† In either the non-catalytic reaction or the catalysed reaction, changing the state of isobutane from the gas phase (44 bar) to the supercritical phase (54 bar) gave remarkably enhanced conversion of isobutane and oxygen. Meanwhile, selectivities for the target products (TBA and isobutene) increased slightly when moving from the gas phase to the supercritical phase. Exceptionally, Pd–C catalyst exhibited obvious changes in both conversion and selectivity of the reaction if the phase changed. When the total pressure was increased from 44 bar to 54 bar, the total yield of TBA and isobutene was enhanced from 0.31 to 2.70%.

All the catalysed reactions showed higher activity than the non-catalytic reactions, which proved the promotional role of the catalysts in the reaction.

More interestingly, if the total pressure of the gas phase reaction was as low as 12 bar, the reaction did not proceed, even if $SiO_2$–$TiO_2$ was utilized. Similarly, for the liquid phase reaction on $SiO_2$–$TiO_2$, the reaction rate was very low, as shown in Table 1.

Generally, the main byproduct of the reaction was acetone. The combustion product, $CO_2$, was formed only in very small amounts. CO was not detected. Lighter hydrocarbons were formed in small amounts as well, and consisted of 98% methane. The total amount of all $C_1$ species was equal to that of acetone, which indicates the decomposition of $C_4$ to $C_3$ species (acetone) and $C_1$ fractions. The carbon balance of the total products was higher than 97%, indicating remarkably low carbon deposition on the catalyst surface.

As indicated in Table 1, this reaction depended greatly on temperature and pressure, which implied the effect of the reaction phase. Fig. 1(*a*) shows a comparison of the reaction performance on $SiO_2$–$TiO_2$ catalyst under 54 bar while the reaction temperature was varied around the critical point (408 K). It is clear that isobutane and oxygen conversions were enhanced remarkably when the state of the isobutane changed from the liquid phase to the supercritical phase. Consequently, TBA yield was enhanced in the supercritical phase. The reason for the high isobutene selectivity on Pd–C catalyst in the supercritical phase is not as yet clear. It is well known that the formed TBA can be dehydrated rapidly on acidic sites of a catalyst, but the carbon support here is generally neutral.

Concerning the selectivity of the products, as exhibited in Fig. 1(*b*), TBA selectivity as well as acetone selectivity was enhanced and isobutene selectivity was suppressed in the supercritical phase reaction on $SiO_2$–$TiO_2$ catalyst.

For the oxidation mechanism in supercritical fluid, it is suggested that dioxygen can attack the most active hydrogen of isobutane to form *tert*-butyl hydroperoxide (TBHP, $Bu^tOOH$). TBHP is known as an oxygen donor in the epoxidation of alkenes.[7] It is inferred that TBHP can form in the supercritical phase from isobutane coexisting with dioxygen. This autoxidation step can proceed without catalyst,[8] which happened in the inductive period during the initial stages of the reaction.

**Table 1** Reaction performance of catalytic oxidation of isobutane by air in the supercritical phase or the gas phase[a]

| Catalyst | Total pressure/ bar | Isobutane conversion (%) | $O_2$ conversion (%) | TBA selectivity (%) | Isobutene selectivity (%) | TBA and isobutene yield (%) |
|---|---|---|---|---|---|---|
| none | 44 | 0.3 | 2.5 | 55.0 | 7.0 | 0.2 |
| none | 54 | 1.2 | 9.9 | 58.1 | 8.1 | 0.8 |
| $SiO_2$–$TiO_2$ | 44 | 2.9 | 24.0 | 59.0 | 5.2 | 1.9 |
| $SiO_2$–$TiO_2$ | 54 | 4.9 | 40.6 | 61.2 | 6.3 | 3.3 |
| $SiO_2$–$TiO_2$ | 12 | 0.0 | 0.0 | 0.0 | 0.0 | 0.0 |
| $SiO_2$–$TiO_2$[b] | 54[b] | 0.1 | 1.1 | 55.5 | 7.7 | 0.1 |
| Pd–C | 44 | 0.5 | 4.2 | 61.2 | 2.1 | 0.3 |
| Pd–C | 54 | 3.1 | 25.6 | 64.8 | 20.1 | 2.7 |

[a] Isobutane: air = 3 : 1, $W/F$ = 10 g h $mol^{-1}$, catalyst weight = 0.5 g, T = 426 K. [b] Liquid-phase reaction where the reaction temperature was 403 K.

TBHP can decompose homolytically, resulting in *tert*-butoxy radical and hydroxide radical. *tert*-Butoxy radical then combines with a third hydrogen from another isobutane to form TBA. TBA can be dehydrated on acidic sites, leading to the increase in isobutene selectivity. For the main byproduct, acetone, it could be derived from decomposition of *tert*-butoxy radical, accompanied by C1 compounds such as CO, $CO_2$ or $CH_4$.

Concerning the role of the catalyst, it is inferred that the catalyst might improve the efficiency of the oxidation of isobutane with TBHP, resulting in the enhanced conversion. Methanol is probably a byproduct, together with acetone, as in some published reports.[7,8] However, in our supercritical phase reaction, not only methanol but also $CO_2$, $CH_4$ formation accompanied acetone formation. It is suggested that the formation route of $CO_2$ and $Ch_4$ is different from that of methanol. Detailed studies on the reaction mechanism will be reported in the near future.

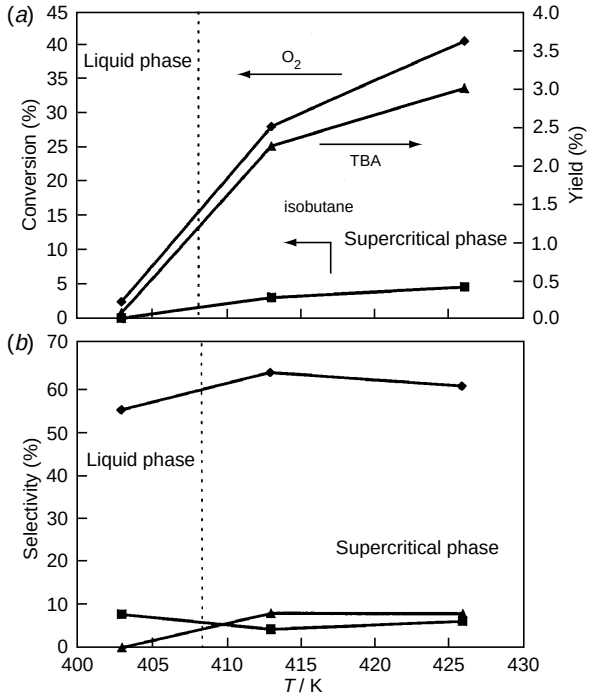

**Fig. 1** Comparison of the reaction performance around the critical point: (◆), TBA, (■) isobutane, (▲) acetone. $SiO_2$–$TiO_2$ catalyst, 54 bar, $W/F$ = 10 g h mol$^{-1}$, catalyst weight = 0.5 g, isobutane : air = 3 : 1.

Because the reactions reported above were conducted with a molar ratio of isobutane to $O_2$ = 15 : 1 (isobutane to air = 3 : 1), it is expected that the TBA yield might be enhanced further if the oxygen partial pressure was increased.[9]

Under the standard reaction conditions, the reaction required 3 h to reach a steady state from the reaction start. Catalyst deactivation was not observed during the supercritical phase reaction even after continuous reaction for 30 h.

## Footnotes

* E-mail: tfan@hongo.ecc.u-tokyo.ac.jp

† A typical flow-type fixed-bed reactor was employed, and the isobutane was fed by a high-pressure pump. Isobutane has a critical temperature of 408.13 K and a critical pressure of 36.48 bar. For the catalytic reaction, representative examples reported here are for reactions on commercially available amorphous $SiO_2$–$TiO_2$ (Fuji Silysia Chemical Co.), and a home-made palladium catalyst (2.5 wt%) supported on active carbon (Shirasagi, Takeda Pharmacy Co.). All products was analysed by gas chromatography (Shimadu GC-14B or Hitachi 163). A capillary column (TC-1) coupled with a flame ionization detector was used for analysis of the oxygenates and heavy hydrocarbons. A molecular sieve column and an active carbon column, with a thermal conductivity detector, were utilized for inorganic gas analysis. Lighter hydrocarbons with determined by an active alumina column with a flame ionization detector. The standard reaction conditions are as follows: ratio of isobutane to air = 3 : 1; $W/F$ (total) = 10 g h mol$^{-1}$; catalyst weight = 0.5 g; reaction temperature = 426 K. The total pressure for the gas phase reaction is 44 bar and that for the supercritical phase is 54 bar. Correspondingly, the partial pressure of isobutane is 33 bar and 41 bar, respectively. The feed ratio of isobutane to air was 3. When the total pressure was higher than 48 bar (36 bar of isobutane and 12 bar of air), the phase of the reaction became supercritical. The reaction at a total pressure of 54 bar was in the supercritical phase.

# Preparation of mesostructured lamellar zirconia

**Yinyan Huang and Wolfgang M. H. Sachtler***

*Ipatieff Laboratory, Center for Catalysis and Surface Science, Northwestern University, Evanston, IL 60201, USA*

**Mesostructured lamellar zirconia is synthesized by using anionic surfactants under hydrothermal conditions.**

Since the discovery by scientists at Mobil of the mesoporous aluminosilicate (MCM-41),[1,2] much attention has been paid not only to mesoporous aluminosilicates, but also to mesoporous oxides of other metals. Many mesoporous transition-metal oxides have been obtained. Huo *et al*.[3] and Ciesla *et al*.[4] report the syntheses of mesostructured oxides of Fe, Mn, Zn, Co, Ni, Al, Sb, W by interaction of a soluble metal solution and an anionic surfactant. Unfortunately, attempts to remove the template used for synthesis, either by leaching or by calcination, have led to the collapse of the mesostructure. Recently the syntheses of mesoporous $TiO_2$, $Nb_2O_5$ and $ThO_2$ with hexagonal pore arrangements and amorphous pore walls have been reported.[5–7] As for mesostructured zirconia, several papers report that this material can only be obtained with amorphous walls[8,9] and irregular pore arrangement. The mesoporosity is, however, lost upon crystallization of the zirconia. Another paper claims the synthesis of mesoporous zirconia with regular pore arrangement based on small-angle XRD.[10] Mesoporous lamellar zirconia was also prepared by a route using neutral amines, but the mesostructure was lost when the samples were calcined to remove the surfactant.[11] The synthesis of mesoporous zirconia using a neutral amine template that was subsequently extracted with ethanol has been reported by us; although no regular pore structure has been obtained, the mesoporosity of this material can be maintained up to 700 °C if the tetragonal modification of zirconia is stabilized by sulfation. Here, we report the synthesis of mesostructured lamellar zirconia, by using soluble zirconium chloride and an anionic surfactant.

Lamellar zirconia is obtained by hydrothermal reaction. In a typical synthesis process, 1.5 g $ZrOCl_2$ was first dissolved in 10 ml water. 1.26 g of sodium 1-hexadecanesulfonate (*n*-$C_{16}H_{33}SO_3Na$) was then dissolved in 10 ml water and mixed with the $ZrOCl_2$ solution under stirring. The surfactant/zirconium molar ratio is *ca*. 0.5 and the mixture has a pH of *ca*. 6. Stirring was continued for 30 min; the mixture was then sealed in a polyethylene bottle and heated at 90 °C for 48 h before final filtering, washing and drying in air.

Besides sodium 1-hexadecanesulfonate, 1-hexadecanesulfonyl chloride (*n*-$C_{16}H_{33}SO_2Cl$) was also used as surfactant for the synthesis of mesostructured zirconia, using the same procedure. In some cases, some $Pt(NH_3)_4(NO_3)_2$ was added to a zirconyl chloride solution before mixing it with the surfactant solution. The Pt loading is *ca*. 1 mass% based on the amount of $ZrO_2$.

The materials have been characterized by small-angle XRD and TEM. Fig. 1(*a*) and (*b*) show the small-angle XRD patterns of mesostructured zirconias synthesized using either the surfactant *n*-$C_{16}H_{33}SO_3Na$ or *n*-$C_{16}H_{33}SO_2Cl$. Their XRD patterns are very similar. The peak at $2\theta = 2°$ clearly indicates the existence of some mesostructure. The peaks at higher diffraction angles are not well resolved. In view of the inaccuracy of the XRD pattern, a *d* value of *ca*. 40 Å is estimated for the first peak.

Though many authors use small-angle XRD to determine the symmetry of the mesostructure, this procedure sometimes leads to inaccurate results. Schüth has shown that a highly resolved XRD pattern can be consistent with a chaotic structure.[12] Therefore, the present work mainly employs TEM to identify the structure of the materials. Fig. 2 shows the TEM image of mesostructured zirconia obtained by using *n*-$C_{16}H_{33}SO_3Na$ surfactant. The lamellar structure is clearly visible. The distance between two layers is estimated to be *ca*. 41 Å. This is consistent with the value obtained from XRD.

The same lamellar TEM image is found with material obtained using *n*-$C_{16}H_{33}SO_2Cl$ as the template. Incorporation of Pt does not change the mesostructure of the materials.

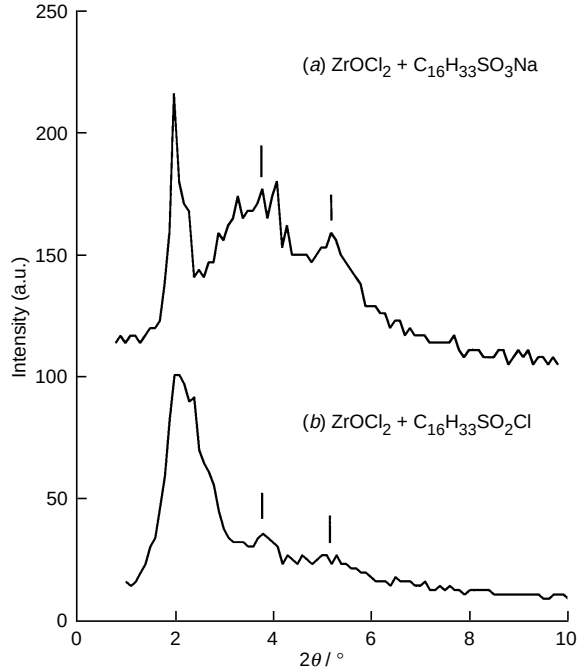

**Fig. 1** Small-angle XRD patterns of mesostructured zirconia synthesized by using surfactant *n*-$C_{16}H_{33}SO_3Na$ (*a*) and *n*-$C_{16}H_{33}SO_2Cl$ (*b*)

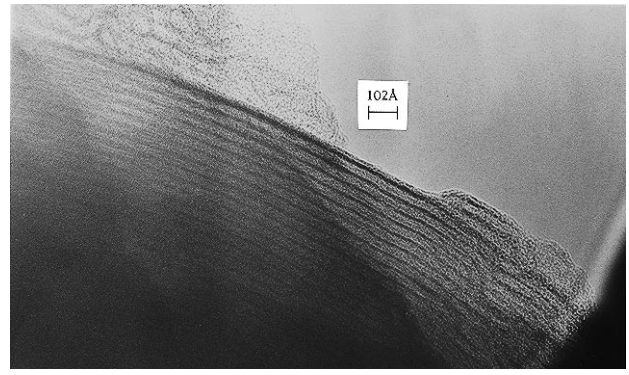

**Fig. 2** TEM image of mesostructured zirconia synthesized with *n*-$C_{16}H_{33}SO_3Na$

The materials were also analysed by thermal gravimetry (TG). As shown in Fig. 3, the surfactant is oxidized in an $O_2$ atmosphere at *ca*. 275 °C. A strong exothermic effect is observed at that temperature. The total mass loss is due to desorption of occluded materials in addition to oxidation of the surfactant. The mass loss corresponding to the oxidation of surfactant is about 50% of the total mass. Based on the TG results, a Zr/surfactant molar ratio of 1.5 is estimated. This is higher than expected for the charge balance of $ZrO^{2+}$ with *n*-$C_{16}H_{33}SO_3^-$. Apparently considerable quantities of water and other species are included in the material.

As *n*-$C_{16}H_{33}SO_3Na$ is dissolved in water, the negative *n*-$C_{16}H_{33}SO_3^-$ ion is formed. The anion can also be formed by hydrolysis of *n*-$C_{16}H_{33}SO_2Cl$. The surfactant anion will react with the $ZrO^{2+}$ cation to form a 'cation–anion composite molecule'. This composite molecule has a low solubility in water and tends to reassemble, forming an ordered structure.

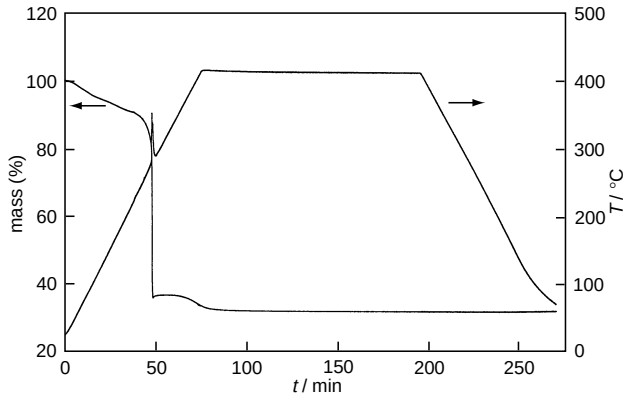

**Fig. 3** TG profile of mesostructured zirconia synthesized with *n*-$C_{16}H_{33}SO_3Na$ registered in a flow of oxygen of 20 ml $min^{-1}$

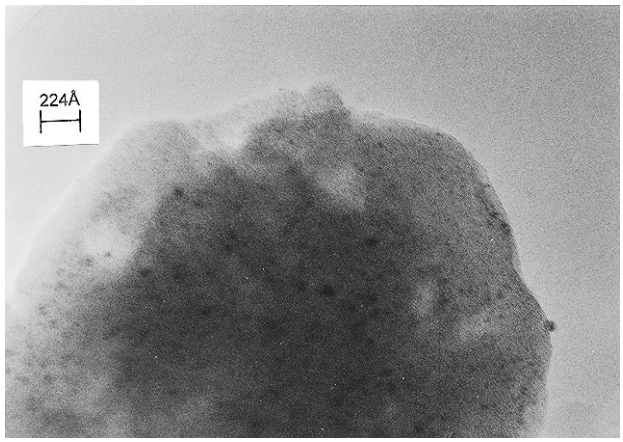

**Fig. 4** TEM image of Pt containing mesostructured zirconia by using *n*-$C_{16}H_{33}SO_3Na$ as surfactant, after calcination at 300 °C in a flow of oxygen of 100 ml $min^{-1}$

Although considerable effort was made to maintain the mesostructure by cautiously removing the surfactant, these attempts failed. Leaching of the material synthesized from *n*-$C_{16}H_{33}SO_3Na$ with an ammonia–ethanol mixture did not work either, whereas such treatment with the material from *n*-$C_{16}H_{33}SO_2Cl$ leads to the gelation of the original material.

Calcination of the materials in air at 500 °C for 6 h results in the collapse of the lamellar structure and the formation of tetragonal zirconia. The characteristic small-angle diffraction peak is lost. Upon calcining these materials in a flow of oxygen (100 ml $min^{-1}$) at 300 °C for 2 h at low ramping rate (0.5 °C $min^{-1}$), XRD analysis shows that the lamellar structure collapses and amorphous zirconia is obtained. TEM confirms that the material contains mainly amorphous zirconia particles and some small particles of tetragonal zirconia. In the case of the Pt-containing materials, highly dispersed Pt metal particles are formed. Fig. 4 shows rather uniform Pt particles dispersed on zirconia.

We gratefully acknowledge financial support from the director of the Chemistry Division, Basic Energy Sciences, US Department of Energy; Grant DE-FGO2-87ER13654 and a grant-in aid from Shell Development Company. We thank Dr Xiandong Wang for helping in TG analysis and Dr Timothy J. McCarthy and Dr Taeghwan Hyeon for taking the TEM images.

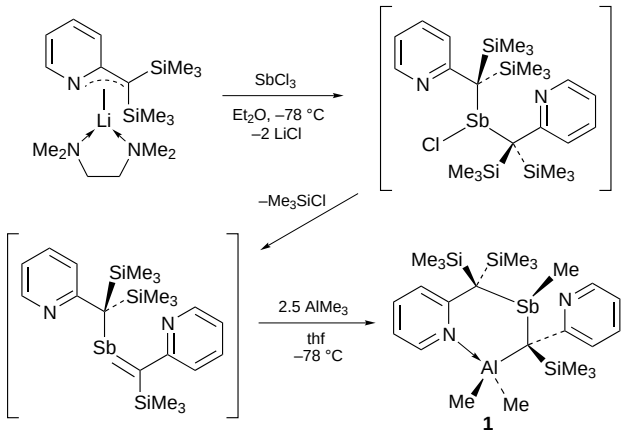
# A *gem*-aluminium(III)/antimony(III) C centre incorporated in a bimetallic six-membered heterocycle



**Philip C. Andrews,[a] Colin L. Raston,*[a] Brian W. Skelton[b] and Allan H. White[b]**

[a] *Department of Chemistry, Monash University, Clayton, Victoria 3168 Australia*

**Reaction of $AlMe_3$ with the implied stibene intermediate (–Sb=C<) formed in the reaction of [(2-pyr)$(SiMe_3)_2$CLi·tmeda] with $SbCl_3$ affords the carboalumination product containing a *gem*-Al/Sb C centre as part of a six-membered heterocycle, [(2-pyr)$(SiMe_3)_2$C–Sb(Me)–(2-pyr)$(SiMe_3)$C–$Al(Me)_2$] 1, structurally authenticated as the (*RS*,*SR*) diastereoisomer.**

The main-group complexes of the bulky alkyl ligand (2-pyr)$(SiMe_3)_2C^-$, R, have been extensively investigated.[1] Such bulky ligands, devoid of a β-hydrogen, are important in the search for unusual and novel main-group chemistry such as low-valent and multiply bonded species due to the kinetic protection offered to the element in question and the presence of a potentially stabilising internal N donor. Thus the variety of complexes isolated and characterised include monomeric, subvalent, hypervalent, electron-deficient and low-coordinate species. Studies by Cowley *et al.*[2] and others[3] have shown that it is possible to stabilise double-bonded species involving group 15 elements using the tri-*tert*-butyl substituted mesityl and $(SiMe_3)_2C^-$ ligands, *e.g.* E′=E, As=P, P=As, As=As, Sb=P. Multiply bonded complexes of this type involving As and P tend to be more stable to oligomerisation than those containing Sb which appear to require a higher degree of steric protection and stabilisation.[4]

We have previously reported that it is possible to synthesise the monomeric $RSbCl_2$ complex from the 1:1 metathetical exchange reaction of $[RLi·(Et_2O)_n]$ and $SbCl_3$ in diethyl ether. However, as was also the case with the arsenic and bismuth complexes, the formation of the monochloride species from the 2:1 reaction was highly problematic with evidence for the low-temperature elimination of $SiClMe_3$ affording an intractable dark red oil.[5] Herein we now report on the synthesis and characterisation of a novel mixed group 13/15 complex **1** (Scheme 1) which was obtained *via* the addition of $AlMe_3$ to a thf solution of this red oil. Such *gem*-diorganometallics are attaining increasing recognition and importance in organic synthesis.[6]

**Scheme 1**

The dark red oil can be consistently generated from the specific 2:1 reaction of crystalline RLi·tmeda and $SbCl_3$ in thf at −78 °C. A red solution is formed over 12 h as the reaction mixture is allowed to warm to ambient temperature. The deep red oil is then obtained when all volatiles are removed *in vacuo* and LiCl removed by the addition of hexane and subsequent filtration. From initial one- and two-dimensional NMR studies it is clear that the red oil is a complex mixture of products; $^{13}C$ NMR revealed at least 5 $SiMe_3$ environments to be present. To date, attempts at obtaining a reproducible crystalline product directly from the oil have been unsuccessful despite varying the polarity of added solvents, *i.e.* hexane to thf, and cooling from 4 to −78 °C. Attempts at distilling any liquid or low-melting point products *in vacuo* (0.1 mmHg) have also been unsuccessful as decomposition to elemental antimony occurs readily above 80 °C. In an attempt to identify any of the products we have submitted the red oil to a series of reactions. One which has been successful is the addition of $AlMe_3$.

The small yellow rod-shaped crystals† of **1**‡ were obtained from the reaction of a thf solution of the red oil with a 2.5-fold excess of $AlMe_3$ (based on the initial quantity of R used) in thf at −78 °C. The crystals cocrystallised with large colourless crystals of $[(Me_3Al)_2(tmeda)]$ at 4 °C in hexane–thf over several days. That the tmeda complex is formed is indicative that all the tmeda is not removed *in vacuo* with other volatiles.

X-Ray diffraction studies on the yellow crystals revealed a novel monomeric mixed aluminium–antimony complex, space group $P2_1/n$, in which both Sb and Al are bound to the same carbon, Fig. 1. A search of the Cambridge Crystallographic Database§ confirms that this is the first mixed group 13/15 complex of its type. Importantly, a stibene (–Sb=C<) intermediate can be invoked to explain the formation of the complex as carboalumination, *viz.* the addition of $AlMe_3$ across the antimony–carbon double bond. A probable mechanism for the formation of **1** is outlined in Scheme 1.

The stibene intermediate contains a modified and an unmodified ligand as a result of $SiClMe_3$ elimination. It has to be assumed that this stibene complex is stable and present in a relatively significant quantity. $^{13}C$ NMR has been, as yet, of limited help in identifying the particular double-bonded carbon with the only markers by which to judge the chemical shift being: (*i*) stibabenzene in which the delocalised C–Sb appears at δ 178.3,[7]¶ which is coincident with both the delocalised C–N and quaternary carbon in the pyridyl ring, (*ii*) a study of several acyclic stibonium ylides[8]‖ reported the $Sb^+–C^- \leftrightarrow Sb=C$ shift to be in the region δ 74.6–93.2 which corresponds well with a lone signal at δ 78.0 in the $^{13}C$ ($C_6D_6$) NMR spectrum of the red oil. Very recently Nixon and co-workers reported[9] the first solid-state structurally characterised acyclic distibene complex, *trans*-1,4-bis(trimethylsiloxy)-1,4-bis(2,4,6-tri-*tert*-butylphenyl)-2,3-distibabutadiene, an interesting point being that the crystals are red.

The crystals of **1** are relatively air stable and melt with decomposition from 88 °C. The solid-state structure is dominated by a six-membered metallocycle [C(12)C(12′)Sb-

C(22′)AlN(11)], Scheme 1, with ring closure being secured by the dative pyridyl N–Al bond. Two chiral centres are present in the molecule, the Sb and the C centre which is *gem* with respect to the $Sb^{III}$ and $Al^{III}$ centres. These are respectively (*R*) and (*S*) or (*S*) and (*R*) in the same molecule with the solid comprised of an enantiomeric mixture.

The Sb–C(22′) distance of 2.167(7) Å is shorter than that of Sb–C(12′), *i.e.* C with two bound trimethylsilyls, which at 2.247(7) Å is longer than that found in $RSbCl_2$, 2.213(5) Å. TheAl–C(22′) bond length is 2.017(6) Å which is longer than those for the bound Me groups, av. 1.978(8) Å. The pyridyl N–Al distance of 2.062(6) Å is unremarkable. Despite the near planarity of the SbC(22′)C(22)N(21) atoms, there is little or no interaction between Sb and N(21) as confirmed by the separation of 2.914(6) Å and the close to tetrahedral angle at C(22′) [Sb–C(22′)–C(22) 106.7(4)°], which can be compared with the analogous bond angle of 94.45° in $RSbCl_2$ where there is a long but definite Sb–N [2.371(7) Å] interaction.

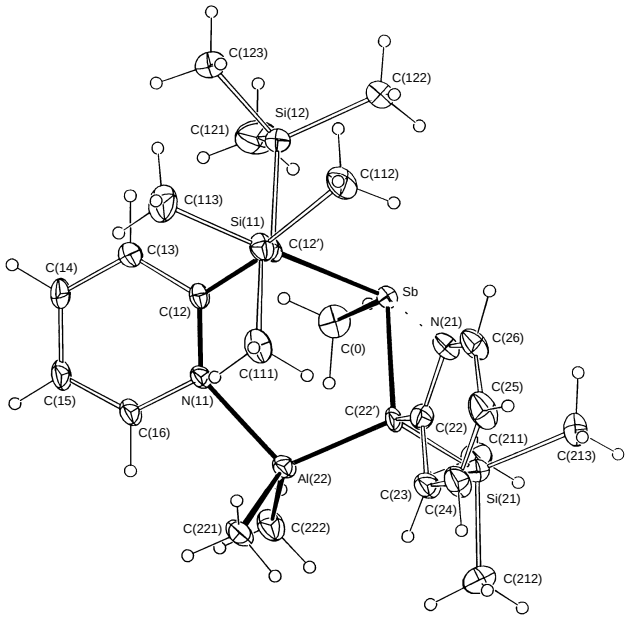

**Fig. 1** Crystal structure of **1** with selected distances (Å) and angles (°): Sb–C(0,12′,22′) 2.178(7), 2.247(7), 2.167(7); Al(22)–N(11), C(22′,221,222) 2.062(6), 2.017(6), 1.975(8), 1.982(8); C(0)–Sb–C(12′,22′) 93.0(3), 97.2(3); C(12′)–Sb–C(22′) 105.3(2); Sb–C(12′)–C(12), Si(11,12) 112.6(4), 117.1(3), 99.9(3); Sb–C(22′)–C(22), Si(21), Al(22) 106.7(4), 108.3(3), 106.7(3); N(11)–Al(22)–C(22′,221,222) 109.6(2), 102.7(3), 102.7(3); C(22′)–Al(22)–C(221,222) 118.3(3), 114.1(3); C(221)–Al(22)–C(222) 107.7(3); Al(22)–N(11)–C(12,16) 137.8(4), 106.6(4); Al(22)–C(22′)–C(22), Si(21) 114.6(4), 115.3(3).

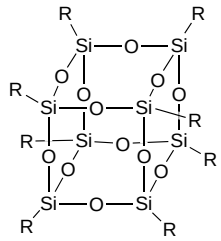
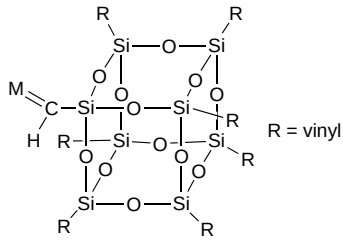
# Cross-metathesis of alkenes with vinyl-substituted silsesquioxanes and spherosilicates: a new method for synthesizing highly-functionalized Si/O frameworks



**Frank J. Feher,* Daravong Soulivong, Andrew G. Eklund and Kevin D. Wyndham**

*Department of Chemistry, University of California, Irvine, CA 92697-2025, USA*



**Highly functionalized silsesquioxanes and spherosilicates of the formulae $[(RCH{=}CH)_8Si_8O_{12}]$ and $[(RCH{=}CHSiMe_2O)_8Si_8O_{12}]$ can be prepared by cross-metathesis reactions of alkenes with readily available vinyl-substituted silsesquioxane and spherosilicate frameworks, $[(vinyl)_8Si_8O_{12}]$ 1 and $[(vinylSiMe_2O)_8Si_8O_{12}]$ 2; the methodology is quite general and is not complicated by self-metathesis reactions of 1 or 2.**

Topologically spherical silsesquioxanes {*i.e.* $[RSiO_{3/2}]_n$} and silicates {*i.e.* $[ROSiO_{3/2}]_n$} have attracted widespread attention as precursors to a variety of interesting compounds and materials, and the number of known frameworks bearing synthetically useful functional groups is growing at an increasingly rapid pace.[1] Numerous methods have been reported for preparing highly functionalized silsesquioxane and spherosilicate frameworks, but the four most common routes are: (i) direct synthesis *via* hydrolytic condensation of $RSiX_3$; (ii) hydrosilylation of hydridosilsesquioxanes; (iii) silylation of spherosilicates; and (iv) synthetic manipulation of organic substituents on other readily available frameworks.

Here, we report a general new strategy for preparing highly functionalized silsesquioxanes and spherosilicates based on cross-metathesis reactions of alkenes[2] with readily available vinyl-substituted silsesquioxane[3,4] and spherosilicate frameworks.[5,6] This strategy offers access to a wide range of synthetically useful compounds, and it provides an important alternative to traditional synthetic methods based on the hydrosilylation of hydridosilsesquioxanes and the silylation of spherosilicates.

**1** R = vinyl
**2** R = $OSiMe_2$vinyl

**5** M = $Ru\{P(C_6H_{11})_3\}_2Cl_2$
**6** M = $Mo(NAr)\{OCMe(CF_3)_2\}_2$

Vinylsilsesquioxane **1**[3] reacts with both $[\{(C_6H_{11})_3P\}_2Cl_2Ru{=}CHPh]$[7] **3** and $[Mo(CHCMe_2Ph)(NC_6H_3\text{-}Pr^i_2\text{-}2,6)\{OCMe(CF_3)_2\}_2]$[8] **4** to produce new compounds exhibiting $^1$H NMR resonances consistent with the formation of new alkylidene complexes. In the case of **3**,† alkylidene resonances attributable to both **5** and $[\{(C_6H_{11})_3P\}_2Cl_2Ru{=}CH_2]$[7] grow in with nearly equal intensities at the expense of the resonance for **3**, but at longer reaction times, **5** is gradually consumed to produce $[\{(C_6H_{11})_3P\}_2Cl_2Ru{=}CH_2]$ as the major (> 95%) ruthenium-containing species. In the case of **4**,‡ $^1$H NMR resonances attributable to two new silyl-substituted alkylidenes grow in at the expense of the alkylidene resonance for **4**. The ratio of these resonances (*ca.* 2 : 1) remains constant at all times, suggesting that they are due to the *anti* (δ 13.50) and *syn* (δ 12.45) rotamers of **6**.[9]

Although it is reasonable to expect the self-metathesis of **1** to be thermodynamically favourable, $^1$H NMR spectra of reaction mixtures containing **1** and either **3** or **4** never exhibit vinylic $^1$H resonances attributable to the formation of products derived from the self-metathesis of **1**. It appears that steric demands by the Si/O framework prevent the formation of metallacyclobutanes containing two adjacent silsesquioxane frameworks. Similar results are observed for spherosilicate **2**.[5] From the standpoint of synthesizing highly functionalized silsesquioxanes and spherosilicates, the practical consequences of this situation are enormous: cross-metathesis of **1** or **2** with monofunctional alkenes should never be complicated by competing oligomerization or polymerization of the vinyl-substituted Si/O frameworks.

The addition of an alkene to solutions containing **1** or **2** and an alkene metathesis catalyst quickly produces new $^1$H resonances attributable to cross-metathesis products. In the case of **1**, **4** and *cis*-oct-4-ene, for example, prominent $^1$H resonances are observed for free pent-1-ene and pent-1-enyl substituents on the $Si_8O_{12}$ framework, as well as the expected secondary metathesis products (*e.g.* $C_2H_2$ and $PhCMe_2CH{=}CHBu$). Similar results were observed upon addition of pent-1-ene, but the amount of ethene was much larger and the rate of productive cross-metathesis was slower.

Table 1 summarizes the results from a number of cross-metathesis reactions performed on a preparative scale using **3** and **4** as catalysts.§ Each reaction was performed under a slight vacuum in order to remove ethene, which greatly slows the rate of productive cross-metathesis and deactivates Schrock-type metathesis catalysts.[10,11] As expected,[12] Schrock's catalyst (*i.e.* **4**) is substantially more active than Grubbs' catalyst (*i.e.* **3**) in cases where the molybdenum alkylidene is compatible with functional groups attached to the alkene. However, the greater functional group tolerance of **3** allows the introduction of functional groups that deactivate **4**. Unfortunately, the rates of cross-metathesis with **3** are currently too slow to be of practical value for the preparation of pure octafunctional derivatives of **1** and **2**.

Both α-alkenes and internal alkenes can be used for the cross-metathesis reaction, but α-alkenes generally: (*i*) undergo cross-metathesis reactions much more readily than internal alkenes; (*ii*) offer a distinct cost advantage over internal alkenes; and (*iii*) undergo self-metathesis to internal alkenes at rates much greater than the rates of cross-metathesis with **1** or **2**. Nevertheless, internal alkenes are attractive starting materials because of their lower volatility and their inability to produce ethene. Except for reactions involving styrene, which appear to produce only *trans*-substituted products, it is important to note that the product in all cases is actually a complex mixture of substitutional isomers containing statistical distributions of *cis*- and *trans*-substituted double bonds. The same thermodynamic mixture of cross-metathesis products appears to form regardless

**Table 1** Cross-metathesis reactions of **1** and **2** with alkenes

| Entry | Si/O Framework | Alkene | Catalyst [amount (%)][a] | Conditions | Conv. (%) | Yield (%) (*trans*/*cis*)[b] |
|---|---|---|---|---|---|---|
| 1 | **1** | *cis*-Oct-4-ene (3 equiv.)[c] | **4** (1.6) | $C_6H_6$, 25 °C, 100 h | 100 | 75[d] (85/15) |

[a] Mol% catalyst based on available $SiCH=CH_2$. [b] *trans*/*cis* ratio for SiCH=CHR groups determined by $^1H$ NMR spectroscopy. [c] Mol equiv. per $SiCH=CH_2$. [d] Isolated yield (quantified by NMR). [e] NMR yield.

of the alkene (*i.e.* internal alkene *vs.* α-alkene) used to prepare a particular octafunctional silsesquioxane. This inseparable mixture of isomers is unavoidable, but it can be transformed into a single octasubstituted product *via* catalytic hydrogenation [Pd/C, 25 °C, 160 psig) (1 psig = Pa). For example, catalytic hydrogenation of the product mixture obtained *via* cross-metathesis of **1** with pent-1-ene affords a high overall yield of $(n\text{-pentyl})_8Si_8O_{12}$ **7**.¶

We have only begun to explore the generality of this cross-metathesis procedure, but it is already clear that it offers an important new route to functionalized silsesquioxanes. It also offers intriguing possibilities for the preparation of new hybrid inorganic/organic materials, such as network polymers derived from metathesis reactions of vinyl-substituted Si/O frameworks with cyclic alkenes (ROMP) and/or dienes (ADMET). These and other potential applications are currently under investigation.

These studies were supported by the National Science Foundation and Phillips Laboratory (Edwards AFB).

* E-mail: fjfeher@uci.edu

† Within 8 min of mixing at 25 °C, the reaction of **3** with a large excess of **1** in $CD_2Cl_2$ exhibits three ruthenium–alkylidene resonances with nearly equal integrated intensities: δ 20.03 (unreacted **3**), δ 18.96 {$[(C_6H_{11})_3P]_2Cl_2Ru{=}CH_2$]} and 23.35 (assigned to **5**). Characteristic resonances for styrene and both *cis* and *trans*-stilbene (derived from self-metathesis of styrene) are also observed. Within 60 min, the resonance for **3** vanishes; after 17 h, only the resonance at δ 18.96 remains.

‡ Within 15 min of mixing at 25 °C, the reaction of **4** with a large excess of **1** in $C_6D_6$ exhibits three major molybdenum alkylidene resonances with relative integrated intensities of 2 : 1 : 2: δ 13.50 (assigned on the basis of chemical shift[9] to the *anti*-rotamer of **6**), 12.45 (assigned to the *syn* rotamer of **6**) and 12.12 (unreacted **4**). Characteristic resonances for $PhCMe_2(CH{=}CH_2)$ are also observed. Within 45 min, the resonance for **4** vanishes. Provided that air is rigorously excluded from the sample, the resonances at δ 13.50 and 12.45 persist indefinitely.

§ All new compounds in Table 1 exhibited satisfactory analytical and spectroscopic data; full details will be reported elsewhere.

¶ Catalytic hydrogenation of $[CH_3CH_2CH_2CH{=}CHSiO_{3/2}]_8$ (19 mg, obtained *via* the cross-metathesis of **1** with pent-1-ene) was performed over 10% Pd/C (7 mg) in ethyl acetate (2 ml) at 160 psi $H_2$ for 2 d at 25 °C. The catalyst was removed by filtration through a short column of silica gel and washed with $CH_2Cl_2$. Rotary evaporation of the filtrate gave **7** in quantitative yield as a colourless oil. For **7**: $^1H$ NMR (500 MHz, $C_6D_6$, 25° C) δ 1.69–1.63 (m, 16 H, $CH_2$), 1.40–1.27 (m, 32H, $CH_2$), 0.88 (t, 40 H, $SiCH_2$ and $CH_3$, *J* 7.3 Hz). $^{13}C\{^1H\}$ NMR (75 MHz, $C_6D_6$, 25° C) δ 35.08 ($CH_2$), 22.84 ($CH_2$), 22.49 ($CH_2$), 14.12 ($CH_3$), 12.55 ($SiCH_2$). $^{29}Si\{^1H\}$ NMR (99 MHz, $C_6D_6$, 25° C) δ −68.2. MS (70 eV, direct inlet; rel int.): *m/z* 984 ($M^+$, 9%).

# Oxidative carbonylation of methane to methyl acetate on a rhodium-doped iron phosphate catalyst

**Ye Wang, Masayuki Katagiri and Kiyoshi Otsuka***

*Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152, Japan*

**The carbonylation of methane with carbon monoxide in the presence of nitrous oxide produces methyl acetate on a rhodium-doped iron phosphate catalyst under atmospheric pressure and at 573–673 K.**

Methane is the main constituent of the abundant natural gas resources. The direct transformation of methane to more useful chemicals or liquid fuels has long been a desirable goal for chemists. However, because methane is a very unreactive molecule, the conversion of methane to useful chemicals has proven to be a great challenge. Although there are many reports of the functionalisation of methane, the most viable process and effective catalyst are still unsettled.[1–5] Recently, we have reported that the conversion of methane is enhanced and methanol is selectively produced by co-feeding a reductant such as hydrogen over an iron phosphate ($FePO_4$) catalyst.[6–8] When nitrous oxide is used as an oxidant in the presence of hydrogen, methane can be selectively converted into methanol with high selectivity at moderate temperatures (*ca*. 620 K).[8] If carbon monoxide is used as the reductant instead of hydrogen, we can expect that the activated carbon monoxide may react with the methanol produced or with reaction intermediates such as methyl species to form acetic acid or methyl acetate. The wasteful consumption of the co-feeding reductant, which is a common problem for many biomimetic monooxygenase catalytic systems, may thus be overcome. Acetic acid is a very important chemical and is produced mainly by the carbonylation of methanol as typically demonstrated in the Monsanto process. If acetic acid or its derivatives such as methyl acetate can be produced directly from methane, the impact on the chemical industry would be significant because the production cost of many chemical products based on acetic acid will become remarkably cheaper. Reports concerning the direct carbonylation of methane to acetic acid are very scarce[9–11] and all these studies have been performed using a high pressure ( > 20 bar) liquid-phase reaction system. The use of expensive reagents such as $FHSO_3$–$SbF_5$,[9] $K_2S_2O_8$[10] and $I^-$ or perfluorobutyric acid[11] is required in these complicated systems. Furthermore, the separation of these expensive reagents or catalysts such as $RhCl_3$ from the solvents is another drawback for these homogeneous reaction systems. Therefore, a simple heterogeneous catalytic system would be more desirable and promising. This communication is the first contribution to attempt direct carbonylation of methane using a simple heterogeneous catalytic system.

The experiments were carried out using a conventional fixed-bed flow reactor (quartz tube) operated at atmospheric pressure. The Rh-doped iron phosphate catalysts with various Rh content were prepared by mixing aqueous solutions of $RhCl_3$ or $Rh(NO_3)_3$, $Fe(NO_3)_3$ and $NH_4H_2PO_4$ and evaporating water from the resultant solution to obtain the catalyst precursors. The precursors were finally calcined at 823 K for 5 h in air. The catalysts were pretreated in an oxygen flow at 723 K in the reactor and the reaction was started by introducing the reactants $CH_4$, $N_2O$ and CO. The outlet gases were bubbled into a water trap cooled with water/ice bath to collect the products, MeOH, $MeCO_2H$ and $MeCO_2Me$. These collected products were analysed by a FID-equipped gas chromatograph with acetonitrile as internal standard. Other components which could not be dissolved in the water trap were analysed by an on-line TCD-equipped gas chromatograph.

Fig. 1 compares the reaction results over $FePO_4$ and various metal-ion-doped $FePO_4$ catalysts at 648 K. Using pure $FePO_4$, a considerable amount of MeOH was formed. We have reported that oxygen species generated from the reductive activation of $N_2O$ on iron sites are responsible for the activation of $CH_4$ at such a moderate temperature.[8] However, the carbonylation products, $MeCO_2H$ and $MeCO_2Me$ were not observed at all on $FePO_4$. This result indicates that another site for the effective activation of CO for the carbonylation is required on the catalyst surface. Thus, many additives have been incorporated into $FePO_4$ to enhance the ability for the activation of CO for the carbonylation. The results in Fig. 1 suggest that rhodium is very specific for the formation of $MeCO_2Me$. Instead of $FePO_4$, a large variety of materials including $SiO_2$, $Al_2O_3$, H-ZSM-5, Ga-H-ZSM-5, H-mordenite, active carbon, $SO_4^{2-}/ZrO_2$, $MoO_3$ and $V_2O_5$ were also used as bases for rhodium. However, none of

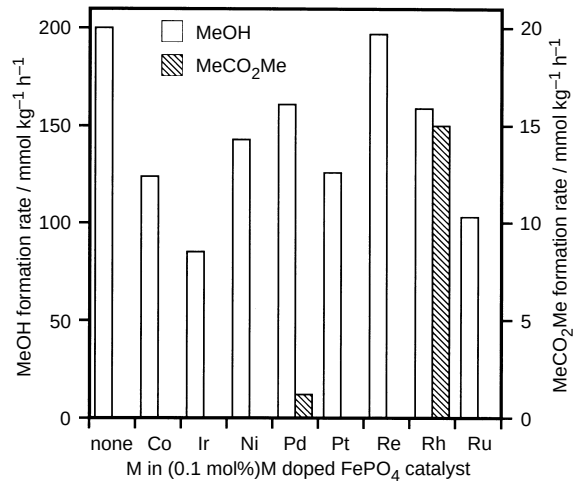

**Fig. 1** Oxidative carbonylation of methane over various metal-ion-doped $FePO_4$ catalysts. *Reaction conditions*: $T$ = 648 K, $P(CH_4)$ = $P$(CO) = 25.3 kPa, $P(N_2O)$ = 12.7 kPa, $W$ = 0.2 g, $F$ = 80 ml min$^{-1}$.

**Table 1** Effect of rhodium content on the formation of methyl acetate from methane[a]

| Rh content (%) | Formation rate/ mmol g$^{-1}$ h$^{-1}$ | | CO conv. (%) |
|---|---|---|---|
| | MeOH | $MeCO_2Me$ | |
| 0 | 200.5 | 0 | 2.5 |
| 0.1 | 125.5 | 16.0 | 2.2 |
| 0.3 | 113.0 | 26.5 | 4.3 |
| 0.5 | 92.0 | 28.5 | 2.5 |
| 1.0 | 90.0 | 21.2 | 2.5 |
| 2.0 | 126.7 | 18.3 | 2.8 |

[a] *Reaction conditions*: $T$ = 648 °C, $P(CH_4)$ = $P$(CO) = 25.3 kPa, $P(N_2O)$ = 12.7 kPa, total flow rate = 80 ml min$^{-1}$.

them showed activity for the carbonylation of $CH_4$. Therefore, $Rh/FePO_4$ is a unique catalyst. Further detailed studies were thus carried out using the $Rh/FePO_4$ catalyst.

In order to increase the rate of the carbonylation reaction, catalysts with various mol% Rh were investigated. As shown in Table 1, an increase in Rh content up to 0.5% increased the formation rate of $MeCO_2Me$ at the expense of MeOH. For the Rh (0.5%)/$FePO_4$ catalyst, the formation rate of $MeCO_2Me$ reached *ca*. one third of that of MeOH. Further increase of Rh content decreased the formation rate of $MeCO_2Me$ as well as the ratio of $MeCO_2Me$ to MeOH. This fact probably indicates that highly dispersed $Rh^{3+}$ on the surface of $FePO_4$ is responsible for the carbonylation reaction.

Naturally, the conversion of CO shown in Table 1 was mainly ascribed to the formation of $CO_2$. Only 1–5% of CO converted took part in the carbonylation reaction. Table 1 shows that the conversion of CO is not changed appreciably by the addition of Rh to $FePO_4$. This result suggests that the direct oxidation of CO into $CO_2$ occurs mainly on the host $FePO_4$.

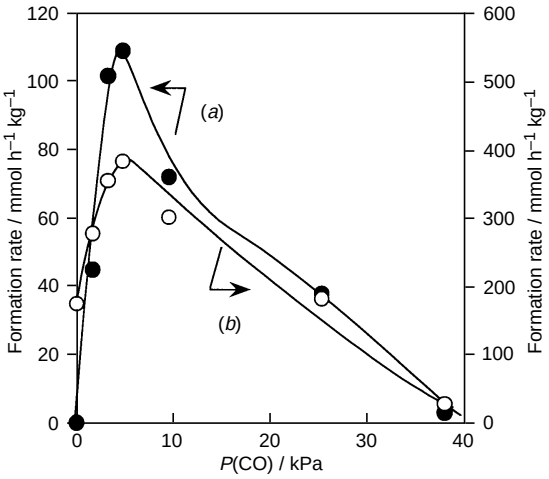

**Fig. 2** Effect of CO pressure on the formation of MeOH and $MeCO_2Me$ on Rh (0.5%)/$FePO_4$ catalyst. (*a*) $MeCO_2Me$, (*b*) MeOH. *Reaction conditions*: $T$ = 648 K, $P(CH_4)$ = $P(N_2O)$ = 25.3 kPa, $W$ = 0.2 g, $F$ = 160 ml min$^{-1}$.

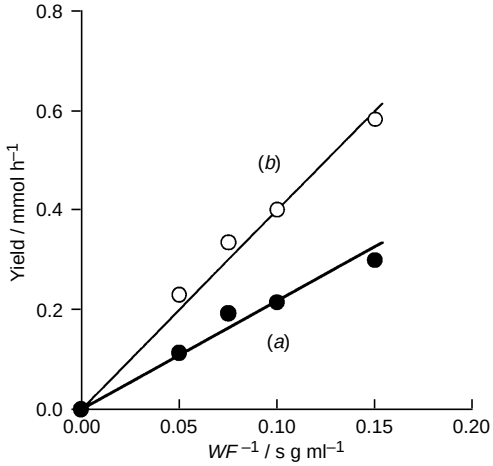

**Fig. 3** Effect of $WF^{-1}$ on the formation of MeOH and $MeCO_2Me$ on Rh (0.5%)/$FePO_4$ catalyst. (*a*) $MeCO_2Me$, (*b*) MeOH. *Reaction conditions*: $T$ = 648 K, $P(CH_4)$ = $P(N_2O)$ = 25.3 kPa, $F$ = 300 ml min$^{-1}$.

Fig. 2 shows the effect of CO pressure on the carbonylation reaction over the Rh (0.5%)/$FePO_4$ catalyst. No $MeCO_2Me$ was produced in the absence of CO. The introduction of CO caused the formation of $MeCO_2Me$. It should be noted that MeOH was also remarkably increased at low partial pressures of CO [P(CO) < 5 kPa]. This result suggests that CO functions not only as a reactant in the carbonylation reaction but also as an activator for the conversion of $CH_4$. Probably, CO reduces $Fe^{III}$ to $Fe^{II}$ on the $FePO_4$ surface and the produced $Fe^{II}$ site acts as the active site for the generation of the active oxygen species from $N_2O$.[6–8] On the other hand, higher pressures of CO are not favourable for the formation of both MeOH and $MeCO_2Me$. Competitive oxidation between CO and $CH_4$ with the active oxygen species must be the main reason.

Whether $MeCO_2Me$ is formed from the direct carbonylation of $CH_4$ or from the carbonylation of the produced MeOH is a key point in the reaction mechanism. Thus, the influence of $WF^{-1}$ (weight of catalyst/flow rate) on the yields of MeOH and $MeCO_2Me$ has been investigated. As shown in Fig. 3, the yields of both MeOH and $MeCO_2Me$ increased almost linearly with increase in $WF^{-1}$. This result indicates that MeOH and $MeCO_2Me$ are formed in parallel from $CH_4$.

The results described above allow us to speculate on a reaction mechanism as follows. $CH_4$ must be activated by the active oxygen species generated on the iron site, producing an Me species as a transient intermediate. This Me species may easily be oxidized to an MeO species on the surface of $FePO_4$. It must also migrate and adsorb on a Rh site where CO is activated. The insertion of CO into Rh–Me may occur on this Rh site, producing Rh–COMe. $MeCO_2Me$ is then formed by the reaction of Rh–COMe with the MeO species produced on $FePO_4$ near this Rh site, while the addition of a proton (probably from OH groups) to the adsorbed MeO produces MeOH. According to this mechanism, the high dispersion of Rh at sites surrounded by iron sties is a key factor for the carbonylation reaction. Further confirmation of this mechanism and the design of catalysts with high concentration of Rh sites with surrounding iron sites are underway.

# Variation of bonding modes in homoleptic tin(II) 1-azaallyls†

**Peter B. Hitchcock, Jin Hu, Michael F. Lappert, Marcus Layh and John Severn**

*The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ*

**The homoleptic tin(II) compounds Sn[N(R)C(Bu$^t$)-C(H)C$_6$H$_3$Me$_2$-2,5]$_2$ 1, Sn[N(R)C(Bu$^t$)C(H)R]$_2$ 2 and R$_2$CC(Ph)N(R)Sn[N(R)C(Ph)CR$_2$] 3 (R = SiMe$_3$) are prepared and structurally characterised.**

The important series of first-row triatom-centred, monoanionic ligands [XYZ]$^-$ include allyl, triazenide and amidinate, with the carboxylate probably the archetype. Open-chain, structurally characterised 1-azaallyl ligands are of recent date.[1] In [Li(LL′)]$_2$,[1] *rac*-[Zr(LL′)$_2$Cl$_2$][2] and *rac*-[Yb(LL′)$_2$],[3] the [LL′]$^-$ ligand behaved in an η$^3$-chelating bridging (Li) or terminal (Zr, Yb) fashion [LL′ = N(R)C(Bu$^t$)C(H)R, R = SiMe$_3$]. We now report that the latter reflects on only one possible mode of terminal 1-azaallyl–metal (M) bonding (**MA**, η$^3$-iminoalkyl), while another, **MB**, represents an η$^1$-enamidometal isomer. This is illustrated by reference to the three homoleptic 1-azaallyltin(II) complexes, having the structures Sn**B**$_2$ **1**, Sn**A**$_2$ **2** and Sn(**A**)**B 3**, the variation in structural types being due to changing the substituents on the NCC skeleton: Sn[N(R)C(Bu$^t$)C(H)C$_6$H$_3$Me$_2$-2,5]$_2$ **1**, Sn[N(R)C(Bu$^t$)C(H)R]$_2$ **2** and R$_2$CC(Ph)N(R)Sn[N(R)C(Ph)CR$_2$] **3** (R = SiMe$_3$).

**MA** **MB**

The yellow (**1**, **2**) and orange (**3**) tin complexes were readily synthesised (78–84%) from SnCl$_2$ and 2 equiv. of Li[N(R)C-(Bu$^t$)C(H)Ar] [obtained[4a] from LiCH(R)$_2$ + Bu$^t$CN, Ar = C$_6$H$_3$Me$_2$-2,5], K(LL′),[1] or Li[N(R)C(Ph)CR$_2$] [prepared[4b] from LiCR$_3$(thf)$_2$ + PhCN] in diethyl ether or pentane solution at ambient temperature. A single-crystal X-ray diffraction study‡ shows that **1** (Fig. 1) is coordinated by two

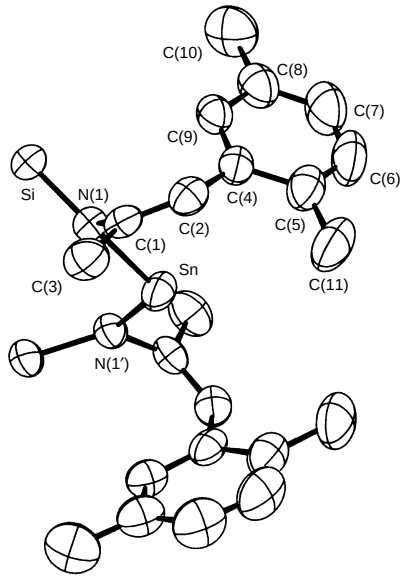

**Fig. 1** Partial molecular structure of **1** (core atoms only)

η$^1$-enamido ligands with the free electron pair pointing away from the ligands. The N(1)–Sn–N(1′) angle of 111.2° is only slightly larger than in the mononuclear tin(II) amides Sn[N(SiMe$_3$)$_2$]$_2$[5] (104.7°) or Sn[N(Me)$_2$(CH$_2$)$_3$CMe$_2$]$_2$[6] (109.7°). The arrangement of the ligands is such that the aromatic rings are within the van der Waals range above and below the Sn atom [Sn–C(2) 3.151, Sn–C(7) 3.188 Å]. A similar interaction has been reported in 1,2-C$_6$H$_4$[N(CH$_2$Bu$^t$)]$_2$Sn.[7] The enamido character of the 1-azaallyl ligand in **1** is evident from the short Sn–N(1), long N(1)–C(1) and a short C(1)–C(2) distance (Table 1), as well as $^{13}$C NMR shifts which are consistent with N(1)–C(1) being a single and C(1)–C(2) a double bond.

Changing the 2,5-dimethylphenyl group of the η$^1$-ligand system in **1** by a trimethylsilyl group alters the ligand bonding mode to η$^3$. Thus the X-ray structure of **2** (Fig. 2)‡ shows that, in contrast to **1**, C(2) and N(1) are both within bonding range of the tin atom but compared to **1** the Sn–N(1) distances are longer (Table 1). The C(1)–C(2) and C(1)–N(1) distances and the $^{13}$C NMR spectral chemical shifts show iminoalkyl rather than enamido character, as evident by comparison with Sn[NC$_5$H$_4$C(SiMe$_3$)$_2$-2]$_2$.[8] It is interesting to note that C(1) is bent towards the metal [the angle between the adjacent planes SnN(1)C(2) and N(1)C(1)C(2) is 37°] leading to a Sn–C(1) distance of 2.729(2) Å. Therefore an alternative description of **2** is as a bent sandwich complex similar to Sn(η-C$_5$Me$_5$)$_2$.[9]

The X-ray structure of crystalline **3**‡ shows that introducing a second trimethylsilyl group at C(2) or C(5) probably increases the steric demand of the ligand to such an extent that the bis(chelate) arrangement is no longer viable; thus, an intermediate situation between that of **1** and **2** is observed, wherein one ligand is η$^3$- and the other is η$^1$-coordinated. Table 1 shows relevant interatomic distances and NMR spectral chemical shifts. Important differences for the η$^3$-coordinated ligand in **3** compared with **2** are a shorter Sn–N(1) and a longer Sn–C(2) distance in **3** and a much smaller dihedral angle between the planes N(1)SnC(2) and N(1)C(1)C(2) of only 12.7°. That a higher coordination number than three in **3** is probably avoided by the increased bulk of the ligand (compared with that in **2**) is also supported by variable-temperature $^1$H and $^{13}$C NMR

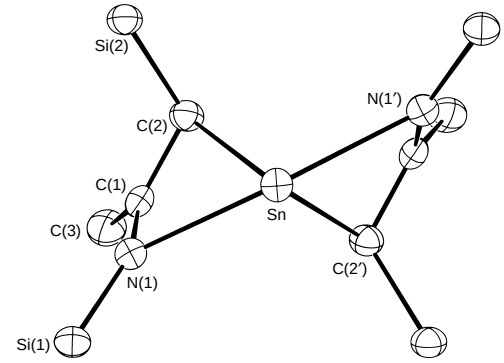

**Fig. 2** Partial molecular structure of **2** (core atoms only) with selected bond angles (°): N–Sn–N′ 146.98(6), N–Sn–C(2) 57.99(6), N–Sn–C(2′) 97.25, C(2)–Sn–C(2′) 89.44(8)

spectroscopic experiments which show the two ligands to be equivalent in solution down to −90 °C, indicating that there is a rapid intramolecular exchange between the $\eta^1$- and $\eta^3$-coordinated ligand. Comparing **2** and **3** with **1** it may be that the preference for the enamido structure in **1** is due to electronic rather than steric reasons.

In conclusion, we believe that the following features (*i*) and (*ii*) are particularly noteworthy. (*i*) Compounds **1**–**3** serve as a good example to demonstrate how comparatively small differences in the backbone of a 1-azaallyl ligand may significantly influence their metal complex bonding modes. (*ii*) Enamido–metal bonding now shown in the tin(II) complexes **1** and **3** has only recently been crystallographically established for some alkali-metal 2-methylpyridine or related derivatives,[10,11] *e.g.*[11] Li[$NC_5H_4${C(SiMe$_3$)Ph}-2](tmen); such structures are widely postulated for group 1 and 2 metal complexes, which when prepared *in situ* are valuable C–C bond-forming synthons;[12] there is NMR spectroscopic structural evidence for [M{N(H)C(Bu$^t$)CHPr$^n$}{OP(NMe$_2$)$_3$}$_x$]$_n$ (M = Li, $x$ = 1 or M = Na, $x$ = 2)[13a] and [Li{N(Ph)C=CH(CH$_2$)$_3$CH$_2$} (thf)$_x$]$_n$ ($x$ = 0, or $x$ = 1 = $n$).[13b] The [$NC_5H_4C(SiMe_3)_2$-2]$^-$ ligand has been found in an $\eta^1$-mode in the homoleptic mercury(II) complex, but it is the tautomeric (*cf.* **MB**) iminoalkyl ligated species.[14]

‡ *Crystal data* for **1**: $C_{34}H_{56}N_2Si_2Sn$, $M$ = 667.68, monoclinic, space group $C2/c$ (no. 15), $a$ = 13.006(4), $b$ = 15.957(3), $c$ = 17.735(10) Å, β = 98.74(3), $U$ = 3638(2) Å$^3$, $Z$ = 4, $D_c$ = 1.22 g cm$^{-3}$, $F$(000) = 1408, λ(Mo-Kα) = 0.710 73 Å, μ = 0.79 mm$^{-1}$. Data were collected at 293(2) K on a Enraf-Nonius CAD4 diffractometer in the ω–2θ mode in the range 2 < θ < 25°. The structure was solved by direct methods (SHELXS 86) and refined by full-matrix least squares on all $F^2$ (SHELXL 93) with absorption correction by ψ-scans. All non-hydrogen atoms were anisotropic, and hydrogen atoms were included in the riding mode with $U_{iso}$(H) = 1.2 $U_{eq}$(C) or 1.5 $U_{eq}$ for Me groups. Final residuals for 3190 independent reflections were $R_1$ = 0.057, $wR_2$ = 0.086 and for the 2442 with $I > 2\sigma(I)$, $R_1$ = 0.037, $wR_2$ = 0.077.

**2**: $C_{24}H_{56}N_2Si_4Sn$, $M$ = 603.8, monoclinic, space group $C2/c$ (no. 15), $a$ = 11.387(5), $b$ = 16.675(6), $c$ = 18.390(8) Å, β = 106.07(3), $U$ = 3355.4 Å$^3$, $Z$ = 4, $D_c$ = 1.20 g cm$^{-3}$, $F$(000) = 1280, λ(Mo-Kα) = 0.710 73 Å, μ = 0.92 mm$^{-1}$. 3060 independent reflections were collected at 173(2) K on a Enraf-Nonius CAD4 diffractometer in the ω–2θ mode in the range 2 < θ < 25°. The structure was solved by heavy-atom methods (SHELXS 86) and refined by full-matrix least squares on $F$ (Enraf-Nonius MolEN) with absorption correction by DIFABS. All non-hydrogen atoms were anisotropic, and hydrogen atoms were included in the riding mode with $U_{iso}$(H) = 1.2 $U_{eq}$(C) or 1.5 $U_{eq}$ for Me groups. Final residuals for 2623 reflections [with $I > 2\sigma(I)$] were $R$ = 0.025, $R'$ = 0.030.

**3**: $C_{34}H_{64}N_2Si_6Sn$, $M$ = 788.1, monoclinic, space group $P2_1/c$ (no. 14), $a$ = 19.249(4), $b$ = 12.400(3), $c$ = 19.820(5) Å, β = 112.83(2), $U$ = 4360(2) Å$^3$, $Z$ = 4, $D_c$ = 1.20 g cm$^{-3}$, $F$(000) = 1664, λ(Mo-Kα) = 0.71073 Å, μ = 0.77 mm$^{-1}$. Conditions for data collection and refinement were identical to those for **1**. Final residuals for 7663 independent reflections were $R_1$ = 0.096, $wR_2$ = 0.106 and for the 5008 with $I > 2\sigma(I)$, $R_1$ = 0.048, $wR_2$ = 0.088.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # New sensor for dissolved dioxygen: a gold electrode modified with a condensation polymer film of β-cyclodextrin hosting cobalt tetraphenylporphyrin

**Francis D'Souza,*[a] Yi-Ying Hsieh,[a] Heang Wickman[a] and Wlodzimierz Kutner*[a,b]**

[a] *Department of Chemistry, Wichita State University, Wichita, KS 67260-0051, USA*
[b] *Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, PL-01-224 Warsaw, Poland*

**A gold electrode, coated with a thin polymer film of a supramolecular complex of β-cyclodextrin and cobalt tetraphenylporphyrin, is used as an electrocatalytic sensor for determination of dioxygen dissolved in water.**

Development of supramolecular transducing systems for catalytic sensor applications is an area of active research.[1] Cyclodextrin (CD) hosts are very appealing with this respect since they can form supramolecular complexes with a broad range of organic and inorganic, both ionic and neutral compounds.[2] Additional advantages arise if a thin cyclodextrin polymer (CDP) film is cast on an electrode surface.[3,4] Importantly, the stability of supramolecular complexes of CDs embedded, *e.g.* by polycondensation, in polymer matrices is virtually the same as that of solution complexes, and in some cases the stability is even increased.[5] Moreover, CDP is soluble neither in aqueous nor in non-aqueous solvent solutions and is resistant to pH changes within a wide range (pH 2–12). The structure of CDP is relatively open, so the CDP films are readily permeable to small molecules or ions present in solution while large ones are repelled.[3,5] The shelf lifetime of CDP film coated electrodes reaches months if films are stored in air of sufficiently high humidity.

Metalloporphyrins, due to their rich and well defined redox behaviour,[6] are suitable for developing redox catalysts and sensors. For instance, monomeric cobalt porphyrins reversibly bind dioxygen and catalytically electroreduce it to peroxide both in homogeneous and heterogeneous systems.[7] Recently, formation of supramolecular complexes of β-cyclodextrin (β-CD) and free-base tetraarylporphyrins have been reported,[8] thus opening the opportunity to develop new catalytic sensor devices. In the present study, we exploit this approach (Scheme 1) by demonstrating that a polymer film of a supramolecular complex of β-CD and cobalt tetraphenylporphyrin, Co(TTP), coated on the surface of a gold electrode, (β-CDP)–[Co(TPP)]/Au, can operate as a voltammetric sensor for determination of dioxygen dissolved in aqueous solution.

**Scheme 1** Schematic representation of catalytic $O_2$ electroreduction at a gold electrode coated with a polymer film of β-cyclodextrin hosting Co(TPP)

The (β-CDP)–[Co(TPP)]/Au electrode was prepared according to a simple one-step procedure developed earlier for the β-CDP films hosting other organic compounds.[10] That is, a *ca.* 0.1 mM Co(TPP)† chloroform solution was equilibrated, by sonication for a few min, with a stock solution of 2% β-cyclodextrin soluble prepolymer (β-CDPS).‡ After partition equilibrium was attained, the stock solution turned pale red–orange. This solution was used to prepare the casting solution which was 1.5% in β-CDPS, hosting Co(TPP), 15 mM in glutaric dialdehyde and 10 mM in HCl. Then, a *ca.* 3 μm thick polymer film was prepared by dispensing a 5 μl sample of the casting solution on the Au electrode surface to form a *ca.* 4 mm diameter circular spot.[3] Polycondensation was carried out for *ca.* 1 h in a water-vapour filled container (*ca.* 40% humidity), to allow for slow water evaporation. The small thickness of the β-CDP film used in the present study is advantageous with respect to the response time of the fabricated sensor.[10b]

Cyclic voltammetry (CV)§ experiments, perofrmed with the use of the (β-CDP)–[Co(TPP)]/Au electrode in deaerated 0.1 M phosphate buffer (pH 5.6),¶ 0.1 M NaCl, exhibited an electro-oxidation peak located at $E_{pa}$ = 0.09 V (potential scan rate, $v$ = 0.1 V $s^{-1}$) corresponding to the $Co^{II}$(TPP)–$Co^{III}$(TPP) redox couple.[6] Multicyclic voltammetry experiments showed no decay of the $Co^{II}$(TPP)–$Co^{III}$(TPP) peak currents with the scan number. This indicates that Co(TPP) is not released from the film into solution, as expected for this water-insoluble catalyst. Logarithmic dependence of the $Co^{II}$(TPP)–$Co^{III}$(TPP) electro-oxidation peak current *vs.* the potential scan rate was linear, with a slope close to 0.5, indicating a semi-infinite diffusion controlled charge transport within the polymer matrix. By analogy to the earlier reported supramolecular CD–porphyrin complexes in solution,[7] one may expect that Co(TPP) is complexed predominately by inclusion of its one or more phenyl rings by the cyclodextrin host site of the polymer rather than through axial ligation of the cobalt centre. Because of the semi-infinite, and not finite, diffusion control of the CV peak current, it is also unlikely that the Co(TPP) solid is present in the form of a suspension in the film.

The voltammetric peak corresponding to electroreduction of dissolved dioxygen at a blank (β-CDP)/Au electrode, *i.e.* in the absence of the Co(TPP) catalyst in the film, occurs at $E_{pc}$ = −0.70 V ($v$ = 0.1 V $s^{-1}$). Interestingly, with the (β-CDP)–[Co(TPP)]/Au electrode, *i.e.* in the presence of the catalyst in the film, this peak is positively shifted due to electrocatalysis and occurs at $E_{pc}$ = −0.45 V ($v$ = 0.1 V $s^{-1}$). A peak current dependence on $v^{\frac{1}{2}}$ for the latter peak is linear, with zero plot intercept, for constant dioxygen concentration, indicating that dioxygen catalytic electroreduction is controlled by semi-infinite diffusion. Fig. 1 shows the effect of the dioxygen concentration on the voltammetric peak current of catalytic dioxygen electroreduction measured at the (β-CDP)–[Co(TPP)]/Au electrode. The catalytic peak current is linearly dependent on the dioxygen concentration for the entire range of

dioxygen concentration (inset in Fig. 1). Voltammetry at the rotating ring-disk (platinum–glassy carbon) electrode, with a (β-CDP)–[Co(TPP)] film coated on the disk, proved that dioxygen is catalytically electroreduced to hydrogen peroxide (Scheme 1). That is, ring current was observed corresponding to the electrooxidation of hydrogen peroxide, which is the electroreduction product at the disk when its potential is scanned from 0.2 to −0.7 V and the ring potential is kept constant at $E_R$ = 0.8 V.[11]

In summary, the Co(TPP) catalyst can be immobilized in a thin β-CDP film cast on the Au electrode surface, and the sensor thus fabricated can be successfully used for detection of dioxygen dissolved in aqueous solution. The catalyst is molecularly dispersed in the polymer matrix forming a supramolecular complex with the β-CD sites and, advantageously, this immobilization is irreversible in aqueous solutions. The catalytic peak current of dioxygen electroreduction is proportional to the dioxygen concentration in solution for the entire range of the dioxygen concentration. The (β-CDP)–[Co(TPP)]/Au electrodes show reproducible results with respect to dioxygen determination after storage for several days in air atmosphere of high humidity. Mechanistic studies on dioxygen binding to cobalt porphyrins bearing different peripheral charges, hosted by the β-CDP matrix, and hydrogen peroxide release will follow.[13]

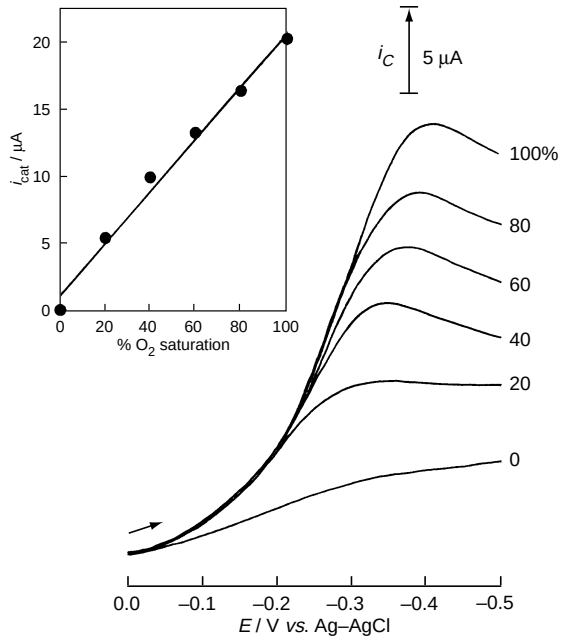

**Fig. 1** Voltammograms for the (β-CDP)–[Co(TPP)] film-coated Au disk electrode for different % $O_2$, indicated for each curve; 0.1 M phosphate buffer (pH 5.6), 0.1 M NaCl; ν 0.1 V $s^{-1}$. Inset is the dependence of the catalytic peak current, $i_{cat}$, of $O_2$ electroreduction *vs.* % $O_2$ saturation of the solution.

† Co(TPP) was synthesized according to the literature procedure (ref. 9).

‡ β-CDPS was from Cyclolab, Cyclodextrin Research and Development Laboratory (Budapest, Hungary).

§ Cyclic voltammetry was performed by using either a Model EC/225 Voltammetric Analyzer of IBM Instruments, Inc. (Danbury, CT) or a Model 263A potentiostat/galvanostat of EG&G PAR (Princeton, NJ) and a typical three-electrode electrochemical cell. A 1.6 mm diameter disk gold electrode of Bioanalytical Systems (West Lafayette, IN) was used as the working electrode. A platinum wire and sodium chloride saturated Ag–AgCl electrode served as the auxiliary and reference electrodes, respectively. All potentials cited are against the Ag–AgCl reference electrode. All measurements were performed for a 0.1 M phosphate buffer (pH 5.6), 0.1 M NaCl solution, at 20 ± 1 °C.

¶ The pH of the working solution was chosen to be 5.6 in order to avoid hydrolysis of glycosidic bonds of the β-CDP polymer which occurs at pH < 2, and also to avoid the pH dependence of the formal redox potential of the $Co^{III}$–$Co^{II}$ couple of Co(TPP) at pH ⩾ 6, as demonstrated in ref. 12.

# Ultrathin oriented zeolite LTA films

**Jonas Hedlund,* Brian Schoeman and Johan Sterte**

*Department of Chemical Technology, Luleå University of Technology, SE-971 87, Luleå, Sweden*

**Ultrathin oriented films of zeolite LTA are prepared on single-crystal alumina supports by a method including adsorption of LTA seeds on the support followed by hydrothermal film crystallization.**

Molecular sieve films have great potential for example as membranes and membrane reactors as well as in sensor applications. Supported films of molecular sieves are usually synthesized by direct crystallization of the zeolite on the support.[1] Most of the work reported concerns the preparation of MFI films[2–8] because of the simplicity of this system and only a few reports treating the preparation of other types of zeolite films have appeared in the literature.[9–12] Independent of zeolite type, these films generally have a thickness exceeding 1 μm. The flux through a membrane or the response time of a chemical sensor is greatly dependent upon the film thickness and hence thin films are preferable in both membrane and sensor applications. The performance of zeolite membranes and sensors is also influenced by the orientation of the zeolite crystals constituting the film. The orientation will affect the diffusion path through the membrane and the adsorption kinetics of a chemical sensor consisting of a supported zeolite film. Recently, a novel method was presented for the preparation of ultrathin films of silicalite-1 on various substrates.[13,14]

Here, we report on the first preparation of an ultrathin oriented zeolite LTA film on a single-crystal alumina(0001) wafer. LTA seeds were prepared by hydrothermal treatment at 63 °C for 63 h of a synthesis solution with the composition $0.22Na_2O : 5.0SiO_2 : Al_2O_3 : 8.0(TMA)_2O : 400H_2O$. The synthesis solution was prepared by first dissolving aluminium isopropoxide (Sigma) and tetramethylammonium hydroxide pentahydrate (Sigma) in a sodium hydroxide solution at room temp. and then mixing this solution with a dilute silica sol (Bindzil 30/220, 31 mass% $SiO_2$ and 0.5 mass% $Na_2O$, Akzo Nobel AB). After synthesis, the seed sol was purified by repeated centrifugation and redispersion in an ammonia solution so as to maintain a pH exceeding 10.5. The sol was finally diluted to a solids content of 2.5 mass% (determined after drying at 100 °C) and adjusted to a pH of 10.7. A polished alumina(0001) wafer (10 × 10 × 0.5 mm, Coating & Crystal

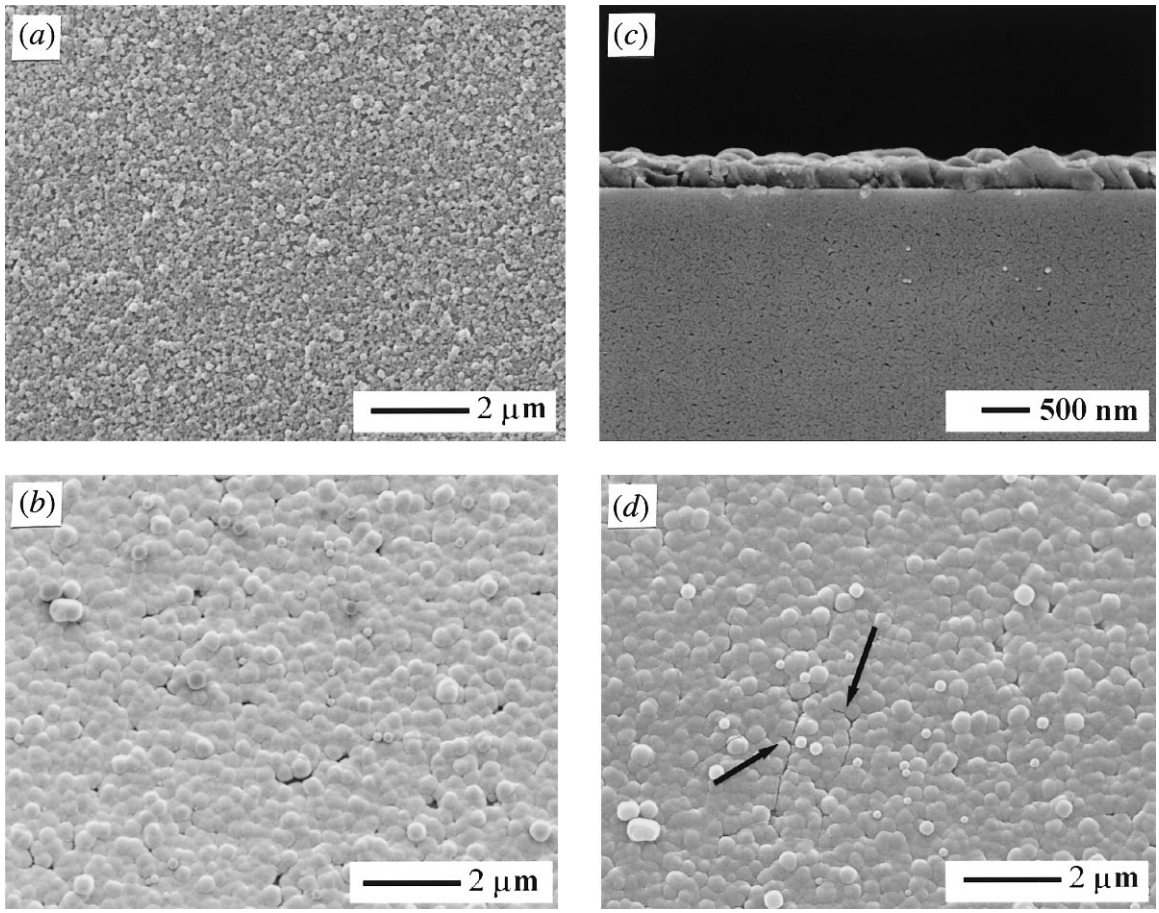

**Fig. 1** SEM micrographs showing the adsorbed zeolite LTA seed crystals after three repeated adsorptions on the substrate surface (*a*), the top view of the film after calcination recorded at an accelerating voltage of 4 kV (*b*), the side view of the film after calcination (*c*) and the top view of the film after calcination recorded at an accelerating voltage of 20 kV with arrows indicating cracks (*d*)

Technology) was mounted vertically in a Teflon holder and treated in acetone in an ultrasonic bath for 5 min followed by rinsing with distilled water. The substrate was boiled for 5 min in a mixture of $H_2O$, $H_2O_2$ and $NH_3$ (5 : 1 : 1 v/v/v of $H_2O$, 30% $H_2O_2$ and 25% $NH_3$), rinsed with distilled water and boiled for 5 min in a mixture of $H_2O$, $H_2O_2$ and HCl (6 : 1 : 1 v/v/v of $H_2O$, 30% $H_2O_2$ and 37% HCl) and finally rinsed with water and a 0.1 M ammonia solution. After the rinsing procedure the wafer was immersed in a 0.4% solution of a cationic polymer (Berocell 6100, Akzo Nobel AB, repeating unit $[CH_2CHOHCH_2NMe_2]^+_n$, $M_w$ = 50 000 g mol$^{-1}$, pH 8.0) for 5 min to reverse the surface charge of the alumina wafer from a negative to a positive value. The charge reversed wafer was rinsed in a 0.1 M ammonia solution to remove excess polymer. The substrate was treated with the LTA seed sol for 5 min to adsorb seed crystals on the charge reversed alumina surface and rinsed in a 0.1 M ammonia solution to remove excess seed crystals. This sequence, charge reversal–adsorption of seeds, was repeated twice to improve the seed coverage on the surface. Film crystallization on the seeded substrate was effected by hydrothermal treatment at 100 °C for 6.3 h in a synthesis solution prepared in the same manner and with the same composition as that used for the synthesis of the seed crystals (*vide supra*). After completion of this treatment, the sample was rinsed with a 0.1 M ammonia solution and dried in air. Samples were calcined at 425 °C for 1 h in air, using a heating and cooling rate of 1 °C min$^{-1}$. Particle size analysis by dynamic light scattering (DLS) was performed on the seed sol and on synthesis solutions after synthesis with a Brookhaven Instruments ZetaPlus. Electron micrographs were recorded with a Philips XL 30 scanning electron microscope (SEM) equipped with a $LaB_6$ emission source. X-Ray diffraction (XRD) data were collected with a Siemens D5000 powder diffractometer equipped with a Göbels mirror, 12 cm soller slit and a secondary LiF monochromator when analysing the film. A primary soller slit and variable slits to keep the illuminated area constant were used when analysing powder samples.

The average crystal size in the LTA seed sol was determined by DLS to be 130 nm with a polydisperisty of 0.1. Fig. 1(*a*) shows a SEM micrograph of the adsorbed LTA seeds on the alumina support after the three adsorption steps. Approximately 80% of the support surface is covered by seeds. The coverage after one and two adsorption steps was approximately 40 and 65%, respectively. Fig. 1(*b*) and (*c*) show top- and side-view SEM micrographs of the calcined LTA film recorded with an accelerating voltage of 4 kV. The film is essentially continuous and free of cracks with a constant thickness of *ca*. 280 nm. Fig. 1(*d*) shows essentially the same area as in Fig. 1(*b*) but recorded with an accelerating voltage of 20 kV. A comparison between the two micrographs reveals that cracks have developed, most likely due to the bombardment of the film with 20 keV electrons in the SEM when recording the micrograph in Fig. 1(*d*). Fig. 2 shows X-ray diffraction patterns of freeze-dried seeds (*a*), the purified and freeze-dried product formed in the bulk of the synthesis solution (*b*) and the film after synthesis [(*c*) and (*d*)]. The powder patterns [(*a*) and (*b*)] were recorded using a θ–2θ scan whereas patterns (*c*) and (*d*) [(*d*) is an enlargement of (*c*)] of the film were recorded with a detector scan at a grazing incidence angle of 1°. From patterns (*a*) and (*b*) in Fig. 2 it is clear that both the seeds and the bulk product consist of well crystallized zeolite LTA. The Si/Al molar ratio of the bulk product was determined by EDS analysis to be 1.1. DLS measurements showed that the average size of the final crystals obtained in the bulk phase at 100 °C was *ca*. 330 nm, *i.e.* considerably larger than the 130 nm seed crystals formed at 63 °C. The difference in crystal size explains the narrower peaks in the diffractogram recorded for the bulk product compared with the peaks in the diffractogram from the seeds. The diffractograms (*c*) and (*d*), of the final film, show that the film consists of oriented zeolite LTA crystals. The only peaks visible in this pattern are those due to (*h*00) reflections or diffraction from planes with large *h* compared with *k* and *l* indicating that the (100) plane of all crystals in the film is essentially parallel to the substrate surface.

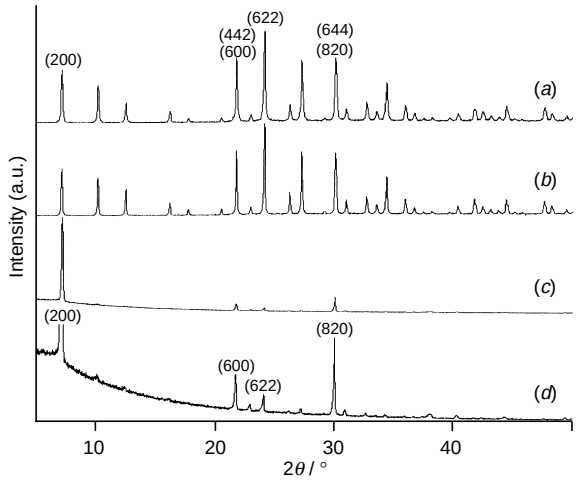

**Fig. 2** X-Ray diffraction patterns of the freeze-dried seeds (*a*), the purified and freeze-dried product formed in the bulk of the synthesis solution (*b*) and the film after synthesis (*c*) and (*d*) [(*d*) is an enlargement of (*c*)]. None of the samples were calcined prior to X-ray diffraction analysis.

The results presented show that the seed film method[13] can be used to synthesize ultrathin, oriented zeolite LTA films in a simple and elegant manner.

We wish to thank the Preem Environmental Foundation and the Swedish Research Council for Engineering Sciences (TFR) for the financial support of this project.

**A one-pot reaction of $Ni^{II}$ 1, $Co^{II}$ 2, $Fe^{II}$ 3 and $Mn^{II}$ 4 with 2,2′-bipyridine (bipy) and azide in water leads to $[M(bipy)(N_3)_2]_n$ chains where the metal ion is alternatively bridged by double end-on (EO) and end-to-end (EE) azido bridges; theoretical analysis of the variable-temperature magnetic susceptibility data of 1 and 4 reveals the occurrence of intrachain alternating ferro- (through EO) and antiferro-magnetic (through EE) interactions.**

A safe strategy in designing alternating chains with ferro- and antiferro-magnetic interactions has been proposed recently,[1] and the first honeycomb-layered materials of formula $[M(bipym)(N_3)_4]$ (M = Mn, Fe, Co; bipym = 2,2′-bipyrimidine)[2] with alternating ferro- (through end-on azido, EO) and antiferro-magnetic (through bischelating bipym) interactions have also been reported. Replacement of bipym by bipy (2,2′-bipyridine) yields chain compounds of formula $[M(bipy)(N_3)_4]$ (M = $Ni^{II}$ **1**, $Co^{II}$ **2**, $Fe^{II}$ **3**, $Mn^{II}$ **4**) with alternating EO and end-to-end (EE) azido bridges and exhibiting ferro- (through EO)[3] and antiferro-magnetic (EE)[4] interactions. Here, we report the synthesis, crystal structure and preliminary magnetic study of compounds **1**–**3**. The magnetic properties of **4**,[5] which is isostructural with **2** and **3**, were reinvestigated for the sake of comparison and the first theoretical analysis of the magnetic behaviour of **1** and **4** through a quantum spin model is also reported.

The one-dimensional compounds were obtained as polycrystalline green (**1**), orange (**2**) and red–brown (**3**) powders by adding an aqueous solution (25 $cm^3$) of $NaN_3$ [2 mmol (**1**) or 10 mmol (**2**, **3**)] to a methanolic solution (5 $cm^3$) containing bipy (1 mmol) and either $Ni(NO_3)_2{\cdot}6H_2O$ (1 mmol, **1**), $Co(NO_3)_2{\cdot}6H_2O$ (1 mmol, **2**) or $FeCl_2$ (1 mmol, **3**). The solid samples were filtered off and thoroughly washed with methanol and diethyl ether (yield *ca*. 50%). X-Ray quality polyhedral (**1**), arrow shaped (**2**) and prismatic (**3**) single crystals were grown by slow diffusion techniques in test (**2**, **3**) or H-shaped (**1**) tubes.†

The structures of **1**–**4** are made up of alternating chains where the metal ions are alternately linked by two EO and two EE azido bridges (Fig. 1).‡ Two nitrogen atoms of the bipy ligand complete a distorted $MN_6$ octahedral environment around each metal atom. The EE and EO bridges are propagated within the chain with a mutual perpendicular arrangement. The value of the M(1)–N(3)–M(1a) angle is 101.5(1) **1**, 100.9(1) **2** and 100.8(1)° **3** in good agreement with the value of 101.0(2)° observed in the parent compound of $Mn^{II}$ **4**.[5] The EE bridges adopt a chair conformation for the M–$(N_3)_2$–M unit. The values of the M(1)–N(6)–N(7) and N(7)–N(8)–M(1b) angles are 118.2(2) and 129.9(3)° in **1**, 127.1(2) and 129.9(2)° in **2** and 126.5(2) and 131.2(1)° in **3** [131.1(5) and 127.3(5)° in **4**]. The dihedral angle between the N(6)N(7)N(8)N(6a)N(7a)N(8a) and MN(6)N(8b) planes is 35.2(1) **1**, 24.9(1) **2** and 23.7(1)° **3** (41.9° in **4**). The intrachain metal–metal separation through EO azido is 3.248(1) **1**, 3.322(1) **2** and 3.367(1) Å **3** [3.455(6) Å in **4**] and that through EE azido is 5.117(2) **1**, 5.279(2) **2** and 5.317(2) Å **3** [5.343(5) Å in **4**]. The shortest interchain metal–metal separation is 8 Å [8.462(3) **1**, 8.115(4) **2**, 8.063(3) Å **3**].

Magnetic susceptibility measurements (290–2 K) on polycrystalline samples of **4** (Fig. 2) are consistent with overall antiferromagnetic behaviour. Least-squares analysis of the $\chi_M T$ data of **4**§ leads to $J_1 = 2.5\ cm^{-1}$, $J_2 = -6.3\ cm^{-1}$ and $g = 2.0$. $J_1$ and $J_2$ are associated with the exchange coupling through EO and EE azido bridges, respectively. The $\chi_M T$ value of **1** (Fig. 3) smoothly increases as the temperature is lowered, attains a plateau at 70 K and quickly decreases in the lower temperature region. The susceptibility curve (inset of Fig. 3) increases monotonically when cooling, attains a shoulder in the temperature range 50–20 K and then increases achieving a maximum at 8.5 K. The shape of the shoulder is field dependent at $T < 50$ K but the temperature of the maximum remains unchanged. The theoretical analysis of the magnetic data of **1**[6] matches well the experimental data in the temperature range 290–55 K. The best fit parameters are $J_1$ (coupling through EO

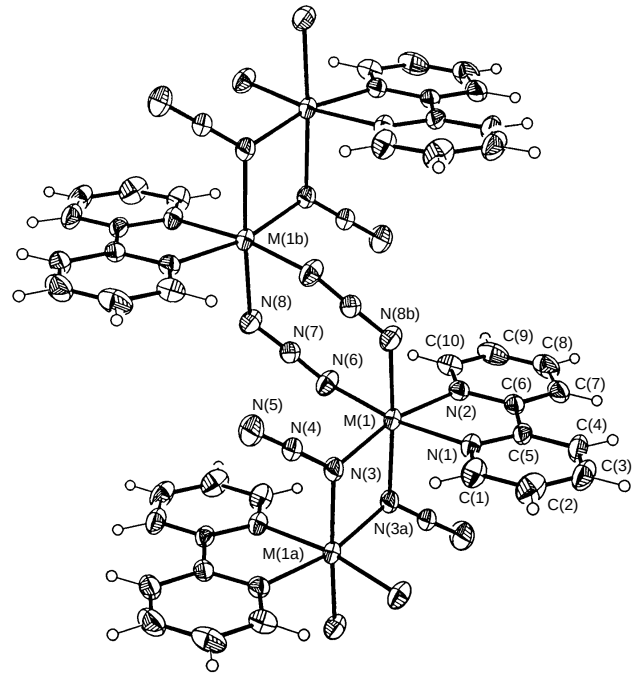

**Fig. 1** Crystal structure of $[M(bipy)(N_3)_2]_n$ (M = Ni **1**, Fe **2**, Co **3**) showing the atom numbering (ellipsoids are at the 30% probability level). The M–N bond lengths vary in the ranges 2.064(3)–2.145(4) Å for **1**, 2.118(2)–2.189(2) A for **2** and 2.132(2)–2.240(2) Å for **3**. The values of the M(1)–N(3)–M(1a) bond angles are 101.5(1) (**1**), 100.9(1) (**2**) and 100.8(1)° (**3**). The EO and EE azide groups are quasilinear [the smallest N(3)–N(4)–N(5) and N(6)–N(7)–N(8) bond angles are 178.1(3) and 176.7(2)°, respectively]. (Symmetry code for **1**: a $-x, 1-y, -z$; b $1-x, 1-y, -z$. Symmetry code for **2** and **3**: a $-x, 1-y, 1-z$; b $1-x, 1-y, 1-z$.)

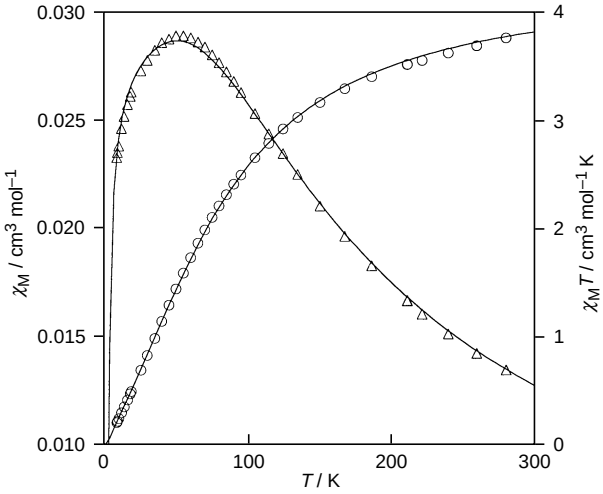

**Fig. 2** $\chi_M T$ (○) and $\chi_M$ (△) *vs. T* plots for complex **4**. The solid line corresponds to the fit to a model outlined in ref. 6.

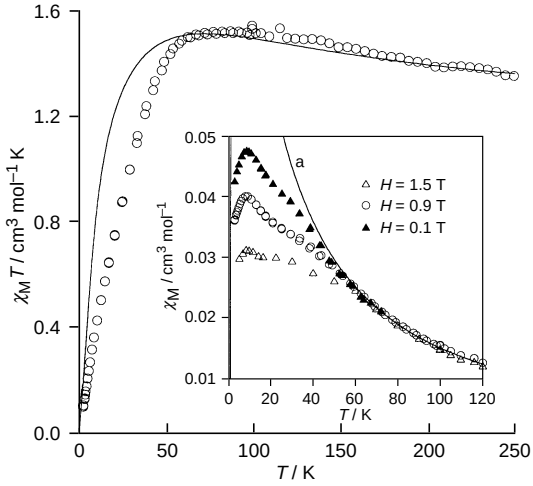

**Fig. 3** $\chi_M T$ *vs. T* plot for complex **1**. The inset shows the field dependence of the susceptibility in the low-temperature region. The solid line corresponds to the fit to a model outlined in ref. 6.

azido) = 26 $cm^{-1}$, $J_2$ (coupling through EE azido) = −2.6 $cm^{-1}$ and $g$ = 2.17. The experimental data are smaller than the calculated ones at $T$ < 55 K due to the occurrence of the mentioned shoulder precluding thus an accurate determination of the values of the exchange coupling parameters. The magnetic behaviour of **2**¶ is exotic too: $\chi_M T$ decreases when cooling down until reaching a minimum at 29 K, then increases to attain a sharp maximum at 12 K and finally decreases very quickly in the lower temperature region. As in **1**, the susceptibility curve also shows a shoulder but at higher temperatures (50–100 K), exhibiting a maximum at 8.5 K under an applied field $H$ of 0.1 T. However, this maximum disappears for $H$ > 0.5 T. Given that all the cobalt atoms in **2** are equivalent, the occurrence of a minimum in the $\chi_M T$ curve cannot be attributed to ferrimagnetism arising from a non-compensation of the local $g$-factors but to a intrachain spin canting. An interchain antiferromagnetic coupling would account for the observed maximum of susceptibility at $H$ < 0.5 T. Stronger fields overcome this antiferromagnetic coupling leading to the observed metamagnetic-like behaviour of **2**. Similar behaviour was observed for **3**. This peculiar behaviour of **1**–**3** is a fascinating feature that could be attributed to the occurrence of competing ferro- and antiferro-magnetic interactions together with a relevant local anisotropy. In the lack of a significant anisotropy, this feature is not observed (in the case of **4** and alternating $Cu^{II}$ chains).[1] Peculiar susceptibility and magnetization curves were also observed for honeycomb-layered materials with alternating intralayer ferro- and antiferro-magnetic interactions.[2] It is interesting to note that the spin vectors in the ferromagnetic chains are aligned parallel to the chain axis whereas in the case of the antiferromagnetic (or ferrimagnetic) chains they are arranged perpendicular to the chain axis in order to reconciliate both the dipolar and exchange interactions.[7] The question at hand concerning the chains exhibiting alternating ferro- and antiferro-magnetic interactions is to know the arrangement of the spin vectors for them. Our feeling is that the peculiar magnetic behaviour of **1**–**3** is related to the competition among the local anisotropy and the dipolar and exchange interactions.

This work was supported by the Spanish DGICYT (Projects PB94-1002 and PB94-0998) and the Italian Ministero dell'Università e della Ricerca Scientifica e Tecnologica.

# Oxidation using [bis(trifluoroacetoxy)]iodobenzene: a new and potentially practical approach to detection of polychlorinated phenols

**Coralie Saby and John H. T. Luong***

*Biotechnology Research Institute, National Research Council Canada, Montreal, Quebec, Canada H4P 2R2*

**A novel oxidation for pentachlorophenol, 2,4,6-trichlorophenol and 2,3,5,6-tetrachlorophenol using [bis(trifluoroacetoxy)]iodobenzene has been developed, and the oxidation products from pentachlorophenol and 2,3,5,6-tetrachlorophenol have been identified as tetrachloro-1,4-benzoquinone; this novel reaction can be applied in electrochemistry using glucose oxidase for sensitive determination and identification of PCP, one of the most toxic polychlorinated phenols.**

Considerable effort, including time-consuming immunoassay, has been directed toward the detection and quantitation of priority chlorinated pollutants such as pentachlorophenol (PCP), 2,3,5,6-tetrachlorophenol and 2,4,6-trichlorophenol.[1,2] Although electrochemical detection has frequently been used because of its simplicity and sensitivity, the oxidation products, generally believed to be quinones or radical products, are prone to polymerization, which results in electrode surface fouling.[3] Direct electrochemical oxidation of chlorophenols also requires an overpotential of +700 to +900 mV, which is sufficiently extreme so as to introduce the possibility of electroactive interference. These drawbacks can be overcome through enzymatic oxidation of chlorophenols, followed by electrochemical reduction of the chlorinated quinones. However, the two enzymes most commonly applied to this assay, tyrosinase and laccase, have been tested and found to be effective only for catechol, hydroquinone, *p*-cresol, 4-chlorophenol and 4-amino-4-chlorophenol.[4,5]

Several chlorophenols could be oxidized by ceric sulfate or chloroperoxidase. The resulting quinones were shown to efficiently recycle glucose oxidase to the oxidized form.[6] However, the PCP oxidation with ceric sulfate or hydrogen peroxide catalysed by chloroperoxidase undergoes polymerization of the oxidation product. Photochemical oxidation with hydrogen peroxide or singlet oxygen often produces a complex mixture of products including quinones, diols and triols, and polyhydroxybiphenyls.[7,8]

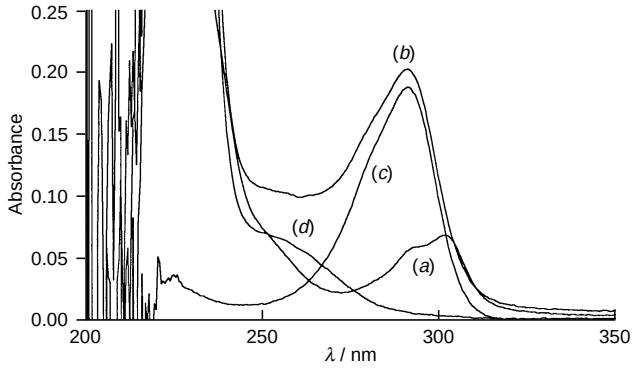

**Fig. 1** UV–Visible (Beckman DU 640 spectrometer) spectrum of (*a*) pentachlorophenol (10 μM), (*b*) the oxidation product of PCP, (*c*) the standard tetrachloro 1,4-benzoquinone (10 μM) and (*d*) [bis(trifluoroacetoxy)]iodobenzene (100 μM after hydrogen peroxide addition). Measurements were performed in 0.1 M acetic buffer, pH 3. Reaction was carried out in 0.1 M acetic buffer, pH 3 for 2 h, with 10 μM pentachlorophenol and 100 μM [bis(trifluoroacetoxy)]iodobenzene. Hydrogen peroxide (88 μM) was added to stop the reaction.

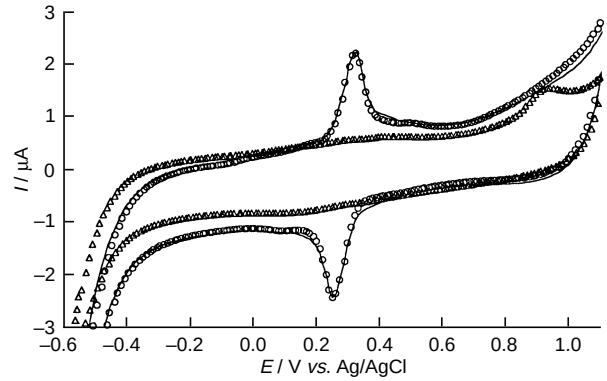

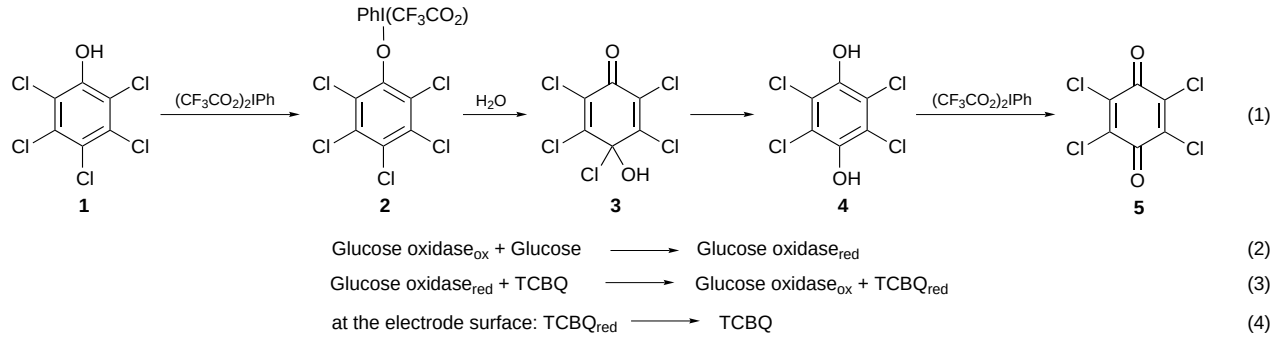

**Fig. 2** Cyclic voltammograms (0.1 M acetic acid, pH 3, 100 mV $s^{-1}$) of (Δ) pentachlorophenol (10 μM), (○) the oxidation product of PCP and (—) the standard solutions of tetrachloro-1,4-benzoquinone (10 μM). Reaction was carried out in 0.1 M acetic buffer, pH 3, for 1 h, with 10 μM pentachlorophenol and 500 μM [bis(trifluoroacetoxy)]iodobenzene. Hydrogen peroxide (440 μM) was added to stop the reaction. Equipment: CV-1B voltammograph (Bioanalytical Systems), platinum wire counter electrode, Ag/AgCl reference electrode and glassy carbon working electrode.

We report here a novel and simple reaction for the oxidation of pentachlorophenol into tetrachloro-1,4-benzoquinone (TCBQ) in aqueous media using [bis(trifluoroacetoxy)]-iodobenzene (BTIB). We also report the ability of TCBQ to oxidize reduced glucose oxidase. Although this hypervalent iodine agent.[9,10] has been used to oxidize various naphthols[11] into the corresponding quinone, no attempt has been made to oxidize chlorinated phenols with BTIB. Reaction of pentachlorophenol with BTIB was performed in 0.1 M acetate buffer, pH 3, at ambient temperature. A large excess of BTIB (molar ratio BTIB/PCP from 10 to 50) must be used to accelerate the reaction (2 h to 30 min). Neutralization of excess BTIB with hydrogen peroxide prevented further reaction of the initial products. Moreover, BTIB reaction by-products (iodobenzene and trifluoroacetate ion) are not electroactive species.

UV–VIS spectral, HPLC and cyclic voltammetric data obtained from the reacted solution demonstrated that the reaction product of pentachlorophenol with BTIB is tetrachloro-1,4-benzoquinone. Over the course of the reaction, the pentachlorophenol peaks at λ = 294 and 303 nm declined [Fig. 1, curve (*a*)] and a more intense absorption peak at 290 nm emerged and intensified [Fig. 1, curve (*b*)]. Both the absorbency profile and maximum wavelength of the PCP oxidation product were confirmed to be identical to those of standard tetrachloro-1,4-benzoquinone [Fig. 1, curve (*c*)]. The HPLC data also indicated that a significant portion of tetrachloro-1,4-benzoquinone was converted to tetrachloro-1,4-hydroquinone during the course of separation [HPLC column; 3.9 mm i.d. × 15 cm stainless steel packed with 10 μ C18 silica gel (μBondapak C18, Waters, Milford, MA), mobile phase: 25% pH 3.0, 0.1 M tartrate buffer + 25% water + 50% MeOH at a flow rate of 0.5 ml $min^{-1}$]. To facilitate the sensitive detection of tetrachloro-

1,4-benzoquinone, this oxidation product was reduced with zinc to tetrachloro-1,4-hydroquinone, which was detected by a glassy carbon electrode, +450 mV *vs.* Ag/AgCl (model LC-44 thin layer electrochemical cell connected to a model CV-1B potentiostat, Bioanalytical Systems, Lafayette, IN). The cyclic voltammogram of the product obtained from the oxidation of PCP by BTIB is identical with that of the standard tetrachloro-1,4-benzoquinone with respect to the oxidation and reduction peaks and the peak to peak separation (Fig. 2).

Another interesting result reported here is the capability of tetrachloro-1,4-benzoquinone to reoxidize glucose oxidase in the presence of excess glucose. As shown in Fig. 3(*a*), glucose oxidase immobilized on a glassy carbon electrode was readily

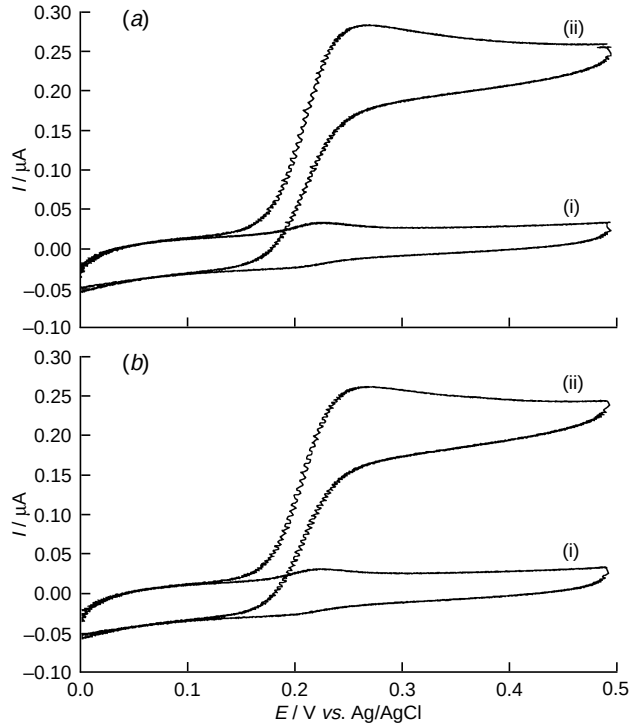

**Fig. 3** (*a*) Cyclic voltammograms of the GOD electrode in 1 μM tetrachloro-1,4-benzoquinone solution [9 ml phosphate buffer (0.3 M, pH 5) and 1 ml acetic acid (0.1 M, pH 3) containing 10 μM tetrachloro-1,4-benzoquinone, 2 mV $s^{-1}$] (i) before and (ii) after addition of 40 mM glucose. The GOD electrode was prepared as follows. After polishing of the glassy carbon electrode, 10 μl of glucose oxidase solution (glucose oxidase: 133 U, glutaraldehyde: 2.5%, 0.1 M phosphate buffer, pH 7) was placed on the surface and covered by a dialysis membrane (MWCO 14000). After drying in water saturated atmosphere for 15 min, the electrode was rinsed with 0.1 M phosphate buffer. (*b*) Cyclic voltammograms of GOD electrode in 1 μM PCP reaction solution [9 ml phosphate buffer (0.3 M, pH 5) and 1 ml 10 μM PCP reaction solution, 2 mV $s^{-1}$] (i) before and (ii) after addition of 40 mM glucose. Reaction was carried out in 0.1 M acetic buffer, pH 3, for 1 h with 10 μM pentachlorophenol and 500 μM [bis(trifluoroacetoxy)]iodobenzene. Hydrogen peroxide (440 μM) was added to stop the reaction.

reduced by its substrate, glucose. TCBQ then recycled the reduced enzyme to its original active form, *i.e.* mediating the rate-limiting electron transfer from the enzyme to the electrode. The oxidation product obtained from the PCP–BTIB reaction was also able to mediate the glucose oxidase–glucose reaction [Fig. 3(*b*)]. Based on the above findings, a mechanism for the oxidation of PCP and the mediating capability of the corresponding oxidation product can be proposed [eqns. (1)–(4)].

Oxidation of phenols often produces a mixture of isomers (1,4- and 1,2-benzoquinone). However, steric hindrance by the $(CF_3CO_2)$IPh species could be the main reason why dechlorination occurs only in position 4. In addition to PCP, BTIB also oxidized two other important chlorophenols: 2,4,6-trichlorophenol and 2,3,5,6-tetrachlorophenol. It should be noted that the 1,4-benzoquinone structure exhibited unique symmetry, and dechlorination of chlorophenols had to occur at position 4 if it was chlorinated. In view of this, both 2,3,5,6-tetrachlorophenol and PCP must yield the same oxidation product, *i.e.* tetrachloro-1,4-benzoquinone. We confirmed that the oxidation product of 2,3,5,6-tetrachlorophenol and pentachlorophenol with BTIB exhibits identical cyclic voltammetric behaviour and similar UV–visible peaks (not shown). The oxidation products of these two chlorophenols also mediated the glucose oxidase–glucose reaction, whereas BTIB and BTIB by-products did not react with reduced glucose oxidase. The detection limit of pentachlorophenol and 2,3,5,6-tetrachlorophenol was determined to be 4 nM, whereas that of 2,4,6-trichlorophenol was 8 nM; the steady state signal was attained within 2–5 min.

We have demonstrated that highly chlorinated phenols can easily be oxidized to quinones. In combination with bioelectroanalytical chemistry, this reaction offers a sensitive method for the determination of these important pollutants.

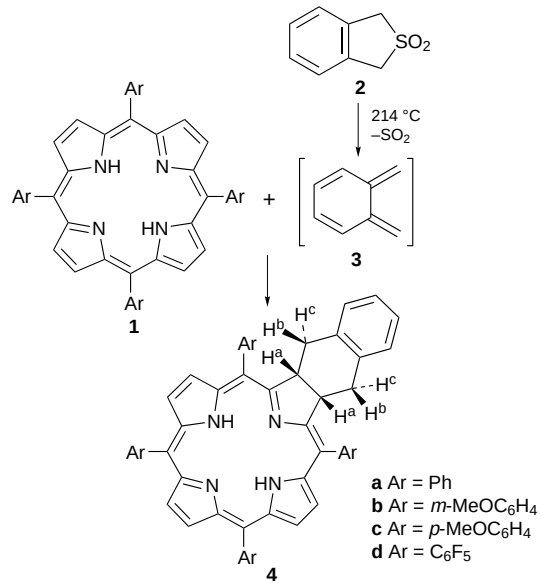
# *meso*-Arylporphyrins as dienophiles in Diels–Alder reactions: a novel approach to the synthesis of chlorins, bacteriochlorins and naphthoporphyrins

**Augusto C. Tomé, Paula S. S. Lacerda, Maria G. P. M. S. Neves and José A. S. Cavaleiro***

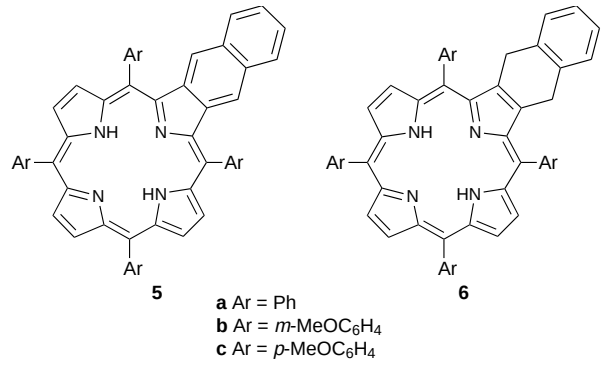


*Department of Chemistry, University of Aveiro, 3810 Aveiro, Portugal*

***meso*-Arylporphyrins participate, as dienophiles, in Diels–Alder reactions with *o*-benzoquinodimethane to yield novel chlorins, bacteriochlorins and naphtho[2,3-*b*]porphyrins.**

The use of porphyrin derivatives as photosensitizers for the photodynamic therapy (PDT) of malignant tumours received a boost with the authorisation, in several countries, of the clinical use of Photofrin, a complex mixture of porphyrins derived from haematoporphyrin.[1] In recent years, several studies related to PDT have been oriented to the search for single substances having strong absorption bands at the red end of the visible spectrum (the so-called second generation photosensitizers). This requirement is because of the greater tissue penetration of light with longer wavelengths.[2] Most of the second generation photosensitizers which have been studied are reduced porphyrins (mainly chlorins and bacteriochlorins) because of their strong absorptions near or above 700 nm.

A versatile route to the synthesis of chlorins is the Diels–Alder reaction of vinyl porphyrins with electron-deficient dienophiles.[3] Bacteriochlorins and isobacteriochlorins can also be prepared by the same type of reaction if a divinylporphyrin is used.[4] All previous studies involving Diels–Alder reactions with porphyrins have considered these macrocycles as the dienes. We now report that *meso*-arylporphyrins can also be used as dienophiles in Diels–Alder reactions.

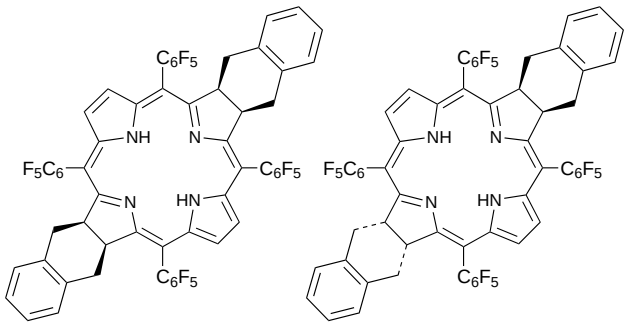


It is known that the peripheral double bonds of the porphyrin macrocycle are partially isolated from the macrocyclic conjugation pathway. The chemistry of these double bonds is, in some aspects, similar to the chemistry of normal alkenes, namely hydrogenation (to give chlorins and bacteriochlorins) and participation in pericyclic reactions (*e.g.* cheletropic reactions with carbenes[4a,5] and concerted reaction with $OsO_4$ to give β,β′-dihydroxychlorins[6]). These observations prompted us to investigate the possible participation of these peripheric double bonds in [4 + 2] cycloadditions, as the 2π electrons component, with very reactive dienes. In fact, we have found that porphyrins behave as dienophiles in the presence of *o*-benzoquinodimethane **3** (a highly reactive diene generated *in situ* by thermal extrusion of $SO_2$ from sulfone **2**) giving chlorins **4** (Scheme 1).†

**Scheme 1**

After heating a solution of *meso*-tetraphenylporphyrin (TPP **1a**, 20 mg) and sulfone **2** (55 mg, 10 equiv.) in 1,2,4-trichlorobenzene (5 ml) at reflux for 7 h under a nitrogen atmosphere, the TLC of the reaction mixture revealed unchanged starting porphyrin and three new compounds. The product with higher $R_f$ and the unchanged starting porphyrin were separated from the other two products by column chromatography (silica); in this way two fractions were obtained. The products in each fraction were then separated by preparative TLC. The main product (26% yield), the one that runs immediately below TPP, was identified as the chlorin **4a**, on basis of its mass, $^1$H and $^{13}$C NMR and visible spectra.‡ Compound **4a** displays $C_2$ symmetric $^1$H and $^{13}$C NMR spectra. The two protons H$^c$ and the two protons H$^b$ appear as doublets of doublets, respectively, at δ 2.62 (*J* 8.3 and 14.2 Hz) and 2.80 (*J* 5.8 and 14.2 Hz). The two H$^a$ protons appear as a multiplet at δ 5.32. The $^{13}$C NMR spectrum shows only 22 signals, which correspond to 'half' of the molecule. From these, two signals correspond to sp$^3$ carbons: δ 33.3 (benzylic carbons) and 48.0 (pyrroline carbons). The mass spectrum shows intense peaks at *m*/*z* 719 ([M + H]$^+$) and 718 ([M]$^+$), and one peak at *m*/*z* 614 (corresponding to TPP, formed by retro-Diels–Alder reaction). The visible spectrum of **4a** also confirms the chlorin-type structure ($\lambda_{max}$ 653 nm).

The product with higher $R_f$, the one runing slightly above TPP, was obtained in 20% yield; its mass spectrum (LSIMS) shows a base peak with *m*/*z* 715 and its visible spectrum shows a pronounced red shift of both Soret and Q bands ($\lambda_{max}$ 442, 525, 555, 606, 662 nm) relative to TPP, as expected for an extended conjugation of the porphyrin π-system. These data indicate that this compound is the naphtho[2,3-*b*]porphyrin **5a**,[7] formed by the autoxidation of chlorin **4a**. This compound was also obtained quantitatively by refluxing a $CHCl_3$ solution of chlorin **4a** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). The third product, the one with smaller $R_f$ obtained in 20% yield, shows a parent ion at *m*/*z* 717 ([M + H]$^+$) in its mass spectrum and a UV–VIS spectrum very similar to that of TPP.



These data are in agreement with structure **6a**, a likely intermediate in the oxidation of **4a** to the naphthoporphyrin **5a**.

Similar results were obtained when porphyrins **1b** and **1c** were used. In both cases, the corresponding chlorins **4**, naphthoporphyrins **5** and porphyrins **6** could be isolated and characterized.

When *meso*-tetra(pentafluorophenyl)porphyrin **1d** was used as dienophile three products were also obtained, together with some unchanged **1d** (*ca*. 35%). The one with intermediate $R_f$ (silica) was identified as the chlorin **4d** on the basis of its $^1$H NMR, mass and electronic spectra.

The two other products show similar mass and electronic spectra, suggesting that they are diastereoisomers (**7**-*cis* and **7**-*trans*).§ Both compounds show the same parent ion at *m*/*z*

**7**-*cis* **7**-*trans*

1183 (FAB$^+$) indicating the addition of two *o*-benzoquinodimethanes per molecule of porphyrin. From the electronic spectra of these 2 : 1 adducts ($\lambda_{max}$ 747 and 761 nm, Fig. 1), it is evident that they are bacteriochlorins (opposite bis-addition) and not isobacteriochlorins (adjacent bis-addition). The $^1$H NMR spectrum of the major isomer (the one with higher $R_f$) is also in agreement with structures **7**. The formation of these bacteriochlorins is in accord with other previous studies; Callot[5] observed opposite bis-addition of methoxycarbonylcarbene to TPP and Cavaleiro *et al.*[4b] have shown that in the Diels–Alder reactions of divinylporphyrins with dienophiles, the formation of bacteriochlorins is more thermodynamically favourable than the formation of isobacteriochlorins.

The addition to porphyrin **1d**, and not to the other ones, of two *o*-benzoquinodimethane species is not an unexpected result since it is known that *o*-quinodimethanes react more easily with electron-deficient dienophiles and, in this respect, porphyrin **1d** is much more 'electron-deficient' than porphyrins **1a**–**c**.

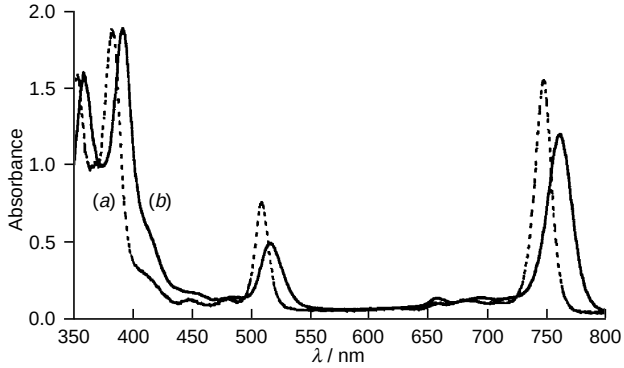


**Fig. 1** Electronic spectra of bacteriochlorins **7**: (*a*) main isomer, (*b*) minor isomer

This work was also extended to 5,15-disubstituted arylporphyrins. In this case it was found that 5,15-bis(*p*-methoxyphenyl)porphyrin also reacts with *o*-benzoquinodimethane **3** to yield the corresponding chlorin as the main product, which was characterized by $^1$H NMR, UV–VIS and mass spectral techniques.

Bacteriochlorins **7** (or other synthetic analogues), because of their strong absorption bands at 747 and 761 nm (Fig. 1) can be considered as potential new photosensitizers in PDT studies. Work is in progress in our laboratory to extend these studies to other *o*-quinodimethanes, especially certain heterocyclic ones, and to other porphyrins.

We thank JNICT, Lisbon, for funding the Research Unit No. 62/94, and the departamental MS and NMR services for spectra.

## Footnotes

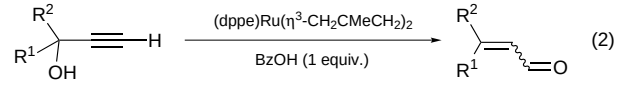
# Selective isomerisation of prop-2-yn-1-ols into α,β-unsaturated aldehydes catalysed by Ru[η³-$CH_2C(Me)CH_2]_2(Ph_2PCH_2CH_2PPh_2$)

**Michel Picquet, Christian Bruneau and Pierre H. Dixneuf***

*Laboratoire de Chimie de Coordination et Catalyse, UMR 6509: CNRS, Université de Rennes, Campus de Beaulieu, F-35042 Rennes, France*

**The complex Ru[η³-$CH_2C(Me)CH_2]_2(Ph_2PCH_2CH_2PPh_2$) is an efficient catalyst precursor for the isomerisation of prop-2-yn-1-ols into conjugated enals under mild conditions in the presence of benzoic acid *via* (*Z*)-3-hydroxyprop-1-en-1-yl benzoates.**

The isomerisation of propynylic alcohols into α,β-unsaturated aldehydes has the potential to offer access to a variety of terpenoids, *e.g.* vitamin A derivatives, as well as perfume and cosmetic components[1,2] [eqn. (1)].



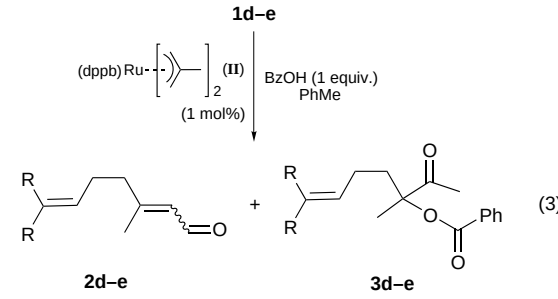
(1)

Such a transformation was first performed in the Meyer–Schuster reaction,[3] which was carried out in acidic medium and catalysed by strong acids.[4] The emergence of metal complex catalysis has allowed the use of catalytic systems based on vanadium(V) oxides[5] or the $Ti(OR)_4$–CuCl–$RCO_2H$ association,[6] operating under milder conditions but still at 125–160 °C. The system $Bu_4NReO_4$–$MeC_6H_4SO_3H$[7] gives isomerisation at room temperature with alcohol dehydration as a side reaction. A new system $MoO_2(acac)_2$–$R_2SO$–$ArCO_2H$ operates at 100 °C and appears to be efficient for the formation of prenal.[8] With these metal oxide catalysts, the suggested key steps involve the coordination of the prop-2-ynylic alcohol oxygen atom to the metal and addition of the metal oxide oxygen atom to the alkyne C(1) carbon atom to generate an allenyloxy intermediate. However, in these reactions the required presence of an acid has never been clearly taken into account in the proposed mechanisms.

We now report a new, efficient method for transformation of prop-2-yn-1-ols into α,β-unsaturated aldehydes catalysed by a (diphosphine)ruthenium(II) complex in the presence of benzoic acid, and we show that the key step involves the regioselective catalytic addition of the carboxylate to the terminal carbon atom of the C≡C triple bond, giving a (*Z*)-3-hydroxyprop-1-en-1-yl benzoate intermediate, followed by thermal elimination of the acid.

The ruthenium(II) electrophilic activation concept[9] has allowed the selective preparation of enol esters[10] and furans[11] from terminal alkynes, and β-oxopropyl esters from prop-2-yn-1-ols.[12] Modification of the catalyst precursors has recently made possible control of the regio- and stereo-selective anti-Markovnikov addition of carboxylic acids to terminal alkynes to give (*Z*)-alk-1-en-1-yl carboxylates.[13,14] An attempt to adapt the latter reaction to the addition of benzoic acid to the terminal sp carbon of prop-2-yn-1-ols in the presence of (diphosphine)-ruthenium(II) catalysts led us to discover the formal selective isomerisation of prop-2-yn-1-ylic alcohols into α,β-unsaturated aldehydes [eqn. (2)].

The reaction of the prop-2-yn-1-ol **1a** ($R^1$, $R^2$ = Me) with 1 equiv. of benzoic acid in the presence of 1 mol% of Ru[η³-$CH_2C(Me)CH_2]_2$(dppe) **I** (dppe = $Ph_2PCH_2CH_2PPh_2$) at 70 °C for 15 h led to the complete transformation of **1a**. Distillation of



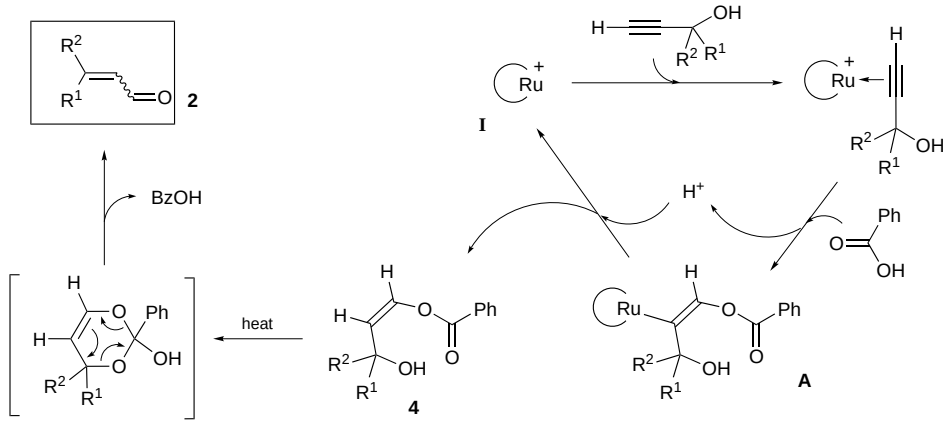
(2)

**1a–f** **2a–f**

**a** $R^1 = R^2$ = Me **d** $R^1$ = Me, $R^2 = CH_2CH_2CH{=}CH_2$
**b** $R^1$ = Me, $R^2$ = Ph **e** $R^1$ = Me, $R^2 = CH_2CH_2CH{=}CMe_2$
**c** $R^1$ = Me, $R^2 = Pr^i$ **f** $R^1 = R^2$ = Ph

the crude product led to the sole α,β-unsaturated aldehyde **2a** (prenal), isolated in 56% yield (method A). Complete transformation of the disubstituted prop-2-ynylic alcohols **1b** and **1c** in toluene under similar conditions led after distillation to the unsaturated aldehydes **2b** (68%) and **2c** (37%) (Table 1). Both isomers were formed in the respective ratios *Z*/*E* = 2 : 1 (**2b**) and 3 : 4 (**2c**). The unsaturated prop-2-yn-1-ols **1d** and **1e** were good substrates for this isomerisation as they led to the best yields in **2d** (75%) and in the terpenoid citral **2e** (73%), formed as a mixture of the *Z* and *E* isomers in the ratio 1 : 2 (Table 1).

This reaction is also catalysed by the analogous Ru[η³-$CH_2$-$C(Me)CH_2]_2$(dppb) complex **II** [dppb = $Ph_2P(CH_2)_4PPh_2$] but the competitive formation of the β-oxopropyl ester **3** was observed [eqn. (3)]. Thus, the reaction of **1e** with BzOH and 1 mol% of **II** afforded **2e** in 18% and **3e** in 50% yield, and **1d** gave 65% of **3d** only.



(3)

**2d–e** **3d–e**

**1e** R = Me → **2e** (18%) + **3e** (50%)
**1d** R = H → **2d** (traces) + **3d** (65%)

The formation of the keto esters **3** corresponds to the known catalytic addition of benzoate to the C(2) carbon of the triple bond followed by intramolecular transesterification.[12] By contrast, the mechanism of the isomerisation **1** → **2** can be proposed as depicted in Scheme 1. As the catalyst **I** is a known precursor favouring the *trans*-anti-Markovnikov addition of carboxylic acids to terminal alkynes,[13,14] the intermediate **A** corresponding to this first step is likely formed. Its protonolysis leads to the (*Z*)-3-hydroxyprop-1-en-1-yl benzoate **4** which gives the α,β-enal **2** *via* thermal elimination of benzoic acid during distillation (Scheme 1).

This process has been demonstrated in the case of **1a** with the following experiments which were monitored by $^1H$ NMR spectroscopy: (i) the reaction of **1a** with benzoic acid at 70 °C without a solvent in the presence of the catalyst **I** (1 mol%) gave the complete transformation of the propynol **1a** after 2 h into **2a**

**Scheme 1**

**Table 1** Ruthenium-catalysed isomerisation of prop-2-yn-1-ols[a]

| | | Yield (%) (*Z*/*E*) | |
|---|---|---|---|
| Prop-2-yn-1-ol | Enal | Method A | Method B |
| **1a** | **2a** | 56[b] | 68[b] |
| **1b** | **2b** | 68 (2:1) | 61 (2:1) |
| **1c** | **2c** | 37 (3:4) | — |
| **1d** | **2d** | 75 (1:2) | — |
| **1e** | **2e** | 73 (1:2) | 81 (2:3) |
| **1f** | **2f** | — | 79[c] |

[a] General conditions: prop-2-yn-1-ol (2.5 mmol), benzoic acid (2.5 mmol), catalyst **I** (1 mol%), toluene (2 ml). Method A: 70 °C, 15 h, distillation under reduced pressure. Method B; 70 °C, 2 h, then 100 °C for 3 h (**2a**), 15 h (**2e**), 22 h (**2b**) and 32 h (**2f**), distillation under reduced pressure. [b] Without solvent. [c] Chromatography over silica gel.

and **4a** (*Z*/*E* = 86 : 14) formed in 7 and 93% yields, respectively, as determined by $^1$H NMR of the crude mixture before distillation; (ii) heating at 100 °C for 3 h of the latter crude mixture containing **2a** and **4a** led to 96% of prenal **2a** (measured by $^1$H NMR spectroscopy) and isolated in 68% yield. These experiments show that the role of the catalyst is to generate the 3-hydroxyalk-1-en-1-yl benzoate **4a**, and that heating of the latter at 100 °C or during distillation in the presence or absence of the ruthenium derivative is the key step for the transformation of **4a** into the unsaturated aldehyde **2a**.

This sequential heating of the reaction mixture in the presence of catalyst **I**, first at 70 °C (catalytic anti-Markovnikov addition) and then at 100 °C (thermal benzoic acid elimination) appears to be the best method to selectively produce α,β-enals (method B). Thus, **1b**, **1e** and **1f** were converted into 3-hydroxyprop-1-en-1-yl benzoates **2** after treatment with benzoic acid in the presence of a catalytic amount of **I** at 70 °C for 2 h, and further heating in the same pot at 100 °C for 22, 15 and 32 h led to the complete transformation of (*Z*)-**4** and the isolation of the α,β-unsaturated aldehydes **2b**, **2e** and **2f** in 61, 81 and 79% respective yields (Table 1). The $^1$H NMR spectroscopic monitoring revealed that only the (*Z*)-esters **4** were converted into α,β-enals **2** on heating, whereas the (*E*)-isomers remained almost unchanged except in the case of **4a**. For example, from **1b**, after 2 h at 70 °C, the catalytic reaction afforded 100% of **4b** (*Z*/*E* = 70 : 30) which led after 22 h at 100 °C to 74% of **2b** (*Z*/*E* = 66 : 34) and 26% of (*E*)-**4b**.

The selective synthesis of α,β-unsaturated aldehydes requires the initial regioselective anti-Markovnikov addition of the benzoate to the triple bond, which raises the question of whether such a key step might also be involved in the previous isomerisations of propynylic alcohols promoted by metal oxides.

# Environmentally friendly catalysis using supported reagents: the fast and selective bromination of aromatic substrates using supported zinc bromide[1]

**James H. Clark,*[a] Joanne C. Ross,[a] Duncan J. Macquarrie,[a] Simon J. Barlow[b] and Tony W. Bastock[b]**

[a] *Department of Chemistry, University of York, Heslington, York, UK YO1 5DD*

**Zinc bromide supported on mesoporous silica or acid-activated montmorillonite is a fast, efficient, selective and reusable catalyst for the *para*-bromination of activated and moderately deactivated aromatic substrates.**

Bromoaromatics are widely used as intermediates in the manufacture of pharmaceuticals, agrochemicals and other speciality chemical products. Traditional methods of aromatic bromination involve the use of non-selective hazardous acidic reagents such as mineral acids and metal halides, which can lead to separation difficulties and unacceptable levels of toxic and corrosive waste. The replacement of such reagents by non-toxic and more selective solid catalysts is very desirable and represents an important goal in the context of Clean Synthesis.[2,3] While some progress has been made in this area, notably through the use of microporous zeolites, improvements in reaction selectivity are at the expense of poor reaction rates or the need for large quantities of catalyst.[4,5] We have discovered that good regioselectivity and excellent reaction rates in the bromination of activated and moderately deactivated aromatics can be achieved through the use of supported zinc bromide catalysts.[6]

Bromination of bromobenzene using elemental bromine in $CCl_4$ in the dark proceeds slowly in the absence of an added catalyst. At 25 °C only 10% conversion of substrate is achieved after 24 h with a selectivity (*p*/*o* isomer ratio) of 4.1. Rates improve at higher temperatures but at the expense of selectivity and complete conversion of substrate within 24 h is only achieved at 76 °C when the formation of tribromobenzene further complicates the reaction. In the presence of 0.067 equiv. of zinc bromide supported on the acid-activated montmorillonite K10 (1.0 mmol $g^{-1}$; catalyst prepared from methanol in the same way as 'clayzic'[7] and dried at 200 °C before use), complete substrate conversion is achieved at 25 °C within 8 h and with a much improved selectivity of 9.6. At higher temperatures, the reaction rate increases but the selectivity falls (Table 1). We then screened a range of commonly used support materials as supports for zinc bromide (Table 1). Of these, mesoporous silica gel gives the best selectivity, along with a good rate of reaction. It is interesting to note that the same type of support proved to be the most effective in developing the Friedel–Crafts catalyst clayzic.[7]

While $CCl_4$ has commonly been used as a solvent in many halogenation reactions, environmental legislation will preclude its use in the future. We next tested likely non-polar and low-polarity alternative solvents (Table 1) and have found that of the non-halogenated solvents, hexane gives a good reaction rate and a reasonable selectivity.

As part of the catalyst optimisation studies we have examined the effect of loading of zinc bromide (Fig. 1). Loading clearly has a major effect on catalyst activity. The optimum loading for the K10 analogue is significantly lower than that for the higher surface area[7] silica gel. Catalyst activity on reuse is also an important variable and we have found that the silica-based catalyst only suffers a relatively gradual decrease in activity and selectivity on use (with an apparent increase in selectivity after the first use). It is important that the catalyst is kept solvent damp in between reactions to avoid deactivation of the catalytic sites (by decantation of the reaction liquors followed by recharging with fresh substrate solution). Total turnover efficiencies (total mole substrate converted per mole equivalent

**Table 1** Comparison of catalytic systems for the bromination of bromobenzene[a]

[a] Reactions carried out using 1.75 mmol $g^{-1}$ $ZnBr_2$ supported on silica (100 Å).

zinc bromide) of $> 40$ over 5 runs can be achieved for 1 h room temperature reactions giving selectivities of $> 8$.

The supported zinc bromide catalysts can be effectively used in the room temperature bromination of other aromatic substrates (Table 2). The bromination of toluene is very slow in the absence of an added catalyst and gives a *p*/*o* ratio (selectivity) of 2.0. On addition of the catalyst [1.75 mmol $g^{-1}$ on silica (100 Å)] there is complete conversion of the substrate within 2 min and an increase in the selectivity to 2.7. The bromination of ethylbenzene is extremely slow in the absence of a catalyst but once the silica–$ZnBr_2$ is added the reaction is complete within 5 min with a selectivity of 2.4. Bromination of *tert*-butylbenzene in the presence of the catalyst is complete within 2 min and has 100% selectivity to the *para*-isomer. For all reactions using alkylbenzene substrates we did not observe any α-brominated products. Chlorobenzene, which is mildly deactivated towards electrophiles, is unaffected by bromine at room temperature but reacts in the presence of the catalyst to give 92.9% conversion to monobrominated products within 80 min with a remarkable selectivity value of 10.

# Catalytic and asymmetric cyclopropanation of styrenes catalysed by ruthenium porphyrin and porphycene complexes

**Wai-Cheung Lo,[a] Chi-Ming Che,*[a] Kin-Fai Cheng*[a] and Thomas C. W. Mak[b]**

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*
[b] *Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong*

**Ruthenium porphyrin and porphycene complexes catalyse stereospecific cyclopropanation of styrenes; high product turnovers with up to 90.8% ee were achieved with the [Ru(P*)(CO)(EtOH)] catalyst ($H_2$P* = chiral $D_4$ porphyrin).**

Metalloporphyrins are well known to be effective catalysts for alkane hydroxylation,[1] olefin epoxidation[2] and cyclopropanation.[3–5] When compared to metallosalens, porphyrin catalysts usually have a greater catalytic stability resulting in higher product turnover numbers.[6] However, their practical applications would require high regio-, stereo- and enantio-selectivities to be achieved. To our knowledge, the best reported chiral metalloporphyrins are the manganese threitol-strapped porphyrins[7] and the iron 'twin-coronet' porphyrins[8] which gave 88 and 89% ee in the epoxidation of 1,2-dihyronaphthalene and 2-nitrostyrene by iodosobenzene, respectively. Herein is described that ruthenium porphyrin and porphycene complexes are effective catalysts for stereospecific cyclopropanation of styrenes. With the $D_4$ porphyrin ($H_2$P*) reported by Halterman and Jan,[9] it is possible to achieve high product turnovers and with up to 90.8% ee which is comparable to the best ee reported with the non-porphyrin chiral metal catalysts.[10–14]

The [Ru(P)(CO)(EtOH)] catalysts (Fig. 1) used in this work were prepared by literature methods.[15,16] Refluxing [$Ru_3(CO)_{12}$] with $H_2$P* in decalin for 8 h gave [Ru(P*)(CO)] in a 90% yield, which was recrystallised from a $CH_2Cl_2$–EtOH mixture to give [Ru(P*)(CO)(EtOH)]. Its structure determined by a X-ray crystal analysis features one of the few structures of chiral ruthenium porphyrins.[17] As shown in Fig. 2, the porphyrin ligand has a pseudo $D_4$ symmetry. The ruthenium atom coordinates with one CO and one EtOH in the axial direction and is in the centre of the mean plane defined by the four nitrogen atoms of the porphyrin ligand. There are two $CH_2Cl_2$ and one EtOH solvent molecules in the unit cell with 0.5 site occupancy. Hydrogen bonding interactions exists between the coordinated EtOH and the EtOH solvent molecules with O–O distance of 2.8 Å in the unit cell. The measured C(85)–O(1) and Ru–O(Et) distances of 1.188(2) and 2.241(2) Å, respectively are comparable to the corresponding values of 1.16(3) and 2.21(2) Å found in [Ru(TPP)(CO)(EtOH)].[18]

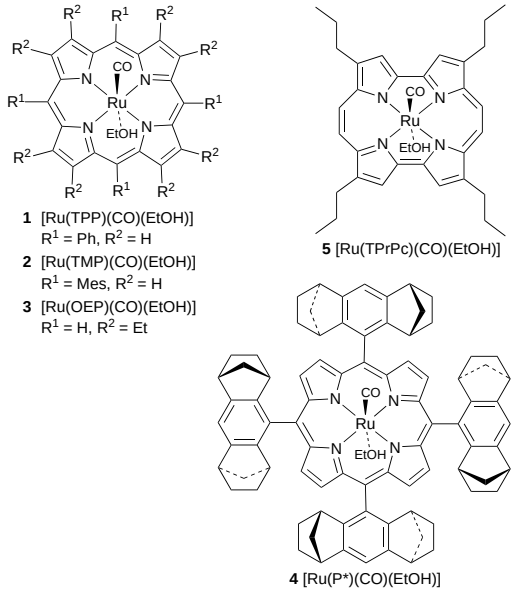

**Fig. 1** Ruthenium porphyrinoid complexes used in the catalytic cyclopropanation of alkenes

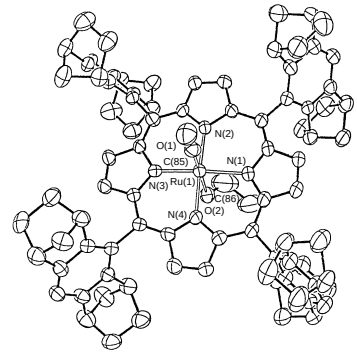
The [Ru(P)(CO)(EtOH)] complexes are excellent catalysts for the cyclopropanation of some styrenes by ethyl diazoester (EDA) with very good diastereoselectivities. The results are listed in Table 1. At a catalyst : EDA : alkene ratio of 1 : 300 : 600, the product yields based on EDA are moderate to good for **1** and **2** but the reactions become less effective for the less bulky catalysts **3** and **5**. A notable point is the high *trans* product selectivity. For example, the *trans* : *cis* ratio of 9.2 obtained from the reaction between styrene and EDA catalysed by **1** is comparable to the value of 9.5 obtained from the same reaction catalysed by [Os(TPP)(CO)(py)][3] but is considerably higher than that of 1.1 by Rh(TPP)I.[4]

In order to optimize the product yield, the reaction between 1,1-diphenylethylene and EDA catalysed by **1** was investigated. The product yield was found to increase with increasing ratio of alkene : EDA. The effectiveness of the catalyst in cyclopropanation is clearly demonstrated by the very high turnover number of 1855 and yield of 92.3% achieved at a catalyst : EDA : diphenylethylene ratio of 1 : 2000 : 20 000.

The ruthenium porphyrins catalysed the cyclopropanation of alk-1-enes and 1,1-disubstituted olefins very efficiently, but alkenes with other substitution patterns were poor substrates. *cis*- or *trans*-β-Methylstyrene could not be cyclopropanated. This shape selectivity is reminiscent of that observed for Os(TTP)-catalysed cyclopropanation[3] but constrasts with the much broader substrate compatibility of rhodium porphyrin-catalysed reactions.[5] In the latter case, only tetrasubstituted alkenes are sluggish substrates.



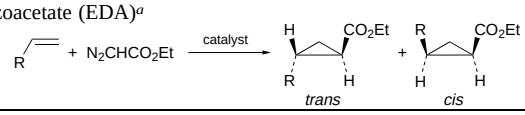


**Fig. 2** Perspective view of [Ru(P*)(CO)(EtOH)]. Selected bond lengths (Å) and angles (°): Ru(1)–N(1) 2.082(2), Ru(1)–N(2) 2.068(2), Ru(1)–N(3) 2.043(2), Ru(1)–N(4) 2.057(2), Ru(1)–C(85) 1.776(2), Ru(1)–O(2), 2.241(1), O(2)–C(86) 1.437(2), C(85)–O(1) 1.188 Å; N(1)–Ru(1)–N(2) 89.6(1), N(1)–Ru(1)–N(3) 173.7(1), N(2)–Ru(1)–N(3) 90.6(1), N(1)–Ru(1)–N(4) 88.9(1), N(2)–Ru(1)–N(4) 174.4(1), N(3)–Ru(1)–N(4) 90.3(1), Ru(1)–C(85)–O(1) 178.4(2)°.

The catalytic enantioselective cyclopropanation of alkenes was investigated using the ruthenium complex of a $D_4$-symmetric porphyrin (Fig. 1). The results are shown in Table 2. The absolute configuration of the product from the reaction between styrene and EDA was determined by comparison with literature data.[10]

With styrene as substrate and at room temperature, a product *trans* : *cis* ratio of 18 : 1 was obtained and the ee of the *trans* product was 87% with absolute configuration of (1*S*,2*S*). A high catalyst turnover number of 1665 was achieved. At 0 °C, the *trans*–*cis* selectivity improved to 24 : 1 and ee of the *trans* product increased to 91%. Similar results with very high *trans*–*cis* selectivities and high enantioselectivities for the *trans* product have also been found with other substituted styrenes. Thus, the bulky aryl groups appended on the porphyrin ring of the catalyst **4** can produce a good steric and chiral environment around the reaction site. The reactive intermediate of the cyclopropanation has also been studied. The reaction of **4** with EDA in benzene at room temperature immediately gave a species showing $\lambda_{max}$ at 407 and 534 nm observed by UV–VIS spectroscopy. This species was unstable and was observed to decay gradually. When monitored with $^1$H NMR, singlets at δ 13.79 and 8.99 were observed. This intermediate species can be tentatively assigned as the carbene complex [Ru(P*)(CH-$CO_2$Et)], with the NMR peaks at δ 13.79 and 8.99 being assigned to the carbene and the pyrrolic protons, respectively. These values are similar to the respective NMR peaks at δ 13.79 and 8.55 of [Ru(TMP)($CHCO_2$Et)].[19] The present work highlights that chiral ruthenium carbene complexes of porphyrins could be generated and spectroscopically characterised.

We acknowledge support from the University of Hong Kong and the Hong Kong Research Grants Council.

† *Crystal data* for [Ru($C_{84}H_{76}N_4$)CO·EtOH]·$CH_2Cl_2$·0.5(EtOH): $C_{89}H_{87}Cl_2N_4O_{2.5}Ru$, $M$ = 1428.6, monoclinic, space group $P2_1$, $a$ = 9.849(1), $b$ = 28.164(2), $c$ = 14.399(1) Å, β = 102.83(1)°, $U$ = 3894(2) Å$^3$, $Z$ = 2, $D_c$ = 1.214 g cm$^{-3}$, λ (Mo-Kα) = 0.71073 Å, $F$(000) = 1492, μ = 3.20 cm$^{-1}$, crystal dimensions 0.40 × 0.40 × 0.40 mm. Intensity data (3.0 < 2θ < 55.0°) were collected on a Rigaku RAXIS IIc imaging-plate system using Mo-Kα radiation (λ = 0.71073 Å) from a RU-200 rotating-anode X-ray generator at room temperature. The data were corrected for absorption and Lorentz polarisation effects. The structure was solved by direct methods and refined by full-matrix least-squares using Siemens SHELXTL PLUS (PC Version). The H-atoms were generated geometrically. 13493 Independent reflections were obtained. 12118 Reflections with $|F_0| > 6.0\sigma(|F_0|)$ were considered observed and used in the structural analysis. The last least-squares cycle was calculated with 933 parameters giving $R$ = 0.071, $R_w$ = 0.089 and goodness of fit = 2.24. The weighing scheme used was $w^{-1} = \sigma^2(F) + 0.0006F^2$. The final Fourier-difference map showed residual extrema in the range of +1.37 to −0.86 e Å$^{-3}$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/396.

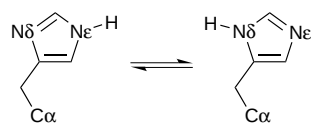
# Coexistence of both histidine tautomers in the solid state and stabilisation of the unfavourable Nδ–H form by intramolecular hydrogen bonding: crystalline L-His-Gly hemihydrate



**Thomas Steiner* and Gertraud Koellner**

*Institut für Kristallographie, Freie Universität Berlin, Takustrasse 6, D-14195 Berlin, Germany*

**The crystal structure of L-His-Gly hemihydrate contains two independent peptide molecules which exhibit different histidine tautomers; the less favourable N(δ)–H form is stabilized by an intramolecular Nδ(*n*)–H···O(*n* + 1) hydrogen bond facilitated by a suitable molecular conformation.**

It is well known that the imidazole moiety of the amino acid histidine (His), if unchanged, may exist in two tautomers (Scheme 1). At pH 7, the Nε–H form is dominant. The microscopic p*K* values are 6.7 for the Nδ–H tautomer, and 6.1 for the Nε–H tautomer (determined by titration experiments on a series of suitable derivates).[1] In consequence, histidine peptide crystals grown from water are normally found with the Nε–H form of His, and if grown at low p*H*, His is positively charged with Nδ and Nε both carrying hydrogen atoms.[2,3] The present communication reports for the first time on the stable coexistence of both tautomers in one peptide crystal structure.

From solution in pure water, the dipeptide L-histidyl-glycine crystallizes as a hemihydrate (L-His-Gly·0.5$H_2O$, **1**), with two peptide molecules and one water molecule per asymmetric crystal unit† (crystal structures of the chloride and dichloride salts have been published previously[4]). Very surprisingly, the two symmetry-independent molecules are found in completely different conformations, and with different tautomers of the histidine imidazole ring (Fig. 1, selection of torsion angles given in the figure legend). The tautomeric identity has been unambiguously determined by location of the hydrogen atoms in difference Fourier calculations and subsequent isotropic refinement, but could in principle also be deduced from the crystal contacts of the non-hydrogen atoms.‡ A section of the crystal packing is shown in Fig. 2, with some geometrical hydrogen bond data given in the figure legend. Molecule **A** adopts a standard elongated conformation and the imidazole moiety is in the expected Nε-H form, very similar to the closely related molecule L-His-L-Ala crystallized from water as a dihydrate.[5] Molecule **B**, on the contrary, is found in a folded conformation as the Nδ–H histidine tautomer [Fig. 1(*b*)]. This is associated with a short and linear intramolecular side-chain to main-chain hydrogen bond Nδ(1)–H··O(2) [for N–H normalized to 1.04 Å: N··O = 2.742(5) Å, H··O = 1.71 Å, N–H··O = 170°]. This situation is exceptional not only from the chemical, but also from the crystallographic point of view: typically in crystal structures with more than one moleule per asymmetric crystal unit, the symmetry-independent molecules may have different conformations, but have the same chemical identities. It is obvious that crystal growth of **1** requires unusually complex mechanisms of molecular recognition at the crystal–solvent interface to incorporate molecules of both identities at the right places. Once incorporated in the crystal, the individual molecules are trapped in their tautomeric form.

**Scheme 1**

Previous surveys have reported that in crystal structures with uncharged His side-chains, *only* the more stable Nε–H tautomer is found[2,3] (conflicting with the present results). Since several relevant crystal structures have been published after the surveys, a new search through the Cambridge Structural Database[6] (CSD) was performed (spring 1996 version, $R$ < 0.08, all hydrogen atoms given, no metal atoms present). Of 39 His residues in 36 crystal structures, 20 are charged. Of the remaining 19 His residues, 18 are found in the Nε–H, and one in the Nδ–H form. The latter occurs in unsolvated L-His-L-Leu, **2**.[7] No previous example of the solid-state coexistence of *both* tautomers is found.

Notably, the backbone and histidine conformation of **2** is almost identical to that of molecule **1B**, and the intramolecular Nδ(1)–H··O(2) hydrogen bond is formed with very similar geometry (N··O = 2.71 Å, H··O = 1.70 Å, N–H··O = 163° for normalized hydrogen position). Since the intermolecular surroundings are very different for **1B** and **2**, it is assumed that

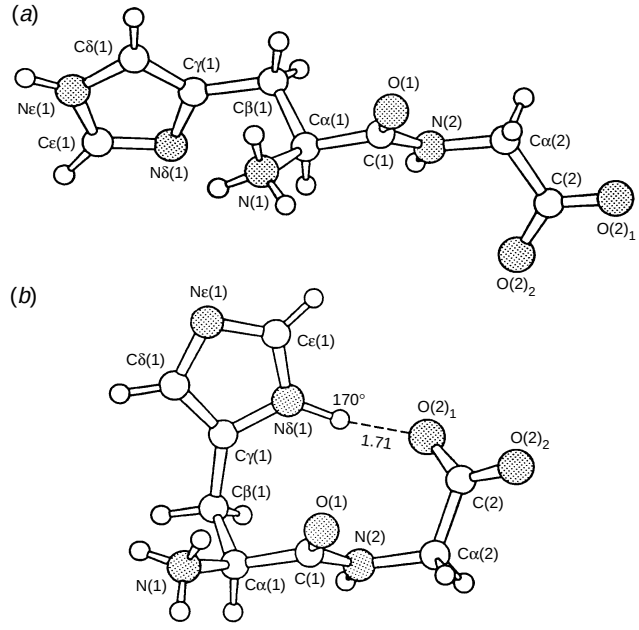


**Fig. 1** Molecular structure and atomic numbering scheme for both peptide molecules in L-His-Gly hemihydrate. (*a*) molecule **A**, (*b*) molecule **B**. The molecules are drawn in the same projection with respect to the peptide bonds. Oxygen and nitrogen atoms are drawn shaded. Selection of torsion angles defining the molecular conformation: Molecule **A**: $\psi_1$ = 147.0(4)°; $\omega_1$ = −178.1(4)°; $\varphi_2$ = 130.4(5)°; N(2)–Cα(2)–C(2)–$O(2)_1$ = −179.8(5)° (corresponds to $\psi_2$); N(2)–Cα(2)–C(2)–$O(2)_2$ = −1.1(7)°; $\chi_1^1$ = −52.4(5)°; $\chi_1^2$ = −58.2(6)°. Molecule **B**: $\psi_1$ = 166.2(4)°; $\omega_1$ = 179.1(4)°; $\varphi_2$ = −78.4(6)°; N(2)–Cα(2)–C(2)–$O(2)_1$ = −27.1(7)°; N(2)–Cα(2)–C(2)–$O(2)_2$ = 154.5(4)° (corresponds to $\psi_2$); $\chi_1^1$ = 69.5(6)°; $\chi_1^2$ = 78.4(6)°.

the occurrence of the less favourable tautomer is not induced by the crystal surrounding, but is closely associated with the conformation, in particular with the formation of a short intramolecular Nδ($n$)–H··O($n$ + 1) hydrogen bond. This interaction appears to stabilize the Nδ–H tautomer to a sufficient degree to allow crystallisation in this form. In a polypeptide chain, this kind of hydrogen bond represents an interaction of His Nδ–H with the carbonyl oxygen atom of the next residue, *i.e.* Nδ($n$)–H···O($n$ + 1). The peptide conformation is required to be close to that of **1B** ($\psi_n$ = 166°, $\varphi_{n+1}$ = −78°, $\psi_{n+1}$ = 155°, $\chi_n^1$ = 69°, $\chi_n^2$ = 78°). This is not an uncommon conformation, and several examples are quoted in ref. 7; a closer examination of these examples, however, shows that all except **1B** and **2** are formed by peptides with charged His residues, where Nδ is protonated irrespective of the conformation.

