Existing methods for the preparation of acyl Meldrum's acid include the reaction of Meldrum's acid **1** with acyl chloride[6] in the presence of a tertiary amine, the reaction of **1** with a carboxylic acid[7] in the presence of a dehydrating agent and the reaction with an *in situ* generated acyl imidazolide.[8] It may be possible to carry out the acylation reaction with commercially available trifluoroacetyl chloride. However, this reagent is rather expensive and somewhat difficult to handle (bp −27 °C). Thus, we employed the imidazolide method for the preparation of trifluoroacetyl Meldrum's acid **2**. The reaction of isolated *N*-trifluoroacetylimidazole[9] with **1** in the presence of imidazole at room temperature afforded **2** in 71% yield.‡ Attempts to generate the acyl imidazolide *in situ*, however, were un-

**Scheme 1** *Reagents and conditions*: i, *N*-trifluoroacetylimidazole (1.1 equiv.), imidazole (1 equiv.); ii, acetone; iii, nitrile–solvent (benzene or toluene) or neat; iv, Bu$^t$OH (1.1 equiv.); v, *N*,*N*′- dimethyl(thio)urea; vi, cat. *p*-TsOH

successful. Treatment of trifluoroacetic acid with carbonyldiimidazole, followed by the reaction with **1**, gave none of the desired compound and recovery of a small amount of **1**.

Compound **2** was found to be labile even at room temperature. Thus, upon standing in chloroform at room temperature for 2 days or refluxing in $CH_2Cl_2$ for 1.5 h in the presence of acetone, 6-trifluoromethyl-2,2-dimethyl-2*H*,4*H*-1,3-dioxin-4-one **3**,[4]§ was obtained in moderate yield. The conversion of **2** to **3** is rationalized in terms of generation of trifluoroacetylketene **4** followed by cycloaddition across the carbon–oxygen double bond of acetone.[10]

The hetero-Diels–Alder reaction of acylketene with a variety of dienophiles is one of the most useful methods for the synthesis of heterocyclic compounds.[2b] Treatment of **2** with dimethylcyanamide in benzene under reflux (1 h) gave 2-dimethylamino-6-trifluoromethyl-4*H*-1,3-oxazin-4-one **5a** in 46% yield. Similarly, **5b** was obtained by the reaction of **2** with anisonitrile (toluene, reflux, 1 h, 60%). Treatment of **2** with a large excess of isobutyronitrile (40 equiv.) under reflux (1 h) gave **5c** in 71% yield. However, the cycloaddition reaction of acylketene with carbon–nitrogen triple bonds is limited to substituted acylketenes. Thus, the reaction of an unsubstituted acylketene such as benzoylketene with an aromatic nitrile gives only dimerized or polymerized products of acylketene and none of the cycloaddition product with nitrile was obtained.[11] The first example of a cycloaddition reaction of an unsubstituted acylketene with a simple nitrile was achieved with the trifluoroacetylketene **4**. These 1,3-oxazin-4-ones would also be useful building blocks for the synthesis of trifluoromethyl-containing nitrogen heterocycles *via* ring transformations.[12]

Reactions of **2** with nucleophiles such as *tert*-butyl alcohol, dimethylthiourea and dimethylurea were examined. Treatment of **2** with 1.1 equiv. of *tert*-butyl alcohol in chloroform at room temperature for 3 days, followed by vacuum distillation, afforded the previously unknown *tert*-butyl trifluoroacetoacetate **6** (80%). When **6** was left without protection from atmospheric moisture, solid **7** was formed. On the basis of the spectral and analytical characteristics, **7** was assigned the structure of the hydrated product of **6**. The hydration of compounds containing the trifluoromethylcarbonyl moiety is a well known phenomenon.[13] However, to the best of our knowledge, this is the first example of the isolation of the hydrated form of a trifluoromethylated β-keto ester.

The reaction with 1,3-dimethylthiourea (THF, room temperature, 24 h) gave the dihydrouracil derivative **9a** (90%) *via* trifluoroacetoacetyl derivative **8a**. Subsequent dehydration of **9a** in toluene under reflux with a catalytic amount of toluene-*p*-sulfonic acid afforded 6-trifluoromethyluracil **10a** (80%). Similarly, 2-oxo analogue **9b** (THF, room temperature, 24 h, 45%) and **10b** (91%) were obtained.

Further investigation of the application of **2** as a convenient method for the synthesis of biologically important heterocycles is in progress.

## Footnotes

† All new compounds gave satisfactory analytical and spectral data.

‡ The procedure for the preparation of **2** is as follows: to a solution of **1** (10 mmol) and imidazole (10 mmol) in 20 ml of $CHCl_3$ was added a solution of *N*-trifluroacetylimidazole (11 mmol) in 20 ml of $CHCl_3$ over a period of 30 min at room temperature. After stirring for an additional 5 min the solution was washed with 10% HCl (10 ml × 3), dried ($MgSO_4$) and the solvent evaporated while maintaining the temperature below 20 °C. Washing the resulting colourless solid with small amount of cold diethyl ether gave analytically pure **2**.

§ Preparation of compound **3** by trifluoroacetylation of *in situ* generated ketene with trifluoroacetic anhydride is reported by Boivin *et al.*,[4] but the reported yield is 8%. Iwaoka *et al.*[3] reported the preparation of 6-trifluoromethyl-4-oxo-4*H*-1,3-dioxine-2-spirocyclohexane from 4,4,4-trifluoro-3-oxobutanoic acid, cyclohexanone and acetic anhydride in the presence of a catalytic amount of sulfuric acid.

# Synthesis and characterisation of $[M_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu\text{-}PH_2)(\mu\text{-}H)]$ (M = Mo, W); a new route to $\mu\text{-}PH_2$ complexes involving novel activation of a bridging diphosphorus ligand

**John E. Davies, Martin J. Mays,* Paul R. Raithby, Gregory P. Shields and Peter K. Tompkin**

*Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW*

**Reaction of the known diphosphorus complexes $[M_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ (M = Mo 1a, W 1b) with M′OH (M′ = Na, K) in thf–water followed by addition of $HBF_4$ affords the new phosphido complexes $[M_2(\eta^5C_5H_5)_2(CO)_4(\mu\text{-}PH_2)(\mu\text{-}H)]$ (M = Mo 3a, W 3b) in good yield; 3a is the subject of a single-crystal X-ray diffraction study.**

The preparation and characterisation of complexes containing naked group 15 ligands has been an active area of research for some years now,[1] although the subsequent reactivity of these complexes has been relatively poorly investigated, being in the main restricted to the coordination of 16-electron fragments to lone pairs present on the main-group fragment.[2] We recently showed with the formation of $[Mo_2(\eta^5\text{-}C_5H_5)_2(CO)_3\{\mu,\eta^3\text{-}PPh_2C(H)SP_2S\}]$ from $[Mo_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu,\eta^2\text{-}P^2)]$ **1a** the hitherto unsuspected potential of naked $P_n$ ligands as precursors to otherwise inaccessible ligands.[3] We now report that the reaction of $[M_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ (M = Mo **1a**, W **1b**) with M′OH (M′ = Na, K) in thf–$H_2O$ gives the dimetallic anions $[M_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu\text{-}PH_2)]^-$ (M = Mo **2a**, W **2b**).† Protonation of **2a**,**b** then affords the new phosphido complexes $[M_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu\text{-}PH_2)(\mu\text{-}H)]$ (M = Mo **3a**, W **3b**) in typically 70–80% yield based on **1a**,**b** (Scheme 1). This new route to $\mu\text{-}PH_2$ complexes avoids the potentially hazardous use of $PH_3$ gas often used in previous syntheses,[4] and to our knowledge there are no previous examples of the preparation of $\mu\text{-}PH_2$ complexes from complexes containing naked phosphorus ligands.

**Scheme 1**

Reaction of a solution of **1a** (400 mg, 0.806 mmol), synthesised by the method of Scherer *et al.*,[5] in thf (80 ml)–water (0.2 ml) with a large excess of M′OH pellets at 80 °C affords an air-sensitive purple solution of $[M']^+[M_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu\text{-}PH_2)]^-$ **2a**. Filtration through a glass sinter followed by addition of a slight excess of $HBF_4{\cdot}OEt_2$ and filtration through silica affords **3a** (289 mg, 0.617 mmol, 77%) as the only isolable product. Similar treatment of a solution of **1b** (400 mg, 0.604 mmol) affords **3b** (268 mg, 0.416 mmol, 69%).

The structure of **3a** has been determined by X-ray diffraction analysis.‡ The molecular structure is shown in Fig. 1, and includes selected bond parameters. The spectroscopic data† for **3a** are consistent with this structure. An 18-electron configuration is achieved at each Mo atom only if an Mo–Mo bond is proposed; the metal–metal distance is increased from 3.0406(8) Å in **1a**[5] to 3.2818(9) Å in **3a**, this being slightly longer than the 3.244(1) Å distance observed in the diphenylphosphido analogue $[Mo_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu\text{-}PPh_2)(\mu\text{-}H)]$ **4**.[6] The MoHMoP core of the complex is essentially planar. The Mo–P bond distances [av. 2.402(1) Å] are slightly shorter than in **4**; this may reflect the reduced steric bulk of the $PH_2$ fragment as compared to the $PPh_2$ fragment.

Both the general applicability of this new, convenient high-yield synthesis of $\mu\text{-}PH_2$ complexes and a comparison of their chemistry to that of the well studied $\mu\text{-}PR_2$ complexes is in progress.

# A new route to the antitumour drug temozolomide, but not thiotemozolomide

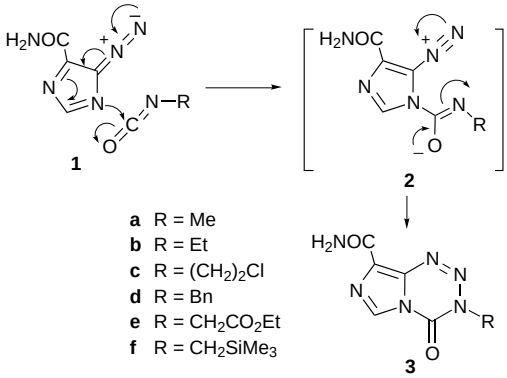
**Yongfeng Wang,[a,b] Philip R. Lowe,[b] William T. Thomson,[c] Jonathan Clark[a] and Malcolm F. G. Stevens*[a]**

[a] *Cancer Research Laboratories, Department of Pharmaceutical Sciences, University of Nottingham, Nottingham, UK NG7 2RD*
[b] *Pharmaceutical Sciences Institute, Aston University, Birmingham, UK B4 7ET*
[c] *Aston Molecules Ltd., 10 Holt Court South, Aston Science Park, Birmingham, UK B7 4EJ*

**Interaction of 5-aminoimidazole-4-carboxamide with alkyl isocyanates yields *N*-substituted 1-carbamoylimidazoles which can be cyclised to imidazo[5,1-*d*][1,2,3,5]tetrazin-4(3*H*)-ones, including temozolomide 3a, on nitrosation; a similar reaction with methyl isothiocyanate, followed by nitrosation, affords the nitrosomethylamino derivative 11 of a new ring-system, imidazo[1,5-*b*][1,2,4]thiadiazole.**

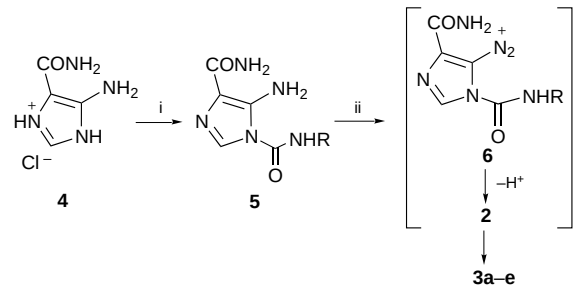
The antitumour drug temozolomide **3a** has shown useful clinical activity against brain tumours[1] and metastatic melanoma,[2] two malignancies hitherto considered poorly treatable.

The original synthesis of temozolomide[3] started with 5-diazoimidazole-4-carboxamide **1** which was reacted with methyl isocyanate following a route to azolotetrazinones originally discovered by Ege.[4] The (presumed) dipolar intermediate **2a** cyclised spontaneously to temozolomide in high yield in a $Me_2SO$–ethyl acetate mixed solvent system at 25 °C (Scheme 1). Analogues of temozolomide **3b**–**d** can be prepared similarly. The diazoimidazole **1** does not react with methyl isothiocyanate in $Me_2SO$ at 40 °C nor in the same solvent containing the Lewis acids zinc iodide and boron trifluoride–diethyl ether or the base triethylamine, so 4-thiotemozolomide (**3a**; O = S) is not available by this route.



Our earlier work to develop alternative syntheses of temozolomide had exploited imidazotetrazinones *e.g.* **3e**,**f** prepared from less volatile 'masked' methyl isocyanates, which can be deprotected under conditions which retain the integrity of the base-fragile ring-system.[5] Here we report a new synthesis of temozolomide starting with 5-aminoimidazole-4-carboxamide hydrochloride **4**, which adapts another route developed by Ege[6] for the synthesis of pyrazolotetrazinones, so obviating the use of the potentially unstable diazoimidazole **1**. A parallel synthesis designed to furnish 4-thiotemozolomide surprisingly took an entirely different path and led to the construction of a new ring-system, imidazo[1,5-*b*][1,2,4]thiadiazole.

Interaction of the free base of **4** with methyl, ethyl, 2-chloroethyl and benzyl isocyanates in $Me_2SO$ or acetonitrile afforded the ureas **5a**–**d**†‡ regioselectively (75–95%) despite the availability of competing sites for carbamoylation. Nitrosative cyclisation of **5a** in 2 M hydrochloric acid in the temperature range 5–25 °C gave a red solution from which temozolomide **3a** precipitated in 30–35% yield. A by-product, 2-azahypoxanthine (15%), is probably formed by competing nitrosative cyclisation to the primary carboxamide group followed by loss of methyl isocyanate. Compared with the ease with which *N*-alkylanthranilamides cyclise to 3-alkyl-1,2,3-benzotriazin-4(3*H*)-ones[7] the yield of temozolomide is disappointing, but accountable for by the weakly acidic nature of the urea proton in the diazonium species **6a** which suppresses generation of the dipolar intermediate **2a**, the presumed precursor to temozolomide. Higher yields of the imidazotetrazinones **3b**–**d** were isolated (50–70%) by cyclisation of the corresponding ureas **5b**–**d**: also we have shown previously[5] that, in the case of the urea **5e** formed from ethyl isocyanatoacetate, cyclisation gave the imidazotetrazine **3e** (93%) consistent with the hypothesis that an electron-withdrawing group R facilitates ionisation of the urea proton, and hence cyclisation (Scheme 2).



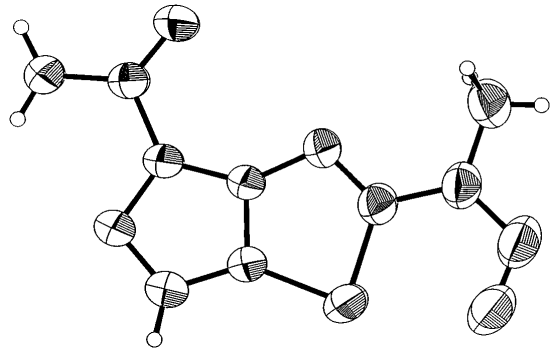
Interaction of the aminoimidazole carboxamide **4** with methyl isothiocyanate gave a thiourea (90%) which on nitrosation with excess nitrous acid at 25 °C gave a red product (85%), originally considered to be thiotemozolomide on the basis of its $^1H$ and $^{13}C$ NMR spectra which were comparable with that of temozolomide. However, elemental and mass spectral analysis confirmed a molecular formula $C_6H_6N_6O_2S$ (thiotemozolomide + 16 mass units). An X-ray structure determination (Fig. 1) revealed that the product was 2-nitrosomethylaminoimidazo[1,5-*b*][1,2,4]thiadiazole-4-carboxamide **11**.

A logical route to this unexpected compound is outlined in Scheme 3. Methylsulfanylcarbamoylation of the free base of amine **4** evidently affords the thiourea **7**†‡ substituted at the exocyclic amino group. Nitrosation of the thiol tautomer **7′** would generate an *S*-nitroso intermediate **8** which might cyclise to the imidazothiadiazole **10** directly (−HNO) or, probably, undergo further oxidation in the excess nitrous acid to the *S*-nitro intermediate **9** which would then cyclise ($-HNO_2$) to afford the bicycle **10**. Further nitrosation of the *sec*-amine group of **10** to afford the nitrosamine **11**‡§ is to be expected, although the exact timing of this step is not clear.

Of the five other imidazothiadiazole ring-systems reported in the literature only one, imidazo[1,2-*b*][1,2,4]thiadiazole,[8] contains an imidazole bridgehead nitrogen atom attached to sulfur.

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, RNCO, $Me_2SO$ or MeCN, 0–25 °C, $NEt_3$; ii, $NaNO_2$ in 2 M HCl, 0–25 °C



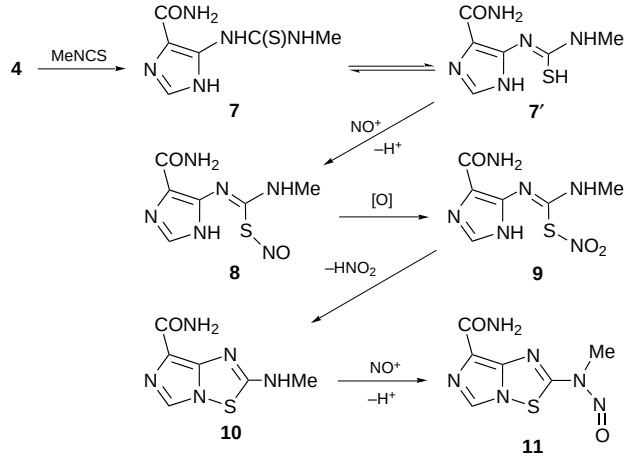


**Fig. 1** ORTEP view of the structure of 2-nitrosomethylaminoimidazo-[1,5-*b*][1,2,4]thiadiazole-4-carboxamide **11**. Displacement elipsoids are shown at the 50% probability level.

**Scheme 3**

This new synthesis of **11** in two steps from the aminoimidazole **4** is notable for the high yield and mild conditions and may be adapted for the synthesis of other examples of this intriguing new bicyclic system.

This work was supported by the Cancer Research Campaign, UK. We thank collaborators at Aston Molecules Ltd, Birmingham, UK and Schering-Plough Research Institute, Kenilworth, New Jersey, USA for helpful discussions.

## Footnotes

† *General experimental method* for ureas **5** and thiourea **7**. A solution or suspension of 5-aminoimidazole-4-carboxamide hydrochloride (0.5 g) and dry triethylamine (1 ml) in dry $Me_2SO$ or acetonitrile (10 ml) was treated dropwise (1 h) with the isocyanate or isothiocyanate (1.2 equiv.) at 10 °C (−10 °C in the case of acetonitrile). The mixture was stirred overnight at 25 °C, quenched with water (25 ml), and products collected and washed successively with water and ethyl acetate. Yields of ureas were **5a** (85%), **5b** (75%), **5c** (70%), **5d** (95%) and the thiourea **7** (85%). Satisfactory microanalytical data were obtained for new compounds.

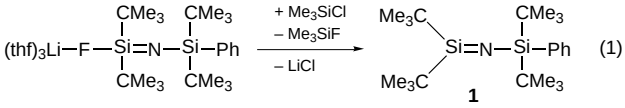
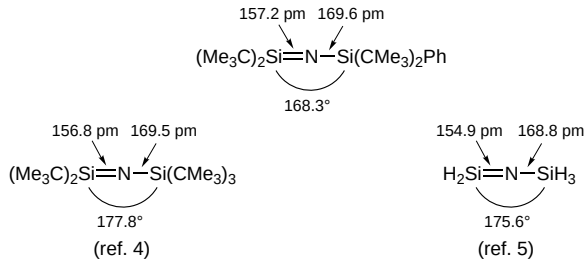
# From monomeric iminosilane to a monomeric aminoalane: synthesis and crystal structures



**Jörg Niesmann,[a] Uwe Klingebiel,*[a] Mathias Noltemeyer[a] and Roland Boese[b]**

[a] *Institut für Anorganische Chemie der Universität, Tammannstr. 4, D-37077 Göttingen, Germany*
[b] *Institut für Anorganische Chemie, Universität-GH Essen, Universitätsstr. 5-7, D-45117 Essen, Germany*

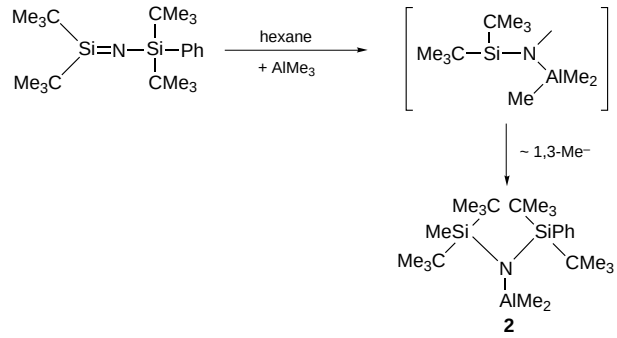


**The reaction between the iminosilane $R_2Si{=}NR'$ [R = $CMe_3$, R′ = $Si(CMe_3)_2Ph$] 1 and $AlMe_3$ in *n*-hexane at −78 °C affords the first monomeric aminodimethylalane $Me_2Al{=}N(R')R''$ [R″ = $Si(CMe_3)_2Me$] 2; the crystal structure of 2 is presented.**

Compounds of multiple bond systems involving heavier main group elements were long considered to be unstable and synthetically inaccessible.[1–3] The first silaethenes and disilenes were synthesised at the beginning of the 1980s, and the first iminosilanes were reported in the mid-1980s.[1–3]

The uncoordinated and thermally stable iminosilane $R_2Si{=}NR'$ [R = $CMe_3$, R′ = $Si(CMe_3)_2Ph$] **1** is formed in quantitative yield in the reaction between the lithiated fluorosilylamine compound and $SiClMe_3$.[1] It is based on a fluorine/chlorine exchange with subsequent thermal LiCl elimination [eqn. (1)].[1]

The crystal structure of **1** shows a trigonal arrangement of the $C_2Si{=}N$ unit around the silicon atom. In solid state the iminosilane is monomeric and the Si=N–Si skeleton is nearly linear (168.3°). The Si–N bond lengths are drastically different. The Si–N single bond is 169.6 pm, and the Si=N double bond is 157.2 pm. The results are consistent with Wiberg's experimental[4] and von Rague Schleyer's calculated[5] results.



Iminosilanes react with Lewis bases, for example, with ethers or tertiary amines with formation of adducts. The adducts are often thermally stable and can be distilled without decomposition.[1,6] Reactions of iminosilanes with Lewis acids are not described so far. We found that di-*tert*-butyl(di-*tert*-butylphenylsilyl)iminosilane **1** reacts with trimethylalane, $AlMe_3$, to give the monomeric aminoalane, $Me_2AlN[Si(CMe_3)_2Me]Si(CMe_3)_2Ph$ **2** (Scheme 1).†‡

Unassociated compounds of the form $R_2M–NR'_2$ (M = B, Al, *e.g.* **2**) have the potential for π bonding between the main group 3 element (M) and nitrogen through overlap of the lone pair on nitrogen with the empty p orbital on boron or aluminium. Such π bonding is well established in molecules containing boron–nitrogen bonds.

The chemistry of the heavier group 3 elements, *e.g.* Al, is dominated by the tendency to form dimers or more highly associated structures. However, three-coordination is achieved by the use of bulky substituents.[7]

For the first time a monomeric aminodimethylalane is obtained by a nucleophilic methanide-ion migration from aluminium to silicon. The methanide-ion migration can be explained by the strong Lewis acidity of the three-coordinate silicon, which must be stronger than the Lewis acidity of the three-coordinate aluminium.

**Scheme 1**

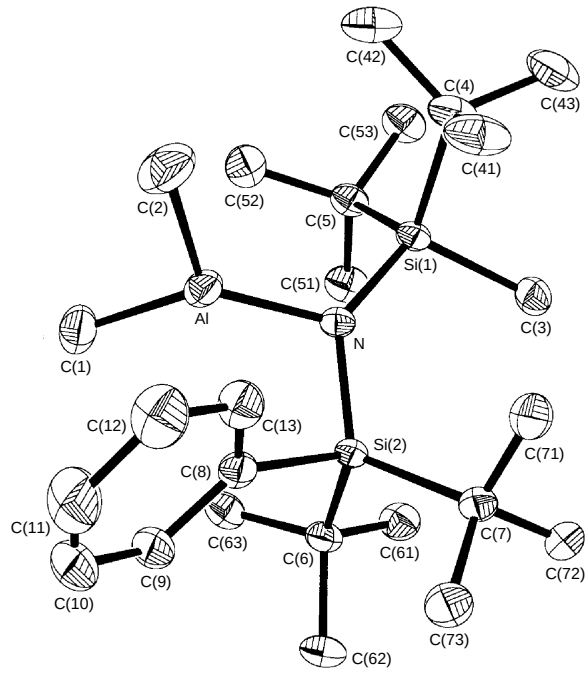


**Fig. 1** Molecular structure of **2** (ORTEP, thermal ellipsoids at the 50% probability level). Principal distances (pm) and angles (°): Al–N 186.9(2), Al–C(2) 195.4(2), Al–C(1) 196.4(2), Al–C(8) 256.4(3), Al–Si(2) 284.43(8), Si(1)–N 175.2(2), Si(2)–N 175.0(2); C(2)–Al–C(1) 108.03(11), C(1)–Al–N 125.66(9), C(2)–Al–N(1) 124.09(10), Σ < Al(1) = 357.8°, Si(2)–N–Si(1) 133.88(9), Al–N–Si(2) 103.56(7), Al–N–Si(1) 122.53(8), Σ < N(1) = 360.0°. Torsion angle C(1)–Al–N–Si(1) −57.5°.

The structure of **2**§ which is depicted in Fig. 1 consists of well separated $Me_2AlN(R')R$ monomers. The Al–N bond length is 186.9 pm. The geometry of the Al atom is nearly planar (sum of angles = 357.8°). The C–Al–C angle is 108.03°. The geometry of the nitrogen centre is also planar (sum of angles = 360.0°) with the widest angle, 133.9°, between the silyl groups. The torsion angle of the C(2)–Al–N–Si(1) axis is −57.5°. There is a weak intramolecular interaction of the electron deficient aluminium atom with the C(8) atom of the phenyl ring facing the metal, Al–C(8) 256.4 pm. This decreases the Al–N–Si(2) angle (103.6°) and brings the Al and Si(2) atoms into close proximity [Al–Si(2) 284.4 pm]. The Al–N bond length is short in comparison to the simple sum of the aluminium and nitrogen covalent radii, *i.e*. 200 pm, which suggests the presence of Al–N $p_\pi$–$p_\pi$ bonding. However, the dihedral angle C(1)–Al–N–Si(1) of −57.5° makes this very limited. Therefore most of the shortening of the Al–N bond should be attributed to the difference of the electronegativity. The Al–N bond length is comparable the Al–N distances of $Bu^t_2AlN$ compounds.[7]

† *Preparative details*. Starting materials: **1**,[8] yellow oil, bp 108 °C (0.01 Torr), trimethylaluminium, 2.0 M solution in toluene. Reaction under dry argon. To 4.31 g (11.5 mmol) of di-*tert*-butyl(di-*tert*-butylphenylsilyl)iminosilane **1**,[8] which was freshly distilled into a Schlenk bulb, was added 60 ml of degassed dry hexane. Then 5.74 ml (11.5 mmol, 2.0 M solution in toluene) trimethylaluminium were added at −78 °C. The solution was stirred at −78 °C for 2 h and at 25 °C for 1 day. After removal of the solvent *in vacuo* ($10^{-2}$ Torr) and recrystallisation of the residue from toluene crystalline compound **2** was obtained in 74% yield; mp 121 °C; MS (EI): *m/z* (%) = 432(30) $[M - CH_3]^+$, 390(100) $[M - C_4H_9]^+$.

‡ *NMR data*: **2** ($C_6D_6$–toluene): $^1$H, δ −0.63 (s, 6H, $AlMe_2$), 0.40 (s, 3H, SiMe), 1.21 (s, 18H, $CMe_3$), 1.23 (s, 18H, $CMe_3$), 6.97– 8.06 (m, 5H, Ar-H); $^{13}$C, δ −0.13 (s, SiMe), 1.82 (br s, $AlMe_2$), 22.83/23.56 (s, $CMe_3$), 30.97/31.54 (s, $CMe_3$), 129.29 [s, Ph (C-3, C-5)], 132.56 [s, Ph (C-4)], 137.60 [s, Ph (C-2, C-6)], 137.65 [s, Ph (C-1)]; $^{29}$Si, δ -3.37 (s, SiPh), 7.13 (s, SiMe).

§ *Crystal data for* **2**: a crystal of size 0.4 × 0.6 × 0.8 $mm^3$ was measured on a STOE/Siemens AED2 four circle diffractometer with Mo-Kα radiation at 153 K. The space group is monoclinic, $P2_1/n$, with unit-cell dimensions $a$ = 11.1930(10), $b$ = 15.601(2), $c$ = 16.622(3) Å, β = 105.750(10)°, $U$ = 2793.6(7) $Å^3$, $Z$ = 4, refined from 30 reflections centred at positive and negative 2θ positions; μ = 0.170 $mm^{-1}$ and $F$(000) = 992. 3401 reflections up to 2θ = 45° were collected, of which 3396 were independent ($R_{int}$ = 0.014). The structure was solved using direct methods (SHELXS) and refined on $F^2$ (SHELX93) with no disorder indicated: $R_1[I > 2\sigma(I)]$ = 0.0347, $wR_2$ = 0.0852; for all 3391 data $R_1$ = 0.0391, $wR_2$ = 0.092, GOF = 1.071.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Reaction of furans with trithiazyl trichloride: new synthesis of isothiazoles

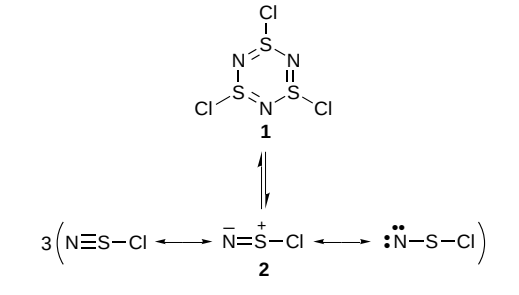
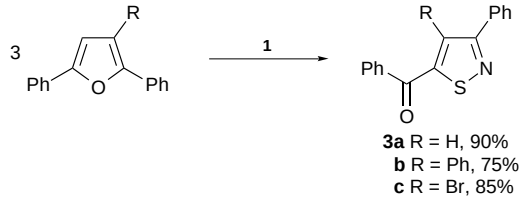
**Xiao-Lan Duan, Charles W. Rees and Tai-Yuen Yue**

*Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*



**Trithiazyl trichloride 1 converts 2,5-disubstituted furans into isothiazoles (*e.g.* 3, 6, 7) regiospecifically and in good yield, providing a new, one-step synthesis of isothiazoles, for which a novel mechanism involving formation and ring-opening of a β-thiazylfuran 4 is proposed.**

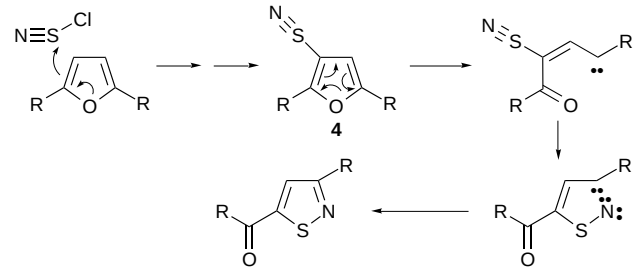
Trithiazyl trichloride **1**[1] is a stable but moisture-sensitive, yellow crystalline solid, prepared by heating ammonium chloride and sulfur with disulfur dichloride, and chlorination of the resulting salt, $S_3N_2Cl_2$.[2] The cyclic trimer **1** is in thermal equilibrium with the highly reactive monomer, thiazyl chloride **2** (Scheme 1). It is reactive towards many simple organic substrates and has considerable potential in the synthesis of sulfur-nitrogen compounds.[3]



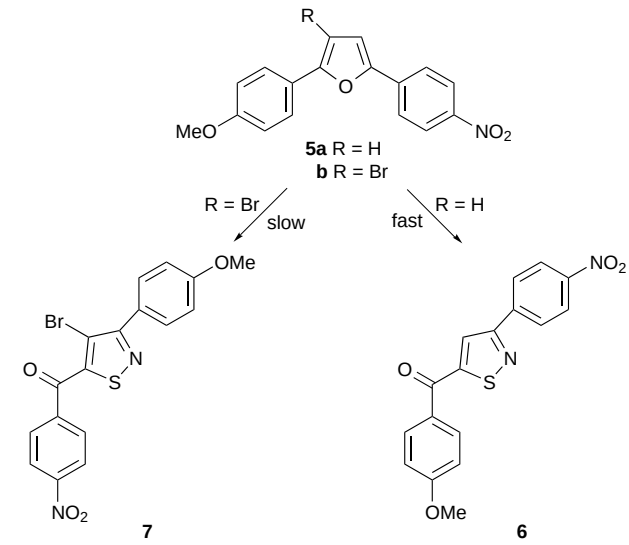
We thought that the monomer **2** might be selectively intercepted by furans in a Diels–Alder reaction.[4] Trithiazyl trichloride **1** reacted very cleanly with 2,5-diphenylfuran in boiling $CCl_4$, converting 3 equiv. into 5-benzoyl-3-phenylisothiazole **3a** in high yield (90%) (Scheme 2). 2,3,5-Triphenylfuran and 3-bromo-2,5-diphenylfuran reacted similarly to give the analogous isothiazoles **3b** (75%) and **3c** (85%). No isomers of the products were detected and so cleavage of the furan ring and incorporation of the S–N unit is apparently regiospecific. This represents a new opening of the furan ring and a new, mild, one-step synthesis of isothiazoles. Closely related, but fully substituted furans, such as 3,4-dibromo-2,5-diphenyl- and 3-bromo-2,4,5-triphenyl-furan did not react with the reagent **1**; clearly a ring hydrogen is required for the formation of HCl, which is evolved during the reactions. 2,5-Bis-(4-methylphenyl)-, 2,5-bis(4-methoxyphenyl)- and 2,5-di-*tert*-butylfuran all gave the analogous isothiazoles in boiling $CCl_4$ or toluene, although in somewhat lower yields (50–60%).

All of these products could have been formed by Diels–Alder reactions with thiazyl chloride **2**, followed by rearrangement of the adduct with loss of HCl,[3] but the above results led us to consider an alternative mechanism. This is based upon electrophilic substitution of the furan ring at an unsubstituted β-position to give a β-thiazyl derivative **4**, which could then rearrange to the isothiazole by a ring-opening, ring-closing mechanism (Scheme 3). We hoped to distinguish between these mechanisms by reacting the trimer **1** with polarised, unsymmetrical 2,5-disubstituted and 2,3,5-trisubstituted furans.

2-(4-Methoxyphenyl)-5-(4-nitrophenyl)furan **5a** in boiling THF gave 5-(4-methoxybenzoyl)-3-(4-nitrophenyl)isothiazole **6** (85%) very cleanly and regiospecifically (Scheme 4). This agreed well with the substitution mechanism (Scheme 3) since the aryl groups at C-2 and C-5 would strongly direct electrophilic attack to C-3, which leads to the observed isomer **6**. However, this result is harder to reconcile with the Diels–Alder mechanism since the expected orientation, based on the polarities of the furan **5a** and thiazyl chloride ($N^+{=}S^-{-}Cl$) would most reasonably lead to the undetected isothiazole isomer. The more nucleophilic furan ring position (C-3) of **5a** was then 'blocked' by bromination to give **5b**, which was treated with the trimer **1** under the same conditions. The reaction of **5b** was considerably slower than that of **5a**, but it too gave only one product, 4-bromo-2-(4-methoxyphenyl)-5-(4-nitrobenzoyl)isothiazole **7** (65%) with the *opposite* regiochemistry. This follows from the substitution mechanism, where the thiazyl substituent is introduced at the only available (deacti-

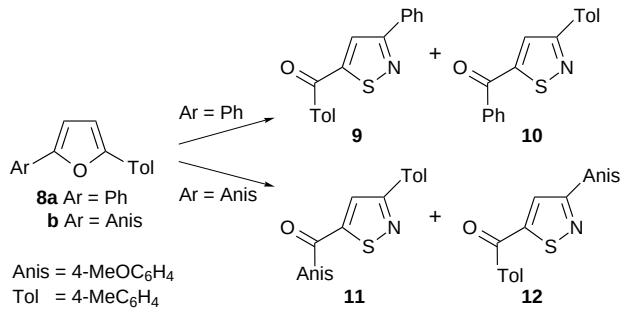


**Scheme 1**

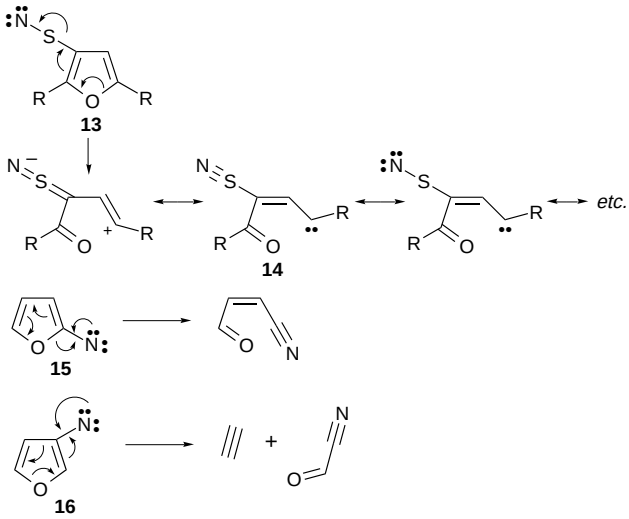


**3a** R = H, 90%
**b** R = Ph, 75%
**c** R = Br, 85%

**Scheme 2**



**Scheme 3**



**Scheme 4**

vated) site, which leads to the observed isomer (Scheme 3). The Diels–Alder mechanism would require the complete reversal of orientation of cycloaddition, on passing from furan **5a** to **5b**, which seems unlikely.

Each of these highly polarised furans gave only one isothiazole; it seemed likely that if the degree of polarisation was reduced both possible isomeric isothiazoles might be formed, and this proved to be so. Thus 2-(4-methylphenyl)-5-phenylfuran **8a** and 2-(4-methoxyphenyl)-5-(4-methylphenyl) furan **8b** were treated with the trimer in boiling THF

**Scheme 5**

**Scheme 6**

(Scheme 5). Detailed analysis of the $^1$H NMR spectra showed that each gave mixtures of two isomeric isothiazoles which were inseparable by chromatography; these were **9** and **10** (3.3 : 1) (56%) and **11** and **12** (3.9 : 1) (65%) respectively. Thus in each case the more electron-releasing aryl group in the furan becomes part of the 5-aroyl group of the major isomer, in agreement with the reaction of the more highly polarised furan **5a**, where only the 'major' isomer was observed. On the mechanism of Scheme 3, substitution of SN should predominate at the ring position adjacent to the more electron-releasing group, which then transforms into the 5-aroyl group, as observed. The expected orientation in the Diels–Alder reaction would have led to the minor rather than the major isomer.

From all this evidence we favour the mechanism of Scheme 3. The initially puzzling step, ready opening of the β-thiazyl furan ring, is comprehensible when the nitrenoid character **13** of this intermediate is considered. The highly reactive thiazyl substituent could induce cleavage of the furan ring (arrows in **4** ≡ **13**) to give the delocalised intermediate **14** which then collapses to the isothiazole (Scheme 6). This unusual ring-opening is somewhat analogous to the well established cleavage reactions of nitrenes (and carbenes) directly attached to furan and other five-membered heterocyclic rings (*cf.* **15** and **16**).[5]

The structures of all the new compounds reported here are based on a detailed analysis and comparison of their spectra, particularly NMR and mass spectra, with model compounds. These data, and syntheses of the compounds, will be presented in a full paper.

We thank Zeneca Specialities, the Commonwealth Scholarship Commission and MDL Information Systems (UK) Ltd for financial support, and the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.

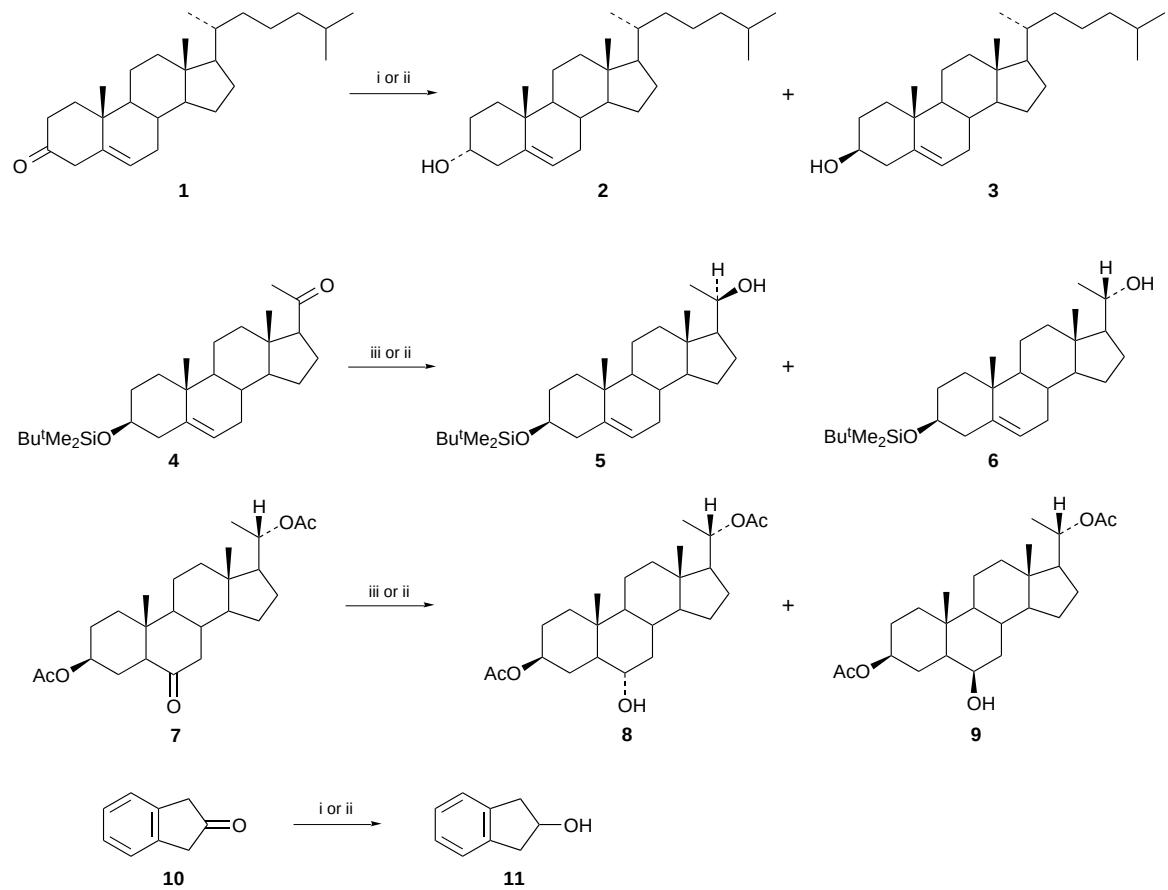
# Trimethylsilyl chloride-accelerated reduction and pinacol coupling of carbonyl compounds by means of samarium diiodide



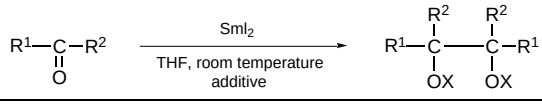
**Toshio Honda* and Miho Katoh**

*Institute of Medicinal Chemistry, Hoshi University, Ebara 2-4-41, Shinagawa-ku, Tokyo 142, Japan*

**The combination of samarium diiodide ($SmI_2$) and trimethylsilyl chloride ($Me_3SiCl$) in THF–HMPA is found to accelerate the reduction of sterically hindered and enolisable ketones, and also to accelerate pinacolisation of the carbonyl compounds depending on the reaction conditions.**

Samarium(II) diiodide, originally introduced by Kagan and co-workers[1] into organic synthesis, has been established as a useful synthetic reagent and a number of interesting reactions have been developed by application of this reagent.[2] $SmI_2$ is a powerful one-electron reducing agent and serves as an effective reductant of carbonyl compounds. $SmI_2$-promoted reduction of carbonyl compounds usually proceeds quickly and completes within a few minutes when the reaction is carried out in the presence of a proton donor such as an alcohol or water in tetrahydrofuran to prevent the formation of the pinacol coupling product.[1–3] During the course of our work on the synthesis of physiologically active compounds employing $SmI_2$, we observed that the reduction of ketones with $SmI_2$ in THF–HMPA was accelerated in the presence of $Me_3SiCl$ to give the corresponding alcohol(s) with Birch-type reduction stereochemistry in good yields.

Treatment of the 3-keto steroid **1** with 3 equiv. of $SmI_2$ in the presence of 3 equiv. of Bu$^t$OH as a proton donor in THF–HMPA at ambient temperature for 10 min afforded the corresponding alcohols [**2** (3α) : **3** (3β) = 28 : 57%].† When this reduction was carried out in the presence of 3 equiv. of $Me_3SiCl$ as an additive instead of Bu$^t$OH under the same reaction conditions, the yield improved to 90% [**2** (3α) : **3** (3β) = 30 : 60%].‡ Interestingly, reduction of the 20-keto steroid **4** with $SmI_2$ and Bu$^t$OH in THF–HMPA at room temperature required 6 h to afford the corresponding alcohols [**5** (20*S*) : **6** (20*R*) = 26 : 23%]. However, reduction of **4** under similar reaction conditions in the presence of $Me_3SiCl$ proceeded within 10 min to provide the alcohols (**5** and **6**)‡ in 93% yield, in a ratio of 1 : 1. The reaction became significantly faster in the presence of $Me_3SiCl$. A dramatic change was observed in the reduction of 6-keto steroid **7**, which on treatment with $SmI_2$ in THF–HMPA gave none of the desired alcohol, although HMPA was recognised to increase the rate of the reaction of $SmI_2$.[4]



**Scheme 1** *Reagents and conditions*: i, $SmI_2$, Bu$^t$OH, THF–HMPA, room temp., 10 min; ii, $SmI_2$, $Me_3SiCl$, THF–HMPA, room temp., 1 min, then $Bu_4NF$, THF, room temp.; iii, $SmI_2$, Bu$^t$OH, THF–HMPA, room temp., 6 h

However, reduction of **7** was carried out with $SmI_2$ and $Bu^tOH$ for 6 h to afford the alcohols [**8** (6α) : **9** (6β) = 39 : 22%) in moderate yields. Moreover treatment for 10 min of **7** with $SmI_2$ in the presence of $Me_3SiCl$ afforded **8** as the sole product‡ in 91% yield. These varied reaction times and yields are reflected by the steric hindrance of the carbonyl groups (6-keto > 20-keto > 3-keto) and the above results clearly suggest that $Me_3SiCl$ accelerates the $SmI_2$-mediated reduction of sterically hindered ketones, although it is premature to present a detailed mechanistic rationale at the present time. This type of reduction was found to be effective to the enolisable ketones. Thus, the reduction of indan-2-one **10** with $SmI_2$ in THF–HMPA at ambient temperature in the presence of $Me_3SiCl$ proceeded within 1 min to give indan-2-ol **11** in 79% yield, whereas similar reduction with $SmI_2$ and $Bu^tOH$ after 10 min afforded **11** in 66% yield. The reduction was typically carried out as follows—to a stirred solution of $SmI_2$ in dry THF (7 $cm^3$), prepared from samarium metal (0.76 mmol) and diiodoethane (0.69 mmol), under argon at room temperature, was added HMPA (0.9 $cm^3$) and the resulting mixture was stirred for a further 15 min. After the successive addition of a solution of ketone (0.23 mmol) in THF (1 $cm^3$) and $Me_3SiCl$ (0.7 mmol), the mixture was stirred for the appropriate time and then treated with saturated aqueous sodium hydrogen carbonate. A stream of air was bubbled through the solution and an excess of Celite and $Et_2O$ were added. The solution was filtered and the filtrate was extracted with ethyl acetate. Evaporation of the solvent followed by treatment of the residue with $Bu_4NF$ (0.5 mmol) in THF (10 $cm^{-1}$) at room temperature afforded the desired alcohol.

The effectiveness of $Me_3SiCl$ for $SmI_2$-mediated pinacol coupling of the ketones in THF was also investigated. HMPA was used as co-solvent to reduce the formation of reduction products.[5] The results are summarised in Table 1 and indicate that the pinacol coupling of both aldehyde and ketone was also accelerated by the presence of $Me_3SiCl$. For example, it was reported that the pinacol coupling of hexyl methyl ketone with $SmI_2$ in THF–HMPA required 24 h to give the corresponding coupling product in 80% yield.[5] However, the same reaction in the presence of $Me_3SiCl$ proceeded within 3 min to give the coupling product in 77% yield (entry 2). Similar results were also obtained (see entires 5, 8 and 10), clearly indicating that $Me_3SiCl$ as an additive accelerated the pinacol coupling compared to the results previously reported.[5] A typical experimental procedure for the pinacol coupling is as follows—to a stirred solution of $SmI_2$ (5.1 mmol) in dry THF (50 $cm^3$), prepared from samarium metal and diiodoethane as above, were added a solution of ketone (1.55 mmol) in THF (2 $cm^3$) and $Me_3SiCl$ (4.7 mmol). The resulting solution was stirred for the appropriate time (see Table 1) under argon at room temperature. The mixture was worked-up as described above to give the coupling product.

In conclusion, we have found that $Me_3SiCl$ is an effective additive for the $SmI_2$-promoted reduction of ketones and also for pinacol coupling. Recently, Kagan and co-workers[6] reported the improved reactivity of $SmI_2$ by catalysis with transition metal salts, in which Barbier-type reactions were found to be accelerated in the presence of such metal salts. $Me_3SiCl$ in this work may play a similar role as the metal salts.

**Table 1** Pinacol coupling of the ketones

| Entry | Starting material R1 | Starting material R2 | Reaction conditions Additive | Reaction conditions Time | Product X | Yield (%)[c] |
|---|---|---|---|---|---|---|
| 1 | $C_6H_{13}$ | Me | — | 12 h | H | 75 |
| 2 | $C_6H_{13}$ | Me | $Me_3SiCl$[a] | 3 min | H | 77 |
| 3 | $C_6H_{13}$ | Me | — | 24 h | H | 80[d] |
| 4 | $C_7H_{15}$ | H | — | 45 min | H | 81 |
| 5 | $C_7H_{15}$ | H | $Me_3SiCl$[a] | 1 min | H[b] / $SiMe_3$ | 37 / 45 |
| 6 | $C_7H_{15}$ | H | — | 3 h | H | 85[d] |
| 7 | $PhCH_2CH_2$ | Me | — | 10 h | H | 78 |

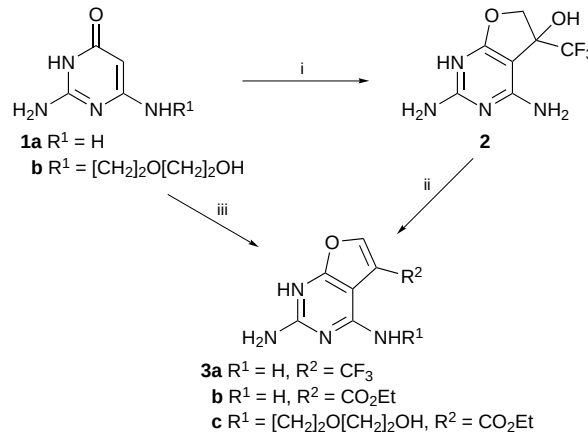
# Synthesis of potential inhibitors of GTP-cyclohydrolase I: an efficient synthesis of 8-substituted 7-deazaguanines

**Colin L. Gibson,† Klaus Paulini and Colin J. Suckling***

*Department of Pure & Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL*



**A novel two step synthesis of 8-substituted 7-deazaguanines is developed and involves the regioselective alkylation of pyrimidinones 1a and 1b with nitrosoalkenes derived from α-halo oximes followed by transoximation to give the 7-deazaguanines 6a–d in 41–65% overall yield**

GTP-cyclohydrolase I catalyses the conversion of GTP into dihydroneopterin triphosphate and involves the opening of the imidazole and ribose rings with the loss of C-8 as formate, and Amadori rearrangement of the ribose portion.[1] Very little is known about the elementary steps of the process but the mechanism has been the subject of some discussion.[2–4] While there is consensus that the first step of the sequence involves attack of a nucleophile at C-8, the nature of the nucleophile ($H_2O$, $cys_{110}$-S-S-$cys_{181}$ or his) is still the subject of speculation. In order to address the issue of the nature of the nucleophile we wished to prepare potential inhibitors of GTP cyclohydrolase that had been designed to give stable tetrahedral nucleophilic C-8 addition intermediates. In this context, we proposed that 7-deazaguanines {pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-ones} would not undergo subsequent imidazole ring opening and that by locating a strongly electron-withdrawing substituent at C-8, would afford stable tetrahedral intermediates.

Linear syntheses of 8-alkyl-7-deazaguanines have been reported involving the condensation of substituted ethyl cyanoacetate derivatives with guanidine hydrochloride.[5] This approach has been exploited by Seela and Chen for the synthesis of 8-methyl-7-deazaguanosine which was used in the synthesis of modified DNA oligionucleotides.[6] More direct convergent syntheses of 8-alkyl-7-deazaguanines have been carried out by the condensation of 2,6-diaminopyrimidin-4(3*H*)-ones with α-halo carbonyl compounds.[7] This latter approach suffers from problems of regiochemistry in that either 7-deazaguanines or furo[2,3-*d*]pyrimidines or mixtures of both are produced. In view of the fact that linear syntheses were unattractively long we carried out an initial study of the viability of the condensation routes involving α-halo ketones carrying α-electron-withdrawing groups. Thus, reaction of 2,6-diaminopyrimidin-4(3*H*)-one **1a** with 3-bromo-1,1,1-trifluoropropanone afforded, exclusively, the dihydrofuro[2,3-*d*]pyrimidine **2** in 67% yield (Scheme 1). The dihydrofuro[2,3-*d*]pyrimidine **2** could be dehydrated to the corresponding furo[2,3-*d*]pyrimidine **3a** (71% from **1a**) by treatment with concentrated sulfuric acid. Similarly, condensation of ethyl bromopyruvate with pyrimidinones **1a** or **1b** yielded the furo[2,3-*d*]pyrimidines **3b** and **3c**, directly, in 92 and 33% yields, respectively.

The failure of pyrimidinones **1a** and **1b** to yield 7-deazaguanines on reaction with α-halo ketones led to an evaluation of alternative novel routes to such species. In this context, nitrosoalkenes, generated *in situ* from α-halo oximes, are powerful electrophiles that have been shown to react with carbon nucleophiles at the β-carbon.[8] Given this reactivity pattern of nitrosoalkenes we anticipated that reaction with 2,6-diaminopyrimidin-4(3*H*)-one would provide short convergent syntheses of 8-substituted 7-deazaguanines. Accordingly, 3-bromo-1,1,1-trifluoropropanone oxime **4a** reacted with excess pyrimidinone **1a** in DMF to afford the C-5 alkylated pyrimidinone **5a** in 80% yield (entry 1, Table 1 and Scheme 2). Similarly, the oximes **4b**–**d** were treated with pyrimidinone **1a** in DMF in the presence of a base (excess **1a**, $Na_2CO_3$ or $Et_3N$) to give the C-5 alkylated pyrimidinones **5c** (57–79%, entries 5–7), **5e**‡ (38%, entry 10) and **5f** (47%, entry 11), respectively. The pyrimidinone **1b** carrying the 2-(2-aminoethoxy)ethanol side chain was also reacted with the oximes **4a** and **4b** in the presence of triethylamine or potassium carbonate to afford the C-5 alkylated pyrimidinones **5b** (43–58%, entries 3 and 4) and **5d** (47–61%, entries 8 and 9), respectively. In the syntheses of the pyrimidinones **5a**–**f** the only products were those derived from nucleophilic substitution of the C-5 position of pyrimidinones **1a** and **1b** at the α-carbon of the halo oximes **4a**–**d**, thus substantiating the potential of this method.

With an efficient method for the syntheses of pyrimidinones **5** with a C-5 alkyl oxime group we turned our attention to the cyclisation of these compounds to give 8-substituted 7-deaza-

[a] Reaction carried out in MeOH at 50–60 °C, 5 min. [b] Reaction carried out in DMF at 100–120 °C without aldehyde. [c] At room temperature. [d] At 60 °C for 96 h. [e] 64 : 36 Mixture of **5e** and **6e**.

guanines **6**. Thermal cyclisation of the trifluoro compound **5a** by heating in DMF at 100–120 °C gave the 8-trifluoromethyl-7-deazaguanine **6a** in 43% yield (Table 1, entry 2).[1] Unfortunately, this thermal procedure was not successful for the remaining oximes as slow decomposition was observed. An alternative method of transoximation involving heating the C-5 alkyl oximes **6a**–**d** with benzaldehyde in aqueous ethanol with a catalytic quantity of hydrochloric acid proved highly successful to afford the 8-substituted 7-deazaguanines **6a** (81%, entry 1), **6b** (71%, entry 3), **6c** (60%, entry 5) and **6d** (49%). The more reactive C-5 alkyl oximes **5b,c** and **d** could also be cyclised to the deazaguanines **6b** (52%, entry 4), **6c** (30%, entry 6) and **6d** (71%, entry 8) using the transoximation procedure with propanal or acetaldeyde. The phenyl substituted oxime **5f** failed to cyclise but underwent decomposition under a variety of conditions.

**Scheme 2** *Reagents and conditions*: i, DMF, base (see Table 1), room temp. 4–72 h; ii, EtOH–$H_2O$, benzaldehyde or acetaldehyde, cat. HCl, heat, 24–72 h

The 8-carboxy-7-deazaguanines **6f** (85%) and **6g** (83%) were also available by lithium hydroxide saponification of the respective esters **6c** and **6d**. Investigation of the 8-substituted 7-deazaguanines **6a**–**d** and **6f,g** and their triphosphorylated derivatives as inhibitors of GTP cyclohydrolase I is currently underway and these results will be reported in due course.

Grateful acknowledgement is made to the European Union for a Human Capital and Mobility Award (K. P.) (contract ERBCHRX CT93-0243).

# Diphosphines with large natural bite angles lead to the formation of non-classical *cis*-(diphosphine)$_2$Ru(H)(H$_2$)$^+$ complexes

**Mirko Kranenburg,[a] Paul C. J. Kamer,[a] Piet W. N. M. van Leeuwen*[a] and Bruno Chaudret*[b]**

[a] *J. H. van't Hoff Research Institute, Department of Inorganic Chemistry, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands*

**The application of diphosphine ligands with large natural bite angles leads to the formation of thermo-labile, non-classical *cis*-(diphosphine)$_2$Ru(H)(H$_2$)$^+$ complexes.**

The discovery of the first $\eta^2$-dihydrogen complex by Kubas *et al.*[1] has led to numerous studies on the factors determining the properties of such complexes. The bond between the transition metal and the $H_2$ ligand is a subtle balance between σ donation and π back-donation. Morris and coworkers have reported several studies on the effect of electronic modifications in diphosphine ligands on the stability of ruthenium dihydrogen complexes and on the acidity of the $H_2$ ligand.[2–9]

So far, few detailed studies have dealt with the effect of geometrical changes on the nature and reactivity of $\eta^2$-dihydrogen complexes.

Recently, Morokuma and coworkers reported that, with an increasing bite angle of the diphosphine, the nature of the (diphosphine)$_2$Ru('H$_3$')$^+$ complexes changes from *trans*-hydrido–dihydrogen to classical trihydride and to *cis*-hydrido–dihydrogen complexes.[10]

We recently developed[11] diphosphines based on xanthene-like backbones that allow the investigation of the effect of large bite angles on the properties of transition-metal complexes (Fig. 1). Here, we report that the geometrical constraints of these rigid bidentate phosphine ligands have a large effect on the structure and stability of ruthenium dihydrogen complexes.

*cis*-(Diphosphine)$_2$RuH$_2$ complexes **1** were prepared from Ru(cod)(cot) (cod = cycloocta-1,5-diene, cot = cycloocta-1,3,5-triene) and 2 equiv. of the diphosphine under 5 kPa $H_2$ (Fig. 2).†

Protonation of (thixantphos)$_2$RuH$_2$ **1a** at 176 K with HBF$_4$·OEt$_2$‡§ results in one product, which exhibits a broad symmetric signal in the $^1$H NMR spectrum at δ −6.7 and a double triplet in the $^{31}$P{$^1$H} NMR spectrum. Based on the $^{31}$P NMR spectrum and the $T_1$(min) for the hydride signal in the high-field region of the $^1$H NMR spectrum (17 ms at 240 K), we assign these signals to a *cis*-Ru(H$_2$)H species (**2a**). Upon raising the temperature slowly from 220 to 260 K, the signals from **2a** decrease and signals of a new species appear (Fig. 3). This new component gives rise to a sharp 14 line signal centred at δ −6.28 in the high-field region of the $^1$H NMR spectrum, and an ABMX splitting in the $^{31}$P{$^1$H} NMR spectrum. At 260 K this is the only species present. The nature of this new species was unambiguously determined by measurement of selective hydride-coupled $^{31}$P NMR as the cationic species (thixantphos)$_2$RuH$^+$ **3a**, resulting from the evolution of $H_2$ [$T_1$ (240 K) 242 ms]. The vacant site probably interacts with the counter ion or a solvent molecule (L).

Upon protonation of (sixantphos)$_2$RuH$_2$ **1b** at 176 K three products are formed as concluded from $^1$H and $^{31}$P NMR. In the high-field region of the $^1$H NMR spectrum one sharp 14 line multiplet centred at δ −5.6, similar to the signal observed for **3a**, and two broad signals located at δ −6.9 (major) and at δ −6.6 (minor) are present. Based on the $^{31}$P NMR spectrum and the $T_1$(min) value of the combined $^1$H signals at −6.9 to −6.6 (23 ms at 200 K), these signals are assigned to two *cis*-Ru(H$_2$)H isomers, **2b** and **2b′**. The ratio of these complexes is 1 (**2b′**) : 4 (**2b**) : 9 (**3b**). Increasing the temperature to 200 K results in a slight decrease of the amount of **2b**, **b′** and an increase of **3b** and at 210 K only the 14 line hydride signal of **3b** remains [$T_1$ (200 K) = 622 ms].

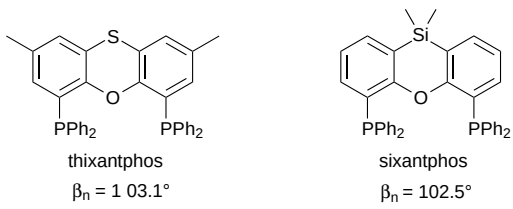

**Fig. 1** Structure and natural bite angles of the ligands. Bite angles calculated using molecular mechanics (CAChe WorkSystem),[12] with a P–Ru bond length of 2.424 Å[10] and a P–Ru–P angle bending force constant of 0 mdyn Å rad$^{-1}$ (1 dyn = 1 × 10$^{-5}$ N). The natural bite angle is defined as the preferred chelation angle determined only by ligand backbone constraints and not by metal valence angles.[13]

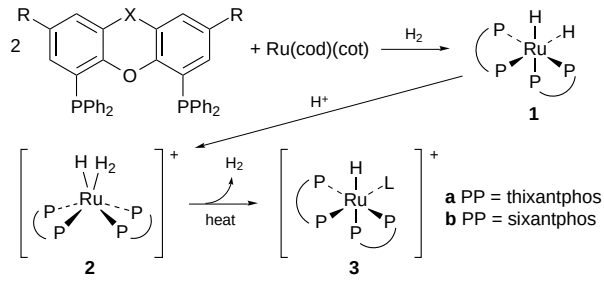

**Fig. 2** Reaction sequence leading to the products investigated

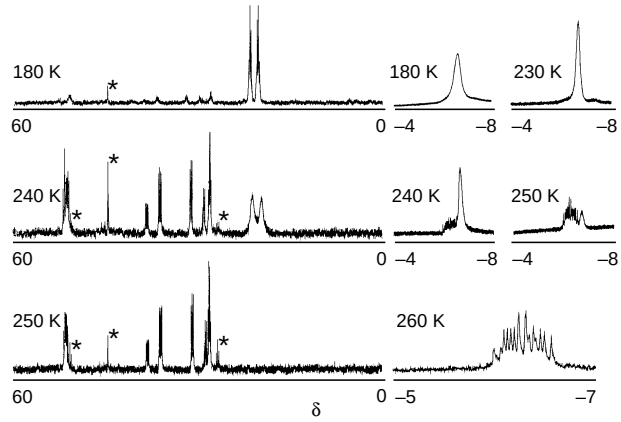

**Fig. 3** Change with temperature of the $^{31}$P{$^1$H} and high-field region of the $^1$H NMR spectra of the reaction mixture arising from protonation of **1a** with HBF$_4$·OEt$_2$; * denotes an impurity

The short $T_1$ values observed for **2** are indicative of the presence of short H–H distances (0.84 Å and 0.89 Å for **2a** and **2b** respectively as calculated from $T_1(H_2)$ and $T_1(H)$: see ef. 6.

Comparison of the $^{31}P\{^1H\}$ NMR spectra obtained for **2a** and **2b** reveals a notable difference in geometry for the complexes of these similar ligands. We used molecular modelling to investigate the possible geometries for these $(diphosphine)_2Ru(H)(H_2)^+$ complexes. The relative orientation of the backbones of the diphosphines when coordinated to the metal centre allows us to distinguish two types of complexes (Fig. 4). In complexes of type **A**, every P nucleus has a different environment, therefore all P nuclei are magnetically inequivalent and an ABMX splitting in the $^{31}P$ NMR spectrum is expected. In complexes of type **B**, we can distinguish two pairs of magnetically different P nuclei and an $A_2B_2$ splitting in the $^{31}P$ NMR spectrum is expected. In type **A** complexes the aromatic rings are more densely packed, compared to type **B** complexes, resulting in energetically favourable π-stacking interactions. This would be the favoured product (as seen in **2b**), but for thixantphos these stabilizing interactions are hampered by the methyl groups on the backbone, resulting in the formation of type **A** only.

The low thermal stability of **2a** and **2b** compared to other $(diphosphine)_2RuH_3^+$ complexes may be explained by the fact that the xantphos-type diphosphines enforce large bite angles, and therefore induce significant distortion of the octahedral ruthenium complex. INDO/1 calculations show that this distortion of the octahedral geometry induced by the xantphos-type diphosphines can lead to less optimal orbital overlap, resulting in decomplexation of $H_2$. Experimentally, for all three $(diphosphine)_2RuH_3^+$ complexes presented here, there is one signal corresponding to the '$H_3$' in the $^1H$ NMR spectra, indicating very rapid exchange as a result of the *cis* relative position of the hydride and dihydrogen ligands, unlike other $(diphosphine)_2MH_3^+$ complexes (M = Fe, Ru, Os), which only coalesce at higher temperatures.[2–7,9,14–17] Addition of $CF_3CO_2D$ to **1** leads for the product to the same $^1H$ and $^{31}P\{^1H\}$ NMR spectra as for protonation with $HBF_4{\cdot}OEt_2$. There is no resolvable H–D coupling, but in the $^{31}P\{^1H\}$ NMR spectrum all signals have small shoulders due to downfield isotopic shifts.

The application of diphosphines with large bite angles in the synthesis of $(diphosphine)_2Ru(H)(H_2)^+$ complexes emphasises the delicate nature of the bonding of $H_2$ to a transition metal. The distortion of the octahedral geometry of the complex favours the hydrogen atom exchange and destabilises the bond of $H_2$ to the metal centre by reducing the back-donation to the $H_2$ ligand. The results reported here provide experimental evidence for the predictions by Morokuma and coworkers[10] that an increase of the P–Ru–P bite angle might lead to a change from *trans*-hydride–dihydrogen complexes[14] to equilibria between *cis* and *trans* complexes,[15] and further to *cis* complexes. Furthermore these results show that tuning a steric parameter such as the natural bite angle of diphosphines dramatically influences the electronic properties of a transition-metal complex.

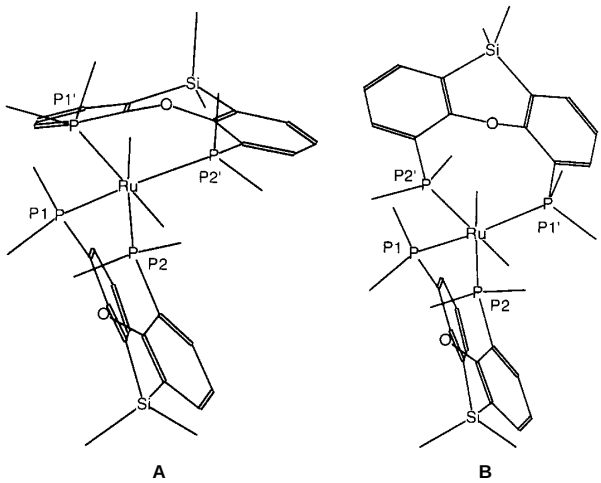

**Fig. 4** Two types of isomer for **2b**. Only $C_{ipso}$ atoms of phenyl groups are shown for clarity.

## Footnotes

† *Synthesis* of starting material: 0.120 g of Ru(cod)(cot) (0.381 mmol) and 2 equiv. of diphosphine were added to a Fisher–Porter bottle. The flask was flushed with argon, and 10 $cm^3$ of thf was added. Upon stirring a bright yellow solution formed, which was flushed with $H_2$, then pressurized to 5 kPa, and heated to 433 K for 20 h, during which time the reaction mixture turned dark brown. After cooling to room temp., the solvent was evaporated, and an extensive washing procedure yielded the pure product **1** (50–60%).

‡ *Protonation experiments*: a solution of **1** (*ca*. 0.01 g, *ca*. 7 μmol) in 0.5 $cm^3$ of $CD_2Cl_2$ was frozen in liquid $N_2$. $HBF_4{\cdot}Et_2O$ was added (3 $mm^3$, 35 μmol). The NMR tube was allowed to warm just to the melting point of the solution, shaken to dissolve the frozen $HBF_4{\cdot}Et_2O$, then immediately lowered into the NMR probe at 180 K. The first $^1H$ and $^{31}P\{^1H\}$ NMR spectra and the $T_1$ measurements were performed at this temperature. Subsequent measurements were performed at 10 K intervals up to 300 K.

§ *Selected NMR data*: $^1H$ and $^{31}P\{^1H\}$ NMR spectra measured in $CD_2Cl_2$ at 300 and 121.5 MHz respectively, except for **3a**, for which a separate experiment was performed in $(CD_3)_2CO$ with $^1H$ and $^{31}P\{^1H\}$ NMR spectra at 400 and 160 MHz, respectively. The $^1H$ data refers to the hydride region. **1a**; δ −8.32 (dt); $^{31}P\{^1H\}$, δ 36.3 (t), 33.5 (t). **2a**; $^1H$, δ −6.69 [br, $T_1$(min) 17 ms (240 K)]; $^{31}P\{^1H\}$, δ 21.7 (apparent t), 20.3 (apparent t). **3a**; $^1H$, δ −6.15 (m); $^{31}P\{^1H\}$, δ 33.5 (m), 35.0 (m), 42.5 (m), 57.2 (m).

# An elusive phase transition in $Na_2RbC_{60}$

**Luigi Cristofolini,[a] Konstantinos Kordatos,[a] Gerard A. Lawless,*[a] Kosmas Prassides,*[a] Katsumi Tanigaki*[b] and Martin P. Waugh[a]**

[b] *NEC Fundamental Research Laboratories, Tsukuba 305, Japan*

**The ternary $Na_2RbC_{60}$ fulleride is studied by variable-temperature solid-state $^{13}C$ and $^{23}Na$ NMR spectroscopies; in addition to the well known orientational order/disorder transition, a phase transformation to a low-symmetry phase which likely contains bonded $C_{60}^{3-}$ moieties is identified at low temperature for the first time.**

Intercalation of solid $C_{60}$ with electron donors, like the alkali metals, results in a wealth of intercalated fulleride salts. All salts with stoichiometry $A_2A'C_{60}$ are metallic and display superconductivity (except $Li_2CsC_{60}$)[1] at critical temperatures as high as 33 K at ambient pressure,[2] surpassed only by the high $T_c$ superconducting oxides. All superconducting salts have been classified into two distinct, strictly cubic, families, distinguished through the orientational state adopted by the $C_{60}^{3-}$ ions in the crystal structure. For large alkali metals (A = K, Rb) occupying the tetrahedral interstices, a merohedrally disordered fcc structure in which the $C_{60}^{3-}$ ions are randomly distributed between two orientations related by 90° rotations about the cubic axes is adopted.[3] The second structural family is encountered when $Na^+$ resides in the tetrahedral interstices and both $Na_2RbC_{60}$[4] and $Na_2CsC_{60}$[5] have been shown to adopt a primitive cubic structure in which the majority of the $C_{60}^{3-}$ ions are rotated counterclockwise by *ca.* 98° about the appropriate [111] cube diagonal, with the remaining adopting minor orientations. Near room temperature, these salts also show a transition to an fcc structure, comprising orientationally disordered quasi-spherical $C_{60}^{3-}$ ions.[6] Here, we report the solid-state $^{13}C$ and $^{23}Na$ NMR spectra of $Na_2RbC_{60}$ in the temperature range 210–350 K. Our results reveal that in addition to the fcc → primitive cubic phase transition near room temperature, further cooling leads to a very slow phase transformation to a novel unsuspected low-symmetry structural form of $Na_2RbC_{60}$.

A high-resolution synchrotron X-ray diffraction profile of the $Na_2RbC_{60}$ sample† at 370 K reveals an fcc structure [$a$ = 14.1402(9) Å, space group $Fm\bar{3}m$] comprising quasi-spherical $C_{60}^{3-}$ ions, as expected. Fig. 1 shows the solid-state $^{13}C$ (MAS, spinning frequency = 6 and 8 kHz) and $^{23}Na$ (static) NMR spectra‡ of $Na_2RbC_{60}$ at 333, 253 and 213 K. The MAS $^{13}C$ NMR spectrum at 333 K [Fig. 1(*a*)] displays a single sharp peak at δ 189, consistent with fast rotational motion of the $C_{60}^{3-}$ ions in the fcc phase.[7] On cooling, a second peak appears gradually at δ 186 [Fig. 1(*a*) inset], with its intensity growing at the expense of the δ 189 resonance which becomes less intense until it completely disappears [Fig. 1(*b*)]. It can be assigned to the primitive cubic phase and remains sharp at 253 K, consistent with rapid large-amplitude librational motions of the $C_{60}^{3-}$ ions about their equilibrium orientations.[7] The temperature dependence of the static $^{23}Na$ NMR spectra mirrors that of $^{13}C$ NMR with the observation of both orientationally disordered (at 333 K) and ordered (at 253 K) phases, characterised by single resonances at δ 198 and 68 and linewidths at half height, $\nu_{\frac{1}{2}}$, of 1500 and 3300 Hz, respectively [Fig. 1(*d*) and (*e*)]. The increased linewidth in the orientationally ordered phase can arise from increased asymmetry due to two contributing factors: (*i*) the space group $Pa\bar{3}$ allows the displacement of the $Na^+$ ions (local symmetry $C_3$) from the ideal tetrahedral ($\frac{1}{4}$, $\frac{1}{4}$, $\frac{1}{4}$) positions along the [111] cube diagonals, and (*ii*) the coordination environment of the $Na^+$ ions is no longer symmetric, as they lie above the centre of a hexagonal face of one $C_{60}^{3-}$ ion and the midpoints of 6:6 bonds of three other neighbouring $C_{60}^{3-}$ ions.[5]

Further cooling to 213 K initially reveals little change in either $^{13}C$ or $^{23}Na$ NMR spectra. However, upon standing at 213 K, a continuous decrease in the intensity of the $^{13}C$ resonance (3 s repetition time, 8 kHz spinning frequency) is observed, until after *ca.* 4 h a plateau is reached at a value of *ca.* 50% of the original intensity. Prolonged time averaging (3700 repetitions)

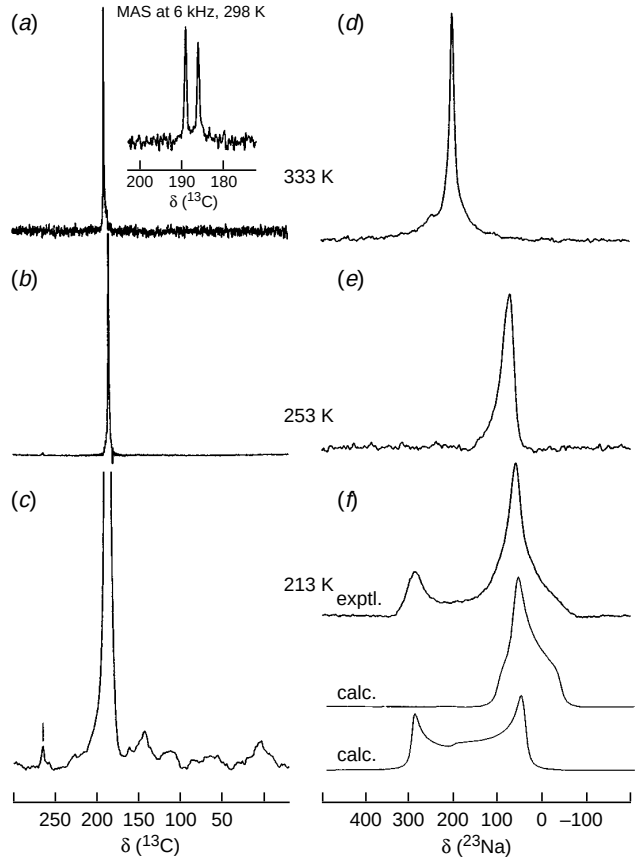

**Fig. 1** The solid-state $^{13}C$ (MAS) and $^{23}Na$ (static) NMR spectra of $Na_2RbC_{60}$: (*a*) $^{13}C$, fcc phase at $T$ = 333 K; the inset shows the spectrum at 298 K whence the two resonances signify coexistence of the fcc and primitive cubic phases. (*b*) $^{13}C$, primitive cubic phase at $T$ = 253 K. (*c*) expanded $^{13}C$, coexistence of primitive cubic and orthorhombic phases at 213 K; the vertical bar marks a spinning sideband. (*d*) $^{23}Na$, fcc phase at $T$ = 333 K. (*e*) $^{23}Na$, primitive cubic phase at $T$ = 253 K. (*f*) $^{23}Na$, coexistence of primitive cubic and orthorhombic phases at 213 K; the simulated spectra of the two resonances are also shown.

revealed numerous new features over the chemical shift range δ 0–250 [Fig. 1(*c*)], implying low crystalline symmetry and substantial distortion of the $C_{60}^{3-}$ ions. The shape of the static $^{23}$Na NMR spectrum also mirrors this change and evolves with time at 213 K; a new feature appears, saturating again after *ca.* 4 h [Fig. 1(*f*)]. Although the two $^{23}$Na resonances partially overlap, they can be separated by judicious choice of the relaxation delay in inversion recovery experiments, as they have very different longitudinal relaxation times, $T_1$ *ca.* 6 and 60 ms, respectively. Simulations of the complete spectrum are included in Fig. 1(*f*), using values of the NMR shift (arising from the combined effects of the chemical shift and the Knight shift), δ 60 and 208, of the quadrupole coupling constant, $(e^2qQ/h)$ = 2.51 and 4.63 MHz, and of the asymmetry parameter, η = 1.0 and 0.03 for the two resonances, respectively. The two phases exist in almost equal amounts.

The above NMR results are consistent with the presence of two phase transitions for $Na_2RbC_{60}$ in the temperature range 210–350 K. Firstly, the fcc → primitive cubic transformation is essentially complete, before a very slow transition, never going to completion, to a low-symmetry highly distorted structure occurs. Complementary high-resolution synchrotron and neutron diffraction experiments are in good agreement with this picture.[8] The low-symmetry phase at low temperature is identified as orthorhombic (space group *Immm*) with lattice constants at 180 K of *a* = 9.3819(8), *b* = 9.943(1) and *c* = 14.559(1) Å; it co-exists with the remaining fraction of the primitive cubic phase with *a* = 14.064(1) Å. The structural results for the orthorhombic phase are indicative of $C_{60}^{3+}$–$C_{60}^{3-}$ bonding in the low-temperature phase, as manifested by the existence of a very short temperature-independent interfullerene separation along *a* (9.38 Å), analogous to the situation encountered in the polymerised phases of $AC_{60}$ (A = K, Rb, Cs) salts[9] which show partial covalent bonding between strongly deformed $C_{60}^{-}$ ions. The broad $^{13}$C NMR spectra of the orthorhombic $Na_2RbC_{60}$ phase are also reminiscent of those measured for polymerised $AC_{60}$.[10] Work is in progress to search for the resonances associated with the bridging C atoms. An orthorhombic phase with comparable lattice dimensions had been observed at high pressures but it was thought that the application of pressure was essential for the phase transition and the resulting interfullerene bonding to occur.[11]

In conclusion, variable-temperature solid-state NMR measurements on $Na_2RbC_{60}$ establish the following sequence of phase transitions in the 210–350 K temperature range at ambient pressure: orthorhombic → primitive cubic → fcc. The NMR results are consistent with highly restricted $C_{60}^{3-}$ ions, most probably due to the formation of bonds between adjacent $C_{60}^{3-}$, as is found in the mono-alkali-metal fullerides. The hitherto unsuspected existence of the orthorhombic phase which completely eluded all earlier studies, presumably because of its slow kinetics, should aid rationalisation of many of the puzzling features of the physical properties of $Na_2RbC_{60}$.[12] In addition, its observation and the associated novel interfullerene bonding should not represent an isolated example, but rather a widespread phenomenon, begging a thorough reinvestigation of sodium (and lithium) fulleride chemistry.

We thank EPSRC for financial support [L. C., M. P. W. (ROPA)].

## Footnotes

† The $Na_2RbC_{60}$ sample used in the present work was prepared by reaction of stoichiometric quantities of $C_{60}$, Na and Rb contained in a sealed tantalum cell inside a sealed glass tube filled with He to 500 Torr at 480 K for 3 h, at 570 K for 12 h and at 620 K for 72 h; after an intermittent regrinding, the sample was annealed at 673 K for 25 days, employing the same experimental setup. Phase purity was confirmed by X-ray diffraction using a Siemens D5000 diffractometer.

‡ Solid-state $^{13}$C and $^{23}$Na NMR experiments with and without magic angle spinning (MAS) in an applied 9.395 T field were performed in the temperature range 210–350 K on a Bruker DMX-400 spectrometer (89 mm wide-bore magnet) with a 4 mm variable temperature double-bearing probe. The 50 mg sample was packed into a zirconia rotor with Kel-F end caps inside a glovebox and spun with $N_2$. A 30° excitation pulse was used for the $^{13}$C NMR experiments while the $^{23}$Na NMR spectra were acquired with a quad-echo pulse sequence.

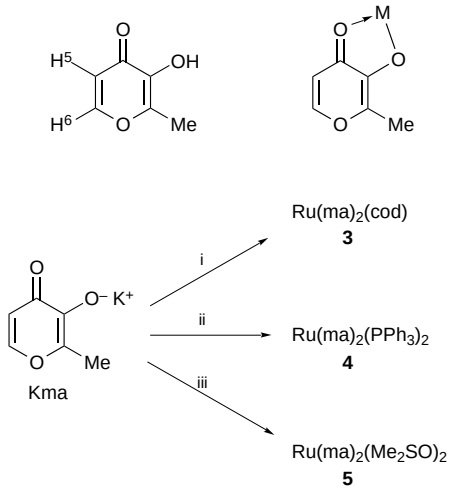
# Ruthenium maltolato complexes

**Michael D. Fryzuk,* Michael J. Jonker and Steven J. Rettig**

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1ZI*

**Two maltol molecules can be deprotonated and coordinated to Ru$^{II}$ to generate a series of octahedral complexes having the general formula Ru(ma)$_2$L$_2$ (ma = C$_6$H$_5$O$_3$; L = PPh$_3$, Me$_2$SO; L$_2$ = cycloocta-1,5-diene); when L = PPh$_3$, a precursor for the dimerization of phenylacetylene is obtained.**



Maltol **1** is a naturally occurring, water-soluble, non-toxic food additive.[1] When deprotonated (p$K_a$ = 8.38),[2] it forms an anionic system capable of acting as a chelating, bidentate, O,O′ ligand of the type shown as **2**.

Because this ligand can confer water solubility on its metal complexes, even when the complexes are uncharged, there have been many reports on the use of this ligand in biological studies. For example, Al(ma)$_3$ has been used in studies related to Alzheimer's disease,[3] Fe(ma)$_3$ has been found to have potential as a treatment for iron-deficiency anaemia[4] and VO(ma)$_2$ has been tested as an insulin mimetic.[5–7] However, little work has been done on the use of this ligand in organometallic type complexes or in homogeneous catalysis.[8–10] Here we report the preparation and structure of a series of octahedral bis(maltolato) complexes of ruthenium[11] and show that one of these complexes shows activity for the dimerization of phenylacetylene.

The reaction of potassium maltolate, Kma (prepared by the addition of KOBu$^t$ to **1** in Et$_2$O), with a variety of ruthenium(II) complexes in organic solvents proved to be successful as a preparative route for the incorporation of the maltolato ligand. Thus, reaction of Kma with [Ru(cod)Cl$_2$]$_x$ in thf led to the formation of Ru(ma)$_2$(cod) **3** as orange–red crystals in 95% yield; similarly, addition of Kma to RuCl$_2$(PPh$_3$)$_3$ and RuCl$_2$(Me$_2$SO)$_4$ generated Ru(ma)$_2$(PPh$_3$)$_2$ **4** and Ru(ma)$_2$(Me$_2$SO)$_2$ **5**, respectively. These reactions are outlined in Scheme 1.

The solid-state structures of the cod complex **3** and the bis(dimethyl sulfoxide) derivative **5** were obtained and are shown in Figs. 1 and 2 respectively, along with selected bond lengths and angles.† Complex **3** is the first alkene complex of ruthenium(II) having only oxygen donors as ancillary ligands to be structurally characterized. Both structures display similar *cis* octahedral geometries; in fact upon close examination of the two structures in the solid state, the same $C_1$ molecular symmetry is found for each derivative. Because the maltolato ligand has two different oxygen donors, it can be considered as an anionic AB bidentate ligand; for an octahedral molecule having the general formula M(AB)$_2$L$_2$ (L = monodentate ligand), such a complex can exist in five stereoisomeric forms (*trans* and *cis* descriptors refer to disposition of L$_2$): two *trans* stereoisomers with $C_{2h}$ and $C_{2v}$ symmetry, respectively and three *cis* stereoisomers two of which have $C_2$ symmetry while the last is completely asymmetric ($C_1$). For the situation where L$_2$ is a symmetrical bidentate ligand, such as cod, only the three *cis* isomers are possible.

From the NMR spectroscopic data, the solid-state structure of **3** is maintained in solution such that only one species is observed and it displays peaks characteristic of a molecule with low symmetry. On the other hand, the bis(phosphine) complex **4** exists as a mixture of three of the possible five stereoisomers; one isomer shows two inequivalent phosphines by $^{31}$P{$^1$H}-NMR spectroscopy and resonances in the $^1$H NMR spectrum that compare to the asymmetric *cis* isomer found for **3** above. The remaining two stereoisomers of **4** have equivalent phosphines and equivalent maltolato ligands and thus could either

**Scheme 1** *Reagents and conditions*: i, [Ru(cod)Cl$_2$]$_x$, thf, 65 °C, 16 h; ii, RuCl$_2$(PPh$_3$)$_3$, thf, 22 °C, 16 h; iii, RuCl$_2$(Me$_2$SO)$_4$, toluene, 90 °C, 16 h

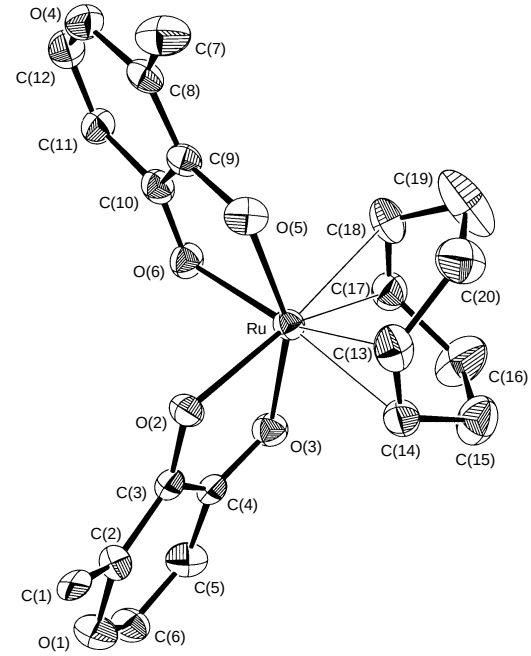


**Fig. 1** X-Ray crystal structure of Ru(ma)$_2$(cod) (**3**) (ellipsoids drawn at the 33% probability level). Selected interatomic distances (Å) and bond angles (°): Ru–O(2) 2.126(4), Ru–O(3) 2.098(5), Ru–O(5) 2.072(4), Ru–O(6) 2.114(4), Ru–C(13) 2.138(5), Ru–C(14) 2.157(7), Ru–C(17) 2.153(7), Ru–C(18) 2.161(6), O(2)–C(3) 1.306(7), O(3)–C(4) 1.288(7), C(3)–C(4) 1.43(1), O(5)–C(9) 1.335(7), O(6)–C(10) 1.262(9), C(9)–C(10) 1.45(1), C(13)–C(14) 1.34(2), C(17)–C(18) 1.46(1); O(2)–Ru– O(3) 79.5(2), O(5)–Ru–O(6) 79.5(2), O(3)–Ru–O(5) 156.0(2), O(2)–Ru–O(6) 92.7(2).

have *trans* or *cis* geometries. The situation for the $Me_2SO$ complex is more complex since isomers are also apparent in the crude reaction mixture but their $^1H$ NMR spectra overlap too much to be able to distinguish them.

While homoleptic maltolato complexes, $M(ma)_n$, are generally water soluble we found that only the bis(dimethyl sulfoxide) complex **5** exhibited any water solubility;[10] both the cod derivative **3** and the bis(phosphine) **4** were insoluble in $H_2O$. These complexes also displayed differences in their reactivity patterns. In this case, addition of phenylacetylene to either the cod complex **3** or the bis(dimethyl sulfoxide) **5** led to no reaction and recovery of starting materials. However, the bis(phosphine) derivative **4** was found to dimerize PhC≡CH to give the two possible linear isomers in a 1:1 ratio with turnover rates of *ca.* 20 $h^{-1}$ (Scheme 2).

Attempts to detect intermediates in this process by monitoring the reaction by $^{31}P\{^1H\}$ NMR spectroscopy were unsuccessful; however, when the dimerization was performed in the presence of excess $PPh_3$ the rate of the dimerization reaction was noticeably retarded. Thus, phosphine dissociation from **4** is required for activity, and this is reasonable given that this 18-electron complex contains two rather large, monodentate ligands. One can speculate further that the mechanism of alkyne dimerization involves a vinylidene intermediate[12,13] as required for the production of both *E* and *Z* isomeric forms of the eneyne product. Internal alkynes were generally found to be unreactive with all three of the bis(maltolato) complexes of Ru.

In this study we have demonstrated that organometallic type complexes and catalytic activity can be observed for Ru derivatives that are stabilized by the maltolato ancillary ligand. In addition, the cyclooctadiene complex **3** represents the first reported alkene-type complex of Ru stabilized by only oxygen donor ligands.

This work was supported by NSERC of Canada. We also acknowledge Johnson Matthey for the loan of Ru salts.

# Unprecedented dimethyl sulfoxide conformational equilibria and kinetics on $[Ir(Me_2SO)_3(\eta\text{-}C_5Me_5)][PF_6]_2$

**Antonio Cusanelli, Urban Frey and André E. Merbach***

*Institut de Chimie Minérale et Analytique, Université de Lausanne, CH-1015 Lausanne, Switzerland*

**Intermolecular dimethyl sulfoxide exchange on $[Ir(Me_2SO)_3(\eta\text{-}C_5Me_5)][PF_6]_2$ 1 proceeds *via* a dissociative mechanism, exclusively from a conformational isomer of 1 (1c) which is itself in equilibrium with a second more compact conformer (1a).**

The coordination chemistry of dimethyl sulfoxide was initially extended to the half-sandwich complexes $[M(Me_2SO)_3(\eta\text{-}C_5Me_5)][PF_6]_2$ (M = Rh, Ir) by Maitlis and coworkers.[1] These workers showed that these complexes were valuable intermediates for the synthesis of related compounds and that, more interestingly, these complexes were capable of rapidly exchanging bound $Me_2SO$ with free $Me_2SO$, although the kinetics of this exchange process were left unexplored. We now report the results of a dynamic $^1H$ NMR study on the iridium complex $[Ir(Me_2SO)_3(\eta\text{-}C_5Me_5)][PF_6]_2$ **1** which provides evidence in support of novel conformational equilibria and kinetics for the dimethyl sulfoxide exchange process.

In solution $Me_2SO$ coordinates to the relatively soft metal centre in **1** exclusively through the sulfur atom. This bonding assignment was initially confirmed by Maitlis and coworkers from IR investigations conducted on both $Me_2SO$ and $(CD_3)_2SO$ analogues of this complex[1] and this assignment is further corroborated by numerous X-ray crystal structures for similar iridium(III) complexes, which in all cases show the $Me_2SO$ ligand to be S bonded.[2] The spectroscopic results we have obtained for **1**† are in complete agreement with this assignment.

The low temperature $^1H$ NMR spectrum of **1**, acquired at 243.2 K in $CD_3NO_2$ containing excess free $Me_2SO$, did not show the expected two resonances corresponding to bound and free $Me_2SO$ respectively, but instead exhibited five resonances at δ 3.16, 3.15, 3.11, 2.99 and 2.56 (Fig. 1); the latter was unequivocally assigned to free solvent and the remaining signals were attributed to **1**.

Also present in this spectrum were two unequally populated resonances at δ 1.79 and 1.64 assigned to two unique $C_5Me_5$ groups. The three resonances at δ 3.16–3.13 integrated to six protons each with respect to the more populated of the $C_5Me_5$ signals whereas the remaining bound $Me_2SO$ resonance at δ 2.99 integrated to 18 protons with respect to the less populated $C_5Me_5$ moiety. Taken together, these results clearly suggest the presence of two stereoisomers of **1** (denoted as major and minor in Fig. 1), each composed of a $C_5Me_5$ group and three $Me_2SO$ ligands.

Considering first the major isomer of **1**, two conformers can account for the three resonance pattern observed for this species and these are depicted as structures **1a** and **1b** in Fig. 2; the symmetry of both structures is defined by a plane bisecting the $C_5Me_5$ centroid, Ir, and an S–O bond such that two $Me_2SO$ molecules and two Me groups are related by the mirror plane.

Upon closer inspection of the low-temperature limit NMR spectrum in Fig. 1, it is evident that the most deshielded resonance has a smaller linewidth at half-height ($\Delta\nu_{1/2}$ 1.7 Hz at 243.2 K) than the two adjacent resonances ($\Delta\nu_{1/2}$ 2.3, 2.2 Hz, respectively, at 243.2 K) which are broader but similar due, most likely, to a small unresolved $^4J_{HH}$ coupling ($^4J_{HH}$ couplings are *ca.* 0.1–0.4 Hz). Thus, one can assign the two broader resonances to the geminal methyl groups of the $Me_2SO$ molecules, labelled as A and B in Fig. 2, which are expected to be coupled. The most deshielded signal is then assigned to the remaining methyl groups, labelled as C in Fig. 2. These experimental results are thus consistent with conformer **1a**, rather than conformer **1b**, since the methyl groups (*i.e.* $Me_C$) in the former structure are expected to be more deshielded because of their close proximity to the ring current induced by the π electrons of the $C_5Me_5$ moiety. In addition, conformer **1a** is also the sterically preferred structure since it minimises the contacts between the bulky $C_5Me_5$ group and the $Me_2SO$ methyl groups.

With respect to the minor isomer of **1**, the single $^1H$ NMR resonance assigned to this conformer (Fig. 1) indicates that all three bound $Me_2SO$ groups in this species have the same

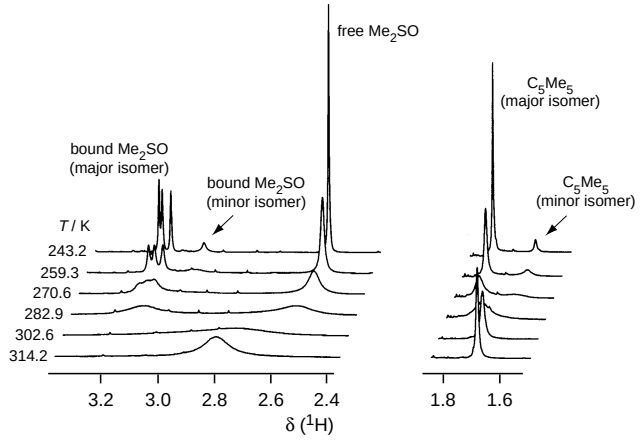

**Fig. 1** Experimental $^1H$ NMR (400 MHz) spectra of **1** (0.010 m) in $CD_3NO_2$ diluent ([free $Me_2SO$] = 0.028 m) at various temperatures

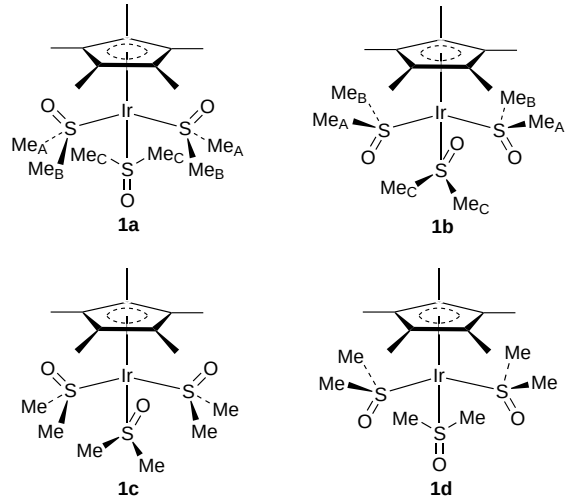

**Fig. 2** Structural representations of the plausible conformers of **1**

chemical environment. This can be accounted for by structures **1c** or **1d**. However, structure **1c** is obviously the less sterically demanding structure and thus we suggest that it is the most likely candidate for the minor isomer of **1**. Finally, and of utmost importance, the major:minor isomer ratio observed for complex **1** is seen to reflect the differing steric demands imposed by the bulky $C_5Me_5$ and $Me_2SO$ groups within the half-sandwich geometry and also supports assigning the major and minor isomers to **1a** and **1c** respectively.

As the temperature was raised to 314.2 K, all five resonances began to broaden, indicating that an intramolecular process and/or an intermolecular exchange(s) with free solvent was occurring over the same temperature interval (Fig. 1). Similar spectra were obtained when the variable-temperature study was repeated without excess $Me_2SO$, thus corroborating the interconversion between the two isomers of **1**. Notably, $^{13}C\{^1H\}$ NMR spectra of **1**, in the absence of free $Me_2SO$, acquired over a similar temperature interval also exhibited behaviour consistent with an interconversion process.

Having assigned the conformational identities of the two conformers of **1**, it is reasonable to conclude that their interconversion between structures **1a** and **1c** proceeds *via* a restricted rotation of the metal–sulfur bond. However, the question which remains unanswered is which of the conformers of **1** participates in the intermolecular exchange with free $Me_2SO$ or are both involved? A two-dimensional $^1H$ NMR EXCSY (exchange correlation spectroscopy) spectrum of **1** in $CD_3NO_2$ at 243.5 K with excess $Me_2SO$ provided the answer (Fig. 3).

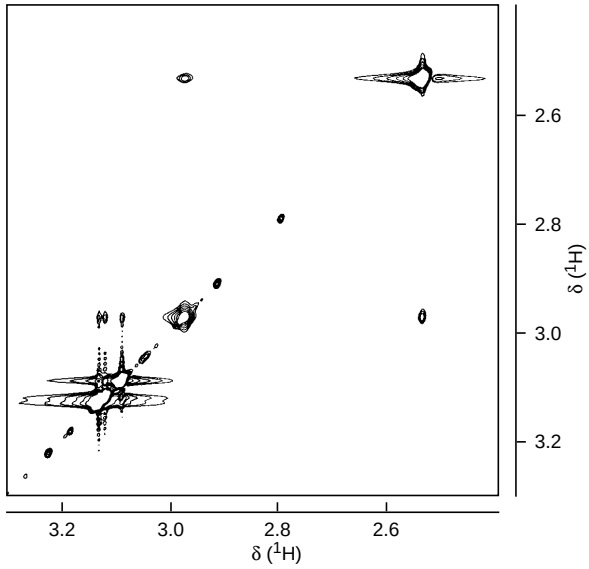

**Fig. 3** Two-dimensional $^1H$ NMR (400 MHz) EXCSY spectrum of **1** (0.010 m) in $CD_3NO_2$ diluent ([free $Me_2SO$] = 0.026 m) at 243.5 K (see Fig. 1)

Under these conditions, the most intense cross-peak relates the resonance of the minor conformer **1c** with that of free $Me_2SO$, confirming that this intermolecular exchange is the fastest process. The cross-peaks between conformers **1a** and **1c** were smaller, and most importantly, the cross-peaks diagnostic of an intermolecular exchange between the major isomer **1a** and free $Me_2SO$ were not observed, thus indicating that (*i*) the interconversion between **1a** and **1c** proceeds by an intramolecular pathway [eqn. (1)] and (*ii*) the exchange with free $Me_2SO$ proceeds solely from conformer **1c** [eqn. (2)].

$$\text{major-}[Ir(Me_2SO)_3(\eta\text{-}C_5Me_5)]^{2+} \underset{}{\overset{k_{intra}}{\rightleftharpoons}} \text{minor-}[Ir(Me_2SO)_3(\eta\text{-}C_5Me_5)]^{2+} \quad (1)$$

$$\text{minor-}[Ir(Me_2SO)_3(\eta\text{-}C_5Me_5)]^{2+} + 3{*}Me_2SO \overset{k_{inter}}{\rightleftharpoons} \text{minor-}[Ir(*Me_2SO)_3(\eta\text{-}C_5Me_5)]^{2+} + 3Me_2SO \quad (2)$$

A detailed kinetic study of complex **1** and other related half-sandwich solvento complexes is presently under way in our laboratory to gain more insight into the mechanistic details of solvent exchange on these complexes.

We thank the Swiss National Science Foundation for financial support.

**A novel conformationally rigid, cobalt-based cationic molecular square achieved *via* self-assembly from tetra(2-pyridyl)thiocarbazone is synthesized and structurally characterized.**

Recently, conformationally rigid, tetranuclear macrocyclic ring systems with approximately 90° bond angles about each corner atom have been prepared in high yields *via* self-assembly from rigidly available precursors, thereby adding a new dimension to supramolecular as well as potentially biomimetic chemistry.[1–7] Hitherto only two related types of supramolecules have been reported. One is a square molecular box bridged by bifunctional nitrogen donors such as 4,4′-bipyridine,[1] 2,6-diazanthracene,[2] 2,6-diazanthracene-9,10-dione,[3] *cis*- or *trans-meso*-dipyridyl porphyrins[4] and the uracil monoanion,[5] where polyvalent iodine or heavy transition metals (Pd and Pt) occupy the corners. A second system is the $n \times n$ inorganic grid bridged by a linear polytopic ligand containing bidentate chelating sites for which the square-matrix arryas are occupied by tetrahedrally coordinating metal centres.[6,7]

In the present work, we report the synthesis and structural characterization of the first example of a cobalt-based cationic molecular square achieved *via* self-asembly with a novel rigid pentadentte ligand containing sulfur and nitrogen donor sites.

When di(pyridyl)ketone was treated with thiocarbazide in methanol at reflux, a yellow solid was readily formed. Elemental analysis supports the formation of the new pentadentate $N_4S$ ligand $(C_5H_4N)_2C{=}NN(H)C(S)N(H)N{=}C(C_5H_4N)_2$, tetra(2-pyridyl)thiocarbazone, $H_2L$. Interaction of $CoCl_2{\cdot}6H_2O$ with $H_2L$ and $NaO_2CMe$ in methanol at boiling temperature gave the tetranuclear complex $[Co(HL)]_4[O_2CMe]_4{\cdot}H_2O$ **1** *via* self-assembly, as shown in Scheme 1.† Macrocyclic complex **1** is a remarkably stable dark brown crystalline solid and is soluble in most organic solvents. An X-ray crystallographic study‡ has unequivocally confirmed the existence of a tetranuclear cationic molecular square in **1**.

In compound **1**, the sulfur atom of the $HL^-$ monocation exhibits twofold positional disorder, and its scattering power is represented by two 'half-atoms' S(1) and S(1′) separated by 0.93 Å. For the sake of clarity, only S(1) is shown in Fig. 1 and referred to in subsequent discussion. The tetranuclear $[Co(HL)]_4^{4+}$ cation is located at the $\bar{4}$ site with four cobalt(II) atoms at the corners of a square of edge length Co···Co of 4.43 Å, each metal centre being octahedrally coordinated by atoms S(1), N(2) and N(3) of one $HL^-$ ligand and S(1a), N(6a) and N(7a) from a second ligand (Fig. 1). These two $HL^-$ ligands bind to cobalt(II) in the *mer* configuration (with pairs of S atoms and pyridyl N atoms each bearing a *cis* relationship, whereas the thiocarbazone N atoms are *trans* to each other) as found in related octahedral cobalt thiocarbazone complexes.[8] The sulfur atoms lie alternately above and below the mid-points of the edges of the square, each being connected to two cobalt atoms with a bond angle Co–S–Co of 151°. The measured C–S bond distance of 1.814(4) Å is within the normal range of a C–S single bond,[9] indicating that the thiocarbazone moiety $HL^-$ adopts the thiol tautomeric form in acting as a mononegative ligand.[10] The C–N and N–N bond distances in $HL^-$ are intermediate between formal single and double bonds (see Fig. 1), pointing to extensive electron delocalization over the entire molecular skeleton. The imino H atom of the $HL^-$ monocation could not be located from the difference Fourier map, and is most likely disordered over both N(1) and N(5) sites. Except for the uncordinated pyridine rings and the disordered sulfur atom, the atoms in the monoanion are nearly coplanar, the mean deviation from the best plane being 0.080 Å. The dihedral angle between two $HL^-$ ligands coordinated to the same $Co^{II}$ atom is exactly 90° due to the symmetry of the $I4_1/a$ space group, the closest intermolecular distance between two $HL^-$ planes coordinated to different $Co^{II}$ centres is 4.43 Å, indicating weak π–π interaction. The crystal structure of **1** consists of a packing of tetranuclear $[Co(HL)]_4^{4+}$ cations

$[Co(HL)_4]^{4+}$ macrocyclic square in **1**

**Scheme 1**

imbedded in a matrix of highly disordered acetate ions and water molecules.

The UV–VIS spectra of **1** in methanol shows a strong broad absorption band at *ca.* 264 nm (log ε = 5.3) which is assigned to intraligand transitions and a quite broad band at *ca.* 490 nm (log ε = 4.2) which might be assigned to an MLCT transition. This result suggests that the square molecular box may be retained in solution. Solid-state spectra in the range 550–850 nm exhibit only a strong bond at *ca.* 600 nm, which can be assigned to d–d transitions of the central metal.

The components used in the construction of the cationic molecular square $[Co(HL)]_4^{4+}$ by self-assembly are novel in several respects. Previous studies generally made use of bidentate nitrogen donor ligands as the edges and iodonium or heavy transition-metal ions as the corners of the square unit. In our synthesis of this type of tetranuclear macrocycle we have introduced a newly designed, rigid pentadentate $N_4S$ ligand for binding to a first-row transition metal, thereby offering the potential of broadening the scope of further work in this area.

This work is supported by the National Nature Science Foundation of China and Hong Kong Research Grants Council Earmerked Grant CUHK 311/94p.

## Footnotes

† Complex **1** was synthesized by combining methanol solutions of $H_2L^1$ (0.44 g, 1 mmol), $CoCl_2·6H_2O$ (0.24 g, 1 mmol) and $NaO_2CMe$ (0.16 g, 2 mmol). The dark brown crystalline solid which formed after refluxing for 2 h was isolated and dried under vacuum to give **1** in 62% yield. Crystals suitable for an X-ray structure determination were obtained from slow evaporation of a DMF solution of **1** in air. Anal. Found: C, 54.1; H, 3.9; N, 19.5. Calc. for $C_{100}H_{80}Co_4N_{32}O_8S_4·H_2O$: C, 53.6; H, 3.7; N, 20.0%.

‡ *Crystal data* for **2**: tetragonal, space group $I4_1/a$ (no. 88); $a$ = 14.467(1), $c$ = 47.411(1) Å, $U$ = 9923(5) Å$^3$, $Z$ = 4, $F(000)$ = 4560, $\mu$ = 0.82 mm$^{-1}$; 5240 independent reflections measured, 2662 observed [$F > 6.0\sigma(F)$], number of parameters = 408; $R$ = 0.057, $R_w$ = 0.079. The intensities were collected at 294 K on a Rigaku Raxis IIC imaging-plate diffractometer using Mo-Kα radiation (λ = 0.710 73 Å) from a rotating-anode generator operating at 50 kV and 90 mA ($2\theta_{max}$ = 55.2°); 60 oscillation frames in the range 0–180°, exp osure time 8 min per frame. The crystal structure was solved by direct methods with distance restraints of C–C = 1.38 ± 0.01 Å and C–N = 1.34 ± 0.01 Å for uncoordinated pyridyl groups. The S atom [site occupancy factor (sof) for S(1) and S(1′) fixed at 0.5] and acetate ions [sof = 0.5 for O(1), O(2), C(24) and C(25) of one acetate group, sof = 1/4 for O(3), O(4) C(26), C(27) and O(5), O(6), C(28) and C(29) of the two other acetate groups with distance restraints of C–C = 1.520 ± 0.005 Å, C–O = 1.254 ± 0.005 Å, O···O = 2.16 ± 0.01 Å], as well as the water molecule (sof = 0.25) were found disordered. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares. Hydrogen atoms were placed in their calculated positions with C–H = 0.96 Å, assigned fixed isotropic thermal parameters and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factor calculation. All computations were carried out on a PC-486 usig the SHELXTL-PLUS program package. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/356.

# A new method for the quantitative determination of zeolitic Brønsted acidity

**Manfred Richter,* Barbara Parlitz, Reinhard Eckelt and Rolf Fricke**

*Institut für Angewandte Chemie, Rudower Chaussee 5, D-12484 Berlin, Germany*

**A new method for the quantitative determination of zeolitic Brønsted acidity is proposed utilizing the specific low-temperature reaction of $NH_4^+$ ions fixed to Brønsted sites with $NO–O_2$ thus preventing the loss of acid sites normally encountered for the conventional temperature-programmed mode of $NH_3$ thermodesorption.**

Acidity is one of the most prominent features established for microporous zeolite materials, besides the geometric diversities of crystal structures, pore sizes and pore arrangements. The term acidity mostly discriminates between sites of Brønsted character (protonic sites) and Lewis character (coordinatively unsaturated surface atoms or ions). For acidity characterization, among others, the temperature-programmed desorption of ammonia (TPDA) is routinely used today.[1,2] Interaction of Brønsted-acid sites with $NH_3$ converts the latter into $NH_4^+$ ions fixed to the zeolite framework, and the energy (equivalent to the temperature of desorption) required to release gaseous $NH_3$ is correspondingly high. Peak positions on the temperature axis during TPDA are indicative of the acid strength of sites whereas the peak areas contain information on the concentration of sites.

Mostly, the contributions of weak and strong acid sites overlap in the desorption profiles. Moreover, certain zeolite structures are thermally labile losing a part of the framework aluminium and thus acid sites. Thus it is reported[3] that calcination of zeolite mordenite at 770 K resulted in a degree of dealumination of about 70%. The thermal conversion of zeolite Y (Si/Al atomic ratio = 2.4) from its $NH_4^+$ form into the $H^+$ form is accompanied by a loss of *ca*. 44% of its framework aluminium.[4]

This obvious drawback can be avoided by utilization of the method proposed in the following. The method is based on the isothermal catalytic low-temperature conversion (CLTC) of zeolite-fixed $NH_4^+$ ions to $N_2$ by reaction with $NO–O_2$ at 373–393 K. Simultaneously, the $NH_4^+$ form of zeolite structures is transformed into the $H^+$ form. Three representative examples will be given (see Table 1) documenting the reliability of the new method.

**Table 1** Brønsted acidity of zeolite structures as determined by conventional TPD of ammonia in comparison with the catalytic low-temperature conversion of zeolitic $NH_4^+$ ions by $NO–O_2$

| Zeolite | Theoretical composition (Na form) | $V_p$[a]/ cm$^3$ g$^{-1}$ | Brønsted acidity/ mmol g$^{-1}$ | | |
|---|---|---|---|---|---|
| | | | TPD of $NH_4^+$ | TPD[b] of $NH_3$ | CLTC[c] of $NH_4^+$ |
| ZSM-5 | $Na_6[Al_6Si_{90}O_{192}]$ (Si/Al = 15.0) | 0.16 | 0.85 | 0.65 | 0.90 |
| Mordenite | $Na_8[Al_8Si_{40}O_{96}]$ (Si/Al = 5.0) | 0.18 | 2.51 | 1.40 | 2.40 |
| Y | $Na_{58}[Al_{58}Si_{134}O_{384}]$ (Si/Al = 2.3) | 0.32 | 3.75 | 1.65 | 3.82 |

[a] Micropore volume from nitrogen adsorption isotherms. [b] Adsorption of $NH_3$ after thermal decomposition of the $NH_4^+$ form and subsequent temperature-programmed desorption (TPD). [c] Catalytic low-temperature conversion of $NH_4^+$ by $NO–O_2$.

Zeolites ZSM-5, Y and mordenite whose ideal compositions and resulting Si/Al atomic framework ratios are given in Table 1, were obtained commercially in their ammonium form. The actual Si/Al framework ratios were determined to be 20.3 (ZSM-5), 2.6 (zeolite Y), and 5.6 (zeolite mordenite).

The CLTC of the $NH_4^+$ ions were performed in an integral flow reactor with a feed containing 0.5 vol.% NO, 10 vol.% $O_2$ and helium as diluent. The gas analysis was accomplished by on-line gas chromatography.

After admission of the $NO–O_2$–He mixture to the $NH_4^+$ form of the zeolite the NO is completely converted to $N_2$ with consumption of $NH_4^+$ ions. The reaction does not proceed in the absence of $O_2$. Obviously, NO has to be oxidized to $NO_2$, at least partially, to enable the subsequent reduction step [eqn. (1)],

$$2\ ZNH_4^+ + NO + NO_2 \rightarrow 2\ N_2 + 3\ H_2O + 2\ ZH^+ \quad (1)$$

where Z symbolizes the zeolite, $ZNH_4^+$ indicates the ammonium form of the zeolite and $ZH^+$ its protonic form. The formation of $NO_2 \cdot NO$ adducts, formally equivalent to $N_2O_3$, has been reported to occur on ZSM-5 either non-promoted or promoted following exposure to NO and $O_2$ at 295 K by Adelmann *et al*.[5]

Fig. 1 shows the result of characteristic experiments, where the $NH_4^+$ forms of three different zeolites representative of wide-pore (Y, MOR) and medium-pore (MFI) structures have been charged with an $NO–O_2$ gas mixture at 383 and 373 K, respectively. Prior to reaction the samples were flushed at 425

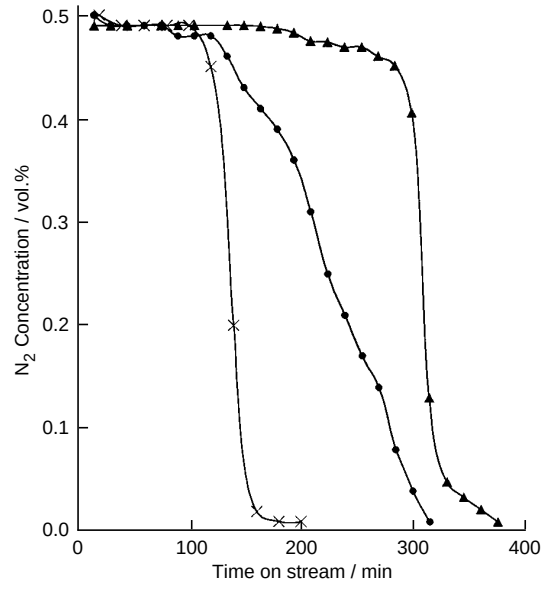

**Fig. 1** Quantitative determination of zeolitic Brønsted acidity by catalytic low-temperature conversion (CLTC) of $NH_4^+$ ions by $NO–O_2$ at low temperatures. Formation of $N_2$ *vs*. time on stream for (×) zeolite ZSM-5 (Si/Al ratio = 20.3), (●) zeolite mordenite (Si/Al ratio = 5.6) and (▲) zeolite Y (Si/Al ratio = 2.6). *Reaction conditions*: sample volume = 3.6 cm$^3$, feed = 0.5 vol.% NO, 10 vol.% $O_2$, carrier gas helium, flow rate = 1 cm$^3$ s$^{-1}$, reaction temperature = 373 K (ZSM-5) or 383 K (zeolite Y, mordenite).

K for 2 h with helium inside the reactor to remove physisorbed water.

All three investigated zeolite structures start with complete conversion of NO to $N_2$ during the first 120 min on stream. According to the concentration of $NH_4^+$ ions (equivalent to the concentration of Brønsted-acid sites) the $N_2$ formation ceases. Note that the reaction temperature in the cases of zeolite Y and zeolite mordenite was slightly higher, 383 K, in order to accelerate the process. Because only one N atom comes from the NO, and the other one from $NH_4^+$ surface ions, the volume concentration of $N_2$ is equal to that of NO, *viz*. 0.5 vol.%. The overall molar amount of $N_2$ formed was determined by numeric integration of the concentration–time curve and corresponds to the concentration of Brønsted-acid sites. The distinctly modified curve shape observed for the mordenite is tentatively attributed to the pore architecture where pores run only parallel to each other without crossings. Further experiments showed that the access of NO–$NO_2$ to the small side channels (2.6 × 3.7 Å) of the mordenite structure is hindered so that the CLTC of $NH_4^+$ ions is further slowed down.

Values given in Table 1 underline that the concentration of Brønsted-acid sites calculated from a thermal decomposition of the $NH_4^+$ form favourably coincides with that derived from the new method. A second run of temperature-programmed desorption following a reloading of the zeolite with gaseous $NH_3$ confirms that during the thermal decomposition of initial $NH_4^+$ ions a dealumination had taken place, most severe for zeolite Y and zeolite mordenite.

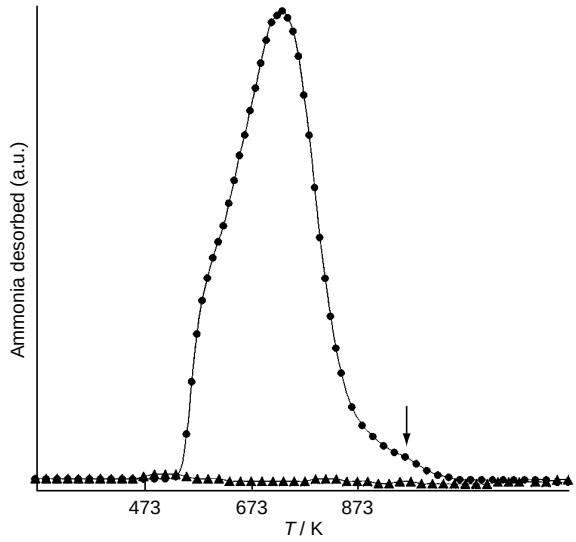

**Fig. 2** Temperature-programmed decomposition of $NH_4^+$ ions fixed to zeolite ZSM-5 before the CLTC (●) and after completion of the reaction (▲) according to curve (×) in Fig. 1. Sample mass = 0.2 g, heating rate = 10 K $min^{-1}$, carrier gas helium, flow rate = 0.5 $cm^3$ $s^{-1}$. The arrow indicates the end of the temperature increase. Decomposition is completed isothermally at 923 K.

The consumption of $NH_4^+$ ions according to eqn. (1) is confirmed for zeolite ZSM-5 by the results shown in Fig. 2. Following an exhaustive treatment of the sample with NO–$O_2$ at 373 K the sample was checked for the presence of residual $NH_4^+$ ions. As can be seen, no ammonia release is observed during temperature-programmed heating, *i.e*. no residual $NH_4^+$ ions remain.

The $NH_4^+$ form of the unused ZSM-5 is thermally decomposed with maximum release of ammonia at around 720 K. The Brønsted acidity calculated on the basis of this desorption profile amounts to 0.85 mmol $g^{-1}$ and is included in Table 1.

This result demonstrates that in turn the treatment by NO–$O_2$ might be utilized for the mild transformation of the zeolitic $NH_4^+$ form into the $H^+$ form which customarily requires temperatures higher than 770 K when performed thermally. The dealumination that accompanies this thermal treatment is demonstrated by the data given in the penultimate column of Table 1. Initial concentrations of Brønsted-acid sites cannot be reproducibly determined.

A further advantageous application of the described method is seen in the abatement of $NO_x$ from exhaust gases by an alternating process including a period of regeneration where the zeolite is reloaded with the required $NH_4^+$ ions.[6,7]

This work was supported by the Federal Ministry of Education, Science, Research and Technology of the FRG and the Berlin Senate, Department for Science, Research and Culture (Project No. 03C3005).

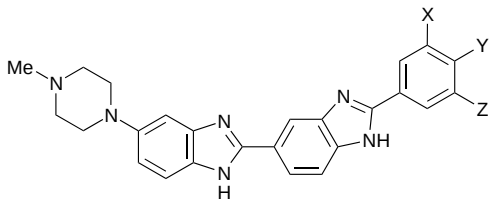
# Unique binding site for bis-benzimidazoles on transfer RNA

**S. E. Sadat Ebrahimi, Amanda N. Wilton and Kenneth T. Douglas*†**

*School of Pharmacy and Pharmaceutical Science, University of Manchester, Manchester, UK M13 9PL*



**Ligands based on bis-benzimidazole structures related to Hoechst 33258 bind to transfer RNA with 1 : 1 stoichiometry and dissociation constants in the micromolar range, their interaction appearing significantly different in nature from that with duplex DNA, based on the ribonucleic acid-induced quenching of their fluorescence.**

With ligand binding to RNA increasingly being recognised as a potential drug target, especially in the HIV field, an understanding of the molecular features which lead to strong, specific binding to RNA is a prerequisite to designing RNA-directed ligands as drug leads.[1,2] Use of *in vitro* selection of RNA sequences can determine preferred RNA sequences and structures (*e.g.* for tobramycin[3]), but this does not produce new RNA-binding structures. The complementary approach is to find novel RNA ligand structures and understand the basis of their binding interaction.[2]

Early studies indicated that netropsin and distamycin bind strongly to the minor groove of DNA but weakly to RNA (probably electrostatically to the phosphate ion sites on the backbone).[4] However, classical DNA-minor-groove ligands such as berenil[5] and benzimidazoles[6] have recently been reported to have strong interactions with RNA duplexes based on melting temperature determinations. However, these studies gave no indication of RNA-specifying interactions. The grooves of DNA and RNA differ in many respects. Thus, 4′,6-diamidino-2-phenylindole (DAPI) binds to AT stretches of B-DNA in the minor groove but intercalates into AU-RNA.[1] Strong evidence that DNA minor groove binders can bind in the tRNA groove is provided by an X-ray diffraction study with netropsin and distamycin, which shows specific hydrogen bonds to G51, U52 and G53 and electrostatic interactions with phosphates P61, P62 and P63 in this region,[7] but binding strengths were not measured. Porphyrins also bind brewer's yeast $tRNA^{Phe}$ in the TψC arm near the T54 and ψ55 residues.[8] Hoechst 33258 **1** binds strongly to B-DNA in AT-rich regions but except for specially designed synthetic oligonucleotides the absolute sequence specificity is low. Thus on calf thymus or plasmid DNA there are many sites for **1**. We now report a contrasting situation for RNA, namely specific binding to a unique site on tRNA of ligands based on **1**, *viz*. the 3,4-dimethoxy **2** and 3,4,5-trihydroxy **3** analogues.

Stock solutions of tRNA (from brewer's yeast, Boehringer Mannheim) were prepared in 0.1 M sodium phosphate buffer pH 7.80. Ligand stock solutions, initially in dimethyl sulfoxide (10 mM), were further diluted with phosphate buffer to the required concentration. Samples for fluorescence studies were filtered through a sterile Nalgene™ 0.2 μm syringe filter. Trihydroxy-Hoechst **3** was from a previous study[9] and 3,4-dimethoxy-Hoechst **2** was synthesised similarly by condensing ethyl 3,4-dimethoxybenzimidic hydrochloride (mp 143.5–145 °C, litr., 142–143 °C,[10] accurate mass, 210.1122. $C_{11}H_{16}NO_3$ requires 210.1130) with 2-(3,4-diaminophenyl)-6-(4-methylpiperazinyl)benzimidazole:[11] **2** was characterised by NMR and mass spectroscopy.‡ UV–VIS spectra were recorded at 25 °C using a Peltier-thermostatted cuvette holder in a Cary model 1E UV-Visible spectrophotometer using the Cary Base System Software and fluorescence emission spectra using a Hitachi F-2000 fluorescence spectrophotometer. The ligands were excited at wavelengths corresponding to their absorption maxima.

In the absorption spectra of a series of mixtures of tRNA (brewers' yeast) and **3** [Fig. 1(*a*)] the $\lambda_{max}$ value of **3** was found to shift from 326 nm to longer wavelength as the proportion of tRNA increased, becoming approximately 338 nm (broad) for a 1 : 1 molar mixture. These UV–VIS spectra were recorded for a series of tRNA : **3** mixtures (prepared from 50 μM stock solutions of **3** and tRNA) varying the molar ratio of the components but keeping a constant total concentration of the components. The absorbance at 360 nm for each ratio, corrected

**1** X = Z = H, Y = OH
**2** X = Y = OMe, Z = H
**3** X = Y = Z = OH

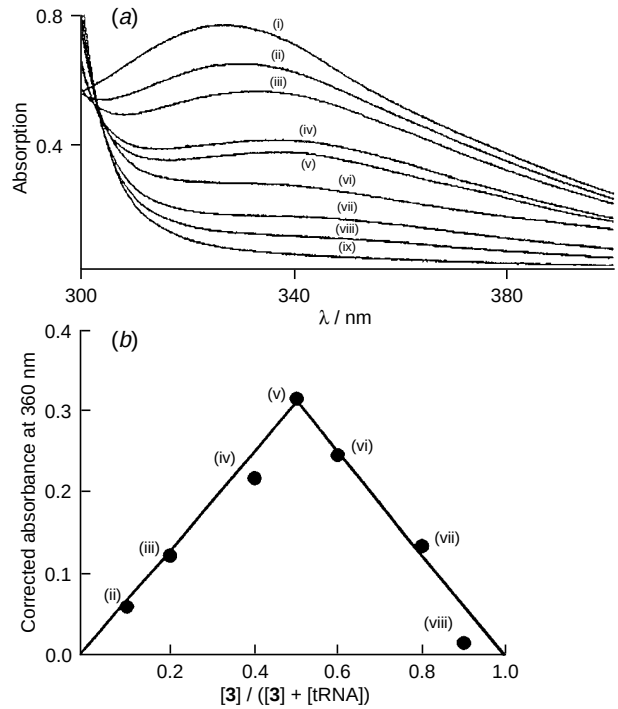


**Fig. 1** (*a*) UV–VIS absorption spectra of 3, 4, 5-trihydroxy-Hoechst **3** and brewer's yeast tRNA (combined concentration 50 μM) in 0.1 M sodium phosphate buffer pH 7.80. Mole fraction of **3**: (i) 1, (ii) 0.9, (iii) 0.8, (iv) 0.6, (v), 0.5, (vi) 0.4, (vii) 0.2, (viii) 0.1 and (ix) 0. (*b*) Job plot of the data from (*a*), corrected as described in the text.

for the contribution from unbound **3** or tRNA assuming 1 : 1 tight binding, plotted against the mole fraction of **3** to produce a Job plot [Fig. 1(*b*)] showed 1 : 1 complex formation and tight binding.

Addition of tRNA to a solution of **2**, **3** or related ligands leads to extensive fluorescence quenching, which is easier to study for some ligands than others depending on the initial fluorescence intensity of the free ligand. A sample of **2** (1 ml of a 10 μM solution in 0.1 M sodium phosphate buffer, pH 7.80) was excited at 338 nm and its fluorescence emission spectrum recorded between 300 and 600 nm after each addition of a series of aliquots of $tRNA^{Phe}$ (20 μl from 100 μM stock). A plot of the change in the fluorescence intensity, corrected for dilution *vs.* [$tRNA^{Phe}$] added was fitted by the equation for a single-site binding [eqn. (1)],

$$\text{Fluorescence } (F) = F_{max}[tRNA^{Phe}]/(K_{diss} + [tRNA^{Phe}]) \quad (1)$$

with a value for $K_{diss}$ of 14.8 + 0.9 μM. There is also evidence of a much weaker binding site(s). The binding site for ligands in this class remains to be identified but the binding is both specific, as shown by the Job analysis for **3**, and reasonably strong based on the dissociation constant determined for **2**. The environment of these bis-benzimidazole ligands on the RNA is clearly different in detail from that on DNA as the fluorescence of Hoechst 33258 is highly enhanced on binding to the minor groove of B-DNA[12,13] in contrast to the strong quenching seen here with tRNA. This may be an indirect effect, as seen for bromouridine quenching in DNA, or may indicate that the angles between the planes of the benzimidazole rings and the terminal aryl groups and their molecular environments differ substantially on DNA and RNA for such compounds. However, in spite of the detailed knowledge of binding interactions and such angles for Hoechst and its congeners in the DNA groove from NMR[12,14,15] and X-ray diffraction[16,17] studies, there is no information on the basis of RNA recognition by this family of structures. The molecular frameworks of **2** and **3** and their specific sequestration of tRNA (selectively occupying a unique run of 4–5 base-pairs out of approximately 75) provides a new lead for analogue design to increase the strength of binding to RNA-based grooves and to understand some aspects of ligand–RNA recognition at an atomic level.

# Template synthesis of $[Cr(en)_3][Te_6]$: a novel polytelluride with a framework structure, whose cavities are filled with a $[Cr(en)_3]^{3+}$ template

**Christian Reisner and Wolfgang Tremel***

*Institut für Anorganische Chemie und Analytische Chemie der Johannes Gutenberg-Universität Mainz, Becherweg 24, D-55099 Mainz, Germany*

**$[Cr(en)_3][Te_6]$ (en = ethylenediamine) is obtained by a template synthesis under solvothermal conditions from $Cr(CO)_6$ and $BaTe_4$; its crystal structure contains a polymeric $Te_6^{3-}$ framework whose pores contain the $Cr(en)_3^{3+}$ template; $[Cr(en)_3][Te_6]$ is the first chalcogenide with a porous three-dimensional framework structure.**

Microporous materials with a three-dimensional framework of condensed $MO_4$ tetrahedra (M = *e.g.* Al, Si, P) have been known for a long time as zeolites. They have great technical importance as molecular sieves and catalysts.[1,2] Their sorptive properties are based on the regular arrangement of cavities with defined diameter and size, which can be varied by the use of templates.[3] On the other hand, the complexing properties of compounds with porous structures can be used for the stabilisation of various cluster species (*e.g.* $Cd_mS_n$ or $Si_8$).[4]

Recent examples of Si- or Al-free compounds with microporous structures based on tetrahedral building elements have been found in the gallophosphate cloverit, whose cavities are formed from twenty-membered rings,[5] in the nitridophosphate $Zn_7[P_{12}N_{24}]Cl_2$[6] and in several transition-metal phosphates.[7] The substitution of tetrahedral structure motifs in known aluminosilicates by octahedral or by square-pyramidal $MO_n$ building groups in early transition-metal phosphates opens the way to a new and versatile structural chemistry.[8] A nice example, the $[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)_7]^{6-}$ polyanion, which can be synthesized by self-assembly from simple reagents and whose structure can be viewed as an inorganic double helix built from vanadium phosphate units, has recently been reported by Haushalter *et al.*[9]

Except for a few examples, all compounds with porous structures are oxidic. This explains their thermal stability and insulating electrical properties. On the other hand, metal chalcogenides (*e.g.* $CuInS_2$, MnQ, CdQ; Q = S, Se, Te) are important materials for electronic devices because of their magnetic or semiconducting properties.[10] Sulfides possess enormous compositional and structural variety.[11,12] Therefore, in view of the utility of microporous oxides in chemical catalysis and the wide applicability of chalcogenides in electronic devices a new class of compounds with a combination of the properties of zeolitic and sulfidic materials should be an attractive synthetic target. Solvothermal methods or reactive flux methods are possible preparative routes to these new materials.† Sheldrick and Braunbeck have described the solvothermal synthesis of chalcogenostannates.[13] Dhingra and Kanatzidis obtained $[PPh_4][M(Se_6)_2]$, a compound with an open-layer structure by reacting gallium, indium and thallium with low-melting polychalcogenide fluxes.[14] Herein we report the synthesis and characterization of $[Cr(en)_3][Te_6]$ **1** whose structure is built up from a polytelluride framework with pores filled by templating $Cr(en)_3^{3+}$ ions.

The title compound was first obtained by the reaction of $Cr(CO)_6$ with an alloy of the nominal composition $BaAs_4Te_4$. Based on the assumption that reactions of polytellurides with hard 3d metal cations (*e.g.* $Cr^{3+}$ or $Mn^{2+}$) only lead to products with isolated oligotelluride anions $Te_n^{2-}$ ($n$ = 2, 3) and $[M(en)_3]^{m+}$ ($m$ = 2, 3), the initial target was the assembly of a framework structure with bridging $AsTe_n$ ($n$ = 3, 4) elements stabilized by templating $Cr(en)_3^{3+}$ cations which are formed by oxidative decarbonylation of $Cr(CO)_6$.[15] Further investigations and the results of the X-ray analysis revealed that **1** represents the crystalline part of the reaction products.‡ It can also be prepared by the reaction of $Cr(CO)_6$ with a melt of nominal composition $BaTe_4$ [eqn. (1)].§

$$Cr(CO)_6 + 2\ BaTe_4 \xrightarrow[\text{closed quartz tube}]{\text{en, 200 °C, 7 d}} [Cr(en)_3][Te_6] + 2\ BaTe + 6\ CO \qquad (1)$$

Whereas reaction of the educts in boiling en under normal pressure yields powder-like products, the combination of the reaction with $Te_x^{2-}$ polytellurides as mineralizers leads to well crystallized products. **1** was removed from the reaction mixture by crystallization and should be the kinetically stable reaction product. The homogeneity of the product was confirmed from Guinier powder data.

The structure of **1** contains a polymeric $[Te_6]^{3-}$ polyanion,[16] whose pores are filled by isolated octahedrally coordinated $Cr(en)_3^{3+}$ cations. The characteristic structural features of the $Te_6^{3-}$ polyanion are puckered sheets of Te atoms parallel to the *ab*-plane which are shown in Fig. 1(*a*) in a projection along [001]. Fig. 1(*b*) shows a view of the structure along [100]. Each of these sheets is made up from $Te_6$ fragments which are linked to each other by Te–Te single bonds [$d_{Te-Te}$ = 2.763(1) Å]. The $Te_6$ fragments contain a central $Te_3$ ring with one exocyclic Te atom bonded to each atom of the ring. The Te–Te distances of 3.138(1) Å within the ring are approximately 0.3 Å longer than a typical Te–Te single bond distance (2.84 Å in the structure of elemental tellurium[17]). A formal bond order of 0.32 can be calculated using Paulings's rule [$d(n) = d(1) - 0.61 \log(n)$, $d(1)$ = 2.796 Å].[18] The exocyclic Te–Te separations of 2.918(1) Å are approximately 0.2 Å longer than typical Te–Te bond distances in polytellurides (*e.g.* $d_{Te-Te}$ = 2.726 Å in $Te_4^{2-}$[19]), but they are comparable with the Te–Te distances in $Te_2$ units encountered in the structures of $K_4M_3Te_{17}$ (M = Zr, Hf).[20] The shortest Te–Te distances of 3.376(1) Å between the layers are much shorter than the sum of the van der Waals radii of 4.4 Å[19] and comparable with the Te–Te distances in the polytelluride cluster $[NbTe_{10}]^{3-}$.[21] According to the results of an MO study these values correspond to significant Te–Te bonding interaction.[22] The computed Pauling bond order is 0.11. Therefore, the Te sheets in the structure of **1** should not be viewed as isolated layers.

An alternative description may be given based on the hierarchy of the bonding. (*i*) Considering only distances in the range of 2.7 Å to 3.0 Å as bonding, the structure consists of isolated $Te_4^{2-}$ chains. This description is in accord with conventional bonding considerations in polychalcogenides. However, the presence of additional partially bonding Te–Te bonding interactions indicates that this description does not allow to fully understand the bonding situation in the $Te_6^{3-}$ polyanion. (*ii*) Alternatively, if we consider all Te–Te distances shorter than 3.15 Å as bonding, a puckered layer structure with $Te_6$ motifs linked by Te–Te single bonds ($d_{Te-Te}$ = 2.763 Å) is

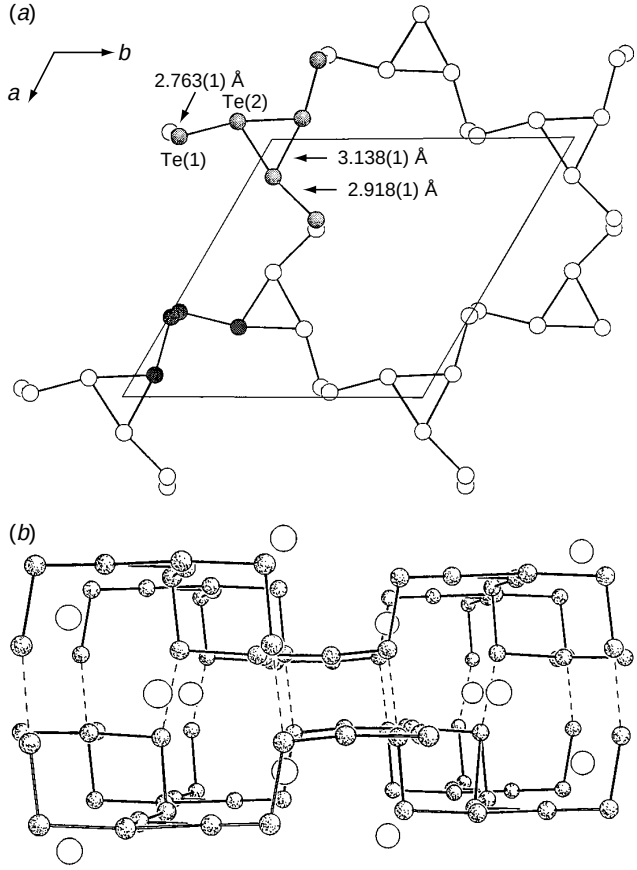

**Fig. 1** (*a*) Structure of the $Te_6^{3-}$ polyanion depicted in a view along [001]. (*b*) Two Te layers in a view along [100]. The positions of the $Cr(en)_3^{3+}$ cations are indicated by open spheres.

found [see Fig. 1(*a*)]. (*iii*) Counting all Te–Te distances shorter than 3.4 Å as bonding leads to a three-dimensional framework structure with pores containing solvated $Cr(en)_3^{3+}$ cations (Λ and Δ isomer, two crystallographically independent cations per unit cell. **1** is air-stable for several weeks. Thermal decomposition starts at 200 °C and is complete at 280 °C. Above 360 °C **1** transforms to other still uncharacterized products.

Although the electronic reasons for the stability of **1** can be rationalized by qualitative MO arguments, the mechanism of its formation is still unclear. The templating properties of the highly charged $Cr(en)_3^{3+}$ seems to be essential for the synthesis of **1**. Attempts to synthesize other related compounds with various $M(en)_3^{2+}$ cations (M = alkaline earth or 3d metal) only yield known chain-like polytellurides. The synthesis of further polytellurides with porous structures by means of coordinating ligands and highly charged cations is currently under investigation.

## Footnotes

† This corresponds to the formation conditions of naturally occurring sulfidic minerals.

‡ *Crystal data* for $[Cr(en)_3][Te_6]$: $C_6H_{12}CrN_6Te_6$, $M$ = 985.8, trigonal, space group $R32$ (no. 155), $Z$ = 6, $a$ = 14.292(2), $b$ = 14.292(2), $c$ = 18.076(3) Å, $U$ = 3197.56 Å$^3$, $D_c$ = 1.536 g cm$^{-3}$. Siemens P4, MoK$\alpha$, $\mu$ = 8.58 mm$^{-1}$, crystal size 0.15 × 0.15 × 0.15 mm, θ–2θ scan, $2\theta_{max}$ = 54°, 5446 reflections collected, 1564 independent reflections, 1485 reflections with $I > 2\sigma(I)$, $R(R_w)$ = 0.021(0.021). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/337.

§ $[Cr(en)_3][Te_6]$: 44 mg of $Cr(CO)_6$ (0.2 mmol) and 259 mg of an alloy with the nominal composition $BaTe_4$ were loaded into a quartz tube (volume *ca.* 20 ml). After introducing 2 ml of en, the tube was sealed under vacuum (*ca.* $10^{-3}$ bar). After 7 days of heating at 200 °C, the tube was cooled at 1 °C min$^{-1}$ and opened. Black cubic crystals could be isolated from the colourless solution. The crystals were washed with tetrahydrofuran and dried *in vacuo*. Yield: 127 mg (63.3%), satisfactory elemental analysis, IR data: (KBr pellet) 3397m, 3480m, 3030s, 2912s, 2870s, 1547s, 1447s cm$^{-1}$.

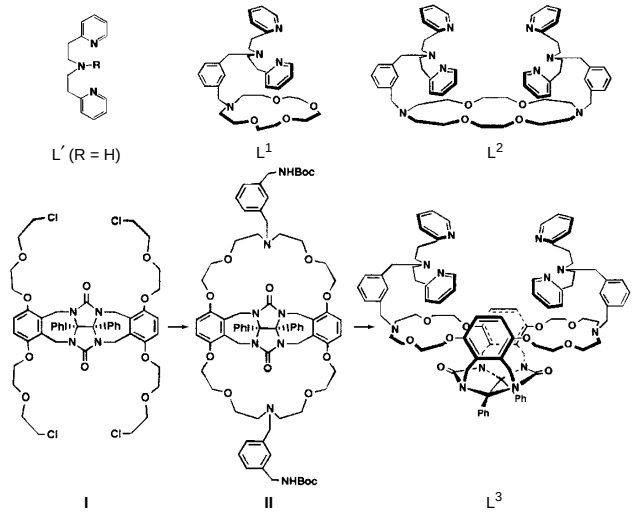
# Novel molecular receptors capable of forming $Cu_2$–$O_2$ complexes. Effect of preorganization on $O_2$ binding



**Robertus J. M. Klein Gebbink,[a] Constantinus F. Martens,[a] Martinus C. Feiters,[a] Kenneth D. Karlin*[b] and Roeland J. M. Nolte*[a]**

**Novel biomimetic copper(I) receptors react with $O_2$ to form metastable $O_2$ complexes and the rate of these reactions depends on the preorganization of the ligands.**

The binding and activation of molecular oxygen by dinuclear copper enzymes has attracted much attention in recent years.[1,2] Using model studies it was proposed,[1d,3] and later confirmed,[4] that molecular oxygen is bound between the two copper centres in the active site of haemocyanin *via* an unusual $\mu$-$\eta^2$:$\eta^2$ binding mode.† Several groups have demonstrated that synthetically derived $Cu_2$–$O_2$ complexes can carry out oxygenation reactions,[5] in particular, upon the ligands of the complex. One aim of our research is to design systems which may be used in oxygenation reactions on exogeneous substrates. For this reason we have attached the previously studied ligand L′[5a–d] (Scheme 1) to particular crown ethers and to a known molecular receptor,‡ for the potential to bind substrates in close proximity of an $Cu_2O_2$ centre. Here, we describe initial studies with three new ligands $L^1$–$L^3$ (Scheme 1) and their copper(I) complexes **1**–**3**, and characterization of their molecular oxygen binding ability.

Ligands $L^1$ and $L^2$ were synthesized from the commercially available crown ethers aza-15-crown-5 and diaza-18-crown-6. The secondary nitrogen atoms of the latter compounds were alkylated with 3-cyanobenzyl bromide, and the cyano groups were reduced with $LiAlH_4$. The resulting primary amines were alkylated with vinylpyridine under high-pressure conditions (15 kbar)[6] using acetic acid as a catalyst, providing pure $L^1$ and $L^2$ in 27 and 58% overall yield, respectively. For the preparation of $L^3$ the tetrachloro compound **I**[7] was subjected to a double ring closure reaction with 2 equiv. of mono-Boc protected *m*-diaminoxylene to give **II**. After removal of the Boc groups with TFA and treatment of the resulting compound with vinylpyridine under high-pressure conditions compound $L^3$ was obtained in 80% overall yield.§

**Scheme 1**

Copper(I) complexes **1**–**3** were synthesized by adding the ligands $L^1$–$L^3$, dissolved in $CH_2Cl_2$, to the appropriate amount of $[Cu^I(MeCN)_4]ClO_4$ under strictly anaerobic conditions. After several precipitations with $Et_2O$ the complexes were isolated as yellow–brown powders. Elemental analysis and spectral data were in agreement with the structures $[Cu^IL^1]$-$ClO_4$ **1**, $[Cu^I_2L^2][ClO_4]_2$ **2** and $[Cu^I_2L^3][ClO_4]_2$ **3**.§

Complexes **1**–**3** all formed metastable $O_2$ adducts in $CH_2Cl_2$ at −85 °C (Scheme 2). The rates of formation of these adducts were quite different, whereas their UV–VIS spectra were very similar (Table 1). Complex **2**·$O_2$ was obtained within 1–2 min after bubbling pre-cooled $O_2$ through a $CH_2Cl_2$ solution of **2** at −85 °C. During the reaction the colour of the solution changed from yellow to purplish green. Under the same conditions the bright orange complex **3**·$O_2$ was formed in 10–20 min. In contrast, both the colour of a solution of **1** and the absorption spectrum of this solution remained initially unchanged. If, however, an $O_2$-saturated solution of this complex was allowed to stand for 3–5 h at −85 °C, an orange complex formulated as $\mathbf{1}_2$·$O_2$ was formed slowly; this diminished $O_2$-binding rate and stoichiometry is in keeping with that observed for other L′ (R = Me, $PhCH_2$, Ph) copper(I) mononuclear complexes.[5c] In view of the spectral and structural similarities with previously reported $Cu_2$–$O_2$ complexes[1c–e,3] we propose that complexes $\mathbf{1}_2$·$O_2$, **2**·$O_2$, and **3**·$O_2$ all contain a peroxo ligand in a (bent) $\mu$-$\eta^2$:$\eta^2$ binding mode; the distinctive absorption around 364 nm

[a] Taken from ref. 9(*b*).

points to this type of binding.¶ The low absorption coefficients observed, particularly in $\mathbf{1}_2\cdot O_2$, are ascribed to lack of complete formation of $O_2$ adducts, and with concurrent temperature dependent decomposition (*vide infra*).

We found that the formation of complex $\mathbf{1}_2\cdot O_2$ can be accelerated if $KClO_4$ is added to the solution containing **1**, before $O_2$ is bubbled through it. In the presence of $KClO_4$ the $O_2$ complex reached its maximum concentration after 30–45 min, whereas without $KClO_4$ it took approximately 5 h for the complex to be formed completely. For 15-crown-5 and related compounds it is known that $K^+$ ions induce the formation of sandwich complexes, as these cations are too large to fit in the crown ether rings. Apparently, $K^+$ ions have the same effect on complex **1**: two mononuclear complexes are brought together and are pre-organized in order to bind one molecule of $O_2$. The proposed structure of such a sandwich complex, as shown in Fig. 1, may represent an intermediate state, more than it represents the final product. The enhanced oxygen affinity of complex **1** in the presence of $K^+$ cations mimics to some extent the allosteric effect of $Mg^{2+}$ ions on the oxygen binding by molluscan haemocyanin.[8] For the formation of $\mathbf{2}\cdot O_2$, and $\mathbf{3}\cdot O_2$ no acceleration effect of $K^+$ ions was observed.

Purging solutions $\mathbf{2}\cdot O_2$ with argon at −85 °C did not result in the decolourization of these solutions. When a solution of $\mathbf{2}\cdot O_2$ was rapidly heated under vacuum a green solution was obtained. These results indicate that the formation of the $O_2$ adducts is an irreversible process. As mentioned above the oxygen complexes are metastable; at −85 °C the loss in absorption intensity in the UV–VIS region was 5–10% after 1 h. Upon warming to room temperature the solutions of the complexes turned green within minutes. The resulting products could all be isolated as pale green powders in reasonable yields. IR and mass spectroscopy indicated that dinuclear copper(II) hydroxide complexes were formed. The starting ligands $L^1$–$L^3$ could be isolated from the corresponding copper(II) complexes after removal of the $Cu^{II}$ ions with aqueous ammonia. Yields were above 70% for $L^1$ and $L^3$, whereas $L^2$ was recovered in approximately 50% yield, indicating that some ligand degradation had occurred.

In summary, we have shown that the new complexes **1**–**3** all form stable $O_2$ complexes, which after warming yield copper(II) complexes in which the ligand remains intact to a major extent. This opens the possibility to use these complexes as oxygenation catalysts for exogeneous substrates, which is currently under study. The $O_2$ affinity and rate of formation of the copper(I) complexes is determined by the degree of pre-organization present in the starting complex.

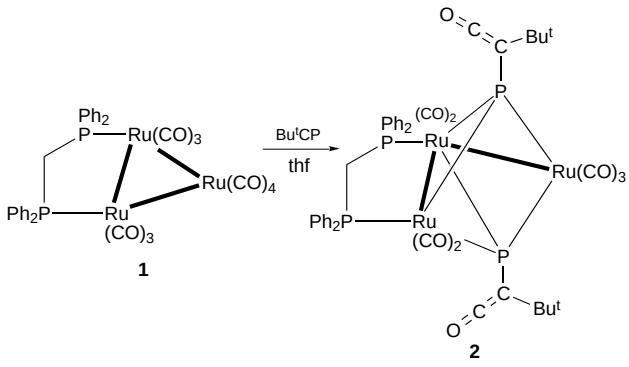
# Novel synthesis of two *tert*-butyl ketenyl phosphinidine ligands on a trinuclear ruthenium framework. X-Ray structure determination of $[Ru_3(\mu\text{-dppm})(CO)_7\{\mu_3\text{-PC(=C=O)Bu}^t\}_2]$

**Lindsay T. Byrne,[a] Julian A. Johnson,[b] George A. Koutsantonis,*[a] Brian W. Skelton[a] and Allan H. White[a]**

[a] *Department of Chemistry, University of Western Australia, Nedlands, Perth 6907, Australia*
[b] *CSIRO Division of Minerals, Port Melbourne, Victoria 3207, Australia*

**The reaction of an excess of $Bu^tC{\equiv}P$ with $[Ru_3(\mu\text{-dppm})(CO)_{10}]$ 1 in refluxing thf gives $[Ru_3(\mu\text{-dppm})(CO)_7\{\mu_3\text{-P(C=C=O)Bu}^t\}_2]$ 2 with two bridging phosphinidine ligands as the major product after chromatography.**



The considerable attention focussed on the chemistry of phosphaalkynes has been manifested in a sharp increase in numbers of papers dealing with the subject over the last ten years. This work is described in several excellent reviews which deal with both organometallic[1–3] and organic aspects.[4,5]

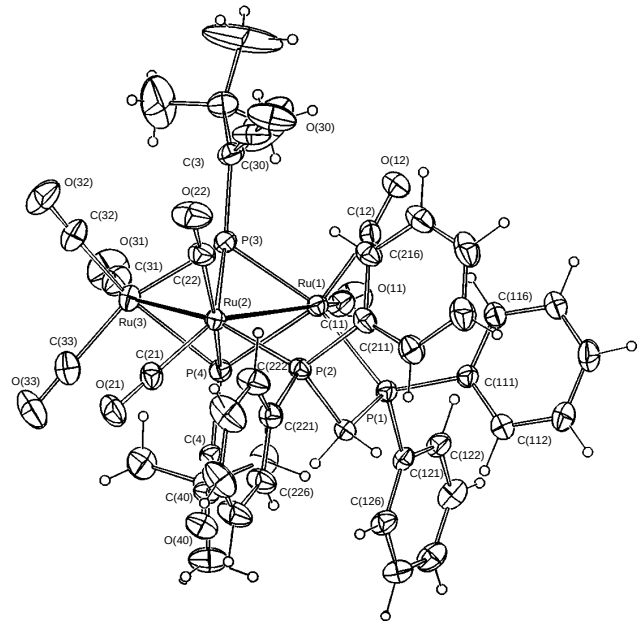
The chemistry of $[Ru_3(\mu\text{-dppm})(CO)_{10}]$ **1** [dppm = 1,2-bis(diphenylphosphino)methane], is characterised by its enhanced reactivity over that of the unsubstituted carbonyl $[Ru_3(CO)_{12}]$. Pyrolysis results in the elimination of benzene from dppm and metallation of one of the remaining phenyl groups.[6] Phosphines readily add to the unsubstituted Ru atom[7–9] and internal and terminal alkynes add readily to the ruthenium triangle.[10] As part of a continuing study of the reactivity of the activated cluster **1**, the reaction with 2-*tert*-butyl-1-phosphaalkyne was examined and the results are reported herein.

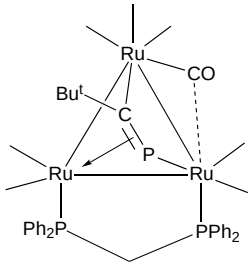
The reaction (Scheme 1)† in refluxing thf gave a mixture of products that are readily separated by thin layer chromatography, the major yellow band providing a moderate yield (*ca.* 27%) of $[Ru_3(\mu\text{-dppm})(CO)_7\{\mu_3\text{-PC(=C=O)Bu}^t\}_2]$ **2**, a 50-electron cluster. The compound remarkably contains two $\mu_3$-$Bu^t$ ketenyl phosphinidine ligands and is noteworthy for the lack of oligomerisation normally exhibited in the reactions of several equivalents of $Bu^tCP$ on transition-metal centres.

The FABMS of **2** showed a molecular ion $M^+$ at *m/z* 1141 that appeared to indicate the incorporation of two $Bu^tCP$ units and the sequential loss of nine CO groups. This latter fact is normally a reliable indication of the number of metal bound carbonyl groups and the fact that **1** readily adds substrates at the unsubstituted ruthenium[9] suggested a localised dimer at that atom occupying one coordination site. This formulation was at odds with the spectroscopic data which indicated the presence of four inequivalent phosphorus atoms. The fact that the phosphinidine ligands were found to be inequivalent was puzzling and seemingly at odds with the solid-state structure. The $^{31}P$ NMR spectrum of **2** contained four resonances that remained essentially unchanged within the temperature range 190 to 360 K indicating that the complex was rigid on the NMR timescale. The $^{31}P$ NMR spectrum was reproducible from a number of different samples and in different solvents. This suggests that the possibility of impurities or other structural isomers can be discounted.

The results of the room-temperature single-crystal X-ray structure study‡ are consistent with the stoichiometry and connectivity as expressed in **2** above and Fig. 1, a pair of substrate carbonyl ligands having been incorporated by the $Bu^tCP$ reactants to form a pair of $Bu^tC(CO)P$ phosphinidine entities. The phosphorus atoms of the latter approach the $Ru_3$ triangle from above and below the plane with approximately equivalent distances to the ruthenium atoms, much more precisely so about P(4). Notwithstanding, the phosphorus atoms are displaced from above the centroid of the triangle (and from

**Scheme 1**





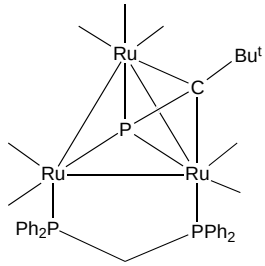


**Fig. 1** Projection of **2** approximately through the $Ru_3$ plane. 20% thermal ellipsoids are shown for non-hydrogen atoms; hydrogen atoms have arbitrary radii of 0.1 Å. Selected bond lengths (Å) and angles (°): Ru(1)–Ru(2) 2.916(1), Ru(2)–Ru(3) 2.831(1), P(3)–Ru(1–3), 2.296(2), 2.381(2), 2.330(2), P(4)–Ru(1–3) 2.380(2), 2.378(2), 2.377(2), Ru(1)–P(1) 2.386(2), Ru(2)–P(2) 2.306(2), P(3)–C(3) 1.807(7), C(3)–C(30) 1.27(1), C(30)–O(30) 1.19(1), P(4)–C(4) 1.809(7), C(4)–C(40) 1.293(9), C(40)–O(40) 1.176(8), Ru(3)–Ru(2)–Ru(1) 83.80(3), P(3)–C(3)–C(30) 114.7(6), P(4)–C(4)–C(40) 113.6(5), C(3)–C(30)–O(30) 179(1), C(4)–C(40)–O(40) 180(1), P(1)–C(0)–P(2) 110.4(3), C(3)–P(3)–Ru(1–3) 121.6(7), 126.9(2), 125.0(3), C(4)–P(4)–Ru(1–3) 129.6(3), 127.3(2), 121.4(3).

**3**

**4**

the dppm) so that they bridge one pair of ruthenium atoms, with the associated Ru···Ru distance lengthened to 3.839(1) Å, and with an unsymmetrical dppm disposition. The major difference observed lies in the Ru(1)–P(*n*)–Ru(3) angles [for $n$ = 3, 112.14(7)°; $n$ = 4, 107.59(6)°] and this possibly affects the observed $^{31}$P NMR resonances for these nuclei. It is of note that the $^{31}$P NMR shifts of μ-phosphido ligands in a series of structurally characterised compounds were greatly affected by small variations in Ru–P–Ru angle.[11] In the dppm ligand the two now inequivalent phosphorus atoms, bound to a pair of inequivalent ruthenium atoms, with inequivalent Ru–P [2.386(2), 2.306(2) Å], lie necessarily to one side of the $Ru_3$ plane so that the molecule's incipient *m* symmetry is lost. Despite this, the pair of phosphinidine ligands are almost eclipsed in projection, with the ketenyl moieties in surprisingly close proximity to other moieties in the coordination sphere [O(30)···O(22), H(216) 2.951(8), 2.69; O(40)···H(0a) 2.66 Å] and adjacent molecules [O(30)···H(0b) 2.50 Å]. The geometries of the Bu$^t$ ketenyl phosphinidine ligands are similar to those observed in $[Re_2Pt(CO)_8(dppe)\{\mu_3\text{-}PC(=C=O)(Bu^t)\}]$[12] and $[Fe_3(CO)_7(Se)(PBu^t)(Bu^tC_2H)\{\mu_3\text{-}PC(=C=O)Bu^t\}]$.[13]

In the absence of oligomerisation it is likely that the formation of **2** results from the stepwise addition of Bu$^t$CP (which can act as either a four- or six-electron donor) units with cleavage of a Ru–Ru bond. Further work is required to determine the mechanism operating in this reaction but a likely sequence of events would involve addition of Bu$^t$CP presumably through the labile equatorial site on the unsubstituted Ru atom, which adopts initially a $\mu_3$-$\eta^2$ (∥) **3** or (⊥) **4** ligating mode followed by addition of the liberated or metal-bound CO to the CP bond, the process being repeated to give the other ligand.

Work is in progress to identify the minor products from this reaction in the belief that they will shed further light on the course of this reaction.

We thank the ARC for financial support and the Department of Chemistry for a start up grant (G. A. K.).

## Footnotes

† *Synthesis of* **2**: an excess of Bu$^t$CP (0.05 ml) was added to a solution of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (0.104 g, 0.107 mmol) in thf (20 ml) and heated to reflux for 40 min. After cooling the solvent was removed *in vacuo*, and the residue was dissolved in the minimum amount of $CH_2Cl_2$ and chromatographed (TLC, silica $GF_{254}$ 0.5 mm; 3 : 1 hexanes–$CH_2Cl_2$). Three bands were resolved but only the major yellow band ($R_f$ 0.6) was isolated, being crystallised from $CH_2Cl_2$–MeOH to give **2** (0.033 g, 27%). # Destruction of cyanobacterial toxins by semiconductor photocatalysis

**Peter K. J. Robertson, Linda A. Lawton, Burkhard Münch and Julien Rouzade**

*School of Applied Science, The Robert Gordon University, St Andrew Street, Aberdeen, UK AB25 1HG*

**The rapid destruction of microcystin, a cyanobacterial toxin, using a titanium dioxide photocatalyst is observed; the process is extremely efficient with high concentrations of toxin completely undetectable within 10–40 min, depending on the initial concentration.**

Cyanobacterial (blue-green algal) toxins are extremely toxic naturally occurring substances which display hepato- and neuro-toxic behaviour.[1,2] Several genera of freshwater cyanobacteria including *Microcystis*, *Oscillatoria*, *Anabaena* and *Aphanizomenon* produce a range of potent natural toxins. These toxins can be classified in two general categories, neurotoxins [*e.g.* anatoxin-a, anatoxin-a(s) and saxitoxins] and hepatotoxins, namely microcystins which are the subject of this investigation. The heptapeptide microcystins are a family of *ca.* 50 congeners which exhibit potent inhibition of protein phosphatase 1 and 2A resulting in a range of clinical symptoms. Acute doses of microcystin, such as that recently experienced by patients undergoing dialysis, results in death due to hepatic failure.[3] Longer-term exposure to sub-lethal levels, however, is suspected of promoting primary liver cancer. The incidence of cyanobacterial blooms in freshwaters, including drinking water reservoirs, appears to have increased over the past few decades due to rising nutrient levels caused by intensive farming practices, sewage generation and detergent usage.[4] Microcystins are chemically very stable[5] and conventional water treatment processes fail to remove them, furthermore the use of more advanced methods such as granular carbon filtration and photochemical degradation have shown only limited efficacy.[6,7] The use of semiconductor photocatalysis for destruction of environmental pollutants is a well established technique with the mineralisation of a wide range of materials being reported.[8] When semiconductors are illuminated with light of an appropriate wavelength, electrons are promoted from the occupied valence band (producing oxidising sites) to the unoccupied conductance band (producing reducing sites). It is believed that hydroxyl radicals are generated at the valence band which promote the mineralisation of the pollutants.[9]

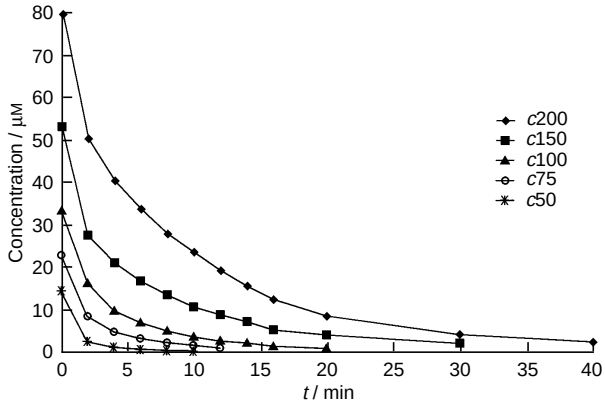

**Fig. 1** The destruction of a range of concentrations of microcystin-LR using a titanium dioxide photocatalyst. Samples were quantified by HPLC using the previously described method of Lawton *et al.* (ref. 11).

**Table 1** Rates of decomposition of microcystin-LR in the presence of $TiO_2$ photocatalyst

| Initial toxin concentration/μM | Initial rate/ μM $min^{-1}$ | Specific activity/ μM $min^{-1}$ $cm^{-2}$ ($\times 10^{-6}$)[a] | Specific rate/ μM $cm^{-2}$ $min^{-1}$ μM $photon^{-1}$ ($\times 10^{-3}$)[b] |
|---|---|---|---|
| 50 | 5.95 | 108.3 | 33.4 |
| 75 | 7.20 | 130.8 | 40.4 |
| 100 | 9.51 | 155.1 | 47.9 |
| 150 | 12.22 | 233.2 | 72.1 |
| 200 | 14.60 | 265.5 | 82.0 |

[a] The specific activity represents the rate of destruction per unit area of catalyst assuming a catalyst surface area of 50 $m^2$ $g^{-1}$. [b] The specific rate represents the rate of destruction per unit area of catalyst per photon absorbed assuming the number of photons absorbed by the reactor as $1 \times 10^{-4}$ photons $min^{-1}$ determined using potassium ferrioxalate actinometry (ref. 19).

We have discovered that this technique is extremely effective in the destruction of microcystin-LR (molecular weight 994)[2] one of the most commonly occurring cyanobacterial toxins. This toxin, a heptapeptide with the generic structure of a microcystin and leucine (L) and arginine (A) in the variable positions, was purified from a natural sample of *Microcystis aeruginosa*.[10] Aqueous solutions of microcystin-LR (pH 4, 306 K) were illuminated in the presence of air and a $TiO_2$ catalyst (1% m/v solution of $TiO_2$ Degussa P-25) using a xenon UV lamp (280 W UVASpot 400 Lamp, Uvalight Technology Ltd, spectral output 330–450 nm). The investigation was performed on a series of solutions containing varying concentration of microcystin-LR. The concentrations (μM) used to evaluate the photocatalytic destruction of microcystin-LR greatly exceeded that which occurs naturally (nM–pM). This, however, enabled us to directly quantify the toxin by HPLC (as described elsewhere[11]) without multi-step processing which is necessary to quantify the much lower levels found in the environment. Very rapid destruction of microcystin-LR was observed for all concentrations (Fig. 1) even at the highest level tested (200 μM) with the toxin virtually undetectable after 40 min. It was found that the initial rate of decomposition was influenced by the initial toxin concentration (Table 1). In fact, at concentrations below those shown the rate of destruction was so rapid that microcystin-LR was undetectable by the first sampling point (2 min). These data suggest that the much lower concentrations which can be present in drinking water will be rapidly removed by this technique. The samples that were illuminated without $TiO_2$ displayed no degradation. As was observed with the initial rates of destruction, the specific rates and specific activities for the process were also reduced with increasing toxin concentration.

The Langmuir–Hinshelwood kinetic rate model has been widely applied to the initial rate of the photocatalytic destruction of a wide series of compounds.[12] Eqn. (1) displays the Langmuir–Hinshelwood kinetic rate law where $r_0$ is the initial rate of disappearance of the substrate and $C_0$ is the initial

substrate concentration, $k$ is the rate constant of the reaction and $K$ is the Langmuir adsorption constant.

$$r_0 = \frac{kKC_0}{1 + kKC_0} \quad (1)$$

The constants $k$ and $K$ may be determined from a plot of $1/r_0$ *vs*. $1/C_0$. If the system obeys the Langmuir–Hinshelwood model this plot should be linear. The intercept of the line provides us with $1/k$ while the slope is equal to $1/kK$. We examined the suitability of applying this model to our system. The reciprocal of initial rate *vs*. initial concentration values for the microcystin decomposition reactions were plotted (Fig. 2) and a linear relationship was observed, confirming that our system does indeed follow the Langmuir–Hinshelwood model. From the graph we determined that $k$ and $K$ for the destruction of microcystin were 19.23 μM min$^{-1}$ and $2.9 \times 10^{-2}$ dm$^3$ μmol$^{-1}$ respectively. Rate and adsorption constants reported for the photocatalytic destruction for other organic compounds are comparable with those reported here.[8,13–15] Examples include 4-chlorophenol ($k$ = 79.3 μM min$^{-1}$, $K$ = $4.88 \times 10^{-3}$ dm$^3$ μmol$^{-1}$),[13] benzene ($k$ = 39 μM min$^{-1}$, $K$ = $1.8 \times 10^{-2}$ dm$^3$ μmol$^{-1}$)[14] perchloroethylene ($k$ = 34 μM min$^{-1}$, $K$ = $8.6 \times 10^{-3}$ dm$^3$ μmol$^{-1}$)[14] and phenol ($k$ = 12.9 μM min$^{-1}$, $K$ = $2.19 \times 10^{-2}$ dm$^3$ μmol$^{-1}$).[15]

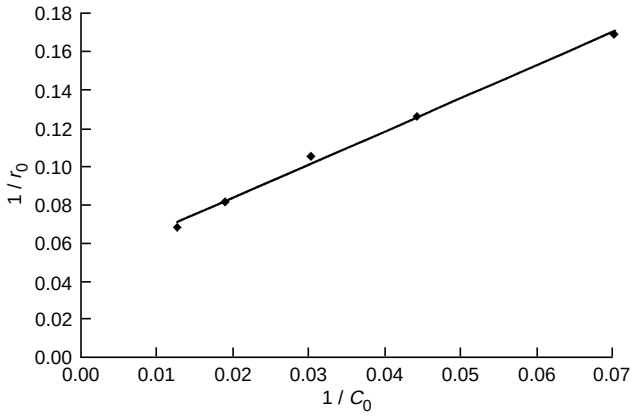

**Fig. 2** Plot of the reciprocal of the initial rate ($1/r_0$) *vs*. the reciprocal of the initial concentration ($1/C_0$)

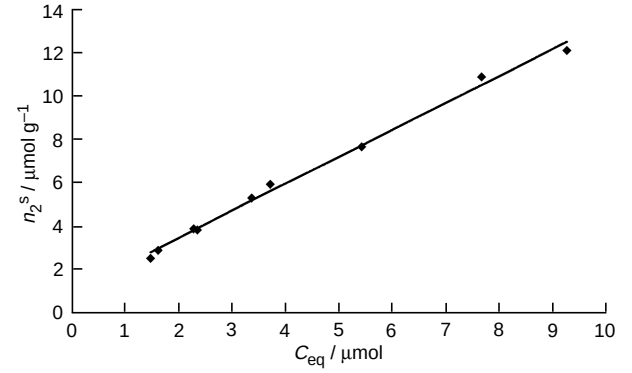

**Fig. 3** Dark adsorption isotherm of microcystin-LR on $TiO_2$. The number of moles of microcystin-LR attached per gram of $TiO_2$ is $n_2^S$ while $C_{eq}$ represents the equilibrium concentration of microcystin after 24 h.

Dark adsorption isotherms, for the adsorption of microcystin on $TiO_2$, were prepared in order to compare the value of the Langmuir adsorption constant determined by this method with that of the constant determined using the initial rates method for the photocatalytic model. Universal bottles containing the toxin solution plus $TiO_2$ were shaken at room temperature in the dark using a flask shaker for 24 h. The dissolved microcystin-LR was separated from the catalyst and quantified by HPLC. The dark adsorption isotherm for microcystin-LR was plotted (Fig. 3) and the $K$ value was found to be $2.9 \times 10^{-4}$ dm$^3$ μmol$^{-1}$. This is 100 times lower than the value obtained using the initial rates method. Similar differences have been observed by other workers.[16,17] It has been proposed that this may be due to photoadsorption reactions at the $TiO_2$ surface or that decomposition of the substrate may not occur exclusively at the catalyst surface but may be promoted by hydroxyl radicals released from the catalyst surface.[16,17]

Preliminary results from our laboratory have shown that this system can also be successfully applied to the destruction of other classes of cyanobacterial toxins.[18] The efficient removal of microcystins and the benefits of the reported removal of other organic contaminants, indicates that photocatalysis is an extremely attractive treatment method for potable water supplies.

We thank J. McElhiney and B. Cornish for assistance with HPLC analysis throughout the project, and S. M. Henderson and C. Edwards (Biotage UK, Hertford) for their collaboration in the purification of microcystin-LR.

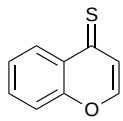
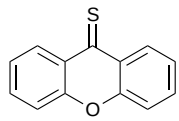
# Photophysics of xanthione and 4*H*-1-benzopyran-4-thione in β-cyclodextrin complexes



**Marek Sikorski,[a,b] Miquel Mir[a] and Francis Wilkinson[a]**

[a] *Department of Chemistry, Loughborough University, Loughborough, Leicestershire, UK LE11 3TU*
[b] *Faculty of Chemistry, University of A. Mickiewicz, 60 780 Poznan, Poland*



**The phosphorescence decays of β-cyclodextrin (β-CD) complexes of xanthione (XT) and 4*H*-1-benzopyran-4-thione (BPT) show that self-quenching and oxygen quenching are not important in such complexes, and that the existence of bimodal inclusion in solid complexes can be identified using the width of the distribution parameter of the Gaussian distribution of the logarithm of the observed rate constants for decay.**

Aromatic thioketones show interesting photochemical behaviour including fluorescence from the second excited singlet state, $S_2$, room temperature phosphorescence from the first excited triplet state, $T_1$, thermally activated delayed fluorescence from the first excited singlet state, $S_1$, and photochemistry arising from the $T_1$ state as well as from the $S_2$ state.[1] In addition, the $S_2$ and $T_1$ states of thiones are quenched at or near diffusion limited rates by a wide variety of substances including ground state thione (self-quenching) and oxygen. Moreover, studies of $S_2$ are complicated by the fact that thione non-radiative decay rates are extremely sensitive to the nature of the solvent since quenching by many common solvents occurs at diffusion-limited rates.[1] Attempts to overcome the self-quenching problem in solution have involved the incorporation of thiones in micelles.[2] In these organised media a decrease in the contribution of the self-quenching process to the decay of $T_1$ states of thioketones was achieved as a consequence of the compartmentalisation process.[2]

Recently, the formation of β-CD inclusion complexes of xanthione (XT) and 4*H*-1-benzopyran-4-thione (BPT) in aqueous solution have been reported.[3] Cyclodextrins (CDs) are cyclic oligosacharides of six to eight α-D-glucose units (α-CD, six; β-CD, seven; γ-CD, eight) that posses internal hydrophobic cavities able to include a great variety of guest molecules in aqueous solutions.[4] These complexes have been used for studying the photophysics and photochemistry of the guest molecules in an organised environment.[5] Here we report a preliminary account on the photophysics of XT and BPT β-CD complexes in water and in the solid state.†

BPT

XT

The absorption spectrum of BPT in water shows a maximum at 376 nm ($S_0 \rightarrow S_2$ band). Upon addition of 0.011 M β-CD, a small blue shift is observed ($\lambda_{max}$ = 373 nm). The absorption spectrum of XT in water could not be recorded by us in 1 cm pathlength cells due to the low solubility ($S = 2.5 \times 10^{-7}$ M, $\varepsilon = 1.5 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$).[2b] The solubility of XT increases upon addition of β-CD and the absorption spectrum was recorded ($S_0 \rightarrow S_2$ band, $\lambda_{max}$ = 406 nm).

Steady-state emission spectra of XT and BPT in air-equilibrated aqueous solution show dramatic changes in the emission intensity upon addition of β-CD to the solution. The positions of the wavelength maxima are collected in Table 1. These changes are depicted in Fig. 1(*a*) for XT. In the case of BPT there is a substantial increase in the $S_2 \rightarrow S_0$ fluorescence and in the $T_1 \rightarrow S_0$ phosphorescence, and a blue shift of the phosphorescence band (not shown). In the case of XT we were able to observe very little emission, if any, without β-CD. However, in the presence of β-CD, $S_2 \rightarrow S_0$ fluorescence and $T_1 \rightarrow S_0$ phosphorescence appear. These results confirm earlier reports[3] about the formation of β-CD inclusion complexes of XT and BPT in aqueous solution and show the protection offered by the β-CD cavity from oxygen quenching of thione molecules in such inclusion complexes. A similar conclusion was reached for other guest molecules in CD inclusion complexes in aqueous media[6] and also for solid state complexes.[7]

Ground state diffuse reflectance absorption spectra of XT–β-CD and BPT–β-CD solid complexes do not show noticeable changes in relation to the spectra observed in aqueous solution in the presence of β-CD (see Table 1). Steady-state emission spectra of XT–β-CD [Fig. 1(*b*)] and BPT–β-CD air-equilibrated solid complexes were recorded (see Table 1). In both cases, $S_2 \rightarrow S_0$ fluorescence and $T_1 \rightarrow S_0$ phosphorescence are observed. The relative intensity fluorescence/phosphorescence is very similar in both cases to that observed for the complexes in aqueous solution. For the sake of comparison fluorescence measurements were performed for XT and BPT on cellulose mechanical mixtures with similar concentrations to those employed for the β-CD solid complexes. Practically no phosphorescence was observed for these mechanical mixtures presumably because in these cases efficient oxygen quenching occurred. Moreover, no emission was observed from XT crystals.

Time resolved phosphorescence of XT–β-CD and BPT–β-CD solid complexes was studied using diffuse reflectance

**Table 1** Spectral properties of XT and BPT in different media

| | Absorption $\lambda_{max}(S_0 \rightarrow S_2)$/nm | Fluorescence $\lambda_{max}(S_0 \rightarrow S_2)$/nm | Phosphorescence $\lambda_{max}(S_0 \rightarrow S_2)$/nm |
|---|---|---|---|
| BPT in water | 376 | 425 | 644 |
| BPT in water + 0.011 M β-CD | 373 | 427 | 628 |
| BPT–β-CD solid complex | 370 | 439 | 618 |

| XT in water + 0.011 M β-CD | 406 | 430–490 | 667 |
| XT–β-CD solid complex | 408 | 457 | 661 |

[a] Solubility too low to be measured ($S = 2.5 \times 10^{-7}$ M, $\varepsilon = 1.5 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$) [ref. 2(*b*)].

laser flash photolysis equipment.‡,[8] The phosphorescence decays were fitted according to the Albery model[9] for dispersive kinetics§ [see Fig. 1(*b*) for XT as example]. The mean rate constants for triplet state decay obtained using the Albery model in the β-CD solid complexes [$k = (2.61 \pm 0.05) \times 10^5$ s$^{-1}$ for BPT and $k = (2.24 \pm 0.01) \times 10^5$ s$^{-1}$ for XT] are comparable to the values previously reported in solution at infinite dilution for BPT[10] and XT.[11] The mean decay constant of a XT–β-CD complex sample with eight times less XT loading was practically identical [$k = (2.04 \pm 0.02) \times 10^5$ s$^{-1}$] to the mean decay constant of the sample with higher loading. Practically identical phosphorescence decay of a XT–β-CD complex sample was observed when the sample was degassed prior to excitation, presumably due to the protection from oxygen quenching offered by the CD in the solid state.[7] These results suggest that self-quenching and oxygen quenching do not play an important role in the photophysics of thioketones in solid β-CD inclusion complexes.

It is interesting to note the difference in the width of the distribution parameter, γ, obtained from fitting to the Albery model the phosphorescence decay of the XT–β-CD and BPT–β-CD complexes ($\gamma = 1.11 \pm 0.02$ for BPT and $\gamma = 0.62 \pm 0.01$ for XT). The higher value for the BPT complex can be attributed to the existence of two non interconverting¶ major orientations of the BPT molecules within the β-CD cavity (see Fig. 2). By contrast, XT can only be fitted within the cavity in one major orientation due to its symmetry. The existence of multimodal inclusion of the guest molecules in the CD cavity has been studied in solution by different methods: electron paramagnetic resonance (EPR),[13] electron nuclear double-resonance (ENDOR),[14] fluorescence methods[15] and theoretical methods.[16]

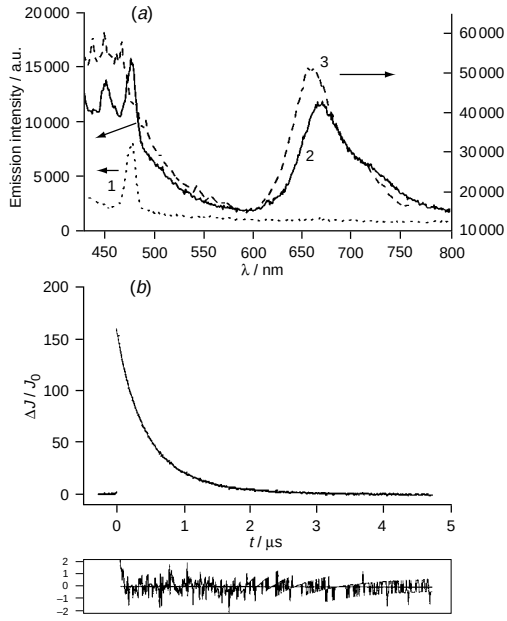

**Fig. 1** (*a*) Steady-state emission spectra of XT ($\lambda_{exc}$ = 410 nm, non deoxygenated samples at room temperature) in water (1), in water with β-CD 0.011 M (2) and in the β-CD complex in the solid state (3). (*b*) Phosphorescence decay trace of the XT–β-CD solid complex at 660 nm and fit according to the Albery model (ref. 9) with the plot of residuals.

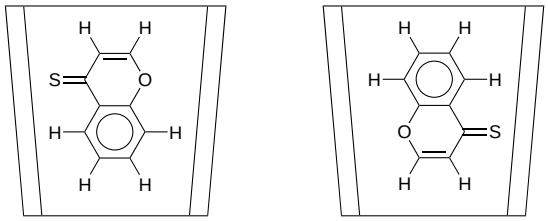

**Fig. 2** Major orientations of the BPT molecules within the β-CD cavity

In summary, the results presented here show that β-CD inclusion complexes in aqueous solution and in the solid state might be a particularly useful media for studying the intramolecular photophysics of aromatic thioketones due to the fact that self-quenching and quenching by oxygen are not important in such inclusion complexes. As far as we know, this is the first reported example of bimodal inclusion in solid state cyclodextrin complexes. The methodology applied in the present work (analysis of the phosphorescence decay according to the Albery model) is a new alternative to the fluorescence method and might be a powerful tool for investigating in the microsecond domain the existence of different inclusion orientations in solid cyclodextrin complexes.‖

## Footnotes

† CD solid complexes were prepared by dissolving a certain amount of the thione in 0.011 M β-CD aqueous solutions under magnetic stirring at 70 °C for 4 h. After evaporation of water *in vacuo* with a rotary evaporator, the solid obtained was dried under vacuum at 40 °C for 4 h. Sample loading were around 0.5–2 mg of the thione per gram of β-CD.

‡ A detailed description of the laser system can be found in ref. 8. The excitation wavelength was 355 nm.

§ Complex kinetics are normally observed in heterogeneous media (*i.e.* solid surfaces, polymer matrices, biological membranes) due to the variety of solute environments, every one with its own decay mode. The Albery model (ref. 9) describes the kinetics of heterogeneous systems by a Gaussian distribution of the logarithm of the observed rate constants with two parameters: the mean rate constant, *k*, and a distribution parameter, γ, that defines the spread of the Gaussian distribution (if $\gamma = 0$, the Albery model becomes a simple first-order exponential decay equation).

¶ The diameter of the β-CD cavity (ref. 4) is 6.0–6.4 Å and the largest diameter of the BPT molecule is *ca* 6.5 Å according to standard bond lengths (ref. 12). Therefore the molecule of BPT does not have inside the solid complex the possibility of interchanging the orientations depicted in Scheme 1.

‖ A lifetime distribution study of xanthone and benzophenone triplets in cyclodextrin complexes in the solid state using an exponential series method has been reported in the literature (ref. 7).

# Catalytic oxidation of methane to methyl hydroperoxide and other oxygenates under mild conditions

**Galina V. Nizova,[a] Georg Süss-Fink,*[b]† and Georgiy B. Shul'pin*[a]‡**

[a] *Semenov Institute of Chemical Physics, Russian Academy of Sciences, ul. Kosygina 4, Moscow 117977, Russia*
[b] *Institut de Chimie, Université de Neuchâtel, Avenue de Bellevaux 51, CH-2000, Neuchâtel, Switzerland*

**Methane is oxidized by air in acetonitrile solution to give methyl hydroperoxide (easily reduced to methanol), formaldehyde and formic acid in the presence of $[NBu_4]VO_3$–pyrazine-2-carboxylic acid as the catalyst and $H_2O_2$ as a promoter.**

The oxidation of saturated hydrocarbons with hydrogen peroxide and molecular oxygen catalysed by transition-metal complexes constitutes a convenient route for the direct transformation of these inert compounds to valuable products such as peroxides, ketones, alcohols and carboxylic acids.[1] Complexes of vanadium are known to catalyse the oxidation of various organic compounds by peroxides.[2,3]

We report here on the efficient oxidation of methane with air catalysed by the combination $[NBu_4]VO_3$–pyrazine-2-carboxylic acid (PCA) in the presence of hydrogen peroxide. The reactions of methane (and of cyclohexane as well) were carried out at various temperatures and pressures.§ The process was monitored by withdrawing aliquots at specific intervals and analysing each sample twice, *i.e.* before and after the addition of an excess of solid triphenylphosphine. This method described by us earlier[3,4] (and used then also by other workers[5]) allows one to detect alkyl hydroperoxides and to measure also the real concentrations of all three products (alkyl hydroperoxide, alcohol and aldehyde or ketone) present in the reaction solution, because usually alkyl hydroperoxides are decomposed in the gas chromatograph to produce the corresponding alcohol and ketone.¶

We have found that the combination of $[NBu_4]VO_3$ and PCA catalyses the oxidation of methane in acetonitrile solution in the presence of air and hydrogen peroxide to produce methyl hydroperoxide, formaldehyde and (after an induction period) formic acid (Table 1). Methyl hydroperoxide slowly decomposes to give methanol and formaldehyde. No methanol peak has been detected after opening the autoclave prior to the reduction with $PPh_3$. After the reduction with $PPh_3$ the MeOH peak appeared, while the concentration of HCHO in the solution dropped. The average rates of oxidation at 20, 40 and 75 °C are 7.5, 30 and 105 turnovers $h^{-1}$, respectively.

**Table 1** Oxidation of methane by air in the presence of $[NBu_4]VO_3$–PCA–$H_2O_2$[a]

| Pressure/bar | | | | Products (concentration/ $10^2$ mol $dm^{-3}$) | | | |
|---|---|---|---|---|---|---|---|
| Methane | Air | *T*/°C | *t*/h | MeOOH | HCHO | $HCO_2H$ | Total turnover[b] |
| 75 | 10 | 23 | 6 | 0.5 | 0.04 | 0 | 54 |
| | | | 16 | 1.3 | 0.13 | 0 | 143 |
| | | | 24 | 1.6 | 0.16 | 0 | 176 |
| 75 | 10 | 40 | 1 | 1.6 | 0.18 | 0 | 178 |

| 40 | 10 | 75 | 4 | 0 | 0.20 | 4.0 | 420 |

[a] Conditions and concentrations of components, see Footnote §. Standard deviations of analytic methods ±20%; value 0 means below detection limit ($0.01 \times 10^{-2}$ for MeOH, MeOOH and HCHO; $0.1 \times 10^{-2}$ mol $dm^{-3}$ for $HCO_2H$). [b] Moles of all detected products per mole of vanadate ion.

The oxidation of methane, catalysed by $[NBu_4]VO_3$–PCA, requires the presence of air and hydrogen peroxide. We believe that hydrogen peroxide, although present in stoichiometric amounts, acts only as a promoter, while molecular oxygen is the oxidant. In order to prove the implication of $O_2$ from air in the oxidation process, we studied the analogous reaction with liquid cyclohexane in the place of methane. When the reaction was carried out in the presence of $H_2O_2$ but in the absence of air ($N_2$ atmosphere, 40 °C, 2 h) no formation of oxygenated products was observed. However, when the reaction vessel was opened to air, the reaction started immediately with the same rate as observed in the presence of air.

Finally, the cyclohexane oxidation under an $^{18}O_2$ atmosphere unambiguously showed a high degree of $^{18}O$ incorporation into the oxygenated products.‖ Thus, according to the GCMS analysis, the measured extent of $^{18}O$ incorporation into cyclohexanol after the reduction with triphenylphosphine is *ca.* 75%. Prior to the reduction with $PPh_3$, the $^{18}O$ labelling of cyclohexanol was noticeably lower (*ca.* 50%), and only *ca.* 5% of $^{18}O$ was found in cyclohexanone. The triphenylphosphine oxide formed from the reduction of the reaction mixture with $PPh_3$ also contained $^{18}O$. On the basis of these results one can assume that all oxygen present in the primary product of the oxidation (alkyl hydroperoxide, ROOH) stems from atmospheric dioxygen. Unlabelled oxygen (*ca.* 25%) detected in the cyclohexanol after the reduction with $PPh_3$ could originate from gaseous $^{16}O_2$, formed by catalytic decomposition of $H_2{}^{16}O_2$ in the reaction vessel. Such a decomposition proceeds rapidly in the injector of the chromatograph at high temperature. Cyclohexanone seems to be formed in the injector from cyclohexyl hydroperoxide completely *via* a mechanism involving the generation of alkyl radicals, R·, which react then with $^{16}O_2$.

We presume that in the presence of catalytic amounts of $[NBu_4]VO_3$–PCA, hydrogen peroxide is an efficient generator of hydroxyl radicals. The radicals HO· thus formed attack the alkane molecule, RH, abstracting a hydrogen atom. As a result, alkyl radicals, R·, are produced which rapidly react with molecules of oxygen to yield peroxyl radicals ROO· (see ref. 6). These latter species can then be transformed into ROOH. Stoichiometric quantities of $H_2O_2$ are presumably required in order to reactivate the catalyst system.

Thus it may be concluded that in the system described in the present work, hydrogen peroxide is only the promoter of the oxygenation, while molecular oxygen is the true oxidant. Such a scheme seems to be operative in many alkane oxidations with $H_2O_2$ in air (small amounts of molecular oxygen necessary for the addition to alkyl radicals can be formed by the decomposition of $H_2O_2$ even if the reaction is carried out in an inert atmosphere[6]). Indeed, previously we have found that alkyl hydroperoxides are formed as main products when higher alkanes are oxidized with $H_2O_2$ in air under the catalysis not only by the vanadium system studied in the present work,[3] but also by manganese porphyrinates, palladium complexes and iron salts,[4c] as well as by methyltrioxorhenium.[7] The reagent

described in this paper is one of the most efficient ones (in terms of catalytic turnovers) for methane oxidation[8] under mild conditions (temperatures below 100 °C).

We thank BASF, the International Science Foundation, INTAS, the Russian Basic Research Foundation and the Swiss National Science Foundation for support and Dr. Arthur Höhn (BASF, Ludwigshafen, Germany) for fruitful discussions.

§ The oxidations were carried out in glass-lined stainless-steel autoclaves with vigorous stirring (volume of the reaction solution = 10 ml, total volume of autoclave = 100 ml). Usually the following concentrations of the reagents were used: $[NBu_4]VO_3$, $1.0 \times 10^{-4}$ mol dm$^{-3}$; PCA, $4.0 \times 10^{-4}$ mol dm$^{-3}$; $H_2O_2$ (35% aq), 0.2 mol dm$^{-3}$. Before the oxidation the autoclave was charged with air and then with methane under appropriate pressures. (**CAUTION**: the combination of air and $H_2O_2$ with organic compounds at elevated pressures and temperatures may be explosive!) The reactions were stopped by cooling with ice and the reaction solution was analysed by GC (DANI-86.10; fused silica capillary column 60 m × 0.25 mm × 0.25 μm, SPB-1; integrator SP-4400). The concentration of formaldehyde was measured spectrophotometrically after its transformation into 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine according to method described in ref. 9.

¶ If an excess of solid $PPh_3$ is added to the reaction solution 10–20 min before the GC analysis, the alkyl hydroperoxide present is completely reduced to the corresponding alcohol. As a result, the chromatogram differs completely from that of a sample not subjected to the reduction (the alcohol peak increases, while the intensity of the ketone peak decreases). If there is no difference between chromatograms of the same sample before and after reduction, this testifies to the absence of an alkyl hydroperoxide in the solution. If, by contrast, the chromatogram prior to the reduction exhibits the peaks for the ketone and the alcohol, whereas after the reduction with $PPh_3$ only a peak for the alcohol is observed, one may conclude that only the alkyl hydroperoxide was present in the solution. This method allows one to determine alkyl hydroperoxides in the presence of hydrogen peroxide.

‖ The reaction was carried out in a sealed ampoule (10 ml) at 20 °C under an atmospheric pressure of $^{18}O_2$ (content 98%, Cambridge Isotope Laboratories) over 3 days; concentrations: cyclohexane, 0.46 mol dm$^{-3}$; $H_2O_2$ (35% aq), 0.2 mol dm$^{-3}$; $[NBu_4]VO_3$, $1.0 \times 10^{-4}$ mol dm$^{-3}$, PCA, $4.0 \times 10^{-4}$ mol dm$^{-3}$. The resulting solution was analysed by GCMS (NERMAG R 30-10, capillary column 50 m × 0.25 mm × 0.25 μm, Carbowax 20M).

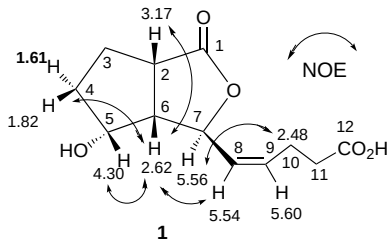
# The isolation and structure of bacillariolide III, an extracellular metabolite of the diatom, *Pseudo-nitzschia multiseries*

**Naiyu Zheng and Yuzuru Shimizu***

*Department of Biomedical Sciences, College of Pharmacy, University of Rhode Island, Kingston, RI 02881, USA*

**The marine diatom, *Pseudo-nitzschia multiseries* was found to excrete a metabolite formed by the cleavage of an eicosanoid, and its structure is determined.**



In the previous papers,[1,2] we reported the isolation and structure determination of two novel eicosanoids from the wild and cultured cells of the diatom, *Pseudo-nitzschia multiseries*,† a causative organism of so-called amnesic shellfish poisoning (ASP).[3] In the continuing study, we have noticed that the organism also produces extracellular metabolites. In this communication, we report the chemical characterization of one of the metabolites, bacillariolide III, **1** and its biosynthetic relationship with the previously reported compounds.

The clonal strain of *P. mutiseries* S2-184-1,‡ which had been isolated from Narragansett Bay in October, 1995 by N.Z., was cultured in F/2 + Si medium at 23 °C under fluorescent illumination (16 h/8 h L/D cycle) and sterile conditions. After centrifugation, the acidified culture medium (pH 3.0) was passed through silica gel C18. The C18 layer was washed with water and extracted with MeOH. The MeOH eluate was successively chromatographed on LH-20 (MeOH) and on silica gel C18 (10% MeCN + 0.5% acetic acid). The fraction which showed a single spot on TLC was passed through Chelex 100 $Na^+$ form to give the $Na^+$ salt of **1**. The free acid was obtained as an amorphous solid after acidification with 0.1 M HCl and extraction with $CHCl_3$. About 2 mg of pure bacillariolide III was obtained from a 20 l batch of culture.

**1**

**2**: 7α-H
**3**: 7β-H

**4** **5** **6** **7**

**Scheme 1** A possible biosynthetic pathway of bacillariolide III, **1**

Bacillariolide III, $[\alpha]_D^{24}$ −25.3 (*c* 0.28, MeOH), UV: end absorption, has the molecular formula of $C_{12}H_{16}O_5$ [*m*/*z* calc. 240.099774; found (EIMS) 240.099646]. The IR spectrum showed absorption bands, ν/cm$^{-1}$ ($CHCl_3$): 3500 (OH), 1770 (γ-lactone) and 1730 (γ-lactone). The $^1H$, $^{13}C$ and HMQC NMR spectra (Table 1) suggested the presence of two carbonyl groups, one disubstituted double bond, four methylene groups and four methine groups, of which two are bearing oxygen atoms. Thus the compound must be bicyclic. From the $^1H$–$^1H$ COSY and HMQC spectra, the entire spin system was easily established as shown in the structure **1**. The relative stereochemistry were established by NOE difference and NOESY experiments (shown on the structure). The geometry of the double bond was concluded as *Z* from the coupling constant of

the olefinic protons (6 Hz), which was also supported by the NOE data. The absolute configuration was assumed by the perceivable biosynthetic relationship of **1** with the co-occurring bacillariolide I, **2**, whose absolute configuration was unequivocally established by the X-ray crystallography of a derivative having a known chirality.[2]

The biosynthetic origin of **1** would never have been easily speculated, had it been a sole metabolite found with the diatom. However, the structures of the two previously isolated compounds, bacillariolide I, **2**, and II, **3**, suggest that **1** is a metabolite derived from bacillariolide I, **2** by the cleavage of the carbon chain at C-12 and C-13. It can be explained by the formation of 12-hydroperoxide **4** and alkoxyl radical **5**, followed by fragmentation to the aldehyde **6**, oxidation to carboxylic acid **7** and reduction to **1** (Scheme 1).§ Such cleavage of the polyene chain by 'homolytic-type' hydroperoxide lyases has been previously found in the algae.[4] Here, we can not rule out the possibility that these 12-hydroperoxide formation and chain cleavage may precede the bicyclic lactone ring formation. However, the large amount of **2** found in the cell, and late appearance of **1** in the medium seems to support the former case.

Interestingly, **1** is strictly an extracellular metabolite and not found in the cells. On the other hand bacillariolide I, **2** and II, **3** are found only in the cells and not in the culture medium, which indicates that **1** is discharged to the outside of the cells as soon as it is biosynthesized. Diatoms are the most abundant microalgae in the oceans in both quantity and number of species. However, in contrast to the case of some other microalgal families, only a very few secondary metabolites have been found in the cells of diatoms.[5,6] We have speculated that those organisms with solid siliceous skeletons tend not to store the metabolites but rather excrete them outside. The finding of a fairly large quantity of **1** and some other metabolites in the medium certainly supports this assumption.

The biological function of this extracellular metabolite is still under investigation, but its structural resemblance with the well-known plant growth regulators, jasmonates[7,8] and cucurbic acid[9] draws our attention. Bacillariolide I is known to possess significant inhibitory activity against phospholipase $A_2$.[6]

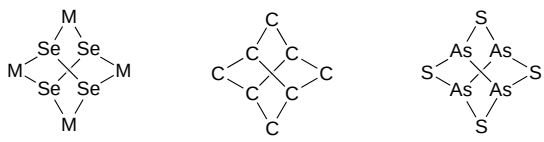
# $[M_4(Se_2)_2(PSe_4)_4]^{8-}$: a novel, tetranuclear, cluster anion with a stellane-like core

**Konstantinos Chondroudis and Mercouri G. Kanatzidis***



*Department of Chemistry, Michigan State University, East Lansing, Michigan 48824, USA*

**The molecular cluster compounds $[M_4(Se_2)_2(PSe_4)_4]^{8-}$ (M = Cd, Hg) form by the reaction of Cd and Hg with basic polychalcophosphate fluxes.**

The polychalcophosphate fluxes are a powerful tool for the synthesis of new ternary and quaternary chalcophosphate compounds.[1–12] In the presence of metal ions, these reactive fluxes give rise to highly anionic $[P_yQ_z]^{n-}$ (Q = S, Se) ligands which bind in an amazing number of ways to the metals, forming new materials.[1] The variation of the flux composition stabilizes different ligands such as $[PQ_4]^{3-}$, $[PSe_5]^{3-}$, $[P_2Q_6]^{4-}$, $[P_2Q_7]^{4-}$, $[P_2Se_9]^{4-}$, *etc*.[1–12] which become the building blocks of various polymeric solid-state structures. Lately, we demonstrated that the same fluxes can be used to provide access to molecular compounds if appropriate conditions are employed.[8] This includes modification (usually increase) of the flux Lewis basicity, which can be achieved by increasing the concentration of the $[P_yQ_z]^{n-}$ ligands in it. Application of this technique to group 12 yielded the tetranuclear, stellane-like $Rb_8[M_4(Se_2)_2(PSe_4)_4]$ (M = Cd, Hg) and herein, we report the synthesis,† structural characterization, optical and thermal properties of this novel complex.

$Rb_8[Cd_4(Se_2)_2(PSe_4)_4]$ and $Rb_8[Hg_4(Se_2)_2(PSe_4)_4]$‡ are isostructural. The single-crystal structure determination was performed on the mercury compound. The discrete $[Hg_4(Se_2)_2(PSe_4)_4]^{8-}$ anion is a tetranuclear complex, of approximate $D_{2d}$ symmetry, containing the relatively rare $[PSe_4]^{3-}$ ligand but also diselenide $Se_2^{2-}$ ligands in a novel cluster arrangement [Fig. 1(*a*)]. The most intriguing feature of the molecule is its stellane-like, $[Hg_4(Se_2)_2]^{4+}$ core, composed of four $Hg^{2+}$ ions and two $Se_2^{2-}$ ligands. In this arrangement every $Se_2^{2-}$ ligand coordinates to all four metals and the two diselenides are perpendicular to each other (Scheme 1, structure **A**). The four metal centres define a perfect 3.612(1)×3.612(1) Å square and the entire molecule resides on a $\bar{4}$ crystallographic site. A similar cage structure, has been observed in the organic molecule tricyclo[3.3.0.0$^{3,7}$]octane,[13,14] (Scheme 1, structure **B**). Its projection is reminiscent of a four-pointed star and because of that is also known as stellane. β-Tetraarsenic tetrasulfide is known to crystallize in discrete $As_4S_4$ molecules with a similar cage structure,[15] only in this molecule the sulfur atoms occupy the four corners of the 'star' (Scheme 1, structure **C**).

The stereoview in the Graphical Abstract can be useful in perceiving the cage core structure. This core acting as a gigantic metal centre is being coordinated by four $[PSe_4]^{3-}$ ligands. Each $[PSe_4]^{3-}$ employs two of its four available donor sites to bind to two neighboring metal atoms. In polyhedral terms, each $[PSe_4]^{3-}$ tetrahedron shares two corners with the four-pointed $[M_4(Se_2)_2]^{4+}$ star giving rise to the $[M_4(PSe_4)_4(Se_2)_2]^{8-}$ formula. Even though the $[PSe_4]^{3-}$ ligand is bidentate, its disposition is such that one of its non-coordinating Se atoms interacts with the diselenide ligand [Fig. 1(*b*)], as evidenced by the Se(3)–Se(5) distance of 3.327(3)Å (van der Waals radii sum is 3.8 Å).[16] In support of this observation the diselenide bond of 2.416(4) Å for Se(5)–Se(5″) is relatively long, for this coordination mode, compared, for example, to $[Hg_7Se_{10}]^{4-}$,[17] where a similarly bound $Se_2^{2-}$ ligand has a 2.349(6) Å bond length. This is consistent with partial electron transfer from the terminal Se(3) atoms to the σ* orbital of the Se(5)–Se(5″) ligand.

**A** $[M_4(Se_2)_2]^{4+}$ **B** Stellane **C** β-$As_4S_4$

**Scheme 1**

In $Rb_8[Hg_4(Se_2)_2(PSe_4)_4]$ the Hg–Se distances average at 2.68(5) Å which compare well with those of $[Hg_7Se_{10}]^{4-}$,[17] and $Hg_2P_2Se_6$.[18] Each cell contains two $[Hg_4(Se_2)_2(PSe_4)_4]^{8-}$ molecules which are separated by the nine-coordinate Rb(1) [range of Rb(1)–Se distances, 3.511(3)–3.800(3) Å; av. 3.661 Å], and by the six-coordinate Rb(2) cation [range of Rb(2)–Se distances, 3.478(3)–3.786(3) Å; av. 3.644 Å]. Selected bond distance and angles are given in the caption of Fig. 1.

$Rb_8[M_4(PSe_4)_4(Se_2)_2]$ (M = Cd, Hg) are insoluble in dmf and acetonitrile but soluble in a solution of crown ether,

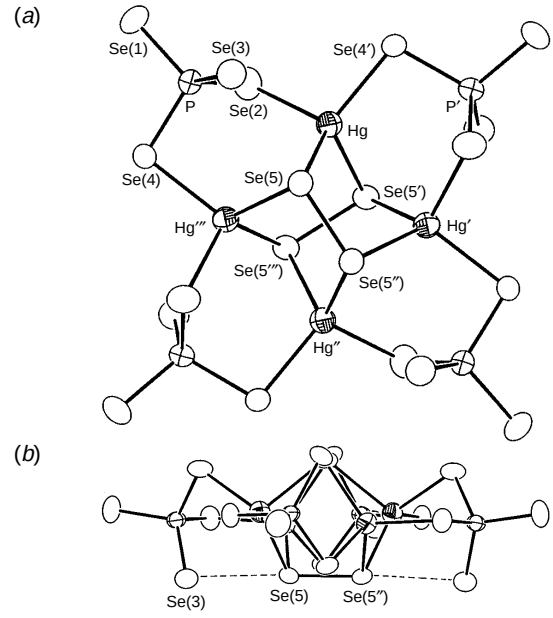


**Fig. 1** (*a*) ORTEP representation and labelling of a single $[Hg_4(Se_2)_2(PSe_4)_4]^{8-}$ anion. Selected bond distances (Å) and angles (°): Hg–Se(2) 2.713(2), Hg–Se(4) 2.623(2), Hg–Se(5) 2.669(2), Hg–Se(5′) 2.725(2), P–Se(1) 2.175(5), P–Se(2) 2.221(5), P–Se(3) 2.184(5), P–Se(4) 2.237(5), Se(5)–Se(5″) 2.416(4), Se(3)–Se(5) 3.327(3); Se(2)–Hg–Se(4) 101.44(7), Se(2)–Hg–Se(5) 114.33(6), Se(2)–Hg–Se(5′) 101.98(7), Se(4)–Hg–Se(5) 125.45(7), Se(4)–Hg–Se(5′) 110.70(6), Se(5)–Hg–Se(5′) 100.84(8), Hg–Se(2)–P 96.5(1), Hg–Se(4)–P′ 97.9(1), Hg–Se(5)–Hg‴ 84.07(6), Hg–Se(5′)–Se(5″) 109.43(7), Se(1)–P–Se(2) 108.7(2), Se(1)–P–Se(3) 111.6(2), Se(1)–P–Se(4) 107.9(2), Se(2)–P–Se(3) 110.9(2), Se(2)–P–Se(4) 107.0(2). (*b*) Perpendicular view of the same molecule. Dashed lines indicate Se– Se interactions.

18-crown-6, in dmf. The solution is green–brown and stable, according to UV– VIS, for up to 2–3 days. The dmf–complexant solution gives a different spectrum from the solid material with one medium absorption at *ca.* 585 nm (2.12 eV) and a shoulder at *ca.* 400 nm (3.10 eV), suggesting that the cluster undergoes rearrangement in solution. The solid-state UV–VIS diffuse reflectance spectrum shows sharp optical gaps consistent with semiconducting behaviour (for M = Cd, $E_g$ = 2.57 eV, whereas for M = Hg, $E_g$ = 2.32 eV). The solid-state IR spectrum shows peaks that are characteristic of both the nature and bonding mode of the $[PSe_4]^{3-}$ ligand.§ Differential thermal analysis (DTA), followed by XRD analysis of the residues, shows incongruent melting at 456 and 413° C for M = Cd and Hg, respectively. The decomposition product is a mixture of the starting compound and amorphous $Rb_xP_ySe_z$ flux. Some CdSe or HgSe should also be formed but they are either amorphous or in concentrations and particle sizes undetectable by XRD analysis.

The extremely high charge of this molecular unit would make its synthesis through conventional 'wet' chemistry very difficult, perhaps prohibitive. This accentuates the value of the flux technique in stabilizing highly charged molecular entities. The novelty of the compositional and structural features of the $[M_4(Se_2)_2(PSe_4)_4]^{8-}$ cluster, provides a stimulating example of the new chemistry that becomes accessible and suggests that the molten alkali-metal polychalcogenide approach has not yet been fully exploited.

Financial support from the National Science Foundation DMR-9527347 is gratefully acknowledged. This work made use of the SEM and TEM facilities of the Center for Electron Optics at Michigan State University.

## Footnotes

† *Syntheses:* $Rb_8[Cd_4(Se_2)_2(PSe_4)_4]$ was synthesized from a mixture of Cd (0.25 mmol), $P_2Se_5$ (0.50 mmol), $Rb_2Se$ (1.00 mmol) and Se (2.50 mmol) heated to 550 °C for 4 d followed by cooling to 150 °C at 2 °C $h^{-1}$. Most of the excess $Rb_xP_ySe_z$ flux was removed with degassed dmf. Following this, the product was washed with *ca.* 2 ml of tributyl phosphine to remove residual Se. Further washing with anhydrous diethyl ether revealed light yellow, needle-like crystals that are air-stable but sensitive in $H_2O$. (Yield *ca.* 66% based on Cd). Microprobe analysis gave an average composition of $Rb_{8.0}Cd_{4.0}P_{4.4}Se_{19.6}$. *Cell data* at 23 °C: $a = b = 17.564(3)$, $c = 7.275(2)$ Å, $U = 2244.3(8)$ Å$^3$.

$Rb_8[Hg_4(Se_2)_2(PSe_4)_4]$ was synthesized from a mixture of HgSe (0.50 mmol), $P_2Se_5$ (0.25 mmol), $Rb_2Se$ (1.00 mmol) and Se (2.50 mmol) heated to 500 °C for 4 d followed by cooling to 150 °C at 2 °C $h^{-1}$. Isolation as above revealed light yellow, needle-like crystals that are air-stable but sensitive in $H_2O$. (Yield *ca.* 78% based on Hg). Microprobe analysis gave an average composition of $Rb_{8.0}Hg_{4.4}P_{4.0}Se_{20.0}$.

‡ *Crystal data* at 23 °C: tetragonal, space group $P4_2/n$ (no. 86) $a = b = 17.654(2)$, $c = 7.226$ (2) Å, $U = 2253.6(9)$ Å$^3$, $Z = 2$, $D_c = 4.699$ g cm$^{-3}$, μ(Mo-Kα) = 380.81 cm$^{-1}$, $2\theta_{max} = 50°$, total data collected, 2162; unique data, 1838; data with $F_o^2 > 3\sigma(F_o^2)$, 1254. Number of variables: 82. An empirical absorption correction based on ψ scans was applied to the data during initial stages of refinement. DIFABS correction was applied after full isotropic refinement as recommended in N. Walker, *Acta Crystallogr., Sect. A*, 1983, **39**, 158. Final $R$, $R_w$ = 0.040, 0.049 (0.46, 0.56 before DIFABS).

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/358.

§ The far-IR spectrum displays three strong absorptions at *ca.* 461, 434 and 417 cm$^{-1}$. These vibrations can be assigned to $PSe_4$ stretching modes and are of diagnostic value in distinguishing this selenophosphate ligand from others.[1,6] Weak absorptions below 200 cm$^{-1}$ can be assigned to M–Se vibrations.[1]

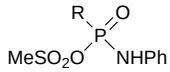
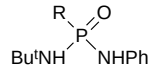
# Sulfonylation in the rearrangement of an *N*-phosphinoyl-*O*-sulfonylhydroxylamine: demonstration of a phosphonamidic-sulfonic anhydride intermediate and $^{18}O$-labelling evidence on how it may be formed

**Martin J. P. Harger**



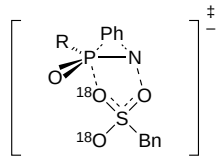
*Department of Chemistry, The University, Leicester, UK LE1 7RH*

**The rearrangement reaction of R(Ph)P(O)NHOSO$_2$Bn (R = PhMeCH) (57% enriched with one $^{18}O$ atom in the SO$_2$ group) with Bu$^t$NH$_2$ in CH$_2$Cl$_2$ gives the sulfonamide BnSO$_2$NHBu$^t$ (43.7% enriched with one $^{18}O$ atom) as one of the products; this indicates a phosphonamidic-sulfonic anhydride intermediate [R(BnSO$_2$O)P(O)NHPh], formed with partial equilibration of the sulfonate oxygen atoms and attacked (in part) at the sulfonyl group.**

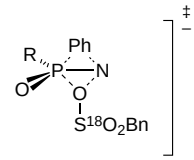


*N*-Phosphinoylhydroxylamines are the phosphorus analogues of hydroxamic acids, and their *O*-sulfonyl derivatives **1** (R = alkyl or phenyl) undergo rearrangement with base,[1] *e.g.* **1** gives **3** with Bu$^t$NH$_2$. The product-forming species may be a transient metaphosphonimidate [RP(O)=NPh], analogous to the isocyanate in a Lossen rearrangement,[2] although some evidence points instead to a phosphonamidic-sulfonic mixed anhydride **2**.[3,4] In principle this anhydride could react with a nucleophile at sulfur rather than phosphorus,[5] but in practice such products have not hitherto been seen. We now report the first direct chemical evidence for a mixed anhydride intermediate in the rearrangement, and $^{18}O$-labelling information on how it may be formed.

**1**



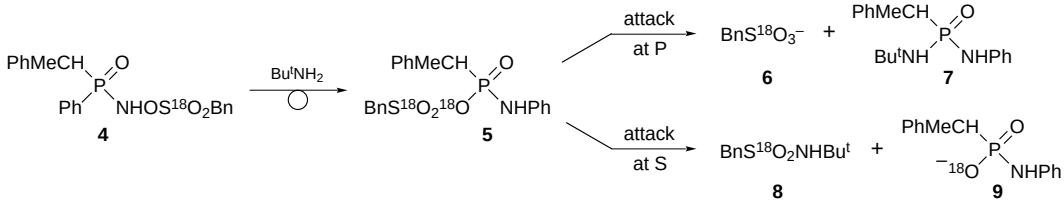
**2**



**3**

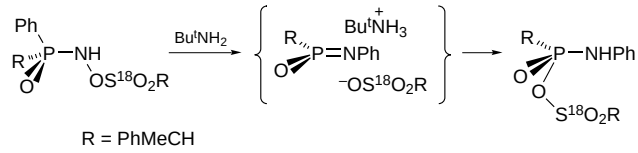
The benzylic sulfonyl derivative **4** was prepared by treating PhMeCH(Ph)P(O)NHOH (mixture of diastereoisomers)[3] with $^{18}O$-enriched BnSO$_2$Cl in pyridine (ice cooling). It was obtained as a mixture of diastereoisomers [$\delta_P$(CDCl$_3$) 42.6 and 41.0 (ratio 5:1); $\delta_H$(CDCl$_3$) 4.61 (major) and 4.19 (both AB; $\Delta\delta$ 0.12 or 0.14 ppm, $J_{AB}$ 14 Hz; SO$_2$C*H*$_2$Ph)] having 57% of the molecules enriched with one $^{18}O$ atom in the sulfonyl (SO$_2$) group [*m/z* (FAB) 416 and 418 (M + H)$^+$; negligible amount of double-labelled material]. With 2 mol dm$^{-3}$ Bu$^t$NH$_2$ (40 equiv.) in CH$_2$Cl$_2$ it gave mainly the 'normal' phosphonamide rearrangement product **7** [$\delta_P$(CDCl$_3$) 22.7 and 22.4 (diastereoisomers, ratio 3:1)] together with the sulfonate anion **6** [$\delta_H$(CDCl$_3$) 4.07 (s, PhC*H*$_2$SO$_3^-$)]. Significantly, however, it also gave a substantial amount (*ca.* 17%) of the sulfonamide product **8** [$\delta_H$(CDCl$_3$) 4.25 (s, PhC*H*$_2$SO$_2$) and 1.36 (s, NBu$^t$)] together with the phosphonamidate anion **9** [$\delta_P$(CDCl$_3$) 19.5].

**10**



**11**

This behaviour is clearly indicative of a phosphonamidic-sulfonic anhydride intermediate **5** and competing attack at the P and S atoms by the Bu$^t$NH$_2$ nucleophile (Scheme 1).



Mass spectrometric examination of the products, after esterification with diazaomethane in the case of the anions, indicated their isotopic enrichment (±0.5%):† **6** had 57.6% one $^{18}O$ atom [methyl ester, *m/z* (EI) 186 and 188 (M$^+$)], **7** had no enrichment [*m/z* (EI) 316 (M$^+$)], **8** had 43.7% one $^{18}O$ atom [*m/z* (CI) 245 and 247 (M + NH$_4$)$^+$] and **9** had 13.7% one $^{18}O$ atom [methyl ester, *m/z* (EI, GC–MS) 275 and 277 (M$^+$)].

For the products of attack at the phosphorus atom of the mixed anhydride, the results are as expected: all the label originally in the substrate **4** ends up in the sulfonate anion **6** and none in the phosphonamide rearrangement product **7**. Of more interest are the products of attack at sulfur, since it is from these that the distribution of the label in the mixed anhydride intermediate can be inferred. With 76% of the available $^{18}O$ label ending up in the sulfonamide product **8**, and only 24% in the phosphonamidate anion **9**, it would seem that, on rearrangement, the label in the sulfonyl group of the substrate **4** is transferred to the bridging and non-bridging positions of the mixed anhydride **5** in a ratio of 24:76.

Concerted rearrangement of the substrate, after removal of a proton (N*H*) by the amine, would most plausibly involve a transition state resembling **10**. This would give rise to a bridging:non-bridging $^{18}O$ ratio of 50:50 in the mixed anhydride. Subsequent scrambling of the label, after formation of the anhydride but before its conversion into product, might reduce the ratio, but not beyond the statistical value of 33:67; the experimentally observed value of 24:76 could never be attained. At the other extreme, if concerted rearrangement involved a transition state resembling **11**, the mixed anhydride would be formed with none of the label in the bridging position (ratio 0:100). In this case, however, subsequent scrambling could give rise to an (average) ratio of 24:76, so long as it occurred at approximately the same rate as the conversion of the

**Scheme 1**

**Scheme 2**

anhydride into product. Such scrambling is certainly not unreasonable; like a phosphonamidic chloride,[6] the phosphonamidic-sulfonic anhydride will tend to react with $Bu^tNH_2$ at phosphorus by a dissociative substitution mechanism (stepwise preassociative elimination-addition).[7] Nonetheless, the geometry of the transition state **11** makes this concerted pathway seem rather improbable.

