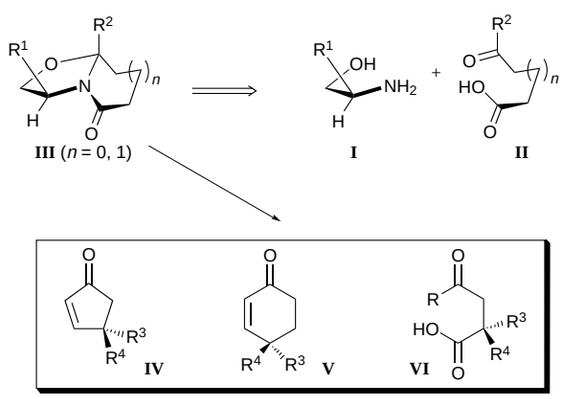
# Chiral bicyclic lactams: useful precursors and templates for asymmetric syntheses[1]



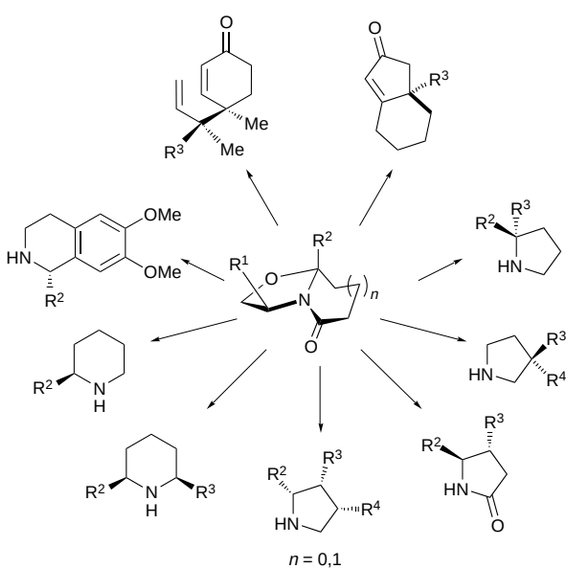
**A. I. Meyers and Gregory P. Brengel**

*Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523, USA*

**A survey of the utilitarian bicyclic lactams is presented. These chiral templates have provided, and continue to provide, access to a plethora of natural and unnatural carbocyclic products in high enantiomeric purity. Their synthetic versatility has recently grown with the development of new methods for the construction of heterocycles. In addition to the cyclopentenone, cyclohexenone and hexahydroindenone systems, products derived from bicyclic lactams now include optically active piperidines, pyrrolidines, pyrrolidinones and tetrahydroisoquinolines. These favourable properties make the bicyclic lactams highly adaptable tools for asymmetric synthesis.**

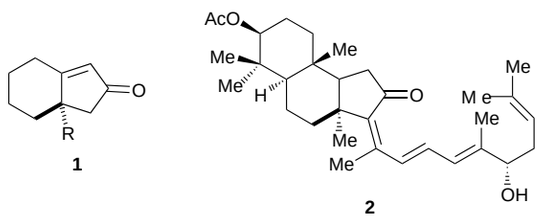
Some recent progress achieved through the use of chiral, nonracemic bicyclic lactams **III** ($n$ = 0,1) has demonstrated that they are extremely useful and versatile building blocks for the preparation of a host of enantiomerically enriched, natural and unnatural products.[2] The preparation of these templates from their corresponding enantiomerically pure amino alcohols **III**, and their earlier utility in the synthesis of compounds containing quaternary stereocentres such as cyclopentenones **IV**, cyclohexenones **V** and carboxylic acids **VI**, has been previously reviewed (Scheme 1).[2a,d]

The synthesis of enantiopure carbocycles, which until recently was the major focus of our program, continues to serve as a vital goal for the development of new synthetic methods *via* bicyclic lactams. Examples of these included in the present discussion will describe enantiopure hexahydroindenones, benzindenones and cyclohexenones containing contiguous stereogenic centres (Scheme 2). The discovery that nitrogen-containing heterocycles could also be efficiently generated from these chiral lactams stimulated recent studies directed toward the syntheses of optically active pyrrolidine and piperidine derivatives. Thus, the reader will find that a large portion of this brief outline has been dedicated to the development and application of methods for the syntheses of enantiopure heterocyclic compounds from 5,5- and 5,6-bicyclic lactams (*vide infra*).



**Scheme 1**

## Recent syntheses of chiral non-racemic carbocycles



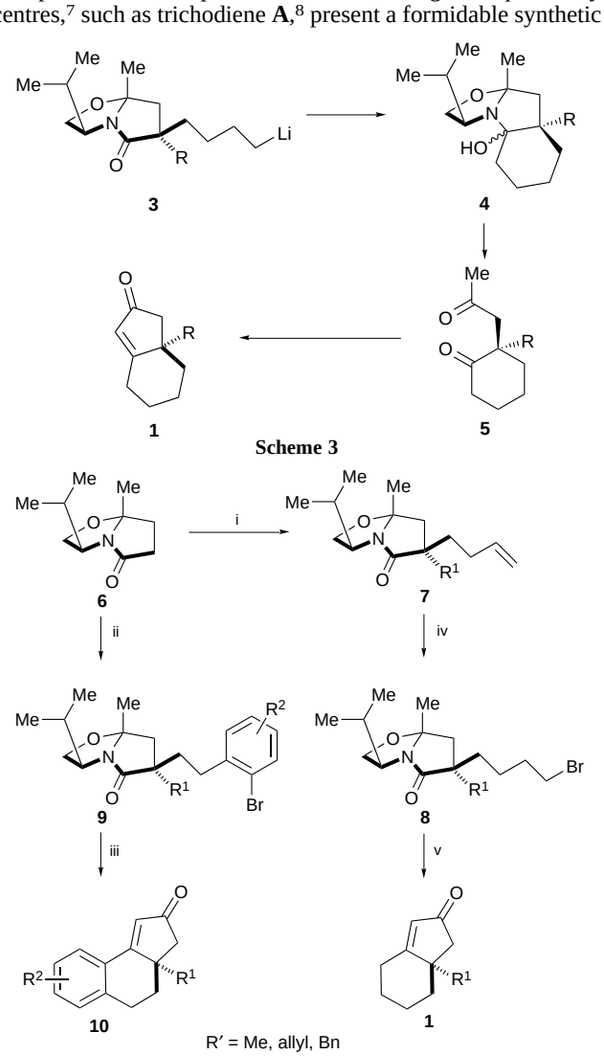
### *Hexahydroinden-2-ones and benz[e]inden-2-ones*

The hexahydroindenone ring system **1**, present in a number of naturally occurring compounds (*e.g.* Stelliferin A **2**[3]) was identified as a viable target for the bicyclic lactams. Since the preparation of enantiopure 3,3-disubstituted cyclopentenones *via* the bicyclic lactam had already been accomplished,[2a,c,h] modifications to access this ring system were investigated (Scheme 3).[4] The requisite bicyclic lactam **3**, which could undergo intramolecular cyclization affording the intermediate alcohol **4**, would serve as a key precursor. After hydrolysis and condensation to **5**, this should provide the desired tetrahydroindenone **1**.

The bromo lactam **8** was prepared *via* a two step process shown in Scheme 4. Thus, alkylation of bicyclic lactam **6** with butenyl bromide, followed by a second *endo* alkylation with an appropriate electrophile, afforded good yields of dialkylated product **7**.[2a,4] The latter was converted to the bromide **8** *via* hydroboration–oxidation followed by bromination in good overall yields. Metal–halogen exchange yielded the alcohol **4** *via* the organolithium **3** (Scheme 3). Hydrolysis to the diketone **5**, followed by base-catalysed condensation, produced optically

**Scheme 2**

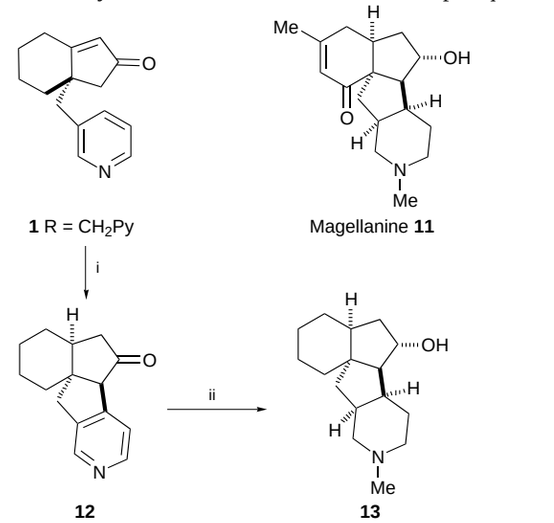
pure hexahydroindenones **1** in modest overall yields. Similarly, alkylation of **6** with the appropriate aryl bromides furnished lactams **9**, and the D ring of the Stelliferin class was accessed in a single step providing the benzindenones **10**. Because epimerization of the quaternary centres was not possible, diastereomerically pure lactams **8** and **9** provided enantiomerically pure products. Further elaboration of **10** should yield Stelliferin A **2**.



*Application of hexahydroindenones to the magellanine framework*

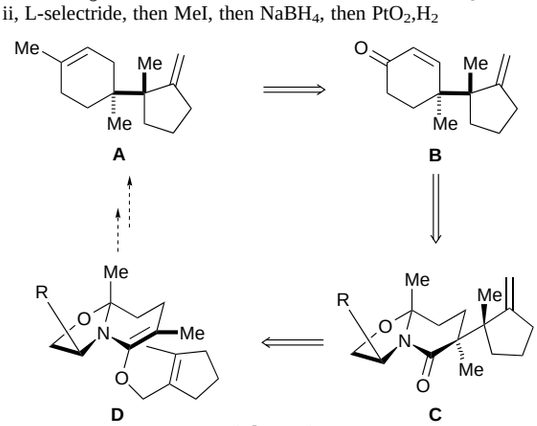
The above sequence leading to the hexahydroindenones has recently been applied to the construction of the Magellanine ring system **11** (Scheme 5).[5] The pivotal compound was the hexahydroindenone **1** (R = $CH_2Py$), which was obtained optically pure by hydrolysis–cyclization of diastereomerically pure lactam **7** (R = $CH_2Py$). Indenone **1** was cyclized *via* an intramolecular 1,4-addition of its enolate to the *N*-acylpyridinium salt and, after reoxidation, gave **12**. Successive stereoselective reductions provided the Magellanine framework **13**, whose structure was confirmed by single crystal X-ray analysis. The synthesis provided (−)-**13** in 13 steps from bicyclic lactam **6**, from which all of its six stereocentres had been derived.

*4,4-Disubstituted cyclohexenones with vicinal stereocentres*[6]



Compounds which possess vicinal stereogenic quaternary centres,[7] such as trichodiene **A**,[8] present a formidable synthetic challenge. Since one might imagine that this compound could be derived from the cyclohexenone **B**, it was envisioned that a bicyclic lactam might serve as a template for its synthesis (Scheme 6). Employment of the 5,6-bicyclic lactam, previously utilized in the synthesis of a number of optically active 4,4-disubstituted cyclohexenones,[2a,e] was feasible only if the properly substituted precursor **C** was available. Since the quaternary stereocentres could not be prepared through the usual dialkylation sequences, it was necessary to seek other means of installing these substituents with the correct stereochemistry. Undoubtedly, some form of the Claisen rearrangement (*e.g.* **D** → **C**) could produce the desired result. Unfortunately, lactam **14** could not, after numerous attempts, be directly *O*-alkylated to afford the Claisen precursor **16** (X = O) (Scheme 7). However, it was soon found that thiolactam **15**, obtained by treatment of **14** with Belleau's reagent,[9] underwent *S*-alkylation quite readily. Formation of the thioenolate with base, followed by addition of the appropriate allylic halides, produced the thioethers **16** (X = S) in good yields. The desired thio-Claisen rearrangement was smoothly implemented *via* thermal conditions to provide the rearranged thiolactams **17**.[10] The facial selectivity of the (3,3)-rearrangement was generally quite high, and the configuration of the new stereocentre was found to result from rearrangement on the *exo* face of the lactam. This is contrary to the *endo* selectivity normally observed during enolate alkylations of other 5,5- and 5,6-bicyclic lactams, however, this appears to be consistent with similar results obtained with these lactams of the type **14**.[2a,j] The subtle factors responsible for *exo* or *endo* selectivity with these lactams are still a matter of continuing investigation.†

The α,α-dialkylated thiolactams **17** were successfully transformed to the cyclohexenones **20** *via* the three step sequence



**Scheme 3**

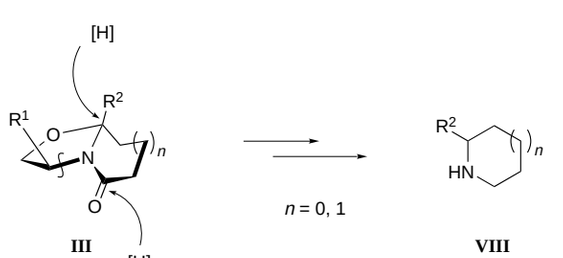
shown in Scheme 8. Generation of the thioiminium salts **18**, followed by reduction and hydrolysis, afforded the keto aldehydes **19** which were directly subjected to aldol cyclization to yield the optically pure ketone **20**, possessing vicinal quaternary centres in good overall yields.

### Syntheses of chiral non-racemic heterocycles



These highly useful[11a–c] substances should be readily obtained if the nitrogen atom present in the chiral auxiliary could be preserved in the final products **VIII** (Scheme 9). This was accomplished by simultaneous reduction of both the carbonyl and aminal centres in the lactams **III**, and was realized for both the 5,5- and 5,6-bicyclic systems. In this manner, enantiomerically pure pyrrolidines and piperidines **VIII** ($n$ = 0,1) were prepared (*vide infra*).

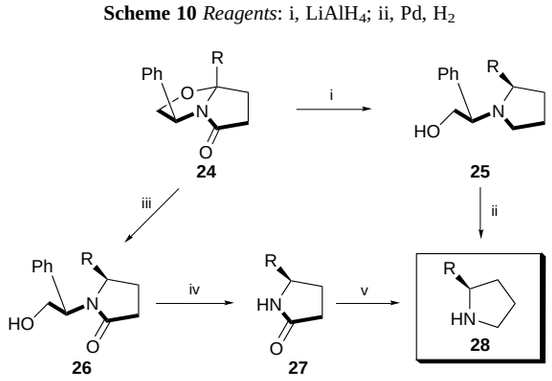
### *Chiral pyrrolidines and pyrrolidinones*



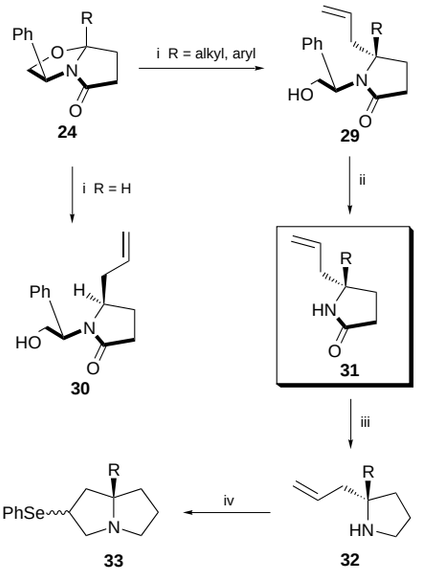
(i) *3-Substituted and 3,3-disubstituted pyrrolidines.* It was found that a number of angular hydrogen, dialkylated bicyclic lactams **21**,[2a] the utility of which had previously been demonstrated in the syntheses of chiral 5,5-disubstituted cyclopentenones,[2c] were simply and efficiently manipulated to provide enantiomerically pure 3,3-disubstituted pyrrolidines **23** (Scheme 10).[12] Specifically, the latter were obtained by reduction of lactams **21** with lithium aluminium hydride, followed by hydrogenolysis of the chiral auxiliary. It was noteworthy that monoalkylated lactams **21** ($R^1$ or $R^2$ = H) were also reduced, with no evidence of epimerization α to the lactam carbonyl group, to provide 3-substituted pyrrolidines **23** ($R^1$ or $R^2$ = H), in high optical purity.

(ii) *2-Substituted pyrrolidines and 5-substituted pyrrolidinones.* The angularly substituted, 5,5-bicyclic lactams **24** could be efficiently converted to 2-substituted pyrrolidines **28** and/or 5-substituted pyrrolidinones **27** by either of two short synthetic sequences (Scheme 11). Thus, treatment of lactam **24** directly with alane, or lithium aluminium hydride, reduced both the carbonyl and aminal centres to the pyrrolidines **25**, as single diastereomers. Hydrogenolysis of the nitrogen benzyl linkage then led to the free 2-substituted pyrrolidines **28** in good overall yields with greater than 98% enantiomeric purity.[11a] The utility of this sequence was recently demonstrated in the total asymmetric syntheses of the natural antibiotics (−)-irniine [R = $(CH_2)_9$Ph] and (−)-bgugaine [R = $(CH_2)_{13}$Me] by Jossang and co-workers.[13]

Alternatively, reduction of **24** by addition of triethylsilane and titanium tetrachloride to pyrrolidinone **26** (Scheme 11), followed by removal of the chiral auxiliary under dissolving metal conditions, provided the corresponding 5-substituted pyrrolidinones **27**, once again in high enantiomeric purity.[11a,14a,b] The pyrrolidinones, if desired, could be further reduced to the 2-substituted pyrrolidines **28**.[14c] Interestingly, both routes yielded pyrrolidines with the same absolute stereochemistry, namely, retention of configuration at the angular position in the lactams **21**.

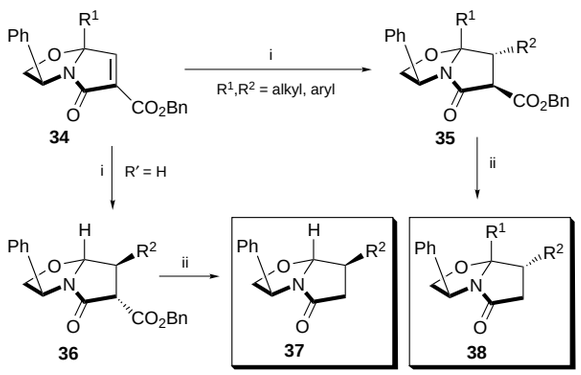
**Scheme 10** *Reagents*: i, $LiAlH_4$; ii, Pd, $H_2$

**Scheme 11** *Reagents*: i, '$AlH_3$'; ii, Pd, $H_2$; iii, $Et_3SiH$, $TiCl_4$; iv, $Li^0$–$NH_3$; v, $LiAlH_4$



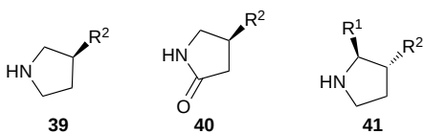
Although this stereochemical result was predictable for the alane reductions, having been previously observed in acetal cleavages,[15] it was surprising for the triethylsilane–titanium(IV) chloride system. Previous studies suggested that this reduction should have occurred in an $S_N2$ fashion to provide products with inversion of stereochemistry.[15] Fortunately, allylsilane additions to both angular hydrogen and angularly substituted bicyclic lactams **24** (Scheme 12) furnished some insight into the mechanism for these reductions (*vide infra*).

(iii) *2,2-Disubstituted pyrrolidines and 5,5-disubstituted pyrrolidinones.* In addition to hydride reductions, it was found that allylsilanes, under strong Lewis acidic conditions, could also be induced to add at the angular position of 5,5-bicyclic lactams **24** to furnish the disubstituted pyrrolidinones **29** and **30** (Scheme 12).[16] As seen for the hydride reductions, when R was either an alkyl or aryl substituent, the addition arose from *endo* entry to the lactam forming products with retention of configuration at the former angular position. Conversely, when the angular substituent was hydrogen, the observed stereochemistry was that from *exo* attack, or inversion of configuration. The chiral auxiliary in **29** may be cleaved under dissolving metal conditions to afford the 5,5-disubstituted pyrrolidinones **31** in good yield and with high enantiomeric excess. Again, if desired, pyrrolidinones **31** may be further reduced to pyrrolidines **32**. As an example of the utility of the newly installed allyl group, cyclization of pyrrolidines **32** was performed affording the backbone of the pyrrolizidine alkaloids **33**,[16b] an important class of natural products due to their potent biological activity.

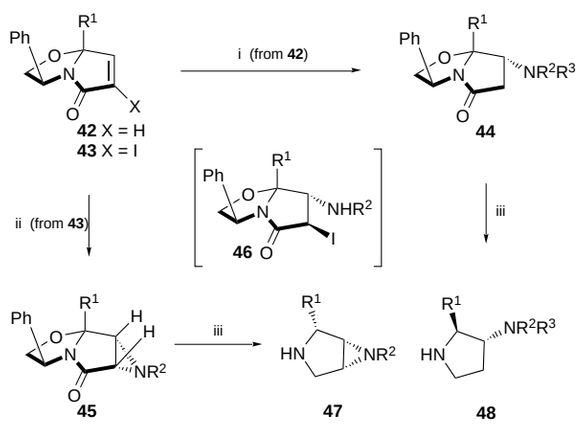


(iv) *Reactions with unsaturated 5,5-bicyclic lactams*. One of the most useful lactam substrates to date has been the unsaturated system **34** (Scheme 13)[2,17] The alkenic moiety has provided a functional handle on which a host of transformations have been carried out, including conjugate additions by various nucleophiles, pericyclic reactions,[2] and oxidations (*vide infra*). These transformations have proved invaluable in placing substituents in the 3- and 4-positions of both pyrrolidines and pyrrolidinones.

(v) *2,3*-trans-*Disubstituted pyrrolidines and 4-substituted and 4,5-disubstituted pyrrolidinones.* Lower order lithiocyanocuprates were found to efficiently add in a 1,4 fashion to activated unsaturated bicyclic lactams **34** producing **35** and **36** in good yields and high diastereoselectivities (Scheme 13).[18a,b] When the angular substituent in **34** was alkyl or aryl, addition proceeded mainly from the *endo* (α) face of the lactam, whereas the angular hydrogen lactams led to products resulting from *exo* (β) addition (**36**). This duality in the stereochemical outcome had been previously observed in cycloadditions to these unsaturated lactams,[2] and is believed to be primarily due to the steric effects created by the angular substituents. The benzyloxycarbonyl group ($R^2$ = $CO_2Bn$), which was found to be necessary for the cuprate additions, was efficiently removed *via* hydrogenolysis and decarboxylation. The resulting lactams **37** and **38** were subsequently converted to the corresponding pyrrolidines **39** and **41** respectively, or pyrrolidinones **40**, by one of the following sequences (Scheme 14).



(vi) *2-Alkyl-3-amino- and 3,4-aziridino-pyrrolidines.* The 3-aminopyrrolidine **48** and 3,4-aziridinopyrrolidine **47** moieties are present in a diverse array of biologically active molecules,[19] and it was believed that these systems could be accessed *via* the unsaturated bicyclic lactam templates. It was observed that a series of primary and secondary amines efficiently added to the β-position of unsaturated lactams **42** to give the amino lactams **44** (Scheme 15).[19a] As previously seen with the cuprate additions, lactams bearing angular substituents (R = alkyl, aryl) led to products resulting from *endo* attack. The groups on the amine could be either chiral or achiral with no effect on the stereoselectivity. Surprisingly, the reaction was found to be irreversible. Thus, if the amino lactam adduct **44** was treated with base, generating the enolate, expulsion of the amine was

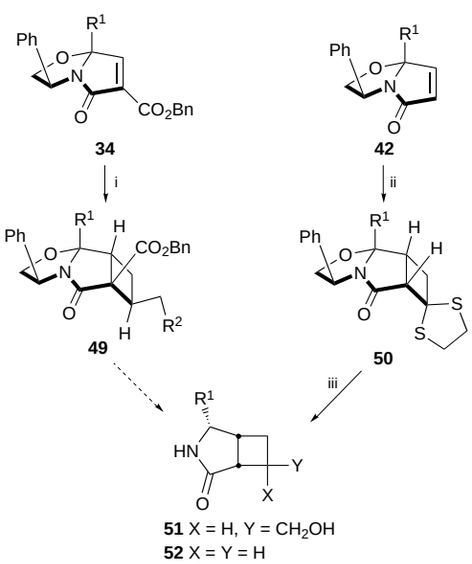


**Scheme 12** *Reagents*: i, (allyl)$SiMe_3$, $TiCl_4$; ii, $Li^0$–$NH_3$; iii, '$AlH_3$'; iv, PhSeSePh

**Scheme 13** *Reagents*: i, $R^2{}_2CuLiCN$; ii, Pd, $H_2$

**Scheme 14** *Reagents*: i, '$AlH_3$', then Pd, $H_2$; ii, $Et_3SiH$, $TiCl_4$, then $Li^0$–$NH_3$

**Scheme 15** *Reagents*: i, $R^2R^3NH$; ii, $R^2NH_2$; iii, '$AlH_3$', then Pd, $H_2$



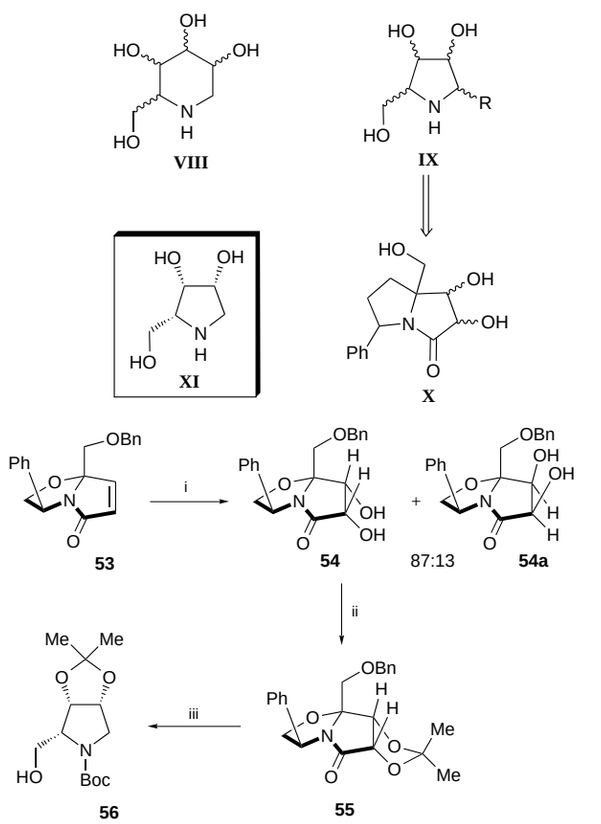
not observed, yet the enolate could be alkylated with an electrophile. This behaviour allowed for further elaboration of the pyrrolidine products (*vide infra*). However, by incorporating an α-halogeno substituent on the unsaturated lactam **43**,[17a] such as iodine, additions of primary amines efficiently led to aziridino products **45**, resulting from nucleophilic displacement of the halide *via* adduct **46**.[19b]

Both the amino and aziridino lactams were transformed to *trans*-2-alkyl-3-aminopyrrolidines **48** and *cis*-2-alkyl-3,4-aziridinopyrrolidines **47**, respectively, by the procedure identical to that used for the preparation of the other chiral pyrrolidine systems (*vide supra*).

(vii) *5-Alkyl-3,4-cyclobutanopyrrolidinones.* Organocuprate reagents and amines were not the only nucleophiles found to efficiently add to the unsaturated bicyclic lactams in a Michael fashion. During continuing studies to develop a diverse array of optically active pyrrolidines, the annulations of 2-methylenedithiolanes and allylsilanes with chiral bicyclic lactams were also investigated (Scheme 16).[20]

2-Methylenedithiolane, in the presence of dimethylaluminium chloride, added to unsaturated lactams **42** affording cyclobutanes **50** in high yields and as single diastereomers after chromatography.[20a] Although the removal of the thioketal to give the cyclobutanone derivatives failed, the dithioacetal could be reduced to the cyclobutane fused lactam, which was readily converted to the pyrrolidinones **52** *via* standard auxiliary removal procedures (*vide supra*). This Lewis acid-mediated annulation is complementary to the earlier photochemical additions of ethylene,[2a] and furthermore, these chiral cyclobutanopyrrolidinones **52** are potentially useful constrained GABA analogues.

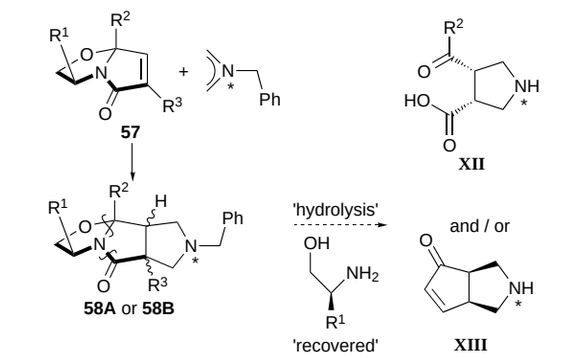
Additions of allylsilanes to the unsaturated ester lactams **34** unexpectedly led to cyclobutane adducts **49** (Scheme 16).[20b] This was surprising in view of earlier reports of allylsilane annulations leading only to cyclopentanes. In fact, the silacyclobutane fused lactams **49** were among the first confirmed examples of this reaction manifold, which until recently was seriously questioned.[21] Although the cyclobutanes derived from triisopropylallylsilane ($R^2$ = $Pr^i_3Si$) are resistant to further chemical manipulation, the trityldimethylsilacyclobutanes ($R^2$ = $Ph_3CMe_2Si$) should allow ready substitution of the silicon moiety by a hydroxy substituent[22] to access chiral hydroxycyclobutanes of type **51**. Studies are currently in progress to evaluate these systems.



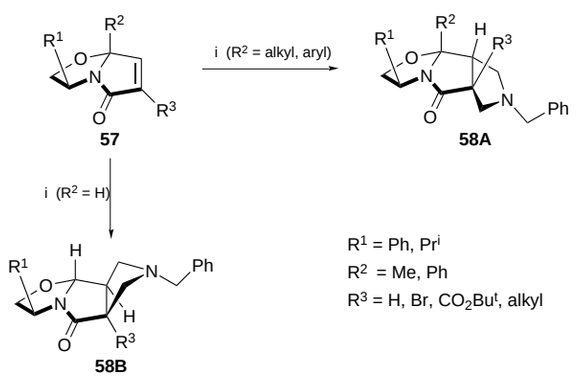
**Scheme 16** *Reagents*: i, (allyl)$R^2$ ($R^2$ = $SiPr^i_3$, $SiMe_2CPh_3$), $TiCl_4$; ii, 2-methylenedithiolane, $Me_2AlCl$, iii, Raney Ni, then $Et_3SiH$, $TiCl_4$, then $Li^0$–$NH_3$

(viii) *Chiral azasugars.* Azasugars **VIII** and **IX** are representative of a general class of compounds that have been reported to exhibit many biological properties including antitumour and anti-HIV activity. As a result, a great deal of interest has recently been generated in developing methods for their efficient syntheses.[23]

In view of this, 1,4-dideoxy-1,4-imino-D-lyxitol **XI** was selected as a target. In order to establish the correct absolute and relative stereochemistry of the hydroxymethyl and hydroxy substituents, the appropriate unsaturated lactam **53** was prepared (Scheme 17). The key step required installation of the *vic*-hydroxy groups in a *syn* fashion to the *endo* face of the lactam. This *cis* dihydroxylation was indeed accomplished, using *N*-methylmorpholine *N*-oxide (NMO) as an oxidant with a catalytic amount of osmium tetroxide, furnishing an 87 : 13 mixture of diastereomers **54** and **54a**. The major product **54**, predicted to be *endo* based on previous additions to unsaturated lactams, was readily separated from its *exo* epimer **54a** providing diastereomerically pure material. After protection of the diol as the acetonide **55**, the key reduction step was addressed. The reduction at the aminal centre required that inversion of configuration take place, in a stereoselective manner, to afford the correct stereochemistry of the hydroxymethyl substituent in **56**. Inversion at the angular position during reductions had been previously observed in the syntheses of cyclobutanes **51** and aziridines **47** (*vide supra*). It was anticipated that the cyclic acetonide **55** would serve as a blocking group and force reduction from the β-face. This was indeed the case, as reduction of **55** with 9-BBN produced, after hydrogenolysis of the auxiliary and protection of the nitrogen, the all-*cis* pyrrolidine **56** as a single diastereomer. Thus **56**, simply a protected version of **XI**, was prepared in a total of eight steps in 12% overall yield in high enantiomeric purity.

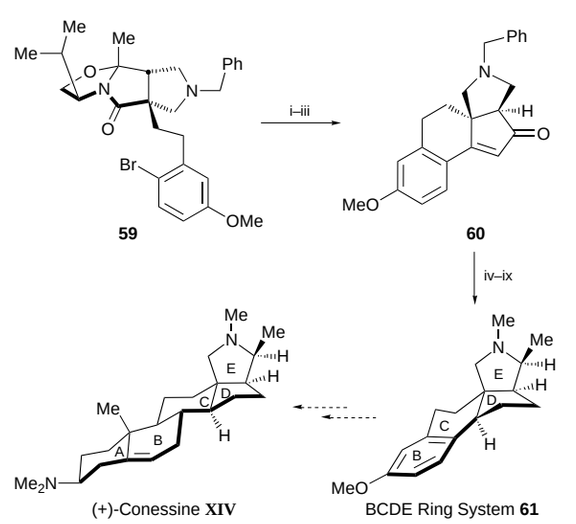


(ix) *3,4*-cis-*Disubstituted pyrrolidines.* It was anticipated that by fusing a pyrrolidine ring to the bicyclic lactam, *via* some type



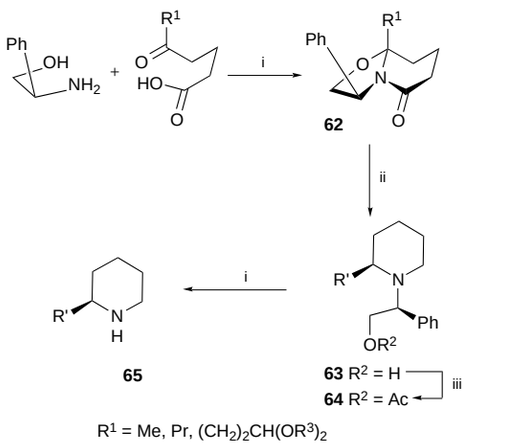
**Scheme 17** *Reagents*: i, $OsO_4$, NMO; ii, 2,2-dimethoxypropane, iii, 9-BBN, then Pd, $H_2$, $Boc_2O$

of [3 + 2] cycloaddition process, recovery of the amino alcohol auxiliary would be possible while still maintaining a nitrogen heteratom in the product. Thus, hydrolysis of the lactam adducts **58**, as previously demonstrated in earlier examples,[2a] would lead to the keto acids **XII** or cyclopentenones **XIII** (Scheme 18). In this manner, the requisite pyrrolidine ring would be in hand, and the amino alcohol auxiliary would not have to be sacrificed.

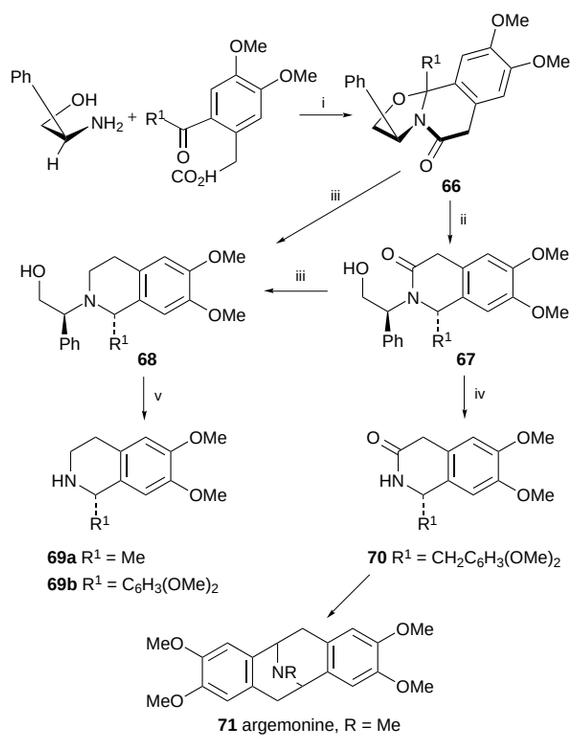


To this end, a study of the cycloaddition of azomethine ylides to chiral unsaturated bicyclic lactams was undertaken.[24] The ylides[25] led to high yields of cycloadducts **58A** and **58B** after addition to a variety of substituted bicyclic lactams **57** (Scheme 19). Once again, the angular substituent $R^2$ was the primary factor in determining *endo* or *exo* selectivity.

**Scheme 18**



**Scheme 19** *Reagents*: i, $(Me_3SiCH_2)(MeOCH_2)(Bn)N$, TFA

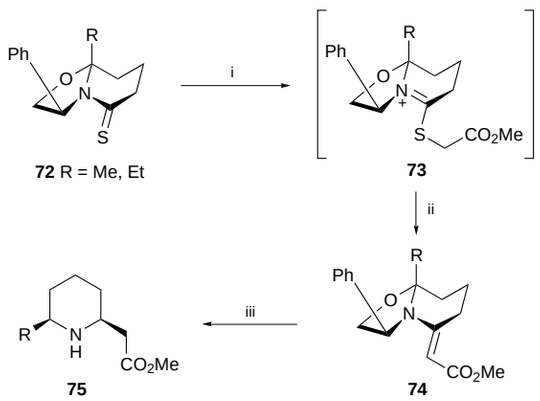


**Scheme 20** *Reagents*: i, $Bu^tLi$; ii, $Bu_4NH_2PO_4$; iii, NaOEt; iv, '$AlH_3$'; v, PhOCOCl; vi, $Bu^tOK$; vii, Pd, $H_2$; viii,$Bu^sLi$, MeI; ix, $LiAlH_4$

(x) *Asymmetric synthesis of conanine BCDE ring system.* (+)-Conessine **XIV**, a known amebicide, is just one in a family of alkaloids isolated from *Holarrhena antidysenterica*.[26] Common to each alkaloid in this family is the Conanine BCDE framework **61**, which contains a 3,4-disubstituted pyrrolidine subunit. A successful asymmetric synthesis of this structure would aptly demonstrate the versatility and utility of the chiral lactam template in pyrrolidine syntheses (Scheme 20).[27] The key step in implementing this sequence was the formation of cycloadduct **59**, containing the necessary bromoaryl side chain and the newly installed pyrrolidine E ring. The latter came directly from an azomethine cycloaddition to the appropriately functionalized unsaturated lactam **57** [$R^2 = (CH_2)_2Ar$].[18b] Other key steps in the synthesis involved construction of the BCD rings. This was accomplished *via* a method previously demonstrated for the preparation of the benz[*e*]inden-2-one ring system.[3] Metal–halogen exchange of aryl bromide **59**, followed by spontaneous cyclization, hydrolysis and aldol condensation, provided the requisite benzindenone **60** in high yield and in enantiomerically pure form. Reduction of the carbonyl group,

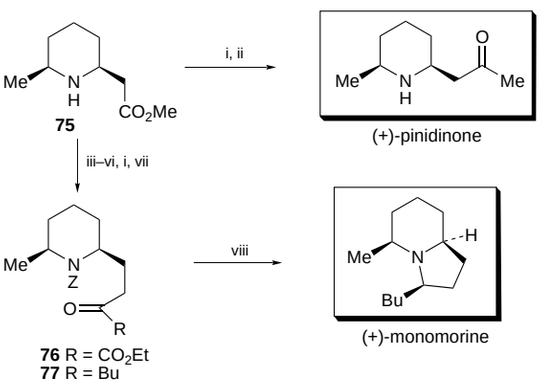
**Scheme 21** *Reagents*; i, heat; ii, Red-Al, heat; iii, $Ac_2O$; iv, $Pd(OH)_2$, $H_2$

**Scheme 22** *Reagents*: i, heat; ii, Red-Al; iii, $LiAlH_4$; iv, $Na^0$–$NH_3$; v, Pd, $H_2$



selective hydrogenation of the unsaturated C–D ring fusion and stereoselective alkylation of the pyrrolidine E ring resulted in the first asymmetric synthesis of the conanine BCDE framework **61**, in optically pure form and in 8% overall yield from **57**. Further elaboration of this framework to (±)–conessine **XIV** has previously been demonstrated.[26]

### *Piperidines and tetrahydroisoquinolines*



(i) *2-Substituted piperidines.* The presence of the piperidine ring system in a host of naturally occurring and biologically active alkaloids has generated considerable interest in the development of new methods for the preparation of these compounds in optically pure form.[11b,c,28a] Due to the success in the preparation of a number of enantiomerically pure pyrrolidines from 5,5-bicyclic lactams **III** ($n$ = 0), it was felt that similar techniques could be applied to the related 5,6-bicyclic lactam.

Red-Al reduction of a number of angular alkyl 5,6-bicyclic lactams **62**, derived from δ-keto acids as shown, furnished the piperidine derivatives **63** in good yields and with high diastereomeric excess (Scheme 21).[28b] Retention of configuration of the angular substituent in **62** was again maintained in the major piperidine products **63**. In all cases, the diastereomers, once converted to the acetates **64**, could be purified to provide, after hydrogenolysis of the chiral axuiliary, the enantiopure 2-substituted piperidines **65** in only two steps from the bicyclic lactam **62**. The efficient and versatile nature of this piperidine synthesis was featured in the total synthesis of natural (−)-pipecoline **65** ($R^1$ = Me), (+)-coniine **65** ($R^1$ = Pr), and the 1-azabicyclic system, (−)-coniceine.[28b,c]

(ii) *1-Substituted tetrahydroisoquinolines.* Owing to the successful preparation of 2-substituted piperidines from simple angular alkyl 5,6-bicyclic lactams **62**, it was proposed that 1-substituted tetrahydroisoquinolines **69** could also be obtained from an appropriately functionalized 5,6-bicyclic lactam

**Scheme 23** *Reagents*: i, $BrCH_2CO_2Me$; ii, $P(OMe)_3$, $Et_3N$, heat; iii, $Pd(OH)_2$, $H_2$

**Scheme 24** *Reagents*: i, MeNHOMe·HCl, $AlMe_3$; ii, MeMgBr; iii, 2Cl; iv, $OH^-$; v, $(COCl)_2$; vi, $CH_2N_2$, AgO; vii, BuMgBr; viii, Pd, $H_2$

(Scheme 22). Although there are a number of routes to the 1-alkylisoquinolines, there are relatively few which install 1-aryl substituents.

The requisite 5,6-bicyclic lactam **66** was simply prepared from the corresponding 2-acylphenylacetic acid and (*S*)-phenylglycinol, and the previously utilized reduction sequence for the piperidines was employed. Thus, reduction of **66** with $LiAlH_4$ to the tetrahydroisoquinoline derivatives **68** occurred with high diastereomeric excesses (Scheme 22). Again, the major products (>95% de) were those with retention of configuration at the angular position of **66**. After purification of the diastereomers by chromatography, hydrogenolysis of the chiral auxiliary provided the tetrahydroisoquinolines **69** in optically pure form.[29a,c] The efficiency of this process was aptly demonstrated in the syntheses of both 1-alkyl- and 1-aryl-tetrahydroisoquinolines, (−)-salsolidine **69a** and (+)-cryptostyline II **69b**, respectively.

Treatment of bicyclic lactam **66** [$R^1$ = $CH_2C_6H_3(OMe)_2$] with Red-Al reduced only the aminal carbon to produce lactam **67** (Scheme 22). Removal of the chiral auxiliary under dissolving metal conditions afforded the free lactam **70** which was further elaborated, *via* reduction and cyclization, to enantiomerically pure (−)-argemonine.[29b]

(iii) *2,6-Disubstituted piperidines.* The presence of biologically active piperidines **71**, containing substitution at both the 2- and 6-positions, has prompted a number of laboratories to pursue new and efficient methods to access these systems in enantiomerically pure form.[11b,c]

If the thiolactam **72** could be induced to undergo an Eschenmoser contraction,[30] a means of transforming the carbonyl group to a carbon–carbon linkage, a useful intermediate for further elaboration might be in hand. In this regard, addition of methyl α-bromoacetate to thiolactams **72**, prepared from oxolactam **62** *via* the Belleau reagent,[9] afforded the intermediate thioiminium salts **73** which, on treatment with triethylamine and trimethyl phosphite, gave the vinylogous urethanes **74** in high yield (Scheme 23). Hydrogenation of **74** with concomitant reduction of the aminal carbon, the C=C, and the benzylic carbon was achieved in a single step using palladium hydroxide to afford the *cis*-2,6-disubstituted piperidines **75** as single enantiomers. The reducible centres were attacked from the *endo* face of the lactam to provide only the *cis* isomers, with net retention of configuration at the former aminal centre. It was also shown that the unsaturated linkage is reduced prior to the aminal linkage.

The synthetic value of piperidines **75** (Scheme 24) was clearly demonstrated in the efficient syntheses of two alkaloids, (+)-pinidinone and the ant trail pheromone (+)-monomorine.[11c,31]

## Conclusions

Bicyclic lactams **III** ($n$ = 0,1) have, once again, proven themselves to be extremely versatile in preparing a host of optically active products (*vide supra*). Their utility is perhaps best exhibited by the shear diversity of compounds (*e.g.* Schemes 1 and 2) that may be accessed through this single set of chiral templates. The ready availability of these building blocks,‡ and their inherent ability to provide a variety of enantiomerically pure carbocycles and heterocycles, makes these bicyclic lactams both an important and general tool for asymmetric synthesis.

**synthetic methods, asymmetric synthesis, heterocycles and total synthesis of natural products. He has been the recipient of the ACS Award in Creativity in Organic Synthesis (1985), an Arthur C. Cope Scholar (1987), and elected to the National Academy of Sciences (1994). He has been Associate Editor of the *Journal of the American Chemical Society* and currently is a University Distinguished Professor and holder of the John K. Stille Chair in Chemistry.**

**Gregory Philip Brengel was born on Long Island, New York in 1968. He received a Bachelors of Science in Chemistry (with honours) from Indiana University in 1990, and carried out research with Professor Jeffrey M. Stryker. He then moved to Colorado State University where he began his doctoral studies with Professor Albert I. Meyers. His dissertation work has resulted in the stereoselective syntheses of cycloalkanols *via* allylsilane annulations to electron deficient alkenes and unsaturated bicyclic lactams. Gregory received his PhD in the autumn of 1996 and is currently employed with Union Carbide in New Jersey.**

## Footnotes

† It has been recently found that 5,5-bicyclic lactams **III**, derived from the Parke–Davis amino alcohol **i** (R = Me, $SiPh_2Bu^t$), undergo almost exclusive *exo* alkylation. The diastereoselectivities in these cases are extremely high and the results of the study will be reported in due course; A. I. Meyers and M. Seefeld, *J. Org. Chem.*, 1996, **61**, 5712. See also G. Roth *et al.*, *J. Org. Chem*., 1996, **61**, 5710. For *exo* selective alkylations of 5,6-bicyclic lactams, see ref. 2(*j*).

i

‡ A wide selection of saturated and unsaturated 5,5-bicyclic lactams **III** (*n* = 0) and **57**, respectively, are now commercially available from either Aldrich Chemical Co. or Salford Ultrafine Chemicals & Research Ltd., Research Park, Manchester (UK).

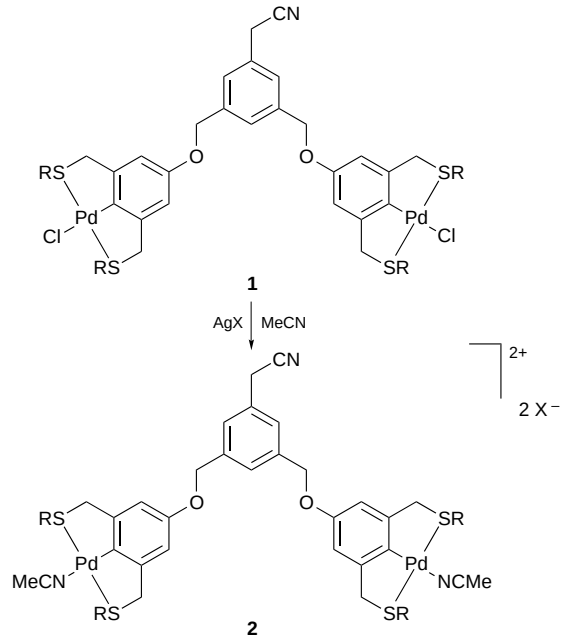
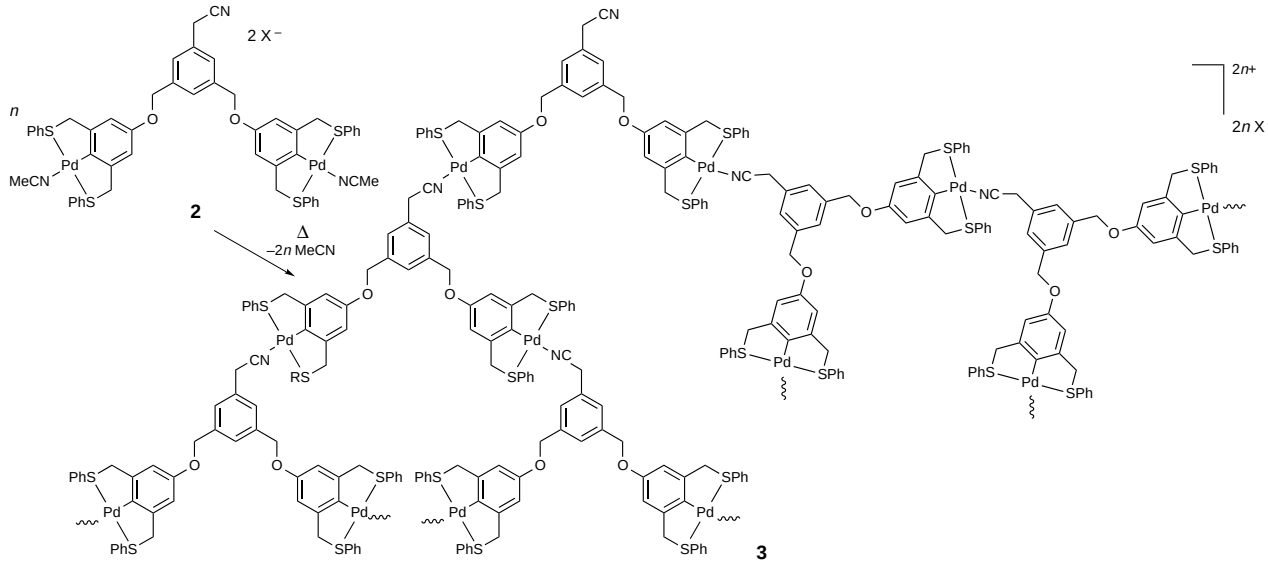
# Self-assembly of hyperbranched spheres; correlation between monomeric synthon and sphere size

**Wilhelm T. S. Huck,[a] Bianca H. M. Snellink-Ruël,[a] James W. Th. Lichtenbelt,[b] Frank C. J. M. van Veggel*[a] and David N. Reinhoudt*[a]**



[a] *Laboratory of Organic Chemistry and Mesa Research Institute, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands*
[b] *AKZO NOBEL Research Laboratories, PO Box 9300, 6800 SB Arnhem, The Netherlands*

**Light-scattering experiments show that the size of self-assembled hyperbranched spheres can be varied from 100 to 400 nm, by variation of the building block structure and/or the counter anions.**



Recently, coordination chemistry has been exploited as a useful tool to form well-defined three-dimensional architectures *via* self-assembly. Transition metals can be used to control the geometry of architectures such as molecular squares,[1] helicates[2] and dendrimers.[3,4] Previously, we have reported the stepwise, non-covalent synthesis of dendrimers of nanosize dimensions *via* assembly of bis-Pd 'pincer' complexes **1** (R = Ph).[5]

The same building blocks can be used for the self-assembly of **2** (X = $BF_4^-$, R = Ph) into very large non-covalent structures. The size distribution of our self-assembled organo-palladium spheres was remarkably narrow (AFM: mean size 200 nm, σ *ca.* 30 nm).[6] These initial results prompted us to systematically study the influence of structural variations in the building block **1** and counter ions ($X^-$) on the size of the spheres, because the bulkiness of the non-coordinating anions and thioether moieties are likely to determine the assembly process.

The different anions were introduced by reacting the Pd–Cl complex **1** with the appropriate silver salt in MeCN (Scheme 1).† AgCl precipitated immediately giving the corresponding acetonitrile complex **2**. We have synthesized phenyl thioether building blocks with $BF_4^-$, $ClO_4^-$, $PF_6^-$, $CF_3SO_3^-$, *p*-$MeC_6H_4SO_3^-$ and $BPh_4^-$ counteranions. For **2b** (R = naphthyl) the $BF_4^-$, $PF_6^-$ and $CF_3SO_3^-$ systems were synthesized.

**Scheme 1** Structural variation in the building blocks

**Scheme 2** Schematic self-assembly of hyperbranched coordination polymers

Only the *p*-$MeC_6H_4SO_3^-$ could be isolated of the alkyl thioethers **2c**, **2d** because the Pd complexes were unstable with $BF_4^-$, $PF_6^-$ and $CF_3SO_3^-$ anions.

Removal of all acetonitrile by repeated evaporation and redissolving the residue in nitromethane results in the intermolecular coordination of the cyano groups of the building blocks to yield hyperbranched coordination polymers **3** (Scheme 2).‡

The size of the resulting assemblies was determined by quasi-elastic light-scattering (QELS). In general, we observed that larger anions or bulkier thioethers, gave smaller spheres (Fig. 1). The naphthyl thioether with $PF_6^-$ and $CF_3SO_3^-$ anions shows a similar decrease in size as the phenyl analogues.§ Comparing the entries for the $PF_6^-$, $CF_3SO_3^-$ and *p*-$MeC_6H_4SO_3^-$ anions it is evident from Fig. 1 that with increasing size of the thioether groups smaller particles are formed.

In addition, AFM and TEM were used to study the shape of some of the assemblies. Spherical assemblies are clearly observed.¶ From AFM data, sizes of 100 (±20) nm for **3b** ($X^-$ = $BF_4^-$) and of 110 (±20) nm for **3b** ($X^-$ = $CF_3SO_3^-$) were measured. This is in good agreement with the QELS data (140 and 104 nm, respectively). The TEM image shows assemblies of 225 nm for **3a** ($X^-$ = *p*-$MeC_6H_4SO_3^-$), in good agreement with QELS data (220 nm).

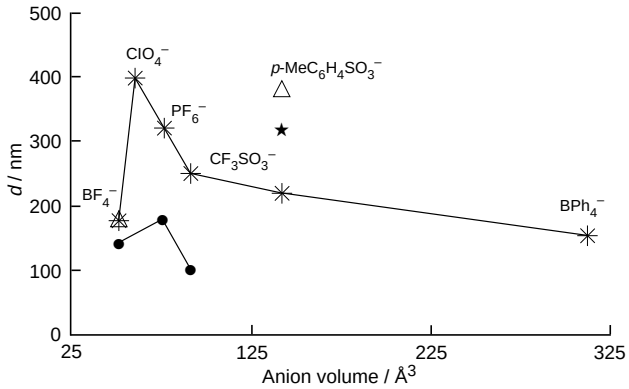


**Fig. 1** Sphere size *vs.* anions as measured by QELS in $MeNO_2$ at room temp. (△ = Et, * = Ph, ★ = Bu$^t$, ● = naphthyl)

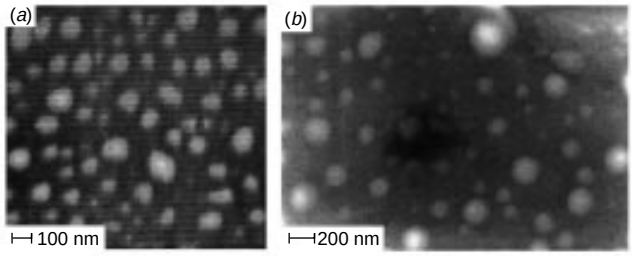

**Fig. 2** (*a*) AFM image of **3b** ($X^-$ = $CF_3SO_3^-$) and TEM image of **3a** ($X^-$ = *p*-$MeC_6H_4SO_3^-$)

The observed size dependency can be rationalized by combining the size of the anion and the distribution of charge in the polyelectrolyte assembly. The assembly process stops when the anions inside the sphere can no longer compensate for the accumulating charges and start to occupy the surface. Consequently, the different sizes of the spheres are determined both by the size and the charge density of the anion and the structure of bis-Pd complex.

The hyperbranched structure with a dense outer surface is supported by disassembly experiments that give information on kinetic stability. When *ca*. 20 equiv. of acetonitrile was added to a nitromethane solution of the spheres, these disassembled slowly in the course of 15–30 min. This slow disassembly indicates that acetonitrile can not easily penetrate the outer shell of building blocks. With a larger nitrile, like benzonitrile, the disassembly process is hardly evident, even after heating to 70 °C for 15 min. These data are indicative that a branching architecture leads to a closely packed surface, as has been observed in dendrimer chemistry.[7]

## Footnotes

† The Pd–Cl complexes were fully characterized by $^1$H and $^{13}$C NMR, FTIR, FAB–MS and elemental analysis. $^1$H NMR shows a characteristic shift at δ 4.5 (br) for the $CH_2S$ protons of the Pd-complex. Coordination of CN to the Pd-centres was evidenced by FTIR (2290 cm$^{-1}$).