It is tempting to speculate on the relevance of such observations for proteins. Side-chain to main-chain His Nδ($n$)··O($n$ + 1) hydrogen bonds do occur in some proteins[8] (normally, however, the charge situation is not unambiguously determined), and might there stabilize the less favourable tautomeric form. More generally, it can be assumed that the Nδ–H form can be effectively stabilized also by other hydrogen bond configurations;§ this assumption is not yet backed up by peptide structure analysis.

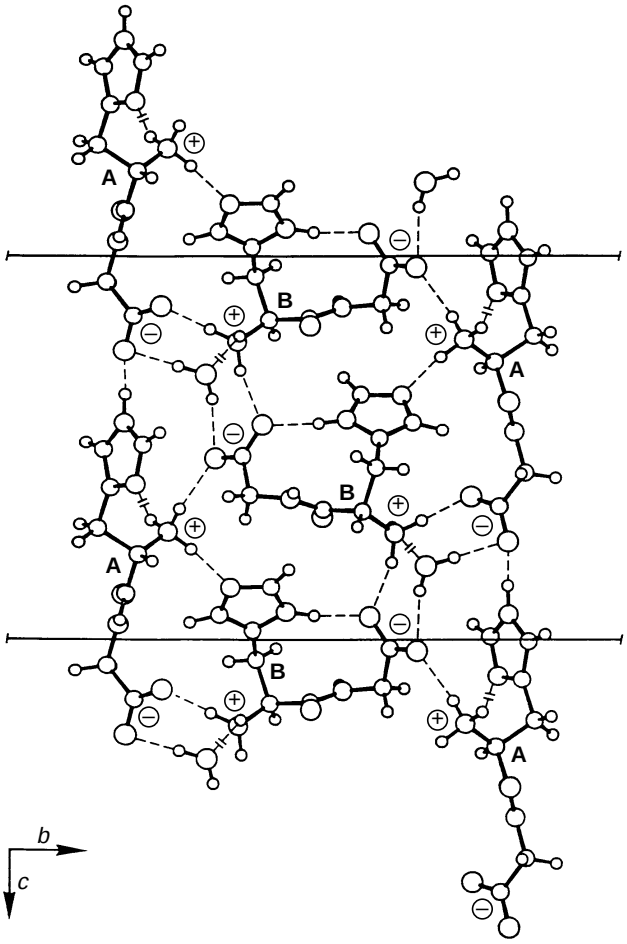

**Fig. 2** Section of the crystal packing, O/N–H··O/N hydrogen bonds are shown as dashed lines. Molecules **A** and **B** are labelled near the Cα(1) atoms. The charge situation is indicated by symbols ⊕ and ⊖. The imidazole rings are involved in the following N–H··O/N hydrogen bond interactions (for normalized hydrogen atom positions with N–H = 1.04 Å): Molecule **A**: Nδ(1) (**A**)··H$_2$–N(1) (**A**) ($x$ − 1, $y$, $z$), H··N = 1.81 Å, N··N = 2.815(6) Å, N–H··N = 160°. Nε(1) (**A**)–H··O(2)$_1$ (**A**) ($x$, $y$, $z$ − 1), H··O = 1.73 Å, N··O = 2.715(6) Å, N–H··O = 156°. Molecule **B**: Nδ(1) (**B**)–H··O(2)$_1$ (**B**) ($x$, $y$, $z$), H··O = 1.71 Å, N··O = 2.742(5) Å, N–H··O = 170°. Nε(1) (**B**)··H$_3$–N(1) (**A**) ($x$, $y$, 1 + $z$), H··N = 1.82 Å, N··N = 2.859(6) Å, N–H··N = 177°.

† A commercial sample of L-His-Gly (Sigma) was dissolved in water; slow evaporation yielded very thin, needle shaped colourless crystals.

*Crystal data*: L-histidyl-glycine hemihydrate, $C_8H_{12}N_4O_3 \cdot 0.5H_2O$; FW = 221.2, space group orthorhombic $P2_12_12_1$, $a$ = 4.9547(6), $b$ = 32.356(6), $c$ = 12.587(4) Å, $V$ = 2017.9(8) Å$^3$, $Z$ = 8, $Z'$ = 2, $D_c$ = 1.46 g cm$^{-3}$. Enraf-Nonius Turbo-CAD diffractometer, room temperature, Ni-filtered Cu-Kα X-rays, ω-scan mode, $\lambda/2 \sin\theta_{max}$ = 0.89 Å, 0.65 × 0.04 × 0.02 mm$^3$ crystal glued to a glass pin, 3436 reflections measured, 2999 unique, 1889 with $I > 2\sigma(I)$, no absorption correction. Structure solution and refinement with standard methods (SHELXS86[10] and SHELXL93[11]). All hydrogen atom positions were located from difference Fourier calculations; to obtain the geometrically most realistic model, the hydrogen atoms were then treated in the riding model,[11] with exception of the hisidine (N)H atoms which were refined unconstrained isotropic, the water H-atoms, which were refined with O–H bond lengths constrained to 0.90(2) Å, and the ammonium groups which were allowed to rotate. Final $R$ = 0.059 (for observed reflections), $\omega R(F^2)$ = 0.148 (for all reflections). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/467.

‡ The tautomeric forms of molecules **A** and **B** can be deduced merely from the configuration of non-hydrogen atoms: Nε(1) (**B**) is in hydrogen bond contact with an ammonium group and can therefore only be non-protonated, and Nδ(1) (**B**) forms a hydrogen bond with a carboxylate group and must therefore carry a hydrogen atom (Fig. 2). For the 'conventional' molecule **A**, the situation is reversed: Nε(1) (**A**) is in hydrogen bond contact with a carboxylate group, and Nδ(1) (**A**) with an ammonium group, inferring the Nε–H tautomer for His(**A**).

§ In the well-defined example of a glutamic acid specific serine protease (Glu-SGP), such a case seems actually to occur: a charge-relay system involving a remarkable triad of presumably uncharged histidine residues was proposed (ref. 9). Based on the configuration of the non-hydrogen atoms, it can be inferred that in this triad, initially two residues are in the Nε–H and one in the Nδ–H form. Upon action of the charge-relay mechanism, the situation is switched to two Nδ–H and one Nε–H tautomer.

# Palladium-catalysed sequential carboxylation–alkoxycarbonylation of acetylenic amines

**Alessia Bacchi,[a] Gian Paolo Chiusoli,[b] Mirco Costa,*[b] Bartolo Gabriele,[c] Carlo Righi[b] and Giuseppe Salerno[c]**

[a] *Dipartimento di Chimica Generale, Analitica e Chimica Fisica, Università, Viale delle Scienze, 43100 Parma, Italy*

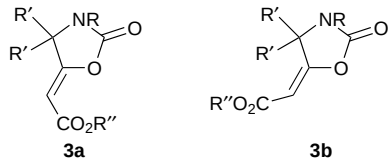
**Carbon dioxide and carbon monoxide react in sequence in an intramolecular carboxy–carbonylation reaction of *N*-alkyl-substituted dialkylpropynylamines, under the catalytic action of palladium iodide–potassium iodide in methanol in the presence of oxygen.**



In the course of our investigation of the palladium-catalysed synthesis of β- and γ-lactams by oxidative carbonylation of acetylenic amines[1] [eqn. (1), R = alkyl, R′,R″ = alkyl], we

(1)

noticed the presence of small amounts of compounds containing an additional oxygen atom, the formation of which was promoted by a little water in the reaction mixture.

These compounds turned out to be (*Z*)- and (*E*)-[(alkoxycarbonyl)methylene]oxazolidin-2-ones **3a** and **3b**† in 2 : 1–3 : 1 ratio. The X-ray structure of one of them (**3a**, R = Bn; R′,R″ = methyl)‡ is shown in Fig. 1. In the crystal of **3a**, the methoxycarbonyl moiety and the five-membered ring are coplanar within 0.2 Å and oxygens O(2) and O(3) are in close contact [O(2)··O(3) 2.835(2) Å] due to the *Z* configuration of the C(2)–C(4) double bond [torsion angle C(3)–C(2)–C(4)–C(5) −175.9(2)°].

The formation of compounds **3** could be attributed to the sequential reaction of one molecule of carbon dioxide and one of carbon monoxide with the triple bond, according to eqn. (2).

(2)

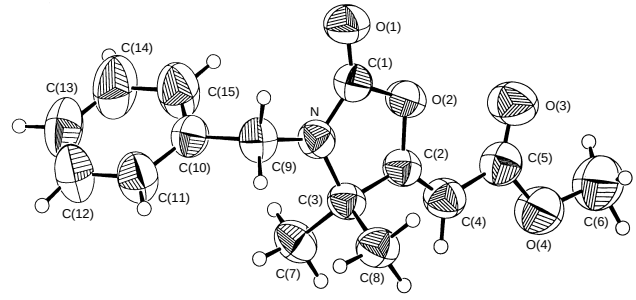
In fact carbon dioxide could originate through decarboxylation of a hydroxycarbonylpalladium species[2] formed in the presence of water [eqn. (3)].

(3)

To test our hypothesis we treated a mixture of carbon dioxide (40 bar), carbon monoxide (5 bar) and air (5 bar) with *N*-(dimethylpropynyl)benzylamine in methanol (20 ml, 0.15 M), with a 100 : 1 molar ratio of amine to catalyst ($PdI_2$ or Pd–C 10% + 10 mol KI per mol of Pd). After stirring at 52 °C for 45 h products **3a** and **3b** (R = Bn; R′,R″ = Me) were obtained in an 88% yield (2 : 1 ratio) by GLC. With R = Bu the yield was 69% (3.2 : 1 ratio). Unconverted substrate (2% for R = Bn, R′ = Me; 4% for R = Bu, R′ = Me), oxazolidinone **4** (3% for R = Bn, R′ = Me; 2% for R = Bu, R′ = Me), β-lactam **1** (only traces for R = Bn; R′,R″ = Me; 4% for R = Bu; R′, R″ = Me) and compounds derived from a trimethoxycarbonylation at the nitrogen and triple bond carbons of starting propynylamines (5% for R = Bn; R′, R″ = Me; 9% for R = Bu; R′,R″ = Me) were present as by-products. A higher pressure of carbon monoxide or higher temperature led to a decrease in the yield of **3**. Under the same conditions as above the use of CO in the absence of $CO_2$ gave a less than 2% yield of **3** (R = Bu; R′,R″ = Me), which increased to 17% (**3a** : **3b** = 3) in the presence of 15% water in the reaction mixture.

The course of the reaction leading to **3a** and **3b** can be interpreted according to Scheme 1, which implies the intermediate formation of a palladium carbamate (anionic iodide ligands are omitted for simplicity).

Products **3a** and **3b** are proposed to originate from different reaction pathways, the former from *cis* attack of palladium carbamate on the triple bond, the latter from *trans* attack of the carbamate anion on the triple bond coordinated to palladium.[3] It was ascertained that isomerization of **3a** into **3b** or *vice versa* did not occur under the reaction conditions. An isomerization of the vinylpalladium precursors of **3** shown in Scheme 1 cannot be excluded but it is not likely in view of the fact that a larger availability of potassium carbamate for *trans* attack on the triple bond obtained by increasing the KI excess led to a decrease of the **3a** : **3b** ratio (for example, from 3.2 to 1.7 for R = Bu; R′,R″ = Me on passing from 10 to 100 KI : Pd molar ratio under the conditions reported in the example above).



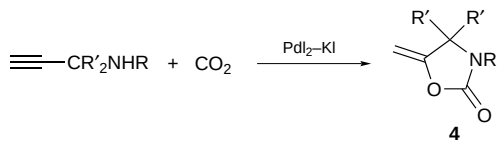


**Fig. 1** ORTEP diagram of **3a** with 50% probability thermal ellipsoids. Relevant distances (Å) and angles (°) are: N–C(1) 1.327(3), C(1)–O(2) 1.399(2), C(2)–O(2) 1.369(2), C(2)–C(3) 1.509(2), N–C(3) 1.467(2), C(2)–C(4) 1.325(3), O(2)–C(1)–N 108.7(2), O(2)–C(2)–C(3) 109.4(1), C(2)–C(3)–N 99.4(1), O(2)–C(2)–C(4) 122.9(2), C(3)–C(2)–C(4) 127.6(2). In the five-membered ring, endocyclic angles centred on the atoms N, C(1), O(2) and C(2) range from 108.7 to 112.7°, while the angle N–C(3)–C(2) is noticeably reduced [99.4(1)°].

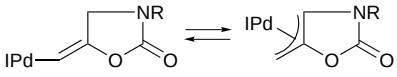
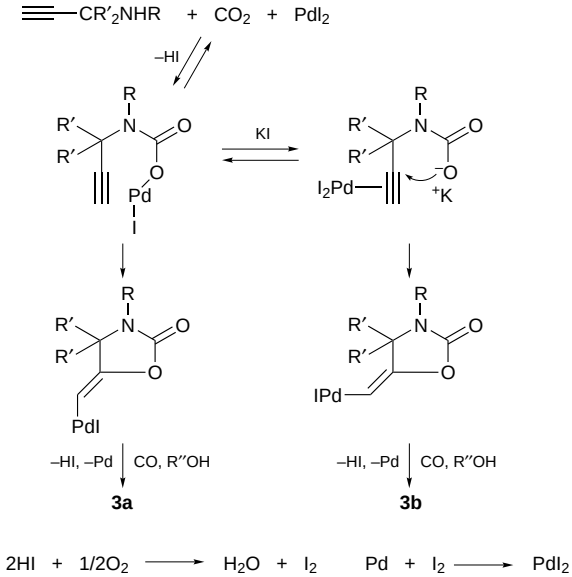


We also caused carbon dioxide (40 bar) to react with the same acetylenic amine (3.0 mmol) in MeOH (20 ml) in the presence of $PdI_2$ (100 : 1 molar ratio to the substrate) and KI (15 : 1 molar ratio to Pd) in the absence of carbon monoxide and oxygen at 75 °C for 24 h. The result was the formation of compound **4** (R = Bu, R′ = Me; 27% yield, 64% unconverted propynylamine) [eqn. (4)], which originates from protonation of the (*Z*)- or (*E*)-vinylpalladium precursor of **3**.

(4)

Although this reaction is catalytic, more satisfactory results were reached under the reported conditions in the presence of air (10 bar), a 58% yield of **4** (R = Bu, R′ = Me) being obtained at 65% conversion.

It is worth noting that in the absence of alkyl groups α to the triple bonds (R′ = H) the introduction of carbon dioxide only and not that of carbon monoxide was observed under the conditions of eqn. (2), compound **4** (61% yield; R = Bn, R′ = H) being formed exclusively. This is likely to be due to stabilization through formation of an allylpalladium complex[4] which, being poorly reactive towards carbon monoxide,[5] undergoes selectively hydrogenolysis [eqn. (5)] (the isomer with an endocyclic double bond was not detected).



**4** (R = Bn, R′ = H) (5)

Compound **4** was previously obtained also by direct incorporation of $CO_2$ under the catalytic action of superbases in aprotic solvents.[6]

The carboxylation–alkoxycarbonylation reported here is the first catalytic reaction in which cabon dioxide and carbon monoxide are caused to react in sequence. A stoichiometric sequence in two steps was described by Carmona[7] in the formation of an anhydride from a metallacyclic complex, CO and $CO_2$.

Financial support by Ministero Pubblica Istruzione (40%) and CNR, Progetto Strategico Tecnologie Chimiche Innovative, is acknowledged. The facilities of Centro Interfacoltà di Misure of the University of Parma have been utilized for NMR determinations.

# Synthesis and X-ray structures of *N*-lithioiminophosphorane·lithium bromide adducts

**Andrei S. Batsanov, Matthew G. Davidson,* Judith A. K. Howard, Sarah Lamb, Christian Lustig and Richard D. Price**

*Department of Chemistry, Science Laboratories, South Road, Durham, UK DH1 3LE*

**Iminophosphorane anions are shown to be novel and very powerful Lewis-base donors to s-block metals by the isolation and structural characterisation of *N*-lithioiminophosphorane·lithium bromide adducts.**

We have recently been interested in the coordination of neutral phosphonium ylides **1a** to lithium compounds.[1] The isoelectronic and isonuclear iminophosphoranes **1b** possess many of the characteristics of phosphorus ylides, with the P–N bond being substantially dipolar in nature[2] which renders them theoretically capable of forming very strong complexes with

$R_3P{=}X \longleftrightarrow R_3P^{+}{-}X^{-}$ (**1**)

**1a** X = $CR'_2$
**b** X = NR′
**c** X = O

lithium compounds. Indeed, iminophosphorane–lithium complexes are calculated to be stronger even than complexes between lithium and phosphine oxides **1c**,[1] the third member of this isoelectronic and isonuclear series, and a class of compound commonly used as strong Lewis-base donors to s-block metals.[3] Furthermore, the facile deprotonation (metallation) of ylides or iminophosphoranes[4] (**1a**, **b**, R′ = H) yields species in which the negative charge on the ylidic carbon or iminic nitrogen atom is enhanced, potentially providing Lewis bases of exceptional strength. With the aim of exploring this avenue to provide unusual and potentially useful ligands for s-block metals we now report the syntheses and structural characterisation of *N*-lithoiminophosphorane compounds as their lithium halide complexes. Our results suggest that $R_3P{=}N^-$ ligands offer potential to be developed as new and powerful Lewis-basic ligands in s-block metal coordination chemistry.

Until now, the isolation and unambiguous characterisation of a *N*-(s-block-metallated) iminophosphorane has not, to our knowledge, been reported. Even the structural characterisation of a simple iminophosphorane moiety acting as a neutral donor to an s-block metal is limited to one recent example of intramolecular coordination.[5] This is surprising since *N*-lithioiminophosphoranes are well known as reagents in both organic and inorganic synthesis, for example, as synthons for $RN^{2-}$[6] and as precursors for a wide variety of *N*-substituted iminophosphoranes containing either inorganic, organometallic or organic residues.[7]

*N*-Lithioiminophosphoranes $[(Ph_3PNLi{\cdot}LiBr)_2{\cdot}4thf]{\cdot}1.5$arene (arene = benzene **3a**, toluene **3b**) were prepared by the reaction of 2 equiv. of BuLi with $Ph_3PNH_2Br$ **2** in arene–thf† and characterised by X-ray crystallography.‡

In the solid state (Fig. 1) **3a** and **3b** are isomorphous and the following discussion will be confined to **3a**, which provided the higher quality X-ray data set. The structure consists of a pseudocubane $Li_4N_2Br_2$ core in which each lithium atom is four-coordinate *via* association to three $\mu_3$-bridging anionic centres and one terminal thf molecule. Similar core structures have been found before for C–Li[8] and O–Li[9] species but complexes **3** are unique as mixed-anion tetramers incorporating organic N–Li fragments. The ability of the *N*-lithioiminophosphorane to solvate LiBr and prevent association of the lithium halide into an infinite $(LiX)_\infty$ lattice§ emphasises the powerful Lewis basicity of the iminophosphorane anion that had been anticipated. One face of the cube ($Li_2Br_2$) is distorted by a fold along the Li(1)···Li(2) axis (angle of fold 30°). This distortion is largely a steric effect due to anion–anion repulsions and has also been seen in other structures containing a $Li_4R_2X_2$ core (X = halogen).[8a,9] Comparison of inter- and intra-ring distances within the core of **3** (average inter- and intra-ring Li–Br distances, 2.738 and 2.603 Å, respectively; average inter- and intra-ring Li–N distances, 1.971 and 2.005 Å, respectively) suggests that the interactions of all four lithium atoms with iminic nitrogen atoms are favoured over those with the bromide anions. While the observed preference for Li–N over Li–Br coordination emphasises the high Lewis basicity of the iminophosphorane anion, such analysis provides no clue as to whether the core is derived from aggregation of two $Li_2Br_2$ rings or from dimerisation of two LiN·LiBr units.

The structural parameters obtained for the complexes **3** provide a useful guide to the geometry of the unknown isolated $Ph_3P{=}N^-$ anion since the interaction with $Li^+$ is substantially electrostatic in nature (which contrasts with the largely covalent interactions found for transition metal complexes). For example, the P–N bond in **3** (average P–N distance, 1.541 Å) is significantly shorter than in the dication of the structure of $\{Ph_3P{=}N[Au(PPh_3)]_3\}^{2+}2BF_4^-$ [P–N distance, 1.62(1) Å] in

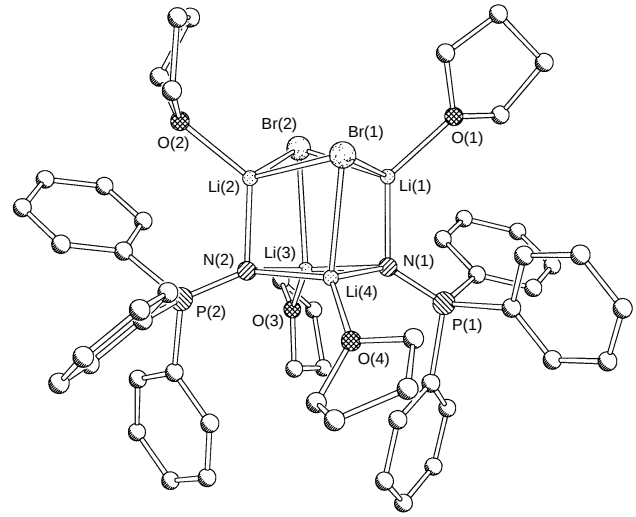

**Fig. 1** Molecular structure of **3a** and **3b** (for clarity, all H atoms and lattice solvent are omitted and only one conformation of disordered thf is shown). Selected bond distances in **3a** [**3b**] (Å): Br(1)–Li(1) 2.605(6) [2.60(1)], Br(1)–Li(2) 2.602(6) [2.60(1)], Br(1)–Li(4) 2.692(6) [2.70(1)], Br(2)–Li(1) 2.596(6) [2.59(1)], Br(2)–Li(2) 2.607(6) [2.60(1)], Br(2)Li(3) 2.784(6) [2.74(1)], N(1)–Li(1) 1.962(6) [1.97(1)], N(1)–Li(3) 1.999(6) [2.01(1)], N(1)–Li(4) 2.019(6) [2.03(1)], N(2)–Li(2) 1.979(7) [2.00(1)], N(2)–Li(3) 1.992(6) [2.02(1)], N(2)–Li(4) 2.010(6) [2.00(1)], O(1)–Li(1) 1.960(6) [1.96(1)], O(2)–Li(2) 1.953(7) [1.97(1)], O(3)–Li(3) 1.963(6) [1.95(1)], O(4)–Li(4) 1.993(6) [1.99(1)], N(1)–P(1) 1.541(3) [1.542(6)], N(2)–P(2) 1.541(3) [1.538(6)].

which the $Ph_3P{=}N^-$ unit also $\mu_3$-bridges three metal atoms.[10] Indeed, the P–N bond in **3** is shorter than in all known transition-metal compounds (distances in the range 1.59–1.66 Å).[10,11] It is also slightly shorter than in the parent iminophosphorane, $Ph_3P{=}NH$,¶ which is consistent with an increased electrostatic attraction between $P^{\delta+}$ and a more negative $N^{\delta-}$ after lithiation. As expected, the P–N bond in **3** is longer than the P–O distance in the isoelectronic but neutral $Ph_3P{=}O$ [P–O distance, 1.46(1),[12a] 1.484(1)[12b] Å].

The solution behaviour of **3** is complicated. Again, the discussion here is confined to **3a**, though the general behaviour is common to both complexes. The cryoscopically determined relative molecular mass (RMM) is concentration dependent, as are the relative intensities of resonances in the $^{31}P$ and $^{7}Li$ NMR spectra (all in benzene solution), indicating that equilibria operate in solution between two or more species. Even at room temperature, four distinct $^{31}P$ and three distinct $^{7}Li$ resonances are observed and one can easily imagine a number of thf-coordinated $(LiN{=}PPh_3)_n$, $(LiBr)_n$ and $[Li_2(Br)(N{=}PPh_3)]_n$ monomers and oligomers that may coexist in solution. Though it is difficult to assign these resonances unambiguously, it is clear from our results that, even in predominantly arene solution, dilithiation of $Ph_3P{=}NH_2Br$ does not give a solution of LiBr-free $(Ph_3P{=}NLi)_n{\cdot}xL$ as has been suggested previously in the protocol for the preparation of primary and secondary amines developed by Cristau *et al.*[6] but instead gives a well defined, stoichiometric 1:1 LiBr complex of the *N*-lithioiminophosphorane. Indeed, *N*-lithioiminophosphoranes prepared directly from *N*-unsubstituted iminophosphoranes to give only $R_3P{=}NLi$,[4] followed by reaction with R′X or $MX_n$ (X = halogen) would result in the formation of a mixed organolithium–lithium halide aggregate in solution in any case. These observations are relevant to the use of *N*-lithioiminophosphoranes in synthesis since the nature of the reactive species present in solution is well known to have an effect on the reactivity and/or selectivity of a reagent in solution.[13]

Preliminary results show that LiCl analogues of **3** are accessible, and that **3** may be used in transmetallation reactions. We are currently investigating further the use of highly polar ylidic and iminic ligands as novel complexants in s-block metal chemistry particularly with a view to achieving solvation of LiF in hydrocarbon solvents.

We thank the EPSRC (PDRA Fellowship and Quota Studentship for A. S. B. and R. D. P., respectively) and Durham University (Postgraduate Scholarship for S. L.).

† *Syntheses*: All manipulations were carried out under a dry $N_2$ atmosphere using Schlenk techniques and an inert atmosphere glove box. Solvents were freshly distilled prior to use. Compound **2** was prepared by slight modification of the method reported by Cristau *et al.*[6] *Typical synthetic procedure for* **3**: to a suspension of **2** (2.5 mmol, 0.90 g) in benzene (15 ml), *n*-butyllithium (5 mmol, 3.2 ml of a 1.6 M solution in hexane) was added at 25 °C. The suspension was stirred for 15 min, during which the solution turned yellow and a white precipitate persisted. Addition of 1.5 ml thf followed by warming to *ca*. 70 °C resulted in complete dissolution of the solid into a yellow solution. Upon storage of this solution for 24 h at 25 °C, colourless blocks of **3a** were obtained.

**3a**: yield 72%, mp 166 °C. $^1H$ NMR (200 MHz, $C_6D_6$): δ 8.0 (m, 6 H, *o*-Ph), 6.9–7.7 (m, 9 H, *m*,*p*-Ph, plus residual $C_6H_6$), 3.6 (qnt, 8 H, α-thf), 1.3 (qnt, 8 H, β-thf). $^{31}P$ NMR (101.2 MHz, $C_6D_6$): (0.01 M), δ 2.0 (s, 1), −1.2 (s, 3.4), −3.9 (s, 1.9), −5.5 (s, 0.4); (0.05 M), δ 1.8 (s, 1), −1.3 (s, 3.5), −4.5 (s, 4.7), −5.5 (s, 0.3); (0.09 M), δ 1.8 (s, 1), −1.3 (s, 4.5), −4.5 (s, 7.8), −5.5 (s, 1.5). $^7Li$ NMR (194.4 MHz, $C_6D_6$): δ 3.13 (s), 1.8–2.1 (m), 1.5–1.8 (m); cryoscopy (benzene, $K_b$ = 5.12 K kg $mol^{-1}$): (0.003 M), $\Delta T$ = 0.042 K, RMM 394 ± 42 [degree of association (relative to $Ph_3P{=}NLi{\cdot}LiBr{\cdot}2thf$), $n$ = 0.75]; (0.008 M), $\Delta T$ = 0.103 K, RMM = 494 ± 20 ($n$ = 0.95); (0.014 M), $\Delta T$ = 0.151 K, RMM = 549 ± 15 ($n$ = 1.05). **3b**: yield 45%, mp 166 °C. $^1H$ NMR (200 MHz, $C_6D_6$): δ 7.95 (m, 6 H, *o*-Ph), 6.9–7.7 (m, 9 H, *m*, *p*-Ph), 3.55 (qnt, 8 H, α-thf), 1.25 (qnt, 8 H, β-thf).

‡ *X-Ray structure determinations*: Yellow crystals of $C_{52}H_{62}Br_2Li_4N_2O_4P_2{\cdot}1.5$arene (arene = $C_6H_6$ **3a**, $C_6H_5Me$ **3b**), are isomorphous, triclinic, space group $P\bar{1}$ (no. 2), $M$ = 1145.7 [1166.8], $a$ = 10.682(1) [10.575(1)], $b$ = 13.758(1) [13.882(1)], $c$ = 22.280(1) [22.398(1)] Å, α = 102.91(1) [100.61(1)], β = 90.85(1) [91.33(1)], γ = 109.74(1) [109.81(1)°], $U$ = 2989.4(4) [3027.5(4) Å$^3$], $Z$ = 2, $D_c$ = 1.27 [1.28] g $cm^{-3}$, μ = 14.6[14.4] $cm^{-1}$, crystal size 0.48 × 0.44 × 0.36 [0.5 × 0.32 × 0.2 mm]. Data collection at $T$ = 150 K, Siemens CCD area detector, graphite-monochromated Mo-Kα radiation, $\bar{\lambda}$ = 0.71073 Å, ω scan mode, $2\theta \leqslant 56°$; Lorentz, polarization and semi-empirical absorption correction[14a] (on Laue equivalents) were applied; min., max. transmission 0.525, 0.638 [0.618, 0.899]; 18255 [14163] total data, 10556 [9818] unique, 8902 [7726] observed [$I \geqslant 2\sigma(I)$]; $R_{int}$ = 0.045 [0.071] before and 0.034 [0.042] after absorption correction. The structures were solved by direct methods and refined by full-matrix least squares against $F^2$, using SHELXTL (Version 5/VMS) software.[14b] Non-H atoms were refined anisotropically (disordered ones isotropically) with all H atoms, 'riding', the disordered solvent in **3b** as rigid bodies; 673 [663] variables *vs*. 10463 [9428] data, $R_w$ ($F^2$, all data) = 0.127 [0.271], $R$($F$, obs. data) = 0.045 [0.079], max. residual Δρ = 0.85 [0.94] e Å$^{-3}$. One solvent molecule is in a general position, another at an inversion centre, in **3b** both are disordered. Two thf rings in **3a** and three in **3b** are also disordered. Atomic coordinates, bond lengths and angles, and thermal parameters for **3a** and **3b** have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/474.

§ Conceptually similar to the so-called ammonium salt route method of preparing Lewis base-complexed inorganic lithium salts.[15]

¶ We have determined the structure of $Ph_3PNH$ by X-ray (at 153 K) and neutron (at 20 K) diffraction and find the P–N distance to be 1.562(3) and 1.582(2) Å, respectively.[16] Another report of the X-ray structure of $Ph_3PNH$ (at 203 K) gives the P–N distance as 1.524(3) Å.[11b]

**The structure of a self-assembled two-dimensional square network complex, $[Cu_2(C_3H_2O_4)_2(H_2O)_2(4,4'\text{-bpy})]\cdot H_2O$, comprising both flexible and rigid ligands and having a large inner cavity of 15.776(3) × 15.786(2) Å, is reported.**

Since the first self-assembly of square supramolecules was reported in 1990,[1a] novel, tetranuclear, cationic macrocycles, with bond angles of *ca*. 90°, have emerged as the newest members of the family of supramolecular assemblies.[1–3] Much less is known about extended two-dimensional systems[4] based on molecular squares, on account of the lack of methods for linking monomer or molecular units. In all these cases, only rigid ligands such as 4,4′-bipyridine are chosen as the bridging ligands, although Fujita *et al.*[1d] and Slone *et al.*[3c] tried to utilize more flexible ligands to link the transition metals, they could not isolate molecular squares but only macrocyclic dinuclear complexes. Flexible organic macrocycles such as crown ethers, cyclophanes, cyclodextrins, calixarenes, clathrates are ubiquitous,[5] and this prompted us to investigate whether it is possible to combine flexible ligands with rigid ligands within a single crystal. Here we report the first X-ray crystal structure of a flexible self-assembled two-dimensional square network $[Cu_2(C_3H_2O_4)_2(H_2O)_2(4,4'\text{-bpy})]\cdot H_2O$ **1** comprising both flexible and rigid bridging ligands and having an inner cavity of 15.776(3) × 15.786(2) Å surrounded by 4,4′-bpy and malonate groups. We thus have introduced a new concept of flexible self-assembly of supramolecules.

When $Cu(C_3H_2O_4)\cdot 2H_2O$† was treated with 4.4′-bipyridine in $H_2O$–EtOH at ambient temperature [eqn. (1)], deep-blue crystals grew within several days.‡ Yields in excess of 90% were obtained and the structure of **1** was solved by single-crystal X-ray diffraction.§

$$2nCu^{2+} + 2nC_3H_2O_4^{2-} + n4,4'\text{-bpy} + 2nH_2O \xrightarrow{H_2O\text{–EtOH}} \mathbf{1} \quad (1)$$

The crystal structure of **1** is shown in Fig. 1 and can be characterized by the following features. (*i*) It consists of two-dimensional networks which are stacked parallel but in a staggered manner on each other along the *z*-axis, with an interplanar separation of 3.785 Å and angle of 45.0°. The packing of the two-dimensional polymers reveals that the small malonate rings in one layer fit exactly into the large 4,4′-bpy rings in the next, it is almost as if the two rings are acting as templates for each other. This feature is very exciting, and this complementarity of the two rings probably explains the unusually high yield of the complex (Fig. 2). (*ii*) Each network involves a small planar square with $Cu^{II}$ ions and malonate ions at each corner and side, respectively; each $Cu^{II}$ is also bridged by one 4,4′-bpy, thus forming a large square with each edge shared by one malonate group and one 4,4′-bpy ligand. The coordination geometry about each $Cu^{II}$ is a slightly distorted square pyramid (the geometric τ value is 0.15[6]). (*iii*) All the planar squares are distorted only to a small extent. The square-planar angles are 89.89(1) and 89.99(1)° in the large square and 89.25(3) and 89.35(3)° in the small one, very close to the ideal square-planar angle of 90°. The inner cavities have dimensions of 15.776(3) × 15.786(2) Å and 4.644(2) × 4.649(2) Å, respectively and no solvent molecules are clathrated in the cavities. Uncoordinated water molecules are distributed statistically. (*iv*) A malonate ion adopts a bridging position which enhances the stability of the two-dimensional network, the third coordinates to the neighbouring Cu atom. (*v*) All coordinated water molecules are nearly perpendicular to the CuNOOO base plane and two adjacent water molecules are arranged in *trans*-coordination, with two water molecules of two opposite corners being on the same side relative to the $Cu_4$ plane.

It is particularly interesting that four $Cu^{II}$ ions and four flexible malonate groups form a small planar square and four six-membered chelate rings *via* self-assembly. We define this phenomenon as flexible self-assembly of supramolecules. Recently, Tosik *et al.*[7] pointed out the conformational flexibility of chelated malonate rings through analyses of the large difference of the typical puckering of the five known $Cu^{II}$-chelated malonate rings. The conclusion can be further confirmed by the variation of bond lengths and angles belonging to the six-membered chelate ring relative to known

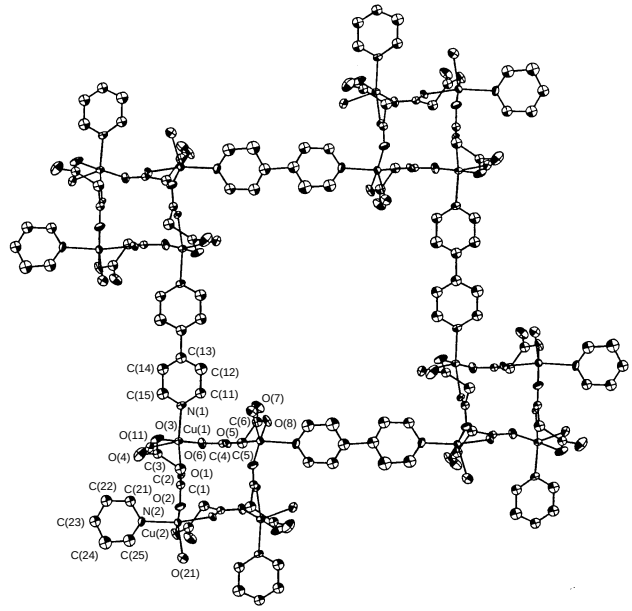

**Fig. 1** ORTEP diagram of **1** with labelling scheme. **Fig. 2** Packing diagram for **1** along the *z*-axis

compounds. Including our compound, reported Cu–O, C–O and C–C distances[7–9] are in the ranges 1.909–1.996, 1.22–1.272, and 1.48–1.530 Å, respectively, and the O–M–O angles[7–10] range from 85.0 to 94.82° in the metal-chelated malonate rings.

In summary, a novel, self-assembled two-dimensional square network complex, $[Cu_2(C_3H_2O_4)_2(H_2O)_2(4,4'\text{-bpy})]\cdot H_2O$, constitutes the first example that comprises both flexible and rigid ligands within one single crystal structure.

† *Preparation of* $Cu(C_3H_2O_4)\cdot 2H_2O$: to a mixture of copper(II) carbonate (2.0 mmol) and hot water (20 ml), malonic acid (1.9 mmol) was added and a dark blue solution was obtained. This was filtered and condensed to 5 ml and a large amount of crystals were obtained. Anal. calc. for $Cu(C_3H_2O_4)\cdot 2H_2O$: C, 17.70; H, 3.47. Found: C, 17.14; H, 3.59%.

‡ *Preparation of* **1**: to an aqueous solution (30 ml) of $Cu(C_3H_2O_4)\cdot 2H_2O$ (1.0 mmol) an ethanol solution (10 ml) of 4,4′-bpy (0.5 mmol) was added. The initially formed very small amount of fine precipitate was filtered off, and the clear filtrate was allowed to stand for several days at ambient temperature to give deep-blue crystals. Yields in excess of 90% were obtained. Anal. calc. for **1**: C, 36.43; H, 3.44, N, 5.31. Found: C, 36.50; H, 3.21; N, 5.09%.

§ *Crystal data* for **1**: $M$ = 2190.68, orthorhombic, space group $P2_12_12_1$ (no. 18), $a$ = 16.348(3), $b$ = 16.364(5), $c$ = 7.570(1) Å, $V$ = 2025.2(8) Å$^3$, $F(000)$ = 1104, $Z$ = 4, $D_c$ = 1.78 g cm$^{-3}$, $T$ = 296 K, μ(Mo-Kα) = 21.7 cm$^{-1}$, λ(Mo-Kα) = 0.710 69 Å. A crystal of approximate dimensions 0.40 × 0.40 × 0.25 mm was mounted on a Rigaku AFC5R diffractometer, using graphite-monochromated Mo-Kα radiation. Cell constants and orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 20 reflections in the range $8 < \theta < 27.5°$, measured by the computer controlled diagonal slit method of centring. Scattering factors were taken from Cromer and Waber.[11] The ω–2θ scan mode with a maximum 2θ value being 50.0° were used to collect intensity data. A total of 2075 reflections were collected, of which 2075 were unique, and 1579 had $I > 3\sigma(I)$ with 199 parameters. The data were corrected for Lorentz-polarization effects, and empirical absorption (from 0.70 to 1.00 in $I$). The structure was solved by direct methods and refined by full-matrix least-squares calculation. Cu atoms were located in the $E$ map, the remaining atoms were located in succeeding difference Fourier syntheses. H atoms of the disordered water were not included, H atoms of the coordinated water were added by difference Fourier synthesis and the other H atoms were placed at calculated positions. All H atoms were unrefined. All calculations were performed on a COMPAQ computer using Mo1EN/PC.[12] Final $R$ = 0.055, $R_w$ = 0.079 (unit weights), goodness of fit = 1.69, max. shift/e.s.d. = 0.02. The minimum and maximum peaks in the final difference Fourier map are at −0.33 and 0.87 e Å$^{-3}$, respectively. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/464.

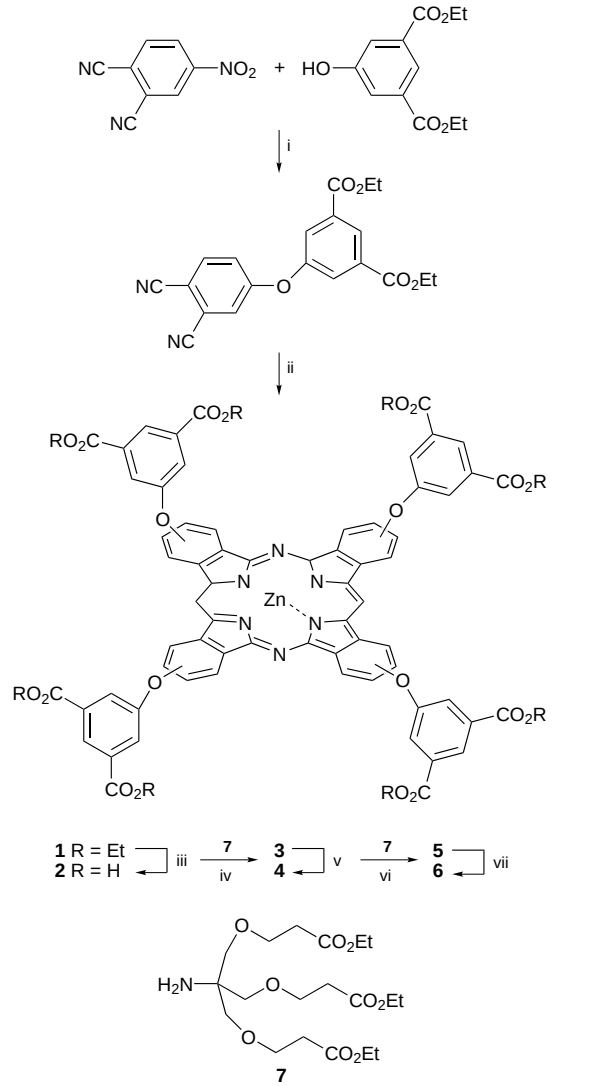
# Dendritic metallophthalocyanines: synthesis and characterization of a zinc(II) phthalocyanine[8]$^3$-arborol

**Mutsumi Kimura,*[a] Kazuaki Nakada,[a] Yuji Yamaguchi,[a] Kenji Hanabusa[a] Hirofusa Shirai[a] and Nagao Kobayashi[b]**

[a] *Department of Functional Polymer Science, Faculty of Textile Science and Technology, Shinshu University, Ueda 386, Japan*
[b] *Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-77, Japan*



**New dendritic metallophthalocyanines are prepared on the basis of Newkome's divergent-growth approach; the number of generations within the dendrimer is found to affect the aggregation behaviour of the zinc(II) phthalocyanine moiety which forms the interior core of the dendrimers.**

The synthesis of dendrimers has recently attracted much interest. Dendrimers have a well defined globular structure with uniform molecular mass.[1] Functional dendrimers have been prepared by the introduction of functional compounds such as metal complexes, fullerenes and biomaterials to the exterior surface and the interior cores of dendrimers.[2] Highly branched dendrimers have provided a unique environment for these functional compounds, giving rise to a variety of new and modified properties.[3] Constructing a dendrimer around a phthalocyanine core could control the aggregation of the complex in aqueous media and modify its photoreactivity. Here, we report the synthesis of the first dendritic zinc(II) phthalocyanines **3**–**6** using cascade polymer methodology. The environment of photoactive zinc phthalocyanine can be controlled through encapsulation in dendrimers.

**3**; R = –OEt
**4**; R = –OLi
**5**; R = –NHC($CH_2OCH_2CH_2CO_2Et$)$_3$
**6**; R = –NHC($CH_2OCH_2CH_2CO_2Li$)$_3$

The polyether–amide dendrimers containing zinc(II) phthalocyanine derivatives were prepared by the method of Newkome *et al.*[4] according to Scheme 1.[4] The starting point for the synthesis of the dendrimers **3**–**6** was the octacarboxylic acid **2** prepared from ester **1**. Reaction of acid **2** with amine **7**, dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBt) in THF at 5 °C affords the first generation dendrimer **3** in 75% yield which was purified by gel permeation chromatography (Biorad Biobeads SX-3, ethyl acetate). The hydrolysis of **3** with LiOH in MeOH–$H_2O$ afforded the first-generation dendrimer **4** bearing 24 carboxylic acid groups. A repeat of this reaction gave the second-generation dendrimers **5** and **6**. Dialysis of the reaction mixture for 2 d after hydrolysis of **3** and **5** in water, followed by freeze-drying, gave the water-soluble dendrimers **4** and **6**. The structures of these compounds were confirmed by $^1$H and $^{13}$C NMR spectroscopies, FTIR, UV–VIS

**Scheme 1** Synthesis of dendrimers **3**–**6**. *Reagents and conditions*: i, $K_2CO_3$, DMF, room temp., 72%; ii, DBU, $ZnCl_2$, *n*-pentanol, reflux, 24 h, 42%; iii, NaOH, $H_2O$–THF, 48 h, 96%; iv, DCC, HOBt, THF, 5 °C, 72 h, 75%; v, LiOH, MeOH–$H_2O$ (1 : 1), 20 °C, 48 h, 96%; vi, DCC, HOBt, THF, 5 °C, 72 h, 70%; vii, LiOH, MeOH–$H_2O$, 48 h, 81%.

and mass spectrometric analysis. Compounds **1**, **3** and **5** were soluble in organic solvents (*e.g.* chloroform, benzene, THF, DMF, acetonitrile) while **2**, **4** and **6** were water-soluble. GPC chromatograms of esters **3** and **5** show a single sharp peak for each dendrimer. These results indicate that the dendrimers are monodispersed. Dendrimer **6** (0.5 mM aqueous solution) was negatively stained, dried and examined using transmission electron microscopy (Fig. 1). The aggregates of small spheres (*ca*. 20 nm diameter) appear as light areas against a darker background. CPK models of **6** predict a highly branched, globular structure, approximately 5 nm in diameter. From the dimensions of **6** *ca*. 30 molecules of the dendrimer per aggregate is estimated.

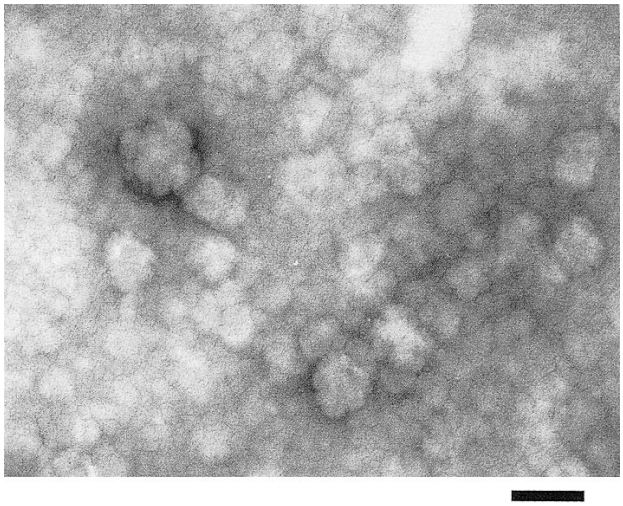


**Fig. 1** Transition electron micrograph of **6**, negatively stained with 2% phosphotungstic acid. Bar = 100 nm; 120 000 × magnification.

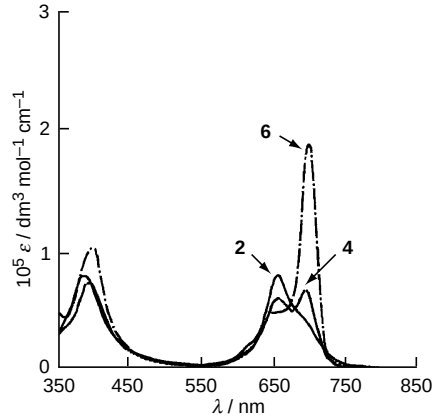

**Fig. 2** UV–VIS spectra of dendritic phthalocyanines **2**, **4** and **6** in aqueous phosphate buffer at pH 7.1

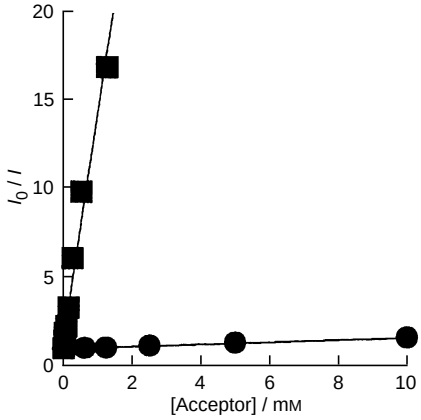

**Fig. 3** Steady-state fluorescence titration of $MV^{2+}$ (■) and SPV (●) into **6** (1.2 μM), excitation 370 nm, emission 674 nm in aqueous phosphate buffer at pH 7.1

The UV–VIS spectra indicate the inner environment of zinc phthalocyanine located within the interior core of the dendrimers. The spectra of **3** and **5** showed a sharp peak at 678.0 nm [log (ε/dm$^3$ mol$^{-1}$ cm$^{-1}$) = 5.47] with a shoulder at 621.0 nm in $CHCl_3$, and were not influenced by the number of the generations. In aqueous media, the UV–VIS spectra of **2**, **4** and **6** were quite different, reflecting the number of generations. Dendrimer **6** showed a Q band at 687.0 nm which is typical of non-aggregated Zn phthalocyanines (Fig. 2). However, a sharp peak was not observed for **2** and **4**. The spectra of **2**, **4** and **6** were little affected upon increasing the pH from 7.1 to 10.5. The broad peak at 622.0 nm, attributed to the aggregation of Zn phthalocyanine, indicates that the complexes interacted hydrophobically in aqueous media.[5] With increasing dendrimer generation, the shielding effect of the dendrimer is enhanced owing to the increased size of the molecular cage. Zinc phthalocyanine exhibits a strong fluorescence peak at 674 nm upon excitation at 370 nm, which is quenched by the addition of methyl viologen ($MV^{2+}$) and propylviologen sulfonate (SPV). Dendrimer **6** displays a strong fluorescence peak in aqueous media, however, **2** and **4** did not fluoresce because of aggregation of zinc phthalocyanine units. Stern–Volmer plots differ using $MV^{2+}$ or SPV as electron-transfer quenching agents (Fig. 3). Addition of a small amount of positively charged $MV^{2+}$ to an aqueous solution of **6** led to efficient fluorescence quenching. On the other hand, only little fluorescence quenching occurred upon addition of zwitterionic SPV. Addition of NaCl drastically diminished the fluorescence quenching by $MV^{2+}$. This behaviour can be explained by a decrease in the local concentration of $MV^{2+}$ adjacent to the dendrimer surface. This efficient quenching of the phthalocyanine fluorescence occurs *via* accumulation of $MV^{2+}$ on the negatively charged dendrimer surface. The fluorescence quenching results suggest an electron-transfer reaction between the zinc phthalocyanine and $MV^{2+}$ through the dendrimer framework. The electron-transfer quenching agents were reduced by **6** under light irradiation in the presence of triethanolamine as a sacrificial donor.

In conclusion, the number of generations affected the aggregation behaviour of the zinc phthalocyanine located in the centre of the dendrimer. The molecular cage inhibited aggregation of the zinc phthalocyanines in aqueous media, and electron transfer was observed through the dendrimer architecture from the zinc phthalocyanine core to $MV^{2+}$ accumulated on the surface of the dendrimer.

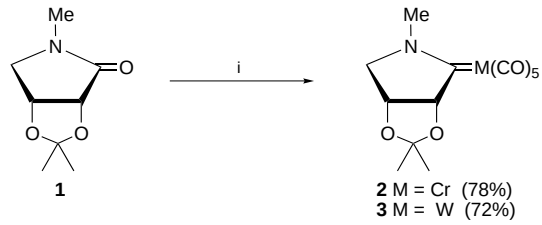
# Metal modified carbohydrates: syntheses of furanosylidene complexes and their aza analogues[1]

**Karl Heinz Dötz,*[a] Wilm-Christian Haase,[a] Markus Klumpe[a] and Martin Nieger[b]**

[a] *Kekulé-Institut für Organische Chemie und Biochemie der Rheinischen Friedrich-Wilhelms-Universität, D-53121 Bonn, Germany*
[b] *Anorganisch-chemisches Institut der Rheinischen Friedrich-Wilhelms-Universität, D-53121 Bonn, Germany*

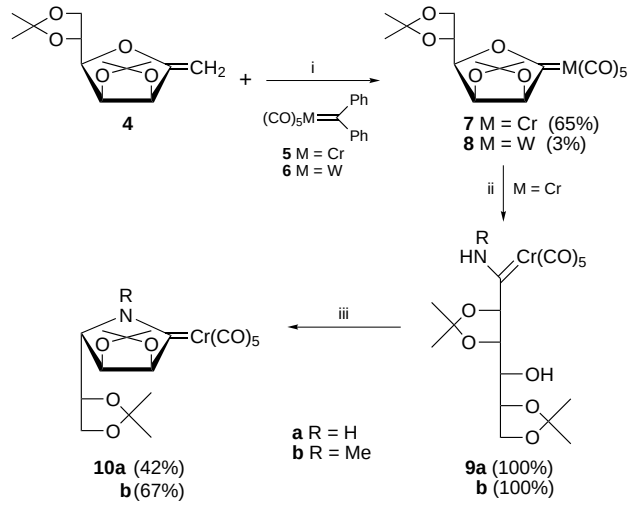
**Alkene metathesis and a sugar lactam electrophile/metalate nucleophile combination have been exploited in the synthesis of furanosylidene complexes and their aza analogues.**

Fischer-type carbene complexes $(CO)_5M{=}C(XR')R$ (M = Cr, W; X = O, NR″) have been developed as useful reagents in stereoselective organic synthesis. Their synthetic potential covers cycloaddition reactions,[2] including benzannulation,[2a] cyclopropanation,[2b,c] and—based on the photolytic generation of ketene equivalents[2d]—addition of imines or oxygen nucleophiles, affording β-lactams or α-amino acids, as well as aldol- and Michael-type addition reactions.[2e,f]



Exploiting the synthetic potential of organometallics in the developing field of C-glycoside chemistry[3] has generally been limited to stannylated and lithiated compounds. Although some encouraging examples of transition metal mediated C-glycosidations have been reported,[4b,c] well-characterized glycosyl complexes are to date only known for manganese,[4c,d] cobalt[4e] and iron.[4f] In this type of compound the anomeric centre behaves as a nucleophile; in contrast, we aimed at the incorporation of an electrophilic metal-carbene functionality into the carbohydrate skeleton. Recently, we reported on the synthesis of the first C-1 carbene complex-functionalized sugars of chromium, iron, molybdenum and tungsten[5] exploiting a strategy that can be applied to acyclic carbohydrates. We now describe two independent routes to cyclic metal glycosylidenes bearing a transition metal-stabilized carbene functionality at the former anomeric carbon atom.

Our first approach is based on the Hegedus route[6] which allows modification of amides and unsubstituted lactams into metal aminocarbenes. We have extended this strategy to a sugar lactam electrophile/metalate nucleophile combination: the reaction of *N*-methyl-2,3-*O*-isopropylidene-D-erythronolactam **1**[7] with $K_2M(CO)_5$ (M = Cr, W) affords the pentacarbonyl[1,4-dideoxy-2,3-*O*-isopropylidene-1,4-methylimino-D-erythrofuranosylidene] complexes **2** and **3** in good yields (Scheme 1).



As neither the classical Fischer route[8] nor the dianion route turned out to be suited for the preparation of oxacycloalkylidene complexes, we focussed on an alkene metathesis approach.[9] The reaction of 2,5-anhydro-1-deoxy-3,4 : 6,7-di-*O*-isopropylidene-D-*manno*-hept-1-enitol **4**[10] with pentacarbonyl(diphenylcarbene) complexes of chromium and tungsten (**5** and **6**)[11] gave the pentacarbonyl(2,3 : 5,6-di-*O*-isopropylidene-D-mannofuranosylidene) complexes **7** and **8** in yields which strongly depend on the metal used (Scheme 2). Glycosylidene complexes **7** and **8** may be regarded as metal-stabilized analogues of the furanoic 'glycosylidene–carbene' intermediates reported by Vasella and co-workers.[12] The pronounced electrophilicity of the metal-carbene moiety favours the addition of nucleophiles. Thus, aminolysis of **7** with ammonia or methylamine generates the open-chain amino(glycosyl)carbene complexes **9a**,**b** offering an unprotected hydroxy group for further functionalization. They readily undergo an intramolecular Mitsunobu reaction[13] and thus provide an access to N-protected and N-deprotected azatalofuranosylidene complexes **10a**,**b** in moderate to good yields. According to X-ray structure analyses† established for **7** and **10b** (Figs. 1 and 2) both complexes adopt a similar envelope-like conformation in the solid state with C(3) being out of plane. Obviously, the epimerization at C(4), which arises from the ring opening/cyclization sequence, has no significant influence on the conformation of the glycosylidene ring. The asymmetric unit of **7** contains two independent molecules which slightly differ in their C(1)–O(1) and C(1)–C(2) bond lengths.

The novel transition metal-stabilized glycosylidene complexes are stable at room temperature and can be handled briefly in air. Their spectroscopic data‡ show the typical characteristics of electrophilic Fischer-type carbene complexes, and as such they are promising reagents for the elaboration of more complex C-glycosidic structures.

Support from the Volkswagen-Stiftung, the Graduiertenkolleg 'Spektroskopie isolierter und kondensierter Moleküle' and the Fonds der Chemischen Industrie is gratefully acknowledged.

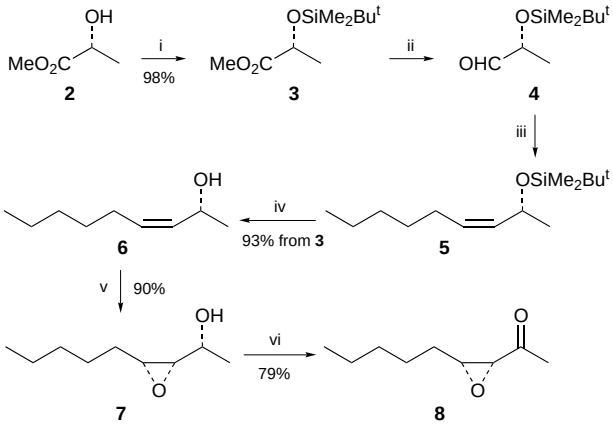
# Asymmetric total synthesis of PM-toxin A, a corn host-specific pathotoxin

**Hiroyuki Hayakawa, Makiko Ohmori, Kiyoko Takamichi, Fuyuhiko Matsuda and Masaaki Miyashita***

*Division of Chemistry, Graduate School of Science, Hokkaido University, Hokkaido 060, Japan*

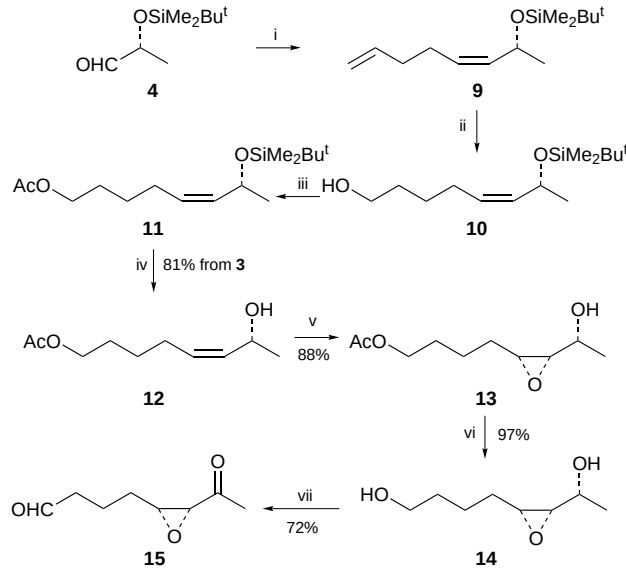
**The first asymmetric total synthesis of PM-toxin A, a corn host-specific toxin produced by the fungal pathogen *Phyllosticta maydis*, starting from D-lactate is described.**



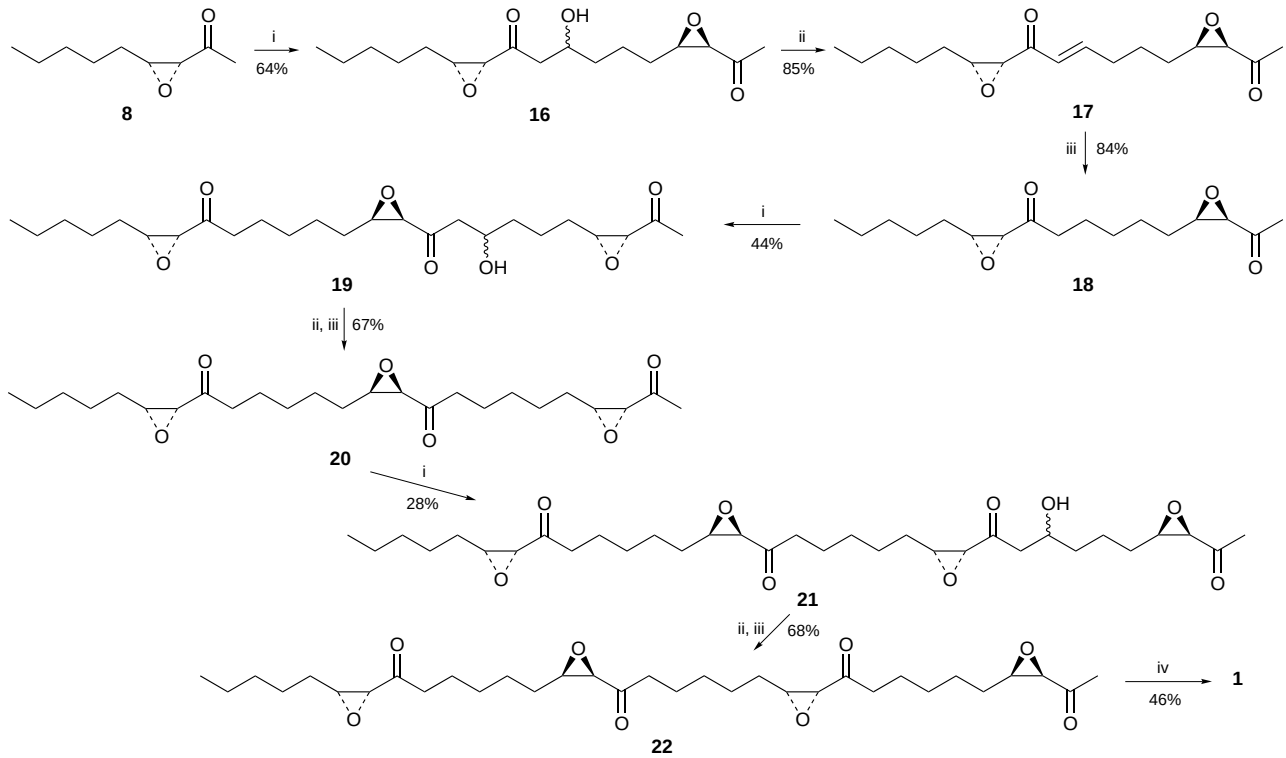
The fungal pathogen *Phyllosticta maydis* produces a corn host-specific pathotoxin, PM-toxin, which was revealed to be the cause of major epidemics of Northern T-corn leaf blight disease in the United States.[1] PM-toxin[2] and the HMT-toxin,[3] produced by the fungal pathogen *Helminthosporium maydis*, race T, are representative corn host-specific toxins.[4] PM-toxin consists of 10–15 components, of which the four major ones—PM-toxin A, B, C and D—have been isolated so far and determined to be linear $C_{33}$ and $C_{35}$ compounds containing a number of characteristic β-ketol (aldol) structures.[2] The unique structures of these corn pathotoxins as well as their marked host-specific toxicity have elicited much attention from biologists and synthetic chemists.[4,5]

PM-Toxin A **1**

We report here the first and highly stereoselective total synthesis of PM-toxin A **1** starting from D-lactate, in which three tandem aldol reactions and the regiospecific organoselenium-mediated reduction of four consecutive α,β-epoxy ketone units are involved as key steps.



The starting methyl D-lactate **2** was treated with $Bu^tMe_2SiCl$ and imidazole in DMF to give **3** in nearly quantitative yield (Scheme 1). Reduction of **3** with DIBAL-H cleanly produced the aldehyde **4** which was subjected to the Wittig reaction with hexyltriphenylphosphonium bromide to give the (*Z*)-alkene **5** along with a trace amount of the (*E*)-isomer. Subsequent treatment of **5** with $Bu_4NF$ in THF afforded the (*Z*)-allylic alcohol **6** in 93% overall yield after purification by silica gel chromatography. Oxidation of the resulting alcohol **6** with MCPBA in $CH_2Cl_2$ gave rise to the α-epoxy alcohol **7** as the sole product in 90% yield, which was submitted to the Swern oxidation resulting in the formation of the desired epoxy ketone **8** in 79% yield. Thus a key compound for the synthesis of PM-toxin A **1** was synthesized in a stereoselective manner.



**Scheme 1** *Reagents and conditions*: i, $Bu^tMe_2SiCl$, imidazole, DMF; ii, DIBAL-H, toluene, −78 °C; iii, hexyltriphenylphosphonium bromide, BuLi, toluene; iv, $Bu_4NF$, THF; v, MCPBA, $CH_2Cl_2$, 0 °C; vi, $(COCl)_2$, DMSO, $CH_2Cl_2$, −78 °C, then $Et_3N$

Another key component **15** was synthesized according to Scheme 2. The Wittig reaction of the aldehyde **4** with pent-4-enyltriphenylphosphonium bromide gave the (*Z*)-alkene **9** along with a minor amount of the (*E*)-isomer. Since the alkenes could not be separated at this stage, the mixture was treated with 9-borabicyclo[3.3.1]nonane (9-BBN) followed by treatment with alkaline $H_2O_2$ to furnish the alcohol **10** as an inseparable mixture of isomers. Subsequent acetylation of **10** with $Ac_2O$ followed by treatment of the resulting acetate **11** with $Bu_4NF$ in THF gave rise to the desired (*Z*)-allylic alcohol **12** in 81% overall yield from **3** after purification by silica gel column chromatography.† Upon epoxidation of the allylic alcohol **12** with MCPBA in $CH_2Cl_2$ the α-epoxy alcohol **13** was exclusively formed in 88% yield. The epoxy alcohol **13** thus obtained was converted to the keto aldehyde **15**, the second key intermediate, by the two step reaction sequence: (i) hydrolysis of the acetate (97%) and (ii) Swern oxidation (72%).

With the key compounds **8** and **15** in hand, we set about the crucial tandem aldol reaction toward the synthesis of tetrakis-epoxy ketone **22**. The first aldol reaction of **8** and **15** with lithium hexamethyldisilazide (LiHMDS) as base smoothly proceeded in THF at −78 °C giving rise to the hydroxy ketone **16** as a diastereoisomeric mixture in 64% isolated yield (Scheme 3). Subsequent treatment of **16** with methanesulfonyl chloride in $CH_2Cl_2$ in the presence of DMAP directly afforded

**Scheme 2** *Reagents and conditions*: i, pent-4-enyltriphenylphosphonium bromide, BuLi, toluene; ii, 9-BBN, THF, 0 °C, then 8 M NaOH, $H_2O_2$; iii, $Ac_2O$, DMAP, pyridine; iv, $Bu_4NF$, THF; v, MCPBA, $CH_2Cl_2$, 0 °C; vi, $NH_3$, MeOH; vii, $(COCl)_2$, DMSO, $CH_2Cl_2$, −78 °C, then $Et_3N$

**Scheme 3** *Reagents and conditions*: i, LiHMDS, THF, then **15**, −78 °C; ii, $MeSO_2Cl$, DMAP, $CH_2Cl_2$; iii, $H_2$, 10% Pd–C, EtOAc; iv, $Na[PhSeB(OEt)_3]$ (16 equiv.), AcOH (24 equiv.), EtOH, 0 °C

the enone **17** in 85% yield, which was then submitted to catalytic hydrogenation over 10% Pd–C in EtOAc, resulting in the formation of the bis-epoxy ketone **18** in 84% yield. Thus the bis-epoxy ketone **18** could be synthesized *via* a three step reaction sequence. The second aldol reaction of **18** and **15** was similarly performed using LiHMDS in THF at −78 °C giving the β-hydroxy ketone **19**‡ in 44% yield. Apparently, the yield of the second aldol reaction is lower than that of the first. The products **19** were similarly converted to the tris-epoxy ketone **20** by the two step reaction sequence of mesylation (80%) and subsequent hydrogenation (84%). The third aldol reaction of **20** and **15** was, as anticipated, reluctant to proceed under similar conditions, resulting in the formation of **21** in 28% yield. The products **21**‡ thus obtained were also converted to the tetrakis-epoxy ketone **22** by the two step reaction sequence of mesylation (90%) followed by catalytic hydrogenation (76%). Although the final aldol reaction suffered from low yield, the critical compound **22** for the synthesis of PM-toxin A **1** was secured in an optically pure form *via* the tandem aldol strategy. Finally, the organoselenium-mediated reduction[6] of the tetrakis-epoxy ketone **22**, the crucial reaction in the present synthesis, was performed by treatment of **22** with benzeneselenol (PhSeH, 16 equiv.) generated *in situ* from sodium (phenylseleno)triethylborate (16 equiv.)[7] and acetic acid (24 equiv.) in ethanol.[6,8] The reduction of four consecutive epoxy ketone moieties occurred regiospecifically at the α-position as expected,[7] and the crystalline PM-toxin A **1** was obtained in 46% isolated yield (68% based on the consumed substrate) after purification by silica gel chromatography. The physical properties of the synthetic compound§ were identical with those of an authentic specimen. Furthermore, $^1H$ and $^{13}C$ NMR spectra of the corresponding tetraacetate derived from the synthetic compound were also identical with those of authentic PM-toxin A tetraacetate. Thus the stereoselective asymmetric total synthesis of PM-toxin A **1** has been achieved by employing tandem aldol reactions and the regiospecific organoselenium-mediated reduction of α,β-epoxy ketone units as key steps.

We acknowledge Professor Y. Kono (Ibaragi University) for providing us with a $^1H$ NMR spectrum of authentic PM-toxin A tetraacetate. We are grateful to the Syourai Foundation and the Hoansya Foundation for their financial support.

# Haem binding and catalytic activity of two-α-helix peptide annealed by trifluoroethanol

**Seiji Sakamoto, Shigeo Sakurai, Akihiko Ueno and Hisakazu Mihara***

*Department of Bioengineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, Nagatsuta, Yokohama 226, Japan*

**A designed two-α-helix peptide His-2α binds effectively $Fe^{III}$–mesoporphyrin (haem) and enhances *N*-demethylase activity of the haem, when the 2α-helix structure is annealed by the addition of 10–20% trifluoroethanol.**

Iron porphyrins occur widely in nature as cofactors of haemproteins and display diverse functions.[1] The specific function of the haemprotein is determined by the microenvironments around the haem.[2] Thus, if we can establish the haem environments by designing polypeptide 3D structures, it will be possible to control the haem functions. So far, considerable effort has been devoted to the conjugation of porphyrin molecules by chelation[3] or covalent linkage[4–6] with designed peptide 3D structures. To develop a mini haemprotein, we here report the design and synthesis of a 2α-helix peptide His-2α, which could bind Fe–mesoporphyrin (haem) in a regulated manner. Furthermore, catalytic activity of the haem that resembled that of peroxidase was significantly increased by the binding with the peptide.

A 14-peptide segment in the peptide was designed to take an amphiphilic α-helix structure in a manner similar to that of a portion of coiled-coil proteins (Fig. 1).[7,8] The two segments were dimerized by disulfide linkage of the $Cys^{16}$ residues. As axial ligands of haem, His residues were introduced at the sixth position instead of Leu to deploy a haem parallel to the helix. The peptide was synthesized by the solid-phase method using the Fmoc strategy and purified with HPLC to high purity (> 98%). The peptide gave a molecular ion peak at *m*/*z* 3529.6 [(M + H)$^+$] (calc. 3529.1) on matrix assisted laser desorption ionization times-of-flight mass spectrometry. The monomer peptide (His-1α) was also synthesized and gave an ion peak at *m*/*z* 1836.9 [(M + H)$^+$] (calc. 1837.2).

The conformation of His-2α ($2.0 \times 10^{-5}$ mol dm$^{-3}$) in buffer (pH 7.4) was almost random due to the introduction of His residues (Fig. 2).† With increasing percentage volume of trifluoroethanol (TFE), which is known to be an α-helix stabilizing solvent,[8] the α-helicity[9] of His-2α gradually increased until it reached about 70% at 30% TFE [Fig. 2(*b*)]. Interestingly, in the presence of the haem, a further increase in α-helicity was observed at 10–20% TFE [Fig. 2(*b*), closed circles]. The largest increase of α-helicity by the addition of haem was obtained at around 15% TFE (1.4-fold). When His-2α was titrated with the haem in 15% TFE, the CD spectra of His-2α changed gradually to that of a typical α-helix structure with an isodichroic point at 204 nm (Fig. 3). The binding constant ($K_a$) in 15% TFE, which was estimated from molecular ellipticities at 222 nm using a single site binding equation,[10] was $2.8 \times 10^5$ dm$^3$ mol$^{-1}$. The addition of 1-methylimidazole (200 equiv.) inhibited the coordination of His-2α with the haem, resulting in the decrease of the α-helicity to the level without the haem. Additionally, there was no significant change in the CD spectra by the addition of haem at acidic pH (2.0–6.0). Because the p$K_a$ of imidazole is about 6.0, the pH effect is attributed to the protonation of His side chains such that they cannot act as ligands. Therefore, we concluded that the increase in α-helicity

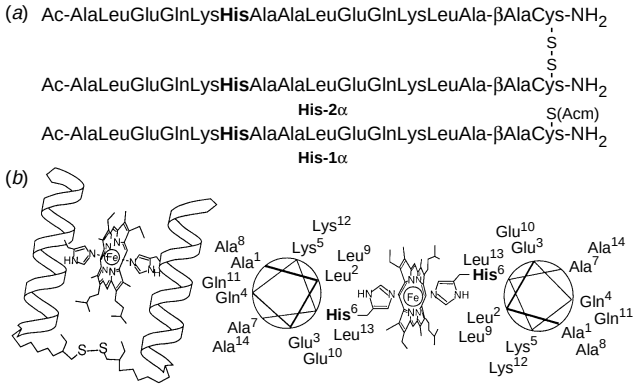

**Fig. 1** Structure of the designed peptides, His-2α and His-1α. (*a*) Amino acid sequences of His-2α and His-1α. (*b*) Illustration of two-α-helix peptide structure bound to the haem and helix wheel drawing of the two 14-peptides in coiled-coil form. Acm = acetamidomethyl.

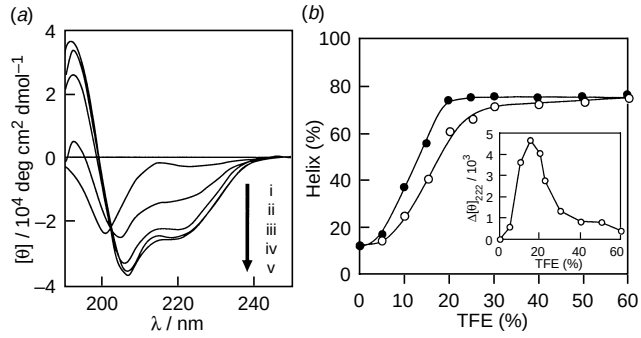

**Fig. 2** (*a*) CD spectra of His-2α with increasing percentage volume of TFE in $2.0 \times 10^{-2}$ mol dm$^{-3}$ Tris HCl buffer (pH 7.4) at 25 °C. i, 0%; ii, 15%; iii, 30%; iv, 60%; v, 97%. [His-2α ] = $2.0 \times 10^{-5}$ mol dm$^{-3}$. (*b*) Effect of TFE content on the α-helicity (○) in the absence and (●) the presence of haem ($2.0 \times 10^{-5}$ mol dm$^{-3}$). Inset: increase in ellipticity at 222 nm by the addition of haem as a function of TFE content.

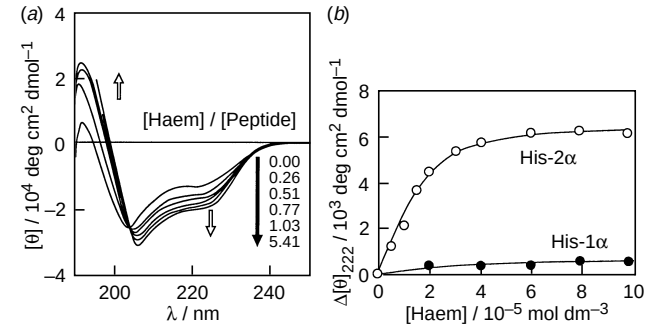

**Fig. 3** (*a*) CD spectra of His-2α with increasing haem concentration in the buffer containing 15% TFE at 25 °C. [His-2α] = $2.0 \times 10^{-5}$ mol dm$^{-3}$. (*b*) Improvement of α-helix for (○) His-2α ($2.0 \times 10^{-5}$ mol dm$^{-3}$) and (●) His-1α ($4.0 \times 10^{-5}$ mol dm$^{-3}$) by the addition of the haem.

of His-2α took place *via* the haem binding by ligation with His residues. In contrast, α-helicity of His-1α was little affected by the addition of haem at any percentage volume of TFE (0–90%), indicating that His-1α could not bind the haem in this concentration.

Titration of the haem with His-2α was also carried out in the buffer containing various amounts of TFE. At 15% TFE, the Soret band at 401 nm increased and the band at around 355 nm decreased upon the addition of His-2α [Fig. 4(*a*)]. That is, an UV–VIS spectrum of the haem was converted from the high spin to the low spin form with an isosbestic point at 390 nm. The decrease in absorbance at 355 nm indicated that the peptide acted to break up haem aggregates.[6] The binding constant for the haem with His-2α was strongly dependent on the TFE content [Fig. 4(*b*)]. His-2α showed the highest binding constant at 15% TFE ($K_a$ = 5.8 × 10$^5$ dm$^3$ mol$^{-1}$). In contrast, His-2α could not bind the haem effectively at < 10% and > 30% TFE ($K_a$ < 3.0 × 10$^4$ dm$^3$ mol$^{-1}$). These TFE titrations revealed that the 2α-helix structure annealed by TFE and the consequent formation of a hydrophobic pocket are important for the haem binding. That is, at the lower TFE content (< 10%), the hydrophobic pocket is not formed, because the conformation of His-2α is predominantly a random-coil. On the other hand, at the higher TFE content (> 30%), the 2α-helix structure is destroyed so that each α-helix segment is free to move. Because there is no hydrophobic pocket at either lower or higher TFE content, the peptide cannot bind the haem effectively. The monomer peptide His-1α and 1-methylimidazole needed a concentration of an order of *ca.* 10$^{-3}$ mol dm$^{-3}$ for the haem binding and did not show such a TFE dependence. These results also confirm that the formation of the 2α-helix structure is essential for the haem binding.

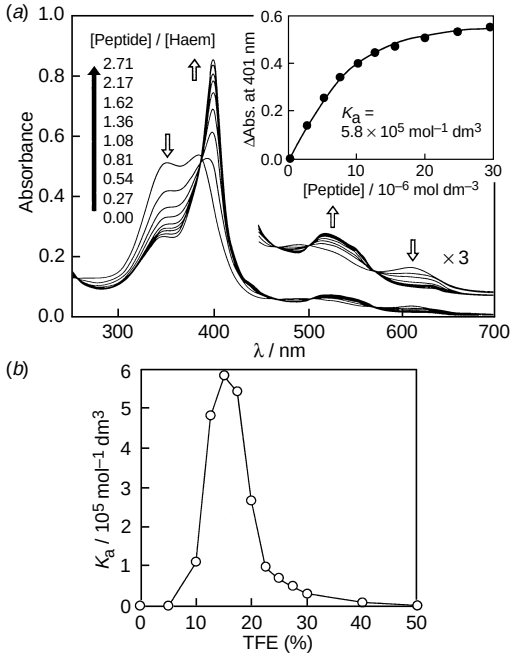

**Fig. 4** (*a*) UV–VIS spectra of the haem with increasing His-2α concentration in the buffer containing 15% TFE at 25 °C. [haem] = 1.0 × 10$^{-5}$ mol dm$^{-3}$. (*b*) Effect of TFE content on the binding constant for His-2α with the haem.

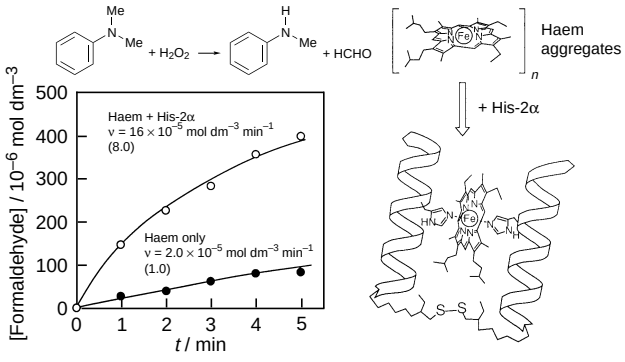

**Fig. 5** Time course of formaldehyde formation catalysed by the haem (○) in the presence and (●) absence of His-2α. The reaction was initiated by addition of hydrogen peroxide (4.9 × 10$^{-3}$ mol dm$^{-3}$) to mixtures of *N*,*N*-dimethylaniline (5.0 × 10$^{-3}$ mol dm$^{-3}$), haem (4.8 × 10$^{-6}$ mol dm$^{-3}$) and His-2α (1.0 × 10$^{-5}$ mol dm$^{-3}$) in 0.1 mol dm$^{-3}$ Tris HCl buffer (pH 7.4) containing 15% TFE at 30 °C. About 80% of the haem was bound to the peptide under the conditions according to the binding constant.

Next, demethylation catalysis of the haem bound to His-2α was demonstrated using *N*,*N*-dimethylaniline as a substrate.[11] As shown in Fig. 5, the initial rate *v* of the reaction in the presence of His-2α (*v* = 16 × 10$^{-5}$ mol dm$^{-3}$ min$^{-1}$) was accelerated by a factor of 8.0, relative to that in the absence of the peptide (*v* = 2.0 × 10$^{-5}$ mol dm$^{-3}$ min$^{-1}$). The acceleration of the reaction was dependent on the TFE content and showed a maximum value at 15% TFE. The *N*-demethylase activity was comparable to that of bilayer-bound cytochrome *c* as reported by Hamachi *et al.*[11] The initial rate was dependent on the concentration of $H_2O_2$, but not on that of *N*,*N*-dimethylaniline. Therefore, the rate-determining step is the reaction between the haem and $H_2O_2$. The peptide seems to enhance the activity by isolating the haem in the peptide structure from the haem aggregates in solution.

In conclusion, the haem binding of the His-peptide was controlled by the peptide conformation with TFE. The catalytic activity was enhanced by the formation of the haem–peptide complex, which might be another kind of catalytic molten globule.[12] The strategy using designed peptides conjugated with functional groups, such as haem, is expected to be applied to the elucidation of the roles of polypeptide 3D structure on the diverse functions of natural proteins, and the obtained information will be useful for the design artificial proteins.

# Effect of hydrogen treatment of active carbon as a support for promoted ruthenium catalysts for ammonia synthesis

**Zhihua Zhong and Ken-ichi Aika***

*Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226, Japan*

**Hydrogen treatment of active carbon (A.C.) at temperatures ranging from 1073 to 1188 K for 12 h is an effective method for eliminating surface impurities, leading to the preparation of useful ruthenium catalysts; for example, 2 mass% Ru–BaO/A.C. (Ba/Ru = 5) yields 2 mmol $NH_3$ $h^{-1}$ $g^{-1}$ at 588 K under 1 atmosphere.**

Many researchers have pursued various alternatives in making pure carbon materials which are used as support material for ruthenium catalysts in the synthesis of ammonia. HSAG (high surface area graphite) was first developed in the UK[1] and the first commercial ammonia plant to use ruthenium catalysts has operated using a type of Ru/HSAG catalyst since 1992 in Canada. The catalyst used has been reported to be very efficient and stable.[2] Ruthenium catalysts supported on carbon-covered alumina (CCA) was found to be substantially improved for the synthesis of ammonia since CCA offers the purity of carbon and eliminates the acidity of alumina.[3,4] More recently, a very active Ru catalyst supported on A.C. which is treated for 2 h at 2173 K in an atmosphere of helium (400 Pa) has been reported.[5,6] The authors suggest that the high activity is due to differences in the support (A.C.) which may have similar properties to HSAG.

In this work, we have successfully eliminated the impurities such as S, N, O and Cl by treating commercial A.C. with hydrogen at moderate temperatures (1073–1188 K). We have used $Ba(NO_3)_2$ and $CsNO_3$ as the promoters because these were found to be the most effective on Ru/A.C. while $Ce(NO_3)_3$ was also used based on the results of our most recent work.[7,8]

Three kinds of granular active carbons (8–12 mesh size, 2 g) were treated in a quartz reactor by increasing the temperature to 1073 or 1188 K at a rate of 5 K $min^{-1}$ under a flow of hydrogen (30 ml $min^{-1}$) and kept at the final temperature for 12 h or more. The Ru/A.C. catalysts were prepared by impregnating A.C. with $[Ru_3(CO)_{12}]$ or $[Ru(acac)_3]$ in THF and finally heated from room temp. to 573 K in 2 h *in vacuo*.[7,8]

All the catalysts (usually 0.2 g) were pre-reduced at 473 K with hydrogen (50 ml $min^{-1}$) for 5 h, then reduced at the corresponding reduction temperatures for 3 h. The ammonia synthesis reaction was performed in a stainless-steel reactor (id = 6.5 mm) under a flow system under atmospheric pressure at 588 K.[7,8] The flow rates of $H_2$ and $N_2$ were set at 45 and 15 ml $min^{-1}$, respectively.

Elemental analysis was also carried out for these three commercially available A.C. samples and the results are shown in Table 1. We can see that the content of the carbon increases dramatically and hydrogen and nitrogen decrease when the reduction treatment is prolonged. The surface areas (BET) and the XRD patterns are only slightly different. Neither sulfur nor halogen can be detected after hydrogen treatment of A.C. (no. 76) at 1123 K for 12 h.

In this work we found that two hydrogen treatment procedures, namely, the treatment of the active carbon and the treatment of the catalyst, influenced the activity of Ru–$Ba^{2+}$/A.C. Hydrogen treatment of A.C. at high temperatures such as 1123 K enabled the elimination or reduction of the surface acidic impurities which withdraws electrons from Ru. Impregnated and decomposed $[Ru_3(CO)_{12}]$ on such active carbon proved effective in the preparation of an efficient catalyst for ammonia synthesis. However, ruthenium catalysts supported on A.C. without the promoter showed almost no activity for the synthesis reaction at 588 K. The effects of hydrogen treatment of A.C. were found to be remarkable only when a promoter such as $Ba(NO_3)_2$ was added. Moreover, the activity was also affected by the reduction temperature of the catalyst, as is shown in Fig. 1. The A.C. used for preparing these samples has been treated differently as is cited in the figure caption. The sample with A.C. which had been treated at such high temperatures as 1188 K was highly promoted by the addition of $Ba(NO_3)_2$. Those samples which had been treated for a longer time at 1188 K showed a more remarkable promotion as can be seen in Fig. 1.

The ammonia activity for the ruthenium catalysts supported on various kinds of A.C. has been shown to be a function of the reduction temperature of the catalyst as indicated in Fig. 2. We have noted here that for the catalysts with non-treated A.C. as the support, the activities varied remarkably owing to the difference in the sulfur and halogen content. However, it is most interesting to note that the catalysts performed much the same after the A.C. was treated with hydrogen at 1123 K for > 24 h. This clearly indicates that the catalytic behavior of the Ru

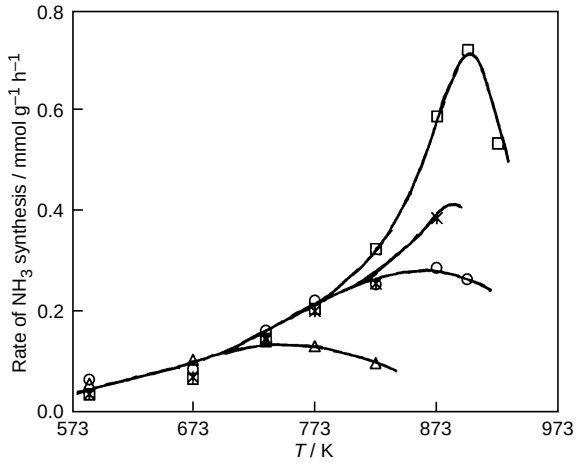

**Fig. 1** Ammonia activity of 1 mass% Ru–15$Ba^{2+}$/A.C. as a function of reduction temperature ($T$). Ru precursor [$Ru_3(CO)_{12}$]. Four kinds of A.C. (#76) were used: (△) non-treated A.C.; (○) A.C. treated at 1073 K for 14 h; (*) A.C. (○) further treated at 1188 K for 20 h; and (□) A.C. (*) further treated at 1188 K for 18 h.

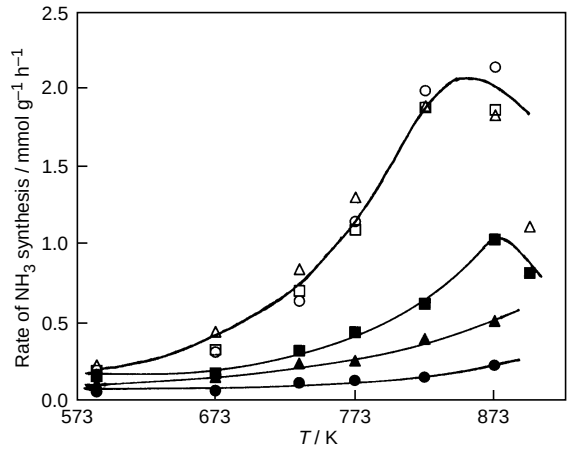

**Fig. 2** Ammonia activity of 2 mass% Ru–5$Ba^{2+}$/A.C. as a function of reduction temperature. Ru precursor [$Ru(acac)_3$]. Solid symbols represent non-treated A.C.; open symbols represent A.C. treated at 1123 K for 48 h; triangles, A.C. #76; circles, #80; squares #75.

catalysts is mainly dependent on the purity of the A.C., while not influenced by the original source or the porosity of the A.C.

The elimination of the impurity species, usually with high electronegativity, reduces the capability of A.C. to withdraw electrons from the Ru atoms and the promoter, and simultaneously enhances the electron donation of the promoter to ruthenium.

Hydrogen treatment at temperatures ranging from 1073 to 1188 K for > 12 h was found to be the significant and decisive factor in removing impurities such as sulfur and halogen left on commercial A.C. during the activation process and/or when adding the binder while the surface area and the porous structure of the A.C. was not affected. This moderate reduction treatment of A.C. (support) doubles or even triples the activities for $Cs^+$-, $Ba^{2+}$- or $Ce^{3+}$-promoted Ru catalysts for ammonia synthesis. Furthermore, the activity increases with prolonged hydrogen treatment. As supports, the different kinds of A.C. exhibited low and quite varied activity for ammonia synthesis owing to differences in impurity content. However, any A.C. treated with hydrogen was found to show equally high activity. Our studies which have been based on detailed and repeated research work have demonstrated that the removal of such impurities such as sulfur and halogens as well as the elimination of the acidic functional groups in A.C. by hydrogen treatment led to higher activity of the ruthenium catalysts, thus paving the way for the preparation of an efficient and effective catalyst for ammonia synthesis.

# Indium-mediated regioselective Markovnikov allylation of unactivated terminal alkynes

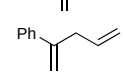
**Brindaban C. Ranu* and Adinath Majee**

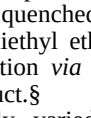
*Department of Organic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700 032, India*

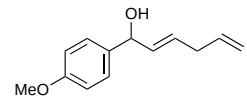
**Allylation of unactivated terminal alkynes by a simple treatment with allyl bromide and indium metal in THF at room temperature produces 1,4-dienes *via* regioselective Marknovnikov addition.**

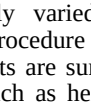
Metal-mediated reactions play a significant role in organic synthesis. Of all the metals, indium has emerged in recent years as the one with most potential because of its advantages with regard to handling, toxicity, reactivity and selectivity.[1] Although indium-mediated carbonyl addition reactions have experienced tremendous growth in recent times,[2] its other interesting domains, including carboindation, still remain less well-explored.[3] Recently, a procedure for allylation of carbon–carbon triple bonds, using indium powder and allylic bromides in DMF at elevated temperature to produce allylalkenols predominantly *via* anti-Markovnikov addition, has been demonstrated.[3a] One serious limitation of this procedure is that the presence of a hydroxyl functionality near the triple bond is essential, and thus nonfunctionalised† or hydroxy-protected alkynes are not susceptible to allylation.[3a] We have observed a very significant effect on the course of the indium-mediated allylation reaction with a change of solvent and modification of the experimental conditions. Thus, unactivated (nonfunctionalised and hydroxy-protected) alkynes underwent efficient allylation *via* Markovnikov addition by simple treatment with allyl bromide and indium metal in THF at room temperature (Scheme 1).

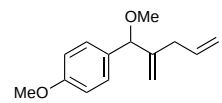
**Scheme 1** *Reagents and conditions*: i, In, THF, room temp.

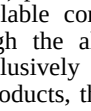


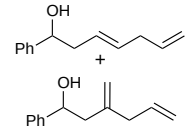


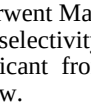


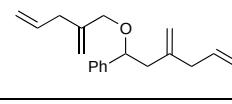












The experimental procedure is very simple. A mixture of alkyne (1 mmol), allyl bromide (8 mmol)‡ and indium metal (1 mmol, cut into small pieces) in THF (2 $cm^3$) was stirred at room temperature until completion of the reaction (TLC). The reaction mixture was quenched with a few drops of dilute HCl and extracted with diethyl ether. Evaporation of the solvent followed by purification *via* silica gel chromatography furnished the pure product.§

Several structurally varied terminal alkynes underwent allylation by this procedure to provide the corresponding 1,4-dienes. The results are summarised in Table 1. Nonfunctionalised alkynes such as hex-1-yne, oct-1-yne and phenylacetylene (entries 1–3) produced Markovnikov addition products as the sole isolable compounds in high yields. Very interestingly, although the alkynols (entries 4, 9 and 11) furnished almost exclusively or predominantly the anti-Markovnikov addition products, the corresponding ethers (entries 5–8, 10 and 12) underwent Markovnikov coupling exclusively. This reversal of regioselectivity with protection of the hydroxy group is very significant from a mechanistic as well as a synthetic point of view.

In general, the reactions are very clean, and no side products were found. No reaction occurred with internal alkynes. THF is found to be the best choice as solvent. Reactions in water and in aqueous THF are not successful. At lower temperature (0–5 °C), no efficient coupling is also observed.

In conclusion, the present procedure provides an efficient and general methodology for indium-mediated allylation of unactivated terminal alkynes. The notable advantages are the mild conditions (room temperature), operational simplicity (one-pot reaction), high yield (75–90%) and excellent regioselectivity (Markovnikov addition). To the best of our knowledge, this is the first report of indium-mediated Markovnikov allylation of uncativated alkynes. We believe this procedure will find useful application in organic synthesis. Further investigations to gain a better understanding of the criteria for selectivity and to broaden the scope of this reaction are in progress.

## Footnotes

* E-mail: ocbcr@iacs.ernet.in

† At higher reaction temperature (150–180 °C) oct-1-yne and phenylacetylene underwent coupling with cinnamylindium in only 12–28% yield [ref. 3(*a*)].

‡ Excess allyl bromide is found to accelerate the reactions considerably; stoichiometric or a slightly larger amount (2–3 mmol) of allyl bromide makes the reactions slow.

§ The alkynes and allyl bromide were freshly distilled before use. A few alkynes, namely hex-1-yne, oct-1-yne, phenylacetylene and prop-2-ynyl alcohol, are commercial materials (E. Merck, Germany) and others were prepared *via* standard procedures. Allyl bromide was also purchased from E. Merck. Indium metal was obtained from SRL, India, as ingots and cut into small pieces whenever required. THF was procured from SD, India, and freshly distilled over sodium–benzophenone.

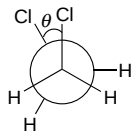
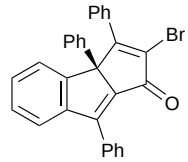
# Isolation of a nearly eclipsed chiral rotamer of 1,2-dichloroethane as an inclusion crystal with a chiral host compound

**Fumio Toda,*[a]† Koichi Tanaka[a] and Reiko Kuroda*[b]‡**

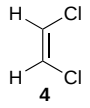


[a] *Department of Applied Chemistry, Faculty of Engineering, Ehime University, Matsuyama, Ehime 790, Japan*
[b] *Department of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153, Japan*

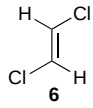
**A nearly eclipsed chiral rotamer of 1,2-dichloroethane has been isolated in a pure state as an inclusion complex crystal with the chiral host compound, (*S*)-(−)-2-bromo-3,3a,8-triphenyl-1,3a-dihydrocyclopenta[*a*]inden-1-one and an X-ray crystal structure of the complex has been studied.**



The conformation of simple acyclic molecules has long been studied, mostly spectroscopically and theoretically.[1] By these studies, it has been established that the energetically most stable rotamer (rotational isomer) around the C–C bond of 1,2-disubstituted ethane is the *trans* form. For example, 1,2-dichloroethane **1** exists in the *trans* form **1a**, the structure of which was elucidated by X-ray analysis of **1** crystallised at 212 K using a miniature zone melting procedure,[2] although the energy difference between the *trans* and *gauche* form of gaseous **1** has been estimated to be small (0.9–1.3 kcal mol$^{-1}$ by experiment and 0.91 kcal mol$^{-1}$ by calculation; 1 cal = 4.184 J).[1] The existence of **1** in the eclipsed form of the two chlorine atoms **1b** ($\theta$ = 0) is excluded, because of its instability due to strong repulsions between not only the chlorine atoms but also hydrogen atoms. The possibility of isolation of the *gauche* form **1b** ($\theta$ = 60°) would also be excluded, and isolation of the *gauche* form has never been reported.



**1a**
*trans*-form



(*M*)-**1b**
eclipsed-form

(*S*)-(–)-**2**

**4**

**6**

We here report isolation of a nearly eclipsed form of **1** as a 1 : 1 inclusion complex crystal with a host compound. Recrystallisation from **1** of the optically active host compound, (*S*)-(−)-2-bromo-3,3a,8-triphenyl-1,3a-dihydrocyclopenta[*a*]-inden-1-one **2**,[3,4] gave their 1 : 1 inclusion complex **3**§ as yellow prisms in quantitative yield (mp 100–104 °C). In comparison, a 1 : 1 inclusion complex **5**§ of **2** and *cis*-1,2-dichloroethylene **4** was also prepared as pale yellow prisms by recrystallization of **2** from **4**. However, *trans*-1,2-dichloroethylene **6** did not form an inclusion complex with **2**. The 1 : 1 host–guest ratio in **3** and **5** was determined by $^1$H NMR spectroscopy, thermogravimetric measurement and elemental analyses.

In order to study the molecular conformation of **1** in **3**, an X-ray crystal structure of **3** was determined.¶ The X-ray analysis established that **1** exists as the nearly eclipsed form **1b** [$\theta$ = 36(2)°] as shown in Fig. 1. This is the first example of the isolation of the nearly eclipsed rotamer. The molecule **1b**, which adopts a conformation between the *gauche* and eclipsed form is chiral. Since **2** is an optically active (*S*)-(−)-host,‖ only one enantiomer of **1b**, the left-handed helical form (*M*)-**1b**,[6] is accommodated in **3**. This is also the first case of the isolation of an optically active rotamer of 1,2-dichloroethane. The reason for this surprising finding that sterically the very unfavourable rotamer can be trapped at room temperature in an inclusion complex was studied by comparison of the molecular and crystal structures of **3** with those of **5**.¶ The crystal structure of **5** is shown in Fig. 2. The two crystal lattice parameters are surprisingly similar, with only the 0.09–0.4% difference as shown in the footnote.¶ The two crystals adopt the same space group of $P2_12_12_1$. The location of the host and guest molecules, as well as their conformation, closely resemble to each other, as expected from the cell parameter comparison. The intramolecular Cl··Cl distance is retained, at 3.205(5) and 3.315(5) Å for **1a** in **3** and **4** in **5**, respectively. The closest contacts between the host and the guest are observed for the C=O oxygen of **2** and the Cl atom of **1b** [3.288(6) Å], and the C=O oxygen of **2** and the Cl atom of **4** [3.247(7) Å].

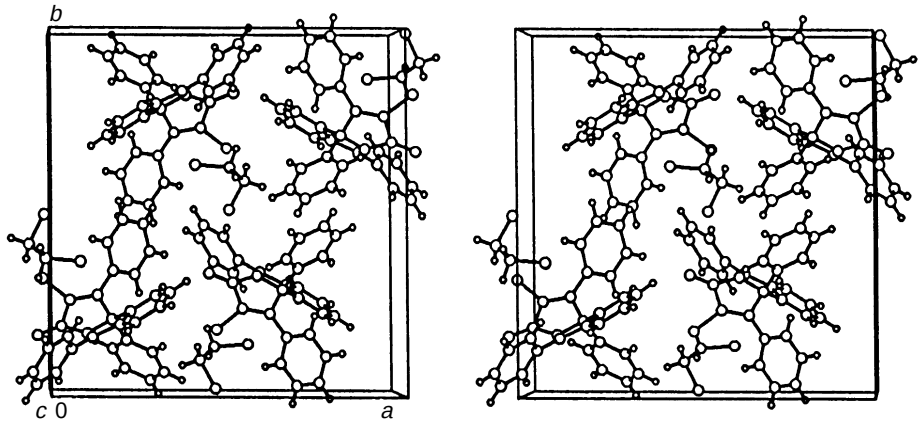


**Fig. 1** Stereoview of the 1 : 1 inclusion complex **3** of **2** and (*M*)-**1b**

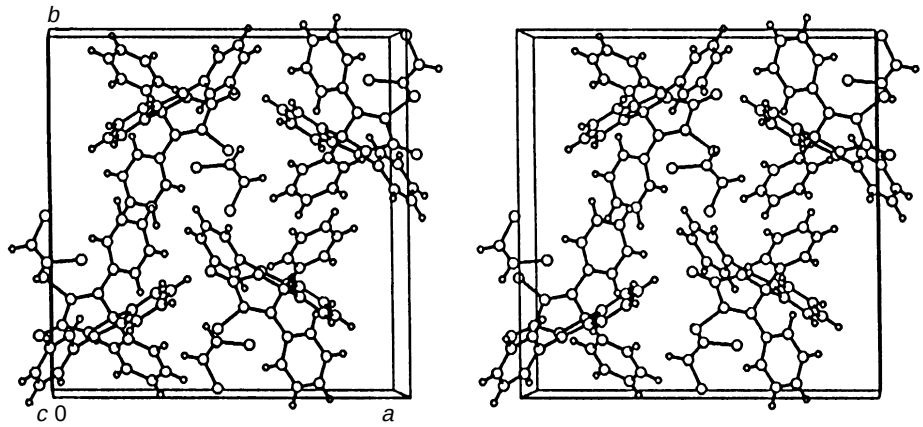

**Fig. 2** Stereoview of the 1 : 1 inclusion complex **5** of **2** and **4**

The dissociation energies of **3** (51 kJ mol$^{-1}$) and **5** (59 kJ mol$^{-1}$), which were estimated from their differential scanning calorimetry data, are also comparable, however, the slightly more stable **5** should be formed a little more readily. In fact, recrystallization of (+)-**2** (40 mg) from a 1 : 1 mixture of **1** (200 mg) and **4** (200 mg) gave **5** (32 mg, 67% yield) exclusively. This is a good example of extremely precise molecular recognition in molecular assembly.

The chlorine atoms of **1** and **4** seem to be the key to deciding whether the inclusion of the guest in the cavity occurs or not. Thus, in the two cases, the two chlorine atoms are located in similar positions. Since the *trans*-isomer of **4** (**6**) cannot be included with **2**, a guest molecule in which the two chlorine atoms are located in a *trans*-position such as **1a** would be unfavourable for accommodation in the cavity of the complex with **2**. Presence of **1b** in **2** also suggests that some electrostatic interaction between the two chlorine atoms is contributing to the stabilisation of the sterically unfavourable eclipsed-form.

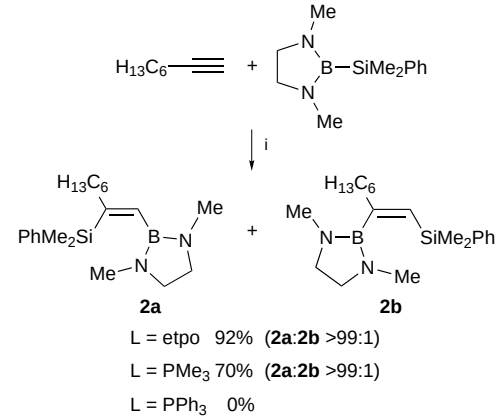
# Palladium-catalysed borylsilylation of alkynes and borylsilylative carbocyclization of diynes and an enyne compound

**Shun-ya Onozawa, Yasuo Hatanaka and Masato Tanaka***

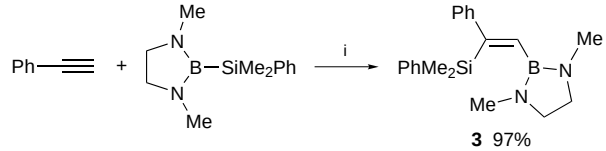


*National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305, Japan*

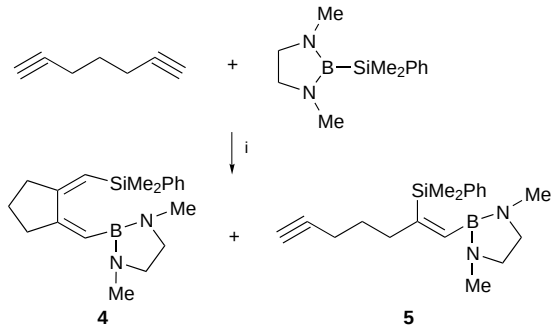
**Addition reactions or addition–carbocyclization reactions of a borylsilane with alkynes, α,ω-diynes or an enyne compound proceed efficiently in the presence of palladium catalysts, $P(OCH_2)_3CEt$ being the ligand of choice.**

Addition reactions of inter-heteroatom bonds such as Si–Si and Sn–Sn to unsaturated carbon bonds are extremely useful for one-step generation of two heteroatom–carbon bonds.[1] Similar chemistry starting with B–B bonds is also rapidly emerging.[2] An obvious extension is addition reactions of bonds comprising two different elements.[3] In a previous paper we disclosed palladium-catalysed addition of borylstannanes to alkynes (borylstannylation) leading to efficient synthesis of 1-boryl-2-stannyl alkenes.[4] α,ω-Diynes also react with borylstannanes, undergoing borylstannylative carbocyclization reactions to afford 1-borylmethylene-2-stannylmethylene cycloalkanes in high yields.[5a] 1,4-Addition of conjugated dienes also proceeds smoothly when $Pd(etpo)_2$ catalyst [etpo = 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane, $P(OCH_2)_3CEt$] is used.[5b] As regards corresponding borylsilylation, however, only unsuccessful results have been reported by Buynak and Geng.[6] While we were studying borylsilylation as a useful extension of the borylstannylation, Ito and co-workers briefly presented successful examples of addition reactions of a borylsilane (4,4,5,5-tetramethyl-2-dimethylphenylsilyl-2-bora-1,3-dioxapentane) to alkynes, mainly using the 1,1,3,3-tetramethylbutyl isocyanide–palladium diacetate catalyst system.[7] Their communication prompted us to report our own results.

A representative procedure for the reaction of alkynes was as follows. A mixture of $Pd_2(dba)_3$ (0.005 mmol; dba = dibenzylideneacetone) and etpo (0.02 mmol), *i.e.* $Pd_2(dba)_3$–etpo catalyst system in which P/Pd = 2, in $C_6D_6$ (0.2 ml) was heated at 80 °C for 5 min, while the colour of the solution was changing from red to green. 1,3-Dimethyl-2-dimethylphenylsilyl-2-bora-1,3-diazacyclopentane **1** (0.2 mmol), oct-1-yne (0.3 mmol) and 1,4-dioxane (20 μl; internal standard for NMR analysis) were added to the resulting solution and the mixture was heated at 80 °C in a sealed NMR tube. NMR and GC–MS analyses of the reaction mixture after 2 h indicated complete consumption of **1** and adduct **2a**† being formed in 92% yield (Scheme 1). Note that the regioselectivity was >99% and that only a trace of isomer **2b** was detected by NMR analysis. Isolation of the product was simple; evaporation of the reaction mixture, addition of hexane (2 ml) to the residue, filtration and distillation of the filtrate afforded nearly pure **2a** in 84% isolated yield, which exhibited satisfactory spectral and analytical data. Observation of an 8% NOE between the allylic protons and the vinylic proton suggested that selective *cis*-addition of the B–Si bond had taken place.



Unlike for the borylstannylation, Pd–$PPh_3$ complexes were not as efficient catalysts; the reaction of oct-1-yne with **1** did not proceed under the same conditions when either $Pd(PPh_3)_4$ or $PdCl_2(PPh_3)_2$ was used as the catalyst. The former did catalyse the reaction at higher temperatures, but the yields were still unsatisfactory, *e.g.* only 78% yield (**2a**/**2b** > 99 : 1) even after heating at 110 °C for 24 h. However the latter, which catalysed the borylstannylation at room temperature, was totally inactive even at 110 °C. We have reported that $PMe_3$ performs better than $PPh_3$ in the platinum-[8] or palladium-catalysed reactions[9] of unsaturated carbon compounds with disilanes or digermanes. The reaction of oct-1-yne with **1** was also better when catalysed by the $Pd_2(dba)_3$–$4PMe_3$ system (70% yield, 80 °C, 2 h) than by the $Pd_2(dba)_3$–$4PPh_3$ system (0% yield, 80 °C, 2 h *vs.* 18% yield, 110 °C, 7 h). However, as the foregoing typical experiment exemplifies, etpo is superior to the other phosphines as the ligand. In view of the decreasing trend of performance etpo > $PMe_3$ > $PPh_3$, the ligand effect in the borylsilylation is concluded to be similar to our previous observation made in the double silylation of acetylenes[9a,b] and quinones[9c] with disilanes and double germylation of acetylenes, dienes and alkenes.[9d]



**Scheme 1** *Reagents and conditions*: i, $Pd_2(dba)_3$ (2.5 mol%), ligand (L/Pd = 2), $C_6D_6$, 80 °C, 2 h

Phenylacetylene appeared to be slightly less reactive towards **1** than oct-1-yne, but the reaction did proceed smoothly at 110 °C in the presence of the $Pd_2(dba)_3$–4etpo catalyst system to give 97% yield of **3**† as the sole product in 2 h (Scheme 2). However, the reaction of dimethyl acetylenedicarboxylate resulted in a complicated mixture.

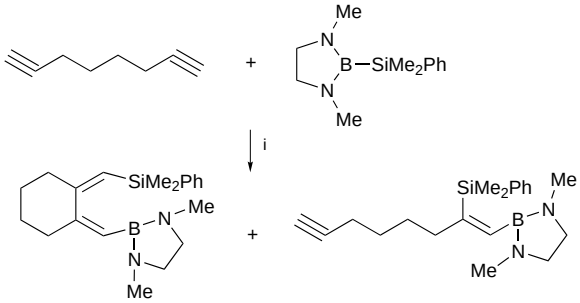
Borylsilylative carbocyclization of hepta-1,6-diyne (0.3 mmol) with **1** (0.2 mmol) was also catalysed smoothly by the $Pd_2(dba)_3$–4etpo system in $C_6D_6$ at 110 °C to afford **4** in 81% yield.† Configurations at the silylmethylidene and borylmethylidene moieties of **4** were confirmed by 19.3 and 18.2% NOEs between the vinylic and allylic protons. A byproduct **5** coming from simple addition of **1** to one of the two acetylenic bonds without carbocyclization was also formed in 18% yield (Scheme 3). The $Pd_2(dba)_3$–$4PMe_3$ system was as active, but less selective (84% total yield after 2 h at 110 °C, **4** : **5** = 30 : 70). The $Pd_2(dba)_3$–$4PPh_3$ system was less active and even less selective (88% total yield after 7 h at 110 °C, **4** : **5** = 26 : 74). $PdCl_2(PPh_3)_2$ was totally inactive at 110 °C.

**Scheme 2** *Reagents and conditions*: i, $Pd_2(dba)_3$ (2.5 mol%), etpo (etpo/Pd = 2), $C_6D_6$, 110 °C, 2 h

**4** **5**

L = etpo, L/Pd = 2, 2 h, 98% (**4**:**5** = 81:19)

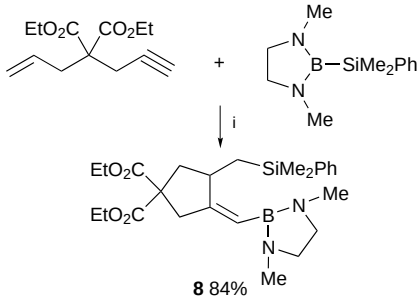
L = etpo, L/Pd = 1, 2 h, 97% (**4**:**5** = 87:13)



L = $PMe_3$, L/Pd = 2, 2 h, 84% (**4**:**5** = 30:70)

L = $PPh_3$, L/Pd = 2, 7 h, 98% (**4**:**5** = 26:74)

**Scheme 3** *Reagents and conditons*: i, $Pd_2(dba)_3$ (2.5 mol%), ligand (L/Pd = 2 or 1), $C_6D_6$, 110 °C



A decrease in the quantity of etpo relative to palladium is envisioned to be favourable to minimize the formation of byproduct **5** if simultaneous coordination of both acetylenic bonds to palladium is a prerequisite for the cyclization leading to **4**. Indeed, the reaction of hepta-1,6-diyne with **1** at etpo/Pd = 1 under otherwise identical conditions resulted in a slight increase in the selectivity for **4**; the **4**:**5** ratio was 87:13, obtained in a 97% combined yield. The reaction of octa-1,7-diyne with **1** was slightly less reactive and much less selective for the cyclization product **6**,† with **7** as the major product (Scheme 4). The selectivity was not appreciably improved even when etpo/Pd = 1, indicating the necessity for a new design of catalyst to circumvent the difficulty of coordination of both acetylenic bonds.

Finally an enyne compound, 4,4-bis(ethoxycarbonyl)hept-6-en-1-yne, also smoothly underwent similar cyclization with **1**

**6** 17% **7** 62%

**Scheme 4** *Reagents and conditions*: i, $Pd_2(dba)_3$ (2.5 mol%), etpo (etpo/Pd = 2), $C_6D_6$, 110 °C, 2 h

**8** 84%

**Scheme 5** *Reagents and conditions*: i, $Pd_2(dba)_3$ (2.5 mol%), etpo (etpo/Pd = 2), $C_6D_6$, 110 °C, 2 h

to give **8**† in 84% yield (Scheme 5). The $^1$H NMR spectrum of the reaction mixture displayed a weak singlet at δ 6.48, suggesting the formation of a small quantity (9%) of a byproduct, which might have come from plain addition of **1** to the triple bond.

Partial financial support from the Science and Technology Corporation (JST) through the CREST program is gratefully acknowledged. We thank Dr T. Sakakura for valuable discussions in the initial stages of the research.

# Lewis acid promoted aziridination of imines with semistabilized sulfonium ylides: highly stereoselective synthesis of vinyl- and ethynyl-aziridines

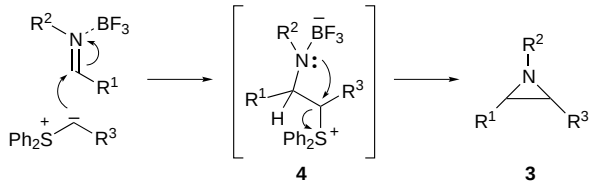
**De-Kun Wang, Li-Xin Dai and Xue-Long Hou***

*Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Lu, Shanghai 200032, P.R.C.*

***cis*-Vinyl- and *cis*-ethynyl-aziridines are furnished in high yields and high stereoselectivity by aziridination of unactivated *N*-aryl or *N*-alkyl imines with S-ylides in the presence of Lewis acids.**

The addition of carbenoids[1] or ylides[2] to a C=N double bond has been demonstrated as a synthetic strategy for asymmetric aziridination in recent years, and is regarded as an alternative methodology to the reaction between nitrenoids and a C=C double bond.[3] However, the ylide and carbenoid methodologies can only be applied to an activated imine, that is to C=N double bonds with an *N*-electron withdrawing group (*N*-EWG), such as *p*-tolylsulfonyl (tosyl),[1a,2] diphenylphosphinyl (DPP)[2a,4] or 2-(trimethylsilyl) ethylsulfonyl (SES).[2a] Although the preparation of aziridines from an unactivated imine with an ylide has been documented, the ylide used is restricted to active ylides such as dimethylsulfonium methide or dimethylsulfoxonium methide, *i.e.* methylene transfer to C=N bond. No report has appeared of the reaction of an unactivated imine with a semistabilized or stabilized ylide. Considering the vigorous conditions required for the deprotection of the tosyl group from the *N*-atom[5] and the difficulties in the preparation of *N*-tosyl,[6a,b] *N*-DPP[6c] and *N*-SES[6d] imines from certain carbonyl compounds, developing a general and facile method for the aziridination of common *N*-alkyl and *N*-aryl imines with stabilized or semistabilized ylides is still a challenge. Encouraged by the successful activation of imines by Lewis acids in the allylation reaction,[7] we examined $BF_3$·$OEt_2$ and $Me_3SiCl$ activation of imines in the ylide reaction for the preparation of vinyl- and ethynyl-aziridines. In a recent paper,[8] ethyl diazoacetate was used to react with a $BF_3$·$OEt_2$ activated imine in the preparation of aziridines, which promoted us to report our own results. Thus, a new and general ylide aziridination of common *N*-alkyl and *N*-aryl imines with semistabilized allylic or prop-2-ynylic sulfonium ylides in the presence of $BF_3$·$OEt_2$ or $Me_3SiCl$ has been successfully realized not only with high yields but also with high stereoselectivity, and disclosed these results herein (Scheme 1).

**Scheme 1**



Treatment of a THF solution of sulfonium salts **2** with 1 equiv. of *n*-butyllithium at −78 °C for 15 min gave a deep-red solution of sulfonium ylide.[9] This was added to an equimolar THF solution of imine **1** and $Me_3SiCl$ (method A) or $BF_3$·$OEt_2$ (method B) at the same temperature with stirring. The temperature of the mixture was allowed to rise to room temperature, and aziridine **3** was formed as the only product. In the absence of $Me_3SiCl$ or $BF_3$·$OEt_2$, no aziridine **3** was formed even on extended stirring under the same conditions. In terms of the yield of aziridine, the reaction proceeded more efficiently using $BF_3$·$OEt_2$ as Lewis acid (method B) than $Me_3SiCl$. The ratio of the *cis*- and *trans*-products was determined by $^1H$ NMR analysis. Our best results were obtained in THF in the presence of 4 Å molecular sieves and are summarized in Table 1.†

As shown, a variety of aromatic aldimines, either *N*-aryl or *N*-alkyl, could be aziridinated with good to excellent yield, but aziridination failed when aliphatic aldimines were used as substrates. The stereoselectivity of the aziridination is strongly dependent on the nature of the group on the nitrogen atom of the imine: *N*-aryl aromatic aldimines gave purely the *cis*-aziridine (entries 1–12), while *N*-alkyl aromatic aldimines gave a mixture of *cis* and *trans* aziridines (entries 17–22). By not using an

[a] All reactions were carried out at −78 °C with a ratio of imine **1**: sulfonium salt **2**: $Bu^nLi$ = 1 : 1.1 : 1.1 on a 0.5 mmol scale in THF with 4 Å molecular sieves. [b] Method A: $Me_3SiCl$ used as activator; Method B: $BF_3$·$OEt_2$ used as activator. [c] Isolated yields based on imine. [d] Determined by 300 MHz $^1H$ NMR analysis.

**Scheme 2**

*N*-tosyl imine, this reaction can be extended to include cyclic imines, such as dihydroisoquinoline (entries 13–16).

Activation of the imine by complexion with the Lewis acids, followed by nucleophilic addition of the ylide, results in the formation of intermediate **4** (Scheme 2). Subsequent ring closure and loss of diphenyl sulfide gave aziridines **3**. Aggarwal[2a] and Yamamoto[10] recently rationalized the fact that the *cis*-aziridine isomer is the thermodynamic product. In our procedure, the *cis* stereoselectivity of the reaction might come from the 1,2-steric interaction in the three-membered ring between the aryl group (this is the largest group) and either of the substitutes. The mixture of *cis* and *trans N*-alkylaziridines may result from weak steric interaction among the substituents on the three-membered ring, thus giving almost no selectivity.

In summary, we have demonstrated an efficient method for the preparation of various α-unsaturated substituted aziridines from aryl imines and semistabilized prop-2-ynylic and allylic sulfonium ylides in the presence of $BF_3$•$OEt_2$ with high *cis*-selectivity. It extends the scope of the ylide route to aziridination, without the need to prepare an *N*-EWG imine, and may also be applied to cyclic imines. In comparison to the recent work of diazoacetate with imines,[8] the present method gives higher yields with high *cis*-stereoselectivity and no sign of the formation of significant amounts of by-product. It represents an improvement over our previous routes[2b,c] and may be applied to the preparation of functionalized aziridines. The introduction of chirality into this reaction is being investigated.

† *Typical experimental procedure*: A 25 ml flask containing a magnetic stirrer bar was charged with sulfonium salt **2m** (240 mg, 0.6 mmol), 4 Å molecular sieves (1 g) and anhydrous THF (4 ml), the mixture was cooled to −78 °C under $N_2$, and treated with $Bu^nLi$ (0.4 ml; 1.6 M in hexanes) (Aldrich) with stirring. After 15 min, a mixture of imine **1a** (91 mg, 0.5 mmol) and $BF_3$•$OEt_2$ (1.0 equiv.) was added at the same temperature and stirring was continued until the temperature rose to room temperature. The reaction mixture was filtered on a short column of neutral $Al_2O_3$ to remove inorganic salts. The filtrate was concentrated and chromatographed on a column of neutral $Al_2O_3$ with light petroleum (bp 60–90 °C)–EtOAc–$NEt_3$ (10 : 1 : 0.5) as eluent to give pure *cis*-**3ma** (135 mg, 92%).

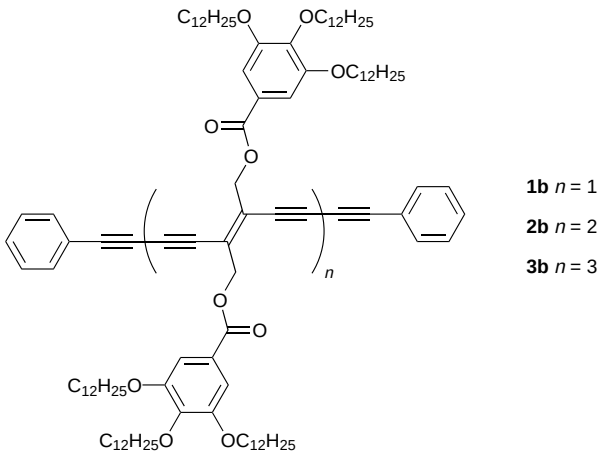
# Synthesis of liquid-crystalline oligotriacetylene derivatives

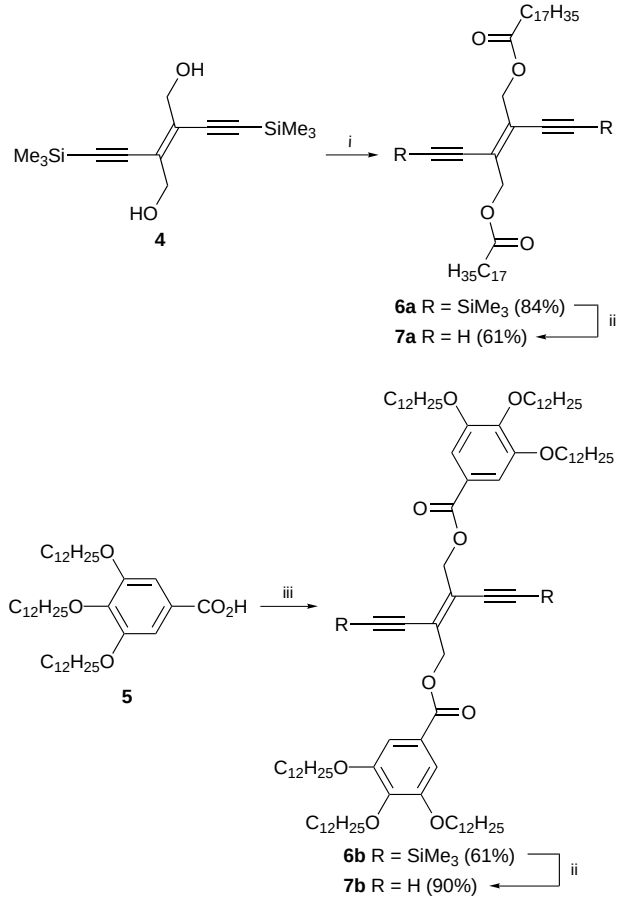
**Jean-François Nierengarten,* Daniel Guillon, Benoît Heinrich and Jean-François Nicoud**



*Groupe des Matériaux Organiques, Institut de Physique et Chimie des Matériaux de Strasbourg, UMR C00460, CNRS, 23 rue du Loess, F-67037 Strasbourg, France*

**(*E*)-Hex-3-en-1,5-diyne derivatives with two or six pendant long alkyl chains have been prepared and their end-capping oligomerisation yields oligomers with a polytriacetylene conjugated backbone; whereas the end-capped mono- and di-mers do not exhibit any liquid-crystalline behaviour, the trimeric derivatives show mesomorphic properties.**

The preparation of oligomers and polymers with extended conjugated carbon cores is currently being intensively pursued,[1] with the aim of generating advanced materials for electronic,[2] photonic,[3] and non-linear optical[4] applications. For many years, polyacetylenes (PA) and polydiacetylenes (PDA) were the only known single-strand conjugated polymers with a non-aromatic all-carbon backbone; however, Diederich and co-workers succeeded recently in the preparation of oligomers and polymers with a polytriacetylene (PTA) backbone.[5] Whereas introduction of bulky substituents in PA leads to loss of conjugation due to distortion from planarity for steric reasons,[6] side chains can be attached on PDA or PTA backbones without any loss of conjugation.[5] PDAs and PTAs are also considerably more stable than PAs.[5] However, the accessibility of PDAs is limited by the requirements resulting from their preparation by topochemical polymerisation of suitably pre-organised butadiynes,[7] while PTAs can be prepared by normal chemical reactions.[5] Here we report the synthesis of PTA oligomers **1**–**3** of defined length substituted with lateral long alkyl chains. The conjugated backbone is a rigid rod that can act as a mesogenic unit and liquid crystalline properties were observed for some of the reported oligomers. The advantage of such a liquid crystal is that many properties (electroluminescence, third order optical nonlinearity *etc*.) associated with the delocalised π-electron system can be enhanced due to the orientational effect induced by the liquid crystal ordering.[8]



**1a** *n* = 1
**2a** *n* = 2
**3a** *n* = 3

**1b** *n* = 1
**2b** *n* = 2
**3b** *n* = 3

The synthesis of the monomers is described in Scheme 1. Diol **4** was prepared in three steps from dimethyl acetylenedicarboxylate as previously reported.[5b] The (*E*)-hex-3-en-1,5-diyne derivatives with pendant long alkyl chains were prepared by dicyclohexylcarbodiimide (DCC)-mediated esterification[9] of stearic acid and acid **5**[10] with diol **4** to give **6a** (84% yield) and **6b** (61% yield), respectively. Subsequent deprotection of **6a** and **6b** with $Bu_4NF$ in wet THF afforded *trans*-endiyne **7a** (61% yield) and **7b** (90% yield), respectively. Whereas compound **7a** is relatively unstable in the neat state, **7b** is an air-stable solid that can be stored at ambient temperature for prolonged periods of time. As previously shown by X-ray

**Scheme 1** *Reagents and conditions*: i, stearic acid, DCC, DMAP, $CH_2Cl_2$, 0 °C to room temp.; ii, $Bu_4NF$, wet THF, 0 °C; iii, **4**, DCC, DMAP, $CH_2Cl_2$, 0 °C to room temp.

crystal structure analysis of some related compounds,[11] the presence of bulky substituents in **7b** isolates the sensitive *trans*-endiyne units and prevents intermolecular reactions that would lead to decomposition.

The PTA oligomers **1a**–**3a** and **1b**–**3b** were prepared *via* end-capping oligomerisation of **7a** and **7b**, respectively. The *in situ* preparation of the Hay catalyst[12] [CuCl–TMEDA–$O_2$ (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine)] in $CH_2Cl_2$ in the presence of **7a** and phenylacetylene furnished a mixture of oligomers, from which **1a**–**3a** were isolated by column chromatography ($SiO_2$, hexane–$CH_2Cl_2$ 3 : 2 to 1 : 2). When a large excess of phenylacetylene (10 equiv.) was used, **1a** and **2a** could be obtained in 25 and 5% yield, respectively. When **7a** and phenylacetylene were used in a 1 : 1 molar ratio, **1a** (9% yield), **2a** (5%) and **3a** (2%) could be isolated. End-capped oligomers **1b**–**3b** were prepared from **7b** and phenylacetylene under Hay coupling conditions in $CH_2Cl_2$ in a similar manner. Starting from phenylacetylene and **7b** in a 10 : 1 ratio, **1b** and **2b** were obtained in 64 and 7% yield, respectively. When a 1 : 1 molar ratio was used, **1b** (15% yield), **2b** (19%) and **3b** (12%) could be isolated by column chromatography ($SiO_2$, hexane–$CH_2Cl_2$ 2 : 1 to 1 : 1). Higher oligomers could also be eluted by using $CH_2Cl_2$ but could not be separated into pure compounds. Whereas the yields for the preparation of **1b**–**3b** are similar to that reported for related reactions,[5a] the yields of **1a**–**3a** are limited by the instability of monomer **7a** as well as by their surprisingly low solubility. All of the spectroscopic studies and elemental analysis results were consistent with the proposed molecular structures.† In spite of the presence of bulky substituents in **2b** and **3b**, their absorption spectra are similar to those of **2a** and **3a**, respectively, showing that there is no loss of conjugation as a result of a distortion from planarity for steric reasons. Compounds **2a** and **2b** show end absorption around 450 nm, and **3a** and **3b** around 500 nm.

Whereas the end-capped mono- and di-mers do not exhibit any liquid-crystalline behaviour, the trimeric derivatives **3a** and **3b** show mesomorphic properties. These have been deduced from optical and X-ray diffraction investigations. Polarised optical microscopy revealed a fluid birefringent phase at room temperature for **3b** and between 80 and 115 °C for **3a**. The clearing temperature was determined to be 40 °C for **3b**. However, in both cases, the birefringent optical textures observed on cooling the samples from the isotropic phase were non-characteristic.[13] Furthermore, the X-ray diffraction pattern of **3b** is typical of a mesomorphic phase with a sharp diffraction peak in the small angle region and a diffuse band in the wide angle region (Fig. 1). For **3a**, the diffraction patterns recorded at various temperature are more complex. The exact structure determination of these mesophases is still in progress.

The preparation of PTA oligomers with pendant long alkyl chains leads to original liquid crystalline derivatives. The synthesis of the corresponding polymers is now under investigation in our laboratory.

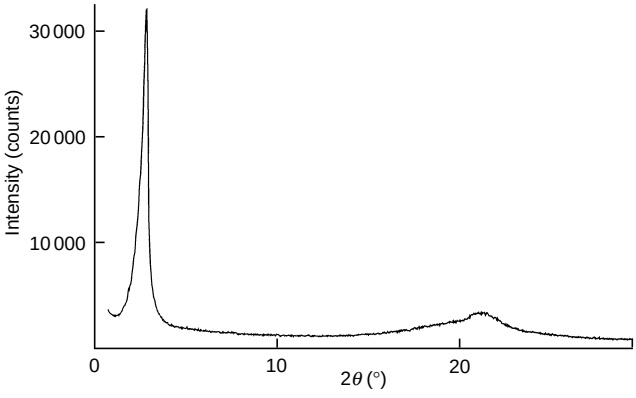


**Fig. 1** X-Ray diffraction pattern of **3b** recorded at 25 °C

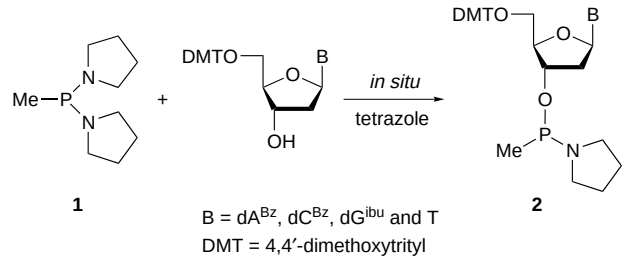
# *In situ* generation of methylphosphonamidites for synthesis of oligonucleotide methylphosphonates

**Zhaoda Zhang,* Alexandra Nichols, Jimmy X. Tang and Jin Yan Tang**



*Hybridon, Inc., 155 Fortune Boulevard, Milford, MA 01757, USA*

**5′-DMT-nucleoside methylphosphonamidites are generated *in situ* by selective activation of methylbis-(pyrrolidino)phosphine 1, and used effectively in the automated synthesis of oligonucleotide methylphosphonates.**

Methylphosphonates or the corresponding mixed backbone oligonucleotides, which contain non-ionic internucleotide linkages, have been successfully used in gene expression studies and have demonstrated their potential for development as antisense therapeutics.[1] Oligonucleotide methylphosphonates are generally prepared using methylphosphonamidite synthons. Since the methylphosphonate backbone is susceptible to hydrolysis by aqueous basic solutions, some modified methods have been developed to improve their synthesis.[2–4] However, a major limiting factor for cost efficient synthesis of oligonucleotide methylphosphonates is the time and cost required to synthesize and purify nucleoside methylphosphonamidites. One potential approach in solving this problem is to generate the methylphosphonamidite *in situ.* Although several laboratories have studied the *in situ* methodology for the syntheses of phosphodiester, phosphorothioate and radiolabelled oligonucleotides,[5–10] to the best of our knowledge none have used *in situ* methods for the synthesis of oligonucleotide methylphosphonates.

In an effort to develop oligonucleotide methylphosphonate analogues as antisense therapeutics, we have investigated the *in situ* approach in order to achieve an economical synthetic process. A series of methylphosphitylating reagents were prepared and examined.[11] We report herein our preliminary results for *in situ* generation of nucleoside methylphosphonamidites using a methylphosphordiamidite, methyl-bis-(pyrrolidino)phosphine[12]† **1**, for oligonucleotide methylphosphonates synthesis.

The *in situ* generation of nucleoside methylphosphonamidites was first studied using $^{31}$P NMR spectroscopy. The reactions were carried out at room temperature using **1** and 5′-DMT-nucleosides (dA$^{Bz}$, dC$^{Bz}$, dG$^{iBu}$ and T) in the presence of tetrazole. The results showed that although **1** was activated by 1 equiv. of tetrazole to react with 5′-DMT-nucleosides immediately, the reaction did not give the desired products (the corresponding 5′-DMT-nucleoside methylphosphonamidites) selectively under these conditions. The major side products were identified as 3′-3′ dimers.‡ To avoid this problem, a series of different reaction conditions were examined. The results show that the corresponding 5′-DMT-nucleoside methylphosphonamidites were formed exclusively by selective activation of **1** using 0.2–0.3 equiv. of tetrazole (Scheme 1). Typically, 0.10 ml (0.045 mmol) of a 0.45 M tetrazole solution in MeCN was added to a solution of 5′-DMT-thymidine (81.7 mg, 0.15 mmol) and **1** (28 mg, 0.15 mmol) in $CDCl_3$ (1.0 ml). After stirring for 10 min at room temperature, the solution was transferred into an NMR tube and examined by $^{31}$P NMR spectroscopy. The NMR results indicated that the corresponding 5′-DMT-thymidine methylphosphonamidite **2**-**T** was formed in a ratio of 97 : 3 as compared to the 3′-3′ dimer. Similar results were obtained for the other 5′-DMT-nucleosides (dA$^{Bz}$, dC$^{Bz}$ and dG$^{iBu}$).

**Scheme 1**

To further evaluate this approach, we prepared *in situ* a 0.1 M solution of 5′-DMT-thymidine methyl(pyrrolidino)phosphonamidite **2**-**T** on a 5 mmol scale.§ To make certain that 5′-DMT- thymidine was exclusively transformed into **2**-**T**, the *in situ* amidite solution was examined using $^{31}$P NMR spectroscopy. Since 5′-DMT-thymidine can not be detected in $^{31}$P NMR spectroscopy, an internal standard had to be used to determine the amount (or concentration) of **2**-**T** generated. In this way, 0.5 ml of a 0.1 M solution of 5′-DMT-thymidine methyl(diisopropylamino)phosphonamidite **3**-**T** (PerSeptive Biosystems, Framingham, MA) in $CDCl_3$ was mixed with 0.5 ml of an *in situ* generated solution of **2**-**T**, and examined by $^{31}$P NMR spectroscopy (Fig. 1).

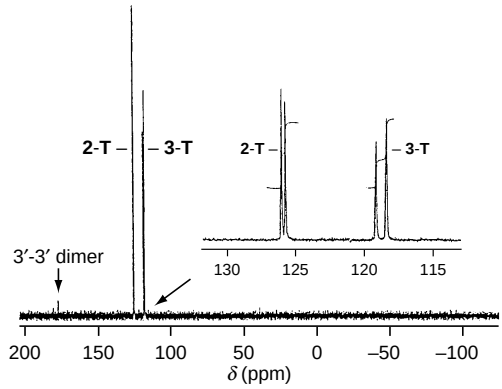


**Fig. 1** $^{31}$P NMR analysis of the methylphosphonamidite **2**-**T** solution generated *in situ*

As Fig. 1 shows, integration for compounds **2**-**T** (δ 126) and **3**-**T** (δ 119) was the same, and the 3′-3′-dimer (δ 177) was formed in less than 3% yield. The NMR results indicated that 5′-DMT-thymidine was almost quantitatively transformed into **2**-**T**, and a 0.1 M solution of **2**-**T** was prepared *in situ.*

To evaluate their effectiveness in automated solid-phase DNA synthesis, a 16-mer of oligonucleotide methylphosphonate, 5′-dT$_s$T$_s$T$_s$T$_s$T$_s$T$_{Me}$T$_{Me}$T$_{Me}$T$_{Me}$T$_{Me}$T$_{Me}$T$_{Me}$T$_{Me}$T$_{Me}$T-3′ **16T**, was synthesized as a model to test the methylphosphonamidite generated *in situ.*¶ This oligomer consists of ten methylphosphonate linkages (PMe) at the 3′-end and five phosphorothioate linkages (PS) at the 5′-end. The coupling efficiency of *in situ* amidite **2**-**T** was studied by measuring

spectrophotometrically the dimethoxytrityl cation (λ 498 nm) released at each cycle and by analysing the final product. The synthesis was carried out using a 0.1 M solution of **2-T** prepared *in situ* (used in the first ten coupling cycles) followed by a commercial 5′-DMT-thymidine-2-cyanoethoxy(*N*,*N*-diisopropylamino)phosphoramidite **T**, (PerSeptive Biosystems). The commercial methylphosphonamidite **3-T** was also examined in the synthesis of **16T** as a comparison. The results showed that methylphosphonate linkages can be synthesized using **2-T** prepared *in situ* with an average stepwise yield of 98%. The coupling yield was the same as that of the commercial methylphosphonamidite **3-T**. The *in situ* amidite 2-T was also found to be stable for at least one week. The capillary gel electrophoresis (CE) result of **16T** synthesized using one week old *in situ* amidite solution was nearly identical to that of freshly prepared *in situ* amidite solution. The CE and $^{31}$P NMR analysis results of the crude oligonucleotide **16T** are given in Figs. 2 and 3.

In summary, our studies show that the methylphosphordiamidite **1** can be selectively activated to react with deoxyribonucleosides, and chemoselectively generate the corresponding deoxyribonucleoside methylphosphonamidites *in situ*. The *in situ* methodology using **1** is easily adapted to the current phosphoramidite approach for the synthesis of oligonucleotide methylphosphonates. This method may find applications in large-scale syntheses of oligonucleotide methylphosphonates and in the synthesis of oligonucleotide methylphosphonate analogues containing modified nucleosides[13] as well as radioisotopically labelled nucleosides .

† Compound **1** was prepared in 79% yield from methyldichlorophosphine and 1-(trimethylsilyl)pyrrolidine. $^{31}$P NMR ($CDCl_3$): δ 64.1.

‡ A 3′-3′ dimer was also synthesized by the reaction of methyldichlorophosphine (1.0 equiv.), 5′-DMT-thymidine (2.5 equiv.) and triethylamine (2.5 equiv) in $CH_2Cl_2$. $^{31}$P NMR ($CDCl_3$): δ 177.5.

§ To 5.0 mmol (2.72 g) of 5′-DMT-thymidine in THF (15.0 ml) was added a solution of **1** (0.93 g, 5.0 mmol) in MeCN (30.0 ml) at room temperature. The solution was stirred for 1 min. To the solution was added dropwise a 0.45 M solution of tetrazole (1.5 mmol, 3.3 ml) in MeCN. The mixture was stirred for 5 min, and then the thymidine methylphosphonamidite solution (0.1 M) was ready to use.

¶ The oligonucleotide methylphosphonate **16T** was synthesized on a 1 μmol scale using an automated synthesizer (Millipore 8909 Expedite™, Bedford, MA). For methylphosphonate linkages the synthesis was carried out using a modified protocol, in which capping was performed after the iodine oxidation step. An oxidizing agent of low water content (0.1 M $I_2$ in THF–lutidine– $H_2O$, 74.75 : 25 : 0.25) was used to minimize backbone hydrolysis.[2] Treatment (2 h) with 7 M ammonia in MeOH at 55 °C was carried out to cleave the oligomer from the support.[3] The mixture was filtered to remove the CPG. After the $NH_3$–MeOH solution was removed by lyophilisation (Speed Vac, Savant Instruments Inc., Farmingdale, NY), the remaining crude products were submitted for CE, RP-HPLC, NMR and MALDI-TOF analysis. MS (MALDI-TOF): calc. for **16T** (M + H) 4867. Found, 4868.

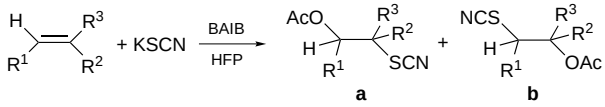
# Hypervalent iodine-induced oxidative nucleophilic additions to alkenes: a novel acetoxy thiocyanation reaction in 1,1,1,3,3,3-hexafluoropropan-2-ol



**Antonella De Mico,[a] Roberto Margarita,[a] Andrea Mariani[a] and Giovanni Piancatelli*[b]**

[a] *Centro CNR di Studio per la Chimica delle Sostanze Organiche Naturali (Associated to Istituto Nazionale di Coordinamento 'Chimica die Sistemi Biologici'), Università 'La Sapienza', P.le A. Moro 5, 00185 Roma, Italy*
[b] *Dipartimento di Chimica, Università 'La Sapienza', P.le A. Moro 5, 00185 Roma, Italy*

**The combination of [bis(acetoxy)iodo]benzene and thiocyanate anion in a polar, protic non nucleophilic solvent such as 1,1,1,3,3,3-hexafluoropropan-2-ol is able to perform an oxidative nucleophilic addition to alkenes, leading to acetoxy thiocyanate derivatives, stereoselectively and with good regioselectivity.**

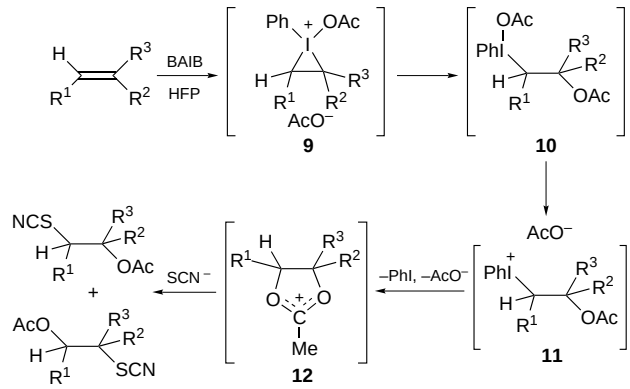
1,1,1,3,3,3-Hexafluoropropan-2-ol (HFP) is described as a non-nucleophilic, strongly ionising solvent,[1] and seems to be the only solvent which is more polar than water on the Reichard $E_T$ scale.[2] The strongly stabilising influence of HFP upon electrophilic intermediates has been utilised to study chemical reactions which proceed *via* the formation of both cations and radical cations.[3,4] Additionally, the weak acidic character of HFP ($pK_a$ = 9.3) has been reported to affect the reactivity of charged nucleophiles.[5]

Our interest in the chemistry of hypervalent iodine(III) reagents[6] prompted us to exploit the reactivity of [bis(acetoxy)-iodo]benzene (BAIB) in HFP. We report herein the use of BAIB, HFP and thiocyanate anion, as nucleophile, to perform a novel stereospecific and regioselective acetoxy thiocyanation reaction with alkenes. The overall transformation is a fast, one-pot formal addition of AcOSCN to a double bond, which must be considered an interesting outcome. (Scheme 1).

**Scheme 1**

The BAIB–KSCN ratio plays a pivotal role on the outcome of the reaction. Since the reactivity of hard nucleophiles exhibits strong deactivation in HFP,[5] an excess of BAIB has to be added to suppress the formation of dithiocyanate derivatives. Parallel experiments in other non-nucleophilic aprotic solvents provided exclusively dithiocyanate derivatives.[6]

Our results clearly show that the reactions proceed *via* a reactive intermediate which is electrophilic in nature, and can be explained by referring to the mechanism described for the hypervalent iodine(III) reagent by Moriarty *et al.*[7] In HFP ($\varepsilon_r$ = 22.3), BAIB may undergo an ionisation process (eqn. 1) and



(1)

then an electrophilic addition to the alkene may follow yielding the intermediate **9**, subsequent addition of the acetoxy anion giving **10** (Scheme 2). An intramolecular $S_N2$ displacement of iodobenzene by the neighbouring acetoxy substituent leads to the cyclic intermediate **12**. Regioselective opening by thiocyanate anion furnishes the acetoxy thiocyanate derivatives.† Competing addition on **9** by thiocyanate leading to dithiocyanates may occur (Table 1, entries 6 and 7). The stereochemical outcome can be explained through the intermediate **12** since other reported mechanisms would yield the *cis* rather than *trans* products.[7,8]

The stereospecificity of the reaction seems to exclude competing radical processes. The formation of 1-(2-thiocyanoethyl)cyclohexene in entry 4, although in low yields (2–5%), reveals the occurrence of an ionic addition pathway since the above product clearly rises from an 1,2 proton shift of the initial formed secondary carbocation to the more stable tertiary one and subsequent elimination.

The acetoxy thiocyanation reaction has proven to be particularly successful with terminal alkenes (R = H), where a high regioselectivity is achieved, meanwhile it is only fair with non symmetrically substituted ones (compare Table 1 entries 2 and 5). Synthetic utility is very important with symmetrical and cyclic systems, where the addition is regio- and stereo-specific. This is also a valid method for the dissymmetrisation of olefinic compounds.

The reaction with methylcyclohexene, a more substituted system, furnishes transposition and elimination products as well as the expected acetoxy thiocyanate. Electron poor systems were recovered unreacted from the reaction medium, while

**Scheme 2**

**Table 1** Acetoxy thiocyanation of alkenes with BAIB–KSCN in HFP

| Entry | $R^1$ | $R^2$ | $R^3$ | Yield[a] (%) | Regio-selectivity (**a**/**b**) | Stereo-specificity |
|---|---|---|---|---|---|---|
| 1 | Butyl | H | H | 90 | 83/17 | — |
| 2 | Hexyl | H | H | 90 | 83/17 | — |
| 3 | Octyl | H | H | 90 | 83/17 | — |
| 4 | Cyclohexyl | H | H | 80 | 63/37 | — |
| 5 | Pentyl | H | Me | 80 | 63/37 | *anti* |
| 6 | –$(CH_2)_4$– | | H | 80[b] | > 99 | *anti* |
| 7 | –$(CH_2)_5$– | | H | 55[c] | > 99 | *anti* |

[a] The reported yields refer to isolated, chromatographically pure compounds. All the structures have been confirmed by IR, $^1$H NMR and $^{13}$C NMR analysis. [b] Additional 10% of *anti* dithiocyanate derivative was isolated. [c] Additional 30% of *anti* dithiocyanate derivative was isolated.

electron rich ones, such as dihydropyran, provided diacetoxy and dithiocyanate derivatives as the main products; this latter reactivity may be ascribed to the high stability of the cationic intermediate. Styrene derivatives immediately underwent a polymerisation process when they were dissolved in HFP; this phenomenon is probably catalysed by the acidity of the reaction medium. All the collected data are in agreement with the suggested reaction mechanism.

In conclusion, our studies on the reactivity in HFP show it to be very promising, and the results broaden the utility of BAIB, opening a route to new synthetic applications in organic chemistry. Research in this field is currently in progress, since acetoxy thiocyanate and dithiocyanate derivatives have been shown to possess good fungicidal activity.

† Typical experimental procedure: a solution of the alkene (1 mmol) in 4 ml of HFP was treated with 1.2 mmol of KSCN and 4 mmol of BAIB and the resulting reaction mixture is stirred at room temperature for 20 min. The reaction was quenched with saturated aqueous $Na_2S_2O_3$ (5 ml) and extracted with EtOAc (4 × 5 ml). The combined organic extracts were washed with aqueous $NaHCO_3$ and brine, dried over anhydrous $Na_2SO_4$, and concentrated under reduced pressure. Column chromatography on $SiO_2$ (light petroleum–EtOAc) afforded pure products.

$^1$H NMR spectra ($CDCl_3$) for **2a**: 5.1 (1 H, m), 3.2 (1 H, dd, *J* 3.9 and 14.0 Hz), 3.0 (1 H, dd, *J* 6.5 and 14.0 Hz), 2.1 (3 H, s), 1.9–1.1 (10 H, m), 0.85 (3 H, t). For **2b**: 4.3 (1 H, dd, *J* 5.1 and 12.0 Hz), 4.2 (1 H, dd, *J* 7.2 and 12.0 Hz), 3.3 (1 H, m), 2.1 (3 H, s), 1.9–1.1 (10 H, m), 0.85 (3 H, t). For **6a**: 4.7 (1 H, dt, *J* 10.3 and 4.6 Hz), 3.1 (1 H, dt, *J* 10.3 and 4.3 Hz), 2.3–2.0 (2 H, m), 2.06 (3 H, s), 1.9–1.1 (6 H, m). For **7a**: 4.9 (1 H, ddd, *J* 9.0, 3.7 and 7.4 Hz), 3.4 (1 H, dt, *J* 9.0 and 3.4 Hz), 2.3–2.0 (2 H, m), 2.08 (3 H, s), 2.0 1.4 (8 H, m).

$^{13}$C NMR spectra ($CDCl_3$) for **2a**: 171.0 (C=O), 112.5 (SCN), 72.2, 37.8, 33.2, 31.4, 28.4, 29.6, 22.4, 21.0, 13.9. For **2b**: 171.0 (C=O), 110.4 (SCN), 66.1, 48.9, 33.2, 31.4, 28.4, 29.6, 22.4, 21.0, 13.9. For **6a**: 170.5 (C=O), 111.1 (SCN), 74.9, 51.5, 32.6, 32.3, 25.7, 23.8, 21.1. For **7a**: 170.5 (C=O), 111.8 (SCN), 77.8, 54.6, 32.5, 32.0, 27.8, 25.7, 22.3, 21.2.

IR spectra ($CHCl_3$, $cm^{-1}$) for **2a**: 2140 (SCN, sharp peak), 1733 (C=O, broad peak). For **2b**: 2140 (SCN, sharp peak), 1735 (C=O, broad peak). For **6a**: 2175 (SCN, sharp peak), 1730 (C=O, broad peak). For **7a**: 2145 (SCN, sharp peak), 1730 (C=O, broad peak).

# Zirconaindane phospholanes: key reagents for the synthesis of mono- or tri-cyclic phosphanes and related species

**M. Zablocka,[a] A. Igau,[b] B. Donnadieu,[b] J.-P. Majoral,*[b] A. Skowronska*[a] and P. Meunier*[c]**

[a] *Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cedex, France*

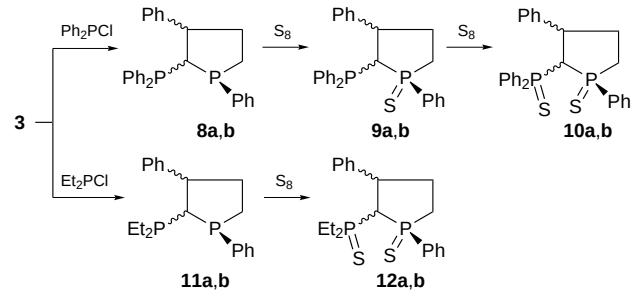
**The zirconaindane phospholane 3 reacts either with $PhSbCl_2$ or $Me_2SnCl_2$ to give tricyclic systems incorporating phosphorus, antimony or tin; the same reaction involving 3 and $R_2PCl$ (R = Ph, Et) leads to acyclic–cyclic diphosphanes.**

There is an extensive literature on the topic of cyclic phosphanes such as phospholanes, phospholenes or phospholes.[1] In contrast only a limited number of fused bicyclic and tricyclic phosphanes have been prepared and only very recently a few tricyclic 1,1-diphosphanes were described.[2] As far as we are aware, fused tricyclic systems incorporating phosphorus and other heavier main group elements, are not known. With this in mind we became interested in developing synthetic routes to these species because of the intrinsic interest in phosphane and polyphosphane derivatives as reagents for mediating organic transformations or as ligands for complex formation and use in catalysis.

This prompted us to initiate the chemistry of the zirconaindane phospholane **3** which was regioselectively prepared *via* the treatment of 1-phenyl-2-phospholene PhP–CH=CHCH$_2$CH$_2$ **1** with the transient (benzyne)zirconocene [($\eta$-$C_5H_5$)$_2$Zr($\eta^2$-$C_6H_4$)] **2**. [2] Here we will detail the formation, from **3**, of unusual phosphorus and antimony (or tin) tricyclic systems as well as that of new acyclic–cyclic diphosphanes.

Reactions of **3** with $PhSbCl_2$ in benzene at 5 °C for 1 h led to the stibaphospholane **4** [$\delta$($^{31}$P) 5.9] which was isolated in 80% yield as its sulfide adduct **5** [$\delta$($^{31}$P) 61.9] (Scheme 1). The formulation of **5** was confirmed by NMR spectroscopy,[3] mass spectrometry (FAB [M + 1]$^+$ 470) and by elemental analysis.