The alternative to these is a non-concerted mechanism (Scheme 2), in which the sulfonate group becomes completely detached from the nitrogen atom before it begins to bond to phosphorus. At the limit this must result in a uniform (statistical) distribution of the label between the three sulfonate oxygen atoms of the mixed anhydride (ratio 33 : 67). Initially, however, the sulfonate oxygen atom (unlabelled) released from the N–O bond will not be equivalent to the other two, because of differences in solvation (by $CH_2Cl_2$ or $Bu^tNH_2$) and/or association (with $Bu^tNH_3^+$). If the new bond to phosphorus is formed before equilibration of the oxygen atoms is complete, and makes preferential use of this (unlabelled) oxygen atom, the mixed anhydride will be formed with less than a third of the available $^{18}O$ label located in the bridging position. The observed result (24% of the available $^{18}O$ in the bridging position) could then reflect a rather modest bias for incorporation of the unlabelled oxygen atom in the new P–O bond, or a strong bias with some subsequent scrambling. There is at least one precedent for a rearrangement involving migration of a sulfonate anion in which the oxygen atom released by bond breaking is preferentially employed in subsequent bond making;[8] in that case, however, it is a cation with which the sulfonate anion recombines, not an uncharged species.

Two conclusions can be drawn from the present study: a phosphonamidic-sulfoninc mixed anhydride **5** is involved in the rearrangement reactions of the hydroxylamine derivative **4**, even at a high amine concentration,‡ and the transformation of **4** into **5** is most probably non-concerted (Scheme 2). Some of the initial metaphosphonimidate intermediate may go directly to the phosphonamide product, by reaction with $Bu^tNH_2$, but some—perhaps most—rapidly recombines with the sulfonate anion to form the mixed anhydride.

I am grateful to Dr G. Eaton for recording mass spectra and Professor P. M. Cullis for advice and encouragement.

## Footnotes

† In all mass spectrometric measurements of $^{18}O$ enrichment, allowance was made for $^{34}S$ and natural abundance $^{18}O$ by comparing directly the spectrum of the enriched material with that of a natural abundance sample.

‡ A high concentration of $Bu^tNH_2$ was used for two reasons. First, it affords a rigorous test of the generality of mixed anhydride formation; at very low amine concentrations a metaphosphonimidate intermediate might have an atypically high disposition towards recombination with the sulfonate anion. Second, it limits the complications associated with the phosphonamidate anion **9** that is released when the amine attacks the mixed anhydride **5** at sulfur. This anion is a powerful nucleophile and competes with $Bu^tNH_2$ for another molecule of **5** (attack at the P atom of **5** produces a symmetrical phosphonamidic anhydride).

# Association of two incomplete cubane $WS_3Cu_3$ clusters in the crystal structures of $[PPh_4]_2[\{(C_5Me_5)WS_3\}_2Cu_6(NCS)_6]$ and $[PPh_4]_2[\{(C_5Me_5)WS_3\}_2Cu_6Br_6]$

**Jianping Lang, Hiroyuki Kawaguchi, Shiho Ohnishi and Kazuyuki Tatsumi***

*Department of Chemistry, Faculty of Science, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464-01, Japan*

**Two double cubane-like clusters, $[PPh_4]_2[\{(C_5Me_5)WS_3\}_2Cu_6(NCS)_6]$ 1 and $[PPh_4]_2[\{(C_5Me_5)WS_3\}_2Cu_6Br_6]$ 2, are self-assembled by the reactions of $[PPh_4][(C_5Me_5)WS_3]$ with CuNCS and CuBr in acetonitrile, respectively, the crystal structures of which consist of two $WS_3Cu_3$ incomplete cubes linked by NCS and Br bridges.**

The linkage of transition-metal clusters has been the subject of recent interest.[1–4] It has been shown that cubane clusters of homo- and hetero-metallic sulfides can be assembled in various ways. An example is the thiolate-bridged double-cubane cluster $[Mo_2Fe_6S_8(SPh)_9]^{3-}$, which was obtained from the reaction of $FeCl_3$ with $[NH_4]_2[MoS_4]$ and NaSPh.[5] The similar self-assembly of $FeCl_3$, $[NBu^n_4]_2[MoS_4]$ and NaSEt gave rise to $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$.[6] Two molecules of the cubane cluster $[Fe_4S_4Cl_4]^{2-}$ were linked upon treatment with $Li_2S$ to generate $[(Fe_4S_4Cl_3)_2S]^{4-}$,[7] while the incomplete cubane-like cluster $[Mo_3S_4(H_2O)_9]^{4+}$ also served as a starting material for the synthesis of double-cubane complexes such as $[(H_2O)_9Mo_3S_4CuCuS_4Mo_3(H_2O)_9]^{8-}$.[8] More recently, the preformed mixed-metal cubane clusters $[MoFe_3S_4Cl_3(Cl_4cat)(L)]^{2-}$ (cat = catechol; L = coordinating solvent molecule) have been assembled into various double-cubane clusters in the presence of the appropriate polycarboxylic acid.[9]

Recently we found a facile route to the organometallic trithiotungsten(VI) complex $[PPh_4][(C_5Me_5)WS_3]$ *via* C–S bond cleavage of ethanedithiolate.[10] The terminal sulfides in $[(C_5Me_5)WS_3]^-$ appear to be more reactive than those of $[PPh_4]_2[WS_4]$, and they react readily with alkyl halides and even with non-activated alkynes such as PhC≡CPh and PhC≡CH. Having noted that $[(C_5Me_5)WS_3]^-$ may be a potential building block for heterometallic sulfide clusters, we examined its reactions with CuNCS and CuBr. In this paper we report two double cubane-like clusters, $[PPh_4]_2[\{(C_5Me_5)WS_3\}_2Cu_6(NCS)_6]$ **1** and $[PPh_4]_2[\{(C_5Me_5)WS_3\}Cu_6Br_6]$ **2**, obtained from these reactions.

Compound **1** was prepared by the following procedure. CuNCS (0.05 g, 0.42 mmol) was added to $[PPh_4][(C_5Me_5)WS_3]$ (0.11 g, 0.14 mmol) in MeCN (20 ml) and the mixture was stirred for 24 h at room temperature. After filtering off insoluble materials, the resultant solution was concentrated to *ca*. 5 ml under reduced pressure, and $Et_2O$ (5 ml) was added. On standing for two days, dark red needles of **1**·MeCN were obtained in 75% yield. Compound **2** was prepared as dark red crystals in 84% yield by a procedure similar to that above, starting from CuBr. **1** and **2** are stable to oxygen and moisture and soluble in MeCN and $Me_2SO$.†

The X-ray analysis of **1**‡ revealed that the asymmetric unit consists of two crystallographically independent halves of $[\{(C_5Me_5)WS_3\}_2Cu_6(NCS)_6]^{2-}$ dianions, two $[PPh_4]^+$ cations, and one MeCN solvent molecule. The structure of one of the two cluster dianions of **1** is presented in Fig. 1, where an inversion centre resides at the centre of the molecule. The structure of the other cluster dianion is nearly the same as that shown in Fig. 1. Three CuNCS molecules are bound to a $(C_5Me_5)WS_3$ fragment, forming a $WS_3Cu_3$ incomplete cubane structure. Two such incomplete cubes are linked *via* interactions between the sulfur end of one NCS ligand in each cluster and three coppers of the other cluster. Thus the NCS sulfur fills a void of the $WS_3Cu_3$ incomplete cubane. The occurrence of triple bridging of the NCS sulfur is unprecedented, although double bridging was observed in the polymeric structures of $[Hpy][Cu_2(NCS)_3]$[11] and $[NEt_4]_3[WS_4Cu_4(NCS)_5]$.[12] The eight-membered Cu(1)N(1)C(11)S(4)Cu(1*)N(1*)C(11*)S(4*) ring is nearly planar. The $(C_5Me_5)WS_3$ unit has a slightly distorted three-legged piano-stool structure, and the $S_3$ plane is parallel (179°) to the $C_5Me_5$ ring. The W–S bond lengths of 2.267(3)–2.290(3) Å fall between the W–S (thiolate) single bonds and W=S double bonds in $[(C_5Me_5)W(S)_2(SCH_2Ph)]$ [2.328(4) *vs*. 2.149(3) Å] and $[(C_5Me_5)W(S)\{SC(Ph)=C(Ph)S\}]^-$ [2.326(2) Å *vs*. 2.186(2) Å].[10] The short W–Cu distances of 2.638(2)–2.682(2) Å suggest a dative interaction between $d^0$ $W^{VI}$ and $d^{10}$ $Cu^I$, which are comparable to those observed in $[NEt_4]_3[WS_4Cu_4(NCS)_5]$ [2.624(2)–2.708(2) Å][12] and $[NEt_4]_3[WOS_3(CuBr)_3(\mu\text{-Br})]$ [2.665(3)–2.681(2) Å].[13] The coordination geometry at each copper atom is approximately trigonal planar, to which an NCS sulfur is weakly bound from the direction perpendicular to the plane. Thus the Cu–S(NCS) bond lengths of 2.742(4)–3.060(3) Å are significantly longer than the Cu–S(sulfide) distances of 2.214(4)–2.249(4) Å in the trigonal plane, and the Cu–S(NCS)–

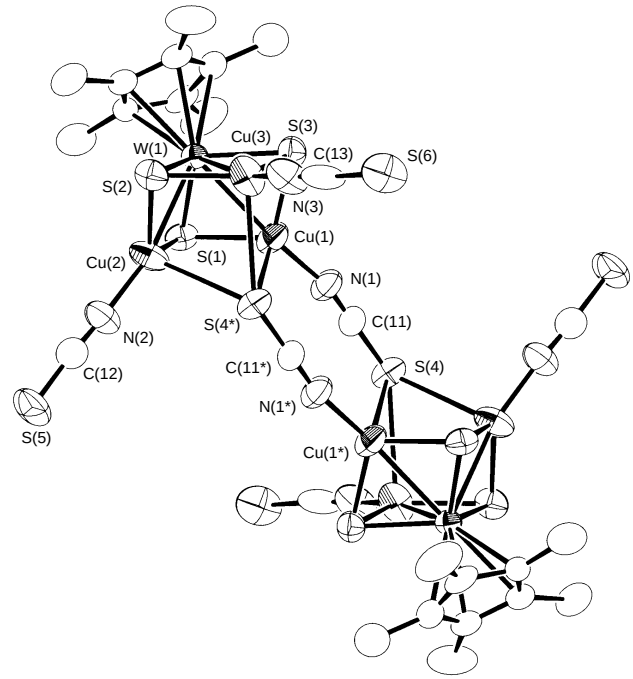

**Fig. 1** ORTEP drawing of one of the two cluster dianions of **1**, with labelling scheme and 50% thermal ellipsoids. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): W–Cu(1) 2.644(2), W–Cu(2) 2.668(2), W–Cu(3) 2.644(2), W–S(av.) 2.281(2), Cu–S(av.) 2.230(2), Cu–S(4*)(av.) 2.952(4), Cu–N(av.) 1.88(3); S–W–S(av.) 105.8(1), S–Cu–S(av.) 109.3(1), S–Cu–S(4*)(av.) 97.4(1), W–S–Cu(av.) 72.0(1), Cu–S(4*)–Cu(av.) 65.7(1), S(4*)–Cu(1)–N(1) 98.4(3), Cu(1)–N(1)–C(11) 168(1), N(1)–C(11)–S(4) 179(1).

Cu angles [61.83(1)–70.34(8)°] are acute compared with the other Cu–S–Cu angles [88.0(1)–95.2(1)°].

The crystal of **2**‡ consists of one discrete $[\{(C_5Me_5)WS_3\}_2Cu_6Br_6]^{2-}$ dianions and two $[PPh_4]^+$ cations. The cluster dianion, shown in Fig. 2, is composed of two incomplete $WS_3Cu_3$ cubes of $[(C_5Me_5)WS_3Cu_3Br_3]^-$, which are interconnected by a four-membered $CuBr_2Cu$ ring. A crystallographic inversion centre is again located at the centre of the dianion. The main framework of the cluster dianion of **2** is similar to that of $[NEt_4]_4[(MoOS_3)_2Cu_6I_6]$.[14] In the $CuBr_2Cu$ ring, the Cu(1)–Br(1*) [or Cu(1*)–Br(1)] bond distance of 2.876(1) Å is 0.52 Å longer than that of Cu(1)–Br(1) [or Cu(1*)–Br(1*)]. Therefore, the interaction between the two incomplete cubes in **2** is weak, as in the case of **1**. A notable difference between the structures of **1** and **2** is that Br(1) [or Br(1*)] of **2** coordinates to one copper of the other incomplete cube while for **1** the terminal sulfur of NCS is bound to three coppers. As a consequence, there are two different types of copper geometries in the cluster dianion of **2**. Cu(2) and Cu(3) are trigonal planar, while Cu(1) adopts a distorted tetrahedral geometry. Owing to the different coordination environment, the W–Cu(1) distance of 2.676(8) Å is slightly longer than those of W–Cu(2) [2.657(8) Å] and W–Cu(3) [2.649(1) Å]. In each $(C_5Me_5)WS_3$ unit, the $S_3$ plane is parallel (178°) to the $C_5Me_5$ ring, and the three W–S distances of 2.280(2)–2.284(2) Å are very close to those of **1**.

The successful syntheses of **1** and **2** in high yields are interesting examples of how relatively complicated clusters can be formed by the self-assembly of two $[PPh_4][(C_5Me_5)WS_3]$ and six CuX (X = NCS, Br) components. As the linkage of two incomplete cubes is weak in either case, they may be cleaved easily in the presence of strong donor ligands such as $PPh_3$, dppm and bipyridine. In fact, **2** reacts readily with $PPh_3$ in acetonitrile to give $[(C_5Me_5)WS_3Cu_3Br_2(PPh_3)_2]$.[15] Details of their reactivity will be described elsewhere.

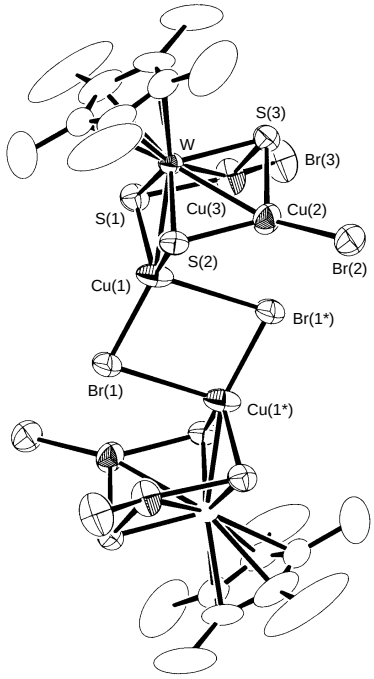

**Fig. 2** ORTEP drawing of the cluster dianion of **2**, with labelling scheme and 50% thermal ellipsoids. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): W–Cu(1) 2.676(8), W–Cu(2) 2.657(1), W–Cu(3) 2.649(1), W–S(av.) 2.282(2), Cu–S(av.) 2.234(2), Cu–Br(av.) 2.308(1), Cu(1)–Br(1*) 2.876(1); S–W–S(av.) 105.8(1), S–Cu–S(av.) 109.2(2), W–S–Cu(av.) 71.2(2), Cu(1)–Br(1)–Cu(1*) 83.00(4), Br(1)–Cu(1)–Br(1*) 97.00(4).

# 2′,3′-Anhydrouridine

**Anwar Miah, Colin B. Reese* and Quanlai Song**

*Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS*

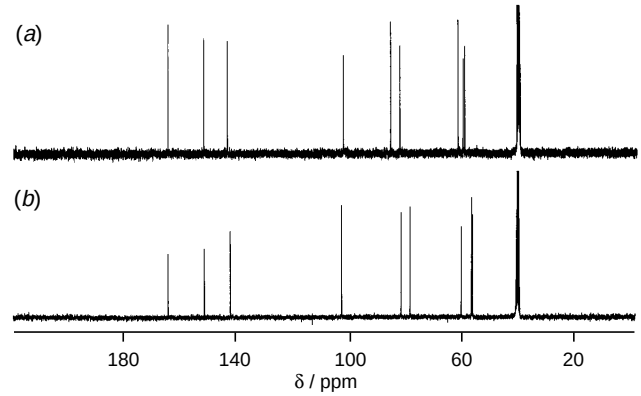
**The previously unreported title compound 4 is readily obtained by treating 2,2′-anhydro-1-β-D-arabinofuranosyluracil 1 with sodium hydride in dry dimethyl sulfoxide at room temperature.**

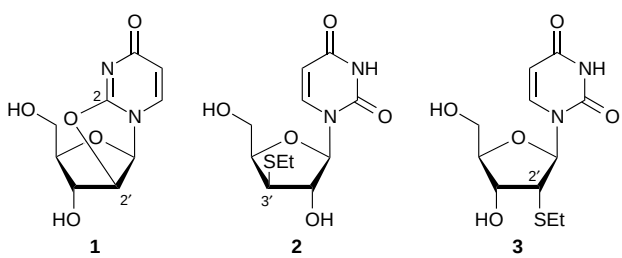
In the course of their early and pioneering studies on the chemistry of pyrimidine anhydronucleosides, Brown, Todd and co-workers reported[1] that when 2,2′-anhydro-1-β-D-arabinofuranosyluracil **1** washeated at 100 °C in *N*,*N*-dimethylformamide (DMF) solution with a very large excess of sodium ethanethiolate, the 3′-ethylsulfanyl derivative **2** was obtained and isolated as a colourless glass in *ca*. 55% yield. We subsequently showed that when the anhydronucleoside **1** was heated in DMF solution at 60 °C with an excess both of ethanethiol and $N^1$, $N^1$, $N^3$, $N^3$-tetramethylguanidine (TMG), 2′-deoxy-2′-(ethylsulfanyl)uridine **3** was obtained and isolated as a crystalline solid in 93% yield.

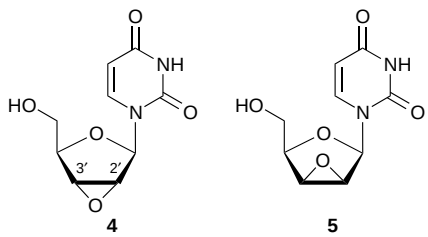
Brown *et al*.[1] rationalized their observations by suggesting that, under their reaction conditions, the 2,2′-anhydronucleoside **1** first isomerized to 2′,3′-anhydrouridine **4** which then underwent nucleophilic attack at C-3′ to give the observed product **2**. At the time of our earlier study,[2] we were unable to explain why the sodium and $N^1$, $N^1$, $N^3$, $N^3$-tetramethylguanidinium salts of ethanethiol should react in a different manner with the 2,2′-anhydronucleoside **1**, and previous attempts[3] to prepare 2′,3′-anhydrouridine **4** have been unsuccessful. We now report that when 2,2′-anhydro-1-β-D-arabinofuranosyluracil[4] **1** was treated with 1.5 equiv. of sodium hydride in dry dimethyl sulfoxide (DMSO) at room temperature for 20 min, it was virtually quantitatively converted into 2′,3′-anhydrouridine **4** which was isolated as a colourless crystalline solid† in 69% yield. The characterization of this epoxy compound **4** is based on microanalytical data (found: C, 47.63; H, 4.34; N, 12.36. $C_9H_{10}N_2O_5$ requires: C, 47.79; H, 4.46; N, 12.38%) and on $^1$H and $^{13}$C NMR spectroscopic evidence. It can be seen from Fig. 1 that the $^{13}$C NMR spectra [$(CD_3)_2SO$] of 2′,3′-anhydrouridine **4** [Fig. 1(*a*)] and the previously reported[5] and much more stable 2′,3′-anhydro-1-β-D-lyxofuranosyluracil **5** [Fig. 1(*b*)] are closely similar. The comparatively high field C-2′ and C-3′ resonance signals (δ 59.5 and 58.9 for the *ribo*-compound **4**; δ 55.9 and 55.6 for the *lyxo*-compound **5**) in the $^{13}$C NMR spectra of these compounds are particularly noteworthy.

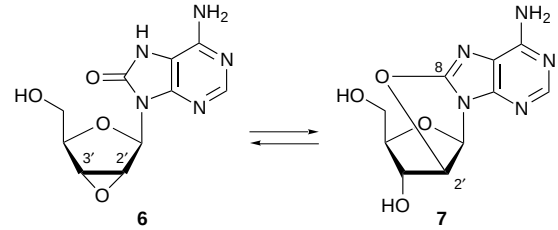
When 2′,3′-anhydrouridine **4** was allowed to stand in triethylamine–methanol (1 : 9 v/v) solution at room temperature, it was quantitatively converted back into the 2,2′-anhydronucleoside **1** within 1 h. The interconversion of compounds **1** and **4** is reminiscent of the previously reported interconversion[6] of 2′,3′-anhydro-7,8-dihydro-8-oxoadenosine **6** and the isomeric 8,2′-anhydronucleoside **7**. Perhaps the reason why the preparation of 2′,3′-anhydrouridine **4** has eluded previous workers is that stringently anhydrous conditions are required if the irreversible conversion of **1** into 1-β-D-arabinofuranosyluracil **8** is to be avoided. It should be added that the preparation of 2′,3′-anhydro-3-*N*-methyluridine **9** has been reported.[7]

When 2,2′-anhydro-1-β-D-arabinofuranosyluracil **1** (1.0 mmol) was allowed to react with sodium ethanethiolate [prepared from ethanethiol (4.0 mmol) and sodium hydride (2.0 mmol)] in dry DMF (10 cm$^3$) solution at room temperature for









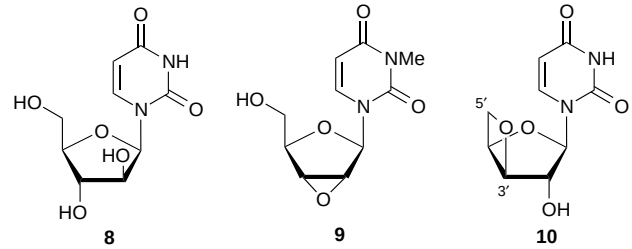


**Fig. 1** $^{13}$C NMR spectra in $(CD_3)_2SO$ of (*a*) 2′,3′-anhydrouridine **4** and (*b*) 2′,3′-anhydro-1-β-D-lyxofuranosyluracil **5**

18 h, 2′-deoxy-2′-(ethylsulfanyl)uridine **3** (mp 184–185 °C, lit.,[2] mp 183.5 °C) was obtained as the sole nucleoside product in 92% isolated yield. The course of this reaction corresponds with that of the previously reported[2] reaction between compound **1**, ethanethiol and TMG. However, when the 2,2′-anhydronucleoside **1** (1.0 mmol) was first treated with sodium hydride (4.0 mmol) in DMF (10 $cm^3$) for 2 h at room temperature and then, following the addition of ethanethiol (2.0 mmol), the reactants were stirred at room temperature for a further period of 18 h, the 3′-ethylsulfanyl derivative **2** (mp 130–132 °C)‡ was obtained in 90% isolated yield. It would therefore seem likely that the discrepancy between the results obtained by us in our previous study[2] and by Brown *et al*.[1] was due to the latter workers' sodium ethanethiolate being contaminated with a strong base (*e.g*. sodium methoxide). Finally, when the 2,2′-anhydronucleoside **1** was heated at 60 °C for 18 h with a five-fold excess of sodium hydride in dry *N*,*N*-dimethylacetamide in the absence of an additional nucleophile, 3′,5′-anhydro-1-β-D-xylofuranosyluracil **10** [mp 214–217 °C (decomp.), lit.,[8] mp 214–216 °C] was obtained and isolated in 62% yield. The fact that 2,2′-anhydro-1-β-D-arabinofuranosyluracil **1** can so easily be converted *in situ* into the isomeric 2′,3′-epoxide **4** makes it a particularly versatile synthetic intermediate.

## Footnotes

† It was not possible to determine the melting point of 2′,3′-anhydrouridine **4** as, on heating, it isomerized back to 2,2′-anhydro-1-β-D-arabinofuranosyluracil **1** before it melted. Compounds **1** and **4** have $R_f$ = 0.12 and 0.44, respectively, in chloroform–methanol (85 : 15 v/v).

**Hydrolytically unstable d³ $[Mn^{IV}(CN)_6]^{2-}$ as the $[N(PPh_3)_2]^+$ salt is crystallographically, spectroscopically, and magnetically characterized.**

The observation of magnetic ordering at relatively high temperature and including ambient temperature,[1] the photo-[2a] and electro-chemical[2b] switching between magnetic states as well as the reversible binding of oxygen[3] has led to a resurgence of interest in cyanometalates. The putative mechanism of spin coupling leading to ferromagnetic behaviour for some of these materials is that of spins on adjacent spin sites residing in orthogonal orbitals in the same spatial region.[4] An example is the ferromagnet $CsNi[Cr(CN)_6]\cdot 2H_2O$ ($T_c$ = 90 K) with the $e_g^2$ spins on each $Ni^{II}$ and orthogonal $t_{2g}^3$ spins on adjacent $Cr^{III}$ sites. Since $Mn^{IV}$ is isoelectronic to $Cr^{III}$, we targeted the preparation of $[Mn^{IV}(CN)_6]^{2-}$.

$K_2[Mn^{IV}(CN)_6]$ has been reported to be prepared from the oxidation of $K_3[Mn^{III}(CN)_6]$ with NOCl and exhibits $\nu_{CN}$ absorptions at 2240 vs and 2150 s $cm^{-1}$ and a room-temperature magnetic moment of 3.93 $\mu_B$.[5a] Although $[Mn^{IV}(CN)_6]^{2-}$ is hydrolytically unstable,[5b] several $[Mn^{IV}(CN)_6]^{2-}$ salts including $K_2[Mn^{IV}(CN)_6]$[5c,d] ($\nu_{CN}$ = 2151 $cm^{-1}$; $\mu_{RT}$ = 3.79 $\mu_B$) and $Mn^{II}[Mn^{IV}(CN)_6]\cdot 1.15H_2O$ have been prepared.[6] The latter is a ferrimagnet below an ordering temperature of 49 K.[5d] In order to develop non-aqueous routes to magnetic cyanometalates we prepared $[N(PPh_3)_2]_2[Mn^{IV}(CN)_6]$ the first structurally characterized simple salt which is stable in MeCN and $CH_2Cl_2$.§

The asymmetric unit of the unit cell‖ consists of a cation and half-anion, Fig. 1. The Mn–C and CN distances average 1.97 and 1.15 Å, respectively, and the *cis*-CNC and MnCN angles average 90.0 and 177.2°, respectively. The Mn–C and CN distances in this structure are comparable with the mean values reported for $Na_4[Mn^{II}(CN)_6]\cdot 10H_2O$ (1.95, 1.16 Å)[7] and $K_3[Mn^{III}(CN)_6]$ (1.98, 1.15 Å).[8] Within the accuracy of the crystal structure determination there is no evidence for a Jahn–Teller distortion as predicted for $^4A$ ground state. The cation is typical with an average PN distance of 1.579 Å and PNP angle of 139.6°. Each anion is surrounded by twelve cations in the solid state.

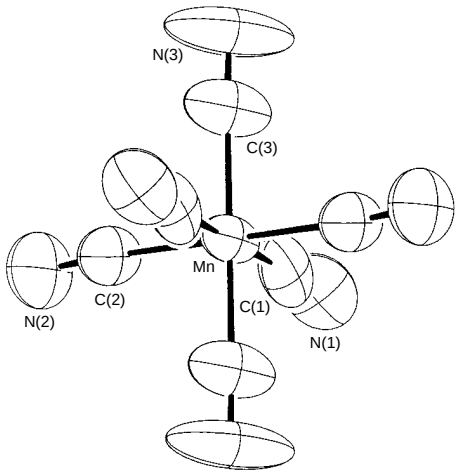

**Fig. 1** ORTEP drawing depicting atom labelling for $[Mn^{IV}(CN)_6]^{2-}$ in $[N(PPh_3)_2]_2[Mn^{IV}(CN)_6]$; atoms shown as 50% probability ellipsoids. Selected bond lengths (Å) Mn–C(1) 1.970(12), Mn–C(2) 1.965(8), Mn–C(3) 1.988(8), C(1)–N(1) 1.176(12), C(2)–N(3) 1.132(9), C(3)–N(3) 1.153(9).

The 2132 $cm^{-1}$ $\nu_{MnC\equiv N}$ absorption for $[Mn^{IV}(CN)_6]^{2-}$ is at higher energy than the 2092 and 2098 $cm^{-1}$ values for $[N(PPh_3)_2]_3[Mn^{III}(CN)_6]$. Coordination to $K^+$ leads to a significant increase in the energy of the $\nu_{C\equiv N}$ absorption, although an overall similar trend is observed for $\nu_{MnC\equiv NK}$: $K_2[Mn^{IV}(CN)_6]$ (2240, 2150 $cm^{-1}$)[5a] and $K_3[Mn^{III}(CN)_6]$ (2129, 2112 $cm^{-1}$).[9]

$[N(PPh_3)_2]_2[Mn^{IV}(CN)_6]$ exhibits a corrected room-temperature magnetic moment of 4.10 $\mu_B$ consistent with being a d³ octahedral complex with isolated anions. The expected six-line hyperfine for $^{55}Mn$ ($I$ = 5/2) is isotropic in the solution, frozen-solution, and even the solid-state spectra and is centred at $g$ = 1.996. This is strong evidence for a well behaved anion which exhibits very little or no distortion in its electronic configuration. At 78 K the electron paramagnetic resonance is 340 G wide with an average hyperfine coupling constant $|A|$ = 68 G, Fig. 2. The derivative peak to peak linewidths are essentially the same for the room-temperature and 78 K spectra with a slight variation from line to line. They proceed as 33, 30, 28, 31, 32, 27 (±1) G, from low to high field. This slight inhomogeneity is expected for manganese ions.[6]

The $Mn^{III/IV}$ couples of the octahedral cyanide anions are fully reversible one-electron events. $[Mn^{IV}(CN)_6]^{2-}$ {and $[Mn^{III}(CN)_6]^{3-}$} have a reversible $Mn^{III/IV}$ couple at $E_{1/2}$ = +0.14 V in MeCN *vs.* SCE, $\Delta E_{pp}$ = 0.09 V (10 mV $s^{-1}$ scan rate) using glassy carbon disk, Pt wire and $Ag/AgCF_3SO_3$ electrodes and ferrocene as an external standard. A reduction wave for the $Mn^{III/II}$ couple was not observed. The presence of any other metal cations affect the electrochemical response by precipitating out a cyanide complex onto the working electrode. By comparison, the $[Fe^{III/II}(CN)_6]^{3/4-}$ $E_{1/2}$ couple in MeCN is −0.42 V *vs.* SCE.[10]

The electronic spectrum of $[Mn^{IV}(CN)_6]^{2-}$ in MeCN, Fig. 3, unlike that of the isoelectronic $[Cr^{III}(CN)_6]^{3-}$,[11] possesses several charge-transfer bands. In contrast to $[Cr^{III}(CN)_6]^{3-}$ which has two d → d transitions at 26 500 ($\varepsilon$ = 90 $M^{-1}$ $cm^{-1}$)

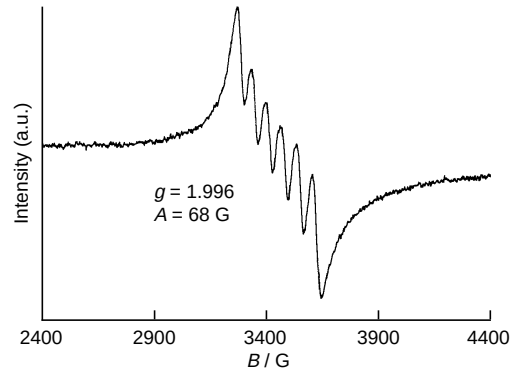

**Fig. 2** EPR spectrum of $[N(PPh_3)_2]_2[Mn^{IV}(CN)_6]$ at 78 K, 1.0 mM in $CH_2Cl_2$ at 9.6464 GHz

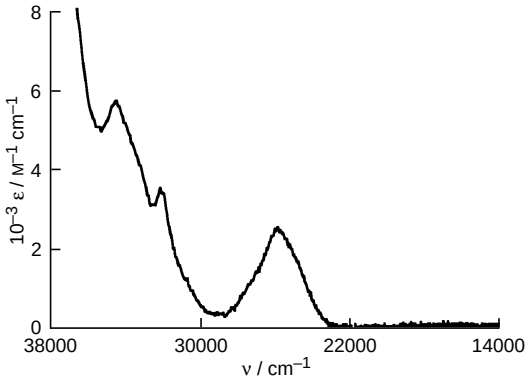

**Fig. 3** Electronic spectrum of $[N(PPh_3)_2]_2[Mn^{IV}(CN)_6]$ in MeCN

and 32 400 cm$^{-1}$ (ε = 65 M cm$^{-1}$) and one intense M → L charge-transfer absorption at 38 000 cm$^{-1}$ (ε = 6240 M$^{-1}$ cm$^{-1}$), $[Mn^{IV}(CN)_6]^{2-}$ possesses an intense band centred at 25 700 cm$^{-1}$ (ε = 2500 M$^{-1}$ cm$^{-1}$) which appears to be at least two overlapping bands. This band tails well into the visible region and is likely to be responsible for the extreme photosensitivity of this compound. There is a second band at 32 000 cm$^{-1}$ (ε = 3500 M$^{-1}$ cm$^{-1}$) and a third at 34 400 (ε = 5700 M$^{-1}$ cm$^{-1}$) on the tail of the aromatic π → π* transitions of the $[N(PPh_3)_2]^+$ cation which obscures the region above 36 000 cm$^{-1}$. This is the first electronic spectrum of a manganese cyanide taken without excess KCN[11] or perchloric acid[12] to prevent decomposition of the hydrolytically unstable anions. Reaction of $[Mn^{IV}(CN)_6]^{2-}$ to form molecule-based magnets is in progress.

§ In a typical experiment a MeCN solution (20 ml) of $[Fe(\eta\text{-}C_5H_5)_2][BF_4]$ (2.42 mmol, 1.00 g) was added to a $CH_2Cl_2$ solution (50 ml of $[N(PPh_3)_2]_3[Mn^{III}(CN)_6]$¶ (2.42 mmol, 4.42 g). The green colour of the $[Fe(\eta\text{-}C_5H_5)_2]^+$ gradually changed over 1.5 h to give a dark orange solution. The product was precipitated with $Et_2O$, isolated and recrystallized from MeCN–$CH_2Cl_2$–$Et_2O$ to give small, yellow needles in 33% yield. IR: $\nu_{CN}$ (Nujol) = 2132 cm$^{-1}$. Raman: $\nu_{CN}$ = 2135 cm$^{-1}$, $\nu_{MC}$ = 365 cm$^{-1}$. mp 142 °C (decomp.). Anal. Calc. for $C_{78}H_{60}MnN_8P_4$: C, 72.73; H, 4.70; N, 8.40. Found: C, 72.49; H, 4.51; N, 8.58%.

¶ $K_3[Mn(CN)_6]$ (1.50 g, 4.57 mmol) was quickly added to a solution of $[N(PPh_3)_2]Cl$ (7.87 g, 13.7 mmol) disolved in 825 ml of water. The precipitated product was recovered by filtration and dried in *vacuo*. Recrystallization from a dry, oxygen-free MeCN solution layered with $Et_2O$ gave large orange–yellow prisms in 77% yield. IR: $\nu_{CN}$(Nujol) = 2092.2098 cm$^{-1}$. Raman: $\nu_{CN}$ = 2099, 2110 cm$^{-1}$, $\nu_{MC}$ = 359 cm$^{-1}$. mp 272 °C (decomp.). Anal. # Control and applications of remote asymmetric induction using allylmetal reagents

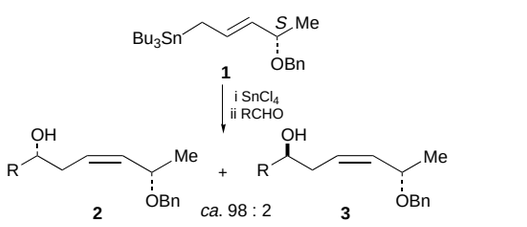
**Eric J. Thomas**

*Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*

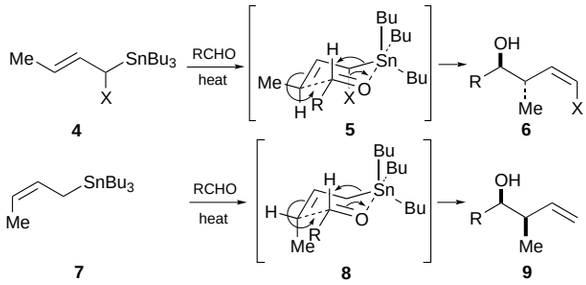
**Treatment of hydroxy- and alkoxy-substituted allylstannanes with tin(IV) halides effects transmetallation and the stereoselective formation of allyltin trihalides. These react with aldehydes and imines derived from glyoxylates with useful levels of remote asymmetric induction. Aspects of this chemistry are discussed, together with the conversion of the products into tetrahydrofurans and dihydropyrans.**

During a study of the chemistry of (*S*)-4-benzyloxypent-2-enylstannane **1**,[1] it was found that stereo- and regio-selective reactions in favour of the 1-substituted *syn*-(*Z*)-5-benzyloxyhex-3-en-1-ols **2** were achieved if the allylstannane was treated with tin(IV) chloride for a few minutes at −78 °C followed by addition of an aldehyde (Scheme 1).[2] This reaction attracted our interest because of its high level of 1,5-asymmetric induction. This review discusses the scope of remote asymmetric induction using allyltin reagents.



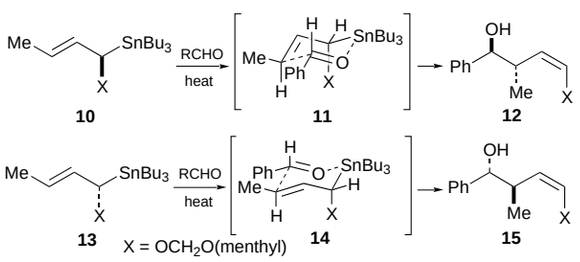
## Background

At the onset of our work, it was known that allylstannanes react with aldehydes on heating and in the presence of Lewis acids.[3,4] The thermal reactions proceed stereo- and regio-selectively and are believed to involve six-membered, cyclic, chair-like, transition structures. For example, the *anti* and *syn* products **6** (X = H) and **9** are obtained from the (*E*)- and (*Z*)-but-2-enylstannanes **4** (X = H) and **7**,[5] consistent with participation of the transition structures **5** and **8**.[5]

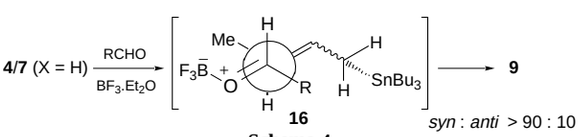


1-Substituted (*E*)-but-2-enylstannanes **4** (X = Me, OR) react with aldehydes on heating (Scheme 2) with excellent stereoselectivity in favour of the *anti*-(*Z*)-but-3-en-1-ols **6** (X = Me, OR).[6,7] The formation of *Z* double bonds in these reactions is consistent with participation of the transition structures **5** (X = Me, OR) in which the substituent next to tin is axial. This preference controls the facial selectivity of reactions of enantiomerically enriched 1-substituted but-2-enylstannanes with aldehydes.[8] Thus the (1*R*)- and (1*S*)-1-alkoxybut-2-enylstannanes **10** and **13** react with benzaldehyde to give the *anti* products **12** and **15** by selective attack on the *Si*- and *Re*-faces of the aldehyde, respectively (Scheme 3). Ozonolysis of these products gives rise to enantiomeric *anti*-aldol products, but the use of this reaction in synthesis is limited to aromatic and secondary aliphatic aldehydes because of the high temperatures required.[8]

Two processes are involved in the Lewis acid promoted reactions of allylstannanes and aldehydes. Boron trifluoride–diethyl ether promotes the reaction at −78 °C, and leads to the formation of the *syn* product **9** from both the (*E*)- and (*Z*)-but-2-enylstannanes **4** (X = H) and **7**,[9] albeit less selectively from the (*Z*)-allylstannanes.[10] This stereoconvergence has been explained in terms of open-chain transition structures, the antiperiplanar arrangement of aldehyde and stannane being proposed by Yamamoto (Scheme 4),[9] although the *gauche* arrangement was suggested by Denmark.[11] In these reactions, the boron trifluoride–diethyl ether is accelerating the reaction by coordinating to the aldehyde.



Other Lewis acids react with the allylstannane to generate more reactive allylmetal reagents which then react with the aldehyde.[4] The transmetallation reactions normally involve SE′ processes so terminal allylstannanes give 1-substituted allylmetal reagents. These react with aldehydes to give linear products, but can be unstable with respect to 1,3-rearrangement to give terminal allyl metal reagents which react with aldehydes to give branched products.[12] For example, the 1-phenylprop-2-enyltin dichloride **18** is generated from the 3-phenylpropenylstannane **17** and butyltin trichloride (Scheme 5), and reacts with aldehydes to give the linear products **20**. On standing it isomerises to the 3-phenyl isomer **19** which gives the *anti* products **21** with aldehydes. Transition structures analogous to **5** are believed to be involved.[13]



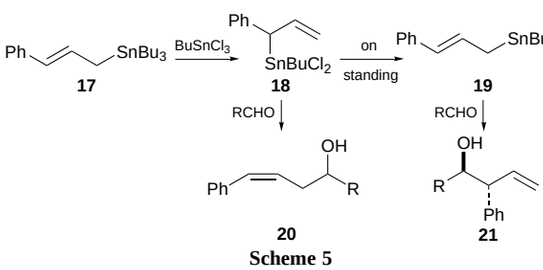
**Scheme 1**

**Scheme 2**

**Scheme 3**

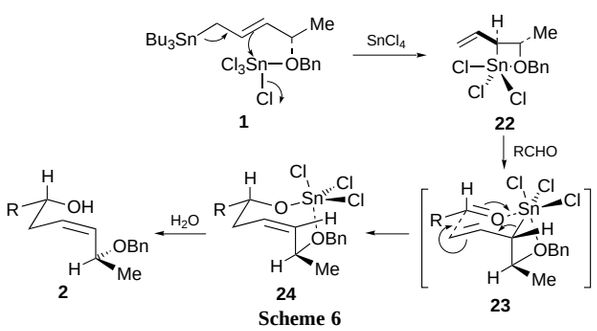
**Scheme 4**

## Remote asymmetric induction in reactions of allylstannanes with aldehydes



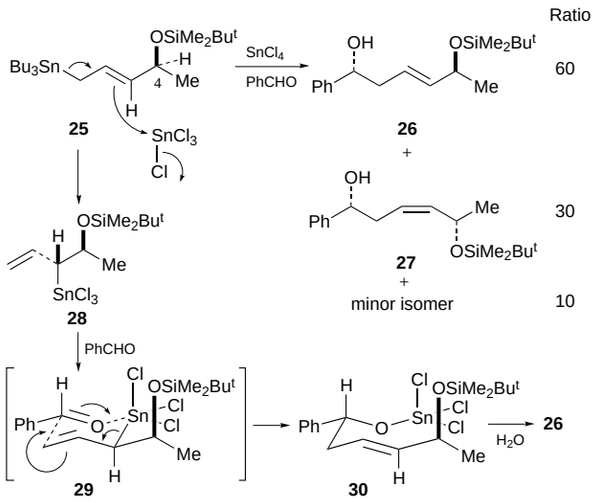
How can the regio- and stereo-selective formation of the 1,5-*syn* products **2** be explained? Since the tin(IV) halide is allowed to react with the stannane before the aldehyde is added, it is believed that transmetallation of the allylstannane is the first step.[14] This transmetallation is thought to involve delivery of the tin(IV) halide to the double bond of the allylstannane by the benzyloxy group to give the allyltin trichloride **22** which contains a four-membered oxastannane ring (Scheme 6). It is suggested that this transmetallation is stereoselective, with the isomer in which the vinyl and methyl groups are *trans*-disposed about the four-membered ring being preferred, perhaps due to kinetic control, although there may also be some equilibration of the *cis* and *trans* diastereoisomers under the reaction conditions. The allyltin trichloride **22** then reacts with the aldehyde *via* the transition structure **23** in which the group next to tin is axial, leading to the formation of the *cis* double bond in the product. Since the reaction between the tin(IV) chloride and an aldehyde is not reversible at −78 °C, this selectivity must be due to kinetic control. The initially formed product, before aqueous work-up, is the medium-ring dioxastannane **24**. Molecular modelling indicates that a *cis* double bond is more readily accommodated in the 8-membered ring of **24** than a *trans* double bond because of strain. If this strain is present in the transition structure **23**, it could account for the faster formation of the *cis* double bonded isomer **2**.[14]

The overall 1,5-asymmetric induction is therefore controlled by the stereoselectivity of the transmetallation step, and the preference of the group next to tin to be axial in the transition structure **23**. Coordination of the tin to the benzyloxy group is important in both of these steps. To investigate this coordination, the behaviour of the 4-*tert*-butyldimethylsilyloxypent-2-enylstannane **25** was investigated.[15]

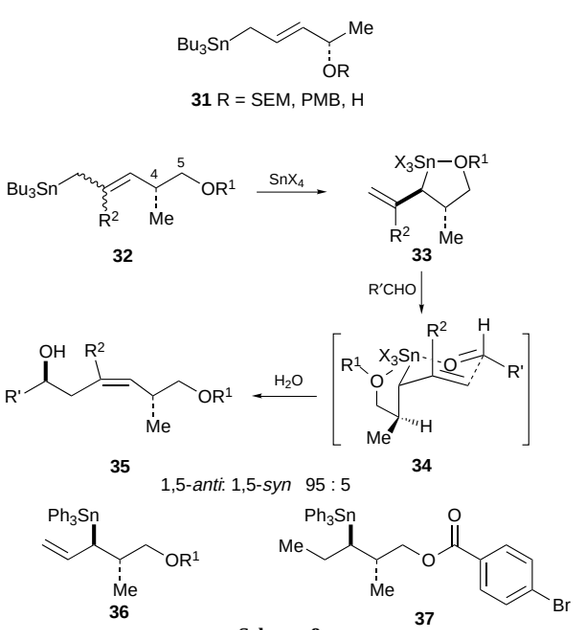


With benzaldehyde three products, the 1,5-*anti*-(*E*)-alkenol **26**, the 1,5-*syn*-(*Z*)-isomer **27** and a minor component which was not fully characterised (ratio 60 : 30 : 10, respectively) were formed (Scheme 7). The formation of the *anti*-(*E*)-alkenol **26** is consistent with participation of the allyltin trichloride **28**, which has the opposite configuration at the tin-bearing carbon to that of the allyltin trichloride **22**, and which reacts with the aldehyde *via* the transition structure **29**. It may be that, in this case, the transmetallation is taking place by intermolecular attack of the tin(IV) chloride on the allylstannane mainly in the conformation in which the allylic hydrogen is in the plane of the double bond. Approach of the tin(IV) chloride to the face away from the bulky silyloxy substituent,[16] would give the postulated intermediate **28**. The formation of the *trans* double bond in the products implies that the *tert*-butyldimethylsilyloxyethyl group adopts the equatorial position in the transition structure **29**. Perhaps, as no medium-ring strain is present, the bulky silyloxyethyl group is simply adopting the less hindered equatorial position.[15]

The scope of the tin(IV) halide-mediated reaction between alkoxy substituted allylstannanes and aldehydes has been widely investigated. The 4-(2-trimethylsilylethoxymethoxy)-, *p*-methoxybenzyloxy-, and hydroxy-pentenylstannanes **31** react with similar 1,5-induction to the 4-benzyloxypent-2-enylstannane **1**, although slightly reduced stereoselectivity is observed in reactions of the hydroxystannane **31** (R = H) with aliphatic aldehydes. Tin(IV) bromide leads to slightly better, and butyltin trichloride to similar, stereoselectivity, although the other Lewis acids investigated to date, $BF_3.Et_2O$, $TiCl_4$, $AlCl_3$, have proved less useful.



The 5-substituted pent-2-enylstannanes **32** ($R^1$ = Bn, PMB, SEM, H; $R^2$ = H) also react with aldehydes with useful levels of 1,5-induction after treatment with tin(IV) chloride or bromide (Scheme 8).[17,18] In this case the major product (*ca*. 95 : 5) is the



**Scheme 5**

**Scheme 6**

**Scheme 7**

**Scheme 8**

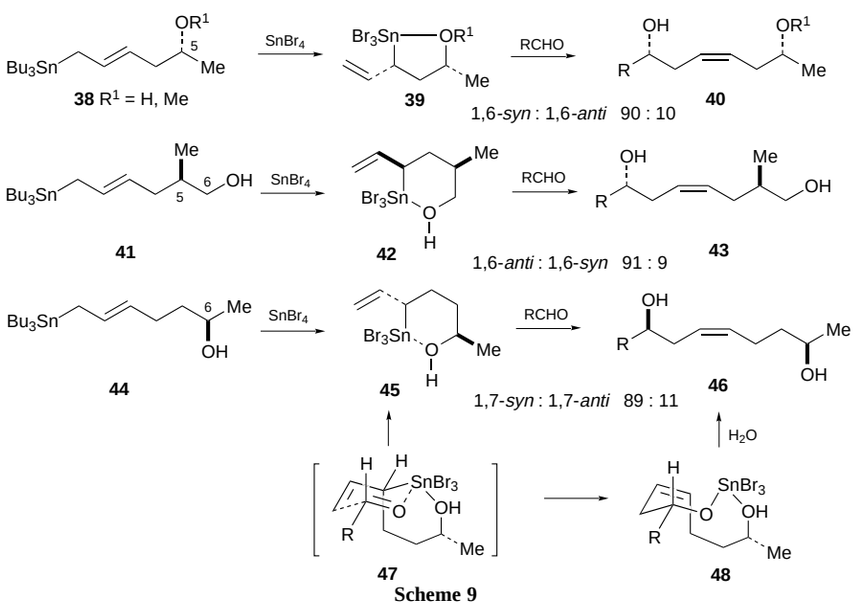
1,5-*anti*-(*Z*) stereoisomer **35** ($R^2$ = H). This is consistent with participation of the corresponding allyltin trihalide **33** ($R^2$ = H) which reacts with the aldehyde *via* the transition structure **34**. The formation of the *cis* double bond implies that the group next to tin is axial, so determining the facial selectivity of the reaction with the aldehyde and the configuration of the hydroxy bearing chiral centre in the product.

In the 5-substituted series, the *tert*-butyldimethylsilyl group has less effect on the overall selectivity, the stannane **32** ($R^1$ = $SiMe_2Bu^t$) giving the 1,5-*anti* product **35** ($R^1$ = $SiMe_2Bu^t$), albeit with reduced stereoselectivity (*ca.* 80 : 20).[15] An alkyl group at C(2) in the allylstannane, or the geometry of the double bond, have little effect. Thus both the (*E*)- and (*Z*)-2-methylpentenylstannanes **32** ($R^2$ = Me) give the 1,5-*anti*-(*Z*) products **35** ($R^2$ = Me) containing less than 2% of their *syn* diastereoisomers.[19]

In this series, the intermediate allyltin trichlorides **33** ($R^2$ = H; X = Cl) have been trapped by phenyllithium. Addition of phenyllithium to the allyltin trichloride from the benzyloxystannane **32** ($R^1$ = Bn; $R^2$ = H) gave the internal triphenylstannane **36** ($R^1$ = Bn) with excellent stereoselectivity (95 : 5) and similar stereoselectivity was observed for the hydroxy- and *tert*-butyldimethylsilyloxy-stannanes **32** ($R^1$ = H, $SiMe_2Bu^t$; $R^2$ = H). The structures of the major trapping products were established by X-ray diffraction of the *p*-bromobenzoate **37** which was prepared from the hydroxystannane **36** ($R^1$ = H) by reduction using diimide and esterification.[20]

This work is of interest since not only does it confirm the configurations originally assigned to the allyltin chlorides **33** on mechanistic grounds, but it also provides the regioisomeric triphenylallylstannanes **36** for transmetallation studies.

Transmetallation of allylstannanes with chiral centres at the 5- and 6-positions generates allyltin trihalides which react with aldehydes with 1,6- and 1,7-induction. In practice better stereoselectivities were observed with hydroxy substituted allylstannanes using tin(IV) bromide rather than tin(IV) chloride as the Lewis acid, although 1,6-induction was also observed for a 5-methoxyallylstannane. Thus the 5-hydroxy- and 5-methoxyhex-2-enyl and the 6-hydroxy-5-methylhex-2-enylstannanes **38** ($R^1$ = H, Me)[21] and **41**[22] were transmetallated with tin(IV) bromide to give allyltin tribromides, which reacted with aldehydes to give the 1,6-*syn* and the 1,6-*anti* products **40** ($R^1$ = H, Me) and **43**, respectively, with useful levels of 1,6-asymmetric induction (Scheme 9). Similarly the 6-hydroxyhept-2-enylstannane **44** gave the 1,7-*syn* products **46** with *ca.* 90 : 10 stereoselectivity.[23]



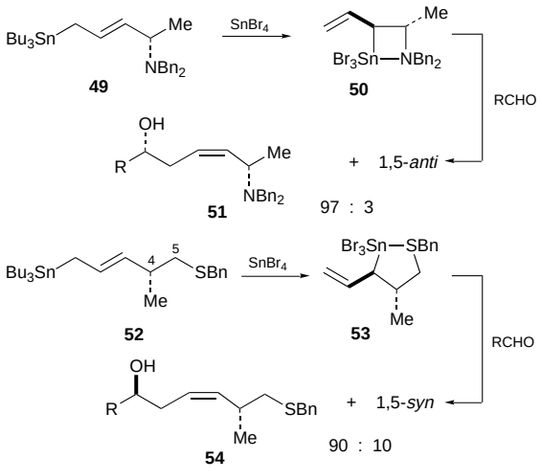
The stereoselectivities of these reactions are consistent with transmetallation giving the allyltin tribromides **39** ($R^1$ = H, Me), **42** and **45**, which react with aldehydes *via* six-membered, chair-like transition states in which the group next to tin is axial, *e.g.* **47** for the reaction of the allyltin tribromide **45**. The transmetallations are believed to generate allyltin tribromide in which the vinyl and methyl groups are both equatorial, as in the six-membered cyclic intermediates **42** and **45**, or pseudo-equatorial, as in the five-membered ring intermediate **39** (*cf.* also **33**), *i.e.* the more stable intermediates are believed to be involved, albeit formed kinetically.

The stereoselectivities of reactions with aldehydes of allylstannanes with nitrogen- and sulfur-containing functional groups have been investigated and found to parallel the reactions of their oxygen analogues. For example, treatment of the 4-aminopent-2-enylstannane **49** with tin(IV) bromide followed by the addition of an aldehyde gave the 1,5-*syn* products **51** with excellent stereoselectivity,[24] and the 5-benzylthiopent-2-enylstannane **52** similarly gave the 1,5-*anti* products **54**, with *ca.* 90 : 10 selectivity (Scheme 10).[25] The allyltin tribromides **50** and **53** are believed to be involved.

Rather different selectivity was observed for 5-acyloxyallylstannanes. The 5-acetoxypent-2-enylstannane **55** (R = Me) gave a mixture of products in which the *anti*-(*E*)-isomer **56** was the major component (Scheme 11).[26] The formation of this product is consistent with participation of the 7-membered ring containing allyltin trichloride **58** which reacts with the aldehyde *via* the transition structure **59**. Perhaps there is enough flexibility to accommodate an incipient *trans* double bond in this transitional structure so that the group next to tin can be equatorial. The use of different acyloxystannanes **55** (R = Ph, $Bu^t$, OMe, *etc*), failed to improve the selectivity to reliably useful levels.[26] The allylstannane **60** also gives rise to *E* double bonds in products from reactions with aldehydes, albeit with only low 1,8-*syn/anti* selectivity.[27]

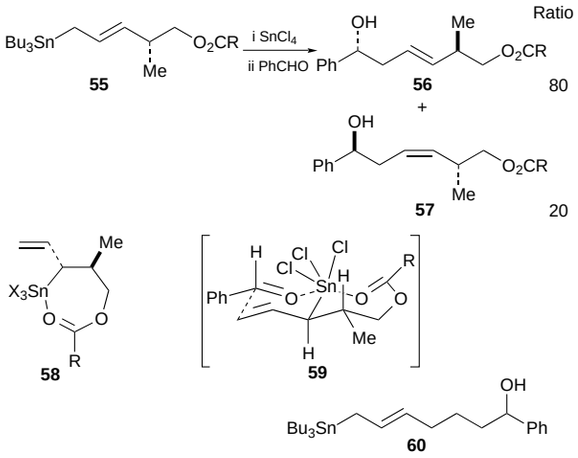
## Remote asymmetric induction in reactions of allylstannanes and imines

Allylstannanes react with imines in the presence of strong Lewis acids,[28] but preliminary investigations showed that allyltin trichlorides did not react at −78 °C with *N*-alkyl and *N*-aryl imines prepared from benzaldehyde. However, the more



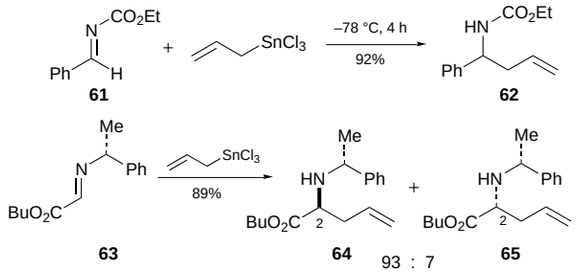
**Scheme 9**

electrophilic *N*-ethoxycarbonyl imine **61** and the chiral imine **63** prepared from butyl glyoxylate reacted efficiently with propenyltin trichloride to give the homoallylic amine derivatives **62** and **64**; (ratio 93 : 7, Scheme 12).[29] Of interest is the facial selectivity observed with the chiral imine **63** which is the opposite of that observed for an allylborane.[30]

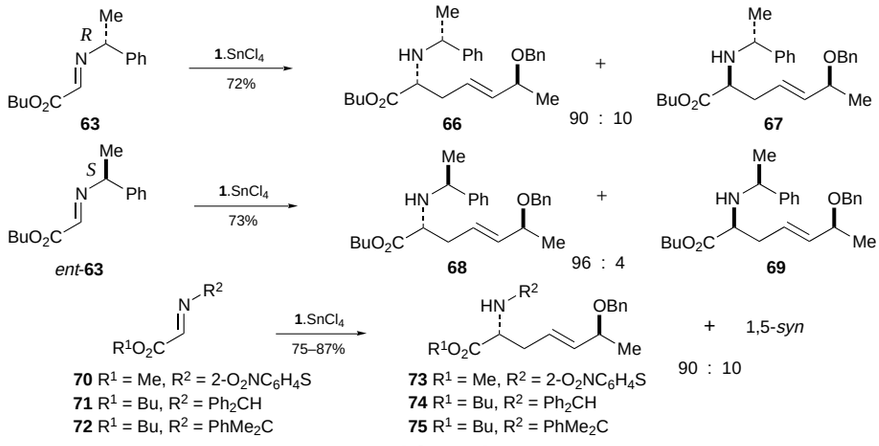


The imine **63** reacted with the allyltin trichloride **22** (Scheme 13) generated from the 4-benzyloxypent-2-enylstannane **1** with effective 1,5-induction in favour of the 1,5-*anti* isomer **66** (selectivity 90 : 10) even though this had involved attack of the allyltin trichloride on the less reactive face of the imine, *cf.* the facial stereoselectivity observed during the reaction of the imine **63** with propenyltin trichloride. With the enantiomeric imine *ent*-**63**, the formation of the 1,5-*anti* product was matched with the facial preference of the imine, and the major product was the 2*R* epimer **68**, selectivity 96 : 4. In both cases, all products isolated from the reactions between the imines **63** and *ent*-**63** were (*E*)-alkenes, in contrast to the selective formation of (*Z*)-alkenols in reactions with aldehydes.[29] The preference for formation of 1,5-*anti* products was maintained for the achiral *N*-arylthio, *N*-benzhydryl and *N*-dimethylbenzyl imines **70**–**72**, which gave the 1,5-*anti* products **73**–**75**, in *ca*. 90 : 10 stereoselectivity.[31]

The mechanisms of these reactions are not clear, although it is supposed that the allyltin trichloride **22** is involved since its formation takes place before addition of the electrophile. By analogy with the boron trifluoride–diethyl ether-promoted reactions of allylstannanes and aldehydes, which give (*E*)-alkenes,[32] perhaps the reaction between the allyltin trichloride **22** and imines involves an open-chain process. The transition structure **76** shows one possible orientation of the allyltin trichloride and the matched imine *ent*-**63** leading to the major product **68**. However, the cyclic transition structure **77** is also consistent with the observed stereoselectivity. In this case, the group on nitrogen, which must be axial if the nitrogen is to be coordinated to the tin, forces the group next to tin into the equatorial position to avoid severe 1,3-diaxial interactions, compare **23** and **77**.[29]



Of interest is the stereoselectivity of the reaction between the 4-*tert*-butyldimethylsilyloxypent-2-enylstannane **25** and imines. The achiral imines **70**–**72** react to give more of the 1,5-*syn* products **78**–**80** (Scheme 14), although the stereoselectivity, being *ca*. 75 : 25, is less than with the benzyloxystannane **1**.[15] The 1,5-*syn* products **81** and **82** are also preferred in reactions with the chiral imines **63** and *ent*-**63** (Scheme 15). This stereoselectivity is consistent with participation of the allyltin trichloride **28** which has the (*R*)-configuration at the tin bearing



**Scheme 10**

**Scheme 11**

**Scheme 12**

**70** $R^1$ = Me, $R^2$ = 2-$O_2NC_6H_4S$
**71** $R^1$ = Bu, $R^2$ = $Ph_2CH$
**72** $R^1$ = Bu, $R^2$ = $PhMe_2C$

**73** $R^1$ = Me, $R^2$ = 2-$O_2NC_6H_4S$

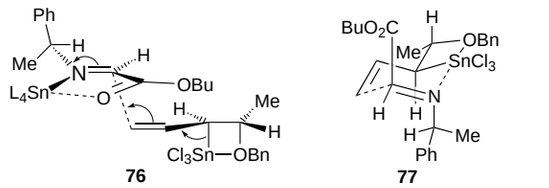
**Scheme 13**

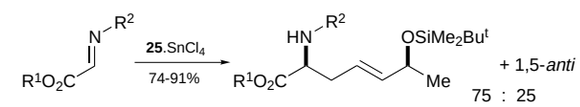
carbon. This prefers to approach the *Si* face of the imine, giving rise to the 1,5-*syn* product (see transition structure **83**).[15]

The allyltin trichloride generated from the 5-benzyloxypent-2-enylstannane **32** ($R^1$ = Bn; $R^2$ = H) reacts with the achiral imines **70** and **71** with useful 1,5-induction in favour of the 1,5-*syn* products **84** and **85** (Scheme 16).[31] With the matched (*R*)-imine **63** this selectivity is enhanced, but it is significantly reduced in reaction with the mismatched (*S*)-imine *ent*-**63**.[29] The formation of these 1,5-*syn* products is consistent with participation of the allyltin trichloride **33** ($R^1$ = Bn; $R^2$ = H; X = Cl) which reacts with the imine through either an open-chain or cyclic transition structure analogous to **76** or **77**.



## Aspects of the chemistry of the products

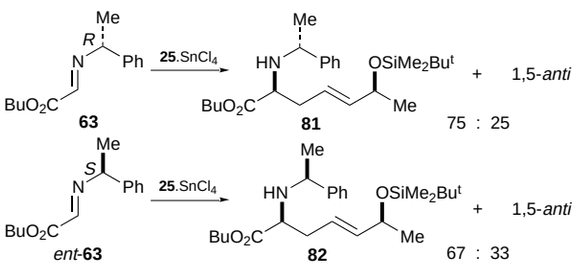
The 4-benzyloxypent-2-enylstannane **1** reacts with chiral 3-alkoxy aldehydes with selectivity controlled by the stannane, not by the aldehyde, *e.g.* the 1,5-*syn* products **91** and **93** were the dominant products from the 3-alkoxybutanals **90** and **92** (Scheme 17), although some matching and mismatching was observed with 2-alkoxy aldehydes.[33] Since remote chiral centres in the aldehyde do not affect the 1,5-*syn*-stereoselectivity, it is possible to use repetitively the remote induction of alkoxystannanes to synthesize open-chain polyols.



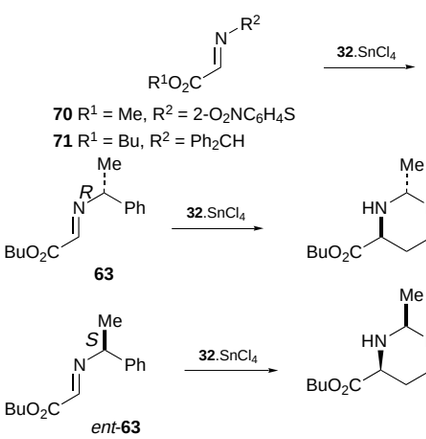
The 4-benzyloxyocta-2,7-dienylstannane **94** gave the 1,5-*syn* product **95** with 2-methylpropanal (*syn* : *anti* selectivity = 95 : 5) (Scheme 18). Protection and hydroboration–oxidation gave the aldehyde **96**, which reacted with the pent-2-enylstannane **1** to give the all-*syn* product **97**. Selective hydrogenation and hydrogenolysis gave the 15-methylhexadeca-2,6,10,14-tetraol **98** containing less than 5% of any other diastereoisomer. The aldehyde **96** was also treated with the stannane **94** to give the 1,5-*syn* product **99** which was protected and taken through to the corresponding aldehyde which gave the hexaol derivative **100** on treatment with the pent-2-enylstannane **1**.[34]

The 1,5-*syn*-alkenols **2** were converted stereoselectively into the all-*syn* epoxides **101** using $VO(acac)_2$ and *tert*-butyl hydroperoxide (Scheme 19).[35] The regioselectivity of hydride reduction of these epoxides was dependent upon the reducing agent. The 1,4- and 1,3-diols **102** and **103** were obtained as a mixture (33 : 67) using diisobutylaluminium hydride, but lithium aluminium hydride gave predominantly (99 : 1), and Red-Al† gave exclusively, the 1,4-diol **102**. Treatment of the 1,4-diol **102** (R = Ph) with lithium diisopropylamide and toluene-*p*-sulfonyl chloride gave the 2,5-*trans*-disubstituted tetrahydrofuran **104** by selective tosylation and displacement of the benzylic hydroxy group, but this sequence gave mixtures of products from other 1,4-diols **102** (R ≠ Ar).[36]

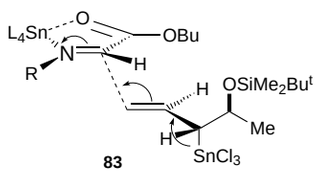
A synthesis of *cis*-2,5-disubstituted tetrahydrofurans, was developed from the alkenols **2**.[36] Treatment with toluene-*p*-sulfonyl chloride in pyridine gave the toluene-*p*-sulfonates **105**, which were oxidised stereoselectively using osmium tetraoxide (Scheme 20). The intermediate diols **106** were not isolated. Instead they cyclised *in situ* to give tetrahydrofurans,



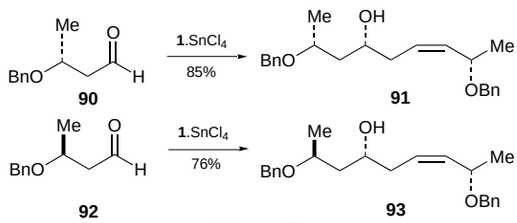
**76** **77**



**70** $R^1$ = Me, $R^2$ = 2-$O_2NC_6H_4S$ **78** $R^1$ = Me, $R^2$ = 2-$O_2NC_6H_4S$
**71** $R^1$ = Bu, $R^2$ = $Ph_2CH$ **79** $R^1$ = Bu, $R^2$ = $Ph_2CH$
**72** $R^1$ = Bu, $R^2$ = $PhMe_2C$ **80** $R^1$ = Bu, $R^2$ = $PhMe_2C$



**Scheme 14**



**Scheme 15**

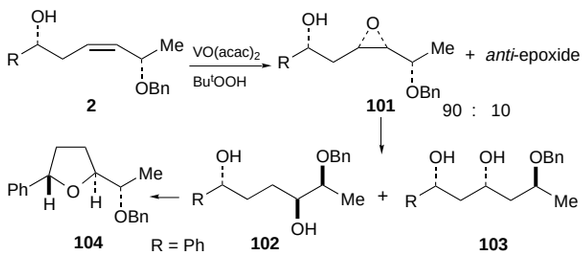
**Scheme 16**

**83**

**Scheme 17**

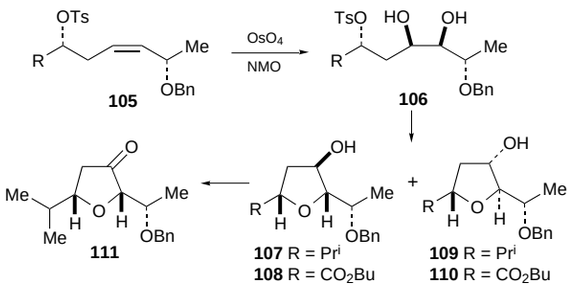
*e.g.* **107** and **109** (ratio 85 : 15) and **108** and **110** (ratio 95 : 5). The stereoselectivity of formation of these tetrahydrofurans is consistent with the diastereofacial selectivity of oxidation of the alkenyl tosylates being controlled by the allylic benzyloxy group, and, for the 5-isopropyltetrahydrofuran **107**, was confirmed by NMR (NOE) studies on the ketone **111**.

This synthesis of tetrahydrofurans **107**–**110** involves three steps from the starting aldehyde, namely reaction with the allylstannane, tosylation and oxidation–cyclisation. This three step sequence was used to give polycyclic tetrahydrofurans. The major tetrahydrofuranyl-2-carboxylate **108** was taken through to the allylstannane **112**. Treatment with tin(IV) bromide and an aldehyde (Scheme 21) proceeded with useful levels (⩽ 90 : 10) of 1,5-induction to give the 1,5-*syn* products **113** (R = Ph, Pr$^i$, $CO_2$Bu), the allylic tetrahydrofuranyl chiral centre controlling the 1,5-induction. Tosylation and oxidation of the 2-hydroxyhexenyltetrahydrofuran **113** (R = Pr$^i$) then gave the bis(tetrahydrofuran) **114** (23%) together with a minor isomer, ratio 87 : 13.[36] As an alternative strategy, the tetrahydrofuranyl-2-carboxylate **108** was converted by protection and reduction into the aldehyde **115** (Scheme 22). This was treated under the usual conditions with stannane **1** and tin(IV) chloride to give the 1,5-*syn* product **116** (74%, no minor isomer being detected by HPLC). Tosylation and oxidation with osmium tetraoxide gave the diol **117** and a minor isomer (85 : 15). Treatment with sodium hydride instigated cyclisation to the bis(tetrahydrofuran) **118**.[36]



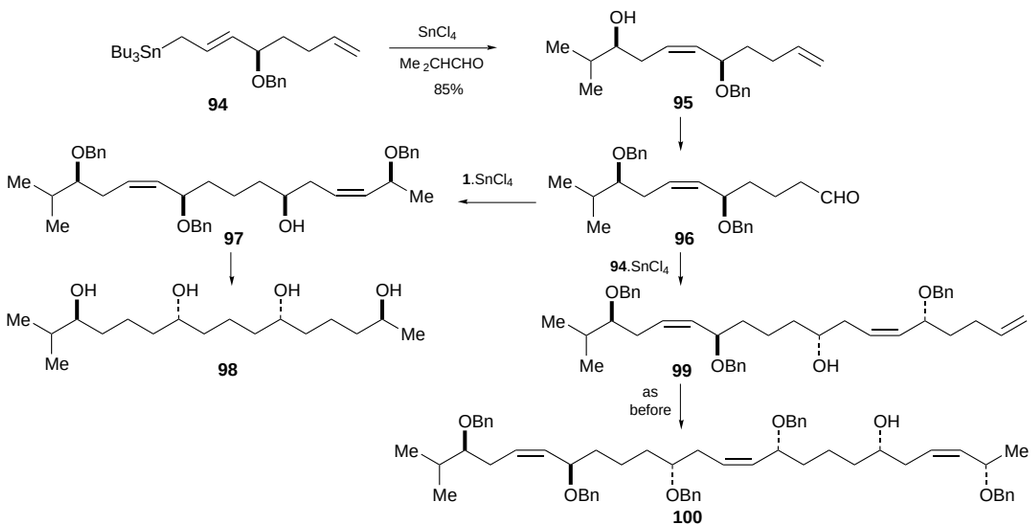
This synthesis of tetrahydrofurans is limited to products prepared from 4-alkoxyalkenylstannanes, since the alkoxy group is important in controlling the stereoselectivity of the oxidation using osmium tetraoxide as well as the reaction of the allylstannane with the aldehyde. However, another route to 2,5-*cis*-substituted tetrahydrofurans has been developed which is applicable to products prepared from 5-alkoxyalkenylstannanes. Epoxidation of the *anti*-alkenol **35** ($R^1$ = Bn, $R^2$ = H, R′ = Pr$^i$) using $VO(acac)_2$ and Bu$^t$OOH gave the *syn* epoxide **119** (Scheme 23). Treatment of this with diphenyldiselenide and sodium borohydride in ethanol gave a mixture of the dihydroxyselenides **120** and **121** corresponding to nonregioselective opening of the epoxide ring by sodium phenylselenide.[37] This mixture was not separated; rather it was treated with perchloric acid which gave the tetrahydrofuran **123** *via* the selenonium ion **122**. Reduction using tributyltin hydride gave the tetrahydrofuran **124**.[38]

Functionalised aldehydes were used in syntheses of dihydropyrans.[39,40] The tin(IV) chloride-promoted reaction of the 4-alkoxypent-2-enylstannane **31** (R = SEM) with toluene-*p*-sulfonyloxyacetaldehyde gave the 1,5-*syn* adduct **125** (Scheme 24). Treatment of this with anhydrous potassium carbonate gave the *syn* epoxide **126** which, on deprotection with trifluoroacetic acid, was converted into the 2,6-*cis*-disubstituted dihydropyran **127** containing *ca*. 20% of its 2,6-*trans* epimer. Conversely, the *anti* epoxide **129** was available *via* treatment of the 1,5-*syn* product **128**, prepared from stannane **31** (R = SEM) and benzoyloxyacetaldehyde, with mesyl chloride and triethylamine followed by saponification and cyclisation using potassium carbonate. Deprotection of this epoxide gave the 2,6-*trans*-disubstituted dihydropyran **130** containing *ca*. 20% of its 2,6-*cis* epimer.[39,40]



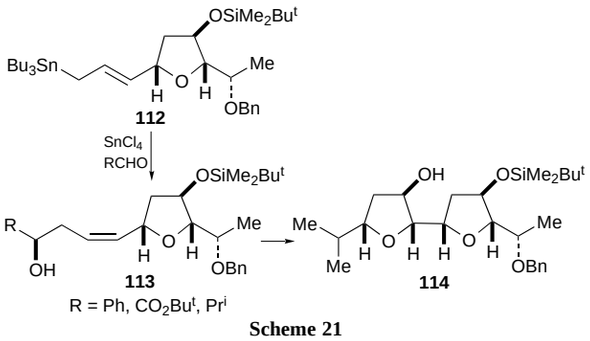
## Remote asymmetric induction using other allylmetal reagents

Although allylstannanes are useful in synthesis, there is often a problem in removing unwanted tin-containing residues from the products and so it was of interest to see whether the intermediate allyltin trihalides, important for remote induction, could be generated stereoselectively from starting materials other than allylstannanes.

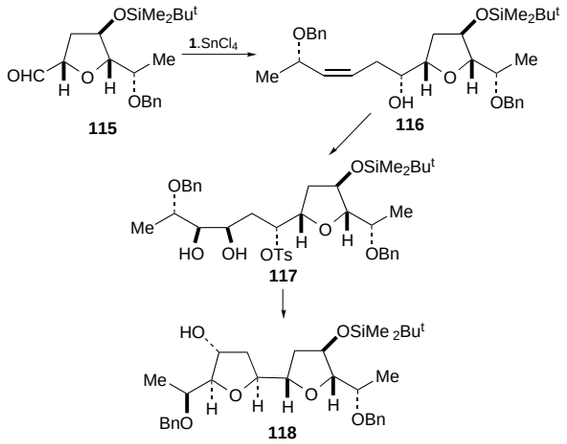


Stannous fluoride promotes reactions between 3-iodopropene and aldehydes, perhaps by formation of allyltin trihalides which

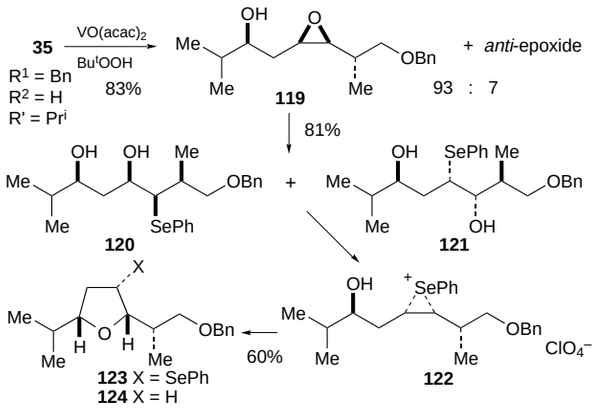
**Scheme 19**



**Scheme 20**



**Scheme 18**



then react with the aldehyde.[41] However, treatment of either the allylic iodide or bromide **131** (X = I, Br) with stannous fluoride, chloride or triflate in the presence of benzaldehyde gave low yields of mixtures of products containing mainly the branched alkenols **132**.[42] The use of metallic tin with the iodide was similarly unsuccessful. However, some success was attained with allylsilanes. The (*Z*)- and (*E*)-pent-2-enylsilanes **134** and **135** were prepared from the aldehyde **133** (Scheme 25). Treatment of the (*Z*)-isomer **134** with tin(IV) chloride at −78 °C for 1–2 h generated an intermediate, perhaps the allyltin trihalide **33** (X = Cl, $R^1$ = Bn, $R^2$ = H), which reacted with benzaldehyde to give the 1,5-*anti* and 1,5- *syn* products **35** (R′ = Ph, $R^1$ = Bn, $R^2$ = H) and **136** (R′ = Ph), ratio 85 : 15. The (*E*)-allylsilane **135** similarly gave the 1,5-*anti* and 1,5-*syn* products **35** (R′ = Ph, $Pr^i$, Et, $R^1$ = Bn, $R^2$ = H) and **136** (R′ = Ph, $Pr^i$, Et), but with slightly reduced selectivity (1,5-*anti* : 1,5-*syn* = *ca*. 75 : 25).[43] Attempts to improve the 1,5-induction of allylsilanes to the levels observed with allylstannanes have not yet proved successful.

## Summary and conclusions

The work outlined in this article shows that 4-, 5- and 6-substituted alkenylstannanes, after transmetallation with tin(IV) halides, react with aldehydes and imines with useful levels of 1,5-, 1,6- and 1,7-asymmetric induction.

Recently, a complementary approach to remote induction using allylstannanes has been introduced based on the chemistry of 2-(substituted-alkyl)propenylstannanes. For example, stereodivergent approaches to 1,4-asymmetric induction were developed based on the chemistry of 2-(1-substituted ethyl)propenylstannanes **137** (P = Me, Ac) and related compounds.[44–47] Advances in this area are expected.

# Selective catalytic oxidation of benzyl alcohols to benzaldehydes with a dinuclear manganese(IV) complex

**Charon Zondervan,[a] Ronald Hage[b] and Ben L. Feringa*[a]†**

[a] *Department of Organic and Molecular Inorganic Chemistry, Groningen Centre for Catalysis and Synthesis, University of Groningen, Nijenborgh 4, 9747 AG Groningen, The Netherlands*
[b] *Unilever Research Laboratory Vlaardingen, PO Box 114, 3130 AC Vlaardingen, The Netherlands*

**A dinuclear manganese(IV) catalyst is capable of oxidising benzylic alcohols to benzaldehydes with very high turnovers numbers (up to 1000) and high selectivities (above 99%).**

A key reaction in synthetic organic chemistry is the transformation of alcohols to aldehydes. Many procedures have been developed over the years, most notably the Oppenhauer and Swern oxidations and reactions utilising high valent metal compounds such as $MnO_2$, ammonium perruthenates and pyridinium chlorochromate.[1] However, almost all require stoichiometric amounts of metal compounds and sometimes co-oxidants, with concomitant environmental problems. Only a few examples are known in which metal complexes are used in a catalytic fashion. Benzaldehydes are obtained from benzyl alcohols with $RuCl_2(PPh_3)_3$[2] and $ZrO(OAc)_2$ using PhIO or *tert*-butyl hydroperoxide as oxidants,[3] and similar results were obtained with $SeO_2$–bis(4-anisyl) selenoxide.[4] A valuable alternative is the $[NBu_4][RuO_4]$–*N*-methylmorpholine oxide system.[5] These procedures typically require 1–10 mol% of catalyst and 100–300 mol% oxidant. Herein we report a novel method for the efficient and highly selective oxidation of benzylic alcohols to benzaldehydes using an active dinuclear manganese(IV) complex as catalyst and hydrogen peroxide or *tert*-butyl hydroperoxide as oxidant.

The excellent bleaching and epoxidation properties of **1** in water[6a] and acetone[6b,c] were recently reported. This complex consists of two manganese(IV) ions held together by three oxo ligands, with both metals bound to an *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane ligand.[7] The intriguing coordination chemistry of this ligand and its analogues has been reviewed.[8]

Initial results of the benzylic oxidation by using 0.6 μM **1**, 5 mM $H_2O_2$ and 0.6 mM benzyl alcohol in acetone in air were quite promising as highly selective aldehyde formation was observed, although the catalytic activity was modest (280 turnovers; entry 1, Table 1). Due to the efficient catalase activity of **1** under these conditions, we anticipated that excess of oxidant is required, but in attempting to increase the turnover number by using a very large excess hydrogen peroxide we only observed formation of benzoic acid (entry 2).‡ This could be overcome by adding 2000 equiv. of oxidant over a 10 h period, which cleanly gave 380 turnovers to benzaldehyde (entry 3). The mononuclear $Mn^{III}$ complex **2** gives a somewhat higher conversion with benzyl alcohol, but the bis(μ-acetato)(μ-oxo) complex **3** was virtually unreactive (entries 4 and 5). Complexes such as **3** are most probably dead ends in the catalytic cycle when, starting with **1** or **2**, traces of benzoic acid are formed during the oxidation reaction. Indeed, addition of a few equivalents of benzoic acid with respect to **1** completely inhibits any turnover on benzylic alcohols when the reaction is carried out under nitrogen atmosphere (entry 6). Exposure to air eventually leads to full conversion to benzoic acid. For practical synthetic applications further improvements with complete conversion to benzaldehydes were highly desirable.

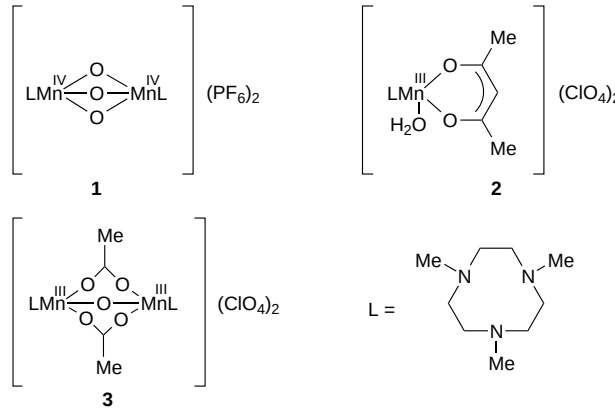

**Table 1** Effects of changing various parameters on the reactivity of benzyl alcohol

| Entry | Catalyst and oxidant[a] | Variation | Turnover[b] | *t*/min | Selectivity[c] |
|---|---|---|---|---|---|
| 1 | **1** + $H_2O_2$ | | 280 | 100 | > 99 |
| 2 | **1** + $H_2O_2$ (80 000 equiv.) | | 1000 | 60 | > 99[d] |
| 3 | **1** | [e] | 380 | 600 | > 99 |
| 4 | **2**[f] + $H_2O_2$ | | 660 | 100 | > 99 |
| 5 | **3**[g] + $H_2O_2$ | | 16 | 60 | > 99 |
| 6 | **1** + $H_2O_2$ | BnOH (2 equiv.) added | 0 | — | — |
| 7 | **1** + $Bu^tO_2H$ | | 0 | — | — |
| 8 | **1** + $Bu^tO_2H$ | Pretreatment with $H_2O_2$ | 480 | 150 | > 99 |
| 9 | **1** + $H_2O_2$ | Pretreatment with $H_2O_2$ | 360 | 150 | > 99 |
| 10 | $H_2O_2$ | No catalyst added | 0 | — | — |

[a] In all cases 1000 equiv. alcohol and 8000 equiv. oxidant were used in acetone in air; the reaction was followed by GC and terminated when conversion ceased to give benzaldehydes as product (the selectivity on aldehyde in all cases was above 99%). [b] Turnover number in mol aldehyde per mol **1**. [c] Selectivity in mol aldehyde per mol converted substrate. [d] Benzoic acid was the only product. [e] 2000 equiv. $H_2O_2$ in acetone were added over a 10 h period. [f] Ref. 9. [g] Ref. 7*b*.

**Table 2** Reactivity of substituted benzyl alcohols using two different procedures

| | | Method A | | Method B | |
|---|---|---|---|---|---|
| Entry | Substrate[a] | Turnover[b] | *t*/min | Turnover[b] | *t*/min |
| 1 | Benzyl alcohol | 360 | 60 | 480 | 150 |
| 2 | 4-Methoxybenzyl alcohol | 710 | 45 | 1000 | 45 |
| 3 | 3,4-Dimethoxybenzyl alcohol | 300 | 60 | 1000 | 20 |
| 4 | 4-(Dimethylamino)benzyl alcohol | — | | 1000 | 20 |
| 5 | 4-Chlorobenzyl alcohol | 700 | 45 | 1000 | 25 |
| 6 | 2-Chlorobenzyl alcohol | 490 | 45 | 1000 | 40 |
| 7 | 2,6-Dichlorobenzyl alcohol | 80 | 90 | — | |
| 8 | 4-Nitrobenzyl alcohol | 530 | 15 | 1000 | 45 |
| 9 | 3-Nitrobenzyl alcohol | 580 | 20 | 1000 | 25 |
| 10 | 2-Nitrobenzyl alcohol | 240 | 15 | 1000 | 35 |
| 11 | 4-Trifluoromethylbenzyl alcohol | 340 | 210 | 600 | 50 |
| 12 | Octan-2-ol | 360 | 100 | 360 | 90 |

[a] In all cases 1000 equiv. alcohol were used in acetone under inert atmosphere; the reaction was followed by GC and terminated when conversion ceased to give benzaldehydes as product (the selectivity on aldehyde in all cases was above 99%). [b] Turnover number in mol aldehyde per mol **1**.

To our surprise we found that the activity is significantly increased by employing a modified procedure. First the catalyst is mixed with 3000 equiv. of hydrogen peroxide in acetone for 30 min during which all hydrogen peroxide is decomposed (probably *via* catalase activity of **1**).§ Addition of an aliquot of substrate and hydrogen peroxide (1000 and 8000 equiv., respectively) to the thus pretreated catalyst leads to quantitative formation of benzoic acid, but under an inert atmosphere to selective formation of benzaldehyde (360 turnovers, entry 9). For substituted benzyl alcohols generally 400–700 turnovers to the corresponding benzaldehydes are found with over 99% selectivity with or without inert atmosphere conditions (Table 2, method A).

Although compound **1** with *tert*-butyl hydroperoxide (TBHP) is not active in the benzylic oxidation (Table 1, entry 7), the use of TBHP as oxidant in the second step, *i.e*. after pretreating **1** with hydrogen peroxide for 30 min, was found to have a highly beneficial influence on both turnover number and reaction rate (Table 1, entry 8). Nearly all substituted benzylic alcohols were fully converted to the corresponding benzaldehydes with excellent selectivities within an hour at room temperature using 0.1 mol% of catalyst **1** (Table 2, method B).¶

From the results with method A, we see a small but distinct steric effect as *ortho*-substituted substrates react more sluggishly than either *meta*- or *para*-substituted benzyl alcohols. In fact 2,6-disubstituted substrates are largely unreactive (entry 7). Substrates with electron-donating properties, *e.g*. (di)methoxy and dimethylamine benzyl alcohol (entries 2, 3 and 4), also appear to react faster under the conditions of method A than those with electron-withdrawing substituents such as nitro and trifluoromethyl groups (entries 8 and 11). The latter one even failed to give full conversion under the conditions of method B. As expected, secondary alcohols are selectively converted to ketones although the outcome is indifferent towards the procedure used. A typical example is given in entry 12.

In conclusion, we have demonstrated that manganese complex **1** is an excellent catalyst or catalyst precursor in novel procedures employing either $H_2O_2$ or TBHP as oxidant for the highly selective and very fast conversion of substituted benzyl alcohols to benzaldehydes. Further studies to elucidate the role of the pretreatment procedure and the exact nature of the catalytic species are in progress.

## Footnotes

† E-mail: feringa@chem.rug.nl

‡ A control experiment showed that **1** is capable of oxidising benzaldehyde to benzoic acid in air. In 90 min, 125 turnovers were found in acetone, whereas a blank reaction, *i.e*. without **1**, gave no reaction at all. 3-Nitrobenzaldehyde is not oxidised by **1** in air, or by **1** and $H_2O_2$ under turnover conditions.

§ From the 16 line spectrum obtained from EPR measurements at 77 K we inferred that **1** is reduced to a dinuclear $Mn^{III}$–$Mn^{IV}$ mixed valent species instantaneously when mixed with excess hydrogen peroxide in acetone, although we do not know if this reaction goes to full completion.[6a] Within 20 min the spectrum gradually changes to ultimately give a 6 line spectrum, indicative of $Mn^{II}$ species.

¶ A general experimental procedure is as follows: 1.0 ml of a 0.6 mM stock solution of crystallised **1** in acetone and 0.5 ml of hydrogen peroxide (30 wt%) are mixed for 30 min at room temperature under a nitrogen atmosphere. Simultaneously 0.6 mmol substrate and 0.5 ml hydrogen peroxide (30 wt%) (method A) or 0.6 mmol substrate and 0.5 ml of aqueous *tert*-butyl hydroperoxide (70 wt%) (method B) are added and the reaction is followed by GC until the maximum conversion is reached (usually within 1 h).

# Efficient preparation of a linear, symmetrical, metal–metal bonded tricobalt compound; should we believe there is a bond stretch isomer?

**F. Albert Cotton, Lee M. Daniels and Glenn T. Jordan IV**

*Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, USA*

**The synthesis in 42% yield of a linear, symmetrical, fully Co–Co bonded [2.3178(9) Å] trinuclear complex $[Co_3(dpa)_4Cl_2]$ [Hdpa = bis(2-pyridyl)amine] is reported, and its crystal structure presented.**

While the preparation, characterization and theoretical study of compounds containing strong, short metal–metal (M–M) bonds has become a major field of inorganic chemistry,[1] the study of compounds with linear chains of three or more bonded metal atoms is still in an embryonic state. The first such compound, which contained the $[Ru_3Cl_{12}]^{4-}$ ion, was first reported[2] in 1980 and the phosphine derivatives of this ion were extensively studied[3] in 1989–1991. Only very recently have other M–M bonded linear trinuclear species been reported.[4–7]

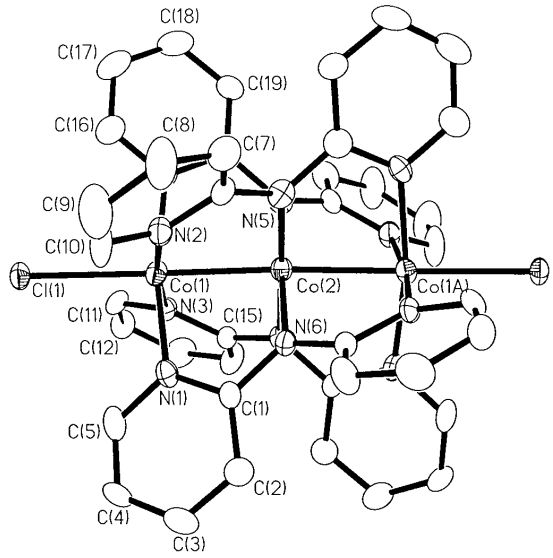

**Fig. 1** A side view of the $[Co_3(dpa)_4Cl_2]$ molecule. Selected bond lengths (Å) and angles (°): Co(1)–Co(2) 2.3178(9), Co(1)–Cl(1) 2.520(2), Co(1)–N(av) 1.991, Co(2)–N(av) 1.903; Co(1)–Co(2)–Co(1A) 177.0(1), Cl(1)–Co(1)–Co(2) 178.44(8).

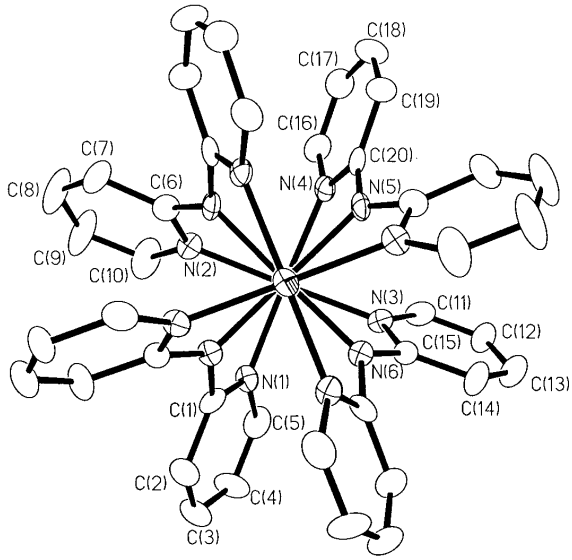

**Fig. 2** A view of the $Co_3(dpa)_4$ portion of the molecule looking down the $Co_3$ axis

One such compound[4] is $[Co_3(dpa)_4Cl_2]$ [Hdpa = bis(2-pyridyl)amine]. The yield quoted was only 2–5% and there were other features (*vide infra*) of the product that caused us concern. Therefore, we decided to look into this matter, beginning with the development of a synthetic method that gives a decent yield.

Our preparative procedure† which has been repeated many times, gives yields on the order of 40%. We have determined the crystal structure‡ of our product, which has the formula $[Co_3(dpa)_4Cl_2]\cdot CH_2Cl_2$, and find it to be significantly different from that previously reported[4] for $[Co_3(dpa)_4Cl_2]\cdot 2CH_2Cl_2\cdot H_2O$. Not only do we find a different space group (*Pnn*2), which is, however, the same space group in which Cu, Ru, and Rh analogues[5,6] crystallize, but we find a rigorously symmetrical molecule as was the case in all other $[M_3(dpa)_4Cl_2]$ compounds.[5–7] Our structure of $[Co_3(dpa)_4Cl_2]$ is shown in Figs. 1 and 2. The Co–Co distances are identical at 2.3178(9) Å as contrasted with values of 2.290(3) and 2.472(3) Å reported for the molecule described in ref. 4.

It is noteworthy that we find $[Co_3(dpa)_4Cl_2]\cdot CH_2Cl_2$ to be crystallographically isomorphous and molecularly isostructural with its symmetric rhodium analogue[5] for which Rh–Rh distances of 2.3920(5) Å were reported. The relationship between the M–M distances in these two isostructural compounds, 2.318 and 2.392 Å for the Co and Rh compounds, respectively, is very similar to that in the $[M_2\{PhNC(Ph)NPh\}_4]$ compounds,[8] where the Co–Co and Rh–Rh distances are, respectively, 2.302(1) and 2.389(1) Å.

One more important observation we made is that the UV–VIS and IR spectra of our compound are the same as those mentioned in ref. 4.

One way to resolve the discrepancy between our structure and that in ref. 4 is to postulate that they are 'bond stretch' isomers, which of course, become identical, one way or the other, in solution. Since all prior claims to this sort of isomerism have turned out to be erroneous (and the whole idea is not credible, anyway) we reject this possibility. There seems no other explanation except to propose that the previously reported structure is in error, although with reported residuals of $R = 0.049$ and $R_w = 0.039$, it is not, *prima facie*, obvious how. We look forward to a full report on the work described two and a half years ago in ref. 4.

## Footnotes

† Bis(2-pyridyl)amine (Hdpa, 0.480 g, 2.80 mmol) was placed in a 100 ml round-bottomed flask and dissolved in 16 ml of thf. The solution was cooled to −78 °C, and then 2.0 ml of 1.4 M LiMe was added. The solution immediately turned milky white, but quickly became a clear pale yellow solution upon warming. Anhydrous $CoCl_2$ (0.275 g, 2.12 mmol) was then

added to the reaction from a solid addition tube. The resulting brown solution was refluxed for 5.5 h, and then stirred overnight. After filtration of the mixture, a dark red powder was collected and washed several times with small portions of thf. The powder was dissolved in $CH_2Cl_2$ and layered with hexanes to yield a large crop of dark green crystals. Additional product was obtained from work-up of the filtrate. The solvent was removed from the filtrate under vacuum, leaving behind a dark residue. The residue was dissolved in 10 ml of $CH_2Cl_2$, filtered to remove LiCl, and layered with hexanes. Crystals from both solutions were collected, washed with hexanes, and dried under vacuum (0.300 g, 0.296 mmol, 42.3% yield). UV–VIS ($CH_2Cl_2$): 323, 390(sh), 568 nm.

‡ *Crystal data* for $[Co_3(dpa)_4Cl_2]\cdot CH_2Cl_2$ (−105 °C): orthorhombic, space group *Pnn*2, $a$ = 12.8145(9), $b$ = 13.955(1), $c$ = 11.1660(9) Å, $U$ = 1996.8(3) Å$^3$, $D_c$ = 1.685 g cm$^{-3}$, $Z$ = 2; CAD4 diffractometer with graphite-monochromated Mo-Kα radiation; ψ-scan absorption correction was made; 1449 unique reflections ($2\theta < 45°$) were measured. Full-matrix least-squares refinement on $F^2$ of positional and anisotropic thermal parameters for all non-hydrogen atoms (287 variables) converged to $R$ = 0.047 and $wR_2$ = 0.084 (all data) with the largest peak in difference map = 0.48(7) e Å$^{-3}$. The absolute configuration was confirmed by the Flack method.[9] Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/355.

# Energy *vs.* electron transfer processes involving a novel cobalt cage complex

**Christian Königstein,*[a,b,c]† Albert W. H. Mau,*[a]‡ Peter Osvath,*[a,b]§ and Alan M. Sargeson*[b]¶**

[a] *Division of Chemicals and Polymers, CSIRO, Clayton, Victoria 3169, Australia*

**A novel cage complex, $[Co(Me_2\text{-}N_3S_3absar)]^{3+}$, able to undergo fast and efficient electron transfer reactions, is examined as an electron transfer agent in photocatalytic systems aimed at generating $H_2$; its electrochemical behaviour and excited state quenching properties are described.**

The ability to capture energy and transfer it *via* redox reactions is a key issue in the photochemical conversion of solar energy. Artificial systems have used the viologens,[1,2] polypyridinium complexes,[3] or cobalt cage complexes[4–6] as electron transfer agents. The high chemical stability of the cobalt cages allows the $Co^{II}$–$Co^{III}$ redox states to be cycled repeatedly without decomposition. Systems using $[Co(sep)]^{3+}$, $[Co(sar)]^{3+}$ (Fig. 1) and their derivatives as electron relay compounds gave comparable rates of $H_2$ formation[4–6] to those using methyl viologen ($MV^{2+}$). Although their overall efficiency of conversion of light to hydrogen ($\phi_{\pm}H_2$) was only *ca.* 10%, their turnover numbers were at least three orders of magnitude higher than those of the viologens, and there is potential for improvement.

The rate of photoinduced $H_2$ formation is controlled by the generation of an excited state S* of the sensitiser (1), and three distinct electron transfer processes [eqns. (2), (3), (3a)].

$$S + h\nu \rightarrow S^* \quad (1)$$

$$S^* + Co^{III} \rightarrow S^+ + Co^{II} \quad (2)$$

$$Co^{II} + H^+ \xrightarrow{Pt/pva} 1/2H_2 + Co^{III} \quad (3)$$

$$Co^{II} + S^+ \rightarrow S + Co^{III} \quad (3a)$$

Step (3) is essentially quantitative in the presence of the colloidal Pt/pva catalyst.[4] The rate constants of the electron transfer processes are governed by the respective reduction potentials and the electron self-exchange rate constants of the reaction partners. As the driving force for eqn. (2) is reduced (*i.e.* the reduction potential of the cobalt complex becomes more negative), energy transfer from the excited state competes with electron transfer. On the other hand, a more negative reduction potential is desirable for $H_2$ evolution [eqn. (3)]. These conflicting demands need to be optimised.

The electron transfer rates of the $CoN_6$ cages are lower than that of $MV^{2+}$, because of their lower self-exchange rates ($k_{11}$ *ca.* 1–5 $M^{-1}\ s^{-1}$),[7] and this is a limiting factor in their use. The $CoN_3S_3$ cages however, have much higher self-exchange rate constants ($k_{11}$ *ca.* $10^4\ M^{-1}\ s^{-1}$),[8,9] but their cobalt(II) complexes are weaker reductants than the $CoN_6$ cages (by *ca.* 350 mV) so $H_2$ production is modest at pH ⩽ 5.[4,10] Synthetic efforts were therefore directed to the preparation of $CoN_3S_3$ cages with contracted cavities,[10] as these should have a more negative reduction potential. Recent efforts to prepare $[Co(Me_2\text{-}N_3S_3sar)]^{3+}$ led to a novel and efficient method of synthesising the contracted cavity cage $[Co(Me_2\text{-}N_3S_3absar)]^{3+}$ ($[CoL]^{3+}$, Fig. 1), in which a methylene unit is missing from the cap.[11] The smaller cavity, and the inductive effect of the apical methyl group lowered the reduction potential by *ca.* 200 mV compared with other $CoN_3S_3$ cages[10] ($E$ = −0.20 V *vs.* NHE, reversible one-electron process).‖ The cobalt(II) complex should reduce protons in the presence of a colloidal platinum catalyst (at pH ⩽ 3), and together with the high electron self-exchange rate ($k_{11} = 1.3 \times 10^4\ M^{-1}\ s^{-1}$),[9] this made it a promising candidate for use as an electron transfer agent for light-induced $H_2$ formation.

Excited-state quenching reactions were studied with both $[Ru(bpy)_3]^{2+}$ and anthracene carboxylate ($AA^-$) as sensitisers. Earlier results with $MV^{2+}$ had shown that $AA^-$ had a much higher cage escape yield ($\phi_{ce}$ = 1) than $[Ru(bpy)_3]^{2+}$ ($\phi_{ce}$ = 0.25).[12] The rate constants for energy and electron transfer involving the excited singlet and triplet states of $AA^-$ with $[CoL]^{3+}$ are shown in Fig. 2. Both the excited $^1AA^-$ and $^3AA^-$ states were quenched by $[CoL]^{3+}$ at pH = 7, but linear Stern–Volmer plots (indicating dynamic quenching) were obtained only for the $^3AA^-$ quenching ($[CoL]^{3+} \leqslant 5 \times 10^{-3}$ M).** The non-linear Stern–Volmer plots obtained for $^1AA^-$ quenching imply some initial ground-state complex formation. This was also concluded from $k_q = 2 \times 10^{11}\ M^{-1}\ s^{-1}$ (obtained for low quencher concentrations where a degree of linearity was observed in the Stern–Volmer plots), which is higher than diffusion limited rate constants (*ca.* $10^{10}\ M^{-1}\ s^{-1}$). Both excited states are capable of reducing $[CoL]^{3+}$ [Fig. 2, $E°(^1AA^{\bullet}\text{–}AA^-)$ = −2.2 V *vs.* NHE, $E°(^3AA^{\bullet}\text{–}AA^-)$ = −0.88 V].[12] However, with an energy of 2.67 eV for the $^1A_1 \rightarrow {}^1T_1$ transition of $[CoL]^{3+}$, energy transfer from $^1AA^-$ to $Co^{III}$ is also possible.

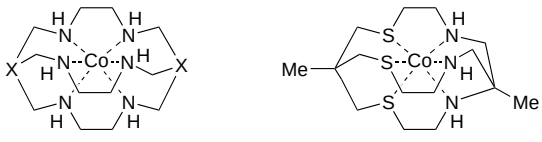

**Fig. 1** Cobalt cage complexes

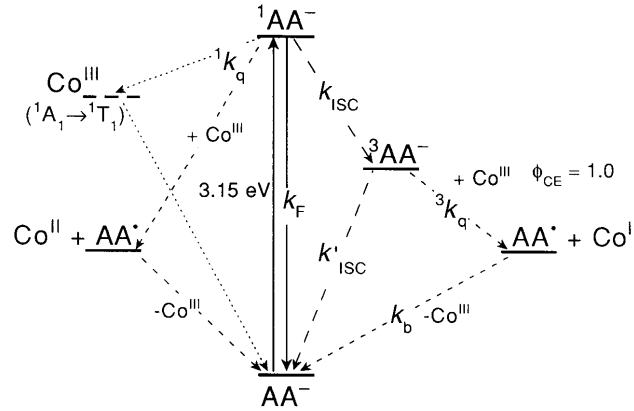

**Fig. 2** Energy and electron transfer processes between $AA^-$ and $[CoL]^{3+}$. Radiative transitions (———), non-radiative transitions (— — —), electron transfer processes (- - - - - -), energy transfer processes (·····). $^{III}Co$ = $[CoL]^{3+}$; $Co^{II}$ = $[CoL]^{2+}$.

$^3AA^-$ quenching to yield $[CoL]^{2+}$ occurs exclusively *via* excited-state electron transfer (efficiency *ca.* 100%, $k_q = 3 \times 10^9$ м$^{-1}$ s$^{-1}$). The very high cage escape yield and the enhanced intensity of the $^1A_1 \rightarrow {}^1T_1$ transition of $[CoL]^{3+}$ ($\lambda_{max}$ = 460 nm, $\varepsilon$ = 640 м$^{-1}$ cm$^{-1}$) allowed us to measure for the first time the bleaching†† of the ground-state absorption of a cobalt(III) cage complex due to electron transfer (Fig. 3). The cage escape yield was determined to be close to unity, and interestingly, the rate constant for the back electron transfer ($k_b = 7 \times 10^8$ м$^{-1}$ s$^{-1}$, Fig. 2) was smaller than that obtained with $MV^{2+}$ ($k_b = 2.7 \times 10^9$ м$^{-1}$ s$^{-1}$).[12] Thus, the overall quantum yield for the light-induced charge separation giving $[CoL]^{2+}$ and AA· is very high. Assuming a quencher concentration of $5 \times 10^{-4}$ м, 13% of the excited singlet state is deactivated *via* electron/energy transfer to $[CoL]^{3+}$, 6% is reemitted as fluorescence, and the yield of triplet formation is 81%. If only the triplet state participates effectively in the electron transfer to $[CoL]^{3+}$, 80% of the initially absorbed photons lead to the charge-separated state ($[CoL]^{2+}$ + AA·). Steady-state photolysis experiments with $H_4$edta as a sacrificial electron donor confirmed the quantum yield of $\eta$ = 0.8 for the formation of $[CoL]^{2+}$. The main contribution to the electron transfer and charge separation is from the $^3AA^-$ state, whereas energy transfer predominates over electron transfer from $^1AA^-$, which is also the case for $MV^{2+}$.[12] Comparing the excitation energy (3.15 eV) with the energy of the products (1.13 eV) after charge separation, 36% of the excitation energy is stored (Fig. 2).

$[CoL]^{3+}$ excited-state electron transfer with $[Ru(bpy)_3]^{2+}$ as photosensitiser ($k_q = 8.9 \times 10^8$ м$^{-1}$ s$^{-1}$) has a comparable quenching rate constant to $MV^{2+}$ ($k_q = 9.6 \times 10^8$ м$^{-1}$ s$^{-1}$),[4] but is higher than those for $Co^{III}N_6$ cages with similar reduction potentials ($[Co(Cl_2\text{-sar})]^{3+}$: $k_q = 2.2 \times 10^8$ м$^{-1}$ s$^{-1}$, $[Co(sep)]^{3+}$: $k_q = 1.4 \times 10^8$ м$^{-1}$ s$^{-1}$),[4] as expected on the basis of the higher self-exchange rates of the $CoN_3S_3$ cages.[8,9]

Unfortunately, the back-electron transfer rate constant and the yield of electron transfer and charge separation could not be measured because of the overlap of the $[CoL]^{3+}$ and $[Ru(bpy)_3]^{2+}$ absorptions at *ca.* 460 nm.

$[CoL]^{3+}$ was able to mediate the photoinduced $H_2$ formation at pH 5 (standard conditions with $MV^{2+}$) with $[Ru(bpy)_3]^{2+}$ as photosensitiser‡‡ ($\eta$ = 0.004) despite the relatively positive potential compared with that of $MV^{2+}$–$MV^{\cdot+}$ ($\eta$ = 0.1; $E°$ = −0.44 V). A similar complex with a potential of *ca.* −0.4 V should give very efficient conversion, and this is now being sought.

Although $AA^-$ does not possess an absorption band in the visible region of the spectrum, as long as energy transfer processes to the $^3AA^-$ state take place, its favourable high cage escape yield can be utilised. Energy transfer from the $^3$MLCT state of $[Ru(bpy)_3]^{2+}$ to $AA^-$ gives the $^3AA^-$ state in very high yield.[13] More efficient storage of solar energy could thus be achieved using a series of molecules designed with the appropriate properties to optimise the efficiency of each step in the system. Antenna molecules which absorb a large part of the solar spectrum[14] can be used to transfer light energy efficiently to anthracene. An assembly consisting of an antenna molecule, anthracene and a stable $CoN_3S_3$ cage of the type described here has the potential for efficient conversion of light energy to chemical energy.

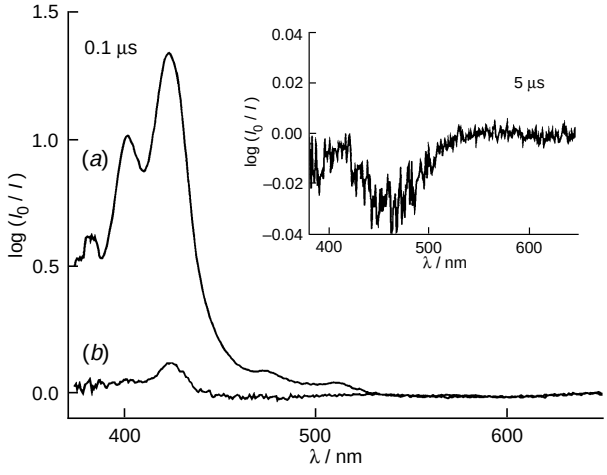

**Fig. 3** Transient absorption spectra. (*a*) $AA^-$ ($5 \times 10^{-4}$ м) in water; 100 ns after laser pulse ($XeF_2$ excimer, 50 mJ pulse$^{-1}$). (*b*) $AA^-$ ($5 \times 10^{-4}$ м) + $[CoL]^{2+}$ ($3.33 \times 10^{-3}$ м); 100 ns after laser pulse. Insert: as (*b*) but 5 μs after laser pulse.

C. K. thanks the 'Fonds zur Förderung der Wissenschaftlichen Forschung' (Project J0951-CHE) for financing his stay both at the ANU and at the CSIRO, Australia.

‖ Cyclic voltammetry was performed in 1.0 м KCl (purged with $N_2$) using an EG & G Princeton Applied Research model 174 A polarographic analyser and a model 175 universal programmer, a platinum flag counter electrode, a Ag/AgCl reference electrode, and either a hanging mercury drop electrode (EG&G PAR model 303) or a F-doped $SnO_2$ covered glass sheet (TCO-glass, electrode area 1.5 cm$^2$) as working electrode. The concentration of $[CoL]^{3+}$ was $4 \times 10^{-3}$ м.

** Stern–Volmer plots of excited singlet state quenching were obtained using fluorescence emission, measured with a Perkin Elmer LS 50 luminescence spectrometer. The kinetics of quenching of $^3AA^-$ and $^3$MLCT of $[Ru(bpy)_3]^{2+}$ were investigated by measuring the lifetime of the triplet–triplet absorption of anthracene at 425 nm, using a 150 W xenon lamp (analysing light), a Bausch & Lomb high-intensity monochromator (1350 grooves mm$^{-1}$), and an AMI 9658b photomultiplier. Transient absorption spectra were obtained using an EG & G Princeton Applied Research Model 1460 optical multichannel analyser. As excitation light ($\lambda_{ex}$ = 351 nm), a Lambda Physik LPX 100 excimer laser was used ($XeF_2$).

†† $[CoL]^{2+}$ has a much weaker absorption at 465 nm ($\varepsilon$ = 100 м$^{-1}$ cm$^{-1}$) and a weak band at 550 nm ($\varepsilon$ = 80 м$^{-1}$ cm$^{-1}$).

‡‡ Buffered solutions (pH 5) containing $3.75 \times 10^{-4}$ м $[Ru(bpy)_3](ClO_4)_2$, $2 \times 10^{-3}$ м electron transfer agent ($MV^{2+}$ or $[CoL]^{3+}$), $5 \times 10^{-5}$ м colloidal platinum catalyst (stabilised by polyvinyl alcohol), and $2 \times 10^{-2}$ м $H_4$edta, were irradiated using a 150 W tungsten lamp. The amount of $H_2$ evolved was measured by GC as described in ref. 4.

# Synthesis and catalytic properties of large-pore Sn-β and Al-free Sn-β molecular sieves

**N. K. Mal and A. V. Ramaswamy***

*National Chemical Laboratory, Pune-411 008, India*

**Sn-β and Al-free Sn-β (large pore, 12-membered ring channels) molecular sieves prepared by hydrothermal synthesis and characterised by XRD, FTIR and sorption techniques are distinguished by their acidic and oxidation properties, in the acetylation of 1,3,5-trimethylbenzene (1,3,5-TMB) with acetyl chloride and in the oxidation of *m*-cresol and 1,3,5-TMB with aqueous $H_2O_2$, respectively.**

Following the synthesis of medium-pore (10-membered ring) TS-1[1] and its use in shape-selective oxidation reactions on a commercial scale in the hydroxylation of phenol,[2] many attempts have been made to synthesize large pore (12 MR), three-dimensional Al-free Ti-β, without much success, unless trivalent metal ions of $Al^{3+}$ were present in the lattice.[3–6] Recently, Camblor *et al.*[7] reported the synthesis of Al-free Ti-β using seed crystals, and this material has been used effectively for the epoxidation of alkenes and for oxidation of relatively bulkier organic substrates.[8] We earlier reported the synthesis of medium-pore Sn-sil-1 (MFI structure), which was found to be less active than TS-1 in the hydroxylation of phenol[9] but more active than TS-1 in the oxidation of ethylbenzene[10] under similar conditions. In this report, for the first time, we describe the synthesis of large-pore, Sn-β and Al-free Sn-β molecular sieves, their characterization by XRD, FTIR and sorption techniques and catalytic activity in the hydroxylation of phenol, oxidation of *m*-cresol and 1,3,5-TMB in presence of aqueous $H_2O_2$ and acetylation of 1,3,5-TMB with acetyl chloride (AcCl).

The hydrothermal synthesis of Sn-β was carried out using gels with the following molar composition: 1.0 $SiO_2$ : 0.0–0.0125 $SnO_2$ : 0.0–0.03 $Al_2O_3$ : 0.52–0.70 TEAOH : 20 $H_2O$. In a typical preparation, 0.71 g of $SnCl_4 \cdot 5H_2O$ (98%, Loba Chem) in 10 g of $H_2O$ was added to 41.7 g of tetraethylorthosilicate (TEOS) (99.9%, Aldrich). After 15 min, 58.9 g of tetraethylammonium hydroxide (TEAOH) (35 mass% aqueous solution, Aldrich) was added under vigorous stirring for 1 h. To this reaction mixture 0.63 g of $Al_2(SO_4)_3 \cdot 16H_2O$ in 15 g $H_2O$ was added and stirred for another 1 h. 8.7 g of $H_2O$ was then added to the clear solution and stirred for 2 h. The resultant clear solution was charged into a stainless-steel autoclave and heated at 415 K under autogenous pressure and static conditions for 10 days to complete the crystallization. The resultant product was filtered, washed with deionized water, dried at 383 K and calcined at 823 K for 16 h. This sample is referred to as A. One more such Sn-β sample was prepared with different Al and Sn contents (Si/Al = 30.0 in gel and 14.7 in crystalline product and Si/Sn = 200 in gel and 150 in crystalline product). Dealuminated Sn-β (sample B) was prepared by refluxing 4 g of sample A with 60 ml of 5 M HCl for 3 h at 383 K. This treatment was repeated once more after filtration. This sample was filtered and washed thoroughly with distilled water until free of all acid and finally dried and calcined at 723 K for 12 h. Sample C was prepared following a similar procedure that was used for the synthesis of sample A, except that 0.5 g of B was added in place of 0.63 g of $Al_2(SO_4)_3 \cdot 16H_2O$. Two β zeolite samples (without Sn) were also prepared with different $SiO_2/Al_2O_3$ ratios (30.0 and 250). Al-free β (or silicalite) was prepared by the dealumination of zeolite-β of $SiO_2/Al_2O_3$ molar ratio of 250.

The XRD profiles of all as-synthesized and calcined samples match well with the BEA topology. No peaks due to $SnO_2$ or crystalline impurity phases are seen. The crystallinity of as-synthesized β is maximum, and this sample was considered to be the reference sample. Sn-β (A), Al-free Sn-β (C), dealuminated Sn-β (B) and dealuminated β (silicalite) are relatively less crystalline (approximately 96, 87, 67 and 55%, respectively) with respect to the reference sample. The SEM micrographs show that the particle size of all the samples is $< 0.3$ μm. The framework IR spectra of Sn samples (in Nujol mull) show a peak at *ca.* 957 $cm^{-1}$ (Fig. 1). This band which is intense in the case of Al-free Sn-β (C), is not observed in Sn-free β-zeolites. This band has been assigned to Si–O–M vibrations or Si–O(H) defect groups promoted by framework M from the possible substitution of heteroatom (M) in the Si–O–Si units.[9,10] $N_2$ adsorption isotherms at 77 K of Sn-β samples are characteristic of microporous materials. The surface areas are typically in the region of 650 $m^2\ g^{-1}$ for all the samples (Table 1). The mesopore (*t*-area) contribution is rather small in the case of Sn-β and Al-free Sn-β samples (35.6 and 57.0 $m^2\ g^{-1}$, respectively) but significant in the dealuminated β samples (120–160 $m^2\ g^{-1}$). The micropore volumes are in the range 0.20–0.25 ml $g^{-1}$ for all samples. The amounts of $H_2O$, *n*-hexane, cyclohexane and *m*-xylene adsorbed on these samples at 298 K and at $p/p_o$ of 0.5 (gravimetric, Cahn electrobalance) are included in Table 1. The comparable sorption capacity of Sn-containing and Sn-free β samples indicates that the micropore volumes are well maintained and that occluded $SnO_2$-type species may not be present in the Sn-containing samples.

The results on the catalytic activity of all the β samples are summarised in Table 2. The catalytic activity of the β, Sn-β and

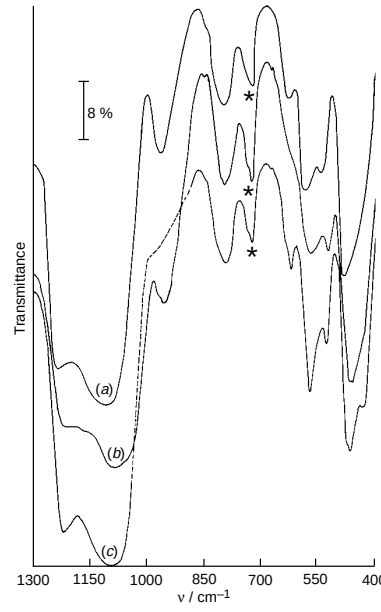

**Fig. 1** FTIR spectra of Al-free Sn-β sample (*a*), Sn-β sample with Si/Al = 28.5 and Si/Sn = 78.8 (*b*) and β sample with Si/Al = 50.3 (*c*). The absorption at 957 $cm^{-1}$ is similar to that observed for Ti-, V- and Sn-MFI and -MEL structures. * Nujol peak.

[a] Catalyst/substrate = 10, 20, 20 mass% in the case of phenol, *m*-cresol and 1,3,5-TMB, respectively; substrate/$H_2O_2$ (mole) = 3.0; solvent/substrate (mole) = 20; reaction time = 15 h; TON is defined as the mole of substrate converted per mole of metal ion (Al + Sn). [b] Batch reactor; $T$ = 348 K; solvent = $H_2O$, $H_2O_2$ efficiency = mol% $H_2O_2$ consumed in the formation of parabenzoquinone, catechol and hydroquinone. [c] Parr autoclave; $T$ = 373 K; solvent = $H_2O$ : acetonitrile (2 : 1), $H_2O_2$ efficiency = mol% $H_2O_2$ consumed in the formation of 2,5-dihydroxytoluene, 3,4-dihydroxytoluene, 3-hydroxybenzyl alcohol and 3-hydroxybenzaldehyde. [d] Batch reactor; $T$ = 348 K; solvent = acetonitrile, $H_2O_2$ efficiency = mol% $H_2O_2$ consumed in the formation of 3,5-dimethylbenzyl alcohol, 3,5-dimethylbenzaldehyde and 2-hydroxy-1,3,5-TMB. [e] Down-flow, fixed-bed reactor; $T$ = 428 K; 1,3,5-TMB/acetyl chloride (AcCl) (mol) = 3.0, WHSV = 1.0 h$^{-1}$, analysis after 1 h run. [f] Product selectivity (mass%) for 3,5-dimethylbenzaldehyde. [g] Conversion (mass%) of acetyl chloride (AcCl). [h] Product selectivity for 2,4,6-trimethylacetophenone.

Al-free Sn-β samples can be rationalised in terms of activity due to acidic properties (depending on the Si/Al ratio) and oxidation properties (isolated $Sn^{4+}$ sites) or a combination of the two. All the Sn-containing samples are active in the hydroxylation of phenol, and oxidation of *m*-cresol and 1,3,5-TMB with aqueous $H_2O_2$ to different degrees. Both deAl-Sn-β (B) and Al-free Sn-β (C) samples show consistantly higher $H_2O_2$ efficiency in all the three test reactions, indicating the absence of acid sites (Si/Al > 3000). Al-free β (silicalite) shows negligible activity in the oxidation of *m*-cresol and 1,3,5-TMB (no active $Sn^{4+}$ ions) and in the acetylation of 1,3,5-TMB (no acidity). In the hydroxylation of phenol and oxidation of *m*-cresol and 1,3,5-TMB, the $H_2O_2$ efficiency over deAl-Sn-β (B) was lower than over Al-free Sn-β (C), while the TON is in the same order. The $H_2O_2$ efficiency in hydroxylation of phenol over Sn-containing β samples was less than that obtained with Sn-sil-1 (MFI structure).[9] This may be due to the more selective nature of the medium-pore Sn-sil-1 than the large pore Sn-containing β samples for relatively small molecules like phenol. In the oxidation of *m*-cresol, 75.4 mol% $H_2O_2$ efficiency could be achieved over Al-free Sn-β and 2-methylhydroquinone was detected as the major product. In the oxidation of *m*-cresol, both deAl-Sn-β (B) and Al-free Sn-β (C) show better $H_2O_2$ efficiency (18.9 and 24.5%, respectively) and TON (7.7 and 6.6, respectively) than Sn-β (A) ($H_2O_2$ efficiency = 4.2% and TON = 1.0). Sn-β (A) is not a good catalyst for the oxidation reaction. 3,5-Dimethylbenzaldehyde was detected as the major product in the oxidation of 1,3,5-TMB.

The β and Sn-β zeolites are active in the acetylation of 1,3,5-TMB with acetyl chloride. Under the conditions of the reaction, the conversion of acetyl chloride is related to the acidity (Si/Al ratio) of the sample. While both Sn-β (Si/Sn = 150 and Si/Al = 14.7) and β (Si/Al = 13.9) give a very high conversion (99.9%) of acetyl chloride, the selectivity for 2,4,5-trimethylacetophenone is higher on Sn-β (94.6%) than on β zeolite (82.0 mass%). The reason for the enhancement of selectivity over Sn-containing β zeolite is not clear at the moment. When the acetylation of 1,3,5-TMB was carried out in the absence of any catalyst (only porcelain beads were loaded in the reactor), the conversion of acetyl chloride was only 5.2%, which is slightly less than over Al-free Sn-β (C) sample (6.4%). This indicates that very weak acidity is associated with $Sn^{4+}$ ions in the zeolite structure.

In conclusion, a large-pore zeolite (BEA) with Sn in the framework has been synthesized for the first time, which is able to catalyse oxidation of bulkier organic substrates with aqueous $H_2O_2$ in the absence of acidity (Al-free state) and acetylation with acetyl chloride when acidic (low Si/Al ratio), with some selectivity advantages due to the presence of $Sn^{4+}$ ions.

Nawal Kishore is thankful to CSIR, New Delhi for a senior research fellowship.

**$[Mo_2(MeCN)_8][BF_4]_4$ reacts with α,ω-dicarboxylic acids $[HO_2C(CH_2)_nCO_2H$, $n$ = 0–8] to form salts with empirical formula $[Mo_2\{O_2C(CH_2)_nCO_2\}(MeCN)_x][BF_4]_2$; the X-ray crystal structure of the butanedioic salt $[Mo_4\{\eta^2\text{-}\mu\text{-}O_2C(CH_2)_2CO_2\text{-}\mu\text{-}\eta^2\}_2(MeCN)_{12}][BF_4]_4\cdot 3MeCN$ is reported together with the use of the complexes as catalysts for the polymerization of norbornene.**

The $Mo^{II}Mo^{II}$ quadruply bonded neutral complex $[Mo_2(\mu\text{-}O_2CMe)_4]$ is known to react with dicarboxylic acids to give insoluble polymeric powders[1] which cannot be fully structurally characterized and which have limited subsequent chemical reactivity. Herein we detail the reactions of the tetracationic $Mo^{II}Mo^{II}$ salt $[Mo_2(MeCN)_8][BF_4]_4$[2] with α,ω-dicarboxylic acids $[HO_2C(CH_2)_nCO_2H$, $n$ = 0–8] to form red, soluble complex salts with empirical formula $[Mo_2\{O_2C(CH_2)_nCO_2\}(MeCN)_x][BF_4]_2$.‡ The tetranuclear butanedioic salt $[Mo_4\{\pi^2\text{-}\mu\text{-}O_2C(CH_2)_2CO_2\text{-}\mu\text{-}\eta^2\}_2(MeCN)_{12}][BF_4]_4\cdot 3MeCN$ **1** represents the first structurally characterized M–M quadruply bonded dicarboxylate complex (Fig. 1).§ The unit cell contains one centrosymmetric complex ion of formula $[Mo_4\{\eta^2\text{-}\mu\text{-}O_2C(CH_2)_2CO_2\text{-}\mu\text{-}\eta^2\}_2(MeCN)_{12}]^{4+}$ along with four $BF_4^-$ counter ions and three MeCN solvent molecules. The $Mo^{II}$ atoms are six-coordinate and their environments are very similar. They are linked by a short [2.1415(6) Å] quadruple bond and, *trans* to this, each has a long interaction with an axial MeCN molecule [Mo(1)–N(50) 2.712(5), Mo(2)–N(60) 2.674(5) Å]. The remaining donors, nitrogen atoms from two MeCN molecules (mean Mo–N 2.162 Å) and an oxygen atom from each of two carboxylate groups (mean Mo–O 2.084 Å) occupy a square plane with *cis* geometry. The two butanedioic dianions each have two bridging functions. First, each of the carboxylate groups bridges the Mo–Mo bond; secondly, each butanedioic ligand links the two halves of the tetranuclear complex together. The coordination environment about each of the quadruply bonded Mo–Mo cores is essentially identical to that of the structurally characterized, red dimolybdenum(II,II) monocarboxylate salt *cis*-$[Mo_2(\mu\text{-}O_2CMe)_2(MeCN)_6][BF_4]_2$.[3] The coordination of the dicarboxylate ligands in **1** is the same as in the tetranuclear ruthenium(I) pentanedioate complex $[Ru_4(CO)_8\{O_2C(CH_2)_3CO_2\}_2(PBu_3)_4]$[4] and the polymeric copper(II) butanedioate complex $\{[Cu_2\{O_2C(CH_2)_2CH_2)_2\}(H_2O)_2]\cdot 2H_2O\}_n$,[5] where again the individual bimetallic centres are spanned by two $^-O_2C(CH_2)_nCO_2^-$ ligands in a *cisoid* fashion.

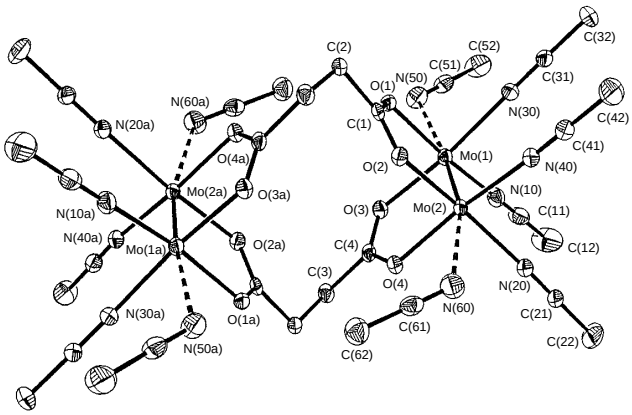

**Fig. 1** Crystal structure of **1**. Selected bond lengths (Å) and bond angles (°): Mo(1)–O(1) 2.091(3), Mo(1)–O(3) 2.088(3), Mo(2)–O(2) 2.080(3), Mo(2)–O(4) 2.077(3), Mo(1)–N(10) 2.162(4), Mo(1)–N(30) 2.172(4), Mo(1)–N(50) 2.712(5), Mo(2)–N(20) 2.163(4), Mo(2)–N(40) 2.152(4), Mo(2)–N(60) 2.674(5), Mo(1)—Mo(2) 2.145(6); O(3)–Mo(1)–O(1) 91.53(12), O(3)–Mo(1)–Mo(2) 91.21(9), O(1)–Mo(1)–Mo(2) 91.10(9), O(3)–Mo(1)–N(10) 88.66(14), O(1)–Mo(1)–N(10) 166.2(2), Mo(2)–Mo(1)–N(10) 102.72(13), O(3)–Mo(1)–N(30) 166.3(2), O(1)–Mo(1)–N(30) 89.18(14), Mo(2)–Mo(1)–N(30) 102.43(11), N(10)–Mo(1)–N(30) 87.4(2), O(3)–Mo(1)–N(50) 86.0(2), O(1)–Mo(1)–N(50) 84.01(13), Mo(2)–Mo(1)–N(50) 174.28(11), N(10)–Mo(1)–N(50) 82.2(2), N(30)–Mo(1)–N(50) 80.5(2), O(4)–Mo(2)–O(2) 90.64(12), O(4)–Mo(2)–Mo(1) 90.70(9), O(2)–Mo(2)–Mo(1) 90.80(9), O(4)–Mo(2)–N(40) 166.2, O(2)–Mo(2)–N(40) 86.00(14), Mo(1)–Mo(2)–N(40) 102.75(11), O(4)–Mo(2)–N(20) 90.11(14), O(2)–Mo(2)–N(20) 168.6(2), Mo(1)–Mo(2)–N(20) 100.52(12), N(40)–Mo(2)–N(20) 90.6(2), O(4)–Mo(2)–N(60) 76.1(2), O(2)–Mo(2)–N(60) 83.3(2), Mo(1)–Mo(2)–N(60) 165.43(11), N(40)–Mo(2)–N(60) 90.2(2), N(20)–Mo(2)–N(60) 85.9(2).

The IR spectrum of the solid (KBr matrix) contained prominent carboxylate $\nu_{asym}$(OCO) and $\nu_{sym}$(OCO) vibrations at 1536 and 1443 $cm^{-1}$, respectively, with the value of $\Delta\nu$(OCO) $\{\nu_{asym} - \nu_{sym} = 93\ cm^{-1}\}$ in keeping with that recorded for complexes in which the carboxylate ligand bridges short M–M bonds {*e.g.* $\Delta\nu$(OCO) = 85 $cm^{-1}$ for $[Mo_2(\mu\text{-}O_2CMe)_4]$}. The $[Mo_2\{O_2C(CH_2)_nCO_2\}(MeCN)_x][BF_4]_2$ complexes with $n$ = 3–8 had $\Delta\nu$(OCO) values in the region 74–99 $cm^{-1}$, suggesting that the dicarboxylate ligands in these species were also bridging bidentate. $\Delta\nu$(OCO) values for the ethanedioate ($n$ = 0) and propanedioate ($n$ = 1) complexes were significantly larger (251 and 155 $cm^{-1}$, respectively), implying a different coordination mode of the dicarboxylate OCO moieties. The shorter hydrocarbon chain linking the two carboxylate functions of the ethanedioate and propanedioate ligands probably imposes steric constraints which inhibit the formation of a discrete tetranuclear entity.

As with *cis*-$[Mo_2(\mu\text{-}O_2CMe)_2(MeCN)_6][BF_4]_2$ complex **1** is quite air-sensitive both in solution (acetonitrile) and in the solid state and therefore must be stored under $N_2$. However, the cyclic voltammogram of **1** in acetonitrile solution and under $N_2$ showed the complex to be electroinactive between the switching potentials of +2.0 to −2.0 V (*vs.* Ag/AgCl).¶

In the presence of $EtAlCl_2$ as a cocatalyst the molybdenum complexes ($n$ = 2–8) catalysed the room temperature ring-opening metathesis polymerization of norbornene (as a solution in chlorobenzene). The reactions were instantaneous, and GPC analysis of the products showed that they comprised mainly a mixture of high molecular mass polymer ($\bar{M}_w$ ranged from 125 000 to 691 000) and low molecular mass oligomers ($\bar{M}_w$ *ca.* 500). $^{13}C\{^1H\}$ NMR spectral analysis of the polymers[6] showed them to have a blocky distribution of *cis* and *trans* double bonds. The *cis* content ($\sigma_c$) of the polymers was in the narrow

range 0.34–0.44, indicating that the microstructure of the polynorbornene was essentially independent of the catalyst composition (*i.e.* the chain length of the dicarboxylate ligand).

‡ Procedures conducted under $N_2$ using dry solvents. $[Mo_2(MeCN)_8][BF_4]_4$ (0.23 mmol), $HO_2C(CH_2)_nCO_2H$ (0.23 mmol) and MeCN (25 $cm^3$) gently heated for 1 h. The red solution was reduced *in vacuo* to low volume and small amounts of $CH_2Cl_2$ (or hexane) added periodically to slowly induce product precipitation.

§ *Crystal data* for **1**: $C_{38}H_{53}B_4F_{16}Mo_4N_{15}O_8$, red plate, crystal dimensions 0.68 × 0.30 × 0.18 mm, triclinic, space group $P\bar{1}$, $a$ = 9.842(1), $b$ = 10.744(1), $c$ = 16.792(2) Å, $\alpha$ = 92.35(1), $\beta$ = 92.77(1), $\gamma$ = 113.65(1)°, $U$ = 1621.1(3) $Å^3$, $\mu$ = 1.617 $mm^{-1}$, $Z$ = 1, $F(000)$ = 782. Data were collected at 153(2) K on a Siemens P4 four-circle diffractometer using graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). Unit-cell parameters were determined by non-linear least-squares refinement of 37 accurately centred reflections ($10 < 2\theta < 25°$). Using 1.2° ω-scans at 6° $min^{-1}$, 6083 reflections were collected in the range $4 < 2\theta < 50°$, 5716 unique reflections ($R_{int}$ = 0.021) were used in the refinement. Crystal stability was monitored by recording three check reflections every 97 reflections and no significant variation was observed, although the crystal cracked towards the end of the data collection. The data were corrected for Lorentz and polarisation effects and a semi-empirical absorption correction was applied ($T_{max}$ = 1.000, $T_{min}$ = 0.838). The structure was solved by direct methods,[7] which revealed most of the structure and the remaining non-hydrogen atoms were located from difference Fourier maps. Hydrogen atoms were inserted at calculated positions (except for those on the partial occupancy acetonitrile) and assigned isotropic temperature factors tied to the equivalent isotropic $U$ of their carrier atoms. The non-hydrogen atoms were refined with anisotropic atomic displacement parameters. All the data were used for refinement on $F^2$ which converged with $wR2$ = 0.1319, GOF = 1.028 and the conventional $R$ = 0.0463 [$I > 2\sigma(I)$] for 404 parameters. 15 restraints were applied to the geometry and anisotropic displacement parameters of the partial occupancy solvent molecule. The final difference map showed no significant residual electron density, the largest peak (1.0 e $Å^{-3}$) being close to Mo(1). All programs used in the structure refinement are contained in the SHELXL-93 package.[8]

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference nunmber 182/354.

¶ Cyclic voltammetry: glassy carbon disc and platinum wire as working and counter electrodes, respectively; Ag/AgCl as reference electrode; MeCN–$[NBu_4][ClO_4]$ as solvent–supporting electrolyte; $E_{\frac{1}{2}}$ = +0.49 V (*vs.* Ag/AgCl) for the ferrocene–ferrocenium couple.

# Hydride and proton transfer reactions in gaseous ion–molecule complexes [$PhCH_2^+$ $HOCH_2CH_2OH$]

**Henri E. Audier,*[a] Fadil Dahhani,[a] Arielle Milliet[a] and Dietmar Kuck*†[b]**

**Benzyl cations and ethylene glycol react in the gas phase and form covalently bound adducts, as shown by slow and site-selective proton exchange, but also undergo irreversible hydride transfer giving two ion–neutral complexes, [$PhCH_3$ $HOCH_2CHOH^+$] and [$PhHCH_3^+$ $HOCH_2CHO$], which interconvert by a rapid and non-selective proton exchange.**

Ion–molecule reactions in the gas phase are often proceeded by hydride transfer from the neutral to the cationic partner of the encounter complex. For example, loss of methane and isobutane from protonated dimethyl ether[1] and protonated alkylbenzenes,[2–4] respectively, have been shown to occur by hydride abstraction within a complex between a cationic and a neutral fragment. In many cases, however, this process is inhibited by a variety of competing reactions; in particular, the cation may react as a proton donor (*i.e*. a Brønsted acid) rather than as a hydride acceptor (*i.e*. a Lewis acid).

A particularly interesting hydride-abstracting agent is the benzyl cation. In contrast to many alkyl cations, in particular *iso*-$C_3H_7^+$ and *tert*-$C_4H_9^+$, benzyl cations cannot react as a proton donor. Moreover, $PhCH_2^+$ is a 'soft' hydride abstractor owing to the relative weakness of the benzylic C–H bonds of toluene, and skeletal rearrangement would lead to an inert isomer, *viz*. the tropylium ion.

Here we present our preliminary results on the ion–molecule reactions between benzyl cations and ethylene glycol, a rare case in which the formation of isomeric covalent and complex-bound intermediates resulting from a hydride transfer reaction can be demonstrated. Benzyl cations were generated in the presence of ethylene glycol in the chemical ionization source of a double-focusing mass spectrometer using water as a reagent gas.‡ Adduct ions of elemental composition $C_9H_{13}O_2^+$ (charge-to-mass ratio *m/z* 153) were formed and then accelerated and separated from all other ions by a fixed, constant magnetic sector field. In general, ions thus selected have lifetimes of at least *ca*. 10–30 μs. A fraction of ions having internal energies slightly above the fragmentation threshold are 'metastable' and may decompose spontaneously within the field-free region following the magnetic sector. The fragmentation products of these metastable ions is determined by scanning the subsequent electrostatic sector field, and the MIKE spectrum[5]§ obtained provides information on the unimolecular reactions occurring during the lifetime of the (adduct) ions.

Metastable adduct ions (*m/z* 153) formed from $C_7H_7^+$ and ethylene glycol undergo essentially three competing reactions: (i) reformation of the reactants to give ions of *m/z* 91, (ii) hydride abstraction to give ions of *m/z* 61, and, as the major contribution, (iii) formation of ions of *m/z* 93, *i.e*. protonated toluene, by a formal double hydrogen transfer.[6,7]

Protonation of 2-benzyloxyethanol yields the same products with different relative contributions (given above in parentheses), an effect which is attributed to the differences in the internal energies of the adduct ions formed by the two alternative routes.[8] Water loss is only a minor process in both cases [9(2)%].

All of the three major reaction channels (i)–(iii) are subject to mass shifts if suitable deuterium labelled precursors are studied. The results of these experiments (Table 1) indicate that only the phenylic and hydroxy group hydrogen atoms undergo exchange whereas the benzylic methylene group participates neither in hydrogen exchange nor in hydrogen transfer steps (*cf*. entries 1 and 2). The metastable adduct ions $C_9H_{13}O_2^+$ form slowly interconverting covalently bound intermediates (**2** and **3**), and rapidly interconverting ion–molecule complexes (**4** and **5**), as illustrated in Scheme 1.

Only one adduct reaction (**1** → **4**) is irreversible. Introduction of methylene group labels in the glycol molecule (entry 3) leads to distinct mass shifts for channels (ii) and (iii) together with a decrease in their relative weight; at the same time, channel (i) does not undergo a mass shift but strongly gains importance. The data clearly show that the benzyl cation abstracts a hydride ion from one of the glycol methylene groups and that this is the rate-determining step of both channels (ii) and (iii). In agreement with this, labelling of the glycol hydroxy groups (entry 4) does not significantly affect the relative weights of the three channels; however, it reveals a proton exchange between the OH groups and the aromatic nucleus [*cf*. *m/z* 61–63 (ii), *m/z* 91–93 (i) and *m/z* 94–95 (iii)].

The existence of a rate-determining step allows us to distinguish two kinds of proton exchange processes. In particular, the formation of $C_7(H,D)_7^+$ is preceded by a slow exchange whereas the ions $C_2(H,D)_5O_2^+$ and $C_7(H,D)_9^+$ generated after hydride transfer are the subject of a relatively fast exchange. Moreover, the data from the (ring-[$^2H_3$])-labelled isotopomer (entry 5) demonstrates that the exchange preceding the re-formation of $C_7H_7^+$ involves only the hydroxy protons and those at the *ortho* positions of the benzene ring, as is evident from the exclusive formation of $C_7H_4D_3^+$ ions (*m/z* 94, instead of ions *m/z* 92–94). In contrast, the other two channels again show much more efficient H/D exchange, apparently involving all of the ring protons.¶ Finally, all the above-mentioned features, including the altered relative weights of the three reaction channels, are confirmed when perdeuteriated benzyl cations are used as precursors (entries 6 and 7); in particular, the slow $H^{OH}/H^{ortho}$ exchange occurring in channel (i) is corroborated by the formation of $C_7HD_6^+$ (*m/z* 97).

The site-specific proton exchange necessarily occurs *via* covalently bound species **2** and **3**.‖ The fact that neither the benzylic methylene nor the *meta* and *para* protons are involved

**Scheme 1**

clearly excludes the intermediacy of the tropylium ion.[9,10] In agreement with this, a *meta*-methyl group strongly enhances the efficiency of the proton exchange owing to an increase of the local proton affinity of the ring positions *ortho* to the side chain.[11,12]

‡ All experiments were performed using a ZAB-2F double focusing mass spectrometer (VG Micromass, Manchester) with reversed Nier-Johnson geometry. Ions were generated by a chemical ionization source at a nominal pressure of *ca.* $10^{-5}$ mbar and at *ca.* 150 °C after introduction of the corresponding benzyl bromide (10 μl), ethylene glycol (10 μl) and water (30 μl).

§ MIKES: Mass-analysed ion kinetic energy spectrometry.

¶ The proton exchange **4** ⇌ **5** is apparently statistical if the predominant interchange of the *ortho* and *para* protons of the aromatic ring and the two oxygen-bound protons of the glycol is assumed. This result is in agreement with the almost identical proton affinities of toluene [190 kcal mol$^{-1}$ [13] (for *para* protonation) and 188 kcal mol$^{-1}$ (for *ortho* protonation[11,12]] and that of hydroxyacetaldehyde [189 kcal mol$^{-1}$ (measured recently in our laboratories)] (1 cal = 4.184 J).

‖ Hydrogen atom transfer giving the complex [6-methylenecyclohexadiene$^{\cdot+}$ ·$OC_2H_4OH$] can be safely discarded as it requires *ca.* 250 kJ mol$^{-1}$ starting from **1**.

# Surface characterisation of zirconium-doped mesoporous silica

**D. J. Jones,[a] J. Jiménez-Jiménez,[b] A. Jiménez-López,[b] P. Maireles-Torres,*[b] P. Olivera-Pastor,[b] E. Rodriguez-Castellón[b] and J. Rozière*[a]**

**Zirconium-doped mesoporous silicas of mole ratio Si/Zr from 50 to 5 are Lewis-acid catalysts, with a linear correlation between the zirconium content and total acidity.**

Much attention has been devoted to the synthesis of new mesoporous materials using surfactants as templates[1,2] since the first reports on MCM-41 type solids.[3] Mesoporous silica displays a hexagonal arrangement of cylindrical channels with diameters that vary between 16 and >100 Å, partially overcoming the small pore dimension limitations of zeolites. The low acidity of siliceous MCM-41 can be enhanced by isomorphous substitution of *e.g.* Al or $Ti^{IV}$ for Si[3–5] which specifically increases the number of Lewis-acid sites. The presence of $Zr^{IV}$ may also increase the acidity but, in addition, its invariable oxidation state may be an advantage compared with *e.g.* substitution with $Ti^{IV}$, in particular with regard to thermal stability.

The preparation of zirconium-containing mesoporous silica assisted by surfactant species (hexadecylamine) and its activity in redox catalysis has recently been described.[6] We report here a synthesis of Zr-doped mesoporous silica using hexadecyltrimethylammonium as template, and describe the total acidity and types of acid site, and structural information derived from X-ray photoelectron spectroscopy (XPS) coupled with depth profile analysis.

Si/Zr MCM-41 type compounds were prepared by adding tetraethoxysilane and zirconium tetrapropoxide to an ethanol–propanol solution at room temperature. Si/Zr ratios of 5, 25 and 50 gave samples SiZr5B, SiZr25B and SiZr50B. The solution was stirred for 15 min and then added to an aqueous solution of hexadecyltrimethylammonium bromide (25 mass%), previously stirred at 80 °C for 30 min. The surfactant/($SiO_2$ + $ZrO_2$) ratio was 0.5. For these samples, the pH was adjusted to 10.5 by addition of tetraethylammonium hydroxide. The resulting gels were stirred at 80 °C for 24 h and then at 25 °C for 48 h. The solids were recovered by filtration and washed with ethanol–propanol. A purely siliceous sample was prepared using the same experimental conditions (SiB). A further sample of Si/Zr ratio 50 was prepared, but the pH was adjusted to 2.8 by the addition of HCl (SiZr50A). All precursors were calcined in air at 540 °C, for 6 h. The ramp rate was 1 °C $min^{-1}$. Complete removal of surfactant was confirmed by elemental and thermogravimetric analyses.

Fig. 1 shows the powder X-ray diffraction patterns of the calcined Si/Zr materials. In all cases, a single diffraction peak was observed, consistent with short-range hexagonal order. Indeed, transmission electron microscopy allows a roughly hexagonal arrangement of pores to be observed. Owing to the breadth of the diffraction line, no correlation between its position and the Zr content was apparent. Neither XRD nor UV spectroscopy showed evidence for zirconium oxide.

Chemical analyses indicated that the Si/Zr ratio in the calcined phases is the same as that in the initial mixture. However, in each case, the ratio of Si/Zr at the surface, as determined from XPS, is higher than this bulk ratio. This is expected, given the greater rate of hydrolysis of Zr alkoxides relative to that of Si alkoxides. Depth profile analysis of sample SiZr25B was performed by etching with an $Ar^+$ gun, and observing the evolution of the Si/Zr ratio with time. After 5 min the surface ratio of 66 decreases to 23, and a constant value of 17 was reached after 15 min [Fig. 2(*a*)]. Single peaks were

[a] At $P/P_0 = 0.97$. [b] Calculated using the Cranston and Inkley method.[8] [c] Reduction in lattice parameter $a_0$ after calcination at 540 °C. [d] Pore wall thickness, $D$, after calcination at 540 °C; $D = a_0 - d_p$(av.), and $a_0 = 2d_{100}/\sqrt{3}$.

observed for both Si 2p and Zr $3d_{5/2}$ and the percentage of oxygen remained constant at 63% throughout the etching treatment. The O 1s peak becomes asymmetric as the amount of Zr in the samples increases. Thus for ZrSi5B, O 1s can be deconvoluted into two components, indicating two different environments for oxygen, *viz.* Si–O–Si (component at 533.0 eV) and Si–O–Zr (530.9 eV) [Fig. 2(*b*)]. The intensity ratio of these two peaks closely matches the surface Si/Zr ratio. In such heteroatom-substituted analogues of siliceous MCM-41 materials, the question arises as to the true incorporation of the heteroatom in the framework, as opposed to its presence as a segregated oxide phase. Here, the XPS signals of O 1s are at least 0.7 eV higher than that of $ZrO_2$ (530.2 eV), strong evidence in favour of the presence of framework zirconium. Further, the binding energies of Zr $3d_{5/2}$ (183.1–183.6 eV) are higher than that of $ZrO_2$ (182.2 eV) and are closer to that of $ZrSiO_4$ (183.3. eV). Preliminary results from extended X-ray absorption fine structure spectroscopy at the zirconium edge show the local structure to differ from that of $ZrO_2$, with evidence for silicon in the next nearest neighbour coordination shell.

The $^{29}$Si MAS NMR spectra of as-prepared SiZr25B shows resonances at δ−107.3, −98.6 and −89.4. After calcination, the increase in intensity of the two lower field resonances relative to that at δ−107.3 can be explained on the basis of the formation of Si–O–Zr bonds, as previously suggested for mixed $ZrO_2$–$SiO_2$ materials.[7]

All calcined compounds exhibited a reversible type IV nitrogen adsorption–desorption isotherm, with a sharp inflection at $P/P_o$ = 0.35–0.40, as is typical for MCM-type mesoporous materials. Table 1 gives the textural parameters derived from the isotherms. Surface areas lie between 973 and 1376 m² g⁻¹. The average pore size of the silica-only compound after calcination at 800 °C is lower by 25% that of its value after calcination at 540 °C. Zirconium-doped samples are more resistant, the average pore size being reduced by 12–17%. Even after calcination at 800 °C, all materials retain their mesoporous character and a high surface area. The wall thicknesses of all zirconium-containing phases are higher than that of the purely siliceous analogue, in agreement with the incorporation of zirconium into the framework. The particularly strong increase observed for the synthesis under acidic conditions may be a result of the synthetic mechanism which controls the precipitation of a solid phase from the gel mixture.

IR spectra of calcined samples after adsorption of pyridine show a virtual absence of Brønsted acid sites, and an increasing number of Lewis-acid sites with an increase in the amount of Zr present. The origin of the Lewis acidity may be attributed to the presence of $Zr^{IV}$ species with low coordination. Total acidity, determined by thermally programmed desorption of $NH_3$ follows the same trend, ranging between 0.17 and 0.77 mmol $NH_3$ g⁻¹. In particular, sample ZrSi5B is considerably more acidic than MCM-41 aluminosilicates.[5] Confirmation of the acidic character of the zirconium-doped samples is provided by their activity in the decomposition of isopropyl alcohol. Whilst purely siliceous MCM-41 (sample SiB) is not active in this reaction, calcined Si/Zr samples displayed, in contrast, a high catalytic activity (30 μmol g⁻¹ s⁻¹ at 200 °C for sample SiZr5B) and a selectivity of 99% towards production of propene, which was maintained after 20 h of reaction (Fig. 3). Inasmuch as both the location and number of active sites are key factors in the observed catalytic properties, knowledge of the ion distribution is essential. In this respect, this study has demonstrated the important contribution that XPS can make in the study of heteroatom-substituted mesoporous materials.

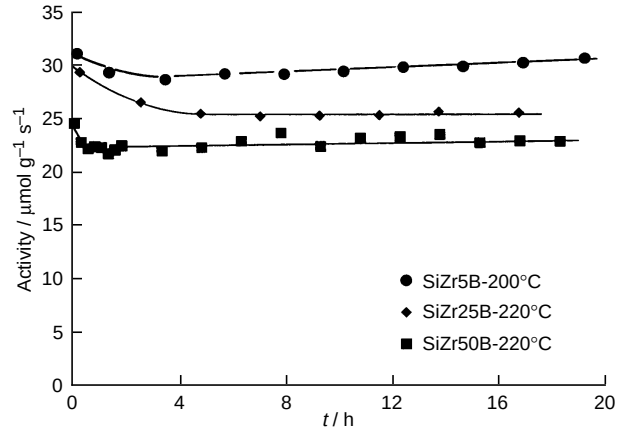

**Fig. 3** Catalytic activity of SiZr50B, SiZr25B and SiZr5B for *iso*- propyl alcohol decomposition as a function of time on stream

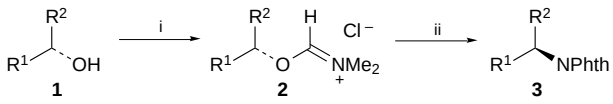
# Nucleophilic substitution of (alkoxymethylene)dimethylammonium chloride with potassium phthalimide; a convenient procedure for the synthesis of imides with inversion of configuration



**Anthony G. M. Barrett,*[a] D. Christopher Braddock,[a] Rachel A. James[a] and Panayiotis A. Procopiou*[b]**

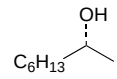
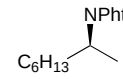
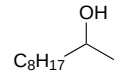
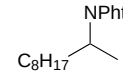
**Secondary alcohols are converted into their phthalimido derivatives with inversion of configuration *via* sequential reaction with (chloromethylene)dimethylammonium chloride and potassium phthalimide.**

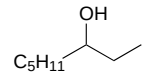
The Mitsunobu reaction is the process *par excellence* for the conversion of secondary alcohols into esters with inversion of stereochemistry.[1] In this reaction an alcohol is treated with diethyl azodicarboxylate, triphenylphosphine and a carboxylic acid to provide the required ester. The reaction can be extended to a wide range of nucleophiles in addition to carboxylic acids to provide a variety of $S_N2$ substitution products. The stereoselective preparation of amines from the corresponding alcohol can be effected *via* formation of the phthalimido derivative.[2] There are however disadvantages associated with the Mitsunobu reaction. Diethyl azodicarboxylate is unstable and potentially explosive and the by-products, triphenylphosphine oxide and diethyl hydrazinedicarboxylate, are of considerable mass making the process non-ideal from the point of view of atom economy.[3] Recently, one of us reported the use of Vilsmeier chemistry to effect the stereospecific cyclisation of hydroxyphenols to provide benzodioxans, dihydrobenzopyrans and dihydrobenzofurans *via* (alkoxymethylene)dimethylammonium salts and intramolecular $S_N2$ displacement by phenoxide.[4] This Vilsmeier chemistry has also been extended to the conversion of alcohols into esters with inversion of stereochemistry.[5,6] Herein we report a further application of this methodology to form the phthalimide derivatives of secondary alcohols.

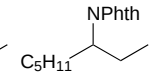


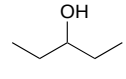


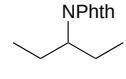


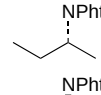


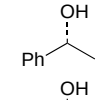


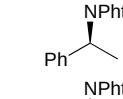


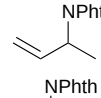












Treatment of a series of secondary alcohols **1** with (chloromethylene)dimethylammonium chloride, generated from oxalyl chloride and dimethylformamide,[7] provided the corresponding imidate salts **2**. These were then treated with potassium phthalimide at 60–70 °C to provide the phthalimide derivative **3** with inversion of stereochemistry (Scheme 1 and Table 1).† Enantiomeric purities (entries 1, 5, and 6) were established by HPLC. Clean inversion of stereochemistry was observed for entries 1 and 5 but substitution of (*R*)-1-phenylethanol proceeded with partial racemisation (entry 6, 72% ee). It is reasonable to speculate that this example either involved a mixed $S_N2/S_N1$ reaction or took place partially *via* the corresponding benzylic chloride. Several solvents were examined in these reactions of which acetonitrile was found to be superior. No reaction was observed in THF whereas reaction in DME or DMF gave the desired product in moderate yield. Furthermore the use of DMF as solvent led to partial racemisation in the preparation of (*S*)-*N*-2-octylphthalamide (58% ee). It is reasonable to assume that such partial racemisation was the result of partial substitution *via* 2-octyl chloride or *via* nucleophilic participation of the solvent (DMF) leading to inverted imidates. The imidate methodology in this paper should be of use as an alternative to the Mitsunobu reaction particularly for larger scale applications as the side products are innocuous (DMF and potassium chloride). The method is mechanistically similar to the synthesis of glycosides[8] and benzyl, allyl and *tert*-butyl ethers[9] *via* trichloroacetimidate activation.

## Footnotes

† In a typical procedure, oxalyl chloride (0.10 $cm^3$, 1.15 mmol) was added dropwise with stirring to a solution of DMF (0.09 $cm^3$, 1.17 mmol) in dry dichloromethane (1 $cm^3$) at 0 °C under nitrogen. After 5 min, the white solid was suspended in dry acetonitrile (30 $cm^3$) and (*R*)-octan-2-ol (0.16 $cm^3$, 1.0 mmol) and potassium phthalimide (1.3 g, 7 mmol) were added sequentially. The reaction mixture was heated to 65 °C for 16 h cooled and filtered. The residue, after rotary evaporation, was chromatographed on silica gel (5% ethyl acetate in hexanes) to provide (*S*)-*N*-2-octylphthalimide (0.25 g, 95%) as a colourless oil.

# A new monoclinic phase of superconducting $Tl_2Ba_2CuO_{6+\delta}$

**D. R. Pederzolli, G. M. Wltschek and J. P. Attfield**

[a] *Interdisciplinary Research Centre in Superconductivity, University of Cambridge, Madingley Road, Cambridge, UK CB3 0HE*
[b] *Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

**High-resolution time-of-flight neutron and synchrotron X-ray powder diffraction studies of the 'orthorhombic' form of the high-$T_c$ superconductor $Tl_2Ba_2CuO_{6+\delta}$ evidence both the orthorhombic (*Fmmm*) phase and a new monoclinic (*F*112/*m*) form at high excess oxygen contents δ.**

$Tl_2Ba_2CuO_{6+\delta}$ (Tl-2201) is the first member of the $Tl_2Ba_2Ca_{n-1}Cu_nO_{4+2n}$ series of high critical temperature ($T_c$) copper oxide superconductors. Unlike the other homologues, which are all tetragonal, Tl-2201 exhibits both tetragonal and orthorhombic symmetries and the physical properties of both forms vary from non-superconducting to superconducting with $T_c$ values up to 90 K.[1] Physical measurements[2] and a resonant synchrotron X-ray diffraction study[3,4] have shown that the two forms have slightly different compositions $(Tl_{2-x}Cu_x)Ba_2CuO_{6+\delta}$. The orthorhombic form obtained at 800–850 °C is cation stoichiometric ($x = 0$) whereas tetragonal Tl-2201 formed above 850 °C has a significant degree of Cu substitution at the Tl site with $x = 0.1$. The synchrotron diffraction study also detected a possible phase separation in orthorhombic Tl-2201, evidenced by small splittings of certain diffraction peaks *e.g.* 040. Here we report further high-resolution synchrotron X-ray and time-of-flight (TOF) neutron powder diffraction studies of 'orthorhombic' Tl-2201. These have led to the discovery of a new monoclinic form of this important superconductor.

A 20 g batch of orthorhombic $Tl_2Ba_2CuO_{6+\delta}$ was synthesised at 820 °C under flowing $O_2$ and quenched to room temperature. Portions of this 'as-prepared' sample were annealed for 5 h under flowing Ar at temperatures between 200 and 700 °C to systematically decrease the excess oxygen content δ, and a further portion was treated under 600 atm $O_2$ pressure at 600 °C to increase δ. Synchrotron X-ray powder diffraction patterns were recorded on diffractometer 9.1 at the Synchrotron Radiation Source, Daresbury, UK and TOF neutron diffraction data were collected from instrument HRPD at the Rutherford Appleton Laboratory, UK. Rietveld refinements[5] were performed using the GSAS package.[6] Diffraction peaks from traces of $BaCO_3$ and $Tl_4O_3$[7] were also observed in some of the profiles and were fitted in the refinements. Magnetisations were measured on a Quantum Design SQUID magnetometer in a field of 500 G.

The neutron diffraction pattern of the as-prepared $Tl_2Ba_2CuO_{6+\delta}$ sample contained small splittings of many *hk*0 and *hkl* diffraction peaks *e.g.* 220 (Fig. 1) although the *h*00 and 0*k*0 diffraction peaks were unsplit. These splittings are inconsistent with orthorhombic symmetry and with the previously reported phase separation model,[4,5] and show that the crystal symmetry is monoclinic. Lowering the symmetry of the structural model from orthorhombic *Fmmm* to monoclinic *F*112/*m* (a non-standard setting of space group *C*2/*m* with the *c*-axis unique) gave a good fit to the profile ($R_{wp}$ = 8.8%). Monoclinic splittings were not observed for the 700 °C Ar-annealed sample (Fig. 1) and the data were fitted by the orthorhombic *Fmmm* model ($R_{wp}$ = 9.7%). Results are summarised in Tables 1 and 2.

The synchrotron X-ray diffraction profiles showed monoclinic splittings for the high pressure $O_2$-annealed, as-prepared, and 200 and 400 °C Ar-annealed Tl-2201 samples, but the 600 and 700 °C Ar-annealed samples were orthorhombic. Good fits to the data with $R_{wp}$ ranging from 5.4 to 9.7% were obtained using the monoclinic *F*112/*m* or orthorhombic *Fmmm* models as appropriate (Table 1).

The Tl-2201 superconductor is notable for having three different macroscopic symmetries due to small variations in chemical composition. The extent of the monoclinic distortion (Table 1) is dependent upon the oxygen content, as the largest

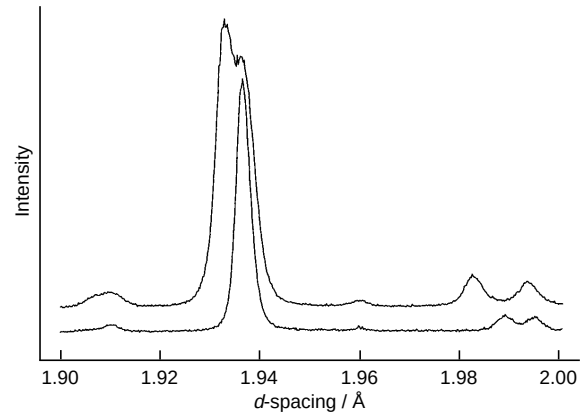

**Fig. 1** Part of the TOF neutron powder patterns of as-prepared (upper curve) and 700 °C Ar-annealed (lower curve) Tl-2201 samples. A monoclinic splitting of the 220 peak ($d$ = 1.935 Å) is seen for the as-prepared sample and the relative magnitudes of the orthorhombic distortions are apparent from the separation of the 208 and 028 reflections at 1.98–2.00 Å.

**Table 1** Cell data for monoclinic (γ > 90°) and orthorhombic (γ = 90°) $Tl_2Ba_2CuO_{6+\delta}$ samples from high-resolution synchrotron X-ray (X) (λ = 0.871 94 Å) and TOF neutron (N) refinements, with e.s.d.s in parentheses. Samples are listed in order of decreasing excess oxygen content δ

[a] These sites are equivalent in orthorhombic *Fmmm* symmetry.

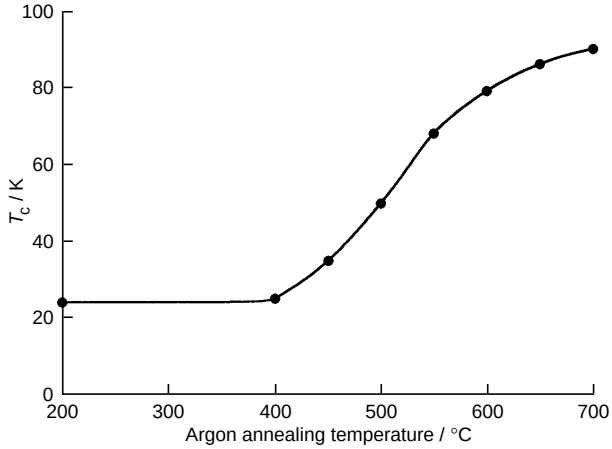

**Fig. 2** Variation of $T_c$ with Ar-annealing temperature in 'orthorhombic' Tl-2201

value of $\gamma = 90.2°$ is found in the sample treated under a high oxygen pressure, whereas the as-prepared material and samples annealed ⩽400 °C under Ar all have $\gamma \approx 90.1°$ and those annealed above 600 °C are orthorhombic. A similar reduction in the orthorhombic distortion, quantified by the orthorhombicity $2(b - a)/(b + a)$, is also observed with decreasing δ. The monoclinic to orthorhombic transition occurs between Ar-annealing temperatures of 400 and 600 °C and is accompanied by a sharp decrease in the orthorhombicity and an abrupt increase in *c* from 23.15–23.16 Å in monoclinic samples to 23.22–23.23 Å in the orthorhombic ones. The maximum slope in the variation of $T_c$ with Ar-annealing temperature (Fig. 2) also occurs within this region, showing that the structural or chemical changes at the monoclinic to orthorhombic transition enhance $T_c$.

Comparing the neutron-refined atomic parameters of the monoclinic as-prepared and orthorhombic 700 °C Ar-annealed $Tl_2Ba_2CuO_{6+\delta}$ samples (Table 2) enables small structural changes to be discerned. The reduction in excess oxygen content from $\delta = 0.192(4)$ to 0.150(6) is consistent with the change from overdoped non-superconducting behaviour to superconductivity with $T_c = 90$ K. This is accompanied by a significant increase in the distance from Cu to the apical oxygen atom O(2) from 2.676(1) Å in the non-superconducting monoclinic structure to 2.702(1) Å in the $T_c = 90$ K orthorhombic sample, whereas the Tl–O(2) distance decreases slightly from 2.012(1) to 2.001(2) Å. Hence, the observed expansion of 0.07 Å in *c* is due to the overall increase of 0.10 Å in the four Cu–O(2) contacts which is partly offset by a total decrease of 0.04 Å of the four Tl–O(2) bonds. This adds to the large amount of evidence for the crucial role of the apical Cu–O bond distance in determining the value of $T_c$ in these notable superconductors.[8,9]

In conclusion, small changes in the amount of excess oxygen in 'orthorhombic' $Tl_2Ba_2CuO_{6+\delta}$ play a critical role in determining the crystal symmetry and electronic properties. Oxygen-rich compositions with $T_c$ values up to *ca.* 50 K are monoclinic whereas less oxidised samples with $T_c$ values of 50–90 K are orthorhombic. The monoclinic to orthorhombic phase change occurs due to loss of interstitial oxygen, whereas the orthorhombic to tetragonal change at higher temperatures involves the loss of $Tl_2O_3$ from the structure accompanied by the substitution of 5% Cu at the Tl site.

# A facile dialkyl ether cleavage and rearrangement under mildly basic conditions during the Williamson synthesis with β-cyclodextrin

**Christopher T. Bibeau, Brian K. Hubbard and Christopher J. Abelt***

*Department of Chemistry, College of William and Mary, Williamsburg, VA 23187-8795, USA*

**Alkyl (9,10-dicyanoanthracenyl-2-methyl) ethers undergo facile transetherification with a variety of alkoxides.**

The ether bond is generally resistant to base cleavage.[1] Well-known exceptions occur when the alkoxide leaving group is stable, as with a phenoxide, and when cleavage relieves strain, as with an epoxide. Benzyl ethers are often used at protecting groups for alcohols.[2] These arylalkyl ethers are stable even with strong bases and are cleaved by catalytic hydrogenation or dissolving metal reduction. Thus, the ether bond should be an ideal linking group in the construction of supramolecular systems, especially when such systems will be used as reaction catalysts requiring their continued molecular integrity. In this paper we report a case involving construction of a cyclodextrin assembly wherein an arylalkyl alkyl ether bond undergoes facile cleavage under relatively mild conditions.

The Williamson ether synthesis can be applied to the regioselective alkylation of β-cyclodextrin (β-CD) at the glucose C2–OH. The regioselectivity arises from the greater acidity of the C2–OH relative to the C3 or C6–OH. The C2 alkoxide is stabilized by an intramolecular H-bond with the C3–OH of an adjacent glucose unit. D'Souza and Rong have shown that β-CD alkoxide will react by nucleophilic substitution with a variety of electrophiles to give C2 ethers.[3] We have applied this reaction to link together a 9,10-dicyanoanthracene (DCA) group with β-cyclodextrin *via* the 2-bromomethyl derivative **1**.[4] The reaction did not give rise to selective substitution at C2; in fact, a 3 : 1 ratio of C6 and C2-ethers was isolated (Scheme 1). In this communication we report the results of several experiments probing the origin of the observed regiochemistry.

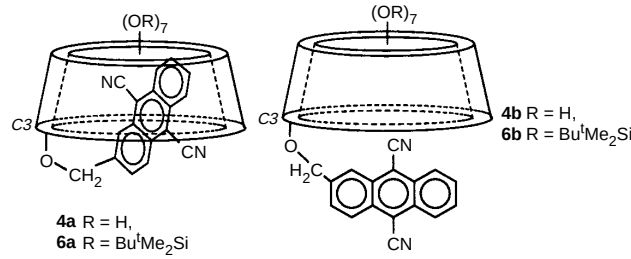
In all of the following experiments the relative proportions of the DCA–β-CD ethers were determined through HPLC analysis of the reaction mixture.† The base used was β-CD alkoxide, and the base strength was controlled by the quantity of NaH used to deprotonate the β-cyclodextrin; for example, a 50% molar excess of NaH was used to generate a 1 : 1 mixture of β-CD C2-alkoxide and C2,C2′-dialkoxide. All reactions were conducted in DMF which was distilled from $CaH_2$ *in vacuo* before use.

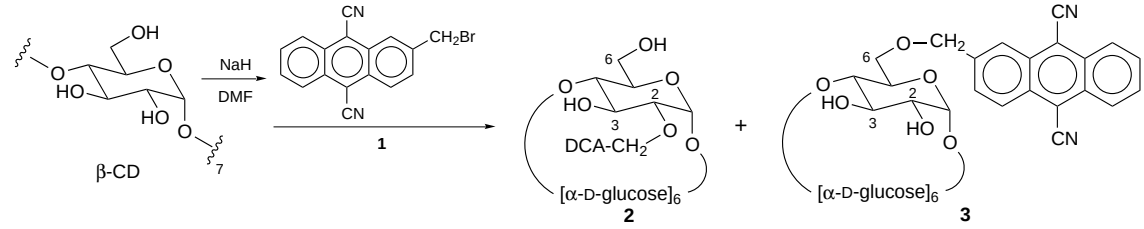
The etherification reaction requires more than stoichiometric base to form ether products. The reaction with 50% excess base was monitored as a function of time. HPLC results reveal that **2** is formed initially, but disappears rapidly with concomitant formation of **3**. Ether formation is nearly complete within 30 min, but the fraction of **3** in the product mixture continues to increase well after this period. Two other unidentified species are revealed by the HPLC results.‡ These species form faster than **3**; then, like **2**, they disappear. We tentatively assign these as C3 ethers **4a,b** (*vide infra*), which are inside–outside (conformational) isomers. The faster eluting compound **4a** is assigned to the inside isomer since its hydrophobic interaction with the reverse-phase layer is less than that of the outside isomer.

Compound **2**, available from our previous work, is isomerized to **3** and **4a**,**b** by cyclodextrin alkoxide solutions. The final product distribution depends upon the initial alkoxide composition. When **2** is treated with β-CD alkoxide, the isomerization proceeds mainly to **4a**,**b**, whereas when a nearly equal mixture of β-CD alkoxide and β-CD dialkoxide is used, **3** becomes the ultimate product.

We set out to determine whether the isomerization was intra- or inter-molecular in nature. For this study we synthesized 6-*O*-per(*tert*-butyldimethylsilyl)-2-*O*-(9,10-dicyanoanthracenyl-2-methyl)-β-cyclodextrin **5**.§ The conditions for the isomerization of **2** were repeated: reaction with a stoichiometric amount of β-CD alkoxide and with 1 : 1 alkoxide/dialkoxide. The product composition at various times was probed by HPLC in two ways: (i) by direct injection of the reaction mixture and (ii) after removal of the silyl ethers with HF. Any product (**2**, **3** or **4a**,**b**) seen in the first set can arise only by an intermolecular process. The mixture from the second determination derives from a combination of both inter- and intra-molecular processes. Treatment of **5** with β-CD alkoxide gives rise to an intramolecular isomerization to the persilylated C3 ethers **6a** and **b**. However, treatment with a β-CD alkoxide/dialkoxide mixture produces **3** *via* an intermolecular process.

The assignment of **4a** and **b** as C3 ethers rests on their appearance in both the isomerization of **2** and especially of **5**. In





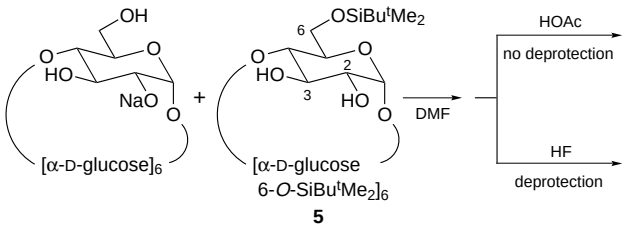


**Fig. 1** 9,10-dicyanoanthracenyl-2-methyl-C3-*O*-β-CD ethers **4a**,**b** and **6a**,**b**

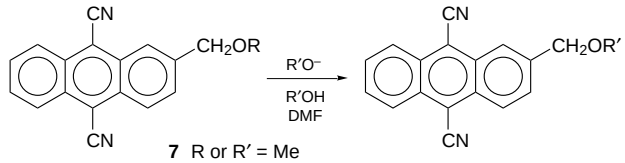
**Scheme 1** Reaction of β-cyclodextrin alkoxide with 2-bromomethyl-9,10-dicyanoanthracene **1**



the latter result, the C3 position is the only one possible for a DCA ether product since the C6 hydroxy groups are blocked and the C2 isomer is the starting material. The faster elution of C3 ethers relative to C2 and C6 ethers in reverse-phase HPLC has been documented.[6] The kinetic stability of a self-included C3 ether has been reported recently for a C3 tethered 2-naphthylmethyl group.[7] The DCA group is longer than the naphthyl group, and the C3-inside ether should be even more kinetically stable than the reported naphthyl ether.

The scope of the transetherification was probed through attempted interconversions of compounds **7**–**9** (Scheme 3).¶ The reactions were conducted in DMF using 1.5 equiv. of alkoxide to mimic the above conditions and were monitored by HPLC.‖ Table 1 shows that ether exchange is a general reaction

| $HOCH_2CH_2$ | Bn | 52 | 23 |

[a] Reaction conditions: [DCA–$CH_2$–OR] = *ca*. 0.01 mol $dm^{-3}$, [R′$O^-$] *ca*. 0.015 mol $dm^{-3}$, [R′OH] = *ca*. 10% *v/v* in DMF, 23 °C. [b] Determined by HPLC results. [c] [R′$O^-$] + [R′OH] = *ca*. 0.01 mol $dm^{-3}$.

for DCA-2-methyl ethers. In fact, both **7** and **8** can be used to prepare the DCA- tethered β-CD **3**.

The electron-withdrawing nature of the DCA group as well as the presence of H-bonding[8] should be important factors in the ether exchange process. Other CD ether tethers without such an electron-withdrawing aryl groups do not undergo isomerization.[3] While substitution of electron-withdrawing groups onto benzyl ethers renders them more reactive than benzyl ethers, usually it is the functional group which is attacked, and ether cleavage still requires forcing conditions. The reactivity of **2** is unusual in that ether bond *migrates* instead of just cleaving. The ease with which the dicyanoanthracenylmethyl group is released may render it a useful protecting group for alcohols. We are pursuing independent syntheses of **4a** and **b**, as well as the mechanism of the transetherification reaction.

## Footnotes

† Compounds **2**[4] and **3** elute at 21.8 and 22.9 min, respectively, from a 250 × 4.6 mm Whatman ODS-3 column using a linear gradient elution (80 : 20 to 50 : 50 $H_2O$–MeCN over 30 min) at 1.0 ml $min^{-1}$. The absorption at 254 nm was detected, and peak area percentages are reported as mole fractions.

‡ Compounds **4a** and **b** show retention times of 18.8 and 19.9 min, respectively.

§ Compound **5** was prepared from per-6-*O*-(*tert*-butyldimethylsilyl)-β-CD[5] by first forming the alkoxide with NaH in THF, then alkylating with **1**. It was purified by HPLC on silica gel, characterized by NMR, and gave satisfactory combustion analysis.

¶ Compounds **7**–**9** were prepared by $Ag_2O$-assisted alcoholysis reactions of **1**.

‖ Compounds **7** and **8** elute at 7.6 and 6.3 min, respectively, from a 250 × 4.6 mm Alltech Econosil column using an isocratic elution ($CHCl_3$) at 0.7 ml $min^{-1}$. Compound **9** elutes at 15.2 min using a linear gradient elution (0–20% MeOH in $CHCl_3$ over 20 min) at 1.0 ml $min^{-1}$. The absorption at 420 nm was detected, and an internal standard was used to determine the yields at 100% conversion.

# A new enzymatic enantioselective synthesis of dialkyl sulfoxides catalysed by monooxygenases

**Stefano Colonna,*[a] Nicoletta Gaggero,[a] Giacomo Carrea[b] and Piero Pasta[b]**

[a] *Istituto di Chimica Organica, Facolta'di Farmacia dell'Universita', Via Venezian 21, 20133 Milano, Italy*
[b] *Istituto di Chimica degli Ormoni, CNR, Via Mario Bianco, 9, 20131 Milano, Italy*

**Numerous dialkyl sulfides were enantioselectively oxidized to optically active sulfoxides catalysed by chloroperoxidase or cyclohexanone monooxygenase.**

The use of sulfoxides as chiral synthons in asymmetric synthesis is well documented and reliable.[1] Intensive research has demonstrated the efficiency of sulfoxides for controlling the stereoselectivity of a large number of reaction types: alkylation of carbanions, Michael addition, aldolisation reactions, cycloadditions, Pummerer rearrangement and so on. Several sulfoxides also have attractive pharmacological or biological activities.[2] There has been extensive research in recent years trying to develop new methods for the preparation of enantiomerically pure sulfoxides.

The wider application of methodologies based on the sulfinyl function is limited, however, by the relative paucity of general one-step procedures for obtaining enantiomerically pure sulfoxides, especially dialkyl sulfoxides.

Alkyl methyl sulfoxides of high enantiomeric purity have been prepared from cholesterol methyl sulfinates. This process requires a separation of diastereoisomers which are then treated with the relevant alkyl Grignard reagent to furnish the optically active sulfoxide.[3] Similarly, diacetone-D-glucose (DAG) has been used to induce chirality at sulfur.[4] Reaction of diastereoisomerically pure DAG-alkyl sulfinates with Grignard reagents gives optically active dialkyl sulfoxides with high ee (up to ⩾98%).[4]

Optical active cyclic sulfites derived from (*S*)-ethyl lactate have also found use in the preparation of optically active dialkyl sulfoxides.[5] In this case two consecutive displacements with Grignard reagents are required before the chiral transfer agent is released, but separation of intermediate sulfinate esters is still required. Optically active oxazolidinones derived from norephedrine and phenylalanine have also been used in a chiral auxiliary based route to dialkyl sulfoxides.[6]

A different approach to optically active sulfoxides involves an asymmetric oxidation of prochiral sulfides by the Sharpless procedure, modified independently by Kagan[7] and Modena;[8] in the case of dialkyl sulfoxides the ee values ranged between 50–71%. A new catalytic asymmetric oxidation by cumyl hydroperoxide using a chiral titanium complex as catalyst has been reported by Kagan recently (68% ee in the case of octyl methyl sulfoxide).[9] The asymmetric sulfoxidation with enantiomerically pure oxaziridines has been little used for the synthesis of optically active dialkyl sulfoxides.[10,11]

An alternative to asymmetric oxidation with chiral chemical oxidants is the enzymatic oxidation.[12] The only systematic study on an enzymatic asymmetric aliphatic sulfoxidation was carried out by May and co-workers.[13] *Pseudomonas oleovorans*, a non-haem monooxygenase, catalyses stereoselective sulfoxidation of methyl thioether substrates. The ee values of the prevailing sulfoxide are in the range 2–88%, depending upon the structure of the second alkyl chain. Apart from the necessity of a terminal methyl group, the biotransformation catalysed by *Pseudomonas oleovorans* suffers from a poor chemical yield.

Here we present a new enzymatic general approach to the synthesis of dialkyl sulfoxides with high ee. The enzymes used were chloroperoxidase from *Caldariomyces fumago* (CPO) and cyclohexanone monooxygenase (CMO) from *Acinetobacter* NCIB 9871, an iron-haem and a flavin-dependent oxidoreductase, respectively.

Previously, we have shown that these enzymes can catalyse the asymmetric sulfoxidation of numerous alkyl aryl sulfides with high enantioselectivity.[14] The versatility of CMO in promoting enantioselective sulfoxidations has been recently exploited also with 1,3-dithioacetals.[15]

Yields and enantiomeric excesses of the CPO and CMO catalysed oxidation of the dialkyl sulfides tested are reported in Tables 1 and 2. Cyclopentyl methyl sulfide **1**, allyl methyl sulfide **3**, isopropyl methyl sulfide **6** and bis(thiomethyl) methane **9** are excellent substrates for CPO in terms of chemical yield and ee. The increase in the size of the cycloalkane bound to the sulfur (cyclohexyl **2** instead of cyclopentyl **1**), leads to an appreciable decrease in chemical and optical yield. The importance of steric factors on chemical yield and ee is confirmed by the results obtained with methyl sulfides with different alkyl chains **4**, **5**. An increase in the branching of the alkyl chain causes similar effects **6**, **7**. These results can be rationalized by taking into account the higher contribution of the competitive spontaneous oxidation of the more hindered starting materials for which the enzymatic oxidation is slower. As already observed for alkyl aryl sulfides,[14] the oxidation of

**Table 1** CPO catalysed oxidation of sulfides to the corresponding sulfoxides [a]

| Sulfide | Conversion (%) | Ee (%) | Configuration |
|---|---|---|---|
| **1** Cyclopentyl methyl sulfide | ⩾98 | ⩾98 | *R*[b] |
| **2** Cyclohexyl methyl sulfide | 85 | 85 | *R* |
| **3** Allyl methyl sulfide | ⩾98 | ⩾98 | *R* |
| **4** Pentyl methyl sulfide | 75 | ⩾98 | *R* |
| **5** Octyl methyl sulfide | 40 | 54 | *R* |

[a] The sulfide (0.42 mmol) and CPO (Sigma) ($6.7 \times 10^{-6}$ mmol) were magnetically stirred in 40 ml of 0.05 mol $dm^{-3}$ citrate buffer, pH 5 at 25 °C for 5 min. $H_2O_2$ (0.42 mmol) in 480 μl of buffer, pH 5, was added in 18 aliquots at 3 min intervals. The reaction was quenched with sodium sulfite, extracted with diethyl ether and dried. The enantiomeric excesses of sulfoxides were determined by chiral HPLC on a Chiralcel OB column (Daicel), using the proper mixture of hexane and propan-2-ol as the mobile phase. The absolute configuration of sulfoxides was determined by comparison with authentic samples prepared by Sharpless oxidation and using chiral HPLC. [b] The absolute configuration of cyclopentyl methyl sulfoxide was determined by analysis of its $^1$H NMR spectrum in the presence of the chiral shift reagent (*S*)-(+)-α-methoxy-α-phenylacetic acid (ref. 17).

**Table 2** CMO catalysed oxidation of sulfides to the corresponding sulfoxides [a]

| Sulfide | Conversion (%) | Ee (%) | Configuration |
|---|---|---|---|
| **1** Cyclopentyl methyl sulfide | 80 | ⩾98 | *R*[b] |
| **2** Cyclohexyl methyl sulfide | 86 | ⩾98 | *R* |
| **3** Allyl methyl sulfide | 82 | ⩾98 | *R* |
| **4** Pentyl methyl sulfide | 58 | 60 | *S* |
| **5** Octyl methyl sulfide | 50 | 50 | *S* |
| **6** Isopropyl methyl sulfide | 75 | ⩾98 | *R* |
| **7** *tert*-Butyl methyl sulfide | 85 | ⩾98 | *R* |
| **8** *tert*-Butyl ethyl sulfide | 30 | 35 | *R* |
| **10** *tert*-Butyl vinyl sulfide | 78 | ⩾98 | *R* |
| **11** Cyclohexyl ethyl sulfide | 8 | 47 | *R* |
| **12** 4-Hydroxyethyl methyl sulfide | 80 | 33 | *R* |

[a] The sulfide (0.1 mmol) was magnetically stirred in 4 ml of 0.05 mol $dm^{-3}$ Tris–HCl buffer, pH 8.6, containing 2 μmol NADPH, 0.4 mmol glucose-6-phosphate, 5 units of CMO and 10 units of glucose-6-phosphate dehydrogenase. After overnight reaction, the solution was extracted with 4 portions (4 ml each) of diethyl ether and the organic extract was dried and evaporated. The enantiomeric excesses of sulfoxides were determined by chiral HPLC on a Chiralcel OB column (Daicel), using the proper mixture of hexane and propan-2-ol as the mobile phase. The absolute configuration of sulfoxides was determined by comparison with authentic samples prepared by Sharpless oxidation and using chiral HPLC. [b] The absolute configuration of cyclopentyl methyl sulfoxide was determined by analysis of its $^1$H NMR spectrum in the presence of the chiral shift reagent (*S*)-(+)-α-methoxy-α-phenylacetic acid.[17]

dialkyl sulfides affords predominantly or exclusively the corresponding (*R*)-sulfoxide.

For CMO promoted sulfoxidation, high enantioselectivity is observed for cycloalkyl methyl sulfoxides (**1**, **2**), and methyl sulfoxides with a linear or branched alkyl chain of up to four carbon atoms (**3**, **6**, **7**). In all these cases the absolute configuration of the prevailing enantiomer is *R*. A longer alkyl chain not only causes a drastic drop in the chemical and optical yield **4**, **5**, but also changes the stereochemical course of the sulfoxidation, since the resulting enantiomer now has the *S* absolute configuration.

The predictive active site model for the cyclohexanone monooxygenase catalysed oxidation of sulfides to sulfoxides, already proposed by us,[16] is compatible with these results but does not offer conclusive evidence due to the high conformational freedoms of dialkyl sulfides.

A comparison of the results obtained in the oxidation of dialkyl sulfides with CPO and CMO leads to the following conclusions: (i), both enzymes exibit high enantioselectivity in the oxidation of cycloalkyl methyl and alkyl methyl sulfides with limited steric requirements; (ii), the two enzymatic systems are enantiocomplementary for pentyl methyl sulfide and for octyl methyl sulfide, leading in all other cases to the (*R*)-sulfoxides; (iii) chloroperoxidase is more convenient than cyclohexanone monooxygenase since it is commercially available, uses hydrogen peroxide as oxidant and does not require the regeneration of the cofactor, as in the case with CMO.

This work was partially supported by EEC Human Capital and Mobility Programme and by COST Programme.

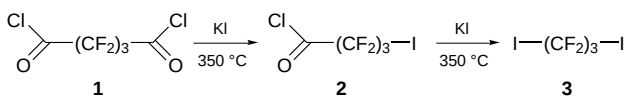
# An ω-functionalized perfluoroalkyl chain: synthesis and use in liquid crystal design

**Sandrine Pensec and François-Genès Tournilhac*†**

*ESPCI (CNRS URA429), Chimie et Electrochimie des Matériaux Moléculaires, 10 rue Vauquelin, 75231 Paris Cedex 05, France*

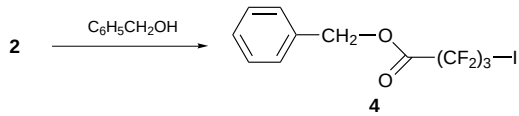
**A multiblock polyphilic compound incorporating a perfluoroalkyl spacer and associating groups at both extremities exhibits smectic A and smectic C mesophases.**

Perfluoroalkyl iodides permit the formation of stable C–C bonds by the Ullman reaction[1] or by free-radical addition to alkenes followed by dehalogenation.[2] They have been widely used in the design of highly fluorinated mesomorphic materials.[3,4] In the course of our research into polyphilic mesogens,[5] the need arose for new molecular architectures incorporating a central perfluoroalkyl bridge. Symmetric α,ω-diiodoperfluoroalkanes are available by several routes[6,7] but, to our knowledge, there is no efficient procedure for the synthesis of a perfluoroalkyl chain bearing two different reactive groups in the α and ω positions.



When reacting perfluoroglutaryl chloride with potassium iodide at 200–400 °C, McLoughlin noticed the formation of some 4-iodoperfluorobutyryl chloride,[7] which was isolated in the form of the free acid (Scheme 1).

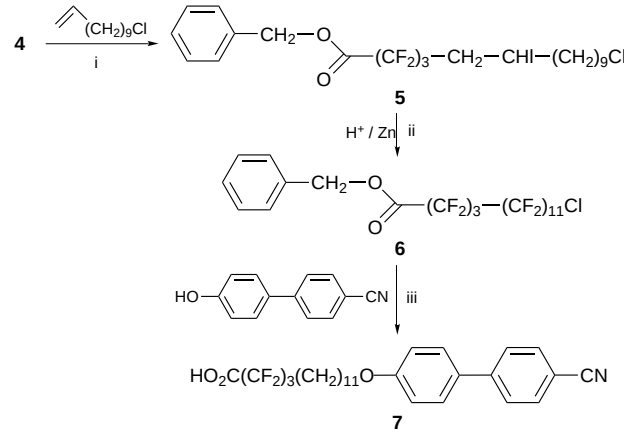
In this original work,[7] relatively high yields (50–60%) of **3** were obtained when using high temperatures and long reaction times. In our experiments, all precautions were taken: (*i*) to stop the progression of the reaction at the optimum time; (*ii*) to avoid the hydrolysis of **2** into the corresponding acid; and (*iii*) to form a versatile derivative of **2** which may be easily purified and characterized.



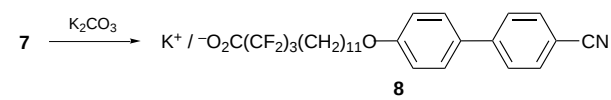
The starting material (hexafluoroglutaryl chloride), obtained from hexafluoroglutaric acid and oxalyl chloride, was vaporized at 220 °C with a nitrogen flow and passed at 350 °C through a glass tube packed with finely ground potassium iodide. The reaction time was determined by the flow of nitrogen. The products were trapped at −78 °C. The degree of conversion estimated by the relative intensities of the 1793 $cm^{-1}$ (C=O stretch) and 1128 $cm^{-1}$ (CF stretch) IR bands; was taken as a criterion for optimizing the reaction time. The products **1**, **2** and **3** were immediately treated with benzyl alcohol in toluene in the presence of pyridine and benzyl-4-iodoperfluorobutanoate **4** was isolated by liquid chromatography with an overall yield of 16% (Scheme 2).‡

Bifunctional spacer units are useful in the chemistry of covalently grafted surfaces, artificial membranes, liquid crystalline polymers, *etc.* Compound **4** allows the preparation of new mesomorphic materials as will be exemplified below.

Polyphilic compounds are made up of a sequence of molecular fragments differing in their chemical nature. In the mesomorphic state, unlike fragments have a tendency to segregate, hence leading to the formation of smectic layers.[4,5,8–10] Perfluoroalkyl chains have been widely used in the design of such materials, but always as end-groups. Starting from benzyl 4-iodoperfluorobutanoate, we have initiated the synthesis of new polyphilic compounds incorporating a perfluoroalkyl spacer in the central part of the molecule. Compound **7** was synthesized in three steps starting from **4** (Scheme 3).



**Scheme 1**



**Scheme 2**

Compound **4** was treated with 1-chloroundec-10-ene in the presence of azoisobutyronitrile (AIBN) to give benzyl 15-chloro-2,2,3,3,4,4-hexafluoro-6-iodopentadecanoate **5** which was in turn reduced to benzyl 15-chloro-2,2,3,3,4,4-hexafluoropentadecanoate **6** using Zn/HCl. Compound **6** was reacted with 4-cyano-4′-hydroxybiphenyl in the presence of $K_2CO_3$ in DMF to give the polyphilic compound **7**.† Compound **7** melts at 124.5 °C and is not mesomorphic. The p$K_a$ value of **7** is < 2. The potassium salt **8** was prepared by treatment with an aqueous solution of $K_2CO_3$ (Scheme 4).

The mesomorphic properties of **8** have been investigated by differential scanning calorimetry, optical microscopy and X-ray diffraction. On cooling from the isotropic phase, birefringence was detected at 186 °C by the growth of *bâtonnets*[11] which gradually merge to form the well known focal conic texture. This mesophase was identified as smectic A since homeotropic domains were also evident in the same temperature range. The focal conic texture is stable down to 135 °C, the temperature at which the focal domains become divided into subdomains showing different interference colours (broken fan texture[12,13]). At the same temperature, the *schlieren* texture appears in the previously homeotropic domains. These texture changes are

**Scheme 3** *Reagents and conditions*: i, AIBN, heptane, 90 °C, 4 h, 81%; ii, isooctane + acetic acid, 110 °C, 2 h, 72%; iii, $K_2CO_3$, DMF, 90 °C, 3 h, then HCl, 68%

**Scheme 4**

characteristic of the smectic A → smectic C transition.[13] This second fluid mesophase is monotropic, it may be observed for a few minutes in the 135–110°C range, whereupon crystallization rapidly occurs.

The DSC trace shows, on heating, two endotherms at 135 and 190 °C with enthalpies of 8.9 and 4.3 kJ mol$^{-1}$ respectively, corresponding to the K → $S_A$ and $S_A$ → I transitions. On cooling the reverse transitions take place at 186 and 123 °C.

Thus, whilst **7** is isotropic in the 135–190 °C range, the appearance of lamellar order in **8** may be related to the segregation of the ionic head from all other hydrophobic moieities.

X-Ray diffraction experiments were carried out on unoriented samples using Cu-Kα radiation. Attempts to investigate **8** in the smectic C phase failed due to its metastable character. The X-ray diffraction pattern recorded at 150 °C in the smectic A phase of **8** is presented in Fig. 1.

At large angles, a broad diffuse ring with a maximum at $2\pi/q = 4.9$ Å ($q = 4\pi \sin\theta/\lambda$) confirms the identification as smectic A and gives an estimate of the average intermolecular distance (*ca.* 5.7 Å). At narrow angles, the diagram shows three 00*l* reflections corresponding to an interlayer distance of 42.2 Å. The distance is intermediate between once and twice the molecular length (32 Å); a partially bilayered packing of the smectic $A_d$ type[14] may therefore be proposed. A similar observation was reported for other rodlike mesogens with ionic head-groups.[15] In $Na^+$ and $K^+$ long-chain carboxylates, a lipidic sublayer thickness 1.3 times greater than the alkyl chain length was interpreted by the formation of a double layer with strongly disordered alkyl chains.[16] In our case, the rigid cyanobiphenyl cores cannot be accommodated in any conformation, however, these fragments usually tend to optimize their packing by partial interdigitation. As already mentioned for polyphilic mesogens with cyanobiphenyl cores, the appearance of the smectic $A_d$ and C phases can be related to the close packing of lengthwise dimers associated through the cyano groups.[9]

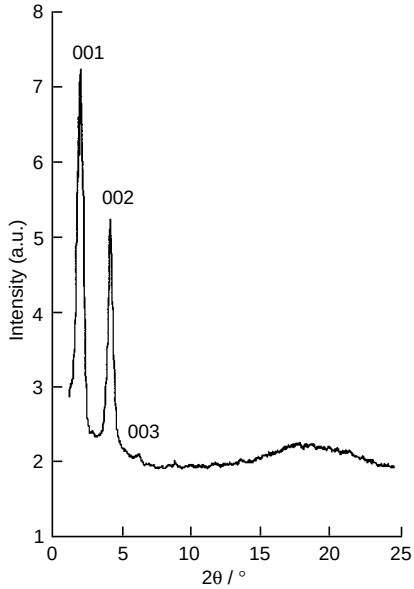


**Fig. 1** X-Ray (Debye–Scherrer) diffraction diagram of compound **8** recorded at 150 °C (densitometric profile of the photographic film)

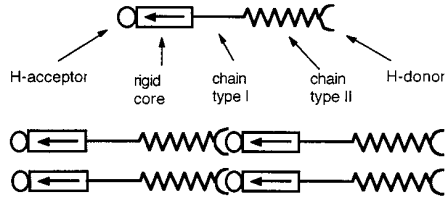

**Fig. 2** Polar rows of molecules expected from polyphilic compounds bearing hydrogen-bond donor and acceptor groups at the extremities

The potentialities of hydrogen-bond associated systems in the design of new mesomorphic architectures have been evidenced by several authors.[17] The synthetic scheme described in this paper permits the grafting of hydrogen-bond donor and acceptor groups at each molecular end of a polyphilic compound. It is noteworthy that polar rows of molecules may be formed in the liquid phases of such materials (Fig. 2).

J. Simon is thanked for helpful and stimulating discussions, D. Lelièvre for her help in X-ray measurements.

# Energy filtered transmission electron microscopy (EFTEM) in the characterization of supported $TiO_2$ photocatalysts

**Alexander Starosud,[a] David P. Bazett-Jones[b] and Cooper H. Langford*[a]**

*Departments of [a]Chemistry and [b]Medical Biochemistry, The University of Calgary, A110-2500 University Dr. NW, Calgary, Alberta, Canada T2N 1N4*

**Energy filtered transmission electron microscopy demonstrates whether $TiO_2$ is on the surface or enters the pore channel system of zeolites.**

The widely studied photocatalyst, $TiO_2$, is often supported, either to simplify material handling or to modify the properties of the catalyst. Our group[1,2] and others[3] have exploited silica and zeolite supports. Our intention has been to modify the catalytic behaviour of the systems through convolution of the very general, non-selective, photocatalytic oxidation activity of $TiO_2$ with the absorption characteristics and specific oxidative catalysis available with high silica zeolites. In order to understand and manipulate such systems, it is necessary to develop tools for the detailed examination of the distribution of $TiO_2$ on and in the supports. In our earlier papers,[1,2] we described the information derivable from scanning electron microscopy, powder X-ray diffraction and vibrational spectroscopy. These indicated that $TiO_2$ thin films or microparticles on the zeolites were the most photoactive. In the case of large silica particles which could be examined in the cross-section, it was possible to gain insight into the behaviour of photocatalytic sites in the interior of the particles.[2] However, a severe limitation was the inability to image the distribution of $TiO_2$ in conventional small zeolite particles.

This communication describes a technique for imaging such a distribution. It exploits energy filtered transmission electron microscopy (EFTEM) (which has been used for mapping other elements[4–6]) to image cross-sections of micron-sized zeolite particles with varying sizes of mesopores which favour different distributions of $TiO_2$. The basis of the technique is that energy losses of electrons that pass through a sample are characteristic of the chemical elements present. Electrons are separated according to energy loss by a spectrometer which also acts as a lens.[7] The Ti-specific ionization edge L2,3 occurs at 456 eV. Consequently, a 430 eV image does not contain any Ti-specific information, whereas a 460 eV image is 'Ti-enhanced'. A net Ti distribution can be determined by subtracting the pre-edge reference image from the post-edge Ti-enhanced image. Samples were imbedded in QUETOL and thin-sectioned with an ultramicrotome to sections 30 nm thick. Energy loss micrographs were recorded with a Zeiss EM902 instrument equipped with an imaging spectrometer. A 500 μm condenser aperture, a 60 μm objective aperture and a 20 eV energy selecting slit aperture were used. Images were recorded at a magnification of 13 000 × on SO-163 electron image film (Kodak). The film was then digitized and analysed as described previously.[7]

We report here on the contrast of a demonstration sample pair that illustrates the power of the technique. Our preferred method[1] for $TiO_2$ loading of zeolites is to stir a colloid of $TiO_2$ with zeolite, remove the solvent and calcine at a moderate temperature (450 °C). Some experiments have suggested that the $TiO_2$ colloids may be labile so that smaller particles in equilibrium with the dominant ones might enter pores of the support which are smaller than the nominal particle size in the colloid, leading to distribution of $TiO_2$ into the particle interior. To test this, we have studied the loading of 'Q-sized' $TiO_2$ particles with diameters of 20–40 Å[8] into two compositionally similar zeolites of the mesoporous MCM-41 family,[9] one of which had an average pore diameter of 20 Å (MCM-20), the other with an average pore diameter of 60 Å (with pores up to 120 Å) (MCM-60). The pore size distributions of these two were measured by $N_2$ absorption in an ASDI RXM-100 catalyst characterization system. Penetration of Q-sized particles into the larger pore-sized MCM-41 should be facile. In contrast, penetration into the smaller pore size (20 Å) requires that the Q-sized colloid is in labile equilibrium with fragments smaller than the nominal particle size.

In Fig. 1, we show the net images (lower) resulting from the subtraction of the pre-edge reference image (upper) from the post-edge Ti-enhanced image (middle). The MCM-60 is shown in Fig. 1(*b*) and images of MCM-20 are shown in Fig. 1(*a*). These two images are representative of a number we recorded, and it must be understood that we do not control the orientation of the particles with respect to cutting direction of the ultramicrotome. A dark region across the centre of the particle shown in Fig. 1(*b*) (lower) indicates that $TiO_2$ particles did not fully penetrate the zeolite but the distribution of light dots clearly reveals deep penetration of $TiO_2$. In Fig. 1(*a*), we see that little penetration of $TiO_2$ into MCM-20 particles occurs.

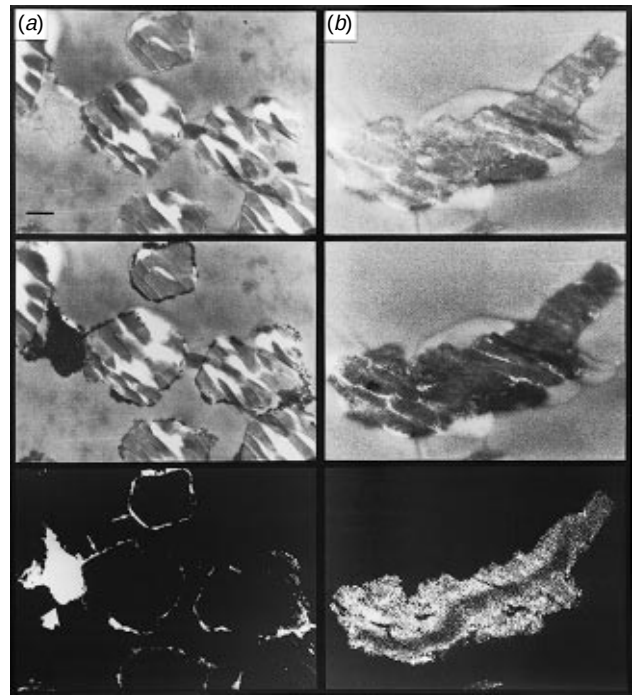

**Fig. 1** Energy filtered images of zeolites MCM-41 with average pore diameters of 20 Å (*a*) and 60 Å (*b*). Pre-edge images were recorded at 430 eV (upper panels), post Ti-edge images were recorded at 460 eV (middle panels). The lower panels show the net images after alignment, subtraction and inversion of contrast (Ti-rich regions shown as white on black background). Scale bar = 210 nm.

The hint that labile equilibration of the colloid particles with smaller $TiO_2$ polycations occurs is refuted. Where the colloid is prepared at particle sizes greater than the pore size, penetration is unimportant. Fig. 1(*a*) also shows that not all of the $TiO_2$ has been distributed in a uniform thin layer over the zeolite (small arrows, lower), but that aggregates of $TiO_2$ can form (large arrow, lower). The spatial detail in these images approaches the resolution limits of the electron microscope at 13 000 $\times$ magnification. Structure in the maps, therefore, is better resolved by about two orders of magnitude than can be obtained with X-ray microanalysis in the scanning electron microscope.

We thank the National Sciences and Engineering Research Council of Canada for support.

# Rearrangement of *p*-methoxybenzyl-protected allylic alcohols to aldehydes

**Johan Wennerberg, Lars Eklund, Magnus Polla and Torbjörn Frejd***

*Organic Chemistry 1, Department of Chemistry, Lund University, S-22100, Lund, Sweden*

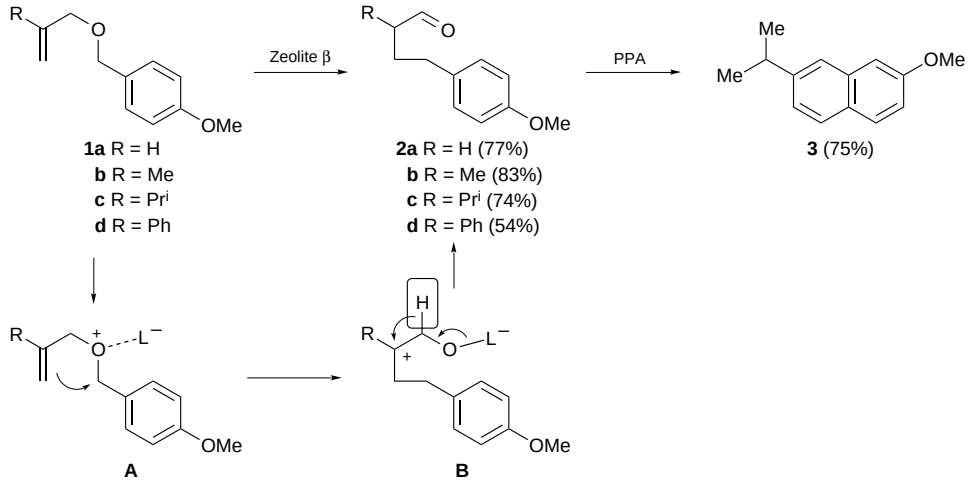
**Allyl *p*-methoxybenzyl ethers undergo an acid-catalysed 1,4-rearrangement to give *p*-methoxyphenylbutyraldehyde derivatives, which can be ring-closed to give substituted naphthalene derivatives.**

During our work with the Lewis acid-induced carbonyl-ene reaction,[1] a key step in our studies towards the synthesis of taxanes,[2,3] we recently discovered a new type of rearrangement (Scheme 1). When a mixture of **1c** and methyl or ethyl glyoxylate was treated with zeolite β or $BF_3{\cdot}Et_2O$, the ene reaction did not occur. Instead, **1c** rearranged to give aldehyde **2c** in good yield, which also occurred in the absence of the alkyl glyoxylate. Although allylic benzyl ethers are a well known class of compounds we were surprised to find that a literature search did not reveal any similar reactions under acidic conditions. One reason for this could be the fact that the reaction does not occur when an unsubstituted benzyl group is used instead of a *p*-methoxybenzyl (PMB) group. Thus, electron rich aromatic rings seems to be necessary. Another reason is that only zeolite β and $BF_3{\cdot}OEt_2$ among fifteen Lewis acids tested effected the rearrangement. The outcome of the reaction is similar to a 1,4-Wittig rearrangement,[4,5] although the reaction conditions and the mechanisms are quite different. While the 1,4-Wittig rearrangement needs strongly basic conditions and is usually a minor side reaction, the present rearrangement proceeds under acidic conditions (zeolite β is an acidic zeolite[6]) and gives moderate to good yields.

We propose the following mechanism; the initial step is the coordination of the Lewis acid (or protic acid) to the ether oxygen (**A**). This possibly leads to increased positive charge at the benzylic carbon, which explains why the *p*-methoxy group is necessary for the charge delocalization. Next, the π-electrons in the double bond attack the benzylic position to form cation **B**, which then undergoes a 1,2-hydride shift to give the aldehyde. The hydride shift was indicated by essentially complete statistical recovery of deuterium at the carbonyl α-position of **2c** after rearrangement of **1c**, which was 50% deuteriated at the allylic methylene group.

We have performed the reaction with four different PMB-protected allylic alcohols. The reaction is very simple to carry out, and easy access to allylic ethers together with the utility of aldehydes of type **2** should make this rearrangement quite useful in organic synthesis.† As a simple demonstration of this we cyclized one of the products, **2c**, using PPA(polyphosphoric acid)[7] to give the naphthalene derivative **3** in good yield. Aromatisation *via* elimination of water followed by oxidation (presumably due to dissolved air) took place directly in the PPA reaction mixture. The scope and limitations, together with various applications, of the described rearrangement will be reported shortly.

This work was financially supported by the Swedish Natural Science Research Council, The Knut and Alice Wallenberg Foundation and The Crafoord Foundation.



## Footnote

† *Typical procedure*: A solution of the PMB-protected allylic alcohol (1.0 mmol) in $CH_2Cl_2$ (2 ml) was stirred together with zeolite β (125 mg activated at 400 °C for 4 h) overnight at room temperature. The resulting orange–red mixture was then filtered through Celite. The Celite was washed with $CHCl_3$ (2 × 5 ml) and the combined organic extracts were concentrated at reduced pressure. The crude materials were purified by column chromatography ($SiO_2$, heptane–ethyl acetate, 95 : 5).

# Oxidation of organic substrates by molecular oxygen mediated by *N*-hydroxyphthalimide (NHPI) and acetaldehyde

**Cathy Einhorn,* Jacques Einhorn, Céline Marcadal and Jean-Louis Pierre**

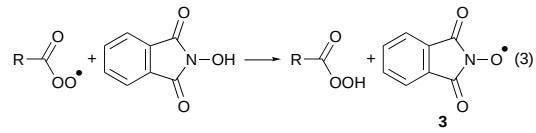
*Laboratoire de Chimie Biomimétique, UMR CNRS 5616, Université J. Fourier, 38041 Grenoble, France*

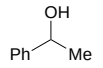
**Various organic substrates, in particular hydrocarbons, are efficiently oxidized under mild conditions using molecular oxygen, *N*-hydroxyphthalimide and acetaldehyde, in the absence of metal catalysts.**

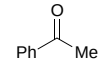
The use of molecular oxygen for the selective oxidation of organic substrates, especially hydrocarbons under mild conditions, is still a major challenge for organic chemistry.[1] It constitutes an environmentally safe alternative to more conventional oxidants used in stoichiometric amounts and is therefore of high economic value in industrial chemistry.[2] Catalysis by transition metal complexes is the main way of controlling the partial oxidation of alkanes, alkenes and aromatic hydrocarbons.[3] Although they have been known for a long time, autoxidations *without transition metal catalysis* are often of low efficiency and selectivity. They proceed *via* a free radical chain mechanism promoted by catalytic amounts of radical initiators.[4] Aldehydes are exceptions among organic compounds as their autoxidation rates are very high with long propagation chains [reactions (1) and (2)] even at room temperature and atmospheric pressure. This property has been used in the so-called 'cooxidation' processes, in which a mixture of an aldehyde and another organic substrate is submitted to molecular oxygen. The autoxidation of the aldehyde then promotes the oxidation of the less reactive partner. Aldehyde-mediated cooxidations have been used for the epoxidation of alkenes,[5] Bayer–Villiger oxidation of ketones[6] and oxidation of alcohols and of some hydrocarbons.[7] We describe herein the oxidation of organic substrates, in particular hydrocarbons, under aldehyde-promoted cooxidation conditions, in the presence of *N*-hydroxyphthalimide (NHPI). NHPI has been used previously as an electron carrier for electrochemical oxidations.[8] More recently various oxidations have been conducted using molecular oxygen and NHPI, generally combined with transition metal salts, under nonelectrochemical conditions.[9] Our new combination of $O_2$–aldehyde–NHPI reveals several interesting features. When a 0.2 M solution of ethylbenzene, acetaldehyde (1 equiv.) and NHPI (0.1 mol%) in MeCN was vigorously stirred at room temperature under an oxygen atmosphere for 48 h, a 26% yield of acetophenone and a 6% yield of 1-phenylethanol were formed, with no further reaction after a longer reaction time. No further oxidation was observed after the addition of a second equivalent of acetaldehyde and an additional 48 h stirring time. No NHPI was recovered at the end of this experiment but an almost quantitative amount of phthalimide was isolated. Surprisingly, the same experiment carried out in the *absence of stirring* led to substantially different results; after keeping the reaction medium under oxygen without any stirring for 48 h the yields of ketone and alcohol were 50 and 6%, respectively, while TLC analysis of the solution indicated only a partial degradation of NHPI. The addition of a second equivalent of acetaldehyde and another 48 h standing period led to increased yields of 67 and 9%, respectively. Obviously the rate of aldehyde autoxidation, controlled by oxygen diffusion in the solution, plays a decisive role in the outcome of the reaction. High aldehyde autoxidation rates lead to fast NHPI degradation, no more ethylbenzene being oxidized after its complete disappearance.

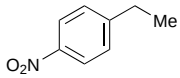
Passive diffusion of oxygen in bulk solutions is very sensitive to geometric characteristics of the reactor and therefore difficulties in the reproducibility and scaling up of such experiments may be anticipated. We found that an efficient and reproducible way to perform such oxidations is to add *slowly* the aldehyde to the vigorously stirred reaction medium; when 1 equiv. of acetaldehyde was added over 5 h to a solution of ethylbenzene and NHPI under oxygen, and fast stirring maintained for an additional 5 h period, a 66% yield of acetophenone and a 4% yield 1-phenylethanol were obtained.† Table 1 shows further examples of oxidations performed under the same conditions: 4-nitro-1-ethylbenzene is oxidized with lower efficiency than ethylbenzene itself (run 3) whereas 4-methoxy-1-ethylbenzene is oxidized almost quantitatively (runs 4, 5). 1-Phenylethanol is oxidized only slowly to acetophenone (runs 6, 7) indicating that a direct pathway leading from ethylbenzene to acetophenone is likely. In the case of cumene, demethylation giving acetophenone competes with hydroxylation (run 8). Indane and isochromane are oxidized almost quantitatively (runs 9, 10). Surprisingly diphenylmethane is oxidized with a lower conversion (49%) than ethylbenzene (70%), with a relatively high alcohol : ketone ratio (run 11). A high conversion (94%) is obtained on the other hand with xanthene (run 12). Inactivated hydrocarbons are oxidized at a slow but nevertheless significant rate: 8% conversion of cyclohexane is observed after a 72 h reaction time, with a 1 : 7 alcohol : ketone ratio (run 13). Adamantane is oxidized almost exclusively to adamantan-1-ol with only trace amounts of adamantan-2-one (runs 14, 15).

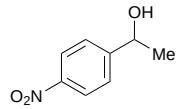
In order to obtain information about the reaction mechanism of this oxidation, several parameters have been investigated. No oxidation occurs in the presence of either hydroquinone or TEMPO (1 mol%), confirming the free radical pathway of the reaction. No oxidation is observed at room temperature with NHPI alone.‡ Cooxidation of ethylbenzene and acetaldehyde (1 equiv.) in the absence of NHPI furnishes, after 48 h, only 7% ketone and 2% alcohol, indicating a strong cooperative effect of both NHPI and aldehyde under cooxidation conditions. Virtually no oxidation is observed when acetaldehyde is replaced by peracetic acid, clearly indicating that the species involved in these oxidations is not the peracetic acid **2** (R = Me) formed *in situ*, but is probably the acetylperoxy radical **1**. This radical **1** may in turn oxidize NHPI to phthalimide *N*-oxyl **3** [reaction (3)], a fairly stable but highly reactive free radical, which has been proposed as a key intermediate in NHPI-mediated oxidations.[8d,8h,9c]

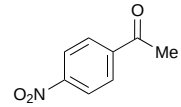


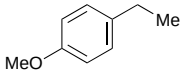


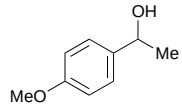


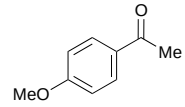


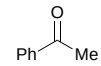


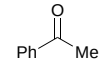


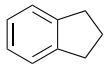


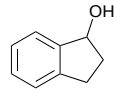


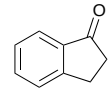


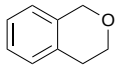


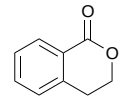


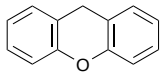


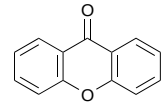


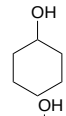


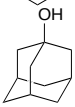












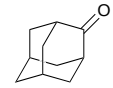


**Table 1** Molecular oxygen oxidation of various substrates mediated by NHPI and acetaldehyde[a]

[a] Performed on a 1 mmol scale, in the presence of 0.1 mmol NHPI, in 3 ml MeCN. A solution of 1 mmol acetaldehyde in 3 ml MeCN was added over 5 h *via* a syringe pump. [b] Including the aldehyde addition period. [c] Determined by calibrated quantitative GLC analysis using an internal standard. [d] Absolute yield determined by GLC.

The new oxidation system developed here allows aerobic oxidation of organic substrates under very mild conditions without any metal catalyst, and will therefore find many applications in synthesis. Further studies on the reaction mechanisms involved here are currently under way.

## Footnotes

† Comparative experiments have been performed with benzaldehyde or isobutyraldehyde but with poorer results.

‡ Autoxidations of benzylic derivatives catalysed by NHPI alone have been described [see ref. 9(*a*)], but they occur at significant rates only at comparatively high temperature (100 °C) in benzonitrile as the solvent.