‡ $^1$H NMR spectra in $CD_3NO_2$ of all assemblies show broad peaks, in agreement with large structures. Addition of $CD_3CN$ sharpened the spectra, which means that the self-assembly and disassembly processes are completely reversible. The original broad spectrum is restored when the solution is evaporated completely and redissolved in acetonitrile-free nitromethane.

§ The size of the anion was calculated using the option for Connolly Surfaces in CERIUS².[8] For unknown reasons the $BF_4^-$ anion behaves anomalously. The anion is, even inside the hyperbranched polymer, probably solvated and therefore appearing larger then the naked anion.

¶ The size distribution could not always be derived from these data because of (extensive) clustering. In the case of **3b** ($X^-$ = $PF_6^-$) only thin films were observed with AFM.

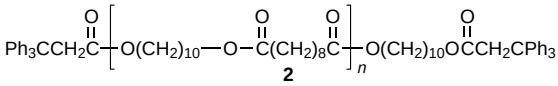
# Synthesis of some new polypseudorotaxanes

**Glynn J. Owen and Philip Hodge***

*University of Manchester, Department of Chemistry, Oxford Road, Manchester, UK M13 9PL*

**Linear polymers are synthesised which have hydroquinol ether units linked by several ethylene oxide units; in some cases the latter also contain ester groups and introduction of the tetracationic cyclophane cyclobis(paraquat-*p*-phenylene) 1 to solutions of the polymers in acetonitrile leads to the formation of polypseudorotaxanes; $^1$H NMR analysis of these solutions at −40 °C showed that in some cases up to 94% of the hydroquinol ether units were threaded through cyclophanes.**



Interest in molecular assemblies of novel topology has increased enormously in recent years.[1–4] Numerous rotaxanes,† pseudorotaxanes† and catenanes have been synthesised.[3] Stoddart's group have exploited the favourable interactions between π-electron-rich moieties such as hydroquinol (HQ) ethers, where the ethers are formally derived from oligoethylene oxides (xEO), and π-electron-poor moieties such as those in the tetracationic cyclophane **1** for the self assembly of many rotaxanes and catananes.[3,5] The interest in molecular assemblies has extended to polymeric systems and various polyrotaxanes and polypseudorotaxanes have been prepared.[3] Polyrotaxanes have, for example, been prepared from polyester **2** and 30-crown-10,[6] and polypseudorotaxanes from polyacrylonitrile and 60-crown-20,[7] and from polymer **3** and β-cyclodextrin.[8] We wish to combine studies of polyrotaxanes and polypseudorotaxanes with our work on the synthesis of macrocycles[9,10] in order to build novel polymeric systems. As a first step we have synthesised polypseudorotaxanes based on polymers with dialkoxyaromatic units linked by several EO groups, plus in some cases ester groups, and Stoddart's cyclophane **1**, and we now report the results. Stoddart *et al.* have previously prepared two types of oligo- or poly-pseudorotaxanes.[11,12] One type was prepared, from compound **4**, which has five hydroquinol ether moieties, by 'threading' on one or two cyclophanes **1**.[11] The second type was prepared from the copolymer **5**, where the degree of polymerisation (DP) was approximately 9, and an excess of cyclophane **1** with respect to the repeat units.[12] With the former type detailed analysis of $^1$H NMR spectra provided proof of rotaxane formation;[11] with the latter type the main evidence of rotaxane formation was the expected colour change.[12] We have now assembled polypseudorotaxanes starting from polymers **6**–**10**, which have average DPs of up to 63, and have shown (i) that despite the relatively small number of end = groups present in most cases, polypseudorotaxanes can be rapidly obtained by 'threading' the polymers with cyclophane **1**, and (ii) that it is possible to obtain polypseudorotaxanes where a substantial fraction of the HQ ether units are present as rotaxane moieties and that this can be as high as 94% at −40 °C. Thus, it is possible for cyclophanes **1** to complex to HQ ether units which are adjacent in the polymer chain. This is the first occasion such 'close packing' of this charged cyclophane has been observed.

**11**

**12** *n* = 3
**13** *n* = 4

**14** X = $CO_2Et$
**15** X = $CH_2OCH_2CH_2OH$

**16**

Polymers **6**, **7**, **10** and **11** were prepared by reacting hydroquinol, 1,5-dihydroxynaphthalene (ND) or 2,5-di-*tert*-butylhydroquinol (DBHQ) with the ditosylate of either triethylene glycol (3EO) **12** or of tetraethylene glycol (4EO) **13** (Table 1). Diester **14** and diol **15** were prepared by reacting hydroquinol with ethyl chloroacetate or 2-(2-chloroethoxy)-ethanol respectively in the presence of potassium carbonate in ethanol. Reaction of diester **14** with diethylene glycol (2EO) in the presence of titanium tetraisopropoxide gave polyester **8**. Polyester **9** was similarly prepared from diol **15** and dimethyl oxalate (DMO). The molecular weights of the various polymers were estimated using gel permeation chromatography, Table 1. The $^1$H NMR spectra of the polymers were consistent with the assigned structures and $\overline{M}_n$ values; no phenolic end-groups were detected.

Attempts to prepare pseudopolyrotaxanes by reacting compound **16** and α,α′-dibromo-*p*-xylene **17** together in acetonitrile in the presence of polymer **6**, *i.e.* by 'clipping',[3] afforded complex mixtures that, by $^1$H NMR spectroscopy and UV spectroscopy, contained pseudopolyrotaxanes but the latter could not be isolated in a pure state.[13]

Polypseudorotaxanes were successfully prepared by 'threading', *i.e.* cyclophane **1** was prepared [from **16** and **17**][14] and purified, then it was added progressively to solutions of the polymers in acetonitrile at 20 °C. In each case the solution immediately became dark red, indicative of rotaxane formation, and as more cyclophane **1** was added the colour generally became more intense as monitored by UV spectroscopy. The solutions were analysed by $^1$H NMR spectroscopy at −40 °C.‡ At this temperature 'shuttling' of the threaded cyclophane was slow on the NMR timescale. In general the signals due to the starting polymer and the free cyclophane **1** were observed to decrease or disappear and signals characteristic of the rotaxane moiety, *i.e.* the HQ ether groups residing in the centre of the cyclophane plus the encircling cyclophane, appeared. The extents of 'threading' achieved with the various polymers are summarised in Fig. 1. It is evident in the cases of polymers **6**, **7** and **9** that up to the point when *ca*. 35% of cyclophane **1** has been added, essentially all the added cyclophane **1** becomes threaded. With polymer **6** the loading achieved, *i.e.* the percentage of HQ ether repeat units that are threaded, reaches a plateau at *ca*. 50% whilst with polymer **7** it reaches a plateau at *ca*. 70%. This latter percentage implies that a substantial fraction of the adjacent HQ ether units in the polymer chain are present as rotaxane moieties. Presumably with polymer **6**, which has only a 3EO spacer unit, such close proximity of the cyclophane rings is seriously inhibited because it results in electrostatic and/or steric interactions between the solvated cyclophanes. The presence of the ester linkage in polymer **8** clearly has an unfavourable effect on the 'threading' because the loading of this polymer, which formally has a 4EO spacer, reaches a plateau at *ca*. 55%, *i.e.* significantly lower than with polymer **7**. Polyester **9** on the other hand, which formally has a 5EO spacer, loads up to *ca*. 94%. Since this polymer has on average 21 HQ units in the chain, the result implies that on average each chain has 20 threaded rings. Similarly polyester **8** has on average, at maximum loading, 37 threaded rings per chain, *i.e.* is a [38]pseudopolyrotaxane. Polymer **10** also threads rapidly but the mixture obtained only dissolved in [$^2H_6$]DMF or [$^2H_6$]DMSO at *ca*. 100 °C. At this temperature the $^1$H NMR spectrum in [$^2H_6$]DMF was broad and whilst it was clear 'threading' occurred an accurate analysis was not possible. As expected on steric grounds, polymer **11** did not thread at all.

**Table 1** Synthesis and characterisation of polymers **6**–**11**

## Footnotes

† Rotaxanes have a rod or chain threaded through rings and end-groups that are sufficiently large to prevent the rings from slipping off. Pseudorotaxanes do not have the large end-groups and so can dissociate.

‡ The $^1$H NMR spectra shifts obtained agree closely with those reported by Stoddart's group for low-molecular-weight analogues,[11,16]

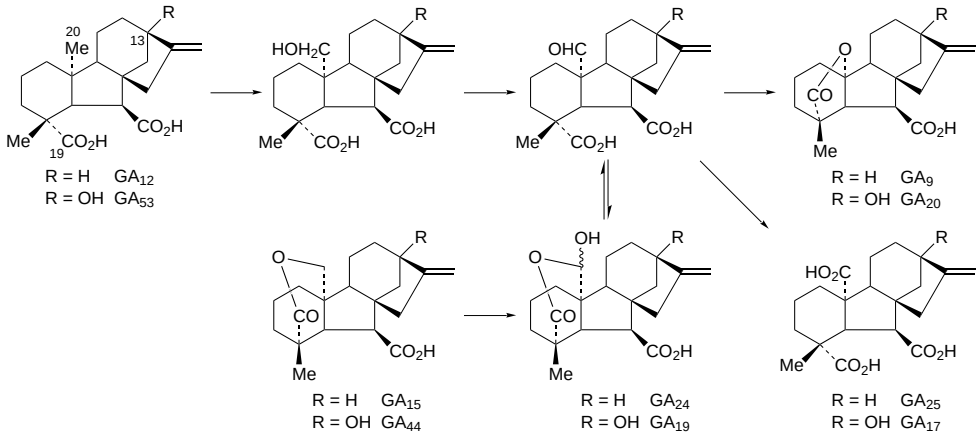
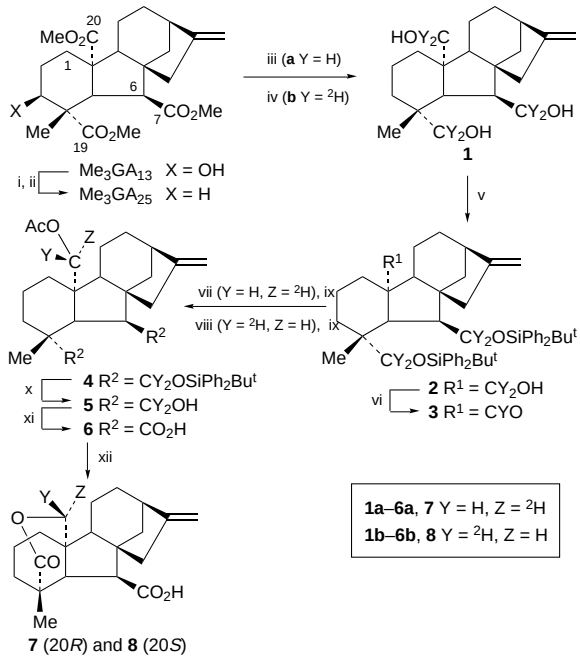
**(20*R*)- and (20*S*)-[20-$^2H_1$]-gibberellins $A_{15}$ and $A_{44}$ have been used to determine the stereochemistry of the conversion to the 20-aldehyde catalysed by gibberellin 20-oxidases.**

The stepwise oxidation and subsequent removal of carbon-20 from $C_{20}$-precursors is one of the most important sequences of reactions in the biosynthesis of biologically active $C_{19}$ gibberellin (GA) plant hormones (Scheme 1). This conversion is unusual in that carbon-20 is lost at the aldehyde oxidation level in a reaction which also involves concerted formation of the 19,10-lactone function, a characteristic structural feature of the $C_{19}$-GAs, such as $GA_9$ and $GA_{20}$. The 20-carboxylic acid is also a biosynthetic product, but is not an intermediate in $C_{19}$-GA formation. Genes encoding GA 20-oxidases have been cloned from several plants.[1–5] These enzymes are 2-oxoglutarate-dependant dioxygenases, an important class of soluble, $Fe^{II}$-containing oxygenases .[6] Functional expression of GA 20-oxidase clones in *E. coli* has provided the means for a detailed study of the mechanism. Although studies in cell-free systems of spinach[7] indicated that more than one enzyme may be involved in the conversion of 20-methyl compounds *via* the 20-alcohol and 20-aldehyde to the $C_{19}$-lactone, all GA 20-oxidases so far cloned are able to convert substrates with 20-methyl functions through to $C_{19}$-lactones and/or 20-carboxylic acids.



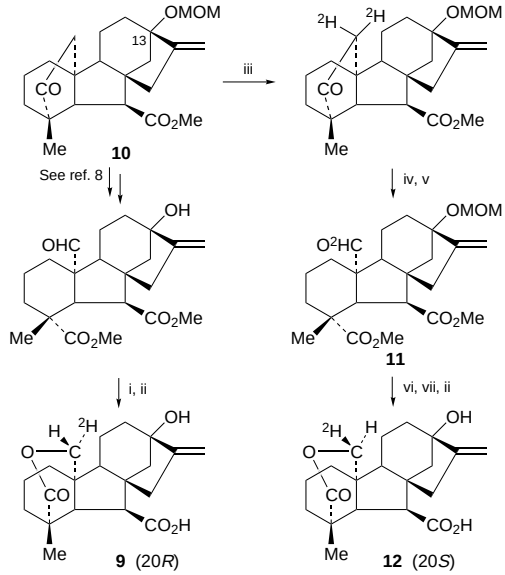
Here we report studies on the stereochemistry of the conversion of the 20-alcohol to the 20-aldehyde. Results are compared in cell-free systems from spinach with those obtained using recombinant enzyme from high-level expression of the *Arabidopsis thaliana* GA 20-oxidase clone At2353[2] in *E. coli* using the pET9d vector;† this enzyme converts $GA_{12}$ to $GA_9$ in high yield.

The syntheses of (20*R*)- and (20*S*)-[20-$^2$H]-$GA_{15}$ are summarised in Scheme 2. The route relies on the use of bulky *tert*-butyldiphenylsilyl (TBDPS) protecting groups to distinguish between the alcohol functions in the triol **1**, allowing manipulation of C-20, the most sterically hindered of the three hydroxymethyl groups. Triol **1** and its [$^2H_6$]-isotopomer **1a** were prepared by $LiAlH_4$ ($LiAlD_4$) reduction of $GA_{25}$ trimethyl ester, itself prepared by deoxygenation of $GA_{13}$ trimethyl ester.



Treatment of **1** with TBDPSCl and imidazole gave the 7,19-*bis*-TBDPS derivative **2** in high yield. Swern oxidation of **2** gave the 20-aldehyde **3**. Reduction of the aldehyde with $NaBD_4$ was stereoselective (see later) and returned the [20-$^2H_1$]-alcohol **4**, which was protected as the acetate, before removal of the TBDPS groups with $Bu_4NF$ to give 7,19-diol **5**. Oxidation to the 7,19-dicarboxylic acid **6** followed by hydrolysis yielded (20*R*)-[20-$^2$H]$GA_{15}$ ($d_1$-65%, $d_0$-35%), in the lactone form **7**. The corresponding (20*S*) isomer **8** ($d_1$-99%, $d_0$-1%), was prepared in an analogous way from **1a,** reducing the 20-deuterio-aldehyde **3a** with $NaBH_4$ as shown in Scheme 2.

The configurations of **7** and **8** were assigned by $^1$H NMR spectroscopy. In fully protio species, the 20-hydrogens resonate at δ 4.12 (d, *J* 12.5 Hz) and 4.48 (dd, *J* 12.5 and 2.5 Hz). The downfield signal was assigned to the 20-*proR* proton by virtue of the long range W-coupling (2.5 Hz) to 1β-H, as confirmed by a difference NOE experiment, which revealed a clear NOE from 6-H to the signal at δ 4.48 and the absence of any enhancement of the upfield doublet at δ 4.12, assigned to the 20-*proS* hydrogen. Both **7** and **8** were labelled stereospecifically.



The corresponding [20-$^2H_1$] isotopomers of the 13-hydroxylated gibberellin, $GA_{44}$ **9** and **12**, were synthesised as shown in

**Scheme 1** Reactions catalysed by GA-20-oxidases

**Scheme 2** Synthesis of (20*R*)- and (20*S*)-[20-$^2H_1$]-$GA_{15}$. *Reagents*: i, KH, $CS_2$, MeI; ii, $Bu_3SnH$; iii, $LiAlH_4$; iv, $LiAl^2H_4$; v, $Bu^tPh_2SiCl$, imidazole; vi, $(COCl)_2$, $Me_2SO$, $Et_3N$; vii, $NaB^2H_4$; viii, $NaBH_4$; ix, $Ac_2O$, pyridine; x, $Bu_4N^+F^-$; xi, Jones oxidn; xii, NaOH, aq. MeOH.

**Scheme 3** Synthesis of (20*R*)- and (20*S*)-[20-$^2H_1$]-$GA_{44}$ *via* $GA_{19}$. *Reagents*: i, $NaB^2H_4$; ii, NaOH, aq. MeOH; iii, $^2H_2O$, $K_2CO_3$; iv, KH, DMF, THF, $O_2$; v, $CH_2N_2$; vi, Dowex 50W($H^+$); vii, $NaBH_4$.

Scheme 3. (20*R*)-[20-$^2H_1$]-$GA_{44}$ **9** ($d_1$-95%, $d_0$-5%) was produced by $NaBD_4$ reduction of $GA_{19}$ dimethyl ester followed by hydrolysis of the esters (2 mol $dm^{-3}$ aq. NaOH–MeOH, 1 : 1, reflux, 2 h). For the synthesis of (20*S*)-[20-$^2H_1$]-$GA_{44}$, the starting point was ketone **10**, an intermediate in the synthesis[8] of $GA_{19}$. Deuterium exchange at C-20, oxidative cleavage[8] and methylation gave [20-$^2H_1$]-$GA_{19}$ dimethyl ester, 13-methoxymethyl ether **11**. Deprotection at C-13 and then reduction of the aldehyde followed by demethylation gave the required (20*S*)-[20-$^2H_1$]-$GA_{44}$ **12** ($d_1$-61%, $d_0$-39%). The stereochemistry at C-20 was assigned by $^1H$ NMR spectroscopy as above.

Incubation of unlabelled $GA_{15}$, as the lactone or as the 20-hydroxy-19-carboxylic acid ('open lactone'),‡ with recombinant At2353 20-oxidase and analysis of the products by GC–MS revealed that only the open lactone was accepted as a substrate by the enzyme. A similar result has been obtained in cell-free systems from *C. maxima* endosperm[9] and pea cotyledons,[10] whereas homogenates of spinach leaves oxidise the closed-lactone form of $GA_{44}$.[7] Although the product of metabolism of $GA_{15}$ open lactone was mainly $GA_9$, under short incubation times§ the intermediate 20-aldehyde $GA_{24}$ was readily detectable by GC–MS.

Incubation§ of (20*R*)- and (20*S*)-[20-$^2H_1$]-$GA_{15}$ **7** and **8,** and $GA_{44}$ **9** and **12** in the open-lactone form‡ with recombinant enzyme and GC–MS analysis of the 20-aldehyde ($GA_{24}$ and $GA_{19}$, respectively) products, revealed that, for both $GA_{15}$ and $GA_{44}$ substrate, there is stereospecific loss of the 20-*proR* hydrogen (Table 1). In contrast, incubation of **9** and **12,** in the closed-lactone form, with the spinach cell-free system[7] and analysis of the 20-aldehyde ($GA_{19}$) produced showed that, in this case, the 20-*proS* hydrogen is lost (Table 1). Thus, this cell-free system contains an enzyme that is capable of oxidising C-20, presumably in the lactone form, and it does so with the opposite stereochemistry to that observed with the recombinant *A. thaliana* protein, which only accepts the open-lactone form. In the lactone form, the 20-*proR* hydrogen is fixed in a severely sterically hindered position under ring B and, thus, it is not surprising that the lactone 20-oxidase, present in spinach, removes the 20-*proS* hydrogen. However, in the enzymes that accept only the 'open-lactone' form, the substrate presumably is held such that the 20-*proR* hydrogen is more exposed.

**Table 1** Deuterium incorporations in enzymic products

| Substrate | $d_1 : d_0$(%) | Enzyme | Product | $d_1 : d_0$(%)[a] |
|---|---|---|---|---|
| **7** (20*R*) Open lactone | 65 : 35 | At2353 | $GA_{24}$ | 0 : 100 |
| **8** (20*S*) Open lactone | 99 : 1 | At2353 | $GA_{24}$ | 97 : 3 |
| **9** (20*R*) Open lactone | 95 : 5 | At2353 | $GA_{19}$ | 0 : 100 |
| **12** (20*S*) Open lactone | 61 : 39 | At2353 | $GA_{19}$ | 50 : 50 |
| **9** (20*R*) Lactone | 95 : 5 | Spinach | $GA_{19}$ | 85 : 15 |
| **12** (20*S*) Lactone | 61 : 39 | Spinach | $GA_{19}$ | 13 : 87 |

[a] $GA_{24}$ and $GA_{19}$ were identified by GC–MS comparison (KRI and spectra), as Me or Me, $Me_3Si$ derivatives, with authetic samples. Due to weak molecular ions isotope enrichments were calculated on $M^+ - 32$ (*m*/*z* 342) for $GA_{24}$ and $M^+ - 28$ (*m*/*z* 434) for $GA_{19}$.

## Footnotes

† Full details of the functional expression and characterisation of GA 20-oxidases will be reported elsewhere.

‡ The lactone-opened form of 20-hydroxymethyl GAs was produced by treatment with 2 mol $dm^{-3}$ NaOH.

§ Recombinant enzyme incubations were carried out in a total volume of 100 μl of TrisCl buffer (1 mol $dm^{-3}$, pH 7.5) containing 70 μl enzyme preparation [45% pure enzyme (estimated from SDS gel), 2.5 mg protein $ml^{-1}$]. GA substrate (5 μg), 2-oxoglutarate (8 mmol $dm^{-3}$), ascorbic acid (8 mmol $dm^{-3}$), dithiothreitol (8 mmol $dm^{-3}$), $FeSO_4$(1 mmol $dm^{-3}$), catalase (2 mg $ml^{-1}$) and bovine serum albumin (4 mg $ml^{-1}$).

# Continuous films of zeolite ZSM-5 on modified gold surfaces

**Svetlana Mintova,[a] Jonas Hedlund,[a] Brian Schoeman,[a] Valentin Valtchev[b] and Johan Sterte*[a]**

[a] *Department of Chemical Technology, Luleå University of Technology, S-97186, Luleå, Sweden*
[b] *Central Laboratory of Mineralogy and Crystallography, Bulgarian Academy of Sciences, 92 Rakovski St., 1000 Sofia, Bulgaria*

**Thin continuous films of zeolite ZSM-5 on gold surfaces are prepared by a novel method including silanization, charge modification and seeding of the surface prior to the hydrothermal crystallization of the zeolite.**

The preparation of continuous films of molecular sieves on various supports, including metallic and other inorganic as well as organic substrate surfaces, has recently attracted considerable attention.[1–5] The great interest in these materials is primarily motivated by their potential advantages in a number of applications such as membranes for separation and catalysis, chemical sensors, acoustic wave devices, and microelectronics.[6–10]

Several methods for the preparation of zeolite films on surfaces have been described.[11–14] Most of these methods involve the direct nucleation and crystallization of the desired zeolite on the substrate surface. A novel method for the preparation of thin zeolite films based upon a three-step procedure was recently presented.[15] In this method, the substrate surface is first treated with a cationic polymer in order to obtain a positive surface charge. Colloidal crystals of zeolite are then adsorbed as a monolayer on the surface by electrostatic attraction. Finally, the adsorbed crystals are induced to grow into a continuous film of intergrown crystals under hydrothermal conditions. Although very flexible and easy to control, this method has the disadvantage that it can only be applied on surfaces which have a substantial surface charge in aqueous solutions. This excludes surfaces of noble metals, a fact that significantly reduces the value of the method in several of the potential applications of zeolite films where films on gold or platinum surfaces would be desirable. Modification of this method to render it applicable for noble-metal substrate surfaces is therefore of great interest.

The purpose of this communication is to present a novel method for the controlled preparation of very thin continuous films of ZSM-5 on gold surfaces. Gold substrates consisting of a gold film with a thickness of approximately 50 nm on the surface of silver plates were prepared by sputtering. The surface of the silver plate was first cleaned for 10 min in acetone in an ultrasonic bath and then in a mixture of water, ammonium hydroxide and hydrogen peroxide (molar composition $280H_2O : 9H_2O_2 : 15NH_3$) for 10 min at room temp. The plates were then rinsed with distilled water and, subsequently, sonicated twice for 15 min in distilled water. Application of the gold film was achieved by sputtering in an MED 020 Coating System (BAL-TEC AG). The Au surfaces were silanized by treating the substrates for 3 h in a methanolic 20 mM γ-mercaptopropyltrimethoxysilane (MPT, OSi Specialties) solution and the silane was then hydrolysed in 0.10 M HCl for 15 h at room temp. The surface charge of the silanized gold surface was modified by treating the initially negative surface with a solution containing 1.0 mass% cationic polymer (Berocell 6100, Akzo Nobel) with the repeat unit $[CH_2CHOHCH_2NMe_2)]^+_n$ and an average molecular mass of 50 000 g $mol^{-1}$ for 1 h. Substrates were then rinsed twice with a 0.10 M ammonia solution to remove excess polymer. In order to adsorb a monolayer of ZSM-5 seed crystals onto the surface of the substrates, the substrates were treated with a purified colloidal suspension (4.5 mass%, pH = 10.5, average crystal size: $d_p$ = 90 nm) of discrete colloidal crystals of ZSM-5 for 1 h.[16] After this treatment, the substrates were rinsed 3 times with 0.10 M aq. $NH_3$, air dried and calcined for 1 h at 250 °C. Finally, the substrates were immersed in a synthesis solution with the molar composition $0.35Na_2O : 25SiO_2 : 0.5Al_2O_3 : 9TPAOH : 405H_2O$ for 40 h in order to induce continued growth (and intergrowth into a continuous film) of the crystals on the surface. The type of zeolite structure was confirmed by XRD with a Philips PW1710-00 powder diffractometer.

Particle size analysis and zeta potential measurements of the ZSM-5 seed sol were performed with a Brookhaven Instruments ZetaPlus. Adsorption of MPT was studied by reflection absorption Fourier transform IR spectroscopy (RAIRS, Perkin Elmer PE 2000 FTIR) and by VASE ellipsometry (J. A. Woolam Co). A Philips XL 30 scanning electron microscope (SEM) equipped with an LaB6 emission source was used for studies of surface morphology and to measure zeolite film thickness. Krypton adsorption was measured at liquid nitrogen temperature using a Micromeritics ASAP 2010 surface area and pore volume analyser.

In Fig. 1, a schematic illustration of the process is shown. The silanization of the gold surface by MPT was performed in solution resulting in a very thin silane layer (Fig. 1A). The RAIRS measurements of the silane layer were performed using an unsilanized substrate as the background and silanized samples as probes. The spectra were almost identical to that reported by Kurth and Bein[17] for adsorption of MPT on

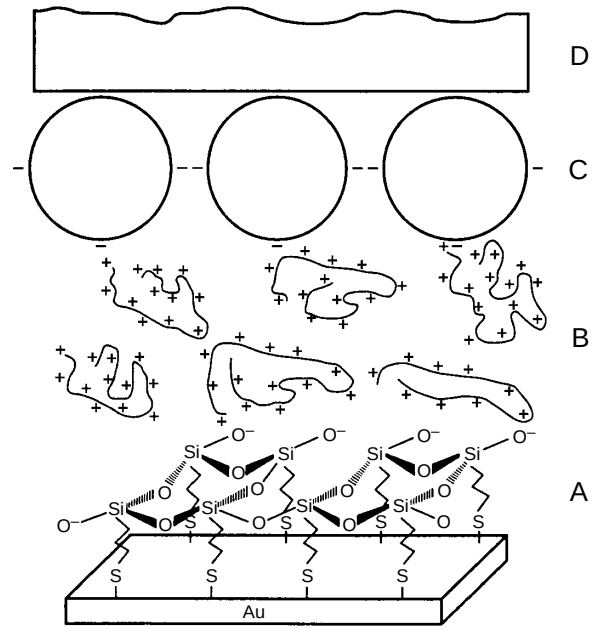

**Fig. 1** Schematic representation of the silanization of an Au surface with MPT (A), charge reversal of the negative siliceous interface to a positively charged interface by means of adsorption of a cationic polymer (B), electrostatic adsorption of negatively charged ZSM-5 crystals on silane-polymer modified Au (C) and the formation of a continuous zeolite film after hydrothermal treatment (D)

oxidized aluminium substrates. From their spectrum they concluded that MPT adsorbed on oxidized alumina is vertically oriented. The thickness of the MPT film was determined by ellipsometry to about 10 Å which is in good correspondence with a vertical orientation of MPT on the gold surface. Hydrolysis of the silane results in the formation of dissociated groups on the surface of the substrate resulting in a surface with a negative surface charge in neutral and alkaline aqueous solutions (Fig. 1A). This substrate surface readily adsorbed an excess of the cationic polymer, Fig. 1B, thus reversing the surface charge to a positive one and facilitating electrostatic adsorption of colloidal ZSM-5 crystals, Fig. 1C. The zeta potential of the colloidal ZSM-5 crystals in the purified sol (pH: 10.5) was determined to −54 mV. Fig. 2(*a*) shows an SEM micrograph of colloidal ZSM-5 crystals adsorbed on the gold substrate surface after modification of this surface by silanization, hydrolysis of the silane and charge reversal by treatment with the cationic polymer. The micrograph shows that the crystals are homogeneously adsorbed in a dense layer on the surface. After adsorption of the seed crystals, the sample was calcined in order to decompose the silane and the cationic polymer and to induce a stronger interaction between the adsorbed seed crystals and the substrate surface. Although the nature of the bonding of the seed crystals to the substrate surface is not entirely clear, the attachment of these crystals after the calcination process is strong enough to keep the zeolite firmly on the surface during the crystallization of the zeolite film. The formation of the zeolite film is achieved by contacting the substrate with adsorbed seed crystals with a synthesis solution with a composition suitable for the crystallization of zeolite ZSM-5 at hydrothermal conditions.[16] This treatment results in a continued growth of the seed crystals and eventually to the intergrowth of these crystals into a dense and continuous film, Fig. 1D. Fig. 2(*b*) and (*c*) show top and side views, respectively, of the final film obtained after 40 h of crystallization. From these and numerous other SEM micrographs it is clear that the ZSM-5 films produced are continuous, free from cracks and that they have an almost constant thickness. The film thickness estimated from the micrograph shown in Fig. 2(*c*) is 200–250 nm. The film thickness of this sample was also calculated from Kr adsorption data using the BET equation and the surface area (500 $m^2\ g^{-1}$) and density (1790 $kg\ m^{-3}$) of pure ZSM-5 as a reference. The value obtained in this manner is 230 nm which is in very good agreement with that measured from the SEM micrograph.

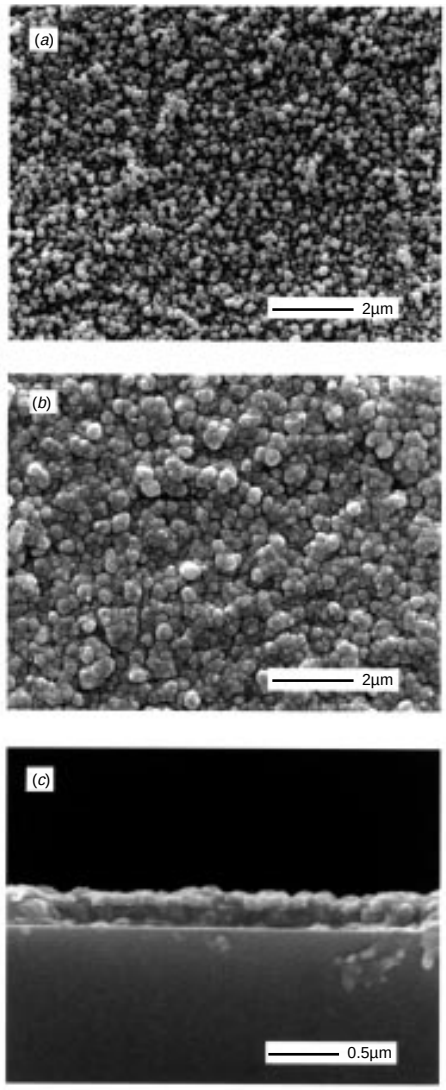

**Fig. 2** SEM micrographs showing the adsorbed 90 nm ZSM-5 seeds on the Au surface (*a*), the top view (*b*) and side view (*c*) of the continuous zeolite film after hydrothermal crystallization

The results presented in this communication show that continuous films of ZSM-5 on gold substrates can be prepared by a procedure involving four steps. The gold surface is first covered with a monomolecular layer of MPT which is hydrolysed under acidic conditions. The surface charge is then reversed by adsorption of a cationic polymer and a monolayer of colloidal seed crystals is adsorbed on the positively charged surface by electrostatic attraction. After decomposition of the silane and the cationic polymer by calcination, the seed crystals are grown into a continuous ZSM-5 film by further crystallization in a synthesis solution at hydrothermal conditions. The method is flexible and easy to control and allows for the preparation of films with a desired thickness of *ca*. 50 nm and upwards. Although only demonstrated in this communication for zeolite ZSM-5 on gold substrates, the method permits preparation of thin films of a number of zeolite types, *e.g*. zeolite-β, -A and -X, on various substrates. The flexible nature of the method employed gives new possibilities for the preparation of zeolite films with different physicochemical characteristics which may be of great interest in a number of applications.

The authors wish to thank the Swedish Research Council for Engineering Sciences (TFR) for financial support. S. M. is indebted to the Wenner-Gren Center Foundation for a scholarship.

# Ruthenium complexes of eilatin: face selectivity in octahedral geometry; synthesis of $[Ru(bpy)_2(eilatin)]^{2+}$ and $[Ru(phen)_2(eilatin)]^{2+}$

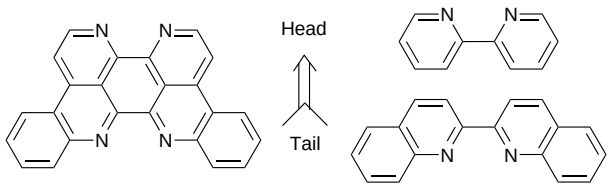
**Amira Rudi, Yoel Kashman,* Dalia Gut, Fabienne Lellouche and Moshe Kol***

*School of Chemistry, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel-Aviv University, Tel-Aviv 69978, Israel*

**Eilatin, a marine alkaloid, is a potentially bifacial ligand that prefers to bind through its less hindered face in sterically demanding geometries as evident by the selective synthesis of two octahedral ruthenium complexes.**

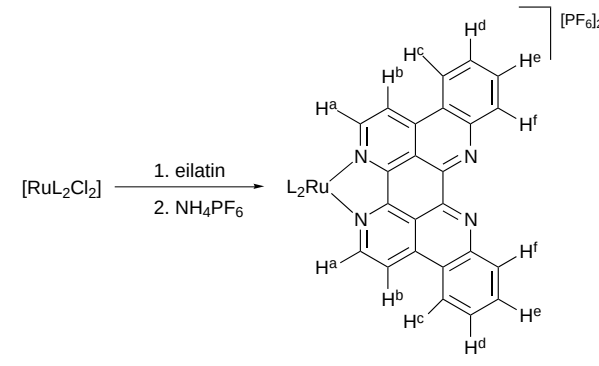
A few years ago, several of us reported the isolation of eilatin **1a**, a marine alkaloid, from the tunicate *Eudistoma sp*.[1] This highly symmetric pyrido[2,3,4-*kl*]acridine was named after the location of its collection, the Gulf of Eilat. The bioactivity of eilatin[2] initiated a synthetic effort which yielded several syntheses,[3,4] the most efficient among them being biomimetic.[4] Herein we report a new aspect of eilatin character, namely its use as a face-selective ligand for transition metals.

The planar heptacyclic eilatin **1a** may be viewed as an all-conjugated 2,2′-bipyridine (bpy) and 2,2′-biquinoline (biq) fused rigidly back-to-back (**1b**). Both bpy and biq can serve as chelating ligands for various metals; however, their different steric bulk leads to different coordination behaviour. Thus, for instance, while both $[Ru(bpy)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ are known compounds, the tris (biq) analogue is stable only for ruthenium,[5] while attempts to prepare the iron complex, $[Fe(biq)_3]^{2+}$, have been unsuccessful.[6] Accordingly, eilatin is expected to behave as a bidirectional ligand exhibiting face preference, depending on the steric crowding around the metal: in sterically demanding geometries such as octahedral or square-planar, eilatin is expected to bind to the metal through its 'head', while in loose geometries such as tetrahedral, both the 'head' and the 'tail' of eilatin are expected to be able to bind. Here, we describe the selective 'head' binding of eilatin to $Ru^{II}$ in octahedral environment.



Octahedral complexes of the type $[RuL_nL'_{3-n}]^{2+}$ (L, L′ = bpy, phen, dppz,[7] HAT,[8] *etc*.) have attracted substantial scientific interest because of their remarkable MLCT properties,[9] directional electron and energy transfer,[10] DNA intercalation,[11,12] ability to serve as building blocks in supramolecular arrays,[13] and more. Reacting $[Ru(bpy)_2Cl_2]$ and eilatin in aqueous methanol and precipitating the product with ammonium hexafluorophosphate yielded $[Ru(bpy)_2(eilatin)][PF_6]_2$ **3a** as a dark green solid (Scheme 1).†

$^1$H NMR indicated the formation of a major product having $C_2$ symmetry in at least 90% selectivity, which was purified by crystallization.‡ Complete assignment of all the protons was possible using $^1$H COSY, NOESY and HMQC two-dimensional NMR techniques. Two pieces of evidence supported the assignment of the major product as the expected 'head' isomer: (*i*) NOE connectivity between the $H^a$ protons of eilatin and $H^6$ and $H^{6'}$ protons of the bipyridine units, indicating that the 'head' of eilatin is directed towards the metal, and (*ii*) ring-current effects on chemical shift: the $H^a$ protons of eilatin are strongly shifted to a higher field relative to free eilatin in $(CD_3)_2SO$, while the other protons are only slightly affected, indicating close proximity of these 'head' protons to the orthogonal bipyridine rings. FABMS was consistent with the proposed mononuclear structure, indicating that the 'tail' side is not coordinated to a second metal atom.



$[Ru(phen)_2Cl_2]$ reacted analogously yielding $[Ru(phen)_2(eilatin)][PF_6]_2$ **3b** as a dark green solid after work-up. The same high selectivity in formation of the major product was observed as for the bipyridine analogue. Using the same type of experiments and reasoning as for **3a** indicated that eilatin was bound 'head-on' in **3b** as well.‡

The $^1$H NMR spectra of **3a** and **3b** exhibit a strong dependence of chemical shift on temperature; this effect is more pronounced when $CD_3CN$ rather than $(CD_3)_2SO$ is used as solvent. Interestingly, different protons exhibit different temperature dependences: while the protons of the bpy or phen ligands in **3a** and **3b**, respectively, are almost unperturbed, the protons of the eilatin ligand (except for $H^a$) shift to lower field upon warming.§ Adding $C_6D_6$ to a $CD_3CN$ solution of the complexes at a constant temperature has the same effect on the chemical shifts as raising the temperature. A possible explanation for this behaviour is the formation of intermolecular π stacks between eilatin ligands in **3a** or **3b**, which are broken as the temperature is raised, or when a competing solvent is added. A similar effect has been reported for $[Ru(bpy)_2(tpphz)]^{2+}$.[14]

The dark green colour of the two eilatin complexes stands in sharp contrast to the orange–red colour of $[Ru(bpy)_3]^{2+}$ and $[Ru(phen)_3]^{2+}$ complexes. Table 1 lists the absorption maxima of free eilatin and its two ruthenium complexes. The two bands responsible for the green colour of **3a** and **3b** are the broad absorption centred at around 420 nm which is attributed to eilatin π–π* bands (perhaps overlapping Ru–bpy and Ru–phen MLCT bands in **3a** and **3b**, respectively), and the absorption at around 580 nm which is attributed to a Ru–eilatin MLCT band. This is one of the lowest energy MLCT bands reported for ruthenium polypyridyl complexes,[9] and is consistent with the

low lying π* orbital of eilatin.¶ This directional electron transfer could be important in the design of molecular devices.

In summary, we have shown that the potentially bifacial ligand, eilatin, prefers to bind through its less hindered face in a sterically demanding octahedral environment. We are currently investigating the electronic properties of the mononuclear complexes as well as the preparation of eilatin-bridged heteropolynuclear complexes.

## Footnotes

† In a typical reaction 17 mg of $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ and 1.5 equiv. of eilatin were heated to reflux in methanol–water for 5 h. Addition of water and evaporation of the methanol precipitated the excess eilatin, which was filtered off. Addition of $NH_4PF_6$ to the dark green aqueous solution precipitated **3a** as a $PF_6$ salt, which was purified by crystallization from an acetonitrile–ether mixture.

‡ *Spectroscopic data* for **1a**, **3a** and **3b**: **1a**, $^1$H NMR [500 MHz, $(CD_3)_2SO$, 298 K]: δ 9.18 ($H^a$), 8.84 ($H^b$), 8.41 ($H^c$), 8.02 ($H^d$), 7.90 ($H^e$), 8.95 ($H^f$). **3a**, $^1$H NMR [500 MHz, $(CD_3)_2SO$, 298 K]: δ 8.14 ($H^a$), 8.74 ($H^b$), 8.17 ($H^c$), 8.07 ($H^d$), 7.99 ($H^e$), 8.77 ($H^f$), 7.88 ($H^6$), 7.69 ($H^5$), 8.29 ($H^4$), 8.94 ($H^3$), 8.88 ($H^{3'}$), 8.17 ($H^{4'}$), 7.43 ($H^{5'}$), 7.98 ($H^{6'}$); FABMS, 771 $[M - 2PF_6 + H]^+$. **3b**, $^1$H NMR [500 MHz, $CD_3CN$–$(CD_3)_2SO$, 302 K]: δ 8.07 ($H^a$), 8.51 ($H^b$), 8.18 ($H^c$), 7.98 ($H^d$), 7.91 ($H^e$), 8.68 ($H^f$), 8.07 ($H^2$), 7.75 ($H^3$), 8.74 ($H^4$), 8.34 ($H^5$,H6), 8.70 ($H^7$), 7.75 ($H^8$), 8.42 ($H^9$); FABMS, 819 $[M - 2PF_6 + H]^+$, 963 $[M - PF_6 + H]^+$.

§ Compare, for example, the effect of temperature on the $^1$H NMR spectra of **3b** in $CD_3CN$. 298 K: δ 8.05 ($H^a$), 7.94 ($H^b$), 7.35 ($H^c$), 7.70 ($H^d$), 7.81 ($H^e$), 8.25 ($H^f$), 8.10 ($H^2$), 7.76 ($H^3$), 8.72 ($H^4$), 8.34 ($H^5$,$H^6$), 8.68 ($H^7$), 7.83 ($H^8$), 8.70 ($H^9$). 330 K: δ 8.07 ($H^a$), 8.23 ($H^b$), 7.89 ($H^c$), 7.89 ($H^d$), 7.89 ($H^e$), 8.48 ($H^f$), 8.12 ($H^2$), 7.76 ($H^3$), 8.70 ($H^4$), 8.33 ($H^5$,$H^6$), 8.67 ($H^7$), 7.80 ($H^8$), 8.55 ($H^9$).

¶ In contrast, the low-energy MLCT is absent from the spectra of pyridophenazine type complexes like $[Ru(bpy)_2(dppz)]^{2+}$[7] and $[Ru(bpy)_2(tpphz)]^{2+}$.[14]

# Thermal isomerization process in benzene gels of L-glutamic acid-derived lipids with spiropyran head groups

**Hiroshi Hachisako,*[a] Hirotaka Ihara,[b] Teruo Kamiya,[a] Chuichi Hirayama[b] and Kimiho Yamada[a]**

[a] *Department of Industrial Chemistry, Kumamoto Institute of Technology, 4-22-1 Ikeda, Kumamoto 860, Japan*

**First-order kinetic behaviour during the thermal isomerization process of lipids with photochromic spiropyran head groups in benzene strongly depends on the dispersion state of the lipids and this enables the determination of their critical aggregation concentrations.**

In recent years, organic gels arising from the formation of highly organized lipid assemblies in organic media have been attracting wide attention.[1–4] It is necessary to evaluate the critical gelling concentration (c.g.c.), at which the solution begins to form gels, as a measure of the stability of the aggregates of self-assembling lipids. In general, gelation has been considered successful if the cooled solution forms a nearly transparent mass that can be inverted without apparent flow.[4] However, this method is not applicable to fluid solutions containing fragmentary gels. On the other hand, the critical aggregation concentration (c.a.c.), at which lipids begin to aggregate, is believed to be almost identical to the c.g.c. However, this has not been verified because of the difficulty in direct evaluation of the c.a.c. in organic solutions (gels) by using conventional evaluation methods for aqueous solutions.† Therefore, an establishment of a direct evaluation method of c.a.c. in organic systems is very important.

On the other hand, it is well known that spiropyran (SP) shows reversible photochromism. Upon UV irradiation, a colourless and non-ionic SP is converted to a coloured and zwitterionic merocyanine (MC). This MC is reconverted to the SP thermally or upon exposure to visible light. We have previously reported that an L-glutamic acid-derived lipid **5** and related lipids with three amide bonds form organic gels through fibrous aggregates composed of a lipid membrane-like highly oriented structure.[1] Our present attention is focused on the application of photochromic behaviour of highly oriented aggregates of the SP-containing lipids **1**–**3** in organic media. Here, we propose an evaluation method for the c.a.c. of the L-glutamic acid-derived lipids with SP head groups, using MC–SP thermal isomerization (decolouration) behaviour in organic media.

SP-containing lipids **1**–**3** form transparent organic gels in benzene at concentrations of $2.0 \times 10^{-2}$ M. Differential scanning calorimetry (DSC) measurements of these gels (heating rate, 2 °C $min^{-1}$; temperature range, 5–100 °C) revealed that these lipids **1**–**3** showed sharp and single endothermic peaks‡ due to a gel-to-sol transition in the heating process in benzene, indicating that these SP-containing lipids self assemble into highly oriented structures in the gel state. Scanning electron micrographs of the cast film of **2** from a benzene solution revealed that the gel was composed of a network structure of fibrous aggregates with diameters of 300–2000 Å, close to those of aggregates of lipid **5** in benzene.[1]

SP-containing lipids **1**–**3** dissolved in benzene at 70 °C were gradually cooled to 20 °C to form gels. When the gels were exposed to UV light for 5 min at room temp. using a high-pressure mercury lamp in conjunction with a Toshiba UV-D35 colour filter ($330 < \lambda < 380$ nm), visible absorption spectral changes due to SP–MC conversion were observed. Fig. 1 shows a typical decolouration process of the UV-exposed lipid **2** in the benzene gel. Similar decolourations were observed in the gels of lipids **1** and **3**. The absorption maxima ($\lambda_{max}$ in benzene) of the

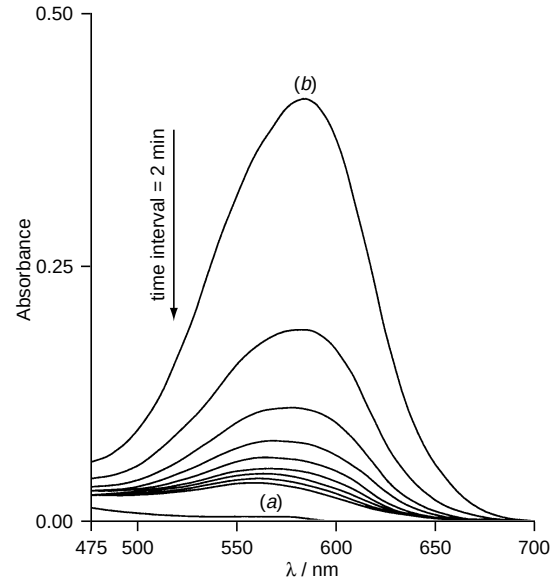

**Fig. 1** Visible absorption spectra of UV-irradiated **2** in benzene. [lipid] = $2 \times 10^{-2}$ M, 20 °C, path length of quartz cell 0.1 mm. (*a*) Before UV-irradiation; (*b*) measured immediately after UV irradiation for 5 min.

resulting MC species depended on the chemical structure of the *N*-substituents (R): 595, 585 and 571 nm for **1**, **2** and **3** respectively. The MC–SP thermal isomerizations were evaluated by first-order kinetic analyses. The plots of the MC–SP conversion process of lipids **1**– **3** in the gel states ($2.0 \times 10^{-2}$ M in benzene) did not obey simple first-order kinetics, whereas good linearities were obtained in the solution state ($1.0 \times 10^{-3}$ M in benzene). Similar deviations from linearity are, in general, observed in many other systems.[5] The first-order rate constants ($k_1$)§ for the MC–SP thermal isomerization for lipids **1**–**3** in benzene were calculated from the slope of these plots and are plotted against lipid concentrations as shown in Fig. 2. The $k_1$ values were remarkably dependent on the lipid concentrations. The critical concentrations shown by the dotted lines in Fig. 2 correspond closely to the critical gelling concentration (c.g.c.) determined by the inversion method.[4] Similar phenomena were observed in toluene. On the other hand, the thermal isomerization rate of the non-gelling SP **4** in benzene was slightly accelerated by increasing the concentration as shown in Fig. 2 and obeyed simple first-order kinetics. This difference can be explained by the fact that lipids **1**–**3** show lipid membrane-like highly oriented aggregation and SP **4** is in a molecularly dispersed state.¶ Fig. 1 shows the hypsochromic $\lambda_{max}$ shift from 585 to 560 nm at the later stage of the decolouration process. This species at 560 nm is ascribable to the H-like aggregates[7] of MC species with head-to-head stacking. These results indicate that the thermal MC–SP isomerization behaviour of the SP-containing lipids is sensitive to the aggregation of the lipid molecules. Therefore, it is concluded that the critical concentrations in Fig. 2 correspond to the c.a.c. of lipids **1**–**3**, respectively. This finding enabled us to detect the c.a.c. directly using first-order kinetics of thermal isomerization instead of *via* an indirect method through evaluation of the c.g.c. by conventional gelation tests, *e.g*. the inversion method.[4] Values of the c.a.c. determined from Fig. 2 were $3 \times 10^{-3}$, $2 \times 10^{-3}$ and $1 \times 10^{-2}$ M for **1**, **2** and **3** respectively. By comparison the corresponding c.g.c. values determined by the inversion method were $4 \times 10^{-3}$, $2 \times 10^{-3}$ and $1 \times 10^{-2}$ M.

In conclusion, we have established a direct method to determine the critical aggregation concentration of organic gels by using first-order kinetic analyses for the thermal MC–SP isomerization process of the component lipids with SP head groups. This finding will also help in clarification of the detailed aggregate structures of a series of organic gel-forming lipids.[1]

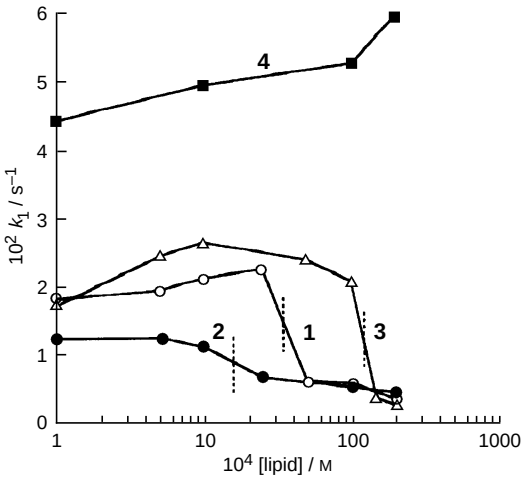

**Fig. 2** Concentration dependence of first-order rate constant ($k_1$) for MC–SP thermal isomerization of lipids **1**–**3** in benzene. 20 °C. Dotted lines indicate the c.a.c. values determined by this method. The error limits of $k_1$ values are within ±10%.‖

## Footnotes

† Surface tension, conductivity, fluorescence (using a fluorescent dye as a microenvironmental probe) and visible absorption spectral measurements (using a solvatochromic dye as a microenvironmental probe), *etc*. are used for the evaluation of c.a.c. in aqueous solution.

‡ Peak-top temperatures: 36 °C for **1**; 39 °C for **2**; 28 °C for **3** in benzene.

§ In the case of deviation from linearity, *e.g*. at $2 \times 10^{-2}$ M in benzene, $k_1$ values were calculated from the first two points and are plotted in Fig. 2.

¶ It has been reported that the thermal MC–SP isomerization is suppressed by aggregation of MC species.[6] Therefore, the retardation of the thermal isomerization rates of **1**–**3** and deviation of their first-order plots from linearity are ascribed to the existence of aggregated MC species.

‖ However, the error limits are much less than the change of $k_1$ values at the critical concentrations; therefore, the c.a.c. is not affected by the error of the of $k_1$ values and the method is safely applied to the determination of c.a.c. (c.g.c.) of the lipids.

# Singlet oxygen production from fullerene derivatives: effect of sequential functionalization of the fullerene core

**Takeshi Hamano,[a] Kensuke Okuda,[a] Tadahiko Mashino,[a] Masaaki Hirobe,[a] Kumi Arakane,[b] Akemi Ryu,[b] Shinrou Mashiko[c] and Tetsuo Nagano*[a]**

[a] *Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan*
[b] *Research Laboratory, KOSÉ Corporation, Azusawa, Itabashi-ku, Tokyo 174, Japan*
[c] *Communication Research Laboratory, Iwaoka, Nishi-ku, Kobe 651-24, Japan*

**Singlet oxygen production efficiency of several laser-excited fullerene derivatives is compared by measuring the 1268 nm emissions; the efficiency was independent of the kind of addends, but it decreased with an increase in the number of addends, and addends at adjacent positions caused a greater decrease than remote addends.**

Fullerene and its derivatives produce singlet oxygen ($^1O_2$, $^1\triangle_g$) by energy transfer with high quantum yield;[1,2,3] [60]fullerene is a more efficient photosensitizer than rose bengal, methylene blue and eosin yellowish (tetrabromofluorescein sodium salt).[4] Singlet oxygen has been postulated to play important roles in many photochemical and photophysical processes in biological systems.[5] For example, it is thought to be responsible for phototoxicity in erythropoietic protoporphyria and for tetracyclin phototoxicity,[5] and it has also been applied for photodynamic therapy of cancer.[5] Thus, it is worthwhile to investigate in detail the photophysical or photochemical properties of fullerene and its derivatives from the standpoint of potential applications to biological systems. In particular, as fullerene derivatives have their UV–VIS absorption maxima at longer wavelengths, and have greater solubility in polar solvents, they may be preferable to the parent compound, [60]fullerene, for pharmaceutical application.[6]

We have already investigated the regiochemistry of several oxidation products of fullerene which were synthesized with the tetraphenylporphinatoruthenium(II) carbonyl–2,6-dichloropyridine-*N*-oxide–HBr system, and reported that [60]fullerene was multiply epoxidized (at least up to pentaepoxide, as determined by FAB mass spectroscopy), and that the second or the third oxygen was introduced at a position adjacent to the existing epoxide (confirmed by $^{13}C$ NMR spectroscopy employing $^{13}C$-enriched samples) (Fig. 1).[7] These epoxides might be good models to evaluate the effect of sequential functionalization on the photosensitizing activity of the fullerene structure. Anderson *et al*. have already reported on singlet oxygen production from dihydrofullerene, and discussed the effect of the functionalization.[2] However, they investigated only one derivative, and did not examine the effect of the number of addends, or the regiochemistry of bis or more highly functionalized fullerenes. We have also synthesized diethyl malonate-derivatized [60]fullerenes (see Fig. 1), which were previously reported by Hirsch *et al*.[8] As they have the addends at positions remote from each other (equatorial or *trans*-3),† they may have different photophysical properties from those of the corresponding epoxides.

In this work, we measured the near-infrared emission spectra corresponding to the $O_2(^1\triangle_g) \rightarrow O_2(^3\Sigma_g^-)$ transition at 1268 nm, which is highly specific to $^1O_2$, in solutions of fullerene derivatives under argon laser excitation (514.5 nm).[4] This is the most reliable method for $^1O_2$ detection developed so far. By this means, the amount of $^1O_2$ generated could be compared among the tested samples. We evaluated the efficiency of singlet oxygen production by calculating the value of emission intensity at 1268 nm/absorption coefficient at 514.5 nm ($I/\varepsilon$). As the absorption coefficient is a measure of the efficiency of a transition to an excited state ($S_1$ at a given wavelength, it can be thought that the $I/\varepsilon$ indicates the emission intensity from an unit of excited species ($S_1$) of sensitizer. That is, we evaluated the total efficiency of singlet oxygen production from the excited species by this value, and this value includes the efficiency of intersystem crossing and energy transfer from triplet state to molecular oxygen.