An analogous exchange reaction performed with **3** and $Me_2SnCl_2$ at 0 °C for 3 h gave the tin–phosphorus containing tricyclic species **6** [$\delta$($^{31}$P) 5.6] which was also fully characterized as its sulfide adduct **7** obtained in 75% yield [$\delta$($^{31}$P) 64.1)] (Scheme 1). NMR data corroborated such an assignment.† Compounds **4**–**7** are the first examples of fused tricyclic systems incorporating phosphorus and antimony or phosphorus and tin in the cyclic skeleton.



**Scheme 1**

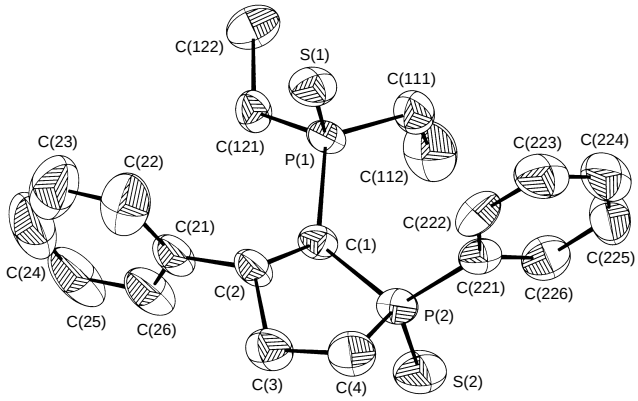
All these reactions proceeded with ring retention. In contrast an exchange reaction with concomitant ring opening was observed when **3** was reacted with a chlorophosphane such as $Ph_2PCl$ at −40 °C for 1 h (Scheme 2). The 1,1-diphosphane **8** was obtained as two isomers **8a**,**b** in a 4 : 1 ratio as shown by $^{31}$P NMR spectroscopy: two doublets at $\delta$ 5.1 (PPh) and −12.0 ($PPh_2$) ($^2J_{PP}$ 7.8 Hz) for the major compound and $\delta$ 3.9 (PPh) and −16.3 ($PPh_2$) ($^2J_{PP}$ 19.5 Hz) for the minor one. Monosulfurization occurred regioselectively on the intracyclic phosphorus atom by adding 1 equiv. of elemental sulfur to **8a**,**b** and led to the adducts **9a**,**b** {two isomers in a 4 : 1 ratio. $\delta$($^{31}$P): 65.5 [P(S)Ph] and −9.6 ($PPh_2$), $^2J_{PP}$ 31.5 Hz (major); $\delta$ 64.1 [P(S)Ph] and −11.8 ($PPh_2$), $^2J_{PP}$ = 31.5 Hz (minor)}. Further addition of a second equivalent of sulfur led predominantly to the formation of the disulfide **10a** {$\delta$($^{31}$P) 65.2 [P(S)Ph] and 43.3 [P(S)$Ph_2$], $^2J_{PP}$ 0 Hz} isolated by silica gel column chromatography.‡ $^{13}$C and $^1$H NMR spectra coupled with mass spectrometry and microanalytical data showed clearly that cleavage of the two zirconium–carbon bonds occurred with grafting of the diphenylphosphino group in $\alpha$ position to the intracyclic P–Ph moiety.

A similar ring opening process initiated also by an exchange reaction between **3** and a chlorophosphane was detected when **3** was reacted with $Et_2PCl$. Addition of sulfur to the resulting 1,1-diphosphanes **11a**,**b** (two isomers) led to the 1,1-dithiodiphosphanes **12a**,**b** (two isomers in 9 : 1 ratio). The major isomer **12a** was isolated by chromatography and fully characterized by NMR,† mass spectrometry and elemental analysis.

X-Ray structures have been obtained for **10a**[3] and for **12a** (Fig. 1):§ they showed similar features for the two derivatives. Indeed substituents on the intracyclic carbon atoms C(1) [P(S)$Ph_2$] and C(2) (Ph) of the phospholane ring are *cis* in both cases [P(1)–C(1)–C(2)–C(21) torsion angle: 85.7° for **10a**, 73.2° for **12a**] while the substituent on C(1) and the phenyl group on the phosphorus atom P(2) are *trans* [P(1)–C(1)–P(2)–C(221) torsion angle: 3.2° for **10a**, 14.0° for **12a**].

Remarkably the regioselectivity of the reaction of phospholene **1** with a more hindered benzyne zirconocene precursor such as ($\eta^5$-Bu$^t$$C_5H_4$)$_2$Zr$Ph_2$ was found to be the same: the zirconaindane phospholane **3″** was formed nearly quantitatively

**Scheme 2**



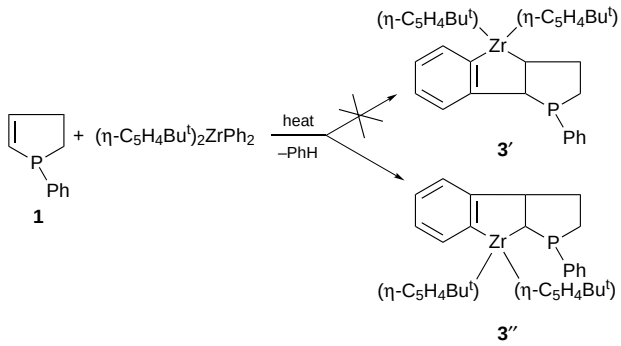


**Fig. 1** Molecular structure (CAMERON[6]) of **12a** with crystallographic numbering scheme. Selected bond lengths (Å) and angles (°): P(2)–C(1) 1.84 (1), P(2)–C(4) 1.80 (1), C(1)–C(2) 1.56 (1), C(2)–C(3) 1.53 (1), C(3)–C(4) 1.50 (2), P(2)–C(221) 1.82 (1); C(1)–P(2)–C(221) 112.8 (5), P(2)–C(1)–C(2) 105.7 (6), P(2)–C(1)–P(1) 124.0 (5).

**Scheme 3**

and no trace of **3′** was detected (Scheme 3). These results can be explained by considering that, whatever the steric hindrance encountered on zirconium, the regioselectivity of the reaction of zirconocene–benzyne complexes with phospholene **1** is governed by the transient formation of a zirconocene stabilized phosphorus benzyne complex leading in the final products **3** and **3″** to a P–Zr dative bond. Moreover, treatment of **3″** with $PhSbCl_2$ also led to the formation of the stibaphospholane **4**.

In conclusion, zirconaindane phospholanes **3** and **3″** appeared to be versatile reagents, leading to new mono- and tricyclic heavier main group element compounds *via* disubstitution reactions with ring retention (formation of **4**–**7**) or monosubstitution reactions with ring opening (formation of **10**, **12**).

§ *Crystal data* for $C_{20}H_{26}P_2S_2$ **12a**: $M$ = 392.49, monoclinic, space group $P2_1/n$, $a$ = 10.944 (1), $b$ = 12.033 (2), $c$ = 16.654 (1) Å, β = 107.114 (8)°, $U$ = 2096.3 Å$^3$, $Z$ = 4, $D_c$ = 1.24 g cm$^{-3}$, μ = 3.94 cm$^{-1}$. Crystal size: 0.35 × 0.15 × 0.35 mm, 1308 measured reflections (2740 independent), $R_{av}$ = 0.047, $R$ = 0.0540, $R_w$ = 0.070 from 1344 reflections with $I > 1.5\sigma(I)$. The data collection was performed at 293 K on a I.P.D.S. STOE diffractometer using graphite-monochromated Mo-Kα radiation for the two compounds. The structures were solved by direct methods using the program SIR92[4] and subsequent Fourier maps. The refinement of models were performed by using full-matrix least-squares techniques with the aid of the package CRYSTALS.[5] All hydrogen atoms were found on difference Fourier maps but they were introduced as fixed contributors with C–H = 0.96 Å and isotropic thermal parameters fixed 20% higher than those of the carbon atoms to which they were attached their positions were recalculated after each cyclic of refinement. For the two structures all non-hydrogen atoms were anisotropically refined. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/506.

# Synthesis of the LTA-type $AlPO_4$ in the presence of the diazapolyoxa macrocycle 'Kryptofix 222'

**L. Schreyeck, F. D'agosto, J. Stumbe, P. Caullet* and J. C. Mougenel**

*Laboratoire de Matériaux Minéraux-ENSCMu-URA 428, 3, rue Alfred Werner, 68093 Mulhouse Cedex, France*

**The LTA-type aluminophosphate can be synthesized from aqueous mixtures in the presence of a single structuring agent, hexaoxa-4,7,13,16,21,24-diaza-1,10-bicyclo[8,8,8]-hexacosane (possibly associated with $F^-$ ion as optional co-template) and is characterized through XRD, SEM, chemical analysis, thermal analysis and solid-state NMR spectroscopy.**

Microporous materials with the LTA structure were first synthesized in their aluminosilicate forms with $Na^+$ and possibly $NMe_4^+$ as templates.[1–4] Low phosphorus-substituted LTA-type aluminosilicates [with P/(P + Si + Al) molar ratios ranging from *ca.* 0.01 to 0.04] were then prepared by Kühl[5] and Lok *et al.*[6] from alkaline media in the presence of the same templates. During the 1990s, microporous LTA-type metallophosphates could be synthesized from near-neutral reaction mixtures but only in the presence of $F^-$ ions which act as co-template by structuring the D4R units of the framework. The synthesis of the gallophosphate was thus achieved in 1992[7] with the dipropylamine as the organic template, this species being incorporated in the large $\alpha$ cage of the structure. In 1994, Sierra *et al.*[8] prepared the aluminophosphate in the presence of two organic structuring agents, namely diethanolamine and tetramethylammonium cation, these species being occluded in the $\alpha$ cage and the sodalite cage respectively.

In this work, the LTA-type aluminophosphate was prepared with the hexaoxa-4,7,13,16,21,24-diaza-1,10-bicyclo[8,8,8]-hexacosane ('Kryptofix 222', hereafter K222) as the only organic template. In opposition to the previous experimental observations concerning the LTA-type metallophosphates, the presence of the co-templating $F^-$ ions is here only optional.

The molar composition of the used gels was 0.5 $Al_2O_3$ : 0.5 $P_2O_5$ : 0.25 K222 : 0.25 or 0 HF : 40 $H_2O$. These gels were prepared by first mixing the phosphoric acid aqueous solution (85 mass% $H_3PO_4$, Prolabo, Normapur) with the aluminium source [pseudoboehmite (Catapal B, 69 mass% $Al_2O_3$–31 mass% $H_2O$, Vista Chemical Co.) or aluminium triisopropoxide (Fluka)] and the required amount of distilled water; this mixture was stirred for 30 min at room temp. before the successive addition of the (optional) HF aqueous solution [40 mass% HF (Prolabo, Normapur)] and K222 (Merck, > 99%). After stirring for 1 or 14 h (depending on whether aluminium triisopropoxide or pseudoboehmite is used, respectively), the gel was finally transferred into a Teflon-lined stainless-steel autoclave which was then heated at 170 °C without agitation in an oil-bath (the time required to reach this temperature is < 5 min). After reaction, the solids were recovered by filtration, washed with distilled water, dried at 60 °C overnight and rehydrated at room temp. for one day at 80% relative humidity. As an example, the recovered mass of solid is *ca.* 120 mg when the gel is prepared with 163 mg of aluminium triisopropoxide, 92 mg of $H_3PO_4$ solution, 10 mg of HF solution, 75 mg of K222 and 560 mg of water. The volume of the autoclave used was *ca.* 20 $cm^3$.

In the presence of HF, fully crystallized samples of LTA-type $AlPO_4$ could be easily synthesized from either aluminium source used. For instance, in the presence of aluminium triisopropoxide, crystallization was already achieved after 6 h of reaction at 170 °C, whereas a large proportion of the recovered product remains amorphous after 1 h of heating.

On the other hand, from fluoride-free reaction mixtures, the formation of pure samples of LTA-type $AlPO_4$ was only possible when pseudoboehmite was used as the aluminium source (after 5 days of heating). When aluminium triisopropoxide was employed, a mixture of the LTA-type $AlPO_4$ and of an unidentified impurity was obtained after 5 days of reaction (this impurity could correspond to a layered compound according to the XRD data and the micrographs), whereas for shorter crystallization times (one or two days) only a partial transformation of the gel into the LTA-type $AlPO_4$ occurred. The reason for this strong influence of the nature of the aluminium source is questionable, but could be related to the difference observed between the initial pH values, *i.e.* close to 3 or 7 according to whether pseudoboehmite or aluminium triisopropoxide were used, respectively (the final pH was systematically close to 7–8).

The crystals prepared from fluoride-free or fluoride-containing mixtures display the same usual cubic shape already found for the other LTA-type materials (Fig. 1). The cubes are more or less truncated, their sizes ranging from < 1 μm to *ca.* 20 μm depending on the synthesis conditions used.

X-Ray diffraction patterns [STOE STADI-P diffractometer, equipped with a curved germanium (111) primary monochromator, Cu-K$\alpha_1$ radiation] of all samples (Fig. 2) are very similar to the pattern characteristic of the cubic LTA structure (space group *Fm*3*c*). Only small differences in the relative intensities are visible between the patterns of the fluoride-containing [Fig. 2(*a*)] and fluoride-free samples [Fig. 2(*b*)], the value of the *a* parameter for the latter being slightly smaller. Both parameter values are close to the value found by Sierra *et al.*[8] for a LTA-type structure aluminophosphate (Table 1).

Only the presence of the original template K222 is detected by solution $^1H$ NMR spectroscopy (Bruker AC250 spectrometer) on samples dissolved in 6 M HCl aqueous solution

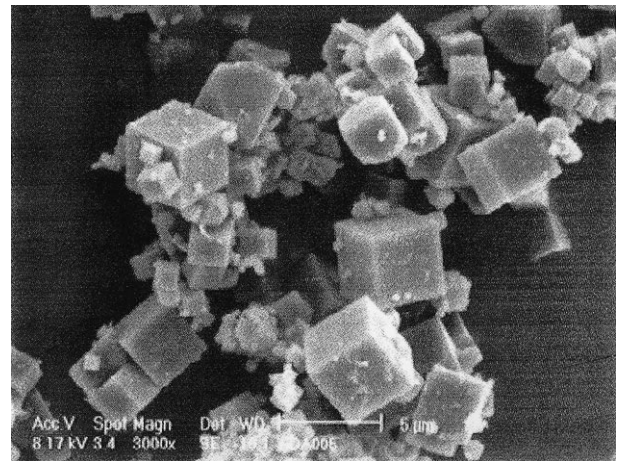

**Fig. 1** Micrographs of crystals of LTA-type $AlPO_4$ prepared at 170 °C from K222 and fluoride-containing media (Philips XL30 microscope)

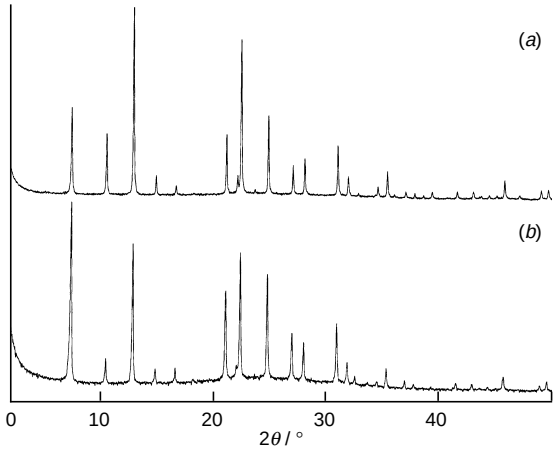

**Fig. 2** XRD patterns of the LTA-type $AlPO_4$ materials prepared in the presence of K222 from fluoride-containing (*a*) or fluoride-free media (*b*)

**Table 1** Values of the *a* parameter for as-made LTA-type $AlPO_4$ samples

| Template(s) occluded | *a*/Å |
|---|---|
| Kryptofix 222 + $F^-$ | 23.867(2) |
| Kryptofix 222 | 23.773(3) |
| Diethanolamine + $NMe_4^+$ + $F^-$[8] | 24.063(3) |

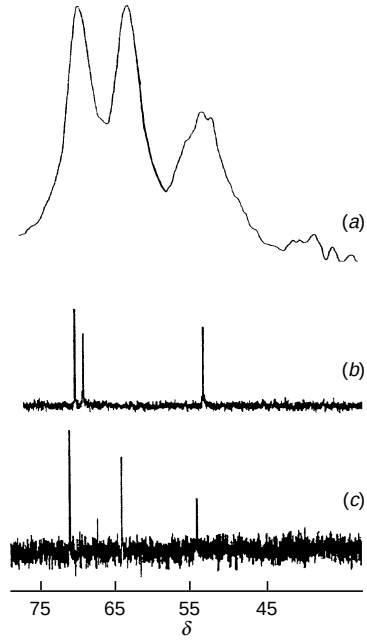

**Fig. 3** $^{13}C$ CP MAS NMR spectrum of an LTA-type $AlPO_4$ sample (*a*) and $^{13}C$ solution NMR spectra of K222 in basic (*b*) or acid (*c*) aqueous solution

(with dioxane as the internal standard). The content of K222 is close to 19 mass%, which corresponds to the incorporation of one K222 molecule per pseudocell (most probably in the large α cage). Samples prepared in the presence or absence of $F^-$ ions display the same $^{13}C$ CP MAS NMR spectrum (Bruker MSL 300 spectrometer) with three peaks at δ *ca.* 71, 65 and 55 (ref. TMS) [Fig. 3(*a*)]. These chemical shift values match more closely with those found for an acidic (pH *ca.* 3) aqueous solution of K222 [Fig. 3(*c*)] than with those measured for a basic (pH *ca.* 11) aqueous solution of K222 [Fig. 3(*b*)]. The K222 is thus probably incorporated in a diprotonated form.

According to the solution $^{19}F$ NMR spectroscopy (performed on samples dissolved in 6 M HCl solution with $CF_3CO_2H$ as the internal standard), the amount of fluoride is close to 1.8 mass% in the samples prepared from fluoride-containing mixtures, whereas, as expected, no fluoride is detectable in samples synthesized from fluoride-free media. Besides, the $^{19}F$ MAS NMR spectrum (not shown) of the fluoride-containing samples displays a unique signal (with sidebands) located at δ *ca.* −95 (relative to $CFCl_3$). Such a chemical shift value is characteristic of $F^-$ ions trapped in the D4R units of the structure of microporous aluminophosphates as previously found by Sierra *et al.*[8] (LTA-type $AlPO_4$) and Schott-Darie *et al.*[9] (AST-type $AlPO_4$). In each pseudocell, the two charges of the organic cation are compensated by two $F^-$ ions, which corresponds to the occupation of two thirds of the D4R units of the structure. In samples containing no fluoride, the positive charges of the organic species might be compensated by $OH^-$ ions.

The TG and DSC curves recorded under air (not shown) on a Setaram TG/DSC11 thermoanalyser are very similar for all samples. The first mass loss observed between 20 and 200 °C is close to 8% and can be probably attributed to the elimination of water, an endothermic signal occurring in this temperature range on the DSC curve. The remainder of the mass loss takes place between 200 and 700 °C (in two steps corresponding to two exothermic peaks at *ca.* 400 and 600 °C on the DSC curve) and amounts to *ca.* 20% which is in good agreement with the organic content determined previously from $^1H$ NMR experiments.

According to X-ray diffraction, on completion of the thermal treatment (*ca.* 750 °C) a partial amorphization occurs together with a partial conversion into tridymite. Even for calcination at lower temperatures, *e.g.* 550 °C for 4 h, a partial collapse of the structure occurs.

Finally from the experimental results above the idealized chemical formula of the unit cell can be written as

$$8\{(Al_{12}P_{12}O_{48})(X^-)_2(K222^{++})(H_2O)_8\}$$
where $X^- = F^-$ or $OH^-$

LTA-type $AlPO_4$ was previously obtained in the presence of three templates, *i.e.* diethanolamine, $F^-$ and $NMe_4^+$, each of them structuring one of the three polyhedra present, *i.e.* the α cage, the D4R unit and the sodalite cage, respectively. In this work, the LTA-type $AlPO_4$ was synthesized in the presence of Kryptofix 222 alone. This species, which is probably incorporated in the α cage, appears thus very well suited to preparation of this material. Although the presence of $F^-$ is clearly optional, the crystallization appears easier when these ions are present in the reaction mixtures. In this case $F^-$ ions are incorporated in the D4R units of the structure as co-templates.

Other organic templates of the same family are currently being tested in synthesis, possibly in association with $F^-$ ions but also with $NMe_4^+$ ions as potential co-templates.

# A computational study on zeolite MCM-22

**Swie Lan Njo,* Henk van Koningsveld and Bastiaan van de Graaf**

*Laboratory of Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands*

**Molecular-mechanics calculations show that the framework of zeolite MCM-22 minimizes to *P*6/*m* symmetry rather than to *P*6/*mmm* or *Cmmm* symmetry.**

MCM-22, first synthesized in 1990,[1] has been applied as a catalyst in several hydrocarbon conversion reactions.[2] Although many studies[3–6] have been dedicated to the elucidation of the framework structure of MCM-22, no structure type code[7] has, as yet, been assigned.

Leonowicz *et al.*,[3] who used high-resolution electron micrographs and synchrotron X-ray diffraction powder data, proposed that MCM-22 comprises two independent multidimensional pore systems. Both systems are accessible through 10-membered rings of tetrahedral (T) atoms. One of the systems is defined by two-dimensional sinusoidal channels, the other consists of large supercages whose inner free diameter is defined by 12-membered rings of T atoms. The structure can be constructed by interconnecting modified dodecasil-1H (DOH) cages extended with a $TO_3$ cap on top $\{4^3 5^6 6^3 [4^3]\}$ and containing a framework T-atom 'buried' inside the cage. Space group *P*6/*mmm* was found to fit best and exhibits T–O–T angles of 180° (Fig. 1). Those T–O–T angles of 180° are avoided when the symmetry is reduced to *Cmmm* (Fig. 1). However, a Rietveld refinement using *Cmmm* symmetry was unsuccessful.

In this study molecular-mechanics calculations are used to get more insight into the relative stabilities of possible structures of zeolite MCM-22. The calculations were carried out on an SG Indigo workstation using the DMM force field incorporated in DELPHI.[8]

Table 1 lists the unit-cell parameters and energies of the proposed *P*6/*mmm* and *Cmmm* structures. The reduction of the symmetry from *P*6/*mmm* to *Cmmm* not only avoids T–O–T angles of 180°, but also leads to a lower energy. Energy minimization of both structures, however, converges to one and the same structure with *P*6/*m* symmetry. The energy minimized structure has T–O–T angles of 180° (as in *P*6/*mmm*) and an energy of −1817.96 kJ $mol^{-1}$ $SiO_2$ (Fig. 1 and Table 1). No structure of minimum energy with *P*6/*mmm* or *Cmmm* symmetry could be found. This might indicate that the actual symmetry of MCM-22 is lower than the proposed ones.

Structures comprising T–O–T angles of 180° should always be treated with care,[9] especially when these angles are constrained to 180° by the space-group symmetry. During minimization, however, no constraints were applied. The *P*6/*m* structure represents a minimum with T–O–T angles of 180°. The question arises whether this result can be ascribed to a force-field artefact. Although the DMM force field has already been applied successfully in earlier studies,[8] a further test on the force field was done by calculating the heats of formation of BEA, FAU, LTA, MEL, MFI and TON. Table 2 shows that the calculated heat of formation of MCM-22 with *P*6/*m* symmetry is comparable with those of the other zeolites. In Fig. 2 the

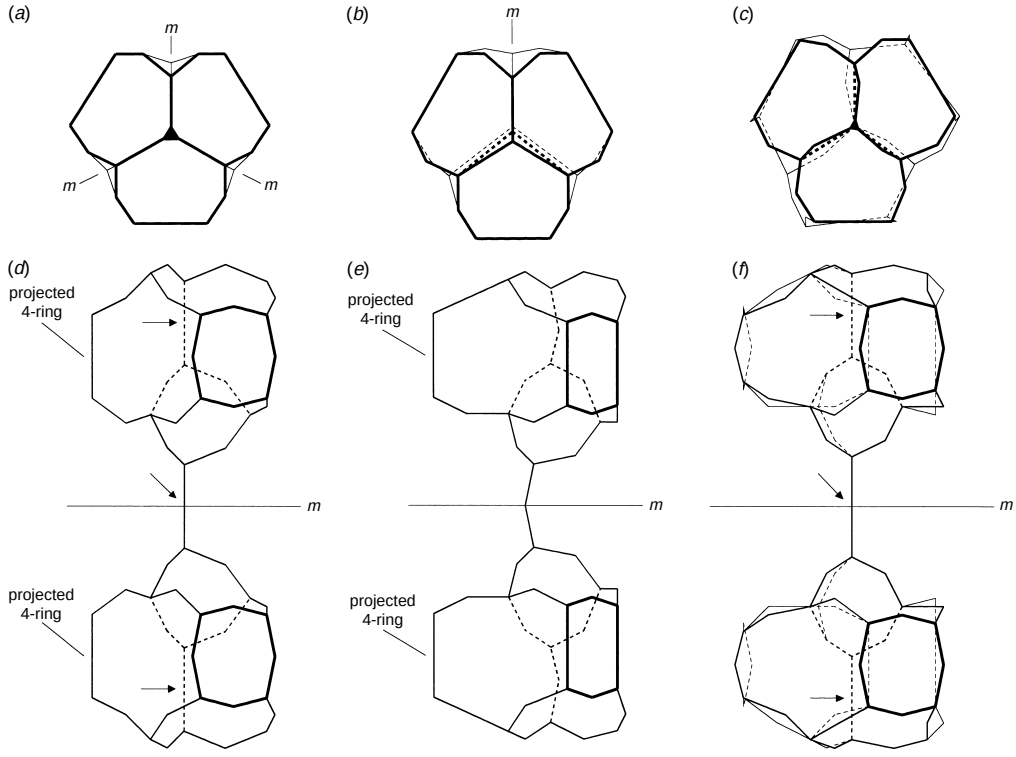

**Fig. 1** Top view (*a*)–(*c*) and side view (*d*)–(*f*) of the $\{4^3 5^6 6^3 [4^3]\}$ cages in the MCM-22 structures exhibiting *P*6/*mmm*, *Cmmm* and *P*6/*m*, respectively. Some symmetry elements are indicated. The cages in structures with *P*6/*mmm* and *P*6/*m* symmetry contain T–O–T angles of 180° (indicated by arrows). In *Cmmm* the corresponding T–O–T angles deviate from 180°.

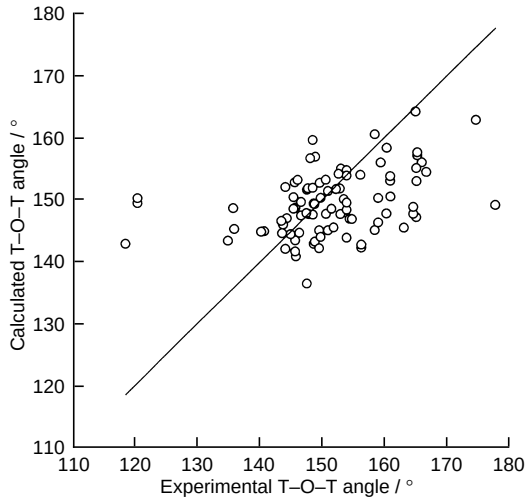

**Fig. 2** Calculated *vs.* experimental[10–15] T–O–T angles: (○) calculated T–O–T angles; (——) $y = x$

calculated T–O–T angles are given as a function of the experimental ones.[10–15] From this figure it is evident that the force field does not tend to overestimate the T–O–T angles. The range of predicted values is smaller than the range of experimental values, which indicates that the 180° angle might indeed be caused by the framework topology. A force-field artefact seems very unlikely and the *P*6/*m* structure might exist.

The calculated XRD patterns in Fig. 3 are only slightly different, which means that very accurate experimental data are necessary to elucidate the precise symmetry and topology. Owing to the size and the shape of the MCM-22 crystals, such an accurate XRD pattern might be difficult to obtain.

In conclusion, the molecular-mechanics calculations show that zeolite MCM-22 having the framework topology as proposed by Leonowicz *et al.*,[3] has *P*6/*m* symmetry. The proposed *P*6/*mmm* and *Cmmm* structures seem to be unstable

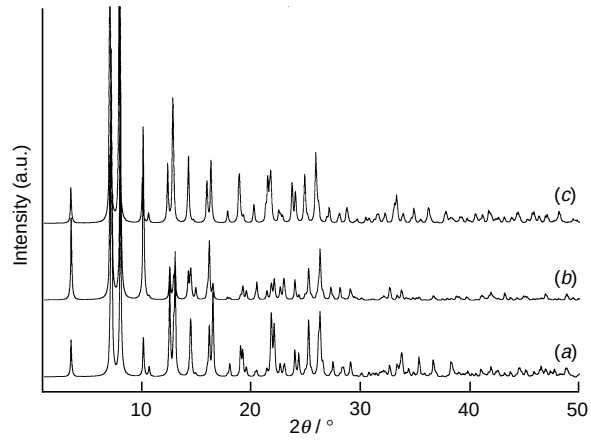

**Fig. 3** Calculated XRD patterns excluding extraframework atoms: (*a*) proposed *P*6/*mmm*;[3] (*b*) proposed *Cmmm*;[3] (*c*) calculated *P*6/*m*

systems. Zeolite MCM-22 might indeed comprise T–O–T angles of 180°.

# Aggregation of carbamato ligands around the $[Co_4O]^{6+}$ core. Synthesis and structure of the cluster $[Co_4O(O_2CNC_9H_{18})_6]$ prepared by a novel oxo-transfer reaction of the nitroxyl free radical 2,2,6,6-tetramethylpiperidin-1-oxyl with $[Co_2(CO)_8]$

**Peter Jaitner,* Christopher Rieker and Klaus Wurst**

*Institute of General, Inorganic and Theoretical Chemistry, University of Innsbruck, A-6020 Innsbruck, Austria*

**The novel oxo-centred tetrahedral cobalt cluster $[Co_4O]^{6+}$ bridged by six carbamato ligands is prepared in high yield when reacting $[Co_2(CO)_8]$ with an excess of the nitroxyl radical 2,2,6,6-tetramethylpiperidin-1-oxyl; the molecular structure of the title compound is determined by a single-crystal X-ray analysis.**

The nitroxyl radical 2,2,6,6-tetramethylpiperidin-1-oxyl (tmpo) is easily oxidized electrochemically (271 mV) in a reversible one-electron step in acetonitrile to the oxoammonium ion.[1] Organic oxoammonium salts characterized by Rey and coworkers[2] have found wide application in selective oxidations of alcohols to aldehydes and ketones as reported by Ma and Bobbit[3] and Semmelhack *et al.*[4] On the other hand, tmpo is a powerful paramagnetic ligand when studying magnetic interactions between metal centres and ligands[5] or in the design of new magnetic materials.[6] We have shown that tmpo is also a valuable spin scavenger of metal carbonyl radicals generating diamagnetic electron-deficient complexes like $[V(CO)_3(tmpo)]$, $[Mn(CO)_3(tmpo)]$ and $[Co(CO)_2(tmpo)]$ **2**, containing a $\eta^2$-bonded tmpo ligand.[7] A metal ($^{51}V$, $^{55}Mn$, $^{59}Co$) NMR investigation revealed that these strained three-membered metallacycles exhibit extremely low metal shieldings.[8] Our preceding work on photolysis of $[Co_2(CO)_8]$ with tmpo in equimolar amounts proved that only the deep red 16-electron metallaoxaziridine $[Co(CO)_2(tmpo)]$ **2** is obtained.[7] But a fourfold excess of tmpo reacts at room temperature with $[Co_2(CO)_8]$ in pentane or benzene in minutes generating the blue carbamato complex $[Co_4O(O_2CNC_9H_{18})_6]$ **1** in high yield (> 80%).

None of numerous attempts to characterize **1** by spectroscopy were conclusive. Standard crystallization procedures failed as well, but suitable single crystals (deep blue plates) were obtained by means of a crystallization box equipped with a heating block described by Hulliger.[10] A single-crystal structure analysis of **1** establishes the structure† shown in Fig. 1.

The molecular structure consists of an oxo-centred tetrahedron of $Co^{II}$ atoms each edge of which is bridged by carbamato ligands. Only one structural determination of a $Co_4(\mu_4\text{-O})$ complex has been reported so far, $[\{Ir(aet)_3\}_4\text{-}Co_4]Br_6$ (aet = 2-aminoethanethiolate),[11*b*] with cobalt–oxygen bond lengths in the range 193–195 pm as found in **1**.

The mechanism of formation of **1** is not yet understood but an excess of tmpo is required for oxo transfer and simultaneously CO insertion into the radical tmpo creating carbamato ligands has to take place. When adding more tmpo to the planar coordinated compound $[Co(CO)_2(tmpo)]$ **2** an immediate colour change to blue **1** is also observed, indicating a stepwise formation of **1** and **2** as an intermediate. Surprisingly, even when performing the reaction of $[Co_2(CO)_8]$ with tmpo without solvent, **1** is formed in high yield. Attempts to identify **1** by mass spectrometry were not informative since no molecular ions or high mass fragments were observed. Only ions such as formamide and other unidentified species were detected. No EPR signal could be observed down to −196 °C. The $^{17}O$ NMR‡ spectrum exhibits two broadened signals at δ 279 and 79. Only very few comparable systems have been studied by $^{17}O$ NMR, making the assignment difficult. We attribute the signal at δ 279 to the oxygens of the carbamato ligand since carboxylates lie in this range.[9] The central $\mu_4$-oxygen at δ 79 is comparable to the shift of the dimeric oxo-bridged $[Re_2(O)_2(\mu\text{-}O)_2(\eta^5\text{-}C_5Me_5)_2]$ [Re-O–Re (δ 104), Re=O (δ 747)] reported by Herrmann and coworkers[9] or to the shift of polyoxometalates containing the $Mo_4(\mu_4\text{-O})$ group (δ 123) studied by Klemperer.[9]

The $M_4(\mu_4\text{-O})$ group is present in many binary metal oxides and is also known in some coordination complexes, such as in the basic metal acetates $[M_4(\mu_4\text{-O})(\mu\text{-}O_2CMe)_6]$ (M = Be, Zn).[11] Compounds containing such oxo bridging groups are of interest in chemistry,[11] biochemistry,[12] magnetochemistry[13] and catalysis.[14] The $Mn_4(\mu_4\text{-O})$ functional group appeared to be unknown for most heavier transition-metal elements but the groups of Puddephatt[15] and Schmidbaur[16] have reported recently new interesting examples containing the elusive $Pd(\mu_4\text{-}O)$[15] and $Au_4(\mu_4\text{-O})$[16] cluster moieties.

In conclusion, this work describes the synthesis and X-ray diffraction of the first complex containing a $Co_4(\mu_4\text{-O})$ group bridged by carbamato ligands. The facile formation of **1** from $[Co_2(CO)_8]$ and tmpo is a surprisingly easy access to a $Co_4(\mu_4\text{-}O)$ cluster; attempts to generalize this chemistry with different

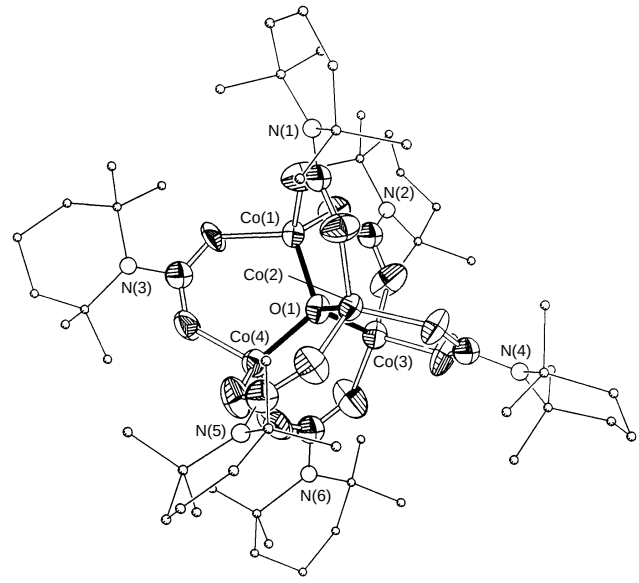

**Fig. 1** Molecular structure of **1**; selected distances (pm) and angles (°): Co(1)–O(1) 193.2(11), Co(2)–O(1) 195.5(10), Co(3)–O(1) 195.2(9), Co(4)–O(1) 193.4(9); Co(1)–O(1)–Co(4) 111.9(5), Co(4)–O(1)–Co(3) 107.8(4), Co(4)–O(1)–Co(2) 108.2(5), Co(1)–O(1)–Co(3) 108.4(5), Co(1)–O(1)–Co(2) 110.3(4), Co(3)–O(1)–Co(2) 110.2(5).

metal carbonyls and oxidizing nitroxyl radicals are under current investigation.

† *Crystal data* for **1**: $C_{60}H_{108}Co_4N_6O_{13}$, $M$ = 1357.24, monoclinic, space group $P2_1/n$, $a$ = 2083.8(5), $b$ = 2964.7(7), $c$ = 2540.7(6) pm, $\beta$ = 114.20(1)°, $U$ = 14.317(6) nm³, $Z$ = 8, Mo-K$\alpha$ radiation ($\lambda$ = 71.073 pm), $D_c$ = 1.259 g cm$^{-3}$ Crystal dimensions: 0.5 × 0.4 × 0.3 mm (blue prism). Data were measured on a Siemens P4 automatic diffractometer with a highly oriented graphite crystal monochromated Mo-K$\alpha$ radiation using $\breve{\omega}$ scans. The structure was solved by direct methods and refined using absorption corrected data to give $R_1$ = 0.0802 for 7092 independent observed reflections [$I > 2\,\sigma(I)$ and 897 parameters. Only the N, O and Co atoms were refined with anisotropic displacement parameters. The crystal structure has been determined and refined in the monoclinic system with X-ray data obtained from a merohedrally twinned crystal, volume ratio 23/5. The twin element can be a twofold rotation axis along $c^*$ or a mirror plane in the $b^*c^*$-plane of the reciprocal lattice (SHELXL-93; TWIN −100 0 − 10 101 or TWIN −100 010 101). The monoclinic $P$-lattice can be transformed to an orthorombic $C$-lattice $a$ = 2083, 8(5), $b$ = 4634.7(10), $c$ = 2964.7(8) pm, but no solution is available in this system.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/475.

# *In situ* probing of surface sites on supported molybdenum nitride catalyst by CO adsorption

**Shuwu Yang, Can Li*, Jiang Xu and Qin Xin***

*State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, PO Box 110, Dalian 116023, China*

**Both molybdenum and nitrogen sites on fresh $Mo_2N/Al_2O_3$ are probed by adsorbed CO giving two characteristic IR bands at 2045 and 2200 cm$^{-1}$, respectively.**

Molybdenum nitride has unique physical and chemical properties, such as, electronic, magnetic and catalytic properties, which are similar to noble metals in many aspects. During the last decade, molybdenum nitride has attracted much attention because of its excellent catalytic activity in a number of hydrogenation reactions,[1] such as $NH_3$ synthesis, hydrotreating, hydrogenolysis and hydrogenation. Specifically supported molybdenum nitrides with high surface areas have been prepared and used in hydrotreating reactions[2–5] and show high potential in industrial applications.

Although molybdenum nitride exhibits a very good catalytic performance, the nature of the surface-active catalytic sites is not well understood. After exposure to air molybdenum nitride is partially oxidized, particularly at the surface,[6] and its surface is very difficult to reduce even with hydrogen at high temperatures, and in most cases, the surface is in an oxynitrided form. In this work, we investigated freshly prepared molybdenum nitride in order to characterize its surface.

A $MoO_3/Al_2O_3$ (10 mass% Mo) sample was prepared by the incipient wetness impregnation technique contacting γ-$Al_2O_3$ ($S_{BET}$ = 230 m$^2$ g$^{-1}$) with an aqueous solution of $(NH_4)_6Mo_7O_{24}$, followed by drying at 393 K overnight and calcination at 773 K for 4 h. The nitrided $Mo/Al_2O_3$ catalyst was prepared by temperature programmed reaction of $MoO_3/Al_2O_3$ with ammonia. The temperature was increased from room temp. to 573 K over 30 min and from 573 to 973 K for 7 h; then the temperature was maintained at 973 K for 2 h. The nitrided sample was cooled to room temperature in flowing ammonia and then passivated in a stream of 1% $O_2$–$N_2$ so as to avoid substantial oxidation. The as-prepared sample is denoted passivated $Mo_2N/Al_2O_3$. The passivated sample was pressed into a self-supporting wafer of mass *ca.* 15 mg. The wafer was placed in a quartz IR cell equipped with $CaF_2$ windows, and nitrided again in the IR cell in flowing ammonia at given temperatures for 1 h. Samples nitrided in the IR cell are denoted as freshly nitrided or renitrided samples, while the passivated $Mo_2N/Al_2O_3$ reduced with $H_2$ at 873 K is denoted reduced passivated sample. The sample was then held *in vacuo* at 773 K for 1 h. Subsequently, the sample was cooled to room temp. and exposed to 10 Torr CO for IR study. All IR spectra were collected at room temp. on a Fourier transform IR spectrometer (Bio-Rad FTS 65A) with a resolution of 4 cm$^{-1}$.

Fig. 1 shows the IR spectra of CO adsorbed on fresh $Mo_2N/Al_2O_3$ at different temperatures [Fig. 1(*b*)–(*f*)] and the IR spectrum of CO adsorbed on reduced passivated $Mo_2N/Al_2O_3$ for comparison [Fig. 1(*a*)]. A broad band at 2180 cm$^{-1}$ and two weak bands at 2100 and 2034 cm$^{-1}$ are observed for the adsorbed CO on reduced passivated $Mo_2N/Al_2O_3$. For the sample renitrided at 573 K, only a weak band appears at 2184 cm$^{-1}$ as a result of CO adsorption. This band shifts only slightly from 2184 to 2173 cm$^{-1}$ for the sample renitrided at 673 K. However, when the passivated $Mo_2N/Al_2O_3$ was renitrided at 723 K, the IR spectrum of the adsorbed CO shows a dramatic change [Fig. 1(*d*)]: four IR bands are observed at 2200, 2157, 2110 and 2045 cm$^{-1}$. For the sample renitrided at 773 K, these four IR bands appear at 2200, 2140, 2090 and 2045 cm$^{-1}$. The two bands at 2140 and 2090 cm$^{-1}$ decline in intensity while the two bands at 2200 and 2045 cm$^{-1}$ grow significantly.

For passivated $Mo_2N/Al_2O_3$ renitrided at 873 K, two IR bands can be seen for the adsorbed CO: a strong band at 2200 cm$^{-1}$ and a broad band at 2045 cm$^{-1}$, and their intensities increase considerably compared with those for $Mo_2N/Al_2O_3$ renitrided at 723 K. The IR intensities of the two bands scarcely decrease under evacuation at room temperature indicating that the adsorbed species are very stable. Both the bands at 2200 and 2045 cm$^{-1}$ can be still observed under evacuation up to 373 K. When the sample is heated to 423 K under vacuum, the band at 2045 cm$^{-1}$ diminishes while the band at 2200 cm$^{-1}$ can still be seen even the temperature is raised to 673 K and disappears only when the temperature is increased to 773 K. This result suggests that the two bands represent two different types of species formed from the CO adsorption on the fresh $Mo_2N/Al_2O_3$.

A study[7] of CO adsorption on reduced $MoO_3/Al_2O_3$ concluded that mainly $Mo^{4+}$ cations were produced when $MoO_3/Al_2O_3$ was reduced at temperatures in the range of 573–773 K. No adsorbed CO on $Mo^0$ was detected for $MoO_3/Al_2O_3$ reduced at temperatures below 973 K. A significant exposure of fully reduced Mo atoms on $MoO_3/Al_2O_3$ was seen

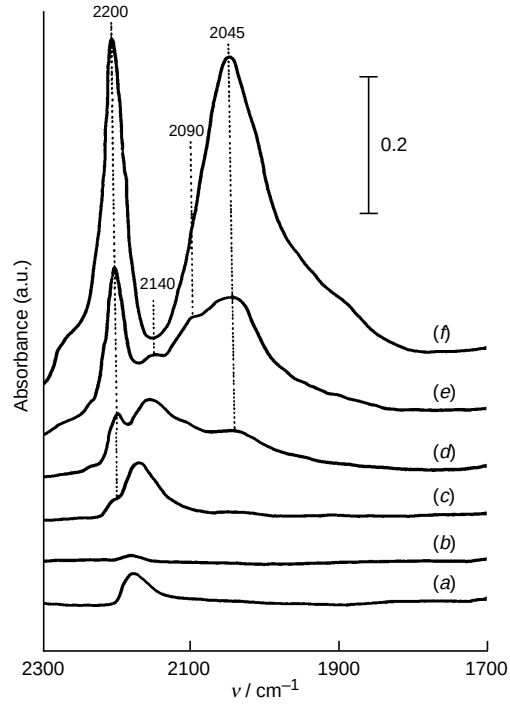

**Fig. 1** IR spectra of CO adsorbed on passivated $Mo_2N/Al_2O_3$ reduced at 873 K (*a*) and on passivated $Mo_2N/Al_2O_3$ renitrided at 573 (*b*), 673 (*c*), 723 (*d*), 773 (*e*) and 873 K (*f*)

only after a reduction above 973 K.[8] In Fig. 1(*a*), the IR band at 2180 $cm^{-1}$ indicates that CO is adsorbed mainly on $Mo^{4+}$ for the reduced passivated $Mo_2N/Al_2O_3$. The IR spectrum is similar to that for $MoO_3/Al_2O_3$ reduced at 873 K but totally different from those of CO adsorbed on the fresh $Mo_2N/Al_2O_3$ samples [Fig. 1(*b*)–(*f*)]. This leads us to conclude that the surface of reduced passivated $Mo_2N/Al_2O_3$ is in highly oxidic form, *i.e.* the surface exists mainly as the oxynitride.

The two characteristic bands at 2045 and 2200 $cm^{-1}$ appear only when the sample is renitrided at temperatures at and above 723 K, and their intensities are enhanced significantly with increase in nitriding temperature. It is obvious that these two bands are related to adsorbed CO on molybdenum nitride. The IR band at 2045 $cm^{-1}$ can be safely assigned to the linearly adsorbed CO on surface molybdenum atoms of fresh $Mo_2N/Al_2O_3$. From the band position and the chemical state of the nitride, the surface molybdenum atom may be partially positively charged.[9–11] By contrast, adsorbed CO on a reduced passivated sample shows IR bands at wavenumbers $>2100$ $cm^{-1}$, indicating that the surface molybdenum atom is in a high valence state characteristic of the oxynitride or oxide form even at a reduction temperature as high as 873 K.

It is also interesting that the strong stable band at 2200 $cm^{-1}$ is observed for fresh $Mo_2N/Al_2O_3$. This band cannot be attributed to CO adsorbed on any molybdenum cation sites since adsorbed CO on molybdenum cations at such a high frequency is easily removed by evacuation even at room temperature. From its vibrational frequency and its high stability,[12] we assign this band to NCO species formed when CO reacts with surface active nitrogen atoms created by *in situ* nitridation. A separate experiment established that the band intensity of the 2200 $cm^{-1}$ band decreased considerably while the band at 2045 $cm^{-1}$ remained unchanged when the fresh catalyst was treated with hydrogen at 773 K. The result is consistent with our assignment of the band at 2200 $cm^{-1}$ to NCO formed *via* reaction between CO and surface nitrogen atoms. Treatment with hydrogen at high temperatures can remove some of the surface active nitrogen atoms; as a result, the band intensity of NCO species is reduced. This result also suggests that a considerable amount of nitrogen atoms are present on the surface of molybdenum nitride, and that they are highly active which may play an important role in catalytic behaviour.

In summary, CO is strongly adsorbed on fresh $Mo_2N/Al_2O_3$ catalyst leading to two IR bands at 2045 and 2200 $cm^{-1}$ which can be assigned to linearly adsorbed CO on molybdenum and nitrogen sites, respectively when the catalyst is nitrided at temperatures above 723 K. Unlike CO adsorbed on reduced passivated $Mo_2N/Al_2O_3$, adsorbed CO on molybdenum nitride is very stable and behaves very similarly to that of group 8 metals. This study proves that fully nitrided molybdenum resembles noble metals; also, its surface nitrogen atoms are in a highly active form and readily react with CO to form surface NCO species. Our results also suggest that *in situ* studies of fresh nitrides are very important in the understanding of the real surface of the fresh nitride, while studies on passivated nitrides can not give correct information for the nitride, but rather, give information for the oxynitride or oxygen covered nitride.

# Novel gold derivatives of titanium carbonyl and structural characterization of a compound containing an unsupported gold–titanium bond: $[Ti(CO)_6(AuPEt_3)]^-$†

**Paul J. Fischer, Victor G. Young, Jr. and John E. Ellis***

*Department of Chemistry, University of Minnesota, Minneapolis, MN 55455, USA*

**Hexacarbonyltitanate(2−) reacts with $(R_3P)AuCl$ (R = $C_6H_{11}$, Et) to provide the first anions of the general formula $[M(CO)_x(AuPR_3)_y]^z$, and a structurally characterized (for R = Et) compound containing a largely unsupported gold–titanium bond.**

Mixed gold–transition metal compounds have been known for over thirty years[1] and now hold a special position in chemistry by virtue of their often intriguing chemical and physical properties.[2] While structurally characterized compounds containing gold–metal bonds are well known for most transition-metal elements, the first example containing titanium was reported only very recently, an unusual bis(alkynyl)titanocene-gold aryl adduct; $[\{(\eta^5\text{-}C_5H_4SiMe_3)_2Ti(C{\equiv}CSiMe_3)_2\}\text{-}Au\{C_6H_2(CF_3)_3\text{-}1,3,5\}]$ **1**.[3] Since the gold atom in this complex was strongly bound to the two alkyne groups, it was required to be in close proximity to the formally $Ti^{IV}$ center. To assess whether the gold–titanium interaction was significant, as claimed,[3] we felt that it was important to obtain and determine the molecular structure of a compound containing a largely unsupported gold–titanium bond. Numerous attempts to prepare the unknown carbonyltitanate $[Ti(CO)_6(AuPPh_3)]^-$, which is analogous to the well established vanadium complex $[V(CO)_6(AuPPh_3)]$,[4,5] by the reaction of $[Ti(CO)_6]^{2-}$ with $(Ph_3P)AuCl$ were uniformly unsuccessful. However, dropwise addition of cold (−50 to −60 °C) solutions of $(R_3P)AuCl$, (R = $C_6H_{11}$, Et) to an equimolar quantity of $[K(15\text{-crown-}5)_2]_2[Ti(CO)_6]$,[6] as a finely divided cold (−50 to −80 °C) solid, provided 20–35% isolated yields of satisfactorily pure $[K(15\text{-crown-}5)_2][Ti(CO)_6(AuPR_3)]$ (R = $C_6H_{11}$ **2a**, Et **2b**), Scheme 1.‡

Compounds **2a,b** are air-sensitive brown to red–brown microcrystalline solids. Both have nearly identical IR spectra in the ν(CO) region in thf, which indicates that the carbonyl products have very similar molecular structures in solution. Carbon-13 NMR spectra of these species in thf are also very similar and show a single carbonyl resonance at $\delta_C$ *ca.* 250 from 25 to −90 °C. To confirm the presence of seven-coordinate titanium in **2a**, a 99% $^{13}CO$ enriched sample was prepared from the known $[Ti(^{13}CO)_6]^{2-}$[6] by the same procedure. The $^{13}C$ and $^{31}P$ NMR spectra of $[^{13}C_6]$**2a** showed the expected doublet ($\delta_C$, +250.3, $^3J_{PC}$ 5 Hz) and a well resolved binomial septet ($\delta_P$, 74.3, $^3J_{PC}$ 5 Hz), respectively, arising from coupling of the six equivalent carbonyl carbons to phosphorus in the coordinated tricyclohexylphosphine group. The equivalence of the carbonyl groups undoubtedly arises from the highly fluxional nature of **2a** in solution. Attempts to grow X-ray quality crystals of **2a** were unsuccessful, but suitable single crystals of **2b** were obtained.§

$$[Ti(CO)_6]^{2-} + (R_3P)AuCl \xrightarrow[-60 \text{ to } 0\ ^\circ C]{\text{thf}} [Ti(CO)_6(AuPR_3)]^- + Cl^-$$

(R = $C_6H_{11}$, Et)

**Scheme 1**

The anion in **2b** (Fig. 1) has an irregular seven-coordinate geometry about titanium. A view down the Ti–Au vector shows an approximate capped trigonal prism, where gold 'caps' carbonyl carbons C(1–4); however, the latter define a substantially non-planar face. The C(1)–Ti–C(2) and C(3)–Ti–C(4) angles of 123.1(3) and 167.1(3)°, respectively, deviate markedly from that expected for an undistorted capped trigonal prism.[7] The origin of this severe distortion is a close approach of one CO group, defined by C(1), to the gold atom. Although the Au–C(1) distance of 2.416(8) Å is outside the range of normal Au–C bond lengths and is significantly longer than the average Au–C($\eta^2$-alkyne) value of 2.23 (1) Å found in complex **1**, other structural and spectral data for crystalline **2b** point to the presence of a very weak 'semibridging' carbonyl–gold interaction. For example, the C(1)–O(1) and Ti–C(1) distances are significantly longer and shorter, respectively, than the other corresponding distances in **2b**, except that for Ti–C(4) (Fig. 1). Also, the slight non linearity of the Ti–Au–P angle of 169.45(6)° and a difference in the solid-state and solution IR spectra of **2b** in the ν(CO) region suggest that this interaction is present. Specifically, the lowest-energy ν(CO) band of **2b** decreases from 1814 $cm^{-1}$ in solution to 1791 $cm^{-1}$ as a mulled solid, which is the trend expected for a weak interaction of this type.[8] By comparison, the shortest carbonyl carbon–gold distance in the closely related $[V(CO)_6(AuPPh_3)]$ is 2.57(2) Å.[5] For the latter complex, there is no IR spectral evidence for any analogous Au–CO interaction in the solid state.[9] The average Ti–C and C–O distances are 2.05(1) and 1.16(1) Å, respectively, which are similar to corresponding values of 2.04(1) and 1.16(2) Å found in a related $Ti^0$ anionic carbonyl $[Ti(CO)_5(SnPh_3)_2]^{2-}$.[10] The Au–P distance in **2b** of 2.295(2) Å is similar to those found in other triethylphosphine gold–metal

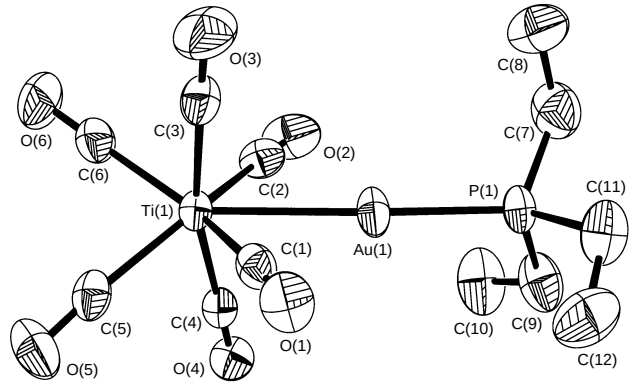

**Fig. 1** Molecular structure of the anion in **2b**. Selected dimensions (Å and °): Ti–C(1) 2.034(9), Ti–C(2) 2.065(9), Ti–C(3) 2.056(9), Ti–C(4) 2.046(8), Ti–C(5) 2.053(9), Ti–C(6) 2.060(9), Ti–Au 2.719(1), Au–P 2.295(2), Au–C(1) 2.416(8), Au–C(2) 2.599(8), C(1)–O(1) 1.175(9), C(2)–O(2) 1.141(9), C(3)–O(3) 1.155(9), C(4)–O(4) 1.155(9), C(5)–O(5) 1.147(10), C(6)–O(6) 1.155(9), P–C(av.) 1.81(1), C–C(av.) 1.48(2); Ti–Au–P 169.45(6), Ti–C(1)–O(1) 173.7(7), Ti–C(2)–O(2) 174.0(8), other Ti–C–O (av.) 177(2).

complexes; *e.g.* in $[Os_3(CO)_{10}(AuPEt_3)_2]$ the distance is 2.287(6) Å.[11] More interesting is the Ti–Au bond length of 2.719(1) Å, which, as expected, is slightly longer than the V–Au distance of 2.690(3) Å in $[V(CO)_6(AuPPh_3)]$,[5] but is 0.276 Å shorter than the Ti–Au separation of 2.995(1) Å reported for compound **1**. On this basis, although the existence of a Ti–Au bond in **1** cannot be ruled out, it is undoubtedly much weaker than that present in $[Ti(CO)_6(AuPEt_3)]^-$. The counter ion in **2b**, $[K(15\text{-crown-}5)_2]^+$, is well separated from anions in the crystalline lattice and has the usual sandwich structure containing formally ten-coordinate potassium ion, with a mean K–O distance of 2.89(5) Å. The latter number is essentially identical to the corresponding value of 2.88(9) Å, recently found in $[K(15\text{-crown-}5)_2][Zr(CO)_4(dppe)(SnMe_3)]$.[12]

Compounds **2a,b** are of additional interest in that they contain the first known anionic complexes of the general formula $[M(CO)_x(AuPR_3)_y]^z$ and may be regarded as structural models[13,14] for the presently unknown hydride, $[Ti(CO)_6H]^-$. All previously reported reactions of homoleptic carbonylmonometalates, *i.e.*, $[M(CO)_x]^{y-}$, with phosphine gold halides have given only neutral compounds of the type $[M(CO)_x(AuPR_3)_y]$. For example, the reaction of $[V(CO)_5]^{3-}$ with fewer than 3 equiv. of $(Ph_3P)AuCl$ invariably gave only the neutral gold cluster species $[V(CO)_5(AuPPh_3)_3]$ and unreacted $[V(CO)_5]^{3-}$.[15] Similar unsuccessful attempts to prepare the still unknown $[Fe(CO)_4(AuPPh_3)]^-$ by the reaction of $[Fe(CO)_4]^{2-}$ with 1 equiv. of $(Ph_3P)AuCl$ yielded only the neutral bis-gold complex, $[Fe(CO)_4(AuPPh_3)_2]$.[16] Very likely the pronounced tendency for $(R_3P)Au$ groups to bind to one another and form Au–Au bonds,[2] a phenomenon recently dubbed 'aurophilicity',[17] accounts for the favored formation of the neutral polygold–metal species in these prior studies. The relatively crowded anionic $Ti(CO)_6$ unit in **2a,b** undoubtedly inhibits attack by a second phosphine gold chloride and may be one reason why we were successful for the first time in obtaining substituted metal carbonyl anions of this type. However, substitution of trialkylphosphinegold chlorides in these reactions for the doubtlessly more electrophilic triphenylphosphinegold chloride may also have been of critical importance in this study. Extensions of this research to zirconium and hafnium will be of interest since well characterized gold derivatives of these metals are presently unknown.

We thank the National Science Foundation and donors of the Petroleum Research Fund, administered by the American Chemical Society for financial support of this research. Also we are grateful to Professor Marcetta Y. Darensbourg for a useful discussion and Ms. Christine Lundby for assistance in the preparation of the manuscript.

‡ A cold (−50 °C) solution of $[(C_6H_{11})_3P]AuCl$ (0.504 g, 0.984 mmol) in thf (50 ml) was added by cannula to cold (−50 °C) and finely divided solid $[K(15\text{-crown-}5)_2]_2[Ti(CO)_6]$ (1.15 g, 0.982 mmol) with stirring. The resulting red–brown reaction mixture was stirred for 14 h while slowly warming to 0 °C. Following filtration at 0 °C, all but about 5 ml of the solvent was removed *in vacuo*. Addition of excess diethyl ether caused precipitation of the brown solid, which was recrystallized from thf–ether to provide 0.406 g (35% yield) of pure **2a**. Satisfactory elemental analysis. IR(thf): ν(CO) 1951 m, 1918 m, 1811 s $cm^{-1}$. IR (Nujol): 1959 m, 1922 (sh), 1870 (sh), 1835 (sh), 1780 s, (br) $cm^{-1}$. $^1H$ NMR (300 MHz, $[^2H_8]$thf 25 °C, $SiMe_4$): δ 3.53 (s, 40 H, 15-crown-5), 2.5-1.8 [m, 33 H, $AuP(C_6H_{11})_3$]. $^{13}C\{^1H\}$(75 MHz): δ 250.2 (d, $^3J_{PC}$ 4.6 Hz, CO), 69.7 (s, 15-crown-5), 34.3 (d, $^1J_{PC}$ = 17 Hz, $C_6H_{11}$), 31.2 (d, $^2J_{PC}$ 3 Hz, $C_6H_{11}$), 28.3 (d, $^3J_{PC}$ 11 Hz, $C_6H_{11}$), 27.1 (s, $C_6H_{11}$) $^{31}P$ (121 MHz, ref. $H_3PO_4$): δ 74.3 [s, $AuP(C_6H_{11})_3$]. Pure **2b** was obtained by a nearly identical procedure in 20% yield. IR (THF): ν(CO) = 1954m, 1918w, 1814s $cm^{-1}$. IR (Nujol): 1954m, 1838 (sh), 1791s $cm^{-1}$. $^1H$ NMR (300 MHz, $[^2H_8]$thf, 0 °C, $SiMe_4$): δ 3.53 (s, 40 H, 15-crown-5), 1.61 (m, 6 H, P**C**$H_2$CH$_3$), 1.09 (dt, *J* 7.5, $^3J_{PH}$ = 18 Hz, 9 H , PCH$_2$**C**$H_3$). $^{13}C\{^1H\}$(75 MHz): δ 249 (s, CO), 69.4 (s, 15-crown-5), 20.0 (d, $J_{PC}$ 20 Hz, P**C**$H_2$CH$_3$), 9.5 (d, $^2J_{PC}$ 4.5 Hz, PCH$_2$**C**$H_3$). $^{31}P$ (121 MHz, ref $H_3PO_4$) 56.8 [br s $AuP(C_2H_5)_3$].

§ *Crystal data* for **2b**: $C_{32}H_{55}AuKO_{16}PTi$, $M$ = 1010.7, monoclinic, space group $P2_1/c$, $a$ = 14.5279(3), $b$ = 15.8275(1), $c$ = 18.7076(3) Å, β = 93.559(1)°, $U$ = 4293.3(1) Å$^3$, $Z$ = 4, $D_c$ = 1.564 g $cm^{-3}$, $F(000)$ = 2040, μ(Mo-Kα) = 3.796 $mm^{-1}$, λ = 0.71073Å, $T$ = 173(2) K. 18 549 reflections measured on a Siemens SMART CCD area detector diffractometer yielded 7415 unique data ($2\theta_{max}$ = 50°, $R_{int}$ = 0.0350, semiempirical absorption corrections). The structure was solved by direct methods and refined by full-matrix least-squares methods on $F^2$ with statistical weighting, anisotropic displacement parameters, constrained isotropic H atoms to give $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ = 0.1213 on all data, conventional $R$ = 0.0531 on $F$ values of 4965 reflections having $F_o^2 > 2\sigma(F_o^2)$, goodness of fit $S$ = 1.020 for all $F^2$ values and 472 refined parameters. Largest difference peak and hole: 0.984, −1.063 e Å$^{-3}$. All calculations were performed using SGI INDY R4400-SC or pentium computers with SHEXTL-Plus V5.0 program suite. Atomic coordinates, bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/489.

# Metal chemistry relevant to the mononuclear molybdenum and tungsten pterin enzymes‡

**Charles G. Young† and Anthony G. Wedd†**

*School of Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia*

**In the light of recent protein crystal structures, metal chemistry underpinning the action of oxygen-atom transfer enzymes which contain molybdenum and tungsten pterin centres is outlined.**

## Introduction

The group 6 metal molybdenum is an essential nutrient for all forms of life while its heavier congener tungsten is essential for certain anaerobic thermophilic bacteria.[1,2] The high solubility of $Mo^{VI}$ and $W^{VI}$ oxyanions in water ensures that the elements are available to biological systems ($10^{-7}$ and $10^{-9}$ mol $dm^{-3}$, respectively, in sea water), despite their low terrestrial elemental abundances.[1]

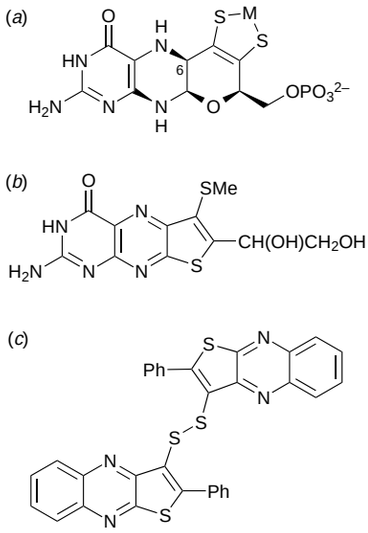
Molybdenum enzymes fall into two general classes: the nitrogenases and the molybdopterin enzymes.[3,4] The former feature the iron–molybdenum cofactor (FeMoco), a cluster of stoichiometry $Fe_7MoS_9$. The latter possess mononuclear molybdenum cofactors (Moco) with metal bound by 1,2-dithiolate links to one or two pterin ring systems [Fig. 1(*a*)].[4–6] An oxidised derivative, urothione [Fig. 1(*b*)], is excreted during normal human metabolism. Known tungsten enzymes are related to the second class.[2]

Most pterin enzymes mediate formal oxygen atom exchange between substrate X and water [eqn. (1)].[7–9]

$$X + H_2O \leftrightarrow XO + 2\,H^+ + 2\,e^- \quad (1)$$

Specific half-reactions for some of the more extensively studied systems are given in Scheme 1. Molybdenum centres operate on C, N, S and As atoms of substrate X[8–10] while the known tungsten centres operate on carbon during its assimilation from various sources.[2,11] There is usually a second reaction centre (*e.g.* flavin, iron–sulfur, cytochrome) for the complementary half-reactions and the two active sites are connected by an internal electron-transfer chain. Two identified roles for the pterin ligand are to participate directly in this intramolecular electron transfer and to tune the redox potential of the site.[6,7,12]

Molecular features of the pterin enzymes have been illuminated by recent crystal structures (Fig. 2).[12–16] These provide a basis for further progress in defining the molecular mechanisms of action. This Article concentrates on the structural and reaction chemistry at the molybdenum and tungsten sites. The value of defining the fundamental chemistry was clear from the first significant modelling experiments. Electron paramagnetic resonance (EPR) signals characteristic of $Mo^V$ appeared upon reaction of $[Mo^{VI}O_4]^{2-}$ and glycolic acids $HECH_2CO_2H$ (E = O, S).[17] Spectral parameters for the sulfur-based system were similar to the so-called 'very rapid' and 'rapid' signals of xanthine oxidase and established a major role for ligand sulfur.[18] The synthetic species generated have now been identified as square-pyramidal $[Mo^VO(SR)_4]^-$ and related species.[19–21]



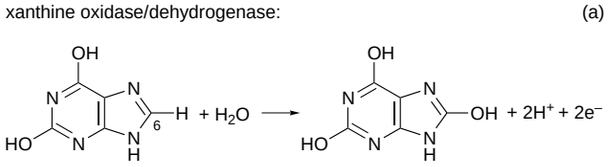


**Fig. 1** (*a*) Pterin centre with pyran ring attached at positions 6 and 7. A 1,2-dithiolate unit capable of acting as a bidentate ligand to metal M occupies positions 1′ and 2′ of the pyran ring. It is represented as an ene-1,2-dithiolate, although this point is speculative as the redox level of the pterin–pyran system is undefined at present. The phosphate substituent is elaborated to a dinucleotide in enzymes from prokaryotic organisms. (*b*) Urothione and (*c*) 2-phenylthieno[2,3-*b*]-quinoxaline.

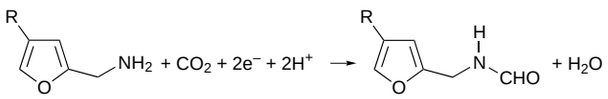
Molybdenum enzymes

xanthine oxidase/dehydrogenase: (a)

xanthine uric acid

sulfite oxidase: $[SO_3]^{2-} + H_2O \rightarrow [SO_4]^{2-} + 2H^+ + 2e^-$ (b)

nitrate reductase: $[NO_3]^- + 2H^+ + 2e^- \rightarrow [NO_2]^- + H_2O$ (c)



dimethyl sulfoxide reductase: $Me_2SO + 2H^+ + 2e^- \rightarrow Me_2S + H_2O$ (d)

Tungsten enzymes[a]

aldehyde oxido-reductase: $RCHO + H_2O \rightarrow RCO_2H + 2H^+ + 2e^-$ (e)

formate dehydrogenase: $HCO_2^- + H_2O \rightarrow HCO_3^- + 2H^+ + 2e^-$ (f)

formylmethanofuran dehydrogenase: (g)

**Scheme 1** [a] Molybdenum versions of these enzymes are also known [*e.g.* compare Fig. 2(*a*) and (*c*)]. In certain bacteria, both molybdenum and tungsten versions can be isolated (see, *e.g.* refs. 4 and 33).

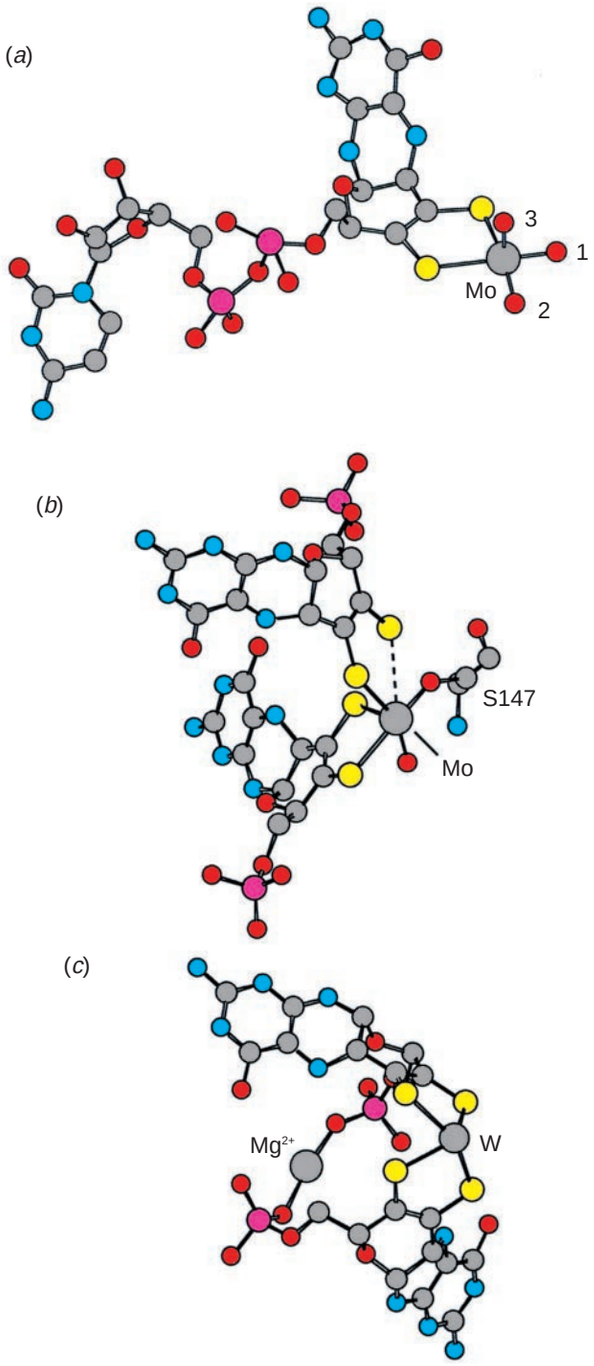


**Fig. 2** Crystal structures: representations of metal centres. Colour code: oxygen, red; nitrogen, blue; sulfur, yellow; phosphorus, magenta; metal atoms (large grey circles) are identified on the figure. (*a*) Aldehyde oxidoreductase from *Desulfovibrio gigas* (resolution = 2.25 Å): a five-coordinate site interpreted as a $Mo^{VI}O_2(OH_2)$ fragment bound to a pterin 1,2-dithiolate.[12] The ligands assigned as oxo are labelled 1 and 3 while that assigned as aqua is labelled 2. The latter has direct access to an extended solvent channel. Data at 1.8 Å resolution is now available, including that for crystals soaked in buffer containing sulfide.[13] Ligand 3 appears to be $S^{2-}$ in these latter forms. (*b*) Oxidised dimethyl sulfoxide reductase from *Rhodobacter sphaeroides* (resolution = 2.2 Å): a distorted trigonal prismatic site with a $Mo^{VI}O(OSer)$ fragment bound to two pterin 1,2-dithiolate ligands.[15] One of the latter bidentate ligands is bound asymmetrically with Mo–S distances of 2.4 and 3.1 Å. (*c*) Aldehyde oxidoreductase from *Pyrococcus furiosus* (resolution = 2.3 Å): the tungsten atom is coordinated to two pterin 1,2-dithiolate ligands whose sulfur atoms lie in an approximate square plane.[14] Two other non-protein ligands (oxo?) may be present to complete a distorted trigonal prismatic site. The two phosphate groups bind to a six-coordinate $Mg^{2+}$ ion.

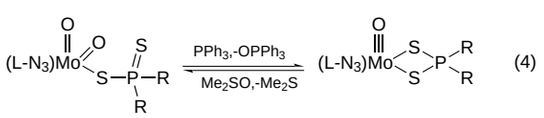
## Background chemistry

High oxidation state metal-oxo chemistry is the key to catalysis of half-reaction (1) in these enzymes (for simplicity, coligands and overall charges are omitted) [eqns. (2) and (3)].

$$X + M^{VI}O \rightleftharpoons XO + M^{IV} \quad (2)$$



$$M^{IV} + H_2O \rightleftharpoons M^{VI}O + 2\,H^+ + 2\,e^- \quad (3)$$

$$X + H_2O \rightleftharpoons XO + 2\,H^+ + 2\,e^- \quad (1)$$

Eqn. (2) represents an oxygen atom transfer (OAT) reaction.[7,8,22] Eqn. (3) is a coupled electron–proton transfer (CEPT) reaction in which the active site is regenerated.[8,9,23] The detailed molecular mechanism employed by an enzyme varies with the nature of its substrate X.

The molybdenum enzymes seem to fall into three families, exemplified by sulfite oxidase, dimethyl sulfoxide reductase and xanthine oxidase (Scheme 1).[4]

The OAT reaction is now well established for molybdenum.[7,8,22] In particular, interconversion of *cis*-$Mo^{VI}O_2$ and $Mo^{IV}O$ complexes is promoted by a range of oxygen atom donors and acceptors *via* associative mechanisms. The ability of a dimethyl sulfoxide reductase enzyme to mediate reaction (2) in either direction has been interpreted in these terms.[24] As illustration, a structurally well characterised catalytic system based upon the trispyrazolylborate ligand L-$N_3$ [see Fig. 3(*a*) for ligand structure] is presented in eqn. (4).[25] The forward and

(4)

reverse reactions are first order with respect to both complex and substrate, consistent with bimolecular reactions involving mononuclear species. The steric bulk of ligand L-$N_3$ and the ambidentate behaviour of the dithiophosphate ligand disfavour comproportionation reaction (5) which complicates many synthetic systems.

$$Mo^{VI}O_2 + Mo^{IV}O \rightarrow [Mo^{V}O]_2(\mu\text{-}O) \quad (5)$$

The CEPT reaction depends upon π bonding in M=O systems permitting dramatic modulation of the p$K_a$ of the O atom upon change of oxidation state of metal M. Formal reduction of a *cis*-

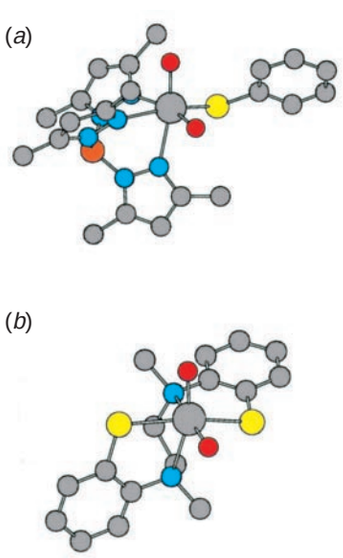


**Fig. 3** Ligands. (*a*) L-$N_3$ = hydrotris(3,5-dimethylpyrazol-1-yl)borate monoanion as present in (L-$N_3$)$MoO_2$(SPh).[36] Colour code: boron, orange. (*b*) L-$N_2S_2$ = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-sulfanylphenyl)ethylenediamine dianion as present in (L-$N_2S_2$)$MoO_2$: *cis*-oxo and *trans*-thiolate ligands.[26]

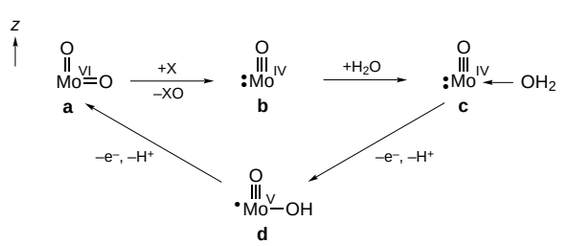
$Mo^{VI}O_2$ centre increases its basicity by population of π* orbitals with significant oxo character. Simple relevant examples are provided in eqn. (6) [L = L-$N_2S_2$ or (L-$N_3$)(SPh)]; Fig. 3.[26,27]

$$LMo^{VI}O_2 + e^- \rightarrow [LMo^{V}O_2]^- \xrightarrow{H^+} LMo^{V}O(OH) \quad (6)$$

### The sulfite oxidase family: $Mo^{VI}O_2$ sites with one pterin 1,2-dithiolate ligand

A number of molybdenum pterin enzymes feature $Mo^{VI}O_2$ fragments bound to a single pterin 1,2-dithiolate [*e.g.* sulfite oxidase, assimilatory nitrate reductase; Scheme 1(b),(c)].[4] In addition, sulfite oxidase has a Mo–S–Cys linkage.[28] While active aldehyde oxidoreductase from *Desulfovibrio gigas* belongs to the [$Mo^{VI}OS$] class (*vide infra*), a crystallised form appears to contain a $Mo^{VI}O_2(OH_2)$ fragment.[12] A plausible model for the active site in sulfite oxidase would have a cysteinyl ligand substitute for $OH_2$ in position 2 of Fig. 2(*a*).

Unfortunately, catalytic intermediates are yet to be detected for enzymes in this family and so mechanism has been inferred from structural information obtained by X-ray absorption spectroscopy and EPR studies of resting forms [*e.g.* $Mo^{VI}O_2$, $Mo^{V}O(OH)$ and $Mo^{IV}O$ centres in sulfite oxidase[8]].



A consensus cycle has evolved in which a 'spectator' oxo ligand[29,30] controls the electronic structure allowing a second oxo ligand to participate in an OAT reaction with substrate X (Scheme 2 **a** → **b**). After coordination of ligand $H_2O$ (**b** → **c**), the catalytic site is regenerated by two CEPT steps (**c** → **d** → **a**). Reductase enzymes would cycle in the opposite direction (*cf.* assimilatory nitrate reductase[31–33]). The OAT chemistry is represented as a concerted two-electron event, the CEPT chemistry as two consecutive ($e^-$, $H^+$) transfers (rather than hydrogen-atom transfers).[34]

A synthetic model based upon $LMo^{VI}O_2Y$ (L = trispyrazolylborate ligand; Y = anionic ligand) permits fine tuning of structural and redox properties *via* variation of Y and the substituents of L.[27,34–36] In particular, complex (L-$N_3$)$Mo^{VI}$-$O_2$(SPh) [Fig. 3(*a*)] catalyses eqn. (1) (X = $PPh_3$) with $O_2$ acting as the formal oxidant.

$$PPh_3 + H_2{}^{18}O + 2O_2 \rightarrow {}^{18}OPPh_3 + 2HO_2 \quad (7)$$

Centres **a**, **b** and **d** of Scheme 2 were isolated or trapped while strong evidence for centre **c** was obtained by $^{18}O$ tracer experiments.[34] The energy profile of the cycle and its molecular mechanism have been examined theoretically.[37] Substrate $PMe_3$ is proposed to approach from a direction perpendicular to the *cis*-$MoO_2$ plane, then rotate to form intermediate $Mo^{IV}$-O($OPMe_3$) with a dihedral angle OMoOP of 0°. This imposes a $(d_{xy})^2$ configuration permitting formation of a stabilising triple bond along the *z* direction to the spectator oxo ligand (Scheme 2). Substitution of product $OPMe_3$ by $OH_2$ proceeds by an associative mechanism leading to intermediate **c**. The direction of approach of the substrate could be under tight steric control at an enzyme site.

The two CEPT steps are mediated normally by internal electron transfer to another redox enzyme site where the formal oxidant binds. In the present model system, the first CEPT step involves comproportionation between **a** and **c** (Scheme 2) to produce 2 equivalents of **d** which are then oxidised by $O_2$. The ligand steric barriers are balanced to allow hydrogen atom transfer between **a** and **c** but to disfavour formation of binuclear species [*cf.* eqn. (5)].

**Scheme 2**

The other system for which good evidence for Scheme 2 is available mimics enzymic reduction of aromatic nitro compounds, a multi-electron process [eqn. (8)].

$$ArNO_2 + 6H^+ + 6e^- \rightarrow ArNH_2 + 2\,H_2O \quad (8)$$

When intercalated into a layered double hydroxide host lattice, the $[Mo^{VI}O_2\{O_2CC(S)Ph_2\}_2]^{2-}$ ion catalyses reaction (8) cleanly.[21] An interpretation consistent with experiment has reductant PhSH inducing the initial CEPT steps (Scheme 2: **a** → **d** → **c**), followed by substitution of substrate $ArNO_2$ for ligand $H_2O$. The OAT step (**c** → **a**) then produces intermediate ArNO which is reduced directly by PhSH.

The OAT step of Scheme 2 (**a** ↔ **b**) has been demonstrated for many enzymic substrates.[7,24,38–40] For example, reduction of $[NO_3]^-$, $Me_2SO$ and $Me_3NO$ *via* electrophilic attack on $Mo^{IV}O$ has been demonstrated in systems with bi- and tridentate ligands.[7,24,38] Oxidation of $[HSO_3]^-$ is effected cleanly by $[Mo^{VI}O_2(mnt)_2]^{2-}$ (Fig. 4) in MeCN–$H_2O$.[40]

### The dimethyl sulfoxide reductase family: $Mo^{VI}O_x$ ($x$ = 1,2) sites with two pterin 1,2-dithiolate ligands

Dimethyl sulfoxide reductases had been assumed to be related to the sulfite oxidase family until recent X-ray crystallographic and absorption data for the enzyme from *Rhodobacter sphaeroides* indicated [Fig. 2(*b*)]:[15,41] (*i*) the presence of two inequivalent 1,2-dithiolate ligands. One is a symmetric bidentate ligand. The other is also bidentate but asymmetrically bound in the oxidised form and monodentate in the reduced form; (*ii*) the presence of a serine sidechain providing a Mo–alkoxo link; (*iii*) that a single oxo ligand (rather than two) is present in the oxidised form and (*iv*) that no oxo ligand (rather than one) is present in the dithionite-reduced form, and that one of the ligands is monodentate.

The situation is somewhat uncertain at the moment as two separate crystal structures of the dimethyl sulfoxide reductase from a closely related organism *R. capsulatus* suggest the presence of two oxo ligands (rather than one) in the oxidised form.[16,42] In addition, there are differences in the detail of the 1,2-dithiolate coordination modes. In one structure, both dithiolate ligands are bidentate and symmetrical,[42] while in the other, one is free and not bound to the molybdenum centre.[16] It is possible that different crystal forms have been examined.

The detailed nature of the individual sites remains to be clarified. Certainly, both $Mo^{VI}O_2$-based models and the dime-

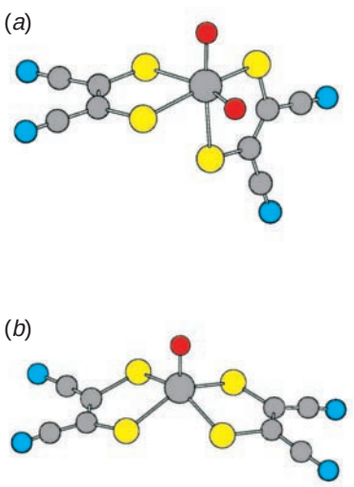


**Fig. 4** Molecular structures (M = Mo, W; mnt = dianion of 1,2-dicyano-1,2-dithioethene)[40,71,72] of (*a*) $[M^{VI}O_2(mnt)_2]^{2-}$ and (*b*) $[M^{IV}O(mnt)_2]^{2-}$

thyl sulfoxide reductase from *R. sphaeroides* can catalyse the OAT reaction (9).[7,22]

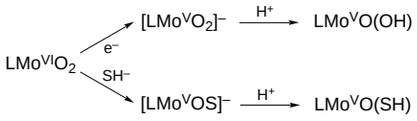
$$PR_3 + OSMe_2 \rightarrow OPR_3 + SMe_2 \quad (9)$$

This enzyme is unusual in that the molybdenum site is its sole redox site. This apparently allows efficient cycling of $PR_3$ oxidation by $Mo^{VI}$ and $OSMe_2$ reduction by $Mo^{IV}$. Equivalent processes are expected to be more difficult to achieve in other enzymes if rapid electron transfer to or from another redox site occurs after each step.

The presence of a $Mo^{VI}O$ site in the enzymes would mean that a controlling spectator oxo ligand is not necessary (*cf.* Scheme 2): the two 1,2-dithiolate ligands and their apparent ambidentate nature may impart an equivalent electronic environment. While the couple $[Mo^{VI}O_2(mnt)_2]^{2-}$–$[Mo^{IV}O(mnt)_2]^{2-}$ (Fig. 4) features two 1,2-dithiolate ligands and is active in OAT reactions, an equivalent $Mo^{VI}O$–$Mo^{IV}$ couple is not known. The $[Mo^{IV}(mnt)_3]^{2-}$ ion is known.[40,43]

Sequence homologies suggest that the serinyl ligand in dimethyl sulfoxide reductase is replaced by a cysteinyl ligand in dissimilatory nitrate reductase and in trimethylamine *N*-oxide reductase (*cf.* sulfite oxidase) and by a selenocysteinyl ligand in formate dehydrogenase.[15,44] This variation is a straightforward method of tuning the active site.

### The xanthine oxidase family: $Mo^{VI}OS$ sites with one pterin 1,2-dithiolate ligand



This class includes the xanthine oxidase/dehydrogenase systems [Scheme 1(*a*)] and the molybdenum aldehyde oxidoreductases which, in contrast to the other enzymes, are able to activate C–H bonds.[4,8,9] A crystal structure of the aldehyde oxidoreductase from *D. gigas* with the active site present in its hydrolysed 'desulfo' form indicates the presence of a five-coordinate site with a $Mo^{VI}O_2(OH_2)$ fragment bound to a pterin 1,2-dithiolate [Fig. 2(*a*)].[12] The aqua ligand has direct access to an extended solvent channel where substrate would be expected to bind. Structures are now available for oxidised and reduced forms of the enzyme and forms in which the thio ligand $S^{2-}$ appears to occupy the apical position in the coordination sphere.[13] X-Ray absorption spectroscopy data for the $Mo^{VI}$ and $Mo^{IV}$ levels of xanthine oxidase/dehydrogenase are consistent with $Mo^{VI}OS$ and $Mo^{IV}O(SH)$ centres. Both $Mo^{V}OS$ ('very rapid') and $Mo^{V}O(SH)$ ('rapid') centres are observed by EPR during catalytic turnover.

The complex $(L\text{-}N_3)MoOS(S_2PPr^i_2)$, synthesised with the sulfur atom donor propylene sulfide [eqn. (10)], provides a structurally characterised example of a relevant *cis*-$Mo^{VI}OS$ centre [Fig. 5(*a*)].[9,45]

$$(L\text{–}N_3)Mo^{IV}O(S_2PPr^i_2) + C_3H_6S \rightarrow (L\text{–}N_3)MoOS(S_2PPr^i_2) + MeCH{=}CH_2 \quad (10)$$

The Mo=S distance is 2.227(2) Å (compared to 2.15–2.25 Å estimated for xanthine oxidase/dehydrogenase by EXAFS) and the structure features a significant stabilising S···S interaction [2.396(3) Å] between the Mo=S and S=P functions. The apical Mo=S link observed in aldehyde oxidoreductase from *D. gigas* appears to be hydrogen bonded to a nearby histidine sidechain which may induce an equivalent stabilisation.[13]

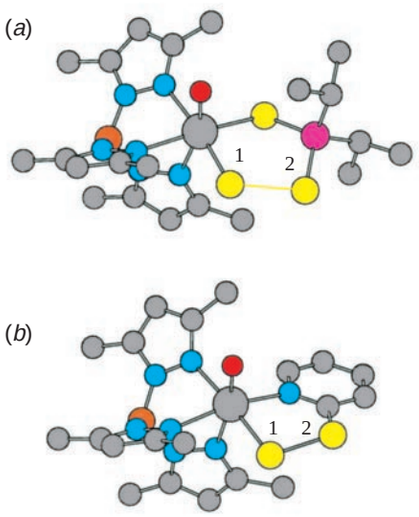
Molybdenum(v) centres have been generated synthetically *via* Scheme 3 [L = $L\text{-}N_2S_2$ or $(L\text{-}N_3)Y$; Fig. 3) and characterised in the solid state or in solution *via* EPR hyperfine interactions in species substituted with $^2H$, $^{17}O$, $^{33}S$, $^{95}Mo$ and $^{98}Mo$.[26,27,34–36,46–48] Combination of the synthetic results with those from enzyme EPR[49,50] and single catalytic turnover experiments[51–53] led to the minimal catalytic scheme shown in Scheme 4 for xanthine oxidase/dehydrogenase under substrate limiting conditions.[9,48]

**Scheme 3**

The resting form was formulated as a *fac*-$Mo^{VI}OS(OH)$ centre.[48] This structure is supported by density functional calculations[54] and is compatible with the structural results for aldehyde oxidoreductase [Fig. 2(*a*)].[13] In this latter case, a nearby glutamic acid residue is available to act as a base for effective conversion of ligand $OH_2$ to OH during turnover. Product uric acid [Scheme 1(*a*)] bound as an anionic ligand $RO^-$ appears in both the $Mo^{IV}$ and $Mo^{V}$ (very rapid) centres of xanthine oxidase. Reduction of the resting form leads to occupation of a highly delocalised MoS $\pi_{xy}$* orbital allowing the thio ligand to become a strongly basic centre facilitating activation of the C–H bond of xanthine.[9,48]

Classification of individual steps as OAT or CEPT chemistry becomes blurred somewhat in this cycle. Generation of bound product may be classified as an OAT step while regeneration of the $Mo^{VI}$ site with $H_2O$ is a CEPT step. The state of protonation of the thio ligand and its role as a base upon reduction is also CEPT chemistry. Further complications are observed when substrate is in excess and can interact with a $Mo^{V}$ form of the enzyme generating the rapid centres [*fac*-$Mo^{V}$-O(SH)(OH)?].[4,48] A detailed molecular mechanism is still evolving.[4,13,55]

Cyanide ion inactivates xanthine oxidase/dehydrogenase under oxidising conditions to produce a 'desulfo' $Mo^{VI}O_2$ centre and $SCN^-$.[8] Complex $(L\text{-}N_3)Mo^{VI}OS(S_2PPr^i_2)$ reacts with cyanide to produce $SCN^-$ quantitatively *via* a formal sulfur atom transfer, forming $(L\text{-}N_3)Mo^{IV}O(S_2PPr^i_2)$ under dry anaerobic conditions and $(L\text{–}N_3)Mo^{VI}O_2(S_2PPr^i_2)$ in the presence of $H_2O$ and $O_2$ [eqn. (11)].[45]



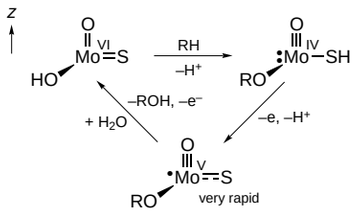


**Fig. 5** Molecular structures of (*a*) $(L\text{-}N_3)Mo^{VI}OS(S_2PPr^i_2)$[45] and (*b*) $(L\text{-}N_3)Mo^{IV}O(pyS_2)$[56]

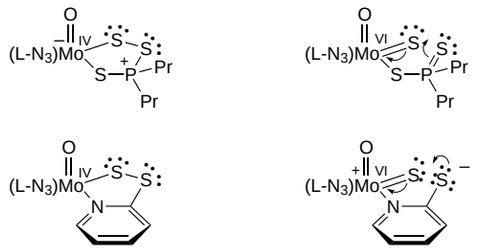
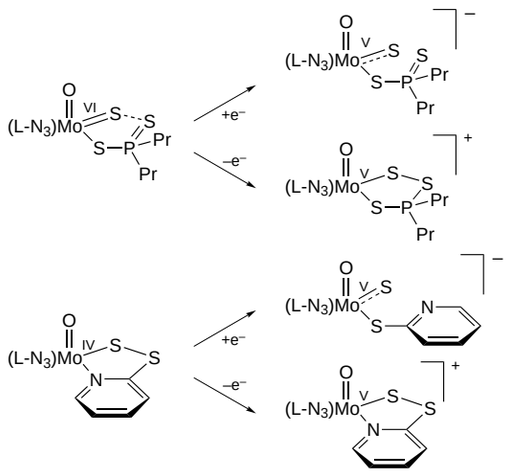
**Scheme 4** For the very rapid centre, the Mo=S notation implies occupation of a MoS $\pi_{xy}$* orbital by the unpaired electron leading to a formal MoS bond order of 1.5[47,48]



$$Mo^{VI}OS + CN^- + H_2O + O_2 \rightarrow Mo^{VI}O_2 + SCN^- + H_2O_2 \quad (11)$$

The structure of (L-$N_3$)MoO($pyS_2$), produced from (L-$N_3$)MoO(pyS) *via* a sulfur atom transfer reaction entirely similar to that of eqn. (10), is shown in Fig. 5(*b*).[56] The Mo–S and the S–S distances of 2.323(2) and 2.108(3) Å, respectively, approach those typical of a single bond (*ca.* 2.4 and 2.05 Å). The compound is best formulated as an oxodithiomolybdenum(IV) species. The alternative formulations for (L-$N_3$)$Mo^{IV}O(pyS_2)$ as a $Mo^{VI}$ species or for (L-$N_3$)$Mo^{VI}OS(S_2PPr^i_2)$ as a $Mo^{IV}$ species are less likely due to the unfavourable charge separations illustrated in Scheme 5. The redox properties of these complexes are fascinating: EPR-active $Mo^V$ species are formed upon reduction or oxidation.[56] Both (L-$N_3$)$Mo^{VI}OS(S_2PPr^i_2)$ and (L-$N_3$)$Mo^{IV}O(pyS_2)$ produce oxothiomolybdenum(V) anions upon reduction and oxodithiomolybdenum(V) cations upon oxidation (Scheme 6).



These examples highlight the facile redox interplay of molybdenum and its sulfur ligands in these systems.[57] It is apparent that the fine details of both the acid–base and redox interactions of the MoOS centre with its co-ligands (including the 1,2-dithiolate function of the pterin, in particular) and with nearby amino acid sidechains[12–16] will be crucial to a molecular understanding of each stage of catalysis in this class of enzymes.

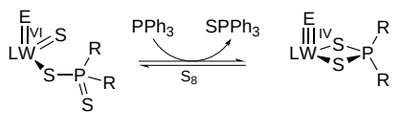
## Tungsten enzymes

The rapid development of this field is due largely to the work of Ljungdahl, Adams, Simon and Thauer.[2,11] Tungsten enzymes are largely restricted to thermophilic organisms, which thrive in niche environments such as hot marine sediments and hydrothermal vents. In these extreme environments, the thermodynamic and kinetic attributes of tungsten appear to enhance the stability and performance of tungsten enzymes over molybdenum enzymes. The unusual biochemistry of the thermophiles is highlighted by their use of sulfur rather than dioxygen as terminal electron acceptor. However, it is in the assimilation of carbon from sources such as carbon dioxide, complex carbohydrates or proteins that the tungsten enzymes play key roles. A sample of half reactions is given in Scheme 1(e)–(g). The specific couples have very low potentials (≤400 mV *vs.* the standard hydrogen electrode[11]).

**Scheme 5**

**Scheme 6**

The best characterised enzyme is the aldehyde oxidoreductase of *Pyrococcus furiosus* [Scheme 1(e)].[58] A crystal structure has revealed a square pyramidal tungsten centre bound to two 1,2-dithiolate bidentate ligands [Fig. 2(*c*)].[14] It was not possible to identify positively the other ligands in the crystallised form. Chemical and EXAFS studies of active forms are consistent with the presence of W=O, W=S and/or W–SH functions.[58–60] These forms lose activity upon treatment with the thiophiles cyanide and arsenite. Redox titrations of active enzyme monitored by EPR suggests that some aspects of the redox chemistry may be based on the pterin ring.[61]



A formate dehydrogenase from *Clostridium thermoaceticum* [Scheme 1(f)] is proposed to feature selenocysteine and 1,2-dithiolate ligands [Fig. 6(*a*)].[62] The tungsten formate dehydrogenases from two *Methanobacterium* strains are resistant to cyanide inactivation.[4] Intriguingly, a molybdenum isoenzyme is not [*cf.* eqn. (11)].

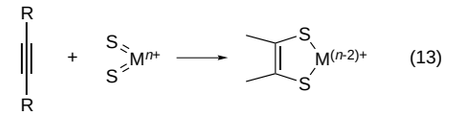
Despite remarkable insights provided by EXAFS and X-ray crystallography, the detailed nature of the active sites in the tungsten enzymes remains uncertain. The presence of oxo, thio, mercapto, thiolato, selenolato and O- and N-donor ligands are all possible. The chemistry is expected to involve tungsten in oxidation states IV–VI as these dominate established compounds bearing the above ligands.

## Thiotungsten chemistry

The $W^{VI}O_2$ group is relatively unreactive and nature may exploit sulfur ligands to enhance the oxidative capacity of tungsten centres. Series of complexes featuring $W^{VI}OS$ and $W^{VI}S_2$ centres bound to ligands L-$N_3$ and L-$N_2S_2$ have been isolated using both high-valent $W^{VI}O_2$ and low-valent $W^0(CO)_x$ complexes as starting points (*e.g.* see Fig. 7).[63–66]

Under similar conditions, the reduction potentials of the $W^{VI}OS$ and $W^{VI}S_2$ complexes are 0.5–0.8 V more positive than those of the $W^{VI}O_2$ analogues and fall into the range observed for related $Mo^{VI}O_2$ species. Terminal thio ligation at $W^{VI}$ clearly facilitates reduction. The oxothio- and dithio-tungsten(VI) complexes are reducible at biologically accessible potentials whereas most of the dioxotungsten(VI) complexes are not.

(12)



The $W^{VI}OS$ and $W^{VI}S_2$ complexes interconvert with $W^{IV}O$ and $W^{IV}S$ species by sulfur atom transfer reactions [*e.g.* eqn. (12); E = O, S; L = L-$N_3$)].

The reaction of cyanide with the $Mo^{VI}OS$ centres of xanthine oxidase/dehydrogenase and (L-$N_3$)$MoOS(S_2PR_2)$ results in the abstraction of thio ligand [eqn. (11)]. In contrast, several tungsten enzymes are not deactivated by cyanide,[4,67] and this may be interpreted to indicate the absence of thiotungsten centres in the enzymes. However, there is no reaction between (L-$N_3$)$WS_2Cl$ and $NEt_4CN$ in refluxing benzene over 24 h. The stability of this thiotungsten complex toward cyanolysis indicates that it is dangerous to dismiss the possible presence of thiotungsten centres in enzymes on the basis of their failure to react with cyanide.

## Tungsten ene-1,2-dithiolate complexes

The formate dehydrogenase enzyme from *C. thermoaceticum* is proposed to feature selenocysteine and 1,2-dithiolate ligands

[Fig. 6(*a*)]. Solutions of (L-$N_3$)$W^{VI}S_2Y$ react with alkynes to form ene-1,2-dithiolate tungsten(IV) complexes [eqn. (13)].

(13)

These remarkably facile reactions are very rapid at room temperature, even with unactivated alkynes and including acetylene. The structure of (L-$N_3$)W(OPh){$S_2C_2(CO_2Me)_2$} confirms the formation of the ene-1,2-dithiolate ligand [Fig. 6(*b*)]. The W–S bond lengths of 2.267(4) and 2.279(4) Å are considerably shorter (by 0.07 Å) than those reported previously for tungsten enedithiolates. The average W–S distance for such compounds is 2.40 Å and the W–$S_{av}$ distance for the above formate dehydrogenase is close to this average at 2.39 Å. The short W–S distances in (L-$N_3$)W(OPh){$S_2C_2(CO_2Me)_2$} are indicative of considerable $d_\pi$–$p_\pi$ bonding between the W and S atoms; the ene-1,2-dithiolate $S_2C_4$-framework is planar. Similar chemistry was recently reported for the complex [(η-$C_5Me_5$)$WS_3$]$^-$ which reacts with alkynes to give [(η-$C_5Me_5$)$WS(S_2C_2R_2)$]$^-$.[68] The complex (L-$N_3$)W(SePh){$S_2C_2$(Ph)(2-quinoxalinyl)} provides a structural and spectroscopic benchmark for the proposed site in the formate dehydrogenase [Fig. 6(*a*)]. Interestingly, it decomposes rapidly in methanolic solution in air to give (L-$N_3$)$WO_2$(OMe), diphenyldiselenide and the disulfide shown in Fig. 1(*c*). This latter species is also formed in the oxidative decomposition of [Mo{$S_2C_2$(Ph)(2-quinoxalinyl)}$_3$]$^{2-}$ in a reaction reminiscent of the formation of urothione upon degradation of the molybdenum cofactor [Fig. 1(*a*),(*b*)].[69] It is possible that degradation of pterin tungsten enzymes might produce urothione.

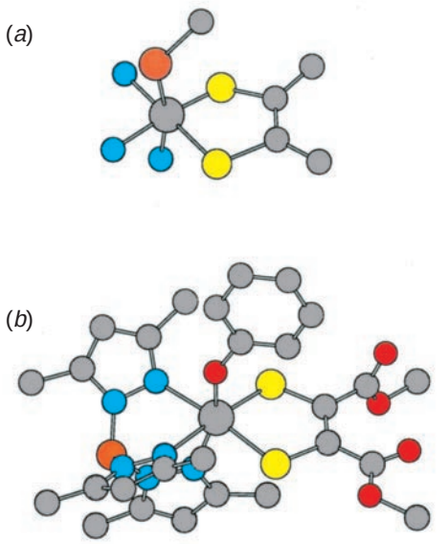


**Fig. 6** (*a*) Proposed structure at the active site of formate dehydrogenase from *Clostridium thermoaceticum*.[62] Colour code: selenium, orange. (*b*) (L-$N_3$)W(OPh){$S_2C_2(CO_2Me)_2$}.[64] Colour code: boron, orange.

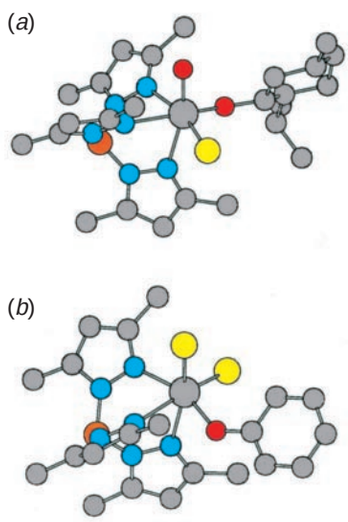

**Fig. 7** Molecular structures[64] of (*a*) (L-$N_3$)$W^{VI}$OS{(−)-mentholate} and (*b*) (L-$N_3$)$W^{VI}S_2$(OPh)

Structural and functional models for the aldehyde oxidoreductase of *P. furiosus* incorporating ene-1,2-dithiolate ligands at high-valent oxotungsten centres have been developed by Nakamura and Sarkar.[70,71] They represent exciting developments in a challenging area of coordination chemistry. The benzene-1,2-dithiolate complex $[W^{VI}O_2(bdt)_2]^{2-}$ converts benzoin to benzil [eqn. (14)].[70]

$$[W^{VI}O_2(bdt)_2]^{2-} + PhCH(OH)COPh \rightarrow [W^{IV}O(bdt)_2]^{2-} + PhCOCOPh + H_2O \quad (14)$$

The ease of this reaction contrasts with the very slow reaction of $[W^{VI}O_2(bdt)_2]^{2-}$ with $PPh_3$ and suggests that reduction of $W^{VI}O_2$ centres may be facilitated by CEPT rather than OAT reactions. Recently, the interconversion of anions $[W^{VI}O_2(mnt)_2]^{2-}$, $[W^{IV}O(mnt)_2]^{2-}$ (Fig. 4) and $[W^{VI}O(\eta^2\text{-}S_2)(mnt)_2]^{2-}$ in enzymatically relevant reactions, such as the oxidation of aldehydes to carboxylic acids, has been demonstrated.[71] The stoichiometries of these bis(ene-1,2-dithiolate)tungsten(VI) complexes are similar to the centre revealed in the aldehyde oxidoreductase [Fig. 2(*c*)] although their coordination geometries deviate from the proposed trigonal-prismatic structure at the enzyme centre. The effects of such variations on the chemistry of the tungsten centres remains to be assessed.

## Conclusions

The recent enzyme crystal structures emphasise the structural diversity available to a cofactor ligand such as the pterin 1,2-dithiolate centre. Further refinement of these structures and the anticipation of new ones in the near future (formate dehydrogenase; xanthine oxidase and dehydrogenase) will further illuminate the fundamental chemistry.

This article has but touched the surface of the chemical diversity exhibited by the molybdenum and tungsten enzymes. This diversity follows from variation of metal, ligand (oxo → thio; serine → cysteine → selenocysteine), pterin redox level and interaction with protein sidechains. Investigations will move to a new sophistication *via* synergy between the enzyme structural work, active site modification by site-directed mutagenesis and continuing development of the fundamental chemistry.

# A tetranuclear cluster sandwiched between edge-bridging cycloheptatrienyl rings: the synthesis and characterisation of $[Ru_4(CO)_7(\mu\text{-}C_7H_7)_2]$

**Dario Braga,[a] Paul J. Dyson,[b] Fabrizia Grepioni,*[a] Brian F. G. Johnson,*[c] Caroline M. Martin,[c] Laura Scaccianoce[c] and Alexander Steiner[d]**

**The reaction of $[Ru_3(CO)_{12}]$ with cycloheptatriene affords $[Ru_4(CO)_7(\mu\text{-}C_7H_7)_2]$ an example of a new class of sandwich cluster which is characterised in the solid-state by single-crystal X-ray diffraction and shown to contain an unusual arrangement of two parallel edge-bridging organic rings.**

The metallocenes and other related sandwich complexes have caught the imagination of chemists since their initial discovery and continue to play an important role in the development of the subject.[1] Over the years sandwich compounds have found applications in a number of areas of technological importance.[2] For some time we have been interested in incorporating clusters of metal atoms between decks of organic rings and have made a number of sandwich clusters in which an octahedral ruthenium unit is sandwiched between two arene rings which bond to single metal atoms of the octahedron.[3–6] A further goal has been to sandwich a cluster between two face-capping rings and while this is yet to be realised a number of clusters containing one face-capping and one terminally coordinated ring have been prepared. However, in these compounds the arenes are not parallel to one another.[7–11] Here, we report the synthesis and full characterisation of a highly unusual tetranuclear cluster, in which a $Ru_4$ tetrahedron is sandwiched between two parallel edge-bridging cycloheptatrienyl rings. As such this represents a new class of sandwich compound.

The ligand-exchange reaction between $[Ru_3(CO)_{12}]$ and $[Mo(CO)_3(\eta^6\text{-}C_7H_8)]$ produced a number of products including green $[Ru_4(CO)_7(\mu\text{-}C_7H_7)_2]$ **1** in 10% yield which has been fully characterised by spectroscopy† and single-crystal X-ray crystallography.‡ Higher yields were subsequently obtained from the direct reaction of $[Ru_3(CO)_{12}]$ and cycloheptatriene.§

The structure of **1** is shown in Fig. 1 and constitutes an unprecedented example of a sandwich compound in which a tetranuclear $Ru_4$ cluster is encapsulated between two cycloheptatrienyl ligands. The ligands edge-bridge two non-contiguous Ru–Ru bonds on the tetrahedron. The Ru–C distances are in the range 1.900(9)–2.663(8) Å; the shortest bonds being with atoms C(3) and C(4) and C(2′) and C(5′) which lie just above the two pairs of Ru atoms. The almost flat rings (maximum elevation from the mean plane 0.14 Å) formally donate seven electrons to the cluster, and the bonding may be described formally as $\mu\text{-}\eta^4:\eta^3$. The $^1$H NMR spectrum in $CDCl_3$ exhibits one signal at $\delta$ 4.18 which may be taken to indicate that all the protons are equivalent on the NMR timescale suggesting the rings rotate freely in solution.

The structure is disordered in the solid state with a crystallographic twofold axis relating the two cycloheptatrienyl rings and generating two interpenetrating images of the cluster core. This disorder is reminiscent of that present in $[Co_4(CO)_{12}]$[12,13] and $[Fe_3(CO)_{12}]$.[14–16] As with these cases, the

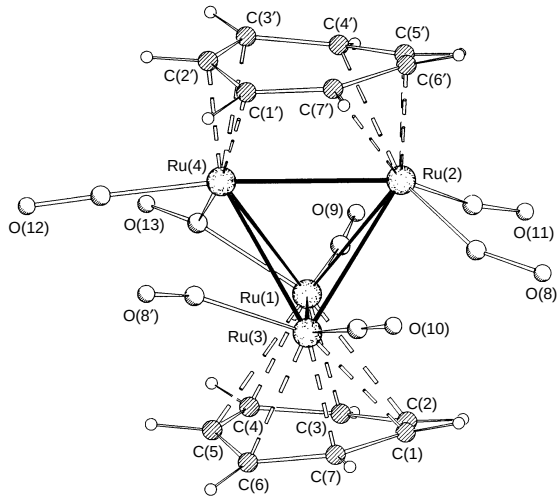

**Fig. 1** The molecular structure of **1** in the solid state showing the atomic labelling scheme, the O atoms of the carbonyl ligands bear the same numbering as their corresponding C atoms. Relevant bond lengths (Å): Ru(1)–Ru(2) 2.853(2), Ru(1)–Ru(3) 2.728(2), Ru(1)–Ru(4) 2.745(1), Ru(2)–Ru(3) 2.868(2), Ru(2)–Ru(4) 2.731(2), Ru(3)–Ru(4) 2.810(2), Ru(1)–C(2) 2.468(9), Ru(1)–C(3) 2.007(8), Ru(1)–C(4) 1.950(8), Ru(1)–Ru(5) 2.663(8), Ru(3)–C(1) 2.384(7), Ru(3)–C(6) 2.247(7), Ru(3)–C(7) 1.926(10), Ru(2)–C(4′) 2.465(8), Ru(2)–C(5′) 1.915(11), Ru(2)–C(6′) 2.175(7), Ru(2)–Ru(7′) 2.639(7), Ru(4)–C(1′) 2.183(7), Ru(4)–C(2′) 1.900(9), Ru(4)–C(3′) 2.332(8), C(1)–C(2) 1.411(1), C(1)–C(7) 1.372(11), C(2)–C(3) 1.330(11), C(3)–C(4) 1.442(11), C(4)–C(5) 1.325(11), C(5)–C(6) 1.426(11), C(6)–C(7) 1.368(11), Ru(2)–C(8) 1.849(8), Ru(3)–C(8′) 1.993(10), Ru(1)–C(9) 1.86(2), Ru(3)–Ru(10) 1.88(2), Ru(2)–C(11) 1.86(2), Ru(4)–C(12) 1.84(2), Ru(1)–C(13) 2.012(13), Ru(4)–C(13) 2.193(13), C(8)–O(8) 1.143(10), C(8′)–O(8′) 1.143(10), C(9)–O(9) 1.14(2), C(10)–O(10) 1.14(2), C(11)–O(11) 1.13(2), C(12)–O(12) 1.13(2), C(13)–O(13) 1.15(2).

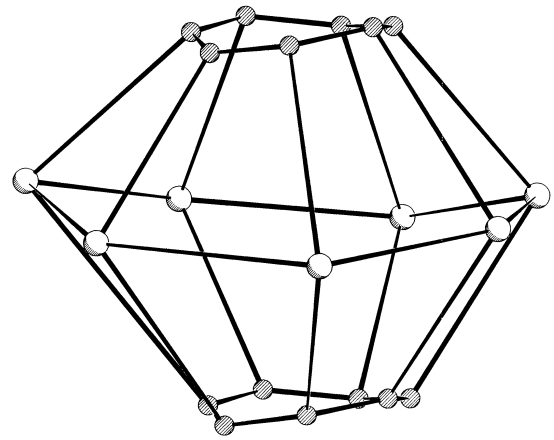

**Fig. 2** The ligand polyhedron formed by the two opposite cycloheptatrienyl ligands and by the seven O atoms of the CO ligands

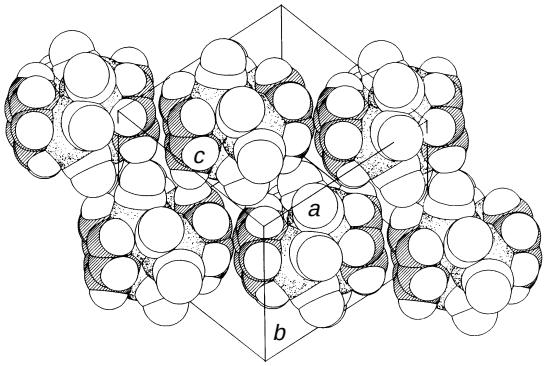

**Fig. 3** Space-filling representation of the molecular piles in the crystal structure of **1**

disorder arises from the invariance of the outer ligand polyhedron with respect to the orientation of the inner cluster unit. The ligand polyhedron is novel and Fig. 2 shows that it corresponds to a hexadecahedron formed by the two opposite cycloheptatrienyl ligands and the 'belt' of seven CO groups. Diffraction data were of sufficient quality to allow resolution of all separate images of the ligand atoms excluding C(8)O(8).

A further point of interest resides in the molecular arrangement in the solid state. Molecules pile along the 101 diagonal of the cell with direct interactions between the rings (mean distance between the ring planes 3.46 Å). This packing arrangement is illustrated in Fig. 3. Similar packing arrangements have been observed for other cluster–arene systems.[17]

We would like to thank the Royal Society for a University Research Fellowship (P. J. D.), MURST (D. B. and F. G.), the EPSRC and the EU for financial support.

## Footnotes

† *Spectroscopic data* for **1**: IR $\nu_{CO}$ ($CH_2Cl_2$) 1961vs, 1813m $cm^{-1}$; $^1H$ NMR ($CDCl_3$) $\delta$ 4.18 (s).

‡ *Structural data* for **1**: $C_{21}H_{14}O_7Ru_4$, $M$ = 782.60, monoclinic, space group = $C2/c$, $a$ = 13.083(4), $b$ = 12.692(4), $c$ = 12.945(3) Å, $\beta$ = 93.22(2)°, $U$ = 2146.1(11) Å$^3$, $Z$ = 4, $D_c$ = 2.422 g $cm^{-3}$, $F(000)$ = 1488, crystal dimensions 0.18 × 0.16 × 0.16 mm, $2\theta_{max}$ = 50°, $\lambda$(Mo-Kα) = 0.710 69 Å, $\mu$(Mo-Kα) = 2.803 $mm^{-1}$, refinement on $(F_0)^2$ for 1886 data and 208 parameters, $wR_2$ = 0.1456 (all data), conventional $R$ = 0.0434. H-atoms were placed in geometrically calculated positions. The program SHELX 93 was used for the structure solution and refinement.[18] On decreasing the temperature to 223 K the orientation matrix is lost and the crystal diffracts poorly. This may indicate the occurrence of a phase transition, possibly associated with metal-frame reorientation, as observed in other carbonyl clusters.[19] Work is in progress to fully assess the phenomenon. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/479.

§ *Synthesis* of **1**: $Ru_3(CO)_{12}$ (0.1 g) and cycloheptatriene (0.5 ml) were dissolved in dry octane (30 ml) and heated to reflux for 5 h and the reaction mixture turned dark brown. The solvent was removed under reduced pressure and the residue dissolved in a minimum amount of $CH_2Cl_2$ and the products purified by TLC on silica plates using $CH_2Cl_2$–hexane (1 : 4, v/v) as the eluent. The dark green band was removed and the product extracted into $CH_2Cl_2$ and characterised as **1** (50%).

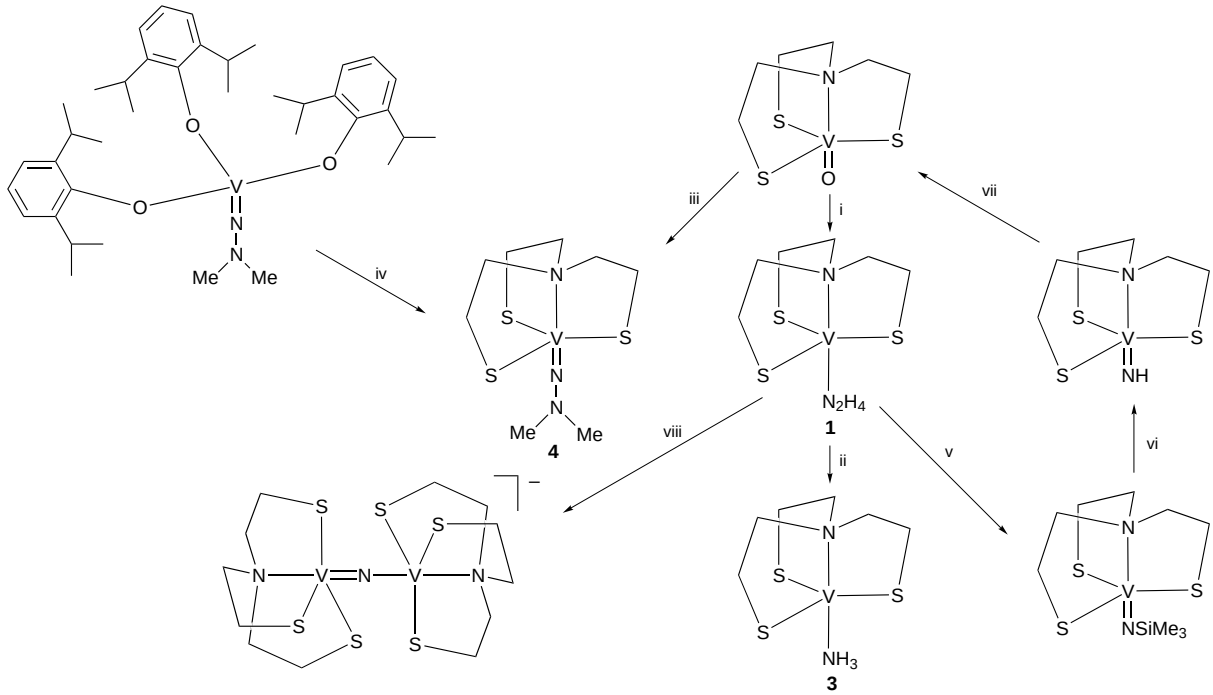
# Vanadium complexes of the $N(CH_2CH_2S)_3^{3-}$ ligand with co-ligands relevant to nitrogen fixation processes

**Sian C. Davies,[a] David L. Hughes,[a] Zofia Janas,[b] Lucjan Jerzykiewicz,[b] Raymond L. Richards,*[a] J. Roger Sanders*[a] and Piotr Sobota[b]**



[a] *Nitrogen Fixation Laboratory, John Innes Centre, Colney Lane, Norwich, UK NR4 7UH*
[b] *Faculty of Chemistry, University of Wroclaw, 14 F. Joliot-Curie Street, 50-383 Wroclaw, Poland*

**Vanadium(III) and vanadium(V) complexes of the tris(2-thiolatoethyl)amine ligand $L^{3-}$ containing hydrazine, hydrazide, imide, ammine, cyanide and isocyanide ligands are synthesised; the complexes $[V(NH_3)L]$ and $[V(NNMe_2)L]$ have been structurally characterised.**

The cofactor of molybdenum nitrogenase contains an $MoFe_7S_9$ cluster with the Mo atom ligated by one nitrogen, three sulfurs and two oxygens[1] and it is thought that the vanadium atom in the analogous vanadium nitrogenase[2] is in a similar environment, as is possibly one of the iron atoms in the third 'iron-only' nitrogenase.[3] The chemistry of V, Mo and Fe centres which carry three sulfurs (plus other ligands) ($MS_3$ sites) is therefore of great importance in understanding the mode of action of these enzymes. In particular, reduction of $N_2$ to $NH_3$ might involve intermediate species $N_2H_m$ and $NH_n$ ($m$ = 0–4, $n$ = 0–3) bound at $MS_3$ sites.[4] Here we report use of the ligand $N(CH_2CH_2S)_3^{3-}$ [$L^{3-}$] to generate a range of complexes of $N_2H_m$ and $NH_n$ and related ligands at $MS_3$ sites, particularly for vanadium, where there is very limited chemistry of reduced nitrogen species at this metal in a sulfur-donor environment.[4,5] Key reactions to generate the vanadium series are shown in Scheme 1. All compounds described in this paper have been characterised by microanalysis and magnetic and spectroscopic data.

Treatment of $[VO(L)]$[6] with four equivalents of anhydrous hydrazine in acetonitrile removes the oxide ligand to give an almost quantitative yield of the complex $[V(NH_2NH_2)L]$ **1** as an insoluble yellow powder. When **1** is heated in suspension in tetrahydrofuran a decomposition/disproportionation reaction takes place giving a dark green, poorly soluble precipitate of composition VL **2** and a yellow solution from which $[V(NH_3)L]$ **3** crystallises on cooling. The structure of **3** is shown in Fig. 1.† The geometry around the V atom is trigonal bipyramidal with the S atoms in equatorial positions and N(4)–V–N(5) almost linear. The V–N(4) bond distance [2.155(8) Å] in **3** is considerably shorter than the corresponding distance in $[VO(L)]$[6] [2.291(6) Å], presumably reflecting the high *trans*-influence of the oxide ligand of $[VO(L)]$ relative to the $NH_3$ ligand in **3**. Individual molecules of **3** are held in chains by hydrogen bonds between the three hydrogen atoms of the ammine ligand and the S atoms of neighbouring molecules.

The formation of **1** probably involves a hydrazide intermediate such as $[V(NNH_2)L]$, since treatment of $[VO(L)]$ with $Me_3SiNHNMe_2$ gives diamagnetic $[V(NNMe_2)L]$ **4**, whose X-ray structure is shown in Fig. 2.† As far as we are aware, this is the first hydrazide of vanadium with sulfur-donor co-ligands. Compound **4** can also be prepared from $[V(OC_2H_3Pr^i_2\text{-}2,6)_3(NNMe_2)]$.[7] The V–$NNMe_2$ distance in **4** is shorter than the

**Scheme 1** *Reagents and conditions*: i, 4 equiv. $N_2H_4$, MeCN, 20 °C; ii, thf, 60 °C; iii, $Me_3SiNHNMe_2$, $CH_2Cl_2$, 20 °C; iv, 1.5 equiv. $H_3L$, hexane, 20 °C; v, excess $N_3SiMe_3$, MeCN, 80 °C; vi, MeCN–$H_2O$, 20 °C; vii, $NMe_4OH$, MeOH, 60 °C, 10 min, then HCl–$Et_2O$; viii, $NEt_4Cl$, MeCN, 80 °C, then excess $NaN_3$, MeCN, 80 °C

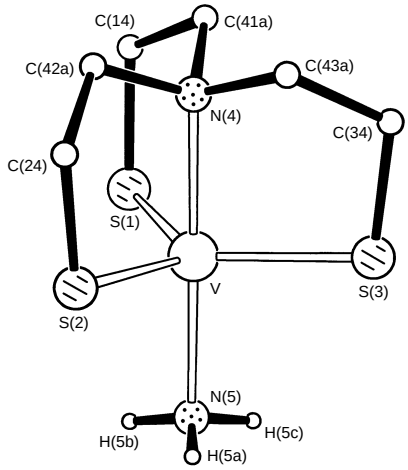


**Fig. 1** The molecular structure of **3**. There is disorder of the three C(4*n*) atoms ($n$ = 1–3); the principal component, with *ca*. 80% occupancy, C(4*n*a) is shown here. Selected bond lengths (Å) and angles (°): V–N(5) 2.154(7), V–N(4) 2.155(8), V–S(1) 2.283(3), V–S(2) 2.285(3), V–S(3) 2.301(3); N(5)–V–N(4) 178.7(3), N(5)–V–S(av.) 93.9(5), N(4)–V–S(av.) 86.1(2).

V–$NH_3$ distance in **3**, and the V–$NS_3$ distance is correspondingly longer in **4** [2.214(3) Å], approaching that in [VO(L)]. The N–N distance of the hydrazide ligand [1.305(5) Å] is in the range generally found in hydrazide complexes of the early transition metals[8,9] and in the only structurally characterised hydrazide complexes of vanadium, $[V(C_5H_5)_2\{NN(SiMe_3)_2\}]$ [1.369(9) Å],[10] the anion $[VCl_2(NH_2NMePh)_2(NNMePh)]^-$ [1.295(17) Å][11] and $[(C_9H_{18}N_2)_2(OSiMe_3)_2V(\mu\text{-}O)VO(OSiMe_3)_2]$ [1.285(3) and 1.245(4) Å].[9] However, whilst there is no doubt of the nature of the $NNMe_2$ ligand in **4**, it is unusual in that the N–C distances appear to be unequal [1.401(15), 1.502(15) Å] and N(3) lies some 0.21 Å out of the plane formed by N(2), C(7) and C(8) (Fig. 2). This phenomenon is under further investigation.

Novel nitride and imide complexes have been obtained from **1** as shown in Scheme 1. The dimer $NBu_4[LV(\mu\text{-}CN)VL]$, the salt $NEt_4[VCl(L)]$ and the adducts [V(NCMe)L] and [V(CNBu$^t$)L] have also been obtained from reaction of **3** with $NBu_4CN$, $NEt_4Cl$, MeCN and CNBu$^t$ respectively.

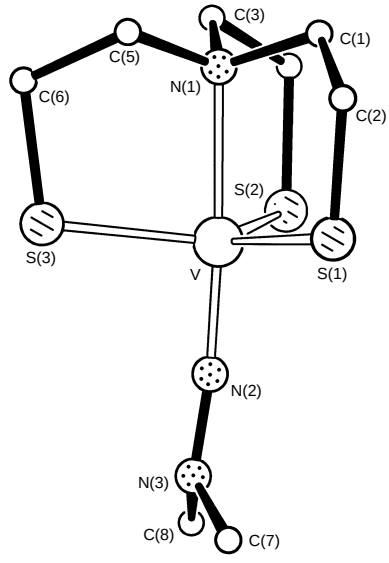

**Fig. 2** The molecular structure of **4**. Selected bond lengths (Å) and angles (°): V–N(1) 2.214(3), V–N(2) 1.681(3), N(1)–C(1) 1.514(9), V–S(1) 2.261(3), V–S(2) 2.273(3), V–S(3) 2.255(2), N(2)–N(3) 1.305(5), N(3)–C(7) 1.401(15), N(3)–C(8) 1.502(15); N(1)–V–N(2) 176.6(2), V–N(2)–N(3) 173.9(4), N(1)–V–S(av.) 84.4(3), N(2)–V–S(av.) 95.6(14)°.

The characterisation of this set of nitrogen-donor ligands at a $VS_3$ site lends further credence to the idea that fixation of $N_2$ could occur at the vanadium site of vanadium nitrogenase,[2,4,5] and we intend to probe this further by study of the interconversion of the various NR (NR = $N_2H_4$, $NH_3$, NH, *etc*.) ligands in these compounds.

We have also prepared $[Fe(NH_2NH_2)L]$ and a very insoluble compound formulated as $Mo(NH_2NH_2)L$ which appears to be polymeric; their properties will be described at a later date.

We thank the British Council, the Polish State Committee for Scientific Research and the BBSRC for support.

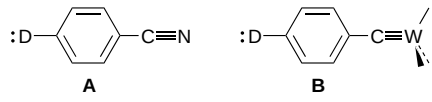
# One-dimensional alignment of organometallic donor–acceptor compounds *via* coordination polymerization. Synthesis and structures of $[W(\equiv CC_6H_4X\text{-}4)(OBu^t)_3]_\infty$ (X = $NMe_2$, SMe)



**Holly A. Brison, Timothy P. Pollagi, Timothy C. Stoner, Steven J. Geib and Michael D. Hopkins***

*Department of Chemistry and Materials Research Center, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA*

**Metal–alkylidyne complexes of the type $W(\equiv CC_6H_4X\text{-}4)(OBu^t)_3$ (X = $NMe_2$, SMe), which are analogues of classic organic donor–acceptor compounds, form infinite-chain structures in the solid state through weak intermolecular dative bonds between the tungsten and donor atoms.**

A design prerequisite for bulk molecular materials that possess second-order non-linear optical responses is that the individual chromophores of which they are composed must be non-centrosymmetrically ordered. One strategy for achieving this order is to incorporate the chromophore, typically a conjugated organic molecule with electron-donor (D) and -acceptor (A) substituents, into a polymer host, upon which the host–guest material is processed to induce temporary alignment of the chromophore dipoles, or *via* chemical bonds into a lattice of appropriate three-dimensional structure.[1] A second approach is to design chromophores that 'self-assemble' into ordered arrays, such as hydrogen-bonded networks of organic compounds[2] or metal coordination polymers.[3]

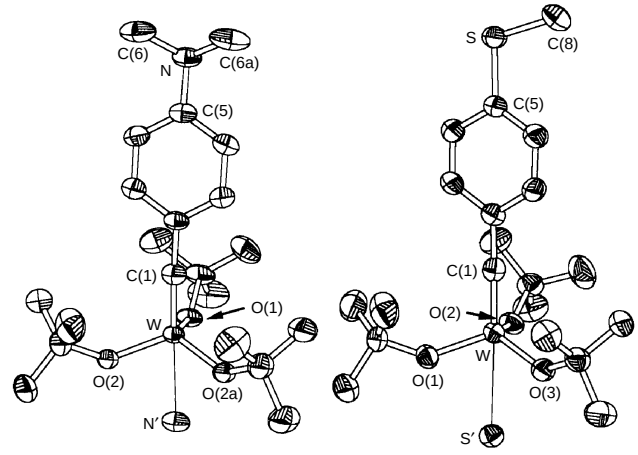
Our interest in developing transition-metal analogues of conjugated organic compounds and polymers[4] led us to inquire if replacing the ubiquitous cyano groups of organic donor–acceptor compounds **A** with metal–alkylidyne groups **B** would serve the dual purposes of broadening the electronic tunability of the acceptor and of affecting one-dimensional A–D···A–D ordering of the chromophores. Alkylidyne complexes of the type $M(\equiv CR)X_3$ (M = Mo, W)[5] are especially interesting in this context because the metal centres are potential electron acceptors (formally $M^{VI}$), and because they weakly coordinate neutral ligands *trans* to the M≡C bond, which can lead to one-dimensional polymeric structures if the alkylidyne R group contains a ligating substituent.[6] Herein we report the syntheses of $W(\equiv CC_6H_4NMe_2\text{-}4)(OBu^t)_3$ **1** and $W(\equiv CC_6H_4SMe\text{-}4)(OBu^t)_3$ **2**, and that these complexes exhibit one-dimensional A–D···A–D polymeric structures in the solid state.

**A** **B**

Compounds **1** and **2** can be prepared from the reaction between $4\text{-}XC_6H_4CN$ (X = $NMe_2$, SMe) and $W_2(OBu^t)_6$[7] in pentane at room temp. Within minutes of combining the reagents the reaction mixture changes from deep red to brown, and white $[WN(OBu^t)_3]_\infty$[8] precipitates. Filtration of the solution and removal of solvent *in vacuo* yields a brown powder. Recrystallization of this material from pentane at −35 °C provides yellow–orange **1** and **2** in 73 and 74% yield (based on $4\text{-}XC_6H_4CN$), respectively.† The $^1H$ and $^{13}C$ NMR data for **1** and **2** are similar to those for the related compound $W(\equiv CPh)(OBu^t)_3$.[9] There is no evidence from the NMR data for static intermolecular interactions among monomers in solution.

Single-crystal X-ray diffraction studies of **1** and **2** reveal them to be polymeric in the solid state, consisting of one-dimensional zigzag chains of monomers connected by weak dative bonds between the donor and tungsten atoms of adjacent molecules.‡ The structures of the repeat units of $[\mathbf{1}]_\infty$ and $[\mathbf{2}]_\infty$ are shown in Fig. 1, and a view of an extended fragment of $[\mathbf{1}]_\infty$ is provided in Fig. 2. The assembly of **1** and **2** into infinite-chain structures does not result in significant structural perturbations to their $WCO_3$ cores: the W≡C bond distances of $[\mathbf{1}]_\infty$ [1.754(7) Å] and $[\mathbf{2}]_\infty$ [1.757(6) Å] are essentially identical to that of $W(\equiv CPh)(OBu^t)_3$ [1.758(5) Å],[10] and there is only a slight flattening of the pyramidal $WO_3$ units of $[\mathbf{1}]_\infty$ and $[\mathbf{2}]_\infty$ as a result of the axial ligation in the polymers [O–W–$O_{av}$: $[\mathbf{1}]_\infty$ 115(1)°, $[\mathbf{2}]_\infty$ 114(2)°, $W(\equiv CPh)(OBu^t)_3$ 111(2)°]. From an electronic standpoint, only small structural perturbations are expected because the intermolecular W···E bonds in $[\mathbf{1}]_\infty$ and $[\mathbf{2}]_\infty$ are extremely long [W···N 2.767(4), W···S 3.079(2) Å]. Steric interactions and packing forces are presumably responsible for the more noticeable distortions, such as the slight 'bowing' of the $E\text{–}C_6H_4\text{–}C{\equiv}W$ unit (Fig. 2).

Despite the long W···N bond distance, the electronic structure of the aniline moiety in $[\mathbf{1}]_\infty$ is significantly altered from that expected for monomeric **1**. Specifically, the nitrogen centres in $[\mathbf{1}]_\infty$ are pyramidal [C(5)–N–C(6) 113.9(3)°, C(6)–N–C(6a) 110.9(6)°], in contrast to the expected planar structure, and the C(5)–N bond distance [1.438(8) Å] is consistent with $sp^3$ hybridization for nitrogen rather than $sp^2$ hybridization [$d(C_{aryl}\text{–}N_{sp^3})$ = 1.43 Å, $d(C_{aryl}\text{–}N_{sp^2})$ = 1.37 Å].[11] This



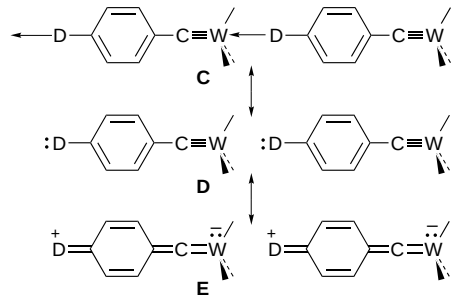


**Fig. 1** Thermal ellipsoid representations (50% probability) of the structures of **1** (left) and **2** (right). The donor atoms of the adjacent molecules are also shown. Selected bond distances (Å) and bond angles (°): for **1**: W–C(1) 1.754(7), W···N 2.767(4), W–O(1) 1.868(4), W–O(2) 1.876(3), C(5)–N 1.438(8); C(5′)–N′–W 107.5(4), N′–W–C(1) 174.2(3), O(1)–W–O(2) 115.2(1), O(2)–W–O(2a) 113.2(2), C(1)–W–O(1) 101.4(3), C(1)–W–O(2) 104.9(1), W–C(1)–C(2) 170.8(5), C(5)–N–C(6) 113.9(3), C(6)–N–C(6a) 110.9(6); for **2**: W–C(1) 1.757(6), W···S 3.079(2), W–O(1) 1.873(4), W–O(2) 1.881(4), W–O(3) 1.894(4), C(5)–S 1.772(5); C(5′)–S′–W 101.9(2), S′–W–C(1) 173.6(2), O(1)–W–O(2) 115.3(2), O(1)–W–O(3) 111.4(2), O(2)–W–O(3) 115.3(2), W–C(1)–C(2) 174.0(4), C(5)–S–C(8) 103.9(3).

**Fig. 2** Tetrameric section of $[W(\equiv CC_6H_4NMe_2\text{-}4)(OBu^t)_3]_\infty$. Atoms are shaded as follows: tungsten, black; oxygen, dotted; carbon, grey; nitrogen, hatched.

indicates that the π interaction between the $NMe_2$ and aryl groups is significantly diminished from what it would be in the monomeric compound. For $[\mathbf{2}]_\infty$, in contrast, the C(5)–S bond distance [1.772(5) Å] is typical of that for an organic thioanisol [$d(C_{aryl}–S)$ = 1.77 Å],[11] suggesting that the S–aryl π-interactions are of comparable magnitude in both the polymer and monomer forms. In principle, strong $D \rightarrow \{C{\equiv}W(OBu^t)_3\}$ interactions should be manifested as a quinoidal distortion of the aryl rings, but the C–C distances {$[\mathbf{1}]_\infty$ 1.378(6)–1.386(6) Å, $[\mathbf{2}]_\infty$ 1.369(8)–1.411(8) Å} are not known with sufficient precision to draw any conclusions on this point. We are presently studying the electronic spectra of these materials to deduce the extent of their $D \rightarrow \{C{\equiv}W(OBu^t)_3\}$ charge transfer.

In summary, we have discovered a class of organometallic analogues of classic organic *para*-phenylene D–A compounds that form one-dimensional solid-state structures. Qualitatively describing the bonding in these polymers requires the use of a third valence-bond canonical structure (**C**) in addition to the two typically invoked for monomeric D–A compounds (**D**, **E**).

From the standpoint of designing non-linear optical materials, achieving the optimum balance among these structures through chemical modifications involves trade offs; attempting to favour intramolecular $D \rightarrow A$ charge transfer (**E**) by increasing the electron-withdrawing capacity of the metal (*e.g.* the use of less strongly donating ancillary ligands) will also strengthen, detrimentally, the intermolecular interactions (**C**). Fortunately, the extremely long W···E bond distances in $[\mathbf{1}]_\infty$ and $[\mathbf{2}]_\infty$ suggest that even a very weak dative interaction is sufficient to affect one-dimensional organization of this class of compounds, and thus that steric modification of the ancillary ligands or of the donor group may allow independent tuning of intra- and inter-molecular charge transfer. Experiments to test this hypothesis are in progress. An additional challenge is to engineer non-centrosymmetric space groups for these materials, as those for **1** and **2** are centrosymmetric; derivatives with chiral ancillary ligands should be important in this context.

We thank the National Science Foundation for supporting this research (Grant CHE-9307013).

# X-Ray absorption and photoelectron spectroscopic observation of intrazeolitic silicon nanoclusters

**J. He, D. D. Klug, J. S. Tse* and K. F. Preston**

*Steacie Institute for Molecular Sciences, National Research Council of Canada, 100 Sussex Drive, Ottawa, Canada K1A 0R6*

**The Si-K near-edge absorption spectra and X-ray photoelectron spectra of silicon nanoclusters encapsulated in the pores of zeolite Y are measured; the intrazeolitic Si clusters display a blue shift of the K-edge (0.5 eV) relative to that of bulk Si and a strong room-temperature photoluminescence, which is consistent with the quantum confinement effect; the number of Si in the as-prepared sample is estimated to be 20 atoms per unit cell of zeolite Y from both XPS and Si K NEXAFS analysis.**

The drive towards nanoscale technology has motivated intense research on Si clusters and nanocrystals.[1] These are new forms of Si that exhibit quantum confinement effects and novel optoelectronic properties, such as efficient room-temperature photoluminescence. Several chemical approaches have been used to prepare these nanostructured forms of Si, including solution-phase synthesis *via* the dehalogenation of halosilanes by alkali metals[2,3] or by the Zintl compound KSi,[4] ultrasonic fracture of electrochemically etched Si wafers (porous Si),[5] gas-phase depositions by either slow combustion[6] or microwave plasma[7] of silanes and molecular sieve encapsulation *via* chemical vapour deposition of gaseous silanes.[8] Except for the molecular sieve encapsulation, these methods produce Si clusters with broad size distribution ranging from several Ångstroms to hundreds of nanometres. With well defined and well ordered cavities and channels, molecular sieves provide a ready access for synthesizing single-sized clusters and assembling cluster arrays periodically.[9]

Recently, Ozin *et al.* reported the synthesis of intrazeolitic Si nanoclusters.[8a] Dehydrated zeolite HY was employed to anchor disilane. FTIR spectroscopy showed that the disilane selectively reacted with the hydroxy group of the Brønsted-acid sites within the supercages. Subsequent thermal treatment of the silane-containing zeolite precursor led, *via* $H_2$ elimination and Si clustering reactions to intrazeolitic Si nanoclusters. The overall process is believed to occur *via* eqn. (1), where Z represents the zeolite framework and Y is zeolite Y.

$$Z{-}OH + Si_2H_6 \xrightarrow[-H_2]{} Z{-}OHSi_2H_5 \xrightarrow[-H_2]{\text{heat}} (Si_nH_m)Y \quad (1)$$

The dimensions of such nanoclusters are too small for standard microscopic (*e.g.* TEM) and diffraction (*e.g.* XRD) techniques to provide detailed structural information. Here, for the first time, we describe direct evidence for the formation of intrazeolitic Si clusters, their electronic properties and average cluster size from the study of Si-K near-edge absorption fine structure and core-level X-ray photoelectron spectroscopy.

The intrazeolitic silicon clusters used in this work were prepared by a procedure similar to that reported previously.[8a] Known quantities of disilane gas were transferred into a closed vessel containing zeolite HY through a vacuum line equipped with a pressure meter.† The mixture was then heated at 100 °C for 40 h. After removing the generated $H_2$ and unreacted disilane, the sample was heated to 550 °C at 1 °C $min^{-1}$ and held at this temperature for 2 h under vacuum ($10^{-3}$ Torr). The resulting solid is an air-stable pale yellow powder. X-Ray diffraction analysis showed that the long-range lattice of the zeolite framework was distorted but that the order of zeolite cavities remained intact.

Si K-edge absorption measurements were performed at the Syncrotron Radiation Center at University of Wisconsin at Madison, WI, using the CSRF beamline and a double-crystal monochromator with InSb(111) crystals.[10] All data were obtained with total electron yield detection and an effective sampling depth of *ca.* 700 Å.[11] Fig. 1 shows Si-K near-edge X-ray absorption fine structure (NEXAFS) data from both as-prepared intrazeolitic silicon clusters and zeolite HY. The edge at 1847 eV is due to the framework $SiO_2$ in zeolite. Two additional absorptions are found in the as-prepared intrazeolitic silicon clusters, *i.e.* at *ca.* 1839 and 1845 eV, respectively. The former is characteristic of a non-oxidized form of silicon and can be unambiguously attributed to the presence of silicon clusters. The intensity of this absorption is size-dependent and increases with the disilane loadings.[12] In their NEXAFS study of surface-oxidized silicon nanocrystals, Schuppler *et al.* assigned the absorption edges at ⩾1843 eV between the crystalline Si (c-Si) and $SiO_2$ thresholds to the interfacial $SiO_x$ ($x < 2$) species.[13] Similarly, the absorption edge at 1845 eV can be attributed to ≡SiO and $=SiO_2$ species which connect silicon clusters to the framework. This assignment was further supported by the *in situ* FTIR study of the encapsulation process indirating that both $HSiO(Si)_2$ and $HSiO_2(Si)$ were found in the intrazeolitic Si clusters.[12] Soft X-ray photoemission spectroscopy of the as-prepared sample showed the presence of $SiO_2$ only and no detectable non-oxidized form of Si in the outer 25 Å of the zeolite particles. This provides confirmation that essentially all of the silicon clusters are within the zeolite pore structure.

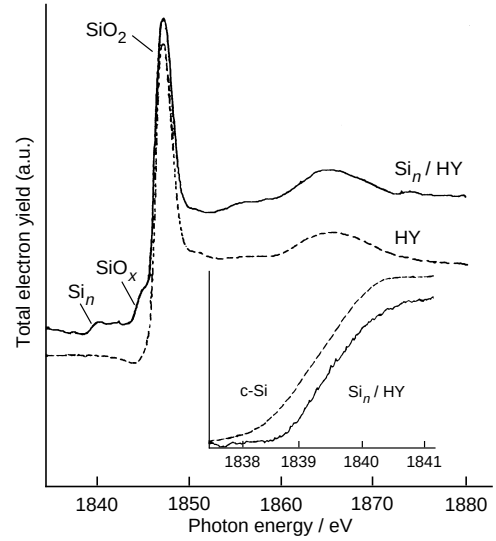

**Fig. 1** Si K-edge NEXAFS data from intrazeolitic silicon clusters ($Si_n$/HY) and zeolite HY. Inset shows the comparison of the Si absorption edges between crystalline Si (c-Si) and silicon clusters.

A detail of the Si K-edge absorption for as-prepared intrazeolitic silicon clusters and c-Si is presented in the inset of Fig. 1. From this it can be seen that the absoption edge for the silicon clusters is *ca*. 0.5 eV higher than that of c-Si. A blue shift in the absorption edge is indicative of a quantum confinement effect where the bottom of the LUMO orbitals (or conduction band) is raised relative to the 1s core level. A similar observation has been reported in the Si K-edge absorption studies of porous-Si (p-Si) samples, whose absorption edge is *ca*. 0.4–0.5 eV higher than that of c-Si.[14]

X-Ray photoelectron spectroscopy (XPS) was used to determine the chemical composition. Fig. 2 shows the XPS spectra from both intrazeolitic silicon clusters and zeolite HY samples. In addition to the peak at the Si 2p binding energy of 102.9 eV, corresponding to $SiO_2$, a weak peak centred at 99.2 eV appears in the intrazeolitic silicon clusters. This peak is characteristic of the Si 2p binding energy for unoxidized Si, reflecting the presence of silicon clusters. The SiO species, indentified by the NEXAFS above, is not observed because its concentration is so low that its peak is overlapped by that of $SiO_2$ in the XPS spectrum. Within the XPS detectable range (the outer 50 Å of the zeolite particles), the contents of $SiO_2$ (framework of zeolite) and Si (silicon clusters) were determined to be 93.19 and 6.81 atom%, respectively. This comparison enables an approximate estimate of the minimum occupancy of Si (as silicon clusters) in the zeolite pores, *i.e. ca.* 20 Si atoms per unit cell.‡ This number is similar to that obtained from the edge jump of the X-ray absorption spectrum.‡

The as-prepared intrazeolitic silicon clusters exhibit a strong room-temperature photoluminescence. Remarkably, its broad spectrum with a peak energy of 2.28 eV (with 488 nm excitation) closely resembles that of the organosilicon cluster, *syn*-tricyclooctasilane (2.25 eV).[15] This tentatively suggests that the structure of the intrazeolitic silicon clusters resembles that of *syn*-tricyclooctasilane. Further investigation into the cluster size and shape is in progress.

In summary, we have demonstrated that Si K-edge absorption spectroscopy is a useful tool for the direct observation of the encapsulation of silicon clusters in zeolite Y and for the study of their electronic properties. XPS provides a means of estimating the content of Si in each unit cell of zeolite.

We are grateful to Mr Regent Dutrisac and Mr Gerald Pleizier for excellent technical assistance, Dr Chris Ratcliffe for valuable discussions, and to Dr Anne McPhee of UOP (Des Plaines, Illinois, USA) for the provision of Y-zeolites.

## Footnotes

* E-mail: tse@ned1.sims.nrc.ca

† Zeolite HY was prepared from commercial zeolite Y (LZ-Y52, $SiO_2/Al_2O_3$ = 4.74) by (*i*) fully exchanging the Na content with $NH_4$ cations to generate $NH_4Y$, (*ii*) slowly heating the $NH_4Y$ to 460 °C at 1 °C $min^{-1}$ increments, (*iii*) maintaining this temperature for 10 h, and then (*iv*) gradually cooling to room temperature; all steps at a pressure $< 10^{-3}$ Torr except (*i*). The HY zeolite contains eight supercages per unit cell. The disilane loadings were calculated according to $4Si_2H_6$ per supercage.

‡ XPS spectra were recorded on the XPS Kratos Axis Instrument, using monochromated Al-Kα radiation. The effective sampling depth is 50 Å. The unit-cell formula for a dehydrated zeolite HY can be expressed as $H_{56}(AlO_2)_{56}(SiO_2)_{136}$. Because the photoemission experiment shows that the non-oxidized form of Si is undetectable in the outer 25 Å of the zeolite, the actual Si content in the body of zeolite should be at least twice as much as that measured by XPS, when compared with the measured $SiO_2$ content in the same sampling depth (50 Å). Therefore, the number of Si atoms per unit cell can be calculated as follows: $2 \times 6.81 \times (135/93.19) \approx 20$.

In Si K-edge absorption spectra, the relative concentrations of Si and $SiO_2$ in the intrazeolitic Si clusters are also directly proportional to their individual edge jumps.[16] Since each unit cell of zeolite contains 136 units of $SiO_2$, the number of Si can thus be estimated to be 13 atoms per unit cell from its edge jump relative to that of $SiO_2$. By adding the contribution of $SiO_x$ species to Si clusters, the Si atoms per unit cell would be *ca*. 20, in agreement with the estimation by XPS data.

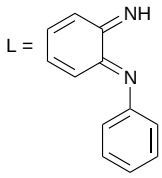
# Ruthenium(III)-promoted oxidative dimerization of aniline to *N*-phenyl-1,2-phenylenediimine. Definitive proof for the template reaction

**Kedar Nath Mitra,[a] Partha Majumdar,[a] Shie-Ming Peng,[b] Alfonso Castiñeiras[c] and Sreebrata Goswami*[a]**

[a] *Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India*
[b] *Department of Chemistry, National Taiwan University, Taipei, Taiwan, Republic of China*
[c] *Departmento de Química Inorgánica, Facultad de Farmacia, Universidad de Santiago de Compostela, 15706-Santiago de Compostela, Spain*



**Two novel examples of ruthenium-promoted oxidative *ortho*-dimerization of aniline are described which demonstrate that the dimerization reaction proceeds *via* coordination of anilines to the metal ion.**

In a recent communication[1] we described unusual examples of osmium-promoted oxidative dimerization of primary aromatic amines [eqn. (1)] to *N*-aryl-1,2-arylenediimine (L). It was

$$[Os^{IV}Br_6]^{2-} \xrightarrow{PhNH_2} [Os^{II}L_2Br_2] \quad (1)$$

**1**

L =

proposed that prior *cis*-coordination of amines to the metal ion is the key step for the dimerization reaction.

Here, we further demonstrate two more novel examples of ruthenium-promoted oxidative dimerization reactions of aniline which established that coordination of amines takes place during the course of reaction.

The first reaction [eqn. (2)] is the reaction of $[Ru(acac)]_3$[2]

$$[Ru(acac)_3] \xrightarrow{PhNH_2} [Ru(acac)_2L] \quad (2)$$

**2**

with neat aniline at 130 °C. Chromatographic work-up of the reaction mixture afforded $[Ru(acac)_2L]$, which was recrystallised from an aqueous acetonitrile solution and obtained as bown needles in 30% yield. Addition of $NEt_3$, which acts as a proton sink, to the reaction mixture increases the yield considerably to 65%. The compound $[Ru(acac)_2L]$ is soluble in common organic solvents and is diamagnetic. The N–H stretch occurs[3] as a sharp feature of moderate intensity in the range 3300–3200 $cm^{-1}$. The presence of a strong C=N stretch near 1600 $cm^{-1}$ characterizes the presence of diimine chromophore in the compound. The $^1H$ NMR spectrum of the complex consists of three methyl resonances at $\delta$ 1.76(3 H), 1.83(6 H) and 2.35 (3 H); resolved aromatic proton resonances between $\delta$ 6.5 and 7.4 and the N–H resonance is observed[4] as a relatively broad singlet at $\delta$ 10.8. Suitable crystals for an X-ray structure determination† were obtained upon slow evaporation of a saturated solution of the compound in hexane, and a view of the molecule is shown in Fig. 1. Ruthenium is coordinated by the four oxygens of two acetylacetonato ligands and by the two nitrogens of a diimine ligand in a distorted octahedral geometry. The imine, C–N bond lengths, average 1.341(8) Å, are considerably shorter than a C–N single bond, 1.433(9) Å. The analytical, spectral and X-ray data collectively conform to the formulation of **2** as $[Ru(acac)_2L$.]

To gain a better insight into the course of above metal-promoted oxidation reaction, we used $RuCl_3 \cdot 3H_2O$ as a starting material to carry out a similar reaction. $RuCl_3 \cdot 3H_2O$ was selected since first, as in $[Ru(acac)_3]$, ruthenium is trivalent and secondly, the chloride salt is much more labile towards substitution than is $Ru(acac)_3$. Therefore, a higher degree of amine coordination was anticipated.

This reaction proceeded very smoothly and recrystallisation of the crude product from dichloromethane–hexane [eqn. (3)]

$$RuCl_3 \bullet 3H_2O \xrightarrow{PhNH_2} [RuCl_2(PhNH_2)_2L] \quad (3)$$

**3**

resulted a highly crystalline compound **3** (yield, 60%), which contains one diimine (L), two *trans*-anilines and two *cis*-chlorides in the co-ordination sphere.

Unlike **2**, compound **3** is sparingly soluble in common organic solvents. The IR spectrum shows[3] multiple sharp $\nu_{NH}$ between 3300 and 3100 $cm^{-1}$, sharp $\nu_{C=C}$ and $\nu_{C=N}$ at 1600 and 1580 $cm^{-1}$ and two $\nu_{Ru-Cl}$ stretches[5] at 360 and 340 $cm^{-1}$. The

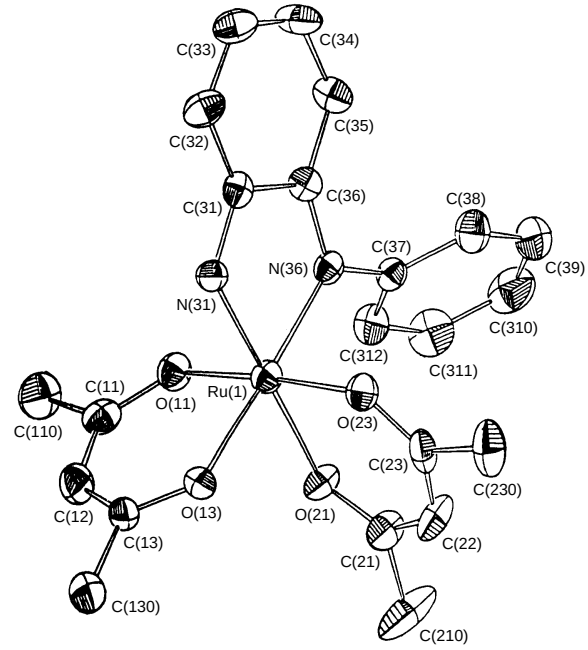


**Fig. 1** Molecular structure of $[Ru(acac)_2L]$ **2** showing the atom numbering scheme. The asymmetric unit consists of two crystallographically distinct molecules. The figure shows a view of molecule 1. Selected bond distances (Å): Ru(1)–N(31) 1.958(5), Ru(1)–N(36) 1.996(5), Ru(1)–O(11) 2.019(5), Ru(1)–O(13) 2.068(4), Ru(1)–O(21) 2.050(4), Ru(1)–O(23) 2.031(5), N(31)–C(31) 1.333(8), N(36)–C(36) 1.352(8), N(36)–C(37) 1.429(8).

$^1$H NMR spectrum shows two doublet NH resonances[6] at $\delta$ 5.09 and 4.84 assigned to $NH_2$. Verification of the composition as well as the geometry of the compound was ascertained by single-crystal X-ray diffraction,† and a view of the molecule is shown in Fig. 2. There are three types of Ru–N distances in the molecule. The two Ru–N(aniline) single bonds are identical and are longer than the Ru–N(imine) bonds indicating a relatively weak bond between Ru and aniline. The two diimine, C=N bonds are much shorter than the C–N bonds. To the best of our knowledge compound **3** represents the first authentic example of aniline coordinated to ruthenium. Indications are strong that it can act as a good starting compound for substitution reactions and for performing reactions at the coordinated aniline.