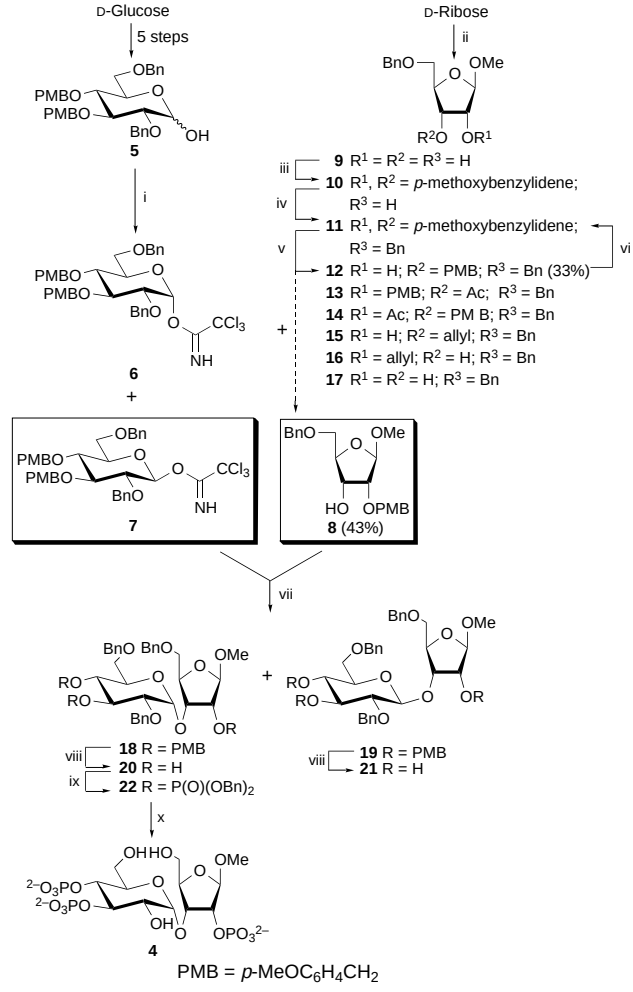
# A disaccharide polyphosphate mimic of 1D-*myo*-inositol 1,4,5-trisphosphate

**David J. Jenkins, Rachel D. Marwood and Barry V. L. Potter*†**

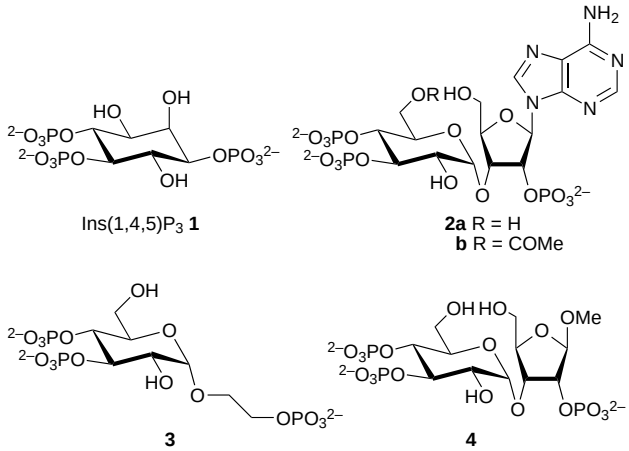
*Department of Medicinal Chemistry, School of Pharmacy & Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY*

**A concise route from D-glucose and D-ribose to a potent sugar polyphosphate second messenger mimic related to adenophostin A is described; a role for the adenine base of the adenophostins is suggested.**



1D-*myo*-Inositol 1,4,5-trisphosphate [Ins(1,4,5)$P_3$, **1**] is a second messenger responsible for increasing the intracellular $Ca^{2+}$ concentration in stimulated cells.[1] Structure–activity studies now allow a good understanding of the relationship between **1** and its receptor.[2] A specific vicinal D-*threo* bisphosphate is essential for activity, while the third phosphate and 6-hydroxy group help to enhance binding affinity.

Most active inositol polyphosphates and related compounds tested at the Ins(1,4,5)$P_3$ receptor exhibit potencies comparable to or less than that of **1**.[2] However, in 1993 a Japanese group reported the isolation of two potently agonistic trisphosphate glyconucleotides from culture broths of *Penicillium brevicompactum*,[3] named adenophostins A and B and identified as **2a** and **2b**, respectively.[4] The structure of **2a** has now been confirmed by total synthesis.[5] Both adenophostins are effective at concentrations 10–100-fold lower than for **1**; these relative potencies are consistent with binding data.[6,7] Thus, **2a** and **2b** are by far the most potent agonists yet described at the Ins(1,4,5)$P_3$ receptor, despite their structural dissimilarity to **1**, and are attractive leads to carbohydrate-based Ins(1,4,5)$P_3$ mimics and receptor modulators.



To elucidate the structural motifs of the adenophostins responsible for their activity we[8] and others[9] prepared the minimal structure **3**, which exhibited a potency 10-fold lower than **1**, demonstrating that while the glucose bisphosphate contained the pharmacophore responsible for $Ca^{2+}$ release, at least part of the adenosine moiety was responsible for the high activity of the adenophostins. Molecular modelling studies on **3** established[9] that the staggered conformation of its bimethylene chain did not allow the 2′-phosphate to mimic the corresponding phosphate of either **1** or **2a**. We report here the synthesis of methyl 3-*O*-(α-D-glucopyranosyl)-β-D-ribofuranoside 2,3′,4′-trisphosphate **4**, in which the adenine ring of **2a** has effectively been deleted, but the third phosphate is held similarly to **2a**, and which should clarify the relative importance of conformational restriction of this phosphate for the potency of **2a**.

2,6-Di-*O*-benzyl-3,4-di-*O*-(*p*-methoxybenzyl)-D-glucopyranose **5** was prepared in five steps from D-glucose.[8b] Reaction of **5** with $Cl_3CCN$ in the presence of $K_2CO_3$[10] gave the α-trichloroacetimidate **6** ($[\alpha]_D$ +13.6) and the crystalline β-anomer **7** (mp 80–81 °C; $[\alpha]_D$ +16.5), separated by flash chromatography, in the ratio of 1 : 2.5, based on isolated products.

With a suitable glycosyl donor in hand, we required **8** as an acceptor. D-Ribose was converted into known[11] **9**. Reaction of **9** with 1.05 equiv. of *p*-methoxybenzaldehyde dimethyl

**Scheme 1** *Reagents and conditions*: i, $Cl_3CCN$, $K_2CO_3$, $CH_2Cl_2$, $N_2$, room temp. 2 h, 65%; ii, MeOH, $H_2SO_4$, room temp., 20 h (β-anomer obtained by crystallisation); iii, *p*-$MeOC_6H_4CH(OMe)_2$, PTSA, DMF, 70 °C, −MeOH, 4 h, 93%; iv, NaH, BnBr, DMF, 3 h, 82%; v, DIBAL-H, $CH_2Cl_2$, room temp., 3 h, 76%; vi, DDQ, $CH_2Cl_2$, 3 Å sieves, room temp., 3 h, 71%; vii, $Me_3SiOSO_2CF_3$, $Et_2O$, 3 Å sieves, room temp., 10 min; viii, DDQ, $CH_2Cl_2$–$H_2O$ (10 : 1), room temp., 1 h, 56%; ix, $(BnO)_2PNPr^i_2$, 1*H*-tetrazole, room temp., 30 min, then MCPBA, −78 °C to room temp., 10 min, 82%; x, $H_2$, Pd–C, 40 psi, MeOH–$H_2O$ 4:1, room temp., 18 h, 70%

acetal,[12] with continuous removal of the liberated MeOH *via* an air condenser,[13] gave the 2,3-*O*-(*p*-methoxybenzylidene) derivative **10** ($[\alpha]_D$ −43.0) as a *ca.* 3 : 2 diastereoisomeric mixture, as judged by NMR. Benzylation of **10** gave **11** ($[\alpha]_D$ −27.2). Cleavage of the acetal with $LiAlH_4$–$AlCl_3$ in refluxing THF,[14] $NaCNBH_3$–$Me_3SiCl$ in MeCN[12] or DIBAL-H in $CH_2Cl_2$[15] all gave the required **8** (mp 42–43 °C; $[\alpha]_D$ +34.6), and the more polar **12** ($[\alpha]_D$ −28.8), in approximately equal proportions, the latter reagent giving by far the best yield. The structures of **8** and **12** were confirmed by preparation of acetates **13** ($[\alpha]_D$ +17.5) and **14** ($[\alpha]_D$ +21.5), the $^1$H NMR spectra of which respectively revealed a triplet at δ 5.13 (*J* 5.3 Hz) corresponding to H-3, and a doublet at δ 5.18 (*J* 4.4 Hz; H-1 presented as a singlet) corresponding to H-2. Although the regioselectivity of acetal cleavage was disappointing, isomer **12** was easily reoxidised to **11** (as a 92 : 8 diastereoisomeric mixture, $[\alpha]_D$ −26.4; diastereoisomers not assigned) using DDQ in dry $CH_2Cl_2$.[16]

A preparation of the related allyl-protected ribosides **15** and **16** by a different route has recently been reported.[17] Anomerisation of methyl 5-*O*-benzyl-2,3-*O*-isopropylidene-β-D-ribofuranoside on acidic hydrolysis, to give a *ca.* 1 : 4 α : β-anomeric mixture of products was described. We found that the more labile *p*-methoxybenzylidene acetal of **11** could be removed without anomerisation by treatment with 80% (*v*/*v*) aqueous acetic acid at 60 °C for 25 min, to give **17** ($[\alpha]_D$ −42.0; lit.[17] −47.7). Therefore, **10** may be a more suitable intermediate than methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside to prepare derivatives of methyl β-D-ribofuranoside substituted at position 5.

Coupling of **7** and **8** was achieved using $Me_3SiOSO_2CF_3$ as promoter.[10] The $^1$H NMR spectrum indicated that although the α-glucopyranosyl compound **18** was the major product (H-1′, δ 5.09, *J* 3.4 Hz), the anomer **19** was present as a *ca.* 20% contaminant which could not be removed at this stage. However, on treatment with DDQ, the required triol **20**‡ (mp 103–105 °C; $[\alpha]_D$ +28.3) could be separated from **21** by column chromatography. Phosphitylation of **20** followed by oxidation gave the trisphosphate **22** ($[\alpha]_D$ +34.7). Compound **22** was hydrogenolysed to give the required trisphosphate **4**§ which was purified on Q Sepharose resin eluting with a 0–1 mol $dm^{-3}$ gradient of triethylammonium hydrogen carbonate, pH 7.5. The triethylammonium salt of **4** eluted at *ca.* 800–850 mmol $dm^{-3}$ buffer. As this form was surprisingly poorly soluble in water, it was converted to the freely soluble hexapotassium salt ($[\alpha]_D$ +67.3 calc. for free acid, $H_2O$, pH 8.5) before quantification by total phosphate assay[18] and biological evaluation.

Preliminary biological evaluation of 'ribophostin' **4** using permeabilised hepatocytes[19] revealed a $Ca^{2+}$-mobilising potency 10-fold better than **3** and very close to that of Ins(1,4,5)$P_3$. Full biological characterisation will be reported elsewhere. Noting that 2′-dephosphorylation of **2a** reduces its binding affinity 1000-fold,[4] this suggests that conformational restriction of the 2′-phosphate alone can engender Ins(1,4,5)$P_3$-like, but not adenophostin-like, potency. Therefore the adenine base of adenophostin plays an important, but as yet undefined, role in enhancing activity. We believe that it probably contributes to the positioning of the ribose phosphate such that it can mimic the 1-phosphate of Ins(1,4,5)$P_3$ in a unique way. Further clarification must now await the synthesis of suitably conformationally restricted compounds for accurate positioning of the 2′-phosphate group.

We thank Dr H. Dietrich for discussions, Dr C. Taylor for preliminary biological evaluations, the Wellcome Trust for a Prize Studentship (R.D.M.) and the BBSRC (Intracellular Signalling Programme) for financial support.

# Absolute stereochemistry of 1,2′-linked bi(naphthoquinone)s

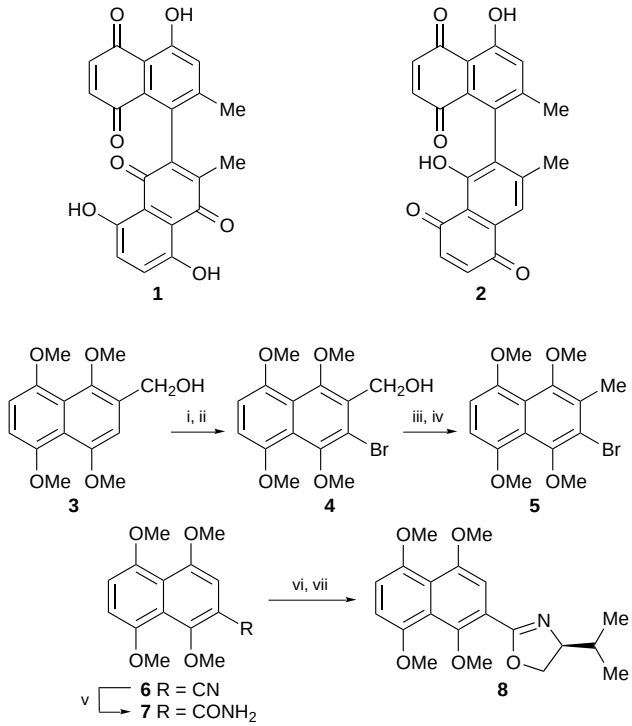
**Robert W. Baker, Song Liu, Melvyn V. Sargent,* Brian W. Skelton and Allan H. White**

*Department of Chemistry, The University of Western Australia, Nedlands, Western Australia 6907, Australia*

**Asymmetric syntheses of the enantiomers of the naturally occurring atropisomerically chiral 1,2′-linked bi(naphthoquinone)s 8′-hydroxyisodiospyrin and isodiospyrin have allowed their absolute configurations to be assigned by X-ray and circular dichroism spectral studies of synthetic intermediates.**

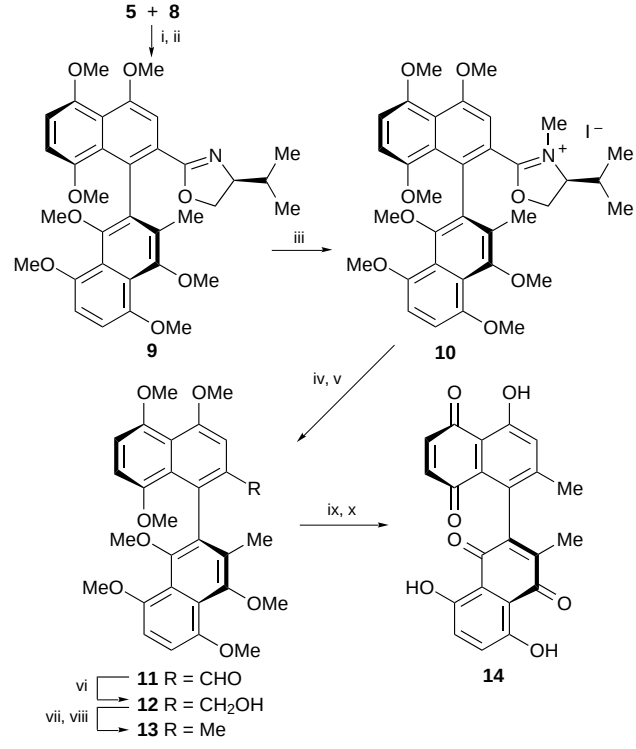
There is a small number of naturally occurring bi(naphthoquinone)s which exhibit axial chirality.[1] Two of these compounds, (−)-8′-hydroxyisodiospyrin **1**[2,3] (which also occurs naturally in racemic form)[3] and (−)-isodiospyrin **2**,[1] are both 1,2′-linked and are of unknown but identical absolute configuration since isodiospyrin has been converted into 8′-hydroxyisodiospyrin in poor yield.[2]

We now report the synthesis of the enantiomers of both of these compounds which have been previously synthesised in racemic form.[4]



The known hydroxymethyl compound **2**,[5] on treatment with Schlosser's base[6] followed by 1,2-dibromo-1,1,2,2-tetrafluoroethane, afforded the bromo compound **4** (Scheme 1), and hence the bromo compound **5**. The known nitrile **6**[5] was converted into the amide **7** which under standard conditions[7] gave the dihydrooxazole **8**.

When the dihydrooxazole **8** was allowed to react with an excess of the Grignard reagent derived from the bromo compound **5** (Scheme 2), a 45% yield of the coupled product resulted which consisted of an inseparable mixture of two diastereoisomers, as shown by the $^1$H NMR spectrum, in the ratio 7 : 1. The major diastereoisomer was predicted to possess structure **9** (*i.e. R*) since the stereochemical outcome of the coupling is controlled by the chelating ability of the *ortho*-substituents (Fig. 1).[8] This stereochemistry was confirmed by an X-ray study† of a sample of the derived iodide **10** (Fig. 2) obtained by crystallisation of the diastereoisomeric mixture to constant specific rotation.



The iodide, enriched in the diastereoisomer **10**, was converted sequentially into the aldehyde **11**, the hydroxymethyl compound **12** and finally into the methyl compound **13**. The Mosher ester[9] of the hydroxymethyl compound indicated the presence of two diastereoisomers in the ratio 7 : 1, thus confirming that no racemisation has occurred during these transformations.

The circular dichroism (CD) spectrum[10] of the methyl compound **13** indicated the *S*-configuration in agreement with both mechanistic prediction and the X-ray study.

The methyl compound was oxidatively demethylated by treatment with ammonium cerium(IV) nitrate and the crude mixture of quinones so obtained was completely demethylated by exposure to aluminium chloride. Fractional crystallisation of the crude product allowed the separation of the (+)-(*S*)

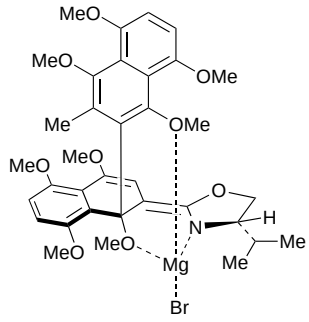
CAN, MeCN, 0–25 °C, 30 min; x, $AlCl_3$, $CH_2Cl_2$, 0–25 °C, 1 h, 45%



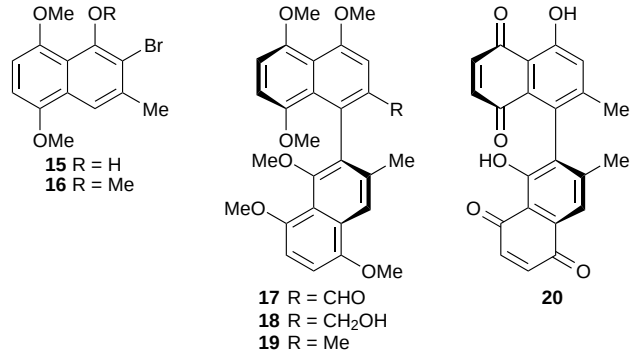


**Fig. 1** Preferred transition state for the coupling reaction leading to diastereoisomer **9**

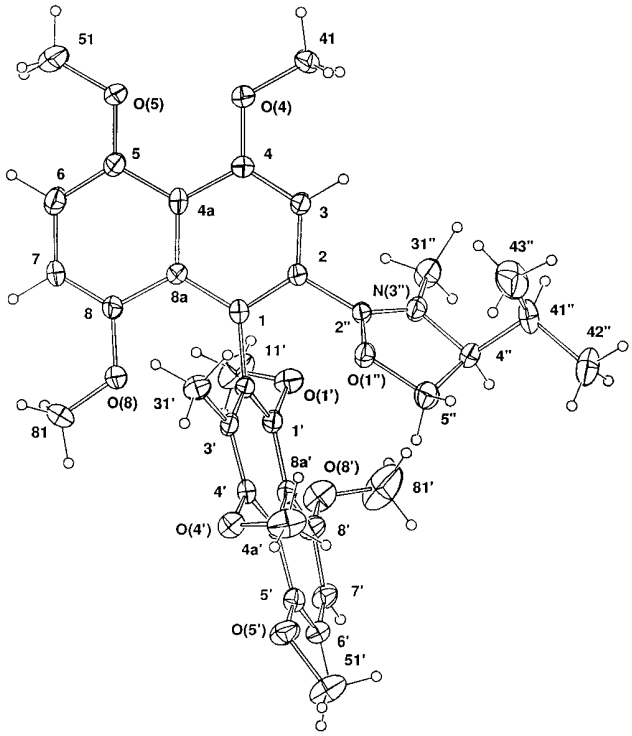

**Fig. 2** The cation of **10** as derived from the X-ray study; 20% thermal ellipsoids are shown for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å. Carbon atom labelling is shown by numbers only. Dihedral angles between central (unprimed) and pendant (fused) ring skeletal planes (prime and double prime): 81.2(2), 54.0(2)°.

enantiomer **14** of 8′-hydroxyisodiospyrin, mp 274 °C, from its less soluble racemate **1**. The spectroscopic properties of these compounds were identical with those of the natural materials.[2–4] Since the (+)-(*S*) enantiomer **14** absorbs strongly at the D-line it was not possible to obtain a precise value for the specific rotation; the CD spectrum (dioxane), however, exhibited maxima at λ 298, 354 and 480 nm (Δε 11.3, 6.9 and 2.4) and minima at λ 265 and 419 nm (Δε −22.8 and −1.4). The natural product thus possesses the *R* configuration.

The synthesis of isodiospyrin followed similar methodology. The required bromo compound **16**, obtained by methylation of the naphthol **15**,[11] was allowed to react as its Grignard reagent with the dihydrooxazole **8**. In this case the diastereoisomeric ratio of the coupled products was 10 : 1. At the stage of the aldehyde **17** in the synthetic sequence optical purification could readily be achieved by crystallisation, as shown by the $^1$H and $^{19}$F NMR spectra of the Mosher ester of the derived alcohol **18** when compared with those of the derivative of the racemic alcohol. These spectral data and those for the Mosher ester of the alcohol **12** allowed the configuration of the alcohol **18** to be assigned as *S*,[12] which was confirmed by the CD spectrum of the methyl compound **19**. Synthetic (+)-(*S*)-isodiospyrin **20**, mp 233 °C (lit.[13] for enantiomer, 233 °C), proved to be identical in physical properties, except rotation {$[\alpha]_D^{20}$ +138 (*c* 0.38, $CHCl_3$) [lit.[13] for enantiomer, −150 (*c* 0.27, $CHCl_3$)]}, with those of an authentic sample of the racemate.‡ The natural product thus possesses the *R* configuration.

## Footnotes

# Highly active ruthenium complexes with bidentate phosphine ligands for the solvent-free catalytic synthesis of *N*,*N*-dimethylformamide and methyl formate

**Oliver Kröcher, René A. Köppel and Alfons Baiker***

*Department of Chemical Engineering and Industrial Chemistry, Swiss Federal Institute of Technology, ETH-Zentrum, CH-8092 Zürich, Switzerland*

**Complexes of the type $[RuCl_2L_2]$ [L = $Ph_2P(CH_2)_nPPh_2$ ($n$ = 1–3), $Me_2P(CH_2)_2PMe_2$] are shown to be highly active and selective catalysts for the synthesis of formic acid derivatives from carbon dioxide, hydrogen and dimethylamine or methanol–triethylamine, respectively, without any additional solvent, affording at 373 K with $[RuCl_2(dppe)_2]$ an extremely high turnover frequency (TOF) of 360 000 $h^{-1}$ in *N*,*N*-dimethylformamide synthesis and a TOF of 830 $h^{-1}$ in methyl formate synthesis.**

Recently, carbon dioxide has gained renewed interest as an ideal source of carbon in synthetic chemistry because of its abundance, low cost and non-toxicity.[1,2] Among the possible valuable chemicals, special attention is given to formic acid and its derivatives like *N*,*N*-dimethylformamide [eqn. (1)] and methyl formate [eqn. (2)].[3,4]

$$CO_2 + H_2 + Me_2NH \rightarrow Me_2NC(O)H + H_2O \quad (1)$$

$$CO_2 + H_2 + MeOH \rightarrow HC(O)OMe + H_2O \quad (2)$$

The progress made up to 1995 in the homogeneously catalysed synthesis of *N*,*N*-dimethylformamide (dmf) and methyl formate from carbon dioxide has been reviewed recently.[3,4] Among various transition-metals investigated, ruthenium and rhodium complexes were found to exhibit high activity. Although remarkable efforts have been made to increase the activity of the catalytic complexes used, the turnover numbers (TON) and turnover frequencies (TOF) achieved remained realtively low.[3,4]

More recently, the use of $[RuCl_2(PMe_3)_4]$ as a catalyst for the synthesis of formic acid, dmf and methyl formate from carbon dioxide, hydrogen and dimethylamine or methanol, respectively, has been reported by Jessop *et al.*[3,5] The application of supercritical carbon dioxide (sc-$CO_2$) as a solvent for hydrogen and the catalyst enabled the authors to produce dmf with overall rates of up to 10000 $h^{-1}$ and methyl formate with overall rates of up to 55 $h^{-1}$. The use of sc-$CO_2$-soluble complexes was reported to be crucially important for achieving high activities. Although the process reported by Jessop *et al.* is far more efficient compared to the liquid-phase synthesis of dmf and methyl formate, overall reaction rates are still relatively low and the catalysts are sensitive to air, which impairs technical utilisation. The aim of our study was to find more active and stable catalysts for the synthesis of dmf and methyl formate, obviating these limitations.

Ruthenium complexes of the type $[RuCl_2L_2]$, with L representing the chelating ligands dppm = $Ph_2PCH_2PPh_2$, dppe = $Ph_2P(CH_2)_2PPh_2$ or dppp = $Ph_2P(CH_2)_3PPh_2$, were prepared,[6] which are easy to characterize, relatively cheap, and stable to water and air.

Table 1 lists the experimental conditions and the catalytic results obtained with the various ruthenium complexes for the synthesis of *N*,*N*-dimethylformamide and methyl formate, respectively. Note that catalytic results presented in Table 1 were confirmed by at least two repetitive experiments. Blank tests without catalyst performed repeatedly throughout the study revealed no catalytic activity.

The synthesis of dmf proceeded very rapidly at 373 K with up to 99% yield and always with 100% selectivity to dmf. Analysis of the gas phase by GC confirmed that no gaseous by-products (CO, $CH_4$) were formed. A TOF of 360 000 $h^{-1}$ could be reached with $[RuCl_2(dppe)_2]$, which is 36 times higher than that with $[RuCl_2(PMe_3)_4]$, the best catalyst reported so far.[3,5] In an experiment using 110 g dimethylamine a maximum TON of 740 000 was achieved, which indicates the upper limit of the catalyst's lifetime under the conditions applied. Calculated on the basis of 1 g of ruthenium, 530 kg dmf can be produced within 2 h. Further improvement in TOF may be possible by optimizing the reaction parameters. High TOFs could also be reached with $[RuCl_2(dppm)_2]$, whereas $[RuCl_2(dppp)_2]$ exhibited much lower activity (Table 1).

The extremely high catalytic activity achieved with such *trans*-$[RuCl_2L_2]$ complexes was not *a priori* expected, since the formation of a monohydride species was reported to be a prerequisite for catalytic activity for this type of hydrogenation

**Table 1** Catalytic properties of ruthenium complexes in the production of *N*,*N*-dimethylformamide and methyl formate from $CO_2$[a]

| Complex (μmol) | Reactant [additive] (mol) | *t*/h | Product | TON[b] | TOF[c]/$h^{-1}$ |
|---|---|---|---|---|---|
| $[RuCl_2(PMe_3)_4]$[d] (6.4) | Dimethylamine (3.80) | 70.0 | dmf | 420 000 | 6 000 |
| $[RuCl_2(dppe)_2]$ (0.58) | Dimethylamine (2.44) | 2.05 | dmf | 740 000 | **360 000** |
| $[RuCl_2(dppe)_2]$ (0.73) | Dimethylamine (0.78) | 0.75 | dmf | 200 000 | 265 000 |
| $[RuCl_2(dppm)_2]$ (1.0) | Dimethylamine (0.72) | 0.50 | dmf | 95 000 | 190 000 |
| $[RuCl_2(dppp)_2]$ (3.1) | Dimethylamine (0.72) | 4.05 | dmf | 10 700 | 2 650 |
| $[RuCl_2(dmpe)_2]$ (8.7) | Dimethylamine (0.72) | 15.0 | dmf | 30 000 | 2 000 |
| $[RuCl_2(PMe_3)_4]$[d,e] (2.9) | Methanol (0.08) [triethylamine] (0.030) | 64.0 | Methyl formate | 3 500 | 55 |
| $[RuCl_2(dppe)_2]$ (3.8) | Methanol (0.74) [triethylamine] (0.370) | 15.5 | Methyl formate | 12 900 | **830** |
| $[RuCl_2(dppe)_2]$[e] (2.3) | Methanol (0.74) [triethylamine] (0.074) | 15.5 | Methyl formate | 10 100 | 650 |

[a] *Reaction conditions*: 500 ml stainless-steel autoclave equipped with magnetically coupled stirrer. Analysis: GC equipped with Supelco SPB-1 fused silica capillary column. $p(H_2)$ = 8.5 MPa, $p(CO_2)$ = 13.0 MPa, $T$ = 373 K. [b] TON = mol product/mol complex. [c] TOF = TON $h^{-1}$. [d] Lit. data[3] for the hitherto best catalyst $[RuCl_2(PMe_3)_4]$. 300 ml autoclave. [e] $T$ = 353 K.

catalyst.[5,7] No conversion of *trans*-$[RuCl_2L_2]$ complexes to the corresponding monohydrides at normal pressure is described in the literature.[8,9] Despite this, $[RuHCl(dppe)_2]$, identified by NMR, could be found in the reactor after pretreatment of $[RuCl_2(dppe)_2]$ with 40 bar of hydrogen and dimethylamine, confirming monohydrides as key intermediates in the catalytic cycle. The monitored pressure in the reactor as well as the catalytic results indicated no further induction period after addition of carbon dioxide.

Jessop *et al.* investigated visually the phase behaviour in the reactor under comparable conditions for different reactants and additives. They found that a supercritical phase of carbon dioxide and hydrogen exists besides a liquid phase, highly swelled by dissolved gases.[5] Thus, high concentrations of carbon dioxide and possibly hydrogen could be assumed in the liquid-amine phase. Leitner *et al.* reported high concentrations of dissolved carbon dioxide in the liquid phase also under subcritical conditions.[10] Due to their insolubility in the sub- or super-critical carbon dioxide, the complexes *trans*-$[RuCl_2L_2]$ are expected to operate in the liquid phase, which is also supported by the fact that the catalysts could only be found in the liquid-product mixture after reaction. Moreover, cleaning of the lower part of the autoclave was sufficient to exclude any activity in subsequent blank tests. Variations of the carbon dioxide partial pressure from super- to sub-critical conditions, using $[RuCl_2(dppe)_2]$ as catalyst, resulted in a decrease of activity from 360 000 $h^{-1}$ (8.5 MPa $CO_2$) to 150 000 $h^{-1}$ (1.8 MPa $CO_2$), but no drastic activity drop was observed, indicating supercritical conditions not to be a necessary prerequisite for high catalytic activity.

Despite their similar solubility properties, the three related complexes $[RuCl_2(dppm)_2]$, $[RuCl_2(dppe)_2]$ and $[RuCl_2(dppp)_2]$ exhibited substantially different activities, with $[RuCl_2(dppp)_2]$ being far less active than $[RuCl_2(dppm)_2]$ and $[RuCl_2(dppe)_2]$ (Table 1). In order to compare the catalytic properties of these complexes, which are insoluble in sc-$CO_2$, with a complex soluble in the supercritical phase, $[RuCl_2(dmpe)_2]$ [dmpe = $Me_2P(CH_2)_2PMe_2$] was prepared,[11] using bidentate methyl phosphine ligands instead of phenyl phosphine ligands. Interestingly, $[RuCl_2(dmpe)_2]$ exhibited similar low activity to $[RuCl_2(dppp)_2]$, suggesting a more pronounced influence of the phosphine ligands than of the catalysts solubility properties.

$[RuCl_2(dppe)_2]$ was also tested for methyl formate synthesis at 353 K and exhibited a 12 times higher activity (TOF = 650 $h^{-1}$) than $[RuCl_2(PMe_3)_4]$ (TOF = 55 $h^{-1}$) under comparable conditions. Increasing the triethylamine concentration and the temperature resulted in an even higher TOF of 830 $h^{-1}$, which is 15 times higher than the best previous results.[5] Analysis of the reaction mixture by $^1H$ NMR spectroscopy revealed the formation of an adduct of formic acid and triethylamine beside methyl formate. Methyl formate synthesis with our complexes is favourable compared to that with $[RuCl_2(PMe_3)_4]$, because higher temperatures can be applied, which is crucial for an effective esterification of the initially formed formic acid.

In conclusion, we can state that ruthenium complexes with bidentate phosphine ligands exhibit much higher activity for the solvent-free synthesis of *N*,*N*-dimethylformamide (dmf) and methyl formate from carbon dioxide than hitherto reported catalytic systems.[3,5] The high concentrations of hydrogen and carbon dioxide in the liquid dimethylamine or methanol–triethylamine phase afford high concentrations of all reactants at the catalytic centres in an ideal reaction design. We have demonstrated that further improvements in the homogeneous hydrogenation of carbon dioxide are achievable not only by developing complexes soluble in the supercritical medium, but also by the utilisation of better suited ligands for this reaction in combination with a solvent-free reaction design.

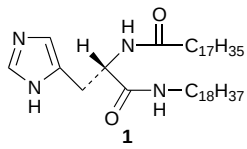
# Boomerang shaped aggregates from a histidine surfactant

**Nico A. J. M. Sommerdijk, Mark H. L. Lambermon, Martinus C. Feiters, Roeland J. M. Nolte* and Binne Zwanenburg***



*Department of Organic Chemistry, NSR-Institute for Molecular Structure, Design and Synthesis, University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands*

**Complexation of copper(II) ions to a long-chain histidine derivative leads to the formation of a new type of chiral architecture having the shape of a boomerang.**

Following the discovery that phospholipid molecules can form vesicular, rod-like, and even helical aggregates,[1] many researchers have shown that similar supramolecular structures can be obtained from synthetic surfactants.[2–5] Here, we report that the synthetic histidine derivative **1** in aqueous solution in the presence of copper(II) triflate forms boomerang-like scrolls. This novel architecture may be an intermediate state in the transformation of closed bilayers to helical structures.

Compound **1** was synthesized from Boc-protected L-histidine following a standard procedure;† **1** was not soluble in water at neutral pH, even at elevated temperatures. Protonation of **1** by dispersion in water adjusted to pH 2.5, led to the formation of very long thin fibres [Fig. 1(*a*)] which assembled side-by-side to yield bundles. Some of them showed a tendency to curl up into a right-handed, twisted structure [Fig. 1(*b*)].

Monolayer experiments indicated that **1** forms stable monolayers. The isotherm recorded at pH 6.5 displayed a sharp increase of the surface pressure at a molecular area of 60 Å$^2$ indicative of a non-compressible state (Fig. 2). When **1** was spread on a subphase adjusted to pH 2.5, the isotherm revealed an increase of the compressibility of the monolayer, as well as an increase in the area per molecule. The formation of a rigid monolayer at pH 6.5 is attributed to the presence of a high degree of preorganisation in the molecules, probably caused by strong intermolecular hydrogen bonds between the imidazole groups and by the formation of so-called amide polymers, *i.e.* linear arrays of hydrogen-bonded amide groups. Protonation of the imidazole groups at pH 2.5 apparently alters this hydrogen-bonding pattern, breaking up the preorganisation in the monolayer. It seems likely that the same strong intermolecular forces prevent the molecules of **1** from dissolving at neutral pH. Here also protonation is required to allow the head-groups of **1** to become hydrated and to form fibres.

**1**

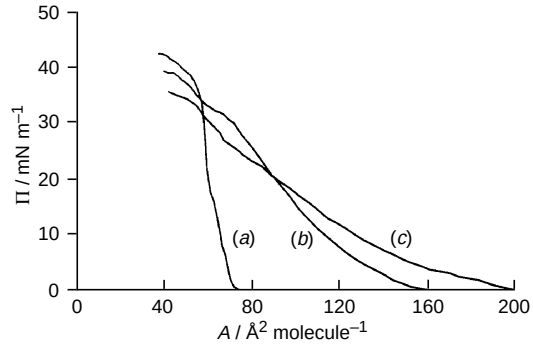


**Fig. 2** Monolayer isotherms of **1** recorded at 20 °C on subphases containing (*a*) water of pH 6.5, (*b*) water adjusted to pH 2.5, and (*c*) 10 mM aqueous copper(II) triflate

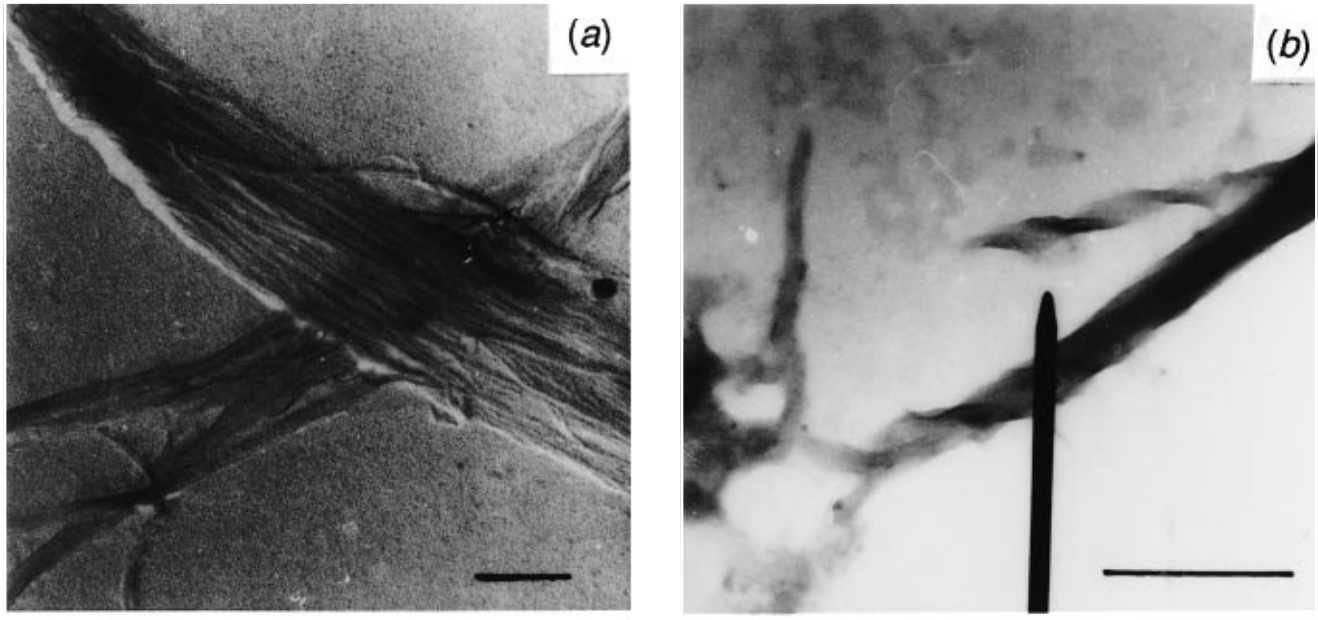

**Fig. 1** Electron micrographs of aqueous 0.1% (m/m) dispersion of **1** adjusted to pH 2.5; bars represent 250 nm

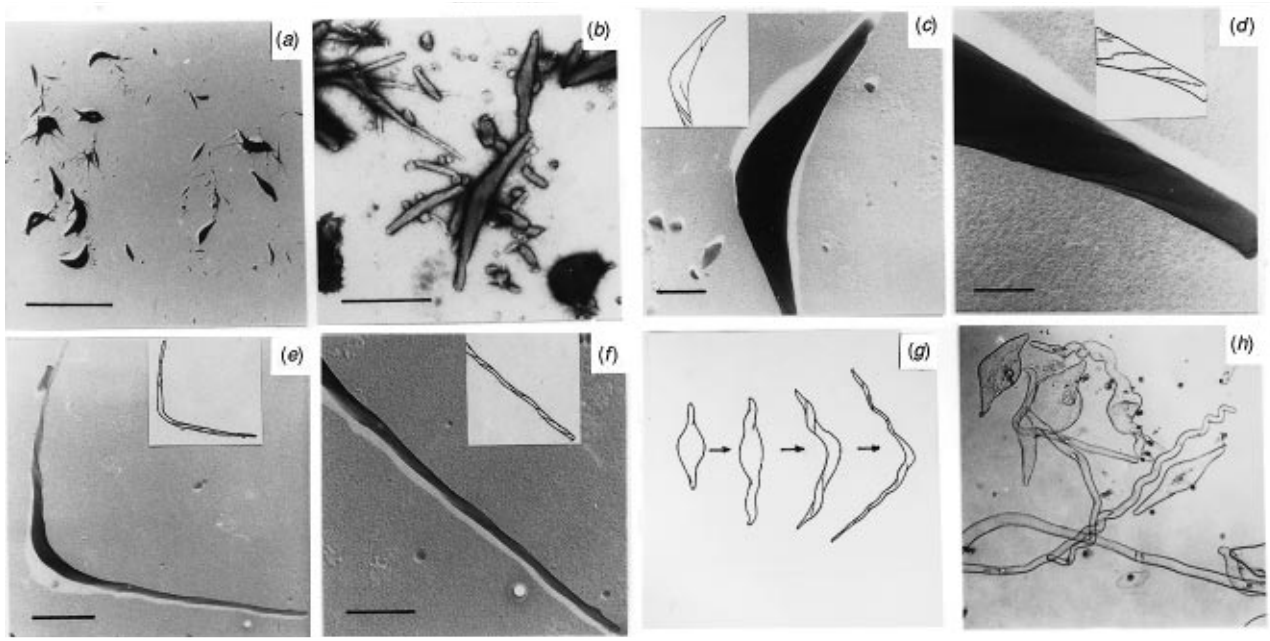

**Fig. 3** (*a*)–(*f*) Transmission electron micrographs of a 0.1% (m/m) dispersions of **1** containing 0.25 molar equivalents of copper(II) triflate. (*a*) Pt shadowing, bar 5 μm, (*b*) negative staining, bar 1 μm, (*c*) Pt shadowing, bar 250 nm, (*d*) Pt shadowing, bar 500 nm, (*e*) Pt shadowing, bar 500 nm, (*f*) Pt shadowing, bar 200 nm. Insets: graphic representations of the observed structures. (*g*) Schematic representation of the process of boomerang formation is deduced from the different observed structures, (*h*) optical micrograph of protoplasts at different stages of growth after addition of fusicoccin, kindly provided by Dr A. N. M. van Amstel.[6]

When copper triflate was added to **1** in a 1:4 ratio,‡ boomerang-like scrolls were generated [Fig. 3(*a*), (*b*)]. These had different thicknesses, but all showed a left-handed turn [Fig. 3(*d*), (*f*)]. Electron micrographs taken of samples stained with 2% uranyl acetate indicated that these scrolls were not massive, but contained an aqueous interior [Fig. 3(*b*)]. The different stages of scroll formation shown in Fig. 3 suggest that these boomerangs are formed by stretching and twisting of the vesicle membranes in a stereospecific manner. According to the overall shape of the scrolls, this twisting starts initially at opposite sides of the vesicle [Fig. 3(*g*)], resulting in a structure with a thickened centre and thin twisted ends [Fig. 3(*c*)], and eventually in thinner species which are also helical in the central part of the aggregate [Fig. 3(*e*)]. The aggregate structures in Fig. 3 show features that strongly resemble the spiral growth of protoplasts induced by the action of fusicoccin as reported by van Amstel [Fig. 3(*h*)].[6]

Remarkably, complexation of copper triflate leads to a monolayer which displays an even higher degree of compressibility, as compared to the monolayers formed on subphases of pure water adjusted to pH 6.5 and 2.5 (Fig. 2). This implies that addition of copper triflate leads to a lower degree of pre-organisation in the two-dimensional surfactant layer. This is most likely due to a preference of hydrogen-bond formation between molecules within the same complex, as opposed to the formation of long linear arrays of intermolecular hydrogen bonds. A similar situation may be present in the three-dimensional aggregates allowing the molecules to pack in such a way that their chirality is expressed at the supramolecular level. The boomerang shaped aggregates may be considered as being metastable states in the transformation of closed bilayer structures of helical ribbons. Further studies are in progress.

The authors thank H. P. M. Geurts for his assistance in performing electron microscopy experiments, W. Wong for providing artwork and Professor G. I. Tesser and P. J. H. M. Adams for the kind donation of Boc-protected L-histidine and helpful discussions.

## Footnotes

† Surfactant **1** was conveniently prepared from Boc-protected L-histidine. One alkyl chain was introduced by a DCC coupling with octadecylamine (yield 60%). Deprotection of this Boc–amide with trifluoroacetic acid and subsequent acylation with *N*-stearoyloxy–succinimide resulted in the introduction of the second alkyl chain (yield 75%). Anal. **1** Calc. C, 74.9; H, 12.0; N, 8.3. Found: C, 74.2; H, 11.5; N, 8.4%.

‡ Comparable ligand systems have been shown to form copper complexes of the type $[Cu(Him)_4]$ (Him = imidazole), see ref. 4*b*.

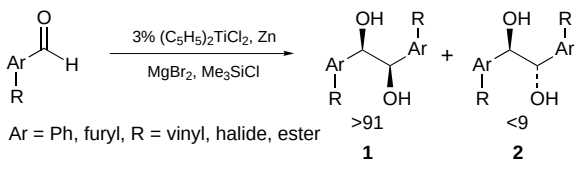
# Pinacol coupling of aromatic aldehydes catalysed by a titanocene complex: a transition metal catalysed radical reaction

**Andreas Gansäuer**



*Institut für Organische Chemie der Georg-August-Universität, Tammannstr. 2, D-37077 Göttingen, Germany*

**A trinuclear complex derived from titanocene chloride and magnesium bromide is an efficient catalyst for the pinacol coupling of aromatic aldehydes; the 1,2-diols are obtained with good diastereoselectivity and a wide variety of sensitive functional groups are tolerated.**

The reductive coupling of carbonyl compounds is the most direct way to 1,2-diols by forming a functionalized carbon–carbon bond.[1] Many stoichiometric reagents for this reaction have been developed[2] and the pinacol coupling has also been applied as a key step in the synthesis of several natural products.[3] To avoid the use of expensive and toxic reagents the development of an efficient transition metal catalysed pinacol coupling is desirable. Here the first titanocene dichloride catalysed pinacol coupling of aromatic aldehydes is described yielding the corresponding 1,2-diols at room temperature in good yields with good diastereoselectivities. Pinacol coupling is not only a shortcut of the otherwise existing two-step sequence, coupling of the aldehydes to an (*E*)-stilbene with stoichiometric amounts of titanium reagents as in McMurry coupling reactions, and a *syn,vic*-dihydroxylation of the central double bond. More importantly the pinacol route to 1,2-diols tolerates certain functional groups that are sensitive to the McMurry reagent and/or to the dihydroxylation reaction. The pinacol coupling used here catalytically uses cheap, readily available, non-toxic reagents.

The only reported catalytic pinacol couplings involve harsh reaction conditions, low selectivities and low functional group tolerance.[4] The catalysts, ruthenium complexes[4a] or samarium iodide,[4b] do not allow control of diastereoselectivity or enantioselectivity by ligand variations.

Based on the ability of cyclopentadienyl-bonded titanium(III) reagents[2a,c] to induce stoichiometric pinacol couplings it seemed possible to develop a catalytic cycle. For this purpose the formed diol has to be removed from titanium with concomitant regeneration of $(C_5H_5)_2TiCl_2$.[5] *In situ* reduction to the titanium(III) reagent then finishes the catalytic cycle.[6] Benzaldehyde coupling in the presence of Zn and $Me_2SiCl_2$ with 10% $(C_5H_5)_2TiCl_2$ gives complete conversion to pinacol after hydrolysis in less than 10 min. $Me_3SiCl$ as additive also gives clean product formation. Without the catalyst, conversion was not observed with $Me_2SiCl_2$ as additive. $Me_3SiCl$ and Zn react to give pinacol over 20 h albeit without diastereoselectivity.[7] Catalylic acceleration of the reaction was therefore significant as was the improvement in diastereoselectivity. Interestingly, however, lowering the temperature at which the catalytic coupling was performed leads to reduced selectivity and pronouncedly longer reaction times. One step in the catalytic cycle was slow and thus a competing, less selective pathway operated. It is known that titanium alkoxides are less selective stoichiometric reagents in pinacol couplings[8] and that both coupling and reduction of $(C_5H_5)_2TiCl_2$ are fast at and below room temperature.[2,6] Thus, silylation is the rate determining step in the catalytic cycle. To improve the diastereoselectivity a solution of benzaldehyde and $Me_3SiCl$ in THF was slowly added to a mixture of $(C_5H_5)_2TiCl_2$ and Zn in THF. The selectivity increased and the yield remained high. Selectivity is further improved by adding 1 equiv. of $MgBr_2$ to the benzaldehyde solution. This gave a tighter dimeric titanium catalyst by replacing Zn with Mg.

**Scheme 1** Titanocene catalysed pinacol coupling of aromatic aldehydes

Diethyl ether and dichloromethane gave inferior results. Other silylating reagents, *e.g.* $Me_2Bu^tSiCl$, did not give any reaction.

Under the optimised conditions a variety of symmetrical 1,2-diols were synthesised in good yields and selectivities and could be obtained diastereomerically pure after a single recrystallisation. Functional groups interfering with McMurry couplings or dihydroxylation reactions such as chlorides, double bonds, phenolate esters and α,β-unsaturated esters are readily tolerated. Although initial experiments were performed on a small scale, the reaction can be readily scaled up and gave the same results using 0.5, 5 or 50 mmol of substrate. In the latter case 320 mg of catalyst was used. This compared favourably with the use of 24.9 g of $(C_5H_5)_2TiCl_2$ in the stoichiometric reaction. In effect $(C_5H_5)_2TiCl_2$ is replaced by the cheaper $Me_3SiCl$. A stoichiometric reductant was needed in both cases. Other stoichiometric or catalytic reagents, *e.g.* $SmI_2$, are even more expensive and less selective. The cheapest source of inherently toxic osmium for a dihydroxylation reaction is about 40 times more expensive than the essentially non-toxic $(C_5H_5)_2TiCl_2$.

Mechanistically it seems reasonable to assume that the catalytically active species in the catalytic cycle is a dimeric

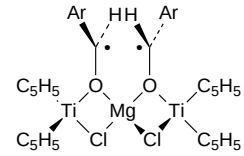


**Fig. 1** Likely catalytically active species for the dimerisation of ketyl radicals both bound to the dimeric titanium catalyst

**Table 1** Coupling of benzaldehyde at 0.1 M in the presence of $Me_2SiCl_2$ or $Me_3SiCl$

titanium complex binding both ketyl radicals. The observed *syn*-selectivity can then be readily explained by minimization of steric interference through *anti*-orientation of the R groups in the complex. This reaction is therefore an example of a transition metal catalysed radical reaction.

This work was generously supported by the Fonds der Chemischen Industrie. I thank Professor R. Brückner for his constant encouragement and generous support.

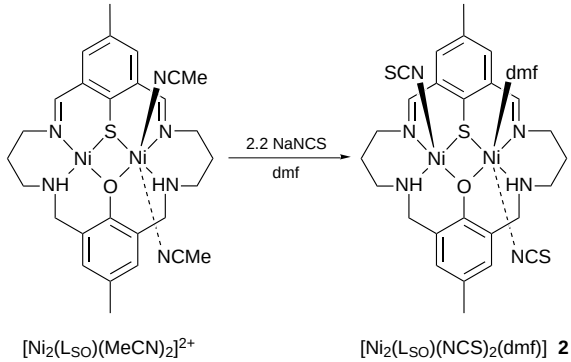
# First example of thiolate-bridged square-pyramidal and octahedral nickel(II) ions: $[Ni_2(L_{SO})(NCS)_2(dmf)]$

**Sally Brooker*† and Paul D. Croucher**



*Department of Chemistry, University of Otago, PO Box 56, Dunedin, New Zealand*

**A structure determination reveals that $[Ni_2(L_{SO})(NCS)_2(dmf)]$ 2 is one of the best structural models to date for the active site of [Ni,Fe] hydrogenases: it also contains the first example of a high-spin thiolate-bound square-pyramidal nickel(II) ion.**

There is currently intense interest in dinickel thiolate-bridged complexes as first-generation models for the active site in [Ni,Fe] hydrogenases,[1] yet only a handful of such complexes have been isolated and fully characterised.[2] The coordination environment of the dinuclear hydrogenase active site is thought to consist of a combination of five-coordinate nickel and six-coordinate iron ions bridged by two thiolate donors (one axial, one equatorial bridge) and one unknown, possibly oxygen-derived, equatorial bridge.[1] Unfortunately the vast majority of nickel mixed-donor thiolate complexes are poor structural models as they exhibit square-planar nickel ion geometries due to the strong ligand field imposed by the thiolate donors.[1–4] There are therefore relatively few examples of geometries other than square planar:[2,5–8] the coordination number five is especially rare, and, to our knowledge, the known examples of this coordination number are all low spin.[2,8] In Schiff-base macrocyclic complexes in which two bridging thiolates are provided this tendency is also observed, with the nickel(II) ions adopting square-planar $N_2S_2$ stereochemistry.[3,4] Clearly the synthesis of complexes which have coordination environments similar to those observed in the metalloprotein is highly desirable. Hence our research efforts are currently directed towards preparing mixed-donor dinickel thiolate-bridged complexes, in which a range of stereochemistries are observed at nickel(II), as first-generation structural models for hydrogenase.[4–7]

Recently we isolated a unique complex, $[Ni_2(L_{SO})(MeCN)_2][ClO_4]_2$ **1**, in which, despite the macrocycle $L_{SO}^{2-}$ providing potentially identical metal-binding environments, two differing geometries were observed for the nickel(II) ions, specifically $N_4SO$ octahedral and $N_2SO$ square planar (Scheme 1).[6] Given that this occurred in the presence of only rather weak ligand field ancilliary ligands (acetonitrile solvent molecules and perchlorate ions) it seemed likely that greater coordination numbers could be imposed on the nickel(II) ions. This paper concerns the intriguing result of adding thiocyanate ions to $[Ni_2(L_{SO})(MeCN)_2][ClO_4]_2$ **1**.

The addition of 2.2 equiv. sodium thiocyanate to an acetonitrile solution of complex **1**[6] causes precipitation of a solid which on recrystallisation from dmf by vapour diffusion of diethyl ether yields $[Ni_2(L_{SO})(NCS)_2(dmf)]$ **2** in which there has been a dramatic alteration in the nickel ion stereochemistries (Scheme 1). The X-ray structure determination reveals that each nickel ion in **2** is bound by an identical set of macrocycle donors (one amine nitrogen, one imine nitrogen, one bridging thiophenolate sulfur and one bridging phenolate oxygen), yet adopts differing stereochemistry (Fig. 1).‡ Ni(1) is octahedral binding one thiocyanate ion and a dmf solvent molecule to the remaining 'axial' sites, whilst Ni(2) is square-pyramidal binding one thiocyanate ion only. Comparison of the Ni–X bond lengths with related complexes[3–8] clearly indicates that Ni(2) is high spin [as is Ni(1)], as does the observation that Ni(2) is 0.26

**Scheme 1** Formation of $[Ni_2(L_{SO})(NCS)_2(dmf)]$ **2**

Å out of the $N_2SO$ donor plane towards the bound thiocyanate ion.[9] The assignment of Ni(2) as high spin is also consistent with a preliminary magnetic measurement of 4.5 $\mu_B$ for **2** at room temperature.[7] This contrasts dramatically with the situation found in **1**: in both **1** and **2** one nickel(II) ion is octahedral, however the second nickel(II) ion is low-spin square planar in **1** whereas it is high-spin square pyramidal in **2**. To our knowledge this is the first example of a thiolate-bound high-spin square-pyramidal nickel(II) ion. Overall complex **2** is currently one of the best first-generation structural models available for the hydrogenase active site.

It is interesting that reaction of $[Ni_2(L_{SO})(MeCN)_2][ClO_4]_2$ with an excess of thiocyanate ions also yields **2**: further thiocyanate ions are not bound at the vacant axial site on the high-spin Ni(2) ion or as a replacement for the dmf molecule on Ni(1). This is presumably due to each nickel ion already satisfying the electroneutrality principle due to the coordination of anionic thiophenolate, phenolate and thiocyanate donors. This interpretation is consistent with the observation that one thiocyanate ion binds to each nickel ion in **2** in contrast with the situation in **1** where both neutral ancilliary ligands bind to just one of the two nickel ions. Once two thiocyanate ions are bound the complex is neutral so lack of solubility may also play an important role in the formation and isolation of **2**.

The macrocycle is very bent: the two phenyl ring planes intersect at 100.5° and the two macrocycle $N_2SO$ donor planes intersect at 143°. This is due in part to the differing geometries of the thiophenolate sulfur and phenolate oxygen atoms;[10,11] the former is tetrahedrally distorted [Ni–S(1)–X 84.6–103.3°] whilst the latter is closer to trigonal planar [Ni–O(1)–X 97.0–124.1°]. However, the Ni(1)–O(1)–Ni(2) angle of 97.0° is the smallest observed to date for a phenolate-bridged dinickel macrocyclic complex, and is far from trigonal.[11] The small Ni–X–Ni angles in **2** should have interesting consequences magnetically and this is under investigation.[7]

In summary, the ligand $L_{SO}^{2-}$ is of intermediate field strength, and the macrocyclic cavity quite flexible, so that it is able to accommodate a combination of either high-spin–high-spin or high-spin–low-spin nickel(II) ions as is demonstrated herein. This is a unique situation and augurs well for the ability of the $L_{SO}^{2-}$ macrocycle to yield further exciting first-generation models for the active site of the [Ni,Fe] hydrogenases. Hence further binding studies are under way, as are redox and XAS investigations.[7]

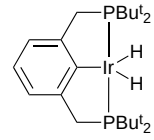
# Catalytic dehydrogenation of ethylbenzene and tetrahydrofuran by a dihydrido iridium P–C–P pincer complex

**Mukta Gupta,†[a] William C. Kaska[b] and Craig M. Jensen*[a]**

[a] *Department of Chemistry, University of Hawaii, Honolulu, HI 96822, USA*
[b] *Department of Chemistry, University of California, Santa Barbara, CA 93106, USA*



**The P–C–P pincer complex, $[IrH_2\{C_6H_3(CH_2PBu^t_2)$-2,6$\}]$ catalyses the transfer dehydrogenation of the donor-bearing substrates, ethylbenzene and tetrahydrofuran at temperatures as low as 150 °C.**

The catalytic dehydrogenation of aliphatic C–H bonds in the presence of functional groups is of major industrial importance. For example, the direct dehydrogenation of ethylbenzene accounts for 85% of the commercial production of styrene.[1] The reaction is carried out commercially at *ca*. 620 °C in the vapour phase over catalysts which primarily consist of iron oxide and potassium salt promoters.[1] Recently there has been considerable interest in the development of higher activity dehydrogenation catalysts which are also more selective for styrene over the degradation products, benzene and carbon.[1] Several soluble metal complexes have been found which catalyse the dehydrogenation of alkanes under moderate conditions.[2–4] However, none of these species have been reported to effect the catalytic dehydrogenation of aliphatic C–H bonds of functionalized substrates. This is apparently due to catalyst deactivation through strong coordinative interactions with donor groups. For example, $[IrH_2\{OC(O)CF_3\}(PPr^i_3)_2]$ effects the dehydrogenation of alkanes to arenes at 150 °C but fails to turnover catalytically since arenes are released from the metal centre only at temperatures at which complex decomposition occurs.[5]

We recently found that the iridium P–C–P pincer complex, $[IrH_2\{C_6H_3(CH_2PBu^t_2)_2$-2,6$\}]$ **1** is a highly active homogeneous catalyst for transfer dehydrogenation of cycloalkanes to alkenes and arenes.[4] In this system, the P–C–P framework of the catalyst is sufficiently robust that decomposition does not occur at temperatures required to achieve arene elimination. It was therefore of interest to explore whether alkylbenzenes and other weaker donor substrates such as cyclic ethers could be dehydrogenated by this catalytic system. We have found **1** will in fact catalyse the transfer dehydrogenation of ethylbenzene and tetrahydrofuran (thf).

Complex **1** was prepared as previously described.[4] The catalytic activity was investigated using solutions consisting of 4 ml of substrate (ethylbenzene, 32.6 mmol; thf, 49.3 mmol) *tert*-butylethene (tbe) (0.2 ml, 1.55 mmol) and **1** (3 mg, 0.005 mmol). The orange solutions were sealed in tubes under argon and fully immersed in an oil-bath for the prescribed reaction periods. The solutions became red upon heating and gradually change colour to yellow–orange during the reaction period. The reactivity was unaffected by the addition of metallic mercury to the solution indicating that metallic iridium is not involved in the hydrogen transfer.[6]

The results of the catalytic dehydrogenation experiments are summarized in Table 1. The products were identified by GCMS‡ analysis and quantified by gas chromatography.‡ Our product quantification balances the number of dehydrogenated C–C bonds within 5% to the amount of tbe hydrogenated to *tert*-butylethane (tba) in all experiments. No significant difference was found in either the amounts or distributions of products upon increasing the reaction time of the 200 °C experiments beyond 0.5 h. The amounts of products obtained in the 150 °C experiments increase over a longer period of time but are limited to lower levels than the 200 °C experiments. These results indicate that the amounts of products that are obtainable by these systems are restricted by thermodynamics. The direct dehydrogenation of ethylbenzene was explored at higher temperatures where a hydrogen acceptor such as tbe is not thermodynamically required. Unfortunately, **1** rapidly decom-

**1**

**Table 1** Catalytic dehydrogenations with **1**

| Substrate | *t*/h | *T*/°C | Products (mol/mol of **1**) | Dehydrogenated/ hydrogenated C–C bonds |
|---|---|---|---|---|
| thf | 1.0 | 150 | Dihydrofurans: 2,3 (46); 3,4 ( < 1) furan (31), tba (103) | 1.05 |

| Ethylcyclohexane[a] | 1.0 | 200 | Ethylcyclohexenes (13), ethylbenzene (43), styrene (76), tba (441) | 1.01 |

[a] An additional 0.2 ml (1.55 mmol) of tbe was added to the reaction mixture after 0.5 h.

poses at temperatures in excess of 200 °C and no dehydrogenation activity was observed.

The catalytic activity of **1** for the dehydrogenation of the functionalized substrates is significantly lower than previously found for cycloalkanes.[3,4] This suggests that arene and oxygen donor interactions with the metal centre inhibit the catalytic system. The findings of product inhibition and tbe concentration sensitivity in the transfer dehydrogenation of cyclooctane and cyclohexane also suggest that the catalytic activity of **1** is inhibited by species bearing donor groups.[3] In order to probe this possibility, the activity of **1** for the transfer dehydrogenation of ethylcyclohexane was investigated. As seen in Table 1, significantly higher styrene production was observed than in the case of ethylbenzene. This is apparently due to the reduced arene concentration in the ethylcyclohexane experiments. Nitrogen has been found to poison the transfer dehydrogenation of cyclooctane by **1**.[3] Similarly, no dehydrogenation of either ethylbenzene or thf was observed in experiments conducted under 1 atm of $N_2$ in place of argon at 150 °C. Thus the catalytic system is sensitive to even the weak donor, $N_2$.

Despite the limitations of this catalytic system, it represents a step forward in the development of improved catalysts for the production of styrene. It is also the first report of a homogeneous catalytic system for dehydrogenation of saturated C–H bonds in presence of functionalization. Modified catalysts of this type could provide an entrance into new chemical processes through previously inaccessible catalytic pathways.

The support of this research by the US Department of Energy Hydrogen Program is gratefully acknowledged.

# Effect of [60]fullerene on the radical polymerization of alkenes

**Sanjiv Mehrotra, Asutosh Nigam and Ripudaman Malhotra***

*Chemistry and Chemical Engineering Laboratory, SRI International, 333 Ravenswood Avenue, Menlo Park, CA 94025, USA*

**AIBN-initiated radical polymerization of 2-cyanoethyl acrylate and cyanovinyl acetate in the presence of [60]fullerene produces copolymers in good yields, whereas for most other vinyl monomers [60]fullerene almost completely inhibits the polymerization.**

The synthesis and isolation of macroscopic quantities of [60]fullerene has stimulated great interest in fullerene polymers. Along with the development of its chemistry, several different polymers incorporating [60]fullerene have been reported consisting of covalently linked fullerenes and copolymers in which fullerenes are a part of the polymer backbone.[1] In all previous reports on radical polymerization of vinyl monomers, conducted mostly with styrene or methyl methacrylate, the yields of polymers formed in solution were either very low or the reaction was completely inhibited.[2,3] It has been suggested that in the case of styrene, the free radicals are trapped by fullerene, and the resulting fullerene radicals do not propagate but instead can terminate. Recently, Camp *et al*. have reported the copolymerization of [60]fullerene and styrene in the presence of a large excess of the initiator AIBN.[4] According to the authors, the radicals from the initiator undergo multiple additions on [60]fullerene, ultimately changing its nature sufficiently such that it would not inhibit polymerization.

We report here findings of our study on AIBN-initiated radical polymerization of a range of vinyl monomers in the presence of [60]fullerene. The objective of this study was to determine how general is the inhibition of radical polymerization by [60]fullerene and to see if the fullerene radicals, which do not readily add to methyl methacrylate and styrene, would add to certain reactive monomers. The vinyl monomers studied were styrene, methyl acrylate, methyl methacrylate (MMA), acrylonitrile, vinyl acetate, 1-vinyl-2-pyrrolidone, 2-cyanoethyl acrylate (CEA) and 1-cyanovinyl acetate (CVA).

In a typical experiment, 60–100 equiv. of vinyl monomer was added to a suspension of [60]fullerene (50 mg, 0.07 mmol) in dry THF (2 ml) under argon atmosphere, followed by the addition of a catalytic amount of AIBN. The reaction mixture was heated under reflux (65 °C) for 22 h, the solvent was evaporated and the weight of the residue was taken as the first indication for the formation of a polymer. Control experiments with these monomers without [60]fullerene were also conducted under otherwise identical conditions. The results for the eight vinyl monomers studied are given in Table 1.

In the absence of [60]fullerene, polymer formation was observed in greater than 75% yield in all cases . However, in the presence of [60]fullerene, polymerization in six out of the eight monomers was substantially inhibited and yielded 15% or less of the polymeric products. For example, the reaction of methyl acrylate produced only 9% of the polymer. The presence of an α-methyl group on the vinyl moiety increases the polymer yield only marginally to 14%. Substitution with cyano, as in acrylonitrile, also did not lead to the production of substantial yields of the polymer in the presence of [60]fullerene. Surprisingly, we found that cyanovinyl acetate gave the polymer in about 50% yield. We wondered if the acetoxy group itself is responsible for this activity, but the polymerization of vinyl acetate was almost completely inhibited by [60]fullerene. Also noteworthy is the reactivity exhibited by 2-cyanoethyl acrylate (65% polymer yield), which is structurally very similar to methyl acrylate. The cyano group in this molecule is remote from the vinyl portion, and points to some cyclic intermediate in which the cyano group stabilizes the intermediate radical. It would be interesting to correlate the polymer formation with the partial reactivity factors of the various vinyl monomers. Unfortunately, we were unable to find literature reports on the partial reactivity factors for CEA and CVA, the two cases where we observed substantial copolymerization.

[60]Fullerene can inhibit the chain propagation by reacting with the initiator radical and/or by terminating the propagating chain. It has been reported that [60]fullerenes react effectively with isobutyronitrile radicals produced by the thermal decomposition of AIBN.[4] Therefore it is possible that [60]fullerene intercepts the initiating radicals in the polymerization reaction. To further understand the role of [60]fullerene as an inhibitor of propagating chains, we conducted the AIBN-initiated polymerization of MMA and quenched it with [60]fullerene at different time intervals. Polymerization of MMA was conducted for 1 or 2 h by heating 615 mg (6.14 mmol) of MMA in dry THF (2 ml) under reflux (65 °C) in the presence of 6 mg (0.036 mmol) of AIBN. Then 50 mg (0.07 mmol) of [60]fullerene was added to these reaction mixtures and heated overnight. The reaction mixture was evaporated to dryness, dissolved in MeCN, filtered to remove unconverted [60]fullerene and dried to recover the copolymers. In contrast to the complete inhibition of MMA polymerization when [60]fullerene was added at the start of the reaction, the yield of the copolymer increased to 264 mg (40%) when [60]fullerene was added following 1 h reaction, and 370 mg (56%) if the addition of [60]fullerene was delayed for 2 h. The number average molecular weights for [60]fullerene–PMMA polymers obtained in these cases were around 8,000 and 22,000 respectively. $^{13}C$ NMR spectra of the product do not show a peak at δ 143 corresponding to the starting [60]fullerene, which suggests complete reaction of fullerene with propagating radical chain. The low yields of polymerization in the above reactions and the difference in molecular weights further confirms that [60]fullerene quenches the propagating chains very effectively.

As mentioned above, the more reactive monomers, CVA and CEA, underwent facile copolymerization with [60]fullerene yielding 53 and 65% of the copolymers, respectively (Table 1).

**Table 1** Effect of [60]fullerene on the yield of polymers from AIBN-initiated polymerization of various vinyl monomers at 65 °C

| Monomer | Polymer yield (%) | |
|---|---|---|
| | With $C_{60}$ | Control |
| Methyl acrylate | 9 | 97 |
| Methyl methacrylate | 14 | 98 |
| Acrylonitrile | 11 | 76 |
| Cyanovinyl acetate | 53 | 92 |
| Vinyl acetate | 9 | 75 |
| 2-Cyanoethyl acrylate | 65 | 99 |
| Styrene | 15 | 85 |
| *N*-vinylpyrrolidone | 8 | 100 |

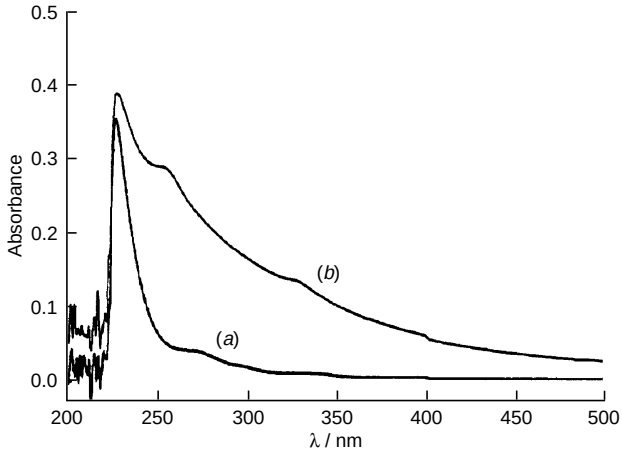

**Fig. 1** UV–VIS absorption spectra of (*a*) poly(2-cyanoethylacrylate) and (*b*) the copolymer formed with [60]fullerene

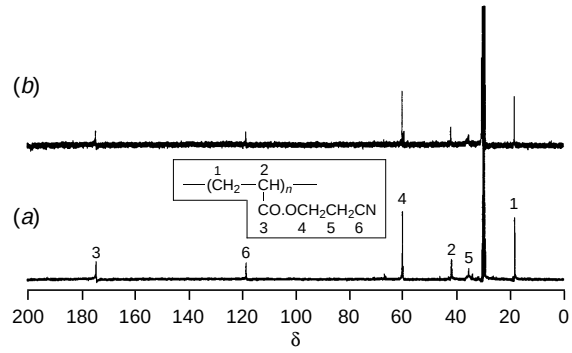

**Fig. 2** $^{13}C$ NMR spectra of (*a*) poly(2-cyanoethyl acrylate) and (*b*) the copolymer formed with [60]fullerene

It was also observed that the initially free flowing reaction mixture became viscous as the reaction proceeded. Evidently, these monomers are reactive enough that fullerene-based radical(s) formed by the addition of a growing polymer chain can add to them and continue the polymerization process. However, before we can make this conclusion, we have to eliminate the possibility of these monomers are undergoing polymerization by a different mechanism, *e.g.* polymerization promoted by traces of moisture. Thus, we attempted polymerization of CVA and CEA in the absence of AIBN and in the presence of traces of water. In none of these cases did we observe any polymerization. Therefore we conclude that the polymerization was indeed following a radical chain pathway.

The copolymer of [60]fullerene and CVA was completely soluble in MeCN. A small amount of material that did not dissolve in MeCN was identified as [60]fullerene. In contrast, only about half of the copolymer of [60]fullerene and CEA was soluble in MeCN. We believe that the insoluble portion has either a branched or a cross-linked structure which is obtained by the multiple addition of propagating chains to the fullerene surface. We also studied the effect of [60]fullerene on the propagating chains of CEA and CVA monomers. Two experiments were conducted for each of these monomers. Polymerization was initiated by heating the monomer in dry THF in the presence of a catalytic amount of AIBN, and [60]fullerene was added to the reaction mixture after 1 h. In one experiment the reaction was quenched immediately, and in the second, the heating was continued for another 22 h. For CVA, the yield of the polymer was only 18% when the reaction was quenched immediately after adding [60]fullerene, and 50% when the mixture was heated for the additional 22 h. These results further show that [60]fullerene does not completely inhibit the polymerization of reactive monomers. CEA, being an even more reactive substrate, yielded 83% of the polymer in the first hour and continued heating after the addition of [60]fullerene did not increase the yield any further. Analogous reactions with MMA yielded 24% of polymer after the first hour and 40% of the polymer if the mixture was heated overnight compared to 98% of the polymer after 22 h in the absence of [60]fullerene and 14% of polymer in the presence of [60]fullerene.

Structural characterization of the copolymers was performed using IR, NMR and UV spectroscopic techniques and thermogravimetric analysis (TGA). The presence of fullerene moieties is evident from the absorption spectra of the copolymers of [60]fullerene with CEA and CVA. Fig. 1 shows the absorption spectra for poly(CEA) and the copolymer formed with [60]fullerene. Whereas the absorption bands of the homopolymers cut off at much shorter wavelengths, the copolymers show broad overlapping bands extending from the UV region to almost 500 nm. Sun and coworkers[2] have also observed a similar broadening of the characteristic absorption bands of fullerenes when incorporated into a polymer matrix. Analogous data (not shown) were obtained for the CVA system. Fig. 2 shows the identical $^{13}C$ NMR spectra of the homopolymer and the copolymers for CEA. The spectrum for the copolymer does not show any signals due to the [60]fullerene moiety. The absence of any fullerene peaks may be due to the fact that the concentration of the fullerene units is very low, which is further exacerbated by the loss of the 60-fold degeneracy of the original [60]fullerene once it has undergone reaction to produce adducts. However, it is also significant that there is no peak at δ 143, corresponding to *free* [60]fullerene, in the case of the copolymer. Thus, the extended UV absorption must be due to the fullerene units that are now a part of the polymer. Again, similar data (not shown) were obtained for the CVA system. Thermal characterization of the polymers showed that the presence of the fullerene did not affect the onset of decomposition, although the char yield was higher with the fullerene copolymers when compared to the homopolymer.

We therefore conclude that [60]fullerene acts as an efficient inhibitor or a retarder in the radical polymerization of most vinyl monomers and results in the formation of [60]fullerene-terminated structures. However, with certain reactive vinyl monomers such as cyanoethyl acrylate and cyanovinyl acetate, it can form copolymers. Evidently, these monomers can add to the fullerene-based radical intermediate to propagate the polymerization. The role of reactivity ratios and general dependence on the structural and chemical nature of the vinyl monomers on polymerization reaction in the presence of [60]fullerene is currently under investigation in more detail in our laboratory.

This work was conducted under the program, 'Advanced Chemical Processing Technology', consigned to the Advanced Processing Technology Research Association from the New Energy and Industrial Technology Development Organization, which is carried out under the Industrial Science and Technology Frontier Program administered by the Agency of Industrial Science and Technology, the Ministry of International Trade and Industry, Japan.

# Dynamics of H/D and D/H exchanges in β-cyclodextrin dodecahydrate observed in real time: effects from zero-point vibrational energy

**Cyclic H/D and D/H exchange processes in crystalline β-cyclodextrin dodecahydrate exposed to $D_2O$ (or $H_2O$) vapour, monitored in real time by the integrated intensity of the O–H Raman stretching band, exhibit different rate constants and activation energies ascribed to different zero-point vibrational energies of OH and OD.**

Crystalline hydrates of β-cyclodextrin (cyclomaltoheptaose, β-CD) are good models for the study of hydration processes in biomolecular structures.[1–8] The water molecules contained in the crystal[1,2] and most of the 21 β-CD hydroxy groups display appreciable positional and/or orientational disorder, with jump rates up to $10^{10}$–$10^{11}$ $s^{-1}$.[4,5] At atmospheres with humidities < 100%, the water content is reduced, and equilibration to changes of humidity takes place within minutes. This shows that, despite the absence of permanent channels, rapid water diffusion takes place in the crystal lattice.[2] If crystalline β-CD hydrate is exposed to an $H_2{}^{18}O$ atmosphere, all water molecules are replaced by the labelled species, showing that there are no 'fixed' water sites.[6] If a sample is exposed to a $D_2O$ atmosphere, complete H(O)/D(O) exchange takes place. Both exchange mechanisms occur on the same timescale, showing that long-range transport must be by diffusing intact water molecules, but since the H/D exchange also extends to β-CD hydroxy groups which are sterically inaccessible to diffusing water molecules, there must be local chains of proton transfer processes.[6] The previous studies were based on measurements on samples in equilibrium at room temperature. In the present work, we present, for the first time, real-time observations on the H/D exchange, and also report on temperature-dependent experiments.

In an H(O)/D(O) exchange experiment, the quantity of H(O) in the sample can be measured by the relative integrated intensity of the O–H Raman stretching band ($I_{OH}$).[7] Recently, we reported on a Raman spectroscopic real-time method to monitor $I_{OH}$,[7] which is here applied to the observation of the H/D exchange kinetics in β-CD dodecahydrate. The experimental setup is shown in Scheme 1.

Crystalline β-CD dodecahydrate† was placed in a closed cell over a reservoir of $D_2O$, and the Raman spectra of the region of O–H and O–D stretching vibrations were recorded at short time intervals (by use of a CCD detector, the 2100–3800 $cm^{-1}$ region could be recorded within *ca.* 1.5 min).‡ As $D_2O$ diffuses into, and $H_2O$ out of, the sample, and H/D exchange processes at the β-CD hydroxy groups take place, $I_{OH}$ continuously decreases, and, in parallel, $I_{OD}$ increases.§ A typical series of spectra is shown in Fig. 1; the invariant central peak represents a complex band of C–H stretching vibrations and is conveniently used as an internal reference intensity. During H(O)/D(O) exchange, the relevant kinetic variable is the fraction of remaining H(O) atoms, θ, which is experimentally measured by $I_{OH}/I_{OH}$(max.). As shown by the inset of Fig. 1, the relative H(O) concentration decreases according to approximate first-order kinetics (here with 50% exchange within 43 min). After equilibration, the $D_2O$ reservoir of the experimental cell was quickly replaced by an $H_2O$ reservoir,¶ so that the reverse exchange process [D(O)/H(O)] could be monitored on the same sample. After equilibration, another H(O)/D(O) exchange experiment could follow, and so on. The results obtained from a two-cycle sequence of experiments H/D → D/H → H/D → D/H are listed in Table 1.

**Scheme 1**

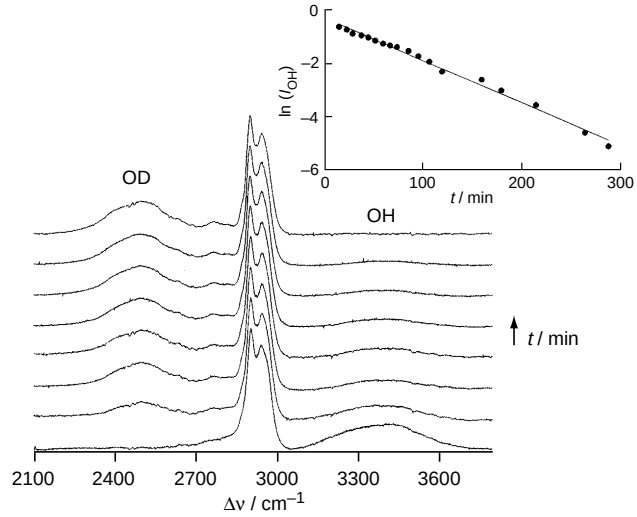

**Fig. 1** Examples of Raman spectra in the relevant spectral region 2100–3800 $cm^{-1}$, for on-line observation of H/D exchange

**Table 1** Results for a two-cycle exchange/back-exchange experiment: sample quantity *ca.* 20 mg, *n* is the number of spectra used, *k* the effective rate constant, and $t_{\frac{1}{2}}$ the time for 50% exchange[9¶]

| Experiment | *n* | $k$/$min^{-1}$ | $t_{\frac{1}{2}}$/min | $t_{\frac{1}{2}}$ (95% confidence) |
|---|---|---|---|---|
| First cycle, H → D | 18 | −0.0160 | 43 | 40–46 |
| First cycle, D → H | 15 | −0.0126 | 55 | 52–59 |
| Second cycle, H → D | 18 | −0.0175 | 40 | 37–43 |
| Second cycle, D → H | 13 | −0.0116 | 60 | 54–67 |

In all experiments, the exchange processes follow first-order kinetics. Although the determination of the $t_{\frac{1}{2}}$ values suffers some uncertainty, the data indicate different rate constants for the H/D and D/H exchange processes (the H/D and D/H values are each clearly outside the other 95% confidence interval), with the D/H process being the slower. Comparing the first and second cycles, the two H/D values are within each other's confidence intervals, as are the two D/H values, showing that the process as a whole can be reproduced cyclically.

As mentioned previously,[6] the macroscopic rate constant $k$ is sample dependent: owing to shorter diffusion paths, the exchange must be faster in samples with larger surface-to-mass ratios. Therefore, when repeating the above experiment with a different sample, the same general behaviour with somewhat different absolute $t_{\frac{1}{2}}$ values must be expected. This was in fact observed for another set of experiments, where again H/D exchange was observed to be faster than the D/H back-exchange.

These observations are in consonance with recent quantum mechanical calculations which indicate that OD hydrogen bonds are stronger owing to a lowering of the zero-point vibrational energy (ZPVE).[10] Therefore, OD hydrogen bonds should be more difficult to break, and D(O)/H(O) substitution should be slower than the reverse process. A consequence is that intact water molecules, which are the carriers of H or D through the lattice, diffuse more slowly when of the $D_2O$ type than of the $H_2O$ type (DHO should be in between these two extremes).

In order to assess the effect of temperature on the exchange rate constants, a different set of experiments was performed. At a number of defined temperatures, crystalline β-CD($H_2O$) dodecahydrate was exposed to the atmosphere over a reservoir of $D_2O$, for 30 min. Then, small samples were removed, sealed in capillary tubes and Raman spectra were recorded (batch method).‖ The fraction of remaining H(O) was determined from $I_{OH}$, allowing the calculation of $k$ and $t_{\frac{1}{2}}$ [from $I_{OH} = I_{OH}(\text{max.}) \exp(-kt)$ with $t$ = 30 min]. Analogous experiments were performed for β-CD($D_2O$) exposed to the atmosphere over $H_2O$. Numerical results are given in Table 2: as expected, the exchanges are appreciably faster at elevated temperatures. In a plot of $1n|1n\theta|$ *vs.* $1/T$, linear correlations are obtained for both processes (Fig. 2), suggesting Arrhenius type dependences of the rate constants. Linear regression calculation obtains activation energies, $E_a$, of 26 kJ mol$^{-1}$ for H/D exchange, and 33 kJ mol$^{-1}$ for D/H back-exchange. Again, this is in consonance with the theoretical calculations mentioned above,[10] which indicate that substitution of H(O) by D(O) lowers both the intramolecular and the intermolecular ZPVE.

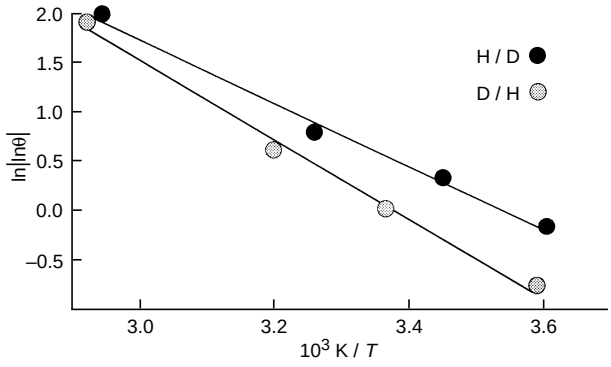

**Fig. 2** $1n|1n\theta|$ *vs.* $1/T$ for H/D [$\theta = I_{OH}/I_{OH}(\text{max.})$] and D/H [$\theta = I_{OD}/I_{OD}(\text{max.})$] exchange experiments

The experimental setup used (Scheme 1) allows the real-time observation of cyclic H/D and D/H exchange processes. Since the data are obtained from the same sample under the same conditions, the macroscopic rate constants for H/D and D/H exchange can be compared directly. The results indicate different rate constants for H/D and D/H exchanges in crystalline β-CD dodecahydrate. Presumably, the origin of this phenomenon is found in the different zero-point vibrational energies of OH and OD. It is of interest that this microscopic effect leads to noticeably different behaviour in the macroscopic diffusion properties.

This work was carried out in the Molecular Physical Chemistry Research Unit No. 70/94, University of Coimbra, financially supported by JNICT, Lisboa. ## Footnotes

†β-CD, kindly donated by Wacker Chemie, München (Germany), was recrystallized by cooling concentrated aqueous solutions in a Dewar flask from *ca*. 80 °C to room temperature. Crystals were taken from the solvent and exposed to an atmosphere of moderate temperature and humidity (*ca*. 25 °C and 60% relative humidity). After equilibration with the atmosphere, crystals were ground, not sieved, to obtain a microcrystalline powder. Care was taken that all samples were prepared similarly.

‡ Jobin-Yvon T64000 Raman spectrometer, subtractive configuration, relevant slit widths set to 300 μm, intermediate slit between pre-monochromator and spectrograph wide open (14 mm), CCD detector, integration time 15 s. An Ar ion laser (Coherent-Innova 300-05 model with power track) provided *ca*. 100 mW at the sample position. Integrated intensities were determined using the machine software.

§ The sum $I_{OH}/I_{OH}(\text{max.}) + I_{OD}/I_{OD}(\text{max.})$ is *ca*. 1.0 at all times (deviations from unity were < 5%), *i.e*. the total number of OH/D oscillators was conserved during the exchange experiments. Separate normalization of each term is required because the OH and OD stretching vibrations have different Raman activities.

¶ Owing to the necessary manipulations at the start of the experiment and at the exchange of reservoirs, the zero point of the time scale is ill defined. Therefore, only data for $t \geqslant 15$ min are used for data analysis; this affects only the intercept, but not the kinetically relevant slope in Fig. 1.

‖ In this series of experiments, each measurement had necessarily to be performed on a different sample. Although all care was used to ensure that close to identical sample conditions were provided each time, the numerical reliability is reduced compared to the data in Table 1, which was obtained from only one sample.

**The supramolecular array formed by co-crystallisation of 1,2-diaminoethane and benzoic acid is investigated by neutron diffraction; the system self-assembles into an unusual layered structure composed of two-dimensional hydrogen-bonded networks sandwiched between layers of edge-to-face stacked aromatic systems; the number of hydrogen-bond donors and acceptors is balanced in the structure.**

The self-assembly of two of more molecular components into well defined, solid-state supramolecular structures has been a topic of considerable recent interest.[1–3] Such 'crystal engineering' involves the attempted regulation of the subtle non-covalent interactions that dictate crystal packing in order to produce new materials showing unusual properties, including novel electrical and optical properties. Co-crystallisation of selected complementary molecules provides one means of generating new extended supramolecular frameworks of this type;[4] such an approach was employed in the study now reported.

Of the variety of intermolecular interactions commonly identified in solid-state supramolecular structures (hydrogen bonding, electrostatic, van der Waals, π–π stacking),[1,2,5–7] hydrogen bonds tend to have the highest strength and selectivity.[1,2]

Here, we report the single-crystal neutron structure of the 1 : 2 molecular assembly formed between 1,2-diaminoethane and benzoic acid.† Crystallisation of this adduct can be effected by slow evaporation of a stoichiometric mixture of the components dissolved in methanol. Large transparent crystals (*ca*. 0.4 × 0.8 × 0.8 cm, mp = 153.5 °C) grew rapidly overnight. The structure of the resulting supramolecular array (Fig. 1 and 2) is predominantly directed by π–π stacking and strong hydrogen-bond formation in which acid protons have transferred onto the amine nitrogens (analogous to 'intermolecular zwitterions') such that each amine in the structure is in its $-NH_3^+$ form. Polarised hydrogen-bond interactions of this type can be very strong[8] and, as often observed in related systems,[7,9,10] all the amine and acid protons within the structure take part in NH···O bonding. In the asymmetric unit as defined, the two independent benzoate moieties attached on opposite sides to a 1,2-diaminoethane moiety (*via* one strong hydrogen bond) lie approximately parallel [interplanar dihedral angle 3.1(2)°]. All hydrogen bonds in the array are very similar with N···O, N–H, H···O, N–H···O all very closely ranged [2.727(5)–2.764(6); 1.02(1)–1.09(1); 1.65(1)–1.78(1); 156(1)–172(1)°].

A two-dimensional planar layer is formed by parallel 'rows' of the acid/amine motifs being stacked side-by-side, each row being offset with respect to the next.

An edge-on projection of this layer is shown in Fig. 1; this illustrates that a pair of benzoate sheets effectively sandwich a sheet of 1,2-diaminoethane molecules parallel to the *ab* plane. The layer is 'stitched' together by hydrogen bonds between adjacent benzoic acids and 1,2-diaminoethanes of different motif units. Each benzoate participates in three strong hydrogen bonds, two to one oxygen in each case, with H···O···H 113.0(6), 112.6(6)°; C–O to that oxygen being slightly longer [1.264(5), 1.265(5) Å] than for those distances to the oxygens which have single hydrogen bonds [1.231(5), 1.241(5) Å]. It is noted that while each side adduct layer is very similar, they are not crystallographically equivalent, although the array has pseudo-symmetry.

Planar layers of acid/amine motifs are in turn stacked such that adjacent layers are bound together by edge-to-face (T-oriented) aromatic stacks in a herringbone arrangement (Fig. 1). The overall pattern of the layers can be expressed as . . .bab′bab′. . . where b and b′ are the non-identical benzoate layers and a is the amine layer. Owing to the proton transfer, a charge separation exists within the hydrogen-bonded layers, so that the amine layer is formally positively charged with the adjacent benzoate face being formally negatively charged.

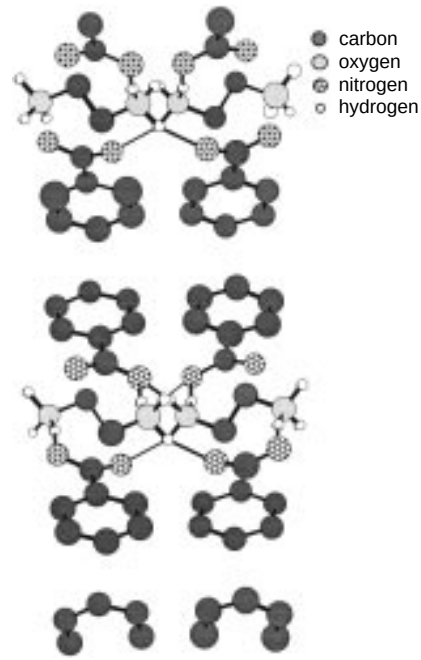

**Fig. 1** The structure of the 1 : 2 adduct between 1,2-diaminoethane and benzoic acid; projection down *a* (*c* horizontal). Only hydrogens participating in NH···O hydrogen bonds are illustrated.

In an attempt to gain further insight into the nature of the proton transfer, hydrogen-bond geometry optimisations were performed on isolated 1 : 2 adducts using density functional theory (DFT) involving the G94 package.[10] At the SVWN5/6-31G* or B3LYP/6-31G* levels of theory[12,13] it is predicted that the protons in the (observed) NH···O bonds are transferred from the amine to the acid moieties, so that the hydrogen bond becomes N···HO in character. Calculations in the presence of a solvent reaction field (either $H_2O$, $CHCl_3$ or methanol) all follow this pattern.‡ This suggests that the proton-transfer (ionic) hydrogen bonds within the solid-state structure are stabilised by the extensive hydrogen-bonding array within the solid-state lattice. Supporting this proposition are the results of similar DFT[14] and semi-empirical[9] calculations on our previously reported cyclam : 4-*tert*-butyl benzoic acid 1 : 2 adduct. In this system the network of NH···O hydrogen bonds is confined within a single adduct and proton transfer is predicted by DFT and semi-empirical calculations.

Finally, the B3LYP/6-31G* calculated dipole moment of a single 1,2-diaminoethane/benzoic acid motif is $6.41 \times 10^{-30}$ C m; this moment, coupled with the non-centrosymmetric nature of the crystalline structure suggests this material may have interesting SHG (second harmonic generation) properties.

In summary, we have demonstrated that benzoic acid and 1,2-diaminoethane self-assemble to discrete 2 : 1 aggregates held together by extensive hydrogen bonding and π-stacking interactions. This study acts as a prototype for the synthesis of a range of other closely related carboxylic acid/diamine arrays, a class of new (charged-separated) assemblies of potential interest as new opto-electronic materials.

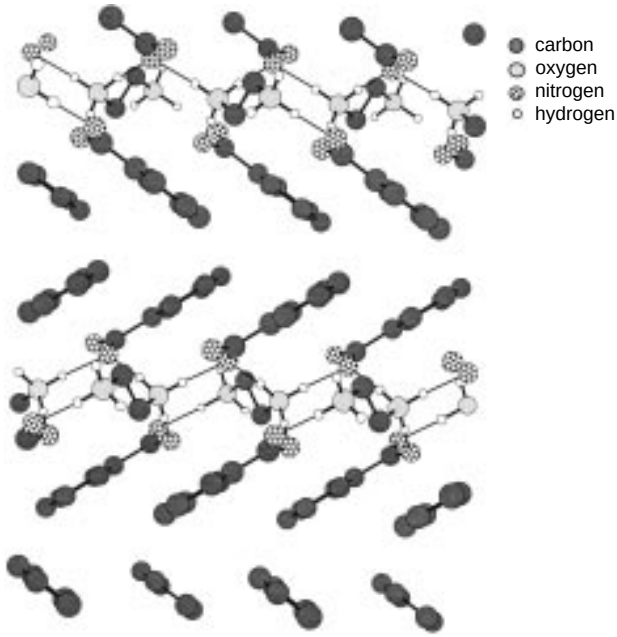

**Fig. 2** The structure of the 1 : 2 adduct between 1,2-diaminoethane and benzoic acid; projection down *b* (*c* horizontal). Only hydrogens participating in NH···O hydrogens bonds are illustrated.

# Construction of a self-assembling porphyrin trimer system

**Yasuhisa Kuroda,*[a] Yusuke Kato[b] and Hisanobu Ogoshi*[b]**

[a] *Department of Polymer Science, Kyoto Institute of Technology, Sakyo-ku, Matsugasaki, Kyoto 606, Japan*
[b] *Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto 606, Japan*

**A quaternary self-assembling system consisted of three porphyrin molecules and one linker molecule is constructed.**

The chemical construction of self-assembling systems is currently of interest to chemists because self-assembly is expected to be essential methodology to overcome the synthetic difficulties encounted in the preparation of highly complicated and ordered molecular systems.[1] Recently, we found a receptor based on a doubly bridged porphyrin molecule (trench porphyrin) which recognizes dialkyl tartrates selectively *via* four point hydrogen bonds.[2] The most important requirement for this system is the core conformations of the tartrate, *gauche* OH/OH and *anti* $CO_2R/CO_2R$, in which two carbonyl and two hydroxy oxygen atoms are practically planar. In contrast, the system is rather insensitive towards the properties of alkyl ester groups.[2] Thus, it is an interesting challenge to extend the system to a large scale assembly by modifying these alkyl moieties. We report here a self-assembling porphyrin trimer system consisting of two different types of porphyrin molecules and one tartrate derivative as a linker molecule.[3]

For this purpose, we designed a new tartrate linker molecule **1** which has two pyridine moieties arranged in a way so that the pyridine and tartrate moieties may act as independent recognition sites for the porphyrin molecules. Compound **1** was prepared by acid-catalysed reaction of L-tartaric acid with an excess of 3-(3′-pyridyl)propanol in toluene. The complex formation between **1** and *meso* trench porphyrin **2** was confirmed by UV–VIS spectroscopic titration showing a red shift of the Soret band of **2** (428 nm) with a clear isosbestic point, giving an association constant of 2300 ± 100 $dm^3\ mol^{-1}$ at 288 K. $^1H$ NMR data (Table 1) reveal further details of the present complex formation. Upon complexation with **2**, two hydroxy and $H_t$ protons (see Fig. 1) of **1** exhibit an unusual upfield shift as previously reported for simple alkyl tartrates.[2] The association constant is estimated to be $>1 \times 10^5$ $dm^3\ mol^{-1}$ at 223 K. In contrast, the proton signals of the pyridyl moiety are observed in the normal aromatic region and show only a 0.1–0.3 ppm upfield shift upon complexation. These observations indicate that **1** complexes with **2** at the tartrate site *via* four hydrogen bonds and the pyridyl moieties practically remain free. Another porphyrin component of the present assembly, octaethylporphyrin Rh complex **3**, also forms a complex with **1** giving a stable 2 : 1 complex which is isolable giving *m/z* of 1729.77 in a FABMS spectrum (calc. for $C_{92}H_{113}N_{10}O_6Rh_2Cl_2$, *m/z* 1729.63). As shown in Table 1, the pyridyl protons of this complex are shifted upfield by 2.0–8.5 ppm with respect to those of free **1**, while the $H_t$ protons show a relatively small upfield shift. The very large upfield shifts of $H_c$ and $H_d$ demonstrate the coordination of the pyridyl moieties of **1** on Rh atoms[4] and that the tartrate moiety does not directly participate in the complex formation. Thus, the tartrate and pyridyl moieties of **1** are confirmed to act as independent binding sites for porphyrins **2** and **3**. Based on these results, we attempted to construct a porphyrin trimer self-assembly. The $^1H$ NMR spectrum of the mixture of **1** (1.0 mM), **2** (1.0 mM) and **3** (2.0 mM) in $CDCl_3$ indicated that, at 223 K, no free pyridyl moieties of **1** were observed and new pyridyl signals (Table 1) appear in addition to those of the 2 : 1 complex of **3** and **1**. This behaviour is independent of the mixing sequences of the three components. It should be noted that both the tartrate and pyridyl moieties simultaneously show large upfield shifts which indicates the binding of the tartrate moiety on **2** and the pyridyl moiety on **3** respectively. Integration data for these protons gives the association constant between **2** and the 2 : 1 complex of **3** and **1** as 3000 ± 500 $dm^3\ mol^{-1}$ at 223 K which is much smaller than that for **2** and **1**, while the pyridyl moieties of **1**

**Table 1** $^1H$ NMR chemical shifts (δ) of **1** in $CDCl_3$ under various conditions[a]

| | Tatrate moiety | | Pyridyl moiety | | | |
|---|---|---|---|---|---|---|
| Host | $H_t$ | OH | $H_a$ | $H_b$ | $H_c$ | $H_d$ |
| none | 4.55 | —[b] | 7.51 | 7.22 | 8.44 | 8.45 |
| **2**[c] | 0.68 | −3.81 | 7.22 | 7.15 | 8.45 | 8.20 |
| | 0.56 | −4.13 | 7.24 | 7.08 | 8.38 | 7.89 |
| **3** | 2.70 | 4.00[d] | 5.52 | 4.65 | 0.20 | −0.06 |
| **2** + **3**[c,e] | 0.02 | −4.18 | 5.13 | 4.59 | −0.15[f] | −0.48 |
| | −0.18 | −4.43 | 5.00 | 4.54 | | −0.73 |

[a] The data are obtained at 223 K except those of **1** (288 K). [b] Unclear. [c] Two signals are observed due to the unsymmetrical structure of **2**. [d] Owing to heavy overlap with the ethyl signals of **3**, the position is assigned from COSY data. [e] [**1**] = [**2**] = $1 \times 10^{-3}$ M; [**3**] = $2 \times 10^{-3}$ M. Under these conditions, *ca*. 60% of **2** forms the assembly with a 1 : 2 complex of **1** and **3**. [f] No separation for $H_c$ was observed.

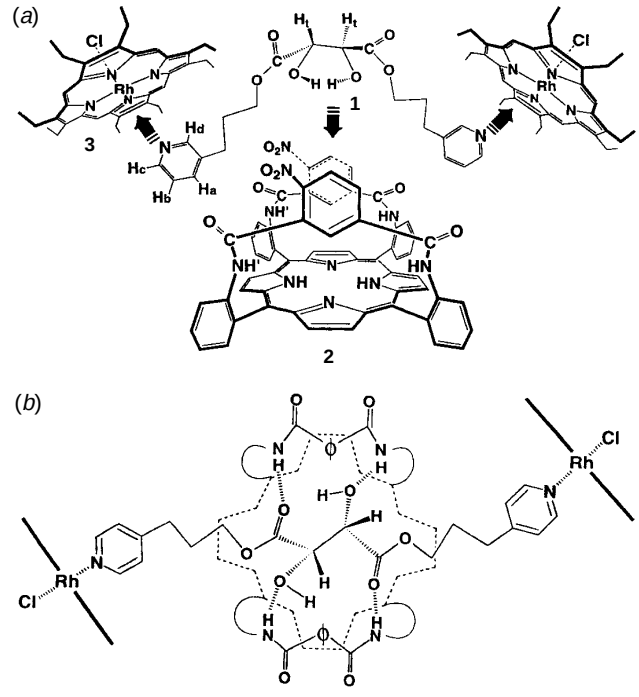

**Fig. 1** Self-assembling porphyrin trimer system. (*a*) Component structures. (*b*) Schematic assembly structure.

quantitatively form complexes with **3** even under the present conditions. Although the smaller association constant suggests the existence of significant steric hindrance between the core porphyrin **2** and the two terminal porphyrins **3** due to the short alkyl chains of **1**, the results clearly indicate that the present system affords the quaternary self-assembly shown in Fig. 1 without any confusion between the different types of binding sites.

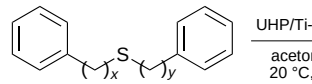
# Ti-beta-catalysed selective oxidation of sulfides to sulfoxides using urea–hydrogen peroxide adduct

**T. Indrasena Reddy and Rajender S. Varma***



*Department of Chemistry and Texas Regional Institute for Environmental Studies (TRIES), Sam Houston State University, Huntsville, TX 77341-2117, USA*

**Ti-Beta zeolite catalyses the selective oxidation of organic sulfides to sulfoxides with urea–hydrogen peroxide adduct (UHP) as oxidant.**

Crystalline microporous titanium silicate 1 (TS-1)[1] has found applications in the catalytic oxidation of a variety of organic compounds[2] with aqueous hydrogen peroxide as an oxygen source. TS-1, the titanium analogue of the ZSM-5 zeolite, is reported to catalyse the oxidation of hydrocarbons,[1,3] arenes,[1,4] alkenes,[2a–d] amines[5] and sulfides.[6a] Apart from their unique catalytic properties, these thermally stable solid materials can be recycled many times without any loss of activity, thus emphasizing their environmentally benign character. However, one serious limitation of catalysis by zeolites is the steric hindrance that stops bulkier molecules from reaching the active sites, as has been highlighted in a recent report that states that thioanisole and ethyl phenyl sulfide can access the catalytic sites for oxidation to the corresponding sulfoxides and sulfones whereas diphenyl sulfide fails under the same conditions.†,‡ Herein we report a thorough study of the oxidation of sulfides that determines the limitations of various oxidative catalysts (TS-1, VS-1 and Ti–beta; Table 1) in terms of their comparative reactivity and selectivity. Benzyl phenyl sulfide, bearing a benzylic methylene group, is used as a substrate in these reactions as it is easy to monitor the relative formation of sulfoxide/sulfone by $^1$H NMR.

In the case of TS-1 and VS-1 (pore size 5.5 Å), no product could be detected, presumably on account of the inability of the substrate to enter the channel. At higher temperature, on the other hand, a poor yield of a mixture of products could be obtained. However, complete conversion to sulfoxides and sulfones occurs with a large pore (6.5 Å) zeolite, Ti-beta[7] (Table 1, entry 7), at room temperature using hydrogen peroxide.§,¶ Finally, selectivity is achieved‖ by replacing the potentially explosive hydrogen peroxide with the safer crystalline urea adduct of hydrogen peroxide (UHP), which compares favourably with existing protocols;[8] UHP adduct is known for the controlled release of the oxidant and is a well recognized source of oxygen.[2a,9]

Under these conditions, a facile and highly selective oxidation of bulkier organic sulfides [diphenyl sulfide, benzyl phenyl sulfide and dibenzyl sulfide, eqn. (1) and Table 2, entries

(1)

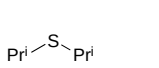
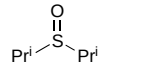
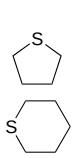
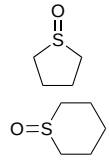
conversion, mass balance and yield = >90%

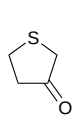
9–11] to the corresponding sulfoxides occurs with UHP in excellent yields.

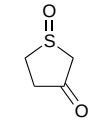


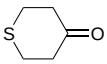


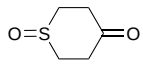


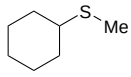


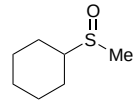


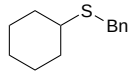


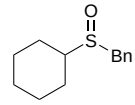


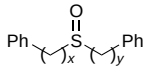












The scope of this protocol was further explored with a variety of sulfides (acyclic, cyclic and aromatic; Table 2) which were selectively oxidized to the corresponding sulfoxides in high yields with more than 95% mass balance. Acyclic and cyclic sulfides (Table 2, entries 1–4) were completely converted to the corresponding sulfoxides in 2 h at room temperature with 1.2 equiv. of UHP and 10 wt% of Ti-beta, whereas cyclic sulfides bearing a carbonyl functionality in their ring (Table 2, entries 5 and 6) required 3–4 h for complete conversion. All aromatic sulfides [as shown in eqn. (1)] produced clean sulfoxides with 100% selectively in 2 h.** Mechanistically, it is believed[2a] that the titanyl (Ti=O) function,[3a] the active site of the titanium silicates, binds with hydrogen peroxide to form a hydroxyhydroperoxo complex. This complex mimics *meta*-chloroperbenzoic acid and provides the required reactive oxygen (O*) species which oxidizes[2,3] sulfides to sulfoxides, generating water as a byproduct. Although it is not known whether the urea adduct (UHP) or free $H_2O_2$ enters the channels, it is known that the UHP complex is in equilibrium with free $H_2O_2$ and that the complex releases $H_2O_2$ at a rate which is, to some extent, solvent dependent.[9] In view of our own data and the background literature,[2a,3a] the use of the urea complex has two main advantages, namely the controlled release of $H_2O_2$ and the anhydrous nature of the oxidant. The sulfides and sulfoxides may enter or leave the zeolite channels at differing rates, but the oxidation undoubtedly occurs inside the zeolite catalyst.[2a,3a]

**Table 1** Oxidation of benzyl phenyl sulfide with 30% aqueous hydrogen peroxide catalysed by Ti- and V-silicates[a]

| Entry | Catalyst | Pore size/Å | *T*/°C | *t*/h | Conversion (%)[b] | Yield (%)[c] | Mass balance (%) |

[a] Reactions were carried out in $(CD_3)_2CO$ with sulfide (1 equiv.), oxidant (1.2 equiv.) and 10 wt% of catalyst. Variation in the amount of catalyst did not increase the conversion and at one stage ( > 50 wt%) it reduced the mass balance instead. [b] Conversions are based on $^1$H NMR spectroscopic analysis of the characteristic methylene signal in the crude reaction mixture (error ±5% of the stated values). [c] Yields refer to isolated products and are based on substrate consumption.

[a] The reactions were carried out in acetone at room temperature with sulfide (1 equiv.), UHP (1.2 equiv.) and 10 wt% of catalyst Ti-beta; all the sulfides reached complete conversion in 2 h except tetrahydrothiophen-3-one (entry 5) and tetrahydrothiopyran-4-one (entry 6), which required 3–4 h. [b] Yields refer to the pure isolated product. [c] Traces of sulfone were observed by $^1$H NMR spectroscopy.

Since a catalytic amount of the zeolite is used in this process and the reaction takes place at room temperature, we conclude that there are no restrictions placed on the sulfoxide as it leaves the channels. Apparently, the more reactive sulfide is oxidized more rapidly than the sulfoxide and the conversion of sulfoxide to sulfone is disfavoured due to the unavailability of a large excess of oxidant and possible steric crowding.

In conclusion, we have shown the versatility of the zeolite Ti-beta as a catalyst for selective oxidation of a variety of sulfides. The substrates which are not oxidized by TS-1 on account of their inaccessability are easily oxidized with this Ti-beta catalyst because of its larger pore size. The advantages of our environmentally benign approach over the conventional methods are the relative ease of separation of the catalyst and its recyclable nature.

We thank Dr M. Sasidharan, NCL, Pune, India for the supply of zeolite catalyst and the Texas Advanced Research Program (ARP) in Chemistry (Grant # 003606-023) and the Retina Research Foundation, Houston for generous support.

## Footnotes

† Thioanisole, under the reported conditions, produced the corresponding sulfoxide and sulfone in 3.55 : 1 ratio. However, diphenyl sulfide does not have access to the catalytic sites, the channel size of the zeolite TS-1 being only 5.5 Å [ref. 6(*a*)].

‡ While writing this manuscript, an article has appeared in which bulky substrates such as diphenyl sulfide and dibenzyl sulfide were oxidized to the corresponding sulfoxides with 30% $H_2O_2$ catalysed by CrS-2 [ref. 6(*b*)].

§ A peroxide test showed complete consumption of hydrogen peroxide.

¶ Various equivalents of hydrogen peroxide were used for the oxidation of benzyl phenyl sulfide. Experiments were carried out in deuteriated acetone and the ratios determined by $^1$H NMR analysis of characteristic signals in the crude reaction mixture (error ±5% of the stated values). Variation in the amount of catalyst used in the reaction did not produce any encouraging results in terms of selectivity.

| | | Yield (%) | |
|---|---|---|---|
| Equiv. $H_2O_2$ | Conversion (%) | Sulfoxide | Sulfone |
| 1.00 | 80 | 87 | 13 |
| 1.25 | 90 | 91 | 09 |
| 1.50 | 100 | 80 | 20 |

‖ Typical experimental procedure: Benzyl phenyl sulfide (100 mg, 0.64 mmol) in acetone (5 ml) was added to a well stirred mixture of UHP (72 mg, 0.77 mmol) and catalyst (10 mg, 10 wt% of sulfide) in the same solvent (10 ml) at 20 °C. This heterogenous mixture was then stirred for 2 h at the same temperature to complete the conversion of the sulfide to the corresponding sulfoxide. The reaction was monitored by TLC. The reaction mixture was then diluted with 10 ml of acetone and the catalyst filtered off and washed with acetone (2 × 5 ml). The combined solution was concentrated under reduced pressure to afford benzyl phenyl sulfoxide in 95% (105 mg, mp 118 °C).

** Other substrates investigated for their chemoselectivity include vinyl, allyl and prop-2-ynyl sulfides where alkenic moieties are preserved in the sulfoxide products. We have also performed the reactions with 1,4-thioxane, 5*H*-thiophen-2-one and thiomorpholine bearing a variety of substituents. The details of this work including stereoselectivity aspects will be published elsewhere.

**Tungsten and molybdenum complexes containing a diphenylsilanediolato ligand are structurally characterised; the overall structures of the anions are conserved in organic solvents.**

The chemistry of heteropolyoxoperoxometalates has received much attention in recent years.[1–8] In the course of systematic investigations of peroxidic $d^0$ transition-metal complexes involving different assembling ligands, model complexes with silicon-based anionic moieties were considered, in relation to attempts to prepare metal complexes supported on and/or inserted in silica. Monomeric silicic acid, $Si(OH)_4$, exists only in dilute aqueous solution; since this polymerizes,[9] $[SiO_4]^{4-}$ or hydrogenosilicates may be thought difficult to use as assembling ligands in the same way as $[HPO_4]^{2-}$,[6] $[HAsO_4]^{2-}$,[7] $[SO_4]^{2-}$,[8] *etc*. In some cases, $Si(OH)_4$ reacts directly and oligomeric species are known to depolymerize *e.g*. in the synthesis of $H_4[SiM_{12}O_{40}](aq)$ (M = Mo, W).[10] The corresponding silicopolyoxoperoxo-molybdates or -tungstates, $[SiO_4\{M_2O_2(\mu\text{-}O_2)_2(O_2)_2]^{4-}$, have been synthesized, but in our hands, are not easily purified. Organodisilanols can model geminal hydroxy groups which are much more reactive on silica surfaces than single silanols. Preliminary results obtained with diphenylsilanediol, $Ph_2Si(OH)_2$, are presented here. This compound is known as a chelating agent, either in mono- or in di- to tetra-meric forms.[11–14] The complexes $[PPh_4]_2[Ph_2SiO_2\text{-}\{M_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]$ (M = W **1** or Mo **2**) can be isolated from water–ethanol mixtures.

'$WO_3{\cdot}H_2O$' (or '$MoO_3{\cdot}H_2O$') was first reacted with a 30% m/v solution of hydrogen peroxide and this solution was then added to ethanolic $Ph_2Si(OH)_2$. After 45 min, slow addition of ethanolic $PPh_4Cl$ precipitated **1** (or **2**) in good yield. The white (yellow) precipitate was filtered off, washed with water and diethyl ether and then air-dried (yields: 75–90%).‡ Crystals of **1** and **2** were grown by slow evaporation of acetonitrile solutions.

**1** and **2** are isomorphous compounds. A representation§ of the dinuclear anion, $[Ph_2SiO_2\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]^{2-}$, is shown in Fig. 1. It consists of an assembling anion, $[Ph_2SiO_2]^{2-}$, and of a dimeric moiety, $\{W_2O_{10}\}$, resulting from the association of two pentagonal bipyramids sharing one edge, O(6)···O(12), of the non-basal planes. Each of these atoms is on the girdle axis of a bipyramid with a typical lengthening of the M–O distances, the other axial positions being occupied by oxo ligands with normal bond lengths.[1–3,6–8] The W atoms are located outside the mean equatorial plane defined by the five O atoms corresponding to two peroxo groups and to the oxygen atom of the assembling ligand {0.375 [0.392] for W(1) [Mo(1)] and 0.366 [0.382] Å for W(2) [Mo(2)], respectively}. There is one non-bridging peroxo group with $\eta^2$ side-bound configuration and one bridging $\mu\text{-}\eta^2:\eta^1$ peroxo group. The Si–O and Si–C bond distances are similar to those found in cyclic siloxanes.

The IR spectra of complexes **1** and **2** show features comparable to those observed for other dinuclear species;[6–8] in addition a strong band at 1586 $cm^{-1}$ is assigned as ν(C–C, phenyl),[12,15] and a very sharp band at 1107 $cm^{-1}$ is due to an in-plane deformation of the phenyl ring with some ν(Si–C) character.[12,15] The phenyl vibrations occur in expected positions. Consistent with the structural data and the existence of two distinct M=O bonds, there are strong ν(M=O) bands at 978s and 964s for **1** and at 968s and 955s for **2**; Si–O stretches appear at *ca*. 926 $cm^{-1}$ as a very strong maximum for both compounds. Bands at 862s for **2** and 841s for **1** are assigned to ν(O–O) of the peroxo ligands and bands at *ca*. 580 and 530 $cm^{-1}$ are assigned to asymmetric and symmetric $[M(O_2)]$ stretches, respectively. For **1** and **2**, comparison of the ν(O–O) and ν(Si–O) vibrations (IR and Raman) in the solid state and MeCN solution suggests that the overall structures of the two anions are conserved in solution.

Epoxidation of cycloalkenes by **1** was markedly more successful than for linear analogues; the larger the cycloalkene ring, the greater the degree of conversion to epoxide. In all

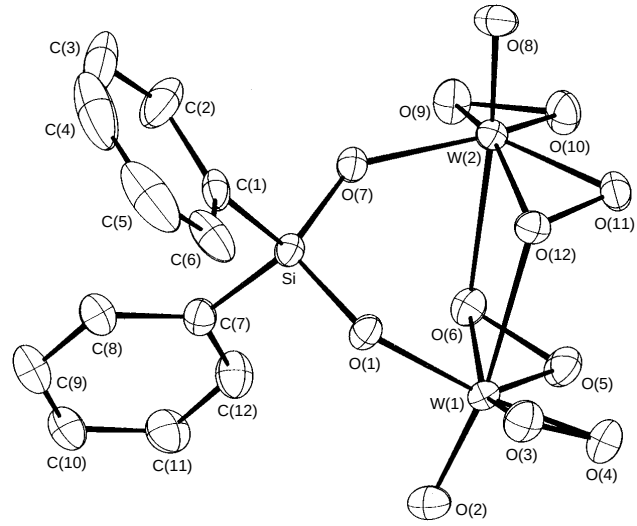

**Fig. 1** CAMERON representation of $[Ph_2SiO_2\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]^{2-}$ showing the atom labelling scheme. Selected bond lengths (Å) for **1** [**2**]: M(1)–O(1) 1.954(3) [1.964(2)], M(1)–O(2) 1.701(4) [1.681(2)], M(1)–O(3) 1.926(4) [1.928(2)], M(1)–O(4) 1.922(4) [1.931(2)], M(1)–O(5) 1.934(4) [1.927(2)], M(1)–O(6) 2.031(4) [2.006(2)], M(1)–O(12) 2.398(4) [2.444(2)], M(2)–O(6) 2.408(4) [2.459(2)], M(2)–O(7) 1.951(3) [1.959(2)], M(2)–O(8) 1.691(4) [1.672(2)], M(2)–O(9) 1.938(4) [1.937(2)], M(2)–O(10) 1.932(4) [1.929(2)], M(2)–O(11) 1.937(4) [1.927(2)], M(2)–O(12) 2.031(4) [2.014(2)], Si–O(1) 1.618(4) [1.619(2)], Si–O(7) 1.616(4) [1.620(2)], Si–C(1) 1.871(5) [1.874(3)], Si–C(7) 1.871(6) [1.884(3)], O(3)–O(4) 1.505(6) [1.481(4)], O(5)–O(6) 1.491(5) [1.470(3)], O(9)–O(10) 1.503(5) [1.473(3)], O(11)–O(12) 1.496(5) [1.468(3)].

cases, the order of increasing activity of PTC systems was $[Ph_2SiO_2(Mo_2O_{10})]^{2-} \ll [Ph_2SiO_2(W_2O_{10})]^{2-} < [HAsO_4(W_2O_{10})]^{2-}$, which confirms the assembling anion effect, but there is also a dramatic influence of the onium moiety.[16] Spectral data show that the diphenylsilanediolato compounds are recovered without any change if, at the end of the reaction, there is an excess of $H_2O_2$. Work is in progress to optimize conversions and selectivities.

Two novel anionic polyoxoperoxo species have been synthesized with $Ph_2Si(OH)_2$, $H_2O_2$–$H_2O$–EtOH and '$WO_3{\cdot}H_2O$' or '$MoO_3{\cdot}H_2O$'. They should be useful to model grafted polyoxoperoxo species which can be obtained on silica surfaces with geminal or single silanols or siloxane bridges and analogous complexes.[16,17]

‡ All new complexes gave satisfactory elemental analyses (C, H, P, Si, Mo/W).

§ *Crystal data and collection parameters*: $C_{60}H_{50}O_{12}P_2SiW_2$ **1**, $M$ = 1420.78, monoclinic, space group $C2/c$ (no. 15), $a$ = 46.380(5), $b$ = 13.345(5), $c$ = 18.988(2) Å, β = 113.259(9)°, $U$ = 10797(7) Å$^3$ (by least-squares refinement on diffractometer angles from 25 centred reflections, 11.5 < 2θ < 12.5), $T$ = 290 K, graphite-monochromated Mo-Kα radiation, λ = 0.710 73 Å, $Z$ = 8, $D_c$ = 1.75 Mg m$^{-3}$, $F$(000) = 5564, yellow parallelepiped with dimensions 0.30 × 0.45 × 0.65 mm, μ(Mo-Kα) = 44.92 cm$^{-1}$, Nonius CAD4 four-circle diffractometer, ω–2θ scans, data collection range 1.0 < θ < 28.0°, three standard reflections showed no significant variation in intensity; 13 009 unique data collected of which 8923 with $(F_o)^2 > 3\sigma(F_o)^2$ were used in all calculations. Corrections were made for Lorentz and polarisation effects, extinction correction was also applied[18] and absorption correction based on DIFABS program[19] applied before anisotropic refinements (min. 0.81, max. 1.24).

$C_{60}H_{50}Mo_2O_{12}P_2Si$ **2**, $M$ = 1244.96, monoclinic, space group $C2/c$ (no. 15), $a$ = 46.331(5), $b$ = 13.343(3), $c$ = 19.027(4) Å, β = 113.35(1)°, $U$ = 10799(7) Å$^3$ (by least-squares refinement on diffractometer angles from 25 centred reflections, 11.5 < 2θ < 12.5), $T$ = 290 K, graphite-monochromated Mo-Kα radiation, $Z$ = 8, $D_c$ = 1.53 Mg m$^{-3}$, $F$(000) = 5045, colourless parallelepiped with dimensions 0.40 × 0.30 × 0.40 mm, μ(Mo-Kα) = 5.94 cm$^{-1}$, Nonius CAD4 four-circle diffractometer with ω–2θ scans, collection range 1.0 < θ < 28°, two standard reflections showed no significant variation in intensity; 13 005 unique reflections measured, 8945 with $(F_o)^2 > 3\sigma(F_o)^2$ were used in all calculations. Lorentz and polarisation effects with extinction correction as above for **1**; absorption correction based on DIFABS program[19] was applied before anisotropic refinements (min. 0.85, max. 1.12).

*Structure solution and refinement*: atomic form factors for neutral W (or Mo), Si, P, O, C and H were taken from ref. 20. Real and imaginary parts of anomalous dispersion were taken into account. The structures were solved by direct methods and subsequent Fourier difference techniques, and refined anisotropically. Refinements were carried out in four blocks by minimising the function $\Sigma w(|F_o| - |F_c|)^2$, where $F_o$ and $F_c$ are the observed and calculated structure factors (program CRYSTALS).[21] All hydrogen atoms were found on difference Fourier maps; their positions were not refined and they were considered with an overall isotropic thermal parameter $0.9_0$ < C–H < $1.0_5$ Å for both **1** and **2**, $U_{iso}$ = 0.074(3) for **1** and 0.075(2) for **2**. The final $R$ factors as defined in ref. 21 were $R$ = 0.034, $R_w$ = 0.037 for **1** and $R$ = 0.032, $R_w$ = 0.034 for **2** for 697 parameters, and unit weighting scheme, GOF = 2.21 for **1** and 2.04 for **2**, maximum Δρ = 0.77 and 0.40 e Å$^{-3}$ for **1** and **2** respectively. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/352.

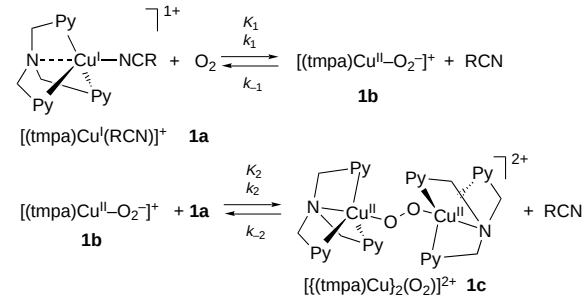
# Copper dioxygen complexes stable at ambient temperature: optimization of ligand design and solvent

**Kenneth D. Karlin,*[a] Dong-Heon Lee,[a] Susan Kaderli[b] and Andreas D. Zuberbühler*[b]**

[a] *Department of Chemistry, The Johns Hopkins University, Baltimore, MD 21218, USA*
[b] *Institute of Inorganic Chemistry, University of Basel, CH-4056 Basel, Switzerland*



**Entropic destabilization of low-molecular mass μ-peroxo-dicopper(II) complexes are overcome using a new binucleating open-chain ligand by the combination of an optimized linking unit with a less competing solvent; complete formation and satisfactory stability at room temperature are thus obtained.**

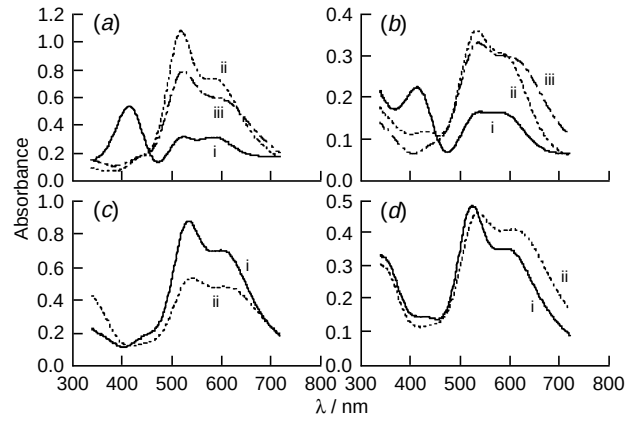
As with efforts by synthetic chemists to design systems which mimic the $O_2$-binding of haemoglobin/myoglobin using modified iron porphyrinates, there has been considerable recent interest in studies of $O_2$-binding by copper complexes,[1,2] relevant to the arthropodal and molluscan haemolymph $O_2$-carrier haemocyanins.[3] In the deoxygenated state, these possess a dinuclear copper(I) centre; oxygenation proceeds *via* oxidative addition, producing a side-on bound μ-$\eta^2$:$\eta^2$-peroxo-dicopper(II) species (Cu···Cu 3.6 Å). Using tridentate nitrogen-containing ligands, synthetic models with this structure and accompanying spectroscopic properties have been generated and characterized at reduced temperatures (either in solution or as isolated solids).[1,2,4]

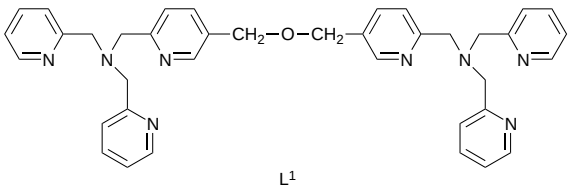
With tetradentate ligands such as tris(2-pyridylmethyl)amine (tmpa), divergent copper–dioxygen structure–spectroscopic types form. Kinetic/spectroscopic studies[5–7] reveal that copper(I) complexes with tmpa, its quinolyl substituted analogues, and binucleating version $L^2$, form sequentially both $Cu:O_2 = 1:1$ [superoxocopper(II)] and 2:1 [peroxodicopper(II)] products, stable only at reduced temperatures (*i.e.* −80 °C); X-ray structure analysis[8] establishes [{(tmpa)Cu}$_2$($O_2$)]$^{2+}$ **1c** (Scheme 1) to possess a *trans*-μ-1,2-peroxo ligation. The quinolyl[5] and dinucleating ligand[6] variations measurably affect $Cu^I_n/O_2$ stoichiometric preferences, reaction rates, and $Cu_n$–$O_2$ structural distortions or strain.[6,7] Here, however, we report dramatic effects upon reaction rates and copper–dioxygen complex stability, elicited by ligand synthetic modification or alteration of reaction solvent. In fact, the long sought goal of generating a fully formed and reasonably stable copper–dioxygen complex at room temperature in solution, has been achieved.

Kinetic–spectroscopic monitoring of [(tmpa)Cu$^I$(RCN)]$^+$ **1a** reacted with $O_2$ in EtCN at −90 °C typically reveals initial {*t ca*. 50 ms, [**1a**] = 0.4 mM; [$O_2$] = 4.5 mM} growth of the band at $\lambda_{max}$ = 410 nm, associated with a 1:1 intermediate adduct [(tmpa)Cu$^{II}$($O_2^-$)]$^+$ **1b** ($k_1 = 1.8 \times 10^4$ M$^{-1}$ s$^{-1}$). The final peroxo product [{(tmpa)Cu$^{II}$}$_2$($O_2^{2-}$)]$^{2+}$ **1c** ($\lambda_{max}$ = 525 nm) subsequently builds up at the expense of **1b** (and **1a**; Scheme 1) such that at *t ca*. 10 s at this temperature, **1b** mostly disappears and **1c** is nearly fully formed. The room-temperature stability of **1c** (and other copper–dioxygen complexes in general)[6,7] is precluded by a highly unfavoured reaction entropy ($\Delta S_{on}° = -220 \pm 11$ J K$^{-1}$ mol$^{-1}$),[6] and the 525 nm absorption essentially disappears, either in favour of Cu$^I$ (short times) or Cu$^{II}$ decomposition products.

These results stand in marked contrast to reactions now carried out in acetone as solvent. At −90 °C, [{(tmpa)Cu$^{II}$}-($O_2^-$)]$^+$ **1b** fully forms within the mixing time of the stopped-flow apparatus (< 2 ms), Fig. 1(*a*), providing a lower limit $k_1 \geqslant 10^6$ M$^{-1}$ s$^{-1}$. This $O_2$-binding to [{(tmpa)Cu$^I$}(Me$_2$CO?)]$^+$ **1a′** at −90 °C is at least comparable with the room-temperature reaction of $O_2$ with deoxyhaemocyanin ($k_{on}$ *ca*. $10^7$ M$^{-1}$ s$^{-1}$).[9] Thus, with the right ligand and medium, there is little, if any, restriction to $O_2$-binding to Cu$^I$, and these observations point to

**Scheme 1**





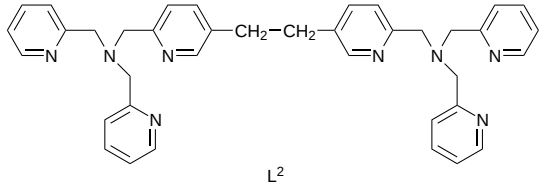


**Fig. 1** Stopped-flow spectral monitoring of the reaction in acetone of $O_2$ (5.1 mM) with (*a*) [(tmpa)Cu$^I$(RCN)]$^+$ (**1a**, 0.9 mM) and (*b*) [$L^2Cu_2$(EtCN)$_2$]$^{2+}$ (**2a**, 0.26 mM). Superoxo formation with some admixture of peroxo complex (2.6 ms after mixing) (i, superoxo −90 °C; ii, peroxo −90 °C; iii, peroxo +20 °C). Reaction of $O_2$ (5.1 mM) with [$L^1Cu_2$(EtCN)$_2$)]$^{2+}$ (**3a**, 0.55 mM) in (*c*) propionitrile or (*d*) acetone (0.28 mM) (i, peroxo −90 °C; ii, peroxo +20 °C).

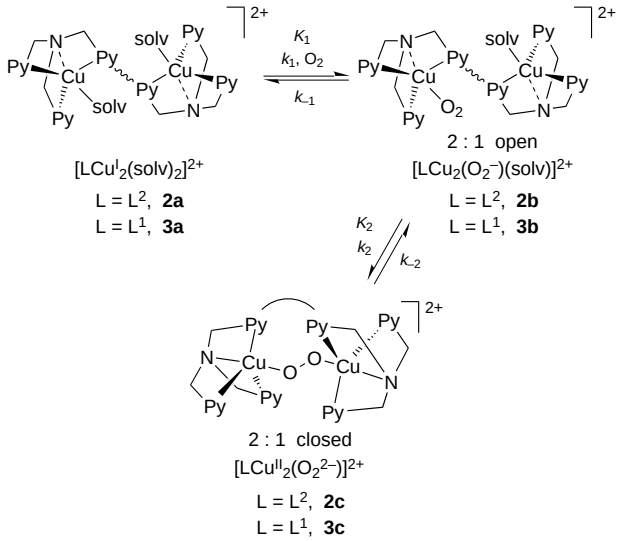
nitrile coordination and rate-limiting dissociation being critical in the chemistry of tripod copper(I) complexes detailed for EtCN solutions.[5–7] The stability of $[\{(tmpa)Cu^{II}\}_2(O_2^{2-})]^{2+}$ **1c** [$\lambda_{max}$ = 525 nm, shoulders at *ca*. 430 and 600 nm; Fig. 1(*a*)][10]† is increased even more dramatically, with $\beta_2 = K_1K_2 \geqslant 5 \times 10^5$ M$^{-2}$ ($5 \times 10^2$ M$^{-2}$ in EtCN) at room temperature. Formation of 70% **1c** is obtained within the mixing time (EtCN: not observable, calculated formation 0.2%). At 20 °C, **1c** decomposes with $t_{1/2}$(decomp.) *ca*. 45 s.



We previously showed that $[L^2Cu_2(EtCN)_2]^{2+}$ **2a** reacts with $O_2$ in EtCN giving both Cu : $O_2$ = 1 : 1 and 2 : 1 intermediates; $[L^2(Cu^ICu^{II})(O_2^-)(EtCN)]^{2+}$ **2b** reacts intramolecularly giving closed peroxo species $[L^2Cu_2(O_2)]^{2+}$ **2c** (Scheme 2).[6] The dinucleating nature of $L^2$ (compared to tmpa) results in considerable reduction of the entropic handicap found for formation of $[\{(tmpa)Cu\}_2(O_2)]^{2+}$ **1c**, by 130–140 J K$^{-1}$ mol$^{-1}$. However comparison of the $\Delta H_{on}°$ for **1c** *vs*. **2c** formation (−81 *vs*. −35 kJ mol$^{-1}$)[6] revealed the latter to be significantly strained, resulting in rearrangement to trimeric $[L^2Cu_2(O_2)]_3^{6+}$. In acetone, **2a** reaction with $O_2$ again results in enhanced stability of copper–dioxygen adducts. As with tmpa, 1 : 1 complex adduct formation occurs within the stopped-flow mixing time even at −90 °C, giving the characteristic $\lambda_{max}$ = 414 nm absorption [Fig. 1(*b*)], assigned to a bis-superoxocopper(II) species $[L^2Cu_2(O_2)_2]^{2+}$ **2b′**. Formation of peroxo complex $[L^2Cu_2(O_2)]^{2+}$ **2c** is essentially complete even at 20 °C [Fig. 1(*b*)], yielding $K_1K_2 > 4 \times 10^3$ M$^{-1}$ (27 M$^{-1}$ in EtCN),[6] but precluding calculation of thermodynamic parameters $\Delta H°$ and $\Delta S°$. Enhanced decomposition of **2c** [$t_{1/2}$(decomp.) *ca*. 4 s] *vs*. $t_{1/2}$(decomp.) *ca*. 40 s for **1c** may reflect the still considerably strained nature of adduct $[L^2Cu_2(O_2)]^{2+}$.

In combination, the new ligand $L^1$,‡ a modification designed to relieve the strain in **2c**, [11] is the most successful in giving a pseudoreversible $Cu_2$–$O_2$ complex stable at room temperature. Curiously, for both EtCN and acetone solvents, there is no spectral indication of any 1 : 1 adducts (*e.g*. **3b**, Scheme 2) upon reaction of dicopper(I) precursor $[L^1Cu_2(MeCN)_2]^{2+}$ **3a**‡ with $O_2$.§ Their formation appears to be inhibited and slow relative to the subsequent reactions leading to peroxo complex $[L^1Cu_2(O_2)]^{2+}$ **3c** ($\lambda_{max}$ = 535 nm). However, in EtCN, formation of **3c** is complete within the experimental mixing time even at −60 °C. Theoretical calculations[11] and preliminary analyses of the present kinetic data suggest that the longer linker arm in $L^1$ indeed relieves the strain observed for $[L^2Cu_2(O_2)]^{2+}$ **2c**, significantly enhancing adduct formation at room temperature to 60% [$K_1K_2$ = 300 M$^{-1}$ *vs*. 27 M$^{-1}$ for $L^2$, Fig. 1(*c*),† with $t_{1/2}$(decomp.) increased to 20 s]. $L^1$ seems to afford significant entropic advantage for formation of $[L^1Cu_2(O_2)]^{2+}$ **3c** compared to $[\{(tmpa)Cu\}_2(O_2)]^{2+}$ **1c**, with little enthalpic loss.

Acetone once more confers additional stability to **3c**. Peroxo formation is immediate and complete within experimental error at room temperature, thus precluding quantitative determination of $K_1K_2$, but we may safely assume that thermodynamic stability is still increased relative to $L^2$ in acetone. In line with this, enhanced persistence of the characteristic $[L^1Cu_2(O_2)]^{2+}$ **3c** spectrum [Fig. 1(*d*); $t_{1/2}$(decomp.) *ca*. 60 s] may be indicative of released strain and leads to the most stable of all copper–dioxygen complexes thus far studied by us.[7]¶

The results further demonstrate the importance in ligand design/modification, here shown to confer solution room-temperature stability to $Cu_2$–$O_2$ complexes. $L^1$ utilizes a dinucleating design which appears to be strain minimized. Acetone is shown to be a remarkable solvent for enhancing rates of formation and thermal stability of $Cu_n$–$O_2$ species, probably by virtue of its poor ability to ligate to $Cu^I$. Further analyses and investigations are aimed at further detailing of factors which can be controlled *via* ligand design (*i.e*. steric, electronic and medium effects), and which are critical to $Cu_n$–$O_2$ formation, structure, stability and reactivity.

We thank the National Institutes of Health (K. D. K.) and Swiss National Science Foundation (A. D. Z.) for financial support of this research.

# Structural consequences of competing noncovalent forces: the out–out conformation of the doubly protonated [2.2.2]cryptand

**Leonard R. MacGillivray and Jerry L. Atwood*†**

*Department of Chemistry, University of Missouri-Columbia, Columbia, Missouri 65211, USA*

**The reaction of [2.2.2]cryptand 1 with 2,6-dihydroxybenzoic acid (dhbH) in toluene affords the complex [1-2H]-[(2,6-dhb)$_2$]; its crystal structure exhibits the first solid state evidence of the out–out form of the doubly protonated macrobicycle and illustrates the role of C–H···O hydrogen bonds in providing additional stability to the cavity of the ligand.**

Although it is now generally accepted that noncovalent interactions (*e.g.* hydrogen bonds, π–π interactions, ion pairs) play an important role in determining the conformation and corresponding ionophoric properties of macro(poly)cyclic receptors (*e.g.* crown ethers, cryptands)[1] in solution,[2a] the gas phase,[2b] and the solid state,[2c] less is known about their structure determining roles in the presence of competing forces.[3] This is, perhaps, not surprising considering the difficulty in generating and analysing discrete, multi-component supramolecular assemblies and delineating the contributions of each interaction to the resulting structure.[4] Indeed, understanding the cooperativity[5] exhibited by noncovalent interactions, especially in the context of molecular recognition processes, promises to yield insight into areas of both chemical and biological relevance including the nucleation and crystallization of molecules[6] and the mechanisms by which the secondary structures of proteins (*e.g.* α-helices) are formed.[3]

Extensive work has demonstrated the self-assembly of proton cryptate complexes of the flexible macrobicyclic ionophore [2.2.2]cryptand **1** with inorganic anions isolated from liquid clathrate media.[7] In particular, we have illustrated the ability of two trifurcated intraionic $N^+$–H···O hydrogen bonds to slow down its rapid in–in, in–out, and out–out equilibrium[8] in solution and reorganize its structure to a chiral, in–in conformation with approximate $D_3$ symmetry in the solid state.[7a] In such a context, recent molecular dynamics simulations have shown the doubly protonated in–in form of **1** to be more stable than its corresponding out–out conformer by 21 kcal mol$^{-1}$.[9] This additional stability has been attributed, in part, to the intraionic $N^+$–H···O hydrogen bonds within the cavity.

As part of our ongoing studies of proton cryptates, we now report the synthesis and X-ray crystal structure of a complex, [**1**-2H][(2,6-dhb)$_2$] **2** (dhb = dihydroxybenzoate, dhbH = dihydroxybenzoic acid), which provides the first solid state evidence of the out–out form of the doubly protonated **1**. The complex exhibits two 2,6-dhb ions which interact with the outer surface of the cryptate *via* two interionic $N^+$–H···$O^-$ hydrogen bonds. As a consequence of these interactions, the ligand has undergone a structural reorganization from the in–in form, by breakage of its internal $N^+$–H···O hydrogen bonds, to the out–out conformation. Furthermore, in response to this reorganization, the ligand has formed four intraionic C–H···O interactions[10] inside its cavity. Such observations provide insight into molecular recognition processes involving hydrogen bond cooperativity where understanding the structural consequences of competing noncovalent forces is of much current interest.[5a,b]

Addition of **1** (0.040 g) to a hot toluene solution (40 ml) containing 2,6-dhbH (0.033 g) according to eqn. (1) immediately yielded a white precipitate **2**. Colourless crystals of **2** suitable for X-ray analysis were obtained by dissolving a portion of the precipitate in MeCN and allowing the solution to evaporate to dryness. The formulation of **2** was confirmed by single-crystal X-ray diffraction‡ and analytical data.§

$$\mathbf{1} + 2(2,6\text{-dhbH}) \rightarrow [\mathbf{1}\text{-2H}][(2,6\text{-dhb})_2]\ \mathbf{2} \qquad (1)$$

An ORTEP perspective of **2** is shown in Fig. 1. *Exo* protonation leads to the formation of two interionic $N^+$–H···$O^-$ hydrogen bonds between constituent ions, and hence, an out–out conformation is adopted by the cryptate. As a result, the cavity of the ligand is substantially distorted from approximate $D_3$ symmetry. This is illustrated by N(1)–CCO and N(2)–CCO torsion angles, which range from −65.6 to 171.1° and −60.0 to 174.4°, and the distances for the edges of each triangular face, which range from 4.228 to 4.931 Å and 4.070 to 4.867 Å, for atoms O(1), O(3), O(5) and O(2), O(4), O(6), respectively.¶ These values compare favourably to those of the *N*,*N*′-dimethyl-**1** diiodide salt[13] and the bisborohydride of **1**[14] which adopt similar *exo* conformations owing to the bulk of the substituents which precludes their entrance in the cavity. The corresponding torsion angles and O···O separations in [$H_3O$]$_2$[**1**-2H][4Cl]·4 $H_2O$ **5** range from −53.7(7) to −58.3(8)° and 3.69(2) to 3.79(2) Å, respectively.[7a] Furthermore, the nonbonding N···N separation (6.33 Å), which is shorter than that of the empty cryptand (6.87 Å),[14] is longer than in **5** (5.71 Å) but comparable to that of **3** (6.67 Å) and **4** (6.77 Å).

The geometry of the cavity of the cryptate in **2** may be attributed to the contributions of four C–H···O hydrogen bonds involving four α-hydrogen atoms, from two different methylene groups, and the four ethereal oxygen atoms which are directed inward toward the cavity. Indeed, Fig. 1 illustrates that *exo* protonation facilitates inversion at each bridgehead nitrogen

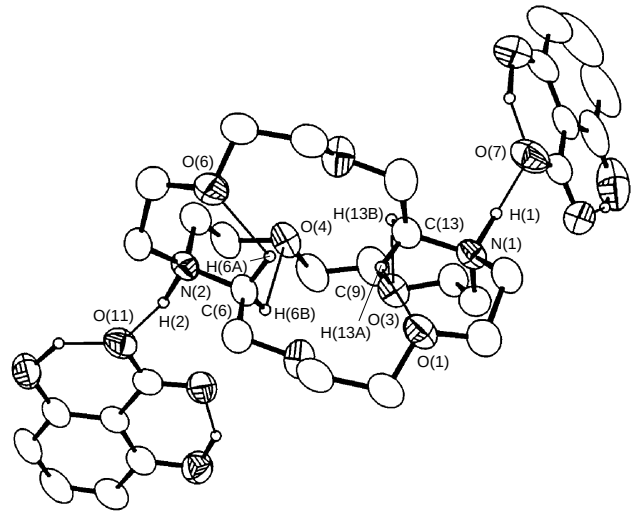

**Fig. 1** X-Ray crystal structure of **2**. Selected interatomic distances (Å) and angles (°): N(1)···O(7) 2.687(4), N(1)–H(1)–O(7) 177(2), N(2)···O(11) 2.689(4), N(2)–H(2)–O(11) 166(2), C(6)···O(4) 3.010(4), C(6)–H(6B)–O(4) 111, C(6)···O(6) 2.919(4), C(6)–H(6A)–O(6) 110, C(13)···O(3) 3.042(4), C(13)–H(13B)–O(3) 117, C(13)···O(1) 2.964(4), C(13)–H(13A)–O(1) 117.

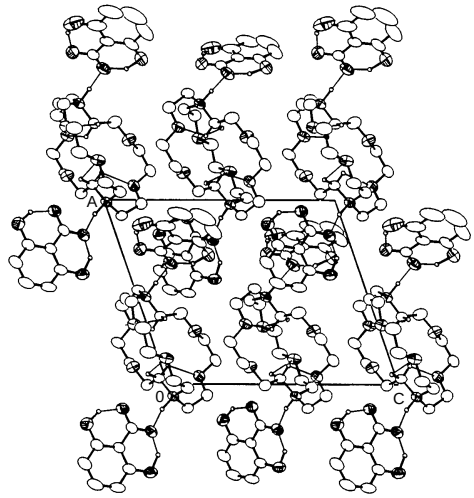

**Fig. 2** Crystal packing of **2** viewed along the crystallographic *b* axis

atom which subsequently enables one methylene group at each end of the cryptate to extend its hydrogen atoms inside the cavity and form the C–H···O interactions‖ The ability of C–H···O hydrogen bonds to provide structural stability to macrocyclic polyether components (*e.g.* cyclophanes) is known[15] and there is growing evidence that such interactions play a role in stabilizing the tertiary structures of biomolecules.[16] To our knowledge, this is the first case in which C–H···O hydrogen bonds have been recognized to impart conformational stability to the out–out topology of **1**.

A view along the crystallographic *b* axis depicting the crystal structure of **2** is shown in Fig. 2. The assembly process results in an alternating assembly of aliphatic and aromatic layers, involving cations and anions, respectively, within the *ac* plane. Interestingly, **5** exhibits a similar layered architecture despite the fact that its proton cryptate adopts the in–in topology.[7a]

The results reported herein lie at the heart of molecular recognition. By simply introducing an appropriate hydrogen bond acceptor along its outer surface, the [**1**-2H]$^{2+}$ ion has undergone a structural reorganization, *via* breakage of its internal N$^+$–H···O hydrogen bonds, to the out–out form which recognizes the anion *via* interionic N$^+$–H···O$^-$ interactions. In response, the cryptate has formed four C–H···O interactions inside its cavity. Such observations may provide insight into understanding those factors which influence the secondary structures of proteins since similar competing noncovalent forces are thought to play a role in contributing to their stability.[3a]

We are grateful for funding from the National Science Foundation, the Natural Sciences and Engineering Research Council of Canada (NSERC) for a research fellowship (L. R. M.) and the International Centre For Diffraction Data for a research scholarship (L. R. M.).

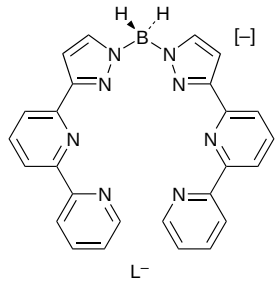
# A dinuclear double-helical complex of potassium ions with a compartmental bridging ligand containing two terdentate N-donor fragments



**Elefteria Psillakis, John C. Jeffery, Jon A. McCleverty* and Michael D. Ward***

*School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

**The compartmental bridging ligand bis{3-[6′-(2,2′-bipyridyl)]pyrazol-1-yl}hydroborate ($L^-$), which contains two chelating terdentate N-donor arms linked by an anionic $–BH_2–$ bridge, forms a dinuclear double-helical complex $K_2L_2$ with $K^+$ ions.**

Recently helicates have become a well known structural motif in supramolecular coordination chemistry.[1–4] They are of particular interest not just for their appealing structures but also because of the processes of molecular recognition and self-assembly that are required for their formation. Their formation requires (*i*) ligands which contain several discrete metal-ion binding domains, and (*ii*) metal ions with specific preferences for particular coordination geometries that match the ligand binding sites. It is the appropriate combination of these two factors which dictates the outcome of the self-assembly process. Thus, a ligand which has two terdentate domains might give a double helicate with a transition-metal ion (coordination number six) but a triple helicate with a lanthanide (coordination number nine).[2–5] In contrast, linear oligopyridines can partition themselves according to the dictates of the metal ion, and give different structures with $Cu^I$ (when the ligand is partitioned into bidentate domains) and $Cd^{II}$ or $Ni^{II}$ (when it is split into terdentate domains).[1]

The requirement of the metal ion for a specific geometry or coordination number is principally controlled by charge/size effects: thus $Cu^I$ and $Ag^I$ have a preference for (usually) four-coordination, whereas transition-metal dications generally prefer six-coordination and lanthanides prefer approximately nine-coordination.[1–5] In contrast the use of s-block metals in double helicates is virtually unknown. The only certain example, recently published by Bell and Jousselin, is a 2 : 2 complex of $Na^+$ with a 'heterohelicene' ligand which is preorganised into a helical shape and therefore inevitably imposes a helical structure on its complexes.[6] The complex was characterised by NMR spectroscopy and mass spectrometry, but not crystallographically. It is also possible that the 1 : 1 adduct of 2,2′ : 6′,2″ : 6″,2‴ : 6‴,2⁗-quinquepyridine with $LiClO_4$ is a double helicate.[7] Cram and coworkers recently described a macrocyclic ligand containing two phenanthroline binding sites that was twisted into a helically chiral conformation by virtue of binaphthyl groups incorporated into the cycle; this imposes a helically chiral geometry on alkali-metal cations due to its preorganisation.[8]

We describe here the preparation of the new compartmental bis-terdentate ligand bis{3-[6′-(2,2′-bipyridyl)]pyrazol-1-yl}-hydroborate ($L^-$) as its potassium salt KL, and the crystal structure of this salt which reveals a double-helical complex of stoichiometry $K_2L_2$. The ligand was prepared by reaction of 6-(3-pyrazolyl)-2,2′-bipyridine[9] with $KBH_4$,† which is the usual route for preparing bidentate bis(pyrazol-1-yl)hydroborates[10] and tridentate tris(pyrazol-1-yl)hydroborates[11] from substituted pyrazoles. All of the spectroscopic and analytical data were consistent with formation of KL, in which two terdentate N-donor arms are linked by an anionic $–BH_2–$ fragment. Even using a fourfold excess of the pyrazole, we found that only the bis(pyrazolyl)borate was obtained, and this is the first example of a bis(pyrazolyl)borate functionalised in this manner so that each arm becomes chelating rather than monodentate. The compound was crystallised by slow evaporation from chloroform to give colourless prisms; the crystal structure is in Fig. 1,‡ and reveals that in the solid state the

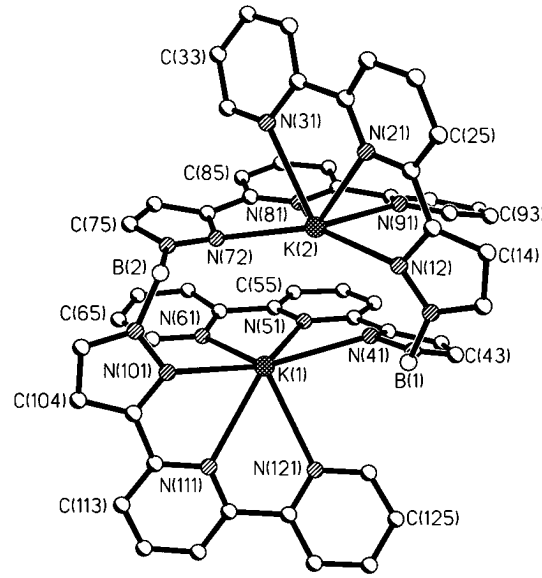


**Fig. 1** Crystal structure of $K_2L_2$. Selected bond lengths (Å) and angles (°): K(1)–N(101) 2.772(5), K(1)–N(41) 2.784(6), K(1)–N(61) 2.816(6), K(1)–N(51) 2.857(5), K(1)–N(111) 2.927(5), K(1)–N(121) 2.956(6), K(2)–N(72) 2.766(6), K(2)–N(12) 2.777(6), K(2)–N(91) 2.802(6), K(2)–N(81) 2.855(6), K(2)–N(31) 2.877(6), K(2)–N(21) 2.890(6), K(1)···K(2) 3.954(2); N(101)–K(1)–N(41) 150.1(2), N(101)–K(1)–N(61) 84.2(2), N(41)–K(1)–N(61) 116.1(2), N(101)–K(1)–N(51) 139.3(2), N(41)–K(1)–N(51) 59.2(2), N(61)–K(1)–N(51) 57.4(2), N(101)–K(1)–N(111) 57.3(2), N(41)–K(1)–N(111) 134.9(2), N(61)–K(1)–N(111) 95.4(2), N(51)–K(1)–N(111) 132.5(2), N(101)–K(1)–N(121) 111.9(2), N(41)–K(1)–N(121) 80.3(2), N(61)–K(1)–N(121) 115.3(2), N(51)–K(1)–N(121) 97.8(2), N(111)–K(1)–N(121) 56.4(2), N(72)–K(2)–N(12) 150.1(2), N(72)–K(2)–N(91) 116.3(2), N(12)–K(2)–N(91) 85.4(2), N(72)–K(2)–N(81) 58.8(2), N(12)–K(2)–N(81) 141.5(2), N(91)–K(2)–N(81) 58.1(2), N(72)–K(2)–N(31) 80.7(2), N(12)–K(2)–N(31) 114.4(2), N(91)–K(2)–N(31) 105.8(2), N(81)–K(2)–N(31) 89.2(2), N(72)–K(2)–N(21) 135.8(2), N(12)–K(2)–N(21) 59.4(2), N(91)–K(2)–N(21) 88.5(2), N(81)–K(2)–N(21) 124.7(2), N(31)–K(2)–N(21) 56.6(2).

compound is in fact a double-helical complex $K_2L_2$. The double-helical structure is emphasised in Fig. 2.

Each $K^+$ ion is coordinated in an irregular six-coordinate environment by two terdentate arms, one from each of the two ligands. The K–N bond distances around K(1) lie in the range 2.77–2.96 Å and those around K(2) lie in the range 2.77–2.89 Å, which are comparable to those found for the $K^+$ complex of one of Bell's cyclic torand ligands based on pyridyl donors[12] and for $[K(phen)_3][BPh_4]$.[13] There are additional weak interactions between K(1) and N(72) [3.469(5) Å] and between K(2) and N(41) [3.437(5) Å], which probably just arise from the steric constraints of the complex and do not represent true bridging behaviour by N(41) and N(71). Each ligand donates one terdentate arm to each of the two metal ions, a binding mode which is facilitated by the flexible $–BH_2–$ 'hinge' at the centre of each ligand. The N–B–N angles are 111.0(6)° at B(1) and 110.3(5)° at B(2), both very close to the ideal tetrahedral value which indicates that this mode of coordination is not imposing any steric strain on the ligands: this is no doubt facilitated by the ability of $K^+$ to tolerate a highly irregular coordination environment. The two terdentate fragments of each ligand are therefore approximately mutually perpendicular.

The structure appears to be stabilised by aromatic π-stacking interactions (3.2–3.6 Å) between near-parallel, overlapping sections of the two ligands. This is a common feature of helical complexes[1–4] but one which is not essential for helicate formation: the matching of metal-ion coordination geometry and ligand donor properties is probably more important.[14] The metal–metal separation [3.954(2) Å] is shorter than that in metallic potassium (4.54 Å) but significantly longer than the sum of two ionic radii for $K^+$ ions (*ca*. 2.7 Å). The crystal contains opposite enantiomers in the unit cell, related by an inversion centre. As with all 'supramolecular' structures based on labile metal ions, the solid-state structure is not necessarily wholly representative of the solution behaviour which could be considerably more complex.

This complex has several unusual features. First, it is to date the only structurally characterised double-helical complex with an s-block metal. Secondly, unlike the helical complexes described by Bell and Jousselin[6] and Cram and coworkers,[8] the helical geometry is not imposed by a preorganised ligand but arises naturally from the assembly of achiral ligands around the metal ions, as normally occurs for the transition-metal and lanthanide based helicates.[1–5] Thirdly, it is an unusual example of alkali-metal coordination by an open-chain nitrogen donor ligand.[13] Although several examples of alkali-metal complexes with exclusively N-donor ligands are known, they usually require highly preorganised ligands such as torands,[12,15] macrocycles[16] and cryptands,[17] where the cavity size is a particularly good match for an alkali-metal cation, and the coordination geometry is particulary unsuited to a transition-metal ion, neither of which is true in $K_2L_2$. It is probable that, considering the predominantly ionic nature of the complex, the affinity of $L^-$ for $K^+$ is enhanced by the negative charge of the ligand.

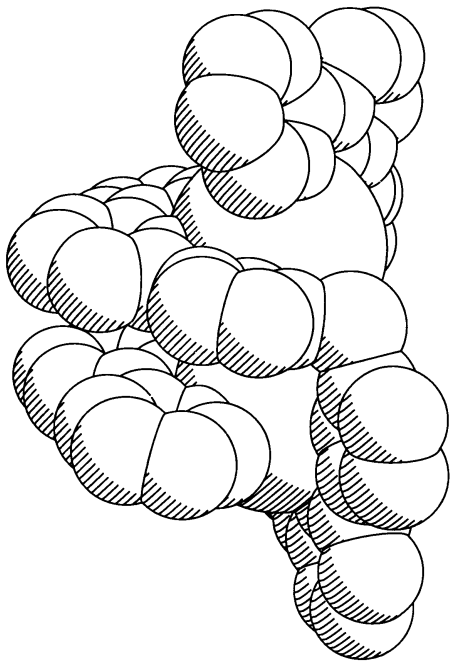

**Fig. 2** Space-filling diagram of $K_2L_2$

## Footnotes

† *Preparation* of $K_2L_2$: a mixture of 6-(3-pyrazolyl)-2,2′-bipyridine (0.25 g, 1.13 mmol) and $KBH_4$ (0.015 g, 0.28 mmol) was finely ground together in a mortar to ensure intimate mixing. The solid mixture was then heated to 190 °C under $N_2$ for 3 h (it melted at *ca*. 120 °C and $H_2$ evolution was observed to start at *ca*. 150 °C). After cooling the mixture the solid was washed with toluene to remove excess unreacted 6-(3-pyrazolyl)-2,2′-bipyridine; the remaining solid was collected by filtration and dried to give KL (0.040 g, 30%). Negative-ion electrospray MS: *m/z* 455 (100%, $L^-$). A satisfactory elemental analysis was obtained.

‡ *Crystal data* for $K_2L_2$: $C_{52}H_{40}B_2K_2N_{16}$, colourless prisms, crystal size 0.40 × 0.25 × 0.10 mm, $M$ = 988.82, triclinic, space group $P\bar{1}$, $a$ = 9.858(2), $b$ = 13.566(2), $c$ = 18.4766(12) Å, α = 87.541(10), β = 85.050(9), γ = 83.102(9)°, $U$ = 2442.5(6) Å$^3$, $Z$ = 2, $D_c$ = 1.345 g cm$^{-3}$, μ(Mo-Kα) = 0.25 mm$^{-1}$. Using a Siemens SMART diffractometer and graphite-monochromated Mo-Kα X-radiation, 11128 data were collected at −100 °C with $2\theta_{max}$ = 46.5°, and merged to give 6871 unique data ($R_{int}$ = 0.067). The data were corrected for absorption effects by an empirical method based on multiple measurements of equivalent reflections. The structure was solved by direct methods, and refined on all $F^2$ data using the SHELX suite of programs (version 5.03). All non-hydrogen atoms were refined with anisotropic thermal parameters. Aromatic C–H hydrogen atoms were included in calculated positions with isotropic thermal parameters 20% higher than those of the parent atoms; the four B–H hydrogen atoms were located directly and their thermal parameters refined freely. Refinement of 665 parameters using 6616 data converged at $R_1$ = 0.088, $wR_2$ = 0.207. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this information should quote the full literature citation and the reference number 182/364.

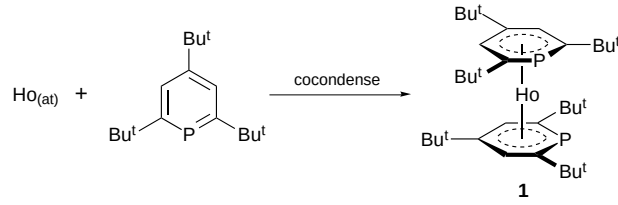
# The first structurally authenticated zerovalent heteroarene complex of a lanthanide; synthesis and X-ray structure of bis(2,4,6-tri-*tert*-butylphosphorin)holmium(O)

**Polly L. Arnold, F. Geoffrey N. Cloke,* Peter B. Hitchcock**

*The Chemistry Laboratory, School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, E. Sussex, UK BN1 9QJ*

**Holmium vapour reacts with 2,4,6-tri-*tert*-butylphosphorin to afford the zerovalent [Ho(η-$PC_5H_2Bu^t_3$-2,4,6)$_2$], the first structurally characterised complex of this class.**

The organometallic chemistry of the lanthanides has seen huge growth in recent years. Initial employment of ligands utilising purely electrostatic bonding was widespread, but recently the use of anionic and neutral π-ligands has emerged to encompass a wide range of complexes.[1,2] The reports of binding of only neutral ligands still remain predominantly in the field of low-temperature matrix-isolation studies, since the highly electropositive metal centre is difficult to stabilise in very low oxidation states.[3–5] Examples of stable compounds where binding to the lanthanide can be regarded as covalent in nature are the bis(tri-*tert*-butylarene) zerovalent lanthanides.[6] These complexes should not be considered as 'metastable' metal atoms isolated in the arene organic cavity, since thermochemical bond energy measurements supported by theoretical calculations have shown that the complexes which form are indeed thermodynamically stable with respect to their constituent metal atom and arenes, and that there is significant back bonding from the metal frontier orbitals.[7,8] The members of the series of f-element bis(η-1,3,5-tri-*tert*-butylbenzene)metal(O) compounds that have not been isolated at room temperature are either those where the promotion energy from $f^n$ to an $f^{n-1}d^1s^2$ configuration for bonding is prohibitively high, or those in which the atomic radius is presumably simply too large to allow kinetic stability through steric saturation.[6] We have been interested in synthesising further examples of these sandwich compounds using a variety of new ligands to access remaining members of the series, and explore the reactivity thereof.



The replacement of a CH moiety by phosphorus is well documented, as is the effect on first-row transition-metal complexes synthesised from the resultant heteroarene.[9] The use of tri-*tert*-butylphosphorin both constrains the mode of bonding interaction to a π-arene type by hindering access to the phosphorus lone pair, and satisfies the requirement of steric saturation at the metal centre for stabilisation of such an electropositive metal.[10–13]

Cocondensation of holmium vapour with an excess of 2,4,6-tri-*tert*-butylphosphorin[14,15] at −196 °C leads to the formation of a dark purple matrix,[16] from which extremely air- and moisture-sensitive purple iridescent crystals of bis(2,4,6-tri-*tert*-butylphosphorin)holmium(O) **1**, can be isolated in gram quantities (45% yield) after work-up and recrystallisation from pentane (Scheme 1).†

The UV–VIS spectrum of **1** shows one absorption at 489 nm, ascribed to ligand-to-metal charge transfer. This is in accordance with prior observations of bathochromic shifts that related heterocyclic systems show with respect to their carbocyclic analogues {$\lambda_{max}$ [Ho(η-$C_6H_3Bu^t_3$-1,3,5)$_2$] = 507 nm}.[17] If the charge-transfer shift to higher energy is taken to imply stronger metal–ligand bonding, then this agrees well with the observation of the capacity of a phosphaarene to act as a better π-electron acceptor but similar electron donor towards a metal.[18,19]

The sandwich complex sublimes ($10^{-5}$ mbar) with around 90% recovery at 160 °C. This remarkable thermal stability enabled single crystals suitable for X-ray structural determination to be grown by vapour-phase diffusion. A Chem 3D representation of the structure is depicted in Fig. 1.‡ It is interesting that although the distortion of the arene from $C_{3v}$ symmetry on inclusion of the large heteroatom is considerable, the *tert*-butyl groups dominate the orientations of crystal packing, thus throughout the molecules in the lattice the phosphorus atoms evenly show 1/3 occupancy and the CH moieties 2/3 occupancy. No preference for *syn* or *anti* conformation of the rings in a single molecule can be inferred. The high solubility of the transition-metal complexes [V(η-$PC_5H_2Bu^t_3$-2,4,6)$_2$] and [Cr(η-$PC_5H_2Bu^t_3$-2,4,6)$_2$] mentioned by Elschenbroich *et al*. frustrated attempts to grow crystals suitable for X-ray structural determination.[13] Extensive disorder meant the data collected for single crystals of the titanium complex synthesised in our laboratory remained insoluble so no meaningful comparisons can be made. Elschenbroich *et al*. showed that in the phosphorus-expanded bis(arene) molecule, a smaller metal fits better if the rings have mutually *syn* rather than *anti* conformations. This is confirmed in our solution studies of the titanium complex, [$r_{cov}$(Ti) = 1.32 Å].[20] The greater size of this metal [$r_{cov}$(Ho) = 1.58 Å][21] is possibly a factor in allowing ready access to all relative conformations of the rings.

It is of interest that twelve of the *tert*-butyl methyl groups are oriented towards the central metal atom providing considerable steric shielding, Fig. 1(*c*), however no significantly short metal–carbon or –hydrogen distances are seen. This geometry was equally noticeable in the structures of [M(η-$C_6H_3Bu^t_3$-1,3,5)$_2$] (M = Ho, Gd, Y)[22] which are isostructural with each other and show little change in ring geometry apart from the expected slight ring C–C bond lengthening upon binding of the ligand. The phosphaarene bond lengths in **1** are consistent with retention of aromaticity in the heteroarene upon complexation, and the rings remain planar apart from the slight inclination of each phosphorus atom towards the metal, bending from the plane described by the five carbon atoms by an angle of 6.7(7)°.

**Scheme 1**

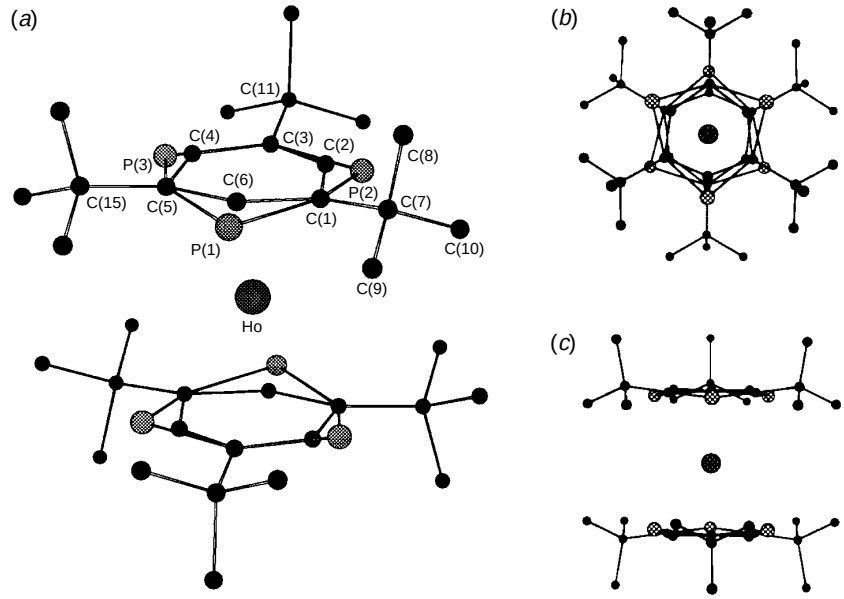


**Fig. 1** (*a*) Chem 3D Representation of the crystal structure of **1**. (*a*) All orientations of P and C have been included, as refined in the structure, allowing for the three-fold disorder: Selected distances (Å) and angles (°): Ho–C(1) 2.649(7), Ho–C(2) 2.587(14), Ho–C(3) 2.633(10), Ho–C(6) 2.58(2), P(1)–C(1) 1.797(10), P(2)–C(1) 1.785(10), P(2)–C(3) 1.760(8), C(1)–C(2) 1.42(2), C(1)–C(6) 1.45(12), C(1)–C(7) 1.495(13), C(2)–C(3) 1.44(2), C(3)–C(4) 1.44(2), C(3)–C(11) 1.52(2), C(7)–C(8) 1.44(2), C(7)–C(9) 1.43(2), C(7)–C(10) 1.39(2); C(1)–P(1)–C(5) 94.1(7), C(1)–P(2)–C(3) 95.9(6), C(2)–C(1)–C(7) 126.1(10), C(2)–C(1)–P(1) 125.8(9), C(7)–C(1)–P(1) 107.8(6), C(1)–C(2)–C(3) 134.0(13), C(4)–C(3)–C(2) 105(2). (*b*) Top view, all disordered atoms refined are included. (*c*) Side view.

The rings are mutually parallel with perfectly staggered *tert*-butyl groups, bent slightly away from the metal (8.8°).

Repeated determinations of the magnetism of a toluene solution of **1** (Evans' method) reproducibly yield an effective magnetic moment of 8.9 $\mu_B$, the solution displaying Curie–Weiss paramagnetism over the temperature range studied (205–355 K) with a value of $\theta = -10.6$ K. This value of the moment is lower than that calculated for the case where spin–spin coupling is small compared to $kT$ (10.75 $\mu_B$), and lower than that found in [Ho($\eta$-$C_6H_3Bu^t_3$-1,3,5)$_2$] (10.10 $\mu_B$) or atomic holmium (9.58 $\mu_B$). The lowering of symmetry of the frontier orbitals inflicted by the heteroatom conceivably allows more extensive degree of distribution of the unpaired electron density away from the metal *via* enhanced spin–orbit coupling; this would lead to the observed lower value for $\mu_{eff}$ in **1** as compared with [Ho($\eta$-$C_6H_3Bu^t_3$-1,3,5)$_2$].

The authors are grateful to Dr A. Abdul-Sada for determination of the mass spectrum of **1** and to the EPSRC for funding.

## Footnotes

† Holmium (0.65 g, 3.9 mmol) was vaporised by resistive heating (alumina crucible, 250 W) and cocondensed with an excess of 2,4,6-tri-*tert*-butylphosphorin (20 g, 76 mmol) at −196 °C. The dark purple matrix was extracted from the vessel at ambient temperature under an argon atmosphere. Removal of free metal by filtration through a bed of Celite and recovery of excess ligand after removal of volatiles under reduced pressure, yielded a dark solid from which extremely air- and moisture-sensitive purple iridescent crystals of bis(2,4,6-tri-*tert*-butylphosphorin)holmium(O) **1**, could be isolated in 45% yield, 1.2 g after recrystallisation from pentane. UV–VIS: $\lambda_{max}$ 489 nm ($\varepsilon$ 1.2 × $10^4$ dm$^3$ mol$^{-1}$). MS (EI): *m/z* 693 (69%) ($M^+$). Elemental analysis: Found C, 56.65; H, 8.47%. $C_{34}H_{58}HoP_2$ requires: C, 58.87; H, 8.43%. The low measured carbon percentage is also found for other complexes of this class, and is attributed to incomplete combustion.

‡ *Crystal data* for **1**: $C_{34}H_{58}HoP_2$, $M$ = 639.7, monoclinic, space group $C2/m$ (no. 12), $a$ = 10.279(3), $b$ = 17.758(3), $c$ = 10.293(2) Å, $\beta$ = 109.70°, $U$ = 1768.9(7) Å$^3$, $T$ = 293(2) K, $Z$ = 2, $D_c$ = 1.30 g cm$^{-3}$, 2 < $\theta$ < 25°, $\mu$(Mo-K$\alpha$) = 2.35 mm$^{-1}$. Dark purple block, crystal size 0.20 × 0.20 × 0.15 mm. Refinement on $F^2$ using SHELXL-93. $R_1$ = 0.048 for 1547 reflections with $I > 2\sigma(I)$, $wR_2$ = 0.126 for all 1621 unique reflections. The molecule lies on a site of 2/*m* symmetry and the $PC_5$ rings show threefold disorder. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/363.

# Polycarbon ligand chemistry. Novel behaviour of μ-η¹,η²$_{\alpha,\beta}$-butadiynyls towards metal fragment additions

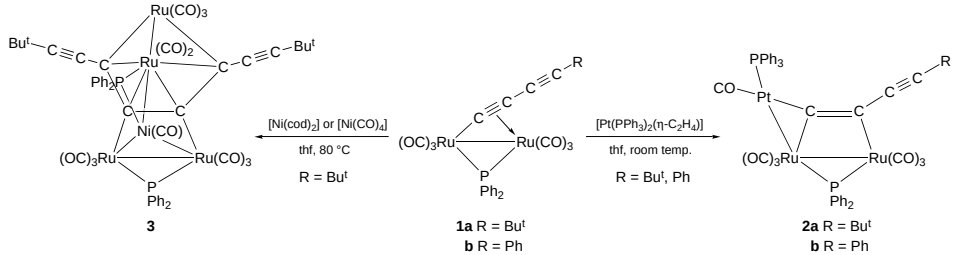
**Peter Blenkiron,[a] Gary D. Enright[a] and Arthur J. Carty*[a,b]**

[a] *The Steacie Institute for Molecular Sciences, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ontario, Canada K1A OR6*

[b] *Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5*

**Reaction of $[Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C{-}C{\equiv}CR)]$ (R = Bu$^t$ 1a, Ph 1b) with the labile complexes $[Pt(PPh_3)_2(\eta\text{-}C_2H_4)]$, $[Pt(dppb)(\eta\text{-}C_2H_4)]$ and $[Ni(cod)_2]$ or $[Ni(CO)_4]$ leads to the heteronuclear derivatives $[Ru_2Pt(CO)_7(PPh_3)(\mu_3\text{-}\eta^1,\eta^1,\eta^1\text{-}C{=}C{-}C{\equiv}CR)(\mu\text{-}PPh_2)]$ 2a,b, $[Ru_2Pt(CO)_6(dppb)(\mu_3\text{-}\eta^1,\eta^1,\eta^1\text{-}C{=}C{-}C{\equiv}CBu^t)(\mu\text{-}PPh_2)]$ 2c and $[Ru_4Ni(CO)_{12}(\mu\text{-}PPh_2)_2(\mu_4\text{-}\eta^1,\eta^1,\eta^2,\eta^4\text{-}Bu^tC{\equiv}CC_4C{\equiv}CBu^t)]$ 3 resulting from addition of a $PtL_2$ fragment and Ni-assisted stoichiometric coupling of two molecules of 1a respectively; the X-ray crystal structures of 2a and 3 are described.**

The ability of ynyl and polyynyl [–C≡CR, –(C≡C)$_x$–] ligands to link metal centres into linear arrays bearing extended carbon–carbon unsaturation has stimulated the designed synthesis of molecular wires and rod-like new materials.[1] These highly unsaturated, carbon-rich chains possess even greater potential for the construction of two- and three-dimensional multimetallic arrays if the full coordinating capacity of the π systems can be exploited.[2,3] Here, we describe the addition of the reactive Pt and Ni reagents $[Pt(PPh_3)_2(\eta\text{-}C_2H_4)]$, $[Pt(dppb)(\eta\text{-}C_2H_4)]$ [dppb = 1,4-bis(diphenylphosphino)butane], $[Ni(cod)_2]$ and $[Ni(CO)_4]$ to the butadiynyl complexes $[Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C{-}C{\equiv}CR)]$ (R = Bu$^t$ **1a**, Ph **1b**).



The σ–π butadiynyl complexes **1a** and **1b** react with $[Pt(PPh_3)_2(\eta\text{-}C_2H_4)]$ in thf to give the trinuclear mixed-metal species $[Ru_2Pt(CO)_7(PPh_3)(\mu_3\text{-}\eta^1,\eta^1,\eta^1\text{-}C{=}C{-}C{\equiv}CR)(\mu\text{-}PPh_2)]$ **2** (**2a** 18%, **2b** 22%) (Scheme 1).† The molecular structure of **2a** (Fig. 1)‡ suggest that **2a,b** are formed from the addition of a $Pt(CO)(PPh_3)$ fragment across the Ru–C$_\alpha$ bond of **1**. Thus **2a** contains the $Ru_2(CO)_6(\mu\text{-}PPh_2)$ unit found in **1** and is connected to Pt *via* Ru(1) to give a bent three-metal atom chain [Pt–Ru(1)–Ru(2) 105.837(17)°; Ru(1)–Pt 2.7725(13) Å]. The hydrocarbyl ligand is bound to all three metal atoms [Pt–C(38) 1.969(6), Ru(1)–C(38) 2.266(5), Ru(2)–C(39) 2.151(5) Å] and may be viewed as a metallated, alkynyl-functionalised μ-vinylidene bridging the Ru(1)–Pt bond *via* C(38) [C(38)–C(39) 1.284(8) Å]. The Pt centre is also ligated by a CO group [Pt–C(1) 1.905(7) Å] evidently scavenged from the reaction mixture and a $PPh_3$ ligand [Pt–P(2) 2.2884(13) Å] *trans* disposed to the Ru–Pt bond. The coordination environment about the Pt is approximately square planar and this moiety serves as a 16-electron fragment giving an overall count of 48 valence electrons for **2**, as found for other linear or bent $M_2Pt$ complexes.[4] The transition from a σ–π bonding mode in **1a** to 3σ attachment in **2a** effects a distortion in the C$_4$ ligand [C(38)–C(39)–C(40) 136.3(5)° *cf.* 164. 9(4)° for the corresponding angle in **1a**[5]], although the outer triple bond length is essentially unchanged at 1.170(9) [*cf.* 1.172(6) in **1a**].

A competing process in the reaction of **1** with $[Pt(PPh_3)_2(\eta\text{-}C_2H_4)]$ is phosphine substitution to give $[Ru_2(CO)_{6-n}(PPh_3)_n(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C{-}C{\equiv}CR)]$ [$n$ = 1 (R = Bu$^t$, 29%), $n$ = 2 (R = Bu$^t$, 13%)].§ Substitution is inhibited by using the chelating Pt complex $[Pt(dppb)(\eta\text{-}C_2H_4)]$ which reacts rapidly at 293 K with a thf solution of **1a** to give the addition product $[Ru_2Pt(CO)_6(dppb)(\mu_3\text{-}\eta^1,\eta^1,\eta^1\text{-}C{=}C{-}C{\equiv}CBu^t(\mu\text{-}PPh_2)]$ **2c** in 54% yield. X-Ray analysis confirmed **2c** as the analogue of **2a** and **2b**.

An isolobal analogy can be drawn between the reaction of **1** with the 14e moiety $Pt(CO)(PPh_3)$ and the well documented addition of d$^{10}$ $ML_2$ fragments to M=C bonds in mono- and poly-nuclear carbene and vinylidene complexes.[6] The Ru(1)=C$_\alpha$ unsaturation in **1a** presumably derives from a contribution of the canonical form Ru$^-$=C=C=C=C$^+$Bu$^t$ to the bonding in **1**.[5]

**1a** also reacted smoothly with the naked nickel precursor $[Ni(cod)_2]$. After 2 h in refluxing thf, work-up gave a single major product $[Ru_4Ni(CO)_{12}(\mu\text{-}PPh_2)_2(\mu_4\text{-}\eta^1,\eta^1,\eta^2,\eta^4\text{-}Bu^tC{\equiv}CC_4C{\equiv}CBu^t)]$ **3**.

The pentanuclear cluster **3** (Fig. 2) originates from the stoichiometric coupling of two molecules of **1a**, together with the incorporation of a single nickel atom which links the two $Ru_2$ units [Ru(2)–Ni 2.6910(16), Ru(3)–Ni 2.7042(17), Ru(4)–Ni 2.6957(16) Å]. The most outstanding feature of **3** is the head-to-head coupling of two butadiynyl ligands to create a C$_8$ chain which is attached to all four Ru atoms. This gives rise to a ruthenole unit formed from the π coordination of the Ru(1)–C(14)–C(13)–C(18)–C(19) ruthenacyclopentadiene ring to Ru(2). Although terminal, mononuclear butadiynyl ligands have been linked *via* oxidative coupling to generate linear C$_8$ chains,[1a,7] we are unaware of any examples of transition-metal mediated synthesis of C$_8$ ligands from binuclear or polynuclear C$_4$ precursors. The metallacyclopentadiene ring contains one long and two short C–C bonds [C(13)–C(14) 1.411(12), C(13)–C(18) 1.457(11), C(18)–C(19) 1.399(11) Å] in common with other crystallographically characterised examples from group 8, with the long bond bridging the Ru(3)–Ru(4) unit. This limited delocalisation extends to the exocyclic C(14)–C(15)

**3** **1a** R = Bu$^t$ **b** R = Ph **2a** R = Bu$^t$ **b** R = Ph

**Scheme 1**

[1.428(13) Å] and C(19)–C(20) [1.441(12) Å] bonds. Interestingly however, no elongation is apparent in the pendant alkynyl groups which exhibit typical $C_{sp}$–$C_{sp}$ bond distances [C(15)–C(16) 1.182(13), C(20)–C(21) 1.186(13)].

Clearly a key step in the formation of **3** is the incorporation of a Ni(CO) moiety. Thus refluxing a thf solution of **1a** with excess $Ni(CO)_4$ indeed gave **3** as the major product, albeit in slightly lower yield {15% *cf.* 20% with $[Ni(cod)_2]$}, possibly suggesting the role of free nickel [*vs.* Ni(CO)] as an intermediate in the assembly of **3**.

It is perhaps surprising that both **2** and **3** contain uncoordinated triple bonds derived directly from the outer alkyne unit of precursor **1**, particularly considering the propensity of $Pt^0$ and $Ni^0$ reagents to form $\eta^2$-coordination complexes with free alkynes. Since sterically congested alkynes form $\eta^2$-coordination complexes with $Pt^0$ and $Ni^0$, it is unlikely that the presence of Bu$^t$ or Ph substituents on the outer alkyne units of **1** account for the lack of complexation at these sites. However, while we believe this to be the first report detailing metal fragment additions to σ–π-butadiynyl complexes, there is evidence that metal aggregation ('clustering') occurs when fragments such as $PtL_2$ (L = $PR_3$, $L_2$ = cod) add to vinylidene and other hydrocarbyl-ligated species.[6] We suggest therefore that while

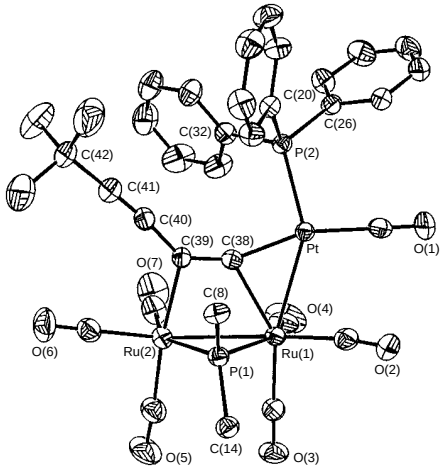


**Fig. 1** Molecular structure of **2a**. For clarity, only the *ipso* carbons of the μ-$PPh_2$ phenyl rings are drawn. Relevant bond parameters: Ru(1)–Ru(2) 2.8407(6), C(39)–C(40) 1.400(8) Å; Ru(1)–P(1)–Ru(2) 74.56(4), Ru(2)–Ru(1)–Pt 105.837(17), Ru(1)–C(38)–Pt 81.46(20), Pt–C(38)–C(39) 153.9(5), C(39)–C(40)–C(41) 172.1(6), C(1)–Pt–C(38) 162.00(24), P(2)–Pt–Ru(1) 149.38(4)°.

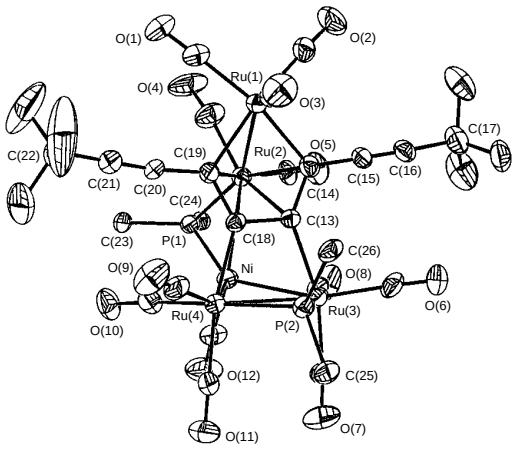

**Fig. 2** Molecular structure of **3**. Relevant bond parameters: Ru(1)–Ru(2) 2.6860(11), Ru(3)–Ru(4) 2.8981(10), Ru(1)–C(14) 2.114(9), Ru(1)–C(19) 2.097(9), Ru(2)–C(13) 2.300(8), Ru(2)–C(14) 2.269(9), Ru(2)–C(18) 2.379(8), Ru(2)–C(19) 2.270(8), Ru(3)–C(13) 2.139(8), Ru(4)–C(18) 2.119(8) Å; Ru(2)–Ni–Ru(3) 91.73(5), Ru(2)–Ni–Ru(4) 100.46(5)°.

**2a**–**c** are likely thermodynamic products and would not rearrange to the expected $\eta^2$-alkyne products, reaction at $C_\alpha$ may be driven by activation associated with μ-$\eta^1$,$\eta^2$ coordination. Such activation also accounts for recently observed regiospecificity in directing nucleophilic attack exclusively at the $C_\alpha$–$C_\beta$ sites[2a,8] in μ-$\eta^1$,$\eta^2$-butadiynyl complexes. These results suggest that metal activation of polyynyl ligands *via* μ-$\eta^1$,$\eta^2$-coordination can direct site specific metal fragment electrophilic attack and new patterns of C–C coupling.

We thank the NRC and NSERC for financial support of this work. We are indebted to G. Lesley and T. B. Marder for a sample of $[Pt(dppb)(C_2H_4)]$.

## Footnotes

† Experimental and spectroscopic data will be made available on the World Wide Web at http://chemistry.rsc.org/rsc/cccpub.htm

‡ *Crystallographic data*: **2a**: crystal grown from $CH_2Cl_2$–*n*-hexane (1 : 4) at –20 °C; $C_{45}H_{34}O_7P_2PtRu_2$, $M$ = 1145.9; monoclinic, space group $P2_1/n$, $a$ = 9.2369(6), $b$ = 23.0550(11), $c$ = 20.7034(8) Å, β = 97.596(5)°, $U$ = 4370.3(4) Å$^3$, $Z$ = 4, $T$ = 295 K, $D_c$ = 1.742 g cm$^{-3}$, $F$(000) = 2211, λ = 1.54056 Å, μ(Cu-Kα) = 12.70 mm$^{-1}$. Intensity data were collected on a crystal of dimensions 0.25 × 0.25 × 0.20 mm mounted on an Enraf-Nonius CAD4 diffractometer using the θ–2θ scan method. The structure was solved (direct methods) and refined (full-matrix least squares) using 6526 observed [$I > 2.5\ \sigma(I)$] reflections to final $R$ and $R_w$ values of 0.031 and 0.041 respectively.

**3**: crystal grown from *n*-hexane at −20 °C; $C_{52}H_{38}O_{12}NiP_2Ru_4$, $M$ = 1379.8; monoclinic, space group $P2_1/c$, $a$ = 11.4833(19), $b$ = 12.460(3), $c$ = 38.055(4) Å, β = 91.016(14)°, $U$ = 5444.3(17) Å$^3$, $Z$ = 4, $T$ = 295 K, $D_c$ = 1.683 g cm$^{-3}$, $F$(000) = 2717, λ = 1.54056 Å, μ(Cu-Kα) = 10.43 mm$^{-1}$. Intensity data were collected on a crystal of dimensions 0.03 × 0.20 × 0.20 mm as for **2a**. The structure was solved (direct methods) and refined (full-matrix least squares) using the 5211 observed [$I > 2.5\ \sigma(I)$] reflections to final $R$ and $R_w$ values of 0.043 and 0.049 respectively. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/338.

§ Performing the reaction with **1a** under a purge of CO gas inhibited the formation of substitution products but gave exactly the same yield of **2a**. For **1b** using a CO purge, **2b** (22%) and the monophosphine complex $[Ru_2(CO)_5(PPh_3)(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{–}C{\equiv}CPh)]$ (36%) were produced.

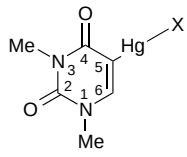
# Hexanuclear hydrolysis products of the uracil nucleobase complex (1,3-dimethyluracil-5-yl)mercury(II) nitrate

**Félix Zamora,[a] Michal Sabat,*[b] Matthias Janik,[a] Christoph Siethoff[c] and Bernhard Lippert*[a]**



[a] *Fachbereich Chemie, Universität Dortmund, D-44221 Dortmund, Germany*
[b] *Department of Chemistry, University of Virginia, Charlottesville, Virginia 22901, USA*
[c] *Institut für Spektrochemie und angewandte Spektroskopie (ISAS), D-44139 Dortmund, Germany*

**(1,3-Dimethyluracil-5-yl)mercury(II) nitrate undergoes, in aqueous solution, hydrolysis to the tris(1,3-dimethyluracil-5-yl)mercurioxonium salt, which dimerizes in two different ways *via* weak Hg···Hg contacts.**

The propensity of mercury(II) salts to undergo hydrolysis with formation of oligo- and poly-meric $[Hg(OH)]_n^{n+}$ or $[HgO]_n$ species is well established.[1] This feature is maintained in complexes of $Hg^{II}$ containing one firmly bound ligand such as a methyl group. Thus, $[MeHg(H_2O)]^+$ forms, among others, the trismethylmercurioxonium cation, $[(MeHg)_3O]^+$,[2] which represents a very flat trigonal pyramid with the oxygen in the apical position.[3] $[(ClHg)_3O]^+$ has a very similar structure.[4] Here we report on hydrolysis products of an analogous complex with a C-bound uracil nucleobase (1,3-dimethyluracil, dmura) which have dimerized *via* one and two Hg···Hg contacts, respectively, of the $Hg_3O$ to give hexanuclear compounds. This feature is reminiscent of the behaviour of phosphinegold(I) oxonium compounds, $[(R_3PAu)_3O]^+$.[5] This appears to be a consequence of the well known tendency of $Au^I$ compounds to form weak Au–Au bonds and has been termed aurophilicity.[6]

We have recently described several examples of dmura nucleobase complexes containing $Hg^{II}$ bound *via* the C-5 position.[7–9] Mercuriation of this site, although not fully unexpected,[10] was unusual considering previous findings.[11,12]

In the course of an NMR study on ligand exchange reactions of X[8] we observed precipitation of a colourless, crystalline compound from aqueous solution, pH 4 in the presence of $X = NO_3^-$.† X-Ray crystallography‡ revealed that the unit cell of the compound contains two different $[L_3Hg_3O]^+$ cations, **I** and **II** (L = 1,3-dimethyluracil-5-yl), each of which has a centrosymmetrically related counterpart (primed atoms), with which it is connected through weak Hg···Hg contacts. Cation **I** represents a very flat pyramid, whereas cation **II** is virtually planar (Fig. 1). Hg···Hg distances within the triangle of **I** range from 3.4705(5) to 3.5859(5) Å. The short contacts of 3.5620(5) Å between neighbouring cations involve Hg(1) and Hg(2′) as well as Hg(2) and Hg(1′) and generate a chairlike arrangement of the six mercury ions. In cation **II** the Hg···Hg separations range from 3.4552(6) to 3.5974(5) Å within the triangle. The closest intercationic Hg···Hg distance, between Hg(6) and Hg(6′) is only slightly longer, 3.6728(8) Å. All these Hg···Hg separations are significantly longer than those found in dinuclear mercury(I) complexes or in mercury clusters with Hg in the oxidation state zero,[13] but are close to or shorter than the sum of two van der Waals radii (1.7–2.0 Å).[14] Hg–O–Hg angles are within the range 116.0(3)–122.5(3)° and compare with those found in $[(MeHg)_3O]^+$ (116°)[3] and $[(ClHg)_3O]^+$ (118.9°).[4] The Hg–O distances are normal (av. 2.05 Å), as are the Hg–C distances to the nucleobases (2.05 Å[7–9]). Views perpendicular to the $Hg_3$ triangles and their centrosymmetrical counterparts (Fig. 2) clearly show that nucleobase stacking is not taking place, thereby excluding this possibility as a driving force for association of trinuclear entities.

Solid-state Raman spectra of Hdmura, [Hg(dmura-$C^5$)($O_2$CMe)] and $[Hg_6(dmura)_2O_2][NO_3]_2$ were compared.§

The $^1$H NMR spectrum of the title compound in $D_2O$, pH* 4.9 [δ H-6, 7.40, $^3J(^1H–^{199}Hg)$ 189 Hz; δ $CH_3$, 3.40 and 3.30] is consistent with an oxygen donor *trans* to C-5 of dmura,[8] but permits no conclusions concerning the nature of the species in solution (monomer, trimer, hexamer).

However, ESI mass spectra¶ of $D_2O$ and $Me_2SO$ solutions of the title compound establish the formulation as $[Hg_6$-

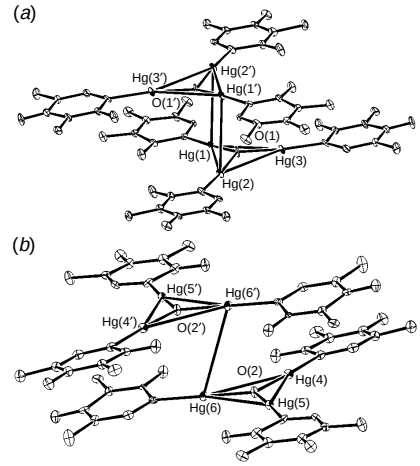


**Fig. 1** Perspective view of centrosymmetrically related cations **I** (*a*) and **II** (*b*) of $[L_3Hg_3O][NO_3]\cdot 2H_2O$ (L = 1,3-dimethyluracil-5-yl). Ellipsoids are at the 30% probability level.

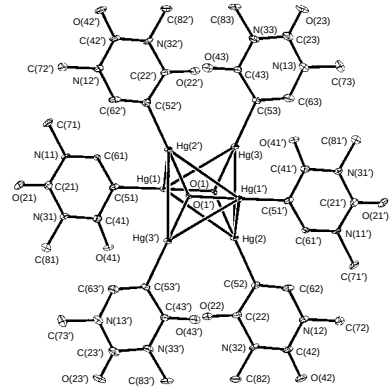

**Fig. 2** View perpendicular to $Hg_3$ triangles of cations **I** indicating that there is no base stacking within pairs of $[L_3Hg_3O]^+$ cations. The situation with cations **II** is similar, but the $Hg_3$ triangles are somewhat shifted.

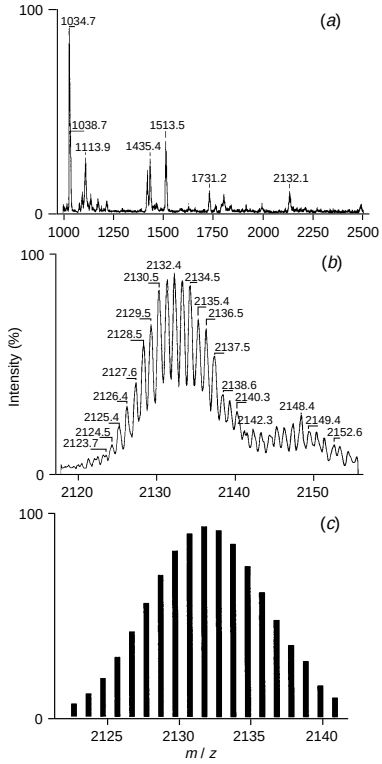

**Fig. 3** Section of ESI mass spectrum of the title compound (*a*), of the $[L_6Hg_6O_2(NO_3)]^+$ peak (*b*) and calculated mass distribution for the latter peak (*c*)

$(dmura)_6O_2][NO_3]_2$ even under the conditions of the experiment: from the mass spectrum recorded of a $Me_2SO$ solution (Fig. 3) the existence of $[Hg_6(dmura)_6O_2(NO_3)]^+$ is evident (*m*/*z* 2132.4), with excellent agreement between observed and calculated isotopic mass distributions. Signals due to $[Hg_3(dmura)_3O]^+$ (*m*/*z* 1034.7) are likewise observed, but the most intense signal centred at *m*/*z* 418.9 corresponds to $[Hg(dmura)(Me_2SO)]^+$. In aqueous solution the parent ion of the hexanuclear species is not observed, but fragments of the latter {$[Hg_4(dmura)_5O]^+$, *m*/*z* 1513.7; $[Hg_5(dmura)_5O_2]^+$, *m*/*z* 1729.5} point to its existence. The trinuclear species gives rise to an intense signal set at *m*/*z* 1035.5.

In conclusion, the solid-state structure of the title compound lends support to the option that $[Hg_3(dmura)_3O]^+$ cations, like $[(R_3PAu)_3O]^+$ cations, undergo association *via* Hg···Hg contacts. These appear to be sufficiently strong to survive ESIMS experiments.

This work was supported by the DFG and the FCI. We thank Dr M. Linscheid, ISAS (Dortmund), for providing the MS facilities, and Dr C. Campana, Siemens Analytical X-Ray Instruments, Inc., Madison, WI, for his help with the data collection and refinement.

## Footnotes

† In a typical experiment [Hg(dmura)($O_2$CMe)] (0.1 mmol) in water (2 ml) was treated with either $KNO_3$ or $AgNO_3$ (0.3 mmol each). From the solution (pH 4), upon standing at room temperature, colourless crystals formed overnight in *ca.* 40% yield. Alternatively, reaction of $Hg(NO_3)_2$ and dmura (1:1, 60 °C, 24 h) in $H_2O$ gave crystals of the title compound in 33% yield. {[Hg(dmura-$C^5$)]$_3$O}$NO_3$·$2H_2O$, $C_{18}H_{25}Hg_3N_7O_{12}$ [Found (Calc.)]: C, 18.9 (19.1); H, 2.2 (2.2); N, 8.6 (8.6) %. IR (KBr) 1341 ν($NO_3^-$), 1617 ν(C=C), 1670 $cm^{-1}$ ν(C=O). $^1$H NMR spectrum [200 MHz, $(CD_3)_2SO$, $SiMe_4$]: δ H-6, 7.35, δ $CH_3$, 3.32 and 3.19; $^3J(^1H–^{199}Hg)$ 190 Hz. $^{199}$Hg NMR [35.79 MHz, $(CD_3)_2SO$, relative to $HgMe_2$] δ −1320.

‡ *Crystal data* for $C_{36}H_{50}Hg_6N_{14}O_{24}$: $M$ = 2266.41, triclinic, space group $P\bar{1}$ (no. 2), $a$ = 10.0050(2), $b$ = 13.7841(2), $c$ = 19.6534(2) Å, α = 99.797(1), β = 95.673(1), γ = 96.313(1) °, $U$ = 2635.48(7) Å$^3$, $Z$ = 2, $D_c$ = 2.86 g $cm^{-3}$, λ(Mo-Kα) = 0.710 73 Å, μ(Mo-Kα) = 175.9 $cm^{-1}$, $F$(000) = 2072, $T$ = 153 K. The structure was solved by direct methods employing the SIR88 program[17] of the teXsan 1.7 software package[18] and refined by using the SHELXTL/PC software package[19] to $R$ = 0.061 ($R_w$ = 0.122) for 14 874 absorption-corrected (empirical corrections; transmission factors 0.23–0.80) reflections with $I > 2\sigma(I)$. A total of 38 024 (26 669 unique, $R_{int}$ = 0.052) reflections were collected in the range $4 \leqslant 2\theta \leqslant 80°$ on a Siemens SMART area detector system using graphite-monochromated Mo-Kα radiation. All non-hydrogen atoms were refined with anisotropic thermal displacement parameters. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/353.

§ Bands at 215 and 109 $cm^{-1}$ are tentatively assigned to ν[Hg–C(dmura)] and ν(Hg–O). The respective modes for $[(MeHg)_3O]^+$ in $H_2O$ are at 570 and 134 $cm^{-1}$.[15] A band at 198 m $cm^{-1}$ in the spectrum of [Hg(dmura-$C^5$)($O_2$CMe)], absent in the spectrum of Hdmura, is assigned to ν[Hg–C(dmura)] from comparison with ν(Hg–Ph) modes.[16] Raman solution spectra could not be obtained due to insufficient solubility.

¶ Electrospray mass spectrometry (ESIMS) was performed on a Finnigan MAT 90 mass spectrometer equipped with an ESI II interface (Finnigan MAT, Bremen, Germany) operating in the positive mode. The mass spectra were acquired from *m*/*z* 250 to 2500 using scan rates between 5 and 100 s $decade^{-1}$ and a resolution between 1000 and 2500. Water and $Me_2SO$ solutions of the title compound were introduced into the ESI source at a flow rate of 0.5 μl $min^{-1}$. The temperature of the desolvation capillary was set to 200 °C.

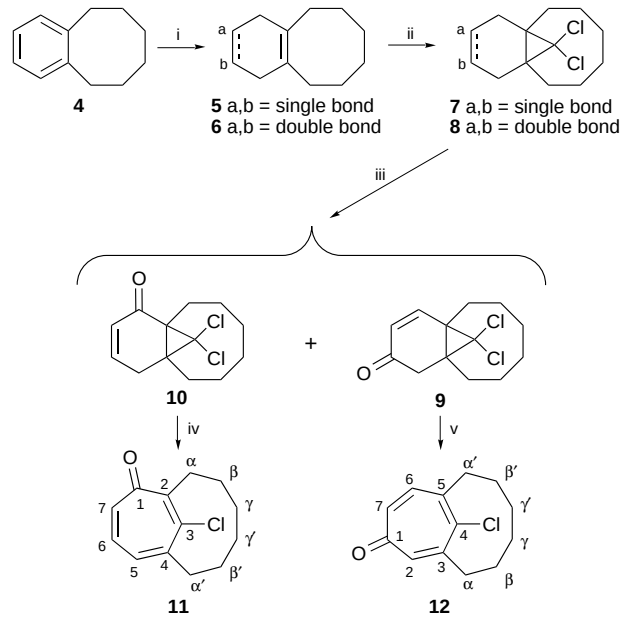
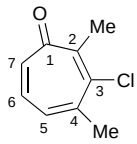
# Synthesis, isolation and spectroscopic characterisation of 3-chloro-[6](2,4)-troponophane: the first 2,4-polymethylene-bridged troponoid

**Martin G. Banwell* and Hans M. Schuhbauer**



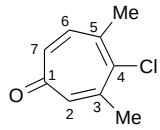
*Research School of Chemistry, Institute of Advanced Studies, The Australian National University, Canberra, ACT 0200, Australia*

**Treatment of the tricyclic enone 10 with perchloric acid results in formation of the title troponophane 11, the first example of a (2,4)-polymethylene bridged troponoid.**



The delocalisation energies per electron within non-benzenoid rings are usually substantially smaller than those associated with comparable benzenoid rings. Consequently, short-bridged non-benzenoid cyclophanes have attracted considerable attention because of the expectation that there is likely to be greater deformation (relative to benzenoid counterparts) of the conjugated carbocyclic ring in accommodating any strain created by the introduction of bridges between non-adjacent ring carbons.[1] There is a further expectation that such deformations will be manifested in unusual reactivity patterns.[1] Studies of troponophanes have been especially interesting in this regard and numerous [*n*](2,7)-troponophanes **1** have been described including trimethylene-bridged systems ($n = 3$).[1,2] Their [*n*](3,5) counterparts **2** are much less common[3] but include a system where $n = 6$.[4] In contrast, [*n*](2,4)-troponophanes **3** remain virtually unknown.[5] Calculations† suggest that for a given value of *n* (where $n \leqslant 6$) the order of stability amongst the '*meta*'-troponophanes is **1** > **2** > **3** meaning that the last system is probably the most strained of the three and, therefore, likely to be the most interesting. Consequently, we now report on the synthesis, isolation, spectroscopic properties and some aspects of the chemistry of the title compound **11**, the first example of a 2,4-polymethylene-bridged troponoid.

The synthesis of compound **11** is outlined in Scheme 1 and follows very much the same strategy as used in the preparation of the isomeric [6](3,5)-troponophane **12**.[4] Thus, Birch reduction of cyclooctene **4**[7] with lithium in liquid ammonia afforded a *ca*. 15 : 1 : 100 mixture of compounds **4**, **5**[8] and **6**[9] which was subjected to reaction with chloroform–potassium *tert*-butoxide in diethyl ether between −30 and 20 °C. In this manner dichlorocarbene adducts **7**[4] (< 1%) and **8** (75% from **4**) (mp 86–88 °C; lit.,[4] mp 87–88 °C) were obtained and these could be separated from one another by fractional crystallisation. Allylic oxidation of alkene **8** was accomplished using the chromium trioxide–3,5-dimethylpyrazole (3,5-DMP) complex,[10] and the enones **9**[4] (44%) and **10**‡ (20%) (mp 97–100 °C) thereby obtained were separated from one another by chromatography on silica.[11] Treatment of a *ca*. 0.3 M chloroform solution of compound **10** with *ca*. 12 equiv. of 70% aq. perchloric acid resulted in its slow (20 h at 20 °C) conversion into the target troponophane **11**§ (71%) which could be isolated by flash chromatography[11] on silica gel ($R_f$ 0.5 in $CH_2Cl_2$) and which was obtained as a light green oil. Enone **9** was subjected to similar conditions in order to provide a sample of the isomeric troponophane **12** which was identical with material obtained previously.[4]



The $^1$H NMR spectrum of compound **11** possessed features strongly suggestive of the presence of a phane system. Thus, the one-proton multiplet at δ 0.43 is assigned to one of the protons associated with $C_\gamma$ of the hexamethylene bridge which is forced to project into the shielding zone of the troponoid ring. In addition, the chemical shifts (δ 3.14–2.93) and the multiplicities of the signals due to three of the four protons attached to $C_\alpha$ and $C_\alpha'$ are reminiscent of those reported for the analogous protons in 13-bromo[7]-metacyclophane[12] and [7](3,7)-tropolonophane.[13] The fourth such proton (attached to $C_\alpha$) resonates upfield, at δ 1.87, by virtue of its projecting into the shielding zone of the adjacent carbonyl group. Spectral comparisons were made with the model compound **13** (mp 52–55 °C)§ (readily prepared by established methods[14] from *o*-xylene). The low field regions in the $^{13}$C NMR spectra of these two compounds were similar although the resonance due to C-1 in troponophane **11** was deshielded by 1.7 ppm relative to its counterpart in tropone **13**, an observation consistent with the expectation that the troponoid ring within the former compound is buckled. In the $^1$H NMR spectra of compounds **11** and **13**, signal multiplicities and coupling constants for the troponoid ring protons were essentially identical but the chemical shifts of the

signals due to two of the troponoid ring protons in **11** were shielded relative to their counterparts in model **13**, a situation similar to that observed previously in comparing troponophane **12** with model compound **14**[4] (Table 1).

The behaviour of troponophane **11** towards cycloaddition processes has been examined but we have yet to obtain convincing evidence of the participation of this compound in any such reaction. In contrast, the isomeric troponophane **12** reacts almost instantaneously with 4-phenyl-3,5-dihydro-1,2,4-triazole-3,5-dione (in $CH_2Cl_2$ at 20 °C) to give adduct **15**§ (mp 210–212 °C) in 95% yield. These observations are consistent with semi-empirical calculations† which suggest that troponophane **12** has a higher lying HOMO than isomer **11** ($\Delta E$ = 0.23 eV) and should, therefore, be more reactive towards electron-deficient dienophiles in normal electron demand Diels–Alder cycloaddition processes.

We thank the Institute of Advanced Studies for financial support including the provision of a post-Doctoral Stipend to H. M. S. for the period from June 1996 to the present. The award of a Deutsche Forschungsgemeinschaft (DFG) Fellowship to H. M. S. for the period from June 1995 to May 1996 is also gratefully acknowledged. We thank Professor L. Radom and members of his group (ANU) for assistance with theoretical calculations and Associate Professor D. Ridley (University of Sydney) for CAS Online substructure searching.

## Footnotes

† AM1 semi-empirical calculations (ref. 6) were carried out using the SPARTAN ver. 4.1.1 software package (as provided by Wavefunction Inc., Irvine, CA. 92715) on a Silicon Graphics workstation.

‡ All new compounds had spectroscopic data [IR, UV (where appropriate), NMR and mass spectrum] consistent with the assigned structure. Satisfactory combustion and/or high resolution mass spectral analytical data were obtained for all new compounds. Reported yields refer to isolated materials.

§ *Selected spectral data* for **11**: $^{13}$C NMR (75 MHz, $C_6D_6$): δ 186.4 (C), 151.7 (C), 148.7 (C), 144.4 (C), 136.6 (CH), 132.9 (CH), 121.4 (CH), 34.5 ($CH_2$), 34.3 ($CH_2$), 29.9 ($CH_2$), 28.7 ($CH_2$), 26.8 ($CH_2$) and 26.4 ($CH_2$); $^1$H NMR (300 MHz, $C_6D_6$): δ 6.44 (d, *J* 11.9 Hz, 1 H, H 7), 6.03 (dd, *J* 11.9 and 6.0 Hz, 1 H, H 6), 5.58 (d, *J* 6.0 Hz, 1 H, H 5), 3.14–2.93 (complex m, 3 H), 1.87 (ddd, *J* 13.7, 8.3 and 3.3 Hz, 1 H), 1.76–1.56 (complex m, 2 H), 1.48–1.22 (complex m, 3 H), 1.18–1.02 (complex m, 2 H), 0.43 (m, 1 H); MS *m/z* (El, 30 eV) 225 (3%) 223 (9) [(M + H)$^+$], 224 (16) 222 (50) [M$^+$], 188 (54) [(M + H − Cl·)$^+$], 187 (100) [(M − Cl·)$^+$] and 159 (45) [(M − CO − Cl·)$^+$]; $\nu_{max}$(NaCl)/cm$^{-1}$ 1626 and 1597; $\lambda_{max}$($CHCl_3$)/nm 266 (log ε 3.99) and 354 (3.54) (HRMS: M$^+$, 222.0815. $C_{13}H_{15}{}^{35}ClO$ requires M$^+$, 222.0811). 5 It has been reported that subjection of α-tropolone to reaction with horseradish peroxidase/hydrogen peroxide affords an oxidatively coupled and tetrameric species which has been assigned a [13](2,4)-troponophane structure (V. Kahn and A. Andrawis, *Phytochemistry*, 1985, **24**, 909). However, in our opinion, this assignment must be viewed with some caution since structural characterisation only involved UV–VIS spectroscopic studies. To the best of our knowledge, this represents the only example of a 2,4-bridged troponoid reported to date.

# Diastereoselective formation of *P* and *M* dicopper(I) double helicates with chiral 2,2′:6′,2″-terpyridines

**Edwin C. Constable,*† Torsten Kulke, Markus Neuburger and Margareta Zehnder**

*Institut für Anorganische Chemie, Spitalstrasse 51, CH-4056 Basel, Switzerland*

**Chiral 2,2′:6′,2″-terpyridines bearing bornyl groups in the 6-position are prepared; these ligands preferentially form *P* or *M* dinuclear double helicates upon coordination to copper(I) which have been structurally characterised.**

Oligopyridines and oligopyridine metal-binding domains are a recurrent feature in metallosupramolecular chemistry.[1] It is now well established that the higher oligopyridines can give multiple helical transition-metal complexes[2] and that 2,2′:6′,2″-terpyridine is a prototype ligand which forms dicopper(I) double helicates.[3] We have recently addressed questions of directionality within helicates assembled from asymmetric ligand threads[4] and now extend these studies to the diastereoselective formation of helicates from chiral ligands. Although preorganised chiral ligands bearing multiple oligopyridine domains have been shown to lead to diastereomeric excesses of multiple helicates,[5,6] this report provides the first fully characterised example of high diastereomeric discrimination in a multi-component self-assembly process.

A pair of enantiomeric 2,2′:6′,2″-terpyridines, $L^1$ and $L^2$, was obtained from the reaction of 6-bromo-6″-methyl-2,2′:6′,2″-terpyridine[7] with the sodium salts of (1*S*)-(−) or (1*R*)-(+)-borneol (prepared *in situ* by reaction of the appropriate alcohols with sodium hydride) in *N*,*N*-dimethylformamide in 52 and 58% yield respectively. These reactions are stereoretentive and allow the facile and selective introduction of functionality from the chiral pool.

The coordination of 2,2′:′,2″-terpyridines to copper(I) in the absence of other good ligands yields dinuclear double-helical $[Cu_2L_2]^{2+}$ species.[3] With the new chiral ligands there are a number of possible double helicates (Fig. 1). Firstly, head-to-head (HH) or head-to-tail (HT) isomers might be expected. Secondly, each double helix is itself chiral and might possess a *P* or an *M* conformation. When chiral ligands are involved, the (*S**)(*S**)-(*M*) and (*S**)(*S**)-(*P*) forms are diastereomers. We hoped that the energy differences between the diastereomers might lead to partial or complete selectivity for the *P* or *M* forms.

The reaction of $L^1$ or $L^2$ with $[Cu(MeCN)_4][PF_6]$ in acetonitrile resulted in the formation of orange–red solutions from which orange solids were precipitated by the addition of $[NH_4][PF_6]$. Mass spectrometric analysis supported the formulation of these solids as $[Cu_2L^1_2][PF_6]_2$ or $[Cu_2L^2_2][PF_6]_2$ respectively. The $^1$H NMR spectra of $CD_3CN$ solutions of the two complexes were similar and indicated, in each case, the presence of two solution species present in a ratio of 6.5 : 1. Molecular modelling studies using parameters derived from structurally characterised $[Cu_2L_2]^{2+}$ double helicates with 2,2′:6′,2″-terpyridines‡ indicated that the enantiomeric (*S*)(*S*)-(*M*)-HT and (*R*)(*R*)-(*P*)-HT helicates should be stabilised with respect to the diastereomers (*R*)(*R*)-(*M*)-HT and (*S*)(*S*)-(*P*)-HT by about 10 kcal mol$^{-1}$ (1 cal = 4.184 J). Furthermore, the modelling studies indicated that the HH isomers would lie very much higher in energy.

Recrystallisation of the crude $[Cu_2L^1_2][PF_6]_2$ or $[Cu_2L^2_2][PF_6]_2$ complexes from acetonitrile by the diffusion of diethyl ether vapour into the solution yielded X-ray quality crystals of compounds shown by $^1$H NMR spectroscopy to contain only the major isomer in each case. Each of the compounds crystallised as bis(acetonitrile) solvates in the non-centrosymmetric space group $P2_12_12$ and the molecular structures of $[Cu_2L^1_2][PF_6]_2\cdot2MeCN$ and $[Cu_2L^2_2][PF_6]_2\cdot2MeCN$ are presented in Fig. 2(*a*) and (*b*).§ The X-ray structural determination confirms the formation of the HT isomers in the solid state and furthermore shows the diastereoselective formation of the predicted (*S*)(*S*)-(*M*)-HT isomer of the $[Cu_2L^1_2]^{2+}$ cation and the (*R*)(*R*)-(*P*)-HT isomer of the $[Cu_2L^2_2]^{2+}$ cation. The solid-state structures of the two enantiomers are identical within experimental error and the gross structural features of the complex cations closely resemble those of previously characterised $[Cu_2L_2]^{2+}$ double helicates with 2,2′:6′,2″-terpyridines[3] although the pitch is dependent on the intermetallic separation; in this case, the copper–copper distance in each of the cations is 2.688(1) Å. The precise coordination geometry in copper(I) tpy double helicates is rather variable,[3] but in this case the two copper centres are equivalent and best described as two-coordinate [Cu(1)–N(1) 1.947(3) Å, Cu(1)–N(3′) 1.940(3) Å, N(1)–Cu(1)–N(3′) 165.2(1)°]. Each copper exhibits longer contacts to N(2) and N(2′) [2.431(2), 2.317(3) Å].

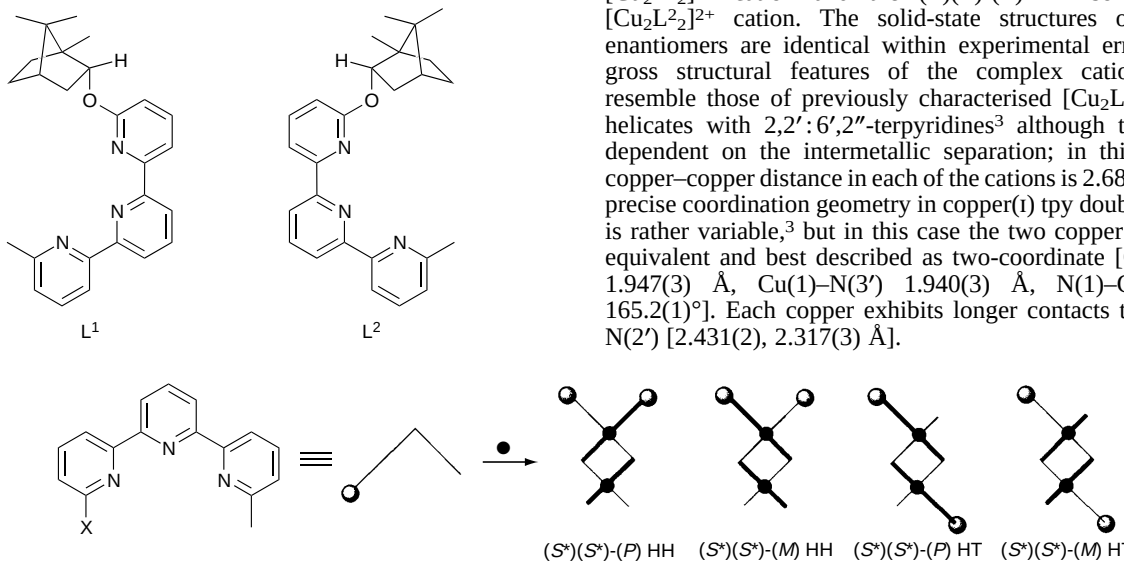

**Fig. 1** The formation of a dinuclear double helicate from the reaction of a chiral 2,2′:6′,2″-terpyridine with copper(I) can yield a pair of diastereomeric HH and a pair of diastereomeric HT compounds. *S** denotes homochiral compounds [*i.e.* either (*S*,*S*) or (*R*,*R*)]; ● = $Cu^I$.