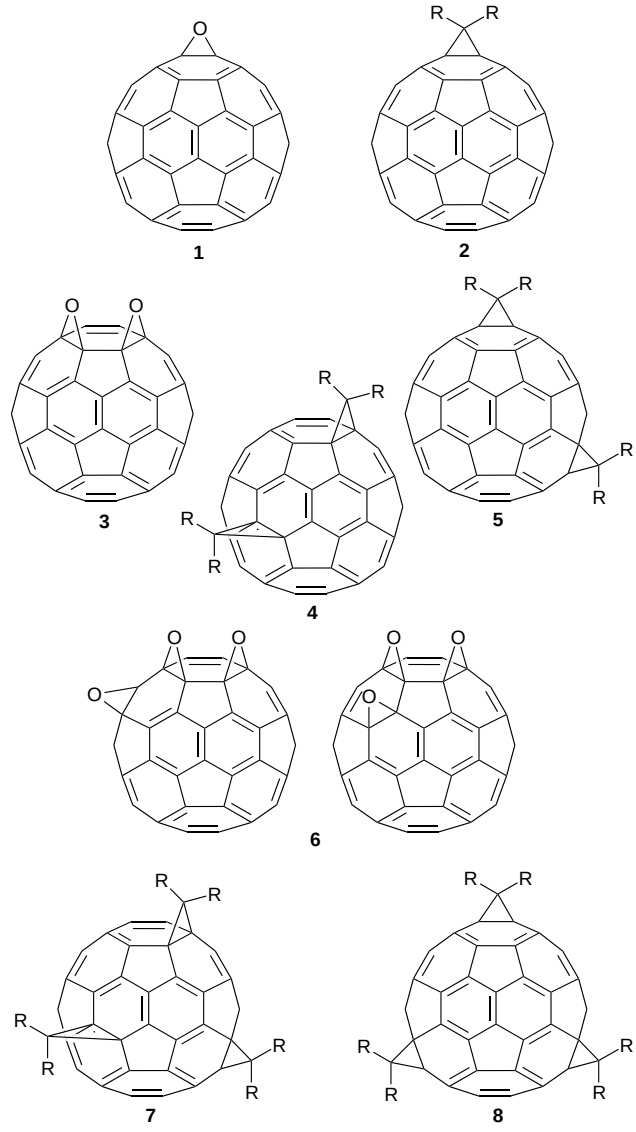

**Fig. 1**

Emission intensity increased in a concentration-dependent manner with all the compounds. The emission was diminished by the addition of excess β-carotene, a specific $^1O_2$ quencher, and was reduced by bubbling $N_2$ into the solution for a few minutes. These results confirm that all the compounds used in this study acted as photosensitizers, and that $^1O_2$ was responsible for the emission at 1268 nm.

First, we examined the effect of the number of addends on $^1O_2$-producing activity. As shown in Table 1, with both the epoxides and the diethyl malonate derivatives, $^1O_2$-producing ability decreased with an increase in the number of substituents. The size of the decrease was different between the two groups, and this will be discussed later. However, the order of diepoxide **3** and triepoxide **6** was exceptional, and the reason for this is still unknown.

Secondly we compared 1,2-epoxy[60]fullerene **1** and bis-(ethoxycarbonyl)[61]fullerene **2**. We did not observe any significant difference between **1** and **2** in $^1O_2$-producing ability. According to Anderson *et al*.,[2] dihydrofullerene had a reduced quantum yield of singlet oxygen production compared with [60]fullererne in $C_6D_6$. Our results are consistent with their report, even though a different laser wavelength was employed. It appears that functionalization of the fullerene core reduced the photodynamic activity, and the effect was not significantly dependent on the kind of addend, oxygen or diethyl malonate. However, it is noteworthy that the emission intensity itself was much greater with **2** than with **1** or [60]fullerene, because **2** has a greater value of ε at 514.5 nm (Table 1). This result suggests **2** would produce much more $^1O_2$ under given conditions, and could have significant implications for the pharmaceutical application of this class of compounds.

Next we compared 1,2;3,4-diepoxy[60]fullerene **3**, and tetra(ethoxycarbonyl)[62]fullerenes (equatorial) **4** and (*trans*-3) **5** in order to evaluate the effect of addend position on the fullerene structure. All three derivatives are bisadducts, but **3** has addends at adjacent positions, while **4** and **5** have them at remote positions. The emission intensity of **4** or **5** was stronger than that of [60]fullerene owing to the high ε value at 514.5 nm but, as expected the photodynamic efficiency was decreased after normalization, as described above. The results in Table 1 show that all of the derivatives have decreased $^1O_2$-producing ability ($I/\varepsilon$) compared with **1** or **2**, but the extent of the decrease was different between the two groups. That is, while **4** and **5** had 20–25% lower activity than **2**, **3** retained only 15% activity compared with that of **1**. This result suggests that a second addend introduced at an adjacent position to the existing one caused a greater perturbation of the electronic structure of the fullerene core than a second addend at a remote position. In the case of trisadducts **6**, **7** and **8**, the result was similar, that is to say, the photodynamic activity of **6** was greatly decreased compared with those of **7** and **8**, because of the proximity of the three addends on the fullerene core.

We also examined multihydroxylated fullerene (fullerenol) prepared by the literature method.[9] No peak was detected in $D_2O$ at concentrations up to about 10 mM (data not shown). This concentration is 10 000 times that of other fullerene derivatives used in this study. Thus, we concluded that extensive derivatization of the fullerene core results in loss of photodynamic activity. This is in accordance with the results reported by Cardullo *et al*. In the report, they showed that a fullerene hexaadduct had no photodynamic activity.[10]

As the results obtained in this study were relative efficiency of $^1O_2$ production of the fullerene derivatives, further investigation will be required for the clarification of their detailed photophysical properties, such as quantum yield of the energy transfer from triplet state to molecular oxygen, in the future.

**Table 1** Photodynamic efficiency of fullerene and its derivatives[a]

| Compound[b] | $I$[c] | $I/\varepsilon$[d] |
|---|---|---|
| $C_{60}$ | 1.0 | 1.0 |
| $C_{60}O$ **1** | 1.21 | 0.74 |
| $BECC_{61}$ **2** | 1.59 | 0.77 |
| $C_{60}O_2$ **3** | 0.29 | 0.11 |
| $TECC_{62}$ (equatorial) **4** | 2.09 | 0.59 |
| $TECC_{62}$ (*trans*-3) **5** | 2.15 | 0.53 |
| $C_{60}O_3$ **6** | 0.42 | 0.22 |
| $HECC_{63}$ (equatorial, equatorial) **7** | 1.71 | 0.42 |
| $HECC_{63}$ (*trans*-3, *trans*-3) **8** | 1.73 | 0.40 |
| $C_{60}O_4$ | 0.12 | 0.06 |
| $C_{60}O_5$ | 0.06 | 0.03 |

[a] The emission intensity at 1268 nm was measured in $CS_2$ solution for photosensitizers excited by Ar laser light at 514.5 nm with 25 mW output power. [b] Abbreviations: $BECC_{61}$ = bis(ethoxycarbonyl)$C_{61}$; $TECC_{62}$ = tetra(ethoxycarbonyl)$C_{62}$; $HECC_{63}$ = hexa(ethoxycarbonyl)$C_{63}$. The nomenclature follows the proposals of Hirsch *et al.* (ref. 8). [c] Emission intensity at 1268 nm. [d] Emission intensity at 1268 nm/absorption coefficient at 514.5 nm (relative value to that of [60]fullerene.

# Synthesis of 3-*O*-sialyl and 6-*O*-sulfo derivatives of dimeric *N*-acetyl lactosamine as specific acceptors for α-L-fucosyltransferases

**Rakesh K. Jain,† Bao-Guo Huang, E. V. Chandrasekaran and Khushi L. Matta***

*Department of Gynecologic Oncology, Rosewell Park Cancer Institute, Elm & Carlton Streets, Buffalo, NY 14263, USA*

**The stereoselective syntheses of 3-*O*-sialyl and 6-*O*-sulfo dimeric lactosamine derivatives 1–4 are accomplished through the use of key glycosyl donors 13 and 15.**

In continuation of our efforts towards the synthesis of biologically important oligosaccharides, we have developed an elegant synthesis of 3-*O*- and 6-*O*-substituted dimeric lactosamine derivatives. **1**–**4**[1] (Fig. 1), which were prepared from the key intermediates **5**–**13** (Fig. 2) by stereoselective transformation, as described in Schemes 1–3. Our approach is based upon the observation that an *O*-acetyl group can be selectively removed in the presence of a 6-*O*-pivaloyl substituent to give 6-*O*-pivaloyl β-D-galactopyranosyl linked compounds. Glycosylation of **5** with **9** under Mukaiyama's conditions ($SnCl_2$–AgOTf)[2] followed by acetylation with pyridine–acetic anhydride afforded the β(1→3) linked disaccharide **14** in 8% yield and the β(1→4) linked disaccharide **15** in 48% yield. The $^1$H NMR spectrum of **15** displayed characteristic signals for H-3, H-1 (δ 5.71–5.67), H-1′ (δ 4.50, d, $J$ = 8.0 Hz), 4 × OAc (δ 2.08, 2.04, 1.93 and 0.86) and 2 × $CMe_3$ (δ 1.25 and 1.17). Isopropylidenation of **11**, using Catelani's procedure,[3] followed by acetylation with pyridine–acetic anhydride and deacetonation provided the acceptor **16** in 66% yield. The $^1$H NMR spectrum gave characteristic signals at δ 5.70 (dd, H-3), 2.10 and 1.09 (2 × OAc) and 1.27 and 1.23 (2 × $CMe_3$). Condensation of the donor **15** with **16** under NIS–triflic acid conditions at −30 °C gave **17** in 76% yield. The $^1$H NMR spectrum of **17** displayed characteristic signals at δ 5.71–5.59 (2 × dd and d, H-3, H-3″ and H-4″), 5.46 (d, $J$ = 8.3 Hz, H-1″), 5.24 (d, $J$ = 8.5 Hz, H-1), 5.09 (dd, H-2‴), 4.97 (dd, H-2′), 4.53 (d, $J$ = 7.9 Hz, H-1‴), 4.43 (d, $J$ = 7.6 Hz, H-1′), 2.10–1.49 (cluster of singlets, 6 × OAc) and 1.25, 1.23 and 1.94 (4 × $CMe_3$) which confirmed a β(1→3) conformation of the newly incorporated glycosidic linkage. De-*O*-acetylation of **17** in MeOH–$CH_2Cl_2$ (1 : 1, *v*/*v*) with MeOH–MeONa (pH 10) at 0 °C provided the acceptor **18** in 95% yield. The $^1$H NMR spectrum gave characteristic signals at δ 5.58–5.69 (2 × dd, H-3″ and H-3), 5.34 (d, H-1″, $J$ = 8.2 Hz), 5.24 (d, H-1, $J$ = 8.4 Hz), 4.82 (dd, H-2′), 4.73 (d, $J$ = 7.8 Hz, H-1‴), 4.35 (d, $J$ = 7.7 Hz, H-1′), 1.84, 1.75 and 1.49 (each s, 3 × OAc) and 1.25, 1.23, 1.22 and 0.97 (each s, 4 × $CMe_3$) confirming the assigned structure.

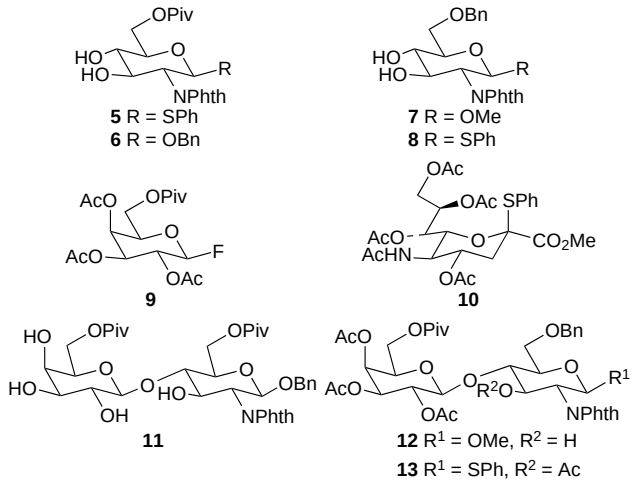

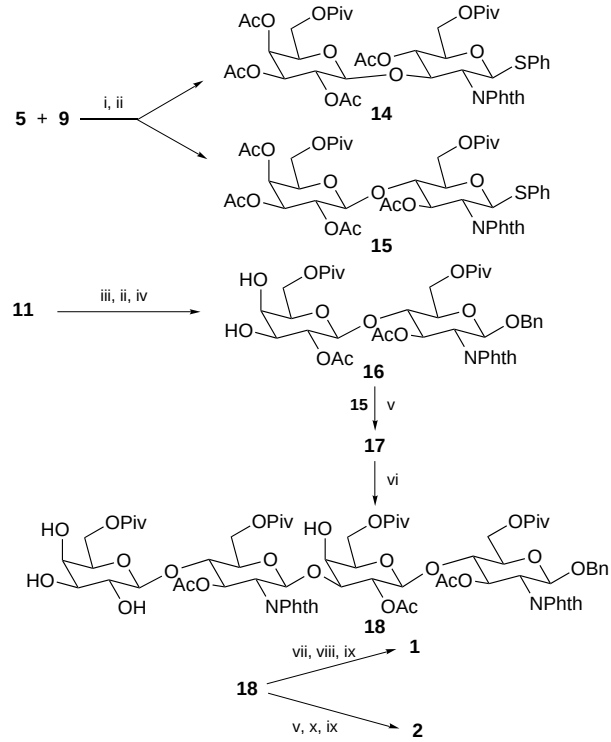

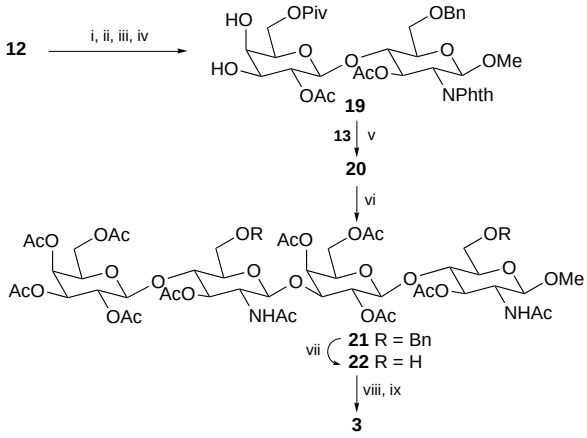

**Fig. 2** Key intermediates **5**–**13** involved in the synthesis of target molecules **1**–**4**

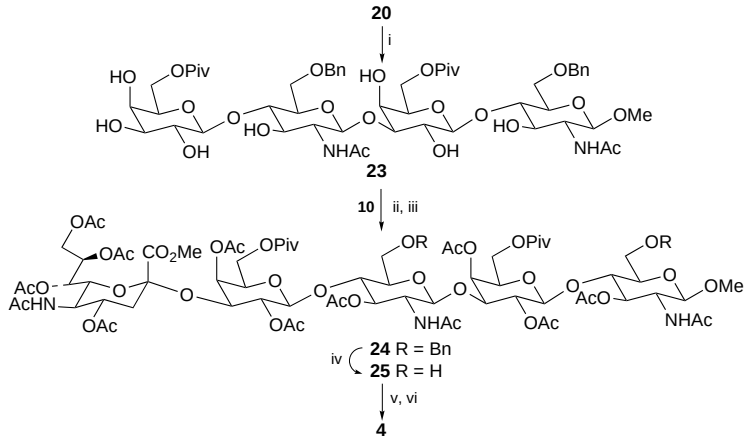
**Scheme 1** *Reactions and conditions*: i, **5** (1.0 equiv.), **9** (1.5 equiv.), AgOTf (1.20 equiv.), 4 Å molecular sieves, $CH_2Cl_2$–toluene (5 : 1, v/v), −15 °C to room temp., 5 h; ii, pyridine–$Ac_2O$ (2 : 1, v/v); iii, 0.15% CSA, DMP, 24 h, MeOH–$H_2O$ (10 : 1, v/v), 100 °C, 6 h; iv, 70% aq. AcOH, 70 °C, 2 h; v, **15** (1.05 equiv.), or **10** (3.0 equiv.), NIS (3.0 equiv.)–triflic acid, −30 °C, 2 h; vi, MeOH–$CH_2Cl_2$ (1 : 1, v/v), MeONa (pH 10), 2 h; vii, $SO_3$–pyridine complex in pyridine (6.0 equiv.), 5 °C, 16 h; viii, MeOH–hydrazine hydrate (4 : 1, v/v), 100 °C, 16 h, $Ac_2O$ (excess), MeOH–$CH_2Cl_2$ (1 : 1, v/v), 0 °C, 1 h; ix, MeOH–MeONa, 24 h; x, LiI (10 equiv.), pyridine, 120 °C, 3 h

**Scheme 2** *Reagents and conditions*: i, MeOH–$CH_2Cl_2$ (1 : 1, v/v), MeONa, 0 °C, 2 h, 85%; ii, DMP, PTS, room temp., 1.5 h, 89%; iii, pyridine–$Ac_2O$ (2 : 1, v/v), room temp., 12 h, 89%; iv, 70% aq. AcOH, 65 °C, 2.5 h, 66%; v, **13** (0.95 equiv.), NIS (3.0 equiv.)–triflic acid, −20 °C, 1 h, 54%; vi, EtOH–hydrazine hydrate (4 : 1, v/v), 100 °C, 16 h, pyridine–$Ac_2O$ (2 : 1, v/v), room temp., 12 h, 84%; vii, 10% Pd–C, $H_2$, MeOH, 16 h; 50%; viii, $SO_3$–pyridine complex in DMF (10 equiv.), 0 °C, 16 h; ix, MeOH–MeONa, 16 h; $Na^+$ resin, 35% from **22**



Removal of both the phthalimido and acetate groups from **20** was accomplished by treatment with hydrazine hydrate in ethanol (1 : 9, v/v) at 80 °C followed by N-acetylation to give **23** in 65% yield. Condensation of sialic acid donor **10** with **23** at −40 °C followed by *O*-acetylation gave **24** in 35% yield (based on **23** consumed). The synthesis of **4** from **24** was achieved by a sequence of reactions similar to those described for the preparation of **3** from **21**. The structures of **1**–**4** were confirmed by $^1H$ and $^{13}C$ NMR spectroscopy.†

Our preliminary examination of Galβ1,4(6-sulfo) GlcNAcβ1,3 Galβ1,4(6-sulfo) GlcNAcβ-O-Me (**3**) and Neu-Acα2,3Galβ1,4(6-sulfo)GlcNAcβ1,3Galβ1,4(6-sulfo) GlcNAcβ-O-Me (**4**) indicated that both of these compounds were equally active as acceptors for human colon tumour α1,3-L-fucosyltransferase.

These investigations were supported by Grant No. CA 63218 awarded by the National Cancer Institute.

For **2**: $[\alpha]_D$ +186 (*c* 0.2, $H_2O$); $^1H$ NMR ($D_2O$, 400 MHz): δ 4.84 (d, *J* = 12 Hz,

**Scheme 3** *Reagents and conditions*: i, EtOH–hydrazine hydrate (9 : 1, v/v), 80 °C, 1 h, MeOH–$Et_3N$–$Ac_2O$ (4 : 2 : 1), room temp., 2 h, 65%; ii, **10** (2.50 equiv.), NIS (3.0 equiv.)–triflic acid, MeCN, −40 °C, 1 h; iii, pyridine–$Ac_2O$ (2 : 1, v/v), room temp., 12 h, 35% based on **23** consumed; iv, 10% Pd–C, $H_2$ MeOH, 24 h; v, $SO_3$–pyridine complex in DMF (10 equiv.), room temp., 2 h; vi, MeOH–MeONa, 48 h; $H_2O$, 4 h, $Na^+$ resin, 56% from **24**

Selective sulfation of **18** with $SO_3$–pyridine complex in pyridine at 5 °C provided the 3-*O*-sulfo compound which upon removal of its phthalimido group (MeOH–hydrazine hydrate, 100 °C) and *N*-acetylation followed by de-*O*-acetylation (MeOH–MeONa) gave the known compound **1** (55% from **18**).[4]

A similar NIS–triflic acid reaction of **18** with sialic acid donor **10** provided the crude pentasaccharide. The conversion of this intermediate into target compound **2** (23% from **18**) was then carried out in 4 steps: (i) LiI–pyridine (methyl ester to acid), (ii) MeOH–hydrazine hydrate (phthalimido group removal), (iii) $Ac_2O$–MeOH–$CH_2Cl_2$ (*N*-acetylation) and (iv) MeOH–MeONa (de-*O*-acetylation).

The synthesis of **3** and **4** (Schemes 2 and 3) involved the glycosylation of **8** with fluoride **9** under conditions similar to those described for the preparation of **15** (from **5**), followed by acetylation to give donor **13** along with some 1⟶3 linked disaccharide. Condensation of **13** with **19** under NIS–triflic acid conditions at −20 °C provided **20** in 54% yield. The formation of **21** from **20** was achieved by the treatment with hydrazine hydrate in ethanol (1 : 4, v/v) at 100 °C followed by acetylation with pyridine–acetic anhydride in 84% yield. The removal of *O*-benzyl (10% Pd–C) gave diol **22** which on sulfation with $SO_3$–pyridine complex in DMF and followed by de-*O*-acetylation gave compound **3** in 35% yield (from **22**).

# Proton migration on the [60]fullerene cage of 1-*tert*-butyl-1,4-dihydro[60]fullerene to yield the 1,2-isomer

**Fiachra Banim, David J. Cardin and Peter Heath**

*Department of Chemistry, University of Reading, Whiteknights, Reading Berkshire, UK RG6 6AD*

**Proton NMR data on the base catalysed rearrangement of 1-*tert*-butyl-1,4-dihydro[60]fullerene to the 1,2-isomer reveal a second order reaction and an activation energy of 56.1 kJ mol$^{-1}$.**

It has been reported that treatment of [60]fullerene with *tert*-butyllithium followed by acid quench gives both 1,2- and 1,4-isomers, and that the 1,4-compound rearranges to the more stable 1,2-isomer over a period of 12 h at 25 °C.[1] We now report that the pure 1,4-isomer is indefinitely stable in the solid form (no detectable rearrangement over eighteen months) while even in solution little conversion to the thermodynamic product occurs over two months in deuteriated chloroform. We also show that the rearrangement of the 1,4-isomer to the 1,2-isomer is base catalysed, and provide kinetic and thermodynamic data on this rearrangement.

1-*tert*-Butyl-1,2-dihydro[60]fullerene is the thermodynamically favoured adduct (by *ca.* 12 kJ mol$^{-1}$ from PM3 calculations[2]) not requiring (unlike the 1,4-adduct) the introduction of a double bond at the 6,5 ring junction (estimated from similar PM3 parameterisation of the MNDO Hamiltonian to add *ca*. 35 kJ mol$^{-1}$).[3] This unfavourable electronic effect is partly compensated by the absence of the eclipsing (steric) interaction that exists between addenda in the 1,2-position. This factor is clearly demonstrated by increasing the steric requirements of the adducts from Bu$^t$C$_{60}$H to a bulky 1-*tert*-butyl-1,4-dihydro-2-(3,6-dicyclopropylcyclohepta-2,4,6-trien-1-yl)[60]fullerene, when the 1,4-derivative becomes more favourable by a predicted 75 kJ mol$^{-1}$ (also from PM3 calculations).

Maximum yields of 1-*tert*-butyl-1-4-dihydro[60]fullerene were obtained if the reaction was acid quenched within 3 h, using toluene as solvent, and the lithium reagent was added in hexanes. After 24 h only the 1,2-isomer was obtainable. (Up to 85 : 15 1,4- : 1,2-adduct could be obtained). The ratio of the 1,4- : 1,2-adducts was not adversely affected when different protic species were introduced *e.g.* water, hydrogen chloride, water–hydrogen chloride, glacial acetic acid or trifluoroacetic acid. In an attempt to form the 1,4-adduct more selectively, the reaction was carried out at elevated temperature (60 °C), but this had little effect, and was not studied in more detail. The proton NMR spectrum of the reaction product shows two *tert*-butyl signals (at δ 2.08 and 1.88) and two 'cage' proton signals (at δ 6.67 and 6.32) in $CDCl_3$. A NOESY NMR experiment established that the lower field resonance at δ 6.67 and the *tert*-butyl resonance at δ 2.08 had a strong transient NOE. We conclude that these resonances represent the 1,2-isomer, which was verified by $^{13}$C NMR.† There was no transient NOE between the fullerenyl proton and the *tert*-butyl group for the second isomer, ruling out the unfavourable 1,6-adduct.[4]

In suitable environments, 1-*tert*-butyl-1,4-dihydro[60]fullerene is stable for prolonged periods of time, but can easily rearrange in the presence of trace impurities. Several acids were explored, but none gave any indication of isomerisation. Treatment of the isomeric mixture with various bases, by contrast, gave an immediate rearrangement reaction.‡ It is interesting to note that variation of the base showed that the p$K_a$ of the fullerenyl (cage) proton of the 1,4-isomer could be crudely estimated at 5.7 > p$K_a$ > 4.15 (these data were obtained in chloroform or deuteriochloroform solution), a range consistent with other estimates for a variety of such cage protons, and rather higher than that calculated recently (3.31) by quantum mechanical methods.[5]

Experiments were conducted using $^1$H NMR as a probe, and perdeuteriated pyridine as base catalyst, reactions being carried out in deuteriochloroform. When deuteriopyridine was added to solutions of the 1,4-isomer, the concentration of the latter was found to decrease, giving an increase in the 1,2-isomer concentration (Fig. 1),§ a *ca*. 96% conversion being generally observed. The 1,4-isomer concentration decayed exponentially with time, and an increase in the concentration of deuteriopyridine increased the rate of reaction.

A linear fit was obtained when the natural logarithm of the concentration of the 1,4-isomer was plotted against time, in agreement with a reaction first order with respect to the fullerene concentration (Fig. 2). A second order reaction was ruled out as a plot of the reciprocal of the substrate concentration with time gave a clearly non-linear relationship (Fig. 2).

A plot of ln $[A]_t$ against time allowed us to calculate $k'$ at different concentrations of deuteriopyridine (Fig. 3).¶ The results show that the reaction is second order overall and first order with respect to both the concentration of 1,4-Bu$^t$C$_{60}$H and deuteriopyridine. The exact value for the rate constant of the

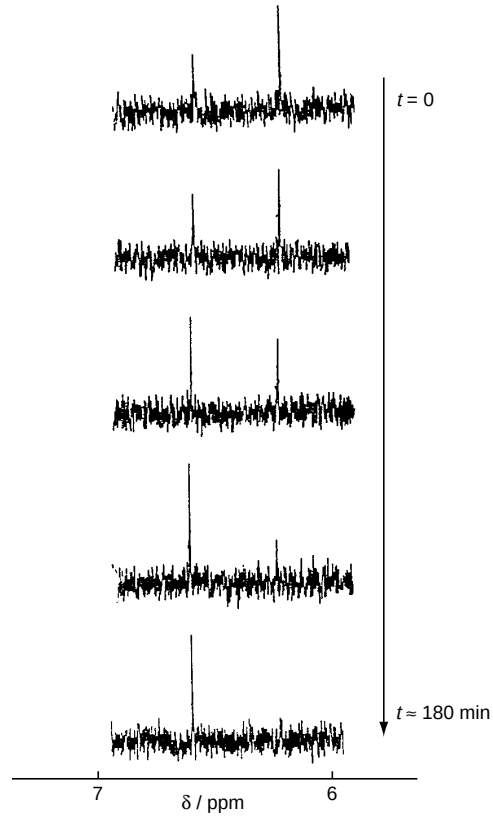

**Fig. 1** Variation of the $C_{60}H$ $^1$H NMR signals during isomerisation, recorded at 21 ± 1 °C in a 0.35 M solution of $C_5D_5N$ in $CDCl_3$

reaction $k_{expt}$ [2.1(1) × $10^{-3}$ $dm^3$ $mol^{-1}$ $s^{-1}$], was calculated from Fig. 3.¶

The rate of consumption of the reactant, 1-*tert*-butyl-1-4,-dihydro[60]fullerene, was determined at different temperatures in the range 20–50 °C for two concentrations. An Arrhenius plot gave an activation energy of 56.1 kJ $mol^{-1}$ (Fig. 4).

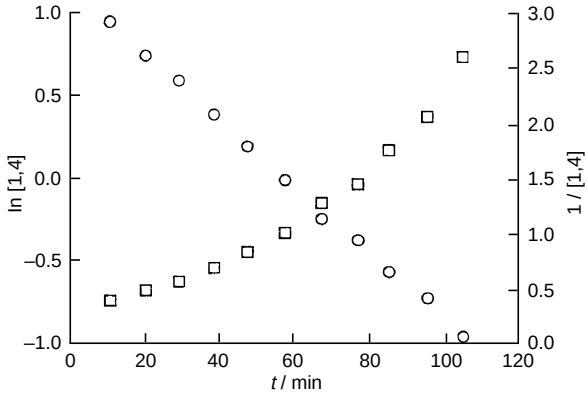

**Fig. 2** First- and second-order plots of the isomerisation reaction of the 1,4-isomer, recorded at 21 ± 1 °C. First order reaction (○) plotted *vs.* ln [1,4] (left axis) and second order reaction (□) plotted *vs.* 1/[1,4] (right axis). Recorded in 0.178.

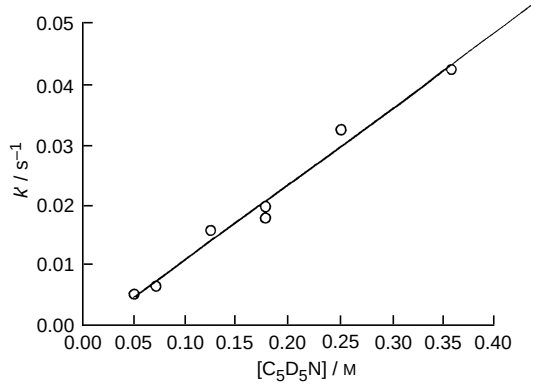

**Fig. 3** Plot of *k′ vs.* [$C_5D_5N$] at 21 ± 1 °C

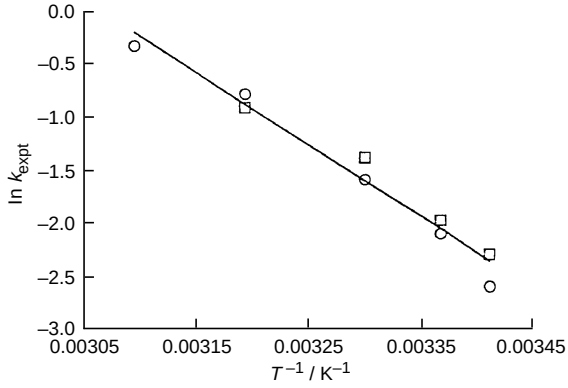

**Fig. 4** Arrhenius plot for the isomerisation reaction of the 1,4-isomer in 0.17 (□) and 0.07 M (○) $C_5D_5N$

In an attempt to elucidate the mechanism of the base catalysed reaction, the fullerenyl proton was substituted by a deuteron. Similar experiments to those employing 1,4-Bu$^t$$C_{60}$H were carried out on the 1,4-Bu$^t$$C_{60}$D derivative, again giving a reaction second order overall; first order with respect to 1,4-Bu$^t$$C_{60}$D and pyridine. The experimental value for the rate of reaction ($k_D$) was only marginally less than $k_{expt}$, yielding a value of *ca.* 1.2 for $k_{expt}/k_D$.

The mechanism of the hydrogen transfer step is currently under investigation. In initial experiments the 1,4-Bu$^t$$C_{60}$D reaction afforded substantially 1,2-Bu$^t$$C_{60}$H, the origin of the H atom (possibly adventitious water) and the details of the transfer are being studied.

We thank the authors of ref. 5 for providing details prior to publication.

## Footnotes

† The $^{13}$C NMR spectrum of pure 1-*tert*-butyl-1,2-dihydro[60]fullerene had 32 resonances indicative of the $C_s$ symmetry of a 1,2 adduct.

‡ Although the 1,4-isomer is stable as described above, on heating a mixture of the 1,2- and 1,4-isomers at 60 °C for 72 h, up to 25% of the 1,4-isomer rearranges. There may be a concerted, non-catalysed reaction also occurring, albeit at a substantially slower rate than the catalysed reaction. This route of rearrangement will be explored further.

§ Quantitative data were taken, however, from the *tert*-butyl signals, which had a substantially better signal-to-noise ratio.

¶ From the plots we can write eqn. (1) for the overall reaction,

$$[A] + [C_5D_5N] \rightarrow [B] + [C_5D_5N] \quad (1)$$

where A = 1,4-Bu$^t$$C_{60}$H and B = 1,2-Bu$^t$$C_{60}$H. This gives eqn. (2).

$$\text{rate of reaction} = k_{expt}\,[B][C_5D_5N] \quad (2)$$

If the concentration of deuteriopyridine is kept constant and the decrease in concentration of 1,4-Bu$^t$$C_{60}$H is monitored, this gives eqn. (3).

$$-d[A]/[A] = k'dt, \text{ where } k' = k_{expt}\,[C_5D_5N] \quad (3)$$

Integration of eqn. (3) gives eqn. (4).

$$\ln [A]_0 - \ln [A]_t = k't, \quad (4)$$

where $[A]_0$ is the concentration of [1,4-Bu$^t$$C_{60}$H] at $t = 0$ and $[A]_t$ is the concentration of [1,4-Bu$^t$$C_{60}$] at time $t$. Eqn. (4) then gives eqn. (5).

$$\ln [A]_t = -k't + \ln [A]_0 \quad (5)$$

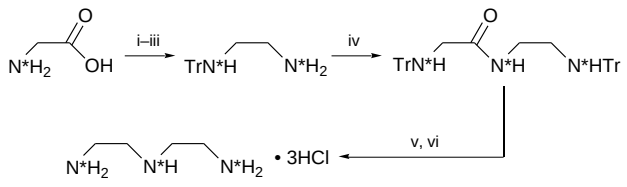
# Recognition of platinum(II) amine complexes by nucleotides: role of phosphate and carbonyl groups in ([$^{15}N_3$]diethylenetriamine)-(guanosine 5′-monophosphate)platinum(II)

**Zijian Guo, Peter J. Sadler*† and Erle Zang**



*Department of Chemistry, Birkbeck College, University of London, Gordon House, 29 Gordon Square, London, UK WC1H 0PP*

**Two-dimensional [$^1$H,$^{15}$N] NMR studies show that in the model monofunctional DNA adduct [Pt([$^{15}N_3$]dien)(5′-GMP-*N*7)]$^{2+}$ [5′-GMP = guanosine 5′-monophosphate, dien = 1,5-diamino-3-azapentane (prepared by a novel synthesis from glycine)], stereospecific hydrogen-bonding interactions involving Pt–NH protons are promoted by deprotonation of both the 5′-phosphate group and N$^1$H of coordinated 5′-GMP.**

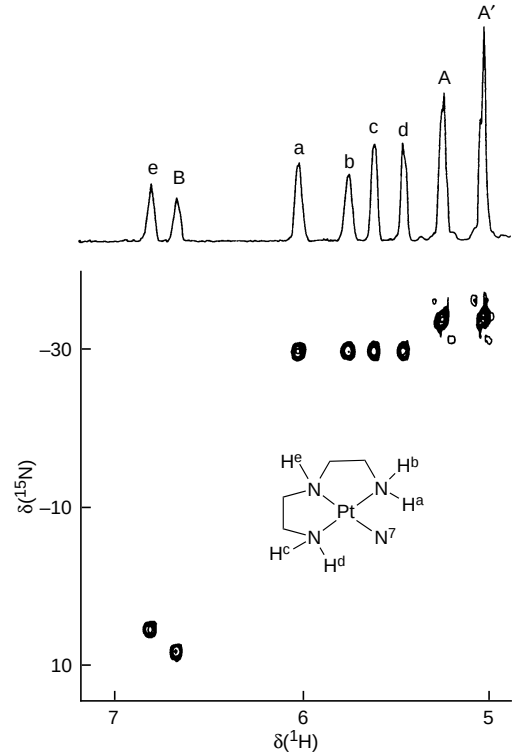
A surprising recent finding is that monofunctional adducts of $[PtCl_2(NH_3)_2]$ (cisplatin) and $[Pt(NH_3)_2(H_2O)_2]^{2+}$ with one of the guanine bases in GG oligonucleotides can be very long lived.[1,2] It is therefore important to understand the factors which lead to stabilization of particular adducts between platinum am(m)ine complexes and DNA. Complexes of [Pt(dien)]$^{2+}$ with nucleotides have been widely studied since they represent stable monofunctional adducts, and the ability of [Pt(dien)]$^{2+}$ to introduce local denaturation of DNA has been demonstrated, for example by Brabec *et al*. using chemical probes.[3]

The NH groups on platinum am(m)ine ligands are thought to play a major role in determining the nature of the adducts *via* hydrogen-bonding interactions with DNA,[4] and we have shown previously that these can be investigated in solution using two-dimensional [$^1$H,$^{15}$N] NMR and $^{15}$N-labelled ligands.[5] Use of this method with dien complexes is complicated by the lack of an efficient synthesis of dien which can be adapted to $^{15}$N labelling. We report here briefly a novel efficient synthesis of [$^{15}N_3$]dien, and show that use of this allows an NMR study of hydrogen-bonding interactions in nucleotide complexes such as [Pt([$^{15}N_3$]dien)(5′-GMP-*N*7)]$^{2+}$. The NMR data implicate both the 5′-phosphate and C$^6$ carbonyl groups in pH-dependent stereospecific interactions with the Pt–$NH_2$ groups.

$^{15}$N-Labelled dien cannot readily be prepared by the Gabriel method[6] since [$^{15}$N]diethanolamine is required as a starting material. The preparation of this from ethylene oxide and excess $^{15}NH_3$ is uneconomic since the yield is low, the product cannot be readily separated from ethanolamine and triethanolamine, and the intermediate 2,2′-dichlorodiethylamine is unstable and difficult to handle. Therefore we have developed the new method shown in Scheme 1, which uses [$^{15}$N]glycine as starting material. The trityl group was used to protect the amino group throughout the synthesis. Amidation of [$^{15}$N]tritylglycine with $^{15}NH_3$ afforded [$^{15}N_2$]tritylglycinamide, which was then reduced to [$^{15}N_2$]monotritylethylenediamine by $LiAlH_4$. 1-([$^{15}$N]Tritylglycyl)-2-([$^{15}N_2$]trityl)ethylenediamine was obtained as a condensation product from [$^{15}N_2$]monotritylethylenediamine and [$^{15}$N]tritylglycine. After reduction and cleavage of the protecting group, the hydrochloride salt of [$^{15}N_3$]dien was obtained in 20% overall yield based on [$^{15}$N]glycine. Full details of the synthesis will be published elsewhere.

**Scheme 1** *Reagents and conditions*: i, TrCl, Tr = Trityl, Pr$^i$OH–$H_2O$, room temp.; ii, ethyl chloroformate, $^{15}NH_3$, $CHCl_3$, room temp.; iii, $LiAlH_4$, thf, room temp.; iv, ethyl chloroformate, $^{15}$N-tritylglycine, $CHCl_3$, room temp.; v, $LiAlH_4$, thf, 75 °C; vi, 4.8 M HCl, reflux

The platinum complex [Pt([$^{15}N_3$]dien)Cl]Cl was prepared according to the literature method for the unlabelled complex.[7] The two-dimensional [$^1$H,$^{15}$N] HSQC NMR spectrum of a fresh solution (*i.e*. prior to hydrolysis) of [Pt([$^{15}N_3$]dien)Cl]$^+$ **1** in $H_2O$–$D_2O$ (9 : 1) showed three sets of cross-peaks at δ 5.23/−33.9, 5.02/−33.9 and 6.65/8.13 (see Fig. 1). On the basis of their shifts,[8] the former two peaks can be assigned to non-equivalent protons on the two $NH_2$ groups, and the latter to the NH group.



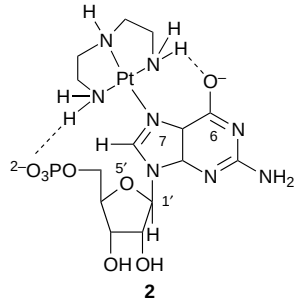


**Fig. 1** Reaction of [Pt([$^{15}N_3$]dien)Cl]$^+$ **1** with 5′-GMP. This two-dimensional [$^1$H,$^{15}$N] HSQC NMR spectrum was recorded 1.2 h after mixing and shows $NH_2$ and NH peaks for complex **1** labelled **A**, **A′** and **B**, respectively, and for the GMP adduct **2** labelled **a**–**e** (all five NH protons are non-equivalent). After 12 h the reaction was complete and only peaks for **2** were observable. The large downfield shift of peak **a** is notable. $^{195}$Pt satellites in both the $^1$H and $^{15}$N dimensions are evident for complex **1** but not for **2** (satellites broaden with increases in molecular size and chemical shift anisotropy). *Conditions*: mol ratio Pt : GMP 0.8 : 1 (5 mM), $H_2O$–$D_2O$ (9 : 1), pH 6.83, 298 K.

As an initial model for DNA binding, we studied the adduct formed from the reaction of 5′-GMP with **1** (5 mM, 1 : 1 mol ratio) at pH 6.8, 298 K. The two-dimensional spectrum after 1.2 h of reaction is shown in Fig. 1, where peaks assignable to the starting material **1** and to the product [Pt([$^{15}N_3$]dien)(GMP-*N*$^7$)]$^{2+}$ **2** are well resolved. Most notable is the presence of five cross-peaks for **2** showing that all the NH protons are magnetically non-equivalent. This might be expected in view of the chirality of the bound nucleotide. In order to understand the origin of the low-field shifts of the peaks for **2**, their pH dependence was studied over the range pH 3–11. There was little change in the $^1$H,$^{15}$N shift of peak **e** assigned to the central NH group over the range pH 3–9.5, but above this pH it broadened and disappeared, probably due to an increased exchange rate. The behaviour of the $NH_2$ peaks **a**, **b**, **c** and **d** is shown in Fig. 2. All four peaks show two-step titrations with p$K_a$ values of 5.58 and 8.54 (averages for peaks **a** and **c**). The shift changes for peaks **a** and **c** are much larger than those for peaks **b** and **d**.

The two p$K_a$ values can be associated with deprotonation of the 5′-phosphate (5.58) and the N$^1$H group (8.54) of coordinated 5′-GMP in **2**. For comparison, the phosphate p$K_a$ value for [Pt(en)(5′-GMP)$_2$]$^{2+}$ is 0.38 units lower than the value for free 5′-GMP (6.20) indicative of the presence of Pt–NH···ℑ-phosphate hydrogen bonding.[5] There are previous reports that the p$K_a$ of N$^1$H of guanine (*ca*. 9.5) is lowered by *ca*. 0.9–1.3 when guanine derivatives are coordinated to Pt$^{II}$ *via* N$^7$.[9] The large low-field PtNH$_2$ $^1$H NMR shifts observed for complex **2** (peaks **a** and **c**) on deprotonation of the N$^1$H group of bound GMP are intriguing since these PtNH$_2$ protons appear to be far away from N$^1$. This can be explained by an increase in the strength of hydrogen bonding between PtNH$_2$ and the C$^6$ carbonyl group due to an increase in electron density at C$^6$O on deprotonation of N$^1$. It is assumed that there is free rotation about Pt–N$^7$ and therefore both $NH_2$ groups are involved in hydrogen bonding. Keto–enol tautomerism could increase the negative charge on C$^6$O, as illustrated in the structure presented for complex **2**. Such hydrogen bonding involving C$^6$O has been found to play a role in determining the structure of Pt am(m)ine nucleotide complexes in the crystalline state, occurring for example in [Pt(dien){AGA-*N*$^7$(2)}],[10] but evidence for its presence in solution has previously proved difficult to obtain. The present data appear to provide evidence for such interactions at pH values close to those of biological relevance. Related NH···carbonyl interactions have been reported to play a major role in the stabilization of ternary complexes of zinc(II) cyclen complexes with thymine derivatives.[11]

The methods described here should also readily allow studies of chelate ring-opening reactions of [Pt([$^{15}N_3$]dien)]$^{2+}$ complexes. These have been the subject of much recent interest.[12] It is notable from our preliminary work that complex **2** showed no evidence for ring opening at pH 3.

We thank the Association for International Cancer Research, Biomolecular Sciences programme of the EPSRC and BBSRC, and EC HCM (ERBCHRXCT920016) and COST (D1-92/0002) programmes for their support for this work, and the MRC and ULIRS for the provision of NMR facilities.

**2**

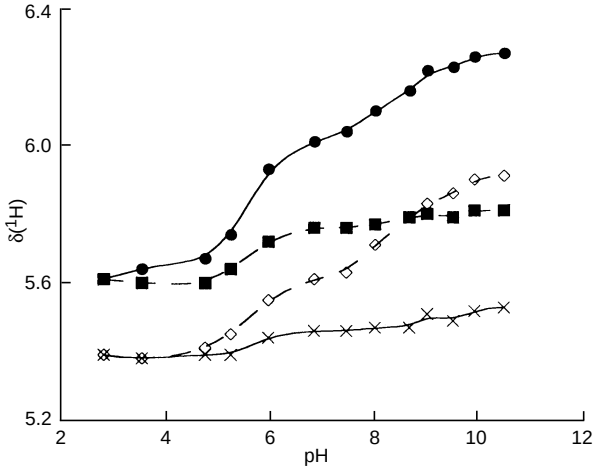

**Fig. 2** Dependence of the NH $^1$H NMR chemical shifts of complex **2** [Pt([$^{15}N_3$]dien)(5′-GMP-*N*$^7$)]$^{2+}$ on pH; peak **a** (●), **b** (■) **c** (◇), **d** (×). The large downfield shifts of two of the resonances between pH 5 and 7 can be associated with deprotonation of the 5′-phosphate group, and between 7 and 9 with deprotonation of N$^1$H of GMP. Little shift of peak **e** (Fig. 1) was observed over this pH range.

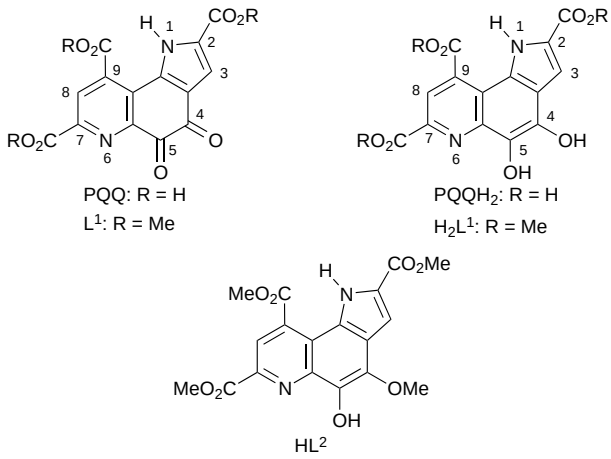
# Catalysis by calcium ion of the reoxidation of reduced PQQ by molecular oxygen



**Shinobu Itoh,* Hirokatsu Kawakami and Shunichi Fukuzumi***

*Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamada-oka, Suita, Osaka 565, Japan*

**Reoxidation of reduced PQQ to the quinone by molecular oxygen is enhanced drastically by $Ca^{2+}$, the interaction of which has been recently demonstrated to exist in the enzyme active site by the X-ray crystallographic analysis of quinoprotein methanol dehydrogenase.**

PQQ (pyrroloquinolinequinone) is a novel coenzyme that was first isolated and identified from bacterial methanol dehydrogenases (MDH, E.C. 1.1.99.8) in 1979.[1] This coenzyme is the redox centre of MDH that catalyses the oxidation of methanol to formaldehyde and donates two electrons to a c-type cytochrome in biological systems.[2] Recently, the crystal structure of MDH from methylotrophic bacteria has been determined by two independent research groups to provide full particulars of the enzyme active centre. According to the reported X-ray structure, there is one calcium ion strongly bound to PQQ through its C-5 quinone carbonyl oxygen, N-6 pyridine nitrogen, and C-7 carboxylate group in the enzyme active site.[3,4]† In this context, we have recently demonstrated that the oxidation of methanol to formaldehyde by coenzyme PQQ is promoted significantly by $Ca^{2+}$, providing valuable insight into the role of $Ca^{2+}$ in the enzymatic alcohol-oxidation mechanism.[5] On the other hand, however, very little is known about the catalytic role of $Ca^{2+}$ in the reoxidation process of reduced PQQ. Here, we report that $Ca^{2+}$ also enhances the oxidation of reduced PQQ to the quinone by molecular oxygen, providing further information on the catalytic function of $Ca^{2+}$ in the enzymatic redox reactions.

The trimethyl ester of reduced PQQ in the quinol form ($H_2L^1$, $2.5 \times 10^{-5}$ mol dm$^{-3}$)[6] is oxidised by molecular oxygen very slowly in anhydrous acetonitrile (MeCN) as shown in Fig. 1 (line *a* in the inset). Addition of $Ca^{2+}$ ($8.2 \times 10^{-3}$ mol dm$^{-3}$) into the $O_2$-saturated MeCN solution of $H_2L^1$ results in significant acceleration of the oxidation rate (line *b* in the inset of Fig. 1). The absorbance at $\lambda_{max}$ = 326 nm due to $H_2L^1$ decreases accompanied by the increase in absorbance due to the quinone $L^1$ (Fig. 1). Quantitative formation of $H_2O_2$ in the final reaction mixture has been confirmed by iodometric titration using NaI. Rates of the reaction of $H_2L^1$ and $O_2$ in the presence of various concentrations of $Ca^{2+}$ in MeCN at 298 K were determined by monitoring the decrease in absorbance at $\lambda_{max}$ = 326 nm due to $H_2L^1$. The rates obeyed pseudo-first-order kinetics in the presence of a large excess of $O_2$ ($1.3 \times 10^{-2}$ mol dm$^{-3}$) and the observed pseudo-first-order rate constant ($k_{obs}$) increases with an increase in [$Ca^{2+}$] to exhibit first-order dependence on [$Ca^{2+}$] at low concentrations, changing to second-order dependence at high concentrations, as shown in Fig. 2.

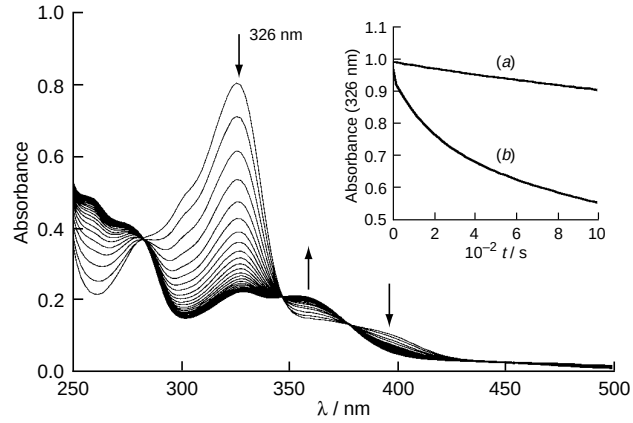


**Fig. 1** Spectral changes observed in the oxidation of $H_2L^1$ ($2.5 \times 10^{-5}$ mol dm$^{-3}$) by $O_2$ ($1.3 \times 10^{-2}$ mol dm$^{-3}$) in the presence of $Ca(ClO_4)_2$ ($8.2 \times 10^{-3}$ mol dm$^{-3}$) in $O_2$-saturated MeCN containing 0.8% $Me_2SO$ at 298 K. Inset: time course of the reaction followed at $\lambda$ = 326 nm under an $O_2$ atmosphere (*a*) in the absence and (*b*) in the presence of $Ca(ClO_4)_2$ ($1.0 \times 10^{-3}$ mol dm$^{-3}$) at 298 K.

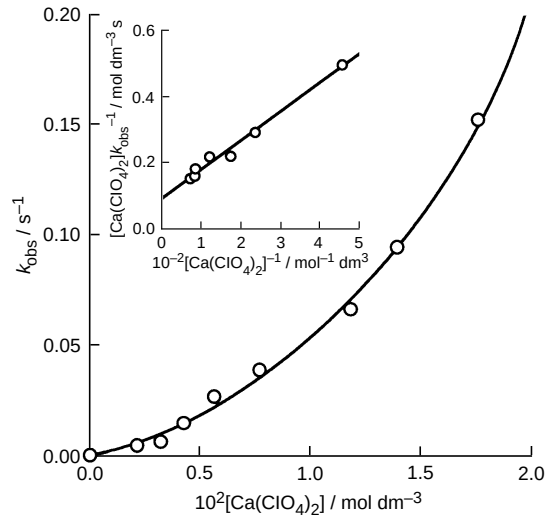

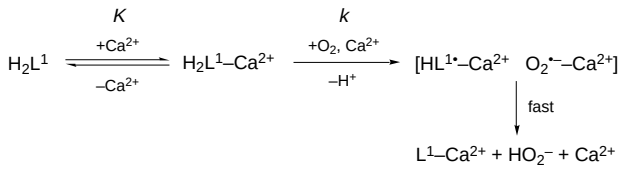

**Fig. 2** Plot of $k_{obs}$ *vs.* [$Ca(ClO_4)_2$] for the oxidation of $H_2L^1$ ($2.5 \times 10^{-5}$ mol dm$^{-3}$) by $O_2$ ($1.3 \times 10^{-2}$ mol dm$^{-3}$) in the presence of $Ca(ClO_4)_2$ in $O_2$-saturated MeCN containing 0.8% $Me_2SO$ at 298 K. Inset: plot of [$Ca^{2+}$]$k_{obs}^{-1}$ *vs.* [$Ca^{2+}$]$^{-1}$ for the reaction.

Addition of $Ca(ClO_4)_2$ to a deaerated MeCN solution of $H_2L^1$ results in a decrease in absorbance at $\lambda_{max}$ = 326 nm due to $H_2L^1$ accompanied by an increase in absorbance at $\lambda_{max}$ = 350 nm due to the $Ca^{2+}$ complex of a reduced species with a clear isosbestic point at 344 nm as the concentration of $Ca(ClO_4)_2$ is raised. From such a spectral change, one can obtain the 1 : 1 complex formation constant $K$ as $1.0 \times 10^2$ mol$^{-1}$ dm$^3$ using the relation $(A - A_0)/(A_\infty - A) = K[Ca^{2+}]$, where $A_0$ is the absorbance of $H_2L^1$ itself and $A_\infty$ is the absorbance of the $Ca^{2+}$ complex. Essentially the same spectral change was observed for 4-methoxy-substituted derivative $HL^2$ in the titration with $Ca(ClO_4)_2$ in deaerated MeCN, from which the $K$ value was determined as $1.1 \times 10^2$ dm$^3$ mol$^{-1}$.

Since the direct reaction with $O_2$ to give a covalent bond is spin forbidden, it has been proposed that the reaction of 1,5-dihydroflavin with $O_2$ occurs *via* an electron-transfer mechanism, resulting in a radical-ion pair, which collapses to form the covalent flavin-4*a*-hydroperoxide after spin conversion.[7,8] In this context, we have recently demonstrated that $Mg^{2+}$ catalyses the electron transfer step from 1,5-dihydroflavin anion to $O_2$ *via* the complex formation of $O_2^{\cdot-}$ and $Mg^{2+}$ to accelerate the overall two-electron oxidation of 1,5-dihydroflavin anion.[9] Thus, $Ca^{2+}$ may also catalyse the electron transfer step from $H_2L^1$ to $O_2$. The contribution of the second-order dependence of $k_{obs}$ on $[Ca^{2+}]$ in Fig. 2 indicates that the $H_2L^1$–$Ca^{2+}$ complex is a reactive electron donor rather than free $H_2L^1$ as shown in Scheme 1. The electron transfer from $H_2L^1$–$Ca^{2+}$ to $O_2$ is catalysed by $Ca^{2+}$ *via* the complex formation of $O_2^{\cdot-}$ and $Ca^{2+}$ as in the case of the $Mg^{2+}$-catalysed oxidation of 1,5-dihydroflavin anion.[9] The electron transfer may be accompanied with deprotonation and followed by fast hydrogen atom transfer to yield $H_2O_2$.

According to Scheme 1, the dependence of $k_{obs}$ on $[Ca^{2+}]$ is derived as $k_{obs} = kK[Ca^{2+}]^2[O_2]/(1 + K[Ca^{2+}])$, where $K$ is the complex formation constant of $H_2L^1$ with $Ca^{2+}$ and $k$ is the rate constant of the $Ca^{2+}$-catalysed oxidation of the reduced form by $O_2$ *via* formation of 1 : 1 complex between $O_2^{\cdot-}$ and $Ca^{2+}$. The kinetic equation can be rewritten as $[Ca^{2+}]k_{obs}^{-1} = (k[O_2])^{-1}[1 + (K[Ca^{2+}])^{-1}]$, where $[Ca^{2+}]k_{obs}^{-1}$ is linearly related to $[Ca^{2+}]^{-1}$. A linear plot of $[Ca^{2+}]k_{obs}^{-1}$ *vs.* $[Ca^{2+}]^{-1}$ is shown in the inset of Fig. 2. From the slope and intercept are obtained the rate constant $k = 8.6 \times 10^2$ dm$^3$ mol$^{-1}$ s$^{-1}$ and the complex formation constant $K = 1.0 \times 10^2$ dm$^3$ mol$^{-1}$. The $K$ value thus obtained agrees perfectly with the $K$ value ($1.0 \times 10^2$ dm$^3$ mol$^{-1}$) determined independently from the titration. Such an excellent agreement supports the validity of Scheme 1, where the $H_2L^1$–$Ca^{2+}$ complex is a reactive species for the oxidation by $O_2$. The spectral changes due to the formation of the $H_2L^1$–$Ca^{2+}$ and $HL^2$–$Ca^{2+}$ complexes are similar to that observed in the pH titration of $PQQH_2$ to $PQQH^-$.[6] Since the $K$ value of $H_2L^1$ is about the same as that of $HL^2$ (*vide supra*), the binding position of $Ca^{2+}$ with $H_2L^1$ and $HL^2$ may be the same. Thus, the coordination of $Ca^{2+}$ may occur to the hydroxy oxygen at the 5 position as well as the pyridine nitrogen at the 6 position, facilitating the deprotonation of C(5)–OH proton to produce a much stronger electron donor than free $H_2L^1$. This may be the reason why the $H_2L^1$–$Ca^{2+}$ complex acts as a reactive electron donor in the $Ca^{2+}$-catalysed electron transfer to $O_2$ (Scheme 1).