It is worthwhile to compare the results of the three reactions (1)–(3). For osmium [eqn. (1)] a bis(diimine) complex was obtained whereas only a monodiimine complex resulted from reaction (2). It is noteworthy that the difference of the oxidation states of the metal ions in the starting compound and the end product is two in reaction (1) but is one in reaction (2). Interestingly, in reaction (3) only two of the four coordinated anilines have undergone oxidative dimerization and notably, the metal centre has undergone only a one-step reduction. From the above results it appears reasonable that the difference in the oxidation levels of the reactant and the product is equal to the number of diimine ligands formed in the reaction.

In conclusion, it may be stated that the above results are a clear manifestation of template dimerization of primary aromatic amines to yield novel coordination complexes of arylene diimines which otherwise are not achievable.[7]

Financial support received from the CSIR, New Delhi is acknowledged. We thank Dr Samaresh Bhattacharya for his suggestions.

# Phosphorus–sulfur–nitrogen heterocycles from diferrocenyl dithiadiphosphetane disulfide

**Mark R. StJ. Foreman, Alexandra M. Z. Slawin and J. Derek Woollins***

*Department of Chemistry, Loughborough University, Loughborough, UK LE11 3TU*

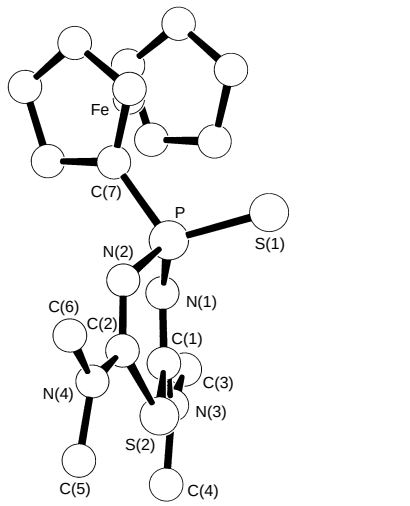
**$FcP(S)S_2P(S)Fc$ undergoes cycloaddition reactions with C–N bonds to generate C–P–N rings including the novel, boat shaped, $PN_2C_2S$ system as well as four-membered $P_2CN$ rings.**

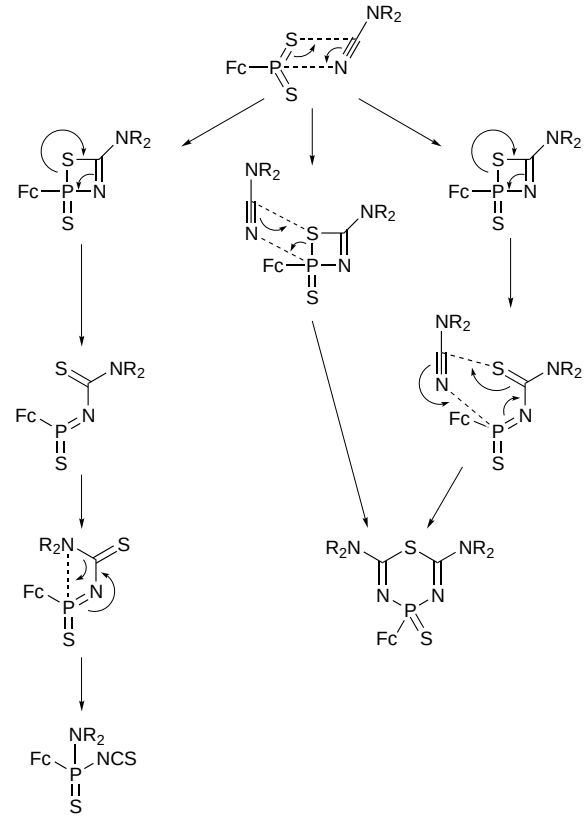
Cycloaddition reactions provide one of the most exciting entries into heterocyclic compounds. We have recently developed[1] a facile synthesis of $FcP(S)S_2P(S)Fc$ **1** (Fc = ferrocenyl) which can be considered as consisting of two $FcPS_2$ units (capable of a wide range of cycloaddition reactions) in solution [eqn. (1)].

(1)

Very few cycloaddition reactions of phosphetane disulfides have been described, though some reactions of Lawesson's reagent **2** with amines,[2] ureas[3] and cyanamides[4] to form sulfur–phosphorus–nitrogen compounds are known. Here we describe the results of our studies into the reactions of cyanamides, and related systems with **1**. The first example of the synthesis (and X-ray structure) of a $PN_2C_2S$ is reported together with a novel, readily generalised, synthesis of the $P_2SN$ ring system.

Thus, the reaction of **1** with dimethylcyanamide gives *P*-ferrocenyl 2,6-bis(dimethylamino)1,3,5,4-thiadiazaphosphorine-4-sulfide **3** in good yield and *P*-ferrocenyl *P*-dimethylamino thiophosphoroisothiocyanate **4** in lower yield.† Both **3** and **4** displayed the expected spectroscopic properties. The X-ray structure‡ of **3** (Fig. 1) confirms the identity of the heterocycle, the $PC_2N_2S$ ring adopts a distorted boat conformation with the P and S(2) atoms at the prow and stern of the boat. The P and S(2) atoms lie 0.48 and 0.30 Å, respectively above the C(1)N(1)C(2)N(2) mean plane [max. deviation 0.007 Å for C(1)] with the C(1)C(2)S(2) and PN(1)N(2) planes being inclined by 15.7 and 30.0°, respectively, to this plane. Within the six-membered ring the bond lengths are in accord with the localised structure drawn in Scheme 1, *i.e.* short C–N bonds [C(1)–N(1) 1.289(6), C(2)–N(2) 1.290(6) Å] and 'normal' single P–N and C–S bond lengths. The angles at the ring nitrogen atoms are close to trigonal whilst the C(1)–S(2)–C(2) angle is significantly contracted at 101.0(2)° and the N(1)–P(1)–N(2) is close to tetrahedral [108.2(2)°]. The exocyclic P=S and ferrocenyl groups occupy (approximate) axial and equatorial sites whilst the $NMe_2$ groups are only slightly out of the central $C_2N_2$ plane of the ring [N(3) and N(4) lie 0.16 and 0.25 Å below the $C_2N_2$ plane and on the opposite side to S(2) and P(1)]. The coplanarity of the $NMe_2$ groups is accompanied by short C–N bond lengths [C(2)–N(4) 1.365(6), C(1)–N(3) 1.335(6) Å] suggesting some degree of delocalisation in this part of the molecule. The cyclopentadienyl rings in the ferrocenyl group are twisted by *ca.* 72° with respect to (w.r.t.) the $C_2N_2$ ring plane. In the structure of **4** (Fig. 2)‡ the phosphorus centre is approximately tetra-





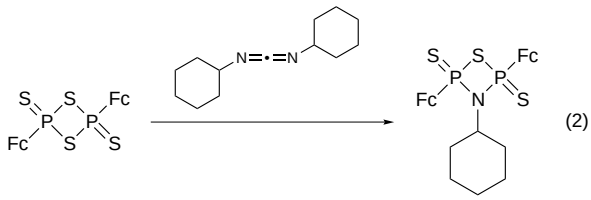


**Fig. 1** X-Ray crystal structure of **3**. Important bond lengths (Å) and angles (°): P–N(1) 1.648(6), P–N(2) 1.664(4), P–S(1) 1.941(2), P(1)–C(7) 1.783(5), N(1)–C(1) 1.289(6), N(2)–C(2) 1.290(6), C(1)–S(2) 1.788(5), C(2)–S(2) 1.771(5), C(1)–N(3) 1.335(6), C(2)–N(4) 1.365(6); N(1)–P–N(2) 108.2(2), P–N(1)–C(1) 122.6(4), P–N(2)–C(2) 121.0(4), N(1)–C(1)–S(2) 125.4(5), N(2)–C(2)–S(2) 127.3(4), C(1)–S(2)–C(2) 101.0(2), S(1)–P–C(7) 111.1(2), N(1)–P–S(1) 114.6(1), N(2)–P–S(1) 113.6(2), N(1)–P–C(7) 104.4(4), N(2)–P–C(7) 103.9(2).

**Scheme 1**

hedral, interestingly P–N(1) is substantially shorter [1.631(4) Å] than P–N(11) [1.700(5) Å] reflecting the difference in electronegativities of the $NMe_2$ and NCS groups. The formation of these products presents a challenge mechanistically; we believe that a series of [2 + 2] reactions are a reasonable explanation for the formation of **3** and **4** (Scheme 1).

The reaction of dicyclohexylcarbodimide with **1** gives [eqn. (2)] 2,4-diferrocenyl-3-cyclohexyl-1,3,2,4-thiaazadiphosphorine-2,4-disulfide **5**.† Alternatively reaction of **1** with

(2)

*N*-(benzylidene)aniline yields the phenyl analogue **6**.† Compounds **5** and **6** display the expected spectroscopic properties. There are only two previous reported examples[5,6] of the crystallographic characterisation of the RP(S)SNP(S)R rings. The X-ray structures‡ of **5** and **6** are isomorphous and we shall only discuss **6**. The molecule (Fig. 3) has crystallographic twofold symmetry and the central $P_2NS$ ring is thus flat with the S(1) and S(1*) atoms lying on opposite sides of the ring. Within the rings the bond lengths are appropriate for P–N and P–S single bonds whilst the internal ring angles [S(2)–P(1)–N(1) 87.8(2), P(1)–N(1)–P(1*) 104.5(4), P(1)–S(2)–P(1*) 79.9(2)°] indicate substantial ring strain. The phenyl substituent is twisted by *ca*. 14° w.r.t. the $P_2NS$ plane in **6**.

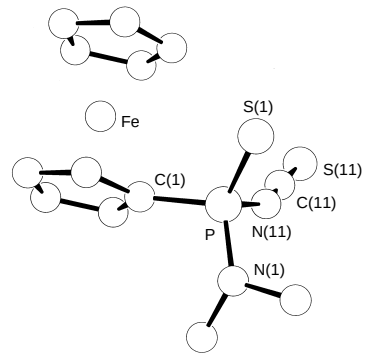

**Fig. 2** X-Ray crystal structure of **4**. Important bond lengths (Å) and angles (°): P–C(1) 1.766(5), P–S(1) 1.914(2), P–N(1) 1.631(4), P–N(11) 1.700(5), N(11)–C(11) 1.166(6), C(11)–S(11) 1.538(7); C(1)–P–S(1) 116.7(2), C(1)–P–N(1) 107.3(2), C(1)–P–N(11) 101.2(2), N(1)–P–S(1) 113.2(2), N(1)–P–N(11) 104.9(3), N(11)–P–S(1) 113.2(2), P–N(11)–C(11) 156.5(6), N(11)–C(11)–S(11) 177.1(6).

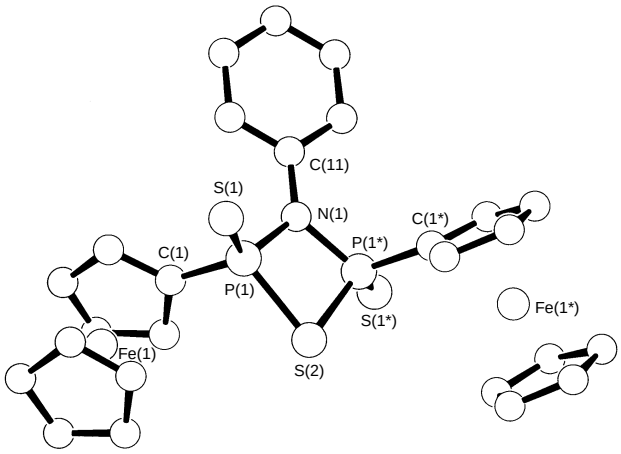

**Fig. 3** X-Ray structure of **6**, **5** is isomorphous (and is not illustrated). Important bond lengths (Å) and angles (°) with values for **5** given in square brackets: P(1)–C(1) 1.789(5) [1.785(6)], P(1)–S(1) 1.917(3) [1.918(3)], P(1)–S(2) 2.098(3) [2.095(3)], P(1)–N(1) 1.704(5) [1.675(5)]; C(1)–P(1)–S(1) 114.3(3) [114.1(2)], C(1)–P(1)–N(1) 108.4(3) [109.2(2)], C(1)–P(1)–S(2) 106.6(3) [105.9(3)], S(1)–P(1)–S(2) 120.1(1) [119.9(1)], S(1)–P(1)–N(1) 116.5(2) [116.7(2)], S(2)–P(2)–N(1) 87.8(2) [87.9(2)], P(1)–N(1)–P(1*) 104.5(4) [105.3(5)], P(1)–S(2)–P(1*) 79.9(2) [79.0(2)].

† **3** and **4**: **1** (2.91 g, 5.2 mmol) and dimethylcyanamide (1.5 g, 21 mmol) were refluxed together in toluene (50 ml) for 8 min. Silica gel chromatography using firstly light petroleum–toluene and then $CH_2Cl_2$ as the eluent gave **3** and **4** (2.6 g, 60 and 0.57 g 15% yields respectively).

**5**: *N*,*N*′-Dicyclohexylcarbodiimide (0.72 g, 3.5 mmol) and **1** (1.9 g, 3.4 mmol) were refluxed in toluene (10 ml) for 7 days. After removal of solvent and chromatography (light petroleum) an orange solid was obtained. This was washed with boiling ethyl acetate to give after filtration **5** (77 mg, 101 μmol, 3%) as a orange solid.

**6**: **1** (3.0 g, 5.36 mmol) and *N*-(benzylidene)aniline (2.0 g, 11.0 mmol) were refluxed in toluene (150 ml) (24 h). After addition of xylenes (100 ml) the reaction was refluxed for a further 64 h. Chromatography on silica, elution with 500 ml of 40% $CH_2Cl_2$ in light petroleum followed by 500 ml of $CH_2Cl_2$, gave a red solid. Recrystallisation from ethyl acetate yielded 0.97 g. 1.57 mmol, 29%.

# Transition-state structural refinement with GRACE and CHARMM: realistic modelling of lactate dehydrogenase using a combined quantum/classical method

**Vicente Moliner,† Alexander J. Turner and Ian H. Williams***

*School of Chemistry, University of Bath, Bath, UK BA2 7AY*

**A transition structure for reduction of pyruvate catalysed by lactate dehydrogenase is refined and characterised in hybrid quantum mechanical/molecular mechanical (AM1/CHARMM) calculations involving a fully flexible active-site region by means of a novel procedure (GRACE), and is remarkably similar to that calculated *in vacuo*.**

The key to understanding of the fundamental processes of enzyme catalysis, or to designing transition-state analogues (as potential drugs) or modified enzymes (with new specificities), is knowledge of transition-state structure and properties. Computational simulation of enzymic reactions[1] provides a valuable tool for investigation of these issues. We report the results of a combined classical/quantum modelling study of a transition structure (TS) for reduction of pyruvate catalysed by lactate dehydrogenase (LDH). A novel computational procedure is employed, which allows the TS to be located with full gradient relaxation of the positions of 1900 atoms of a solvated enzyme–substrate complex utilising a hessian involving displacements of 147 atoms in the active site. The resulting TS shows remarkable structural similarity to that determined in earlier molecular orbital (MO) calculations[2–4] for the reaction *in vacuo*.

LDH is an NAD-dependent enzyme catalysing the interconversion of pyruvate and lactate. The X-ray crystal structure of its inhibitor-bound ternary complex has been determined,[5] and its mechanism has been the subject of many experimental[6] and several theoretical studies.[2–4,7–9] Although the reaction rate of the wild-type enzyme with pyruvate at room temperature is actually limited by a conformational transition, the chemical step involves hydride transfer (HT) from the nicotinamide ring of NADH to the carbonyl C atom of the substrate. The Empirical Valence-Bond theoretical study by Warshel[7] presupposed that HT to pyruvate occurs first, followed by protonation on the carbonyl O atom of the substrate from His-195. However, all previous MO studies,[2–4,8,9] performed using a variety of *in vacuo* models, concur that proton transfer (PT) precedes HT. These contradictory conclusions beg the question: what influence does the protein environment have upon the reaction mechanism?

We have employed a hybrid theoretical technique in which a quantum mechanical (QM) description of the chemical bond making and breaking events is combined with a molecular mechanics (MM) treatment of the surrounding protein and solvent. The first phase of this work used the CHARMM24 program[10] as described previously for reactions in aqueous solution[11] and in a solvated enzyme active site.[12] Computational limitations made it impractical to include the entire LDH protein in the calculations, so we selected a pseudo-sphere of 1900 atoms of enzyme, co-factor, substrate and solvent centred around the substrate, hydride donor and proton donor groups. This system was divided into a QM region of 39 atoms (the shaded portion of Fig. 1 comprising pyruvate, the nicotinamide ring of NADH and part of His-195), treated by the AM1 semiempirical MO method,[13] and a MM region, comprising the rest of the protein (CHARMM24 potentials) and the solvent water (TIP3P).[14] Two link atoms were inserted where the QM/MM boundary intersected covalent bonds (indicated as ● in Fig. 1). The QM/MM total energy surface shown in Fig. 2 was

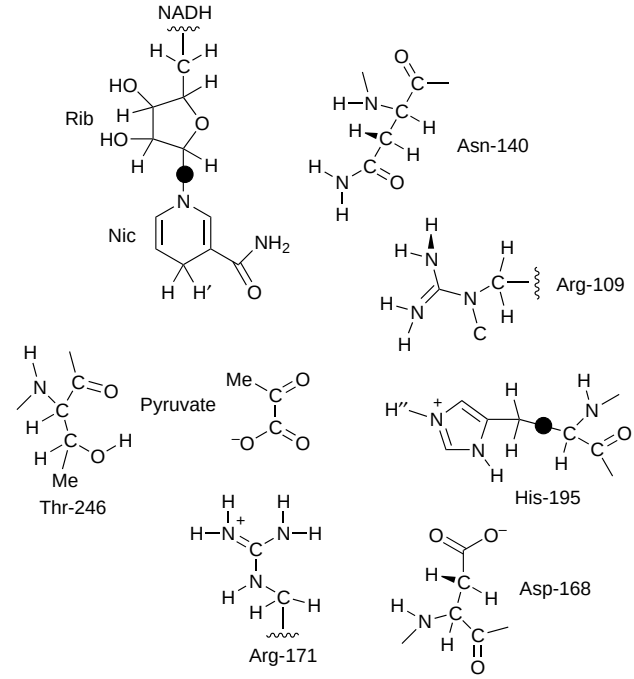

**Fig. 1** LDH active site. The shaded region corresponds to the QM atoms; the two link atoms are indicated as ●.

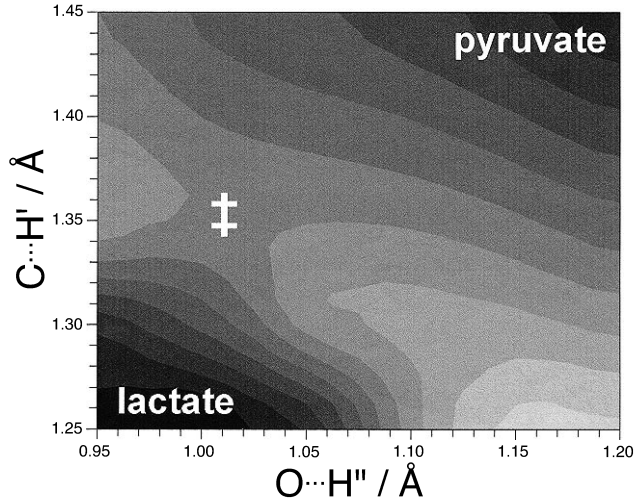

**Fig. 2** QM/MM total energy contour map (dark = low energy; light = high energy) for LDH-catalysed pyruvate reduction by NADH obtained as a function of hydride transfer and proton transfer coordinates by means of grid searches using CHARMM

constructed from a grid formed by pairs of rigid internal-constraint values for the making bond distances C··H′ and O··H″, from the carbonyl C atom of pyruvate to the H′ atom of the nicotinamide ring (hydride donor), and from the carbonyl O atom of pyruvate to the H″ atom of His-195 (proton donor), respectively. At each grid point relaxation of the entire hybrid QM/MM potential was performed to the constrained local minimum. At the surface of the pseudo-sphere, a solvent boundary potential was employed to prevent evaporation of water molecules, and harmonic restraints were applied to protein atoms disconnected from the backbone, owing to truncation, in order to preserve the enzyme structure. All non-bonded interactions were included.

The approximate TS, corresponding to the saddle point on Fig. 2, was then refined, using our newly developed GRACE‡ software. A partial-rational-function-operator/adopted-basis-Newton-Raphson method was employed, utilising a hessian matrix of order 441 × 441, describing the curvature of the QM/MM energy hypersurface for a sub-set of the system (larger than that shown in Fig. 1), together with a diagonal hessian plus updates for the rest of the system. A detail of the refined TS is shown in Fig. 3. The r.m.s. residual gradient on the 147 atoms in the sub-set is less than 0.1 kcal $mol^{-1}$ $Å^{-1}$ in the optimized structure, while on the remaining 1753 atoms it is less than 0.005 kcal $mol^{-1}$ $Å^{-1}$; these residual gradients are lower than the commonly accepted convergence criterion for optimized geometries of small molecules in quantum chemistry.[15] Finally, the intrinsic reaction coordinate[15] path was determined from the TS in each direction, leading to pyruvate and to lactate, in order to demonstrate conclusively that the reported structure is indeed a TS for the correct reaction. It is this capability to refine and characterise TSs precisely within a large flexible domain of the reacting system which distinguishes the present work from other recently published QM/MM applications to enzymic reactions.[16]

The transition vector ($\nu^{\ddagger}$ = 568*i* $cm^{-1}$) for the TS of the LDH-catalysed reaction involves motion of both the transferring hydride H′ and proton H″, indicating a concerted mechanism. However, PT is much further advanced (Pauling bond order $n_{O\cdots H''}$ = 0.81) than HT ($n_{C\cdots H'}$ = 0.33). This is remarkably similar to the TS found in a gas-phase AM1 supermolecule calculation for a *N*-methyl-1,4-dihydronicotinamide–pyruvate–(methylguanidinium)–methylimidazolium complex.[3] The PT and HT components occur in perpendicular planes, the degree of HT is essentially the same (*cf.* 0.31),[3] but PT is slightly earlier (*cf.* 0.93 for specific acid catalysis).[3] The TS for this reaction appears to be a robust entity, the essential features of whose structure are invariant to the nature of its environment.

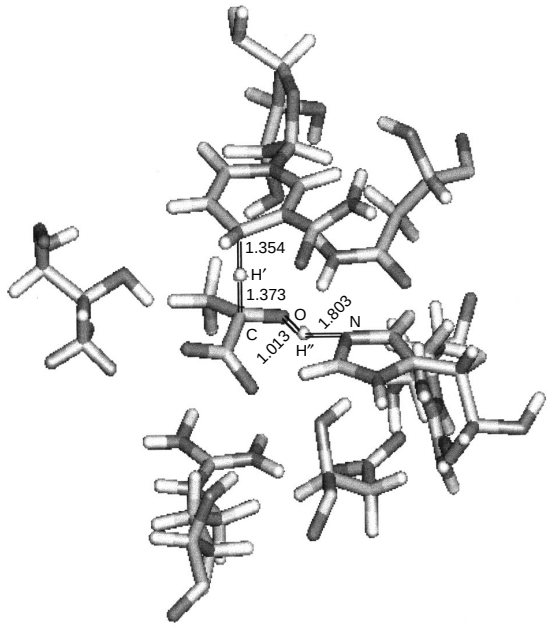

**Fig. 3** QM/MM transition structure refined using GRACE for LDH-catalysed pyruvate reduction by NADH (distances in Å)

Finally, several active site residues, notably Arg-109 and Asn-140, display considerable mobility over the range of structures spanned by the energy surface in Fig. 2. We have evidence that the TS reported here is only one of a family of structures of similar energy which differ in regard to conformations of amino acid sidechains; the transition state for the enzymic reaction represents an average of the properties of these many, nearly degenerate TSs. This insight emerges only as a consequence of the flexible model of the active site employed in this study.

We are grateful to the Leverhulme Trust for a Visiting Fellowship (V. M.), the BBSRC for a Studentship (A. J. T.), SmithKline Beecham for an equipment donation, and Glaxo-Wellcome and the EPSRC for financial support. We thank Dr Tim Dafforn for supplying us with initial coordinates for the LDH–NADH–pyruvate ternary complex.

‡ GRACE is a powerful extension to Tool Control Language (TCL), which uses free format data structures and cache technology to interface QM packages (like CADPAC, GAMESS or GAUSSIAN) with CHARMM (or CHARMm) or with its own routines for investigation of QM/MM energy surfaces. The structured programming advantages of TCL are augmented by many novel features including a range of powerful optimisers for minima and saddle points, IRC paths and vibrational frequencies.

# New chain architecture for a one-dimensional aluminophosphate, $[H_3NCH_2CH_2NH_3][AlP_2O_8H]$

**Ian D. Williams,*[a] Jihong Yu,[a,b] Qiuming Gao,[b] Jiesheng Chen[b] and Ruren Xu*[b]**

[a] *Department of Chemistry, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong*
[b] *Key Laboratory of Inorganic Hydrothermal Synthesis, Department of Chemistry, Jilin University, Changchun, China*

**A new type of one-dimensional aluminophosphate polymer chain is found for $[H_3NCH_2CH_2NH_3][AlP_2O_8H]$ containing fused $Al_2P_2$ four-membered rings, with terminal $PO_4H$ side-groups.**

The chemistry of aluminophosphates templated by organic amines continues to yield unexpected results, with the recent report of a new stoichiometry ($Al_3P_5$) from an alcoholic system,[1] and that through use of basic conditions, the known $[AlP_2O_8]^{3-}$ formulation can exist as a two-dimensional sheet with large 20-membered rings.[2] Previously aluminophosphates based on $[AlP_2O_8]^{3-}$ were only found as variably protonated one-dimensional polymer chains consisting of $Al_2P_2$ rings corner shared at Al [Fig. 1(*a*)].[3–5] We now report a new type of chain architecture for the one-dimensional ALPO $[H_3NCH_2CH_2NH_3][AlP_2O_8H]$ **1** which has a linear arrangement of fused (edge-shared) $Al_2P_2$ four-membered rings, and ($PO_4H$) side groups [Fig. 1(*b*)].

Compound **1** was synthesised from a predominantly alcoholic solvent system, utilising a gel composition of 1.0 $Al(OPr^i)_3$ : 12.5 $H_3PO_4$ : 5.0 en : 80 EG : 12.5 $H_2O$. Crystals of **1** suitable for a single-crystal X-ray structure determination† were obtained after heating this mixture for 14 days at 180 °C under autogeneous pressure in a Teflon-lined autoclave. The compound formed is essentially phase-pure, based on powder X-ray diffraction.

The structure of **1** is shown in polyhedral representation in Fig. 2. It consists of one-dimensional $[AlP_2O_8H]^{2-}$ polymeric anions, made up of tetrahedral $AlO_4$ and $PO_4$ units. These are connected in a zigzag ladder arrangement of fused $Al_2P_2$ four-membered rings, with pendant $PO_4H$ side groups. Thus there are both terminal and triply bridging phosphate groups, with connectivities to Al of one and three. This is different from the previously published structures of $[AlP_2O_8]^{3-}$ type anions in which both phosphates are chemically similar simple bridges linked to two Al. The $Al_2P_2$ rings in **1** have all four Al and P coplanar with two bridging oxygens (adjacent) above and two below the ring plane. The ring has dihedral angles of 75.4° to its adjoining neighbours, to create the zigzag effect.

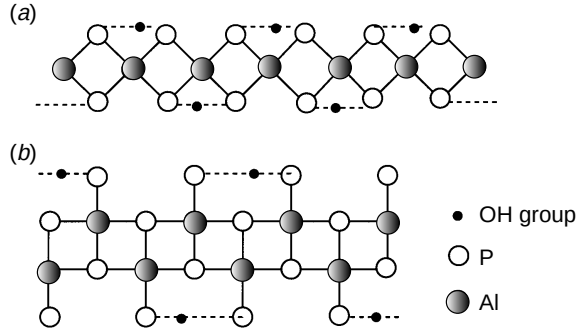

**Fig. 1** Schematic representation of $[AlP_2O_8H]^{2-}$ polymers; (*a*) corner- and (*b*) edge-shared four-membered ring chain

The metric parameters for this compound are well determined (data : parameter ratio *ca.* 20 : 1) and allow reasonably detailed analysis of the aluminophosphate bonding. Fig. 3 shows a fragment of the chain with atom labelling scheme. The aluminate group has one short Al–O distance [Al(1)–O(4) 1.685(1) Å] associated with an almost linear bridge to the terminal phosphate [Al(1)–O(4)–P(1) 171.8(1)°]. The other three Al–O bonds are in the range 1.741–1.746(1) Å and have angles at oxygen of 137.5–139.7(1)°. The shortening implies stronger p–d π bonding between Al and O for the sp hybridised oxygen bridge; interestingly no shortening is observed for P(1)–O(4) compared to the other P–$O_{bridge}$ bonds [P–O 1.535–1.544(1) Å]. There are four oxygens terminal to the phosphorus atoms, three on the $PO_4H$ side group. One of these has a longer bond [P(1)–O(1) 1.578(1) Å], and an associated hydrogen atom, so is assigned as P–OH. The other three P–$O_{terminal}$ bonds, which involve the oxygen atoms O(2), O(3) and O(8), are shorter [1.499–1.509(2) Å] and can be thought of as a mixture of P=O and P–$O^-$ canonical forms.

The one-dimensional chains are hydrogen-bonded to and separated by ethylene diammonium ions, with all six $NH_3$ protons acting as simple hydrogen-bond donors to the O(2), O(3) and O(8) terminal oxygens which carry substantial negative charge. The chains are also in van der Waals contact with two neighbours through the terminal phosphates, but there are no intermolecular P–OH···O=P (or P–OH···$^-$O–P) hydrogen bonds. Rather these are intramolecular [O(1)–H(1)···O(2) 2.641 Å] along the individual one-dimensional strand, as indicated in the Figures.

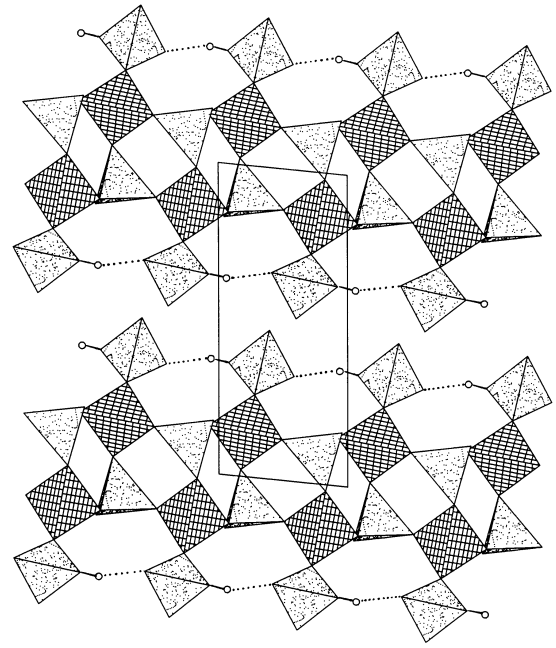

**Fig. 2** Polyhedral view of $[H_3NCH_2CH_2NH_3][AlP_2O_8H]$ **1** along the *b*-axis showing neighbouring anion chains

Isomerism within ALPO systems is a well known phenomenon, with a wealth of structures known for the neutral three-dimensional $AlPO_4$-*n*,[6] and the two-dimensional $[Al_2P_3O_{12}]^{3-}$ [7,8] and $[Al_3P_4O_{16}]^{3-}$ systems.[9] The isomer types are affected by the organo-templates which are usually amines, as well as the reaction conditions. Variables such as temperature, pressure, time and solvent system, as well as gel composition and concentration have profound effects, even for the same organic template. Thus, in addition to compound **1**, a number of other low-dimensional ALPOs have been formed using ethylenediamine (en), including a $[Al_3P_4O_{16}]^{3-}$ phase,[10] the isostructural one-dimensional polymers of the classical type [Fig.1(*a*)] $[H_3NCH_2CH_2NH_3][AlP_2O_8H]\cdot H_2O$[11] and $[NH_4][H_3NCH_2CH_2NH_3][AlP_2O_8]$,[5] as well as the salt $[NH_4][H_3NCH_2CH_2NH_3]_4[Al(PO_4)_4]$.[11] These last two also require the decomposition of en to form ammonia.

The promotion of low dimensionality in aluminophosphate materials by use of non-aqueous solvent systems has been discussed by Ozin and coworkers,[1] who also demonstrated that the one-dimensional polymer $[H_3NC_5H_9]_5[Al_3P_5O_{20}H]$ can be transformed in the solid state to the two-dimensional compound $[H_3NC_5H_9]_2[Al_2P_3O_{12}H]$. In the present case, the solvent system is predominantly ethylene glycol and a large excess of phosphoric acid is used, which may account for the low Al : P ratio of 1 : 2, compared to the other phases templated by ethylenediamine.

The existence of the $PO_4H$ side-groups in **1** indicates a low level of polyhedral condensation, which may have implications for the mechanism of build-up of ALPO polymers with higher levels of complexity. It should be noted that ribbons of fused four-membered rings, topologically equivalent to the 'ladder' structure of **1**, may be found in various higher dimensional ALPOs, for example in many of the $[Al_3P_4O_{16}]^{3-}$ and $AlPO_4$-*n* phases. The current structure would seem to be ideally set up for condensation of $AlO_4$ units across the P′–OH···O–P hydrogen bonded bridges (Fig. 3) to form new $Al_3P_3$ six-membered rings, another commonly featured ALPO structural sub-unit.

To our knowledge, however, terminal phosphate groups have not been seen previously for polymeric ALPO systems, although they exist in the molecular ion $[Al(PO_4)_4]^{9-}$.[11] We predict the recent findings of novel stoichiometries and dimensionalities in ALPO materials is likely to continue, if the phosphate components may also exist in this terminal mode, connected to a single aluminate, rather than as two-, three- or four-connected tetrahedral building blocks.

The authors wish to thank the Research Grants Council (H. K.) and National Natural Science Foundation of China for financial support and Dr. Zhenyang Lin for useful discussions.

# The use of palladium on porous glass for catalytic coupling reactions

**Jintong Li, Albert W.-H. Mau and Christopher R. Strauss***

*CSIRO Division of Molecular Sciences, Private Bag 10, Clayton South MDC, Victoria 3169, Australia*

**Palladium on porous glass is a useful heterogeneous catalyst for liquid phase organic coupling reactions which can be carried out in the presence of air, without the need for solubilizing and activating ligands.**

Catalysts of palladium, its complexes and its salts, are well recognized for activation of C–H bonds towards coupling reactions.[1–3] In this regard, the Heck reaction of an aryl or vinyl halide with an alkene in the presence of palladium derivatives has been the subject of intensive study and there is growing interest in synthetic transformations of terminal alkynes *via* homo- or hetero-couplings of the Glaser, Eglington or Chodkiewicz–Cadiot type.[4–6]

However, commercial development, particularly of Heck reactions, has not progressed as rapidly as could have been expected, most likely because of low turnover numbers and low turnover frequencies.[7] The susceptibility of palladium catalysts to poisoning also necessitates the use of relatively large amounts (1–5 mol%) of expensive metal to ensure acceptable conversions.[8] Attempts at overcoming these disadvantages have involved the use of organopalladium complexes, usually containing phosphine ligands, as homogeneous catalysts.[1–3] Although such complexes can be difficult to separate from product mixtures and to recover from reaction media,[9] some recent success has been obtained with methods employing homogeneous two-phase catalysis.[10] Nonetheless, many phosphine ligands are thermally unstable, even at temperatures as low as 120 °C,[11] so maximum reaction temperatures are limited. In some cases, aryl groups emanating from degraded phosphines can react with olefinic starting materials, thereby affecting the course of the reaction.[12,13] Benefits of phosphine-free palladium catalysts have been discussed.[14]

In ongoing research into the development of technologies for environmentally benign chemistry,[15] we have investigated palladium metal on porous glass tubing as a catalyst for chemical syntheses. The catalyst may be similar to the membrane developed for hydrogen separation by Uemiya *et al.*,[16] and analogous to the platinum on porous glass used by Sun and Khang for dehydrogenation of cyclohexane.[17] Although such catalysts do not appear to have been employed for coupling reactions their potential advantages, including mechanical and thermal stability, solvent resistance, reusability, longevity, and obviation of air- and temperature-sensitive ligands have strong appeal.

Our *ca.* 0.18% palladium on porous glass tubing could be used for reactions conducted continuously or batchwise. It offered resistance to oxidative deterioration and could be re-used several times for repeat or different reactions. Examples, mostly carried out in the presence of air, with either conventional heating or under microwave irradiation in a novel pressure-tight batch reactor (MBR),[18] are compiled in Table 1.† Turnover numbers for entries 1–8 in this table were calculated from single, non-exhaustive reaction runs and have been compiled to show that the palladium was catalytic. For the Heck coupling of 4-bromoacetophenone with styrene, when the same sample of catalyst was re-used several times, or when the molar ratio of catalyst to reactants was substantially decreased (*e.g.* 0.02 mol% Pd was used for entry 9, Table 1), the turnover

**Table 1** Example reactions and conditions (*N*,*N*-dimethylacetamide as solvent)

| Entry | Starting material(s) | *T*/°C | *t*/h | Major product(s) | Conversion (%) | Turnover number |
|---|---|---|---|---|---|---|
| 1 | PhI + $CH_2$=CH–$CH_2$OH | 120[a] | 3 | $PhCH_2CH_2CHO$ + PhCH=CHCHO + by-products (52 : 30 : 18) | 99 | > 100 |
| 2 | PhI + $PhCH=CH_2$ | 180[a] | 1.5 | *trans*- + *cis*-PhCH=CHPh + $(Ph)_2CH=CH_2$ (83 : 1 : 16) | 100 | > 100 |
| 3 | PhI + phenylacetylene | 100[b] | 88 | 1,2-diphenylacetylene | 95[c] | > 100 |
| 4 | 4-bromobenzaldehyde + phenylacetylene | 100[b] | 24/72/96 | 4′-formyl-1,2-diphenylacetylene | 79[c]/86[c]/100[c] | > 100 |
| 5 | 4-bromoacetophenone + phenylacetylene | 140[b] | 12/100 | 4′-acetyl-1,2-diphenylacetylene | 55[c]/87[c] | > 100 |
| 6 | 4-bromoacetophenone + 1-hexyne | 100[a]/ 140[a] | 6/2 | 1-(4′-acetyl)phenylhex-1-yne + by-products[d] (51 : 49) | 16/73 | *ca.* 100 |
| 7 | 2-bromopyridine + phenylacetylene | 140[b] | 48/100 | 2-(2-pyridyl)-1-phenylacetylene | 55[c]/83[c] | *ca.* 100 |
| 8 | phenylacetylene | 150[b] | 48 | 1,4-diphenylbuta-1,3-diyne + homo-addition product (93 : 7) | 71 | *ca.* 100 |
| 9 | 4-bromoacetophenone + styrene | 180[e] | 12 | *trans*- + *cis*-4′-acetyl-1,2-diphenylethylene + 1-(4-acetylphenyl)-1-phenylethylene (91 : 2 : 7) | 98 | 4000 |

[a] Carried out in air, with the MBR. [b] Carried out in air, with conventional heating. [c] 1,4-diphenylbuta-1,3-diyne and a homo-addition product ($M_w$ 204) of phenylacetylene were present. [d] Some of these were formed by addition of hex-1-yne to the product. [e] Conventional heating, under argon.

numbers were an order of magnitude greater than the other values shown in Table 1.

The regioselectivity of Heck reactions was consistent with Heck's observation that terminal alkenes yield about 80 : 20 mixtures of 1- and 2-arylated alkenes when there are no major steric influences (see entries 2 and 9, Table 1).[3] Also in agreement with previous findings,[19] Heck reaction of iodobenzene with allyl alcohol afforded 3-phenylpropionaldehyde as the major product (entry 1, Table 1). However, *trans*-3-phenylprop-2-enal was also produced and in greater abundance than the expected regioisomer 2-phenylpropionaldehyde.[3] To our knowledge, this olefinic aldehyde has not been reported from the same reactants under Heck conditions. Air present during the reaction may have played a role, an aspect which will require further investigation.

Similarly with Heck reactions, internal alkynes can be obtained by coupling of aryl iodides or bromides with terminal acetylenes under palladium catalysis.[5] However, typical requirements for high amounts of catalyst (1–5 mol% Pd) and co-addition of copper salts (also 1–5 mol% in Cu) can diminish the industrial viability of such procedures.[8] New moisture-stable phosphapalladocycles, without copper salts, recently afforded a high yielding coupling of 4-bromoacetophenone with phenylacetylene, albeit under a single set of satisfactory conditions. When alternative starting aryl halides and alkynes were used, reaction either did not proceed or was only moderately successful in most cases.[8]

With palladium on porous glass, neither copper salts nor activating ligands were necessary. Conversions for the coupling of phenylacetylene with iodobenzene and with 4-bromobenzaldehyde were nearly quantitative (entries 3 and 4, respectively, Table 1) and were satisfactory for phenylacetylene with 4-bromoacetophenone (entry 5, Table 1) and 2-bromopyridine (entry 7, Table 1). Although several of these results were comparable with those of Herrmann *et al.*, the coupling of 4-bromoacetophenone with phenylacetylene in dimethylacetamide (DMA) with NaOAc as base and also the reaction of this ketone with hexyne proceeded with palladium on porous glass (see entries 5 and 6, Table 1) where it had failed with the phosphapalladocycles.[8]

Homocoupling of phenylacetylene[20] was apparent in all reactions involving this alkyne, so not surprisingly, 1,4-diphenylbuta-1,3-diyne was formed quite efficiently in the absence of other reactants (entry 8, Table 1). Thermal addition products of ($M_w$ 204) were also formed in relatively low amounts in all reactions involving phenylacetylene.

The above results show that palladium on porous glass is a useful catalyst for synthetic coupling reactions, and suggest that it could have applications in other reactions catalysed by palladium, *e.g.* dehydrogenation[17] and hydrogenation.

We thank Mr L. Bagnell for carrying out experiments for entry 9 in Table 1.

† Prewashed porous glass tubing (7 mm o.d., 4.8 mm i.d. tubing with 250 $m^2\ g^{-1}$ internal surface area, 28% porosity; 2.54 g) was allowed to stand overnight in an aqueous solution (50 ml) of $[Pd(NH_3)_4]Cl_2$, containing 110 ppm in palladium. It was then removed, washed three times with deionised water and immersed in a solution comprising $NaBH_4$ (2.0 g) in deionised water (100 ml), at room temperature for up to 5 h. In a typical experiment, a mixture of 4-bromoacetophenone (5 mmol) and phenylacetylene (8 mmol) in *N*,*N*-dimethylacetamide (50 ml) containing NaOAc (8 mmol) and 0.18% Pd on porous glass (2.54 g glass; 0.043 mmol Pd) was heated with stirring for 100 h in air at 140 °C. At regular intervals, samples were withdrawn for analysis by GC and GC–MS. See entry 5, Table 1.

# The first observation of thermal transformation of strained paracyclophane into the Dewar isomer

**Masahiro Okuyama, Masakazu Ohkita and Takashi Tsuji***

*Division of Chemistry, Graduate School of Science, Hokkaido University, Sapporo 060, Japan*

**The kinetic stabilization of the [4]paracyclophane structure in the 2,5-bis(dicyanomethylene)-2-ene derivative permits the first observation of thermal isomerization of a strained paracyclophane to the Dewar valence tautomer; the activation free energy for the process is 18.3 ± 0.3 kcal mol$^{-1}$ at −20 °C.**

Isomerization of benzene to the Dewar valence tautomer is a highly endothermic process and the benzene ring is expected to be extremely bent in its late transition state.[1,2] A similar distortion of the benzene ring is effected in paracyclophane bridged by a short side chain,† and recent theoretical calculations suggest that the Dewar form becomes almost isoenergetic to or slightly higher in energy than the benzene form when the bridging chain is shortened to tetramethylene [–$(CH_2)_4$–].[3] Thus, it is suggested that thermal isomerization of the latter to the former is, at least, energetically feasible in [4]paracyclophane. [4]Paracyclophane and its derivatives have successfully been generated,[4,5] but their extreme thermal instability has impeded the observation of their possible cyclization to the Dewar forms.[4] We recently succeeded in stabilizing the skeleton of [4]paracyclophane in the 2,4-bis(dicyanomethylene)-2-ene derivative **1a** to permit the measurement of its $^1$H NMR spectrum for the first time.[6] We report here that **1a** and **1b** undergo thermal isomerization to the Dewar forms **2a**,**b**, respectively, and that their lifetimes in dilute solution are essentially limited by the above reactivity in the absence of air.

Compound **2a** in diethyl ether–isopentane glass at 77 K exhibits a characteristic absorption band with fine structure in the wavelength region of λ = 300–390 nm [Fig. 1(*a*)]. Irradiation of the glassy mixture with a 365 nm light source leads to the generation of **1a** exhibiting broad absorption in the 280–420 nm range at the expense of **2a**, as clearly displayed in the difference spectrum [Fig. 1(*b*)].[6] When the resulting mixture was thawed, briefly warmed up to room temperature, and refrozen at 77 K in the dark, the difference spectrum obtained from the absorptions before and after the heating was a near mirror image to the first one, as shown in Fig. 1(*c*), indicating the nearly quantitative thermal reversion of **1a** to **2a**. The half-life of **1a** at −20 °C is 15 ± 5 min and, accordingly, the activation free energy for the isomerization of **1a** to **2a** is $\Delta G^{\ddagger}$ = 18.3 ± 0.3 kcal mol$^{-1}$ at the same temperature.‡ The agreement of this energy barrier with a recent theoretical value (22 kcal mol$^{-1}$) for the isomerization of parent [4]paracyclophane **3** to 1,4-tetramethylene Dewar benzene **4**[3b] is extremely good, especially when a slightly higher exothermicity for the process from **1a** to **2a** as compared to that from **3** to **4** is taken into account. Similar photochemical generation of **1b** from **2b** and its clean thermal reversion at ambient temperature was also observed by UV–VIS spectrometry.

For such thermal unimolecular transformation to be observed the process must be exothermic. To gain information on the structures and energetics of **1** and **2**, computational analysis was undertaken. Geometrical optimization was carried out for truncated systems **1c** and **2c** using the GAUSSIAN 94 program package[7] since *ab initio* computations for **1a** and **2a** to reasonable accuracy exceeded the capacity of available computers. The optimized structures of **1c** and **2c** at the MP2/6-31G* and B3LYP/6-31G* levels are all $C_{2v}$ symmetric and the former lies higher in energy than the latter by 14.3 kcal mol$^{-1}$ at the MP2/6-13G* level and by 14.4 kcal mol$^{-1}$ at the B3LYP/6-13G* level, proving the exothermicity of the process from **1** to **2**.§ The deformation angles α and β, which give a measure of the degree to which the benzene ring is bent, and the interatomic distance between the bridgehead carbons, C(1) and C(6), in **1c** are 27.4 and 44.5°, and 2.700 Å at the MP2/6-31G* level and 28.6 and 43.0°, and 2.686 Å at the B3LYP/6-31G* level.¶ The diminution of this interatomic distance by further distortion of the benzene ring as compared to that in **1a** will certainly result in a lowered energy barrier to isomerization to the Dewar form, and hence in a diminished lifetime of the

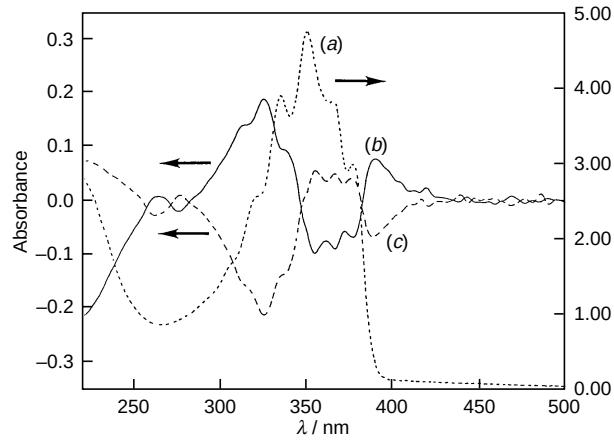

**Fig. 1** UV–VIS absorption spectra in diethyl ether–isopentane (1 : 1) at 77 K: (*a*) for **2a**; (*b*) difference spectrum obtained from the spectra before and after the irradiation of **2a** with 365 nm light; (*c*) difference spectrum obtained from those before and after the subsequent brief heating of the photolysed mixture to room temperature

benzene form.‖ Thus, **1** represents almost a limiting case of experimentally accessible strained paracyclophanes.

We acknowledge the Ministry of Education, Science and Culture of Japan for a Grant-in-Aid for Scientific Research (No. 06453031). T. T. thanks the Computer Center of the Institute for Molecular Science for the use of the NEC HSP computer.

## Footnotes

* E-mail: tsuji@science.hokudai.ac.jp

† The isomerization path has been predicted by calculations to have $C_{2v}$ symmetry (ref. 2).

‡ The photochemical isomerization of **2a** to **1a** is reversible and the latter constitutes only *ca*. 6% of the mixture in a photostationary state. The observation of the cycloreversion by another method, *e.g.* $^1$H NMR spectroscopy, was, therefore, experimentally difficult.

§ The total electronic energies of **1c** and **2c** are −461.563666 and −461.586464 a.u. at the MP2/6-31G* level and −463.095426 and −463.118401 a.u. at the B3LYP/6-31G* level, respectively.

¶ Other geometrical parameters for **1c** calculated at the MP2/6-31G* level (those at the B3LYP/6-31G* level in parenthesis; bond length in Å and bond angle in degrees): C(1)–C(2) = 1.496 (1.507), C(2)–C(3) = 1.497 (1.505), C(3)–C(4) = 1.385 (1.377), C(1)–C(8) = 1.413 (1.410), C(7)–C(8) = 1.391 (1.392), C(1)–C(2)–C(3) = 113.31 (113.00), C(2)–C(3)–C(4) = 138.58 (138.64), C(8)–C(1)–C(9) = 117.10 (116.98), C(1)–C(8)–C(7) = 117.60 (117.32).

‖ The interatomic distance between the reaction centres in the transition state for the benzene–Dewar benzene isomerization has been calculated to be in a range of 2.0–2.2 Å (refs. 2, 3).

# Anodic co-oxidation of urazole and ferrocenes: first trapping of cyclopentadienols

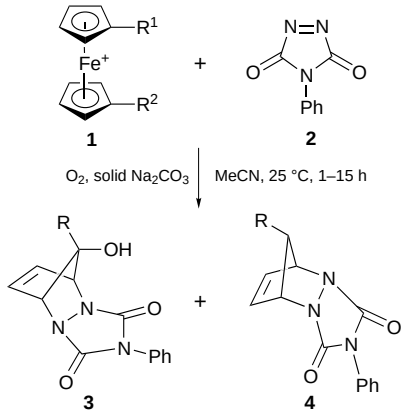
**Jocelyn Lorans,[a] Fabrice Pierre,[a] Loïc Toupet[b] and Claude Moinet*[a]**

[a] *Laboratoire 'Electrochimie et Organométalliques', UMR CNRS 6509, Université de Rennes 1, 35042 Rennes cedex, France*
[b] *Laboratoire de Physique Cristalline, Université de Rennes 1, 35042 Rennes cedex, France*

**Cyclopentadien-5-ols, the major products resulting from decomposition of some ferrocenium cations by molecular oxygen, are regio- and stereo-selectively trapped by 4-phenyl-1,2,4-triazoline-3,5-dione.**

In oxygenated organic solvents, ferrocenium cations are unstable[1] and can easily be used for generating substituted cyclopentadienes in the presence of very reactive dienophiles. The strong dienophilic character of cyclic α-carbonyl azo compounds is well known.[2–6] These are generally prepared by chemical oxidation of the corresponding hydrazino compounds using lead(IV) acetate[7,8] or *tert*-butyl hypochlorite.[9–11] We report herein the co-oxidation of ferrocenes and a triazolidine-dione (urazole) in a flow cell fitted with a graphite felt porous anode.[12] Electrolyses were performed in acidified MeCN (2% $H_2SO_4$); solid sodium carbonate and oxygen were added to the solution of triazolinedione and ferrocenium cations at the outlet of the cell. Decomposition of ferrocenium cations proceeded *via* unexpected cyclopentadien-5-ols as major products which were trapped *in situ* with 4-phenyl-1,2,4-triazoline-3,5-dione (Scheme 1). To the best of our knowledge, this reaction has never been reported before. Theoretical calculations show that the three cyclopentadienol isomers should be very unstable.[13] Previously, cyclopentadienol has only been postulated as an intermediate during a thermal retro-Diels–Alder reaction.[14]

Decomposition of ferrocenium cation **1a** in the presence of triazolinedione **2** was complete after 1 h and gave a mixture of **3a** and **4a**. The yield of **3a** increased as the molar ratio triazolinedione : ferrocenium cation increased, whereas the yield of **4a** was practically unchanged (Table 1). The $^1$H and $^{13}$C NMR spectra of **3a** show a regio- and stereo-selective addition. X-Ray analyses show that **3a** results from an *exo* addition (Fig. 1) and **4a** from an *endo* addition. Compound **4a** is identical to the Diels–Alder adduct prepared by a different method using **2** and freshly distillated cyclopentadiene.[8]



1,1′-Dialkylated ferrocenium cations **1b** and **1d** decomposed more slowly than **1a** and gave, after reaction with **2**, compounds **3b** and **3d** respectively. The $^1$H and $^{13}$C NMR spectra of **3b** and **3d** and the X-ray analysis of **3b** (Fig. 2) indicate a regioselective *exo*-addition like that for **3a**. After decomposition of mono-alkylated ferrocenium cation **1c** and reaction with **2**, a mixture of **3a** and **3d** was isolated. Compounds **3a** and **3d** were separated by column chromatography. Adduct **4a** was not detected.

The rate of decomposition of acetylferrocenium **1e** and 1,1′-diacetylferrocenium **1f** was much faster. Thus **1f** gave a mixture of unidentified products and **1e** gave **3a** in poor yield (12%).

**Table 1** Composition of mixtures from decomposition of ferrocenium cations **1** in the presence of 4-phenyl-1,2,4-triazoline-3,5-dione **2**

| Substrates (molar ratio) | Products (% yield[a]) |
|---|---|
| **1a** + **2** (1 : 1) | **3a** (46) + **4a** (12) |
| **1a** + **2** (1 : 2) | **3a** (69) + **4a** (14) |
| **1a** + **2** (1 : 3) | **3a** (80) + **4a** (15) |
| **1b** + **2** (1 : 2) | **3b** (41) |
| **1c** + **2** (1 : 2) | **3a** (24) + **3d** (45) |
| **1d** + **2** (1 : 2) | **3d** (52) |

| **1f** + **2** (1 : 2) | — |

[a] Calculated from initial ferrocene.

**Scheme 1**

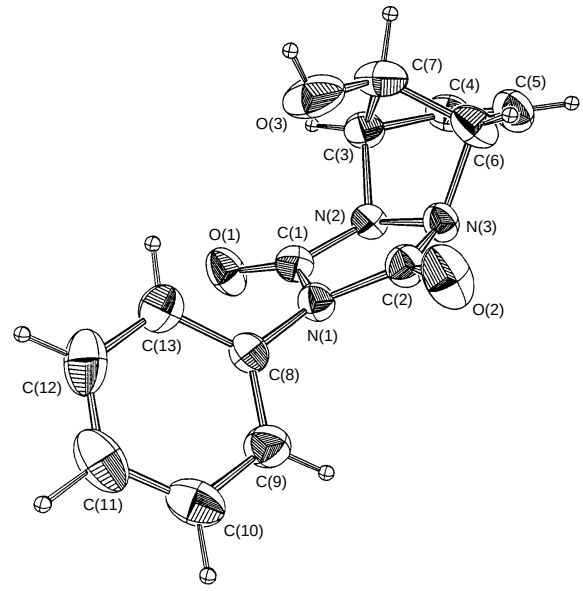

**Fig. 1** X-Ray structure of **3a**

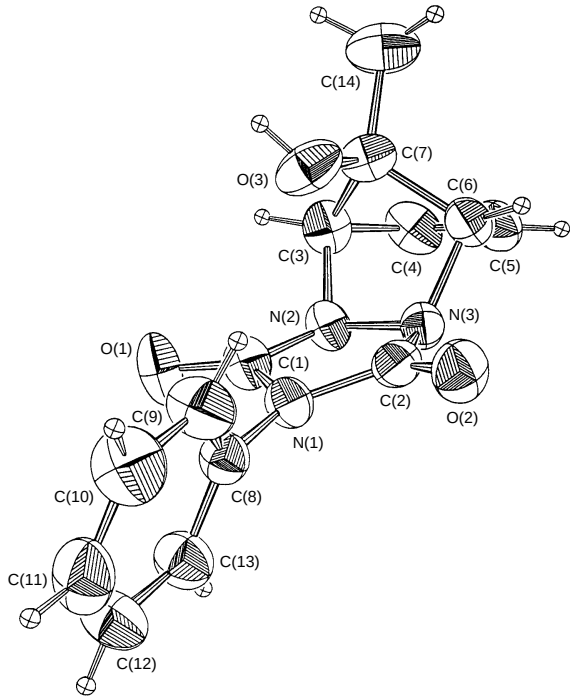

**Fig. 2** X-Ray structure of **3b**

Decomposition of ferrocenium cation is probably initiated *via* radical coupling with molecular oxygen as previously suggested.[1] After rearrangement and chemical evolution, cleavage of the iron and the formed cyclopentadienol ligand takes place, whereas only limited decomplexation of the second ligand (in case of **1a**) leads to free cyclopentadiene. To support this hypothesis, we note that the oxygen decomposition of ferrocenium cations in MeCN gave a brown precipitate characterised as an iron salt; elemental analyses of this salt showed the presence of one cyclopentadienyl ligand.[15]

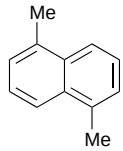
# Locked-in methyl groups in 1,5-dimethylnaphthalene close to the melting point



**Chick C. Wilson***

*ISIS Department, CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, UK OX11 0QX*

**Single crystal neutron diffraction shows that the methyl group conformations in 1,5-dimethylnaphthalene are unchanged, with a hydrogen atom in the molecular plane, even as the crystal approaches the melting point.**

Our recent work on variable temperature single crystal neutron diffraction using rapid data collection methods is aimed at changing the overall energy content of the system and monitoring structural changes. These can involve either the internal vibrations of the molecule as indicated by anisotropic thermal parameters, or the order-disorder characteristics of parts of the molecule. These neutron studies have focused on hydrogen atom motions[1] and ordering,[2,3] and the present work represents our first attempt at examining a steric effect using this technique.

We have chosen to study 1,5-dimethylnaphthalene **1**, in which a steric interaction between the methyl groups and the neighbouring hydrogen atoms is likely to occur, reducing the propensity of the methyl groups to freely rotate in the crystal structure. The aim of the present work was to extend previous neutron diffraction measurements of the structure of **1** to higher temperatures and to use the hydrogen thermal parameters to examine the methyl group rotation as the temperature approaches the melting point. The original X-ray study[4] found that the methyl groups in the title compound are sterically 'frozen' into a single orientation, a conclusion supported by room temperature neutron diffraction measurements.[5] There was, however, the expectation that these methyl groups would start to rotate from this orientation before the crystal melts ($T_m$ = 353 K) with the rotation predicted to set in above 290 K, but this has not been examined until now.

**1**

To this end, we have collected single crystal neutron diffraction data from the title compound at a series of temperatures, on the SXD at ISIS.[6]† Large single crystals were grown by repeated recrystallisation from an acetone solution of **1** purchased from the Aldrich Chemical Company. Since the samples are volatile, a crystal of dimension 3 × 2 × 2 mm was sealed in a glass capillary and mounted in standard fashion on a Displex helium refrigerator. Initial data frames confirmed the unit cell and space group to be in agreement with previous work. A limited data set was collected at 100 K, followed by full data sets at 290 and 320 K. To allow the final data set to be collected as close to the melting point as practicable, a second crystal was mounted identically to the first and placed into the same cooling device on the instrument. A series of data frames were then collected as the sample was heated from room temperature through the melting point. The intensities of a group of strong reflections in this frame were monitored and significant reduction in intensity found to set in at around 340 K, approximately 10 K below the melting point. It was therefore decided to collect the data at 340 K and the original sample was remounted in identical fashion, heated to this temperature and diffraction data collected.

At all temperatures data were collected and reduced to structure factors in the standard fashion.[6] The structural model from which refinement began was that of ref. 5, but in addition the methyl hydrogens were located in all cases using Fourier calculations, which were computed using the GSAS program.[7] Refinement of the crystal structure at each temperature was carried out by least-squares methods in GSAS, using anisotropic thermal parameters on all atoms (Fig. 1). The data/

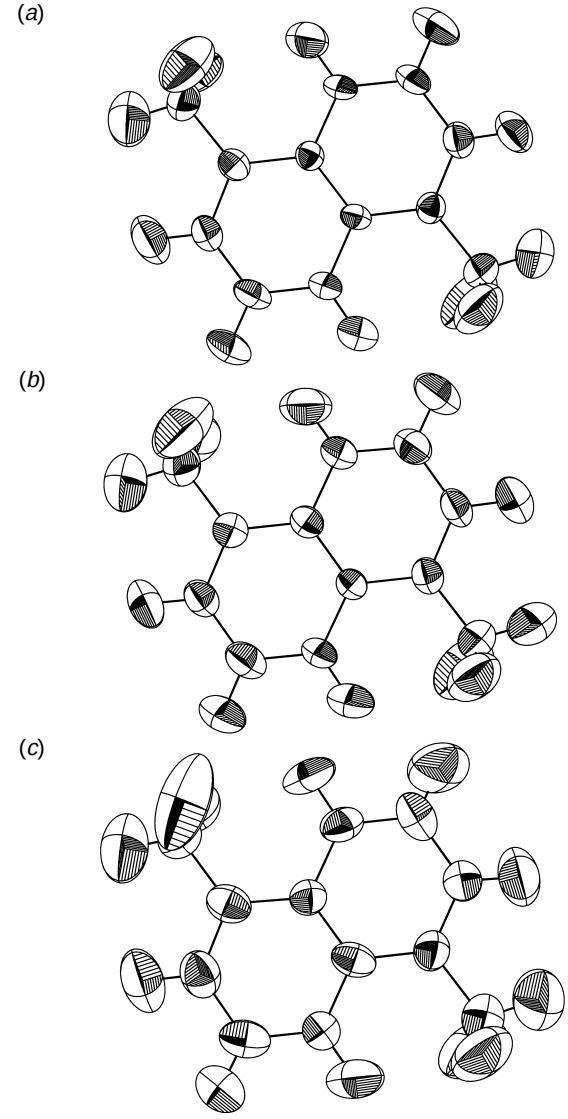


**Fig. 1** ORTEP (ref. 10) views of the refined structure of 1,5-dimethylnaphthalene at (*a*) 290, (*b*) 320 and (*c*) 340 K. The ellipsoids are plotted at 50% probability. The plot shows the equilibrium orientation of the methyl groups to be unchanged with increasing temperature.

parameter ratio for the 340 K data set is rather low, due to the fact that the crystal was progressively decreasing in volume as the data collection proceeded; in fact the inter-frame scale factors show that approximately 50% of the crystal was lost during the two days of data collection at 340 K.

The refined anisotropic thermal displacement parameters were subjected to rigid body analysis using the TLS method,[8,9] in which the two methyl groups were treated as undergoing torsional motions about the C–C bonds connecting them to the naphthalene ring. Although the precision of the TLS analysis is rather low, particularly at 340 K because of the low data/parameter ratio, it permits the general trend with temperature to be observed (Fig. 2).

Two major points emerge from the refinements. First, the equilibrium orientation of the methyl groups is essentially the same at all temperatures, and the in-plane hydrogen atom found at room temperature[5] remains in-plane even at 340 K. This observation was confirmed both from the refinements using the room temperature structural model as starting point, and also was clearly indicated by the Fourier calculations, in which the six methyl hydrogens were unambiguously located at all temperatures with no indication of significant atomic density in any other chemically plausible position around these groups.

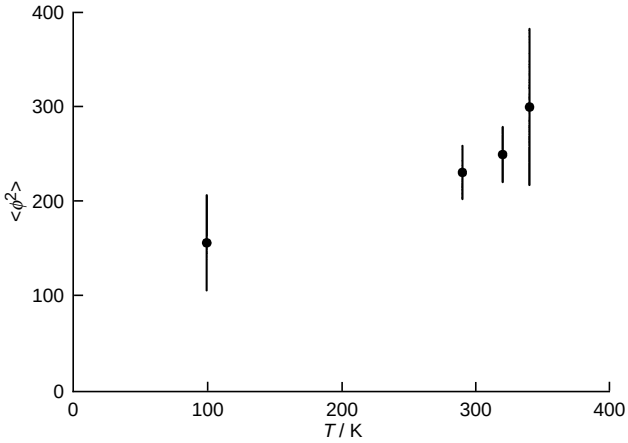

**Fig. 2** The average mean square torsional amplitude $<\phi^2>$ for the two methyl groups in 1,5-dimethylnaphthalene as a function of temperature

Secondly, the torsional motions of both methyl groups broadly increase with temperature as expected. However, there is an indication of the effect of steric clashes in the relatively low magnitude of these librations even close to melting (compare $<\phi^2>_{340\ K} = 300°^2$ for **1** with $<\phi^2>_{330\ K} = 940°^2$ for a molecule with a methyl group undergoing unhindered rotation, *e.g.* paracetamol[1]).

In conclusion, we clearly have in 1,5-dimethylnaphthalene a sterically hindered molecule in which the propensity of the methyl groups to undergo large torsional oscillations at high temperature is frustrated by steric effects. The methyl groups appear to be restrained in a single equilibrium orientation even close to the melting point, undergoing progressively larger but still hindered vibrations.

# Stereochemical observations on the bromate induced monobromopentahydroxylation of benzene by catalytic photoinduced charge transfer osmylation. A concise synthesis of (±)-pinitol

**Pierre M. J. Jung, William B. Motherwell* and Alvin S. Williams**

*Christopher Ingold Laboratories, Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*

**The use of lower temperatures in the title reaction favours the formation of the *neo* diastereoisomer of the deoxybromoinositol whose diisopropylidene derivative can be converted in three steps to (±)-pinitol.**

We have recently described the first examples of a direct stereocontrolled polyhydroxylation pathway from arenes to cyclitols based on catalytic photoinduced charge-transfer osmylation and featuring the use of barium chlorate as a stoichiometric reoxidant.[1] Here we also reported the single unoptimised experiment shown in Scheme 1, whereby the selection of sodium bromate as an alternative 'co-oxidant' led to apparent suppression of the normal third osmylation sequence leading to the *meso* derivative, *allo*-inositol hexaacetate **1**, and formation of the two deoxybromoinositols **2** and **3** in a highly diastereoselective manner and in a combined yield of 18.8%. We now present the results of a study which was designed to probe the stereochemical origins of this unusual monobromopentahydroxylation reaction, together with the elaboration of these readily available products in a concise synthesis of (±)-pinitol.

Casual inspection of the products formed in Scheme 1 clearly suggests that they may be formally derived by the *trans* addition of hypobromous acid at some intermediate stage following the initial formation of the osmate ester of benzene diol. In the first instance, we were therefore intrigued to discover whether bromohydrin formation could be encouraged at the diene stage through an increase in the concentration of bromate anion, particularly since the isolation of minor amounts of the bromoconduritols C **4** and F **5** implied that such a pathway was possible. A systematic study revealed, however, that even at very high concentrations of bromate (2.65 M *cf.* 0.22 M Scheme 1) there was no essential change, either in the relative ratio of *allo*-inositol hexaacetate **1** to brominated products **2** and **3**, or in the diastereoisomeric ratio **2**:**3**.

By way of contrast however, as shown in Table 1, the influence of temperature on the reaction was shown to exert a highly significant effect, with the *neo* diastereoisomer **2** predominating at lower temperature and the *chiro* derivative **3** favoured at higher temperatures.

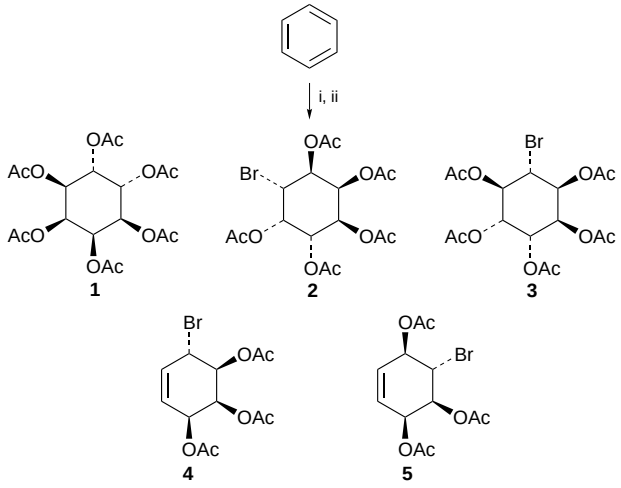

**Table 1** Yields and relative ratios of products as a function of temperature[a]

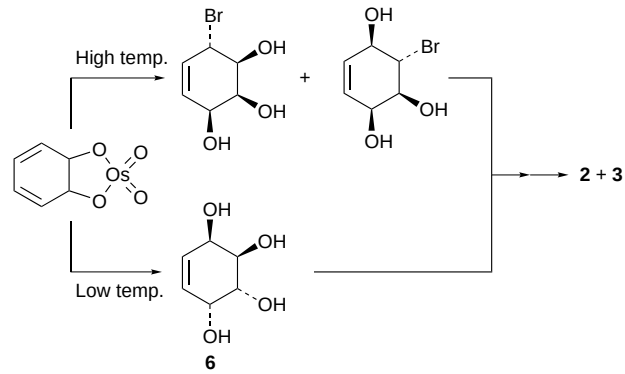
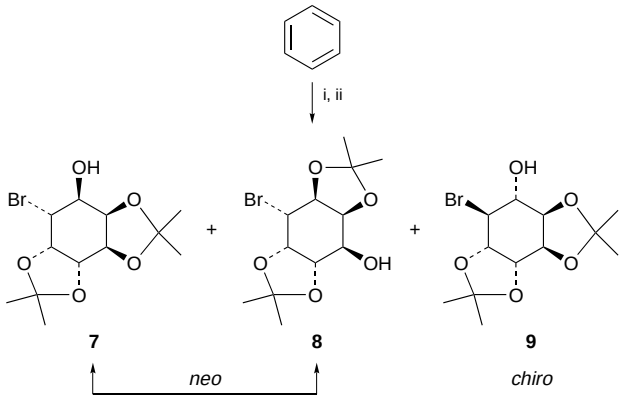
| | Product yield (%) | | Relative ratio |
|---|---|---|---|
| *T*/°C | **1** | **2** + **3** | **2**:**3** |
| 2 | 5.1 | 12.6 | 2:1 |
| 15 | 7.4 | 16.3 | 1:1 |
| 30 | 7.7 | 18.8 | 1:5 |
| 45 | 5.7 | 16.4 | 1:5 |



[a] All reactions were run at 0.36 M concentration of bromate using $OsO_4$ (1.3 mol%) as catalyst with irradiation for 43 h.

A variety of reasons lead us to believe that this crossover in the diastereoisomeric ratio may be explained by the bifurcated reaction pathway shown in Scheme 2, whereby the low temperature reactions tend to pass *via* the intermediacy of conduritol E **6**, or an osmate ester derived therefrom, while formation of bromoconduritols **4** and **5** intervenes effectively at higher temperature.

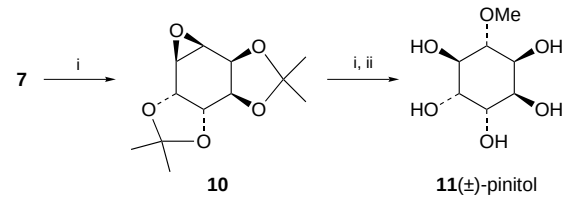


Thus, a significant clue was provided in a parallel low temperature experiment (2 °C) using chlorate anion (0.22 M) as the oxygen atom transfer reagent. Under these conditions, chlorohydrin formation is not observed, and osmylation of the third double bond in the *anti*-tetrol is sufficiently slow to permit isolation of significant amounts of both the inositol and conduritol acetates [**1** 6.1%, **6** (tetraacetate) 4.1%]. We therefore speculated that bromate disproportionation was

**Scheme 1** *Reagents and conditions*: i, $OsO_4$ (cat.), *h*ν, $NaBrO_3$ (0.22 M), 45 °C; ii, AcOH, $Ac_2O$, (**1**) 7.7%, **2**:**3** 5.1:1, 18.8%, **4**:**5**, 1:5, 2.3%

**Scheme 2**

**Scheme 3** *Reagents and conditions*: i, $OsO_4$ (cat.), *h*ν, $NaBrO_3$ (0.22 M), 15 °C; ii, acetone, TsOH, $H_2O$, (**7**) 8%, (**8**) 6.7%, (**9**) 2.5%



slower at lower temperatures and that the deoxybromoinositols **2** and **3** were formed by addition of hypobromous acid to conduritol E **6** during the work up stage, which involved a reductive quench of bromate residues with sodium metabisulfite. Indeed, this very combination has recently been shown to be an excellent method for bromohydrin formation.[2] Some support for this hypothesis came from an experiment in which a vast excess of cyclohexene was added as a sacrificial alkene following a photoosmylation at 2 °C, and prior to the addition of metabisulfite. In this instance, the relative proportion of the isolated bromohydrin acetates was significantly lower than before [**2** + **3**; 6.2%, compare 12.6% (Table 1)], and counterbalanced by the corresponding isolation of conduritol E (tetraacetate, 8.6%).

While the results presented in Table 1 clearly demonstrate that diastereoisomeric crossover has occurred, it should be noted that the strongly ionising conditions employed in the acetylation step almost certainly promote neighbouring group participation.[3] This aspect was highlighted when the products from a bromate driven photoosmylation reaction at 15 °C were isolated as their isopropylidene derivatives by treatment of the crude reaction mixture with acetone and toluene-*p*-sulfonic acid. (Scheme 3).

The supposition that the isolated ratio of deoxybromocyclitols from this experiment [**7** + **8** (*neo*, 14.7%) : **9** (*chiro*, 2.5%); 5.9 : 1] is probably a more appropriate reflection of the initial product distribution prior to derivatisation was also supported by a further blank experiment in which reaction of conduritol E **6** with sodium bromage–sodium metabisulfite was followed by neutralisation with sodium hydroxide and subsequent acetylation under less ionising acidic conditions with acetic anhydride in acetic acid to give **2** and **3** (72%, ratio **2** : **3**, 6.3 : 1).

From a preparative standpoint, irrespective of the fact that two competing pathways are operating, it is apparent that experimental conditions can be selected to favour either the *neo* or the *chiro* series as the major diastereoisomer. Moreover, in practical terms, a single recrystallisation of a mixture of **2** and **3** from EtOH at room temperature gives pure **3**, while advantage can be taken of the known relative insolubility of *neo*-inositol[4] to precipitate the parent bromocyclitol from **2** by simple acid catalysed hydrolysis using HCl in MeOH.

The ready availability of these protected building blocks in a single one-pot operation offers a variety of possibilities for further synthetic manipulation in the important cyclitol area. By way of illustration, we elected to prepare (±)-pinitol **11**, the

**Scheme 4** *Reagents and conditions*: i, $K_2CO_3$, MeOH, heat 2 h, 83%; ii, $Al_2O_3$, MeOH, heat 24 h; iii, $H_2O$, THF, HCl (cat), 60% from **10**

3-*O*-methyl ether of *chiro*-inositol, with both enantiomers occurring in various plant sources. (+)-Pinitol has been shown to possess significant hypoglycemic and antidiabetic activity in diabetic albino mice.[5] Previous syntheses of pinitol, either in racemic form[6] or of either antipode,[7,8] have relied on the use of *cis*-dienediols available by microbial oxidation of arenes using *Pseudomonas putida*.

Thus, as shown in Scheme 4, ring closure of the bromohydrin **7** to epoxide **10** was smoothly accomplished using $K_2CO_3$ in MeOH (83%). The regiospecificity of the subsequent ring-opening of the epoxide with alumina in MeOH is governed by the necessity for a *trans* opening *anti* to the neighbouring isopropylidene groups and finds precedent in Hudlicky's elegant enantiodivergent synthesis of both antipodes.[8] An acidic work up to this reaction led to *in situ* deprotection to afford (±)-pinitol **11** in 60% isolated yield from **10**. The overall sequence therefore requires three operations and five discrete steps from benzene.

In summary, the present study has shown that the influence of temperature in the catalytic photoinduced charge transfer osmylation of benzene may be usefully controlled, either in the reaction using chlorate anion as oxidant to suppress tertiary osmylation at lower temperature and hence favourer conduritol E production, or to influence the stereochemical outcome in the bromate reaction leading to *neo* and *chiro* deoxybromoinositols.

We thank the EPSRC for the award of a postdoctoral fellowship (P. M. J. J.) and B. P. for the award of a studentship (A. S. W.). We also wish to acknowledge stimulating and helpful discussions with Dr H. A. J. Carless.

# Chiral salen manganese complex encapsulated within zeolite Y: a heterogeneous enantioselective catalyst for the epoxidation of alkenes

**María J. Sabater, Avelino Corma,* Antonio Domenech, Vicente Fornés and Hermenegildo García**

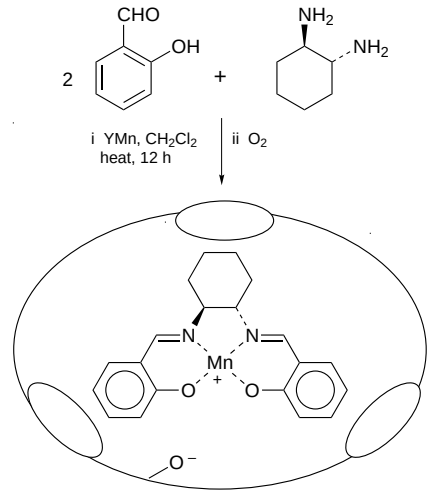
*Instituto de Tecnología Química C.S.I.C.-U.P.V., Apartado 22012, 46071-Valencia, Spain*

**A chiral (salen)$Mn^{III}$ complex [salen: *trans*-(*R*,*R*)-1,2-bis(salicylideneamino)cyclohexane] analogous to Jacobsen's catalyst is prepared inside the supercages of zeolite Y, showing catalytic activity very similar to that of the chloride complex in the homogeneous phase.**

The use of chiral catalysts has become a powerful methodology in modern synthetic organic chemistry.[1] In this regard, the Sharpless epoxidation of allylic alcohols constituted an authentic breakthrough in this field.[2,3] More recently, Jacobsen and co-workers expanded the scope of the catalytic asymmetric epoxidation to unfunctionalized alkenes with high stereocontrol by using chiral (salen)Mn complexes.[4]

A further logical improvement of this homogeneous catalytic method would consist of the incorporation of the catalyst on to an inorganic support, making it possible to perform the reaction heterogeneously.[5,6] In the present work, we have successfully accomplished for the first time the preparation of a chiral (salen)manganese complex analogous to the Jacobsen catalyst into the supercages of large pore Y zeolite.† The resulting (salen)Mn complex entrapped within Y zeolite exhibits similar catalytic activity as the same complex under homogeneous conditions.

The pore structure of Y zeolite consists of almost spherical 13 Å cavities interconnected tetrahedrally through smaller apertures of 7.4 Å diameter. Molecular modelling predicts that both the salen ligand [salen: *trans*-(*R*,*R*)-1,2-bis(salicylideneamino)-cyclohexane] or the corresponding (salen)$Mn^{III}$ complex can be easily accomodated inside the supercages of Y zeolites. Analogously, it is predicted that the actual Jacobsen's catalyst having four *tert*-butyl groups on the phenyl rings does not fit into the Y zeolite supercages.



The synthesis of the (salen)$Mn^{III+}$ in the intracrystalline cages of zeolite Y is outlined in Scheme 1. Basically it consists of the condensation of optically active *trans*-(*R*,*R*)-1,2-diamino-cyclohexane and salicylaldehyde around $Mn^{II}$ metal ions resident in the supercages (1 $Mn^{2+}$ every 5 supercages) and a final oxidation step.

Other alternative protocols were found to be less efficient. If both reagents were added simultaneously, an unfavourably large excess of uncomplexed ligand was formed. On the other hand, if chiral diaminocyclohexane was the first reactant added to MnY, the IR spectrum of the corresponding zeolite predominatly showed the bands of unreacted amine.

Samples of (salen)$Mn^{III}$ complex in zeolite Y were fully characterized by thermogravimetry–differential scanning calorimetry (TG–DSC), diffuse reflectance and FTIR spectroscopies and cyclic voltammetry (CV). Thus, the salen/$Mn^{III}$ ratio of the solids quantified by TG–DSC was 1.3 indicating a slight excess of the uncomplexed ligand. The IR spectrum of the zeolite guest after the synthesis shown in Scheme 1 was compared with those recorded for authentic samples of the salen ligand and (salen)$Mn^{III}$Cl (Fig. 1).

As it can be seen from Fig. 1, the spectrum of the (salen)$Mn^{III}$-Y sample coincides with that of the chloride salt of the same complex, thus establishing the purity and identity of the (salen)$Mn^{III}$-Y zeolite. In contrast, the most characteristic band associated with the salen ligand appearing at 1500 $cm^{-1}$ is absent for the zeolite sample, indicating that the amount of uncomplexed ligand is below the detection limit of this technique.

Direct support for the +3 oxidation state of Mn ions as well as their complexation by salen was obtained by electrochemical techniques.[7] The electrochemical behaviour of the (salen)$Mn^{III}$ intrazeolite complex in $Me_2SO$ showed an equilibrium potential of −0.32 V *vs.* SCE. This value matches that recorded for the same complex in a homogeneous phase. Notably, the redox potential of the uncomplexed $Mn^{3+}/Mn^{2+}$ pair would be far more positive. Accordingly, MnY did not show any electrochemical activity .

**Scheme 1**

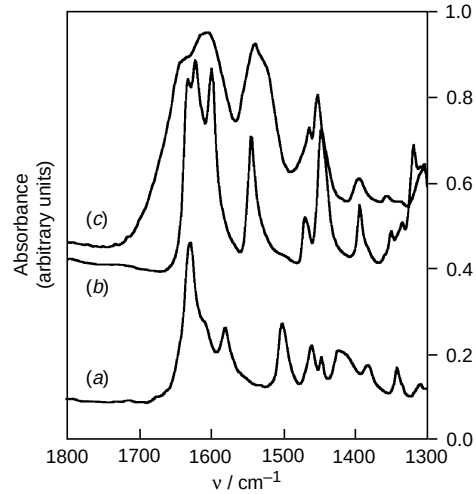


**Fig. 1** Aromatic region of the FTIR spectra of (*a*) the salen ligand, (*b*) (salen)$Mn^{III}$Cl and (*c*) (salen)$Mn^{III}$-Y complexes. Note that the 1535 $cm^{-1}$ absorption characteristic of the complex is present in the spectrum of (salen)$Mn^{III}$-Y sample. In contrast, the salen ligand has a specific 1500 $cm^{-1}$ band as the most distinctive absorption.

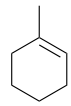
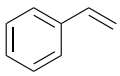
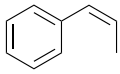
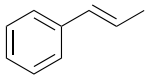
EPR measurements confirmed the disappearance of the majority of $Mn^{2+}$ ions from the initial MnY to the final (salen)$Mn^{III}$-Y sample.

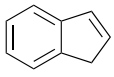
In order to determine the performance of the (salen)manganese complexes encapsulated in Y zeolite, the epoxidation of four prochiral alkenes was tested and the results compared with those obtained under homogeneous conditions (Table 1).











The oxidations were carried out in the presence of catalytic amounts of the (salen)$Mn^{III}Cl$ complex (5 mol%) or 90 mg of the heterogeneous (salen)$Mn^{III}$-Y system by using NaOCl in $CH_2Cl_2$ at 5 °C. Higher reaction temperatures led to a significant decrease in asymmetric induction as well as a dramatic decrease in the epoxide selectivity.

The reactions showed a high chemoselectivity except for compound **1**. Indeed, in most of the cases at 5 °C epoxides were obtained as the main or sole products as detected by GC analysis. Notably, by-products commonly observed for other non-enantioselective zeolite-catalysed epoxidations arising from epoxide scission were absent.[8]

The lower reaction rates obtained with the (salen)$Mn^{III}$-Y heterogeneous catalyst compared to the homogenous counterpart could have been anticipated in view of the restrictions imposed on the diffusion substrate and products through the micropores of the solid, especially when the reaction is run at low temperatures.

With regard to the enantioselectivity, the trisubstituted olefin **1** and styrene **2** gave poor enantiomeric excess. This agrees with previous data on the performance of the Jacobsen's catalyst.[9,10] In contrast, conjugated *trans* olefin **3** and the cyclic indene **4** were epoxidized in moderate to good enantioselectivity both in the homogeneous and the heterogeneous catalysis.

**Table 1** Asymmetric epoxidation of alkenes **1**–**4** catalysed by the (*R*,*R*)-(salen)$Mn^{III}$ complex and NaOCl as oxidant in the homogeneous and heterogeneous phases

| Entry | Olefin[a] | Catalyst[b] | Conversion (%)[c,d] | Epoxide selectivity (%)[c] | Ee (%) |
|---|---|---|---|---|---|
| 1 |  | (salen)$Mn^{III}Cl$ | 37 | 65 | 8 |
| 2 | **1** | (salen)$Mn^{III}$-Y | 11 | 65 | 5 |
| 3 |  | (salen)$Mn^{III}Cl$ | 47 | 80 | 27 |
| 4 | **2** | (salen)$Mn^{III}$-Y | 40 | 61 | 20 |
| 5 |  | (salen)$Mn^{III}Cl$ | 28 | 100 | 74[e] |
| 6 | *cis*-**3** | (salen)$Mn^{III}$-Y | 5 | 76 | 58[e] |
| 7 |  | (salen)$Mn^{III}Cl$ | 23 | 90 | 41 |
| 8 | *trans*-**3** | (salen)$Mn^{III}$-Y | 11 | 100 | 24 |
| 9 |  | (salen)$Mn^{III}Cl$ | 30 | 100 | 60 |
| 10 | **4** | (salen)$Mn^{III}$-Y | 20 | 96 | 50 |

[a] Reactions were run at 5 °C in $CH_2Cl_2$. [b] (salen)$Mn^{III}Cl$, 5% mol; (salen)Mn-Y, 90 mg of catalyst with a complex content of 3.8%. [c] Determined by quantitative capillary GC analysis. [d] Reaction time: 2–3 h using (salen)$Mn^{III}Cl$ and 12–15 h for (salen)$Mn^{III}$-Y catalyst. [e] Ee of *trans* epoxide.

Although the ees obtained using (salen)$Mn^{III}$-Y and (salen)-$Mn^{III}Cl$ follow the same pattern, we consistently noticed somewhat lower values for the zeolite-bound catalyst. This can be interpreted as a combination of two unfavourable factors: (i) the occurrence of a non-catalysed, unselective epoxidation route in the liquid phase and/or (ii) the existence of residual amounts of uncomplexed $Mn^{2+}$ acting as catalytic sites.

The above point raises the question of how to assess that the reaction is taking place inside the zeolite micropores. The simplest straightforward way to address this point is to determine the inactivity of the heterogeneous (salen)$Mn^{III}$-Y catalyst by using reagents of larger dimensions than the pore windows of zeolite host. Under these conditions the homogeneous (salen)$Mn^{III}Cl$ counterpart must be still an efficient epoxidation catalyst.

Thus, we found that a iodosylbenzene derivative obtained by basic hydrolysis of [bis(trifluoroacetoxy)iodo]benzene[11] gives very similar results to those presented in Table 1 using NaOCl in the presence of (salen)$Mn^{III}Cl$. However, FABMS established that the structure of this iodosylbenzene sample was not monomeric but likely to be a cyclic oligomeric precursor of PhIO. Therefore, this bulky reagent would be size excluded from the 7.4 Å faujasite pore windows. Accordingly, no conversion could be observed in the epoxidation of alkenes **2**–**4** in the presence of (salen)$Mn^{III}$-Y catalyst. In addition, this lack of activity of the (salen)$Mn^{III}$-Y catalyst compared to the 43% conversion achieved using (salen)$Mn^{III}Cl$ indicates that no leaching of Mn ions from the interior of the zeolite to the solution occurs and also that the external surface sites play a very minute role in the overall catalytic process. To further establish the lack of Mn leaching, we performed chemical analysis of the liquid phase after the reaction. No Mn ions could be detected.

All the enantioselective enzymatic systems in nature have in common the incorporation of the active sites into a confined space defined by the tertiary protein structure. Our chiral (salen)$Mn^{III}$-Y catalyst mimics this strategy: the rigid, inorganic framework of the zeolite determines the reaction cavity surrounding the active complex.

# Stereoselectivity and mechanism of $Cu^{2+}$ transfer between chiral, multidentate ligands

**Klaus Bernauer* and Marie-Fabiola Gilet**

*Laboratoire de Chimie Inorganique et Analytique, Institut de Chimie, Université de Neuchâtel, Av. de Bellevaux 51, 2000 Neuchâtel, Switzerland*

**The ligand-exchange kinetics between the enantiomers of [Cu(alamp)] or [Cu(promp)] and (*S*)-pdta are measured by CD spectroscopy; three different reaction intermediates are proposed, involving the three different states of N-protonation of pdta; at pH < 7 an associative mechanism involving a cage-like, hydrogen-bonded intermediate is suggested for [Cu(alamp)] in which the metal ion is transferred in a single rate limiting step from one ligand to the other.**

Stereoselectivity has not been used to investigate metal-ion-transfer reactions in aqueous solutions. Only two communications concerning stereoselective metal-ion transfer in organic solvents are reported in the literature. Kurganov *et al.*[1] observed rate differences in the dismutation of copper(II) complexes with N-substituted optically active diamines in acetonitrile and in nitrobenzene and Warmuth and Elias[2] reported stereoselective ligand exchange of nickel(II) Schiff-base complexes in acetone. In the following, we present some preliminary results of the stereoselective ligand exchange between the chiral copper(II) complexes of deprotonated *N*,*N*′-[(pyridine-2,6-diyl)bis(methylene)]bis(alanine) [alamp ($L^1$)] or *N*,*N*′-[(pyridine-2,6-diyl)bis(methylene)]bis(proline) [promp, ($L^2$)] and (*S*)-1,2-diaminopropanetetraacetic acid [(*S*)-$H_4$pdta ($H_4L^3$)] according to eqn. (1). From the known protonation constants of the ligands[3] and

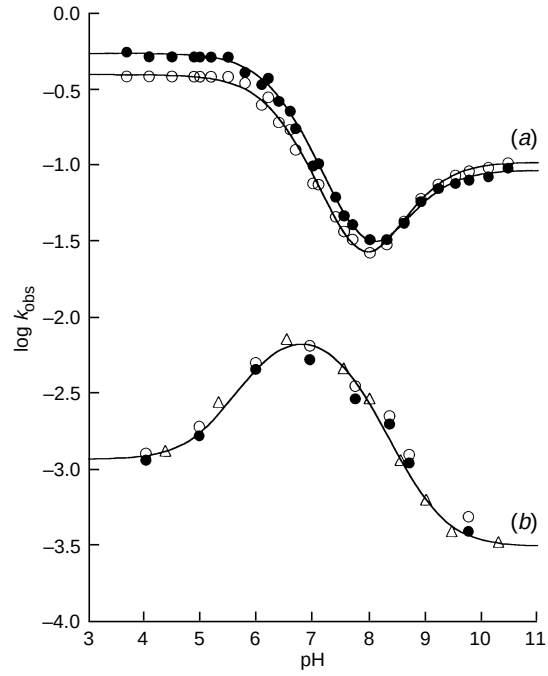
$$[CuL] + (S)\text{-}H_n\text{pdta}^{(4-n)-} \rightleftharpoons [Cu\{(S)\text{-pdta}\}]^{2-} + H_mL^{(2-m)-}$$

$$L = (R,R)\text{- or } (S,S)\text{-}L^1,\ (R,R)\text{- or } (S,S)\text{-}L^2 \qquad (1)$$

the formation constants of $[CuL^1]$, $[CuL^2]$[4] and $[CuL^3]^{2-}$,[5] it can be calculated that the equilibrium (1) lies to more than 96% to the right, and that the concentration of free $Cu^{2+}$ is < 1% over the whole pH range from 4 to 11 under the measurement conditions. Reaction rates are determined under pseudo-first-order conditions, the exchange ligand $H_n\text{pdta}^{(4-n)-}$ being initially present in a tenfold excess. The rate of the reaction is best measured by the change of the intensity of the circular dichroism (CD) at $\lambda$ = 607 nm, at which the product complex has no CD signal.

From the observed rate constants, represented as a function of pH in Fig. 1,† the following conclusions can be drawn: (*i*) for both $[CuL^1]$ and $[CuL^2]$ the reaction takes place by at least three different pathways corresponding to the two protonated and the entirely deprotonated form of pdta as indicated in Scheme 1; (*ii*) with $L^1$ as the ligand the reaction is fastest with $H_2pdta^{2-}$, whereas the relative rates with $[CuL^2]$ are $Hpdta^{3-} > H_2pdta^{2-} > pdta^{4-}$; (*iii*) all the reactions show small but significant stereoselectivity, which is highest for the exchange reaction between $[CuL^1]$ and $H_2pdta^{2-}$ in the pH range 4–7. The ratio of the observed rate constants for the two diastereoisomeric couples is $k_\Delta/k_\Lambda = 1.3 \pm 0.1$ {$k_\Delta$ stands for the reaction between [Cu{(*R*,*R*)-$L^1$}] and (*S*)-pdta}.

The observed stereoselectivity clearly indicates an associative mechanism but the concentration of the intermediate must be low, the rate of the reaction having linear dependence up to a pdta concentration of 0.03 M ($K_i \leqslant 3$ dm$^3$ mol$^{-1}$). However, the most interesting observations are: (*i*) the acceleration of the reaction involving $[CuL^1]$ by the presence of the two N–H protons on the exchange ligand, protons which have to be replaced by the metal ion, and (*ii*) the striking difference in the selection of the most favourable reaction pathway for $[CuL^1]$ and $[CuL^2]$. The only difference between the two complexes able to influence this mechanistic selection is the presence of the two N–H groups in the former, groups which are replaced by alkyl residues in the latter. It becomes therefore evident that in



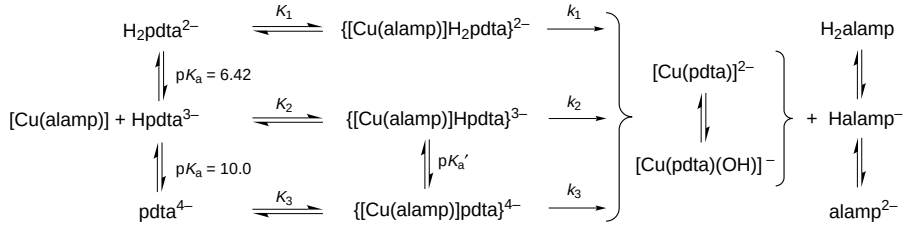


**Fig. 1** Observed rate constants for the reaction between [Cu(alamp)] (*a*) or [Cu(promp)] (*b*), with (*S*)-pdta as a function of pH. $[Cu^{2+}] = 1 \times 10^{-3}$ M, [alamp] or [promp] $= 1 \times 10^{-3}$ M, [(*S*)-pdta] $= 1 \times 10^{-2}$ M, [buffer] = 0.2 M {pH = 4.0–5.5 (acetate, values extrapolated to zero buffer concentration), 5.6–6.5 [2-morpholinoethanesulfonic acid monohydrate (MES)], 6.6–7.9 [3-morpholino-2-hydroxypropanesulfonic acid (MOPSO)], 8.1–10.1 (borate)}. Buffer concentration refers to the ionic constituent. $T$ = 20 °C; (○) (*R*,*R*)-ligand, (●) (*S*,*S*)-ligand, (△) *rac*-pdta.

**Scheme 1**

the exchange with [CuL[1]] the N–H groups of both ligands, $H_2pdta^{2-}$ and alamp are important for stabilising an intermediate containing four hydrogen bridges, a possible structure of which is shown in Fig. 2. Such an intermediate cannot be formed with [CuL[2]].

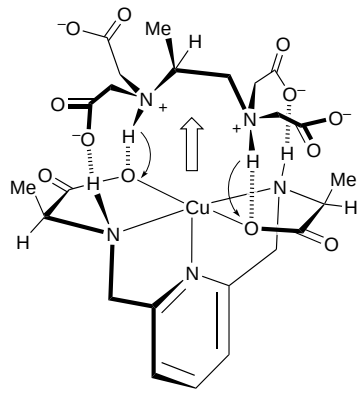

**Fig. 2** Possible transition state in metal-ion transfer between [Cu{(*S*,*S*)-alamp}] and (*S*)-$H_2pdta^{2-}$

Whereas metal-ion transfer between multidentate ligands usually takes place by multistep substitutions, involving intermediates containing dangling groups,[6,7] the proposed hydrogen-bonded intermediate allows a transfer in a concerted single-step reaction avoiding any intermediate solvation and desolvation steps except the elimination of the coordinated water molecule from the starting copper(II) complex. Furthermore, the simultaneous transfer of the two protons ensures the conservation of the local charge distribution during the reaction.

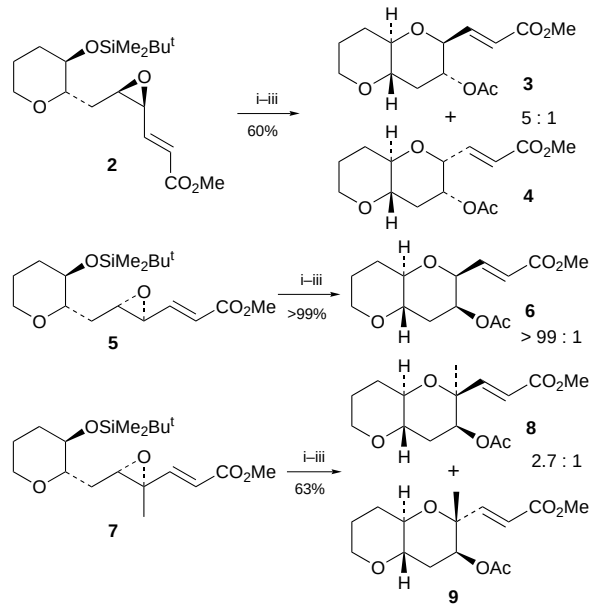
# Stereocontrolled synthesis of the HIJ ring system of ciguatoxin

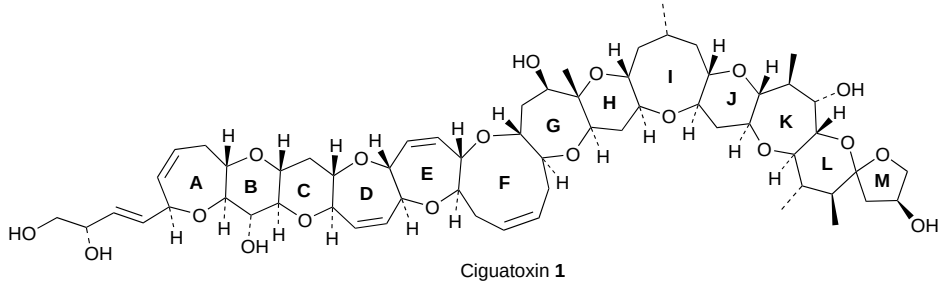
**Tohru Oishi, Kenji Maeda and Masahiro Hirama***

*Department of Chemistry, Graduate School of Science, Tohoku University, Sendai 980-77, Japan*



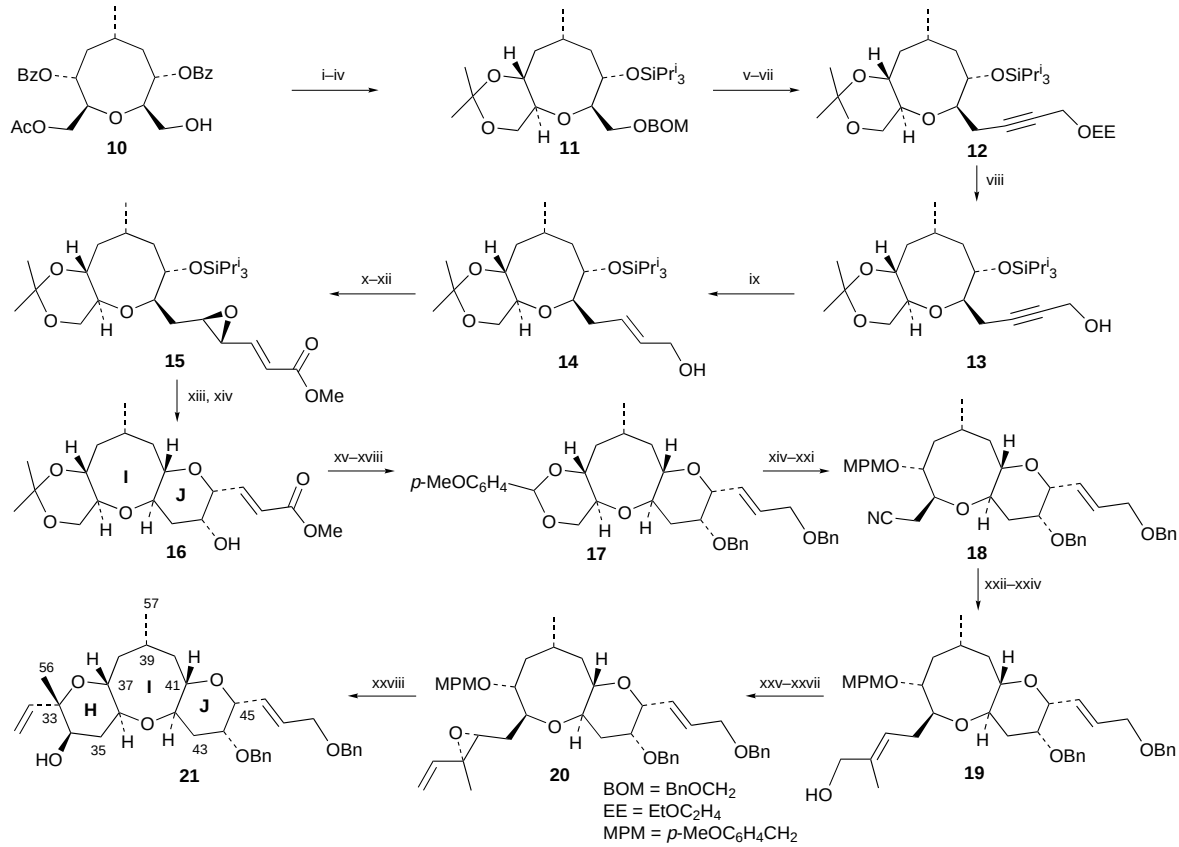
**Divergent synthesis of the HIJ ring framework 21 of ciguatoxin 1 starting with oxocane 10 is achieved using the palladium- and acid-catalysed cyclization reactions of hydroxy epoxides.**

Ciguatoxin **1** is the principal toxin which causes ciguatera poisoning.[1] Its unique structure and agonist activity against $Na^+$ channels have attracted considerable attention from synthetic organic chemists.[2] Although numerous synthetic studies of fragments of **1** have been reported, the central medium rings, such as the F and I rings, have eluded synthesis until very recently.[3,4] We describe herein the first divergent synthesis of the HIJ ring system of **1** *via* stereocontrolled palladium-[5] and acid-catalysed[6] cyclization reactions of hydroxy epoxides starting with the methyl oxocane I ring.[3]



The palladium-catalysed cyclization procedure[5] was examined first to construct the H and J rings. *cis*-Epoxide **2** and *trans*-epoxide **5**, and trisubstituted *trans*-epoxide **7** were subjected to a cyclization reaction as models for constructing the J and H rings, respectively (Scheme 1).† While complete stereocontrol was realized for **5** to give **6** (> 99 : 1), lower selectivities were observed for **2** and **7** to give mixtures of **3** and **4** (5 : 1), and **8** and **9** (2.7 : 1), respectively. The *trans*-epoxide **15** was therefore used to construct the J ring, and we chose acid-catalysed cyclization technology to prepare the H ring.

Optically active oxocane **10**[3] was converted to **11** *via* protection of the primary alcohol as a benzyloxymethyl (BOM) ether, removal of the acyl groups and subsequent protection of the 1,3-diol as the acetonide and of the remaining secondary alcohol as a triisopropylsilyl ether in 83% overall yield (Scheme 2). The BOM group of **11** was removed by hydrogenolysis and the resulting primary alcohol was converted to the trifluoromethanesulfonate, which was immediately treated with the lithium acetylide generated from **22** in THF–dimethylpropyleneurea (DMPU) (6 : 1) at −78 °C[7] to give the adduct **12** in 68% overall yield. Selective removal of the ethoxyethyl (EE) group with pyridinium toluene-*p*-sulfonate (PPTS) in propanol[8] produced **13** in quantitative yield. The prop-2-ynyl alcohol **13** was partially reduced with sodium dihydrobis(2-methoxyethoxy)aluminate (Red-Al)[9] to give the *trans*-allylic alcohol **14**. Sharpless asymmetric epoxidation of **14** using D-(−)-diethyl tartrate (DET) gave the corresponding α-epoxide exclusively, and successive oxidation of the primary alcohol with a $SO_3$–pyridine complex and Wittig olefination gave **15** in 88% overall yield. Stereospecific construction of the J ring was achieved by the palladium-catalysed cyclization.[5] Treatment of **15** with tetrabutylammonium fluoride in THF, followed by solvent exchange to $CH_2Cl_2$ and addition of a catalytic amount of $Pd(PPh_3)_4$, gave **16** within 5 min as a single diastereoisomer in 93% yield in two steps.‡ The stereochemistry of the resulting alcohol with a non-natural orientation could be readily inverted by reduction of the corresponding ketone with $NaBH_4$.[10]



Having completed the synthesis of the I and J ring system, we were now in a position to construct the H ring. The ester **16** was reduced with DIBAL-H, the resulting alcohols were protected as benzyl ethers, and transformation of the acetonide into *p*-methoxybenzylidene acetal gave **17** in 90% overall yield. Regiospecific reductive cleavage of the benzylidene acetal with DIBAL-H furnished the *p*-methoxybenzyl (MPM) ether, and the resulting primary alcohol was converted to the methanesulfonate, which was then treated with sodium cyanide to yield the nitrile **18** in 91% overall yield. Extension of the side chain *via* DIBAL-H reduction and Wittig olefination with (carbethoxyethylene)triphenylphosphorane gave the α,β-unsaturated ester, which was reduced to allylic alcohol **19** in 98% overall yield. Sharpless asymmetric epoxidation of **19** furnished the corresponding hydroxy epoxide and further oxidation to the aldehyde and Wittig olefination gave **20** in 75% overall yield. Finally, treatment of **20** with 2,3-dichloro-5,6-dicyano-

1,4-benzoquinone (DDQ) in $CH_2Cl_2$ and water (20 : 1) resulted in cleavage of the MPM ether, and spontaneous cyclization of the resulting hydroxy epoxide prevailed under the weakly acidic conditions to afford **21** in 88% yield.§ The overall yield of **21** from **10** was 25% in 28 steps. Thus each step effectively proceeded in good yield (⩾95% yield).

In conclusion, we have demonstrated that the appropriate combination of stereoselective pyran formation methodologies allows us to synthesize the central HIJ ring system of **1** starting with oxocane **10**. Further synthetic studies directed towards **1** are in progress in our laboratory. We thank the Uehara Memorial Foundation, The Naito Foundation, and the Ministry of Education, Science and Culture, Japan for financial support.

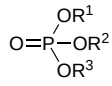
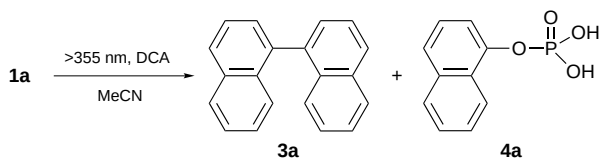


# Photoinduced electron-transfer reactions of tri-1-naphthyl phosphate and di-1-naphthyl methylphosphonate sensitised by 9,10-dicyanoanthracene

**Mitsunobu Nakamura,*[a]† the late Reizo Dohno[a] and Tetsuro Majima*[b]**

[a] *Department of Engineering Science, Himeji Institute of Technology, Shosha 2167, Himeji, Hyogo 671-22, Japan*
[b] *The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka 8-1, Ibaraki, Osaka 567, Japan*

**1,1′-Binaphthyl is formed by photoinduced electron-transfer reactions of tri-1-naphthyl phosphate and di-1-naphthyl methylphosphonate sensitised by 9,10-dicyanoanthracene in MeCN, while no reaction occurs in the case of mono-1-naphthyl and di- or tri-phenyl esters.**



Photochemical reactions of organophosphorus compounds have been widely studied from the mechanistic and synthetic points of view.[1] Recently much attention has been paid to the photoreactivities of caged compounds of phosphates and phosphonates with an aryl substituent as a chromophore *in vivo*.[2] Radical cations of trivalent phosphorous compounds such as phosphines or phosphites generated in photoinduced electron-transfer reactions have been found to be oxidised by MeOH.[3] Although photoinduced electron-transfer reactions of organic compounds have been extensively investigated,[4,5] little is known about aryl phosphates and phosphonates. Electron-transfer reactions of aryl phosphates and phosphonates are of particular importance in relation to the caged compounds *in vivo*. We report here the photoinduced electron-transfer reactions of phosphates **1** and methylphosphonates **2** with aromatic substituents sensitised by 9,10-dicyanoanthracene.

**1a** $R^1 = R^2 = R^3$ = 1-naphthyl
**b** $R^1 = R^2 = R^3$ = 4-methoxy-1-naphthyl
**c** $R^1 = R^2$ = Et, $R^3$ = 1-naphthyl
**d** $R^1 = R^2$ = Et, $R^3$ = 4-methoxy-1-naphthyl
**e** $R^1$ = H, $R^2 = R^3$ = 4-$MeOC_6H_4$
**f** $R^1$ = Me, $R^2 = R^3$ = 4-$MeOC_6H_4$

An argon-saturated MeCN solution containing of $5 \times 10^{-5}$ M of 9,10-dicyanoanthracene (DCA) and $1 \times 10^{-3}$ M of tri-1-naphthyl phosphate **1a** was irradiated with a medium-pressure Hg lamp using a $BiCl_3$–HCl filter (cutoff < 355 nm) for 1 h (conversion 15%) to give 1,1′-binaphthyl **3a** and 1-naphthyl phosphate **4a** with a 1 : 1 ratio and a qunatum yield of 0.0013 (Scheme 1). Similarly both **3a** and **4a** were formed as the main products in the photoreaction of a di-1-naphthyl methylphosphonate **2a** and DCA mixture.

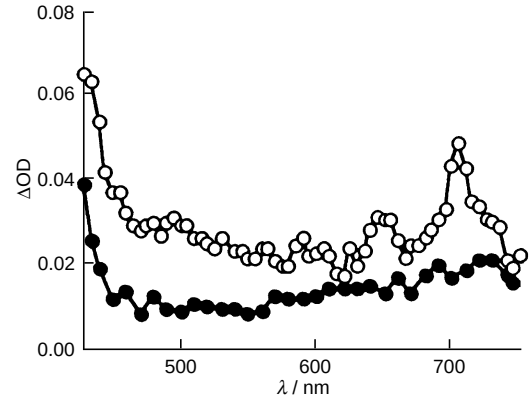
4,4′-Dimethoxy-1,1′-binaphthyl **3b** was formed in the cases of tris(4-methoxy-1-naphthyl) phosphate **1b** and bis(4-methoxy-1-naphthyl) methylphosphonate **2b**, while no reaction

**Scheme 1**

occurred in the cases of mono-1-naphthyl (**1c**, **1d**) and diphenyl derivatives (**1e**, **1f**, **2c**, **2d**). These results show that the photoreaction occurs only in the compounds with two or three naphthyl substituents linked by an O–P(O)–O chain. Since fluorescence of $^1$DCA* was completely quenched with **1** or **2** and the free-energy change of the quenching is exergonic with $\Delta G_{et} = -15$ or $-25$ kcal mol$^{-1}$ (1 cal = 4.184 J), respectively, electron transfer proceeds from **1** or **2** to $^1$DCA* to give radical cations of **1** or **2** (**1**$^{\cdot+}$ or **2**$^{\cdot+}$) and radical anion of DCA (DCA$^{\cdot-}$) at the diffusion-controlled rate.‡

Laser flash photolyses of a mixture of DCA and **1a** were performed to clarify the reaction mechanism of the formation of **3a** and **4a**.§ The transient absorption spectrum in the range of 430–750 nm with a peak at around 700 nm was observed at 20 ns after a 4 ns flash in argon-saturated MeCN (Fig. 1). The 700 nm peak was completely quenched, while an absorption in the range of 430–500 nm was observed even in oxygen-saturated MeCN. The 430–500 nm band disappeared in the presence of *trans*-4,4′-dimethoxystilbene (DMS) with formation of DMS$^{\cdot+}$.[5] The 700 nm band is assigned to DCA$^{\cdot-}$, while the 430–500 nm band is assigned to **1a**$^{\cdot+}$. The assignments were confirmed by the measurement of **1a**$^{\cdot+}$ formed during γ-radiolysis of **1a** in a butyl chloride rigid matrix at 77 K.¶ The quantum yield of **1a**$^{\cdot+}$ formation was measured to be $\phi = 0.04$–$0.07$ from that of DMS$^{\cdot+}$ fromation in the presence of DMS. The smaller value suggests that the back electron-transfer in the radical ion pair of DCA$^{\cdot-}$ and **1a**$^{\cdot+}$ is significantly exergonic with $\Delta G_{-et} = -50$ kcal mol$^{-1}$ and occurs more favourably than the solvent separation to give DCA$^{\cdot-}$ and **1a**$^{\cdot+}$.

The decay of **1a**$^{\cdot+}$ should correspond to the formation of **3a**. Unfortunately, the optical densities of the 430–500 nm band due to **1a**$^{\cdot+}$ were too small to be analysed. Pulse radiolysis of **1a** in 1,2-dichloroethane at room temperature (Fig. 2) was performed to clarify the formation of **3a** from **1a**$^{\cdot+}$.‖ The transient absorption spectrum assigned to **1a**$^{\cdot+}$ with sharp bands at 400 and 430 nm and a broad band at 550–750 nm was observed



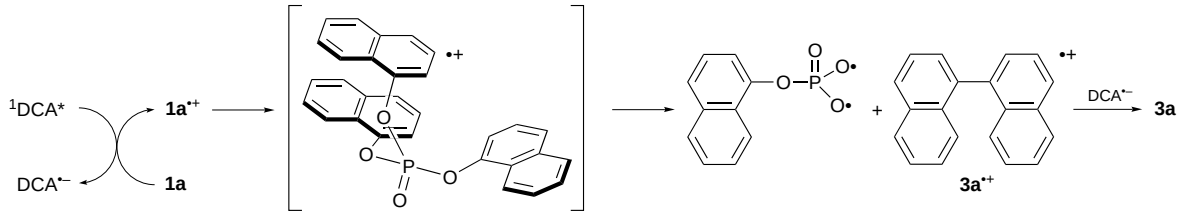


**Fig. 1** Transient absorption spectra immediately after a flash during laser flash photolysis of **1a**–DCA in (○) argon-saturated and (●) oxygen-saturated MeCN

**Scheme 2**

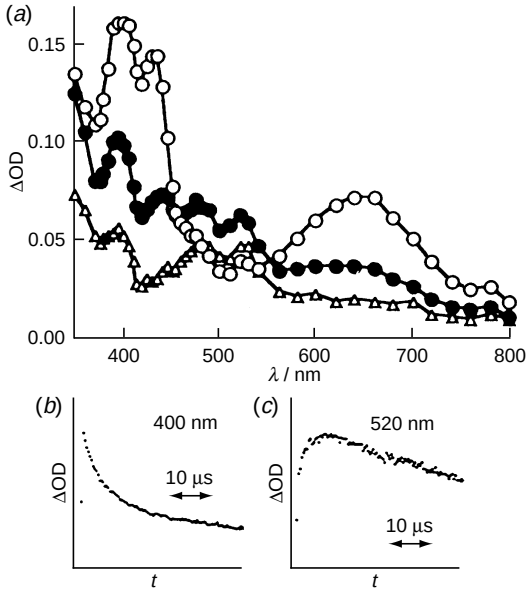

**Fig. 2** (*a*) Transient absorption spectral changes during pulse radiolysis of **1a** in argon-saturated 1,2-dichloroethane: (○) immediately after the pulse, (●) 5 μs after the pulse, and (Δ) 20 μs after the pulse. Kinetic traces illustrating the time profiles of (*b*) $\Delta OD_{400}$ and (*c*) $\Delta OD_{520}$.

immediately after an 8 ns pulse, and decayed with formation of new bands at 480 and 520 nm assigned to **3a**$^{\bullet+}$ at the first-order rate constant of $k = 8.9 \times 10^4$ s$^{-1}$.

On the other hand, the spectrum of **1c**$^{\bullet+}$ showed sharp bands at 390 and 440 nm and a broad band at 550–700 nm, was slightly different in the shape and peak wavelength from that for **1a**$^{\bullet+}$, and decayed without formation of any new bands. It is well known that naphthalene$^{\bullet+}$ dimerises with a neutral naphthalene to form a π-dimer radical cation with a 580 nm band at the equilibrium constant of $K = 520$ M$^{-1}$ in PhCN,[6] and that 1,3-di-1-naphthylpropane$^{\bullet+}$ forms a stable intramolecular dimer radical cation.[7] Phosphate **1a** in the singlet excited state forms intramolecularly a face-to-face excimer between two naphthyl groups.[1c] Therefore, a face-to-face structure between two naphthyl groups is suggested to be present in **1a**$^{\bullet+}$, decomposing into **3a**$^{\bullet+}$.

Consequently, electron transfer from **1a** to $^1$DCA* occurs to give **1a**$^{\bullet+}$ and DCA$^{\bullet-}$, **1a**$^{\bullet+}$ with the face-to-face structure between two naphthyl groups decomposes to **3a**$^{\bullet+}$ and the residue, and **3a** is finally formed as the stable product from the reduction of **3a**$^{\bullet+}$ with DCA$^{\bullet-}$ (Scheme 2).

We thank Professor Setsuo Takamuku and Professor Yoshiki Okamoto for helpful discussions, Dr Akito Ishida, Mrs Sachiko Tojo and Miss Tomoko Hashikawa for their help with the experiments, and the members of the Radiation Laboratory of ISIR, Osaka University, for running the linear accelerator. This work was partly supported by the Saneyoshi Scholarship Foundation (M. N.) and a Grant-in-Aid (No. 08240229) from the Ministry of Education, Science, Sport and Culture of Japan (T. M.).

## Footnotes

‡ Since the Stern–Volmer constants, $k_q\tau$, in the fluorescence quenching of $^1$DCA* by **1** and **2** were found to be 270–320 M$^{-1}$ for **1** and **2**, $k_q$ = (1.6–2.1) × 10$^{10}$ M$^{-1}$ s$^{-1}$ was calculated to be approximately equal to the diffusion-controlled rate constant from the lifetime of $^1$DCA*, τ = 14.9 ns using the literature value (ref. 5). The oxidation potentials, $E^{ox}_{1/2}$, of **1** and **2** were measured by cyclic voltammetry at a platinum electrode in dry MeCN with 0.1 M $Et_4NClO_4$ as a supporting electrolyte. The free energy changes, $\Delta G_{et}$, were calculated by using the Rehm–Weller equation (refs. 5 and 8).

§ Laser flash photolyses of the sample solutions were performed at room temperature by a flash at 355 nm (5 ns, 20 mJ pulse$^{-1}$) obtained by the third-harmonic oscillation from a Nd : YAG laser (ref. 9).

¶ γ-Radiolyses of the samples in degassed butyl chloride at 77 K were performed by a $^{60}$Co γ source; concentration of substrate, 10$^{-3}$ to 10$^{-2}$ M (ref. 10).

‖ Pulse radiolyses of the sample solutions were performed at room temperature using an electron pulse (8 ns, 28 MeV) obtained from a linear accelerator at Osaka University (ref. 11).

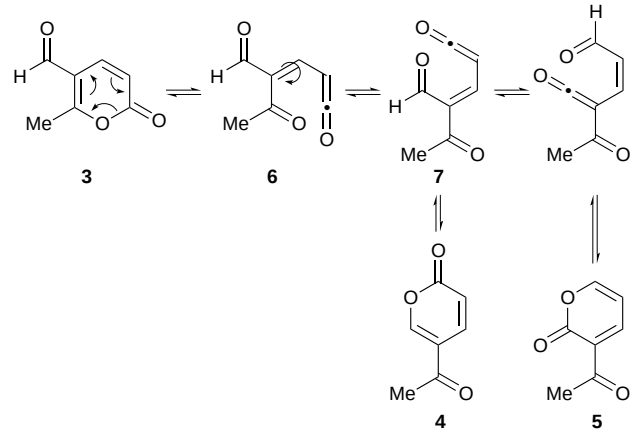
# New thermal rearrangements of vinylogous ketoketenes and related intermediates

**Gary A. Cartwright, Robert O. Gould and Hamish McNab***

*Department of Chemistry, The University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

**2-Oxopyran-5-carbaldehydes (*e.g.* 3) containing a trapping group in the 5-position rearrange thermally by a sequence involving electrocyclic ring opening, *E*/*Z* isomerisation and ring closure; a similar strategy has enabled the first cases of thermal interconversion of pyran-2-ones and 2-pyridones, and of automerisation of 2-pyridones to be identified.**



Studies of the thermal chemistry of unsaturated ketenes have provided in recent years many examples of unusual molecular rearrangements.[1] The ketoketene system **1** (R = Ph) undergoes 1,3-aryl shifts,[2] and its vinylogue **2**, which can be generated by ring opening of pyran-2-ones under flash vacuum pyrolysis (FVP) conditions,[3] shows 1,5-hydrogen shifts which serve to equilibrate 3- and 5-substituted pyran-2-one isomers (Scheme 1). Pyran-2-thione similarly rearranges quantitatively to thiapyran-2-one.[3] Here we demonstrate that in the presence of an appropriate trapping group the potential for thermal rearrangement in vinylogous ketoketenes is more extensive than has been previously recognised, due to the possibility of thermal *E*–*Z* isomerisation.[4] In addition, this strategy has provided the first examples of equilibration of pyran-2-ones and 2-pyridones, and of automerisation in the 2-pyridone system.

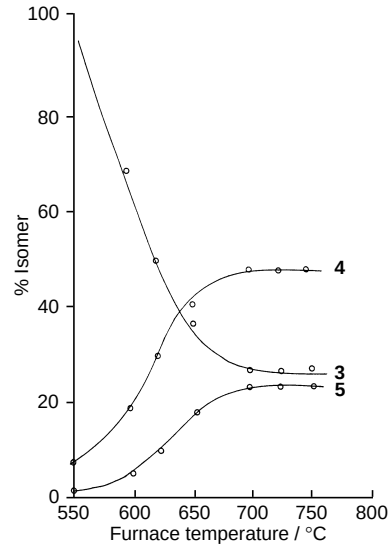
**1**

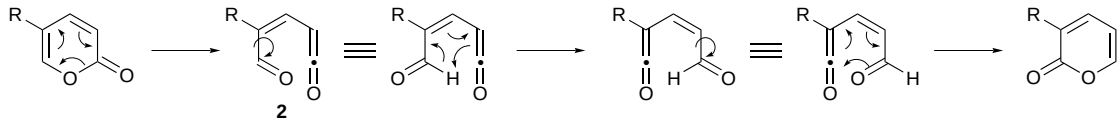
Thus 6-methyl-2-oxopyran-5-carboxaldehyde **3**† was synthesised in 79% yield by the reaction of diazomethane with 2-oxopyran-5-carbaldehyde[5] (*cf.* ref. 6). This compound lacks a good migrating substituent at the 6-position and therefore cannot give rearrangement products by the standard Pirkle mechanism (Scheme 1). Nevertheless, FVP of **3** at 550–750 °C gave rise to a quantitative mixture of the isomers **3**, **4** and **5** which were not separated but could be readily identified by characteristic[7] coupling constants in the $^1$H NMR spectra of the mixtures. Thus the 5-acetyl compound **4** showed $^3J_{3,4}$ (10.0 Hz), and the 3-acetyl derivative **5** showed typical values of $^3J_{4,5}$ (6.8 Hz) and $^3J_{5,6}$ (5.0 Hz) which compare well with data for α-pyrone itself ($^3J_{3,4}$ 9.4, $^3J_{4,5}$ 6.3 and $^3J_{5,6}$ 5.0 Hz).[7] Methyl signals of **4** and **5** occurred at $\delta_H$ 2.42 and 2.61 respectively, positions typical of acetyl groups. The formation of **4** is readily explained by *Z* to *E* isomerisation[4] of the alkene function of the ring-opened intermediate **6**, followed by collapse *via* electrocyclisation involving the initial aldehyde substituent (Scheme 2). An extension of the mechanism by 1,5-H-shift in the newly generated intermediate **7** gives the third isomer **5** after similar electrocyclic ring closure. The ratio of **3**:**4**:**5** at equilibrium (> 700 °C; Fig. 1) presumably reflects the relative stereoelectronic effects of the ring substituents; pyrones with certain other 5-carbonyl-containing substituents apparently do not rearrange significantly to the 3-isomers at high temperatures.[3]

In order to apply this methodology to pyran-2-one–2-pyridone equilibria, a 5-imino-substituted pyrone was required. The substrate **8** was therefore synthesised by condensation of the appropriate aldehyde (prepared in 60% yield by Rosenmund

**3** **6** **7** **4** **5**

**Scheme 2**





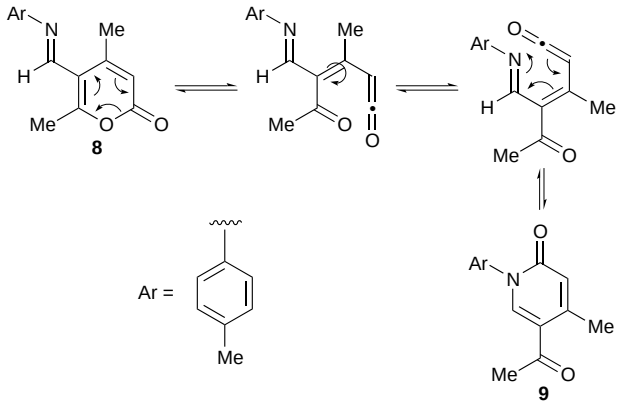


**Fig. 1** Equilibration of **3**, **4** and **5** by FVP of **3** at different furnace temperatures

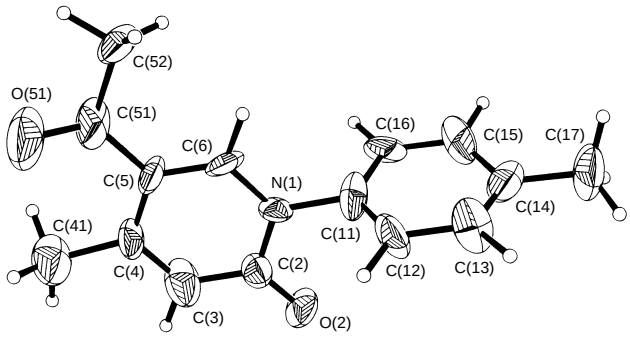
**2**

**Scheme 1**

reduction of the corresponding acyl chloride) with *p*-toluidine (90%). FVP of **8** at 650 °C gave a quantitative yield of a single rearranged pyridone **9** (Scheme 3) whose structure was confirmed by X-ray crystallography‡ (Fig. 2). Assuming that there is little significant difference in the thermodynamic properties of the acetyl and aldimine substituents, the pyridone ring system appears to be overwhelmingly favoured thermodynamically with respect to the related pyrone.

**Scheme 3**



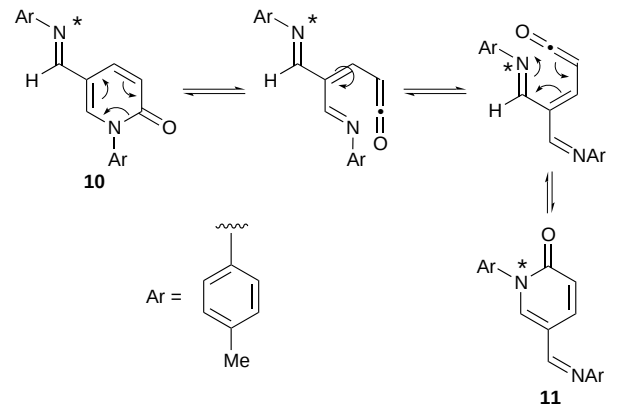


**Fig. 2** Thermal ellipsoid plot of **9** showing the crystallographic numbering scheme

In contrast to the situation with pyran-2-one and thiopyran-2-one systems,[3] very little is known of the thermal behaviour of 2-pyridones except for some fragmentation reactions under forcing conditions.[8] It is clear from the above result that 2-pyridones are unlikely to ring open under such mild conditions as their *O*-analogues, but we were interested to determine the general feasibility of this process. Accordingly, we reacted *p*-toluidine with 2-oxopyran-5-carbaldehyde and condensed the resulting oxopyridine carbaldehyde (56%) with $^{15}$N-labelled *p*-toluidine to give the imine **10** (96%) ($\delta_N$ −63.76 relative to external nitromethane). Reversing this sequence gave an authentic sample of the labelled pyridone **11** ($\delta_N$ −198.19). FVP of **10** at 750 °C, conditions under which the pyrones were completely equilibrated, gave just 4% of the automerised species **11** as shown by the small peak at $\delta_N$ −198.19 in the $^{15}$N NMR spectrum of the pyrolysate (Scheme 4). This result nevertheless establishes for the first time that thermal electrocyclic ring opening of the 2-pyridone system is a viable, albeit high energy, process. The rearrangement was much more pronounced (37%) at 850 °C, but the $^{15}$N NMR spectrum was confused by many other peaks due to decomposition products.

**Scheme 4**

We are grateful to British Petroleum International Ltd. for a Research Studentship (to G. A. C.) and to Dr D. Reed for the $^{15}$N NMR spectra, which were obtained through the S.E.R.C. (now E.P.S.R.C.) supported University of Edinburgh high-field NMR service.

## Footnotes

† All new compounds were characterised by their spectra and by elemental analyses, unless otherwise stated.

‡ *Crystal data* for **9**. $C_{15}H_{15}NO_2$, $M$ = 241.28, orthorhombic, space group $P2_12_12_1$, $a$ = 5.557(4), $b$ = 9.645(4), $c$ = 24.272(10) Å, $V$ = 1300.9 Å$^3$ (from setting angles for 10 *h*0*l* and 10 0*kl* data, 2θ = 8–24°, λ = 0.71073 Å), $Z$ = 4, $D_{calc}$ = 1.232 g cm$^{-3}$, $T$ = 295K, colourless needle, 0.85 × 0.2 × 0.08 mm, μ = 0.077 mm$^{-1}$, $F$(000) = 512. Data collection and processing—Stoë STADI-2 2-circle diffractometer, graphite monochromated Mo-Kα X-radiation, $T$ = 295K, ω-scans with ω-range (2.0 + 0.5 sinμ/tanθ)°, 1039 unique reflections ($2\theta_{max}$ 50°, $0 \leqslant h \leqslant 6$, $0 \leqslant k \leqslant 10$, $0 \leqslant l \leqslant 26$) giving 547 with $F \geqslant 4\sigma(F)$ for use in all calculations. No significant crystal decay or movement was apparent, and no absorption correction was made. Structure solution and refinement—automatic direct methods[9] located all non-hydrogen atoms which were then refined anisotropically; hydrogen atoms were inserted in calculated positions with fixed atomic displacement parameters of $U$ = 0.05 Å$^2$ (C–H = 1.08 Å). Only the torsion angles of the methyl groups were refined. At final convergence, $R$, $R_w$ = 0.075, 0.026 respectively, $S$ = 1.12 for 173 refined parameters and the final difference synthesis showed no peak or trough outside ±0.3 e Å$^{-3}$. An extinction parameter was refined, converging to 4.0 × 10$^{-4}$. No absorption corrections were made. The weighting scheme $w^{-1} = \sigma^2(F)$ gave satisfactory agreement analyses; in the final cycle, the maximum δ/σ was 0.07. Inlaid[10] atomic scattering factors were used, molecular geometry calculations utilised CALC,[11] and Fig. 2 was produced by SHELXTL.[12] Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/477.

**The title reaction is catalysed by $Pd_{0.08}Cs_{2.5}H_{1.34}PVMo_{11}O_{40}$ at temperatures as low as 423–593 K, and the catalytic rate, which reached a maximum at 573 K, is $1.2 \times 10^{-4}$ mol $h^{-1}$ $g^{-1}$, *ca.* $3 \times 10^2$ times higher than $FePO_4$, the most active catalyst previously reported.**

The activation and functionalization of methane has attracted much attention owing to its abundance in natural gas and low reactivity.[1–8] Recently, there has been a renewed interest in the direct conversion of methane into oxygenates.[6–19] Various catalysts have been tested with a variety of oxidants in heterogeneous[9–17] and homogeneous systems.[18–20]

The utilization of molecular oxygen for the oxidation of methane is a rewarding goal since it has the highest content of active oxygen and forms no by-products. However, direct oxidation with molecular oxygen cannot be achieved using heterogeneous catalysts under atmospheric pressure because the high temperatures and pressures required, which induce radical formation, needed for the activation of methane and/or oxygen leads to overoxidation of the oxygenated products. Therefore, a lowering of the reaction temperature is a key requirement for selective oxidation. We have reported the direct oxidation of lower alkanes with molecular oxygen catalysed by heteropoly compounds, but oxidation of methane was unsuccessful.[21]

On the other hand, reductants such as aldehyde,[22] hydrogen[23] and zinc[24] promoted the oxidation of alkanes and alkenes with molecular oxygen and significantly lowered the reaction temperature in homogeneous systems. However, concerning catalytic oxygenation of methane with dioxygen in the presence of reductants in heterogeneous systems, only the $FePO_4$–$O_2$–$H_2$ system has been studied;[15] Even in this system, a temperature as high as 623 K was required which is much higher than for homogeneous systems. Here we report the selective oxygenation of methane into formic acid with a $O_2$–$H_2$ mixture at temperatures as low as 423–593 K.

$H_{3+x}PV_xMo_{12-x}O_{40}$ heteropolyacids were obtained commercially from Nippon Inorganic Colour and Chemical Co., Ltd. The other reagents used were of analytical grade and used without further purification.

The catalysts were prepared as follows: 3.6 $cm^3$ of an aqueous solution of palladium nitrate (0.08 mol $dm^{-3}$) was added dropwise to 60.0 $cm^3$ of an aqueous solution of $H_4PVMo_{11}O_{40}$ (0.06 mol $dm^{-3}$), followed by the addition of 56.3 $cm^3$ of an aqueous solution of caesium carbonate (0.08 mol $dm^{-3}$) at 323 K and the powder samples were carefully collected and the resulting suspension evaporated to dryness at 323 K. The actual composition of the powder is $Pd_{0.08}Cs_{2.5}H_yPVMo_{11}O_z$, but are designated $Pd_{0.08}Cs_{2.5}H_{1.34}PVMo_{11}O_{40}$ according to the stoichiometry of the starting materials.

Catalytic reactions were performed in a flow reactor. Prior to the reaction, 120 mg of catalyst was treated in an O2 stream (60 $cm^3$ $min^{-1}$) for 1 h at 573 K. The reactions were performed at atmospheric pressure and the feed gas typically consisted of 28 vol% methane, 14 vol% $O_2$ with the balance $N_2$, and the total flow rate was 22 $cm^3$ $min^{-1}$. The gases at the outlet of the reactor were analysed by FID (equipped with methanizer) and a TCD gas chromatograph. Selectivity was calculated on the $C_1$ (methane)-basis. The products were formic acid, methanol and $CO_x$. Similar products were observed for the other heteropoly catalysts used. The conversion and the selectivity data were collected after 2–5 h of reaction, when nearly steady-state conversion and selectivity were obtained for each catalyst.

Fig. 1 shows the temperature dependency of the conversion and selectivity for $Pd_{0.08}Cs_{2.5}H_{1.34}PVMo_{11}O_{40}$. It is noted that the reaction proceeded even at 423 K. The conversion of methane monotonously increased with increase in the reaction temperature and reached a maximum at 573 K. The rate for the methane conversion at 573 K was $1.2 \times 10^{-4}$, *ca.* $3 \times 10^2$ greater than that of the most active heterogeneous catalyst ($FePO_4$) reported previously.[15] The selectivity to formic acid was > 67%. Such high selectivity towards formic acid has not been reported previously in heterogeneous oxidation of methane.[1–8] The highest yield of formic acid was obtained at 573 K. $Pd_{0.08}Cs_{2.5}H_{1.34}PVMo_{11}O_{40}$ also catalysed the oxidation of ethane into acetic acid under similar conditions. Similar conversion and selectivity with reaction temperature were observed for $Pd_{0.08}Cs_{2.5}H_{3.34}PV_3Mo_9O_{40}$.

An increase in the yield of formic acid was achieved by further $V^{5+}$-substitution. The conversions for $Pd_{0.08}Cs_{2.5}H_{0.34+x}PV_xMo_{12-x}O_{40}$ ($x$ = 0, 1, 2 and 3) were 0.08, 0.08, 0.10 and 0.14%, respectively and increased with $V^{5+}$ substitution. The selectivities to formic acid were 46, 70, 76 and 60% for $x$ = 0, 1, 2 and 3, respectively, and the highest selectivity to formic acid was observed at $x$ *ca.* 2. It follows that the substitution of $V^{5+}$ for $Mo^{6+}$ in $Pd_{0.08}Cs_{2.5}H_{0.34}PMo_{12}O_{40}$ resulted in the enhancement of formic acid production and the yield reached a maximum at $x$ = 2–3.

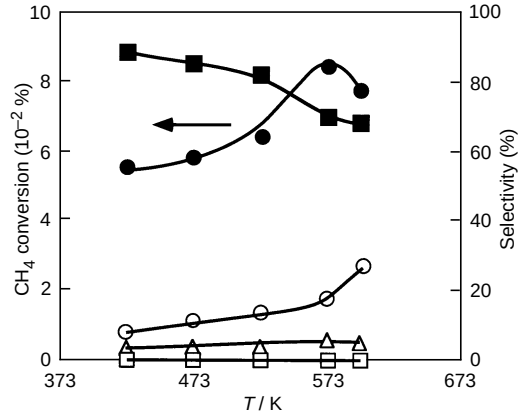

**Fig. 1** Temperature dependence of conversion and selectivity; catalyst, $Pd_{0.08}Cs_{2.5}H_{1.34}PVMo_{11}O_{40}$. Conversion of methane (●) and selectivities towards formic acid (■), methanol (□), CO (△) and $CO_2$ (○).

No selective oxidation proceeded in the absence of Pd or when carbon monoxide was used instead of hydrogen. The addition of 1.9 vol% hydrogen peroxide instead of a gaseous mixture of $H_2$ and $O_2$ led to similar conversion and selectivity to oxygenates. This suggests that the active oxygen species arises from hydrogen peroxide formed by an $H_2$–$O_2$ reaction catalysed by Pd. Reports that Pd in acidic medium catalyses the reaction of dioxygen with dihydrogen to form hydrogen peroxide,[25] and the fact that heterpolyacids and their caesium salts are strongly acidic[26] supports this hypothesis. Formic acid is formed by the liquid-phase oxidation of methane with hydrogen peroxide catalysed by $H_4PVMo_{11}O_{40}$;[27] this suggests that successive oxidation of methane *via* hydrogen peroxide can be catalysed by heteropolyacids.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan.

# NMR structural analysis of a β-hairpin peptide designed for DNA binding

**Allister J. Maynard and Mark S. Searle***

*Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD*

**NMR and circular dichroism (CD) spectroscopy shows that an unconstrained 16 residue linear peptide folds autonomously in water into a β-hairpin: the designed peptide adopts a conformation that mimics the anti-parallel β-sheet DNA binding motif of the *met* repressor protein dimer with key residues for DNA recognition presented in the same positions and orientations principally on one face of the β-hairpin template.**

Recent studies have shown that small peptides of 14 to 17 residues, derived from the Bovine Immunodeficiency Virus (BIV) Tat protein[1] and HIV Rev protein,[2] can bind to nucleic acids with high affinity as β-hairpin or α-helical structures inserted into the major groove of RNA. Such model systems open up the possibility of using designed peptides or non-peptidic analogues for sequence specific recognition of nucleic acids in a therapeutically beneficial manner, either through blocking transcription factor binding[3] or by delivering some reactive functional group to the surface of DNA or RNA where single or double strand damage could be inflicted.[4]

The *met* repressor protein dimer represents a novel class of DNA binding proteins that recognise DNA in a sequence specific manner through insertion of a two stranded anti-parallel β-sheet into the major groove.[5] The key residues for binding and recognition by the *met* repressor are shown in Fig. 1(*a*). We have designed a linear 16-residue peptide analogue of this binding motif, that incorporates all of these key residues, by linking two β-strands *via* a two residue turn sequence such that the 16-mer can fold to form a β-hairpin structure [Fig. 1(*b*)] with the correct anti-parallel alignment of β-strands. The most abundant two residue turns in the protein structure data base are of the type I′ variety with the sequence NG particularly favoured.[6,7] To remove some of the sequence degeneracy inherent in the peptide and aid structural analysis by NMR, a tyrosine has been introduced at position 3 on the non-binding face (in place of Ile in the native sequence) to provide a good NMR probe for folding through long range NOEs. Here we describe the characterisation of the 16-mer [Fig. 1(*b*)], which we show by NMR and CD is appreciably folded in aqueous solution, representing one of only a few examples of short peptides that adopt compact folded β-structures in water.[6,8]

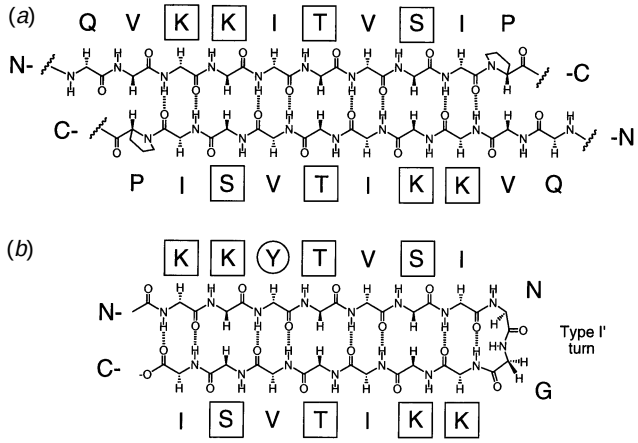

**Fig. 1** (*a*) Anti-parallel alignment of the two β-strands of the DNA recognition motif of the *met* repressor protein dimer. Key residues for DNA binding and recognition are highlighted in square boxes. (*b*) Designed 16 residue β-hairpin analogue of (*a*). Peptides were synthesised on a 0.1 mM scale using standard F-moc solid-phase protocols followed by purification by reverse phase HPLC using an Applied Biosystems Aquaphore Octyl column (10 mm × 100 mm). Purity was assessed by mass spectral analysis and $^1$H NMR spectroscopy.

The *N*-acetylated 16-mer [Fig. 1(*b*)] has been studied by far-UV circular dichroism (CD) spectroscopy in aqueous solution at pH 4.0 and 7.5 μM concentration. A significant negative ellipticity at 216 nm suggests that the peptide forms a high proportion of folded structure in purely aqueous solution with the absorption profile reminiscent of β-structure (both turn and sheet) in equilibrium with some random coil (negative ellipticity below 198 nm)[9] (data not shown). Addition to the peptide of small amounts of methanol (< 20% v/v) produces a significant deepening of the minimum at 216 nm and formation of a maximum at 200 nm indicative of a displacement of the equilibrium already present in aqueous solution further towards the folded state, as has been reported for a number of other model peptide systems.[10]

The most conclusive evidence for folded structure is the observation of long range NOEs between residues in the anti-parallel strands of the β-hairpin. A full resonance assignment has been possible using established procedures,[11] allowing such

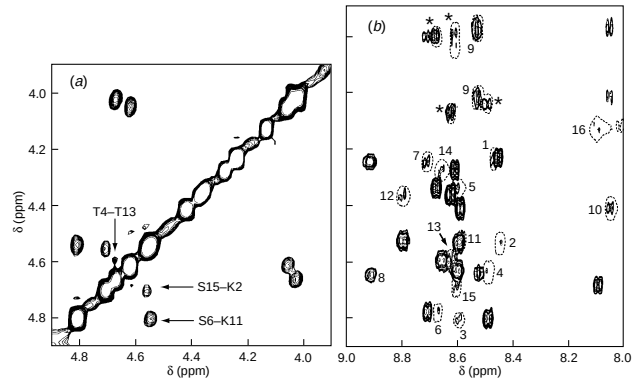

**Fig. 2** (*a*) Portion of the NOESY spectrum (200 ms mixing time) of the 16-mer at 278 K illustrating cross-strand αα(i,j) NOEs as highlighted. The intensity of the T4–T13 NOE cross-peak is distorted due to its position close to the diagonal; (*b*) Finger-print regions (NH to Hα) of NOESY (200 ms) and TOCSY spectra (overlayed) of the 16-mer. TOCSY data are plotted as a single broken contour. In general, αN(i,i) NOEs (occuring at the same positions as TOCSY cross-peaks) are very weak for residues in extended β-strands (residues 1–7 and 10–16), while αN(i,i + 1) sequential interresidue NOEs are much more intense. Note: for N8 and G9 NOEs αN(i,i) and αN(i,i + 1) are of comparable intensity reflecting their positions in the β-turn. Asterisks mark the position of NH to Hβ cross-peaks in both NOESY and TOCSY. TOCSY NH to Hα cross-peaks are numbered according to the sequence: N-Ac-K$^1$K$^2$Y$^3$T$^4$V$^5$S$^6$I$^7$N$^8$G$^9$K-$^{10}$K$^{11}$I$^{12}$T$^{13}$V$^{14}$S$^{15}$I$^{16}$. $^1$H NMR spectra were recorded at 500 MHz on a Bruker DRX500 spectrometer using standard phase sensitive 2D NMR pulse sequences. Attenuation of the residual solvent peak in NOESY and TOCSY spectra recorded in 90% $H_2O$ solution was achieved by presaturation. The sodium salt of trimethylsilyl propionate was used as an internal chemical shift reference.

long range interactions to be identified. The main chain alignment shown in Fig. 1(*b*) brings a number of Hαs of non-hydrogen bonded residues into close proximity. Accordingly, several intense interstrand αα(i,j)† interactions are readily detected in both NOESY and ROESY spectra recorded in aqueous solution. In Fig. 2(*a*), NOEs are identified between Ser6-Lys11, Thr4-Thr13 and Lys2-Ser15 that are fully consistent with the proposed anti-parallel alignment of the peptide chain. These observations are substantiated by studies in 90% $H_2O$ solution were cross-strand long-range NN(i,j)† interactions between residues involved in hydrogen bonding are also evident (Lys1-Ile16, Val5-Ile12 and Ile7-Lys10). The first of these interactions (Lys1-Ile16) illustrates that even the two terminal residues are held in close proximity for an appreciable proportion of the time, indicative of the peptide adopting a well-defined conformation in aqueous solution. While these NOEs provide evidence for long range order in the peptide chain, the intensity of NOEs between adjacent residues provide additional support for local order between nearest neighbours. The majority of residues give rise to intense αN(i,i + 1) sequential NOEs but very weak (or undetected) NN(i,i + 1) and αN(i,i) interactions [Fig. 2(*b*)], consistent with the involvement of many residues in an extended β-strand conformation.[12] In the random coil these NOEs are expected to be much more similar in intensity due to averaging over a large number of conformational states.[12] Significantly different NOE intensities are observed for residues at the centre of the sequence where, for example, a strong sequential NN(i,i + 1) NOE between G9 and K10, together with similar intensity αN(i,i) and αN(i,i + 1) NOEs for N8 and G9 [Fig. 2(*b*)], are diagnostic of the involvement of these residues in a β-turn.

Chemical shift values for Hα resonances have been widely used as an indicator of folded structure in solution.[6,8,10] Positive deviations from tabulated random coil values[11] generally correlate with residues found in extended β-strand conformations, while negative (upfield) shifts are associated with residues in α-helices or β-turn conformations.[13] In the present case, positive deviations (Δδ) are evident for residues 2–7 and 10–15, while negative (upfield) shifts are identified for residues at the centre of the sequence. The plot of Δδ *versus* amino acid sequence clearly has the characteristic appearance of a β-hairpin, that is, two β-strands separated at the centre of the sequence by a turn. More pronounced effects are apparent in the presence of low concentrations of methanol reflecting the effects of the organic solvent in displacing the equilibrium towards the folded state (Fig. 3). We have established that all

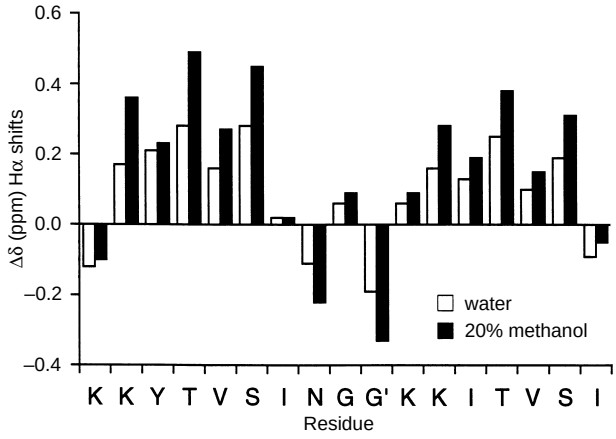

**Fig. 3** Deviations of CαH chemical shifts from random coil values in aqueous solution and 20% v/v methanol, pH 4.5 and 278 K

chemical shifts and line widths are independent of sample concentration over a *ca*. 300-fold dilution range (8.0 to 0.03 mM), indicating that the reported effects are a consequence of folding of the monomeric peptide rather than the formation of aggregates.

We have shown unambiguously by CD and NMR experiments that the designed peptide forms a high proportion of folded structure in purely aqueous solution with the desired alignment of the peptide backbone. The 16-mer represents one of only a few examples of short linear peptides that are able to adopt compact folded β-hairpin structures in water, providing a useful model system for probing β-sheet forming interactions relevant to protein folding mechanisms, with the added potential for DNA recognition.

We acknowledge the EPSRC (studentship to A. J. M.), The Royal Society, Nuffield Foundation and the Department of Chemistry at the University of Nottingham for financial support. We thank John Keyte for peptide synthesis and Dr Gary Sharman for helpful discussions.

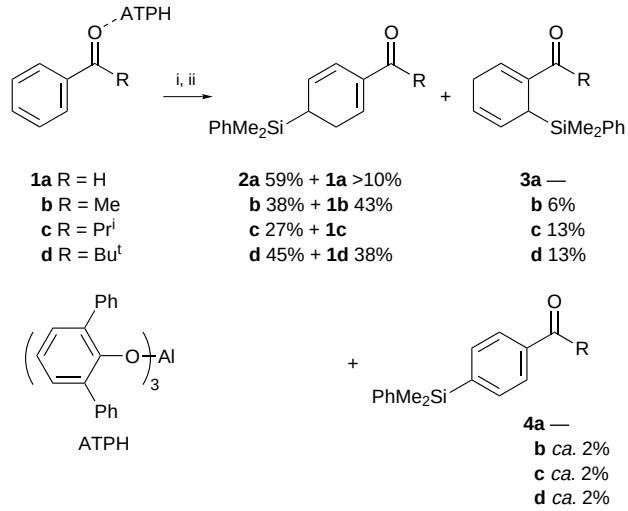
# A new synthetic route to allylsilanes: the reaction of silyllithium reagents with aromatic carbonyl compounds and aluminium tris(2,6-diphenylphenoxide) (ATPH)

**Susumu Saito,[a] Kazuto Shimada,[a] Hisashi Yamamoto,*†[a] Eduardo Martínez de Marigorta[b] and Ian Fleming*[b]**

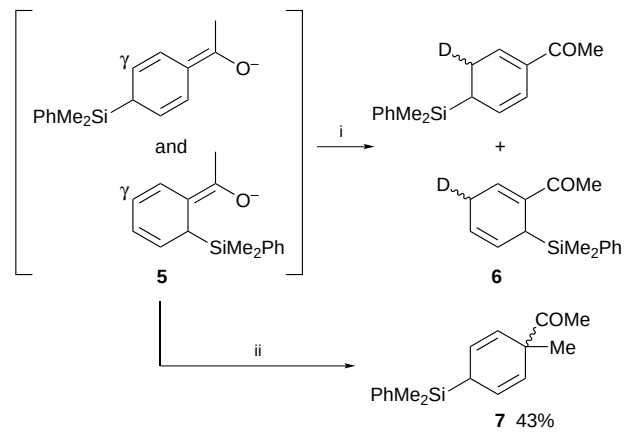
[a] *Graduate School of Engineering, Nagoya University, CREST, Japan Science and Technology Corporation (JST), Furo-Cho, Chikusa, Nagoya 464-01, Japan*
[b] *Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW*

**Conjugate 1,6-addition of silyllithium reagents to aromatic carbonyl substrates in the presence of the carbonyl protector aluminium tris(2,6-diphenylphenoxide) (ATPH) gives allylsilanes.**



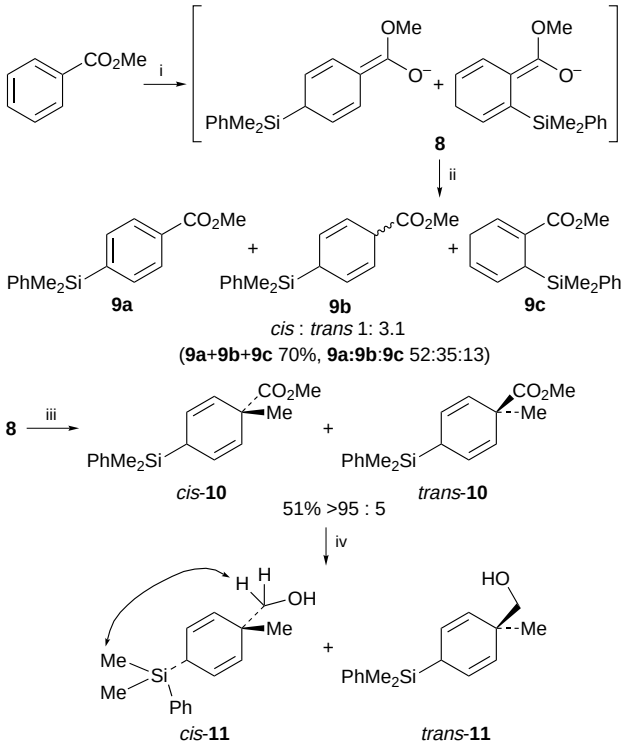
Allylsilanes are versatile synthetic intermediates,[1] and several methods are available to prepare these reagents.[2] We recently described the conjugate addition of several alkyllithiums to aromatic carbonyl compounds complexed with aluminium tris(2,6-diphenylphenoxide) (ATPH),[3] in which the Lewis acid effectively blocks carbonyl carbons from nucleophilic attack. This result led us to explore the possibility of using this strategy for the synthesis of allylsilanes using silyllithium reagents[4,5] in place of the alkyllithium reagents. We report here that the 1,6-addition of silyllithium reagents to the aromatic carbonyl compound–ATPH complex, and subsequent enolate capture with an appropriate electrophilic reagent, does provide a route to functionalised allylsilanes (Scheme 1).