The formation of the HT rather than HH isomers minimises steric interactions between the chiral substituents. The origin of the diastereoselectivity is not so easy to understand; no single interaction appears to be responsible, and, in contrast to previous studies[6] there is no obvious steric destabilisation of the less-favoured helicate. We are currently further studying the origin of this selectivity.

In conclusion, we have unambiguously demonstrated the diastereoselective formation of *P* or *M* helicates upon the coordination of chiral helicands to copper(I). We are currently extending these studies to increase the diastereoselectivity and to observe similar effects with chiral derivatives of higher oligopyridines.

‡ Modelling studies were initially made using the previous structural determinations[3] as a starting point. Once the structural determinations made in this paper had been made, the Cu–Cu distances were constrained to 2.70 Å. Calculations were made using the MM2 implementation in Chem 3D Pro version 3.5 or the Universal Force Field Implemented in Molecular Simulations Cerius$^{2TM}$ software.

§ *Crystal data*: $[Cu_2L^1{}_2][PF_6]_2 \cdot 2MeCN$: orange crystal, $C_{56}H_{64}Cu_2F_{12}N_8P_2$, $M$ = 1298.18, orthorhombic, space group $P2_12_12$, $a$ = 8.475(1), $b$ = 28.268(2), $c$ = 12.286(1) Å, $U$ = 2943.5(3) Å$^3$, $Z$ = 2, $D_c$ = 1.46 g cm$^{-3}$, $F(000)$ = 1336, λ = 1.54180 Å, μ(Cu-Kα) 2.14 mm$^{-1}$. Intensity data were collected by the ω–2θ scan method (4.2 < 2θ < 154°); for a crystal of dimensions 0.10 × 0.50 × 0.65 mm at room temp.; of 3250 (3238 independent) reflections measured, 2790 [$I \geqslant 3\sigma(I)$] were used in the structure solution. The structure was solved by direct methods using SIR92 (A. Altomare, G. Cascarano, G. Giacovazzo, A. Guagliardi, M. C. Burla, G. Polidori and M. Camalli, *J. Appl. Crystallogr*., 1994, **27**, 435) and refined using CRYSTALS (D. J. Watkin, J. R. Carruthers and P. Betteridge, Chemical Crystallography Laboratory, Oxford, UK) to give final $R$ and $R_w$ values of 0.0513 and 0.0570 respectively (Chebychev polynomial weighting: J. R. Carruthers and D. J. Watkin, *Acta Crystallogr., Sect. A*, 1979, **35**, 698).

$[Cu_2L^2{}_2][PF_6]_2 \cdot 2MeCN$: orange crystal, $C_{56}H_{64}Cu_2F_{12}N_8P_2$, $M$ = 1298.18, orthorhombic, space group $P2_12_12$, $a$ = 8.475(1), $b$ = 28.231(2), $c$ = 12.284(1) Å, $U$ = 2932.7(4) Å$^3$, $Z$ = 2, $D_c$ = 1.47 g cm$^{-3}$, $F(000)$ = 1336, λ = 1.54180 Å, μ(Cu-Kα) 2.15 mm−$^1$. Intensity data were collected by the ω–2θ scan method (4.2 < 2θ < 154°); for a crystal of dimensions 0.10 $^1$ 0.45 × 0.65 mm at room temp.; of 3188 (3174 independent) reflections measured, 2444 [$I \geqslant 3\sigma(I)$] were used in the structure solution. The structure was solved by direct methods using SIR92 and refined using CRYSTALS to give final $R$ and $R_w$ values of 0.0679 and 0.0626 respectively (Chebychev polynomial weighting).

Atomic coordinates, bond lengths and angles, and thermal parameters for both structures have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/334.

**Mesoporous zirconia is synthesized with anionic templates.**

The success of Mobil scientists in the surfactant-assisted synthesis of mesoporous molecular sieves[1,2] with hexagonal or cubic ordering of the pore system and high temperature stability has been followed by an enormous amount of research worldwide. An array of cationic surfactants (such as quaternary alkylammonium) with chains containing, typically, twelve carbon atoms interact with an inorganic anionic or cationic oligomer (or polymer) to form a solid in which small-angle X-ray scattering reveals the existence of an ordered system of pores.

The basic principles of these syntheses have been reviewed by Huo *et al*.[3] who have distinguished the interaction between cationic or anionic surfactant with anionic or cationic metal oligomers on the basis of studies involving a large variety of metals other than silicon. Three kinds of structures have been characterized by their X-ray patterns, namely, hexagonal, lamellar and cubic. A high spacing reflection is easily observed in the range 2θ 2–4°, whereas the other Bragg reflections, on which the differentiation between the structures is based, are more difficult to observe because of their intrinsic lower intensity and the broadening due to disorder. Removal of the surfactant does not necessarily keep the hexagonal or cubic structure intact, as desirable for producing high-area solids.

The incorporation of titanium[4] and of zirconium[5] in hexagonal mesoporous silica has been proposed to circumvent the lack of stability of mesoporous titania or zirconia. However, hexagonally packed transition-metal mesoporous molecular sieves of pure niobium, titanium or tantalum oxide have been synthesized with octadecylamine by Antonelli and Ying.[6,7] The preparation of pure mesoporous zirconia with surface area of *ca*. 300 $m^2\ g^{-1}$ at 500 °C has been achieved by Knowles and Hudson[8] using tetramethyl alkylammonium surfactants and zirconyl chloride. Starting from Zr sulfate or propoxide, Schüth[9] and Ciesla *et al*.[10] have obtained a hexagonal mesoporous zirconia of a quality corresponding to that of the silica analogue using alkyl tetramethylammonium surfactants as templates. Reddy and Sayari[11] obtained either hexagonal or lamellar phases of templated zirconia using either quaternary ammonium surfactants or acidified primary alkylamine, respectively. Sachtler and coworkers[12] have used a primary acidified ($C_{16}$) alkylamine. The ordering of the pores was far from perfect but the sulfation of the 'as-synthesized precursor' remarkably stabilizes the structure. After sulfation the X-ray diagram characteristic of tetragonal $ZrO_2$ appears at about 600 °C.

Except in this latter work, the formation of structurally 'ordered' walls has not drawn much attention. Since the stability of tetragonal $ZrO_2$ appears to be driven by particle size,[13,14] the onset of crystallization of the wall in the monoclinic phase could give information on the thickness of the walls between pores. At 500 °C, particles with diameters > 16 nm undergo the tetragonal to monoclinic transformation.[15]

Here, we report on the synthesis of mesoporous zirconia using two anionic surfactants. As far as we know such synthesis has not been achieved up to now and it may be that the elimination of this category of surfactants could be easier. The preparation was as follows. The source of zirconium was a 70% m/m solution of zirconium propoxide in propanol. The two 'straight alkyl chain' surfactants were: $C_{12}H_{25}OP(OH)_2$ ($M$ = 266), abbreviated $P_{12}$ and $C_{12}H_{25}OSO_3Na$ ($M$ = 288), abbreviated $S_{12}$, respectively. The $P_{12}$ solution was left at pH = 3, namely, the original pH of the solution. The initial pH of the $S_{12}$ solution was adjusted by HCl at about 3. The propanolic zirconium alkoxide solution was added slowly to the surfactant solution until the molar ratio S/Zr was 0.16. The mixture was transferred into a hydrothermal bomb where it was heated between 90 and 120 °C for about 12 h. The products of the reaction, called, in short, either $P_{12}$ or $S_{12}$ solids, were dried at 140 °C or calcined at 500 °C.

Low-angle X-ray scattering in the range 2θ 0.8–10° was obtained with a Scintag Θ–Θ X-ray diffractometer (Cu-Kα) fitted with a solid-state detector and the following set of slits: 0.5, 0.3, 0.2 and 0.07°. For medium-angle X-ray scattering (2–70°), the slits were 3, 2, 0.5 and 0.3°. Fig. 1 shows a diffraction line corresponding to spacing at about 47 Å after drying at 140 °C. After calcination at 500 °C, the spacing generally increases, but sometimes, as observed for the $S_{12}$ solid, the ordering disappears.

The $N_2$ adsorption–desorption isotherms were obtained with an automated physisorption instrument operated in a static mode (Omnisorp 100, Coulter Co.). All measurements were performed after outgassing at 150 °C under vacuum down to a residual pressure better than $10^{-4}$ Torr. During calcination in air at 500 °C, all organics were burned as proved by the analysis of residual carbon (Table 1). The typical shape expected for mesoporous solids is observed in Fig. 2(*a*), namely, for the $S_{12}$ and $P_{12}$ solids dried at 140 °C. The *t*-plot specific surface area is in excess of 500 $m^2$. A broad maximum in the porosity distribution function d$V$/d$r$ *vs*. $r$, the radius of the pore, is observed at 2$r$ *ca*. 35 Å. As shown in Table 1, for these solids over 70% of the porous volume is in pores with diameters between 10 and 100 Å, even in $P_{12}$ calcined at 500 °C, in spite of a *ca*. 50% loss in mesoporosity [Fig. 2(*b*)]. The qualitative agreement between the small-angle X-ray scattering data is

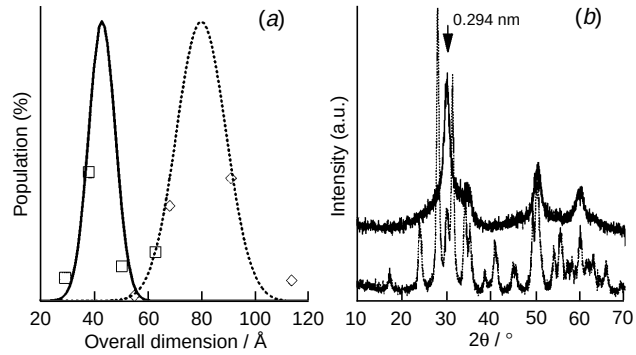

**Fig. 3** (*a*) Gaussian-fitted distribution of the dimension (Å) of the hexagons observed in the HRTEM pictures of the $P_{12}$ and $S_{12}$ solids dried at 140 °C (□, maximum at *ca*. 43 Å). The distribution with maximum at *ca*. 80 Å is observed for $P_{12}$ calcined at 500 °C (◇). (*b*) XRD obtained for $P_{12}$ (—) or for $S_{12}$(---) solids calcined at 500 °C. The reflection at 2.94 Å is characteristic of the trigonal structure.

striking, particularly when comparing the development of macroporosity due to the sintering of $S_{12}$ at 500 °C.

The materials were examined with high-resolution transmission electron microscopy (HTREM, 200 kV). On a microphotograph (Fig. 4) obtained with $P_{12}$ dried at 140 °C, a network of more or less organized pseudo-hexagonal pores is observed. In Fig. 3(*a*), the measured distribution of the overall dimension (Å) of the pseudo-hexagonal pores in $P_{12}$ or $S_{12}$ is fitted to a Gaussian distribution with a maximum at *ca*. 44 Å and a width of 7 Å. Upon calcining $P_{12}$ at 500 °C, the maximum of the distribution shifted towards 80 Å while the width doubled. Again, this is in qualitative agreement with the low-angle scattering data in Fig. 1(*b*) and the isotherms shown in Fig. 2(*b*). The loss of mesoporosity in solid $S_{12}$ calcined at 500 °C is supported by the disappearance of the network of pseudo-hexagons in the corresponding HRTEM picture (not shown). The comparison [Fig. 3(*b*)] of the X-ray scattering data of $P_{12}$

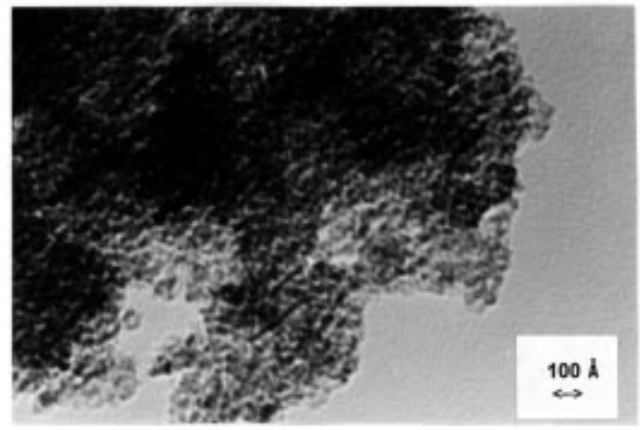

**Fig. 4** HRTEM picture of mesoporous zirconia obtained with $P_{12}$ template

and $S_{12}$ solids calcined at 500 °C provides some insight into the sintering observed for $S_{12}$, since in this sample the phase transformation from a tetragonal to monoclinic structure is evident while $P_{12}$ is at the onset of crystallization. The thickness of the walls between pseudo-hexagons increases from approximately 10 Å to *ca*. 20 Å (HRTEM). $^{31}$P NMR spectroscopy shows that the phosphate remains in the solid after calcination at 500 °C.

Scanning electron microscopy revealed that $P_{12}$ and $S_{12}$ consist mainly of a collection of polygonal particles, of diameter 4–10 μm. Spherical particles in this range of dimensions appear upon sintering $S_{12}$ at 500 °C.

Thus, it may be concluded that mesoporous zirconia can be prepared by hydrolysing the zirconium propoxide in the presence of anionic surfactants (alkyl-phosphate and -sulfate) and subsequent ageing.

The partial support of DOE grant DE-FG02-90 ER1430 is gratefully acknowledged.

# Epoxide ring opening of α,β-epoxysilanes with prop-2-ynyl sulfide dianion—synthesis of (11*R*,12*S*,5*Z*,7*E*,9*E*,14*Z*)-dihydroxyeicosa-5,7,9,14-tetraenoic acid

**Yuichi Kobayashi, Kiyoshi Shimizu and Fumie Sato***

*Department of Biomolecular Engineering, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama 226, Japan*

**A new methodology for synthesis of lipoxygenase metabolites possessing *vic*-diol substructures coupled with the conjugated alkene system is developed and successfully applied to the synthesis of (11*R*,12*S*,5*Z*,7*E*,9*E*,14*Z*)-dihydroxyeicosa-5,7,9,14-tetraenoic acid (DiHETE).**

The biological importance of the lipoxygenase pathways of arachidonic acid metabolism has been repeatedly reviewed.[1] Since these metabolites are available only in minute quantities from biological sources, their total synthesis for further evaluation of their biological properties has attracted much interest.[2] The lipoxygenase metabolites are characterised by monool, *vic*-diol, or epoxide substructures coupled with a conjugated alkene system. So far, a number of syntheses of the monool and epoxide metabolites have been published. However, much less attention has been directed toward the *vic*-diol metabolites (Fig. 1).[3–5]

On the basis of Wicha's finding,[6,7a] we recently reported that reaction of the γ-trimethylsilyl epoxy alcohols **3** and the anions derived from **2**, in which the leaving group (Y) is attached at the α carbon, affords silyl ethers **4** ($R^4$ = $SiMe_3$) or free alcohols **4** ($R^4$ = H) after hydrolysis (Scheme 1).[8] Taking into account these results and the ready availability of optically active **3**[9] (> 99% ee) in large quantities by the kinetic resolution of the corresponding racemic allylic alcohols using the Sharpless epoxidation,[10] we envisaged that, if *anti*,*trans* enyne **6** were prepared by reaction of the *anti* epoxy alcohol **3** and dianion derived from a prop-2-ynylic compound **5** (where L is a leaving group), hydroboration of **6** ($R^3$ = $R^4$ ≠ H) and subsequent palladium-catalysed coupling reaction[11] with *cis* iodide **7** would furnish DiHETE **1** stereoselectively (Scheme 2). We recently applied a similar palladium-catalysed coupling reaction to the highly stereoselective construction of leukotriene $B_4$ ($LTB_4$) and its derivatives.[2b,12] Herein we report the substantiation of our postulate, exemplified by the facile synthesis of (11*R*12*S*)-DiHETE **14**, a metabolite of the 12-lipoxygenase cascade of arachidonic acid.[4a,13]

Requisite *anti* γ-silyl epoxy alcohol **9** (> 99% ee), the enantiomer of the intermediate for synthesis of $LTB_4$,[12a] was prepared by the kinetic resolution of racemic allylic alcohol DL-**8** in 43% yield based on DL-**8**.[9] Since we had no prior knowledge of the leaving group (L) of **5** and the requisite reaction conditions to afford the key intermediate **10** with *trans* alkene geometry, we examined reaction of **9** or the α-ethoxyethyl ether of **9** with the dianion derived from **5** [L = SPh, S(O)Ph] and BuLi. The reaction proceeded smoothly when **9** and 3 equiv. of **5** (L = SPh) were used in THF. However, after hydrolysis of the *vic*-diol monosilyl ethers under acidic conditions, the ratio of the desired enyne **10** and the *cis* isomer **15** incidentally produced was a disappointing 66 : 34 by $^1$H NMR spectroscopy (Table 1, entry 1).

Other prop-2-ynyl sulfides were then tried (entries 2–4) and *tert*-butyl sulfide **5** (L = $SBu^t$) was finally found to show high stereoselectivity. Thus, **9** was added to a THF solution of the dianion of **5** (L = $SBu^t$) generated by using 2 equiv. of BuLi (1 h, −15 °C). The solution was stirred at −15 °C for 2 h and then at room temp. for 12 h to give the product which, upon treatment with dil HCl, furnished **10** and **15** in a ratio of 89 : 11 (entry 4). Both isomers were easily separated by column chromatography on silica gel [$R_f$ values: **10**, 0.67; **15**, 0.57 (hexane–$Et_2O$ = 2:5)] and **10** [$\alpha]_D^{23}$ +1.8 (*c* 0.56, $CHCl_3$)] was isolated in 70% yield. Addition of HMPA resulted in low stereoselection (entry 5).

| 4 | *syn* | $C_5H_{11}$ | SPh | **16a** | 87 : 13 | 84 |
| 5 | *anti* | $CH_2C{\equiv}CC_5H_{11}$ | SBu$^t$ | **16b** | 84 : 16 | 79 |
| 6 | *anti* | $(CH_2)_2Ph$ | SBu$^t$ | **16c** | 90 : 10 | 92 |
| 7 | *anti* | $CH_2OBn$ | SBu$^t$ | **16d** | 89 : 11 | 71 |

[a] See footnote *a* to Table 1. [b] In all cases, *trans* and *cis* isomers were separated by chromatography and characterized by $^1$H NMR. [c] Combined yields of *trans* and *cis* enynes **16** after chromatography.

To complete the synthesis, the hydroxy groups of **10** were protected [Bu$^t$Me$_2$SiCl, imidazole, DMF, 45 °C] to afford the disilyl ether **11** {$[\alpha]_D^{25}$ −2.8 (*c* 1.06, $CHCl_3$)} in 85% yield. Hydroboration of **11** with disiamylborane (1.5 equiv., 0 °C, THF) and subsequent coupling with the iodide **12** (2.3 equiv.) in the presence of $Pd(PPh_3)_4$ (0.1 equiv.) and excess of aqueous LiOH at 35 °C furnished 11,12-DiHETE disilyl ether **13** in 96% yield. Finally, desilylation of **13** with $Bu_4NF$ afforded in 90% yield (11*R*,12*S*)-DiHETE **14** ($^1$H NMR,[4a,13a] UV[4c]), whose chemical purity was > 95% by RP-HPLC.

In the above paragraphs, we described the synthesis of 11,12-DiHETE **14**, in which the key intermediate **10** was synthesized from **9** and the *tert*-butyl sulfide **5** (L = SBu$^t$) (Table 1, entry 4). By using the general strategy proposed in Scheme 2, synthesis of other DiHETEs **1** and their analogues as well as metabolites possessing the DiHETE substructure such as lipoxins should be possible. Thus, stereoselectivity of the key reaction was briefly examined by using various *anti* and/or *syn* γ-silyl epoxy alcohols **3** ($R^3$ = H) and prop-2-ynylic sulfides **5** (L = SBu$^t$, SPh) (Scheme 3) under the reaction conditions described above. Results are summarised in Table 2. With synthetically useful stereoselectivities and good yields were produced *trans* enynes **16a**–**d** in all cases when *tert*-butyl sulfide **5** (L = SBu$^t$) was used (entries 1 *vs.* 2, 3 *vs.* 4, 5–7). In every case, the major *trans* enyne and the minor *cis* isomer were

**Scheme 3**

separated easily by chromatography. Interestingly, higher *trans* selectivity was observed in the case of *syn* **3** ($R^1$ = $C_5H_{11}$, $R^3$ = H) (entries 1 and 3). It is also noteworthy that the sense of the *trans* alkenes afforded as the major product in our system was *opposite* to that reported by Wicha *et al*.[7]

We gratefully acknowledge receipt of the Daiichi Pharmaceutical Award in Synthetic Organic Chemistry, Japan.

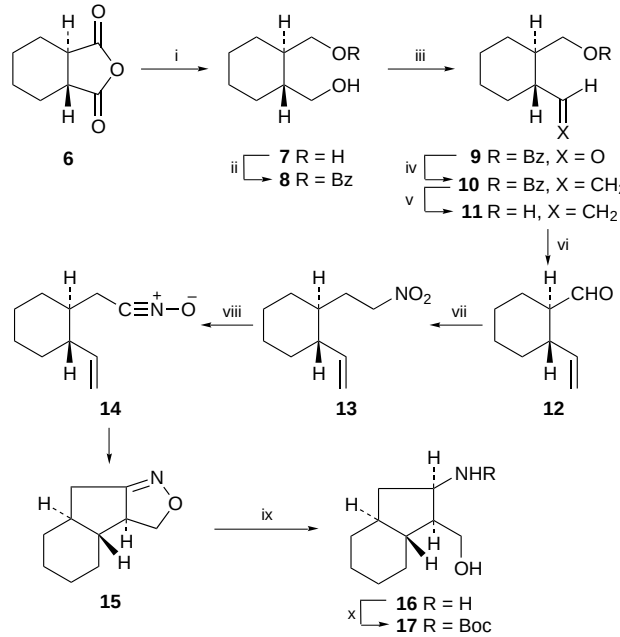
# Novel nitrile oxide cycloaddition approach towards papuamine: stereoselective synthesis of a potentially useful *trans*-hydrindane intermediate

**Arabinda Saha and Anup Bhattacharjya***

*Indian Institute of Chemical Biology, 4 Raja S. C. Mullick Road, Calcutta 700 032, India*



**In a potentially useful approach to the marine alkaloid papuamine 1, a known *trans*-hydrindane intermediate 17 has been synthesised in racemic form using a model sequence of reactions involving a nitrile oxide cycloaddition as a key step.**

Papuamine **1**, a unique $C_2$-symmetric pentacyclic alkaloid, was isolated from the marine sponge *Haliclona sp*.[1,2] The presence of two disubstituted *trans*-hydrindane units of identical chirality and a central diazadiene ring makes papuamine a challenging target for synthesis. A crucial task in such a synthesis is the stereoselective construction of the disubstituted *trans*-hydrindane unit incorporating four chiral centres. Three recent syntheses[3–5] of optically active papuamine have solved this problem either by reductive amination of suitably substituted *trans*-hydrindanone derivatives[3,4] or by utilising a highly stereoselective iminoene reaction.[5] We envisaged a novel and expedient strategy (Scheme 1) towards **1** involving the intramolecular cycloaddition of the bis-nitrile oxide **4** to give a bis-isoxazoline derivative **3**, which could be elaborated to the papuamine skeleton by reductive cleavage to **2** followed by the incorporation of a $C_3$-unit. The future success of this approach is critically dependent on the fidelity of the sequence **4** → **3** → **2**. We herein report an unusually simple but efficient synthesis of a racemic *trans*-hydrindane intermediate **17**, which is the racemate of an intermediate used[3] for papuamine, *via* the model sequence of conversions **14** → **15** → **17** involving a highly stereoselective, intramolecular, nitrile oxide cycloaddition and subsequent reduction of the isoxazoline ring (Scheme 2).

**Scheme 1**

The diol **7**, which was easily obtained from (±)-**6** by reduction with $LiAlH_4$, was monobenzoylated and the resulting alcohol **8**† was oxidised[6] with PCC to the aldehyde **9**. Wittig methylenation of **9** gave the olefinic ester **10**, which on deprotection furnished the alcohol **11**. Oxidation of **11** by PCC led to the aldehyde **12**, which was converted to the nitro compound **13** *via* a known protocol[7] involving reaction with nitromethane, acetylation and reduction with sodium borohydride without purification of any of the intermediate products. The conversion of **6** to **12** was effected *via* the above route in order to adapt this strategy for preparing enantiomerically pure intermediates required for the synthesis of optically active papuamine. The construction of the crucial *trans*-hydrindane skeleton was then achieved by the treatment of **13** with phenyl isocyanate leading to the formation of the nitrile oxide **14**, which underwent cycloaddition to furnish the isoxazoline **15**‡ as the exclusive product. The gross structure of **15** was

**Scheme 2** *Reagents and conditions*: i, $LiAlH_4$, THF, 90%; ii, NaH (1 equiv.), then BzCl (1 equiv.), 82%; iii, PCC, neutral alumina, $CH_2Cl_2$, 96%; iv, $Ph_3PMe^+I^-$, BuLi, THF, 70%; v, NaOH, MeOH, $H_2O$, 96%; vi, PCC, neutral alumina, $CH_2Cl_2$, 92%; vii, $CH_3NO_2$, KF, then $Ac_2O$, then $NaBH_4$, EtOH (68% overall); viii, PhNCO, $C_6H_6$, 72%; ix, $LiAlH_4$, $Et_2O$, 88%; x, $Boc_2O$, EtOAc, 90%

established on the basis of $^1H$ and $^{13}C$ NMR spectral data. The stereochemistry of the newly formed chiral centre in the isoxazoline ring could not be determined unambiguously from the spectral data, although it could be tentatively assigned on the basis of the stereochemical outcome observed in the cycloaddition of analogous nitrile oxides.[8] The unambiguous assignment of the structure of **15** was provided by its reductive cleavage with $LiAlH_4$, resulting in the formation of the amino alcohol **16**, which was isolated as the Boc derivative **17**. A comparison of the IR, $^1H$ and $^{13}C$ NMR spectra of **17** with those of an intermediate reported[3] by Barrett *et al*. established the identity of the two derivatives. The high stereoselectivity observed in the reduction of the isoxazoline ring in **15** was in accord with the results obtained in similar reductions with $LiAlH_4$.[9]

The fact that the corresponding *N*-deprotected *O*-benzylated derivative of **17** was involved in the synthesis[3] of papuamine by Barrett *et al.* indicates the practical importance of the strategy. Moreover, since the work described above established the successful conversion of **13** to **16**, the synthesis of papuamine **1** from **5** appears to be a distinct possibility and is in progress.

We are indebted to Professor A. G. M. Barrett for providing the copies of the IR, $^1H$ and $^{13}C$ NMR spectra of **17**. A. S. gratefully acknowledges the award of a Research Associateship by CSIR, India. We are grateful to Dr A. Patra for the 300 MHz $^1H$ NMR spectrum of **17**. Thanks are due to Mr P. P. Ghosh Dastidar, Dr R. C. Yadav and Dr R. Mukhopadhyay for NMR and mass spectral analyses.

## Footnotes

† All new compounds were liquids and were characterised by GC, IR, mass, and $^1H$ NMR spectral analyses; satisfactory $^{13}C$ NMR spectral data were recorded for **10**, **13**, **15** and **17**. The 300 MHz $^1H$ NMR and a 25 MHz $^{13}C$ NMR spectra of compound **17** were identical with those provided by Professor Barrett.

‡ *Selected spectral data* for **15**: $^1H$ ($CDCl_3$; 100 MHz): δ 2.48–2.84 (m, 1 H), 3.20–3.52 (m, 1 H), 3.80 (dd, *J* 8 and 12 Hz, 1 H) and 4.48 (dd, *J* 8 and 10 Hz, 1 H); $^{13}C$ ($CDCl_3$; 25 MHz): δ 25.8, 25.9, 27.7, 30.7, 31.4, 49.4, 49.9, 61.3 and 170.7.

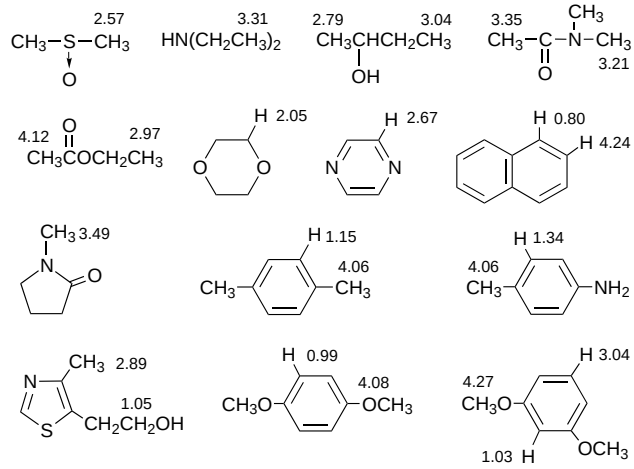
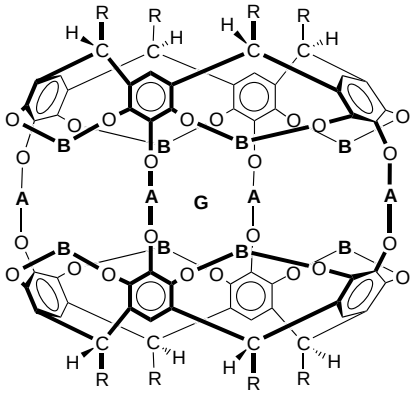
# The first water-soluble hermicarceplexes



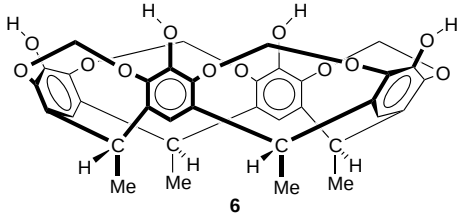
**Juyoung Yoon and Donald J. Cram***



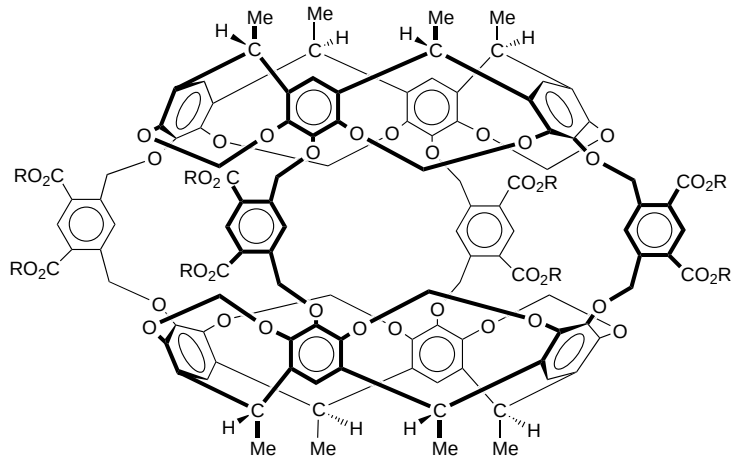
*Department of Chemistry and Biochemistry, University of California, Los Angeles, CA 90095-1569, USA*

**The synthesis of the first water-soluble hemicarcerand and its spectral and binding properties with 14 guests in water are described.**

Many hemicarcerands and hemicarceplexes of general structures **1** and **1**⊙G, respectively, have been reported in which the carbon chains of the bridging A groups, the spanning B groups, the feet (R groups) and guests (G) have been widely varied.[1] The host which binds the largest number and variety of guests is **2** [A = $(CH_2)_4$, B = $CH_2$, R = $CH_2CH_2Ph$].[2] Recently a family of hosts has been synthesized in which A = 3-$CH_2C_6H_4CH_2$, B = $(CH_2)_n$ (*n* = 1–3) and R = $(CH_2)_4Me$.[3] Of the hundreds of known hemicarceplexes,[4] all have been too lipophilic to be soluble in water. If hemicarcerands are to be candidates for drug delivery systems, they should not only bind a wide variety of guests but they and their complexes should be soluble in water not far from physiological pH values. Here we report the synthesis, spectra and host-binding properties toward representative organic guests of the first water-soluble hemicarcerand **4**.†,‡

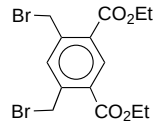


For complexation studies, a stock 1.5 mmol $dm^{-3}$ solution of octaacid **4** in 0.1 mol $dm^{-3}$ deuteriated sodium borate buffer (adjusted to pH 9 with NaOD in $D_2O$)[7] was prepared, and its 400 MHz $^1$H NMR spectrum was recorded. About 10 equiv. of each listed guest were added to the host solution, the pH was again adjusted if necessary, and the $^1$H NMR spectrum of the aqueous solution was taken at 25 °C. The effects of incarceration for 14 guests on important signals in their $^1$H NMR spectra in $D_2O$ at 25 °C are recorded in values of Δδ, which equals $\delta_{free} - \delta_{complexed}$. These Δδ values (ppm) are placed close to their assigned protons in the 14 guest formulas. The fact that the exchange of places of free and incarcerated guest was slow on the NMR time scale allowed the inner-phase guests to be differentiated from those in the bulk phase. Complexation appeared to be complete in a few minutes for all guests formulated except naphthalene, whose limited solubility in $D_2O$ made dissolution of the solid in $D_2O$ the rate-limiting step rather than complexation. The insolubility of naphthalene in $D_2O$ coupled with the 12 h it took for all of the free host to become complexed indicates that complexation was the cause of dissolution of naphthalene in $D_2O$. All complexes were 1 : 1, a conclusion drawn from peak intensity comparisons.



**1** ⊙G, **2**⊙G, A = $(CH_2)_4$, B = $CH_2$, R = $CH_2CH_2Ph$

**3** ⊙G, A = 3-$CH_2C_6H_4CH_2$, B = $CH_2$, R = $CH_2CH_2Ph$



**6**

**4** R = H

**5** R = Et

**7**

The four salts $Me_4NBr$, $PhNMe_3Br$, $BnNMe_3Br$ and 3-$MeC_6H_4CO_2Na$ failed to complex **4** in $D_2O$ buffer, probably because $D_2O$ solvates their charges much better than does the interior of **4**. Although the release of many inner-phase-solvating water molecules for each host and from bulk-phase water for each guest molecule would provide a substantial entropic driving force for complexation of the cations the enthalpic solvation energies of their charges by water appear to be dominant in inhibiting complexation.

The guests formulated that are incarcerated in **4** which is dissolved in $D_2O$ provide a wide range in size, polarity and water solubility. The smallest one is $Me_2SO$ containing 4 heavy atoms (non-hydrogen), which is highly polar, is miscible with $D_2O$ in all proportions, and is a good hydrogen bond acceptor. The next largest are $MeCH(OH)CH_2Me$ and $(MeCH_2)_2NH$ with 5 heavy atoms, which are both moderately polar, good hydrogen bond acceptors and donors, and are rather soluble in $D_2O$. Of the four guests containing 6 heavy atoms, $MeCONMe_2$ and $MeCO_2Et$ are highly polar, $O(CH_2CH_2)_2O$ and $C_4N_2H_4$ (1,4-diazine) are polarizable, all are highly soluble in $D_2O$, and are excellent hydrogen bond acceptors. The only 7-heavy atom guest is $C_5H_9NO$ (*N*-methylpyrrolidinone or NMP), which is very polar, water soluble and a good hydrogen bond acceptor. Of the two guests containing 8 heavy atoms, 4-$MeC_6H_4NH_2$ and 1,4-$(Me)_2C_6H_4$, the former is of intermediate polarity, is somewhat soluble in $D_2O$ and is a good hydrogen bond acceptor and donor, whereas the latter is slightly polarizable, slightly soluble in $D_2O$, and is a poor hydrogen bond acceptor. The only 9-heavy atom guest is 4-methyl-5-(2-hydroxyethyl)thiazole, which is an intermediate in the synthesis of vitamin $B_1$ and is a sedative. This guest is rather polar, is very soluble in water, and is a good donor and acceptor of hydrogen bonds. Of the three 10-heavy atom guests that complexed **4**, 1,4-dimethoxybenzene and 1,3-dimethoxybenzene are relatively nonpolar compounds slightly soluble in $D_2O$ with low hydrogen bond-accepting ability, whereas naphthalene is even less polar, is an even poorer hydrogen bond acceptor, and is essentially insoluble in $D_2O$.

Corey–Pauling–Koltun (CPK) molecular models of the 14 guests listed can be pushed, the larger ones only with difficulty, through the portals of CPK models of **4** containing new atom connectors which survive the encapsulation. Experimentally, the 1 : 1 complexes all appeared stable at ambient temperature in the medium containing excess guest in which they were prepared. It is likely that other guests that complex **3** and are stable in $CDCl_3$ at 25 °C should be stable as complexes of **4** in $D_2O$ at 25 °C, since the hosts' interiors are essentially the same. The only guests common to this study and those involving **3** are 1,4-$Me_2C_6H_4$ and 1,4-$(MeO)_2C_6H_4$, whose complexes with **3** were stable to formation at high temperatures and even isolation, but decomplexed rapidly enough at 25 °C in $CDCl_3$ to inhibit recording reportable $^1$H NMR spectra. Particularly with these two lipophilic guests, we expect hydrophobic binding to contribute more stability to **4**⊙G in $D_2O$ than solvophobic binding in $CDCl_3$ does to **3**⊙G.

The $^1$H NMR results provide the following interesting conclusions. (1) All inner volumes occupied (on average) by guest protons of **4**⊙G are shielding, but vary widely. At the extremes, the β protons of **4**⊙naphthalene (in $D_2O$) give a Δδ value of 4.24, whereas the α protons give 0.80 ppm. Similarly, the six methyl protons of **4**⊙1,3-$(MeO)_2C_6H_4$ provide a Δδ value of 4.27, while the Ar–H flanked by the two MeO groups gives 1.03 ppm. Model examination of both complexes shows that the longer axes of both guests must be aligned along the longer (polar) axis of the inner phase of **4**, and the shorter guest axes along the shorter equatorial axis of **4**. The seven-heavy atom MeOCCCOMe moiety of 1,3-$(MeO)_2C_6H_4$ is the longest axis of this guest. These alignments place the β protons of naphthalene and the methyl protons of 1,3-$(MeO)_2C_6H_4$ in the highly shielding polar caps of **4**, and the α protons of naphthalene and the methoxy-flanked Ar–H protons of 1,3-$(MeO)_2C_6H_4$ in the much lower shielding, bridge region of the inner phase of **4**. The other Δδ values lend themselves to similar analysis. (2) The patterns of Δδ values for the protons of the same guest incarcerated in **2**⊙G and **4**⊙G in eight sets of available comparisons are very similar, although those of **2**⊙G without exception are between 0.02 and 0.38 ppm higher valued than those of **4**⊙G. This reflects the fact that although the cavities of **2** and **4** are similarly shaped, the $O(CH_2)_4O$ bridges of **2** are one atom shorter than the 3-$OCH_2C_6H_4CH_2O$ bridges of **4**. (3) Generally the Δδ values for all the complexes fall into three groups. Values of 1 ± 0.3 are observed for protons that do not terminate chains [*e.g.* $CH_2$ of **4**⊙4-methyl-5-(2-hydroxyethyl)thiazole, Δδ = 0.88, or Ar-H of 1,4-$(MeO)_2C_6H_4$, Δδ = 0.99 ppm], are close to the centre of the guest, and therefore cannot approach closely the generally shielding inner surfaces of the cavities. Values of Δδ = 2–3 ppm are found for protons which are forced to occupy the equatorial regions of the host (*e.g.* $CH_2$ protons of NMP), or are small enough to average many locations by rapid rotations within the host's cavity [*e.g.* protons of $Me_2SO$, $O(CH_2CH_2)_2O$ or 1,4-diazine]. Values of 3.0–4.5 ppm occur for guests whose protons are forced into the faces of the host's aryl groups [*e.g.* the β protons of naphthalene, the Me protons of $MeCO_2Et$ and of $MeCONMe_2$].

The authors warmly thank the NIH for grant GM 12640 which supported this research.

## Footnote

† Tetrol **6**[5] (1 equiv.) was stirred under argon at 25 °C with 2.1 equiv. of dibromide **7**[6] in dry *N*-methylpyrrolidinone (NMP)–$Cs_2CO_3$ for 24 h under high dilution conditions. An additional 1.5 equiv. of **7** were added and the stirring continued at 40 °C for 24 h. The mixture was filtered, the filtrate was evaporated under high vacuum, and the residue was dissolved in $CHCl_3$. The mixture was filtered, the filtrate was evaporated to *ca.* 5 ml and mixed with 100 ml of MeOH which precipitated octaester **5**. This material was filtered and purified by chromatography on a TLC plate (silica gel–$CH_2Cl_2$) to give a 15% yield of **5**. This ester was hydrolysed to give octaacid **4** in THF–1 mol $dm^{-3}$ aqueous KOH–18-crown-6 (4 h at reflux). The solvent was evaporated, and the aqueous solution acidified to pH 1 with 1 mol $dm^{-3}$ aqueous HCl. The octaacid **4** was extracted with EtOAc, the organic layer was dried, and the solvent evaporated to give pure **4** in 90% yield.

‡ New compounds, **4** and **5**, gave elemental analyses within 0.30% of theory, and the expected $^1$H NMR spectra and FABMS (*m/z*, $M^+ + H$).

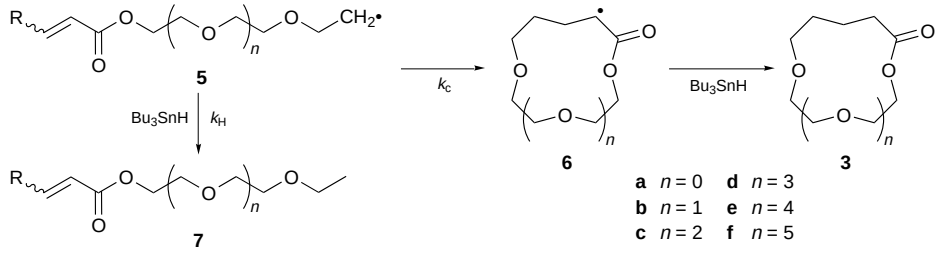
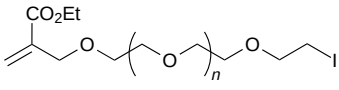
**ω-Iodopolyoxaalkyl acrylates and related compounds undergo radical cyclisation when treated with tributylstannane to afford substituted macrocylic polyethers.**

3-Oxahex-5-enyl radicals ($CH_2$=$CHCH_2OCH_2CH_2$·) undergo *exo* cyclisation about 25 times more rapidly at 80 °C than do hex-5-enyl radicals.[1,2] Similarly the 2-allyloxyphenyl radical cyclises much more rapidly than its all carbon analogue.[3] The effect of an oxygen atom in the chain on the rates of cyclisation of these and related species has been attributed to the decrease in the strain energy of the cyclisation transition structures resulting from the replacement of a carbon atom by oxygen,[1,4] an hypothesis supported by molecular mechanics calculations.[4] These observations suggested that the ring closure of radicals derived from suitable polyether precursors might proceed relatively rapidly. Here we show that such radicals do indeed cyclise more readily than their all-carbon analogues, and that this method provides a viable alternative to ionic reactions as a route to macrocyclic polyethers of potential utility as ionophores.

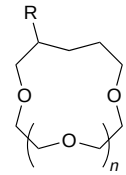


Suitable radical precursors **2a–j** were readily prepared from ethylene glycol oligomers. In a typical example, treatment of the monotosylate of tetraethylene glycol[5] with acryloyl chloride and Hünig's base gave the acrylate **1** (92%) which was converted into the iodide **2c** (95%) on stirring with sodium iodide in acetone. In some cases the oligomeric ethylene glycol was first esterified by treatment with an acid chloride and triethylamine and the iodide was then prepared *via* the mesylate. Heating of each of the compounds **2b–j** with 1.1 molar equivalents of tributylstannane (0.01 mol $dm^{-3}$) and AIBN as catalyst in benzene under reflux for 2 h gave the corresponding cyclic polyethers **3b–j** (and in some cases **4g–j**), but no cyclised product could be obtained from **2a**. Uncyclised products formed by direct hydrogen atom transfer to the initially formed radicals were also detected. Their formation allowed the estimation of the rate constants for cyclisation on the basis of the mechanism shown in Scheme 1. Accurate GC analysis of the product mixtures and treatment of the data in the usual way[6] gave values of $k_c/k_H$ which, when combined with the rate constant for hydrogen transfer from tributylstannane to a primary radical ($k_H$ = 6.3 × $10^6$ $dm^3$ $mol^{-1}$ $s^{-1}$ at 80 °C),[7] gave $k_c$ at 80 °C. The results presented in Table 1 show that the radicals **5b** and **5c**, respectively, cyclise 30 and 10 times faster than their all-carbon-chain analogues ($k_c$ = 4.8 × $10^3$ and 1.2 × $10^4$ $s^{-1}$ at 80 °C, calculated from data in the literature[8]).

Each of the substrates **2b–f** undergoes exclusive *endo* cyclisation to give **3b–f**, but substrates **2g–j** bearing an activating substituent at the remote end of the acrylate double bond also undergo some *exo* cyclisation. Interestingly, the maleate ester **2h** and the corresponding fumarate **2g** cyclise with slightly different *endo* : *exo* ratios of 43 : 57 and 58 : 42, respectively. As measured approximately by NMR the ratio was 1 : 1 for cyclisation of **2i**. In an attempt to improve the *endo* : *exo* selectivity we examined the behaviour of the ester **2j**[9] bearing the bulky *tert*-butyl group. However, once again the **3j** : **4j** ratio was about 1 : 1.



Consideration of the competing reactions available to the various radicals involved in these cyclisations suggested that the



**Scheme 1**

formation of cyclised products should be improved by conducting the experiments with very low concentrations of both the iodoacrylate and $Bu_3SnH$, thus respectively decreasing of the formation of oligomers and the rate of hydrogen atom transfer to uncyclised radicals. Because such high dilution conditions require the use of very large quantities of solvent for the production of small amounts of products, they are of no interest for preparative purposes. However, the same effect was obtained by the separate slow addition with syringe pumps of both $Bu_3SnH$ and iodoacrylate to a solution of AIBN in benzene (method A). Under these conditions cyclised products were isolated in modest to good yield (Table 2). In an alternative procedure the precursors were heated with 1.1 molar equivalents of $Bu_3SnH$ (0.01 mol $dm^{-3}$), AIBN and sodium tosylate (method B). The role of the sodium tosylate is still uncertain but it certainly promotes cyclisation. Each of these methods is suitable for the convenient preparation of macrocyclic polyethers on a gram scale.

| Radical | $k_c \times 10^{-4}/s^{-1}$ | Radical | $k_c \times 10^{-4}/s^{-1}$ |
|---|---|---|---|
| **5b** | 15 ± 4 | **5c** | 13 ± 1 |
| **5d** | 5.1 ± 0.8 | **5e** | 10 ± 2 |
| **5f** | 3.0 ± 04 | | |

**Table 2** Formation of macrocyclic polyethers by radical cyclisation

| Substrate | Ring size | Products [yield (%)] |
|---|---|---|
| **2a** | 9 | **3a** |
| **2b** | 12 | **3b** (78[a]) |
| **2c** | 15 | **3c** (72[a], 78[b]) |
| **2d** | 18 | **3d** (70[a], 87[b]) |
| **2e** | 21 | **3e** (63[a], 90[b]) |
| **2f** | 24 | **3f** (30[a]) |
| **2g** | 12/11 | **3g** (37[a] **4g** (21[a]) |
| **2h** | 12/11 | **3h** (43[a,c]) **4h** (57[a,c]) |
| **2i** | 15/14 | **3i** (36[d]) **4i** (36[d]) |
| **2j** | 15/14 | **3j** (29[d]) **4j** (29[d]) |

[a] Method A (see text); isolated yields. [b] Method B (see text); yields determined by GC with an internal reference. [c] Relative yield; for this reaction the absolute yield was not determined. [d] Method B; total yield determined by GC; relative yields by NMR.

Finally we examined the preparation of macrocycles that do not contain a lactone group within the ring and hence should be able to survive robust manipulation of the side chain. Thus treatment of the ester **8** with $Bu_3SnH$ in the usual way gave **10** (64%) with a rate constant for cyclisation of $k_c = 2 \times 10^4\ s^{-1}$ at 80 °C, while **9** gave **11** (87%). An advantage of products such as **10** and **11** is that the side chain can be readily converted into functionality suitable for tethering the macrocycle to other ionophores or to fluorescent agents. Thus **11** readily underwent hydrolysis with KOH in methanol to afford the acid **12** (84%) while reduction with LAH in THF gave the alcohol **13** (79%).

In conclusion it appears that, as in the case of simple hexenyl species, the introduction of oxygen atoms into suitable long chain precursors enhances the rate of radical cyclisation sufficiently to allow the preparation of substituted macrocyclic polyethers in modest to good yield under convenient experimental conditions. These results therefore complement those describing other applications of radical macrocyclisation in synthesis.[10,11] Preliminary experiments indicate that some of the macrocyclic polyethers described above may be useful as complexing agents.

We gratefully acknowledge technical assistance from Mr Robert Longmore and the award of a Commonwealth Postgraduate Scholarship to K. D. and of a BDI Scholarship by CNRS and Région Aquitaine to A. P.

# Synthesis, characterization and photophysical properties of $[OsO_2(mes)_2(NC)Ru(bpy)_2(CN)]$

**Jack Y. K. Cheng, Kung-Kai Cheung and Chi-Ming Che***

*Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*

**A novel heterometallic complex comprising of a $d^2$ $OsO_2(mes)_2$ and a $d^6$ $Ru(bpy)_2(CN)_2$ fragment is prepared and characterized by X-ray analysis; its photophysical properties are measured.**

The design of new heterometallic complexes for photoinduced atom transfer reactions has received current interest. One of our approaches is to link a low-valent metal–polypyridine to a high-valent metal–oxo fragment *via* self-assembly reactions.[1] The former would serve as a good light absorber while the latter functions as an oxygen atom transfer agent.

In this context, the cyanide ion, which is known to form stable complexes with metal ions in both high and low oxidation states would be a good bridging ligand.[2] Described herein are the structure and photophysical properties of the first heteronuclear $Ru^{II}Os^{VI}$ $[OsO_2(mes)_2(NC)Ru(bpy)_2(CN)]$ **1** formed by reaction of $[OsO_2(mes)_2]$ (mes = mesityl)[3] with $[Ru(bpy)_2(CN)_2]$ (bpy = 2,2′-bipyridine).[2]

Upon slow evaporation of a solution of $[OsO_2(mes)_2]$ and $[Ru(bpy)_2(CN)_2]$ in dichloromethane–methanol at 0 °C, brown needle crystals† of **1** were obtained (yield 95%) and the structure was characterized by X-ray analysis.‡ Fig. 1 shows a perspective view of the molecule. The osmium atom adopts a distorted square-pyramidal geometry with an average Os–O distance of 1.700 Å and O–Os–O angle of 144.9(2)°. These are comparable to values of 1.720 Å and 147.5(3)° in the related complex $[\{OsO_2(mes)_2\}_2(pyz)]$[4] which has a square-pyramidal geometry at the Os atom. Although the measured N–C–Ru angle of 177.7(4)° is close to 180°, the Os–N–C angle of 160.5(4)° reveals that the Ru–C≡N–Os array is not quite linear. The N–C and Ru–C distances for the bridging cyanide are both 0.04 Å shorter than that of the terminal cyanide. The IR data are in accord with the X-ray structure with ν(C≡N) stretches at 2088.5 and 2072.8 $cm^{-1}$, at higher frequencies relative to $[Ru(bpy)_2(CN)_2]$ [ν(C≡N) 2067.4, 2052.9 $cm^{-1}$]. The ν(Os=O) stretches are at 893.1 and 884.6 $cm^{-1}$, which are comparable to the related value of 900 $cm^{-1}$ for $[\{OsO_2(mes)_2\}_2(\mu\text{-pyz})]$.

Complex **1** is soluble in common organic solvents such as dichloromethane and methanol. Similarly to the reported $[OsO_2(mes)_2L]$ complexes (L = 1,10-phenanthroline or *N*,*N*,*N*′,*N*′-tetramethylethylenediamine),[5] the equilibrium reaction [eqn. (1)] exists in solution and dissociation is suppressed by addition of an excess of $[OsO_2(mes)_2]$.

$$[OsO_2(mes)_2(NC)Ru(bpy)_2(CN)] \rightleftharpoons [OsO_2(mes)_2] + [Ru(bpy)_2(CN)_2] \quad (1)$$

Fig. 2 shows the absorption spectra of solutions of $[Ru(bpy)_2(CN)_2]$ in the presence of various concentrations of $[OsO_2(mes)_2]$. The MLCT band of $[Ru(bpy)_2(CN)_2]$ shifts to a higher energy (461 to 436 nm) upon addition of $[OsO_2(mes)_2]$ (0 to 10-fold excess). A similar experiment with $[Ru(bpy)_3]Cl_2$ has also been done but its MLCT band does not change even in the presence of tenfold excess of $[OsO_2(mes)_2]$. Thus the progressive blue shift is evidence for the formation of the dimeric species **1** in solution.[6]

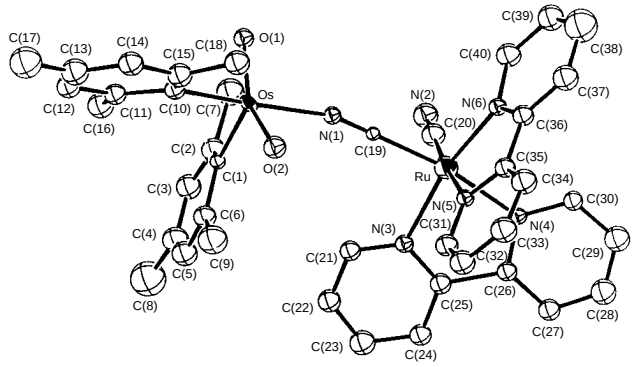

**Fig. 1** A perspective view of **1** (thermal ellipsoids at 40% probability level). Selected bond lengths (Å) and angles (°): Os–O(1) 1.704(3), Os–O(2) 1.696(3), Os–N(1) 2.235(4), Os–C(1) 2.063(5), Os–C(10) 2.108(4), Ru–N(3) 2.064(4), Ru–N(4) 2.113(4), Ru–C(19) 1.972(4), Ru–C(20), 1.992(4), N(1)–C(19) 1.143(6), N(2)–C(20) 1.145(6); O(1)–Os–O(2) 144.9(2), O(1)–Os–N(1) 88.5(1), O(1)–Os–C(1) 110.4(2), O(1)–Os–C(10) 91.5(2), N(1)–Os–C(1) 87.1(2), N(1)–Os–C(10) 173.4(2), C(1)–Os(1)–C(10) 99.1(2), C(19)–Ru–C(20) 89.5(2), Os–N(1)–C(19) 160.5(4), Ru–C(19)–N(1) 177.7(4), Ru–C(20)–N(2) 178.6(4).

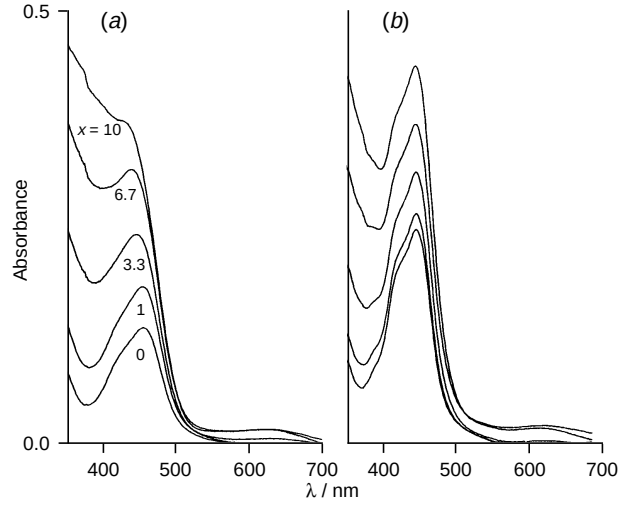

**Fig. 2** UV–VIS absorption spectra of (*a*) $[Ru(bpy)_2(CN)_2]$ ($2.0 \times 10^{-5}$ mol $dm^{-3}$) and (*b*) $[Ru(bpy)_3]Cl_2$ ($2.0 \times 10^{-5}$ mol $dm^{-3}$) at various concentrations of $[OsO_2(mes)_2]$. Ratio of the $OsO_2(mes)_2$ : Ru complexes = 1 : *x*.

Complex **1** in the solid state is non-emissive at 298 and 77 K. In solution, it gives an emission at the same energy as that of $[Ru(bpy)_2(CN)_2]$ measured under similar conditions. However, the lifetime and intensity of the emission are much reduced. Fig. 3 shows $\phi_0/\phi$ and $\tau_0/\tau$ *vs.* [quencher] plots for $[Ru(bpy)_2(CN)_2]$ and $[Ru(bpy)_3]Cl_2$ with $[OsO_2(mes)_2]$ as quencher ($\phi$ and $\tau$ are emission intensity and decay lifetime, respectively). It is interesting that the decay time Stern–Volmer quenching constant, $K_{SV}^{\tau}$ {deduced from the slope of the plot of $\tau_0/\tau$ *vs.* concentration of $[OsO_2(mes)_2]$} for both complexes are similar (1038 and 1098 $dm^3\ mol^{-1}$). The value of the Stern–Volmer quenching constant, $K_{SV}^{\phi}$ {deduced from the slope of the plot of $\phi_0/\phi$ *vs.* concentration of $[OsO_2(mes)_2]$} for $[Ru(bpy)_3]Cl_2$ (1842 $dm^3\ mol^{-1}$) is slightly larger than the $K_{SV}^{\tau}$ value, presumably this is due to the overlap of the absorption spectrum of $[OsO_2(mes)_2]$ with the excitation spectrum of $[Ru(bpy)_2(CN)_2]$. Interestingly, the Stern–Volmer plots for $[Ru(bpy)_2(CN)_2]$ are not linear and exhibits upward curvature characteristic of a system showing both static and dynamic quenching.[7] The static quenching is assigned to ground-state complex formation of $[OsO_2(mes)_2(NC)Ru(bpy)_2(CN)]$ from $[OsO_2(mes)_2]$ and $[Ru(bpy)_2(CN)_2]$ in solution. This heterometallic complex in the solid state is non-emissive suggesting that the long-lived emissive MLCT state of the $Ru(bpy)_2(CN)_2$ chromophore is completely quenched by the $OsO_2(mes)_2$ unit *via* the bridging cyano group. Because the $K_{SV}^{\tau}$ values for $[Ru(bpy)_3]Cl_2$ and $[Ru(bpy)_2(CN)_2]$ are similar, we propose that the dynamic quenching mechanism which represents the collision of $[OsO_2(mes)_2]$ and the excited ruthenium partner through diffusion would be outer sphere in terms of electron- and/or energy-transfer.

Previous studies showed that the $Ru(bpy)_2(CN)_2$ chromophore could be easily functionalized *via* cyanide bridge formation with a suitable choice of adducts [Pt(dien)[2b] or $Ru(NH_3)_5$[2b]] but Ru–CN–M (M = Lewis acid) adduct formation were found not to substantially modify the excited-state properties of the $Ru(bpy)_2(CN)_2$ chromophore.[2b,6] In this work, the excited state of **1** which localizes at the ruthenium centre should be MLCT in nature. This excited state is rapidly quenched by intramolecular energy and/or electron transfer pathways. If intramolecular energy transfer proceeds, the quenching product is $[OsO_2(mes)_2]$*. If intramolecular electron transfer proceeds, the quenching product is either the reduced or oxidized species of $[OsO_2(mes)_2]$. In any case, the energetic or reactive site shifts from ruthenium to the Os–oxo moiety. The rich oxidation chemistry and photochemistry of high-valent osmium–oxo complexes are well documented in literature.[9] Thus formation of an activated five-coordinate osmium–oxo complex through intramolecular electron- and/or energy-transfer would provide an entry to a new class of metal–oxo photooxidants with good light absorbing properties.

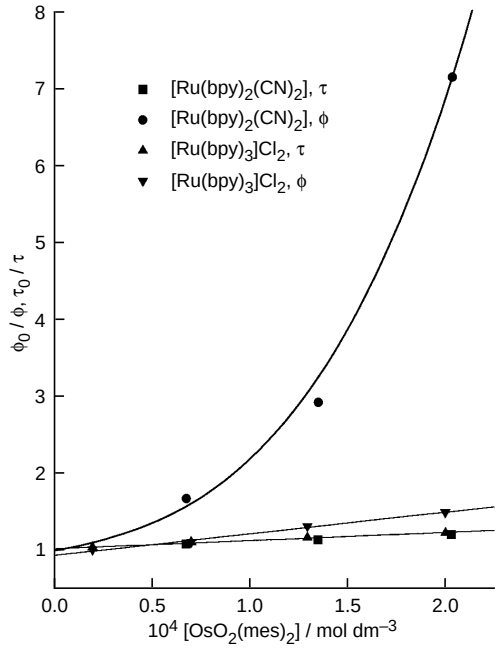

**Fig. 3** Plots of $\phi_0/\phi$ and $\tau_0/\tau$ *vs.* $[OsO_2(mes)_2]$ for complex **1**

## Footnotes

† A mixture of $[OsO_2(mes)_2]$ (60 mg, 0.13 mmol) and $[Ru(bpy)_2(CN)_2]$ (50 mg, 0.11 mmol) in dichloromethane–methanol (1 : 1, 10 ml) was stirred for 1 h. The solvent was slowly evaporated to dryness in a water bath (25 °C) to give a brown microcrystalline solid which was washed with diethyl ether (3 × 10 ml). This was recrystallized by slow evaporation of a dichloromethane–methanol mixture at 0 °C to afford brown needle crystals; yield 97 mg (95%). $^1$H NMR ($CD_3OD$): δ (bpy) 9.61 (d, 2), 8.52 (d, 2), 8.46 (d, 2), 8.09 (t, 2), 7.94 (t, 2), 7.58 (m, 4), 7.29 (t, 2), (mes) 6.92 (s, 4), 2.43, (s, 6), 2.32 (s, 12). IR ν(C≡N) 2088.5s, 2072.8s; ν(Os=O) 893.1s, 884.6s, 849.1m. Anal. Calc. for $C_{40}H_{38}N_6O_2OsRu$: C, 51.88; N, 9.08; H, 4.14. Found: C, 50.91; N, 8.90; H, 3.98%.

‡ *Crystal data*: $[C_{40}H_{38}N_6O_2OsRu{\cdot}2CH_3OH]$; $M_r$ = 990.133, monoclinic, space group $P2_1/c$ (no. 14), $a$ = 17.421(3), $b$ = 10.194(3), $c$ = 23.259(3) Å, β = 95.91(2)°, $U$ = 4108(1) Å$^3$, $Z$ = 4, $D_c$ = 1.601 g cm$^{-3}$, μ(Mo-Kα) = 35.03 cm$^{-1}$, $F$(000) = 1968, $T$ = 301 K. A brown crystal of dimensions 0.25 × 0.20 × 0.30 mm was used for data collection at 28 °C on a MAR diffractometer with a 300 mm image plate detector using graphite-monochromated Mo-Kα radiation (λ = 0.710 73 Å). 7804 unique reflections were obtained from a total of 33 227 measured reflections. 5747 reflections with $I > 3\ \sigma(I)$ were considered observed and used in the structural analysis. All 54 non-H atoms were refined anisotropically. Hydrogen atoms of the methanol molecules were not found but 38 H atoms of the complex molecule at calculated positions with thermal parameters equal to 1.3 times that of the attached C atoms were not refined. Convergence for 487 variable parameters by least-squares refinement on $F$ with $w = 4F_0^2/\sigma^2(F_0^2)$, where $\sigma^2(F_0^2) = [\sigma^2(I) + (0.018\ F_0^2)^2]$ for 5747 reflections with $I > 3\sigma(I)$ was reached at $R$ = 0.035 and $wR$ = 0.043 with a goodness-of-fit of 1.61 $(\Delta/\sigma)_{max}$ = 0.04 for atoms of the complex molecule. The final difference Fourier map was featureless, with maximum positive and negative peaks of 0.66 and 1.24 eÅ$^{-3}$ respectively. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference nubmer 182/350.

**The homoleptic, square-planar, $d^7$, 15-electron species $[NBu_4][Ni^{III}(C_6Cl_5)_4]$ 2 is obtained by low-temperature oxidation of $[NBu_4]_2[Ni^{II}(C_6Cl_5)_4]$ 1 with $Cl_2$.**

In the last few years the chemistry of $Ni^{III}$ has evolved very rapidly[1,2] partly because of its relevance to some metalloprotein systems.[3,4] In spite of this burgeoning development, organometallic compounds of $Ni^{III}$ are still extremely rare, the only isolated examples of this class of compounds being, to our knowledge, those reported by van Koten and coworkers.[5] They contain a single Ni–C bond and are stabilised by using polydentate ligands. We now report on the synthesis and characterisation of the first homoleptic organometallic nickel(III) compound, which contains four non-assisted Ni–C σ bonds.

Low-temperature chlorination of the substrate $[NBu_4]_2[Ni^{II}(C_6Cl_5)_4]$ **1**[6] renders the complex $[NBu_4][Ni^{III}(C_6Cl_5)_4]$ **2**, which has been isolated as a green solid in good yield.† Complex **2** is air- and moisture-stable but because of its rather limited thermal stability it is best formed and handled at low temperature. At room temperature it readily decomposes both in solution and in the solid state, undergoing reductive elimination of $C_6Cl_5$–$C_6Cl_5$.‡ This observation is of particular interest because of its relevance to the nickel-mediated synthesis of biaryls, which has been shown to proceed in some instances *via* unstable aryl intermediates of $Ni^{III}$.[7]

The **2**–**1** couple is not only chemically but also electrochemically related by a reversible redox process at a remarkably low potential ($E_{1/2}$ = −0.11 V).§ The IR spectrum of **2** shows the absorptions corresponding to the X-sensitive mode of the $C_6Cl_5$ group and to the ν(Pt–C) mode[8] at higher wavenumbers than those observed for the nickel(II) parent compound (*cf.* **1**, 813 and 581 $cm^{-1}$; **2**, 827 and 603 $cm^{-1}$, respectively). This shift can be associated with the increase in the oxidation state of the metal centre in keeping with previous observations in the perhalogenophenyl chemistry of palladium and platinum.[8a,9]

The structure of the anion $[Ni^{III}(C_6Cl_5)_4]^-$ as found in the diethetate **2**·2$Et_2O$ by X-ray diffraction methods is shown in Fig. 1.¶ The Ni atom is in an almost square-planar environment. The $C_6Cl_5$ groups define a helix around the metal centre with two possible orientations, Δ and Λ, both of which are present in the crystal measured (centrosymmetric space group). The mean dihedral angle formed by the $C_6Cl_5$ groups and the coordination plane is 63.2(3)°. The mean Ni–$C_{ipso}$ distance [200.7(8) pm] is slightly longer than found in other pentachlorophenyl derivatives of $Ni^{II}$ (mean value 192.2 pm).[10] This seeming elongation is at variance with the expected dependence of the M–C distance on the oxidation state of M. This difference, however, must be treated with caution because it could merely be due to the recently demonstrated flexibility of bond distances.[11] The EPR spectrum of a powder sample of **2** is given in Fig. 2‖ in which two features can be observed: one at *ca.* 340 mT having a parallel character and the other one at *ca.* 230 mT having a perpendicular character. This spectrum can be interpreted as due to a paramagnetic $S$ = 1/2 entity in an axial symmetry including only an anisotropic electronic Zeeman interaction and can be described with the following spin-Hamiltonian $H = \mu_B[g_\perp(S_xB_x + S_yB_y) + g_\parallel S_zB_z]$, where $\mu_B$ is the Bohr magneton and $g_\parallel$ = 1.92 and $g_\perp$ = 2.84. This would imply a low-spin (strong ligand field) situation for the $3d^7$ ion. Since the $Ni^{III}$ centre in **2** is in a square-planar environment, the unpaired electron should be expected to occupy an $a_{1g}$ ($z^2$) orbital.[12] In terms of the crystal-field approximation, a second order of perturbation for such an ion would give $g_\parallel = g_e$ and $g_\perp = g_e - 6\lambda/\Delta$, where λ is the spin–orbit constant and Δ the difference in energy between the $a_{1g}$ ($z^2$) and $e_g$ (*xz*,*yz*) orbitals. Since $\lambda < 0$ for $Ni^{III}$, the former expression predicts that $g_\perp > g_e$ while $g_\parallel$ lies close to the free-electron value in agreement with our observation.** This behaviour is in keeping with that reported for other nickel(III) species,[13] the only remarkable feature being in our case the high *g* anisotropy observed.

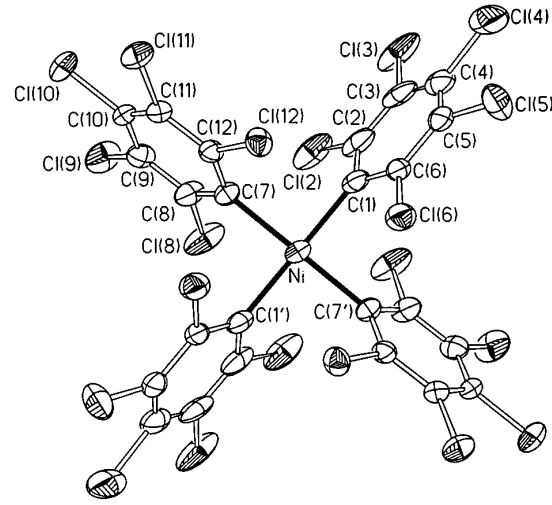

**Fig. 1** Thermal ellipsoid diagram of the anion of **2**. Selected distances (pm) and angles (°): Ni–C(1) 200.1(8), Ni–C(7) 201.4(7); C(1)–Ni–C(7) 90.1(3), C(1)–Ni–C(1′) 178.6(5), C(7)–Ni–C(1′) 90.0(3), C(7)–Ni–C(7′) 178.9(4).

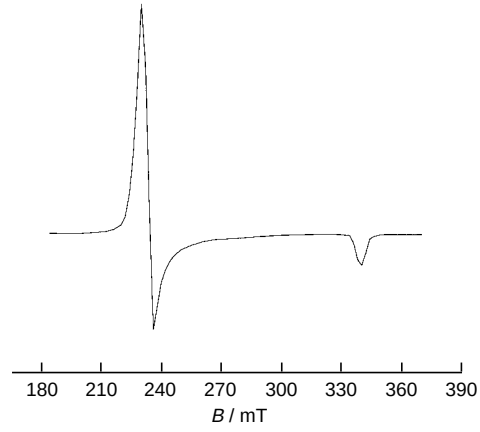

**Fig. 2** EPR spectrum of a powder sample of **2** (X-band, 77.3 K)

It can be concluded that the pentachlorophenyl group is a ligand especially well suited to stabilising unusual oxidation states, at least in the platinum-group metals.[9,14] Studies aimed at testing the reactivity of this unprecedented nickel(III) compound are in progress.

We thank the Dirección General de Enseñanza Superior (Projects PB95-0003-CO2-01 and PB95-0792) for financial support.

## Footnotes

† *Experimental procedure*: to a yellowish suspension of $[NBu_4]_2[Ni^{II}(C_6Cl_5)_4]$ **1** (0.5 g, 0.32 mmol) in $CH_2Cl_2$ (7 $cm^3$) at −40 °C was added $Cl_2$ dissolved in $CCl_4$ (0.18 mmol). The system changed immediately to green and, after addition of MeOH (20 $cm^3$) at −80 °C, the resulting green solid was filtered off in a low-temperature device, subsequently washed with cold $Et_2O$ (3 × 10 $cm^3$) and dried (**2**, 70% yield). Anal. Found: C 36.5, H 2.8, N 1.1; $C_{40}H_{36}Cl_{20}NNi$ requires: C 37.0, H 2.8, N 1.1%. IR(Nujol; $cm^{-1}$): selected absorptions associated with the $C_6Cl_5$ groups:[8] 827vs (X-sensitive vibr.), 675vs, 603s [ν(Pt–C)] and 275m.

‡ The fate of the metal-containing fragment could not be determined so far and hence we still do not know whether this reductive elimination process takes place inter- or intra-molecularly.

§ The cyclic voltammogram of **1** at 100 mV $s^{-1}$ scan rate in 0.1 M $NBu_4PF_6$ shows $E_{pa}$ = −0.055 V and $E_{pc}$ = −0.168 V *vs*. SCE.

¶ *Crystal data* for **2**·2$Et_2O$: $C_{48}H_{56}Cl_{20}NNiO_2$, $M$ = 1446.65, monoclinic, space group $C2/c$ (no. 15), $a$ = 1987.3(2), $b$ = 2167.8(1), $c$ = 1487.2(1) pm, β = 110.026(5)°, $U$ = 6.031(2) $nm^3$, $Z$ = 4, $F$(000) = 2940, $D_c$ = 1.593 g $cm^{-3}$, λ(Mo-Kα) = 71.073 pm, 344 parameters refined with 5300 reflections with $I > 2\sigma(I)$ to $R$ = 0.0736, $R_w$ = 0.1577. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/365.

‖ EPR data were taken on a Varian E-112 spectrometer working in the X-band. Measurements at liquid-nitrogen temperature (77.3 K) were taken using a quartz immersion Dewar. The magnetic field was measured with a Bruker ER035M gaussmeter. The diphenylpicrylhydrazyl resonance signal [$g$ = 2.0037(2)] was used to determine the microwave frequencies.

** Other contributions such as charge-transfer, covalency, *etc*. can modify the principal $g$-values so as to make the crystal-field description inadequate. In fact, either positive or negative $g$-shifts are observed for square-planar low-spin $d^7$ complexes.[12]

# Selective transformations of alkynes with ruthenium catalysts

**Christian Bruneau and Pierre H. Dixneuf***

*Laboratoire de Chimie de Coordination et Catalyse, URA CNRS 415, Université de Rennes, Campus de Beaulieu, 35042 Rennes, France*

**The electrophilic activation of terminal alkynes by suitable ruthenium(II) catalyst precursors has provided selective access to enol esters, functional dienes, ketoesters and furans. The step-by-step modification of the ligands of simple complexes such as (arene)$RuCl_2(PR_3)$, $[Ru(\mu\text{-}O_2CH)(CO)_2(PR_3)]_2$ or (diphosphine)$Ru(allyl)_2$, has allowed the determination of efficient catalytic conditions for regio- and stereo-selective additions to alkynes. The utilization of electron-rich ruthenium(II) complexes containing the bulky pentamethylcyclopentadienyl ligand, has made possible the catalytic carbon–carbon bond forming reaction from alkynes and allyl alcohol to give unsaturated aldehydes.**

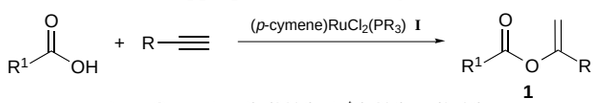
## Introduction

Transition-metal complexes are powerful catalysts for organic synthesis and polymerization, for when the suitable ligands are associated with the metal centre, they can offer chemio-, regio- or stereo-selectivity under mild conditions. During the last decade, ruthenium catalysts have brought a tremendous contribution to organic synthesis not only for enantioselective hydrogenation with chiral ruthenium complexes[1] or for mild oxidation reactions,[2] but also for the activation of simple unsaturated hydrocarbon molecules to produce functional derivatives[3–5] or polymers,[6] thus avoiding the use of toxic reagents. As ruthenium catalysts tolerate most functional groups they have been used to promote new methods for carbon–heteroatom and carbon–carbon bond formation by combination of two substrates with atom economy.[7]

Our experience in the stoichiometric activation of alkynes by organoruthenium derivatives[8] has offered an evaluation of the electrophilicity of ruthenium(II) precursors in activation processes. These studies have aided progress towards the field of catalysis for the selective transformation of alkynes for which several aspects have been considered: (i) the study of simple catalytic additions to alkynes provided by electrophilic activation with ruthenium(II) complexes in order to achieve excellent regioselectivity and avoid the formation of by-products; (ii) the possibility of step-by-step modification of the catalyst, by using tunable ligands, in order to create activity at the metal centre and favour regioselectivity; and (iii) the formation from alkynes of simple reagents that are useful synthetic intermediates or polymer precursors.

Here, we describe some aspects of ruthenium-catalysed syntheses: the Markovnikov and *anti*-Markovnikov additions to alkynes, the synthesis and uses of the resulting enol esters, the recovery of the ruthenium catalysts, the stereoselective transformation of prop-2-yn-1-ols and the synthesis of functional furans, dienes or unsaturated aldehydes. All these reactions are performed using air-stable ruthenium catalysts which can be easily prepared and used in organic synthesis.

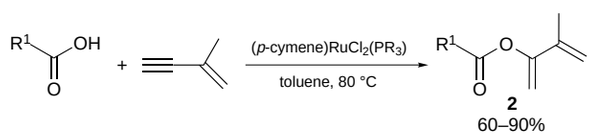
## Ruthenium-catalysed synthesis of enol esters *via* selective addition of carboxylic acids to alkynes



Enol esters have specific industrial applications as monomers for the production of various polymers and copolymers.[9] They are also useful reagents for carbon–carbon and carbon–heteroatom bond formation *via* the generation of enolates or acylation reactions. Although mercury(II)-assisted carboxylation of alkynes[10] constitutes an efficient route to enol esters, an environment-friendly process would be preferred. We have considered the possibility of electrophilic activation of alkynes by ruthenium(II) complexes towards the addition of carboxylates. While $RuCl_3 \cdot xH_2O$ can be used to catalyse the addition of carboxylic acids to phenylacetylene at 120 °C with no regioselectivity,[11] by contrast, (arene)$RuCl_2(PR_3)$ **I** complexes emerged as very efficient catalysts for the regioselective Markovnikov addition of carboxylates to the internal carbon of the triple bond of terminal alkynes, and the production of alk-1-en-2-yl esters **1** (Scheme 1).[11,12] A variety of carboxylic acids can thus be added directly to aliphatic alkynes such as hex-1-yne and propyne at 80–100 °C in toluene.

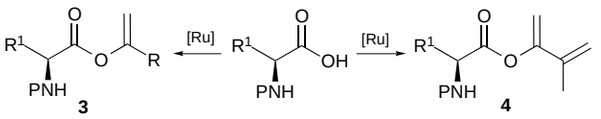
The ruthenium-catalysed addition of carboxylic acids has been used for the production of functional dienes, the 2-acyloxy-1,3-dienes **2** from conjugated enynes (Scheme 2).[13]

In the presence of (arene)$RuCl_2(PR_3)$ catalysts, these reactions took place under mild conditions and without racemization of the substrates. Thus, the addition of optically pure *N*-protected aminoacids led to optically pure *N*-protected amino acid enol **3**[14] and dienol **4**[13] esters in good yields and high regioselectivity (Scheme 3).



### *Uses of enol esters as acylation reagents*

Enol esters have been used in a variety of reactions involving carbon–carbon bond formation, such as acylation of carbonyl compounds,[15] palladium-catalysed allylation,[16] arylation[17] and aldol-type condensation,[18] cyclopropanation,[19] Diels–Alder cycloaddition[20] and hydroformylation.[21] However, the most widespread use of enol esters in organic synthesis is in the acylation of alcohols and amines,[22] including enzymatic chemistry.[23] Alk-2-enyl esters are much more reactive than alkyl esters and can be used as efficient acylating reagents. In addition, they release a neutral ketone as the only by-product and therefore are appropriate for the acylation of substrates

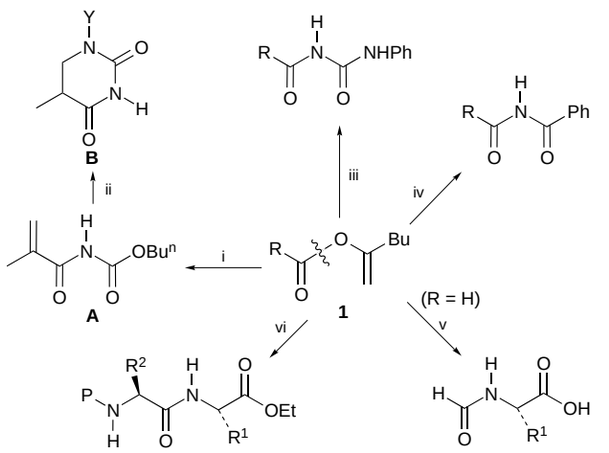


R = *n*-$C_4H_9$; R = Ph (92%), $Bu^t$ (78%), H (94%)
R = Me; R = Ph (87%), $C_6H_4Cl$-*p* (58%)

**Scheme 1**

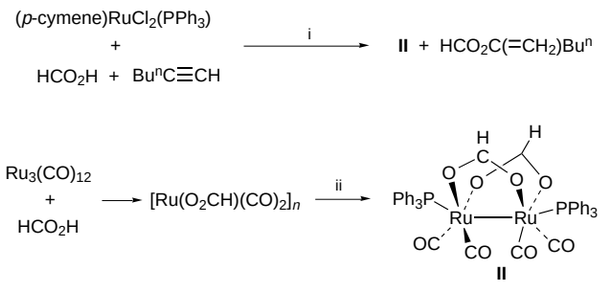
**Scheme 2**

P = Boc ($Bu^tO_2C$-) or Z ($PhCH_2O_2C$-)



**Scheme 3**

sensitive to acids (from acyl chloride or anhydrides) or bases (such as dimethylaminopyridine).

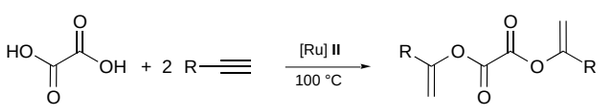


Thus, hex-1-en-2-yl formate is an efficient and easy-to-handle formylating reagent for the preparation of formamides at room temperature from primary and secondary amines, and esters from alcohols at 50 °C in the presence of catalytic amounts of imidazole (Scheme 4).[24] The *N*-formylation of unprotected amino acids was also possible in THF at 70 °C, and formyl-leucine, -alanine, -phenylalanine and -glycine were prepared in 84, 91, 87 and 91% isolated yields, respectively. Esters of amino acids were also efficiently acylated by enol esters derived from *N*-protected amino acids to produce dipeptides.[25] Compounds of the type $H_2NC(O)Y$ (Y = alkyl, aryl, OR, $NR_2$), which could not be acylated by enol esters, react upon the addition of a stoichiometric amount of NaH, allowing the one-pot acylation of amides, carbamates and ureas in high yields.[26] Of special interest is the butyl methacryloylcarbamate **A**, which reacts readily with primary amines to afford dihydropyrimidinediones **B** (Scheme 4).[27]

However, (arene)$RuCl_2(PR_3)$ **I** complexes were not efficient catalysts for the addition of oxalic acid and α-hydroxy acids to terminal alkynes. The use of the binuclear derivative $[Ru(O_2CH)(CO)_2(PPh_3)]_2$ **II**, an easy-to-handle, air-stable ruthenium complex produced by treatment of (*p*-cymene)-$RuCl_2(PPh_3)$ with formic acid in the presence of hex-1-yne or by reaction of $[Ru(O_2CH)(CO)_2]_n$ with $PPh_3$[26] according to Scheme 5, made possible the addition of oxalic acid to hex-1-yne and propyne at 100 °C to afford dihex-1-en-2-yl **5** and diisopropenyl **6** oxalates, respectively (Scheme 6).[28] Compounds **5** and **6** actually led to a variety of α-dicarbonyl compounds by stepwise reactions with alcohols (**C**), amines (**D**) or aminoalcohols (**E**) (Scheme 7).

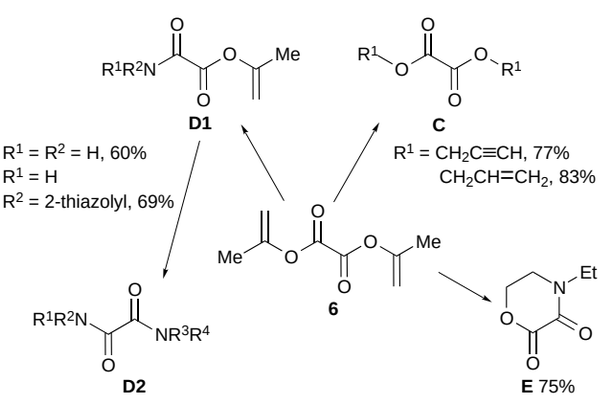
Mandelic acid could also be added to alkynes in the presence of **II** to afford alk-1-en-2-yl mandelates **7** in THF, whereas

**Scheme 4** Acylation of nucleophiles with enol esters. *Reagents and conditions*: i, NaH, $H_2NCO_2Bu^n$, room temp.; ii, Y-$NH_2$, room temp.; iii, NaH, $H_2NCONHPh$, room temp.; iv, NaH, $H_2NCOPh$, room temp.; v, $H_2NCHR^1CO_2H$, THF, 70 °C; vi, $H_2NCHR^1CO_2Et$, KCN (cat.), room temp.



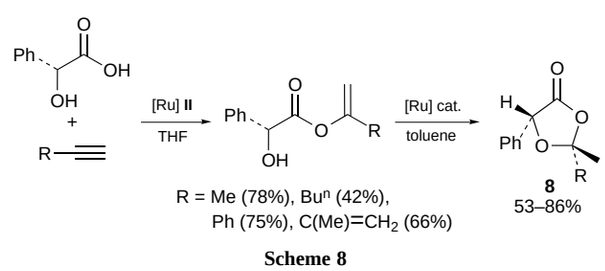
**Scheme 5** Preparation of complex **II**. *Reagents and conditions*: i, 60 °C; ii, $PPh_3$, $Et_2O$, reflux, 4 h.

dioxolanones **8** were formed stereoselectively in toluene *via* a subsequent ruthenium(II) electrophilic activation of the double bond of the enol ester **7** towards the addition of the hydroxy group (Scheme 8).[29]

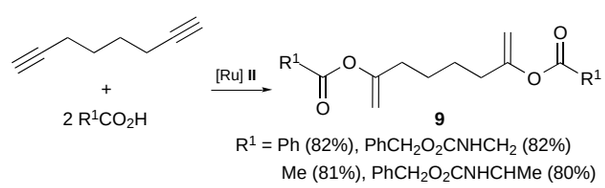


$[Ru(O_2CH)(CO)_2(PR_3)]_2$ complexes appeared to be the best catalysts for the Markovnikov addition of carboxylic acids to unfunctionalized alkynes, especially the terminal unconjugated octa-1,7-diyne which was transformed into the dienyl esters **9** in >80% isolated yields after reaction at 80 °C for 8 h (Scheme 9).

Alkenylruthenium complexes, such as (hexamethylbenzene)RuCl($PMe_3$)[C(OMe)=CHR] **III** (R = Me, Ph), prepared from the reaction of ($\eta^6$-$C_6Me_6$)$RuCl_2(PMe_3)$ with terminal alkynes in the presence of $NaPF_6$ in methanol followed by deprotonation with $Bu^tOK$, also appeared to be very good catalyst precursors. These alkenylruthenium complexes were very efficient for the preparation of dioxolanones **8** with good diastereoselectivity.[30] They were particularly active for the preparation of enol **10** and dienol **11** methacrylates (Scheme 10), both of which are excellent precursors for the preparation of polymers by copolymerization and polycondensation, respectively.[30]



For the above reactions to be economically useful, easy recovery of the ruthenium catalyst is required. A simple solution



**Scheme 6**

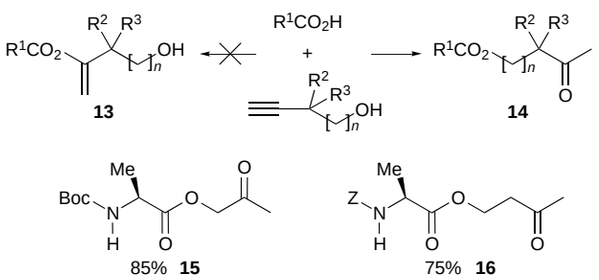
**Scheme 7**

**Scheme 8**

**Scheme 9**

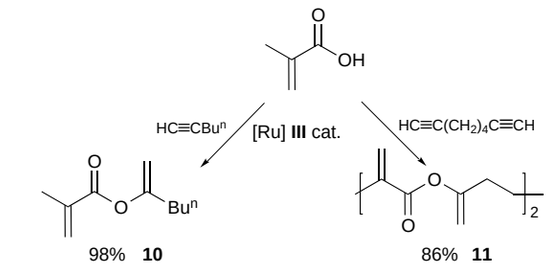
was found to be modification of the solubility of the ruthenium catalyst. The easy coordination of the polymeric diphenylphosphinoalkane $Ph_2P(CH_2CH_2)_nCH_2CH_3$, prepared by BuLi-initiated polymerization of ethene followed by reaction with $Ph_2PCl$, led to the preparation of the binuclear ruthenium complex $[Ru(O_2CH)(CO)_2\{Ph_2P(CH_2CH_2)_nCH_2CH_3\}]_2$.[31] This complex (**IV**; $n$ = 50) was soluble in toluene at 100 °C and catalysed the addition of carboxylic diacids to terminal alkynes (Scheme 11). When the reaction mixture was cooled to room temperature the complex became insoluble, the diester **12** was isolated and the catalyst could be recovered unchanged by simple filtration and used again at least six times without loss of activity and regioselectivity.

### *Mechanism*



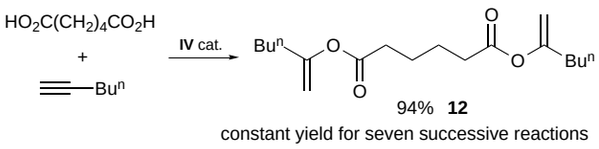
Although the catalytic mechanism has not yet been determined fully, an important feature for the addition of the carboxylate to C(2) of terminal alkynes is the presence of a monophosphine coordinated to the ruthenium centre. The nature of the phosphine does not seem to be crucial, as $PMe_3$, $PBu_3$ and $PPh_3$ led to similar results. We have shown by performing cross-reactions that the carboxylate ligand attached to the ruthenium centre in either $[Ru(O_2CR)(CO)_2(PPh_3)]_2$ or (arene)Ru-$Cl(O_2CR)$ complexes did not add to the alkyne, but only to the carboxylate generated from the free carboxylic acid used as reagent. The fact that the reaction proceeds *via* external attack of the nucleophilic carboxylate to the electrophilically activated alkyne rules out the possibility of insertion of the triple bond into an Ru–O(carboxylate) bond.

### Catalytic synthesis of ketoesters



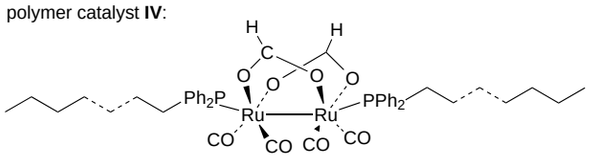
The ruthenium(II)-catalysed addition of carboxylic acids to prop-2-ynylic and but-3-ynylic alcohols did not lead to the expected hydroxy enol esters **13**, but to ketoesters **14** (Scheme 12).[32] At 60 °C, (arene)$RuCl_2(PPh_3)$ complexes catalysed the addition of N-protected amino acids to prop-2-ynylic[33] and but-3-ynylic[32] alcohols to give β-oxopropyl **15** and γ-oxobutyl **16** esters without racemization. For the addition of carboxylic acids to sterically hindered alkynols, the use of $[Ru(O_2CH)(CO)_2(PPh_3)]_2$ **II** was required, as exemplified by the selective transformation of steroids **17** containing both an alkynyl and a hydroxy group attached to C(17). In that case, the addition took place without racemization and with retention of the configuration of C(17) and led to steroids **18** (Scheme 13).[34] The mechanism of this reaction involves the addition of the carboxylate to C(2) of the alkyne followed by internal transesterification. When the geometry of the starting hydroxy alkyne did not allow the intramolecular transesterification, hydroxylated enol esters were formed. This was confirmed by the addition of carboxylic acids to (*E*)-3-methylpent-2-en-4-yn-1-ol, which selectively afforded the hydroxylated 2-carboxy-1,3-dienes **19** in good yields (Scheme 14).[32]

### Catalytic synthesis of furans

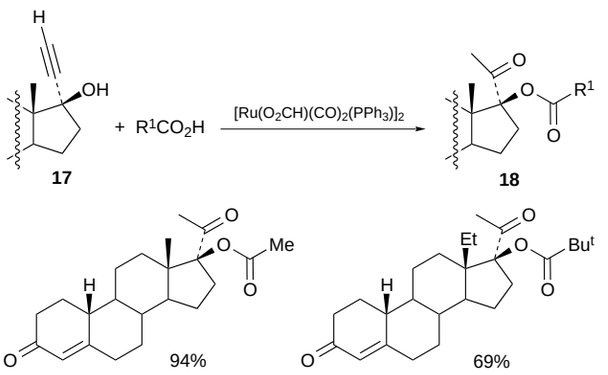


(*Z*)-3-Methylpent-2-en-4-yn-1-ol has suitable geometry for the intramolecular addition of the hydroxy group to the triple bond, under electrophilic ruthenium-catalysis conditions. Indeed, at 60 °C in the presence of a catalytic amount of (*p*-cymene)Ru-$uCl_2(PPh_3)$ **I**, furan **20** was formed selectively (Scheme 15),resulting from cyclization of the starting enynol.[35] This reaction, which took place under neutral conditions, corresponded to the first ruthenium-catalysed Markovnikov intramolecular addition of a hydroxy group to a non-activated terminal triple bond. We have shown that the absence of a base and the relatively low reaction temperature ( < 110 °C) made

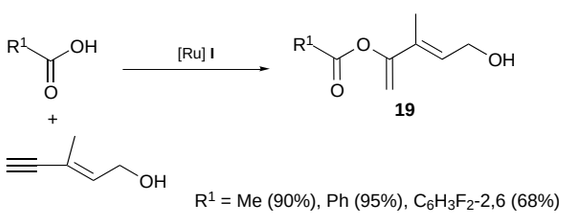
**Scheme 12**



**Scheme 10**



constant yield for seven successive reactions



polymer catalyst **IV**:

**Scheme 11**

**Scheme 13**

**Scheme 14**

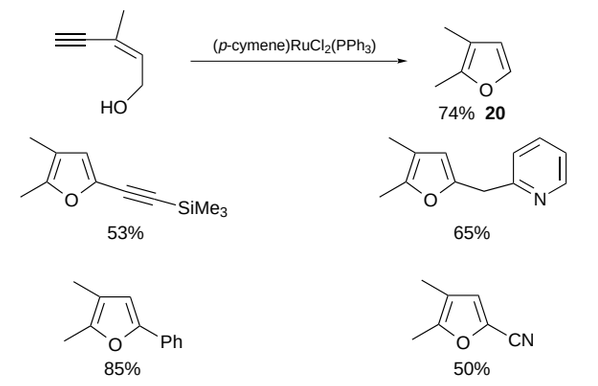
possible the cyclization of enynols containing trimethylsilylethynyl or cyanide groups,[36] the starting (*Z*)-enynols being easily prepared by reaction of organometallic derivatives with the corresponding (*Z*)-aldehyde resulting from the oxidation of the unsubstituted (*Z*)-enynol.

### Synthesis of (*Z*)-enol esters: *anti*-Markovnikov addition of carboxylic acids to alkynes

After developing the catalytic Markovnikov addition of carboxylic acids to terminal alkynes, it became a challenge to perform the *anti*-Markovnikov addition corresponding to the reverse regioselectivity. The idea was to generate vinylidene–ruthenium species able to make the terminal carbon of the alkyne electrophilic. Such an example of activation of terminal alkynes was shown in the regioselective synthesis of vinylic carbamates **21** by the reaction of secondary amines, $CO_2$ and terminal alkynes in the presence of (arene)$RuCl_2(PR_3)$ catalyst precursor (Scheme 16), which can be explained *via* the formation of a ruthenium–vinylidene [Ru=C=CHR$^1$] active species.[37]

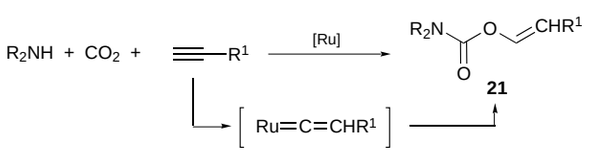
Our approach to the reversal of the regioselectivity of the addition to alkynes was to modify the ruthenium catalysts, first by introducing hydrocarbon ligands, labile under acidic conditions, to provide vacant coordination sites, and secondly by replacing the monophosphine ligands by bidentate diphosphines which are known to stabilize intermediate organometallic catalytic species. New ruthenium complexes containing two allylic ligands and a tunable diphenylphosphinoalkane were prepared according to a known method (Scheme 17).[38]

The step-by-step lengthening of the hydrocarbon chain from one to four carbons between the two diphenylphosphino groups made it possible to observe important differences in the catalytic behaviour of these catalyst precursors. The complex (dppb)Ru(2-methylallyl)$_2$ was shown to be the best catalyst precursor, in terms of reactivity and regioselectivity, for the addition of benzoic acid to the C(1) of terminal alkynes in good yields in toluene at 65 °C (Table 1).[39]



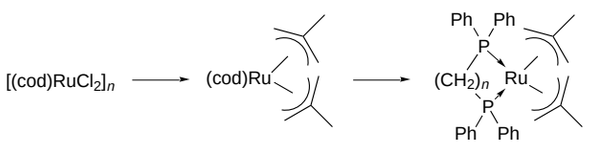
Moreover, the stereoselectivity was excellent and (*Z*)-enol esters of type **22** could be obtained in > 95% stereoselectivity (Scheme 18). The regio- and stereo-selectivities of this addition were very dependent on (i) the bulkiness of both the carboxylic acid and the alkyne, (ii) the reaction temperature, and (iii) the acidity of the carboxylic acid. In general terms, we have shown that the lower the reaction temperature, the higher the regio- and stereo-selectivities, but a minimum temperature had to be found to obtain a reasonable reaction rate.[40]

Saturated and unsaturated aliphatic acids, and substituted aromatic acids have allowed the preparation of a variety of new (*Z*)-enol esters upon addition to hex-1-yne and phenylacetylene. The absence of racemization under mild temperature conditions made it possible to synthesise optically pure (*Z*)-enol amino acid esters **23** from N-protected amino acids. In the presence of catalytic amounts of (dppb)Ru(2-methylpropenyl)$_2$, this reaction could be extended to octa-1,7-diyne to stereoselectively produce (*Z*,*Z*)-1,8-dienyl esters **24**, by contrast to the isomers **9**. This *anti*-Markovnikov addition could be extended to conjugated enynes when bulky carboxylic acids were used. The most efficient catalyst precursor was (dppb)Ru(2-methylallyl)$_2$ which led to 1-carboxy-1,3-dienes **25** at 40–65 °C in good yields and very high stereoselectivity with benzoic and *N*-protected amino acids (Scheme 19).



The addition of carboxylic acids to trimethylsilylacetylene was also possible in the presence of (dppb)Ru(2-methylpropenyl)$_2$ as catalyst precursor, but in this special case, the bulkiness of the alkyne allowed a more rapid reaction at 50–60 °C in the presence of (dppe)Ru(2-methylallyl)$_2$ as catalyst, affording functional trimethylsilylated alkenes in > 98% regio- and stereo-selectivity. The same reactivity was observed in the addition to bulky methyl prop-2-yn-1-yl ethers. By using (dppe)Ru(2-methylpropenyl)$_2$ as catalyst precursor, the rate of the reaction could be improved drastically and 81% yield of the (*Z*)-benzoate **26** was obtained with 100% stereoselectivity for the (*Z*)-isomer (Scheme 20).

The presence of an additional functionality close to the triple bond did not affect the reaction; (*Z*,*Z*)-4-methoxybuta-1,3-dienyl esters **27** were prepared at 65 °C in toluene in the presence of (dppb)Ru(2-methallyl)$_2$ as catalyst precursor with stereoselectivities > 97% from (*Z*)-1-methoxybut-1-en-3-yne (Scheme 21).



It is noteworthy that (diphosphine)Ru(2-methylpropenyl)$_2$ complexes were not able to promote the regioselective addition of carboxylic acids to the terminal carbon of the triple bond of prop-2-ynylic alcohols. Only ketoesters were formed, indicating that the regioselectivity of the addition of carboxylic acids was influenced by the presence of the hydroxy group as with (*p*-cymene)$RuCl_2(PPh_3)$ or $[Ru(O_2CH)(CO)_2(PPh_3)]_2$. This

**Scheme 15**

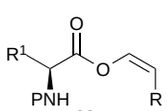
| $Ph_2PCH_2CH_2CH_2CH_2PPh_2$ (dppb) | 2.5 | 98 | 2 | 0 |

behaviour clearly exhibited the determinant role of the hydroxy group of alkynols.

This method offers the first stereoselective synthesis of (*Z*)-enol esters in one step from terminal alkynes and carboxylic acids. These (*Z*)-esters are formally masked aldehydes allowing the functionalization at C(1) of terminal alkynes: two equivalents of secondary amines reacted with (*Z*)-enol esters at room temperature to afford (*E*)-enamines **28** in very high yields (Scheme 22). This two-step synthesis of enamines from terminal alkynes and amines represents a complementary method to the mercury-catalysed addition of amines to alkynes which leads to enamines resulting from the addition of the amine to the internal carbon of the triple bond.

### Catalytic synthesis of unsaturated aldehydes and acetals: oxidative coupling of allyl alcohol with alkynes



The coupling of terminal alkynes with allyl alcohol promoted by $RuCl(PPh_3)_2(C_5H_5)$–$NH_4PF_6$ to afford unsaturated ketones has been demonstrated to result from the formation of the ruthenium–vinylidene intermediate $[Ru{=}C{=}CHR(PPh_3)(C_5H_5)]^+$, followed by the addition of the alcohol to the electrophilic carbene carbon atom.[41] We have shown that the use of an analogous ruthenium(II) catalyst, $RuCl(cod)(C_5Me_5)$ **V**, which contains a labile ligand (cod = cycloocta-1,5-diene) and an electron-donating, bulky $C_5Me_5$ group led to a quite different reaction. The carbon–carbon coupling of the C≡C and the C=C bonds led to the formation of γ,δ-unsaturated aldehydes **29a** and **29b** (Scheme 23).[42] It is noteworthy that the reaction can be carried out in water (allyl alcohol–water, 1 : 8) to achieve the best yields, and that the formation of the branched isomer was always favoured, it was the only product from the bulky *tert*-butylacetylene (Table 2).

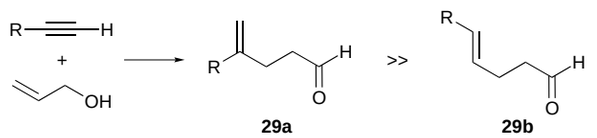
**Scheme 21**

**28**



**Scheme 22**

The reaction when applied to symmetrically substituted alkynes, constituted an excellent method for the production of the corresponding γ,δ-unsaturated aldehydes **30** (Scheme 24).[43] Moreover, it showed that the reaction was not restricted to terminal alkynes and did not involve a vinylidene intermediate. The experiments suggested that the mechanism involved the displacement of cod and the oxidative coupling of C≡C and C=C bonds to generate intermediate **F** or **G**. The bulkiness of the R group favoured the formation of **F** and thus that of isomer **29a**.

It is noteworthy that the ruthenium(IV) precursor, $RuCl_2(\eta^3\text{-}CH_2CH{=}CH_2)(C_5Me_5)$, also catalysed the above reaction. However, the precursor was expected to partially form ruthenium(II) species *via* the loss of allyl chloride, but in the presence of ruthenium(IV) species, the aldehydes were transformed into the corresponding acetals with allyl alcohol.

### Conclusion

The selective catalytic reactions described show that slight modifications of ruthenium(II) catalyst precursors allow the activation of alkynes, to achieve high regioselectivity in the

formation of carbon–heteroatom bonds. By contrast, the use of electron-rich ruthenium(II) complexes favours the formation of carbon–carbon bonds by oxidative coupling of C≡C and C=C bonds. The tolerance of ruthenium(II) complexes for functional groups, which we observed in the synthesis of enol esters, carboxydienes, ketoesters, steroids, furans and unsaturated aldehydes, may presage an important development of the use of ruthenium complexes in catalysis and polymerization in the near future.

**Christian Bruneau graduated as Engineer in chemistry in Rouen (1974) and obtained his Doctorate degree at the National School of Chemistry in Rennes (ENSCR). He was appointed research engineer at CNRS in 1980, and since 1986 he has been developing his research at the University of Rennes (URA CNRS 415) in the field of homogeneous catalysis by transition-metal complexes. His main research interests are in activation of alkynes, catalytic transformations of $CO_2$ and carbonates and enantioselective hydrogenation.**

**The recent research interests of Pierre Dixneuf are in the fields of activation of molecules by metal complexes, especially ruthenium derivatives, for selective organic catalysis and the design of unsaturated, carbon-rich organometallics. He was born in Anjou and studied in Rennes (Bretagne). He prepared his doctorate with Professor R. Dabard and did postdoctoral research in Brighton with Professor M. F. Lappert. Professor in Rennes since 1978, he is now the head of a Research Unit, associated with the CNRS, on molecular chemistry and electrochemistry: 'Organometallics and catalysis'. He has been honoured by the awards of the A. von Humboldt Foundation and the French Académie des Sciences. He is a 1996 Laureate of the JSPS (Japan) invited fellowship.**

# The trityl group as a removable steric buttress in cycloaddition reactions

**Nandeo Choony, Anjum Dadabhoy and Peter G. Sammes***

*Molecular Probes Unit, Department of Chemistry, Brunel University, Uxbridge, UK UB8 3PJ*

**The trityl group is utilised as an effective, temporary, steric buttress in an intramolecular Diels–Alder reaction between an alkene and furan ring.**

Steric buttresses have been utilised to accelerate intramolecular cycloaddition reactions but those used hitherto have not been readily removed.[1] Herein we report an example of steric buttressing as an aid to a cycloaddition reaction that is otherwise thermodynamically disfavoured; subsequent to the cycloaddition reaction the steric buttress may be removed.

The example involves the attempted cycloaddition of *N*-allylfurfurylamine **1** to the cycloadduct **2**. Heating compound **1** at various temperatures does not show any sign of the cycloadduct product **2**.† This lack of cycloaddition is consistent with several reported attempts at a range of similar intramolecular cycloaddition reactions between isolated alkene bonds and the furan ring.[2] For example, Gshwend *et al.* attempted to prepare the related cycloadduct **3** from the corresponding amide **4** but found that this spontaneously ring opened to form the allyated furfurylamine **5**.[3]

In previous work we have shown that cycloadditions may be encouraged by use of appropriate steric buttressing; an example is with compound **6**, which undergoes cycloaddition to the adduct **8**, whereas the parent compound **7**, in which the methyl buttresses are absent, does not undergo cycloaddition.[4]

We argued that, by restricting the degrees of conformational freedom in the reacting arms of compound **1**, cycloaddition would also be more favourable. The protected amine derivatives **9**–**12** were therefore prepared, using variably sized protecting groups, and their behaviour to cycloaddition examined. Solutions of the protected amines were heated at various temperatures (100–135 °C), monitoring for the appearance of the expected cycloadducts **13**–**16** and thermodynamic equilibration by use of $^1$H NMR spectroscopy.

Of the derivatives, the *N*-trityl derivative **9** showed the greatest degree of cycloaddition (97.5%) (Table 1). The cycloadduct **13** showed a consistent $^1$H NMR spectrum—loss of the allyl group and furan protons and replacement by the higher field protons of the tricyclic product. Use of the smaller benzhydryl protecting group, as in **10**, gave an approximately 50 : 50 ratio of cyclised product **14** to the uncyclised material at equilibrium and use of the benzyl derivatives **11** and **12** gave even less of the required cycloadducts.

The trityl group could be easily removed from the cycloadduct, by brief treatment with warm ethanolic hydrochloric acid,[5] to produce the secondary amine **2**. The latter amine was stable for considerable periods at room temperature but, on heating, reverted to the open form **1**. The stereochemistry about the bridgehead proton suggested the depicted stereoisomer was formed (Fig. 1).

**Table 1** Thermal equilibration of amines **1**, **9**–**12**

| Starting amine | Product[a] | Yield of product (%) isolated | Cyclisation conditions | Open : cyclic[b] |
|---|---|---|---|---|
| **1** | **2** | 0 | 110 °C, toluene, several days | 100 : 1 |
| **9** | **13** | 85 | 110 °C, toluene, 40 h | 2.5 : 97.5 |
| **10** | **14** | 35 | 135 °C, xylene, 34 h | 50 : 50 |
| **11** | **15** | —[c] | 135 °C, xylene, 60 h | 98 : 2 |
| **12** | **16** | —[c] | 135 °C, xylene, 60 h | 90 : 10 |

[a] Isolated by column chromatography. [b] Estimated by 360 MHz $^1$H NMR spectroscopy after thermal equilibration. [c] Isolation not attempted.

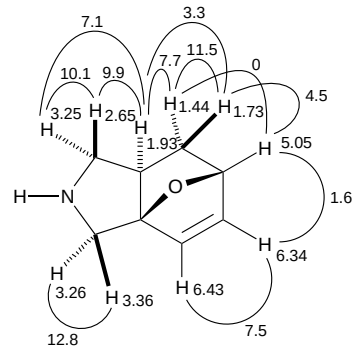

**Fig. 1** Chemical shifts and coupling constants for the amine **2**

As a cross-check, the cyclic amine **2** was also converted into the protected forms **14** and **15**; on heating these the thermal equilibrium between the open and closed forms was re-established.

Molecular models show that the trityl group and its derivatives are particularly bulky, thus restricting the conformational freedom of the diene and dienophile groups into ones where they are forced into close proximity. We are currently studying the use of the trityl group as a steric buttress in other modes of cycloaddition.

We thank the British Council for support of this work (to N. C.).

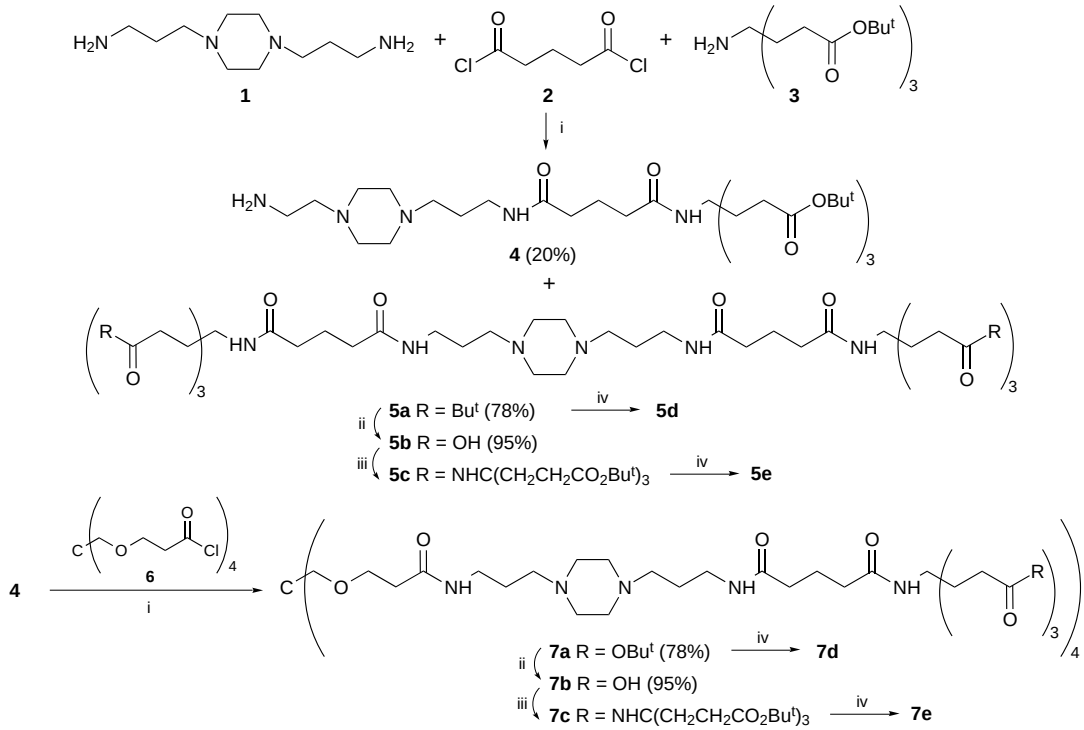
# Approaches towards specifically functionalized cascade macromolecules: dendrimers with incorporated metal binding sites and their palladium(II) and copper(II) complexes

**George R. Newkome,* Jens Groß, Charles N. Moorefield and Barry D. Woosley**

*Center for Molecular Design and Recognition, Department of Chemistry, University of South Florida, Tampa, Florida 33620-5250, USA*



**Construction of ligand functionalized branched building blocks has afforded entrance to a series of dendrimers possessing multiple, internally incorporated piperazine moieties, which readily form $Pd^{II}$ and $Cu^{II}$ complexes.**

Metallodendrimer coordination spheres,[1–6] which are not completely filled, are of particular interest with regard to utilitarian aspects. We herein report the synthesis of related two- (**5a**,**c**) and four-directional (**7a**,**c**) dendrimers possessing specifically localized piperazine subunits and their complexation to afford $Cu^{II}$ and $Pd^{II}$ complexes.

*N*,*N*′-Bis(3-aminopropyl)piperazine **1**, as the metal binding site,[7] and the tris(*tert*-butyl ester)[8] **3** are readily linked in a one-pot reaction with glutaric acid dichloride **2** to form the extended building block **4**† and the colourless, two-directional dendrimer **5a**† in moderate yields (20 and 30%, respectively; Scheme 1). Amidation of **4** with the tetrakis(acyl halide) **6**, prepared from the corresponding tetraacid,[9] afforded (78%) the related four-directional dodecaester dendrimer **7a**† as a colourless solid. Hydrolysis of the *tert*-butyl esters **5a** and **7a** using formic acid generated (> 95%) the corresponding 6- (**5b**)† and 12-acid (**7b**).† Reaction of these polyacids with building block **3** under typical peptide coupling conditions (DCC, 1-BHT)[10] transformed each to the corresponding next higher 18- (**5c**)† and 36-ester (**7c**)† homologues.

Stable, orange microcrystalline $Pd^{II}$ complexes (**5d**,**e**) were formed upon stirring solutions of the 6- (**5a**) and 12-ester (**5c**) in MeCN at 25 °C with added $Pd(MeCN)_2Cl_2$. $^{13}C$ NMR Spectra (Fig. 1) provide direct evidence of a successful complexation at the piperazine binding loci due to the appearance of a new set of signals; titration of the free ligands by controlled addition of the metal salt can be conveniently followed by the observation of these absorptions. Evidence for complexation is provided by significant downfield shifts (3 and 1.2 ppm) for the C1 and C2 piperazine carbon atoms; however, the upfield shift (1.8 and 0.2 ppm) for C4 and C5, respectively, as well as the shift ($\Delta\delta$ = 0.6 ppm) for the innermost amido carbonyls support a further contribution to the coordination sphere. It is postulated that for metal chelation, the piperazine ring adopts the boat conformation[11] facilitating an overall compression of the molecular framework (Fig. 2).

Broadened, equatorial and axial $^1H$ NMR signals of the uncomplexed, rapidly interconverting piperazine ring are enveloped by a triplet assigned to the adjacent aminomethyl moiety (shaded region; Fig. 3). Whereas in the metal-complexed ring, there is a downfield shifted signal attributed to

**Scheme 1** *Reagents and conditions*: i, $EtPr^i_2N$, THF, 25 °C, 24 h; ii, $HCO_2H$, 25 °C, 12 h, then 40–50 °C, 3 h; iii, DCC, 1-HBT, 25 °C, then DMF, amine **3**, 25 °C, 48 h; iv, $Pd(MeCN)_2Cl_2$, MeCN, 25 °C

the equatorial protons ($\Delta\delta$ = 1.4 ppm) with a concomitant upfield shifted signal for the axial protons ($\Delta\delta$ = 0.05 ppm); geminal coupling in each signal suggests a frozen bond configuration in the complex. The triplet assigned to the adjacent methylene moiety is observed to broaden and shift downfield. Further, participation of the more closely juxtaposed amido moiety is evident from an observed upfield shift of the amide proton ($\Delta\delta$ = 0.35 ppm); the more distant amide proton adjacent to the branching centre is only slightly shifted ($\Delta\delta$ = 0.04 ppm downfield) upon complexation.

Similar first order patterns ($^{13}$C NMR) are found for the metal-free four-directional dendrimers **7a** and **7c**; however, upon complexation, only at early stages of the addition of the Pd salt was the spectral data of interest. Compared to the NMR spectra of the two-directional dendrimers, the signals exhibit enhanced broadening attributed to the presence of four competing adjacent binding sites. As the metal : ligand ratio increases above 1.2 equiv. (4 : 1 maximum), the metal complexes become markedly less soluble in diagnostic solvents further inhibiting NMR complexation monitoring. After addition of 4 equiv. of Pd salt, the resultant bright yellow complex precipitates from MeCN.

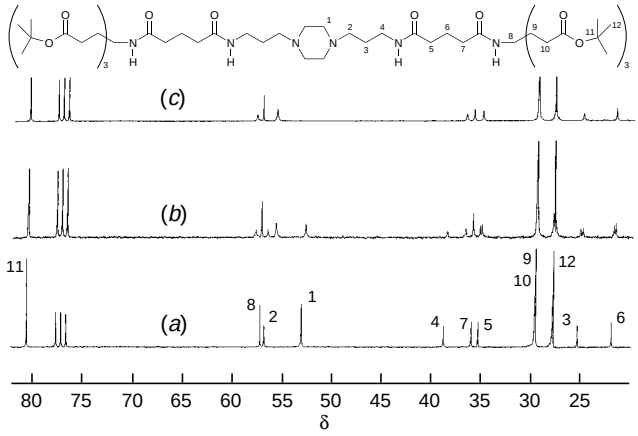


**Fig. 1** (*a*) $^{13}$C NMR Spectrum of the two-directional ligand **5a**; (*b*) with added 0.5 equiv. $PdCl_2(MeCN)_2$; (*c*) with 1 equiv. of $PdCl_2(MeCN)_2$

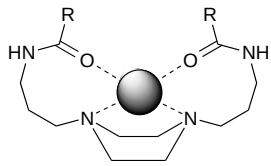

**Fig. 2** Pictorial representation of the metal centre depicting the interaction of the juxtaposed amido groups

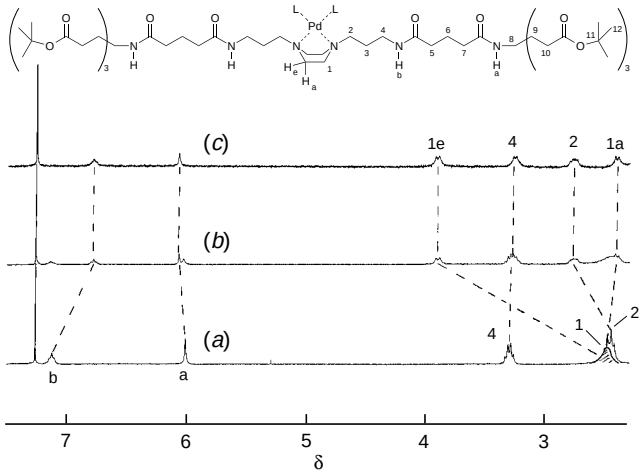

**Fig. 3** (*a*) Partial $^1$H NMR spectrum of ligand **5a** without added metal salt where the shaded region depicts H1 absorption for clarity; (*b*) with 0.7 equiv. of added $PdCl_2(MeCN)_2$; (*c*) with 1 equiv. of added $PdCl_2(MeCN)_2$

The related $Cu^{II}$ complexes were easily obtained by treating absolute EtOH solutions of either **5a,c** or **7a,c** with anhydrous $CuCl_2$ resulting in translucent olive-green solutions that exhibit excellent solubility in common organic solvents (*e.g.* $CHCl_3$). The signals ($^{13}$C NMR) do not significantly shift in contrast to those of the corresponding Pd complexes but significantly broaden and decrease in intensity due to presence of the new paramagnetic metal centre. For hexaester **5a** containing 1 equiv. of $Cu^{II}$ or dodecaester **7a** containing 4 equiv. of $Cu^{II}$, all of the internal carbon resonances disappear, while the outer carbon absorptions identifying the branching portion of these macromolecules remain as sharp, first-order patterns.

These specifically localized metal centres afford insight into their use as metallo-unimolecular micelles and metallospheres and superclusters,[12] as well as suggesting the use of dendrimers for ordered networks. Also, similarly constructed bipyridine-based dendrimers are currently under investigation.

# Chiral discrimination in the oxidation of ferrocenes by cytochrome c peroxidase

**Sheila J. Sadeghi,[a] Gianfranco Gilardi,[a] Giovanni Nicolosi[b] and Anthony E. G. Cass[a]†**

[a] *Department of Biochemistry, Imperial College of Science, Technology & Medicine, South Kensington, London, UK SW7 2AY*
[b] *Istituto per lo Studio delle Sostanze Naturali di Interesse Alimentare e Chimico-Farmaceutica, Valverde CT, Italy*

**Cytochrome c peroxidase shows a two-fold difference in its reaction rate with enantiomers of a chiral ferrocene; the enantiomeric selectivity is reversed by a single site specific change in the surface charge of the enzyme.**

Chiral recognition is a fundamental property of many biological molecules and many examples have been reported in the literature, including enzyme–substrate and ligand–receptor interactions.[1–3] Previous reports of chiral discrimination in electron transfer reactions between small redox proteins and chiral metal complexes have described small but significant differences in kinetic enantioselectivity (10–20%) which has been used to probe the pathway(s) of electron transfer.[4–6] Electron transfer between redox enzymes and small molecules has also been extensively studied in the context of electrochemical sensors[7–9] and ferrocenes have been particularly exploited in the role of mediators between enzymes and solid electrodes. Although differences in electron transfer rates are seen with different ferrocenes there does not appear to be a simple relationship between the structure of the mediator and its reactivity.[10] There is a clear dependence of the rate of protein-mediator electron transfer on both the redox potential difference and the nature of the group(s) substituting the cyclopentadienyl rings. One particular feature of ferrocenes that has not been explored with respect to the kinetics of electron transfer is their property of planar chirality when substituted with two different groups on the same cyclopentadienyl ring. Previously it has been shown that lipases can distinguish between two enantiomers in the esterification of ferrocenyl alcohols.[11] We report here the significant chiral discrimination shown by the enzyme cytochrome c peroxidase (CCP) with two ferrocene enantiomers and the reversal of this chiral specificity by a site specific change in the surface charge on the protein.

The yeast CCP used in this work was expressed in *E. coli*, purified by a previously published method[12] and had a turnover number (horse heart cytochrome as the substrate) of 200 $s^{-1}$. The mutation of a surface aspartate residue to a lysine residue employed the polymerase chain reaction and was confirmed by DNA sequencing. The synthesis of both (*S*)- and (*R*)-1-hydroxymethyl-2-dimethylaminomethylferrocene (HMDMF) was as described by Nicolosi *et al.*[13] Rates of reaction between the two enantiomers of HMDMF and CCP were estimated by cyclic voltammetry. Both enantiomeric ferrocenes exhibited quasi-reversible one-electron voltammograms with mid-point potentials of 390 mV (*vs.* SCE), a peak separation of 61 mV, peak currents proportional to the square root of the potential sweep rate. The latter observation confirming that the mass transport of mediator is occurring under conditions of planar diffusion. Upon addition of hydrogen peroxide to a solution of the mediator there was no change in the observed voltammograms showing that hydrogen peroxide does not give rise to significant oxidation currents on glassy carbon in the operating potential region. However, on addition of the CCP to a solution of mediator containing hydrogen peroxide, a characteristic catalytic wave with an enhanced reduction current and no oxidation peak was seen. Both the change in the appearance of the voltammogram and the increased current are consistent with catalytic regeneration of oxidised mediator in the diffusion layer as observed previously with non-chiral ferrocenes.[14,15] The absence of diffusional peaks in the cyclic voltammograms under conditions of enzyme turnover are consistent with the cathodic currents arising from enzymatically generated, rather than electrochemically generated, ferrocenium ions.

Fig. 1 shows the catalytic currents obtained in the system containing CCP and either (*S*)- or (*R*)-HMDMF as diffusional electron transfer mediators in the presence of hydrogen peroxide. It can be seen clearly from Fig. 1 that the *R*-enantiomer acts as a faster electron transfer mediator than the *S*. The catalytic current for (*R*)-HMDMF is about two-fold higher than that of (*S*)-HMDMF.

When the limiting currents in the cyclic voltammograms are plotted against the square root of the enzyme concentration a linear relationship is observed, consistent with the expected behaviour in an enzyme coupled system.[10] For each enantiomer the overall second order rate constant for the reaction between reduced mediator and oxidised enzyme was determined from the scan rate dependence of the catalytic currents at five different enzyme concentrations.[16] The values for the rate constants showed a significant ($P < 0.001$) difference between the two enantiomers with (*R*)-HMDMF reacting approximately twice as fast as (*S*)-HMDMF (Table 1). This difference in rate constants is comparable to that observed by Marx-Tibbon *et al.*[17] for the reaction of *N,N*-dimethyl-1-ferrocenylethylamine

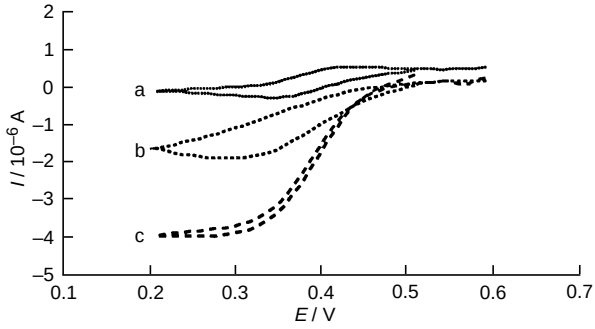

**Fig. 1** Cyclic voltammogram of (*a*) 0.5 mM (*R*)-HMDMF in phosphate buffer (50 mM, pH 6.5) containing 2 mM hydrogen peroxide; (*b*) 0.5 mM (*S*)-HMDMF together with 2 mM hydrogen peroxide after addition of 0.7 μM CCP; and (*c*) 0.5 mM (*R*)-HMDMF together with 2 mM hydrogen peroxide after addition of 0.7 μM CCP. All voltammograms were recorded at 5 mV $s^{-1}$ on a glassy carbon electrode with an area of 0.125 $cm^2$.

**Table 1** Rate constants for the reaction of cytochrome c peroxidase wild type and mutant enzymes with both enantiomers of 1-hydroxymethyl-2-dimethylaminomethylferrocene

| | *R*-Enantiomer | *S*-Enantiomer |
|---|---|---|
| Wild Type CCP | $(2.9 \pm 0.4) \times 10^6$ $dm^3$ $mol^{-1}$ $s^{-1}$ | $(1.6 \pm 0.2) \times 10^6$ $dm^3$ $mol^{-1}$ $s^{-1}$ |
| D34K CCP | $(5.9 \pm 0.5) \times 10^6$ $dm^3$ $mol^{-1}$ $s^{-1}$ | $(14.8 \pm 1) \times 10^6$ $dm^3$ $mol^{-1}$ $s^{-1}$ |

(a ferrocene with a chiral side chain) with glucose oxidase, although this work has recently been the subject of a reinterpretation by Boudillon *et al*.[18]

The rates of reaction of the enantiomers of HMDMF with a mutant of CCP (Aspartate 34 to Lysine) were also determined. Aspartate 34 is a negatively charged residue, situated on the surface of CCP and has been implicated in its reaction with its physiological partner, cytochrome c on the basis of the crystal structure of the complex.[19] When the rate constants for this mutant were evaluated with the artifical ferrocene donor two striking observations were made, firstly the values for both enantiomers were increased, showing that this mutant turned over the ferrocene substrates more rapidly than the wild type enzyme. More interestingly the chiral preference of the enzyme was reversed with the *S*-enantiomer now being the faster substrate. In fact in this mutant the rate of reaction with the *S*-enantiomer is increased by an order of magnitude compared with the wild type. The corresponding rate constants for (*R*)- and (*S*)-HMDMF are also reported in Table 1. We have also investigated the reaction of this mutant with non-chiral ferrocenes[20] and, as might be anticipated, differences in rate are observed reflecting the different interactions of the two forms with the mediator. If however substrate chirality was not implicated in the reaction we should observe that both enantiomers would exhibit the same change in rate, in contrast to the observations here where quite different increases are seen.

These data clearly show that not only is there a specific molecular recognition event occurring between the chiral ferrocenes and CCP but also that this interaction is exquisitely sensitive to a specific surface charge on the CCP. Calculated potential maps were obtained for wild type and D34K CCP using the finite difference method introduced by Sharp and Honig[21] and show large changes in the proteins' electrostatic fields around the site of mutation the analysis of which will be published in detail elsewhere.

We thank Professor T. Poulos for the gift of the pT7CCP plasmid.

# Alkali metals on nanoporous carbon: new solid-base catalysts

**Mark G. Stevens and Henry C. Foley***

*Center for Catalytic Science and Technology, Department of Chemical Engineering, University of Delaware, Newark, Delaware, USA*

**Caesium entrapped in nanoporous carbon is not pyrophoric, is thermally stable towards desorption up to 773 K, but retains its ability to produce hydrogen from water, and is a strong basic catalyst, providing a greater than 9 : 1 ratio of the less stable *cis*-but-2-ene over the *trans* isomer in the isomerization of but-1-ene at 273 K.**

Materials produced from alkali metals and carbon have been of interest to researchers for many years. Graphite intercalation compounds of alkali metals have been extensively studied[1] and shown to be active basic catalysts in reactions such as side-chain alkylation,[2] but-1-ene isomerization[3] and amine synthesis.[4] Unfortunately, these materials were found to be pyrophoric, had relatively low surface area, and exfoliated at reaction temperature.[5] A catalytically active caesium fulleride, $C_{20}Cs_6$, has been reported, but it was found to be highly air-sensitive.[6]

Carbogenic molecular sieves (CMS) are chemically inert solids that contain nanopores,[7,8] formed from aromatic nanodomains, arranged chaotically in space. Here, we show that alkali metals introduced into a CMS structure adsorb in these nanopore spaces, and that curvature effects within the CMS pores provide for a much higher thermal stability, and that these materials are exceptionally active base catalysts in double-bond migration.

CMS samples were prepared pyrolitically from polyvinylchloride–polyvinyldichloride-, poly(furfuryl alcohol)- and poly(furfuryl alcohol)–poly(ethylene glycol) mixtures.[7–10] A poly(furfuryl alcohol)–poly(ethylene glycol) mixture (PFA–PEG) produces material that forms a nanopore structure similar to the PFA carbons, with a pore-size distribution centred around 0.5 nm. However, the addition of PEG results in the formation of transport porosity[11] with a second distribution centred around 10 nm, that allows access to catalytic sites contained in the nanopores.[12] Cs was chosen as the catalytic metal because it is the most electropositive element and its covalent atomic diameter (0.48 nm) is close to the nanopore size of the CMS (*ca*. 0.5 nm). Since Cs is strongly electropositive, a significant portion of the Cs may be ionized (crystallographic diameter 0.34 nm), which should add to the compound's stability.

The synthesis of the Cs/CMS material was achieved by vapour-phase deposition.† The base-catalysed isomerization of but-1-ene to but-2-ene, which begins with the abstraction of the allylic proton to form the *cis* or *trans* form of the allyl anion,[13] was used to probe for catalytic activity. Since the *cis* form of this intermediate is more stable than the *trans* form, *cis*-but-2-ene is formed predominantly in base catalysis, although *trans*-but-2-ene is more stable thermodynamically.

Samples containing 3–42 mass% Cs in CMS‡ were synthesized. The thermal stability of these materials was demonstrated by heating them in vacuum to temperatures as high as 773 K; the Cs did not desorb from the CMS. In contrast Cs is lost rapidly from Cs/graphite compounds, which exfoliate readily.[5]

Results of magnetic susceptibility and EPR measurements show a significant population of unpaired electrons exists in these materials. When a 17% Cs/CMS sample was exposed to 100% humidity at 288 K it absorbed 850 mg $g^{-1}$ of water. When submerged in oxygen-free water, a 9.2% Cs sample produced sufficient hydrogen to indicate that 26% of the Cs was still active for water reduction.§ Hence, the Cs is active and accessible. Yet, unlike metallic Cs and graphite Cs compounds, Cs/CMS is not pyrophoric, even at 40% Cs loading.

A wholly nanoporous pyrolized polyvinylchloride–polyvinyldichloride carbon impregnated with 14% Cs showed no catalytic activity for but-1-ene isomerization¶ at 298 K, but did show activity at higher temperatures (18% conversion at 523 K). When transport porosity is added to the CMS, making the Cs in the nanopores more accessible, the reaction took place at low temperatures (Table 1). The catalysts were found to be stable, with a reaction turnover of > 30 (30 mol of but-2-ene produced per mol of Cs) before deactivation. To determine the global, first-order rate constant for the reaction we diluted the butene feed to 33 mol% but-1-ene in argon. From differential conversion experiments¶ on a 9% Cs sample we determined an apparent first-order rate constant ($k_a$) of 0.07 $s^{-1}$ $g^{-1}$ and a *cis* : *trans* ratio of 9.1 at 273 K. This combination of high bacisity with reduction activity and the lack of pyrophoricity makes Cs/CMS extraordinarily interesting and useful.

**Table 1** Average conversion on 4.5 g catalyst and *cis*/*trans* ratio of the product gas for the isomerization of 15 $cm^5$ $min^{-1}$ butene to *cis*- and *trans*-but-2-ene at 298 K and 1 bar. Six datapoints (gas chromatography) were collected from the flow reactor over a 2 h period and averaged

| Catalyst | Conversion (%) | *cis*/*trans* ratio |
|---|---|---|
| 3% Cs-PFA–PEG | 13% | 2.3 |
| 10% Cs-PFA–PEG | 75% | 3.3 |
| 11% Cs-PFA–PEG | 60% | 4.9 |
| 18% Cs-PFA–PEG | 90% | 2.8 |
| 21% Cs-PFA–PEG | 87% | 3.7 |

## Footnotes

† After a sample of the CMS was heat-treated in vacuum at 450 °C for 24 h, Cs vapour was introduced into the carbon at moderate temperature (350 °C) at its vapour pressure (*ca*. 10 mmHg). The temperature was held at 350 °C under static vacuum for 24 h.

‡ Galbraith Laboratories, Inc. provided metal analysis *via* plasma emission spectroscopy for the determination of alkai-metal loading.

§ A 2 g sample of catalyst was submerged in 20 ml of deionized, oxygen-free, water, without exposure to air. Gas evolved. The gas was quantified and determined to be hydrogen by gas chromatography. The water and catalyst were titrated with 0.0125 M sulfuric acid to calculate the amount of Cs present as CsOH.

¶ We constructed a computer-controlled, tubular, flow reactor. For the initial experiments: the reactor was loaded in an inert atmosphere with 4.75 g of catalyst. Technical grade but-1-ene (Matheson gas company) flowed at 15 $cm^3$ $min^{-1}$ at atmospheric pressure. For the kinetic experiments: the reactor contained 3.0 g of catalyst. Technical grade but-1-ene flowed at 20 $cm^3$ $min^{-1}$, mixed with 40 $cm^3$ $min^{-1}$ argon at atmospheric pressure. Analysis was performed *via* gas chromatography.

# Formation of an intermediate during the hydrothermal synthesis of ULM-5 studied using time-resolved, *in situ* X-ray powder diffraction†

**Robin J. Francis,[a] Stephen J. Price,[a] Stephen O'Brien,[a] Andrew M. Fogg,[a] Dermot O'Hare,*[a]‡ Thierry Loiseau[b] and Gerard Férey[b]**

[a] *Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*
[b] *Institut Lavoisier, IREM UMR C 173, Université de Versailles, 45 Avenue des Etat-Unis, 78035 Versailles, France*

***In situ* energy dispersive X-ray diffraction studies on the hydrothermal synthesis of the oxyfluorinated gallophosphate, ULM-5, show that when orthophosphoric acid is used as a starting material ULM-5 forms rapidly after an initial induction period, whereas when phosphorus pentoxide is used as a starting material a previously unobserved crystalline intermediate is formed, which subsequently reacts to form ULM-5; conditions have been identified in which this intermediate is relatively long lived and this has allowed the subsequent isolation of a pure sample of this intermediate.**

Microporous materials are an academically and industrially important class of materials due to their great utility as catalysts and absorbents.[1,2] These properties arise from their unique three-dimensional open-framework structures which consist of a regular array of uniform pores and channels. ULM-5 is a microporous oxyfluorinated gallophosphate $\{Ga_{16}(HPO_4)_{14}(PO_4)_2(OH)_2F_7{\cdot}4NH_3CH_2CH_2NH_3{\cdot}6H_2O\}$ containing large 16-membered rings and interconnecting 8-membered rings.[3] The 16-membered rings form oval channels with a free aperture of 12.20 × 8.34 Å. ULM-5 is synthesised hydrothermally; gallium oxide, a phosphorus source and hydrofluoric acid are reacted in water at 180 °C in the presence of the templating agent 1,6-diaminohexane.

Over the past few years much interest has focused on the synthesis of new open-framework materials with particular catalytic and ion-exchange properties. Unfortunately, although some mechanistic theories have been proposed,[4,5] the synthesis of new structure types is hampered by the fact that the fundamental processes occurring during hydrothermal syntheses are not well understood, and there is very little knowledge of the transformations occurring during the formation of the product phase. In an effort to gain a greater understanding of these reactions we have recently developed an apparatus capable of studying hydrothermal reactions *in situ*, using time-resolved energy dispersive synchrotron X-ray diffraction (EDXRD).[6,7] As has been pointed out by ourselves and others previously,[6–9] such non-invasive *in situ* measurements offer many advantages over other *ex-situ* techniques, since they allow the direct observation of crystalline intermediate and product phases, which avoids the possibly complicating effects of sample work-up.

As part of our on-going program of studying hydrothermal syntheses of microporous materials *in situ*, we have undertaken a study of the formation of ULM-5 under a variety of synthetic conditions in order to gain a greater understanding of the dynamics of crystal growth and nucleation. Here we report the importance of the phosphorus source on the reaction pathway, and the observation of the formation of a crystalline intermediate phase when phosphorus pentoxide is used as the source.

All reactions were performed using a reaction mixture of initial composition $Ga_2O_3 : P_2O_5 : 2HF : 1,6DAH : 80H_2O$. Using orthophosphoric acid as the phosphorus source there is a short induction period, which presumably is partially due to reactant dissolution and partially due to a build up in pressure, after which pure ULM-5 is observed to rapidly and smoothly crystallise. No crystalline intermediates are observed to form at any stage. A plot of the integrated intensity of the 002 reflection is shown in Fig. 1. The main feature of note is the extremely rapid nature of the crystallisation after the induction period. The half-life of crystallisation at this temperature is under 1 min, and the reaction is essentially over 40 min after the onset of crystallisation. Initial analysis of the kinetic data suggests that the formation of ULM-5 under these conditions is an essentially diffusion limited process. We have also performed this reaction at other temperatures down to 130 °C, and whilst there is a general trend to longer induction times at lower temperatures the crystallisation kinetics after induction are essentially identical over this temperature range.

However, dramatically different behaviour was observed when the reaction was performed under identical conditions except for the replacement of orthophosphoric acid with phosphorus pentoxide as the phosphorus source. Under these conditions a highly crystalline intermediate phase is observed to form which then subsequently reacts to form ULM-5. The course of the reaction at 180 °C is shown as a three-dimensional plot in Fig. 2, and a plot of the integrated intensity of the 13.1 Å reflection and the ULM-5 final product 002 reflection is shown in Fig. 3. As can be seen from Fig. 3 after an induction time of approximately 5 min, the intermediate forms rapidly, the intensity of the diffraction peaks reaching a maximum intensity after just 15 min. The intensity of these peaks then immediately begins to decrease together with concomitant growth of peaks belonging to the product (ULM-5). Although not conclusive, the high degree of correlation between the decay of the intermediate and growth of the product peaks is good evidence for the two phases being related, and the intermediate phase directly converting into the final product. The transformation is much slower than both the initial formation of the intermediate

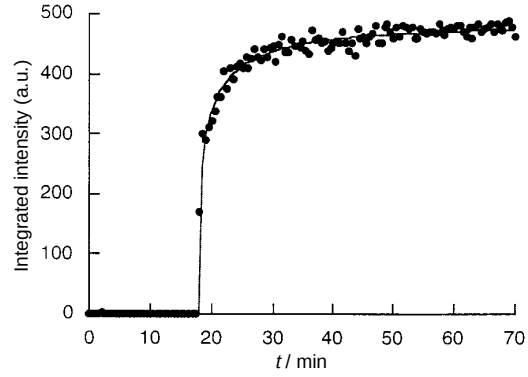

**Fig. 1** Plot of intensity of the (002) Bragg reflection of ULM-5 as a function of time using orthophosphoric acid as a starting material. The solid line is a fit to the Avrami equation $I = A\exp[-k(t - t_0)]^{0.4}$, where $t_0$ is the induction time.

and the formation of ULM-5 when orthophosphoric acid is used as a starting material, taking over 2 h to go to completion.

The same reaction was also performed at lower temperatures. Broadly similar behaviour was observed; an intermediate being formed which converts to the final product. However, although the initial growth occurs at virtually the same rate, the transformation to product was much slower at lower temperatures. At 150 °C the beginnings of a 'plateau' in the intensity of the intermediate peak could be seen, and by 130 °C this plateau in intensity is pronounced, with the intermediate being stable for approximately 30 min. Conversion into the final product does not occur until after 40 min into the reaction at this temperature.

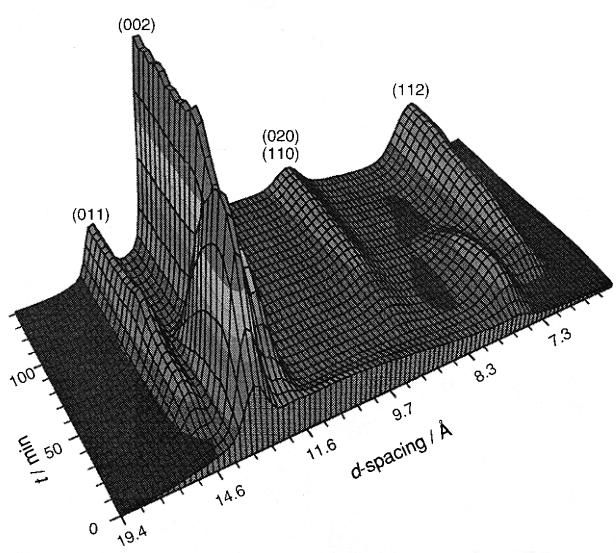

**Fig. 2** Three-dimensional plot showing the EDXRD spectra as a function of time during the synthesis of ULM-5 using phosphorus pentoxide as a starting material. The peak labels correspond to the indices of the Bragg reflections of ULM-5. The experiments were performed on station 16.4 of the UK SRS at Daresbury Laboratory, Warrington. Each spectrum was acquired in 60 s at a diffraction angle of $2\theta = 1.22°$. Details of the experimental apparatus and station design have been published previously.[6,10]

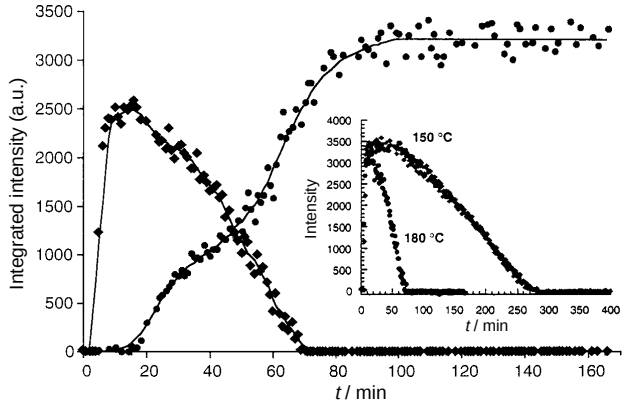

**Fig. 3** Plot of the intensity of the (100) Bragg reflection of the intermediate (◆) and the (002) Bragg reflection (●) of ULM-5 as a function of temperature at 180 °C. Solid lines are for guidance only and have no physical significance. Inset: Plot of intensity of the (100) reflection of the intermediate at 180 and 150 °C.

The determination of conditions in which the intermediate is relatively stable opened up the possibility of isolation of this material by quenching of the reaction during the early stages before the conversion to the final product has begun, assuming that the material does not transform during the quenching procedure. In an attempt to do this another reaction was performed at 150 °C in which the reaction cell was removed from the heating block when the diffraction peaks due to the intermediate were observed to reach the maximum intensity, and the cell was then quenched with cold water. Powder X-ray diffraction of the material obtained from the quenched autoclave showed that the intermediate phase had indeed been successfully isolated. The X-ray diffraction pattern of this isolated phase could be tentatively indexed on the orthorhombic cell with lattice parameters $a = 20.274$, $b = 13.125$, $c = 24.550$ Å. Interestingly, two of these parameters are closely related to two of the cell parameters in ULM-5 which is also orthorhombic with $a = 10.252$, $b = 18.409$ and $c = 24.639$ Å (*i.e.* $a' \approx 2a$ and $c' \approx c$). This suggests that the two materials may be closely structurally related. Structural studies on this material are being carried out in order to determine the relationship between this material and ULM-5, but these have been hampered by the fact that the isolated product is metastable and transforms to another unknown material on standing for a few days at room temperature.

In conclusion, these *in situ* experiments are a dramatic illustration of the complexity of hydrothermal syntheses, and how subtle changes in the reaction conditions, such as the use of slightly different starting materials, can greatly affect the course of these reactions. It also demonstrates the unique ability of *in situ* experiments to gain information not available using other techniques.

We would like to thank DRAL for a CASE studentship (R. J. F.) and the use of the Synchrotron radiation source facility, and Dr S. M. Clarke, and the technical staff at Daresbury Laboratory for helping in the design and construction of the experimental cell.

# Oxidative quenching of excited-state tetrakis(μ-pyrophosphito)diplatinate(II) tetraanion by iodine atom transfer from iodopentacyanocobaltate(III)

**Alexander D. Kirk* and Le-Zhen Cai**

*Department of Chemistry, University of Victoria, PO Box 3065, Victoria, BC, V8W 3V6, Canada*

**Iodopentacyanocobaltate(III) oxidatively quenches excited state tetrakis(μ-pyrophosphito)diplatinate(II) tetraanion *via* iodine atom transfer.**

The bridged binuclear complex $[Pt_2(pop)_4]^{4-}$ (pop = $H_2P_2O_5^{2-}$) has attracted great interest due to its distinctive excited-state properties. The triplet excited state $^3A_{2u}$ {denoted as $[*Pt_2(pop)_4]^{4-}$} is known to be a strong oxidant and reductant, and has biradical character.[1–3] Quenching studies have shown that the excited state can be quenched by energy transfer, electron transfer, or atom transfer mechanisms.[4] The latter mechanism has been observed for organic quenchers, such as RX, ROH (X = Cl, Br, I; R = alkyl, aryl),[5] but quenching by coordination complexes has invariably occurred *via* energy or electron transfer. During a detailed study[6] of salt effects on the quenching interaction between $[Pt_2(pop)_4]^{4-}$ and the anions $[Co(CN)_5X]^{3-}$ (X = I, Br, Cl, $N_3$), we saw evidence for atom transfer in the quenching of $[*Pt_2(pop)_4]^{4-}$ by $[Co(CN)_5I]^{3-}$. The finding provides new insight into the deactivation of excited-state metal complexes and further illustrates the rich photochemistry of this platinum dimer.

In our initial approach, the lifetime of $[Pt_2(pop)_4]^{4-}$ in deaerated 0.500 M KCl–0.010 M $HClO_4$ solution was measured using a nitrogen laser, wavelength shifted† by a separate cell containing quinine sulfate to provide 370 nm, fast decay pulses to excite preferentially $[Pt_2(pop)_4]^{4-}$. The $[Co(CN)_5I]^{3-}$ quencher, dissolved in 0.500 M KCl–0.010 M $HClO_4$ solution, was delivered in μl aliquots from a microburette directly into the $[Pt_2(pop)_4]^{4-}$ solution. The high electrolyte concentration served to promote[6] the anion–anion interaction and the choice of chloride established a chloride–iodide competition required to demonstrate the occurrence of atom transfer. The second-order quenching rate constant $k_q$ was calculated from the Stern–Volmer plot and was found to be $2.1 \times 10^8$ $M^{-1}$ $s^{-1}$ at 22.0 ± 0.1 °C for the above ionic strength.

When a deaerated solution of $2.9 \times 10^{-5}$ M $K_4[Pt_2(pop)_4]$, $1.7 \times 10^{-4}$ M of $K_3[Co(CN)_5I]$ and 0.500 M KCl–0.010 M $HClO_4$ was irradiated by a Hg lamp at 370 nm, the absorption bands at 370 and 262 nm were bleached, accompanied by the development of new bands at 328 and 438 nm (Fig. 1). Reaction terminated when the light source was removed, showing that a genuine photochemical reaction not a thermal or photocatalytic process occurs. The peaks diminished were those of reactant $[Pt_2(pop)_4]^{4-}$, $\lambda_{max}$ (ε) = 369 nm ($3.4 \times 10^4$ $M^{-1}$ $cm^{-1}$), and quencher $[Co(CN)_5I]^{3-}$, $\lambda_{max}$ (ε) = 262 nm ($1.8 \times 10^4$ $M^{-1}$ $cm^{-1}$), and the spectral changes showed that quencher and $[Pt_2(pop)_4]^{4-}$ reacted in a 2 : 1 molar ratio. The product peaks could be attributed to $[Pt_2(pop)_4I_2]^{4-}$. They appeared at 328 and 438 nm which compares well to literature results for $[Pt_2(pop)_4I_2]^{4-}$, $\lambda_{max}$ (ε) = 331 nm ($4 \times 10^4$ $M^{-1}$ $cm^{-1}$) and 438 ($1.7 \times 10^4$),[8] and had the correct ratio, experiment $A_{328}/A_{438}$ = 2.2 (lit.[8] $\varepsilon_{331}/\varepsilon_{438}$ = 2.4). Moreover, the amount of product $[Pt_2(pop)_4I_2]^{4-}$ formed was equal to the amount of $[Pt_2(pop)_4]^{4-}$ consumed, $(\Delta A/\varepsilon)_{[Pt_2(pop)_4I_2]^{4-}}$: $(\Delta A/\varepsilon)_{[Pt_2(pop)_4]^{4-}}$ = 1.0 ± 0.1. It can be concluded that $[*Pt_2(pop)_4]^{4-}$ is oxidatively quenched by $[Co(CN)_5I]^{3-}$ to form $[Pt_2(pop)_4I_2]^{4-}$. The quantum yield for this photooxidation was calculated to be 0.083 ± 0.002.

Formation of $[Pt_2(pop)_4I_2]^{4-}$ in 0.5 M chloride is most unlikely *via* oxidative electron transfer and halide ion scavenging of the resulting mixed-valence Pt dimer. The result suggests a mechanism involving direct I atom transfer from $[Co(CN)_5I]^{3-}$ to form $[Pt^{II}Pt^{III}(pop)_4I]^{4-}$ [eqn. (1)].

$$[*Pt_2(pop)_4]^{4-} + [Co(CN)_5I]^{3-} \xrightarrow{k_{AT}} [Pt^{II}Pt^{III}(pop)_4I]^{4-} + [Co(CN)_5]^{3-} \quad (1)$$

The mixed valence species $[Pt^{II}Pt^{III}(pop)_4I]^{4-}$ can then form the observed $[Pt_2(pop)_4I_2]^{4-}$ product either by disproportionation or by further reaction with $[Co(CN)_5I]^{3-}$. The species $[Co(CN)_5]^{3-}$ will quickly undergo acid-catalysed decomposition to give $Co^{II}$(aq) and HCN under our conditions.[9]

The above mechanistic ambiguity was resolved in our second approach, which also avoided possible mechanistic complications at the high chloride concentration needed for the competition study. A solution of $2 \times 10^{-5}$ M $[Pt_2(pop)_4]^{4-}$ and $2 \times 10^{-4}$ M $[Co(CN)_5I]^{3-}$ in nitrogen-degassed 0.01 M $HClO_4$–saturated $KClO_4$ solution was flash photolysed with a 25 mJ, 10 ns pulse at 355 nm with monitoring of the triplet $[Pt_2(pop)_4]^{4-}$ emission at 514 nm, its excited-state absorption at 460 nm (fast), the $[Co(CN)_5I]^{3-}$ ground-state absorption at 280 nm and the development of $[Pt_2(pop)_4I_2]^{4-}$ product absorption at 460 nm (slow). The absorption and emission from the triplet excited state decayed exponentially with the quenched lifetime, 4.9 and 5.1 μs respectively, while the ground-state absorption of $[Co(CN)_5I]^{3-}$ decreased with the same lifetime (4.7 μs), Fig. 2(*a*). This proves the direct reaction of $[Pt_2(pop)_4]^{4-}$ triplet state with $[Co(CN)_5I]^{3-}$ consistent with eqn. (1). The transient

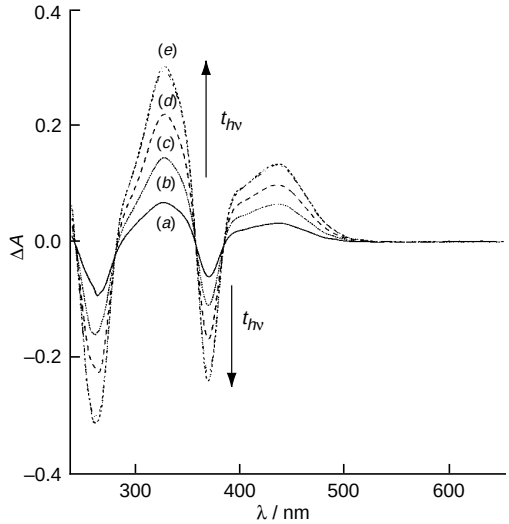

**Fig. 1** Absorbance change with the reaction of $[*Pt_2(pop)_4]^{4-}$ by $[Co(CN)_5I]^{3-}$ in 0.50 M KCl–0.010 M $HClO_4$ solution. Irradiation time: (*a*) 30, (*b*) 60, (*c*) 90, (*d*) 120 s; (*e*) kept in dark for 120 s after (*d*).

that results leads to $[Pt_2(pop)_4I_2]^{4-}$ which grows in with a 0.5 ms lifetime (see below), but no further reaction of $[Co(CN)_5I]^{3-}$ occurs (monitored at 280 nm) as shown in Fig. 2(*b*). This proves that the dominant second step of the reaction is a disproportionation process [eqn. (2)].

$$2[Pt^{II}Pt^{III}(pop)_4I]^{4-} \longrightarrow [Pt_2(pop)_4I_2]^{4-} + [Pt_2(pop)_4]^{4-} \quad (2)$$

not further reaction with $[Co(CN)_5I]^{3-}$ such as a second atom transfer [eqn. (3)].

$$[Pt^{II}Pt^{III}(pop)_4I]^{4-} + [Co(CN)_5I]^{3-} \xrightarrow{k_{AT}} [Pt_2(pop)_4I_2]^{4-} + [Co(CN)_5]^{3-} \quad (3)$$

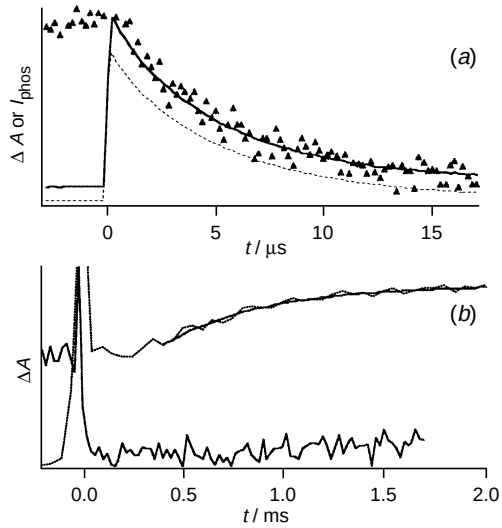

**Fig. 2** Transient signals on flash photolysis of $2 \times 10^{-5}$ M $[Pt_2(pop)_4]^{4-}$ and $2 \times 10^{-4}$ M $[Co(CN)_5I]^{3-}$ in nitrogen-degassed 0.01 M $HClO_4$–saturated $KClO_4$ solution with a 25 mJ, 10 ns pulse at 355 nm. (*a*) (---) $[*Pt_2(pop)_4]^{4-}$ emission at 514 nm; (—) $[*Pt_2(pop)_4]^{4-}$ absorption at 460 nm; (▲) $[Co(CN)_5I]^{3-}$ absorption at 280 nm. (*b*) (—) $[Co(CN)_5I]^{3-}$ absorption at 280 nm; (···) $[Pt_2(pop)_4I_2]^{4-}$ absorption at 460 nm.

The disproportionation step should be simple second order, but given the noise level of the data, Fig. 2(*b*), the time evolution is indistinguishable from an exponential decay with a lifetime of 0.5 ms for these conditions.

In conclusion, both approaches show that direct iodine atom abstraction occurs in this system. A full paper with results on the salt and specific ion effects in the quenching of $[*Pt_2(pop)_4]^{4-}$ by $[Co(CN)_5I]^{3-}$ and other pentacyanocobaltate complexes has been submitted.[6]

## Footnote

† At 337 nm $[Pt_2(pop)_4]^{4-}$ has a much smaller molar absorptivity than $[Co(CN)_5I]^{3-}$. To quench the lifetime of $[Pt_2(pop)_4]^{4-}$ to half of its initial value, the quencher concentration should be about $10^{-3}$ M, while the concentration of $[Pt_2(pop)_4]^{4-}$ should be about $3 \times 10^{-4}$ M to achieve an absorbance of 0.3 at 337 nm. Under such conditions the iodo complex would absorb 90% of the light, possibly leading to the photolysis of the quencher, as well as serious inner filter effects in the Stern–Volmer study. Quinine sulfate has a strong absorption between 320 nm and 340 nm ($\log \varepsilon = 4$) and emits at 370 nm, where $\varepsilon\{[Pt_2(pop)_4]^{4-}\} \gg \varepsilon\{[Co(CN)_5I]^{3-}\}$, and has[7] a fluorescence lifetime of 19.2 ns, short enough to avoid distortion of the 9 μs emission decay curve of $[*Pt_2(pop)_4]^{4-}$.

# A new route to polyselenoether macrocycles. Catalytic macrocyclization of 3,3-dimethylselenatane by $[Re_2(CO)_9]$

**Richard D. Adams* and Kenneth T. McBride**

*Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, USA*

**3,3-Dimethylselenatane, $SeCH_2CMe_2CH_2$, DMSe is cyclooligomerized catalytically at 115 °C in the presence of $[Re_2(CO)_9(SeCH_2CMe_2CH_2)]$ to yield three new polyselenoether macrocycles 3,3,7,7-tetramethyl-1,5-diselenacyclooctane, 3,3,7,7,11,11-hexamethyl-1,5,9-triselenacyclododecane, 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetraselenacyclohexadecane and polymer of DMSe; all three macrocycles are characterized crystallographically; in all cases the *gem*-dimethyl groups are directed toward the exterior of the rings; interestingly, some methylene groups are directed to the interior.**

In recent studies we have shown that $[Re_2(CO)_9(NCMe)]$ and other third-row transition-metal carbonyl complexes can serve as effective catalysts for the ring-opening cyclooligomerization of thietanes to polythioether macrocycles.[1] Polythioether macrocycles have attracted attention for their ability to serve as ligands for transition metals.[2] Polyselenoether macrocycles have an equally good potential to serve as ligands,[3] but the number of known polyselenoether macrocycles is very small.[4]

We have now found that $[Re_2(CO)_9(SeCH_2CMe_2CH_2]$ **1** serves as a catalyst for the ring-opening macrocyclization of 3,3-dimethylselenatane, $SeCH_2CMe_2CH_2$, DMSe, to yield three new polyselenoether macrocycles.† 15.0 mg of **1** was dissolved in 0.750 g of DMSe[5] and the solution was heated to 115 °C for 8 h.‡ This yielded a residue of 340 mg after removal of the unreacted DMSe. The products were separated by TLC to yield 4.3 mg of 3,3,7,7-tetramethyl-1,5-diselenacyclooctane **2**, 104.1 mg of 3,3,7,7,11,11-hexamethyl-1,5,9-triselenacyclododecane **3** and 12.0 mg of 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetraselenacyclohexadecane **4**. The remainder is believed to be polymer of DMSe. For **3** this is equivalent to 12.0 turnovers or 1.5 turnovers $h^{-1}$.

All three macrocycles were characterized crystallographically, and structural diagrams of each are shown in Figs. 1–3, respectively.§ In all three structures the *gem*-dimethyl groups are directed toward the exterior of the ring. In the solid state **2** and **4** both contain a crystallographically imposed centre of

**Scheme 1**

symmetry. All Se–C distances are similar, Se(1)–C(1) 1.961(8) and Se(1)–C(3) 1.974(8) Å for **2**; Se(1)–C(1) 1.965(8), Se(1)–C(9) 1.953(9), Se(2)–C(3) 1.952(9), Se(2)–C(4) 1.957(9), Se(3)–C(6) 1.97(1) and Se(3)–C(7) 1.97(1) Å for **3**; and Se(1)–C(1) 1.961(9), Se(1)–C(6) 1.967(9), Se(2)–C(3) 1.961(9) and Se(2)–C(4) 1.956(9) Å for **4** and all are similar to those found in the unsubstituted selenoether macrocycles: [12]ane$S_4$, [18]ane$Se_6$, [16]ane$Se_4$, [24]ane$Se_6$ and [14]ane$Se_4$.[4c] It has been suggested that *gem*-dimethyl groups on the ring of polythioether macrocycles will force the sulfur atoms to turn toward the interior of the ring and enhance their ligand properties.[6] This is only partially supported by the results for the selenium compounds described here. Although conformations of **3** and **4** differ from those of their unsubstituted sulfur and selenium homologues 1,5,9-trithiacyclododecane¶ and 1,5,9,13-tetraselenacyclohexadecane,[4c] the selenium atoms are not directed inward. In fact, it is methylene groups, C(4) on **3** and C(3) on **4**, that are most dramatically turned toward the interior of the macrocycles.

In the absence of **1**, no significant amounts of the macrocycles or polymer are formed from DMSe under these conditions. We feel that the mechanism involves a series of ring opening additions of DMSe to the DMSe ligand in a $Re_2(CO)_9$ complex followed by a recyclization, similar to that established for the macrocyclizations of thietane[1c] and 3-methylthietane,[1f] see Scheme 1. To date, our studies have been limited to DMSe due to the lower stability of the less substituted selenatanes. Efforts to prepare metal complexes of these new macrocycles are now in progress.

These studies were supported by the Division of Chemical Sciences of the Office of Basic Energy Sciences of the US Department of Energy.

## Footnotes

† $[Re_2(CO)_9(\overline{SeCH_2CMe_2CH_2})]$ **1** was obtained in 88% yield from the reaction of $[Re_2(CO)_9(NCMe)]$ with 3,3-dimethylselenatane in hexane at reflux for 2 h.

*Analytical data*: **1**, $^1$H NMR ($CDCl_3$): δ 3.58 (d, 2 H, $J_{HH}$ 9.4 Hz), 3.20 (d, 2 H, $J_{HH}$ 9.7 Hz), 1.41 (s, 3 H), 1.22 (s, 3 H). # A supramolecular motif in the solid-state structure of a difunctional thallium(I) amide defined by weak Tl···Tl attractions

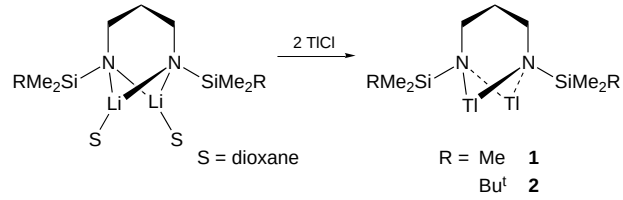
**Konrad W. Hellmann, Lutz H. Gade,* Roland Fleischer and Dietmar Stalke**

*Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany*



**The crystal structure of the difunctional thallium(I) amide $CH_2[CH_2N(Tl)SiMe_3]_2$ 1 reveals a pattern of aggregation based on weak attractive metal–metal interactions, a situation which appears to be influenced by the degree of exposure of the thallium centres; this is evidenced by the solid-state structure of the more shielded analogue $CH_2[CH_2N(Tl)SiBu^tMe_2]_2$ 2 which features no significant Tl···Tl contacts.**

The utilization of intermolecular interactions which generate specific supramolecular motifs has greatly enhanced the systematic approach to both the understanding and the design of highly organized molecular arrays in solids.[1] Intermolecular hydrogen bonding as well as ionic or dipolar interactions have been the most widely employed 'directional forces' in this context.[2] More recently, the attractive interactions between heavy closed-shell metal centres (with $d^{10}$ or $d^{10}s^2$ configuration) and the way they affect the intermolecular aggregation in solids have been investigated.[3] While compounds of monovalent gold have provided the most spectacular objects of study in this context, the neighbouring metals in the Periodic Table, in particular thallium(I), seem to be equally capable of aggregation through (mainly dispersive) metal–metal attraction.[4] The nature of these weak metal–metal interactions in thallium(I) compounds has been the subject of some debate,[5,6] although there is little doubt about their role in molecular aggregation.

The accessibility of the thallium(I) amides *via* metal exchange with well established alkali-metal analogues[7] prompted us to study their structural chemistry in more detail, in particular, with regard to the modes of aggregation defined by metal–metal interactions. That dispersive thallium(I)··· thallium(I) attractions may indeed strongly influence the solid-state structures of polyfunctional thallium(I) amides was recently demonstrated by the drastic distortions of the ligand framework which the tripodal Tl–amide $MeSi[SiMe_2N(Tl)Bu^t]_3$ displays in its crystal structure.[8] In this case, a highly flexible ligand system permitted rather unpredictable molecular shapes and thus molecular units aggregating in the crystal. In order to study intermolecular structural motifs in a meaningful and more systematic way, we chose a simpler difunctional Tl amide the molecular structure of which did not allow for significant geometrical rearrangement.

Stirring a solution of $CH_2[CH_2N(Li)SiMe_3]_2(dioxane)_2$ with TlCl in dioxane at room temp. for 3 h led to a complete metal exchange. The work up of the crude product mixture by extraction with toluene afforded a deep-orange solution from which a red, highly air-sensitive, crystalline solid could be obtained at −30 °C (yield 70%), the analytical data of which were consistent with its formulation as $CH_2[CH_2N(Tl)SiMe_3]_2$ **1** (Scheme 1). The results of variable-temperature NMR studies and cryoscopic measurements in benzene indicated that the compound is monomeric in solution.† It may also be sublimed at 60 °C and $10^{-2}$ mbar without decomposition. A single-crystal X-ray structure analysis, however, revealed a truly remarkable pattern of molecular packing in the crystal (Fig. 1).‡

As indicated in Scheme 1, the monomeric unit of the difunctional thallium amide has the expected molecular structure in which the two amido-N atoms and the two thallium(I) centres form a puckered four-membered ring, the metal atoms occupying rather exposed positions thus generating the poten-

**Scheme 1** Synthesis of **1** and **2** by Li/Tl exchange

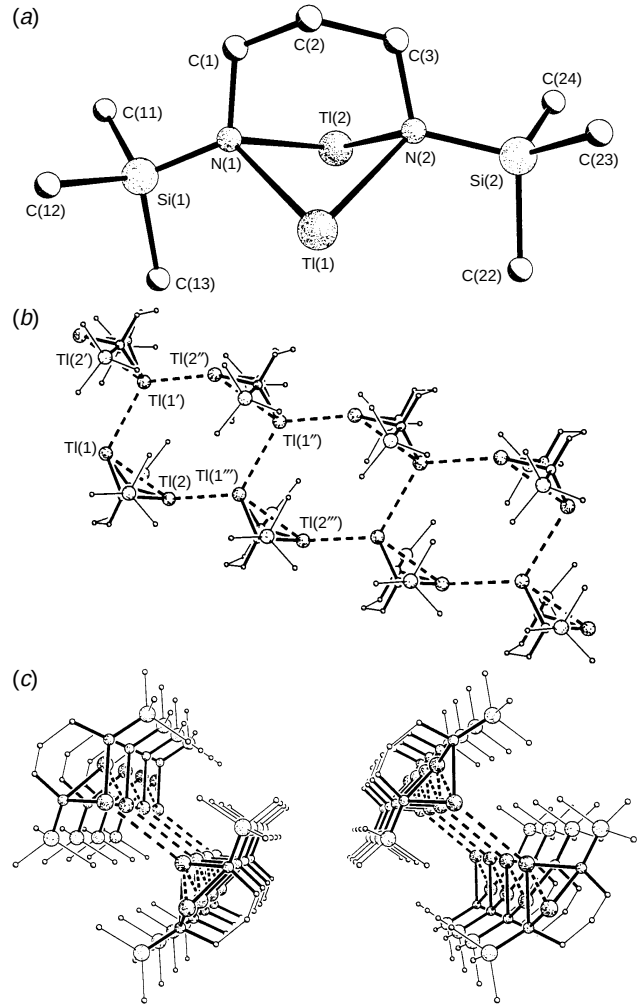


**Fig. 1** Crystal structure of **1**. Molecular structure (*a*) and aggregation in the crystal viewed along the crystallographic *b* axis (*b*) and *a* axis (*c*). Selected bond lengths (Å) and interbond angles (°) of the molecule: Tl(1)···Tl(2) 3.490(3), Tl(1)–N(1) 2.469(14), Tl(1)–N(2) 2.408(13), Tl(2)–N(1) 2.475(12), Tl(2)–N(2) 2.457(13); N(1)–Tl(1)–N(2) 74.8(4), N(1)–Tl(2)–N(2) 73.9(4), Tl(1)–N(1)–Tl(2) 89.8(4), Tl(1)–N(2)–Tl(2) 91.7(4).

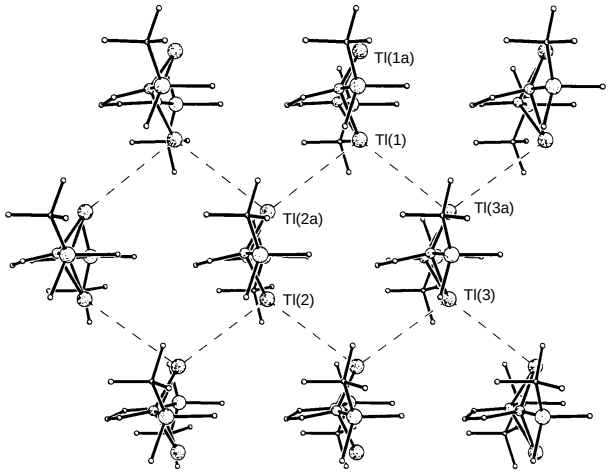

**Fig. 2** Packing of **2** in the crystal viewed along the *c* axis. Selected bond lengths (Å) and interbond angles (°) of the molecule: Tl(1)···Tl(1′) 3.4800(7), Tl(1)–N(1) 2.405(7), Tl(1)–N(1′) 2.481(7); N(1)–Tl(1)–N(1′) 74.7(3), Tl(1)–N(1)–Tl(1′) 90.8, intermolecular Tl···Tl > 4.70.

tially 'sticky ends' for aggregation [Fig. 1(*a*)]. The fairly short Tl···Tl distance of 3.490(2) Å is probably a consequence of the bridging ligands tying the two metals together rather than due to significant bonding interaction although it is rather close to the interatomic distances found in α-thallium (3.408 and 3.457 Å).[9]

In the solid the molecular units of **1** aggregate *via* Tl···Tl contacts to form infinite, double-stranded bands [Fig. 1(*b*,(*c*)]. The two strands consist of monomers facing each other and occupying translationally displaced positions generating a one-dimensional grid consisting of distorted hexagons of metal–metal contacts. In the resulting planar bands one of the two metal atoms in the monomers not only forms a direct contact to its neighbour within a strand [Tl···Tl 3.775(3) Å] but also across to the opposite strand [Tl···Tl 3.697(3) Å].

In order to assess the importance of the relative exposure of the thallium(I) centres in the structure of **1** for the aggregation in the solid the structurally analogous Tl–amide $CH_2[CH_2N(Tl)SiBu^tMe_2]_2$ **2** containing the bulkier silyl substituent $Bu^tMe_2Si$ at the amido functionalities was synthesized using the identical procedure outlined for **1** (yield 74%).† The crystal structure of **2** has revealed a packing in the solid which appears to be entirely dictated by the molecular shape rather than metal–metal contacts as found for **1** (Fig. 2).‡

The shortest intermolecular Tl···Tl distances of over 4.7 Å are testimony to the absence of significant metal–metal interaction in the crystal. With the exception of the somewhat greater shielding of the $Tl_2N_2$-unit in the molecule the overall molecular shapes of **1** and **2** are closely related. This is to be seen in the context of a notion put forward by von Schnering who pointed out that aggregations *via* heavy metals in a molecule may in fact arise from the requirements of crystal packing dictated by the shape of the whole molecule, a situation aptly described as the 'umbrella effect'.[10] The fact that the molecules containing the more exposed metal atoms display structural motifs characterized by metal–metal contacts, while those less favoured in doing so by nature of their more shielded molecular structure do not, supports the relevance of such weak interactions between the heavy metals in the structure of compound **1**.

We thank the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm 'Polyeder'), for financial support and Professor H. Werner (Würzburg) for his continued interest and support of this work.

**The photocatalytic reaction occurring in aqueous deaereated suspensions saturated with $CO_2$ and containing polycrystalline semiconductors, bare or loaded with Pt or Cu, affords 2-hydroxybenzoic acid and catechol as the main products.**

Many studies[1–6] have reported the photocatalytic reduction of $CO_2$ in both gas–solid and liquid–solid heterogeneous systems using mild experimental conditions and in the presence of $H_2O$. The solids used as photocatalysts were polycrystalline semiconductors, and bare Cu-doped $TiO_2$ (anatase) proved to be the most suitable.[6] Light organic compounds, such as for instance $HCO_2H$, MeOH and $CH_4$, were obtained as the main products and their relative ratios depended on the type of photocatalyst and experimental conditions used.

However, very few studies[7,8] can be found on the insertion of $CO_2$ in organic aromatic substrates using photochemical methods. The heterogeneous photocatalytic insertion of $CO_2$ into aromatic molecules, to the best of our knowledge, has not yet been reported.

Here preliminary results are reported on the production of 2-hydroxybenzoic acid (salicylic acid) by the photocatalytic reaction between $CO_2$ and phenol in aqueous deaerated suspensions containing a polycrystalline semiconductor, bare or loaded with Pt or Cu. Catechol was produced together with 2-hydroxybenzoic acid and its amount depended on the catalyst used.

The experimental runs were performed in a Solarbox manufactured by CO.FO.ME.GRA., Milan, equipped with a 1500 W Xe lamp, simulating the solar spectrum. Pyrex photoreactors (50 ml) containing 25 ml of aqueous phenol (8.2 g $l^{-1}$) solutions at pH = 5.85 saturated with $CO_2$ were used for each run. The photon flux provided by the lamp was measured in the locations of the photoreactors by means of the standard potassium ferrioxalate actinometric method which gave $6.6 \times 10^{-7}$ Einstein $s^{-1}$ with oscillations of only *ca.* 3%. The photocatalyst (2 g $l^{-1}$) was suspended in the phenol solution and magnetically stirred.

The solids used as photocatalysts were: anatase $TiO_2$ (Merck), $TiO_2$ (P25 Degussa), Cu-doped $TiO_2$ (P25 Degussa), Rutile $TiO_2$ (Tioxide), $WO_3$ (Carlo Erba, RPE), Pt-doped $WO_3$ (Carlo Erba, RPE), ZnO (BDH) and $SiO_2$ (BDH). The runs lasted 4 h and samples were withdrawn for HPLC analyses. The analyses were carried out after filtration through 0.45 μm cellulose acetate membrane (HA, Millipore) and subsequent centrifugation. One run lasted 8 h (anatase $TiO_2$ Merck) and it was contemporaneously performed using five identical photoreactors: two of them were used for analyses carried out after 1 and 2 h of illumination, the other three for analyses carried out after 4, 6 and 8 h.

Typically the filtered samples were injected into a chromatograph composed of a Varian model 9010 pump, a Varian 9050 UV–VIS detector and a 10 μm Econosil C18 (Alltech) 250 × 4.6 mm i.d. column. Isocratic elution with methanol–$H_3PO_4$ 0.05 mass% aqueous solution was performed at 1 ml $min^{-1}$. The products were monitored at λ = 254 nm.

The results are shown in Table 1. It can be seen that the most significant formation of 2-hydroxybenzoic acid was obtained by using anatase $TiO_2$ (Merck), while Pt(2 mass%)–$WO_3$ favoured the formation of catechol $TiO_2$ (Degussa P25, *ca.* 80% anatase and 20% rutile) was found to be less photoactive than anatase $TiO_2$ (Merck) which could be due to the higher oxidant properties of $TiO_2$ (Degussa P25) with respect to $TiO_2$ (Merck). The high oxidant properties of $TiO_2$ (Degussa) when used as photocatalyst for degradation reactions of organic molecules carried out in aqueous media are well known. The runs carried out using the other solids showed the formation of significantly smaller amounts of the above compounds. As expected, no 2-hydroxybenzoic acid, only traces of catechol, were found when the insulator oxide $SiO_2$ was used. Moreover, the poor photoactivity of bare $WO_3$ should be noted in comparison with the corresponding sample Pt(2 mass%)–$WO_3$ in the presence of which the biggest production of catechol was observed. The presence of Pt on the surface of $WO_3$ particles modifies the adsorption of the reagents, but in this case the major role consists in enhancing the lifetime of the photoproduced electron–hole pairs, due to its high work function.[9] The electrons migrate from $WO_3$ to Pt, giving rise to reduction reactions. The trend of the photoactivity of the samples is not much different if the BET specific surface areas of the powders reported in Table 1 are considered, *i.e.* if the specific photoactivity of the samples is calculated.

The results suggest that the photoreactivity is strongly influenced by both the surface physico-chemical and the electronic properties of the catalysts. The adsorption phenomena, indeed, are of primary importance for $CO_2$ photoactivation and they are related to several factors such as, for instance, the presence of catalytic metals, the surface acid–base properties, the zero charge potential and the surface hydroxylation.

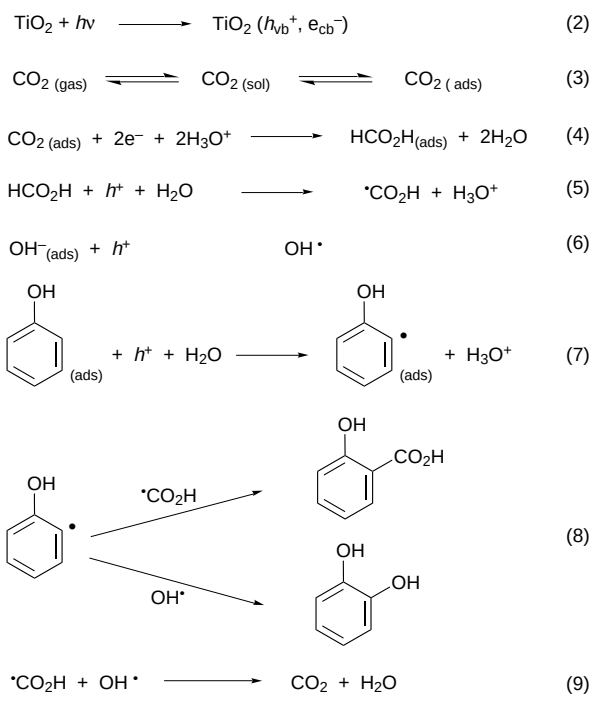
In Fig. 1 the concentrations of 2-hydroxybenzoic acid and catechol *vs.* illumination time are reported when anatase $TiO_2$ (Merck) is used as photocatalyst.

It can be seen that the production of 2-hydroxybenzoic acid approaches the maximum value asymptotically. This could be

**Table 1** Average 2-hydroxybenzoic acid and catechol concentrations per hour and BET specific surface areas (SA) of the photocatalysts used

| Catalyst | Surface area/ $m^2\ g^{-1}$ | 2-Hydroxybenzoic acid/μmol $l^{-1}\ h^{-1}$ | Catechol/ μmol $l^{-1}\ h^{-1}$ |
|---|---|---|---|
| Anatase $TiO_2$ (Merck) | 10.5 | 371.2 | 44.31 |
| $TiO_2$ (P25 Degussa) | 44 | 64.2 | 3.5 |
| Cu (0.1 mass%)–$TiO_2$ (P25 Degussa) | 50 | 27.9 | 22.7 |
| Rutile $TiO_2$ (Tioxide) | 20 | 13.6 | 8.5 |
| $WO_3$ (Carlo Erba, RPE) | 15.5 | 18.5 | — |
| Pt (2.0 mass%)–$WO_3$ (Carlo Erba, RPE) | 16.4 | 117.7 | 1118.2 |
| ZnO (BDH) | 4 | 9.4 | — |
| $SiO_2$ (BDH) | n.d.[a] | — | traces |

[a] N.d. = not determined.



due to a decrease of $CO_2$ concentration in the batch discontinuous reacting system and/or to the competition of the photoreaction affording catechol.

By taking into account the experimental results it is evident that $CO_2$ is reduced by means of a photocatalytic reaction. The reduction process could be given by eqn. (1), where the redox

$$CO_2 + e^- + H_3O^+ \rightarrow \cdot COOH + H_2O \quad (1)$$

potential, $E^0_{redox}$ is −1.52 V *vs*. SHE.[10] Nevertheless the thermodynamic level of the conduction bands of the semiconductors used is more positive than −1.52 V and, even if the adsorption energy of $CO_2$[11] and the formation of surface states is considered, the difference between the thermodynamic level of eqn. (1) and the conduction bands of the used semiconductors is too high and, consequently, the above reduction reaction is not likely.

A more likely hypothesis for the reaction mechanism could be given by eqns. (2)–(9).

The thermodynamic potential of eqn. (4) is in standard conditions equal to −0.11 V *vs*. SHE. This last value is closer to those of the conduction bands of the used semiconductors. Anatase $TiO_2$, for instance, has the thermodynamic level of the conduction band equal to *ca*. −0.1 V *vs*. SHE,[12] while the conduction band of $WO_3$ (no variation is induced by the presence of Pt) is equal to 0.26 V *vs*. SHE (−0.059 V for each pH unity).[13]

The formation of $H_2$ as opposed to $HCO_2H$ according to eqn. (4) is thermodynamically less likely because $E_{H+/H2}$ is equal to −0.34 V *vs*. SHE in our experimental conditions (pH = 5.85). In the above mechanism, moreover, the competion among various adsorbed species for the oxidation process is taken into consideration and the occurrence of this competition could explain the different ratios of 2-hydroxybenzoic acid and catechol obtained by using different oxides.

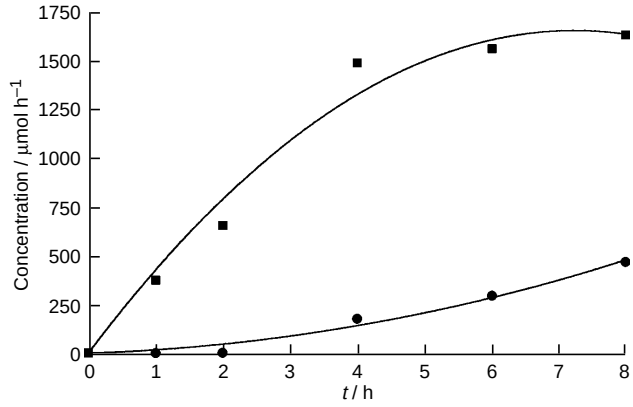


**Fig. 1** Concentration *vs*. illumination time of 2-hydroxybenzoic acid (■) and catechol (●) when anatase $TiO_2$ (Merck) was used

It should be noticed that OH radicals can attack catechol and 2-hydroxybenzoic acid further, giving rise to formation of other oxidation compounds and subsequent opening of the aromatic ring[14,15] and/or to attack methanoic acid with formation of carbon dioxide and water, eqn. (9).

Finally, it is also worth to notice that HPLC analyses indicate the presence of unidentified products and work is in progress to clarify the mechanistic aspects of the photocatalytic reaction.

**The Henry and separation constants and heat of adsorption of $N_2$ and $O_2$ in faujasite are calculated in a non-empirical way; they show fair agreement with experiment taking into account the extreme sensitivity of the configuration integral to small variations in interaction energy values.**

Zeolites are of utmost importance both as catalysts, essentially due to the acidic properties of their bridging hydroxy groups,[1,2] and as adsorbents due to their adsorption properties.[3] Present-day quantum chemistry already allows non-parametrized, highly accurate *ab initio* calculations on the acidic properties using the supermolecule approach yielding interaction energies and spectroscopic properties used as acidity indicator (*e.g.* IR frequency and intensity shifts).[4–6] The calculation of the adsorption behaviour and the thermodynamic quantities associated with it (Henry constant, separation constant, heat of adsorption) was up to now, essentially due to computational reasons, performed using model interaction potentials[7–9] and various models involving adjustable parameters.[10,11]

In this contribution we report the, as far as we know, first *ab initio* calculations of Henry constants, separation constants and heats of adsorption. The methodology is described and applied to the adsorption behaviour of $O_2$ and $N_2$ in the large cavities of a faujasite large cavity for which experimental data are available.[12,13] Its extension to less symmetrical cases and cation distributions will be straightforward.

The starting point in the evaluation of the above mentioned properties is the Henry constant expression, based on an evaluation of the ratio of the partition functions of the free and adsorbed gas.[14,15] Neglecting vibrational corrections upon adsorption and applying the ideal gas law for the non-adsorbed gas one arrives at the following expression for the Henry constant $K$ [eqn. (1)], where $B$ is the number of cavities

$$K = \frac{BI}{aRT} \tag{1}$$

in which the adsorption process can take place per mass zeolite, $R$ the ideal gas constant and $T$ the absolute temperature. The factor $a$‡ = 1 in the case of a monoatomic gas, $4\pi$ for a linear molecule and $8\pi^2$ for a non-linear molecule. $I$ is the configuration integral [eqn. (2)], where $E$ represents the interaction

$$I = \int \exp[-E(\boldsymbol{r},\boldsymbol{\phi})/RT]\mathrm{d}\boldsymbol{r}\ \mathrm{d}\boldsymbol{\phi} \tag{2}$$

energy molecule–zeolite cage when the centre of gravity of the molecule is at position $\boldsymbol{r}$ and the molecular orientation characterized by angles gathered in a vector $\boldsymbol{\phi}$. The integration is performed over all positions $\boldsymbol{r}$ in the faujasite cavity and for each position over all orientations.

The cage was chosen as to represent a faujasite Y zeolite, using hydroxy groups as terminators and showing a Si/Al ratio of 3, with bruto-formula $Na_{16}Si_{36}Al_{12}O_{120}H_{48}$.

Four of the 16 $Na^+$ ions are localized in site II with a tetrahedral orientation towards the centre of the large cavity. The interaction of the molecules ($N_2$ and $O_2$) with the cage were calculated using the 'molecule in point charge environment' approach as often used in the study of molecular crystals.[17] The point charges of the cage atoms were obtained with the ChelpG method[18] at an STO 3G[19] level. A scaling procedure was then introduced in order to account for the change in potential when removing the terminating hydroxy groups in order to be able to fully exploit the symmetry of the cage (*vide infra*): all charges were multiplied by a constant yielding the 'correct' potential at the centre of the cage (*i.e.* the potential at the centre of the cavity with the terminating hydroxy groups still present).§ This procedure is based on the idea that the artificial terminators (hydroxy groups) might perturb the real symmetry of the cage due to the presence of the hydrogen atoms.

Being able to fully exploit the cage symmetry, a cubic grid of points in the cage has been created by selecting points at a 0.5 Å distance along $x$, $y$ and $z$ axis, thereby performing the integration over $\boldsymbol{r}$ in eqn. (2) *via* a numerical procedure of evaluating the interaction energy $E$ of molecules at the centre of each cube, inserting it in the $\exp(-E/RT)$ expression and multiplying it by the elementary volume $\Delta V$ of 0.125 Å.$^3$ The integration over all orientations is ensured by performing the above-mentioned interaction energy calculation once with the molecule aligned along the $x$- as ($E_x$), once along the $y$-axis ($E_y$), and once along the $z$-axis ($E_z$) and multiplying each contribution $\exp(-E_\alpha/RT)$ ($\alpha = x, y, z$) by $4\pi/3$. Symmetry is exploited by considering only 1/24th part of the zeolite cage (*cf.* ref. 7) using a self-developed algorithm to select those grid points contained in a polyhedron with the following vertices: the centre of the cavity and the position of the cations at $S_{II}$, $S_{III}$ and $S_{IV}$.

In this way 321 points were selected and the integral (2) was replaced by the sum given in eqn. (3), where $g_i$ is a weight

$$I \approx \frac{4\pi}{3} \sum_i [\exp(-E_{x,i}/RT) + \exp(-E_{y,i}/RT) + \exp(-E_{z,i}/RT)]\ \Delta V_{gi} \tag{3}$$

factor taking the value 1,4, 12, or 24 for a point at the centre of the cavity, at an edge, on a side, or inside the '1/24' sector.

Moreover those points were rejected for which the distance to the $Na^+$ ions in the sector is smaller than the sum of the equilibrium distance $Na^+\cdots X_2$ (X = N, O) and half of the equilibrium distance of $X_2$ (both values being calculated at a 6-31G* level lead to spheres around the $Na^+$ cation of 2.50 (X = N) and 2.52 Å (X = O) respectively, in order to account for the deficiency in the short-range behaviour of the point charge model. At these distances, the true interaction energy will in most cases be repulsive so that in reality very small terms add to the sum in eqn. (3). We prefer to stick to this approximation rather than introducing a repulsive part in the point-charge potential, which will inevitably lead to some adjustable parameters in the procedure.

All interaction energies were calculated at the HF-631G* level[19] with equilibrium distances for $N_2$ and $O_2$ at the same level (1.0784 and 1.1677 Å respectively) using RHF and UHF[19] procedures for $N_2$ and $O_2$ respectively.

The configuration integrals $I$ (in m$^3$) for $N_2$ and $O_2$ at 298.15 K resulting from (3) were: $1.937\ 10^{-23}$ m$^3$ for $N_2$ and 6.335

$10^{-25}$ m$^3$ for $O_2$. The larger value for $N_2$ is in line with 6-31G* calculated stabilization energy for a linear molecule cation complex, taking basis set superposition errors[21] into account ($\Delta E$ = −6.98 *vs.* −5.11 kcal mol$^{-1}$, 1 cal = 4.184 J).

Using eqn. (1) the following values for Henry constants and the separation constant $\alpha$ [$=K(N_2)/K(O_2)$] were obtained at 298.15 K;¶ $K(N_2)$ = 37.87 × $10^{-6}$ mol kg$^{-1}$ Pa$^{-1}$, $K(O_2)$ = 7.78 × $10^{-6}$ mol kg$^{-1}$ Pa$^{-1}$, $\alpha$ = 4.87: the corresponding experimental values, for an NaY zeolite with an Si/Al ratio of 2.43 are,[12,13] 2.58 × $10^{-6}$, 1.01 × $10^{-6}$ mol kg$^{-1}$ Pa$^{-1}$ and 2.56, respectively.

The theoretical values reproduce the higher value of the Henry constant for $N_2$ as compared to $O_2$ whereas both values are roughly one order of magnitude too large, their ratio (separation constant) being of the correct order.

At this point the extreme sensitivity of $K$ to the interaction energy values appearing in the exponent should be realized. It is easily checked that, assuming a position independent difference between theoretical and experimental values, a difference of only 1.4 kcal mol$^{-1}$ accounts for an order of magnitude difference in $K$ at 298.15. In view of the parameter-free evaluation of $K$ the result is therefore pleasing, certainly when compared with literature results often adjusting interaction potentials to experimental Henry constants.

Moreover, when applying the Van't Hoff's eqn. (4)[15] the

$$\frac{\partial \ln K}{\partial T} = \frac{\Delta H^\circ}{RT^2} \qquad (4)$$

temperature range 250–310 K, recalculating for each temperature $K$ *via* eqn. (1) and (3) an almost perfect linear plot of ln $K$ *vs.* 1/$T$ is found as shown in Fig. 1 for $O_2$. The resulting heats of adsorption, $-\Delta H^\circ$, are 28.8 and 18.0 kJ mol$^{-1}$ respectively, whose order of magnitude and sequence is in reasonable agreement with the experimental values of 19.5 and 16.5 kJ mol$^{-1}$.

In view of the fast increase in computational software and hardware, *e.g.* in the application of density functional theory,[22] to problems of charge distribution[23] we consider the results of these first non-parametrized evaluations of thermodynamic quantities describing adsorption in zeolites as highly promising, offering possibilities in developing tailor-made materials (cations, structure, *etc.*) using computer experiments.[24]

P. G. and G. B. wish to thank their colleague Professor R. Schoonheydt (Laboratory for Surface Science and Catalysis, Catholic University of Leuven) for providing the Cartesian coordinates of the zeolite cage and Professor R. Kieboom of the Mathematics Department of the Free University of Brussels for advice in constructing the algorithm for selecting grid points. Dr G. Destree from the Computer Center of the Free University of Brussels is thanked for help in the automation of the interaction energy calculations. F. D. P. and C. V. A. are indebted to the Belgian National Science Foundation (NFWO) for a post-doctoral research fellow (F. D. P.) and Research Director (C. V. A.) position, respectively.

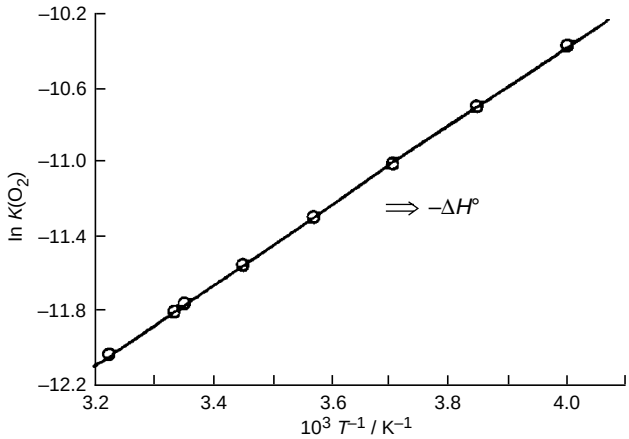

**Fig. 1** Plot of ln $K(O_2)$ *vs.* 1/$T$ calculated for $T$ in the range 250–310 K

## Footnotes

† E-mail: pgeerlin@vnet3.vub.ac.be

‡ Originating from the rotational partition function.

§ In a later stage the cage charges were recalculated at the 3-21G[19] level, using one of the author's MIA method[20] in order to speed up this 2008 basis functions problem. As the linear correlation coefficient $r$ of STO 3G and 3-21G charges amounts to 0.988, no fundamental difference between each result can be expected.

¶ The $B$ value was computed starting from the bruto formula of the unit cell [$Na_{48}$ $(AlO_2)_{48}(SiO_2)_{144}$]: taking into account that eight large cavities are present in the unit cell $B$ = 3.8275 × $10^{20}$ g$^{-1}$.

# A novel porphyrin based fluorescent chemosensor using a molecular recognition approach

**Francis D'Souza,*† Golapalli R. Deviprasad and Yi-Ying Hsieh**

*Department of Chemistry, The Wichita State University, Wichita, KS 67260-0051, USA*

**Free-base porphyrin covalently linked to quinone exhibits enhanced fluorescence on coupling the quinone with hydroquinone, primarily due to the unfavourable conditions for an electron transfer reaction between the singlet excited porphyrin and the newly formed quinone–hydroquinone entity.**

Fluorescent chemosensors are compounds with a fluorophore, binding site and a well-defined mechanism for communication. In general, these molecular systems possess binding ability coupled with photophysical–photochemical properties.[1] Two types of metal ion sensing chemosensors are known in literature:[1,2] (i) heterocycles bearing chelating arrays of donor atoms, the intrinsic chemosensors and (ii) systems in which the donor atoms remain insulated from the fluorophore π-system, the conjugate chemosensors. Some studies have also reported anion sensing fluorophores which often involve the inherent quenching property of the analyte.[1,3] On the other hand, neutral analyte sensing devices are found to be rare due to the limited availability of systems possessing complementary binding sites with an electrostatic handle on them.[4] Here we report a porphyrin based fluorescent chemosensor, where H-bonds and charge-transfer interactions are primarily responsible for stabilizing the quinone–hydroquinone complex (Fig. 1) and demonstrate enhanced fluorescence emission of porphyrin upon coupling the quinone with hydroquinone.

The quinone appended porphyrin, 5,10,15-triphenyl-20-(3,6-dioxocyclohexa-1,4-dienyl)porphyrin‡ **1a** was synthesized by the chemical oxidation of 5,10,15-triphenyl-20-(2,5-dihydroxyphenyl)porphyrin[5] using an excess of 2,6-dichloro-3,5-dicyano-1,4-benzoquinone (DDQ). The UV–VIS spectrum of **1a** in benzonitrile revealed spectral features similar to that reported for porphyrin–quinone systems in literature.[6] Addition of hydroquinone (10 equiv.) to the solution of **1a** revealed a small red shift of *ca*. 2 nm without any dramatic changes in the ε values, indicating the absence of any interactions between the added hydroquinone and the porphyrin ring. $^1$H NMR studies revealed quinone–hydroquinone coupling. The singlet peak corresponding to the aromatic protons of the free hydroquinone exhibited a multiplet pattern with a net deshielding of nearly 0.1 ppm on forming the quinone–hydroquinone complex, while the porphyrin ring protons experience a small shielding. The binding constant calculated from the $^1$H NMR data is found to be 13.1 dm$^3$ mol$^{-1}$ in $CDCl_3$ at 25 °C.

Compound **1a** is found to be weakly fluorescent ($\phi_f < 0.01$) and this has been ascribed to the photoinduced intramolecular electron transfer from the excited singlet-state porphyrin, the donor, to the appended quinone, the acceptor.[7] Interestingly, as shown in Fig. 2, addition of 1,4-hydroquinone to the solution of **1a** exhibits a drastic enhancement of the porphyrin fluorescence intensity§ and the two bands at 652 and 720 nm correspond to the free-base porphyrin emission.[8] After addition of 8 equiv. of 1,4-hydroquinone, the fluorescence emission reaches a maximum and further addition results in no appreciable changes. At the saturation point, the calculated fluorescence quantum yield,¶ $\phi_f$ is found to be 0.25 and is nearly twice that of the unsubstituted meso-tetraphenylporphyrin,[8] $H_2TPP$ ($\phi_f$ = 0.13).‖

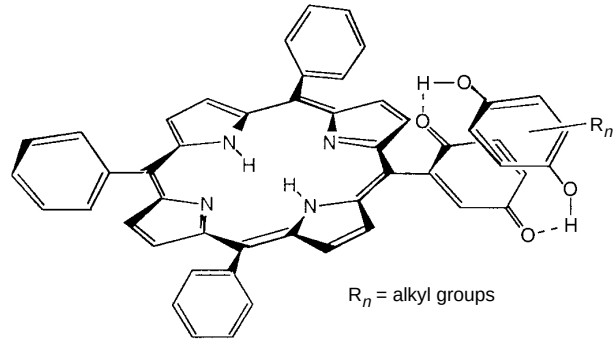

**Fig. 1**

Recently, we demonstrated a hydroquinone–quinone complexation in hydroquinone appended zinc porphyrin with intermolecularly added quinones.[5] Efficient fluorescence quenching of the zinc porphyrin was observed upon coupling the hydroquinone with substituted quinones. Electrochemical studies demonstrated that the reduction potential of the hydroquinone–quinone complexes are negatively shifted by 500–800 mV compared to that of the free quinones used for pairing. Based on the electrochemical reduction potentials of the newly formed hydroquinone–quinone redox couple, the optimum concentration of quenchers needed to saturate the fluorescence intensity and the calculated free-energy change, an excited-state electron transfer was suggested to be the quenching mechanism.[5] The present system, however, differs from the earlier one studied, in that the quinone entity is directly attached to the porphyrin π-system. In addition, it possesses a quinone–hydroquinone pair with a low reduction potential,** a free-base porphyrin with high oxidation potential†† and low energy of singlet-singlet emission compared to that of zinc porphyrin.[8] The net result of this redox tuning and altered photophysical property is the inhibition of fluorescence quenching due to intramolecular electron transfer. The calculated free energy change for an electron transfer from the excited free-base porphyrin to the quinone–hydroquinone complex, using the Rehm and Weller equation,[10] is found to be endergonic by *ca*. 0.33 V. As a result, the added hydroquinone upon complexing with quinone, inhibits the excited-state electron transfer in **1a** and consequently enhances the porphyrin fluorescence emission.[11]

Under normal conditions, one would expect the $\phi_f$ of **1a** in presence of hydroquinone to be close to that of the unsubstituted free-base porphyrin, $H_2TPP$; however, in the present study, the calculated $\phi_f$ is nearly two times that of $H_2TPP$ [see Fig. 2(*h*)]. This additional fluorescence enhancement could be attributed to the mode of attachment of the quinone–hydroquinone to the porphyrin macrocycle and the nature of the charge-transfer interactions. Spectroscopic studies on the hydroquinone–quinone complexes have shown substantial charge-transfer interactions between the hydroquinone as a donor and benzo-

quinone as an acceptor.[12] This suggests that when the linkage is through quinone, the partial negative charge residing on the quinone would interact with the porphyrin π-system and might be responsible for fluorescence enhancement. If this is correct, then one would expect higher $\phi_f$ on fully reducing the quinone of **1a** instead of the partial negative charge of the quinone–hydroquinone complex. The following electrochemical studies suggest that this is more likely the case.

The cyclic voltammogram†† of **1a** in PhCN exhibits four well separated one-electron reductions (Fig. 3). The first two processes corresponding to the reduction of the appended benzoquinone are located at $E_{1/2} = -0.51$ and $-0.93$ V respectively[13] while the latter two processes corresponding to the porphyrin ring reductions[14] are located at $E_{1/2} = -1.41$ and $E_{pc} = -1.83$ V *vs*. SCE respectively at a scan rate of 0.1 V $s^{-1}$. In order to generate a neutral free-base porphyrin linked to quinone anion radical, bulk electrolysis of **1a** was carried out at an applied potential of $-0.75$ V, a potential slightly more negative than the first reduction potential of the appended benzoquinone. After completion of the electrolysis, the fluorescence spectrum of the one-electron reduced product was recorded [see Fig. 2(*i*)]; the emission intensity was nearly 10% more than that observed for **1a** in the presence of excess of hydroquinone, suggesting that the interactions between the partially or fully reduced quinone and the porphyrin macrocycle could be responsible for additional fluorescence enhancement. However, further studies are needed to fully understand the mechanistic details of fluorescence enhancement in this novel system and these studies are in progress.

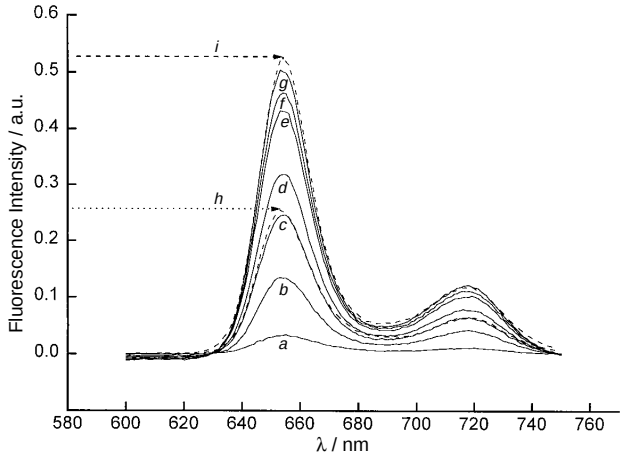

**Fig. 2** Fluorescence emission spectrum of (*a*) compound **1a** (1 μM) in PhCN, $\lambda_{ex}$ = 514 nm. Spectra (*b*)–(*g*) represent the emission spectrum of **1a** on increasing addition of hydroquinone (1 μM aliquots). Spectra (*h*) and (*i*) represent the emission spectrum of $H_2$TPP and the one-electron reduced product of **1a** in PhCN.

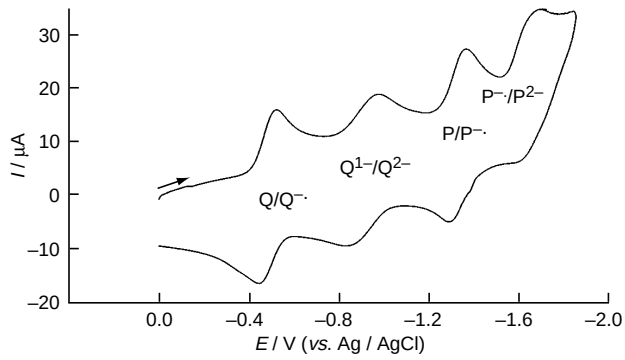

**Fig. 3** Cyclic voltammogram of compound **1a** in benzonitrile, 0.1 M TBAP, scan rate = 0.1 V $s^{-1}$

‡ $\delta_H(CDCl_3)$ 8.90 (m, 8 H, pyrrole-H), 8.20 (s, 6 H, *ortho*-H of the triphenyl entity), 7.75 (m, 9 H, *meta*- and *para*-H), 7.29, 7.60, 8.38 (d, d and s, 3 H, quinone-H) and −2.78 (s, 2 H, imino-H). $\lambda_{max}$ (PhCN)/nm (log ε) 414.6 (5.85), 511.6 (4.31), 542.2 (3.77), 590.3 (3.75) and 649.8 (3.66).

§ Addition of excess of hydroquinone to a solution of $H_2$TPP resulted in no appreciable changes in the fluorescence emission.

¶ Fluorescence quantum yields were calculated using the method described in ref. 9.

‖ Use of other alkyl substituted hydroquinones resulted in a similar fluorescence enhancement.

** Reduction of the quinone–hydroquinone complex in PhCN occurs at $E_{1/2} = -1.26$ V *vs*. SCE.

†† The first reversible oxidation of **1a** in PhCN, 0.1 M TBAP occurs at $E_{1/2}$ = 1.01 V *vs*. SCE.

‡‡ Cyclic voltammograms were obtained on a EG & G Model 263 A potentiostat using a three-electrode system. A glassy carbon electrode was used as the working electrode. A platinum wire served as the counter electrode, and Ag/AgCl was used as the reference electrode.

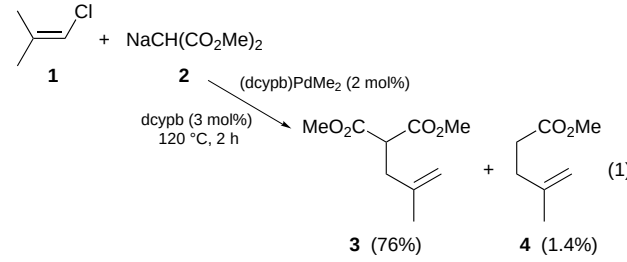
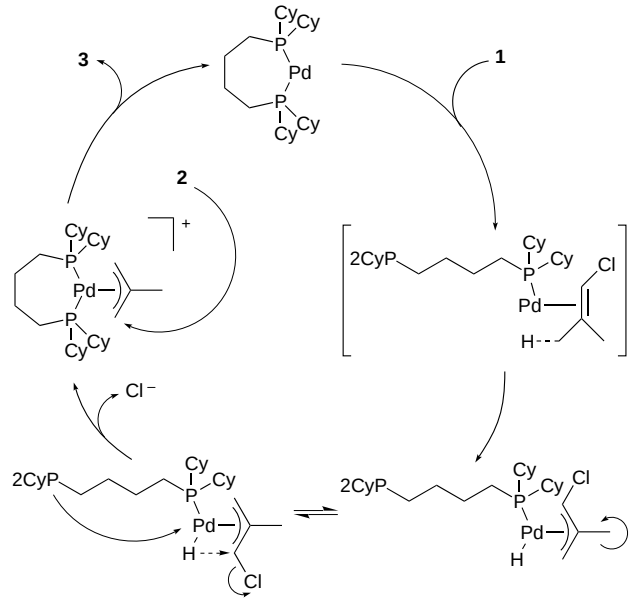
# Regioselective palladium-catalysed coupling reactions of vinyl chlorides with carbon nucleophiles

**Manfred T. Reetz,* Klaus Wanninger and Marcus Hermes**

*Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm Platz 1, D-45470 Mülheim/Ruhr, Germany*

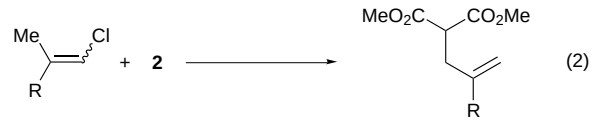


**Vinyl chlorides bearing methyl groups in the 2-position can be activated catalytically by palladium(0)-complexes of 1,4-bis(dicyclohexylphosphino)butane, the process involving vinyl–allyl isomerization *via* CH-activation followed by nucleophilic attack of C-nucleophiles on the intermediate palladium–π-allyl species.**



The palladium-catalysed activation of carbon–chlorine bonds in Heck reactions of chloro-aromatics is of great industrial interest because these substrates are much cheaper than the considerably more reactive bromo or iodo analogues.[1] One interesting approach recently published by Milstein makes use of the 1,4-bis(diisopropylphosphino)butane bidentate ligand (dippb), which is believed to open and reclose reversibly with respect to palladium complexation during the catalytic cycle.[2] While the quest for higher efficiency and broader synthetic scope continues in this area, very little is known concerning the catalytic activation of vinyl chlorides.[3] Here we report a serendipitous finding according to which this class of compounds can be induced to undergo unusual C–C bond forming reactions with carbon nucleophiles such as sodium malonates.[4]

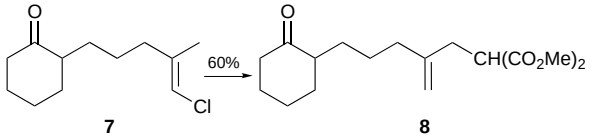
In initial attempts to perform a Heck reaction of 1-chloro-2-methylprop-1-ene **1** with styrene, we essentially used the Milstein protocol described for chlorobenzene, except that dippb was replaced by a geometrically and electronically similar ligand which is more readily available, namely 1,4-bis-(dicyclohexylphosphino)butane (dcypb). However, only 5–20% of the Heck coupling product 1,1-dimethyl-4-phenylbutadiene was formed. Speculating that the problem could be due to the formation of a catalytically non-active palladium–π-allyl species following Heck-type C–C bond formation, we repeated the reaction in the presence of sodium dimethylmalonate **2** as a carbon nucleophile in hope of inducing a tandem Heck[5]–allyl substitution process [2 mol% $Pd(OAc)_2$, 5 mol% dcypb, DMF, 150 °C, 18 h]. To our surprise none of the expected tandem reaction product was observed, the major products being 2-methylallylmalonic acid dimethyl ester **3** (55%) and its decarboxylated form **4** (20%). Since styrene is not involved, the reaction was repeated in the absence of this olefin at a lower temperature [2 mol% $Pd(OAc)_2$, 5 mol% dcypb, DMF; 120 °C, 18 h]. Again the methallylated products **3** (70%) and **4** (12%) were formed. Other ligands are less effective, the yields of **3**/**4** being lower, as in the case of $PPh_3$ (8%/3%), 1,2-bis(diphenylphosphino)ethane (4%/5%) and 1,4-bis(diphenylphosphino)butane (32%/26%). In further optimization it was discovered that the best catalyst system is the dimethylpalladium complex of the ligand (dcypb) $PdMe_2$ (2 mol%) in the presence of additional dcypb (3 mol%) at 120 °C, 2 h, leading to products **3** (76%) and **4** (1.4%) eqn. (1).†



A plausible mechanism involves palladium-catalysed isomerization of the otherwise non-reactive vinyl chloride **1** to methallyl chloride followed by classical palladium-catalysed allylic substitution in which the malonate participates as the carbon nucleophile. Separate NMR experiments revealed that the reaction is initiated by thermolytic decomposition of (dcypb)$PdMe_2$ with formation of (dcypb) Pd° (or its dimer).[4] It is likely that the reactive palladium(0)-catalyst then coordinates to the double bond of **1** and induces CH-activation in one of the methyl groups, the first step in the isomerization. Methallyl chloride may not actually be set free, since palladium can remain coordinated to the π-allyl system, chloride being expelled with intermediate formation of $[Pd\{\eta^3\text{-}(CH_2CMe{=}CH_2)\}(dcypb)]^+$. Indeed, upon heating (dcypb)$PdMe_2$ in the presence of **1** as the sole reaction partner, this cationic palladium–π-allyl species was identified as the major product by NMR spectroscopy; its $BF_4^-$ salt was synthesized by an independent route and its structure proven by X-ray structural analysis.[4] Scheme 1 shows a possible catalytic cycle which is in accord with all of the present data, including the observation that other ligands are less effective.

Regioselectivity and therefore the possibility of two different products becomes relevant in the case of unsymmetrically substituted vinyl chlorides. In order to test whether the reaction is regioselective, substrates **5** [eqn. (2)] were subjected to the isomerization–substitution reaction. In all cases complete regioselectivity was observed in that CH-activation occurs solely at the methyl groups.

**Scheme 1**



(2)

**5** **6**

**a** *E*, R = cyclo-$C_6H_{11}$ 75%

**b** *Z*, R = cyclo-$C_6H_{11}$ 65%

Finally, more highly functionalized substrates such as **7** [eqn. (3)] are also amenable to the reaction. In this case a small

(3)

**7** **8**

amount of a double bond isomer was also observed (14%). Substrates bearing groups larger than methyl do not react analogously, probably due to steric reasons. The bulky ligands due not tolerate additional alkyl groups in the substrate, *e.g*. in the palladium–π-allyl species (Scheme 1).

In summary, vinyl chlorides having at least one methyl group in the 2-position can be activited catalytically using palladium(0)-complexes of 1,4-bis(dicyclohexylphosphino)butane. The gross features of the mechanism involve vinyl–allyl isomerization *via* CH-activation at the methyl groups followed by classical nucleophilic attack by sodium malonate on the intermediate cationic palladium–π-allyl species. The results suggest that the catalytic activation of otherwise inert vinyl chlorides should be possible in other types of processes using palladium or other transition metal catalysts.

## Footnote

† *Typical procedure*: A dry 25 ml Schlenk tube under an argon atmosphere is charged with **1** (0.5 ml, 5 mmol), (dcypb)$PdMe_2$ (58 mg, 0.1 mmol), dcypb (68 mg, 0.15 mmol), **2** (5 mmol) in DMF (5 ml) and heated to 120 °C for 2 h. The mixture is diluted with ethyl acetate (15 ml), treated successively with 10% HCl solution, water and $NaHCO_3$ and NaCl solutions and dried over $MgSO_4$. Most of the solvent is removed and the residue analysed by gas chromatography. **3** is purified by chromatography (silica, pentane–$Et_2O$ 4 : 1).

# A novel method of preparing thiol-derivatised nanoparticles of gold, platinum and silver forming superstructures

**K. Vijaya Sarathy, G. U. Kulkarni and C. N. R. Rao***

*Jawaharlal Nehru Centre for Advanced Scientific Research, Jakkur, Bangalore 560 064, India*

**Thiol-derivatised nanoparticles of Au, Pt and Ag (diameter 1–10 nm) forming superstructures, are prepared by the acid-facilitated transfer of well characterized particles in a hydrosol to a toluene layer containing the thiol.**

Nanoparticles of gold and other noble metals are attracting much attention because of their potential applications in microelectronics.[1,2] Several wet chemical methods have been reported in the recent years, for the preparation of colloidal metal sols.[3,4] The methods generally involve the reduction of the relevant metal salt in the presence of a suitable surfactant, the surfactant being useful in the control of the growth of the metal particles. Thiol-derivatised nanoparticles of noble metals are particularly fascinating in that they can be recrystallised from the parent solution; they often self-assemble into cross-linked structures or superlattices on removal of the solvent.[2,5] Since the first report on the synthesis of thiol-derivatised nanoparticles,[6] the common practice is to first extract the metal ions from the aqueous medium to a hydrocarbon (toluene) layer by means of a phase-transfer reagent such as tetraoctylammonium bromide and then to carry out the reduction with $NaBH_4$ in the presence of an alkanethiol. Here, the nucleation and growth of the metal particles as well as the attachment of the thiol molecules occur nearly simultaneously. Metal particles prepared in this manner generally contain nitrogenous surface impurities due to the phase-transfer reagent,[6] which render it difficult to obtain good superstructures. What would be desirable is a procedure wherein one can transfer the well characterized metal nanoparticles from a hydrosol to a non-polar medium containing the thiol. We have indeed found such a direct procedure to be feasible and have successfully prepared thiol-derivatised nanoparticles of Au, Ag and Pt of desired size distributions.

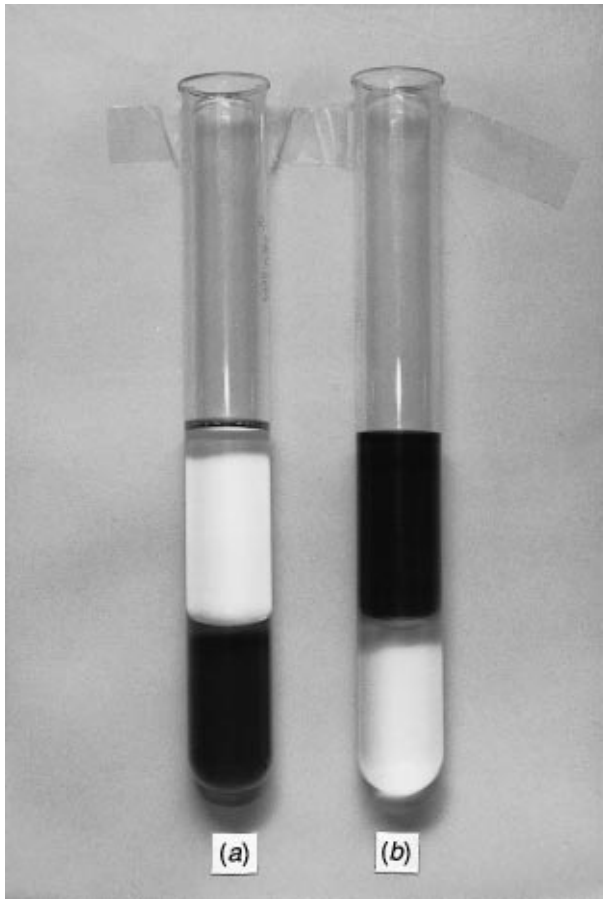

**Fig. 1** Immiscible layers of (*a*) the gold hydrosol (at the bottom) and the clean toluene solution containing the thiol (on top). (*b*) Thiol-derivatised Au sol in toluene (on top) and the clean aqueous solution at the bottom.