**Scheme 1**

The present study was financially supported in part by a Grant-in-Aid for Scientific Research on Priority Area (08249223) and a Grant-in-Aid for General Scientific Research (08458177) from the Ministry of Education, Science, Sports, and Culture of Japan. We also thank Takeda Science Foundation for financial support.

## Footnote

† The presence of $Ca^{2+}$ in the enzyme active site has been also suggested for other PQQ-dependent enzymes such as ethanol dehydrogenase from *Pseudomonas aeruginosa* and glucose dehydrogenase from *Acinetobacter calcoaceticus*, see ref. 10.

# An air-stable, primary alkylphosphine: $FcCH_2PH_2$ [Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$]

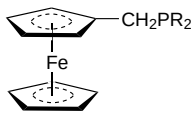
**Nicholas J. Goodwin, William Henderson*† and Brian K. Nicholson**

*Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand*

**Sodium metabisulfite-mediated elimination of formaldehyde from the ferrocene-derived hydroxymethylphosphine $FcCH_2P(CH_2OH)_2$ yields the primary phosphine $FcCH_2PH_2$, which has been fully characterised, including an X-ray crystal structure; the phosphine is completely air-stable.**

Phosphine ligands containing ferrocene moieties are attracting interest for their coordination chemistry,[1] with significant recent emphasis on applications of metal complexes of chiral ferrocenylphosphines in asymmetric catalysis.[2] In a recent communication[3] we described the synthesis of the air-stable, crystalline hydroxymethylphosphine $FcCH_2P(CH_2OH)_2$ **1** from readily accessible $FcCH_2NMe_3^+I^-$ and $P(CH_2OH)_3$, and reasoned that this compound should be a versatile precursor for the synthesis of a wide range of other ferrocene-derived phosphines. Here we report that **1** can be used to synthesise the remarkably air-stable, crystalline primary alkylphosphine $FcCH_2PH_2$ **2**.

Reaction of **1** with 1 mol equiv. of aqueous sodium metabisulfite was carried out in a two-phase aqueous–light petroleum (bp 60–80 °C) mixture, at reflux. $FcCH_2PH_2$ **2** was isolated from the light petroleum layer in 60% yield. It is particularly noteworthy that this reaction may be carried out in air; indeed the use of an inert (dinitrogen) atmosphere provides no significant increase in yield or purity of the product. The synthesis of **2** demonstrates the use of $P(CH_2OH)_3$ as a masked, easily handled $PH_3$ equivalent. Orange crystals of **2**, of analytical purity,‡ and suitable for a single-crystal X-ray structure determination,§ were obtained by sublimation of the product *in vacuo*, onto a water-cooled coldfinger.



The molecular structure, shown in Fig. 1 together with selected bond distances and angles, unambiguously confirms **2** as the primary phosphine. Examination of the Cambridge Crystallographic Database[4] indicates that only two other X-ray structure determinations of free primary phosphines have been reported previously.[5] The P–C bond distance of **2**, 1.850(3) Å, is identical within experimental error to the P–C bond lengths calculated (1.8574 Å)[6] and measured by electron diffraction (1.858 ± 0.003 Å)[7] for $PH_2Me$.

The $^{31}P$ NMR spectrum ($CDCl_3$) of **2** shows a resonance at δ −129, showing a large $^1J$(PH) coupling of 194 Hz in the proton-coupled spectrum. This chemical shift is comparable with those of other primary phosphines, which give $^{31}P$ NMR resonances in the region δ −110 to −160.[8] The positive-ion electrospray mass spectrum (1 : 1 MeCN–$H_2O$) yielded the oxidised ion $\mathbf{2}^+$, as observed for other (low-basicity) ferrocene-derived species.[9]

Primary phosphines are typically highly air-sensitive; many derivatives, particularly those containing lower alkyl groups, are pyrophoric. Only a very small number of primary phosphines are known to us to have been reported as air-stable,[10] including other sterically unhindered primary phosphines of the type $[RR'_2N(CH_2)_nPH_2]I$.[11] Phosphine **2** appears to be completely air-stable both in the solid and solution states. The reasons for this are not immediately obvious, but the inclusion of the redox-active ferrocenyl group may be important in kinetically stabilising the phosphine towards oxidation. The structure of **2** shows that the $PH_2$ group is directed away from the Fe atom so there is no intramolecular interaction which would account for its lack of susceptibility to oxidation. After exposure of solid **2** to air at room temp. for 48 days no oxidation products could be detected by $^{31}P$ NMR.

In view of the air-stability of **2**, it was of interest to see whether it possessed typical ligand properties towards transition-metal centres. Preliminary studies suggest that the coordination chemistry of **2** is not significantly compromised by the factors that lead to its air-stability, since the *cis*-$[Mo(CO)_4(\mathbf{2})_2]$ complex **3** can be prepared by the thermal reaction of $Mo(CO)_6$ with **2** in decalin at 100 °C. Complex **3**, which is also air-stable, has been characterised by NMR spectroscopy ($^{31}P\{^1H\}$ NMR, $CDCl_3$, $\delta_P$ −63.2], electrospray mass spectrometry (negative-ion mode in MeOH with added NaOMe; $[M - H]^-$ at *m/z* 673), and by a single-crystal X-ray diffraction study, full details of which will be published separately.

The method of formaldehyde abstraction from **1** can also be extended to the synthesis of the secondary phosphine $FcCH_2PH(CH_2OH)$ **4**, when 0.5 mol equiv. of sodium metabisulfite is used. This phosphine is readily characterised by the doublet resonance [$^1J$(PH) 205 Hz] observed in the proton-coupled $^{31}P$ NMR spectrum at δ −50.7. In contrast to **2**, phosphine **4** cannot be readily sublimed under the same conditions, the lower volatility of **4** being presumably due to the presence of relatively strong hydrogen bonding involving the hydroxymethyl group. However, it is worth noting that the attempted conversion of **1** to **2** by pyrolysis (dynamic vacuum, 120 °C, < 0.05 mmHg) led to sublimation of mainly unreacted **1**, together with some **2** and **4**.

**1** R = $CH_2OH$
**2** R = H

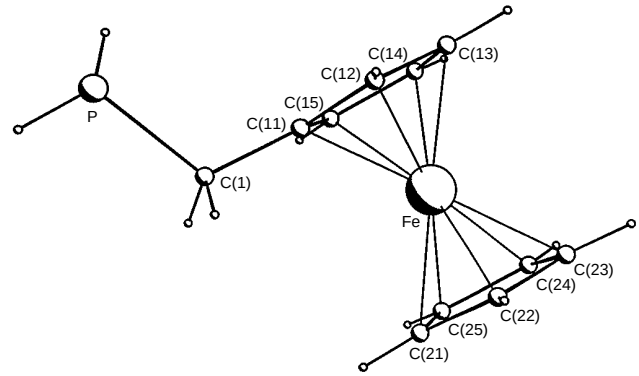


**Fig. 1** Molecular structure of $FcCH_2PH_2$ **2**, with atom numbering scheme. Selected bond lengths (Å) and angles (°): C(11)–C(1) 1.492(4), C(1)–P 1.850(3), Fe–C 2.022(3)–2.042(2), av. 2.035 Å; C(11)–C(1)–P 113.7(2).

In summary, the simplicity of synthesis and ease of handling of **2** make it ideal for studying the reactivity of a primary phosphine. The inclusion of the ferrocene centre will permit the ready development of organophosphine derivatives having excellent redox properties.

We thank the University of Waikato and the New Zealand Lottery Grants Board for financial support, Albright & Wilson Ltd., UK for a gift of $P(CH_2OH)_4Cl$, Professor Ward Robinson (Univerisity of Canterbury) for the X-ray data sets, and Professor Alistair Wilkins (University of Waikato) for GC–MS data. N. J. G. thanks the William Georgetti Trust for a scholarship.

## Footnotes

# $NMe_4V_3O_7$: critical role of pH in hydrothermal synthesis of vanadium oxides

**Thomas G. Chirayil, Elizabeth A. Boylan, Marc Mamak, Peter Y. Zavalij and M. Stanley Whittingham*†**

*Chemistry Department and Materials Research Center, State University of New York at Binghamton, Binghamton, NY, 13902, USA*

**pH is critical in the formation of new mixed-valence vanadium oxides, $NMe_4V_3O_7$, $NMe_4V_4O_{10}$ and the dioxide $Li_xV_2O_4{\cdot}H_2O$, with $NMe_4^+$ cations or water molecules residing between vanadium oxide layers.**

In the last few years there has been much effort placed on the synthesis of new transition-metal oxides that might be active hosts for intercalation reactions. There is particular interest in oxides that react readily with lithium and might find application as cathodes in advanced lithium batteries.[1] Reis *et al*.[2] built on the pioneering work of Gunter *et al*.[3] and showed that two different tungsten oxides could be formed by hydrothermal reaction, and that pH controlled the phase formed. Subsequently, Guo *et al*.[4] expanded this work to molybdenum and discovered a new layered molybdenum oxide when tetramethylammonium ions were in the reaction medium. Most recently, several new vanadium oxide structures were formed also using the tetramethylammonium ion, including a new layered vanadium dioxide and $NMe_4V_4O_{10}$, both of which contain vanadium in square pyramids.[5] These two phases have now been completely characterized.[6–8]

In a systematic study of the impact of the pH of the reaction medium on the vanadium oxides formed, we have found that a whole range of new materials are formed. In this study the reactants $V_2O_5$, $NMe_4OH$, and LiOH in a molar ratio of 1 : 2 : 1 in water were acidified with acetic acid and heated at 185 °C in a Teflon-lined Parr reactor for 3 days; typically 20 g of reactants were reacted in 70 ml of water. X-Ray diffraction of the products formed showed that at least six different phases were formed depending on the initial pH. The pH range for the products is shown in Fig. 1. At the highest pH, 10, the known $Li_3VO_4$ is formed;[9] in this structure all the metal atoms are in tetrahedral sites. As the pH is lowered the new phase $NMe_4V_3O_7$ is formed whose structure is described below. This phase is also formed in the absence of lithium ions. At a pH of *ca*. 5 the new layered vanadium dioxide compound $Li_xV_{2-\delta}O_{4-\delta}{\cdot}H_2O$ is found, as reported earlier.[5–7] Lowering the pH further leads to the formation of another tetramethylammonium vanadate, $NMe_4V_4O_{10}$ whose structure we reported recently.[5,8] At the highest acidities two new compounds are formed, both of which contain tetramethylammonium ions; they appear to have layer structures with repeat distances of 11.5 Å and 19.1 Å at pH 3.3 and 2.6 respectively. We are presently trying to determine their structures from powder diffraction data.

Crystals of the trivanadate, $NMe_4V_3O_7$, have a lath-like appearance and their structure was determined by Rietveld analysis of powder diffraction data. It is related to that recently reported for $(DABCO)V_6O_{14}$,[10,11] (DABCO = 1,4-diazabicyclo[2.2.2]octane) but has some significant differences. The structure contains zigzag strings of edge-sharing $VO_5$ square pyramids; these strings are joined together by $VO_4$ tetrahedra, as indicated schematically in Fig. 2. The structure has lattice parameters of $a$ = 18.478, $b$ = 6.552, $c$ = 8.427 Å and $\beta$ = 91.1°, in space group $P2_1/n$; $b$ is the dimension along the chain, $c$ that perpendicular to the chain but in the plane of the vanadium oxide sheet, whereas $a$ is twice the distance between the sheets. The tetramethylammonium ions reside between the vanadium oxide layers, as indicated in Fig. 3. The sheets are almost planar in direct contrast to those of the DABCO hexavanadate $C_6H_{14}N_2V_6O_{14}{\cdot}H_2O$ which are highly puckered, leading to a longer $a$ and a shorter $c$ axis, $a$ = 19.20, $c$ = 7.547 Å and $\beta$ = 111.3°, whereas the dimension along the chain remains almost unchanged, $b$ = 6.625 Å.[10] This buckling is common for vanadium oxides, being also observed for the alkali-metal vanadium oxides.

The tetramethylammonium ions are lost on heating the trivanadate to 350 °C, with loss of the structure. However, at

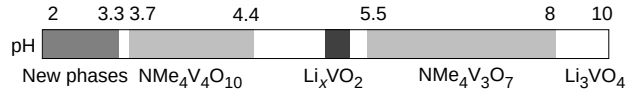

**Fig. 1** Structures formed as a function of the pH of the reaction medium

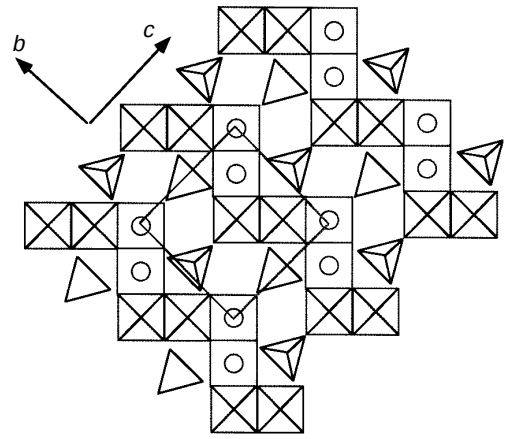

**Fig. 2** Schematic representation of the stucture of $NMe_4V_3O_7$, showing the zigzag chains of $VO_5$ square pyramids, joined together by $VO_4$ tetrahedra. The tetrahedra are shown separated from the chains for clarity. ☒ = $VO_5$ pyramid, apex up; ⊡ = $VO_5$ pyramid, apex down; ◬ = $VO_4$ tetrahedron, apex up; and △ = $VO_4$, apex down.

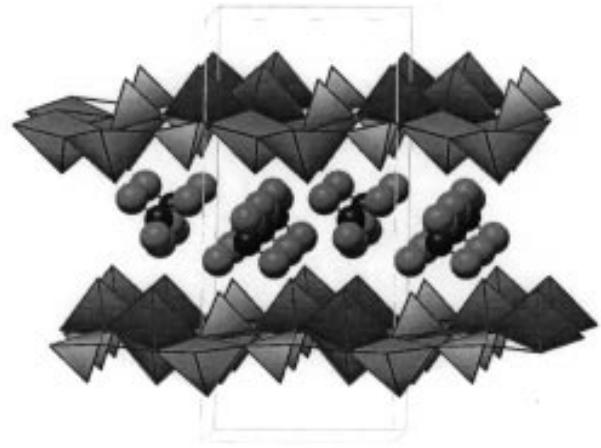

**Fig. 3** Side-view of $NMe_4V_3O_7$ looking down the $b$ axis

around 200 °C prior to the loss of the organic cations the structure takes up an additional oxygen atom to give the fully oxidized phase $NMe_4V_3O_8$. This appears to have a triclinic structure. Just like the tetravanadate, $NMe_4V_4O_{10}$, we have been unable so far to ion-exchange the tetramethyl ammonium ions out of the structure. In contrast the tetramethylammonium ions are expelled from the layered vanadium dioxide, $Li_xV_{2-\delta}O_{4-\delta}\cdot H_2O$, during synthesis; the structure is not formed in the absence of tetramethylammonium ions. This dioxide readily and reversibly undergoes dehydration and redox reactions with lithium[7] and organic molecules.

Some trends in the structures formed can be seen. $Li_3VO_4$ has all the vanadium in tetrahedral sites. As the pH is lowered the first phase formed, $NMe_4V_3O_7$, has vanadium in both tetrahedral and square-pyramidal sites. At still lower pH all the vanadium is found in square pyramids. Although the structures of the two phases formed under the most acidic conditions are not known it is probable by comparison with cluster complexes formed under similar acidic conditions that some of the vanadium will be found in octahedral sites. These cluster complexes often remain in solution during the hydrothermal reaction, and precipitate from the filtrate after standing under ambient conditions for several days; an example is $[NMe_4]_4$-$Li_2V_{10}O_{28}\cdot 12H_2O$, whose structure is also layered. It contains $V_{10}O_{28}$ clusters arranged in sheets together with $Li(H_2O)_4$ tetrahedra; the tetramethylammonium ions reside between these sheets.[12]

In conclusion, change of pH of the reaction medium in the hydrothermal synthesis of vanadium oxides results in a wide range of new structures, indicating the richness of the hydrothermal approach.[13] The first layered vanadium oxide[5] containing an organic species, $NMe_4V_4O_{10}$, has spawned a wide range of new compounds, including the dioxide $Li_xVO_2$ and $NMe_4V_3O_7$ whose structure is reported here. In addition, Nazar has recently found[14] an additional compound, $[NMe_4]_5V_{18}O_{46}$, which we have not yet seen in this investigation. Within the last year a number of other organic molecule–vanadium oxide complexes have been reported,[15] but so far only the tetramethylammonium ion has been found to form more than one structure type.

# Changeover in a multimodal copper(II) catenate as monitored by EPR spectroscopy

**Frank Baumann,[a] Aude Livoreil,[b] Wolfgang Kaim*[a] and Jean-Pierre Sauvage*[b]**

[a] *Institut für Anorganische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-70550 Stuttgart, Germany*
[b] *Laboratoire de Chimie Organo-Minérale, URA 422 du CNRS, Institut le Bel, Université Louis Pasteur, 4, rue Blaise Pascal, 67070 Strasbourg, France*

**The electrochemically triggered rearrangement of a copper catenate is monitored by EPR spectroscopy; the initially generated tetrahedral copper(II) complex (with higher *g*-factor components and lower metal hyperfine splitting) is converted to a stable five-coordinate copper(II) species, within a few minutes at room temperature, in anhydrous MeCN.**

Molecular systems whose shape and internal motions can be controlled externally by applying a chemical or physical signal are fascinating.[1] They can be regarded as mimics of metalloproteins which may undergo drastic conformational changes (folding–unfolding), triggered by electron transfer from or onto an electrophore of the enzyme.[2]

Some of us have recently described a copper catenate which can experience a substantial yet controlled conformational change (gliding of one ring within the other), the process being induced electrochemically.[3] Indeed, transition-metal complexes are particularly suited for the design of such systems, since changes in the metal oxidation state can, at least in some cases, cause its coordination geometry to rearrange significantly.[4] The principle of the presently studied system is indicated in Fig. 1.

The square scheme of Fig. 1 contains alternating electrochemical steps and rearrangements, the latter steps leading to the most stable geometry of each oxidation state: four-coordinate for $Cu^{I}$ ($CuN_4^{+}$) and five-coordinate for $Cu^{II}$ ($CuN_5^{2+}$).

The isomerization of the compound from the $CuN_4^{2+}$ form to the $CuN_5^{2+}$ form involves an intramolecular change of the coordination number of the central metal ion from four to five. Such a change necessarily implies an altered coordination geometry and thus a modification of the d-orbital splitting pattern. For $Cu^{II}$ as the central ion, such a change may easily be monitored by EPR spectroscopy, considering the well established correlations[5] between crystallographically determined structures and the d-orbital situation as deduced from EPR data, in particular *g* factors and $^{63,65}Cu$ hyperfine coupling constants.

In the present EPR monitoring experiment (Fig. 2), the copper(I) form, $CuN_4^{+}$, with four-coordinate $d^{10}$ metal (distorted tetrahedral)[3] was oxidized to the paramagnetic copper(II) state $CuN_4^{2+}$ ($d^9$ configuration) in an electrolysis cell for EPR measurements (platinum anode in 2 mm capillary for EPR measurements; $CaH_2$-dried acetonitrile–0.1 M $NBu_4PF_6$). Following brief electrolysis at 293 K (5 min), the mixture was

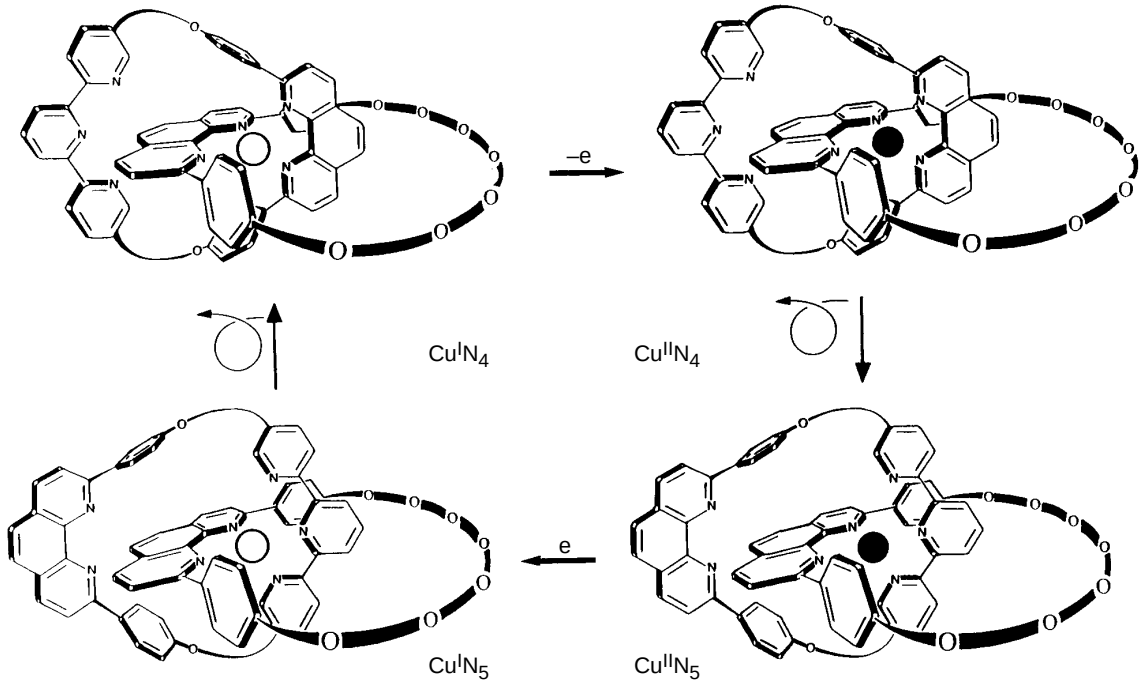

**Fig. 1** Electrochemically induced molecular rearrangements undergone by the copper catenate. The subscript 4 or 5 indicates the number of nitrogen atoms coordinated to the metal. White circles represents $Cu^{I}$ and black circles $Cu^{II}$. The organic backbone is a [2]catenate, consisting of two different interlocking rings. One ring incorporates a single chelate unit dpphen, whereas the other cycle contains two coordinating fragments (a dpphen unit and a terpy moiety; terpy = 2,2′:6′,2″-terpyridine).

immediately cooled to 110 K to form a glassy frozen solution. The initial anisotropic EPR spectrum is characterized by a relatively small $A_{\|}$ value of 12.1 mT and comparatively high $g$ components $g_{\|}$ = 2.276 and $g_{\perp}$ = 2.0735; $a_{\perp}$ and possible $^{14}N$ superhyperfine splitting could not be determined due to the linewidth. These values, corresponding to the 'metastable' form $CuN_4^{2+}$, are characteristic of four-coordinate $Cu^{II}$ in a distorted tetrahedral arrangement; similar numbers were measured for related complexes consisting of the same chelating units such as 2,9-diphenyl-1,10-phenanthroline (dpphen): the copper(II) state of catenate $[Cu(Cat_{30})]^{2+}$ ($g_{\|}$ = 2.282, $g_{\perp}$ = 2.075, $A_{\|}$ = 11.9 mT) and the non-catenate species $[Cu(dpphen)_2]^{2+}$ ($g_{\|}$ = 2.283, $g_{\perp}$ = 2.067, $A_{\|}$ = 12.2 mT).[6] In repeated cooling (110 K, EPR measurement) and warming cycles (308 K, 30 s, rearrangement reaction), there was a clear change in the EPR spectrum (Fig. 2), indicating the gradual formation of a new copper(II) species with quite different EPR characteristics. The hyperfine coupling component $A_{\|}$ = 16.6 mT is much larger than the value of 12.1 mT observed for the initial $CuN_4^{2+}$ form, whereas the $g$ components $g_{\|}$ = 2.233 and $g_{\perp}$ = 2.045 are smaller. These numbers are more in the typical range for geometrically relaxed copper(II) complexes,[5] which implies close to square-planar or, more likely, square-pyramidal geometry ($CuN_5^{2+}$). A structurally relevant five-coordinate complex, $[Cu(\eta^3\text{-L})(\eta^2\text{-L})][ClO_4]_2$, containing the potentially terdentate 2,6-bis(benzimidazol-2′-yl)pyridine ligand L and showing square-pyramidal configuration at the metal ion, has $g_{\|}$ = 2.23, $g_{\perp}$ = 2.03 and $A_{\|}$ = 16.7 mT.[7]

The EPR response illustrated in Fig. 2 thus supports the interpretation of a slow geometrical relaxation, $CuN_4^{2+} \rightarrow CuN_5^{2+}$, following the rapid heterogeneous oxidation of the copper(I) form (with preferred four-coordination), leading to the copper(II) state with its preferred five-coordinate geometry. The observed spectral differences are not only obvious (Fig. 2), they can also be rationalized straightforwardly, at least in a qualitative way. Both the $A_{\|}$ and $g$ value differences between the two copper(II) states support the above interpretation. According to eqn. (1) (where $j = x, y$ or $z$ coordinate, $\lambda$ is the spin–orbit coupling constant, $\Delta E_i$ is the energy separation between ground state $y_0$ and excited state $y_i$, and $L_j$ is a spin–orbit operator) and similar such approximations, high $g$ factors imply a small energy difference between the singly occupied molecular orbital (SOMO) and close-lying fully occupied MOs. Such a situation may be expected for a coordination geometry derived from the tetrahedron ($CuN_4^{2+}$) where the set of triply degenerate ($t_2$) or at least three close-lying uppermost d orbitals are occupied by five d electrons in a $d^9$ situation. On the other hand, the square or square-pyramidal geometry causes a large energy splitting between the SOMO ($d_{x^2-y^2}$) and the close-lying occupied d orbitals;[5] this splitting reduces the total energy of the system (Jahn–Teller effect) and leads to $g$ factors closer to the free electron value of $g_e$ = 2.0023, as observed here for the $CuN_5^{2+}$ state of the bimodal system.

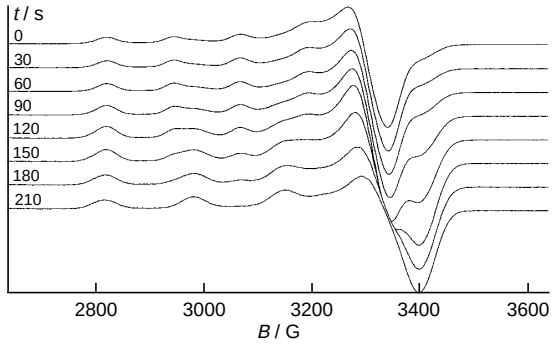

**Fig. 2** EPR spectra at 9.5938 GHz of the electrogenerated copper(II) state in acetonitrile–0.1 M $NBu_4PF_6$, following repeated cycling between cooling to 110 K (EPR measurements) and warming to 308 K (30 s, rearrangement reaction)

$$g = g_e + 2\lambda \sum_i \frac{\langle \psi_0 | L_j | \psi_i \rangle \langle \psi_i | L_j | \psi_0 \rangle}{\Delta E_i} \quad (1)$$

# Oxidation of NO to $NO_2$ on a Pt-MFI zeolite and subsequent reduction of $NO_x$ by $C_2H_4$ on an In-MFI zeolite: a novel de-$NO_x$ strategy in excess oxygen

**Masakazu Iwamoto,* Angel M. Hernandez and Tetsu Zengyo**

*Catalysis Research Center, Hokkaido University, Sapporo 060, Japan*

**Intermediate addition of reductant ($C_2H_4$) into an NO+$O_2$ stream between an oxidation catalyst for NO to $NO_2$ (Pt-MFI) and a reduction catalyst for $NO_x$ to $N_2$ (In-MFI), a so-called IAR method, is shown to be very effective in selectively reducing NO to $N_2$ in the presence of excess oxygen.**

The selective catalytic reduction of NO by hydrocarbons (SCR–HC) in the presence of excess oxygen is a potential method to remove $NO_x$ from various exhausts.[1] Although there have been many discussions on the reaction mechanism of the SCR–HC, the concept that NO is oxidized to $NO_2$ by oxygen and then the resulting $NO_2$ reacts with hydrocarbons to form an active intermediate is widely suggested on various catalysts.[2,3] Several efforts have been devoted to separate the functions of catalysts; for example, platinum and $Mn_2O_3$ are reported to be active for the oxidation of NO to $NO_2$ in the reaction system NO + $O_2$ + $CH_4$ on Pt/In/MFI[4] and NO + $O_2$ + $C_3H_6$ on $Mn_2O_3$ + Ce-MFI,[5] respectively. One of the most significant problems in these systems is that the oxidation catalyst for NO might be active for oxidation of the hydrocarbons, which would result in a decrease in the efficiency of the reductant. In the case of $CH_4$ as reductant, Pt can be used for NO oxidation because of the low oxidation activity of Pt towards $CH_4$.[4] With $C_3H_6$, $Mn_2O_3$ or $CeO_2$ should be employed because Pt or the other oxide catalysts are too active for $C_3H_6$ oxidation.[5]

It is well known that diesel exhausts contain very small amounts of unburned hydrocarbons. Thus addition of fuels or hydrocarbons into the diesel exhausts is required to reduce NO by the SCR–HC method. On the basis of the above reaction mechanism and the necessity of hydrocarbon addition, we propose here a novel strategy to reduce NO selectively, *viz*. the intermediate addition of a reductant into the NO-containing exhaust between an oxidation catalyst of NO and a reduction catalyst to $N_2$ (IAR method). In the present experiments Pt-MFI and In-MFI catalysts[6] have been employed as the model oxidation and reduction catalysts, respectively, in the reaction system NO + $O_2$ + $C_2H_4$.

Platinum and indium ion-exchanged MFI zeolites were prepared by a conventional method from aqueous tetraammineplatinum(II) nitrate and indium(III) nitrate solutions, respectively. The Si/Al molar ratio of the parent MFI zeolite was 11.7. The ion-exchange levels of Pt-MFI and In-MFI prepared were 101 and 83%, respectively. The zeolites were pressed, crushed and sieved to obtain particles of 250–425 μm. Catalytic reduction was carried out in a conventional flow system with twin quartz reactors and the flow diagram is shown in Fig. 1. The twin reactors were placed in a single furnace. The Pt-MFI catalyst was mounted in the first reactor and the In-MFI in the second. A mixture of NO, $O_2$ and He (balance) (total flow rate, 124 cm$^3$ min$^{-1}$) was introduced into the first reactor. The reductant, $C_2H_4$, diluted in He (26 cm$^3$ min$^{-1}$) was then added into the NO + $O_2$ mixture between the first and the second reactors. One can change the flow route of the NO + $O_2$ mixture to the bypass from the first reactor to evaluate the effect of the first catalyst bed. Before the catalytic reaction, the catalysts were pretreated *in situ* at 773 K for 3 h in a He flow. The reactants were 1000 ppm of NO, 857 ppm of $C_2H_4$, 2% of $O_2$ (helium balance) and the total flow rate of gases was 150 cm$^3$ min$^{-1}$. A gas chromatograph was employed to measure the respective concentrations of ethene, nitrogen, nitrous oxide, carbon dioxide and carbon monoxide. An $NO_x$ analyser was used to determine the degree of oxidation of NO to $NO_2$.

First, the effectiveness of Pt-MFI as the oxidation catalyst of NO was investigated and the results are plotted in Fig. 2. The conversion of NO to $NO_2$ on Pt-MFI was maximal at 523 K. Decrease in conversion at higher temperatures is due to the limitation of the equilibrium as clearly shown in Fig. 2. In the absence of the Pt-MFI catalyst, only a very small amount of $NO_2$ was produced under the present experimental conditions. One can therefore conclude that the Pt-MFI zeolite is a very active catalyst for the oxidation of NO to $NO_2$ and the catalytic activity is much higher than reported previously.[5,7] After the pretreatment, X-ray diffraction analysis of the Pt-MFI catalyst showed the formation of Pt particles on the MFI zeolite, which is in good agreement with a previous report.[8] The reproducibility of the results of Fig. 2 was very good within the temperature range 473–873 K and no deactivation of the Pt-MFI catalyst upon $NO_2$ formation was observed.

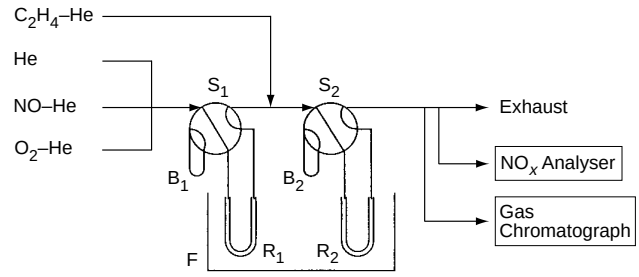

**Fig. 1** Flow system for SCR–HC by IAR method. B1 and B2, bypaths of the reactors; F, furnace; R1 and R2, reactors; S1 and S2, six-way valves.

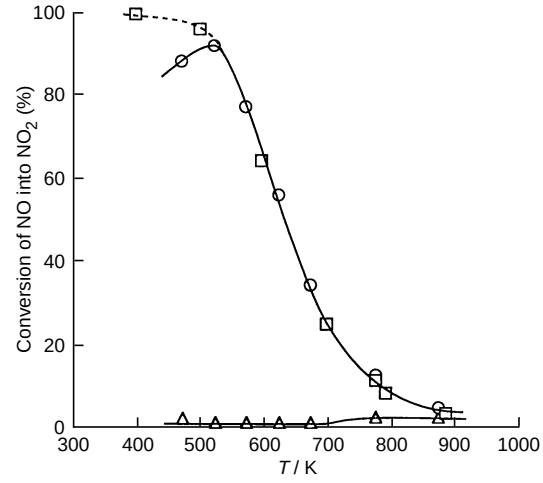

**Fig. 2** $NO_2$ formation in the NO + $O_2$ reaction on Pt-MFI (○). NO to $NO_2$ conversions without Pt-MFI (△) and under equilibrium (□) are also shown.

In Fig. 3, the activities of four kinds of catalytic systems are shown: (*i*) a series combination of the Pt-MFI catalyst (0.4 g) and the In-MFI catalyst (0.4 g) (Pt/In), (*ii*) the In-MFI catalyst alone (0.4 g) (In), (*iii*) physically mixed Pt-MFI (0.4 g) and In-MFI (0.4 g) catalysts (Pt + In) and (*iv*) a series combination of the Pt-MFI catalyst (0.4 g) and the parent Na-MFI catalyst (0.4 g) (Pt/Na). Fig. 3 clearly shows the great difference between the results of the Pt/In and the In systems. With Pt-MFI as the oxidation catalyst, the catalytic activity of In-MFI for NO reduction was greatly enhanced at 473–623 K. At the same time conversion levels of $C_2H_4$ also increased. It is evident that the increments of NO and $C_2H_4$ conversions are due to the formation of $NO_2$ on Pt-MFI. Fig. 3 also indicates formation of $N_2O$ at 473–623 K. This might suggest the easy formation of $N_2O$ in the presence of $NO_2$, although the reaction mechanism is, as yet, not clear.

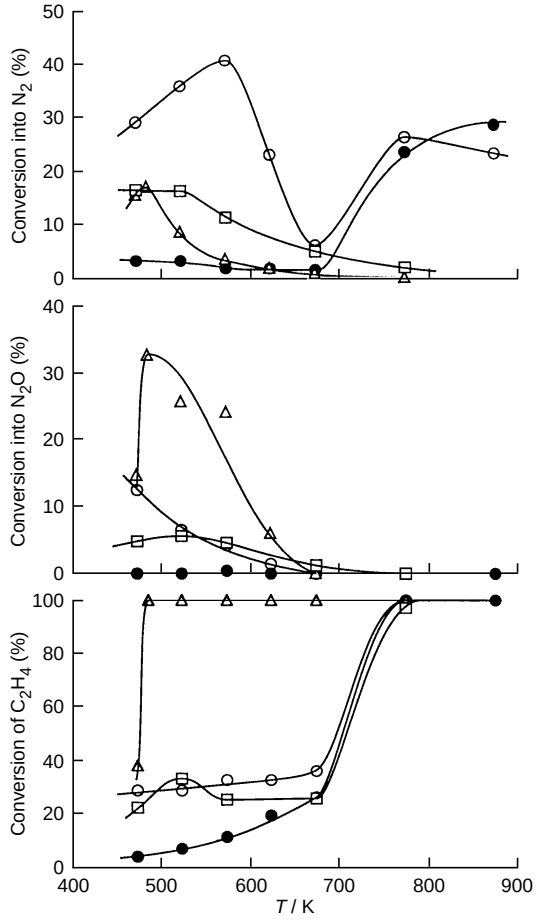

**Fig. 3** Reduction of NO by the IAR method on Pt/In (○), In (●), Pt + In (△) and Pt/Na (□) systems. The experimental conditions are described in the text.

The results on the Pt/In and In systems at 773–873 K were approximately the same. Taking the small amount of $NO_2$ formed at 773–873 K (Fig. 2) into consideration, the activity in this temperature region would result from the catalysis of In-MFI itself to the NO + $O_2$ + $C_2H_4$ mixture.

The results of the Pt/In system can be compared with those of the Pt + In system. The degree of conversion of NO to $N_2$ for the latter was much lower than that of the former as shown in Fig. 3, and almost the same as that of the Pt-MFI alone, as reported in a previous paper.[8] Therefore it follows that only Pt-MFI in the mixture of Pt-MFI and In-MFI is the active phase while In-MFI is essentially inactive. In addition, the results on the Pt/Na system reveal that indium ions are more effective than sodium ions in promotion of the catalytic reaction of $NO_2$ with hydrocarbons.

In conclusion, the results show the great effectiveness of the IAR method to reduce NO by hydrocarbons in the presence of an excess of oxygen. Although the effect of water addition to the system is yet to be investigated, it is clear that there is no longer a need to develop or search for catalysts which can oxidize NO to $NO_2$ but not oxidize the reductant, if we employ this method. There are many possible combinations of oxidation and reduction catalysts, depending on the condition of the exhausts and the nature of the reductants.

# Molybdenum and tungsten carbides as catalysts for the conversion of methane to synthesis gas using stoichiometric feedstocks

**Andrew P. E. York, John B. Claridge, Attila J. Brungs, Shik Chi Tsang† and Malcolm L. H. Green***

*The Catalysis Centre, Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*

**Molybdenum and tungsten carbides are extremely active and stable catalysts for the dry reforming, partial oxidation and steam reforming of methane to synthesis gas using stoichiometric feedstock; no bulk carbon deposition was observed.**

Recent estimates indicate that world reserves of natural gas will outlast those of oil by a considerable period.[1] Current industrial use of methane as a chemical feedstock proceeds by initial conversion to carbon monoxide and hydrogen (synthesis gas) by either steam reforming[2] [eqn. (1)] (a large scale process) or by dry reforming, [eqn (2)]; a further route is *via* partial oxidation [eqn. (3)].

$$CH_4 + H_2O = CO + 3\ H_2 \quad \Delta H^{\ominus}_{298} = +206\ \text{kJ mol}^{-1} \quad (1)$$

$$CH_4 + CO_2 = 2\ CO + 2\ H_2 \quad \Delta H^{\ominus}_{298} = +247\ \text{kJ mol}^{-1} \quad (2)$$

$$CH_4 + \tfrac{1}{2}O_2 = CO + 2\ H_2 \quad \Delta H^{\ominus}_{298} = -38\ \text{kJ mol}^{-1} \quad (3)$$

Nickel catalysts are used industrially for both the methane steam and dry reforming reactions because of their fast turnover rates, long term stability and low cost.[2] However, they have a major drawback since the nickel catalysts also catalyse carbon formation *via* methane decomposition and CO disproportionation, both of which lead to catalyst deactivation and the plugging of the reformer tubes by carbon deposits. Thus, in practice large excesses of oxidants are used in order to prevent carbon deposition. This results in synthesis gas with $H_2/CO$ and $CO_2/CO$ ratios which are not optimal for further conversion to major end products, such as methanol or gasoline. Considerable effort has been concentrated on exploring catalysts for eqns. (1)–(3) which are resistant to carbon formation at or near stoichiometric reactant ratios. Previously, sulfur passivated nickel catalysts[3] and noble metal catalysts[4–7] have been shown to exhibit kinetic resistance to carbon formation, but the low activities of sulfur passivated nickel and the high costs and limited availability of the noble metals have limited their application.

In the last 20 years, group VI transition metal carbides have been found to be active catalysts, comparable to platinum group metal catalysts for a number of reactions. Here we describe new catalysts, based on carbides of molybdenum and tungsten, for the reforming of methane using stoichiometric feedstocks at slightly elevated pressures. No carbon deposition is observed, and the consequential selectivities and conversions to carbon monoxide and hydrogen are those predicted by thermodynamic considerations.

The high surface area carbide catalysts were prepared by temperature programmed reduction of the oxides or supported oxides in a flow of methane or methane–hydrogen mixture, as previously described for β-$Mo_2C$,[8] WC[9] and $Mo_2C/Al_2O_3$.[10] Normally the catalysts were prepared *in situ* and tested immediately.

Table 1 shows the results obtained for the dry reforming of methane to synthesis gas with carbon dioxide, using β-$Mo_2C$ ($S_g$ = 91 $m^2\ g^{-1}$) and WC ($S_g$ = 39 $m^2\ g^{-1}$) as catalysts at both ambient and elevated pressure. The initial synthesis gas yields very closely approach those predicted from thermodynamic considerations, if carbon deposition is discounted.[7] At ambient pressure catalyst deactivation occurred, and this was clearly observable after 8 h [Fig. 1(*a*)]. Powder XRD (not given) showed that the initial β-$Mo_2C$ was converted to $MoO_2$, which has only very low activity for methane dry reforming. However, when the experiment was run at slightly elevated pressure

**Table 1** Catalytic performance of molybdenum and tungsten carbides for various methane reforming reactions

| Catalyst | $CH_4$: oxidant | Pressure/ bar | *T*/K | C[$CH_4$][a] (%) | Y[CO][b] (%) | $H_2/CO$[c] |
|---|---|---|---|---|---|---|
| β-$Mo_2C$ | 1 : 1[d] | 1.0 | 1120 | 92.4 | 92.5 | 0.93 |
| β-$Mo_2C$ | 1 : 1[d] | 8.3 | 1120 | 62.5 | 69.5 | 0.78 |
| WC | 1 : 1[d] | 8.3 | 1120 | 62.7 | 68.7 | 0.79 |
| 5% $Mo_2C/Al_2O_3$ | 1 : 1[d] | 8.3 | 1120 | 65.2 | 70.1 | 0.81 |
| β-$Mo_2C$ | 2 : 1[e] | 4.0 | 1170 | 94.7 | 89.6 | 2.01 |
| β-$Mo_2C$ | 2 : 1[e] | 8.7 | 1170 | 88.0 | 80.7 | 2.02 |
| WC | 2 : 1[e] | 8.7 | 1170 | 87.5 | 78.2 | 2.04 |
| 5% $Mo_2C/Al_2O_3$ | 2 : 1[e] | 8.7 | 1170 | 90.6 | 82.5 | 2.00 |
| β-$Mo_2C$ | 1 : 1[f] | 1.0 | 1220 | 91.5 | 90.1 | 3.08 |
| β-$Mo_2C$ | 1 : 1[f] | 8.3 | 1220 | 81.8 | 77.7 | 3.07 |
| WC | 1 : 1[f] | 8.3 | 1220 | 81.9 | 77.8 | 3.06 |
| 5% $Mo_2C/Al_2O_3$ | 1 : 1[f] | 8.3 | 1220 | 82.1 | 77.9 | 3.05 |

[a] C[$CH_4$] = (% conversion of $CH_4$ into all products). [b] Y[CO] = amount of CO in products)/(amount (C) in reagents.) [c] $H_2/CO$ = (amount of $H_2$ in products)/(amount of CO in products). [d] Dry reforming with carbon dioxide (inlet GHSV = 2.8 × $10^3\ h^{-1}$). [e] Partial oxidation with air (inlet GHSV = 5.2 × $10^3\ h^{-1}$). [f] Steam reforming with water (inlet GHSV = 2.8 × $10^3\ h^{-1}$).

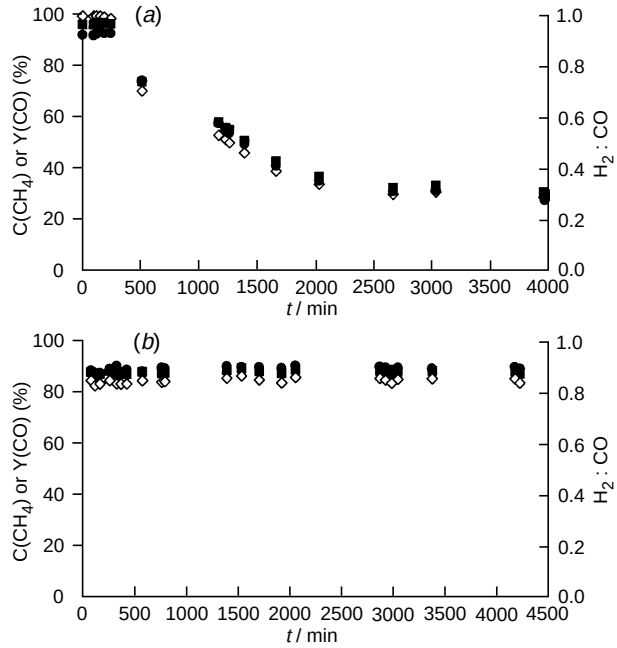

**Fig. 1** Catalyst stabilities for the dry reforming of methane ($T$ = 1220 K; $CH_4:CO_2$ = 1; GHSV = 2.8 × $10^3\ h^{-1}$); (*a*) pressure = 1 atm; (*b*) pressure = 8.3 atm; (■) Y[CO], (◇) C[$CH_4$], (●) $H_2:CO$

(about 8 bar), high activity was maintained for the duration of the experiments (typically 144 h), with no observable deterioration in the catalysts [Fig. 1(*b*)] providing, at least, an initial idea of the long term stability of the catalysts, although longer experiments need to be conducted. XRD studies of the quenched catalyst after use showed no trace of of $MoO_2$. Further, a high resolution transmission electron microscopy (HRTEM) study of the pre- and post-catalysis samples indicated that no bulk carbon deposition had occurred on the catalyst. In contrast, HRTEM examination of used nickel catalysts show the presence of large amounts of whisker carbon.[4] Activity studies of our carbide catalysts and of supported noble metal catalysts, for the dry reforming of methane under differential conditions (*i.e.* conversion kept < 10%), show that β-$Mo_2C$ has comparable activity on a gram basis to that of 5% Ir–$Al_2O_3$, which is well known as an active catalyst for steam and dry reforming.[5] Indeed, the relative activity of a number of the reforming catalysts has been established as: Ru > Rh > Ir ≈ $Mo_2C$ > WC > Pd > Pt.[5,11,12]

Table 1 also shows the results obtained for β-$Mo_2C$, WC and $Mo_2C$–$Al_2O_3$ as catalysts for the partial oxidation and steam reforming reactions, also at slightly elevated pressures. Again the reaction yields approach predicted thermodynamic equilibrium values, and have been carried out for 72 h or more without any evidence of macroscopic carbon deposition or catalyst deactivation. In the corresponding reactions at ambient pressure, catalyst deactivation was always observed due to the formation of inactive $MoO_2$.

The stabilisation of the active metal carbide phase under slightly elevated pressures is surprising since, although the carbides can be synthesised from the oxides by methane at high temperatures (> 1000 K), they are very reactive towards oxidation by oxygen, carbon dioxide and water.

We can offer no clear reasons to account for the high catalytic activity of the early transition metal carbides for the methane reforming reactions, nor for their resistance to macroscopic carbon formation. However, catalytic similarities between early transition metal carbides and the noble metals, which are active for steam reforming, have been noted before.[13–16]

# Dynamics of adduct formation of hydroquinone under oxidative conditions observed by laser spectroscopy

**Victor Nadtochenko† and John Kiwi**

*Institute of Physical Chemistry II, Swiss Federal Institute of Technology, Lausanne 1015, Switzerland*

**Hydroxylated products of hydroquinone ($H_2Q$) are induced *via* $[Fe(ox)_3]^{3-}$–$H_2O_2$ under light and detected in the visible region by laser spectroscopy; reaction of hydroxyl radicals with ($H_2Q$) is observed leading to adduct formation.**

During the past few years the photochemistry of tris(oxaloferrate) has been studied.[1,2] Work has been reported recently[3,4] of the reactions of this complex with organic compounds using steady-state photolysis, flash photolysis and stopped-flow in the millisecond region and at longer times. Here, we report on the reactions of $[Fe(ox)_3]^{3-}$–$H_2O_2$ with hydroquinone ($H_2Q$) from the nanosecond timescale upwards. The findings reported here aim to further our understanding[4–7] about the mode of intervention of $[Fe(ox)_3]^{3-}$ during the degradation of $H_2Q$ in oxidative media.

$FeCl_3$, dihydrooxalic acid and hydroquinone were all Fluka p.a. and used as received. Laser photolysis was carried out using the second harmonic (λ = 347 nm) of a JK-2000 ruby laser operated in the Q-switched mode. The pulse width was *ca.* 10 ns and the energy *ca.* 10 mJ per pulse. The detection of the transient absorption changes was performed *via* an EGG photomultiplier with a rise time of *ca.* 5 ns. The basic system for kinetic spectroscopy detection has been described previously.[8]

Fig. 1(*a*) presents the transient species after the laser pulse for the traces (*i*) $H_2Q$ (40 mM) reacting with $H_2O_2$ (0.29 mM), (*ii*) $[Fe(ox)_3]^{3-}$ reacting with $H_2O_2$ (0.29 mM), (*iii*) the transient decay of $[Fe(ox)_3]^{3-}$ (0.6 mM) back to the ground state or to a metastable longer lived[6] intermediate $[(ox)_2Fe(ox^{\cdot-})]$ **I** (Scheme 1).

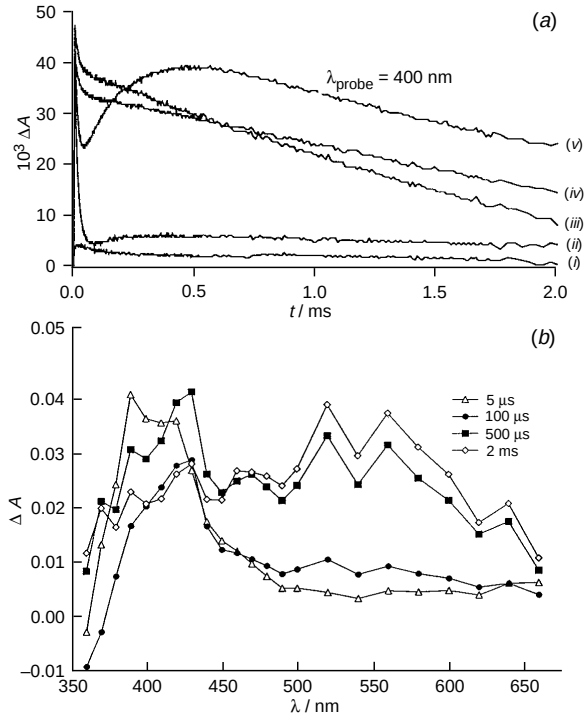

**Fig. 1** (*a*) Laser transients for different solutions of $[Fe(ox)_3]^{3-}$, $H_2O_2$ and hydroquinone ($H_2Q$). For other experimental details see text. (*b*) Transient decay spectra as a function of λ for the system $Fe(ox)_3^{3*-}$ [oxalate (0.6 mM)–$Fe^{3+}$ (18 mM), $H_2Q$ (40 mM) and $H_2O_2$ (0.29 M) at pH 6.5].

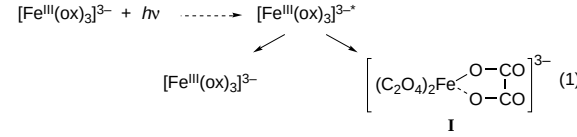
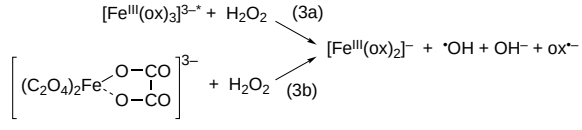


Trace (*iv*) in Fig. 1(*a*) shows $[Fe(ox)_3]^{3-}$ decay in the presence of $H_2Q$ (40 mM) where a quenching effect is noticeable. Finally, to this solution is added $H_2O_2$ (0.29 M) and the result is shown in Fig. 1(*a*) trace (*v*). The lifetimes (τ) of $[Fe^{III}(ox)_3]^{3-*}$ and **I** are *ca.* 5 μs and 2 ms, respectively, at neutral pH. The disappearance of the initial transient absorption is followed by the formation of a coloured species within *ca.* 600 μs. This is observed only in trace (*v*) for the complete chemical system $[Fe(ox)_3]^{3-}$–$H_2O_2$–$H_2Q$. It is not possible to rationalize this result in terms of formation of ·OH radicals by the usual Fenton mechanism [eqn. (2)][1,4] since (*a*) the

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + {}^{\cdot}OH; \quad k_2 = 41\text{–}75\ M^{-1}\ s^{-1} \qquad (2)$$



characteristic time for the reaction is about $10^3$ times longer[9] than the values observed in Fig. 1(*a*) when $[Fe(ox)_3]^{3-}$–$H_2O_2$ is photolysed in solution and (*b*) the observed rise time of the coloured product in Fig. 1(*a*) is seen to be close to the lifetime of the transient $[Fe(ox)_3]^{3-*} + H_2O_2$ as shown in Fig. 1(*a*) trace (*ii*). It is therefore impossible to assign the observed ·OH radical formation to the mechanism of eqn. (2) since only fast intermediates having lifetimes of microseconds would be able to hydroxylate $H_2Q$. Radical formation could be accounted for by reaction of $[Fe^{III}(ox)_3]^{3-*}$ or **I** with $H_2O_2$[6] (Scheme 2).

It has been previously reported[10] that $k_{OH + H_2Q} = 1.2 \times 10^{10}$ $M^{-1}\ s^{-1}$. Since $H_2Q$ (40 mM) was used in Fig. 1(*a*), trace (*i*), the characteristic time for ·OH radical attack would be *ca.* $2.1 \times 10^{-9}$ s. The second pathway of Scheme 2 [eqn. (3*b*)] therefore should be the limiting step for ·OH radical formation when $[Fe^{III}(ox)_3]^{3-*}$ reacts with $H_2O_2$ under light leading subsequently to adduct formation with $H_2Q$ as observed in trace (*v*) of Fig. 1(*a*). This conclusion is confirmed by the near independence observed for the formation of the coloured product of $H_2Q$ on the $H_2Q$ concentration in the range 2–40 mM at fixed $H_2O_2$ and $[Fe^{III}(ox)_3]^{3-}$ concentrations [as shown in Fig. 2(*b*)].