Treatment of the precomplexed salt **1a** of benzaldehyde and ATPH with phenyldimethylsilyllithium ($PhMe_2SiLi$)[5] at −78 °C produced, after stirring for 30 min and quenching with concentrated hydrochloric acid at −78 °C, selective 1,6-addition to give allylsilane **2a** in 59% yield.‡ When a similar procedure was applied to aromatic ketones **1b**–**d**, 1,6-addition products **2b**–**d** were accompanied by small amounts of the 1,4-addition products **3b**–**d**§ and the aromatised silylated products **4b**–**d** (Scheme 1). These results suggest that the γ-carbon of the carbonyl substrate was selectively protonated by way of dienolate intermediates, which was confirmed by quenching the intermediates **5** in the acetophenone series at low-temperature with deuterated acid to give the monodeuterated products **6** (Scheme 2).

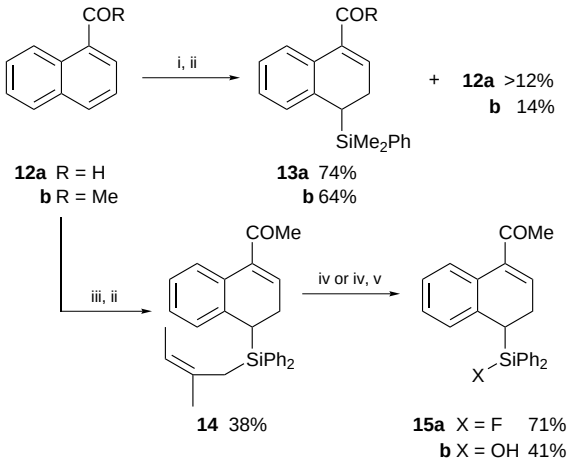


When the generation of dienolate **5** was followed by treatment with an excess of methyl trifluoromethanesulfonate (10 equiv.) at −78 °C for 1 h, the α-methylated product **7** was formed in 43% yield after the usual low-temperature acidic work-up. Methylation occurred predominantly at the α-carbon, in contrast to the exclusive γ-protonation with hydrochloric acid (Scheme 2).

Similarly, phenyldimethylsilyllithium underwent conjugate addition to methyl benzoate in the presence of ATPH with high 1,6-selectivity (1,6 : 1,4 = 87 : 13), but relatively low regioselectivity on protonation to give a mixture (52 : 35 : 13) of the regioisomeric pentadienyl silanes **9** (Scheme 3), including a stereoisomeric mixture (*cis* : *trans* = 1 : 3.1) in the case of the α-protonated product **9b**. The *cis* : *trans* ratio was determined by $^1$H NMR spectroscopy and assigned by a NOESY measurement. In contrast, methylation of the dienolate intermediates **8** gave *cis*-**10** regio- and stereo-selectively, with the methyl group entering *anti* to the resident silyl group. This finding is similar to the alkylation of cyclic enolates having a silyl group adjacent to the nucleophilic centre, which are highly selective for attack by the incoming electrophile *anti* to the silyl group.[6] The relative stereochemistry of *cis*-**10** was assigned by a NOESY measurement by converting the mixture **10** into the alcohols **11** by reduction with diisobutylaluminium hydride (DIBAL-H).



1,6-Addition also took place, in somewhat higher yield, with 1-naphthaldehyde **12a** and with 1-acetonaphthone **12b** to give the adducts **13** (Scheme 4). In an attempt to prepare the hydrate of an aromatic ring, we also carried out the reaction with the latter substrate using the more easily functionalised 2-methylbut-2-enyldiphenylsilyl group[7] to give the adduct **14**. Functionalisation of the silyl group was carried out using protodesilylation at the exocyclic allylsilane unit to give the



**Scheme 1** *Reagents*: i, $PhMe_2SiLi$; ii, HCl, $H_2O$

**Scheme 2** *Reagents*: i, DCl, $D_2O$; ii, $MeOSO_2CF_3$

**Scheme 3** *Reagents and conditions*: i, ATPH, toluene, $PhMe_2SiLi$, −78 °C, 30 min; ii, conc. HCl, −78 °C to room temp.; iii, $MeOSO_2CF_3$ (10 equiv.), −78 °C, 1 h; iv, DIBAL-H, 0 °C

**Scheme 4** *Reagents and conditions*: i, ATPH, toluene, $PhMe_2SiLi$, −78 °C; ii, conc. HCl, −78 °C to room temp.; iii, ATPH, toluene, 2-methylbut-2-enyldiphenylsilyllithium, −78 °C; iv, $BF_3$·AcOH, $CH_2Cl_2$, −10 °C; v, KF, $H_2O_2$, MeOH–THF, 0 °C

silyl fluoride **15a** in 71% yield. Subsequent treatment under Tamao's conditions[8] with potassium fluoride and hydrogen peroxide in THF–MeOH produced hydroxy silane **15b** in fair yield, but not the naphthalene hydrate (Scheme 4). A method for efficiently transforming the silyl group into a hydroxy group is still under investigation.

We thank the Ministry of Culture, Science, Education and Sports of Japan and the Basque Government for providing financial support.

‡ *Typical experimental procedure*: benzaldehyde ($51 \times 10^{-3}$ cm³, 0.5 mmol) was added to a solution of ATPH (0.55 mmol) in toluene (4.0 cm³) at −78 °C under argon, and the resulting orange solution of the ATPH–benzaldehyde complex was stirred at this temperature for 10 min. A solution of phenyldimethylsilyllithium (0.35 mol dm⁻³ in THF, 2.86 cm³, 1.0 mmol) was added at −78 °C, and the reaction mixture was stirred at this temperature for 30 min. The reaction was quenched with concentrated hydrochloric acid (12 mol dm⁻³; 1.5 cm³) at −78 °C, stirred at room temperature for 15 min, diluted with water (4.5 cm³) and extracted with diethyl ether ($3 \times 15$ cm³). The organic layer was dried ($Na_2SO_4$) and concentrated. The residue was purified by column chromatography on silica gel ($CH_2Cl_2$–hexane to give the 1,6-adduct **2a** (59% isolated). *Selected data* for **2a**: $R_f$ = 0.35 ($CH_2Cl_2$–hexane, 1 : 2); $\nu_{max}$ (film)/cm⁻¹ 1682, 1250, 1115. $\delta_H$ ($CDCl_3$, 300 MHz) 9.22 (1 H, s, CHO), 7.55–7.30 (5 H, m, SiCPh), 6.44 (1 H, t, *J* 5.6, SiCHCH$_2$C*H*), 6.28 (1 H, d, *J* 9.6, SiCHCHC*H*), 5.92 (1 H, dd, *J* 5.2 and 9.6, SiCHC*H*), 2.77 (1 H, ddd, *J* 3.9, 10.8 and 18.9, C$H_A$H$_B$), 2.48 (1 H, ddd, *J* 5.7, 5.7 and 18.9, CH$_A$$H_B$), 2.07 (1 H, m, SiCH), 0.32 (6 H, s, $SiMe_2$); $\delta_C$($CDCl_3$) 190.7, 145.7, 138.2, 136.6, 133.8, 131.1, 129.3, 127.8, 116.6, 24.5, 23.9, −4.8 and −5.0 (Found: C, 74.2; H, 7.6. $C_{15}H_{18}OSi$ requires C, 74.3; H, 7.5%).

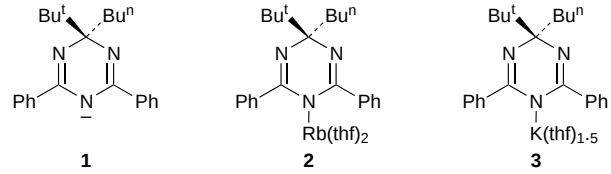
# Exploiting a substituted dihydrotriazinide as a novel bulky ligand: synthesis and crystal structure of a rubidium complex with an unprecedented tetrameric cyclic core

**William Clegg,[a] Allison M. Drummond,[b] Robert E. Mulvey*[b] and Paul O'Shaughnessy[a]**

[a] *Department of Chemistry, University of Newcastle, Newcastle-upon-Tyne, UK NE1 7RU*
[b] *Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL*

**A metal exchange reaction between the alkoxide Bu$^t$ORb and a dihydrotriazinidolithium complex in tetrahydrofuran (thf) has yielded the first reported triazinidorubidium species, in the bis(thf) solvate of 4-*n*-butyl-4-*tert*-butyl-2,6-diphenyl-1,4-dihydro-*s*-triazinido-1-rubidium, which exists as a unique cyclic tetramer in the solid state having an unprecedented sixteen-membered (NCNRb)$_4$ ring core.**



We introduced the dihydrotriazinide **1** in 1993 with a view to shedding light on the intermediate steps involved in alkyllithium-induced cyclotrimerisation reactions of aromatic nitriles.[1] More recently our focus has shifted towards developing this anion as a novel, sterically-encumbered ligand on account of its interesting combination of features. These include (*i*) three heteroatom (N) binding sites; (*ii*) two sterically-flexible Ph sidearms available for π and/or agostic bonding; (*iii*) a bulky, branched [Bu$^n$(Bu$^t$)C] tail, and (*iv*) the possibility of inducing chirality at the saturated ring C atom by metallating only one adjacent N site. **1** made an immediate impact in this role through its participation in the metal derivative, **3**, which established a new type of structure formally designated a 'potassium potassate'.[2] In attempting to extend this work to other metals, we have succeeded in synthesising a rubidium complex employing **1** as a ligand, the surprising structure of which provides the basis for this communication. Structural information on air-sensitive Rb compounds[3] is meagre in comparison to the mountain of data available on lighter alkali-metal congeners (particularly those of lithium[4]), reflecting the lower stability of the former and the greater handling difficulties that this presents. Hitherto only two tetrameric Rb complexes have been reported, as most other aggregates have polymeric constitutions. Moreover, both tetramers, [(Bu$^t$ORb)$_4$][5] and [(Me$_3$SiORb)$_4$],[6] display cubane-based architectures. This background serves to put the novelty of the new complex **2** into perspective, as it, in contrast, adopts an unprecedented cyclic, sixteen-membered (NCNRb)$_4$ ring arrangement. Furthermore, its tetrameric constitution also sets it apart from all other known dihydrotriazinidoalkali-metal structures, which exist as monomers, dimers or polymers.[7]

**Scheme 1**

Scheme 1 shows the simple metal exchange strategy used in the synthesis of **2** (anhydrous and anaerobic conditions were employed throughout). Upon isolation the colourless/pale yellow crystals of **2** were taken directly from the mother-liquor and coated in an inert oil prior to undergoing an X-ray diffraction examination. Characterisation of air- and moisture-sensitive **2** was completed by elemental analyses and a $^1$H NMR spectroscopic study.†

Anion–cation contacts [N(1)–Rb(1) 2.978(3)Å] alternate with longer dative N(2A)–Rb(1) ones [3.033(3)Å] to make up the cyclic tetramer within the crystal structure of **2** (Fig. 1).‡ The molecule possesses tetragonal ($S_4$ or $\bar{4}$) symmetry. With respect to its N centres, the dihydrotriazinide assumes a bis-monodentate, bridging role leaving the N(3) centre unligated. Dimensions within the $C_3N_3$ ring show that there is a degree of π-delocalisation about the N(2)C(2)N(1)C(1)N(3) fragment, such that the structural formula of **2** as written represents only one possible mesomeric form, though the dominant one. The $C_3N_3$ ring is essentially planar (root mean square deviation

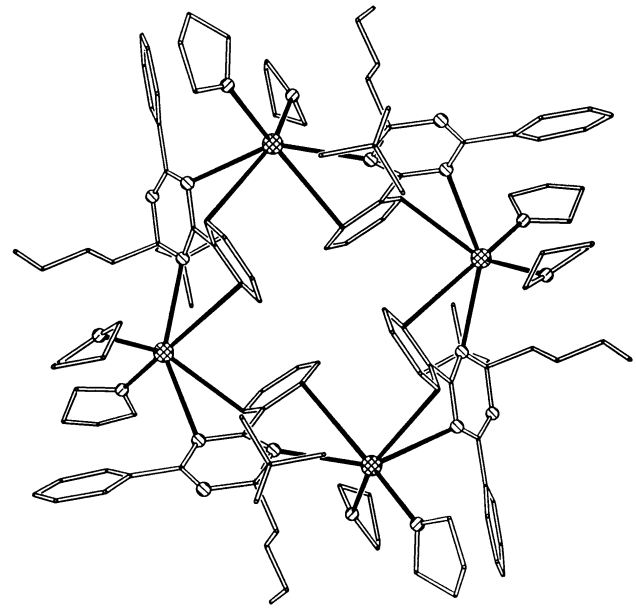


**Fig. 1** The structure of the tetrameric molecule without hydrogen atoms. Selected dimensions (Å and °): Rb(1)–N(1) 2.978(3), Rb(1)–N(2A) 3.033(3), Rb(1)–O(1) 2.824(3), Rb(1)–O(2) 2.811(3), Rb(1)–C(11) 3.352(3), Rb(1)–C(15A) 3.380(3), N(1)–C(1) 1.369(4), N(1)–C(2) 1.362(4), N(2)–C(2) 1.304(4), N(2)–C(3) 1.471(4), N(3)–C(3) 1.481(4), N(3)–C(1) 1.295(4), N(1)–Rb(1)–N(2A) 148.19(7), O(1)–Rb(1)–O(2) 110.00(10), C(11)–Rb(1)–C(15A) 90.17(9); symmetry operator A: $\frac{1}{2}+y$, $\frac{1}{2}-x$, $\frac{1}{2}-z$.

0.017 Å). The coordination sphere of the Rb cation involves opposing sides of two equivalent triazinide ligands (Fig. 2). A pair of thf molecules also bind to Rb. Accompanying these Rb–heteroatom bonds are a number of Rb–C interactions. As is often the case with organometallic derivatives of alkali metals, the coordination number and geometry are not entirely clearly defined, with a range of Rb–C distances and with some close contacts a necessary consequence of others. In this structure, however, one phenyl group on each triazine ring lies between two Rb cations in such an orientation that each *ortho* C atom forms a bond with one metal ion [C(11)–Rb(1) 3.352(3) Å, C(15)–Rb(1B) 3.380(3) Å], giving a primary coordination number of six for Rb. Each Rb cation is thus chelated by one N atom and one phenyl *ortho*-C atom of two triazinide ligands. The disposition of the ligands relative to the cations generates other close Rb–C contacts, notably 3.450(3) Å for C(10) and 3.573(3) Å for C(2), which presumably also contribute to the overall ligand–metal bonding. All other Rb–C distances are > 3.6 Å. The second phenyl group on each triazine is not involved in metal coordination; these four groups occupy positions at the periphery of the structure and form a 'paddle wheel' arrangement. In effect, the thf ligands lie *cis* to each other in view of the relatively small O–Rb–O bond angle [110.12(10)° *cf* 180° in an ideal *trans* situation]. More open, but still well short of being linear, are the N-Rb-N contacts [angle 148.12(7)°] which link the four monomeric fragments together into a cyclic ring. To achieve this ring closure, the Rb cation sits out of the mean planes of both attached $C_3N_3$ rings, by 1.750 and 1.160 Å.

Turning to a comparison of bond dimensions with those in other structures, the N–Rb distances in **2** lie between those of the two asymmetric N–Rb bonds in the amide $[\{[RbN(SiMe_3)_2{\cdot}1.5\ dioxane]_2\}_\infty]$ (2.946, 3.141 Å).[8] The C–Rb contact distances in **2** are also typical of those found in structures with delocalised aryl groups, *e.g.* 3.351–3.643 Å in $[(Ph_3CRb{\cdot}pmdeta)_\infty]$;[9] 3.14–3.57 Å in $[(PhCH_2Rb{\cdot}pmdeta)_\infty]$.[10]

The cyclic, oligomeric nature of the structure of **2** provides an interesting contrast with the zigzag, polymeric chain arrangement preferred by the potassium counterpart **3**.[2] Given that the precursor to **2**, $[(Bu^tORb)_4]$ is isostructural with $[(Bu^tOK)_4]$,[5] it would not have been unreasonable to assume that **2** and **3** might adopt a common structural motif. However, it is important to recognise that these butoxides are three-dimensional 'stacked-ring' structures, which are not greatly affected by the size differential between the metals (ionic radii: $Rb^+$ 1.52 Å, $K^+$ 1.38 Å). On the other hand, structures with one-dimensional heteroatom–metal connectivities, as in **2** and **3**, can be profoundly affected. In **2** this is manifested in the addition of extra solvent ligands (metal : thf ratio 1 : 2, *cf* 1 : 1.5 in **3**), and in an increased number of metal–ligand interactions (primary coordination number of Rb = 6; *cf*. 4 or 5 for K in **3**).

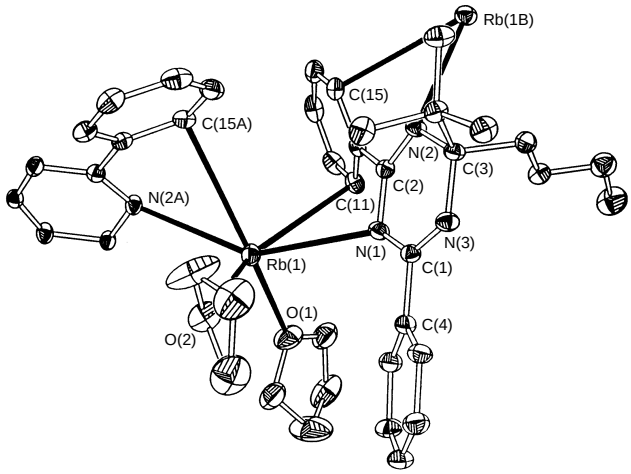

**Fig. 2** Thermal ellipsoid plot at 30% probability, showing the asymmetric unit of **2**, together with one adjacent $PhC_3N_3$ unit to complete the coordination of Rb(1), and the adjacent Rb atom to complete the bonding environment of the triazine ligand. Hydrogen atoms are omitted, and key atoms are labelled.

In conclusion, the special ligating ability of **1** has been further demonstrated by the determination of the crystal structure of a rubidium complex exhibiting a novel cyclic tetrameric arrangement. From this evidence, **1** can be regarded as a novel alternative to conventional bulky nitrogen ligands such as the amide $[(Me_3Si)_2N^-]$. This prospect now calls for a full investigation of the coordination chemistry of **1** with other metal partners.

We thank the EPSRC and the University of Strathclyde for supporting this work.

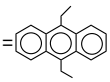
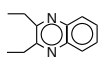
# Dissymmetric new hemicarcerands containing four bridges of different lengths



**Juyoung Yoon, Carolyn B. Knobler, Emily F. Maverick and Donald J. Cram***

*Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095-1569, USA*



**Three new hemicarcerands 1–3 each with one unique eight-atom-long bridge and three identical six-atom-long bridges are reported along with a crystal structure of 2⊙$PhNO_2$, a totally dissymmetric host with nitrobenzene as encapsulated guest.**

A prior paper reported the syntheses and characterizations of seven new hemicarcerands **4**–**6**, **8**–**11** and 36 new hemicarceplexes with diol **12** as starting material.[1] The crystal structure of **8**⊙4-$MeC_6H_4OMe$ indicated it to be somewhat disordered but essentially isostructural with more than 25 hemicarceplexes of **7**⊙guest containing 4 $O(CH_2)_4O$ bridges.[2,3]

**1**, A = $(CH_2)_6$; **2**, A = 4-$CH_2C_6H_4CH_2$; **3**, A =  ; **4**, A = $CH_2$;

**5**, A = $(CH_2)_2$; **6**, A = $(CH_2)_3$; **7**, A = $(CH_2)_4$; **8**, A = $(CH_2)_5$;

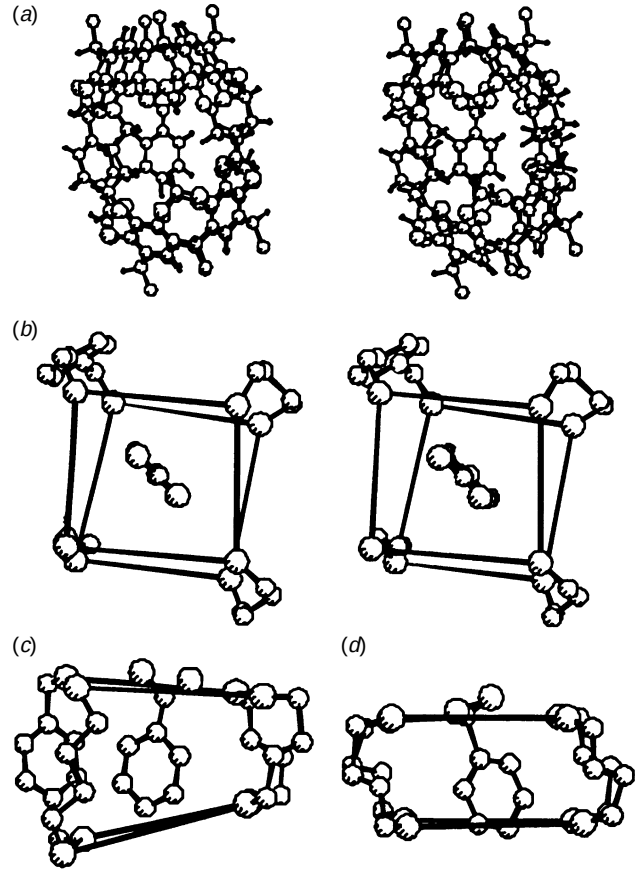
**9**, A =  ; **10**, A =  ; **11**, A =  ; **12**, A = H H

Examination of Corey–Pauling–Koltun (CPK) models of possible unique bridges whose lengths, steric requirements and rigidities would seriously disrupt the isostructural pattern of the standard $[O(CH_2)_4O]_3$ bridges provided $O(CH_2)_6O$, *p*-$OCH_2C_6H_4CH_2O$ and 9,10-$(OCH_2)_2$-anthracene as candidate moieties. In *N*-methylpyrrolidinone (NMP) as solvent and $Cs_2CO_3$ as base, at temperatures of 55–70 °C, diol **12** reacted respectively with $TsO(CH_2)_6OTs$ (Ts = tosyl), 4-$ClCH_2C_6H_4CH_2Cl$ and 9,10-$(ClCH_2)_2$-anthracene to give after chromatographic purification (thick layer plate, $CHCl_3$/silica gel), **1**⊙$CHCl_3$ (78%), **2**⊙$CHCl_3$ (80%) and **3** (empty, 78%).†,‡ In **1**–**3** the unique bridges are all eight atoms long and of varying degrees of rigidity and steric requirements. Formally, the two portals that flank the unique bridge are 28-membered rings, while the other two are 26-membered rings.

The fact that **1** and **2** were isolated as their complexes with $CHCl_3$ rather than with NMP inside indicates either that the final bond-making process occurred in an empty cavity, or that guest exchange, host⊙NMP + $CHCl_3$ → host⊙$CHCl_3$ + NMP, took place during the chromatographic purification conducted at 25 °C. In contrast, empty **3** was isolated as the product of completing the shell closure. In CPK models, both NMP and $CHCl_3$ easily enter and depart the inner phase of **1**–**3**, although the two benzo groups of the anthracene-containing bridge in **3** substantially narrow its two flanking portals. Experimentally a 400 MHz $^1H$ NMR spectrum of **3** in $CDCl_3$ at 25 °C gave two sets of host signals ($OCH_2O$ protons) in an intensity ratio of 2.8 : 1 attributed to empty **3** (2.8) and **3**⊙$CDCl_3$ (1). When the solution was warmed to 55 °C, the signals due to **3**⊙$CDCl_3$ disappeared, but reappeared when the solution was cooled to 25 °C. When $CDCl_2CDCl_2$ and $(CD_2)_4O$ were each substituted for $CDCl_3$ in similar experiments, only signals for empty **3** were observed at both 25 and 55 °C. Apparently, these two molecules are too large to enter **3** at these temperatures.

When **2**⊙$CHCl_3$ was heated in $PhNO_2$ as solvent at 150 °C for 3 days, **2**⊙$PhNO_2$ was formed.† The complex crystallized as **2**⊙$PhNO_2$·5$PhNO_2$, whose crystal structure was determined at −98 °C. The remarkable feature of the crystal structure is not that *R* (0.22) is so large, but that a solvated complex of molecular mass 3037 which contains no symmetry element and is disordered could be determined at all. Fortunately the disorder is concentrated in the least interesting parts of the structure (the eight feet and the five solvate molecules).§ In Fig. 1 are shown a stereo side-view of **2**⊙$PhNO_2$ (*a*) a stereo end-view of the bridges and guest (*b*), and a side-view of the bridges and guest (*c*). Included for comparison is a side-view of the bridges and guest of **7**⊙$PhNO_2$ (*d*), reported earlier.[2]

Substitution of one conformationally mobile, six-atom-long $O(CH_2)_4O$ bridge in **7** by the relatively rigid eight-atom-long *p*-$OCH_2C_6H_4CH_2O$ bridge in **2** both desymmetrizes and



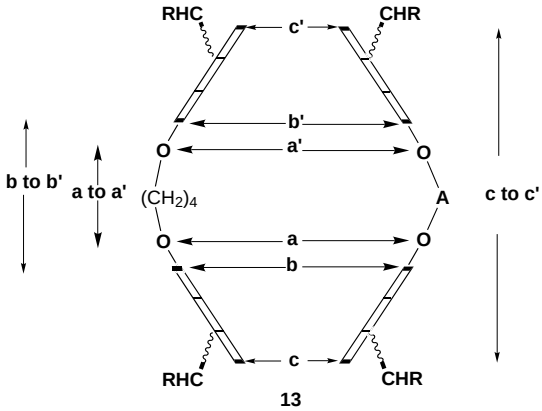


**Fig. 1** (*a*) Side stereoview of **2**⊙$PhNO_2$. R groups in host **2** are represented by C atoms. (*b*) Top stereoview of bridges and guest. (*c*) Side-view of bridges and guest. (*d*) Side-view of bridges and guest of **7**⊙$PhNO_2$.

introduces strain into those parts of the host that define its cavity. Although strain distributes itself as evenly as possible, the polycyclic aryl-rich character of the bowls resists deformation more than the more linear bridges. The distances defined in diagram **13** substantiate this expectation. For example, the lengths (and maximum spread in values) of the four edges of the oxygen best planes **a** and **a′** visible in Fig. 1(*b*) average 6.25 (0.57) and 6.46 (0.49) Å, respectively, in **2**⊙$PhNO_2$, as compared to 6.31 (0.09) Å in **7**⊙$PhNO_2$. The lengths (and maximum spread in values) of the two diagonals of planes **a** and **a′** average 8.84 (0.47) and 9.12 (0.79) Å respectively in **2**⊙$PhNO_2$, as compared to 8.92 (0.07) Å for plane **a** (and **a′**) in **7**⊙$PhNO_2$. Thus the maximum spread in edge and diagonal distances for planes **a** and **a′** are 5 to 11 times larger for **2**⊙$PhNO_2$ than for **7**⊙$PhNO_2$. The **b**–**c** and **b′**–**c′** average bowl depths for **2**⊙$PhNO_2$ and **7**⊙$PhNO_2$ vary only from 2.47 and 2.44 for the former to 2.43 Å in the latter complex. Likewise, the maximum out-of-planes **a** and **a′** oxygen distances and spreads are small, 0.06 and 0.11 Å (spreads, 0.12 and 0.20 Å) respectively for **2**⊙$PhNO_2$, and 0.04 Å (spread, 0.08 Å) for **7**⊙$PhNO_2$.

**13**

The bowl-to-bowl bridge lengths **b**–**b′** for **2**⊙$PhNO_2$ average 7.46 with a maximum spread of 2.00 Å, whereas **7**⊙$PhNO_2$ gives values of 6.46 and 0.14 Å, respectively. Thus the stressed **2**⊙$PhNO_2$ complex gives a factor of 14 more spread in its bridge lengths than does **7**⊙$PhNO_2$. More interestingly, one of the two $O(CH_2)_4O$ bridges that flank the *p*-$OCH_2C_6H_4CH_2O$ bridge (length, 8.51 Å) in **2**⊙$PhNO_2$ is 7.98 Å long, compared to the 6.46 Å average length of the four bridges in **7**⊙$PhNO_2$, and the other two $O(CH_2)_4O$ bridges in **2**⊙$PhNO_2$ (6.51 and 6.82 Å). The two oxygen squares in the views of the bridges resemble a slightly opened book in **2**⊙$PhNO_2$, whereas in **7**⊙$PhNO_2$, the similar side-view resembles a closed book [Fig. 1(*b*)–(*d*)].

How does the long $O(CH_2)_4O$ bridge in **2**⊙$PhNO_2$ become that way, and what are the consequences for the cavity shape? In all but two [all four bridges were $O(CH_2)_5O$[5] or $OCH_2CH_2OCH_2CH_2O$[6]] of our prior crystal structures involving tetrol bowls of the type incorporated in **1**–**12**, the unshared electron pairs of the oxygens that terminate the four bridges face inward toward the cavity. This places their attached carbon chains outside the cube defined by the eight oxygens, as in **7**⊙$PhNO_2$. CPK molecular model examinations show that such conformations minimize bridge lengths, whereas when the electron pairs face outward, the carbon chains turn inward, the bridge lengths increase, and the cavities narrow in their equatorial dimensions because the methylenes encroach on the corners of the cavities. The top and side views of the bridges show that in contrast to the other three bridges of **2**⊙$PhNO_2$, two of the methylenes of the long $O(CH_2)_4O$ bridge are turned inward to accommodate its adjacent, outward-turned but longer *p*-$OCH_2C_6H_4CH_2O$ bridge. As a result of the longer bridge lengths (av., 7.46 Å) in **2**⊙$PhNO_2$ as compared to **7**⊙$PhNO_2$ (av., 6.46 Å), the average **c**–**c′** distance which measures cavity length in the former complex is 12.15 Å, significantly longer than the 11.28 Å length in the latter complex.

The $PhNO_2$ guest's best plane is diagonally arranged in the cavities so as to be roughly coplanar with the oxygens of diagonally located bridges. Molecular model examination indicates that diagonal arrangements avoid collisions of the guest atoms with the enforced inward-turned single hydrogens of the eight $OCH_2O$ spanners. Of the two possible diagonal locations, the one including the *p*-$OCH_2C_6H_4CH_2O$ bridge (length, 8.51 Å) is occupied by the $PhNO_2$ guest (see both top- and side-views in Fig. 1), thus avoiding the inward-turned $O(CH_2)_4O$ bridge (length 7.98 Å).

The ways in which **2** modifies its structure to accommodate its single longer bridge provide insights about the degrees of freedom available to transition states for entries and exits of guests from the inner phases of hemicarcerands.

Attempts to obtain crystals suitable for structure determination of host **3** failed. However, a molecular model of **3** can be assembled only in a conformation whose 9,10-$(OCH_2)_2$-anthracene bridge resembles that found for the *p*-$OCH_2C_6H_4CH_2O$ bridge of **2**⊙$PhNO_2$. A comparison of the complexing properties of hosts **1**–**3**, **8** and **10** will be reported in a future paper.

The authors warmly thank the NIH for Grant GM 12640 which supported this research.

† These new compounds have elemental analyses within 0.30% of theory, and the expected $^1$H NMR spectra and FAB (*m*/*z*, $M^+ + H$) mass spectra.

‡ These procedures were patterned after those leading to **4**–**6** and **8**–**11**.[1] Probably initially NMP solvent molecules served as guests during addition of the fourth bridge, but underwent exchange with $CHCl_3$ during chromatographic purification to provide **1**⊙$CHCl_3$ and **2**⊙$CHCl_3$.

§ *Crystal data*: the crystal structure of **2**⊙$PhNO_2$·5$PhNO_2$ (crystallized from $CHCl_3$–$PhNO_2$, determined at 175 K): triclinic, space group $P\bar{1}$, $a$ = 20.241(5), $b$ = 26.350(5), $c$ = 15.143(3) Å, $\alpha$ = 98.84(2)°, $\beta$ = 95.01(2)°, $\gamma$ = 94.26(2)°, $V$ = 7918(3) Å$^3$, $Z$ = 2, 20676 unique reflections, 11944 > 4$\sigma(F)$, maximum $2\theta$ = 120°, Cu-K$\alpha$ radiation, and was refined to $R$ = 0.22 (SHELXL93[4a]). The precision of the intensities is severely affected by the high background, due to the capillary containing the crystal and the ice that collected on it. The structure was solved by direct methods (SHELXS90[4b]). All non-hydrogen atoms have been refined isotropically. All hydrogen atoms were refined with fixed C–H distances (0.93–0.98 Å) and with fixed displacement parameters (1.2 $U_{iso}$ of the attached C atom). One molecule of $PhNO_2$ is located in the host cavity; there are five additional molecules of $PhNO_2$ per host molecule, two of which are probably disordered or low occupancy. In addition, high displacement parameters for three of the eight 'feet' ($CH_2CH_2Ph$ groups) indicate disorder.

Atomic coordinates, bond lengths and angles, and displacement parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/466.

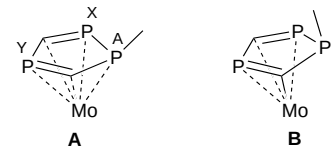
# First syntheses, structural and theoretical studies of $\eta^5$-1,2,4-triphosphole metal tricarbonyl complexes of Cr, Mo and W

**Vinicius Caliman,[a] Peter B. Hitchcock,[a] John F. Nixon,*[a] Laszlo Nyulaszi*[b] and Nurgun Sakarya[a]**

[a] *School of Chemistry, Physics, and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*
[b] *Department of Inorganic Chemistry, Technical University of Budapest, H-1521 Budapest, Hungary*

**Evidence for an $\eta^5$-ligated 1,2,4-triphosphole ring system which exhibits some aromatic character is presented *via* the first syntheses, structural and theoretical studies of $\eta^5$-1,2,4-triphosphole metal tricarbonyl complexes of zero-valent Cr, Mo and W.**



Although phospholes, $RPC_4H_4$, are known to be non-aromatic ring systems,[1] it has recently been shown by theoretical calculations[2] that stepwise replacement of the C=C double bonds by conjugatively similar P=C units[3] increases the planarity and aromatic character of the five-membered ring system owing to a combination of ring strain effects and a lower inversion barrier at the $\sigma^3\lambda^3$-phosphorus. Thus, the recently synthesized[4] di-*tert*-butyl-1,2,4-triphosphole $P_3C_2Bu^t_2CH(SiMe_3)_2$ **1** (which to date is the only known triphosphole), is expected to exhibit greater aromatic character than the parent phosphole. Here we present the first results which support this proposal exemplified by (*i*) the synthesis and structural characterisation of the compounds $[M(CO)_3\{\eta^5\text{-}P_3C_2Bu^t_2CH(SiMe_3)_2\}]$ (M = Cr **2**, Mo **3**, W **4**) in which the ring acts as a 6e donor to the metal and (*ii*) theoretical calculations on the parent 1,2,4-triphosphole $HP_3C_2H_2$ **5** and its hypothetical complex $[M(CO)_3(\eta^5\text{-}HP_3C_2H_2)]$ (M = Mo) **6**. These triphosphole metal tricarbonyl complexes can therefore be considered as being closely related to the long-known $[M(CO)_3(\eta^6\text{-arene})]$ compounds.

Treatment of $P_3C_2Bu^t_2CH(SiMe_3)_2$ **1** with $[M(CO)_4(\eta^4\text{-nbd})]$ (M = Cr, Mo; nbd = norbornadiene) in tetrahydrofuran affords the red complexes $[M(CO)_3\{\eta^5\text{-}P_3C_2Bu^t_2CH(SiMe_3)_2\}]$ (M = Cr **2**, Mo **3**).† Likewise reacting **1** with $[W(CO)_5(thf)]$ gives $[W(CO)_3\{\eta^5\text{-}P_3C_2Bu^t_2CH(SiMe_3)_2\}]$ **4**. Complexes **2** and **3** were also prepared directly from **1** and the appropriate $[M(CO)_3(\eta^6\text{-chp})]$ complex, (M = Cr, Mo; chp = cycloheptatriene).

The $^{31}P\{^1H\}$ NMR spectra of **2**–**4**† each showed the characteristic pattern of lines expected for [AXY] spin systems, significantly chemically shifted from **1** but with $^1J_{PAPX}$, $^2J_{PAPY}$ and $^2J_{PXPY}$ coupling constants similar in magnitude to values found for the free di-*tert*-butyl-1,2,4-triphosphole **1**.[4]

Compounds **2** and **3** were also fully structurally characterised by single-crystal X-ray diffraction studies‡ and the molecular structure of **3** is shown in Fig. 1. Specially noteworthy is the observation that in both **2** and **3** the metal tricarbonyl fragment is coordinated to all five atoms of the 1,2,4-triphosphole ring system which is planar. The distances between the metal and the plane of the ring defined by P(1)P(2)P(3)C(1)C(2) are 1.799 and 1.962 Å for **2** and **3** respectively, and the sums of the bond angles around the formally $sp^3$-hybridised phosphorus atom are 356.6° for **2** and 352.2° for **3**. The metal to $\sigma^3\lambda^3$-phosphorus [P(2)] distance in both structures **2** and **3** is significantly shorter than to the $\sigma^2\lambda^3$ phosphorus ring atoms P(1) and P(3). The 1,2,4-triphosphole rings in complexes **2**–**4** can therefore be considered as donating six electrons to the metal centre. As expected the P–C and P···P bond lengths within the coordinated 1,2,4-triphosphole lie between the values expected for single and double bonds, and are quite close to those found in both the penta- and hexa-phosphaferrocenes $[Fe(\eta^5\text{-}P_3C_2Bu^t_2)(\eta^5\text{-}P_2C_3Bu^t_3)]$ and $[Fe(\eta^5\text{-}P_3C_2Bu^t_2)_2]$ which contain the $\eta^5$-ligated aromatic di- and tri-phospholyl anions.[5] Prior to this work transition-metal complexes of phospholes had only involved ligation of the ring *via* the phosphorus lone pair electrons and/or through the diene system.[1]

We have also carried out theoretical studies in order to better understand the interaction between the 1,2,4-triphosphole ring system and the group 6 metal tricarbonyl moieties. Geometry optimization§ of the tricarbonyl Mo complex **6** of the hypothetical H-substituted triphosphole $HP_3C_2H_2$ **5** resulted in two different structures at the Hartree–Fock level (HF) of the theory. One of them involved $\eta^5$-ligation of the ring to the metal (A) while the other utilised $\eta^4$-coordination (B). The

$\eta^4$-coordinated compound was more stable only by 0.02 kcal $mol^{-1}$ (1 cal = 4.184 J) however on reoptimization using the density functional method, only the $\eta^5$-structure was obtained, even when starting from the $\eta^4$-HF optimized geometry. Although only the $\eta^5$-complex was also obtained experimentally (*vide infra*), in agreement with the density functional calculations, this computational behaviour indicates that the $\eta^4$-complex should not be much less stable than its $\eta^5$-counterpart, and furthermore the 1,2,4-triphosphole ring

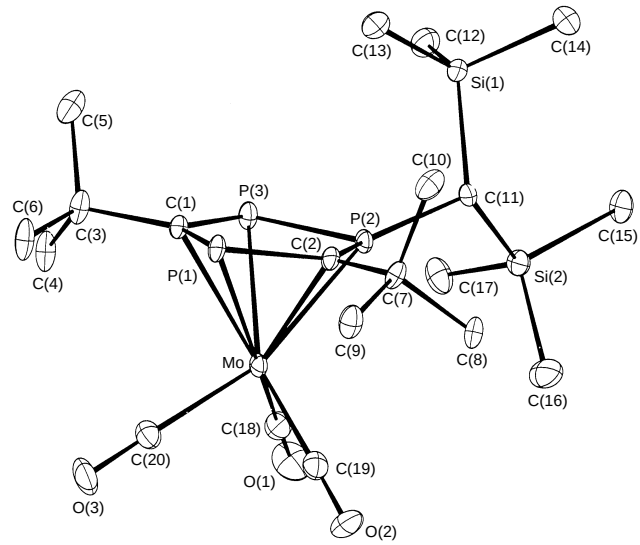


**Fig. 1** Molecular structure of **3**. Selected bond lengths (Å) and angles (°): P(2)–P(3) 2.105(3), P(2)–C(2) 1.745(7), P(3)–C(1) 1.767(7), P(1)–C(2) 1.761(7), P(1)–C(1) 1.777(8), P(2)–C(3) 1.799(7); P(2)–P(3)–C(1) 94.2(3), P(1)–C(1)–P(3) 124.1(4), C(1)–P(1)–C(2) 99.6(3), P(1)–C(2)–P(2) 116.6(4), P(3)–P(2)–C(2) 105.5(3), P(3)–P(2)–C(3) 120.7(3), C(2)–P(2)–C(3) 126.0(4).

[a] X-Ray structural data for **1** from ref. 4. [b] X-Ray structural data refers to complex **3**.

systems are borderline cases between aromatic and non-aromatic molecules. Interestingly attempts to synthesise complexes involving different ligating modes of the di-*tert*-butyl-1,2,4-triphosphole ring, for example $[M(CO)_5(\eta^1\text{-}RP_3C_2Bu^t_2)]$ or $[M(CO)_4(\eta^4\text{-}RP_3C_2Bu^t_2)]$ [R = $CH(SiMe_3)_2$; M = Cr, Mo, W] using either $[M(CO)_5(thf)]$, $[M(CO)_4(\eta^4\text{-nbd})]$, or $[M(CO)_3(\eta^6\text{-chp})]$ as precursors, only led to the tricarbonyl complexes **2**–**4** and no other intermediates could be detected when the reactions were carefully monitored by $^{31}P$ NMR spectroscopy.

Calculations on the hypothetical complex $[Mo(CO)_3(\eta^5\text{-}HP_3C_2H_2)]$ **6** show that it exhibits remarkable stability towards dissociation to 1,2,4-triphosphole **5** and $Mo(CO)_3$ (39.91 and 27.22 kcal $mol^{-1}$ at the HF and DFT levels respectively); and for comparison the stabilization of the corresponding benzene complex $[Mo(CO)_3(\eta^6\text{-}C_6H_6)]$ was calculated to be 33.82 and 24.21 kcal $mol^{-1}$ respectively at the above two levels.

The calculated structural characteristics§ (Table 1) of the $\eta^5$-complex (A) are comparable to the values obtained experimentally from the X-ray structural analyses on **2** and **3**, however, the P···P separation and some of the Mo–P and Mo–C bond lengths are not reproduced particularly well by the calculations. Similarly, the structures of the parent triphosphole calculated at the HF and B3LYP levels had considerably longer single bond lengths than in the X-ray structure of the alkylated derivative (Table 1). This behaviour is in accordance with an increased aromaticity, due to the alkylation. Indeed, the bis(trimethylsilyl)methyl group has a partial flattening effect on the $\sigma^3.\lambda^3$-phosphorus.[6] The increased planarity then enhances the aromaticity of the system. Changes in bond lengths upon complexation of the 1,2,4-triphosphole ring to the metal centre are well accounted for by the calculations, *i.e.* the formal double bonds become slightly longer, while the other bond lengths only undergo small changes. The $\eta^5$-nature of complex **6** is also clearly shown by the Wiberg covalent bond indices[7] listed in Table 1, from which it is evident that all Mo–C and Mo–P indices are of similar magnitude. Comparing the parent and the complexed triphosphole, the largest change is again in the Wiberg indices of the formal double bond, in accordance with its increasing length noted above.

The present results clearly provide the first evidence for an $\eta^5$-ligated 1,2,4-triphosphole ring system which exhibits some aromatic character, and complements the recently reported[8] ready displacement of naphthalene by the di-*tert*-butyl-1,2,4-triphosphole **1** from the zerovalent ruthenium complex $[Ru(\eta^6\text{-}C_{10}H_8)(\eta^4\text{-}C_8H_{12})]$ to afford $[Ru\{\eta^5\text{-}P_3C_2Bu^t_2[CH(SiMe_3)_2]\}(\eta^4\text{-}C_8H_{12})]$, in which the triphosphole also behaves as a 6e donor.

We wish to thank the Brazilian Government (*via* CNPq) and the Turkish Government for financial support (to V. C. and N. S. respectively); EPSRC for general support for phosphaalkyne chemistry; to OTKA T 014555 and to the Royal Society for financing our collaborative UK–Hungary studies.

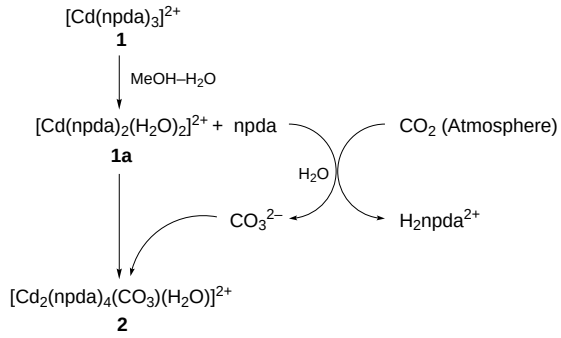
# Carbon dioxide activation: synthesis and characterization of a cadmium(II) dinuclear complex with a novel μ-carbonato bridge



**Chandi Pariya,*[a]† Vedavati G. Puranik[b] and Nirmalendu Ray Chaudhuri*[a]‡**

[a] *Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India*
[b] *Division of Physical Chemistry, National Chemical Laboratory, Pune 411 008, India*

**The cadmium(II) complex of *N′*-isopropyl-2-methylpropane-1,2-diamine (npda), $[Cd(npda)_3][ClO_4]_2$ 1 in aqueous methanol absorbs $CO_2$ from air to form a cadmium(II) dinuclear complex, $[Cd(npda)_4(CO_3)(H_2O)][ClO_4]_2{\cdot}H_2O$ 2, the first ever example of a μ-carbonato cadmium(II) diamine complex which is characterized by elemental analysis, IR and crystal structure determination.**

Transition metals bound to $CO_2$ and reactions of the resulting complexes have been of much interest in connection with utilization of $CO_2$.[1–3] A large-scale method of reducing $CO_2$ similar to photosynthesis in green plants, has, as yet, not been developed. The benefit of reduction of $CO_2$ in the atmosphere can be doubled if $CO_2$ can be absorbed and harvested as a chemical feedstock.[4,5] Development of metal–$CO_2$ chemistry derived much of its inspiration from such a challenging possibility. However, most prepared and characterized transition-metal complexes containing $CO_2$[6–12] and a variety of bridging carbonates[13–17] are air-sensitive. Here we describe: (*a*) the first example of a cadmium complex which can spontaneously react with $CO_2$ under atmospheric conditions in the presence of a base, and (*b*) structural characterization of the resultant dinuclear complex featuring a novel μ-carbonato group bridging two cadmium ions.

In the course of our studies[18–21] on the synthesis, characterization and thermal investigation of transition-metal (nickel, copper, zinc and cadmium) complexes of *N′*-isopropyl-2-methylpropane-1,2-diamine (npda), we reported[20] that only cadmium(II) perchlorate generates tris-diamine species with excess npda, $[Cd(npda)_3][ClO_4]_2$ **1** being obtained as a white powder. When a methanolic solution of **1** was stirred in air and its volume reduced, colourless crystals formulated as $[Cd_2(npda)_4(CO_3)(H_2O)][ClO_4]_2{\cdot}H_2O$ **2** were obtained in good yield.§ Complex **2** was also prepared from $[Cd(npda)_3][ClO_4]_2$ by passing a stream of carbon dioxide or by addition of carbonate in methanolic solution. The ease of formation of this unusual bimetallic complex may be attributed to the unique steric features of npda, since no effort was made to promote reaction with $CO_2$, nor has such bridging been observed previously for other cadmium complexes featuring different ligands.

**Scheme 1**

Complex **2** gave satisfactory elemental analysis and its IR spectrum showed the presence of amine as well as carbonate[16] groups, the latter being absent in **1**. The tris-diamine complex **1**, when dissolved in an aqueous medium, dissociates into $[Cd(npda)_2(H_2O)_2][ClO_4]_2$ **1a**[20b] and npda, to release the excessive steric congestion owing to the bulky substituents of a third npda ligand. It appears that complex **1a** is a very active species for reaction with $CO_2$ in the presence of npda; the latter is supposed to act also as a base, which would raise the concentration of $CO_2$ in solution. Although at a first glance it might appear that the complex **2** is generated by the interaction of the bis-complex and $CO_2$ as the metal : npda ratio in **2** was 1 : 2, the formation of **2** from a simple bis-complex was not observed. The proposed mechanistic pathway for this reaction is shown in Scheme 1.

The initial loss of a ligand unit leads to a coordinatively unsaturated intermediate, $[Cd(npda)_2]^{2+}$ which coordinates to two molecules of water to form $[Cd(npda)_2(H_2O)_2]^{2+}$. The released npda reacts with $CO_2$ to form $CO_3^{2-}$ [$CO_2 + H_2O +$ npda $\rightarrow$ $CO_3^{2-}$ (aq) + $H_2npda^{2+}$] and eventually yields $[Cd_2(npda)_4(CO_3)(H_2O)]^{2+}$.[14]

The crystal structure of **2** revealed the presence of a novel, bridging tridentate carbonate, and presented an excellent opportunity to study the configuration and interactions of the two npda ligands in an octahedral configuration. Fig. 1 shows a view and atom-numbering scheme of the dication $[Cd_2(npda)_4(CO_3)(H_2O)]^{2+}$ containing a novel μ-carbonato bridge, which is associated in the crystal with two perchlorate ions and a water molecule of crystallization.

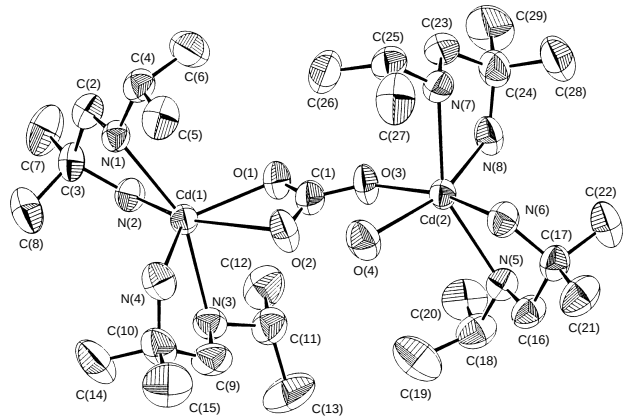


**Fig. 1** ORTEP diagram of complex **2**. Thermal elipsoid are drawn at 50% probability, the water molecule and perchlorate ions are not shown for clarity. Selected bond distances (Å) and angles (°): Cd(1)–O(1) 2.172(4), Cd(1)–O(2) 2.768(4), Cd(1)–N(1) 2.389(4), Cd(1)–N(2) 2.324(4), Cd(1)–N(3) 2.407(5), Cd(1)–N(4) 2.324(4), Cd(2)–O(3) 2.238(3), Cd(2)–O(4) 2.351(4), Cd(2)–N(5) 2.385(5), Cd(2)–N(6) 2.386(4), Cd(2)–N(7) 2.403(5), Cd(2)–N(8) 2.309(4), C(1)–O(1) 1.278(6), C(1)–O(2) 1.279(7), C(1)–O(3) 1.268(6); O(1)–Cd(1)–O(2) 51.46(3), O(3)–Cd(2)–O(4) 82.8(2), N(2)–Cd(1)–N(1) 75.0(2), N(4)–Cd(1)–N(3) 75.8(2), N(5)–Cd(2)–N(6) 75.0(2), N(8)–Cd(2)–N(7) 73.7(2), O(1)–C(1)–O(2) 119.7(4), O(1)–C(1)–O(3) 118.7(5), O(2)–C(1)–O(3) 121.6(5).

In the dinuclear complex cation both cadmium atoms have a significantly distorted octahedral coordination with $N_4O_2$ chromophores. Distortions from ideal octahedral geometry are due to the two bidentate diamines and the asymmetric nature of the bridging carbonato ion, the smallest *cis* angle being 51.46(3)° [O(1)–Cd(1)–O(1)]. The carbonato moiety is planar and the C–O bond distances are almost equal [av. 1.278(6) Å] unlike those in bidentate carbonate systems.[17] A three-dimensional network of intra- and inter-molecular hydrogen bonds involving water molecules, amine nitrogen atoms and perchlorate ions stabilizes the crystal packing; the shortest hydrogen bond is O(1w)···O(1) (1 +*x*, *y*, *z*) 2.812(3) Å.

We thank Dr A. Sarkar, Division of Organic Chemistry (Synthesis), National Chemical Laboratory, Pune for helpful discussions and also Professor T. P. Singh, All India Institute of Medical Science, New Delhi is acknowledged for preliminary data (complex **2**) on the crystal structure determination. One of us (C. P.) thanks Professor Chung-Sun Chung, Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan, ROC for encouragement.

§ *X-Ray structure determination*: a colourless crystal of approximate dimensions 0.2 × 0.3 × 0.6 mm was used for the data collection on a PC controlled Enraf-Nonius CAD-4 single-crystal X-ray diffractometer (293 K) with graphite-monochromated Mo-Kα radiation using ω–2θ scan mode and 1° $min^{-1}$ scan speed. Unit-cell parameters were refined from 25 least-squares fitted machine-centred reflections in the range 18 < 2θ < 30°. Three standard reflections measured every hour showed < 4% variation in intensity. The structure was solved by direct methods using NRCVAX[22] and refined by full-matrix least-squares techniques on $F^2$ using SHELXL-93[23] to $R$ = 0.0280, $R_w$ = 0.075 from 5358 unique reflections, from a total number of 5558 reflections collected. Least-squares refinement of scale, position and anisotropic thermal parameters for non-hydrogen atoms was carried out. The hydrogen-atom positions were geometrically fixed and confirmed by difference Fourier analysis. Each hydrogen atom was assigned the same isotropic thermal parameter as the atom to which it was bonded.

*Crystal data* for **2**: $C_{29}H_{76}Cd_2Cl_2N_8O_{13}$, $M$ = 1036.6, monoclinic, space group $P2_1$, $a$ = 9.338(8), $b$ = 12.888(1), $c$ = 20.493(3) Å, $\beta$ = 101.78(4)°, $U$ = 2414(2) Å$^3$, $Z$ = 2, $D_c$ = 1.426 Mg $m^{-3}$. Final $R$ [$I > 2\sigma(I)$] $R_1$ = 0.0280 and $R_w$ = 0.0754; $w = 1/\sigma^2[(F_o^2) + (0.0499p)^2 + 0.6831p]$, where $p = (F_o^2 + 2F_c^2)/3$. Number of refined parameters is 486. The 'Flack parameter' is 0.083(3).[24] CCDC 510.

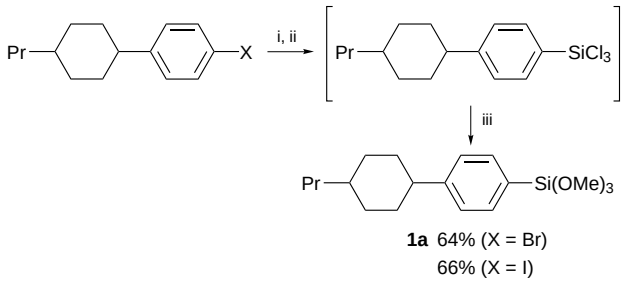
# Preparation of functionalized biaryl compounds *via* cross-coupling reactions of aryltrialkoxysilanes with aryl bromides



**Koichi Shibata,* Kazutoshi Miyazawa and Yasuyuki Goto**

*Chisso Petrochemical Corporation, Specialty Chemicals Research Center, 5-1 Goi Kaigan, Ichihara, Chiba 290, Japan*

**Aryltrimethoxysilanes react with aryl bromides in the presence of fluoride ion and palladium catalysts to give the corresponding biaryl compounds in good yields with high chemoselectivity.**

Many functional organic materials and natural bioactive organic compounds contain biaryl units in their structures. In particular, the proportion of biaryl compounds in liquid crystalline compounds is high, and many biaryl-type liquid crystalline compounds have been developed.[1] In recent years, considerable interest in the construction of functionalized biaryl components *via* aryl–aryl coupling reactions has been aroused.[2]

Arylboronic acids are known to undergo cross-coupling reactions with aryl halides.[3] Recently, pentacoordinate aryl silicates activated by fluoride ion have been shown to exhibit high reactivity in coupling reactions, and different kinds of pentacoordinate aryl silicates have been used for aryl–aryl cross-coupling reactions.[2c,2f,4]

**Scheme 1** *Reagents and conditions*: i (X = Br) Mg (1.1 equiv.), THF, 50 °C, 2 h; (X = I) BuLi (1.0 equiv.), hexane, −70 °C, 2 h; ii (X = Br) $SiCl_4$ (1.5 equiv.), 0 °C to room temp., 17 h; (X = I) $SiCl_4$ (2 equiv.), −70 °C to room temp., 17 h; iii, MeOH (8.0 equiv.), pyridine (8.0 equiv.), 0 °C, 30 min

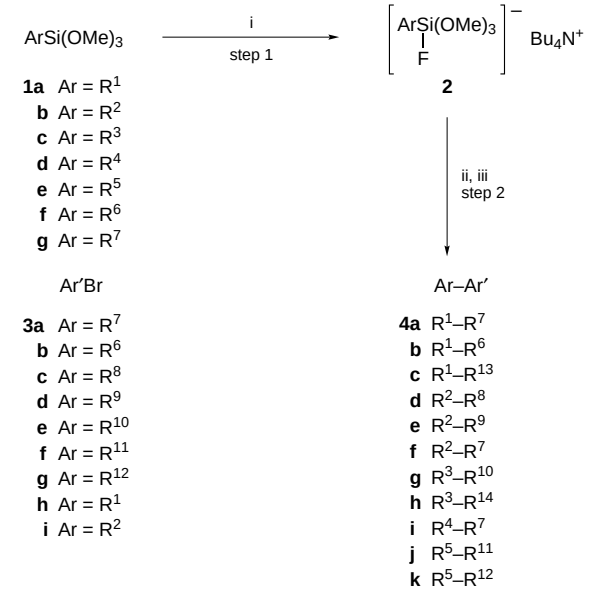


**Table 1** Preparation of biphenyl **4a** from **1a** and **3a**[a]

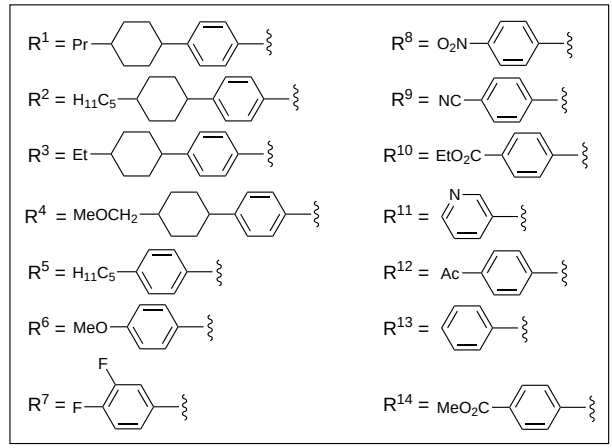

| Entry | Catalyst (mol%) | Step 2 Solvent | *t*/h | Yield of **4a** (%) |
|---|---|---|---|---|
| 1[b] | $Pd(OAc)_2$ (5) | DMF | 3 | 2 |
| 2 | $Pd(OAc)_2$ (10) | THF–DMF | 3 | 49 |
| 3 | $Pd(Ph_3P)_4$ (5) | THF–DMF | 3 | 71 |
| 4[c] | $Pd(Ph_3P)_4$ (5) | THF-Toluene | 10 | 91 |
| 5 | $Pd(Ph_3P)_4$ (5) | THF | 3 | 19 |

| 9 | $Pd(OAc)_2$ (5)–$Ph_3P$ (10) | Toluene[d] | 3 | 89 |
| 10 | $Pd(OAc)_2$ (5)–$Ph_3P$ (15) | Toluene[d] | 3 | 90 |
| 11 | $Pd(OAc)_2$ (5)–$Ph_3P$ (20) | Toluene[d] | 3 | 80 |

[a] TBAF (1.05 equiv.) was used as a fluoride ion source, and Step 1 was carried out in THF for 30 min at room temperature, unless otherwise noted. [b] Step 1: KF (5 equiv.) was used instead of TBAF and the reaction was carried out for 3 h at 100 °C in DMF; Step 2: Reaction was carried out for 3 h at 120 °C. [c] Reaction time of Step 2 was 10 h. [d] Before Step 2, THF was removed under reduced pressure.

Here we report the reactivity of a new type of pentacoordinate aryl silicate, aryl(fluoro)trimethoxosilicate(1−) **2**, which was easily obtained from aryltrimethoxysilane **1** and a fluoride ion source. At the outset, preparation of **1a** was attempted in several ways, and reactions using tetrachlorosilane gave **1a** in acceptable yields after distillation (Scheme 1).[4] Other arylsilanes **1b**–**g** were also prepared using this method and they were so stable that no decomposition occurred during ordinary aqueous work-up. Although direct reaction of the aryl Grignard or lithium reagent with tetramethoxysilane could afford **1a**, its yield was low (*ca.* 35%).[5] The main product of the reaction was diaryl(dimethoxy)silane.

4-(*trans*-4-*n*-Propylcyclohexyl)-3′,4′-difluorobiphenyl **4a**, which is used in active matrix liquid crystal displays, was

**Scheme 2** *Reagents and conditions*: i, $Bu_4NF$ (1.05 equiv.); ii, Ar'Br (**3a**–**i**) (1.2 equiv.); iii, Pd catalyst, reflux

chosen as a model compound, and cross-coupling reactions of 4-(*trans*-4-*n*-propylcyclohexyl)phenyltrimethoxysilane **1a** with 1-bromo-3,4-difluorobenzene **3a** were attempted.[6] Arylsilane **1a** was stirred with KF in DMF and then the reaction mixture was reacted with **3a** for 3 h at 120 °C in the presence of a catalytic amount of palladium(II) acetate [$Pd(OAc)_2$]. However, the yield of the desired product **4a** was only 2% (Table 1, entry 1). When the fluoride ion source and the solvent were changed to tetrabutylammonium fluoride (TBAF)† and THF–DMF mixed solvents, respectively, the yield of **4a** increased to 49% (entry 2). In addition, changing of the catalyst to tetrakis-(triphenylphosphine)palladium(0) [$(Ph_3P)_4Pd$] gave **4a** in 71% yield (entry 3). Under theses conditions, reactions were carried out in several solvents (entries 4–6), and toluene was found to be the best solvent (entry 6).

Although the yield of **4a** was 46% when $Pd(OAc)_2$ was used as a catalyst, the addition of $Ph_3P$ had a remarkable effect (entries 8–11). The best molar ratio of $Pd(OAc)_2$ and $Ph_3P$ was 1 : 3, which gave **4a** in 90% yield (entry 10). From the above results, it can be seen that $(Ph_3P)_4Pd$ and $Pd(OAc)_2$–$Ph_3P$ are good catalysts for the reaction. Taking the price, stability and simplicity of handling into account, $Pd(OAc)_2$–$Ph_3P$ is the more practical.

The reactions of several arylsilanes **1** with aryl bromides were investigated next under the conditions used in Table 1, entry 10 (Scheme 2). They proceeded with high chemoselectivity and the results are summarized in Table 2.

All reactions gave the desired biaryl derivatives in good yields except entry 2. In particular, when **3a** was used, **4a**, **4f**, and **4i** were obtained in more than 82% yield within 10 h (entries 1, 5 and 7). In general, as liquid crystalline compounds having fluorine atoms on their aromatic rings are known to exhibit good properties, the present reaction is very useful for the preparation of fluorinated liquid crystalline compounds.[6,7]

**Table 2** Preparation of a variety of biaryl compounds[a] **4**

| Entry | **1** | **3** | *t*/h | Product (% yield) |
|---|---|---|---|---|
| 1[b] | **1a** | **3a** | 3 | **4a** (90) |
| 2 | **1a** | **3b** | 10 | **4b** (61), **4c** (29) |
| 3 | **1b** | **3c** | 25 | **4d** (74) |
| 4 | **1b** | **3d** | 30 | **4e** (87) |
| 5 | **1b** | **3a** | 10 | **4f** (92) |
| 6 | **1c** | **3e** | 30 | **4g** (84), **4h** (4) |
| 7 | **1d** | **3a** | 30 | **4i** (82) |
| 8 | **1e** | **3f** | 30 | **4j** (72) |
| 9 | **1e** | **3g** | 30 | **4k** (84) |
| 10 | **1f** | **3h** | 30 | **4b** (75) |
| 11 | **1g** | **3i** | 30 | **4f** (78) |

[a] $Pd(OAc)_2$ (5 mol%)-$Ph_3P$ (15 mol%) was used as catalyst and the reactions were carried out in toluene. [b] The same data as shown in Table 1, entry 10.

The reaction of 4-bromoanisole **3b** with **1a** gave not only the desired **4b** (61%) but also the demethoxylated product **4c** (29%; entry 2). Although the mechanism of demethoxylation has not been elucidated, it is most probable that demethoxylation occurs before the formation of the new $sp^2$–$sp^2$ bond because the reaction of the reverse combination of entry 2 showed no formation of **4c** (entry 10).

In these reactions, homo-coupling products were not detected and other byproducts were also very rare, which made purification of the products straightforward. Another advantage of this reaction system is that **1** is very resistant to hydrolysis, and thus can be stored for a long time without special precautions to exclude moisture.

# $[H_3N(CH_2)_3NH_3]Fe_2O(PO_4)_2$: a novel layered iron phosphate containing tetramers of $FeO_5$ trigonal bipyramids

**Kwang-Hwa Lii* and Yuh-Feng Huang**

*Institute of Chemistry, Academia Sinica, Taipei, Taiwan*

**The synthesis and characterization of a layered iron phosphate is described; the structure consists of novel $Fe_4O_{16}$ clusters formed of four $FeO_5$ trigonal bipyramids, which are linked into two-dimensional sheets through phosphate tetrahedra with propanediammonium cations between the sheets.**

A large variety of molybdenum and vanadium phosphates with layered and open frameworks have been synthesized under mild hydrothermal conditions using organic amines as templates.[1,2] It is reasonable to assume that the formation of these solids will occur with other d-block elements. Iron phosphates exist as minerals and have a rich crystal chemistry. A large number of ternary iron phosphates have been synthesized under high temperature, high pressure hydrothermal conditions.[3] Little work, however, has been carried out on the organically templated iron phosphates and, to our knowledge, only three phases, namely $[H_3N(CH_2)_2NH_3]_{0.5}[Fe(OH)PO_4]$,[4] $[HN(CH_2CH_2)_3NH]_3[Fe_8(HPO_4)_{12}(PO_4)_2(H_2O)_6]$[5] and $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$,[6] have been synthesized. The latter is particularly interesting because the structure contains large tunnels with 20-ring windows and its framework metal atom density is smaller than the very open faujasite. Here we describe the synthesis and characterization of a novel amine encapsulating FePO, which has a layer structure and contains a hitherto unknown tetramer of $FeO_5$ trigonal bipyramids.

Hydrothermal treatment of $FeCl_3\cdot 6H_2O$ (2.5 mmol), $H_3PO_4$ (7.5 mmol), $H_2N(CH_2)_3NH_2$ (14 mmol), *n*-butanol (7 ml) and water (3 ml) for 3 days at 160 °C followed by slow cooling at 5 °C $h^{-1}$ to room temperature produced $[H_3N(CH_2)_3NH_3]Fe_2O(PO_4)_2$, **1**, as orange plate crystals and a very small amount of a pale yellow material. The yellow material was $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$,[5] as indicated from powder X-ray diffraction measurements. A small orange crystal was used to determine its structure by single-crystal X-ray diffraction.† The orange crystals were manually separated from the yellow material to give pure **1** as judged by visual microscopic examination and by comparison of the X-ray powder pattern to the pattern simulated from the atomic coordinates derived from single-crystal study. The yield of **1** was 94% based on iron. Chemical analysis confirmed the amount of 1,3-diaminopropane (Found: C, 9.22; H, 2.99; N, 7.08. Calc. C, 9.15; H, 3.07; N, 7.11%). The IR spectrum (KBr) showed N–H and C–H stretches at 3090 and 2945 $cm^{-1}$, respectively Thermal gravimetry in air showed a mass loss in two steps. In the first step over 280–400 °C a mass loss of 11.0% was observed which corresponded to the release of one mol of $C_3H_4$ (Calc. 10.2%) due to the decomposition of diprotonated 1,3-diaminopropane. The product contained $NH_4^+$ as confirmed by the presence of a band at 3360 $cm^{-1}$ for the N–H stretch and disappearance of the band at 2945 $cm^{-1}$ for the C–H stretch in the IR spectrum of the sample heated to 350 °C. A powder X-ray pattern of the sample indicated that it was amorphous. The second step in TG (400–750 °C, mass loss 13.0%) was attributed to the release of one mol of $H_2O$ and two mol of $NH_3$ (Calc. 13.2%). The final decomposition product at 800 °C was $FePO_4$. The room-temperature Mössbauer spectrum of **1** is a doublet with $\delta$ (isomer shift) = 0.35 mm $s^{-1}$ (relative to iron foil at 300 K), $\Delta E_Q$ (quadrupole splitting) = 0.92 mm $s^{-1}$, and $\Gamma$ (full width at half-height) = 0.32 mm $s^{-1}$. The isomer shift is consistent for iron(III) phosphates.[7] Variable-temperature magnetic susceptibility measurements on a powder sample showed that $\chi_M T$ decreased with decreasing temperature and the value at 300 K was only 19% of the spin-only value, indicating large antiferromagnetic interactions so that $\chi_M$ is significantly reduced from the expected non-interacting moment even at room temperature.

The structure consists of anionic sheets of formula $[Fe_2O(PO_4)_2]^{2-}$ in the *bc*-plane with charge compensating propanediammonium cations between the sheets (Fig. 1). The sheets are constructed from tetramers of $FeO_5$ trigonal bipyramids, which are joined to four other tetramers by the bridging phosphate ligands as shown in Fig. 2. Each sheet has a double-layered structure. Within a layer, $FeO_5$ trigonal bipyramids share corners with $PO_4$ tetrahedra, in an alternating manner to form eight-sided windows. Infinite tunnels are formed along the [100] direction, in which the organic molecules are located. The molecules are locked in their positions by hydrogen bonds to phosphate oxygens [$d_{N(1)-O(5)}$ = 2.81, $d_{N(2)-O(1)}$ = 2.84, $d_{N(2)-O(4)}$ = 2.83 Å]. The tetramer contains a dimer of edge-sharing trigonal bipyramids which further links at the shared

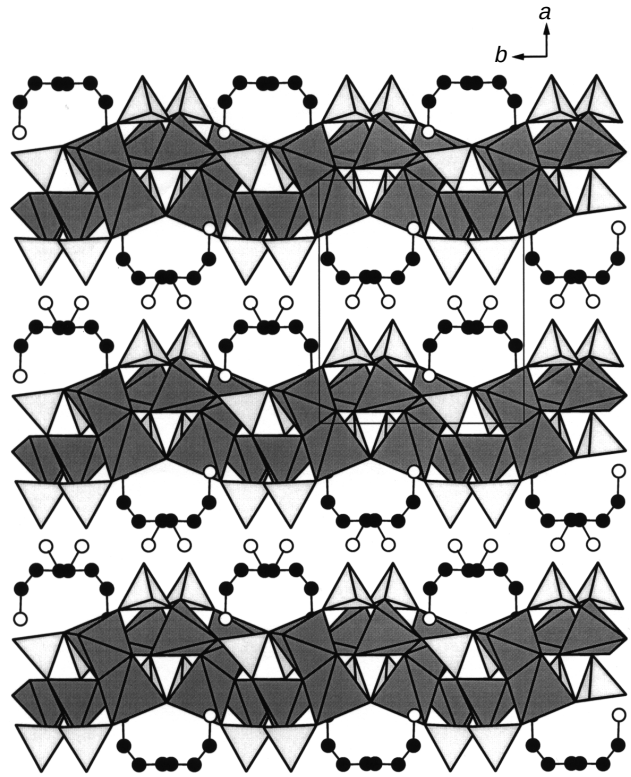

**Fig. 1** Polyhedral view of the structure of **1** along the [001] direction. Polyhedra with darker shade, $FeO_5$ trigonal bipyramids; tetrahedra with lighter shade, $PO_4$; solid circles, C atoms; open circles, N atoms.

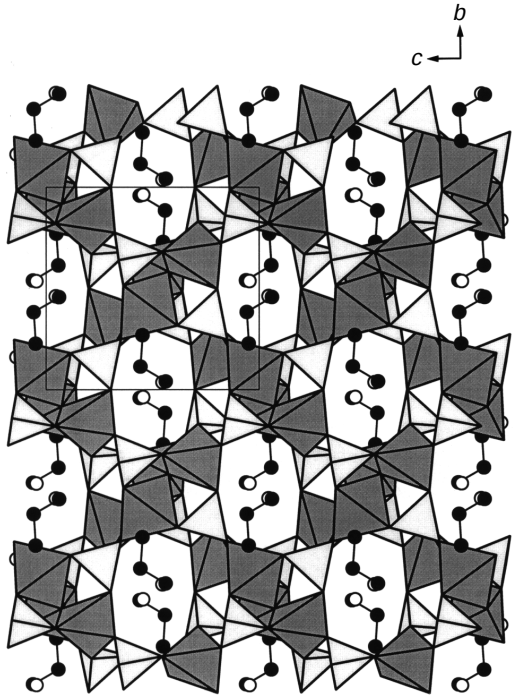

**Fig. 2** Section of a sheet in **1** showing the connectivity between the iron–oxygen clusters

corners to two other trigonal bipyramids forming a $Fe_4O_{16}$ cluster (Fig. 3). The tetramer possesses $\bar{1}$ symmetry located at the midpoint of the shared edge. The $P(1)O_4$ group is tetradentate. Two of the phosphate oxygens bond to two Fe atoms of a cluster in a bridging mode, while the other two bridge to two Fe atoms of an adjacent cluster. The $P(2)O_4$ group coordinates to three Fe atoms of two different clusters through three oxygen donors; the fourth oxygen, O(5), is present as a pendant P=O unit and projects into the interlamellar region. Average Fe–O and P–O bond lengths are typical for their polyhedra, with Fe(1)–O 1.934, Fe(2)–O 1.949, P(1)–O 1.538 and P(2)–O 1.542 Å, in accord with the sum of ionic radii, $r(^{V}Fe^{3+})$ = 0.58, $r(^{IV}P^{5+})$ = 0.17 and $r(^{III}O^{2-})$ = 1.36 Å.[8]

The most remarkable structural feature of $[H_3N(CH_2)_3NH_3]Fe_2O(PO_4)_2$ is the presence of a novel $Fe_4O_{16}$ cluster formed of four $FeO_5$ trigonal bipyramids. Although five-coordination with trigonal-bipyramidal geometry is frequently found in iron phosphates, iron–oxygen clusters formed of only $FeO_5$ trigonal bipyramids are very rare. To our knowledge, $Fe_3PO_7$ is the only other iron phosphate which contains clusters

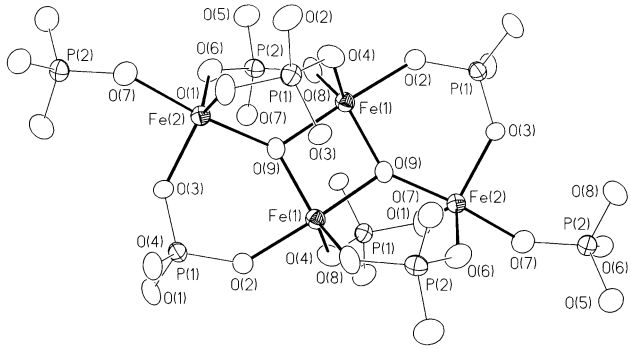

**Fig. 3** The tetranuclear iron cluster in **1**; thermal ellipsoids are shown at 60% probability

of $FeO_5$ trigonal bipyramids.[9] The $Fe_3PO_7$ structure consists of $Fe_3O_{10}$ clusters of edge-sharing $FeO_5$ trigonal bipyramids. The polyhedral linkage in the octahedral tetramers in the mineral leucophosphite, $K_2[Fe_4(OH)_2(H_2O)_2(PO_4)_4]\cdot 2H_2O$[10] and the organically templated iron phosphate $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$[5] is similar to that in **1**. The tetranuclear $Fe_4O_{16}$ core in the iron arsenate $Cs_3Fe_5O(OH)(AsO_4)_5$[10] has the same structure as that of the molecular tetramer $[\{Ti(OEt)_4\}]$,[12] in which four $MO_6$ octahedra are joined by shared edges. This new phosphate, $[H_3N(CH_2)_3NH_3]Fe_2O(PO_4)_2$, further expands the variety of structures in the iron phosphate phase space which contain clusters of Fe–O polyhedra linked *via* phosphate tetrahedra. The incorporation of bulky organic templates, as compared to cations like the alkali metals, apparently increases the size and complexity of the framework. We are continuing the exploratory synthesis of new FePO frameworks with structure directing organic templates.

† *Crystal data* for $[H_3N(CH_2)_3NH_3]Fe_2O(PO_4)_2$: monoclinic, space group $P2_1/c$, $a$ = 11.6591(8), $b$ = 9.5718(7), $c$ = 10.1158(7) Å, $\beta$ = 99.963(2)°, $U$ = 1111.9(2) Å$^3$, $Z$ = 4, $M_r$ = 393.79, $D_c$ = 2.352 g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 29.4 cm$^{-1}$, $\lambda$ = 0.710 73 Å, graphite monochromator, crystal dimensions: 0.075 × 0.075 × 0.012 mm. The crystal was mounted on a Siemens Smart-CCD diffractometer equipped with a normal focus, 3 kW sealed-tube X-ray source. Intensity data were collected in 1200 frames with increasing $\omega$ (width of 0.30° per frame). Of the 2603 unique reflections collected ($2\theta_{max}$ = 57.5°), 1770 reflections were considered observed [$I > 3.0\sigma(I)$] after Lorentz polarization and semiempirical absorption corrections using the SHELXTL-PC program package ($T_{min, max}$ = 0.773, 0.912).[13] The structure was solved by direct methods: the Fe and P atoms were first located and the C, N, and O atoms were found in the final difference Fourier map. The H atoms were not located. Refinement (164 variables) was performed by full-matrix least-squares analysis, with anisotropic thermal parameters for all atoms. $(\Delta\rho)_{max, min}$ = 0.90, −0.80 e Å$^{-3}$. The reliability factors converged to $R(F)$ = 0.055, $R_w(F)$ = 0.063 and GOF = 1.39. CCDC 182/508.

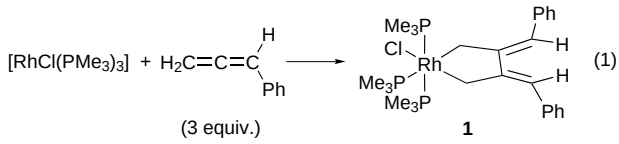
# New rhodacyclopentane with phenylvinylidene substituents, *mer*-[Rh{$CH_2C(=CHPh)C(=CHPh)CH_2$}Cl($PMe_3$)$_3$]. Structure and formation through concerted cycloaddition of phenylallene molecules to [RhCl($PMe_3$)$_3$]



**Kohtaro Osakada,* Jun-Chul Choi, Susumu Sarai, Take-aki Koizumi and Takakazu Yamamoto***

*Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226, Japan*

**[RhCl($PMe_3$)$_3$] reacts with an excess of phenylallene to give a new rhodacyclopentane, *mer*-[Rh{$CH_2C(=CHPh)C(=CHPh)CH_2$}Cl($PMe_3$)$_3$] 1, which is not obtained *via* the reaction of [RhCl(η²-$CH_2$=C=CHPh)($PMe_3$)$_3$] 2 with phenylallene.**

Several complexes of Ti, Ta, Co, Ir and Ni have been reported to undergo addition of two alkene molecules to give the corresponding saturated metallacyclopentanes.[1] Similar formation of metallacycles from the 2 : 1 reaction of allene and transition-metal complexes is much less common,[2] while the reaction is involved as a crucial step in cyclooligomerization of allene or substituted allene promoted by metal complexes.[3] Chlororhodium(I) complexes catalyze polymerization[4] or cyclooligomerization[5] of 1,2-dienes depending on the ligands bonded to the Rh center. Formation of a rhodacyclopentane from allene would be intriguing in relation to the the mechanism of the above cyclooligomerization of the 1,2-dienes catalyzed by Rh complexes. Here, we report the addition of phenylallene to [RhCl($PMe_3$)$_3$], to give a novel rhodacyclopentane which is structurally characterized.

[RhCl($PMe_3$)$_3$] reacts with 3 equiv. of phenylallene to give *mer*-[Rh{$CH_2C(=CHPh)C(=CHPh)CH_2$}Cl($PMe_3$)$_3$] **1** as shown in eqn. (1).†

The reaction mixture does not contain any other rhodacyclopentanes that would be formed through addition of phenylallene in a different orientation of the double bonds. Fig. 1 shows the molecular structure of **1** which has an octahedral coordination around the Rh center with three $PMe_3$ ligands at meridional coordination sites.‡ Three C–C bond distances in the five-membered chelate ring are quite similar, while the Rh–C(1) bond [2.16(1) Å] is longer than the Rh–C(10) bond [2.061(1) Å] owing to a larger *trans* influence of $PMe_3$ relative to Cl. The C–C bond distances [1.49(2) Å] are significantly longer than the corresponding bond of the platinacyclopentane prepared from dimerization of cycloheptatetraene in the presence of a platinum(0) complex.[2b] Both of the two C=C double bonds in **1** have *Z* structure owing to less steric congestion around the *s-cis* diene moiety than the other possible geometry of the double bonds.

The $^{13}C\{^1H\}$ NMR spectrum gives rise to signals due to the $CH_2$ carbons at $\delta$ 22.26 and 13.21. The former peak, with a large $J$(CP) value (77 Hz), is assigned to the carbon bonded *trans* to $PMe_3$ and the latter to carbon *trans* to Cl. Two $^1H$ NMR signals due to the $CH_2$ hydrogens are observed at $\delta$ 3.02 and 2.11, which are assigned to the $CH_2$ group *trans* to $PMe_3$ and *trans* to Cl, respectively, based on the $^1H$–$^{13}C$ COSY spectrum. The other $^1H$ and $^{13}C$ NMR signals as well as the $^{31}P\{^1H\}$ NMR spectrum are in accord with the structure obtained by X-ray crystallography.

Reaction of a reduced amount of phenylallene with [RhCl($PMe_3$)$_3$] has been examined in order to obtain an insight for the pathway of reaction (1). Reaction in a 1.2 : 1 ratio in hexane results in the formation of [RhCl(η²-$CH_2$=C=CHPh)($PMe_3$)$_3$] **2** which is isolated as the hexane insoluble product.§

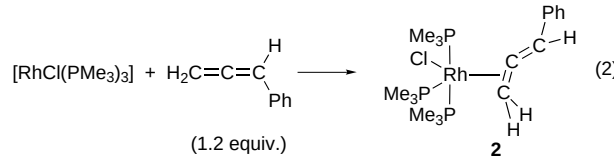


Fig. 2 shows the molecular structure of **2** which shows a trigonal-bipyramidal coordination around the Rh centre with P(1) and P(3) at the apical positions.‡ Elongation of the π-coordinated C=C double bond [$CH_2$=C 1.406(9), C=CHPh

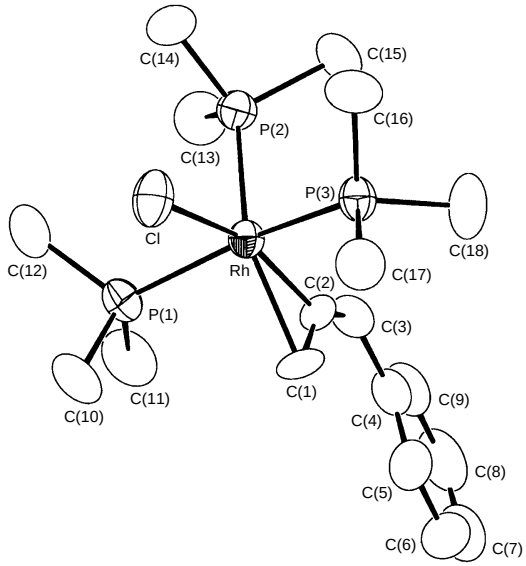

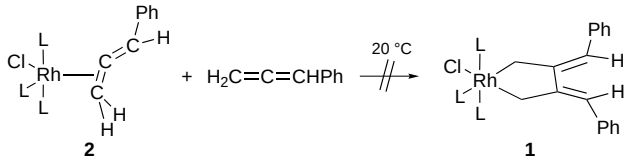

**Fig. 2** ORTEP drawing of **2** at 50% probability level. Selected bond distances (Å) and angles (°): Rh–Cl 2.540(2), Rh–P(1) 2.320(2), Rh–P(2) 2.323(2), Rh–P(3) 2.325(2), Rh–C(1) 2.126(7), Rh–C(2) 1.988(6), C(1)–C(2) 1.406(9), C(2)–C(3) 1.353(9); Cl–Rh–P(1) 84.79(7), Cl–Rh–P(2) 97.80(7), Cl–Rh–P(3) 83.36(7), Cl–Rh–C(1) 118.3(2), Cl–Rh–C(2) 158.0(2), C(1)–Rh–C(2) 39.8(3), P(1)–Rh–P(2) 96.74(7), P(2)–Rh–P(3) 96.94(7), P(1)–Rh–P(3) 162.98(7), C(1)–C(2)–C(3) 142.1(7).

**Scheme 1**

1.353(9) Å] as well as a bend of the cumulated double bonds [C(1)–C(2)–C(3) 142.1(7)°] indicate the presence of significant back-donation from the Rh center to the phenylallene ligand. The $^1$H NMR spectrum of **2** above 25 °C shows partial liberation of a $PMe_3$ ligand to afford a square-planar rhodium(I) complex [Rh($\eta^2$-$CH_2$=C=CHPh)Cl($PMe_3$)$_2$] **3** which is isolated from the mixture and characterized by X-ray crystallography.¶

Reaction of **2** and phenylallene in a 1 : 2 molar ratio in toluene for 8 h at 20 °C does not give **1** but causes quantitative recovery of **2** as shown in Scheme 1.

The results are in contrast with previous reports indicating that several transition-metal complexes containing π-coordinated alkenes react further with alkenes to give the corresponding metallacyclopentane.[1*d*,*f*,*g*] The present study has disclosed that the π-coordinated phenylallene complex **2**, with an 18 electron Rh center, is not a precursor of the metallacycle **1** in reaction (1) and that formation of **1** proceeds through direct cycloaddition of two phenylallene molecules to [RhCl($PMe_3$)$_3$].

This work was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan.

## Footnotes

† To a toluene (8 ml) solution of [RhCl($PMe_3$)$_3$] (158 mg, 0.43 mmol) was added phenylallene (150 mg, 1.3 mmol) at room temp. The initial pale yellow solution gradually turned pale brown accompanied by deposition of an off-white solid which was collected by filtration after the reaction for 8 h, and dried *in vacuo* to give **1** (203 mg, 79%).

‡ *Crystal data*: for **1**: $C_{27}H_{43}ClP_3Rh$, $M_r$ = 598.92, orthorhombic, space group *Pbca* (no. 61), $a$ = 35.023(6), $b$ = 13.823(3), $c$ = 12.155(2) Å, $U$ = 5884 Å$^3$, $Z$ = 8, $D_c$ = 1.353 g cm$^{-3}$, $\mu$(Mo-Kα) = 8.37 cm$^{-1}$ (graphite-monochromated radiation, $\lambda$ = 0.71069 Å), $F$(000) = 2496. The data collection was made on a Rigaku AFC5R diffractometer at ambient temperature (293 K) using $\omega$ scan mode for Lorentz and polarization effects. An empirical absorption correction ($\psi$ scan) was applied. Of the unique 5877 reflections with $2\theta \leqslant 55°$, 1959 reflections with $I > 3\sigma(I)$ were used in the refinement. A total of 289 parameters (non-hydrogen atoms modelled anisotropically) were refined with $w = [\sigma(F_o)]^{-2}$. Hydrogen atoms were placed in idealised geometries and included in the structure calculation without refinement of the parameters. The structure converged to $R$ = 0.054 and $R_w$ = 0.044. For **2**: $C_{18}H_{35}ClP_3Rh$, $M_r$ = 482.75, orthorhombic, space group $P2_12_12_1$ (no. 19), $a$ = 12.926(2), $b$ = 15.979(2), $c$ = 11.307(3) Å, $U$ = 2336 Å$^3$, $Z$ = 4, $D_c$ = 1.373 g cm$^{-3}$, $\mu$(Mo-Kα) = 10.36 cm$^{-1}$ (graphite-monochromated radiation, $\lambda$ = 0.71069 Å), $F$(000) = 1000. The data collection and absorption correction were carried out similarly to **1**. Of the unique 2528 reflections with $2\theta \leqslant 55°$, 2066 reflections with $I > 3\sigma(I)$ were used in the refinement. A total of 208 parameters were refined with $w = [\sigma(F_o)]^{-2}$ and the structure converged to $R$ = 0.038 and $R_w$ = 0.029. Treatment of hydrogen atoms is similar to **1**. CCDC 182/513.

§ To a hexane (8 ml) dispersion of [RhCl($PMe_3$)$_3$] (115 mg, 0.31 mmol) was added phenylallene (44 mg, 0.38 mmol) at room temp. Stirring the mixture for 26 h led to separation of a yellow solid which was collected by filtration and dried *in vacuo*. Recrystallization from thf–hexane afforded **2** as yellow crystals (85 mg, 57%).

¶ Dissociation of $PMe_3$ from **2** is not thermodynamically favoured. The equilibrium constant for **2** = **3** + $PMe_3$ is 5.1 × 10$^{-4}$ l mol$^{-1}$ even at 60 °C and is probably much smaller near 25 °C although precise equilibrium constant was not feasible. Crystallographic results of **3** which show a square-planar coordination around the Rh center will be reported separately.

# Uracil quartet formation through non-covalent interaction with a neutral metal ammine complex

**Holger Witkowski, Eva Freisinger and Bernhard Lippert***

*Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany*

**Cocrystallization of 1-methyluracil (Hmura) and *trans*-$[PtCl_4(NH_3)_2]$ yields an adduct of composition $[PtCl_4(NH_3)_2]\cdot 2$ Hmura with two types of uracil quartets, one of which is relevant to that formed in tetraplex RNA.**

Nucleobase quartets, in particular of guanine (G), have been the subject of considerable interest.[1] More recently, the existence of uracil (U)[2] and thymine (T)[3,4] quartets in four-stranded RNA and DNA helices has been demonstrated applying NMR spectroscopy. Both $G_4$ and $T_4$ quartets require the presence of alkali- or alkaline-earth metal cations in their center for stabilization. Although probably more stable than $T_4$ quartets owing to the absence of the 5-methyl group, $U_4$ quartets appear not to have been considered intrinsically stable entities. Their formation in RNA is certainly aided by an existing $(G_4)_n$ core, with $U_4$ layered on top.

Here we report the X-ray crystal structure analysis of a 1-methyluracil (Hmura) adduct of the neutral metal complex *trans*-$[PtCl_4(NH_3)_2]$† which reveals the presence of two types of uracil quartet structures.‡ There are two crystallographically independent $Pt^{IV}$ entities, Pt(1) (on a fourfold axis) and Pt(1′) (on a *S*4 axis), the structures of which are normal (Fig. 1). Both octahedral metal complexes are sandwiched between two uracil quartets (I, II), each in such a way that the $NH_3$ groups form hydrogen bonds to four exocyclic oxygen atoms of the Hmura bases. Specifically, in quartet I N(7) and N(8) ammine protons of two Pt units form hydrogen bonds with four O(2) oxygens (Fig. 2). In quartet II N(7′) ammine protons are hydrogen bonded to four O(4) oxygens (Fig. 3). In both cases, the four oxygens form a square [dimensions 3.643(4) × 3.643(4) Å between O(2) sites in I; 3.443(5) × 3.443(5) Å between O(4) sites in II]. Distances between the ammine N atoms and these oxygens are 3.052(4) Å [N(7)–O(2)] and 3.149(5) Å [N(8)–O(2)] for I, as well as 2.948(4) and 3.047(4) Å [N(7′)–O(4)] for II. Although protons at the $NH_3$ ligands were not located, the scenario, $NH_3$ group above a square of acceptor sites, probably indicates dynamically disordered H atoms of the $NH_3$ groups.[5] Both quartets are strongly non-planar. Quartet I has roughly the shape of a cup, with O(2) atoms representing its bottom, while quartet II is saddle-shaped. Only II displays the four cyclic H bonds between N(3) and O(4) sites of adjacent nucleobases [3.059(6) Å] seen in RNA uracil quartets and therefore can be considered a model of it.[6] It is to be noted that each Hmura takes part in both types of quartets.

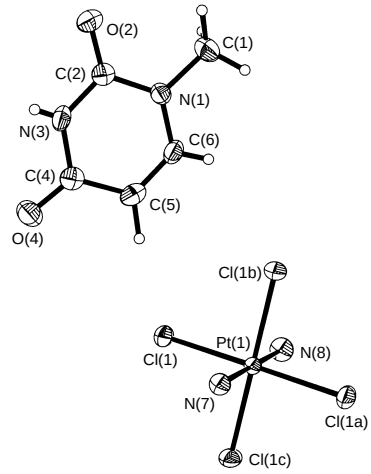

**Fig. 1** Molecular structure of the *trans*-$[PtCl_4(NH_3)_2]$ entity and of the Hmura ring. Selected bond lengths (Å) and angles (°) for the Pt complex: Pt(1)–N(7) 2.069(6), Pt(1)–N(8) 2.064(7), Pt(1)–Cl(1) 2.3137(10), N(7)–Pt(1)–N(8) 180.000(1), N(7)–Pt(1)–Cl(1) 89.85(3), N(8)–Pt(1)–Cl(1) 90.15(3). The geometry of the Hmura ring does not differ significantly from published data.[7]

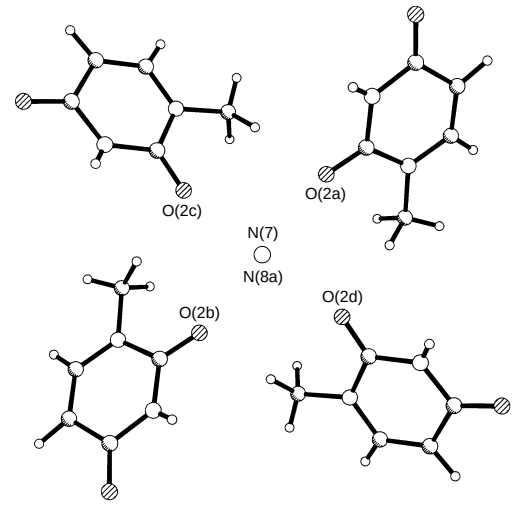

**Fig. 2** View of quartet I; N(7) and N(8) ammine groups are 1.636(7) Å above and 1.810(7) Å below the plane formed by the four O(2) oxygen atoms

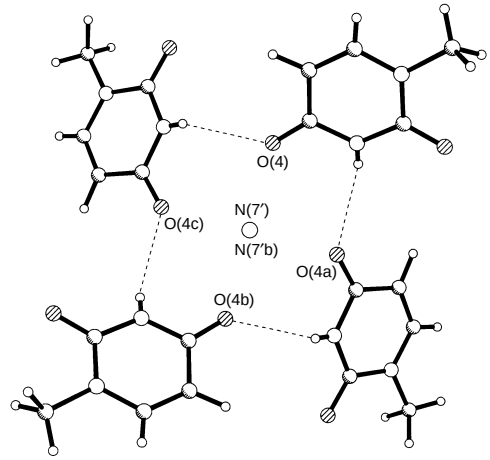

**Fig. 3** View of quartet II with cyclic N(3)H···O(4) hydrogen bonds indicated. The N(7′) ammine groups of Pt(1) are 1.751(5) Å each below and above the plane formed by the four O(4) oxygen atoms. The four uracil bases are markedly non-planar and form angles of 44° between each other.

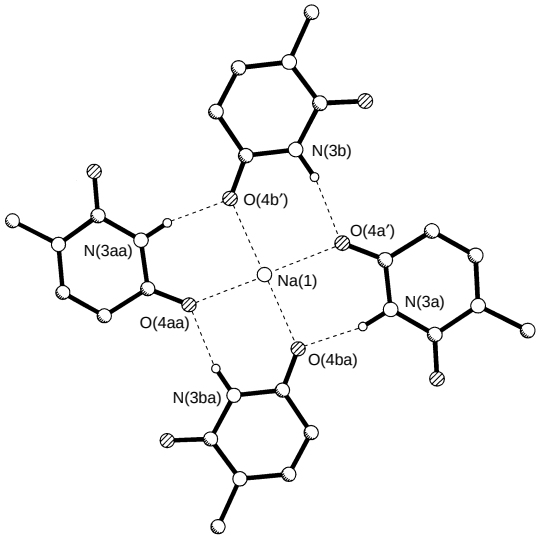

**Fig. 4** View of quartet III as found in $[Na(Hmura)_4][AuCl_4]$. The four Hmura bases are coplanar with Na(1). The protons at the N(3) sites are at calculated positions. Selected interatomic distances (Å): O(4a′)···N(3b) 2.83(2), O(4a′)···O(4b′) 3.28(2), O(4a′)···Na(1) 2.336(7), O(4b′)···Na(1) 2.301(8).

The difference in hydrogen-bond formation between Hmura [pairwise N(3)H···O(4) hydrogen bonds of 2.814(2) Å] and that observed in $[PtCl_4(NH_3)_2]\cdot 2$Hmura is also reflected in differences in the IR spectra.§

In the course of this work, it occurred to us that we had, without recognizing it then,[8] prepared a planar uracil quartet III already two years prior to the first report of $U_4$ in a RNA tetraplex.[2] In $[Na(Hmura)_4][AuCl_4]$[8] (Fig. 4) the four O(4) oxygens form a square of 3.28 Å and four hydrogen bonds, between N(3) and O(4) sites of *ca.* 2.83 Å, with $Na^+$ in the center.

In summary, the apparent ease of quartet formation of Hmura in the presence of suitable partners (Pt–$NH_3$ groups, $Na^+$) suggests that $U_4$ structures in RNA may be more readily formed than generally anticipated. Stabilization may not only be brought about by a $G_4$ support and/or alkali-metal ion binding, but also by additional hydrogen bonding. The $NH_3^+$ group of lysine, which is ubiquitous in many nucleic acid binding proteins, could be a candidate in this respect. Finally, $[PtCl_4(NH_3)_2]\cdot 2$Hmura represents, to the best of our knowledge, the first example of a neutral metal ammine complex interacting with a nucleobase in a specific manner. Hydrogen bonding of cationic metal complexes, *e.g.* of $[Co(NH_3)_6]^{3+}$ with DNA is known to have dramatic effects on the DNA stucture.[9]

We thank the Deutsche Forschungsgemeinschaft (DFG) and the Fonds der Chemischen Industrie (FCI) for financial support of this work.

† *trans*-$[PtCl_4(NH_3)_2]\cdot 2$Hmura was obtained in two ways: (*a*) *trans*-$[Pt(NH_3)_2$(mura-$N^3$)$_2]$ (0.65 mmol; obtained from *trans*-$[Pt(NH_3)_2(H_2O)_2][NO_3]_2$ and 2–3 equiv. of Hmura in a similar way to the *cis*-isomer)[10] was suspended in water (10 ml) at 40 °C; 4 M HCl (4 ml) was added dropwise until all the solid was dissolved. Heating was continued for 1 h and a pale yellow precipitate {*trans*-$[PtCl_2(NH_3)_2]$ identified by IR spectroscopy} was removed by filtration. Slow evaporation of the filtrate at room temp. gave crystals of *trans*-$[PtCl_4(NH_3)_2]\cdot 2$Hmura in 12% yield. Oxidation has apparently been brought about by air. Satisfactory elemental analyses were obtained for C, H and N {*trans*-$[PtCl_4(NH_3)_2]\cdot 2$Hmura, $C_{10}H_{18}Cl_4N_6O_4Pt$. Found (Calc.) C, 19.1 (19.27); H, 2.9 (2.91); N, 13.5 (13.49)%}.

(*b*) To a solution of *trans*-$[PtCl_4(NH_3)_2]$[11] (0.3 mmol) in water (10 ml) was added Hmura (0.6 mmol); the mixture was briefly heated until all solid material had dissolved. Slow evaporation at room temp. gave crystals of *trans*-$[PtCl_4(NH_3)_2]\cdot 2$Hmura (identified by IR spectroscopy) in 93% yield.

‡ *Crystal data*: $C_{10}H_{18}Cl_4O_4N_6Pt$; $M$ = 623.19, tetragonal, space group $P4/n$, $a = b$ = 15.496(2), $c$ = 7.580(2) Å, $U$ = 1820.2(6) Å$^3$, $Z$ = 4, $F(000)$ = 1192; $D_c$ = 2.274 Mg m$^{-3}$; $\mu$(Mo-K$\alpha$) = 8.326 mm$^{-1}$ yellow cube; size, 0.15 × 0.15 × 0.15 mm. Data collection and processing: Enraf-Nonius-Mach3 diffractometer (graphite-monochromated Mo-K$\alpha$ radiation), $T$ = 293(2) K; $\omega$–2$\theta$ scans; $\theta$ range 2.63–24.97°; index ranges $-13 \leqslant h \leqslant 18$, $-13 \leqslant k \leqslant 18$, $0 \leqslant l \leqslant 9$; 3280 reflections measured, 1600 independent ($R_{int}$ = 0.0259); 1356 observed [$F_o > 4\sigma(F_o)$]. Structure solution and refinement: Patterson syntheses (SHELXS-86[12]), full-matrix least squares on $F^2$ (SHELXL-93[13]); hydrogen atoms found in difference Fourier synthesis and refined isotropically, all other atoms anisotropic; 140 parameters refined; empirical absorption correction ($\psi$-scans); min., max. corrections 0.5515, 0.9972; $R_1$ = 0.0306; $wR_2$ = 0.0496 (all data); max., min. residual electron density 0.596, −0.764 e Å$^{-3}$. Atomic coordinates, bond length and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). Any request to the CCDC for this material should quote the full literature citation and the reference number 182/505.

§ The IR spectrum of *trans*-$[PtCl_4(NH_3)_2]\cdot 2$Hmura (KBr pellet; Bruker FTIR spectrometer IFS 28) and that of Hmura[14] differ, as expected, but the former is not a simple superposition of spectra of Hmura and *trans*-$[PtCl_4(NH_3)_2]$.[15] This is particularly well seen in the 900–700 cm$^{-1}$ region, *e.g.* Hmura: 870s (br), 805s, 757s, 722m; *trans*-$[PtCl_4(NH_3)_2]$: 878m (br); *trans*-$[PtCl_4(NH_3)_2]\cdot 2$Hmura: 823s, 782s, 758m, 738w, 719m. Similarly, in the Raman spectra (solid state; Jobin Yvon, T 64000; Spectra Physics laser, $\lambda$ = 514.5 nm) both the intense $\nu$(Pt–Cl) and $\nu$(Pt–N) modes[15] of *trans*-$[PtCl_4(NH_3)_2]$ and the characteristic Hmura ring modes have undergone shifts as compared to the pure components.

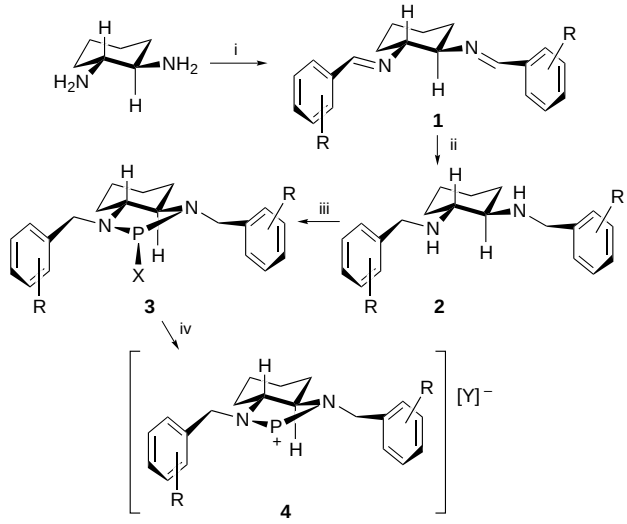
# Chiral phosphorus(III) triflates†

**Victoria A. Jones, Mark Thornton-Pett and Terence P. Kee***



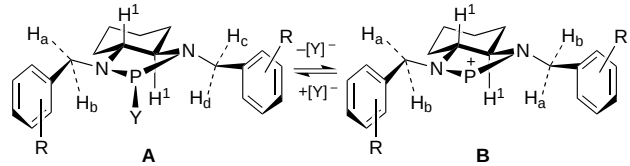
*School of Chemistry, University of Leeds, Woodhouse Lane, Leeds, UK LS2 9JT*

**A $C_2$-symmetric bicyclic diazaphospholidine framework supports a phosphorus centre within an inherently chiral environment which displays both solution- and solid-phase behaviour consistent with ambiphilic phosphenium character.**

In recent years, chemists have become increasingly interested in main-group analogues of carbenes,[1] principally those of Si,[2] Ge,[3] Sn,[4] As[5] and P.[6] Indeed of these heterocarbenes, the phosphorus analogues, $\sigma^2\lambda^3$ phosphenium cations, have received significant attention over the past 20 years and much is known of their organic and coordination chemistry.[7] However, we report here a class of phosphenium compound which possesses the significant 'added value' of chirality; an effective $\sigma^2\lambda^3$ phosphorus atom possessing both electrophilic and nucleophilic properties contained within a chiral, $C_2$-symmetric, coordination sphere; an environment which, for the first time, opens up significant possibilities in asymmetric synthesis, analysis and catalysis.[8]

The appropriate synthetic procedures are outlined in Scheme 1.[9]

Various experiments shed light upon the nature of the interaction between phosphorus and trifluoromethylsulfonate (triflate) in **4a**[OTf]. A single $^{31}$P NMR resonance is observed at $\delta$ +271.1 (0.54 mol dm$^{-3}$, 300 K, $CH_2Cl_2$), well within the range expected for two-coordinate phosphenium cations ($\delta$ 110–515)[7] along with intriguing, non-linear concentration-dependent $^{31}$P NMR behaviour at room temp.; a 24-fold increase in concentration from 0.025–0.6 M results in a $\Delta\delta$ of +5.98 ppm. We interpret such behaviour as evidence of a dynamic interaction between phosphorus and triflate oxygen(s) at room temperature leading to a more 'naked' phosphenium cation with slightly lower frequency $\delta_P$ at higher dilution. Consistently, $^{31}$P NMR chemical shifts of **4a**[OTf] (0.3 mol dm$^{-3}$, $CH_2Cl_2$), reveal a linear dependence upon temperature between 295 K ($\delta_P$ 269.2) and 203 K ($\delta_P$ 274.2) with a slope of $-5.4 \times 10^{-2}$ ppm K$^{-1}$; higher temperatures presumably favouring uncoordinated phosphenium cation as suggested by the low-frequency perturbation of $\delta_P$. This behaviour contrasts with the configurationally stable $\sigma^3\lambda^3$ phosphorus derivative **3a**-Ph which shows linear behaviour but in the opposite direction with $\Delta\delta$ of +4.2 ppm between 203 and 298 K and slope $+4.6 \times 10^{-2}$ ppm K$^{-1}$.



**Scheme 1** *Reagents and conditions*: i, ArCHO; Ar = functionalised phenyl (Ph **a**, 4-NMe$_2$C$_6$H$_4$ **b**, 1-C$_{10}$H$_7$ **c**, 2-C$_{10}$H$_7$ **d**, 4-MeOC$_6$H$_4$ **e**); ii, LiAlH$_4$, thf; iii, PX$_3$ (X = Cl, Br, I), NEt$_3$ (2 equiv.); iv, AlCl$_3$ or Me$_3$SiOSO$_2$CF$_3$ (TMSOTf). [Y] = [AlCl$_4$]$^-$, [OTf]$^-$

Further evidence for a dynamic interaction between phosphorus and triflate in **4a**[OTf] is revealed upon examination of the $^1$H NMR spectrum. Should **4a**[OTf] possess a static covalent or slowly exchanging configuration at phosphorus, then the methylene hydrogens on each benzyl substituent (H$_a$, H$_b$) should express themselves as two distinct [ABX] patterns (Scheme 2; **A**, X = P Y = triflate). Indeed, in the configurationally fixed derivative **3a**-Ph (Y = Ph; Scheme 2; **A**, Y = Ph), two [ABX] patterns are indeed observed centred at $\delta$ 4.31 ($^2J_{HH}$ 14.7, $^3J_{PH}$ 14.6 Hz) and 3.67 ($^2J_{HH}$ 14,9, $^3J_{PH}$ 12.7 Hz). However, between 300 and 200 K only a single [ABX] pattern is observable for the methylene hydrogens of **4a**[OTf] centred at $\delta$ 4.55 ($^2J_{HH}$ 14.5, $^3J_{PH}$ 11.3 Hz), behaviour consistent with local $C_2$ symmetry at the phosphorus atom of **4a**[OTf] caused presumably by rapid exchange of coordinated (Scheme 2, **A**) and uncoordinated triflate (Scheme 2, **B**). It is possible to perturb the interaction between phosphorus and triflate in solution *via* $^{31}$P NMR titration experiments. Thus, addition of 10 equiv. of NBu$^n_4$[OTf] to a $CH_2Cl_2$ solution of **4a**[OTf] (0.02 mol dm$^{-3}$, 300 K) results in a small perturbation to $\delta_P$ $\Delta\delta$ of +4.4 ppm.

Presumably, this perturbation reflects a dynamic process such that higher concentrations of triflate favour increased interactions with phosphorus and consequently, a shift in $\delta_P$ to high frequency.

$^{19}$F NMR and solution conductivity studies are also supportive of this conclusion. Variable-temperature $^{19}$F NMR studies on **4a**[OTf] ($CD_2Cl_2$, 203–293 K, referenced to $C_6F_6$ at $\delta$ −162.9) reveal behaviour which parallels that of ionic NBu$^n_4$[OTf] more closely than covalent Me$_3$SiOTf (Fig. 1). Me$_3$SiOTf and NBu$^n_4$[OTf] possess solution molar conductivities $\Lambda$ (thf, 296 K, 0.11 mol dm$^{-3}$) of 0.03 and 3.14 $\Omega^{-1}$ cm$^2$ mol$^{-1}$, respectively, whilst the corresponding measurements under the same conditions for **4a**[OTf] reveal a molar conductivity $\Lambda$ of 0.43 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. It is clear that **4a**[OTf], although formally a weak electrolyte and less conducting than the ionic triflate NBu$^n_4$[OTf], is a stronger electrolyte than Me$_3$SiOTf by a factor of 14; consistent with significant yet dynamic solution interaction between phosphorus and trfilate in **4a**[OTf].[10]

A single-crystal X-ray study of racemic **4a**[OTf] reveals a formally two-coordinate trivalent phosphorus centre in which

**Scheme 2** Relationship between coordinated (**A**) and uncoordinated (**B**) in **4**[Y]; Y = *e.g.* [AlCl$_4$]$^-$, [O$_3$SCF$_3$]$^-$, [C$_5$H$_5$N]

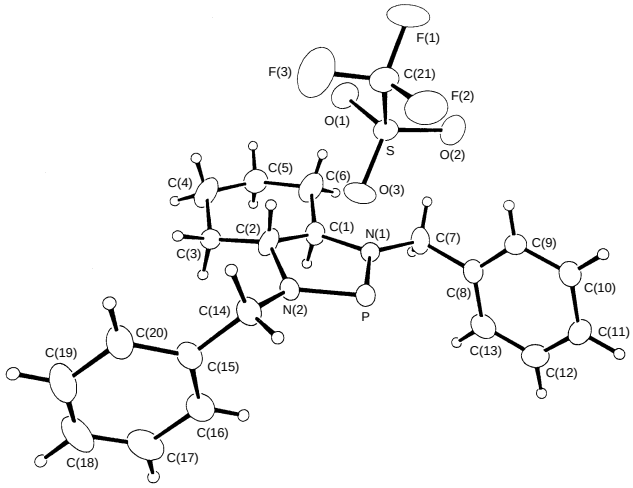

**Fig. 2** Molecular structure of **4a**[OTf] with atom numbering scheme. Selected bond lengths (Å) and angles (°): P–N(1) 1.616(3), P–N(2) 1.625(3), N(1)–C(1) 1.465(5), N(1)–C(7) 1.468(5), N(2)–C(2) 1.470(5), N(2)–C(14) 1.469(5), P–O(1) 2.841(5), P–O(3′) 2.755(5). N(1)–P–N(2) 94.9(2), C(1)–N(1)–C(7) 119.6(3), C(1)–N(1)–P 113.5(3), C(7)–N(1)–P 126.5(3), C(2)–N(2)–C(14) 121.0(3), C(2)–N(2)–P 112.8(3), C(14)–N(2)–P 121.4(3).

both nitrogen atoms possess significant $sp^2$ character as evidenced by their trigonal-planar environment, the deviations of N(1) and N(2) from the best-fit planes connecting atoms P(1)C(1)C(7) and P(1)C(2)C(14) are −0.05 and +0.19 Å, respectively [sum of angles around N(1) and N(2), 359.6 and 355.2°, respectively (Fig. 2)]. Such trigonal planarity is expected to facilitate effective delocalisation of formal positive charge on phosphorus through P–N π-bonding. Arguably the most interesting features are connected with the phosphorus–triflate interaction. P(1) has close contacts to one oxygen atom of each of two triflate groups in the crystal at distances of 2.841 and 2.755 Å; these interactions are well within the van der Waals distance for a phosphorus–oxygen interaction (*ca*. 3.35 Å) but are nevertheless > 1 Å longer than expected for a single P–O covalent bond (*ca*. 1.63 Å).[11] Furthermore, the two O–P bond vectors are directed along the axes expected for interaction with opposite lobes of a vacant phosphorus 3p orbital of a formally $\sigma^2\lambda^3$ phosphenium cation [the angles between the P–O vectors and normals to the plane N(1)P(1)N(2) are 11.5 and 10.2°]. The conclusion from the solid state is that phosphorus–triflate interactions are present although likely to be significantly weaker than for a formal P–O single covalent bond,[12] in agreement with solution data.

Ambiphilic behaviour may be demonstrated for **4a**[OTf] by its interaction with (*i*) $BH_3$·thf to afford a species with a direct P–B linkage, presumably {*N*,*N*′-[*trans*-1,2-$C_6H_{10}(NCH_2Ph)_2$]-$PBH_3$(thf)}[OTf] ($\delta_P$ 96.2, peak separationn 85 Hz resulting from $^1J_{PB}$, thf, 0.34 mol $dm^{-3}$) and (*ii*) pyridine to afford the adduct {*N*,*N*′-[*trans*-1,2-$C_6H_{10}(NCH_2Ph)_2$]P-$NC_5H_5$}[OTf] ($\delta_P$ 168.3, $CH_2Cl_2$, 0.075 mol $dm^{-3}$).[12] Variable-temperature $^{19}F$ NMR experiments on the latter reveal behaviour commensurate with ionic triflate character (Fig. 1) whilst $^1H$ NMR spectroscopy reveals that pyridine exchange is rapid on the NMR timescale at 300 K; a single [ABX] pattern being observed for the benzyl methylene hydrogens. We are currently building upon these preliminary observations to examine the potential of chiral phosphenium salts such as **4a**[OTf] in asymmetric synthesis, analysis, coordination chemistry and catalysis.

We thank the EPSRC for financial support, Albright and Wilson Ltd, for generous gifts of chemicals, Dr Mimi Hii (Dyson Perrins) for several valuable suggestions and Professeur Sylvain Juge (Cergy-Pontoise, France) for most enlightening exchanges of information.

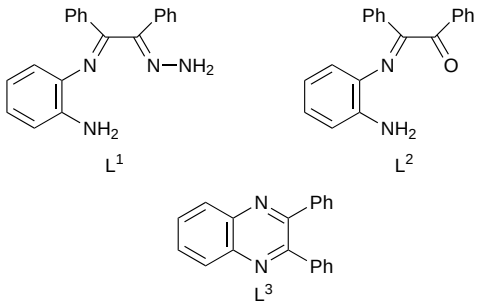
# First example of a copper(I)–water bond. Synthesis and structure of polymeric poly-μ-2,3-diphenylquinoxaline–(aqua)copper(I) cation

**Jnan P.Naskar,[a] Sanchita Hati,[a] Dipankar Datta*[a] and Derek A. Tocher*[b]**

[a] *Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India*
[b] *Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*



**The perchlorate salt of the poly-μ-2,3-diphenylquinoxaline(aqua)copper(I) cation containing a discrete $Cu^+$–$OH_2$ bond is synthesised and characterised structurally.**

In terms of Pearson's hard–soft classification of Lewis acids and bases, $Cu^+$ is generally accepted as 'soft' while $H_2O$ is 'hard'.[1] Consequently, according to the hard–soft acid–base (HSAB) principle of Pearson,[1–3] there is an inherent incompatibility between the $Cu^+$ ion and $H_2O$. This statement is supported by the experimental observation that the $Cu^+$ ion disproportionates in water ($\log K = 6.00$) into metallic copper and $Cu^{2+}$ [eqn. (1)].[4] Hence while water is a very common ligand in the

$$2Cu^+ \overset{K}{\rightleftharpoons} Cu^{2+} + Cu^0(s) \quad (1)$$

chemistry of the 'borderline' $Cu^{2+}$ ion, ligation of water to a copper(I) center is hitherto unknown.[5] However, the HSAB principle only considers relative stability and does not preclude the possibility of a bond between $Cu^+$ and $H_2O$ altogether. Herein for the first time we report a copper(I) complex having a discrete $Cu^+$–$OH_2$ bond.

The novel copper(I) complex has been obtained during attempts to develop the copper(II) chemistry of the Schiff base $L^1$ of 1,2-phenylenediamine (opda) and benzilmonohydrazone (bmh). When copper(II) perchlorate hexahydrate is reacted with an equimolar quantity of $L^1$, generated *in situ* in ethanol, the C=N bonds are hydrolysed giving rise to $L^2$ and free hydrazine, opda and benzil. Subsequently $L^2$ cyclises with the elimination of a water molecule resulting in formation of 2,3-diphenylquinoxaline $L^3$. Reaction of opda with benzil also yields $L^3$.[6] The hydrazine formed *in situ* reduces $Cu^{2+}$ to $Cu^+$. One of the products isolated from this reaction mixture is the perchlorate salt of the polymeric cationic copper(I) complex of $L^3$ and water, $\{[CuL^3(H_2O)]ClO_4 \cdot 0.5C_2H_5OH\}_n$ **1**. Subsequent investigation demonstrates that compound **1** is formed in good yield by reaction of copper(II) perchlorate hexahydrate with $L^3$ in the presence of excess hydrazine hydrate.†

Compound **1** is diamagnetic and orange–red [$\lambda_{max}$ (Nujol mull): 390 nm]. It is indefinitely stable in air in the solid state. However, in solution, it is almost immediately oxidised to give a faint green solution. Its structure, as revealed by X-ray crystallography,‡ consists of an infinite polymeric chain cation (Fig. 1), where adjacent copper(I) centers are bridged by the aromatic nitrogens of $L^3$, and perchlorate anions which are not coordinated to the copper. Each copper atom is coordinated through nitrogen to two molecules of $L^3$ and a water molecule completes the coordination sphere (Fig. 2). The coordination of the copper is best described as distorted linear $CuN_2$ with a weak interaction with water. Alternatively the coordination might be viewed as distorted trigonal planar. The three angles around copper vary considerably from those expected in a regular environment [N(1)–Cu(1)–N(2) 152.5(2)°, N(1)–Cu(1)–O(1) 107.6(2)°, N(2)–Cu(1)–O(1) 99.8(2)°]. There is no precedent for a $Cu^+$–$OH_2$ bond in the literature with which the Cu(1)–O(1) bond length [2.154(6) Å] observed here can be compared. However, from the bond valence sum models,[7,8] in a symmetric $CuO_3^+$ chromophore, the ideal $Cu^+$–O bond length is calculated to be 1.99 Å. Thus the Cu(1)–O(1) bond in **1** is longer than expected. On the other hand, the $Cu^+$–N bonds [Cu(1)–N(1) 1.952(4) Å, Cu(1)–N(2) 1.968(5) Å] in **1** are slightly shorter than that expected (1.98 Å) for a symmetric $CuN_3^+$ moiety.

Compound **1** provides a rare example of a copper(I) complex with a neutral oxygen donor coordinated to the metal. There are, to the best of our knowledge, only two other examples[9,10] and in these the O donor atom belongs to acetone, which is much

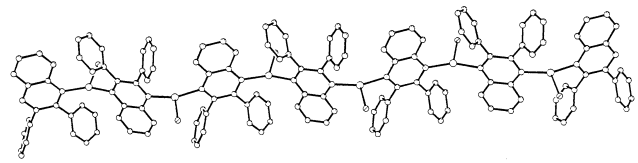


**Fig. 1** The polymeric cation in **1**; H atoms are omitted for clarity

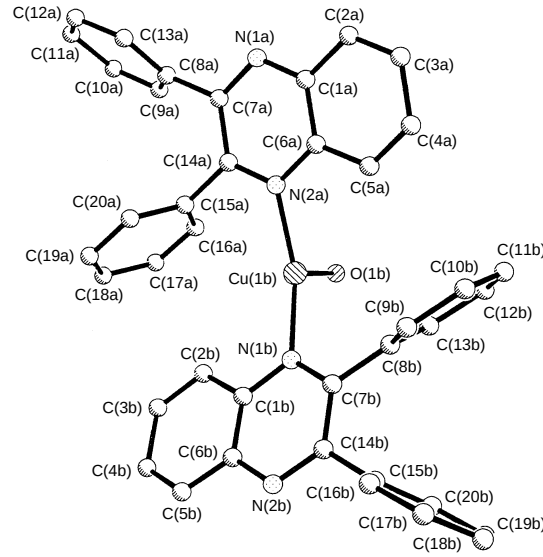

**Fig. 2** The coordination sphere of the copper(I) ion in **1**; H atoms are omitted for clarity

'softer' than water. It may be noted in passing that the $Cu^+$ ion does not disproportionate in acetone to any significant extent (log $K$ − 1.50).[4]

† A 5 ml ethanolic solution of 0.370 g (1 mmol) of $Cu(ClO_4)_2·6H_2O$ was added to a 20 ml ethanolic solution of 0.282 g of L[3] (1 mmol). The resulting bluish green solution was heated to boiling. To this hot solution, 0.05 ml of hydrazine hydrate (4 mmol) diluted in 5 ml of ethanol was added dropwise with constant stirring. The resulting deep orange reaction mixture was stirred for 5 min and then left in the air. (Initially a small amount of white precipitate appeared which dissolved during stirring.) After 30 min, the deep orange–red crystalline compound precipitated was filtered, washed with 2 ml of ethanol and dried *in vacuo* over fused $CaCl_2$. Yield, 0.290 g (60%). Satisfactory analytical data was obtained.

‡ *Crystal data* for $C_{21}H_{19}ClCuN_2O_{5.5}$ **1**: $M_w$ = 486.37, orthorhombic, space group $P2_12_12$, $a$ = 12.996(3), $b$ = 17.392(3), $c$ = 9.183(2) Å, $U$ = 2075.6(7) Å$^3$, $Z$ = 4, $D_c$ = 1.56 g cm$^{-3}$, $\mu$ = 1.22 mm$^{-1}$. 2685 reflections collected on an automated four-circle diffractometer (Nicolet R3mV; Mo-Kα, $\lambda$ = 0.710 73 Å, 2$\theta$ 5–55° at 20 °C) and were corrected for Lorentz and polarisation effects, and empirically for absorption. The structure was solved by Patterson methods (SHELXS-86[11]) and refined using alternating least-squares and difference-Fourier techniques (SHELXL-93,[12] refinement based on $F^2$). In the latter stages a disordered solvent molecule (ethanol) was observed to lie about the twofold axis at (1.0, 0.5, $z$). The best refinement was obtained with a net occupancy of 0.5 for this molecule. The non-hydrogen atoms (except those of the ethanol) were refined anisotropically while the hydrogens of the organic ligand were placed in idealised positions. The final cycle of least-squares refinement included 268 parameters and did not shift any parameter by more than 0.01 times its standard deviation. The final residuals were $R$ = 0.0564 and $wR_2$ = 0.1538, observed data [$I \geqslant 2\sigma(I)$] and $R$ = 0.0675 and $wR_2$ = 0.1742, for all data. The absolute structure was determined using SHELXL-93 procedures [absolute structure parameter −0.02(3)]. CCDC 182/520.

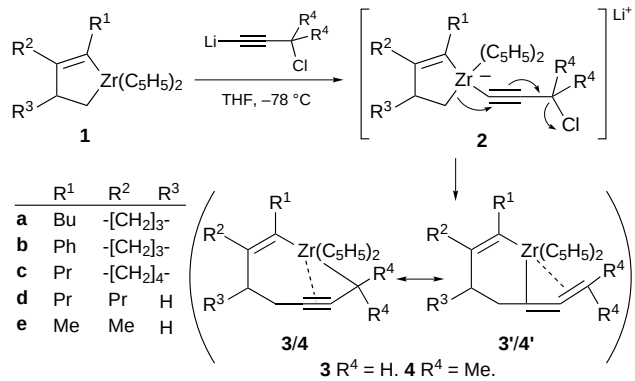
# Tandem insertion of allenyl carbenoids and aldehydes into zirconacycles: an unexpected cyclisation

**George J. Gordon and Richard J. Whitby***

*Department of Chemistry, Southampton University, Southampton, Hants, UK SO17 1BJ*

**Allenyl carbenoids (3-chloro-1-lithioalk-1-ynes) insert into zirconacyclopentanes and zirconacyclopentenes to afford cyclic η³-allenyl/prop-2-ynyl zirconocene complexes which give allenyl, alkynyl or cyclised-alcohol products on addition of aldehydes activated with boron trifluoride–diethyl ether.**

The formation of zirconacyclo-pentanes and -pentenes by co-cyclisation of 1,*n*-dienes and 1-en-*n*-ynes, or reaction of zirconocene η²-alkene or -alkyne complexes with alkenes or alkynes comprises a useful C–C bond forming method.[1] For efficient use in organic synthesis methods for further elaboration of the carbon–zirconium bonds in these intermediates are required. Carbonylation,[2] isocyanide insertion,[3] addition of aldehydes,[4] and copper catalysed reactions[5] have been reported recently. We have described the tandem insertion of lithium chloroallylides and a variety of electrophiles into mono- and bi-cyclic zirconacyclo-pentanes and -pentenes to provide highly elaborated organic products.[6] We have also reported the insertion of prop-2-ynyl carbenoids (1-chloro-1-lithioalk-2-ynes) into zirconacycles.[7] We now describe the tandem insertion of allenyl carbenoids (3-chloro-1-lithioalk-1-ynes) and aldehydes into zirconacycles to afford a variety of alkyne, allene, and unexpected cyclised products.

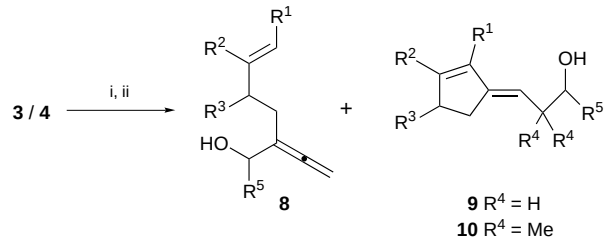


A variety of zirconacyclopentenes **1** were synthesised, either by intramolecular co-cyclisation of 1,6- or 1,7-enynes induced by zirconocene but-1-ene,[8] or by addition of alkynes to *in situ* generated zirconocene ethylene.[9] After cooling to −78 °C, dropwise addition of 3-choroprop-1-yne followed by lithium 2,2,6,6-tetramethylpiperidide generated the unstable allenyl carbenoid, 1-lithio-3-chloroprop-1-yne, which underwent insertion into the alkyl C–Zr bond of the zirconacyclopentenes **1**, presumably *via* an 18 electron zirconate intermediate **2**, to afford the ring expanded products **3a–e** (Scheme 1). In the same way insertion of 1-lithio-3-chloro-3-methylbut-1-yne gave the zirconacycles **4a** and **4e**. The bonding in the zirconocene η³-prop-2-ynyl/allenyl complexes **3** and **4** may be described in terms of the two contributing resonance structures **3**/**4** and **3′**/**4′** (Scheme 1).[7,10] Relative contributions of the two structures vary. The $^{13}C$ NMR shifts of the prop-2-ynyl/allenyl components of **3a** ($\delta_C$ = 103.3, 104.3 and 46.8) and **4a** ($\delta_C$ = 127.9, 176.6 and 87.3) demonstrate the much greater contribution of the allenyl form when $R^4$ = Me. η³-Prop-2-ynyl/allenyl complexes of transition metals are rare, and have recently been reviewed.[11]

Protonation of **3a**,**b**, and **e** required several hours stirring with excess methanol and gave a mixture of terminal allene **5** and internal alkyne **6** products,† favouring the later (Scheme 1). Protonation of **4a** was fast, and gave exclusively the allene **7**.

Reaction of the η³-prop-2-ynyl complexes **3** and **4** with aldehydes activated with boron trifluoride–diethyl ether was examined. For example **3a** gave an excellent overall yield (based on the starting enyne) of the allenol **8a** ($R^5$ = Pr) when reacted with butyraldehyde (Scheme 2). The regiochemistry of addition to the η³-moiety is the opposite of that observed in the elaboration of analogous η³-allyl complexes.[6] Much to our surprise reaction of **3a** with benzaldehyde gave a quite different product which proved to be the cyclised dienol alcohol **9a** ($R^5$ = Ph). Generally, reaction of complexes **3** with alkyl aldehydes gave only the allene product **8**, whereas benzaldehyde gave either the dienol **9**, or a mixture of **8** and **9** (Table 1). The *gem*-dimethyl substituted complexes **4a** and **4e** gave only the dienols **10** with either aliphatic, or aromatic aldehydes (Table 1).

In addition to extensive NMR studies (including H–H and C–H COSY) on most of the allenol and dienol products, the structure of **9d** ($R^5$ = Ph) was further proven through degradation. Ozonolysis followed by dimethyl sulfide work-up gave undeca-4,5,8-trione and 3-phenyl-3-hydroxypropanal. The stereochemistry of the exocyclic alkene in **10e** ($R^5$ = Ph) was proven by NOE studies, in particular a 9.6% enhancement between the vinylic methyl group and the adjacent vinylic hydrogen. All the dienol products were formed as single isomers.



A likely mechanism for the cyclisation to afford the dienol products **9** and **10** is given in Scheme 3. Addition of the boron trifluoride complex of the aldehyde to the terminus of the prop-2-ynyl system generates both an alkyne, and a cationic

zirconium species. Intramolecular insertion of the pendant alkyne into the carbon–cationic zirconocene bond in **11** to give **12** has some precedent.[12] The final step, formation of the oxazirconacycle **13** (which is likely to be relatively stable towards hydrolysis), is speculation, but may explain why work-up with $D_2O$ or MeOD fails to give deuterated product (DCl causes decomposition).

Application of the tandem insertion of 1-lithio-3-chloroalk-1-ynes and aldehydes to zirconacyclopentane systems highlighted further reactivity and product selectivity variations. Co-cyclisation of hepta-1,6-diene using zirconocene but-1-ene gave the zirconacycle **14**. Insertion of 1-lithio-3-chloroprop-1-yne or 1-lithio-3-chloro-3-methylbut-1-yne afforded the ring expanded zirconacycles **15** and **16** respectively (Scheme 4). Addition of aldehydes activated with boron trifluoride–diethyl ether gave the bicyclic enol products **17** and/or the alkynols **18** (Table 2). Both products arise from insertion at the terminus of the prop-2-ynyl system in marked contrast to the results from unsaturated zirconacycles (Table 1). The structure of **17c** was proven by ozonolysis to give bicyclo[3.3.0]octan-3-one and 2,2,5-trimethyl-3-hydroxyhexanal, each prepared by independent synthesis.

In summary, we have shown that the insertion of 1-lithio-3-chloroalk-1-ynes (allenyl carbenoids) into zirconacyclopentenes and pentanes affords unusual cyclic $\eta^3$-prop-2-ynyl/allenyl complexes. Further elaboration by the addition of boron trifluoride activated aldehydes gives a variety of products, some of which result from intramolecular insertion into a proposed intermediate cationic zirconocene.

We thank the EPSRC for a quota award. R. J. W. thanks Pfizer UK and Zeneca for generous uncommitted financial support.

**$Cu^{I}$ ions and ligand L self-assemble to generate in solution a mixture of the double helical 1, triangular 2 and square grid 3 complexes, from which 1 has been crystallized and its crystal structure determined.**

Within the field of supramolecular inorganic chemistry, self-assembly provides direct access to complex architectures comprising spatially and geometrically well defined arrays of metal ions.[1,2] Widely diverse morphologies have been obtained, such as helicates,[1,2c] pseudorotaxane racks,[3] ladders,[4] grids,[5] rings[6] and cages.[7] In order to design species presenting specific structural and functional features, it is of great importance to establish the rules by which control of the self-assembly process can be achieved through chemical programming by means of suitable components and assembling algorithms. Mixtures of ligands and metal ions that combine preferentially into one out of a range of possible self-assembled species provide an opportunity for studying how ligand design and choice of metal ion can influence the product distribution and thus the self-assembly pathway.[6,8]

On the other hand, mixtures of ligands and metal ions may yield mixtures of complexes resulting from the reversible combination of the different constituents. Such a situation represents a process of dynamic combinatorial chemistry (DCC) of inorganic supramolecular type, making potentially available a wide variety of combinations representing the members of a virtual combinatorial library (VCL).[6a,b,9] Of special interest is then the possibility to select and express a given member of the VCL for specific purposes, for instance by means of external factors. In the inorganic domain, such behaviour has been observed in the assembly of circular helicates.[6a,b]

We present here a case where a mixture of a ligand and of metal ions yields in solution a collection of self-assembled species, from which a single product can be isolated in the solid state by appropriate adjustment of the conditions.

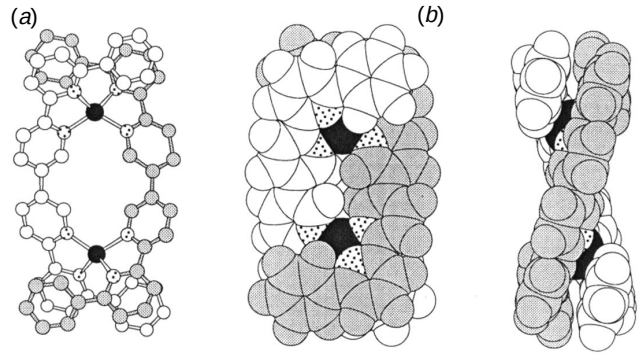
When nitromethane was added to a 1 : 1 mixture of ligand L† and $[Cu(MeCN)_4]PF_6$ and the mixture stirred at ambient temperature under argon for 24 h, a dark brown–orange colour rapidly developed indicative of the coordination of $Cu^{I}$ to L. Removal of solvent under vacuum yielded a dark brown solid which upon analysis by electrospray mass spectrometry showed clearly the formation of the oligomeric complexes $[Cu_nL_n]^{n+}$ ($n$ = 2, 3, 4) as the dominant species present at $1 \times 10^{-4}$ mol $dm^{-3}$ in $CH_2Cl_2$.‡ The $^1H$ NMR spectrum of the product in $CD_2Cl_2$ consisted of a complicated pattern of sharp peaks characteristic of an equilibrium mixture of slowly exchanging species. Detailed analysis of the data ($^1H$–$^1H$ COSY measurements) indicated the presence of three major species in proportions roughly equal to 6 : 4 : 3 for **1**, **2** and **3**, respectively. In addition a minor compound was also present (*ca.* 5%); the relative amounts appeared to be insensitive to changes in concentration. In $CD_3NO_2$ solution, the spectrum simplified to give nine broad bands corresponding to ligand L in a single chemical environment and indicative of medium-fast exchange between different copper(I) containing entities. In $CD_3CN$ solution, the peaks sharpened indicating rapid equilibration of the species on the NMR timescale.

When a nitromethane solution of the above reaction mixture was layered with benzene and left to stand, all the material present crystallised as large dark brown blocks. A crystal structure determination§ showed that the product was the binuclear complex **1** composed of two ligands L wrapped in a helical arrangement around two $Cu^{I}$ ions separated by 7.579 Å (Fig. 1). Both ligands are seen to be curved when viewed perpendicular to their mean planes and have therefore to adopt a strained conformation in order to coordinate both $Cu^{I}$ ions. There are four intramolecular stacking interactions (within 3.5 Å) between each phenyl ring and a terminal pyridine ring of the partner ligand. The coordination polyhedron about each $Cu^{I}$ ion is highly distorted and intermediate between tetrahedral and square-planar geometries, with Cu–N bond lengths of 2.017(9)–2.132(9) Å and N–Cu–N angles of 75.9(4)–78.8(4)° (chelate ring) and 110.9(4)–144.6(4)° (interligand). In addition, the crystals were found to be homochiral, so that the complex has undergone spontaneous resolution upon crystallisation.

Redissolution of the crystals in $CD_2Cl_2$ results in instant regeneration of a $^1H$ NMR spectrum identical to that of the crude reaction mixture prior to crystal growth as described above, showing that complex **1** rapidly opens in solution to form an equilibrium mixture of products. The proportions of each species and the preferential crystallisation of only **1** result from an interplay of enthalpic, entropic and crystal packing factors.

On the basis of the structure of **1** as well as of the spectrometric data, the other two substances present in solution may be considered to be the triangular complex **2** and the square [2 × 2] grid type structure **3** (Scheme 1).

In conclusion, a 1 : 1 combination of L with $Cu^{I}$ generates in solution an equilibrating mixture of the self-assembled inorganic architectures **1**, **2** and **3**, which converts into the single species **1** in the solid state upon crystallisation. These features represent an attractive illustration of a dynamic combinatorial chemistry process, yielding an inorganic supramolecular library of complexes from which a single member may be trapped by crystallisation. The latter result is also of interest with respect to



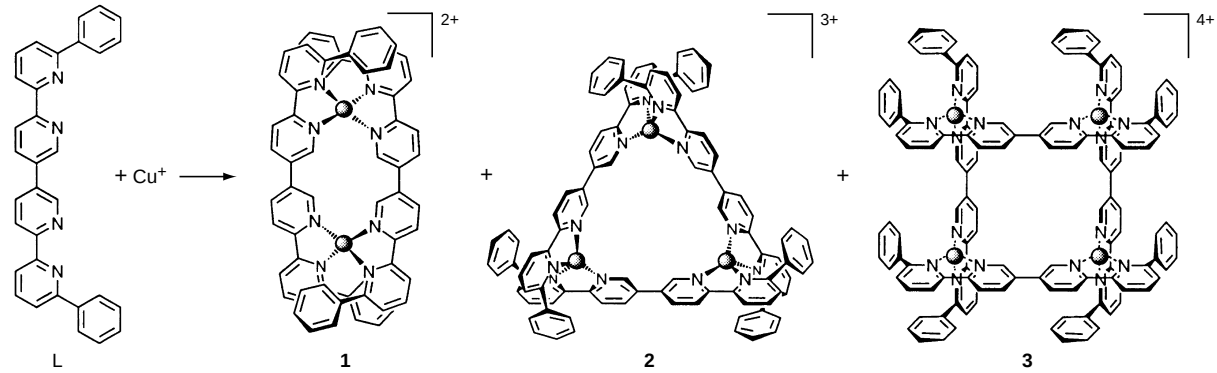


**Fig. 1** Crystal structure of the double-helical complex **1**; (*a*) ball-and-stick, (*b*) space-filling representations

**Scheme 1** Self-assembly of an equilibrating mixture of the double-helical **1**, triangular **2** and square [2 × 2] grid **3** complexes from L and $Cu^{I}$. Complexes **2** and **3** can in principle exist in different interwoven structures; only one structure is shown here.

crystal engineering and the investigation of the factors that dictate solid state selection processes.

We thank Annick Dupont-Gervais, Emmanuelle Leize and Alain Van Dorsselaer for the electrospray mass spectrometric measurements.

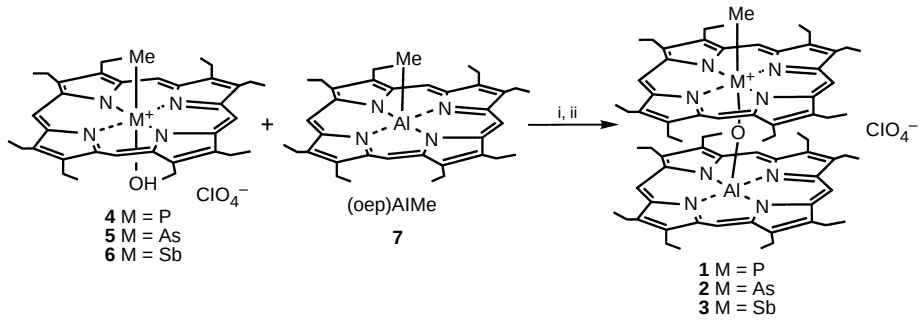
# Synthesis of μ-oxo-bridged group 15 element–aluminium heterodinuclear porphyrins [(oep)(Me)M–O–Al(oep)]$ClO_4$ (M = P, As, Sb) and X-ray crystal structure of [(oep)(Me)As–O–Al(oep)]$ClO_4$

**Go Yamamoto, Ryo Nadano, Wataru Satoh, Yohsuke Yamamoto* and Kin-ya Akiba***

*Department of Chemistry, Faculty of Science, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima, 739, Japan*

**μ-Oxo-bridged group 15 element–aluminium heterodinuclear porphyrins, [(oep)(Me)M–O–Al(oep)]$ClO_4$ (M = P, As, Sb), are synthesized by the reaction of [(oep)(Me)M(OH)]-$ClO_4$ with (oep)AlMe.**



μ-Oxo-bridged dinuclear porphyrins bearing a transition metal such as Fe, Ru, Mn, V, or Ti have been investigated extensively because of their relation to biological systems.[1,2] Recently, a μ-oxo-bridged dinuclear porphyrin skeleton containing boronic acids has been reported to be useful for molecular recognition of saccharides.[3] However, only a few synthetic methods are available for the synthesis of μ-oxo-bridged dinuclear transition-metal porphyrins, and μ-oxo-bridged dinuclear porphyrins bearing main-group elements have not been reported. Here we report a new synthetic route to μ-oxo-bridged group 15 element–aluminium heterodinuclear porphyrins, [(oep)(Me)M–O–Al(oep)]$ClO_4$ (M = P **1**, As **2**, Sb **3**), and the X-ray crystallographic structure of **2**.

Recently we reported that the hydroxy protons of [(oep)(R)-P(OH)]$^+X^-$ were relatively acidic and easily removed by treatment with DBU to generate (oep)(R)P=O which were stable, and the double bond character of the P=O bond was confirmed by an X-ray analysis of (oep)(Et)P=O. In fact, the p$K_a$ value of [(oep)(Et)P(OH)]$^+X^-$ was determined to be *ca.* 7–8 in water.[4] The corresponding arsenic porphyrins also showed similar behavior in acid–base treatment[5] although the corresponding antimony porphyrins did not show the formation of such double-bonded compounds.[6] Since aluminium porphyrins bearing an alkyl group are known to be reactive towards alcohols and phenols bearing acidic protons,[7] it was of interest to examine whether the acidic hydroxy groups in [(oep)(R)-M(OH)]$^+X^-$ (M = P, As) were reactive toward (oep)AlMe in spite of the anticipated steric hindrance.

To our delight the reaction of [(oep)(Me)P(OH)]$ClO_4$ **4** with (oep)AlMe **7** proceeded smoothly under reflux in dichloromethane for 1.5 days, and the expected μ-oxo-bridged P/Al heterodinuclear porphyrin **1** was isolated in 62% yield (Scheme 1). The compound was stable to atmospheric moisture and chromatographic treatment [neutral $Al_2O_3$, benzene–$CH_2Cl_2$–MeOH (15 : 6 : 1)] and characterization was carried out by elemental analysis and NMR spectroscopy.† The reaction of the corresponding arsenic porphyrin **5** with **7** proceeded slowly and **2** was obtained in 49% yield after 4 days in refluxing dichloromethane. The difference of the reactivity between **4** and **5** can be related to the acidity of the hydroxy group in **4** and **5**, **4** being more acidic than **5** since the methyl protons of **4** shifted upfield faster than those of **5** upon addition of DBU (in portions) to a mixture of **4** and **5** in $CDCl_3$. As expected, the reaction of the least acidic antimony porphyrin [(oep)(Me)-Sb(OH)]$ClO_4$ **6** with **7** was very sluggish and only 7% of **3** was obtained after 2 weeks in refluxing 1,2-dichloroethane. $^1$H NMR of the μ-oxo-bridged heterodinuclear porphyrin [(oep)-(Me)M–O–Al(oep)]$ClO_4$ showed characteristic methyl signals at very high fields ($\delta$ −7.96 in **1**, −7.94 in **2**, −7.92 in **3**) which were even higher than those of the starting [(oep)(Me)M-(OH)]$ClO_4$ ($\delta$ −5.79 in **4**, −5.63 in **5**, −6.13 in **6**) probably due to the ring current effect of the aluminium porphyrin nucleus.

Crystals of **2** suitable for X-ray analysis were obtained by recrystallization from dichloromethane–dibutyl ether. X-Ray structural analysis‡ of the compound was carried out on the basis of the centrosymmetric *C*2/*c* group, showing the required twofold axis passed through the C–As–O–Al bond. Fig. 1 shows an ORTEP drawing of a single molecule of **2** (solvent dichloromethane omitted for clarity). Since the As, O and Al atoms lie on the crystallographic twofold axis the As–O–Al bond is explicitly linear. The average torsional angle between N(1)–As–Al–N(3) and N(2)–As–Al–N(4) is 15.3°, the structure of **2** can be represented in terms of a near-eclipsed conformation.[2] The interplanar distance between the mean planes of the porphinato cores is 3.71 Å.

It is interesting that the As–O [1.690(3) Å] and Al–O [1.731(3) Å] bond distances in **2** are shorter than the As–O distance [1.826(6) Å] in **5**,[5] and the reported Al–O distance [1.789(3) Å] in [(diporphyrin biphenylene)CoAl(OEt)],[8] respectively. Similar shortening has been considered to be due to sp hybridization of the oxo oxygen and $d_\pi$(M)–$p_\pi$(O)–$d_\pi$(M)

**Scheme 1** *Reagents and Conditions:* i, see text; ii, $NaClO_4$, $CH_2Cl_2$, MeCN

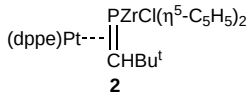
# Hydrozirconation of an η²-ligated phosphaalkyne. A new synthetic route to η²-ligated phosphaalkenes

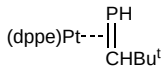


**Maria Helena A. Benvenutti, Nathalie Cenac and John F. Nixon***

*School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, Sussex, UK, BN1 9QJ*

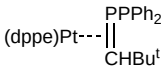
**The phosphaalkyne complex [Pt(dppe)(η²-Bu$^t$C≡P)] undergoes ready hydrozirconation with [ZrHCl(η⁵-$C_5H_5$)$_2$] to give the metallaphosphaalkene complex [Pt(dppe){η²-Bu$^t$CH=PZrCl(η⁵-$C_5H_5$)$_2$}] which is a useful precursor for the synthesis of η²-phosphaalkene complexes.**

The recent report of the formation of a phosphaalkenyl ruthenium(II) complex by hydroruthenation of the phosphaalkyne Bu$^t$C≡P[1,2] prompts us to describe the first examples of the facile conversion of the η²-ligated Bu$^t$C≡P by a synthetic route which offers considerable potential for the synthesis of a range of η²-ligated Bu$^t$CH=PX derivatives.



Thus treatment of [Pt(dppe)(η²-Bu$^t$C≡P)] **1**[3] with the Schwartz reagent, [ZrHCl(η⁵-$C_5H_5$)$_2$], quantitatively affords the η²-ligated metallaphosphaalkene complex [Pt(dppe){η²-Bu$^t$CH=PZrCl(η⁵-$C_5H_5$)$_2$}] **2** which occurs as a single isomer.†

**2**



It is interesting to note that the [ZrCl(η⁵-$C_5H_5$)$_2$] fragment adds solely to the phosphorus atom which is at the positive end of the dipole in uncoordinated Bu$^t$C≡P. Hydrozirconation of phosphaalkenes $R_2C{=}PR'$ has been the subject of a very recent review,[3] where it was pointed out that the course of these reactions depends strongly on the nature of the substituents attached to phosphorus or carbon.

Treatment of **2** with $H_2O$ at −60 °C in thf for 1 h readily affords the yellow η²-phosphaalkene complex [Pt(dppe)(η²-Bu$^t$CH=PH)] as a 3 : 1 mixture of *cis*- and *trans*-isomers **3a** and **3b**.‡ The uncoordinated phosphaalkene is unknown.

**3**

The synthetic potential of the intermediate **2** in the generation of other phosphaalkene complexes is illustrated by its reaction with $Ph_2PCl$ leading to ready elimination of [$ZrCl_2$(η⁵-$C_5H_5$)$_2$] and formation of the diphenylphosphino-phosphaalkene complex [Pt(dppe)(η²-Bu$^t$CH=P$Ph_2$)] **4** as a mixture of *cis*- and *trans*-isomers.§

**4**

The field of metallaphosphaalkene complexes has recently been reviewed by Weber[4] but the synthesis of **2** represents a new approach; furthermore as discussed elsewhere,[5] the reactivity of **2** towards halogeno-compounds offers considerable synthetic potential to generate other metallaphosphaalkene complexes by treatment with appropriate metal halides.

We thank both the EPSRC and the EEC/CNPq for their financial support of other aspects of phosphaalkyne chemistry research at Sussex.

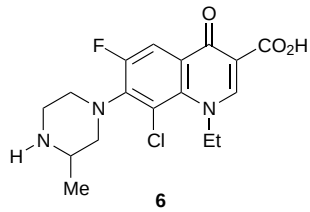
# The photochemistry of lomefloxacin. An aromatic carbene as the key intermediate in photodecomposition

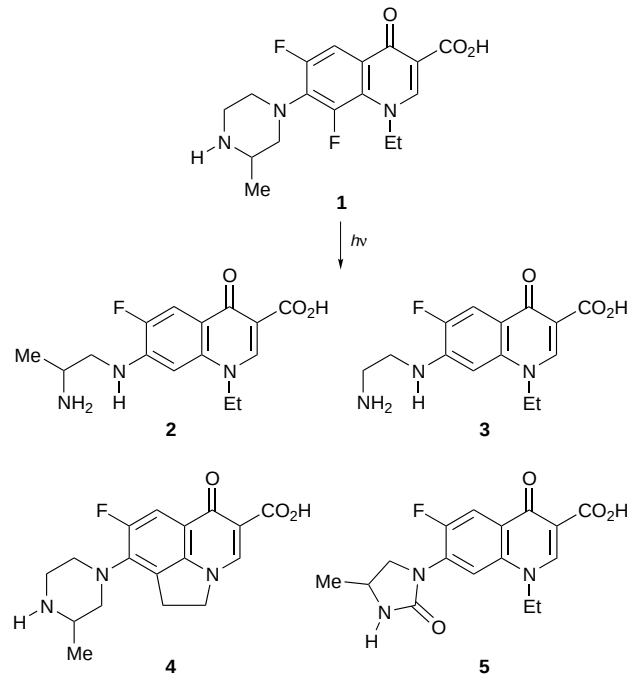


**E. Fasani, M. Mella, D. Caccia, S. Tassi, M. Fagnoni and A. Albini***

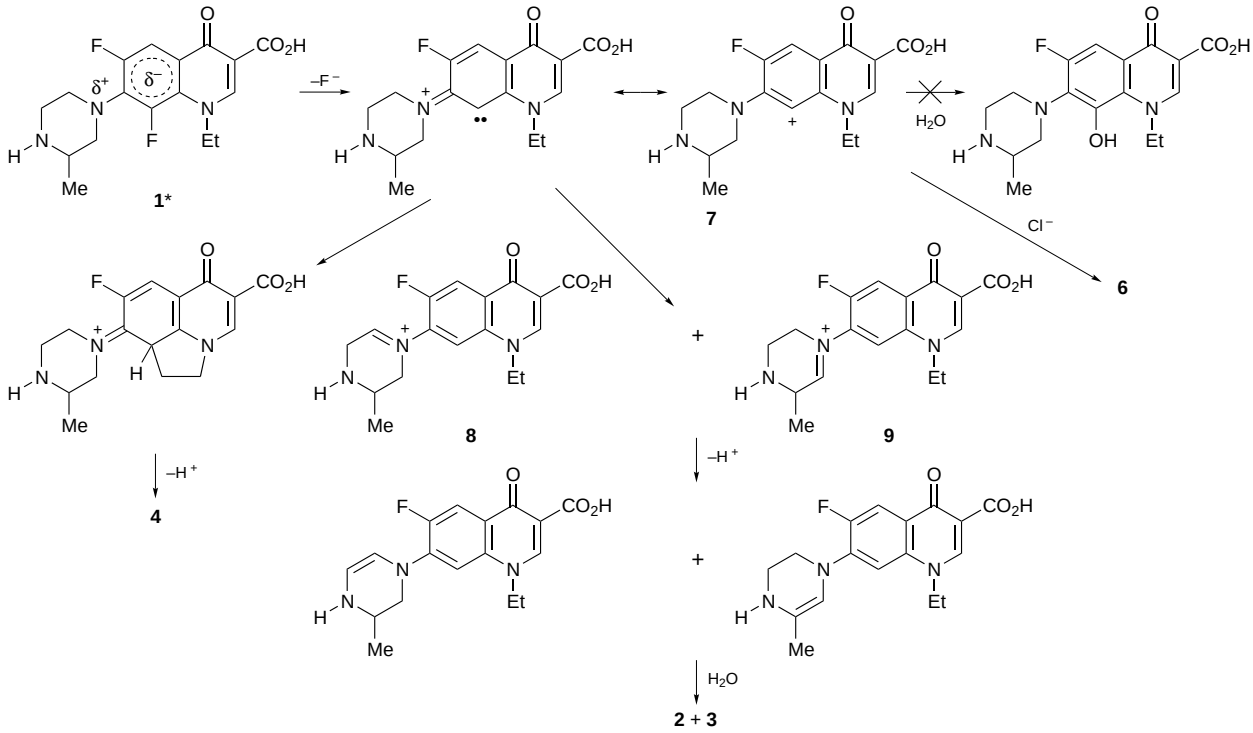
*Department of Organic Chemistry, University of Pavia, Via Taramelli 10, 27100 Pavia, Italy*

**Irradiation of the 6,8-difluoroquinolone antibiotic lomefloxacin causes selective heterolytic defluorination from position 8 and leads to products rationalized as arising from the cation either *via* nucleophile addition or intramolecular carbene C–H insertion and hydrogen transfer.**

The strong antibacterial activity of fluoroquinoles (FQ) has led to their large-scale use in medicine.[1] A major drawback of this relatively new class of antibiotics is their phototoxic effects.[2–8] There are indications that reactive oxygen species, such as singlet oxygen, superoxide anion or hydroxyl radical, play a role in some cases.[9–14] However, this is not necessarily the main mechanism underlying such an effect. As an example, it has recently been reported that in the case of lomefloxacin **1**, which is not only more phototoxic than other FQs but also more photomutagenic and carcinogenic,[15,16] the phototoxic effect is not related to singlet oxygen and superoxide anion generation[17] and furthermore photoinduced single strand breaks in plasmid DNA are actually *decreased* in the presence of oxygen.[18] This suggests that oxygen activation is not involved, and that a different mechanism operates; it has also been noted that fluoride ion is liberated during the photolysis of **1**.[18] An investigation of the photochemistry of **1** was thus warranted. As is shown in the following, a detailed product study demonstrates the unusual photochemical behaviour of this molecule and suggests a mechanism for the toxic and particularly the carcinogenic/mutagenic activity.