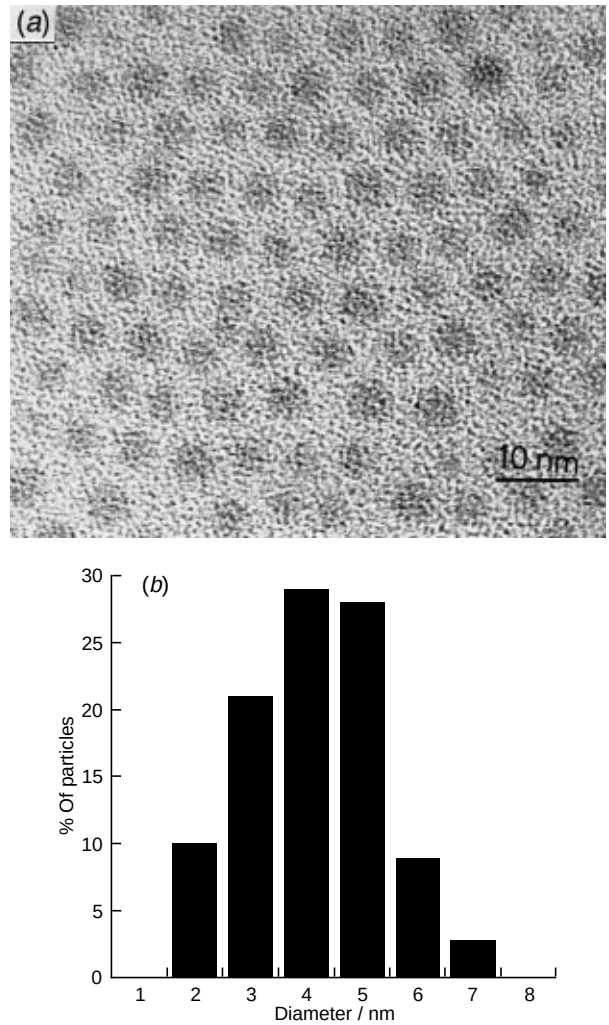

**Fig. 2** (*a*) TEM image of the thiol-derivatised Au nanoparticles forming a superstructure. (*b*) Histogram showing the size distribution.

In a typical preparation, a hydrosol containing small clusters of Au was first prepared by the reduction of chloroaurate ions (2.2 ml of 25 mM aqueous solution) using partially hydrolysed tetrakis(hydroxymethyl) phosphonium chloride (THPC),[7] having prepared the latter by adding 1 ml of a fresh 50 mM solution of THPC in water to 47 ml of 6.38 mM NaOH solution. To the gold sol so obtained, 100 ml of a 0.25 mM solution of dodecanethiol in toluene (Au : S = 2 : 1) was added, to obtain two immiscible layers consisting of the transparent organic phase containing the thiol on the top and the coloured hydrosol at the bottom. To this biphasic mixture, 125 ml of conc. HCl was added under stirring. This resulted in a remarkably swift movement (within 3 min) of the Au nanoparticles to the hydrocarbon layer containing the thiol. Clearly, the gold particles have an inherent attraction to the thiol molecules. This could be seen vividly by the complete transfer of colour across the interface to the hydrocarbon layer as shown in Fig. 1. The gold sol in toluene was shaken with water several times to remove traces of HCl and evaporated to *ca*. 2 ml in a rotary evaporator. The excess thiol was removed by the addition of 350 ml of ethanol (95%). The dark brown solid thus obtained was filtered, washed with ethanol and dispersed in 10 ml of toluene for further investigations. The UV–VIS spectrum of the toluene sol of gold showed a broad band at *ca.* 520 nm due to plasmon absorption just as the hydrosol. The core-level X-ray photoelectron spectrum showed the Au $4f_{7/2}$ binding energy at 84 eV, corresponding to the $Au^0$ state. There was a feature at 163.5 eV due to S 2p showing that the thiol molecules were chemisorbed on the gold surface. There was no evidence of a feature due to P 2p from THPC in the spectrum, unlike in the particles from the hydrosol which showed the feature at *ca*. 133 eV. It appears that the role of HCl in the present procedure is to cleanse the surface of the Au particles and facilitate their transfer to the hydrocarbon layer.

Fig. 2(*a*) shows the transmission electron microscope (TEM) image (recorded with JEOL JEM3010, Japan) of the thiol-derivatised Au nanoparticles obtained by placing a drop of the toluene sol on the holey carbon grid. The particles are nearly spherical with a mean diameter of 4.1 nm. The size distribution obtained, with the help of a Quantimat image analyser, is quite narrow as can be seen from the histogram in Fig. 2(*b*). Furthermore, the nanoparticles assemble into a superstructure as revealed by Fig. 2(*a*). The centre-to-centre nearest-neighbour distance between the nanoparticles is nearly constant at *ca*. 5.5 nm, throughout the superstructure domain. The X-ray diffraction pattern of a film of this material exhibits a low-angle peak corresponding to a *d*-spacing of *ca*. 5 nm. In order to examine whether the individual nanoparticles were crystalline or not, nanoparticles deposited on thin flakes of layered $MoSe_2$ were observed by TEM. The images showed Moiré patterns arising from the interference between the crystallographic planes of $MoSe_2$ and those of the nanoparticles, thereby establishing the crystallinity of the individual particles.

We have been able to prepare thiol-derivatised nanoparticles of Au with different mean diameters in the 1–10 nm range, by varying the concentration of $HAuCl_4$ in the initial hydrosol, by employing the present procedure. We have also prepared Au hydrosols with other reducing agents such as citric acid[8] and thiol-derivatised them by this procedure. The citric acid procedure, however, seems to yield nanoparticles of different shapes (spherical, triangular, pentagonal, hexagonal and rod-like) with varying sizes (*ca*. 25–50 nm).

We have prepared thiol-derivatised nanoparticles of Pt and Ag by the present procedure, by starting with hydrosols obtained with $NaBH_4$ as the reducing agent. Fig. 3(*a*), shows a typical TEM image of thiol-derivatised Pt nanoparticles. These particles are spherical with a narrow size distribution, the mean diameter being 4.4 nm. The figure also reveals a superstructure similar to that of Au in Fig. 2(*a*). A TEM image of thiol-derivatised Ag nanoparticles is shown in Fig. 3(*b*). The image shows that the Ag particles are not as spherical as those of Au and Pt and resemble the Ag particles prepared under vacuum.[9]

The authors thank the Department of Science and Technology for support of this research.

**A bis(acetonitrile)iron(II) complexes with 1,3-dimethyl-1,3-propanediylidenebis(2-pyridylmethanamine) undergoes a nucleophilic addition to the nitrile carbon on addition of triethylamine to a nitrile solution yielding mono(acetonitrile)iron(II) complex with a novel pentadentate polyimine ligand.**

A tetradentate ligand containing a 1,3-diimine moiety, 1,3-dimethyl-1,3-propanediylidenebis(2-pyridylmethanamine), L, which is formally derived from acetylacetone and 2-(aminomethyl)pyridine, is expected to coordinate to metal ions leaving two coordination sites for other ligands. In this report, we describe the synthesis of the iron(II) complex with this ligand and its reaction products with acetonitrile and [$^2H_3$]acetonitrile and their structures obtained by X-ray crystallography.

The iron(II) complex, *trans*-[FeL(MeCN)$_2$][ClO$_4$]$_2$·MeCN **1** was prepared in moderate yield (50–60%) under strict anaerobic and dehydrated conditions by successive additions of precursor tridentate ligand MeCOCH$_2$C(Me)=NHCH$_2$C$_5$H$_4$N and 2-(aminomethyl)pyridine to an acetonitrile solution of [Fe(MeCN)$_6$]$^{2+}$ prepared *in situ*.† These crystals were not stable under air and even stored in a vacuum were potentially explosive.

The structure of **1** was determined by X-ray crystallography and that of the cation is shown in Fig. 1.‡ Two acetonitriles coordinate *trans* to each other to form a distorted octahedral geometry. The six-membered chelate ring of the 1,3-diimine moiety is almost planar with a mean deviation of 0.042 Å and a largest deviation of 0.076(6) Å at C(8). The two pyridine rings swing away from each other in order to evade the intramolecular repulsion between two 6-position hydrogen atoms on each pyridine to give a dihedral angle of 30.95° between two pyridine rings as found for *trans*-bis(bipyridine)palladium complexes.[1]

This complex showed a C≡N stretching band at 2244 cm$^{-1}$ and weak absorption band at 527 nm ($\varepsilon$ = 150 dm$^3$ mol$^{-1}$ cm$^{-1}$) for an acetonitrile solution. The variable-temperature $^1$H NMR spectra of this compound§ exhibited seven signals which obey non-Curie dependency similar to that reported about intersystem crossing polypyridyl ferrous complexes.[2]

The C–C bond formation between a coordinated tetradentate ligand and a (coordinated) acetonitrile occurred at room temperature within 2 h on addition of a small amount of triethylamine to an acetonitrile solution of **1**. Orange crystals of the iron(II) complex of 2-(1-iminoethyl)-1,3-dimethyl-1,3-propanediylidenebis(2-pyridylmethanamine), L′, [FeL′(MeCN)][ClO$_4$]$_2$·thf, **2** were used for crystal structure determination. These are two crystallographically independent molecular ions with almost identical structures and two thf molecules in the asymmetric unit: one of the molecular ions is shown in Fig. 2.‡ The tetradentate moiety adopts *cis*-β coordination and the

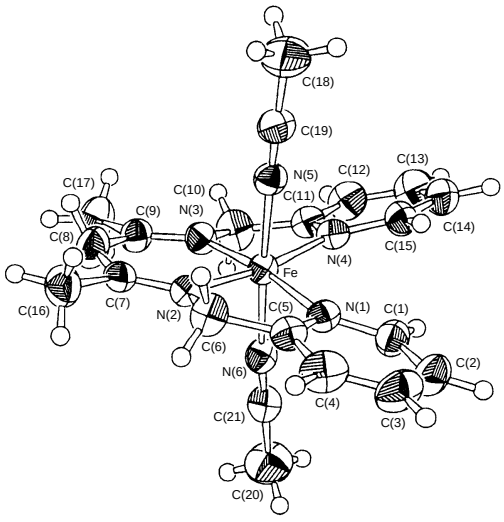

**Fig. 1** Molecular structure of the cation of **1** showing the atom numbering scheme

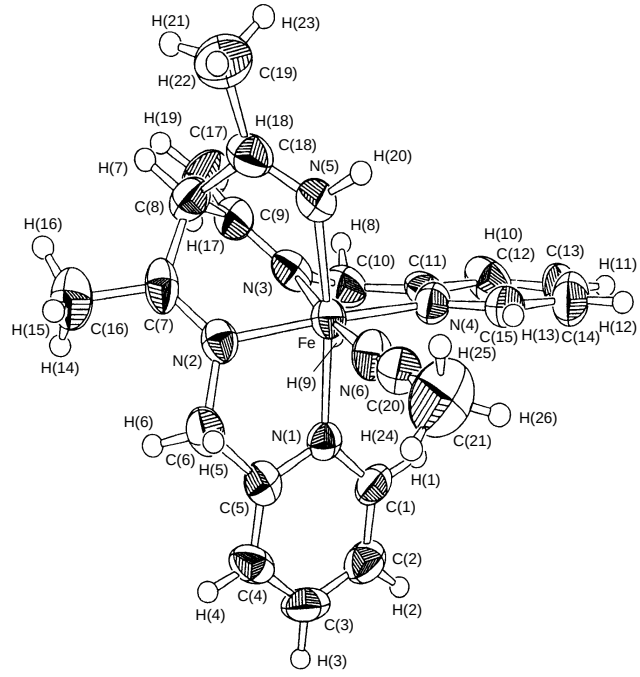

**Fig. 2** Molecular structure of one of the crystallographically independent cations of **2** showing the atom numbering scheme

acetonitrile was fused to the central carbon atoms of the 1,3-diimine moiety. One trigonal face is occupied by the three isolated imines which are linked to the tetrahedral C(8) and the C=N bond distances are N(2)–C(7) 1.31(1), N(3)–C(9) 1.28(1) and N(5)–C(18) 1.29(1) Å. The six-membered chelate rings of FeN(2)C(7)C(8)C(9)N(3) changed to a boat conformation due to the tethering methylimino group. The two pyridine rings coordinate *cis* to each other and the dihedral angle between the two pyridine planes was 94.07°.

Complex **2** gave broad $^1$H NMR spectra at room temperature but the spectra showed sharp signals at −10 °C. A new signal at δ 11.14 is assigned to the coordinated C=NH. The complex prepared from [$^2H_3$]acetonitrile in place of acetonitrile showed a spectrum which lacked the methyl signal at δ 2.48.§

The addition reaction of acetonitrile closely related to this has been reported by Riley and Busch.[3] The reaction conditions for preparation of acetonitrile adducts of macrocyclic tetraimine iron(II) complexes preclude the use of nitriles other than acetonitrile. However, the isolation of **1** allows the reaction with other nitriles as solvents, in place of acetonitrile, *e*.g. [$^2H_3$]acetonitrile in this experiment. The reaction mechanism may be *via* nucleophilic attack of a carbanion formed at the central carbon of the 1,3-diimine moiety either to the acetonitrile coordinated to the apical position and activated by the iron(II) centre as proposed by Riley *et al*. or to a bulk acetonitrile followed by coordination of imine nitrogen to the apical position. This can be resolved by the kinetics of this reaction. The use of a variety of nitriles for the preparation of iron(II) complexes with this new class of pentadentate ligands are now under study.

## Footnotes

† *Experimental procedure*: **1**; $Fe(ClO_4)_2\cdot 6H_2O$ (8.02 g, 95%, 0.021 mol) was placed in a 250 ml Schrenck and a mixture of orthoethylformate (23 ml) and acetonitrile (46 ml) was added. The mixture was stirred at 50 °C overnight. $MeCOCH_2C(Me)=NHCH_2C_5H_4N$ (3.99 g, 0.021 mol) and 2-(aminomethyl)pyridine (2.16 g, 0.019 mol) were added successively. After the mixture was stirred for 2 h at 50 °C, the mixture was cooled and dehydrated diethyl ether was added. Pale-red crystals were obtained which were stored *in vacuo*. Yield, 6.97 g (0.11 mol), 53.8%.

**2**; five drops of triethylamine was added through a syringe to an acetonitrile (8 ml) solution of **1** (266 mg, 0.404 mmol). After stirring at room temp. for 2 h, the reaction mixture was concentrated to dryness. The remaining orange solid was dissolved in 5 ml of acetonitrile, thf (40 ml) was added and the separated orange crystals were collected and stored *in vacuo*. Yield, 235 mg (84.4%). Anal. Calc. for $C_{21}H_{26}Cl_2FeN_6O_8\cdot C_4H_8O$: C, 43.56; H, 4.97; N, 12.19. Found: C, 43.04; H, 4.79; N, 12.02%.

‡ *Crystal data* for **1** and **2**: reflections were collected on a Rigaku AFC7R diffractometer using graphite-monochromated Mo-Kα radiation (λ = 0.710 69 Å), at $T$ = 293 K to $2\theta_{max}$ = 55.0°. **1**; $C_{23}H_{29}Cl_2FeN_7O_8$, $M$ = 658.28, triclinic, space group $P\bar{1}$, $a$ = 12.361(3), $b$ = 12.415(2), $c$ = 10.472(2) Å, α = 94.68(1), β = 112.19(1), γ = 80.41(2)°, $U$ = 1467.1(6) Å$^3$, $Z$ = 2, $D_c$ = 1.490 g cm$^{-3}$, $F(000)$ = 680, μ = 7.53 cm$^{-1}$. Data were corrected for absorption and extinction. $R_w = \{\Sigma w(F_o - F_c)^2/\Sigma wF_o^2)\}^{1/2}$ = 0.055, $R = \Sigma|F_o - F_c|/\Sigma|F_o|$ = 0.050 for 3399 reflections with $I/\sigma(I) > 3.0$.

**2**: $C_{25}H_{34}Cl_2FeN_6O_9$, $M$ = 689.33. monoclinic, space group $P2_1/a$, $a$ = 19.235(2), $b$ = 16.044(3), $c$ = 20.732(3) Å, β = 102.91(1)°, $U$ = 6236(1) Å$^3$, $Z$ = 8, $D_c$ = 1.468 g cm$^{-3}$, $F(000)$ = 2864.00, μ = 7.13 cm$^{-1}$. Data were corrected for absorption and extinction. $R_w$ = 0.068, $R$ = 0.082 for 7115 reflections with $I/\sigma(I) > 3.0$. # Self-assembly and X-ray structure of a ten-component, three-dimensional metallosupramolecular cage

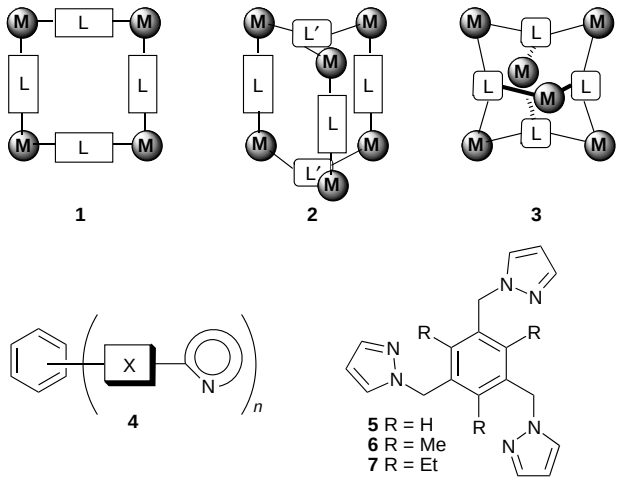
**Chris M. Hartshorn and Peter J. Steel***

*Chemistry Department, University of Canterbury, Christchurch, New Zealand*



**Reaction of 1,3,5-tris(pyrazol-1-ylmethyl)-2,4,6-triethylbenzene 7 with palladium chloride results in the self-assembly of a three-dimensional cage; an X-ray crystal structure determination shows that the cage is comprised of an octahedral arrangement of six palladium atoms bridged by a tetrahedral network of four molecules of the ligand and contains a (disordered) guest molecule of dimethyl sulfoxide.**

The use of metal ions to control the self-assembly of multicomponent supramolecular structures of varying architecture is a subject of much current investigation;[1] particular recent attention has focused on the formation of species with internal cavities.[2] Since 1990, several groups have reported the construction of various molecular squares, represented schematically by structure **1**.[3] Lehn and coworkers[4] subsequently reported the formation of a three-dimensional cylindrical molecular box **2**, comprised of six metal ions and two types of bridging ligand. Fujita *et al.* have since reported the assembly of a five-component molecular cage[5] and, most recently, a ten-component adamantanoid-type cage **3** comprised of six metals with four identical bridging ligands.[6] We now report the formation and X-ray structure of a constitutionally similar but topologically different $M_6L_4$ cage.

We are currently engaged in a detailed study[7] of the coordination chemistry of a series of polyheteroaryl-substituted arenes **4**, which consist of various heterocyclic rings attached *via* spacer groups, X, to a central arene core, and have reported the syntheses of a number of poly(pyrazolylmethyl)benzenes.[8] We have also shown that the mesitylene-derived ligands **5** and **6** are able to encapsulate an octahedral metal atom, with simultaneous $\eta^6$-arene coordination and tripodal chelation to the pyrazole rings.[9] We have now extented this study to examine the complexes of these ligands with metal ions of different coordination geometry. In an effort to pre-organise the three pyrazole rings on the same side of the benzene ring,[10] we have now synthesised the triethyl analogue **7**, by trisbromomethylation[11] of 1,3,5-triethylbenzene, and subsequent phase-transfer-catalysed reaction with pyrazole.†

Reaction of **7** with palladium chloride gave immediate precipitation of an orange product,‡ which, on dissolution in $Me_2SO$, gave a $^1H$ NMR spectrum that showed significantly different chemical shifts from those of **7**, but retained the threefold symmetry. This was difficult to explain in terms of a square-planar palladium complex of low-nuclearity. Single crystals of this compound were grown by diffusion of acetone into an $Me_2SO$ solution of the solid, but these decomposed instantaneously upon removal of the solvent. After many attempts, a crystal was successfully tranferred to the low-temperature stream of a four-circle diffractometer with only minor decomposition.§

Fig. 1 shows a perspective view of the major component of the contents of the asymmetric unit of this structure.¶ It consists of a ten-component, three-dimensional metallosupramolecular cage comprised of six *trans*-dichloropalladium units bridged by four molecules of **7**. The six palladium atoms are arranged in a pseudo-octahedral array, while the four molecules of **7** form a tetrahedrally disposed internal core of benzene rings of approximately 4.7 Å internal radius. Within this core resides a single (disordered) $Me_2SO$ molecule (not shown in Fig.1). The potential $T_d$ symmetry is not crystallographically imposed, and is destroyed by differing conformations of the ethyl groups; specifically, one of the ligands has all three terminal methyl groups directed towards the internal core, while the other three ligands have one methyl group directed outside the core. This, along with the presence of the $Me_2SO$ guest and intermolecular interactions, results in a significant reduction in symmetry

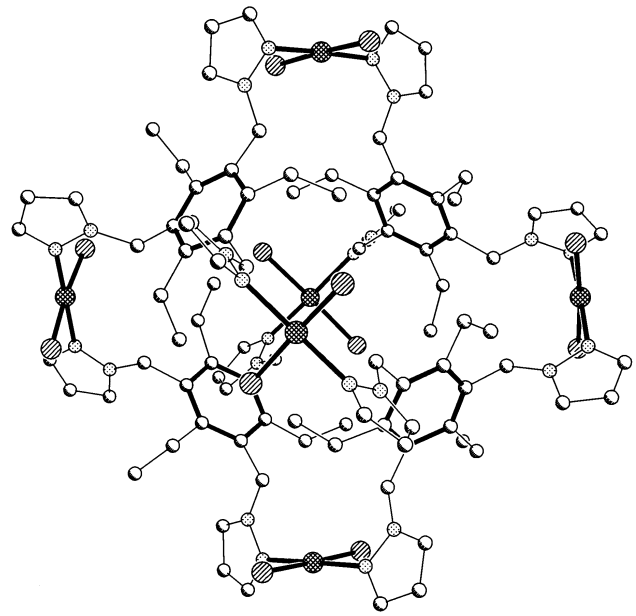


**Fig. 1.** Perspective view of the X-ray crystal structure; hydrogen atoms and solvate molecules not shown for clarity

in the solid state. For example, the diagonally opposite palladium atoms have separations ranging from 13.26 to 15.54 Å (Fig. 2). We believe that this cage structure is maintained in solution, which explains the symmetry observed in the NMR spectra and the slight broadening of the signals due to the methyl and methylene protons.

This molecule represents the second example of a $M_6L_4$ supramolecular adamantanoid cage, and serves to demonstrate the generality of such assembly processes; examples are also known of stoichiometrically inverted $M_4L_6$ compounds.[12] It is also the first X-ray structure of a free cage of this sort; in the previous example,[6] a low-precision X-ray structure of a clathrate complex with four adamantanyl carboxylate ions was determined. Although constitutionally similar to the previously reported $M_6L_4$ cage, the present structure is topologically quite different in shape. This is primarily a consequence of the different coordination geometries of the palladium atoms in the two compounds. In the only other example,[6] the bridging ligands were obligatorily *cis*-coordinated to the palladiums, due to the presence of chelating ethylenediamine ancillary ligands; in the present case, the ligands are *trans*- coordinated, which has the effect of making the palladiums more exposed on the surface of the cage. Furthermore, the methylene spacer groups in **7** impart greater flexibility to the ligand and, combined with the fact that the coordinating nitrogen is adjacent to the spacer group, allows for more compact packing within the cage; in the earlier case[6] the diagonally opposite palladiums were separated by *ca*. 19 Å.

The internal core of four tetrahedrally arranged benzene rings is reminiscent of that in the recently synthesised $C_{36}H_{36}$ spheriphane molecule which has covalently bonded ethylene bridges linking the benzenes and a radius of the internal cavity (as measured from the centroids of the rings) of 2.84 Å.[13] In the present case, the nature of the bridges expands this core to a radius of approximately 4.7 Å and allows for the incorporation of an $Me_2SO$ guest molecule. The octahedral arrangement of the six metals is also related to that in the hexacoordinated palladium and platinum complexes of $C_{60}$, wherein the diagonally opposite metals are separated by *ca*. 11.2 Å and the internal core has a diameter of only 3.51 Å.[14]

In conclusion, we have shown that, upon reaction with palladium chloride, the ligand **7** self-assembles into a ten-component metallosupramolecular cage. Studies directed towards the assembly of related structures employing other bridging ligands, including dissymmetric and asymmetric examples, are currently in progress.

# Polymerized gels and 'reverse aerogels' from methyl methacrylate or styrene and tetraoctadecylammonium bromide as gelator

**Weiqiang Gu,[a] Liangde Lu,[a] George B. Chapman[b] and Richard G. Weiss*[a]**

*Departments of Chemistry[a] and Biology,[b] Georgetown University, Washington, DC 20057-1227, USA*

**The low molecular mass gelator, tetraoctadecylammonium bromide, can be removed from polymerized gels of methyl methacrylate or styrene to leave mesoscopic channels with submicrometre diameters.**

Recently, we observed that very small concentrations of several tetraalkylammonium salts, some containing a cholesteryl or aromatic unit[1] and others having four *n*-alkyl chains,[2] gel a variety of organic liquids in a thermo-reversible fashion. Subsequently, we discovered that methyl methacrylate (MMA) and styrene (STY) are among them. Here, we report (*i*) the polymerization of gels of MMA and STY in which the gelator is tetraoctadecylammonium bromide (TOAB),[2] (*ii*) a comparison of the gel properties before and after polymerization, and (*iii*) the successful removal of the gelator molecules, leaving the polymerized matrix with vacant submicron cross-sectional channels.

Typically, low molecular mass gelators organize into long, thin strands that assemble into colloids.[3] When the colloids fill the sample volume and are in contact with each other, the liquid component is immobilized on a macroscopic scale by surface tension, but remains isotropic on a microscopic (molecular) scale.[4] Gels can be converted to aerogels by evaporation of the liquid when the gelator strands have sufficient mechanical strength not to collapse under the force of gravity. This case is usually limited to high molecular mass (*i.e.* polymeric), inorganic gelators;[5] collapsed aerogels (*i.e.* xerogels) are usually obtained from gels with low molecular mass gelators.[6] The sizes of the channels created in an aerogel are dependent upon how extensive is the gelator network, but they are not uniform.[7]

If, instead, the gelator strands were removed and the liquid component were frozen in place, reverse aerogels, in which the cross-sections of channels are more uniform and less dependent upon the gelator concentration, would result. We report the formation of reverse organoaerogels from TOAB gels after polymerization of the liquid component.

The recipe for gels with monomeric liquid components is MMA or STY containing 8 vol% divinylbenzene (DVB, a cross-linking agent), 7 vol% ethylvinylbenzene, 1 mass% benzoin ethyl ether (the photoinitiator), and 0.1–2.0 mass% of TOAB.† The mixtures were flame-sealed under vacuum in 0.4 × 4.0 mm (id) × *ca.* 2 cm Kimax flattened-capillary tubes after being degassed by two freeze–pump–thaw cycles. The capillaries were heated in a hot water-bath (near 90 °C) until the solids dissolved. After agitating the solutions to homogenize the components, they were cooled either by quenching in an ice/water–bath or by placing them in the air; the cooling protocol was important in determining the sizes of the strands and their colloids (*vide infra*). Below *ca.* 1 mass% of TOAB, the samples were viscous, partially gelled materials that are better described as sols (or fracture gels). Polymerization was effected by irradiation of the capillaries in a water-bath (to maintain a near ambient temperature) at 320–360 nm for 5 h (MMA) or 14 h (STY). The stiff, solid samples were removed by breaking the capillary tubes with a metal object.

The unpolymerized and polymerized gels in the capillaries were examined by optical microscopy (× 50; *ca.* × 83 including photo to negative size ratio) between crossed polars using a full-wave plate for enhanced contrast. At 2 mass% TOAB, it is possible to detect colloids (*ca.* 500 μm in diameter) of the slower cooled MMA gels [Fig. 1(*a*)]. In general, their appearance was not affected markedly by polymerization [Figs. 1(*a*) and (*b*)]. Although the strands are less extensive in samples with lower concentrations of TOAB, there is no apparent concentration dependence on their cross-sectional dimensions when the same cooling procedure was followed [Fig. 2(*a*) and (*b*)]. The strand cross-sections are smaller and the strand lengths are shorter when samples are cooled more rapidly [Figs. 1(*a*) and 3].

Since the long axes of strands of other gels have been oriented by allowing gelation to occur in strong magnetic fields,[8,9] we reheated (unpolymerized) STY and MMA gels (with 0.5 or 1.0 mass% TOAB) to 87 °C, far above the gel–liquid phase transition temperature, in a 6.3 T magnetic field and allowed them to cool slowly to room temperature. By optical microscopy, the strand networks seemed more homogeneously dispersed (probably due to more careful and slower cooling), but there was no indication of alignment.

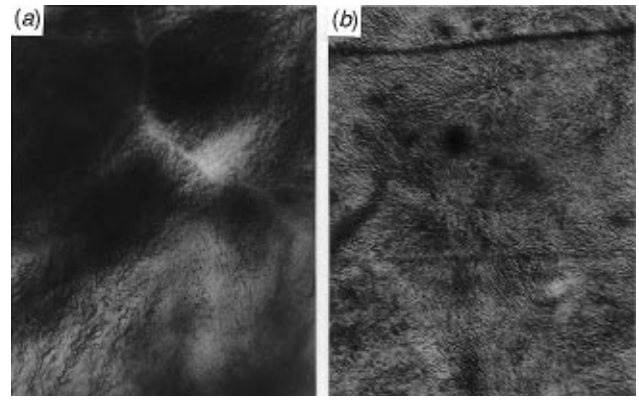

**Fig. 1** Optical micrographs of a 2 mass% TOAB/MMA gel prepared by the slower cooling method before (*a*) and after (*b;*) polymerization

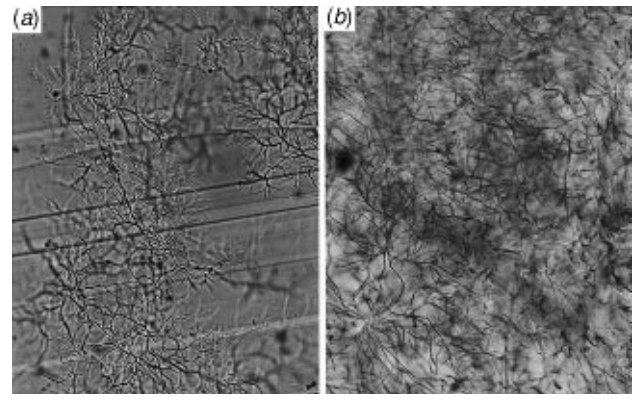

**Fig. 2** Optical micrographs of 0.1 (*a*) and 2.0 mass% (*b*) TOAB/STY gels prepared by the slower cooling method and polymerized

Polymerized MMA and STY gels with 2 mass% TOAB were heated and cooled between crossed polars while being observed under an optical microscope. Since the glass transition temperatures ($T_g$) of non-cross-linked MMA and STY are $\geqslant$100 °C,[10] and $T_g$ of a polymerized cross-linked STY gel was found to be *ca*. 130 °C by DSC, the TOAB, mp 97–102 °C, should melt before its polymer matrix becomes malleable. The birefringence associated with the TOAB strands of the polymerized MMA gel was lost between 89 and 94 °C. Cooling from 100 °C resulted in reappearance of birefringence in most of the strands near 90 °C. During the second heating, the birefringence was lost at a slightly higher temperature range and only about half reappeared upon cooling. Very similar results were obtained with a polymerized STY gel. In both cases, we suspect that gelator molecules from some strands merge, leading to larger but fewer domains. Based upon the proximity of the melting points, we conjecture that TOAB molecules are packed in similar fashions in bulk crystalline and strand phases. This is not always the case with low molecular mass gelators.[11]

When refluxed in *tert*-butyl alcohol (bp 83 °C), a polymerized STY gel lost a large fraction, but not all, of the TOAB molecules in its strands. Residual TOAB strands were evident by optical microscopy, even when no more could be leached from the gel; refluxing with fresh aliquots of alcohol was continued until no precipitate was detected upon addition of $AgNO_3$. Thus, some of the strands are in environments that have no contact with the surface of the polymerized sample through other strands.

All of the TOAB was removed rapidly and at room temperature from 1 or 2 μm thick slabs of the polymer (cut from the bulk with a diamond knife) placed in *tert*-butyl alcohol. Cross-sectional diameters of the strands (before TOAB removal) appeared to be the same as the channels (after TOAB removal). However, when the slabs were refluxed in *tert*-butyl alcohol, the channels were slightly wider than the strands. Widening of the channels may be due to coincidental loss of some unpolymerized liquid-component molecules with the TOAB. The average strand sizes in MMA and STY polymerized gels as a function of TOAB concentration and cooling protocol (during initial gel formation) are shown in Table 1. The data, from optical microscopic observations ($\times$ 645) of the narrowest and widest strands in 1 μm slabs, demonstrate that the cross-sections are not uniform, but can be made to diameters that are within a small range. It is unclear as yet whether the strands are twined multiples of a smaller unit or are the result of stochastic nucleation processes. In other studies, we[4] and others[3] have found that the former is the norm. It is also possible that the strands were distorted somewhat during the sectioning into slabs or may have suffered much more severe changes due to friction of the knife (*e.g*. local heating to above the polymer $T_g$ or tearing of the strand borders): even at 2 mass% TOAB, strands were not visible by optical microscopy in the faster cooled (polymerized) MMA gels before cutting; however, strands (or strand-like objects) were easily detected in the slabs. Since the MMA was gelled, strands must have been present, but may have been too small to be seen at the highest magnification of our optical microscope. Regardless, the data indicate that fast-cooling leads to somewhat narrower strands.

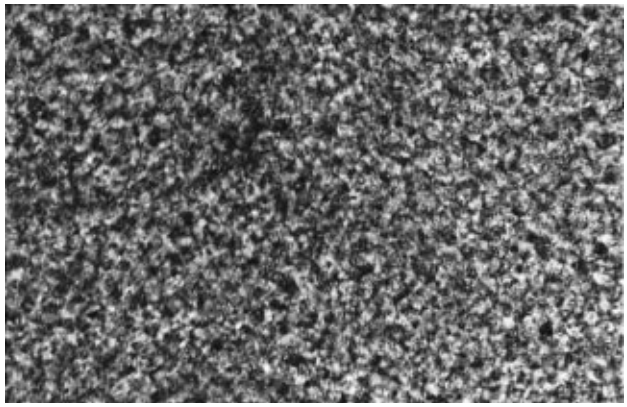

**Fig. 3** Optical micrograph of a 2 mass% TOAB/MMA gel prepared by the faster cooling method before polymerization

**Table 1** Approximate range of strand cross-sections in 1 μm thick slabs of polymerized gels as a function of TOAB concentration and cooling protocol (see text) of the unpolymerized samples from the isotropic to the gel phase

| TOAB (mass%) | Monomer | Cooling protocol | Cross-sectional range/μm |
|---|---|---|---|
| 2.0 | STY | Faster | 0.24–0.5 |
| 2.0 | STY | Slower | 0.5–1.5 |
| 0.5 | STY | Faster | 0.5–1.0 |
| 0.5 | STY | Slower | 0.5–1.0 |
| 0.1 | STY | Faster | 0.5–0.7 |
| 0.1 | STY | Slower | 0.5–1.0 |
| 2.0 | MMA | Faster | 0.3–0.5 |
| 2.0 | MMA | Slower | 0.4–1.0 |
| 0.5 | MMA | Faster | 0.24 |
| 0.5 | MMA | Slower | 0.24–1.2 |
| 0.1 | MMA | Faster | –[a] |
| 0.1 | MMA | Slower | 0.24–1.4 |

[a] No objects clearly identifiable as strands were observed.

The slabs with vacated channels have potential applications as membranes, and the bulk polymers, even with partial removal of the gelator molecules, may be useful as selective adsorbers and complexing agents for chromatography[12] and selective guest reactions.[13] Future efforts will be directed to make reverse aerogels whose channels are narrower and have greater cross-sectional uniformity (*i.e*. organic zeolites).

The authors from the Chemistry Department thank the National Science Foundation for its support of this research. We are also grateful to Professors M. C. Feiters and R. J. M. Nolte of Katholieke Universiteit Nijmegen who agreed to concurrent publication of their work[14] and ours.

# Organogel formation and molecular imprinting by functionalized gluconamides and their metal complexes

**Rudi J. H. Hafkamp,[a] Bas P. A. Kokke,[a] Iris M. Danke,[a] Hubertus P. M. Geurts,[b] Alan E. Rowan,[a] Martinus C. Feiters[a] and Roeland J. M. Nolte*[a]**

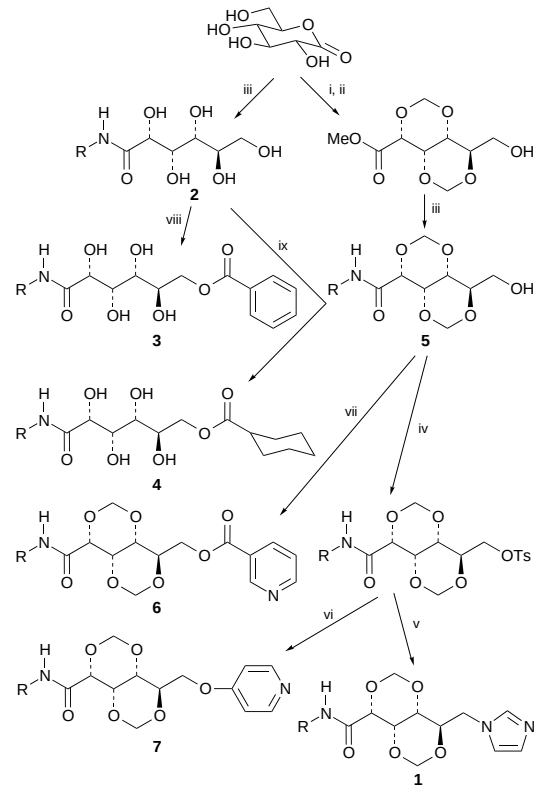
[b] *Central Electron Microscopy Facility, University of Nijmegen, Toernooiveld, NL-6525 ED Nijmegen, The Netherlands*

**Functionalized gluconamides and their metal complexes are shown to give supramolecular assemblies, in some cases chiral, and to form organogels in a large variety of organic solvents, *e.g.* methacrylate mixtures which can be polymerized, as well as *o*-xylene, chloroform, ethyl acetate, ethanol and tetrahydrofuran.**



Gluconamides are known to form suprastructures in water.[1] We have recently shown[2] that the self-assembly behaviour of the imidazole-functionalized *N*-octylgluconamide **1a** in water can be tuned. Dispersion of the compound in water at pH 8.5 results in fibres and hollow tubuli, whereas at low pH vesicles are formed. We report here that further functionalization of gluconamides with different head-groups and the addition of metal ions result in diverse suprastructures which induce gelation in a large variety of organic solvents.

In recent years, a relatively broad range of compounds has been found to gelate organic solvents.[3] Gluconamide **2a** has been reported to aggregate into bilayer scrolls and form an unstable organogel in *o*-xylene.[4] We find, however, that a number of ester derivatives of **2a**, *viz*. the benzoate **3a** and the cyclohexanoate **4a** (*cf.* Scheme 1 for structures and outline of preparations)† form stable organogels in a number of solvents, *e.g.* *o*-xylene, chloroform, and ethyl acetate (Table 1). In chloroform, **3a** yields fibres or bundles of fibres which do not exhibit chirality [Fig. 1(*a*), (*b*)]. In contrast, **4a** in ethyl acetate [Fig. 1(*c*)] is able to express its molecular chirality in the suprastructure, resulting in helical fibres. From electron microscopic investigations, we propose that these fibres consist of double and multiple-stranded helices, and that the knobs at the end of the fibres represent hairpin-like turns of these helices.

In contrast to the functionalized gluconamides with free hydroxy groups, most of the bis-methylene protected *N*-*n*-octylgluconamide derivatives investigated, including the imidazolyl derivative **1a** as well as the 6-hydroxy analogue **5a** and the benzoate and picolinate (**6**) esters thereof, did not form organogels (Table 1). We decided to investigate the palladium(II)[8] and platinum(II) complexes of the pyridine-functionalized gluconamides **6** and **7**. *trans*-[Pd(**7b**)$_2$Cl$_2$] was soluble in chloroform but precipitated in water. In thf a rigid gel was obtained, which showed helical ribbons (width 36 nm) with a regular twist (pitch 110 nm) and a (maximum) aspect ratio of 25 [*cf.* Fig. 1(*d*)].

*trans*-[Pd(**6b**)Cl$_2$] dissolved in thf without giving a gel. It is not clear why [Pd(**7b**)$_2$Cl$_2$] forms an organogel in thf and [Pd(**6b**)$_2$]Cl$_2$ does not. A slight difference is expected between the conformations of [Pd(**7b**)$_2$Cl$_2$] and [Pd(**6b**)$_2$Cl$_2$], because in the latter compound the pyridyl ring is *meta*-substituted and the connection to the carbohydrate is *via* an ester group. These differences can cause a bend in the overall shape of the molecule which is not favourable for gelating solvents according to the rule of thumb: 'gelators of organic fluids should have the capability of adopting rodlike shapes in their extended conformations'.[9] We have also prepared the Pt complex, *trans*-[Pt(**7b**)$_2$Cl$_2$], and find that it gelates thf, toluene, and methanol at concentrations of 1, 2, and 5 mg ml$^{-1}$, respectively. For all gels, TEM showed fibres with approximately the same diameters as **7a**, but without a helical twist. In toluene, these non-helical fibres in turn self-assemble in a hierarchical process to give μm-sized twisted superstructures [Fig. 1(*e*)].

We were interested in using the organogels to prepare membranes with pores by the technique of 'imprinting'.[10] Using this approach, **3a** and **4a** (1% m/v) were dissolved in a warm mixture of methyl methacrylate and *n*-butyl methacrylate (1 : 4, v/v) containing 0.5% (m/v) polymerization catalyst (benzoin ethyl ether), as adapted from the literature.[11] Well defined aggregates with high aspect ratios were formed and gelated this solvent mixture. The organogel was transferred into gelatin cups and readily polymerized overnight with UV light (λ = 365 nm) in a refrigerator (5 °C), yielding a rigid polymer matrix. Using a glass knife and a diamond microtome, slabs of this polymer matrix were sliced in thin coupes (90 nm) which were allowed to float on a water surface before they were transferred

**Scheme 1** R = *n*-octyl **a** or *n*-hexadecyl **b**. **Fig. 1** TEM pictures (Pt shadowing) of a dried gel of **3a** in chloroform: (*a*) network of fibres (bar 1.5 μm), (*b*) bundles of whisker-type fibres (bar 240 nm), (*c*) TEM picture (Pt shadowing, bar 110 nm) of a dried gel of **4a** in ethyl acetate, (*d*) TEM picture (Pt shadowing, bar 63 nm) of a helical ribbon formed by the complex $[Pd(\mathbf{7b})_2Cl_2]$ in thf, (*e*) SEM picture (Au coated, white bar 1 μm) of super helices formed on slowly cooling a gel of $[Pt(\mathbf{7b})_2Cl_2]$ in toluene (*f*) TEM pictures of imprinted pores of **4a** (bar 1.35 μm)

to electron microscopy grids. According to TEM the coupes show well defined pores [Fig. 1(*f*)]. Apparently, the gluconamide suprastructures disassemble and are removed from the polymeric matrix in water. Although dispersions of compound **4a** form helical aggregates [Fig. 1(*c*)], the pores observed in the polymeric matrix did not have helical charcter [Fig. 1(*f*)]. It should be noted that the size of the pores is approximately one

**Table 1** Gelation behaviour of functionalized gluconamides in organic solvents[a]

| Compound/ solvent | *o*-Xylene | $CHCl_3$ | EtOAc | EtOH |
|---|---|---|---|---|
| **1a** | R | S | S | S |
| **2a** | G | I | I | R |
| **3a**[b] | G | G | G | G |
| **4a** | G | G | G | S |
| **5a** | T | S | S | S |
| **6a** | S | S | S | S |

[a] G, gelates forming a high-viscosity mixture upon cooling; I, insoluble; R, recrystallizes within 1 h upon cooling; S, dissolves without gelation; T, gives a turbid mixture with slightly increased viscosity upon cooling. [b] Compound **3a** also forms gel in methanol, acetonitrile, acetone, dioxane, dichloromethane, toluene and benzene. It recrystallizes from water, dissolves without gelation in thf, and is insoluble in *n*-hexane and in diethyl ether.

order of magnitude larger than that of the helical fibres. The increase in size as well as the loss of chirality are probably due to shrinking of the methacrylate gel during polymerization.

In conclusion, we have shown that functionalized gluconamides and their metal complexes form a variety of chiral and non-chiral aggregates in a large variety of organic solvents and polymerizable methacrylate mixtures, and that it is possible to make imprints of the gluconamide assemblies.

We thank Professor R. G. Weiss (Georgetown, USA) for discussing his results with us prior to publication, and agreeing to concurrent publication of their work[12] and ours.

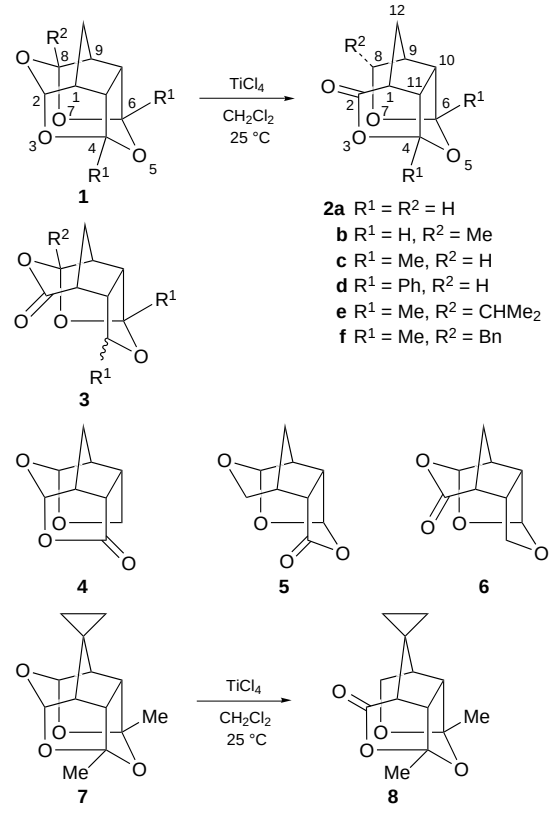
# A novel hydride rearrangement of the acetal group of tetraacetal tetraoxa-cages mediated by Lewis acids

**Hsien-Jen Wu* and Jyh-Haur Chern**

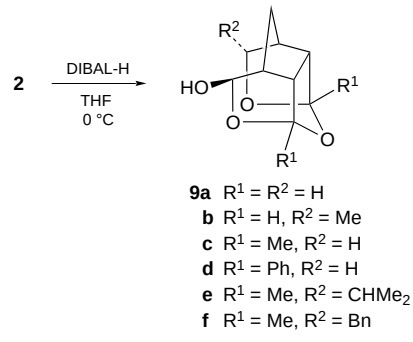
*Department of Applied Chemistry, National Chiao Tung University, Hsinchu, Taiwan, China*

**Treatment of tetraoxa-cages 1a–f with Lewis acids such as $TiCl_4$, $AlCl_3$, $BF_3{\cdot}OEt_2$ and $MeSO_3H$ in dichloromethane at 25 °C gives the rearrangement products 2a–f in 90% yields regioselectively and stereoselectively; a novel hydride rearrangement of the acetal group of tetraacetal tetraoxa-cages mediated by Lewis acids.**



The reaction chemistry of acetals has been greatly expanded by the use of Lewis acidic promoters, particularly in conjunction with silicon-containing nucleophiles.[1,2] Usually, acyclic and monocyclic acetals, especially the acetal groups in monosaccharide derivatives, are the objects for study. Recently, we accomplished the synthesis of novel oxa-cage compounds, such as diacetal trioxa-cages,[3] triacetal trioxa-cages,[4] tetraacetal tetraoxa-cages,[5] tetraacetal pentaoxa-cages[6] and pentaacetal pentaoxa-cages (the pentaoxa[5]peristylanes).[7] All these oxa-cages contain acetal and ketal groups. As part of a program that involves the synthesis, chemistry and applications of new heterocyclic cages, we report here a novel hydride rearrangement of the acetal group of the tetraacetal tetraoxa-cages **1** mediated by Lewis acids.

Reaction of the tetraacetal tetraoxa-cages **1a–f** with two equivalents of Lewis acids, such as $TiCl_4$, $AlCl_3$, $BF_3{\cdot}OEt_2$ and $MeSO_3H$ in dichloromethane at 25 °C for 3 h gave the novel hydride rearrangement products **2a–f** in 90–95% yields regioselectively and stereoselectively (Scheme 1). No detectable amount of the other regioisomer **3** was obtained. In the case of the unsubstituted (parent) compound **1a**, no detectable amount of the other regioisomers **4**, **5** or **6** was obtained. We attribute the high regioselectivity of the hydride rearrangement to the angle strain of the unusually large bond angle of C(2)–O(13)–C(8) of the tetraoxa-cages **1a–f**. While the other C–O–C bond angles of the tetraoxa-cages **1** are between 111°–108°, the C(2)–O(13)–C(8) bond angle is 117.5°, remarkably larger than ordinary bond angles about $sp^3$-hybridized atoms.[5a] In the cases of both **1a** and **1b**, with no alkyl substituents on C(4) and C(6), the hydride rearrangement still took place regioselectively between C(2) and C(8). Thus, a steric hindrance factor for the regioselective hydride rearrangement of **1** to **2** was excluded. Treatment of the tetraoxa-cage **7** with $TiCl_4$ under the same reaction conditions gave **8** in 90% yield. A three-membered spiro ring on the apical carbon did not interfere with the hydride rearrangement.



The IR spectra of **2a–f** showed strong absorption at 1770 $cm^{-1}$ for the five-membered lactone carbonyl group. The $^1H$ NMR spectrum of **2a** revealed two doublets at δ 6.04 and 5.97 for the two acetal protons on C(4) and C(6) and two doublets of doublets at δ 4.13 and 3.50 for the methylene protons on C(8). The $^{13}C$ NMR spectrum of **2a** diplayed a singlet at δ 179.09 for the lactone carbonyl, two peaks at δ 112.31 and 106.38 for the acetal carbons C(4) and C(6) and one peak at δ 71.59 for the methylene carbon C(8).

The stereochemistry of the alkyl group on C(8) of **2b**, **2e** and **2f** was assigned on the basis of the following chemical transformation of **2a–f** and NOE experiments of **2b**. Irradiating the methyl group on C(8) of **2b** gives 8.6% enhancement of the intensity of the C(9) proton. Reduction of **2a–f** with DIBAL-H in dry THF at 0 °C gave compounds **9a–f** stereoselectively in 85–90% yields (Scheme 2). The stereochemistry of the hydroxy group and the alkyl substituent on C(8) was proven by X-ray analysis of the crystalline compound **9b** (Fig. 1).† Hence, the stereochemistry of the alkyl substituent on C(8) of **2b**, **2e** and **2f** was confirmed.

A reaction mechanism is proposed for the hydride rearrangement from **1** to **2** (Scheme 3). Coordination of $TiCl_4$ to the oxygen atom O(13) of **1** followed by cleavage of the C(8)–O(13) bond gives the oxonium ion **10**. Fragmentation of **10** to a monocyclic species **11** followed by zipping back up to

**Scheme 1**

**Scheme 2**

the stereoisomer **12** and a subsequent (fast) intramolecular hydride transfer gives **2**.

In summary, we have discovered a novel hydride rearrangement of the acetal group of tetraacetal tetraoxa-cages mediated by Lewis acids. The hydride rearrangement is found to be regio- and stereo-selective. We attribute the highly regioselective hydride rearrangement to the unusually large bond angle of C(2)–O(13)–C(8) of the tetraoxa-cages **1**.

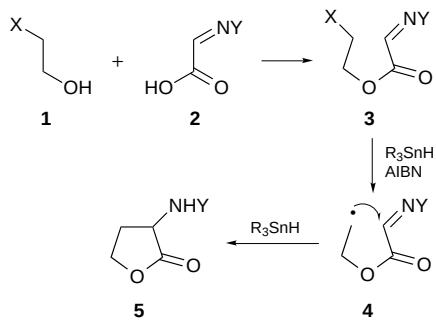
# Preparation of α-(2,2-diphenylhydrazino)- and α-(benzyloxyamino)-lactones by radical cyclization: use of glyoxylic acid diphenylhydrazone and glyoxylic acid *O*-benzyloxime

**Derrick L. J. Clive* and Junhu Zhang**



*Chemistry Department, University of Alberta, Edmonton, Alberta, Canada T6G 2G2*

**Glyoxylic acid diphenylhydrazone (2, Y = $NPh_2$) and the corresponding *O*-benzyloxime (2, Y = OBn) are easily esterified in high yield by β-bromo alcohols, and the resulting esters undergo radical cyclization to α-(2,2-diphenylhydrazino) or α-(benzyloxyamino) lactones on treatment with tributyltin hydride; the initial radical can be formed by homolysis of a carbon–selenium bond as well as a carbon–bromine bond and, when applied to appropriate alcohols, the esterification–radical closure sequence can also be used to make six- or seven-membered lactones.**

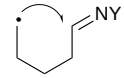
We report here the synthesis of α-hydrazino lactones (**5**, Y = $NPh_2$) and the corresponding *O*-benzylhydroxylamines (**5**, Y = OBn) by the radical cyclization process summarized in Scheme 1 (X = Br, SePh). The radical precursors **3** are readily accessible by DCC-mediated coupling of glyoxylic acid diphenylhydrazone (**2**, Y = $NPh_2$)[1] or *O*-benzyloxime (**2**, Y = OBn)[2] with β-bromo or β-(phenylselanyl) alcohols (**1**, X = Br or SePh), themselves easily made from alkenes (NBS–$H_2O$,[3] PhSeX[4]) or epoxides ($Me_2BBr$,[5] PhSeNa[6]). The glyoxylic acids **2** (Y = $NPh_2$ or OBn) are stable, crystalline reagents, formed in high yield (90–96%) from glyoxylic acid.†

Both the coupling reaction (**1** + **2** → **3**) and the radical closure (**3** → **4** → **5**) generally proceed in good yield. Most of our work has been done with hydrazone acid **2** (Y = $NPh_2$), but related experiments with the *O*-benzyloxime acid **2** (Y = OBn) were also successful; however, we have not made a sufficiently extensive comparison to identify which series (hydrazone or oxime) is generally more efficient. Likewise, the superiority of bromides over selenides for the radical closure step has also not yet been firmly established.

Formation of carbocycles — specially five-membered rings — by radical closure onto a carbon–nitrogen double bond is well-established with oxime ethers,[7] but to a much lesser extent with diphenylhydrazones.[8,9] In the case of hydrazones there is evidence to suggest[8a] that hydrazone amides and semicarbazides **6** (Y = NHCOPh or $NHCONHNH_2$) close more efficiently than do the corresponding diphenylhydrazones; however, in this preliminary work we used diphenylhydrazones. The ring closure shown for **4** (Scheme 1) requires the indicated proximity of the carbon radical and the carbon–nitrogen double bond; this conformation is adequately accessible because of the sufficiently low rotational barrier about ester C(O)–O single bonds.[10]

X = Br, SePh, Y = $NPh_2$, OBn

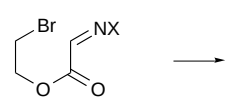
**Scheme 1**

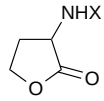


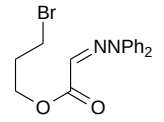
Our reaction produces lactones bearing an α-nitrogen substituent (Table 1). When the starting alcohol **1** is cyclic, the stereochemical outcome at the newly-created ring junction is determined by the stereochemistry of the original hydroxy-bearing carbon in **1**, but for both cyclic and non-cyclic starting alcohols the degree of stereoselectivity α to the lactone carbonyl is low,[11] at least under the thermal conditions we have used (see footnotes to Table 1).

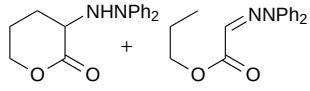
Experiments with indane derivative **15a** (see Table 1) revealed the intervention of a 1,2-acyl migration[12] which, in this case, must be especially fast because of the fact that it leads—*via* a readily accessible and favourable geometry—to a benzylic radical. Entry 6 of Table 1 shows an application to carbohydrates, and also serves as an example of 7-*exo* closure. Presumably, favourable geometrical constraints are operating in this case, but are absent in **9a** (6-*exo* closure), where an appreciable amount of reduction occurs before cyclization.

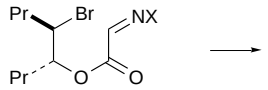
All the coupling experiments to generate the radical precursors **3** were done by addition of DCC (5.5 mmol) and DMAP (0.5 mmol) to a solution of the appropriate alcohol (5.5 mmol) and reagent **2** (Y = $NPh_2$ or OBn) (5 mmol) in $CH_2Cl_2$. After 6–12 h at room temperature, the esters could be isolated in the yields shown. The radical cyclizations were conducted by simultaneously adding toluene solutions‡ (double syringe pump, 9-10 h) of $Bu_3SnH$ (1.73 mmol, 0.173 M) and AIBN (0.12 mmol, 0.012 M) to a refluxing solution of the substrate (1.15 mmol, 0.016 M) in the same solvent. At the end of the addition refluxing was continued for an arbitrary period of 2–3 h (except for **8a**, where this period was 5 h).

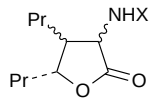


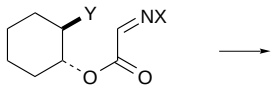


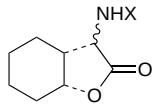


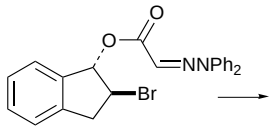


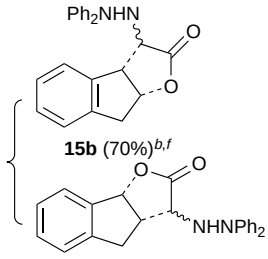


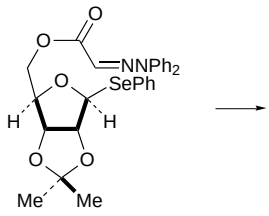


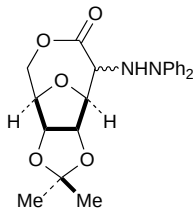












α-Hydrazino- and α-(hydroxyamino)-γ-lactones (*cf.* substructure **5**) are not well-known; neither are the corresponding δ-lactones.[13] In principle, these α-substituted lactones can be modified in various ways and, in the case of **7b** for example, hydrogenolysis (10% Pd–C, THF-aqueous HCl 6 M) gave homoserine γ-lactone hydrochloride[14] (81% after crystallization from acetone).

All new compounds were characterized by spectroscopic methods, including accurate mass measurements. The isomers of **11b** (four), **14b** (two) and **15b** (two) were chromatographic-

**6** Y = NHCOPh, $NHCONHNH_2$

**Table 1** Yields for coupling reaction to form hydrazones or oximes, and for radical cyclization

| Hydrazone or oxime (yield) | Lactone (yield) |
|---|---|
| 1  **7a** X = $NPh_2$ (80%) **8a** X = OBn (82%) |  **7b** X = $NPh_2$ (75%) **8b** X = OBn (51%) |
| 2  **9a** (72%) |  **9b** (50%) **9b** (20%) |
| 3  **10a** X = $NPh_2$ (98%) **11a** X = OBn (*ca.* 100%) |  **10b** X = $NPh_2$ (82%)[a] **11b** X = OBn (78%)[b,c] |
| 4  **12a** X = $NPh_2$, Y = Br (90%) **13a** X = $NPh_2$, Y = SePh (85%) **14a** X = OBn, Y = Br (88%) |  **12b** X = $NPh_2$ (70%)[d] **13b** X = $NPh_2$ (*ca.* 20%)[d] **14b** X = OBn (64%)[b,e] |

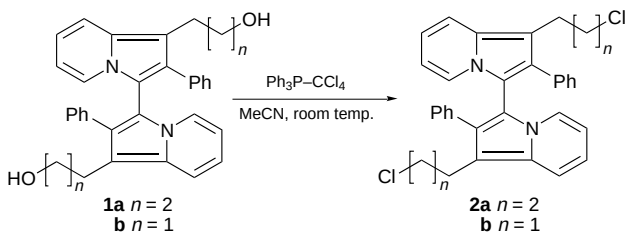
# Chlorination of enantiomerically pure 1,1′-bis(hydroxyalkyl)-3,3′-biindolizines: conservation of chirality by thermal treatment

**Helmut Sonnenschein,*† Fritz Theil, Thomas Kreher and Angela Köckritz**

*Institut für Angewandte Chemie Berlin-Adlershof, Abt. Organische Synthese, Rudower Chaussee 5, D-12484 Berlin, Germany*

**Enantiomerically pure 1,1′-bis(hydroxyalkyl)-3,3′-biindolizines 1 racemize unexpectedly by reaction with tetrachloromethane–triphenylphosphine at room temperature affording the corresponding dichloro compounds 2, whereas the chirality is preserved at higher reaction temperatures.**



Axial-chiral ligands, especially binaphthyls, play an important role in asymmetric synthesis.[1] Recently, we reported the chirality of biindolizines[2] and the enzyme-catalysed kinetic resolution of racemic bis(hydroxyalkyl)biindolizines.[3] To further extend the utility of this new chiral source, *e.g.* as chiral modifiers and complex ligands in homogeneous catalysis, we attempted the preparation of derivatives of the non-racemic chiral diols **1a** and **1b**.

First attempts using the racemic diols (±)-**1a** and (±)-**1b** showed that the chlorination with triphenylphosphine and tetrachloromethane[4] is a useful method for the synthesis of the corresponding racemic bis(chloroalkyl)biindolizines (±)-**2a** and (±)-**2b**, respectively. By addition of acetonitrile to the reaction mixture the conversion takes place at room temperature.

Application of these mild conditions to the conversion of the enantiomerically pure diols (−)-**1a** and (+)-**1b** to the corresponding dichloro compounds surprisingly resulted in complete racemization‡ affording (±)-**2a** and (±)-**2b**, respectively, despite the fact that there are four or five bonds between the chirality axis and the reacting carbon atom.

The reaction at higher temperatures revealed an unusual and unexpected behaviour of the enantiomerically pure diols (−)-**1a** and (+)-**1b** depending on the reaction conditions. Reaction of (−)-**1a** with an ee of 98% in refluxing tetrachloromethane in the absence of acetonitrile furnished the dichloro compound (−)-**2a**§ with an ee of 96%. In order to investigate the influence of acetonitrile on the outcome of the reaction, acetonitrile was added to the refluxing solution of the diol (−)-**1a** and triphenylphosphine in tetrachloromethane. This treatment did not influence the enantiomeric excess of the dichloro compound (−)-**2a** (ee 98%) formed, but as expected, the reaction rate was drastically increased.

In comparison with (±)-**1a** the diol (±)-**1b** is less reactive. Only in the presence of acetonitrile does the chlorination proceed in good yields. In contrast to the results described before, the conversion of the diol (+)-**1b** with an ee of 98% led, in the presence of triphenylphosphine in refluxing tetrachloromethane and subsequent addition of acetonitrile, to a partial racemization affording the dichloro compound (+)-**2b**§ with an ee of only 63%. Therefore, it seemed promising to enhance the reaction temperature to suppress further racemization. This was realised by addition of triphenylphosphine to a refluxing solution of (+)-**1b** in tetrachloromethane–toluene–acetonitrile (2:5:1) yielding (+)-**2b** with an ee of 87%. These results clearly demonstrate that increased reaction temperatures suppress the racemization during the chlorination of (−)-**1a** and (+)-**1b** to (−)-**2a** and (+)-**2b**, respectively, under the described conditions. The results are summarized in Table 1.

**1a** *n* = 2
**b** *n* = 1

**2a** *n* = 2
**b** *n* = 1

**Scheme 1** Chlorination of **1a** and **1b** by $PPh_3$–$CCl_4$

Results published recently by K. Fuji *et al*. on the unexpected racemization of 8-diphenylphosphinoyl-8′-methoxy-1,1′-binaphthyl[5] illustrate the difficulties in explaining such a surprising loss of axial chirality. Based on the crystal structure, the authors suggest that a strong destabilisation of the ground state of this compound is responsible for the racemization.

The different substitution of the biindolizines **1** and **2** should not have an influence on the configurational stability as a result of the different torsion angles between the coupled heterocyclic systems. Each enantiomer of **2a** and **2b** exists independently. There is every indication that in our case both the twisted and normally rotation-hindered aromatic systems are each forced to occupy coplanar configurations during the time-scale of the conversion of the biindolizines. Such a coplanar transition state or intermediate could be explained by intramolecular interactions between the 'α- and ω-end' of the molecule. Particularly, a strong strained cyclic species is imaginable, cancelling the twisting of the coupled indolizines.

We have no evidence concerning the nature of such a cyclic species and thus can only speculate. Possibly, the low reactivity of **1a** and **1b** is responsible for the formation of a cyclic transition state or intermediate. Therefore, only the bifunctional intermediate $Ph_3P^+CCl_2P^+Ph_3$, $2Cl^-$ **3**[4] reacts with the diol to give the dichloro compounds **2a** and **2b** quickly at room temperature. Fig. 1 shows the imaginable addition product **4**—formed by reaction of the diol **1b** with the described dication **3**—causing a small torsion angle between the two heterocyclic systems. At higher temperatures this intermediate is unfavoured because the system reacts before **4** is formed. This assumption is in accordance with our observation that the less reactive diol **1b** tends to racemize even at higher temperatures. Obviously, even in refluxing tetrachloromethane the reaction partially takes place *via* a coplanar intermediate such as **4**. Only more drastic conditions allowed an almost complete chirality conservation.

**Table 1** The influence of the reaction conditions on the degree of racemization by chlorination of non-racemic **1a** and **1b**

| | | Product ees under various reaction conditions (%) | | |
|---|---|---|---|---|
| Product **2** | Ee of starting material (%) | $CCl_4$–MeCN (5:1), room temperature | $CCl_4$–MeCN (30:1), reflux | $CCl_4$–MeCN–PhMe (2:1:5), reflux |
| **a** | 98 | 0 | 98 | — |
| **b** | 98 | 0 | 63 | 87 |

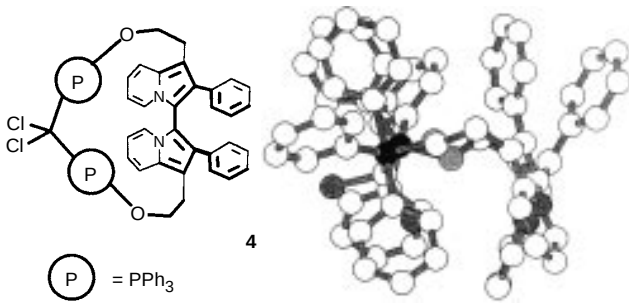


**Fig. 1** Structures of the assumed cyclic intermediate **4** generated through HYPERCHEM (release 4, $MM^+$, optimised by Polak-Ribiere)

Nevertheless, we have found a possible method to prevent the unexpected racemization and to obtain the 1,1′-bis(chloroalkyl)-3,3′-biindolizines **2a** and **2b** in high enantiomeric excess. We are also looking for other chlorination methods to obtain enantiomerically pure dichloro compounds.

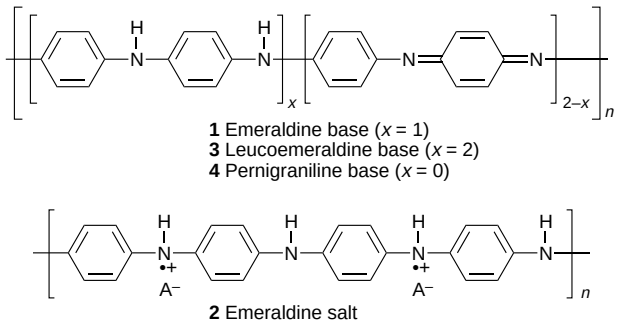
# Concurrent reduction and modification of polyaniline emeraldine base with pyrrolidine and other nucleophiles

**Chien-Chung Han* and Rong-Chyuan Jeng**

*Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300, Republic of China*



**Polyaniline emeraldine base 1 can be easily modified by pyrrolidine and other nucleophiles, *e.g.* piperidine, morpholine, alkane-1-thiols and mercaptoacetic acid, presumably *via* a concurrent reduction and substitution mechanism.**

Among other conducting polymers, polyanilines are of particular interest in light of their unique electro-optical properties and market potential.[1,2] Although undoped (neutral) polyaniline, *i.e.* the emeraldine base **1** (Scheme 1), can be solution processed more easily than other conducting polymers, doped (conductive) polyanilines, *i.e.* the emeraldine salts **2**, cannot be processed easily. The difficulty encountered in solution processing the emeraldine salts **2** has recently been alleviated by an *in situ* de-doping and re-doping process,[3,4] and also by a counter-ion induced solubility approach.[4–6] In our previous attempt to develop the *in situ* de-doping and re-doping solution processing chemistry,[7] we found that many Lewis base solvents, *e.g.* pyrrolidine, piperidine and morpholine, are highly effective solvents for emeraldine salts[8] and emeraldine base.[9] Highly conductive coatings with good optical quality can be directly prepared from the fresh pyrrolidine solutions of emeraldine base **1** or emeraldine salts **2**. In those previous works, we also found some mysterious aging phenomena happened to those cyclic amine solutions. The polyaniline coatings prepared from such aged solutions were somehow less conductive.

In this work, we explore the nature of this aging chemistry to find possible means for prevention. These results actually suggest a very interesting concurrent reduction and substitution chemistry between polyaniline and nucleophiles. This new chemistry provides a facile approach for modifying a polyaniline backbone with various electron-donating groups, *e.g.* amino, alkylthio and alkoxy.

When polyaniline emeraldine base **1** was stirred in pyrrolidine for 96 h, the solution's colour gradually changed from blue to purple, and finally to purple–brown. The resultant polymer was precipitated with a large amount of $Et_2O$, collected, rinsed with copious amounts of acetone, and then dried at 90 °C under dynamic vacuum for 12 h to remove any solvent residues. The obtained polymer sample was free of the strong odour of pyrrolidine and had no weight loss up to 130 °C by thermogravimetric analysis. The solid state $^{13}C$ CPMAS (cross-polarization magic angle spinning) NMR spectrum of the resultant polymer, Fig. 1, strongly suggests that emeraldine base **1** has been reduced and the pyrrolidino substituents subsequently added. The new $sp^3$ carbon signals at *ca.* δ 25 and 52 are similar to those chemical shifts of pyrrolidine,† confirming the presence of pyrrolidino fragments. Correspondingly, a decrease in the peak intensity of *ca.* δ 157 (the characteristic peaks of the imine quinoid rings assigned by Kaplan *et al.*[10]) and an increase at *ca.* δ 135 and 120 (characteristic peaks of the amine benzenoid rings[10]) confirmed the reduction of polyaniline. These results suggest that some of the imine quinoid rings are converted to amine benzenoid rings while introducing pyrrolidino substituents. Except for no $sp^3$ carbons, similar NMR signal variation behaviour in the aromatic region [Fig. 1(*d*)] was observed when emeraldine base **1** was reduced by hydrazine to form leucoemeraldine base **3**. Our NMR results clearly indicated that the amounts of new $sp^3$ carbons and the degrees of reduction of emeraldine base **1** simultaneously increased with reaction time. Thus, the above results strongly suggest that the reduction and substitution events were actually concurrent.

The IR spectroscopic results in Fig. 2 also verify the presence of pyrrolidino substituents. The intensity of the newly appeared $sp^3$ C–H stretching peaks among 2800–3000 $cm^{-1}$, as caused by the pyrrolidino attachment, increased with the reaction time.

**Scheme 1**

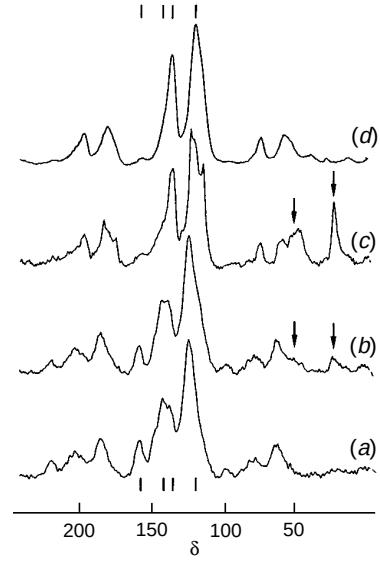


**Fig. 1** Solid state $^{13}C$ CPMAS NMR spectra for various polyanilines measured at 50.3 MHz at a spinning speed of about 3 kHz. The NMR spectrum (*a*) is for emeraldine base; (*b*) and (*c*) are for emeraldine bases after reacting with pyrrolidine for 10 min and 96 h, respectively; and (*d*) is for leucoemeraldine base. Vertical bars are placed at δ 157, 143, 135 and 120. Arrow marks are placed at δ 52 and 25.

Also, the relative degrees of reduction of the resulted polyanilines increased simultaneously with reaction time, as indicated by the increase in intensity at around 1500 $cm^{-1}$ (C=C stretching vibration of amine benzenoid rings) relative to that at 1600 $cm^{-1}$ (C=C stretching vibration of imine quinoid rings).[11] The new peaks at 960 $cm^{-1}$ and the shoulder at 925 $cm^{-1}$ might be caused by the newly formed 1,2,4-trisubstituted benzene ring.[12] The reduction phenomenon of emeraldine base **1** induced by pyrrolidine has also been confirmed by UV–VIS spectroscopy. The fact that polyaniline emeraldine **1** was slowly reduced by pyrrolidine toward the less conductive leucoemeraldine form explains why the polyaniline coatings prepared from the aged solutions were less conductive.

The same concurrent reduction and substitution chemistry is applicable to other cyclic amine systems, *e.g.* piperidine and morpholine. In both cases, $^{13}C$ CPMAS NMR and IR spectroscopy confirmed that the resultant polymers (after thoroughly washed and dried) were partially reduced and substituted with piperidino and morpholino fragments, respectively. The $^{13}C$ NMR for the piperidine-treated polyaniline showed new $sp^3$ carbons at *ca.* δ 25 and 52 and those for the morpholine-treated polyaniline at *ca.* δ 52 and 68, similar to those chemical shifts of piperidine and morpholine, respectively.† A model compound, *N,N′*-diphenylphenylene-1,4-diimine, also reacted with pyrrolidine *via* the same reductive substitution chemistry, yielding a pyrrolidino-substituted *N,N′*-diphenylphenylene-1,4-diamine.‡

This chemistry can also be extended to other nucleophile systems, *e.g.* thiols and alcohols. Our preliminary results indicate that alkanethiols, such as dodecane-1-thiol and butane-1-thiol, react at a much higher rate (*ca.* 1000 times faster) than amines. Since dodecane-1-thiol contains greater number of $sp^3$ carbons, the IR spectrum for the dodecanethiol-treated polyaniline, Fig. 2(*d*), showed much stronger $sp^3$ C–H stretching vibration signals among 2800–3000 $cm^{-1}$. Although the above polymer was identified by elemental analysis to contain 20.7 mol% of dodecylthio group basing on aniline repeat unit, it was free of any odour of thiol. The cyclic voltammograms of the resultant polymers did not behave any more like the unsubstituted polyaniline, but rather resembled to the polyanilines substituted with electron-donating groups, such as polyanisidine and polyphenetidine. The nature of the S atoms in the sample was characterized by X-ray photoelectron spectroscopy. The S 2p line was measured to be at 163.5 eV, confirming the formation of sulfide, but not disulfide or thiol.§ These dodecylthio-substituted leucoemeraldine bases can be converted back to their corresponding emeraldine forms by oxidaton with *m*-chloroperoxybenzoic acid. Additional dodecylthio groups can be attached by repeating the reductive substitution chemistry with dodecane-1-thiol. We have found that the multiple reduction–oxidation modification cycles can be most conveniently carried out by an electrochemical process. In another example, we have also succeeded in attaching mercaptoacetic acid to the backbone of polyaniline, forming a self-doping polyaniline. The carboxylic acid groups remained at the polyaniline backbones even after thorough de-doping treatments with bases.

A possible reaction mechanism is as follows. Protonation of the imine nitrogen could possibly promote the nucleophilic attack of pyrrolidine (and other nucleophiles) at the *meta*-position of the protonated quinoid ring, followed by a 1,3-proton shift of the *meta*-proton to the *para*-imine nitrogen and, ultimately, a conversion of the less stable quinoid ring to the more stable benzenoid.

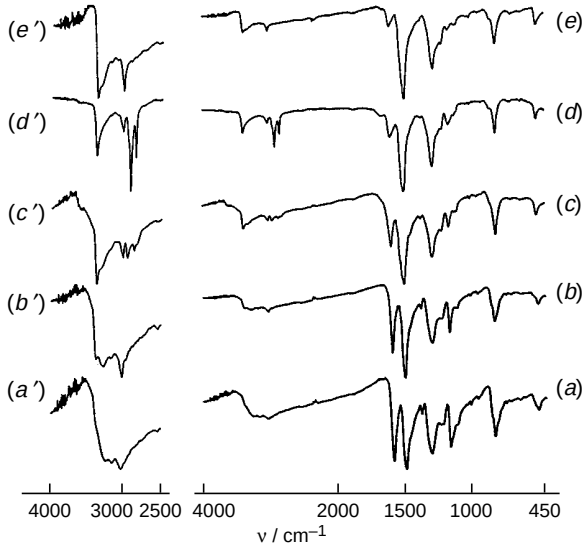

**Fig. 2** IR spectra for various polyanilines are obtained in the transmission mode using KBr pellets at a nominal resolution of 8 $cm^{-1}$ and co-adding 16 scans, IR trace (*a*) is for emeraldine base; (*b*) and (*c*) are for the emeraldine bases after reacting with pyrrolidine for 10 min and 96 h, respectively; and (*e*) is for leucoemeraldine base. Trace (*d*) is for the dodecanethiol-modified emeraldine base. Those corresponding blowup spectra for the 2500–4000 $cm^{-1}$ regions (with arbitrary magnifications) are displayed in traces (*a′*)–(*e′*).

## Footnotes

† For pyrrolidine, $\delta_C$ 25.64 and 47.20; for piperidine, $\delta_C$ 25.21, 27.32 and 47.53; for morpholine, $\delta_C$ 46.61 and 68.15.

‡ $^{13}C$ NMR data for pyrrolidino-substituted *N,N′*-diphenylphenylene-1,4-diamine, $\delta_C$ 24.8, 47.5, 112.3, 113.6, 117, 122.5, 128.9, 131.1, 143.7 and 146.5; for *N,N′*-diphenylphenylene-1,4-diamine, $\delta_C$ 115, 118.2, 119.6, 128.93, 136.4, and 144.8. For *N,N′*-diphenylphenylene-1,4-diimine, $\delta_C$ 120.25, 120.38, 124.35, 125.04, 125.08, 125.29, 136.39, 137.7, 149.8, 149.83, 157.84 and 157.9, complicated by the presence of both *E* and *Z* forms (ref. 13).

§ The S 2p line was reported to be 163.66 eV for poly(phenylene sulfide) and 163.50 eV for poly(ethylene sulfide); 164.4 eV for phenyl disulfide and 164.1 eV for butyl disulfide; 163.1 eV for thiophenol and 161–163 eV for alkanethiols (ref. 14).

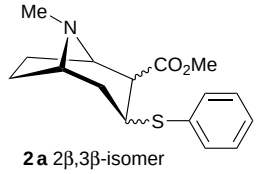
# Synthesis of the isomers of (1*R*)-3-(phenylthio)tropane-2-carboxylic acid methyl ester. A new class of ligands for the dopamine transporter

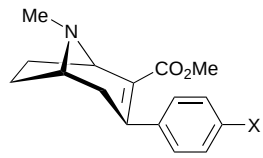
**Mohan Thiruvazhi,[a] Philip Abraham,[a] Michael J. Kuhar[b] and F. Ivy Carroll[a*]**



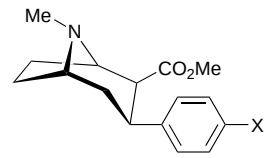
[a] *Chemistry and Life Sciences, Research Triangle Institute, Post Office Box 12194, Research Triangle Park, NC 27709, USA*
[b] *National Institute on Drug Abuse, Addiction Research Center, Post Office Box 5180, Baltimore, MD 21224, USA*

**The syntheses of all four isomers of (1*R*)-3-(phenylthio)tropane-2-carboxylic acid methyl ester are described; the 2β,3β-isomer shows high affinity for the cocaine binding site on the dopamine transporter.**

The behavioural and reinforcing properties of (−)-cocaine **1a** are attributed to its inhibition of dopamine (DA) reuptake.[1,2] We and others have reported that analogues of 3β-(phenyl)tropane-2β-carboxylic acid methyl ester **1b** (WIN 35,065-2) were more potent than cocaine in inhibiting radioligand binding to the cocaine binding site on the dopamine transporter (DAT).[3] However, to the best of our knowledge cocaine analogues possessing a sulfur substituent directly attached to the C-3 position on the tropane ring have not been reported.

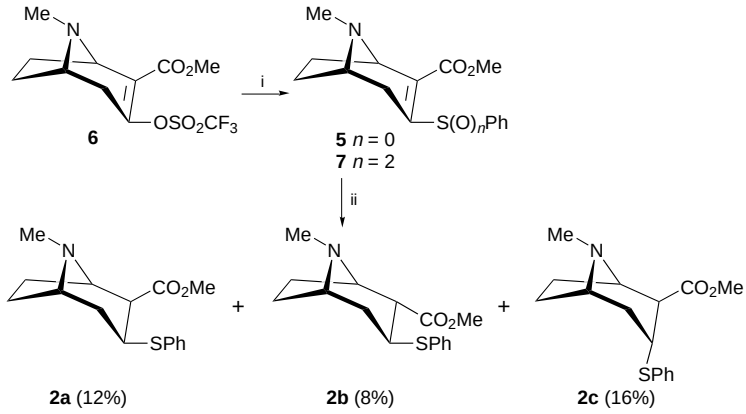


**1a** R = OC(O)Ph
**b** WIN 35,065-2: R = Ph

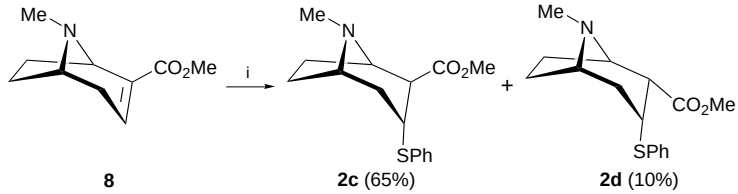


**2 a** 2β,3β-isomer
**b** 2α,3β-isomer
**c** 2β,3α-isomer
**d** 2α,3α-isomer

Here we describe the synthesis of the four possible isomers of (1*R*)-3-(phenylthio)tropane-2-carboxylic acid methyl ester **2a**–**d**. Compound **2a** has the same stereochemistry as **1b** and differs from **1b** by having a sulfur atom between the 3β-phenyl group and the tropane ring system.



We recently reported that samarium iodide reduction of tropene **3** provided a new synthesis of **4**.[4] This result suggested that the synthesis of (1*R*)-3-(phenylthio)trop-2-ene-2-carboxylic acid methyl ester **5** followed by its reduction with samarium iodide[4,5] might afford the 2β,3β isomer **2a**. We found that treatment of (1*R*)-3-(trifluoromethylsulfonyloxy)trop-2-ene-2-carboxylic acid methyl ester **6**[4] with the sodium salt of thiophenol in THF gave **5** in 86% yield (Scheme 1).† We also found that the sodium salt of benzenesulfinic acid displaced the trifluoromethylsulfonyloxy substituent from **6** to afford the 3-(phenylsulfonyl)trop-2-ene-2-carboxylic acid methyl ester **7** in 78% yield.[6] At −78 °C, slow syringe-pump addition of a methanolic solution of **5** to samarium iodide in THF gave 85%



**3**

**4**

**Scheme 1** *Reagents and conditions*: i, for **5**: NaSPh, THF (86%); for **7**: benzenesulfinic acid sodium salt, DMF (78%); ii, $SmI_2$, inverse addition, MeOH −78 °C

**Scheme 2** *Reagents*: i, PhSH, $Et_3N$

of a 15 : 3 : 1 ratio of **2a**, **2b** and **2c**, respectively. None of the 2α,3α isomer **2d** was produced. Silica gel flash column chromatography[7] [$Et_3N$–$Et_2O$–hexanes (1 : 9 : 10)] was used to separate **2b** ($R_f$ 0.25, 8%) from **2a** and **2c** ($R_f$ 0.35). The **2a** and **2c** isomers were separated by HPLC on a silica gel column using $Et_3N$–$Pr^iOH$–hexanes (1 : 99 : 1900) as the eluent system to afford individual isomers **2a** and **2c** in 12 and 16% yields, respectively. The 2β,3β isomer **2a** had mp 55–57 °C (fusion) and $[\alpha]_D$ −83.19 (*c* 0.47, MeOH) for its (+)-tartrate salt. The (+)-tartrate salt of compound **2b** had mp 143–144 °C and $[\alpha]_D$ +49.9 (*c* 0.22, MeOH), and **2c** (+)-tartrate had mp 53–58 °C (fusion) and $[\alpha]_D$ of −37.17 (*c* 0.955, MeOH).

The 2α,3α isomer **2d** was prepared as shown in Scheme 2. Nucleophilic addition of thiophenol to anhydroecgonine methyl ester **8**[8] in the presence of $Et_3N$ gave, after 24 h, the 2β,3α isomer **2c** and 2α,3α isomer **2d**. Silica gel flash chromatography using $Et_3N$–$Et_2O$ (1 : 4) gave **2c** ($R_f$ 0.91, 65%) and **2d** ($R_f$ 0.29, 10%), respectively. Compound **2d** had mp 179–180 °C and an $[\alpha]_D$ +60.4 (*c* 0.106, MeOH) for its hydrochloride salt. Reaction times of several days afforded, after purification, a 1.2:1 ratio of **2c** and **2d** in 75% overall yield. In either case, the nucleophile shows complete preference for an α-face attack on **8**, possibly due to steric hindrance provided by the *N*-methyl group. The formation of two products may be a consequence of complete facial bias during protonation of the intermediate enol ester to give **2c** followed by partial base-catalysed epimerization of H-2 to afford **2d**. Again, the base-catalysed epimerization of **2c** at C-2 could be forced by an unfavourable steric repulsion between the *N*-methyl and the 2-methoxycarbonyl group. Basic conditions encourage facile elimination of thiophenol from **2d** to give **8**. Neither of the isomers **2a** or **2b** were observed in the above reaction when the sodium salt of thiophenol was replaced by the lithium or magnesium salts.

Two dimensional NMR experiments (COSY and HETCOR) aided in chemical shift assignments, while the *J* values and NOESY experiments were used to decipher the stereochemical relationship of the C-2 and C-3 substituents in the **2a**–**d** isomers. For example, **2b** has a large $J_{2,3}$ value of 12.0 Hz, expected for their *anti* disposition. On the contrary, $J_{2,3}$ for **2a**, **2c** and **2d**, were 5.2, 1.1 and 6.9 Hz, respectively. Most importantly, H-2 in **2b** showed an NOE with N-Me and H-$4_{ax}$, while H-3 showed an NOE with H-$6_{ax}$ and H-$7_{ax}$. The observed NOE results are possible *only if* **2b** exists in a chair conformation with H-2 and H-3 in diaxial positions (Fig. 1). Using similar arguments, **2a**, **2c** and **2d** were shown to possess the relative stereochemistry and conformation as displayed in their corresponding structures. It was also interesting to note that the proton spectra patterns of **2a**–**d** resemble those of the corresponding cocaine isomers.[9]

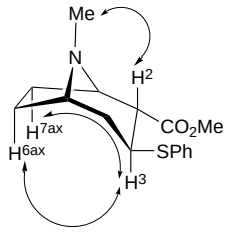


**Fig. 1** Structure of **2b** with selected NOE effects

Binding data on **2a**–**d** revealed that the 2β,3β isomer **2a** was the most potent ($IC_{50}$ 14.3 nm $dm^{-3}$) at the cocaine binding site of the dopamine transporter. The other isomers **2c** ($IC_{50}$ 183 nm $dm^{-3}$), **2d** ($IC_{50}$ 222 nm $dm^{-3}$) and **2b** ($IC_{50}$ 613 nm $dm^{-3}$) were only moderately potent. It is interesting to note that **2a** is slightly more potent than the lead compound, WIN 35065-2 ($IC_{50}$ 23 nm $dm^{-3}$). Since substitution of the phenyl group of the WIN 35,065-2 series was found to increase potency,[3] substituted phenyl analogues of **2a**, and even **2c**–**d**, may be more potent. Studies along this line are underway, and results will be reported in due course.

This research was supported by the National Institute on Drug Abuse, Grant DA05477. We thank Dr Jason P. Burgess for performing the two dimensional NMR experiments, and Dr Pravin Kotian and Dr Yigong Gao for help in the synthesis of **2d**.

# Synergistic oxidation of cyclohexane and hydrogen sulfide under Gif conditions

**Derek H. R. Barton,* Tingsheng Li and John MacKinnon**

*Department of Chemistry, Texas A&M University, College Station, TX 77843-3255 USA*

**Saturated hydrocarbons and hydrogen sulfide can be synergistically oxidised by oxygen (or air) to give efficiently ketones (and the corresponding alcohols) and sulfur in the presence of a Gif catalyst based on $Fe^{II}$, picolinic acid and 4-*tert*-butylpyridine with acetonitrile as solvent at room temperature and nearly neutral pH.**

We report an unusual reaction in which cyclohexane is oxidised to cyclohexanol and cyclohexanone whilst at the same time hydrogen sulfide is converted to sulfur. The only oxidant needed is oxygen or air.

In recent publications[1,2] we have presented a coherent theory of Gif ketonization chemistry. From the practical point of view the selective functionalization of hydrocarbons to furnish ketones, or other derivatives selectively substituted at secondary positions, requires the right kind of carboxylate ligands as, for example, in picolinic acid.[1] Exactly two picolinic acids are bonded to $Fe^{III}$ as determined by quantitative $^{13}C$ NMR studies.[3] There is also an essential need for a certain kind of pyridine ligand as, for example, in 4-*tert*-butylpyridine or in pyridine itself. One of these ligands[2] is bonded to $Fe^{III}$. In practise, about 15 equiv. per $Fe^{III}$ of the pyridine base give optimal results. As solvent the inert acetonitrile is satisfactory.

There are two ways in which the activated iron species can be formed.[1] The first is by addition of superoxide to $Fe^{II}$. This has been well established by electrochemical studies.[4] The second is by substitution chemistry on $Fe^{III}$ by $H_2O_2$.

It occurred to one of us (D.H.R.B.) that if $Fe^{II}$ and $O_2$ would furnish superoxide (and $Fe^{III}$) then the latter would react with more $Fe^{II}$ to make the activated iron species and hence permit entry to Gif ketonization chemistry. If the $Fe^{III}$ formed in the first step could be reduced by $H_2S$ to give $Fe^{II}$ and sulfur then it should be possible to concert the oxidation of saturated hydrocarbons to ketone (and alcohol) with the oxidation $H_2S$ to sulfur. Indeed we have recently established that $Fe^{III}$ is rapidly reduced to $Fe^{II}$ by $H_2S$.[5]

In this way we would be able to coordinate the oxidation of (say) cyclohexane to cyclohexanone (and alcohol) with the removal of toxic hydrogen sulfide from (say) natural gas. The methane and ethane in the natural gas would not react under Gif conditions as evidenced by prior experiments.

For those not initiated into the unusual reactivity seen in Gif chemistry (the Gif paradox) the above sequence might seem improbable.[6] However, whatever oxidation species is present does have a special affinity for saturated hydrocarbons. The latter activates the iron reagent to attack the secondary position and make a species which is not a radical. We still formulate this as an iron–carbon bond.[7]

Be all this as it may, the experimental facts confirm the hypothesis. Using hydrogen sulfide and oxygen, cyclohexane is converted to cyclohexanone and cyclohexanol at the same time that hydrogen sulfide is oxidised to sulfur (see Table 1).

In contrast to our prior work[6] there is no limitation on the conversion. The formation of ketone and alcohol remains quantitative even up to a conversion of 36%. In blank experiments cyclohexanone is not transformed into any other derivatives as it is in prior Gif chemistry.[8] Thus the limit of 20–30% on the convertion previously observed[6] no longer pertains. Cyclohexanol is slowly converted into cyclohexanone. It did not seem likely that carbon radicals would be playing a role in the presence of excess $H_2S$ and its derived radical H–S·. Indeed the addition of excess LiCl afforded no trace of cyclohexyl chloride. Of course, a blank experiment showed that cyclohexyl chloride did not react under the conditions of the oxidation. In agreement with Minisci[9] we accept that carbon radicals react rapidly with $Fe^{III}$–Cl species to make chloride.

As an industrial process, the selective oxidation of hydrocarbons is known to be very inefficient. The Dupont process converts cyclohexane to cyclohexanol and cyclohexanone in a 4% yield with 80% selectivity. The remaining 16% consists of various ring cleavage products and over oxidation products. The conversion is carried out at high temperatures (160 °C) and pressure (15 bar).[8] In this new system the reaction is carried out at room temperature and atmospheric conditions. Hydrogen sulfide (2–2.5 ml $min^{-1}$) and oxygen (25 ml $min^{-1}$) were simultaneously passed through a standard solution containing $Fe^{III}Cl_3$ (1 mmol), picolinic acid or its *N*-oxide (PA-N-oxide) (4 mmol), cyclohexane (20 mmol) and 4-*tert*-butylpyridine (15 mmol) in acetonitrile (33 ml). After a period of time the solution was filtered from the sulfur deposited and the mixture analysed. The efficiencies of the hydrocarbon oxidation are summarized in (Table 1).

Cyclohexane was oxidised to cyclohexanol and cyclohexanone with a 36% conversion after 9 h (Table 1, entry 3). When PA-N-oxide was used as a ligand, a conversion of 33% was achieved in 6 h (Table 1, entry 6). This oxidation procedure can be applied to different hydrocarbons (Table 1, entries 7 and 8).

**Table 1** Efficiency of oxidation of hydrocarbons with hydrogen sulfide and oxygen

| Entry | Hydrocarbon | mmol | Ligand | *t*/h | Ketone[a]/ mmol | Alcohol[a]/ mmol | Conversion (%) |
|---|---|---|---|---|---|---|---|
| 1 | Cyclohexane | 20 | Picolinic acid | 3 | 2.10 | 1.87 | 19.9 |
| 2 | Cyclohexane | 20 | Picolinic acid | 6 | 2.76 | 2.57 | 26.7 |
| 3 | Cyclohexane | 20 | Picolinic acid | 9 | 3.00 | 4.13 | 35.7 |
| 4 | Cyclohexane | 30 | PA-N-oxide | 2 | 2.65 | 3.15 | 19.3 |
| 5 | Cyclohexane | 30 | PA-N-oxide | 4 | 4.18 | 4.52 | 29.0 |
| 6 | Cyclohexane | 30 | PA-N-oxide | 6 | 4.97 | 4.90 | 32.9 |
| 7 | Cyclododecane | 20 | Picolinic acid | 6 | 4.01 | 2.41 | 32.1 |
| 8 | Cyclododecane | 20 | PA-N-oxide | 4 | 2.47 | 1.97 | 22.2 |

[a] The products were analysed by GC, naphthalene was used as internal standard.

Cyclododecane was converted to cyclododecanone and cyclododecanol with a 32% conversion after 6 h. Elemental sulfur was also formed and filtered.

A major limitation with hydrocarbon oxidation was over oxidation of the oxygenated products.[6,10] Blank experiments were carried out to investigate the inherent stability of the products of oxidation. The results are summarized in Table 2.

Both cyclohexanone and cyclododecanone were stable under the oxidative conditions outlined above. It was also shown that the ketone produced as the major oxidation product (Table 1) was not the result of over oxidation of the alcohol. Since essentially no over oxidation occurs over 36 h the possibility of nearly 100% conversion of the hydrocarbon is now a realistic target.

**Table 2** Stability of oxygenated products in hydrogen sulfide Gif oxidation[a]

| Starting material | Recovered ketone (%) | Recovered alcohol (%) | Others (%) |
|---|---|---|---|
| Cyclohexanone | 98.6 | — | —[a] |
| Cyclohexanol | 1.5 | 98.5 | —[b] |
| Cyclododecanone | 95.6 | — | 4.4[c] |

[a] $Fe^{III}Cl_3 \cdot 6H_2O$ (1 mmol), ligand (4 mmol), ketone or alcohol (20 mmol), 4-*tert*-butylpyridine (15 mmol), MeCN (33 ml). Oxygen and hydrogen sulfide were passed through the homogeneous solution for 4 h. The products were analysed by GC, naphthalene was used as internal standard. [b] Not detected. [c] Four diketones in minor amounts.

**Table 3** Conversion of cyclohexane to oxygenated products on a 784 mmol scale[a]

| Entry | *t*/h | Cyclohexanone/ mmol | Cyclohexanol/ mmol | Total/ mmol | Conversion (%) |
|---|---|---|---|---|---|
| 1 | 4 | 15.97 | 4.91 | 20.88 | 2.66 |

| 11 | 15 | 15 | 4 | 0.60 | 0.36 | 11 |

[a] $Fe^{II}Cl_2 \cdot 4H_2O$ (1 mmol), ligand (3 mmol), hydrocarbon (20 mmol), 4-*tert*-butylpyridine (15 mmol), MeCN (33 ml). Oxygen and hydrogen sulfide were passed through the homogeneous solution for 4–8 h. The products were analysed by GC, naphthalene was used as internal standard. The $H_2S$ is the total passed.

The oxidation of cyclohexane was not only limited to a 20 mmol scale. A large scale experiment was carried out (Table 3).

After 36 h the conversion of the hydrocarbon to ketone and alcohol was 14.33%. The lower conversion value was a result of a decrease in the rate of the reaction due to the increased hydrocarbon to solvent ratio. After filtration of the reaction mixture, 625 mmol of sulfur was obtained. In other experiments using variable $H_2S$ and $O_2$ flow rates the sulfur formed was quantified (Table 4).

When the flow rates of one or both of $H_2S$ and $O_2$ were varied from that of the standard flow rate (Table 4, entry 4), the total amount of ketone and alcohol decreased. A reasonable correlation between the amount of $H_2S$ used and that of sulfur obtained was seen.

We have developed an efficient new procedure for the selective oxidation of hydrocarbons to the corresponding ketone and alcohol by simply passing through a stream of oxygen and hydrogen sulfide. At the same time we have provided an efficient route to dispose of hydrogen sulfide gas. This synergistic oxidation of hydrocarbons and removal of hydrogen sulfide provides a route for the nearly quantitative conversion of hydrocarbons to their oxygenated products. It is a significant improvement on our original work.[10]

Although there is considerable prior work on the oxidation of saturated hydrocarbons by non-haem systems[11] the normal substitution pattern according to the C–H bond strength is followed. Gif chemistry is a separate subject.[1,6,12] In the present work, as in general,[1] if the picolinic acid or the pyridine base are omitted from the system then very little oxidation takes place. A detailed mechanistic discussion has not been presented. The reactions differ from normal only in the enhancement of alcohol relative to ketone.

We thank Quest International, the Welch Foundation, the N.S.F and the Schering Plough Corporation for the support of this work.

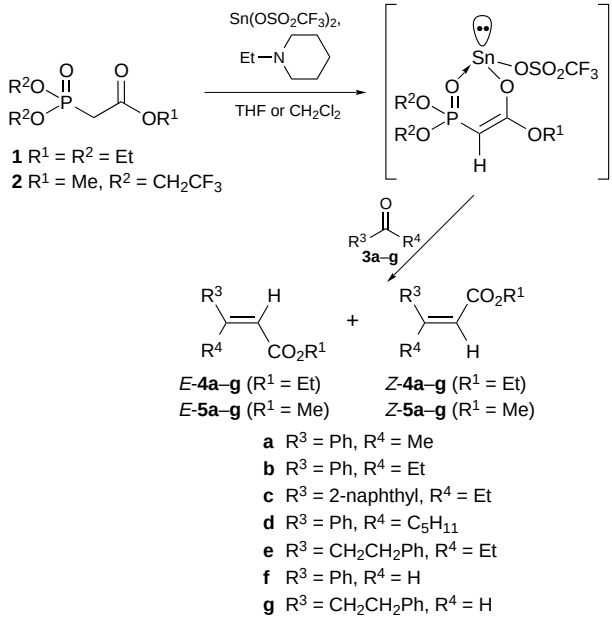
# New reaction mode of the Horner–Wadsworth–Emmons reaction using $Sn(OSO_2CF_3)_2$ and *N*-ethylpiperidine

**Shigeki Sano, Kenji Yokoyama, Mari Fukushima, Tetsuo Yagi and Yoshimitsu Nagao***



*Faculty of Pharmaceutical Sciences, The University of Tokushima, Sho-machi, Tokushima 770, Japan*

**Excellent *Z* or *E* selectivity is observed in the Horner–Wadsworth–Emmons reactions of methyl bis(trifluoroethyl)phosphonoacetate 2 with aryl alkyl ketones 3a–d or aldehydes 3f,g using $Sn(OSO_2CF_3)_2$ in the presence of *N*-ethylpiperidine, which should have a different reaction mode to those using sodium hydride.**

The Horner–Wadsworth–Emmons (HWE) reaction is one of the most efficient methods for the preparation of α,β-unsaturated esters.[1] The reactions of aldehydes with phosphonates bearing α-substituents that stabilise the carbanion preferentially furnish the corresponding *E*-alkenes. Various bases such as sodium hydride, butyllithium and sodium ethoxide have been employed in order to generate the phosphonate carbanions. In similar HWE reactions, mild olefination procedures using lithium and magnesium salts[2] in the presence of tertiary amines or with lithium hydroxide[3] are also available. Interestingly, the reactions of methyl bis(trifluoroethyl)phosphonoacetate **2**[4] or ethyl diphenylphosphonoacetate[5] with aldehydes selectively yield *Z*-alkenes. However, the stereoselectivity of their HWE reactions with ketones has never been investigated in detail because of their low reactivity and low stereoselectivity.[6]

Herein we describe the stereochemical outcome in the HWE reactions of ethyl diethylphosphonoacetate **1** and methyl bis(trifluoroethyl)phosphonoacetate **2** with some aryl alkyl ketones **3a**–**e** and aldehydes **3f**,**g** using $Sn(OSO_2CF_3)_2$ in the presence of *N*-ethylpiperidine, as shown in Scheme 1.† The results are shown in Tables 1–3.‡

The conventional HWE reactions of aryl alkyl ketones **3a**–**d** with phosphonate **1** in the presence of sodium hydride in THF at 0 °C and then at room temperature gave the corresponding α,β-unsaturated esters **4a**–**d** with modest *E* selectivity (Table 1, entries 1–4). On the other hand, treatment of **3b**–**d** and **1** with $Sn(OSO_2CF_3)_2$ in the presence of *N*-ethylpiperidine in THF at 0 °C afforded *Z*-alkenes **4b**–**d**, respectively, in a highly selective fashion (Table 2, entries 2–4). Under both sets of reaction conditions described above, the HWE reactions of aldehydes **3f**,**g** with **1** gave **4f**,**g** in the usual highly *E*-selective manner (Table 1, entries 6 and 7; Table 2, entries 6 and 7). Poor stereoselectivity was observed in both reaction systems for ketone **3e** (Table 1, entry 5; Table 2, entry 5). A significant

[a] Conditions: $CH_2Cl_2$, 0 °C, **2**/$Sn(OSO_2CF_3)_2$/*N*-ethylpiperidine/**3** (1.4 : 1.68 : 1.54 : 1). [b] Isolated yields. [c] $^1H$ NMR (400 MHz, $CDCl_3$) analysis. [d] HPLC analysis (TSK-GEL Silica 60, hexane–propan-2-ol. [e] −78 °C. [f] No reaction.

improvement in the selectivity and yield was found when Still's reagent, methyl bis(trifluoroethyl)phosphonoacetate **2**, was used under the $Sn^{II}$-promoted (Tables 2 and 3). In particular, the reactions of **3a–d** with **2** employing $Sn(OSO_2CF_3)_2$ and *N*-ethylpiperidine in $CH_2Cl_2$ at 0 °C afforded the corresponding *Z*-alkenes **5a–d** in a more highly selective manner (Table 3, entries 1–4) than those carried out in THF (Table 2, entries 8–11). The reactions using the NaH procedure resulted in low *Z*-selectivity (Table 1, entries 8–11). The HWE reactions of aldehydes **3f,g** with **2** in the presence of NaH in THF at −78 °C gave *Z*-**5f,g** with similar good selectivity to that using Still's reagent (Table 1, entries 13 and 14). The same reactions employing $Sn(OSO_2CF_3)_2$ and *N*-ethylpiperidine in THF or $CH_2Cl_2$ at −78 °C, on the contrary, gave *E*-**5f,g** with fairly good selectivity, as we anticipated (Table 2, entries 13 and 14; Table 3, entry 6). Surprisingly the stereoselectivity of **5f,g** in the $Sn^{II}$-promoted reactions of **3f,g** with **2** [THF, 20–22 h, **2**/$Sn(OSO_2CF_3)_2$/*N*-ethylpiperidine/**3f** or **3g** (1.4 : 1.68 : 1.54 : 1)] was variable depending on the reaction temperatures as follows; *E* : *Z* ratio (temperature, yield) of **5f** = 33 : 67 (0 °C, 90%), 19 : 81 (−30 °C, 72%), 12 : 88 (−45 °C, 68%), 26 : 74 (−56 °C, 62%), 71 : 29 (−65 °C, 57%) and 89 : 11 (−78 °C, 62%); *E* : *Z* ratio (temperature, yield) of **5g** = 6 : 94 (0 °C, 85%), < 1 : > 99 (−40 °C, 53%) and 95 : 5 (−78 °C, 44%). However, the similar $Sn^{II}$-promoted reaction of **3f** in $CH_2Cl_2$ always afforded the *E*-alkene **5f** (*E* : *Z* = 78 : 22 to 94 : 6) irrespective of the reaction temperature (room temperature to −78 °C). The NaH-promoted reactions of **3f,g** in THF also always gave the corresponding *Z*-alkenes **5f** [*E* : *Z* = 28 : 72 (0 °C) and 15 : 85 (−78 °C)] and **5g** [*E* : *Z* = 18 : 82 (0 °C) and 8 : 92 (−78 °C)], respectively.

On the basis of the experimental results described above, the high *Z*-selectivity in the $Sn(OSO_2CF_3)_2$-mediated HWE reactions of ketones **3a–d** with **1** and **2** can be rationalised in terms of six-membered transition state **A** (*e.g.* **3b**) involving $Sn^{II}$ chelation (Fig. 1). Another possible transition state **B** favouring *E*-selectivity will be disadvantageous due to 1,3-diaxial steric repulsion between the ethyl (or other alkyl) group and the $R^1O$ group. This speculative consideration is supported by the fact that 1-methyl-1-phenylcyclohexane exhibits an axial preference for the phenyl group in spite of the relatively large *A* value of the phenyl group (2.87 kcal $mol^{-1}$) compared with the ethyl group (1.8 kcal $mol^{-1}$).[7] The *E*-selectivity in the $Sn(OSO_2CF_3)_2$-mediated HWE reactions of aldehydes **3f,g** with **1** in THF at 0 °C, with **2** in THF at −65 to −78 °C and with **2** in $CH_2Cl_2$ at room temperature to −78 °C may also be explained in terms of six-membered transition state **C** (*e.g.* **3f**). The $Sn^{II}$-promoted HWE reactions of the reactive reagent **2** with aldehydes **3f,g** in THF at higher reaction temperatures than −65 °C seem to proceed in a non-chelation-controlled manner like the case of NaH.

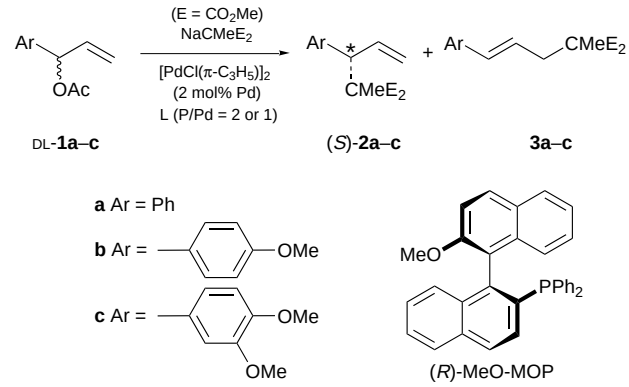
# Regio- and enantio-selective allylic alkylation catalysed by a chiral monophosphine–palladium complex



**Tamio Hayashi,* Motoi Kawatsura and Yasuhiro Uozumi**

*Department of Chemistry, Faculty of Science, Kyoto University, Sakyo, Kyoto 606-01, Japan*

**Allylic alkylation of racemic 1-arylprop-2-enyl acetates [ArCH(OAc)CH=$CH_2$] with the sodium enolate of dimethyl methylmalonate in the presence of a palladium catalyst coordinated with (*R*)-2-diphenylphosphino-2′-methoxy-1,1′-binaphthyl [(*R*)-MeO-MOP] proceeds with high branch selectivity (90%) to give chiral products [ArC*H(Nu)CH=$CH_2$] of up to 87% ee.**

Palladium-catalysed allylic substitution reactions including catalytic asymmetric reactions have attracted considerable attention owing to their synthetic utility and mechanistic interest.[1] One of the major problems in developing catalytic asymmetric allylic substitutions is undesirable regiochemistry which limits the substitution patterns of allylic substrates. As a typical example, the substitution with soft carbon nucleophiles that proceeds through π-allylpalladium intermediates containing one substituent at the C-1 position produces the linear isomer rather than the branch isomer.[1] It follows that the reaction cannot be extended to asymmetric synthesis because the linear isomer lacks the chiral carbon centre. The regioselectivity in forming the branch isomer is usually very low except when methyl is the substituent.[2] Here we report that the use of 2-diphenylphosphino-2′-methoxy-1,1′-binaphthyl (MeO-MOP),[3] which is a sterically bulky chiral monophosphine ligand, for the allylic alkylation of 1-arylprop-2-enyl acetates **1** reversed the regiochemistry to give branch isomers **2** with high selectivity and up to 87% ee in this new allylic alkylation system.

The results obtained for the allylic substitution of racemic 1-arylprop-2-enyl acetates DL-**1** in the presence of palladium–phosphine complexes (Scheme 1) are summarized in Table 1. The reaction of DL-1-phenylprop-2-enyl acetate **1a** with the sodium salt of dimethyl methylmalonate in THF at −20 °C in the presence of 2 mol% of palladium catalyst generated from $[PdCl(\pi\text{-}C_3H_5)]_2$ and 1,2-bis(diphenylphosphino)ethane (dppe) gave linear isomer (*E*)-**3a** with 93% regioselectivity (entry 1). The linear selectivity (79–85% regioselectivity) was also observed in the reaction with a palladium catalyst coordinated with triphenylphosphine (entries 2 and 3). It is noteworthy that the reaction catalysed by palladium–$PPh_3$ requires 2 equiv. of triphenylphosphine (to Pd) for the allylic substitution to proceed smoothly. With 1 equiv. of triphenylphosphine, the reaction stops at about 60% conversion. The opposite regioselectivity was observed in the same substitution reaction of **1a** by use of MeO-MOP as a ligand, which gave branch isomer **2a** with 79% regioselectivity at −20 °C (entries 4 and 5). With the palladium–MeO–MOP catalyst, the ratio of phosphine to palladium did not affect either the catalytic activity or the regioselectivity. Higher regioselectivity in forming the branch isomer was observed in the reaction of 1-arylprop-2-enyl

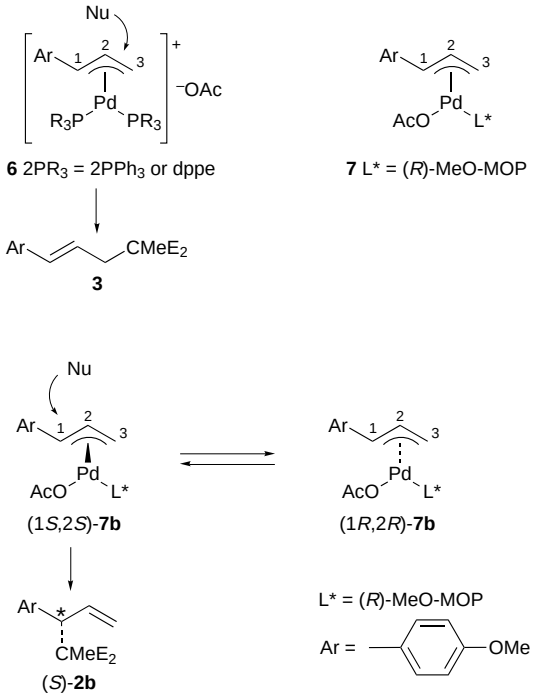
[a] All reactions were carried out in THF under nitrogen: THF (1.0 ml), allylic acetate (0.20 mmol), $NaCMe(CO_2Me)_2$ (0.40 mmol), $[PdCl(\pi\text{-}C_3H_5)]_2$ (0.002 mmol) and phosphine ligand. [b] Isolated yield by silica gel column chromatography. [c] The ratio was determined by $^1H$ NMR analysis of the products. [d] Determined by GLC analysis with CP Cyclodex β236M after demethoxycarbonylation of one of the two methoxycarbonyl groups. [e] Specific rotations of **2a** (entry 6), **2b** (entry 12) and **2c** (entry 13) were $[\alpha]_D^{20}$ +46.4, +50.3 and +45.0 (*c* 1.1–1.8, $CHCl_3$), respectively. [f] Determined by HPLC analysis with Chiralpak AD (hexane–propan-2-ol = 9 : 1). [g] Determined by HPLC analysis with Chiralcel OD-H (hexane–propan-2-ol = 9 : 1).

acetates **1b** and **1c** which contain methoxy group(s) on the aromatic ring (entries 10–13). At the reaction temperature of −30 °C, 1-(4-methoxyphenyl)prop-2-enyl acetate **1b** gave branch isomer **2b** with 90% regioselectivity (entry 12). The enantiomeric purity of **2b** determined by a chiral stationary phase column (Chiralpak AD) was 87% ee and its absolute configuration was assigned to be (+)-(*S*) by correlation with known (*R*)-(−)-4-(4-methoxylphenyl)tetrahydro-2*H*-pyran-2-one[4] **4** by way of (*R*)-(+)-dimethyl (1-arylprop-2-enyl)malonate **5** (Scheme 2). Here again the palladium catalyst containing dppe or triphenylphosphine gave linear isomer **3b** preferentially (entries 7–9). The reaction of allylic acetate **1c** in the presence of MeO-MOP at −30 °C also gave the corresponding alkylation product **2c** of 85% ee with high branch selectivity (entry 13). Thus, chiral monodentate phosphine ligand, MeO-MOP, is playing a key role on the high branch selectivity in the catalytic allylic alkylation of 1-arylprop-2-enyl acetates. This type of asymmetric alkylation is considered to be difficult with chelating bisphosphine ligands so far used mostly for the asymmetric allylic alkylation which proceeds by way of palladium intermediates containing 1,3-disubstituted π-allyl moieties such as 1,3-diphenyl.[1,5]



The preferential formation of linear isomers in the allylic alkylation of **1** catalysed by palladium–dppe or palladium–$PPh_3$ is as expected because cationic [π-(1-aryl)allyl]bis-(phosphine)palladium(II) intermediate **6** formed by oxidative addition of **1** to bis(phosphine)palladium(0) will undergo nucleophilic attack on the less hindered end of the π-allyl, namely, C-3 position of π-(1-aryl)allyl group (Scheme 3). It gives the thermodynamically more stable product **3** where the double bond is conjugated with aromatic ring. On the other hand, the reaction with MeO-MOP ligand should proceed *via* neutral [π-(1-aryl)allyl](acetato)(phosphine)palladium(II) intermediate **7** because the steric bulkiness of the MOP ligand does not allow the palladium to form a cationic bis(phosphine) complex which is analogous to **6**.

Ar = 4-$MeOC_6H_4$, E = $CO_2Me$

**3**

**Scheme 3**

The π-allylpalladium complex **7b** (Ar = 4-$MeOC_6H_4$) was prepared by mixing the [π-(1-aryl)allyl](acetato)palladium(II) dimer with 1 equiv. (to Pd) of (*R*)-MeO-MOP and it was characterized by $^{31}P$ and $^1H$ NMR spectra. In $CDCl_3$ at −50 °C the complex exists as a mixture of isomers in a ratio of 9 : 1.† The main isomer has substituted carbon (C-1) of the π-allyl *trans* to the phosphorus atom of MeO-MOP and the unsubstituted carbon (C-3) *cis* to phosphorus, which is determined by a large coupling constant ($J$ = 8.2 Hz) between C-1 proton and phosphorus and no couplings between C-3 protons and phosphorus. Our structural studies of related PdCl(π-allyl)-(MeO-MOP) complexes[6] also showed that the unsubstituted π-allyl carbon adopts the *cis* position to phosphorus. The nucleophile attacks the C-1 carbon which is more weakly bonded to palladium due to a stronger *trans* influence of phosphine ligand to give branch product preferentially. The stoichiometric reaction of π-allylpalladium complex **7b** with the sodium enolate of dimethyl methylmalonate in THF at −20 °C gave (*S*)-**2b** of 90% ee with 88% regioselectivity, which is in good agreement with the catalytic reactions in terms of both regio- and enantio-selectivity.

We thank the Ministry of Education, Japan, for a Grant-in-Aid for Scientific Research for partial financial support of this work.

## Footnote

† *Selected NMR data* for the major isomer of **7b**: $^1H$ NMR ($CDCl_3$ at −50 °C) δ 1.51 (s, 3 H), 1.56 (d, $J$ = 11.6 Hz, 1 H, *anti*-H on C-3), 2.66 (d, $J$ = 6.3 Hz, 1 H, *syn*-H on C-3), 3.03 (s, 3 H), 3.28 (m, 1 H, H on C-2), 3.89 (s, 3 H), 5.41 (dd, $J_{H-H}$ = 13.5 Hz, $J_{H-P}$ = 8.2 Hz, 1 H, H on C-1), 6.87–8.10 (m, 26 H). $^{31}P$ NMR ($CDCl_3$ at −50 °C) δ 23.2 (s). $^{31}P$ NMR for minor isomer of **7b**: δ 24.8 (s).

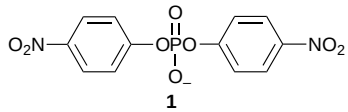
# Actinide (uranyl) hydrolysis of phosphodiesters

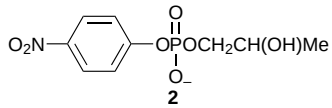
**Robert A. Moss,* Kathryn Bracken and Jing Zhang**

*Department of Chemistry, Rutgers University New Brunswick, New Jersey 08903, USA*



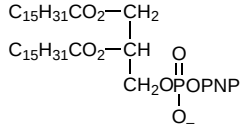
**Uranyl ($UO_2^{2+}$) cations mediate the hydrolysis of aggregated and non-aggregated *p*-nitrophenyl phosphodiesters in mildly acidic aqueous solutions (pH 4.9) with rate enhancements > 1000 at 37 °C.**

The past several years have witnessed intensive study of the lanthanide ion catalysis of phosphodiester hydrolysis, stimulated by the drive to develop synthetic nucleases.[1] The activated phosphodiester, bis(*p*-nitrophenyl) phosphate **1** (BNPP), has been a favourite model substrate,[2–4] although lanthanides and their complexes have also cleaved DNA,[5,6] phosphonates[7] and phosphate monoesters.[8] RNA, and the RNA model substrate **2**, have also been catalytically cleaved by lanthanides[1] and other metal cations.[9–11]

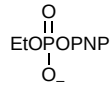


Recently, we reported that the $Eu^{3+}$ or $La^{3+}$–$H_2O_2$ cleavages of liposomal phosphodiester **3** were accelerated 50–70 times, relative to the non-aggregated model phosphodiester **4** (PNP = *p*-nitrophenyl).[12] Binding of the cationic lanthanide ions to the anionic liposomes afforded additional catalysis above that normally expected from the lanthanides.

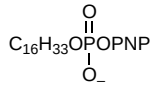
Although many lanthanide and transition metal cations have been examined as catalysts for the hydrolysis of phosphodiesters, the actinide uranyl ($UO_2^{2+}$) cation has not.† This is surprising because $UO_2^{2+}$ is known to bind strongly to various nucleotides,[14] as well as DNA,[15] with P–O–U bonding a key feature.[14] Indeed, $UO_2^{2+}$ bound between the phosphate groups of stacked DNA strands mediates photolytic, oxidative cleavage of the DNA.[15] Moreover, $UO_2^{2+}$ catalyses the oligomerization of nucleotide 5′-phosphoroimidazolides and 5′-thiophosphoroimidazolides *via* U–O–P–Im complexes in which the electrophilic uranium activates the substrate to nucleophilic attack at P by an incoming 2′-OH nucleophile.[16]‡



The clear implication is that $UO_2^{2+}$ should bind activated phosphodiesters and predispose these substrates to hydrolytic cleavage. Here, we report that this inference is correct: substrates **1**–**4**, as well as the micellar phosphodiester **5**, are indeed hydrolysed by $UO_2^{2+}$ in mildly acidic aqueous solutions, with additional catalysis apparent for the aggregated substrates **3** and **5**. These are the initial examples of phosphodiester hydrolysis mediated by uranyl cations, and also feature the first metal ion cataysed hydrolysis of a micellar phosphodiester **5**.



**1**



**2**

**3**

**4**

**5**

The RNA model, 2-hydroxypropyl *p*-nitrophenyl phosphate **2**,[18] was efficiently hydrolysed in the presence of excess $UO_2^{2+}$ at 37 °C, pH 4.9±0.1.§ The exact conditions appear in Table 1, where kinetic data for comparable hydrolyses mediated by the lanthanide cations, $Eu^{3+}$ and $Tm^{3+}$, are also collected. Note that these comparisons are under identical conditions in the absence of buffer ions.¶

$UO_2^{2+}$ mediates the quantitative (UV, HPLC) cleavage of substrate **2** with an observed rate constant ($2.2\times10^{-4}$ $s^{-1}$) that is at least 6700 times greater than that for the uncatalysed reaction, where the rate constant for the uncatalysed hydrolysis of **2** is determined at pH 7,[1a] and must be presumed to exceed the value at pH 4.9. (Hydrolysis was not observed over 4 days in the absence of $UO_2^{2+}$ at pH 4.9.) The $k_{rel}$ values in Table 1 are therefore minima. Moreover, the uranyl-catalysed hydrolysis is also 3.5–4.5 times faster than lanthanide cleavage brought about by Eu or Tm cations under these conditions.

Hydrolysis of **2** involves cyclization with displacement of the leaving group by intramolecular OH attack[1] on the metal-bound and activated phosphate. Accordingly, $UO_2^{2+}$ cleavage of ethyl *p*-nitrophenyl phosphate, **4**,[12] which lacks the neighbouring hydroxy is *ca.* 16 times slower ($k_{obs} = 1.4 \times 10^{-5}$ $s^{-1}$) than the hydrolysis of **2** under the conditions of Table 1. Nevertheless, cleavage of **4** is at least 420 times faster than the uncatalysed hydrolysis of **2** at pH 7.

Interestingly, the $UO_2^{2+}$-mediated hydrolyses of **2** and **4** are *ca.* 3.7 times faster than analogous $Eu^{3+}$-catalysed processes (Table 1 and ref. 12). At the low pH used in the present reactions, the lanthanides ($pK_a \sim 8.0$)[19] bear $H_2O$ rather than OH groups and most likely express only electrophilic catalysis due to P–$O^-$ binding; nucleophilic assistance from M–OH would be suppressed. However, $UO_2^{2+}$ has $pK_a$ *ca.* 4.2–6.1 in aqueous solution, depending on ionic strength, added salts and ligand association.[19] Therefore, both electrophilic ($M^+$, external $H_2O$) and nucleophilic (M–OH) components may contribute to uranyl cation catalysis at pH 5.

$UO_2^{2+}$ precipitates with BNPP **1** or the aggregated substrates **3**[12] or **5**.‖ However, addition of 0.1 equivalents of *N*-hexadecyl-*N*,*N*′,*N*′-trimethylethylenediamine (HTMED)[12,20] solubilizes the uranyl cations, presumably in a mixed HTMED-substrate aggregate, thus making it possible to obtain stable $UO_2^{2+}$-substrate solutions. Neither tetramethylethylene diamine nor cetyltrimethylamine solubilizes $UO_2^{2+}$ under our conditions; only a long-chain diamine succeeds, indicating the dependence of solubilization on both cation chelation and HTMED

**Table 1** Kinetics of the metal ion catalysed hydrolysis of **2**[a]

| Catalyst | $k_{obs}/s^{-1}$ | $k_{rel}$ | % Cleaved at 20 h |
|---|---|---|---|
| None[b] | $3.3 \times 10^{-8}$ | 1.0 | — |
| $UO_2(NO_3)_2$ | $2.2 \times 10^{-4}$ | 6700 | 100 |
| $EuCl_3$ | $4.8 \times 10^{-5}$ | 1450 | 75 |
| $TmCl_3$ | $6.2 \times 10^{-5}$ | 1900 | 78 |

[a] Conditions: [**2**] = $1 \times 10^{-4}$ mol $dm^{-3}$, [catalyst] = $1 \times 10^{-3}$ mol $dm^{-3}$, 0.01 mol $dm^{-3}$ aq. KCl, pH 4.9 ± 0.1, 37 °C. [b] Data from ref. 1(*a*) at pH 7.0, 37 °C.

**Table 2** Kinetics of the uranyl ion catalysed hydrolysis[a]

| Substrate | $k_{obs}/s^{-1}$ | $k_{rel}$ | % Cleaved at 20 h |
|---|---|---|---|
| **1** | $9.5 \times 10^{-6}$ | 5.6 | 84 |
| **2** | $1.5 \times 10^{-5}$ | 8.8 | 95 |
| **3** | $1.1 \times 10^{-4}$ | 65 | 95 |
| **4** | $1.7 \times 10^{-6}$ | 1.0 | 72 |
| **5** | $1.1 \times 10^{-4}$ | 65 | 92 |

[a] Conditions: [substrate] = $1 \times 10^{-4}$ mol dm$^{-3}$, [HTMED] = $1 \times 10^{-4}$ mol dm$^{-3}$, [$UO_2^{2+}$] = $1 \times 10^{-3}$ mol dm$^{-3}$, $2 \times 10^{-3}$ mol dm$^{-3}$ HEPES buffer, 0.01 mol dm$^{-3}$ KCl, pH 4.9 ± 0.1, 37 °C. Kinetic data were obtained at 317 nm.

coaggregation. We are thus able to measure the $UO_2^{2+}$ hydrolytic rate constants collected in Table 2.**

Note first that the $UO_2^{2+}$ catalysed cleavages of **2** and **4** are slower by factors of *ca.* 15 and 8, respectively, relative to reactions in the absence of HTMED (*cf.* Table 1 and above), presumably because the electrophilic character of the uranyl cation is attenuated by chelation with HTMED. Most importantly, however, Table 2 reveals the additional reactivity inherent in the liposomal **3** and micellar **5** phosphodiester substrates, both of which are hydrolysed 65 times more rapidly than **4** in the presence of $UO_2^{2+}$. This aggregate catalysis is undoubtedly due to the binding of the metal cations to the anionic aggregates, assisted by the HTMED which probably forms part of a coaggregate. The cleavage of liposomal **3** by the lanthanide, $Eu^{3+}$, is similarly enhanced by a factor of 56, relative to **4**.[12]

The $UO_2^{2+}$-mediated hydrolyses of **3** and **5** at pH 5 (Table 2) occur at similar rates to the $Eu^{3+}$ reaction with **3** ($k_{obs}$ = $2 \times 10^{-4}$ s$^{-1}$, pH 5.6, 25 °C) at similar reactant concentrations.[12] Relative to substrate **2** in the absence of $UO_2^{2+}$ (Table 1), the actinide plus aggregate catalysis affords a kinetic advantage of > 3300 in the hydrolysis of substrates **3** and **5**.

Finally, we note that both the *exo*- and *endo*-liposomal *p*-nitrophenylphosphate functional groups of **3** are quantitatively cleaved by $UO_2^{2+}$-HTMED in a uniphasic kinetic process at both 25 and 37 °C ($T_c$ of **3** is 42 °C[12]); there is no evidence of the *exo*-liposomal-specific cleavage observed with 'naked' $Eu^{3+}$ at 25 °C.[12] Presumably, the difference originates in the obligatory presence of HTMED, which can chelate $UO_2^{2+}$ and rapidly ($> k_{hydrol}$) transport it across the liposomal bilayer to mediate *endo*-liposomal cleavage. Alternatively, the HTMED molecules could disrupt the integrity of the liposomal membrane, permitting uranyl cation permeation. $Eu^{3+}$ cleavage of liposomal **3** also becomes complete and uniphasic in the presence of HTMED for related reasons.[12]

We are grateful to Professor Paolo Scrimin (University of Padua) for a gift of HTMED, and to both Professors Scrimin and John Brennan (Rutgers University) for helpful discussions. We thank the U.S. Army Research Office for financial support.

## Footnotes

† Martell (ref. 13) reported the rapid cleavage of the fluorophosphonate Sarin by the 1,8-dihydroxynaphthalene-3,6-disodium sulfonate (DNS) complex of $UO_2^{2+}$. Phosphodiester substrates, however, are much less reactive than fluorophosphonates. Indeed, we find substrates **2** and **3** to be quite unreactive to the $UO_2^{2+}$–DNS complex at either pH 5 or 7 ($k_{hydrol} \ll 1x10^{-6}$ s$^{-1}$), with hydrolysis < 50% complete after 5 days at 37 °C.

‡ After our current work had been completed, it was reported that the actinide $Th^{4+}$ accelerates the hydrolyses of various nucleotide phosphomonoester and -diester bonds in acidic aqueous solutions (ref. 17).

§ $UO_2^{2+}$ precipitates as polynuclear metal hydroxide gels at pH ≥ 5.3 (ref. 19) restricting us to pH *ca.* 5.0. Below pH 4.0, no hydrolysis of the phosphodiester substrates was observed over 24 h.

¶ Hydrolyses were followed spectrophotometrically between 200–600 nm; and kinetics were measured at both 290 nm (disappearance of substrate) and 317 nm (appearance of *p*-nitrophenol). Pseudo-first-order rate constants (measured over 20 h) are reported as means of 2 or 3 runs ($r > 0.997$), with reproducibility within ±10%. The pH, adjusted with 0.1 mol dm$^{-3}$ HCl, was buffered by the metal cations and varied no more than 0.2 pH units during the course of reaction. The percentage cleavage was determined from the concentration of liberated *p*-nitrophenoxide ion, measured at pH 12 (400 nm), after 20 h of reaction.

‖ Substrate **5** (mp 165 °C, decomp.) was prepared by phosphorylation of hexadecanol with 4-nitrophenyl phosphorodichloridate ($CH_2Cl_2$, $Et_3N$, 0–25 °C, 3.5 h), followed by methanolysis to hexadecyl methyl *p*-nitrophenyl phosphate. The methyl group was removed by reaction with LiBr in refluxing acetone (48 h), affording white crystalline **5** (Li salt), which was characterized by NMR and elemental analysis.

** HEPES buffer (2 mmol dm$^{-3}$) is present in these runs because it is necessary in the preparation of liposomal **3** (ref. 12). The buffer alone does not solubilize $UO_2^{2+}$ in the presence of substrates **1**, **3** or **5**, nor does it alter the reactivity of the cation toward **2** or **4**. Control experiments also show that HTMED alone does not induce cleavage of the substrates.

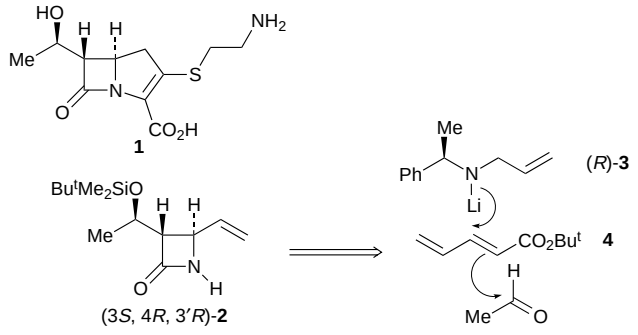
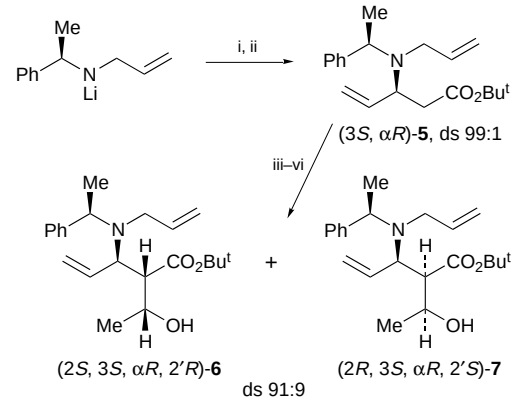
**The highly stereoselective conjugate addition of lithium (α*R*)-(α-methylbenzyl)allylamide 3 to (*E*)-*tert*-butyl penta-2,4-dienoate 4, followed by a stereoselective aldol reaction with acetaldehyde, are the key steps in the synthesis of the known β-lactam intermediate, (3*S*,4*R*)-3-[(*R*)-1-(*tert*-butyldimethylsilyloxy)ethyl]-4-vinylazetidin-2-one 2, for elaboration to thienamycin and its derivatives.**



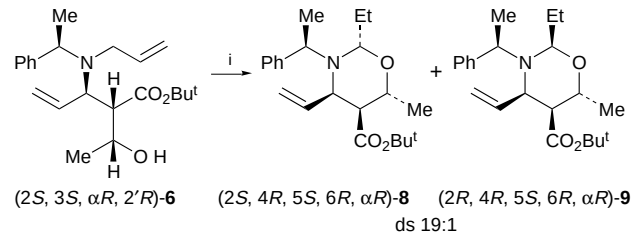
The carbapenems are an important class of β-lactam antibiotics with broad-spectrum potency and stability to β-lactamases. (+)-Thienamycin **1**, the first member of the family to be discovered,[1] has been the subject of numerous syntheses, with the *trans* stereochemistry of the protons in the β-lactam ring and the 3-[(*R*)-1-hydroxyethyl] side chain presenting a considerable synthetic challenge.[2] This key β-lactam framework is also found in the 1β-methylcarbapenems[3] and the tribactams,[4] antibiotics of current interest due to their enhanced chemical and metabolic stabilities.

A concise approach to this β-lactam framework is *via* a conjugate addition-aldol condensation strategy. Yamamoto *et al*. have used lithium *N*-benzyltrimethylsilylamide to give a key β-lactam intermediate as a single diastereomer,[5] but with the wrong absolute stereochemistry, and lithium (α-methylbenzyl)benzylamide,[6] developed in our laboratories, to give a β-lactam with the correct absolute stereochemistry but, due to the requirement of removing the *N*-benzyl groups by hydrogenation, without the possibility of incorporating an unsaturated side chain necessary for further synthetic elaboration.[7]



We have recently developed lithium (α*R*)-(α-methylbenzyl)allylamide **3** specifically for the synthesis of homochiral β-amino acids and β-lactams[8] and its application to the synthesis of carbapenem intermediates has already been demonstrated.[9] In particular, the use of this reagent to generate β-lactams with unsaturated side chains suggested its application in the synthesis of the known β-lactam intermediate, (3*S*,4*R*)-3-[(*R*)-1-(*tert*-butyldimethylsilyloxy)ethyl]-4-vinylazetidin-2-one **2**[10,11] for the synthesis of thienamycin, *via* a conjugate addition–aldol condensation approach (Scheme 1).

Addition of lithium (α-methylbenzyl)allylamide (*R*)-**3** to (*E*)-*tert*-butyl penta-2,4-dienoate **4**,† followed by quenching with aqueous ammonium chloride, gave the β-amino adduct (3*S*,α*R*)-**5** in 87% yield with no 1,2- nor 1,6-addition being observed (Scheme 2). Analysis of the 500 MHz $^1$H NMR spectrum of the crude addition product showed the diastereoselectivity (ds) to be 99 : 1. Treatment of the adduct (3*S*, α*R*)-**5** with LDA in THF at 0 °C for 2 h followed by cooling to −78 °C and quenching with acetaldehyde gave only two of the four possible diastereomeric aldol products, (2*S*,3*S*,α*R*,2′*R*)-**6** and (2*R*,3*S*,α*R*,2′*S*)-**7**, in a 4 : 1 ratio by analysis of the 500 MHz $^1$H NMR spectrum of the crude reaction mixture. To improve the stereoselectivity of the aldol reaction a series of transmetallating reagents were investigated. The best selectivity was achieved using trimethyl borate, giving the same two diastereomers but with an improved ratio of 91 : 9 (Scheme 2), in accordance with the results from Asao *et al*. using lithium (α-methylbenzyl)benzylamide,[7] attesting to the structural similarity of the intermediate enolates. These were separable by flash chromatography to give (2*S*,3*S*,α*R*,2′*R*)-**6** as a single diastereomer in 75% yield.

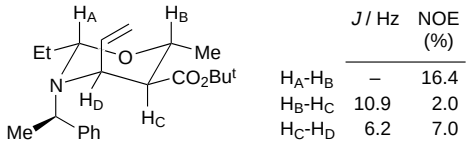


The absolute stereochemistry of (2*S*,3*S*,α*R*,2′*R*)-**6** was determined by treatment with tris(triphenylphosphine)rhodium(I) chloride in toluene under anhydrous conditions. This gave cyclisation to a 19:1 mixture of the perhydro-1,3-oxazines, (2*S*,4*R*,5*S*,6*R*,α*R*)-**8** and (2*R*,4*R*,5*S*,6*R*,α*R*)-**9**, diastereomeric at the newly formed C2 aminol centre, in 90% yield (Scheme 3). The cyclisation presumably occurs by intramolecular trapping of an intermediate imminium species, in equilibrium with the enamine generated in the isomerisation of the allyl double bond, by the 2′-hydroxy group.‡ Analysis of the coupling constants in the 500 MHz $^1$H NMR spectrum of the major diastereomer

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, $CH_2$=CHCH=$CHCO_2Bu^t$ **4**, ii, aq. $NH_4Cl$, 87%; iii, LDA, iv, $B(OMe)_3$, v, MeCHO, vi, aq. $NH_4Cl$, 82%

**Scheme 3** *Reagents and conditions*: i, $(PPh_3)_3RhCl$, 90%



(2*S*,4*R*,5*S*,6*R*,α*R*)-**8** allowed determination of the two stereocentres formed in the aldol reaction ($H_B$-$H_C$, *J* 10.9 Hz, ax–ax coupling; $H_C$-$H_D$ *J* 6.2 Hz, ax–eq coupling) and NOE analysis verified the expected equatorial stereochemistry of the ethyl group at the aminol centre ($H_A$–$H_B$, 16.4%) (Fig. 1).

Although treatment of this mixture of perhydro-1,3-oxazines with aqueous hydrochloric acid gave only the desired β-amino acid (2*S*,3*S*,α*R*,2′*R*)-**10** in 92% yield, verifying that they were diastereomeric only at C2, it proved more efficient to first remove the allyl group from the aldol product (2*S*,3*S*,α*R*,2′*R*)-**6** with tetrakis(triphenylphosphine)palladium(0) and *N*,*N*-dimethylbarbituric acid[12] to give the deallylated product in 98% yield. Since the deprotection proceeds *via* a π-allyl cation there is no opportunity for cyclisation to a perhydro-1,3-oxazine. Hydrolysis of the *tert*-butyl ester with trifluroacetic acid then gave the β-amino acid (2*S*,3*S*,α*R*,2′*R*)-**10** in 97% yield (Scheme 4). Despite its polar nature and the possibility of a zwitterionic form the acid was readily extracted into ethyl acetate, presumably because of its ability to intramolecularly hydrogen bond.

Treatment of β-amino acid (2*S*,3*S*,α*R*,2′*R*)-**10** with 2,2′-dipyridyl disulfide and triphenylphosphine[13] gave cyclisation to the β-lactam (3*S*,4*R*,α*R*,3′*R*)-**11** in 98% yield (Scheme 4). Protection of the hydroxy group with *tert*-butyldimethylsilyl chloride proceeded in 98% yield and was followed by removal of the *N*-α-methylbenzyl group using sodium in liquid ammonia[14] to give the known intermediate (3*S*,4*R*,3′*R*)-**2** in 95% yield. The specific rotation, $[\alpha]_D^{22}$ −25.9 (*c* 1.06, $CHCl_3$), of (3*S*,4*R*,3′*R*)-**2**, was in excellent agreement with the literature value, $[\alpha]_D^{25}$ −24.5 (*c* 1.05, $CHCl_3$), as was the spectroscopic data.§

In summary, the key β-lactam intermediate (3*S*,4*R*,3′*R*)-**2** for the synthesis of thienamycin and its derivatives has been synthesised in seven steps and 58% overall yield from lithium (α-methylbenzyl)allylamide (*R*)-**3** and (*E*)-*tert*-butyl penta-2,4-dienoate **4**. The highly diastereoselective conjugate addition of the lithium amide (*R*)-**3** to the unsaturated ester **4**, followed by a selective aldol reaction with acetaldehyde, constructed all three stereocentres with the correct absolute stereochemistry in two steps. Since the conjugate addition of the lithium amide has been shown to be highly selective to a wide range of α,β-unsaturated esters this methodology can be applied to the synthesis of the key β-lactam frameworks of a variety of carbapenems.

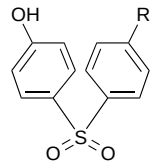
# A supramolecular carpet formed *via* self-assembly of bis(4,4′-dihydroxyphenyl) sulfone†

**Caitlin Davies,[a] Richard F. Langler,*[a] C. V. Krishnamohan Sharma[b] and Michael J. Zaworotko*[b]**



[a] *Department of Chemistry, Mount Allison University, Sackville, New Brunswick, Canada E0A 3C0*
[b] *Department of Chemistry, Saint Mary's University, Halifax, Nova Scotia, Canada B3H 3C3*

**Bis(4,4′-dihydroxyphenyl) sulfone 1 exploits its tetrahedrally disposed complementary hydrogen bonding sites to generate a unique doubly interwoven molecular carpet architecture in the solid state.**

The concept of rational design of 2D and 3D frameworks has evoked considerable interest in recent years as many functional properties of solids are dependent on crystal packing.[1,2] A particularly interesting and relevant problem that has been addressed by several groups concerns the preparation of open cage and/or interwoven networks.[3–5] While the former is desired in the context of porous solids, the latter is an associated phenomenon which invariably occurs if > 50% of a solid would otherwise be empty. Such interpenetration (or catenation) is appreciated for its aesthetic appeal and offers potential host materials if guest molecules can be exploited to prevent interpenetration.[6] Understanding and predicting interpenetration patterns therefore constitutes an important aspect of crystal engineering.

Self-assembly can be an effective strategy for crystal engineering but it requires careful control over molecular symmetry and functionality.[3] In general, tetrahedral molecules with rigid complementary hydrogen bonding sites adapt diamondoid architecture with levels of interpenetration based on the relative size of superdiamondoid cage and the volume of the tecton.[7] We report herein an alternate motif for such compounds which occurs if there is flexibility present in the tecton: interwoven 2D square grids.[8]

A solution of bis(4-chlorophenyl) sulfone (4.0 g) and sodium hydroxide (4.0 g) in $Me_2SO$ (160 ml) and water (40 ml) was maintained at 100 °C for two months. Extractive workup with diethyl ether furnished a mixture of unchanged chloro sulfone, bis(4-hydroxyphenyl) sulfone **1** and 4-chlorophenyl (4′-hydroxyphenyl) sulfone **2**. Chloroform elution on silica gel furnished pure **1** (2%) and **2** (50%).

**1** R = OH
**2** R = Cl

Non-centrosymmetric crystals of **1** were obtained from acetone–$CHCl_3$ (mp 247–249 °C). The crystal structure‡ reveals an infinite 2D hydrogen bonded network sustained by interaction between hydroxy and sulfone groups (O···O 2.705(7), 2.800(3) Å, Fig. 1). The network generates square cavities with *ca.* 8 × 10 Å dimensions, large enough to facilitate generation of a 2-fold interwoven molecular carpet (Fig. 2). The entangled 2D grids are stabilized by van der Waals and herringbone interactions. A 3D diamondoid architecture is also feasible but presumably packs less efficiently in the absence of an appropriate guest.

The molecular carpet architecture of **1** demonstrates how molecules with flexible hydrogen bonding sites can self-assemble to yield 2D interwoven networks as an alternative to 3D diamondoid architectures. Such networks would be expected to have clay-like intercalation properties and, if appropriate guests can be used to eschew interpenetration, large cavities within the grid.[9] The critical importance of complementarity amongst the hydrogen bonding sites is illustrated by what happens if one hydroxy substituent of **1** is replaced by a chloro substituent. 4-chlorophenyl (4′-hydroxyphenyl) sulfone **2** exhibits a less predictable but nonetheless intriguing crystal structure.§ Compound **2** crystallizes from $CHCl_3$ (mp 150–151 °C) in the non-centrosymmetric space group *P*1 with, remarkably, four molecules in the asymmetric unit. There are two discrete hydrogen bonding motifs: i, simple linear hydrogen bonding between sulfone and hydroxy groups [2.898(6) Å]; ii, cyclic hydrogen bonding involving two of the sulfone O atoms and three hydroxy groups, possibly with two of the hydroxy groups being disordered [Scheme 1, O···O: 2.838(6), 2.881(6),

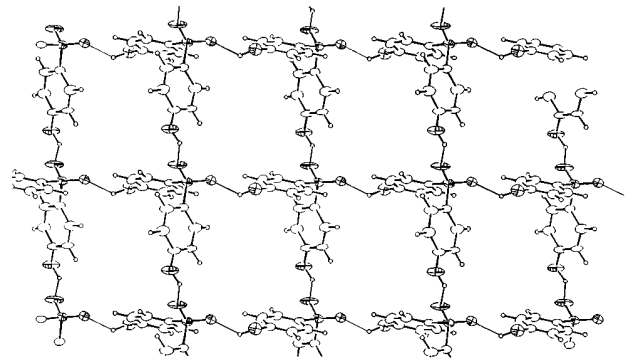


**Fig. 1** ORTEP diagram of **1** illustrating a single hydrogen bonded network

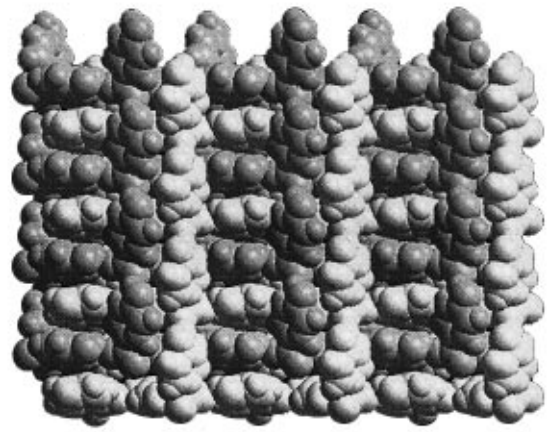

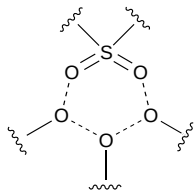

**Fig. 2** A space filling diagram of the interwoven supramolecular carpet architecture of **1**. The two independent grids are colour coded for clarity.

**Scheme 1**

3.019(6), 2.913(6) Å]. Furthermore, there are two different kinds of aryl–aryl stacking interactions: between chlorophenyl and hydroxyphenyl groups and between adjacent chlorophenyl groups. The mean interplanar distances and dihedral angles of these two stacking interactions are 3.74 and 3.60 Å, 2.9 and 3.4° respectively.

Compounds **1** and **2** illustrate clearly the importance of self-assembly to crystal engineering. Compound **1** demonstrates how tetrahedral moieties with complementary hydrogen bonding sites are capable of self-assembling into a predictable 2D motif if the hydrogen bonding sites are robust and flexible. However, **2** demonstrates how even minor changes in functionality can lead to unusual and unpredictable crystal packing.

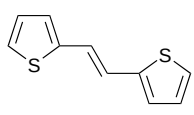
# Bandgap control through reduction of bond length alternation in bridged poly(diethienylethylene)s

**Hugues Brisset, Philippe Blanchard, Bertrand Illien, Amédée Riou and Jean Roncali***

*Ingénierie Moléculaire et Matériaux Organiques, CNRS UMR 6501, Université d'Angers, 2 Bd Lavoisier, F-49045 Angers, France*

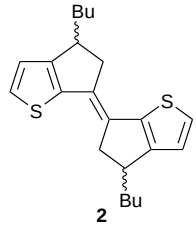
**X-Ray structure analysis of a new rigid dithienylethylene shows that the observed reduction of the HOMO–LUMO gap results from a relaxation of bond length alternation.**

In recent years, the control of the bandgap (*E*g) of linearly π-conjugated systems has become one of the main challenges for synthetic chemists involved in the field of organic conductors. Since *E*g governs the intrinsic electronic properties of the π-conjugated system, progress in this area constitutes the key to many fundamental and technological problems and in the longer term to the possible achievement of intrinsic metallic conductivity.



In addition to the degree of coplanarity of the π-conjugated backbone, the degree of bond length alternation (BLA) related to the difference between the average length of single and double bonds (δ*r*) represents the main contribution to the existence of a finite bandgap in π-conjugated polymers.[1]

Poly(isothianaphthene) was one of the earliest and most successful attempts at reducing *E*g in poly(heterocyclic) conjugated polymers.[2] The fusion of the benzene and thiophene rings leads to an increase in the quinoid character of the poly(thiophene) backbone, to the detriment of its aromaticity. This results in a relaxation of BLA accompanied with a reduction of *E*g from 2.0–2.2 eV for poly(thiophene)[3] to 1.1 eV.[4] While this approach is still widely used,[5] recent years have witnessed the emergence of other strategies, such as the introduction of electron-withdrawing groups at selected positions of the π-conjugated backbone[6] or the rigidification of the π-conjugated system.[7]

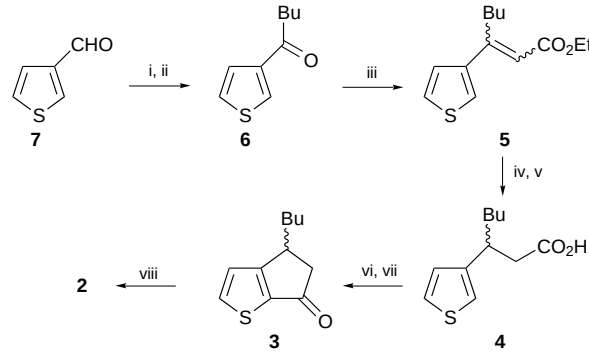


Recently, we have shown that the covalent bridging of the thiophene rings with the central double bond of dithienylethylene **1** leads to a reduction of the bandgap of the corresponding electrogenerated polymer from 1.80 to 1.40 eV.[8] However, the origin of this decrease in *E*g was not clearly identified.

We report here the synthesis and X-ray structural characterization of a new substituted bridged DTE **2**.† Experimental and theoretical data show unequivocally that the observed narrowing of the HOMO–LUMO gap results from a reduction of BLA induced by the rigidification of the DTE molecule.

The synthesis of 6,6′-bis(4-butyl-4,5-dihydro-6*H*-cyclopenta-[*b*]thienylidene) **2** is depicted in Scheme 1. 3-Pentanoylthiophene **6** was obtained by reaction of butylmagnesium bromide with thiophene-3-carbaldehyde **7** followed by oxidation of the resulting secondary alcohol with chromium trioxide. Wittig–Horner olefination of **6** with ethyl diethylphosphonoacetate gave a mixture of *Z* and *E* isomers of the α-unsaturated ester **5**. Saponification of **5** followed by reduction of the double bond with sodium amalgam and acidification gave carboxylic acid **4**.

**1**



**2**

Conversion of **4** into the corresponding acid chloride and intramolecular Friedel–Crafts acylation yielded cyclic ketone **3** as a racemic mixture. The target compound **2** was then obtained as a mixture of diastereomers by McMurry dimerization of **3**.‡

Fig. 1 shows the ORTEP view of the *meso* form of 2.§ Molecules **1**[9] and **2** belong to the $C_i$ molecular point group. In both cases the thiophene ring is almost planar and there is a dihedral angle value of 3° between the thiophene ring average plane and the C1–C1′ double bond. The invariance of this angle shows that the reduction of *E*g observed for the polymers derived from bridged precursors[8] is not related to an enhancement of the planarity of the DTE moiety.

Comparison of the bond distances along the conjugated path for **1** and **2** (Table 1) shows that the bridging of the DTE molecule induces a deformation of the thiophene ring with a 0.031 and 0.044 Å shortening of the C5–C6 and C3–C6 bonds,

**Table 1** Selected bond lengths for compounds **1** and **2** along the conjugated path

| | Length/Å | |
|---|---|---|
| Bond | **1** | **2** |
| C4–C5 | 1.351(8) | 1.350(1) |
| C5–C6 | 1.44(1) | 1.409(8) |
| C6–C3 | 1.40(1) | 1.356(8) |
| C3–C1 | 1.457(7) | 1.440(7) |
| C1–C1′ | 1.309(8) | 1.335(6) |
| δ*r*/Å | 0.095 | 0.078 |

**Table 2** Anodic peak potentials[a] and computed HOMO–LUMO gaps for **1** and **2**

| Compound | *E*pa/V | $E_{HOMO}$/eV | $E_{LUMO}$/eV |
|---|---|---|---|
| **1** | 1.10 | −8.58 | −0.63 |
| **2** | 0.72 | −8.16 | −0.59 |

[a] Substrate ($10^{-3}$ M) in $Bu_4NPF_6$–MeCN (0.1 M), scan rate 100 mV $s^{-1}$, Pt electrodes, saturated calomel electrode.

respectively. On the other hand, the length of the C3–C1 single bond in the linker group decreases by 0.017 Å while that of the C1–C1′ central double bond increases by 0.026 Å. These various bond length modifications lead to a decrease of δ*r* from 0.095 Å for **1** to 0.078 Å for **2**.

Table 2 lists the values of the anodic peak potentials (*E*pa) for **1** and **2** together with the computed values of the HOMO and LUMO energies.¶ As for the parent unsubstituted analogue of **2**, the bridging of the DTE molecule leads to a *ca*. 0.40 V negative shift of *E*pa.[8] This difference, which nicely agrees with the 0.42 eV increase in $E_{HOMO}$, shows that the smaller HOMO–LUMO gap of bridged DTEs is related to an increase in $E_{HOMO}$.

These results, which confirm the efficiency of the rigidification approach for controlling *E*g, provide the first conclusive evidence that the bandgap of conjugated polymers is adjustable *via* bond length control.

## Footnotes

† The synthesis and characterization of poly(**2**) and other small bandgap polymers derived from substituted bridged DTEs will be published elsewhere.

‡ Satisfactory analytical and spectroscopic data were obtained.

§ *Crystal data* for **2**: $C_{22}H_{28}S_2$, $M_W$ = 356.58, monoclinic, *P*21/*n*, *Z* = 2, *a* = 11.891(7), *b* = 5.284(15), *c* = 15.89(2) Å, β = 100.98(7)°, *V* = 980(3) Å$^3$, λ = 0.71069 Å. Data collection: Data collection was carried out by zig-zag ω scan technique (2.5 ⩾θ⩾ 30°) on an Enraf-Nonius Mach III diffractometer. Conditions of measurements were $t_{max}$ = 40 s, range *h*, *k*, *l* (*h* 0,16; *k*, 0,7; *l*, −22,22). Intensity control reflections were measured every 2 h without appreciable Decay (0.15%). 3182 Independent reflections were collected from which 1071 correspond to $I > 3\sigma(I)$. Structure refinement: After Lorentz and polarisation corrections the structure was solved by direct methods (SIR) which reveal all the non-hydrogen atoms. After anisotropic refinement of all the C and S atoms, the coordinates of H atoms were determined from the HYDRO program. The whole structure was refined by full-matrix least-square techniques {refinement on *F*, *x*, *y*, *z*, $U_{ij}$ for S and C atoms, *x*, *y*, *z* and *U* fixed for H atoms; 109 variables and 1071 observations, weighting scheme: non-Poisson contribution with $w = 1/\sigma(F_0)^2 = 4F_0^2/[\sigma(I)^2 + (0.04\ F_0^2)^2]$· with the resulting *R* = 0.078, *R*w = 0.090}. All calculations were performed using the MolEN package.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/362.

¶ AM1 (ref. 10) calculations have been based on X-ray structures, however, since some hydrogen atoms were not experimentally defined, hydrogen atoms of all molecules were optimized at the AM1/RHF level using VAMP 5.51, (Oxford Molecular Ltd. England).

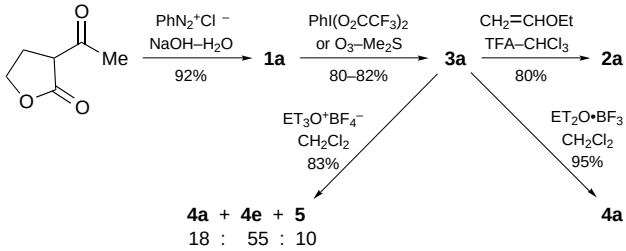
# Oxidation of 2-phenylhydrazono-γ-butyrolactone: a novel ring expansion rearrangement leading to tetrahydro-1,3-oxazine-2,4-dione derivatives

**Derek H. R. Barton* and Wansheng Liu***

*Department of Chemistry, Texas A&M University, College Station, Texas 77843, USA*



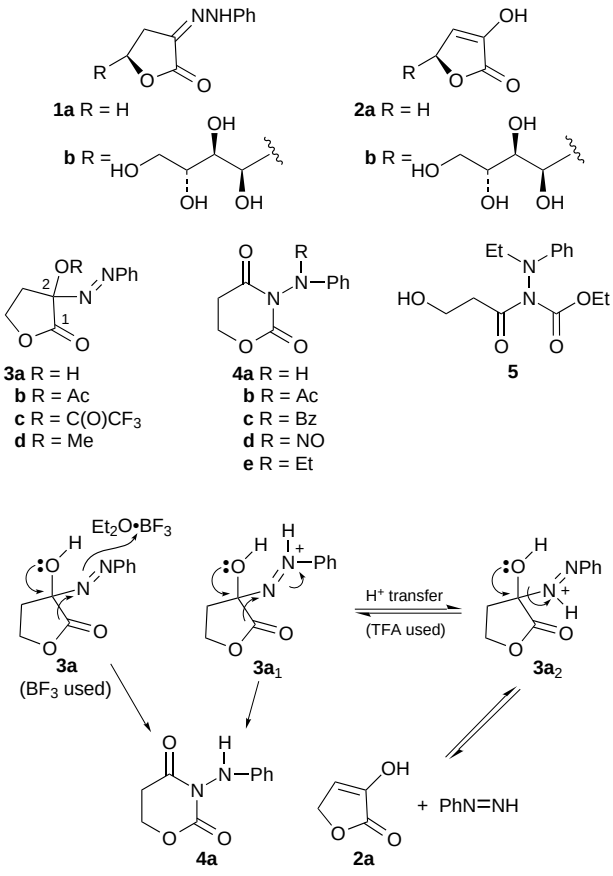
**2-Hydroxy-2-phenylazo-γ-butyrolactone 3a, prepared from oxidation of phenylhydrazone 1a, either decomposes to form α-keto-γ-butyrolactone 2a in 80% yield or rearranges to tetrahydro-1,3-oxazine-2,4-dione derivative 4a in 95% yield under different conditions.**

The chemistry of 1,3-oxazines has been of interest since the 1950s.[1] Preparative schemes for many 1,3-oxazine derivatives, especially tetrahydro-1,3-oxazines, were patented mainly as a result of their interesting biological activities. In addition to the synthetic utility of 5,6-dihydro-4*H*-1,3-oxazines,[2] another fact which makes 1,3-oxazine chemistry important is that some antibiotics contain the 1,3-oxazine ring.[1,3,4]

Tetrahydro-1,3-oxazine-2,4-diones are normally synthesized from β-hydroxy acids by reaction with sodium cyanate, followed by cyclization with thionyl chloride.[5] Alternative preparations utilize the reaction of oxetanes with either isocyanates or *S*-alkylthioureas. Here we report an unexpected rearrangement reaction leading to tetrahydro-1,3-oxazine-2,4-dione derivatives.

During the synthetic studies of 3-deoxy-D-*manno*-2-octulosonic acid (KDO), we encountered the sugar derivative 2-phenylhydrazono-γ-lactone **1b**.[6] Many failed attempts at the conversion of **1b** to KDO precursor **2b** prompted us to study oxidation of 2-phenylhydrazono-γ-butyrolactone **1a** (Scheme 1).[7] When **1a** was oxidized with bis(acetoxy)iodobenzene in ACOH, 2-acetoxy-2-phenylazo-γ-butyrolactone **3b**† was isolated as a bright yellow oil in 98% yield. Oxidation with bis(trifluoroacetoxy)iodobenzene (BTIB) in TFA afforded 2-trifluoroacetoxy-2-phenylazo-γ-butyrolactone **3c**, which hydrolysed with facility when exposed to air at room temperature. When the oxidation of **1a** by BTIB was carried out in MeCN–MeOH (5 : 1), crystalline 2-methoxy-2-phenylazo-γ-butyrolactone **3d** was obtained in 63% yield.

When **1a** was oxidized by BTIB in MeCN–MeOH (5 : 1), aqueous work-up with sodium hydrogen carbonate furnished 2-hydroxy-2-phenylazo-γ-butyrolactone **3a** in 80% yield after column chromatography. Ozonolysis of **1a** in methanol at −50 °C for 30 min followed by $Me_2S$ work-up also afforded **3a** in 82% yield. This intermediate behaved differently from the acyclic counterparts.[8] At room temp. **3a** decomposed to form two products, *i.e.* the expected 2-keto-γ-butyrolactone (so-called α-tetronic acid[9]) in the 2-enol tautomeric form **2a** by $^1$H and $^{13}$C NMR spectroscopy, and an unexpected rearrangement product tetrahydro-1,3-oxazine-2,4-dione derivative **4a**.



**Scheme 1**

The intermediate **3a** was surprisingly stable in the presence of $Et_3N$. By $^1$H NMR, only 10% decomposition was observed ten days after $Et_3N$ had been added to a $CDCl_3$ solution of **3a** at room temp. This suggested that **3a** does not readily decompose by loss of $PhN{=}N^-$ anion.[10] A simple explanation is that the formation of a carbonyl group in a five-membered ring α- to another carbonyl group is disfavoured by the strong dipole–dipole interaction. In contrast, in open chain compounds this transformation takes place easily[8] since the opposed dipole moments in the product cancel each other.

In $CDCl_3$, **3a** decomposed very rapidly to **2a** and **4a** when catalysed by TFA. The decomposition was much slower in both $Me_2CO$ and MeOH than in $CHCl_3$. The formation of phenyldiazene or the protonated congeners was readily observed by $^1$H NMR. When 1,4-benzoquinone, which is known to aid the decomposition by electron transfer of phenyldiazene,[11] was used with TFA, **2a** became the major product.

The above results suggested that a high concentration of TFA favoured rearrangement, whereas 1,4-benzoquinone promoted fragmentation. We propose that two different protonated forms of **3a**, *i.e.* $\mathbf{3a}_1$ and $\mathbf{3a}_2$, resulted in molecular rearrangement and elimination of phenyldiazene, respectively (Scheme 2). Re-

**Scheme 2**

moval of phenyldiazene by 1,4-benzoquinone drove the equilibrium between **3a**$_1$ and **3a**$_2$ towards the formation of **2a**. It is known that phenyldiazene reacts with 1,4-benzoquinone in a stoichiometry of approximately 2:1.[12] This is supported by the observation that half an equiv. of 1,4-benzoquinone produced a higher **2a** : **4a** ratio. Apparently, 1,4-benzoquinone reduced the formation of benzene. In addition to quinones, ethyl vinyl ether in the presence of TFA was found to be highly effective in favouring the formation of **2a**. It was assumed that the driving force came from the trapping of phenyldiazene by the carbocation $EtO^+Me$, which is generated by the reaction of ethyl vinyl ether and TFA. A preparative experiment gave crystalline **2a** in 80% yield when **3a** was treated with TFA in the presence of excess ethyl vinyl ether in $CHCl_2$. Considering the difficulties encountered by others in attempts to convert 2-oximino-γ-butyrolactone to **2a**,[9] we conclude that the present procedure from the phenylhydrazone provides an attractive alternative. In principle it constitutes an efficient method of preparing 2-keto-γ-butyrolactones from simple, commercially available starting materials.[13]

Interestingly, **3a** readily rearranged to crystalline **4a** in 95% yield when treated with $BF_3{\cdot}Et_2O$ in $CH_2Cl_2$ at room temp. To our knowledge, this seems to be the first example of a 1,2-migration of an oxycarbonyl group from carbon to azo-nitrogen. Similarly, when **3a** was treated with Meerwein's salt ($Et_3O^+BF_4^-$),[14] three products were isolated: **4a** (18%), *N*′-ethylated derivative **4e** (55%), and *N*′,*O*-bis-ethylated derivative **5** (10%). When the reaction between **3a** and $BF_3{\cdot}Et_2O$ was carried out in $CDCl_3$ and followed by NMR, it was observed that an intermediate formed immediately when $BF_3$ was added, and then gradually decomposed to **4a** at room temp. The proposed mechanism is illustrated in Scheme 2.

Compound **4a** was readily acylated and nitrosated at the *N*′-position to give crystalline derivatives. Although the reaction between **4a** and $Ac_2O$–pyridine–DMAP was very sluggish even at elevated temperatures, the *N*′-acetyl derivative **4b** was readily obtained in quantitative yield at room temp. when **4a** reacted with neat acetyl chloride. The benzoyl derivative **4c** was also obtained quantitatively when benzoyl chloride was used at 60 °C. When **4a** was treated with isoamyl nitrite in $CH_2Cl_2$ at room temp., *N*′-nitroso compound **4d** was obtained quantitatively after 10 min.

Reduction of the *N*′-nitroso derivative **4d** by zinc in AcOH gave **4a** and unsubstituted tetrahydro-1,3-oxazine-2,4-dione[15] in a 1:1 ratio. The NMR and GC–MS spectra of the latter were in agreement with the literature data. This supported the proposed structure of **4a**. When **4d** was treated with zinc in AcHO–pyridine at 0 °C, **4a** was obtained in 66% yield after 30 min.

The structure of **4a** was further verified through degradation reactions. Hydrolysis of **4a** by NaOH in MeOH furnished methyl β-(hydroxypropionyloxy)propionate [$HO(CH_2)_2$-$CO_2(CH_2)_2CO_2Me$] in 61% yield. The product was identical by IR, $^1$H, and $^{13}$C NMR to an authentic sample prepared from β-propiolactone.[16] Similarly, methanolysis of **4b** in the presence of potassium carbonate gave *N*-acetylphenylhydrazine [$PhN(Ac)NH_2$[17]] in 62% yield.

In conclusion, a novel rearrangement reaction provided efficient entry to interesting *N*-substituted tetrahydro-1,3-oxazine-2,4-dione derivatives. It is conceivable that the reaction may be extended to the construction of other related heterocyclic compounds.

Financial support from the National Institutes of Health and the Schering-Plough Corporation is gratefully acknowledged.

## Footnote

† All new compounds gave satisfactory $^1$H and $^{13}$C NMR spectra, and microanalytical data.

# Bis(amido)calix[4]arenes in the pinched cone conformation as tuneable hydrogen-bonding anion receptors

**Beth R. Cameron and Stephen J. Loeb*†**

*Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ontario, Canada N9B 3P4*

**Calix[4]arene units functionalized at the 1,3-positions of the upper rim with amido groups, –NHC(O)X, act as neutral, hydrogen-bonding receptors for hydrogen sulfate, dihydrogen phosphate, acetate, benzoate, nicotinate, oxalate, terephthalate, isophthalate and fumarate with binding strength and selectivity tunable by varying the electron-withdrawing ability of the terminal substituent X (X = $CH_2Cl$, $CHCl_2$, $CCl_3$).**

Increased interest in the molecular recognition of anionic substrates has led to the synthesis and evaluation of a variety of anion receptors.[1] The most common employ ammonium or guanidinium binding sites while recently electron-deficient, Lewis acid centres such as tin,[2] boron,[3] mercury,[4] silicon[5] and the uranyl ion[6] have received attention. Although some of these systems are quite efficient receptors, it is interesting to note that anion binding by proteins is most commonly achieved *via* neutral amide functions employing the hydrogen-bond accepting properties of the amido NH group.[7] Indeed, some very efficient anion ($Cl^-$, $H_2PO_4^-$) receptors containing both Lewis acidic centres and amide binding sites have been reported recently.[6,8]

A major disadvantage to employing the amide function –NHC(O)– is the rigid directionality of the NH group which makes if difficult to incorporate into a highly structured framework such as a macrocycle.[9] This problem can be overcome by including the amide function as a terminal group on the upper-rim of a calix[4]arene framework.[10] We report herein the syntheses of bis(amido)calix[4]arene-based anion receptors which exhibit a selectivity for carboxylate ions, particularly benzoate derivatives, over tetrahedral oxyanions.

Receptors **2** and **3** were prepared by the reaction of 5,17-bis-(amino)-25,26,27,28-tetrapropoxycalix[4]arene with 2.5 equiv. of dichloroacetyl chloride or trichloroacetyl chloride in a manner similar to the published procedure for **1**.[11]‡§

Initially, the anion complexation properties of receptor **1** were investigated using $^1$H NMR spectroscopy and association constants were measured for a variety of simple anions (Table 1). In each case, the anion–receptor stoichiometry was confirmed to be 1 : 1 by a Job plot. These results indicate a preference for the Y-shaped carboxylate anions acetate and benzoate over tetrahedral-shaped anions, $H_2PO_4^-$, $ReO_4^-$ and $HSO_4^-$. For example, addition of 1 equiv. of $[Bu_4N^+][C_6H_5CO_2^-]$ to a $10^{-3}$ mol $dm^{-3}$ solution of **1** in $CDCl_3$ resulted in a dramatic downfield shift of 1.33 ppm for the amide NH proton and a moderate downfield shift of 0.12 ppm for the $CH_2Cl$ resonance. Whereas, the same experiment using $H_2PO_4^-$ resulted in much smaller downfield shifts of 0.90 and a 0.07 ppm for the NH and $CH_2Cl$ resonances.

It is reasonable to assume that increasing the acidity of the amide proton by introducing more effective electron-withdrawing groups in the terminal position would enhance anion binding. This was investigated by measuring the binding of benzoate ion with a series of receptors differing only in the terminal substituent X, in the NHC(O)X group (X = $CH_2Cl$, $CHCl_2$, $CCl_3$) (Table 2). Receptor **2** exhibits the highest association constant with downfield shifts of 2.38 and 0.73 ppm observed for the NH and $CHCl_2$ resonances in the $^1$H NMR spectrum of **2** upon addition of 1 equiv. of benzoate anion. The replacement of hydrogen by chlorine results in a *ca*. 50-fold increase in association constant.

The benzoate anion binds in a bidentate fashion to the two amide protons present on the upper rim of the calix[4]arene (Fig. 1). In order for this to occur, the calix[4]arene must exist in the pinched cone conformation in which the rings bearing the amide groups are essentially parallel. This is clearly demonstrated by observed changes in the $^1$H NMR spectra upon anion binding. The $^1$H NMR spectrum of **2** exhibits a singlet for the four aromatic protons on the amido substituted rings and an unresolved multiplet for the six protons on the unsubstituted rings. Addition of benzoate ion results in an upfield shift of the substituted ring protons and a downfield shift and resolution of

**5** X = $CHCl_2$
**6** X = $CCl_3$

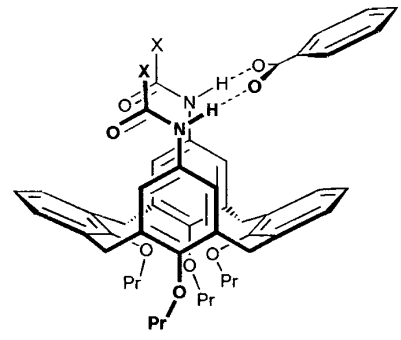

**Fig. 1**

the protons on the unsubstituted ring. Also, the $OCH_2$ resonances which overlap in **2** resolve into two distinct triplets and the $CHCl_2$ protons are systematically shifted downfield upon anion binding (Fig. 2). These changes can be attributed to a perturbation of the see-saw motion between the two pinched cone conformers of the calix[4]arene skeleton. This conformational isomerism is usually ignored in calix[4]arene chemistry, although the energy barrier to this interconversion was measured to be *ca*. 40 kJ $mol^{-1}$.[12] Thus, anion coordination freezes the calixarene unit in the pinched cone conformation with the substituted rings parallel and allows for two linear hydrogen bonding interactions between receptor and anion.

Surprisingly, the presence of three chloro substituents results in absolutely no binding of the anion as is evident from the absence of any change in the $^1$H NMR spectrum. Since the model compound **6** also showed no change in the $^1$H NMR spectrum with the addition of 10 equiv. of benzoate anion, it is likely that the amide protons in receptors **3** and **6** are inaccessible for the approach of the anion due to steric crowding of the trichloromethyl substituents rather than an inability of **3** to achieve the appropriate pinched cone conformation.

Association constants for various other mono-carboxylate anions with receptor **2** are given in Table 3 These results demonstrate that receptor **2** is not only selective for carboxylate ions but has a particular affinity for the benzoate ion. Examination of CPK models suggested a more open conformation might provide a suitable geometric fit for some dicarboxylates. The binding of receptor **2** with dicarboxylate ions was investigated and results are also given in Table 3.

A Job plot of receptor **2** with oxalate anion showed 1 : 1 complexation. The changes evident in the aromatic region of the spectrum of **2** are opposite to those demonstrated with the benzoate anion. This suggests that the calix[4]arene exists in a pinched cone conformation in which the unsubstituted rings are parallel. This allows accommodation of the dianion and still maintains a 1 : 1 stoichiometry. In contrast, the larger dicarboxylate anions (isophthalate, terephthalate, fumarate) were found by Job plots to bind with an anion–receptor ratio of 1 : 2. $^1$H NMR Spectra show the same trends observed for benzoate and suggest that the calixarene receptors can be assembled around the anion with a similar coordination mode for each carboxylate group.

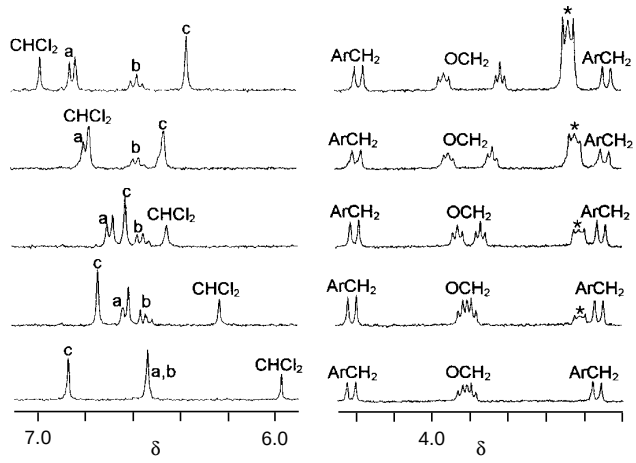

**Fig. 2** $^1$H NMR spectra of stepwise addition of 0.0 (bottom), 0.25, 0.50, 1.0 and 2.0 equiv. of $[Bu_4N][C_6H_5CO_2]$ to receptor **2** (* = peak due to $Bu_4N^+$ cation). Aromatic H-atoms a, b and c are assigned as in Fig. 1.

**Table 3** $K_{ass}$ Values of **2** with monocarboxylate and dicarboxylate anions

| Anion | Benzoate[a] | Nicotinate[a] | Acetate[a] | Oxalate[a] | Isophthalate[b] | Terephthalate[b] | Fumarate[b] |
|---|---|---|---|---|---|---|---|
| $K_{ass}$ 1 | 5160 | 821 | 609 | 707 | $> 10^6$ | $> 10^6$ | $> 10^6$ |

[a] Stoichiometry is 1 : 1. [b] Stoichiometry is 1 : 2 and values are $\beta(K_1K_2)$.

In summary, neutral, hydrogen-bonding anion receptors can be derived from a pair of terminal amido groups built into a calix[4]arene framework. The pinched cone conformation is flexible enough to allow for the binding of a variety of anions and the acceptor properties of the amido group can be tuned by varying the electron-withdrawing nature of the terminal substituent. These new receptors are selective for Y-shaped carboxylate ions over tetrahedral anions and show a particular preference for benzoate derivatives.

We thank the Natural Science and Engineering Council of Canada and the Petroleum Research Fund administered by the American Chemical Society for financial support of this research.

‡ All new compounds were successfully characterized by $^1$H and $^{13}$C NMR spectroscopy, LSIMS and elemental analysis. $^1$H NMR Titrations: varying amounts of stock solutions of anionic guests (0.0125 mol $dm^{-3}$) were added to 0.1 $cm^3$ aliquots of host solutions (0.005 mol $dm^{-3}$ stock solutions) and were made up to 0.5 $cm^3$ with solvent to maintain a constant volume and thus a constant host concentration of 0.001 mol $dm^{-3}$. Anion–receptor ratios were varied from 0.1–10. $K_{ass}$ Values were determined using the chemical shift of the amide proton as the probe. Values were fitted using the program EQNMR[13] with errors < 10% for $K_{ass}$ > 100 and errors < 5% for $K_{ass}$ < 100.

§ *Selected data* for **2**: $^1$H NMR ($CDCl_3$) δ 7.87 (s, NH, 2 H), 6.87 (s, ArH, 4 H), 6.54 (s, ArH, 6 H), 5.97 (s, $CHCl_3$, 2 H), 4.43 (d, $ArCH_2$, 4 H), 3.82 (m, $OCH_2$, 8 H), 3.13 (d, $ArCH_2$, 4 H), 1.91 (m, $CH_2$, 8 H), 0.97 (m, Me, 12 H); $^{13}$C NMR ($CDCl_3$) δ 161.62, 156.10, 154.90, 136.24, 134.07, 129.87, 128.14, 122,36, 121.29, 76.84, 66.96, 31.00, 23.23, 23.14, 10.36, 10.20; LSIMS *m/z* $[M + H]^+$ = 845. For **3**: $^1$H NMR ($CDCl_3$) δ 8.23 (s, NH, 2 H), 7.19 (s, ArH, 4 H), 6.37 (m, ArH, 6 H), 4.45 (d, $ArCH_2$, 4 H), 3.95 (t, $OCH_2$, 4 H), 3.73 (t, $OCH_2$, 4 H), 3.15 (d, $ArCH_2$, 4 H), 1.91 (m, $CH_2$, 8 H), 1.05 (t, Me, 6 H), 0.92 (t, $CH_3$, 6 H); $^{13}$C NMR ($CDCl_3$) δ 159.15 (CO), 155.61, 155.59, 137.27, 133.21, 129.65, 127.87, 122.43, 120.98 (ArC), 93.06 ($CCl_3$), 77.05, 76.85 ($OCH_2$), 31.08 ($ArCH_2$), 23.45, 23.08 ($CH_2$), 10.67, 10.05 ($CH_3$); LSIMS *m/z* $[M]^+$ = 913.

**Hexagonal, cubic and lamellar aluminoborate mesophases containing octahedral aluminium and tetrahedral boron are prepared and characterized for the first time.**

Since the first synthesis of mesoporous silica,[1] there has been intense activity in the design and synthesis of a variety of mesoporous solids.[2–4] These studies have also unravelled the mechanism of formation of these materials by means of supramolecular templating involving an unusual combination of surfactant aggregates and anionic silicate species.[4,5] By varying the pH or the surfactant to silica ratio, hexagonal, cubic and lamellar forms of silica mesophases have been prepared.[6] Besides ionic surfactants, neutral amines[7] and polyalkene oxides[8] have been employed to synthesise the mesophases. The strategy to prepare silica-based mesophases has been extended to prepare a variety of mesoporous metal oxides such as $Al_2O_3$,[8] $TiO_2$[9,10] and $ZrO_2$[11] and $Nb_2O_5$.[12] $AlPO_4$ which is isoelectronic with $SiO_2$ has provided the basis for a distinct family of microporous materials.[13] However, efforts to make hexagonal mesoporous $AlPO_4$ have not been successful; instead, only lamellar $AlPO_4$ has been obtained.[14] We considered it most worthwhile to explore the synthesis of the mesoporous phases of the analogous aluminoborates containing the $AlBO_4^{2-}$ species. There has been some effort[15] to make microporous aluminoborates with different B/Al ratios, but the products do not seem to have been adequately characterized. Here, we report the first successful synthesis and characterization of mesoporous aluminoborate phases in hexagonal, cubic and lamellar forms. It has been possible to remove the surfactant from the hexagonal phase and expand the pore size of the hexagonal phase by using aliphatic hydrocarbons as solubilizing agents.

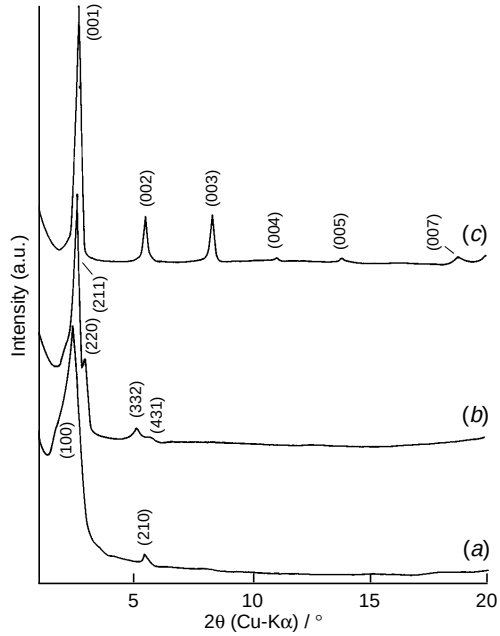

**Fig. 1** X-Ray diffraction patterns of the aluminoborate mesophases: (*a*) hexagonal, (*b*) cubic and (*c*) lamellar

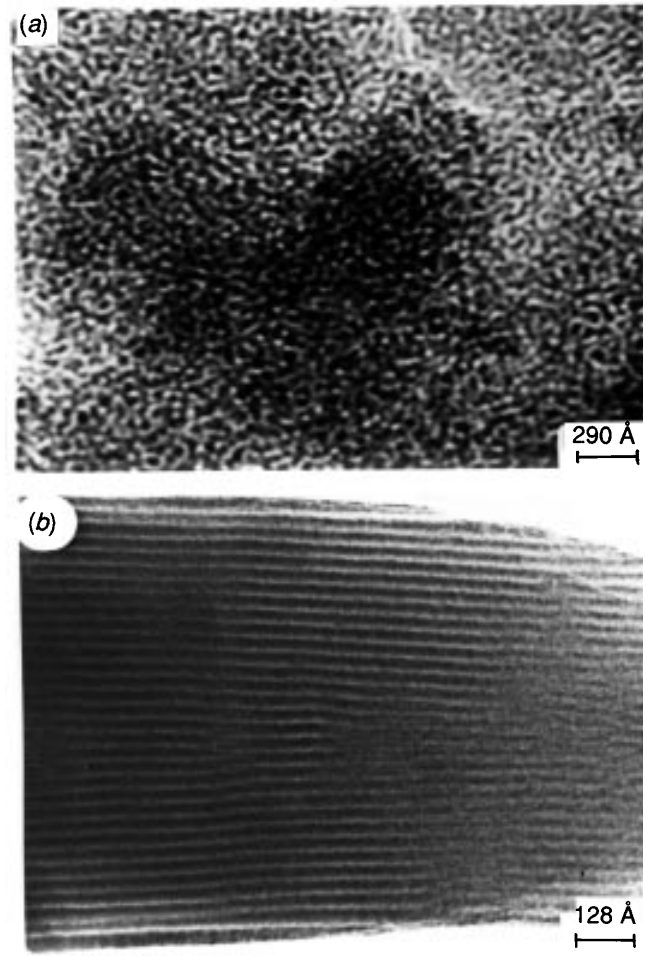

**Fig. 2** TEM images of (*a*) hexagonal and (*b*) lamellar aluminoborate mesophases

Mesoporous aluminoborate phases could not be obtained when cationic surfactants or long-chain amines were employed for the synthesis. They could however be prepared by employing sodium dodecyl sulfate (SDS) as the surfactant. In a typical preparation, to a solution containing Ca, Al and B in 1 : 1 : 1 molar ratio, prepared by dissolving appropriate quantities of CaO and $Al(NO_3)_3$ and boric acid in aqueous nitric acid, sodium dodecyl sulfate (1.0 mol with respect to Ca or Al) was added under stirring. Ammonia was added to the resulting turbid solution under constant stirring to reach the desired value of pH. The resultant gel was maintained at room temperature for 48 h. The product so obtained was washed several times with distilled water and dried at 100 °C in a hot air oven. X-Ray diffraction (XRD) patterns of the dried solids were recorded with a Rich–Seifert (model XRD 3000TT) instrument. Fig. 1 shows the XRD patterns of the products obtained at different pH values. The XRD pattern of the product obtained at pH 2 [Fig. 1(*a*)] is characteristic of a hexagonal phase with a $d_{100}$ value of 36.1 Å ($a_0$ = 41.7 Å). The XRD pattern of the product

obtained at a pH of 3.5 [Fig. 1(*b*)] corresponds to that of a cubic phase. This pattern could be indexed with $a$ = 83.5 Å. The XRD pattern of the product obtained at pH *ca*. 5.5 [Fig. 1(*c*)] is characteristic of a lamellar phase and accordingly exhibits the various 00*l* reflections ($d_{001}$ = 32.5 Å). The scanning electron micrographs of the hexagonal and lamellar phases exhibit characteristic differences in morphology, the lamellar form showing the flaky structure. The transmission electron microscope (TEM) image (recorded with a JEOL JEM 3010 microscope) reveals the presence of disordered hexagonal pores with an opening of *ca*. 32 Å with a wall thickness of *ca*. 11 Å [Fig. 2(*a*)]. The TEM image of the lamellar phase shows an interlayer separation of *ca*. 32 Å [Fig. 2(*b*)].

EDAX analysis of the aluminoborate mesophases showed the Ca : Al molar ratio to be 1 : 1, while an ICP analysis gave a Al : B molar ratio of 1 : 1. Thermogravimetry showed the loss of water by 150 °C and of the surfactant by 600 °C. Based on the mass loss data and assuming the Ca : Al : B molar ratio to be 1 : 1 : 1, the composition of the aluminoborate–surfactant adduct works out to be $CaO{\cdot}0.5Al_2O_3{\cdot}0.5B_2O_3{\cdot}0.6SDS{\cdot}1.5H_2O$. The %mass of boron from the ICP analysis (3.15 ± 0.25%) is also consistent with the theoretical value of 3.2% based on the empirical formula. The IR spectrum of this adduct showed a boron–oxygen stretching band in the region 900–1100 $cm^{-1}$ due to $BO_4$ tetrahedra. The IR band characteristic of $BO_3$ units in the region 1200–1400 $cm^{-1}$ was absent. Significant structural information was obtained by means of $^{27}Al$ and $^{11}B$ MAS NMR spectra (recorded with a Bruker MSL-300 spectrometer) of the hexagonal aluminoborate mesophase. The $^{27}Al$ NMR signal is centred around δ 0.0 [Fig. 3(*a*)], characteristic of an octahedral environment of Al.[16] The $^{11}B$ NMR signal is also centred around δ 0.0 [Fig. 3(*b*)] suggesting a tetrahedral environment for boron.[17]

By heating the as-prepared hexagonal mesophase to 300 °C, we could remove some of the surfactant without destroying the structure. Thus, the XRD pattern of the resulting product shows the mesoporous structure with a $d_{100}$ value of 35.2 Å. We could however remove the surfactant by refluxing the hexagonal mesophase with acidified ethanol for 3 h. The removal of the template was confirmed by the absence of mass loss over the temperature range where the template is normally removed as well as by the XRD pattern. The removal of the surfactant from the hexagonal phase was confirmed by the IR spectra,which showed the near-absence of bands arising from $CH_2$ groups. Accordingly, the surface area of the hexagonal aluminoborate obtained by calcination was *ca*. 100 $m^2\ g^{-1}$ and that of the sample obtained by alcohol extraction was 470 $m^2\ g^{-1}$; their XRD patterns were not identical.

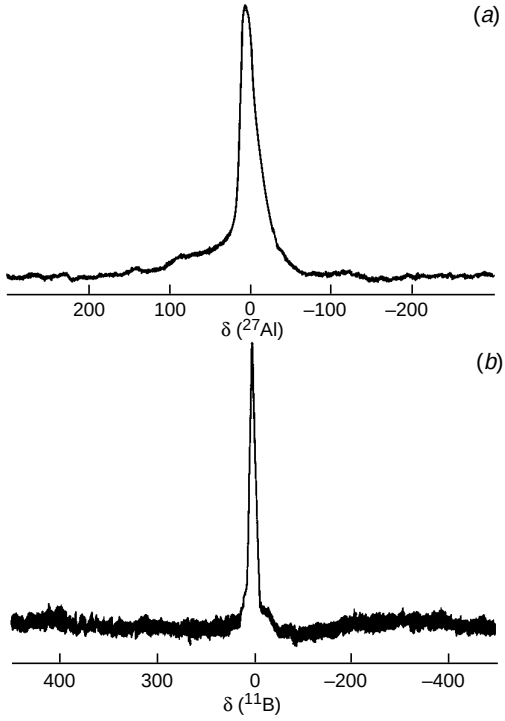

**Fig. 3** MAS NMR spectra of mesoporous aluminoborate: (*a*) $^{27}Al$ spectrum and (*b*) $^{11}B$ spectrum

We have been able to expand the pore size of the hexagonal mesoporous aluminoborate by the use of *n*-alkanes as solubilizing agents. For this purpose, we added the alkane along with the surfactant solution to the acidic solution containing Ca, Al and B, maintaining the molar ratio of the alkane to the surfactant to be 1 : 1. This molar ratio was found to be optimal for expanding the pore size. The XRD patterns gave $d_{100}$ values of 49.0 and 56.6 Å respectively with *n*-octane and *n*-hexadecane, compared to the value of 36.1 Å obtained in the absence of the alkanes.

We have also varied the Al : B ratio and obtained hexagonal mesoporous phases with Al : B ratios down to 0.5 : 1.5. By using $Na^+$ as the cation instead of $Ca^{2+}$, a hexagonal mesoporous phase with a Na : Al : B ratio of 2 : 1 : 1 was obtained with a $d_{100}$ value of 35.5 Å.

# Preparation of porous hafnium oxide in the presence of a cationic surfactant

**Ping Liu,[a] Jun Liu[b] and Abdelhamid Sayari*[a]**

[a] *Department of Chemical Engineering and CERPIC, Université Laval, Ste-Foy, Qc, Canada, G1K 7P4*
[b] *Pacific Northwest National Laboratory, Richland, WA 99352, USA*

**A thermally stable mesostructured hafnium oxide is synthesized for the first time.**

Shortly after the discovery of M41S mesoporous materials,[1] the supramolecular templating approach was extended to the synthesis of non-silica based materials.[2] Stucky and coworkers[2,3] synthesized a variety of oxides of Pd, W, Mo and Fe, but obtained only a limited number of three-dimensional mesostructures. However, the surfactants in these materials could not be removed without the collapse of the structure. Recently, Antonelli *et al.*[4–6] successfully synthesized mesoporous niobium and tantalum oxides using a ligand-assisted templating approach. The surfactant was removed by solvent extraction using a mixture of nitric acid and isopropyl alcohol. Mesoporous alumina has also been obtained by using either non-ionic polymer surfactants[7] or long-chain carboxylic acids[8] as templates.

Hexagonal mesoporous zirconium oxide has been synthesized by Sayari and coworkers.[9,10] While the as-synthesized material was not stable upon removal of the surfactant, it was successfully stabilized by a post-synthesis treatment with potassium phosphate. After air calcination, a Zr–P oxide with a surface area as high as 500 $m^2\ g^{-1}$ was obtained. Independently, Ciesla *et al.*[11] reported similar results. In addition, they obtained a pure zirconium oxide with a surface area of 280 $m^2\ g^{-1}$ using zirconium isopropoxide in the presence of large amounts of ammonium sulfate and hydrochloric acid.

Hafnium oxide is useful for the preparation of strong acid catalysts similar to sulfated zirconia.[12] Here, we report the first synthesis of porous hafnium oxide, using the surfactant templating approach. In a typical synthesis, 2.68 g of $HfCl_4$ was hydrolysed in 10 g of water. To this solution, 0.82 g of cetyltrimethylammonium bromide (CTAB) in 8 g of water was added followed by a solution of 4.4 g of $(NH_4)_2SO_4$ in 24 g of water. After stirring for 10 min, the pH of the solution was adjusted to 2.1 by adding 1.4 g of 30 mass% ammonia. The gel was then stirred for 30 min before being transferred to a Teflon-lined autoclave and heated statically for 24 h at 373 K. The solid was recovered by filtration and washed with large amounts of water, followed by drying at room temperature for 24 h.

X-Ray powder diffraction was performed on a Siemens D5000 diffractometer. The XRD pattern of the solid shows an intense peak at a low angle ($d \gg 4.0$ nm) along with a shoulder [Fig. 1(*a*)]. This pattern is characteristic of a mesophase with a pore system lacking long-range order. Fig. 2(*a*) shows the transmission electron microscopy (TEM) image of the as-synthesized material. As seen, the pore structure has no long-range order which is consistent with the XRD data. This is reminiscent of HMS[13] and MSU[14] mesoporous materials.

FTIR and EDX showed that the material calcined in air at 773 K for 2 h was carbon free. Its surface area as determined from $N_2$ adsorption isotherm (Fig. 1, insert) was 204 $m^2\ g^{-1}$. Taking the molecular mass difference between $HfO_2$ and $ZrO_2$ (104 *vs.*

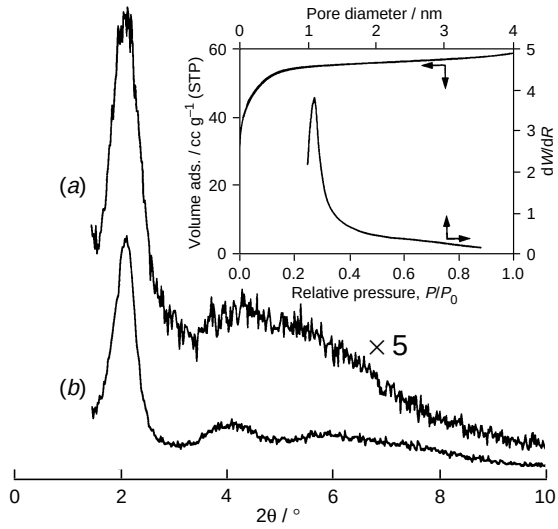

**Fig. 1** Powder X-ray diffraction patterns of mesostructured hafnium oxide prepared at (*a*) 373 K and (*b*) room temperature. Insert: nitrogen adsorption–desorption isotherm and pore size distribution for the sample prepared at 373 K.

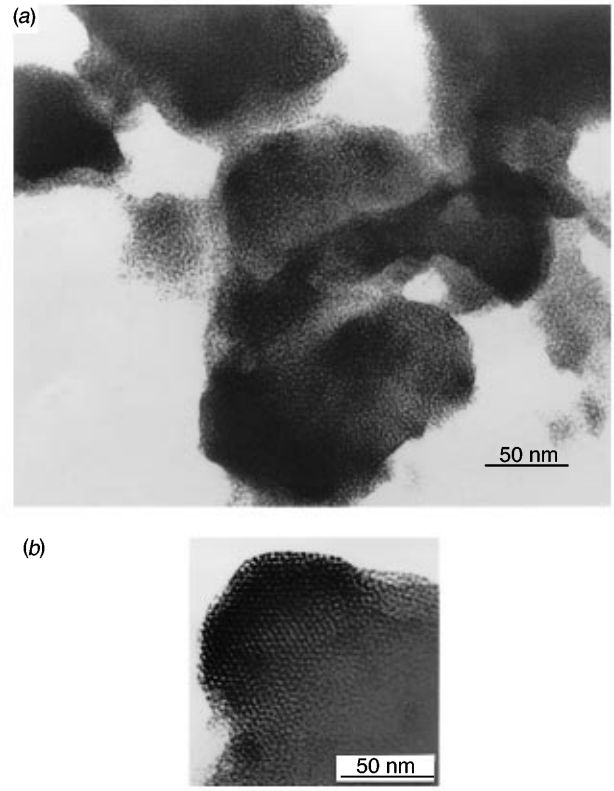

**Fig. 2** Transmission electron micrographs of as-synthesized samples prepared at (*a*) 373 K and (*b*) room temperature

72) into account, this surface area is comparable to that obtained for pure zirconium oxide (280 $m^2$ $g^{-1}$).[11] The pore diameter calculated from the adsorption isotherm using the Horvath–Kawazoe model[15] was *ca*. 1.1 nm (Fig. 1, insert). This is also comparable to the pore diameter of $ZrO_2$.[9] An extensive contraction of the inorganic structure took place during the removal of the surfactant at high temperature.

The effects of pH and synthesis temperature on the final morphology were also investigated. It was found that a pH higher than 1.5 is essential for the formation of the mesostructure. Mesostructured $HfO_2$ can also be prepared at room temperature. In one synthesis, 2.68 g of $HfCl_4$ was hydrolysed in 10 g of water. A solution of 0.82 g of CTAB in 8 g of water was added followed by 4.4 g of $(NH_4)SO_4$. The mixture was stirred for 10 min before adding 1.2 g of 30 mass% ammonia. After stirring for 30 min, 30 g of water was added and the gel was stirred for 10 min. The pH of the final mixture was around 1.6. As inferred from XRD data [Fig. 1(*b*)] and confirmed by TEM [Fig. 2(*b*)], this mesostructure is much more ordered and the hexagonal pore structure can be easily seen. However, the materials thus obtained were found to be thermally unstable. This indicates that hydrothermal treatment at 373 K or a higher pH of the synthesis gel enhances the polymerization of the inorganic species and improves the stability.

In conclusion, we have for the first time synthesized a thermally stable porous hafnium oxide. The high surface area of this material would be useful for the preparation of strong acid catalysts.

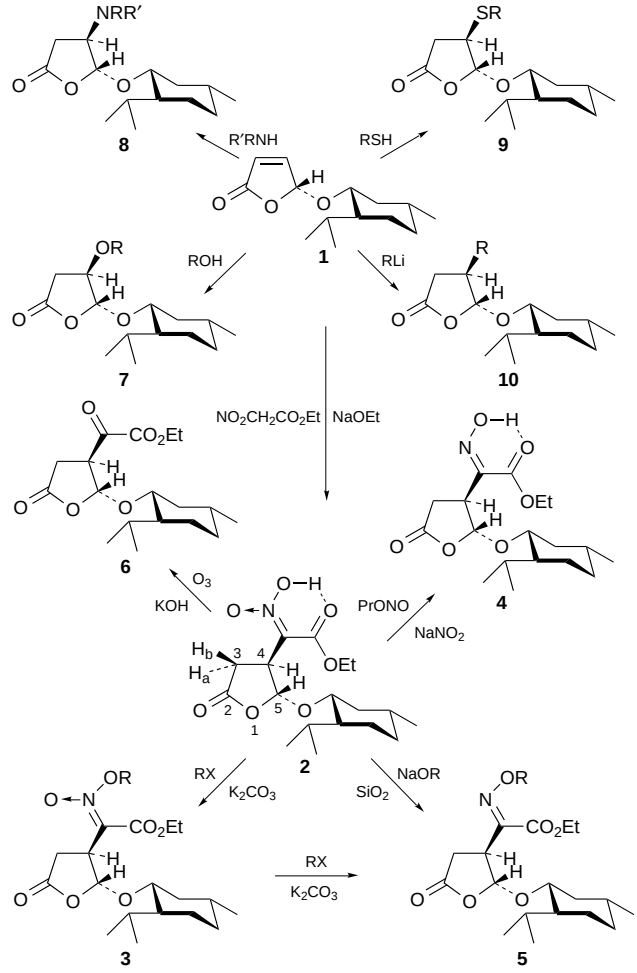
# Correlation between optical rotation sign and conformation of γ-butyrolactones

**Fu-An Kang* and Cheng-Lie Yin**

*Department of Chemistry, Beijing Normal University, Beijing 100875, PRC*

***trans*-4,5-Disubstituted-γ-butyrolactones are found to adopt different conformations by NMR spectroscopy; their optical rotation signs are found to depend on the conformations they assume.**



Since the beginning of the study of optically active substances, many attempts have been made to devise a method for calculating optical activity or at least to learn how to predict the sign of rotation. Although some empirical rules[1] concerning the optical activities have been found, the nature of optical activity of chiral molecules is still a problem that has not been solved. Empirical methods[2] for the prediction of the sign and amount of rotation based on bond refractions and polarizabilities of groups in a molecule have been suggested, which has given fairly good results in quite a few cases. Here we report our discovery of the correlation between optical rotation sign and conformation of *trans*-4,5-disubstituted-γ-butyrolactones.

Recently, in the study of the physical and spectral properties of a series of *trans*-4,5-disubstituted-γ-butyrolactones **2**–**10** derived from (*R*)-(−)-5-[(1*R*)-menthyloxy]furan-2(5*H*)-one[3] **1** (Scheme 1), we found that the optical rotation signs of the γ-butyrolactones correlate strictly with the relative order of the chemical shifts of the $C_3$ methylene protons $H_{3a}$ and $H_{3b}$ in the range of δ 2.0–3.0, as the substituent on the $C_4$ atom changes from one series to another. That is, the optical rotation signs of compounds **2**,[4] **3**,[4] **4**,[5] **5**[4] are all positive, where $H_{3a}$ resonates at higher magnetic field than $H_{3b}$, or δ $H_{3a}$ < δ $H_{3b}$; while the optical rotation signs of compounds **6**,[5] **7**,[5] **8**,[6] **9**,[7] **10**[8] are all negative, where $H_{3a}$ resonates at lower magnetic field than $H_{3b}$, or δ $H_{3a}$ > δ $H_{3b}$ (Table 1). This phenomenon appears somewhat confusing and unlikely considering that there is only one difference, the $C_4$ substituent, among these compounds. The possibility of the anisotropic effects of the $C_4$ substituents can be removed, because, although compounds **2**–**5** and compound **6** all have double bonds (C=N or C=O bonds), they still lead to a different relative order of the chemical shifts of $H_{3a}$ and $H_{3b}$.

There seems to be only one interpretation for the interesting transposition of the chemical shifts of the $C_3$ methylene protons $H_{3a}$ and $H_{3b}$, which is that the two series of compounds **2**–**5** and compounds **6**–**10** assume different conformations, respectively. γ-Butyrolactone is a five-membered ring and it is not surprising that it should adopt an envelope conformation. The preference for coplanarity of the lactone group[9] implies that the stable conformations of the γ-butyrolactone are restricted to an enantiomeric pair, in which the $C_4$ atom is either below (conformation I) or above (conformation II) the lactone plane (Fig. 1). The hydrogens or substituents at $C_3$, $C_4$ and $C_5$ atoms are expected to adopt quasi-axial or quasi-equatorial positions.[10]

In conformation I, $H_{3b}$, $H_4$ and $H_5$ are quasi-axial protons, while $H_{3a}$, menthyloxy and $R^1$ adopt the quasi-equatorial positions. On the contrary, in conformation II, $H_{3a}$, menthyloxy and $R^2$ assume the quasi-axial positions, while $H_{3b}$, $H_4$ and $H_5$ are quasi-equatorial protons. According to the proposed model[11] of the anisotropic effect of the carbonyl group, the quasi-equatorial protons of the $C_3$ methylenes in both conformations I and II should be in the shielding region of the $C_2$ carbonyl group while the corresponding quasi-axial protons should be in the deshielding region. As a result, in the two conformations I and II, the quasi-axial proton on the $C_3$ methylene is expected to resonate at lower magnetic field than the corresponding quasi-equatorial proton. Since for compounds **2**–**5** the relative order of the chemical shifts of $H_{3a}$ and $H_{3b}$ is δ $H_{3a}$ < δ $H_{3b}$, it is self-evident that compounds **2**–**5** all assume conformation I. And because, for compounds **6**–**10**, the relative order of the chemical shifts of $H_{3a}$ and $H_{3b}$ is δ $H_{3a}$ > $H_{3b}$, it can also be seen that compounds **6**–**10** all adopt conformation II. Apparently, this result agrees with the previous observations that in steroidal α-acetoxy ketones,[12] α-halo ketones[13] and α-bromo cyclohexanones,[14] the α-protons of the carbonyl groups resonate at lower magnetic fields when axial than when equatorial.

In both conformations I and II, the geminal coupling constants of the $C_3$ methylene protons $H_{3a}$ and $H_{3b}$ alter in a narrow range, or $^2J_{3a,3b}$ = 15–18 Hz. $H_{3a}$, $H_{3b}$ and $H_4$ protons

[a] Unless otherwise indicated, the specific rotations were measured at 578 nm at 25 °C. [b] Determined at 589 nm at 20 or 25 °C. [c] $\Delta\delta = \delta H_{3a} - \delta H_{3b}$.

$R^1$ = $C(NO_2H)CO_2Et$, $C(NO_2R)CO_2Et$, $C(NOH)CO_2Et$, $C(NOR)CO_2Et$
$R^2$ = $COCO_2Et$, OR, NRR′, SR, R
$R^3$ = menthyloxy

**Fig. 1**

constitute a typical ABX coupling system with the vicinal coupling constants $^3J_{3a,4}$ = 10.8–11.5 and $^3J_{3b,4}$ = 3.2–3.7 Hz in conformation I, and $^3J_{3a,4}$ = 5.8–9.4 and $^3J_{3b,4}$ = 1.2–1.8 Hz in conformation II. In both cases, the quasi-axial proton is deshielded 0.2–0.7 ppm by the $C_2$ carbonyl group with respect to the quasi-equatorial proton, which is in contrast to the situation of a six-membered ring where an equatorial proton is generally deshielded 0.1–0.7 ppm by the C–C bonds with respect to the corresponding axial proton.[15]

The conformational analysis of the *trans*-4,5-disubstituted-γ-butyrolactones described above is partially confirmed by the X-ray analysis of (4*R*,5*R*)-(−)pyrrolidin-4-yl-5-[(1*R*)-menthyloxy]-γ-butyrolactone, mp 134.6–134.8 °C, $[\alpha]^{20}_D$ −150 (*c* 1.0, $CHCl_3$).[6] Its ORTEP plot shows that it adopts an envelope conformation with the $C_4$ atom deviating above the lactone plane and $H_{3a}$, menthyloxy and pyrrolidinyl assuming the quasi-axial positions, which is exactly consistent with the predicted conformation II.

If the substituents $R^1$, $R^2$ and $R^3$ were displaced with hydrogens, it would be obvious that conformer I and conformer II should be enantiomers, or that one is the mirror image of the other. Since the absolute configuration of the $C_4$ and $C_5$ atoms are the same in both conformations I and II, therefore it appears to be significant that the optical rotation signs of the γ-butyrolactones depend on the conformations they assume rather than on the substituents on the lactone ring, in other words, conformer I creates a right-handed rotation, while conformer II results in a left-handed rotation. Because of the widespread occurrence of γ-butyrolactone rings in nature, *e.g.* in carbohydrates, steroids, alkaloids, nucleic acids and many other natural products, we think the conformational analysis of γ-butyrolactones by NMR spectroscopy and the correlation between optical rotation sign and conformation of γ-butyrolactones will be useful for prediction of optical activity and conformation of such compounds.

We thank Professor Yu-Ying Yin for helpful discussions. Financial support provided by the National Science Foundation and the Doctoral Program Foundation of the State Education Commission is gratefully acknowledged.

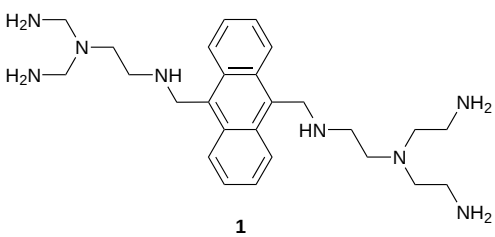
# Fluorescent sensor of imidazole and histidine

**Luigi Fabbrizzi,* Giancarlo Francese, Maurizio Licchelli, Angelo Perotti and Angelo Taglietti**

*Dipartimento di Chimica Generale, Università di Pavia, via Taramelli 12, 27100 Pavia, Italy*



**The dizinc(II) complex of an octamine containing the anthracene subunit binds both the imidazolate anion and the imidazolate moiety of L-histidine, and signals the binding through the fluorescence quenching of the fluorophore.**

The design of multicomponent fluorescent systems able to detect the presence and monitor concentration changes of biologically active small molecules, in particular natural amino acids, is highly desirable. A fluorescent sensor of γ-amino-buyric acid has recently been reported.[1]

We have recently developed a receptor capable of recognising histidine in the presence of any other natural amino acid.[2] The receptor contains two $Cu^{II}$ ions prepositioned within a poly-aza macrocycle. Recognition is based on the fact that the imidazole residue of histidine, in an aqueous solution adjusted to pH 9, deprotonates and bridges the metal centres. This situation is in some ways reminiscent of Cu-Zn superoxide dismutase (CuZn-SOD), in which a $Cu^{II}$ and a $Zn^{II}$ ion are bridged by the imidazolate residue of a histidine fragment.

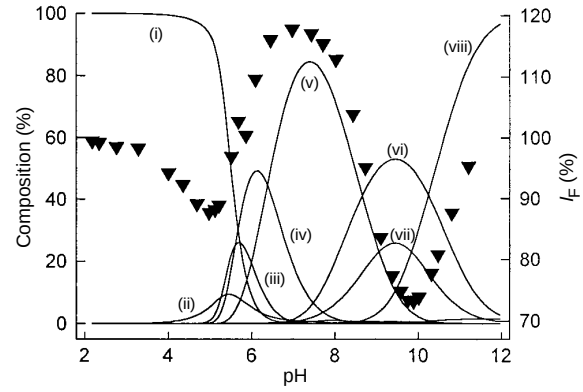
We considered that the octamine **1**† could provide a convenient framework for the construction of a fluorosensor for histidine, as (i) it offers two quadridentate binding sites for $Cu^{II}$ ions, leaving each metal centre coordinatively unsaturated and an open position for a further ligand (*i.e.* one of the two nitrogen atoms of an imidazolate subunit) and (ii) the anthracene fragment linking the tetraamine subunits gives an intense and characteristically structured fluorescent emission, suitable for signalling the occurrence of the receptor–substrate interaction.

The pH titration experiments were carried out on an aqueous solution containing **1** (1 equiv.) and $Cu^{2+}$ (2 equiv.), in the absence and in the presence of 1 equiv. of imidazole (imH). Non-linear fitting of the titration curve in the absence of imH indicated the formation of the dimetallic species $[Cu^{II}_2L]^{4+}$ at pH 4. This is present as the major species in the 5–7 pH interval; at higher pH, hydroxide-containing species form. In the presence of imH, an imidazolate-containing dimetallic species $[Cu^{II}L(im)]^{3+}$ formed as a major species between pH 7–11. However, whereas the $[Cu^{II}_2L]^{4+}$ system appears to be an excellent receptor for imidazole, it cannot function as a fluorosensor since the $Cu^{II}$ ions fully quench anthracene fluorescence in both the $[Cu^{II}_2L]^{4+}$ and the $[Cu^{II}L(im)]^{3+}$ complexes, and thus any monitoring of the recognition process through the variation of the fluorescent emission is prevented. Thus, we considered the use of a pair of $Zn^{II}$ ions as binding sites for imidazole in the octamine receptor **1**. $Zn^{II}$ is photophysically inactive and is expected to display some affinity towards a bridging imidazolate fragment, as it shows in the CuZn-SOD enzyme.

**1**

Further pH titration experiments were carried out on an aqueous solution containing **1** (1 equiv.) and $Zn^{2+}$ (2 equiv.), in the absence and in the presence of 1 equiv. of imH. Non-linear fitting of the titration curve in the absence of imH indicated the formation of stable dimetallic complexes at pH ⩾5. In particular, the complex of the neutral ligand $[Zn^{II}_2L]^{4+}$ forms at pH 5.5 and is present as the major species between pH 7–8.5. At pH ⩾9, hydroxide-containing complexes dominate: $[Zn^{II}_2L(OH)]^{3+}$ and $[Zn^{II}_2L(OH)_2]^{2+}$. Each hydroxide ion should be bound to the $Zn^{II}$ centre and should result from the deprotonation of a coordinated water molecule.

Fig. 1 displays the distribution diagram of the species present at equilibrium in the system containing 1 equiv. of **1**, 2 equiv. of $Zn^{II}$ and 1 equiv. of imH.‡ It is seen that at pH 7 the imidazolate-containing species $[Zn^{II}_2L(im)]^{3+}$ forms and exists as the dominant species in the pH 9–10 interval (60%), prevailing over the $[Zn^{ii}_2L(OH)]^{3+}$ complex (20%). A titration experiment was then carried out in a spectrofluorimetric cuvette, by adding standard NaOH to a solution containing 1 equiv. of **1**, 2 equiv. of $Zn^{II}$, 1 equiv. of imidazole and excess acid. The variation of the relative fluorescence intensity $I_F$ (%) with the increasing pH profile is shown in Fig. 1 and can be explained as follows: in the pH 2–4 interval, **1** is present exclusively as $LH_6^{6+}$ species. It is suggested that in each tetramine subunit of **1** the three peripheral amine groups (two primary and one secondary) are protonated and the central tertiary nitrogen atom is not. This situation would minimize electrostatic repulsions. In these circumstances, it seems possible that an electron transfer (eT) process from the lone pair of the tertiary nitrogen atom of each tren subunit to the excited anthracene moiety (An*) takes place, thus competing with radiative deactivation and partially quenching fluorescence. On addition of standard base (pH 4–5), the two secondary amine groups which are close to the anthracene subunit deprotonate, making the electron transfer to An* more effective and thus inducing a progressive $I_F$ decrease. However, at pH 5, zinc-containing species begin to form (see the corresponding distribution curve in Fig. 1) and the $Zn^{II}$-bound



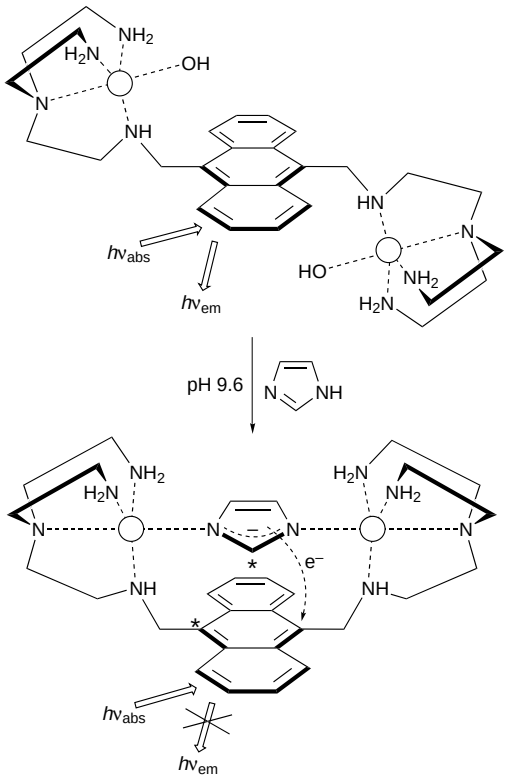


**Fig. 1** Left vertical axis, pH dependence of the concentration of species present at equilibrium for the system **1** (L, 1 equiv.)–$Zn^{II}$ (2 equiv.)–imidazole (imH) in aqueous 0.1 M $NaClO_4$ at 25 °C: (i) $[LH_6]^{6+}$; (ii) $[LH_5]^{5+}$; (iii) $[Zn^{II}_2(LH_2)]^{6+}$; (iv) $[Zn^{II}_2(LH)]^{5+}$; (v) $[Zn^{II}_2L]^{4+}$; (vi) $[Zn^{II}_2L(Im)]^{3+}$; (vii) $[Zn^{II}_2L(OH)]^{3+}$; (viii) $[Zn^{II}_2L(OH)_2]^{2+}$. Right vertical axis (full triangles), pH dependence of the fluorescence intensity of the solution ($I_F$).