Fig. 1(*b*) shows the absorbances of the products formed after the laser pulse. Different transient lifetimes and absorbances (*A*) were observed as a function of λ due to the existence of different coloured intermediate transients between 350 and 550 nm. The

**Scheme 1**

**Scheme 2**

signals in Fig. 1(*b*) at λ = 450 nm and beyond would correspond to oxidized $H_2Q$–OH adducts in agreement with work by Adams and Michael[10] using pulse radiolysis. The spectrum at 5 μs after the pulse is mainly due to the initial quenching of the binary system $[Fe(ox)_3^{3-}]$–$H_2Q$ by $H_2O_2$. Kinetics of $H_2Q$ hydroxylation consistent with the observations can be rationalized by Schemes 1–3. The rate constants used have been previously reported.[11–13]

Under the experimental conditions used, $[H_2O_2] \gg [Fe^{2+}]$, $[H_2O_2] \gg [ox^{2-}]$ and $[H_2O_2] \gg [\cdot OH]$. The solution for this

$H_2Q + {}^{\bullet}OH \dashrightarrow H_2Q\text{–}OH(adduct)$ $k_4 = 1.2 \times 10^{10}\,M^{-1}s^{-1}$ (4)

$H_2O_2 + {}^{\bullet}OH \dashrightarrow HO_2^{\bullet} + H_2O$ $k_5 = 1.3 \times 10^{7}\,M^{-1}s^{-1}$ (5)

$ox^{2-} + {}^{\bullet}OH \dashrightarrow OH^- + ox^{\bullet-}$ $k_6 = 2 \times 10^{6}\,M^{-1}s^{-1}$ (6)

${}^{\bullet}OH + {}^{\bullet}OH \dashrightarrow H_2O_2$ $k_7 = 5.3 \times 10^{9}\,M^{-1}s^{-1}$ (7)

${}^{\bullet}OH + Fe^{2+} \dashrightarrow OH^- + Fe^{3+}$ $k_8 = 3 \times 10^{8}\,M^{-1}s^{-1}$ (8)

**Scheme 3**

$$[Fe(ox)_3^{3-*}] / dt = -k_q[Fe(ox)_3^{3-*}] - k_a[H_2O_2][Fe(ox)_3^{3-*}] \quad (9)$$

$$d[{}^{\bullet}OH] / dt = k_a[H_2O_2][Fe(ox)_3^{3-*}] - k_5[{}^{\bullet}OH][H_2O_2] - k_4[{}^{\bullet}OH][H_2Q] \quad (10)$$

$$d[adduct] / dt = k_4[{}^{\bullet}OH][H_2Q] \quad (11)$$

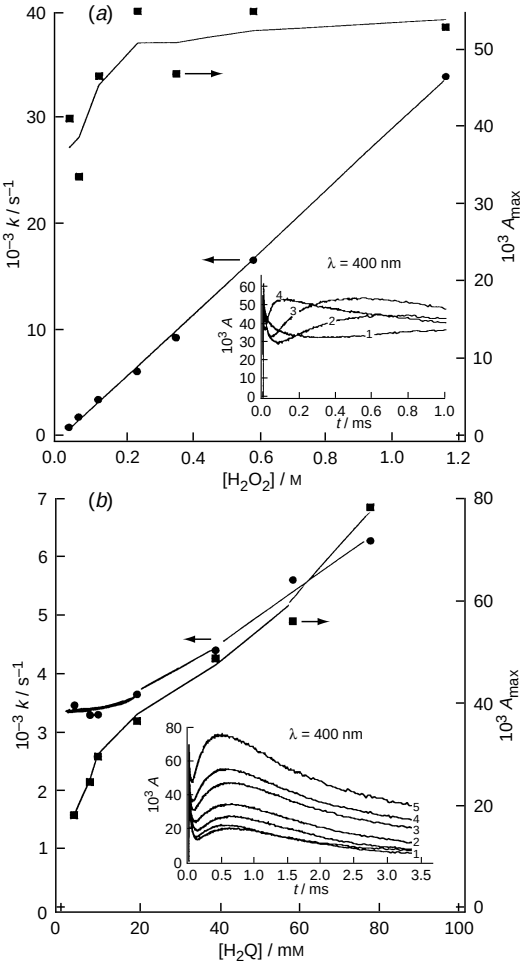


**Fig. 2** (*a*) Dependency of the reciprocal rise time of hydroquinone adducts (●) and absorbance $A_{max}$ (■) *vs.* $H_2O_2$ concentration. The same solution as in Fig. 1(*b*) was used. The insert shows the transient at λ = 400 nm when $H_2O_2$ is added at concentrations of (*i*) 0.029, (*ii*) 0.12, (*iii*) 0.58 and (*iv*) 1.16 M. (*b*) Dependency of the reciprocal rise time of hydroquinone ($H_2Q$) adducts (●) and absorbance $A_{max}$ (■) as a function of $H_2Q$ concentration. The insert shows the transient at λ = 400 nm when $H_2Q$ has been added in the following concentrations: (*i*) 10, (*ii*) 20, (*iii*) 39, (*iv*) 59 and (*v*) 79 mM.

system of differential equations can be stated in a simplified form

$$\Delta A(t) = A_{max} - (\text{cte}) \exp\{-(k_q + k_a[H_2O_2])t\} \quad (12)$$

where $A_{max} = k_4k_a[H_2O_2][H_2Q][Fe(ox)_3^{3*-}]_0/(k_q + k_a[H_2O_2])(k_5[H_2O_2] + k_4[H_2Q])$ and (cte) $= k_4k_a[H_2O_2][H_2Q][Fe(ox)_3^{3-*}]_0/\{[(k_5[H_2O_2] + k_4[H_2Ql]) - k_q + k_a[H_2O_2])](k_q + k_a[H_2O_2])\}$.

Fig. 2(*a*) and (*b*) show the dependency of the reciprocal rise time $k/s^{-1}$ and maximum amplitude for the coloured products ($A_{max}$) as a function of $H_2O_2$ and $H_2Q$ concentrations. Fig. 2(*a*) shows the dependency for $k/s^{-1}$ *vs.* [$H_2O_2$] for a solution oxalate 18 mM–$Fe^{3+}$ 0.6 mM at pH 6.5 and [$H_2Q$] = 59 mM. The insert in Fig. 2(*a*) shows the traces due to the coloured adduct formation (*A*) for different concentrations of added $H_2O_2$ in the millisecond range. The linear dependency of $k/s^{-1}$ *vs.* $H_2O_2$ in Fig. 2(*a*) with slope 2.9 ± 0.4 × $10^5$ $M^{-1}$ $s^{-1}$ is observed to be close to the value of the quenching reported[5] for $[Fe(ox)_3]^{3-*}$. This suggests the formation of ·OH radicals in reaction (3) as the limiting step for $H_2Q$ hydroxylation. This result is consistent with the relation $k/s^{-1} = k_q + k_a[H_2O_2]$. In the latter equation at high $H_2O_2$ concentrations $k_a[H_2O_2] > k_q$, the value of $A_{max}$ would be independent of the oxidant concentration. In effect Fig. 2(*a*) shows that the value of $A_{max}$ is almost independent of $H_2O_2$ concentration above *ca.* 0.25 M.

Fig. 2(*b*) shows the rate constant when experiments similar to those in Fig. 2(*a*) were carried out. The $H_2O_2$ concentration was kept constant at 0.145 M while the concentration of $H_2Q$ was varied in the range 2–78 mM. The growth of the transient at λ = 400 nm is shown in the insert. The value of $A_{max}$ near saturation at $H_2Q$ concentrations of 20–40 mM further increases at [$H_2Q$] > 40 mM. A kinetic model over the entire concentration range studied in Fig. 2 is not capable of accounting for all the features associated at higher $H_2Q$ concentrations.

This work has presented insight into adduct formation of $H_2Q$–OH. Fast hydroxylation of $H_2Q$ can only be explained by the presence of the ·OH radicals due to the fast reaction rate of ·OH with $H_2Q$.[10]

# Nanogram-scale derivatization of hydroxy groups for highly sensitive HPLC/MS/CD detection

**Ning Zhao,[a] Jin-Song Guo,[a] Lee-Chiang Lo,[a] Nina Berova,[a] Koji Nakanishi,*[a] Garner T. Haupert,[b] M. Warrack[c] and Adrienne A. Tymiak*[c]**

**A strategy for performing submicrogram-scale structural studies of saponins and related compounds is worked out by: (*i*) naphthoylation to sensitize HPLC detection by fluorescence as well as configurational studies by exciton coupled CD; and (*ii*) ω-cyanoundecanoylation to increase LC/MS sensitivity (*ca*. 100-fold).**

The specific binding of plant-derived digitalis glycosides by mammalian Na,K-ATPase (sodium pump) raised the possibility that a mammalian analogue of digitalis might exist. Hamlyn *et al*. reported a molecule from human plasma which by mass spectrometry (MS), chromatographic behaviour, *etc*., was undistinguishable from the plant saponin ouabain **1** (ouabain-like compound or OLC).[1] We had also isolated from bovine hypothalamus an inhibitor of the Na,K-ATPase (hypothalamic inhibitory factor or HIF). Similar to ouabain, HIF had an L-rhamnoside moiety but sub-μg scale characterizations showed that it was some isomer of ouabain.[2] Since rhamnosidic saponins are unknown as natural products from mammalian sources, it became important to compare HIF, OLC and ouabain **1** directly. This was performed by converting 300–400 ng of each into their penta-2-naphthoates upon which it was found that the HPLC retention times of HIF and OLC pentanaphthoates were identical but differed from that of ouabain 2′,3′,4′,1,19-pentanaphthoate. Most uniquely, although ouabain **1** exhibited a typical positively split exciton couplet in its circular dichroic spectrum (CD) at 235 nm, *i.e.* 245 nm (Δε +209 $M^{-1}$ $cm^{-1}$)/229 nm (Δε −170), those of HIF and OLC were devoid of any clear Cotton effects (!), thus showing that the arrangements of the five naphthoates are such that the spatial interactions are intramolecularly cancelled.[3] In summary, HIF and OLC are in all likelihood identical but differ from ouabain **1**.

Subsequent rhamnosidation/naphthoylation studies of ouabagenin and CD measurements of the pentanaphthoates coupled with CD computations† suggest the possibility that the genins of HIF and ouabain **1** may indeed be different. Because of the extremely limited amount of the mammalian cardiotonic factor(s) available from natural sources (*e.g.* 5 kg of bovine hypothalamus yields 1 μg of HIF),[3] our strategy is to hydrolyse HIF with naringinase, determine the genin structure by highly sensitive methods, and eventually synthesize the genin and attach the rhamnose. The final structure will be compared with the natural sample by HPLC and CD of its pentanaphthoate and bioassay of the saponin.

In the following, we describe two-step derivatizations of hydroxy groups leading to facile HPLC collection, and increased LC/MS and CD sensitivities. The reaction conditions are chosen to perform partial derivatization with the fluorescent naphthoate chromophores, and this is followed by further acylation of the less reactive hydroxy group with an MS sensitivity-enhanced moiety. Since all properties of HIF are very similar to those of ouabain **1**, suggesting the close similarity (or identity?) of the two genins, ouabagenin is employed as a model. In our previous studies, the HIF hydroxy groups were converted into naphthoates because of many favourable attributes:[4] high derivatization yield (90–95%), fluorescence, intense UV absorption and hence favourable chromophore for exciton coupled CD,[5,6] *etc*. Because a positively charged nitrogen atom greatly enhances the sensitivity in ionspray MS, we first sought to employ 2-quinaldates, with UV properties similar to those of 2-naphthoates, thus simplifying the interpretation of exciton coupled CD, *i.e.* $\lambda_{max}$ of quinaldate in acetonitrile at 235 nm (ε 37 000 $M^{-1}$ $cm^{-1}$) *cf.* naphthoate at 234 nm (ε 58 000). Ouabagenin 1,3,19-triquinaldate **3**, which was prepared in a high-yield microscale reaction using conditions similar to those described for the naphthoate (see below), gave an intense split CD slightly weaker than that of the trinaphthoate: quinaldate **3**,‡ UV $\lambda_{max}$ in acetonitrile at 235 nm (ε 109 000 M $cm^{-1}$); CD 231 (Δε +125), 241 nm (−186), *A* (amplitude) −311, *cf.* trinaphthoate, $\lambda_{max}$ in acetonitrile at 231 nm (ε 147 000); CD 227 (+250), 240 nm (−292), *A* −542. Although the MS sensitivity of triquinaldate **3**

**Scheme 1** One-pot/two-step reaction (naphthoylation and 11-cyanoundecanoylation) of ouabagenin **2**. *Reagents*: i, 2-naphthoylimidazole, DBU, MeCN; ii, $[NC(CH_2)_{10}CO]_2O$, DBU, DMAP.

was enhanced, the quinaldate approach was abandoned because of the much weaker fluorescence.

Compound **4** was designed to overcome the disadvantages of **3**. In a one-pot/two-step reaction (Scheme 1), naphthoylation of ouabagenin was followed by 11-cyanoundecanoylation to give the strongly fluorescent **4**, 85% yield; 231 nm (ε 158 000 M cm$^{-1}$); CD 227 (+260), 240 (−317), $A$ −577; $\lambda_{ex}$ = 234 nm, $\lambda_{em}$ = 360 nm).§ A typical reaction is performed as follows. Ouabagenin (*ca.* 1 μg, dried in a silylated vial), was dissolved in 120 μl anhydrous acetonitrile, and treated with 2-naphthoylimidazole (3 mg) and DBU (0.4 μl). The reaction mixture was stirred for 1 h at room temperature followed by the addition of 11-cyanoundecanoic anhydride (5 mg),¶ and a catalytic amount of DMAP. After stirring for a further 8 h at room temperature, the reaction was quenched by adding 1 ml of 1 : 4 acetonitrile–water. After removal of acetonitrile, the mixture was applied to a Waters $C_{18}$ SepPak cartridge, and then washed sequentially with acetonitrile–water mixtures: 10 ml of 1 : 4, 10 ml of 2 : 3, 8 ml of 4 : 1 and 1 ml of 9 : 1. The final product was eluted with 4 ml acetonitrile, loaded onto a Vydac $C_{18}$ column (4.6 × 250 mm, 10 μm) and eluted isocratically with acetonitrile–water 82 : 18 at 1 ml min$^{-1}$. The products were detected by a fluorescence detector (Hewlett Packard 1046A fluorescence detector, $\lambda_{ex}$ = 234 nm, $\lambda_{em}$ = 360 nm). As depicted in Fig. 1(*a*), the HPLC peaks of ouabagenin trinaphthoate **3** overlap with the asterisked naphthoylation reaction byproducts, whereas the tetranaphthoate peak does not; introduction of the hydrophobic undecanoyl chain increases the retention time leading to no overlap [Fig. 1(*c*)]. Furthermore, **4** offered increased LC/MS detectability.‖ Whereas the limit of detection (LOD) for ouabagenin trinaphthoate was *ca.* 25 ng by single ion monitoring ionspray LC/MS, as little as 300 pg of acyl derivative **4** could be detected under the same conditions. Only part of the sensitivity enhancement observed with **4** is accounted for by increased hydrophobicity since LODs of 0.7 and 0.3 ng were measured for ouabagenin tetranaphthoate and 11-undecanoyl ouabagenin trinaphthoate, respectively.

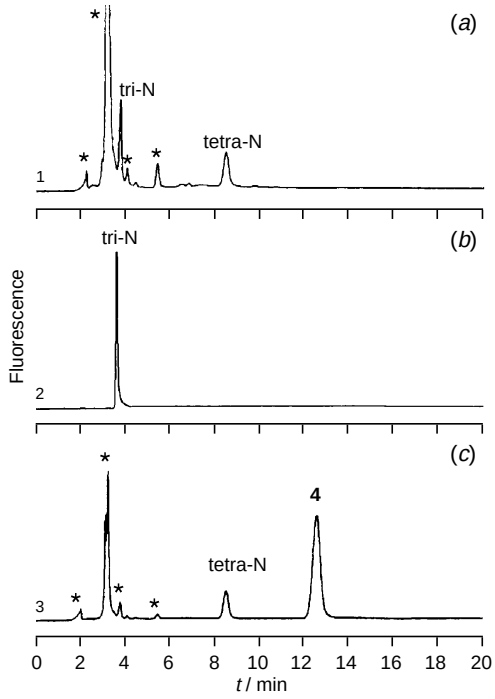

**Fig. 1** Fluorescence-detected HPLC profiles: (*a*) reaction mixture of naphthoylation of ouabagenin; (*b*) authentic ouabagenin trinaphthoate; (*c*) reaction mixture of one-pot/two-step derivatization. Asterisked peaks (*) are from reagents. tri-N = ouabagenin trinaphthoate; tetra-N = ouabagenin tetranaphthoate.

In summary, a general sub-μg derivatization/HPLC/MS/CD approach has been developed. The intense and fluorescent UV chromophore increases the sensitivity of fluorescence-detected HPLC and CD measurements, while the cyanoundecanoyl side chain increases the hydrophobicity to facilitate HPLC/MS analysis as well as increasing the MS sensitivity by *ca*. 100-fold as compared to a substrate without nitrogen. Application of this one-pot/two-step approach in HIF characterization is under way. It is clear that, with some modification, this approach is applicable to the identification, characterization, *etc.*, of other hydroxylated compounds.

The studies were supported by NIH grant GM 34509.

**NaY zeolite membrane grown hydrothermally on the surface of a porous alumina substrate shows a high alcohol selectivity in pervaporation, a membrane-based liquid separation process, of alcohol–benzene, cyclohexane or methyl *tert*-butyl ether.**

Pervaporation, a membrane process, has gained widespread acceptance in the chemical industry as an effective process for separation of azeotropic mixtures.[1] The process operates with a liquid feed, which contacts the upstream membrane face, and a vapour permeate under vacuum or a stream of inert gas and has been applied to the dehydration of organic liquids (ethanol, isopropyl alcohol, ethylene glycol, *etc*.) and many fundamental studies have been carried out.[2] Application of pervaporation to separate organic liquid mixtures such as aliphatic–aromatic hydrocarbons or alcohols–ethers, however, are still very limited because of the swelling of polymer membrane. On the other hand, membranes made from inorganic materials are generally superior to organopolymeric materials in thermal and mechanical stability, and chemical resistance. Among inorganic materials, zeolites are promising candidates as high-performance membranes because of the unique characteristics of zeolite crystals such as molecular sieving, ion exchange, selective adsorption and catalysis. Although there are many recent reports[3] on the preparation of zeolite membranes and gas permeation through them, only a limited number of publications[4–6] deal with pervaporation studies. Recently, we have reported a high pervaporation performance of NaA zeolite membrane for the separation of water–organic liquid mixtures.[6,7] Here, we report the synthesis of NaY zeolite membrane and its application to pervaporation.

NaY zeolite membrane was grown hydrothermally on the surface of a porous cylindrical alumina support (Nikkato Corp., 12 mm outer diameter, 1.5 mm thickness, 1.3 μm average pore size). The aluminosilicate gel used in the synthesis of NaY zeolite membrane was prepared by mixing a water-glass solution and alkaline aluminate solution as described in the literature.[8] After formation of the gel, the reaction mixture was stored at ambient temperature for 12 h. The molar composition of the resulting gel was $SiO_2/Al_2O_3$ = 10, $Na_2O/SiO_2$ = 1.4 and $H_2O/Na_2O$ = 60. The porous support was coated by a water slurry of seed crystals of NaY zeolite (HSZ-320NAA from Tosoh Co.) and then dried at 60 °C for 12 h. After ageing, the gel was poured into a polypropylene vessel and the support was placed in the gel. After hydrothermal treatment at 100 °C for 5 h, the support was taken out, washed with water and dried under reduced pressure.

The formulation of the NaY zeolite was verified by X-ray diffraction (XRD) with Cu-Kα radiation using a Shimadzu XD-D1 diffractometer. The XRD pattern of the NaY membrane grown on an alumina support consists of strong peaks corresponding to NaY zeolite and weak peaks of the alumina support. The surface of the membrane was examined by scanning electron microscopy (SEM) using a Hitachi S-2300 instrument. The surface of the alumina support was completely covered with randomly oriented, intergrown NaY zeolite crystals, 0.5–1 μm in size. The thickness of the membrane was about 20 μm judging from the cross-sectional view of the SEM image.

Pervaporation experiments were carried out using the apparatus described elsewhere.[6] The feed was introduced to the outer side of the zeolite membrane in a stainless-steel module that was placed in a thermostatted air-bath. Throughout the experiment the flow rate of the feed was held at 30–37 $cm^3$ $min^{-1}$. The effective membrane area was 47 $cm^2$ and the downstream pressure was maintained below 13.3 Pa. The membrane performance was evaluated by the permeation flux ($Q$/kg $m^{-2}$ $h^{-1}$) and the separation factor (α). The permeation flux was calculated by weighing the permeate collected by a liquid-nitrogen trap. The separation factor was determined as $\alpha_{A/B} = (Y_A/Y_B)/(X_A/X_B)$ where $X_A$, $X_B$, $Y_A$ and $Y_B$ denote the mass fraction of components A and B in the feed and the permeate, respectively, where A is the species which is preferentially pervaporated.

Table 1 shows the flux and the separation factor of pervaporation for liquid mixtures through NaY zeolite membrane together with previously reported pervaporation results for water–ethanol mixtures through NaA zeolite membranes.[6,7] The NaA zeolite membrane was highly selective for permeating water preferentially with high permeation flux because of the micropore filling of water in the zeolite pores or the intercrystalline pores between zeolite crystals to afford water-selective permeation through the membrane. NaY zeolite membrane also preferentially permeated water from water–alcohol mixtures. However, both the separation factor and the flux of the NaY zeolite membrane were lower than for the NaA zeolite membrane, probably due to the hydrophobic properties of NaY zeolite. On the other hand, NaY zeolite membrane showed a high alcohol selectivity for several feed mixtures with methanol or ethanol. Especially high separation factors were observed for methanol–methyl *tert*-butyl ether (MTBE) separation. In Fig. 1 pervaporation selectivity expressed as methanol mole fraction in the permeate is shown as a function of methanol mole fraction in the feed mixture. It can be observed that pervaporation through NaY zeolite membrane ensures MTBE enrichment in the feed phase by preferential methanol transfer. The corresponding vapour–liquid equilibrium (VLE) curve[9] is also shown and displays large deviation from ideality. This non-ideal behaviour results in the formation of a vapour–liquid azeotrope of composition 68.5 mol% MTBE at 51.27 °C and

**Table 1** Pervaporation performance of NaY zeolite membrane

| Zeolite | Feed solution (A/B) (mass% of A) | $T$/°C | α(A/B) | $Q$/kg $m^{-2}$ $h^{-1}$ |
|---|---|---|---|---|
| NaY | Water–Ethanol (10) | 75 | 125 | 1.59 |
| | Methanol–Benzene (14) | 50 | 1 400 | 0.62 |
| | Methanol–MTBE (10) | 50 | 7 600 | 0.32 |
| | | 40 | 6 500 | 0.21 |
| | Ethanol–Benzene (10) | 50 | 740 | 0.15 |
| | Ethanol–Cyclohexane (14) | 50 | 540 | 0.19 |
| NaA[a] | Water–Ethanol (10) | 75 | 10 000 | 2.15 |

[a] Ref. 6.

atmospheric pressure.[9] It is clear that pervaporation through NaY zeolite membrane can break up the azeotrope and is more selective than distillation (VLE).

Pervaporation flux and separation factors of NaY zeolite membrane for methanol–MTBE mixtures at 50 °C are plotted against the feed composition in Fig. 2. High separation factors were obtained over a wide range of feed compositions. The flux increased from 0.17 kg $m^{-2}$ $h^{-1}$ at 5.3 mol% methanol composition to 0.32 kg $m^{-2}$ $h^{-1}$ at 23 mol% composition while it was almost constant over the range 23–73 mol% composition. It is well known that the overall selectivity of a pervaporation process is determined by mobility selectivity and sorption selectivity. For methanol–MTBE mixtures, the kinetic diameters of these two molecules are approximately 0.38 and 0.62 nm, respectively, and are smaller than the intrinsic NaY zeolite pores of 0.74 nm.[8] Therefore, the sorption process presumably determines the pervaporation performance. Methanol sorption into the membrane increases with increasing methanol feed concentration and increasing sorption causes an increase in the pervaporation flux. When the methanol sorption approaches saturation, the flux becomes constant as shown in Fig. 2. Thus, the high selectivity of NaY zeolite membrane may be attributed to the selective sorption of methanol into the membrane.

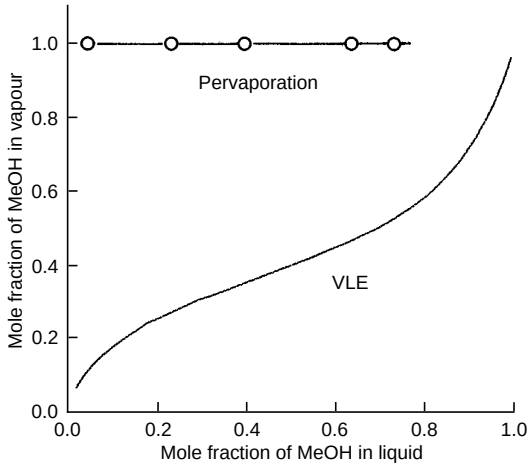

**Fig. 1** Pervaporation selectivity at 50 °C through NaY zeolite membrane and vapour–liquid equilibrium (VLE) at 101 kPa in the methanol–MTBE system

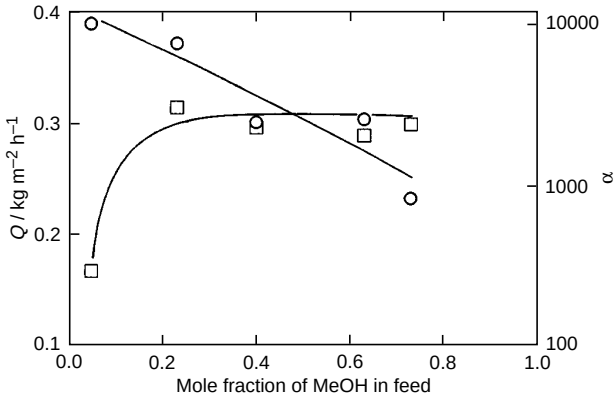

**Fig. 2** Flux $Q$ (□) and separation factor α (○) as a function of methanol feed concentration for pervaporation of methanol–MTBE mixtures through NaY zeolite membrane at 50 °C

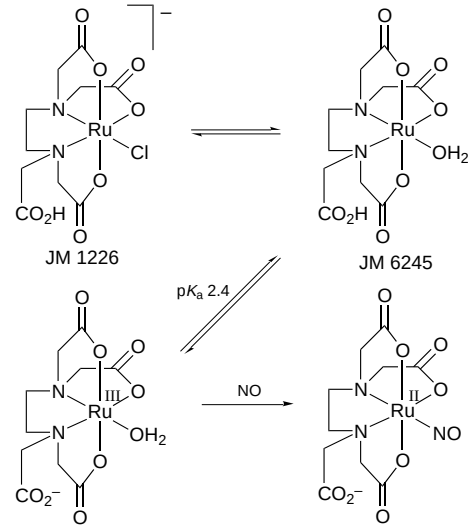
# Kinetics of nitric oxide scavenging by ruthenium(III) polyaminocarboxylates: novel therapeutic agents for septic shock

**Nathan A. Davies,[a] Mike T. Wilson,[a] Elizabeth Slade,*[b] Simon P. Fricker,[b] Barry A. Murrer,[b] Nigel A. Powell[b] and Graham R. Henderson[b]**

[a] *School of Biological and Chemical Sciences, Main Campus, University of Essex, Wivenhoe Park, Colchester, UK CO4 3SQ*
[b] *Johnson Matthey Technology Centre, Blount's Court, Sonning Common, Reading, Berks, UK RG9 4NH*

**The reaction of two representative ruthenium(III) polyaminocarboxylates with nitric oxide are rapid ($k$ > $10^7$ $M^{-1}$ $s^{-1}$ at pH 7.4 and 7.3 °C) forming tight ($K$ = $10^8$ $M^{-1}$) ruthenium(II) mononitrosyls.**

In the last decade nitric oxide (NO) has been found to be an essential component in many physiological processes and dysfunction in NO metabolism has been associated with a number of disease states such as epilepsy, arthritis, hypertension and septic shock.[1,2] In particular, overproduction of NO is implicated in the catastrophic drop in blood pressure associated with septic shock. This hypotension does not always respond well to conventional therapy such as intravenously administered adrenaline and dopamine.[3] Novel therapeutic approaches have largely concentrated on the development of inhibitors of the enzyme, inducible nitric oxide synthase (iNOS).[4] An alternative, however, is to remove NO by use of a specific, high affinity, non-toxic scavenger.



NO is a well characterised ligand for transition metals, having a high affinity for ferrous haem, indeed the biological effects of NO in regulation of blood pressure are brought about by the interaction of NO with the haem iron of the enzyme guanylate cyclase.[1] Ruthenium has a high affinity for NO and forms more nitrosyls than any other metal.[5] A strategy has been adopted in which ruthenium is chelated with suitable ligands which confer water solubility, allowing rapid *in vivo* clearance and unlike iron, low toxicity, whilst providing an available binding site for NO. The polyaminocarboxylates satisfy these requirements as ligands.

We have shown that the ruthenium(III) polyaminocarboxylates K[Ru(Hedta)Cl],[6] JM1226, and [Ru(Hedta)($H_2O$)],[6,7] JM6245 (Scheme 1) will reduce the level of nitrite in the cell culture medium of RAW264 macrophage cells stimulated to produce NO, and reverse lipopolysaccharide (LPS) induced hypotension in rats.[8,9]

Here, we report the NO binding properties of JM1226 and JM6245, JM1226 is water soluble at mM concentrations, forming a pale yellow solution in phosphate buffer over the pH range 6.5–8.0. Storage of JM1226 in phosphate buffer at pH 7.4 for more than 5 h at room temperature resulted in a change in the absorption spectrum due to formation of a dark green species. This green species is attributed to formation of a mixed valence $Ru^{III}Ru^{IV}$ μ-oxo dimer.[10] All experiments were therefore performed with freshly prepared solutions.

The absorption spectra of JM1226 at all pH values examined (6.5–8.0) are identical to the corresponding spectra for JM6245, indicating that the chloride is rapidly replaced in aqueous solution and that the mechanism of reaction of JM1226 with NO proceeds *via* the formation of the aqua species, JM6245, Scheme 1.

On addition of an aqueous NO solution to a solution of JM1226 a small change is observed in the near-UV region of the spectrum, leading to a loss of absorbance at 290 nm and an increase in absorbance below 270 nm, with an isosbestic point at 272 nm. We have utilized this absorbance change to determine the binding stoichiometry of NO to $Ru^{III}$ and to obtain an estimate of the binding affinity. Fig. 1 shows a titration of JM1226 (100 μM) with NO. The inset to Fig. 1 demonstrates that NO forms a 1:1 adduct with JM1226/

**Scheme 1** The proposed mechanism for the reaction of JM1226 with NO involves formation of the aqua complex, JM6245. Substitution at the aqua position is thought to proceed by associative ligand substitution[7] to give the ruthenium(II) mononitrosyl.

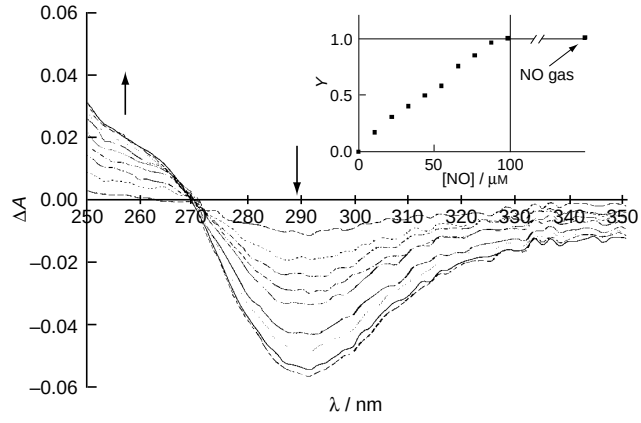


**Fig. 1** Difference spectrum of JM1226 in phosphate buffer (50 mM) at pH 7.4 titrated against an aqueous NO solution of known concentration calculated by titration of ferrous myoglobin with the NO solution.[11] Inset: the binding curve of JM1226 (100 μM) and NO is calculated for the absorbance change at 290 nm and indicates a 1:1 Ru–NO complex is formed. The fractional saturation, $Y$, is defined as $Y = (A - A_0)/(A_\infty - A_0)$, where $A_0$ and $A_\infty$ are absorbances in the absence and presence of saturating NO and $A$ is the absorbance after the addition of a sub-saturating concentration of NO.

JM6245. The affinity is high and cannot be determined from this figure directly, however the linearity of the binding curve approaching saturation indicates that the binding constant is $> 10^8$ M$^{-1}$. These findings are consistent with formation of a strong Ru–NO bond.[5]

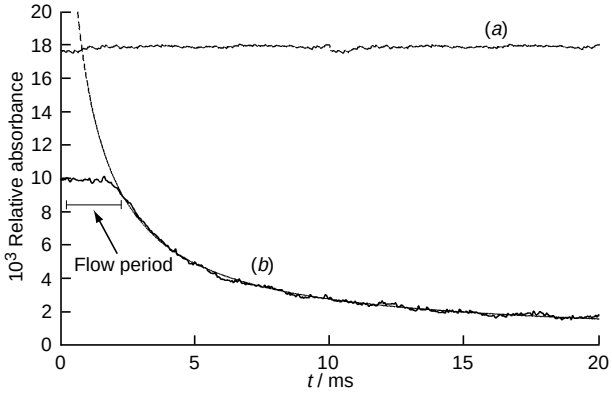

**Fig. 2** Change in absorbance of an anaerobic solution of JM1226 (25 μM) with time, in the absence (*a*) and presence (*b*) of NO (25 μM) in phosphate buffer (50 mM), pH 7.4 at 7.3 °C. The fit is to a second-order rate equation, traces are an average of six measurements. Spectra were recorded on an Applied Photophysics DX17 stopped-flow spectrometer with a measured deadtime of 1 ms.

**Table 1** Calculated second-order rate constants from stopped-flow experiments. All experiments were conducted in phosphate buffer (50 mM) at the pH and temperature stated. Errors represent standard deviation, $n = 6$, in each case

| Compound | pH | *T*/°C | $10^{-7}$ *k*/M$^{-1}$ s$^{-1}$ |
|---|---|---|---|
| JM1226 | 8 | 7.7 | 3.33 ± 0.17 |
| JM1226 | 7.4 | 7.3 | 2.24 ± 0.05 |
| JM1226 | 6.5 | 7.4 | 1.39 ± 0.01 |
| JM6245 | 8 | 7.2 | 3.29 ± 0.14 |
| JM6245 | 7.4 | 7.2 | 1.95 ± 0.06 |
| JM6245 | 6.5 | 7.5 | 2.18 ± 1.06 |

The binding of NO by JM1226/6245 is extremely rapid, Fig. 2, Table 1. As expected JM1226 and 6245 yield, within experimental error, the same rate constants and the reactions display little, if any, pH dependence. At room temperature most of the reaction occurs within the dead time of the apparatus (1 ms), hence the rate measurements were made at 7 °C. At this temperature we see a rapid NO concentration-dependent loss in absorbance, the amplitude of which is consistent with the spectral change on formation of the Ru–NO complex, Fig. 1. At wavelengths below the isobestic point (272 nm, Fig. 1) we observed an increase in absorbance (not shown) with the same course as that shown in Fig. 2 confirming that the process depicted in the figure is a result of the rapid binding of NO to the ruthenium complex. At pH 7.4 and 7.3 °C the rate constant is *ca*. $2 \times 10^7$ M$^{-1}$ s$^{-1}$, we therefore estimate that at physiological temperature the rate constant will exceed $10^8$ M$^{-1}$ s$^{-1}$.

We have shown that at physiological pH JM1226/JM6245 binds NO tightly and rapidly to form a stable 1 : 1 ruthenium(II) mononitrosyl. These properties confirm the pharmacological observations in a model of LPS induced endotoxic shock,[8] that ruthenium(III) polyaminocarboxylate complexes have potential as NO scavengers in NO mediated diseases.

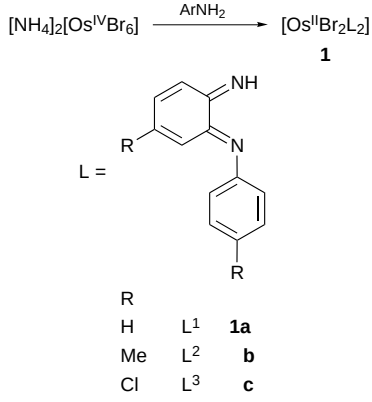
# Osmium(II) complexes of *N*-aryl-1,2-arylene diimines formed *via* *ortho*-dimerization of $ArNH_2$: synthesis, structure and redox properties

**Kedar Nath Mitra and Sreebrata Goswami*†**

*Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India*

**A family of *ortho*-arylene diimine chelates, $[OsBr_2L_2]$ (L = *N*-aryl-1,2-arylene diimine), which represent the first examples of osmium–quinonediimine complexes, are isolated from the reaction of $[NH_4]_2[OsBr_6]$ with aromatic amines, $ArNH_2$.**



Here, we wish to introduce novel examples of bivalent osmium compounds of *N*-aryl-1,2-arylene diimines (L) which are formed *via* the template synthesis of L with osmium (Scheme 1). The compounds, $[OsBr_2L_2]$ **1**, represent the first examples[1] of osmium compounds of the *o*-arylene diimine family. This class of diimine[2] and dioxolene[3] complexes exhibits many interesting properties because of their redox propensities owing to the considerable mixing between metal and ligand orbitals. It may be noted[4] here that the above diimine ligands cannot be formed directly from the corresponding aminoarenes ($ArNH_2$).

In a typical experiment 0.25 g of $[NH_4]_2[OsBr_6]$ was mixed with a large excess of amine, $ArNH_2$ (*ca*. 0.5 g) and the resultant mixture was heated in an oil-bath at 130–135 °C in air for 1 h. After the removal of the excess of amine, the crude product was purified on a silica gel column eluting with chloroform–acetonitrile (9 : 1). Finally, the product was recrystallized from dichloromethane–hexane. Dark shiny crystals of $[OsBr_2L_2]$ **1** were obtained in *ca*. 50% yield.

The formation of **1** *via* the unusual oxidative *ortho*-dimerization reaction, $ArNH_2 \rightarrow L$, has been authenticated by the structure determination of a representative example, *viz*., $[OsBr_2L^1{}_2]$. A view of the molecule is shown in Fig. 1. The coordination sphere consists of $OsBr_2N_4$. Two bromides are *cis* to each other and the aryl-substituted imines are also in relative *cis* positions. The imine C–N bonds[5] [av. 1.323(19) Å] are shorter than the two C–N single bonds [C(19)–N(4), C(7)–N(2), av. 1.437(13) Å] present in the same molecule. Moreover, the average C–C lengths [1.349(26) Å] at positions that would have localized double bonds for the diimine form of the ligands are significantly shorter than the other C–C lengths [av. 1.418(20) Å] of the same ring. It is apparent from the structural data that there is very little delocalization in the coordinated diimine ligands with correspondingly no ambiguity in the bivalent oxidation state of osmium. The molecule approximates to overall $C_2$ symmetry. The twofold axis bisects the Br(1)–Os–Br(2) vector, as well as the N(2)–Os–N(4) vector.

All the osmium diimine compounds analysed satisfactorily. the $^1$H spectral features of the diamagnetic complexes consist of one relatively broad singlet resonance near δ 13.5, assignable[6] to NH (*e.g.* at δ 13.304 for **1b**), sharp methyl resonances (for **1b**) at δ 2.380 and 2.404 and resolved aromatic resonances in the range δ 6.5–8.0. Interestingly, each type of proton of L showed only one signal indicating magnetic equivalance of the two ligands in solution as found in the solid state. The electronic spectra of the complexes showed multiple charge-transfer transitions[7] occurring in the near-IR and visible regions [*e.g.* data for **1a** : λ/nm (ε/dm$^3$ mol$^{-1}$ cm$^{-1}$) 1150 (650), 900(780), 605(sh, 4310), 500(20050), 375(7290)].

Cyclic voltammetry of $[OsBr_2L_2]$ showed two oxidations and one reduction wave in the potential range 2.0 to −1.8 V *vs*. SCE. The two responses on the positive potentials are reversible ($\Delta E_p$ 60–65 mV, $i_{pa} = i_{pc}$) and assigned to successive one-electron transfers at the metal centre. The irreversible ligand reductions occur at negative potential. The potentials of the above couples shift anodically as the electron withdrawing ability of the substituent increases. For example, the potential of the $Os^{III}$–$Os^{II}$ couple shifts from 0.70 V for **1a** to 0.94 V for **1c**. This potential, 0.94 V for an $Os^{III}$–$Os^{II}$ couple, is one of the highest reported[8] in $[OsX_2\ L'_2]$ (X = Cl, Br; L′ = bidentate

**Scheme 1**

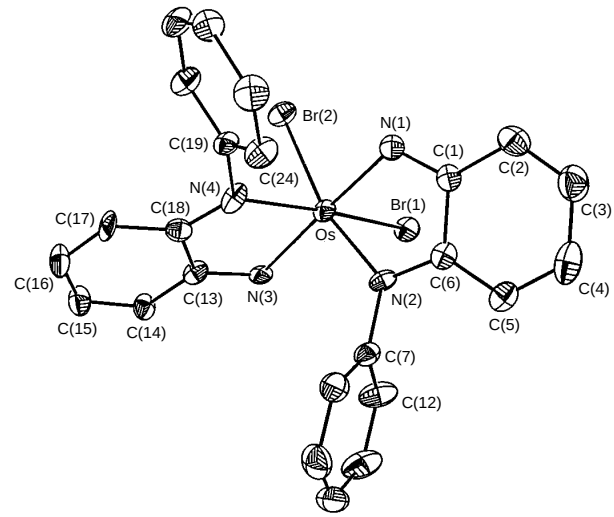


**Fig. 1** Molecular structure of $[OsBr_2L^1{}_2]$ showing the atom numbering scheme. Selected distances (Å) and angles (°): Os–Br(1) 2.519(2), Os–Br(2) 2.523(3), Os–N(1) 1.998(11), Os–N(2) 2.000(11), Os–N(3) 1.994(10), Os–N(4) 2.017(11), N(1)–C(1) 1.317(19), N(2)–C(6) 1.338(19), N(2)–C(7) 1.417(15), N(3)–C(13) 1.325(19), N(4)–C(18) 1.312(20), N(4)–C(19) 1.458(11); Os–N(1)–C(1) 116.7(7), Os–N(2)–C(6) 115.5(8), N(1)–C(1)–C(6) 113.6(12), N(2)–C(6)–C(1) 114.1(12), N(1)–Os–N(2) 77.9(4), N(3)–Os–N(4) 76.6(4), Os–N(3)–C(13), 118.2(6), Os–N(4)–C(18) 117.5(7), N(3)–C(13)–C(18) 112.8(12), N(4)–C(18)–C(13) 113.8(13).

ligand) systems. This may be attributed to the very strong π interactions between the metal and low-lying acceptor-ligand orbitals. This effect is also reflected in the short Os–N distance[7] (av. 2.002 Å) in $[OsBr_2L^1{}_2]$.

One-electron coulometric oxidation of **1a** at 0.9 V afforded a brown solution which can be quantitatively reduced to **1a** by electrolysis at 0.5 V. The brown solution of $\mathbf{1a}^+$ displayed a rhombic EPR spectrum with three distinct resonances at $g$ = 2.693, 2.401 and 1.638 indicating[9] the trivalent $d^5$ state of osmium in $\mathbf{1a}^+$.

The formation of L from $ArNH_2$ involves the transfer of four electrons and four protons. Therefore, a total of eight electrons and eight protons are released for the formation of two L in **1**. In contrast, the metal oxidation levels in $[NH_4]_2[OsBr_6]$ and **1** differ only by two units. The mechanism of the above reaction is, as yet, not established. However, we wish to note here that the above reaction does not proceed in an $N_2$ atmosphere in the absence of $O_2$. Presumably, *cis*-coordination of two aniline molecules followed by oxidative dimerization with the formation of a C–N bond in the presence of $O_2$ would be a plausible path for the formation of L in the above reaction. Osmium promoted oxidation of amine to imine by $O_2$ is known[10] in the literature. Interestingly, and as expected, 2,6-dimethylaniline did not react with $[OsBr_6]^{2-}$ under identical conditions.

Preliminary experiments indicate that compounds **1** serve as excellent starting materials for the syntheses of tris-chelates of osmium(II) diimines, the photochemistry and electrochemistry of which are of interest in contemporary research.[11] Detailed studies are in progress and will be reported elsewhere.

We are grateful to Professor A. Chakravorty and thank Dr P. Ghosh, IACS, Calcutta for their help in the X-ray analysis of **1a**. Financial support received from the UGC, New Delhi is acknowledged.

## Footnotes

† E-mail: icsg@iacs.ernet.in

‡ *X-Ray structure determination*: X-ray quality crystals (0.4 × 0.3 × 0.25 mm) of $[OsBr_2L^1{}_2]$ were obtained by slow diffusion of a dichloromethane solution of the complex into hexane. Cell parameters were obtained by least-square fits of 30 machine centred reflections. Data were collected ($3 \leqslant 2\theta \leqslant 43°$) on a Nicolet R3 m/V diffractometer (295 K) with graphite-monochromated Mo-Kα radiation (λ = 0.710 73 Å). Two check reflections were measured after 198 reflections did not show any significant change in intensity over 25 h exposure to X-rays. Data were corrected for Lorentz-polarization effect and absorption (azimuthal scan). Of the 2953 reflections collected 2858 were unique and 2386 reflections satisfying $I > 2\sigma(I)$ were used for structure solution by the Patterson heavy atom method using the SHELXTL-PLUS program[12] package on a MicroVax II computer. Refinement was done by the full-matrix least-squares method. All non-hydrogen atoms were made anisotropic. Hydrogen atoms were added at calculated positions and refined with fixed $U$ = 0.08 Å$^2$.

*Crystal data* for **2a**: $C_{24}H_{20}Br_2N_4Os$, $M$ = 712.2, triclinic, space group $P\bar{1}$, $a$ = 10.464(6), $b$ = 11.778(6), $c$ = 12.595(10) Å, α = 103.86(5), β = 112.72(6), γ = 107.79(4)°, $U$ = 1245.3(10) Å$^3$, $Z$ = 2, $D_c$ = 1.991 g cm$^{-3}$, $R$ = 0.046, $R'$ = 0.0521.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/298.

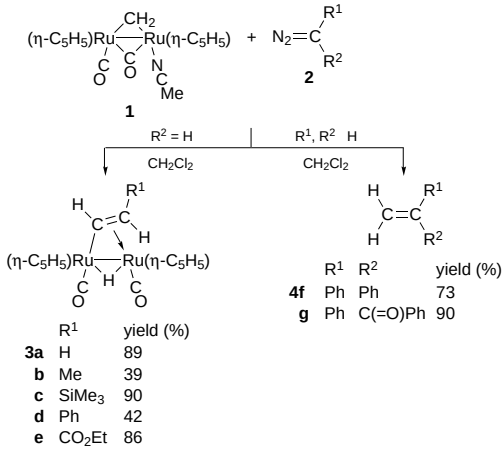
# Specific alkylidene coupling of the labile diruthenium bridging methylene complex $[(\eta\text{-}C_5H_5)_2Ru_2(\mu\text{-}CH_2)(CO)_2(MeCN)]$ with diazoalkanes ($N_2{=}CR_2$) giving alkenic products



**Munetaka Akita,*[a] Ruimao Hua,[a] Selby A. R. Knox,*[b] Yoshihiko Moro-oka,*[a] Sadahiro Nakanishi[a] and Michael I. Yates[b]**

[a] *Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226, Japan*
[b] *School of Chemistry, University of Bristol, Bristol, UK BS8 1TS*

**Reaction of the labile diruthenium bridging methylene complex $[(\eta\text{-}C_5H_5)_2Ru_2(\mu\text{-}CH_2)(\mu\text{-}CO)(CO)(MeCN)]$ with diazoalkanes ($N_2{=}CR^1R^2$) results in specific C–C coupling to give alkenic products, *i.e.* the bridging alkenyl complex $[(\eta\text{-}C_5H_5)_2Ru_2(\mu\text{-}CH{=}CHR^1)(\mu\text{-}H)(CO)_2]$ ($R^2$ = H) or alkene $CH_2{=}CR^1R^2$ ($R^1$, $R^2 \neq$ H).**

C–C coupling mediated by transition-metal–alkylidene species is involved in many useful stoichiometric and catalytic organic transformations such as alkene cyclopropanation, metathesis and acetylene polymerization,[1] and most of the active species are mononuclear [$M{=}CR_2$] with an electrophilic vacant p orbital.[2a,b] In contrast, polynuclear bridging alkylidene species [$M_n(\mu\text{-}CR_2)$] appear to be sluggish with respect to C–C coupling, in particular, coupling with another $CR_2$ species, though they are recognized as better model compounds for surface-bound methylene species.[3] This is probably due to the σ character of the M–$CR_2$ bonds,[2c] and few successful examples of alkylidene coupling on a polynuclear system have been reported so far.[3] Herein we disclose the effective and specific C–C coupling of a labile diruthenium bridging methylene species $[(\eta\text{-}C_5H_5)_2Ru_2(\mu\text{-}CH_2)(\mu\text{-}CO)(CO)(MeCN)]$ **1**[4] with diazoalkanes ($N_2{=}CR^1R^2$ **2**), a reaction relevant to the carbon-chain propagation mechanism of catalytic CO hydrogenation.

When an ethereal solution of diazoalkane **2** was added to the labile bridging methylene species **1** at room temp. an instantaneous reaction took place with gas evolution (Scheme 1). In the case of the reaction with monosubstituted diazoalkane [$N_2{=}CR^1H$ (**2** $R^2$ = H); $R^1$ = H **a**, Me **b**, $SiMe_3$ **c**, Ph **d**, $CO_2Me$ **e**], the bridging alkenyl complexes $[(\eta\text{-}C_5H_5)_2Ru_2(\mu\text{-}CH{=}CHR^1)(\mu\text{-}H)(CO)_2]$ **3a**–**e**†,‡ were isolated in good yields after TLC separation. The products **3** were readily characterized on the basis of the NMR data† [(*i*) the separated $C_\alpha H_\alpha$ and $C_\beta H_\beta$ signals of the bridging alkenyl ligand ($\mu\text{-}C_\alpha H_\alpha{=}C_\beta H_\beta R^1$) and (*ii*) the hydride signal appearing around δ −15] and the absence

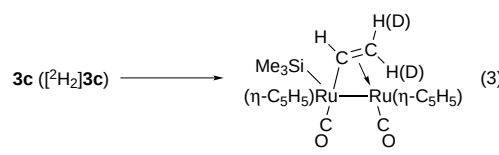
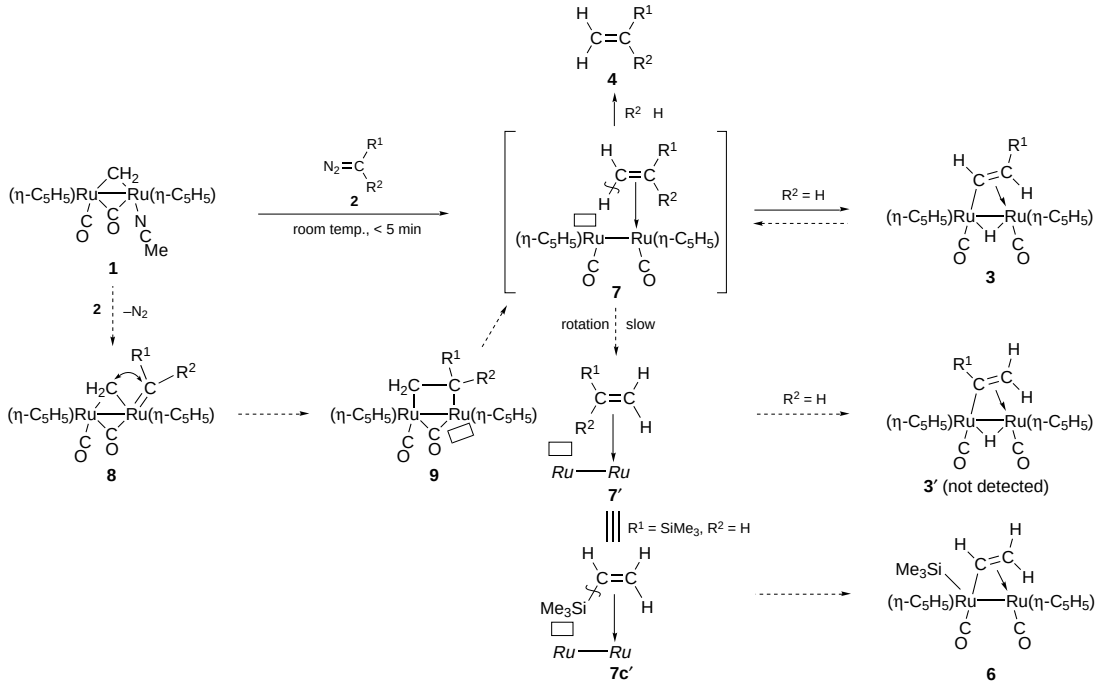
**Scheme 1**

of a bridging CO stretching vibration. Derivatives of **3** including the structurally characterized **3b** have been previously obtained by a different route.[5] The reaction of **1** with disubstituted diazoalkane **2** [$R^1$ = $R^2$ = Ph **f**; $R^1$ = Ph, $R^2$ = C(=O)Ph **g**] afforded alkene $CH_2{=}CR^1$ $R^2$ **4f**,**g** and only a complicated mixture of organometallic products; the μ-H signal of **3** could not be detected.



It is remarkable that the reaction conditions of the present C–C coupling are much milder than those of the thermal C–C coupling of the di(μ-alkylidene) complexes, $[(\eta\text{-}C_5H_5)_2Ru_2(\mu\text{-}CR_2)(\mu\text{-}CHR)(CO)_2]$ **5** (R = Me **a**,[6a] H **b**[6b]) (> 200 °C), and that the selectivity as well as the yield is superior to those of the latter systems.

In order to obtain an insight into the reaction mechanism, labelling experiments using $[^2H_2]$**1** (μ-$CD_2$) and $[^{13}C]$**1** (μ-$^{13}CH_2$) were carried out. Treatment of $[^2H_2]$**1** with **2a**,**c** produced $[^2H_2]$**3a**,**c** where the $H_\alpha$ and μ-H atoms were deuteriated completely [Scheme 2, eqn. (1)]. Similarly, the $^{13}C$-labelled methylene carbon atom in $[^{13}C]$**1** became the α carbon atom of the bridging alkenyl ligand in $[^{13}C]$**3a** [Scheme 2, eqn. (2)]. These labelling studies confirm that the C–C coupling is specific and that the α-CH and μ-H moieties in **3** come from the bridging $CH_2$ ligand in **1**.



**Scheme 2** *C = $^{13}C$ enriched

It is also notable that thermolysis of the β-silylethenyl complex **3c** at 100 °C afforded the isomeric silyl–ethenyl complex **6** [eqn. (3)]. The rearrangement of $[^2H_2]$**3c** turned out to be specific as indicated by the formation of $[^2H_2]$**6** with the two β-methylene hydrogen atoms being deuteriated completely. Thus the β-$CH_2$ moiety in **6** originated from the μ-$CH_2$ ligand in **1**.

**6** ($[^2H_2]$**6**)

**Scheme 3** *Ru* = Ru(η-$C_5H_5$); □ = coordinatively unsaturated site

The specific alkylidene coupling and rearrangement can be interpreted in terms of the reaction mechanisms summarized in Scheme 3, involving the coordinatively unsaturated alkene species **7** as a key intermediate. Oxidative addition of a C–H bond in **7** would lead to the μ-alkenyl complex **3**, while in the case of the reaction with disubstituted diazoalkane (**2f**, **g**), the alkene **4** may be eliminated from the diruthenium centre due to the steric repulsion. The absence of the regioisomer **3′** and the results of the labelling experiments indicate that the C–H oxidative addition giving **3** must take place before the unsymmetrical structural information of **7** is lost (*e.g. via* rotation of the alkene ligand leading to **7′**). Because (*i*) the di(μ-alkylidene) complex **5** does not undergo C–C coupling under the present reaction conditions and (*ii*) the symmetrical structure of **5** cannot explain the results of the labelling experiments, the unsymmetrical η¹-alkylidene-μ-alkylidene species **8** and the dimetallacyclobutane **9** are plausible precursors of **7**. The different reactivities of complexes **8** and **5**, which have the same composition, may be attributed to the relative facility of migratory insertion *cf.* reductive elimination. Finally, thermolysis of the β-silylethenyl derivative **3c** is proposed to occur *via* reductive elimination to regenerate **7** with subsequent rotation of the alkene ligand (**7c′**) followed by oxidative addition of the Si–C bond giving rise to the silyl–ethenyl complex **6**.