Irradiation ($\lambda$ > 310 nm) of lomefloxacin **1** ($10^{-4}$ M) in argon-flushed phosphate buffer (pH 7.4) up to 90% conversion gave several products. These were transformed into the corresponding *N*′-ethylcarbamates by treatment with ethyl chloroformate, extracted with chloroform, esterified by treatment with diazomethane and chromatographically separated. In this way, the main photolysis products were recognised as the two diamines **2** and **3**, accompanied by minor amounts of the tricyclic derivative **4** and a trace of the imidazolonyl derivative **5** (Scheme 1). Irradiation of the hydrochloride of **1** in argon-flushed water (pH 4.3) gave the 8-chloro derivative **6** as one of the main products.†



**6**

Inspection of **2**–**5** shows that two processes occurred in all cases, *viz* (i) reductive defluorination selectively at position 8, and (ii) modification of an *N*-alkyl chain, either the piperazinyl group (products **2**, **3** and **5**) or the 1-ethyl group (product **4**). Since the photoproducts are themselves FQs, competitive light-absorption by the products and the starting material occurred. However, when the irradiation was limited to a lower conversion (35%) the ratio of products was essentially the same. Furthermore, we found that **1** ($\Phi_{dec}$ 0.65) was far more sensitive to irradiation than all the monofluoro FQs we examined under these conditions ($\Phi_{dec}$ < 0.03) and also than compounds **2**–**5**, which are monofluoro derivatives. Thus, these products arose from a monophotonic reaction, and both processes (i) and (ii) occurred in a single reaction rather than *via* two sequential photoinitiated steps. Furthermore the product distribution was again similar in air-equilibrated solution. On the other hand, irradiation of the monohydrochloride omitting the buffer gave product **6**, conserving the piperazine ring intact and with substitution of a chloro group for the 8-fluoro atom.

The mechanism we propose is indicated in Scheme 2. The reaction proceeds from the short-lived singlet excited state and is by far the main decay path ($\Phi_{react} \approx 0.65$, $\tau_{fluo}$ < 1 ns, little influence of dissolved oxygen, thus $\Phi_{isc}$ is low and the triplet has little role in the reaction). Homolysis of the C–F bond is obviously out of question (bond dissociation energy C–F = 125 kcal $mol^{-1}$, energy of signlet excited **1** = 81 kcal $mol^{-1}$). Thus heterolytic loss of $F^-$ is involved, and the mechanism proposed must explain also the other modification occurring concurrently. The singlet state has an internal charge transfer character (strong Stokes shift, 6000 $cm^{-1}$) and the zwitterionic form is important in **1***. Loss of fluoride leads to cation **7**, for which mesomeric carbocationic and carbene forms can be considered. In phosphate buffer we isolated no product arising from the carbocation (such as phenols), but that product **6** formed when the nucleophile is chloride substantiates this path. On the other hand a striking indication for carbene reactivity comes from the structure of product **4**, obviously resulting from well precedented carbene C–H insertion[19] into the conforma-

**Scheme 1**

**Scheme 2**

tionally suitable δ position. Products **2** and **3** also arise from the carbene *via* intramolecular hydrogen transfer to give the rearranged cations **8** and **9**. These deprotonate to enediamines, which in turn are hydrolysed, whether in solution or during work up, to the observed diamines. Compound **5** also results from demolition of the piperazinyl chain coupled with defluorination.

There are only a few precedents for photoinduced defluorination in aromatic or heterocyclic chemistry, *viz* those of *N*-formyl-4-fluorotryptophan methyl ester[20] and of some dimethoxyfluorobenzenes,[21] both involving related activation by electron-donating groups. The peculiarly high photoreactivity of lomefloxacin with respect to other FQs (see above) is certainly due to the selective defluorination from position 8, apparently due to activation by both the adjacent amino groups, which increase the zwitterionic character of the singlet excited state and facilitate the fragmentation indicated in Scheme 2. Studies in progress in this laboratory show however that this type of reactivity is rather general, and defluorination accompanied by alkylamino chain degradation also takes place in FQs containing only the 6-fluoro group, although with a lower efficiency.‡

The fact that cation **7** exhibits carbene chemistry dominated by *intramolecular* C–H insertion and hydrogen transfer strongly suggests that the cause of the observed carcinogenic/mutagenic effect of this drug is formation of a covalent bond by direct reaction of excited **1** with DNA through a related *intermolecular* process.

Partial support of this work by the Istituto Superiore di Sanità, Rome, is gratefully acknowledged.

FEATURE ARTICLE

# A new generation of homogeneous arene hydrogenation catalysts†

**Ian P. Rothwell**

*Department of Chemistry, 1393 Brown Building, Purdue University, West Lafayette, IN 47907-1393, USA*

**The homogeneous hydrogenation of a variety of arene substrates can be catalysed by hydride derivatives of niobium and tantalum. A key feature of these catalysts is the presence of bulky ancillary aryloxide ligation. The systems demonstrate high regio- and stereo-selectivity in the hydrogenation of benzenes and polynuclear aromatic hydrocarbons. A unique characteristic of the niobium compounds is an ability to rapidly hydrogenate arylphosphine ligands, providing a new procedure for the synthesis of cyclohexylphosphine ligands.**

## Introduction

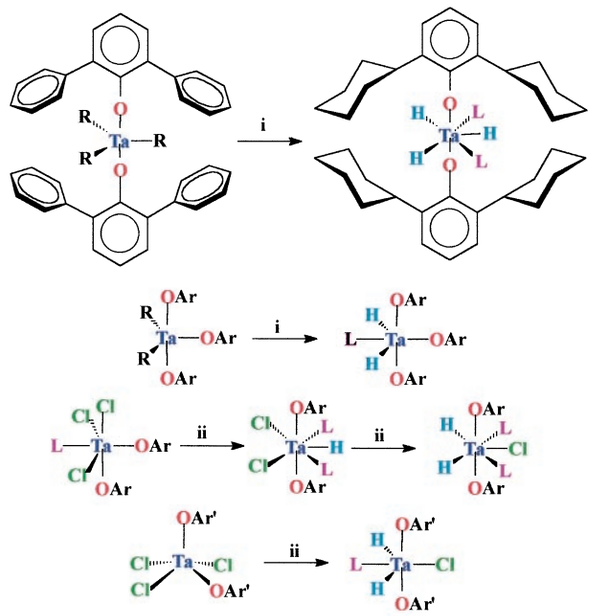
The field of arene hydrogenation chemistry will soon be entering its second century. The initial work of Sabatier on the interaction of finely divided nickel with ethylene was stimulated by Mond's earlier discovery of $[Ni(CO)_4]$.[1] Instead of isolating an ethylene derivative of nickel, serendipity led Sabatier to uncover the high activity of finely divided nickel for carrying out the hydrogenation of a variety of unsaturated organic substrates.[2] In 1901 with co-worker Senderens he 'attacked a case of hydrogenation, which up to that time had not been realized by any method, that of benzene'.[1] Not only did the experiment succeed, but the product obtained by the complete hydrogenation of benzene was, in fact, much purer (mp of 6 °C) than the sample of cyclohexane previously isolated by Markovnikov from Caucasian petroleum that had a mp of −11 °C![1,3] In subsequent papers Sabatier applied the method to a variety of mononuclear and polynuclear aromatic hydrocarbons with great success.[3] The discovery and development of this 'Sabatier method' led to the Nobel Prize (shared with Grignard) in 1912.

Following Sabatier's work, a variety of heterogeneous catalysts for arene hydrogenation was developed. Historically significant was the work of Adams on finely divided 'platinum-oxide, platinum black' (Adam's catalyst)[4] and the process of selectively digesting alloys to generate finely divided samples of metals (*e.g.* Raney nickel) by the industrial chemist Murray Raney.[5] The conversion of benzene to cyclohexane still represents the most important industrial hydrogenation reaction and is today carried out chiefly using a combination of Raney nickel and $Ni/Al_2O_3$ catalysts.[6] The product cyclohexane is primarily utilized in the production of adipic acid.

A more efficient utilization of sometimes expensive metals involves depositing the metal or its compounds onto suitable supports. Recently a number of materials obtained by attaching organometallic compounds to oxide surfaces have been shown to be highly active arene hydrogenation catalysts.[7]

The development of homogeneous catalysts capable of hydrogenating arene substrates has lagged well behind the heterogeneous systems. Following the original discovery of the so-called Wilkinson's catalyst[8] the field of homogeneous transition-metal catalysed alkene hydrogenation has grown into a large and sophisticated area of chemistry.[9] Despite this there is a relative dearth of systems that will hydrogenate benzene rings.[10,11] The majority of these systems are based upon middle and later transition metals and in some situations successful reactivity is limited to polynuclear aromatic hydrocarbon substrates. In certain cases, valuable mechanistic studies have been carried out,[10,12] although not all of these systems have been proven to be homogeneous. One system of particular note is an allyl–cobalt catalyst developed by Muetterties *et al.*[10] where NMR experiments led to the conclusion that the $C_6D_6H_6$ obtained by treating $C_6D_6$ with $H_2$ was an all-*cis* isotopomer.[13] This result has recently been confirmed using ion–molecule chemistry.[14] The hydrogenation of aromatics by Ziegler type catalysts utilizing nickel or cobalt alkoxides, acetylacetoates or carboxylates and trialkylaluminium activators has been known for some time.[15] The most significant of these is the 'Dimersol' process developed by the Institut Francais du Petrole (IFP), a homogeneous system that appears to be a viable alternative to heterogeneous technology for the large scale hydrogenation of benzene.[15]

During our studies of the early d-block metal chemistry that can be supported by sterically bulky aryloxide ligation[16] we discovered that mixed hydrido aryloxide derivatives of niobium and tantalum would carry out the intra- and inter-molecular hydrogenation of arene rings. This Feature Article highlights both the synthetic utility of the new catalysts as well as our present mechanistic knowledge.



## Synthesis and characterization of niobium and tantalum hydrido aryloxides

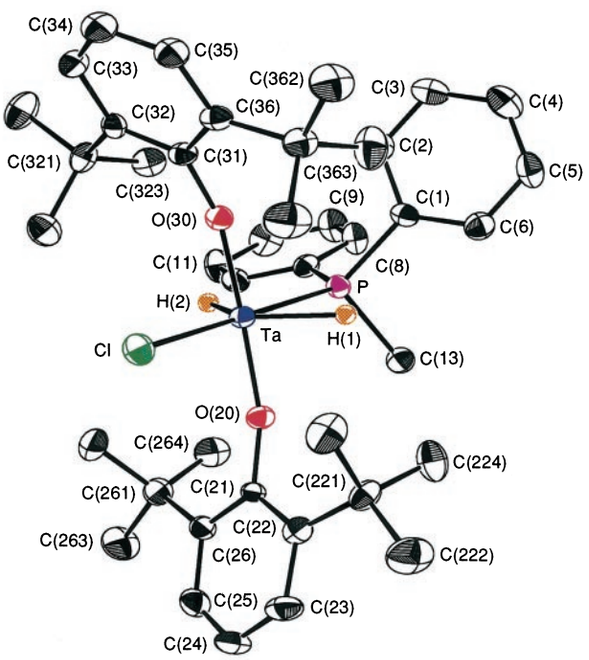
Of the many strategies available for the synthesis of transition-metal hydrides, two procedures are successful at generating mixed hydrido aryloxide derivatives of niobium and in particular tantalum (Scheme 1).[17] The first involves the high-pressure hydrogenolysis[18] of hydrocarbon solutions of mixed alkyl/aryloxides, typically in the presence of phosphine donor ligation. In some instances the hydrogenolysis is slow even under forcing conditions and only the alkyl precursor is reclaimed. In the case of aryloxide ligation containing *ortho*-phenyl substituents, the products isolated contain 2,6-dicyclohexylphenoxide groups (Scheme 1).[19] Under no circumstances have we detected the hydrogenation of phenyl rings either *meta* or *para* to the aryloxide oxygen or of the phenoxide nucleus itself. This is a highly significant result as it shows that these reaction mixtures do not contain small amounts of indiscriminate, possibly heterogeneous, arene hydrogenation catalysts. This selectivity coupled with an analysis of the stereochemistry of the reaction utilizing $D_2$ reagent gas and isolation of intermediates (*vide infra*) shows that the hydrogenation occurs in an intramolecular fashion within the niobium or tantalum compound itself.[19]

The second route to hydride derivatives involves treatment of the corresponding chloro aryloxides with $Bu^n_3SnH$ in the presence of a donor phosphine (Scheme 1).[17] In the case of niobium, evolution of $H_2$ and formation of hydrogenation inactive $d^1$ species such as all-*trans*-$[Nb(OC_6H_3Pr^i_2\text{-}2,6)_2Cl_2(L)_2]$ (L = tertiary phosphine) takes place,[20] whereas discrete $d^0$ hydride compounds can be isolated for tantalum. The reaction does not lead to total substitution of all Ta–Cl bonds, but the procedure can be readily scaled up as well as modified by the use of commercially available $Bu^n_3SnD$ to produce the corresponding deuteriated derivatives.[17]

The $d^0$ hydrides so far isolated fall into two broad categories. With two moderately bulky aryloxides, seven coordinate bis(phosphine) derivatives are isolated. These compounds contain a pentagonal-bipyramidal structure with mutually *trans*-axial phenoxide oxygen atoms (Scheme 1). The characteristically low field chemical shift of the Ta–H resonances not only aids in characterization, but careful analysis of the hydride signals shows these molecules to be stereochemically rigid on the NMR timescale.[17]

With the bulkier 2,6-di-*tert*-butylphenoxide or with three 2,6-diisopropylphenoxide ligands, six-coordinate mono(phosphine) species are generated (Scheme 1). The two structurally characterized examples show a distinct distortion away from octahedral geometry (*e.g.* Fig. 1).[17] In both cases the mutually *trans* hydride ligands are bent towards the Ta–P bond. These X-ray diffraction results are supported by IR studies which confirm the acute H–Ta–H angles (intensities of the symmetric and asymmetric stretching vibrations).[17] The origins of these distortions are beyond the scope of this review, but theoretical analysis points to σ bonding effects (not π bonding) as being important.[21]

**Scheme 1** OAr = 2,6-diisopropyl, OAr′ = 2,6-di-*tert*-butylphenoxide, L = tertiary phosphine, R = $CH_2C_6H_4Me$-4. *Reagents and conditions*: i, $H_2$ (1200 psi), 80 °C; ii, $Bu^n_3SnH$, L.



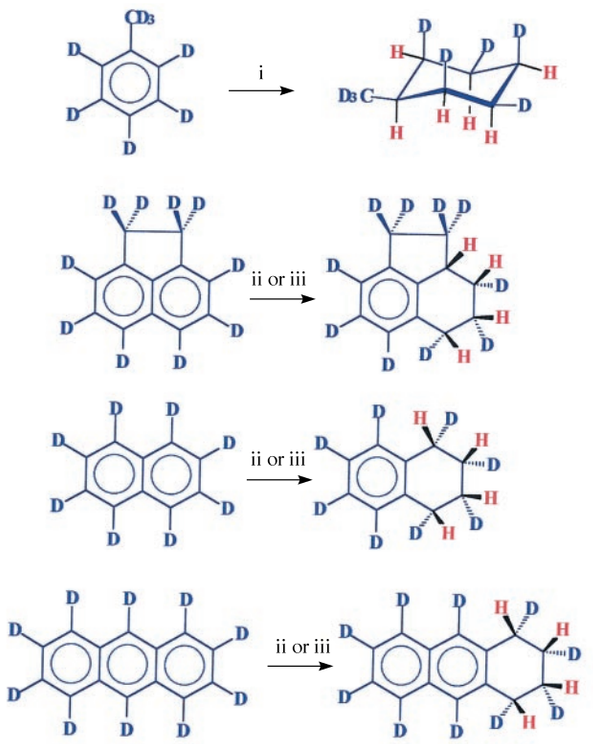


**Fig. 1** ORTEP view of $[Ta(OC_6H_3Bu^t_2\text{-}2,6)_2Cl(H)_2(PMePh_2)]$

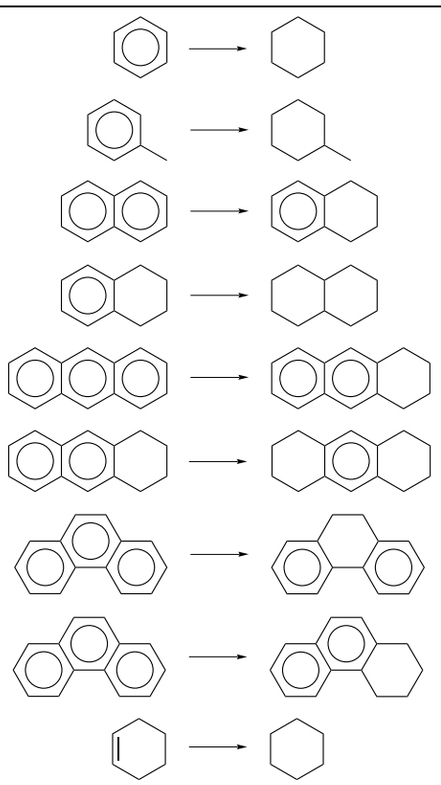
## Intermolecular hydrogenation of arene rings: regio- and stereo-selectivities

Hydrocarbon solutions of the isolated tantalum trihydrides $[Ta\{OC_6H_3(C_6H_{11})_2\text{-}2,6\}_2(H)_3(PMe_2Ph)_2]$ and $[Ta(OC_6H_3\text{-}Pr^i_2\text{-}2,6)\}_2(H)_3(PMe_2Ph)_2]$ will catalyse the hydrogenation of naphthalene and anthracene at 80 °C under a hydrogen pressure of 50–1500 psi (psi ≈ $6.895 \times 10^3$ Pa).[24] When the hydrogenation of naphthalene is carried out in $C_6D_6$ solvent in a high-pressure 5 mm $^1H$ NMR tube, complete conversion of 20 equiv. of naphthalene to tetralin occurs with no decrease in the intensity of the tantalum hydride signals in the $^1H$ NMR spectrum. Only trace amounts of cyclohexane are formed in this reaction, indicating a much slower attack on the benzene solvent. In the cases of anthracene, almost exclusive formation of 1,2,3,4-tetrahydroanthracene precedes formation of 1,2,3,4,5,6,7,8-octahydroanthracene with no detectable quantities of 9,10-dihydroanthracene (typical of radical catalysts[22] and Birch type reductions[23]) being formed.

These hydride catalysts exhibit strong inhibition by added phosphine and this sensitivity to even trace amounts of free phosphine hinders kinetic analysis of the reactivity. This observation is consistent with an initial dissociation of at least one Ta–$PR_3$ bond in the seven-coordinate hydrides prior to substrate hydrogenation.

The hydrogenation of $[^2H_8]$naphthalene, $[^2H_{10}]$anthracene and $[^2H_{10}]$acenaphthene by hydride $[Ta\{OC_6H_3(C_6H_{11})_2\text{-}2,6\}_2(H)_3(PMe_2Ph)_2]$ produced single isotopomers as shown (Scheme 2).[24] Analysis of the $^1H$ and $^{13}C$ NMR spectra confirmed a highly selective, all-*cis* hydrogenation had oc-



**Scheme 2** *Reagent and conditions*: i, $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]/3Bu^nLi$, 80 °C, 1200 psi $H_2$, ii, $[Ta(OC_6H_3Pr^i\text{-}2,6)_3(H)_3(PMePh_2)_2]$, 80 °C, 1200 psi $H_2$; iii, $[Nb(OC_6H_3Ph_2\text{-}2,6)_2(CH_2C_6H_4Me\text{-}4)_3]$, 80 °C, 1200 psi $H_2$

curred with no H/D scrambling within either unreacted substrate or products. The all-*cis* nature of [$^2H_8$]tetralin has also been confirmed by ion–molecule techniques.[25]

The hydrogenolysis of alkyls of stoichiometry $[M(OAr)_2R_3]$ and $[M(OAr)_3R_2]$ (M = Nb, Ta) would be expected to generate base-free tri- and di-hydrides respectively. Although hydrides of this stoichiometry have not been isolated, the solutions thus generated are more active arene hydrogenation catalysts than the phosphine adducts, with niobium showing higher activity than tantalum and a stereoselectivity identical to that found for isolated tantalum catalysts such as $[Ta\{OC_6H_3(C_6H_{11})_2\text{-}2,6\}_2(H)_3(PMe_2Ph)_2]$ (Scheme 2).

An alternative, more synthetically straightforward procedure for carrying out the hydrogenation of arene substrates involves mixing the chloride precursors $[Nb(OAr)_3Cl_2]$ and $[Nb(OAr)_2Cl_3]$ (ArO = 2,6-diisopropyl-, 2,6-diphenyl- or 2,3,5,6-tetraphenyl-phenoxide) with 2–3 equiv. of Bu$^n$Li followed by exposure to $H_2$.[26] This procedure allows the hydrogenation to be carried out under milder conditions where hydrogenolysis of Nb–$CH_2SiMe_3$ and Nb–$CH_2Ph$ bonds is slow. The niobium catalysts obtained by these methods demonstrate almost identical regio- and stereo-selectivity compared to the tantalum hydride systems.[24] Individual experiments as well as competition reactions show the relative rates of attack on arene substrates shown (Table 1).

**Table 1** Relative rates of hydrogenation of aromatic hydrocarbons compared to benzene at 100 °C

[a] $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$/3Bu$^n$Li, 100 °C, 0.464 mmol Nb, 190 mmol $C_6H_6$ (409 per Nb), volume 20 ml, 1 h, 1200 psi $H_2$, analysed by GC. [b] $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$/3Bu$^n$Li, 100 °C, 0.464 mmol Nb, 95 mmol $C_6H_6$ (200 per Nb), 95 mmol $C_6H_5Me$ (200 per Nb), volume 20 ml, 1 h, 1200 psi $H_2$, analysed by GC. [c] $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$/3Bu$^n$Li, 100 °C, 0.464 mmol Nb, 190 mmol $C_6H_6$ (409 per Nb), 9.5 mmol substrate (20 per Nb), volume 20 ml, 1–6 h, 1200 psi $H_2$, analysed by GC and corrected for concentration of substrate. [d] $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$/3Bu$^n$Li, 25 °C, 0.464 mmol Nb, 95 mmol $C_6H_6$ (200 per Nb), 95 mmol Nb, 95 mmol $C_6H_8$ (200 per Nb), volume 20 ml, 1–6 h, 1200 psi $H_2$, analysed by GC.

These results indicate that selectivity is determined by the coordination affinity of the arene ring and steric factors. Anthracene is hydrogenated faster than naphthalene to initially produce 1,2,3,4-tetrahydroanthracene. Attack on this (essentially a 2,3-disubstituted naphthalene) yields exclusively octahydroanthracene. Consistent with this is the preference for attack on the unsubstituted ring of 2-methylnaphthalene.[24] The hydrogenation of naphthalene by the alkyl precursors $[Nb(OC_6H_3Ph_2\text{-}2,6)_2(CH_2C_6H_4Me\text{-}4)_3]$ in cyclohexane only occurs at temperatures above 50 °C but reaches a plateau of maximum activity above 100 °C (Fig. 2).

Further hydrogenation of tetralin produces predominantly *cis*-decalin (*cis*/*trans* = 9) but at a rate an order of magnitude slower than the formation of tetralin. The hydrogenation of benzene by the $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]$/3Bu$^n$Li system is slower than initial attack on naphthalene. A drop in activity is again observed at too high a temperature, possibly indicative of thermal instability of the catalyst. Toluene undergoes hydrogenation 2.5 times slower than benzene and the methylcyclohexane produced by hydrogenation of [$^2H_8$]toluene has been shown by NMR methods to be the all-*cis* isotopomer (Scheme 2).

These catalysts also show high activity for the hydrogenation of alkenes and dienes. The hydrogenation of cyclohexene occurs much faster and under much milder conditions than the corresponding hydrogenation of aromatic substrates (Table 1).

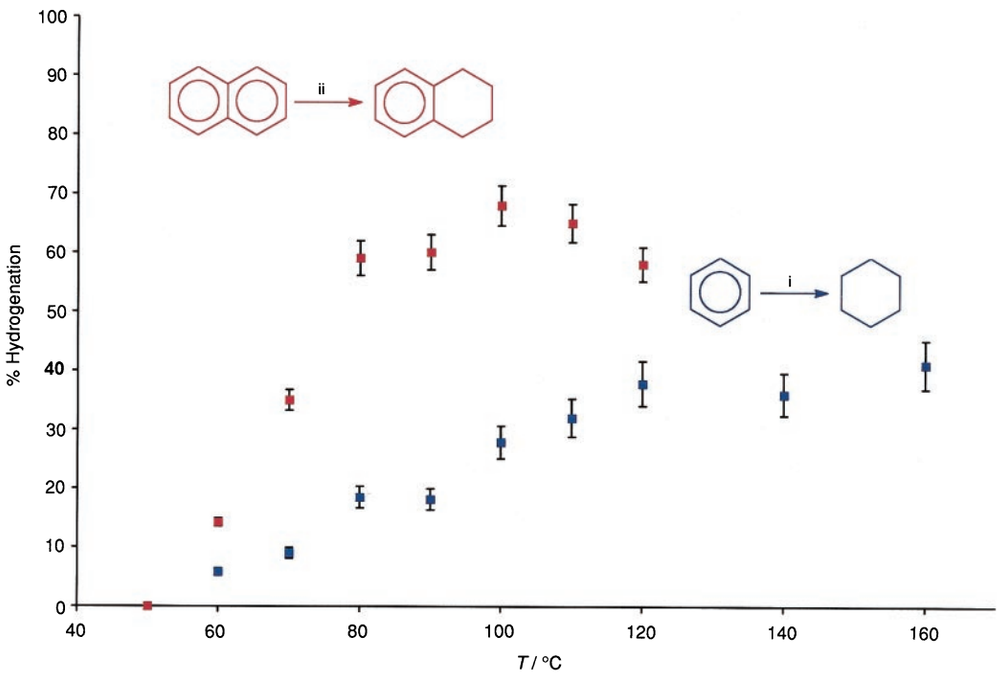
All of these catalysts/precursors suffer from a sensitivity to protic impurities and dioxygen. In order for catalytic activity to be achieved and maintained the substrates, solvents and equipment must be thoroughly dried and the reaction set up with precautions being taken to prevent contamination by air or moisture. This normally requires the pressure reactors being charged and assembled within a Dri-Lab facility.

## Mechanistic considerations

A preference to undergo substitution reactions rather than addition chemistry is a defining characteristic of aromatic compounds. Consideration of the heats of formation (kcal mol$^{-1}$, cal = 4.184 J) of gaseous benzene (19.8), cyclohexa-1,3-diene (25.6), cyclohexene (−0.9) and cyclohexane (−29.4)[27] show that the generation of cyclohexa-1,3-diene is the problematic (endothermic) step in the hydrogenation of benzene. Furthermore, on purely thermodynamic arguments it appears a daunting task to design a combination of catalyst and conditions which will lead to only the partial hydrogenation of benzene. The success of Birch reductions[23] and related reactions at stoichiometrically generating partially hydrogenated products (typically 1,4-dienes) is due to the much higher electron affinity of the arene substrate over the products. The conversion of benzene to cyclohexene is thermodynamically favourable, and the monoene is a highly desired product. Recently there has been some success in the development of heterogeneous catalysts for converting benzene into cyclohexene.[28] Thermodynamic analysis of the stoichiometric reaction of a transition-metal dihydride with ethylene followed by oxidative addition of $H_2$ shows that both steps can be exothermic leading to a viable catalytic cycle. In contrast although the corresponding reaction with benzene to produce cyclohexa-1,3-diene may conceivably be exothermic, such a dihydride must be thermodynamically unstable with respect to loss of $H_2$. The partial saturation of fused-ring aromatic compounds does not suffer from as dramatic a loss of resonance stabilization, *e.g.* conversion of naphthalene to 1,2-dihydronaphthalene is exothermic. This accounts for the more facile hydrogenation of polynuclear aromatic hydrocarbons by heterogeneous and homogeneous systems compared to single ring aromatics. This hypothesis is given strong support in the reaction chemistry of main-group hydride reagents. In particular the mammoth body of work dealing with the stoichiometric hydroboration of alkenes[29] contrasts with the Lilliputian studies

involving arene substrates.[30] A large number of transition-metal hydride compounds are stable in aromatic solvents. When reactivity does occur, it commonly involves aromatic C–H bond activation either *via* oxidative-addition pathways (sometimes preceded by $H_2$ elimination)[31] or else by σ-bond metathesis with highly electrophilic $d^0$ metal hydrides.[32]

Our attempts to understand these Group 5 metal-catalysed reactions has led us to volunteer the mechanistic pathways shown in Scheme 3. We have attempted with some success to isolate and study some of the reasonable intermediates in this catalytic cycle. Considerable experimental evidence has been obtained that the niobium and tantalum aryloxides can strongly bind to cyclohexa-1,3-diene intermediates produced by transfer of two hydrogen atoms to an arene ring. An intramolecular example of this is the formation of a chelated cyclohexadiene species generated *via* attack on an *ortho*-phenyl phenoxide ligand by an intermediate niobium dihydride.[19] Although we have as yet not detected the stoichiometric, intermolecular attack of an isolated niobium or tantalum hydride on a benzene ring, a series of cyclohexa-1,3-diene derivatives can be readily obtained by reduction methods (Scheme 4).[33] The structural parameters for these species indicate a significant contribution



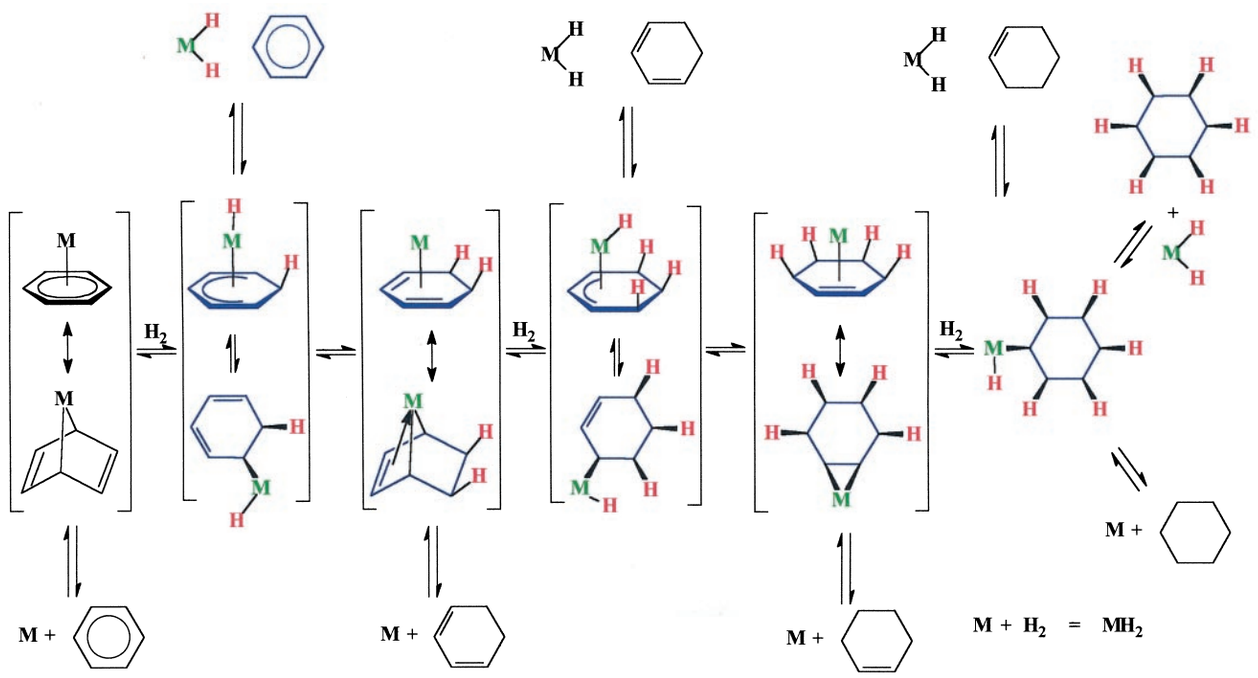


**Fig. 2** Temperature dependence of the hydrogenation of benzene and naphthalene. *Reagents and conditions*: i, $[Nb(OC_6HPh_4-2,3,5,6)_2Cl_3]/3Bu^nLi$, 0.464 mmol Nb, 190 mmol $C_6H_6$ (409 per Nb), volume 20 ml, 6 h, 1200 psi $H_2$; ii, $[Nb(OC_6H_3Ph_2-2,6)_2(CH_2C_6H_4Me-4)_3]$, 0.1 mmol, 20 mmol $C_{10}H_8$ (200 per Nb), volume 3 ml, $C_6H_{12}$ solvent, 6 h, 1200 psi $H_2$.

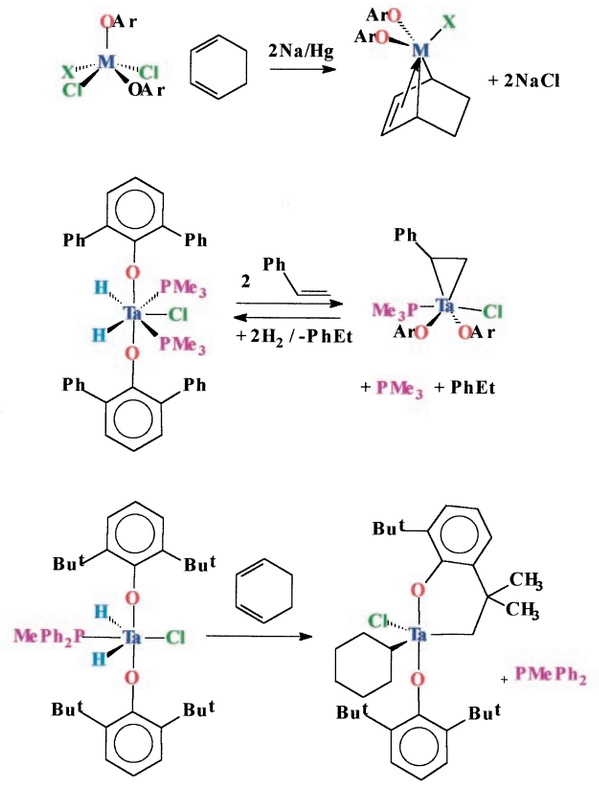


**Scheme 3**

from a metallanorbornene ($d^0$ metal) bonding picture.[34] Some important observations are the fact that dissociation or displacement of cyclohexa-1,3-diene from these compounds is difficult and that they react with $H_2$ under very mild conditions to liberate cyclohexane. Species of this type are, therefore, reasonable intermediates during the catalytic cycle, but are found to react rapidly with $H_2$ under the conditions at which arene hydrogenation is carried out.[33] The strong binding of the cyclohexa-1,3-diene fragment to niobium and tantalum metal centres also accounts for the preference for an all-*cis* hydrogenation in intermolecular arene hydrogenation. The niobium compound [Nb($OC_6H_3Pr^i_2$-2,6)$_3$($\eta^4$-$C_6H_8$)] will catalyse the hydrogenation of cyclohexa-1,3-diene and cyclohexene under very mild conditions. Mechanistic studies show that cyclohexa-1,3-diene is hydrogenated selectively over cyclohexene. Furthermore labelling studies show that intermediate cyclohexene is not released during the hydrogenation of cyclohexa-1,3-diene.[33,35] In contrast the less active catalyst [Nb($OC_6H_3$-$Pr^i_2$-2,6)$_2$Cl($\eta^4$-$C_6H_8$)] converts cyclohexa-1,3-diene into cyclohexene prior to formation of cyclohexane. These results show how slight changes in the ligand environment of a homogeneous catalyst can lead to dramatically different selectivity.

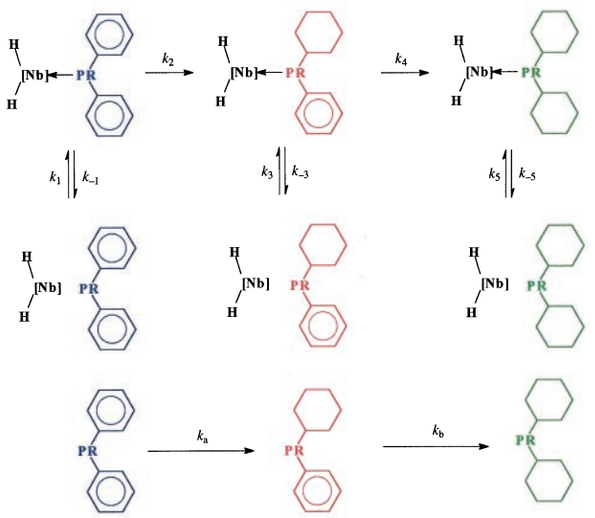
The proposed mechanistic pathway (Scheme 3) proceeds next *via* a cyclohexene complex. Although no cyclohexene complex has yet been isolated, the stoichiometric reaction of the tantalum dihydride [Ta($OC_6H_3Ph_2$-2,6)$_2$Cl(H)$_2$($PMe_3$)$_2$] with styrene has been shown to produce 1 equiv. of ethylbenzene and a styrene complex (Scheme 4).[36]

The solid-state structure of this product shows the presence of a tantacyclopropane ring and in solution dissociation or exchange of bound styrene is slow, again showing how formally $d^2$ fragments such as [M(OAr)$_3$] or [M(OAr)$_2$Cl] will strongly bind to unsaturated groups.[36] Treatment of the styrene complex with $H_2$ regenerates the initial dihydride along with another equivalent of ethylbenzene (Scheme 4). The final, partially hydrogenated intermediate in the catalytic cycle is a cyclohexyl–metal species (Scheme 3). The stoichiometric reaction of

**Scheme 4** M = Nb, Ta; OAr = 2,6-diisopropylphenoxide; X = Cl, OAr

cyclohexa-1,3-diene with dihydride [Ta($OC_6H_3Bu^t_2$-2,6)-Cl(H)$_2$($PMePh_2$)] produces a stable cyclohexyl compound (Scheme 4); the third equivalent of hydrogen originating by C–H bond activation (cyclometallation) of one of the 2,6-di-*tert*-butyl phenoxide ligands.[37]

Clearly much more mechanistic work is needed on these and other model systems to gain a better understanding of the arene hydrogenation chemistry. In particular mention should be made of an alternative mechanistic pathway involving initial activation of the arene by coordination to a $d^2$ metal fragment. This reaction certainly has precedence in Group 5 metal chemistry, particularly in the work of the Wolczanski[38] and Wigley[34,39] groups. The extremely reactive $d^2$ [Ta(silox)$_3$] species will coordinate and activate a multitude of unsaturated substrates including benzene and heterocyclic compounds.[38] During studies of alkyne oligomerization, Wigley and co-workers have shown that strong bonding of arenes takes place to $d^2$ [Ta(OAr)$_2$Cl] fragments and a tantalanorbornadiene bonding picture has been proposed.[34] The hydrogenolysis of one of the metal–carbon bonds in this species would generate the same cyclohexadienyl hydride as formed by insertion of a $d^0$ metal–hydride bond across benzene (Scheme 3). During our studies of the chemistry of low-valent aryloxides of tungsten we have isolated a series of 16-electron compounds in which $\eta^6$-binding of an *ortho*-phenyl ring of a 2,3,5,6-tetraphenylphenoxide ligand occurs.[40] These compounds react with certain ketones to produce products that can be considered as originating from a tungstanorbornadiene ground-state structure.[41] Reaction with $H_2$ takes place under very mild conditions to produce an *ortho*-cyclohexene ring.[40] Our present knowledge of species such as [Nb($OC_6H_3Pr^i_2$-2,6)$_3$] and [Ta($OC_6H_3Pr^i_2$-2,6)$_2$Cl] is that they undergo rapid intramolecular dehydrogenation of *ortho* $Pr^i$ groups even in the presence of benzene.[36,42] Clearly further studies are needed to determine conclusively whether one or both of these pathways are operating in these catalytic systems.



## Catalytic hydrogenation of arylphosphines: a novel case of heteroatom insensitivity

When the tantalum dihydride [Ta($OC_6H_3Pr^i_2$-2,6)$_3$-(H)$_2$($PMePh_2$)] is heated under hydrogen pressures for days, the stepwise formation of the cyclohexylphosphine species [Ta($OC_6H_3Pr^i_2$-2,6)$_3$(H)$_2${PMe($C_6H_{11}$Ph)}] and [Ta($OC_6H_3$-$Pr^i_2$-2,6)$_3$(H)$_2${PMe($C_6H_{11}$)$_2$}] is observed by $^1$H and $^{31}$P NMR spectroscopy.[17] In the field of transition-metal mono-, di- and poly-hydride chemistry the phosphine ligand is a dominant ancillary.[43] Furthermore, by far the vast majority of alkene hydrogenation catalysts contain phosphine ligation as a critical component, particularly systems where a chiral phosphine auxiliary causes asymmetric hydrogenation of a prochiral substrate. In none of these situations has the hydrogenation of aryl groups attached to phosphorus been documented. Any vexing interference by arylphosphines typically involves cyclometallation of arene CH bonds,[44] $\pi$-complexation with the metal[45] or hydrogenolysis of P–C bonds leading to inert metal phosphide species.[46] The niobium arene hydrogenation systems exhibit much greater activity than the tantalum hydrides for the hydrogenation of arylphosphines. This reactivity has been utilized to develop a new synthetic procedure for the formation of cyclohexylphosphines from their cheaper, readily available phenylphosphine counterparts.[47] The success of the niobium compounds for carrying out the reaction is remarkable and must rely on a number of important features. The coordination of the substrate phosphine ligand acts as a 'Trojan Horse' bringing in close proximity to the metal the aryl group. However, carrying out the total saturation of the phenyl ring undoubtedly necessitates breaking at various stages the Nb–P bond. The success of the reaction not only depends on facile exchange of substrate/product phosphine groups within the metal coordination sphere, but also on the fact that the much greater basicity

of cyclohexylphosphines must be offset by their larger cone angle.[48] A much stronger binding of one of the product phosphine ligands could effectively shut down the catalysis. We have also studies the course of these reactions by $^{31}P$ NMR analysis at intermediate stages of hydrogenation. In no cases have we been able to detect significant quantities of cyclohexadienyl- or cyclohexenyl-phosphine compounds. The build up and decay of intermediate cyclohexylphenylphosphines can be readily illustrated by a reaction profile in which the fraction of products is plotted against the fraction hydrogenation of the sample. Some interesting information can be gained from these plots. In the case of the hydrogenation of $PPh_3$ by the catalyst system $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]/3Bu^nLi$ the dramatic build up of the final intermediate $PPh(C_6H_{11})_2$ can be seen (Fig. 3).

This reaction profile can be simulated accurately using a simple kinetic model involving sequential first-order rate constants.[26] The success of this kinetic model for the reaction places constraints on the rate constants within a more complex model in which rates of phosphine coordination and dissociation are included. Although many regimes can exist for this model, the restraint that the rates of phosphine association/dissociation are faster than the rate of saturation of the arene ring means that the first-order constants from the simple model are proportional to the product of the formation constants of the metal phosphine and the rate of arene ring hydrogenation. This is highlighted in Scheme 5 for an alkyldiphenylphosphine. The low relative rate of hydrogenation of $PPh(C_6H_{11})_2$ (Fig. 3) may, therefore, be ascribed either to a low formation constant for the bulky phosphine and/or relatively slow attack on the P–Ph group within this particular ligand. By exploiting this reaction profile we have been able to synthesize the deuteriated compounds $[P(C_6H_5)(C_6H_5D_6)_2]$ and $[P(C_6D_5)(C_6D_5H_6)_2]$ and show that the reaction occurs in a predominantly all-*cis* fashion for attack at both phenyl rings.[26] The detection of non-all-*cis* stereoisomers is almost certainly a consequence of the intermediate regiochemistry of the reaction.[19]

Due to the much documented lack of inversion of configuration at phosphorus under ambient conditions, substrates of stoichiometry $RPPh_2$ are prochiral. We find that the build up of the intermediate, chiral (unresolved) alkyl, phenyl, cyclohexylphosphine can be enhanced by increasing the bulk of the alkyl substituent (Table 2). In the case of $[Pr^iPPh(C_6H_5D_6)]$, labelling studies again show a predominance of all-*cis* hydrogenation.[26] The use of phosphines with chiral alkyl groups leads to diastereomeric pairs. Analysis by $^{31}P$ NMR indicates a slight diastereomeric excess for the alkyls so far examined (Fig. 4, Table 2), showing the successful transfer of chirality from a carbon atom to an adjacent phosphorus centre.[49]

**Scheme 5** If $k_1$, $k_{-1}$, $k_3$, $k_{-3} \gg k_2$, $k_4$ then $k_a/k_b = (k_1/k_{-1})k_2/(k_3/k_{-3})k_4$

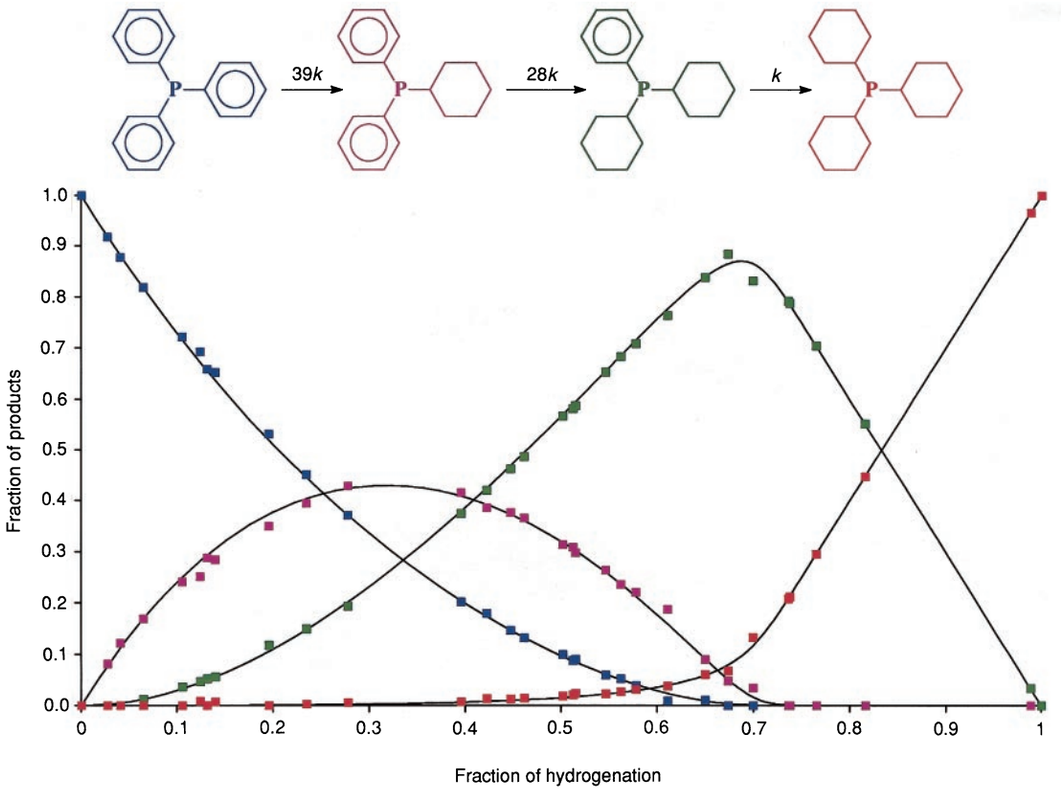


**Fig. 3** Reaction profile for the hydrogenation of $PPh_3$ by $[Nb(OC_6HPh_4\text{-}2,3,5,6)_2Cl_3]/3Bu^nLi$, 0.464 mmol Nb, 190 mmol $C_6H_6$ (409 per Nb), 9.5 mmol $PPh_3$ (20 per Nb), volume 20 ml, 60 °C, 1200 psi $H_2$

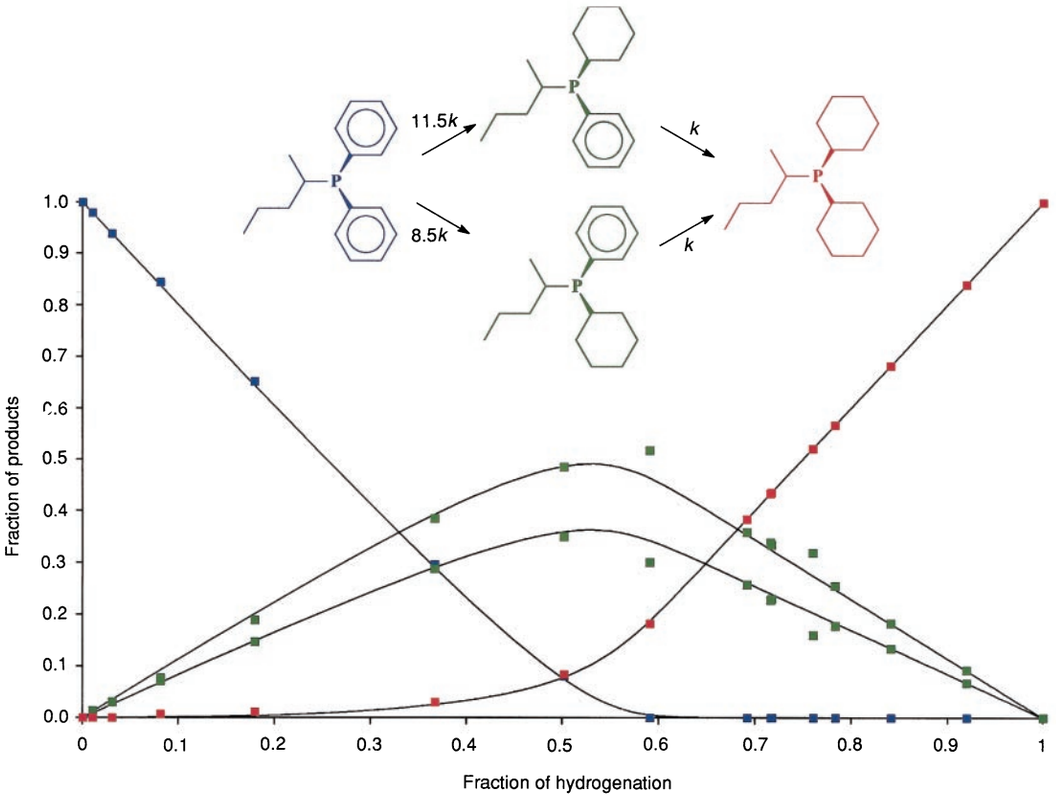

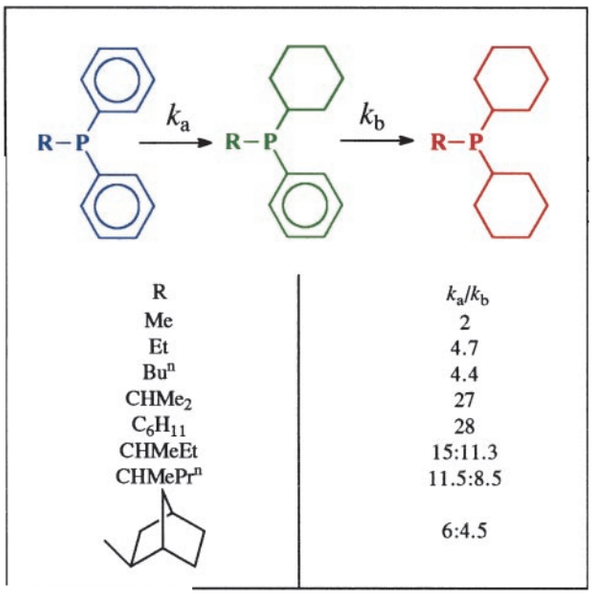

**Fig. 4** Reaction profile for the hydrogenation of [(s-$C_5H_{11}$)$PPh_2$] by [Nb($OC_6HPh_4$-2,3,5,6)$_2Cl_3$]/3Bu$^n$Li, 0.464 mmol Nb, 190 mmol $C_6H_6$ (409 per Nb), 9.5 mmol [(s-$C_5H_{11}$)$PPh_2$] (20 per Nb), volume 20 ml, 60 °C, 1200 psi $H_2$

**Table 2** Ratio of rate constants for hydrogenation of alkyldiphenylphosphines[a]

| R | $k_a/k_b$ |
|---|---|
| Me | 2 |
| Et | 4.7 |
| Bu$^n$ | 4.4 |
| $CHMe_2$ | 27 |
| $C_6H_{11}$ | 28 |
| CHMeEt | 15:11.3 |
| $CHMePr^n$ | 11.5:8.5 |
|  | 6:4.5 |

[a] [Nb($OC_6HPh_4$-2,3,5,6)$_2Cl_3$]/3Bu$^n$Li, 60 °C, 0.464 mmol Nb, 190 mmol $C_6H_6$ (409 per Nb), 9.5 mmol $RPPh_2$ (20 per Nb), volume 20 ml, 1200 psi $H_2$, analysed by $^{31}$P NMR and $k_a/k_b$ obtained by simulation.

The mild conditions used in these studies will not lead to racemization on the timescale of the experiment. It is clearly possible to envision adapting these systems for catalytically generating enantiomeric excesses of chiral phosphine ligands.

The hydrogenation of the bis(phosphine) substrates $Ph_2P(CH_2)_nPPh_2$ ($n$ = 1–6) leads to the corresponding cyclohexyl derivatives. The reactions profile for the hydrogenation of dppm by [Nb($OC_6H_3Pr^i_2$-2,6)$_2Cl_3$]/3Bu$^n$Li shows the build up of product dcpm even at low fraction hydrogenation.[26] This indicates that in this case the rate of hydrogenation of the P–Ph group is faster than the rate of dissociation from the catalytically active site.

# Crystal engineering: the effects of π–π interactions in copper(I) and silver(I) complexes of 2,7-diazapyrene

**Alexander J. Blake,[a] Neil R. Champness,*[a] Andrei N. Khlobystov,[a,b] Dmitri A. Lemenovskii,[b] Wan-Sheung Li[a] and Martin Schröder*[a]**

[a] *Department of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD*

**The ligand 2,7-diazapyrene (L) is used to construct three- and two-dimensional arrays with $Cu^{I}$ and $Ag^{I}$ ions: $\{[Cu^{I}L_2]PF_6\}_\infty$ shows an adamantoid network with three interpenetrating networks, while $\{[Ag^{I}L_2(MeCN)_2]BF_4\}_\infty$ forms linear chains of $[AgL]_\infty$ units linked by apparent π–π stacking and Ag···Ag interactions between adjacent diazapyrene ligands to form two-dimensional sheets.**

Crystal engineering and the design of solid-state architectures has become an area of increasing interest over recent years.[1–4] Much study has been centred upon the use of supramolecular contacts, particularly hydrogen-bonding, between suitable molecules to generate multi-dimensional arrays or networks.[1–3] In comparison, the design of inorganic networks has been less well developed.[4–8] We have been investigating the effect of ligand functionality upon the construction of two- and three-dimensional arrays and, in particular, adamantoid or super-diamondoid networks based upon copper(I) complexes.[8] We were interested in monitoring the effects of ligand bulk and the potential of π–π stacking interactions in controlling network geometry. With this in mind we chose the ligand 2,7-diazapyrene (L)[9] as a potentially useful building block in the construction of multi-dimensional architectures. We report herein the first structurally characterised examples of metal complexes with L.

2,7-diazapyrene L

The reaction of $[Cu(MeCN)_4]PF_6$ with L in MeCN–PhCN afforded unusual triangular-shaped red crystals suitable for X-ray analysis. The crystal structure shows† the complex $\{[CuL_2]PF_6\}_\infty$ to form a three-dimensional adamantoid network in which each $Cu^{I}$ centre is co-ordinated in a tetrahedral geometry to four diazapyrene ligands, Cu–N 2.044(9)Å. The spaces within each adamantoid network are filled by two other adamantoid networks and the three interpenetrating arrays related to each other by a 90° rotation (Fig. 1). This form of interpenetration contrasts with that observed for other copper(I) adamantoid networks which are related to each other by simple translation.[5,6,8] Adjacent lattices interact with each other *via* face-to-face π–π interactions between 2,7-diazapyrene ligands which are arranged so that the N···N axes of the ligand are at 90° to one another. The distance between aromatic rings is 3.469 Å, compared with a value of 3.450 Å for the free ligand which we have structurally characterised.[10] The positive charge of the metallo-ligand lattice is balanced by $PF_6^-$ counter anions which were found to be disordered around a threefold axis. The counter anion site was also found to be partially occupied with three-quarters of the $PF_6^-$ anion sites filled.†

The three independent interpenetrating lattices observed for $\{[CuL_2]PF_6\}_\infty$ contrasts with the four observed for $\{[Cu(4,4'\text{-bipy})_2]BF_4\}_\infty$[5] and five for $\{[Cu(bpe)_2]BF_4\}_\infty$ [bpe = 1,2-*trans*-(4-pyridyl)ethene].[8] 2,7-Diazapyrene is a slightly shorter linker than 4,4′-bipy, giving a Cu···Cu distance of 10.904 Å along the edges of each adamantoid unit in $\{[CuL_2]PF_6\}_\infty$ compared to 11.166 Å for $\{[Cu(4,4'\text{-bipy})_2]BF_4\}_\infty$.[5] Athough the decrease in the number of interpenetrating lattices might in principle be explained by the decrease in the length of the linking ligand, this seems unlikely given such a small decrease in Cu···Cu distance. Increasedπ–π interactions between adjacent lattices should encourage more

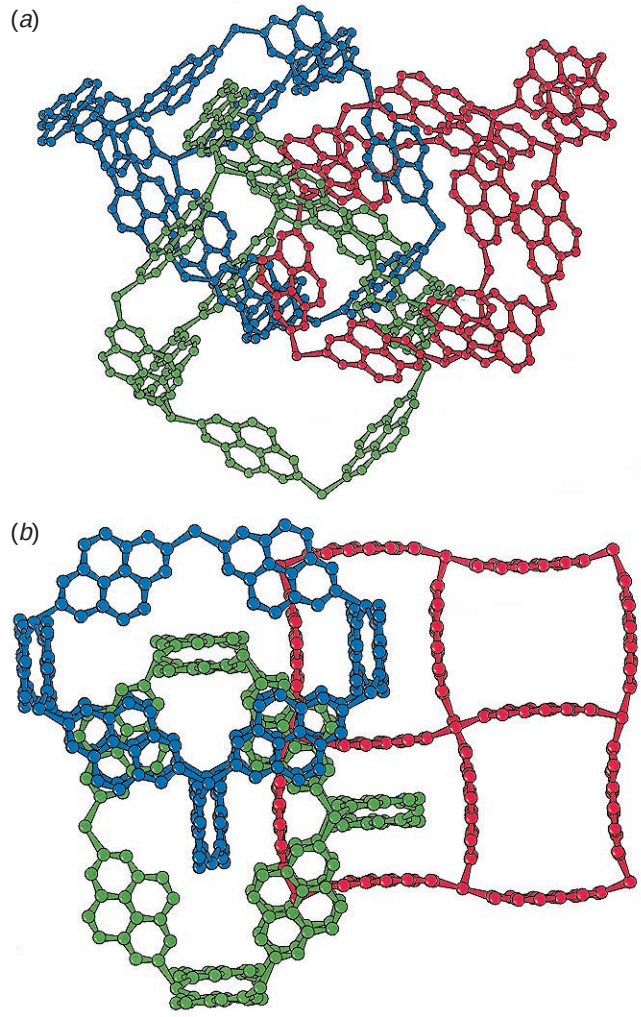

**Fig. 1** Two views of the structure of $\{[CuL_2]PF_6\}_\infty$ (L = 2,7-diazapyrene) showing three interlocking adamantoid cages. $PF_6^-$ anions omitted for clarity.

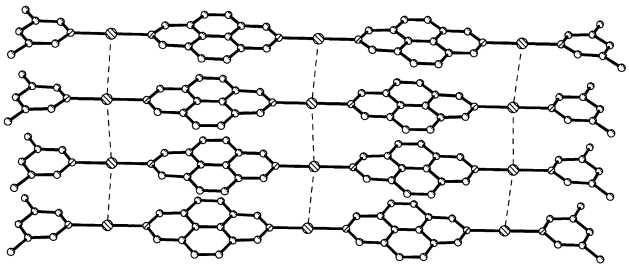

**Fig. 2** View of the structure of $\{[AgL(MeCN)_2]BF_4\}_\infty$ (L = 2,7-diazapyrene); MeCN molecules and $BF_4^-$ anions have been omitted for clarity

efficient packing which would be expected to lead to increased numbers of independent lattices rather than the decrease observed here. Thus, the decrease in the number of interpenetrating lattices in $\{[CuL_2]PF_6\}_\infty$ can be rationalised by the greater lateral steric bulk of L reducing the volume within any given adamantoid lattice that can be filled by other symmetry related lattices. This represents the identification of another factor controlling the degree of interpenetration in adamantoid lattices.[8,11]

The related silver(I) complex $\{[AgL(MeCN)_2]BF_4\}_\infty$ was obtained by reaction of L with $AgBF_4$ in 1 : 1 or 2 : 1 ligand-to-metal ratios. The structure of the complex shows† linear chains of alternating $Ag^I$ ions and L (Fig. 2). These chains are linked together *via* face-to-face π–π interactions between 2,7-diazapyrene ligands in which the ligand N···N axes are parallel to each other with a separation of 3.380 Å: a separation of 3.450 Å is observed in the X-ray structure of the metal-free L.[10] This π–π interaction also enforces the formation of apparent Ag···Ag interactions of 3.641(2) Å. Bonding between adjacent chains is further strengthened by MeCN ligands which bridge adjacent Ag centres, Ag–N 2.871(4), 2.926(4) Å, to form two-dimensional sheets. The enforced formation of Ag···Ag interactions in this structure is in sharp contrast to the analogous complex $\{[Ag(4,4'\text{-bipy})]BF_4\}_\infty$ in which $Ag^I$ ions on adjacent linear chains are staggered thereby precluding the formation of Ag···Ag interactions or π–π stacking between bipyridyl ligands.[12]

We thank the EPSRC for support.

† Stoe Stadi-4 four-circle diffractometer, graphite-monochromated Mo-Kα radiation, $\omega$–$\theta$ scans, $\theta_{max}$ = 25°. Both structures were solved using direct methods[13] and all non-H atoms were located using subsequent difference-Fourier methods.[14] In both cases hydrogen atoms were placed in calculated positions and were allowed to ride on their parent atoms.

*Crystal data* for $\{[CuL_2]PF_6\}_\infty$: $C_{28}H_{16}CuF_6N_4P$, $M$ = 616.96, cubic, space group $I\bar{4}3d$ (no. 220), $a$ = 19.505(7) Å, $U$ = 7421(5) Å$^3$, $Z$ = 12, $F$(000) = 3720, $D_c$ = 1.657 g cm$^{-3}$, $\mu$(Mo-Kα) = 1.020 mm$^{-1}$. A red triangular crystal (0.28 × 0.27 × 0.23 mm). Numerical absorption corrections were applied to the data ($T_{min}$ 0.7004, $T_{max}$ 0.7487), 603 unique reflections [$R_{int}$ = 0.096], of which 485 had $I \geqslant 2\sigma(I)$, were used in all calculations. A correction for crystal decay (4%) was applied during data reduction. The $PF_6^-$ anion was found to be disordered around a threefold axis and the equatorial F atoms were split over four sites of occupancy 0.15, 0.11, 0.22, 0.52. In order to balance charges the occupancy of the $PF_6^-$ anion was required to be 0.25 (rather than 0.333 on a threefold site), see main text. This was further justified by the improvements which resulted in the overall refinement model, for example $R_1$ decreased from 0.068 to 0.063. The weighting scheme $w^{-1} = [\sigma^2(F_o^2) + (0.052P)^2 + 51.4P]$, $P = (\max(F_o^2,0) + 2F_c^2)/3$ was adopted. At final convergence[14] $R_1$ [$I > 2\sigma(I)$] = 0.0629, $wR_2$ (all data) = 0.1509 for 104 parameters, $S$ = 1.20, $(\Delta/\sigma)_{max}$ = 0.003, $\Delta\rho_{max}$ = 0.40 e Å$^{-3}$.

For $\{[AgL(MeCN)_2]BF_4\}_\infty$: $C_{18}H_{14}AgBF_4N_4$, $M$ = 481.01, monoclinic, space group $C2/c$ (no. 15), $a$ = 21.660(7), $b$ = 11.380(2), $c$ = 7.263(3) Å, $\beta$ = 100.93(3)°, $U$ = 1757.8(10) Å$^3$, $Z$ = 4, $F$(000) = 952, $D_c$ = 1.818 g cm$^{-3}$, $\mu$(Mo-Kα) = 1.198 mm$^{-1}$. A pale yellow plate (0.23 × 0.15 × 0.05 mm). Absorption corrections based upon $\psi$-scans were applied to the data ($T_{min}$ 0.8202, $T_{max}$ 0.9336), 1283 unique reflections [$R_{int}$ = 0.030], of which 1283 had $F_o \geqslant 4\sigma(F_o)$, were used in all calculations.The methyl carbon of the acetonitrile solvent molecule was found to be disordered over two equally occupied sites.The weighting scheme $w^{-1} = [\sigma^2(F_o^2) + (0.0246P)^2 + 8.19P]$, $P = [\max(F_o^2,0) + 2F_c^2]/3$ was adopted. At final convergence[14] $R_1$ [$I > 2\sigma(I)$] = 0.0393, $wR_2$ (all data) = 0.0809 for 148 parameters, $S$ = 1.04, $(\Delta/\sigma)_{max}$ = 0.002, $\Delta\rho_{max}$ = 0.58 e Å$^{-3}$.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # A tetranickel(II) macrocyclic complex incorporating five different bridging groups‡

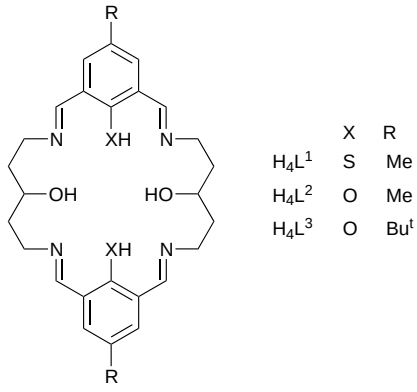
**Paul E. Kruger† and Vickie McKee***



*Chemistry Department, Queen's University, Belfast, Northern Ireland, UK, BT9 5AG*

**The synthesis and crystal structure of the tetranickel(II) complex $[Ni_4(L^1)(OH)(MeCO_2)_3(MeCO_2H)]$ is reported, where $H_4L^1$ is a macrocyclic ligand incorporating thiophenolate, alkoxo and imine donors; the faces of the tetranickel array are differentiated and two of the nickel ions share three monatomic bridges (S,O,O).**

As part of a programme to synthesise and investigate polynuclear arrays, we have characterised tetranuclear macrocyclic complexes of ligands $H_4L^2$ and $H_4L^3$ containing phenoxo and alkoxo bridging groups.[1] The properties of these arrays can, in principle, be modified by varying the donor groups, size of the macrocycle, nature of the metal ions *etc*. In this way the assemblies can be tuned to give control over various aspects of metal–metal interactions, redox properties and exogenous ligand binding. Here, we report the synthesis and characterisation of a neutral tetranickel(II) complex of $H_4L^1$, a new ligand in which the phenol donors are replaced by the larger and softer thiophenol group.

The tetranickel(II) complex was prepared by a template route. Solid $Ni(MeCO_2)_2{\cdot}4H_2O$ was added to 2,6-diformyl-4-methylthiophenol[2,3] in refluxing isopropyl alcohol under an inert atmosphere, followed by dropwise addition of 1,5-diamino-3-hydroxypentane[4] in methanol–isopropyl alcohol solution. After refluxing for 20 h, the volume of the solution was reduced, the brown powder filtered off, and recrystallised from chloroform–dichloromethane containing a small amount of methanol (yield *ca*. 30%). Microanalytical data were consistent with the formulation $[Ni_4L^1(OH)(MeCO_2)_3(MeCO_2H)]{\cdot}1.5\ H_2O$. The secondary ion mass spectrum confirms the presence of fragments containing the $[Ni_4L^1(OH)]^{3+}$ core. Clusters centred at: *m*/*z* 924 (15), 888 (20), 829 (100, base peak) and 770 (35) are assigned to $[Ni_4L^1(OH)(MeCO_2)_2(H_2O)_2]^+$, $[Ni_4L^1(OH)(MeCO_2)_2]^+$, $[Ni_4L^1(OH)(MeCO_2)]^+$ and $[Ni_4L^1(OH)]^+$, respectively. Dark brown crystals of the methanol solvate, $[Ni_4L^1(OH)MeCO_2)_3(MeCO_2H)]{\cdot}MeOH$, suitable for X-ray diffraction studies§ were obtained by slow diffusion of diethyl ether into a dmf–methanol solution of the complex. The asymmetric unit contains one $[Ni_4L^1(OH)(MeCO_2)_3(MeCO_2H)]{\cdot}MeOH$ complex (Fig. 1). The four coplanar nickel(II) ions are each coordinated to one thiophenolate sulfur, one alkoxy oxygen and one imine from the macrocycle and to a central $\mu_4$-hydroxo group, O(3). Six-coordination is completed by three bridging acetate ligands and one acetic acid group. The macrocyclic donors are *fac* for Ni(1) and Ni(4) but *mer* for Ni(2) and Ni(3). The coordinated acetic acid molecule forms a one-atom bridge between Ni(2) and Ni(3) and is also quite strongly hydrogen-bonded to a macrocyclic alkoxy donor [O(62)···O(2) 2.516(7) Å]. The description of this bond as $RCO_2H{\cdots}OR'$ rather than $RCO_2^-{\cdots}HOR'$ is made on the basis of an electron density peak 1.14 Å from O(62) and 1.46 Å from O(2) which is assigned to the carboxylic acid hydrogen. Similar coordinated acetic acid molecules are found in the related phenolate complex,[5] $[Ni_4L^3(OH)(MeCO_2)_3(MeCO_2H)_2]{\cdot}DMF{\cdot}H_2O$. The three acetate ligands act as conventional *syn-syn* three-atom bridges between pairs of nickel ions on the same side of the macrocyclic ring; one of the acetate ions is hydrogen-bonded to the solvent methanol [O(41)···O(71), 2.806(7) Å]. The oxygen atom of the central $\mu_4$-hydroxo group projects 0.581(4) Å from the plane of the four nickel ions into the cavity bounded by the three acetate ligands (Fig. 2) and is prevented from interacting with any other species. A sharp peak at 3598 $cm^{-1}$ in the infrared spectrum is consistent with this environment and assigned to the $\nu_{OH}$ vibration.[6] The hydroxo hydrogen atom was located unambiguously from difference Fourier maps.

Each nickel ion is linked to the next *via* three bridging groups. For Ni(1)···Ni(2) and Ni(3)···Ni(4) these are one alkoxo, one hydroxo, one 1,3-acetato group; for Ni(1)···Ni(4), thiophenolato, hydroxo and 1,3-acetato, while Ni(2) and Ni(3) are linked by three single-atom bridges [S(2), O(3) and O(61)], so that they share one octahedral face (Fig. 3). This geometry is not unusual where all three bridges are light atoms and there are several examples where all three are sulfur donors.[7] However, the only other example containing three mixed sulfur/light atom bridges is at the active site of the [NiFe] hydrogenase from *Desulfovibrio gigas* where two cysteine thiolates and a putative oxo species form three monatomic bridges between the Ni and Fe centres.[8] While the complex described in this paper is not

intended to model the biosite, it does provide some indications as to how accurate active site mimics could be achieved.

In Schiff-base ligands derived from 2,6-diformylthiophenols the large sulfur donor must be accommodated without appreciable expansion of the relatively inflexible thiophenol–diimine unit. This requirement generally causes the sulfur atom and the imine groups to lie on opposite sides of the plane of the phenyl ring with geometry similar to that at S(1).[3,9–11] The deviations from the plane of the phenyl ring (Fig. 2) are much greater at S(2), presumably as a consequence of the face-sharing geometry of Ni(2) and Ni(3). Overall, the complex is markedly unsymmetric; the faces of the tetranickel array can be distinguished and two different Ni sites can be identified. One face is closed by the three acetato ligands; on the other side access to Ni(1) and Ni(4) is blocked by the apical thiolate donor S(1) but Ni(2) and Ni(3) have one site occupied only by the neutral acetic acid group. The solubility of the neutral complex in chloroform–dichloromethane suggests that the anionic ligands remain coordinated in solution, at least in these solvents.

Details of the magnetic properties of the present complex will be discussed along with those of related complexes[5] but, in summary, the nickel ions are high-spin and the complex shows net antiferromagnetic coupling, very similar in magnitude to that observed in more symmetrical tetranickel(II) arrays.[5,12,13] Murray and coworkers[12,13] have modelled this behaviour in terms of isolated pairs of dimers each with a single $J$ of *ca.* $-30$ $cm^{-1}$.

We are grateful to the EPSRC for financial support and to Boujemaa Moubaraki and Keith S. Murray, Monash University, for the magnetic data.

§ *Crystal data*: $[Ni_4L^1(OH)(MeCO_2)_3(MeCO_2H)]\cdot MeOH$, $C_{37}H_{50}N_4Ni_4O_{12}S_2$, brown–green block, 0.60 × 0.53 × 0.32 mm, monoclinic, space group $P2_1/n$, $a$ = 11.105(2), $b$ = 18.297(3), $c$ = 20.027(3) Å, $\beta$ = 93.52(1)°, $U$ = 4061(1) $Å^{-3}$, $Z$ = 4, $\mu$ = 1.996 $mm^{-1}$, $F(000)$ = 2160. Using graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å) at 153(2) K, a total of 6009 reflections was collected in the range $4 < 2\theta < 50°$. Data were corrected for Lorentz and polarisation effects and a semiempirical aborption correction, based on $\psi$-scans, was applied ($T_{max}$ = 0.980, $T_{min}$ = 0.558). The structure was solved by direct methods[14] and refined by full-matrix least squares on $F^2$, using all 5278 independent reflections ($R_{int}$ = 0.0583). All the non-hydrogen atoms were refined with anisotropic atomic displacement parameters and hydrogen atoms bonded to carbon were inserted at calculated positions, hydrogen atoms bonded to oxygen were located from difference Fourier maps and not further refined. Refinement converged with $wR_2$ = 0.1351, GOF = 1.124 (all data) and $R_1$ = 0.0481 ($2\sigma$ data). All programs used in the structure refinement are contained in the SHELXL-93 package.[15] Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/507.

# Mesoporous M41S materials in capillary gas chromatography

**M. Raimondo, G. Perez,* M. Sinibaldi, A. De Stefanis and A. A. G. Tomlinson***

*Institutes of Chromatography and Materials Chemistry, Rome Research Area, CNR, C.P. 10 Monterotondo Staz., 00016 Rome, Italy*

**M-41S materials anchored to glass capillary columns *via* sol–gel techniques can be advantageously utilised for gas chromatographic separations.**

Rapid advances in preparing mesoporous materials such as those of the M41S class (particularly MCM-41[1]), pillared clays (PILCs) and analogues are due to their use as catalysts, especially in clean technology. However, MCMs have still to find practical application in this field, and it is possible they may instead be useful in others, such as separation technology. PILCs (pillared clays, which are micro/mesoporous) can separate inert gas mixtures and hydrocarbons,[2] which suggested using M41S solids in chromatographic separations, and in particular as stationary phases for gas–solid chromatography (GSC). Apart from benthone 34,[3] and differently from packed columns (where zeolites have been in use for some time)[4] other attempts to analyse liquid hydrocarbon mixtures by GSC on zeolites or expanded solids in general have failed, because strong sorption of individual components and/or their catalytic transformation due to intrinsic high acidity (at the relatively high temperatures required for elution) constitute limitations. Following successful use of mordenite in ion-exclusion chromatography,[5] we have found that it is possible to coat GC capillary columns with mesoporous silica-based MCM-41, which can separate organic molecules.

The MCM-41 used was prepared as in the original patent[6] and gave the reported XRPD and BET $N_2$ (specific surface area = 995 $m^2\ g^{-1}$). Fig. 1 shows both XRPD and an AFM image of the material. The latter shows that from toluene MCM-41 aggregates to form roughly platelet-shaped bundles of varying dimensions (typically 50–80 × 150–200 nm).

In a typical column preparation, a fused silica capillary (1 m long, 200 μm id; Composite Metal Services, UK) was modified with the silanizing agent, sulfanylpropyltrimethoxysilane [$(MeO_3)Si(CH_2)_3SH$, Aldrich] as follows. One end of the capillary was immersed in a vial containing 6 mol $dm^{-3}$ HCl and the solution allowed to flow through under pressure for 3 h. The capillary was then washed with water and silanizing agent

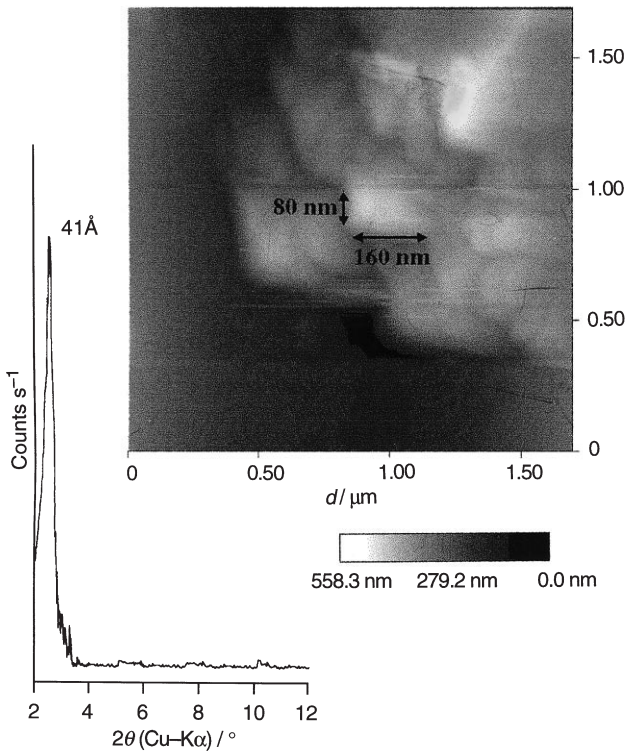

**Fig. 1** XRPD of MCM-41 utilised and AFM image showing the MCM morphology [conditions: Digital Nanoscope III instrument, deposit from ambient toluene suspension onto muscovite mica (001), followed by heating at 200 °C for 3 h; tapping mode]

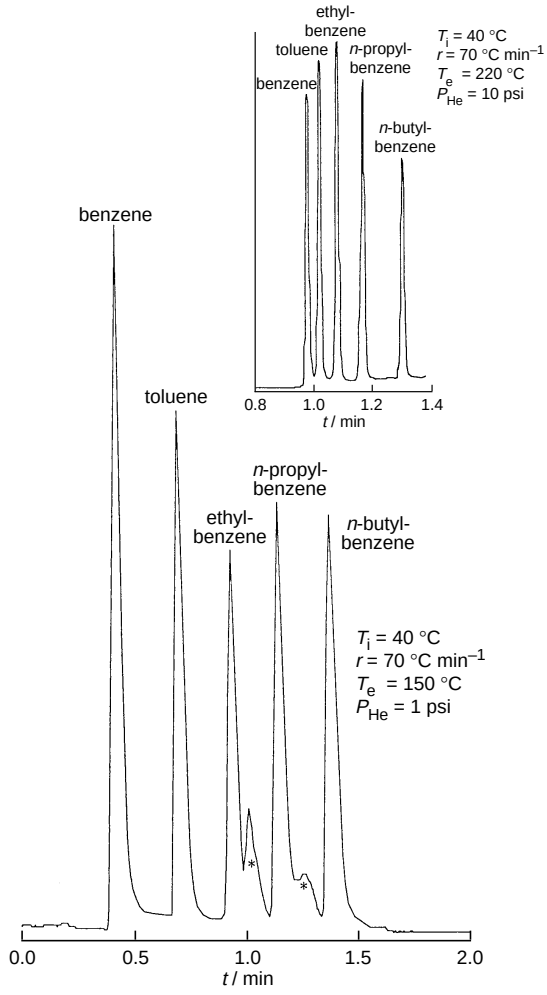

**Fig. 2** GC separation of hydrocarbon mixture on the MCM-41 film capillary column. Inset shows separations performed on a HP-1 type (polydimethylsiloxane) column; conditions: $l$ = 25 m, id = 0.53 mm. * = impurities.

by dipping one end of the tube, kept *ca*. 20 cm higher than the other end, into the reagent. The capillary was sealed using a sodium silicate solution and heated overnight (100 °C). After cooling, both ends of the capillary were cut, the solution decanted, and the capillary was dried, and then filled with a well shaken suspension of 0.5 g of the MCM-41 in dry toluene. The capillary was sealed and left to react at 60 °C overnight. After completion of the reaction, both ends of the capillary were cut and it was connected to a chromatographic delivery pump (Perkin Elmer, series 400 model) washed with hexane and $Pr^iOH$ and dried under He.

Fig. 2 shows a typical separation of a light hydrocarbon mixture (1 : 1 : 1 : 1 : 1): separation is achieved at much lower temperatures, with much shorter retention times and on shorter columns (1 m) rather than the 25–30 m of conventional capillary columns (inset). In control experiments, no separation was possible on capillaries which were identical, except for the MCM-41 attachment step. That separation indeed occurs within the MCM-41 cavities and by a mechanism depending on the proton affinities of the compounds, is neatly demonstrated in Fig. 3. For both benzene–diethyl ether and benzene–heptane mixtures there is inversion in elution order compared with standard GC on polydimethylsiloxane (insets). It is well known that oxygen-containing molecules are retained strongly on zeolites due to onium ion formation,[7] as is also benzene (*via* arenium ion formation[8]). It appears this is also the case for M41S materials. The generality of the behaviour (whether other porous silicas can be used) and other anchoring agents and separations are under investigation and the acidity of anchored MCM-41 is being modulated by cation exchange in order to maximise peak symmetry and separation factors.

# Ionic liquid–polymer gel catalytic membrane

**Richard T. Carlin* and Joan Fuller**

*Covalent Associates, Inc., 10 State Street, Woburn, Massachusetts, 01801, USA*

**A novel catalytic membrane for heterogeneous hydrogenation is fabricated by incorporating palladium into a gas-permeable ionic liquid–polymer gel composed of 1-*n*-butyl-3-methylimidazolium hexafluorophosphate and poly(vinylidene fluoride)–hexafluoropropylene copolymer.**

We have recently described the preparation and properties of novel ionic liquid–polymer gel electrolytes for application in a variety of electrochemical devices.[1] The gels are freestanding, flexible films composed of an air-stable, room-temperature ionic liquid and poly(vinylidene fluoride)–hexafluoropropylene copolymer [PVdF(HFP)]. The ionic liquids consist of a perfluorinated anion (*e.g.* $BF_4^-$, $CF_3SO_3^-$, $PF_6^-$) and a 1,3-dialkylimidazolium cation (*e.g.* 1-ethyl-3-methylimidazolium) and can have either hydrophilic or hydrophobic character.[2] Although many of the synthetic routes to the ionic liquids require expensive, environmentally undesirable reagents, such as silver salts, we have developed convenient, low-cost routes to high-purity hydrophilic and hydrophobic ionic liquids which make them readily available for research and commercial applications.[3]

A series of ionic liquids based on the 1-*n*-butyl-3-methylimidazolium cation ($BMI^+$) were recently demonstrated to be versatile solvents for homogeneous catalysis.[4] The catalysis was performed in a two-phase liquid–liquid design which greatly facilitates product recovery while maintaining the catalyst in the reactive ionic liquid phase. Gas-permeable membranes can also function as two-phase catalyst systems and can be engineered to enhance the desired chemical reactions.[5] The non-volatile ionic liquids have already been demonstrated as effective membrane materials for gas separations when supported within a porous polymer support.[6] Additionally, while ionic liquids composed of perfluorinated anions have only recently garnered interest as reaction media, other ionic liquids, particularly moisture-sensitive chloroaluminates, are well documented to be effective solvents for organic, inorganic and electrochemical reactions.[7] The efficacy of chloroaluminates as media for organometallic preparations is illustrated by recent reports of reductive carbonylation[8] and Friedel–Crafts acylation[9] of cyclopentadienyl complexes.

To take advantage of the ionic liquids as catalyst solvents and of the ruggedness of the ionic liquid–polymer gels, we have prepared ionic liquid–polymer gels containing a heterogeneous palladium catalyst. These composite materials were tested as a propene hydrogenation catalyst in a membrane configuration.

A typical ionic liquid–polymer catalytic membrane was prepared by mixing 0.044 g 10 mass% Pd on activated carbon (Pd/C, Aldrich), 1.08 g $BMIPF_6$,[3,4] and 0.576 g PVdF(HFP) (Kynar Flex 2801-00, Elf Atochem) with 3 ml 4-methylpentan-2-one (MP) under ambient conditions. This mixture was poured into an aluminium weighing pan of 5 cm diameter and was gelled by heating on a hot plate set at *ca.* 75 °C. The MP was allowed to evaporate overnight in ambient air. The final composite membrane was a flexible, dimensionally stable film with thickness *ca.* 0.06 cm and area *ca.* 14 $cm^2$, giving a total palladium metal loading of only *ca.* 0.3 mg $cm^2$. The ionic liquid imparts ionic conductivity and flexibility to the otherwise insulating, rigid PVdF(HFP) copolymer.

Fig. 1 shows two optical images of the membrane taken at 200× magnification with an inverted metallurgical microscope. The left-hand image was taken using reflected light and shows a few black Pd/C catalyst particles protuding through the otherwise featureless polymer gel surface. The right-hand image, taken in transmitted light with the focal plan positioned inside the membrane, clearly shows individual Pd/C particles dispersed throughout the membrane interior.

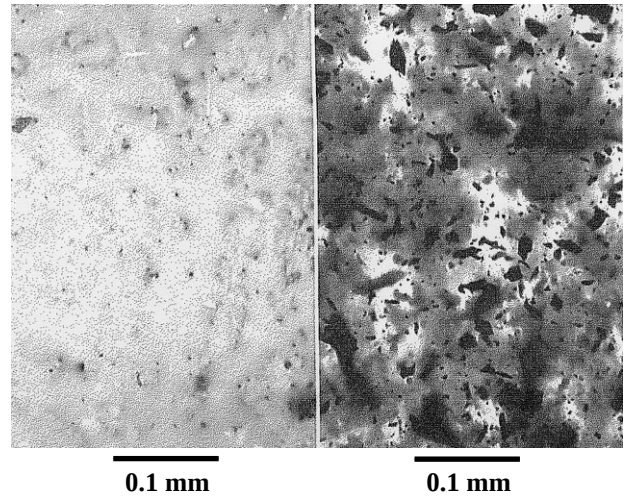

**Fig. 1** Optical images at 200× magnification showing the surface (left, reflected light) and interior (right, transmitted light) of the ionic liquid–polymer catalytic membrane

The ionic liquid–polymer membrane was loaded into a catalyst membrane reactor† and evaluated using propene hydrogenation as a model reaction. The propene permeability coefficient ($P_{propene}$) for the membrane was 300 barrers.‡ Fig. 2 summarizes the data collected for propene hydrogenation as a function of time, where $t_R = 0$ corresponds to the initial introduction of $H_2$ over the permeate side of the membrane. The flux of propene through the membrane decreased as the flux of propane increased, while the total flux (flux propene + flux

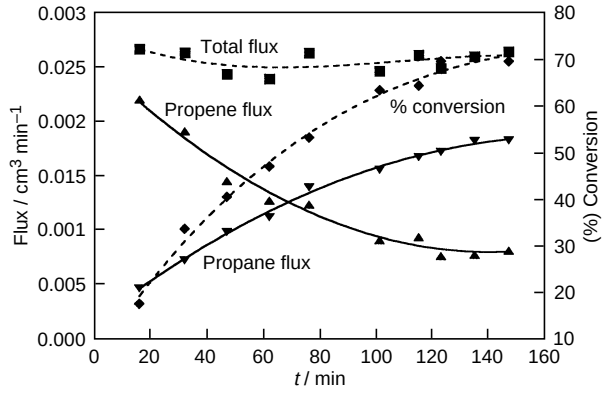

**Fig. 2** Plots of propene flux ( ▲ ), propane flux (▼), total flux (■) and % conversion (◆) as a function of time

propane) remained constant throughout the experiment. The conversion reached 70% after 2 h and remained constant after this time. We attribute the gradual rise in catalytic activity to the fact that the Pd/C particles are uniformly distributed throughout the ionic liquid–polymer gel structure, and so $H_2$ on the permeate side of the membrane must diffuse through the membrane interior to the catalyst sites. The time dependence of the fluxes for propene and propane follows $t^{1/2}$ behaviour, consistent with a diffusion-controlled model.

Ionic liquid–polymer gel membranes are a versatile matrix for exploring catalytic processes in the presence of a variety of ionic liquids.[1] Also, because the high ion concentration (*ca*. 3 M) is not detrimental to catalytic activity, these gel electrolytes may be useful for electrocatalytic applications.

## Footnotes

* E-mail: 73474.64@compuserve.com

† The membrane reactor was a Gelman 47 mm inline filter holder fitted with Swagelock Quick-Connect couplings for connection to feed and permeate gases. The filter holder used an O-ring sealing mechanism which gave an effective membrane area of 9.6 $cm^2$. During membrane experiments, the feed side of the membrane was contacted with static propene gas at 1 atm, while the permeate side was swept with $H_2$ at 10.5 $cm^3\ s^{-1}$ STP. The permeate gases were vented through a manual sample loop which was used to inject 1 ml samples into a gas chromatograph for analysis with a silica gel column and a TCD detector.

‡ 1 barrer = $10^{-10} \times 1\ cm^3$ (STP) cm $cm^{-2}\ s^{-1}\ cmHg^{-1}$.

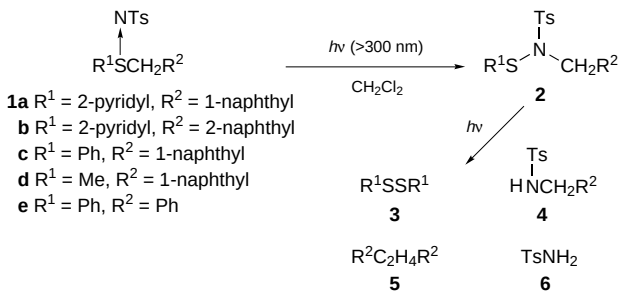
# Photo-Stevens rearrangement reaction of *S*-naphthylmethyl-*N*-*p*-tosylsulfimides

**Hiroyuki Morita,* Hideo Kamiyama, Miho Kyotani, Takayoshi Fujii, Toshiaki Yoshimura, Shin Ono and Choichiro Shimasaki**



*Department of Chemical and Biochemical Engineering, Faculty of Engineering, Toyama University, 3190 Gofuku, Toyama 930, Japan*

**Photolysis sulfimides unexpectedly led to Stevens rearrangement products.**

In the thermal reaction of sulfimides, the products derived *via* Stevens rearrangement were reported to be formed.[1] In the photolysis of sulfimides, however, it is reported that nitrenes are initially generated *via* a photo-induced cleavage of the S–N linkage.[2] In contrast to this mechanistic route for photolytic decomposition of sulfimides, another route *via* Stevens rearrangement was recently reported for the particular case of a cyclic sulfimide derivative, *i.e.* *N*-tosylnaphtho[1,8-*de*]-1λ⁴,3-dithiin-1-imine, which rearranged to naphtho[1,8-*ef*]-[1,4,2]dithiaazepine, followed by de-imination to give *N*-*p*-tosylaldimines and naphtho[1,8-*cd*]-1,2-dithiole quantitatively.[3] In this reaction the driving force apparently results from formation of a stable cyclic disulfide *via* the through-space interaction between the two sulfur atoms at the 1,8-positions of naphthalene.

In order to study more precisely and photolytic behaviour of acyclic sulfimide derivatives, we prepared several *S*-naphthylmethyl-*N*-*p*-tosylsulfimides and carried out their photolysis using a high-pressure mercury lamp with a Pyrex filter under nitrogen.† When **1a**‡ was irradiated in degassed MeOH under these conditions, the major products were dipyridyl disulfide **3a** and *N*-(naphthylmethyl)toluene-*p*-sulfonamide **4a**.§ In view of the formation of **4a**, the reaction is considered to pass through a rearrangement mechanism, *i.e.* a Stevens-type rearrangement as depicted in Scheme 1. Here we report the first examples of this photo-induced Stevens rearrangement reaction in *S*-naphthylmethyl-*N*-*p*-tosylsulfimide derivatives.

*S*-Aryl- or *S*-alkyl-*S*-naphthylmethyl-*N*-*p*-tosylsulfimides **1a**–**e** were prepared by the reaction of the corresponding sulfides with the sodium salt of *N*-chlorotoluene-*p*-sulfonamide (Chloramine T) in MeCN in high yields. Photolysis of *S*-naphthylmethyl-*N*-*p*-tosylsulfimides in degassed $CH_2Cl_2$ was carried out under the previously described conditions for 2 h. The results are summarized in Table 1. The photolyses of *S*-pyridyl-, *S*-phenyl- and even *S*-methyl-*S*-(1-naphthylmethyl)- or *S*-(2-naphthyl-methyl)-*N*-*p*-tosylsulfimide derivatives **1a**–**d** (entries 1–4) were found to lead to the Stevens rearrangement product **2**, as well as **3** and **4**, which are formed by photolysis of **2** in a secondary photochemical step, while in the photolysis of *S*-benzyl-*S*-phenyl-*N*-*p*-tosylsulfimide **1e** (entry 5), the reaction

**Scheme 1**

did not proceed at all. This result suggests that a napthyl group is necessary in this reaction as a useful chromophore to accept photoirradiation and to initiate the photoreaction. Therefore, measurements of the UV–VIS spectra of **1a**–**d** were carried out and showed, as expected, the existence of a strong absorption band ($\log\varepsilon = 4.9$) around 230 nm, extending beyond the 300 nm region as shoulders, while **1e** showed no absorption beyond 300 nm.

A further study of the photolysis of *S*-(2-pyridyl)-*S*-(1-naphthylmethyl)-*N*-*p*-tosylsulfimide **1a** in several solvents was carried out under the same conditions. The products formed were found to depend significantly on the nature of solvents used. In aprotic solvents such as $CH_2Cl_2$ and MeCN, the primary rearranged product **2a**¶ was formed as the major product; however, in acetone the secondary products **3a** and **4a** were the major products, presumably due to acceleration of the photochemical excitation of **2a** by probable triplet sensitization of acetone, as suggested by Guo and Jenks in the photolysis of sulfoxide.[4] Meanwhile, in alcoholic solvents, another mechanistic path is apparently involved and toluene-*p*-sulfonamide **6**, as well as the products **3a** and **4a** *via* Stevens-type rearrangement, was formed predominantly. One possibility for this mechanism is the nitrene pathway, which would immediately lead to sulfonamide **6** and the corresponding sulfide, which is observed to decompose to **3a** and **5a** under the same conditions. Another possibility is a pathway involving the initial protonation at the iminonitrogen atom of the sulfimide and subsequent

formation of an alkoxysulfonium salt (counter anion $TsNH^-$) which eventually decomposes to the corresponding sulfide and a carbonyl compound.‖ A similar mechanism was suggested by Oae in the case of the thermolysis of *N*-*p*-tosylsulfimides in MeOH.[1a]

In order to confirm the mechanistic pathway of this photoreaction, the product distribution in the course of photolysis of **1a** in $CH_2Cl_2$ under the previously described conditions was determined by quantitative analysis with HPLC. The result is illustrated in Fig. 1; the amount of starting sulfimide **1a** decreased gradually, and three new species appeared. Two were found to be di(2-pyridyl) disulfide **3a** and *N*-(1-naphthylmethyl)toluene-*p*-sulfonamide **4a** by comparing their HPLC retention times and their spectral data with those of authentic compounds prepared or separated by chromatography. The third species showed a maximum after 40 min and then gradually decreased. This probably points to the existence of the intermediate **2** in this reaction, which apparently reacted to give the products **3a** and **4a**. Therefore, the reaction mixture was separated by HPLC after 40 min photolysis and the product corresponding to this intermediate was identified as **2a**. Further, in order to clarify that **2a** is exactly the intermediate of this reaction, photolysis of **2a** thus separated was carried out under the same conditions to afford the expected products **3a** and **4a** in good yields. All these results indicate clearly that this reaction proceeds *via* a photo-induced Stevens rearrangement to afford the intermediate **2a**, which subsequently decomposes to dipyridyl disulfide **3a** and *N*-(1-naphthylmethyl)toluene-*p*-sulfonamide **4a** together with a small amount of product **5a** *via* direct cleavage of the S–$CH_2$ linkage.

We are now pursuing further studies to clarify the limitations and the detailed mechanism of this reaction.

† All photolyses were carried out in 9 mm i.d. Pyrex glass tubes, sealed with a septum under nitrogen atmosphere at room temperature, with irradiation from a 400 W high-pressure mercury lamp.

‡ Compound **1a** was prepared by the following procedure: a solution of pyridyl naphthylmethyl sulfide and Chloramine T (1.5 equiv.) in 100 ml of MeCN was refluxed for 6 h. After removal of MeCN, washing with water to remove excess Chloramine T and drying, *S*-pyridyl-*S*-naphthylmethyl-*N*-*p*-tosylsulfimide was obtained in 88% yield, mp 164 °C (AcOEt–hexane). *Selected data* for **1a**: $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ 2.20 (s, Me, 3 H), 4.46 (dd, *J* 13 Hz, 1 H), 5.34 (dd, *J* 13 Hz, 1 H), 6.63–6.65 (m, 2 H), 7.17–7.34 (m, 5 H), 7.48–7.58 (m, 3 H), 7.75–7.84 (m, 2 H), 7.97–8.08 (m, 2 H), 8.31–8.33 (m, 1 H), 8.70–8.72 (m, 1 H); $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ 21.3, 54.8, 122.1, 122.9, 123.7, 125.1, 125.5, 125.7, 126.1, 127.0, 127.8, 128.8, 128.8, 129.5, 130.0, 131.2, 131.3, 133.6, 138.9, 140.8, 149.9; $\nu_{max}$ (KBr)/cm$^{-1}$ 1280, 1100 ($SO_2$), 980 (SN); Calc. for $C_{23}H_{20}N_2O_2S_2$: C, 65.68; H, 4.79; N, 6.66. Found: C, 65.52; H, 4.84; N, 6.49%.

§ *Selected data* for **4a**: $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ 2.45 (s, Me, 3 H), 4.53 (d, *J* 1 Hz, $CH_2$, 2 H), 4.63 (d, *J* 2 Hz, NH, 1 H), 7.25–7.35 (m, 4 H), 7.46–7.51 (m, 2 H), 7.77–7.90 (m, 5 H); $^{13}$C NMR (100 MHz, $CDCl_3$); $\delta$ 21.5, 45.4, 123.2, 125.1, 126.0, 126.7, 126.9, 127.2, 128.7, 129.1, 129.7, 131.1, 133.7, 136.4, 143.5; $\nu_{max}$ (KBr)/cm$^{-1}$ 1330, 1160 ($SO_2$), 3300 (NH); *m/z* 311 ($M^+$); Calc. for $C_{18}H_{17}NO_2S$: C, 69.42; H, 5.50; N, 4.49. Found: C, 69.51; H, 5.62; N, 4.33%.

¶ *Selected data* for **2a**: $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ 2.44 (s, Me, 3 H), 6.70—6.73 (m, 1 H), 6.81–6.83 (m, 1 H), 6.99–7.03 (m, 1 H), 7.30–7.36 (m, 3 H), 7.47–7.49 (m, 1 H), 7.57–7.61 (m, 1 H), 7.65–7.67 (d, *J* 2 Hz, 1 H), 7.74–7.76 (d, *J* 2 Hz, 1 H), 7.85–7.88 (m, 2 H), 8.08–8.10 (m, 1 H), 8.44–8.47 (m, 1 H); $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ 21.6, 55.8, 118.3, 119.9, 123.8, 124.8, 125.7, 126.7, 127.9, 128.5, 129.3, 129.6, 129.7, 130.0, 131.9, 133.5, 135.0, 136.1, 144.3, 148.1, 160.6; $\nu_{max}$(KBr)/cm$^{-1}$ 1351, 1165 ($SO_2$); *m/z* 78 ($C_5H_5N^+$), 127 ($C_{10}H_7^+$), 141 ($C_{10}H_7CH_2^+$), 155 ($Ts^+$), 156 ($C_{10}H_7CH_2NH^+$), 311 ($TsNHCH_2C_{10}H_7^+$), 420 ($M^+$); Calc. for $C_{23}H_{20}N_2O_2S_2$: C, 65.68; H, 4.79; N, 6.66. Found: C, 65.86; H, 4.79; N, 6.60%. The methylene protons ($CH_2C_{10}H_7$) were not observed in the $^1$H NMR spectrum, even after varying the solvent, although all other analytical and combustion data confirmed this structure.

‖ In MeOH the formation of paraformaldehyde was observed.

**The first dodecanuclear heterobimetallic cage cluster with a central $\mu_6$-S ligand, containing the core $[\{M_2Ag_2S_2O_2(edt)_2\}_3(\mu_6\text{-}S)]^{2-}$ (M = Mo, W; $H_2$edt = ethane-1,2-dithiol), is synthesized and characterized; the average Ag–$\mu_6$-S bond length of the core $[\{Mo(W)_2Ag_2S_2O_2(edt)_2\}_3(\mu_6\text{-}S)]^{2-}$ is 2.528 (2.531) Å.**

The chemistry of heterometallic cluster compounds has attracted considerable attention for their uses as models for the active sites in a variety of metalloenzymes and their potential applications as functional materials in several fields.[1] Heterometallic cluster compounds containing $[MS_4]^{2-}/M'^{+}$ (M = Mo, W; M′ = Cu, Ag) have been extensively studied.[2] At present, some polynuclear $M^{VI}$–Ag–S (M = Mo, W) cluster compounds such as $NEt_4[(PPh_3)_2Ag(\mu\text{-}S)_2Mo(\mu\text{-}S)OCu(CN)]$ (butterfly),[3] $[\{Ag(PPh_3)\}_3MoS_4Cl]$ (cubane-like),[4] $[Ag_6M_2S_6O_2(Me_3CS)_2(PPh_3)_4]$ (double-cubane-like),[5] $[M_2S_8Ag_4(PPh_3)_4]$ (cage),[6] $[W_4Ag_5S_{16}\cdot Nd(dmf)_8]_n$ (one-dimensional chain)[7] and $[WS_4Ag\cdot NH_3C(CH_2OH)_3\cdot H_2O]_n$ (double chain)[8] have been characterized. A few $M^{V}$–Ag–S complexes such as $[M_2AgS_4(edt)_2(PPh_3)]^-$ (incomplete cubane-like)[9] and $[\{(PPh_3)Ag\}_2Mo_2S_4(tdt)_2]$ (cubane-like)[10] have been reported. However, no non-polymeric M–Ag–S (M = Mo, W) complexes with more than nine metal centers have, as yet, been synthesized.

Herein the syntheses and characterization of novel dodecanuclear heterobimetallic clusters $[NEt_4]_2[\{M_2Ag_2S_2O_2(S_2C_2H_4)_2\}_3(\mu_6\text{-}S)]\cdot CH_2Cl_2\cdot MeCN$ (M = Mo **1**, W **2**) with cage cores $[\{M_2Ag_2S_2O_2(S_2C_2H_4)_2\}_3(\mu_6\text{-}S)]^{2-}$ (M = Mo, W) are described, the first molybdenum(v) or tungsten(v)–silver clusters containing a $\mu_6$-S ligand. To our knowledge, this type of cluster containing $\mu_6$-S is rare in molybdenum or tungsten(v)–copper(silver) clusters, the only example being $[NEt_4]_2[Mo_6Cu_6S_6(\mu_6\text{-}S)O_6(S_2)_6]$ synthesized by our group;[11] reaction of $AgNO_3$ with $[NEt_4]_2[Mo_2S_2O_2(S_2)_2]$ did not lead to an analogous Mo–Ag complex.

The starting material $[NEt_4]_2[Mo_2O_2S_2edt_2]$ **3** was prepared according to ref. 12 and $[NEt_4]_2[W_2S_4(edt)_2]$ **4** was obtained by published procedure;[13] all other chemicals were purchased. Both compounds **1** and **2** were synthesized in the air by the 'spontaneous self-assembly' method. To the solution of $[NEt_4]_2[Mo_2S_2O_2(edt)_2]$ **3** (0.356 g, 0.5 mmol in 20 ml MeCN–20 ml $CH_2Cl_2$) was added $AgNO_3$ (0.17 g, 1.0 mmol in 20 ml MeCN–20 ml $CH_2Cl_2$), and the mixture was stirred for 0.5 min. Then two drops of an $(NH_4)_2S$ solution (containing 8% S) were added, the reaction mixture was stirred for 5 min, and the resulting brown precipitate was filtered off. The orange filtrate was allowed to stand at room temp. in the air for 5 days after which 0.06 g of red crystals of **1** were obtained.† Similarly, to a solution of $[NEt_4]_2[W_2S_4(edt)_2]$ **4** (0.470 g, 0.5 mmol in 20 ml MeCN–20 ml $CH_2Cl_2$) was added four drops of aqueous $H_2O_2$ (30% $H_2O_2$) under stirring for 2 h, $AgNO_3$ (0.17 g, 1.0 mmol in 20 ml MeCN–20 ml $CH_2Cl_2$) was then added and the mixture was stirred for 0.5 min. Two drops of $(NH_4)S$ solution were added and the reaction mixture stirred for 5 min, and the resulting brown precipitate was filtered off. The yellow filtrate was allowed to stand at room temp. in the air for 5 days after which 0.07 g of orange crystals of **2** were obtained.†

X-Ray structure analysis‡ revealed the existence of the cage core of $[\{M_2Ag_2S_2O_2(edt)_2\}_3(\mu_6\text{-}S)]^{2-}$ (M = Mo, W), a tripolymer consisting of three $[M_2S_2O_2(edt)_2]^{2-}$ and two $Ag^+$ fragments, with an S atom in the center binding to six Ag atoms. Cluster **1** is isomorphous with the corresponding tungsten cluster **2** and only the structure of **1** is thus described. An ORTEP drawing of the anion of **1** is shown in Fig. 1. From the configuration of the twelve metal atoms and all the S atoms, the core can be described as a cage with an $S^{2-}$ at its center. The cage has two windows each composed of a puckered $Ag_3S_6C_6$ 15-membered ring which is composed of three Ag atoms combining three $^-SC_2H_4S^-$ units; the $S^{2-}$ ion can enter the cage through the window and is coordinated to six Ag atoms, forming $\mu_6$-S. The Ag–$\mu_6$-S distances range from 2.504 to 2.556 Å, av. 2.528 Å (in **2** the av. Ag–$\mu_6$-S length is 2.531 Å). There are three weak Ag–Ag metal–metal bonds with Ag(1)–Ag(2), Ag(3)–Ag(4), Ag(5)–Ag(6) 3.0652, 3.0354, 3.0799 Å, respectively; angles Ag(1)–$\mu_6$-S–Ag(2), Ag(3)–$\mu_6$-S–Ag(4), Ag(5)–$\mu_6$-S–Ag(6) are 74.24, 74.13, 75.18°, respectively.

Each Mo atom displays tetragonal-pyramid (*TPY*) coordination geometry, with two S atoms of $^-SC_2H_4S^-$ ($S_{edt}$), two bridging S atoms of binuclear molybdenum ($S_{br}$) and one terminal oxygen atom. The oxygen atom occupies the axial position of each *TPY* and the four remaining sulfido atoms are

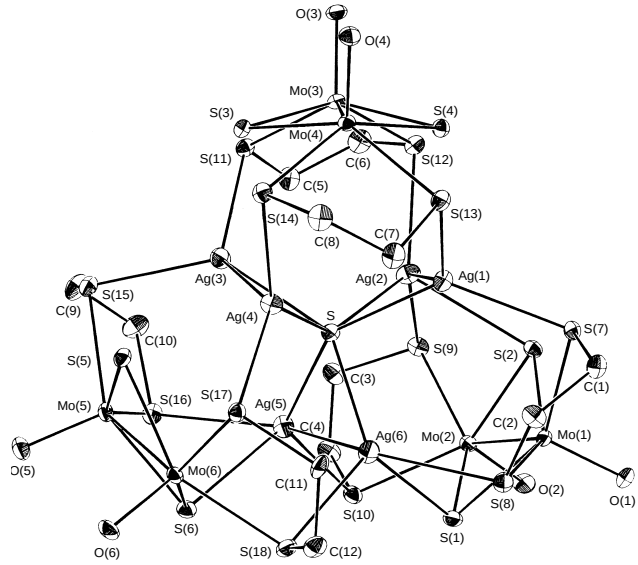

**Fig. 1** ORTEP diagram of $[\{Mo_2Ag_2S_2O_2(edt)_2\}_3(\mu_6\text{-}S)]^{2-}$ (10% displacement ellipsoids). Selected distances (Å) and angles (°): Mo(1)–Mo(2) 2.8861(14), Mo(3)–Mo(4) 2.8859(13), Mo(5)–Mo(6) 2.8802(14), Mo–$S_{edt}$ (av) 2.438(3), Ag(1)–Ag(2) 3.0652(14), Ag(3)–Ag(4) 3.0354(14), Ag(5)–Ag(6) 3.0799(15), Ag(1)–S 2.556(3), Ag(2)–S 2.523(3), Ag(3)–S 2.533(3), Ag(4)–S 2.504(3), Ag(5)–S 2.539(3), Ag(6)–S 2.510(3), Ag(5)–S(16) 2.694(3), Ag–$S_{edt}$ (av) 2.584(3), S(1)–Ag(6) 2.794(3), S(2)–Ag(2) 2.721(3), S(3)–Ag(3) 2.863(3), S(4)–Ag(1) 2.853(3), S(5)–Ag(4) 2.889(3), S(6)–Ag(5) 2.758(3); Ag(1)–S–Ag(2) 74.24(8), Ag(3)–S–Ag(4) 74.13(9), Ag(5)–S–Ag(6) 75.18(9), $S_{br}$–Mo–$S_{br}$ (av) 101.73(11), $S_{edt}$–Mo–$S_{edt}$ (av) 81.27(11).

equatorial. The average $S_{br}$–Mo–$S_{br}$ angle is 101.73°. Each Mo atom is chelated by one $^{-}SC_2H_4S^{-}$ forming a five-membered ring, and the average Mo–$S_{edt}$ and average $S_{edt}$–Mo–$S_{edt}$ angle are 2.438 Å and 81.27°, respectively. The average Mo–Mo distance of 2.8841 Å is almost the same as in $[M_2Ag$-$S_4(edt)_2(PPh_3)]^{-}$[9] (2.881 Å) and slightly longer than in $[NEt_4]_2[Mo_2S_4(edt)_2]$[17] (2.863 Å).

Each $^{-}SC_2H_4S^{-}$ is coordinated by two Ag atoms through its two S atoms with Ag–$S_{edt}$ ranging from 2.496 to 2.694 Å, and the average Ag–$S_{edt}$ distance is 2.584 Å.

It is interesting that the distances of six $S_{br}$ atoms of the three $[Mo_2S_2O_2(edt)_2]$ moieties of cluster **1** to the corresponding Ag atoms are different, and all are longer than the longest Ag–$S_{edt}$ [Ag(5)–S(16) 2.694(3) Å] or the longest Ag–$\mu_6$-S distance [Ag(1)–S, 2.556(3) Å]. Two $S_{br}$ atoms of one $[Mo_2S_2O_2(edt)_2]$ are also weakly bonded to the corresponding Ag atoms [S(1)–Ag(6) 2.794(3), S(1)–Ag(2) 2.721(3) Å] while only one $S_{br}$ atom of a second $[Mo_2S_2O_2(edt)_2]$ is bonded [S(6)–Ag(5) 2.758(3) Å], the other $S_{br}$ atom of this $[Mo_2S_2O_2(edt)_2]$ shows a longer Ag···$S_{br}$ non-bonding distance [S(5)–Ag(4) 2.889(3) Å]; for the third $[Mo_2S_2O_2(edt)_2]$, none of $S_{br}$ atom bonds to Ag [S(4)···Ag(1) 2.853(3), S(3)···Ag(3) 2.863(3) Å]. The three longer Ag···$S_{br}$ non-bonding distances suggest that there is only weak interaction between Ag(1) and S(4), Ag(3) and S(3), Ag(4) and S(5). Therefore, there are three four-coordinate Ag atoms in compound **1** [Ag(2), Ag(5), Ag(6)]; (two $S_{edt}$, one $S_{br}$ and $\mu_6$-S atom) to give a distorted tetrahedral geometry [angles S–Ag–S are in the wide range 68.00(10)–128.11(10)°]. The other Ag atoms [Ag(1), Ag(3), Ag(4)] are three-coordinate, each being coordinated by three S atoms ($\mu_6$-S and two $S_{edt}$).

This research was supported by grants from the State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, the Chinese Academy of Sciences, and the Science Foundations of the Nation and Fujian Province.

† *Spectroscopic data* for **1**: IR (KBr pellet): $\nu$/cm$^{-1}$: $\nu$(Mo–μ-S) and $\nu$(Mo–$\mu_3$-S) 468.6 m, 439.7 m; $\nu$(Mo–O) 954.6 s. UV (dmf solution): $\lambda$/nm ($\varepsilon$/dm$^3$ mol$^{-1}$ cm$^{-1}$): 266 ($3.7 \times 10^4$), 302 ($3.8 \times 10^4$).

For **2**: IR (KBr pellet): $\nu$/cm$^{-1}$: $\nu$(W–μ-S) and $\nu$(W–$\mu_3$-S) 464.8 m, 424.3 m; $\nu$(W–O) 962.3 s. UV (dmf solution): $\lambda$/nm ($\varepsilon$/dm$^3$ mol$^{-1}$ cm$^{-1}$): 280 ($3.17 \times 10^4$), 340 ($1.45 \times 10^4$).

‡ For all structural analyses, all calculations were performed on a Indyworkstation of a silicon Graphics instrument with SHELXTL program.[14] The structure was solved by direct methods, and the positions of Mo/W and Ag atoms were obtained from E maps. The remaining non-hydrogen atoms were located from successive difference Fourier maps. The refinement of structures was performed by full least-squares techniques on $F^2$ using SHELXL-93.[15] Data were corrected with program SADABS.[16]

*Crystal data*: **1**: $C_{31}H_{69}Ag_6Cl_2Mo_6N_3O_6S_{19}$, $M_r$ = 2482.29, tetragonal, space group $I4_1/a$, $a = b$ = 42.013(4), $c$ = 16.034(2) Å, $U$ = 28301.4 Å$^3$, $Z$ = 16, $D_c$ = 2.331 g cm$^{-3}$, $T$ = 293(2) K; $\lambda$(Mo-Kα) = 0.710 73 Å, $\theta$ range 1.93–23.26°. Siemens Smart CCD diffractometer, ω scan. 10 141 unique reflections were used in the refinement and 7231 reflections with $I > 2\sigma(I)$ used to calculate $R$ and $R_w$. The last successful full-matrix least-squares refinement with anisotropic thermal parameters for Mo, Ag, S, O, C atoms of the cluster core, isotropic thermal parameters for all N, C, Cl atoms of the cations and the solution molecule (538 variables) converged to $R$ = 0.0499, $R_w$ = 0.1062, GOF = 1.079 (no attempt was made to locate hydrogen atoms).

**2**: $C_{31}H_{69}Ag_6Cl_2N_3O_6S_{19}W_6$, $M_r$ = 3010.26. $a = b$ = 42.0176(6), $c$ = 16.0098(3) Å, $U$ = 28265.0 Å$^3$, $D_c$ = 2.830 g cm$^{-3}$, $T$ = 293(2) K, $\theta$ range 1.37–23.24°. 10 126 unique reflections were used in the refinement and 7609 reflections with $I > 2\sigma(I)$ used to calculate $R$ and $R_w$. Anisotropic thermal parameters for W with other details as above. $R$ = 0.0586, $R_w$ = 0.1440, GOF = 1.020. CCDC 182/517.

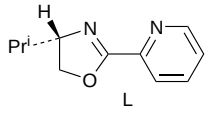
# Chiral arene ruthenium complexes as asymmetric Diels–Alder catalysts



**David L. Davies,* John Fawcett, Shaun A. Garratt and David R. Russell**

*Department of Chemistry, University of Leicester, Leicester, UK LE1 7RH*

**The cation [RuCl(L)(η⁶-mes)]⁺ [L = 4-isopropyl-2-(2-pyridyl)-1,3-oxazoline] is synthesised diastereoselectively; treatment with $AgSbF_6$ gives a dication which is an enantioselective catalyst for the asymmetric Diels–Alder reaction between methacrolein and cyclopentadiene.**

Recently, much attention has focussed on the development of chiral Lewis-acid catalysts for a variety of carbon–carbon bond-forming reactions.[1] Impressive results have been reported for Diels–Alder reactions mostly with titanium, aluminium or boron based catalysts.[2] Such catalysts have a number of drawbacks *viz*. they are often extremely sensitive to water, hence are generally employed at high catalytic loadings (often *ca*. 20%); also, attempts to understand the mechanisms of catalysis and selectivity are hampered by the complexity of the chemical behaviour of the catalyst, *e.g.* formation of oligomers, ligand-exchange reactions. Recently some transition-metal and lanthanide complexes have been described as promising catalysts for these reactions.[3] Half-sandwich complexes have been extensively used in stoichiometric and catalytic organic transformations often with impressive asymmetric induction. Indeed, half-sandwich complexes of Rh and Fe with chiral phosphorus ligands have recently been shown to be asymmetric catalysts for Diels–Alder reactions.[4]

Bisoxazolines have given high enantioselectivity in a number of asymmetric catalytic processes, for example copper catalysed cyclopropanation and aziridination[5] and more recently Diels–Alder reactions;[3b,c,f] whilst phosphino-oxazolines work well in palladium-catalysed allylic substitution.[5c,6] However, the use of these types of ligands with half-sandwich complexes is less well studied, the first arene ruthenium complexes with bisoxazoline ligands having been reported recently.[7]

L

Refluxing L with $[RuCl_2(\eta^6\text{-mes})]_2$ (mes = 1,3,5-trimethylbenzene) in methanol in the presence of $NaSbF_6$ or $KPF_6$ gives [RuClL(η⁶-mes)]X (X = $SbF_6$, $PF_6$) in good yield.† The complexation of the ligand is highly diastereostereoselective, only one of two possible diastereomers being observed by $^1H$ NMR spectroscopy. The X-ray structure was carried out to determine which diastereomer was formed. The structure of the cation with selected bond distances and angles is shown in Fig. 1.‡ The ruthenium has a pseudo-octahedral geometry with L coordinated such that the isopropyl substituent is on the same side as the chloride rather than the arene to miminise unfavourable steric interactions. The Ru–N(1) oxazoline and Ru–N(2) pyridine bond lengths are the same, as found previously for other 2-iminopyridine complexes.[8] The use of L-valine in the ligand preparation means that the configuration at the chiral carbon is (*S*) and the structure shows that the ruthenium is also (*S*) (based on the priority arene > Cl > $N_{ox}$ > $N_{py}$).[9] There is no evidence for formation of the other diastereomer in the NMR spectrum and thus it is assumed that this geometry is retained in solution and the configuration at ruthenium is stable in $CD_2Cl_2$ solution as found for related iminopyridine complexes.[8b]

In order for the complex to be used as a Lewis-acid catalyst the chloride must be removed, this is easily done by treating with $AgSbF_6$ in acetone–water to give $[Ru(H_2O)L(\eta^6\text{-mes})][SbF_6]_2$ **2**.† The $^1H$ NMR spectrum of **2** in $[CD_2Cl_2$–$(CD_3)_2CO$ 10 : 1] shows a broad singlet at $\delta$ 5.40 due to coordinated water with free water from the NMR solvent at $\delta$ 1.81. The observation of separate signals for free and co-ordinated water indicates that water exchange is relatively slow on the NMR timescale.

Complex **2** catalyses the Diels–Alder reaction between methacrolein and cyclopentadiene (Table 1).§ The reaction proceeds rapidly at room temp. (essentially quantitative conversion in < 45 min monitored by $^1H$ NMR) at low catalyst loading (as little as 0.5 mol%) and with good *exo* : *endo* selectivity (⩾95 : 5) and good enantioselectivity (ee 70%) (entry 1). As can be seen from entries 2, 5 and 7 increasing the catalyst ratio to 5 mol% has very little effect on the *exo* : *endo* ratio or on the enantioselectivity. However, reducing the temperature of the reaction to 0 °C (entries 3, 6 and 8) or −20 °C (4 and 9) leads to small improvements in the enantioselectivity. The major product is identified as (1*R*,2*S*,4*R*)-2-methylbicyclo[2.2.1]hept-5-ene-2-carbaldehyde by comparison of the sign of the optical rotation [$\alpha$], and the GC behaviour of the acetal formed from (2*R*,4*R*)-pentanediol with literature values.[3b] The absolute configuration of the major *exo* product can be rationalised by assuming that the methacrolein coordinates in the preferred *S–trans* conformation with the aldehyde H pointing towards the

[a] NMR tube reaction, yield from integration. [b] r.t. = Room temperature. [c] Isolated yield.

arene ring; the alternative orientation formally obtained by a 180° rotation about the Ru–O bond would be disfavoured due to steric interactions between the vinyl substituent and the arene. Attack of the cyclopentadiene is expected to occur at the *Re* face of the methacrolein, the *Si* face being shielded by the isopropyl of L which is consistent with the observed major product. Further studies to try and identify the actual catalyst, *i.e.* with methacrolein coordinated, to extend the range of substrates and to optimise the enantioselectivity are currently underway.

We thank the University of Leicester for a studentship (S. A. G.) and Johnson Matthey for a loan of $RuCl_3$.

Satisfactory elemental analysis (C, H, N).

‡ *Crystal data* for **1**: $C_{20}H_{26}ClF_6N_2OPRu$, $M$ = 591.92, orthorhombic, space group $P2_12_12_1$, $a$ = 8.461(1), $b$ = 9.330(1), $c$ = 29.347(4) Å, $U$ = 2316.5 Å$^3$, $Z$ = 4, $D_c$ = 1.697 g cm$^{-3}$, $\mu$ = 0.925 mm$^{-1}$, $F$(000) = 1192, graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). Data collected on a Siemens P4 diffractometer at 190 K. 3080 reflections collected with 5 < $\theta$ < 25°, 2881 unique ($R_{int}$ = 0.027). A $\psi$-scan absorption correction was applied. The structure was solved by Patterson methods and refined using full-matrix least squares on $F^2$ (SHELXL-96). Anisotropic displacement parameters used for all atoms, hydrogens included in calculated positions (C–H 0.96 Å), with isotropic displacement parameters set to 1.2 $U_{eq}$(C). Final $R_1$ = 0.0406, $wR_2$ = 0.0838 for all data). CCDC 182/521.

§ NMR tube experiments (in air): methacrolein (*ca.* 0.25 mmol) was added to a suspension of **2** (1.25, 2.5, 5, or 12.5 μmol) in $CD_2Cl_2$ (0.5 cm$^3$) which lead to rapid dissolution of **2** to give a yellow solution. The solution was transferred to an NMR tube and 2,6-di-*tert*-butylpyridine (1 equiv./mol catalyst) and cyclopentadiene (0.5 mmol) were added. The $^1$H NMR spectrum was run immediately and then repeated after suitable time intervals. Schlenk reactions (under $N_2$). Methacrolein (1 mmol) and 2,6-di-*tert*-butylpyridine (1 equiv./mol catalyst) were added to a suspension of **2** (0.01, 0.02, or 0.05 mmol) in $CH_2Cl_2$ (2 cm$^3$). The resulting yellow solution was cooled to the appropriate temperature before addition of cyclopentadiene (2 mmol). At the end of the reactions, the mixture was passed through a silica plug, the solvent was removed and the product was obtained as a colourless oil. The *exo : endo* ratio was determined by NMR spectroscopy and the enantiomeric excess was determined by GC after conversion to the acetal with (2*R*,4*R*)-pentanediol.[3b] The catalyst could also be prepared *in situ* from complex **1** and 1 equiv. of $AgSbF_6$ in $CH_2Cl_2$, filtration through Celite into a Schlenk tube to remove AgCl and then addition of the reagents as described above.

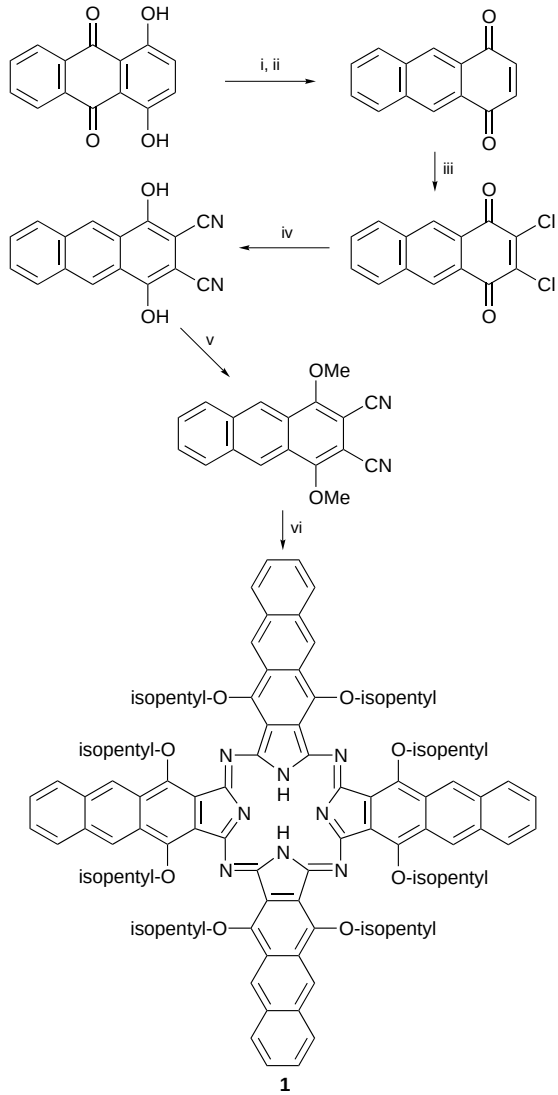
# The synthesis of a symmetrically substituted α-octa(isopentoxy)anthralocyanine



**Peter V. Bedworth,[a] Joseph W. Perry[a,b] and Seth R. Marder*[a,b]**

[a] *Beckman Institute, 139-74 California Institute of Technology, Pasadena, CA 91125, USA*
[b] *Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109, USA*

**α-Octa(isopentoxy)anthralocyanine has been synthesized and is found to have an unprecedented low-energy Q-band absorption and a low first oxidation potential.**

In an effort to synthesize dyes that may find use in optical limiting devices[1,2] we have been investigating phthalocyanine complexes (Pcs). The Pcs have a region of relatively weak absorption from *ca*. 450–650 nm which falls between their Q and B bands. In addition, in this same spectral region they have strong excited-state absorption in their singlet manifold and even stronger absorption in their triplet manifold.[1] Consequently, in this spectral range the molecules are relatively transparent under weak irradiation, but under intense irradiation, such as from a pulsed laser source, it is possible to create a significant excited-state population that will be relatively opaque in the same spectral range. When the Pcs are functionalized with heavy atoms it is also possible to enhance the intersystem crossing rate so as to generate a large triplet population. Since the excited-states of these molecules are strongly absorbing, and it is possible to saturate the ground to excited-state transition, they are referred to as reverse saturable absorbers (RSAs) and are useful in optical limiting devices.[1,3,4] For certain applications where it is important to protect sensors from intense laser pulses in the 600–900 nm range, it is necessary to move the transparency window (the region between the high energy side of the Q band and the low energy side of the B band) to lower energy. It has been demonstrated that the transparency window of the phthalocyanines can be tuned by a number of structural modifications.[5] One approach is to benzannulate the phthalocyanine molecules and another is to substitute the rings with electron donors, thereby shifting the Q and B bands and therefore the transparency window to lower energy. We have also attempted to make these molecules soluble in common organic solvents despite structural features that would impart limited solubility. This is necessary in order to make dyes that are useful for many device configurations. Octaalkoxyphthalocyanines and octaalkoxynaphthalocyanines,[5] as well as a number of alkyl substituted anthralocyanines,[6–9] have been previously described. Here we describe the synthesis, linear optical properties and electrochemistry of α-octaisopentoxyanthralocyanine **1**.

The synthetic pathway to octaalkoxyanthralocyanine **1** is shown in Scheme 1. The method is analogous to the synthesis of the octaalkoxynaphthalocyanines and tetra-*tert*-butylanthralocyanine.[9] The anthracene-1,4-dione was prepared by literature methods.[10,11] For 2,3-dichloroanthracene-1,4-dione, the method of Langa was modified. Chlorine gas was added in a vigorous stream to a solution of anthracene-1,4-dione in boiling acetic acid, which was interrupted for 20 min every 5 min, until the reaction was deemed complete as evidenced by $^1$H NMR spectroscopy. The red solution with yellow crystalline precipitate was allowed to cool to ambient temperature and then filtered. The yellow crystalline solid was dried under vacuum (0.01 Torr) over KOH, to give the title compound in 75% yield.[10,11] 2,3-Dicyano-1,4-dihydroxyanthracene was prepared in moderate yield by treating 2,3-dichloroanthracene-1,4-dione with an excess of KCN in hot EtOH.[12] *O*-Methylation was accomplished with dimethyl sulfate in the presence of $K_2CO_3$. The synthesis of **1** from 2,3-dicyano-1,4-dimethoxyanthracene was analogous to the synthesis of the corresponding α-octaalkoxynaphthalocyanine to yield 15% of the desired product after purification. As was consistent with the reactivity of other alkoxy Pcs,[13] we observed complete *trans* alkoxylation of the methyl group by the isopentyl group from the solvent (there were no observable singlet methyl resonances by $^1$H NMR spectroscopy) under the reaction conditions.[13] It is also important to note that **1** is fairly sensitive to silica gel. Thus, the isolated yield of **1** is significantly reduced if chromatography is performed at conventional flow rates and accordingly, flash

**1**

**Scheme 1** *Reagents and conditions*: i, $NaBH_4$, MeOH; ii, $H_2O$, HCl; iii, $Cl_2$, AcOH, reflux; iv, KCN, EtOH; v, dimethyl sulfate, $K_2CO_3$, acetone; vi, lithium isopentoxide, isopentyl alcohol, reflux

chromatography techniques are necessary. All compounds gave satisfactory spectroscopic and analytical data.†

The UV–VIS/NIR spectrum of **1** (Fig. 1) shows a small splitting between the $Q_x$ and $Q_y$ bands and the bands are sharp, characteristic of phthalocyanines. The Q bands for **1** occur at 980 and 954 nm. These bands are red shifted about 110 nm compared to the analogous octaalkoxynaphthalocyanine and red shifted 80 nm compared to the tetra-*tert*-butylanthralocyanine.[6] The B bands of **1** are bathochromically shifted compared to the B bands of the octabutoxynaphthalocyanine, giving solutions of **1** a pleasant violet hue. The transparency window has moved about 100 nm bathochromically compared to the Npcs.[6]

The cyclic voltammogram of **1** (Fig. 2) shows four quasi-reversible redox events; those at $E_{1/2}$ = −1279 and −1039 mV we attribute to sequential one electron reductions and those at 35 and 366 mV we attribute to sequential one electron oxidations. The separation of the inner-most redox events correlates well with the energy of the Q band. We have shown that through a systematic approach we have moved the transparency window of a Pc to a region centred about 700 mm. This will allow for the investigation of the utility of this compound and derivatives thereof as the active elements for optical limiters in a particularly important spectral range.

We thank the Air Force Office of Scientific Research and the US Wright Patterson Air Force Base for funding this effort. P. V. B. thanks The James Irvine Foundation for a postdoctoral fellowship.

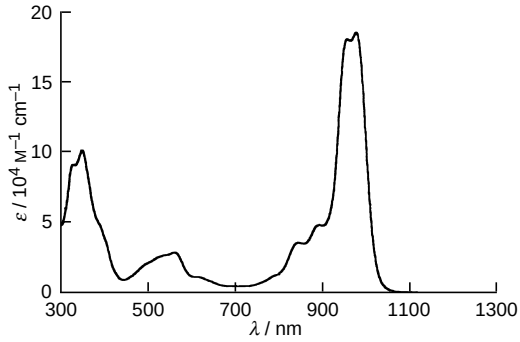


**Fig. 1** The absorption spectrum of **1** in toluene

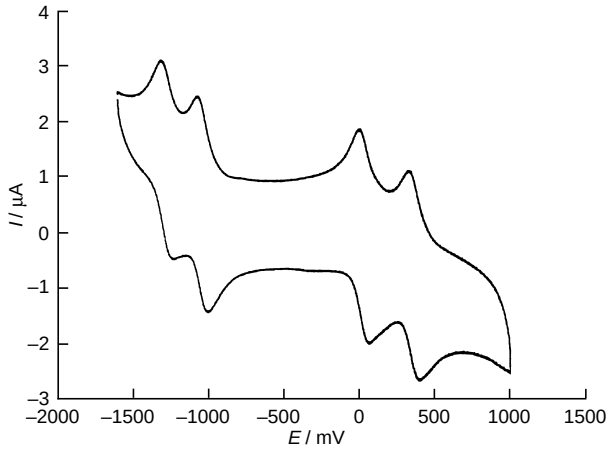

**Fig. 2** Cyclic voltammogram of **1** in $CH_2Cl_2$, Ag/AgCl (aq.), 0.1 M $Bu_4NPF_6$, 500 mV $s^{-1}$, $V_{init.}$ = −600 mV. Four quasi-reversible redox events at $E_{1/2}$ = −1279, −1039, 35 and 366 mV are observed. The $E_{1/2}$ of ferrocene was found to be 514 mV under these conditions.

† *2,3-Dicyano-1,4-dimethoxyanthracene*. To a slurry of 2,3-dichloroanthracene-1,4-dione (50 g, 185 mmol) in EtOH (1 l) at 60 °C under argon was added a solution of KCN (61 g, 925 mmol) in water (240 ml). The mixture was stirred at 60 °C for 2 h then filtered. The solution was then cooled and neutralized with 3 M HCl (carefully in a hood with a sodium hypochlorite trap). The brown solid precipitate was collected and dried overnight over KOH under vacuum. To a mixture the crude 2,3-dicyano-1,4-dihydroxyanthracene (34 g) and $K_2CO_3$ (76 g, 548 mmol) in acetone (150 ml) was added dimethyl sulfate (40 ml, 411 mmol). The mixture was heated to reflux for 3 h then poured into water. The brown solid residue was further washed with water then dried under vacuum over $P_2O_5$. The bright yellow product was collected by sublimation then recrystallized from MeOH to give 5 g of the title product. $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ 8.85 (s, 2 H), 8.14 (4 line m, 2 H), 7.69 (4 line m, 2 H), 4.39 (s, 6 H); $\nu_{max}$(KBr)/cm$^{-1}$ 3062, 2949, 2226, 1452, 1351, 1029, 886, 749; $\lambda_{max}$($CHCl_3$)/nm 404, 388, 370.

*Compound 1*. To a slurry of 2,3-dicyano-1,4-dimethoxyanthracene (2 g, 6.9 mmol) in anhydrous isopentyl alcohol (40 ml) at 25 °C under argon was added lithium (5 mg). The mixture was heated to reflux for 1 h then allowed to cool to room temperature and acetic acid (10 ml) was added and stirred overnight at room temperature under argon. The mixture was neutralized with deoxygenated saturated aqueus $NaHCO_3$ and extracted with deoxygenated methylene $CH_2Cl_2$. The organic layer was washed with deoxygenated water then dried with $Na_2SO_4$ (if $MgSO_4$ was used a considerable amount of AncMg was formed). The solvent was removed *in vacuo* and the residue was quickly chromatographed (solvent flow rate was about four times as fast as a standard flash column, if chromatography was run at a conventional rate the yield was greatly attenuated) on a short (125 × 45 mm) silica gel column with deoxygenated solvent (1 : 1, cyclohexane–$CH_2Cl_2$) to give 10% yield (0.29 g, 0.18 mmol) of the title compound; $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ 9.6 (br m, 8 H), 8.44 (br m, 8 H), 7.76 (br m, 8 H), 5.35 (m, 16 H), 2.19 (br q, *J* 7 Hz, 16 H), 2.26 (nonet, *J* 7 Hz, 4 H), 1.5 (br s, 24 H), 1.1 (br d, *J* 6 Hz, 36 H), 0.92 (br s, 12 H); $^{13}$C NMR (75 MHz, [$^2H_6$]THF): $\delta$ 151.2, 133.4, 130.1, 129.9, 127.4, 124.8, 76.5, 40.5, 26.4, 23.4 (two quarternary carbons not observed); $^{13}$C NMR DEPT 90 (125 MHz, [$^2H_6$]THF): $\delta$ 129.88, 127.36, 124.84, 26.43; FAB MS $C_{105}H_{116}N_8O_8$: Calc., 1602.87. # Novel α-iodination of functionalized ketones with iodine mediated by bis(tetra-*n*-butylammonium) peroxydisulfate

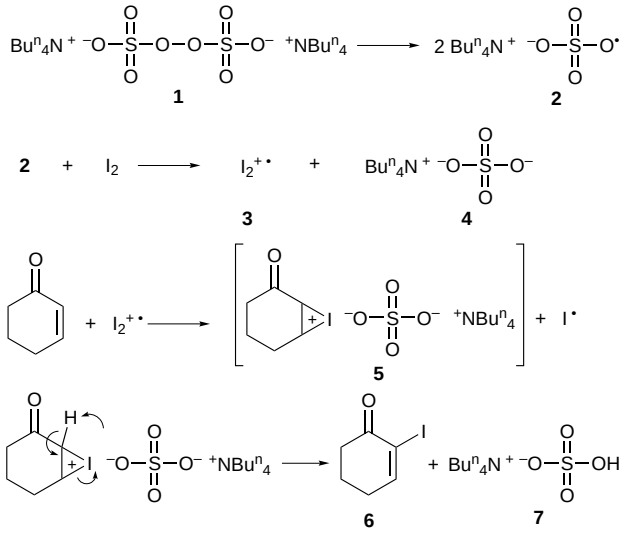
**Je Pil Whang, Seung Gak Yang and Yong Hae Kim***

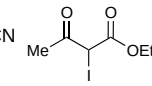


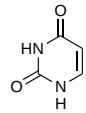
*Department of Chemistry, Korea Advanced Institute of Science and Technology, Taejon, 305-701, Korea*

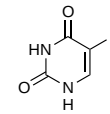
**α,β-Unsaturated ketones, β-keto esters and uracil derivatives react with iodine in the presence of bis(tetra-*n*-butylammonium) peroxydisulfate under mild conditions in MeCN at 25 °C to give the corresponding α-iodinated products in good yields.**

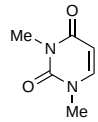
α-Haloenones and α-halo ketones are highly reactive and versatile intermediates for the generation of α-carbon substituted enones[1] and ketones.[2] α-Halo ketones have been well studied and documented, but only a few reports on the preparation of α-iodoenones have been reported, which employ iodine–ceric ammonium nitrate[3] and $I_2$–pyridine–$CCl_4$.[4] The reactivity of α-iodine is higher, especially in transition metal mediated reactions, than the corresponding bromo or chloro derivatives, while functionalization of the 5-position of uracils or uridines is important for the synthesis of chemotherapeutic agents[5] and synthetic oligonucleotide probes.[6] Bis(tetra-*n*-butylammonium) peroxydisulfate **1** has been successfully prepared and turns out to be a useful source of tetra-*n*-butylammonium sulfate radical **2**,[7]† which is readily convertible to sulfate anion by one electron transfer from a substrate. Working on the supposition that activation of iodine by **2** might be possible, various enones, ketones, and uracils were examined in the reaction system.

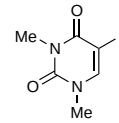
**Scheme 1**

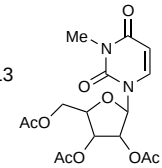


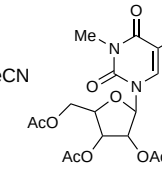




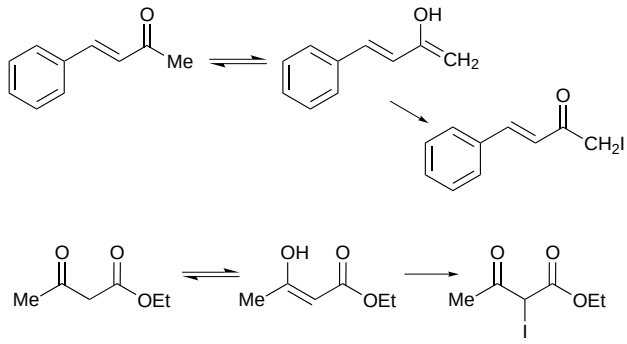








**Scheme 2**



We have found that α,β-unsaturated ketones, β-keto esters and uracil derivatives reacted with $I_2$ in the presence of **1** to give the corresponding α-iodo α,β-unsaturated ketones, α-iodo β-keto esters and 5-iodouracil products respectively in good yields (Scheme 1).

An example of the procedure is as follows. A solution of cyclohex-2-ene-1-one (1.0 mmol, 1.0 equiv.) in 5 ml of dried MeCN was added at room temperature to a solution of bis(tetra-*n*-butylammonium) peroxydisulfate (1.0 mmol, 1.0 equiv.) and $I_2$ (1.0 mmol, 1.0 equiv.) in 5 ml of dried MeCN. The reaction mixture was monitored by thin layer chromatography with stirring at room temperature. When the reaction was completed,

**Table 1** α-Iodinations with $I_2$ and bis(tetra-*n*-butylammonium) peroxydisulfate in MeCN at 25 °C

| Entry | Reactant | $I_2$/ equiv. | **1** equiv. | *t*/h | Solvent | Product | Yield (%)[a] |
|---|---|---|---|---|---|---|---|
| 1 |  | 0.5 | 0.5 | 5 | MeCN |  | 48 |
| 2 | | 0.5 | 1.0 | 5 | MeCN | | 60 |
| 3 | | 1.0 | 0.5 | 5 | MeCN | | 54 |

[a] Isolated yield; purified by column chromatography.

**Scheme 3**

the mixture was poured into 10% aqueous sodium bisulfate (30 ml) and extracted with ethyl acetate (30 ml × 3). The organic layer was washed with $H_2O$ (40 ml × 3) and dried over anhydrous $MgSO_4$. After filtration and concentration under reduced pressure, the residue was purified by flash column chromatography (silica gel 230–400 mesh, EtOAc–*n*-hexane, 1 : 10, v/v) to give 2-iodocyclohex-2-en-1-one (85%). All the products were identified by their $^1$H NMR and/or $^{13}$C NMR and mass spectra.

Optimization of the iodinations indicates that 1 equiv. each of substrate, iodine and **1** affords the best results. The results obtained are summarized in Table 1.

The reaction mechanism is not clear. It appears to be initiated by cleavage of **1** to give **2**.[7]† The sulfate radical **2** may react with $I_2$ to form a cationic iodine radical **3** and the sulfate anion **4**. The cyclic enone then reacts with **3** to form an iodine-bridged intermediate **5**. A sulfate anion **4** may abstract the α-proton from intermediate **5** to form the products **6** and **7**,‡ as shown in Scheme 2.

It is of interest that α,β-unsaturated methyl ketones gave the methyl-iodinated products (95%, entry 9) instead of iodination at the double bond, and a β-keto ester afforded an α-iodinated product (90%, entry 10). These reactions appears to proceed *via* their enol forms (Scheme 3).

This work was supported by generous grants from the Center for Biofunctional Molecules of KOSEF.

† Bis(tetra-*n*-butylammonium) peroxydisulfate was prepared from 2.0 equiv. of tetra-*n*-butylammonium hydrogen sulfate and 1.0 equiv. of potassium peroxydisulfate in water at room temperature. It was extracted with $CH_2Cl_2$, dried over anhydrous $MgSO_4$ and then concentrated to give **1**, which was dried under vacuum for one day.

‡ In the iodination of cyclohex-2-en-1-one, **7** was isolated in 80% and its identity confirmed; mp 170–172 °C (*Aldrich Catalogue Hand Book of Fine Chemicals*, 1996–1997, mp 171–173 °C).

**Electron diffraction studies of a [(dioctadecyl)carbamoylmethyl]guanidinium toluene-*p*-sulfonate (DG) monolayer reveal that the regularity of the molecular arrangement and the size of crystalline domains are controlled through binding of aqueous α,ω-dicarboxylates with various spacer lengths.**

Morphological and structural control of monolayers at the air–water interface is crucial for their applications in molecular electronics, optical devices and biomedical uses.[1,2] It has been demonstrated that patterning of monolayer components within a monolayer is realized through molecular recognition between monolayer components and aqueous templates.[3,4] We describe here that this concept is extended to control of regularity of the molecular arrangement in a monolayer. Dialkylguanidinium monolayers have been shown to strongly bind aqueous sodium α,ω-dicarboxylates through hydrogen and ionic bonding.[5] These interactions are expected to affect molecular packing, as inferred from π-*A* isotherms. Diffraction techniques are a powerful tool for evaluating the molecular packing in a monolayer.[3,6,7]

**DG**

dicarboxylate

Figs. 1(*a*)–(*f*) show electron diffraction (ED) patterns† of a **DG** monolayer‡ on pure water and on 0.1 mM aqueous solutions of sodium oxalate ($n$ = 0), malonate ($n$ = 1), succinate ($n$ = 2), glutarate ($n$ = 3) and adipate ($n$ = 4).§ Each monolayer was transferred by the horizontal drawing-up method[6] onto a hydrophilic SiO substrate,¶ after compressing up to a surface pressure of 30 mN m$^{-1}$.‖ The ED pattern of the **DG** monolayer on pure water was an amorphous halo, indicating that the monolayer is in an amorphous state. This may be caused by electrostatic repulsion among ionic hydrophilic groups of the **DG** molecules.[7] The elemental ratio of oxygen and nitrogen atoms (O/N) obtained by X-ray photoelectron spectroscopic analysis of a multilayered film of the monolayer revealed that the hydrophilic groups of the **DG** molecules are dissociated, with $TsO^-$ replaced with a $OH^-$ counterion.** On the other hand, the ED pattern of the monolayer on aqueous sodium oxalate displays a crystalline arc, indicating that crystallization of the monolayer is induced by the oxalate template. Apparently, electrostatic repulsion among the positive hydrophilic groups is weakened by tight binding of the rigid oxalate template, inducing transformation from the amorphous to the crystalline state. **DG** monolayers on aqueous malonate and succinate are also in the crystalline state. However, the arc of these ED patterns is broader along the azimuthal direction than that of the monolayer on oxalate. This broadening suggests reduction in the size of the crystallites†† formed in the monolayer and a random alignment of the crystallographical axes of the crystallites. It appears that the bridging effect of two neighbouring monolayer components is lessened owing to the relatively flexible methylene spacers connecting the two carboxylate groups in malonate and succinate. In the cases of glutarate and adipate with longer methylene spacers, the corresponding ED patterns are again amorphous haloes. The bridging effect must be reduced even more due to the longer methylene chains between the two carboxylate units. These

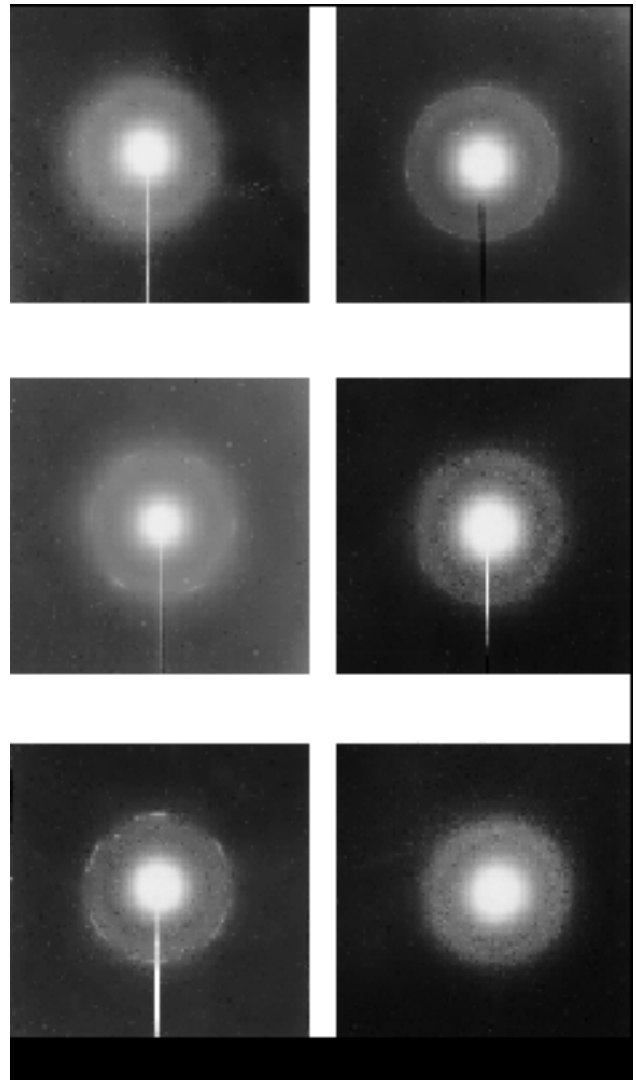

**Fig. 1** ED patterns of each **DG** monolayer (*a*) on pure water, (*b*) on aqueous oxalate, (*c*) on aqueous malonate, (*d*) on aqueous succinate, (*e*) on aqueous glutarate and (*f*) on aqueous adipate

structural changes based on ED pattern analyses were reflected in the π-*A* isotherms, as shown in Fig. 2. The shapes of these π-*A* isotherms‡‡ are affected by the presence and the nature of the dicarboxylates: the averaged molecular area of the monolayers on oxalate and malonate at a surface pressure of 30 mN $m^{-1}$ was smaller than that on pure water, and again increased as the number of the spacer methylene groups in the dicarboxylates increased from succinate to adipate. Therefore, the molecular area of the monolayer, evaluated from π-*A* isotherms, is smaller in the crystalline state (on aqueous oxalate, malonate and succinate) than that in the amorphous one (on pure water, aqueous glutarate and adipate). The expanded region observed in the π-*A* isotherm on pure water was much reduced on aqueous dicarboxylates. This change supposedly comes from suppression of free molecular translational movement at low surface pressures by binding of the hydrophilic groups of the **DG** molecules to dicarboxylates.

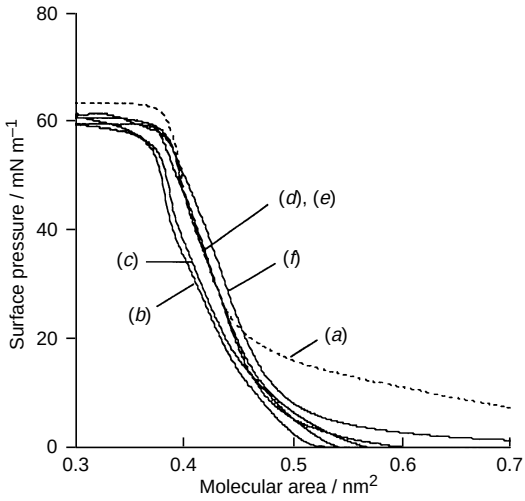

**Fig. 2** π-*A* Isotherms of each **DG** monolayer (*a*) on pure water, (*b*) on aqueous oxalate, (*c*) on aqueous malonate, (*d*) on aqueous succinate, (*e*) on aqueous glutarate and (*f*) on aqueous adipate

Fig. 3 shows a schematic representation of the relationship between the mode of host–guest interaction and the monolayer morphology. **DG** molecules are randomly arranged in the monolayer on pure water, because the **DG** monolayer can not crystallize owing to electrostatic repulsion among the cationic head groups. In the case of the **DG** monolayer on a template molecule without a spacer group, the **DG** monolayer crystallizes and the molecules form large crystalline domains, because the cohesive effect among the hydrophobic groups in **DG** molecules and the tight bridging of the two monolayer components act cooperatively. In the case of the **DG** monolayer on template molecules with spacer groups, the bridging effect is lessened, and the monolayer is composed of small crystalline domains and/or the positional order in the monolayer deteriorates.

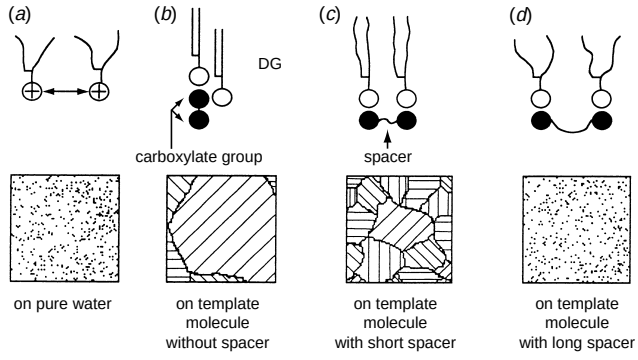

**Fig. 3** Schematic representation of the aggregation structure of each **DG** monolayer. Points and lines express the random and the regular molecular arrangement of **DG** molecules in the monolayer, respectively.

In summary, the molecular ordering and the size of crystalline domains in guanidinium monolayers can be controlled by aqueous dicarboxylates with different methylene bridge lengths. Preliminary observation of the monolayer by atomic force microscopy also confirms the presented results. The details on their molecular images are now under investigation.

† ED patterns in this study are for a monolayer transferred onto the hydrophilic SiO substrate, not for a floating monolayer on a water surface. However, the structure of the transferred monolayer is considered to be the same as that of the floating monolayer (see ref. 6). ED patterns were recorded with a Hitachi H-600S transmission electron microscope, operating at an acceleration voltage of 75 kV and with a beam current of several μA. The electron beam was several μm in diameter.

‡ Benzene–ethanol (80 : 20) was used as the spreading solvent. Compression was started 10 min after spreading at a rate of 0.2 mm $s^{-1}$ by using a computer-controlled film balance system FSD-50 (USI System, Fukuoka). The subphase temperature was kept at 293 ± 0.2 K. Surface pressures were measured by a Wilhelmy plate which was calibrated with the transition pressure of an octadecanoic acid monolayer.

§ Subphase pH was *ca.* 6 and the strongly basic **DG** was protonated. Dicarboxylates were added with equivalent NaOH into subphase, thus they must be the sodium salt (see ref. 5).

¶ The hydrophilic SiO substrate was prepared by vapour deposition of SiO onto a Formvar thin layer, with which an electron microscope grid was covered on a glass slide.

‖ The transfer ratio for each monolayer was unity, indicating that the SiO substrate is completely covered with each monolayer.

** Replacement of the $TsO^-$ counterion by $OH^-$ was strongly suggested by the absence of an S atom and the O/N ratio of 0.44 in the XPS data of the transferred LB film.

†† The broadness of arc along the azimuthal direction on the ED pattern results from the existence of a large number of crystalline domains with different crystallographical axes. The diameter of the electron beam was constant in this study. Therefore, the broader arc observed on the present ED pattern indicates a size reduction of the crystalline domain in monolayer.

‡‡ Highly water-soluble dicarboxylates do not make any contribution to the molecular area. Thus, the molecular area (abscissa in Fig. 2) is based on the number of **DG** molecules.

# Preparation of 5-trimethylsilyl-1,3-phenylenebis[diazo(4-pyridyl)methane] and magnetic properties of its 1:1 copper(II) complex after photolysis

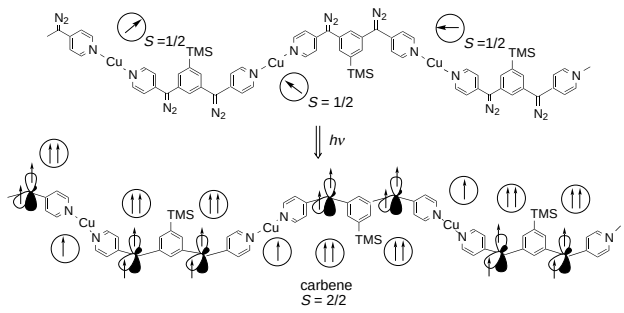
**Satoru Karasawa,[a] Masakazu Tanaka,[a] Noboru Koga*[a] and Hiizu Iwamura*[b]**

[a] *Faculty of Pharmaceutical Sciences, Kyushu University, Maidashi, Higashi-ku, Fukuoka 812-82, Japan*
[b] *Institute for Fundamental Research in Organic Chemistry, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812-81, Japan*

**Photolysis of a paramagnetic 1:1 complex of copper(II) with 5-trimethylsilyl-1,3-phenylenebis[diazo(4-pyridyl)methane] produces a ferromagnetic chain consisting of an alternating array of 3d spins of $Cu^{II}$ and 2p spins of the quintet dicarbenes.**

Formation of metal complexes carrying free radical ligands has been proved to be a powerful design strategy for ordering heterospin systems consisting of 2p and 3d spins.[1,2] Based on this strategy, diazobis(4-pyridyl)methane **1** was designed and prepared.[3] The pyridine units are used to construct a polymeric chain structure by ligation with metal ions and the diazo moiety is photolyzed to produce the carbene unit which plays an important role as a triplet spin source as well as a magnetic coupling unit. 1 : 1 complexes of bis(hexafluoroacetylacetonato)-manganese(II) and -copper(II), $Mn(hfac)_2$ and $Cu(hfac)_2$, with **1** became one-dimensional ferri- and ferro-magnetic chains, respectively, upon photolysis.