**Scheme 1**

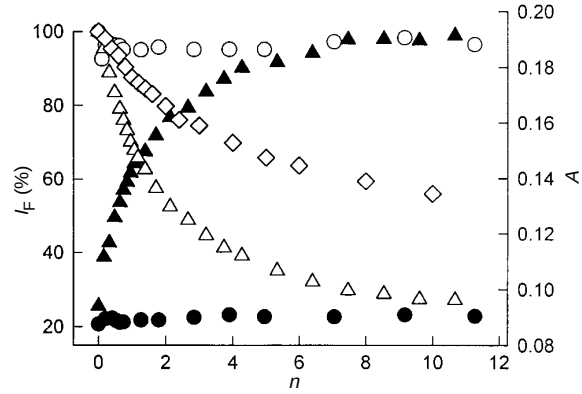

**Fig. 2** Variation of the relative fluorescence intensity ($I_F$, left vertical axis) and of the absorbance at 300 nm ($A$, right vertical axis) during the titration of $9 \times 10^{-6}$ M $[Zn^{II}_2L]^{2+}$, buffered at pH 9.6, with imidazole, histidine and acetate: (△) $I_F$ (imidazole); (▲) $A$ (imidazole); (○) $I_F$ (acetate); (●) $A$ (acetate); (◇) $I_F$ (L-histidine). $n$ = number of equivalents of the added substrate.

lone pairs of the anthrylamine groups (the secondary and the tertiary ones, in particular) are no longer available for the eT quenching mechanism, allowing fluorescence to revive. At pH 7.0–7.5, where $[Zn^{II}_2L]^{4+}$ is present as a major species, $I_F$ reaches its maximum value. The formation of the imidazolate bridged complex $[Zn^{II}_2L(im)]^{3+}$ then induces a substantial fluorescence quenching. In particular, the minimum of the anthracene emission intensity corresponds to the maximum concentration of $[Zn^{II}_2L(im)]^{3+}$, at around pH 10. We ascribe this effect to the occurrence of an eT process from a π-orbital of the electron rich $im^-$ moiety to a π-orbital of the photo-excited anthracene fragment within the $[Zn^{II}_2L(im)]^{3+}$ adduct. The photophysical effects associated with $im^-$ binding by the $[Zn^{II}_2L]^{2+}$ receptor are outlined in Scheme 1.

Molecular modelling indicates that the imidazolate and anthracene fragments in the $[Zn^{II}_2L(im)]^{3+}$ adduct are quite close. In particular, a distance of 3.2 Å is calculated between the closest atoms of the two subunits; these are labelled with an asterisk in Scheme 1.

The fluorescence quenching that follows $im^-$ binding opens the way to fluorescent sensing of imH and of any molecule bearing an imidazole residue. To demonstrate this, an aqueous solution containing 1 equiv. of **1** and 2 equiv. of $Zn^{II}$ was adjusted to pH 9.6 with CHES buffer and was titrated with a solution of imH. Anthracene fluorescence was observed to decrease according to the profile displayed in Fig. 2. Non-linear fitting of the $I_F$ *vs.* equiv. substrate curve indicates the formation of a 1 : 1 receptor–substrate adduct, *i.e.* $[Zn^{II}_2L(im)]^{3+}$, with a conditional constant of 3.65 ± 0.04 log units. The formation of the $[Zn^{II}_2L(im)]^{3+}$ adduct could also be followed spectrophotometrically, by monitoring an increase of the absorption band at 300 nm. The absorbance *vs.* equiv. substrate profile, shown in Fig. 2, is specularly symmetric to the $I_F$ *vs.* equiv. substrate profile and gives the same log$K$ value (3.65 ± 0.09). It should be noted that titration with 1-methylimidazole, which *cannot* undergo deprotonation, did not induce any modification of the anthracene fluorescent emission, confirming that signalling is promoted by Zn–Zn bridging of the $im^-$ fragment.

Spectrofluorimetric titration of $[Zn^{II}_2L]^{2+}$ with L-histidine induced a fluorescence quenching similar to that produced by imidazole (see Fig. 2): the shallower $I_F$ *vs.* equiv. substrate profile corresponds to a lower value for the binding constant (log$K$ = 2.92 ± 0.01), which may reflect the existence of some steric repulsions between by the imidazole-appended amino acid fragment and the receptor framework. Interestingly, the titration profile is not modified when the solution contains an excess of any other amino acid. As an example, addition of L-histidine to a solution buffered at pH 9.6 and containing the receptor $[Zn^{II}_2L]^{2+}$ plus 10 equiv. of L-glycine produced an $I_F$ *vs.* equiv. substrate profile superimposable onto that given in Fig. 2. The lack of interference may be due to the fact that the only anionic group any amino acid other than histidine can offer, *i.e.* the carboxylate fragment, does not display bridging tendencies towards the dimetallic core of $[Zn^{II}_2L]^{2+}$. Indeed, titration of a solution of $[Zn^{II}_2L]^{2+}$ with acetate did not induce any decrease of the fluorescent emission and did not cause any change of the absorbance at 300 nm nor at any other wavelength in the UV–VIS region. Thus, $[Zn^{II}_2L]^{2+}$ recognizes and senses L-histidine in the presence of any other natural amino acid.

## Footnotes

† The octamine **1** was prepared as follows: 9,10-dichloromethylanthracene[3] (1.5 g, 5.4 mmol) and tris(2-aminoethyl)amine (tren, 4.73 g, 32.4 mmol) were dissolved in toluene (50 ml) and the solution was refluxed under magnetic stirring for 6 h. After cooling to room temperature, the resulting yellow–orange solution was filtered, then the solvent and the excess tren were distilled off at reduced pressure, giving **1** as an orange oil (72%); $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): δ 1.85 (br s, NH and $NH_2$), 2.3–2.9 (m, 24 H, $CH_2N$), 4.67 (s, 4 H, benzylic), 7.2–7.5 (m, 4 H, aromatic), 8.1–8.4 (m, 4 H, aromatic).

‡ The equilibrium constants were obtained by processing data of pH titration experiments with the non-linear least-squares program HYPERQUAD[4] and were used to calculate the distribution curves shown in Fig. 1.

**The reaction of LiBu$^n$ with $[(mes)_2P(H)=O]$ affords the diorganophosphinate complex $[(mes)_2P(=O)_2Li\cdot 2thf]$ 1 and $[(mes)_2PLi]$, however, addition of $[Cd\{N(SiMe_3)_2\}_2]$ to the mixture gives the diorganophosphinite complex $[\{(Me_3Si)_2N\}Cd\{(mes)_2P=O\}_2Li\cdot 2thf]$ 2; the formation of these complexes illustrates that the ligand functionality of 1 can be controlled by the character of the coordinated metal ion.**

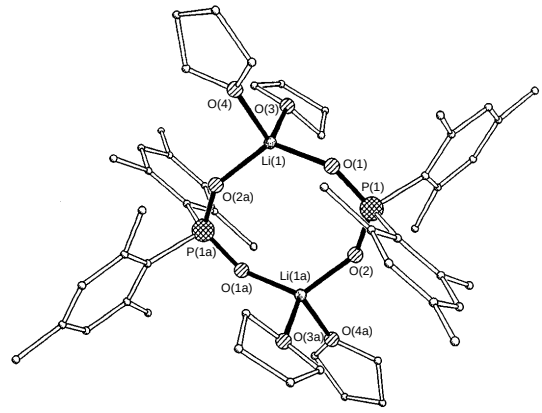
Although a large number of transition- and main-group metal complexes containing diorganophosphinate ligands, $[R_2P(=O)_2]^-$, have been structurally characterised,[1] only transition-metal complexes of the diorganophosphinites, $[R_2P=O]^-$, have so far been investigated.[2,3] In comparison to the variety of metal coordination modes observed for $[R_2P(=O)_2]^-$ [terminal metal–O, bridging (μ-O, μ-O), and bidentate], almost all of the structurally characterised $[R_2P=O]^-$ complexes contain a (μ-O, μ-P) metal bridging mode. Our current interest in this ligand set is in its potential for forming stabilised main-group metal–P bonded complexes and heterobimetallic systems. As a prelude to more extensive studies, we embarked on an investigation of the influence of the character of main-group metal ions on the coordination mode of the $[R_2P=O]^-$ ligand.

We report here the surprising finding that lithiation of $[(mes)_2P(H)=O]$ with LiBu$^n$ (1:1 equiv.) in thf affords the diorganophosphinate complex $[(mes)_2P(=O)_2Li\cdot thf]_2$ **1**. However, addition of $[Cd\{N(SiMe_3)_2\}_2]$ to the $[(mes)_2P(H)=O]$–LiBu$^n$ mixture gives the heterobimetallic diorganophosphinite complex $[\{(Me_3Si)_2N\}Cd\{(mes)_2P=O\}_2Li\cdot 2thf]$ **2**.† The very different ligand functionalities exhibited appear to stem from the disproportionation reaction of the diorganophosphinite anion to the diorganophosphinate anion in solution (Scheme 1).‡ Although this disproportionation may be implicated in the formation of $[R_2PH]$ and $[R_2P(OH)=O]$ during base hydrolysis of $[R_2PCl]$,[4] the metal-dependent selection of these ligands (observed in **1** and **2**) has not previously been reported.

A low-temperature X-ray crystallographic study of **1**§ (Fig. 1) shows that the complex has the dimeric structure $[(mes)_2P(=O)_2Li\cdot 2thf]_2$, composed of planar eight-membered $[LiO_2P]_2$ rings. The Li–O bond lengths in **1** are similar to those occurring in lithium alkoxides and related compounds (Li–O av. 1.881 Å; *cf.* range 1.80–2.10 Å for other Li–O bonds).[5] The bridging mode of the $[(mes)_2P(=O)_2]^-$ anion and the dimeric structure of **1** are typical of a variety of diorganophosphinate complexes containing a range of main-group and transition metals.[1]

A low-temperature X-ray crystallographic study of **2**§ shows it to have the heterobimetallic structure $[\{(Me_3Si)_2N\}Cd\{(mes)_2P=O\}_2Li\cdot 2thf]$ (Fig. 2). Molecules of **2** are composed of puckered heterocyclic $[Cd(PO)_2Li]$ rings, resulting from the bridging of the Cd and Li centres by the two $[(mes)_2P(=O)]^-$ ligands. The trigonal-planar Cd centre is attached slightly unsymmetrically to the P atoms of these bridging ligands [Cd–P(1) 2.579(5), Cd(1)–P(2) 2.609(3) Å] and to a terminal $(Me_3Si)_2N$ group [Cd–N(1) 2.136(7) Å]. Presumably, the distortion of the $[Cd(PO)_2Li]_2$ ring occurs principally in order to facilitate complexation of the pseudo-tetrahedral $Li^+$ cation by the O atoms of the $[(mes)_2PO]^-$ ligands [1.90(2) Å] (while at the same time minimising the steric confrontation between the mesityl groups and the Li-attached thf ligands). Although a number of transition-metal complexes containing $[R_2P=O]^-$ ligands have been structurally characterised,[2,3] **2** is the first non-transition-metal example and, to our knowledge, the first containing a $P^V$–Cd bond.[6]

The occurrence of the $[(mes)_2P(=O)_2]^-$ anion in **1** and the $[(mes)_2P=O]^-$ anion in **2** can be interpreted in terms of the way in which the underlying thermodynamics of metal–ligand bond formation affects the equilibrium between these anions. The presence of the small, highly charged $Li^+$ cation will tend to shift this reaction towards the diorganophosphinate, with strong Li–O bonding being maximised in **1**. In **2**, the scales are tipped towards the diorganophosphinite anion since the P/O donor set offered will provide optimum bonding with the soft Cd and hard Li metal cations. It is interesting, in the light of this current work, that the few synthetic studies of the oxidation of metal diorganophosphides indicate that the hardness or softness of the metal present has some bearing on the phosphorus oxyanions produced. Thus, oxidation of $[Me_2In(PPh_2)]_2$ with pyridine-*N*-oxide gives the diorganophosphinate $[Me_2In\{(O)_2PPh_2\}]_2$,[1l] whereas the $O_2$ oxidation of $[Pd(\mu\text{-}PBu^t_2)(P\text{-}Bu^t_2H)_2]$ gives the mixed-ligand complex $[Pd(Bu^t_2PO_2)(Bu^t_2\text{-}PO)_2H]$.[1o]



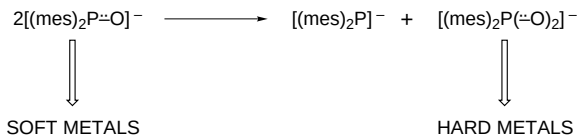


**Fig. 1** Molecular structure of **1**. Hydrogen atoms have been omitted for clarity. ## Footnotes

† [(mes)$_2$PH=O] was prepared by an alternative method to that reported in the literature, by the direct hydrolysis of [(mes)$_2$PCl] [generated *in situ* from (mes)MgBr and $PCl_3$ (2 : 1 equiv.) in $Et_2O$] with $H_2O$. The crystalline phosphinous acid was obtained in 72% yield.

*Syntheses*: **1**: a solution of [(mes)$_2$P(H)=O] (0.57 g, 2.0 mmol) in thf (10 ml) was reacted with LiBu$^n$ (1.3 ml, 2.0 mmol, 1.6 mol dm$^{-3}$ in hexanes) under argon. The yellow solution was reduced to dryness under vacuum, leaving a white solid. The solid was redissolved in hexane (10 ml) and a few drops of thf (*ca*. 0.5 ml). Storage at 20 °C (72 h) gave (reproducably) large crystalline blocks of **1** {first batch, 0.14 g, 16%, based on [(mes)$_2$P(H)=O] consumed}.

**2**: a solution of [(mes)$_2$P(H)=O] (1.43 g, 5.0 mmol) in thf (10 ml) was reacted with LiBu$^n$ (6.3 ml, 5.0 mmol, 1.6 mol dm$^{-3}$ in hexanes) under argon. To the yellow solution produced was added neat [Cd{N(SiMe$_3$)$_2$}] (1.0 ml, 5 mmol). Stirring at room temp. (15 min) gave a colourless solution which was reduced *in vacuo* to *ca*. 10 ml. Storage at 5 °C (24 h), gave air-sensitive crystalline cuboids of **2** (2.00 g, 80%).

‡ Variable-temperature $^{31}$P NMR studies show that the composition of the LiBu$^n$–[(mes)$_2$P(H)=O] reaction mixture is far from simple and that it changes with ageing. However, the intermediate formation of [(mes)$_2$POLi] is confirmed by the observation of a weak 1 : 1 : 1 : 1 quartet (δ *ca*. −71.0) at −80 °C ($^1J_{^{31}P^7Li}$ *ca*. 75 Hz). Storage under argon at 20 °C results in gradual broadening of the resonances originally at δ *ca*. −41 and another peak at δ −182.4 starts to predominate (after *ca*. 72 h). This is consistent with the formation of [(mes)$_2$PLi], produced by the reaction shown in Scheme 1.

§ *Crystal data*: **1**: $C_{52}H_{76}Li_2O_8P_2$, $M$ = 904.95, triclinic, space group $P\bar{1}$, $a$ = 9.934(3), $b$ = 11.423(4), $c$ = 13.084(5) Å, α = 68.04(4), β = 68.91(4), γ = 71.09(4)°, $U$ = 1233.6(8) Å$^3$, $Z$ = 1, $D_c$ = 1.199 Mg m$^{-3}$, λ = 0.710 73 Å, $T$ = 153(2) K, μ(Mo-Kα) = 0.138 mm$^{-1}$. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated rapidly cooled crystal[8] of dimensions 0.5 × 0.5 × 0.3 mm by the θ–ω method (3.69 ⩽ θ ⩽ 25.02°). Of a total of 5998 collected reflections, 4331 were independent. The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ to final values of $R_1$ [$F > 4\sigma(F)$] = 0.045 and $wR_2$ = 0.123 (all data);[9] largest peak, hole in the final difference map = 0.285, −0.321 e Å$^{-3}$.

**2**: $C_{50}H_{78}CdLiNO_4P_2Si_2$, $M$ = 994.59, monoclinic, space group $C2/c$, $a$ = 14.683(5), $b$ = 22.611(5), $c$ = 17.538(5) Å, β = 114.244(5)°, $U$ = 5374(3) Å$^3$, $Z$ = 4, $D_c$ = 1.229 Mg m$^{-3}$, λ = 0.710 73 Å, $T$ = 153(2) K, μ(Mo-Kα) = 0.550 mm$^{-1}$. The procedure was identical to that for **1** with crystal dimensions 0.3 × 0.2 × 0.2 mm (2.50 ⩽ θ ⩽ 22.49°). Of a total of 4426 collected reflections, 3518 were independent. The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ to final values of $R_1$ [$F > 4\sigma(F)$] = 0.064 and $wR_2$ = 0.179 (all data). Largest peak, hole in the final difference map = 0.805, −1.788 e Å$^{-3}$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Tetrakis(cyclopentamethylenedithiocarbamate-*S*,*S*′)technetium(v) bromide, an unusual eight-coordinate complex of technetium(v)

**Reaction of the ligand dicyclopentamethylenethiuram disulfide with [$NBu_4$][$TcOCl_4$] results in the formation of a unique eight-coordinate technetium(v) species.**

The use of the metastable isotope of technetium ($^{99m}$Tc) in diagnostic imaging is well documented.[1] Technetium forms complexes in a variety of oxidation states, of which $Tc^{V}$ is the best characterized. One of the reoccurring features of the $Tc^{V}$ oxidation state is the stability of the $TcO^{3+}$ unit, which can be transferred from compound to compound. We examined the reaction of $TcOCl_4^-$ anion with the ligand dicyclopentamethylenethiuram disulfide (Scheme 1) to determine if carbamates would be useful functional groups to include in a new class of technetium(v) chelants.

To our surprise the product was a stable eight co-ordinate cation **1** (Fig. 1) in which the oxygen had been removed from the technetium. Even more puzzling, the oxidation state of the metal had not changed. Four cyclopentamethylenedithiocarbamate groups from the cleaved ligand became bound, to give the large cation. Although eight coordination is known for rhenium(v),[2] eight-coordinate $Tc^{V}$ is uncommon.[3,4]

The reaction of morpholine-*N*-carbodithioate anion with [$NBu_4$][$TcOCl_4$] gives tetrakis(morpholine-*N*-carbodithioato-*S*,*S*′)technetium(IV).[4] The formation of this paramagnetic compound occurs by the ligand anion acting as a reducing agent and formation of the ligand disulfide. The compound was remarkably stable and attempts to oxidize it to a cation of $Tc^{V}$, of the type reported here, were unsuccessful. Under somewhat different conditions $TcOCl_4^-$ reacts with dialkyldithiocarbamates (dtc) to give the substitution, and hydrolysis products [$Tc_2O_3$(dtc)$_4$].[5] Xanthate complexes of $Tc^{III}$ are known in which the technetium is surrounded by three xanthate ligands and one triphenylphosphine.[6] Baldas *et al.*[7] synthesised a compound similar to the xanthate species, demonstrating that pertechnetate could be reduced in the presence of sodium diethyldithiocarbamate to give a tris(diethyldithiocarbamato)technetium(III) species in which carbon monoxide is coordinated on the technetium. Until now there has been no solid evidence for eight-coordinate dithiocarbamatetechnetium(v) species.

**Scheme 1** Synthesis of **1**

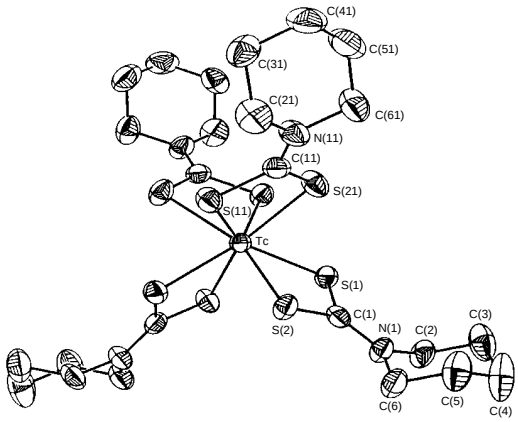

**Fig. 1** 50% thermal ellipsoid diagram of **1**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Tc–S(1) 2.491(2), Tc–S(2) 2.463(2), Tc–S(21) 2.482(2), Tc–S(11) 2.494(2); S(2)–C(1)–S(1) 109.0(4), S(2)–Tc–S(1) 77.30(6), S(21)–C(11)–S(11) 109.3(4), S(21)–Tc–S(11) 79.57(7).

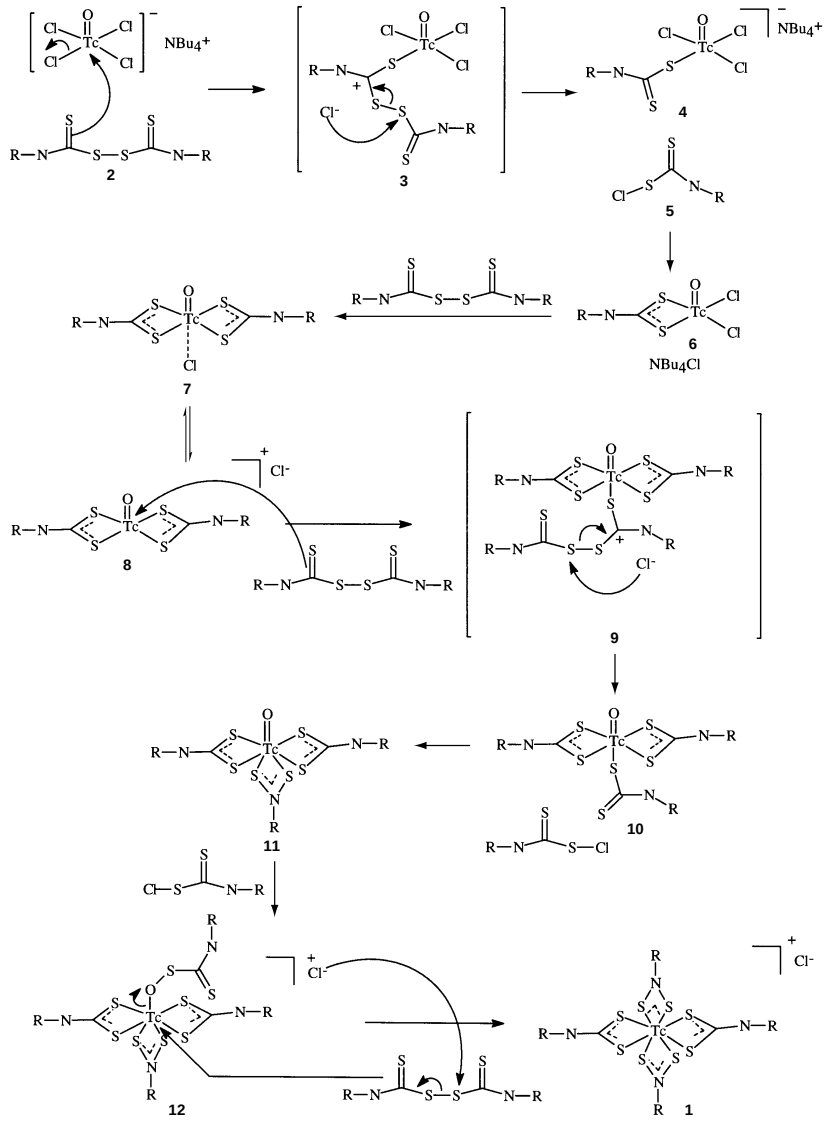
Compound **1** was obtained by addition of a dichloromethane solution of [$NBu_4$][$TcOCl_4$][8] to a dichloromethane solution of the ligand. The product was crystallized from acetone as a bromide salt. Slow evaporation of the acetone solution of the bromide salt provided large, dark red X-ray quality crystals in reasonable yield (67%).‡

Compound **1** co-crystallized with its bromide counter ion, which was confirmed by neutron activation analysis, and a disordered acetone molecule. Its shape is a distorted square antiprism with Tc–S distances ranging between 2.463(2) and 2.494(2) Å which are consistent with other technetium thiocarbamates. The four S–Tc–S angles range between 77.30 and 79.57° and the S–Tc–S angles are all approximately 109°.



The electrospray mass spectrum of **1** contained the parent peak as well as fragmentation peaks which corresponded to sequential losses of carbamate groups. The $^1$H and $^{13}$C NMR spectra of compound **1** were relatively simple, with the $^{13}$C NMR spectrum showing only four signals.

A possible mechanism for the formation of **1** is shown in Scheme 2. The driving force for this process is the formation of Tc–S bonds coupled with the cleavage of relatively weak S–S bonds by nucleophilic chloride ion. The first step of the proposed mechanism involves nucleophilic attack of the dithiocarbamate disulfide **2** on $TcOCl_4^-$. Because of the aprotic solvent nucleophilic chloride ion may react with the disulfide of intermediate **3** to give the technetium(v) species **4** and compound **5**; the cyano analogue of **5** has been reported.[9] Intermediate **4** converts to **6**, a typical reaction for dithiocarbamates. The sequence is repeated until species **7** is formed. We have prepared the rhenium analogue of **7** and observed that it equilibrates in solution to the cation **8**.[10] Intermediate **8** reacts with another dithocarbamate to form the neutral species **10** which converts to **11**. Because of the electron density supplied by the three dithiocarbamate ligands, the Tc–O bond should be sufficiently polarized to react with a molecule of the reactive species **5**. The resulting species **12** would then be susceptable to nucleophilic attack by another molecule of **2** to give the title compound **1**.

# Metal hurdling in transition-metal complexes of 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tpt) and 2,4,6-tris-(2-pyridyl)pyrimidine (tpp)

**Andrew Gelling, Matthew D. Olsen, Keith G. Orrell,* Anthony G. Osborne and Vladimir Šik**

*Department of Chemistry, The University, Exeter, Devon, UK EX4 4QD*

**$^1$H NMR two-dimensional exchange spectroscopy (EXSY) reveals that in palladium(II) and platinum(II) complexes of the ligands 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tpt) and 2,4,6-tris(2-pyridyl)pyrimidine (tpp), a highly novel type of fluxion occurs in which the metal moiety hurdles a C–C bond and moves from one edge of the central ligand ring to an adjacent edge; this process is accompanied by 1,4 metallotropic shifts analogous to those found in complexes of 2,2′:6′,2″-terpyridine.**

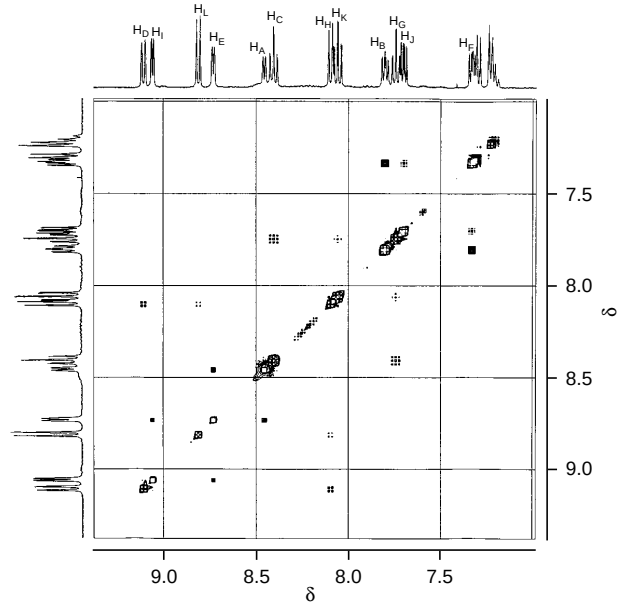
Since our discovery that 2,2′:6′,2″-terpyridine (terpy) acts as a fluxional bidentate ligand to certain metals[1–4] we have revealed analogous 1,4 metallotropic shifts in a range of rhenium(I) or platinum(IV)[5–7] complexes of N,N,N-ligands based on combinations of pyridine, pyrazole, pyrimidine and 1,3,5-triazine rings. Recently we have presented NMR evidence that the metallotropic shift in 2,2′:6′,2″-terpyridine complexes occurs through a purely associative process.[8] We have now turned our attention to transition-metal complexes of the related trigonal planar ligands 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tpt) and 2,4,6-tris(2-pyridyl)pyrimidine (tpp).

The presence of more than one N heteroatom in the central ring in these ligands allows for much greater variety of fluxionality compared to terpy complexes. In the $^1$H two-dimensional EXSY spectrum of the complex [Pt($C_6F_4CF_3$-*p*)$_2$(tpt)] at 393 K, in addition to the exchanges of $H_A$–$H_D$ (ring 1) with $H_E$–$H_H$ (ring 2) associated with the 1,4 metallotropic shift, exchange of $H_E$–$H_H$ (ring 2) with $H_I$–$H_L$ (ring 3) was also observed (Fig. 1 and Scheme 1). This second exchange between uncoordinated pyridyls can only be rationalised by a movement of the metal moiety from one side of the pyridyl–triazine C–C bond of the chelate ring to the other. Such 'hurdling' of the C–C bond by the metal moiety can be achieved in two ways, either by full dissociation of the metal centre from the ligand followed by recombination, or, by partial dissociation, by the breaking of a single metal–nitrogen bond (that to the triazine), followed by 180° rotation of the metal-bound pyridyl about the pyridyl–triazine bond, followed by recombination of the metal to the new triazine nitrogen. The first process would lead to an equal probability of the metal recoordinating at nitrogens on any pair of adjacent rings, and hence exchange between hydrogens of all pyridine rings would occur with equal rates. As this is not seen, in fact no exchange between the hydrogens of rings 1 and 3 (Scheme 1 and Fig. 1) is observed, we conclude that the second partially dissociative process occurs with the metal effectively hurdling the pyridyl–triazine bond and recoordinating to the triazine.

Rates of the metallotropic shift and rotational hurdling processes were found, by high-temperature quantitative $^1$H two-dimensional EXSY experiments, to be comparable. A combination of the two processes enables the metal moiety to move completely round the outside of the triazine ring passing through structures **i**–**vi** (Scheme 1). The rate of the metallotropic shift relative to that of the rotation was found to increase more rapidly with temperature leading to a slightly higher activation energy ($\Delta G^{\ddagger}$) than for the hurdling process (Table 1).

In the complex [Pd($C_6F_4CF_3$-*p*)$_2$(tpt)] metallotropic shifts and metal hurdling processes occur at measurable rates at ambient temperatures. Consequently, $^{19}$F one-dimensional bandshape analysis (of $CF_3$ signals) over a temperature range 293–403 K enabled the metallotropic shift to be monitored, and a $^1$H two-dimensional EXSY experiment at room temperature provided an estimate of the activation energy for the hurdling process (Table 1).

Metal complexes of the pyrimidine-based ligand tpp differ in two fundamental ways from those of tpt. Firstly, while all tpt chelate complexes are degenerate with equal populations of coordination species, in tpp complexes the two coordination species are chemically different and so differing populations are expected. Surprisingly, there was a very great imbalance in populations, namely 99 : 1. It is known that in the X-ray crystal structure of terpyridine the nitrogens adopt a *trans*,*trans* configuration,[9] and, by analogy, this will be the preferred configuration in tpp. This can be achieved by rotation of the pyridyls attached to the 4- and 6-positions of the pyrimidine ring. However, when the 2-position pyridyl ring is coplanar with the other rings, its nitrogen donor is inevitably *cis* to one of the pyrimidine nitrogens and thus ideally placed to effect metal chelation. Thus, in Scheme 1, complexes **i** and **ii** are strongly preferred over **iii** and **vi**. The second major difference from the tpt complexes is that no combination of metallotropic shifts and rotational hurdling will allow the metal to move completely round the ligand. Only one rotation and two 1,4 shifts are



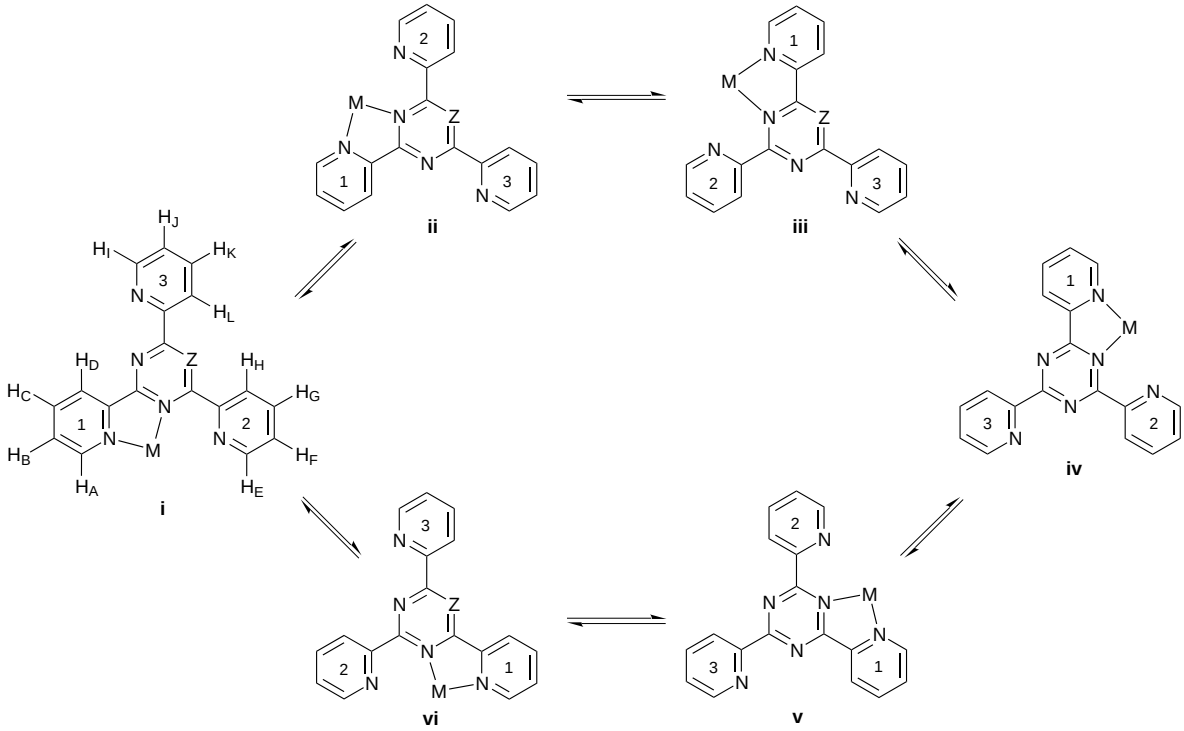


**Fig. 1** $^1$H NMR two-dimensional EXSY spectrum (at 393 K, mixing time 0.8 s) of [Pt($C_6F_4CF_3$-*p*)$_2$(tpt)] in $CDCl_2$, $CDCl_2$ showing exchanges due to both the 1,4 metallotropic shift ($H_A$–$H_D$ ⇌ $H_E$–$H_H$) and the rotational hurdling process ($H_E$–$H_H$ ⇌ $H_I$–$H_L$). The unlabelled signals at δ 7.2–7.3 are due to an unknown impurity.

**Scheme 1** The exchange pathways for both the 1,4 metallotropic shift and rotational hurdling processes in [M($C_6F_4CF_3$-*p*)$_2$L] complexes [M = Pt or Pd; L = tpt (Z = N) or tpp (Z = CH). Individual rings are numbered to show how exchange affects their chemical environments. In the case of L = tpt the metal can travel completely round the ligand exchanging all six structures **i**–**vi** while in the L = tpp complexes this motion is restricted to only four of them **i**–**iii** and **vi** as coordination to Z = CH is impossible.

**Table 1** Activation energy data for both the 1,4 metallotropic shift and hurdling rotation

| Complex | $\Delta G^{\ddagger}$ (1,4 shift)[a]/ kJ mol$^{-1}$ | $\Delta G^{\ddagger}$ (hurdling)/ kJ mol$^{-1}$ |
|---|---|---|
| [Pt($C_6F_4CF_3$-*p*)$_2$(tpt)] | 102.7 ± 0.4[b] | 92.5[c] |
| [Pd($C_6F_4CF_3$-*p*)$_2$(tpt)] | 72.0 ± 0.2[d] | 73.7[e] |
| [Pt($C_6F_4CF_3$-*p*)$_2$(tpp)] | 117.7[f,g] | 113.0[g] |
| [Pd($C_6F_4CF_3$-*p*)$_2$(tpp)] | 69.0[f,h] | —[i] |

possible, since complexes of type **iv** and **v** in Scheme 1 do not exist for tpp complexes.

The $^1$H two-dimensional EXSY spectrum of the complex [Pt($C_6F_4CF_3$-*p*)$_2$(tpp)] at 413 K shows exchange of the signals $H_E$–$H_H$ (ring 2) with $H_I$–$H_L$ (ring 3); such an exchange between signals of major solution species can only be due to the presence of the rotational hurdling process as the 1,4 metallotropic shift would exchange signals of major and minor species. Despite the very low populations of the minor species and the fact that not all their signals could be unambiguously detected in the one-dimensional spectrum, all exchange cross peaks due to the 1,4 metallotropic shift could be observed in the two-dimensional EXSY spectrum leading to the identification of the chemical shifts of all hydrogens in the minor species. Rates of metallotropic shift and rotational hurdling are again of comparable magnitude, although the calculated activation energies are slightly higher than for the tpt complexes (Table 1), presumably reflecting the differing basicities of the pyrimidine and triazine centres.

Both metal hurdling and 1,4-shifting processes were also detected in [Pd($C_6F_4CF_3$-*p*)$_2$(tpp)], this time at room temperature as in the case of the Pd$^{II}$–tpt complex. In contrast, no evidence of the metal hurdling process was found for the octahedral complex [ReBr(CO)$_3$(tpt)]; only the 1,4-shift process occurs. This implies that axial ligands on the metal sterically prevent the metal moiety from rotating over (or under) the pyridyl–triazine C–C bond. Presumably the same negative result would be found for the isoelectronic metal moiety $PtBrMe_3$.

# Asymmetric catalytic intramolecular hydroacylation of 4-substituted pent-4-enals to β-substituted cyclopentanones

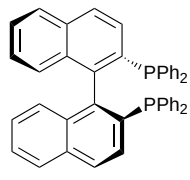
**Richard W. Barnhart, David A. McMorran and B. Bosnich**

*Department of Chemistry, The University of Chicago, 5735 South Ellis Avenue, Chicago, Illinois 60637, USA*

**The catalyst, [Rh(*S*,*S*-Me-duphos)(acetone)$_2$]$^+$, rapidly and efficiently converts 4-substituted pent-4-enals bearing primary and secondary substituents to the corresponding cyclopentanones and for a variety of substituents the ee was found to range from 93 to 96% at 25 °C.**

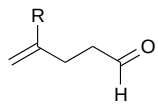
Asymmetric catalytic intramolecular hydroacylation involving the conversion of pent-4-enals to cyclopentanones (eqn. 1) is

(1)



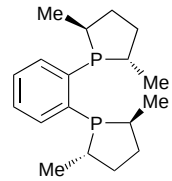
potentially an important transformation because it provides pivotal precursors for the generation of elaborate molecules. Generally, cationic rhodium(I) complexes bearing chelating diphosphines provide catalysts which have high turnover frequencies and numbers.[1,2] In contrast, analogous complexes bearing unidentate phosphines give poor turnover numbers[3] because decarbonylation of the substrate leads to the formation of stable monocarbonyl rhodium complexes which are catalytically inactive. In order to achieve efficient catalysis with chelating diphosphine rhodium(I) complexes, two vacant or virtually vacant coordination positions are required in order to allow ready access of the substrate to the metal.[1,2] This is usually achieved by hydrogenation of the dialkene (norbornadiene or cycloocta-1,4-diene) complex to produce the cationic disolvento catalyst. Weakly bound solvento complexes give the highest rates. Generally, high yields and rapid turnover frequencies are observed for substrates bearing substituents at the 3- and 4-positions whereas substituents at the 2- and 5-positions hinder the rate of hydroacylation.

We recently reported that the *S*-binap (**1**) catalyst, [Rh(*S*-binap)(solvent)$_2$]$^+$, where solvent is dichloromethane or acetone, is a very efficient and highly enantioselective catalyst for certain 4-substituted pent-4-enals **2**.[4] In particular, when R is a tertiary carbon or tertiary silicon group, cyclopentanone products are produced in > 99% ee and in quantitative chemical yield. Similarly, when R is an ester group, essentially enantiomerically pure products are also produced and when R is a ketone, very high ees are observed. Significantly, all of these high enantioselectivities occur at 25 °C and at low catalyst loadings and given the consistency of the results, it would appear that the binap catalyst will give essentially enantiomerically pure cyclopentanones for any tertiary or ester R group and will give high ees for ketonic substituents.

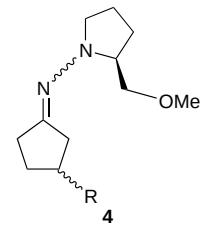


The binap catalyst, however, gives modest ees for substrates bearing a primary or secondary R group and we sought to find a catalyst which would serve to produce consistently high ees for these substituents. The rhodium(I) complex incorporating *S*,*S*-Me-duphos, **3**, proved to be effective for these substrates. The catalytic precursor, [Rh(*S*,*S*-Me-duphos)(NBD)]$PF_6$, where NBD is norbornadiene, was isolated as crystals and the catalyst, [Rh(*S*,*S*-Me-duphos)(acetone)$_2$]$PF_6$, was generated by hydrogenation of the NBD ligand in acetone solution. Addition of the 4-substituted pent-4-enals at 25 °C to these solutions causes rapid catalysis in nearly all cases and quantitive chemical yields are observed.

In Table 1, we list the results obtained for a variety of substrates, one class where primary alkyl groups are present α to the vinyl group (entries 1–6) and the other where a secondary carbon is bound to the vinyl group (entries 7–10). All reactions were carried out in acetone, with substrate concentrations of 0.15–0.2 mol dm$^{-3}$, and the time to completion data are listed for 5 mol% catalyst loadings. The times listed in Table 1 were obtained from $^1$H NMR spectroscopy and no side products were detected. For large scale experiments, 2 mol% catalyst loadings were employed and the % ee was determined by $^{13}$C NMR spectra of the Samp[5] derivatives **4**. The absolute configurations were determined by comparing the optical rotations with those reported. Where the absolute configuration was unknown, it was assumed that the $^{13}$C NMR chemical shifts of the Samp diastereoisomers would be consistent throughout as they were found to be for those cyclopentanones of known configuration.[6]



Aside from entry 6 where the substrate carries a phenyl group, all of the reactions are essentially complete upon mixing at 25 °C. It will be noted that all of the products have the same absolute configuration, that all ees are consistently high and vary very little over a variety of substituents. It seems reasonable to conclude that the Me-duphos catalyst is likely to provide high enantioselectivity for any 4-substituted pent-4-enal bearing a primary or secondary carbon atom substituent. Using the Et-duphos catalyst gave similar ees for these substrates. Because the catalytic turnover frequency is so high for most of the substituents, we investigated the enantioselectivity at −10 °C for two substrates. The time of reaction and the ees are given in the square brackets (Table 1). At −10 °C, the ee is raised to 98% in both cases, suggesting that essentially optically pure products are accessible by manipulation of the catalytic conditions. Further, catalysis proceeds even at 0.5 mol% loading, although at 25 °C, 2 h were required for complete conversion of the butyl substrate (entry 3). No side products were observed. It is probable that the low turnover frequency for the phenylated substrate (entry 6) is due to the formation of the catalytically inactive π-aryl complex of the catalyst.[7]



**1**

[a] For > 95% completion. [b] Results obtained at −10 °C, all other entries refer to 25 °C.

In the context of the consistency of the results listed in Table 1 and those reported for the binap catalyst, it is interesting that the Me-duphos catalyst gives modest ees at 25 °C for substrates bearing tertiary groups. Thus, when the R substituent in the substrate **2** is Bu$^t$, $Me_3Si$ or $PhMe_2Si$, the Me-duphos catalyst gives the corresponding *S*-cyclopentanones with ees of 44, 64 and 61%, respectively. As for the case of the binap catalyst, the Me-duphos catalyst gave moderate ees for 4-aryl substituted pent-4-enals. It was found that for the substrates where R = phenyl, *p*-tolyl, *p*-methoxyphenyl and *o*-methoxyphenyl, the ees were 46 (*R*), 72 (*R*), 70 (*R*) and 54% (*S*), respectively, using the *S*,*S*-Me-duphos catalyst. The chiraphos catalyst remains the most effective for these aryl bearing substrates where the ees range from 65 to 78%.[4]

The probable mechanism for hydroacylation is outlined in Scheme 1.[8] Except for the final reductive elimination step to produce the product, all of the steps are reversible. As was shown previously,[8] however, these reversible steps are not at equilibrium but the enantioselectivity is to some extent controlled by these steps. Thus the enantioselectivity is controlled by a complex mix of rate constants and it is not possible to identify a particular intermediate which determines the ee, and, consequently, there is no guiding principle that can be postulated for the origins of the enantioselection.

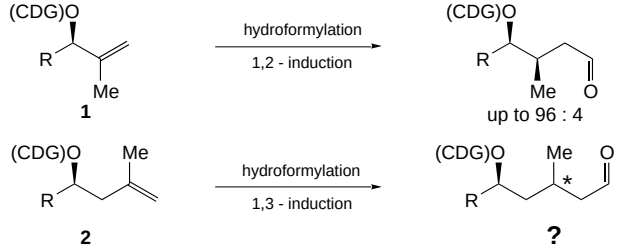
# Substrate directed diastereoselective hydroformylation of acyclic homomethallylic alcohols

**Bernhard Breit**

*Fachbereich Chemie, Philipps-Universität Marburg, Hans-Meerweinstr., D-35043 Marburg, Germany*

**Diastereoselective hydroformylation of acyclic homomethallylic alcohols with the aid of a catalyst directing group is achieved and the stereochemical outcome of this reaction is rationalized by analysing the preferred substrate conformation in solution.**

Transition metal catalysed C–C bond forming reactions provide efficient ways to build carbon backbones in organic synthesis. These reactions also allow the generation of stereogenic centres, be it with the aid of a chiral catalyst[1] or by substrate based asymmetric induction.[2] The latter approach is not frequently utilized,[3] but its potential may be enhanced by the introduction of a catalyst directing group, a group that binds reversibly to the catalytically active metal species, and positions it selectively at one of the diastereotopic faces of the substrate.[4,5]



We recently found that *o*-diphenylphosphinobenzoic acid may be used as an effective catalyst directing group in stereoselective hydroformylation of methallylic alcohols **1** (Scheme 1).[5] In this process high 1,2-asymmetric induction is realized by means of the catalyst directing group. We report now that this approach allows also for high 1,3-asymmetric induction in the hydroformylation of homomethallylic alcohols **2** by use of the same catalyst directing group.

To probe 1,3-asymmetric induction homomethallylic alcohols seemed to be particularly interesting substrates, because hydroformylation delivers an acyclic structural fragment with hydroxy and methyl substituted stereocentres in a 1,3 relation. Such a structural motif is widespread, especially in polyketide natural products, and therefore of significant synthetic importance.[6]

Starting from readily available homomethallylic alcohols[7] we introduced the catalyst directing *o*-DPPB group employing the DCC–DMAP coupling method.[8] The resulting homomethallylic *o*-DPPB esters **3** were subjected to hydroformylation conditions using 0.7 mol% of $Rh(CO)_2acac$–$P(OPh)_3$ as the catalyst. The hydroformylation proceeded smoothly to give the corresponding aldehydes **4** in good to excellent yields and with *anti*-diastereoselectivities of up to 91%.†‡

Interestingly a significant dependence of the diastereoselectivity on the reaction temperature was observed. Thus the isopropyl derivative **3a** at 90 °C gave only a 70 : 30 ratio (entry 3). Lowering the reaction temperature to 70 °C and even further to 50 °C improved the diastereomeric ratio from 87 : 13 to 91 : 9 favouring the *anti*-aldehyde (entries 1 and 2). Furthermore no significant influence of the diastereoselectivity on the nature of the substituent R could be detected. Thus primary and secondary alkyl as well as aryl substituents were tolerated and gave diastereomer ratios independant on the nature of R of *ca.* 91 : 9. Remarkable is the hydroformylation of the alkenyl substituted derivative **3f**, in which a 1,1-disubstituted alkene could be reacted chemo-, regio- and stereo-selectively in the presence of a trisubstituted alkene to give the *anti*-aldehyde **4f** in 85% yield and a diastereomeric ratio of 90 : 10 (entry 8).

The observed independence of the diastereoselectivity on the nature of the substituent R seemed to indicate that a conformational preference inherent to the homomethallylic system itself might be the origin of the observed 1,3 asymmetric induction. To test this hypothesis we examined the preferred conformation of the homomethallylic *o*-DPPB ester substrate **3a** in solution at 25 °C. Determination of coupling constants as well as 2D-NOESY spectra showed compound **3a** to have a preferred conformation **A** (Scheme 3) in agreement with MM3 calculations. The driving force for this conformation is the minimization of 1,3-allylic strain and the avoiding of *syn*-pentane interactions.[9] If we assume a coordination of the rhodium catalyst between the catalyst directing group and the alkene as indicated (Scheme 3), hydroformylation would provide the

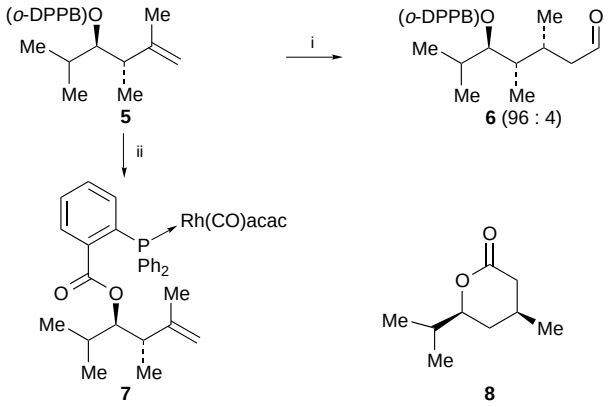
[a] For a general experimental procedure see ref. 5. [b] Isolated yields after column chromatography. [c] Determined by NMR spectroscopy of the crude reaction mixture.



**Scheme 2** *Reagents and conditions*: i, 0.7 mol% $[Rh(CO)_2acac/4\ P(OPh)_3]$, 20 bar $H_2$–CO (1 : 1), toluene, *o*-DPPB = *ortho*-diphenylphosphinobenzoate

**3a A** (**7 A**) **3a B** (**7 B**)

*anti*-**4** (**6**) *syn*-**4** (**6**)

**Scheme 3** Preferred conformation for **3a** and **7** in $CDCl_3$ solution at 25 °C determined by 2D-NOESY NMR spectra and selective $^1H$ NMR decoupling experiments. The indicated coordination of the rhodium catalyst to phosphine and alkene is hypothetic.

**Scheme 4** *Reagents and conditions*: i, 0.7 mol% $[Rh(CO)_2acac/4\ P(OPh)_3]$, 20 bar $H_2$–CO (1 : 1), toluene, 50 °C, 7 d, 91%; ii, $Rh(CO)_2acac$, benzene, 25 °C, 15 min, 99%

*anti*-aldehyde **4** as was found experimentally. The less preferred conformation **B** should give rise to complexation of the opposite diastereotopic alkene face, *i.e.* to the formation of the corresponding *syn*-aldehyde **4**.§

Consequently the replacement of $H_b$ in **3a** by a methyl substituent should favour conformation **A** even more, because the alternative conformation **B** would develop, in addition to the *syn*-pentane interaction between the alkenic methyl substituent and the oxygen substituent, a repulsive 1,3-allylic strain between the additional methyl substituent and the $sp^2$-hybridized $CH_2$-fragment. To investigate such a conformational situation as close as possible to hydroformylation catalysis, we prepared the rhodium complex **7** by reacting alcohol **5** with stoichiometric amounts of $Rh(CO)_2acac$. 2D-NOESY and selective proton decoupling experiments showed rhodium complex **7** to have preferentially the conformation **A** at 25 °C in $CDCl_3$ (Scheme 3).

When **5** was hydroformylated at 50 °C, the *anti*-aldehyde **6** was obtained in 91% yield with a diastereomeric ratio of 96 : 4 (Scheme 4). Thus the additional methyl substituent, which disfavours conformer **B**, gives rise to a significantly higher diastereoselectivity in agreement with our model.

This work was supported by the Fonds der Chemischen Industrie (Liebig stipend for B. B.), the Otto Röhm Gedächtnisstiftung and by the Deutsche Forschungsgemeinschaft (SFB 260). We thank Professor R. W. Hoffmann for his generous support, BASF and Degussa for their gifts of chemicals and M. Dauber for his skilful experimental assistance.

## Footnotes

† For a general procedure see ref. 5.

‡ All compounds were characterized by NMR spectroscopy and elemental analyses. The relative stereochemistry was assigned for **4a** by transformation to the known lactone **8** (ref. 10).

§ On going from 30 to 90 °C the vicinal coupling constants for $H_aH_c$ and $H_bH_c$ change from 9.0/4.1 Hz to 8.4/4.6 Hz. These data indicate a change in conformer populations for **3a** when going to the higher temperatures, which is reflected in the temperature dependence of the diastereoselectivities of the hydroformylation reaction.

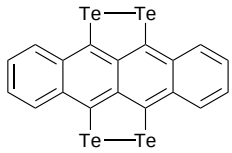
# Crystal structures and electrical conductivities of cation-radical salts of a tellurium-containing donor: 3,4-dimethylanthra [1,9-*cd* : 4,10-*c′d′*]bis[1,2]-ditellurole



**Masahiro Nakata,[a] Akiko Kobayashi,*[a] Taro Saito,[a] Hayao Kobayashi,[b] Kazuo Takimiya,[c] Tetsuo Otsubo[c] and Fumio Ogura[d]**

**The crystal structures and conducting properties of various cation-radical salts of a tellurium-containing polyacene donor molecule, 3,4-dimethylanthra[1,9-*cd* : 4,10-*c′d′*]bis-[1,2]ditellurole, are described; the $Br^-$ salt shows a relatively high conductivity at room temperature.**

In the field of molecular conductors, systems based on tellurium-containing donor molecules have not received as much attention as systems based on sulfur- or selenium-containing donors.[1] Only a few conducting complexes with tellurium-containing donors have been reported, including the cation-radical salts of hexamethylenetetratellurafulvalene (HMTTeF)[2] and the tetratellurafulvalene (TTeF)–TCNQ complex.[3] By incorporating heavy chalcogen atoms such as tellurium into donor molecules, a new metallic system with a wider bandwidth and a higher dimensionality is expected to appear.[1] In particular, a polyacene donor molecule containing *peri*-ditellurium bridges might reflect the atomic character of tellurium more directly than a donor with a tetratellurafulvalene framework, and is expected to show novel physical properties. Tetratellurotetracene (TTeT) is well known as a donor molecular containing *peri*-ditellurium bridges,[4] but few cation-radical salts or charge transfer complexes of TTeT have been reported because of its extremely poor solubility.[5] We report here the first examples of cation radical salts of a polyacene donor with *peri*-ditellurium bridges, 3,4-dimethylanthra-[1,9-*cd* : 4,10-*c′d′*]bis[1,2]ditellurole (2,3-dimethyltetratel-luroanthracene: 2,3-DMTTeA), the synthesis of which was first reported by Takimiya and co-workers.[6] 2,3-DMTTeA is an unsymmetrical polyacene molecule with an anthracene framework, two Te–Te bridges and two methyl groups. The solubility of 2,3-DMTTeA in organic solvents is high due to the two methyl groups. Therefore, we can examine the complexes of this donor with the usual chemical or electrochemical methods using organic solvents.

Single crystals of the cation-radical salts were obtained by electrochemical oxidation of 2,3-DMTTeA in a THF solution of $Bu_4N$ (Table 1). A standard H-shaped cell and platinum electrodes were used and a constant current (0.1–1.0 μA) was applied for 7–15 days. Needle- or plate-shaped black crystals grew on the anode.

TTeT

2,3-DMTTeA

The electrical resistivities of the salts were measured by a four-probe method along the donor-stacking axes of the single crystals. The resistivities of all the salts showed semiconducting temperature dependence. However, the $Br^-$ salt has quite a high room temperature conductivity ($1.3 \times 10^3$ S cm$^{-1}$) and a very low activation energy (0.010 eV) (Fig. 1). Room temperature conductivities, activation energies and stoichiometries of the salts are listed in Table 1.

X-ray structure analyses were performed on neutral 2,3-DMTTeA and its cation-radical salts with $ClO_4^-$, $BF_4^-$, $ReO_4^-$, $PF_6^-$, $AsF_6^-$ and $Br^-$ counter anions.†,‡ The $BF_4^-$ and $ReO_4^-$ salts are isomorphous with the $ClO_4^-$ salt, and the $PF_6^-$ salt is isomorphous with the $AsF_6^-$ salt. The common feature to all the structures is the disorder of the donor molecules caused by their unsymmetrical shape, which makes the 2,3-DMTTeA molecules appear as if they have a tetracene framework instead of their actual anthracene framework. One possible reason why the donor molecules have this orientational disorder is that the formation of the Te···Te network is dominant in the construction

**Table 1** Composition and electrical conductivities of 2,3-DMTTeA salts

| Anion | Donor : anion ratio | Form | $\sigma_{293}$/S cm$^{-1}$ | $E_a$/eV |
|---|---|---|---|---|
| $ClO_4^-$ | 3 : 2[a] | plate | $7.1 \times 10^{-3}$ | 0.16 |
| $BF_4^-$ | 3 : 2[a] | plate | $9.7 \times 10^{-3}$ | 0.17 |

[a] Determined from the X-ray crystal structure analysis. [b] Determined by elemental analysis.

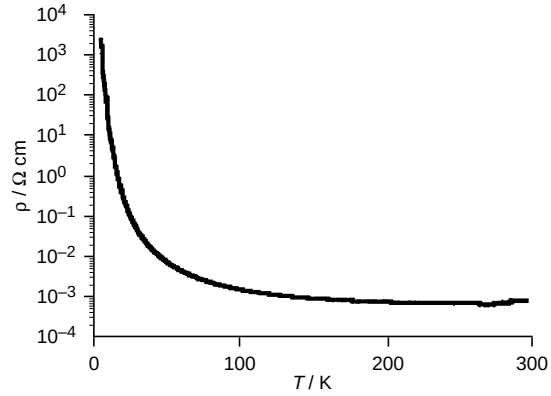

**Fig. 1** Electrical resistivity of $(2,3\text{-DMTTeA})_2Br$

of the crystal structures. This disorder, which is absent from the sulfur or selenium isologue of 2,3-DMTTeA,[6b] is considered to reflect the character of tellurium atoms. In addition, the anions are also disordered in the $AsF_6^-$ and $Br^-$ salts. In spite of their disordered structures, however, all were refined with *R* factors of 3–9%, because the donor molecules contain heavy tellurium atoms.

The structure of $(2,3\text{-DMTTeA})_3(ClO_4)_2$ is shown in Fig. 2. There are donor stacks along the *c* axis, and in each stack, two crystallographically independent donor molecules, A and B in Fig. 2, overlap with their long axis 90° rotated. This rotated overlapping arrangement causes the very small value of the calculated intermolecular overlap integral§ between A and B ($< 1 \times 10^{-3}$). On the other hand, B and B′, which are crystallographically equivalent, are almost eclipsed and the overlap integral between them is $10 \times 10^{-3}$, so they may be regarded as forming a dimer. The weak interaction between A and B causes the dimer to be isolated, which causes the poor conductivity of this salt.

The $AsF_6^-$ salt has donor stacks along the *a* axis. There is a short interstack Te···Te contact (3.83 Å) which is shorter than the intermolecular Te···Te distance within the stack (4.16 Å). Therefore, two-dimensional character is expected in its conducting properties.

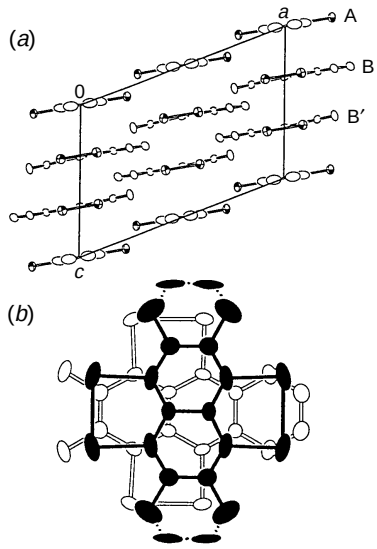

**Fig. 2** (*a*) Crystal structure of $(2,3\text{-DMTTeA})_3(ClO_4)_2$ projected onto the *ac* plane. $ClO_4^-$ anions are omitted for clarity. (*b*) Overlapping mode of the donor molecules of $(2,3\text{-DMTTeA})_3(ClO_4)_2$ projected onto the molecular plane. While molecule A (coloured black) has a disordered tetracene structure, molecule B (coloured white), is not disordered.

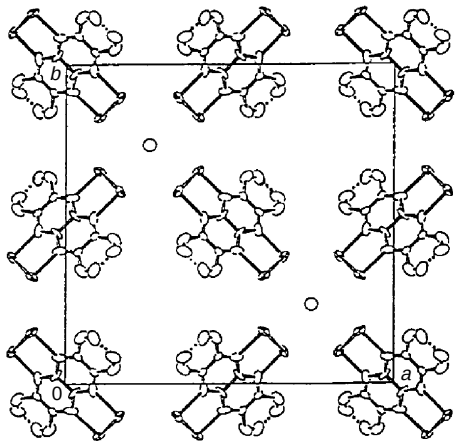

**Fig. 3** Crystal structure of $(2,3\text{-DMTTeA})_2Br$ projected onto the *ab* plane

In the $Br^-$ salt (Fig. 3), the donor stacking structure is isomorphous with the tetragonal structure of $(TSeT)_2Cl$, reported by Shibaeva and Kaminskii in 1978 (TSeT = tetraselenotetracene).[7] There exist donor stacks along the *c* axis, and in each stack there are very close Te···Te intermolecular contact (3.70 Å). Between neighbouring stacks, however, no short contacts are found. Therefore, this structure may be called quasi-one-dimensional. In addition, the $Br^-$ anions are disordered along the *c* axis, which is responsible for the semiconducting property of this salt.

We have obtained the first single crystals of the molecular conductors based on a donor molecule with *peri*-ditellurium bridges. The higher conductivity of the $Br^-$ salt suggests the possibility of molecular metals with novel tellurium-based conduction passways, if the disorder in the crystal structure can be eliminated.

## Footnotes

† *Crystal data* for 2,3-DMTTeA: monoclinic, space group $P2_1/c$, $a$ = 9.976(5), $b$ = 5.137(1), $c$ = 16.186(1) Å, β = 104.28(2)°, $V$ = 803.8(3) Å$^3$, $Z$ = 2, $D_c$ = 2.944 g cm$^{-3}$, $R$ = 0.057 for 1200 reflections. For $(2,3\text{-DMTTeA})_3(ClO_4)_2$: monoclinic, space group $C2/m$, $a$ = 16.538(3), $b$ = 14.681(2), $c$ = 11.612(4) Å, β = 111.48(2)°, $V$ = 2623(1) Å$^3$, $Z$ = 2, $D_c$ = 2.958 g cm$^{-3}$, $R$ = 0.037 for 2568 reflections. For $(2,3\text{-DMTTeA})(AsF_6)_{0.2}$: monoclinic, space group $P2_1/a$, $a$ = 4.155(2), $b$ = 19.898(3), $c$ = 11.572(7) Å, β = 94.85(9)°, $V$ = 953.3(6) Å$^3$, $Z$ = 2, $D_c$ = 2.614 g cm$^{-3}$, $R$ = 0.066 for 1400 reflections. For $(2,3\text{-DMTTeA})_2Br$: tetragonal, space group $P4_2/ncm$, $a$ = 18.655(2), $c$ = 5.438(3) Å, $V$ = 1892(1) Å$^3$, $Z$ = 2, $D_c$ = 2.641 g cm$^{-3}$, $R$ = 0.093 for 578 reflections.

The data were collected on a Rigaku automated four-circle diffractometer (AFC5R, AFC7R) with graphite monochromated Mo-Kα radiation. The structures were solved by direct methods (SHELX86, SIR92) and refined by full-matrix least-squares methods using reflections with $I \geqslant 3\sigma(I)$.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 1822/382.

‡ Intramolecular bond lengths of the neutral 2,3-DMTTeA: Te–Te = 2.664(2), C–Te = 2.11(1) Å.

§ Intermolecular overlap integrals were calculated using the HOMO obtained by the extended Hückel MO calculation.

# Reaction control and potential tuning in a supercritical fluid

**Anthony A. Clifford,* Kate Pople, William J. Gaskill, Keith D. Bartle and Christopher M. Rayner**

*School of Chemistry, University of Leeds, Leeds, UK LS2 9JT*

**A maximum is found in the ratio of *endo*- to *exo*- products *vs.* density in the Diels–Alder reaction between cyclopentadiene and methyl acrylate in supercritical carbon dioxide and is explained by the adjustment of the position of the nearest-neighbour solvent molecules with respect to the transition states.**

There have been a number of previous investigations of product ratio in supercritical fluids and these have been reviewed in a recently published study.[1] Many of these have concentrated on the critical region. In some cases, the lowering of diffusion coefficients in the critical region at finite concentrations can give rise to rapid changes of product ratio with density, as has been observed in the photo-Fries rearrangement of naphthyl acetate in supercritical carbon dioxide.[2] In other cases, rapid changes are seen as a function of pressure, but these largely reflect the rapid change in density with pressure, and as a function of density changes in product ratio are less dramatic. In this study we report an interesting maximum in product ratio, which occurs at a density rather higher than the critical density.

Experimental measurements on the Diels–Alder reaction between methyl acrylate and cyclopentadiene were carried out at 308 and 313 K in carbon dioxide at various pressures. A 50 ml vessel (Autoclave Engineers) with a magnetically coupled stirrer was used, which was modified in-house to improve the temperature control and pressure measurement. $CO_2$ was added from an HPLC pump with a cooled head and an injection valve in the supply line (Rheodyne) for adding reagents. Connecting tubes were heated to the reaction temperature to prevent condensation in them. For each experiment 200 μl of methyl acrylate was added at the beginning, the vessel pressurised with $CO_2$ and allowed to reach temperature equilibrium over half an hour. 100 μl of cyclopentadiene, prepared just beforehand from the dimer, was then added through the injection valve and more $CO_2$ added to raise the pressure another 4–5 bar. The reaction was then carried out for 4 h, after which the reaction mixture was released, trapped in HPLC grade acetone, kept at 195 K and analysed by GC. The reactions were carried out at lower dilutions than some previous experiments[3] to avoid the danger of two phases being present.

We now consider a system in which there are two competing bimolecular reactions in which the two products are stereo-isomers. The ratio of products obtained is equal to the ratio of rate coefficients, defined in terms of mole fractions, $k_x'/k_x''$. By manipulating the equations for transition-state theory applied to supercritical fluids[5] it can be shown that the partial derivative of the logarithm of this ratio with molar volume, $V$, at constant temperature and composition is given by eqn. (1).

$$RT\left(\frac{\partial \ln\left(k_x'/k_x''\right)}{\partial V}\right)_{T,x} = \left(\frac{\partial p}{\partial x_2}\right)'_{T,V} - \left(\frac{\partial p}{\partial x_2}\right)''_{T,V} \qquad (1)$$

The quantities $(\partial p/\partial x_2)_{T,V}$, which do not come under the definition of partial molar quantities, but which can be conveniently called tuning functions, are partial derivatives of the pressure with respect to the mole fraction of the appropriate transition state. Equations for the variation with $V$ of other equilibria and individual reaction rates can also be written in terms of these functions.

Expressions for the tuning functions can be obtained in terms of an equation of state. The van der Waals equation is used below for analysing the experimental data. These tuning functions pass from negative at low density to positive at high density as the mean distance between the transition states and their nearest-neighbour solvent molecules moves from the attractive region of their mutual pair potential, through its minimum to its repulsive region. The functions therefore describe the manipulation of the transition-state solvation energy *via* the density. In the case of competing reactions, a difference in two tuning functions is important, as shown in eqn. (1). This difference is related to the change in pressure as one transition state is replaced by the other and represents the difference of the potential tuning behaviour of the two transition states.

Experimental data for the ratio of *endo*- to *exo*- product are plotted against the solution density in Fig. 1. The range of values of the ratio is no different than that which can be obtained by changing the solvent in the liquid-phase reaction.[5] However, by controlling the density, this range can be obtained in a single solvent. At the temperatures of this study, 1, 4 and 9 K above the critical temperature of carbon dioxide, inaccuracies in pressure measurement and fluctuations in pressure because of temperature instability cause large errors in the estimation of the density. Estimations of this effect are shown by horizontal error bars, which are large near the critical density, but are smaller than the point sizes at higher densities. Further errors in the measurement of the product ratio of 5%, or 0.2, are not shown.

The curves shown in Fig. 1 are theoretical curves obtained from eqn. (1) using tuning functions calculated from the van der Waals equation of state, with simple combination rules for the parameters, to give a ratio of the rate constants, eqn. (2),

$$\frac{k_x'}{k_x''} = \left(\frac{k_x'}{k_x''}\right)_0 \exp\left(-\frac{b_2' - b_2''}{V - b_1} - \frac{2\sqrt{a_1}\left(\sqrt{a_2'} - \sqrt{a_2''}\right)}{RTV}\right) \qquad (2)$$

where $a_1$ and $b_1$ are the van der Waals parameters for the solvent, $a_2'$, $b_2'$, $a_2''$ and $b_2''$ are those for the two transition states and $(k_x'/k_x'')_0$ is the rate coefficient ratio in ideal gas conditions as $V \rightarrow \infty$. Thus the equation has three unknown parameters: $(k_x'/k_x'')_0$, $(b_2' - b_2'')$ and $[\sqrt{a_1}(\sqrt{a_2'} - \sqrt{a_2''})]$, which were obtained by fitting the data at 313 K. A value for $b_1$ for $CO_2$ of $31.33 \times 10^{-6}$ m$^3$ mol$^{-1}$, obtained from its critical volume, was used. The same three parameters obtained were then used to produce curves for both temperatures in Fig. 1, on the assumption that $(k_x'/k_x'')_0$ will not change significantly between the two temperatures, as is expected from reaction behaviour in the liquid phase.[5]

The rising part of the curve at lower densities is associated with the difference between the attractive forces of the two transition states and the steeper falling part with repulsion differences. A more physically transparent investigation can be made using the virial theorem of Clausius, which leads to the same relationship between tuning functions and the inter-molecular pair potential, as will be reported later. The interpretations can be summarised as follows. In a compressible medium such as a supercritical fluid it may often be possible, by controlling the density, to vary the mean distance between a

solute species and its nearest-neighbour solvent molecules within a range where their mutual pair potential energy is changing significantly. This statement is substantiated by calculations of the naphthalene–carbon dioxide pair correlation function in a supercritical fluid.[6] The solvation energy of the solute can therefore be controlled by the density of the medium and this will cause variations in a physical or chemical equilibrium or, if the species is a transition state, the rate of a chemical reaction. We suggest that the present study demonstrates that the effect of this 'potential tuning' is significant and observable for two competing reactions under accessible conditions. Recent results on absolute rate constants, which show a minimum in the reaction rate *vs.* density,[7] can also be explained by this effect, which is not particularly associated with the region around a critical point or line or with the critical density.

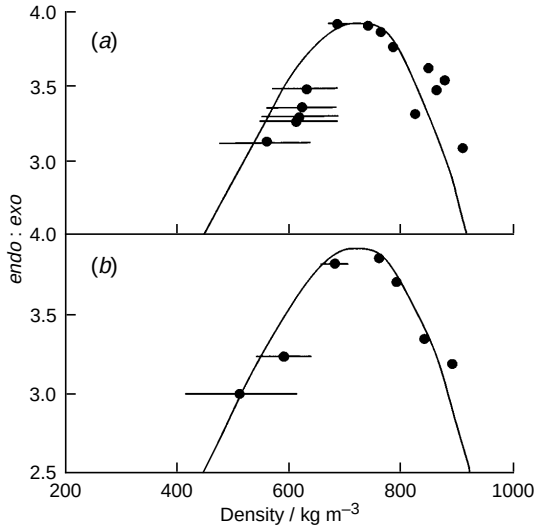

**Fig. 1** Experimental data (points) for the ratio of *endo*- to *exo*- product from the reaction of methyl acrylate and cyclopentadiene in carbon dioxide at (*a*) 308 and (*b*) 313 K. The curve shows predictions from the van der Waals equation, fitted to the experimental points at 313 K. Horizontal bars show errors in the calculated density, which are large near the critical density of 466 kg $m^{-3}$.

# A squaraine-based near-infrared absorbing sensor for the selective detection of transition and other metal ions in aqueous media†

**K. George Thomas, K. J. Thomas, S. Das* and M. V. George**

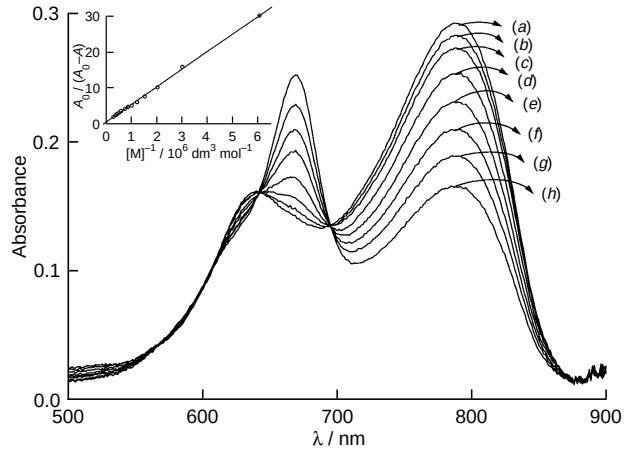
*Photochemistry Research Unit, Regional Research Laboratory (CSIR), Trivandrum 695 019, India*

**A near infrared absorbing cationic squaraine dye 1 is shown to be capable of detecting trace amounts of transition and lanthanide metal ions in aqueous media, even in the presence of alkali and alkaline earth metal ions.**

Design of fluorescent or chromogenic chemosensors for the selective detection of low concentrations of ions is an active area of research.[1–6] With a few exceptions,[3,4] most of the studies have been concerned with non-aqueous solutions of ions. Moreover, most of the chromophores hitherto reported suffer from the requirement of short wavelength excitation. For detection of metal ions in naturally occurring systems, particularly for intracellular applications, near-infrared absorbing water soluble chemosensors would be highly desirable.[2] In the course of our studies on the design of squaraine-based fluoro- and chromo-ionophores,[6] we have observed that a newly reported[7] squaraine dye, **1**, is highly suited for such applications. This dye is water soluble, has a very strong absorption in the near-infrared region and is capable of quantitatively and selectively detecting trace amounts of metal ions.‡ Complexation of **1** by different metal ions gives rise to a new absorption band, which in most cases is characteristic of the metal ion involved. Using this simple procedure, trace amounts of metal ions such as $Cu^{2+}$, $Hg^{2+}$, $Pb^{2+}$, $Mn^{2+}$, $La^{3+}$, $Eu^{3+}$, $Tb^{3+}$, $Gd^{3+}$ and $Lu^{3+}$ can be detected selectively.

The cationic dye **1** possesses two absorption maxima centred around 790 and 640 nm in a mixture (4 : 1) of water and acetonitrile at pH 6.7. Lowering the pH of the solution leads to a decrease in the intensities of these bands which is accompanied with the formation of a new band centred around 690 nm. The p$K_a$ of **1** has been evaluated as 4.9, based on these pH dependent spectral changes and the probable structures of the acid/base species in equilibrium with each other are shown in Scheme 1.

Addition of low concentrations of copper ions to a solution of **1** in a mixture (4 : 1) of water and acetonitrile at pH 6.7, where the dye is predominantly in its deprotonated form, led to a decrease in the intensities of the absorption maxima at 790 and 640 nm, which was accompanied by the formation of a sharp new band around 670 nm (Fig. 1). It has been observed that even addition of 50 nM (4 ppb) of $Cu^{2+}$ leads to a notable change in the absorption spectrum. Benesi–Hildebrand analysis of the complex formation, studied by following the changes in absorption spectra on addition of copper ions, indicated a 1 : 1 dye to metal stoichiometry with a stability constant of $1.5 \times 10^5$ $dm^3\ mol^{-1}$. Similarly, complexation of **1** with other metal ions leads to the formation of a new absorption band characteristic of the metal ion involved. It may be noted that the pH of the solution remains unchanged on addition of metal ions. The absorption maxima and equilibrium constants measured for different metal ions are shown in Table 1. With the exception of the complexes of $Hg^{2+}$ and $Cu^{2+}$ which have a maximum at 670 nm, the other complexes have their own characteristic absorption maxima. This is specially important with reference to the lanthanides investigated, since it is known that lanthanides when complexed with most chromogenic agents have similar absorption spectra and are therefore difficult to distinguish.[8] In the present study, however, there is a marked difference in the absorption maxima of the complexes of the dye with the various lanthanides studied (Table 1). The minimum concentration detectable for $Cu^{2+}$, $La^{3+}$, $Eu^{3+}$, $Tb^{3+}$, $Gd^{3+}$ and $Lu^{3+}$ is > 50–80 nM, for $Hg^{2+}$ is > 2 μM, for $Pb^{2+}$ is > 20 μM and for $Mn^{2+}$ is > 50 μM.



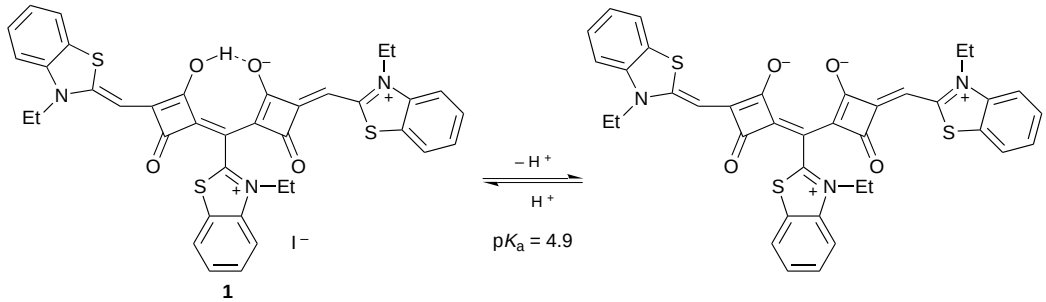


**Fig. 1** Effect of $Cu^{2+}$ concentrations on the absorption spectrum of **1** (4.7 μM) in $H_2O$–MeCN (4 : 1): $[Cu^{2+}]$ (*a*) 0, (*b*) 0.15, (*c*) 0.3, (*d*) 0.6, (*e*) 1.2, (*f*) 1.8, (*g*) 2.4, (*h*) 3.0 μM. Inset shows the plot of $A_0/(A_0 - A)$ *vs.* $1/[Cu^{2+}]$

**1**

**Scheme 1**

**Table 1** Complexation properties of **1** with various metal cations in $H_2O$–MeCN (4 : 1)

| Cation | $Cu^{2+}$ | $Hg^{2+}$ | $Pb^{2+}$ | $Mn^{2+}$ | $Zn^{2+}$ | $La^{3+}$ | $Eu^{3+}$ | $Gd^{3+}$ | $Tb^{3+}$ | $Lu^{3+}$ |
|---|---|---|---|---|---|---|---|---|---|---|
| $\lambda_{max}$/nm | 670 | 670 | 732 | 720 | 718 | 735 | 733 | 727 | 724 | 732 |
| log $K_s$[a,b] | 5.19 | 3.90 | 3.52 | 2.87 | — | 5.90 | 5.75 | 5.44 | 5.23 | 5.24 |
| Charge density | 2.778 | 1.818 | 1.667 | 2.500 | 2.703 | 2.953 | 3.158 | 3.198 | 3.250 | 3.529 |

[a] Benesi–Hildebrand equation for 1 : 1 complex formation between dye and metal ion, $A_0/(A_0 - A) = [E_L/(E_L - E_{mL})]\ \{1/(K_s[M]) + 1\}$, was used for determining the stability constant. $K_s$ is the stability constant, $A_0$ and $A$ are the absorbance of dye solution (790 nm band was followed) in the absence and presence of metal ions, $[M^{n+}]$. $E_L$ and $E_{mL}$ are the molar extinction coefficient of the free ligand and the complex respectively. All the $K_s$ values reported are within the experimental error of ±5%. [b] Complexes of all the metal ions studied except with $Cu^{2+}$ and $Mn^{2+}$ are stable in $H_2O$–MeCN (4 : 1) and the solutions were kept for 15 min for equilibration before carrying out the measurements. In the case of $Cu^{2+}$ and $Mn^{2+}$, the measurements were carried out immediately after the addition of the metal ions.

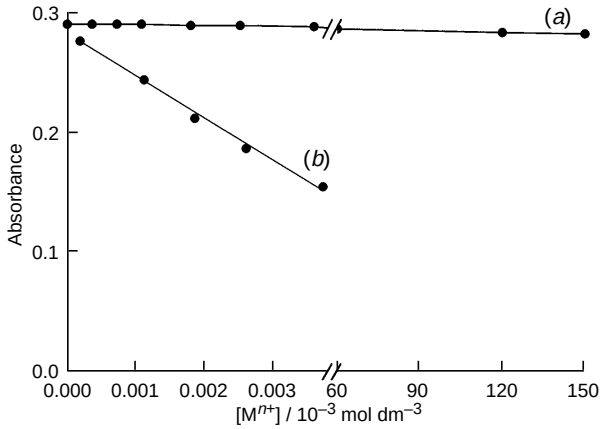

**Fig. 2** Determination of $Cu^{2+}$ in the presence of $Na^+$ using **1** (4.7 μM) in $H_2O$–MeCN (4 : 1) following the absorbance at 790 nm: (*a*) effect of addition of $Na^+$ (up to 150 mM); (*b*) effect of addition of $Cu^{2+}$ containing 150 mM of $Na^+$

An interesting feature of this extremely simple method of detecting trace amounts of metal ions is that although $Hg^{2+}$ and $Cu^{2+}$ complexes absorb at the same wavelengths, the differences in equilibrium constants for complex formation permit the analysis of low concentrations of $Cu^{2+}$ (> 50 nM) even in the presence of 1 μM of $Hg^{2+}$. The equilibrium constants listed in Table 1 indicate that the selectivity among the heavy metal ions is relatively high whereas within the lanthanide series it is not appreciable. The absorption spectrum of **1** was found to be unaffected by the addition of alkali and alkaline earth metal ions. For example, Fig. 2, curve (*a*) shows that addition of $Na^+$ ions up to 150 mM does not have any significant effect on the absorption spectrum of **1**. However, addition of even nM quantities of $Cu^{2+}$ (> 50 nM) to the above solution containing 150 mM of $Na^+$ [curve (*b*)] causes a decrease in the intensities of absorption of the dye accompanied by the formation of the 670 nm band characteristic of $Cu^{2+}$–dye complex. Thus, trace amounts (*ca.* 50 nM) of metal ions like $Cu^{2+}$ can be detected even in the presence of mM concentrations of $Na^+$, $Li^+$, $K^+$ and $Ca^{2+}$ (Fig. 2).

In the anionic form of the dye **1**, the oxygen atoms of the two cyclobutane rings are ideally located to yield the suitable geometry for strong complexation with metal ions. The intense absorption band observed in the NIR region of squaraines is essentially due to the intramolecular charge transfer transition which is primarily confined to the $C_2O_4$ unit.[9] The hypsochromic shift in the absorption spectra, upon complexation, can therefore be attributed to a reduction in the electron-donating ability of the $O^-$ atoms on complexation by the metal ions. Comparison of the shift in absorption maxima with charge density of the metal ions within the lanthanide series as well as between other metal ions (Table 1) indicate that, with the exception of $Cu^{2+}$ and $Hg^{2+}$, the hypsochromic shift does indeed increase with increasing charge density of the metal ion.

In conclusion, we have observed that the cationic squaraine dye **1** can act as a near-infrared absorbing chromogen for detecting trace amounts of toxic and environmentally hazardous metal cations such as $Cu^{2+}$, $Hg^{2+}$, $Pb^{2+}$ and $Mn^{2+}$ as well as several lanthanide metal ions in aqueous media. We are currently working on the synthesis and study of newer derivatives of the cationic squaraine dye, which can potentially yield a new class of chromogens for the selective and quantititative detection of metal ions, both for biological and environmental applications.

We thank the Council of Scientific and Industrial Research and the Department of Science and Technology, Government of India, for support.

## Footnotes

† This is contribution No. RRLT-PRU-70 from the Regional Research Laboratory, Trivandrum.

‡ Since the dye and dye–metal ion complexes undergo a slow precipitation and loss in absorption in aerated aqueous media all experiments were carried out in argon-purged 4 : 1 water–acetonitrile mixtures.

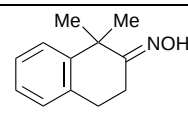
# Fluorinative α-cleavage of cyclic ketoximes with diethylaminosulfur trifluoride: an efficient synthesis of fluorinated carbonitriles

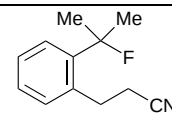
**Masayuki Kirihara, Kanako Niimi and Takefumi Momose***

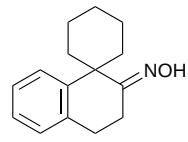
*Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani 2630, Toyama 930-01, Japan*

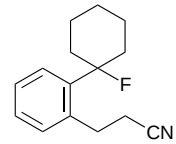
**Diethylaminosulfur trifluoride effects ready cleavage of cyclic ketoximes to fluorinated carbonitriles.**

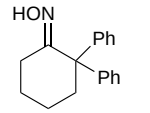
Fluorinated organic compounds are widely used in scientific and industrial fields. Since the preparative methods for organofluorine compounds remain limited to a few procedures, new fluorinating agents and methodology are required.[1] Since diethylaminosulfur trifluoride (DAST), a reagent converting aliphatic alcohols into alkyl fluorides, has been introduced into organic synthesis,[2] there have been several reports concerning new fluorinating methods.[3–9] Among the methods, we reported the reaction of DAST with tertiary cyclopropyl silyl ethers causing ring opening to give allylic fluorides.[10]

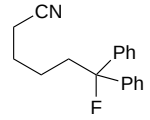


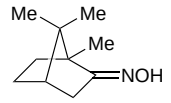


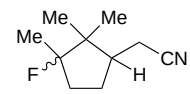


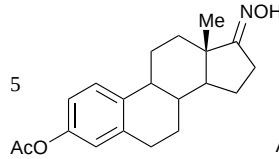


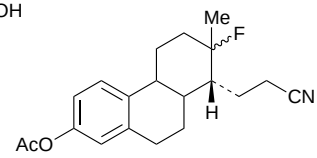


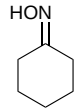






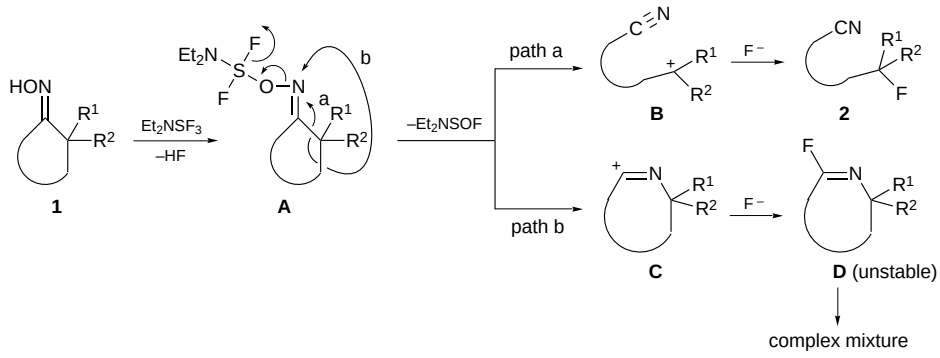






Here we describe a novel reaction involving the treatment of cyclic ketoximes **1** with DAST to cause a ring fragmentation resulting in the formation of fluorinated carbonitriles **2**.† The methodology has also provided an efficient route to tertiary fluorides or fluoroalkenes. The results are summarized in Table 1.

The presence of substituent(s) capable of stabilising a carbocation at the position α to the oximino carbon is essential to obtain fluorinated carbonitriles. An oxime lacking such substituents afforded a complex mixture (*e.g.* run 6 in Table 1). In the cases of runs 4 and 5, the products were a 1 : 1 mixture of stereoisomers. The results suggest that the reaction is a kind of Beckmann fragmentation (abnormal Beckmann rearrangement)[11] involving a carbocation intermediate.



A postulated reaction mechanism is depicted in Scheme 1. The first step is the nucleophilic displacement of a fluorine in DAST by the oxygen of the oximino substrate **1** with elimination of hydrogen fluoride. Next, the elimination of diethylaminosulfino fluoride from the intermediate **A** causes the bond cleavage and gives a carbocation intermediate **B**. Finally, the fluoride ion attacks **B** to afford the fluorinated carbonitrile **2** (path a). In the case of compounds lacking substituents to stabilise the α-carbocation, the reaction proceeds through a mechanism similar to that of the 'normal' Beckmann rearrangement. The carbon–carbon bond *anti* to the oximino leaving group in the intermediate **A** migrates to the nitrogen atom to afford the carbocation **C**. The fluoride ion attacks **C** to give an unstable compound **D**, which leads to a complex mixture (path b).

Compounds bearing a sulfur functionality **3** at the position α to the oximino carbon reacted with DAST to cause the fragmentation efficiently leading to α-fluoro sulfides **4**. Since α-fluoro sulfides **4** were not stable, they were subjected, without purification, to oxidation with MCPBA. The resulting sulf-

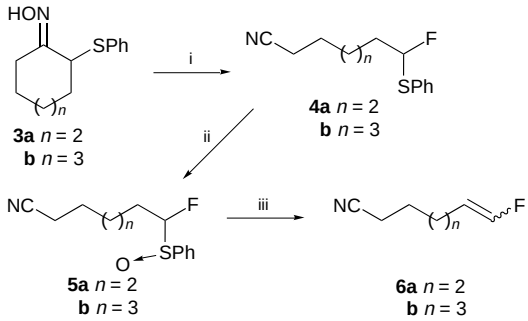


**Table 1**

oxides **5** were heated in a sealed tube at 160 °C to afford fluoroalkenes **6** in high yields (Scheme 2).

## Footnote

† A typical experimental procedure is as follows: to a solution of oxime (1.0 mmol) in dichloromethane (3 ml) was added DAST (1.0 mmol) at −78 °C under an inert atmosphere, and the reaction mixture was stirred for 30 min. A saturated sodium hydrogen carbonate solution was added to the reaction mixture, and the resulting mixture was extracted with dichloromethane. The extract was dried over anhydrous sodium sulfate, filtered, and evaporated to afford the crude product. Purification by chromatography (silica gel, hexane–dichloromethane) gave a pure sample.

# Supported BINOLate salts as base catalysts. Preparation and use in the Michael reaction

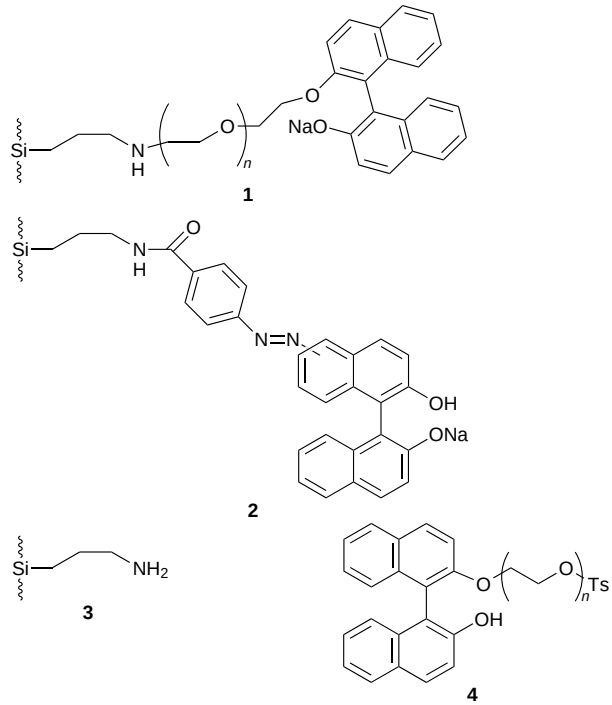
**Duncan J. Macquarrie†**

*Department of Chemistry, University of York, Heslington, York, UK YO1 5DD*

**Two silica supported BINOL complexes are prepared, both of which are active catalysts in the Michael reaction.**

The use of derivatives of 1,1′-naphthalene-2,2′-diol (BINOL) as base catalysts has recently been disclosed.[1,2] In particular, the use of podand-substituted salts of BINOL has led to efficient base catalysts for the Michael reaction.[2] As part of a programme aimed at the development of heterogenised base catalysts for use in the synthesis of fine chemicals, we have prepared two BINOL derivatives supported on silica **1** and **2**, and evaluated them in the Michael reaction.

The first catalyst, **1**, was prepared from γ-aminopropylsilica[3] (AMPS, **3**) and **4**, prepared by known methods[4,5] from the commercially available poly(ethylene glycol) methacrylate (Aldrich, $M_n$ = 306) by tosylation, displacement with the Na salt of BINOL, hydrolysis of the methacrylate, retosylation and displacement of the tosylate with **3** under reflux in toluene overnight (Fig. 1). Deprotonation of the BINOL unit was achieved by stirring with 1.5 equiv. NaOH in methanol (0.05 mol dm$^{-3}$) for 4 h, followed by exhaustive washing with methanol to remove excess base and physisorbed material. Thermogravimetric analysis (TGA) and elemental analysis were in agreement and indicated a loading of 0.2 mmol g$^{-1}$. The product was further analysed by $^{13}$C–CPMAS (300 MHz, δ 8.67, 18.00, 42.93 aminopropyl; 69.57 PEG, 127.04 + weak signal at 137–140 BINOL unit). The Diffuse Reflectance FTIR (DRIFT) spectrum of the product displayed the expected peaks for the BINOL unit at 1603, 1579 and 1510 cm$^{-1}$.



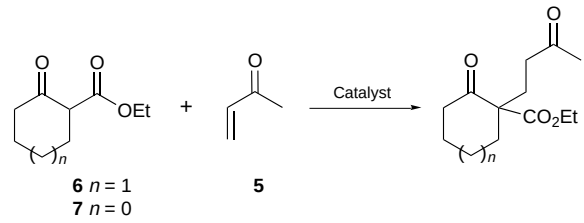


**Fig. 1** structures of the silica supported catalysts and precursor

The second catalyst, **2**, was prepared, also from **3**, in four steps (amide formation with 4-aminobenzoic acid,[3] diazotisation[6] and coupling with BINOL at pH 7, followed by deprotonation). The deprotonation procedure was the same for both catalysts. Elemental analysis was consistent with the proposed catalyst structure at a loading of 0.3 mmol g$^{-1}$, in accordance with weight loss as measured by TGA. Diffuse reflectance UV–VIS (DRUV) spectroscopy indicated a peak at 520 nm, which corresponds well to the diazo coupling product from 4-aminobenzoic acid and BINOL after physisorption on silica. Diffuse reflectance IR spectroscopy showed peaks at 1653 and 1565 cm$^{-1}$ (amide) and 1600, 1585 and 1506 cm$^{-1}$ (aromatics). The position of attachment of the N=N unit to the BINOL ring system is, as yet, unknown.

The products were evaluated as catalysts in the reaction of but-3-en-2-one **5** with the β-diketones ethyl cyclohexanone 2-carboxylate **6** and ethyl 2-oxocyclopentane-2-carboxylate **7** (Scheme 1). The catalyst (0.25 g), was added to a solution of diketone (10 mmol) and but-3-en-2-one (14 mmol) in solvent (15 ml). The reaction was stirred at room temp. and monitored

**Scheme 1** Michael addition between β-diketones and but-3-en-2-one, catalysed by supported BINOL catalysts

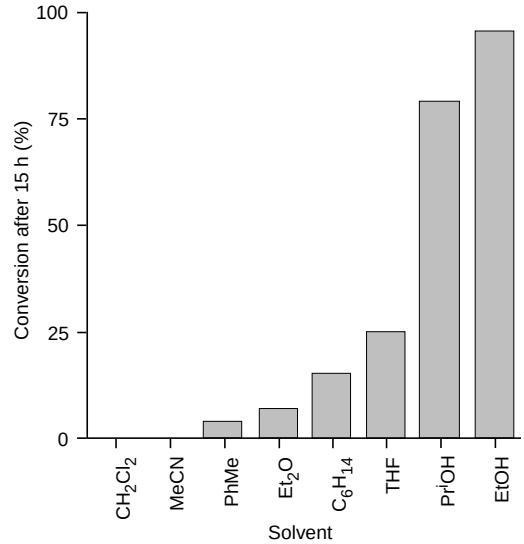

**Fig. 2** Solvent dependence in the reaction between **5** and **6** at room temp. (15 ml solvent, 0.2 g dodecane as internal standard, 14 mmol **5** and 10 mmol **6**). The reaction in isopropanol was complete after 24 h.

by GC using dodecane as internal standard. The reaction of **6** using **1** as catalyst was evaluated first and displayed a remarkable solvent dependence (Fig. 2). No reaction takes place in dichloromethane or in acetonitrile, with no product being detected even after 72 h. This is remarkable since the homogeneous version of this catalyst is used in dichloromethane.[2] Toluene is poor, and ethers (diethyl ether and THF) are slightly better. The best solvents by far are alcohols, with ethanol being particularly effective, complete reaction being achieved after 15 h (Fig. 2). It is possible that the oxygen-containing solvents are better able to interact with the PEG chain, particularly the hydrogen-bonding alcohols. The relatively good performance of hexane is puzzling (we have recently observed such anomalous behaviour in different systems[7]), and it may be due to partitioning effects. Isopropanol effected complete transesterification of the product under the reaction conditions. The product can be isolated by filtration of the catalyst and normal work-up, in yields typically 5–8% lower than the GC yield. Reuse of catalyst (after decantation of the supernatant) has been studied (Table 1), and there is a gradual slowing of reaction with repeated reuse (up to four uses). Conversions are close to complete and fall off only slightly with reuse. Compound **7** reacts more rapidly under the same conditions, reaction being complete after 8 h, as opposed to 15 h with **6**. Similar slowing of reaction was observed upon reuse.‡

Compound **2** was also evaluated in the above reactions, and was found to be slightly less active [reactions took 28 h (**6**) and 15 h (**7**) respectively]. Reuse was also successful, with less reduction in performance being observed than with **1**. While a thorough solvent study has not yet been carried out on this catalyst, reaction in dichloromethane does proceed, albeit slowly, to the extent of 8% in 24 h.§

Future work will concentrate on further optimisation of the systems and extension of the methodology to other phenols, Michael reactions and to enantioselective chiral BINOL systems.

D. J. M. thanks the Royal Society for the award of a University Research Fellowship.

**Table 1** Catalyst reuse in the reaction of **5** with **6** and **7**[a]

| Catalyst | Substrate | Conversion (%) | *t*/h |
|---|---|---|---|
| **1** | **6** | 97 | 15 |
| **1** (1 reuse) | **6** | 98 | 16 |
| **1** (2 reuses) | **6** | 99 | 19 |
| **1** (3 reuses) | **6** | 96 | 23 |
| **1** | **7** | 99 | 8 |
| **2** | **6** | 98 | 28 |
| **2** (1 reuse) | **6** | 98 | 29 |
| **2** (2 reuses) | **6** | 96 | 28 |
| **2** (3 reuses) | **6** | 97 | 30 |
| **2** | **7** | 99 | 15 |

[a] Reactions were carried out in 15 ml ethanol at room temp. with dodecane as internal standard, using 0.25 g catalyst, 10 mmol keto ester and 14 mmol enone. Isolated yields were 3–8% lower than the reported GC yields.

## Footnote

† E-mail address: djm13@york.ac.uk

‡ Turnover numbers for **1** and **2** can thus be estimated to be of the order of 800 and 530, respectively.

§ Leaching does not appear to be a problem with either catalyst, since reactions which were interrupted before completion by removal of catalyst did not procceed after removal of the catalyst.

# Stereospecific propene polymerisation catalysis using an organometallic modified mesoporous silicate

**Jonathan Tudor and Dermot O'Hare*†**

*Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*

**The mesoporous silicate, MCM-41 is modified by grafting the chiral alkene polymerisation catalyst *rac*-ethenebis(indenyl)zirconium dichloride onto the surfaces of the mesopore and used to produce highly isotactic polypropene with a unique spherulite morphology.**

Since homogeneous catalysts for alkene polymerisation were first reported in 1957,[1] there has been much interest both in academic and industrial circles in the application and evolution of new catalytic systems. Polypropene is probably the most marketable and versatile of the polyalkenes produced industrially and is found in many industries from the automotive trade to the leisure industry. Of the three forms of polypropene, the highly ordered, high molecular mass isotactic form is the most important. Under homogeneous conditions isotactic polypropene can be produced by chiral *ansa*-metallocenes such as *rac*-EBI–zirconium dichloride {EBI = 1,2-bis(inden-1-yl)-ethane} in combination with a co-catalyst, methylaluminoxane (MAO). Compared to polypropenes produced by classical heterogeneous Ziegler–Natta catalysts, molecular masses and melting points are low, making their products of little commercial worth for most technical applications. Kaminsky reported a silica-supported metallocene catalyst which yielded isotactic polypropene with high molecular masses and high melting points.[2] This is in contrast to previous studies of metallocenes supported on silica, where high activities for polymerisation were reported, but with low molecular masses and low melting points.

We have recently reported that the cationic zirconocenium alkene polymerisation catalyst, $[Zr(\eta\text{-}C_5H_5)_2Me(thf)]BPh_4$ can be readily ion-exchanged into modified charged 2 : 1 layered silicates.[3] With propene, the catalyst system produces atactic polymer with molecular masses some 25% greater than the homogeneous analogues, but with significantly lower activities. In an effort to produce new propene polymerisation catalyst systems which yield high molecular mass polypropylene with even greater specific isotacticities we have investigated the catalytic activity of mesoporous silicates with included chiral *ansa*-metallocenes.

As an alternative host support material we have investigated the use of the siliceous mesoporous material MCM-41.[4] The internal walls of MCM-41 are lined with silanol groups, the chemistry of which the chemist can exploit to develop modified materials; there has already been reports in the literature of the encapsulation of organometallic species inside the host channels.[5–7]

Incorporation of *rac*-[$ZrCl_2$(EBI)] into MCM-41 was achieved by heating a saturated solution of *rac*-[$ZrCl_2$(EBI)] with a suspension of a pre-treated MCM-41 suspension. The pre-treatment involves initial dehydration of the as-prepared materials and then subsequent treatment of the anhydrous material with an excess of a toluene solution of MAO at 50 °C for 24 h, followed by filtration, washing with toluene and drying under vacuum to give a white, air sensitive mesoporous material. The Al content as determined by elemental microanalysis, gave a loading of 6.1 mmol (Al) $g^{-1}$ of silicate, the C : H : Al ratio being 2.50 : 2.95 : 1. The final organometallic–silicate complex has a Zr loading of 0.35 mmol $g^{-1}$‡ as evidenced by elemental microanalysis. Inspection of the powder X-ray diffraction pattern after modification of the MCM-41 with MAO and then with *rac*-[$ZrCl_2$(EBI)] reveals that the reactions do not destroy the hexagonal framework of the mesoporous material; although the peak width at half maximum suggests a slight loss in crystallinity.

The material has been successfully used in the polymerisation of propene to yield highly isotactic polypropene. The results of polymerisation runs are outlined in Table 1; to serve as a comparison, polymerisation tests were also undertaken on the homogeneous system, *rac*-[$ZrCl_2$(EBI)] and *rac*-[$ZrCl_2$(EBI)] supported on a MAO modified clay.§ From the data it appears that the polymer properties are little affected by grafting the metallocene to the mesopore. This implies that during the course of the reaction between metallocene and the MCM-41 support, the metallocene has remained essentially structurally intact on the mesoporous material. However, due to the nature of the support, the possibility of there being active sites on the external surfaces of the mesopore which could be responsible for the polymerisation cannot be ignored.

Inspection of Table 1 reveals several interesting properties of the isotactic polypropene produced by the three different forms of *rac*-[$ZrCl_2$(EBI)]. With respect to activity, the homogeneous system proves to be the most active. Out of the two supported catalysts, the clay support proves to be more active than the mesoporous support by about threefold. A diffusion limiting effect could be partly responsible for the lower activity; whereby active metal centres located toward the centre of the mesoporous channels are effectively screened from approaching monomer units by active centres closer to the channel ends, which harbour growing polymer chains. The number average molecular masses ($M_n$) also vary for each sample. The clay-supported catalyst produced the highest $M_n$ value, with the values for the MCM-41 support slightly lower, but both of these showed an approximate fourfold increase in the number average molecular mass of the polypropene relative to the homogeneous system. The isotacticity of the three polymer samples has been investigated using $^{13}C$ solution NMR spectroscopy. The homogeneously produced polymer is the least isotactic, the two supported samples producing similar spectra indicative of highly isotactic polypropene. Differential scanning calorimetry of the polymer samples reveals that the MCM-41 produced material has the highest melting point of the three polymers at 141 °C, compared to melting points of 128 °C for polymer

**Table 1** Propene polymerisation activities and polymer properties

| Material[a] | Loading mmol (Zr) $g^{-1}$ | Activity Kg mol (Zr h)$^{-1}$ | $\bar{M}_n$[b]/(GPC) | Polydispersity |
|---|---|---|---|---|
| 1 | 0.35 | 1163 | 11849 | 1.95 |
| 2 | 2.39 | 4941 | 3110 | 1.91 |
| 3 | 0.14 | 3033 | 14038 | 1.92 |

[a] 1 = MCM-41–MAO–*rac*-[$ZrCl_2$(EBI)], 2 = *rac*-[$ZrCl_2$(EBI)], 3 = clay–*rac*-[$ZrCl_2$(EBI)]. [b] GPC *vs.* polystyrene, 140 °C in 1,2-dichlorobenzene, ratio of Zr : MAO was 1 : 1000 in each case.

produced homogeneously and 135 °C for the polymer produced by *rac*-[$ZrCl_2$(EBI)] supported on a layered silicate clay.

To assess morphological differences between the three isotactic polymer samples, scanning electron microscopy (SEM) was used. Figs. 1 and 2 show micrographs of homogeneously and MCM41 produced polymer samples, respectively. Inspection of the micrographs reveals striking differences between the two samples. The polymer produced by the homogeneous system (Fig. 1) consists of particles with a very porous open structure and appears to be composed entirely of sub-particles around 1 μm. A similar structure is observed for polymer produced by the clay support, except that the average particle size is much larger at *ca*. 10 μm. The micrograph also reveals the plate-like morphology of the clay material has been replicated in the polymer. The SEM micrograph for the MCM-41 produced IPP (Fig. 2) exhibits some quite remarkable

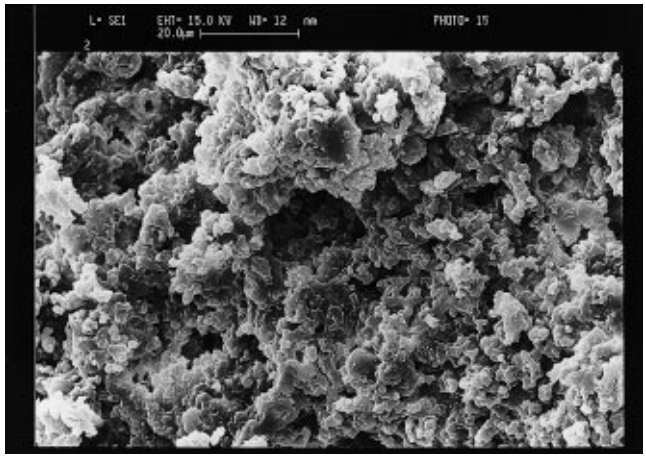

**Fig. 1** SEM micrograph of isotactic polypropene produced by a homogeneous solution of [$ZrCl_2$(EBI)]

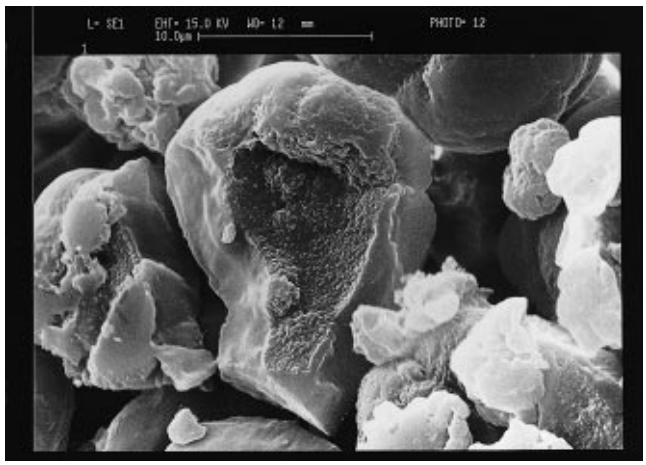

**Fig. 2** SEM micrograph of isotactic polypropene produced by MCM-41 supported [$ZrCl_2$(EBI)] showing the spherulite structure. The internal structure of the spherulites can be seen by examining a crushed particle.

features. The catalyst produces spherulite particles of approximate diameter 10 μm. The internal structure of the polymer grains can also be probed by crushing it at −120 °C and then re-examining the sintered particles with SEM. The micrograph of such a broken particle is shown in Fig. 2. This clearly shows that the very fine scale of the internal structure of the polymer is substantially different from the external structure; suggesting that the polymer consists of a distinct core and shell arrangement, a feature which is atypical for most homogeneously produced polymers. Similar freezing and sheering of the homogeneous and clay samples shows no difference between their internal and external morphology. The MCM-41 produced polymer was also studied under crossed polarising microscope. From the optical micrograph the sphericular nature of the polymer becomes clear from the large birefringent regions of the central particle. Spherulites are a morphological feature of bulk crystallised polymers with a large number of lamellar crystallites radiating in all directions from one central nucleus with well defined boundaries. The observation of birefringence in the optical measurement indicates a general tangential arrangement of the chains within the spherulites.

In conclusion, we have demonstrated the effectiveness of MCM-41 in providing a solid support for the homogeneous chiral catalyst *rac*-[$ZrCl_2$(EBI)] and its application toward controlling polymer morphology. Hence, polypropene produced by the MCM-41 derived catalyst consists of entirely of spherulite particles, with a distinct shell and core morphology. The polymer is highly isotactic and exhibits higher melting points than the corresponding homogeneous and clay supported system.

We would like to thank V. Murphy for polymer analysis, and Shell UK for financial assistance.

# Conformational change of protein cytochrome b-562 adsorbed on colloidal gold particles; absorption band shift

**An enormous and continuous shift of a surface plasmon resonance of gold particles is observed when protein cytochrome b-562 is adsorbed on to the surface.**

Organic–inorganic nanostructured composites provide a rich source of new functional materials for fundamental research and applications.[1–5] Examples include ordered mesoporous molecular sieves synthesized *via* a liquid-crystal surfactant template;[1,2] a low-cost, high-efficiency solar cell system of nanocrystallites covered by a chlorophyll derivative or related natural porphyrins;[3,4] and a polydiacetylene shell layer synthesized on a template of nanosized gold particles.[5] Although many interesting functional materials have been synthesized, it is still not clear how these organic functional molecules are deposited on, or affected by a solid boundary surface of nanoparticles; or what conformations and orientations are adopted. If the mechanism by which organic molecules are adsorbed on the solid surface of nanoparticles is clarified, it will open a wide opportunity in studying the basic physics and chemistry of nanostructure composite materials.

Here, we disclose our recent findings for optical coupling in an organic–inorganic nanostructure composite system of the protein cytochrome b-562 and colloidal gold particles. Although many studies, especially surface enhanced Raman scattering (SERS),[6–8] have been carried out for protein adsorption on solid surfaces, direct optical measurement at the protein's molecular level and conformational study of the protein on the surface of gold particles has scarcely been reported.

An aqueous gold colloidal solution was prepared by reduction of $HAuCl_4$ ($5 \times 10^{-3}$ mass%, solution 1) with citric acid (0.15 mass%, solution 2).[9] Solution 1 (750 ml) was heated at 100 °C for 12 min in an oil bath, and then solution 2 (37.5 ml) added. After *ca*. 2 min the boiling solution turned blue, and after 3 min became reddish purple. At this stage, the mean particle size was 31.0 nm with a narrow size distribution according to both transmission electron microscopy (TEM) and dynamic light scattering.[10,11] The dynamic light scattering method is a useful tool for measuring particle sizes in the range from 10 nm to several μm.

Cytochrome b-562 solutions of various concentrations were prepared (0.0003–0.16 g $l^{-1}$). The solution (0.2 ml) was added to the gold colloidal solution (20 ml) with vigorous stirring. Cytochrome b-562 is a small cylindrical[12] haem protein (height 5.0 nm, diameter 2.5 nm; Fig. 1) found in the periplasm of *Escherichia coli* with a chromophore (protohaem IX) about 3.5 nm from the base. A significant absorption occurs at 418 nm and smaller absorbances at 530 and 560 nm.

The surface plasma resonant absorption band of gold particles is located at *ca*. 530 nm.[13] The plasmon absorption band (at 530 nm) of the original 31.0 nm gold colloidal suspension was red-shifted and broadened upon adsorption of the protein. When only a small amount of the protein was added, much less than for full monolayer coverage, the interaction is weak and only a small shoulder emerged at *ca*. 650 nm. However, with increasing quantity of the protein, the interaction becomes stronger and the new peak is broadened and shifted to long wavelength (up to 750 nm).

Upon further addition of protein the absorption spectrum unexpectedly returned to that of the original colloidal solution and the absorption peak of isolated cytochrome b-562 appeared at *ca*. 418 nm arising from solution-phase protein. At this stage, composite particles and isolated protein co-exist and interaction between them becomes weak eventually non-existant at high protein concentration.

We introduce the concept of effective coverage to describe the status of adsorbed protein cytochrome b-562 on the surface of gold particles taking into account factors such as the shape of the protein and the protein electrostatic repulsive force to effect full coverage.

The effective coverage $\beta = 1.0$ and $\beta = 2.0$ refer to full coverage of cytochrome b-562 on the surface of gold particles in 'side-on' and 'tail-on' conformations respectively.

Fig. 2 shows the shifting of the long-wavelength absorption peak position as a function of the protein's effective coverage β. In the present experiment, as all of the protein is adsorbed on the particle surfaces, the surface coverage is linearly proportional to the amount of protein added to the solution. As the protein

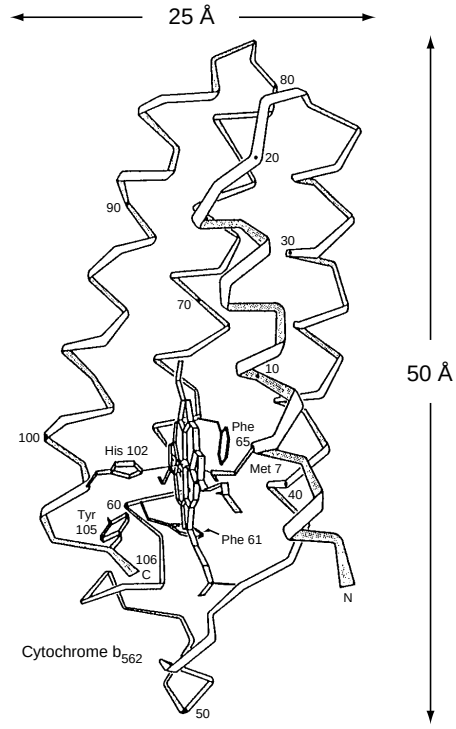

**Fig. 1** Schematic structure of cytochrome b-562

coverage increases, the peak position moves to longer wavelength until it reaches 750 nm and the effective coverage β at this point is 1.0, where the particle surface is covered by proteins in a 'side-on' conformation. The expected size of such a structure is verified by dynamic light scattering measurements. Further addition of the protein moves the peak back to its original position at 530 nm, although the composite particle size increases monotonously with the protein coverage. This indicates that the phenomenon of $\lambda_{max}$ moving back to its original value is not a consequence of separation of the protein and gold particles. We propose that the protein's adsorption conformation on the surface changes at a certain concentration. A model is proposed which considers two adsorption conformations of cytochrome b-562 on the gold surface. Namely, the 'side-on' conformation predominates at low concentrations ($\beta < 1.0$) while the 'tail-on' conformation predominates at high concentrations ($1 < \beta < 2$).

Different conformations of the protein lead to differences in the interaction distance between the gold surface and the interior chromophore of cytochrome b-562. In other words, the interaction between the gold particles and cytochrome b-562 depends strongly on the distance between the surface and the chromophore. The red-shift to 750 nm and spectral broadening occurred only for the 'side-on' conformation because the short separation in this case.

The model of the conformation change of the protein was supported by particle size measurement as determined by dynamic light scattering. Initially the diameter of the gold particles is 31.0 nm and it increases with protein coverage (Fig. 2). The composite particle size was 36 nm at the maximum spectral shift of the plasmon absorption band. At this stage, the protein b-562 is in a 'side-on' conformation on the gold surface. Since in such a conformation the width of the protein is 2.5 nm the value of 36 nm ($= 31 + 2 \times 2.5$ nm) is as expected for monolayer coverage. As the concentration is raised further the absorbed protein molecules start shifting conformation and eventually at a particle size of 40 nm, the interaction was so weak that the optical absorption spectrum was almost the same as the intrinsic absorption spectrum of the gold particles. The effective coverage β at this stage is 2.0 corresponding to effective full coverage of cytochrome b-562 on the surface of the gold particles in the 'tail-on' conformation. A size of 40 nm is also in accord with such a conformation. Further addition of protein leads to no change and no second layer coverage is observed with the additional protein isolated in solution as reflected by the absorption band od 418 nm.

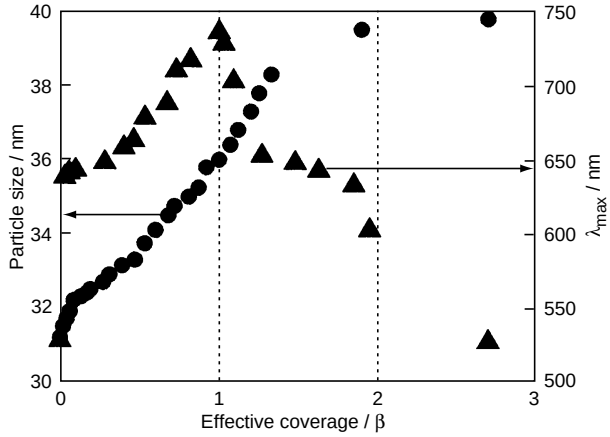

**Fig. 2** Changes of particle size and peak position of the longer wavelength plasmon band with surface protein effective coverage β

To summarise, changes in conformation of adsorbed protein have been optically detected, for the first time, by the shift of the resonant plasmon absorption arising from the distance-sensitive dielectric interaction between the protohaem within the protein and the gold surface.

**A binuclear ruthenium–manganese complex is synthesised; upon illumination the ruthenium transfers an electron to an external acceptor, then retrieves it by intramolecular electron transfer from the manganese.**

A key enzyme in green plant photosynthesis is Photosystem II (PSII).[1] Upon illumination, the chlorophyll $P_{680}$ in PSII transfers an electron to a series of acceptors, to give the $P_{680}^{+}$ cation which is then reduced back to $P_{680}$ by electron transfer (ET) (mediated by tyrosine-z) from a cluster of four manganese ions. After four consecutive ET events, the cluster recovers all four electrons in one step by oxidizing two water molecules to molecular oxygen.[2] We decided to study if simple model systems could be prepared, where a ruthenium(II) tris bipyridyl type complex on illumination transfers an electron to an external acceptor,[3,4] then recovers an electron by internal ET from a coordinated manganese ion. The bimetallic ruthenium(II) manganese(II) complex **1b** (Scheme 1) was found to be one model system of this type, and a suitable starting point for the development of multinuclear $RuMn_n$ complexes.

Our synthetic route started with the bridging ligand 1,2-bis[4-(4′-methyl-2,2′-bipyridyl)]ethane (Mebpy–Mebpy),[5] which was first treated with $[Ru(bpy)_2Cl_2]$[6] in refluxing methanol to give $[Ru(bpy)_2(Mebpy–Mebpy)]Cl_2$ **1a**.[7] On treatment with $MnCl_2$ in acetonitrile, **1a** gave the binuclear $Mn^{II}Ru^{II}$ complex **1b**. Complex **1b** was characterized by electrospray ionization mass spectrometry (ESIMS), elemental analysis and X-band electron paramagnetic resonance (EPR) techniques. The distance between $Mn^{II}$ and $Ru^{II}$ in **1b** was estimated by molecular mechanics calculations to *ca.* 13 Å for the most extended conformation, which should allow efficient electron transfer.[8]

**Scheme 1** Proposed pathway for the electron transfer following irradiation of **1b** in the presence of $MV^{2+}$ in acetonitrile solution; (*i*) photoinduced intermolecular electron transfer, generating $Ru^{III}$ and $MV^{+\cdot}$; (*ii*) intramolecular electron transfer from $Mn^{II}$ to $Ru^{III}$

Comparison of the emission spectra of **1b**, **1a** and $[Ru(bpy)_3]^{2+}$[9] in acetonitrile solution showed that the wavelength of the emission maximum (*ca.* 615 nm) was essentially the same in all three cases, but the emission was considerably quenched in **1b** ($\tau \approx 260$ ns) compared to **1a** ($\tau \approx 980$ ns) and $[Ru(bpy)_3]^{2+}$. The manganese thus interacts with the excited state of ruthenium complex, but it does not quench the emission completely.

Flash photolysis experiments in the presence of 5–10 mM of an acceptor, methyl viologen ($MV^{2+}$), were performed in an acetonitrile solution of **1a**, **1b** and $[Ru(bpy)_3]^{2+}$, respectively. Following a laser flash ($\lambda_{ex} = 458$ nm), a rapid electron transfer from $Ru^{II}$* to $MV^{2+}$ took place[4] (Scheme 1, step i) with a lifetime of *ca.* 200 ns for complex **1a**. The regeneration of $Ru^{II}$ (monitored by the absorption at 452 nm) and the decay of the $MV^{+\cdot}$ radicals (monitored by the absorption at 600 nm) followed similar second-order kinetics with rate constants of *ca.* $5.0 \times 10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$. Thus the products of the charge separation recombine on the timescale of a few hundred μs when a few μM of the products were created. The behaviour of $[Ru(bpy)_3]^{2+}$ was identical. For the bimetallic $Mn^{II}Ru^{II}$ complex **1b**, the $MV^{+\cdot}$ radical was generated, and decayed with the same rate as in the experiments with **1a** and $[Ru(bpy)_3]^{2+}$.† In contrast, the regeneration of $Ru^{II}$ from the photoproduced $Ru^{III}$ was found to be one order of magnitude faster than for **1a** and $[Ru(bpy)_3]^{2+}$. This means that the photo-oxidized $Ru^{III}$ moiety in **1b** must have received an electron from another source than $MV^{+\cdot}$, and one that is not present in **1a** and $[Ru(bpy)_3]^{2+}$.

Analysis of the transient absorbance recovery traces for **1b** over the concentration range examined {[**1b**] = $(2–10) \times 10^{-5}$ M} revealed a concentration independant first-order kinetic process with a rate constant $k = 1.5 \times 10^5$ s$^{-1}$. This we ascribe to the intramolecular ET from the $Mn^{II}$ moiety to the photogenerated $Ru^{III}$ moiety (Scheme 1, step ii). Separate experiments were performed in order to prove that the $Mn^{II}$ moiety could be oxidized to $Mn^{III}$ by $Ru^{III}$. Both manganese(II) ($S = 5/2$) and ruthenium(III) species give rise to distinct EPR spectra. When equimolar amounts of $[Ru(bpy)_3]^{3+}$ and complex **1b**, which contains $Mn^{II}$, were reacted, both EPR signals disappeared, showing that the reactants had been converted completely to the corresponding ruthenium(II) and manganese(III) species. The decay of $MV^{+\cdot}$ radical in the photolysis experiment with **1b** was probably due to recombination with $Mn^{III}$.

We would like to thank the Swedish Natural Science Research Council and the Knut and Alice Wallenberg Foundation for supports and Drs G. Stenhagen and J. Mårtensson, Chalmers University of Technology, for ESIMS measurements.

## Footnote

† In experiments without $MV^{2+}$ no products of the Ru-quenching by Mn were seen. Thus, even if the quenching mechanism could be reductive, the $Mn^{III}$–$Ru^{I}$ recombination would be much faster, so that the production of $MV^{+\cdot}$ *via* diffusional encounter with $Ru^{I}$ would be negligible.

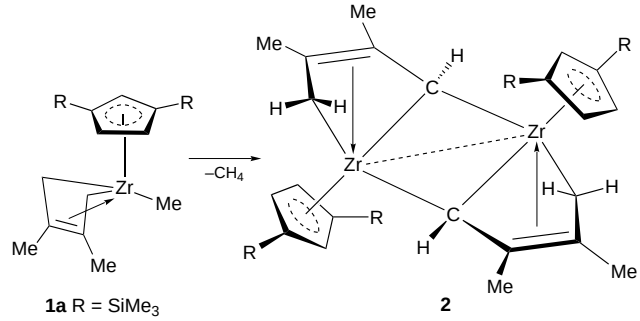
# Facile α-C–H activation in 14-electron zirconium half-sandwich compounds: evidence for a new catalyst deactivation pathway

**Gerardo Jimenéz Pindado, Mark Thornton-Pett and Manfred Bochmann***



*School of Chemistry, University of Leeds, Leeds, UK LS2 9JT*

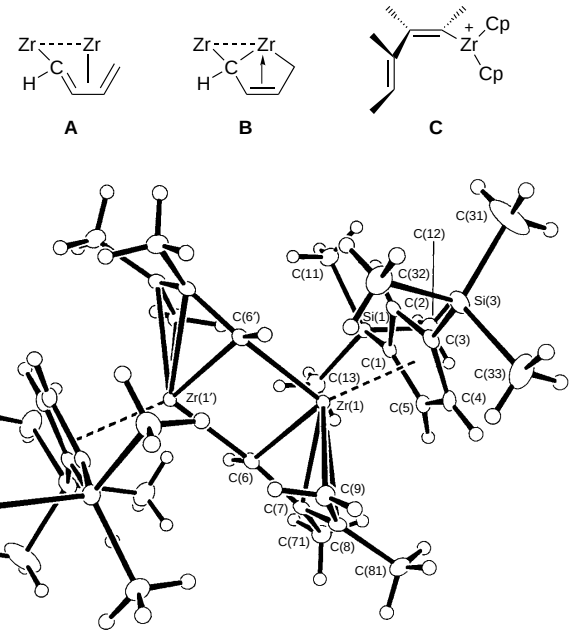
**The electron-deficient zirconium diene complex [Zr(Cp″)Me($C_4H_4Me_2$-2,3)] [Cp″ = $C_5H_3(SiMe_3)_2$-1,3] cleanly eliminates methane to give an unusual dinuclear dienyl complex [Zr(Cp″)(μ-η¹ : η⁴-$C_4H_3Me_2$-2,3)]$_2$, characterised by a new type of μ-η¹ : η⁴-butadienyl coordination mode; the complex and its zwitterionic reaction product with $B(C_6F_5)_3$ provide support for catalyst deactivation processes involving alkane elimination reactions.**

Electron deficient group 4 metallocene and half-sandwich complexes are known to give rise to extremely active alkene polymerisation catalysts.[1] The activity profile of these catalysts typically shows a very high initial activity, followed by an exponential decay to a lower steady-state level after some time. Little is known however about the nature of the deactivation processes involved. The kinetics of propene polymerisation with [Zr(η-$C_5H_5)_2Cl_2$]–methylaluminoxane catalysts suggest a catalyst deactivation process which is second order in [Zr].[2] We have previously shown two types of C–H activation processes which may be relevant in this context: α-C–H activation leading to dinuclear cationic μ-$CH_2$ zirconium fulvalene complexes,[3] and the formation of μ-$C_2H_4$-bridged species by a β-elimination process.[4] We report here the facile decomposition of a neutral catalyst precursor *via* an α-C–H activation process, to give a dinuclear dienyl complex exhibiting a novel μ-η¹ : η⁴-butadienyl coordination mode.

The reaction of [Zr(Cp″)Cl(η⁴-2,3-dimethylbutadiene)] [Cp″ = $C_5H_3(SiMe_3)_2$-1,3] with methyllithium in diethyl ether affords the methyl complex [Zr(Cp″)Me(η⁴-2,3-dimethylbutadiene)] **1a** which can be isolated at room temperature as a red solid in > 80% yield. The analogous hafnium complex **1b** is similarly obtained as a spectroscopically pure yellow oil.† These isolated compounds are thermally more stable than related $C_5Me_5$ derivatives which have to be kept below 0 °C.[5] However, monitoring the behaviour of **1a** by NMR spectroscopy over a period of time revealed a slow clean transformation to a new product at room temperature, with elimination of methane. Attempts to recrystallise **1a** from light petroleum at −16 °C led to the isolation of deep red crystals of [Zr(Cp″)(μ$_2$-η¹ : η⁴-$C_4H_3Me_2$-2,3)]$_2$ **2** in *ca.* 40% yield, evidently formed by abstraction of a methylene hydrogen from the diene ligand (Scheme 1).

Compound **2** was identified spectroscopically† and shows a characteristic $^{13}C$ NMR resonance at δ 175 for the μ-CHR carbon. Single-crystal X-ray diffraction‡ confirmed the dinuclear structure of **2** and revealed the novel coordination mode of the butadienyl ligand (Fig. 1). Each half of the molecule forms a (cyclopentadienyl)zirconium(butadienyl) sandwich with an almost symmetrical μ-CHR bridge [Zr(1)–C(6) 2.216(2), Zr(1)–C(6′) 2.191(2) Å]. The four sp²-hydridised carbon atoms of the butadienyl moiety are coplanar and η⁴-coordinated. As in mononuclear diene complexes[6] the bonding in the dienyl moiety may be described by two resonance structures **A** and **B**, with a significant contribution of a zirconacyclopentene resonance structure **B** to account for the bond length distribution within the $C_4$ unit. The [Zr(dienyl)]$_2$ moiety in **2** closely resembles the 'envelope' structure of a Zr(diene) complex in which one diene α-hydrogen is replaced by a zirconium atom. The geometry of the butadienyl ligand in **2** contrasts sharply with that in the zwitterionic 16-electron metallocene complex [{($C_6F_5)_3BC_5H_4$}(η-$C_5H_5$)Zr($C_4HMe_4$-1,2,3,4)] where the dienyl ligand is η¹-bonded, with a long C(2)–C(3) single and short C(1)–C(2) and C(3)–C(4) double bonds (**C**), and where coordination of an *o*-F atom of a $C_6F_5$ unit is favoured over the interaction of the diene with the metal centre.[7] The Zr–Zr distance of 3.1516(5) Å in **2**, with a formal electron count of 14 per Zr centre, is short compared to the metal–metal distance in 16 electron metallocene dimers such as [($C_5H_4Me)_2$ZrH(μ-H)]$_2$ (3.46 Å);[8] to our knowledge there are

**Scheme 1**



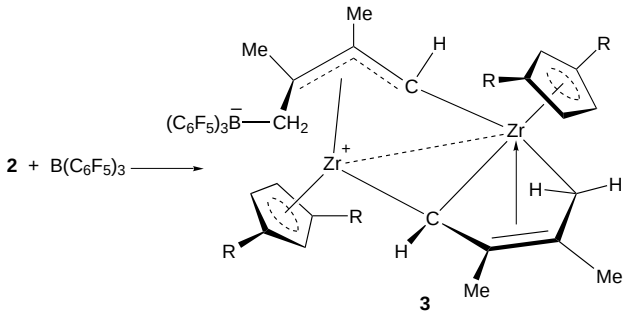


**Fig. 1** Crystal structure of **2** (H atoms omitted for clarity). Selected bond lengths (Å) and angles (°): Zr(1)–Zr(1′) 3.1516(5), Zr(1)–C(1) 2.497(2), Zr(1)–C(2) 2.501(2), Zr(1)–C(3) 2.556(2), Zr(1)–C(4) 2.558(2), Zr(1)–C(5) 2.520(2), Zr(1)–C(6′) 2.191(2), Zr(1)–C(6) 2.216(2), Zr(1)–C(7) 2.470(2), Zr(1)–C(8) 2.480(2), Zr(1)–C(9) 2.289(2), C(6)–C(7) 1.435(3), C(7)–C(8) 1.409(3), C(8)–C(9) 1.443(3) Å; C(6)–Zr(1)–C(6′) 88.69(8), Zr(1)–C(6)–Zr(1′) 91.31(4°), H(6)–C(6)–C(7) 115(2)°, C(6)–C(7)–C(8) 122.1(2)°, C(7)–C(8)–C(9) 123.7(2)°.

**Scheme 2** R = $SiMe_3$

only two previous examples of dinuclear 14-electron complexes with comparable Zr–Zr bond lengths.[9] Evidently electron deficiency significantly favours metal–metal interactions. The hafnium compound **1b** decomposes less cleanly than **1a**, to give a mixture of products which could not be separated. There was, however, no evidence for the formation of a dinuclear hafnium analogue of **2**.

Treatment of **2** with $B(C_6F_5)_3$ leads to the zwitterionic complex **3** (Scheme 2). Only one of the two butadienyl ligands is attacked by the borane, even in the presence of an excess of $B(C_6F_5)_3$. At −50 °C the $^{19}F$ NMR spectrum shows six signals for the *o*-F atoms of three different $C_6F_5$ substituents, indicative of hindered rotation; there is however no evidence for an *ortho*-F···Zr coordination, unlike in the structurally related zwitterionic allyl complex $[Zr(\eta\text{-}C_5H_5)_2(\eta^3\text{-}CH_2CHCHCH_2\text{-}B(C_6F_5)_3]$.[10]

Toluene solutions of **1a** do not react with ethene (1 bar) at 0 °C§ but on addition of 1 equiv. of $B(C_6F_5)_3$ catalyse the polymerisation of ethene with a productivity of $3 \times 10^4$ g PE (mol Zr)$^{-1}$h$^{-1}$. Related allyl complexes $[Zr(Cp'')(\eta^3\text{-allyl})(\text{diene})]$ are similarly active.[11] By contrast, complex **3** is inactive under identical conditions, though some polymerisation takes place on warming to 64 °C. These findings support the notion that, apart from hydrolysis reactions and the intervention of nucleophilic impurities, deactivation of metallocene-type polymerisation catalysts is linked to the formation of dinuclear products as a result of a number of C–H activation pathways.

We thank the EPSRC and the Science and Education Ministry of Spain for support of this work.

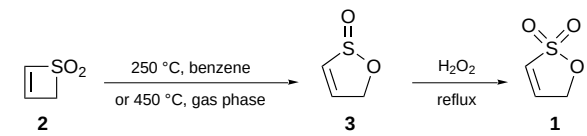
# Synthesis and Diels–Alder reactions of α,β-unsaturated γ-sultone

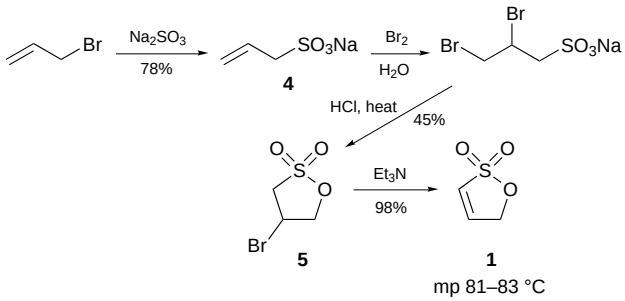
**Albert W. M. Lee,* W. H. Chan,* L. S. Jiang and K. W. Poon**

*Department of Chemistry, Hong Kong Baptist University, Kowloon Tong, Kowloon, Hong Kong*



**An efficient synthesis of prop-1-ene 1,3-sultone 1 and its Diels–Alder reactions are reported; ring-opening reactions of the cycloadducts with nucleophiles and transformations to the sultams were also investigated.**

Sultones are cyclic esters of the corresponding hydroxysulfonic acid, the sulfur analogues of lactones. The preparation and chemistry of saturated sultones of 4- to 6-membered ring sizes are relatively well studied.[1] However, there is less investigation of the chemistry of the unsaturated sultones, in particular, the α,β-unsaturated γ-sultone prop-1-ene 1,3-sultone **1**. We have long been interested in the uses of sulfur-containing functional groups for the activation of acetylenic or vinyl moieties resulting in useful synthons for organic synthesis.[2] We here report a synthesis of **1**, its Diels–Alder reactions and some further transformations of the cycloadducts.



There are only limited accounts in literature for the synthesis of **1**. Thermolysis of thiete 1,1-dioxide **2** yielded sultine **3** which could be oxidized to **1** (Scheme 1).[3] It had also been reported that distillation of 3-hydroxyprop-1-ene-1-sulfonic acid, which was synthesized from prop-2-ynyl alcohol *via* free radical sulfitation, also afforded **1**.[4] These reported procedures were not efficient and practical enough for the laboratory synthesis of the compound. Our synthesis of **1** is shown in Scheme 2. Sodium prop-2-enesulfonate **4** could be prepared from allyl bromide and sodium sulfite in good yield.[5] Bromination of **4** in water gave the dibromide which was not isolated. Vacuum distillative cyclization of the dibromide under acidic conditions afforded β-bromo sultone **5** in 45% isolated yield from **4**. Treatment with amine base in benzene solution at room temperature afforded **1**† as a white crystalline solid in good yield.

The dienophilicity of unsaturated sultone **1** in the Diels–Alder reaction was investigated. Sulfonate has been used as an activating group for olefinic dienophiles, for example, vinyl sulfonates were found to be reactive dienophiles in both intermolecular[6] and intramolecular[7] Diels–Alder reactions. The results of Diels–Alder reactions of **1** towards a series of simple dienes are summarized in Table 1.‡ For a reactive diene such as cyclopentadiene, despite the slow reaction rate, reaction with **1** could take place at room temperature with moderate *endo* : *exo* selectivity. At a higher temperature, the reaction could be completed in 4 h. The *endo*-**6** and *exo*-**7** isomers could be easily separated by column chromatography. For less reactive dienes, elevated temperature or sealed tube conditions were used. In the cases of cyclohexa-1,3-diene and 2,3,4,5-tetrachloro-1,1-dimethoxycyclopentadiene, the *endo*-isomers were the only isolated products. For unsymmetrical dienes, 1 : 1 inseparable mixture of regioisomers resulted.

The sultone cycloadduct could be further manipulated by ring-opening with various nucleophiles such as alcohols, amines and thiols at the γ-position. Selected examples are depicted in Schemes 3 and 4. The alkoxide reacted smoothly with cycloadducts **6** and **8** at room temperature to afford the ring opening products **9a**,**b** in quantitative yields. Similarly, amine and thio compounds also reacted with the cycloadducts in

**Scheme 4**

methanol solution to afford the ring-opening products **10** and **11**, respectively. Compounds **10a** and **10b** were further cyclized to sultams **12a** and **12b** in good yield upon treatment with $POCl_3$ in THF. In this regard, unsaturated sultone **1** could be viewed as the synthetic equivalent of unsaturated sultam **13**[8] as dienophile in the Diels–Alder reaction.

Financial support from the Research Grant Council (HKBC 136/94P) is gratefully acknowledged.

# Lanthanide(III) triflates as recyclable catalysts for atom economic aromatic nitration

**Francis J. Waller,*[a] Anthony G. M. Barrett,*[b] D. Christopher Braddock[b] and Dorai Ramprasad[a]**

[a] *Air Products and Chemicals, Inc., 7201 Hamilton Boulevard, Allentown, PA 18195-1501, USA*

**Lanthanide(III) triflates catalyse (1–10 mol%) the nitration of a range of simple aromatic compounds in good to excellent yield using stoichiometric quantities of 69% nitric acid; the only by-product is water and the catalyst can be readily recycled by simple evaporation.**

Nitration of aromatic compounds is an immensely important industrial process.[1] The nitroaromatic compounds so produced are themselves widely utilised and act as chemical feedstocks for a great range of useful materials such as dyes, pharmaceuticals, perfumes and plastics. Unfortunately nitrations typically require the use of potent mixtures of concentrated or fuming nitric acid with sulfuric acid leading to excessive acid waste streams and added expense. Alternatively, nitric acid may be used in conjunction with strong Lewis acids such as boron trifluoride.[2] The Lewis acid is used at or above stoichiometric quantities and is destroyed in the aqueous quench liberating large amounts of strongly acidic by-products. With chemists under increasing pressure to perform atom economic processes[3] with minimal or no environmentally unfriendly by-products, development of novel catalyst systems that facilitate aromatic nitrations in this manner should be of great importance.[4]

Lanthanides have found increasing use as mild and selective reagents in organic synthesis.[5] In particular, lanthanide(III) triflates[6,7] have been used to good effect as Lewis acids in Diels–Alder,[8] Michael,[9] Friedel–Crafts[10] and Mukaiyama[11] reactions. For the Mukaiyama reaction the optimum solvent system was found to be aqueous THF; the catalyst was recycled *via* aqueous work-up and used repeatedly with little detriment to rate or yield. The compatibility of lanthanide(III) triflate salts with water and yet their apparent ability to function as strong Lewis acids is somewhat paradoxical. We sought to harness this water tolerant Lewis acidity and herein report the use of catalytic quantities of lanthanide(III) triflates for the nitration of a range of simple aromatic compounds in good to excellent yield using a stoichiometric amount of 69% nitric acid where the only by-product is water. Furthermore the catalyst is readily recycled by a simple evaporative process.

Ytterbium(III) triflate was selected as the most promising candidate for the proposed nitrations. Accordingly a range of simple aromatic compounds were treated with 1 equiv. of 69% nitric acid in 1,2-dichloroethane heated at reflux in the presence of 10 mol% ytterbium(III) triflate.The results are shown in Table 1. No dinitrated products were observed in any case and in accord with this the system failed to nitrate nitrobenzene. In the control experiments with no catalyst, only slow reaction occurred and no more than 10% of nitrated products were observed. Ytterbium triflate was found to be effective even at catalyst loadings as low as 1 mol% and with *m*-xylene the reaction had proceeded to 80% conversion after 12 h.

The following procedure is representative. Nitric acid (69%; 192 μl, 3.0 mmol) was added to a stirred suspension of ytterbium(III) triflate (186 mg, 0.30 mmol) in 1,2-dichloroethane (5 ml). The suspension dissolved to give a two phase system in which the aqueous phase was the more dense. Toluene (240 μl, 3.0 mmol) was added and the stirred mixture was heated at reflux for 12 h. During the reaction a white solid precipitated and the organic phase became yellow, and after 12 h no phase boundary was apparent. The solution was allowed to cool and diluted with water. The yellow organic phase was dried ($MgSO_4$) and evaporated to give nitrotoluene (390 mg, 95%). The colourless aqueous phase was evaporated to give ytterbium(III) triflate as a white free-flowing solid (183 mg, 98%).

A series of other metal triflate salts were screened for catalytic activity (Table 2). Scandium triflate was found to have comparable catalytic activity to that of the corresponding ytterbium salt, but praseodymium, europium and lanthanum triflates, although active, were found to be somewhat less effective.

The recovered catalyst was found to be active for further nitrations with no reduction in rate or yield and with no change in selectivity. The results from four successive nitrations with *m*-xylene are shown in Table 3. On one occasion the white precipitate obtained from the nitration mixture with lanthanum(III) triflate consisted of crystals of the known lanthanum(III) triflate nonahydrate.[12]† These crystals were also found to have an identical diffuse reflectance IR spectrum to that of the amorphous recovered material and also that of the commercial

**Table 1** Nitration of aromatics in the presence of ytterbium(III) triflate[a]

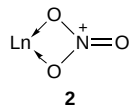
| Pr | 65 | 88 | 12 |
| Sc | 85 | 85 | 15 |
| Yb | 88 | 85 | 15 |



[a] All reactions performed with 10 mol% lanthanide(III) triflate, 1 equiv. each of *m*-xylene and 69% nitric acid in refluxing dichloromethane (15 ml) for 18 h. [b] Commercially available hydrated forms. [c] GC analysis.

available lanthanide salt.‡ As expected the crystals were found to catalyse the nitration reaction.

The nature of the *de facto* nitration agent is not known at present. The different rates with various lanthanide triflates indicate that the metal centre is involved. Nitric acid–triflic acid mixtures are known to effect nitration[13] but free triflic acid seems unlikely in our system since ytterbium(III) triflate yields a near-neutral solution when dissolved in water.§ The relative ratios of the various nitroaromatic isomers produced are fully consistent with electrophilic attack by $NO_2^+$ or more probably an $NO_2^+$ carrier of the type **1**[1]. However, bidentate lanthanide nitrates **2** are well characterised compounds,[14] and nitration

**1**

**2**

may proceed *via* direct attack of such a (protonated) species. Bidentate metal nitrates have been implicated in nitrations with titanium tetranitrate[15] and ceric ammonium nitrate[16] where the arene is thought to attack the metal bound nitrate species directly.

In conclusion, we have demonstrated the catalytic use of lanthanide(III) triflates for the atom economic nitration of simple aromatic substrates where the only by-product is water. The catalyst is readily recyclable and we believe this to be a major step forward in the area of clean technology for aromatic nitration.

The Imperial College group thank Air Products and Chemicals, Inc. for support of our research under the auspices of the joint Strategic Alliance, Glaxo Group Research Ltd. for the most generous endowment (to A. G. M. B), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, the EPSRC and Dr David Williams and Dr Andrew J. P. White for the single crystal X-ray structure determination of lanthanum(III) triflate nonahydrate.

**Table 3** Recycled ytterbium(III) triflate[a]

| Run | Conversion (%)[b] | Mass of catalyst/mg[c] |
|---|---|---|
| 1 | 89 | 190 ( > 100) |
| 2 | 81 | 152 (82) |
| 3 | 90 | 127 (68) |
| 4 | 88 | 115 (62) |

[a] All runs performed with 3 mmol *m*-xylene, 10 mol% ytterbium triflate (run 1) and 1 equiv. of nitric acid in refluxing 1,2-dichloroethane (5 ml) for 5 h. [b] GC analysis. The isomeric ratio of 4- and 2-nitroxylene was unchanged throughout (85:15 respectively). [c] Mass of ytterbium(III) triflate recovered from each run. The figures in parenthesis indicate the percentage recovery which were not optimised.

## Footnotes

† A single crystal X-ray diffraction showed the material to be identical with the known lanthanum(III) triflate nonahydrate where the nine water molecules occupy the first co-ordination sphere in a tricapped trigonal prism arrangement with triflate counterions

‡ Aldrich chemical company

§ The pH of a 0.08 M solution of ytterbium(III) triflate in water was determined to be 6.40.[7]

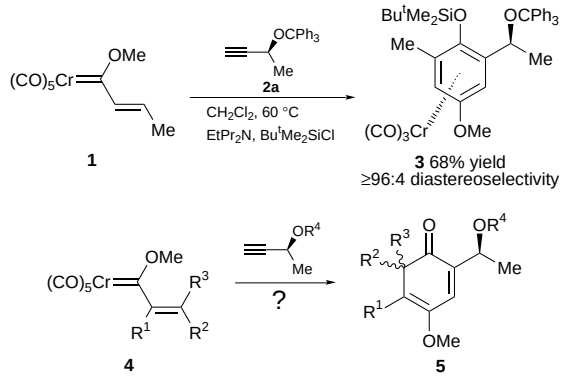
# 1,4-Asymmetric induction in the formation of cyclohexadienones by chirality transfer from a transiently installed chromium–stereospecific electrocyclic ring closure of a metal complexed vinyl ketene

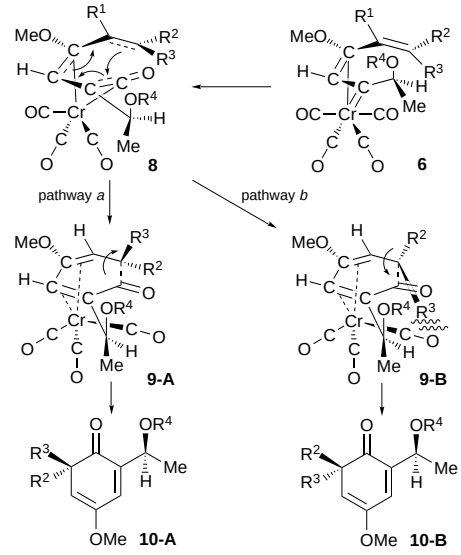


**Richard P. Hsung,[a] John F. Quinn,[a] Brian A. Weisenberg,[a] William D. Wulff,*[a] Glenn P. A. Yap[b] and Arnold L. Rheingold[b]**

[a] *Department of Chemistry, Searle Chemistry Laboratory, The University of Chicago, Chicago, Illinois 60637, USA*
[b] *Department of Chemistry, University of Delaware, Newark, Delaware 19716, USA*

**The cyclohexadienone annulation of a β,β-disubstituted vinyl chromium carbene complex and a chiral prop-2-ynylic ether results in high 1,4-asymmetric induction at the newly formed quaternary carbon; the stereochemical information from the prop-2-ynylic ether is initially transfered to the chromium coordination sphere and then to the quaternary carbon of the cyclohexa-2,4-dienone.**

We recently reported the first examples of an asymmetric synthesis of an arene chromium tricarbonyl from a benzannulation reaction.[1,2] The formation of the arene complex **3** occurs *via* 1,2-induction from the prop-2-ynylic carbon to the chiral centre of the complexed arene (Scheme 1). This success prompted us to investigate the cyclohexadienone annulation of β,β-disubstituted vinyl carbene complexes **4** with chiral prop-2-ynyl ethers.[3] We report here that this reaction occurs with significant 1,4-asymmetric induction and that the sense of induction provides the first experimental determination of the stereoselectivity associated with the elctrocyclic ring closure of a metal complexed vinyl ketene intermediate.



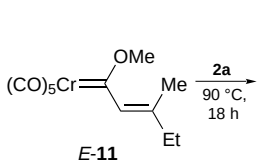
The expectation that a 1,4-asymmetric induction would occur with high fidelity was not at all clear for several reasons. First, the vinyl carbene complex **4** may undergo *cis–trans* isomerization. Although rates of isomerization for β,β-disubstituted complexes have not been reported, it is known that the *cis*-propenyl complex (**4**, $R^3$ = Me, $R^2$, $R^1$ = H) will isomerize to the *trans*-propenyl complex **1** at a rate competitive with its reaction with pent-1-yne.[4] This unpropitious result does not bode well for the stereoselective synthesis of the cyclohexadienone **5**. Additionally, the stereochemistry associated with the electrocyclic ring closure of the vinyl ketene complex has not been previously discussed or examined experimentally.[5] According to the most likely mechanism,[5,6] the ring closure occurs *via* a six electron electrocyclic reaction of the vinyl ketene complex **8** (Scheme 2). However, since the arene complex **3** must be derived from the vinyl carbene intermediate **6** and not its diastereoisomer **7** (not shown), and since only a single diastereoisomer of **3** is formed, it is likely that only one diastereoisomer of the vinyl ketene complex is formed. Therefore, while the selective formation of **3** reveals that the chiral centre on the prop-2-ynylic alkyne must induce a stereoselective coordination of the chromium, the selective formation of cyclohexadienone **5** requires that the chromium in ketene complex **8** induces a selective electrocyclic ring closure. This could occur by either pathway *a* or *b* as indicated in Scheme 2.

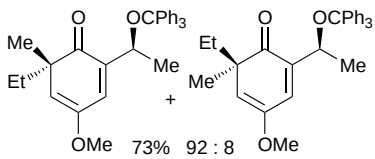
**Scheme 1**

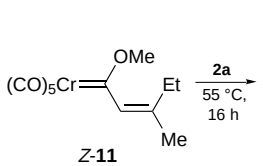
The reactions of carbene complexes **11** and **12** with alkyne **2** are both stereoselective and stereospecific (Table 1). Complex *E*-**11** gives cyclohexadienone **13** with an α-ethyl group (92 : 8) while the *Z*-isomer gives cyclohexadienone **14** with a β-ethyl group (91 : 9). The reaction of complex **12** is also stereospecific. The isomerically pure *E*-**12** gave a 90 : 10 mixture of **15** and **16** and a 60 : 40 mixture[8] of *E*-**12** and *Z*-**12** gave a 68 : 32 mixture of **15** and **16**. In both cases, the substituent $R^3$ *syn* to the carbene unit is selectivity incorporated *syn* to the trityloxy group when the product is drawn as shown. If the alkoxy substituent $R^4$ is changed from $CPh_3$ to TBS the selectivity drops from 9 : 1 to 4.6 : 1. This appears to be due to electronics rather than sterics.[1,9] When a heptane solution of *E*-**11** was heated at 90 °C for 14 h no isomerization could be detected. Likewise, when *E*-**12** was heated in heptane at 85 °C for 11 h no isomerization could be detected. These results suggest that the carbene complexes do not isomerize under the reaction conditions.

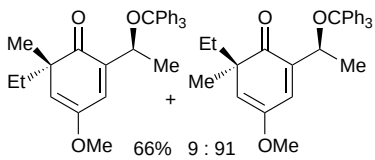
The stereochemical assignments for the dienones were made on the basis of an X-ray structure of dienone **15a**.† Correlation of the $^1$H NMR spectra of **15a** and **16a** with **13** and **14** then leads to the assignment of the major product from the reaction of complex *E*-**11** as the cyclohexadienone **13**. In a similar fashion

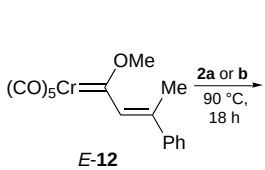
**Scheme 2**

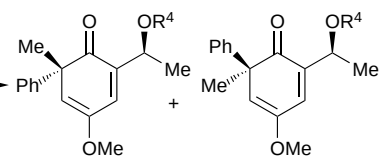




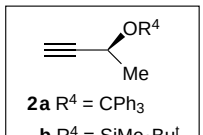








the stereochemistry of the major product from the reaction of *E*-**12** with **2b** was assigned as **15b**. The stereochemistry of the cyclohexadienone products allows for an assignment of the direction of the electrocyclic ring closure. The favoured pathway is thus with the rotation of the substituent $R^3$ up and away from the metal centre in the vinyl ketene complex **8** to give the cyclohexadienone metal complex **9**-**A**. Downward rotation of $R^3$ (pathway *b*) is apparently disfavoured due to severe close-contacts with the metal and its ligands. The overall stereo-induction begins with the prop-2-ynylic chiral centre which leads to a stereospecific coordination of the chromium to the lower face of the vinyl ketene complex **8**. This in turn leads to stereo-induction in the formation of the quaternary carbon centre formed in the ring closing step. This represents an overall 1,4-induction with a stereochemical relay *via* a transiently installed metal centre.



An alternative mechanism for the observed stereo-induction involves a 16 $e^-$ $\eta^2$-vinyl carbene complex which could be derived from decoordination of the double bond in **6**, followed by the formation of the vinyl ketene complex **8** according to the allochemical mechanism.[10] This would involve a 1,2-induction in the formation of an $\eta^2$-coordinated vinyl ketene complex. This possibility is not considered here because of evidence which suggests that the allochemical mechanism is not operative when hexane is the solvent.[6a] The less than complete stereoselection observed in these reactions may not necessarily be due to rotation of $R^3$ through the metal centre in the vinyl ketene complex **8**. Rather, it may reflect the level of stereoselection associated with the introduction of the metal to a particular face of the vinyl carbene species in intermediate.‡

In the light of the synthetic importance of both the benzannulation reaction and the cyclohexadienone annulation, further studies on the mechanism of these reactions are being pursued. Additionally, synthetic applications for the stereospecific cyclohexadienone annulation are being explored.

This was supported by the National Institutes of Health (GM 33589)

**Table 1** 1,4-Induction with stereoisomerically pure vinly carbene complexes[a2]

| Carbene complex[b] | Cyclohexadienones |
|---|---|
|  *E*-**11** (68%) |  **13** 73% 92 : 8 **14** |
|  *Z*-**11** (56%) |  **13** 66% 9 : 91 **14** |
|  *E*-**12** (57%) |  **15** **16** |

72% 90 : 10 $R^4$ = $CPh_3$
68% 80 : 20[c] $R^4$ = $CPh_3$
65% 68 : 32[d] $R^4$ = $CPh_3$
73% 82 : 18 $R^4$ = $SiMe_2Bu^t$
49% 66 : 34[c] $R^4$ = $SiMe_2Bu^t$

[a] Reaction carried out under argon with carbene complex (0.01 mol $dm^{-3}$) and alkyne (1.3 equiv.) in heptane; *E*-**11** 90 °C, 18 h; *Z*-**11** 55 °C, 16 h; *E*-**12** 90 °C, 18 h. [b] Made from the corresponding vinyl iodides in the indicated yields. The vinyl iodides were made by the method of Negishi (ref. 7) each with greater than 98% diastereoisomeric purity as determined by capillary GC and $^1$H NMR spectroscopy. The isomeric purity of the carbene complexes was determined by $^{13}$C NMR spectroscopy to be ≥ 98% for *E*-**11** and *Z*-**11** and ≥ 97% for *E*-**12**. [c] Reaction performed in the presence of 3.0 equiv. of $Bu_3P$. [d] Reaction of a 60 : 40 mixture of *E* and *Z* isomers of complex **12** which was prepared in 8% yield by Michael addition in a manner similar to that reported for a related complex, ref. 8.

**Absolute rate constants were determined for reactions of mesitylmethylchlorocarbene, which affords intramolecular products derived from 1,2-H migration, 1,2-mesityl migration, and C–H insertion; at −35 or −70 °C, however, the intrusion of intermolecular channels affords azine and carbene dimer, complicating interpretations of the kinetics.**

Over the past dozen years, the chemistry of benzylchlorocarbene, **1**, has provided a rich complement of contemporary puzzles in carbene chemistry.[1] Continuing kinetics studies have raised questions about the relevance of carbene/alkene complexes,[2] excited carbene precursors[3] and quantum mechanical tunnelling[4] during the 1,2-H migration of **1**, as well as the origin(s) of curved Arrhenius correlations[4b,c,5] and abnormal kinetic isotope effects[4] in these same rearrangements.

Our own interest in these matters[1b,d] impelled us to open a new investigation from the perspective of the related mesitylmethylchlorocarbene, **2**. Although our results partly accord with findings in the benzyl system, they raise important questions concerning the influence of competitive intermolecular carbene reactions at moderately low temperatures.

Carbene **2** and [α,α-$^2H_2$]-**2** were generated by photolysis or thermolysis of the corresponding diazirine precursors,[6] **3** and [α,α-$^2H_2$]-**3**: $\lambda_{max}$ (pentane) 342, 348 (346 for [$^2H_2$]-**3**), 358 nm; $\varepsilon_{342}$ = 50 dm$^3$ mol$^{-1}$ cm$^{-1}$ ($CDCl_3$). For the generation of **2**, we initially employed diazirine solutions with $A_{342}$ *ca.* 1.0–1.1; [**3**] *ca.* 0.02 mol dm$^{-3}$. Photolysis of **3** (isooctane, 25 °C, λ > 300 nm) was continued until the diazirine was destroyed, and afforded products **4**–**7**, attributed to carbene **2** in > 96% yield.

The product distributions from carbenes **2** and [$^2H_2$]-**2** were determined relative to an internal decane standard (±2%) and appear below. We obtained 1,2-H-rearranged alkenes *Z*- and *E*-(2-chloroethenyl)mesitylene (**4** and **5**), 1,2-mesityl shifted (1-chloroethenyl)mesitylene (**6**) and methyl insertion product 2-chloro-1,3-dihydro-4,6-dimethylindane (**7**). Thermolysis [pentane, sealed tube, 80 °C (**3**) or 100 °C ([$^2H_2$]-**3**), 36 h] led to distributions that were quite similar to those from photolysis. Comparison of the yields of (**4** + **5**) *vs.* (**6** + **7**) from **2** and its [α,α-$^2H_2$] analogue point to a substantial primary kinetic isotope effect (KIE) associated with the H(D) shift. This is discussed below.

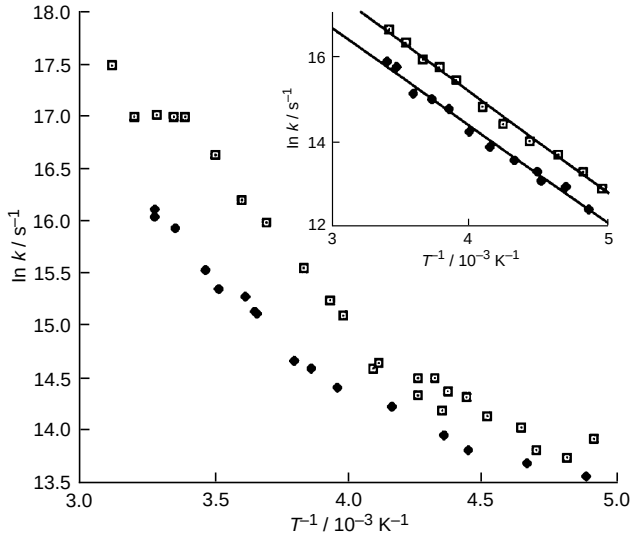
| | **4** | **5** | **6** | **7** |
|---|---|---|---|---|
| **2**: | 58 | 19 | 5 | 18 (%) |
| [$^2H_2$]-**2**: | 36 | 14 | 11 | 39 (%) |

Photolyses of **3** in the presence of 2-methylbut-1-ene led to **4**–**7** and the carbene/alkene addition products, *Z*- and *E*-1-chloro-1-mesitylmethyl-2-ethyl-2-methylcyclopropanes. When photolyses of **3** or [$^2H_2$]-**3** were performed in the presence of increasing concentrations of the alkene in isooctane, correlations of (addition/intramolecular products) *vs.* [alkene] were curved for each of the intramolecular products. However, the inverse correlations of (intramolecular/addition products) *vs.* 1/[alkene] were each linear.

If we assume that the second product-forming intermediate (in addition to carbene **2**) demanded by these results is excited diazirine **3***,[3] rather than a carbene/alkene complex,[2] then the *y*-intercepts of the inverse correlations give the partitions of **3*** between $N_2$-loss to **2** or direct formation of **4**–**7**.[1b,c,3] Product formation from **3*** is then (**4** + **5**) 17.5; **6**, 1.4; and **7**, 4.7%. From [$^2H_2$]-**3***, the corresponding values are 24.5, 3.4 and 10.6%, respectively. The balance of each product comes from the carbene, and the 'raw' product yields can be 'corrected' and renormalized to afford carbene-only distributions:[7] (from **2**) (**4** + **5**), 74.3; **6**, 5.7; **7**, 20.0%; (from [$^2H_2$]-**2**) (**4** + **5**), 45.4; **6**, 12.7; **7**, 41.9%. These data are used below to partition the global rate constants for carbene decay.

Global rate constants for the disappearance of carbenes **2** or [$^2H_2$]-**2** were obtained by laser flash photolysis (LFP) at 351 nm of the diazirines in isooctane. Carbene decay was followed directly at 310–313 nm and from −70 to 47 °C. Rate constants are considered accurate to ±10%.

Fig. 1 illustrates the Arrhenius correlations of ln *k vs.* $T^{-1}$ for the carbene decays. Linearity is observed for **2** down to *ca.* −40 °C, and for [$^2H_2$]-**2** to *ca.* −20 °C, after which the observed rate constants begin to level off with convergence at *k ca.* 9 × 10$^5$ s$^{-1}$ (ln *k ca.* 13.7). This behaviour resembles that of **1** and



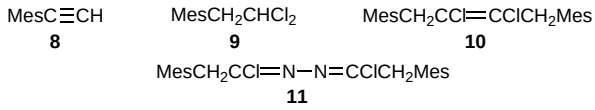


**Fig. 1** Arrhenius correlations for the decays of carbenes **2** (□) and [α,α-$^2H_2$]-**2** (◆); $A_{342}$ *ca.* 1.0. Inset: Arrhenius correlations for the decays of carbenes **2** (□) and [α,α-$^2H_2$]-**2** (◆); $A_{342}$ *ca.* 0.5.

[$^2H_2$]-**1**, where leveling occurs at −40 and −10 °C, respectively, with convergence at *k ca.* $1.2 \times 10^7$ $s^{-1}$.[4b] Note, in both cases, that Arrhenius curvature begins at a higher temperature for the [α,α-$^2H_2$] carbene.

At 25 °C, the global rate constant for decay of **2** is $2.4 \times 10^7$ $s^{-1}$, which can be partitioned as $1.8 \times 10^7$ $s^{-1}$ for H-shift to **4**/**5**, $1.4 \times 10^6$ $s^{-1}$ for 1,2-mesityl shift to **6**, and $4.8 \times 10^6$ $s^{-1}$ for insertion to **7**. For [$^2H_2$]-**2**, the corresponding total rate constant is $8.2 \times 10^6$ $s^{-1}$, and the partitioned rate constants are $3.7 \times 10^6$ $s^{-1}$ (1,2-D shift), $1.0 \times 10^6$ $s^{-1}$ (1,2-mesityl shift), and $3.4 \times 10^6$ $s^{-1}$ (insertion). The global rate constants are somewhat smaller than those reported for **1** ($6.2 \times 10^7$ $s^{-1}$) and [$^2H_2$]-**1** ($2.1 \times 10^7$ $s^{-1}$) at 25 °C.[4b]

Our partitioned rate constants afford a large KIE for 1,2-H or 1,2-D shifts of **2** at 25 °C; $k_H/k_D$ = 4.8. Product distributions were not corrected for incursion of **3*** at other temperatures, so that those global rate constants cannot be accurately partitioned to reflect carbene-only product formation. From the global rate constants for decay of **2** or [$^2H_2$]-**2** (Fig. 1), $k_H/k_D$ appears to decrease with decreasing temperature, as was reported for **1**.[4b] As shown below, however, this picture is deceptive.

Thus far, the chemistry of mesitylmethylchlorocarbene closely parallels that of benzylchlorocarbene.[1a,2,4a,b] An important divergence occurs, however, for product formation at low temperature. Photolyses of **3** and [$^2H_2$]-**3** were carried out at 30, 0, −35 and −70 °C. At the two higher temperatures, **4**–**7** accounted for > 96% of the products from either **2** or [$^2H_2$]-**2**. However, at −35 or −70 °C, product mixtures became increasingly complex, with up to six new products formed. Of these, we have identified **8**–**11**.

Acetylene **8**, also present in 2% yield in the 25 °C photolysis of **3**, appears to be an elimination product of **4**, **5** or **6**. Dichloride **9** results from reaction of **2** with HCl. The chromatographically inseparable mixture of 15 : 85 carbene dimer **10** and azine **11** (from **2** + **3**) was identified by NMR, GC–MS, microanalysis and exact mass measurements. Yields of **8** and **9** were low (⩽2%) under all conditions; whereas (**10** + **11**) constituted 2.5 and 11.2% of the products at −35 and −70 °C, respectively. For [$^2H_2$]-**2**, dimer/azine formation was already apparent at 0 °C (2.1%), and increased to 8.5 and 16% at −35 and −70 °C. Analogous azine formation has also been observed from benzylfluorodiazirine and benzylfluorocarbene.[8]

Azine formation was discounted as a complicating factor in the chemistry of carbene **1**,[4b] but it cannot be ignored here. Moreover, azine formation will be more marked, and commence at higher temperatures with [$^2H_2$]-**2**, which has a threefold lower rate constant for decay at 25 °C than does **2**; intramolecular reactions compete less efficiently with intermolecular reactions for the deuteriated carbene.

Azine (and dimer) formation are initially observed for **2** at −35 °C and for [$^2H_2$]-**2** at 0 °C. Arrhenius curvature (Fig. 1) becomes apparent at similar temperatures (−40 and −20 °C). These correspondences are not coincidental; with decreasing temperature the intramolecular reactions of the carbenes are slowed sufficiently so that the effectively temperature independent intermolecular azine formation gains in importance, causing significant curvature and levelling in the Arrhenius correlations. Consistent with this explanation, we find that twofold dilution of diazirines **3** and [$^2H_2$]-**3** ($A_{342}$ = 0.5 in isooctane, [diazirine] *ca.* 0.01 mol $dm^{-3}$) leads to Arrhenius correlations for both carbenes that are linear to −70 °C (inset, Fig. 1).

These new correlations afford $E_a$ = 4.8 kcal $mol^{-1}$ (1 cal = 4.184 J), log *A* = 10.7 $s^{-1}$ and $\Delta S^*(298)$ = −11.4 e.u. for **2**, and analogous values of 4.6 kcal $mol^{-1}$, 10.2 $s^{-1}$ and −13.7 e.u. for [$^2H_2$]-**2**. Of course, these data contain contributions from all carbene decay channels, but they are similar to the activation parameters determined for carbene **1**.[4b] Importantly, with the disappearance of Arrhenius curvature, the temperature dependence of the KIE for **2**/[$^2H_2$]-**2** no longer exhibits a marked decrease with decreasing temperature. It is also interesting to note from the activation parameters that $k_H/k_D$ for the disappearance of **2**/[$^2H_2$]-**2** (at least from the global rate constants) is controlled by entropic, not enthalpic factors.

In the cases of **1** and [$^2H_2$]-**1**, Arrhenius curvature was attributed to increasing intervention of carbenic reaction with the isooctane solvent and/or 1,2-H shift tunnelling.[4b] However, no products of carbene/isooctane reactions were observed.[4b] Moreover, in preliminary experiments, we have observed the formation of azine (up to 30%) in photolyses of benzylchlorodiazirine ($A_{344}$ = 0.7) at −70 °C in isooctane, under conditions analogous to those used in the photolysis of **3**. In the light of our findings with carbene **2**, it seems likely that azine formation is a major cause of the Arrhenius curvature observed in the H-shift reactions of **1**.

We do not exclude tunnelling as a contributory factor to the Arrhenius curvature. Tunnelling is surely involved in the rearrangements of **1** in argon matrices at 20–30 K,[4a] and may be important in the rearrangements of $CH_3CCl$ and $CD_3CCl$ at temperatures that are much closer to ambient.[4c,d]

In conclusion, the intramolecular chemistry of mesitylmethylchlorocarbene parallels that of benzylchlorocarbene, but the increasing product complexity and azine formation at low temperatures suggest important revisions to previous interpretations of the rearrangement kinetics of the latter carbene. We are continuing our studies of carbenes **1**, **2** and their fluoro analogues.

We are grateful to the National Science Foundation for financial support, to Professors J. L. Goodman, M. T. H. Liu and M. S. Platz for helpful discussions, and to Dr L. Maksimovic for technical assistance.

# A hydrodynamic AFM flow cell for the quantitative measurement of interfacial kinetics

**Barry A. Coles,* Richard G. Compton, Jonathan Booth, Qi Hong and Giles H. W. Sanders**

*Physical and Theoretical Chemistry Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QZ*

**A novel liquid flow cell is developed which allows atomic force microscopy images to be obtained under defined and modelled hydrodynamic flow conditions, enabling measured reaction fluxes to be compared with those calculated from proposed heterogeneous reaction mechanisms.**

AFM of reacting surfaces has been carried out without defined flow conditions, for example by Hansma and coworkers[1] who observed that steps on a calcite surface under aqueous solution moved laterally as dissolution proceeded. This technique is extremely powerful since it can identify key structural features, for example steps or etch pits, which contribute to the dissolution process. This approach remains qualitative since no attempts have been reported in which quantitative measures of the reaction flux are related to a chemical model of the interfacial reaction. The latter dictates defined hydrodynamics and mass transport so that the variations of concentrations in space and time above the surface can be modelled.

The value of defined hydrodynamic conditions has been demonstrated by measurements in channel flow cells[2] in which a laminar flow of solution passed through a rectangular channel with a calcite crystal forming part of one wall. The reaction was monitored electrochemically by an electrode flush with the wall and immediately downstream of the calcite surface. Precise knowledge of the flow pattern enabled it to be shown that the reaction between $H^+$ and calcite was a first-order heterogeneous reaction of $H^+$. However, the channel geometry does not facilitate simultaneous observation of the changes in surface topography or a direct physical measurement of the rate of surface dissolution, since the insertion of a scanning probe would invalidate the analytic expression for flow velocities.

We have developed a novel flow cell, based on the standard Topometrix[3] Discoverer liquid immersion cell, in which AFM images may be obtained in the presence of a flowing liquid and in which the flow pattern may be calculated. The standard cell has tangential inlet and outlet ports at the periphery of a large irregular volume, so that the flow in the vicinity of the scanning cantilever is unpredictable. We have redesigned the cell by the addition of a new inlet port so that solution can be delivered through a precisely shaped and positioned stainless-steel duct directly to the front of the cantilever chip (Fig. 1). The liquid jet is aligned parallel to the front of the cantilever support chip and transverse to the cantilever. This gives a partly free field flow, not confined except by the sample below and the cantilever chip to one side, so the flow pattern is complex and is not amenable to an analytic solution. Such flow fields can however be solved using computational fluid-dynamics programs.

We report here preliminary studies in which the flow field was calculated by two-dimensional simulations, together with experimental data to demonstrate the validity of this design. Initial studies of an inclined jet using the FLOTRAN[4] and subsequently FIDAP[5] programs showed that a satisfactory flow field would be set up. In particular, it was confirmed that all of the solution reaching the surface of the sample will be fresh solution from the jet with no mixture or entrainment of the surrounding bulk solution, which is an essential requirement for full characterisation. Initial tests of the cell using a gold calibration microgrid also confirmed that AFM images could be obtained under flow conditions without detectable deterioration of image quality up to the highest flow rates used.

In the first study, the flow behaviour has been confirmed over a wide range of flow rates by determining the limiting current at a $1 \times 1$ mm platinum electrode which was placed in the sample position, Fig. 2. An aqueous solution of 5 mM potassium hexacyanoferrate(II) with 1 M KCl was used, and the limiting current for the reversible one-electron oxidation to hexacyanoferrate(III) determined for volume flow rates in the range 0.029 to $1.4 \times 10^{-5}$ cm$^3$ s$^{-1}$, with a stainless-steel jet of internal dimensions $0.057 \times 0.057$ cm.

The FIDAP simulation was based on a two-dimensional finite element model of a section of fluid $5.86 \times 3.06$ mm, including the cross-section of the jet tube and bounded below by the sample surface. The remaining boundaries represented the bulk fluid in the cell and permitted free flow. The model comprised 6564 elements of graded size, with a fine element mesh in regions of high gradients of velocity or of concentration, such as at the edges of the electrode. The simulation for a flow rate of 0.0014 cm$^3$ s$^{-1}$ is shown in Fig. 2 as a streamline contour plot,

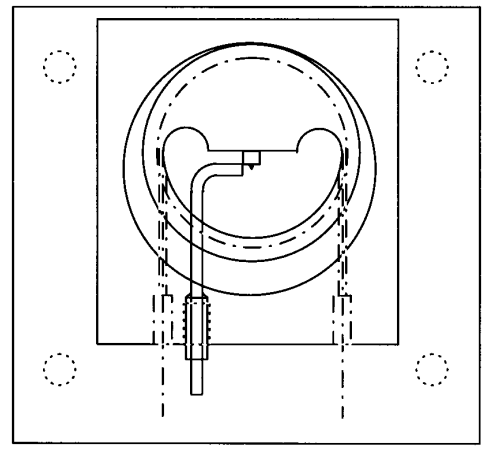

**Fig. 1** Top view of the Topometrix sample cell showing the new inlet duct

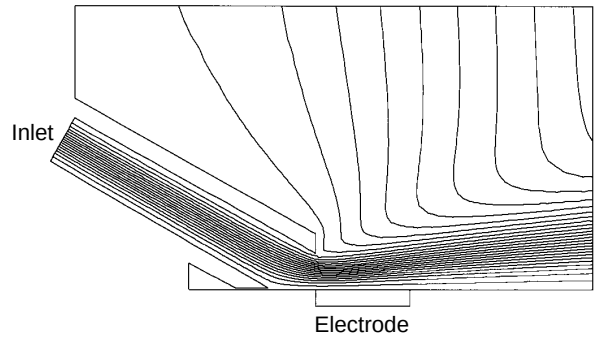

**Fig. 2** The two-dimensional cross-section of solution modelled with FIDAP, showing jet and electrode positions, with streamline contours for a flow rate of 0.0014 ml s$^{-1}$

indicating that the jet flows near to the surface, moving away from it at a fairly shallow angle; as the flow rate is lowered, this angle increases and the jet broadens. The flux of hexacyanoferrate(II) to the electrode was calculated using FIDAP, by setting concentration boundary conditons of 5 mM at the inlet to the jet tube, and of zero, corresponding to the limiting current condition, at the electrode surface. Fig. 3 shows the simulated and the experimental limiting currents as a function of (flow rate)$^{1/2}$. For this two-dimensional approximation, it was assumed that the effective electrode width was 0.45 mm due to the narrower jet. On this basis good agreement was obtained over more than three orders of magnitude of flow rate, broadly confirming the simulated behaviour.

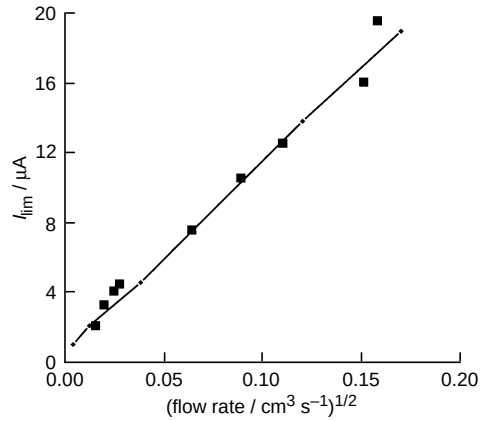

**Fig. 3** Experimental (■) and simulated (—) limiting currents as a function of (flow rate)$^{1/2}$

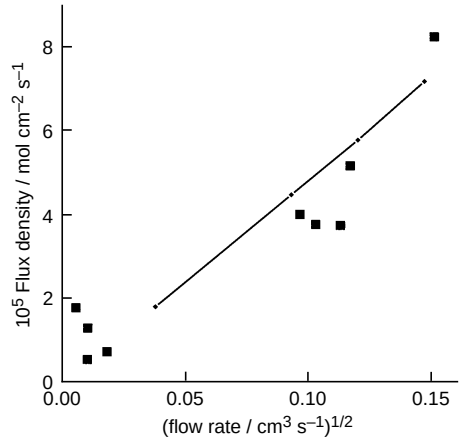

**Fig. 4** Dissolution rate of calcite determined by AFM (■) and simulated (—) as a function of (flow rate)$^{1/2}$

The second study was the dissolution of a calcite surface in 0.98 mM aqueous HCl as a function of flow rate. By monitoring the change of the Z-piezo voltage during successive scans of the AFM image, the rate of recession of the surface and hence the flux of reacted material could be determined for different flow rates assuming a density of 2.71 g cm$^{-3}$ for calcite. For the simulation (again two-dimensional), the dissolution reactions were expressed by eqns. (1)–(3) and the reaction flux at the scan location was calculated using the backward implicit finite difference (BIFD) method[6] with the rate constants $K_{H_2CO_3} = 1.72 \times 10^{-4}$ M (this value is corrected for activity coefficients[2]), $k_3 = 20$ s$^{-1}$, and variable $k_1$, and with the fluid velocities taken from a FIDAP simulation. Fig. 4 shows the AFM determined flux rates together with the FIDAP/BIFD simulated values plotted against (flow rate)$^{1/2}$ for the case of $k_1 = 0.035$ cm s$^{-1}$.

$$H^+(aq) + CaCO_3(s) \rightarrow Ca^{2+}(aq) + HCO_3^-(aq) \quad (1)$$

$$H^+(aq) + HCO_3^-(aq) \rightleftharpoons H_2CO_3(aq) \quad (2)$$

$$H_2CO_3(aq) \rightarrow H_2O + CO_2(aq) \quad (3)$$

This is in excellent agreement with the value (0.043 ± 0.015) cm s$^{-1}$ deduced from independent channel flow cell experiments[2] and confirms the validity of the hydrodynamic AFM approach.

We have shown that this novel design for an AFM flow cell is practicable and gives good agreement between experimental and calculated results using a two-dimensional finite element fluid-dynamics simulation of the complex flow field. A full three-dimensional flow simulation, while requiring substantial computer resources, should further improve accuracy, and work on this is in progress. This new cell should prove of value to AFM users for mechanistic investigations in many areas of solid/liquid reactions, allowing physical and structural changes to the surface to be related directly to proposed reaction mechanisms and rate constants.

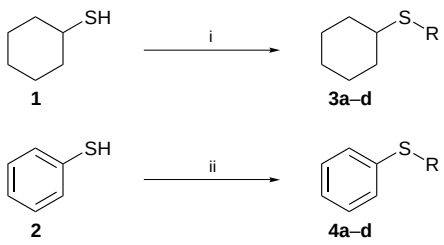
# Synthesis of organic sulfides using Ce-exchanged NaY catalyst

**T. Indrasena Reddy and Rajender S. Varma***

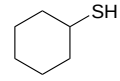
*Department of Chemistry and Texas Regional Institute for Environmental Studies (TRIES), Sam Houston State University, Huntsville, TX 77341-2117, USA*

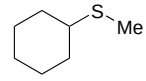


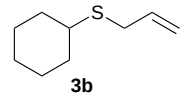
**Synthesis of organic sulfides from thiols and alkyl halides is achieved using Ce-exchanged zeolite catalyst, Ce(72%)NaY.**

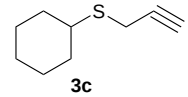
While investigating the chemoselectivity aspects of oxidation reactions utilizing titanium silicates, we required various sulfides bearing unsaturated functionalities. There are few general methods available for the preparation of organic sulfides; however those available include phase-transfer procedures[1,2] and reactions using supported reagents on alumina.[3] Sodium sulfide impregnated on alumina facilitates the synthesis of symmetrical sulfides,[3] whereas base-catalysed alkylation of thiols using sodium hydroxide 'doped' alumina gives unsymmetrical sulfides.[3] 3-Aminopropyl(triethoxy)silane-modified basic montmorillonite clay has been used to catalyse the reaction of benzyl chloride with various thiols to produce unsymmetrical sulfides.[4] Recently, another approach has been described that uses a Pd catalyst with aryl thiocyanate-derived samarium thiolates for the synthesis of unsymmetrical sulfides.[5]

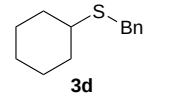
In continuation of our efforts to develop environmentally benign synthetic protocols using microwave (MW) irradiation[6] and zeolite materials,[7] we explored the synthesis of the requisite sulfides with unsaturated functionalities on solid supports. Since our attempts with sodium hydroxide 'doped' alumina and other solid supports produced only poor yields of unsaturated sulfides,[6] we focused our efforts on zeolite molecular sieves, particularly metal-exchanged Y zeolites which are weakly basic.[7a,8]

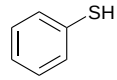


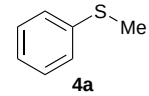


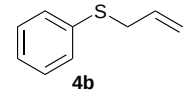


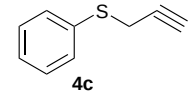


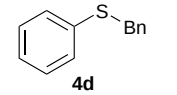












The use of various zeolite catalysts in organic transformations is a growing area of interest.[9,10] The Na form of faujasites (ex. X and Y), a class of zeolite catalyst, is almost neutral in nature. However, a basic character can be introduced by increasing the alumina content of the catalyst framework, thereby increasing the population of counter cations and their radii.[7a,11,12] Furthermore, the electrostatic interaction between the metal cation and the organic guests within the zeolite supercage has been well studied.[13,14] In this context, we have initiated a program exploiting the interactions of exchanged rare-earth cations of the faujasites with the included organic guest molecules in the supercages. Our main aim is to identify the conditions in which such an interaction could create sufficient polarization of the organic guests inside the supercages to facilitate chemical transformations. In line with our expectations, when a hexane solution of thiophenol **2** and benzyl bromide was refluxed in the presence of cerium-exchanged NaY (or NaX) zeolite, the benzyl phenyl sulfide was produced in 92% yield† (Scheme 1). These encouraging results prompted us to explore the use of the cerium-exchanged NaY zeolite, Ce(72%)NaY, for the synthesis of unsymmetrical sulfides.

Briefly, the preparation of the Ce-exchanged catalyst involved the treatment of zeolite NaY[15]‡ with aqueous cerium chloride solution (prepared using double distilled and deionized water with pH adjusted to 5.0) at 95 °C for 8 h. After cooling to room temperature, the exchanged catalyst was filtered off and washed with water. The percentage of $Na^+$ exchange was determined (35%) by conventional gravimetric analysis of the aqueous filtrate; this procedure is repeated twice, resulting in a maximum exchange of 72%. The Ce(72%)NaY was dried at

**Scheme 1** *Reagents and conditions*: i, RX, hexane, Ce(72%)NaY, reflux, 14–16 h; ii, RX, hexane, Ce(72%)NaY, reflux, 8–10 h

**Table 1** Synthesis of unsymmetrical sulfides using zeolite catalyst Ce(72%)NaY†

| Entry | Thiols | Alkyl halides | Sulfides[a] | Yield (%)[b] |
|---|---|---|---|---|
| 1 |  **1** | MeI |  **3a** | 75 |
| 2 | |  |  **3b** | 83 |
| 3 | |  |  **3c** | 77 |
| 4 | | BnBr |  **3d** | 84 |
| 5 |  **2** | MeI |  **4a** | 82 |

| 7 | |  |  **4c** | 79 |
| 8 | | BnBr |  **4d** | 92 |

[a] Products exhibited spectral data compatible with assigned structures. [b] Isolated and unoptimised yields.

120 °C for 4 h and its crystalline structural integrity was discerned by X-ray analysis.[8a]

The freshly activated Ce(72%)NaY§ was used for the alkylation of cyclohexanethiol **1** and thiophenol **2** with a variety of alkyl halides such as iodomethane, allyl bromide, prop-2-ynyl bromide and benzyl bromide to provide corresponding sulfides in high yields (Table 1). The heterogeneous catalytic method described herein is attractive since it compares favourably with other reported protocols[2–4] in terms of yield. The reactions with thiophenol require 8–10 h to reach completion, whereas in the case of aliphatic compounds such as cyclohexanethiol, a relatively longer time period of 14–16 h is necessary.

In conclusion, we have demonstrated the versatility of cerium-exchanged NaY zeolite as an efficient catalyst for the synthesis of organic sulfides. These thermally stable crystalline inorganic materials are safe to handle and environmentally benign. Their recyclable nature and ease of manipulation, entailing a simple filtration step, illustrate some of the added advantages of zeolite catalysts.

We are grateful to the Texas Advanced Research Program (ARP) in Chemistry (Grant no. 003606-023) and the Retina Research Foundation, Houston for generous support.

## Footnotes

† Typical experimental procedure: Thiophenol (200 mg, 1.81 mmol), benzyl bromide (373 mg, 2.18 mmol) and freshly activated catalyst (40 mg, 20 mass% of thiophenol) in hexane (15 ml) was stirred for 12 h at reflux temperature to complete conversion. The progress of the reaction was monitored by TLC. The reaction mixture was cooled to room temperature, the catalyst was filtered off and washed it with hexane (3 × 10 ml). The combined solution was concentrated at reduced pressure to afford benzyl phenyl sulfide in 92% (330 mg, mp 45–47 °C).

‡ Zeolites NaX and NaY were obtained from Union Carbide Corporation, USA. The $SiO_2/Al_2O_3$ ratio is 2.52 in NaX and 4.20 in NaY.

§ These reactions have also been carried out using Ce(72%)NaX catalyst with almost equal efficiency.

# Highly luminescent neutral *cis*-dicyano osmium(II) complexes

**Jack Y. K. Cheng, Kung-Kai Cheung and Chi-Ming Che***

*Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*

**Two highly luminescent neutral *cis*-dicyanoosmium(II) complexes are prepared by photoinduced oxygen atom transfer reactions of *trans*-$[OsO_2(CN)_2(dpphen)]$ with $PPh_3$ and $Me_2SO$; their MLCT excited states are emissive with long lifetimes (0.20–1.99 μs) and high quantum yields [(40–1.8) $\times 10^{-2}$] and the emission maxima show pronounced solvatochromism.**

Luminescent metal complexes with high emission quantum yields and which could function as molecular building blocks for polynuclear metal complexes find useful applications in supramolecular chemistry and photocatalysis.[1] However, examples of these complexes are sparse in literature. In this context, we were attracted to the wide applications of $[RuL_2(CN)_2]^2$ (L = 2,2′-bipyridine or 1,10-phenanthroline) as building blocks for polynuclear cyano-bridged metal complexes and the striking luminescent properties of $[Os^{II}L_x(P–P)_{3-x}]^{2+}$ (P–P = diphosphine, $x$ = 1 or 2).[3] Herein is described the formation of highly luminescent neutral cyanoosmium(II) complexes which have the combined features and properties of both $[RuL_2(CN)_2]$ and $[Os^{II}L_x(P–P)_{3-x}]^{2+}$. These complexes are anticipated to provide a new entry to supramolecular photochemistry.

$[OsO_2(CN)_2(dpphen)]$ **1** (dpphen = 4,7-diphenyl-1,10-phenanthroline) was prepared from dpphen and $[OsO_2(CN)_2(OH)_2]^{2-}$ following the reported literature method.[4] As with other dioxoosmium(VI) complexes,[4,5] it has a long-lived and emissive excited state [lifetime 1 μs; quantum yield $5 \times 10^{-4}$; $\lambda_{max,\,em}$ 650 nm].

Under UV irradiation, complex **1** oxidizes $PPh_3$ and $Me_2SO$ to give $OPPh_3$ and $Me_2SO_2$, respectively. For the photoreaction of **1** in neat $Me_2SO$, removal of the solvent after photolysis gave an orange solid, which was recrystallized from MeOH–$Et_2O$ to give $[Os(CN)_2(Me_2SO)_2(dpphen)]\cdot 2H_2O$ **2**. Similar photoreaction with $PPh_3$ gave $[Os(CN)_2(PPh_3)_2(dpphen)]$ **3**.†

Fig. 1 shows a perspective view of **2**.‡ The structure features a rare example of $Os^{II}$–CN and $Os^{II}$–$Me_2SO$ complexes. The coordination geometry of the Os atom is slightly distorted octahedral with the cyanide ligands *cis* to each other. The Os–C bond of 2.00(1) Å is comparable to that of 2.023 Å in $[AsPh_4]_2[Os(PPh_3)_2(CN)_4]\cdot 2MeCN\cdot 2H_2O$.[6] The two $Me_2SO$ ligands are S-bonded to the Os atom. They are *trans* to each other with S–Os–S angle of 174.1(2)°. The Os–S distance of 2.293(3) Å is similar to the related distances of 2.31(2) Å in $[Os(S_7)(PMe_3)_3]$[7] and 2.261 Å in $[Ru(Me_2SO)_3Cl_3]^-$ (S-coordinated).[8] To our knowledge, no X-ray structure of an $Os^{II}$–$Me_2SO$ complex has been reported in the literature. $[Os(Me_2SO)_3Cl_3]$[9] has been proposed to be O- and S-coordinated while the structure of $[Os(bpy)_2(MeSO)_2]^{2+}$ is unknown.[3b]

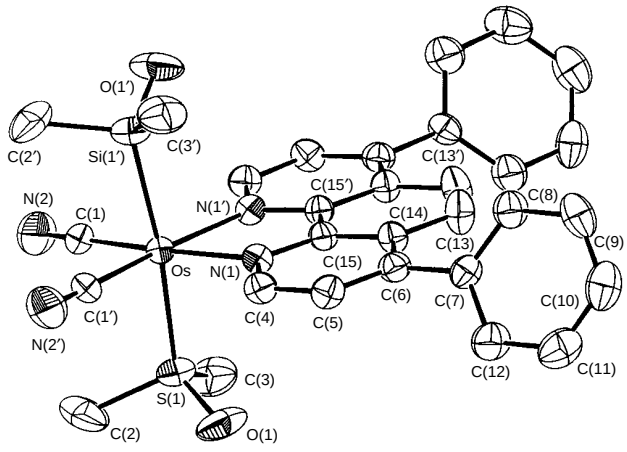

**Fig. 1** A perspective view of **2** (40% probability ellipsoids): Os–S(1) 2.293(3), Os–N(1) 2.111(8), Os–C(1) 2.00(1); S(1)–Os–S(1′) 174.1(2), S(1)–Os–C(1) 87.7(3), S(1)–Os–N(1) 91.1(2), N(1)–Os–C(1) 94.5(4), C(1)–Os–C(1′) 94.6(6)

Complexes **2** and **3** are luminescent in the solid state and in solution with emission maxima ranging from 710 to 564 nm. The spectral data are listed in Table 1. The two complexes display a strong absorption band in the UV region ($\lambda_{max}$ *ca*. 300 nm, $\varepsilon > 10^5$ dm$^3$ mol$^{-1}$ cm$^{-1}$) and a moderate intense absorption band at the visible region ($\lambda_{max}$ *ca*. 440 nm, $\varepsilon > 10^3$ dm$^3$ mol$^{-1}$ cm$^{-1}$) with a tailing at 500–600 nm, the latter is ascribed to the Os $d_\pi$–$\pi^*$ MLCT transition.[10] Both the absorption and emission spectra are strongly affected by the solvent and both the emission lifetime and quantum yield decrease as the solvent polarity decreases.

Plots of 1n $k_{nr}$ *vs*. $E_{em}$ for complexes **2** and **3** in various solvents are shown in Fig. 2. Except for the data of **2** in protic solvents, a linear correlation between 1n $k_{nr}$ and $E_{em}$ values is observed suggesting that the non-radiative decay is governed by the energy-gap law.[11] The slope of $-6.8$ eV$^{-1}$ and intercept of

[a] Gutmann's solvent acceptor number.[14b] Measurements at room temperature. [b] Spin-allowed MLCT absorption maximum.

27 agree with similar values of *ca.* −7.5 $eV^{-1}$ (slope) and 28–30 (intercept) of complexes $[OsX_4L]$ and $[OsX_2L_2]$ (X ≠ CO) in which cases the non-radiative decay is dominated by the ligand-based C–C vibrational stretch modes (*ca.* 1350 $cm^{-1}$).[12] Complex **2** shows derivation from the linear correlation in protic solvents. Presumably, a change of dominant acceptor vibration for non-radiative decay is attributed to the hydrogen-bonding interaction between the solvent and $Me_2SO$.[2c]

For both complexes, the plots of absorption and emission energy *versus* Gutmann's solvent acceptor number, AN, are shown in Fig. 3. Good linear relationship is observed in each case. The absorption and emission spectra shift to higher energy with increasing AN. This implies the donor–acceptor interaction between the solvent and the complexes. The donor–acceptor interaction results in decrease of the σ-donating ability of the cyanide ligand (and/or $Me_2SO$ ligand).

Most osmium(II) polypyridine complexes are known to be stable towards photosubstitution reaction. However, it has been noted that the $[Os(bpy)_2(Me_2SO)_2]^{2+}$ complex is photochemically unstable and this has been ascribed to its MLCT and low-lying d–d states being close in energy.[3b] Complexes **2** and **3** were found to be stable even after photolysis in acetonitrile for 2 days. Presumably, the $Os^{II}\rightarrow CN$ π-back bonding increases the d–d state energy relative to the MLCT emitting state.[13]

We acknowledge support from the University of Hong Kong, the Croucher Foundation, and the Hong Kong Research Grants Council.

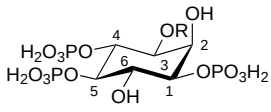
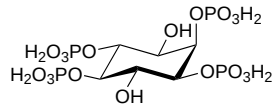
# Investigation of the inframolecular acid–base properties of D-*myo*-inositol 1,3,4,5-tetrakisphosphate and DL-*myo*-inositol 1,2,4,5-tetrakisphosphate

**Philippe Guédat,[a] Gilbert Schlewer,[a] Elisabeth Krempp,[a] Andrew M. Riley,[b] Barry V. L. Potter[b] and Bernard Spiess[a,b]**



[a] *Laboratoire de Pharmacochimie Moléculaire, UPR 421 du CNRS, Faculté de Pharmacie, 74, route du Rhin, B.P. 24, 67401 Illkirch Cedex, France*

[b] *Department of Medicinal Chemistry, School of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY*



**The protonation processes of the individual phosphate groups in two regioisomeric inositol polyphosphates, D-*myo*-inositol 1,3,4,5-tetrakisphosphate and DL-*myo*-inositol 1,2,4,5-tetrakisphosphate, have been investigated by $^{31}$P NMR titration experiments; the results are compared to those from D-*myo*-inositol 1,4,5-trisphosphate.**

D-*myo*-Inositol 1,4,5-trisphosphate [Ins(1,4,5)$P_3$] **1** (Fig. 1) produced in response to stimulation of a wide variety of cellular membrane receptors, exhibits well-known second messenger properties.[1,2] Besides Ins(1,4,5)$P_3$ a host of inositol polyphosphates, among them D-*myo*-inositol 1,3,4,5-tetrakisphosphate [Ins(1,3,4,5)$P_4$] **2**, have also been characterised in the cytoplasm of many cell types. While the role of Ins(1,4,5)$P_3$ and its calcium mobilising ability is well-defined in many tissues, the physiological role of Ins(1,3,4,5)$P_4$ remains a matter of much debate and controversy. In some cases Ins(1,3,4,5)$P_4$ potentiates the Ins(1,4,5)$P_3$-induced response,[3,4] while in others it inhibits calcium signalling.[5] A main route to resolving the precise function of Ins(1,3,4,5)$P_4$ is to identify the molecular nature of its receptor[6,7] and recently a specific Ins(1,3,4,5)$P_4$ binding protein has been characterised and denoted as GAP1$^{IP4BP}$.[8] A complementary method is to focus on the ligand itself and to compare its physico-chemical properties with those of Ins(1,4,5)$P_3$. In this respect, Ins(1,2,4,5)$P_4$ **3**, a regioisomer of Ins(1,3,4,5)$P_4$ and a potent analogue of Ins(1,4,5)$P_3$,[9,10] is also worthy of consideration. A fundamental difference in the binding of both Ins(1,4,5)$P_3$ and Ins(1,3,4,5)$P_4$ to their specific or putative receptors respectively is the effect of pH. The affinity of the former for its receptor is increased by raising the pH,[11] whereas the inverse occurs for the latter.[6] A consideration of the acid–base properties of these ligands is of prime importance in gaining reliable knowledge of the binding mechanisms and we have therefore chosen for investigation two regioisomeric inositol tetrakisphosphates, differing only in the substitution position of a single phosphate group, but with strikingly different biological properties.

Herein we present the protonation constants as well as a picture of the protonation process of the individual phosphate groups for Ins(1,3,4,5)$P_4$ and Ins(1,2,4,5)$P_4$ (IP4s). The results will further be compared to the acid–base behaviour of Ins(1,4,5)$P_3$.[12,13] The study was performed in 0.2 mol dm$^{-3}$ KCl at 37 °C, a medium that mimics the ionic strength and temperature conditions encountered in the cell.

R = H, Ins(1,4,5)$P_3$ **1**
R = $PO_3H_2$, Ins(1,3,4,5)$P_4$ **2**

Ins(1,2,4,5)$P_4$ **3**

**Fig. 1** Structure of inositol polyphosphates (D-isomers are shown)

The logarithms of the stepwise protonation constants for the studied ligands ($L^{n-}$), $K_y$, referring to the equilibria $H_{y-1}L^{(n-y+1)-} + H^+ \Leftrightarrow H_yL^{(n-y)-}$ are listed in Table 1. In comparison with the constants determined for Ins(1,4,5)$P_3$,[13] an additional phosphate group raises the first protonation constant by two orders of magnitude. This is clearly the result of the increase in negative charge density on the *myo*-inositol ring phosphates that electrostatically stabilises the binding of the first proton. However, by considering the values in Table 1, it can be observed that both IP4s display nearly the same overall basicities, Ins(1,3,4,5)$P_4$ showing only a slightly more pronounced basic character over Ins(1,2,4,5)$P_4$. While a simple examination of these macroscopic protonation constants seems to indicate a similar acid–base behaviour it is therefore necessary to investigate the protonation process of the two IP4s at an 'inframolecular' level, *i.e.* at each individual phosphate group.

In a previous work[14] we showed that $^{31}$P NMR spectroscopy gives easy access to the protonated fraction $f_{i,p}$ of a phosphate group in position *i* on the inositol ring if the observed chemical shift for the resonance $\delta_i^{obs}$ depends on the electronic effects accompanying the deprotonation of this group. The value of $f_{i,p}$ can then be calculated from eqn. (1),

$$f_{i,p} = \frac{\delta_i^{obs} - \delta_{i,d}}{\delta_{i,p} - \delta_{i,d}} \quad (1)$$

where $\delta_{i,p}$ and $\delta_{i,d}$ correspond to the chemical shifts of the protonated and deprotonated fractions of the phosphates in position *i*, respectively. The previous condition can be checked by the superimposition of the $\bar{p} = f(pH)$ curves calculated from both the potentiometric and NMR data according to eqns. (2) and (3), respectively.

$$\bar{p} = \frac{C_H - [H^+] + [OH^-]}{C_L} \quad (2)$$

**Table 1** Logarithms of the stepwise protonation constants for D-Ins(1,3,4,5)$P_4$ and DL-Ins(1,2,4,5)$P_4$ in KCl 0.2 mol dm$^{-3}$ ($H_2O$) at 37 °C[a]

| log $K_y$ | Ins(1,4,5)$P_3$ | Ins(1,3,4,5)$P_4$ | Ins(1,2,4,5)$P_4$ |
|---|---|---|---|
| $y$ = 1 | 7.85 | 9.92 ± 0.02 | 9.39 ± 0.02 |
| $y$ = 2 | 6.40 | 7.66 ± 0.02 | 7.65 ± 0.02 |
| $y$ = 3 | 5.31 | 6.36 ± 0.02 | 6.06 ± 0.02 |
| $y$ = 4 | – | 5.23 ± 0.02 | 5.23 ± 0.02 |
| $N(n)$ | – | 4(221) | 2(198) |

[a] These constants were determined by potentiometry (see ref. 12) where the pH measurements are processed by the program SUPERQUAD (ref. 16). The constants are the result of $N$ experiments including a total number of $n$ observations. The standard deviations are given by SUPERQUAD. The values for Ins(1,4,5)$P_3$ were taken from ref. 13.

$$\bar{p} = \sum_{i=1}^{i=N} f_{i,\mathrm{p}} \qquad (3)$$

In these eqns., $\bar{p}$ is the mean number of protons bound per mole of IP4 and $C_H$ and $C_L$ correspond to the analytical concentrations of the acid and IP4, respectively.

For Ins(1,3,4,5)$P_4$ and Ins(1,2,4,5)$P_4$ both potentiometric and NMR $\bar{p} = f(\mathrm{pH})$ curves superimpose well from pH 2 to 8.5 (curves not shown). Above this pH a slight difference is noted indicating that $\delta_i^{obs}$ comprises, in addition to the protonation effect, another effect presumably due to conformational changes. Consequently, the $f_{i,\mathrm{p}} = f(\mathrm{pH})$ curves strictly describe $f_{i,\mathrm{p}}$ below pH 8.5 and give a good approximation of it above this pH.

The $f_{i,\mathrm{p}} = f(\mathrm{pH})$ curves for the studied IP4s are shown in Fig. 2. It can be seen that, even though the overall basicities of the IP4s are similar, the protonation fraction curves differ markedly indicating distinct protonation processes. Ins(1,2,4,5)$P_4$ exhibits almost monophasic (P1 and P2) and biphasic (P4 and P5) curves which resemble those of the corresponding bisphosphates. The general pattern of these curves attests to the independence of the two bisphosphate moieties. However, compared to Ins(1,4,5)$P_3$, the basicities of P4 and P5 appear inverted. The $f_{i,\mathrm{p}} = f(\mathrm{pH})$ curves for Ins(1,3,4,5)$P_4$ are much more complicated due to the strong interaction between phosphates P3, P4 and P5. As expected, P3 and P5 behave similarly, whereas P4, which experiences the highest density of negative charge, shows a very peculiar protonation process already observed for P5 in Ins(4,5,6)$P_3$.[15] The monophasic appearance retained by the P1 curve attests to the independence of this phosphate group. Consideration of the protonation fraction curves allows a detailed investigation of the protonation state of each individual phosphate group at any pH. Thus, at a near physiological pH (7.50), for Ins(1,3,4,5)$P_4$ and Ins(1,2,4,5)$P_4$ the percentage of protonated phosphates are P1 (5%), P3 (50%), P4 (60%), P5 (60%) and P1 (60%), P2 (15%), P4 (70%), P5 (35%), respectively. Large differences can be observed, especially in the basicity of P1 and P5 which are common to both IP4s. The observation that P5 is much more basic for Ins(1,3,4,5)$P_4$ than Ins(1,2,4,5)$P_4$ may be of biological significance. Indeed, it has been suggested that the increase in affinity of Ins(1,4,5)$P_3$ for its receptor when the pH rises may be caused by the ionization of the P5 phosphate group.[12] Therefore, binding of Ins(1,2,4,5)$P_4$ to the Ins(1,4,5)$P_3$ receptor could also be favoured by a low protonation state of the P5 phosphate at physiological pH. In constrast to Ins(1,4,5)$P_3$, for Ins(1,3,4,5)$P_4$, specific binding decreases steadily from pH 5.5 to 9.0. Moreover, these specific binding data *vs*. pH could be roughly superimposed on the P3 and P5 NMR titration curves (*e.g*. at pH 7.5, $f_{5,\mathrm{p}}$ *ca*. 60% and specific binding *ca*. 65%).[6] It is therefore likely that, if the protonation state of Ins(1,3,4,5)$P_4$ is involved in its binding to a specific protein, the observed high basicity of P5 will undoubtedly advantage such a binding. The results described herein which demonstrate the acid–base requirements needed for the observation of either an Ins(1,2,4,5)$P_4$ type or an Ins(1,3,4,5)$P_4$ type of biological activity may be of great help to chemists who aim at the synthesis of potent analogues. Further studies on the influence of the ionic environment of the IP4s on their acid–base and conformational properties are in progress and will be reported in due course.

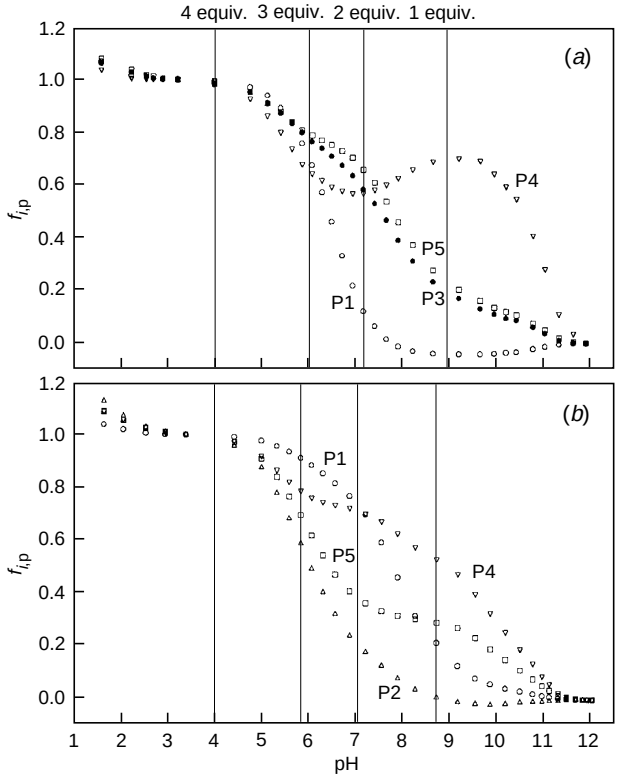


**Fig. 2** Protonation fraction curves $f_{i,\mathrm{p}}$ as a function of pH in KCl 0.2 mol $dm^{-3}$ (99.9% $D_2O$) at 37 °C for D-Ins(1,3,4,5)$P_4$ (*a*) and DL-Ins(1,2,4,5)$P_4$ (*b*). The vertical lines correspond to the theoretical addition of 1–4 equiv. of protons. These curves were calculated according to eqn. (1) from $^{31}P$ NMR titrations carried out at 121.497 MHz on a Bruker 300 DPX FT spectrometer. Chemical shifts were measured relative to an external 85% orthophosphoric reference. Resonance peaks of D-Ins(1,3,4,5)$P_4$ and DL-Ins(1,2,4,5)$P_4$ were assigned by performing proton phosphorus 2D correlation experiments at pH 1.62, 2.25, 7.92, 12.00 and 1.65, 5.93, 7.90, 11.65, respectively. The assignment of the proton resonances was done on the basis of the chemical shifts and the coupling patterns confirmed by $^1H$–$^1H$ COSY experiments. The titrations were performed as previously indicated[14] but on a volume of 0.45 ml instead of 2 ml. Ins(1,2,4,5)$P_4$ was prepared as described in ref. 9 and the synthesis of Ins(1,3,4,5)$P_4$ will be published elsewhere.

# Synthesis and characterisation of the potassium 1,1-dithiolate $C_{12}H_{20}N_2S_2K_2$: a novel $K_{12}S_{12}$ cluster compound

**Norbert Kuhn,*[a] Gerd Weyers[a] and Gerald Henkel[b]**

[a] *Institut für Anorganische Chemie der Universität Tübingen, Auf der Morgenstelle 18, D-72076 Tübingen, Germany*
[b] *Fachbereich 6 (Chemie) der Universität-GH Duisburg, Lotharstr. 1, D-47048 Duisburg, Germany*

**The carbene adduct 1 reacts with potassium to give the potassium 1,1-dithiolate 2; its tetrahydrofuran adduct exhibits a cage structure consisting of a hexagonal $K_6S_6$ prism incorporated into a twelve-membered $K_6S_6$ ring connected both by direct K–S bonds and vinylidene type bridges.**

Organoalkali-metal compounds are generally made up of ring- and ladder-type fragments.[1] Although a limited number of one- and multi-dimensional ladder structures have been identified for potassium thiolates,[2] compounds of this class containing ring fragments were previously unknown.

By reduction of the carbene adduct **1**[3] with potassium in tetrahydrofuran we have now obtained† the potassium 1,1-dithiolate **2** as a yellow air-sensitive solid. A single-crystal X-ray structural analysis‡ of the solvate complex $\mathbf{2}\cdot 2C_4H_8O\cdot 1/3K_2S_2$ revealed the presence of a hexagonal prism with the composition $K_6S_6$ as the central unit surrounded by a twelve-membered $K_6S_6$ ring consisting of alternating potassium and sulfur atoms (Fig. 1). Hexagonal prisms have frequently been observed in $Li_6X_6$ compounds (X = C, N, O, Si, Te)[1] but for potassium they have to date only been realised in a single structure with a $K_6O_6$ core.[4] Previously, hexagonal prisms of the $M_6S_6$ type were only known in the chemistry of the transition metals.[5] Of the two sulfur atoms of each dithiolate ligand, one is part of the twelve-membered ring while the second sulfur atom is incorporated into the hexagonal prism. Therefore, the rings and the prisms are connected both through vinylidene bridges and direct K–S bonds. The observed potassium–sulfur contacts (3.023–3.308 Å) are in the expected range. In the hexagonal prism, alternating K–S bond lengths are observed [K(1)–S(1a) 3.023(3), K(1)–S(1b) 3.192(3) Å] for the six-membered rings. Their mean value corresponds well both to the distance of the two six-membered rings in the prism [K(1)–S(1) 3.107(4) Å] as well as to the K–S bond lengths of the surrounding $K_6S_6$ ring [K(2)–S(2) 3.115(3), K(2)–S(2b) 3.098(3) Å]. The longest K–S distance is observed for the connection of the $K_6S_6$ ring and prismatic fragments [K(2)–S(1) 3.308(5) Å]. In comparison to the metal structure,[6] the metal–metal separations are, in part, shortened by up to 0.75 Å and for K(1)–K(2) (3.937 Å) reach the calculated and observed bond lengths for $K_2$.[7] Even under the aspects of electrostatic K–S interactions,[8] however, such a close approach is not unusual.[9]

A comparison of the 1,1-dithiolate fragment in **2** (Fig. 2) with the structure of the carbene adduct **3**[3] reveals a markedly changed distribution of the π electrons; the coplanar orientation of the $CS_2$ fragment in **2** to the five-membered ring, the significant shortening of the C(1)–C(2) bond [1.375(13) Å] by about 0.12 Å in comparison to that of **3**, and the lengthening of the C–S bonds [C(12)–S(1) 1.803(8) Å, C(12)–S(2) 1.764(11) Å] by the same order of magnitude are all indications of the presence of an exocyclic C–C double bond in **2**. This is further substantiated by the relative widening of the angle N(1)–C(1)–

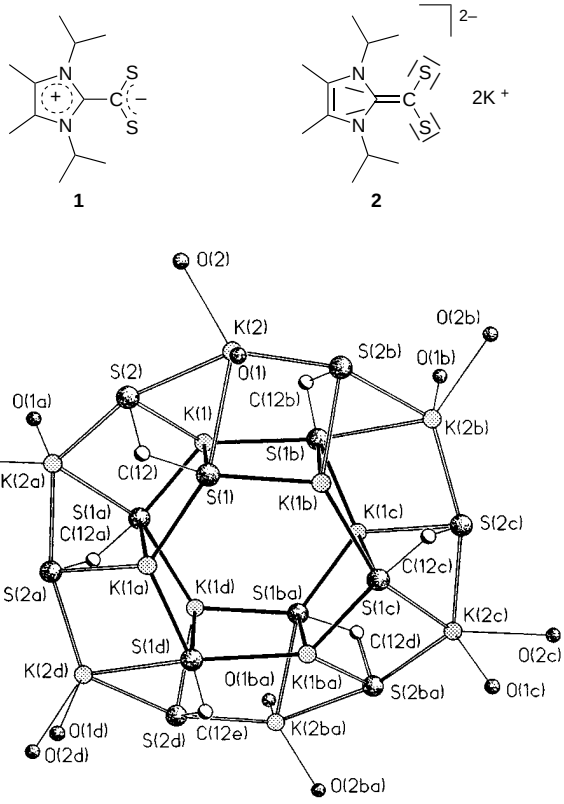

**Fig. 1** The $K_{12}S_{12}O_{12}$ core in crystals of $\mathbf{2}\cdot 2C_4H_8O\cdot 1/3K_2S_2$. Selected bond lengths (Å): K(1)···K(2) 3.937(4), K(1)···K(1a) 4.105(4), K(1)···K(1b) 4.105(4), K(1)···K(2a) 4.212(4), K(1)–S(1) 3.107(4), K(1)–S(2) 3.193(4) K(1)–S(1a) 3.023(3), K(1)–S(1b) 3.192(3), K(2)–S(1) 3.308(5), K(2)–S(2) 3.115(3), K(2)–K(2b) 3.098(3), K(2)–O(1) 2.782(13), K(2)–O(2) 2.810(13).

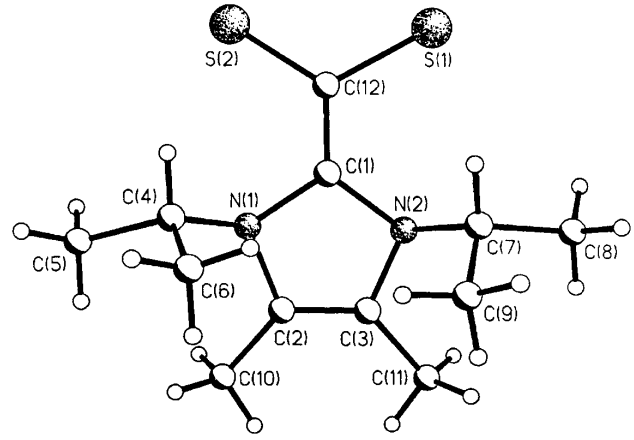

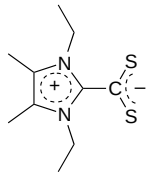

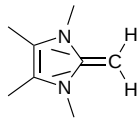

**Fig. 2** The structure of the 1,1-dithiolate anion in crystals of $\mathbf{2}\cdot 2C_4H_8O\cdot 1/3K_2S_2$. Selected bond lengths (Å) and angles (°): C(1)–C(12) 1.375(13), C(12)–S(1) 1.803(8), C(12)–S(2) 1.764(11), C(1)–N(1) 1.455(10), N(1)–C(2) 1.454(15), C(2)–C(3) 1.310(16), C(3)–N(2) 1.428(11), N(2)–C(1) 1.428(15); S(1)–C(12)–S(2) 117.6(5), S(1)–C(12)–C(1) 118.0(8), S(2)–C(12)–C(1) 124.4(7).

**4**

N(2) [109.3(7)°] and, above all, by the marked contraction by around 12° of the angle S(1)–C(12)–S(2) [117.6(5)°]. The ethylene structure causes a strong steric interaction between the isopropyl substituents and the sulfur atoms which results in a pronounced protrusion of the carbon atoms C(4) and C(7) by 1.112 and 1.023 Å, respectively, out of the plane defined by the five-membered ring. As a consequence from steric hindrance, the methyl protons of the isopropyl substituents appear as two broad signals in the NMR spectrum. We consider this reorientation of the $CS_2$ fragment upon reduction of the carbene adduct (in **3** the planes of the ring and the $CS_2$ fragment are perpendicular to each other) to be in a causal relationship with the quasireversibility that can be recognized in cyclovoltammetric studies.[10] It certainly proceeds in concert with the electron transfer and increases the activation barrier. The close analogy to the structure of the methyleneimidazoline **4**,[11] which reacts similarly to an ylide, excludes the take-up of π-electron density by the five-membered ring as is typical for conventional 1,1-dithiolates and makes the electronic argument for the bending of the isopropyl groups ($sp^3$ hybridisation of the nitrogen atoms) less favourable.

The geometry of **2** is indicative of a bonding situation that can be intepreted with regard to the electron distribution as an '*umpolung*' in comparison to conventional 1,1-dithiolates. We will report elsewhere on the results of cyclic voltammetry and the chemical properties of **2** which all support this hypothesis.

## Footnotes

† All reactions were performed under anaerobic and anhydrous conditions; **1** was prepared by a published procedure.[3]

To a suspension of 1.026 g (4 mmol) **1** in 30 ml tetrahydrofuran 0.20 g (5.12 mmol) potassium were added. The mixture was stirred for 16 h at room temperature. After separation of excess potassium and reducing to a small volume *in vacuo*, 30 ml diethyl ether were added. The resulting yellow solid was filtered off and washed three times with 20 ml of diethyl ether to give 1.562 g (81%) $C_{20}H_{40}K_2N_2O_2S_2$ (**2**·2$Et_2O$), identified by potassium and sulfur analysis. $^1H$ NMR (250 MHz, [$^2H_8$]tetrahydrofuran, $SiMe_4$ ext.): δ 4.74 [m, 2 H, C*H*$(CH_3)_2$], 1.72 [s, 6 H, 4,5-$CH_3$], 1.24, 1.05 [2 br s, 12 H, CH(C*H*$_3)_2$]; in addition, signals at δ 3.38 (q) and 1.10 (t) are observed arising from 2 equiv. of $Et_2O$. The compound decomposes readily in polar solvents like acetone and acetonitrile. At *ca.* 90 °C, potassium sulfides and unidentified organic compounds are formed. Crystals of **2**·2$C_4H_8O$·1/3 $K_2S_2$ have been obtained by slow evaporation of a tetrahydrofuran solution of **2**·2$Et_2O$.