The present study reveals that alkylidene units on a polynuclear system can be coupled with each other in a quite specific manner under very mild reaction conditions, if they are incorporated into the metal system in an appropriate way. In the present case, the C–C coupling is most probably realized *via* migratory insertion of the η¹-alkylidene-μ-alkylidene species **8**. A similar alkylidene coupling leading to an alkenic intermediate may occur on a heterogeneous catalyst surface, and, recently, a vinyl species has been proposed as an initiator of the carbon-chain propagation.[3e]

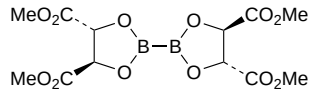
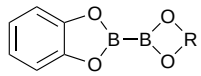
# Reaction between rhodium(III) bisboryls and diborane(4) compounds: evidence for a σ-bond metathesis process

**Todd B. Marder,*[a] Nicholas C. Norman,*[b] Craig R. Rice[b] and Edward G. Robins[b]**

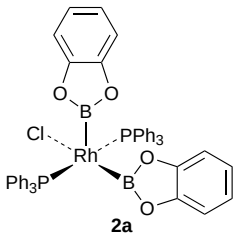


[a] *The University of Waterloo, Department of Chemistry, Waterloo, Ontario, Canada, N2L 3G1*
[b] *The University of Bristol, School of Chemistry, Bristol, UK BS8 1TS*

**The rhodium bis(boryl) complex [RhCl(PPh$_3$)$_2${B(cat)}$_2$] (cat = 1,2-O$_2$C$_6$H$_4$) reacts with the diborane(4) compounds B$_2$(O$_2$R)$_2$ {O$_2$R = 1,2-O$_2$C$_6$H$_3$Me-4, 1,2-O$_2$C$_6$H$_2$Bu$^t_2$-3,5 and dimethyl-L-tartrate [OCH(CO$_2$Me)CH(CO$_2$Me)O]} affording unsymmetrical metal bis(boryls) [RhCl(PPh$_3$)$_2${B(cat)}{B(O$_2$R)}] and diborane(4) compounds (cat)B–B(O$_2$R), one possible mechanism for which involves σ-bond metathesis.**



The oxidative addition of the B–B bond in certain diborane(4) compounds to low-valent transition-metal centres is now well established and results in metal bis(boryls) of the general formula [L$_n$M{BR$_2$}$_2$] some of which are active catalysts for the diboration of alkenes and alkynes.[1] During studies of the reactivity of metal boryls, we recently demonstrated that reversible oxidative addition–reductive elimination of B$_2$(cat)$_2$ **1a**[2] (cat = 1,2-O$_2$C$_6$H$_4$) occurs with the rhodium(III) tris(boryl) complex [Rh(PMe$_3$)$_3${B(cat)}$_3$],[3] and also that the platinum(II) bis(boryl) compound *cis*-[Pt(PPh$_3$)$_2${B(cat)}$_2$] reacts with the diborane(4) species B$_2$(1,2-O$_2$C$_6$H$_3$Bu$^t$-4)$_2$ **1b** to give the platinum bis(boryl) complex *cis*-[Pt(PPh$_3$)$_2${B(1,2-O$_2$C$_6$H$_3$-Bu$^t$-4)}$_2$] presumably *via* reductive elimination of **1a** followed by oxidative addition of **1b**.[1c] Reductive elimination of **1a** from the rhodium(III) bis(boryl) complex [RhCl(PPh$_3$)$_2${B(cat)}$_2$] **2a**[1a] in the presence of isocyanides has also been observed.[1f] In order to gain further insight into the factors which influence the oxidative addition–reductive elmination reaction of B–B bonds with transition-metal centres, we undertook a study of the reaction between complex **2a** and a series of diborane(4) compounds, preliminary results for which are described herein.



**1a** R$_4$ = H
**b** R$_4$ = 4-Bu$^t$-3,5,6-H$_3$

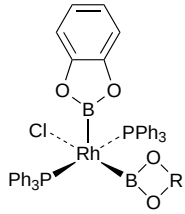
**h** O$_2$R = tartrate



**2a**

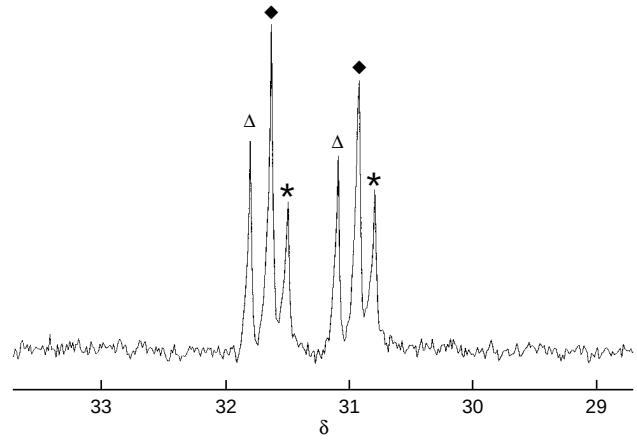
**2f**

**2b** O$_2$R = 1,2-O$_2$C$_6$H$_3$Me-4
**d** O$_2$R = 1,2-O$_2$C$_6$H$_2$Bu$^t_2$-3,5

**2c** O$_2$R = 1,2-O$_2$C$_6$H$_3$Me-4
**e** O$_2$R = 1,2-O$_2$C$_6$H$_2$Bu$^t_2$-3,5
**g** O$_2$R = tartrate

The reaction between **2a** {generated *in situ* from the reaction between equimolar ratios of either [RhCl(PPh$_3$)$_3$] **3a** or [{RhCl(PPh$_3$)$_2$}$_2$] **3b** and **1a** in CH$_2$Cl$_2$ solution}[1a] and 1 equiv. of the diborane(4) compound B$_2$(1,2-O$_2$C$_6$H$_3$Me-4) **1c** was followed by $^{31}$P NMR spectroscopy which revealed the formation, after 2 h, of three products in a ratio of 1:2:1 (Fig. 1). One of these products was unreacted **2a** (δ 31.15, $J_{Rh–P}$ 112.9 Hz)[1a] and a second (δ 31.45, $J_{Rh–P}$ 114.8 Hz) was identified as the symmetrical bis(boryl) compound [RhCl(PPh$_3$)$_2${B(1,2-O$_2$C$_6$H$_3$Me-4)}$_2$] **2b**, prepared and identified independently from the reaction between **3b** and **1c**. The third, and major, product (δ 31.30, $J_{Rh–P}$ 114.8 Hz) we propose to be the mixed or unsymmetrical bis(boryl) complex [RhCl(PPh$_3$)$_2${B(cat)}{B(1,2-O$_2$C$_6$H$_3$Me-4)}] **2c** on the basis of the $^{31}$P NMR chemical shift, which is intermediate between those of the two symmetrical bis(boryls) **2a** and **2b**, and the value of $J_{Rh–P}$ which is almost identical to those of **2a** and **2b**. An identical $^{31}$P NMR spectrum to that shown in Fig. 1 was observed for the reaction between equimolar amounts of **2b** and **1a**.

Whilst the formation of the unsymmetrical bis(boryl) complex **3c** was unexpected, the generality of the reaction was



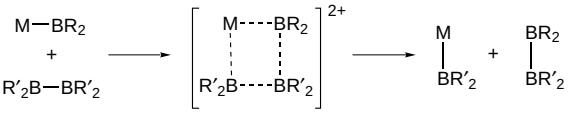


**Fig. 1** A $^{31}$P{$^1$H} NMR spectrum of the reaction between **2a** and **1c** in CH$_2$Cl$_2$ solution showing the presence of the compounds **2a** (*), **2b** (△) and **2c** (◆). Chemical shift and coupling constant data are given in the text. All spectra were recorded on a JEOL GX 400 spectrometer.

established with further examples. Thus the reaction between **2a** and $B_2(1,2\text{-}O_2C_6H_2Bu^t_2\text{-}3,5)_2$ **1d** afforded both the symmetrical species $[RhCl(PPh_3)_2\{B(1,2\text{-}O_2C_6H_2Bu^t_2 3,5)\}_2]$ **2d** (δ 31.85, $J_{Rh-P}$ 114.9 Hz)[1a] and the unsymmetrical compound $[RhCl(PPh_3)_2\{B(cat)\}\{B(1,2\text{-}O_2C_6H_2Bu^t_2\text{-}3,5)\}]$ **2e** (δ 31.70, $J_{Rh-P}$ 114.9 Hz) as well as unreacted **2a**, although in this case **2a** was present as the major species, the ratio of **2a** : **2e** : **2d** being *ca*. 7 : 1 : 1, and the reaction was observed to be considerably slower, taking about 24 h to reach completion.† Similarly, the reaction between **2a** and $B_2(tart)_2$‡ [tart = dimethyl L-tartrate, $OCH(CO_2Me)CH(CO_2Me)O$] **1e** afforded, in addition to unreacted **2a**, the symmetrical compound $[RhCl(PPh_3)_2\{B(tart)\}_2]$ **2f** (δ 32.05, $J_{Rh-P}$ 116.8 Hz) (prepared and identified independently from the reaction between **3b** and **1e**) and the unsymmetrical species $[RhCl(PPh_3)_2\{B(cat)\}\{B(tart)\}]$ **2g** (δ 31.55, $J_{Rh-P}$ 114.9 Hz), although the formation of **2f** was very slow and was only observed after about 9 days at which time the ratio of **2a** : **2g** : **2f** was 21 : 16 : 1.§ Interestingly, the reaction between **2f** and **1a** showed initial formation of **2a** and the unsymmetrical bis(boryl) **2g** was only observed after 6 days at which time the ratio of **2a** : **2g** : **2f** was 5 : 1 : 5.

All of these results imply that a scrambling of the diborane(4) compounds is occurring in solution in the presence of rhodium, further evidence for which was the observation and identification, by high-resolution mass spectrometry,¶ of the unsymmetrical diborane(4) compounds (cat)B–B(1,2-$O_2C_6H_3$Me-4) **1f**, (cat)B–B(1,2-$O_2C_6H_2Bu^t_2$-3,5) **1g** and (cat)B–B(tart) **1h** in their respective reaction solutions; no such compounds were observed in the absence of rhodium.

In terms of possible reaction mechanisms, we suspect that an oxidative addition–reductive elimination pathway, analogous to those described in the introductory paragraph, does occur since, in the reaction between **2f** and **1a**, the symmetrical bis(boryl) compound **2a** was observed prior to the appearance of the unsymmetrical species **2g**. The fact that unsymmetrical bis(boryls) and diborane(4) compounds are observed in all reactions, however, implies that an additional reaction mechanism must also be operating since simple oxidative addition–reductive elimination cannot afford such mixed products. Possible mechanisms which might account for the formation of the observed products include a double diborane(4) oxidative addition to give a rhodium(V) tetraboryl species such as $[RhCl(PPh_3)_n\{B(cat)\}_2\{B(O_2R)\}_2]$ ($O_2R$ = 1,2-$O_2C_6H_3$Me-4, 1,2-$O_2C_6H_2Bu^t_2$-3,5 and dimethyl-L-tartrate), or reductive elimination of ClB(cat) from a symmetrical bis(boryl) (for example, **2a**) followed by oxidative addition of diborane(4) to give a rhodium tris(boryl) complex $[Rh(PPh_3)_n\{B(cat)\}\{B(O_2R)\}_2]$, reductive elimination from either of which could afford the observed products. Whilst we cannot rule out either of these two possible mechanisms at this stage (particularly in view of the slowness of reactions involving **1d** and **1e** where the presence of trace amounts of undetected intermediates is a possibility), we note firstly the unlikelihood of the formation of a rhodium(V) complex in the former mechanism {although compounds which are formally rhodium(V) such as $[RhH_2(SiEt_3)_2(\eta\text{-}C_5Me_5)]$ have been described by Fernandez and Maitlis},[4] and, secondly, the lack of any evidence for oxidative addition of ClB(cat) to rhodium(I) triphenylphosphine centres (in this and other systems studied) which would subsequently be required in the latter mechanism in order to give the observed rhodium chloride bis(boryls). At this stage, the mechanism we prefer as the simplest explanation for these observations is one involving σ-bond metathesis, as shown in Scheme 1. Thus, whilst we have no direct evidence for this mechanism, we note that such mechanisms have been proposed by Smith[1d] to account for the reaction between **1a** and the platinum metallacyclopentane complex *cis*-$[Pt(PPh_3)_2\{(CH_2)_4\}]$ which affords *cis*-$[Pt(PPh_3)_2\{B(cat)\}_2]$ and (cat)$B(CH_2)_4$B(cat), and by Hartwig *et al.* in discussing the reaction between $[RuMe(PMe_3)_2(\eta\text{-}C_5H_5)]$ and HB(cat).[5] Furthermore, we note that complexes such as **2a** may be compared to the ruthenium(IV) alkylidene species of the form $[RuCl_2(=CR_2)(PR_3)_2]$ characterised by Grubbs and co-workers[6] which are known to be active alkene metathesis catalysts.

**Scheme 1**

Further studies relating to these observations are in progress, but the preliminary results described herein indicate the potential mechanistic complexity of systems involving metal boryls and diborane(4) compounds which will be an important consideration in any reactions in which metal boryls are employed as catalysts in diboration reactions.

Du Pont De Nemours and Co., Inc. are also thanked for generous supplies of rhodium salts.

## Footnotes

† We attribute the fact that the reaction between **2a** and **1d** is considerably slower than that between **2a** and **1c** to the fact that **1d** is much more sterically demanding than **1c**, consistent with which is the related observation that whilst **3a**,**b** react in minutes with **1a**, the corresponding reaction between **3a**,**b** and **1d** takes nearly 1 h to reach completion; steric congestion at the rhodium centre is also likely to favour a preponderance of the bis-B(cat) complex **2a** as observed.

‡ Compound **1e** was prepared from $B_2(NMe_2)_4$ and dimethyl-L-tartaric acid, $HOCH(CO_2Me)CH(CO_2Me)OH$, according to the general preparative routes described in ref. 2 and references therein; full details will be described in a future publication.

§ The slowness of this reaction is consistent with the observation that the reaction between **3a**,**b** and **1e** takes several days to go to completion.

¶ (cat)B–B(1,2-$O_2C_6H_3$Me-4) **1f** $C_{13}H_{10}B_2O_4$, ($M^+$) calc. *m/z* 252.076. Found *m/z* 252.076; (cat)B–B(1,2-$O_2C_6H_2Bu^t_2$-3,5) **1g** $C_{20}H_{24}B_2O_4$, ($M^+ - {}^{12}C^1H_3$) calc. *m/z* 335.163. Found *m/z* 335.163.

# On the crystal structure of κ-alumina

**Hans-Leo Gross and Werner Mader***

*Institut für Anorganische Chemie der Universität Bonn, Römerstraße 164, 53117 Bonn, Germany*

**The idealized structure of κ-alumina is determined on the basis of lattice images by high-resolution electron microscopy and by applying crystallographic considerations and constraints of crystal chemistry.**

κ-Alumina was first observed in X-ray powder diffraction spectra of dehydration products of gibbsite by Stumpf *et al.*[1] in 1950. The unit-cell parameters as well as the space group of κ-alumina remained undetermined until 1991 when Liu and Skogsmo[2] performed electron diffraction on $Al_2O_3$ material generated by CVD. These authors determined the crystal system to be orthorhombic crystallising in the space group $Pna2_1$. The number of formula units is $Z = 8$ and a stacking sequence ABAC of closed-packed oxygen layers is the only possible one to be in accordance with that space group. Later, the lattice parameters were determined more precisely by means of X-ray powder diffraction to be $a = 0.4834$, $b = 0.8310$, $c = 0.8937$ nm by Halvarsson.[3] However, the crystal structure of κ-$Al_2O_3$, *i.e.* the cation distribution, was unknown up to now.

In the present study, κ-$Al_2O_3$ was produced by internal oxidation of a Nb–Al alloy with 5 atom% aluminium under the following conditions: $T = 1450$ °C, $p(O_2) = 10^{-4}$ mbar, $t = 30$ min. Using this method,[4] aluminium is internally oxidized to give $Al_2O_3$ precipitates within the metallic (Nb) matrix. Besides the modifications α-$Al_2O_3$ and θ-$Al_2O_3$, plate-like precipitates of κ-$Al_2O_3$ were observed using transmission electron microscopy (TEM). In the course of our TEM study we confirmed the results obtained by Liu and Skogsmo.[2] Furthermore, we were able to obtain high-resolution lattice images of κ-$Al_2O_3$ in different zone axes in order to obtain information on the (projected) cation distribution. The point-to-point resolution of 0.2 nm of the electron microscope (Philips CM30 SuperTwin, operated at 300 kV) does not allow the cations to be imaged separately. However, applying crystallographic considerations, the large amount of possible structural models can be reduced to only five structures, as outlined in the following.

Applying the ABAC stacking sequence and setting oxygen to (0,0,0), the positions of all the other oxygen ions in the idealized (undistorted) closed-packed anion sublattice are fixed. The *b* axis is parallel to a closed-packed direction in the oxygen layer and its length is three times the oxygen diameter. The *a* axis corresponds to the distance between two oxygen ions perpendicular to the closed-packed direction, while the *c* axis is parallel to the stacking direction of the layers (see Fig. 1). Since only one general position with multiplicity $M = 4$ exists in $Pna2_1$, four oxygen sites are symmetrically equivalent leaving six of the 24 anions in the unit cell symmetry-independent. This results in six independent octahedral sites and twelve tetrahedral sites, respectively. Owing to the stoichiometry, four of these independent interstitial sites have to be occupied resulting in 3060 principally possible structures calculcated by combination theory. (*i*) First we stipulate that the number of cations between the pairs of oxygen layers A–B, B–A, A–C, and C–A are identical. (*ii*) We can also exclude face-sharing and edge-sharing of $AlO_4$ tetrahedra with other tetrahedra as well as with $AlO_6$ octahedra, such elements do not exist in the structural chemistry of aluminium oxides. (*iii*) Since in aluminium oxides, aluminium preferentially occupies octahedral sites, a maximum value of 1 : 1 as the ratio of the occupied tetrahedral to octahedral sites is assumed. (*iv*) Cation layers showing exclusively tetrahedral occupation do not exist in the known aluminium oxides, and can be definitely excluded.

Following the boundary conditions (*i*)–(*iv*) for the cation occupation, five of the 3060 possible structures for κ-$Al_2O_3$ remain. Structures I–IV show only octahedrally coordinated aluminium, whereas structure V exhibits octahedral and tetrahedral coordination of aluminium with a ratio of 3 : 1. The latter structure is the structure we propose for κ-$Al_2O_3$. One indication of this structure is the spacing of 0.2234 nm of the closed-packed layers of κ-$Al_2O_3$, which corresponds better with the value of 0.2284 nm in the spinel aluminas relative to the value of 0.2165 nm in corundum. An even more substantial indication are the values of the Coulomb energies calculated for the five possible structure models and for corundum using the MAPLE program package.[5] The Coulomb energies are as follows. Structures I–IV: 3846–4024 kcal mol$^{-1}$. Structure V: 4232 kcal mol$^{-1}$. Corundum: 4354 kcal mol$^{-1}$ (cal = 4.184 J).

The proposed structure of κ-$Al_2O_3$ is shown in Fig. 1. From this it can be deduced that the most promising orientation for determining the cation positions is lattice imaging along [100] because the channels in the structure can be imaged best. A lattice image of κ-$Al_2O_3$ along [100] is shown in Fig. 2. The image simulation for a crystal thickness of 3.9 nm and focus setting of −78 nm shows very good matching with the observed image. Under these imaging conditions the brightest dots correspond to the channels between the octahedral double chains in the structure. The curved bright contrasts above represent the region of low atomic density, *i.e.* low scattering power along the chains of the $AlO_4$ tetrahedra. The dark contrast in the image corresponds to a region of high scattering power, produced in particular by the Al atoms, and forming intersecting dark lattice fringes of the planes (011) and ($0\bar{1}1$), respectively.

The crystal structure of κ-$Al_2O_3$ (Fig. 1) is isomorphous to that of $FeGaO_3$,[6] where aluminium occupies the iron and

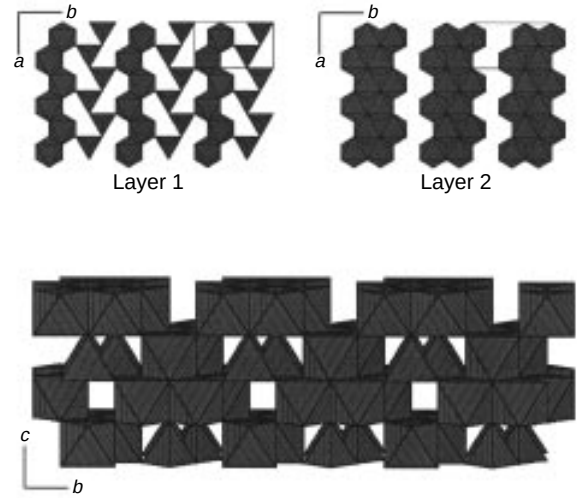

**Fig. 1** The idealized crystal structure of κ-$Al_2O_3$

gallium sites in the iron gallium oxide structure. The structure can be described as constituted by two different layers 1 and 2, which are stacked alternately along the direction of the *c* axis. Layer 1 consists of single chains of edge-sharing $AlO_6$ octahedra, which are connected *via* single chains of corner-sharing $AlO_4$ tetrahedra. Layer 2 is built up by edge-sharing $AlO_6$ octahedra, which are arranged as double chains parallel to the *a* axis, leaving channels of unoccupied octahedra in between. The repeat unit (length = *c* axis) contains four layers stacked as 121′2′, where the layers 1′ and 2′ are distinguished from the layers 1 and 2 by a rotation of 180° around the $2_1$-screw axis. In this structure the channels of unoccupied octahedra in layer 2 are bridged by the chains of tetrahedra of the adjacent layer 1.

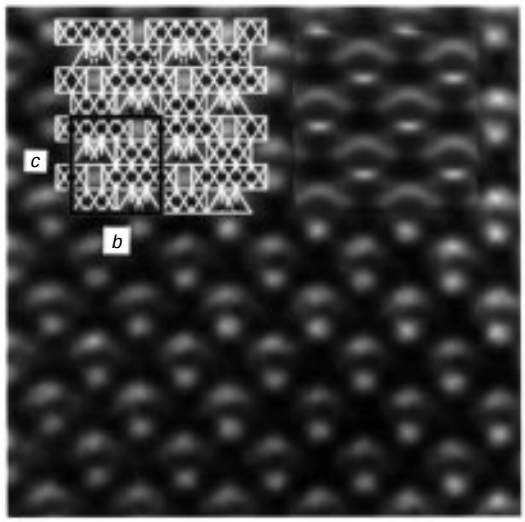

**Fig. 2** Lattice image of κ-$Al_2O_3$ along [100] with inserted image simulation, aluminium atoms and unit-cell dimensions

Further examinations using quantitative electron diffraction are currently being performed in order to evaluate the exact atomic coordinates of κ-$Al_2O_3$.

The help of Dr J. Mayer (MPI für Metallforschung, Stuttgart) in the electron microdiffraction is kindly acknowledged. We also thank Dr W. Assenmacher and Dr B. Freitag for experimental support and fruitful discussions. The financial support of the Ministerium für Wissenschaft und Forschung, NRW, Germany, under contract No. 10300892, is kindly acknowledged.

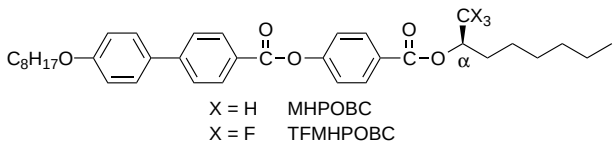
# Direct transition from $S_A$ to antiferroelectric, ferroelectric or unknown phases of diastereomeric liquid-crystalline molecules with varying enantiomeric purities

**Koichi Mikami,*[a]† Tomoko Yajima,[a] Masahiro Terada,[a] Yoshiichi Suzuki[b] and Ichiro Kobayashi[b]**

[a] *Department of Chemical Technology, Tokyo Institute of Technology, Meguro-ku, Tokyo 152, Japan*
[b] *Central Research and Development Laboratory, Showa Shell Sekiyu K.K., 123-1 Shimokawairi, Atugi, Kanagawa 243-02, Japan*

**The phase sequences of diastereomeric α-trifluoromethyl-β-methyl-substituted liquid-crystalline molecules critically depend on the enantiomeric purities (% ee) not only for *ul*- but also for *lk*-diastereomers, to show eventually an unknown phase in the racemic region of either an *ul*- or an *lk*-diastereomer.**

New types of liquid-crystalline (LC) phases such as ferroelectric[1] (F) ($S_{C*}$), antiferroelectric[2] (AF) ($S_{C_A*}$), ferrielectric[3] ($S_{C_\alpha*}$ and $S_{C_\gamma*}$), and twist-grain boundary[4] (TGB) phases have recently been discovered in chiral LC molecules. Amongst these, the AF phase has been studied intensively both experimentally and theoretically, due to its potential applications in electro-optic devices.[5,6] However, only a limited number of AFLC molecules have been reported so far (Fig. 1) such as the methyl-substituted aryl ester (MHPOBC)[5a] and its trifluoromethyl analogue (TFMHPOBC),[5b] which bear a chiral alkyl terminus with a single stereogenic centre. In these, the direct phase transition from $S_A$ to $S_{C_A*}$ takes place in high enantiomeric excess (% ee) and the $S_{C*}$ phase occurs between the $S_A$ and $S_{C_A*}$ phases in the racemic region.[7] In order to investigate the relationship between molecular asymmetry and AFLC properties, we designed α-trifluoromethyl-β-methyl-substituted aryl esters which are diastereomers with double stereogenic centres. We report the intriguing feature that their phase sequence critically depends on the enantiomeric excesses (% ee) not only for *ul*- but also for *lk*-diastereomers.[8] Surprisingly, we also found a direct phase transition from $S_A$ to an unknown phase which shows an intriguing electro-optic response in the racemic composition for both diastereomers.



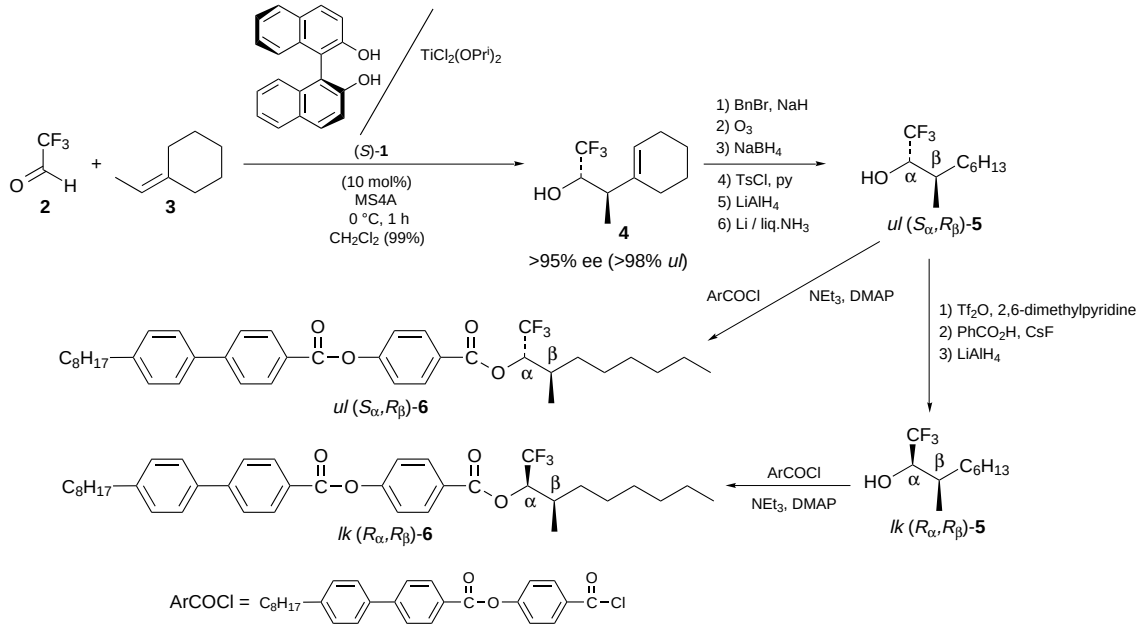


**Fig. 1**

Both enantiomers of diastereomeric LC molecules were synthesised through a chiral titanium complex-catalysed carbonyl–ene reaction[9] of fluoral **2** with ethylidenecyclohexane **3**,[10] using an (*S*)- or (*R*)-binaphthol-derived chiral titanium catalyst [(*S*)- or (*R*)-**1**][11] (Scheme 1). The *ul*($S_\alpha$,$R_\beta$)-alcohol **4** was thus obtained in an almost quantitative yield in more than 95% ee and 95% de, by the use of the (*S*)-binaphthol–titanium catalyst [(*S*)-**1**]. Protection of the alcohol, ozonolysis, reduction and deprotection led to the *ul*($S_\alpha$,$R_\beta$)-diastereomer **5** in an essentially stereopure form (> 95% ee, > 95% de). Inversion of the stereochemistry of a α-hydroxy group through the triflate derivative with benzoic acid by catalysis with caesium fluoride[12] produced an *lk*($R_\alpha$,$R_\beta$)-diastereomer **5** again in a stereochemically pure form (> 95% ee, > 95% de). Condensation of *ul*- and *lk*-**5** with 4-chlorocarbonylphenyl 4′-octyloxybiphenyl-4-carboxylate gave the diastereomeric LC molecules *ul*($S_\alpha$,$R_\beta$)- and *lk*($R_\alpha$,$R_\beta$)-**6**, respectively.

The phase sequences and transition temperatures for **6** were measured for varying enantiomeric excesses for the *ul*- and *lk*-

**Scheme 1**

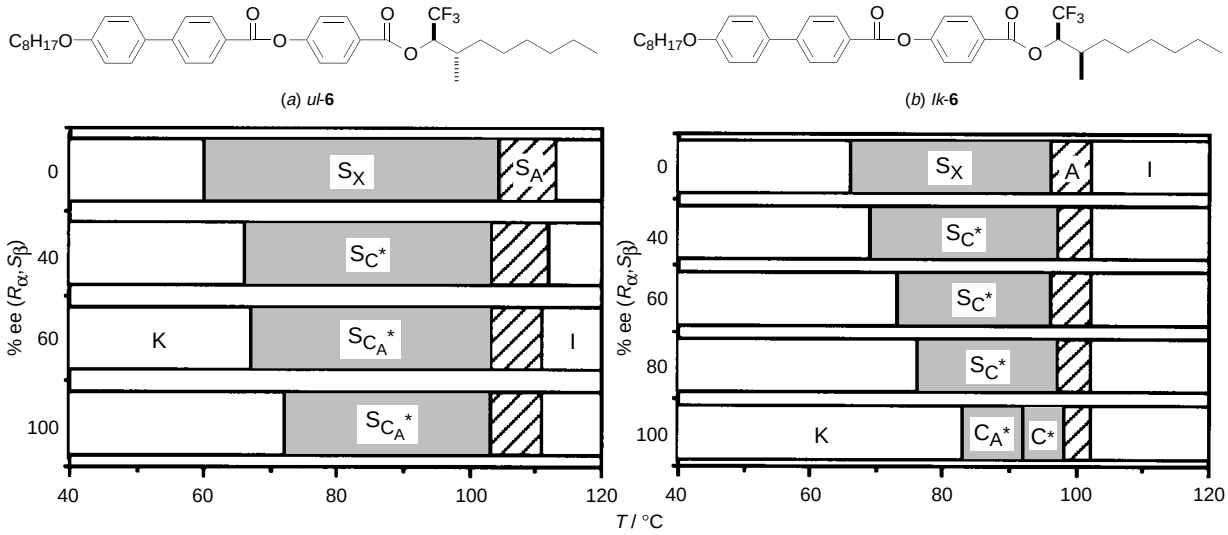

**Fig. 2**

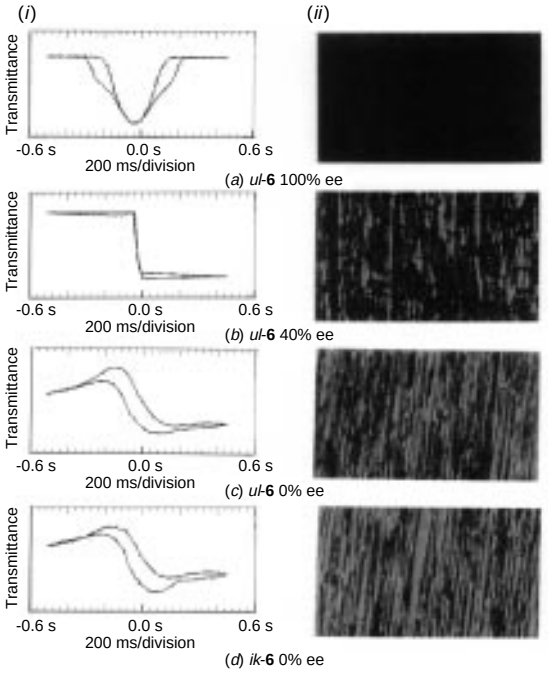

**Fig. 3** (*i*) Electro-optic switching characteristic at 90 °C and (*ii*) photomicrographs of the liquid-crystalline phases at 90 °C

diastereomers (Fig. 2). The phase transition from $S_A$ to $S_{C_A^*}$ takes place for medium-to-high enantiomeric excesses (60–100% ee) of the *ul*-diastereomer [Fig. 2(*a*)]. Interestingly, the transition from $S_A$ to $S_{C^*}$ takes place without any transition from $S_{C^*}$ to $S_{C_A^*}$ at low enantiomeric excess (40% ee). By contrast, the opposite *lk*-diastereomer shows the transition from $S_A$ to $S_{C^*}$ even in the enantiopure form (100% ee) [Fig. 2(*b*)]. Thus, the $S_{C_A^*}$ phase is likely to be stabilised in the *ul*-diastereomer. Surprisingly, an unknown phase appears in the racemic region of either the *ul*- or the *lk*-diastereomer. The phase in question is, therefore, referred to as $S_X$.

The *ul*-diastereomer **6** shows an AF double-loop hysteresis [Fig. 3(*i*)(*a*)] in the medium-to-high enantiomeric range (60–100% ee) and, by contrast, in the low enantiomeric purity (40% ee), a single-loop-hysteresis, characteristic of FLC [Fig. 3(*i*)(*b*)]. However, the electro-optic responses of $S_X$ phases of racemic LC diastereomers show an intriguing type of hysteresis for both *ul*- and *lk*-diastereomers [Fig. 3(*i*)(*c*) and (*d*)]. Furthermore, the kinds of texture in the $S_X$ phases [Fig. 3(*ii*)(*c*), (*d*)] are quite different from those in the $S_{C_A^*}$ [Fig. 3(*ii*)(*a*)] and $S_{C^*}$ [Fig. 3(*ii*)(*b*)] phases.

In summary, we have demonstrated the first proof that the appearances of antiferroelectric, ferroelectric and unknown phases are controlled by tuning the enantiomeric excesses in diastereomeric liquid-crystalline molecules.

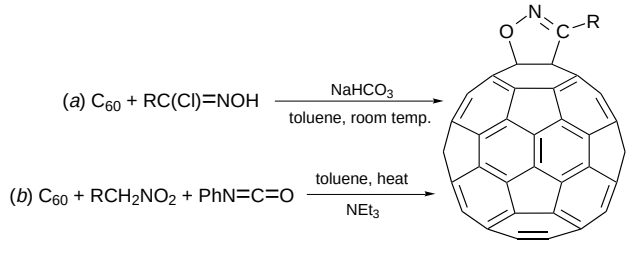
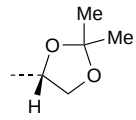
# Cycloaddition of nitrile oxides to [60]fullerene

**Tatiana Da Ros,[a] Maurizio Prato,*†[a] Fabiola Novello,[b] Michele Maggini,[b] Marco De Amici[c] and Carlo De Micheli[c]**



[a] *Dipartimento di Scienze Farmaceutiche, Università di Trieste, Piazzale Europa 1, 34127 Trieste, Italy*
[b] *Centro Meccanismi di Reazioni Organiche del CNR, Dipartimento di Chimica Organica, Università di Padova, Via Marzolo 1, 35131 Padova, Italy*
[c] *Istituto Chimico-Farmaceutico, Università di Milano, Viale Abruzzi 42, 20131 Milano, Italy*

**The addition of nitrile oxides to [60]fullerene is examined and it is found that the reaction products regenerate [60]fullerene under relatively mild conditions; the result is potentially useful for better control of fullerene functionalization.**

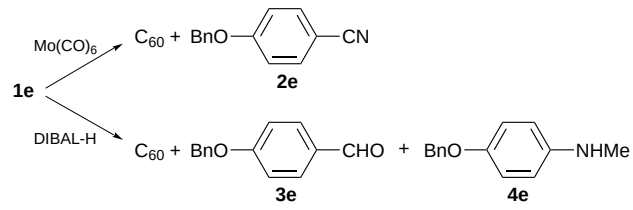


The use of fullerenes as frameworks for molecular assemblies is becoming increasingly popular.[1,2] The regiochemistry of multiple additions has been the subject of thorough investigations[3,4] and methodologies for the octahedral[4,5] or tetrahedral[6] functionalization of [60]fullerene have been successfully developed. However, complete control over the addition chemistry of fullerenes has yet to be reached, especially as new discoveries continue to emerge.[7,8] In connection with this, the reversibility of some reactions has been shown to be useful to reach challenging new targets.[6,9] Here we report that the products of the cycloaddition of nitrile oxides to [60]fullerene can regenerate quantitatively [60]fullerene under specific conditions and that this fact may be used to better control fullerene chemistry.

According to previous reports,[10,11] nitrile oxides, generated under different conditions, add readily to [60]fullerene giving rise to fullerene-fused isoxazolines (Scheme 1).‡

The most common way to generate nitrile oxides is the dehydrochlorination of hydroximoyl chlorides, which, in turn, can be prepared from the corresponding aldehydes (path *a*, Scheme 1, compounds **1a**–**e**, **h**, **i**). Alternatively, nitrile oxides can be efficiently prepared by dehydration of primary nitroalkanes (path *b*, Scheme 1, compounds **1f**, **g**). We have prepared, *via* path *a*, an optically active fullerene derivative, starting from the corresponding homochiral hydroximoyl chloride, readily available from D-mannitol[12] (**1i**, Scheme 1).

**a** R = $CH_2OCH_2CH_2OCH_2CH_2OMe$
**b** R = 9-anthryl
**c** R = COPh
**d** R = $CO_2Et$
**e** R = $C_6H_4$-4-OBn
**f** R = $CH_2CO_2Bu^t$
**g** R = $CH_2CH_2CO_2Me$
**h** R = $CH_2CH_2CH_2CH_2N(Boc)CH_2CO_2Bu^t$
**i** R =

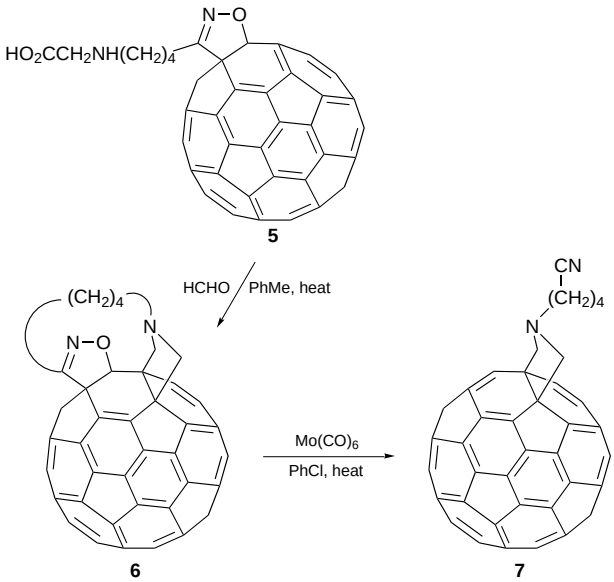


**Scheme 1**

Fullerene-fused isoxazolines (isoxazolinylfullerenes) are relatively stable and revert back to [60]fullerene only at very high temperatures (280–400 °C).[10] Compounds **1** are also stable to acids. Addition of 10 equiv. of trifluoroacetic acid to a solution of **1d** in chlorobenzene under reflux gave only traces of [60]fullerene after 10 d. Addition of *N*-phenylmaleimide as a retrocycloaddition trapping agent did not result in the formation of the corresponding adduct, even in chlorobenzene under reflux.

Conventional isoxazolines are versatile synthons in many transformations, as they are reduced under a variety of conditions to a range of functional groups (*e.g.* amino alcohols, amino carbonyls, nitrile alcohols, *etc.*).[13] On the contrary, isoxazolinylfullerenes appear to be resistant to further functionalization.[10] This could be due to two reasons. First of all, functionalities spatially close to the fullerene sphere have been found to be less reactive than usual.[14] Furthermore, if the N–O bond opens up, a hydroxy functionality directly attached to [60]fullerene would be generated. A single hydroxy group on a fullerene is presumed to be unstable, and is expected to eliminate.[7] Thus, it is not surprising that, when isoxazolines **1a**–**i** were treated with $Mo(CO)_6$ under conditions that usually favour N–O bond cleavage (anhydrous chlorobenzene under reflux for 24 h),[15] [60]fullerene was recovered quantitatively. The addition of protic solvents (either water or methanol, 0.025 M) accelerates the reaction.[15] Under these conditions, the reaction completed in 2 h. The reaction of **1e** with $Mo(CO)_6$ was investigated as a representative example (Scheme 2). Nitrile **2e** (identified by comparison to an authentic sample) was recovered quantitatively along with [60]fullerene. This result can be tentatively explained by initial N–O bond cleavage followed by expulsion of the fragments from [60]fullerene. More extended work will be necessary to clarify the detailed mechanism.

A similar result was obtained with the treatment of **1** with DIBAL-H (diisobutyl aluminium hydride, 10 equiv.) at room temperature in toluene. In this case, the reaction of **1e**, besides the quantitative production of [60]fullerene, yielded aldehyde **3e** and amine **4e** (identified by comparison with authentic samples) in 31 and 64% isolated yields respectively. Whereas aldehyde **3e** was probably formed by DIBAL-H reduction of



**Scheme 2**

nitrile **2e**, amine **4e** could have been formed from the rearrangement of nitrile oxide to the corresponding isocyanate[16] which was then reduced to **4e**. In any case, all attempts to trap the transient nitrile oxide under reductive conditions failed.

In light of the results reported here, several applications of the addition of nitrile oxides to fullerenes can be envisioned. The solubility of [60]fullerene, which is a real problem in a number of instances, can be improved by the temporary addition of a solubilizing appendage (see, for example, **1a**, Scheme 1). The examples reported here may be considered an attractive alternative to known methodologies.[17] In fact, the trioxanonane chain in **1a** can be easily attached *via* the corresponding nitrile oxide cycloaddition and then easily removed, in one single step, under two very different conditions, either of which are compatible with the reactivity of [60]fullerene and also with that of most functional groups. Furthermore, the use of a chiral chain (**1i**) can be used to chemically resolve racemic mixtures of chiral fullerenes or fullerene derivatives.[18]

As an example of the potential of the described methodology, isoxazoline **1h** was treted with trifluoroacetic acid to afford the corresponding glycine derivative **5** (as a trifluoroacetate salt) in quantitative yield (Scheme 3). When **5** was heated to reflux in toluene in the presence of 10 equiv. formaldehyde,[19] a single product was isolated by chromatography in 67% yield. Structure **6** is tentatively assigned to this product, based on analytical and spectroscopic data, with the help of AM1 optimization.§ Once treated with $Mo(CO)_6$, **6** led to **7** as the only isolated product. The structure of **7** was confirmed by the reaction of *N*-(4-cyanobutyl)glycine and formaldehyde with [60]fullerene.[19] Scheme 3 shows a specific site-directed functionalization of [60]fullerene using a temporary anchor point.

# A new type of layered aluminium phosphate $[NH_4]_3[Co(NH_3)_6]_3[Al_2(PO_4)_4]_2$ assembled about a cobalt(III) hexammine complex

**Keith R. Morgan, Graeme J. Gainsford and Neil B. Milestone**

*Industrial Research Limited, PO Box 31-310, Lower Hutt, New Zealand*

**The formation of a novel layered aluminium phosphate containing a new type of layer stoichiometry is reported; the reaction is carried out under basic conditions using cobalt hexammine as a template.**

There have been a number of reports on the synthesis of microporous solids where metal complexes have been used as templating agents. Balkus *et al*.[1] synthesized a zeolite with the faujasite structure using metal phthalocyanine complexes as templating agents. Balkus and Shepelev[2] have used a bis(cyclopentadienyl)cobalt(III) complex to form a nonasil molecular sieve and more recently Freyhardt *et al*.[3] formed a novel large-pore high silica zeolite using bis(pentamethylcyclopentadienyl)cobalt(III) hydroxide. In order for a metal complex to be useful as a templating agent the metal complex must be stable under the reaction conditions. Cobalt(III) complexes are inert to substitution and remain stable at relatively high temperatures. We recently used this property to form a unique layered aluminium phosphate[4] about the chiral metal complex cobalt tris(ethylenediamine), $[Co(en)_3]^{3+}$. This was the first reported example where a metal complex was used as a template to form a layered structure. Bruce *et al*. have found that the cobalt tris(propylenediamine) complex[5] and the cobalt bis(diethylenetriamine) complex[6] can also act as a template to form a chiral layered material. We found that if either isomers of $[Co(en)_3]^{3+}$ was resolved and used as the template in the hydrothermal reaction then no crystalline material was formed. This suggests that there is no lattice compatible with the resolved complex, and that both isomers are required to obtain a stable structure.

The metal complex $[Co(en)_3]^{3+}$ is reasonably stable under the hydrothermal conditions used in these types of preparations. The cobalt hexammine complex, $[Co(NH_3)_6]^{3+}$, is not as stable and undergoes decomposition in boiling water with the loss of ammonium ion. The complex is, however, stable in concentrated ammonium ion solutions at temperatures up to 150 °C.

The reaction of aluminium oxyhydroxide, (0.5 g), $[Co(NH_3)_6]Cl_3$ (1 g) and 85% phosphoric acid (1.9 g) in concentrated ammonium hydroxide (10 ml) at 150 °C for 12 h resulted in the formation of long orange needles, up to 1 cm in length, large purple plates and a minor amount of unidentified small blue plates. The purple plates were identified by powder XRD as $NH_4CoPO_4$.[7] Since the colour of the orange needles suggested that the complex had acted as a template for formation of the structure and not undergone decomposition, this material was further characterised by single-crystal X-ray crystallography.†

The orange needles have a layered structure with the metal complex positioned between the layers. Water and ammonium ions fill the voids between the layer and the metal complex [Fig. 1(*a*)]. The composition of the layers is, however, different to those layered aluminium phosphates that have been reported to date, which have either the compositions $Al_3(PO_4)_4^{3-}$ (refs. 4–6, 8–11) or $Al_2(PO_4)_3^{3-}$ (ref. 12) and a range of unique layer topologies. The composition of this new layered phase is $Al_2(PO_4)_4^{6-}$. In most of the layered aluminium phosphates, the aluminium is tetrahedrally bonded through an oxygen to four phosphorus atoms. The structure described by Chippindale *et al*.[12] is unusual as it contains both tetrahedrally and trigonal-bipyramidal aluminium. In the $[Al_3(PO_4)_4^{3}]_n$[4–6,8–11] layered material the phosphorus is bonded through three oxygens to aluminium giving one non-coordinated P–O bond. In the $[Al_2(PO_4)_3^{3-}]_n$[12] layers there are two types of phosphorus. One type is bonded to four oxygens of which three are bonded to aluminium, the other is bonded to four oxygens but only two of these are bonded to aluminium.

For the structure reported here, $[Al_2(PO_4)_4^{6-}]_n$, there are two unique phosphorus atoms with each bonded to four oxygens. Only two of these oxygens are bonded to aluminium, the other two are nominally P–O double bonds. The solvent system of concentrated ammonium hydroxide used for forming the $Al_2(PO_4)_4^{6-}$ lattice is highly basic favouring P–O double bond formation. The $Al_2(PO_4)_4^{6-}$ lattice is the most basic type of the layered aluminium phosphates reported to date. There are three types of rings in the structure: two small four-membered rings and a large 20-membered ring [Fig. 1(*b*)]. The metal complexes reside within the larger ring. The density of the material is similar to that of the other layered aluminium phosphates.

There is an extensive hydrogen-bonding network involving the non-coordinated phosphoryl oxygens, the coordinated amines, the ammonium ions and the water molecules [O(phosphate)···N 2.71–2.96 Å], [O(4A)···O(water) 2.66 Å]. Six of the eight phosphoryl oxygens bind to more than one hydrogen. One

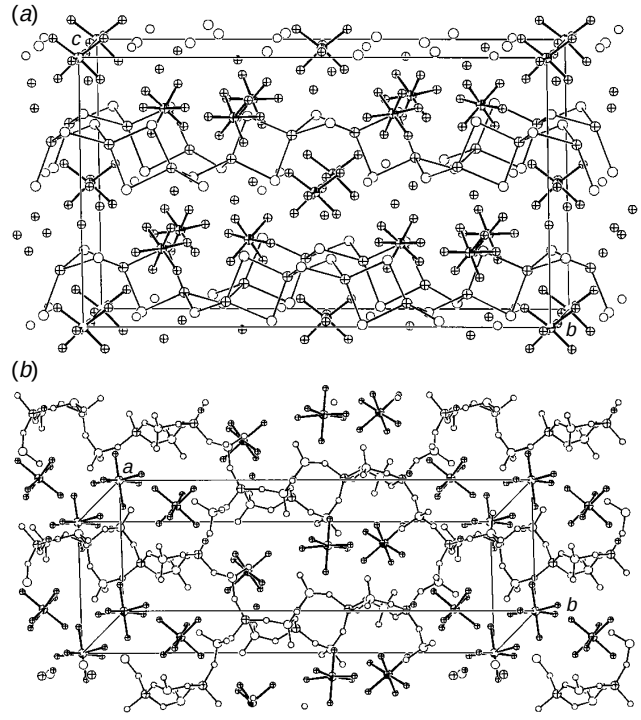

**Fig. 1** Views of structure: (⊕) N, (⊕) Al, (◯) P, (○) $H_2O$, (◒) Co. (*a*) View edge on to the $Al_2(PO_4)_2^{6-}$ layers; $PO_4$ and $AlO_4$ tetrahedron are shown linked as single atoms and hydrogens have been excluded. (*b*) View normal to the plane of just one layer at $z \approx 0.25$.

of the metal complexes is partially disordered and is bound weakly to one of the phosphoryl oxygens and the water molecule.

The layered phase $[NH_4]_3[Co(NH_3)_6]_3[Al_2(PO_4)_4]_2$ represents a new lattice type and layer topology. It is likely that a hydrothermal synthesis under similar basic conditions in the presence of suitable templates could yield other $Al_2(PO_4)_4^{6-}$ phases having different layer topologies.

## Footnote

† *Crystal data* for $[NH_4]_3[Co(NH_3)_6]_3[Al_2(PO_4)_4]_2 \cdot 2H_2O$: orthorhombic, *Aba2*, $a$ = 9.502(2), $b$ = 29.699(6), $c$ = 17.210(3) Å, $Z$ = 4, $D_c$ = 1.97 g cm$^{-3}$. 3845 reflections collected at 130(2) K on a Nicolet P4 diffractometer using Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å, graphite monochromator). The structure was solved by a direct method (SHELXS-90[13]) using empirical absorption-corrected data, and anisotropic temperature factors for the Co, P and Al atoms. During refinement a minor twinned component was detected; the twinned proportion parameter refined to 0.89(4).[14] Located ammine hydrogen atoms were refined[14] with isotropic temperature factors 1.2 times their parent nitrogen. The structure was refined on $F_0^2$ (358 parameters, 3324 independent reflections) to a conventional $R$ of 0.047 [$F_0 > 4\sigma(F_0)$]. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Surface adsorption in the gas–solid reaction between NO and $LaBaSrCu_2O_{6-\delta}$

**F. Munakata,*[a] Y. Akimune,[a] Y. Shichi,[b] M. Akutsu,[b] H. Yamaguchi[b] and Y. Inoue[b]**

[a] *Material Research Laboratory, Nissan Research Center, Nissan Motor Co. Ltd., 1 Natsushima-cho, Yokosuka 237, Japan*
[b] *Research Department, Nissan ARC Ltd., 1 Natsushima-cho, Yokosuka 237, Japan*

**The chemical state of NO over $LaBaSrCu_2O_{6-\delta}$ investigated by X-ray photoelectron spectroscopic analysis suggests the surface adsorption of $NO_2^-$ corresponds to NO trapped by oxygen vacancies.**

Since the discovery of high-$T_c$ superconducting cuprates,[1] a number of studies have been made on layered cuprates. The physical and chemical properties of layered cuprates have drawn attention in relation to their superconducting properties. Some of these oxides have been studied in the applications of $NO_x$ decomposition catalysis and gas sensors.[2–8] The catalytic applications of cuprates have been studied by Misono and coworkers[2–4] and by Shimada *et al*.[5] for direct decomposition or reduction of nitric oxides. These studies suggested that the redox properties of copper ions and the resultant oxygen vacancies may play an important role in the catalytic conversion of NO. Also, Machida *et al*.[9–11] have reported that rapid NO absorption by $BaCuO_{2+\delta}$ takes place through solid–gas reactions to produce barium nitrate and nitrite. By contrast, Misono and coworkers[12,13] suggested the possibility of NO uptake *via* direct incorporation into bulk $YBa_2Cu_3O_y$. They indicated that the NO–CO reaction took place through absorption owing to the defective structure of the layered cuprate. Recently, Machida *et al*.[14] reported the absorption–desorption properties of nitric oxide over the layered cuprate $La_{2-x}Ba_xSrCu_2O_6$ ($0 \leqslant x \leqslant 1.0$). These results suggest that the desorption process of NO contrasts to conventional NO absorption–desorption systems in the following ways: (*a*) NO absorption is not associated with the formation of nitrates or nitrites of barium and (*b*) the desorption temperature of $N_2$ is much higher than that of $O_2$. Therefore, it is worthwhile to study the adsorbed states of NO over $La_{2-x}Ba_xSrCu_2O_6$ in order to understand the absorption–desorption mechanism of NO over layered cuprates. Also, this mechanism indicates the existence of oxygen solubility in $La_{2-x}Ba_xSrCu_2O_6$. It is important to consider the oxygen non-stoichiometry effects for the adsorption–desorption properties of NO over $La_{2-x}Ba_xSrCu_2O_6$. However, the relation of the NO adsorption–desorption properties with the oxygen non-stoichiometry in $La_{2-x}Ba_xSrCu_2O_6$ has not been clearly defined.

In the present study, the surface adsorption of NO over $LaBaSrCu_2O_{6-\delta}$ was investigated by X-ray photoelectron spectroscopy (XPS) in order to understand the absorption–desorption process of NO over layered cuprate. We also discuss the chemical states of adsorbed nitric oxide near the surface of this compound and the effects of oxygen partial pressure on this surface reaction.

Powdered $LaBaSrCu_2O_{6-\delta}$ was prepared by coprecipitation of the citrates of the elements. After calcination at 1073 K for 5 h in air, the powder was ground and then heated at 1273 K for 10 h in air. The crystal phase of the powder was determined by powder X-ray diffraction (XRD) and the single-phase X-ray diffraction profiles are shown in ref. 14. The NO adsorbed samples were prepared by annealing at 627 K for 1 h upon introduction of 0.5 vol.% NO–5 vol.% $O_2$–94.5 vol.% $N_2$ or 0.5 vol.% NO–99.5 vol.% $N_2$. These powders were pressed into pellets, and analysed by X-ray photoelectron spectroscopy and powder X-ray diffraction. X-Ray photoelectron spectra (XPS) were measured using a commercial spectrometer (PHI ESCA-5600) with a base pressure in the chamber of *ca*. $10^{-12}$ atm. The X-ray source was monochromated Al-K$\alpha$ radiation (1486.6 eV) and the combined energy resolution was *ca*. 0.3 eV. Core-level binding energies were referenced to the C 1s peak at 284.5 eV to account for the surface charge-up, especially in the cases of samples that were poor electrical conductors.

The samples were prepared in a variety of process conditions as follows: (*a*) at 1273 K for 10 in air (sample A), (*b*) annealing sample A at 627 K for 1 h in the presence of 0.5 vol.% NO–99.5 vol.% $N_2$ (sample B), and (*c*) annealing sample A at 627 K for 1 h in the presence of 0.5 vol.% NO–5 vol.% $O_2$–94.5 vol.% $N_2$ (sample C). Fig. 1 shows N 1s XPS core-level spectra for these samples. The N 1s XPS peak was not detected for sample A. In Table 1, the binding energies of N 1s XPS core-level spectra are summarized for samples B and C, $NaNO_2$,[15] $Ba(NO_3)_2$[16] and $Sr(NO_3)_2$.[16] The data in Table 1 suggest that the N 1s XPS spectra of nitrates occur in the range $407 < E_b < 408$ eV, and those of nitrites at $E_b \approx 404$ eV. The N 1s XPS peak for sample B is observed at 403.1 eV, similar to that for $NaNO_2$ ($Na^+NO_2^-$).[15] It was considered that the N 1s XPS peak at *ca*. 404 eV indicated the surface adsorption of $NO_2^-$ corresponding

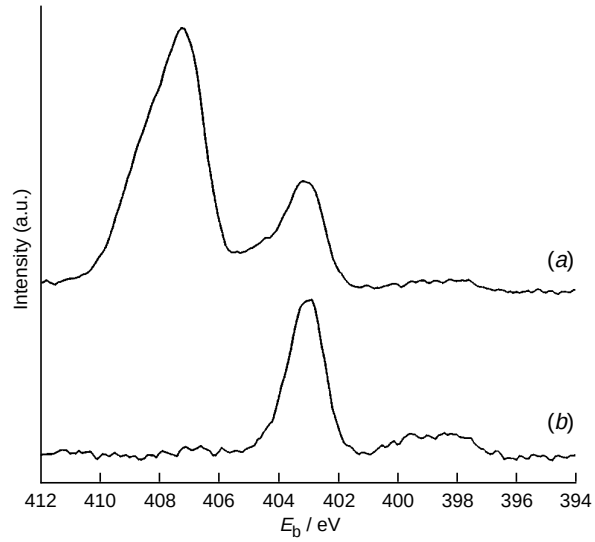

**Fig. 1** N 1s XPS core-level spectra for samples after NO absorption: (*a*) annealing at 627 K for 1 h after introducing 0.5 vol.% NO–5 vol.% $O_2$–94.5 vol.% $N_2$ and (*b*) annealing at 627 K for 1 h after introducing 0.5 vol.% NO–99.5 vol.% $N_2$

**Table 1** Binding energies of N 1s XPS core-level spectra

| | $E_b$/eV |
|---|---|
| Sample B | 403.1 |
| Sample C | 403.1, 407.3 |
| $NaNO_2$ | 403.9 |
| $NaNO_3$ | 407.4 |
| $Ba(NO_3)_2$ | 407.5 |
| $Sr(NO_3)_2$ | 408.1 |

to NO adsorption. Sample B showed an X-ray diffraction profile similar to $LaBaSrCu_2O_{6-\delta}$ and there were no additional reflections. The N 1s XPS peaks for sample C are observed at 407.3 and 403.1 eV, the former being similar to the N 1s XPS peak for $NaNO_3$ ($Na^+NO_3^-$).[15] On the other hand, the X-ray diffraction profile of sample C showed additional reflections due to the formation of barium and/or strontium nitrate, $(Ba_{0.5}Sr_{0.5})(NO_3)_2$.[17] The occurrence of the N 1s XPS peak at *ca*. 407.3 eV showed the formation of nitrates of $(Ba,Sr)(NO_3)_2$ in sample C. This process may be represented using Kröger–Vink notation [eqn. (1)]

$$4NO(g) + Ba_{Ba}^{x} + Sr_{Sr}^{x} + 2O_O^x + 3O_2(g) \rightarrow 2(Ba_{1/2}Sr_{1/2})(NO_3)_2 + V_{Ba}'' + V_{Sr}'' + 2V_O^{\cdot\cdot} \quad (1)$$

where V and g denote vacancy and gas, respectively. To simplify the discussion, the valences of Ba, Sr and O ions were assumed to be, respectively, +2, +2, and −2 on the lattice sites. The formation of nitrate is a consequence of the $NO–O_2$ atmosphere, according to eqn. (1). In the absence of $O_2$, the formation of nitrates and nitrites of Ba, Sr and Cu was not observed.