To extend and improve these metal–carbene spin systems, we designed a 1,3-benzenediylbis[diazo(4-pyridyl)methane] derivative **2** carrying a bulky trimethylsilyl group at position 5 to attenuate the interchain antiferromagnetic interaction and also coupled this photoresponsive ligand with $Cu(hfac)_2$ to give $[Cu(hfac)_2{\cdot}\mathbf{2}]$ in which the generated quintet carbenes are expected to interact with the copper ions ferromagnetically, as illustrated in Scheme 1.



1,3-Dibromo-5-trimethylsilylbenzene was lithiated with $Bu^tLi$ in anhydrous diethyl ether and reacted with 4-cyanopyridine, followed by hydrolysis with aq. $H_2SO_4$. The dipyridyl diketone thus obtained was converted to diazo compound **2** by a usual procedure[3] *via* the corresponding dihydrazone. Compound **2** was crystallized from diethyl ether as red bricks [mp = 109 °C (decomp.)] and its molecular structure was investigated by X-ray analysis.† The molecular structure of **2** has a mirror plane passing through C(8) and C(10) in the benzene ring and the pyridyl groups are directed to the opposite side of the trimethylsilyl group. The dihedral angle between the pyridyl groups and the benzene ring is 44.86° (Fig. 1).

In the EPR spectrum after photolysis of **2** in frozen 2-methyltetrahydrofuran, signals characteristic of quintet dicarbene[4] with a zero-field splitting parameter $D$ in the range 0.07–0.13 $cm^{-1}$ were observed in addition to weak signals due to a monocarbene. The intensities of the quintet signals decreased according to Curie behaviour in the temperature range 10–74 K, suggesting that the quintet is a ground state. By mixing a solution of $Cu(hfac)_2$ in MeOH and **2** in MeOH–$CH_2Cl_2$, the 1 : 1 complex $[Cu(hfac)_2{\cdot}\mathbf{2}]$ was obtained as brown microcrystals. Although no structural information‡ for the complex was obtained, it is reasonable to assume an infinite chain structure since in the two pyridyl nitrogens are ligated to two different metal ions to produce chain structures in the corresponding manganese(II) complex, $[Mn(hfac)_2{\cdot}\mathbf{2}]$† (Fig. 2), prepared under similar conditions and the analogous $[Cu(hfac)_2{\cdot}\mathbf{1}]$.[5]

A microcrystalline sample (*ca*. 0.5 mg) of $[Cu(hfac)_2{\cdot}\mathbf{2}]$ was used for magnetic measurements on a SQUID susceptometer. The sample placed inside the sample compartment of the susceptometer was irradiated at 5–7 K with second harmonic light ($\lambda$ = 532 nm) from a Nd/YAG laser through an optical fiber.[5] After iradiation for 10 h, followed by SQUID measurements, IR absorptions of the sample at 2068 $cm^{-1}$ due to the diazo groups of $[Cu(hfac)_2{\cdot}\mathbf{2}]$ disappeared completely.

The temperature dependences of the molar magnetic susceptibility $\chi_{mol}$ per formula unit of $[Cu(hfac)_2{\cdot}\mathbf{2}]$ are shown in Fig. 3 in the form of $\chi_{mol}T$ *vs.* $T$ plots before and after irradiation, and subsequent annealing at 300 K. Before irradiation, $\chi_{mol}T$ values are nearly constant at 0.55 ± 0.03 emu K $mol^{-1}$ in the temperature range 2–200 K. These values are close to that ($\chi_{mol}T$ = 0.38 emu K $mol^{-1}$) calculated for a dilute $S = \frac{1}{2}$ paramagnet, indicating that the d electrons of $Cu^{II}$ are magnetically isolated.

The $\chi_{mol}T$ values after the photolysis of $[Cu(hfac)_2{\cdot}\mathbf{2}]$ for 10 h increased continuously with decrease in temperature from 100 K, reached a maximum value of 23.4 emu K $mol^{-1}$ at 5.0 K, and decreased below 5 K. This behavior is reversible up to 100 K after which the $\chi_{mol}T$ values decreased at different rates as observed in Fig. 3. In a consecutive measurement for the same sample left at 300 K, $\chi_{mol}T$ showed the behavior prior to

**Scheme 1**

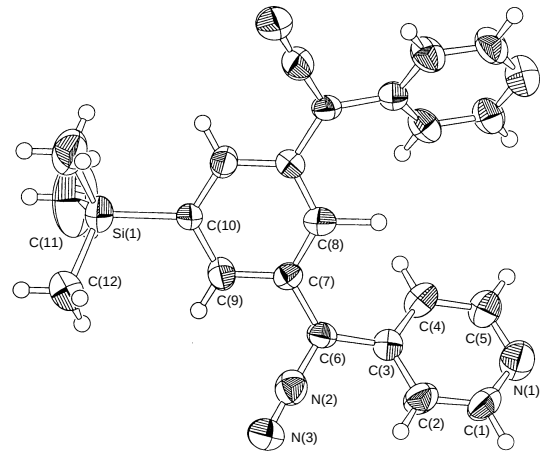


**Fig. 1** ORTEP drawing of ligand **2** at 30% probability

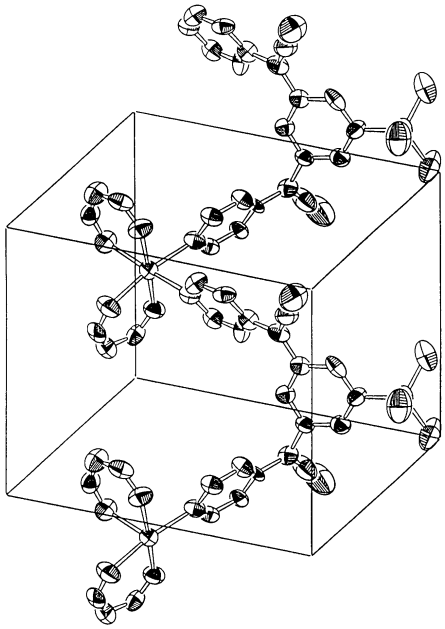

**Fig. 2** ORTEP drawing of [Mn(hfac)$_2$·**2**] at 30% probability

irradiation. A maximum value of 23.4 emu K mol$^{-1}$ after irradiation for 10 h far surpasses the theoretical value of 4.37 emu K mol$^{-1}$ for an $S = 5/2$ species expected for a single unit produced by ferromagnetic interaction between Cu$^{II}$ ($S = 1/2$) and a quintet carbene ($S = 4/2$) in the complex. The increase of $\chi_{mol}T$ as the temperature was decreased from 100 to 5 K clearly demonstrates an increase of the correlation length of the ferromagnetic coupling along the one-dimensional heterospin chain with decreasing temperature. The decrease of $\chi_{mol}T$ below 5 K might be caused by an interchain antiferromagnetic interaction.

Taking into account the temperature independent $\chi_{mol}T$ values above 100 K and those in a consecutive measurement after annealing the sample at 300 K, we interpret the irreversible

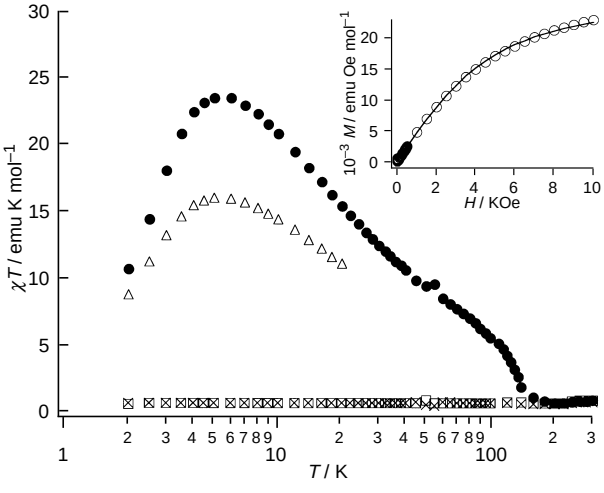

**Fig. 3** Temperature dependences of $\chi_{mol}T$ per formula [Cu(hfac)$_2$·**2**] for a powder sample before (□) and after irradiation for 2 (△) and 10 h (●), and then annealing at 300 K for 1 h (×). The field dependence of magnetization $M$ for [Cu(hfac)$_2$·**2**] at 5 K is given in the inset. The solid curve is the theoretical fit § ($S = 17.25 \pm 0.01$).

change of $\chi_{mol}T$ at 100 K as indicating a chemical loss of the generated carbene centers.

In order to estimate the ferromagnetic correlation length, the field dependences of magnetization $M$ for the same sample of [Cu(hfac)$_2$·**2**] after irradiation for 10 h at 5 K were investigated. A theoretical curve represented by a Brillouin function§ was fitted to the experimental data by a least-squares method to give $S = 17.25 \pm 0.06$, as indicated by the solid curve in the inset of Fig. 3. This value corresponds to a ferromagnetic coupling of *ca*. seven units at 5 K along the chains. This estimate of the correlation length obtained from the $M$–$H$ plots is consistent with that (*ca*. 7 units)¶ from the maximum value at 5 K in the $\chi_{mol}T$–$T$ plot.

Although it can not be stated at the present stage if the bulkiness of the trimethylsilyl group was effective in weakening the antiferromagnetic interchain interaction, [Cu(hfac)$_2$·**2**] did show a higher maximum $\chi_{mol}T$ compared to the corresponding unsubstituted copper complex.[6] It is concluded that the photochemical generation of two triplet carbene centers coupled ferromagnetically to each other through the *m*-phenylene ring and consequent magnetic coupling of these 2p spins with 3d spins of Cu$^{II}$ through the pyridine rings established a one-dimensional ferromagnetic chain (Scheme 1).

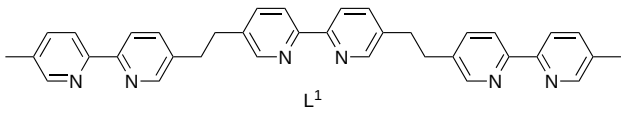
# A cyclic supramolecular complex containing eight metal ions, twelve bridging ligands, and an anion encapsulated in the central cavity



**Peter L. Jones, Kate J. Byrom, John C. Jeffery, Jon A. McCleverty* and Michael D. Ward***

*School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

**Reaction of the bis-bidentate ligand bis{3-(2-pyridyl)pyrazol-1-yl}dihydroborate ($L^-$) with cobalt(II) or nickel(II) salts results in formation of complexes $[M_8L_{12}X]X_3$ (X = $ClO_4$, $PF_6$), which have a cyclic structure with one anion encapsulated in the central cavity.**

The assembly of structurally sophisticated, high-nuclearity coordination complexes from the reactions of relatively simple ligands with suitable metal ions is a burgeoning field. The principles of molecular recognition between components, and how the steric information contained in the number/orientation of ligand binding sites and the stereoelectronic preferences of the metal ion combine to give the final structure, are becoming better understood.[1]

In some systems there is only one optimal structure for the supramolecular species defined by a particular metal/ligand combination. Such systems are exemplified by Lehn's molecular grids[2] and molecular cylinders:[3] there is only one way in which the twin conditions (*i*) all of the ligand binding sites being occupied, and (*ii*) all of the metal ions being coordinated in their preferred coordination environment, can be fulfilled. In contrast in other systems a wide variety of stoichiometries and therefore structures are possible, all of which can fulfil the above requirements. These systems are exemplified by Lehn's molecular rings.[4,5] For example the ligand $L^1$ has three bidentate chelating binding sites with flexible spacers between them. Coordination to metal ions having a preference for six coordination gave various complexes with a 1 : 1 metal : ligand stoichiometry but with very different structures: notably the triple helicate $[Ni_3(L^1)_3]^{6+}$ and the molecular ring $[Fe_5(L^1)_5Cl]^{9+}$, which contains a chloride ion tightly bound in the cavity at the centre of the ring.[5]

$L^1$

We describe here the preparation and characterisation of complexes of bis{3-(2-pyridyl)pyrazol-1-yl}dihydroborate} ($L^-$) with $Ni^{2+}$ and $Co^{2+}$ which are octanuclear molecular rings containing encapsulated anions. The ligand $L^-$ was prepared† as its potassium salt in high yield by reaction of 3-(2-pyridyl)pyrazole with $KBH_4$.[6] Since it contains two bidentate compartments linked by a flexible spacer, it could act as a tetradentate chelate to one large metal ion, or act as a bridge in oligonuclear species.[7] With $Ni^{II}$ and $Co^{II}$, both of which prefer pseudo-octahedral tris-chelate coordination, a 2 : 3 metal : $L^-$ stoichiometry is likely in the absence of other ligands.

Reaction of KL with $Co(O_2CMe)_2{\cdot}4H_2O$ (1 : 1 ratio) in MeOH afforded a red–brown solution from which a solid precipitated on addition of $KPF_6$. Analytical data suggested the empirical formulation $[Co_2L_3][PF_6]$. A material analysing as $[Ni_2L_3][PF_6]$ was similarly prepared from KL and $Ni(NO_3)_2{\cdot}6H_2O$ in MeOH followed by precipitation with $KPF_6$. The yields of these were subsequently optimised (50–60%) by use of a 2 : 3 metal : ligand ratio in the preparation. Examination of both complexes by electrospray (ES) mass spectrometry (MeCN; 5 V cone voltage) showed a strong peak at *m/z* 1410 in each case. These correspond to the species $[Co_8L_{12}(PF_6)]^{3+}$ (calc. for most abundant peak: 1409.7) and $[Ni_8L_{12}(PF_6)]^{3+}$ (calc. for most abundant peak: 1409.0); no other reasonable combination of metal, ligand, counter ion and charge corresponds to these values, and the +3 charge was confirmed by the $\frac{1}{3}$-integral spacing between isotopic components of the peaks. Numerous fragmentation peaks were also observed. The highest mass peaks indicate in both cases formation of a $\{M_8L_{12}\}$ species which is associated with one anion; no anion-free peaks corresponding to $[M_8L_{12}]^{4+}$ were observed. Exactly similar behaviour was observed for $[Fe_5(L^1)_5Cl]^{9+}$, where loss of chloride was never observed by ESMS.[5]

This result suggested that a $\{M_8L_{12}\}$ molecular ring may have formed, containing one tightly bound anion in the central cavity. Accordingly we attempted to crystallise these complexes, but crystals of the hexafluorophosphate salts could not be obtained. The cobalt(II) complex was therefore re-prepared as the perchlorate salt, $\{[Co_2L_3][ClO_4]\}_n$. After several attempts small crystals were grown from MeCN–diethyl ether which were just suitable for X-ray diffraction, and a partial structral determination showed the complex to be $[Co_8L_{12}(ClO_4)][ClO_4]_3$ in agreement with the ESMS data.‡ Despite the poor quality of the data the gross structure of the complex cation is quite clear (Fig. 1), consisting of a $\{Co_8L_{12}\}$ ring with a perchlorate ion in the central cavity, and bears obvious similarities to Lehn's $[Fe_5(L^1)_5Cl]^{9+}$ complex. Each ligand L acts as a bridge between two adjacent metal ions, with an alternating pattern of one and then two bridging ligands

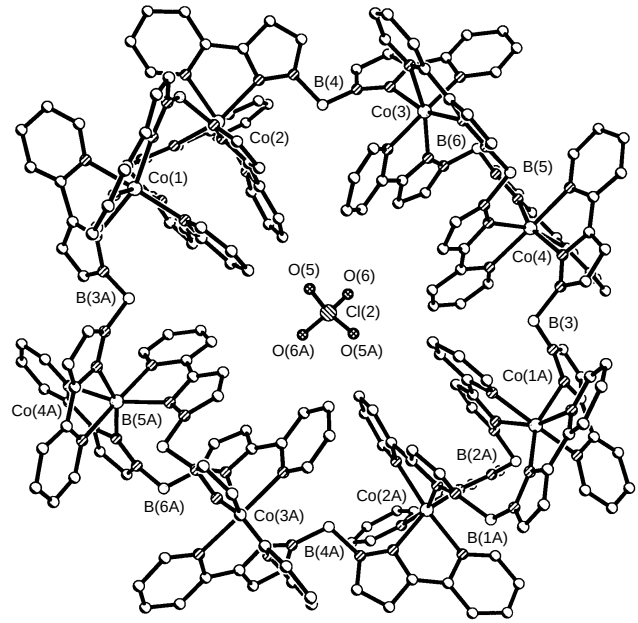


**Fig. 1** Crystal structure of the $[Co_8L_{12}(ClO_4)]^{3+}$ cation

between each adjacent pair of metals (see Fig. 2). Each metal is six-coordinated by three bidentate chelating fragments, each from a different ligand, and all ligand binding sites are used. The complex cation lies astride a twofold axis which is perpendicular to the plane of the ring and passes through the Cl atom of the encapsulated perchlorate anion; it is chiral, with all eight metal centres having the same absolute chirality (△ in the figure) and is therefore a helical ring.

Attempts to examine the solution properties of $[Co_8L_{12}(ClO_4)][ClO_4]_3$ by NMR spectroscopy were not very successful. Although $^1$H NMR spectra of high-spin cobalt(II) complexes can give useful structural information,[8] the $^1$H NMR spectrum of $[Co_8L_{12}(ClO_4)][ClO_4]_3$ in $CD_3CN$ was broadened to the point where individual signals were not detectable. $^{31}$P and $^{19}$F NMR spectra of $[Ni_8L_{12}][PF_6]_4$ showed only one signal in each case at the same position observed for $NH_4PF_6$. If one anion remained in the ring and did not exchange in the NMR timescale, then two resonances in a 3:1 ratio would be expected; if the ring were intact but exchange of the anion fast, a single shifted signal would be seen. These observations suggest that the kinetic lability of the metal centres results in dissociation of the ring in solution, and that its formation with the encapsulated anion occurs during crystallisation (or at least evaporation of the solvent, as in ESMS).

The formation of this structure raises an important question: does the central anion (perchlorate or hexafluorophosphate) act as a template to control the size of the ring by dictating the assembly pathway, or is the ring a particularly stable structure which forms on its own and then subsequently traps whatever appropriately sized guest can be found in the reaction medium? In the former case the use of a different templating anion could lead to the assembly of a differently sized ring (at least in the solid state); in the latter case, formation of a particular ring size means that a size-specific host is formed which could be of use in, for example, selective extraction or recognition of anions. We note that poly(guanidinium) strands can assemble around templating sulfate anions to give double helicates,[9] and that other examples of molecular recognition of small guest species by cyclic coordination complexes having large central cavities are known.[10]

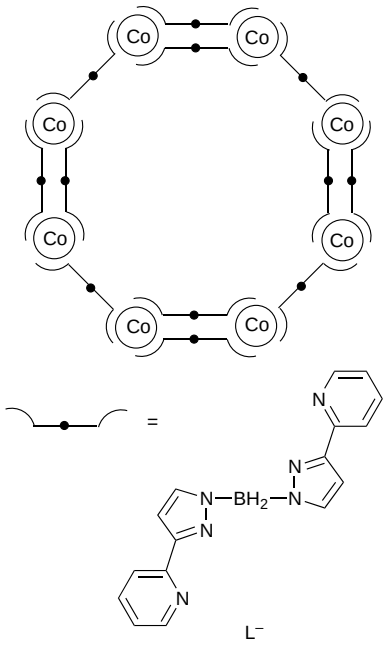

**Fig. 2** Schematic drawing of the octanuclear ring showing the alternating disposition of bridging ligands along the edges

We thank the EPSRC and Unilever Research for financial support, and Mr C. Carraz and Dr J. Fleming for the NMR experiments.

† Potassium bis[3-(2-pyridyl)pyrazolyl]dihydroborate KL. A mixture of 3-(2-pyridyl)pyrazole (3.50 g, 24.1 mmol) and $KBH_4$ (0.49 g, 9.0 mmol) was ground together finely with a mortar and pestle and then gradually heated to 150 °C. Melting occurred at *ca*. 120 °C, at which point evolution of $H_2$ commenced. The temperature was maintained at 150 °C for 30 min, after which time $H_2$ evolution had ceased. The solid white mixture was cooled and 100 cm$^3$ of warm toluene was added. The suspension was stirred vigorously overnight to allow the excess unreacted 3-(2-pyridyl)pyrazole to dissolve. The product was filtered off as a white solid, which was washed further with several portions of toluene and then hexane, and dried. Yield of KL: 2.48 g (81%). Negative-ion FAB MS: *m/z* 301 [$L^-$]. Satisfactory analytical and $^1$H NMR data were obtained.

‡ *Crystallographic details*. $[Co_8L_{12}(ClO_4)][ClO_4]_3 \cdot n$(disordered solvent), small orange blocks grown from MeCN–diethyl ether. A crystal of dimensions 0.1 × 0.1 × 0.05 mm was mounted on a Siemens SMART diffractometer under a stream of $N_2$ at −100 °C. Orthorhombic, space group *Pbcn*; $a$ = 31.89(2), $b$ = 18.719(4), $c$ = 41.11(1) Å; $U$ = 24 540(27) Å$^3$; $Z$ = 4; $\mu$ = 0.72 mm$^{-1}$. 108 409 reflections were measured with $2\theta_{max}$ = 46.5°; after merging these gave 17 602 unique data with $R$(sigma) = 0.223. Many factors combined to make this a poor structure. The crystals were small and diffracted weakly; they lost solvent instantly on removal from the mother-liquor and decomposed partially during the transfer to the diffractometer, even when coated with paraffin oil saturated with the recrystallisation solvent mixture; there was substantial disorder in the free counter ions and the large number of lattice solvent molecules; the number of parameters was large (174 non-hydrogen atoms in the asymmetric unit). The lattice solvents were best approximated as four MeCN and two $Et_2O$ molecules per asymmetric unit (*i.e.* eight MeCN and four $Et_2O$ per $\{Co_8L_{12}(ClO_4)\}^{3+}$ unit). The best level of refinement achievable so far was $R_1$ = 0.19, goodness-of-fit 1.233. Consequently the full structural details are not of publishable quality, and it is not possible to extract precise bond lengths and angles. However the complex cation is sufficiently well defined to be quite certain about its gross structure.

# Intramolecular proton transfer from a cation to the associated, structurally characterised, hydride-containing anion $[(PPh_3)_2(H)Ru(\mu\text{-}H)(\mu\text{-}Cl)_2Ru(H)(PPh_3)_2]^-$ to give an $\eta^2$-$H_2$ complex

**Kenneth S. MacFarlane, Ajey M. Joshi, Steven J. Rettig and Brian R. James***

*Department of Chemistry, University of British Columbia, Vancouver, British Columbia, V6T 1Z1, Canada*

**The previously unknown, dinuclear, ionic ruthenium(II) species [Hdma][$(PPh_3)_2$(H)Ru(μ-H)(μ-Cl)$_2$Ru(H)-($PPh_3$)$_2$]·dma 1 (dma = *N*,*N*-dimethylacetamide) is characterised by X-ray crystallography; in solution, intramolecular proton transfer from the cation to the anion gives the known molecular hydrogen complex [$(PPh_3)_2(\eta^2\text{-}H_2)$Ru(μ-H)(μ-Cl)$_2$Ru(H)($PPh_3$)$_2$] 2.**

A general method for preparing dihydrogen complexes is protonation of transition-metal hydride species,[1] a process that can be viewed as the reverse of heterolytic cleavage of $H_2$. There are reported examples of an equilibrium between a molecular hydrogen complex and the corresponding hydride [*i.e.* M($\eta^2$-$H_2$) ⇌ M($H^-$) + $H^+$], and some include intramolecular proton transfer from the $\eta^2$-$H_2$ ligand to a co-ligand, which acts as a base.[2] To our knowledge, there are no examples where this proton transfer is from a cation to the associated anion of a transition-metal complex. The closest related example is proton transfer from cyclohexanol to the anionic $[RuH_3(PPh_3)_3]^-$ to generate $[Ru(\eta^2\text{-}H_2)(H)_2(PPh_3)_3]$.[3] We report here, the X-ray crystal structure of the ionic complex [Hdma][$(PPh_3)_2$(H)Ru(μ-H)(μ-Cl)$_2$Ru(H)($PPh_3$)$_2$]·dma **1**,† which in solution undergoes proton transfer to give the known complex [$(PPh_3)_2(\eta^2\text{-}H_2)$Ru(μ-H)(μ-Cl)$_2$Ru(H)($PPh_3$)$_2$] **2**.[4]

Red prisms of **1** were serendipitously grown in a dma filtrate that was left at *ca*. 20 °C for several months. The reactants were $[RuCl_3(PPh_3)_2(dma)]$·dma,[5] and 1 equiv. of dppb [1,4-bis(diphenylphosphino)butane], left under 1 atm $H_2$. A pink coproduct, established by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy and elemental analysis‡ to be the ionic complex [Hdma][(dppb)Cl-Ru(μ-Cl)$_3$RuCl(dppb)] **3**, was also isolated; the anion of **3** has been previously characterised by X-ray crystallography within a complex where the associated cation was 1,1,3-trimethyl-2,3-dihydroperimidinium.[6]

The molecular structure of **1** is shown in Fig. 1. The dinuclear anion, with a $C_2$ axis, contains one bridging and two terminal hydrides. The cation $[Hdma]^+$, the proton of which was not located or included in the model, has been studied previously by X-ray diffraction within *N*,*N*-dimethylacetamidonium chloride;[7] the cation here is different from that found for **1**, as the $H^+$ is located between the O and Cl, with strong hydrogen bonds. The dma sites in **1** are occupied 50% by a neutral molecule and 50% by a $[Hdma]^+$ moiety. The IR spectrum (KBr pellet) of crystalline **1** shows a strong broad $\nu_{C=O}$ at 1647 $cm^{-1}$, close to that found for free dma solvent (1640 $cm^{-1}$). For comparison purposes, the $\nu_{C=O}$ band in [Hdma]Cl was observed at 1670 $cm^{-1}$.[7]

The Ru–μ-H bond length of 1.72 Å observed in **1** is similar to that observed for one side of the unsymmetrical hydride bridge in [L($\eta^2$-$H_2$)Ru(μ-H)(μ-Cl)$_2$Ru(H)($PPh_3$)$_2$] (1.71 Å); L = a phosphorus–nitrogen chelating, ferrocene-based ligand,[4] but is significantly longer than the other Ru–μ-H bond length in the $\eta^2$-$H_2$ species (1.49 Å). The Ru–terminal hydride bond length (1.59 Å) is similar to that in the species containing L.[4] The locations of the hydrogen atoms in **2** and the analogous [{P($C_6H_4$Me-*p*)$_3$}$_2$($\eta^2$-$H_2$)Ru(μ-H)(μ-Cl)$_2$Ru(H){P($C_6H_4$Me-*p*)$_3$}$_2$] complex were not established in earlier X-ray crystallographic studies; however, these complexes did not contain a $C_2$ axis.[4,8,9] For **1** and the molecular (L)($\eta^2$-$H_2$) complex,[4] the hydride and the $\eta^2$-$H_2$ ligands were located. Of note, complex **2** has recently been studied by X-ray crystallography using CCD detection with all the hydride and $\eta^2$-$H_2$ hydrogens now located.[10] Comparison of the bond lengths and angles of **1** with those of **2**[10] are entirely consistent with the formulation of **1** as [Hdma][$(PPh_3)_2$(H)Ru(μ-H)(μ-Cl)$_2$Ru(H)($PPh_3$)$_2$]·dma.

The Ru–Ru bond length of 2.83 Å in **1** is the same as that in **2** (from the partial structure) and is in the range generally reported for a Ru–Ru single bond (2.632–3.034 Å).[4] The Ru–Cl–Ru (69.20°) and Cl–Ru–Cl (81.58°) bond angles of **1** are also indicative of a Ru–Ru single bond within the general class of dinuclear $Ru_2$ complexes containing face-sharing bioctahedra.[11]

$^{31}P\{^1H\}$ and $^1H$ NMR spectroscopic studies on $[^2H_8]$toluene solutions of the crystalline sample of **1** show spectra essentially

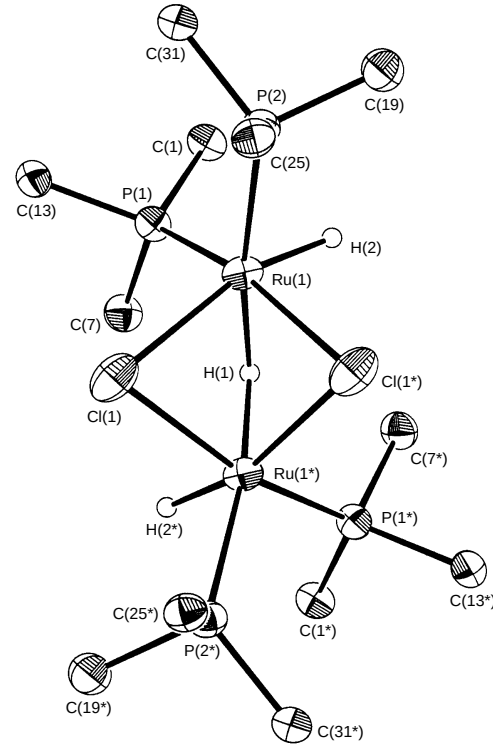

**Fig. 1** ORTEP plot of the anion of [Hdma][$(PPh_3)_2$(H)Ru(μ-H)(μ-Cl)$_2$Ru(H)($PPh_3$)$_2$]·dma **1**. Thermal ellipsoids for non-hydrogen atoms are drawn at 33% probability (some of the phenyl carbons have been omitted for clarity); * refers to the symmetry operation: $-x$, $y$, $\frac{1}{2} - z$. Selected bond lengths (Å) and angles (°): Ru(1)–Ru(1*) 2.8251(5), Ru(1)–Cl(1) 2.510(1), Ru(1)–Cl(1*) 2.4649(9), Ru(1)–P(1) 2.2576(9), Ru(1)–P(2) 2.3483(9), Ru(1)–H(2) 1.59(3), Ru(1)–H(1) 1.72(3); Cl(1)–Ru(1)–Cl(1*) 81.58(4), Ru(1)–Cl(1)–Ru(1*) 69.20(3), Ru(1*)–Ru(1)–H(2) 109.1(9), Ru(1*)–Ru(1)–H(1) 35(1), H(1)–Ru(1)–H(2) 86(1).

identical to those of the neutral $\eta^2$-$H_2$ complex **2**, thus demonstrating conversion of **1** into **2** in this solvent (Scheme 1). The $^{31}P\{^1H\}$ spectrum of **1** in $C_7D_8$ at 20 °C shows two broad resonances at $\delta$ 71.3 and 46.3, while at −89 °C the spectrum gives an ABCD spin system, the data corresponding exactly to those previously observed for **2**;[4,8,9] the 20 °C spectrum also shows a small amount (*ca*. 5%) of another species associated with an AB pattern ($\delta_A$ 56.8, $\delta_B$ 54.7, $^2J_{AB}$ 30 Hz) and this possibly results from the presence of **1**.

$$[Hdma]^+[(PPh_3)_2(H)Ru(\mu\text{-}H)(\mu\text{-}Cl)_2Ru(H)(PPh_3)_2]^-\bullet dma$$

**1**

$$\downarrow$$

$$2\ dma + [(PPh_3)_2(\eta^2\text{-}H_2)Ru(\mu\text{-}H)(\mu\text{-}Cl)_2Ru(H)(PPh_3)_2]$$

**2**

**Scheme 1**

The $^1H$ NMR spectrum of **1** in $C_7D_8$ at 20 °C shows a single broad resonance in the hydride region at $\delta$ −12.8, but at −79 °C signals are seen at $\delta$ −8.7 (br d), −12.6 (br s) and −17.3 (br s), and these data correspond to those for the μ-hydride, $\eta^2$-$H_2$ and terminal hydride, respectively, of **2**, as established by the $T_1$ measurements and exchange-spectra simulations for these protons [similar data are found for the $P(C_6H_4Me\text{-}p)_3$ analogue].[4,8,9] Two other resonances of lower intensity observed at $\delta$ −14.9 (t, $^2J_{PH}$ 31.1 Hz) and $\delta$ −17.7 (br s) could again be attributed to the terminal- and bridging-hydrides of **1**. We have been unable to detect the $^1H$ resonance for the proton of $[Hdma]^+$. {Of interest, the resonance for the proton of this cation in a $CH_2Cl_2$ solution of [Hdma]Cl has been reported at $\delta$ 12.[7] The $[H(dma)_2]^+$ cation is also known, *e.g.* within $[H(dma)_2][AuCl_4]$ where $\delta_H$ was reported at −17.45,[12,13] but we have repeated this work and find $\delta_H$ at +18}.

The observation of NMR signals that are consistent with the presence of small amounts of **1** in Scheme 1 implies an equilibrium reaction, but unfortunately this could not be confirmed by measuring the $^{31}P\{^1H\}$ NMR spectra of **2** in $C_7D_8$ solutions containing several equivalents of dma; only signals due to **2** were seen (trace water in the added dma could complicate these measurements on the 'reverse' process).

Nevertheless, despite our failure to establish Scheme 1 as an equilibrium, the spectral and X-ray structural data taken together demonstrate unequivocally the proton-transfer reaction shown in the forward reaction.

$[(PPh_3)_2(\eta^2\text{-}H_2)Ru(\mu\text{-}H)(\mu\text{-}Cl)_2Ru(H)(PPh_3)_2] + 2\ PSH^+\ Cl^-$

**Scheme 2**

Of note, we have reported two synthetic routes to the $\eta^2$-$H_2$ complex **2** (Scheme 2).[4,8] In retrospect, in light of the data given here, the solid-state product from Scheme 2(*a*) should be reformulated as the ionic complex **1**, while in solution the neutral species **2** would be present. Reaction in the absence of dma allows the isolation of the neutral complex **2** in the solid state [Scheme 2(*b*)].

A key step in the mechanism of the well known hydrogenation catalyst $[Ru(H)Cl(PPh_3)_3]$ is initial dissociation of a phosphine ligand to generate species containing the '$Ru(PPh_3)_2$' moiety,[8,9] but whether dinuclear species such as the anion of **1**, or the $\eta^2$-$H_2$ complex **2**, play any role in the catalysis still remains to be established.

We thank the Natural Sciences and Engineering Council of Canada for financial support, and Johnson Matthey Co. and Colonial Metals Inc. for loans of $RuCl_3\cdot 3H_2O$.

# Hydrothermal synthesis and structural characterization of $[Cu(en)_2]_2Cu_7Cl_{11}$: a three-dimensional open-framework copper halide with occluded $[Cu(en)_2]^{2+}$ cations

**Jeffrey R. D. DeBord,[a] Ying-jie Lu,[a] Christopher J. Warren,[a] Robert C. Haushalter*[a] and Jon Zubieta*[b]**

[a] *NEC Research Institute, 4 Independence Way, Princeton, NJ 08540, USA*
[b] *Department of Chemistry, Syracuse University, Syracuse, NY 13244, USA*

**A new type of three-dimensional open-framework copper chloride, prepared simply by the hydrothermal treatment of $CuCl_2 \cdot H_2O$ and en, is built up from unusual chloride bridged $Cu_4$ tetramers connected by $CuCl_{3/3}$ units and has voids in the framework that are filled with charge-compensating $[Cu(en)_2]^{2+}$ cations.**

While the utility of the aluminosilicate zeolites[1] derived from their shape selective absorptivities, reactive acid sites and substantial chemical and thermal stability remains unsurpassed, recent synthetic efforts have sought to expand the chemical reactivity and catalysis associated with open framework inorganic materials to a variety of new systems. Early efforts produced the large class of aluminophosphate materials.[1d,2] In hopes of increasing the chances of observing new types of shape selective catalysis by incorporating d-block elements into these materials as stoichiometric framework constituents, organically templated solids such as molybdenum phosphates,[3] vanadium phosphates,[4] cobalt phosphates[5] and vanadium oxides[6] have recently been prepared. It appears that the organic templates used in the syntheses not only fulfill the requirement of leaving a molecular sized void in the framework upon post-synthesis removal, but are essential for the synthesis by providing a species that can allow the crystal to grow *via* charge neutralization at the crystal/solution interface by virtue of possessing a suitable shape and charge to volume ratio. Such incorporation of an organic molecule will necessarily induce a large degree of structural complexity into the system by virtue of the relatively large number of framework atoms required to totally encapsulate the large molecule. We report here an extension of this concept of templating a three-dimensional anionic framework with bulky cations to the copper halide system with the hydrothermal synthesis and structural characterization of $[Cu(en)_2]_2Cu_7Cl_{11}$ **1** (en = ethylenediamine), a three-dimensional copper halide open-framework material with entrained $[Cu(en)_2]^{2+}$ cations.

The halide $[Cu(en)_2]_2Cu_7Cl_{11}$ **1** is prepared from the extremely simple reaction of $CuCl_2 \cdot 2H_2O$, en and water in a mole ratio of 1 : 1.4 : 148 at 170 °C for 4 days, and is isolated as purple crystals.† The X-ray structural analysis of **1**‡ shows the material to be an open-framework solid with a topologically unique framework composed of copper and chlorine. The formulation of the framework as all diamagnetic $Cu^+$ with entrained $Cu(en)_2^{2+}$ ($d^9$ S = 1/2) centers is supported by magnetic measurements which show the compound to be paramagnetic with $\mu_{eff}$ (300 K) = 2.43(1) $\mu_B$ and $\theta = -4.0(3)$ K.

The framework of **1** is constructed from the unusual $Cu_4$ tetrameric building blocks (Fig. 1) which contain copper tetrahedrally coordinated by chloride ligands. The tetramer is composed of a dimer of edge-sharing $CuCl_4$ tetrahedra, with the two Cl atoms which form the shared edge also coordinated to two copper atoms from a corner-sharing dimer of $CuCl_4$ tetrahedra, which results in these two Cl atoms connecting the dimers in a $\mu_3$ fashion. The tetramers are linked into a covalently bonded three-dimensional lattice by three coordinate Cu atoms (Fig. 2). The Cu atoms in these three-coordinate sites display slightly pyramidal trigonal coordination, with the Cu displaced 0.41 Å above the least-square plane of the three Cl atoms, and are crystallographically disordered into two sites on either side of this plane.

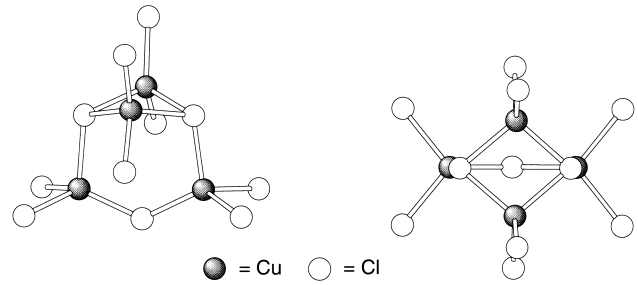

**Fig. 1** Two views of the $Cu_4$ tetramer found in $[Cu(en)_2]_2Cu_7Cl_{11}$ **1** which is composed of two-edge sharing $CuCl_4$ tetrahedra, the two bridging chloride ligands of which also form two vertices from a corner-sharing pair of $CuCl_4$ tetrahedra, thereby adapting a $\mu_3$ coordination mode

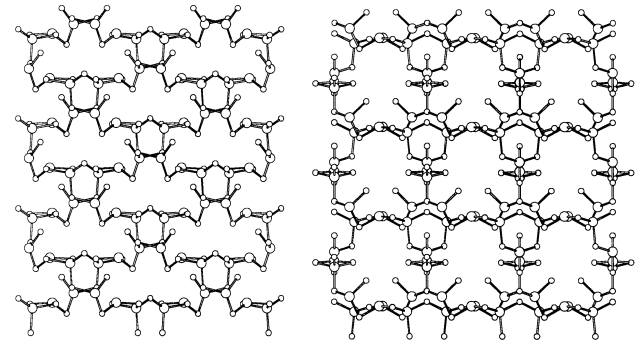

**Fig. 2** Two views of the structure of $[Cu(en)_2]_2Cu_7Cl_{11}$ **1** 45° apart and parallel to the *ab* plane showing the manner in which the $Cu_4$ tetramers are linked by the $CuCl_{3/3}$ groups; the $[Cu(en)_2]^{2+}$ cations have been omitted for clarity

The three-dimensional copper halide framework can be conceptually envisioned as being built up in space group $P4_2nm$ from the aforementioned tetramers connected along the $4_2$ screw axis *via* the trigonal $CuCl_{3/3}$ bridges into rectangular spirals. These spirals are in turn intertwined with another crystallographically identical spiral to give copper halide double helices as shown in Fig. 3. Unlike the recent example of chiral inorganic double helices found in the vanadium phosphate $[NH_2Me_2]K_4[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)_7] \cdot 4H_2O$[7] mirror images of the double helix in the title compound must also exist in the crystal since $P4_2nm$ is not an enantiomorphic space group. In fact, each double helix is fused with and is surrounded by four identical double helices of the opposite handedness that

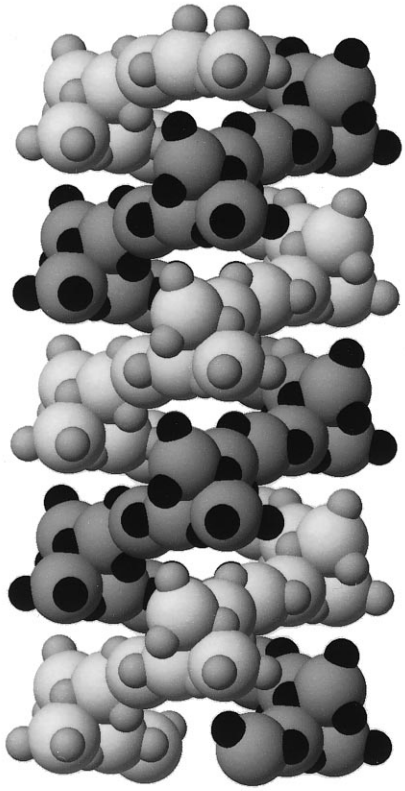

**Fig. 3** The copper halide double helices in $[Cu(en)_2]_2Cu_7Cl_{11}$ **1**

are related to one another by the mirror planes present on (110) and $(\bar{1}10)$.

This connectivity generates voids in the framework that are filled by charge-compensating $[Cu(en)_2]^{2+}$ cations. The $[Cu(en)_2]^{2+}$ cations interact with the framework not only *via* two long axial Cu–Cl interactions at 2.77 and 2.80 Å, but also with numerous interactions in the range 3.3–3.6 Å from the N atoms of the en to the Cl atoms of the framework which are presumably N–H···Cl hydrogen bonds. Bond angles for these N–H···Cl interactions range from 153.3 to 171.7°, further supporting the existance of hydrogen bonds.

The hydrothermally mediated, cation-directed crystallization of covalently bonded three-dimensional framework materials with large occluded cations has been extended to the halide system with the synthesis and structural characterization of $[Cu(en)_2]_2Cu_7Cl_{11}$ **1**. It is clear that highly crystalline materials with covalently bonded three-dimensional frameworks as reported here would be very difficult to prepare at room temp. The increased solvating ability of water at higher temperatures is definitely necessary to provide the environment required for the assembly of covalent three-dimensional solids from simple precursor crystal growth. Since these reaction conditions or starting materials could hardly be simpler, this method should be applicable to the preparation of a very large number of new solids with potentially interesting or useful molecular seiving, photochemical or catalytic properties. This method has yielded a variety of large copper halide clusters, one-dimensional polymers and layered solids with coordinated organic ligands, which will be reported shortly.

The work at Syracuse University was supported by NSF Grant CHE-9318824.

† *Experimental procedure*: ethylenediamine (0.20 ml, 0.0042 mol) was added to a solution of $CuCl_2 \cdot 2H_2O$ (0.51 g, 0.003 mol) in 8 ml water contained in a 23 ml polytetrafluoroethylene-lined Parr acid digestion vessel. The vessel was sealed and heated to 170 °C for four days under autogeneous pressure. After cooling, purple crystal were isolated and washed with water. Powder X-ray diffraction shows the product to be monophasic.

‡ *Crystal data for* **1**: Tetragonal, space group $P4_2nm$, $a$ = 13.241(2), $c$ = 8.953(2) Å, $V$ = 1569.7(5) Å$^3$, $Z$ = 8, $M_w$ = 300.56 g mol$^{-1}$, $D_c$ = 2.544 g cm$^{-3}$. The structure was solved by direct methods and refined using full-matrix least squares on $F^2$ with SHELXTL. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The final refinement was based on 1294 reflections with $I > 2.0\sigma(I)$ and converged with $R(R_w)$ = 0.0362(0.0843). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/490.

# New molecular superconductor containing paramagnetic chromium(III) ions

**Lee Martin,[a] Scott S. Turner,[a] Peter Day,*[a] Frank E. Mabbs[b] and Eric J. L. McInnes[b]**

[a] *Davy Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albemarle Street, London, UK W1X 4BS*
[b] *EPSRC cw EPR Service Centre, Department of Chemistry, University of Manchester, UK M13 9PL*

**The molecular charge-transfer salt β″-(bedt-ttf)$_4$[(H$_2$O)Cr(C$_2$O$_4$)$_3$]·PhCN [bedt-ttf = bis(ethylenedithio)tetrathiafulvalene], containing paramagnetic Cr$^{III}$ ions ($S$ = 3/2), is a superconductor with $T_c$ = 6.0(5) K.**

Superconductivity can be destroyed by magnetic fields, through break up of $S$ = 0 Cooper pair charge carriers. This is true whether the field is applied externally by a magnet, or arises internally from magnetic moments within the lattice.[1] However there is evidence to suggest that $S$ = 1 Cooper pairs can coexist with strong magnetic fields. To explore this antagonism between magnetism and superconductivity we have been systematically preparing molecular charge-transfer salts in which layers consisting of stacks of the organic donor molecule bedt-ttf [bis(ethylenedithio)tetrathiafulvalene] are interleaved by layers containing anionic transition-metal complexes which are paramagnetic. Among many bedt-ttf charge-transfer salts we found one containing paramagnetic high-spin Fe$^{III}$ ions which was a superconductor below 8.5(3) K.[2] The compound in question, β″-(bedt-ttf)$_4$[(H$_2$O)Fe(C$_2$O$_4$)$_3$]·PhCN **1**, contains the trigonally distorted-octahedral [Fe(C$_2$O$_4$)$_3$]$^{3-}$ with $S$ = 5/2, which is one of numerous known oxalate complexes of d-block elements. It is therefore pertinent to seek other examples with different magnetic moments to compare the effect of such a change on the superconducting critical temperature. Here we report that the corresponding Cr$^{III}$ compound, with a lower magnetic moment ($S$ = 3/2) is indeed a superconductor, but with a slightly lower $T_c$ that the Fe$^{III}$ compound.

Crystals of (bedt-ttf)$_4$[(H$_2$O)Cr(C$_2$O$_4$)$_3$]·PhCN **2** were grown from solutions generated electrochemically in H-shaped cells at a constant current of 1 μA using wet PhCN as solvent and [NH$_4$]$_3$[Cr(C$_2$O$_4$)$_3$]·3H$_2$O as supporting electrolyte. The solvent was saturated with bedt-ttf, excess solid being placed at the base of the anode arm of the H-cell. Black needle shaped crystals grew on the Pt anode. The structure of this new charge-transfer salt[3] is isostructural to that of **1**, featuring alternate layers of bedt-ttf cations, and layers containing [Cr(C$_2$O$_4$)$_3$]$^{3-}$, H$_2$O and PhCN. The cation layers adopt the β″ packing arrangement, with stacks of bedt-ttf having numerous short intermolecular S···S distances. The anion layers have a honeycomb arrangement of [Cr(C$_2$O$_4$)$_3$]$^{3-}$ with their outer oxygens hydrogen-bonded to the water molecules. Within each layer there is exclusively one chiral form of [Cr(C$_2$O$_4$)$_3$]$^{3-}$ and successive layers contain alternating Δ and Λ enantiomers. The PhCN molecules occupy hexagonal cavities with the CN groups parallel, causing an elongation of the hexagonal network along the *b*-axis.

Susceptibility measurements were performed on a Quantum Design MPSM7 SQUID magnetometer on randomly oriented polycrystalline samples within a gelatin capsule, and the data was collected on a Hewlett-Packard 486/33N PC. In fields > 0.01 T the susceptibility from 300 to 4 K is well fitted by the Curie–Weiss law together with a temperature-independent Pauli contribution to give a Curie constant of 1.956(2) emu K mol$^{-1}$ (1.875 is expected for Cr$^{3+}$, $S$ = 3/2). The fitted Weiss constant of −0.21(1) K indicates a very weak antiferromagnetic interaction between Cr centres. The Pauli contribution is 0.0016(3). In a plot of $\chi^{-1}$ *vs.* T there is a distinct change of slope near 150 K, probably indicative of a minor structural phase transition. In contrast, upon cooling the sample in zero applied field and measuring the susceptibility in a field of 5 × 10$^{-4}$ T whilst warming, the response is diamagnetic from 1.75 to 6.0 K indicating the presence of superconductivity. Type II superconducting behaviour is observed upon recooling as flux is trapped inside the sample and the susceptibility is less negative (Fig. 1). As the applied field is increased, the diamagnetism decreases, until at 0.002 T a Curie tail begins to develop as the high susceptibility of the Cr$^{3+}$ obscures the superconducting transition. The superconducting transition is completely suppressed by fields greater than 0.01 T, when the susceptibility obeys the Curie–Weiss law from 1.75 K to room temperature.

Polarised optical reflectivity of single crystals was recorded at room temp. using a Perkin Elmer 1710 spectrometer fitted with a Spectra Tech microscope and a KRS5 polariser. When the electric vector is both parallel and perpendicular to the needles axis of the crystal, the spectrum of **2** shows a high metallic reflectivity at frequencies below *ca.* 3800 cm$^{-1}$ with weak sharp vibrational features superimposed (Fig. 2). Several of the latter are assigned[4] to the [Cr(C$_2$O$_4$)$_3$]$^{3-}$: an O–C–O stretching vibration as 1270 and 1320 cm$^{-1}$, an O–C–O symmetric stretching vibration at 1390 cm$^{-1}$ and an O–C–O asymmetric stretching vibration at 1645 cm$^{-1}$. The other weak vibrational modes due to bedt-ttf and PhCN can be assigned by comparison with published data.[5] The metallic reflectivity has been fitted to a Drude expression[6] for free electrons with a damping term for the charge carrier motion. A value of 3570 cm$^{-1}$ is calculated for the plasma frequency.

The EPR spectra of a polycrystalline sample were recorded at X- and K-band from 4 to 300 K on a Bruker ESP300E spectrometer. Cooling was achieved *via* a BVT2000 variable-temperature unit (300–100 K) or an Oxford Instruments ESR910 cryostat (< 100 K). Spectrum simulations were achieved *via* in-house software.[7] At each temperature the spectrum consisted of separate resonances attributable to the localised Cr$^{3+}$ and to the conduction electrons. The relative

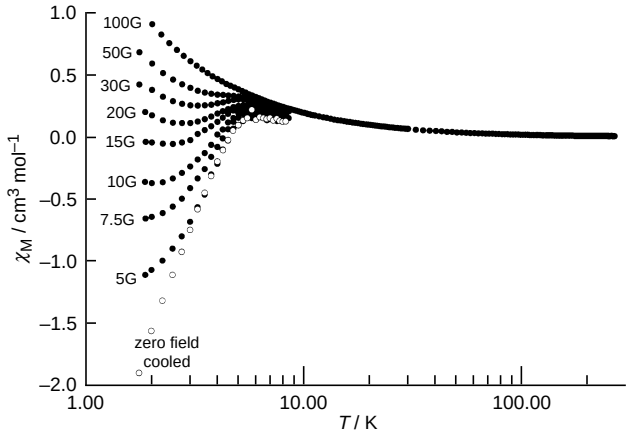

**Fig. 1** Temperature variation of the magnetic susceptibility of **2** in fields from 0 to 0.01 T. Open circles are zero-field cooled data and filled circles are field-cooled data.

intensities of the resonances arising from each of these vary with temperature, see Fig. 3. Those for the conduction electrons decrease with decreasing temperature, in contrast to those due to the chromium centres which increase. The observation of spectra from the two different centres indicates that interaction between them remains weak over the whole temperature range. The resonance due to the conduction electrons consists of a single line at $g = 2.006(1)$ comparable with the free-electron $g$ value, whereas the spectrum relating to $Cr^{3+}$ is complex. Simulations of the $Cr^{3+}$ resonances at both X- and K-band resulted in acceptable fits only if the presence of two different Cr centres in a 1 : 1 ratio was assumed. These two centres have the same $g$ values (2.00) but significantly different zero-field splitting parameters; $|D| = 0.52$ cm$^{-1}$, $|E/D| = 0.07$ cm$^{-1}$ and $|D| = 0.70$ cm$^{-1}$, $|E/D| = 0.16$ cm$^{-1}$. Since $|D|$ is more sensitive to changes in the electronic environment about Cr than $g$, there are two types of coordinated chromium differentiated by very small structural changes, probably in the O–Cr–O angles rather than bond distances. This is apparently in contradiction to the crystal structure. However the latter was refined from room-temperature data and it is likely that there is a structural phase transition to a lower symmetry on cooling, as already indicated by the bulk susceptibility data. The fact that the ratio of the two metal centres is 1 : 1 points to the possibility that the origin of this effect may be the interaction of each chiral form with the bedt-ttf layers.

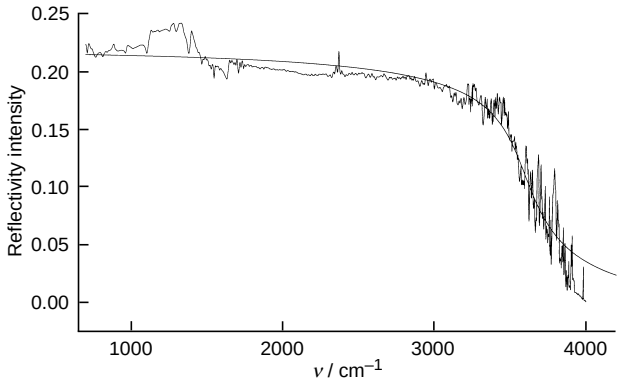

**Fig. 2** Reflectivity of a crystal of **2** with the electric vector of the incident light parallel and perpendicular to the needle axis. The line is a fit to a damped Drude expression.

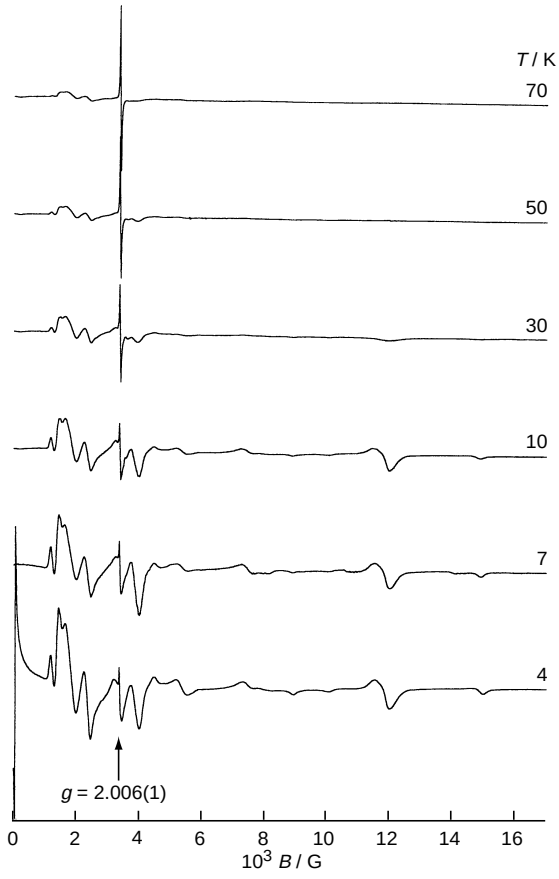

**Fig. 3** X-Band EPR spectra of a polycrystalline sample of **2** in the temperature range 70–4 K

An interesting feature of the EPR at X-band is a line with inverted phase compared to the rest of the spectrum near to zero frequency at the lowest temperatures. The origin of this feature is unknown and is the subject of further investigations. However, similar features have been observed in the EPR of high-temperature cuprate[8] superconductors as well as bedt-ttf[9] and $C_{60}$[10] based superconductors. It has been suggested to be due to the formation of weak links and closed superconducting loops between grains and is considered to be a marker for the onset of superconductivity.[11] Detailed investigations of the EPR spectra of **1** and similar materials will be reported in subsequent articles.

In conclusion we have found that replacing Fe by Cr in the paramagnetic molecular superconductor **1** brings about a small decrease in $T_c$ and $H_c$ despite the smaller magnitude of the paramagnetic moment embedded in the lattice. Thus, given that the unit-cell constants of **1** and **2** are essentially identical, there is no simple relationship between the strength of the local magnetic binding energy of the Cooper pairs. We are continuing to explore this intriguing family of superconductors, including synthesis of examples containing only closed-shell metal ions.

We are grateful to Professor W. Hayes of the Clarendon Laboratory, Oxford, for access to IR reflectivity equipment. We thank Professor M. B. Hursthouse and Dr S. J. Coles of the EPSRC X-ray Crystallography Service, Cardiff, for communication of results. One of us (S. S. T.) thanks Dr P. Harper for discussions on Drude theory. The work is supported by the EPSRC.

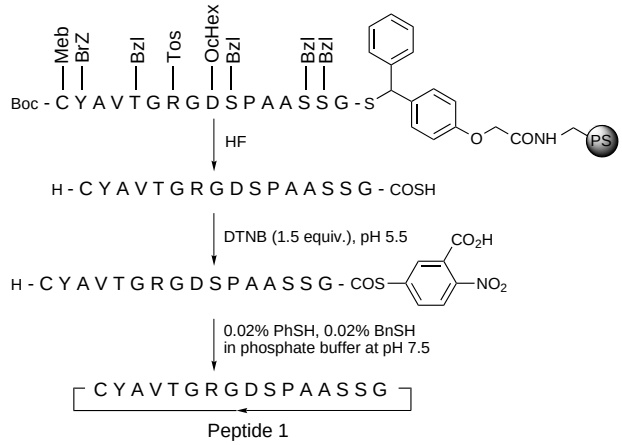
# Chemoselective backbone cyclization of unprotected peptides

**Julio A. Camarero and Tom W. Muir***

*Laboratory of Synthetic Protein Chemistry, The Rockefeller University, 1230 York Avenue, New York, NY 10021, USA*



**A fully unprotected 15 residue peptide containing an N-terminal Cys residue and a C-terminal thioester moiety is cleanly converted to the corresponding head-to-tail cyclic peptide in aqueous buffers at around neutral pH.**

Cyclic peptides have restricted conformational flexibility compared to their linear counterparts, a feature which makes them of great interest in studying the structure–activity relationships of bioactive peptides.[1,2,3] Classical solution-based approaches to the synthesis of amide-cyclized peptides rely on fully protected linear precursors which are selectively activated and cyclized under conditions of high dilution.[4] Although this methodology has been used with satisfactory results in the synthesis of small cyclic peptides,[5] its application to the cyclization of larger peptides is constrained by the decreasing solubility of fully protected peptides as their size increases. To overcome these solubility problems, many researchers have utilized a variety of minimal protection strategies.[6] However, cyclization of minimally protected fragments *via* conventional carboxylate activation chemistries can lead to the accumulation of unwanted side-products, resulting in the desired material being generated in only moderate yield.[6]

In a recent report, Tam and co-workers describe a powerful new route to cyclic peptides in which unprotected peptide precursors are chemoselectively cyclized in aqueous solution.[7] This approach utilizes a thiazolidine-forming[8] intramolecular chemical ligation reaction, and was used to generate a series of cyclic peptides in good yield from soluble linear peptide precursors.[7] Here we describe a complementary methodology which facilitates the rapid and quantitative backbone cyclization of fully unprotected peptides in aqueous solution. Our cyclization strategy is based on an intramolecular native chemical ligation reaction,[9] and therefore requires the presence of an N-terminal Cys† residue and a C-terminal thioester moiety within the linear peptide precursor. We have successfully applied this new cyclization approach to the generation of backbone cyclized model peptide **1**, the sequence of which is derived from the tenth type 3 module of Fibronectin, and contains the RGD motif known to be involved in binding to the integrin class of cell adhesion receptor.[10]

The synthetic strategy used to generate cyclic peptide **1** is illustrated in Scheme 1. The fully protected linear precursor was assembled manually by stepwise SPPS using the *in situ* neutralization/HBTU [2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate] activation protocol for Boc chemistry.[11] The synthesis was carried out on a Boc-Gly-(thioester handle)-aminomethyl-polystyrene resin[12,13] on a 0.1 mmol scale. After the synthesis was complete, the cleavage and total deprotection was accomplished by treatment with anhydrous HF–*p*-cresol (95 : 5, 10 ml, 0 °C for 1 h). Following trituration with cold diethyl ether, the crude peptide-$^{\alpha}$thioacid was extracted with 0.1% TFA in MeCN–$H_2O$ (1 : 1, 15–20 ml) and lyophilised. Analysis of the crude material by analytical C18 reverse-phase HPLC (10–40% B‡ over 30 min) gave a major peak whose mass was consistent with that of the expected peptide-$^{\alpha}$COSH [calculated molecular weight (av. isotope comp.) = 1444.5 Da; found = 1443.9 ± 0.1 Da]. In order to transform the $^{\alpha}$thioacid function into an active $^{\alpha}$thioester, the lyophilised crude material (65 mg, 45 μmol) was dissolved in a buffer containing 6 M GuHCl, 0.1 M sodium phosphate, pH 5.5 (30 ml), and a solution of DTNB [5,5′-dithiobis(2-nitrobenzoic acid)] in 0.1 M phosphate buffer, pH 5.5 (15 ml of a 5 mM solution, 1.5 equiv.) was added at room temperature. The thioesterification reaction was complete after 30 min,§ and the major product was characterized by ESMS (electrospray mass spectrometry) as being the desired peptide-$^{\alpha}$thioester [calculated molecular weight (av. isotope comp.) = 1607.6; found = 1605.9 ± 0.1 Da]. Upon completion, the reaction was quenched by the addition of 0.1% TFA in $H_2O$, and the peptide-$^{\alpha}$thioester product purified by preparative HPLC (C18 reverse-phase HPLC column, 18–23% B over 45 min at 50 ml min$^{-1}$) in high purity [10 mg, 6.2 μmol, Fig. 1(*a*)]. It is worth noting that the lower p$K_a$ of the $^{\alpha}$thioacid group relative to the cysteine sulfhydryl group ensures that the predominant reaction with DTNB at pH 5.5 is thioesterification and not disulfide formation.[14]

Cyclization of the linear peptide precursor (containing the necessary N-terminal Cys and C-terminal thioester group) to give peptide **1** was accomplished under high dilution conditions as follows. The purified peptide-$^{\alpha}$thioester was dissolved to a final concentration of *ca*. 50 μM in a freshly degassed buffer (pH 7.5) containing 0.1 M sodium phosphate, 1 mM EDTA, and both PhSH and BnSH at a concentration of 0.02% v/v.¶ In order to monitor the course of the reaction, small aliquots (100 μl) of the reaction mixture were periodically removed, quickly quenched by addition of 10% TFA in $H_2O$ (20 μl), and then analysed by analytical C18 reverse-phase HPLC. Under these conditions, the backbone cyclization reaction was found to be completely chemoselective, since only the desired cyclomonomeric peptide **1** was obtained [Fig. 1(*b*)]. Moreover, cyclization proceeded extremely fast and the linear starting material was cleanly converted to the cyclic product within 10 min [Fig. 1(*c*)]. Cyclic peptide **1** was purified by semipreparative C18 reverse-phase HPLC (10–40% B over 45 min at ml min$^{-1}$) and characterized by ESMS [calculated molecular weight (av.

**Scheme 1**

isotope comp.) = 1408.5 Da; found = 1408.4 ± 0.6 Da] and tryptic digestion.‖

In summary, we have described a practical new strategy which allows fully unprotected peptides to be cyclized in a head-to-tail manner in aqueous solution at neutral pH. In the example described, cyclization was observed to be both clean and rapid, and afforded the desired cyclic peptide **1** in excellent yield. As with intermolecular native chemical ligation,[9] this intramolecular cyclization reaction can be performed in the presence of all naturally occurring amino acid side-chains, including additional cysteine sulfhydryls. The compatibility of this cyclization chemistry with native protein folding conditions coupled with recent advances in the total chemical synthesis of proteins,[15] suggests a potentially straightforward route to circular versions of small proteins and protein domains.

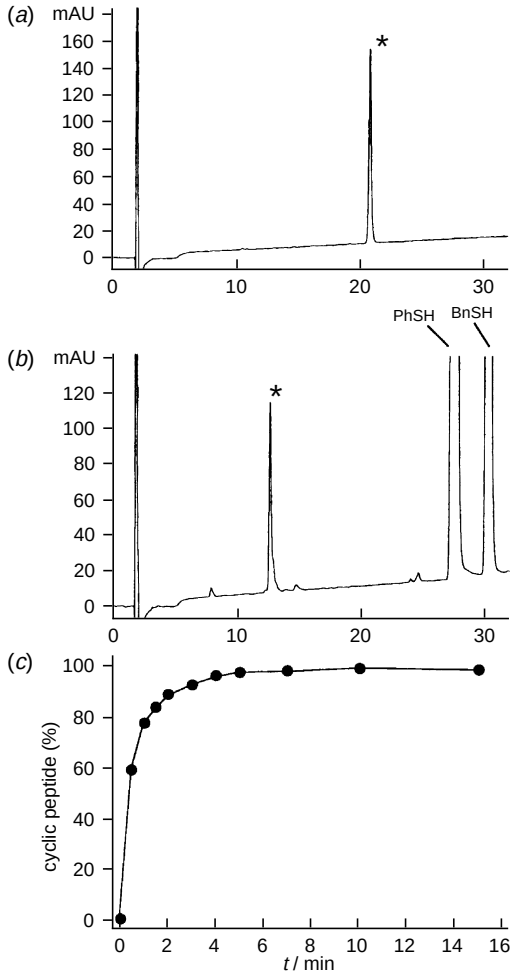


**Fig. 1** Reverse-phase HPLC analysis of peptide **1** cyclization. (*a*) peptide-$^{\alpha}$COSNB after HPLC purification. (*b*) cyclization reaction after 15 min. (*c*) progress of the cyclization reaction. The desired product in each panel is indicated by an asterisk.

† A more general approach to native (amide-forming) chemical ligation that extends the technique beyond the originally reported X-Cys ligation site to X-Gly and Gly-X ligation sites has been described recently.[16]

‡ Where A = 0.1% TFA in $H_2O$ and B = 0.1% TFA in MeCN : $H_2O$ (9 : 1 v/v).

§ Thioesterification of peptide-$^{\alpha}$thioacids with aryl disulfides such as DTNB goes *via* an acyl disulfide intermediate.[17]

¶ Inclusion of BnSH and PhSH in the ligation buffer results in the *in situ* conversion of the 2-nitrobenzoic peptide-$^{\alpha}$thioester (peptide-$^{\alpha}$COSNB) into the corresponding benzyl and phenyl peptide-$^{\alpha}$thioesters through trans-thioesterification.[18] The presence of these aromatic thio cofactors was found to eliminate unwanted peptide-$^{\alpha}$thioester hydrolysis.

‖ Trypsin hydrolysis in 0.1 M Tris HCl buffer pH 8.5 at the unique Arg residue yielded only a single product, as expected for a cyclomonomeric structure, that did not co-elute with the peptide **1** and gave a molecular peak 18 Da higher than the cyclic peptide [molecular weight calculated (av. isotope comp.) = 1426.5 Da; found = 1426.4 ± 0.6 Da].

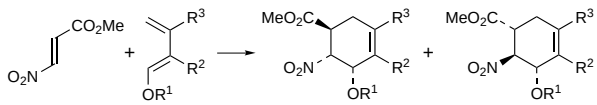
# Enhancement of *endo* selectivity in Diels–Alder reactions of methyl (*E*)-3-nitroacrylate with (*E*)-1-oxybuta-1,3-dienes

**Richard J. Stoodley* and Wai-Hung Yuen**



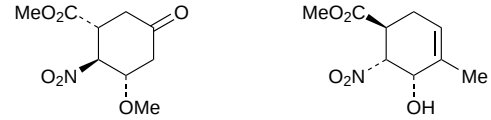
*Department of Chemistry, UMIST, PO Box 88, Manchester, UK M60 1QD*

**(*E*)-1-Acetoxybuta-1,3-dienes show enhanced *endo* selectivity in Diels–Alder reactions with methyl (*E*)-3-nitroacrylate compared with (*E*)-1-methoxybuta-1,3-dienes and (*E*)-1-trimethylsilyloxybuta-1,3-dienes.**

In foundation studies, Danishefsky[1] established that Diels–Alder reactions of the nitroacrylate **1** with 1-oxybuta-1,3-dienes are highly regioselective but poorly stereoselective. For example, the cycloaddition involving the diene **2a** (in PhH) led to a 50 : 50 mixture of the *endo*-nitro cycloadduct **3a** and the *exo*-nitro cycloadduct **4a**; mixtures of the cycloadducts **3b**/**4b** and **3d**/**4d** were also produced in the corresponding reactions of the dienes **2b** and **2d**, although the ratios were not specified. With the intention of utilising cycloadducts of types **3** and/or **4** for the synthesis of carbasugars (particularly, 4-aminocarbapyranoses), we have sought to control the stereochemical outcome of the cycloadditions. The results described herein illustrate a means of producing *endo*-nitro cycloadducts of type **3** in preference to their *exo*-nitro counterparts of type **4**.

Table 1 summarises the outcome of Diels–Alder reactions of the nitroacrylate **1**[2] with the 1-oxybuta-1,3-dienes **2a**,† **2b**,† **2c**,†‡ **2d**,† **2e**,[3]§ **2f**,¶ **2g**,[4] **2h**,[5] **2i**,[6] **2j**,[7] **2k**,[8] **2l**[9] and **2m**.‖ From the results, it is clear that the *O*-substituent plays a significant role in determining the *endo* : *exo* selectivity.** Thus, an *O*-acetyl substituent is considerately more effective than an *O*-methyl or *O*-trimethylsilyl group (which are comparable) in promoting the formation of *endo*-nitro cycloadducts. It is also evident that the 3-substituent is influential. Thus, for dienes with comparable *O*-substituents, *endo*-nitro group selectivity increases in the order H > Me > OAc > $OSiMe_2R$. Finally, it should be noted that dienes featuring a 2-methyl group generally show a higher *endo*-nitro group selectivity than their 2-unsubstituted counterparts.

**Table 1** Selectivity of Diels–Alder reactions involving the nitroacrylate **1** and the dienes **2a**–**m**[a]



**1** **2** **3** **4**

| Diene **2** | $R^1$ | $R^2$ | $R^3$ | Cyclo-adducts | Ratio[b] | Yield (%)[c] |
|---|---|---|---|---|---|---|
| **a** | Me | H | H | **3a/4a** | 67 : 33 | 67 |
| **b** | $SiMe_3$ | H | H | **3b/4b** | 68 : 32 | — |
| **c** | Ac | H | H | **3c/4c** | > 95 : 5 | 71 |
| **d** | Me | H | $OSiMe_3$ | **3d/4d** | 35 : 65 | — |
| **e** | Me | H | $OSiMe_2Bu^t$ | **3e/4e** | 33 : 67 | — |
| **f** | Ac | H | $OSiMe_2Bu^t$ | **3f/4f** | 74 : 26 | 73 |
| **g** | Ac | H | OAc | **3g/4g** | 82 : 18 | 57 |
| **h** | $SiMe_3$ | H | Me | **3h/4h** | 50 : 50 | — |
| **i** | Ac | H | Me | **3i/4i** | 85 : 15 | 69 |
| **j** | $SiMe_3$ | Me | H | **3j/4j** | 85 : 15 | — |
| **k** | Ac | Me | H | **3k/4k** | 92 : 8 | 64 |
| **l** | Me | Me | $OSiMe_3$ | **3l/4l** | 52 : 48 | — |
| **m** | Ac | Me | $OSiMe_2Bu^t$ | **3m/4m** | 83 : 17 | 71 |

[a] The reactions were performed in dry dichloromethane (*ca*. 5 $cm^3$) using the nitroacrylate (1 mmol) and the diene (1 mmol). [b] The cycloadduct ratio was determined by 300 MHz $^1H$ NMR spectroscopic analysis of the crude product. [c] The yield refers to the purified cycloadduct mixture (the ratio was unaltered) isolated after silica gel column chromatography.

From a preparative context, the following points are of note. It was possible to isolate the ensuing cycloadducts in a pure state by crystallisation: **3a**†† (17% yield), mp 68–70 °C; **3c**†† (68% yield), mp 88–90 °C; **3i**†† (54% yield), mp 118–120 °C; and **3k**†† (60% yield), mp 88–90 °C. When the crude silylated cycloadduct mixtures **3d**/**4d** and **3j**/**4j** were subjected to hydrolysis, crystallisation of the products gave compound **5** (34% yield), mp 110–112 °C (lit.,[1] 110–112 °C), and compound **6**†† (42% yield), mp 108–110 °C, in pure states.

**5** **6**

The results reported are of both synthetic and mechanistic interest. In a synthetic context, they illustrate that *O*-substituent tuning can have a notable impact on *endo* : *exo* selectivity in cycloaddition reactions involving (*E*)-1-oxybuta-1,3-dienes of type **2** and the nitroacrylate **1**. Specifically, *O*-acetyl substituents are more effective than *O*-methyl/silyl groups in promoting the formation of *endo*-nitro cycloadducts of type **3**. From a mechanistic standpoint, the results suggest that the degree of 'electron richness' of a diene is an important consideration in *endo* : *exo* selectivity issues. In particular, electron-rich dienes favour the formation of *exo*-nitro cycloadducts of type **4**. Recently, Node and co-workers have noted[10] that *exo*-nitro group selectivity is a feature of Diels–Alder reactions of Danishefsky's diene **2d** and (*E*)-nitroalkenes (bearing alkyl or aryl groups) but they suggest that the *endo* transition state is destabilised by electrostatic repulsion between the silyloxy group of the diene and the nitro group of the dienophile.

† The dienes **2a**–**d** were purchased from Aldrich.

‡ The reaction of the diene **2c** with the ethyl ester counterpart of the nitroacrylate **1** has been studied by Shin and co-workers (ref. 11). Although the cycloadduct ratio was not specified, the ethyl ester analogue of the *endo*-nitro cycloadduct **3c** was isolated in 57% yield.

§ The diene **2e** was prepared by a modification of the literature route (ref. 3) in which (*E*)-4-methoxybut-3-en-2-one was treated with *tert*-butyldimethylsilyl triflate and triethylamine (ref. 12).

¶ The diene **2f** was prepared from (*E*)-4-acetoxybut-3-en-2-one (ref. 4) in a manner analogous to that employed in the synthesis of the diene **2e**.

‖ The diene **2m** was prepared from (*E*)-4-acetoxy-3-methylbut-3-en-2-one [obtained by acetylation (ref. 4) of the sodium salt of (*E*)-4-hydroxy-3-methylbut-3-en-2-one (ref. 13)] in a manner similar to that used in the synthesis of the diene **2e**.

** In general, the cycloadducts were differentiated by the appearance in the NMR spectrum of the double doublet at *ca*. δ 4.90, attributed to the nitro-bearing methine proton; coupling constants (*J*) of *ca*. 4 and 12 Hz were

observed for *endo*-nitro cycloadducts of type **3** and of *ca*. 8 and 11 Hz for *exo*-nitro cycloadducts of type **4**.

†† All new compounds displayed analytical and spectral properties that supported their assigned structures.

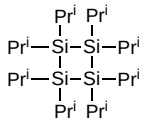
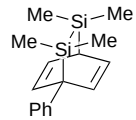
# Photo-induced silylene-transfer reactions of cyclic organosilanes to phenanthraquinone

**Masahiro Kako, Masumi Ninomiya and Yasuhiro Nakadaira***

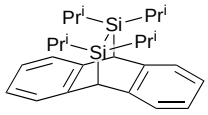


*Department of Chemistry, The University of Electro-Communications, Chofu, Tokyo, 182, Japan*

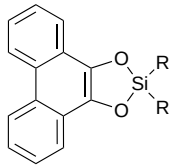
**Cophotolysis of cyclic organosilanes 1–4 with phenanthraquinone gave silylene insertion products *via* radical displacement at the silicon atoms of organosilanes by the photochemically excited phenanthraquinone.**



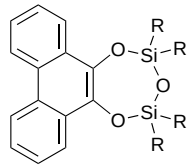
Electron-transfer reactions of heavier group 14 organometallic compounds have been studied extensively from the mechanistic and synthetic viewpoints.[1] For these reactions, electron-deficient carbonyl compounds, especially *p*-benzoquinones, are frequently used as electron acceptors.[2,3] We and the other groups found that the photoreactions of some disilane and digermane derivatives with *p*-benzoquinones underwent electron-transfer processes to produce *O*-silylated and *O*-germylated *p*-benzoquinones.[2] On the other hand, it was reported that the photolysis of α-diketones with alkyl and allylic stannanes afforded exclusively the alkylated and allylated α-ketols without giving any stannylated products.[3] These previous results prompted us to investigate the photoreaction of organosilanes and *o*-benzoquinones, which serve as good silylene traps due to their s-*cis* α-diketone structures.[4] We now report the photoreaction of cyclic organosilanes **1–4** with phenanthraquinone (PQ), providing the first example of silylene transfer reactions induced by photoexcited triplet *o*-benzoquinones.



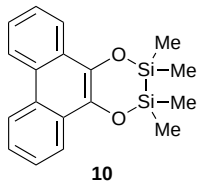
**1**



**2**



**3**



**4**

**5** R = Me
**7** R = Pr$^i$

**6** R = Me
**8** R = Pr$^i$

**10**

Irradiation of a solution (MeCN–$CH_2Cl_2$ = 4 : 1) of dodecamethylcyclohexasilane **1** ($1.1 \times 10^{-2}$ M) and PQ ($3.5 \times 10^{-2}$ M) in a sealed tube with two 500 W tungsten-halogen lamps (passing through an aqueous $NaNO_2$ filter, cutoff < 400 nm) afforded dioxasilolene **5**,† as a silylene adduct of PQ, along with a minor amount of trioxadisilepine **6**. In the case of photolysis of cyclotetrasilane **2**, dioxasilolene **7** was produced, whereas the corresponding trioxadisilepine **8** was not formed at all, as summarized in Table 1. We detected no other product derived from PQ while substantial amounts of PQ were recovered after the photolyses.

It is well-known that ultraviolet photolysis of **1** produces free dimethylsilylene, which can be trapped readily by α-diketones to afford trioxadisilepine derivatives.[4] However, **1** is entirely inert to the visible light employed in the present photolyses. Furthermore, the present reaction does not seem to involve free dimethylsilylene because the cophotolysis of **1** and PQ in the presence of $Et_3SiH$, a common silylene trap, did not give any $Et_3SiMe_2SiH$.[4b]

Since the reaction was efficiently quenched by addition of anthracene, the triplet PQ is suggested to be the key intermediate as judged by the comparison of the singlet and the triplet energies of PQ ($E_S$ = *ca.* 54, $E_T$ = *ca.* 48 kcal mol$^{-1}$)[5] and those of anthracene ($E_S$ = *ca.* 76, $E_T$ = *ca.* 43 kcal mol$^{-1}$).[6] Meanwhile, the consumption of **1** was suppressed by addition of 1,4-diazabicyclo[2.2.2]octane (DABCO), which has a lower oxidation potential ($E_{ox}$ = +0.70 V *vs.* SCE) than that of **1** ($E_{ox}$ = +1.45 V *vs.* SCE). The free energy changes ($\Delta G$) for the electron-transfer from cyclosilanes to the triplet PQ are given in Table 2.‡ These data suggest that the reaction may proceed *via* a partial or complete electron-transfer from the cyclosilanes to the photoexcited PQ at least in a polar solvent, such as MeCN. In fact, the silylene-transfer reactions were found to proceed substantially faster in MeCN than in benzene, as shown in Table 1.

We propose the following mechanism on the basis of Pedulli's result that photoexcited ketones are capable of cleaving Si–Si bonds of polysilanes *via* $S_H2$ type radical displacement at the silicon atoms.[8] Thus, the photochemically

**Table 1** Photo-induced silylene-transfer reactions of cyclosilanes to PQ

[a] Based on the consumption of silanes.

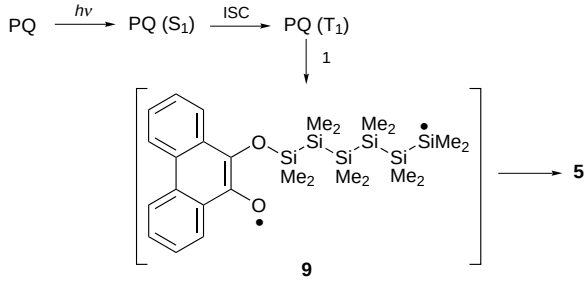

**Table 2** The free energy changes ($\Delta G$) for the electron-transfer from cyclosilanes to PQ

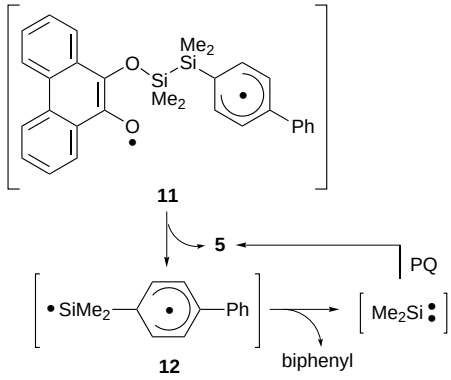
| | $E_{ox}$/V *vs.* SCE | $\Delta G$/kcal mol$^{-1}$ in MeCN | in $C_6H_6$ |
|---|---|---|---|
| **1** | +1.45 | −1.41 | +17.84 |
| **2** | +1.00 | −11.79 | +7.47 |
| **3** | +0.42 | −25.16 | −6.0 |
| **4** | +1.17 | −7.9 | +11.4 |



excited PQ attacks one of the silicon atoms of **1** to afford a biradical intermediate **9**. At the initial interaction, a partial or complete electron-transfer from **1** to the triplet PQ may take place in polar solvents as mentioned above. Subsequent intramolecular O–Si bond formation in **9** would provide **5** as illustrated in Scheme 1. The yields of **5** indicate that a molecule of **1** donates more than an equimolar amount of silylene units to PQ. We obtained polymeric products containing silane fragments in these reactions, which might have arisen from framentation of the starting materials. In addition, the photoreaction of **1** and PQ in the presence of $CCl_4$ gave $Cl(Me_2Si)_nCl$ ($n$ = 4–6), which would substantiate the present mechanism involving the silyl radical intermediates.[9]

There seemed to be three possible pathways leading to **6**: (i) intramolecular cyclization in **9** could afford **10**, which would be susceptible to atmospheric oxidation to give **6**, (ii) addition of free dimethylsilylene to **5** could give rise to **6** *via* **10**, and (iii) dimethylsilanone,[10] if formed in the course of reaction, could insert into **5** to produce **6**. However, the intermediate **10** was never detected in the photolysates while all trapping experiments for free dimethylsilylene and dimethylsilanone were not successful. When the reaction was carried out under an aerobic atmosphere, the yields of **6** increased while those of **5** decreased. The residual molecular oxygen plays an important role in the formation of **6**. Since **5** is stable in the air, it is suggested that molecular oxygen should be incorporated, probably as some radical species, to afford **6** during the photoreactions. Further investigations are in progress to clarify the mechanism.

Recently, it has been demonstrated that 7,8-disilabicyclo[2.2.2]octa-2,5-diene **3**, which is known as a disilene precursor,[10] also acts as a good electron donor.[11] Therefore, we anticipated that cophotolysis of **3** with PQ would produce selectively the corresponding disilanylene adduct **10**. Interestingly, the silylene adduct **5** was obtained along with **6** instead of **10**. Moreover, in contrast to the case of **1**, the intermediacy of free dimethylsilylene was evidenced by the formation of $Et_3SiMe_2SiH$ in the cophotolysis of **3** with PQ in the presence of $Et_3SiH$. Based on the mechanism proposed for **1**, the reaction of **3** is interpreted as shown in Scheme 2. The initially formed adduct **11** would collapse to afford **5**, **12**, free dimethylsilylene and biphenyl successivley. It should be noted that free dimethylsilylene could contribute to the formation of **5** and **6**. Compound **4** gave a similar result, although no trioxadisilepine **8** was obtained as the case of **2**.

**Scheme 1**

**Scheme 2**

In summary, we have indicated that silylene-transfer reactions take place between cyclic organosilanes **1**–**4** and the photochemically excited triplet PQ. The formation of free dimethylsilylene is noteworthy since there has been no precedent of generation of free silylenes induced by photoexcited carbonyl compounds as far as we know.

This work was supported in part by Grants-in-Aid from the Ministry of Education, Science, and Culture in Japan. We thank Toshiba Silicon Co. Ltd. for a gift of organosilicon reagents.

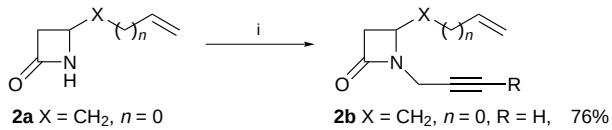
# Enyne metathesis for the facile synthesis of highly functionalised novel bicyclic β-lactams

**Anthony G. M. Barrett,*[a]† Simon P. D. Baugh,[a] D. Christopher Braddock,[a] Kevin Flack,[a] Vernon C. Gibson*[a]‡ and Panayiotis A. Procopiou[b]**

[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*
[b] *Department of Medicinal Chemistry, Glaxo Wellcome Research and Development Ltd, Gunnels Wood Road, Stevenage, Hertfordshire, UK SG1 2NY*

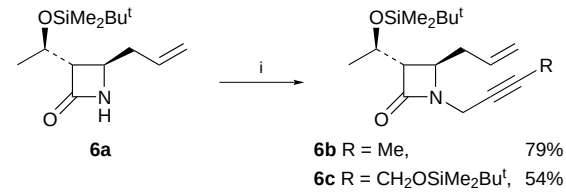
**A wide range of bicyclic β-lactam systems have been prepared *via* the enyne metathesis reaction using catalytic quantities of *trans*-$(Cy_3P)_2Cl_2Ru{=}CHPh$ (Cy = cyclohexyl).**



The elaboration of carbon skeletons *via* the construction of carbon–carbon bonds represents one of the most important endeavours in synthetic organic chemistry. The use of catalytic quantities of ruthenium[1] and molybdenum[2] carbenes as pioneered by Grubbs *et al.* for ring-closing metathesis (RCM)[3] is exemplary in this respect and is finding increasing use as the key synthetic step *en route* to polyfunctional natural products.[4] As a variant on RCM of dienes, Kinoshita and Mori have demonstrated the catalytic ability of ruthenium carbene **1** to generate conjugated dienes (with concomitant rearrangement of the carbon skeleton) from enynes.[5] Recently we have reported the use of ring-closing and cross metathesis for the preparation of novel monocyclic and bicyclic β-lactams in a synthetically fast and efficient manner.[6,7] The possibility of utilising enyne metathesis as a route into highly functionalised bicyclic β-lactams appeared attractive and herein we disclose our results in this arena.

**1**

Cy = cyclohexyl



A broad range of enyne substrates were synthesised by two general routes. The previously prepared 4-substituted lactams **2a**–**5a**[6–8] were treated with prop-2-ynyl bromides in the presence of potassium hydroxide and tetrabutylammonium bromide to give variously functionalised enyne substrates **2b**–**5b**, **2c** (Scheme 1).§ Chiral, non-racemic enynes **6b** and **6c** were produced in an analogous fashion (Scheme 2). The *N*-allylated azetidinones **9** and **10** were synthesised using a modified procedure of Basak and Khamrai[9] for the introduction of the prop-2-ynyl group followed by *N*-allylation in the usual manner (Scheme 3).

Attempts to bring about the cyclisation of the parent enyne **2b** were unsuccessful even with catalyst loadings of up to 10 mol% **1**: only starting material was recovered (Table 1, entry 1). However, the non-terminal enyne **2c** was found to undergo metathesis with as little as 1 mol% carbene **1**, albeit in 20% yield. Increasing amounts of catalyst gave increasing quantities of products and at 10 mol% catalyst **1** an 88% yield of **12** was obtained (Table 1, entry 2).¶ Under similar conditions enyne substrates **3b**–**6b**, **6c**, **9** and **10** furnished dienes **13**–**19** in similarly excellent yields (Table 1, entries 3–9). The range of

functionalities and steric bulk tolerated by this reaction, combined with the high yields obtainable for these cyclisations, make this a valuable addition to the procedures currently available for synthesising such complex β-lactam structures. Further applications of alkene and enyne metathesis will be reported in due course.

**Table 1** Enyne metathesis using ruthenium carbene **1**[a]

# (BEDT-TTF)($F_1$TCNQ) and (BEDT-TTF)($F_2$TCNQ)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5): all-organic metals down to 2 K

**T. Hasegawa,[a] K. Inukai,[a] S. Kagoshima,[a] T. Sugawara,[a] T. Mochida,[b] S. Sugiura[c] and Y. Iwasa[c]**

[a] *Department of Pure and Applied Sciences, The University of Tokyo, Komaba, Meguro, Tokyo 153, Japan*
[b] *Institute for Molecular Sciences, Myodaiji, Okazaki 444, Japan*
[c] *Japan Advanced Institute of Science and Technology, Tatsunokuchi, Ishikawa 923-12, Japan*

**Crystal structures and solid-state properties are reported for all-organic metals, (ET)(F1) and (ET)(F2)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5), which are isostructural with each other and preserve metallic states down to 2 K.**

Cation-radical salts derived from the organic donor, bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF or ET), have attracted considerable interest because of the rich variations of the crystal structures and the two-dimensionality of their electronic structures, affording various solid-state properties such as superconductivity,[1] fermiology,[2] *etc.* In contrast to most ET salts, represented as (ET)$_2$X (X = inorganic counter anion), investigated so far, the advantage of the title materials, which are ET-based donor–acceptor (DA) type charge-transfer (CT) complexes, is that the organic acceptor molecules can be designed by chemical modification to have variable electron affinity or molecular polarizability, which may enable control of the crystal structures and electronic properties.

TCNQ and its fluorinated derivatives, 2-fluorotetracyanoquinodimethane ($F_1$TCNQ, abbreviated F1) and 2,5-difluorotetracyanoquinodimethane ($F_2$TCNQ, F2), are chosen for this purpose. Among these CT complexes, the structure and properties of (ET)(TCNQ) have been investigated, and the strong electron–electron correlations are found to be responsible for its metal–insulator transition at *ca.* $T$ = 330 K.[3,4] To investigate the fluorine-substitution effect on (ET)(TCNQ), the following two types of single crystals for the DA complexes have been synthesized; the CT compounds (ET)($F_n$TCNQ) ($n$ = 0, 1, 2) and the ternary CT compounds (ET)($F_n$TCNQ)$_x$(TCNQ)$_{1-x}$ ($0 < x < 1$). It is noted that the electron affinity of $F_n$TCNQ can be controlled by the number ($n$), without changing the molecular volume significantly.[5]

$F_1$TCNQ and $F_2$TCNQ were synthesized using a new route reported by Uno *et al.*[6] Single crystals of (ET)($F_n$TCNQ) ($n$ = 0, 1, 2) were obtained by slow cooling of concentrated solutions of the salts in chlorobenzene or 1,1,2-trichloroethane. Among (ET)($F_n$TCNQ) ($n$ = 0, 1, 2), a low electrical resistivity was observed in (ET)(F1), of the order of $10^{-2}$ Ω cm at room temp. Conversely, the resistivity of a single crystal of (ET)(F2) is extremely high, *ca.* $10^5$ Ω cm. Such dependence of the resisitivty on $n$ is not directly associated with change of the electron affinity of $F_n$TCNQ,[7] but is attributed to the drastic variation of their crystal structures.

Fig. 1 shows the crystal structure of (ET)(F1)† from which it is seen that the donors and acceptors form sheets independently along the 010 plane. The ET molecules are stacked face-to-face along the *c*-axis, and arranged side-by-side along the [100] and the [101] directions [Fig. 1(*b*)]. The intermolecular S···S distance is found to be 3.48 Å between ETs aligned along [101] and 3.71 Å along [100], indicating the two-dimensional nature of the conducting sheet. Molecular packing of ETs is uniform in the sheets, which is in contrast to most other ET-based conductors. In (ET)(TCNQ), for example, ET molecules are dimerized in their two-dimensional donor sheets.[3]

The effect of fluorine substitution becomes more apparent in (ET)(F2)$_x$(TCNQ)$_{1-x}$ ($0 < x < 1$). The electrical resistivity of the compaction sample becomes lowest (*ca.* $10^{-2}$ Ω cm) at *x ca.* 0.5 being 50 times smaller than that of (ET)(TCNQ), and *ca.* $10^5$ times smaller than that of (ET)(F2), as seen in the inset of Fig. 3.

X-Ray powder diffraction patterns were measured to investigate the crystal structures of (ET)(F2)$_x$(TCNQ)$_{1-x}$. The samples used for the measurements were obtained by evaporating the solvent from the whole concentration solution, ensuring that the nominal ratio of the ingredients in solution is identical to the chemical composition of the sample.‡ The results are presented in Fig. 2 for (ET)(F2)$_x$(TCNQ)$_{1-x}$ **2′** at *x ca.* 0.5, together with those of (ET)(F2) **1**, (ET)(F1) **2** and (ET)(TCNQ) **3**. The structures of **1**, **2** and **3** are clearly different from each other. In the ternary system, on the other hand, the highest conductive compound, (ET)(F2)$_x$(TCNQ)$_{1-x}$ **2′** (*x ca.* 0.5), is considered to be isostructural with **2**.§ This means that the introduction of a fluorine into each TCNQ, on the average, commonly gives isostructural compounds. The diffractograms for the samples at *x ca.* 0.25 and 0.75 clearly show that they are composed of two phases, *e.g.* **1** + **2′**.

Fig. 3 shows the temperature dependence of the electrical resistivity of single crystals of (ET)(F1) and of the crystalline flake samples of (ET)(F2)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5), obtained by slow cooling of concentrated solutions. Metallic properties are preserved down to 2 K. $R$(room temp.)/$R$(4.2 K) is *ca.* 70 and 30 for (ET)(F1) and (ET)(F2)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5), respectively, providing unambiguous evidence for good metallic character down to 4.2 K.

Finally we speculate as to why the introduction of a fluorine into TCNQ commonly stabilizes the structure of a highly conducting phase. Although the orientation of $F_1$TCNQ is

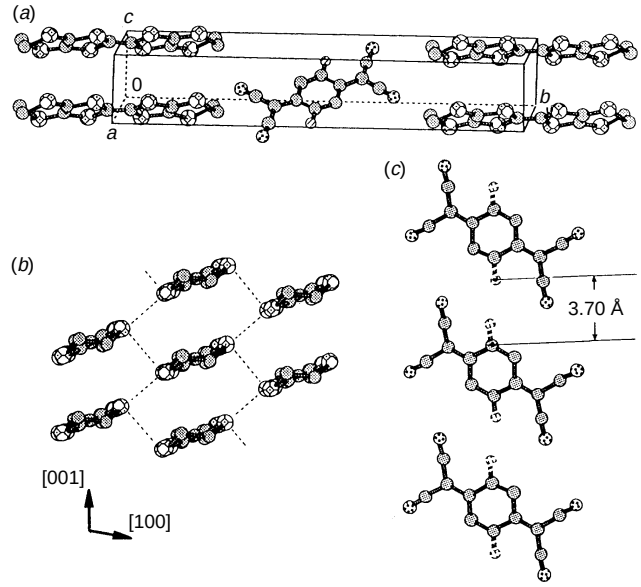

**Fig. 1** (*a*) Crystal structure of (ET)(F1); (*b*) view of molecular packing of ETs along the long molecular axis; (*c*) molecular arrangement of F1

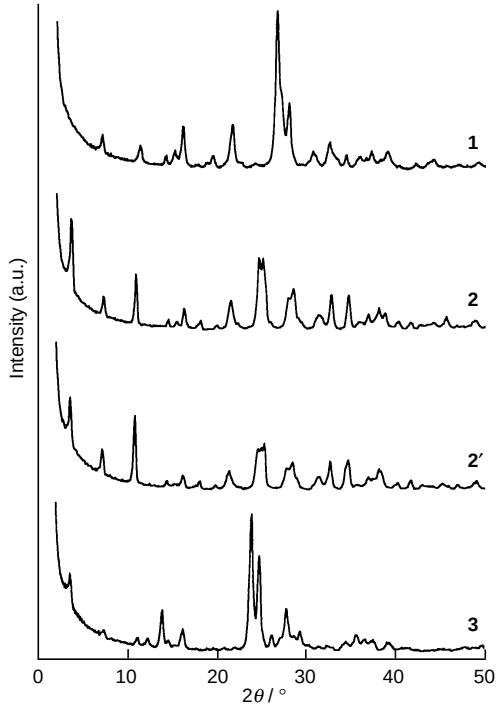

**Fig. 2** X-Ray powder diffraction pattern of (ET)(F2)$_x$(TCNQ)$_{1-x}$ **2′** (*x ca.* 0.5) in comparison with those of (ET)(F$_n$TCNQ) (*n* = 0, 1, 2). (ET)(F2) **1**, (ET)(F1) **2** and (ET)(TCNQ) **3**. The structure of (ET)(F2)$_x$(TCNQ)$_{1-x}$ **2′** (*x ca.* 0.5) is similar to that of (ET)(F1) **2**.

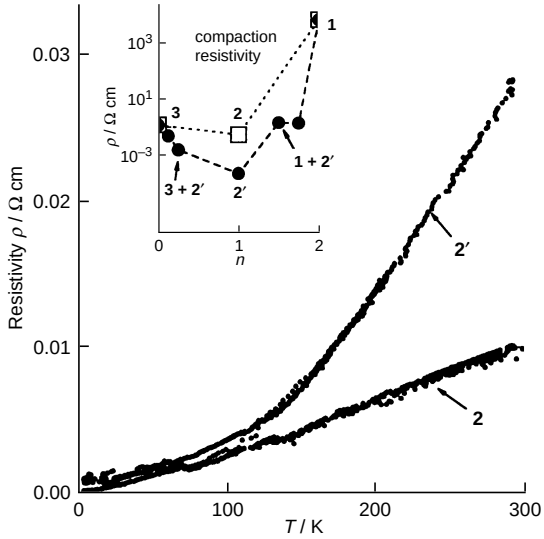

**Fig. 3** Temperature dependence of electrical resistivity for an (ET)(F1) single crystal and (ET)(F2)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5) crystalline flake sample. Inset shows compaction electrical resistivity *vs.* average number (*n*) of F atoms per TCNQ. Open squares are for (Et)(F$_n$TCNQ) (*n* = 0, 1, 2) and filled squares for (ET)(F2)$_x$(TCNQ)$_{1-x}$.

disordered in (ET)(F1), the intermolecular F···C distance of 3.70 Å [Fig. 1(*c*)], which is shorter than the sum of the van der Waals radii of the F···H–C arrangement,[8] strongly suggests the presence of a local structure represented as ···(TCNQ)F···(TCNQ)F···(TCNQ)F···, based on the hydrogen-bond-like interaction between CH and F. A similar local structure is also expected in (ET)(F2)$_x$(TCNQ)$_{1-x}$ to form a ···F(TCNQ)F···(TCNQ)···F(TCNQ)F···(TCNQ)··· arrangement, which accounts for the exclusive formation of the (ET)(F1) structure when one fluorine is introduced per TCNQ (at *x ca.* 0.5).

In summary, we obtained two kinds of ET-based all-organic metals, (ET)(F1) and (ET)(F2)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5), preserving metallic states down to 2 K. Between them, (ET)(F2)$_x$(TCNQ)$_{1-x}$ (*x ca.* 0.5) is an all-organic ternary metal and is isostructural with (ET)(F1), in both of which the specific hydrogen-bond-like interaction is suggested to stabilize the structures affording highly conductive compounds.

The authors are grateful to N. Itoh and A. Sasaki for their experimental assistance. This work is supported by a Grant-in-Aid for Scientific Research on Priority Area from the Ministry of Education, Science and Culture of Japan.

# Configurationally guided peptide conformational motifs: crystal structure of a $L^{\alpha}D^{\beta}L^{\beta}D^{\alpha}D^{\beta}L^{\alpha}$ type hexapeptide fold

**F. Fabiola,[a] V. Pattabhi,[a] S. Rawale,[b] E. B. Raju[b] and S. Durani*[b]**

**A new concept in macromolecular design is described, using sequence configuration as the tool to control the topology of a compact polymer chain fold.**

Residue configuration as a sequence variable provides a promising tool for the design of novel peptide conformational motifs. Illustrating the concept, we describe here a configurationally guided $L^{\alpha}D^{\beta}L^{\beta}D^{\alpha}D^{\beta}L^{\alpha}$ type peptide conformational motif. Residue preferences in the Ramachandran diagram[1] remain fundamental to the stereochemical outcome of peptide chain folding. Genetically encodable poly-L-configurational peptides are required in forming the familiar α-helix and β-sheet motifs,[2] because every residue needs to occur in the same left half of the Ramachandran diagram. The alternating L,D-configurational gramicidin A forms β-helical channel or β-double helical pore motifs,[3,4] while the alternating L,D-configurational cyclic peptides of Ghadiri and co-workers are self-organizing nanotubular structures,[5] because consecutive residues occur in the opposite halves of the Ramachandran diagram [see Fig. 1(*a*)]. The type II and type II' β-hairpins, being $L^{\beta}L^{\beta}D^{\alpha}L^{\beta}$ and $L^{\beta}D^{\beta}L^{\alpha}L^{\beta}$ type motifs based on the positional preferences for L- or D-configurational residues and their conformational states,[6] are most reliably approached by using sequence configuration as the design strategy.[7–9] Control of peptide chain folding *via* sequence configuration is thus a promising tool to achieve the design of unnatural peptide conformational motifs.

The L- and D-configurational residues in the hexapeptide Boc-L-Leu[1]-D-Val[2]-L-Pro[3]-D-Asp[4](OMe)-D-Val[5]-L-Leu[6]-NHMe† are noted to occur in the preferred halves of the Ramachandran diagram [Fig. 1(*b*)]. The configurational sequence LDLDDL combines with the conformational sequence αββαβα to produce the $L^{\alpha}D^{\beta}L^{\beta}D^{\alpha}D^{\beta}L^{\alpha}$ type motif, which has a compact backbone fold and a specific pattern of interpeptide hydrogen bonds‡ (Fig. 2). In its architectural plan, the motif may either be recognized as a consecutive type II-II' β-turn anchoring an unusual $L^{\alpha}D^{\beta}$ type dipeptide fold, or as a type II' β-hairpin with D configurational arms bracketed by L configurational residues in α type conformational states. An almost ideal type II' β-turn has Val[5]-Leu[6] as its corner residues ($\phi$ = 72, $\psi$ = −117° for D-Val[5] against the ideal values 60 and −120°, and −81 and −14° for L-Leu[6] against the ideal values −90 and 0°) and the $i + 3 \rightarrow i$ type hydrogen bond between the methylamide NH and the Asp[4] CO. An almost ideal type II β-turn has Pro[3]-Asp[4] as its corner residues ($\phi$ = −64, $\psi$ = 129° for L-Pro[3] against the required −60 and 120 , and 72 and 19° for D-Asp[4] against the requirement 90 and 0°) and the $i + 3 \rightarrow i$ type hydrogen bond between the Val[2] CO and the Val[5] NH. The D-configurational valines in the first and fourth position of this β-turn element are in the β region of the right half of the Ramachandran diagram ($\phi$ = 126, $\psi$ = −92° for Val[2] and 72 and −117° for Val[5]) and with an additional hydrogen bond between the Val[2] NH and the Val[5] CO. The segment Val-Pro-Asp(OMe)-Val is thus a $D^{\beta}L^{\beta}D^{\alpha}D^{\beta}$ type β-hairpin, being an enantiomer of the naturally occurring $L^{\beta}D^{\beta}L^{\alpha}L^{\beta}$ type hairpin with a type II' β-turn and L-configurational arms and a diastereoisomer of another naturally occurring but stereochemically less preferred $L^{\beta}L^{\beta}D^{\alpha}L^{\beta}$ type hairpin with a type II β-turn and L-configurational arms.[10] Leu[1] at the N-terminal end has α-helical type torsional angles ($\phi$ = −66, $\psi$ = −45° against the ideal values −57 and −48°) and has its NH hydrogen bonded to the Val[5] CO, which also participates in a bifurcated hydrogen bond with the Val[2] NH.

The Val[2] and Val[5] side chains are in a stack-like arrangement, while the Leu[6] side chain and Boc group are in a parallel arrangement, together describing a molecular cleft which accommodates the side chain of an Asp[4](OMe) from another molecule, providing for intermolecular packing. The masking of the Asp carboxylate and consequent suppression of its

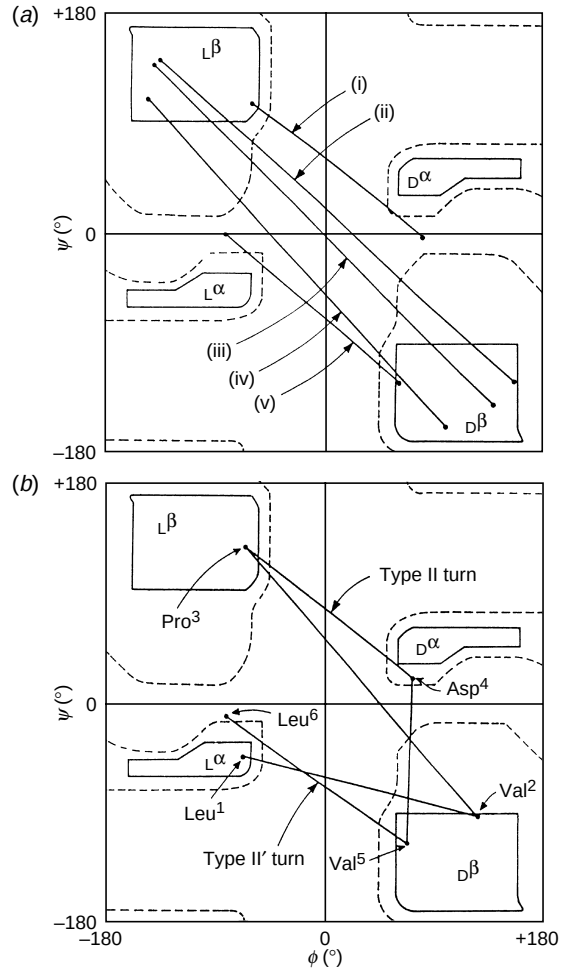

**Fig. 1** The regions in the Ramachandran diagram favoured for L- and D-configurational residues. (*a*) The requirement of $\phi$ and $\psi$ angles for (i) type II β-turn, (ii) gramicidin β-double helical pore, (iii) Ghadiri's octapeptide nanotubular structure, (iv) gramicidin β-helical channel and (v) type II' β-turn. (*b*) The $\phi$ and $\psi$ angles in the hexapeptide Boc-L-Leu-D-Val-L-Pro-D-Asp(OMe)-D-Val-L-Leu-NHMe.

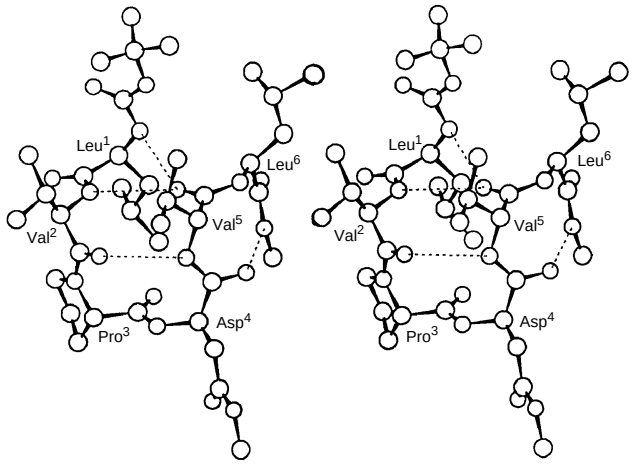

**Fig. 2** Stereodiagram of the molecular structure of the hexapeptide Boc-L-Leu-D-Val-L-Pro-D-Asp(OMe)-D-Val-L-Leu-NHMe

tendency to hydrogen bond with a main chain NH is apparently a factor in the extended conformation of the Asp side chain and in its participation in this specific intermolecular packing arrangement. Intermolecular packing also features hydrogen bonds involving the Leu[6] NH and the CO group of Boc moiety from one molecule and, respectively, the Leu[1] CO and Asp[4] NH groups from two different molecules.

A most remarkable feature of the $L^{\alpha}D^{\beta}L^{\beta}D^{\alpha}D^{\beta}L^{\alpha}$ type motif is that its α-helix-favouring leucines occur in the $\alpha$ conformational region and its β-sheet-favouring valines occur in the β conformational region, while its turn-favouring Pro and Asp moieties occur in a β-turn element.[11] Thus the effects of structural origin, manifested in protein folding, are possibly operative over and above the effects of configurational origin, and will require consideration as part of the overall design strategy for the approach to other possible configurationally-guided peptide conformational motifs.

The project funding was from Department of Science and Technology, and Department of Atomic Energy, Government of India.

† The peptide synthesis was by solution phase methodology, the purification was by RP-HPLC on a C-18 column eluting with water–MeOH, and characterization was by NMR and mass spectrometry.

‡ Colourless rectangular crystals (0.75 × 0.15 × 0.2 mm) obtained from aq. MeOH were used for intensity data collection on an Enarf-Nonius CAD4 diffractometer with Cu-Kα ($\lambda$ = 1.5418 Å) radiation. The crystals were monoclinic, space group $P2_1$, with cell parameters $a$ = 10.059(1), $b$ = 18.864(2), $c$ = 12.586(1) Å; $\beta$ = 91.62(5)°, $V$ = 2383.9 Å, $Z$ = 2, and diffracted up to 63°. The structure was solved using SHELXS-86 (ref. 12) and refined using SHELXS-93 (ref. 13). Hydrogens were refined as riding over the heavier atoms. The final $R$-factor was 0.046 ($wR$ = 0.1254) for 3415 observed reflections with $F_o \geqslant 4\sigma(F_o)$. CCDC 182/504.

# Stepwise synthesis of tetrasubstituted hydrazines

**Leif Grehn,[a] Hans Lönn[b] and Ulf Ragnarsson*[a]**

[a] *Department of Biochemistry, University of Uppsala, Biomedical Center, Box 576, S-751 23 Uppsala, Sweden*

**A new triprotected hydrazine reagent has been made and applied in alkylation/acylation reactions for stepwise synthesis of tetrasubstituted derivatives in high purity and yield.**

In continuation of our efforts aiming at the simple synthesis of substituted hydrazines by a repetitive method,[1] we now present a first, easily made hydrazine derivative **3** with three *orthogonal* protecting groups. This reagent and products thereof allow alkylation and acylation and intermediate selective removal of protecting groups to take place under mild conditions and essentially quantitatively in all individual steps. Although, so far, our major efforts have been directed towards optimizing the overall reaction scheme with respect to the yield and purity of the intermediates **5**–**8** and products **10**, it is evident that this procedure affords simultaneously a high degree of molecular diversity.

**Scheme 1** *Reagents and conditions*: i, CbsCl, pyridine, 94%; ii, $Boc_2O$, DMAP, MeCN, 93%

The starting material for the key reagent **3** is Z-substituted hydrazine **1**, liberated from the corresponding hydrochloride.[2] Using commercially available 4-cyanobenzenesulfonyl (Cbs) chloride,[3] this is easily converted to **2** with two amide functions of obviously different acidity (Scheme 1),[4] which therefore allows regioselective reaction with $Boc_2O$ in the presence of DMAP at the sulfonamide nitrogen[5] to give the triprotected

**Scheme 2** *Reagents and conditions*: i, $R^1OH$, $PPh_3$, DEAD, THF, 80–99%; ii, Al(Hg), $CO_2$, aq. $Et_2O$, 92–99%; iii, $R^2X$ (X = Br or I), $K_2CO_3$–NaOH, $Bu_4NHSO_4$, $C_6H_6$, 92–100% or 2,4-$(O_2N)_2C_6H_3F$, $K_2CO_3$, $Bu_4NHSO_4$, MeCN, 85–97%; iv, TFA, $CH_2Cl_2$, 93–99%; v, $R^3Cl$, pyridine, 86–99%; vi, TFA (reflux); vii, $R^4{}_2O$ or 4-$FC_6H_4SO_2Cl$ (reflux), 72–98%

[a] From **8a**. [b] From **8b**. [c] From **8d**.

derivative **3** with three different protecting groups. The overall yield of **3** from **1** is 87%.†

Compound **3** easily undergoes the Mitsunobu reaction with alcohols,[6] thereby giving rise to triprotected monosubstituted hydrazines **4** (Scheme 2). From compounds of this type the Cbs group can be cleaved reductively with Hg-activated aluminium to provide crystalline intermediates **5**, which are alkylated as previously described[1] under phase transfer conditions to give 1,2-diprotected 1,2-disubstituted hydrazine intermediates **6**. These differ from those described earlier in one important respect, namely, that their Boc and Z groups can be removed selectively in optional order. So far, we prefer to remove the Boc group first under mild acidic conditions *via* compounds **7** and subsequently acylate the latter to **8**. Finally, these can be deprotected under stronger acidic or catalytic hydrogenolysis conditions to give substances **9**, although we normally prefer to acylate them without isolation directly to the final products **10**.

A relatively large number of compounds **4**–**10** have been prepared to investigate and exemplify this scheme, all of which are listed in Table 1. No indication whatsoever of incomplete selectivity in the removal of the protecting groups in intermediates **4** and **6** has been detected. Alkylations and acylations of **5**, **7** and **9** were performed as described previously.[1] As can be seen from the table, all steps proceed very satisfactorily and few intermediates are obtained in less than 90% yield.

Mono- and di-alkylated hydrazines are extensively used as precursors in the synthesis of heterocycles.[7] Recently, Han and Janda also applied this methodology in their synthesis of α-aza amino acids.[8] Highly substituted hydrazines have found a number of practical applications.[9]

Although not demonstrated experimentally here, several other reactions of the amino group in addition to alkylation and acylation can be envisaged to be useful in this context, but we have confined ourselves to exemplify a few additional functional groups which can be introduced easily using the present conditions. Considering the large number of alkylating and acylating agents available, it seems reasonable to assume that the new reagent can be used for construction of chemical libraries. Further modification of functional groups present in compounds such as **10** could additionally increase the potential for molecular diversity inherent in these, at first glance, simple compounds.

We thank the Swedish Natural Science Research Council, the National Board for Industrial and Technical Development and Astra Draco AB for generous financial support.

# The photogeneration of aryltropylium ions: a potential photo-switch for supramolecular assemblies based on donor–acceptor interaction

**Uwe Pischel,[a] Werner Abraham,*[a] Wolfram Schnabel[b] and Uwe Müller[c]**

[a] *Humboldt-University, Institute of Chemistry, Hessische Str. 1-2, D-10115 Berlin, Germany*

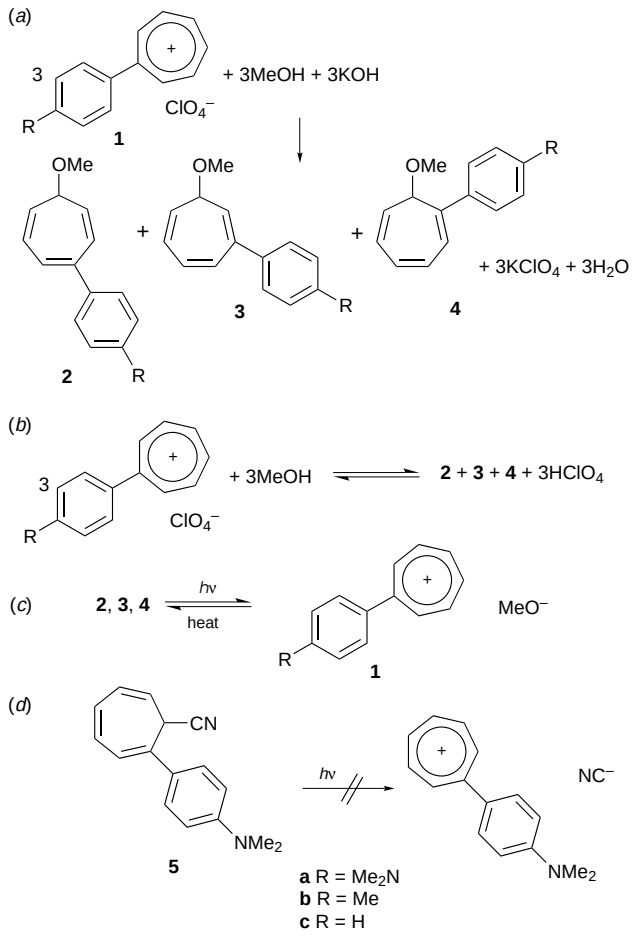
[c] *Martin-Luther-University Halle, Institute of Organic Chemistry, Geusaer Str., D-06217 Merseburg, Germany*

**The photogeneration of aryltropylium cations with lifetimes strongly depending on the donor capacity of the aryl substituent has been achieved by photolysing the corresponding 7-methoxycycloheptatrienes 2, 3 and 4.**

Switchable supramolecular assemblies such as rotaxanes[1] and catenanes[2] comprise a fascinating challenge in the field of supramolecular chemistry.[3] We are designing macrocycles[4] and rotaxanes with arylcycloheptatriene building blocks which can easily be transformed to tropylium ions by thermal hydride transfer.[5] In contrast to cycloheptatyrienes, tropylium ions are strong electron-acceptors which can be used to recognize donor partners within rotaxanes or catenanes.



Here we report on the generation of tropylium ions by photochemical heterolytic cleavage of the C–O bond in cycloheptatriene derivatives **2**, **3** and **4**. Provided the cycloheptatriene is regenerated by the fast nucleophilic attack of the methoxy ion or methanol (see Scheme 1), the acceptor can be switched 'on' and 'off' by a photochemical and a thermal step, respectively.

So far the only known example is the dibenzosuberenyl cation, which can be obtained by laser flash photolysis of the parent alcohol in trifluoroethanol.[6] Our design of precursors of tropylium cations is based on cycloheptatriene derivatives containing effective leaving groups and substituents capable of stabilizing tropylium ions. Halides and azide are inappropriate leaving groups because cycloheptatriene derivatives containing these groups are converted into tropylium ions upon dissolution in polar solvents.[7] In the present work CN and MeO were chosen as leaving groups and aryl groups as stabilizing substituents. 7-Methoxy-*x*-aryl cycloheptatrienes ($x$ = 1, 2, 3) were prepared by the reaction of the corresponding aryltropylium ions with a base in methanol solution. Typically, the reaction of 4-dimethylaminophenyltropylium perchlorate **1a** with KOH results in the formation 3-(4-dimethylaminophenyl)-7-methoxycyclohepta-1,3,5-triene **2a** and the isomers **3a** and **4a** in the ratio **2a**:**3a**:**4a** = 1:1:0.7. Compound **2a** was isolated from the isomeric mixture, obtained by reaction of **1a**, by recrystallization from hexane at low temperature.

Three experiments were performed to study the photogeneration of aryltropylium ions with the aid of a ruby laser (Korad Model K1 QS2, $\lambda$ = 347 nm, flash duration 20 ns) or a flashed xenon lamp (band filter 1602 and 810, Jenaer Glaswerk Schott & Gen., nominal wavelength $\lambda_{ex}$ = 340–380 nm, flash duration 15 μs): (i) Compounds **2a** or **5** were irradiated in MeCN or MeOH solution. (ii) The mixture of isomers (**2**, **3** and **4**) obtained by the reaction of **1** with KOH in MeOH according to reaction (*a*) in Scheme 1 was irradiated *in situ*. (iii) A dilute solution of **1a** in MeOH ($2 \times 10^{-5}$ mol $l^{-1}$) was irradiated in the absence of a base. Under these conditions the equilibrium (*b*) in Scheme 1 is shifted almost completely to the right side, *i.e.* the solution contains the isomers **2a**, **3a** and **4a** apart from a very small amount of the tropylium ion.

Notably, apart from **5** all other cycloheptatriene derivatives yielded the tropylium ion upon UV irradiation. Obviously, CN is not as effective a leaving group as the methoxy group.

In the case of **2a** [experiment (i)] the photogeneration of **1a** according to reaction (*c*) in Scheme 1 was evidenced by the formation of the characteristic optical absorption of the tropylium ion ($\lambda_{max}$ = 570 nm) during the flash (see Fig. 1). Simultaneously with the transient absorption a photocurrent was formed indicating the generation of ionic species (**1a** and $MeO^-$). The quantum yield $\Phi$(ion) = 0.1 for the generation of **1a** in MeOH solution was determined† with the aid of the extinction coefficient of **1a** $\varepsilon_{567} = 4.7 \times 10^4$ l mol$^{-1}$ cm$^{-1}$. The transient absorption at $\lambda_{max} \approx 570$ nm increased linearly with the absorbed dose per flash, indicating that the heterolytic bond cleavage in **2a** is not due to a biphotonic effect but results from a one photon excitation. Noticeably, at constant absorbed dose, the transient absorption at $\lambda_{max} \approx 570$ nm is much weaker in MeCN than in MeOH indicating different ion yields in the two solvents. In this connection it is interesting to note that other carbenium ions were also found to be generated with higher yields in MeOH than in MeCN solution.[8]

**Scheme 1**

Irradiation of the isomers **2a**, **3a** and **4a** *in situ* [experiment (ii)] also resulted in the formation of the transient absorption spectrum of **1a**.

The tropylium ion generated as described above turned out to be unusually long-lived. Compound **1a**, generated by photoexcitation of **2a** in MeOH solution [experiment (i)] disappeared according to second order kinetics: $k_2 = 2 \times 10^6$ mol$^{-1}$ s$^{-1}$, corresponding to a first half-life of 0.3 s at [**1a**] = $1.7 \times 10^{-6}$ mol l$^{-1}$. Obviously, the rate of decay of **1a** is determined by the neutralization reaction, **1a** + MeO$^-$ in this case. In the case of experiment (iii) the disappearance followed exactly first order kinetics with a pseudo-first order rate constant: $k_1 = 0.3$ s$^{-1}$. In this case the rate of disappearance is determined by the reaction of **1a** with MeOH because methoxy anions produced in the primary photolytic act are scavenged by protons [see reaction (*b*) in Scheme 1]. With aid of $k_1 = 0.3$ s$^{-1}$, the bimolecular rate constant $k_2 = k_1$/[MeOH] = $1.2 \times 10^{-2}$ l mol$^{-1}$ s$^{-1}$ is obtained for the reaction **1a** + MeOH.

Compounds with substitutents **b** and **c** on the aryl group were examined *via* experiment (ii), *i.e.* **1b** and **1c** were converted into the corresponding isomer mixtures **2b**, **3b**, **4b** and **2c**, **3c**, **4c**, respectively, by reaction with KOH (1 equiv.) in MeOH, and the reaction mixtures were irradiated. The transient absorption spectra recorded in these cases posses maxima at the positions expected[5] for the tropylium ions **1b** and **1c** ($\lambda$ = 370 and 395 nm, respectively). The first-order lifetimes are definitely shorter than in the case of **1a**: $\tau$ = 270 μs (**1b**) and 190 μs (**1c**). The large differences in the lifetimes of **1a**, **1b** and **1c** are explained in terms of an increased stability of the tropylium ion with increasing electron-donor power of the substituent at the aryl group. This assumption is substantiated by the reduction potentials measured *vs.* SCE: −0.40 (**1a**), −0.19 (**1b**) and −0.17 V (**1c**).[9]

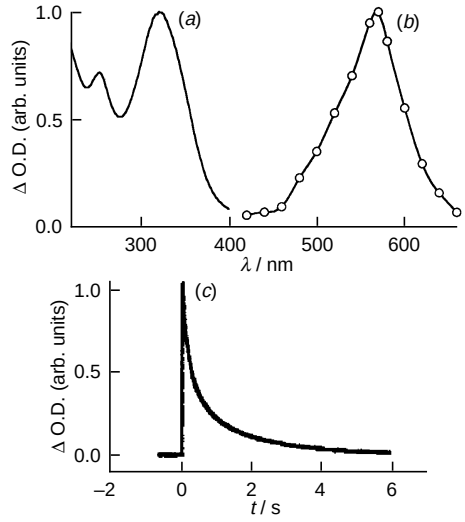


**Fig. 1** (*a*) Optical absorption spectrum of **2a** in MeOH; (*b*) transient absorption spectrum recorded 250 ms after irradiation of **2a** in MeOH with a 15 μs flash ($\lambda_{ex}$ = 340–380 nm); (*c*) decay of the transient absorption at 570 nm

In conclusion, the quantum yield of ion generation is large enough and the lifetime of photogenerated tropylium ions is long enough to allow intramolecular rearrangements in rotaxanes or catenanes containing arylcycloheptatriene building blocks. Concerning the applicability of such systems as photoswitches, system-optimizing appears necessary with respect to long-term performance. Regarding compound **2a**, the switch cycle can be repeated several times. However, irradiation of **2a** with 10 laser flashes ($5.7 \times 10^{-5}$ E l$^{-1}$ flash$^{-1}$, flash duration 20 ns) reduces the intensity of the transient optical absorption due to **1a** by a factor of 2.

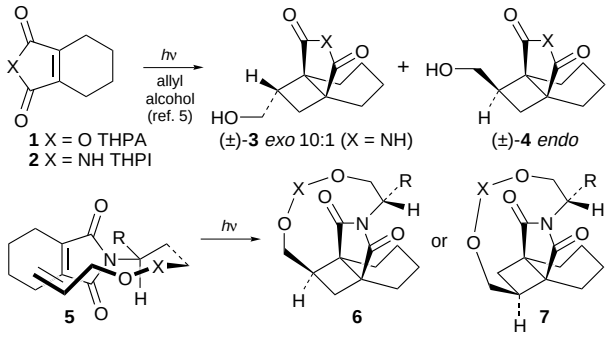
# Diastereoselective intramolecular photochemical [2 + 2] cycloaddition reactions of tethered L-(+)-valinol derived tetrahydrophthalimides

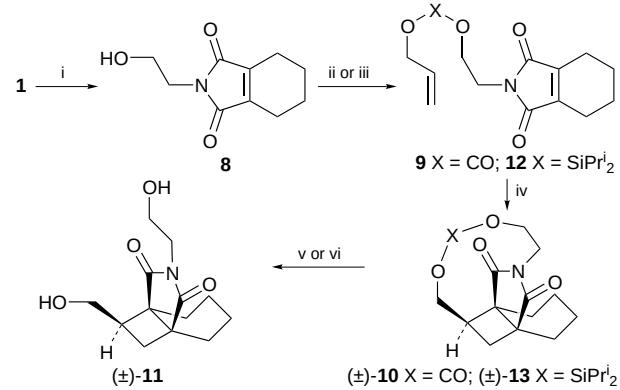
**Kevin I. Booker-Milburn,* Sirin Gulten and Andrew Sharpe**



*School of Chemical Sciences, University of East Anglia, Norwich, Norfolk, England, UK NR4 7TJ*

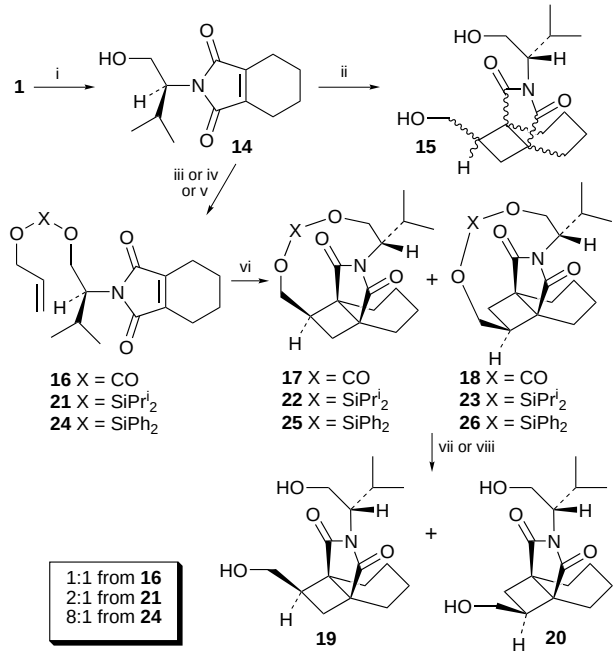
**Intramolecular photochemical [2 + 2] cycloaddition of allyl alcohol linked to amino acid derived 3,4,5,6-tetrahydrophthalimides, either *via* a carbonate or silicon tether, gives the corresponding cyclobutanes in excellent yield with diastereoselectivities as high as 8 : 1.**

Asymmetric [2 + 2] photocycloaddition using chiral auxiliaries and chiral additives is far less developed than other areas of asymmetric synthesis. Although a number of systems have been studied,[1] there exist very few methods for the preparation of enantiomerically pure cyclobutanes compared to the corresponding thermal [4 + 2] and [3 + 2] cycloaddition reactions. Both Fleming[2] and Crimmins[3] have reported the use of silicon tethers in controlling regio- and stereo-selectivity in [2 + 2] photocycloadditions. Very recently Piva and Pete[4] reported some promising results using chiral hydroxy acids as spacers for controlling asymmetric intramolecular [2 + 2] photocycloadditions. We now disclose our own results in this area involving the diastereoselective intramolecular [2 + 2] cycloaddition reactions of alkenols tethered to L-(+)-valinol derived tetrahydrophthalimides.



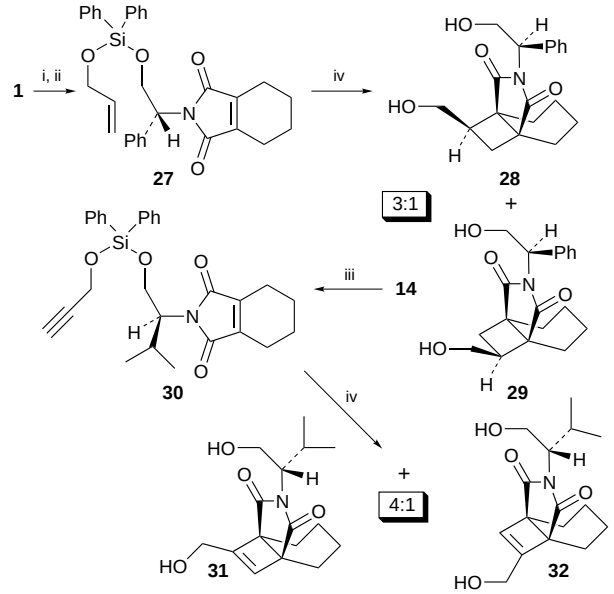
We recently reported[5] that 3,4,5,6-tetrahydrophthalic anhydride (THPA, **1**) and the corresponding imide (THPI, **2**) underwent efficient intermolecular photocycloaddition with alkenols to give the corresponding cyclobutanes in excellent yields with diastereoselectivities as high as 10 : 1. The major isomer in all cases was the *exo* isomer **3** which, due to the absence of any absolute stereochemical control, was formed as a racemic mixture (only one enantiomer drawn for clarity). We then elected to study the cycloaddition reactions of alkenols linked to THPI derivatives in order to achieve two goals: (i) the selective formation of the *endo* isomer **4** and (ii) by the use of chiral linkers, control the absolute stereochemistry of **4**. If the cycloadducts **6** or **7** could be formed selectively from **5** then cleavage of the tether (X) would lead to the synthesis of enantiopure *endo* cycloadducts (Scheme 1).

Initially we investigated the use of ethanolamine as a linker and found that heating THPA with ethanolamine in toluene gave the tetrahydrophthalimide derivative **8** in 96% yield. Reaction of **8** with allyl chloroformate gave the carbonate tethered tetrahydrophthalimide **9** in good yield (84%). Irradiation† of **9** in MeCN for just 90 min resulted in the exclusive formation of the (±)-*endo* cycloadduct **10** in excellent yield (95%, only one enantiomer drawn for clarity). Hydrolysis to the diol **11**, followed by NOE studies, confirmed the highly selective *endo* mode of cycloaddition obtained by use of a carbonate tether. Synthesis of the silicon tethered[2] variant **12** (X = $SiPr^i_2$) was achieved by treatment of **8** with 2 equiv. of $Cl_2SiPr^i_2$ followed by an excess of allyl alcohol (53% overall). Irradiation of **12** again gave the (±)-*endo* cycloadduct **13** as the sole product in 74% yield. Treatment of **13** with $Bu_4NF$ yielded the diol **11** in excellent yield (82%) (Scheme 2).



**Scheme 1**

With the *exo*/*endo* selectivity problem solved we then turned our attention to the use of tethered chiral ethanolamines to control the diastereoselectivity of the *endo* selective cycloadditions and ultimately the enantioselectivity upon removal of the chiral ethanolamine. Treatment of **1** with L-(+)-valinol gave the tetrahydrophthalimide **14** in excellent yield (95%). Irradiation of **14** with allyl alcohol gave rise to a complex mixture (75%) of four cycloadducts which by NMR spectroscopy appeared to be the various possible *exo* and *endo* diastereoisomers of **15**. This was not too surprising as it would be expected that there would be little stereochemical control exerted by the valinol unit during an intermolecular photocycloaddition. Reaction of **14** with allyl chloroformate as before gave the carbonate **16** in moderate yield (61%). Irradiation of **16** gave two cycloadducts (**17** and **18**) which upon hydrolysis (74%) were shown by $^1$H NMR spectroscopy to be an inseparable 1 : 1 mixture‡ of the diastereomeric diols **19** and **20**. Although this result was disappointing in terms of asymmetric induction, the overall yield in the photocycloaddition step was high (90%) and the irradiation times were short (60 min), thus indicating that the basic photocycloaddition was not hampered by the introduction of a chiral centre in the linker. Synthesis of the $SiPr^i_2$ tethered variant was carried out as before to give **21** in 71% yield. Irradiation (90 min) of **21** gave a mixture of the cycloadducts **22** and **23** (74%) which, upon treatment with $Bu_4NF$, gave the diols **19** and **20** as an inseparable mixture of diastereoisomers (87%) in a ratio of 2 : 1 although it was not possible to assign which was the major isomer. Encouraged by these results we decided



**Scheme 2** *Reagents and conditions*: i, ethanolamine, toluene, heat, 96%; ii, allyl chloroformate, pyridine, THF, 0 °C, 84% for **9**; iii, $Cl_2SiPr^i_2$ (2 equiv.), $Et_3N$, $CH_2Cl_2$, then allyl alcohol (4 equiv.), 53% for **12**; iv, *h*ν, MeCN, 95% for **10**, 74% for **13**; v, KOH (1.2 equiv.), EtOH–$H_2O$ (1 : 1), 64% from **10**; vi, $Bu_4NF$, THF, 82% from **13**

to try and increase the diastereoselectivity of the cycloaddition by changing the nature of the groups on silicon. Thus treatment of **14** with $Cl_2SiPh_2$ in DMF followed by treatment with an excess of allyl alcohol gave the $SiPh_2$ tethered variant **24** in 60% overall yield. Irradiation (60 min) of **24** gave an excellent yield (82%) of the two cycloadducts **25** and **26** which, upon treatment with $Bu_4NF$, gave the diastereomeric diols **19** and **20** in 97% yield and in a very pleasing ratio of 8 : 1. Again it was not possible to assign which was the major diastereoisomer, although it was the same as that obtained with the diisopropyl tether (Scheme 3).

**Scheme 3** *Reagents and conditions*: i, L-(+)-valinol, toluene, heat, 95%; ii, *h*ν, allyl alcohol, MeCN, 6 h, 75%; iii, allyl chloroformate, pyridine, THF, 3 h, 0 °C, 61% for **16**; iv, $Cl_2SiPr^i_2$, $Et_3N$, $CH_2Cl_2$, then allyl alcohol (4 equiv.), 71% for **21**; v, $Cl_2SiPh_2$ (2 equiv.), $Et_3N$, DMF, then allyl alcohol (4 equiv.), 60% for **24**; vi, *h*ν, MeCN, 60–90 min, 90% for **17**/**18**, 74% for **22**/**23**, 82% for **25**/**26**; vii, KOH (1.2 equiv.), EtOH–$H_2O$ (1 : 1), 74% from **17**/**18**; viii, $Bu_4NF$, THF, 87% from **22**/**23**, 97% from **25**/**26**

**Scheme 4** *Reagents and conditions*: i, (*R*)-(−)-2-phenylglycinol, toluene, heat, 97%; ii, $Cl_2SiPh_2$ (2 equiv.), $Et_3N$, MeCN, then allyl alcohol (4 equiv.), 46%; iii, $Cl_2SiPh_2$ (2 equiv.), $Et_3N$, MeCN, then prop-2-yn-1-ol (4 equiv.), 58%; iv, *h*ν, MeCN, 5–6 h, then $Bu_4NF$, THF, 83% overall for **28**/**29** and 38% overall for **31**/**32**

In order to study the effects of other chiral ethanolamines, **1** was treated with (*R*)-(−)-2-phenylglycinol to give the corresponding tetrahydrophthalimide (97%). Treatment of this with $Cl_2SiPh_2$ in DMF followed by an excess of allyl alcohol gave the $SiPh_2$ tethered phthalimide **27** in 46% overall yield. Irradiation gave a high yield of cycloaddition products (89%) which, upon cleavage with $Bu_4NF$ (93%), afforded the diastereoisomeric diols **28** and **29** in a ratio of 3 : 1. This clearly demonstrates that the valinol unit is superior to phenylglycinol in controlling diastereoselectivity during photocycloaddition. Finally, treatment of the valinol derivative **14** with $Cl_2SiPh_2$ followed by treatment with an excess of prop-2-ynyl alcohol gave the $SiPh_2$ tethered alkynol variant **30** in moderate overall yield (58%). Irradiation of **30** gave a 46% yield of the corresponding cyclobutenes which, upon desilylation with $Bu_4NF$ (81%), gave the diastereoisomeric diols **31** and **32** in a ratio of 4 : 1. Although the ratio was not as good as in the allyl alcohol case (**24**) this is, to the best of our knowledge, the first example of this type of diastereoselective cyclobutene formation (Scheme 4).

In summary, L-(+)-valinol derived tetrahydrophthalimides containing silicon tethered alkenol and alkynol units have been shown to undergo efficient, diastereoselective intramolecular [2 + 2] photocycloadditions. Present studies are concerned with the assignment of the absolute configuration of the major diastereoisomer from these cycloadditions in order gain some information about the transition state, and hopefully increase the diastereoselectivity by investigating different reaction conditions. We are also investigating the efficient hydrolytic removal of the valinol linker so that ultimately it can be used as a true chiral auxiliary in the enantioselective, photochemical synthesis of highly substituted cyclo-butanes and -butenes.

We would like to thank the Canakkale Onsekiz Mart University, Turkey (S. G.) and the EPSRC (GR/K15985) (A. S.) for financial support of this work.

† Glassware consisted of a standard, water cooled, pyrex immersion well photochemical apparatus of 100 ml reaction volume. All reactions were carried out in dry, degassed MeCN (100 ml) with concentrations of between 0.01–0.036 M in substrate. Irradiations were performed using a 125 W medium-pressure mercury vapour lamp obtained from Osram HQL (MBF-U) bulbs. All new compounds were fully characterised by IR, $^1$H NMR and $^{13}$C NMR spectroscopy, and either elemental analysis or HRMS.

‡ The diastereoisomeric ratio was readily ascertained by $^1$H NMR spectroscopy from comparison of the integrals of the two pairs of diastereotopic Me groups present in the various mixtures of **19** and **20**.

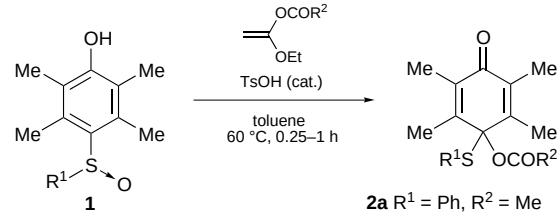
# A novel efficient sulfenylation method using quinone mono-*O,S*-acetals under mild conditions

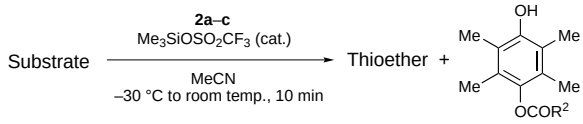


**Masato Matsugi, Kentoku Gotanda, Kenji Murata and Yasuyuki Kita***

*Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-oka, Suita, Osaka 565, Japan*

**A novel method for sulfenylation induced by aromatization of quinone mono-*O,S*-acetals is described.**

It is important to introduce sulfur effectively into organic compounds, as many biologically active compounds contain sulfur functions.[1] Although many methods for sulfenylation have been reported to date,[2] a mild sulfenylation reaction under neutral conditions is not readily available. Under these circumstances, we report here a novel sulfenylation reaction using quinone mono-*O,S*-acetals which gives high yields under almost neutral conditions.



We have already reported that various quinone mono-*O,S*-acetals **2**, which are intermediates in aromatic Pummerer rearrangement, could be isolated easily in high yields.[3] These compounds readily aromatize by reaction with various nucleophiles, giving sulfenylation products. Therefore, we examined

[a] Yields refer to pure isolated products by column chromatography; phenol derivatives **3a** or **3b** were almost quantitatively formed as by-products in all cases.
[b] Diphenyl disulfide was formed as a by-product.

the possibility that **2** might act as an effective reagent for the sulfenylation of various nucleophiles under mild conditions. The starting quinone mono-*O*,*S*-acetals **2a–c** were prepared by Pummerer reaction of the corresponding sulfoxide **1** with 1-ethoxyvinyl esters.[4] A higher yield was obtained with **2b** and **2c** than **2a** (Scheme 1).[3]

First we examined the ability of quinone mono-*O*,*S*-acetals **2a–c** for sulfenylation by the use of cyclic silyl enol ethers **4a**,**b** and found that **2a–c** were excellent sulfenylating reagents which gave the target thioethers in quantitative yields (Table 1, entries 1–4).† The generality of this sulfenylation reaction was confirmed using various acyclic silyl enol ethers **6a–e** with **2b** (Table 1, entries 5–9). This sulfenylating reagent also reacted easily with electron-rich aromatic compounds such as **8a–e** and heteroaromatic compounds **10a–c**, and the corresponding thioethers were obtained by direct sulfenylation (Table 1, entries 10–17). These sulfenylation reactions were completed within 10 min at −30 °C to room temperature under nearly neutral conditions, giving thioether derivatives in almost quantitative yields. In addition, as a side product, the hydroquinone derivative **3** was easily removed by treatment with weak aqueous alkali.

In conclusion, we have succeeded in developing novel sulfenylating reagents by taking advantage of activation on the sulfur atom based on aromatization. These reagents might be applied to the synthesis of biologically active substances having sulfur functions and labile functions that are sensitive to basic or acidic conditions.

# Montmorillonite K-10 and KSF as remarkable acetylation catalysts

**Ai-Xiao Li, Tong-Shuang Li* and Tian-Hui Ding**

*Department of Chemistry, Hebei University, Boading 071002, Hebei Province, P.R. China*

**Montmorillonite K-10 and KSF catalyse the acetylation of alcohols, thiols, phenols and amines with acetic anhydride in excellent yield.**

The protection of hydroxy, thiol and amino groups by the formation of esters and amides is of great importance in organic synthesis.[1] Although a variety of procedures use the transesterification methodology,[2] the acylation of alcohols and phenols is routinely carried out using acid anhydrides or acid chlorides in the presence of tertiary amines such as triethylamine and pyridine.[3] DMAP is particularly noteworthy as an efficient catalyst for the acylation of tertiary alcohols.[4] Recently, Vedejs and co-workers reported tributylphosphine to be a similar catalyst for the acylation of alcohols.[5] In addition to the above catalysts, protonic acids such as toluene-*p*-sulfonic acid[6] and Lewis acids such as zinc chloride,[7] cobalt chloride[8] and scandium trifluoromethanesulfonate[9] are also known to catalyse the acylation of alcohols and phenols. Nevertheless, there is still a great demand for acid catalysts to generate esters under mild conditions.

Montmorillonite clays, a class of inexpensive and noncorrosive solid acids, have been used as efficient catalysts for a variety of organic reactions.[10] In a recent study on the preparation of 1,1-diacetates from aldehydes catalysed by montmorillonite clays, we found that hydroxy groups were protected as acetates in hydroxy-containing aromatic aldehydes.[11] In connection with our ongoing work on montmorillonite clay catalysis,[12] we now give a preliminary account of our study of the acetylation of alcohols, phenols, thiols and amines catalysed by montmorillonite K-10 and KSF.

As shown in Table 1, a series of alcohols, phenols, thiols and amines were acetylated with acetic anhydride under catalysis by montmorillonite K-10 and KSF. Generally K-10 worked better than KSF in terms of reaction time, temperature and/or yield

**Table 1** Acetylation of alcohols, phenols, thiols and amines with acetic anhydride catalysed by K-10 and KSF

[a] Acetic anhydride: substrate (mol : mol). [b] All products were identified by their $^1$H NMR spectra and/or by comparison of their bp or mp with authentic samples. [c] Isolated yield. [d] Net yield, conversion rate of the material is 27.5%.

(entries 1, 5, 13, 16 and 29). Primary and secondary alcohols and phenols can be easily acetylated at room temperature or in refluxing $CH_2Cl_2$ or $CHCl_3$. No selectivity between primary and secondary hydroxy groups was observed (entries 4 and 6). Different results were obtained for several tertiary alcohols. For example, triphenylmethanol remained unchanged even when the reaction was performed in refluxing $CCl_4$ for 2 h (entry 7). *tert*-Butyl alcohol gave 2-methylpropene (entry 8). 3β-Methyl-5α-cholestan-3α-ol afforded mainly 3-methyl-5α-cholest-2-ene, with a minor amount of 3α-acetoxy-3β-methyl-5α-cholestane (27% net yield based on 27.5% conversion rate) (entry 10). The hydroxy equatorial epimer, 3α-methyl-5α-cholestan-3β-ol, gave the corresponding acetate in better yield (23%) and 3-methyl-5α-cholest-2-ene (entry 9). It is noteworthy that 3-methyl-5α-cholest-2-ene was the exclusive dehydration product in both reactions. These results indicated that K-10 and KSF were not efficient catalysts for acetylation of tertiary alcohols. Polyhydroxy compounds were transformed into the corresponding polyacetates (entries 3, 4, 6, 22, 23, 24 and 25). In the presence of K-10 or KSF, thiols and amines were also converted into the corresponding acetamides and thioacetates (entries 12, 13, 26, 27, 28 and 29). Acetylation of thiols was slower than hydroxy groups (entry 11). Amino groups could be preferentially acetylated in the presence of hydroxy groups (entry 26).

In a typical procedure, a mixture of octan-1-ol (650 mg, 5.00 mmol), K-10 (or KSF) (purchased from Fluka and used directly) (100 mg) and acetic anhydride (1.02 g, 10.0 mmol) was stirred at room temperature for 1 h (or 4 h). The catalyst was removed by filtration and washed with $CH_2Cl_2$. The solvent was evaporated under reduced pressure. The residue was purified by column chromatography on silica gel to give octyl acetate (813 mg, 96%).

In conclusion, K-10 and KSF are good acetylation catalysts for primary and secondary alcohols, phenols, thiols and amines but not for tertiary alcohols. The present method has the additional advantages of mild conditions, high yield, easy separation and inexpensive and environmentally friendly catalysts.

# Aggregation of fluoroalkyl units: synthesis of gelling fluoroalkylated end-capped oligomers containing hydroxy segments possessing metal ion binding and releasing abilities

**Hideo Sawada,*[a,b] Toshihiro Tanimura,[a] Shinsuke Katayama[b] and Tokuzo Kawase[c]**

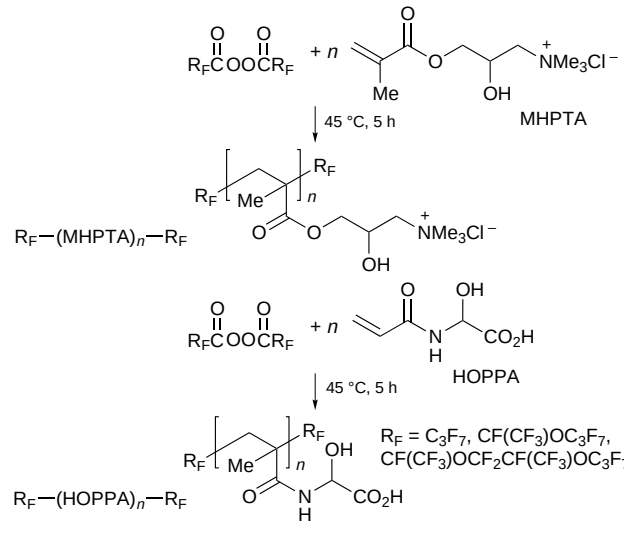
**New fluoroalkylated end-capped oligomers containing 2-hydroxypropyltrimethylammonium or carboxy(hydroxy)-methylamido segments, which are prepared from the reaction of fluoroalkanoyl peroxides with the corresponding monomers, can cause gelation where strong aggregation of the fluoroalkyl segments is involved in establishing the physical gel network, not only in water but also in organic media under the non-crosslinked conditions, and had a high metal ion binding and releasing power.**

Recently there has been increased interest in organofluorinated polymeric materials, especially partially fluoroalkylated macromolecules, because of their unique properties such as high solubility, surface activity and biological activity, which cannot be achieved using the corresponding non-fluorinated macromolecules or perfluorinated polymers.[1] From such a viewpoint, we have been studying the synthesis of fluoroalkylated end-capped oligomers using fluoroalkanoyl peroxides as key intermediates,[2] and these partially fluoroalkylated compounds have been demonstrated to be able to reduce the surface tension of water,[3] and to be potent and selective inhibitors of HIV type-1 *in vitro*.[4] Therefore, it is of interest to develop such compounds. In the course of our studies for the synthesis and applications of fluoroalkylated end-capped oligomers, we have found that fluoroalkylated oligomers containing not only trimethylammonium and hydroxy segments but also hydroxy and carboxy segments can cause gelation in aqueous and organic media under non-crosslinked conditions. More interestingly, these fluoroalkylated oligomers were also found to have high metal ion binding and releasing power. The results are described herein.



A series of fluoroalkylated oligomers containing trimethylammonium and hydroxy segments [$R_F$–(MHPTA)$_n$–$R_F$] were prepared *via* the reactions of fluoroalkanoyl peroxides with 3-methacryloxy-2-hydroxypropyltrimethylammonium chloride (MHPTA).† Similarly, we succeeded in preparing a series of fluoroalkylated oligomers containing hydroxy and carboxy segments *via* the reaction of fluoroalkanoyl peroxides with 2-hydroxy-2-[(1-oxoprop-2-enyl)amino]acetic acid (HOPPA), as shown in Scheme 1.‡

The results for the reaction of fluoroalkanoyl peroxides with MHPTA and HOPPA are shown in Table 1. As shown, perfluoropropylated and perfluorooxaalkylated MHPTA or HOPPA oligomers were obtained in moderate to excellent yields under very mild conditions. The perfluoropropylated and perfluoro-1-methyl-2-oxapentylated MHPTA oligomers (entries 1–3, Table 1) were soluble in water, and we were able to measure their molecular weights by GPC analyses [$\bar{M}_n$ ($\bar{M}_w$/$\bar{M}_n$) = 2630 (3.02) (entry 1); 2060 (3.86) (entry 2); 6760 (11.0) (entry 3)]. However, in perfluoro-1-methyl-2-oxapentylated MHPTA oligomers, the oligomers with larger molar ratios of MHPTA to peroxide (entries 4–9) formed gels or became 'gel-like' with not only water but also MeOH, EtOH, DMF and DMSO, and we were unable to measure their molecular weights owing to the high viscoelacticity of the fluids or the gel formation. A corresponding non-fluorinated MHPTA oligomer [–(MHPTA)$_n$–] was completely soluble in these solvents.

In fluoroalkylated HOPPA oligomers, not only perfluoropropylated but also perfluorooxaalkylated HOPPA oligomers were found to cause gelation with water, DMF and DMSO under non-crosslinked conditions. It is important to note that the corresponding non-fluorinated HOPPA oligomers [–(HOPPA)$_n$–] forms no gels with these solvents.

We have measured the minimum concentrations ($C_{min}$) of these oligomers necessary for gelation in water at 30 °C according to the method reported by Hanabusa *et al.*,[5] and the results are shown in Table 1.

As shown, the amount ($C_{min}$) of a fluoroalkylated oligomer necessary to gel 1 l of water was 7–330 g, and the oligomers with greater molar ratios of MHPTA (or HOPPA) to peroxide or longer perfluorooxaalkylated oligomers were found to exhibit higher gelling ability. These results strongly suggest that the main driving forces for gelation are the synergistic interactions between aggregations of fluoroalkyl units in oligomers and the intermolecular hydrogen bonding between hydroxy or carboxy segments, including the interactions of OH and $N^+$ groups. On the other hand, the corresponding non-fluorinated oligomers could not form a physical gel network in these media owing to the absence of the aggregation of fluoroalkyl units. Hitherto, it was known that some macromolecules cause chemical and physical gelation in aqueous solutions, but the application of these compounds to organogels has been limited. The striking characteristic of our present oligomers as gelling agents is the

[a] Yields are based on the starting materials (MHPTA or HOPPA) and the decarboxylated peroxide unit ($R_F$–$R_F$). [b] gel-like = highly vicoelastic fluid.

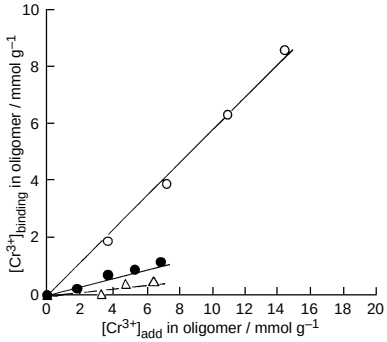

**Fig. 1** Relationship between relative amounts of $Cr^{3+}$ binding to fluoroalkylated oligomers and initial $Cr^{3+}$: (○) $R_F$–$(MHPTA)_n$–$R_F$ [$R_F$ = $CF(CF_3)OC_3F_7$ (entry 7)], (●) $R_F$–$(HOPPA)_n$–$R_F$ [$R_F$ = $CF(CF_3)OCF_2CF(CF_3)OC_3F_7$ (entry 16) and (△) $R_F$–$(MHPTA)_n$–$R_F$ [$R_F$ = $CF(CF_3)OC_3F_7$ (entry 6)]

ability to harden not only water but also organic polar solvents. This feature is attributable to the fact that fluoroalkyl segments are solvophobic in aqueous and organic media, and enhance aggregation due to strong interaction between the fluoroalkyl segments.

From both fundamental and technological standpoints, it is interesting to study the adsorptive properties against metal ions of our new fluoroalkylated oligomer gels. Thus, we performed quantitative measurements of the uptake of $Cr^{3+}$ (15–60 mmol dm$^{-3}$) by the $R_F$–$(MHPTA)_n$–$R_F$ (entry 7, Table 1) hydrogel. The metal ion concentration of the supernatant liquid after the incubation (at 25 °C for 24 h) was determined spectrophotometrically using a calibration curve, and the results are shown in Fig. 1.