‡ *Crystal data* for $C_{20}H_{36}K_{2.667}N_2O_2S_{2.667}$ (**2**·2$C_4H_8O$·1/3$K_2S_2$), $M$ = 526.27, trigonal, space group $P\bar{3}$, $a$ = 19.145(8), $c$ = 13.753(6) Å, $U$ = 4365.55 Å$^3$, $Z$ = 6, $D_c$ = 1.201 g cm$^{-3}$, μ(Mo-Kα) = 0.63 mm$^{-1}$, Siemens P4RA four-circle diffractometer, rotating anode generator, Mo-Kα radiation (λ = 0.710 73 Å), graphite monochromator, scintillation counter, $T$ = 150 K, empirical absorption corrections; direct methods, full matrix least-squares refinements, non-hydrogen atoms anisotropic, H atoms at idealized positions, one common isotropic temperature factor for H within each residue, one extinction parameter, one scaling factor; transmission range 0.714–0.516, $2\theta_{max}$ = 48°, ω scan, crystal dimensions *ca.* 0.75 × 0.65 × 0.21 mm, 3556 unique reflections, $R(R_w)$ = 0.0884 (0.0857) for 2358 reflections with $I > 2\sigma(I)$, 287 variables. The atomic displacement parameters indicate a possible disorder of the $C_4H_8O$ molecules which could not be resolved in terms of a physically meaningful superposition. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallograpic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Methods for attaching metal-capped sp carbon chains to metal clusters: synthesis, structure and reactivity of rhenium–triosmium carbon complexes $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(CC)_nOs_3(CO)_{10}H]$

**Stephen B. Falloon, Atta M. Arif and J. A. Gladysz***

*Department of Chemistry, University of Utah, Salt Lake City, Utah 84112, USA*

**Reactions of $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)\{(C{\equiv}C)_nH\}]$ and $[Os_3(CO)_{10}(NCMe)_2]$ give the title $Re(CC)_nOs_3$ complexes ($n$ = 1–3, 83–61%); a crystal structure ($n$ = 1), and IR and NMR properties, indicate contributions by neutral Re–$(C{\equiv}C)_n$–$(Os_3)$ and zwitterionic $^+Re{=}(C{=}C)_n{=}(Os_3)^-$ resonance forms.**

There has been much recent interest in unsupported sp carbon chains that span two transition metals.[1–4] These wire-like assemblies offer intriguing possibilities for molecular-level devices.[5] To date, nearly all such compounds feature monometallic endgroups. However, polymetallic endgroups might confer special attributes, including enhanced electronic coupling or communication between the termini, or greater capacitance in the case of good electron reservoirs. Indeed, two-dimensional superlattices of alkynyl- and aryl-linked metal clusters are under active pursuit in other laboratories, with the ultimate aim of nanoelectronic digital circuits.[6]

We were attracted by the architectural versatility of trimetallic clusters, which allow three $\eta^1$ modes of carbon chain attachment: (*i*) a $\mu_1$ link to one metal; (*ii*) an edge-bridging $\mu_2$ link to two metals; (*iii*) a face-bridging $\mu_3$ link to three metals. In the second and third modes, the ligating carbon does not necessarily remain sp hybridized. It should also be emphasized that there is extensive literature on metal cluster carbide complexes,[7] some of which provide models for surface-bound intermediates in heterogeneously catalysed commodity chemical processes. However, only a few contain sp carbon segments that span otherwise unconnected polymetallic termini.[3d,8–10]

**Scheme 1** Syntheses of $Re(CC)_nOs_3$ complexes. *Reagents and conditions*: i, $Os_3(CO)_{10}(NCMe)_2$, $CH_2Cl_2$, 20 °C; ii, $n$ = 2, hexane, reflux.

As shown in Scheme 1, the chiral, racemic rhenium ethynyl complex **1**[11] and triosmium complex $[Os_3(CO)_{10}(NCMe)_2]$ were reacted in $CH_2Cl_2$ at room temperature. After 3 h, chromatography gave an orange, air-stable product **2** (78%). The labelled complex $[^{13}C_2]$**2** was similarly prepared.† Spectroscopic data suggested the composition $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(CC)Os_3(CO)_{10}H]$. In particular, a diagnostic hydride ligand $^1H$ NMR signal (δ −16.7), and ten terminal CO $^{13}C$ NMR signals (δ 184–171), were observed. However, the ReC $^{13}C$ signal was between those of **1** and the cationic vinylidene complex[12] $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(=C{=}CH_2)]BF_4$ [δ 245.4 *vs.* 98.0 and 330.4, $J_{CP}$ 8.8 *vs.* 15.8 and 9.5 Hz ($CH_2Cl_2$, $C_6D_6$, $CH_2Cl_2$]; Re*C*C at δ 124.2 *vs.* 116.0 and 116.1). The IR $\nu_{NO}$ value showed a similar relationship (1667 *vs.* 1637–1629 and 1728–1711 $cm^{-1}$).

Many reactions of terminal alkynes and triosmium complexes $[Os_3(CO)_{10}L(L')]$ (L/L′ = CO or NCMe) have been reported.[13] However, to our knowledge no adducts analogous to **2** have previously been isolated. Thus, a crystal structure was determined.‡ The molecular structure, and key metrical parameters, are given in Fig. 1. The hydride and ReCC terminus symmetrically bridge the same two osmiums, with the $Os_3$ and $ReOs_2$ planes roughly orthogonal (105°). The rhenium–carbon bond [1.964(9) Å] is shorter than in complexes of formula $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(C{\equiv}CX)]$ [2.079(9), 2.037(5), 2.032(7) Å],[2a,c,d] but longer than in analogous cationic species with $Re{=}C(=C)_n$ linkages [1.909(7), 1.91(1), 1.916(7) Å].[2d,4a] Also, the carbon–carbon bond is longer than those in disubstituted organic alkynes and alkynyl complexes [1.252(12) Å *vs.* mean values of 1.192(12) and 1.210(13) Å].[14]

To help clarify these bonding issues, the IR spectra of **2** and $[^{13}C_2]$ **2** were compared. A 1705 $cm^{-1}$ band shifted to 1632 $cm^{-1}$ (calc for $\nu_{^{13}C^{13}C}$, 1637 $cm^{-1}$). Other absorptions in the 2100–1600 $cm^{-1}$ region were unaffected. These $\nu_{CC}$ values confirm that the $C_2$ bridge has appreciable double bond character. Hence, **2** is best described as a hybrid of the neutral and zwitterionic resonance forms **A** and **B** in Scheme 1. Also,

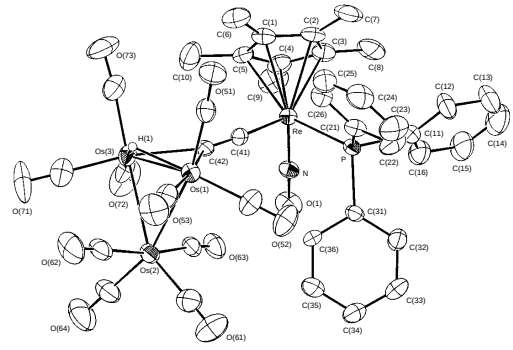

**Fig. 1** Molecular structure of **2**·0.5$C_6H_{14}$. Selected bond distances (Å) and angles (°): Re–P 2.395(2), Re–N 1.757(7), Re–C(41) 1.965(9), Os(1)–Os(3) 2.7933(7), Os(1)–H(1) 1.79(9), Os(3)–H(1) 1.82(9), Os(1)–C(42) 2.150(9), Os(3)–C(42) 2.164(9), C(41)–C(42) 1.252(12); N–Re–P 90.5(2), N–Re–C(41) 97.5(3), C(41)–Re–P 94.4(2), C(42)–C(41)–Re 174.2(7), C(42)–C(41)–Os(1) 139.3(7), C(42)–C(41)–Os(3) 140.0(7).

the P–Re–C(41) and C(42)–Os(1)–Os(3) units were nearly coplanar [angle 14.5(5)°], consistent with a frontier-orbital-derived conformational minimum as commonly observed for $^{+}$Re=C adducts such as **B**.[2d]

The extension of this simple procedure to higher carbon chains was investigated (Scheme 1). A similar reaction of the butadiynyl complex **3**[2a] and $[Os_3(CO)_{10}(NCMe)_2]$ gave the $ReC_4Os_3$ species **4** (83%) as a red–orange powder.† A low-temperature reaction of the hexatriynyl complex **5**[2b] afforded the corresponding $ReC_6Os_3$ species **6** (62%) as a thermally labile red–brown powder. However, the analogous octatetraynyl complex[2b] gave a multitude of products. Mass spectra of **4** and **6** showed intense molecular ions, and many NMR and IR properties were close to those of **2** (NMR: OsH δ −13.10, −15.90; ReC δ 242.9, 204.9; $PPh_3$ δ 21.6, 22.3 *vs.* 21.0; IR $\nu_{NO}$ 1662, 1663 $cm^{-1}$). Low-temperature $^{13}C$ NMR spectra were complicated by decoalescence phenomena, and practical routes to labelled $^{13}C_4$ or $^{13}C_6$ derivatives are unavailable. Thus, most $C_x$ NMR signals could only be provisionally assigned.

The stabilities of **2**, **4** and **6** decreased with increasing chain length. We sought to probe the nature of these decomposition pathways. When **4** was refluxed in hexane, CO was evolved. Work-up gave the nonacarbonyl complex $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(CCCC)Os_3(CO)_9(H)]$ **7** in 57% yield. Although material suitable for a crystal structure could not be obtained, the formulation was supported by microanalysis, mass spectrometry, NMR [(OsH δ δ22.34; ReC 242.9 (d, $J_{CP}$ 11.5 Hz)] and IR ($\nu_{NO}$ 1663 $cm^{-1}$).† A structure consistent with these data is given in Scheme 1. Analogous adducts of $Os_3(CO)_9H$ and other CCR ligands (R = H, $Me_3$, *etc.*) have been previously characterized.[13,15] All exhibit OsH NMR signals near δ −23, and IR $\nu_{CO}$ band patterns similar to **7**.

Additional properties of **2**, **4**, and **6** were compared. UV–VIS spectra showed progressive red shifts of the longest wavelength band [λ/nm, hexane (ε/$dm^3$ $mol^{-1}$ $cm^{-1}$): **2**, 316 (20 000), 350 (21 000), 384 (18 000); **4**, 296 (20 000), 388 (7500), 500 (4900); **6**, 306 (18 000), 516 (3600)]. No absorptions were significantly solvatochromic (hexane, $CH_2Cl_2$, acetonitrile). Cyclic voltammograms ($CH_2Cl_2$–$NBu_4BF_4$, 100 mV $s^{-1}$) showed partially reversible oxidations with $E°$ values of 0.78, 0.43, and 0.44 V, respectively (ferrocene standard, $E°' = 0.46$ V). These have no counterparts in triosmium complexes $[Os_3(CO)_{10}L_2]$, and are much less favourable thermodynamically than oxidations of $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(C{\equiv}CX)]$ complexes.[2] This may be due to the zwitterionic character.

While this work was in progress, the reaction of the tungsten butadiynyl complex $[(\eta^5\text{-}C_5H_5)W(CO)_3(C{\equiv}CC{\equiv}CH)]$ and triruthenium complex $[Ru_3(CO)_{10}(NCMe)_2]$ was briefly described.[16] In contrast to Scheme 1, a π adduct of the C≡CH moiety formed. This rearranged in refluxing benzene to a $[WC_4Ru_3(CO)_9H]$ complex analogous to **7**. Tungsten alkynyl complexes $[(\eta^5\text{-}C_5R_5)W(CO)_3(C{\equiv}CR')]$ and $[Os_3(CO)_{10}(NCMe)_2]$ react in refluxing toluene to give tetranuclear products of formula $(\eta^5\text{-}C_5R_5)WOs_3(CO)_{11}(C{\equiv}CR')$].[17]

We have demonstrated that sp carbon chains with $Os_3(CO)_{10}$ endgroups are easily constructed. However, the $\eta^1,\mu_2$ assemblies are labile. From some standpoints this is desirable, as other architecturally interesting carbon complexes can be readily accessed. However, from the perspective of long-lived molecular devices, this is undesirable. Hence, future efforts would be best directed at trimetallic systems with less dissociable spectator ligands, a more restricted set of binding modes, and higher kinetic barriers. Regardless, the new $Re(CC)_nOs_3$ complexes described above have numerous interesting properties, and further investigations are ongoing.

We thank the Department of Energy for support of this research.

## Footnotes

† All new complexes were characterized by IR and NMR ($^1H$, $^{13}C$, $^{31}P$) spectroscopy, as summarized (with crystallographic data) in supplementary material provided to the reviewers and available from the author. Solid samples showed a marked tendency to retain hexane, even after vacuum drying. Correct microanalyses could be obtained for solvates of **2**, **6** and **7**. *Representative data*: IR ($cm^{-1}$, hexane) 2091m, 2054s, 2039m, 2005vs, 1981m, (sh) 1969m, 1705m, 1667m. NMR (δ, $CD_2Cl_2$): $^1H$ 7.99, 7.40, 7.26 (m, 3 Ph), 1.74 (s, $C_5Me_5$), −16.70 (s, OsH); $^{13}C\{^1H\}$ {for [$^{13}C_2$] **2**} 245.4 (dd, $J_{CP}$ 8.8, $J_{CC}$ 64.5 Hz ReC), 183.9, 183.8, 182.8, 181.9, 179.4, 178.4, 175.3, 172.8, 172.4, 170.7 (s, 10 CO), 135.6 (br d, *o*-Ph), 132.1 (br d, *ipso*-Ph), 129.3 (s, *p*-Ph), 128.5 (br d, *m*-Ph), 124.2 (d, $J_{CC}$ 64.5 Hz, ReCC), 104.8 [s, $C_5(CH_3)_5$], 10.2 [s, $C_5(CH_3)_5$]; $^{31}P\{^1H\}$ 21.0s.

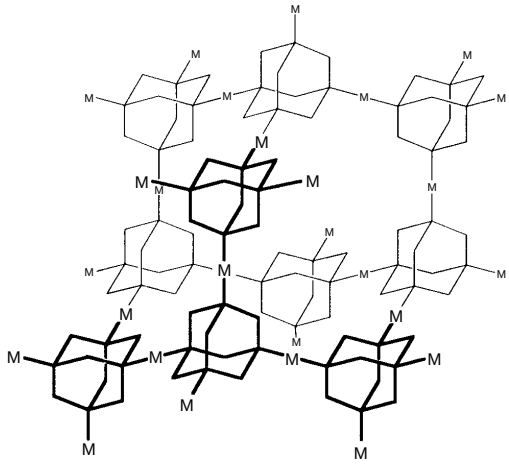
# Self-assembly of a three-dimensional network from two-dimensional layers *via* metallic spacers: the (3,4)-connected frame of $[Ag_3(hmt)_2][ClO_4]_3\cdot 2H_2O$ (hmt = hexamethylenetetramine)



**Lucia Carlucci, Gianfranco Ciani,* Dorothea W. v. Gudenberg, Davide M. Proserpio and Angelo Sironi**

*Dipartimento di Chimica Strutturale e Stereochimica Inorganica and Centro CNR, Via G. Venezian 21, 20133 Milano, Italy*

**$AgClO_4$ reacts with hexamethylenetetramine (hmt) in ethanol–$CH_2Cl_2$ in the ratio 1 : 1 to yield the two-dimensional polymer [Ag(hmt)] $ClO_4$, consisting of hexagonal meshed layers, while a twofold excess of $AgClO_4$ produces $[Ag_3(hmt)_2]ClO_4]_3\cdot 2H_2O$, in which $Ag^I$ ions intercalate between the sheets of the two-dimensional polymer, joining them as spacers to give a three-dimensional (3,4)-connected open network of uncommon topological type.**

The recent efforts in the field of crystal engineering of networked materials based on polymeric coordination compounds[1,2] have been devoted to the use of novel polydentate ligands. In contrast to the more common frameworks based on metal centres and bidentate organic rods, the presence of polyhapto bases also introduces organic centres in addition to the metallic ones, which can give rise to new and varied topological types. Very interesting frames have been assembled with large trihapto trigonal ligands, such as 2,4,6-tris(4-pyridyl)-1,3,5-triazine,[3] 1,3,5-tris(4-ethynylbenzonitrile)-benzene[4] and tricyanomelamine.[5] With polydentate bases L (of hapticity greater than two) the topology of the array may also be entirely determined by the ligands, when the metals (such as diagonal $Ag^I$ and $Cu^I$) do not occupy nodes of the net, but work as simple spacers (L–M–L metallic synthons).† In this concern a potentially tetradentate ligand such as hexamethylenetetramine (hmt) seems quite suitable for the preparation of supertetrahedral networks with metallic synthons (see Scheme 1), paralleling the supramolecular organic chemistry of adamantyl templates with different synthons,[6] well exemplified by the fivefold interpenetrated frame of the adamantane-1,3,5,7-tetracarboxylic acid.[7]

Working on these lines we have reacted hmt with different $Ag^I$ salts of non-coordinating anions and we have recently described the polymeric $[Ag(hmt)]PF_6\cdot H_2O$,[8] containing a three-dimensional triconnected frame topologically related to the prototypal $SrSi_2$. We report here that hmt reacts with $AgClO_4$ in the ratio 1 : 1 to yield the two-dimensional polymer $[Ag(hmt)]ClO_4$ **1**, while a twofold excess of $AgClO_4$ gives $[Ag_3(hmt)_2][ClO_4]_3\cdot 2H_2O$ **2**, in which metal ions (with their counter-ions and water molecules) intercalate between sheets like those of **1**, joining them (as spacers) to give a three-dimensional (3,4)-connected network of uncommon topological type.

**Scheme 1**

Compound **1** can be obtained in large yields, as needle shaped colourless crystals, on layering over a $CH_2Cl_2$ solution of hmt an ethanolic solution of $AgClO_4$ (molar ratio 1 : 1). The crystal structure of **1**‡ consists of two-dimensional infinite layers of hexagonal meshes formed by alternate triconnected silver ions and hmt molecules [Fig. 1(*a*)]. These layers are similar to those present in the polymeric $[Ag(hmt)]NO_3$),[9] the main difference being the stronger Ag–O($NO_3^-$) interactions, 2.593(8) and 2.62(1) Å, *vs*. the Ag···O($ClO_4^-$) ones in **1**, 2.796(5) Å. It is noteworthy that the rings in the sheets present a rare conformation of the boat type [see Fig. 2 (*a*)], instead of the usual chair conformation (grey arsenic-like or black phosphorus-like layers).

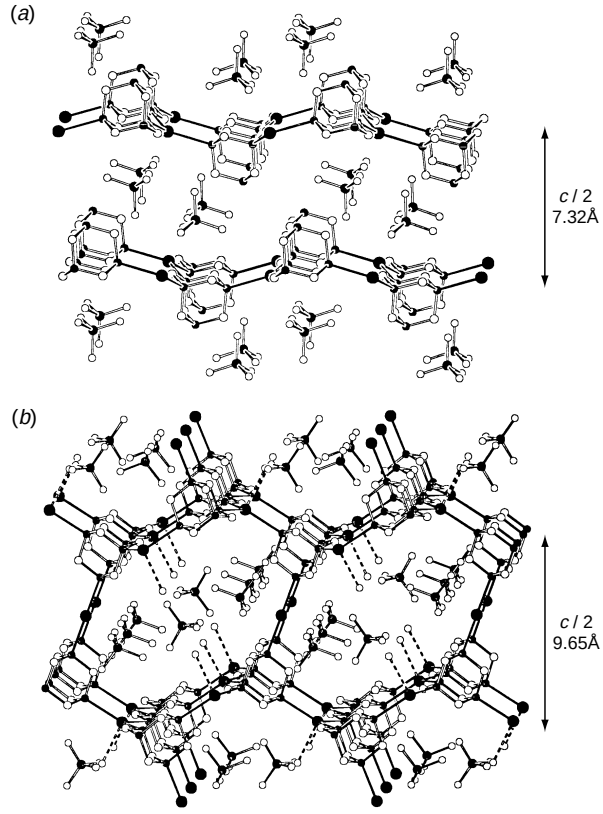


**Fig. 1** A SCHAKAL view of the stacking of the two-dimensional layers in compounds **1** (*a*) and **2** (*b*). In **2** only one of the two locations of the statistically disordered $ClO_4^-$ and $H_2O$ (see text) is shown for clarity.

On performing the above reaction with an $AgClO_4$ : hmt ratio of 2 : 1 we have observed the initial formation of crystals of **1**, but on allowing the solution to concentrate by evaporation the reaction further proceeds giving fine multifaced crystals of **2**, investigated by X-ray diffraction analysis.‡

The structure of **2** consists of an open three-dimensional cationic network formed by [Ag(hmt)] hexagonal layers as in **1**, joined by biconnected silver ions, which coordinate to the free N atoms of the hmt ligands [Fig. 1(*b*)]. The Ag–N bond lengths for these spacers, 2.223(5) Å, are shorter than those involving the other silver ions, 2.355(5)–2.396(4) Å [2.326(5)–2.373(4) Å in **1**]. On passing from **1** to **2** a relative sliding of the layers takes place, together with a change of the ring conformation from boat to chair (to give black phorphorus-like layers) and, what is particularly interesting, the interlayer separation increases from 7.32 to 9.65 Å. Guest water molecules occupy the large, approximately hexagonal, channels [Fig. 1(*b*)] and interact with the silver ions of the layers [Ag–O bond lengths of 2.467(10) Å]. Thermal analyses have shown that these water molecules can be reversibly removed from the crystals by thermal activation.§

From the topological point of view the three-dimensional framework of **2** is a (3,4)-connected net, comprised of triconnected (silver ions of the layers) and tetraconnected (hmt molecules) centres in the ratio 1 : 1 [Fig. 2,(*b*)]. The topological type can be assigned, following the pioneering ideas of Wells,[10] on considering that the shortest circuits starting and ending on each centre are all three 6-gons for the triconnected silver ions and 6-gons and 8-gons in the ratio 5 : 1 for the hmt ligands, hence $(6^3)(6^5,8)$. Wells has described four nets with this connectivity and has classified that one here reported as $(6^3)(6^5,8)$-b,[10] space group *Pnnm*, in its highest symmetry. Though this seems to be one of the more simple (3,4)-connected nets we have been able to find only one net with the same topology, namely InS (triconnected S and tetraconnected In).[12]

We have not isolated the supertetrahedral $[Ag_2(hmt)]$ hypothetical frame of Scheme 1, but compound **2** represents at least a step in that direction. Factors such as, *inter alia*, the tendency of the metal ions to achieve coordination numbers higher than two and that of hmt to be less than tetradentate, as in **1** and in $[Ag(hmt)]PF_6 \cdot H_2O$, can operate against the desired goal. Nevertheless, interesting networks joined exclusively *via* metallic synthons will probably assume some relevance in the near future.

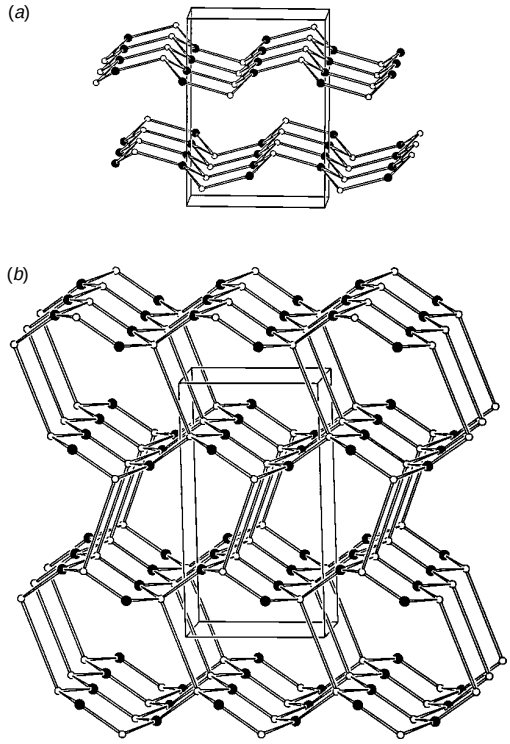

**Fig. 2** A schematic view, approximately down the **a** axis, of the two-dimensional layers in **1** (*a*) and of the three-dimensional network $(6^3)(6^5,8)$-b in **2** (*b*). Filled spheres = $Ag^I$ open spheres = baricentres of the hmt molecules.

## Footnotes

† We call metallic synthon, extending the term used for the supramolecular interactions in organic systems by Desiraju,[6] the interaction of two polydentate organic bases mediated by a metal ion (or complex) which, dedicating only two coordination sites to the net, does not influence its topology. Hoskins and Robson have previously considered this kind of interaction.[1a] However, the networks exclusively based on organic molecules (as centres) and metallic synthons are quite rare.

‡ *Crystal data*: **1**; orthorhombic, *Pmcn* (no. 62), $a$ = 6.484(2), $b$ = 10.636(3), $c$ = 14.651(3) Å, $U$ = 1010.4(5) Å$^3$, $Z$ = 4, $D_c$ = 2.285 Mg m$^{-3}$, Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). The data collection was performed at 293 K on an Enraf-Nonius CAD-4 diffractometer, by the $\omega$-scan method, within the limits $3 < \theta < 25°$. The structure was solved by direct methods (SIR92) and refined by full-matrix least-squares analysis (SHELX93). The final agreement index $R$ was 0.0274 for 674 independent significant [$I > 3\sigma(I)$] absorption corrected data. Anisotropic thermal factors were assigned to all the non-hydrogen atoms.

**2**; orthorhombic, *Pnnm* (no. 58), $a$ = 6.533(2), $b$ = 10.453(2), $c$ = 19.293(8) Å, $U$ = 1317.5(7) Å$^3$, $Z$ = 2, $D_c$ = 2.365 Mg m$^{-3}$. The structure was solved by direct methods and refined by full-matrix least-squares analysis. One of the perchlorato anions and the solvated water molecule, which is hydrogen bonded to it, form a pair statistically disordered about a mirror plane. The final agreement index $R$ was 0.0453 for 1158 independent significant [$I > 3\sigma(I)$] absorption corrected data. Other experimental features are as in **1**.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/378.

§ Differential scanning calorimetry (DSC) shows an endothermic peak at *ca.* 120 °C and thermogravimetric analysis (TGA) gives a mass loss in the range 70–130 °C corresponding to two water molecules per formula unit. Decomposition of the compound begins above 200 °C. Samples heated to 140 °C and left in air for a few hours display again the same DSC peak.

# A combinatorially developed reducing agent

**Fredric M. Menger,* Craig A. West and Julia Ding**

*Department of Chemistry, Emory University, Atlanta, Georgia 30322, USA*

**An automated search of thousands of combinatorially-functionalized polymers bearing dihydropyridine groups defines a few active examples that can reduce a ketone in water.**

Recently we introduced a new approach to reaction dynamics in which a huge library of randomly-functionalized polymers was screened for catalytic activity toward phosphate ester hydrolyses.[1] Rate enhancements as large as $3 \times 10^4$ were thereby uncovered (exceeding those reported for a corresponding catalytic antibody). It was argued that the approach provides an alternative to the classical method of synthesizing enzyme models in which multiple functional groups are in the proper juxtaposition to effect catalysis. Such synthetic work can be extremely time consuming, and there is no guarantee, even when the desired compound is in hand, that it will perform as hoped.

The details are simple. Two commercially available polymers, poly(allylamine) (PAA, MW = 50–60 kD) and poly(ethylenimine) (PEI, MW = 25 kD), were randomly derivatized, *via* amide bonds, by a mixture of three or four carboxylic acids selected from Fig. 1. EDCI, a water-soluble carbodiimide, was used as the coupling agent. From 20–60% of the polymer amino groups were functionalized, the remainder being left untouched. For example, a polymer might be constructed with 10% naphthyl groups, 15% imidazole groups, 5% octyl groups and 5% butanol groups (using Nap, Imi, Oct and BuOH in Fig. 1, respectively). All kinetic runs were carried out at pH 7.2 where the free amino groups, being largely protonated, solubilize the polymer in water. In addition, any unprotonated amino groups could act as ligands for metals (*e.g.* $Cu^{+2}$) that were added to the system.

Aqueous solutions of polymer, EDCI, and the various carboxylic acids were made available to an automatic pipeting device. A computer program directed the device to dispense the reactants (including 96 different concentration ratios of carboxylic acids) into a set of test tubes for a 24 h incubation at 55–60 °C. No unreacted carboxylic acid was detected by TLC after this time. The resulting polymers were 'randomly' substituted in the sense that no control was exercised over the functionalizations. In actual fact, however, the positioning of the four substituents, and the subsequently added metal ion, may not be 'random' in the strict meaning of the word. For example, when one amino group is derivatized with an octanoyl group, the adjacent amino groups may become more prone to receiving other octanoyl groups owing to hydrophobic attraction. To preclude confusion about the meaning of 'random', compounds will henceforth be called 'combinatorial polymers'. Each combinatorial polymer is, of course, a complex system[2] composed of a mixture of polymeric variations that is impossible to separate. Even if we could isolate a pure component, it would be extremely difficult to sequence it because (unlike proteins) the polymer chain cannot be subdivided. Fortunately, our goals are directed primarily toward function. A polymer system that serves a useful function is of great interest even in the absence of detailed structural information.

It was clear that, in order for combinatorial polymers to become something other than a curiosity, they must be able to do more than catalyse the ever-popular ester hydrolysis. For this reason we have been examining eliminations, condensations and redox systems of synthetic utility. This article focuses on the conversion of ketones to alcohols *via* combinatorial polymers having a reductive capacity. Reducing capabilities were imparted to the polymers by incorporating (simultaneously with the other diverse functionalities) a 5 or 10% content of the dihydropyridine DHP. Dihydropyridines are well known from NADH models[3–8] to convert activated ketones into alcohols. The hope, therefore, was to construct active sites that promote enzyme-like reductions within their confines.

Combinatorial polymers were screened for their ability to homogeneously reduce benzoylformic acid ($PhCOCO_2^-$) to

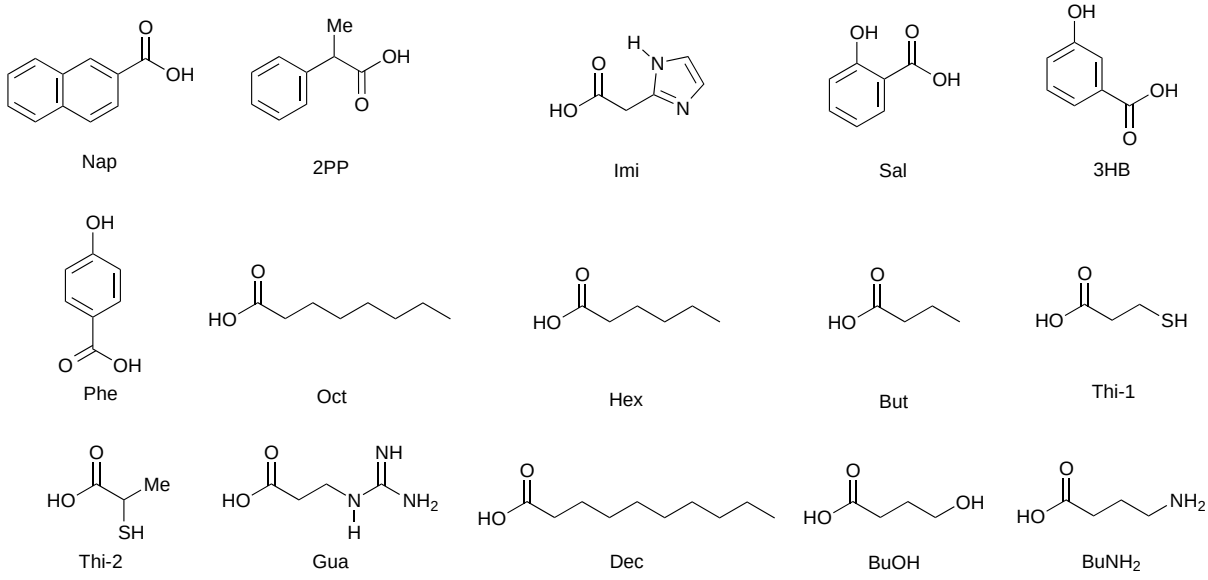

**Fig 1** Carboxylic acids used to derivatize the polyamines

**Table 1** Five active polymers taken from a library of over 8000, most of which were inactive[a]

| Polymer | Side-chains[b] | Activity (%) |
|---|---|---|
| PEI | 2.5% Imi, 5% Hex, 7.5% Nap, 2.5% Thi-1, 5% $Zn^{+2}$ | 30 |
| PEI | 15% Hex, 2.5% Gua, 2.5% BuOH, 5% $Mg^{+2}$ | 33 |
| PEI | 2.5% Imi, 15% Nap, 2.5% Hex, 5% $Mg^{+2}$ | 34 |
| PAA | 10% Imi, 2.5% Hex, 10% Nap, 10% Thi-2, 10% $Zn^{+2}$ | 42 |
| PAA | 2.5% Gua, 7.5% Hex, 7.5% Nap, 2.5% Thi-2, 10% $Cu^{+2}$ | 28 |

[a] Each activity is an average from three polymers created *de nova*. The uncertainty in the values is 6 in absolute %. [b] Symbols are defined in Fig. 1. Percentages represent the composition of solutions from which the polymers were made.

mandelic acid [$PhCH(OH)CO_2^-$]. A total of 96 runs at a time were carried out side-by-side within the 400 μl wells of a microtiter plate. Each well contained the following components dissolved in a pH 7.2 TRIS buffer at 24 °C: 50 μl of a functionalized polymer (corresponding to 2.4 mM of the dihydropyridine); 100 μl of 1.25 mM $Cu^{+2}$, $Mg^{+2}$ or $Zn^{+2}$; and 150 μl of 0.021 M benzoylformic acid. Reactions were monitored periodically, with an ICN MCC/340 scanner, at 340 nm for the disappearance of the dihydropyridine chromophore. Data, recorded as percentage yield, refer to the percent of oxidized dihydropyridine after 5 days when all the reactions had ceased. The percentage yield varied from 0–50% depending upon the polymer functionalization. A yield of 23%, for example, indicates that 23% of the 25–100 dihydropyridine sites per polymer chain were active. A larger scale reaction, worked up by column chromatography on silica (MeOH–$CHCl_3$–$H_2O$, 30 : 60 : 4) gave a product identified as mandelic acid by $^1H$ NMR spectroscopy. GLC analysis of mandelic acid (as the methyl ester) gave a percentage yield that corresponded to that calculated from the dihydropyridine chromophore.

Among a total of 8198 polymers tested, 92% were considered inactive ( < 10% yield). Activities of 10–20, 20–40 and > 40%, were found in 7, 1 and 0.3% of the polymer population, respectively. Two of the most active polymers ( > 25%) were: (*a*) PEI; 5% DHP; 2.5% Imi; 15% Nap; 2.5% Thi-1; 5% $Zn^{+2}$. (*b*) PAA; 10% DHP; 10% Imi; 2.5% Hex; 10% Nap; 10% Thi-2; 10% $Zn^{+2}$. By contrast, the following two were inactive: (*a*) PEI; 5% DHP; 5% Imi; 5% BuOH; 5% Nap; 5% Sal; 5% $Zn^{+2}$ or 5% $Mg^{+2}$; (*b*) PAA; 10% DHP; 5% Dec; 5% Gua; 7.5% 2PP; 5% Sal; 10% $Zn^{+2}$. Table 1 lists five additional reactive polymers; note that recipes for PAA and PEI are, in general, not the same.

The multitude of inactive systems can be regarded as 'controls' in that, apart from polymer composition, they duplicate the reaction conditions. Moreover, mixtures of individual components that simulated the high-activity polymers were all found to be inert. Thus, a polymer was functionalized only with the DHP. No reducing capabilities were observed with this polymer when (after purification from EDCI by GPC) it was mixed with an appropriate combination of free acids in Fig. 1 plus a metal ion. Clearly, a polymeric ensemble of functionalities is necessary for activity. Lack of disappearance of the DHP chromophore in the control also demonstrated the stability of DHP to hydrolysis. A single run with poly(ethylenimine) of low molecular weight (7 kD) was also carried out. This polymer, endowed with a 'favourable' substituent ratio with respect to the 25 kD polymer, gave no reaction. Although a useful combinatorial polymer of low molecular weight might well exist, one would have to discover its recipe in a separate and distinct set of screenings.

To assess the reproducibility of the combinatorial polymers, two people each prepared the ten best polymers discovered by the other. Yields were reproduced within a factor of two and usually much better. The same was true when duplicating a full set of 96. Although not all the variables affecting the polymer functionalizations have been systematically investigated, it is known that the reaction conditions are critical. For example, the presence of a dioxane cosolvent in the functionalization mixtures has a profound effect upon the activity of the resulting polymer. This is hardly surprising; polymer sequences would be expected to have a high solvent sensitivity. Sequences could also be sensitive to the order in which functionalities are placed onto the polymer, but this point has not yet been tested.

Thousands of activity data are best summarized by the following generalizatons. (*a*) A metal ion is necessary for activity. (*b*) All high-activity polymers possess at least one hydrophobic side-chain (Nap Oct, *etc.*). (*c*) Imi or Gua is found in most but not all reactive polymers. (*d*) Percentages within a single set of functionalities can be important. For example, PEI with 2.5% Imi, 15% Nap and 2.5% Thi-1 (plus 10% $Mg^{2+}$) had an activity of 40%. The same system but with 10% Imi, 2.5% Nap, and 7.5% Thi-1 had an activity of only 1.3%. (*e*) No active poly(allylamines) were observed when they contained oxalic or malonic acid even in concert with other seemingly 'beneficial' combinations. (*f*) A thiol or hydroxy group often assists the reduction. Coincidentally, no doubt, alcohol dehydrogenase also requires a dihydropyridine (NADH), a metal ion ($Zn^{2+}$ coordinated to two thiolates), a histidine and a serine.[9]

The half-life of our better reductions is about 2 h. This is fast relative to many other 'NADH models'[3] which, in order to obtain any reaction at all, require aprotic solvents rather than water, as used in our experiments.

The potential for combinatorial reactivity seems unlimited. In the specific case at hand, one can contemplate: (*a*) achieving true catalysis *via* an external reducing agent that regenerates the dihydropyridine units of high-activity polymers; (*b*) discriminating between two ketones (*e.g.* reducing $PhCOCO_2^-$ but not $PhCOCO_2Me$) or between two similar ketones in the same molecule [*e.g.* reducing $MeCO(CH_2)_2CO(CH_2)_3Me$ to $MeCO(CH_2)_2CHOH(CH_2)_3Me$]; (*c*) stereoselectively reducing ketones with chiral polymers (*e.g.* polymers based on poly-L-lysine or on PAA with chiral substituents).

Low cost is an important virtue of combinatorial polymers. Once an active polymer is discovered, it can be prepared in large amounts and in a single step without specialized biochemical methods.

We thank the National Science Foundation for support of this work.

# Asymmetric hydroformylation catalysed by platinum complexes of new chiral bisphosphites

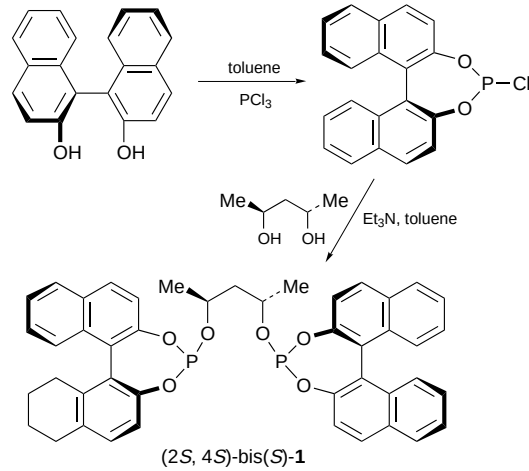
**Stefánia Cserépi-Szücs and József Bakos***

*Department of Organic Chemistry, University of Veszprém, H-8201 Veszprém, PO Box 158, Hungary*

**Asymmetric hydroformylation of styrene using bis(phosphite)$PtCl_2$–$SnCl_2$ systems gives branched aldehydes with high enantioselectivity (up to 91%).**

Asymmetric hydroformylation is a convenient synthetic method for obtaining optically active aldehydes from olefinic substrates.[1] These aldehydes are attractive building blocks in organic synthesis.[2] Most compounds which have been developed for chiral modification of catalysts are chiral derivatives of aryl- or alkyl-phosphines; less work has been done with less electron-rich ligands such as phosphites. For asymmetric hydroformylation of olefins, chiral diphosphine–$Rh^{I}$,[3] diphosphine–$Pt^{II}$,[4] bisphosphite–$Rh^{I}$[5] or phosphinephosphite–$Rh^{I}$[6] have mostly been used. Surprisingly, however, there have been no reports on the application of bisphosphite–$Pt^{II}$–$SnCl_2$ complexes for asymmetric hydroformylation. This system may reasonably be expected to represent an alternative to the diphosphine system because the less electron-rich phosphites may cause dramatic changes in the reactivity and selectivity.

Here we report the synthesis and spectroscopic characterization of new bisphoshites, which afforded highly active platinum catalysts for asymmetric hydroformylation. The highest enantioselectivity (91%) was obtained with the platinum(II)–$SnCl_2$ catalytic system associated with (2*S*,4*S*)-bis(*S*)-**1** and its enantiomer (2*R*,4*R*)-bis(*R*). These ligands are of particular interest, because they contain a chiral centre in the backbone and a chiral axis in the terminal groups. In this regard, these model ligands show the exploration of chiral cooperativity.

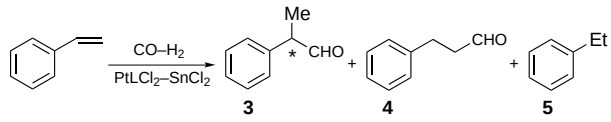


The reaction of racemic 1,1′-bi-2-naphthol with excess $PCl_3$ in toluene catalysed by 1-methylpyrrolidin-2-one gave phosphorochloridite (*S*,*R*)-6-chlorodinaphtho[*d*,*f*][1,3,2]dioxaphosphepine. Two equivalents of the racemic dioxaphosphepine were reacted with optically pure (2*R*,4*R*)-pentane-2,4-diol in the presence of triethylamine to give a diastereoisomeric mixture of 2,4-bis[dinaphtho[*d*,*f*][1,3,2]dioxaphosphepin-6-yloxy]-pentane. Diastereoisomers were obtained in a 1 : 2 : 1 ratio showing that the chiral pentanediol does not induce diastereoselectivity in the bisphosphite formation. Separation of the diastereoisomers was not successful.

In the $^{31}P$ NMR{$^{1}H$} spectrum of the product at ambient temperature, six lines are observed with relative intensities and splitting consistent with the expected three diastereoisomers. An explanation is that four resonances arise from the *meso* form, (2*R*,4*R*)-(*S*,*R*) = (2*R*,4*R*)-(*R*,*S*). The 2D homonuclear $^{31}P$ COSY NMR spectrum of the product confirms the existence of coupling ($^{6}J_{P–P}$ 9.5 Hz) between the P atoms (δ 149.0 and 153.6) six bonds apart.[7] Two singlets [δ 153.6 for (2*R*,4*R*)-bis(*R*)-**1** and 147.1 for (2*R*,4*R*)-bis(*S*)-**2**]) are attributed to the presence of the other two diastereoisomers. This was supported by the NMR spectra of the optically pure diastereoisomers obtained from (*S*)-6-chlorodinaphtho[*d*,*f*]-[1,3,2]dioxaphosphepine and (2*S*,4*S*)- (Scheme 1) or (2*R*,4*R*)-pentane-2,4-diol, respectively. In these cases the other two diastereoisomers were not detected by $^{31}P$ NMR. This implies that the diastereoisomers (**1** and **2**) were obtained in optically pure form. Optical resolution of 1,1′-bi-2-naphthol was carried out by using (*R*,*R*)-(+)-2,3-dimethoxy-*N*,*N*,*N*′,*N*′-tetramethylsuccinamide as a host compound[8] or (8*S*,9*R*)-(−)-*N*-benzylcinchonidium chloride as a resolving agent.[9]

Phosphites **1** and **2** in $CD_2Cl_2$ form phosphite–platinum complexes. The $^{31}P$ NMR{$^{1}H$} spectrum of $PtCl_2$[(2*S*,4*S*)-bis(*S*)-**1**] yields a characteristic satellite 'triplet' pattern (δ 87.5, $J_{Pt–P}$ = 5672 Hz) and of $PtCl(SnCl_3)$[2*S*,4*S*)-bis(*S*)-**1**] exhibits a P–P coupling pattern ($J_{P–P}$ = 20 Hz) with well separated chemical shifts (δ 98.0 and 89.1) and large inequivalent P–Pt coupling constants (5580 and 4420 Hz) as expected for inequivalent P atoms in positions *trans* to the chloro and $SnCl_3$ ligands, respectively. Reaction of $PtCl_2(PhCN)_2$ with both **1** and **2** afforded only the expected *cis* mononuclear eight-membered complexes without any oligomeric species. Oligomeric platinum complexes of diphospholes, dibenzophospholes and bisbinaphthophospholes have been reported with *trans* P–Pt–P disposition.[10]

In a typical experiment the autoclave was filled with solvent, alkene and the catalyst precursor. Catalysts were prepared *in situ* by simple mixing $PtCl_2(PhCN)_2$ in toluene or in dichloromethane with the ligands, while anhydrous $SnCl_2$ was used as co-catalyst. It was then purged with syn gas [$CO–H_2$ (1 : 1)] and pressurised. Catalytic reactions were carried out under classical conditions to give a mixture of the branched (*b*, 2-phenylpropanal) and the normal (*n*, 3-phenylpropanal) regioisomers and hydrogenated (ethylbenzene) products. At the end of the reaction the autoclave was cooled and depressurised. The reaction mixture was directly vacuum distilled to remove the catalyst. The reaction mixture and the distilled products were analysed by GC. The enantiomeric excess was determined by GC using a chiral capillary column.



Some representative results are given in Table 1. When **1** or **2** was used as the ligand in platinum catalysed asymmetric hydroformylation of styrene, the absolute configuration of central chirality in the bridge is of primary importance in asymmetric induction (Table 1). In the case of (2*S*,4*S*)-bis(*S*)-**1**, there is a cooperative effect of the axial chirality of the terminal 1,3,2-dioxaphosphepine groups and the central chirality of the

(2*S*, 4*S*)-bis(*S*)-**1**

**Scheme 1**

**Table 1** Enantioselective hydroformylation of styrene catalysed by bis(phosphite)$PtCl_2$-$SnCl_2$ complex [100 atm. of $H_2$–CO (1 : 1), P/Pt: 2.05, $SnCl_2$/Pt: 1.0][a]

[a] Reactions were carried out in the given solvent [*ca.* 2.5 mol $dm^{-3}$, except in $CH_2Cl_2$ (8.35 mol $dm^{-3}$)] in a 20 ml stainless-steel autoclave under an atmosphere of $H_2$ and CO (1 : 1) at 100 atm. initial total pressure. [b] Conversions and composition of the reaction mixture (*b* : *n* : *h* branched : normal : hydrogenated) were determined by GC (SPB-1) using decane as an internal standard. [c] Determined by GC analysis (β-DEX, 30 m, id. 0.25 mm) of the corresponding acid. [d] Determined by the sign of optical rotation of the corresponding aldehyde.

backbone. The highest enantioselectivity (91% *R*) was obtained with the platinum(II)–$SnCl_2$ catalytic system associated with (2*S*,4*S*)-bis(*S*)-**1** and its enantiomer (2*R*,4*R*)-bis(*R*)-**1** (matched constellation).[11] Reactions with (2*R*,4*R*)-bis(*S*)-**2** (mismatched constellation) resulted in much lower enantioselectivities. Up until now the highest enantioface discrimination (86.3% ee) has been reported[4b] for the hydroformylation of styrene to hydratropaldehyde with the platinum–Sn system [(*R*,*R*)-BCO-DBP]$PtCl_2$ [BCO-DBP = 5,5′-(bicyclo[2.2.2]octane-2,3-diyldimethyl)bis(5*H*-benzo[*b*]phosphindole)].

Addition of $SnCl_2$ is essential for catalytic activity. The role of the $SnCl_2$ co-catalyst in promoting the key steps of Pt–Sn-catalysed hydroformylation, such as the alkene insertion, the CO insertion and the hydrogenolysis of acyl complexes, has been thoroughly investigated.[12] A dramatic increase in reaction rate and a slight decrease in enantioselectivity were found when the reaction temperature was increased. Regioselectivity was almost independent of reaction temperature.

In spite of the high hydrogenation activity of the catalyst, we were able to find a catalytic system with remarkably high hydroformylation activity. For example, in dichloromethane at 60 °C, hydroformylation rates of *ca.* 1100 and 530 turnovers $h^{-1}$ at 54 and 88% of conversion were observed in combination with high enantioselectivity (75% ee), respectively. Surprisingly when $Rh(CO)_2(acac)$ was used as a catalytic precursor (100 atm. and 60 °C) both diastereoisomers afforded the same preferred *R* enantiomer in the product with the same regioselectivity (81 : 19 *b*/*n*), enantioselectivity (16% ee) and with complete chemoselectivity.

Financial support from the Hungarian National Science Foundation (OTKA-T016269) and the Ministry of Culture and Education (MDM-698/95) is gratefully acknowledged. We are grateful to Mr Béla Édes for skillful assistance in the catalytic experiments.

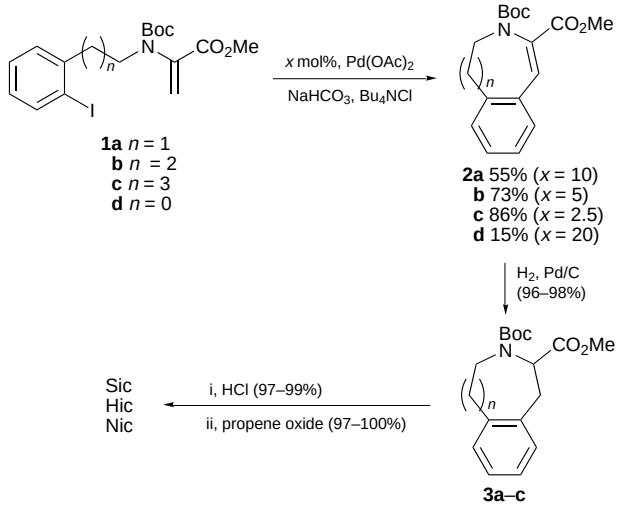
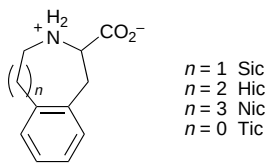
# Application of 7-*endo*, 8-*endo* and 9-*endo* radical cyclisations to the synthesis of conformationally constrained amino acids and comparison with the corresponding Heck reactions



**Susan E. Gibson (née Thomas),[a]† Nathalie Guillo[a] and Matthew J. Tozer[b]**

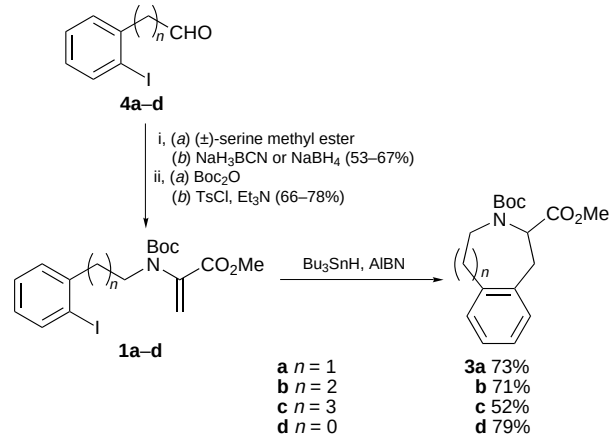
[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*
[b] *James Black Foundation, 68 Half Moon Lane, London, UK SE24 9JE*



**Radical cyclisation of substrates 1a–c proceeds smoothly to give seven-, eight- and nine-membered rings 3a–c in 73, 71 and 52% yield respectively; comparison of these results with those obtained using the intramolecular Heck reactions suggests that the two cyclisation methods provide complementary approaches to medium-sized rings.**

The formation of seven-, eight- and nine-membered rings *via* radical cyclisation methods is generally believed to be difficult and hence of marginal synthetic use.[1] Indeed, whilst there are several hundred examples of high-yielding radical-based five- and six-membered ring-forming reactions,[1a] examples of the formation of seven-membered rings by this approach are relatively rare,[1a,2] and most of them proceed in moderate yield. A mere handful of eight-membered ring syntheses have been reported,[1a,3] and, to the best of our knowledge, there are only two reports to date of radical-mediated nine-membered ring-forming reactions.‡,[3c,4]

We recently synthesised Sic, Hic and Nic,[6] novel analogues of the well-established and readily-available conformationally constrained phenylalanine analogue Tic. Our approach to Sic, Hic and Nic utilised an intramolecular Heck reaction on substrates **1a–c** to create the required seven-, eight- and nine-membered rings in 55, 73 and 86% yield catalysed by 10, 5 and 2.5 mol% of palladium acetate respectively (Scheme 1),



**Scheme 1**

reactions which represent rare examples of the use of the Heck reaction to create seven-, eight- and nine-membered rings.[7] The products of the Heck reaction (**2a–c**) were hydrogenated to **3a–c** which in turn were deprotected to give the required amino acids. Subsequent incorporation of Tic, Sic, Hic and Nic into a cholecystokinin-B/gastrin receptor antagonist revealed a significant difference in biological activity between the Nic-containing ligand and the other ligands,[8] the source of which is currently being actively pursued.

In view of the moderate yield and high catalyst loading of the reaction used to synthesise the seven-membered ring and the current interest in comparing the outcome of radical cyclisations and Heck reactions on a given substrate,[2d,9] we decided to explore the possibility of using radical reactions to create the required rings. Despite the poor precedent for the use of radical cyclisations to generate seven-, eight- and nine-membered rings, we were somewhat encouraged by the relatively high cyclisation rates observed for aryl radicals[1] and the established ability of captodative radicals to influence the *endo*/*exo* selectivity of radical reactions,[2a] and thus the radical cyclisation of substrates **1a–c** was attempted.

Substrates **1a–c** were synthesised as described previously[6] from the iodo aldehydes **4a–c** and (±)-serine methyl ester. Preliminary experiments indicated that slow addition of $Bu_3SnH$ to the aryl iodide was the preferred experimental procedure and thus a mixture of $Bu_3SnH$ (1.1 equiv.) and AIBN (0.1 equiv.) in nitrogen-saturated benzene was added over 1 h to a solution of **1a** and AIBN (0.1 equiv.) in nitrogen-saturated benzene maintained at 80 °C to give a reaction mixture 0.008 M in **1a**. The reaction mixture was heated under reflux for a further 1 h. Subsequent solvent removal, addition of DBU in diethyl ether, titration with etheral iodine (0.1 M), silica gel filtration[10] and column chromatography gave a colourless oil which was identified as the cyclic product **3a** by microanalysis and comparison of its $^1H$ and $^{13}C$ NMR spectra with those of a fully

**Scheme 2**

characterised sample of **3a** prepared previously.[6] Encouraged by the 73% yield obtained for **3a**, which represents a considerable improvement on the Heck approach to **3a**, an identical procedure was applied to substrates **1b** and **1c**. Gratifyingly, these reactions proceeded surprisingly smoothly to give the eight-membered ring **3b** in 71% yield and the nine-membered ring **3c** in 52% yield (Scheme 2).

In order to provide a fuller comparison between the intramolecular Heck reaction and the radical cyclisation method, the palladium-catalysed and the $Bu_3SnH$-promoted reactions of substrate **1d** were examined. As anticipated from the results described above, the Heck reaction required large quantities of palladium catalyst (20 mol%) to produce a poor yield (15%) of the six-membered ring **2d** (obtained as an inseparable 1 : 1 mixture with 1-methoxycarbonyl-1-methyl-2-(*tert*-butoxycarbonyl)-1,2,3-trihydroisoindole, a product of the *exo* mode of cyclisation), whilst the radical cyclisation proceeded much more smoothly to give a high yield (79%) of the novel Tic precursor **3d**.

In conclusion, 6-*endo*, 7-*endo*, 8-*endo* and 9-*endo* radical cyclisations have been used to synthesise precursors to conformationally constrained amino acids. Furthermore, comparison of the yields obtained and the catalyst loadings used for the conversion of **1** to **2** with the yields obtained for the conversion of **1** to **3** suggests that radical cyclisations and intramolecular Heck reactions provide complementary approaches to the synthesis of medium-sized rings.

We gratefully acknowledge financial support from the James Black Foundation.

# Activation of water by permethyltungstenocene; evidence for the oxidative addition of water

**Myungok Yoon and David R. Tyler***

*Department of Chemistry, University of Oregon, Eugene, Oregon 97403-1253, USA*

**Water oxidatively adds to photogenerated [W($\eta^5$-$C_5Me_5$)$_2$] to form [WH(OH)($\eta^5$-$C_5Me_5$)$_2$]; continued irradiation converts [WH(OH)($\eta^5$-$C_5Me_5$)$_2$] to [WO($\eta^5$-$C_5Me_5$)$_2$].**

Oxidative addition is a potentially important reaction for the activation of water in solar energy conversion schemes and in other homogeneous catalytic cycles involving water.[1–3] Here, we report the oxidative addition of water to [W($\eta^5$-$C_5Me_5$)$_2$] and, by analogy, to [Mo($\eta^5$-$C_5H_5$)$_2$]. Oxidative addition reactions of water are uncommon for both thermodynamic and kinetic reasons.[4] In fact, only a few well characterized systems involving oxidative addition of water to organometallic complexes have been reported. For example, Milstein *et al.*[2] demonstrated the oxidative addition of water to several iridium(I) complexes [eqn. (1)] and Yoshida[1] reported the oxidative addition of water to rhodium(I) hydrido complexes [*e.g.* eqn. (2)].

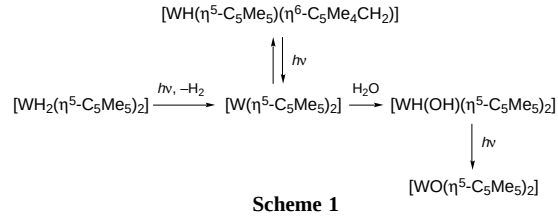
$$[Ir(PMe_3)_4]^+ + H_2O \rightarrow \textit{cis}\text{-}[Ir(PMe_3)_4(H)(OH)]^+ \quad (1)$$

$$[RhH(PPr^i_3)]_3 + H_2O \xrightarrow{py} [RhH_2(py)_2(PPr^i_3)_2(OH)] \quad (2)$$

Oxidative addition of water has been proposed in several other studies,[3,5] generally as part of longer reaction pathways, but these reactions are not understood mechanistically, and oxidative addition has not been established with certainty in these systems.

Our interest in the oxidative addition of water to [Mo($\eta^5$-$C_5H_5$)$_2$] was piqued when, as part of a water-splitting project, we found that irradiation of [MoH$_2$($\eta^5$-$C_5H_5$)$_2$] in acetonitrile–water formed [MoO($\eta^5$-$C_5H_5$)$_2$] and $H_2$ in quantitative yield.[6]

$$[MoH_2(\eta^5\text{-}C_5H_5)_2] + H_2O \xrightarrow[MeCN]{h\nu} [MoO(\eta^5\text{-}C_5H_5)_2] + 2H_2 \quad (3)$$



It is well established that irradiation of [MH$_2$($\eta^5$-$C_5H_5$)$_2$] (M = Mo, W) forms $H_2$ and [M($\eta^5$-$C_5H_5$)$_2$],[7] and a consideration of possible mechanisms for reaction (3) led us to hypothesize that oxidative addition of water to [Mo($\eta^5$-$C_5H_5$)$_2$] was involved. In order to investigate this hypothesis, we studied the photochemistry of the related [WH$_2$($\eta^5$-$C_5Me_5$)$_2$] molecule rather than [MoH$_2$($\eta^5$-$C_5H_5$)$_2$] because [WH(OH)($\eta^5$-$C_5Me_5$)$_2$] is a relatively stable molecule, whereas [MoH(OH)($\eta^5$-$C_5H_5$)$_2$] has not been reported.[8] {Note that the[WH(OH)($\eta^5$-$C_5Me_5$)$_2$] was prepared by $LiAlH_4$ reduction of [WO($\eta^5$-$C_5Me_5$)$_2$], not by reaction of water with the [W($\eta^5$-$C_5Me_5$)$_2$] intermediate.}

Irradiation of [WH$_2$($\eta^5$-$C_5Me_5$)$_2$] in $CD_3CN$ (37 mM; $\lambda$ > 340 nm) in the presence of water (3.7 M) for 7.5 h caused a colour change from yellow to yellow–green.†‡ $^1H$ and $^{13}C$ NMR analysis (Table 1) of the solution showed the presence of the oxidative addition product [WH(OH)($\eta^5$-$C_5Me_5$)$_2$] (12%), as well as [WO($\eta^5$-$C_5Me_5$)$_2$] (12%), [WH($\eta^5$-$C_5Me_5$)$_2$($\eta^6$-$C_5Me_4CH_2$)] (9%), and unreacted [WH$_2$($\eta^5$-$C_5Me_5$)$_2$] (67%), eqn. (4) and Scheme 1. [WH($\eta^5$-$C_5Me_5$)($\eta^6$-$C_5Me_4CH_2$)] is the known intramolecular C–H oxidative addition product that forms from the [W($\eta^5$-$C_5Me_5$)$_2$] intermediate.§ The formation of this product indicates that [W($\eta^5$-$C_5Me_5$)$_2$] is forming as an intermediate in the reaction, as planned. Continued irradiation of the reaction solution for a total of 15 h caused the solution to turn green ($\lambda_{max}$ = 596 nm), at which point $^1H$ and $^{13}C$ NMR analysis showed [WH(OH)($\eta^5$-$C_5Me_5$)$_2$] (27%), an increased amount of [WO($\eta^5$-$C_5Me_5$)$_2$] (59%), and unreacted [WH$_2$($\eta^5$-$C_5Me_5$)$_2$] (14%).

$$[WH_2(\eta^5\text{-}C_5Me_5)_2] \xrightarrow[CD_3CN\text{–}H_2O]{h\nu} [WH(OH)(\eta^5\text{-}C_5Me_5)_2] + [WO(\eta^5\text{-}C_5Me_5)_2] + [WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)] \quad (4)$$

The results above show that water oxidatively adds to the photogenerated [W($\eta^5$-$C_5Me_5$)$_2$] intermediate, and they also suggest that [WH(OH)($\eta^5$-$C_5Me_5$)$_2$] is an intermediate on the pathway from [WH$_2$($\eta^5$-$C_5Me_5$)$_2$] to [WO($\eta^5$-$C_5Me_5$)$_2$]. Consistent with this latter hypothesis, irradiation of [WH(OH)($\eta^5$-$C_5Me_5$)$_2$]¶ (28 mM; $\lambda$ > 340 nm) in $CD_3CN$–$H_2O$ ([$H_2O$] = 3.7 M) for 7.5 h gave [WO($\eta^5$-$C_5Me_5$)$_2$] as the only product {38% yield with 62% [WH(OH)($\eta^5$-$C_5Me_5$)$_2$] still unreacted}, eqn. (5).

$$[WH(OH)(\eta^5\text{-}C_5Me_5)_2] \xrightarrow[CD_3CN\text{–}H_2O]{h\nu} [WO(\eta^5\text{-}C_5Me_5)_2] \quad (5)$$

**Scheme 1**

[a] For comparison to the other complexes, only the $C_5Me_5$ and hydride resonances are reported in this Table. For the complete spectrum, see footnote ¶.

Also consistent with the hypothesis, irradiation ($\lambda > 340$ nm; 7.5 h) of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ (22 mM) in dry $CD_3CN$ gave $[WO(\eta^5\text{-}C_5Me_5)_2]$ (19%), $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (10%), and a small amount of $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ (1%), with 70% of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ still unreacted.‖

$$[WH(OH)(\eta^5\text{-}C_5Me_5)_2 \xrightarrow[CD_3CN]{h\nu} [WO(\eta^5\text{-}C_5Me_5)_2] + [WH_2(\eta^5\text{-}C_5Me_5)_2] + [WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)] \quad (6)$$

Several additional experiments provided further insights into the reactions presented in Scheme 1. Irradiation ($\lambda > 340$ nm) of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (37 mM) for 7.5 h in $CD_3CN$ containing only small amounts of water (59 mM) gave $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ (58%) as the major product along with a small amount of $[WO(\eta^5\text{-}C_5Me_5)_2]$ (3%) and unreacted $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (39%). {Irradiation ($\lambda > 340$ nm) of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (22 mM) for 23 h in dry $CD_3CN$ gave $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ as the only product.} The formation of $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ was reversible, however, as irradiation of this compound in $CD_3CN$ (16 mM; $\lambda > 340$ nm) for 7.5 h in the presence of a large excess of water (3.7 M) gave $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ (21%) and $[WO(\eta^5\text{-}C_5Me_5)_2]$ (79%). Continued irradiation for a total of 18 h gave complete conversion to $[WO(\eta^5\text{-}C_5Me_5)_2]$. In the reverse reaction, it is suggested that reductive elimination of a C–H bond occurs to give $[W(\eta^5\text{-}C_5Me_5)_2]$, which then reacts with $H_2O$ to form $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ and then $[WO(\eta^5\text{-}C_5Me_5)_2]$.

The mechanism for the conversion of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ to $[WO(\eta^5\text{-}C_5Me_5)_2]$ is uncertain. One possibility is a mechanism suggested by Bercaw and Parkin for the thermal conversion of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ to $[WO(\eta^5\text{-}C_5Me_5)_2]$ (at 80 °C).[10] Their mechanism is shown in reactions (7) and (8).

$$2\,[WH(OH)(\eta^5\text{-}C_5Me_5)_2] \rightarrow [WH_2(\eta^5\text{-}C_5Me_5)_2] + [W(OH)_2(\eta^5\text{-}C_5Me_5)_2] \quad (7)$$

$$2\,[W(OH)_2(\eta^5\text{-}C_5Me_5)_2] \rightarrow [WO(\eta^5\text{-}C_5Me_5)_2] + H_2O \quad (8)$$

The products of reaction (6) are consistent with this pathway. According to this mechanism $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ is formed in a secondary photolysis by irradiation of $[WH_2(\eta^5\text{-}C_5H_5)_2]$, not by a route involving reductive elimination of water from $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$. It is not obvious, however, why the mechanism would be photochemically activated. Another possible mechanism is a 1,2-elimination of $H_2$ from $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$. Consistent with this pathway is the observation that $[WO(\eta^5\text{-}C_5Me_5)_2]$ is the only product formed by irradiation of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ in the presence of an excess of water [eqn. (5)]. However, the formation of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ in eqn. (6) is not accounted for by this mechanism.

In summary, the spectroscopic observation of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ provides convincing evidence for the oxidative addition of water to $[W(\eta^5\text{-}C_5Me_5)_2]$ and by analogy to $[Mo(\eta^5\text{-}C_5H_5)_2]$. The $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ molecule is photoreactive and it is converted to $[WO(\eta^5\text{-}C_5Me_5)_2]$. We are continuing to investigate the mechanisms of these reactions and their applications to water splitting.

Acknowledgment is made to the Department of Energy for the support of this research.

## Footnotes

† $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ and $[WO(\eta^5\text{-}C_5Me_5)_2]$ were prepared by literature procedures.[8]

*Spectroscopic data*: $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (see also Table1 and refs. 8 and 9). $^{13}C\{^1H\}$ NMR ($C_6D_6$, 300 MHz, in ppm relative to $SiMe_4$): δ 12.40 (s, $CH_3$), 90.09 (s, $CCH_3$). $^{13}C\{^1H\}$ NMR ($CD_3CN$): δ 12.42 (s, $CH_3$), 91.05 (s, $CCH_3$). $^{13}C\{^1H\}$ NMR ($CD_3CN$–$H_2O$; 15 : 1): δ 12.10 (s, $CH_3$), 90.96 (s, $CCH_3$). EIMS (70 eV): *m/z* 454 ($M^+ - 2$, 100% with correct isotope pattern). UV–VIS (MeCN) $\lambda_{max}$ = 281 nm (ε = 7221 $dm^3\ mol^{-1}\ cm^{-1}$).

$[WO(\eta^5\text{-}C_5Me_5)_2]$ (see also Table 1). $^{13}C\{^1H\}$ NMR ($CD_3CN$): δ 11.72 (s, $CH_3$), 99.02 (s, $CCH_3$). $^{13}C\{^1H\}$ NMR ($CD_3CN$–$H_2O$; 15 : 1): δ 11.49 (s, $CH_3$), 99.38 (s, $CCH_3$). UV–VIS (MeCN) $\lambda_{max}$ = 596 nm (ε = 113 $dm^3\ mol^{-1}\ cm^{-1}$). In addition to the NMR spectra, the band at 596 nm was a useful diagnostic that indicates the formation of $[WO(\eta^5\text{-}C_5Me_5)_2]$ in a reaction.

‡ A typical photolysis experiment was performed as follows. To an NMR tube attached to a stopcock was loaded 10 mg of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (21.9 μmol) and $CD_3CN$ (0.6 ml) in a dry box. Distilled water (40 μl, 2.2 mmol), which had been degassed by three freeze–pump–thaw (FPT) cycles, was syringed into the tube under $N_2$. After the resulting solution was degassed by two FPT cycles, the tube was flame-sealed. During the photolysis, the solution in the NMR tube was cooled with ice–water and shaken frequently. The solutions were irradiated using a high-pressure Hg arc lamp (200 W) fitted with a water filter and a UV cutoff filter (Corning Glass CS 0-52). When the chemical resonances of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ overlapped with those of solvents, the amount of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ was estimated by subtracting integrations corresponding to solvent, which in turn were calculated using their ratios to added $SiMe_4$ in stock NMR solvents.

§ The complex $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ was reported to form from $[W(\eta^5\text{-}C_5Me_5)_2]$ in (*a*) photolysis of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ in pentane,[9] (*b*) reaction of $[W(H)Cl(\eta^5\text{-}C_5Me_5)_2]$ with MeLi in toluene at 100 °C,[8] (*c*) reaction of $[WCl_2(\eta^5\text{-}C_5Me_5)_2]$ with MeLi in $C_6D_6$ at 80 °C,[8] and (*d*) reaction of $[WCl_2(\eta^5\text{-}C_5Me_5)_2]$ with Na–Hg in thf.[9b]

¶ The preparation of $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ was modified from the literature procedure[8] as follows. Diethyl ether (20 ml) was added to a mixture of $[WO(\eta^5\text{-}C_5Me_5)_2]$ (240 mg; 0.51 mmol) and $LiAlH_4$ (180 mg; 4.75 mmol) at −77 °C. The reaction mixture was warmed to room temp. and stirred for 2 h, producing an orange–brown solution. After unreacted $LiAlH_4$ was filtered off, and solvent was removed, the residual solid was chromatographed on basic alumina.[6b] The first fraction (hexanes) was $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ (45.9 mg, 0.10 mmol, 19.6%). The second fraction (hexanes–ether = 1 : 1) was $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (9.3 mg, 0.02 mmol, 3.9%), and the third fraction was a negligible amount of unreacted $[WO(\eta^5\text{-}C_5Me_5)_2]$. The last fraction (ether–thf = 1 : 1) was $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ (51.5 mg, 0.11 mmol, 21.4%). $^1H$ NMR data for $[WH(\eta^5\text{-}C_5Me_5)(\eta^5,\eta^1\text{-}C_5Me_4CH_2)]$ in $CD_3CN$: δ 1.87 [15 H, s, $C_5(Me)_5$], 1.51, 1.80 and 2.06 [each 3 H, s, $C_5(Me)_4CH_2$], 2.01 [3H, d, $C_5(Me)_4CH_2$, $J_{HW(H)}$ = 3 Hz], 2.87 and 3.08 [each 1 H, m, $C_5(Me)_4CH_2$], −12.39 (1 H, br m, $J_{WH}$ = 93 Hz). Spectroscopic data for $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ (see also Table 1). $^{13}C\{^1H\}$ NMR ($CD_3CN$): δ 13.14 (s, $CH_3$), 108.43 (s, $CCH_3$). $^{13}C\{^1H\}$ NMR ($CD_3CN$–$H_2O$; 15 : 1): δ 13.36 (s, $CH_3$), 109.30 (s, $CCH_3$). IR (KBr pellet, $cm^{-1}$): 2973m, 2904s, 2860m, 2725w, 1906m (WH), 1378s, 1265m, 1102w, 1070w, 1024m, 934w, 872m, 801m, 692w. The resonance of the OH proton could be located at δ −0.51 ($C_6D_6$), which broadens upon addition of a stoichiometric amount of water or ethanol, and disappears with addition of an excess of water.

‖ Further irradiation for a total of 30 h produced a solution containing a decreased amount of $[WH_2(\eta^5\text{-}C_5Me_5)_2]$ (1%), an increased amount of $[WH(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]$ (18%), $[WO(\eta^5\text{-}C_5Me_5)_2]$ (49%), and unreacted $[WH(OH)(\eta^5\text{-}C_5Me_5)_2]$ (42%).

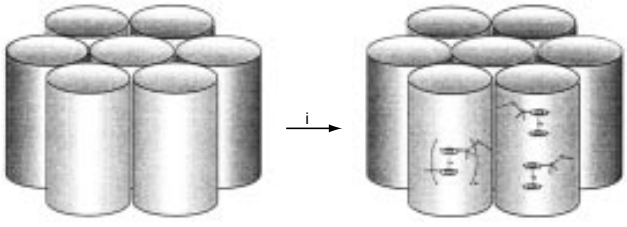
# Modification of MCM-41 *via* ring opening of a strained [1]ferrocenophane

**Stephen O'Brien, Jonathan Tudor, Stephen Barlow, Mark J. Drewitt, Stephen J. Heyes and Dermot O'Hare*†**

*Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR*

**The walls of the mesoporous silicate MCM-41 can be functionalised with ferrocenyl end groups by reaction with an alkane solution of (1,1′-ferrocenediyl)dimethylsilane; the product is studied by solid-state NMR and EXAFS spectroscopies.**



The synthesis, characterisation and potential uses of the new generation of mesoporous silicates has attracted considerable interest in recent years.[1,2] The size of the channels (diameters of 20–100 Å) allows the catalytic conversion of substrates much larger than previously possible using zeolites. The immobilisation of transition-metal catalysts on the surface is possible by utilising the reactivity of the hydroxy groups on the pore walls (an estimated 8–27% of the silicons are silanols in MCM-41[3,4]).

Bein and coworkers reported the surface attachment of a trimethylstannyl complex in MCM-41,[5] and Thomas and coworkers successfully achieved the inclusion of titanium dioxide nanoparticles inside the channels of MCM-41 using an organotitanium precursor.[6]

Here we report on the use of the ring-opening reaction of the strained metallocenophane [Fe{(η-$C_5H_4$)$_2$$SiMe_2$}][7,8] as a high-yield, low-temperature method of functionalising mesoporous silicates.

The functionalisation of a silica surface with (1,1′-ferrocenediyl)dimethylsilane, was first reported by Wrighton and coworkers[7] and utilises the susceptibility of [1]ferrocenophanes to nucleophilic attack by the hydroxy groups on the surface of the silica wall. It has been found previously that reaction of [1]ferrocenophanes with nucleophiles can lead, depending on the reaction conditions, to oligomeric and high molecular mass species[8,9] as well as stoichiometrically ring-opened species.

MCM-41 was prepared according to the published procedure.[10] It was activated at 540 °C for 8 h and then heated to 150 °C under a vacuum of $10^{-4}$ Torr for 6 h. Treatment with a pentane solution of [Fe{($C_5H_4$)$_2$$SiMe_2$}] for 24 h under nitrogen gave an orange powder (Scheme 1). The orange solid was then washed repeatedly with dry pentane until the pentane extracted remained colourless. Trace amounts of ferrocene were recovered from the pentane washings. The proportion of [1]ferroceneophane converted to ferrocene was 4–5%, while the rest was immobilised within the host. Elemental analysis indicated that a high loading of the organometallic guest into the silicate had been achieved, typical analysis gives 8.28 mass% Fe. XRD showed the product to be a slightly less well defined hexagonal phase than the original MCM-41 used, with a lattice constant, $a$ = 45.8 Å. Reaction with iodine vapour under vacuum immediately turned the solid green, indicating facile oxidation of the ferrocenyl units.

**Scheme 1** *Reagents and conditions*: i [Fe{(η-$C_5H_4$)$_2$$SiMe_2$}] in pentane, room temp., 24 h

The ferrocenyl-functionalised MCM-41 **1** was investigated using $^{13}C$ and $^{29}Si$ solid-state NMR and Fe K-edge EXAFS spectroscopy. The room-temperature solid-state CP MAS $^{29}Si$ NMR is shown in Fig. 1(*b*). Four resonances can be observed, the two closely spaced signals at δ −101.1 and −108.0 can be assigned as two convoluted broad signals representative of the silica framework, consisting mainly of $Q_3$ and $Q_4$ units with the presence of a very little $Q_2$ [where $Q_n$ is defined as $Si(OSi)_n(OH)_{4-n}$]. A comparison with the $^{29}Si$ NMR of the original mesoporous silicate showed that the intensities of $Q_2$ and $Q_3$ had decreased significantly. This was confirmed by a significant decrease in the ν(OH) adsorptions in the IR spectrum. The signal at δ 7.0 can be assigned as an $(O)_3SiR$ (R = alkyl) in accordance with previously reported chemical shifts for such species.[1,11] The remaining narrow signal at δ −6.5 has a longer relaxation than its neighbours, and hence some ring-down can be observed at this acquisition time. This resonance has been assigned to the bridging silicon atoms present in small oligomeric units of poly(ferrocenylsilane) with the first unit

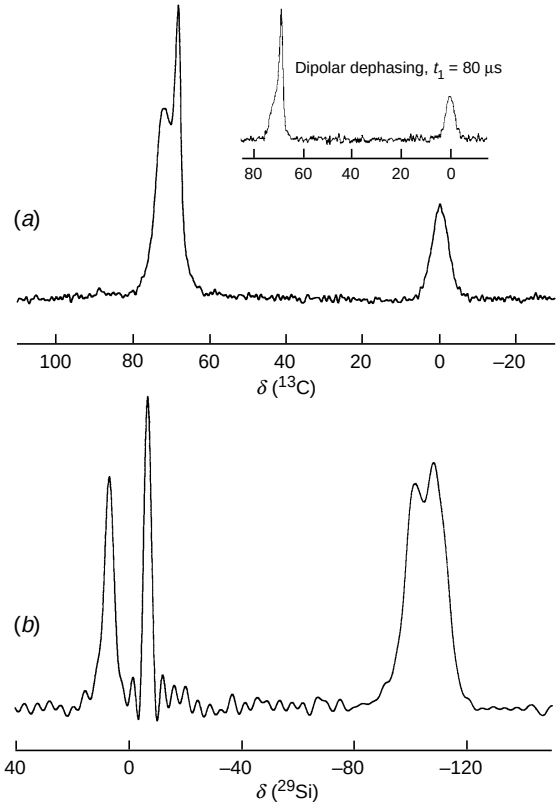


**Fig. 1** (*a*) Room-temperature 50.32 MHz solid-state $^{13}C$ CP MAS NMR spectra of [Fe{(η-$C_5H_4$)$_2$$SiMe_2$}]/MCM-41 **1** with spinning rate of 2.66 kHz. Contact times were 1 ms and recycle delay 2 s. (*b*) Room-temperature 39.76 MHz solid-state $^{29}Si$ CP MAS NMR spectrum of [Fe{(η-$C_5H_4$)$_2$$SiMe_2$}]/MCM-41 **1** at a spinning rate of 2.47 kHz. Contact time 2 ms and recycle delay 3 s. Recorded on a Bruker MSL200.

bound to the channel wall by comparison to the value of δ −6.4 quoted for the shift of poly(ferrocenylsilane) in $C_6D_6$ solution.[8] The narrower linewidth, suggesting longer spin–spin relaxation time, is consistent with a model of a molecule that exhibits more motional averaging relative to its counterparts, and this would be possible through rotation about a bond to the silicon atom.

The room-temperature solid-state $^{13}C$ CP MAS NMR spectrum of **1** is shown in Fig. 1(*a*). Three broad resonances are observed, all of which are broader than those of the related crystalline ferrocene compounds. The broadness is due to the range of chemically different environments in which the molecules are located, giving rise to an envelope of peaks with very similar chemical shifts. The isotropic chemical shifts are at δ −0.1, 68.6 and 72.1 with full widths at half maximum (FWHM) of 234, 105 and 220 Hz respectively. The widths can be compared with those of the solid-state NMR of the [1]ferrocenophane which were measured as 180.7 Hz (δ 77–79.5, $C_5H_4$), 30.3 Hz (δ 34.4, cyclopentadienyl C–Si) and 58.3 Hz (δ −2.5, $CH_3$). The signal at δ −0.1 can be assigned to the methyl carbons attached to bridging silicon atoms, be they bonded to the wall of the silicate *via* an oxygen or to another ferrocenyl unit (expected chemical shifts of δ *ca*. 0.4 and −0.5, respectively). The set of peaks downfield is due to cyclopentadienyl carbons of the modified ferrocene analogue. The sharper, more clearly defined peak at δ 68.6 is the free $C_5$ ring comparable to the chemical shift observed for the cyclopentadienyl ring formed from the ring-opening reaction of (1,1′-ferrocenediyl)dimethylsilane with $CD_3OD$. Cross-polarization and dephasing techniques (described by Alemany *et. al.*[12]) were employed to discern between the carbon atoms in the system. These experiments showed that the broad peak at δ 72.1 exhibited rapid dephasing [see Fig. 1(*a*), inset] and so we assign this signal to the CH groups of the static cyclopentadienyl ring grafted to the walls. Dephasing was slower for the neighbouring signal, indicating an attenuated $^{13}C$–$^{1}H$ dipolar coupling, as a result of greater motional freedom in the form of ring rotation. The methyl carbons attached to the silicon demonstrated an attenuation of effective $^{13}C$–$^{1}H$ coupling owing to rapid rotational motion.

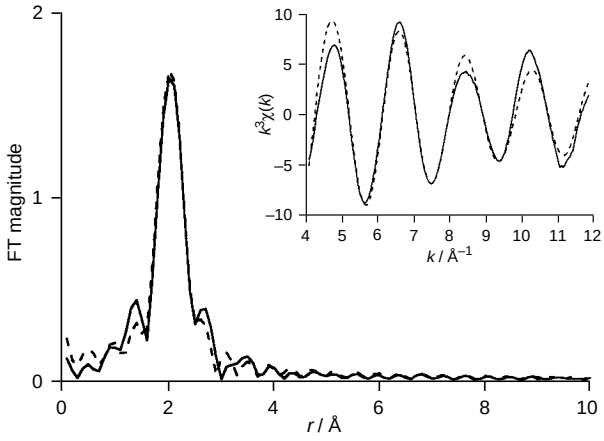

**Fig. 2** Fourier transform of the K-edge transmission EXAFS spectrum (shown in inset) for the [Fe{(η-$C_5H_4$)$_2$$SiMe_2$}]/MCM-41 **1**, together with best fit (—) experiments, (---) theory. Data was collected on station 8.1 [equipped with a Si(220) monochromator and ion chambers for obtaining data in transmission mode] of the CLRC synchrotron radiation source, Daresbury (2 GeV with typical current ranging from 150 to 250 mA). Data analysis was carried out using curved-weight theory[13] to obtain the structural parameters outlined in Table 1.

**Table 1** EXAFS structural parameters for [Fe{(η-$C_5H_4$)$_2$$SiMe_2$}]/MCM-41 **1**[a]

| Atom type | $N^b$ | $r^c$/Å | Error (%) | $\sigma^{2\,d}$/Å$^2$ | Error (%) |
|---|---|---|---|---|---|
| C | 10 | 2.045 | 0.1 | 0.0073 | 1 |
| C | 2 | 2.555 | 1 | 0.0098 | 4 |

[a] $R$ factor for refinement = 22.0 defined as $R = \int|\chi^T - \chi^E|k^3dk / \int|\chi^E|k^3dk \times 100\%$ (T = theory, E = Experiment). [b] $N$ = coordination number. [c] $r$ = interatomic distance. [d] σ = Debye–Waller factor.

The Fe K-edge EXAFS of **1** was recorded on Station 8.1 at the SRS Daresbury Laboratory. Fig. 2 shows the observed and best fit to the model described below. The analysis was initially conducted by postulating a model of ferrocene for the Fe centre, and therefore selecting a single shell (coordination sphere) of ten carbon atoms using standard scattering treatment of the EXAFS data.[13] Refinement gave a bond distance appropriate and comparable to that observed in crystals of ferrocene (Fe–$C_{av}$ 2.045 Å). The best fitting was achieved by including an additional second shell of two carbon atoms. This shell is thought to arise from neighbouring rather than bonding carbon atoms (most likely from methyl groups attached to the silicon atoms) or as result of multiple scattering complications due to collinearity of the cyclopentadienyl carbons.

In conclusion, we have demonstrated the use of strained ferrocenophanes to functionalise mesoporous silicates. Both solid-state NMR and EXAFS spectroscopy indicate that the organometallic guest has remained intact within the silicate structure and is tethered to the silicate wall *via* Si–O linkages.

We thank the EPSRC for access to the SRS, Daresbury Laboratory and Dr Mosselmans for his help with the EXAFS experiments. We also thank EPSRC for studentships (S. O'B., J. T., S. B.).

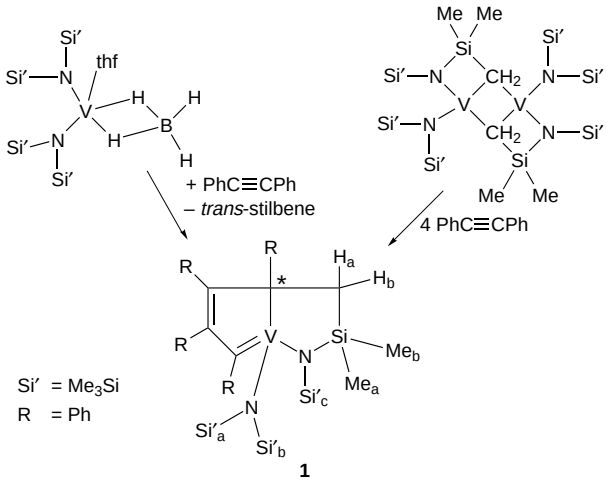
# Formation of a vanadium(v) bicyclic carbene–amide complex *via* insertion of alkyne into a V–C bond

**Mark Moore,[a] Sandro Gambarotta,*[a] Glenn Yap,[b] Louise M. Liable-Sands[b] and Arnold L. Rheingold*[b]**

[a] *Department of Chemistry, University of Ottawa, Ottawa, Ontario K1N 6N5, Canada*
[b] *Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716, USA*

**Reaction of $[(Me_3Si)_2N]_2V(thf)(BH_4)$ with excess diphenylacetylene leads to the formation of the bicyclic carbene complex $(Me_3Si)_2NVN(SiMe_3)SiMe_2CH_2C(Ph)C(Ph)C(Ph)C(Ph)$ 1 which is isolated as brown diamagnetic crystals cocrystallized with *trans*-stilbene; the same compound *trans*-stilbene-free is also prepared *via* reaction of $\{[(Me_3Si)_2N]V[\mu\text{-}CH_2SiMe_2N(SiMe_3)]\}_2$ with 4 equiv. of diphenylacetylene.**



A very large part of the organometallic chemistry of vanadium has been developed with the utilization of cyclopentadienyl ligands[1] with which it is possible to stabilize reactive functions such as carbenes[2] and hydrides.[3] Nitrogen donor based ligands (amides, amidinates) provide a convenient and accessible alternative to the cyclopentadienyl ligand systems, since they significantly enhance the reactivity of the vanadium centre,[4] stabilize rare vanadium species such as dinitrogen,[5] azide,[6] nitride,[7] metallacyclic[8] and alkyl complexes[9] or assist the metal in hydrogen-transfer reactions.[5c,10]

Here we describe the formation and the unusual NMR feature of a unique bicyclic vanadium(v) derivative supported by silazanate ligand, which is also a rare example of a vanadium carbene complex.[2]

According to Scheme 1, the reaction of $[(Me_3Si)_2N]_2V(thf)(BH_4)$[11] with diphenylacetylene in hexane proceeds rapidly at room temperature to yield a brown solution from which dark diamagnetic crystals of **1** were isolated in low yield.† The presence of *trans*-stilbene in the lattice in the ratio 2 : 1, as shown by the X-ray crystal structure,‡ was confirmed by $^1H$ NMR spectroscopy.

The complex is monomeric and features a distorted tetrahedral geometry around the vanadium atom which is combined in two fused five-membered metallacycles (Fig. 1). One intact amide group occupies the fourth coordination site of vanadium. One metallacycle is formed *via* linkage of a $CH_2$ unit from a trimethylsilylamide function with a carbon atom at one end of the coupled tolane units. The second metallacycle is composed of two diphenylacetylene units forming a tetraphenylvanadacyclopentadiene ring. The geometry around three of the four carbon atoms is trigonal planar, suggesting an $sp^2$ hybridization for these atoms. Conversely, the fourth carbon atom shared with the first ring is tetrahedral and chiral. The vanadium atom is also chiral and the enantiomer is present as a second molecule in the triclinic cell together with one molecule of stilbene.

At this stage, we are unable to provide a non-speculative explanation for the formation of **1**. However, the production of *trans*-stilbene during the formation of **1** suggests that the first step of the reaction is probably the hydrogenation of diphenylacetylene Complex **1** could also be prepared without *trans*-stilbene and in significantly higher yield (44%)† by reacting the previously reported dinuclear vanadacycloazabutane $\{[(Me_3Si)_2N]V[\mu\text{-}CH_2SiMe_2N(SiMe_3)]\}_2$[8] with 4 equiv. or an excess of diphenylacetylene. In this case, the formation of **1** is simply the result of the insertion of two molecules of diphenylacetylene into the $V–CH_2$ bond of the metallacycle followed by a tautomeric reorganization of the macrocycle into the bicyclic structure. The formation of **1** from both reactions suggests that perhaps $\{[(Me_3Si)_2N]V[\mu\text{-}CH_2SiMe_2N(SiMe_3)]\}_2$ is produced as a transient intermediate of the reaction of $(Me_3Si)_2N]_2V(thf)(BH_4)$ with diphenylacetylene after the initial formation of *trans*-stilbene. The addition of only

**1**

**Scheme 1**

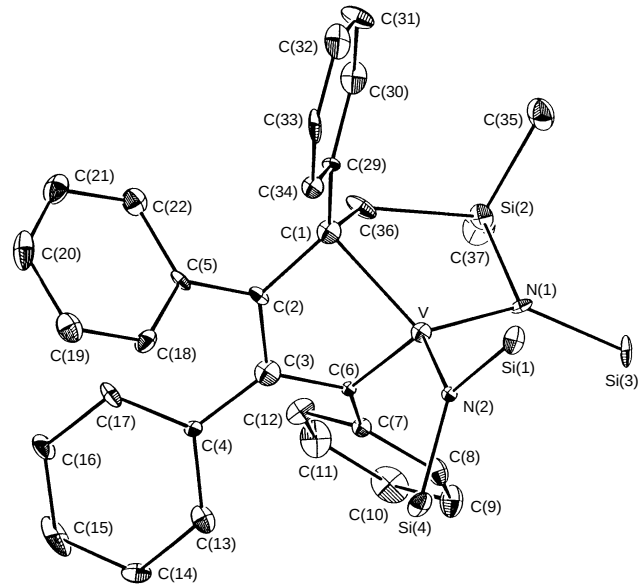


**Fig. 1** ORTEP plot of **1**. Thermal ellipsoids are drawn at the 50% probability level. Selected bond distances (Å) and angles (°): V–N(1) 1.849(5), V–N(2) 1.889(5), V–C(1) 2.092(7), V–C(6) 1.876(7), N(1)–Si(2) 1.729(5), Si(2)–C(36) 1.918(7), C(1)–C(36) 1.541(9), C(1)–C(2) 1.467(9), C(2)–C(3) 1.43(1), C(3)–C(6) 1.406(9); V–N(1)–Si(2) 99.3(3), V–C(1)–C(36) 85.4(4), V–C(1)–C(2) 90.5(4), N(1)–V–N(2) 111.9(2), N(2)–V–C(6) 116.4(3), V–C(6)–C(3) 100.1(5), Si(2)–C(36)–C(1) 123.4(5), C(2)–C(3)–C(6) 117.0(6), C(1)–C(2)–C(3) 119.0(6).

1 equiv. of tolane to $\{[(Me_3Si)_2N]V[\mu\text{-}CH_2SiMe_2N(SiMe_3)]\}_2$ still gave the diamagnetic and pentavalent **1** albeit in lower yield. This behaviour is remarkably different from that of the monomeric pyridine adduct $[(Me_3Si)_2N]V[\mu\text{-}CH_2SiMe_2N(SiMe_3)](py)$, which reacts with diphenylacetylene to give a monoinserted vanadium(III) paramagnetic species.[10]

The diamagnetism of **1** indicates a formal oxidation state (+5) for the vanadium centre, which implies the existence of a formal V–C double bond. Since the rigid structure observed in the solid state is reasonably expected to be maintained in solution, the crystal structure also provides the key to interpreting the remarkable NMR features of complex **1**. The intact group features two sharp singlets ($Si'_a$ and $Si'_b$) at δ 0.63 and 0.61, consistent with the fact that the two $SiMe_3$ groups point respectively above and below the folded molecular plane. The $SiMe_3$ of the second amide group ($Si'_c$) exhibits a rather broad singlet centred at δ −0.05. Remarkably, the two methyl groups of the silicon atom engaged in the formation of the first metallacycle ($CH_{3a}$ and $CH_{3b}$) give rise to two widely separated signals at δ 0.32 and −0.82. Even more surprising, the two enantiotopic hydrogens of the methylene group ($H_a$ and $H_b$) produce two doublets positioned far apart from each other at δ 2.85 and −1.43. HQMC experiments clearly indicate that these two protons are attached to the same carbon atom resonating at δ 20.4 in the $^{13}C$ NMR spectrum. The $^{51}V$ NMR resonance was located as a rather broad line (1800 Hz) at δ +1318.8.[12] Variable-temperature spectra show the expected broadening of the line (4300 Hz at 210 K) but also a significant downfield shift of about 100 ppm. Some of the hydrogen lines of the $^1H$ NMR spectrum also significantly broaden and shift at low temperature, suggesting the presence of fluxionality. At low temperature, the line at δ −0.05, attributed to the three methyl groups of the $Si'_c$ group, collapsed and resolved into three sharp resonances at δ 0.39, −0.18 and −0.51. However, under the same conditions, the resonances arising from $CH_{3a}$ and $CH_{3b}$ and the two enantiotopic methylene protons ($H_a$ and $H_b$) broadened only slightly. In contrast to the minor line broadening, the resonance at δ 2.85 shifted by about 1 ppm to higher field while the resonance at δ −0.82 shifted by only 0.3 ppm in the same direction. The crystal structure showed that one of these two enantiotopic protons is considerably closer to the vanadium centre than the other [V–H(59) 2.73, V–H(60) 3.11 Å]. A similar feature has been observed with the two methyl groups $CH_{3a}$ and $CH_{3b}$. However, no significant variation of the chemical shift was found over a range of temperature for these two methyl groups.

This work was supported by the National Science and Engineering Council of Canada (NSERC) through a strategic and operating grant. We are grateful to Professor D. Rehder (Hamburg) for helpful discussions.

## Footnotes

† *Synthesis and characterisation*: *Method A.* A blue solution of $[(Me_3Si)_2N]_2V(thf)(BH_4)$ (6.26 mmol) in hexane (70 ml) was treated with diphenylacetylene (20.56 mmol) at room temp. The resulting brown mixture was stirred overnight. A light brown material was removed by filtration and the resulting dark brown solution was kept at −30 °C for several weeks. Dark crystals of $\mathbf{1}\cdot 0.5\ C_{14}H_{12}$ were obtained (0.2 g, 0.7 mmol, 8%). Anal. Calc. (found) for $C_{47}H_{61}N_2Si_4V$: C 69.07 (70.40), H 7.52(7.63), N 3.43 (3.20)%.

*Method B.* A suspension of $\{[(Me_3Si)_2N]V[\mu\text{-}CH_2SiMe_2N(SiMe_3)]\}_2$ (2.0 g, 2.6 mmol) in hexane (50 ml) was reacted with diphenylacetylene (1.86 g, 10.4 mmol) at room temperature. The mixture was stirred overnight at room temperature, during which time the colour had changed to brown. After 24 h, the mixture was filtered to eliminate a small amount of brown insoluble material. The resulting intense red–brown solution was concentrated to approximately 15 ml until incipient crystallization of a brown material. The solution was allowed to stand overnight at 4 °C to yield a crop of brown crystals of $\mathbf{1}\cdot 0.5C_6H_{14}$ (1.66 g, 2.1 mmol, 44%). Spontaneous loss of hexane prevented accurate and reproducible analytical data from being obtained. IR (Nujol, KBr plates) ν/cm$^{-1}$: 1593s, 1491vs, 1252s, 1112m, 1088m, 1029s, 955vs, 889vs, 870s, 849s, 799s, 700m. Samples were pumped *in vacuo* to eliminate the hexane resonances from the NMR spectra. $^{51}V$ NMR ($C_6D_6$, 131.4 MHz, 25 °C: δ 1318.8. $^1H$ NMR ($C_6D_6$, 500 MHz, 25 °C): δ 7.59–6.60 (series of m, 20 H, phenyl), 2.85 (d, 1 H, $H_a$), 0.63 (s, 9 H, $Me_3Si_a$), 0.61 (s, 9 H, $Me_3Si_b$), 0.32 (s, 3 H, $CH_{3a}$), −0.05 (s, 9 H, $Me_3Si_c$), −0.82 (s, 3 H $CH_{3b}$), −1.43 (d, 1 H, $H_b$). $^{13}C$ NMR ($C_6D_6$, 125 MHz, 25 °C): δ 318.17 (quat. carbene), 145.95 (quat. C ring), 140.87 (quat. C ring), 135–123 (Ph), 90.10 (quat. chiral C), 20.45 ($CH_AH_B$), 5.64 ($Me_3Si_A$, $Me_3Si_B$), 5.46 ($Me_3Si_C$), 3.30 ($CH_{3A}$), 0.47 ($CH_{3B}$).

# Some influences of fluorine in bioorganic chemistry

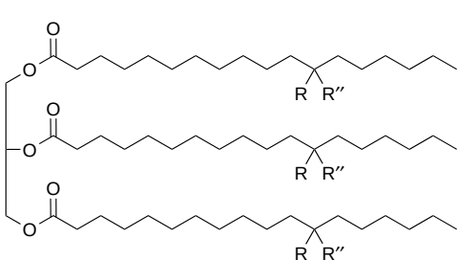
**David O'Hagan[a]† and Henry S. Rzepa[b]‡**

[a] *Department of Chemistry, Science Laboratories, South Road, Durham, UK DH1 3LE*
[b] *Department of Chemistry, Imperial College of Science Technology and Medicine, London, UK SW7 2AY*

**The stereochemical outcome on processing fluorinated substrate analogues by enzymes can often be controlled by electronic and stereoelectronic factors associated with the fluorine atom.**

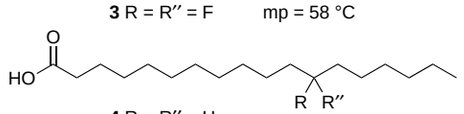
Substitution of a hydrogen atom or a hydroxy group by fluorine in enzyme substrate analogues has been widely practised in various arenas of bioorganic and medicinal chemistry. It is very difficult however to generalise on the relative abilities of fluorine to act as a hydrogen or hydroxy group mimic and various factors have to be considered in each circumstance. The van der Waals radii of fluorine (1.47 Å) lies between oxygen (1.57 Å) and hydrogen (1.2 Å)[1] and thus fluorine appears to have a particularly close isosteric relationship to oxygen while being larger than hydrogen. However, in solid state X-ray structures, fluorine and hydrogen often interchange, and scanning tunnelling microscopy analyses of monofluorinated stearic acids deposited on graphite show very little distortion in two dimensional packing, suggesting a very close isosteric relationship between hydrogen and fluorine.[2] Consistent with this, the steric impact of replacing hydrogen by fluorine is never too great and binding of analogues to target proteins is not normally impeded. Thus despite the size anomoly fluorine emerges as a reasonable hydrogen mimic.

The ability of fluorine to act as a hydroxy group mimic is less clear and is discussed at some length below. Despite a good size correlation between fluorine and oxygen the electrostatic influence of fluorine is much weaker than that of oxygen, and this compromises its hydrogen bonding ability, a limitation of particular significance in enzyme substrate binding.



Our work has focused on exploring the behaviour of organofluorine compounds in the bioorganic arena, with a particular emphasis on investigating geometric and stereoelectronic effects which emerge as a consequence of replacing fluorine for hydrogen or oxygen. Stereoelectronic effects, which are generally lower energy phenomenon, are considerably attenuated by indiscriminate solvent interactions (H-bonding, electrostatic, dipolar *etc.*) in solution. The anomeric effect serves as a good example.[3] However the enzyme environment is significantly less polar than aqueous solvent[4] where relative permittivities in the range 15–20 have been estimated and can be compared to 78.5 for water.[5] After binding, the substrate is largely desolvated, with the substrate reaction centre proximate[6,7] and exposed to the cofactor, enzyme or second substrate without intervening solvent. Indeed it has been argued,[8] in the extreme, that enzyme reactions are more closely modelled in the gas phase rather than in the solution state due to these factors. Thus the low polarity of the enzyme active site and the possibilities of conformational control offer an attractive environment in which to assess the stereoelectronic influence of the fluorine atom.

## 1 Steric and geometric effects in CF, $CF_2$ and $CF_3$ systems



### *1.1 The CF for CH and $CF_2$ for $CH_2$ replacement*

Despite the larger van der Waals radii for fluorine over hydrogen, the experimental evidence suggests that, in general terms, the substitution of a single fluorine for a hydrogen atom introduces only small steric and geometric perturbations relative to the hydrocarbon counterpart.[2] Dehydrofluorinated (CH for CF) enzyme substrate analogues usually have a high affinity for their target protein. For example selectively β-fluorinated α-amino acids have been widely explored as suicide substrates[9–11] for decarboxylases, racemases and transaminases, and other fluorinated amino acids are assimilated biochemically into proteins.[12] Fluoroacetyl-CoA is an excellent acetyl-CoA mimic for citrate and malate synthases (see section 3.4) and fluoropyruvate is a pyruvate surrogate for L-lactate dehydrogenase.[13] Thus the fluorine for hydrogen substitution is not generally detrimental to binding, however the high electronegitivity of fluorine can have dramatic mechanistic consequences which can lead to mechanistic deviations and enzyme inhibition.[9–11]

Replacement of a methylene for a difluoromethylene group ($CH_2$ for $CF_2$) can be much more dramatic than the single substitution. In a recent study[14] in Durham we have compared the physical properties of tristearins **2** and **3** containing one and two fluorine atoms substituted for the C-12 methylene hydrogens of the hydrocarbon chain. The melting points of these tristearins are shown in Fig. 1. Substitution of one fluorine atom at C-12, in **2**, has very little effect on the melting point, polymorphic phase behaviour and X-ray powder diffraction pattern (data not shown) when compared to tristearin **1** itself, however introduction of the second fluorine atom in **3** leads to a significant lowering of the melting point (72 *vs*. 58 °C) and the polymorphic phase behaviour and X-ray powder diffraction pattern become quite different. The stability of Langmuir films of the corresponding fluorinated stearic acids **4**–**6** was also investigated. 12-Fluorostearic acid **5**, like stearic acid **4**, formed a stable monolayer on the surface of aqueous subphase, however the monolayer of 12,12-difluorostearic acid **6** was unstable and susceptible to collapse/reorganisation at comparable surface pressures, indicative of significant conformational disorder.

**1** R = R″ = H mp = 72 °C
**2** R = H, R″ = F mp = 73 °C
**3** R = R″ = F mp = 58 °C

**4** R = R″ = H
**5** R = H, R″ = F
**6** R = R″ = F

**Fig. 1** Melting points of tristearins

A similar lowering in the melting points (by *ca*. 6–10 °C) of $CF_2$-labelled diacylphosphatidylcholines relative to their hydrocarbon counterparts has also been noted[15] and the phenomenon appears to be general. We attribute this to an increased conformational flexibility of the hydrocarbon as a consequence of $CF_2$ substitution (Fig. 2). Crystallographic[16] and theoretical evidence[17] support a widening of the C–$CX_2$–C angle from the $sp^3$ tetrahedral angle (109.5°) in the hydrocarbon to *ca*. 115–119° in the $CF_2$-hydrocarbon systems. This angle widening is also apparant from the structures of C–$CH_2$–P, C–CHF–P and C–$CF_2$–P phosphonates where the C–C–P angles are 112, 113 and 116° respectively (see section 2.2). The extended zig-zag conformation is favoured in a hydrocarbon chain as disfavoured *gauche* conformations bring 1,4-hydrogens into close contact (*ca*. 1.8 Å) (Fig 3).[18] However, angle widening at the substituted carbon in the $CF_2$-containing hydrocarbon chains results in increasing this 1,4-H···H distance and in turn lowers the energy of attainment of a *gauche* conformation. A complementary situation occurs when sulfur[19] (but not oxygen) is introduced into a hydrocarbon as the increased C–S bond length (1.8 Å) over that for C–C (1.5 Å) or C–O (1.4 Å) increased the 1,4-hydrogen distance to 2.4 Å and relaxes this interaction.

### *1.2 The $CF_3$ for $CH_3$ replacement*

It is generally appreciated that the methyl and trifluoromethyl groups bear very little steric resemblance. A comparison of the molar volumes of a series of related compounds[20] with various substituents, and with a $CF_3$ group, reveals a size closer to the isopropyl rather than methyl group. Seebach has argued[21] that the $CF_3$ group is between two and three times larger than $CH_3$ when the van der Waals hemispheres of these groups are considered (Fig 4). Other assessments[22] suggest a steric influence close to that of an isopropyl group. However there are several cases in asymmetric synthesis[23] where the directing influence of the $CF_3$ group has been assessed relative to other substituents and a close analogy with the phenyl ring or even a *tert*-butyl group has been found. Of course the origin of this apparantly gross steric effect must be attributed in no small part to polar and electrostatic influences, in a given situation. Such factors are discussed below (section 2.3) in an assessment of lipase resolutions of $CF_3$ containing compounds. On balance the various lines of evidence place $CF_3$ significantly larger than methyl and a good upper estimate would equate it with the isopropyl group. Thus the substitution of one, two and three hydrogen atoms on carbon, by fluorine, becomes increasingly distorted in maintaining an isogeometric profile between the fluoro- and hydro-carbon series.

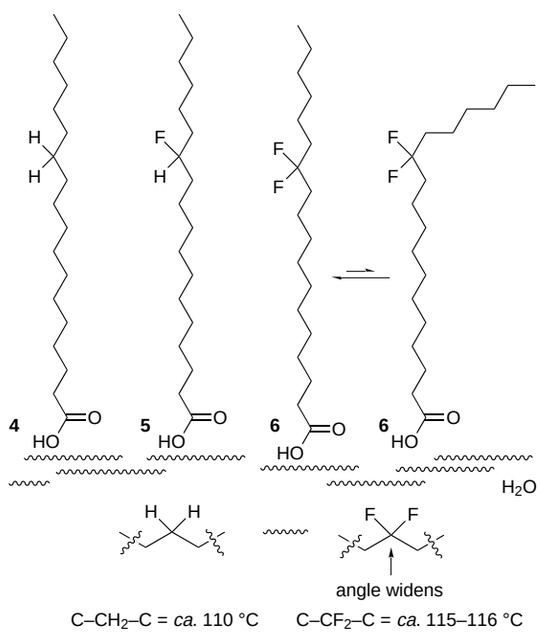


**Fig. 2** Schematic representation of C-12 fluorinated stearic acids on the surface of water. The $CF_2$ stearate **6** posesses significant conformational disorder.

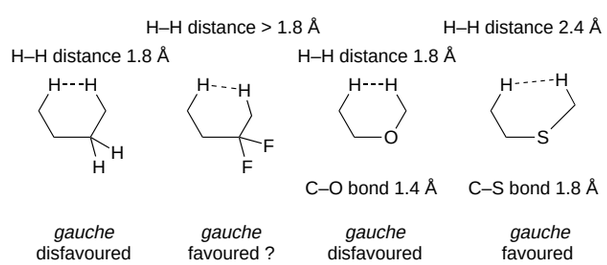

**Fig. 3** Schematic representation of 1,4-hydrogen interactions and the preference for *gauche* or zig-zag conformations

## 2 Electrostatic effects

Despite one extra lone pair, the higher electronegativity and lower polarisibility of fluorine attenuate its electrostatic influence in comparison with oxygen. So despite their apparent similarity in size, electrostatics emerge as a significant factor underlying the limited ability of fluorine to mimic a hydroxy group. In bioorganic chemistry hydrogen bonding is probably the most significant area in which electrostatic interactions are involved, certainly when considering enzyme substrate binding interactions.

### *2.1 Fluorine as a hydrogen bonding acceptor*

The capacity of organically bound fluorine to act as an oxygen surrogate (*e.g.* an OH mimic) and enter into hydrogen bonding as an acceptor has been widely discussed.[24,25] Recent theoretical calculations[26] have measured the strength of an optimum F··H bond (1.9 Å) to be 2.38 kcal $mol^{-1}$ in an adduct between fluoromethane ($CH_3F$) and water as shown in Fig. 5. Interestingly, the strength of the optimum interaction (1.95 Å) between fluoroethene ($CH_2$=CHF) and water was only 1.48 kcal $mol^{-1}$, suggesting that the C($sp^3$)–F··H interaction is stronger than the C($sp^2$)–F··H interaction. In strength therefore, F··H hydrogen bonds are clearly weaker than O··H hydrogen bonds, which are conservatively estimated[27] to be *ca*. 5 kcal $mol^{-1}$, but are stronger than O/NH–π interactions.[28,29] The weaker F··HO over O··HO interaction appears to be due to the higher nuclear charge on the F nucleus compacting the surrounding lone pairs.

Calculations[30] measuring the difference in electrostatic potentials around methanol and fluoromethane (Fig. 6) with distance from the nucleus reinforce the view that the C($sp^3$)–

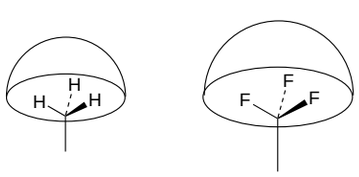

**Fig. 4** Van der Waals hemisphere volumes comparing $CH_3$ and $CF_3$ (ref. 21)

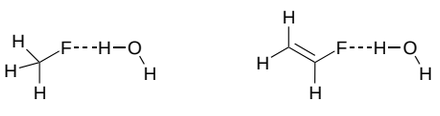

**Fig. 5** Calculated strengths of C($sp^3$)–FH··H and C($sp^2$)–F··H bonds

F···H bond strength is half that of the H···O value. The reduced electrostatic influence of fluorine requires that an incoming hydrogen bond donor must approach the fluorine nucleus more closely than oxygen, and the resulting increase in the nuclear–nuclear repulsions does not allow a strong hydrogen bond to be formed. Thus a best case scenario suggests that fluorine can contribute up to about one half of the binding energy of a hydrogen bond to oxygen. A recent[31] and controversial discussion[32] on low barrier hydrogen bonding (LBHB) suggests that in transition states of enzyme mediated reactions, O···H···O bonds can contribute upto 10–20 kcal mol$^{-1}$ although these arguments appear increasingly tenuous.[33] However if this latter situation is close to reality then the replacement of OH for fluorine would be inadequate if a hydrogen bond was important in stabilising a transition state on the enzyme surface.

Surveys[34] of the organofluorine compounds logged in the Cambridge Crystallographic Data Centre (CCDC) have revealed relatively few situations where fluorine is involved in short contacts to hydrogens. Short contacts between fluorine and less acidic H–C protons are most common whereas those between fluorine and the more acidic O–H or N–H protons are rare, clearly for statistical reasons (*i.e.* more CHs than OH or NHs) but also, acidic hydrogens prefer to find an oxygen or nitrogen acceptor in preference of fluorine. Thus the theoretical and crystallographic evidence force the conclusion that fluorine is a poor hydrogen bond acceptor with only a moderate capacity to replace oxygen (or nitrogen) in this role. In a desolvated and preorganised enzyme cavity, where the fluorine atom is predisposed towards an acidic hydrogen (donor) then these circumstances may amount to an optimal situation for F···H bonding. There are examples in the bioorganic literature which clearly suggest that fluorine is replacing OH as a hydrogen bond acceptor, however they are few and more often than not the substitution proves detrimental.[35]

### *2.2 $CF_2$-phosphonates*

Phosphate groups are susceptable to hydrolysis by the action of phosphatase enzymes; thus phosphonates, where the bridging oxygen is replaced by carbon, have been explored as phosphatase stable phosphate mimics.[36] A particular refinement of this strategy has been developed by Blackburn[37] and involves the replacement of the bridging oxygen atom by a $CF_2$ substituent. This is attractive as the fluorine atoms reintroduce the electronegativity lost on removal of the oxygen atom. The degree of electronegativity can be assessed from the p$K_a$ values of the second deprotonation of the phosphonate groups. These values are summarised for the phosphate and various phosphonates in Fig. 7. The $CF_2$-phosphonate (p$K_a$ = *ca.* 5.64) is approximately one p$K_a$ unit more acidic than the phosphate group it is designed to mimic. The CHF-phosphonate value (p$K_a$ = *ca.* 6.2) is much more closely matched and the $CH_2$-phosphonate (p$K_a$ = 7.6) is a p$K_a$ unit less acidic. It is generally assumed that the phosphate unit will be fully ionised on protein binding, thus the increased acidity of the $CF_2$-phosphonate is not judged detrimental in this respect and often $CF_2$-phosphonates emerge as excellent phosphate surrogates.

Crystal structures[16,38] of the aminophosphonic acids **7**, **9** and **10** reveal that the P–C–C angle of the $CF_2$-phosphonate (116°) is closer than that of the $CH_2$- (112°) and CHF- (113°) phosphonates to the C–O–P angle (118°) of the phosphate group of **8**. Thus the $CF_2$-phosphonate appears to approximate the geometry of the phosphate group most closely in the series, at least in the ground state. Therefore on geometric and ionic grounds the $CF_2$-phosphonate emerges as a good phosphate mimic. On the other hand the substitution of oxygen for $CF_2$ will have an increased steric impact, as the fluorine atoms are resident in the space previously occupied by the lone pairs of oxygen.

The electrostatic profile of the CHF and $CF_2$ groups in comparison to oxygen must also be considered when evaluating these systems. A recent theoretical analysis by Thatcher and Campbell[39] compared the negative electrostatic profile of the phosphate group with the CHF-phosphonate by superimposing the two. Fluorine has a suppressed electrostatic influence relative to oxygen, but placing it one C–F bond length out from the oxygen extends the centre of its electrostatic influence a little beyond that of oxygen when comparing oxygen and C–F. Also the area of maximum negative density for CHF-system is asymmetrically displaced from that of oxygen in the phosphate, by about 1 Å, due to the stereogenic centre. Although the comparison did not extend to the $CF_2$ system, an extrapolation of Thatcher's results suggests that the $CF_2$ group will have at least a similar, and possibly greater, electrostatic influence than the phosphate oxygen. Comparative molecular electrostatic potentials (MEPs) of the CHF- and $CF_2$-phosphonates of the aminophosphonic acids **11** and **12** respectively were evaluated by one of us[40] and reinforces the notion that the $CF_2$ phosphonate has a significant electrostatic influence (see Fig. 8), in this case on chiral recognition of the substrate *via* the asymmetric binding of the aryl group into a cyclodextrin cavity.

In the case of the CHF-phosphonate **11** the presence of fluorine induces an asymmetric negative potential (red area) on one side of the aryl π-face. This asymmetry is much less evident for the $CH_2$-phosphonate **13**.[40]

In a recent study[38,41] at Durham, using phosphonates as phosphate mimics, we have drawn the conclusion that an electrostatic interaction between an enzyme and its substrate emerges as an important factor in binding. The $CH_2$ and CHF-phosphonate analogues **15** and **16** of *sn*-glycerol-3-phosphate **14** have a greater affinity than the $CF_2$-phosphonate analogue **17** for the enzyme glycerol-3-phosphate dehydrogenase. The enzyme is NAD dependant and oxidised the secondary alcohol of each of the phosphonates to their corresponding dihydrox-

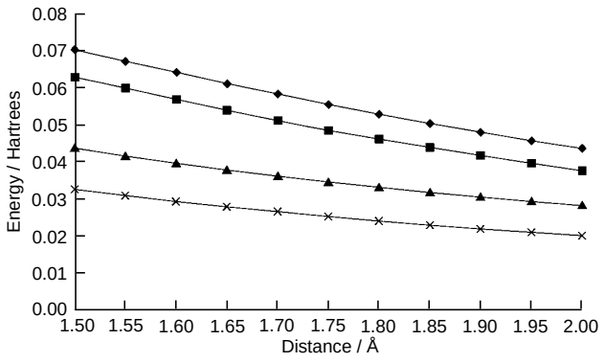

**Fig. 6** A plot of calculated electrostatic potential values at the B3LYP/6-31G(d,p) level for methanol (◆), hydroxyethene (■), fluoromethane (▲) and fluoroethene (X) as a function of distance (Å) from the F/O nucleus. The maximum value of the potential at this distance is shown.

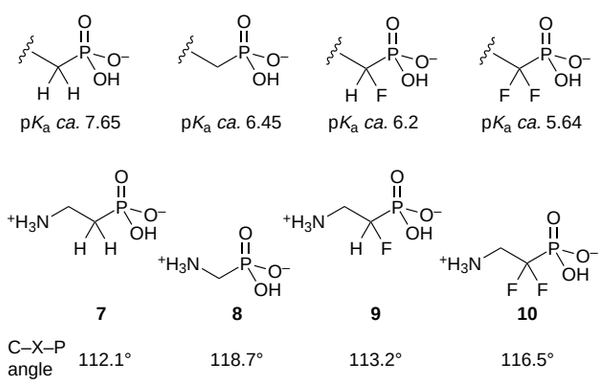

**Fig. 7** Phosphate/phosphonate acidity (second deprotonation) and C–X–P angles as obtained from the X-ray structures of compounds **7**–**10**

yacetone phosphate analogues. The relative $V_{max}$ and $K_m$ values are given in Fig. 9. The maximal rates are similar for each substrate, but the $K_m$ value for the CHF-phosphonate analogue is significantly lower than the natural phosphate substrate **14** (0.17 *vs*. 0.29 mM). This low value correlates with previous data[42] on the $CH_2$-phosphonate **15** and it is perhaps surprising that replacing the bridging oxygen of the phosphate, by carbon, leads to a higher binding affinity. Intriguingly glycerol-3-phosphate dehydrogenase appears to be unoptimised in its binding of the phosphate group of the natural substrate **14**, revealing a sensitivity to the electrostatic influence of oxygen, a situation that relaxes with the $CH_2$- and CHF-phosphonate analogues. The poorer performance of the $CF_2$-phosphonate **17** analogue, now with two fluorine atoms, is consistent with an even greater electrostatic influence impacting on the surface of the protein.

Phosphonate analogues of phosphotyrosine have been prepared and incorporated into peptides as phosphatase resistant SH-2 domain inhibitors, in the only other example[43] where $CH_2$-, CHF- and $CF_2$-phosphonates have been compared directly in a biological system. The ability of phosphotyrosine residues to bind such domains is important in signal-transducing molecules. A series of pentapeptide analogues (Gly-pX-Tyr-Val-Pro-Met-Leu) were assessed for their ability to bind the C-terminal SH-domain of phosphatidylinositol-3-kinase and were found to bind in the following order; CHOH < $CH_2$ < CHF < $CF_2$ = O where the $CF_2$-phosphonate was the optimal phosphate mimic in this case. Different biological systems respond differently to the CHF- and $CF_2$-phosphonate analogues and clearly each has to be assessed individually.

### *2.3 Electrostatic or steric influences in lipase resolutions?*

Lipases and other hydrolytic enzymes have been widely used for the kinetic resolution of ester racemates.[44] In general terms the effectiveness of such resolutions is interpreted on the basis of steric interactions between the surface of the protein and the substrate. Indeed steric models for the more widely used lipases have been proposed and refined by identifying hydrophobic and hydrophilic compatible regions.[44] Pig liver esterase is a good example.[45] Such models are used successfully in a predictive way to assess the viability and stereochemical preference of a particular resolution. On the other hand, the kinetic resolution of some $CF_3$ containing substrates are not so easily rationalised by steric models. For example the *Candida rugosa* lipase (formerly *C. cyclindracea* and also MY-Lipase) esterifies/desterifies the *R*-enantiomer of phenethanol **18** in preference to the *S*-enantiomer.[46]

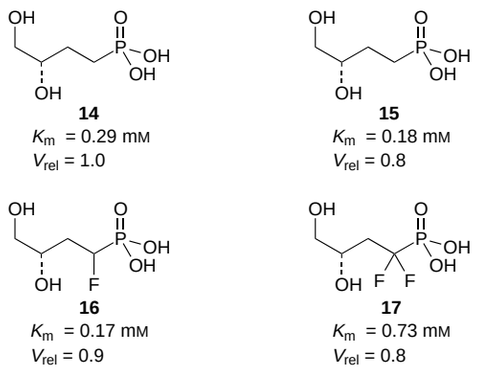
For trifluorophenethanol however the enzyme prefers alcohol (*R*)-**19** of the opposite configuration (**19** also posesses the *R*-configuration due to a change is assignment priorities).[47] A steric interpretation then suggests that the $CF_3$ group is larger than the phenyl ring, however as discussed above (section 1.3), various methods of comparison reinforce the trend Ph > $CF_3$ > $CH_3$ > H for the steric influence of these substituents. The $CF_3$ group is larger than the methyl group and will compete more

**11** X = CHF
**12** X = $CF_2$
**13** X = $CH_2$

**Fig. 8** *Ab initio* electrostatic potential map at the B3LYP/6-31G level for (*a*) the phosphonate **11**, contoured at 0.025 Hartree and (*b*) the F-epimer of **11**. An active three dimensional view of these diagrams encoded in VRML is available *via* the enhanced electronic version of this article. See http://chemcomm.clic.ac.uk/ for further details.

favourably than $CH_3$ with Ph in steric terms, however it is still smaller than Ph. Thus steric factors alone cannot account for this reversal phenomenon with **19**. If the electrostatic influence of the various substituents is considered then the trend $CF_3$ > Ph > $CH_3$ emerges. The electrostatic influence of the $CF_3$ group is of course greater than $CH_3$ and it will exert greater repulsion on for example an alkoxide nucleophile (on the enzyme), or on another area of negative density on the protein surface. Also, in an intriguing interplay the $CF_3$ group in **19** is predicted to reduce the electrostatic influence on one face of the aromatic ring. This was shown in a study by one of us on the chiral resolving agent (*S*)-2,2,2-trifluoro-1-(9-anthranyl)ethanol (Pirkle's reagent).[48,29]

The X-ray structure of **20** shown in Fig. 10 has the $CF_3$ group lying perpendicular to the plane of the anthracene ring. A molecular electrostatic potential map calculated for **20** also shown in Fig. 10 revealed a distinct difference in the negative potential of the two π-faces of the aromatic. The face *anti* to the $CF_3$ group is reduced in electron density relative to the face *syn* to the $CF_3$ group (Fig. 2). The decreased electrostatic potential on the *anti* face is rationalised by negative hyperconjugation due to overlap of the π-orbital system with the σ*-orbital



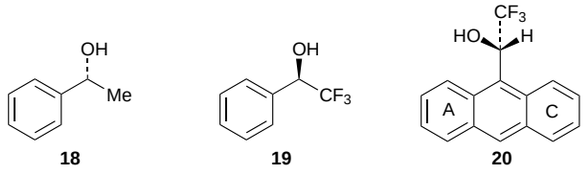


**Fig. 9** Kinetic data on **14**–**17** as substrates for glycerol-3-phosphate dehydrogenase[41]

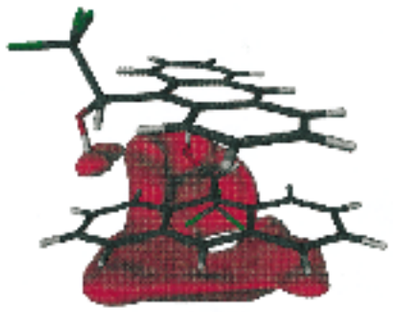

**Fig. 10** The X-ray structure of **20** showing the dimeric self-interaction, with a superimposed negative electrostatic potential computed (B3LYP/6-31G, contoured at 0.0175 Hartree) for a single molecule shown in red. The +ve potential is not shown. Note in particular the asymmetry of the π-system, and the coincidence of the residual −ve potential on one face with the position of the πH–O interaction from the second molecule. An active three dimensional view of this diagram encoded in VRML is avaialble *via* the enhanced electronic version of this article. See http://chemcomm.clic.ac.uk/ for further details.

associated with the C–$CF_3$ bond. Thus the $CF_3$ group has a synergic effect in possessing a significant electrostatic influence of its own and also depleting that on one face of the aromatic ring. The induced asymmetry extends not only to the two π-faces, but to differentiating between rings A and C on the aromatic system, as a consequence of further interaction between the $CF_3$ group and the adjacent OH group. The crystal structure shows a OH··π hydrogen bond to the edge of ring A, precisely where the maximum in the negative electrostatic potential on this face is computed to occur. Thus the role of the $CF_3$ group could be regarded as focusing the role of the two aromatic faces into a π-stacking side and hydrogen bond accepting side. A similar directing influence of a $CF_3$ group towards an electrophile was observed in the π-facially stereoselective epoxidation of phenyltrifluoromethylpropenol.[49]

In the case of the $CH_3$- and $CF_3$-phenethanols **18** and **19** the combined steric, but particularly electrostatic impact of the substituents is now predicted to follow $CF_3$ > $Ph_{CH_3}$ > $Ph_{CF_3}$ > $CH_3$. This trend is entirely consistent with the observed stereochemical preferences of the *Candida rugosa* lipase for **18** and **19**.

## 3 Stereoelectronic effects

### *3.1 The Fluorine anomeric and Anh–Eisenstein effects*

The anomeric effect[50] which in carbohydrates recognises the preference for an axial over an equatorial conformation at the O–C–O anomeric carbon, extends to O–C–F and N–C–F systems.[51] The molecular orbital explanation for the anomeric effect suggests that the lone pair on oxygen lying *anti*-parallel to the C–X bond donates electron density into the $\sigma^*_{C-X}$ orbital in a stabilising hyperconjugative interaction as illustrated in Fig. 11. Theoretical studies on fluoromethanol ($HOCH_2F$),[51] fluoromethyl methyl ether ($MeOCH_2F$)[52,53] and fluoromethylamine ($FCH_2NH_2$)[54] suggest a stabilisation of around 6.0 kcal $mol^{-1}$ and X-ray structure data of appropriate compounds[51,52] indicate a consequent shortening of the C–O bond and lengthening of the C–F bond consistent with the hyperconjugation hypothesis.

Anh and Eisenstein,[55] in a theoretical study investigating transition states for hydride attack to 2-chloropropionaldehyde, have suggested that the most stable transition state will have the HOMO of the nucleophile approaching the carbonyl LUMO where the p-orbitals are co-aligned with the σ*-orbital of the vicinal C–Cl bond. An *anti*-parallel approach of the nucleophile to the C–Cl bond is preferred to accommodate mixing of the developing σ-bond electrons with the σ*-orbital of the C–Cl bond and relaxation of any electrostatic repulsion between the halogens, as shown in Fig. 12. This set-up allows negative hyperconjugation where the electron density of the nucleophile is accommodated in the antibonding orbital (σ*-LUMO) associated with the C–Cl bond. The effect was further

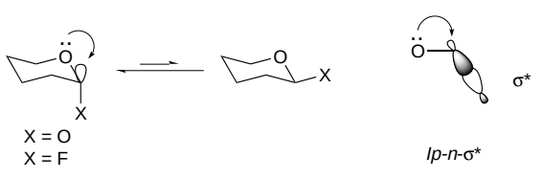

**Fig. 11** A molecular orbital representation of the anomeric effect

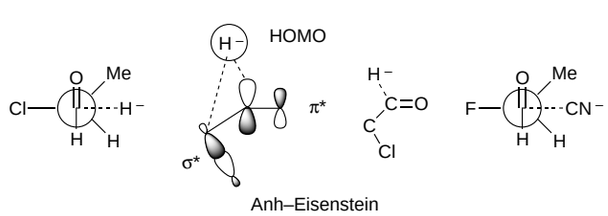

**Fig. 12** A molecular orbital description of Anh–Eisenstein type stabilisation of a nucleophile approaching an α-haloaldehyde

evaluated[56] for fluorine in a theoretical study by Wong and Paddon-Row, on transition state geometries of cyanide attack to 2-fluoropropionaldehyde. This effect emerges as an important one in interpreting the stereoselective processing of fluorinated substrates in certain enzyme reactions and is discussed in the next section.

### *3.2 Anh–Eisenstein stabilisation in enzyme reactions*

The ability of lipases to mediate kinetic resolutions by hydrolysis of racemic or *meso* esters has been widely practiced.[45] Active site models have been mapped for the common lipases which identify areas of hydrophobicity and regions that can accommodate small medium and large groups.[44] In general the lipase active site is considered to accommodate a particular substrate enantiomer on the basis of fit and electronic compatibility to the surface of the protein, and this in turn leads to preferential binding and hydrolysis of a single enantiomer. However the lipase resolutions[57,58] of α-fluoro esters shown in Fig. 13 illustrate that in each case the lipase can distinguished completely between the fluorine and hydrogen atoms. This is difficult to reconcile on the basis of a spacial active site model, as the steric influence of fluorine over hydrogen would not be expected to lead to such a high level of selectivity.

On the other hand we have proposed[59] that these resolutions can be rationalised on the basis of Anh–Eisenstein type stabilisation. Each of the enantiomers of the α-fluoro ester give rise to one of two diastereoisomeric transition states where the serine alkoxide nucleophile of the lipase attacks the ester carbonyl. The nucleophile can either approach *anti* to the C–F bond in one case (as shown in Fig. 13) or *gauche* to the C–F bond for the other enantiomer (interchange H for F). *Ab initio* calculations have been used to model the transition states of these hydrolytic reactions. Methoxide was selected as the nucleophile (serine hydroxide surrogate) and methyl 2-fluoropropionate as the substrate ester. It emerged that the transition state with the nucleophile approaching *anti* to the C–F bond, is more stable by up to 2.8 kcal $mol^{-1}$ than the diastereomeric transition state where the hydrogen and fluorine atoms are interchanged. The energy differential between these transition states is sufficient to give 100 : 1 selectivity and can fully account for the observed high enantioselectivities (99% ee).

In a further exploration of Ahn–Eisenstein type stabilisation in an enzyme reaction we have investigated the selectively fluorinated substrate analogue **23** for the enzyme cyclohexenylcarbonyl-CoA reductase.[60] This NADPH dependant enzyme was isolated from *Streptomyces collinus* and operates on the biosynthetic pathway to the antibiotic ansatrienin.[61] The enzyme reduces cyclohexenylcarbonyl-CoA **21** to the corresponding cyclohexane ring product **22**, and offers an ideal framework in which to explore stereoelectronic effects. Hydrogen is added in an *anti* manner across the double bond with hydride from the co-factor delivered to the *si*-face as illustrated in the Fig. 14. In substrate **23** the fluorine at C-3 can occupy two sites. The diastereoisomer where fluorine is sited at C-3 antiperiplanar to the incoming hydride should accommodate the nucleophile, due to Anh–Eisenstein type stabilisation, relative to the diastereisomeric transition state with fluorine in a *gauche* position.

The requisite C-3 fluorinated substrate analogue was synthesised as a 1 : 1 epimeric mixture at C-3.[60] A number of interesting features emerged from the kinetic analysis of this system. The fluorinated substrate had a $K_m$ value of 44 μM indicating a good affinity for the enzyme relative to the natural substrate ($K_m$ = 25 μM). Intriguingly the $V_{max}$ of the fluorinated substrate was five times greater than that of the natural substrate. This observation can be rationalised by the electronegative fluorine atom rendering the site of hydride delivery more electropositive and lowering the transition state energy. This conclusion was reinforced by kinetic isotope data utilising deuterium labelled cofactor (NADP$^2$H). The natural substrate displayed a kinetic isotope effect of $k_H/k_D$ = 3 consistent with hydride delivery as the rate limiting step in the reaction. However this isotope effect was reduced to $k_H/k_D$ = 1.3 with the fluorinated substrate. Thus the transition state energy for hydride delivery, the highest barrier on the reaction course, is lowered as a result of fluorine substitution at C-3, and hydride delivery is now competing with another step (*e.g.* co-factor binding/debinding) as the rate limiting step.

On the issue of Anh–Eisenstein stabilisation, the enzymatic reduction of the fluorinated substrate was monitored by $^{19}$F NMR spectroscopy. The stereospecificity of the enzyme reaction, and the preference of the SCoA group to adopt an equatorial conformation, dictate that (3*R*)-**23** will deliver the product **24** with the fluorine atom axial, and (3*S*)-**23** will deliver **24** with the fluorine atom equatorial. Thus the diastereoisomeric products can be distinguished readily by $^{19}$F NMR spectroscopy. In the early stages of the reaction there was indeed a small but significant bias in favour of the axial over the equatorial product as predicted *i.e.* at 20% conversion the axial–equatorial ratio was 1.3 (*ax–eq* = 1.3) (see Fig. 5). As the reaction progressed towards > 50% conversion then this ratio reduced to *ax–eq* = 1.0 as expected, as both diastereoisomers of **23** are progressed through the reaction. The stereochemical bias in the early stages of the reaction is consistent with Anh–Eisenstein type hyperconjugation favouring the product **24**, with fluorine in an axial position.

### *3.3 The* gauche *and* cis *effects*

Perhaps the most widely discussed stereoelectronic effects associated with organofluorine compounds are the *gauche*[62,63]

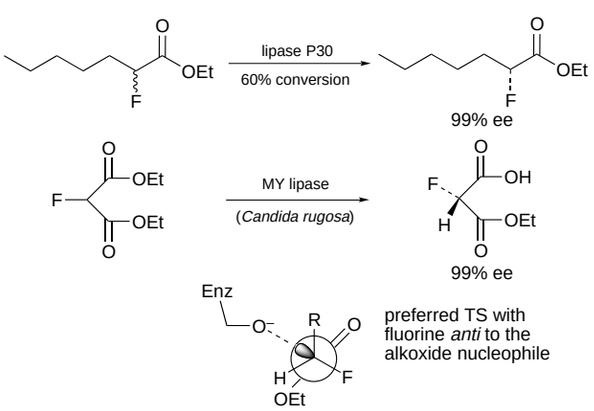

**Fig. 13** The high stereospecificity displayed in the resolution of α-fluoro esters is rationalised by Anh–Eisenstein type stabilisation in the transition state

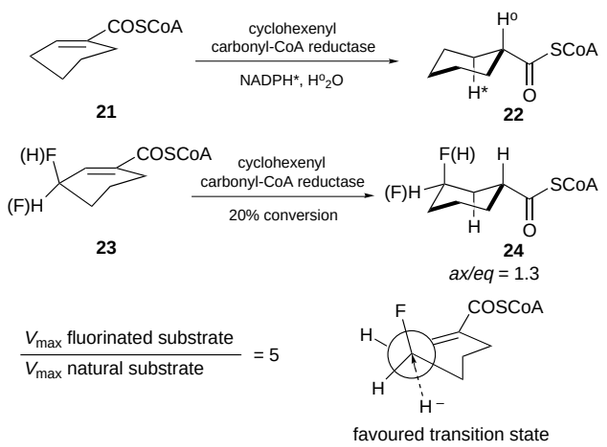

**Fig. 14** Cyclohexenylcarbonyl-CoA reductase. Processing of the fluorinated substrate **23** displays a stereochemical bias favouring **24** with fluorine in an axial position.

and *cis* effects.[64] The *gauche* effect recognises that the lowest energy conformation for 1,2-difluoroethane has the fluorine atoms *gauche* rather than *anti* parallel to each other as illustrated in Fig. 15. The *cis* effect is probably related in origin, and recognises that the *cis* geometric isomer is more stable than the *trans* by about 1–2 kcal mol$^{-1}$. Various hypotheses[65,66] exist to rationalise these observations.[67]

### *3.4 The* cis *effect in enzyme chemistry; citrate synthase*

Citrate synthase, an enzyme of the Kreb's cycle, catalyses the reaction between acetyl-CoA and oxaloacetate to generate citric acid. Fluoroacetyl-CoA, where one hydrogen of the methyl group of acetyl-CoA is replaced by a fluorine atom, is an excellent substrate for the enzyme, generating (2*F*,3*R*)-fluorocitrate **25** as a single stereoisomer[68] as illustrated in Fig. 16. It is this reaction which accounts for the toxicity of fluoroacetate,[69] where the resultant (2*R*,3*R*)-fluorocitrate inhibits aconitase, the next reaction of the Kreb's cycle, and also impedes citrate transport across mitochondrial membranes. The high stereospecificity of this reaction attracted our interest, particularly as a related reaction mediated by malate synthase does not show the same level of stereochemical discrimination. Malate synthase also utilises fluoroacetyl-CoA in place of acetyl-CoA and mediates a condensation with glyoxal to generate two diastereoisomers (2*R*,3*R*) and (2*R*,3*S*) of 3-fluoromalate in an approximately a 3 : 4 ratio.[70,71] Thus in this case the enzyme does not control the stereochemistry of the new chiral centre generated as a consequence of fluorine substitution. These aldol reactions must proceed *via* enzyme bound enol or enolate intermediates of fluoroacetyl-CoA, and clearly these enols can have *Z* or *E* geometries. The high level of stereospecificity, delivering the *R* absolute stereochemistry to C-2 of fluorocitrate **25**, dictates that the *E* enol or enolate of fluoroacetyl-CoA is generated exclusively by citrate synthase, whereas for malate synthase the enzyme appears unable to control this *E*/*Z* geometry to the same extent.

We have calculated[72] the relative energies of such enols and enolates by computational methods. High level *ab initio* calculations demonstrate a significant difference (*ca*. 4 kcal mol$^{-1}$) in the relative energies of the neutral *E* and *Z* enols generated in a model system from $FCH_2C(O)SH$, whereas this differential was significantly reduced (*ca*. 1.8 kcal mol$^{-1}$) when the charged enolate intermediates were considered. Thus it would appear that the (2*R*)-stereochemistry in the resultant (2*R*,3*R*)-fluorocitrate arises because the enzyme acts as a general acid and protonates the developing enolate to generate an enzyme bound enol. The intermediacy of a neutral enol in citrate synthase has previously been proposed[73] and is supported by X-ray structure[74] and experimental evidence.[75] X-Ray structural analysis of the enzyme has identified His-274 as the most likely candidate for this general acid as shown in Fig. 17.

The increased stability of the *E* over the *Z* enol in the model system does not have its exclusive origin in an intramolecular bridging hydrogen bond between oxygen and fluorine, as the enol energy is not significantly perturbed when the hydrogen is bridging or turned away from the fluorine atom. Alternatively the stabilisation would appear to be an example of the *cis* effect where the harder fluorine and oxygen atoms pair in preference to the hard/soft interaction between fluorine and sulfur. A corollary of this analysis is that malate synthase, which is less able to control the stereochemistry at the new fluorogenic centre, will have an intermediate with more enolic than enol character. This however remains to be determined.

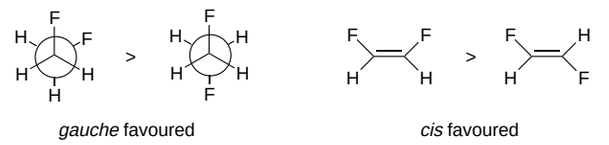

**Fig. 15** The *gauche* and *cis* effects favour a *syn* relationship between vicinal fluorine atoms

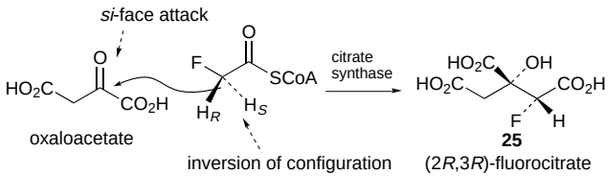

**Fig. 16** Citrate synthase generates (2*R*,3*R*)-fluorocitrate **25** as a single stereoisomer after condensation of oxaloacetate and fluoroacetyl-CoA

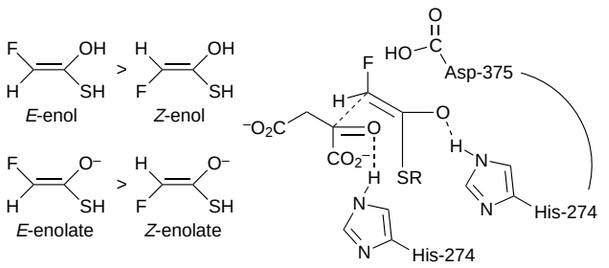

**Fig. 17** The *E* enol of $FCH_2C(O)SH$ is more stable than the *Z* enol which is in turn more stable than the *E* enolate followed by the *Z* enolate. This suggests that the high stereochemical control exhibited by citrate synthase in processing fluoroacetyl-CoA involves an enzyme bound *E* enol intermediate.

## 4 Summary

We have rationalised that the stereoelectronic influence of fluorine can control completely, or influence partially, the stereochemical outcome of given enzyme reactions after an F for H replacement. Interpreting or predicting the behaviour of fluorinated compounds is complex and has led to the term flustrates (fluorine containing substrates) being coined.[21,76] However, a greater appreciation of the electronic and stereoelectronic properties of organic fluorine renders the behaviour of these compounds more interpretable.

## Acknowledgements

The studies over the last few years have involved many coworkers and we thank them warmly for their collaboration.

**David O'Hagan was born in Glasgow in 1961 and received his BSc from the University of Glasgow in 1982. After graduating with a PhD from the University of Southampton with J. A. Robinson in 1985 he spent a post-doctoral year at the Ohio State University with H. G. Floss. He moved to the University of Durham in 1986 where he is now a Senior Lecturer. His research interests include bioorganic fluorine chemistry, biotransformations and investigations into the biosynthesis of plant, fungal and bacterial secondary metabolites.**

**Henry S. Rzepa was born in London in 1950, and received both his BSc and PhD degrees from Imperial College, in 1971 and 1974. Following a post-doctoral period with Michael Dewar at the University of Texas, Austin, he returned to Imperial College, where he is now a Reader in Organic Chemistry. His research interests include the theoretical study of stereoelectronic effects, structural studies of unusual forms of hydrogen bonding such as π-facial interactions and those responsible for chiral recognition, and novel applications of the Internet to chemistry.**

# Synthesis, structural characterisation and preliminary magnetic studies of a tetraicosanuclear cobalt coordination complex

**Euan K. Brechin, Steven G. Harris, Andrew Harrison, Simon Parsons, A. Gavin Whittaker and Richard E. P. Winpenny***

*Department of Chemistry, The University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

**The highest nuclearity complex containing cobalt consists of cubic-close packed planes of hydroxide, methoxide or chloride anions, bridging cobalt(II) centres; preliminary magnetic studies indicate a high-spin ground state and the possibility of superparamagnetic behaviour.**

Polymetallic compounds of metals in high oxidation states have been reported which contain as many as 154 metal centres.[1] High-nuclearity clusters of low oxidation states rival these species in size, with chalcogenide bridged complexes involving 146 metals structurally characterised.[2] Complexes where the metals are in moderate oxidation states do not approach these behemoths in nuclearity, with the largest reported being an $Fe_{40}$ compound.[3]

The route to one of the largest of these complexes, Powell's $Fe_{19}$ 'crust' **2**,[4] involves arresting the formation of iron hydroxide in an aqueous solution by addition of a polydentate ligand; the rate of nucleation can be controlled by pH and by the iron : ligand ratio. We reasoned that an alternative procedure would be to perform reactions in solvents with a known propensity for absorbing atmospheric moisture which might thus serve as a source of bridging hydroxides. The solvent we chose for these experiments was ethyl acetate, from which an $Fe_{17}$ complex has previously been synthesised using this approach.[5] Ethyl acetate can contain up to 3% by mass of dissolved water; in these experiments the water content is around 0.1%.

Reaction of $CoCl_2$ (3.9 mmol) with Na(mhp) (Hmhp = 2-methyl-6-hydroxypyridine) (8 mmol) in MeOH (40 ml) for 24 h at 290 K, followed by evaporation to dryness gives an uncharacterised purple paste. Dissolution of this paste in ethyl acetate, followed by filtration, gave purple crystals† in 3 days. The synthesis is reproducible, however the yield varies between 5 and 20%, possibly depending on the exact water content of the EtOAc used. Structural analysis‡ reveals a complex of formula $[Co_{24}(\mu_3\text{-}OH)_{14}(\mu\text{-}OH)_4(\mu_3\text{-}OMe)_2(\mu_3\text{-}Cl)_2Cl_4(mhp)_{22}]$ **1** (Fig. 1) which has a centrosymmetric structure related to many minerals, and indeed to **2**.[4] The cages pack parallel to the crystallographic *ab*-plane.

The structure is based on $[Co_3(OH)_4]^{2+}$ cubes with one corner missing, and in some cases with one of the hydroxide vertices occupied by methoxide or chloride groups. The array is therefore held together by OH bridges. Of the twelve crystallographically independent Co sites, five [Co(1), Co(2), Co(3), Co(4), Co(5)] have a coordination geometry close to a regular octahedron. There are no chelating ligands attached to these metal sites. Three further sites [Co(6), Co(7), Co(8)] have one chelating ligand and four monodentate ligands attached, and have more distorted octahedral geometries. Co(12) also has one chelating ligand and three further contacts, and is probably best described as based on a distorted tetrahedral geometry [four bonds between 1.971(5) and 2.265(3) Å] with one much longer contact [2.884(5) Å]. The final three distinct sites [Co(9), Co(10), Co(11)] each have two chelating mhp ligands attached, with in each case the bond to the O-donor much longer than the bond to the N-donor of the group. Two further monodentate ligands lead to a coordination geometry best described as involving four short contacts in a distorted tetrahedral array [1.971(5)–2.282(3) Å] and two longer contacts [2.310(5)–3.022(5) Å]. The shortest Co···Co contact observed in **1** is 3.014(3) Å between Co(7) and Co(11).

The exterior of the molecule is covered by twenty-two pyridonate ligands. These adopt three distinct bonding modes: binucleating, binding to differing Co atoms through the N- and O-donors; chelating to one Co atom and then bridging to a second Co through the exocyclic O atom; trinucleating, binding to one Co through the ring nitrogen only, and bridging two further Co centres through the oxygen. Such behaviour is typical for these ligands, and perhaps explains why such a simple bridging ligand can stabilise such a large metal–hydroxide structure where previously it has been suggested a polydentate ligand is required.

Preliminary magnetic studies§ of **1** have been performed [Fig. 2(*a*)]. At room temperature the value of the product $\chi_m T$ is *ca*. 63 emu K mol$^{-1}$ ($\chi_m$ is the molar magnetic susceptibility). We assume that this value corresponds to that for 24 non-interacting $S = 3/2$ centres, which would lead to a calculated value of 64.8 emu K mol$^{-1}$ [assuming $g = 2.4$, which is reasonable for high-spin $Co^{II}$]. $\chi_m T$ declines steadily until 30 K where it increases sharply to a value of 62 emu K mol$^{-1}$ at 8 K.

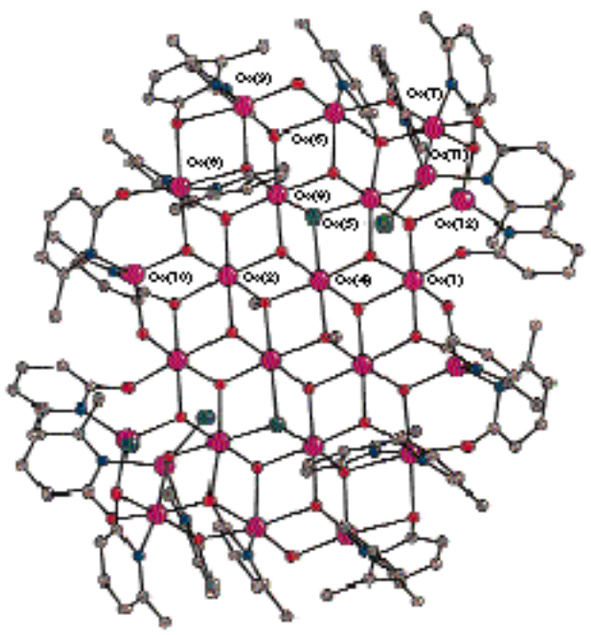

**Fig. 1** The structure of **1** in the crystal. Selected bond length ranges (Å): Co–O(hydroxide) 1.971–2.194, Co–O(methoxide), 2.054–2.120, Co–O(mhp), 2.019–2.376, Co–N(mhp), 2.024–2.246, Co–Cl, 2.265–2.608 Å (av. esd 0.005 Å). These ranges treat Co(9)–Co(12) as four-coordinate and exclude the longer contacts. (Co, magenta; O, red; N, blue; Cl, green; C, grey. Figure drawn using CAMERON.[9])

Below this temperature it falls again, possibly due to intermolecular interactions or zero-field splitting within the spin ground state. If the 8 K value is due to a non-degenerate spin state we can estimate that this is approximately an $S = 9$ state, however further experiments are required to confirm this estimation. Given the structural resemblance between **1** and **2**,[4] a high-spin state would be unsurprising as the latter has a ground state of at least $S = 33/2$. More exciting are differences observed between the field-cooled and zero-field cooled *M/H* curves of **1** [Fig. 2(*b*)] (*M* = magnetisation, *H* = applied field). This provides evidence for freezing of the spins and may be an indication of superparamagnetic behaviour. Such behaviour has been observed for nanoscale cobalt particles prepared in inverse micelles[10] and for a dodecanuclear manganese complex.[11]

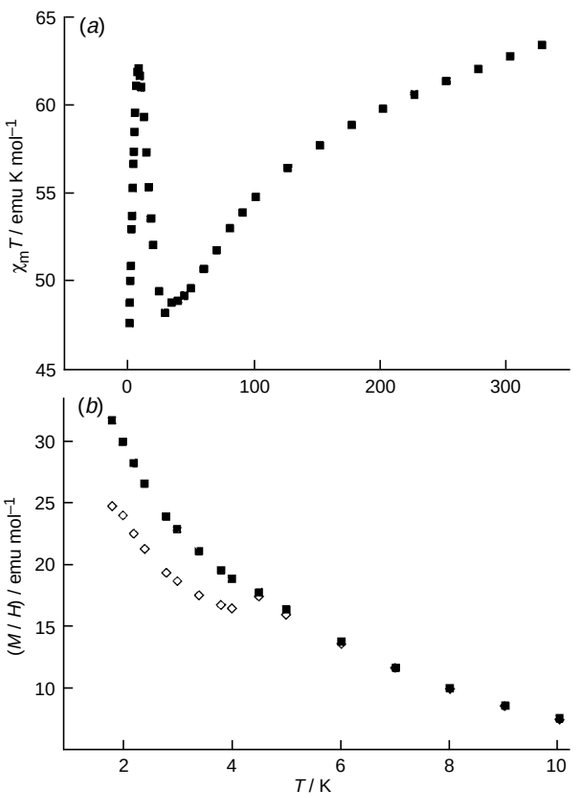

**Fig. 2** (*a*) Plot of $\chi_m T$ *vs*. *T* for **1** measured in a 1000 G field. (*b*) Plot of *M/H vs*. *T* for **1** measured in a 100 G field; zero-field cooled *M/H* shown as open diamonds, field-cooled as filled squares. (*M/H* = $\chi_m$ if *M* is linear with *H*).

Further studies are being undertaken to confirm this behaviour.

We thank the EPSRC for funding for a diffractometer and SQUID suspectometer, for a post-doctoral fellowship (to A. G. W.) and for studentships (for E. K. B. and S. G. H.).

# Self-assembly of a tetranuclear macrocyclic copper(II) complex

**Paul V. Bernhardt* and Lathe A. Jones**

*Department of Chemistry, University of Queensland, Brisbane, 4072, Australia*

**A dinuclear macrocyclic complex is synthesized *via* the one-pot reaction of dipotassium nitroacetate, formaldehyde and a linear tetraamine copper(II) complex; the X-ray crystal structure of the product reveals an association of two dinuclear complexes to form a novel tetracopper(II) species.**

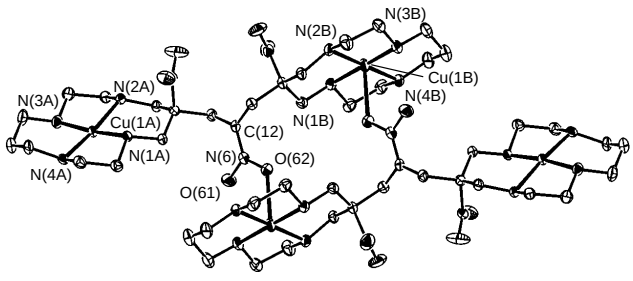
Reactions of metal templates such as $[M(en)_2]^{2+}$ or $[M(2,3,2\text{-tet})]^{2+}$ (M = $Ni^{II}$, $Cu^{II}$; en = ethane-1,2-diamine, 2,3,2-tet = 1,4,8,11-tetraazaundecane) with formaldehyde and a nitroalkane 'locking' fragment have emerged as versatile and effective synthetic routes toward pendant-armed macrocycles.[1] More recently, the range of locking fragments has been extended to include primary amines,[2] amides and sulfonamides[3] and heterocycles.[4] These molecules effect ring closure after reaction of formaldehyde with the coordinated primary amines to produce 14-membered macrocyclic rings based upon the well known cyclam (1,4,8,11-tetraazacyclotetradecane) framework, with the pendant groups arising from substituents on the locking fragments. In principle, this approach may be extended to bifunctional locking groups to generate alkyl-bridged dinuclear complexes, and one report of this type of chemistry is known using dinitro alkanes in this role.[5]

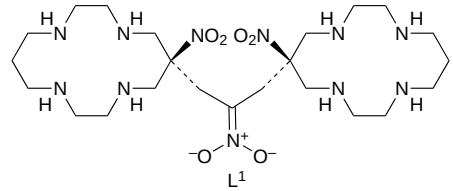
Here we report a new method of generating binuclear complexes *via* one-pot metal-directed reactions of dipotassium nitroacetate, formaldehyde and a tetraaminecopper(II) complex. An aqueous solution of $Cu(NO_3)_2{\cdot}3H_2O$ was stirred while an equimolar amount of 2,3,2-tet was added dropwise. To the resulting purple solution was added aqueous formaldehyde (2 equiv.) and $K_2(O_2CCHNO_2)$ (1 equiv.). The mixture was heated with stirring at 50 °C for 20 h before being filtered. Ion-exchange chromatography of the reaction mixture yielded two products; the first being the mononuclear complex $[CuL^2][ClO_4]_2$ ($\lambda_{max}$ = 518 nm, $\varepsilon$ = 84.2 $dm^3\ mol^{-1}\ cm^{-1}$) followed by the major product, the dimeric $[Cu_2L^1]_2[ClO_4]_3Cl_3$ ($\lambda_{max}$ = 510 nm, $\varepsilon$ = 137 $dm^3\ mol^{-1}\ cm^{-1}$ per Cu centre). The first crop of $[Cu_2L^1]_2[ClO_4]_3Cl_3$ was obtained in 13% yield (of solid compound), but further crops precipitated on standing. The solution properties of both products are typical of cyclam-type complexes of $Cu^{II}$, with respect to their visible electronic maxima and resistance to acid catalysed dissociation (3 M HCl) over a period of several weeks.

X-Ray quality crystals† of the dimer $[Cu_2L^1]_2[ClO_4]_3Cl{\cdot}6H_2O$ were obtained by slow evaporation of an aqueous solution of the complex containing an excess of $NaClO_4$ and NaCl. The crystal structure analysis shows that two dicopper(II) complexes have assembled into a dimeric tetranuclear species (Fig. 1). The pairs of covalently linked macrocyclic planes are twisted relative to each other by an approximate angle of 50° and the Cu···Cu distance is 11.32 Å. Interestingly, the central C atom [C(12)] is deprotonated and the resulting nitronate group forms an intermolecular coordinate bond to an adjacent $Cu^{II}$ centre [2.412(6) Å]. The geometry of each unique $Cu^{II}$ ion is best described as distorted tetragonally elongated octahedral, with anions occupying the remaining coordination sites. The nitronate group and adjacent atoms $[C(C)CNO_2]$ form a planar structure. In addition, a lengthening of the N–O bonds (*ca.* 0.1 Å) and shortening of the C–N bond (*ca*. 0.2 Å) relative to the nitro groups appended to each macrocyclic ring was found. These observations lead to the conclusion that the C–N bond in this functional group has essentially double-bond character.

The formation of $[Cu_2L^1]^{3+}$, and its crystallisation as a dimeric tetranuclear complex, is remarkable, and was unexpected. The crystallisation of $[Cu_2L^1]_2^{6+}$ involves the assembly of 22 different molecules {4 × $[Cu(2,3,2\text{-tet})]^{2+}$, 6 × $(O_2CCHNO_2)^{2-}$, 12 × $CH_2O$} into one supramolecular unit in a one-pot reaction, which illustrates the efficiency of metal-directed reactions of this kind. Dipotassium nitroacetate $K_2(O_2CCHNO_2)$ and its derivatives are unstable toward decarboxylation in aqueous solution.[8] In this case, condensation of three $(O_2CCHNO_2)^{2-}$ ions with two equivalents of formaldehyde followed by decarboxylation generates the molecule 1,3,5-trinitropentane *in situ*. Decarboxylation may occur either before or after the formaldehyde/nitroacetate condensation. The latter mechanism is more likely, *i.e.* 1,3,5-trinitropentane-1,3,5-tricarboxylate is initially formed as an intermediate, since metal-directed reactions of nitromethane (the decarboxylation product of nitroacetate) with formaldehyde under similar conditions do not lead to macrocyclic species. Similarly, the formation of $[CuL^2]^{2+}$ most likely involves the nitrocarboxylate substituted macrocycle as an intermediate which decarboxylates in the final step. Analogous processes have been observed in *gem*-diacid substituted tetraamine complexes.[9]

The electron paramagnetic resonance (EPR) spectra of $[CuL^2]^{2+}$ and $[Cu_2L^1]^{3+}$ [Fig. 2(*a*) and (*c*)] as frozen solutions are quite different, with the latter being consistent with a weakly





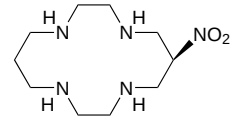


**Fig. 1** Drawing of the $[Cu_2L^1]_2^{6+}$ cation (anions and H-atoms omitted); ellipsoids are drawn at the 30% probability level

$L^1$

$L^2$

dipole–dipole coupled dicopper(II) complex. Simulation of the EPR spectrum of $[Cu_2L^1]^{3+}$ [Fig. 2(*b*), $g_{\|} = 2.17$, $A_{\|} = 205$ G; $g_{\perp} = 2.035$, $A_{\perp} = 50$ G] was achieved with the program DISSIM,[10] which also yielded a Cu···Cu separation of 11.0 Å and a twist angle between the two macrocyclic planes of 80°. The simulation indicates that the compound exists as discrete dicopper(II) complexes in solution and not as the tetranuclear dimer identified in the solid-state structure. In addition, the relative twist angle between the two macrocycles derived from the simulation is *ca*. 30° greater than that identified in the X-ray crystal structure. That is, formation of the tetranuclear dimer perturbs slightly the relative positions of the two covalently linked macrocyclic planes. The EPR spectrum of the mononuclear analogue $[CuL^2]^{2+}$ [Fig. 2(*a*)] is better resolved and typical of an isolated $d^9$ complex in a pseudo-axial ligand field. The similarity between the spectra of $[Cu_2L^1]^{3+}$ and $[CuL^2]^{2+}$ indicates that the two metal centres in $[Cu_2L^1]^{3+}$ are only weakly interacting at this internuclear separation (11 Å), and that dipole–dipole coupling merely acts to broaden what is essentially a mononuclear spectrum.

We have shown that the nitroacetate dianion is a potentially useful synthetic intermediate which, in conjunction with formaldehyde, may generate multifunctional carbon acids *in situ* capable of simultaneously cyclising and bridging two metal centres. Furthermore, this reagent offers a route towards mono-C-substituted ($–NO_2$) macrocycles such as $[CuL^2]^{2+}$ which have been much more difficult to prepare than disubstituted ($–NO_2$, –Me) analogues derived from nitroethane and formaldehyde. Further work is continuing utilising this novel reagent to effect macrocyclic ring closure.

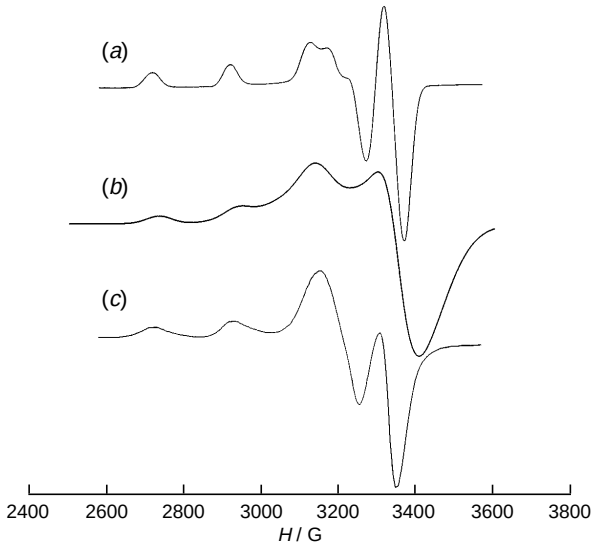

**Fig. 2** (*a*) Experimental EPR spectrum of $[CuL^2]^{2+}$, (*b*) simulated EPR spectrum of $[Cu_2L^1]^{3+}$ and (*c*) experimental EPR spectrum of $[Cu_2L^1]^{3+}$; frequency = 9.272 GHz, $T = 77$ K, solvent water–dimethylformamide (2 : 1)

We gratefully acknowledge Mr David Hunter for his assistance with the EPR spectral measurements and we thank the Energy Research and Development Corporation and the University of Queensland for financial support.

# Synergetic effect of nickel and platinum supported on silica in catalytic methanol decomposition

**Yasuyuki Matsumura,[a] Kenkichi Kagawa,[b] Yoshikazu Usami,[b] Masanobu Kawazoe,[b] Hiroaki Sakurai[a] and Masatake Haruta[a]**

[a] *Osaka National Research Institute, AIST, Midorigaoka, Ikeda, Osaka 563, Japan*

**Alloy formation of nickel and platinum leads to a synergetic effect in the decomposition of methanol to carbon monoxide and hydrogen over silica supported metal catalysts.**

Methanol is recognized as an alternative energy carrier as well as an important chemical feedstock. Methanol decomposition to hydrogen and carbon monoxide is very beneficial in saving energy because the industrially produced waste heat can be utilized to increase the heating value of a fuel. Methanol decomposition is also applicable in vehicles (on-board reforming) to increase the fuel efficiency and reduce the amount of formaldehyde by-product.[1] Catalysts containing nickel have been reported to be active for this reaction,[2–6] however, further improvement is still necessary especially for the application to the recovery of waste heat. Studies on the surface science of the nickel–platinum single-crystal alloy suggest a synergetic effect of the alloy towards some catalytic reactions such as hydrogenation,[7–9] although the effect was not evident on a nickel–platinum alloy supported on alumina.[10] Here, we show the coexistence of nickel and platinum on silica results in a significant improvement in the catalytic activity of methanol decomposition.

Catalysts were prepared by the impregnation technique from an aqueous solution of $Ni(NO_3)_2{\cdot}6H_2O$ (Mitsuwa Chemical, GR grade) and/or $H_2PtCl_6$ (Kanto Chemical, GR grade) using silica (Fuji Silicia, ID G) as a support. The resulting solids were calcined in air at 500 °C for 5 h after being vacuum-dried for 1 day. The samples were further washed five times in boiling water for 1 h to remove chloride ion, and dried at 300 °C for 5 h. The residual chlorine content in the catalysts was found to be < 40 ppm (emission spectral analysis). The prepared catalysts listed in Table 1 all contain 10% Ni by mass.

Catalytic experiments were performed in a fixed-bed continuous flow reactor operated under atmospheric pressure at 250 °C. The catalyst was sandwiched with quartz wool plugs in a quartz tube reactor (i.d., 10 mm) whose contribution to the reaction was negligible. After reducing the sample (0.50 g) in a flow of 10 vol.% hydrogen in argon at 500 °C for 1 h, methanol was fed in an argon carrier stream at a concentration of 20 vol.% with a total flow rate of 2.5 $dm^3\ h^{-1}$. The reactant and products were analysed with two on-stream Ohkura 802T gas chromatographs equipped with TC detectors. An activated carbon (2 m, Ar carrier) column and a Porapak T (2 m, He carrier) column were employed in the analyses.

The surface areas of the catalysts were measured by the conventional BET nitrogen adsorption method. Powder X-ray diffraction (XRD) patterns of the catalysts removed from the reactor after reaction were recorded on a Rigaku Rotaflex 20 diffractometer using nickel-filtered Cu-Kα radiation. X-Ray photoelectron spectra (XPS) of the catalysts after reaction were recorded on a Shimadzu ESCA 750 instrument. The samples were sputtered with argon ions (2 kV, 0.5 min) prior to measurement to eliminate surface contaminants. Charge correction of the XPS data was accomplished by assuming that the binding energy of the C 1s peak is 284.6 eV.

Methanol was decomposed mainly to carbon monoxide and hydrogen with methane detected as a by-product over the catalysts containing nickel and/or platinum at 250 °C (Table 1). The specific surface areas of the catalysts were in the range 172–191 $m^2\ g^{-1}$. The catalysts containing both nickel and platinum were more active than those containing only one of the metals revealing a significant synergetic effect between nickel and platinum. The catalytic activity was 95.3% at 3 mass% loading of Pt.

XRD peaks attributed to metallic nickel were recorded in the pattern of $Ni/SiO_2$ at $2\theta = 44.1°$ [Ni(111)] and 51.4° [Ni(200)].[11] The lattice parameter, *a* of 0.355 nm (*Fm*3*m*) is slightly larger than that for nickel metal (0.352–0.354 nm).[12] In the case of $Pt/SiO_2$ XRD peaks at $2\theta = 39.7$ and 46.2° were observed.[11] Although 1- and 2-$PtNi/SiO_2$ contained platinum, no peaks attributable to platinum could be been in the patterns which were very similar to that of $Ni/SiO_2$. However, the patterns for 3- and 4-$PtNi/SiO_2$ were significantly different from the samples containing lower amounts of platinum. Peaks for nickel were shifted to lower values at $2\theta = 43.5 \pm 0.3°$ and $50.8 \pm 0.3°$ with considerably lower intensities and with broad and asymmetric shapes. The stronger peak at $2\theta = 43.5°$ can be deconvoluted into two peaks at 43.2 and 43.7°, showing that

[a] BET surface area. [b] Binding energy. [c] Atomic ratio calculated from the XPS peak areas using atomic sensitivity factors of 3.0 for Ni $2p_{3/2}$ and 4.4 for Pt 4f.[14] Atomic ratios calculated from the chemical composition are given in parentheses.

there are two crystalline phases in the metal. The lattice parameters (*a*) are tentatively calculated as 0.362 and 0.358 nm, respectively. Deconvolution of the peak at 50.5° was impossible because of its weak intensity. The *a* parameter for $Ni_{23}Pt_2$ is 0.3564 nm (*Fm*3*m*) which is discernibly smaller than the above values,[12] and the change in the XRD pattern suggests that a phase transition of a Ni–Pt alloy such as $Ni_{23}Pt_2$ to new phases such as $Ni_3Pt$ (space group *Pm*3*m*) occurs at high platinum content.[12,13] It should be noted that the surface atomic ratio of Pt/Ni for 3- or 4-PtNi/$SiO_2$ obtained by XPS analyses was considerably lower than the ratio calculated from the chemical composition while the value for 1- or 2-PtNi/$SiO_2$ was close to that expected from the composition (Table 1). This implies that the concentration of platinum in the bulk of 3- or 4-PtNi/$SiO_2$ is higher than the chemical composition (Pt/Ni ratio = 0.17 and 0.22, respectively) and formation of $PtNi_3$ may well be possible in the bulk.

The binding energy of Pt $4f_{7/2}$ in the XPS of Pt/$SiO_2$ was 70.7 eV, but PtNi/$SiO_2$ were appreciably higher in energy (Table 1). This shows that platinum in PtNi/$SiO_2$ is not present as a separate single phase on the surface of silica but rather interacts with nickel. The difference in the binding energies of Pt $4f_{7/2}$ between 1- and 2-PtNi/$SiO_2$ and those for 3- and 4-PtNi/$SiO_2$ reflect more clearly on the difference in the catalytic activity than does the change in the XRD patterns. Hence, it is strongly indicated that platinum and nickel form an alloy on the surface of silica and this is the active phase for methanol decomposition. The binding energy of Ni $2p_{3/2}$ for all the samples was at 852.8 ± 0.2 eV except for 4-PtNi/$SiO_2$ for which it was at 853.5 eV. This higher binding energy may account for the lower catalytic activity of 4-PtNi/$SiO_2$ relative to 3-PtNi/$SiO_2$. Binding energies for Si 1s and O 1s were 103 ± 0.2 and 532.8 ± 0.2 eV, respectively, for all the samples.

K. K., Y. U. and M. K. gratefully acknowledge financial support from the New Energy and Technology Development Organization.

# The first Diels–Alder adduct of [60]fullerene with a tetrathiafulvalene

**Josep Llacay,[a] Montserrat Mas,[a] Elies Molins,[a], Jaume Veciana,[a] Dave Powell[b] and Concepció Rovira*[a]**

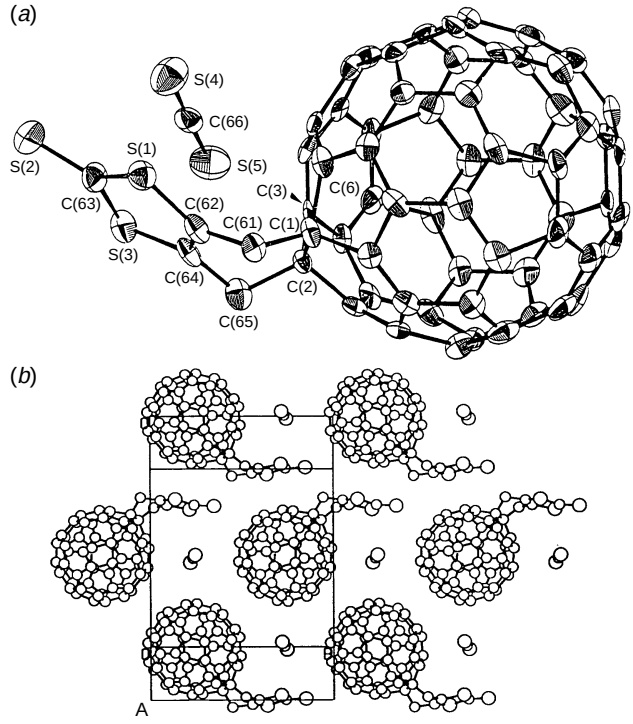
**A Diels–Alder adduct of [60]fullerene and a tetrathiafulvalene (TTF) derivative is synthesised by direct reaction of [60]fullerene with a TTF diene precursor; the crystal structure of the formal intermediate 1,3-dithiole-2-thione derivative of [60]fullerene reveals short contacts between the [60]fullerene and 1,3-dithiole-2-thione moieties.**

In the search for intramolecular energy and electron transfer phenomena in [60]fullerene donor-containing molecules, some electron donor fragments have been covalently linked to the fullerene core.[1–5] Only in very few cases has reliable evidence of thermal or photoinduced intramolecular electron-transfer processes been reported.[3–5] One of the strongest donors that can be attached to the [60]fullerene skeleton is tetrathiafulvalene (TTF). This attachament has been achieved for some compounds, in which the donor TTF moiety is linked by only one single bond to the [60]fullerene through a pyrrolidine bridge, but no electron transfer process has been observed.[6] With the aim of promoting an intramolecular electron transfer we sought to develop a novel type of TTF derivative of [60]fullerene in which the TTF core is directly attached by two σ-bonds to the ball giving rise to a different and more rigid spatial orientation of the HOMO of the TTF addend with respect to the LUMO of [60]fullerene.

Diels–Alder functionalisation of [60]fullerene was chosen in order to reach our goal, since it has been one of the most successful methods for a double attachment of a large variety of substituents[2,7] and it has recently been demonstrated that some Diels–Alder bichromophoric systems undergo energy and electron-transfer phenomena.[5] As a first approach, the thione **1** with a thermolabile sulfone group was used as a diene precursor. We synthesised the compound **1**† by the same procedure used in the synthesis of the parent selenone,[8] and the adduct formation with [60]fullerene was achieved by refluxing a two-fold excess of [60]fullerene with **1** in chlorobenzene–benzonitrile (10 : 1). Chromatographic separation on silica gel ($CS_2$–$CHCl_3$, 10 : 1) afforded the target compound, the Diels–Alder adduct **2**,† as a 1 : 1 clathrate with $CS_2$ in a 41% yield.

The crystallisation of **2**·$CS_2$ by vapour diffusion of pentane into an *o*-dichlorobenzene solution surprisingly gave the **2**·$CS_2$ clathrate back as brilliant dark plates, indicating the very high stability of this clathrate.‡ The crystal structure of thione **2** is shown in Fig. 1.§ As for other adducts,[9] the cyclohexene ring formed by the cycloaddition of the diene derived from thione **1** to the reactive 6,6-ring junction of [60]fullerene shows a boat conformation [Fig. 1(*a*)]. Nevertheless, the angle determined by the two mean planes defined by C(1)–C(2)–C(61)–C(65) and C(61)–C(65)–C(62)–C(64) is smaller (109.2 (4)°) than those found (*ca* 130°) in three other related compounds for which the X-ray structure has been solved so far.[2,9] This small angle gives rise to short intramolecular S···C distances (3.915–4.036 Å) between the sulfur atoms S(1) and S(3) of the addend and C(1), C(2), C(3) and C(6) of the [60]fullerene moiety. If similar short



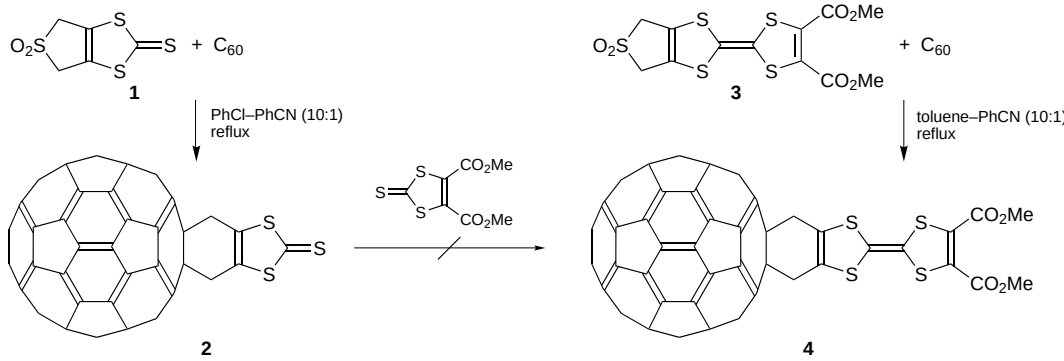


**Fig. 1** Molecular and X-ray crystal structure of **2**·$CS_2$: (*a*) asymmetric unit and, (*b*) crystal packing of **2**·$CS_2$, view perpendicular to the *bc* plane

**Scheme 1**

**Table 1** $E_{1/2}$ Values (V *vs.* $Fc^+/Fc$) of the redox couples of [60]fullerene and compounds **2**–**4** in $CH_2Cl_2$ solutions (0.1 M, $TBAPF_6$), room temp., Pt working and counter eletrodes

| Redox couple | $E^{0/1-}$ | $E^{1-/2-}$ | $E^{2-/3-}$ | $E^{0/1+}$ | $E^{1+/2+}$ |
|---|---|---|---|---|---|
| $C_{60}$ | −0.98 | −1.36 | −1.83 | — | — |
| **2** | −1.03 | −1.41 | −1.93 | — | — |
| **4** | −1.08 | −1.46 | −1.97 | 0.18 | 0.65 |
| **3** | — | — | — | 0.33 | 0.63 |

distances are maintained in the corresponding [60]fullerene–TTF derivatives an intramolecular electron-transfer phenomenon could be expected. The crystal packing of **2**·$CS_2$ consists of parallel intercalated planes (along *a*) of connected chains of molecules along the *b* axis formed by intermolecular close contacts [3.45(3) Å] between sulfur atoms of the thiocarbonyl group and carbon atoms of the contiguous [60]fullerene [Fig. 1(*b*)]. Solvent molecules show some short S···C contacts with two surrounding adduct molecules in addition to the contacts with the adduct inside the asymmetric unit.

Unfortunately, all attempts to perform a phosphite-mediated coupling of thione **2** in order to synthesise [60]fullerene–TTF derivatives have so far been unsuccessful.¶ So, we moved to the key compound **3** as a TTF diene precursor. The asymmetric TTF derivative **3**† was synthesised by a Wittig based methodology[10] in acceptable yield and the corresponding diene indeed undergoes a Diels–Alder addition to [60]fullerene yielding our target compound **4**† as a dark brown solid (47%).

All electroactive compounds here described were studied by cyclic voltammetry. The results are reported in Table 1. In the experimental conditions employed, compounds **2** and **4** show three one-electron reversible reduction waves due to the stepwise reduction of the fullerene moiety. The first reduction potentials of both compounds are slightly shifted cathodically compared to those of [60]fullerene, as observed in many [60]fullerene adducts in which one double bond has been saturated.[11] As expected, compound **4** shows two additional reversible oxidation processes corresponding to the formation of radical cation and dication of the TTF moiety.

The UV–VIS spectra of compounds **2** and **4** clearly show a weak band around 430 nm characteristic of [60]fullerene cycloderivatives.[12] For compound **4** an additional weak and broad band appears at 482 nm (log ε = 3.43) which is not shifted significatively with the modification of the solvent polarity**.** The last result, together with the normal shift of the first reduction potential of **4** in relation with [60]fullerene, does not permit us to assign the extra band to an intramolecular electron-transfer process, as occurs in the case of 1,3-diphenylpyrazolo[4′,5′:1,2][60]fullerene.[3]

We have already synthesised some other TTF derivatives containing the sulfone group precursor of diene group on one side of the TTF core and different atoms (H, Me) on the other side. These compounds have better donor properties than compound **3**‖ and the synthesis and characterization of their corresponding [60]fullerene adducts has been recently performed in our laboratory with the aim of tuning the energy gap between the HOMO of the TTF addend and the LUMO of the [60]fullerene moiety. The study of the photoinduction of electron transfer in [60]fullerene adducts is being pursued.

HRMS (FAB) calc. for $C_{72}H_{10}O_4S_4$: 1065.946. Found: 1065.951.

‡ Thermogravimetric analysis reveals that the loss of solvent takes place between 120 and 190 °C giving rise to the solvent free adduct **2** that is completely stable up to 390 °C.

§ *Crystal data* for **2**: $C_{68}H_3S_3{\cdot}CS_2$, $M$ = 956.9; monoclinic, $P2_1/n$, $a$ = 15.167(2), $b$ = 13.670(2), $c$ = 17.701(2) Å; β = 105.76(2)°; $V$ = 3532.0(8) Å$^3$; $Z$ = 4; $D_c$ = 1.80 g cm$^{-3}$; μ(Mo-Kα) = 3.9 cm$^{-1}$, $2\theta_{max}$ = 47.4°, giving 5342 unique reflections. A dark brown plate of dimensions 0.29 × 0.12 × 0.08 mm was used. The structure was solved by direct methods (SHELXS-86) yielding $R$ = 0.056, $R_w$ = 0.127 for 1838 independent reflexions with $F > 4\sigma(F)$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/385.

¶ Besides homocoupling of **2**, heterocoupling with distinct thiones and ketones similar to **1** using a variety of different phosphites and solvents, have been performed. In all cases compound **2** was recovered almost quantitatively.

‖ First oxidation potentials (*vs* $Fc^+/Fc$) are $E^{1/2}$ = 0.01 V for the donor with Me substituents and $E^{1/2}$ = 0.02 V for the donor with no substituents.

# Biosynthesis of tetraponerine-6. Evidence that two different pathways are operating in the biosynthesis of the two tetraponerine skeletons

**C. Devijver,[a] J. C. Braekman,[a] D. Daloze[a] and J. M. Pasteels[b]**

[a] *Laboratory of Bio-organic Chemistry, Faculty of Sciences, CP160/07, University of Brussels, Av. F. D. Roosevelt, 50, B-1050 Brussels, Belgium*

[b] *Laboratory of Animal and Cellular Biology, Faculty of Sciences, CP 160/12, University of Brussels, Av. F. D. Roosevelt, 50, B-1050 Brussels, Belgium*

**Evidence is presented showing that tetraponerine-6 2a from *Tetraponera* sp. ants is biosynthesized from two molecules of putrescine and a seven-carbon moiety coming from an eight-carbon polyacetate chain through decarboxylation, in contrast with tetraponerine-8 1a, which derives from one putrescine unit and a twelve-carbon polyacetate precursor.**

The tetraponerines are a group of eight tricyclic alkaloids isolated from the poison gland of the Neo Guinean ant *Tetraponera* sp.[1] Structural and synthetic work from our laboratories[2–4] showed that these compounds are distributed into two families, which are based either on the 5-alkyldecahydropyrido[1,2-*c*]pyrrolo[1′,2′-*a*]pyrimidine† skeleton **1** (tetraponerines-3, -4, -7 and -8) or on the 5-alkyldecahydrodipyrrolo[1,2-*a*:1′,2′-*c*]pyrimidine† skeleton **2** (tetraponerines-1, -2, -5 and -6) (Fig. 1). In each family, the compounds differ from each other by the length of the alkyl chain (propyl or pentyl) and (or) by the configuration of the carbon atom to which it is attached.

Incorporation experiments with *Tetraponera* sp. ants using sodium [1-$^{14}$C]- and [2-$^{14}$C]-acetate, L-[U-$^{14}$C]glutamic acid, L-[U-$^{14}$C]ornithine hydrochloride, and [1,4-$^{14}$C]putrescine dihydrochloride, followed by chemical degradation of radioactive tetraponerine-8 (T-8) **1a**, the major alkaloid of the venom, allowed us to propose a biosynthetic pathway for this alkaloid.[5] It was found that acetate is a precursor of the entire carbon skeleton of T-8, but it is incorporated through two different pathways: the pyrrolidine ring of T-8 comes from acetate by its conversion, *via* the tricarboxylic acid cycle, into L-glutamic acid **3**, L-ornithine **4** and putrescine **5**, whereas the twelve remaining carbon atoms appear to be derived from a polyacetate precursor, for which a compound such as **6** is a likely candidate (Scheme 1).

The presence of alkaloids based on two different, albeit closely related, skeletons in one and the same organism is intriguing, particularly with respect to their biosynthesis. We now report our results from biosynthetic studies conducted on tetraponerine-6 (T-6) **2a**, which show that the two tetraponerine skeletons **1** and **2** are assembled *via* two different pathways.

We had to repeat the incorporation experiments with [1,4-$^{14}$C]putrescine dihydrochloride, since the sample of T-6 **2a** isolated from the first experiment[5] decomposed before it could be submitted to chemical degradation. Thus, 1000 *Tetraponera* sp. ants were starved for three days, then fed with a 1 mol dm$^{-3}$ sucrose solution containing [1,4-$^{14}$C]putrescine dihydrochloride (specific activity: 114 Ci mol$^{-1}$; total activity: 50 μCi). They were killed ten days later by dropping them into methanol. Using the already described[2] extraction and purification scheme, four of the tetraponerines (T-8 **1a**, T-4 **1b**, T-6 **2a** and T-5 **2c**) could be isolated in pure state. All were radioactive. Their specific activity and specific incorporation rate (SIR) are reported in Table 1 (experiment 2), together with the values measured from the first incorporation experiment[5] for T-8 (experiment 1). Table 1 shows that the specific incorporation rates of the four alkaloids isolated from experiment 2 are of the same order of magnitude as that of T-8 **1a** from the first experiment.[5] A closer inspection, however, shows that, in experiment 2, the specific incorporation rates of T-6 **2a** and T-5 **2c** are nearly twice that of T-8. Compound T-6 **2a** (6.50 mg), which in this experiment was found to be the major alkaloid of the venom, was then diluted with racemic synthetic[4] material (23.91 mg) as carrier, and divided into two parts, each of which was separately submitted to a degradation scheme analogous to that devised for T-8[5] (Scheme 2). This procedure allowed us to split the molecule into three moieties:‡ *N*-methylpyrrolidine **9**, comprising C-4 to C-7, *N*-tosyl-*p*-bromophenacylprolinate **10**, comprising C-1 to C-3, C-9 and C-10, and *p*-bromophenacylhexanoate **11**, comprising C-8 and C-11 to C-15 of T-6 (Scheme 2). The specific activities and relative specific activities (RSA) of compounds **9** to **11**, and of the two

degradation intermediates **7** and **8** (Scheme 2), calculated by using a 100% value for the RSA of **7**, are reported in Table 2.

Surprisingly, the radioactivity of T-6 **2a** was equally divided between *N*-methylpyrrolidine **9** and the olefin **8**. This was in complete contrast with our previous results on putrescine incorporation in T-8 **1a** (experiment 1),[5] where the olefin corresponding to **8** was not labelled at all. Moreover, after oxidative cleavage of the double bond of **8**, only the *N*-tosyl-*p*-bromophenacylprolinate **10** was found to be radioactive, whereas no activity was found in **11**. It turns out that, during the biosynthesis of T-6 **2a**, putrescine serves as precursor to both pyrrolidine rings. To confirm that different pathways are indeed operating in the biosynthesis of T-6 and T-8, the sample of T-8 **1a** (5.70 mg) isolated from the second incorporation experiment was also diluted with cold synthetic material,[6] and submitted to the usual degradation scheme. The results obtained were in complete agreement with those already reported for this alkaloid,[5] confirming that all the label from putrescine was located in the pyrrolidine ring of T-8, with no radioactivity detected at any other position of the molecule.

**Scheme 3** Biogenetic scheme proposed for tetraponerine-6 **2a**

These results allow us to propose a biogenetic hypothesis for the formation of tetraponerine skeleton **2** in *Tetraponera* sp. ants. Thus, whereas skeleton **1** presumably originates from the condensation of a twelve-carbon polyacetate precursor with one putrescine unit (Scheme 1), skeleton **2** is formed by reaction of two putrescine units with an eight-carbon polyacetate chain, with concomitant decarboxylation (possibly under enzyme control, Scheme 3).

# Synthesis of ferrisilicate with the MCM-22 structure

**Peng Wu, Hong Lin, Takayuki Komatsu and Tatsuaki Yashima***

*Department of Chemistry, Tokyo Institute of Technology, Ookayama 2-12-1, Meguro-ku, Tokyo, 152, Japan*

**A new ferrisilicate molecular sieve with the MCM-22 structure is synthesized in Al-free form and exhibits low activity as a solid-acid catalyst and significant activity for the selective catalytic reduction of NO with $NH_3$.**

A new zeolite MCM-22 patented recently[1] has been proposed to contain two independent pore systems, both of which are accessed through rings composed of ten tetrahedral (T) atoms.[2] One of these pore systems consists of large supercages of 12-membered rings. This unique pore structure of the aluminosilicate MCM-22 means it is an interesting catalyst for a wide variety of acid-catalysed reactions.[3–5]

Isomorphous substitution of other elements for Si or Al into the silica based zeolite framework to prepare the corresponding metallosilicates is an effective way to modify the activity and selectivity of zeolite catalysts. Isomorphous substitution of Ga, Fe, As, Ti, V, Sn, *etc.* into the framework has already been reported. Among these metallosilicates, ferrisilicates have been used as both solid-acid catalysts and oxidation catalysts. The acid strength of MFI type (ZSM-5 type) ferrisilicate is moderate and weaker than that of the Ga and Al analogues.[6] More importantly, we have reported that MFI type ferrisilicate is a more selective catalyst than $Fe^{3+}$-exchanged ZSM-5 and iron oxide supported on silicalite in the oxidative dehydrogenation of alkanes,[7] and that it is also an active catalyst for the selective catalytic reduction (SCR) of NO with $NH_3$ in the presence of $O_2$.[8] Ferrisilicates have been synthesized for MFI,[6] beta,[9] MOR (mordenite),[10] FER (ferrierite), *etc.*,[11] but, as yet, not for the MCM-22 topology. Here, we report for the first time, the synthesis of iron-substituted MCM-22 zeolite and its physicochemical and catalytic properties.

MCM-22 type ferrisilicate (Fe-MCM-22) was synthesized using fumed silicon dioxide (Cab-o-sil M7D) as the source of silicon to obtain an Al-free material (Si/Al > 10 000). Hexamethyleneimine (HM) and $Fe(NO_3)_3 \cdot 9H_2O$ were used as the template and iron source, respectively. In a typical synthesis, silicon dioxide and sodium hydroxide were dissolved in an aqueous solution of HM with stirring for 2 h. The resultant mixture was then added dropwise into an aqueous solution of $(Fe(NO_3)_3$. The mixture was stirred for another 2 h to obtain a clear gel. The pH of the final gel was *ca*. 12 and its molar composition was $SiO_2 : 0.03\ Fe_2O_3 : 0.15\ Na_2O : 45\ H_2O$. The gel was then transferred into a Teflon autoclave and heated at 408 K for 11 days under stirring (60 rpm). The resultant solid product was filtered and washed thoroughly with deionized water, dried at 403 K and calcined in air at 753 K for 5 h to remove the template. The Na form of the zeolite thus obtained was transformed into the H form by ion exchange with 0.1 M $NH_4NO_3$ followed by calcination in air at 723 K for 2 h. A reference sample of the Al analogue, Al-MCM-22, was synthesized according to ref. 12. These two samples were characterized with XRD, IR, $N_2$ adsorption and catalytic studies.

Fe-MCM-22 was nearly white, indicating the absence of iron oxides within the crystals. The XRD pattern of Fe-MCM-22 was very similar to that of its aluminosilicate analogues reported previously[12] except that the relative peak intensities were somewhat different (Fig. 1). Its framework IR spectrum was also similar to that of Al-MCM-22. Upon substitution of Fe for Al, some vibration bands were shifted to lower wavenumbers which can be taken as evidence that Fe ions are present in the tetrahedral framework sites since Si–O–Fe vibrations are weaker than those of Si–O–Al. The internal asymmetric vibration has been reported to show a larger shift than the external one upon the substitution of Fe for Al in beta and MOR.[9,10] However, the extent of the shift of these two vibrations was reversed for MCM-22 (Table 1), which may be due to the unique structure of the MCM-22 zeolite. From $N_2$ adsorption experiments, Fe-MCM-22 had a comparable micropore volume and specific surface area to Al-MCM-22. These data were also similar to those reported for MCM-22 aluminosilicates[4] and is a clear indication that Fe-MCM-22 has a high degree of crystallinity.

If trivalent $Fe^{3+}$ ions are incorporated into the silicate framework, Si(OH)Fe hydroxy groups must be generated when Fe-MCM-22 was exchanged into the H form. Fig. 2 shows IR spectra of both H-form Fe-MCM-22 and H-form Al-MCM-22 in the hydroxy region. For Al-MCM-22 [Fig. 2(*a*)], the bands at 3748 $cm^{-1}$ (external silanols), 3730 $cm^{-1}$ (internal silanols), 3663 $cm^{-1}$ (associated with extraframework Al species) and 3621 $cm^{-1}$ [the structural Si(OH)Al hydroxy groups] were

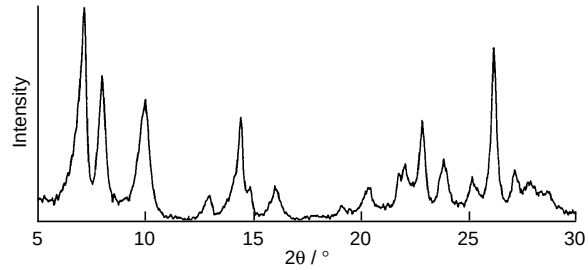

**Fig. 1** X-Ray diffraction pattern of Fe-MCM-22

**Table 1** Physicochemical and catalytic properties of Fe-MCM-22 and Al-MCM-22

| | | $N_2$ adsorption | | $\nu_{asym}/cm^{-1}$ | | Catalytic activity/mol% | |
|---|---|---|---|---|---|---|---|
| | Si/M ratio in gel | Micropore/ ml $g^{-1}$ | Surface area/ $m^2\ g^{-1}$ | External | Internal | *o*-Xylene[a] isomerization | Toluene[b] methylation |
| Fe-MCM-22 | 15 | 0.197 | 544 | 1229 | 1089 | 6.1 | 23.9 |
| Al-MCM-22 | 15 | 0.203 | 551 | 1244 | 1092 | 67.5 | 81.6 |

[a] *o*-Xylene isomerization: cat., 0.4 g; *W/F* = 7.2 g h $mol^{-1}$; *T* = 573 K; He, 20 ml $min^{-1}$; time on stream (TOS) = 1 h. [b] Toluene methylation: cat., 0.4 g; *W/F* = 6.8 g h $mol^{-1}$; *T* 573 K; MeOH–toluene molar ratio = 2 : 1; He, 20 ml $min^{-1}$; TOS = 1 h.

clearly distinguished. Fe-MCM-22 [Fig. 2(*b*)] exhibited a characteristic band at 3637 $cm^{-1}$. This band was removed completely after pyridine adsorption followed by desorption at 423 K, while a band due to pyridinium ions was observed at 1550 $cm^{-1}$. This allows us to assign the band at 3637 $cm^{-1}$ to structural Si(OH)Fe groups with Brønsted acidity. Hence, the above results are considered as strong proof of the incorporation of $Fe^{3+}$ ions in the framework. The higher wavenumber of Si(OH)Fe groups suggests that the Brønsted acidity of Fe-MCM-22 is much weaker than that of Al-MCM-22 and Fe-MCM-22 showed very low activity for *o*-xylene isomerization (catalysed by Brønsted-acid sites having at least medium strength), while it exhibited a relatively higher activity for toluene methylation (proceeds even over weak Brønsted-acid sites) at the same reaction temperature (Table 1).

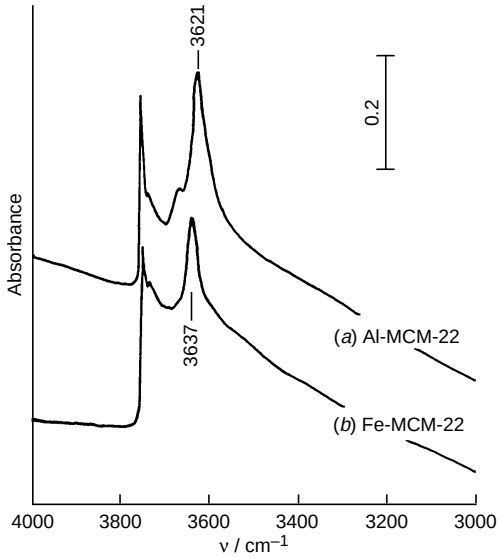

**Fig. 2** IR spectra in the hydroxy region

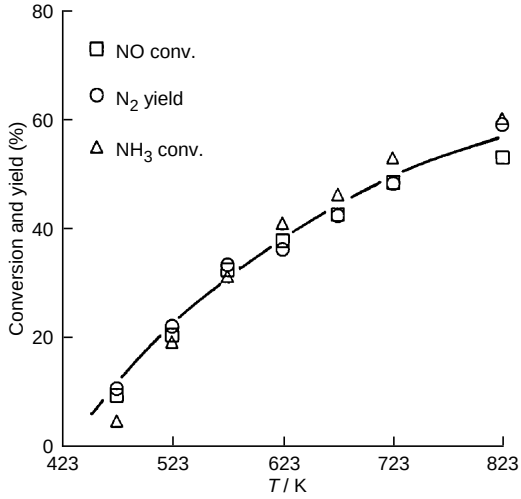

**Fig. 3** NO reduction over Fe-MCM-22 with $NH_3$ in the presence of $O_2$. *Reaction conditions*: cat. 0.1 g; feed, NO (0.1%), $NH_3$ (0.1%), $O_2$ (2%), He (balance); total flow rate, 500 ml $min^{-1}$.

Further, Fe-MCM-22 was also tested for the selective catalytic reduction of NO with $NH_3$ in the presence of $O_2$. It is obvious from Fig. 3 that Fe-MCM-22 is an effective catalyst for NO reduction with $NH_3$ as a reductant. The activity of Fe-MCM-22 was even *ca*. 10% higher than that of MFI-type ferrisilicate (Si/Fe = 25) below 600 K (the temperature region where NO reduction occurred selectively for MFI-type ferrisilicate). It should be noted that Al-MCM-22 only showed NO conversion of less than 5% at the temperatures studied. Thus, the active sites must be the framework $Fe^{3+}$ ions, as reported previously for MFI type ferrisilicate.[8] NO conversion, $N_2$ yield and $NH_3$ conversion correlated well with each other even at high temperatures, indicating that the reduction of NO by $NH_3$ occurred selectively. This result also verifies that extraframework Fe species are negligible in Fe-MCM-22 since we have observed that iron oxide species supported on MFI type silicalite exhibits activity for the oxidation of $NH_3$ by $O_2$ to form NO but no activity for the reduction of NO.[8] As Fe-MCM-22 can be synthesized with relatively high Fe content (Si/Fe = 15), it is anticipated that more active catalysts for SCR of NO can be obtained by exchange with other transition-metal ions into Fe-MCM-22.

To summarize, a new ferrisilicate possessing the MCM-22 structure has been hydrothermally synthesized. Fe-MCM-22 is a weak solid acid but is an effective catalyst for the selective reduction of NO.

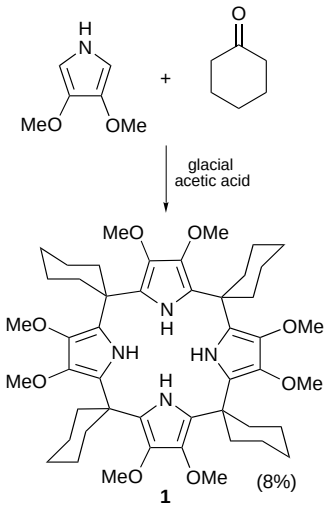
# Calix[4]pyrroles: *C*-rim substitution and tunability of anion binding strength

**Philip A. Gale, Jonathan L. Sessler,* William E. Allen, Nicolai A. Tvermoes and Vincent Lynch**

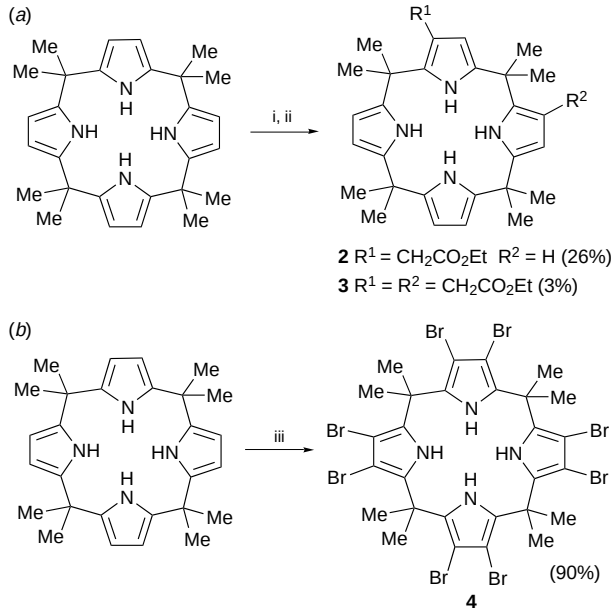


*Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712-1167, USA*

**Electron-rich and electron-deficient *C*-rim substituted calix[4]pyrroles 1–4 are synthesised and the anion binding ability of these receptors is found to be dependent upon the *C*-rim substituents.**

Stimulated by how nature utilises anions in numerous biochemically important systems such as chloride channels,[1] proteins[2] and as polyanions for the storage and transmission of genetic information,[3] the molecular recognition of anionic guest species is an area of coordination chemistry attracting increasing interest.[4–7] As part of a programme aimed at the synthesis of new easy-to-make anion binding agents, and exploiting our recent discovery that calix[4]pyrroles (*meso*-octaalkylporphyrinogens; first synthesised in 1886 by Baeyer[8]) are effective and selective anion binding agents both in solution and in the solid state,[9,10] we decided to investigate whether the anion binding ability of these latter materials could be tuned by appending functional groups to the carbon rim (*C*-rim) of the calixpyrrole. Previously, Jacoby *et al*. have investigated modification of the *meso*-octaakylporphyrinogen skeleton using organometallic methodologies.[11] We adopted two strategies for the synthesis of *C*-rim calix[4]pyrroles: firstly, synthesis from 3,4-disubstituted pyrroles and ketones, and secondly, direct modification of the *C*-rim of a pre-synthesised calix[4]pyrrole.

Using the first strategy, 3,4-dimethoxypyrrole[12] was condensed with cyclohexanone in glacial acetic acid. Removal of the acid *in vacuo* and subsequent purification of the residue by column chromatography (silica gel, $CH_2Cl_2$ eluent) afforded the novel β-octamethoxy-*meso*-tetraspirocyclohexylcalix[4]-pyrrole **1** as a white powder in 8% yield (Scheme 1).



Following the second strategy, *meso*-octamethylcalix[4]pyrrole was dissolved with stirring in dry THF under an Ar atmosphere, and the flask cooled to −78 °C. A solution of butyllithium in hexanes (4.0 equiv.) was added dropwise to the calixpyrrole solution and after 30 min, 4.0 equiv. of ethyl bromoacetate were also added. The reaction was stirred for a further 1 h at −78 °C and then allowed to warm to room temperature. Purification by column chromatography (silica gel, $CH_2Cl_2$ eluent) afforded two isolable products. The first proved to be *C*-rim monoester **2** (formed in 26% yield) and the second the diester **3** (3% yield) [Scheme 2(*a*)]. Surprisingly, $^1$H and $^{13}$C NMR experiments showed that the diester **3** present in the fraction collected was a single isomer. Support for the proposed 1,3-substitution pattern of **3** was obtained from X-ray crystallographic analysis even though the quality of the crystals did not permit a complete refinement.

**Scheme 1**

β-Octabromo-*meso*-octamethylcalix[4]pyrrole **4** was synthesised in 90% yield by reaction of *meso*-octamethylcalix[4]pyrrole with *N*-bromosuccinimide (NBS) in dry THF heated at reflux [Scheme 2(*b*)]. Single crystals of compound **4** were grown by slow evaporation of a dilute dichloromethane solution of the macrocycle (Fig. 1).† The structure reveals that compound **4** exists in a chair-like flattened 1,2-alternate conformation in the solid state (*i.e*. the dihedral angles between pyrrole rings and plane through the calixpyrrole *meso*-carbon atoms are 66.8, 5.8, −66.8 and −5.8°).

Analyses of the solution phase anion binding properties of calix[4]pyrroles **1**, **2** and **4** were made using $^1$H NMR spectroscopic titrations carried out in $CD_2Cl_2$. Data analysis and stability constant determinations were then made using the EQNMR computer program fitting the binding profiles to a 1 : 1 calixpyrrole–anion solution complex model.[13] The results are summarised in Table 1. Compound **1** has lower stability constants with fluoride and chloride than *meso*-tetraspirocyclohexylcalix[4]pyrrole.[9] This may be due to the electron-donating ability of the eight *C*-rim methoxy groups causing a decrease in the acidity of the pyrrole NH protons and hence reducing anion binding ability. Likewise compound **2** shows lower stability constants for the complexation of fluoride, chloride and dihydrogen phosphate anions than does *meso*-

**Scheme 2** *Reagents*: i, BuLi (4 equiv.), THF; ii, $BrCH_2CO_2Et$ (4 equiv.); iii, NBS, THF

octamethylcalix[4]pyrrole.[9] In this case the reduction in anion binding strength (with the respect to *meso*-octamethylcalix[4]pyrrole) may be due to unfavourable interactions between the bound anion and the lone pair electrons on the oxygen atoms of the *C*-rim ester group.

In contradistinction to receptors **1** and **2**, compound **4** exhibits higher stability constants for the binding of fluoride, chloride and dihydrogen phosphate anions than does *meso*-octamethylcalix[4]pyrrole under the same conditions. This may be due to the electron-withdrawing nature of the eight *C*-rim bromine atoms increasing the acidity of the pyrrole NH protons and thus enhancing anion binding ability.

In summary, we have shown that the anion binding ability of the calix[4]pyrroles can be tuned by appending different groups to the carbon or *C*-rim of the calixpyrrole. Receptors with an increased anion binding ability such as **4** may have potential uses as anion sequestering agents (*e.g.* in removal of phosphate pollutants from aqueous environments) while those with decreased anion binding ability (compounds **1** and **2**) could prove useful as HPLC column media since in this latter application low affinity constants and fast complexation–decomplexation rates generally lead to efficient separation of substrates.[14] In any event the fact that compounds **2** and **3** come 'prefunctionalised' with ester groups should facilitate the attachment of other substituents, making it easier to use the calix[4]pyrroles in a range of applications.

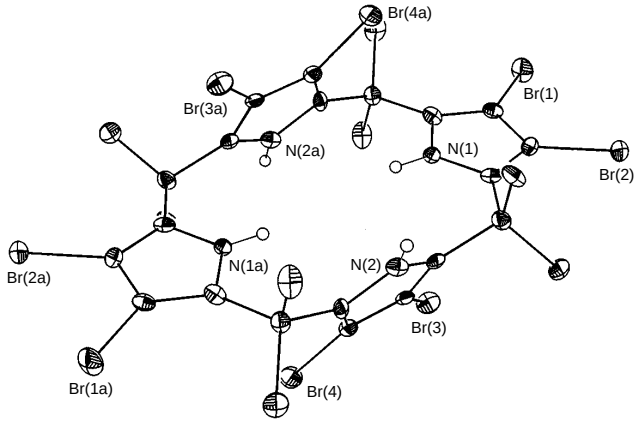


**Fig. 1** View of $C_{28}H_{28}N_4Br_8$ **4** showing the flattened 1,2-alternate conformation. Thermal ellipsoids are scaled to the 30% probability level.

**Table 1** Stability constants for compounds **1**, **2** and **4** with anionic substrates[a] in $CD_2Cl_2$ at 298 K

| | Stability constant/dm$^3$ mol$^{-1}$ | | |
|---|---|---|---|
| Anion | **1** | **2** | **4** |
| Fluoride | 1.7 (±0.2) × $10^2$ | 1.1 (±0.2) × $10^3$ | 2.7 (±0.4) × $10^4$[b] |
| Chloride | < 10 | 47 (±1) | 4.3 (±0.6) × $10^3$ |
| Dihydrogen-phosphate | —[c] | < 10 | 6.5 (±0.4) × $10^2$ |

[a] Anions were added as 0.03 M $CD_2Cl_2$ solutions of their tetrabutylammonium salts to 3 mM solutions of the receptor in $CD_2Cl_2$ with concentration changes being accounted for by EQNMR (ref. 13). In determining the stability constants, the possible effects of ion pairing (if any) were ignored. [b] Estimated value. The NH proton resonance broadened considerably during the titration, forcing the frequency of the resonance to be noted manually. This value should, therefore, be treated with caution. [c] Not determined.

# Ruthenium catalysed hydrogenation of dimethyl oxalate to ethylene glycol

**Herman T. Teunissen and Cornelis J. Elsevier***

*Anorganisch Chemisch Laboratorium, J. H. van't Hoff Research Instituut, Universiteit van Amsterdam, Nieuwe Achtergracht 166, NL-1018 WV Amsterdam, The Netherlands*

**Dimethyl oxalate is efficiently hydrogenated to ethylene glycol under mild conditions [$p(H_2)$ 70 bar; 100 °C] using a ruthenium catalyst based on $Ru(acac)_3$ and $MeC(CH_2PPh_2)_3$.**

The homogeneous hydrogenation of esters to alcohols is a difficult process and only a few papers dealing with this subject have appeared.[1–3] Anionic ruthenium hydride catalysts have been described by Grey *et al.*[1] and neutral ruthenium catalysts were reported by Matteoli *et al.*[2,3] In general, drastic conditions are required for the efficient conversion of an ester to the corresponding alcohol, unless the ester is activated by electron-withdrawing substituents. Thus, the hydrogenation of methyl glycolate (MGL) to ethylene glycol [EGL, eqn. (1)] requires drastic conditions [$p(H_2)$ 200 bar; 180 °C][2] while dimethyl oxalate (DMO) is relatively easily reduced to MGL [eqn.(2)].

$$MeO_2CCH_2OH + 2\ H_2 \rightarrow HOCH_2CH_2OH + MeOH \quad (1)$$

$$MeO_2CCO_2Me + 2\ H_2 \rightarrow MeO_2CCH_2OH + MeOH \quad (2)$$

We report a ruthenium based homogeneous catalyst which is able to homogeneously catalyse the hydrogenation of DMO to EGL under substantially milder conditions.

Exploratory experiments were based on the $Ru(acac)_3$ system, described by Hara and Wada for the hydrogenation of anhydrides to lactones.[4] These experiments revealed that an active catalyst can be generated *in situ* from $Ru(acac)_3$ and a donor ligand in MeOH in the presence of zinc. Zinc was added to initiate a fast reduction of the acetylacetonate complex. The influence of ligands on the catalytic activity of this system was explored in detail and is shown in Table 1.†

From Table 1 it is evident that ruthenium catalysts with phosphine ligands (except tricyclohexylphosphine, entry 7) show a higher activity than with the nitrogen or arsenic compounds (entries 3–6). The applied phosphine ligands induced remarkable differences in terms of catalytic activity as a function of their coordination properties. More specifically, the activity of the ruthenium–phosphine catalysts in the hydrogenation of DMO (expressed as turnover frequency) increases in the order $P(C_6H_{11})_3 < Ph_2PC_2H_4PPh_2 < PPh_3 < PhP(C_2H_4PPh_2)_2 \approx [CH_2P(Ph)C_2H_4PPh_2]_2 \ll MeC(CH_2PPh_2)_3$. The extraordinary effect of the $MeC(CH_2PPh_2)_3$ ligand[5] on the catalytic activity is evident from the formation of EGL in high yield which was not observed in any previous experiment. (Note that the hydrogenation of MGL to EGL is not as activated by an electron-withdrawing substituent as the hydrogenation of DMO to MGL, *vide supra*.) Our catalytic system consisting of $Ru(acac)_3$ and the tridentate ligand $MeC(CH_2PPh_2)_3$ (entry 11) is considerably better with respect to the selectivity of EGL formation and the turnover frequency when compared with the catalytic properties of the best known system so far, *i.e.* $Ru(CO)_2(AcO)_2(PBu_3)_2$.[2] Furthermore, our system displays catalytic activity under relatively mild conditions. The catalytic properties of the ruthenium catalyst derived from $MeC(CH_2PPh_2)_3$ indicate that a ruthenium complex with a *fac* coordinating ligand is essential for high catalytic activity. This conjecture is supported by the relatively low catalytic activity of the $PhP(C_2H_4PPh_2)_2$ and $[CH_2P(Ph)C_2H_4PPh_2]_2$ derived systems, in which the ligands can coordinate either in a *fac* or *mer* fashion to ruthenium.

The $Ru(acac)_3$–$MeC(CH_2PPh_2)_3$ system was explored in more detail with respect to the influence of the hydrogen pressure, the substrate to catalyst ratio, and the role of zinc. From Table 2 it is clear that the turnover number increases from 160 (entry 1) to 642 (entry 3) when the Ru : DMO ratio decreases from 1.19 to 0.18%. As is seen from entries 8 and 9, decreasing the Ru : DMO ratio from 0.20 to 0.15 leads to significantly lower catalytic activity; the turnover frequency decreases from 53.5 to 15.5 $h^{-1}$.

As expected, the $H_2$ pressure has a significant influence on the turnover number and turnover frequencies. Decreasing the $H_2$ pressure from 70 to 20 bar (entries 3–5) leads to a decrease of the turnover frequency by a factor 3.6. Comparing the experiments in entries 3 and 6 (and 7 and 8), the influence of

[a] Conditions: 100 °C, $p(H_2)$ = 70 bar, 16 h, ligand (1.1–1.6 equiv.). [b] Used as received (commercial quality). [c] $p(H_2)$ = 38 bar. [d] $p(H_2)$ = 20 bar. [e] Distilled from $CaH_2$ under nitrogen.

zinc in obtaining reasonable to good yields of EGL and high turnover numbers is demonstrated; the turnover number decreases by a factor 1.8 when zinc is omitted.‡ Finally, the methanol quality is important for the catalytic activity of our system (entries 7–9). Comparing the experiments of entries 3 and 8 on the one hand and the experiments of entries 6 and 7 on the other shows that the highest catalytic activity is observed in dry methanol, regardless of the presence of zinc. Altogether, a turnover frequency of 53.5 is reached with our catalytic system in the presence of zinc in dry MeOH.

In conclusion, we have demonstrated that a highly reactive catalyst for the hydrogenation of dimethyl oxalate to ethylene glycol can be generated *in situ* from $Ru(acac)_3$ and $MeC(CH_2PPh_2)_3$ in methanol under $H_2$ pressure, which is the most efficient homogeneous catalyst for the hydrogenation of dimethyl oxalate to ethylene glycol.

We are grateful to the Innovation Oriented Research Programme (IOP-katalyse) for their financial support of this research. Dr J. G. de Vries (DSM) and Dr M. J. Doyle (SRTCA) are gratefully acknowledged for stimulating discussions.

† *General procedure*: a home-built stainless steel autoclave was charged with the amount of ruthenium precursor, ligand, zinc and substrate indicated. The autoclave was then flushed with nitrogen several times, after which the solvent was introduced *via* a cannula. Subsequently, the autoclave was pressurized with hydrogen and heated for a specific period (see Tables). The values of the $H_2$ pressure are given at room temperature. The reaction products were characterized by GC–MS while the yields were determined by GC with an internal standard.

‡ Employing zinc in the absence of $Ru(acac)_3$ gave no hydrogenation of DMO whatsoever.

# Tyrosine nitration and peroxonitrite (peroxynitrite) isomerisation: $^{15}$N CIDNP NMR studies

**A. R. Butler,*[a] T. J. Rutherford,[a] D. M. Short[a] and J. H. Ridd[b]**

**In the presence of tyrosine, peroxonitrous acid forms nitrite, nitrate and 3-nitrotyrosine by radical processes.**

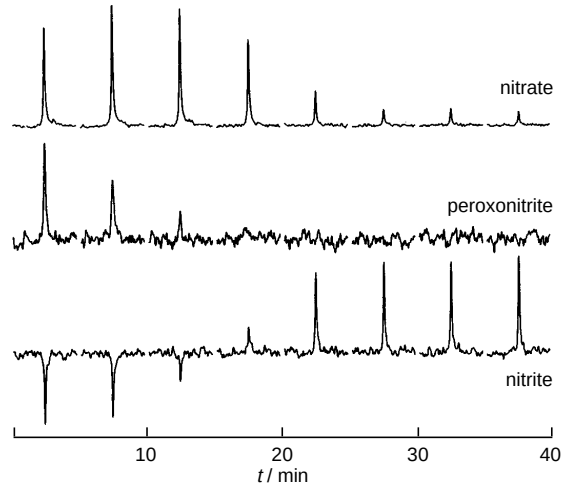
One of the most interesting developments in our understanding of the role of nitric oxide in animal physiology is the emergence of peroxonitrite ($ONOO^-$, sometimes called peroxynitrite), formed by reaction of nitric oxide with superoxide, as an important cytotoxic agent.[1] Also, peroxonitrite appears to bring about tyrosine nitration[2] which may have consequences for the process of tyrosine phosphorylation. The presence of nitrated tyrosine residues has been suggested as a marker for peroxonitrite activity.[3] The formation of $NO_2^+$ has been proposed as an essential step in tyrosine nitration by peroxonitrite[4] but, for a substrate as activated towards electrophiles as tyrosine, there are well established alternative pathways. For example, we have observed that the nitration of *N*-acetyltyrosine by dilute nitric acid is a nitrous acid catalysed process and must occur either by nitrosation followed by oxidation or by a radical mechanism. The use of the CIDNP has proved very useful in probing further the mechanisms of such reactions.[5] Nitration of tyrosine with $^{15}$N-labelled nitric acid containing catalytic quantities of nitrite, and examination of the $^{15}$N NMR spectrum immediately after reaction, gave a very large inverted signal for 3-nitrotyrosine, which slowly changed to the normal signal. It is possible to make a number of mechanistic deductions from this observation but it is sufficient, in this preliminary communication, to note that there must be a substantial radical pathway in the formation of 3-nitrotyrosine. We now turn to an examination of nitration by peroxonitrite where both radical and ionic pathways have been suggested.

$^{15}$N-labelled peroxonitrite in alkaline solution was prepared by the method of Leis *et al.*[6] and allowed to react with tyrosine at 25 °C and pH 12. EDTA was present to prevent complications due to a metal-catalysed decomposition pathway.[7] The reaction was followed from changes in the $^{15}$N NMR spectrum using a 500 MHz Varian Unity instrument. The quoted chemical shifts are downfield from liquid ammonia at 25 °C and were measured relative to [$^{15}$N]nitrobenzene ($\delta_N$ 370.3) as an external standard. The identification of the signals was carried out by spiking with authentic samples of $^{15}$N-labelled material.