In Table 2, the binding energies of Cu $2p_{3/2}$ XPS core-level spectra are summarized for samples A, B and C, CuO[18] and $Cu(NO_3)_2$.[19] The XPS core-level spectra of samples A, B and C were similar to the spectrum of CuO in ref. 18. Also, the binding energy of the XPS core-level spectrum of Cu $2p_{3/2}$ in sample C is similar to that of $Cu(NO_3)_2$.[19] The binding energy of the Cu $2p_{3/2}$ XPS core-level spectrum of sample B was different from 933.7 eV (the binding energy of $Cu^{2+}$ ion in CuO) upon NO adsorption. As the formation of nitrates or nitrites was not observed in sample B, this result may reflect the intercalation of NO molecules into the layer structure.

Machida *et al.*[14] reported that NO absorption over $La_{2-x}Ba_xSrCu_2O_6$ was considered to proceed *via* intercalation of NO molecules into the layer structure. However, these compounds containing absorbed NO begin to desorb $NO–NO_2$ above 573 K.[14] It is considered that the present results shown in Fig. 1 and Table 2 reflect the adsorption–desorption reaction of NO near the surface. Therefore, the N 1s XPS peak at *ca*. 404 eV suggests surface adsorption of $NO_2^-$ resulting from NO absorption. Thus, this NO adsorption (or intercalation) near the surface induces a change of the chemical state of the Cu ions. On the other hand, layered cuprates have a large number of oxygen vacancies in the lattice as reflected in the chemical formula $LaBaSrCu_2O_{6-\delta}$.[14] Yasuda *et al*.[20] reported a mechanism in which the active sites for decomposition of NO over valency-controlled $La_2CuO_4$-based mixed oxides where coordinatively unsaturated $Cu^{2+}$ ions on the surface are easily oxidized to $Cu^{3+}$ upon NO adsorption. Misono and coworkers[2–4] and Shimada *et al*.[5] suggested that the redox characteristics of copper ions and the resultant oxygen vacancies should play an important role in the surface reaction of NO. Also, it is suggested that the chemical shift of Cu 2p XPS peak in Table 2 is related to the change of oxidation state of Cu ions which is caused by NO adsorption. Therefore, to explain the results of sample B, as shown in Fig. 1 and Table 2, we propose that NO gas is trapped by oxygen vacancies neighbouring the coordinatively unsaturated Cu ions on the surface of $LaBaSrCu_2O_{6-\delta}$.

**Table 2** Binding energies of Cu $2p_{3/2}$ XPS core-level spectra

| | $E_b$/eV |
|---|---|
| Sample A | 934.0 |
| Sample B | 933.1 |
| Sample C | 934.0 |
| $Cu(NO_3)_2$ | 935.5 |
| CuO | 933.0 |

In conclusion, the chemical state of NO over $LaBaSrCu_2O_{6-\delta}$ was investigated by X-ray photoelectron spectroscopy (XPS) and the results are interpreted as follows.

(*i*) The N 1s XPS peak was seen at a binding energy of *ca*. 404 eV for the sample annealed in 0.5 vol.% $NO–N_2$ and also seen at two binding energies of *ca*. 403.1 and 407.1 eV for the sample annealed in 0.5 vol.% NO–5 vol.% $O_2–N_2$.

(*ii*) From the X-ray-diffraction profile of the sample annealed in 0.5 vol.% NO–5 vol.% $O_2–N_2$, it is proposed that the N 1s XPS peak at 407.1 eV results from the formation of nitrates of Ba and/or Sr.

(*iii*) The N 1s XPS peak at *ca*. 403.1 eV suggests the surface adsorption of $NO_2^-$ group corresponding to NO trapped by oxygen vacancies.

# Ruthenium porphyrin encapsulated in modified mesoporous molecular sieve MCM-41 for alkene oxidation

**Chun-Jing Liu,[a] Shou-Gui Li,[a] Wen-Qin Pang[b] and Chi-Ming Che*[a]**

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*
[b] *Department of Chemistry, Jilin University, Changchun, China 130023*

**Ruthenium(II) *meso*-tetrakis(4-chlorophenyl)porphyrin encapsulated in MCM-41 modified with 3-aminopropyltriethoxysilane is a stable catalyst for alkene oxidation by *tert*-butyl hydroperoxide with high product turnovers.**

A useful means to improve the stability and selectivity of metalloporphyrin catalysts is by encapsulation in microporous materials such as zeolites.[1–5] However, the commonly employed zeolite Y has a small pore size and encapsulation of metalloporphyrins of second- and third-row transition metals is difficult. In this context, the large pore size of the MCM-41 mesoporous materials[6] is advantageous. Herein is described the encapsulation of a ruthenium porphyrin in modified MCM-41, and its catalytic properties.

MCM-41 was synthesized by a literature method[6] and was characterized by its XRD pattern, which shows a very strong peak at $d$ = 39.74 Å. [RuL(CO)(EtOH)] [$H_2$L = *meso*-tetrakis(4-chlorophenyl)porphyrin] was prepared according to the literature method.[7]

Direct encapsulation of [RuL(CO)(EtOH)] in MCM-41 was unsuccessful, presumably due to the interaction of the neutral ruthenium(II) porphyrin and the channel surface of MCM-41 being weak. To resolve this problem, the surface of MCM-41 was modified by using 3-aminopropyltriethoxysilane (APTES) as shown in Scheme 1. The modified MCM-41 characterized by IR (stretching and bending of the $NH_2$ group at 3470 and 1634 $cm^{-1}$), elemental analysis (found: C, 6.96; N, 2.49%) and XRD is designated as MCM-41(m).

In a typical experiment, MCM-41 (0.1 g) was mixed with a chloroform solution of APTES (10 ml, 0.1 M) and stirred at room temp. for 8–12 h. The MCM-41(m) was filtered and washed with chloroform and dichloromethane. As shown in Fig. 1, its XRD pattern is essentially the same as that of MCM-41.

MCM-41(m) exhibits a powerful encapsulation ability. Stirring a mixture of MCM-41(m) (0.1 g) and [RuL(CO)(EtOH)] (10 mg) in $CH_2Cl_2$ (10 ml) at room temp. for 1 h gave the encapsulated product containing 8.3 mass% of [RuL(CO)], designated 8.3 mass% Ru/M-41(m) (IR, $\nu_{C\equiv O}$ 1952.4 $cm^{-1}$; UV–VIS $\lambda_{max}$ 411, 528 nm). Products with different mass% [RuL(CO)] were obtained by varying the amount of [RuL(CO)(EtOH)] used in the reaction. The amount of [RuL(CO)] in Ru/M-41(m) was determined by dissolving the latter in an aqueous solution of HF (3 mass%) followed by extraction with dichloromethane. The UV–VIS absorption spectrum of the $CH_2Cl_2$ extract was essentially the same as that of [RuL(CO)(EtOH)] in $CH_2Cl_2$ ($\lambda_{max}$ 411.2, 528.8 nm). The solid diffuse-reflectance UV–VIS† and FT Raman spectra‡ of Ru/M-41(m) are very similar to those of [RuL(CO)], indicating that the molecule remains intact during the process of encapsulation.

As shown in Fig. 1, the XRD pattern of 8.3 mass% Ru/M-41(m) exhibits the characteristic peaks of MCM-41 but no peaks due to [RuL(CO)]. This indicates that the MCM-41 structure is retained and that the [RuL(CO)] molecules should be dispersed in the channels.

The immobilization of [RuL(CO)] onto the channel surface of MCM-41 is attributed to a ligand exchange reaction as shown in Scheme 2.

This suggestion is supported by the following experiments. First, [CuL] containing no axial ligands was found not to be encapsulated in MCM-41(m). Secondly, MCM-41 modified by trimethylsilation does not encapsulate [RuL(CO)(EtOH)], due to the conversion of surface –OH to –$SiMe_3$ groups which have little coordination ability.[6,8]

Ru/M-41(m) catalyses alkene oxidation by *tert*-butyl hydroperoxide (TBHP). In a typical experiment, a mixture of alkene (0.2 g), TBHP (0.1 g), Ru/M-41(m) (0.05 g, $5.84 \times 10^{-5}$ mmol) and dichloromethane (2 ml) in a sealed vial was stirred for 24 h under a nitrogen atmosphere at room temp. Products were analysed and quantified by gas–liquid chromatography and/or

| | Benzaldehyde | 59 | 0.27 | Trace | — |

[a] Product yields were determined by GC and based on TBHP consumed. [b] The yield was determined by $^1$H NMR spectroscopy with 1,1-diphenylethylene as internal standard.

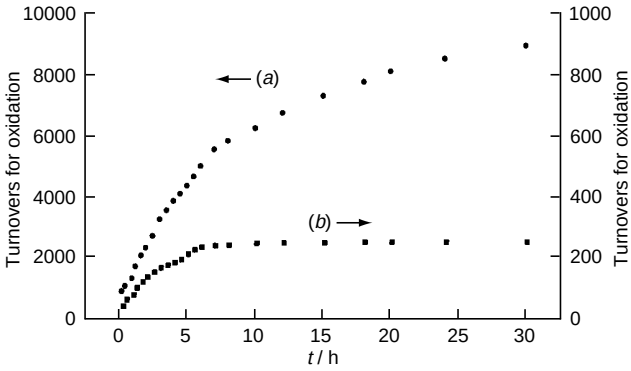

**Fig. 2** Time course of oxidation for norbornene by TBHP with (*a*) 0.1 mass% Ru/M-41(m) and (*b*) [RuL(CO)(EtOH)]

$^1$H NMR spectroscopy. Control experiments using [RuL(CO)(EtOH)] or MCM-41(m) as catalyst and under identical reaction conditions were also performed. TBHP in the absence of catalyst and/or MCM-41(m) showed very little catalytic activity compared with Ru/M-41(m).[9]

Ru/M-41(m) with a ruthenium content ranging from 0.1 to 8.3 mass% showed good catalytic activity. In norbornene oxidation, turnovers of *exo*-norbornene oxide with 0.1, 5 and 8.3 mass% Ru/M-41(m) as catalyst are 9003, 303 and 216, respectively, suggesting that the catalytic activity is high at low ruthenium content. Presumably this is due to efficient site isolation and diffusion pathways during the reaction. Owing to its better catalytic activity, the 0.1 mass% Ru/M-41(m) catalyst was used for further oxidation experiments. Table 1 compares the results obtained for the oxidation of norbornene (bicyclo-[2.2.1]hept-2-ene), cyclooctene, cyclohexene, styrene, *cis*- and *trans*-stilbenes catalysed by 0.1 mass% Ru/M-41(m) and free [RuL(CO)(EtOH)]. In general the product turnovers are 20–40 times higher with the former.

A typical time course for norbornene oxidation is shown in Fig. 2. With 0.1 mass% Ru/M-41(m), norbornene was oxidized to the *exo*-norbornene oxide at a rate of 300 turnovers $h^{-1}$ *cf.* 38 turnovers $h^{-1}$ with [RuL(CO)(EtOH)]. Also [RuL(CO)(EtOH)] was unstable and was completely deactivated after 6 h. By contrast, the 0.1 mass% Ru/M-41(m) catalyst appeared to be very stable and its catalytic activity did not change appreciably even after 48 h of reaction. Embedding of [RuL(CO)] molecules and their isolation from each other in the channels of MCM-41(m) precludes formation of stable inactive μ-oxo dimers. This may partly explain the stability of Ru/M-41(m) in the TBHP oxidation reaction. It is of note that the 0.1 mass% Ru/M-41(m) catalyst could be easily recovered by filtration and washing with $CH_2Cl_2$.

From Table 1, *trans*-stilbene oxide was the major product of *trans*-stilbene oxidation. However, oxidation of *cis*-stilbene catalysed by 0.1 mass% Ru/M-41(m) gave *trans*-stilbene oxide as the major product, in contrast to [RuL(CO)(EtOH)] for which an essentially 1 : 1 mixture of *cis*- and *trans*-stilbene oxides was obtained. This could be a consequence of the steric constraints imposed by the straight channels of MCM-41(m) which would favour the formation of linear *trans*-stilbene oxide.

We acknowledge supports from the Hong Kong Research Council and the University of Hong Kong.

# $[Fe_3Cu(SPr^i)_6Cl_3]^{2-}$: a novel mixed-metal thiolate complex with a 'truncated' adamantane-like structure

**Hans-Oscar Stephan,[a,b] Gerald Henkel[b] and Mercouri G. Kanatzidis*[a]**

[a] *Department of Chemistry, Michigan State University, East Lansing, MI 48824, USA*

**Reaction of $[Fe_2(SPr^i)_6]^{2-}$ with $FeCl_2$ and CuCl in a 1:1:1 molar ratio in hot tetrahydrofuran gives the complex anion $[Fe_3Cu(SPr^i)_6Cl_3]^{2-}$ which contains a $Fe_3Cu$ pyramidal core; the structure, magnetic properties and the solution $^1H$ NMR spectrum are reported.**

The chemistry of homometallic thiolate complexes has been developed to a remarkable extent in the last 20 years.[1,2] Nevertheless, there are amazingly few reports on analogous heterometallic clusters. The reason may be that these clusters are not as straightforward to stabilize as the homometallic ones because, in addition to the usual problems one has in isolating these labile complexes and crystallizing them, one is also faced with the problem of phase separation which leads to a mixture of homometallic complexes. To date, the most notable examples are $[Au_3Cu_3(SCH_2CH_2)_4]^{2-}$,[3] $[Au_2Cu_4(SCH_2CH_2)_4]^{2-}$,[3] $[Au_2Ag_4(SCH_2CH_2)_4]^{2-}$,[3] $[Cu_6In_3(SEt)_{16}]^{-}$,[4] $[Eu_2M_2(SPh)_8(py)_6]$ (M = Cd, Hg)[5] and $[Eu_2Zn_2(SPh)_8(thf)_6]$[5] as well as $[CuIn(ER)_4(PPh_3)_2]$[6] (E = S, Se). Focussing attention onto the chemistry of heterometallic thiolate complexes is now timely because, in addition to the novel properties and structures one might encounter, they could serve as molecular precursors to high-quality ternary heterometallic solids. This was shown earlier in the case of $[CuIn(ER)_4(PPh_3)_2]$ which leads cleanly to the photovoltaic material $CuInSe_2$.[6]

Our approach towards this class of complexes is to react well defined homometallic thiolate precursors with readily available sources of the heterometal such as metal halides.

Very recently, we found that the reaction of $[NMe_4]_2[Mn_2(SPr^i)_6]$[7] with CuCl gives the remarkable anion $[Mn_4Cu_4(SPr^i)_{12}(\mu_4\text{-}S)]^{2-}$.[8] The core of this cluster consists of a distorted $Mn_4Cu_4$ metal cube which is stabilized with an interstitial $\mu_4$-S ligand and edge-bridging thiolate ligands. Encouraged by this result, we started to explore the chemistry of the analogous $Fe^{2+}Cu^+$ system and discovered the novel mixed-metal cluster $[NMe_3(CH_2Ph)]_2[Fe_3Cu(SPr^i)_6Cl_3]$ **1**. Complex **1** is best accessible by a reaction of $[Fe_2(SPr^i)_6]^{2-}$ with solid $FeCl_2$ and CuCl (molar ratio 1:1:1) in hot tetrahydrofuran and can be isolated as orange–brown crystals upon addition of $[NMe_3(CH_2Ph)]Br$.†

The structure‡ of the tetranuclear cluster **1** is shown in Fig. 1. It contains a $Fe_3Cu$ trigonal pyramid with idealized $C_{3v}$ symmetry. The three Fe atoms define the vertices of the basal triangular plane with Fe···Fe separations of 3.852 Å. The apex of the pyramid is occupied by the Cu atom (Fe···Cu 3.205 Å). This metal core is held together by six thiolate groups. The observed Fe–S and Cu–S distances of 2.345 Å and 2.241 Å, respectively, are similar to the corresponding bond lengths in homoleptic homometallic Fe[9] and Cu[10] thiolate clusters. In contrast to the Fe atoms which each bind to terminal Cl ligands (Fe–Cl 2.313 Å) to adopt a tetrahedral coordination [S–Fe–S(Cl) 109.3°], the Cu atom resides inside the 'upper' $S_3$ face and thus has a trigonal planar environment (S–Cu–S 119.9°). This is the reason why the overall shape of **1** appears to be a truncated adamantane.

Complex **1** is a structural derivative of homometallic thiolate adamantanes of the formula $[M_4(SR)_6X_4]^{2-}$ (X = halogen).[7,11,12b] The central core of these complexes is an $M_4$ tetrahedron of tetrahedrally coordinated metal atoms. The formal replacement of one of these metal sites with a trigonal-planar M′ centre results in the loss of one terminal ligand. At the same time, the idealized symmetry of the $M_3M'$ core drops to $C_{3v}$ since M′ is shifted towards the centre of the cluster. However, the symmetry of the entire cluster is $C_3$ rather than $C_{3v}$, because of the orientation of the organic groups. The cluster shows the (3,−1,−1,−1) pattern§ with three axially oriented ligands within the basal $Fe_3S_3$ ring. The three $CuFe_2S_3$ rings have one axially disposed group each. This situation leads to a 'paddlewheel'-like arrangement of the thiolate ligands attached to Cu. The $C_3$ axis of the molecule thus runs through the Cu atom and the centre of the basal $Fe_3$ triangle.

Since **1** can be considered as an $[Fe_3(\mu\text{-}SR)_3(SR)_3Cl_3]^{3-}$ cluster which is stabilized by the incorporation of an additional $Cu^+$ ion, its structure is reminiscent of the trinuclear Fe clusters

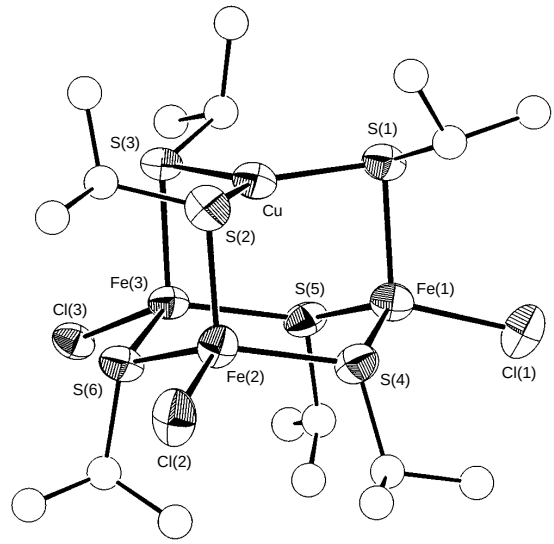

**Fig. 1** ORTEP plot of $[Fe_3Cu(SPr^i)_6Cl_3]^{2-}$ with labelling scheme. Selected bond distances (Å) and angles (°): Cu–Fe(1) 3.145(3), Fe(1)–Fe(2) 3.849(3), Cu–Fe(2) 3.234(3), Fe(1)–Fe(3) 3.851(3), Cu–Fe(3) 3.235(3), Fe(2)–Fe(3) 3.857(3), Cu–S(1) 2.228(4), Cu–S(2) 2.233(4), Cu–S(3) 2.261(4), Fe(1)–Cl(1) 2.307(5), Fe(1)–S(1) 2.334(5), Fe(1)–S(4) 2.356(5), Fe(1)–S(5) 2.347(4), Fe(2)–Cl(2) 2.313(4), Fe(2)–S(2) 2.345(5), Fe(2)–S(4) 2.334(4), Fe(2)–S(6) 2.355(4), Fe(3)–Cl(3) 2.321(4), Fe(3)–S(3) 2.350(4), Fe(3)–S(5) 2.343(4), Fe(3)–S(6) 2.344(4); S(1)–Cu–S(2) 127.6(2), S(1)–Cu–S(3) 114.4(2), S(2)–Cu–S(3) 117.9(2), S(1)–Fe(1)–S(4) 109.0(2), S(1)–Fe(1)–S(5) 99.9(2), S(4)–Fe(1)–S(5) 118.9(2), S(2)–Fe(2)–S(4) 103.1(2), S(2)–Fe(2)–S(6) 102.3(2), S(4)–Fe(2)–S(6) 119.7(2), S(3)–Fe(3)–S(5) 102.4(2), S(3)–Fe(3)–S(6) 104.2(2), S(5)–Fe(3)–S(6) 119.2(2), Cu–S(1)–Fe(1) 87.1(2), Cu–S(2)–Fe(2) 89.9(2), Cu–S(3)–Fe(3) 89.1(1), Fe(1)–S(4)–Fe(2) 110.3(2), Fe(1)–S(5)–Fe(3) 110.4(2), Fe(2)–S(6)–Fe(3) 110.4(2).

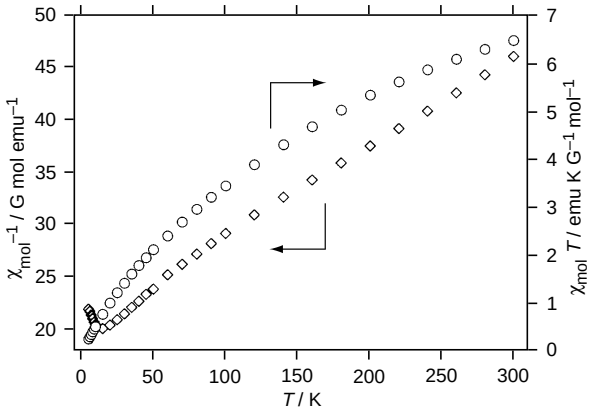

**Fig 2** Magnetic data for $[NMe_3(CH_2Ph)]_2[Fe_3Cu(SPr^i)_6Cl_3]$. The susceptibilitiy data were recorded on a powdered sample in the temperature range 5–300 K in a 2 kG applied magnetic field.

of composition $[Fe_3(\mu\text{-}SR)_3Cl_6]^{3-}$.[12] These clusters, however, exhibit strictly planar $Fe_3S_3$ rings with very large Fe–S–Fe bridging angles of *ca.* 140°. To examine if this major structural difference is reflected in the magnetic properties of **1**, we measured magnetic susceptibility data for $[NMe_3(CH_2Ph)]_2[Fe_3Cu(SPr^i)_6Cl_3]$ (Fig. 2). The data show antiferromagnetic exchange interactions with Curie–Weiss behaviour within the temperature range 120–300 K. The Weiss constant is calculated to be $\theta = -246$ K. The susceptibility data for $[Fe_3(\mu\text{-}SPh)_3Cl_6]^{3-}$,[12b] compare very well with the behaviour observed for **1**. Obviously, neither the presence of $Cu^+$ ions in **1** nor the fact that the Fe–S–Fe bridging angles in **1** are about 30° smaller than in $[Fe_3(\mu\text{-}SPh)_3Cl_6]^{3-}$, are followed by major changes in the magnetic behaviour.

The solution $^1$H NMR spectrum of $[NMe_3(CH_2Ph)]_2[Fe_3Cu(SPr^i)_6Cl_3]$ in $CD_3CN$ at room temperature was recorded. Since the isotropic shift of the SC*H*$Me_2$ signal is a function of the local magnetic moment of the iron atoms, we expected two signals, one in the neighbourhood of δ 163 in the downfield region of the spectrum. This value can be calculated from the known magnetic moments[12b] and paramagnetic shifts[9b] of the $CH_2$ groups of $[Fe(SEt)_4]^{2-}$ and $[Fe_4(SEt)_{10}]^{2-}$. In fact, we observed one resonance at δ 161 and an additional signal at δ 87. While the first peak most probably arises from SC*H*$Me_2$ ligands bridging two paramagnetic Fe atoms **1**, that at δ 87 could tentatively be assigned to SC*H*$Me_2$ ligands bridging one diamagnetic Cu and one paramagnetic Fe atoms.

In summary, we have presented the first mixed-metal FeCu thiolate complex, with a structure reminiscent of adamantane. This cluster might act as a useful starting material to novel mixed-metal thiolates or sulfido/thiolato compounds. In particular, the synthesis of mixed-metal cubanes of the formula $[Fe_3CuE_4(SR)_3]^{2-}$ (E = S, Se, Te), in which one iron atom of the $[Fe_4E_4]$ parent cluster core is replaced by a $Cu^+$ ion, might be accessible by reaction of **1** with elemental chalcogen.

† *Synthesis of* $[NMe_3(CH_2Ph)]_2[Fe_3Cu(SCPr^i)_6Cl_3]$. To a slurry of $NaSPr^i$ (0.59 g, 6 mmol) in 25 ml MeCN was added solid $FeCl_2$ (0.25 g, 2 mmol) and the mixture was stirred for 2 h. Then $[NMe(CH_2Ph)]Br$ (0.46 g, 2 mmol) was added and the stirring continued for 24 h. The solvent was evaporated and replaced by 25 ml of thf. Then, the mixture was filtered and the resulting solution of $[NMe_3(CH_2Ph)]_2[Fe_2(SPr^i)_6]$ was heated to its boiling point. Solid $FeCl_2$ (0.13 g, 1 mmol) and CuCl (0.10 g, 1 mmol) were added and the mixture was boiled for 20 min whereupon a small amount of a black precipitate was filtered off. The volume of the solution was reduced to *ca.* 15 ml. After stirring for 2 days at room temperature, the crude product precipitated. This material was recrystallized from MeCN–$Et_2O$ (1:5) to give 0.35 g (33%) of the desired compound. More material can be recovered from the mother-liquor to give an overall yield of 60%. The single crystal used for the X-ray structure determination was obtained from a solvothermal reaction of $[NMe_3(CH_2Ph)]_2[Fe_2(SPr^i)_6]$ with 2 equiv. of CuCl in thf at 80 °C.

‡ *Crystal data*: $[NMe_3(CH_3Ph)]_2[Fe_3Cu(SPr^i)_6Cl_3]$, monoclinic, space group $P2_1/n$ with $a$ = 10.846(4), $b$ = 12.018(5), $c$ = 41.23(1) Å, $\beta$ = 94.97(2)°, $U$ = 5354(3) Å$^3$, $Z$ = 4, $D_c$ = 1.351 g cm$^{-3}$ and $\mu$ = 15.9 cm$^{-1}$. Single-crystal X-ray diffraction data were collected (at −110 °C) on a Nicolet P3 four-circle diffractometer (Mo-K$\alpha$ radiation) with ω-scans, $4 < 2\theta < 45°$, and 3764 reflections with $F_o^2 > 3\sigma(F_o^2)$. An empirical absorption correction (DIFABS, N. Walker and D. Stuart, *Acta Crystallogr., Sect. A*, 1983, **39**, 158) was applied as recommended. The number of variables were 477, and final $R$, $R_w$ = 0.070, 0.045. The structure was solved with SHELXS86 and was refined with the TEXSAN Structure Analysis Package (Molecular Structure Corporation, 1985) of crystallographic programs. Sigma weights were used. The isopropyl group attached to S(5) is disordered over two positions. The structure of the $[NMe_3(CH_2Ph)]^+$ cations is normal and there are no bonding cation–anion contacts. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/292.

§ An adamantane-like cluster of composition $[M_4(\mu\text{-}SR)_6X_4]^{2-}$ (X = Cl, Br, I, SR) is built up of four fused $M_3S_3$ rings in chair conformation in which the organic group bound to the μ-S atoms can either be axially or equatorially oriented. There are four independent conformers for $M_4(\mu\text{-}SR)_6$ cages which are symbolized by the following orientation patterns: (3,−2,−1,−0), (2,2,2,0), (3,−1,−1,−1) and (2,−2,−1,−1). The four numbers within the parentheses represent the number of axially oriented groups in each of the four $M_3(SR)_3$ six-membered rings. The most common one is (2,−2,−1,−1), while all other adamantane-like Fe thiolates known so far adopt the (3,−2,−1,−0) pattern.

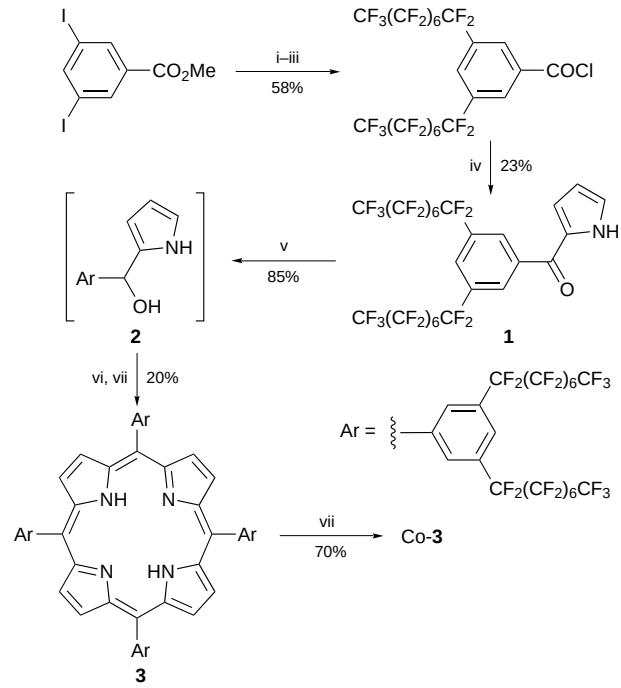
# Cobalt tetraarylporphyrin-catalysed epoxidation of alkenes by dioxygen and 2-methylpropanal under fluorous biphasic conditions

**Gianluca Pozzi,*† Fernando Montanari and Silvio Quici**

*Centro CNR and Dipartimento di Chimica Organica e Industriale dell'Università, Via Golgi 19, I-20133 Milano, Italy*

**The aerobic epoxidation of alkenes with 2-methylpropanal can be carried out under fluorous biphasic conditions, in the presence of the perfluorocarbon soluble cobalt complex of tetraarylporphyrin 3 as catalyst.**



Catalysis under homogeneous two-phase conditions has been recognized as a viable alternative for many important chemical processes.[1] Several approaches to liquid–liquid biphasic catalytic reactions have been proposed, and among them the so-called 'fluorous biphase system' (FBS)[2] stands out for its peculiar characteristics. In this approach the low miscibilities of fluorocarbons with most organic solvents allows segregation of a catalyst soluble in the fluorocarbon phase from substrates and products dissolved in the organic phase. The FBS method shows appealing general features, such as the employment of nontoxic, reusable perfluorocarbons and the easy separation of catalyst from reactants and products.[3] Moreover, the inertness of perfluorocarbons and the high solubility of oxygen in these fluids would be particularly helpful in oxidation reactions.[4] In spite of this, the only examples of true FBS oxidation reported so far concern some simple reactions of phosphines and sulfides,[5] and the photooxidation of alkenes to hydroperoxides in the presence of a perfluorocarbon-soluble sensitizer.[6] The availability of efficient oxidation catalysts soluble in fluorocarbons is essential for applying the FBS concept to other synthetically useful reactions, such as the epoxidation of alkenes and hydroxylation of alkanes. These last reactions can be carried out under mild condition using a combination of molecular oxygen and reducing agent in the presence of transition metal complexes.[7] Here we report the synthesis of the perfluorocarbon-soluble tetraarylporphyrin **3**, bearing eight $C_8F_{17}$ chains, and the use of its cobalt complex Co-**3** as epoxidation catalyst under fluorous biphasic conditions.‡

All attempts to apply well-established synthetic procedures[8] to the preparation of **3** failed, as was found in the case of *meso*-perfluoroalkylporphyrins.[9] The synthesis of **3**, outlined in Scheme 1, was thus carried out by condensation of the pyrrole derivative **2**, according to a procedure originally devised by Kuroda and Ogoshi,[10] The presence of $Zn(OAc)_2$ as templating agent in the cyclisation step turned out to be essential for obtaining the porphyrin in reasonable yield. After removal of zinc, the free-base porphyrin **3** was metalated to form the cobalt complex Co-**3** according to a classical procedure.[11],§ Both **3** and Co-**3** were insoluble in common organic solvents, whereas they were easily dissolved in perfluorocarbons.¶

It is known that $Co^{II}$-tetraarylporphyrins are capable of binding dioxygen reversibly yielding oxygenated $Co^{III}$-complexes.[12] The UV-VIS spectra of Co-**3** in $CF_2ClCFCl_2$ and perfluorohexane both showed a broad Soret band with two maxima at 405 and 427 nm. The splitting of the Soret band as well as its breadth were consistent with the coexistence of $Co^{II}$ and $Co^{III}$ species in the aerated solutions.[13]

Co-**3** proved to be an efficient catalyst for the fluorous biphasic epoxidation of alkenes by molecular oxygen and 2-methylpropanal as reducing agent. Reaction conditions and results are detailed in Table 1.

Reactions were carried out at room temperature in flasks carefully shielded from direct sunlight. A solution of Co-**3** in

| 7 | Dodec-1-ene | 14 | 48 | 92 |
| 8 | Dodec-1-ene[f] | 14 | 60 | 87 |

[a] Conditions: [substrate] = 0.1 mol $dm^{-3}$ in MeCN; [2-methylpropanal] = 0.2 mol $dm^{-3}$ in MeCN; [Co-**3**] = 0.0001 mol $dm^{-3}$ in perfluorohexane; volume of MeCN = 1 ml; volume of perfluorohexane = 1 ml; stirring rate = 1300 rpm; $T$ = 25 °C. Reactions were carried out in the dark. [b] Determined by GC using the internal standard method. [c] Selectivity = (moles of epoxide)/(moles of substrate converted). Epoxides were identified by comparison with authentic samples or by GC–MS. [d] Reaction carried out in the absence of Co-**3**. [e] Using the perfluorohexane layer recovered from entry 2. [f] Using 3-methylbutanal instead of 2-methylpropanal.

perfluorohexane was added to a solution of alkene in MeCN containing a twofold excess of aldehyde with respect to the substrate. The resulting biphasic mixture was vigorously stirred under atmospheric pressure of dioxygen. Co-**3** was completely partitioned in the fluorous phase, as shown by the UV–VIS spectra of the two layers. At the end of the reaction, the two phases were easily separated and the MeCN layer was analysed by gas chromatography (GC). It is worthwhile noting that under these conditions, but in the absence of Co-**3**, alkenes did not react (Table 1, entry 1). In the presence of the perfluorocarbon soluble catalyst, high alkene conversions were generally obtained, epoxides being the major products.‖

As reported for reactions carried out under homogeneous conditions, the present procedure is less suited for unsubstituted terminal alkenes such as dodec-1-ene (entry 7) than for other substrates. Nevertheless, epoxide yields were still satisfactory, and could even be increased by raising the aldehyde–alkene ratio[7] or by choosing different aldehydes (entry 8).

Cobalt complexes of *meso*-tetraarylporphyrins have been recently used as homogeneous catalysts for the aerobic oxidation of organic substrates in the presence of 2-methylpropanal.[14] The positive effect of running the reaction under fluorous biphasic conditions can be appreciated by comparing the present results with those reported in the cited reference. We were able to use a much higher substrate–catalyst ratio (1000 : 1) than that previously reported (20 : 1). Moreover, after complete conversion of cyclooctene the perfluorocarbon layer, recovered by simple phase separation, could be used as such for a second run, without decreasing either the substrate conversion or the selectivity for cyclooctene oxide (entry 3).

Our current efforts are aimed at the synthesis of metal complexes of non-porphyrinic perfluorocarbon-soluble ligands, to be used as catalysts for hydrocarbon oxygenations in the presence of simple oxygen atom donors.

This work was supported by the European Community (Human Capital and Mobility Program-Contract No. ERBCHRXTC 94-0492). Fluorocarbon fluids were generously supplied by 3M Italia.

## Footnotes

‡ Introduction of one perfluoroalkyl tail on each *meso*-aryl group is not sufficient to impart solubility in perfluorocarbons (G. Pozzi and M. Miglioli, unpublished results).

§ *Selected data* for **1**: $^1$H NMR ($CDCl_3$): δ 9.64 (br s, 1 H), 8.30 (s, 2 H), 7.95 (s, 1 H), 7.22 (m, 1 H), 6.78 (m, 1 H), 6.39 (m, 1 H); $^{19}$F NMR ($CDCl_3$; $CFCl_3$): δ −81.3 (t, *J* 9 Hz, 3 F), −111.5 (t, *J* 13 Hz, 2 F), −121.6 (br s, 2 F), −122.3 (m, 6 F), −123.3 (br s, 2 F), −126.7 (br s, 2 F); $^{13}$C NMR ($CDCl_3$): δ 105–118 (m, $C_8F_{17}$), 112.0, 119.9, 126.6, 128.2, 130.2, 130.5, 130.8, 139.7, 181.2. For **3**: $^1$H NMR ($CF_2ClCFCl_2$, $C_6D_6$): δ 8.77 (s, 8 H), 8.72 (s, 8 H), 8.36 (s, 4 H), −2.85 (s, 2 H); $\lambda_{max}$ ($CF_2ClCFCl_2$) 413 nm (ε $7.2 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$). (Calc. for $C_{108}H_{22}F_{136}N_4$: C, 32.76; H, 0.56; N, 1.41; F, 65.27. Found: C, 32.72; H, 0.60; N, 1.34; F, 64.24%). For Co-**3**: $\lambda_{max}$ ($CF_2ClCFCl_2$) 405 nm (ε $1.6 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$), 427 (ε $1.6 \times 10^4$). The acid-sensitive alcohol **2** was not purified and it was used directly for the cyclisation step.

¶ The following perfluorocarbons, available from 3 M, were tested as solvents: FC-72 (mainly perfluorohexane, bp 56 °C), FC-75 (mainly perfluorobutyltetrahydrofuran, bp 102 °C), FC-43 (mainly perfluorotributylamine, bp 174 °C).

‖ Although the exact role of the metal complex in the epoxidation of alkenes by dioxygen with co-oxidation of aldehydes is still a matter of debate (see W. Nam, H. J. Kim, S. H. Kim, R. Y. N. Ho and J. S. Valentine, *Inorg. Chem*., 1996, **35**, 1045), consistent literature data demonstrate that its presence is crucial for ensuring conversion of linear alkenes and for obtaining high epoxide yields without using large amounts of aldehyde.

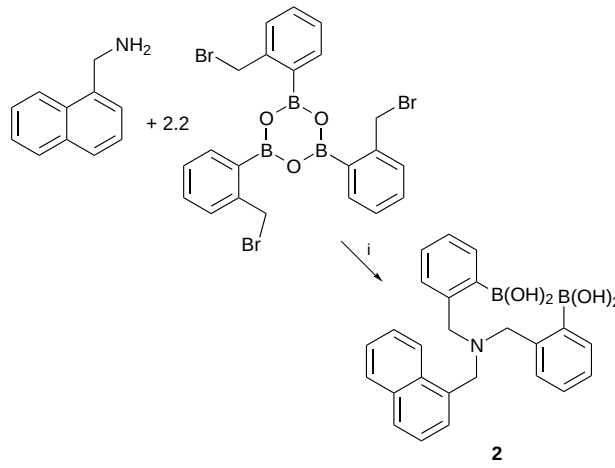
# Novel fluorescence sensor for 'small' saccharides

**Tony D. James,*[a] Hideyuki Shinmori[b] and Seiji Shinkai[b]**

[a] *The University of Birmingham, School of Chemistry, Edgbaston, Birmingham, UK B15 2TT*
[b] *Department of Chemical Science and Technology, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan*

**The small binding pocket of compound 2 can exclude 'large' saccharides such as D-glucose, whereas 'small' saccharides such as D-sorbitol are strongly bound as 1 : 1 complexes; the binding events can be sensitively monitored by changes in the fluorescence intensity.**



The development of boronic acid receptors for saccharides has recently gained much attention.[1] One problem with many of these systems is that they only function in basic aqueous media. Wulff was the first to report that a neighbouring nitrogen enhances the formation of boronate esters even under neutral pH conditions.[2] In a series of recent papers we employed the interaction between boronic acid and amine[3–7] to create photoinduced electron transfer (PET)[8,9] sensory systems for saccharides. When saccharides form cyclic boronate esters with boronic acids, the acidity of the boronic acid is enhanced[10] and therefore the Lewis acid–base interaction between the boronic acid and the tertiary amine is strengthened. The strength of this acid-base interaction modulates the PET from the amine (acting as a quencher) to anthracene (acting as a fluorophore). These compounds show increased fluorescence at pH 7.77 through suppression of the photoinduced electron transfer from nitrogen to anthracene on saccharide binding; a direct result of the stronger boron–nitrogen interaction.[3–7]

With diboronic acid **1** glucose selectivity was predicted from CPK models and then observed experimentally.[4] With other diboronic acids chiral discrimination[5] and metal ion allosterism[6] have been achieved. In these systems the formation of a 1 : 1 intramolecular complex which is classified as a saccharide-containing macrocycle was shown to be the important fluorescent species and the origin of the circular dichroism (CD) activity. With this work we have reduced the size of the cleft in order to modulate the selectivity of the boronic acid unit towards 'small' saccharides. From CPK models glucose cannot easily bind as a cyclic 1 : 1 complex with diboronic acid **2** and should be excluded from the binding pocket.

Compound **2** was synthesised from 1-aminomethylnaphthalene according to Scheme 1 and characterised using IR and $^1$H NMR spectral evidence and elemental analysis.

The absorption spectrum (25 °C, $H_2O$–MeOH, 300 : 1 v/v) and $\lambda_{max}$ were not affected over a large pH range (pH 1.7–11.8). The p$K_a$ values were determined using fluorescence spectroscopy (excitation 296 nm). The pH dependence of the relative fluorescence intensity ($I/I_0$; emission maximum 347 nm) is illustrated in Fig. 1. In the absence of saccharides, the $I/I_0$ is nearly constant from pH 1.5 to 8.0. Judging from the pH dependence of **1** a change from $\mathbf{2H}^+$ to **2** (*cf.* Scheme 2) should cause a large decrease in the fluorescence intensity. This means that deprotonation of $\mathbf{2H}^+$ occurs in a more acidic region. On the other hand, the $I/I_0$ gradually decreases above pH 8.0. This reflects the dissociation of boronic acid groups to $\mathbf{2}^-$ and $\mathbf{2}^{2-}$.

In the presence of saccharides, the $I/I_0$ increases from pH 4.0 and reaches a maximum at around pH 8.0. This change is ascribed to the intensified B–N interaction caused by the saccharide binding to the boronic acid group. Since the largest $I/I_0$ increase was observed at around pH 8.0, we determined the association constants ($K$) at pH 8.0 from plots of $I/I_0$ *vs.*

| Propane-1,3-diol | *a* | 1 | — |
| **3**[b] | *a* | 2 | 2 |

[a] The *K* could not be determined because of the small fluorescence change. [b] $H_2O$–MeOH, 2 : 1 v/v (because of low solubility in water).

saccharide concentration (Fig. 2). The results are summarised in Table 1.

Examination of Table 1 reveals two important features of compound **2** as a PET sensor: that is, (i) **2** shows selectivity towards 'small' saccharides and (ii) only when they possess two binding sites (*i.e.* two diol units associative with a boronic acid) and they are not separated (*i.e.* the number of carbons separating the two diols, $\Delta n = 0$ in Table 1), do a large fluorescence increase and a large *K* value result. Glycerine and propane-1,3-diol, which have only one binding site, cannot enhance the fluorescence intensity. D-Glucose ($\Delta n = 1$) and mannitol derivative **3** ($\Delta n = 2$), in which two binding sites are separated by one or two carbons, cannot enhance the fluorescence either. Other compounds which can enhance the fluorescence intensity have two (or more than two) binding sites and $\Delta n = 0$ without exception. Even in those compounds with a choice of binding site, $\Delta n = 0$–2, the most stable complex should be the one with $\Delta n = 0$.

The formation of the cyclic structures is further supported by the fact that the complexes become CD active. For example, **2** ($1 \times 10^{-5}$ mol dm$^{-3}$) in the presence of sorbitol (0.10 mol dm$^{-3}$) gave $[\theta]_{max}$ $-2.16 \times 10^4$ deg cm$^2$ dmol$^{-1}$ for D-sorbitol and $2.16 \times 10^4$ deg cm$^2$ dmol$^{-1}$ for L-sorbitol at 228 nm (25 °C, pH 8.0 with 50 mmol dm$^{-3}$ phosphate buffer).

In conclusion we have clearly demonstrated that the selectivity of a diboronic acid cleft towards saccharides can be modified in a controlled manner by the correct spacing of two boronic acid units. This work illustrates the power of the synthetic saccharide sensor. Unlike enzymatic systems, selectivity can be designed for one particular saccharide. This offers the possibility of monitoring the concentrations of biologically important saccharides which are less abundant than D-glucose, in a variety of industrial and medicinal applications.

T. D. J. wishes to acknowledge the Royal Society for support through the award of a University Fellowship.

# Synthesis of poly(anthracene-2,6-diyl) and a copolymer containing alternately anthracene-2,6-diyl and *p*-phenylene units

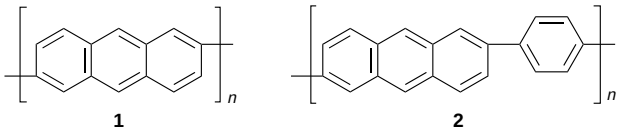
**Philip Hodge,* Gerald A. Power and M. A. Rabjohns**

*Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL*

**The title polymers 1 and 2 are synthesised *via* precursor polymers assembled by organometallic couplings using a Diels–Alder adduct of 2,6-dibromoanthracene.**

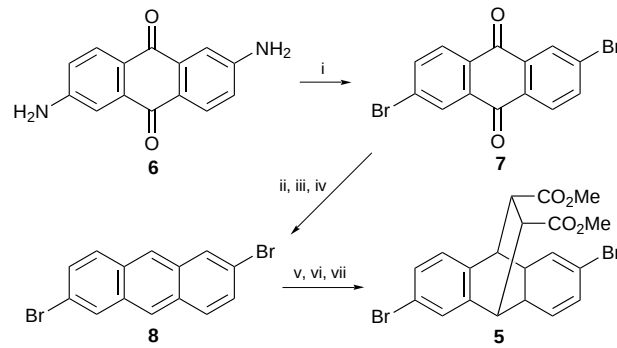
Polymers with extended π-electron systems have long been of interest for theoretical reasons and also for possible applications in micro- and opto-electronics.[1] The synthesis of such polymers is, however, often complicated by their insolubility. In several such cases syntheses *via* precursor polymers have been successful.[2,3] In this type of approach a soluble readily characterised precursor polymer is synthesised which on heating, for example, is converted into the insoluble target polymer. A classical example is the Durham synthesis of polyacetylene.[2] Polymers with extended π-electron systems which electroluminesce are now also of interest as they may form the basis of electroluminescent display devices.[4] Examples of such polymers are various poly(phenylenevinylene)s.[5,6]

Many anthracene moieties are photoluminescent and polymers containing such units as part of a larger π-electron system are also likely to be electroluminescent. The only reported polymers where anthracene units are in the backbone and conjugated are some oligo(anthracene-9,10-diyl)s,[7] and some polyquinolines.[8] We now report syntheses, *via* precursor polymers **3** and **4** respectively, of poly(anthracene-2,6-diyl) **1** and a copolymer **2** containing alternately anthracene-2,6-diyl and *p*-phenylene units. The syntheses exploit the retro-Diels–Alder reaction. This has been exploited before, both in the synthesis of polymers with extended π-electron systems[2,8,9] and in the synthesis of polymers with nonconjugated anthracene moieties.[10,11]



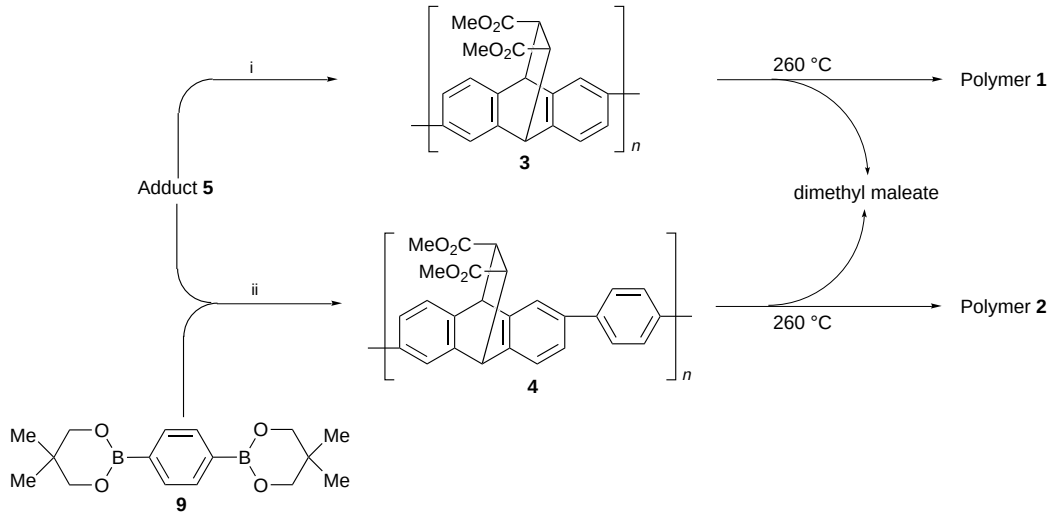
The synthesis of the Diels–Alder adduct **5** was conveniently achieved as outlined in Scheme 1. Thus, commercially available 2,6-diaminoanthraquinone **6** was converted into 2,6-dibromoanthraquinone **7** (60% yield) using a Sandmeyer reaction and the product **7** was reduced to 2,6-dibromoanthracene **8** (60% overall yield) by successive sodium borohydride reductions and acid catalysed dehydrations.[12] Treatment of compound **8** with an excess of maleic anhydride in xylene at reflux temperature gave the Diels–Alder adduct, which was then treated with methanol at reflux to give the half ester. The latter reacted smoothly with an $Et_2O$ solution of diazomethane to give the diester **5** (59% overall yield from compound **8**). This indirect route from compound **8** to diester **5** proved to be the most convenient route for obtaining a sufficient quantity of pure diester **5** for the subsequent synthetic work. Treatment of Diels–Alder adduct **5** in *N*,*N*-dimethylacetamide 80 °C with nickel(0)[13–15] gave precursor polymer **3** in 86% yield (Scheme 2). The infrared and $^1$H NMR spectra of the product were consistent with structure **3**. By gel permeation chromatography (GPC) the polymer had, relative to polystyrene standards, a number average molecular weight ($\overline{M}_n$) of 2700, a weight average molecular weight ($\overline{M}_w$) of 5400 and a peak molecular weight ($M_p$) of 5200. The $\overline{M}_w$ value corresponds to an average degree of polymerisation ($\overline{DP}$) of 17.

Copolymerisation of Diels–Alder adduct **5** and the 2,2-dimethylpropane-1,3-diol diester **9** of benzene-1,4-diboronic acid using a palladium(0) catalyst (Suzuki reaction)[16–18] gave precursor polymer **4** in 84% yield (Scheme 2). The infrared and $^1$H NMR spectra were consistent with structure **4**. By GPC the polymer had $\overline{M}_n$ 2300, $\overline{M}_w$ 5700 and $M_p$ 3000. The $\overline{M}_w$ value corresponds to a ($\overline{DP}$) of 28.



The precursor polymers **3** and **4** were soluble in many common solvents including THF and chloroform.

Conversions of the precursor polymers **3** and **4** into the target polymers **1** and **2** were achieved by thermal retro-Diels–Alder reactions which eliminated dimethyl maleate and produced the desired anthracene moieties. The reactions were monitored by thermogravimetric and spectroscopic methods. Thermogravimetric analysis showed that for both precursor polymers the onset on dimethyl maleate loss was at around 220 °C. Isothermal heating at atmospheric pressure showed that dimethyl maleate loss was significantly faster from polymer **4** than from polymer **3**. Heating polymer **3** at 260 °C for 3 h resulted in a weight loss corresponding to 73% of the theoretical maximum dimethyl maleate loss for this polymer. Similar treatment of polymer **4** at 240 °C for 1 h showed 95% of the theoretical maximum dimethyl maleate loss. It should be noted that these experiments were carried out at atmospheric pressure and that the observed weight losses would almost certainly be significantly greater for experiments carried out *in vacuo*. In all of these experiments both precursor polymers converted into the final polymers without melting.



Having established the temperatures at which the retro-Diels–Alder reaction occurred, films of precursor polymers **3** and **4** were cast on sodium chloride discs and quartz discs in order to follow the reactions by FTIR and UV spectroscopy, respectively. On heating *in vacuo* for 12 h and 260 °C the clear polymer films were seen to change from colourless to an intense

**1** **2**

**Scheme 1** *Reagents and conditions*: i, *tert*-butyl nitrite, copper(II) bromide, MeCN, 80 °C; ii, $NaBH_4$, MeOH; iii, 5 M HCl, 90 °C, 6 h; iv, $NaBH_4$, $Pr^iOH$; v, maleic anhydride, *p*-xylene, 132 °C, 18 h; vi, MeOH, 56 °C, 16 h; vii, $CH_2N_2$, $Et_2O$, 20 °C

**Scheme 2** *Reagents and conditions*: i, $[Ni(PPh_3)_2Cl_2]$, $PPh_3$, Zn, 2,2′-bipyridyl, *N*,*N*-dimethylacetamide, 80 °C; ii, $[Pd(PPh_3)_4]$, toluene, aqueous potassium carbonate (2 M)

yellow. The final films were transparent and free from cracks. With both precursor polymers **3** and **4** the ester carbonyl stretch at 1747 $cm^{-1}$ was completely lost on heating and new bands due to anthracene moieties appeared respectively at 1623 $cm^{-1}$ and 1635 $cm^{-1}$. The UV spectrum of polymer **3** shifted from $\lambda_{max}$ 267 nm (absorbance arbitrarily assigned 1.00) to $\lambda_{max}$ 315 and 442 nm (relative absorbances 1.76 and 0.67). For polymer **4** there was a shift from $\lambda_{max}$ 294 nm (absorbance arbitrarily assigned 1.00) to $\lambda_{max}$ 322 and 427 nm (relative absorbances 1.48 and 0.62). This data is consistent with the formation of the desired final polymers **1** and **2**.

The electrical conductivities of polymers **1** and **2**, measured as thin films, were $<10^{-4}$ S $cm^{-1}$, but both showed significant conductivities after n- or p-type doping. Thus, after doping with potassium naphthalenide polymers, **1** and **2** had conductivities of $4.0 \times 10^{-2}$ and $1.4 \times 10^{-3}$ S $cm^{-1}$ respectively, and after doping with ferric chloride they had conductivities of $1.2 \times 10^{-1}$ and $5.5 \times 10^{-2}$ S $cm^{-1}$. It is evident that for a given dopant polymer **1** has the greater conductivity. When thin films were irradiated with UV light (366 nm), both polymers **1** and **2** gave a yellow–green luminescence.

We thank the EPSRC for financial support.