As shown, $Cr^{3+}$ was found to bind strongly to the fluoroalkylated oligomer hydrogel with *ca.* 60% binding ratio [based on the relative amount of $Cr^{3+}$ binding to gel ($[Cr^{3+}]_{binding}$/oligomer) and relative amount of initial $Cr^{3+}$($[Cr^{3+}]_{add}$/oligomer)]. The $R_F$–$(MHPTA)_n$–$R_F$ (entry 6, Table 1) hydrogel possessing a higher $C_{min}$ value than entry 7 had a weaker $Cr^{3+}$ binding power (*ca.* 10% binding ratio) under similar conditions. The $R_F$–$(HOPPA)_n$–$R_F$ (entry 16, Table 1) hydrogel was also shown to have a $Cr^{3+}$ binding power (*ca.* 17% binding ratio) as shown in Fig. 1. However, fluoroalkylated oligomers (entries 8 and 11) possessing higher $C_{min}$ values than entries 6, 7 or 16 were found to have poor $Cr^{3+}$ binding power. From these results, it can be said that the fluoroalkylated oligomer networks in the hydrogels possessing lower $C_{min}$ values are likely to bind strongly to the metal ion, since stronger aggregation of the fluoroalkyl segments is necessary for the establishment of the physical gel network to exhibit lower $C_{min}$ value.

More interestingly, it was found that $Cr^{3+}$ can be easily released from the $Cr^{3+}$-bound $R_F$–$(MHPTA)_n$–$R_F$ (entry 7, Table 1) hydrogel into water with *ca.* 60% releasing ratio (the ratio based on the relative amount of $Cr^{3+}$ released into water and relative amount of $Cr^{3+}$ binding to gel) after the incubation at 25 °C for 24 h. On the other hand, $Cr^{3+}$ was not released from the $Cr^{3+}$-bound $R_F$–$(HOPPA)_n$–$R_F$ hydrogels under similar conditions. This is because the interaction of $Cr^{3+}$ and $R_F$–$(HOPPA)_n$–$R_F$ hydrogels is ionic, whereas the main driving force for $Cr^{3+}$ binding to $R_F$–$(MHPTA)_n$–$R_F$ is coordination between $Cr^{3+}$ and OH segments.

Thus it has been demonstrated that our new fluoroalkylated oligomers containing hydroxy segments can cause gelation under non-crosslinked conditions, and that the aggregation of fluoroalkyl units in water and/or organic media becomes a new driving factor for gelation in addition to well-known interactions such as hydrogen bond and ionic interactions. In addition, it has been shown that these new fluoroalkylated oligomer hydrogels have high metal-binding or releasing power. Thus, these fluorinated oligomer gels are expected to prove useful in various fields as novel fluorinated functional materials.

# Efficient coupling reactions of allylamines with soft nucleophiles using nickel-based catalysts

**Hervé Bricout, Jean-François Carpentier and André Mortreux***

*Laboratoire de Catalyse Hétérogène et Homogène, Groupe de Chimie Organique Appliquée, URA CNRS 402, ENSCL, BP 108-59652 Villeneuve d'Ascq Cedex, France*

**Substitution reactions of *N,N*-diethylallylamine 1 with soft nucleophiles such as active methylene compounds 2a–c and piperidine 5 proceed much more rapidly in the presence of Ni(dppb)$_2$ [dppb = 1,4-bis(diphenylphosphino)butane] as catalyst than with comparable palladium systems.**

Recently we reported the effectiveness of preformed Ni$^0$-bisphosphine catalysts for the rearrangement of dialkyl allylmalonate derivatives,[1a] a recently discovered case of nucleophilic allylic substitution which proceeds *via* C–C bond cleavage.[1b] In this special reaction, nickel catalysts proved to be more active than comparable palladium systems, suggesting the superior ability of the former to activate allylic substrates having a poor leaving group. Here we report that such nickel-based systems are much more efficient than palladium catalysts for coupling of allylamines[2] with so-called 'soft' nucleophiles.[3]

The comparative study was performed using the simple *N,N*-diethylallylamine **1** and active methylene compounds **2a–c** as shown in eqn. (1). The results are summarized in Table 1. In all cases, the reaction was totally selective for allylation products, although a mixture of monoallylation (**3a–c**) and diallylation (**4a–c**) products was obtained. Using 2 mol% of Ni(dppb)$_2$ generated from Ni(COD)$_2$ and 2 mol equiv. of the diphosphine gave allylation products of dimethyl malonate **2a** in virtually quantitative yield with an initial activity of 50 h$^{-1}$ (turnover frequency, TOF) at 80 °C in THF (entry 1). Additional base such as BSA [BSA = *N,O*-bis(trimethylsilyl)acetamide] did not affect the reaction (entry 2). On the other hand, a significant increase in the catalytic activity arose upon adding tetrabutylammonium perchlorate as a promoter (5 equiv. with respect to Ni) (entry 3), in direct line with our previous observations on nickel-catalysed coupling reactions of allylic alcohol derivatives.[4] Changing the solvent to DMF further increased the catalytic activity, so that the completion time decreased to 20 min at 80 °C (entry 4), allowing the reaction to be performed at 50 °C (entry 5). At this temperature, the best catalytic activity was observed by combining the solvent effect of DMF and the promoting effect of [NBu$_4$][ClO$_4$] (entry 6). Surprisingly, in light of palladium literature,[2b–h] the *in situ* formation of the allyl ammonium salt *via* addition of acetic acid proved somewhat detrimental (entry 7). The use of palladium catalysts led to poorer results. As a matter of fact, no reaction at all occurred using the *in situ* combination Pd(OAc)$_2$–PPh$_3$ (1 : 5) in THF with BSA as a base (entry 8). Modest activity was obtained with this catalytic system in DMF, which was slightly improved upon adding acetic acid (entries 9 and 10). The *in situ* combination Pd(OAc)$_2$–dppb (1 : 3) showed the best performance of the palladium catalysts tested (entry 11), but the latter is still at least ten times less active than the best nickel-based

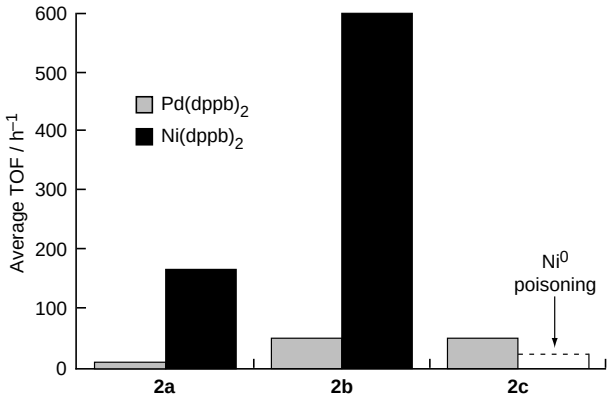

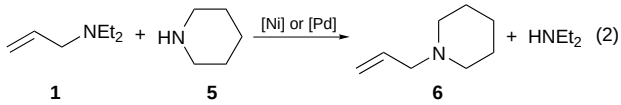

**Fig. 1** Average turnover frequencies of nickel and palladium catalysts for the coupling of **1** with **2a**–**c** (see Table 1 for reaction conditions)

system for this reaction. A similar trend, with even more marked differences between nickel and palladium catalysts, was observed for the alkylation of **1** with methyl acetoacetate **2b**. The simple system using $Ni(dppb)_2$ as the catalyst and DMF as the solvent allowed the reaction carried out with 2 mol% to Ni to be completed within 5 min at 80 °C and with an average activity of 100 $h^{-1}$ at 50 °C (entries 12 and 13).† The *in situ* combination $Pd(OAc)_2$–dppb proved once again to be the most effective palladium catalyst (entries 14–17), but its performance at 80 °C was still lower than that of the above nickel system at 50 °C. However, nickel catalysts proved inefficient for the coupling of **1** with acetylacetone **2c** (entry 18), because of a rapid catalyst poisoning evidenced by the gradual shift in the colour of the solution from orange–yellow [typical colour of $Ni(dppb)_2$] to pale green [$Ni^{II}$ species, possibly $Ni(acac)_2$]. Although it must be pointed out that **2c** is the most acidic compound among active methylene compounds **2a**–**c**, there is no definitive evidence that this catalyst decay occurs *via* an oxidative protolysis of nickel intermediates.‡ Anyway, the catalyst poisoning was still observed in the presence of an excess of **1** ([Ni] : [**1**] : [**2c**] = 1 : 75 : 50). No comparable phenomenon was observed with palladium catalysts, such as the *in situ* combination $Pd(OAc)_2$–dppb, which afforded alkylation products **3c**/**4c** with performance similar to that observed for the coupling of **1** with **2b** (entry 19). Fig. 1 summarises the overall performance of best Ni–dppb and Pd–dppb systems.

The results of the exchange reaction between **1** and piperidine **5** to give *N*-allylpiperidine **6** (eqn. 2) bring further evidence of

the general ability of nickel catalysts to promote nucleophilic substitution of allylamines (Table 2). We found that the aforementioned trends for the nickel-catalysed coupling of **1** with active methylene compounds **2a**, **b** proved also to be true for this exchange reaction. A notable exception arose from the beneficial effect of added acetic acid as expected from the literature.[2b–h] Namely, the formation of **6** was best conducted by using $Ni(dppb)_2$ as the catalyst, DMF as the solvent and by adding 1 equiv., of AcOH with respect to **1** (Table 2, entry 5). The most efficient palladium catalyst found [*in situ* combination $Pd(OAc)_2$–dppb, 1 : 3] took at least 20 times longer for the exchange reaction to go to completion than the latter nickel-based system under the same conditions (entry 6).

In conclusion we have demonstrated that $Ni(dppb)_2$ easily generated from $Ni(COD)_2$ and 2 equiv. of the bisphosphine is generally a much more active catalyst than comparable palladium systems for substitution of allylamines with 'soft' nucleophiles. Two explanations can be proposed for this trend: (i) the higher ability of nickel catalysts to activate allylic substrates having a poor leaving group, *i.e.* here the C–N bond, and/or (ii) the lower propensity of Ni to be coordinated by amines, thus resulting in larger amounts of active Ni–phosphine species. The limitation of these nickel-based systems lies in the sensitivity of nickel intermediates towards acetylacetone.

## Footnotes

* E-mail: mortreux@ensc-lille.fr

† In a typical experiment (Table 1, entry 13), to $Ni(COD)_2$ (36 mg, 0.13 mmol) in a 50 ml glass reactor equipped with a Teflon cap was added a degassed solution of dppb (111 mg, 0.26 mmol) in DMF (12.5 ml) under nitrogen. After 15 min of magnetic stirring, **1** (0.74 g, 6.5 mmol), **2b** (1.13 g, 9.75 mmol) and heptane (1.00 g, 10 mmol, GLC internal standard) were added. The solution was stirred at 50 °C and the reaction was monitored by quantitative GLC analysis of aliquot samples. Coupling reactions involving a co-reagent and exchange reactions of **1** with piperidine were carried out in a similar manner. *In situ* palladium catalysts were prepared by mixing $Pd(OAc)_2$ with a degassed solution (THF or DMF) of the phosphine ligand. The resulting yellow solution was stirred for 15 min at room temperature before use.

‡ Such a degradation of nickel intermediates could be rationalised as follows:

$$Ni^0(dppb) + 2\ acacH \rightarrow Ni(acac)_2 + H_2 + dppb$$

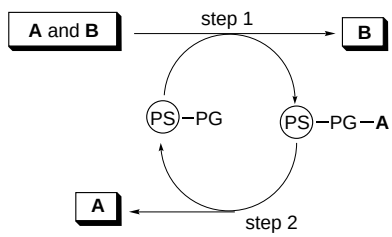
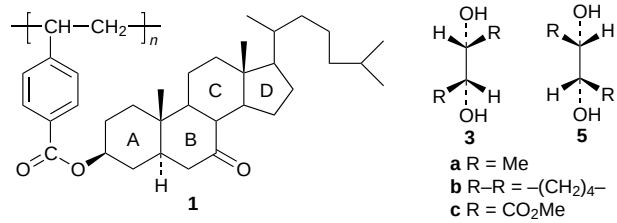
# Partial separation of enantiomeric 1,2-diols *via* ketal formation with a polymer-supported chiral ketone

**Ian D. Clarke and Philip Hodge***

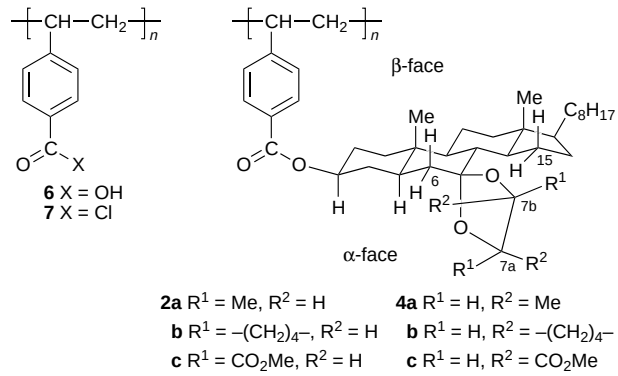


*Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL*

**Partial separations of the (*R*,*R*)- and (*S*,*S*)-enantiomers of butane-2,3-diol, *trans*-cyclohexane-1,2-diol and dimethyl tartrate were achieved *via* ketal formation with a polymer-supported 7-keto steroid; in each case one enantiomer reacted in higher yield than the other and release of the diols from the support gave diol fractions significantly enriched in one enantiomer**



In recent years many organic reactions have been carried out which involve polymer-supported (PS) species.[1] The most well known examples are those involved in 'solid phase' peptide syntheses.[2] The latter can be viewed as examples of organic reactions using PS substrates and also as examples of the use of PS protecting groups (PS-PGs),[3] in this case for carboxylic acids. Reactions involving PS substrates are currently of great interest in combinatorial chemistry.[4,5] Organic reactions involving PS reagents and PS catalysts have also been studied extensively.[1]



An application of PS species which has received little attention is the use of PS-PGs to achieve separations by the procedure summarised in Scheme 1. In step 1 the mixture of compounds to be separated, **A** and **B**, is treated with a PS-PG which selectively binds **A** to the support. Those components, **B**, of the mixture that fail to bind to the support are recovered. In step 2, the components of the original mixture, **A**, bound to the support are released by carrying out the appropriate 'deprotection' procedure. Thus, **A** is separated from **B** and the PS-PG is available for re-use. This method of achieving separations is less laborious than column chromatography and potentially it could be automated. Examples of this separation procedure being used in organic chemistry include the use of a PS-diol to separate 3-keto steroids from 17- and 20-keto steroids,[6] and of a PS-boronic acid to separate the *cis*- and *trans*-isomers of cyclohexane-1,2- and -1,3-diols.[7]

This communication is concerned with the separation of mixtures of *enantiomeric* diols *via* ketal formation with a PS chiral ketone. The PS chiral ketone selected for this initial study was an ester **1** of 3β-hydroxy-5α-cholestan-7-one. Inspection of Dreiding models of the ketals **2** derived from PS-ketone **1** and diols **3** indicates that the **R¹** groups at the 7b-position will experience significant steric interactions with the D-ring (especially the 15α-hydrogen) whilst the **R¹** groups at the 7a-position will not experience any significant non-bonding interactions with other parts of the steroid nucleus. In the ketals **4** derived from diols **5** the **R²** groups at the 7b-position may experience minor non-bonding interactions with the 6α-hydrogen whilst those at the 7a-position will again not experience any significant interactions. Thus, the PS ketone **1** is expected to bind diols **5** more readily than diols **3**. The presence of two **R** groups in each diol is necessary to ensure that one **R** group is present at the crucial 7b-position.

**Scheme 1**

Gel-type polystyrene beads crosslinked with 2% of divinylbenzene and containing carboxylic acid residues **6** (1.10 mmol $g^{-1}$), were prepared from commercial blank crosslinked beads *via* lithiated polystyrene.[8,9] The carboxylic acid groups **6** were converted into acid chloride residues **7**, the latter reacted with 3β-hydroxy-5α-cholestan-7-one,† and the unreacted residues **7** capped with MeOH essentially as described before.[13] This gave polymer beads containing residues **1** with a loading (0.60 mmol $g^{-1}$), similar to that reported before.[13]

Ketal formation (step 1) was achieved by treating mixtures of enantiomeric diols in toluene at reflux temperature with PS ketone **1** in the presence of a catalytic amount of toluene-*p*-sulfonic acid (PTSA). The reaction was carried out for 56 h in an apparatus equipped with a Dean–Stark trap. At the end of the reaction period the beads were filtered off and unbound diol recovered. The ketalisation yield, *i.e.* the percentage of supported ketone converted into the ketals, was estimated from the amount of unbound diol. The bound diol was released (> 97% recovered) by treating the PS ketal at 20 °C for 22 h with wet dioxane containing a catalytic amount of PTSA. All diol fractions were shown to be > 98% pure by $^1$H NMR spectroscopy. The percentage enantiomeric excesses of diol samples (ees) were estimated by polarimetry and/or chiral GC. The results are summarised in Table 1.

The separation of the (*R*,*R*)- and (*S*,*S*)-butane-2,3-diols was studied initially: see entries 1–7. It is evident that both diols

bound to the beads, but that, as expected, the (*S*,*S*)-diol **5a** bound in higher yields. The ketalisation yield was, however, only 57% even when equimolar amounts of (*S*,*S*)-diol **5a** and ketone **1** were used (entry 1). This may be due in part to some of the bound ketone being inaccessible due to steric crowding.[13] The diol recovered from the beads had a 42% ee of the (*S*,*S*)-diol **5a**. With an equimolar amount of racemate (*i.e.* 0% ee) as the starting material (entry 2) the diol recovered from the beads had a 39% ee of the (*S*,*S*)-diol **5a**. This rose to a 47% ee when the recovered diol was recycled (entry 3). The initial result (entry 2) indicates that 65% of the original (*S*,*S*)-diol **5a** bound to the beads whereas 29% of the (*R*,*R*)-diol **3a** bound, *i.e.* the yield ratio for the enantiomers was 2.2 : 1.

Apart from resolving racemates, other useful applications of the present type of system could involve raising the ee of reaction products from asymmetric syntheses. This might be achieved either by *concentrating* the major enantiomer or by *removing* the minor enantiomer. Starting with a mixture of butane-2,3-diol enantiomers having an 80% ee of the (*S*,*S*)-isomer **5a**, see entry 4, the diol recovered from the beads had a 90% ee. Similarly a starting material with 90% ee gave a product of 94% ee. This rose to a 97% ee when the recovered diol was recycled (entry 6). Thus through three cycles (entries 4–6) the ee of the (*S*,*S*)-diol **5a** was raised from 80 to 97%. Attempts to remove the (*S*,*S*)-enantiomer **5a** from a mixture having an 80 ee of the (*R*,*R*)-enantiomer **3a** was less successful (entry 7). After treating a five-fold excess of the mixture with the beads, the ee of recovered *unbound* diol had increased to only 82%. Evidently the binding of the preferred (*S*,*S*)-diol **5a** was almost entirely offset by the large proportion of the (*R*,*R*)-diol **3a** present.

**Table 1** Separation *via* ketal formation with PS keto steroid **1**

| | Starting material[a] | | | | Recovered diol[b] | |
|---|---|---|---|---|---|---|
| Entry | **3**,**5** | Ee (%) | Enantiomer in excess | Ketalisation yield (%) | Ee (%)[c] | Enantiomer in excess |
| 1[d] | **a** | 0 | — | 57 | 42 | *S*,*S* |
| 2 | **a** | 0 | — | 47 | 39 | *S*,*S* |
| 3 | **a** | 39 | *S*,*S* | 37 | 47[e] | *S*,*S* |
| 4 | **a** | 80 | *S*,*S* | 43 | 90[f] | *S*,*S* |
| 5 | **a** | 90 | *S*,*S* | 49 | 94 | *S*,*S* |
| 6 | **a** | 94 | *S*,*S* | 42 | 97[e] | *S*,*S* |
| 7[g] | **a** | 80 | *R*,*R* | 90[h] | 82[i] | *R*,*R*[g] |
| 8 | **b** | 0 | — | 11 | 55[f] | *S*,*S* |
| 9 | **b** | 80 | *S*,*S* | 20 | 92 | *S*,*S* |
| 10 | **c** | 0 | — | 9 | 72[e] | *R*,*R* |

[a] Except where indicated otherwise, ratio of diol to ketone was 1 : 1. [b] Except where indicated otherwise, the diol fraction examined was that obtained by deketalisation. The recoveries were > 97%. [c] Unless indicated otherwise, the ees were determined both by polarimetry and chiral GC. The results were in close agreement (±1%). Polarimetry was based literature values (ref. 14): $[\alpha]_D^{20}$ +13.0 (neat) for **5a**; $[\alpha]_D^{20}$ + 36.7 (*c* 0.45 in $H_2O$) for **5b**; $[\alpha]_D^{20}$ + 20.0 (*c* 20 in $H_2O$) for **5c**. Chiral GC was carried out using a CP-Chirosil-DEX CB stationary phase. [d] Ratio of diol to ketone was 2 : 1. [e] Ee determined by polarimetry only. [f] Ee determined by GC only. [g] This experiment used a five-fold excess of the diol and focused on the *unbound* diol. [h] Percentage of starting material *not* bound. [i] The *unbound* diol fraction was examined.

The ketalisation yields were lower starting with racemic mixtures of the (*R*,*R*)- and (*S*,*S*)-*trans*-cyclohexane-1,2-diols and dimethyl (*R*,*R*)- and (*S*,*S*)-tartrates (entries 8–10) but the recovered diols had higher ee, 55 and 72% respectively, than with butan-2,3-diol. Thus, the more significant the steric interactions the greater the discrimination between the enantiomers but the lower the chemical yield. It should be noted here that with a perfect discrimination between the enantiomers and all the ketone residues of **1** fully available, starting with racemates the ketalisation yields would be only 50%. As expected the enantiomers which bound in the higher yields were the (*S*,*S*)-enantiomer **5b** and (*R*,*R*)-enantiomer **5c**. The results using the racemates as starting materials indicate yield ratios of 6.9 : 1 with the enantiomeric diols **5b** and **3b** and 6.1 : 1 with the enantiomeric diols **5c** and **3c**.

The keto steroid had no tendency to detach from the beads under the reaction conditions used in this study. Thus, no steroid was detected by $^1$H NMR spectroscopy in any of the diol fractions. Indeed, the FT–IR spectrum of the PS ketone **1** at the end of the experiments was indistinguisable from that when first prepared. All the above results were obtained with one batch of resin, thus demonstrating that the PS ketone **1** can be recycled.

This initial study shows that significant separations of enantiomers can be achieved using the procedure outlined in Scheme 1. The procedure could undoubtedly be automated. Future work is being directed towards identifying chiral molecules which are more discriminating between the enantiomers and which permit higher loadings to be achieved.

We thank the EPSRC for financial support.

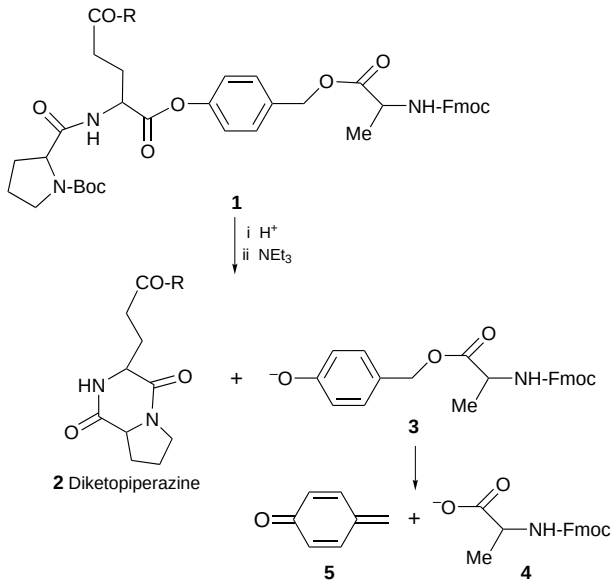
# A pH cleavable linker for zone diffusion assays and single bead solution screens in combinatorial chemistry

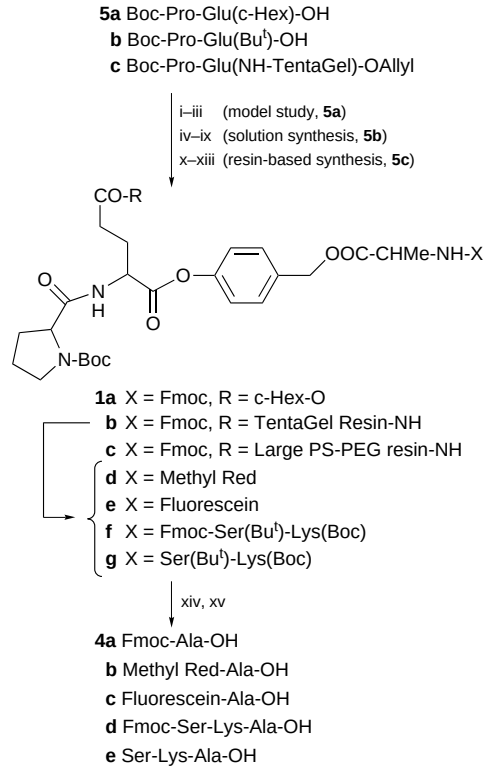


**Butrus Atrash and Mark Bradley***

*Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ*

**A safety catch linker has been developed that allows efficient compound release into buffered aqueous solutions and agarose gels.**

Linkers, acting as the selectively cleavable bridge between the solid support and the compound of interest, play a pivotal role in solid phase, combinatorial and peptide chemistry. This role is fundamental, not only in dictating the range of chemistry which can be carried out, but also in determining the particular screening approach to the library in question.[1] At the present time there are a limited number of linkers available that are 'biocompatible' in terms of linkers being directly cleavable within the assay. The best known examples are light cleavable linkers;[2] the internal imidazole catalysed, ester cleavable linkers of Frank[3] and the iminodiacetic acid based linkers of Lebl.[4] All of these have a number of attractive features but also limitations for screening.



We now report the development of a highly efficient linker which cleaves at pH 8, following acidic (safety catch) activation. The activated linker rapidly cleaves in buffered solution and within agarose gel within a time frame that allows the gel to set before compound release but fast enough to allow complete cleavage within a few hours. The key mechanistic features of the linker **1** are diketopiperazine **2** formation, taking place at pH 7–8, which releases a derivatised hydroxymethylphenol(ate) **3**. This then undergoes a facile 1,6-elimination process to give the product **4** and the quinone methide by-product **5** (see Scheme 1). The process was initially investigated in solution using **1a** (R = cyclohexylO) which was synthesised as shown in Scheme 2. Cleavage was monitored by TLC following removal of the Boc group and treatment with $NEt_3$, and resulted in rapid cleavage (< 1 h) of the linker and quantitative release of Fmoc-Ala-OH.

**Scheme 1**

Having ascertained the practicalities of cleavage the first resin-based experiments were initiated by the synthesis of **1b** and by its simple derivatisation to give **1d**–**g**† to look at the ensuing release of **4a**–**e**. The linkers were initially synthesised in solution and attached to the resin prior to derivatisation since in our view quantification of linker efficiency/kinetics is most reliable with homogeneous material coupled to the solid support. Subsequently the solution synthesis was replaced by an efficient resin based synthesis as shown in Scheme 2.

Cleavage from the resin was followed by UV analysis in real time, RP-HPLC [with samples being removed and quenched (0.1% TFA) before injection] and quantification using internal standards. Although TentaGel is compatible with most solvents and hence a wide range of compounds, we were interested in the variation of cleavage rate with a number of different compounds. Compounds released in this study included Fmoc-Ala-OH, Methyl Red-Ala-OH, Fluorescein-Ala-OH and two tripeptides Fmoc-Ser-Lys-Ala-OH and H-Ser-Lys-Ala-OH. The

**Scheme 2** *Reagents and conditions*: i, 4-$HOC_6H_4CHO$, DCC, 98%; ii, $NaBH_3CN$, 65%; iii, Fmoc-Ala, DCC, DMAP, 68%; iv, 4-$HOC_6H_4CHO$, DCC, 90%; v, $NaBH_3CN$, 80%; vi, Fmoc-Ala, DCC, DMAP, 79%; vii, $CF_3CO_2H$–$CH_2Cl_2$ (1 : 1), 100%; viii, $Boc_2O$, 60%; ix, TentaGel Resin-S $NH_2$ or 'big' PS-PEG-$NH_2$ beads, DIC, HOBt; x, $Pd(PPh_3)_4$, dimedone; xi, 4-$HOC_6H_4CHO$, DCC; xii, $NaBH_3CN$; xiii, Fmoc-Ala, DCC, DMAP; xiv, $CF_3CO_2H$–$CH_2Cl_2$ (1 : 1); xv, $K_2HPO_4$ (50 mM, pH 8)

resins used were TentaGel-S-$NH_2$ and aminomethyl polystyrene beads (150–300 μm, 2 mmol $g^{-1}$) made water-compatible by the method of Hudson.[5] Cleavage results are shown in Fig. 1.

The half-lives of cleavage from TentaGel-S-$NH_2$ in 50 mM phosphate buffer (pH 8.0) ranged from 10–75 min depending on the compound being cleaved with yields greater than 70% in all cases.‡ As with photocleavable linkers[6] we observed that hydrophobic compounds were released much more slowly into the aqueous assay solution than hydrophilic, a factor which must have implications for single bead library screening. The intermediate **3** was identified by HPLC and ES-MS in the cleavage of **1b**. The large water compatible beads **1c** were studied for the release of Fmoc-Ala-OH. The half-life for cleavage in this case was 800 min, which compares with 75 min for Fmoc-Ala-OH being released from TentaGel resin. Clearly the difference illustrates the effect of bead size on the diffusion of materials into and out of the large beads (these beads swell to about 600–700 μm in water), but also we believe it is associated with the smaller PEG chains on our larger beads compared to those found on TentaGel.

Beads **1b**,**e** were used in a zone diffusion type assay. The Boc safety catch was removed and the beads added to molten agarose (45 °C) and poured into petri dishes. Fluorescent zones were clearly visible around beads **1e** after 2–3 h in the agarose gel. Beads **1b** were left in the gel for 12 h, following which 5% TFA–$H_2O$ was added, the gel melted and the beads removed and thoroughly washed. Fmoc analysis indicated that 70% of the material had been cleaved from the resin. Since the half-life of cleavage for **1b** in solution is 75 min this experiment demonstrates that materials are cleaved into the agarose gel with relatively good efficiency, although as expected more slowly than into free solution.

In summary, we have developed what we believe is a practical example of a "pH" labile linker for solid phase and combinatorial chemistry. Importantly we have shown that the linker is stable to the base treatments required during Fmoc peptide chemistry and that it is efficiently cleaved in buffered aqueous solutions following synthesis. The one negative side is the quinone methine that may need quenching in the assay. We believe that linkers of this type have huge potential in solid phase chemistry for the screening of compound libraries using single bead solution screens and zone diffusion assays.

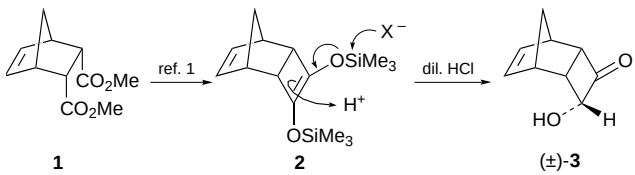
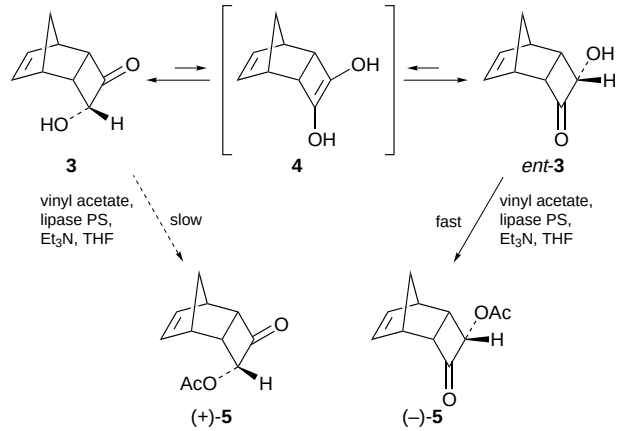
# Lipase–triethylamine-mediated dynamic transesterification of a tricyclic acyloin having a latent *meso*-structure: a new route to optically pure oxodicyclopentadiene

**Takahiko Taniguchi and Kunio Ogasawara***



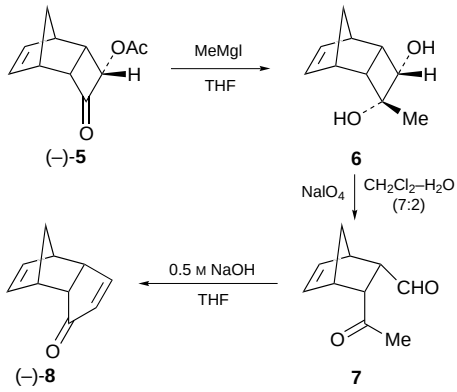
*Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-77, Japan*

**The racemic tricyclic acyloin (±)-*endo*-3-hydroxytricyclo[4.2.1.0$^{2,5}$]non-7-en-4-one has been dynamically resolved *via* the transient formation of the *meso*-enediol isomer under lipase–triethylamine-mediated kinetic transesterification conditions to give the single chiral acetate (−)-*endo*-3-acetoxytricyclo[4.2.1.0$^{2,5}$]non-7-en-4-one, serving as a precursor of (−)-oxodicyclopentadiene, in excellent optical and chemical yields.**



During the preparation of the racemic tricyclic acyloin 3-hydroxytricyclo[4.2.1.0$^{2,5}$]non-7-en-4-one (±)-**3** starting from *endo*-2,3-bis(methoxycarbonyl)bicyclo[2.2.1]hept-5-ene **1** by employing the acyloin condensation,[1] we observed[2] that an acid hydrolysis of the bis-trimethylsilyloxy intermediate **2** furnished stereoselectively the single racemic acyloin (±)-**3** having an *endo*-hydroxy group (Scheme 1).† The *endo*-hydroxy configuration of **3** did not change even in the presence of triethylamine, which brought about complete deuterium exchange of the methine hydrogen on the acyloin functionality with deuterium oxide within 10 h. This seemed to be due to facile equilibration between the acyloin **3** and the transient *meso*-1,2-enediol intermediate **4** followed by convex-face selective protonation of the latter under weak basic conditions. Since the analogues of **3** having cyclopentenol and cyclohexenol rings in place of the four-membered ring have been found to be kinetically better discriminated than those having an *exo*-hydroxy group under lipase-mediated transesterification conditions,[3] we assumed that dynamic kinetic resolution[4,5] should take place in a facile manner to give a single enantiomeric *endo*-acetate **5**. The racemic acyloin (±)-**3** might be subjected to the transesterification conditions in the presence of an appropriate lipase under favourable equilibrium conditions,[6] thus generating the transient enediol **4** having *meso* symmetry. We report herein the first example of the lipase-mediated dynamic transesterification of the racemic acyloin **3** leading to the highly optically enriched single *endo*-acetate (−)-**5** *via* the transient generation of the *meso*-enediol **4** in reaction with vinyl acetate in THF containing a catalytic amount of triethylamine (Scheme 2).

When the racemic acyloin **3** was stirred with vinyl acetate (1.2 equiv.) in THF containing triethylamine[3b,5a,7] (0.1 equiv.) in the presence of lipase PS‡ (*Pseudomonas* sp. immobilized on Celite, Amano) for 48 h at room temperature, transesterification occurred to give the optically active *endo*-acetate (−)-**5**, $[\alpha]_D^{24}$ −120.7 (*c* 2.0, $CHCl_3$), in 75% yield accompanied by a minor amount of 5-hydroxy-4-oxatricyclo[5.2.1.0$^{2,6}$]dec-8-en-3-one§ (10%) which was separated by silica gel column chromatography. The optical yield of the product was determined to be 97% ee by HPLC (chiral column CHIRALCEL OD, 5% Pr$^i$OH–hexane) indicating clearly that the dynamic kinetic resolution took place as expected. When the reaction was carried out without triethylamine, simple kinetic resolution occurred to give the same *endo*-acetate (−)-**5**, $[\alpha]_D^{26}$ −120.3 (*c* 1.0, $CHCl_3$), (> 99% ee, CHIRALCEL OD, 5% Pr$^i$OH–hexane) in 45% yield leaving 53% of the optically enriched starting acyloin (+)-**3**, $[\alpha]_D^{27}$ + 190.5 (*c* 0.9, $CHCl_3$) (92% ee, CHIRALCEL OD, 5% Pr$^i$OH–hexane); thus, this result indicates that the amine accelerated the equilibrium between **3** and *ent*-**3** *via* the *meso*-1,2-enediol **4**. When the racemic acyloin (±)-**3** was stirred with vinyl acetate in the same THF–triethylamine medium without the lipase, the transesterification which competes with the enzymatic reaction, although it occurred, proceeded very slowly to give the racemic *endo*-acetate (±)-**5** in less than 3% yield, leaving most of the starting material untouched after 48 h at room temperature. Taking these observations into account, we concluded that triethylamine is requisite for the present dynamic transesterification and the actual enantioselectivity exerted by the enzyme was higher than that observed.



Having established the efficient dynamic kinetic transesterification of the racemic acyloin (±)-**3** having a latent *meso*-structure, the optically active acetate (−)-**5** thus obtained was next transformed into optically active oxodicyclopentadiene **8** so as to determine the absolute configuration of the resolved product as well as to probe its synthetic utility. Thus (−)-**5** was treated with excess MeMgI in THF to give the diol **6**, $[\alpha]_D^{26}$ −15.7 (*c* 0.6, $CHCl_3$), in nearly quantitative yield. Treatment of the diol **6** with sodium periodate gave the keto aldehyde **7** which was immediately exposed to diluted aqueous sodium hydroxide[8] to give the known oxodicyclopentadiene (−)-**8**, mp 74 °C, $[\alpha]_D^{26}$ −154.0 (*c* 1.0, $CHCl_3$) [lit.,[3b] mp 76 °C, $[\alpha]_D^{29}$ −158.5 (*c* 1.0, $CHCl_3$)] (> 99% ee by HPLC: CHIRALCEL OB, 10% Pr$^i$OH–hexane), in 50% overall yield by intramolecular aldolization.[8] Since optically active oxodicyclopentadiene **8** is

**Scheme 1**

**Scheme 2**

**Scheme 3**

interconvertible into the enantiomer[8] and used as a versatile chiral building block,[9] the present transformation constitutes the determination of the absolute structure of the chiral acetate (−)-**5** as shown and an alternative synthesis of optically active oxodicyclopentadiene[3b,9,10] **8** (Scheme 3).

In conclusion, we have demonstrated that the tricyclic racemic acyloin *endo*-3-hydroxytricyclo[4.2.1.0$^{2,5}$]non-7-en-4-one (±)-**3** is dynamically acylated with vinyl acetate in an enantiospecific manner *via* the transient *meso*-enediol **4** in THF containing triethylamine in the presence of lipase to give the single *endo*-acetate (−)-**5**, proving itself as a potential chiral building block[2] and serving at the same time as the precursor of versatile chiral oxodicyclopentadiene **8**. We are currently working on extension of the present dynamic kinetic resolution to other acyloins having latent *meso* structure as well as to the acyloins having latent prochirality, and on exploitation of the chiral acyloin acetates obtained for the construction of a variety of optically active molecules.

# Luminescence from ytterbium(III) and its complexes in solution†

**Andrew Beeby, Rachel S. Dickins, Stephen Faulkner, David Parker* and J. A. Gareth Williams**

*Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

**Time-resolved studies of luminescence from ytterbium in solution are reported offering opportunities for luminescent imaging in the near IR, and allowing the use of a wide range of aromatic antennae to sensitise the metal centre; the luminescence of the solvated ion and of a wide variety of complexes is examined, both by direct excitation and by inter- and intra-molecular energy transfer.**

Time-resolved luminescence of lanthanide complexes has been of interest for some years.[1–3] However, interest has centred almost exclusively on the sensitised luminescence of complexes of $Eu^{III}$ and $Tb^{III}$. Such complexes have the advantage of possessing long luminescent lifetimes, but they are excited by long-wavelength UV radiation over the same range ($\lambda$ < 360 nm) as biological molecules. This seriously limits the utility of such complexes for direct *in vivo* applications. An additional problem arises from the relatively large energy gap between the emissive and ground states, which requires the use of aromatic antennae with relatively high triplet state energies to sensitise the metal efficiently.[4]

Lanthanides which emit at longer wavelengths have relatively small energy gaps between the excited and the ground state. This allows the use of antennae with much lower triplet state energies, avoiding the competitive excitation of biological chromophores. Time-resolved luminescence from neodymium has been studied recently by deconvolution of the detector response from a nitrogen-cooled germanium diode, allowing the resolution of lifetimes as short as 30 ns. Emission spectra over the range 800–1800 nm were obtained.[5] Ytterbium is another lanthanide which offers the possibility of long-wavelength luminescence. There is only one excited state and it is luminescent ($^2F_{5/2}$) emitting at 980 nm $^2F_{5/2}$–$^2F_{7/2}$). The $Yb^{III}$ ion is not readily reduced ($E_{1/2}$ = −1.35 V, *cf.* −0.35 V for $Eu^{III/II}$), so that competitive photoinduced electron transfer to the Yb from an excited singlet state of an antenna is not likely to occur. Ytterbium luminescence in the solution state has been largely neglected, and reports have concentrated on measurement of the emission spectra of simple systems with no time resolution.[6,7] We have examined the time-resolved luminescence from the ytterbium ion in a variety of solvents by direct excitation or energy transfer from co-dissolved chromophores, and describe examples of intramolecular energy transfer from energy-matched aryl groups in stable complexes with aza-macrocycle based ligands.

Initially, the possibility of intermolecular energy transfer from co-dissolved 4-carboxypropylpyrene ($\lambda_{exc}$ = 355 nm, $\tau$ = 0.34 μs in 50 : 50 MeOH–$H_2O$) and 9-hydroxymethylanthracene ($\lambda_{exc}$ = 266 nm, $\tau$ = 0.81 μs in MeOH) was investigated. Deconvolution and fitting of the decay curves was used to establish the lifetime of emission from the ytterbium centre. Deconvolution from the detector response was made possible by measuring the detector response using a short-lived pump (in our case the laser dye **DCM**). The lifetime was determined by minimising residuals and reduced $\chi^2$ over a range of lifetimes.‡[5] The lifetimes shown in Table 1 are much longer than those of neodymium in aqueous and methanolic solutions {*cf.* $\tau_{H_2O}[Nd(NO_3)_3]$ = 30 ns, $\tau_{MeOH}[Nd(NO_3)_3]$ = 70 ns}.[5] These differences relate to the more facile quenching of $Nd^{3+}$ by energy-matched O–H and C–H oscillators.[5]

Demonstration of direct excitation with ytterbium is more difficult. The absorption and emission spectra of ytterbium are very similar owing to the fact that there is only one readily populated excited state of ytterbium. The ytterbium ion was selectively excited using the output from a YAG driven optical parametric oscillator (OPO) producing photons at 970 nm. Emission was observed in the low energy tail of the emission band by using a 1055 nm interference filter with a 40 nm bandpass.§ As can be seen from the data in Table 1, the lifetimes are solvent dependent. The lifetime is longer in strongly coordinating solvents, such as $Me_2SO$, in which the ligating group stretching harmonics do not correspond well to the energy of the Yb $^2F_{5/2}$ state.

Meshkova and coworkers have reported the use of (2-pyridazo)-2-naphthol in the luminescent determination of ytterbium, but reported no time-resolved studies.[7,8] The 1 : 1 complex of the azo dye with ytterbium was prepared and the lifetime of the luminescence measured. Deconvolution techniques were employed to obtain the lifetime of the known 3 : 1 complex[9] with dibenzoylmethane ($\lambda_{exc}$ = 532 nm, $H_2O$). The luminescent lifetime of the pyridazo complex increased from 557 to 1250 ns on solvent deuteriation. This effect occurs

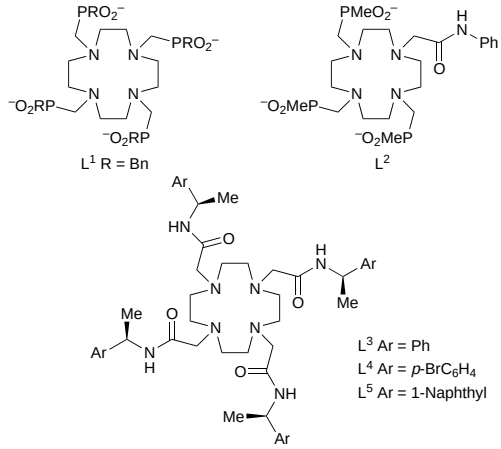

**Table 1** Lifetimes of ytterbium complexes and salts in protiated and deuteriated solvents (293 K; errors on lifetimes are ± 15%)

| Complex[c] | Solvent | Lifetime[a,b]/μs | $\lambda_{exc}$/nm |

| $[YbL^4]^{3+}$ | $H_2O$ | 0.77 | 266 |
| | $D_2O$ | 7.48 | 266 |
| $[YbL^5]^{3+}$ | $H_2O$ | 0.83 | 266 |
| | $D_2O$ | 5.00 | 266 |
| $[Yb(nta)_2]^{3-}$ | $D_2O$ | 8.10 | 970 |
| $[Yb(edta)_2]^{5-}$ | $D_2O$[d] | 10.9 | 970 |
| | $H_2O$ | 2.18 | 970 |
| $[Yb(dtpa)]^{2-}$ | $D_2O$[d] | 8.23 | 970 |
| | $H_2O$ | 0.73 | 970 |

[a] For excitation at 970 nm, decay curves were observed using a 1050 nm interference filter with a 40 nm bandpass with the aid of a polariser to block scattered light from the laser source. [b] Lifetimes were independent of the concentration of dissolved oxygen. [c] dbm = dibenzoylmethane anion, nta = nitrilotriacetate and dtpa = diethylenetriamine pentaacetate. [d] The rate constant for luminescent quenching in these cases was shown to be directly proportional to the mole fraction of $H_2O$ present in $H_2O$–$D_2O$ mixtures.

because the complex formed in solution does not completely encapsulate the metal centre. This allows close diffusion of solvent molecules which quench the luminescence due to coupling between the O–H oscillators and the metal centre. Relaxation *via* O–D oscillators is much less efficient, since only higher harmonics overlap with the metal excited state and the Frank–Condon overlap factor is less favourable. The lifetime of the dibenzoylmethane complex was similarly affected by the nature of the solvent.

In developing probes for long-wavelength luminescence one aim is to provide new methods for the imaging of biological systems. It is necessary that the complexes formed should be kinetically stable and that vibrational quenching by energy-matched oscillators should be minimised. With this in mind, we have investigated the behaviour of complexes of a variety of [12]aneN$_4$ based ligands (L$^1$–L$^5$) and selected acyclic chelating agents . The lifetimes of these complexes have been determined

and are reported in Table 1. The longest lifetimes were observed for the complex of the tetrabenzyl phosphinate, [YbL$^1$]$^-$, ($\tau_{H_2O}$ = 4.5 μs; $\tau_{D_2O}$ = 9.0 μs independent of [O$_2$]) and may be related to the complete encapsulation of the metal centre by the ligand. Recent crystallographic studies on complexes of L$^1$ with Y, Eu, Gd and Yb have shown that there are no coordinated water molecules.[10] Thus quenching of the metal centre is greatly reduced, and a relatively long lifetime is observed, with a small difference between the lifetimes in protiated and deuteriated solvents.[13] The residual quenching effect ($\Delta k_{H_2O/D_2O} = 1.11 \times 10^5\ s^{-1}$) can be assigned to a contribution from closely diffusing, unbound water molecules. This complex is particularly hydrophobic and probably sets a lower limit on this 'outer-sphere' quenching effect.[2,3] Complexes of the related mono-amide triphosphinate L$^2$ with Eu and Tb allow a hydrogen-bonded water molecule to approach the metal centre more closely.[11] This leads to an increased difference between the lifetimes in protiated and deuteriated solvents, and results in slightly shorter lifetimes in water than are observed with the tetraphosphinate. The ytterbium complexes of the tetramide ligands L$^3$–L$^5$ (ref. 12) and dtpa show considerably shorter lifetimes. The presence of one Yb-bound water molecule in these cases is in accord with published crystallographic information on related structures.[14]

The quenching effect of O–H oscillators on the rate constants for ytterbium luminescence may be fitted to eqn. (1),

$$q = A(k_{H_2O} - k_{D_2O}) - B \qquad (1)$$

where $q$ is the number of water molecules coordinated to the metal, $k_{H_2O}$ the quenching rate constant in H$_2$O, $k_{D_2O}$ that in D$_2$O, $A$ is a constant reflecting quenching sensitivity and $B$ is a term representing the quenching effect of outer-sphere water molecules ($0.1 < B < 0.3$). The results in Table 1 allow $A$ to be estimated to be 1.0 μs. Similar empirical relationships have been devised for analogous complexes of europium and terbium,[13] and were modified recently in light of the definition of an outer-sphere quenching effect.[2,3]

In summary, stable complexes of ytterbium have been shown to undergo emission in the near-IR on a microsecond timescale. Such behaviour renders ytterbium complexes attractive candidates for luminescent imaging *in vivo*, particularly since time-gating is possible using existing technologies and sensitised excitation is possible in the range 450–600 nm. In addition, the luminescence method allows the assessment of the hydration state of ytterbium complexes in solution. The results of selected *in vivo* imaging experiments using such systems are under investigation.

‡ Measurement of lifetimes was carried out using the signal observed with a nitrogen-cooled germanium photodiode/amplifier (North Coast EO-817-P) operating in high-sensitivity mode. Decays were analysed by iterative reconvolution and non-linear least-squares analysis of the instrument response profile with a single exponential function, and in all cases gave good fits, as judged by the randomness of three residuals and a satisfactory reduced $\chi$-squared value. Further experimental details and a discussion of the validity of the method can be found in ref. 5.

§ However, the short duration spike arising from scattered light was still sufficiently intense that short lifetimes could not be measured by direct excitation of the metal centre using the established procedures, since the decay was completely subsumed by the spike. Lifetimes in deuteriated solvents or in H$_2$O–D$_2$O mixtures (see Table 1) could, however, be determined by discarding the early data points and fitting the remaining points to an exponential decay.

# Accelerated Diels–Alder reaction of quinones generated *in situ* by a modified electrode in an aqueous sodium dodecyl sulfate micellar system

**Kazuhiro Chiba,* Madoka Jinno, Ayako Nozaki and Masahiro Tada**

*Laboratory of Bio-organic Chemistry, Tokyo University of Agriculture and Technology, 3-5-8 Saiwai-cho, Fuchu, Tokyo 183, Japan*

**Diels–Alder reaction of *in situ* generated quinones with dienes is accomplished in excellent yield in an aqueous sodium dodecyl sulfate solution by selective electrooxidation on a glassy carbon electrode modified by cation-exchange resin.**

A solvent system which possesses internal solvent pressures induces rate acceleration of intermolecular cycloaddition processes.[1] Previously we produced varied cycloadducts *via* electrochemically-generated intermediates in a lithium perchlorate–nitroalkane solution, which was found to accelerate cycloaddition reactions.[2] Aqueous solutions were also shown to be powerful media for Diels–Alder reactions which involved hydrophilic dienes and/or dienophiles.[3] An aqueous solution can also be a facile electrolytic medium for large scale reaction systems, although the acceleration properties of aqueous media are less effective for many organic compounds which are insoluble in water. In addition, dispersion of lipophilic or easily oxidizable compounds in the electrolytic medium often prevents electron transfer by coating, and oxidatively decomposing on, the electrodes. We therefore envisioned that the desired cycloaddition reaction should proceed at the interface of or inside of a micelle in which less polar, easily oxidizable dienes

could be maintained. Here we report our findings, which show that an aqueous sodium dodecyl sulfate (SDS) micellar system can realize the oxidative generation of unstable quinones and the marked acceleration of their cycloaddition with varied dienes.

In a preliminary study, the acceleration properties of emulsifiers for Diels–Alder reactions were examined. An equimolar mixture of quinone (**1** or **2**) and myrcene **3** in benzene or MeCN gave no product after 40 h standing at 25 °C,[4] but very small amounts of cycloadducts were obtained in water even though the starting materials scarcely dissolved (Scheme 1). Although the Diels–Alder reaction was slightly accelerated by some emulsifiers, only SDS was found to accelerate significantly the cycloaddition reaction, which was further promoted by an increase in SDS concentration (Table 1).

As SDS also played a role as supporting electrolyte in water, the dispersion of SDS could be directly applied to the electrolytic system. The anode (glassy carbon, 60 × 20 mm) was firstly coated with Nafion,† and surface sulfonic acid moieties were converted to sulfonamide groups by treating with phenyl(ethyl)amine and DCC in dry MeCN (2 h at room temp.). Electrochemical oxidation was performed in a dispersion of ethyl 3,4-dihydroxybenzoate **7** (1.0 mM) and **10** (1.5 equiv.) in 20 mM SDS in 15 ml of 0.5% acetic acid using the modified anode and a Pt plate (10 × 10 mm) as the cathode in an undivided cell (2.2 F $mol^{-1}$, 0.8 V *vs.* SCE). In this reaction system, water soluble hydroquinones were directly oxidized on the electrode in the presence of dienes to yield the desired cycloadducts **16-24** (Table 2). Although dienes **12**, **13** and **14** were labile on a bare glassy carbon anode, giving cycloadducts in low yield (0–30%), the modified electrode successfully gave the desired products **20**–**23**. Hydrophobic hydroquinones **8** and **9** were barely oxidized in the micellar system, although the selective oxidation of hydroquinones followed by the cycloaddition reaction with dienes proceeded after addition of cerium(III) sulfate (0.02 equiv.) to the electrolytic system (1.2 V *vs.* SCE). It is presumed that $Ce^{IV}$ was effectively generated at the electrode, thus oxidizing the hydrophobic hydroquinones at the interface of the SDS micelle (Fig. 1). Although hydrophilic *p*-quinones which possess electron withdrawing groups were unstable in aqueous media due to Michael addition of $H_2O$, it was found that hydrophobic *p*-quinone generated by cerium oxidation in the SDS micelle gave the desired cycloadducts in excellent yields **29** and **30**. This result showed that decomposition of quinones by the addition of $H_2O$ was prevented in the hydrophobic micelle to give cycloadducts with dienes selectively.

**Table 2** Electrochemical generation and cycloaddition of quinones with dienes in the micellar solution

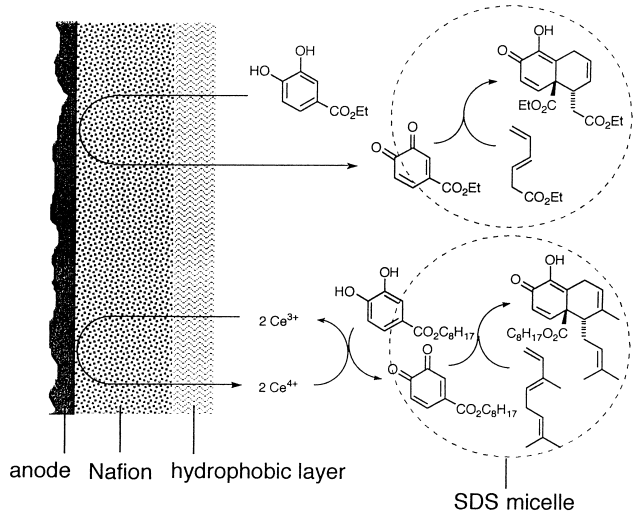

**Fig. 1** Proposed mechanism of Diels–Alder reaction of *in situ* generated quinones in the SDS micellar system using the modified electrode

In conclusion, the electrochemical generation of quinones and subsequent Diels–Alder reaction was accomplished to give varied cycloadducts in a simple, moderate aqueous SDS solution in which the Diels–Alder reaction was markedly accelerated. The modified anode in the SDS micellar solution provided selective oxidation of hydroquinones to give the desired products in high yields (84–100%) and current efficiency (88–96%).

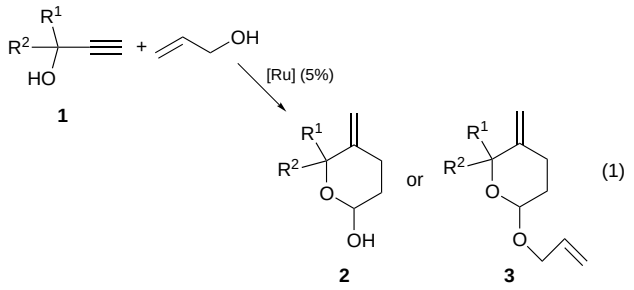
# Ruthenium catalysed formation of 2-alkoxy-5-methylenetetrahydropyrans

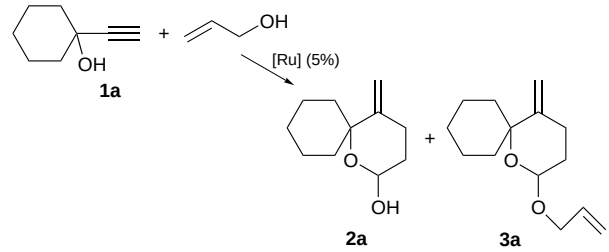


**Sylvie Dérien, Beatriz Gomez Vicente and Pierre H. Dixneuf***

*UMR 6509 CNRS-Université de Rennes 1, Laboratoire de Chimie de Coordination et Catalyse, Campus de Beaulieu, 35042 Rennes, France*

**The regioselective carbon–carbon coupling of prop-2-yn-1-ols with allyl alcohol is achieved in the presence of the ruthenium(II) catalyst RuCl(cod)($C_5Me_5$) and leads to either 2-hydroxy- or 2-allyloxy-5-methylenetetrahydropyrans.**

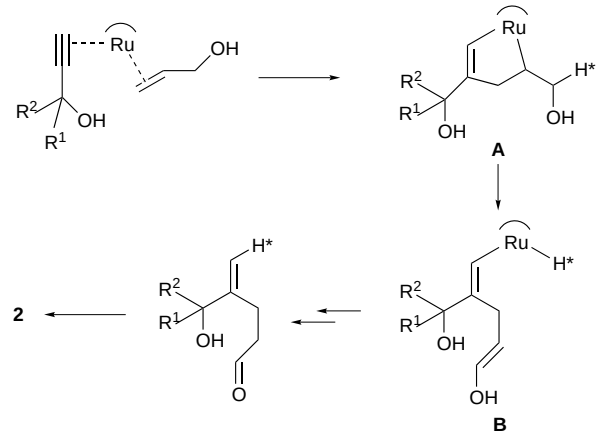
The tetrahydropyran skeleton is a key structure in intermediates for the synthesis of natural products such as terpenoids, pheromones, antibiotics and other biologically active compounds.[1] The 2-alkoxy-5-methylenetetrahydropyrans have been used to give access to 3-hydroxypyran-4-ones, flavouring components,[2] aggregation pheromones,[3] members of the tricothecanes[4] and to precursors of cytotoxic and antitumour active vernolepin.[5] The 2-alkoxytetrahydropyrans are usually conveniently constructed from sugars.[3,4]



We now report a novel, general method leading to new 2-hydroxy- or 2-alkoxy-5-methylenetetrahydropyrans. It is based on a regioselective ruthenium catalysed C–C coupling of prop-2-yn-1-ols with allyl alcohol, with atom economy, according to eqn. (1).

The carbon–carbon bond coupling of C≡C and C=C bonds on a ruthenium(II) centre has already been reported to preferentially lead to linear derivatives[6] and we have shown by contrast that the reaction of terminal alkynes with allyl alcohol in the presence of ruthenium(IV) and ruthenium(II) catalyst precursors led to γ,δ-unsaturated aldehydes[7] with a branched/linear ratio up to 4 : 1.

The reaction of the prop-2-yn-1-ol **1a** (2.5 mmol) with 3 equiv. of allyl alcohol, in the presence of 5 mol% of RuCl(cod)($C_5Me_5$) catalyst[8] (cod = cycloocta-1,5-diene) affords a mixture of **2a** and **3a** below 90 °C. However, when a large excess of allyl alcohol is used (5 ml) the same reaction, performed above 45 °C, leads to the selective formation of the mixed acetal **3a** (Scheme 1). The latter was obtained after 1 h at 80 °C in 80% yield; by contrast, when the reaction was performed at 25 °C (30 min), only the hemiacetal **2a** (80%) was obtained.



These results show that the hemiacetal **2a** is first selectively produced and that further heating in an excess of allyl alcohol selectively leads to the 2-allyloxy acetal **3a**. The reaction corresponds, after displacement of the cod ligand, to the *regioselective* oxidative coupling of the alkyne C≡C and allyl alcohol C=C bonds on the ruthenium centre, leading to **A**, followed by β-elimination involving the exocyclic methylene group, giving the intermediate **B** (Scheme 2). The latter, on reductive elimination, should form a branched γ,δ-unsaturated aldehyde which cyclises into the six-membered hemiacetal **2**. It is noteworthy that the presence of a hydroxy group at the α-position of a terminal C≡CH bond allows the regioselective coupling leading only to the branched isomer, a regioselectivity phenomenon not observed before.[6,7] A ruthenium allenylidene intermediate (Ru=C=C=$CR_2$) usually produced by metal activation of prop-2-yn-1-ols (HC≡$CR_2$OH) followed by water elimination[9] can be ruled out. Indeed the reaction of MeC≡C-$CH_2$OH with allyl alcohol according to the conditions shown in Table 1 also affords the cyclic hemiacetal of type **2** with an exocyclic ethylidene group.

| | | | |
|---|---|---|---|
| allyl alcohol: 3 equiv. | 90 °C, 5 h | — | 30% |
| allyl alcohol: 5 ml | 45 °C, 3 h | 45% | 35% |
| | 45 °C, 20 h | — | 77% |
| | 80 °C, 1 h | — | 80% |
| | room temp., 30 min | 80% | — |

**Scheme 1**

The conditions in Table 1, applied to a variety of prop-2-yn-1-ols with an excess of allyl alcohol, can be used to produce selectively either the corresponding 2-hydroxy- **2** or 2-allyloxy-tetrahydropyrans **3**, respectively. Prop-2-ynyl alcohol **1b** leads to a low yield of **2b** (42%) but **1c** affords selectively **2c** (70%) or **3c** (55%). When unsymmetrically substituted derivatives **1d**–**f** ($R^1 \neq R^2$) were used, diastereoisomers were formed in good yields (51–78%) in the ratio 60 : 40 for both **2d**–**f** and **3d**–**f**

**Scheme 2**

**Table 1** Results of reaction of **1** and allyl alcohol to give **2** and **3**[a]

| | | | Reaction at room temp. | | Reaction at 80 °C | |
|---|---|---|---|---|---|---|
| Alkynol | $R^1$ | $R^2$ | *t*/h | Product (% yield)[b] | *t*/h | Product (% yield)[b] |
| **1a** | $-[CH_2]_5-$ | | 0.5 | **2a** (80) | 1 | **3a** (80) |

| **1e** | Me | $CH_2CHMe_2$ | 2 | **2e** (78)[c] | 5 | **3e** (51)[c] |
| **1f** | Me | $[CH_2]_2CH{=}CMe_2$ | 2 | **2f** (68)[c] | 3 | **3f** (72)[c] |
| **1g** | Me | Ph | 3 | **2g** (73) | 5 | **2g** (60) **3g** (11) |

[a] Reaction conditions: **1** (2.5 mmol) in allyl alcohol (5 ml) was treated with [RuCl(cod)($C_5Me_5$)] (0.125 mmol, 5 mol%) under the conditions shown. [b] Isolated yields after silica gel chromatography. All compounds were fully characterised by spectroscopic methods. [c] Diastereomeric ratio of 60 : 40 determined by $^1$H NMR.

derivatives. This ratio corresponds to the anomer ratio usually obtained from sugar derivatives. However, from the phenyl derivative **1g** only one diastereoisomer **2g** was obtained either at 25 °C (3 h) in 73% yield or at 80 °C (5 h) in 60% yield. In that case the presence of the aryl group slowed down the formation of the allyloxy acetal, and the derivative **3g** could only be observed in 11% yield at 80 °C for 5 h. NOE experiments showed the relative *trans* arrangement of the phenyl group and the OH group of **2g**.

This one-pot ruthenium catalysed regioselective C–C coupling reaction followed by cyclisation takes place with atom economy,[10] and offers a new route to functional tetrahydropyran derivatives. On the basis of the known reactions involving 2-alkoxytetrahydropyrans obtained from sugars,[1] this selective catalytic formation of 2-alkoxy-5-methylenetetrahydropyrans has potential for organic synthesis.

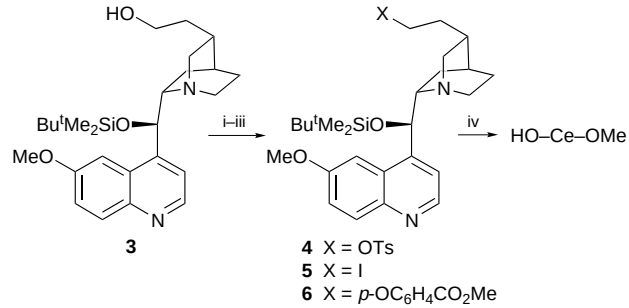
**Thermodynamically-controlled transesterification of a predisposed cinchonidine building block with a more flexible extended quinine monomer leads to a combinatorial mixture of 11 macrocyclic receptors which is analysed by electrospray mass spectrometry; similar results with alkaloid–cholate mixtures demonstrate the generality of the approach.**

We have recently shown that thermodynamically-controlled transesterification can lead to efficient synthesis of oligomeric macrocycles,[1,2] and that when the monomeric building blocks are suitably predisposed a single product may dominate even when other oligomers are kinetically accessible.[3] For example, the cinchonidine monomer **1** (HO–Cc–OMe) is

**1** HO–Cc–OMe

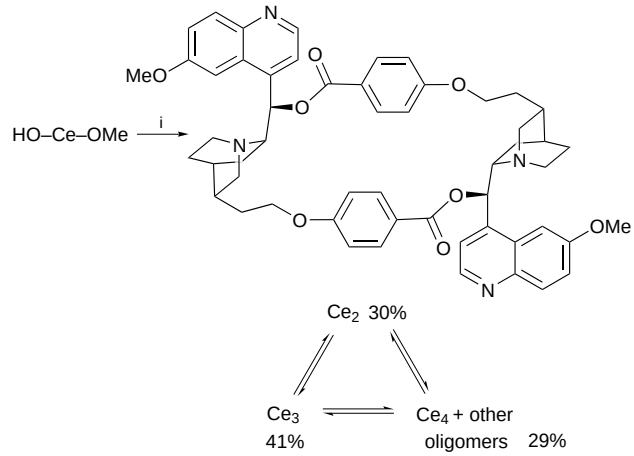


**2** HO–Ce–OMe

predisposed to give almost exclusively the cyclic trimer under thermodynamic control. We now report that the extended quinine monomer **2** (HO–Ce–OMe), in which this predisposition is slightly relaxed, gives access to a wider range of homomacrocycles; more importantly it allows the development of thermodynamically-controlled receptor libraries by combination with other building blocks such as **1**.

In order to relax the predisposition of **1**, we elected to extend the cinchonidine monomer at the 11-position. The chosen extension, a methyl 4-hydroxybenzoate moiety, serves several functions: it is compatible with our transesterification conditions; it programs into the molecule added length to increase the size of any cavity formed and allow access to cyclic dimer; introduces a little extra flexibility; and is still rigid enough to prevent formation of cyclic lactone monomer. Synthesis of **2** started from the previously prepared 11-alcohol **3**.[2] This was converted into the tosylate **4** with tosyl chloride and triethylamine (77% yield), which on heating with NaI in acetone gave 9-*O*-*tert*-butyldimethylsilyl-10,11-dihydro-11-iodo quinine **5** in 86% yield. Compound **5** was converted into **6** (75%) by stirring with methyl 4-hydroxybenzoate, 18-crown-6 and $K_2CO_3$, and removal of the $Bu^tMe_2Si$ group using $Bu_4NF$–THF gave the extended monomer **2** in 78% yield (Scheme 1).

The result of submitting monomer **2** to transesterification under thermodynamic control[2] was a mixture of mainly cyclic dimer ($Ce_2$) : trimer ($Ce_3$) : tetramer ($Ce_4$) and higher oligomeric quinines, with a mass ratio of 30 : 41 : 29 respectively† (Scheme 2). Even though there is still a distinct preference for cyclic trimer,‡ the extension unit has allowed access to cyclic dimer (not previously seen even in kinetic cyclisations of **1**[4]) and tetramer under thermodynamic control, demonstrating the expected relaxation of predisposition.



Under thermodynamic control, mixtures of cinchonidine monomer **1** and preorganised xanthenes self-sort to give good yields of cyclic trimer and dimer respectively because the homo-products are stabilised.[3] However, the relaxed constraints of the extended monomer **2** combined with predisposed **1** lead to quite a different outcome: thermodynamic transesterification of **1** and **2** under the usual conditions led to a combinatorial library of macrocycles, as observed by electrospray mass spectrometry§ (Fig. 1). The mass spectrum contains two of the three possible dimers, all possible trimers and small amounts of all the possible tetramers. It is unwise to draw precise quantitative conclusions from peak intensities since individual species have different inherent detectabilities in electrospray mass spectra, but there are systematic and interpretable deviations from the expected statistical distribution of hetero : homo oligomers. The extended quinine homo-dimer is seemingly favoured over the hetero dimer, which is not surprising given that **1** cannot form homo dimer at all. The trimers show the expected weighting towards the cinchonidine homo trimer but the more promiscuous monomer **2** gives access to two new hetero trimers. To a first approximation, it appears that the tetramers are formed in statistical proportions.

**Scheme 2** *Reagents and conditions*: i, KOMe, 18-crown-6, toluene, reflux, 1 h.

To further examine the idea of relaxation of predisposition monomers **1** and **2** were individually mixed with the cholate monomer **7**, which has enough flexibility to allow access to a

**7** **8**

$R^1$ = OBn
$R^2$ = $OCH_2OCH_2CH_2OMe$

range of cyclic oligomers.[1] Transesterification produced a cocktail of all the possible hetero oligomers of both **1** and **2** with **7**, which is consistent with the idea that if there is enough flexibility in one component then that is generally sufficient to give a range of macrocycles. We had already demonstrated that mixing of **1** with the highly preorganised xanthene monomer **8** leads to self-sorting.[3] To examine how powerfully preorganised **8** is we allowed it to react in the presence of extended quinine monomer **2**: the result was predominantly self-sorting, indicating that preorganised monomers such as **8** find it difficult to form mixtures with monomers that do not have the correct 'bite size' or flexibility.

These results demonstrate that it is possible to generate combinatorial libraries of macrocyclic receptors even when one of the building blocks is predisposed to produce just a single product. By mixing only two monomers we observe 11 cyclic products, showing how large libraries of macrocycles can be

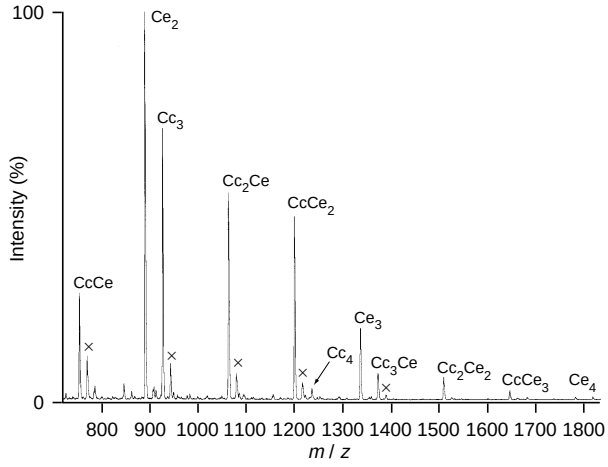

**Figure 1** Electrospray mass spectrum of the thermodynamic cyclisation reaction mixture of **1** (HO–Cc–OMe) and **2** (HO–Ce–OMe). Peaks marked (×) are $NH_4^+$ adducts of molecular ions.

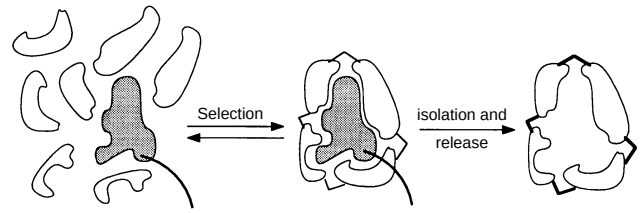

**Fig 2** Schematic representation of a thermodynamic selection approach to receptors

obtained quickly from a small number of monomers. The way is now open for creating thermodynamically controlled macrocyclic receptor libraries (Fig. 2), with the possibility of thermodynamic templating to bias the library towards robust, covalent receptors with good binding properties.[5-7] If the guest is tethered in some way it should also be possible to isolate the receptors from an otherwise hopelessly complex mixture.

We thank Merck, Sharp and Dohme and the EPSRC for generous financial support. We also thank Drs P. A. Brady and D. G. Hamilton for cholate and xanthene samples.

† Determined by 400 MHz $^1$H NMR spectroscopy of the reaction mixture after work up and dissolution in $CDCl_3$: The chemical shifts for $H_{2'}$ were: dimer ($Ce_2$: δ 8.77), trimer ($Ce_3$: δ 8.74) and higher oligomers ($Ce_{4+}$: δ 8.70–8.73).

‡ In the absence of significant enthalpic differences in the stability of oligomers, simple entropic considerations lead to an expected order of abundance monomer > dimer > trimer > tetramer *etc*.

§ ES-MS were obtained on a VG BioQ triple quadrupole apparatus (VG Bio Tech Ltd, Altrincham, UK). The electrospray source was heated to 70 °C and the sampling cone voltage ($V_c$) was 105 V. Samples were introduced into the mass spectrometer source with an LC pump (Shimadzu LC-9A LC pump) at a flow rate of 4 μl $min^{-1}$ of MeCN–$H_2O$ (1 : 1). Calibration was performed using protonated horse myoglobin. Scanning was performed from *m/z* 200 to 2000 in 10 s. The data system was operated as a multichannel analyser, and several scans were summed to obtain the final spectrum. No hetero oligomers are detected in the electrospray mass spectra of control mixtures of homo oligomers.

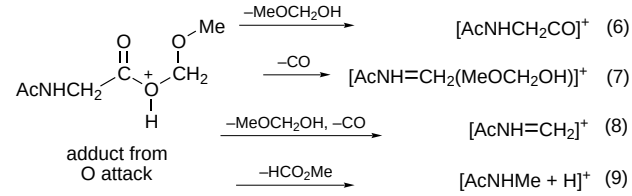
**Methoxymethyl cations and simple *N*-acyl amino acids and dipeptides react in the gas phase to form $[M + MeOCH_2]^+$ ions which fragment *via* a number of pathways including amide bond cleavage.**

A major goal in modern mass spectrometry is the development of techniques to structurally characterize molecules of biological significance. As part of our ongoing research into the gas phase electrophilic modification of biomolecules and model compounds,[1,2] we became interested in designing reagents to sequence biomolecules *via* specific *gas phase* ion–molecule reactions. Thus for peptides, the ultimate aim is to develop site specific ion–molecule reactions to cleave the peptide bonds in an analogous fashion to solution phase chemistry such as the Edman technique.[3–5] Although at first glance such an effort may seem ambitious, we were encouraged during a recent flowing afterglow study on the rates of ion–molecule reactions of the methoxymethyl cation. In particular, we rediscovered a reaction[6] which leads to products arising from amide bond cleavage [eqns. (1)–(3)].



Here we present preliminary results designed to address the question: can the methoxymethyl cation be used to cleave peptide bonds in the gas phase? Experiments were performed on a VG ZAB-2HF reverse sector tandem mass spectrometer.[7] Methoxymethyl cations, which were generated in the chemical ionization source using $MeOCH_2CH_2OMe$ as the CI gas, were allowed to react with peptides and model systems introduced *via* a direct insertion probe. Typical source conditions were: source temperature = 250 °C; electron energy = 70 eV; emission current = 200 mA; source pressure = $7 \times 10^{-4}$ Torr, measured on the source ion gauge. In each case, three major alkylated product ions $[M + MeOCH_2]^+$, $[M + Me]^+$ and $[M + CH]^+$ were formed, consistent with previous studies.[2b,6] In order to gain some insights into the regioselectivity of attack by $MeOCH_2^+$, collisional activated mass-analysed ion kinetic energy (CA-MIKE) spectra were carried out on each of the $[M + MeOCH_2]^+$ ions using argon as the collision gas (at a pressure of $2 \times 10^{-6}$ Torr).

The first model systems we chose to study were the *N*-acyl derivatives of glycine and alanine (Table 1).‡ The $[M + MeOCH_2]^+$ ions of these systems both fragment *via* loss of $CH_2CO$ and $MeCO_2CH_3$. These losses are best rationalized as occuring *via* attack at the amide nitrogen atom to give a nitrogen adduct which then undergoes amide bond cleavage as shown in eqn. (4) [*c.f.* eqn. (3)] and eqn. (5) [*c.f.* eqn. (1)]. Further

products due to loss of $MeOCH_2OH$, $[MeOCH_2OH + CO]$ and $HCO_2Me$ (this loss might arise from hydride ion transfer followed by a proton transfer[8]) are also observed which may arise from initial attack at the C terminus to give an oxygen adduct which then undergoes the fragmentations shown in eqns. (6)–(9). Thus the methoxymethyl cation not only cleaves amide

bonds, but also cleaves the C–OH bond of the carboxylic acid group.

We next turned our attention to the $[M + MeOCH_2]^+$ ions of the free dipeptides glycylglycine, glycylalanine and alanylglycine, which all only fragment to form $[M + CH]^+$ ions as the major product with $[M + Me]^+$ ion formation as a minor reaction channel (Table 1). The lack of attack by the methoxymethyl

[a] (*) Designates an ion with an intensity of less than 1.

cation onto the peptide bond with concomitant fragmentation is consistent with the known gas phase reactivity of glycine[2a] as well as the basicity of the various functional groups within dipeptides. For example, *ab initio* calculations have shown the following basicity order for glycylglycine: N-terminal amino group > oxygen of amide group > nitrogen of amide group > carboxyl carbonyl oxygen).[9]

In order to make the peptide bonds in these dipeptides more susceptible to attack by the $MeOCH_2^+$ ion, we have examined the effects of moderating the gas phase reactivity of the N-terminal amino group *via N*-acetylation. Thus the $[M + MeOCH_2]^+$ ions of *N*-acetyl derivatives‡ of glycylglycine, glycylalanine and alanylglycine not only decompose to form $[M + CH]^+$ and $[M + Me]^+$ ions, but more importantly, several other product ions resulting from amide bond cleavage were observed (Table 1 and Fig. 1). In particular, the CA-MIKE spectra of the $[M + MeOCH_2]^+$ ions of these *N*-acetyl derivatives indicate that attack by the methoxymethyl cation onto the heteroatom adjacent to a C=O group followed by bond cleavage are general. Thus attack at all three sites (labelled as 1–3 in Fig. 2) occurs, thereby providing *complete* sequence information. Consequently distinction between *N*-acetylglycylalanine and *N*-acetylalanylglycine is readily made (Fig. 1). Interestingly, cleavage of the peptide bonds in these instances gives rise to fragments ions (Fig. 2) where the charge is retained at the C terminus (*i.e.* modified Y ions such as $[Y_n + CH]^+$ and $[Y_1 + CH_3OCH_2]^+$ are formed), while the only fragment ion in which the charge is retained at the N terminus is that due to cleavage of the C terminus OH bond to give a $B_3$ ion [for sequence ion nomenclature, see ref. 4(*a*)]. Thus not only does the methoxymethyl cation cleave the peptide bonds, but it cleaves them in a specific fashion, thereby simplifying the mass spectra.

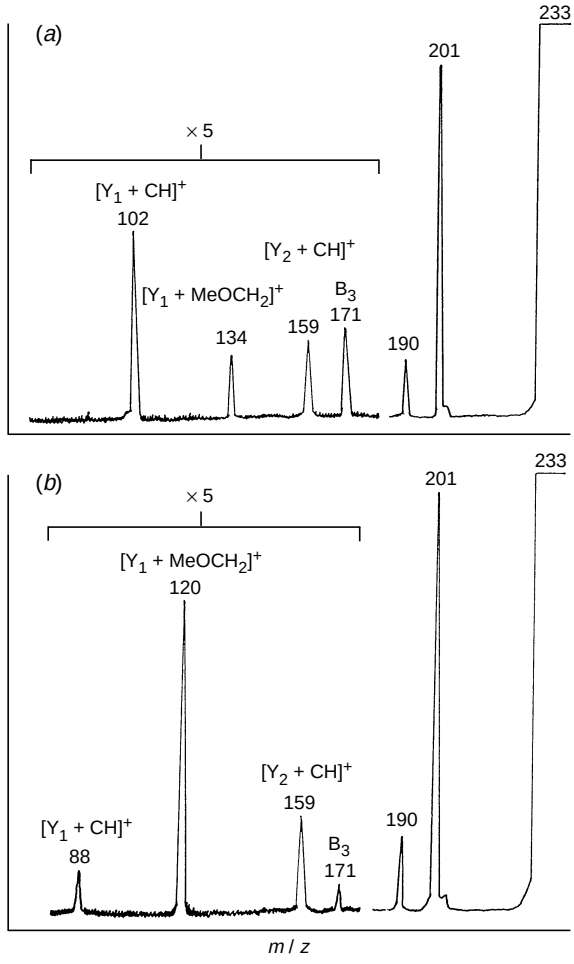

**Fig. 1** CA-MIKE spectra of the $[M + MeOCH_2]^+$ ions of (*a*) *N*-acetylglycylalanine and (*b*) *N*-acetylalanylglycine

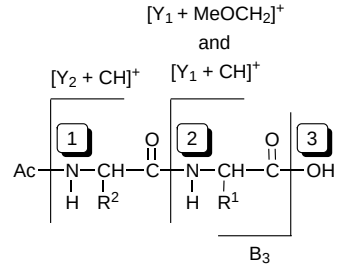

**Fig. 2**

Further work is required to determine the general utility of these reactions to sequence small peptides in the gas phase *via* cleavage of their peptide bonds (the inherent limitations of volatility of the peptide could potentially be overcome using laser desorption CI[10]). In particular the effects of residues with potentially reactive side chains (*e.g.* lysine, aspartic acid *etc*.) need to be investigated. Future studies will also examine the modes of reactivity of other reagent ions such as $ClCH_2^+$.

† Part 8 of the Series 'Gas Phase Ion Chemistry of Biomolecules'.

‡ *N*-Acetyl derivatives were prepared *via* a modified literature procedure (D. P. Knapp, *Methods Enzymol.*, 1990, **193**, 314): The α-amino acid or dipeptide (0.002 mol) was dissolved in 2 ml of 2 M NaOH and chilled in an ice bath. Upon complete dropwise addition of acetic anhydride (2 ml), the mixture was stirred for a further 10 min followed by careful acidification to pH < 4 with $H_2SO_4$. The solution was allowed to warm to room temperature and extracted with EtOAc (3 × 25 ml). The combined EtOAc layers were dried with anhydrous $Na_2SO_4$ and the solvent was removed *in vacuo*. The resultant *N*-acetyl derivatives were purified *via* recrystallization from MeOH. All other compounds were of reagent grade obtained commercially and were used without further purification. $H_2{}^{15}NCH_2CO_2H$ (99 atom% $^{15}N$) and $H_2NCD_2CO_2H$ (98 atom% D) were both obtained from Cambridge Isotope Laboratories.

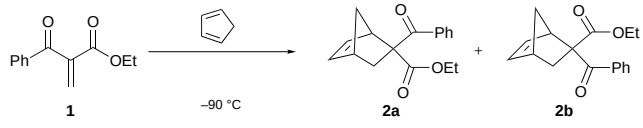
# Enantioselective catalytic Diels–Alder reaction of ethyl 2-benzoylacrylate with chiral bis(oxazoline)– or mono(oxazoline)–magnesium complex

**Yuko Honda,[a] Tadamasa Date,[b] Hajime Hiramatsu[b] and Masashige Yamauchi*[a]**

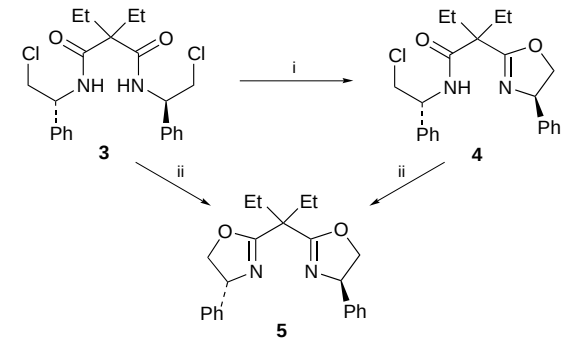
[a] *Faculty of Pharmaceutical Sciences, Josai University, Keyakidai, Sakado, Saitama 350-02, Japan*
[b] *Analytical Research Laboratory, Tanabe Seiyaku C., Ltd, Kashima, Yodogawaku, Osaka 352, Japan*



**The magnesium catalysed Diels–Alder reaction of 2-benzoylacrylate gave the *endo*-adduct enantioselectively with bis(oxazoline) 5 as a $C_2$-symmetric ligand or mono-(oxazoline) 4 as a non-$C_2$-symmetric ligand.**

A great deal of effort has been invested in enantioselective Diels–Alder reactions catalysed by chiral Lewis acids, and tremendous advances have been achieved in recent years.[1] $C_2$-Symmetric ligand–metal complexes have proven to be excellent catalysts, and in most cases *N*-α,β-unsaturated acyloxazolidinones have been used as two-point dienophile binding agents in these reactions.[2] Recently, non-$C_2$-symmetric phosphinoaryloxazolines have been shown to be effective ligands for Pd-catalysed asymmetric allylic substitution.[3] We have reported a highly diastereoselective and *endo/exo* selective Diels–Alder reaction of (1′*R*,2′*S*,5*R*)-5-methyl-2-methyl-2-(1-phenylethyl)cyclohexyl 2-benzoylacrylate with cyclopentadiene catalysed by a Lewis acid.[4] This suggests that an enantioselective Diels–Alder reaction should occur using ethyl 2-benzoylacrylate **1**,[5] a two-point binding dienophile, in the presence of a chiral Lewis acid. Herein, we describe the magnesium-catalysed Diels–Alder reaction of **1**, as dienophile, with cyclopentadiene using *N*-[(1*R*)-2-chloro-1-phenylethyl]-2-ethyl-2-[(4*R*)-4-phenyl-4,5-dihydro-1,3-oxazol-2-yl]butyramide **4** as a non-$C_2$-symmetric chiral ligand and bis(oxazoline) **5** as a $C_2$-symmetric chiral ligand.

Our initial efforts were focussed on the possibility that ethyl 2-benzoylacrylate **1** should be a good two-point binding dienophile in an enantiomeric Diels–Alder reaction with cyclopentadiene by use of bis(oxazoline) **5**–magnesium complex. In the reaction with the complex prepared from **5**, $MgI_2$ and $I_2$ (co-catalyst) in $CH_2Cl_2$ at room temperature by Corey's procedure,[2b] the enantioselectivity was not particularly high (Table 1, entry 1), but the selectivity was much improved with the complex prepared in refluxing MeCN (entry 2). The diastereoisomers showed one spot by TLC and could not be resolved by column or medium pressure chromatography, but the ratio was determined by $^1$H NMR spectroscopy as mentioned in our previous report,[4] and in most cases only the *endo*-isomer was obtained (Table 1).



As **1** proved to be a suitable dienophile, we next examined the reaction using *N*-[(1*R*)-2-chloro-1-phenylethyl]-2-ethyl-2-[(4*R*)-4-phenyl-4,5-dihydrooxazol-2-yl]butyramide **4** as a chiral ligand. Compound **4** was synthesized by treatment of dichloride **3** with an equimolar amount of NaOH in MeOH–$H_2O$ at 60 °C. In contrast to the fact that most of the bis(oxazoline)s used as chiral ligands are oily materials, the mono(oxazoline) **4** exists as colourless prisms (mp 127–128 °C from EtOAc) and is therefore easy to handle. The reaction with the complex prepared from **4**:$MgI_2$:$I_2$ (1:1:1) in $CH_2Cl_2$ at room temperature also gave poor enantioselectivity (entry 3). When the reaction was performed with the complex prepared in refluxing MeCN, the ee increased to 87% (entry 4). Interestingly, the enantioselectivities of the reactions with the complex prepared from $MgI_2$:**4**:$I_2$ (1:2:2) were almost equal or slightly higher (entries 5,6). It is well known that head or tail enrichment may occur during chromatography on achiral columns of samples containing an excess of one enantiomer.[2i,6] We therefore collected all the Diels–Alder adducts before $^1$H NMR and HPLC analyses. After separation of the *endo* adduct by preparative HPLC, if necessary, the enantioselectivities were determined by analytical HPLC.‡ Furthermore, the ligands

were recovered almost quantitatively from column chromatography as the last fraction. The absolute configuration of **2a** was confirmed by treatment of **2a** with bromine in $CCl_4$ to give bromo-lactone **6**, whose absolute structure was determined by X-ray crystallography (Fig. 1).§

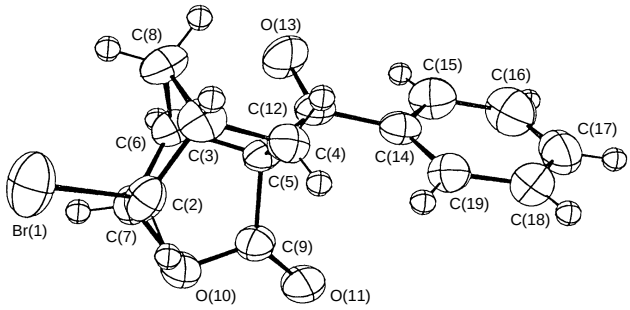

**Fig. 1** ORTEP diagram of **6**

The almost perfect diastereoselectivity of the reaction can be rationalised to be due to the steric hindrance of the benzene ring situated nearly perpendicular to the ene in the fixed metal-chelated enedione as mentioned earlier.[4] However, the reaction mechanism giving high enantioselectivity using mono(oxazoline) is unclear. An attempt to capture the complex of the Lewis acid–chiral ligand or Lewis acid–ligand–dienophile in crystal form has not been successful. Further investigations to clarify the precise structures of the catalysts formed from **4** : $MgI_2$ : $I_2$ (1 : 1 : 1 and 2 : 1 : 2) and the reaction mechanism as well as to develop other asymmetric reactions using this complex are now in progress.

† General experimental procedure: a mixture of the ligand, $MgI_2$ and $I_2$ in the solvent was treated under the conditions shown in Table 1. The solvent was removed and the resulting complex was dissolved in $CH_2Cl_2$ (1.0 ml) and cooled at −90 °C. To this solution **1** (1 mmol) in $CH_2Cl_2$ (1.5 ml) was added and stirred for 30 min, then cyclopentadiene (1.5 mmol) in $CH_2Cl_2$ (2.5 ml) was added slowly for a period of 3 h. After the reaction was completed the reaction mixture was quenched with water and washed with 5% aqueous $Na_2S_2O_3$. The organic layer was dried and evaporated. The resulting residue was subjected to column chromatography to yield the adducts.

‡ Preparative HPLC was carried out with a JASCO Megapak SIL-10 column (1.0 × 25 cm; eluate 5% AcOEt in hexane) and analytical HPLC with a Daisel CHIRALCEL OD column (0.46 × 25 cm; eluate 0.1% propan-2-ol in hexane).

§ *Crystal data* for **6**: $C_{15}H_{13}O_3Br$, $M$ = 321.16, orthorhombic, space group $P2_12_12_1$, $a$ = 10.935(1), $b$ = 18.884(1), $c$ = 6.326 (1) Å, $U$ = 1287.7(2) Å$^3$, $Z$ = 4, $D_c$ = 1.66 g cm$^{-3}$, $\mu$(Cu-K$\alpha$) = 4.37 mm$^{-1}$. Reflections were measured on a Rigaku AFC5R diffractometer in the range 4.7 < $\theta$ < 65.1° (Cu-K$\alpha$ radiation) with the $\omega$–2$\theta$ scan technique, 2154 reflections were used for all calculations. The structure was solved by direct methods [SHELX-86 (ref. 7)] and refined anisotropically on $F^2$ (SHELXL-93 (ref. 8)]. All hydrogen atoms were refined for all parameters; $wR_2(F^2)$ = 0.0773 with $R(F)$ = 0.0303 for 225 parameters. The absolute configuration was determined Flack's $\chi$-parameter (ref. 9) −0.02(2). # Non-ionic [2]rotaxanes containing methylated α-cyclodextrins

**Akira Harada,* Jun Li and Mikiharu Kamachi**

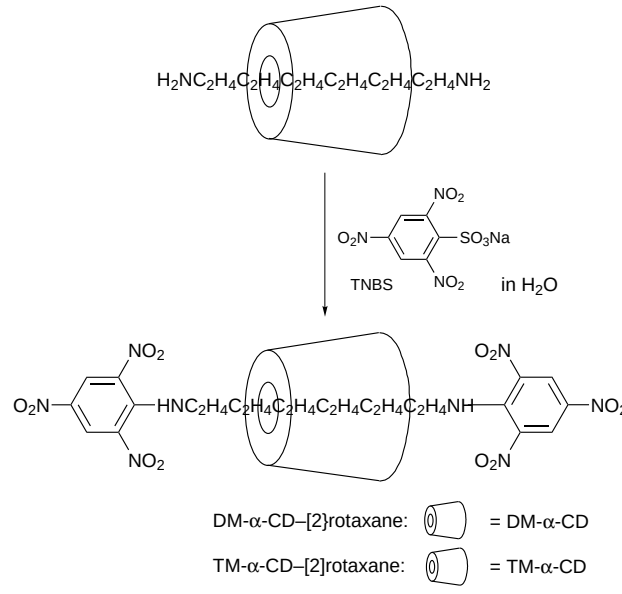
*Department of Macromolecular Science, Graduate School of Science, Osaka University, Toyonaka, Osaka 560, Japan*

**Non-ionic [2]rotaxanes have been prepared from complexes of oligoethylene derivatives with methylated α-cyclodextrins by capping them with trinitrophenyl groups as stoppers.**

Recently, much attention has been focused on the construction of interlocked molecular structures, such as rotaxanes and catenanes, because of their unique structures and properties.[1] Crown ethers,[2] cyclodextrins (CD),[3] cyclophanes[4] and cucurbituril[5] have been used as ring components of rotaxanes. Symmetric[6] and asymmetric[7] [2]rotaxanes containing α-CD and methylated β-CD have been prepared and characterized. However, all the [2]rotaxanes are ionic and in some cases their stoppers are metal complexes which are in equilibrium with dissociation states, so rings may come off. To obtain non-ionic [2]rotaxanes, it is necessary to design a dumbbell part which consists of neutral stoppers and a neutral axle. We chose a 2,4,6-trinitrobenzenesulfonic acid sodium salt (TNBS) as a stopping agent and diaminohexaethylene dihydrochloride (DAHE-2HCl) as an axle because TNBS is large enough to prevent dethreading and DAHE-2HCl is long enough to penetrate a methylated α-CD cavity. Moreover, TNBS and the amino groups of DAHE react easily with each other to give a covalent C–N bond in aqueous solution under mild conditions. 2,6-Di-*O*-methyl-α-CD (DM-α-CD) and 2,3,6-tri-*O*-methyl-α-CD (TM-α-CD) were chosen as ring molecules, because they are highly soluble in water and are able to form complexes with oligoethylene derivatives in aqueous solutions. Here we report the first preparation of non-ionic [2]rotaxanes based on the formation of the inclusion complexes.

α-CD forms complexes with ω, ω′-diaminoalkanes to give crystalline complexes. However, DM-α-CD and TM-α-CD did not form crystalline complexes, forming instead soluble complexes with ω, ω′-diaminoalkanes in an aqueous solution, although DAHE is insoluble in water. DAHE could be dissolved in aqueous solutions of DM-α-CD or TM-α-CD. The molar ratio of DAHE dissolved to the methylated α-CD is 1 : 1, indicating formation of 1 : 1 complexes. The complexes were allowed to react with TNBS to prevent dethreading of the cyclodextrins (Scheme 1). The products precipitated from water and were collected and purified by preparative thin layer chromatography (TLC) on $SiO_2$. This gave two kinds of [2]rotaxanes containing DM-α-CD and TM-α-CD, respectively. The [2]rotaxanes were obtained in high yields; 42% for DM-α-CD-[2]rotaxane and 48% for TM-α-CD-[2]rotaxane.

The products were characterized by elemental analysis, UV–VIS, $^1$H NMR, $^{13}$C NMR and FAB mass spectra.† TLC of the products on $SiO_2$ plates (90 : 10, $CHCl_3$–MeOH) revealed single spots in each case. The products showed absorptions at 417 and 347 nm, indicating that the 2,4,6-trinitrophenyl groups were substituted on the axles. The UV–VIS spectra as well as the $^1$H NMR spectra and elemental analyses revealed that the ratio between the methylated α-CD and DAHE-$TNP_2$ was 1 : 1.



The $^1$H NMR spectrum of TM-α-CD-[2]rotaxane shows that it is composed of TM-α-CD, an HE chain and trinitrophenyl end groups in the proper ratios, that is, a single TM-α-CD unit, one HE chain and two TNP end groups. The peaks of TM-α-CD and DAHE-$TNP_2$ in the spectrum of [2]rotaxane show some shifts compared with those of its components, indicating that TM-α-CD and a HE chain are imprisoned in a single molecule. The $^1$H NMR spectrum of DM-α-CD-[2]rotaxane showed similar results.

Fig. 1 shows the $^{13}$C NMR spectrum of DM-α-CD-[2]rotaxane together with those of DM-α-CD and DAHE-$TNP_2$. The spectrum shows that the compound is composed of a single DM-α-CD and a single DAHE-$TNP_2$ unit. The C(c) and C(d) resonances of the TNP group split into two peaks, respectively. One is due to the TNP group at the small side of DM-α-CD and another is due to the TNP group at the larger cavity side. The C(e) resonance of the HE chain also separates into two peaks for the same reason. The resonances of the HE backbone split into a more complex pattern indicating that the HE chain is included in the cavity of DM-α-CD.

The FAB MS spectra of the two [2]rotaxanes are characteristic of DM-α-CD-[2]rotaxane and TM-α-CD-[2]rotaxane, respectively. In addition to peaks for the molecular ions and those with sodium, fragmentation peaks for the components are also observed.

The solubilities of the two [2]rotaxanes are quite different from those of their components. The [2]rotaxanes are insoluble in water, although DM-α-CD, TM-α-CD, TNBS and even complexes of DAHE with methylated α-CDs are soluble in water. The rotaxanes are soluble in most organic solvents such as chloroform, benzene, DMSO and DMF. The solubilities of the rotaxanes in organic solvents are higher than the thread and stopper molecule DAHE-$TNP_2$. The rotaxanes do not dethread into their components in any solvents, because the stopper group is covalently bound to the thread.

In conclusion, new neutral non-ionic [2]rotaxanes containing methylated CDs were prepared by utilizing the complex formation of derivatives of ω,ω′-diaminoalkane and methylated α-CDs in high yields. The rotaxanes obtained here have the simplest structures of such supramolecular compounds containing CDs reported, which enables us to study the basis of

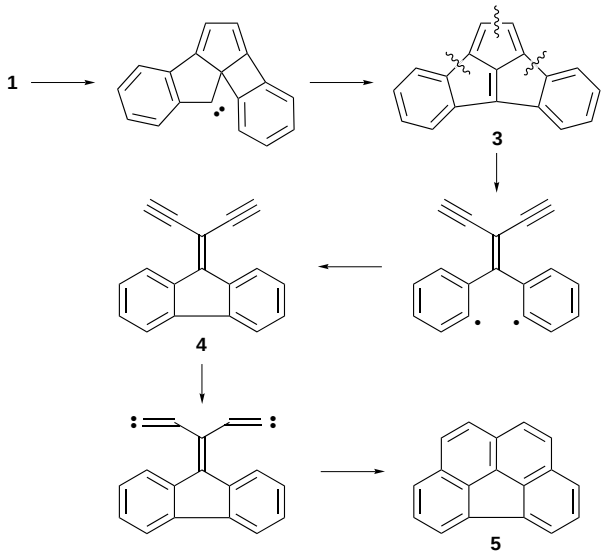
# From phenylenes to acenes: flash vacuum pyrolytic isomerization of angular [3]phenylene to benzo[*ghi*]fluoranthene

**Adam J. Matzger and K. Peter C. Vollhardt***

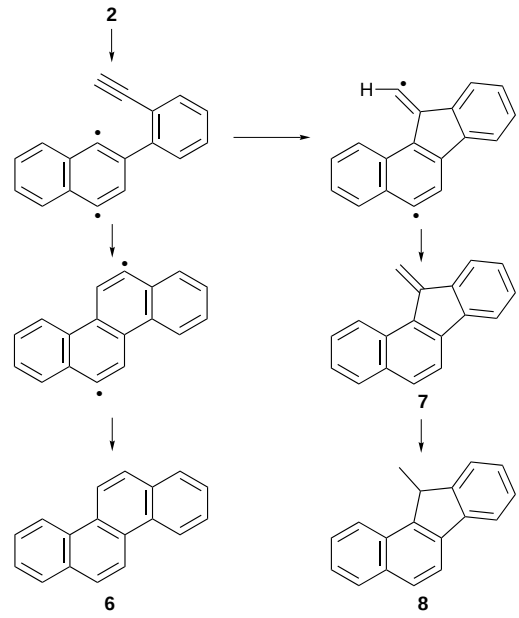
*Department of Chemistry, University of California at Berkeley and the Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 94720-1460, USA*

**The flash vacuum pyrolysis of angular [3]phenylene and bis(2-ethynylphenyl)ethyne produces benzo[*ghi*]fluoranthene and chrysene, respectively.**

Recently there has been much attention focused on the thermal interconversion of aromatic hydrocarbons because of its relevance to the formation of fullerenes[1] and environmental pollutants.[2] In connection with this, the fate of **1**[3] was of great interest because of its inherent strain and thus, its potential to equilibrate with its linear conterpart,[4] undergo retrocyclization to **2**,[5] or cascade into known $C_{18}H_{10}$ manifolds.[1,2]



**1** **2**



Initial experiments, in which **1** was sublimed through a quartz tube at 780 °C, resulted in essentially complete recovery of starting material. This result is not surprising, considering that **1** was first synthesized by pyrolytic methods at 800 °C.[6] Remarkably, however, at 1000 °C, the major isolable product was the unanticipated isomer benzo[*ghi*]fluoranthene **5** (10%),[7] in addition to minor quantities of chrysene ($C_{18}H_{12}$) **6** (2.5%) and fluoranthene ($C_{16}H_{10}$) (1%). A proposed mechanism for the transformation of **1** to **5** is outlined in Scheme 1. The first steps involve isomerization to dibenzoacepentalene **3**,[8] a formal Stone–Wales rearrangement.[1*a*] Stepwise or concerted cleavage of the five membered rings would afford diethynyldibenzofulvene **4** after phenyl radical recombination. The last two steps have their closest analogy in the synthesis of corannulene by flash vacuum pyrolysis (FVP) of an etheno-bridged, trimethylsilyl-protected derivative of **4**.[9]† The origin of chrysene may be **2** (*vide infra*). Significantly, **5** is not the product that might be expected on the basis of the results of the pyrolysis of biphenylene,[10] namely cyclopent[*hi*]acephenanthrylene (which has been shown to be inert to rearrangement to **5** under our conditions),[1*d*] presumably a consequence of the regioselectivity of the initial 1,2-shifts enforced by the proximity of the two four-membered rings.

As a control experiment, the FVP of **2** was executed. At 780 °C, all of the starting material had been consumed and chrysene **6** constituted the major isolated product (1.9% yield), none of **5** being present. A possible pathway from **2** to **6** is patterned after that proposed by Bergman in the solution thermolysis of the corresponding parent dienetriyne to form naphthalene (Scheme 2).[11] In the latter, the added hydrogen in the product is supplied by the solvent. The absence of an obvious hydrogen source in the FVP of **2** explains the low yield of **6**. Deuterium labelling of the terminal triple bonds‡ supported the proposed mechanism by furnishing only [5,11-$^2H_2$]chrysene. Note that neither **1** nor **3** are formed even at 1000 °C.

To further corroborate the fate of **2**, it was heated in benzene solution (205 °C) in the presence of cyclohexa-1,4-diene. Surprisingly, the major product was not **6** (2.5%), but rather 11-methyl-11*H*-benzo[*a*]fluorene **8** (19%).[12]§ We propose that the initially formed 1,4-didehydronaphthalene from **2** bifurcates to not only undergo 6-*endo*-digonal but also 5-*exo*-digonal

**Scheme 1**

**Scheme 2**

closure to form the five membered ring (Scheme 2). The resultant diradical would then be capped with hydrogen from cyclohexa-1,4-diene to provide the reactive fulvene **7** which undergoes fast transfer hydrogenation under the reaction conditions to yield **8**.[13] Further evidence for the intermediacy of **7** is found in the thermolysis of **2** in MeOH at 217 °C, in which the methyl group of the solvent is the hydrogen source. In this case 11-(2-hydroxyethyl)-1*H*-benzo[*a*]fluorene¶ is formed (26%) along with **6** (4.3%). This product is suggested to arise by trapping of **7** with ·$CH_2OH$, followed by H abstraction from MeOH. The absence of products arising from 5-*exo* closure in the gas phase pyrolysis suggests that equilibration of the two diradicals to give the more stable didehydrochrysene is rapid under the conditions employed and/or that decomposition of the dibenzofulvene occurs in the absence of a good hydrogen donor.

Finally, we note that the observed conversion of phenylene **1** to the cyclopenta fused polycyclic benzenoid **5** constitutes the first of a series of potential conversions of larger phenylenes to semifullerenes.

## Footnotes

* E-mail: vollhard@cchem.berkeley.edu

† This report describes **5** as a side product, resulting from loss of $C_2$. Consistent with this finding is our observation of fluoranthene in the pyrolysis of **1**.

‡ Synthesized from bis[2-(trimethylsilylethynyl)phenyl]ethyne using MeOD and $K_2CO_3$.

§ GC–MS indicates that most of the diradicals formed add to cyclohexadiene or benzene rather than being trapped as **4** or **5**, thus accounting for the low combined yield of these products (21.5%).

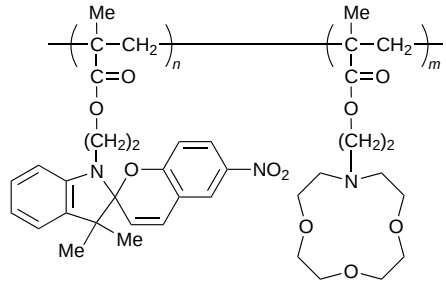
# Drastic metal-ion enhancement in photoinduced aggregation of copolymers carrying crown ether and spirobenzopyran moieties



**Keiichi Kimura,* Miwa Sumida and Masaaki Yokoyama**

*Chemical Process Engineering, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565, Japan*

**Metal ion complexation of the crown ether moiety of crown ether–spiropyran copolymer 1 brings about the enhanced aggregation of its merocyanine moiety, formed by photoisomerization of its spiropyran, which results in reversible polymer precipitation.**

Spirobenzopyran derivatives, typical photochromic compounds,[1] when isomerized to their corresponding merocyanine forms, tend to aggregate.[2] The aggregation of the merocyanine isomers is enhanced in polymers carrying spirobenzopyran moieties on their side chains.[3]

Spirobenzopyran derivatives incorporating a monoazacrown ether moiety are attractive materials which can realize photochemical control of cation complexation.[4,5] Since an easy way to combine a spirobenzopyran moiety with a crown ether moiety is copolymerization of vinyl monomers carrying their corresponding functional moieties, we have designed such polymers **1** carrying side chains with monoaza-12-crown-4 and spirobenzopyran moieties. During the course of investigating the cation complexation and photochromism of the crown ether–spiropyran copolymer **1**, we have discovered an intriguing phenomenon. Herein we report the reversible photoinduced aggregation and precipitation of polymer **1** enhanced dramatically by cation complexation of its crown ether moieties.

**1** *n* / *m* = 1

Radical copolymerization of an equimolar amount of the corresponding vinyl monomers of monoaza-12-crown-4 and spirobenzopyran[6] afforded crown ether–spiropyran copolymer **1** which possessed a composition of almost 1 : 1 (spiropyran–crown ether unit) and a number average molecular weight of $1.3 \times 10^4$ (polystyrene standard). The cation complexing ability of **1** toward alkali metal ions, which was estimated by a conventional solvent extraction technique, is in the order $Na^+ > K^+ > Li^+$, as shown in Fig. 1. The crown ether–spiropyran copolymer **1** has a very different ion selectivity from its corresponding monomeric crown ether, *N*-benzylmonoaza-12-crown-4 (10-benzyl-1,4,7-trioxa-10-azacyclododecane). The higher cation complexing ability toward $Na^+$ and $K^+$ than $Li^+$ is probably due to the easy formation of intrapolymer 2 : 1 (crown ether ring–metal ion) complexes with $Na^+$ and $K^+$ by cooperative action of two neighbouring crown ether rings, as was the case with poly(12-crown-4) derivatives.[7] Intrapolymer sandwich-type complex formation promotes cation binding and thereby cation extraction.

UV irradiation (300–400 nm) causes isomerization of the spiropyran moiety of **1** to its corresponding merocyanine from, which in turn brings about aggregation of the resulting zwitterionic merocyanine moieties. This phenomenon was suggested in absorption spectral changes of a THF solution of crown ether–spiropyran copolymer **1**. The behaviour of the merocyanine aggregation of **1** in the presence of an equimolar amount of alkali metal perchlorate is distinct from that in the absence of any metal salt, as illustrated by the absorption maximum difference for its merocyanine moiety after 5 min of UV irradiation (Fig. 2). In the absence of metal ions, the photoirradiation caused an increase in the absorption peak around 600 nm assigned to the non-aggregated merocyanine moiety, which shifted gradually to shorter wavelength (560 nm) after prolonged photoirradiation. The blue shift of the merocyanine absorption peak can be attributed to the formation of H-type aggregates.[3] Further UV irradiation caused little change in the absorption spectrum. In a solution containing $Li^+$ ions, on the other hand, the absorption around 560 nm attributed to H-type aggregation appeared after only 5 min of irradiation, with a colour change of the solution from colourless to purple. Further irradiation decreased the absorption with a slight red shift, and then purple-coloured polymer started to precipitate from the solution. The modest blue shift in a solution containing $Na^+$ ions indicates that the H-type aggregate formation is sluggish in the system containing $Na^+$ ions as compared with that containing $Li^+$ ions. Since, in a solvent in which they are moderately soluble (*e.g.* THF), polymer molecules of **1** generally cast in a contracted form in the absence of metal ions, the photoisomerized merocyanine moieties are likely to form intramolecular aggregates in a polymer chain. In the presence of

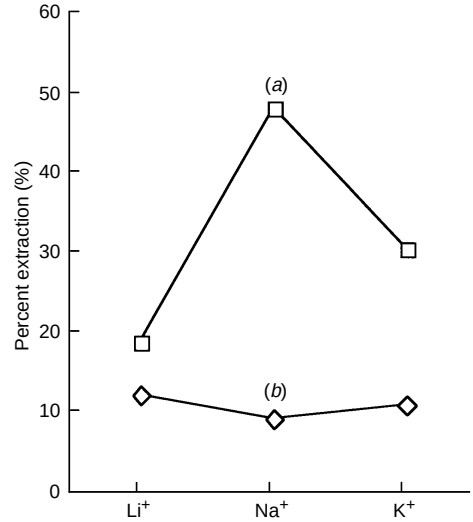


**Fig. 1** Cation extraction (*a*) by crown ether–spiropyran copolymer **1** and (*b*) comparison with *N*-benzylmonoaza-12-crown-4. Aqueous phase: 0.1 mol $dm^{-3}$ alkali metal hydroxide, $7 \times 10^{-5}$ mol $dm^{-3}$ picric acid. Organic phase: $2.1 \times 10^{-3}$ mol $dm^{-3}$ crown ether unit in 1,2-dichloroethane. Extracted for 15 min in the dark.

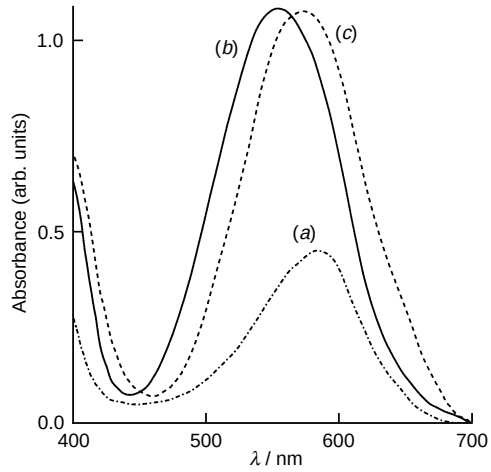

**Fig. 2** Absorption spectra of crown ether–spiropyran copolymer **1** in THF (*a*) without metal ion, (*b*) with $LiClO_4$, and (*c*) with $NaClO_4$, after UV irradiation for 5 min. Polymer **1** and metal perchlorate: $4 \times 10^{-4}$ mol $dm^{-3}$ each in THF. UV light: 300–400 nm.

metal ions, however, the polymer chains carry positive electric charges due to cation complexation with its crown ether moieties, and therefore the polymer chains expand due to intramolecular electrostatic repulsion among the cationic charges.[8,9] The expansion of the polymer chains increases the probability of formation of an interpolymer merocyanine aggregate while suppressing the intramolecular (intrapolymer) one. Thus, the interpolymer merocyanine aggregation induces crosslinking of **1**, finally leading to the polymer precipitation.

Very interestingly, the polymer precipitate formed on UV irradiation in the presence of the metal ion can be dissolved again by subsequent visible light irradiation (for 20 min), leaving the solution almost transparent. This means that the UV-induced precipitation and visible light-induced dissolution of polymer **1** in the presence of $Li^+$ ions is quite reversible. This is also the case in the presence of $Na^+$ ions, although the UV-induced merocyanine aggregation and precipitation is not as easy as in the $Li^+$ system. This is probably because polymers carrying a 12-crown-4 moiety at the side chain tend to form intramolecular 2 : 1 (crown ether ring–metal ion) complexes with $Na^+$.[7,10] This intramolecular formation of the sandwich-type complexes suppresses more or less the polymer chain expansion which is required for the interpolymer merocyanine aggregation.

Thus, reversible photocontrol in the precipitate formation of crown ether–spiropyran copolymer **1**, based on cation complexation-induced merocyanine aggregation, has been realized in THF solutions containing metal ions. Further studies are now under way to elucidate the properties of the polymer precipitate.

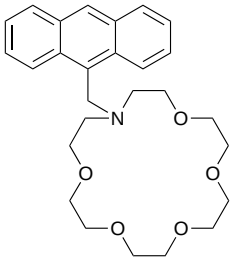
# Selective D-glucosamine hydrochloride fluorescence signalling based on ammonium cation and diol recognition

**Christopher R. Cooper and Tony D. James***

*The University of Birmingham, School of Chemistry, Edgbaston, Birmingham, UK B15 2TT*

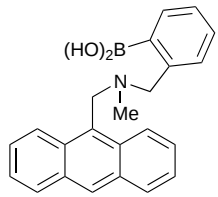
**Fluorescent photoinduced electron transfer sensor 1 with monoaza-18-crown-6 ether and boronic acid receptor units shows selective fluorescent enhancement with D-glucosamine hydrochloride in aqueous solution at pH 7.18.**

The development of fluorescent receptors for saccharides has recently gained much attention.[1] In a series of recent papers the interaction of boronic acid and amine[2–6] has been used to create photoinduced electron transfer (PET)[7,8] sensory systems for saccharides. When saccharides from cyclic boronate esters with boronic acids, the acidity of the boronic acid is enhanced[9] and therefore the Lewis acid–base interaction between the boronic acid and the tertiary amine is strengthened. The strength of this acid–base interaction modulates the PET from the amine (acting as a quencher) to anthracene (acting as a fluorophore). These compounds show increased fluorescence at neutral pH through suppression of the photoinduced electron transfer from nitrogen to anthracene on saccharide binding; a direct result of the stronger boron–nitrogen interaction.[2–7]



**Scheme 1** *Reagents and conditions*: i, NaH, $Me_3SI$, DMSO, room temp., 80%; ii, LiBr, MeCN, 60 °C, quant.; iii, $MeSO_2Cl$, $Et_3N$, $CH_2Cl_2$, −10 °C, 93%; iv, 1-aza-18-crown-6, $K_2CO_3$, NaI, MeCN, reflux, 50%; v, MeOH, $MeNH_2$, room temp., quant.; vi, $NaBH_4$, MeOH, room temp., quant.; vii, $K_2CO_3$, MeCN, reflux, 30%; viii, EtOH–$H_2O$ (1 : 2), pH 7.3, quant.

In a recent paper de Silva reports[10] on how two different binding sites can be used to develop a selective fluorescent sensor for γ-aminobutyric acid. The system consists of an azacrown ether (ammonium binding site) and guanadinium (carboxylate binding site). This work shows how two different receptor sites can be used to obtain high selectivities for molecules containing multiple functional groups. We have previously shown how two boronic acid binding units can be used in the selective recognition of glucose[3] and the chiral discrimination of monosaccharides.[4] Here we extend our work on boronic acid fluorescent sensors by the incorporation of a second and *different* binding site. The incorporation of a second binding site will allow the development of sensors for a variety of biologically important molecules containing saccharide fragments.



Sensor **1** consists of monoaza-18-crown-6 ether as a binding site for the ammonium terminal of D-glucosamine hydrochloride, while a boronic acid serves as a binding site for the diol (carbohydrate) part of D-glucosamine hydrochloride. The nitrogen of the azacrown ether unit can participate in PET with the anthracene fluorophore; ammonium ion binding can then cause fluorescence recovery. This recovery is due to hydrogen bonding from the ammonium ion to the nitrogen of the azacrown ether. The strength of this hydrogen bonding interaction modulates the PET from the amine to anthracene. As explained above, the boronic acid unit can also participate in PET with the anthracene fluorophore, and diol binding can also cause fluorescence recovery. The anthracene unit serves as a rigid spacer between the two receptor units, with the appropriate spacing for the glucose moiety.[3] This system is expected to behave like an AND logic gate[11] in that fluorescence recovery will only be observed when two chemical inputs are supplied; for this system the two chemical inputs are an ammonium cation and a diol group. Compound **1** was synthesised as outlined in Scheme 1. The fluorescence of compound **1** varies as a function of pH giving a p$K_a$ of 7.32 (water, 0.05 $mol^{-1}$ $dm^{-3}$ tetramethylammonium chloride); under the same conditions the p$K_a$ of D-glucosamine hydrochloride is 7.56. Binding studies were carried out in a 33.2% (w/w) ethanol–water buffer[12] at pH 7.18. This pH was chosen to balance the protonation of the azacrown ether and deprotonation of the D-glucosamine hydrochloride. At low pH the sensor is protonated and no signal is observed, conversely at higher pH the D-glucosamine hydrochloride is present predominantly as free amine and will not bind strongly with the azacrown ether.

The stability constants for compounds **1**, **2** and **3** with D-glucose and D-glucosamine hydrochloride are given in Table 1. The curves from which the constants were calculated are shown in Fig. 1 and 2.

Compound **2**[13] does not display any fluorescence enhancement or have a binding constant with D-glucose because it has no saccharide binding site. D-glucosamine hydrochloride binding with compound **2** is also not observed under the experimental conditions, because the buffer solution saturates with

**2**

**3**

**Table 1** Stability constants for D-glucose and D-glucosamine hydrochloride with **1**, **2** and **3**

| | log $K_a$ ($r^2$; data points) | | |
|---|---|---|---|
| | **1** | **2** | **3** |
| D-Glucose | —[a] | —[a] | 2.92 (0.996; 8) |
| D-Glucosamine hydrochloride | 3.31 (0.997; 8) | < 1[b] | 2.70 (0.999; 7) |

[a] No fluorescence switching is possible. [b] No fluorescence change observed up to the solubility limit (0.1 mol $dm^{-3}$).

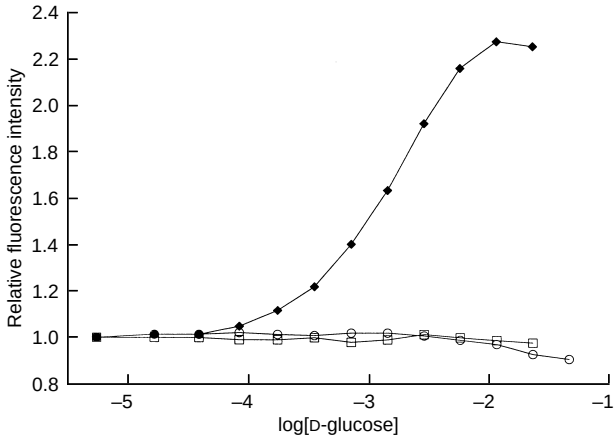


**Fig. 1** Fluorescence intensity–log[D-glucose] profile of (○) **1**, (□) **2** and (◆) **3** at 25 °C; $3.33 \times 10^{-6}$ M of **1**, **2** or **3** in EtOH–$H_2O$ (1 : 2), pH 7.18, $\lambda_{ex}$ 372 nm, $\lambda_{em}$ 425 nm

D-glucosamine hydrochloride before the binding event can be observed, giving an upper limit on the log$K_a$ for D-glucosamine hydrochloride of 1. As expected compound **3** shows a fluorescence enhancement with D-glucose (log$K_a$ = 2.92) and D-glucosamine hydrochloride (log$K_a$ = 2.70). With D-glucose the boronic acid has a choice of binding either the 1,2- or 4,6-diols, but with D-glucosamine hydrochloride binding with just the 4,6-diol is possible. The stability constant of **3** with D-glucose is higher than that observed with D-glucosamine hydrochloride, reflecting the known selectivity of boronic acids for the 1,2-diol of D-glucose.[14] Compound **1** shows a fluorescence increase with D-glucosamine hydrochloride (log$K_a$ = 3.31), but no increase with D-glucose. The result clearly demonstrates that for a fluorescent output *both* a diol *and* ammonium group must be present in the guest. The stability of the D-glucosamine hydrochloride complex with compound **1** is greater than that with compound **3**. (log$K_a$ = 3.31 *versus* 2.70) This increase in stability can be attributed to co-operative binding by the boronic acid and azacrown ether.

With this work we have demonstrated that the boronic acid PET system can be used in combination with other binding sites

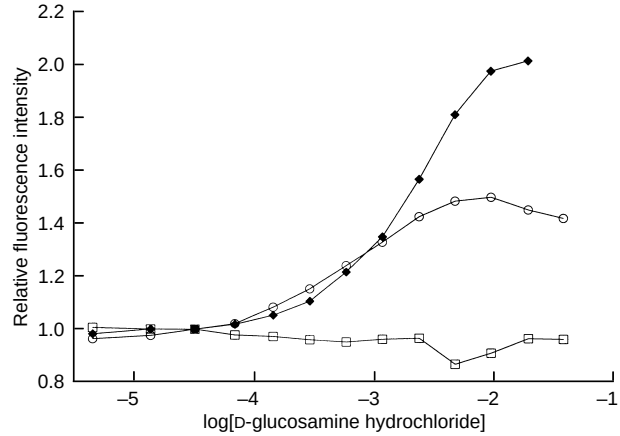

**Fig. 2** Fluorescence intensity–log[D-glucosamine hydrochloride] profile of (○) **1**, (□) **2** and (◆) **3** at 25 °C; $3.33 \times 10^{-6}$ M of **1**, **2** or **3** in EtOH–$H_2O$ (1 : 2), pH 7.18, $\lambda_{ex}$ 372 nm, $\lambda_{em}$ 425 nm

to create new and selective receptors for important biological molecules. We believe that this unit will be increasingly used as a general building block in molecular receptor design.

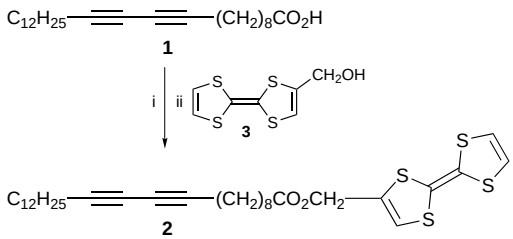
# Synthesis and solid-state polymerization of a diacetylene containing a tetrathiafulvalene group

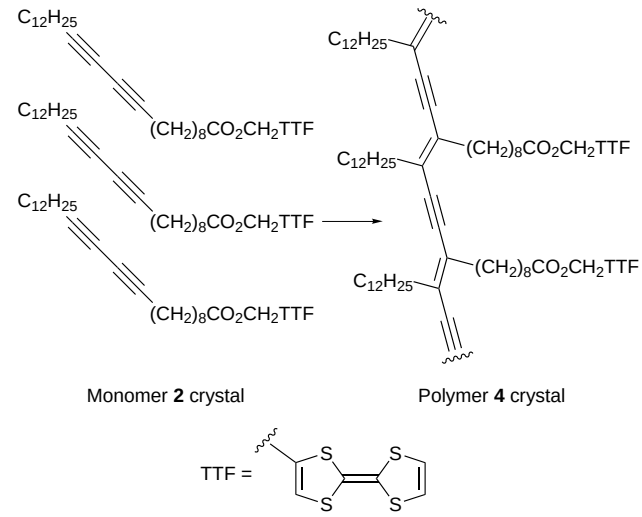
**Satoru Shimada,*[a]† Atsushi Masaki,[a] Kikuko Hayamizu,[a] Hiro Matsuda,*[a] Shuji Okada[b] and Hachiro Nakanishi[b]**

[a] *National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba, Ibaraki 305, Japan*
[b] *Institute for Chemical Reaction Science, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai, Miyagi 980, Japan*



**A diacetylene containing a tetrathiafulvalene substituent has been synthesized and can be readily polymerized in the solid state to yield a novel polydiacetylene.**

Polydiaceteylenes (PDAs), which are highly regular conjugated polymers produced by solid-state polymerization, have been attracting much attention because of their electrical transportation and third-order nonlinear optical properties.[1] We have investigated the synthesis of PDAs having aromatic[2] and alkynyl groups,[3] and heteroatoms[4] directly bound to $sp^2$ carbons of the conjugated main chain in order to modulate the electronic structures and thereby modify the electrical and optical properties. Meanwhile, tetrathiafulvalene (TTF) and analogous derivatives are also of interest because they have large electron-donating properties and form highly conductive charge-transfer complexes, which in some cases can be superconducting. Therefore we designed a PDA, obtained by solid-state polymerization, with TTF moieties contained in the side groups. Such a molecular design would have both a conjugated polymer main chain and electron-donating side chains. However, the incorporation of TTF units into the side chains of PDAs has been essentially unexplored so far.[5] Here we report the first example of a PDA derivative containing TTF groups in the substituents.



The monomer **2** of PDA was prepared in two steps as shown in Scheme 1. 4-(Hydroxymethyl)tetrathiafulvalene **3**[6] was used as a building block for TTF. Treatment of pentacosa-10,12-diynoic acid **1** with oxalyl chloride in $CH_2Cl_2$ quantitatively afforded the corresponding acid chloride. Addition of the acid chloride of **1** to a $CH_2Cl_2$ solution of hydroxymethyltetrathiafulvalene **3** with triethylamine at room temperature gave the diacetylene derivatives **2**‡ in poor yield (< 10%). However, the condensation reaction proceeded more smoothly to give **2** in 80% yield when 4-dimethylaminopyridine was used as base at 40 °C.[7]

The redox behaviour of monomer **2** was investigated by cyclic voltammetry. (electrolyte $Bu_4NPF_6$, *vs.* SCE, in MeCN at 25 °C) The monomer **2** exhibits two quasi-reversible redox couples at approximately $E^{1/2}{}_1$ +0.30 and $E^{1/2}{}_2$ +0.67 V, redox behaviour typical of the TTF system.[7]

The colour of the bulk crystals of monomer **2** changed to dark blue from light yellow after exposure to UV with a low-pressure mercury lamp (4 W) or $^{60}$Co γ-ray irradiation. This indicated clearly that the crystal structures of the monomers were suitable for solid-state polymerization, proceeding *via* 1,4-addition as shown in Scheme 2.[1]

**Scheme 1** *Reagents and conditions*: i, $(COCl)_2$, $CH_2Cl_2$, room temp., 3 h; ii, DMAP, $CH_2Cl_2$, reflux, 12 h

**Scheme 2**

A detailed study of the solid-state polymerization of monomer **2** stimulated by $^{60}$Co γ-ray irradiation (dose rate *ca.* 9.8 KGyh$^{-1}$) was achieved by gravimetry after extraction of the unreacted monomer using benzene, the polymer being insoluble in this solvent, as shown in Fig. 1. The polymer content of the crystals increased with the γ-ray dose up to 250 KGy, to about 72% conversion. However, the rate of polymerization became slow for doses in excess of 250 KGy. This polymerization curve for the monomer **2** is similar to that reported for nonadeca-2,4-diynoic acid[8] and tricosa-10,12-diynoic acid.[9]

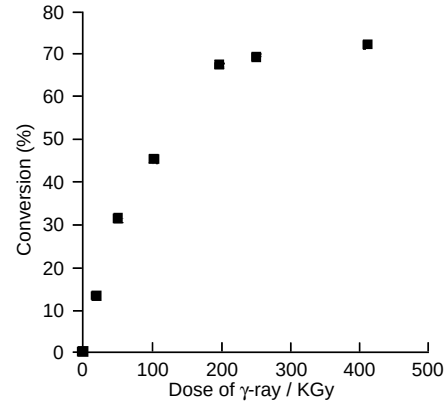


**Fig. 1** Time–conversion curve for solid-state polymerization of diacetylene **2** induced by $^{60}$Co γ-ray irradiation

The decoupled magic angle cross-polarised solid-state high resolution $^{13}C$ NMR spectrum of the reaction product after a 500 KGy radiation dose was measured at 50.2 MHz. The spectrum is consistent with the chemical structure of polymer **4** shown in Scheme 2. In particular, the carbon signals at $\delta$ 102 and 130 correspond to the acetylenic and alkenic carbons of the conjugated backbone of the polymer **4**, respectively, and are comparable to those found in poly(dodeca-5,7-diyne-1,12-diol bis{[(butoxycarbonyl)methyl]urethane}) in the red phase.[10]

By X-ray diffraction techniques it was established that polymer **4** produced by 500 KGy radiation is still similar in crystal structure to monomer **2**.

In conclusion, a novel diacetylene containing a TTF moiety was synthesized and subsequently polymerized in the solid state to yield a novel PDA with TTF groups located in the polymer side chains. Investigations into the physical properties of this PDA are in progress.

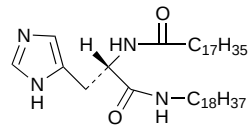
# Supramolecular expression of chirality in assemblies of gemini surfactants

**Nico A. J. M. Sommerdijk, Mark H. L. Lambermon, Martinus C. Feiters, Roeland J.M. Nolte*† and Binne Zwanenburg***



*Department of Organic Chemistry, NSR-Institute for Molecular Structure, Design and Synthesis, University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands*

**Supramolecular expression of chirality occurs in mixtures of an L-histidine derivative and the (*S*,*S*) isomer of a phosphatidic acid-based gemini surfactant, but not in mixtures of this histidine derivative and the (*R*,*R*)- or (*R*,*S*)-gemini surfactant.**

Gemini surfactants are amphiphilic molecules containing two hydrophilic head groups and two long aliphatic chains, which are linked by a rigid[1,2] or flexible spacer,[3,4] and as such have potentially interesting properties.[1] Theoretical calculations[5] and recent experimental results[6,7] indeed indicate that 'geminis' behave differently from normal surfactants, which opens the way for new applications.

**1**

**2**

In a previous paper we showed that gemini surfactants based on phosphatidic acid (see **1**) can undergo stereodependent fission or fusion in the presence of calcium ions.[8] Here we report that these surfactants are capable of recognising a long chain L-histidine derivative, leading to a stereodependent expression of molecular chirality at the supramolecular level.

The (*R*,*R*), (*S*,*S*) and (*R*,*S*) forms of compound **1** were synthesised as described elsewhere.[8] All three stereoisomers of **1** formed bilayer aggregates when they were dispersed in water. Histidine surfactant **2** alone could not be dispersed in water to form distinct aggregates due to its low solubility.‡ When **2** (25 or 50 mol%) was mixed with the (*R*,*S*) isomer of **1** and dispersed in water at pH 6.5, vesicles with diameters ranging from 150 to 750 nm were generated. Increasing the concentration of **2** to 75 mol% led to the formation of extended bilayers and multilayer structures. In contrast, at all concentrations aqueous dispersions of **2** and the (*R*,*R*) isomer of **1** yielded irregularly shaped, rod-like structures with an average diameter of 30 nm and a length of 0.2–2.0 μm [Fig. 1(*a*)]. When **2** and the (*S*,*S*) isomer of **1** were mixed, helical structures together with planar bilayer aggregates were found in samples containing 25 mol% of **2** [Fig. 1(*b*)]. In samples containing 50 and 75 mol% of **2**, the aggregates tended to form twisted structures [Fig. 1(*c*)], but no distinct morphologies could be detected in the bulk of the material.

Further experiments revealed that the helical structures were only generated when the concentration of **2** was between 25 and 35 mol%, with the optimum lying at 30 mol%. Right-handed helices with a pitch of approximately 90 nm and a thickness of *ca*. 40 nm were observed exclusively [Fig. 1(*d*)].§ When the concentration of **1** deviated from 30 mol%, the observed helices were shorter and many of them contained defects [Fig. 1(*c*)]. The fact that the pitch and the thickness of the helices were similar in all cases suggests that their formation occurred in a precise manner, requiring a distinct ratio of the two surfactants, rather than a variable one. Since a concentration of 30 mol% of **2** appeared to be optimal, 1 : 2 complexes of **2** and (*S*,*S*)-**1** are probably the building blocks from which the helices are constructed.

Monolayer experiments revealed that **2** forms stable monolayers at the air–water interface. The surface area–surface pressure isotherms displayed a transition to a non-compressible state at relatively low surface pressure (Fig. 2). This suggests

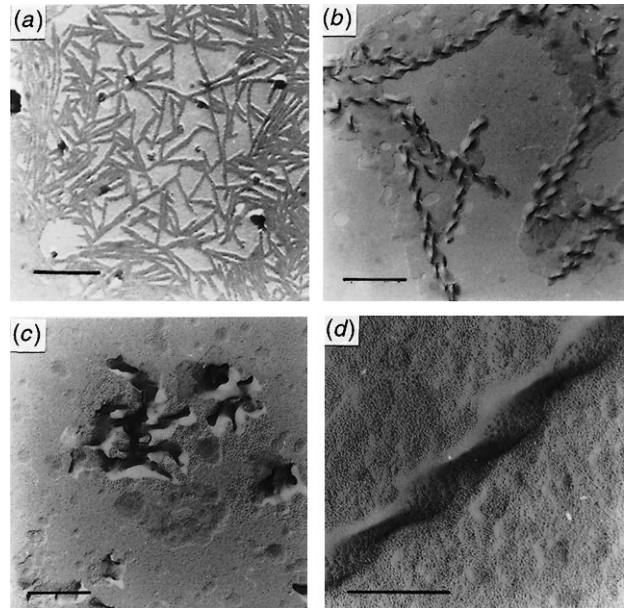


**Fig. 1** Transmission electron micrographs [Pt shadowing, (*a*)–(*c*) bars represent 400 nm, (*d*) bar represents 100 nm] of mixtures of (*a*) (*R*,*R*)-**1** and **2** (75 mol%), (*b*) (*S*,*S*)-**1** and **2** (25 mol%), (*c*) (*S*,*S*)-**1** and **2** (50 mol%) and (*d*) (*S*,*S*)-**1** and **2** (30 mol%)

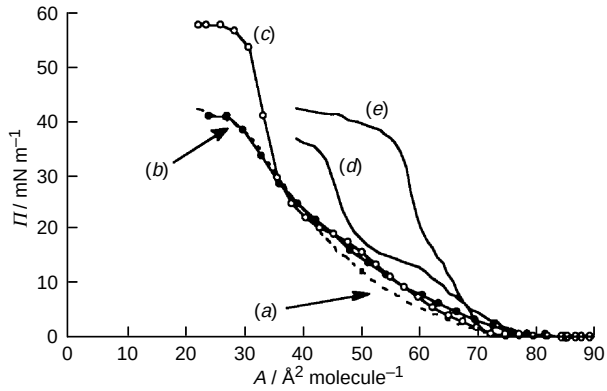

**Fig. 2** Monolayer isotherms recorded at 20 °C of mixtures of (*S*,*S*)-**1** and **2** on a sub-phase of pH 6.5: (*a*) 25, (*b*) 33, (*c*) 50, (*d*) 75 and (*e*) 100 mol% **2**

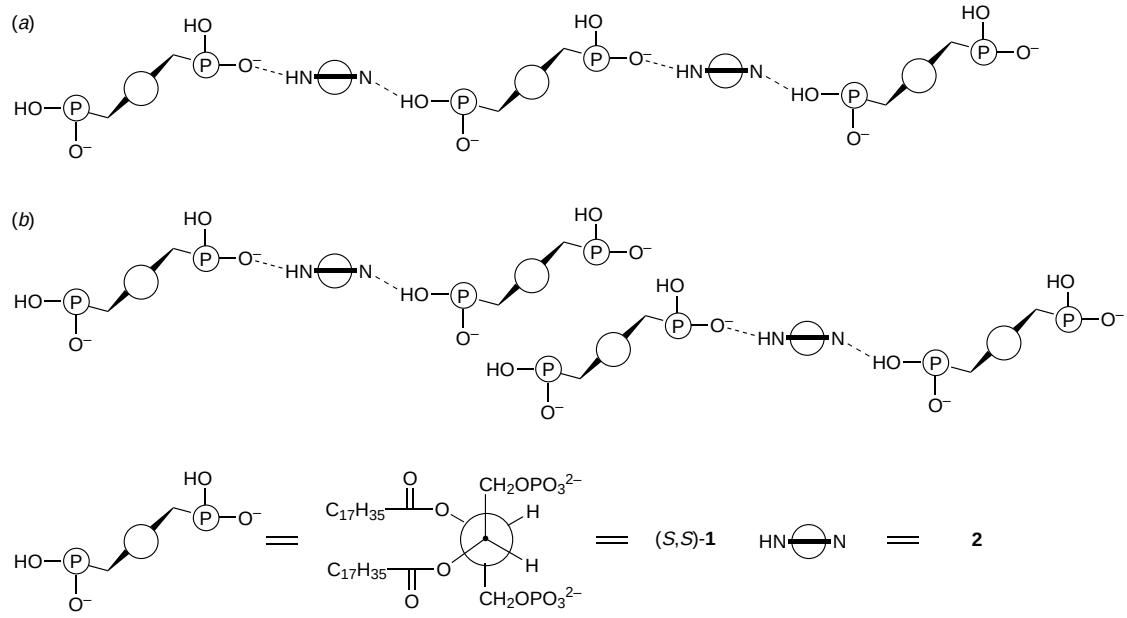

**Fig. 3** Schematic representation of (*a*) a 1 : 1 complex and (*b*) a 1 : 2 complex of **2** and (*S*,*S*)-**1**

that in the monolayer the molecules of **2** have a high degree of organisation, probably because they are linked by strong intermolecular hydrogen bonds *via* their imidazole groups, assisted by the formation of so-called amide polymers, *i.e.* linear arrays of hydrogen bonds between the amide groups of **2**. Mixing **2** with an increasing amount of (*S*,*S*)-**1** led to a gradual increase in the compressibility of the monolayer and to a gradual change in the overall shape of the isotherm. At a concentration of 33 mol% of **2**—this is the concentration at which helices start to be observed—the isotherm did not change further and showed the highest degree of compressibility.¶ These results can be rationalised as follows: the (*S*,*S*) isomer of **1** preferentially adopts an extended conformation in which the phosphate groups have an *anti* orientation.[8]‖ It is likely therefore that in a 1 : 1 mixture highly ordered, linear arrays of pairs of (*S*,*S*)-**1** and **2** are present, interconnected by hydrogen bonds, both between the head groups and the neighbouring amide groups [Fig. 3(*a*)]. In this way the molecules will be confined to their positions in a two dimensional lattice. In a mixture containing 33 mol% of **2**, however, individual 2 : 1 complexes of (*S*,*S*)-**1** and **2** may be formed, allowing both translational and rotational freedom of the complexes with respect to each other [Fig. 3(*b*)]. The complexes are thus free to adopt orientations in which the average molecular area is minimised, and in which chirality is accumulated by close packing of the stereogenic centres. This asymmetric packing of the building blocks probably extends over long distances, leading to the formation of helical aggregates.

The authors thank H. P. M. Geurts for assistance in performing the electron microscopy experiments and Professor G. I. Tesser and P. J. H. M. Adams for the kind donation of Boc-protected L-histidine and for helpful discussions.

## Footnotes

‡ Surfactant **2** was prepared from Boc-protected L-histidine. One alkyl chain was introduced by a DCC coupling with octadecylamine (yield 60%). Deprotection of the Boc-amide with trifluoroacetic acid and subsequent acylation with *N*-(stearoyloxy)succinimide resulted in the introduction of the second alkyl chain (yield 75%). Calc. for **2** ($C_{42}H_{80}O_2N_4$): C, 74.9; H, 12.0; N, 8.3. Found: C, 74.2; H, 11.5; N, 8.4%.

§ In mixtures containing 1–10 mol% of **2** planar bilayers and a small amount of fibres were observed, suggesting that only a small fraction of (*S*,*S*)-**1** is interacting with **2**, leading to the formation of these fibres.

¶ Monolayers of mixtures of **1** and **2** were inspected by Brewster angle microscopy. No chiral domains were detected.

‖ The p$K_a$ values of (*S*,*S*)-**1** were determined to be 1.8 and 10.2, implying that at pH 6.5 the molecules are in the monoprotonated state (ref. 9).

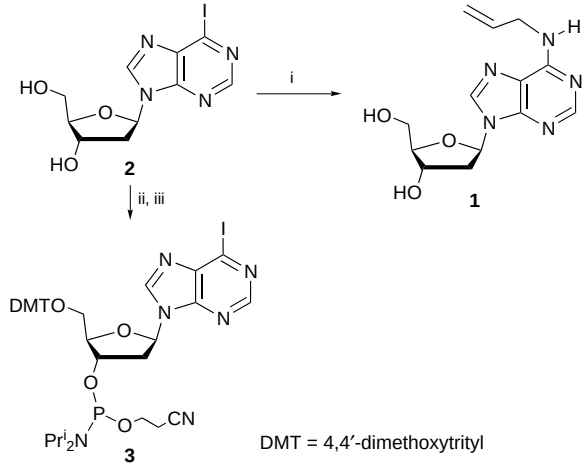
# A self-cleaving DNA nucleoside

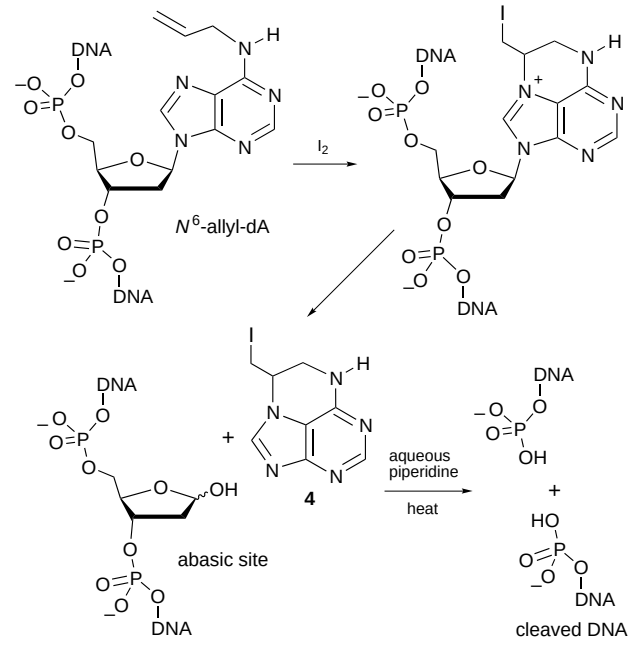
**Vineet Gupta and Eric T. Kool***

*Department of Chemistry, University of Rochester, Rochester, NY 14627, USA*



**An allyl-modified nucleoside has been shown to self-alkylate and depurinate on treatment with iodine and heat; placement in DNA strands yields site-directed cleavage of the DNA.**

Much attention has been focused on the development of methods for cleavage of DNA or RNA strands at specific sites. One common approach taken is the use of a reactive group which is delivered to specific sequences in a nucleic acid target by attachment of the reactive group to a DNA-binding ligand with known sequence preference.[1] One goal of such work has been the hybridization-directed cleavage of biologically harmful nucleic acid sequences, resulting in possible therapeutic applications.[2] Another application is the cutting of chemically- or enzymatically-synthesized DNA at positions which cannot be processed by known restriction endonuclease enzymes,[3] which can also be useful as a tool in the study of nucleic acid structure and function.



Our design of a self-cleaving DNA base was inspired by Maxam–Gilbert alkylation of purines. Alkylation at $N^7$ (or other ring nitrogens) by dimethyl sulfate results in depurination with formation of an abasic deoxyribose, and subsequent heating in aqueous base gives strand cleavage with loss of the sugar residue. In principle, direction of an alkylating group to a specific purine under mild conditions could enable facile and specific chain cleavage. We envisioned that placement of an allyl function near nucleophilic ring nitrogens might allow for such alkylation if a mild electrophilic activating reagent could be found. The reagent must be reactive enough to activate the alkylation functionality, but not so reactive that it modifies natural DNA.

We synthesized the nucleoside $N^6$-allyl-dA **1** to test this possibility (Scheme 1). This compound was obtained from iodopurinedeoxyriboside **2** by substitution with allylamine. After some experimentation we arrived at iodine as a mild electrophilic reagent for activating the double bond.[4] We found that $I_2$ reacts rapidly with $N^6$-allyl-dA in neutral aqueous solution or in DMSO at room temperature. This reaction was monitored by 300 MHz proton NMR in [$^2H_6$]DMSO. In addition, nuclear Overhauser enhancements were observed between H-8 and protons on methyl substituents added to the terminus of the allyl group (data not shown), establishing that the cyclization occurs on the $N^7$ nitrogen rather than the $N^1$ position. The $^{13}$C NMR spectrum confirms the structure having the 6-membered-ring product. After 24 h at room temperature, or after 30 min heating (90 °C), a second new adenine-derived compound is observed in the NMR spectrum. We surmised that this is the cyclized base **4** which had been eliminated from the sugar; to test this we independently synthesized this compound by treating allyladenine with iodine. NMR and HPLC studies confirmed its identity. The second byproduct of the reaction in DMSO is hydroxymethylfuran, also identified by comparison to an authentic sample. The four natural DNA nucleosides did not react under these conditions as monitored by NMR spectroscopy; this is not unexpected, since iodine is a commonly-used reagent in the oxidative step of DNA synthesis.

We then incorporated $N^6$-allyl-dA into synthetic DNA strands to test whether this chemistry could be carried out in the polymer. Since iodine is used in the standard synthesis cycle, we added the allyl functionality immediately after synthesis of the DNA chain, by first incorporating the iodopurine phosphoramidite **3**.[5] We treated the resulting DNA attached to the solid CPG-support with neat allylamine (65 °C, 18 h) and followed this with a standard 12 h ammonia treatment to remove any remaining protecting groups. Two different sequences, containing one and two allyl-modified dAs respectively, were synthesized. Enzymatic digestion of these strands to the nucleosides followed by HPLC analysis showed that the $N^6$-allyl-dA was present in these strands in the expected ratio, with no evidence

**Scheme 1** *Reagents and conditions*: i, allylamine (neat), room temp.; ii, 4,4′-dimethoxytrityl chloride, $Pr^i_2EtN$, $CH_2Cl_2$; iii, *N*,*N*-diisopropyl-*O*-cyanoethylphosphoramidic chloride, $Pr^i_2EtN$, $CH_2Cl_2$

**Scheme 2**

of any other derivatives such as deoxyadenosine or deoxyinosine (data not shown). This establishes that the postsynthetic addition of the amine proceeds with high (≥95%) conversion. The iodopurine **3** is thus an efficient vehicle for incorporation of amine nucleophiles into DNA.[6]

The expected products of self-cleavage of the sequence 5′-dTTTTTTA*TTTTT are 5′-dTTTTTTp and 5′-pdTTTTT (Scheme 2). We synthesized these fragments as authentic samples for comparison on high-resolution gels. The second modified strand had the sequence 5′-dTTTTTTTA*TTTTTTA*TTTTT, containing two possible cleavage sites. The result of iodine treatment with ABI oxidizing solution followed by heating with piperidine was efficient and clean chain cleavage for both sequences (Scheme 2). Experimentation with solvents and reaction conditions established that most selective cleavage occurred using 20 mM $I_2$ and 66 μM DNA strand concentration.† High-resolution polyacrylamide gels show the cleavage (Fig. 1), and separate gels show that the products co-migrate with the authentically synthesized fragments. Reversed-phase HPLC analysis also confirmed this finding. Control reactions show (Fig. 1) that the presence of the allyl function in the DNA is necessary for cleavage, as is iodine treatment of the DNA. Examination of the reaction products indicates that cleavage is not completely selective for the allyl-substituted base, with some background cleavage also occurring at other bases. Experiments with a third oligonucleotide of mixed sequence (5′-pdGTCAGTCAA*GTCAGTCAp) (data not shown) showed that this was more pronounced for purine-containing DNA. This nonselective iodine reaction was somewhat surprising because of the common use of iodine in DNA synthesis; however, it seems possible that altering conditions beyond those we examined, or using a more selective electrophile, might lead to increased specificity for allyladenine.

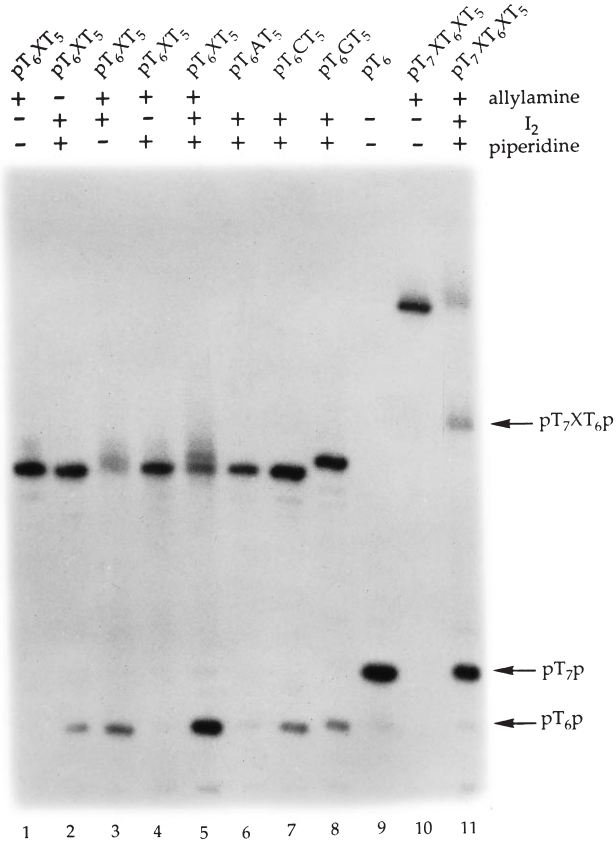


**Fig. 1** Cleavage assay of two DNA sequences containing **1** by denaturing gel electrophoresis. All the sequences were 5′-$^{32}$P labelled. Lanes 1–5 show the reactions with the sequence 5′-$T_6A^*T_5$, lanes 6–8 the reactions with control DNA molecules, lane 9 the product marker and lanes 10–11 the reactions with DNA sequence 5′-$T_7A^*T_6A^*T_5$. Lane 1: no reaction. Lane 2: reaction of allyl untreated 5′-$T_6A^*T_5$ with both $I_2$ and piperidine. Lane 3: reaction of 5′-$T_6A^*T_5$ only with $I_2$. Lane 4: reaction of 5′-$T_6A^*T_5$ only with piperidine. Lane 5: reaction of 5′-$T_6A^*T_5$ with $I_2$ as well as piperidine. Lanes 6–8: reaction of 5′-$T_6AT_5$, 5′-$T_6CT_5$ and 5′-$T_6GT_5$ respectively with both $I_2$ and piperidine. Lane 10: no reaction. Lane 11: reaction of 5′-$T_7A^*T_6A^*T_5$ with both $I_2$ and piperidine. Lanes 3, 5 and 11 clearly show the cleavage of modified DNA to the expected products. Some non-specific cleavage can be seen in lanes 2, 6, 7 and 8.

A few other reports of methods for generating abasic (depurinated or depyrimidinated) sites or for site-directed cleavage in DNA exist in the literature.[7] The present method represents an alternative cleavage strategy which, unlike most of the previous approaches, allows essentially normal base pairing prior to the cleavage. Studies aimed at finding strategies for decreasing associated nonspecific cleavage are currently underway.

† Conditions for reactions on DNA: (1) Allylamine treatment—1 ml of allylamine (neat) was added to CPG bound DNA (1 μmol synthesis) and the mixture was kept at 65 °C for 18 h. It was lyophilised and treated with $NH_4OH$ at 55 °C for 12 h, lyophilised and gel purified. (2) Iodine treatment—5′-$^{32}$P labelled DNA sequence (200 pmol, 66 μM) was dissolved in 3 μl of 20 mM $I_2$ solution (20% v/v pyridine, 10% v/v water, 70% v/v THF), and incubated at 4 °C for 10 min. The mixture was then diluted with 150 μl $H_2O$ and heated at 90 °C for 6 h. (3) Piperidine treatment—100 μl of a 1.0 M aq. piperidine solution in $H_2O$ was added and the mixture heated at 90 °C for 30 min, and lyophilised.

# An unusual imine (N=C) alkylalumination reaction

**Pingrong Wei and David Atwood***

*Center for Main Group Chemistry, Department of Chemistry, North Dakota State University, Fargo, North Dakota 58105, USA*

**Addition of 3 equiv. of $AlMe_3$ to a heptadentate Schiff-base ligand made from salicylaldehyde and bis(2-aminoethyl)-ethylenediamine ($H_3L^1$) results in an unusual alkylalumination of one of the imine bonds; addition of 2 equiv. of $B(OMe)_3$ or $AlMe_3$ to one of these ligands leads to the formation of bimetallic derivatives containing four- and five-coordinate metals, respectively.**

In the course of our explorations of group 13 Schiff-base chelate complexes we have discovered an unusual imine (N=C) alkylalumination reaction. Schiff-base ligands (and the salen class, in particular) form a wide range of complexes with transition[1] and main-group metals.[2] One of the reasons why these ligands are so useful is because they do not undergo further reactions after coordinating a metal. In fact, transition-metal complexes of the reduced form of the salen ligand (the salan class)[3] are difficult to isolate because they dehydrogenate back to the Schiff-base derivative when exposed to air.[4]

In turning our attention to ligands possessing multiple (more than four) binding sites we examined those derived from the condensation of 3 equiv. of salicylaldehyde (with H or Bu$^t$ at the 2,4-positions, or Cl at the 4-position, of the aryl ring) with bis(2-aminoethyl)ethylenediamine. The resulting ligands are denoted $H_3L^1$, $H_3L^2$ and $H_3L^3$, respectively. We had intended to prepare neutral bi- and tri-metallic derivatives of these ligands for potential catalytic applications. Previously reported group 13 complexes with this[5] and related systems[6] have focused on charged compounds useful in medicinal applications.

In the present work, two neutral bimetallic derivatives, $(HL^2)[B(OMe)_2]_2$ **1** and $L^1AlMe(AlMe_2)$ **2**, could be prepared in good yields using the appropriate stoichiometry (Scheme 1).† The X-ray data for **1** was such that a full solution could not be obtained. However, the overall morphology of the molecule is clear (Fig. 1). The formation of **1** follows similar reactions for bimetallic salen derivatives.[7] This is not the case for **2** for which the $^{27}Al$ NMR data indicates that only five-coordinate aluminium is present ($\delta$ 65.40). In the $^1H$ NMR there are two Al–Me shifts in a 1 : 2 ratio. This data can tentatively be attributed to the structure shown in Scheme 1. Surprisingly, in reactions with 3 equiv. of the aluminium reagent, one of the N=C bonds undergoes an unusual alkyalumination reaction in the formation of trimetallic derivative **3** (Scheme 1, Fig. 2).

In the structure‡ one portion of the molecule coordinates an $AlMe_2$ unit by an oxygen and imine nitrogen, forming a six-