The initial signal from peroxonitrite ions at $\delta_N$ 554.6 decreased exponentially with time, showing no sign of nuclear polarisation, and two product signals appeared: one from nitrite ions at $\delta_N$ 609.1 in emission and one from nitrate ions at $\delta_N$ 375.9 showing evidence of enhanced absorption (Fig. 1). The UV–VIS spectra of the solutions showed the formation of 3-nitrotyrosine; this absorbs at $\delta_N$ 375.3 (very close to nitrate ions) under these conditions but the amount formed is insufficient to contribute significantly to that signal. When tyrosine is absent or replaced by *O*-methyltyrosine, the only reaction observed is the slow conversion of peroxonitrite ions to nitrate ions without any evidence of nuclear polarisation.

The main features of these observations can be explained by the reaction pathway shown in Scheme 1. The absence of nuclear polarisation in the peroxonitrite ions suggests that the initial homolysis of peroxonitrite is essentially irreversible; this also accords with AMI calculations on the relative energies of the possible transition states. The fact that the nitrate and nitrite ions show nuclear polarisation of opposite phase indicates that one product is derived from reaction within the $NO_2^{\bullet}$–$^{\bullet}OH$ encounter pair and the other from reaction after dissociation of this radical pair. From Kaptein's rules[8] as applied to the $^{15}$N nucleus[9] and from the *g*-values of the $NO_2^{\bullet}$ and $^{\bullet}OH$ radicals,[10] it follows that the reaction within the encounter pair should give an enhanced absorption signal and that from the dissociated radicals should give an emission signal; this accords with the observed spectra of the nitrate and nitrite ions. Tyrosine appears to be involved in two ways: first, the conjugate base of tyrosine reduces the dissociated radicals by an electron transfer reaction and, secondly, the tyrosyl radical so formed reacts directly with the $NO_2^{\bullet}$ and $^{\bullet}OH$ radicals. The relatively low yield of 3-nitrotyrosine may be a consequence of the high reactivity of $^{\bullet}OH$ radicals towards tyrosyl radicals. In the absence of tyrosine, the dissociated $NO_2^{\bullet}$ and $^{\bullet}OH$ radicals are considered to recombine to form nitrate ions and, since only one product is formed, nuclear polarisation would not be expected.

The scheme is similar to that proposed by Pryor and Squadrito.[11] Nitrophenols are known to be formed by the reaction of phenoxy radicals with nitrogen dioxide[12] and aromatic hydroxylation by peroxonitrite ions has been des-



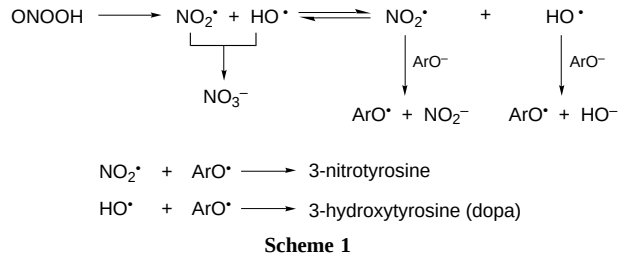


**Fig. 1** Variation of signals with time in the $^{15}$N NMR spectrum for the reaction of peroxonitrite (0.1 mol dm$^{-3}$) with L-tyrosine (0.025 mol dm$^{-3}$). [NaOH] = 0.15 mol dm$^{-3}$.

**Scheme 1**

cribed previously.[13] It is clear from our observations that one pathway, perhaps the only pathway, in the reaction of peroxonitrite ions with tyrosine in alkaline solution is a radical one. The small concentration of nitrotyrosine formed unfortunately precludes any observation of nuclear polarisation in this product but it is reasonable to infer that this nitration is also a radical reaction.

We thank the Wellcome Trust for NMR facilities, the BBSRC for a studentship to D. M. S. and the Rollo Trust for consumables.

# Synthesis and aqueous solution properties of novel hydrophilic–hydrophilic block copolymers based on tertiary amine methacrylates

**V. Bütün, N. C. Billingham and S. P. Armes***

*School of Chemistry, Physics and Environmental Science, University of Sussex, Falmer, Brighton, UK BN1 9QJ*

**A series of near-monodisperse novel diblock copolymers based on tertiary amine methacrylates has been synthesised using group transfer polymerisation chemistry; subtle differences in basicity between the two blocks lead to interesting aqueous solution behaviour, including pH-induced micellisation and very high surface activity.**

Over the last decade or so group transfer polymerisation[1,2] has become recognised as an excellent method for the synthesis of methacrylate (co)polymers of controlled structure and narrow molecular weight distribution. Recently we have used this technique to prepare well-defined homopolymers and block copolymers based on 2-(dimethylamino)ethyl methacrylate (DMAEMA).[3,4] DMAEMA homopolymer is a weak polybase which is soluble at neutral pH or in acidic media due to protonation of the tertiary amine groups. Functionalisation of the DMAEMA residues is possible: for example, quantitative derivatisation under mild conditions has been recently achieved using propane-1,3-sultone to yield near-monodisperse polysulfopropylbetaines.[5] Here we describe the block copolymerisation of DMAEMA with a related tertiary amine methacrylate, 2-(diethylamino)ethyl methacrylate (DEAEMA) (Scheme 1). Although structurally very similar to DMAEMA, the DEAEMA monomer is immiscible in water and DEAEMA homopolymers are completely insoluble at neutral pH. On the other hand, DEAEMA homopolymers readily dissolve in acidic aqueous solution (*ca*. pH 2) due to protonation of the tertiary amine residues. Here it is demonstrated that the subtle difference in chemical structure between these two tertiary methacrylate comonomers has profound implications for the aqueous solution behaviour of DMAEMA–DEAEMA block copolymers.

**Scheme 1**

A series of DMAEMA–DEAEMA block copolymers was prepared using group transfer polymerisation under similar conditions to those previously described.[4] All copolymerisations were carried out using 1-methoxy-1-trimethylsilyloxy-2-methylprop-1-ene (MTS) as initiator and tetrabutylammonium bibenzoate (TBABB) catalyst at 25 °C in dry THF using Schlenk techniques. The DMAEMA monomer was polymerised first and quantitative yields were obtained in all syntheses. The molecular weights, polydispersities and copolymer compositions of the resulting block copolymers are summarised in Table 1. Narrow molecular weight distributions were obtained in all cases ($M_w/M_n \leqslant 1.15$) as judged by gel permeation chromatography (THF eluent, PMMA standards, RI detector). The actual copolymer compositions as determined by $^1$H NMR spectroscopy corresponded closely (within experimental error) to those expected from the comonomer feeds. As far as we are aware, these are the first reported examples of diblock copolymers in which both block components are polybases.

For reasons outlined above, these DMAEMA–DEAEMA copolymers behave as hydrophilic–hydrophobic blocks in aqueous solution at neutral pH. One of the problems in studying the micellisation behaviour of such copolymers is that water-miscible co-solvents (THF, alcohols, DMF *etc.*) are normally required for efficient dissolution in aqueous solution. Even then, the hydrophobic component usually ensures that the majority of the copolymer chains exist as micellar aggregates, rather than as molecularly dissolved chains. Thus there is little opportunity to study the kinetics of micellisation under true equilibrium conditions. Recently there have been several reports[6–8] of the

[a] As determined by $^1$H NMR spectroscopy in $CDCl_3$. [b] As determined by GPC in THF [RI detector; calibrated with poly(methyl methacrylate) standards].

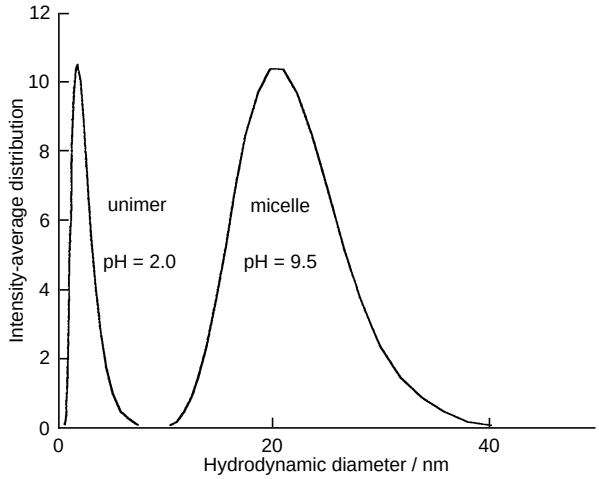

**Fig. 1** Hydrodynamic size of a 72:28 DMAEMA–DEAEMA block copolymer (dissolved in dilute HCl as a 1.0% w/v solution at 25 °C and then tritated to pH 9.5 using KOH)

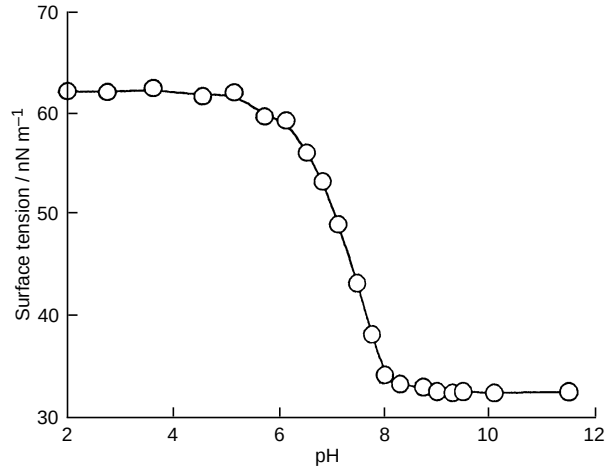

**Fig. 2** Variation of surface tension with solution pH for a 1.0% w/v aqueous solution of a 72:28 DMAEMA–DEAEMA block copolymer. The block copolymer was first dissolved in dilute HCl and the solution pH was then adjusted by addition of KOH.

synthesis of hydrophilic–hydrophilic block copolymers which can be dissolved as unimers in aqueous solution and then aggregated into micelles. One way of inducing micellisation is by raising the solution temperature to the cloud point of the least hydrophilic block component. Alternatively, Martin *et al.*[8] have shown that poly(2-vinylpyridine-block-ethylene oxide) copolymers can be molecularly dissolved in acidic media (hydrophilic protonated 2-vinylpyridine residues) and then aggregated into micelles by adding base (hydrophobic deprotonated 2-vinylpyridine residues). The DMAEMA–DEAEMA blocks described here exhibit similar behaviour but their synthesis is much more controlled, with only minimal levels ( < 5%) of DMAEMA homopolymer contamination indicated by GPC analyses. In contrast, Martin *et al.* reported that the single block copolymer example synthesised in their laboratory contained 30% poly(2-vinylpyridine) homopolymer. In this latter case the homopolymer contaminant is the less hydrophilic block, which profoundly affects the micellisation behaviour of the block copolymer.

Examination of a 1.0% w/v solution of the 72:28 DMAEMA–DEAEMA block in dilute HCl (pH 2) by dynamic light scattering confirmed very weak light scattering and unimer sizes (see Fig. 1). However, adjusting this solution to pH 9.5 with KOH produced much more intense light scattering due to the formation of micelles of around 20 nm diameter with a narrow size distribution. We believe that the DEAEMA block becomes hydrophobic and forms the micelle core, with the still-solvated DMAEMA chains forming the micellar corona. This micellisation proved to be completely reversible: the subsequent addition of acid resulted in complete dissolution of the micelles. Preliminary surface tension *vs.* pH data for the same 72:28 copolymer obtained using a Kruss K10ST surface tensiometer (very similar results were obtained using both plate and ring methods) are shown in Fig. 2. As the solution pH is increased the block copolymer becomes significantly more surface active. Presumably the deprotonated hydrophobic DEAEMA block becomes adsorbed strongly at the air–water interface, thus lowering the surface tension of the solution. Above pH 8 the limiting surface tension of this solution is approximately 32–33 mN $m^{-1}$ (gentle agitation produces a large volume of long-lasting foam), which is similar to that obtained with small molecule surfactants but relatively low compared to most other synthetic water-soluble block copolymers. For example, Baines *et al.*[3] reported that the limiting surface tension obtained for a 1.0% w/v aqueous solution of an 80:20 DMAEMA–methyl methacrylate block copolymer of comparable molecular weight was only 46 mN $m^{-1}$. Similarly, a surface tension plateau of *ca.* 42 mN $m^{-1}$ was observed by Teyssie and co-workers[9] for a sulfonated glycidyl methacrylate–methyl methacrylate block copolymer with a similar hydrophilic–hydrophobic balance.

Provided that the DMAEMA content of the copolymer is greater than approximately 50 mol% these DMAEMA–DEAEMA block copolymers can be dispersed directly into water at around neutral pH to form micelles of around 15 nm diameter. However, DEAEMA-rich block copolymers are insoluble under these conditions. In this context it is noteworthy that the limiting surface tension obtained with the 72:28 DMAEMA–DEAEMA block dissolved directly into water is *ca.* 33 mN $m^{-1}$ at a copolymer concentration of 0.15% w/v. These surface tension data suggest that such hydrophilic–hydrophilic block copolymers may have interesting applications as novel surfactants or emulsifiers.

In summary, a series of new polybase block copolymers has been synthesised using GTP chemistry. These copolymers can be molecularly dissolved in aqueous solution without the use of co-solvents. They exhibit reversible pH-induced micellisation and are remarkably surface active at around neutral pH.

We wish to thank the Turkish government for funding a studentship for V. B. and Sussex University for project consumables support. An EPSRC ROPA grant (GR/K86855) was used to purchase the argon ion laser for the dynamic light scattering studies.

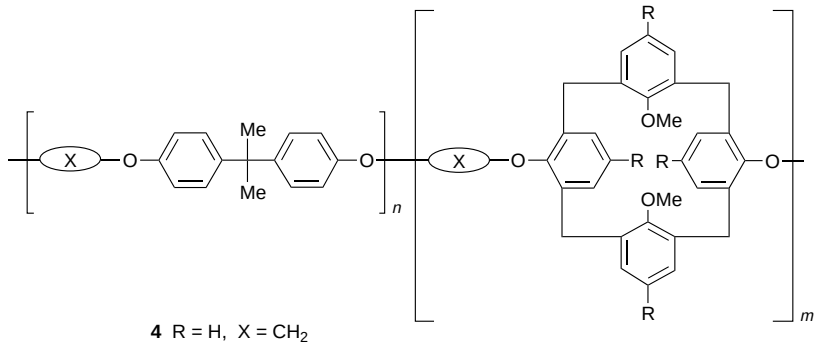
**The synthesis of 1,3-dimethyl calix[4]arene–bisphenol-A copolyethers and copolyesters with variable amounts of the macrocycle in the chain is described; the receptor ability of the copolyethers 4 toward silver(I) ions was one hundred-fold that of calix[4]arene tetrapropyl ether 3.**

Compared with the considerable interest during recent years in the use of calixarene monomers as platforms for the construction of supramolecular receptor assemblies,[1] there are few studies on calixarene-containing polymers, most of which exhibit the macrocycle moiety as an appendage of the polymer chain.[2] This issue has been addressed in recent reports. One of these describes the synthesis and the cation receptor properties of low molecular weight calixcrown telomers with different chain backbones such as ether, ester, amide and siloxane;[3] a second deals with the synthesis of oligomers by ruthenium-catalysed metathesis of alkenyl substituted calixarenes;[4] and the third describes the optical properties produced by the incorporation of an upper-rim derivatized calix[4]arene in a water-soluble antenna polyacrylate.[5] It thus appears that calixarene insertion in a polymer chain may give rise to new materials where the intrinsic properties of the macrocycle are enhanced and efficiently exploited. Among the broad range of applications of calixarene-based polymers, one can foresee their use as sensors for chemical and biochemical species,[6] as substrates for the construction of membranes for selective transport of ions,[7] and as antioxidant additives of other polymeric materials.[8] We report here the first synthesis of high molecular weight copolyethers and copolyesters incorporating 1,3-(distal)calix[4]arene and bisphenol-A moieties in the chains in different ratios and describe preliminary studies of the receptor properties of these materials.[9]



**1** R = H
**2** R = Bu$^t$

**3**

A mixture of 1,3-dimethyl calix[4]arene **1**, bisphenol-A and NaH in a minimum amount of anhydrous THF was stirred at room temperature for 0.5 h, then concentrated. The suspension of the sodium salts in toluene was treated with tetrabutylammonium hydrogensulfate and dibromomethane (10 equiv.) at 60–80 °C for 16 h to give the copolyether **4** (50–60% yield) after reprecipitation from a large volume of acidified methanol. The $M_w$ of this material ranged between 15 000 and 24 000 (determined by GPC analysis referenced to polystyrene standards) depending on the reaction temperature and the amount of the phase transfer reagent (40–80 mol%), and the polydispersity ($M_w/M_n$) was between 4 and 8. $^1$H NMR analysis revealed that the calixarene content in the polymer chains varied depending on the phenolic monomers ratio. Typically a 0.5 : 1 molar ratio of **1** and bisphenol-A led to a copolyether containing 25% of **1** with respect to bisphenol-A whereas a 1:1 ratio gave 50% content.† Higher ratios (2 : 1 up to 10 : 1) did not increase the calixarene content but produced a substantial decrease in yield of the isolated material (20%). Copolyether **5** ($M_w$ 10 000, *ca.* 60% yield) was prepared from 1,3-dimethyl *p-tert*-butylcalix[4]arene **2** by the same procedure. This calixarene proved to be less reactive than **1** in the copolymerization process, thus resulting in low incorporation in the polymer chains to a 20% maximum content. Copolyethers **4** and **5** were semicrystalline materials with a melting temperature range of 210–250 °C and were soluble in chloroform and toluene at room temperature. These copolyethers showed glass transition temperatures between 80 and 120 °C depending on the molecular weight. They showed rather complex $^1$H NMR spectra both at low (−40 °C) and high temperatures (120 °C) indicating that the calixarene units exist in numerous statistical conformations, each one being determined by its adaptability to the complex arrangement of the polymer chains in solution.

Treatment of the mixture of the sodium salts of **1** (0.5 equiv.) and bisphenol-A (1 equiv.) with terephthaloyl chloride (1 equiv.) under the above conditions (toluene, $Bu_4NHSO_4$, 60 °C, 16 h) gave, after a similar purification, the copolyester **6** in 66% yield. The soluble fraction of the recovered material (*ca.* 20% in $CHCl_3$ at room temperature) showed a $M_w$ of *ca.* 21 000 (GPC

**4** R = H, X = $CH_2$
**5** R = Bu$^t$, X = $CH_2$
**6** R = H, X = *p*-CO($C_6H_4$)CO

analysis). The calixarene content appeared to be 24% from its $^1$H NMR spectrum. This content increased to 50% in the copolymer obtained under the same conditions but starting from a 1 : 1 ratio of the phenolic monomers.‡ Both polymers were soluble only in 1,1,2,2-tetrachloroethane at 120 °C.

The $Ag^+$ binding properties of the calixarene containing copolyether **4** were compared with those of the known[10] calix[4]arene tetrapropyl ether **3** using the picrate extraction procedure[11] originally described by Cram and coworkers.[12] Recent work by Ikeda *et al.*[13] has demonstrated that $Ag^+$ is bound to cone and partial-cone calixarenes by π-donor participation of the phenyl rings. Results of two-phase extraction measurements with **4** at 50% calixarene content showed linear correlations between the calixarene concentration and the picrate exchange between the aqueous and organic phase (Fig. 1). We noted also that the extraction by the calixarene in the copolymer is about one hundred-fold that of the tetrapropoxy derivative **3**.§ The involvement of the calixarene in the picrate extraction was proved by the same efficiency shown by a two-fold more concentrated solution of the copolyether **4** at 25% calixarene content.¶ Finally, the decreased concentration of $Ag^+$ in the aqueous layer was confirmed by atomic absorption spectroscopy.

The more pronounced extraction of $Ag^+$ by the calixarene moiety in the copolyether **4** than in the compound **3** suggests that in the former there are more units of the macrocycle with the required conformation for cation–π-interaction. Unfortunately the complexity of the NMR spectra of the polymeric materials did not allow more detailed study. The binding properties of the copolyester **6** could not be studied because of its low solubility in organic solvents at room temperature.

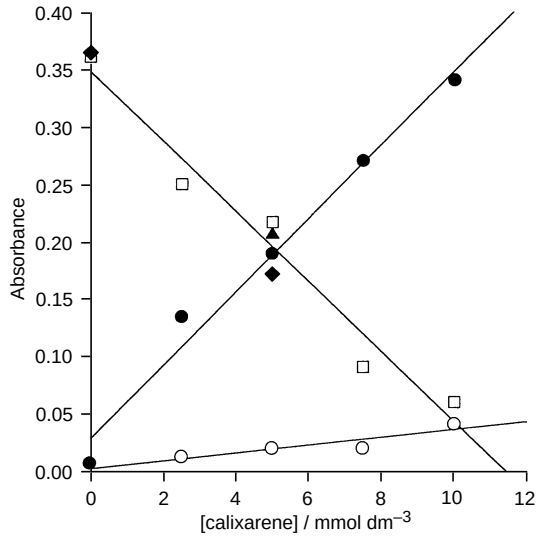


**Fig. 1** Absorbance changes of: (*a*) aqueous solution of $AgNO_3$ ($10^{-2}$ M) and picric acid (2.38 $10^{-3}$ M) extracted with the $CHCl_3$ solutions of **4** with (□) 50% and (◆) 25% calixarene content; (*b*) the corresponding $CHCl_3$ solutions of **4** with (●) 50% and (▲) 25% calixarene content; (*c*) $CH_2Cl_2$ solution of compound **3** (○) after extraction of the above aqueous solution (λ = 356 nm)

# The ′onium butyltriphenylborates as novel donor–acceptor initiators for free radical photopolymerization

**Yasumasa Toba,[a]† Madoka Yasuike[b] and Yoshiharu Usui[a]***

[a] *Graduate School of Science and Engineering, Ibaraki University, 2-1-1 Bunkyo, Mito, Ibaraki 310, Japan*
[b] *Tsukuba Research Laboratories, Toyo Ink Mfg. Co., Ltd., 27 Wadai, Tsukuba, Ibaraki 300-42, Japan*

**Novel donor-acceptor initiators, ′onium butyltriphenylborates, containing both an ′onium cation (electron-accepting radical generator) and a butyltriphenylborate anion (electron-donating radical generator) within the same molecule, are synthesized and investigated for the photopolymerization of an acrylic monomer mixture.**

In order to obtain an efficient free radical generating system for many areas of photosensitive materials research, a more efficient initiator or initiator system (*i.e.* a combination of sensitizer and initiator) which generates free radicals for polymerization is required. Many such initiators or initiator systems have been investigated.[1]

Most well known initiator systems are based on photoinduced electron-transfer reactions and are either electron-donating sensitizer/electron-accepting initiators (*e.g.* ′onium salts)[2,3] or electron-accepting sensitizer/electron-donating initiators (*e.g.* borates or amines).[3,4]

The above initiator systems generate the free radical after a photo-induced electron-transfer from the electron-donating sensitizer to the electron-accepting initiator (or from electron-donating initiator to electron-accepting sensitizer) by light irradiation. The free radical comes from decomposition of the initiator and produces polymerization.

The cation radical (or anion radical) of a sensitizer produced by the reaction is usually inert to free radical polymerization. However, if one utilizes the inert cation radical (or anion radical) of the sensitizer, generating an active free radical for radical polymerization, the quantum efficiencies of the radical generation will be increased, and furthermore, the resulting polymerization will be extremely efficient.

Herein we report the discovery that the ′onium butyltriphenylborates containing both an ′onium cation (electron-accepting radical generator) and a borate anion (electron-donating radical generator) within the same molecule are novel donor–acceptor initiators for extremely efficient free radical photopolymerization.

The novel donor–acceptor initiators diphenyliodonium butyltriphenylborate **1** or dimethylphenacylsulfonium butyltriphenylborate **2** were prepared by the reactions of diphenyliodonium chloride or dimethylphenacylsulfonium bromide with lithium butyltriphenylborate,[5] respectively.‡ Both the ′onium borates were characterized by spectroscopic data and elemental analyses.§

The absorption spectra of **1** in $CH_2Cl_2$ and MeCN are shown in Fig. 1. For comparison, the absorption spectra of tetrabutylammonium butyltriphenylborate **3**, an electron-donating initiator, and diphenyliodonium hexafluorophosphate **4**, an electron-accepting initiator, in $CH_2Cl_2$ are also presented.

Compound **1** in $CH_2Cl_2$ exhibits a weak absorption in the 320–400 nm region, while **3** and **4** in $CH_2Cl_2$ do not exhibit absorption in the same region. The weak absorption is not observed in MeCN which is a polar solvent. It is important that the enhanced absorptivity of **1** in $CH_2Cl_2$ is reproducible and is quite clearly unique to **1** in the non-polar solvent.

We attribute the weak absorption observed for **1** in $CH_2Cl_2$ to an ion-pair charge transfer transition from the butyltriphenylborate anion to the diphenyliodonium cation. Also the spectrum of **2** in $CH_2Cl_2$ showed a slightly greater absorptivity in the 270–350 nm region, in contrast to **3** and dimethylphenacylsulfonium tetrafluoroborate **5** which do not exhibit transitions in the same region. However, both ′onium borates **1** and **2** exist primarily as ion-pairs in $CH_2Cl_2$ and as free ions in MeCN.

In order to reveal the capability of the ′onium borates as free radical polymerization initiators, we carried out the photopolymerization of tetrahydrofurfuryl acrylate (THFA). 4,4′-Bis(dimethylamino)benzophenone (MK), 2-chlorothioxanthone (CTX) and 3,3′-carbonylbis(7-diethylaminocoumarin) (KCD) were used as the sensitizers. The photopolymerization was monitored in IR spectroscopy.[6] To obtain the percentage of double bond conversion ($\gamma$), the initiator, sensitizer, THFA and solvent were placed in a sealed KBr cell. The sample was irradiated with light (365 nm) from a high pressure mercury lamp passed through a band pass filter. The IR spectra were taken before and after the irradiation and the absorbances corresponding to an acrylic bending mode at 810 $cm^{-1}$ were used for the calculations of $\gamma$ [eqn. (1)], where $A_0$ and $A_t$

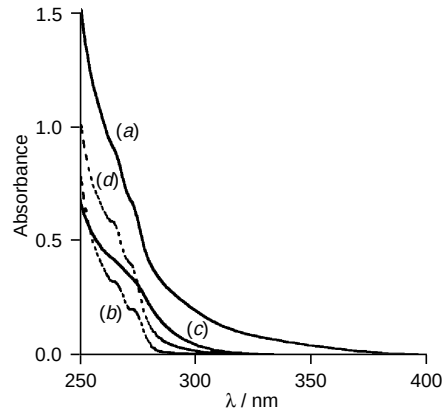
$$\gamma = (A_0 - A_t)/A_0 \quad (1)$$

are the absorbances corresponding at 810 $cm^{-1}$ before and after the irradiation, respectively. The rate of polymerization ($R_p$) was obtained from the slope ($\Delta\gamma/\Delta t$) of the linear part of the time–$\gamma$ curve measured by this setup [eqn. (2)]. The values of $R_p$ were measured below a $\gamma$ of 10%. $[THFA]_0$ is the THFA concentration before the light exposure.

$$R_p = [THFA]_0 (\Delta\gamma/\Delta t) \quad (2)$$

The relative rates of polymerization, calculated using eqns.(1) and (2), are summarized in Table 1. The ′onium borates **1** or **2** clearly show much higher performances as initiators for the polymerization of THFA than **3**, **4** or **5** with any of the sensitizers.

The most pronounced difference was observed with the results of $R_p$ in $CH_2Cl_2$. The $R_p$ in $CH_2Cl_2$ increased about



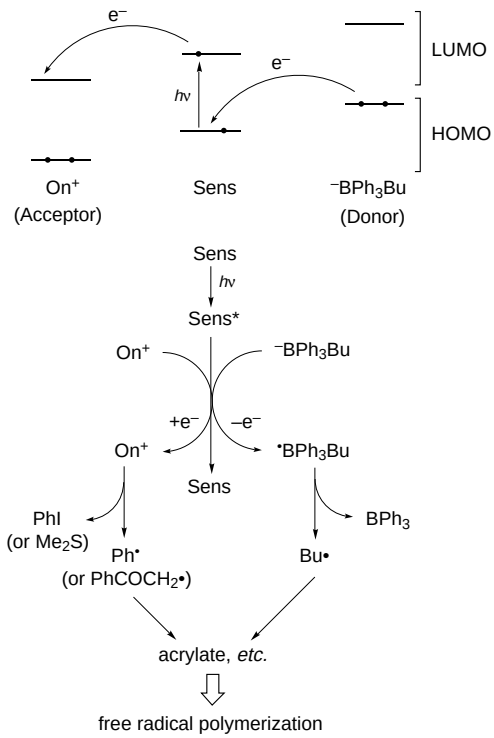


**Fig. 1** UV–VIS absorption spectra of (*a*) **1**, (*b*) **3**, (*c*) **4** in $CH_2Cl_2$ and (*d*) **1** in MeCN. Solution concentrations = $1.0 \times 10^{-4}$ mol $dm^{-3}$.

**Table 1** Rate of photopolymerization of THFA with various sensitizers and initiators in MeCN[a]

| Run | Sensitizer[b] | Initiator | $R_p$[c]/mol dm$^{-3}$ s$^{-1}$ |
|---|---|---|---|
| 1 | MK | **1** | 5.1 (16)[d] |
| 2 | | **2** | 4.6 (15)[d] |
| 3 | | **3** | 0.58 (0.69)[d] |
| 4 | | **4** | 0.21 (0.26)[d] |
| 5 | | **5** | 0.062 |
| 6 | CTX | **1** | 15 |
| 7 | | **2** | 11 |
| 8 | | **3** | 4.0 |
| 9 | | **4** | 2.2 |
| 10 | | **5** | 0.26 |
| 11 | KCD | **1** | 0.29 |
| 12 | | **2** | 0.26 |

[a] Radiant power of the light emission at 365 nm was 1.6 mW cm$^{-2}$; $[THFA]_0 = 9.18 \times 10^{-1}$ mol dm$^{-3}$; $[Initiator]_0 = 1.43 \times 10^{-2}$ mol dm$^{-3}$. [b] [Sensitizer] corresponds to the amount required for 50% transmittance at 365 nm. [c] Rate of polymerization. [d] In $CH_2Cl_2$.

**Scheme 1**

three-fold over the $R_p$ in MeCN (runs 1 and 2) with the ′onium borate initiators. The reason is that both the ′onium borates exist primarily as ion-pairs in $CH_2Cl_2$ and as free ions in MeCN. The photo-induced electron-transfer reaction between the sensitizer and the ′onium borate in $CH_2Cl_2$ occurs more efficiently than does the reaction in MeCN. CTX is a more effective sensitizer than MK or KCD. The photopolymerization with KCD and **3**, **4** or **5** were too poor to measure $R_p$ using this apparatus.

Our postulated reaction mechanism for the sensitizer and the ′onium borate in MeCN is depicted in Scheme 1. Thus, the sensitizer absorbs light at 365 nm which initially generates the excited state of the sensitizer (Sens*). Next, Sens* accepts an electron from a butyltriphenylborate in the ′onium borate, and at the same time, donates an electron to an ′onium cation in the ′onium borate. Consequently, the produced butyltriphenylboranyl radical and ′onium radical decompose to form the butyl radical and phenyl (or phenacyl) radical. These radicals initiate polymerization in the presence of a suitable monomer (*e.g.* THFA). This is also supported by the analysis of the products from the photolysis of the ′onium borates. Conversely, the reaction in $CH_2Cl_2$ would occur as the ion-pair complex of ′onium borates.

Thus, we have demonstrated not only that the ′onium borates are efficient donor–acceptor initiators for free radical photopolymerization but also the generating procedure for the free radicals.

‡ *General procedure*: A 100 ml round-bottom flask equipped with a Teflon-covered magnetic stirring bar was charged with diphenyliodonium chloride or dimethylphenacylsulfonium bromide (20 mmol) dissolved in water (10 ml). To the flask, lithium butyltriphenylborate (20 mmol) was added with stirring. Diphenyliodonium butyltriphenylborate **1** or dimethylphenacylsulfonium butyltriphenylborate **2** rapidly precipitated. Compound **1** or **2** was collected by filtration and recrystallized from a $CH_2Cl_2$– heptane (1 : 4). The yields were 43% for **1** and 87% for **2**, respectively.
§ Satisfactory elemental analyses have been obtained. *Selected spectroscopic data* for **1**: $\delta_H$ [270 MHz; $(CD_3)_2SO$; $Me_4Si$] 0.68–1.00 (m, 7 H, *Pr*$CH_2B^-$), 1.11–1.27 (m, 2 H, $CH_2B^-$), 6.68–6.78 (m, 3 H, *p*-PhB$^-$), 6.84–6.94 (m, 6 H, *m*-PhB$^-$), 7.14–7.24 (m, 6 H, *o*-PhB$^-$), 7.47–7.57 (m, 4 H, *o*-PhI$^+$), 7.60–7.70 (m, 2 H, *p*-PhI$^+$), 8.17–8.27 (m, 4 H, *m*-PhI$^+$); For **2**: $\delta_H$ [270 MHz; $(CD_3)_2SO$; $Me_4Si$] 0.68–1.00 (m, 7 H, *Pr*$CH_2B^-$), 1.11–1.27 (m, 2 H, $CH_2B^-$), 2.94 (s, 6 H, $Me_2S^+$), 5.40 (s, 2 H, $COCH_2S^+$), 6.68–6.78 (m, 3 H, *p*-PhB$^-$), 6.84–6.94 (m, 6 H, *m*-PhB$^-$), 7.14–7.24 (m, 6 H, *o*-PhB$^-$), 7.58–7.68 (m, 2 H, *m*-PhCO), 7.73–7.83 (m, 1 H, *p*-PhCO), 7.97–8.07 (m, 2 H, *o*-PhCO).

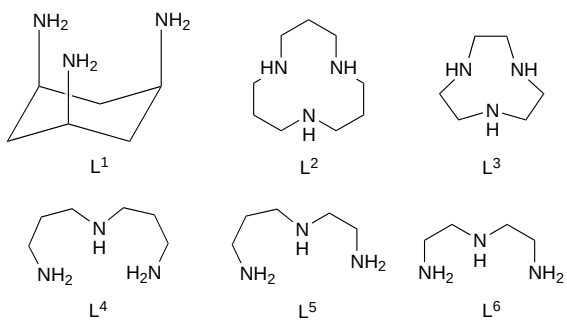
# Hydrolytic cleavage of DNA by a novel copper(II) complex with *cis,cis*-1,3,5-triaminocyclohexane

**Toyofumi Itoh, Hiroyuki Hisada, Tomoyuki Sumiya, Masami Hosono, Yoshiharu Usui and Yuki Fujii***



*Graduate School of Science and Engineering, Ibaraki University, 2-1-1, Bunkyo, Mito, Ibaraki 310, Japan*

**Copper(II) complex with *cis,cis*-1,3,5-triaminocyclohexane effectively promotes the hydrolytic cleavage of phage DNA with a rate constant of 4.34 ± 0.77 $h^{-1}$ at pH 8.1 and 35 °C.**

The development of reagents which hydrolytically cleave nucleic acids under mild conditions is currently attracting great interest in the field of artificial nucleases,[1–3] as such a process has the advantage that it produces fragments which may be religated enzymatically. Recently, it has been demonstrated that many chelate compounds of transition metals ($Fe^{2+}$, $Co^{3+}$, $Cu^{2+}$, $Zn^{2+}$) and lanthanides ($La^{3+}$, $Ce^{4+}$, $Eu^{3+}$, $Tm^{3+}$, $Yb^{3+}$, $Lu^{3+}$) are capable of promoting the hydrolytic cleavage of RNA[2,4] and DNA;[2,5–7] however, DNA hydrolysis is much slower compared with RNA hydrolysis. This is mainly because the phosphate diester linkage of DNA is kinetically more stable than that of RNA toward hydrolysis.[8] The best enhanced rate constant for DNA hydrolysis by a metal chelate is in the range 0.18–0.25 $h^{-1}$,[7] and a more active metal chelate is therefore required.

Recently, Burstyn and coworkers reported that copper(II)–macrocyclic triamine ($L^3$) complexes promote the hydrolytic cleavage of plasmid DNA,[6] however, the rate constant is estimated to be 0.04–0.09 $h^{-1}$ at 50 °C from the half life of the hydrolysis.[6a] In order to improve the DNA hydrolysis capacity of copper(II) complexes, we have studied the hydrolysis of lithium 2,4-dinitrophenyl ethyl phosphate (DEP) and phage φx174 DNA† by copper(II) complexes of triamine ligands ($L^1$–$L^6$), and found that a novel copper(II) complex of *cis,cis*-1,3,5-triaminocyclohexane[9,10] ($CuL^1$) has a high potential for DNA hydrolysis: the hydrolysis rate constant reached 4.3 $h^{-1}$ at 35 °C.

Fig. 1 shows agarose gel electrophoresis patterns for the cleavage of φx174 DNA after treated with $CuL^1$ at pH 8.1 and 35 °C for 5 h. The initial concentration of DNA was set at 7 μmol $dm^{-3}$ base pairs, and the concentration of $CuL^1$ was varied from 0 to 70 μmol $dm^{-3}$. The conversion of form I (supercoiled) to form II (nicked) was observed with the increase in concentration of $CuL^1$, and the formation of form III appeared in the presence of 35 and 70 μmol $dm^{-3}$ $CuL^1$ (lanes 6 and 7). The complete disappearance of form I was observed in lanes 5–7 (14–70 μmol $dm^{-3}$ $CuL^1$). On the other hand, $CuL^2$–$CuL^6$ were mostly ineffective under the conditions employed, indicating that only $CuL^1$ effectively enhances the cleavage of φx174 DNA.

A typical time course for DNA cleavage by $CuL^1$ is shown in Fig. 2. The cleavage products were separated by agarose gel electrophoresis and quantified by densitometry after staining with ethidium bromide. The decrease of form I fitted well to a single exponential decay curve. The increase of form II also fitted to a single exponential curve, although the deviation of form II was somewhat larger than that of form I. From these curve fits, the hydrolysis rate constants at a complex concentration of 70 μmol $dm^{-3}$ were estimated to be 1.46 ± 0.22 $h^{-1}$ ($R^2$ = 0.954) for the decrease of form I and 1.82 ± 0.33 $h^{-1}$ ($R^2$ = 0.939) for the increase of form II. Similarly, the hydrolysis rate constants for φx174 DNA in the presence of 7, 14, 140, 210 and 280 mmol $dm^{-3}$ $CuL^1$ were obtained, and are plotted in Fig. 3.

The plots of the rate constants against the concentrations of $CuL^1$ allowed a Michaelis–Menten analysis for φx174 DNA, and gave $k$ = 4.34 ± 0.77 $h^{-1}$, $K_m = 9.55 \times 10^{-5}$ mol $dm^{-3}$ for the decrease of form I, and $k$ = 4.16 ± 0.44 $h^{-1}$, $K_m = 5.75 \times 10^{-5}$ mol $dm^{-3}$ for the increase of form II. The obtained rate constants were similar to each other, and are about twenty times higher than the highest values reported previously for the rate

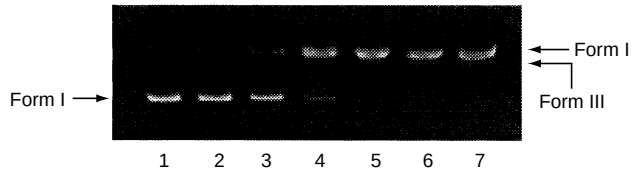


**Fig. 1** Agarose gel electrophoresis patterns for the cleavage of φx174 DNA by $CuL^1$. Conditions: 7 μmol $dm^{-3}$ DNA base pairs; 0–70 μmol $dm^{-3}$ $CuL^1$; 10 mmol $dm^{-3}$ HEPES buffer; pH 8.1; 35 °C; reaction time, 5 h. Lane 1: DNA control. Lane 2: DNA + 0.7 μmol $dm^{-3}$ $CuL^1$. Lane 3: DNA + 3.5 μmol $dm^{-3}$ $CuL^1$. Lane 4: DNA + 7 μmol $dm^{-3}$ $CuL^1$. Lane 5: DNA + 14 μmol $dm^{-3}$ $CuL^1$. Lane 6: DNA + 35 μmol $dm^{-3}$ $CuL^1$. Lane 7: DNA + 70 μmol $dm^{-3}$ $CuL^1$.

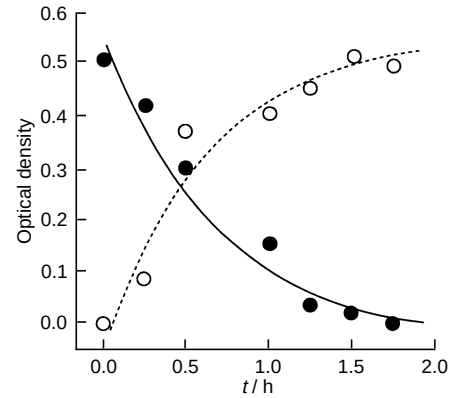

**Fig. 2** Time course of DNA cleavage by $CuL^1$ at pH 8.1 (10 mmol $dm^{-3}$ HEPES buffer) and 35 °C in the presence of 7 μmol $dm^{-3}$ φx174 DNA and 70 μmol $dm^{-3}$ $CuL^1$: (●) form I; (○) form II; solid line, single exponential curvefit for the decrease of form I; dashed line, single exponential curvefit for the increase of form II

constant for DNA hydrolysis by a metal chelate,[7] although the metal and experimental conditions, including employed DNA, were not necessarily the same as those of our experiment.

In Table 1 are summarized the results of the hydrolysis of the phosphate diester DEP by $CuL^1$–$CuL^6$. The hydrolysis of DEP was followed by monitoring the increase in the visible absorbance at 400 nm caused by the release of 2,4-dinitrophenolate ion at pH 8.1 (50 mmol $dm^{-3}$ HEPES buffer) and 25 °C, and analysed by using a reference method.[10] The hydrolysis rate was first order with respect to the concentration of both DEP and CuL. The apparent second order rate constants thus obtained are listed in Table 1.

Table 1 shows that all of the investigated CuL complexes are capable of hydrolysing the phosphate diester linkage, and that $CuL^1$ has a high hydrolysing capacity.‡ In addition, we observed that DNA cleavage by $CuL^1$ is not affected by the presence or absence of $O_2$. This fact indicates that no oxidative process is involved.[6] Hence, these data strongly support the suggestion that DNA cleavage by $CuL^1$ proceeds *via* a hydrolysis mechanism. On the other hand, we found the following discrepancies between DEP and DNA hydrolysis: (i) the former is first order-dependent on complex concentration, but the latter is saturation-dependent on complex concentration; (ii) the former is greatly enhanced by not only $CuL^1$ but also $CuL^2$ and $CuL^3$, but the latter is specific toward $CuL^1$.

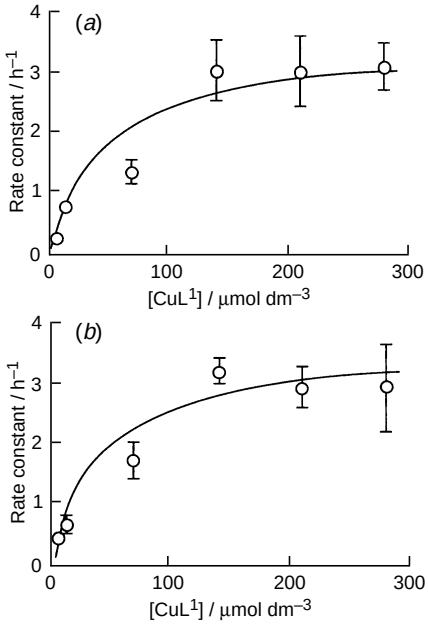

**Fig. 3** Saturation kinetics for cleavage of φx174 DNA by 7–280 μmol $dm^{-3}$ $CuL^1$ at pH 8.1 and 35 °C: (*a*) decrease of form I; (*b*) increase of form II

**Table 1** Rate constants ($k_{app}$) of hydrolysis of DEP by $CuL^1$–$CuL^6$ at pH 8.1 (50 mmol $dm^{-3}$ HEPES), ionic strength = 0.1 M ($NaClO_4$) and 25 °C

| Complex | $k_{app}$/$dm^3$ $mol^{-1}$ $s^{-1}$ |
|---|---|
| $CuL^1$ | $(1.2 \pm 0.1) \times 10^{-2}$ |
| $CuL^2$ | $(1.4 \pm 0.1) \times 10^{-2}$ |
| $CuL^3$ | $(7.1 \pm 0.2) \times 10^{-3}$ |
| $CuL^4$ | $(0.4 \pm 0.1) \times 10^{-4}$ |
| $CuL^5$ | $< 10^{-4}$ |
| $CuL^6$ | $< 10^{-4}$ |

Although we have no clear explanation for these data, one explanation is the possibility of a polymer effect for DNA, with specific reaction sites for $CuL^1$.

We thank Professor M. Kodama (Hirosaki University) and Professor M. Chikira (Chuo University) for their helpful suggestions. This work was partly supported by a Grant-in-Aid for Scientific Research No. 0764735 from the Ministry of Education, Science and Culture of Japan.

## Footnotes

† Phage φx174 RFI DNA was purchased from Sigma Co. Ltd.

‡ We also confirmed the following facts: (i) free copper(II) ions produce almost no cleavage of φx174 DNA at concentrations below 2 μmol $dm^{-3}$ of copper(II) ion under the employed conditions, and (ii) the concentration of free copper(II) ion is less than 1.1 μmol $dm^{-3}$ under our experimental conditions [copper(II) ion exists as over 97.5% $CuL^1$ and $CuL^1$ (OH) species] on the basis of the calculation using the following deprotination and stability constants determined by potentiometric titration at 35 °C; $K_1 = [H^+][H_2L^{2+}]/[H_3L^{3+}] = 10^{-6.94}$, $K_2 = [H^+][HL^+]/[H_2L^{2+}] = 10^{-8.69}$, $K_3 = [H^+][L]/[HL^+] = 10^{-9.75}$, $K_{ML} = [CuL^{2+}]/[Cu^{2+}][L] = 10^{10.55}$, $K_{MHL} = [CuHL^{3+}]/[Cu^{2+}][HL^+] = 10^{6.47}$, $K_a = [CuL(OH)^+][H^+]/[CuL^{2+}] = 10^{-8.40}$.

# Substituted α,β,γ-triazatetrabenzcorrole: an unusual reduction product of a phthalocyanine

**Junzhong Li, Lakshminarayanapuram R. Subramanian and Michael Hanack***

*Institut für Organische Chemie, Lehrstuhl für Organische Chemie II, Universität Tübingen, Auf der Morgenstelle 18, D-72076 Tübingen, Germany*

**4,5-Dipentyldiiminoisoindoline 1 reacts with hexachlorodisilane ($Si_2Cl_6$) to give the ring-contracted hydroxysilicon-α,β,γ-triazatetrabenzcorrole 4 which in solution photolyses giving the ring cleavage compounds 5 and 6; the stability of triazatetrabenzcorroles 4 and 7 with silicon and germanium as central elements is studied by UV–VIS spectroscopy.**

Many of the properties of metallophthalocyanines (PcM) such as semiconductivity, photoconductivity and catalytic properties rely upon the redox properties of the PcM species.[1,2] As a result, the redox chemistry of PcM has been investigated in detail, both by chemical and electrochemical methods with phthalocyanines containing redox inactive as well as redox active metals centres.[3–5] Accordingly, negative ions of Pc or PcM with low valent state metals such as $PcCo^{I}$ and $PcSn^{II}$ have been found,[6–8] however, the basic structure of the resulting reduced macrocycle remained the same.

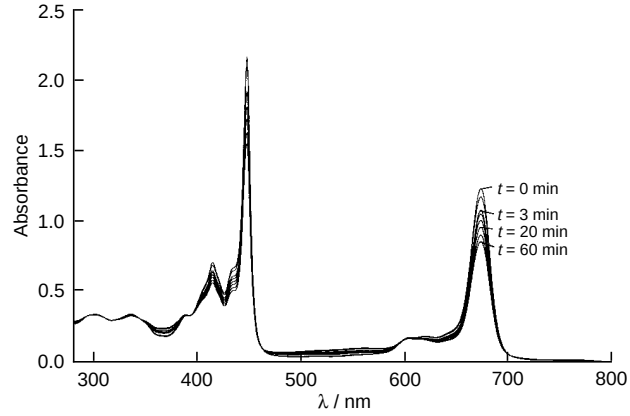
In 1986, Fujiki *et al.*[9] ascertained for the first time that the earlier reported $PcGe^{II}$,[10] produced by reducing $PcGeCl_2$ with $NaBH_4$, did not retain the phthalocyanine moiety but was a phthalocyanine-like tetrapyrrole macrocycle, namely hydroxygermanium(IV)-α,β,γ-triazatetrabenzcorrole (TBCGeOH) **2**. However, probably due to the report[9] that the stability of TBC complexes with different central elements follows the sequence TBCGeOH **2** ≫ TBCSiOH **3** > TBCAl > TBCGa, and also that the authors[9] succeeded in obtaining only the pure TBCGeOH **2**, no further reports on TBC macrocycles could be found to date.

As part of our ongoing studies to synthesize precursors for polymers containing Pc units,[1,2,11,12] 4,5-dipentyldiiminoisoindoline **1** was treated with $Si_2Cl_6$ to examine the potential of producing phthalocyanine dimers with an Si–Si bond. Unexpectedly, during purification of the reaction mixture by flash chromatography (silica gel, $CHCl_3$), besides obtaining $(C_5H_{11})_8PcSi(OH)_2$, a deep green solid was also isolated which displayed a very sharp absorption at 448 nm (Soret band) with an intensity nearly twice that of the Q band in its electronic spectrum (Fig. 1), which was later found to be the typical UV–VIS spectrum of TBC macrocycles.[9] The mass spectral, $^1H$ NMR, IR and elemental analysis further proved that the compound obtained in this reaction is hydroxysilicon 4,5,11,12,18,19,25,26-octapentyl-α,β,γ-triazatetrabenzcorrole (PTBCSiOH) **4**.† Further studies carried out by treating $Si_2Cl_6$ with **1** in different ratios indicated that if the ratio reached *ca.* 1 : 1, only PTBCSiOH **4** was obtained in 35% yield (Scheme 1). It seems that the excess of $Si_2Cl_6$ reacted with an intermediate phthalocyanine to form the TBC derivative **4** (*vide infra*).

The mechanism for the formation of the TBC macrocycles by reaction of a reducing agent such as $NaBH_4$ with, for example, $PcGeCl_2$ has not been proven experimentally, although in the original work[9] a mechanism for the Pc ring contraction was proposed. $Si_2Cl_6$ is a known deoxygenating reagent, for example, it has been used to produce phosphine from phosphine oxide[13] and phosphine sulfides.[14] On the other hand, $Si_2Cl_6$ is very sensitive to water, affording products in which the Si–Si bond is broken or an oxygen is inserted into the Si–Si bond. As a result, during the reaction of **1** with $Si_2Cl_6$ the dihydroxysilicon phthalocyanine $(C_5H_{11})_8PcSi(OH)_2$ and/or μ-oxo dimers $[(C_5H_{11})_8PcSi(OH)]_2O$ will be produced first, and then reduced by an excess of $Si_2Cl_6$ to form PTBCSiOH **4**. Indeed, in the reaction of $Si_2Cl_6$ with the isoindoline **1** in a ratio of 1 : 2, $(C_5H_{11})_8PcSi(OH)_2$ was isolated by flash chromatography. The assumption that $(C_5H_{11})_8PcSi(OH)_2$ was formed first and then reduced by $Si_2Cl_6$ was confirmed by reacting $(C_5H_{11})_8PcSi(OH)_2$ with $Si_2Cl_6$ in quinoline and isolating PTBCSiOH **4** from the reaction mixture.

PTBCSiOH **4** is stable in the solid state under ambient conditions. However, air saturated solutions of **4** are found to be light sensitive. Of particular interest is that the green solution of **4** in, for example, $CHCl_3$ changed from green to red under light after some time. The resulting 'photolysis' products were separated on silica gel with a mixture of $CHCl_3$ and $CH_2Cl_2$ (v:v, 3:2) as eluent to give a purple and a red compound. Based on mass spectroscopy, IR, UV–VIS and $^1H$ NMR data, the purple **5**‡ and the red **6**† compounds were characterized as cleavage products of the 1,2-double bond of compound **4**. As a result, the central coordinated element is lost. The overall reaction is shown in Scheme 1.

The UV–VIS spectra of PTBCSiOH **4** (Fig. 1) and PTBCGeOH **7** [produced by reducing $(C_5H_{11})_8PcGeCl_2$ with $NaBH_4$ according to a literature method[9]] (Fig. 2) in $CHCl_3$ under air with irradiation at different times were determined in order to investigate the influence of the central element on the stability of TBC complexes under these conditions. In contrast to the earlier report,[9] it is evident both from the decrease in intensity of the Soret and the Q bands that PTBCSiOH **4** is more stable than the germanium complex **7** under the same conditions. As a ring contracted entity of Pc, the TBC ring will prefer the central element with a smaller radius than that of Pc. Obviously Si, with a smaller radius than Ge, forms a more stable complex with the TBC macrocycle than Ge, though the accurate radius of the internal hole of the TBC ring is not known. Fujiki *et al.*[9] did not succeed in producing pure unsubstituted



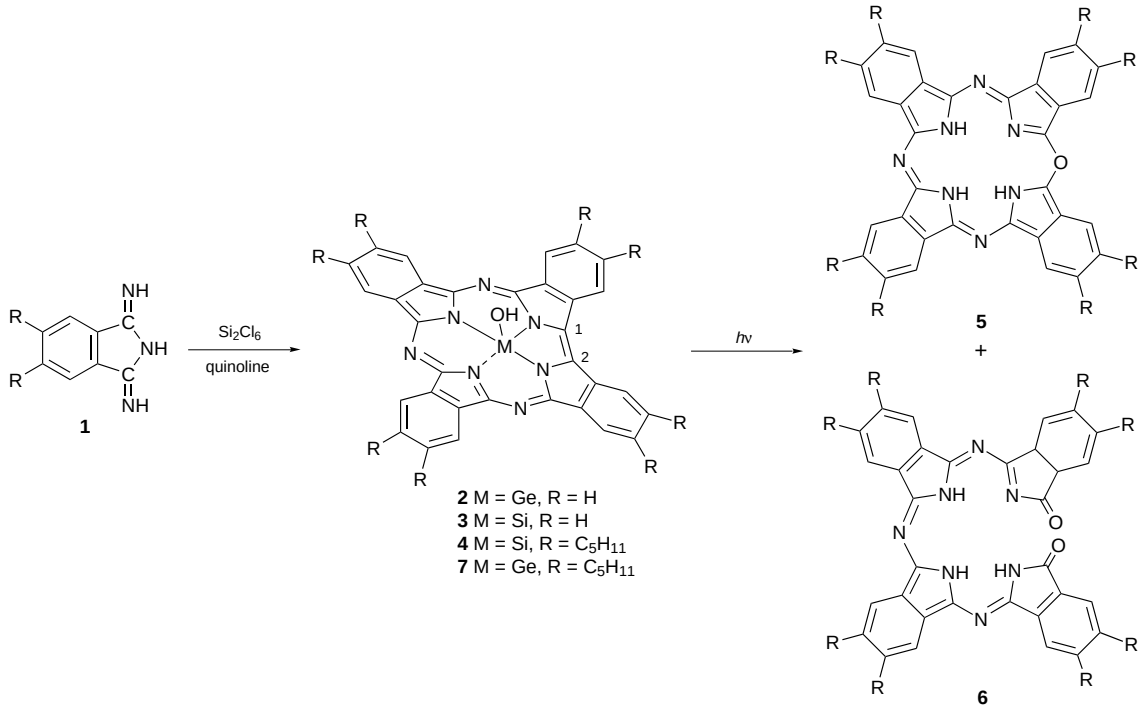


**Fig. 1** Changes in the electronic absorption spectra of PTBCSiOH **4** in $CHCl_3$ under air upon irradiation with light (λ = 650–730 nm) at room temperature

**Scheme 1** Synthetic scheme for PTBCSiOH and its photolysis products

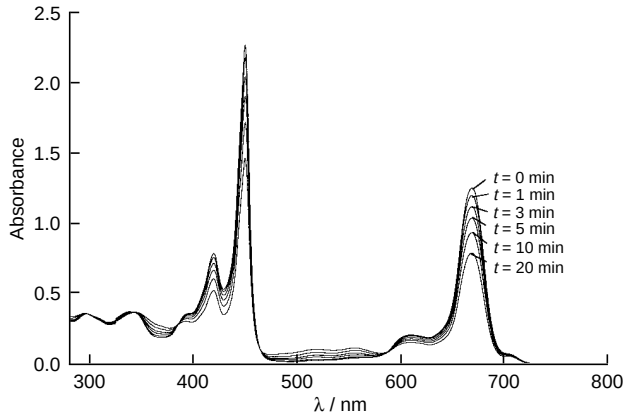

**Fig. 2** Changes in the electronic absorption spectra PTBCGeOH **7** in $CHCl_3$ under air upon irradiation with light (λ = 650–730 nm) at room temperature

TBCSiOH **3** by reducing $PcSiCl_2$ with $NaBH_4$, however, pure substituted PTBCSiOH **4** was obtained by using $Si_2Cl_6$, which shows that reducing agents have an influence on the formation of TBC derivatives from the corresponding Pc complexes. The reason for the conflicting results of Fujiki *et al.*[9] and ourselves on the stability of TBC complexes of Si and Ge might be due to the use of an unsubstituted **3** and a substituted **4** respectively in illumination experiments.

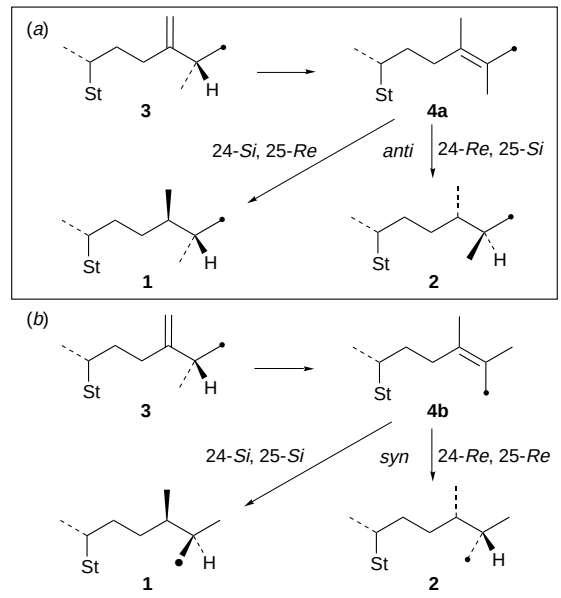
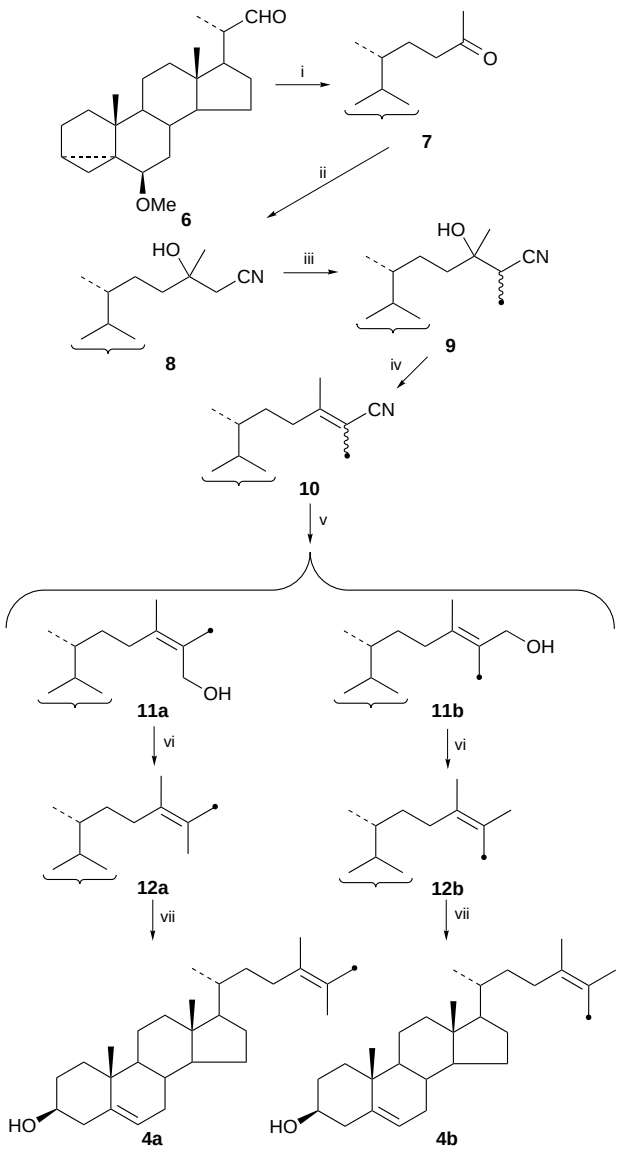
**Feeding of chemically synthesized [26-$^{13}$C]- and [27-$^{13}$C]-labelled 24-methyldesmosterols to tissue cultures of *Oryza satiba* and *Catharanthus roseus* followed by $^{13}$C NMR analysis of the biosynthesized sterols reveals that reduction of the 24(25)-double bond giving either campesterol or dihydrobrassicasterol takes place in an *anti*-manner.**



Plant sterols are characterized by a C-24 alkyl substituent (methyl, ethyl, methylene or ethylidene) which originates from *S*-adenosylmethionine by a single or double *trans*-methylation reaction with an olefinic precursor.[1] Accumulated evidence suggests that the final step of the side chain biosynthesis of 24-methylsterols, campesterol **1** and dihydrobrassicasterol **2**, in higher plants is the reduction of 24-methyl-$\Delta^{24(25)}$-sterol (*e.g.* 24-methyldesmosterol **4**).[1,2] The $\Delta^{24(25)}$-sterol is proposed to be formed by the isomerization of 24-methyl-$\Delta^{24(28)}$-sterol (*e.g.* 24-methylenecholesterol **3**) which in turn is produced by the transfer of the methyl group of *S*-adenosylmethionine to a $\Delta^{24(25)}$-sterol such as desmosterol **5** (Scheme 1).[1] Similar reduction of 24-ethyl-$\Delta^{24(25)}$-sterol is proposed for sitosterol biosynthesis. Recently, we offered evidence supporting an intermediary role of 24-methyl-$\Delta^{24(25)}$-sterol in the biosynthesis of campesterol as well as dihydrobrassicasterol in tissue cultures of *Catharanthus roseus* and *Oryza sativa*.[3] Furthermore, we assigned the $^{13}$C NMR chemical shifts of the C-26 and -27 diastereotopic methyl groups of **3** and showed that the isopropylidene (*E*)- and (*Z*)-methyl groups of **5** *pro-S* and *pro-R* methyl groups of **3**, respectively, in the above two tissue cultures.[4] The same steric course in the conversion of lanosterol into 24-methylenelanosterol was reported with *Zea mays*.[5] On the other hand, the C-2 of mevalonate [*via* (*E*)-methyl group of **5**] turns the *pro-S* methyl group of **1** and *pro-R* methyl groups of **2**, whereas C-6 of mevalonate [*via* the (*Z*)-methyl group of **5**] becomes the *pro-R* methyl group of **1** and *pro-S* methyl groups of **2** with cultured cells of *Physalis perviana*[6] and *Amsonia elliptica*.[2] We also obtained the same results on the origin of the diastereotopic methyl groups of **1** and **2** by feeding (*E*)- and (*Z*)-Me $^{13}$C-labelled desmosterols to cultured cells of *C. roseus* and *O. sativa*. Thus, the biosynthetic pathway of 24-methylcholesterols in higher plants can be summarized as depicted in Scheme 1.



**Scheme 1** Proposed biosynthetic pathway of 24-methylcholesterols. The dots indicate the carbon derived from C-2 of mevalonate.

The steric course of the isomerization from $\Delta^{24(28)}$ to $\Delta^{24(25)}$ (**3** → **4**) and the stereochemistry of the subsequent reduction of $\Delta^{24(25)}$ (**4** → **1** and **2**) remain unclear. Two possible mechanisms can be drawn for the conversion of **3** to **1** and **2**: (*a*) *pro-S*-Me at C-25 of **3** becomes (*E*)-Me of **4** in the double bond isomerization reaction and the reduction proceeds in an *anti*-mode; (*b*) *pro-S*-Me at C-25 of **3** becomes (*Z*)-Me of **4** and the reduction occurs in a *syn*-mode (Scheme 2). We now report that mechanism (*a*) operates in tissue cultures of *O. sativa* and *C. roseus*.

(*E*)-Me $^{13}$C-labelled **4a** and (*Z*)-Me $^{13}$C-labelled **4b** 24-methyldesmosterols were prepared (Scheme 3). Methyl ketone **7** was obtained from well known C-22-aldehyde **6**[7] in four steps. Reactions of **7** with the MeCN anion gave adduct **8**. Methylation of the adduct using $^{13}CH_3I$ (99% $^{13}$C) afforded $^{13}$C-labelled **9** which was dehydrated to give a mixture of (*E*)- and (*Z*)-tetrasubstituted olefin **10**. Stepwise reduction of the olefin mixture with DIBAL-H *via* the corresponding aldehyde gave a mixture of allyic alcohols **11a**,**b**. The geometric isomers were separated by a silica gel Lobar column, affording the less polar (*E*)-alcohol **11a** and the more polar (*Z*)-isomer **11b**. The (*E*)-geometry of **11a** was determined by NOE studies in which irradiation of 28-$H_3$ (δ 1.67) caused the enhancement of the signal intensity of the $CH_3$ resonance at δ 1.73 (d, $J$ = 126 Hz). Similarly, irradiation of 28-$H_3$ (δ 1.71) of **11b** resulted in the enhancement of the intensity of oxymethylene proton signal at

**Scheme 2** Two possible routes for the formation of 24-methylcholesterol

**Scheme 3** Synthesis of regiospecifically labelled 24-methyl-$\Delta^{24(25)}$-cholesterols **4a** and **b**. *Reagent and conditions*: i, acetone, LDA, then MsCl, $Et_3N$, then DBU, then $H_2$, Pd–C (50%); ii, LDA, MeCN (91%); iii, LDA, $^{13}CH_3I$ (41%); iv, $SOCl_2$ (100%); v, DIBAL-H (19% **11a**, 25% **11b**); vi, MsCl, LiCl, lutidine; LAH (70%); vii, TsOH, $H_2O$ (80%).

δ 4.11 (d, $J$ = 4.6 Hz), thus establishing the (*Z*)-geometry for **11b**. The alcohols **11a**,**b** were converted into the (*E*)-Me and (*Z*)-Me $^{13}$C-labeled sterols **4a** ($\delta_C$ 20.51) and **4b** ($\delta_C$ 19.98), respectively, *via* **12a** and **12b**.

Feeding of **4a** to cultured cells of *O. sativa* was carried out as described previously.[3] HPLC separation of the resulting sterol fraction gave a mixture of campesterol and dihydrobrassicasterol. The partial $^{13}$C NMR spectrum of the mixture is shown in Fig. 1. Compound **4b** was similarly incubated to give the same 24-methylcholesterol mixture (Fig. 1).

$^{13}$C Assignments of the diastereotopic methyl groups of **1** and **2** were established previously.[8] Thus, it is evident from Fig. 1 that the (*E*)-methyl of **4** becomes the *pro-S*-methyl of **1** and the *pro-R*-methyl of **2**, whereas the (*Z*)-methyl of **4** becomes the *pro-R*-methyl group of **1** and the *pro-S*-methyl group of **2**. Similar feeding experiments of **4a**,**b** using cultured cells of *C. roseus* led to the same results for the metabolic fates of the isopropylidene methyl groups (data not shown).

These findings demonstrate for the first time that stereospecific hydrogen attack on 24-*Si*, 25-*Re* face of 24-methyldesmosterol **4** affords campesterol **1**, whereas dihydrobrassicasterol **2** is produced by 24-*Re*, 25-*Si* attack of hydrogen on the same 24(25)-olefin **4**. It should be noted that an *anti*-mode of hydrogen addition occurs in both cases.

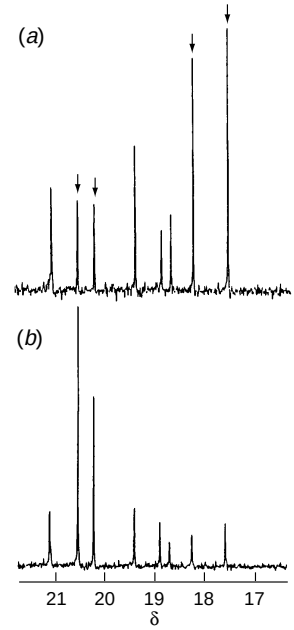


**Fig. 1** $^{13}$C NMR spectra (part) of metabolically formed 24-methylcholesterol fractions. (*a*) [(*E*)-Me-$^{13}$C]-**4a**, (*b*) [(*Z*)-Me-$^{13}$C]-**4b**. Signals indicated by arrows: *pro-S*-Me (δ 18.26) and *pro-R*-Me (δ 20.19) of **1**, *pro-S*-Me (δ 20.50) and *pro-R*-Me (δ 17.60) of **2**.

These results imply that the double bond migration from **3** to **4** should proceed in such a manner that the *pro-R* methyl of **3** becomes (*Z*)-methyl group of **4** while the *pro-S* methyl of **3** becomes (*E*)-methyl group of **4** [Scheme 2(*a*)]. The metabolic correlation of C-26 and C-27 in 24-methylcholesterol biosynthesis in *O. sativa* and *C. roseus* can be summarized as: C-2 of mevalonate → (*E*)-Me of **5** → *pro-S*-Me of **3** → (*E*)-Me of **4** → *pro-S*-Me of **1** and *pro-R*-Me of **2**; C-6 of mevalonate → (*Z*)-Me of **5** → *pro-R*-Me of **3** → (*Z*)-Me of **4** → *pro-R*-Me of **1** and *pro-S*-Me of **2** (Scheme 1).

It has been reported that one of the olefinic methyl groups of **4**, which appeared at higher field [δ 19.93, now assigned to (*Z*)-methyl group] in the $^{13}$C NMR spectrum, was derived from an intact [$^{13}C_2$]acetate molecule with tissue cultures of *P. periviana*,[6] which coincides with our present results.

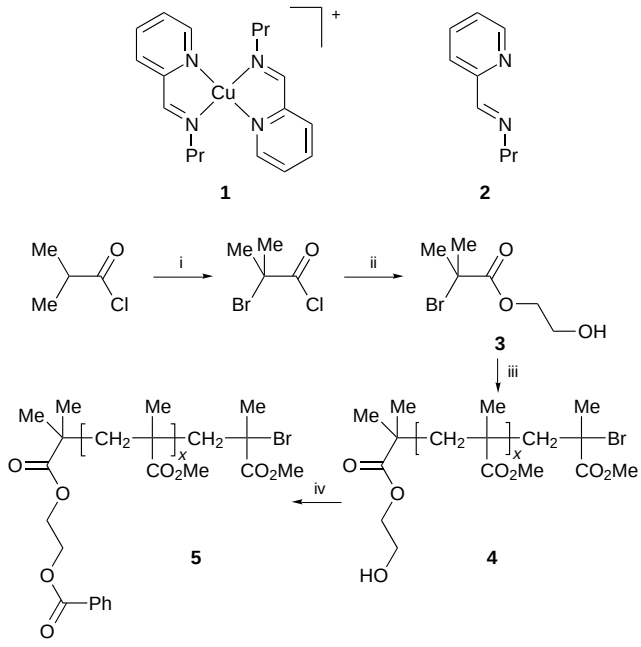
# Monohydroxy terminally functionalised poly(methyl methacrylate) from atom transfer radical polymerisation

**David M. Haddleton,*† Carl Waterson, Peter J. Derrick, Christina B. Jasieczek and Andrew J. Shooter**



*Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL*

**Atom transfer radical polymerisation (ATRP) of methyl methacrylate with a pyridinecarbaldehyde imine copper(I) catalyst and hydroxy functional alkyl bromide initiator leads to α-hydroxy functional PMMA with controlled $M_n$ and PDI < 1.20 without the use of protecting group chemistry.**

Atom transfer radical polymerisation (ATRP) is a rapidly emerging method of obtaining pseudo-living polymerisation of vinyl monomers with controlled $M_n$ and narrow molecular weight distribution (MWD).[1–5]

It has been developed from atom transfer chemistry in organic synthesis, *e.g*. intramolecular cyclisation, and is a development of the Kharash reaction.[6] Complexes of a range of metals have been demonstrated to be useful including $Ru(PPh_3)_3Br_2$,[1] CuBr–bipyridine[2,3] and $Ni[C_6H_3(CH_2NMe_2)_2$-2,6]Br.[7] In a previous communication we have demonstrated that pyridine-2-carbaldehyde imine copper(I) complexes such as **1** are very effective for ATRP of methyl methacrylate (MMA) in conjunction with ethyl 2-bromoisobutyrate.[8] The objective of this work was to replace the initiator, ethyl 2-bromoisobutyrate, with a hydroxy containing alkyl bromide so as to produce α-hydroxy terminally functionalised PMMA without the need to employ protecting group chemistry.

2-Hydroxyethyl 2′-methyl-2′-bromopropionate‡ **3** was prepared as shown in Scheme 1. Atom transfer radical polymerisation of MMA using **3** as initiator in conjunction with **2** and CuBr was carried out at 90 °C in xylene, MMA : **3** = 20 : 1, **2** : CuBr : **3** = 3 : 1 : 1, to give PMMA of structure **4**. Polymerisation was stopped at low conversion, 7.65%, after 70 min, so as to reduce the amount of termination by radical–radical reactions (reaction A; Table 1). $^1$H NMR data (Fig. 1), clearly shows the presence of the hydroxyethyl ester group, originating from **2** and the methoxy α to the bromo group at the propagating end at δ 4.18, 3.82 and 3.74 respectively. The number average molecular mass, $M_n$, can be calculated directly from NMR which gives a value of 2430 which compares excellently with that obtained from size exclusion chromatography against PMMA standards of 2320, PDI = 1.12 (when precipitated into hexanes $M_n$ = 2960, PDI = 1.12). This excellent agreement indicates that the product has structure **4**. This is confirmed by matrix-assisted laser desorption-ionisation time of flight mass spectrometry, Fig. 2. We see one series of peaks in the MALDI-

[a] All reactions carried out with **2** : CuBr : **3** = 3 : 1 : 1. [b] 20 ml MMA in 40 ml xylene, [c] 5 ml MMA in 6 ml xylene. [d] From gravimetry. [e] After precipitation, otherwise as taken from reaction flask.

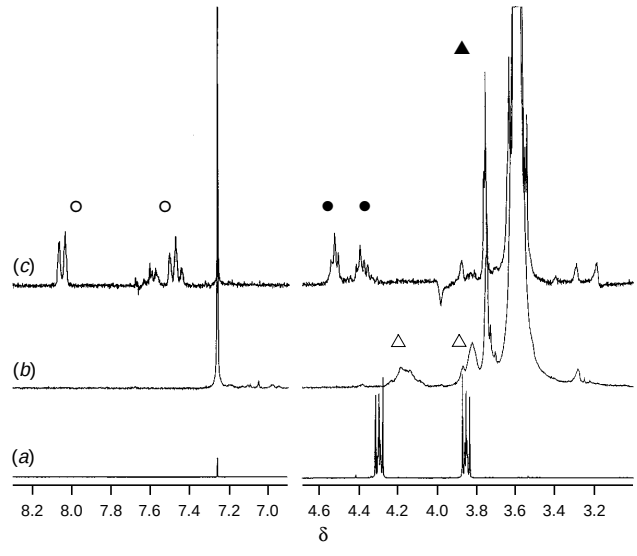

**Fig. 1** Selected region from the $^1$H NMR spectra of (*a*) **3**, (*b*) **4** (△ = $CH_2O$ groups and ▲ = OMe α to Br), (*c*) **5** (● = $CH_2O$ groups, ▲ = OMe α to Br and ○ = aromatic protons from benzoyl group)

TOF MS indicating only one predominant structure, *i.e*. **4**. For example, the peaks at *m/z* 1319.0 and 1419.2 correspond to lithium adducts of **4** where $x$ = 10 and 11 respectively, calculated *m/z* 1318.3 and 1418.4. Control over $M_n$ and PDI is obviously not affected detrimentally by the presence of the primary alcohol group present in the initiator, which might have been expected to complicate the reaction by coordination to the copper catalyst. Indeed the PDI is narrower and the rate of polymerisation faster with **3** than that obtained using a non-functional initiator. Thus ATRP with **1** as catalyst can be utilised to give PMMA of structure **4** as the only detectable product under these conditions. The hydroxy group can be further reacted with benzoyl chloride to give **5** quantitatively.

The terminal benzoyl group of **5** is observed by $^1$H NMR, Fig. 1(*c*), and is detected by SEC with UV detection at 200 nm, **4** shows no absorption at this wavelength. MALDI-TOF MS shows a new series of peaks corresponding to **5**, *e.g*. peaks are

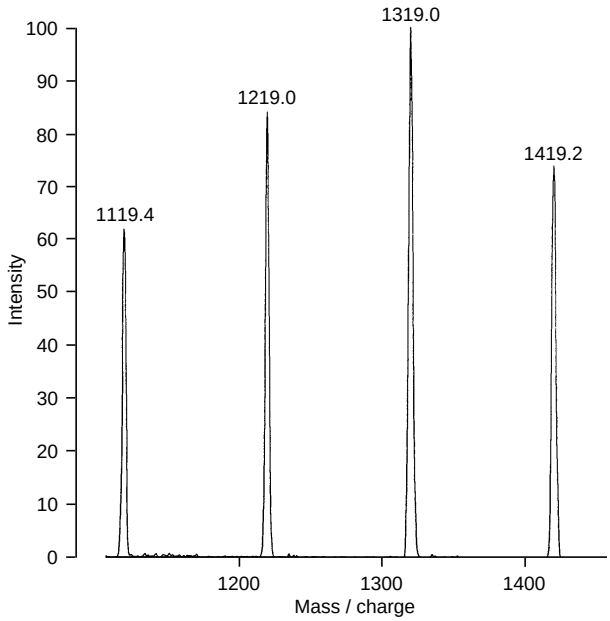

**Fig. 2** Partial MALDI-TOF MS of **3** between $x$ = 8 and 11, peaks correspond to lithium adducts of molecular ions with no observable fragmentation

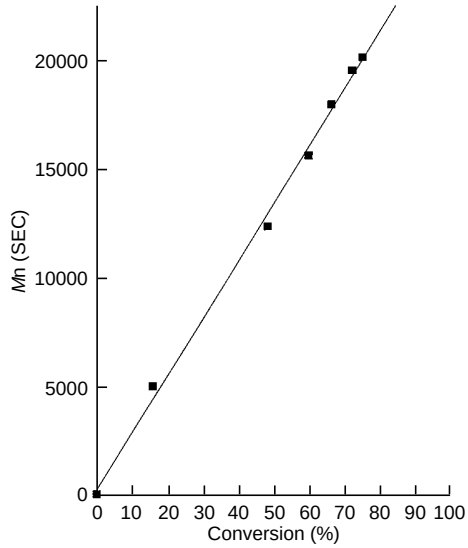

**Fig. 3** Plot showing how $M_n$ from SEC increases with conversion for experiments D–K

now observed at *m/z* 1423.0 and 1522.8 for $x$ = 10 and 11, calculated *m/z* 1422.3 and 1522.4; this reaction is quantitative and no peaks from residual **4** are observed. When the reaction is carried out at a higher MMA : **3** ratio for 120 min a higher molecular weight polymer is produced, *M*n = 4540, PDI = 1.22, as expected (reactions B and C). Again analysis shows terminal hydroxy functionality.

Living or pseudo-living polymerisations have a low rate of termination relative to rate of propagation. This is demonstrated by following a reaction with time (reactions D–K; L is the final product from this reaction). Fig. 3 shows that $M_n$ increases linearly with conversion, up to approx. 80%, whilst PDI remains narrow for reaction with MMA : **3** = 200. In this case the expected $M_n$(theory) at 100% conversion = [100/1 × 100.14 (mass of MMA)] + 220 (mass of end groups) = 20 248. The PDI is broader than would be expected for a true living polymerisation with fast initiation (theoretically 1 + 1/DP). However, PDI does not increase with increasing conversion as would be expected for a reaction with significant termination and this is most probably due to slow initiation relative to propagation.[9]

In summary, atom transfer radical polymerisation with **1** as catalyst and **3** as initiator leads to α-hydroxy functional PMMA. The presence of the hydroxy group during the polymerisation does not reduce the control over the polymerisation, and a narrow PDI polymer with controlled $M_n$ is obtained.

We thank the EPSRC (C. W. GR/K65652, C. B. J. GR/K04606, A. J. S. CASE award) and Courtaulds for funding. We also thank the late Dr Andrew McCamley who proved a source of inspiration and ideas during this work.

## Footnotes

# $^{13}$C MAS NMR observation of photoproducts in zeolites and their further reaction on acid sites

**Jinhua Zhang, Thomas R. Krawietz, Timothy W. Skloss and James F. Haw***

*Laboratory for Magnetic Resonance and Molecular Science, Department of Chemistry, Texas A&M University, College Station, Texas 77843, USA*

***In situ* $^{13}$C MAS NMR characterization following UV irradiation of two FAU zeolites with adsorbed benzaldehyde or acetophenone and toluene allows observation of photoproducts and subsequent acid-catalysed chemistry.**

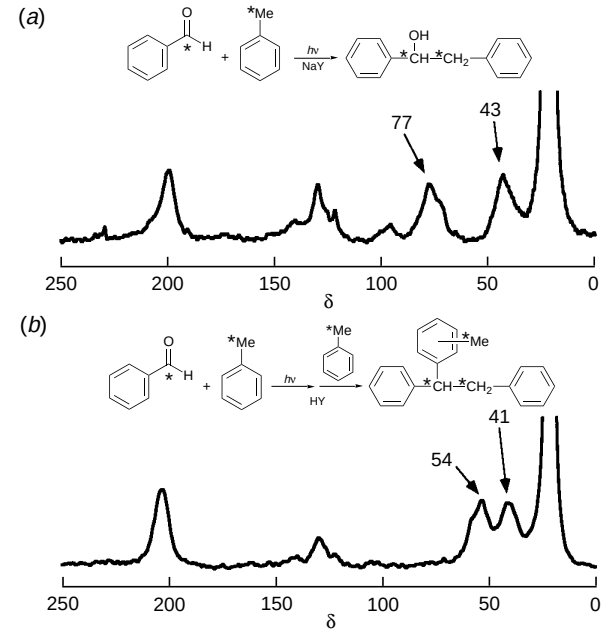
Photochemistry of organic compounds included in zeolites and other constrained media is of continuing interest. Many previous investigations have focused on the influence of framework topology and the charge compensating cation of the zeolite on the resulting photoproduct yield and distribution.[1–9] The zeolite is typically selected so as to be otherwise unreactive toward the reactants or photoproducts. Procedures used in diverse, published reports naturally vary; however, in many of the previous studies, the zeolite was irradiated in a slurry of excess reactant, and the products identified *ex situ* following liberation by extraction or destruction of the framework. Here we report $^{13}$C MAS NMR characterization of the photoproducts of benzaldehyde or acetophenone with toluene in two FAU type zeolites, with topologies dominated by 13 Å supercages interconnected through 7.4 Å pore openings.

[α-$^{13}$C]Benzaldehyde and [α,β-$^{13}C_2$]acetophenone were obtained from Isotec, [α-$^{13}$C]toluene from Cambridge Isotope Labs and spectrophotometric grade toluene from Spectrum Chemicals. The zeolite catalysts, USY (ultrastable-Y in the acid form, UOP, Si/Al = 5.5) and NaY (Strem, Si/Al = 2.6), were loaded inside a quartz reaction tube (18 mm diameter, 250 mm length, with an axial valve on one end) and were activated using a previously described procedure.[10] The carbonyl-containing reagent was adsorbed at a loading of one molecule per zeolite supercage. The catalyst was then exposed to an excess of toluene vapour for 30 min to achieve saturation coverage (*ca*. 4 molecules per supercage). The sample container was then sealed, dismounted from the vacuum line, and set up for UV irradiation.

Ultraviolet light from a 500 W mercury vapour arc lamp system (Oriel, Stratford, CT) was filtered by a dichroic mirror to attenuate wavelengths longer than 400 nm then passed through a safety shutter and into a liquid filter (0.85 M aqueous $CoSO_4$). Estimated filtered UV light intensity calculated from the Oriel optical handbook was 37 mW nm$^{-1}$ near the peak at 254 nm, with a total intensity of 250 mW between 245 and 265 nm. The axis of the quartz reaction tube was placed normal to the path of filtered UV light and positioned with the sample in the centre of the beam. During UV exposure, the sample was rotated with one end angled down, at one revolution per second. No significant thermal heating was observed. Published NMR studies of benzaldehyde,[11] other ketones[12] and aldehydes[13] on zeolites suggest little or no thermal reactivity at 298 K for the species studied here.

Fig. 1 reports the $^{13}$C MAS NMR spectra of [α-$^{13}$C]benzaldehyde and [α-$^{13}$C]toluene on zeolites NaY and USY after UV irradiation. On zeolite NaY, chemical shifts of δ 77 and 43 indicate that the major photoproduct is the asymmetric coupling product 1,2-diphenylethanol **1** which forms from hydrogen abstraction between benzaldehyde and toluene.[14] Compound **1** is not stable in an acidic environment, and on zeolite USY undergoes a Friedel–Crafts reaction with a second toluene molecule, forming the isomeric triphenylethanes **2** and **3**, with resonances at δ 54 and 41, respectively.

Representative $^{13}$C MAS NMR spectra of [α,β-$^{13}C_2$]acetophenone and natural abundance toluene on zeolites NaY and USY are shown in Fig. 2. In analogy to the benzaldehyde reaction, the major photoproduct of acetophenone and toluene on NaY was 1,2-diphenylpropan-2-ol **4** (δ 75). In the acidic zeolite, however, further reaction led not to Friedel–Crafts products analogous to **2** and **3**, but rather 1,2-diphenylpropane **5**, and other products by the reaction of a (formal) benzyl cation



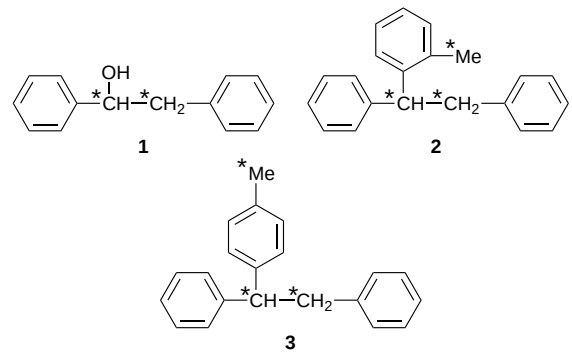


**Fig. 1** 50.1 MHz $^{13}$C CPMAS NMR spectra of the products of [α-$^{13}$C]benzaldehyde and [α-$^{13}$C]toluene on FAU zeolites measured at 298 K following 4 h of UV irradiation (also at 298 K). (*a*) Spectrum of product on zeolite NaY acquired with 5000 transients at a spinning speed of 5000 Hz. (*b*) Spectrum of products on zeolite USY acquired with 4000 transients at a spinning speed for 5000 Hz. (★ Denotes $^{13}$C labelled atoms.)

with toluene. The latter included triphenylmethane as established by other experiments with labeled toluene.

For the cases studied here, the photoproducts observed in the zeolite by NMR were identical to those found *ex situ* in previous studies, but this need not be the case in future work where acid digestion of the zeolite might cause degradation of the photoproducts. Additionally, by matching the acid zeolites with non-acidic controls, we were able to characterize the combination of photochemistry and thermally-activated processes on acid sites. The possibility exists for using photochemistry to synthesize otherwise sterically-excluded adsorbates specifically for the study of carbenium ions or other intermediates[15] formed in a second thermal step.[16] Application of *in situ* NMR methodology to the emerging area of photocatalysis[17,18] should expand research of highly reactive photoproducts.

We acknowledge the National Science Foundation (Grant No. CHE-9528959) for financial support of this work.

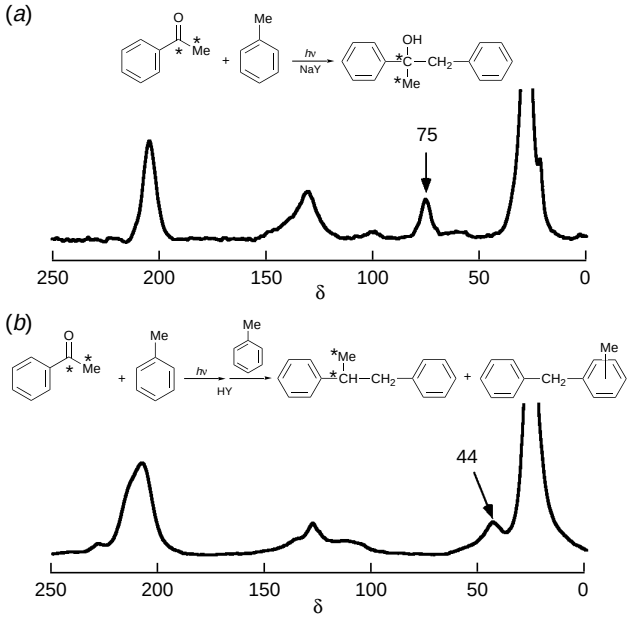

**Fig. 2** 50.1 MHz $^{13}C$ CP MAS NMR spectra of [α,β-$^{13}C_2$]acetophenone and natural abundance toluene on FAU zeolites measured at 298 K after 4 h of UV irradiation (also at 298 K). (*a*) Spectrum of product on zeolite NaY acquired with 1200 transients at a spinning speed of 3600 Hz. (*b*) Spectrum of product on zeolite USY acquired with 1200 transients at a spinning speed of 4500 Hz. The resonance at δ 44 did not survive 50 μs of dipolar dephasing (not shown) supporting the assignment indicated. (★ Denotes $^{13}C$ labeled atoms.)

# $^7$Li NMR studies on a lithiated non-graphitizable carbon fibre at low temperatures

**K. Tatsumi,*[a] J. Conard,[b] M. Nakahara,[c] S. Menu,[b] P. Lauginie,[b] Y. Sawada[a] and Z. Ogumi[d]**

[a] *Osaka National Research Institute, 1-8-31 Midorigaoka, Ideka, Osaka 563, Japan*

**$^7$Li NMR spectra of a lithiated non-graphitizable carbon fibre measured at temperatures below 200 K display three different signals and the NMR shift of one of the signals is larger than that of Li metal below 163 K.**

Much attention has been focused on carbonaceous materials, *e.g.* graphite, petroleum cokes and carbon fibres, as a host for the $Li^+$ ion, because carbon is one of the most promising anodes for secondary lithium batteries.[1,2] Both electrode potential and capacity of carbon anodes in organic electrolytes are dependent on the nature of the carbon used. Artificial carbon materials are classified into graphitizable (soft) and non-graphitizable (hard) carbons according to the degree of crystallinity by heat treatment.[3] In graphitizable carbons, graphite and carbons having the graphite-like stacking sequence of graphene layers to some extent give the lowest electrode potential (0–0.3 V *vs.* $Li/Li^+$) during electrochemical insertion of $Li^+$ ion.[4–7] The electrochemical capacity of graphite is limited to one lithium atom per six carbon atoms, *i.e.* $LiC_6$.[2,4]

On the other hand, non-graphitizable carbons heat-treated between 1000 and 1300 °C give a capacity higher than $LiC_6$. In addition, the carbons have a significant capacity in the potential range between 0 and 0.1 V, though the carbons have little amount of crystallites of the graphite-like stacking sequence.[8–10] Therefore, non-graphitizable carbons have been thought to have lithium storage sites different from the sites of lithium insertion into graphitizable carbons. $^7$Li NMR methods have been used for analyses of Li in carbon materials.[5,8,11–13] Yamazaki *et al.* reported that lithium species in a non-graphitizable carbon, which showed a band at δ 90 in $^7$Li NMR measurements at room temperature, consist of two species of lithium (δ *ca.* 190 and 20 at 140 K).[13] In the previous work,[8] it was shown that non-graphitizable carbon fibres also give capacity higher than $LiC_6$ with a significant capacity below 0.1 V. Here, we report the first $^7$Li NMR data indicating three different lithium species in a non-graphitizable carbon fibre. Furthermore one of the lithium species gave a NMR shift larger than that of Li metal at temperatures below 163 K.

The non-graphitizable carbon fibre (FIP Petoca, nominal diameter 10 μm) prepared from an isotropic petroleum pitch was heat-treated at 1200 °C under a nitrogen atmosphere. The reversible capacity of the carbon fibre between 0 and 2.5 V was $x = 1.25$ for $Li_xC_6$ with a significant capacity, $x = 0.73$, between 0 and 0.1 V. The carbon fibre electrode was dried at 130 °C under vacuum for 24 h and then electrochemically reduced to 0 V in 1 mol $dm^{-3}$ solution of $LiClO_4$† in ethylene carbonate (EC)–diethylcarbonate (DEC) (1 : 1, v/v) according to the procedure previously reported.[8] The carbon fibre fully lithiated to 0 V was washed with DEC and dried under vacuum for 15 min and then put into a NMR sample tube; the sample tube was sealed by an epoxy resin. All procedures for sample preparation were performed in an Ar-filled dry box. The sample was served for $^7$Li NMR measurements using a wide line probe of a NMR spectrometer (CMX-200H Chemagnetics). NMR shift was measured in ppm against LiCl (δ 0) used as an external standard.

The fully lithiated carbon fibre (reversible capacity $Li_{1.25}C_6$) showed a signal at δ 111 in the $^7$Li NMR spectrum at 298 K [Fig. 1(*a*)]. The lithium species at δ 111 is quite different from those in graphitizable carbons, which give a peak between δ 7 and 45.[5,11] The shift of the signal at δ 111 (298 K) was independent of temperature from 298 to 243 K, whereas the shift increased with a temperature drop from 243 to 123 K. A new band appeared at δ 18 at temperatures lower than 243 K. The intensity markedly increased with lowering temperature. In addition, the spectra below 163 K showed a very broad signal at δ *ca.* 270.

The spectra below 203 K can be simulated by three Lorentzian peaks. The deconvoluted components for the spectrum at 143 K consisted of three signals at δ 18, 192 and 281 (Fig. 2). As seen in Fig. 1, the spectra showed high reversibility between cooling and heating; no spectral hysteresis was detected during a cyclic change of temperature. Moreover, all the signals were deconvoluted to Lorentzian line shapes. Since NMR peaks fitting to Lorentzian lines are observed for liquid- or gas-phase species, the present results suggest that

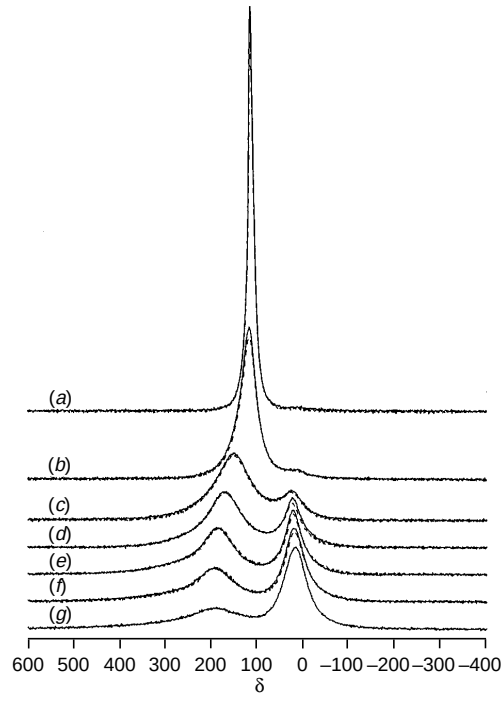

**Fig. 1** $^7$Li NMR (77.8375 MHz, relative to LiCl, δ 0) spectra for the fully lithiated carbon fibre recorded at (*a*) 298, (*b*) 243, (*c*) 203, (*d*) 183, (*e*) 163, (*f*) 143 and (*g*) 123 K; solid line, at the direction of cooling; dashed line, heating

lithium atoms in the carbon fibre are diffusive. These results thus indicate that the variation observed in the spectra is likely ascribed not to a crystalline phase transformation but to exchange of lithium nuclei among lithium atoms at different sites, and that the rate of exchange is slowed down on the timescale of NMR observation at low temperature, in agreement with the observed line broadening. The $^7$Li NMR spectra at low temperature indicate that the fully lithiated non-graphitizable carbon fibre contains three different lithium species.

$^7$Li NMR shift of the signals determined by the curve fitting simulations is plotted as a function of temperature in Fig. 3. In general, $^7$Li NMR shift for a lithium species in graphene layers is independent of temperature[11] as well as lithium metal,[14] and the shift for lithium in the fully lithiated graphitizable carbon heat-treated at 1000 °C was δ 18.[5] Although the peak position

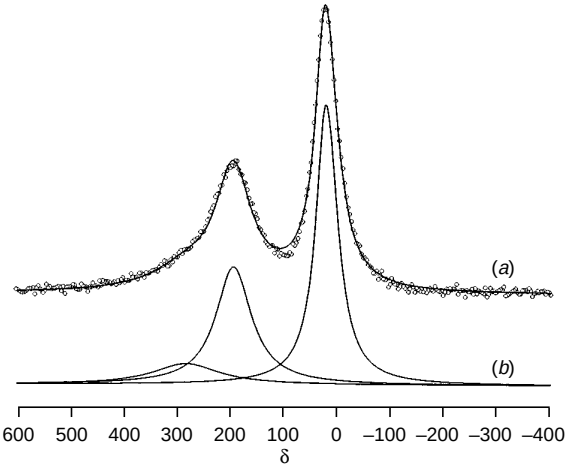

**Fig. 2** $^7$Li NMR spectra of the fully lithiated carbon fibre at 143 K: (*a*) experimental (○) and simulated (solid line) spectra; (*b*) deconvoluted spectra

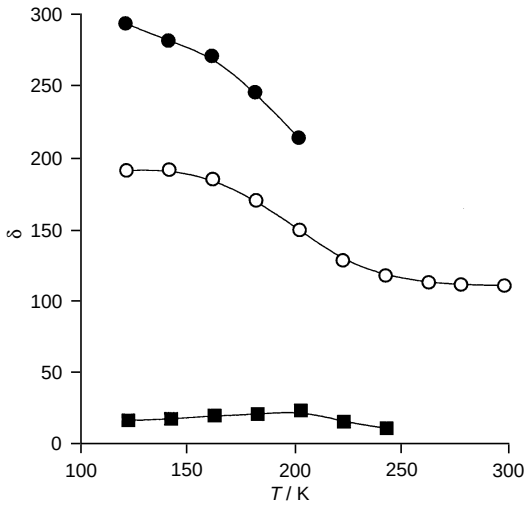

**Fig. 3** $^7$Li NMR shift of the signals determined by the curve fitting simulations as a function of temperature: the signals in the highest (●), the middle (○) and the lowest (■) fields in Fig. 2

in the lowest field in Fig. 2 showed considerable temperature dependence, the signal at δ 18 is inferred to be ascribed to the lithium species in crystalline graphene layers in the carbon fibre. On the other hand, the other signals are quite novel because NMR shift of the two signals increased with lowering temperature below 243 K. Furthermore, the shift of the signal in the highest field is higher than that of lithium metal (δ 262)[14] at low temperatures below 163 K. Although the structure of the lithium species of each peak is not clear at present, high shifts of the signals are explained as a Knight shift and correspond to lithium species with metallic character. Non-graphitizable carbons are considered to have microcavities between the crystalline grains.[3] Therefore, lithium species corresponding to the signals in the middle and the highest fields are inferred to be ascribed to lithium clusters formed in the microcavities of the non-graphitizable carbon fibre. The existence of the lithium species with metallic character is consistent with the result that the carbon fibre showed a significant capacity near 0 V. These features of the non-graphitizable carbon fibre are attractive as an anode material for advanced lithium-ion batteries.

The authors are grateful to Drs Toshifumi Kawamura and Tomiji Hosotubo, Petoca Co. Ltd., for preparing the non-graphitizable carbon fibre.

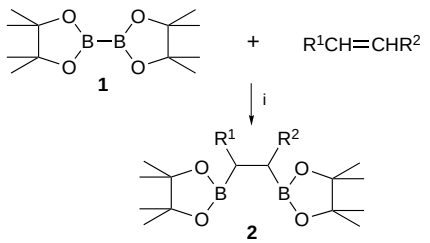
# Diboration of alkenes with bis(pinacolato)diboron catalysed by a platinum(0) complex†

**Tatsuo Ishiyama, Masafumi Yamamoto and Norio Miyaura***

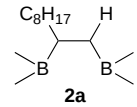
*Division of Molecular Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060, Japan*

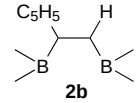


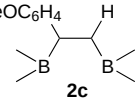
**Bis(pinacolato)diboron selectively adds to terminal alkenes and cyclic alkenes having internal strain to provide bis(boryl)alkanes in 76–86% yields in the presence of a catalytic amount of $Pt(dba)_2$ at 50 °C.**

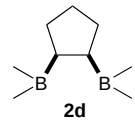
Increasing attention has been recently focused on the transition-metal-catalysed addition reactions of boron–heteroatom reagents, such as thioboranes,[1] stannylboranes,[2] or silylboranes[3] to alkenes or alkynes, as a direct procedure for preparing organoboron compounds from unsaturated hydrocarbons. We have recently reported the platinum(0)-catalysed addition of bis(pinacolato)diboron **1** to alkynes[4,5] and the conjugated addition to alka-1,3-dienes.[6] The proposed mechanism *via* the oxidative addition of **1** to the platinum(0) complex followed by insertion of an unsaturated C–C bond into the B–Pt–B complex was fully substantiated by Marder and coworkers[7] and Iverson and Smith.[8] However, the extension of this protocol to alkenes has been somewhat troublesome. Phosphine-based platinum(0) catalysts failed because the insertion of an alkene into the B–Pt bond is too slow to develop the catalytic cycle, and rhodium(I) catalysts suffered from side-reactions resulting from β-hydride elimination.[9] In 1995, Baker *et al*. first demonstrated a practical method for the diboration of styrene derivatives with a phosphine–gold(I) catalyst.[9] However, the previous observation,[6] that $Pt(dba)_2$ (dba = dibenzylideneacetone) exhibits much higher catalytic activity than $Pt(PPh_3)_4$ in diboration of 1,3-dienes, prompted us to investigate the platinum(0)-catalysed diboration of alkenes (Scheme 1). The platinum(0) complex $Pt(dba)_2$ is found to be an excellent catalyst allowing alkene insertion into the B–Pt bond under mild conditions.

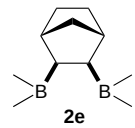
The diboration of aliphatic and aromatic terminal alkenes, and some cyclic alkenes having internal strain was readily achieved with $Pt(dba)_2$ (Table 1).‡ When dec-1-ene (1.5 equiv.) was allowed to react with **1** (1.0 equiv.) in toluene at 50 °C in the presence of 3 mol% $Pt(dba)_2$, the addition proceeded to completion within 1 h to afford the desired 1,2-bis(boryl)decane **2a** in 82% yield together with two unidentified products (4 : 1 ratio, *ca*. 15%), presumably arising from the β-hydride elimination reported in the rhodium(I)-catalysed diboration of styrene.[9] Among the platinum catalysts we examined, $Pt(dba)_2$ was the most efficient; combination with other ligands such as $PPh_3$, $AsPh_3$ or $P(C_6H_{11})_3$ showed no advantages over $Pt(dba)_2$ itself.





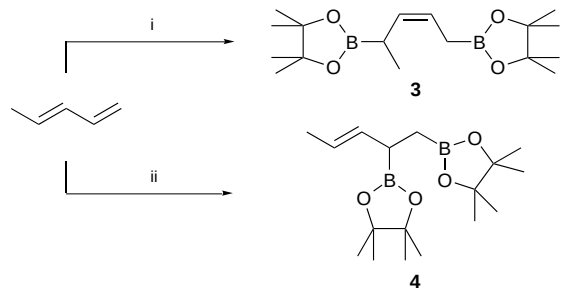






Styrene and 4-methoxystyrene provided **2b** and **2c** with accompanying by products (*ca*. 10%). The addition to 4-methoxystyrene was apparently slower than to styrene itself, the order of which is consistent with the relative reactivity observed on the insertion of arylacetylenes to the B–Pt–B complex.[8]

Cyclopentene (1.5 equiv.) and norbornene (3.0 equiv.) underwent a clean reaction with no byproducts. The *cis*-addition of **1** was established from the $^1H$ NMR spectrum of **2d** and its oxidation to *cis*-cyclopentane-1,2-diol. However, additions to other internal alkenes were slow, as anticipated from the order of alkene reactivity in transition-metal-catalysed reactions. Cyclooctene gave 1,2-bis(boryl)cyclooctane in low yield, but all attempts in the diboration of oct-4-ene, stilbene, cyclohexene or 2-methylpropene were unsuccessful.



**Scheme 1** *Reagents and conditions*; i, $Pd(dba)_2$, toluene, 50 °C, 1 h

**Table 1** $Pt(dba)_2$-catalysed diboration of alkenes[a]

| Alkene | Product | Yield (%)[b] |
|---|---|---|
| Dec-1-ene |  **2a** | 82 |
| Styrene |  **2b** | 86 |
| 4-Methoxystyrene |  **2c** | 76[c] |
| Cyclopentene |  **2d** | 85 |
| Norbornene |  **2e** | 85[c] |

[a] All reactions were carried out at 50 °C for 1 h with $Pt(dba)_2$ (3 mol%), **1** (1.0 equiv.), alkene (1.5 equiv.), and toluene (6 ml), unless otherwise noted. [b] Isolated yields based on **1**. [c] 3.0 equiv. of alkene was used.

**Scheme 2** *Reagents and conditions*: i, **1**, $Pt(PPh_3)_4$, toluene, 80 °C, 84%; ii, **1**, $Pt(dba)_2$, toluene, room temp., 92%

It is interesting that $Pt(dba)_2$ directed 1,2-addition to certain conjugated dienes, whereas 1,4-addition through a π-allylplatinum(II) intermediate is an energetically more favourable process. The 1,4-addition to penta-1,3-diene at 80 °C with $Pt(PPh_3)_4$ to give **3** was consistent with our previous report,[6] but the same reaction with $Pt(dba)_2$ selectively produced the 1,2-addition product **4** at room temperature (Scheme 2).

Further studies are in progress to elucidate the mechanism and possible synthetic applications.

# Synthetic studies towards peptidyl nucleoside antibiotics: first synthesis of a polyoxamic acid derivative enabling direct coupling with α-amino acid esters

**Claudio Palomo,* Mikel Oiarbide and Aitor Esnal**

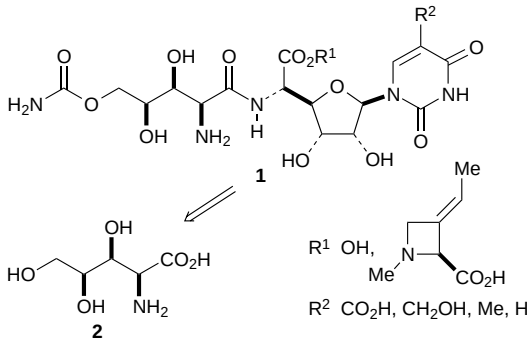
*Departamento de Química Orgánica, Facultad de Química, Universidad del País Vasco, Apdo. 1072, 20080 San Sebastián, Spain*

**The reaction of the Mukaiyama's aldehyde-derived *N*-benzyl imine with an hydroxyketene equivalent followed by exposure of the resulting α-hydroxy β-lactam to NaOCl and 2,2,6,6-tetramethylpiperidinyl-1-oxyl (TEMPO) provides a novel α-amino acid *N*-carboxy anhydride formally derived from polyoxamic acid.**

The polyoxin **1** family of nucleoside antibiotics, Fig. 1, has as a common structural feature a dipeptide comprised of an unusual hydroxylated α-amino acid, commonly named polyoxamic acid **2**, linked to one of the related nucleoside α-amino acids.[1] As a consequence of the potent antifungal activity associated with this type of peptidyl nucleosides[1,2] many methods for the preparation of **2** have been proposed over the last few years.[3] However, most of them involve a large number of steps and, therefore, a practical short route to this amino acid still remains of interest. On the other hand, and most important, all of these methods deal with the synthesis of the amino acid in its free form rather than with the generation of a simultaneously amino-protected and carboxy-activated species ready for a subsequent acylation reaction. Consequently, it would be more desirable and also a conceptually new approach to peptidyl nucleoside antibiotics if the synthesis of the polyoxamic moiety could be combined with a peptide coupling step.[4] Here we disclose our initial results on the first synthesis of polyoxamic acid that fulfils all of these requirements.

As Scheme 1 illustrates, the approach takes advantage of the facile construction of an α-hydroxy β-lactam *via* standard [2 + 2] cycloaddition of hydroxyketene equivalents with imines,[5] followed by its quantitative conversion into an α-amino acid *N*-carboxy anhydride (NCA) according to our recently reported method.[6] For the first step of the synthesis we elected to use the imine **3** derived from Mukaiyama's aldehyde, already incorporating the trihydroxylated subunit of the desired amino acid and, at the same time, providing chirality to the corresponding NCA precursor.† Thus, the cycloaddition reaction of acetoxyketene, generated from acetoxyacetyl chloride and triethylamine, with the imine **3** and subsequent saponification of the acetoxy group of the resulting crude product furnished the crystalline α-hydroxy β-lactam **4** [mp 98–102 °C, $[\alpha]_D^{25}$ −12.9 ($CH_2Cl_2$, *c* 1.0)] in 90% yield over the two steps. Likewise, the reaction of benzyloxyketene, generated from benzyloxyacetyl chloride and triethylamine, with the imine **3** gave **5** [mp 74–76 °C, $[\alpha]_D^{25}$ +1.6 ($CH_2Cl_2$, *c* 1.0)] in 85% yield. In each case a single diastereoisomer was produced as judged by $^1$H NMR analysis of the crude reaction products. The relative *cis*-disposition of the substituents at the $C_3$ and the $C_4$ positions of the β-lactam ring was determined by the value of the proton NMR coupling constant ($J_{3,4}$ = 5 Hz) and the absolute configuration of both β-lactams **4** and **5** was primarily established by the assumption of an uniform stereochemical outcome with regard to that observed in closely related reactions.[7,8] Further, chemical correlation of both **4** and **5** with the known 4-formyl derivative **6**[8] confirmed the assignment.

To complete the synthesis of the polyoxamic acid skeleton the 3-hydroxy β-lactam **4** was converted into the NCA **7** by using a solution of commercial bleach and a catalytic amount of 2,2,6,6-tetramethylpiperidinyl-1-oxyl (TEMPO). The transformation occurred almost instantaneously (1–2 min)‡ *via* an intermediate α-keto β-lactam which underwent chemoselective Baeyer–Villiger rearrangement to produce **7** in almost quantitative yield in a single pot operation. That is, from the readily available imine **3** a simultaneously amino-protected and carboxy-activated form of polyoxamic acid is obtained in 90% overall yield. From this approach two key elements are especially noteworthy. First, the creation of the α-amino stereogenic centre of the polyoxamic acid with virtually complete diastereoselectivity as compared with the reported procedures employing Mukaiyama's aldehyde as the starting



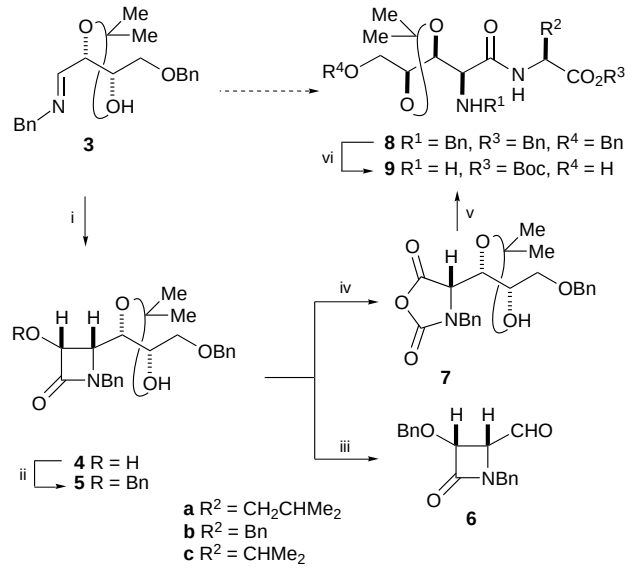


**Fig. 1**

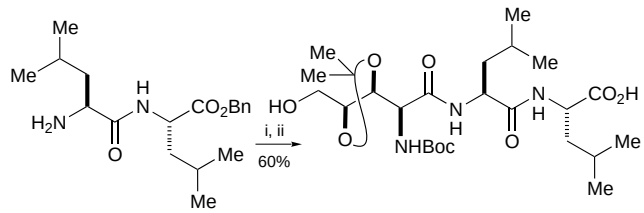
**Scheme 1** *Reagents and conditions*: i, $AcOCH_2COCl$, $Et_3N$, $CH_2Cl_2$, 0 °C → room temp., 16 h then LiOH (6 equiv.), $H_2O_2$ (18 equiv.), THF–$H_2O$, 0 °C, 3 h, 90% or $BnOCH_2COCl$, $Et_3N$, $CH_2Cl_2$, 0 °C → room temp., 16 h, 85%; ii, BnBr, NaH, DMF, −20 °C; iii, **5** with $HO_4Cl$, wet THF, room temp., 2–4 h, then $NaIO_4$, $H_2O$–$Me_2CO$, 0 °C, 2 h; iv, **4** with NaOCl, $CH_2Cl_2$, TEMPO (cat.), $NaHCO_3$, KBr, $KH_2PO_4$–$K_2HPO_4$ (pH 7.0), 0 °C, 1 min; v, (*S*)-$H_2NCH(R^2)CO_2Bn$, $CH_2Cl_2$, room temp., 24 h; vi, $H_2$, Pd–C (10% w/w), $(Boc)_2O$, EtOH, room temp., 24 h



material[3c–g] and, second, the generation, for the first time, of the polyoxamic acid **2** as an active species allowing further coupling reactions. On pursuing this latter aspect, however, the coupling of **7** with an α-amino acid ester was essentially a question of whether epimerization at the α-centre of the NCA **7** could take place; if not, the approach would open up a new and short route to peptidyl nucleoside antibiotics. We were gratified to observe that the reaction of freshly prepared **7** with (*S*)-leucine benzyl ester in dichloromethane as solvent at room temperature for 24 h proceeded with no appreciable epimerization§ to give the desired peptide **8** in 85% yield. The reaction of **7** with both (*S*)-phenylalanine and (*S*)-valine benzyl ester also led to the formation of the corresponding coupling peptides in 86 and 90% yield, respectively. The peptide products were then transformed into their Boc-derivatives **9** for characterization purposes.

The reaction time for the coupling process could be shortened by using a more polar solvent such as DMF, but under these conditions isomerization at the $C_\alpha$ of the NCA occurred¶ giving rise to an equimolar mixture of epimers. This observation prompted us to examine further the influence of the nature of the solvent upon the degree of isomerization. To this end we carried out parallel experiments using an array of common solvents with different polarities. As the results in the Table 1 show, an increase of μ, the dipolar moment of the solvent, leads to increased isomerization, the largest isomerization being when the coupling was performed in HMPA. It thus appears that dipeptide products with the unnatural configuration at the $C_\alpha$ position of the polyoxamic acid might also be obtained from this approach, albeit some further improvement would be required. Finally, as Scheme 2 illustrates, the method can also be applied to the synthesis of tripeptides containing the polyoxamic framework as part of the backbone. Therefore, it is expected that more complex amino acid derived peptides could be made accessible from this approach without the necessity to previously prepare each individual non-proteinogenic α-amino acid.

**Table 1** Solvent effect on the coupling of **7** with (*S*)-LeuOBn[a]

| Entry | Solvent | μ[b] | **8** : *epi*-**8**[c] |
|---|---|---|---|
| 1 | $Et_2O$ | 4.34 | 100 : 0[d] |
| 2 | $CH_2Cl_2$ | 5.17 | 100 : 0[d] |
| 3 | MeCN | 11.48 | 85 : 15 |
| 4 | $MeNO_2$ | 11.88 | 92 : 8 |
| 5 | DMF | 12.88 | 50 : 50 |
| 6 | $Me_2SO$ | 13.00 | 51 : 49 |
| 7 | HMPA | 18.48 | 28 : 72 |

## Footnotes

† For a conceptually different β-lactam route to the unnatural enantiomer of polyoxamic acid, see ref. 3(*k*).

‡ Prolonged exposure of **4** to the reaction conditions causes a reduction in chemical yield.

§ Under these reaction conditions the degree of isomerization was determined to be less than 0.5% by HPLC analysis of the crude reaction nature and comparison with the chromatogram of a sample containing the mixture of epimers, the latter prepared by carrying out the coupling reaction in DMF as solvent, see text.

¶ The possibility of the isomerization of the other labile Cα stereocentre of the amino ester residue under these reaction conditions was ruled out by comparison of the HPLC retention times and NMR spectra of the crude product obtained by coupling of the NCA **7** with both optically pure and racemic amino esters.

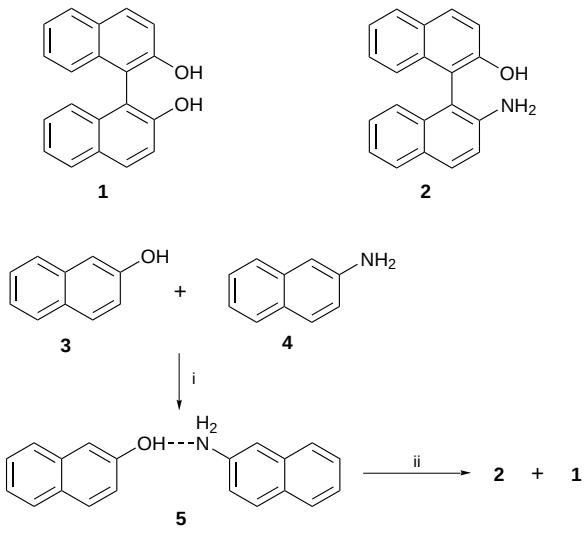
# Novel two-phase oxidative cross-coupling of the two-component molecular crystal of 2-naphthol and 2-naphthylamine



**Kuiling Ding,*[a] Qiguo Xu,[a] Yang Wang,[a] Jinxia Liu,[a] Zhengyan Yu,[a] Baoshi Du,[a] Yangjie Wu,*[a] Hideko Koshima[b] and Teruo Matsuura[b]**

[a] *Department of Chemistry, Zhengzhou University, Zhengzhou 450052, P. R. China*
[b] *Department of Materials Chemistry, Faculty of Science and Technology, Ryukoku University, Seta, Otsu 520-21, Japan*

**Two-phase reaction of a two-component molecular crystal of 2-naphthol and 2-naphthylamine suspended in aqueous $Fe^{3+}$ solutions gives a cross-coupling product, 2-amino-2′-hydroxy-1,1′-binaphthalene, with good selectivity.**

Solid-state organic reactions occurring in the ground state have attracted recent attention in organic synthesis.[1] For example, Toda *et al*. reported that a powdered mixture of 2-naphthol and $FeCl_3·6H_2O$ gave 1,1′-bi-2-naphthol **1** in 95% yield.[2] We have developed a two-phase (solid–liquid) oxidative coupling reaction of 2-naphthol and 6-bromo-2-naphthol suspended in aqueous $Fe^{3+}$ solutions which gives the corresponding 1,1′-bi-2-naphthols in up to 95% yield.[3] Here we report a novel oxidative cross-coupling reaction using a two-component molecular crystal composed of 2-naphthol and 2-naphthylamine *via* a similar solid–liquid process leading to 2-amino-2′-hydroxy-1,1′-binaphthalene **2**, which is a key catalytic ligand for asymmetric synthesis.[4] The present method is the first example of the ground-state reaction using two-component molecular crystals, in contrast to their known excited-state (photo)reactions.[5]

The molecular crystal **5** was obtained by the slow evaporation of an equimolar solution of 2-naphthol **3** and 2-naphthylamine **4** in methanol–acetone (1 : 1, v/v) at room temperature or by melting a 1 : 1 molar mixture of the component compounds followed by resolidification of the melt. Elemental analysis of **5** showed the composition of 2-naphthol and 2-naphthylamine present to be 1 : 1. The melting point of **5** is 127–129 °C which is higher than those of 2-naphthol (120–123 °C) and 2-naphthylamine (108–110 °C). Powder X-ray diffraction (PXD) results and the IR spectra of crystal **5** are quite different from those of the sum of the component compounds. All these results indicate the formation of a molecular compound between 2-naphthol and 2-naphthylamine. Particularly, the $\nu_{NH}$ absorptions at 3375, 3290 and 3170 $cm^{-1}$ in the IR spectrum of 2-naphthylamine become two absorption bands at 3350 and 3260 $cm^{-1}$ in the molecular compound **5** and the $\nu_{OH}$ absorption at 3250 $cm^{-1}$ for 2-naphthol disappears in the spectrum of **5**. It can be deduced that the formation of the molecular compound was caused by hydrogen bonding between the OH and $NH_2$ groups.

**Scheme 1** *Reagents and conditions*: i, acetone–methanol, evaporation, room temp; ii, $Fe^{3+}$–$H_2O$, 55 °C

The oxidative coupling of 2-naphthol **3** reported previously was carried out using a suspension of the substrate in aqueous $Fe^{3+}$ solution.[3] We applied this method to the synthesis of 2-amino-2′-hydroxy-1,1′-binaphthalene **2** *via* oxidative cross-coupling of molecular crystal **5**. In a typical run, a suspension of finely powdered **5** (2.87 g, 10 mmol) in water (50 ml) containing $FeCl_3·6H_2O$ (10.80 g, 40 mmol) was stirred at 55 °C for 6 h under an argon atmosphere. After cooling, the solid material was collected quantitatively by filtration and washed with distilled water to remove $Fe^{3+}$ and $Fe^{2+}$. The solid was chromatographed on an activated charcoal column (100 × 18 mm, 10 g of activated charcoal) using acetone as eluent. The eluent was evaporated and the residual solid was recrystallized from benzene to afford pure **2** (2.0 g, 70%) as colourless needles. Elemental analysis, IR, $^1H$ NMR and $^{13}C$ NMR data were consistent with the structure **2**. This procedure was also applied to the large-scale synthesis of **2**, using **5** (11.5 g, 40 mmol), $FeCl_3·6H_2O$ (43.2 g, 160 mmol) and water (200 ml) at 55 °C for 6 h, to gave 7.15 g of **2** (65% isolated yield).

The selectivity and efficiency of the reaction under various conditions were also examined. The results obtained by the HPLC analysis of the products are summarized in Table 1. In a typical run carried out at 55 °C for 6 h (entry 1), the conversion of 2-naphthol **3** was quantitative and the yield of cross-coupling product **2** was highest. When the reaction was conducted at

**Table 1** Oxidative cross-coupling of **5**

| Entry | $Fe^{3+}$ : **5** | *T*/°C | *t*/h | Conversion of **3** (%) | Yield (%)[a] **2** | **1** |
|---|---|---|---|---|---|---|
| 1 | 4 : 1 | 55 | 6 | 100 | 82 | 14 |
| 2 | 4 : 1 | 55 | 3 | 98.0 | 79 | 13 |
| 3 | 4 : 1 | room temp. | 6 | 98.4 | 71 | 14 |
| 4 | 2.2 : 1 | 55 | 3 | 94.8 | 71 | 19 |
| 5[b] | 4 : 1 | 55 | 3 | 97.0 | 63 | 19 |
| 6[c] | 4 : 1 | 55 | 3 | 81.8 | 31 | 23 |
| 7[c] | 4 : 1 | 55 | 3 | 77.2 | 42 | 30 |
| 8[c] | 4 : 1 | 55 | 3 | 96.8 | 57 | 18 |
| 9[d] | 4 : 1 | 55 | 5 | 100 | 39 | 39 |
| 10[e] | 4 : 1 | 55 | 3 | 96.4 | 78 | 20 |

[a] Yields were obtained by HPLC and based on the amount of consumed **3**. [b] Ultrasound (25 KHz) was applied. [c] $Fe_2(SO_4)_3·9H_2O$, $NH_4Fe(SO_4)_2·12H_2O$ and $NH_4FeCl_4·6H_2O$ were used as oxidants. [d] The reaction was conducted in the solid state. [e] **3** and **4** were added to aqueous $FeCl_3$ solution separately.

room temperature for 6 h (entry 3), the yield and the selectivity for the formation of **2** apparently decreased in comparison with those at 55 °C. At the lower molar ratio of $FeCl_3 \cdot 6H_2O$ to **5** (entry 4) the yields of **2** and **1** were unaltered. Under ultrasonic application (entry 5) no improvement of the yield and selectivity of the formation of **2** were observed. Although three other kinds of $Fe^{3+}$ salts were also used as oxidants (entries 6, 7 and 8), the yield and the selectivity for the formation of **2** were poor in every case. A total solid-state reaction was carried out by grinding a mixture of $FeCl_3 \cdot 6H_2O$ and **5** (4 : 1) in a mortar at 55 °C for 5 h (entry 9), the conversion of 2-naphthol **3** was quantitative, but the yield and the selectivity of the formation of **2** were low. This is interpreted by the fact that with the progress of the reaction the powdered mixture became glassy, a state in which the original arrangement of the component molecules in the crystal lattice may be altered.

It is interesting to note that when the crystals of 2-naphthol **3** and 2-naphthylamine **4** were separately added to the solution of $FeCl_3 \cdot 6H_2O$ in water and the suspension was stirred at 55 °C for 3 h (entry 10), the yield of **2** was comparable to that obtained by the reaction of molecular **5** (entry 2). In order to clarify this phenomenon, a suspension of a mixture of 2-naphthol and 2-naphthylamine in water without the presence of oxidant was stirred at 55 °C for 1 h. The solid collected by filtration showed the same melting point and IR spectrum as those of **5**. It can be concluded that in the case of entry 10 the actual reacting species is molecular **5** and as a result it gave the same yield and selectivity of the product as those obtained from the reaction of **5**.

We are grateful to the Research Foundation of National Education Committee and the Natural Science Foundation of Henan Province for Outstanding Young Scientists for financial support of this work.

# Synthesis of 7-deaza-8-bromo cyclic adenosine 5′-diphosphate ribose: the first hydrolysis resistant antagonist at the cADPR receptor

**Victoria C. Bailey,[a] Jaswinder K. Sethi,[b] Antony Galione[b] and Barry V. L. Potter*[a]**

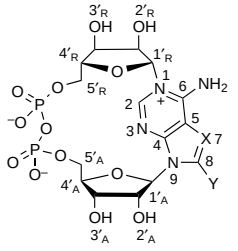
[a] *Department of Medicinal Chemistry, School of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY*

[b] *Department of Pharmacology, University of Oxford, Mansfield Road, Oxford, UK OX1 3QT*

**7-Deaza-8-bromo cyclic adenosine 5′-diphosphate ribose is synthesised from 7-deazaadenosine *via* 7-deaza-8-bromo nicotinamide adenine dinucleotide; it is both a more potent antagonist than the 8-bromo derivative and has the advantage of chemical and enzymatic hydrolytic stability.**

Cyclic adenosine 5′-diphosphate ribose (cADPR, **1**, Fig. 1) is a $Ca^{2+}$-mobilising agent known to act *via* ryanodine receptors to release internal stores of $Ca^{2+}$ in a wide variety of cell types,[1–3] independent of the second messenger *myo*-inositol 1,4,5-trisphosphate.[4] The role of cADPR is not yet fully understood, but it may act as a second messenger for a number of receptor agonists, including nitric oxide.[5] The binding protein for cADPR is unknown, and there is doubt whether cADPR acts directly at the ryanodine receptor, although its action involves calmodulin.[6] Hence it is important to build up a structure–activity profile for cADPR in relation to $Ca^{2+}$ release and to design molecules to probe its biological role.

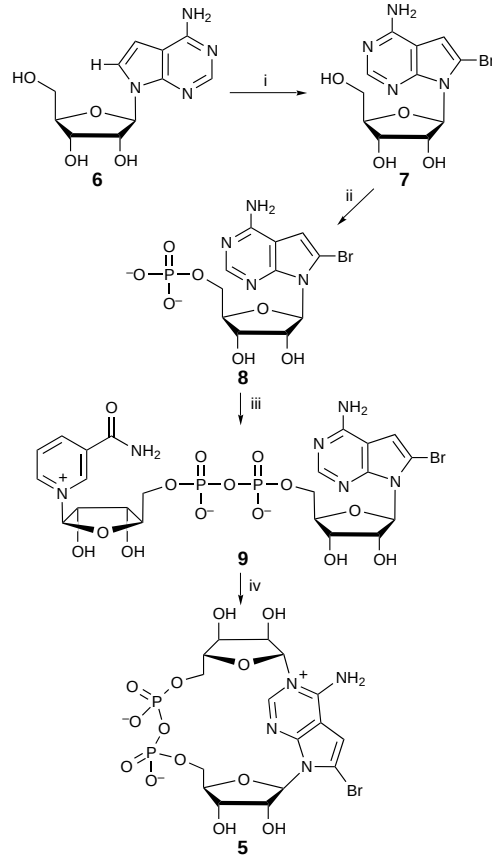
Analogues substituted at the 8-position including the 8-bromo **2** and 8-amino **3** derivatives are documented as antagonists at the cADPR receptor.[7] Importantly, 8-amino-cADPR inhibits cardiac excitation–contraction coupling.[8] Recently, we reported 7-deaza-cADPR **4** as the first partial agonist, highlighting the N-7 position as an essential motif for effective $Ca^{2+}$ release.[9] Furthermore, 7-deaza-cADPR is resistant to both chemical and enzymatic hydrolytic attack, a property desirable to confer upon an antagonist, to improve its physiological value. We have combined these two modifications and we now report 7-deaza-8-bromo-cADPR **5** as the first hydrolysis resistant cADPR antagonist.



There is no effective chemical synthesis of cADPR, the only published route produces the correct stereoisomeric product in very low yield.[10] We, like others, have relied upon a chemoenzymatic route to develop structural diversity[7,11] utilising *Aplysia* ADP-ribosyl cyclase.[12] The enzyme is extremely flexible in its substrate specificity.[11–13]

7-Deazaadenosine (Tubercidin, **6**) was selectively brominated at the pseudo-8-position (6-position) using *N*-bromosuccinimde (Scheme 1). After chromatography, dry **7** was phosphorylated at the 5′-hydroxy group using essentially the general method described by Yoshikawa *et al.*[15] The novel **8**‡ was purified by ion exchange chromatography using triethylammonium hydrogen carbonate buffer (TEAB). Owing to the increased hydrophobic nature of the modified purine ring (an extra CH group and the bromo substituent), **8** eluted at a higher concentration of buffer than expected, namely 250–300 mM TEAB as opposed to the 200–250 mM observed for adenosine 5′-monophosphate, and was not contaminated by inorganic phosphate, often a problem with this method.

Dicyclohexylcarbodiimide coupled **8** to nicotinamide mononucleotide (NMN).[16] The novel pyrophosphate **9**† was purified from monophosphates and symmetrical pyrophosphates by ion exchange chromatography. 7-Deaza-8-bromo-$NAD^+$ eluted at 120–150 mM TEAB as its triethylammonium salt.



Finally, the $NAD^+$ analogue was cyclised using the *Aplysia* enzyme.[11] 7-Deaza-8-bromo-$NAD^+$ cyclised at a similar rate to cADPR. The product was purified by ion exchange chromatography, at 130–150 mM TEAB, as the triethylammonium salt.

Phosphates **8**, **9** and **5**‡ were quantified using total phosphate analysis[9,17] from which the extinction coefficients were calcu-

**1** X = N, Y = H, cADPR
**2** X = N, Y = Br, 8-Bromo-cADPR
**3** X = N, Y = $NH_2$, 8-Amino-cADPR
**4** X = CH, Y = H, 7-Deaza-cADPR
**5** X = CH, Y = Br, 7-Deaza-8-bromo-cADPR

**Fig. 1** Structures of cADPR **1**, 8-bromo-cADPR **2**, 8-amino-cADPR **3**, 7-deaza-cADPR **4** and 8-bromo-7-deaza-cADPR **5**

**Scheme 1** *Reagents and conditions*: i, NBS, KOAc, DMF, 10 min, 40%; ii, $PO(OEt)_3$ 50 °C, 15 min, then $POCl_3$ (1.5 equiv.), 0 °C, 2 h, then $H_2O$, 44%; iii, DCC, NMN, pyridine–$H_2O$ (4 : 1), 7 d, 28%; iv, 1.5 mM solution in 25 mM HEPES, ADP-ribosyl cyclase, 30 min, 31%

lated, and used to quantify reaction yields and solutions for the biological evaluation of **5**.

The pharmacology of **5** was investigated using sea urchin egg homogenate.[18] 7-Deaza-8-bromo-cADPR antagonised the action of 100 nM cADPR-induced $Ca^{2+}$ release (Fig. 2), desensitised the receptor, and was apparently more potent and efficacious than 8-bromo-cADPR ($IC_{50}$ values of 0.73 ± 0.05 and 0.97 ± 0.04 μM respectively). Furthermore, it was resistant to chemical hydrolysis and induced antagonism even after being incubated in buffer at 85 °C for 90 min. HPLC analysis of a control incubation showed that 7-deaza-8-bromo-cADPR was still present confirming that cyclic material, and not a metabolite, caused antagonism even after heat treatment. In contrast, after identical treatment, 8-bromo-cADPR was no longer able to induce antagonism and HPLC showed no cyclic material remaining. Resistance to enzymatic hydrolysis was tested by pre-incubating the antagonist with homogenate overnight, when an aliquot was removed and its ability to antagonise cADPR-induced $Ca^{2+}$ was tested. Whilst the 8-bromo-cADPR antagonism had reduced significantly, 7-deaza-8-bromo-cADPR was still a significant antagonist. Full biological details will be reported elsewhere.

In 7-deaza analogues of adenosine the glycosidic bond is more resistant to acid catalysed hydrolysis than in adenosine.[19] Similarly, the increased hydrolytic resistance of 7-deaza analogues of cADPR is thought to arise from increased stability of the N1 ribosyl linkage. The N1 position of 7-deazaadenosine is more basic than that of adenosine ($pK_a$ = 5.2 and 3.6 respectively[20]) and similarly this position is more basic in the 8-bromo substituted analogues than in adenosine ($pK_a$ = 4.02 for 8-bromoadenosine[21]). The combination of modifications, therefore, makes the heterocycle substantially more basic at N1 than in adenine. Hydrolysis of the N1 ribosyl linkage probably involves participation of a ribosyl oxygen lone pair to form a carbocation which is then captured by water. The ability of the N1-ribosyl linkage to be hydrolysed should therefore depend upon the leaving group ability of the purine. The more acidic the purine, the better leaving group it will be and, conversely, with the more basic character of N1 in 7-deaza-8-bromo-cADPR, the harder it will be to cleave the N1 ribosyl bond.

Combined modifications at the 7 and 8 positions of cADPR thus produce slightly better antagonistic properties, with the marked added advantage of hydrolytic resistance. One of the most commonly employed antagonists, 8-amino-cADPR, is unsuitable for microinjection work due to its chemical instability.[22] 7-Deaza-8-bromo-cADPR, resistant to both chemical and enzymatic hydrolysis, should be a powerful tool to investigate the cADPR signalling pathway and complements our poorly hydrolysable agonist, cyclic aristeromycin diphosphate ribose.[13]

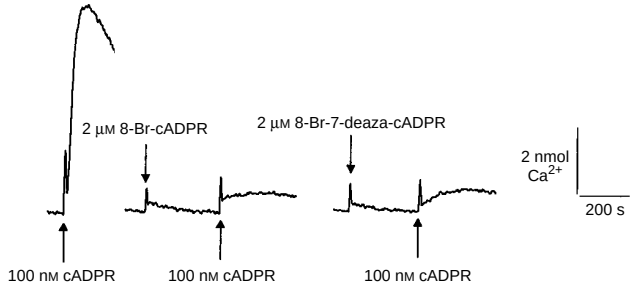


**Fig. 2** *Lytechinus pictus* egg homogenates (2.5% v/v) (ref. 18) containing Fluo-3 (3 μM) were incubated at 17 °C. Homogenate (500 μl) was challenged with cADPR (final concentration 100 nM). $Ca^{2+}$ release was monitored by a change in fluorescence. 7-Deaza-8-bromo-cADPR was tested for its antagonism by pre-treating the homogenate (500 μl) with the sample (final concentration 2 μM) 3 min prior to addition of cADPR (final concentration 100 nM). A subsequent addition of cADPR (100 nM) demonstrated the desensitisation of the $Ca^{2+}$ release mechanism. The traces shown are representative of several such experiments.

We thank the Medical Research Council for a Project Grant (A. G., B. V. L. P.) and two studentships (V. C. B., J. K. S.). A. G. is a Wellcome Trust Fellow and B. V. L. P. is a Lister Institute Research Professor.

## Footnotes

**Synthesis and crystal structure of $[C_6H_{10}N_2]Pb_2I_6{\cdot}3thf$ which contains a novel lead iodide polymeric anion with a double-chain structure.**

There is increasing interest in the study of magnetic, electronic and optoelectronic properties of low-dimensional organic–inorganic hybrid compounds.[1–3] Studies suggest that complex systems consisting of organic and inorganic components have great potential for the creation of functional materials utilizing the wide variety of properties associated with each component.[4,5] Lead(II) iodide compounds are of particular interest due to their significant third-order optical non-linear properties.[6–9]

Although there is significant interest in the physical properties of low-dimensional lead iodide compounds, relevant information regarding their crystal structure, properties and synthesis is limited.[10–12] Our current research is focused on the synthesis of low-dimensional organic–inorganic post-transition-metal iodides with the possibility of incorporating interesting properties associated with the organic and inorganic moieties. This research is motivated by the possibility of tuning properties of inorganic solid-state materials by incorporating polarizable organic moieties. Moreover, important structure–property relationships between low-dimensional structural derivatives and their parent inorganic material can be established.

The compound $[C_6H_{10}N_2]Pb_2I_6{\cdot}3thf$ **1** was prepared by reacting *p*-nitroaniline and $PbI_2$ in solution. The synthesis of **1** starts with dissolving *p*-nitroaniline (0.59 g, 4.33 mmol) and lead(II) iodide (1.00 g, 2.17 mmol) in 8 ml of concentrated 57 mass% aqueous hydriodic acid diluted with acetonitrile. The addition of hydriodic acid increases the solubility of $PbI_2$ in polar organic solvents. The resulting solution was warmed to 60 °C and slowly cooled to 20 °C during which the solution turns dark red-brown, and the formation of a brown precipitate was observed. The precipitate was collected and redissolved in tetrahydrofuran (thf) at 60 °C. The resulting clear red–brown solution was allowed to slowly cool, from 60 to −10 °C over 7 days, and orange parallelepiped crystals were formed. The air-sensitive orange crystals were preserved in the mother-liquor. All reactions were carried out under nitrogen atmosphere and all solvents were degassed before use. Direct reaction of *p*-phenylenediammine and $PbI_2$ in acetonitrile–HI and/or thf does not lead to the formation of compound **1** and could be attributed to the low solubility of the diamine in the organic–HI solvents.

Compound **1** crystallizes in space group $P\bar{1}$.† The asymmetric unit was found to consist of a $[Pb_2I_6]^{2-}$ unit (part of a polymeric chain), two half-molecules of *p*-phenylenediammonium dications, $[C_6H_{10}N_2]^{2+}$, situated about inversion centres, and three molecules of thf solvent. One of the thf molecules was found to be significantly disordered over two distinct sites, with population factors of 70 : 30. The crystal structure of **1** features double chains of *cis*-edge-sharing $PbI_6$ octahedra, $[Pb_2I_6^{2-}]_\infty$, that run along the *a* axis, as shown in Fig. 1. There are three types of I atoms defined by their connectivity to Pb: terminal [I(5), I(6)], double bridged [I(3), I(4)] and triple bridged [I(1), I(2)]. Also, there are two types of Pb atoms, defined by their location in the chain: 'outer' [Pb(1)], bonded to terminal iodides; and 'inner' [Pb(2)] bonded only to bridging iodides. The shortest Pb–I distances (3.05, 3.13 Å) are those between the terminal iodides and Pb(1). The I–Pb–I angles are nearly perpendicular around Pb(1) (84.7–94°) and Pb(2) (83.1–91.4°) with the 'outer' $PbI_6$ octahedra exhibiting the largest deviation from ideal symmetry. The structure of the polymeric anion, $[Pb_2I_6^{2-}]_\infty$, can be regarded as a $<110>$ section of the layered $CdI_2$ type structure. The lead iodide chain is reminiscent of the antimony iodide chains in $[PPh_4]Sb_3I_{10}$ and $[(Me_2N)_3C_3]Sb_3I_{10}$.[13] These $[Sb_3I_{10}^{1-}]_\infty$ complex chains are structural derivatives of the $CdI_2$ type structure but differ in the way the layered structure is excised into chains. The lead iodide double chains in **1** correspond to the higher-order double chain $[M_2I_6]_\infty$ which has not been previously observed. It is important to note that the polymeric anion chain in **1** constitutes a direct structural link between molecular lead iodide complexes to the inorganic solid compound $PbI_2$ ($CdI_2$ type).

An important aspect of the crystal structure of **1** is its organic–inorganic heterostructure. It is dominated by cooperative hydrogen bonding between *p*-phenylenediamine dications with terminal and double-bridging iodines of the inorganic double chain as shown in Fig. 2. The hydrogen bond distances range from 3.56 to 3.83 Å suggesting that any interaction between them is not very strong.[14] The two half-molecules of organic dications in the asymmetric unit generate two inequivalent dications. One type of dication acts as bridge between nearest neighbouring $[Pb_2I_6]^{2-}$ double chains through hydrogen bonding interactions between the amino group and the terminal iodides. These extended interactions result in stair-like layers formed by hydrogen-bonded dications and $[Pb_2I_6^{2-}]_\infty$ chains. The stair-like layered organic–inorganic heterostructure lies nearly parallel to the $<011>$ plane as shown in Fig. 3. The remaining *p*-phenylenediamine dications and solvent molecules (thf) lie between the layers of hydrogen-bonded organic cations and inorganic chains.

During the initial stages of this research, our intention was to introduce push–pull type cations and molecules like *p*-nitroaniline into $PbI_2$. However, in addition to the protonation of the amine groups, we observe that *p*-nitroaniline is reduced to

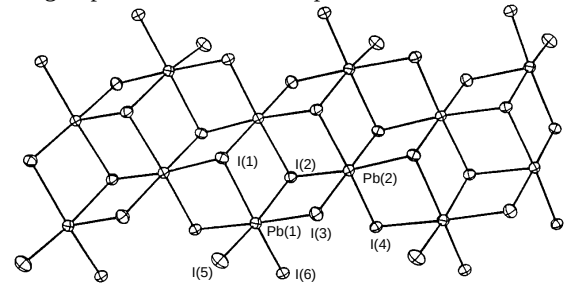

**Fig. 1** ORTEP representation of the structure of the linear polymeric chain in **1** (ellipsoids are drawn at 50% probability). Important distances (Å) and angles (°) are: Pb(1)–I(1) 3.378(1); Pb(1)–I(2) 3.458(1), Pb(1)–I(3) 3.178(2), Pb(1)–I(5) 3.052 (2), Pb(1)–I(6) 3.126(1), Pb(2)–I(2) 3.264(2), Pb(2)–I(3) 3.178(2), Pb(2)–I(4) 3.154(1), I(1)–Pb(1)–I(2) 86.4(1), I(1)–Pb(1)–I(3) 93.3(1), I(1)–Pb(1)–I(5) 87.9(1), I(1)–Pb(1)–I(6) 169.3(1), I(2)–Pb(1)– I(3) 84.1(1), I(2)–Pb(1)–I(5) 174.1(1), I(2)–Pb(1)–I(6) 85.7(1), I(3)–Pb(1)–I(6) 93.1(1), I(2)–Pb(2)–I(3) 88.0(1), I(2)–Pb(2)–I(4) 91.4(1), I(3)–Pb(1)–I(5) 94.0(1).

*p*-phenylenediamine in the presence of hydriodic acid and $PbI_2$. The well known reduction of nitroarenes to primary arylamines in the presence of metal (Sn, Zn, or Fe) and acid (HCl) involves the oxidation of the metals.[15] In this work, the reduction of the nitro group involves oxidation of the iodide ions ($2I^- \rightarrow I_2$). The formation of $I_2$ is observed from the dark red colour of the solution upon the reaction of the inorganic and organic components. Furthermore, the observed reduction of the nitro group by iodide is catalysed by the metal iodide, $PbI_2$. This is indicated by several follow-up experiments wherein catalytic amounts of the metal iodide were needed to initiate the nitro reduction/iodide oxidation reaction. An examination of known oxidation potentials of $Pb^{II}$ and $I^-$ ($Pb^{2+} \rightarrow Pb^{4+} + 2e^-$, $E° = -1.69$ V; $2I^- \rightarrow I_2 + 2e^-$, $E° = -0.53$ V)[16] further supports the better reducing ability of $I^-$. The overall nitroaniline/$I^-$ redox reaction is given by eqn. (1).

$$p\text{-}H_2NC_6H_4NO_2 + 6HI \rightarrow p\text{-}H_2NC_6H_4NH_2 + 3I_2 + 2H_2O \quad (1)$$

The IR spectrum of **1** recorded in KBr contains characteristic bands associated with the phenyl group and a very broad band at 3200 $cm^{-1}$ indicating the presence of protonated amine groups. Furthermore, the characteristic band associated with the aromatic nitro group, around 1300 $cm^{-1}$, is not observed.

The synthesis of **1**, a direct structural derivative of $PbI_2$, is just the first member of a family of compounds with low-dimensional chain structures derived from the layered $PbI_2$ structure. Its novel layered heterostructure attests to the importance of cooperative hydrogen bonding in the crystal structures of organic–inorganic halides. Studies are under way to relate the optical properties of **1** to the unique properties of $PbI_2$.

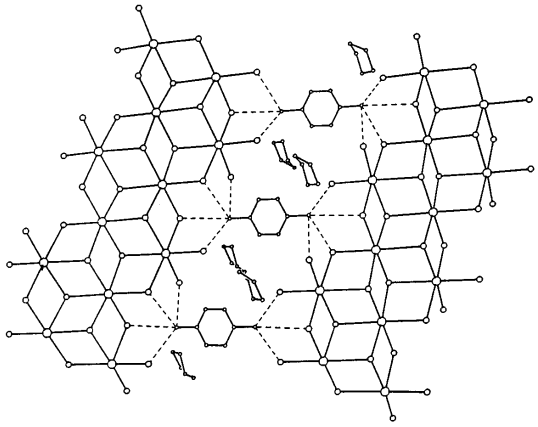

**Fig. 2** View of two nearest neighbouring $[Pb_2I_6^{2-}]\infty$ chains and the bridging *p*-phenylenediamine dications. Hydrogen-bonding interactions, represented by the nearest N···I distances that range between 3.65 and 3.83 Å, are indicated by dashed lines.

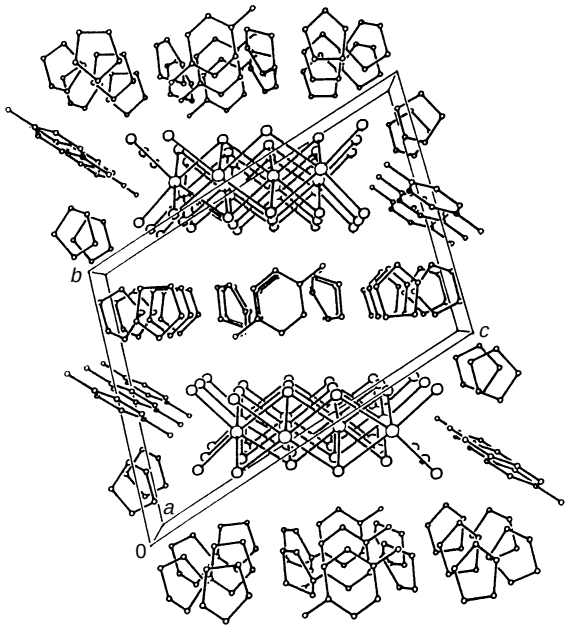

**Fig. 3** A plot of the structure showing the unit-cell packing as viewed into the *a* axis. Only the major orientation of the disordered thf is shown.

This material is based in part on work supported by the Robert A. Welch Foundation and the Texas Center for Superconductivity at the University of Houston. We thank Dr James Korp for help with crystallography.

† Single-crystal X-ray analysis was carried out on a crystal with dimensions *ca.* 0.12 × 0.16 × 0.32 mm mounted in a stream of dry $N_2$ gas at −50 °C. Monochromated Mo-Kα radiation was used and intensities were measured using the θ–2θ scan technique. The intensities of standard reflections were monitored and they showed no significant changes. Lorentz and polarization corrections, and absorption corrections based on 10 ψ-scans were applied.

*Crystal data*: $M$ = 1502.32, $a$ = 8.322(1), $b$ = 13.076(2), $c$ = 17.037(4) Å, $\alpha$ = 70.64(1), $\beta$ = 83.86(1), $\gamma$ = 72.31(1)°, $U$ = 1666 $Å^3$; $Z$ = 2; $D_c$ = 2.99 g $cm^{-3}$, $\mu$ = 156.9 $cm^{-1}$, $\lambda$ = 0.710 73 Å, $2\theta_{max}$ = 45°; total data collected = 4321, reflections observed = 3180 ($I > 3\sigma I$); 259 variables; $R$ = 0.041, $R_w$ = 0.041. All calculations were made using the Nicolet SHELXTL PLUS (1987) crystallographic package. Hydrogens could not be located in difference maps, and no attempt was made to include them in ideal positions. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/400.

# Molecular structure of diphenylbis(9,10-phenanthrenesemiquinonate)tin(IV), an organometallic diradical complex

**Andrei S. Batsanov,[a] Judith A. K. Howard,[a] Martyn A. Brown,[b] Bruce R. McGarvey[b] and Dennis G. Tuck*[b]**

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*
[b] *Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ontario, Canada N9B 3P4*

**The title compound, formed in the reaction between hexaphenylditin and 9,10-phenanthrenequinone, is shown to be an organotin(IV) diradical; its X-ray structure and EPR spectra are reported.**

Substituted *ortho*-quinones can oxidize main-group elements or their low-oxidation state compounds, yielding semiquinone or catecholate complexes, characterised chemically and crystallographically.[1] The oxidation has been shown to proceed *via* successive one-electron transfer reactions,[2] involving semiquinone derivatives as important intermediates, conveniently detectable by electron paramagnetic resonance (EPR) spectroscopy. Some more unusual products were isolated, *e.g.* an oxygen-bridged tetrachlorocatecholate derivative $[(Cl_4C_6O_2)TePh]_2O$ from the reaction between $Ph_2Te$ and $Cl_4C_6O_2$.[3]

The present work is a part of our study of reactions of $Sn_2Ph_6$ with various *o*-quinones and of $Ph_2SnCl_2$ or $Ph_3SnCl$ with sodium semiquinonates,[4] and of the redistribution processes which follow these reactions. The resulting systems comprise $SnPh_4$ and various radical and diradical species, identified by their EPR spectra. In particular, the reaction between equimolar amounts of $Sn_2Ph_6$ and 9,10-phenanthrenequinone (pq) in refluxing dichloromethane (1 h) yielded a brown solid, identified as $Ph_3Sn(psq)$ (psq = 9,10-phenanthrenesemiquinone). The residual solution (strongly EPR active) after about 5 days at room temperature deposited dark brown shiny crystals suitable for an X-ray diffraction study,† which proved them to be $Ph_2Sn(psq)_2$ **1**.‡ On the available evidence we believe that the primary reaction is given by eqn. (1), and the subsequent

$$Sn_2Ph_6 + pq \rightarrow Ph_3Sn(psq) + Ph_3Sn^{\cdot} \qquad (1)$$

processes include ligand redistribution to give the diradical.

The tin atom in **1** has a distorted *cis*-octahedral coordination (Fig. 1). The sensitive indicators of the oxidation state of the chelating ligand are known[2,5] to be the lengths of the C–O bonds (av. 1.23, 1.29 and 1.35 Å for the *o*-benzoquinone, *o*-semiquinone and catecholate) and the intervening C–C bond (1.53, 1.44 and 1.40 Å, respectively). Thus, the corresponding C–O and C–C distances in **1** [mean 1.291(6) and 1.44(1) Å] characterise it unequivocally as a semiquinone complex of tin(IV). The Sn–C distances in **1** (2.16 Å) are essentially equal and within the range (2.09–2.19 Å) observed in other $R_2Sn(O–O)_2$ complexes, *viz*. R = Me, O–O = tropolonate (**2**);[6,7] R = Me, O–O = kojate (6-hydroxymethyl-4*H*-pyran-4-on-3-olate) (**3**);[7] R = Me, O–O = maltolate (3-hydroxy-2-methyl-4*H*-pyran-4-oate) (**4**)[8] and R = Ph, O–O = maltolate (**5**).[8] On the other hand, Sn–O bonds formed by each semiquinone ligand show considerable non-equivalence (Δ) in length. Formally, such a ligand forms one covalent and one dative bond, and their unequal contribution can explain this difference. As Haaland[9] pointed out, a dative bond can have half the enthalpy of the corresponding covalent one and be 0.2 Å (or more) longer. Its length is also very sensitive to inductive effects of other ligands, increasing with their electron donating ability. Indeed, Δ in diphenyl complexes (0.08 Å in **1**, 0.16 Å in **4**) is much smaller than in dimethyl ones (0.34 Å in **3**, 0.28 Å in **5**) in accordance with the values of $\sigma_I$, −0.01 for Me and 0.12 for Ph.[10] However, in both polymorphs of **2**, Δ is only 0.04 Å, probably due to electron-poor character of the tropilium ring itself. It is noteworthy that the shorter Sn–O bonds are invariably in *trans*-positions to the less polar (Sn–C) ones, while exactly the opposite is observed in psq complexes of transition metals,[11] in accordance with the view[12] that in Sn complexes, less electronegative ligands exercise *cis*-influence, rather than *trans* (as for d elements).

The EPR spectra of the solution obtained finally in the reaction of $Sn_2Ph_6$ and pq show the presence of three species. The room temperature solution spectrum which shows hyperfine structure is predominantly that of the primary reaction product identified as the $Ph_3Sn(psq)$ monoradical, but the frozen solution spectrum showed, in addition to the $S = 1/2$ resonance ($g = 2.07$), both a fine structure and a resonance at half-field, indicating the presence of diradical species. The fine structure of the central resonance showed the presence of two such species, with $D = 63$ and $104 \times 10^{-4}$ cm$^{-1}$ respectively. The lower $D$ value is very close to that of *trans*-$Cl_2(dbsq)SnSn(dbsq)Cl_2$ ($dbsq^{\cdot-}$ = 3,5-di-*tert*-butylorthosemiquinonate anion)[1a] and is presumably from the analogous $Ph_2(psq)SnSn(psq)Ph_2$ compound with a Sn–Sn bond. The higher $D$ value can be assigned to **1**. It is of the same order as those observed for $Cd(dbsq)_2L$ (L = py, tmen, bipy) and related

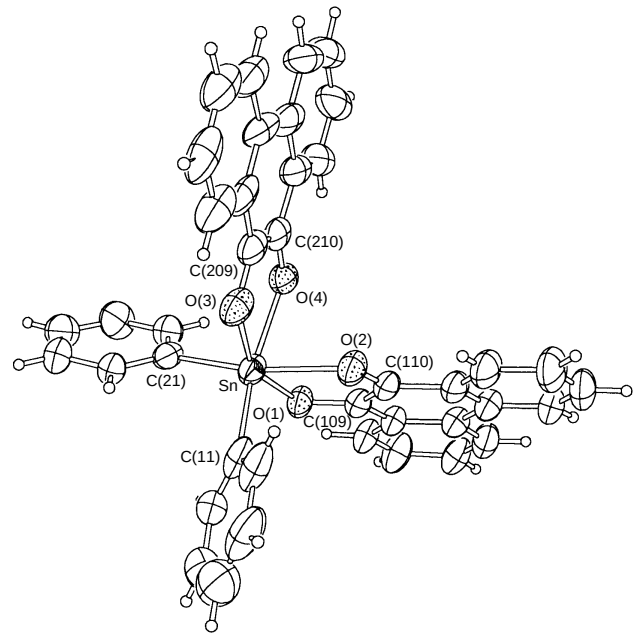

**Fig. 1** Molecular structure of $Ph_2Sn(psq)_2$ **1**, showing 50% probability ellipsoids. Selected bond distances (Å) and angles (°): Sn–O(1) 2.127(5), Sn–O(2) 2.210(5), Sn–O(3) 2.137(5), Sn–O(4) 2.214(5), Sn–C(11) 2.160(9), Sn–C(21) 2.157(7), O(1)–C(109) 1.298(8), O(2)–C(110) 1.284(9), O(3)–C(209) 1.296(10), O(4)–C(210) 1.287(9), C(109)–C(110) 1.446(10), C(209)–C(210) 1.430(12); O(1)–Sn–O(2) 75.8(2), O(3)–Sn–O(4) 76.0(2), C(11)–Sn–O(4) 164.7(3), C(21)–Sn–O(2) 163.8(3).

molecules,[13] but slightly smaller; the difference may be due to the larger size of psq$^{\cdot-}$ compared with dbsq$^{\cdot-}$.

# Formation of platinum nanorods and nanoparticles in uniform carbon nanotubes prepared by a template carbonization method

**Takashi Kyotani,* Li-fu Tsai and Akira Tomita**

*Institute for Chemical Reaction Science, Tohoku University, 2-1-1 Katahira, Sendai 980-77 Japan*

**Template technique makes it possible to prepare Pt metal-filled uniform carbon nanotubes in which the metal is present as either nanorods or nanoparticles.**

Carbon tubes at the nanometre level have now been characterized as a new carbon material. Specifically, metal-filled carbon nanotubes could have a variety of industrial applications, as reviewed by Freemantle.[1] Thus the preparation and application of such filled nanotubes are now becoming a very challenging area of research. Carbon nanotubes have been prepared thus far mainly using an arc-discharge evaporation technique[2,3] or by thermal decomposition of benzene vapour,[4] and there have been several attempts to insert metal into the tubes prepared by the arc-discharge evaporation technique.[5–8] Recently, we have prepared carbon nanotubes by a template carbonization technique using an anodic aluminium oxide film,[9,10] which has an array of parallel and straight channels with a diameter of nanometre level and has been often utilized as a template to synthesize nanomaterials.[11–17] The most striking feature of our carbonization method is that it allows one to produce monodisperse carbon nanotubes with uniform length, diameter and thickness. Here, we attempt to prepare Pt metal-filled uniform carbon nanotubes with the template method using an anodic oxide film.

An oxide film was prepared by electro-oxidation of an aluminium plate (purity 99.99%) at a cell voltage of 20 V in sulfuric acid. The diameter and thickness of the resulting film were 15 mm and 75 μm, respectively, and its channel diameter was found to be *ca*. 30 nm. The film was placed in a vertical quartz reactor. The reactor temperature was raised to 800 °C under $N_2$ flow and then propene gas (2.5% in $N_2$) was passed through the reactor. The thermal decomposition of propene in the uniform straight channels of the anodic oxide film resulted in carbon deposition on the channel walls. After 3 h decomposition the reactor was cooled to room temp. and the film was taken out. Pt was loaded on this carbon-deposited film by the following evaporation method. The film was impregnated with an ethanol solution of hexachloroplatinic acid ($H_2PtCl_6 \cdot 6H_2O$) at room temp. for 3 h and then ethanol was evaporated at 80 °C under an $N_2$ flow with the film immersed in the solution. The reduction of chloroplatinic acid in the channels was performed by the following two methods; heat treatment at 500 °C under $H_2$ flow or stirring with an excess of a 0.1 M $NaBH_4$ aqueous solution at room temperature. After the reduction, the carbon-deposited film was washed with an excess of a 46% HF solution at room temp. to dissolve the anodic aluminium oxide template. As a result, a Pt metal/carbon nanotube composite was obtained as the insoluble fraction.

Fig. 1(*a*) and (*b*) show bright-field TEM images at different magnifications for the Pt/carbon tube composite prepared at 500 °C. These two images indicate the presence of uniform carbon nanotubes and their outer diameter and wall thickness can be estimated to be 30 nm and *ca.* 5 nm, respectively. Although some of the tubes are empty, the others are filled with many rod-like materials which are observed as dark images. The low-magnification TEM image [Fig. 1(*a*)] indicates that these nanorods are more abundant in the end of the tube hollows, where some of them are > 1 μm in length. Their structure was investigated by electron diffraction and X-ray powder diffraction (XRD). Fig. 1(*c*) shows the electron diffraction pattern which was taken from the TEM image [Fig. 1 (*b*)]. The pattern presents the diffraction from Pt metal crystallites as clear spots together with carbon 002 diffraction as a pair of strong arcs. Some of the spots from the fcc structure of Pt metal and carbon 002 arcs are labelled in the figure. This pattern confirms the dark material to be Pt metal. The appearance of the diffraction for Pt as clear spots, not as rings, indicates the high crystallinity of the Pt nanorods. The small number of these diffraction spots suggests the presence of only a few Pt crystallites in the area of Fig. 1(*b*). The XRD analysis also confirmed the reduction of chloroplatinic acid to Pt metal. From the peak width of the Pt(111) diffraction, the average crystallite size was calculated to be *ca.* 30 nm.

The TEM photographs of the composite reduced by $NaBH_4$ solution at room temp. are displayed in Fig. 2. Like the composites reduced at 500 °C, Pt metal is observed only in the carbon tube hollows and some tubes appear to be completely

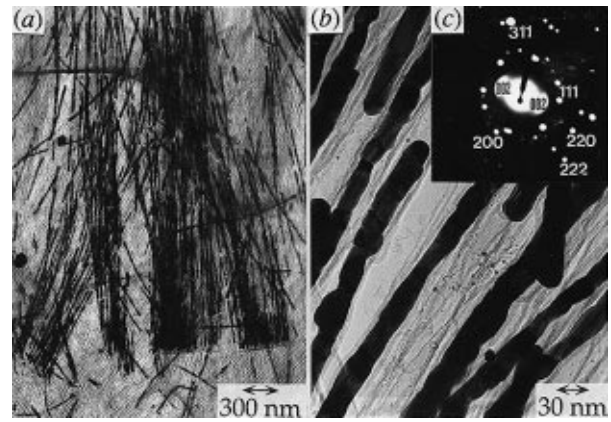

**Fig. 1** (*a*), (*b*) TEM photographs for Pt/carbon tube composites reduced at 500 °C; (*c*) electron diffraction pattern taken from the TEM image (*b*)

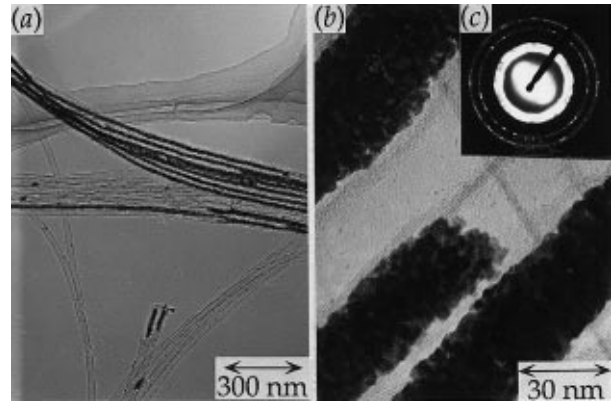

**Fig. 2** (*a*), (*b*) TEM photographs for Pt/carbon tube composites reduced at room temp; (*c*) electron diffraction pattern taken from the TEM image (*b*)

filled with the metal. There is, however, some difference in microscopic features between the two Pt metals prepared at different temperatures [Figs. 1(*b*) and 2(*b*)]. The Pt metal reduced at room temp. appears to consist of very fine particles of size 2–5 nm, which is in good agreement with the calculated value from the XRD analysis. The electron diffraction pattern of the Pt metal gives further information on its structure. The pattern [Fig. 2(*c*)] exhibits a set of diffraction rings from Pt metal (these rings can be indexed [from the inside as] 111, 200, 220, 311 reflectance fcc Pt), together with a pair of carbon 002 arcs. It is noteworthy that the diffraction from Pt metal did not appear as clear spots, but as concentric rings, each of which consists of a large number of very small spots. This finding suggests that the metal reduced by $NaBH_4$ solution is comprised of many fine crystallites, which accords with the microscopic difference between the two types of Pt metal.

For the above two types of composites, Pt was loaded by the evaporation to dryness method. On the other hand, when the impregnated film was removed from the chloroplatinic acid solution and then dried, less Pt was loaded in the carbon tubes Fig. 3 shows the bright-field TEM image of the composite prepared by this loading method, where the reduction of Pt was performed with $NaBH_4$ solution at room temp. The image does not reveal rod-like Pt metal, but rather, very fine Pt particles in the hollows. Some of Pt particles form agglomerates with each other and the size varies from 1 to 4 nm.

Although the carbon nanotubes prepared by our template technique are not structurally perfect, their length, diameter and thickness are controllable and monodisperse. Here, by applying the template technique, we have succeeded in preparing Pt metal-filled uniform carbon nanotubes in which the metal is present as either nanorods or nanoparticles. It should be noted that no Pt metal was observed on the outside wall of the tubes. This is due to the preparation procedure, *viz*., chloroplatinic acid as the Pt metal precursor was loaded into the carbon-deposited alumina film before dissolution of the alumina by HF; thus there is no other space for Pt to be loaded except within the channels.

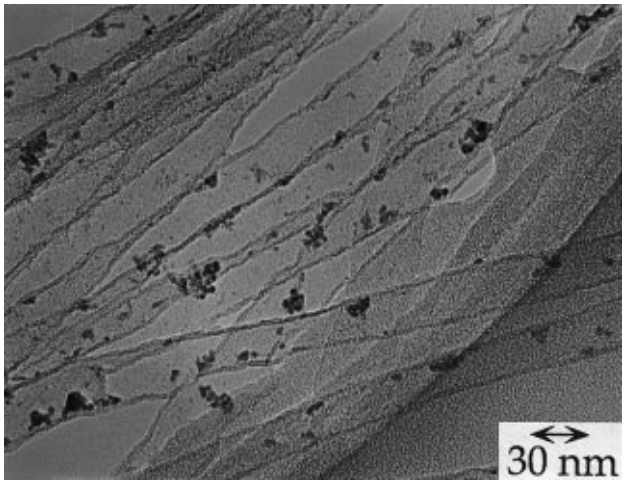

**Fig. 3** Bright-field TEM image of Pt nanoparticles in carbon tubes

We thank the High Voltage Electron Microscope Laboratory of Tohoku University for microscopical analysis. # The novel heterometallic polymeric helical chain cluster $\{[W_3Ag_3S_{12}]\}_n[Nd(Me_2SO)_8]_n$

**Qun Huang, Xintao Wu* and Jiaxi Lu**

*State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, Fuzhou, Fujian 350002, P.R. China*

**$\{[W_3Ag_3S_{12}]\}_n[Nd(Me_2SO)_8]_n$, showing a novel helical chain configuration and derived from the influence of the dimension of the cation on the self-assembly of $[WS_4]^{2-}$ and $Ag^+$, is described.**

Polymeric transition-metal chalcogenides have attracted much attention because of their possible properties directly derived from their peculiar solid-state structures.[1,2] For example, low-dimensional chalcogenides with the general formula $MCu_{2n}S_{n+1}$ (where M is a monovalent metal) were found to have relatively high conductivity, and furthermore an interesting structural relationship also found.[3,4] The general polymeric configuration of W(Mo)–Ag–S complexes is linear, such as in $(PPh_4)AgMoS_4$,[5] $\{[AgMS_4]\}_n[4\text{-Hmpy}]_n$[6] and $\{[AgWS_4]\}_n[H_3NC(CH_2OH)_3]_n[dmf]_{2n}$.[7] Recently, we have found that the self-assembly of ammonium tetrathiotungstate and silver nitrate is subject to the appropriate small molecules and the valence state of the cation, which is very rare for polymeric transition-metal chalcogenides; for example, water molecules are conducive to the transformation of the single linear chain $\{[WS_4Ag]\}_n[H_3NC(CH_2OH)_3]_n[dmf]_{2n}$[7] to the double chain $\{[WS_4Ag]\}_n[H_3NC(CH_2OH)_3]_n[H_2O]_n$,[7] and the divalent cation $[Ca(Me_2SO)_6]^{2+}$ and the trivalent cation $[Nd(dmf)_8]^{3+}$ are conducive to the zigzag chain $\{[W_4S_{16}Ag_4]\}_n[Ca(Me_2SO)_6]_n$[8] and the one-dimensional chain $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$,[9] respectively. Herein, the synthesis and crystal structure of the polymeric cluster complex $\{[W_3Ag_3S_{12}]\}_n[Nd(Me_2SO)_8]_n$ **1** with a novel helical chain configuration are reported, which is derived from the influence of the dimension of the cation on the self-assembly of ammonium tetrathiotungstate and silver nitrate.

The reaction of $(NH_4)_2[WS_4]$ and $AgNO_3$ in the presence of $Nd^{3+}$ in $Me_2SO$–MeCN solution (molar ratio of 2 : 4 : 1) leads to orange crystals of complex **1** in 45% yield after allowing the orange–red filtrate to stand in air for one day.† As in the synthesis of $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$,[9] the trivalent lanthanide cations $Nd^{3+}$, which are oxygenphilic, were also employed as complementary cations. The resulting larger complex cations $[Nd(Me_2SO)_8]^{3+}$ are smaller than the cations $[Nd(dmf)_8]^{3+}$ of the one-dimensional polymeric cluster $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$. As a consequence of their smaller size, the cations $[Nd(Me_2SO)_8]^{3+}$ induce $WS_4^{2-}$ and $Ag^+$ to self-assemble into $[(W_3Ag_3S_{12})^{3-}]_n$ helical chains rather than $[(W_4S_{16}Ag_5)^{3-}]_n$ one-dimensional chains. The synthesis of complex **1** clearly shows that the self-assembly of $WS_4^{2-}$ and $Ag^+$ is very flexible and subject to the size of the complex cation.

Complex **1** crystallizes in the monoclinic system with space group $P2_1/n$.‡ An ORTEP drawing of a portion of the anion is shown in Fig. 1. The configuration of the polymeric anion can be viewed as a helical chain which is propagated along the crystallographic *b* axis. For clarity, the simplified diagram is shown (Fig. 2) with S atoms omitted. It is seen that the chain turns at each W atom.

All the W atoms are coordinated by one terminal S, two μ-S and one $\mu_3$-S atoms with an approximately tetrahedral geometry [106.7(2)–113.2(2)°]. However, the coordination tetrahedron around the Ag atoms, formed by two μ-S and two $\mu_3$-S atoms, is much more distorted, the coordination angles ranging from 88.4(2) to 143.8(2)°. The average W–Ag–W and Ag–W–Ag angles are 167.63(7) and 93.26(5)°, respectively. The bond lengths W–$S_t$, W–μ-S and W–$\mu_3$-S differ with average values being 2.136, 2.201 and 2.235 Å, respectively. By comparison, the W–$S_t$, W–μ-S and W–$\mu_3$-S bond lengths are 2.128, 2.190 and 2.248 Å in $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$,[9] 2.146, 2.199 and 2.250 Å in $\{[W_4S_{16}Ag_4]\}_n[Ca(Me_2SO)_6]_n$,[8] and 2.144, 2.217

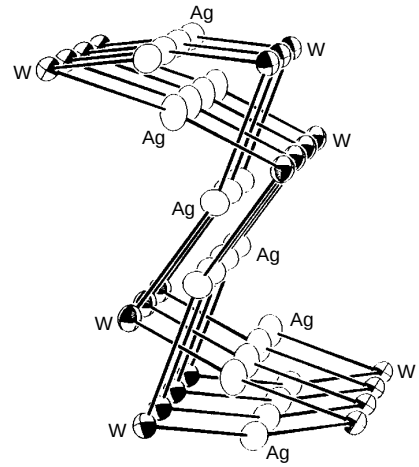

**Fig. 2** Simplified diagram of the anionic helical chain. For clarity, the sulfur atoms are omitted.

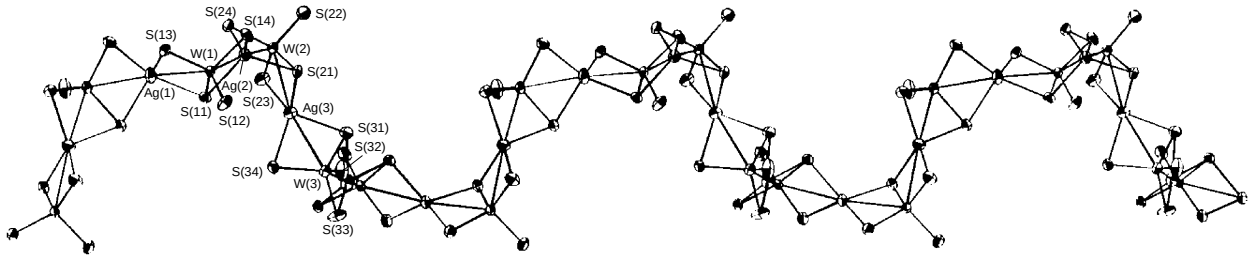

**Fig. 1** ORTEP drawing of a portion of the anion of $\{[W_3Ag_3S_{12}]\}_n[Nd(Me_2SO)_8]_n$ with atomic labelling (20% displacement ellipsoids)

and 2.242 Å in $[\{Ag(PPh_3)\}_3WS_4\{S_2P(OEt)_2\}]$,[10] respectively. The average Ag–S length of 2.564 Å is comparable to the values observed in other polymeric complexes, such as 2.548 Å in $\{[W_4S_{16}Ag_4]\}_n[Ca(Me_2SO)_6]_n$,[8] 2.565 Å in $\{[WS_4Ag]\}_n[H_3NC(CH_2OH)_3]_n[H_2O]_n$,[7] and 2.543 Å in $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$.[9] However, the average W–Ag length of 2.970 Å is longer than those found in the linear chain complexes $\{[WS_4Ag]\}_n[H_3NC(CH_2OH)_3]_n[dmf]_{2n}$[7] (2.931 Å) and $\{[WS_4Ag]\}_n[NH_4]_n$[9] (2.928 Å), but comparable to those in $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$[9] (2.964 Å) and in $\{[W_4S_{16}Ag_4]\}_n$-$[Ca(Me_2SO)_6]_n$[8] (2.969 Å).

The single-crystal diffraction analysis shows that one trivalent cation $[Nd(Me_2SO)_8]^{3+}$ is related with the cyclic anionic unit $[W_3Ag_3S_{12}]^{3-}$. The trivalent cations $[Nd(Me_2SO)_8]^{3+}$ are arrayed among the anionic helical chains; these cations are well separated from each other and from the anionic chains. The packing diagram of the unit cell is shown in Fig. 3. Each $Nd^{III}$ atom is coordinated by eight $Me_2SO$ molecules. The average Nd–O bond length is 2.41 Å, and the O–Nd–O angles vary between 64.8(7) and 146.1(6)°; these are comparable to those of another trivalent complex cation $[Nd(dmf)_8]^{3+}$ (average Nd–O lengths of 2.43 Å and O–Nd–O angles between 70.4 and 144.8°) in $\{[W_4S_{16}Ag_5]\}_n[Nd(dmf)_8]_n$.[9] The shortest distance between two Nd atoms is 11.01 Å.

# Molecular and electronic structure of a mixed-valent class II, dinuclear complex containing a linear $[Fe^{II}–O–Fe^{III}]^{3+}$ core

**Michael Müller, Eckhard Bill, Thomas Weyhermüller and Karl Wieghardt***

*Max-Planck-Institut für Strahlenchemie, PO Box 101365, D-45413 Mülheim an der Ruhr, Germany*

**One-electron reduction of $[\{LFe^{III}(Ph_2acac)\}_2(\mu\text{-}O)][BPh_4]_2$ $\mathbf{1}[BPh_4]_2$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane, $Ph_2acac^-$ = 1,3-diphenylpropane-1,3-dionate) in $CH_2Cl_2$–toluene by 1 equiv. of cobaltocene produces the mixed-valent complex $[\{LFe(Ph_2acac)\}_2(\mu\text{-}O)][BPh_4]\cdot C_6H_5Me$ $\mathbf{2}[BPh_4]\cdot C_6H_5Me$ which is characterized by X-ray crystallography; 2 has an $S = \frac{1}{2}$ ground state (antiferromagnetically coupled high-spin $Fe^{III}$ and high-spin $Fe^{II}$ with $J = -65$ cm$^{-1}$) and exhibits class II behaviour according to the Robin and Day classification.**

Mixed-valent $Fe^{II}Fe^{III}$ forms have been spectroscopically identified for the non-haem metalloproteins hemerythrin, the R2 subunit of ribonucleotide reductase and methane monooxygenase.[1] In their active sites an antiferromagnetically exchange coupled pair of a high-spin iron(II) and a high-spin iron(III) bridged by a μ-hydroxo or a μ-oxo group give rise to a characteristic, EPR-active $S = \frac{1}{2}$ ground state with $g$ values $< 2.0$. We have recently reported the first μ-hydroxo bridged, mixed-valent complex $[L_2Fe_2(\mu\text{-}OH)(\mu\text{-}O_2CBu^t)_2][ClO_4]_2$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane) which displays a rhombic EPR signal at 10 K with $g$ values of 1.95, 1.52 and 1.43.[2] A structurally characterised dincuclear complex containing a linear $[Fe^{II}–O–Fe^{III}]^{3+}$ core has not been described to date. Here we report the molecular and electronic structure of such a species.

The reaction† of $[LFe^{III}Cl_3]$[3] and potassium 1,3-diphenylpropane-1,3-dionate (1 : 1) in MeCN–$H_2O$ (8 : 1) yields upon addition of $NEt_3$ and $NaClO_4$ orange crystals of $[\{LFe^{III}(Ph_2acac)\}_2(\mu\text{-}O)][ClO_4]_2$ $\mathbf{1}[ClO_4]_2$ which was converted to $\mathbf{1}[BPh_4]_2$ by metathesis. One-electron reduction of $\mathbf{1}[BPh_4]_2$ in dry $CH_2Cl_2$–toluene by 1 equiv. of cobaltocene† afforded deep-green microcrystals of $[\{LFe(Ph_2acac)\}_2(\mu\text{-}O)]BPh_4\cdot C_6H_5Me$ $\mathbf{2}[BPh_4]\cdot C_6H_5Me$ which crystallises in the triclinic space group $P\bar{1}$ with two formula units per unit cell.‡ Two independent μ-oxo atoms [O(1) and O(4)] lie on a crystallographic centre of symmetry and, consequently, both $Fe^{II}$–O–$Fe^{III}$ cores are linear. The methylene carbon atoms C(1)–C(6) of the macrocyclic amine coordinated to Fe(1) and Fe(1′) display small, 'normal' anisotropic thermal parameters ($U_{eq} \approx 0.029$ Å$^2$) whereas those of the corresponding atoms of the macrocycle coordinated to Fe(2) and Fe(2′) are significantly larger ($U_{eq} \approx 0.062$ Å$^2$). The five-membered Fe–N–C–C–N chelate rings adopt either (λλλ) or (δδδ) conformation. In the monocation composed of Fe(1) and Fe(1′) these two conformations are related by a crystallographic inversion centre and the resulting achiral *meso* isomer is ordered (Fig. 1). In contrast, the other cation comprising Fe(2) and Fe(2′) shows a static disorder because the two enantiomeric forms, (λλλ)FeFe(λλλ) and (δδδ)FeFe(δδδ), occupy this position. Note that a statistical ratio of the two diasteriomeric forms of 1 : 1 is expected from the synthesis. The $Fe–O_{oxo}$ distances at 1.877(1) and 1.901(1) Å are slightly longer than in oxo-bridged diiron(III) complexes (*ca.* 1.80 Å).[4]

The cyclic voltammogram of $\mathbf{1}[ClO_4]_2$ in MeCN (0.1 M $NBu_4PF_6$) in the potential range +1.3 to −1.8 V *vs.* $Fc^+$–Fc displays one reversible one-electron transfer wave at $E_{1/2} = -0.966$ V *vs.* $Fc^+$–Fc which is assigned to the couple **1**–**2**.

From temperature-dependent magnetic susceptibility measurements using a SQUID magnetometer (4–300 K) an $S = 0$ ground state was established for $\mathbf{1}[ClO_4]_2$ with $J = -95$ cm$^{-1}$, $g = 2.0$ (fixed) and a paramagnetic impurity ($S = 5/2$) of 2,6% ($H = -2J\cdot S_1\cdot S_2$, $S_1 = S_2 = 5/2$). This antiferromagnetic coupling is typical for complexes with a linear $[Fe^{III}–O–Fe^{III}]^{4+}$ core.[4] For $\mathbf{2}[BPh_4]\cdot C_6H_5Me$ a similar antiferromagnetic coupling was detected yielding an $S = \frac{1}{2}$ ground state with $J = -65$ cm$^{-1}$, $g = 2.0$ (fixed) ($S_1 = 5/2$, $S_2 = 2$) and a weakly coupled ($J = -10$ cm$^{-1}$) dincuclear $Fe^{II}_2$ impurity of 5% which most probably corresponds to the fully reduced, μ-OH bridged form of **2**.

The $S = \frac{1}{2}$ ground state for $\mathbf{2}[BPh_4]\cdot C_6H_5Me$ was confirmed by its X-band EPR-spectrum measured at 4 K in $CH_2Cl_2$. A rhombic signal is observed (Fig. 2) at $g$-values of 1.99, 1.93 and 1.84. In contrast, $\mathbf{1}[ClO_4]_2$ is EPR silent.§ The rhombic signal of **2** displays a significantly narrower spread of $g$-values as compared to the μ-hydroxo bridged $Fe^{II}Fe^{III}$ species in ref. 1. This observation agrees nicely with spectra reported for the mixed-valent μ-oxo- and μ-hydroxo-bridged mixed-valent forms of the R2 subunit of ribonucleotide reductase, methane monooxygenase and hemerythrin.[1]

The electronic spectrum of $\mathbf{2}[BPh_4]$ in $CH_2Cl_2$ solution displays an intervalence absorption maximum at 635 nm ($\varepsilon = 1.2 \times 10^3$ M$^{-1}$ cm$^{-1}$) which is absent in the spectrum of **1**. A similar but much weaker maximum has been observed at 1350 nm ($\varepsilon = 138$ M$^{-1}$ cm$^{-1}$) for the μ-hydroxo bridged analogue.[2]

Temperature-dependent zero-field Mössbauer spectra of crystalline samples of $\mathbf{1}[ClO_4]_2$ and $\mathbf{2}[BPh_4]\cdot C_6H_5Me$ characterise **2** as a class II mixed-valent species.

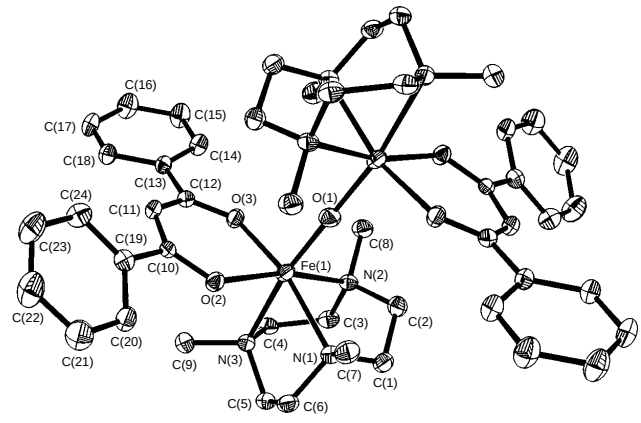

**Fig. 1** Structure of one of the monocations in crystals of $\mathbf{2}[BPh_4]\cdot C_6H_5Me$ at 100(2) K (the ordered *meso* form is shown). Selected bond lengths (Å) and angles (°) with estimated standard deviations in parentheses: Fe(1)–O(1) 1.877(1), Fe(1)–O(2) 2.063(2), Fe(1)–O(3) 2.056(2), Fe(1)–N(1) 2.232(3), Fe(1)–N(2) 2.234(3), Fe(1)–N(3) 2.341(3); Fe(1)–O(1)–Fe(1′) 180.

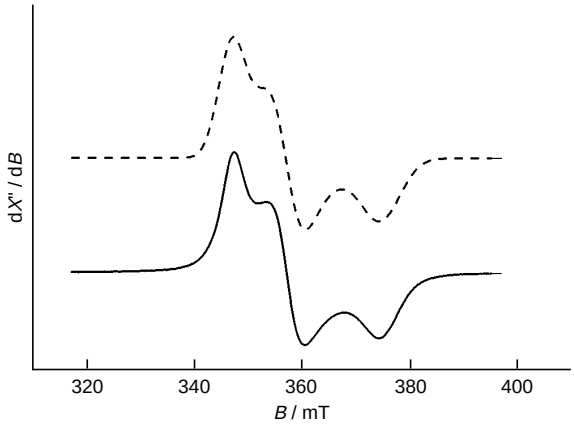

**Fig. 2** X-Band EPR spectrum of **2**[$BPh_4$]·$C_5H_5Me$ in $CH_2Cl_2$ at 4 K: the solid line represents the experimental spectrum and the dashed line is a simulation with $g_x$ = 1.99, $g_y$ = 1.93, $g_z$ = 1.84 (with linewidths: $w_x$ = 2.93, $w_y$ = 3.30, $w_z$ = 4.12 mT).

At temperatures > 200 K the spectra of **2** consist of a symmetric quadrupole doublet with isomer shift δ = 0.78 mm $s^{-1}$ and quadrupole splitting $\Delta E_Q$ = 0.37 mm $s^{-1}$. This value of δ is intermediate between that of **1** (δ = 0.48 mm $s^{-1}$, $\Delta E_Q$ = 1.30 mm $s^{-1}$ at 80 K) and that of the diiron(II) reference compound [$L_2Fe^{II}_2$(μ-OH)(μ-$O_2$CMe)$_2$][$ClO_4$][5] (δ = 1.15 mm $s^{-1}$ at 77 K). Due to the observed temperature-dependent line broadening in the spectrum of **2** we propose that this species exhibits class-II type[6] dynamic valence detrapping of the [$Fe^{II}$–O–$Fe^{III}$]$^{3+}$ core with electron hopping at 200 K being fast on the Mössbauer timescale ($10^{-7}$ s) rather than quantum-mechanical valence delocalisation (class III).[7] The Mössbauer linewidths of **2** increase drastically with decreasing temperature (Γ = 0.47 mm $s^{-1}$ at 200 K, 0.76 mm $s^{-1}$ at 160 K and 1.16 mm $s^{-1}$ at 120 K). Further lineshape distortions at temperatures < 40 K can be assigned to the onset of spin-relaxation processes. Therefore, it is not possible to record unperturbed quadrupole spectra in the slow limit of electron hopping at cryogenic temperatures (< 10 K).

## Footnotes

† *Preparation of complexes*: To a mixture of MeCN (80 ml) and water (10 ml) was added [$LFe^{III}Cl_3$] (1.0 g, 3.0 mmol) and K[$Ph_2$acac] (1.0 g, 3.8 mmol) with stirring at ambient temperature. To the deep-red solution were added a few drops of $NEt_3$. After 2 h of stirring the orange–yellow solution was filtered and $NaClO_4$ (1.0 g) was added. Within a few days orange crystals of **1**[$ClO_4$]$_2$ were obtained in 67% yield (1.10 g). **1**[$BPh_4$]$_2$ was prepared from an acetone solution of **1**[$ClO_4$]$_2$ by adding $NaBPh_4$.

The following reduction was performed under strictly anaerobic conditions (argon) using Schlenk glassware. A solution of **1**[$BPh_4$]$_2$ (0.3 g, 0.20 mmol) and [Co(η-$C_5Me_5$)$_2$] (0.05 g, 0.25 mmol) in dry, deoxygenated $CH_2Cl_2$ (40 ml) was stirred at room temp. for 30 min. From the deep-green solution yellow microcrystals of [Co(η-$C_5H_5$)$_2$][$BPh_4$] precipitated which were filtered off under argon. After addition of dry, $O_2$-free toluene (40 ml) and reduction of the reaction volume by slow evaporation deep-green crystals of **2**[$BPh_4$]·$C_6H_5Me$ precipitated (0.05 g, 20%) which were suitable for X-ray crystallography. Satisfactory elemental analyses for all complexes were obtained.

UV–Vis spectra: **1**[$ClO_4$]$_2$ in MeCN: $\lambda_{max}$ = 283 nm (ε = 3.9 × $10^4$ $M^{-1}$ $cm^{-1}$), 367 (2.9 × $10^4$), 432 (1.65 × $10^4$), 510 (2.2 × $10^3$).

**2**[$BPh_4$]·$C_6H_5Me$ in $CH_2Cl_2$: $\lambda_{max}$ = 228 nm (2.5 × $10^4$ $M^{-1}$ $cm^{-1}$), 362 (1.7 × $10^4$), 635 (1.2 × $10^3$).

‡ *Crystal data*: $C_{79}H_{92}BFe_2N_6O_5$ **2**[$BPh_4$]·$C_6H_5Me$, $M$ = 1328.1, triclinic, space group $P\bar{1}$, $a$ = 11.193(2), $b$ = 15.181(3), $c$ = 22.123(3) Å, α = 83.30(2), β = 88.76(2), γ = 69.77(2)°, $U$ = 3502.5(10) $Å^3$, $Z$ = 2, $D_c$ = 1.259 g $cm^3$, λ(Mo-Kα) = 0.710 73 Å, $F$(000) = 1410, μ = 0.47 $mm^{-1}$, $T$ = 100(2) K, 11311 independent reflections were used in the refinement of which 7254 were observed [$F_0 > 4\sigma(F_0)$]; $R$ = 0.053.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/391.

§ The sample investigated displayed a weak signal at $g$ = 4.3 at 10 K due to the mononuclear impurity ($S$ = 5/2).

# Formation of $H_2SO_4$ from $SO_3$ and $H_2O$, catalysed in water clusters

**E. V. Akhmatskaya, C. J. Apps, I. H. Hillier, A. J. Masters, N. E. Watt and J. C. Whitehead***

*Chemistry Department, University of Manchester, Manchester, UK M13 9PL*

**Computer simulations predict the facile conversion of $SO_3$ to $H_2SO_4$ in small water clusters having in excess of about twelve solvent molecules, in line with experiment.**

The gas-phase reaction of $SO_3$ with water vapour is considered to be the final stage in the tropospheric oxidation of $SO_2$ to form acid rain and sulfuric acid aerosols. These are important in heterogeneous stratospheric chemistry and ozone depletion, and also in climatology through the nucleation of cloud droplets in the lower troposphere which can scatter both incoming solar radiation and IR radiation from the Earth's surface.

Recent *ab initio* calculations[1] have shown that the barrier for the 1 : 1 reaction of $H_2O + SO_3$ is quite high (32 kcal $mol^{-1}$, cal = 4.184 J), and is considerably lowered (to 11.5 kcal $mol^{-1}$) by the catalytic effect of a second water molecule, enabling a six-membered transition state to be achieved. It is of interest from the point of view of atmospheric chemistry to know the minimum number of water molecules, in a water cluster containing $SO_3$, needed to allow for the facile formation of sulfuric acid.

Studies of reactions using aqueous clusters are a convenient way to study the transition from the gas phase to the condensed liquid phase and thereby investigate the effect of solvation on the dynamics of a reaction in a controlled and systematic manner. Hofmann–Sievert and Castleman[2] have studied the gas-phase reaction of $SO_3$ with small water clusters ($n$ = 2–10) and we first report here an experimental study of the reactivity of $SO_3$ attached to larger water clusters ($n \approx 200$). The details of the experiment have been fully described previously.[3,4] Briefly, a single $SO_3$ molecule is deposited using the pick-up method onto a large water cluster formed by a supersonic molecular beam expansion of pure water vapour at *ca* 1.2 bar. Downstream from the expansion region the beam is detected by an electron-impact ionisation quadrupole mass spectrometer after a flight time of *ca*. 0.5 ms. The mass spectrum (Fig. 1) of pure gas-phase $SO_3$ and of the $SO_3(H_2O)_{200}$ cluster, clearly show the $SO_3$ to be converted into $H_2SO_4$ by reaction with the cluster. A similar behaviour was found by Hofmann-Sievert and Castleman[2] for the smaller clusters and the identity of the reaction product confirmed with electric deflection studies.

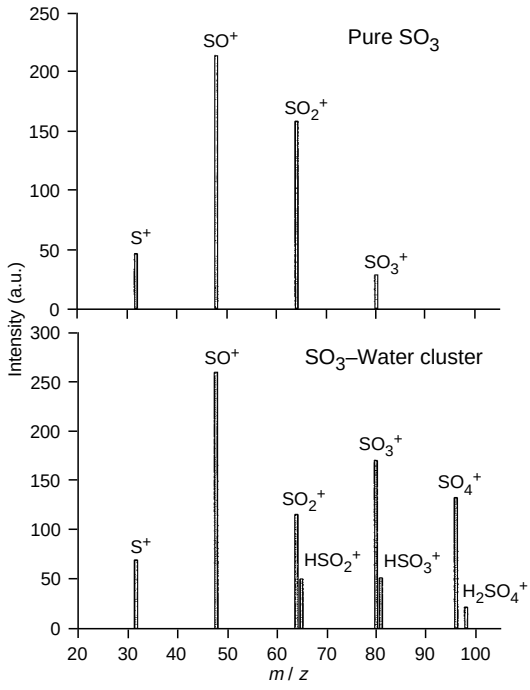

**Fig. 1** Comparison of the mass spectrum for gas-phase $SO_3$ (upper panel) with $SO_3$ attached to a water cluster. The pick-up source pressure was 7 mbar and the water clusters were formed at a stagnation pressure of *ca*. 1.2 bar.

Thus the cluster beam studies show that the conversion to sulfuric acid is a facile process, although the theoretical study with just two water molecules suggests a considerable barrier for the reaction in the $SO_3(H_2O)_2$ cluster. To understand the extent to which further solvation of the $SO_3(H_2O)_2$ cluster may affect the barrier height we have carried out Monte Carlo simulations of the $SO_3(H_2O)_{2+n}$ cluster, in which the calculated ground- and transition-states of the $SO_3(H_2O)_2$ cluster are solvated by a further $n$ water molecules described by a molecular mechanical potential. In brief, the structures of the $SO_3(H_2O)_2$ moiety, predicted from the *ab initio* calculations are kept fixed, the appropriate atomic charges for them are obtained by the usual CHELPG method,[5] using a 6-311 + G(d,p) basis, and the $n$ solvating water molecules are described by a TIP3P potential.

The calculated charge distribution of the $SO_3(H_2O)_2$ entities predicts a greater polarity for the transition state, leading to a correspondingly greater average intermolecular interaction in the $SO_3(H_2O)_2(H_2O)_n$ cluster containing the transition state compared to reactant. With ten additional water molecules we find this differential transition-state stabilisation to be 10.0 kcal $mol^{-1}$, from the Monte Carlo simulation. This quantity will essentially counterbalance the internal energy difference (11.5 kcal $mol^{-1}$) identified by the *ab initio* calculations on $SO_3(H_2O)_2$. Thus we predict that $SO_3$, solvated by approximately twelve water molecules will be converted to sulfuric acid with little or no energy barrier.

Thus, although it has long been recognised that bulk solvent can have profound effects on the rate of chemical reactions, we here show that in fact large catalytic effects can be achieved in quite small solvent clusters.

We thank EPSRC and NERC for support of the research.

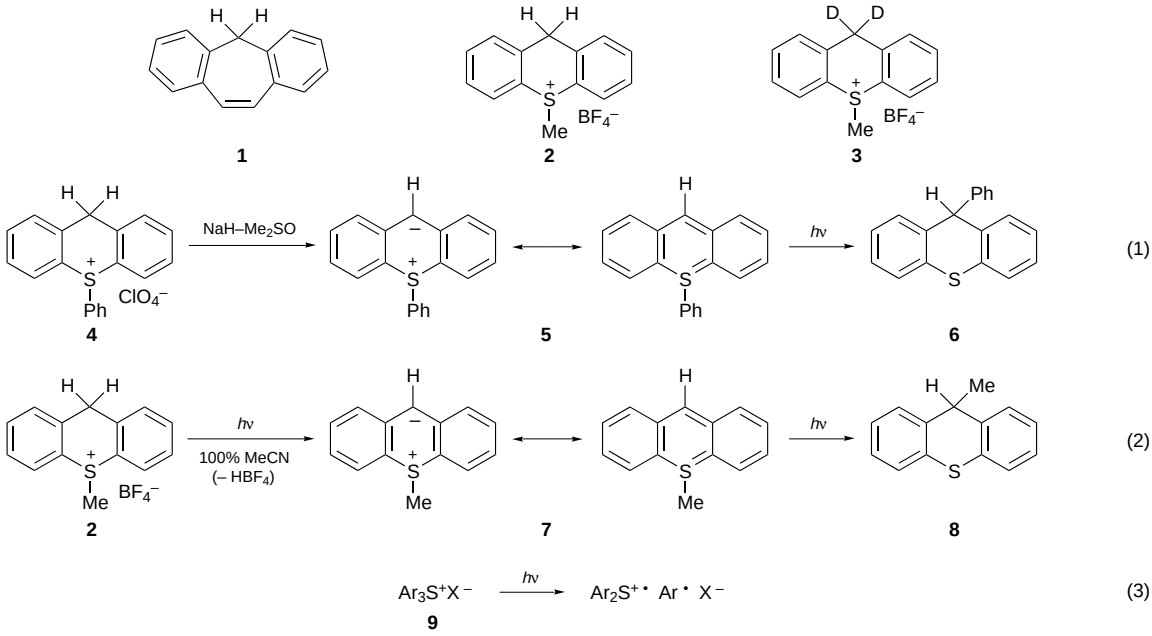
# Excited state carbon acids: irreversible photodeprotonation of the benzylic protons of 10-methyl- and 10-phenyl-thioxanthenium salts

**Darryl Brousmiche, Deepak Shukla and Peter Wan***



*Department of Chemistry, Box 3065, University of Victoria, Victoria, British Columbia, Canada V8W 3V6*

**The first examples of irreversible photodeprotonation of a C–H bond to generate a formal carbanion, *via* photolysis of thioxanthenium salts, is reported, which gives the corresponding sulfonium ylide (thiaanthracene) and acid ($HBF_4$ or $HClO_4$).**

Carbanions and their associated carbon acids are of fundamental importance in chemistry. Carbanions are most commonly generated *via* deprotonation of the corresponding carbon acid although this process is generally slow.[1] We have reported[2] that the benzylic protons of dibenzosuberene **1** and related compounds are vastly more acidic in the excited singlet state than in the ground state, and hence can be deprotonated efficiently by water (in MeCN; $k_d$ *ca.* $2 \times 10^8$ $dm^3$ $mol^{-1}$ $s^{-1}$) on excitation, to give a formally antiaromatic (8π) carbanion. Photodeprotonation rates approaching the diffusion controlled limit have been measured using primary amines such as ethamine as deprotonating base.[3] However, in all cases reported so far the deprotonation is entirely reversible; direct evidence for carbanion formation was obtained by observation of deuterium exchange of the methylene protons with deuteriated solvent in recovered substrate. Attempts to detect the intermediate carbanion by nanosecond laser flash photolysis have so far been unsuccessful, presumably due to the very short lifetimes (in the ground state) of these photogenerated, formally anti-aromatic, (8π) carbanions. One approach in making the photodeprotonation step irreversible is to make the incipient carbanion longer lived or designing a carbanion that once formed rearranges to a stable product. To this end, we have chosen to study the potential excited state carbon acid behaviour (of the benzylic protons) of 10-methylthioxanthenium tetrafluoroborate, **2** and **3**, and 10-phenylthioxanthenium perchlorate **4**, systems that have the required 8π (anti-aromatic) electron count in the internal cyclic π-array for the incipient carbanion.† We show that photolysis of these compounds in MeCN results in efficient deprotonation of the benzylic proton, giving rise to a long-lived formal carbanion (an ylide), and formation of $HBF_4$ or $HClO_4$. As such, these are the first examples of excited state carbon acids that undergo irreversible dissociation of the C–H proton, with detectable formation of acid.

The thioxanthenium salts **2**–**4** were made according to procedures published by Mislow and co-workers.[4] Treatment of **2** and related thioxanthenium salts with available benzylic protons with a strong base (*e.g.* NaH–$Me_2SO$ or an organometallic reagent) is known to result in deprotonation of the benzylic proton, to give the unstable but highly coloured thiaanthracene **5** ($\lambda_{max}$ = 388 and 497 nm), which subsequently rearranges to the corresponding stable 9-substituted thioxanthene **6** [eqn. (1)].[4,5] The half-lives of some thiaanthracenes generated in basic $Me_2SO$ range from 1 min to several hours at 22 °C.[4b] These results indicate that the p$K_a$s of the benzylic protons of these compounds are significantly lower than those of thioxanthene or dibenzosuberene **1**, which have estimated p$K_a$s in the 30–35 range.[2]

Photolysis of initially colourless $10^{-3}$ M solutions of **2**–**4** in dry MeCN (254 nm; argon-purged solutions) gave deep orange solutions, with visible absorption bands at *ca.* 380 and 485 nm (Fig. 1). No changes were observed without photolysis. These visible bands are identical to those observed for known thiaanthracenes (*e.g.* **5**).[4] However, whereas thermally generated thiaanthracenes in basic media are relatively short-lived, when photogenerated in 100% MeCN, they show no evidence of decay for several days. Additional evidence that thiaanthracenes are indeed photogenerated was obtained by taking the

$^1$H (300 MHz) NMR spectrum of an exhaustively photolysed sample of **2** in $CD_3CN$ (254 or 300 nm; 45–60 min), which showed formation of **8** with yields of up to 60% [eqn. (2)]. The thermal rearrangement of thiaanthracenes under basic conditions to the more stable 9-substituted thioxanthenes is well-known, as discussed above. It seems reasonable to propose that formation of **8** from **7** in an exhaustively photolysed sample of **2** is due to secondary photolysis of **7**. Indeed, the UV–VIS absorption bands of **7** (Fig. 1) was readily bleached when irradiated at 366 nm. A quantum yield of *ca.* 0.1 was measured (at low conversion) for the formation of **7** from **2** in MeCN using UV–VIS spectrophotometry to monitor the progress of the reaction ($\lambda_{excit}$ = 280 nm; potassium ferrioxalate actinometry).

Formation of **7** from photolysis of **2** in 100% MeCN‡ implies loss of a proton from the benzylic position to form $HBF_4$. The increase in acidity of a photolysed solution in 100% MeCN was monitored by diluting aliquots at various photolysis times (at 254 nm) with an equal volume of $H_2O$ and measuring the pH. An initial pH of 4.5 was observed which decreased to pH 3.4 after 5 min of photolysis, which represents about 50% conversion. No changes in pH were observed without photolysis. These results are consistent with excited state carbon acid deprotonation of the benzylic protons of **2**. That this deprotonation step is in fact the product forming step was the finding that the corresponding deuteriated substrate **3** gave a reduced amount of **7**, as monitored by UV–VIS spectrophotometry. This can be quoted as an isotope effect on the quantum yield for forming **7**, *viz.* $\Phi_H/\Phi_D$ = 1.39 ± 0.05, which is a small primary isotope effect for C–H(D) bond cleavage. We have observed a similarly small primary isotope effect for benzylic C–H(D) bond cleavage for dibenzosuberene **1** using ethanolamine as deprotonating base in which the rate is close to the diffusion controlled limit.[3] The small isotope effect was interpreted as being due to an earlier transition state for proton removal by ethanolamine compared to water as base.[3] In the present case, we believe thioxanthenium salts **2**–**4** have early transition states for photodeprotonation of the C–H bond although additional studies are warranted to substantiate this claim.

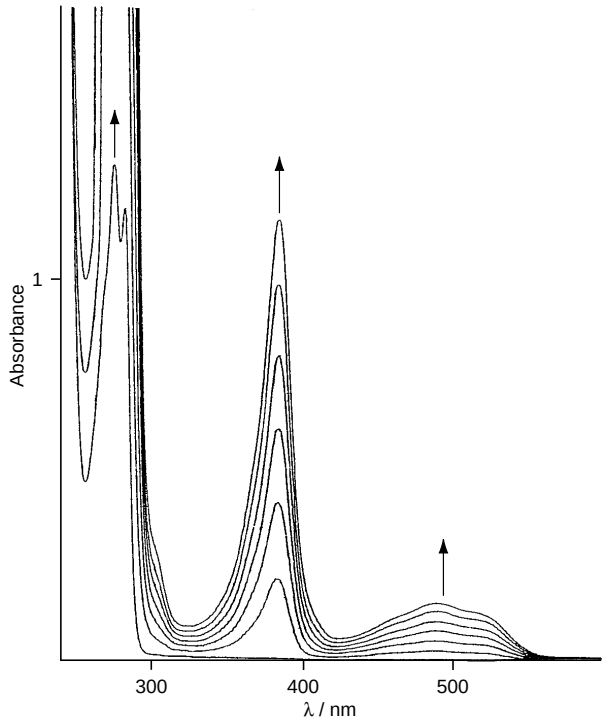


**Fig. 1** UV–VIS traces showing formation of thiaanthracene **7** (visible bands at 383 and 485 nm) from photolysis of **2** in 100% MeCN ($\lambda_{excit}$ = 254 nm; each trace represents about 15 s photolysis)

Recent intense interest in the photochemistry of triaryl and trialkyl sulfonium salts is due to the fact that photolysis of many of these compounds results in efficient generation of a strong Brønsted acid which effectively initiates cationic polymerization and is therefore useful in photoimaging systems and related applications.[6] The commonly accepted mechanism[6] for Brønsted acid production in the photochemistry of triarylsulfonium salts **9** (and for some mixed alkylaryl systems) is the initial aryl–sulfur bond homolysis, to generate an aryl (or alkyl) radical and a diarylsulfinium radical cation [eqn. (3)].§ Subsequent transformations of these species gives rise to the observed Brønsted acid. For example, intramolecular recombination of the radical pair *via* radical attack of Ar· onto one of ring positions of $Ar_2S^{+\cdot}$ results in overall loss of a proton from that ring position.[6a,b] Indeed, we are aware of two reports[6e,f] which show that photolysis of **2** and **4** results in generation of acid *via* the commonly accepted mechanism discussed above for triarylsulfonium salts. However, the results of our study demonstrate that photoacid production from these compounds arises from excited state carbon acid dissociation which may be regarded as a new mechanism for the production of Brønsted acid from photolysis of triarylsulfonium salts.

We acknowledge support of this research by the Natural Sciences and Engineering Research Council (NSERC) of Canada. D. B. thanks the University of Victoria for a graduate fellowship.

## Footnotes

† All dissociating excited state carbon acids reported by us[2,3] so far require an incipient carbanion that is cyclically delocalized with 8π electrons. One of the lone pairs of the sulfur atom of **2**–**4** is used for bonding with the methyl or phenyl group while the second lone pair of electrons can come into π conjugation on deprotonation of the benzylic proton giving rise to an 8π system, which is formally an ylide or a thiaanthracene.

‡ We have avoided photolysis in aqueous MeCN and other protic solvents owing to the possibility of thermal solvolytic decomposition of the substrates.

§ However, Crivello and Lam[6d,g–i] and Crivello and Lee[6d,j] have shown that the mechanisms for photoacid generation from dialkylphenacylsulfonium and dialkyl-4-hydroxyphenylsulfonium salts involve formal loss of a C–H and O–H proton, respectively, rather than *via* the standard mechanism shown in eqn. (3). The mechanism for the deprotonation from the C–H bond in the former does not appear to involve an excited state carbon acid.[6d,j]

**The centred icosahedral twelve-coordinate samarium cluster formed by six bis(L-prolinato)nickel(II) ligands is synthesized and its crystal structure determined.**

Heteronuclear and/or polynuclear complexes are interesting materials due to their structures and properties. Various preparation methods have been proposed in order to obtain such polynuclear complexes. One such method was the preparation of complexes from the interaction of two or more moles of *cis*-$[M(am)_4(OH)_2]^+$ [where $(am)_4$ is a single tetradentate amine ligand, two bidentate amines, or four monodentate amines] with metal halides; [1–4] the bis-hydroxo complexes which are used as ligands can be coordinated to the other metals *via* the hydroxo oxygen atoms. Recently Winpenny and coworkers have reported studies where they have attempted to link mononuclear and/or small polynuclear compounds into larger units; especially, they have been exploring the coordination chemistry of ligands derived from 2-hydroxypyridine (2-pyridone) with first-row transition metals.[5–12] In this work, an amino acid complex was used as a ligand in order to synthesize a new heteronuclear complex.

Amino acids have two or more types of coordination atoms and can act as various bridging ligands.[13–19] Taking advantage of the properties of the amino acid ligands, the synthesis of an amino acid bridging heterometal complex was applied. A lanthanoid ion, a hard acid, and a bis-amino acidato complex were chosen for the purpose of preparing the heterometal complex, and they were mixed in a non-aqueous solvent with poor coordination ability.

The samarium–nickel complex containing bis(L-prolinato)-nickel(II) moieties $[Ni(pro)_2]$: synthesized according to a modified published procedure for $Cu(pro)_2$ [20]] was prepared by reacting 1 mmol of samarium perchlorate dissolved in 20 $cm^3$ of methanol with a six-fold excess of $[Ni(pro)_2]$. Evaporation of the solvent gave purple tetrahedral crystals of $[Sm\{Ni(pro)_2\}_6][ClO_4]_3\cdot 6MeOH$.†

Four $ClO_4^-$ ion sites must exist in the unit cell, since the crystals are cubic (space group: $F23$) and the $ClO_4^-$ ions lie on the three-fold axes. However, this contradicts the result of gravimetric analysis for $ClO_4^-$ using tetraphenylarsonium chloride [Found: 12.33%. Calc. for $[Sm\{Ni(pro)_2\}_6][ClO_4]_3\cdot 6MeOH$, 12.63%]. Therefore, the occupancy of each $ClO_4^-$ site was fixed at 0.75 when the structure was refined.

The methanol molecules are considered to be loosely trapped in the lattice, as revealed by their extremely large thermal parameters, which leads to immediate decomposition upon filtering.

The coordination environments around the Sm and Ni atoms in the complex is shown in Fig. 1 and a stereoscopic view is shown in Fig. 2. Each nickel atom is surrounded by six atoms: two amino nitrogens, two carboxylate oxygens, which form chelate rings with the nitrogen atoms, and two carboxylate oxygen atoms which link the neighbouring nickel atoms. The samarium atom is coordinated to twelve oxygen atoms. The six $Ni(pro)_2$ units are coordinated to the icosahedral metal centre *via* two chelating carboxylate oxygen atoms.

By contrast to most twelve-coordinate complexes which are distorted icosahedral owing to restricted ligand bite size, $[Sm\{Ni(pro)_2\}_6]^{3+}$ shows icosahedral geometry, owing to the larger bite size of the $Ni(pro)_2$ moieties. All the Sm–O bond lengths are 2.691(3) Å, while the average of the nearest neighbouring O···O is 2.83 Å (ratio O···O/Sm–O = 1.05); angles between two adjacent metal–ligand bonds are in the range 62.8(3)–65.1(1)° (av. = 63.4°); *cf.* ideal icosahedral angle between two adjacent metal(M)–ligand(L) bonds of 63.43° and ideal ratio of L–L/M–L of 1.0515.[21] Lanthanoid ions capable of forming twelve-coordinate compounds are $La^{3+}$,[22]

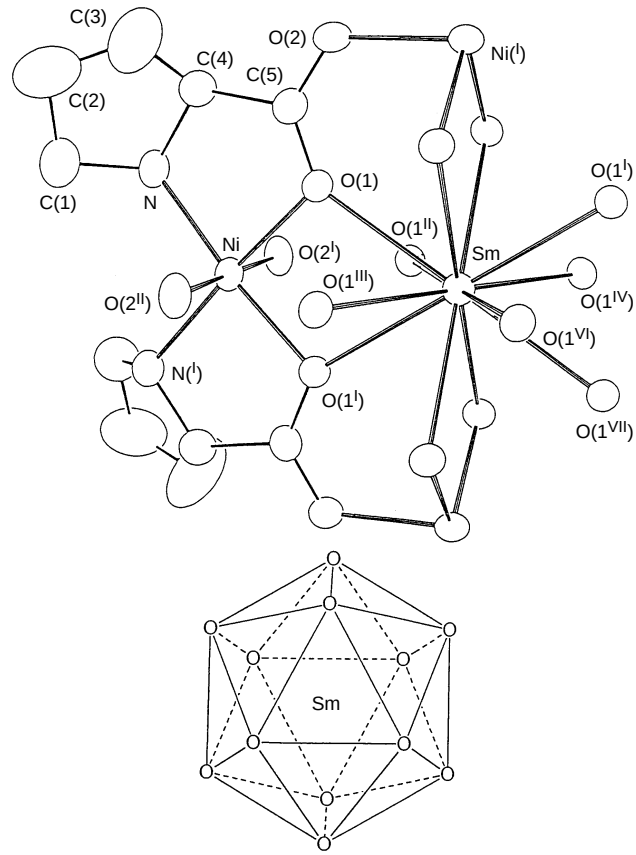

**Fig. 1** ORTEP plot around the Sm and Ni atoms in $[Sm\{Ni(pro)_2\}_6]^{3+}$ showing 50% thermal ellipsoids in the atom numbering scheme. Selected bond distances (Å) and angles (°): Sm–O(1) 2.688(3), Ni–O(1) 2.026(3), Ni–O(2) 2.053(4), Ni–N 2.060(5), O(1)–C(5) 1.295(7), O(2)–C(5) 1.234(7), N–C(1) 1.57(1), N–C(4) 1.496(8), C(1)–C(2) 1.46(2), C(2)–C(3) 1.43(2), C(3)–C(4) 1.37(3), C(4)–C(5) 1.514(8), O(1)–O(1I) 2.874(7), O(1)–O(1II) 2.77(2), O(1)–O(1III) 2.86(2); O(1)–Sm–O(1I) 64.6(1), O(1)–Sm–O(1II) 62.0(4), O(1)–Sm–O(1III) 64.3(4), O(1)–Sm–O(1IV) 116.6(1), O(1)–Sm–O(1V) 115.4(1), O(1)–Sm–O(1VI) 117.11(9), O(1)–Sm–O(1II) 178.5(5), O(1)–Ni–O(1I) 90.4(2), O(1)–Ni–O(2I) 90.1(4), O(1)–Ni–O(2II) 89.1(4), O(1)–Ni–N 84.4(2), O(1)–Ni–NI 172.5(4), O(2II)–Ni–N 85.4(5), O(2II)–Ni–NI 95.2(5), N–Ni–NI 101.2(3), Ni–O(1)–C(5) 114.5(4), NiI–O(2)–C(5) 123.5(3), O(1)–C(5)–O(2) 126.3(5).

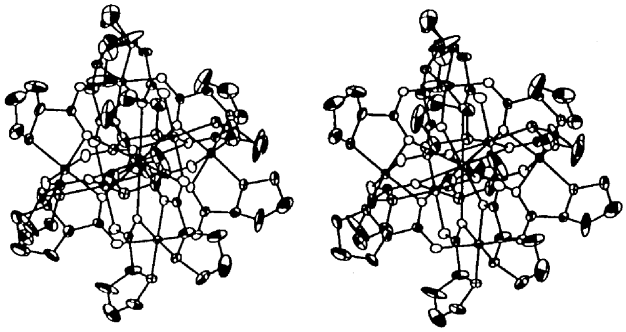

**Fig. 2** Stereoscopic view of $[Sm\{Ni(pro)_2\}_6]^{3+}$

$Ce^{3+}$,[23] $Ce^{4+}$,[24] $Pr^{3+}$,[25] and $Nd^{3+}$[26] whereas it is very difficult to prepare twelve-coordinate complexes of samarium even with $NO_3^-$. Very recently a 'twelve-coordinate' Sm complex with tris[3-(2-pyridyl)pyrazol-1-yl]hydroborate (L), $[SmL_2]BPh_4$, was reported.[27] However, half of the twelve Sm–N bond lengths in the complex are extremely long: av. 2.95 Å *cf.* 2.66 Å (av.) for the shorter set of bonds. Therefore, the complex reported here is very novel. The samarium–oxygen bond lengths in the present complex, 2.691(3) Å, are a little longer than in other eleven- and ten-coordinate samarium complexes,[28–30] which may arise from restriction imposed by the $6[Ni(pro)_2]$ cage structure and the high coordination number.

It was confirmed that the icosahedral cluster structure was retained after loss of methanol molecules from the crystals, based on diffraction data of slightly decayed crystals. Moreover, the structure was also retained in alcohol and acetonitrile solutions; UV–VIS spectra of solutions are perfectly consistent with the powder diffuse reflection spectrum. Cyclic voltammetry‡ of the complex in acetonitrile exhibited reversible waves at *ca.* −1.5 V and complicated irreversible waves at > 0.5 V. The reversible waves imply that $Sm^{3+}$ in the complex shows a Nernstian reduction. The complicated irreversible waves suggest that the nickel atoms interact with each other and that the icosahedral cluster structure may decompose when $Ni^{2+}$ is oxidized to $Ni^{3+}$ in the $Ni(pro)_2$ units.

Future work will be aimed at investigating the magnetochemistry of this complex.

We wish to express our gratitude to Professor F. S. Howell of Sophia University for correcting the manuscript. The present work was supported by Grants-in-Aid for Scientific Research on Priority Area 'New Development of Rare Earth Complexes' Nos. 08220224, 07230230, and 06241228 from the Ministry of Education, Science, Sports and Culture.