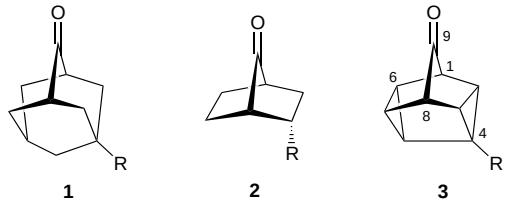
# 4-Substituted norsnoutanones: a new probe system for evaluating electronic effects in π-facial selectivity in nucleophilic additions

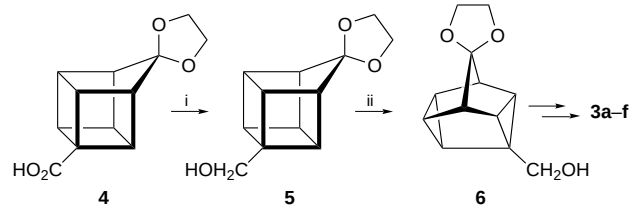
**Goverdhan Mehta,*[a] Chebolu Ravikrishna,[a] Bishwajit Ganguly[b] and Jayaraman Chandrasekhar*[b]**



[a] *School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*
[b] *Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India*

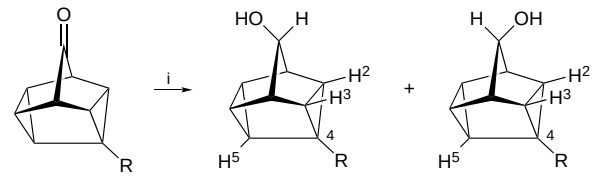
**Remotely substituted norsnoutanone derivatives show significant and consistent π-face selectivity in nucleophilic additions, revealing the interplay of orbital and electrostatic effects.**

Precise and predictable delineation of the various factors that can control π-face selectivities in additions to trigonal carbon centres has been a subject of intense scrutiny in recent years, as the desymmetrization of the two faces of the planar carbonyl/alkene group is a fundamental paradigm of stereoselective synthesis.[1] While the influence of steric factors in π-facial control is fairly well understood, the nature and role of the long range electronic effects (*e.g.* orbital *vs*. electrostatic) on face-selection is a matter of ongoing debate. In order to segregate the steric and electronic components, various research groups have devised substrates wherein the two π-faces are virtually isosteric with minimal conformational uncertainties and which can be electronically perturbed through distal modifications.[2–4] Among the systems that have been examined in detail, the sterically unbiased 5-substituted adamantan-2-ones **1**[4] and *endo*-substituted norbornan-7-ones **2**[3] have provided valuable insights into the factors governing the π-face selectivity during nucleophilic additions. Yet the relative importance and subtle interplay of various electronic factors in controlling face-selectivity remains controversial,[1] thus underscoring the need to examine newer systems.



Herein we introduce 4-substituted norsnoutanone **3** (pentacyclo[4.3.0.0$^{2,4}$.0$^{3,8}$.0$^{5,7}$]nonan-9-one), a substrate with sterically unbiased π-faces and a distal substituent to desymmetrize and exert long range electronic perturbation, as a probe to study electronic control of face-selectivity. The pentacyclic system **3** has some interesting features and, in some ways, can be regarded as a hybrid of **1** and **2**. As the overlay diagram of the energy minimized **1**–**3** (R = CN) indicates, the substituent in **3** is farthest removed from the stereoinduction centre. Furthermore, the substituent at the 4-position in **3** is three bonds away (*cf*. three- and two-bond separation in **1** and **2**, respectively) from the C(9) carbonyl group, but it is linked through cyclopropane bonds which are expected to be better transmitters of electronic effects. Here we disclose our findings that in **3**, the C(4) substituent indeed exerts a dominant influence on the face-selectivity during nucleophilic additions. We also provide the results of calculated transition-state energetics for hydride addition to 4-substituted norsnoutanones that aid in the interpretation of the observed face-selectivities.

We have synthesized six derivatives **3a**–**f** for the present study from the homocubanone-4-carboxylic acid ketal **4**. LAH reduction to **5** and Ag$^{I}$ mediated rearrangement furnished the required framework **6**.[5] The hydroxymethyl functionality in **6** was elaborated through unexceptional but multi-step functional group modifications to furnish **3a**–**f** (Scheme 1).[6]



Pentacyclic ketones **3a**–**f** were subjected to hydride reduction with sodium borohydride to furnish (*E*)-**7a**–**f** and (*Z*)-**8a**–**f** alcohols in near quantitative yield; the diastereoselectivities are shown in Scheme 2.[6] The observed *E* : *Z* ratios were determined through $^1$H NMR analyses and remained insensitive to changes in the reaction solvent. The stereostructures of **7a**–**f** and **8a**–**f** have been unambiguously deduced on the basis of (i) the deshielding (*ca*. 0.3 ppm) of H(5) in *E*-alcohols compared to *Z*-alcohols, (ii) the relative deshielding of the H(2) and H(3) protons in *Z*-alcohols compared to *E*-alcohols, and (iii) the deshielding (7–8 ppm) of the quaternary C(4) carbon resonances in the *Z*-series compared to *E*-series. These observations were further fortified through selected shift reagent (LIS) studies.

The observed diastereoselectivities (Scheme 2) indicate a profound effect and consistent trend in the face-selectivity induced by the remote C(4) substituent. While strong electron-withdrawing groups (e.g. cyano, ester) exhibit marked preference for the *syn*-face approach of the hydride to furnish the (*E*)-alcohols, such preference is diminished in the moderately electron-withdrawing substituents present in **3c**–**e**. In the case of the alkyl-substituted derivative **3f** there is a marginal preference for *anti*-face addition. While these observations are generally similar to those reported for the adamantanone **1** and the norbornanone **2** derivatives, there are two notable features. There is a marked *increase* in the face-selectivity in **3** (*cf*. for

| Relative energy[a]/kcal mol$^{-1}$ | 0.1 | 0.1 | 0.0 (0.2) | −0.1 (0.1) |

[a] A positive value indicates *syn*-face addition transition state is more stable. Values in parentheses correspond to relative energies obtained by replacing LiH by a point charge at the location of the hydride.

**Table 2** MNDO Relative energies for *syn* and *anti* face addition calculated using the charge and hydride models as well as with LiH addition transition state geometries for substituted adamantanones, norbornanones and norsnoutanones[a]

| Substrate | Relative energy/kcal mol$^{-1}$ | | | Experimental *syn* : *anti* ratio[b] |
|---|---|---|---|---|
| | Charge | Hydride | Transition state | |
| **1** R = CN | 1.3 | 0.9 | 0.2 | 68 : 32 |
| **2** R = CN | 1.8 | 1.4 | 0.5 | 88 : 12 |
| **3** R = CN | 3.5 | 1.7 | 0.5 | 84 : 16 |
| **1** R = CH=$CH_2$ | −1.0 | 0.0 | 0.0 | — |
| **2** R = CH=$CH_2$ | −2.8 | −0.4 | −0.2 | 36 : 64[c] |
| **3** R = CH=$CH_2$ | 1.0 | 0.5 | 0.1 | 60 : 40 |

[a] A positive value indicates preference for *syn*-face addition. [b] For reduction with $NaBH_4$ or $LiAlH_4$. [c] For the divinyl derivative.

R = $CO_2$Me, *E* : *Z* ratios: 57 : 41 for **1**, 68 : 32 for **2** and 79 : 21 for **3**) despite the distal nature of the substituent. Another significant difference is that while the *endo*-vinyl and methoxymethyl substituents in the case of the norbornyl system **2** are, contrary to expectation based on Cieplak model, *anti*-directing, they are *syn*-directing in **3**, in keeping with the inductively withdrawing nature of these substituents.

To test some of the commonly used computational procedures for predicting face-selectivity and to interpret the observed results, transition-state energetics for LiH addition to two representative substrates **3b** and **3d** were calculated. Structures with vanishing gradients and a Hessian of 1 were optimized using MNDO[7] and *ab initio* (3-21G basis)[8] methods. Energies were also computed at HF and MP2 levels with the 6-31G* basis set.

At all levels of theory, the 4-cyano substituent in **3b** is correctly predicted to induce a clear *syn*-face selectivity for nucleophilic attack (Table 1). The energy differences are consistent with the observed product ratio. Much smaller relative energies (generally favouring *syn*-face addition) are computed for the vinyl derivative **3d**. The consistency of the MNDO procedure becomes evident when the results for **3d** are compared with those obtained for the *endo*-vinyl substituted norbornanone (Table 2). In the latter, *anti*-face addition is predicted to be favoured by 0.2 kcal mol$^{-1}$, as is indeed found experimentally.[3a]

Two procedures were used to examine the electrostatic effects in these systems. The LiH unit in the *ab initio* optimized transition state was replaced by a point negative charge (magnitude the same as the Mulliken charge) at the hydride location. The corresponding relative energies computed with the 6-31G* basis set reflect the differences in the electrostatic response between the nucleophile and the substrate at the transition state. These values for **3b** are smaller than the transition state energy differences but, significantly, are in the same direction (Table 1). Similar results were earlier obtained for the norbornanones.[9] An alternative approach[3b] to modelling electrostatic effects through a point negative charge and a hydride ion at an assumed distance from the ground state geometry of the substrate provides further insights. Due to the inherent assumptions in these models, unambiguous but exaggerated energy differences are obtained. In all the derivatives considered, the hydride model yields the same facial-selectivity as the transition state relative energies (Table 2), while the charge model reproduces the general trends.

The observed and calculated results can be understood by considering three factors. Cieplak-type hyperconjugative interactions[10] should favour *syn*-face addition in all the substrates with electron-withdrawing groups. Since these groups polarize the adjacent carbon atoms as well as the nearby *exo*-face hydrogen atoms, electrostatic interactions with the nucleophile would reinforce the *syn*-face preference. However, a direct through-space repulsive interactions between the nucleophile and the substituent is also possible, favouring *anti*-face approach. In the norbornanones, all three factors are important and their relative contributions determine the observed *syn*-face preference for the cyano and *anti*-face attack in the vinyl derivatives. All the interactions are reduced in the adamantanone series. Interestingly, the direct interaction between the nucleophile and the substituent is effectively eliminated in the norsnoutanones for geometric reasons. Hence, residual electrostatic and orbital effects favour *syn*-face approach in both **3b** and **3d**.

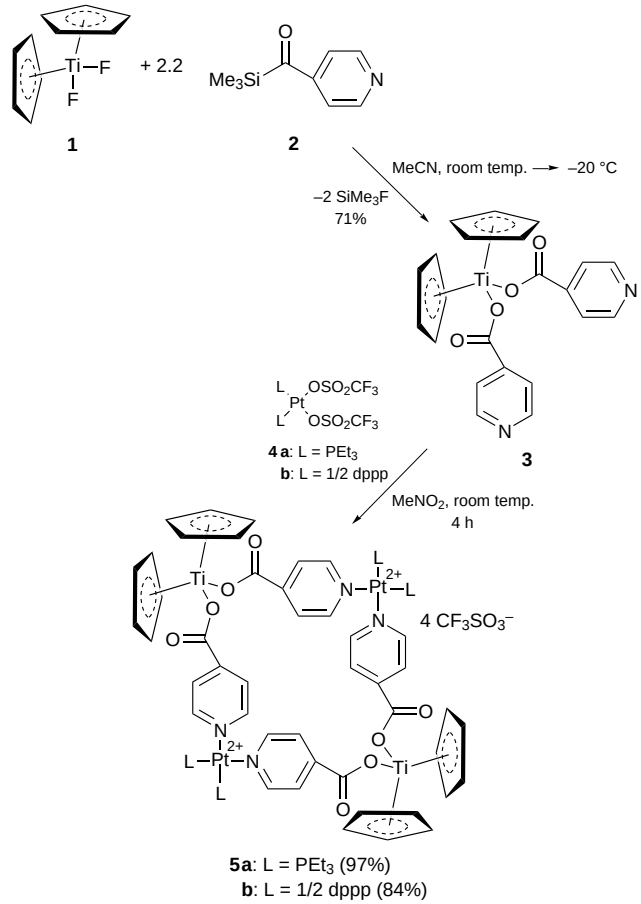
# Heterobimetallic early–late transition-metal tetrameric metallomacrocycles *via* self assembly



**Peter J. Stang*† and Neal E. Persky**

*Department of Chemistry, The University of Utah, Salt Lake City, Utah 84112, USA*

**Interaction of [Ti(η-$C_5H_5$)$_2$($O_2CC_5H_4N$)$_2$] with square-planar *cis*-[Pt($PR_3$)$_2$($OSO_2CF_3$)$_2$] in $MeNO_2$ gives mixed Ti–Pt tetrameric metallomacrocycles, *via* self assembly, in excellent yields.**

Dative metal–ligand coordination is becoming an increasingly important motif in the construction of discrete supramolecular species with well defined shapes and geometries.[1] The self assembly of diverse molecular squares with variable cavities using transition metals and the appropriate bidentate ligands as building blocks are elegant recent examples of the application of the above concept. To date all molecular squares have been constructed with the aid of either late-transition metals, like Pt and Pd,[2,3] Re,[4] or early-transition metals such as W and Cr,[5] or the main group element iodine[6,7] in its trivalent $I^{III}$ form.[8] Here, we report the formation *via* modular self assembly of the first examples of early–late transition-metal hybrid Ti–Pt hetero-bimetallic tetranuclear macrocycles.

Interaction of the known[9] Ti(η-$C_5H_5$)$_2$ complex **3** with the *cis*-square-planar platinum bistriflate complexes **4**[2] in $MeNO_2$ (0.12 M) at room temp. for 5 h afforded the desired novel macrocycles **5** in excellent isolated yields *via* self assembly, as shown in Scheme 1.‡ Work-up proceeded by simply reducing the solvent to *ca*. 2 ml under vacuum and subsequently precipitating and washing the macrocycles with diethyl ether. Macrocycles **5a**, **5b** are stable, orange, microcrystalline solids, characterized by spectroscopic means and, in the case of **5a**, by liquid secondary ion mass spectrometry (LSIMS). All spectral data are consistent with the proposed structures. Particularly characteristic of **5** are the respective single, sharp singlets (with appropriate Pt satellites) in the $^{31}$P NMR spectrum and the downfield shift of the pyridine hydrogens of **3** upon complexing to Pt in **5**, in particular the α-H shift of *ca*. 0.5 ppm and the β-H of *ca*. 0.3 ppm downfield in **5a** relative to precursor **3**. Most importantly the LSIMS of **5a** shows an $(M - 2\ OSO_2CF_3)^{2+}$ signal at *m/z* = 1002.6 whose experimental isotope pattern very closely matches the calculated value (Fig. 1), leaving little doubt about the tetranuclear nature and identity of this interesting metallomacrocycle. Fig. 2 displays an MM-2 minimized ball-and-stick (*a*) and space-filling model (*b*) of **5a**, illustrating the shape and cavity of this unique heterobimetallic metallomacrocycle with both square-planar Pt and distorted tetrahedral Ti as the shape-defining corner units.

**Scheme 1** Synthesis of macrocycle **5**; dppp = 1,3 bis(diphenylphosphino)propane

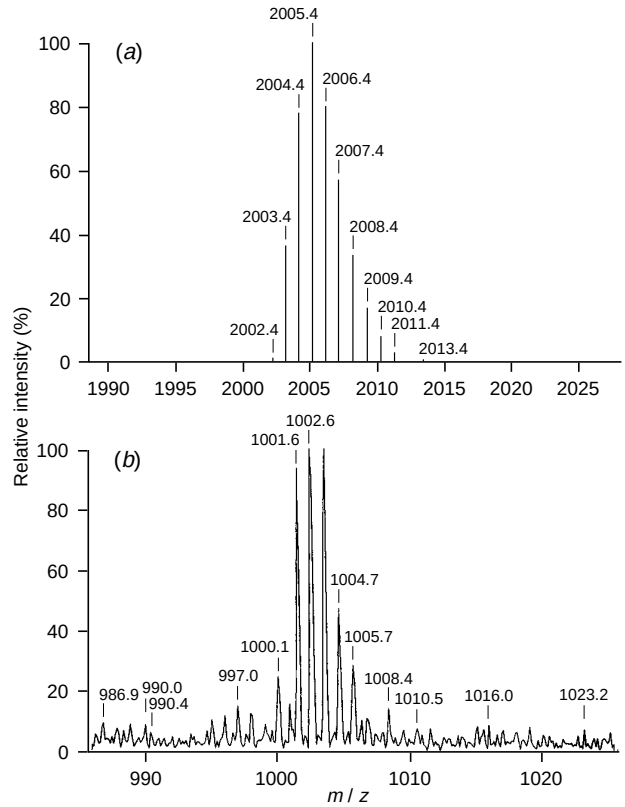


**Fig. 1** Selected region of the calculated (*a*) and experimental (*b*) LSIMS of macrocycle **5a** showing an $(M - 2\ OSO_2CF_3)^{2+}$ signal at *m/z* 1002.6

In summary, the first example of novel mixed Ti–Pt heterobimetallic tetranuclear metallomacrocycles are reported *via* self assembly from readily available precursors. LSIMS, along with spectral and physical data, are used to unambiguously characterize these new supramolecular species.

Financial support by the NSF (CHE-9529093) and the loan of $PtCl_2$ by Johnson-Matthey are gratefully acknowledged as is the A. von Humboldt Foundation and the hospitality of Professor M. Regitz during the summer of 1996.

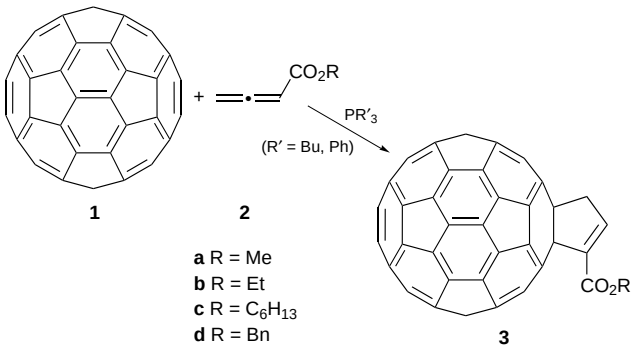
# Phosphine-catalysed [3 + 2] cycloadditions of buta-2,3-dienoates with [60]fullerene

**Lian-He Shu,[a] Wei-Quan Sun,[a] Dan-Wei Zhang,[a] Shi-Hui Wu,*[a] Hou-Ming Wu,[b] Jing-Fei Xu[b] and Xia-Fei Lao[b]**



[a] *Department of Chemistry, Fudan University, Shanghai 200433, P.R. China*

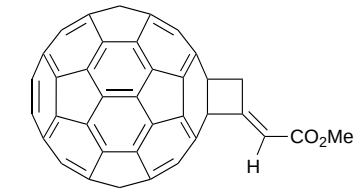
**[60]Fullerene reacts with buta-2,3-dienoates in the presence of phosphine to form alkyl 3′*H*-1,2-([1′,2′]cyclopenta)-[60]fullerene-5′-carboxylates.**

Cycloaddition reactions provide the most successful methodologies for the functionalization of fullerene.[1] A number of 1,3-dipoles, such as diazomethanes,[2] azides[3] and azomethine ylides[4] are known to react with [60]fullerene. Here we describe the phosphine-catalysed [3 + 2] cycloadditions of buta-2,3-dienoates with [60]fullerene. The [3 + 2] cycloadditions of buta-2,3-dienoates with electron-deficient alkenes have been reported by Zhang *et al*. recently.[5] This reaction provides a very efficient route to the synthesis of cyclopentene. Here [60]fullerene was used as the dipolarophile and the expected products were obtained with good yields (Scheme 1).

The reaction of [60]fullerene with **2a** and tributylphosphine was carried out at room temperature under nitrogen. Isolation on silica gel using toluene as eluent afforded **3a**† and unreacted [60]fullerene. The yield of **3a** was 42% (95% based on consumed [60]fullerene). For **2b**, **2c** and **2d**, the reactions were carried out at 80 °C and triphenylphosphine was used as catalyst. The yields (corrected for the recovered fullerene, shown in parentheses) for **3b**, **3c** and **3d** were 78 (81.6), 52 (89) and 88.5% (92%), respectively.

The FD-MS spectrum of **3a** gives the molecular ion peak at *m*/*z* 818 ($C_{65}H_6O_2$, 100%). In the FT-IR spectrum, the absorption bands for the alkenic and the carbonyl groups are located at 1638 and 1722 $cm^{-1}$, respectively. The $^1H$ NMR spectrum [600 MHz; $CS_2$–$(CD_3)_2CO$, 10 : 1] of **3a** shows three signals at δ 3.87 (3H, s, OMe), 4.61 (2H, d, *J* 2.64 Hz, $CH_2$) and 7.77 (1H, t, *J* 2.64 Hz, =CH). The $^{13}C$ NMR spectrum [150.9 MHz; $CS_2$–$(CD_3)_2CO$, 10 : 1] shows 35 signals in total, of which two signals are found to be overlapped. Peaks at δ 48.28, 52.09, 69.91, 72.08 and 163.13 are obviously due to the methylene group, the methoxy group, the two $sp^3$ carbons of the cage and the carbonyl group, respectively. The $^{13}C$ NMR spectrum is also consistent with the proposed structure, as $C_s$ symmetry requires 32 signals for the fullerene skeleton.



**Scheme 1**

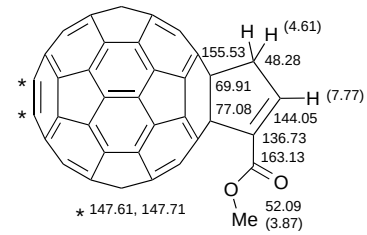
Compound **3b** is almost insoluble in solvent, and only FT-IR and $^1H$ NMR spectra were obtained. For **3c** and **3d**,‡ all the spectra agree the proposed structure.

Recently, the phosphine-mediated reaction of but-2-ynoates with [60]fullerene was reported by Liou *et. al*.[6] The authors declared that [2 + 2] cycloaddition product **4** was formed from the reaction of [60]fullerene with methyl but-2-ynoate. The phosphine-catalysed [3 + 2] cycloadditions of but-2-ynoates and electron-deficient alkenes have been reported in literature.[5] Both the products and intermediates of this reaction have been proved to be the same as those of the reactions of buta-2,3-dienoates. This suggested to us that compound **4** was probably the same as **3a**. In fact, the FD-MS, FTIR, $^1H$ NMR and $^{13}C$ NMR spectra of **3a** are almost identical to those of **4**.

In order to prove our assumption, compound **4** was prepared from the reaction of methyl but-2-ynoates with [60]fullerene by the procedure described by Liou. It is reasonable to conclude that compound **4** is indeed identical to **3a**, for a mixture of **3a** and **4** showed only one peak by HPLC.§ This result encouraged us to check the structure of **3a** more carefully.

The cyclopentene structure of **3a** is further substantiated by the HMQC and HMBC NMR spectra. Assignable NMR spectral data are shown in Fig. 1. In the HMQC spectrum, the alkenic proton at δ 7.77 is found to be connected to the carbon atom at δ 144.05. In the HMBC spectrum, the alkenic proton (δ 7.77) shows correlations with both of the $sp^3$ carbons of the fullerene cage, which indicates that there are two or three bonds between this proton and the two carbon atoms. The structure with a four-membered ring **4** is ruled out, for the alkenic proton is either three or four bonds away from the addition site; this means that the HMBC spectrum for **4** would give only one correlation peak between the alkenic proton and the addition site carbons. The reasoning which led to the four-membered

**4**



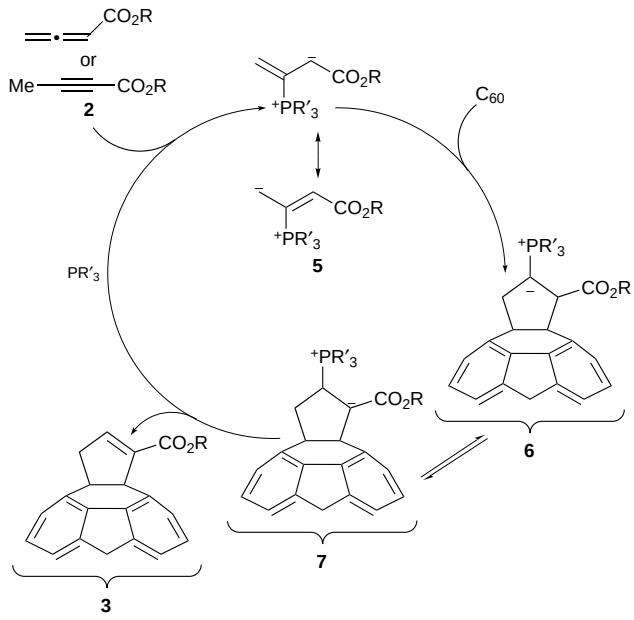


**Fig. 1** $^{13}C$ NMR and $^1H$ NMR (in parentheses) data for **3a**

**Scheme 2**

ring structure was that Liou assigned the small coupling constant observed to an allylic coupling. In fact, in the spectra of smaller rings, the coupling constant between aliphatic and alkenic protons (C$H_2$–C*H*=C) is quite small.[7] For example, the $J_{1,5}$ of cyclopentene is 2.1 Hz.[8]

A possible mechanism for the reaction is outlined in Scheme 2. As reported by Zhang *et. al*.,[5] phosphine first reacts with buta-2,3-dienoate or but-2-ynoate to form **5**, and then a [3 + 2] cycloaddition occurs. Product **3** is given with the regeneration of phosphine.

This work was supported by the National Science Foundation of China. We thank Professor Xiyan Lu of the Shanghai Institute of Organic Chemistry for kindly providing methyl but-2-ynoate and helpful discussions.

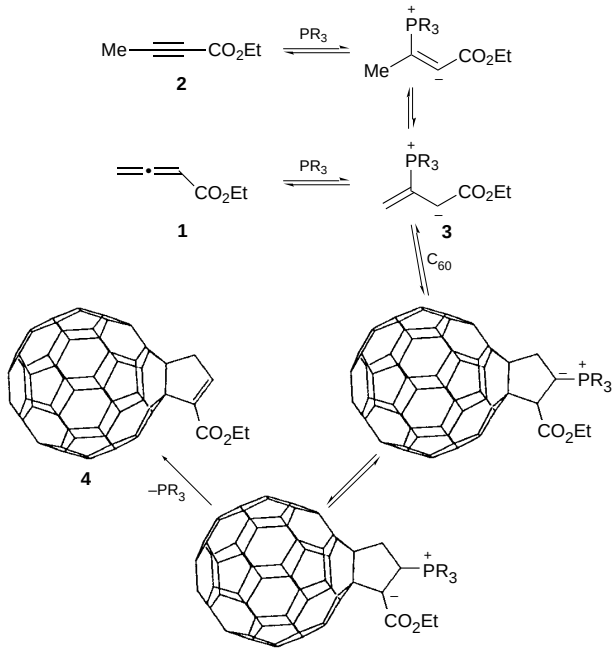
# Phosphine-catalysed cycloaddition of buta-2,3-dienoates and but-2-ynoates to [60]fullerene

**Bryan F. O'Donovan, Peter B. Hitchcock, Mohamed F. Meidine, Harold W. Kroto, Roger Taylor and David R. M. Walton**

*School of Chemistry, Physics and Environmental Science, University of Sussex, Falmer, Brighton, East Sussex, UK BN1 9QJ*



**In the presence of phosphine catalysts, ethyl buta-2,3-dienoate and ethyl but-2-ynoate undergo [3 + 2] as opposed to [2 + 2] dipolar cycloaddition to [60]fullerene.**

Cycloadditions have proved to be the most generally useful method yet devised for attaching organofunctional groups to fullerenes.[1] In these processes the cage often behaves as the electron deficient component, so that alkenes bearing electron-withdrawing groups serve as useful models for reactions. Recently Zhang and Lu[2] described a novel [3 + 2] annulation technique for preparing cyclopentenes, based on the phosphine-catalysed cycloadditions of buta-2,3-dienoates and but-2-ynoates to electron-deficient alkenes. We have successfully applied their methodology to [60]fullerene.

In a typical reaction, ethyl buta-2,3-dienoate **1** (21.26 mg, 0.19 mmol, 1.7 equiv.) and 5 mol% of tributylphosphine (1.92 mg, 9.5 μmol) were added successively to a solution of [60]fullerene (80.4 mg, 0.11 mmol) in toluene (200 $cm^3$), and the mixture was stirred at ambient temperature under nitrogen for 17 h. Thin layer chromatography (TLC) (silica) of a sample of the resulting red–brown solution revealed the presence of unreacted [60]fullerene and one major product **4**. Removal of the solvent *in vacuo* and flash chromatography (toluene–hexane, 7:3; silica gel) of the residue gave [60]fullerene, followed by **4** (43%, pure by TLC). Use of **1** in excess of 1.7 equiv. resulted in a lower yield of **4** due to a marked increase in the proportion of products arising from multiple cycloadditions to the cage.

When ethyl but-2-ynoate **2** was used instead of **1**, forcing conditions (refluxing benzene, 20 h) were required to produce **4**, albeit in lower yield (23%). At ambient temperature, all of the [60]fullerene was recovered together with unwanted byproducts due to slow decomposition of **2**.

Tricyclohexylphosphine ($PCy_3$) and $PBu_3$ showed comparable catalytic activity in the cycloaddition of **1** to [60]fullerene, whereas reaction was much slower with triphenylphosphine ($PPh_3$). The difference is greater with **2**; in this case $PPh_3$ appears not to catalyse the reaction. These observations are in line with the greater nucleophilicity of $PBu_3$ and $PCy_3$ relative to $PPh_3$ and are compatible with Scheme 1.

**Scheme 1**

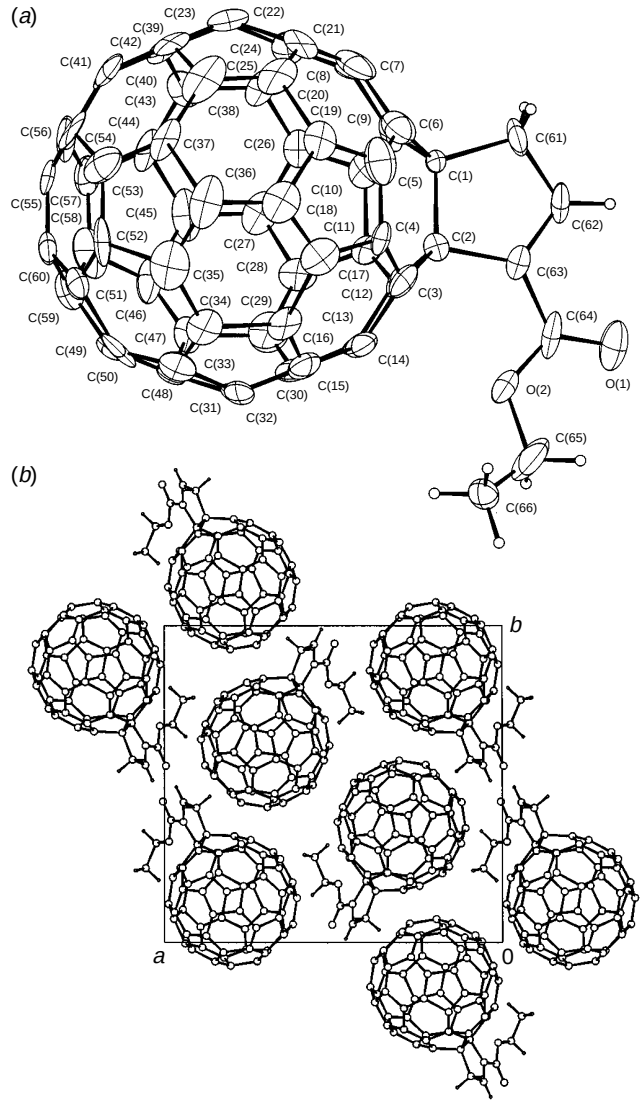


**Fig. 1** (*a*) X-Ray crystal structure of **4** and (*b*) representation of the crystal packing in the unit cell

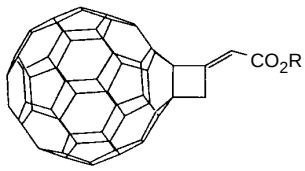
The EI-MS of **4** displays the anticipated molecular ion peak at *m*/*z* 832, together with peaks at *m*/*z* 804 and 759 corresponding to loss of ethene and the ethyl carboxylate moiety, respectively.



The FT-IR spectrum of **4** reveals a strong absorption at 1715 $cm^{-1}$ due to the ester carbonyl group. The 577 $cm^{-1}$ band, characteristic of the parent fullerene, is split into several weaker signals which, in conjuction with the strong 527 $cm^{-1}$ band, is commensurate with addition across the [6,6] double bond in [60]fullerene.

The $^1H$ NMR spectrum of **4** (300 MHz; $CS_2$–$CDCl_3$, 1 : 1) exhibits a triplet at δ 7.98 (*J* 2.6 Hz) due to the β vinyl proton, which is coupled to the adjacent methylene protons giving rise to a doublet at δ 4.77 (*J* 2.6 Hz).The ethyl group resonances are as expected: δ 4.53 (*J* 7.1 Hz, q) and δ 1.59 (7.1 Hz, t).

The high field $^{13}C$ NMR (125.76 MHz; $CS_2$–$CDCl_3$, 4 : 1) of **4** shows signals corresponding to the ethyl group (δ 14.49, 47.75), the methylene carbon (δ 61.29), and the fullerene cage $sp^3$ carbons (δ 69.54, 76.55). The $sp^2$ region exhibits 32 signals, one of which, the carbonyl carbon (δ 163.03), was assigned on the basis of its chemical shift. A further two signals (δ 128.34, 136.60) were assigned on the basis of $^{13}C\{^1H\}$ decoupling to the unsaturated carbons of the cyclopentene ring. The remaining 28 signals† correspond to the carbons of the fullerene core; two of single intensity, 24 of double intensity and two of quadruple intensity. Assuming that the latter are due to the incidental overlap of two sets of double intensity signals, and that the single intensity peaks correspond to the carbons which lie on the mirror plane, the number of resonances is consistent with the expected $C_s$ symmetry of the molecule.

Slow evaporation of a toluene–$CS_2$ solution of **4** yielded black needle-like crystals, suitable for X-ray analysis, on the basis of which the structure of **4** was conclusively assigned‡ (Fig. 1).

Recently Liou and Cheng[3] described the $PCy_3$-mediated reaction of alkyl 2-ynoates to [60]fullerene, and formulated the products as arising from a formal [2 + 2] cycloaddition generating **5**, as opposed to **4**. The authors based their structural conclusions exclusively on NMR evidence. We repeated this procedure with ethyl but-2-ynoate (reaction at ambient rather than the reflux temperature; 10-fold excess of ynoate) and found the NMR spectra of the product to be identical in all respects to **4**. We thus conclude that Liou and Cheng assigned the incorrect structure to the cycloadduct. It is noteworthy that Zhang and Lu[2] obtained only products arising from [3 + 2] as opposed to [2 + 2] cycloadditions of ynoates and butadienoates with electron-deficient alkenes

**5**

A viable mechanism for the reaction as originally proposed[2] is presented in Scheme 1. Nucleophilic attack of the tertiary phosphine on the β allenic or acetylenic carbon atom, followed by a prototropic shift (or series of shifts in the case of the ynoate substrate) generates the dipolar intermediate **3**, which undergoes a [3 + 2] cycloaddition to [60]fullerene. A further prototropic shift in the initial cycloadduct and subsequent β-elimination of the phosphine generates **4**.

† *Selected spectroscopic data* for **4**; $^{13}C$ NMR: δ 156.00, 149.74, 148.33, 147.25, 147.15, 146.23, 146.20, 146.08, 145.95, 145.90, 145.46, 145.26, 145.17, 145.08, 144.95, 143.76, 144.37, 142.65, 142.61, 142.36, 142.11, 142.02, 141.94, 141.49, 140.21, 139.18, 135.52, 134.53.

‡ *Crystal structure data* for **4**: $C_{66}H_8O_2$, *M* = 832.7, orthorombic, space group $P_{na}2_1$ (no. 33), *a* = 18.531(3), *b* = 17.253(3), *c* = 10.022(5) Å, *U* = 3204(2) $Å^3$, *Z* = 4, $D_c$ = 1.73 g $cm^{-3}$, *F*(000) = 1680. Crystal size 0.2 × 0.2 × 0.02 mm, Mo-Kα radiation, λ = 0.71073 Å, μ = 0.1 $mm^{-1}$. Data collected on an Enraf-Nonius CAD4 diffractometer at 293 K. There were 2984 unique reflections measured for 2 < θ < 25°, with 1672 having $I > 2\sigma(I)$. Non-H atoms were located by direct methods (SHELXS-86) and refined on $F^2$ with all reflections (SHELXL-93). H-atoms were included in riding mode. The structure is disordered in the ratio 76 : 24, with the minor sites related to the major sites by reflection through a plane perpendicular to the *c* axis and passing through the centroid of the $C_{60}$ sphere. The coordinates for the minor occupancy molecule were generated from those of the major sites and then refined as a rigid body with isotropic thermal parameters. Final residuals were *R*1 = 0.062 [for $I > 2\sigma(I)$] and *wR*2 = 0.186 (for all data).

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/304.

# Efficient and unique cooperation of three zinc(II) ions in the hydrolysis of diribonucleotides by a trinuclear zinc(II) complex

**Morio Yashiro,* Akira Ishikubo and Makoto Komiyama***

*Department of Chemistry and Biotechnology, Graduate School of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan*

**A trinuclear $Zn^{2+}$ complex is prepared using a ligand having six pyridine moieties, *N*,*N*,*N*′,*N*′,*N*″,*N*″-hexakis(2-pyridylmethyl)[tris(2-aminoethyl)amine] ($L^3$), and efficiently hydrolyses diribonucleotides at pH 7 and 50 °C, showing much greater activity than a dinuclear $Zn_2L^2$ complex.**

A number of enzymes for phosphoester hydrolysis have two or three $Zn^{2+}$ ions in the catalytic centre.[1] Therefore, polynuclear metal complexes are expected to be useful as catalysts for the hydrolysis of nucleic acids. We have recently reported that a dinuclear zinc(II) complex with *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)-2-hydroxy-1,3-diaminopropane ($L^2$, Fig. 1) efficiently hydrolyses a diribonucleotide, the high activity arising from the cooperation of two $Zn^{2+}$ ions.[2]

It is important to elucidate the cooperation effect of three zinc(II) ions in phosphoester hydrolysis, since three $Zn^{2+}$ ions have been suggested to participate in enzymatic reactions.[1b] Thus, a new ligand $L^3$ was designed in this study.† $L^3$ is expected to bind three $Zn^{2+}$ ions, since each of the three dpa ($L^1$) units in $L^3$ should bind to $Zn^{2+}$ [dpa = bis(2-pyridylmethyl)amine].[3] Here, we report that the trinuclear complex $Zn_3L^3$ hydrolyses diribonucleotides much more efficiently than the dinuclear $Zn_2L^2$ complex.

The trinuclear zinc(II) complex was prepared in an aqueous solution by mixing $Zn(NO_3)_2$ and $L^3$ in a molar ratio of 3 : 1, and was characterized by $^1$H NMR spectroscopy. A mixture of $Zn(NO_3)_2$ (15 mM) and $L^3$ (5 mM) in $D_2O$ (pD 7) gave a very simple $^1$H NMR spectrum;‡ the six 2-pyridylmethyl moieties in $L^3$ were observed as one set of sharp signals, indicating the formation of a complex in which all the 2-pyridylmethyl moieties are equivalent. In contrast, when the concentration of $Zn(NO_3)_2$ was < 15 mM, the $^1$H NMR spectrum gave complicated signals, corresponding to the formation of several complex species having lower symmetries. These observations indicate the formation of a trinuclear complex having three-fold symmetry in a 3 : 1 $Zn(NO_3)_2$–$L^3$ mixture (Fig. 1).

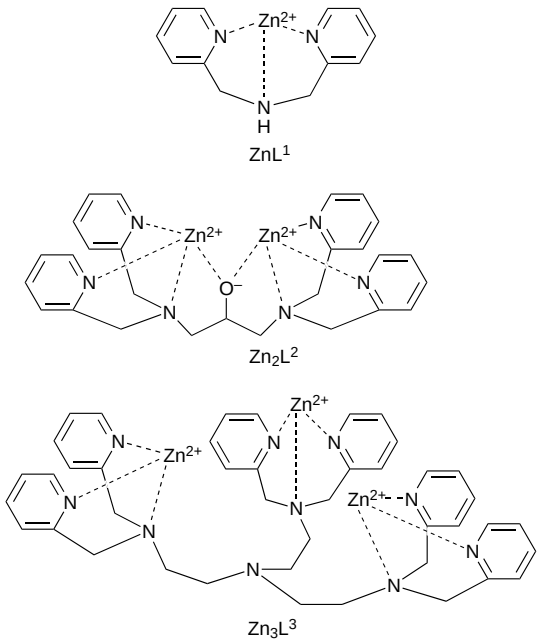

**Fig. 1** Structures of ligands. The proposed coordination modes of $Zn^{2+}$ are also shown. The drawn structures of the complexes are only partial, and additional molecules coordinating at the remaining sites of $Zn^{2+}$ are not specified.

Hydrolysis of ribonucleotide dimers, NpN′, by $Zn_3L^3$ was conducted at 50 °C and pH 6.9 (50 mM Hepes buffer).§ The reactions were followed by reversed-phase ODS HPLC. The products were nucleoside (N′), 3′- and 2′-monophosphates (3′-, 2′-NMP), and the 2′,3′-cyclic monophosphate (2′,3′-cNMP).¶ The reactions showed satisfactory pseudo-first-order kinetics.

The rate of NpN′ hydrolysis by the $Zn(NO_3)_2$–$L^3$ complex system is largely dependent on the metal ion-to-ligand ratio. Fig. 2 shows the rate constants for ApA hydrolysis at various concentrations of $L^3$ and a constant $Zn^{2+}$ concentration {[$Zn(NO_3)_2$] = 15 mM}. The maximal rate was observed at a ratio [$Zn(NO_3)_2$] : [$L^3$] = 3 : 1 indicating that the phosphoester hydrolysis is primarily promoted by the trinuclear $Zn_3L^3$ complex.

The results of hydrolyses of various diribonucleotides by the trinuclear complex are listed in Table 1 and for comparison, equivalent data for the dinuclear $Zn_2L^2$ complex are also listed. The trinuclear complex hydrolyses diribonucleotides efficiently, showing a considerable dependence on the structure of the substrate. For all the substrates examined, the activity of the trinuclear complex is much greater than that of the dinuclear complex. The half-life of CpA hydrolysis by the trinuclear $Zn_3L^3$ complex is 16 min (*cf.* 3 h for the dinuclear $Zn_2L^2$ complex).

Further, the trinuclear $Zn_3L^3$ complex-catalysed hydrolysis is unique in product formation with 3′-NMP preferentially formed

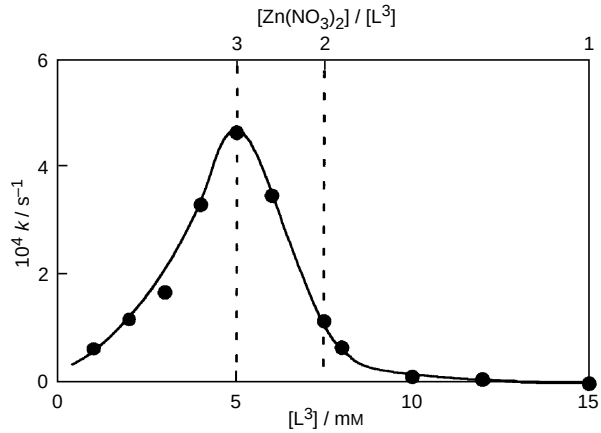

**Fig. 2** Rate constants for ApA hydrolysis with various concentrations of $L^3$ at a constant $Zn^{2+}$ concentration {[$Zn(NO_3)_2$] = 15 mM} at pH 6.9 and 50 °C

over 2′-NMP. In the hydrolysis of CpA, ApA, GpA and GpC, the formation ratio of 3′-NMP to 2′-NMP is > 90%. These results are significant, since 3′-NMP/2′-NMP selectivities are low in hydrolysis by $Zn_2L^2$.

Trinuclear metal centres have been found in crystals of P1 nuclease,[1a] phospholipase C,[1b] and alkaline phosphatase.[1c] On the basis of their crystal structures, participation of three $Zn^{2+}$ ions in the catalytic process has been proposed.[1b]‖ Although cooperative effects of two metal ions in phosphoester hydrolyses have been directly observed by using dinuclear complexes,[2,4] the cooperation of three metal ions in the catalytic process has not yet been clarified. The present results clearly show the efficiency of the trinuclear zinc(II) cluster in phosphoester hydrolysis.

In conclusion, a novel trinuclear zinc(II) complex is prepared using $L^3$. Because of the high efficiency and the selective formation of the 3′-monophosphate, the trinuclear zinc(II) complex is a unique catalyst for the hydrolysis of RNA.

This work was partially supported by Grants-in-Aid for Scientific Research on Priority Areas No. 08232219 and 08249206 from the Ministry of Education, Science and Culture.

**Table 1** Hydrolysis of diribonucleotides (NpN′) by polynuclear zinc(II) complexes at pH 6.9 and 50 °C[a]

| Substrate | $10^5$ $k$/s$^{-1}$ | $t_{1/2}$/s | 3′-NMP : 2′-NMP |
|---|---|---|---|
| $Zn_3L^3$ | | | |
| CpA | 72 | 960 | > 9 : 1 |
| ApA | 46 | 1400 | 9 : 1 |
| GpA | 26 | 2700 | 9 : 1 |
| UpA | 16 | 4500 | 7 : 3 |
| ApG | 17 | 4100 | 8 : 2 |

| ApA | 5 | 15 000 | 6 : 4 |
| GpA | 5 | 15 000 | 6 : 4 |
| UpA | 6 | 12 000 | 6 : 4 |
| $ZnL^1$ | | | |
| ApA | —[b] | —[b] | |

[a] $[Zn(NO_3)_2]$ = 15 mM, $[L^3]$ = 5 mM or $[L^2]$ = 7.5 mM, [NpN′] 0 = 0.1 mM. [b] No reaction after 24 h.

## Footnotes

† $L^3$ was prepared from tris(2-aminoethyl)amine and 2-picolylaldehyde in methanol, with subsequent reduction by $NaBH_3CN$ at room temp. and was isolated as a perchlorate salt.

**CAUTION**: although the perchlorate salt is moderately stable, it is a potential hazard and should therefore be handled with care and in small quantities. Anal. Calc. for $C_{42}H_{54}Cl_6N_{10}O_{24}$: C, 38.93; H, 4.20; N, 10.81. Found: C, 38.60; H, 4.37; N, 10.53%. $^1$H NMR (270 MHz, $D_2O$) δ 2.93 (6 H, t, *J* 6.5 Hz), 3.20 (6 H, t, 6.5), 3.79 (12 H, s), 7.30 (6 H, d, 7.8), 7.32 (6 H, t, 7.8), 7.77 (6 H, t, 7.8), 8.34 (6 H, d, 7.8).

‡ $^1$H NMR (270 MHz, $D_2O$, 50 °C) δ 2.91 (6 H, br), 2.94 (6 H, br), 4.17 (12 H, s), 7.57 (6 H, d, 7.8), 7.64 (6 H, t, 7.8), 8.15 (6 H, t, 7.8), 8.53 (6 H, d, 7.8).

§ Diribonucleotides, CpA, ApA, GpA, UpA, ApG and GpC, were purchased from Sigma.

¶ 2′,3′-cNMP is readily hydrolysed to 3′- and 2′-NMP, and is observed as an intermediate.

‖ Participation of three $Zn^{2+}$ in the phosphoester hydrolysis has been also suggested on the basis of the structure of a complex consisting of an inorganic phosphate and three mononuclear zinc(II) complexes (T. Koike, S. Kajitani, I. Nakamura, E. Kimura and M. Shiro, *J. Am. Chem. Soc.*, 1995, **117**, 1210).

# X-Ray crystallographic structure determination of some unique chiral sultam derivatives

**Hiroko Kakuda,*[a] Takanori Suzuki,[a] Yoshio Takeuchi[a] and Motoo Shiro*[b]**

[a] *Toyama Medical & Pharmaceutical University, Sugitani 2630, Toyama 930-01, Japan*
[b] *Rigaku Corporation, Matsubara 3-9-12, Akishima, Tokyo 196, Japan*

**X-Ray diffraction analyses of the novel structures of chiral sultams 1–3 reveal that the nitrogen atom in the *N*-sulfonamido sultam 1 is planar, whereas the N–H bond in the *N*-unsubstituted sultam 2 and the N–F bond in the *N*-fluoro sultam 3 are nonplanar on the side of the smaller alkyl substituent, contrary to expectation.**

In the course of developing new reagents for stereoselective fluorination,[1] we prepared several structurally interesting chiral sultam derivatives. Among those, we chose three representative sultams for X-ray analysis, *N*-sulfonamido sultam **1**, *N*-unsubstituted sultam **2** and its *N*-fluoro analogue **3**. Compounds **1** and **2** are synthetic intermediates for the potential fluorinating reagent **3**. In addition to the orientation of the N–F bond in **3**, the determination of the complete molecular structure is crucial for elucidation of the steric course of the asymmetric fluorination employing this reagent.

The molecular structures of compounds **1**, **2** and **3** are shown in Figs. 1, 2 and 3, respectively.† The sums of the bond angles around the nitrogen atom in these compounds are 359.4, 336.6 and 315.0°, respectively. Therefore, the configuration at the nitrogen atom in **1** is almost planar, while it is pyramidal in **2** and **3**.

The bond lengths N(2)–S(3) and N(2)–S(20) in **1** are 1,684(5) and 1.654(5) Å, respectively (Fig. 1). The latter is shorter than the former owing to the tendency of the nitrogen atom to donate its lone pair to the 3d orbital of S(20). Therefore, the presence of the exocyclic sulfonamido substituent contributes to the planarity of the nitrogen atom. Configurationally stable, pyramidal nitrogen atoms were observed when they are part of a three- to five-membered ring and when attached to electronegative substituents.[2] It is, however, not the case if the exocyclic

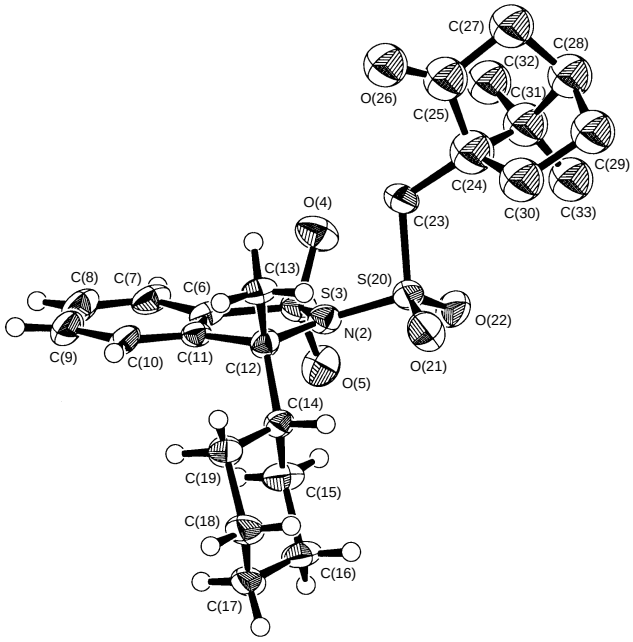

**Fig. 1** ORTEP diagram of **1** with 50% thermal ellipsoids. Two of minor disordered contributions of camphor moiety are omitted for clarity. Selected bond distances (Å) and angles (°): N(2)–S(3) 1.684(5), N(2)–S(20) 1.654(5), N(2)–C(12) 1.523(8); S(3)–N(2)–S(20) 117.6(3), S(3)–N(2)–C(12) 115.6(4), C(12)–N(2)–S(20) 126.2(4).

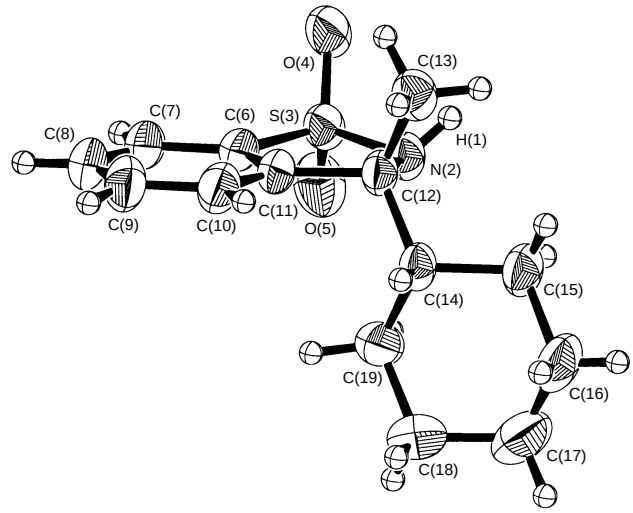

**Fig. 2** ORTEP diagram of **2** with 50% thermal ellipsoids. Selected bond distances (Å) and angles (°): N(2)–S(3) 1.620(2), N(2)–C(12) 1.487(4); S(3)–N(2)–C(12) 115.6(2), S(3)–N(2)–H(1) 108(2), C(12)–N(2)–H(1) 113(2).

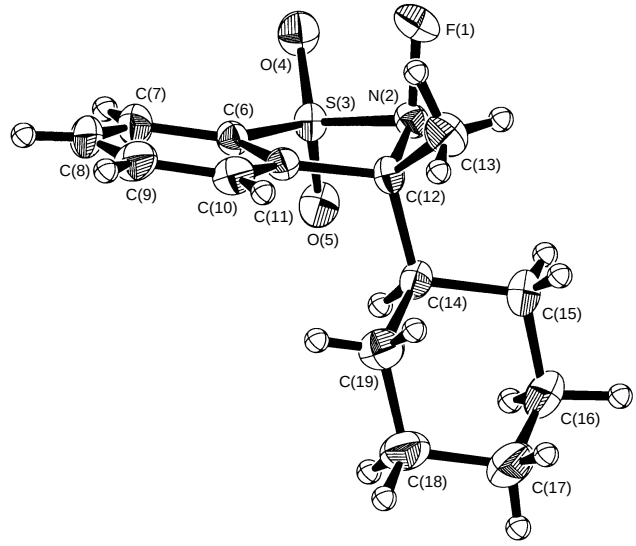

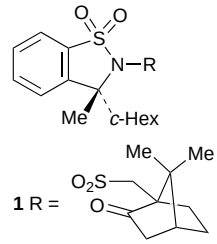

**Fig. 3** ORTEP diagram of **3** with 50% thermal ellipsoids. Selected bond distances (Å) and angles (°): N(2)–F(1) 1.435(3), N(2)–S(3) 1.738(2), N(2)–C(12) 1.523(4); F(1)–N(2)–S(3) 102.3(2), F(1)–N(2)–C(12) 105.7(2), S(3)–N(2)–C(12) 107.0(2).

substituent has an atom that interacts with the nitrogen lone pair, such as the sulfur atom of the sulfonyl in **1**.

The nitrogen atom in compound **2** (Fig. 2) apparently has $sp^3$ character based on the bond angles. The orientation of the amide proton is *syn* to the methyl group, namely, the lone pair of the nitrogen takes a position on the side of the larger alkyl substituent. Thus, the nitrogen pyramid is tilted in the opposite direction compared to a previous report,[2] although the reason is as yet unclear. The absence of the electronegative and rather bulky *N*-substituent such as a camphorsulfonyl group results in shortening the N(2)–S(3) distance [1.620(2) Å] and the N(2)–C(12) distance [1.487(4) Å] in **2**.

The structure of **3** was determined at 152 K (Fig. 3) since the thermal motion of the cyclohexyl group was high at room temperature. The nitrogen atom in **3** was found to be highly pyramidalized. The N(2)–S(3) bond [1.738(2) Å] is much longer than that in **1** and **2**, presumably owing to the highly electronegative character of the fluorine atom. The N(2)–F(1) bond [1.435(3) Å] is slightly elongated [*cf.*[3] 1.406(16) Å for F–$NR^1R^2$]. The dihedral angles F(1)–N(2)–C(12)–C(14) and F(1)–N(2)–C(12)–C(13) are −161.8(2) and −40.9(3)°, respectively. Therefore, the fluorine is antiperiplanar with the cyclohexyl group. The dihedral angles F(1)–N(2)–S(3)–O(4) and F(1)–N(2)–S(3)–O(5) are 30.5(2) and 159.4(2)°, respectively. Consequently, the nitrogen lone pair seems to bisect the O(4)–S(3)–O(5) angle, probably due to optimal orbital overlap with the d-orbital of the sulfur atom. The nitrogen atom is at a distance of 0.449 Å from the least-squares plane defined by S(3), C(6), C(11), C(12) and the five-membered ring has an envelope conformation. As a result, the N–F bond of **3** is nearly perpendicular to the least-squares plane (85.8°).

This work was partially supported by a Grant-in-Aid for Scientific Research (No. 07807193) from the Ministry of Education, Science and Culture, Japan.

## Footnotes

† *Crystal data* for **1**: $C_{24}H_{33}NO_5S_2$, $M$ = 479.65, orthorhombic, $a$ = 14.344(2), $b$ = 22.415(2), $c$ = 7.608(3) Å, $U$ = 2446(1) Å$^3$, $T$ = 163 K, space group $P2_12_12$ (no. 18), filtered Cu-Kα radiation, λ = 1.54178 Å, $Z$ = 4, $D_c$ = 1.302 Mg m$^{-3}$, $F$(000) = 1024, colourless prism, dimensions 0.35 × 0.20 × 0.10 mm, μ(Cu-Kα) = 2.259 mm$^{-1}$, Rigaku AFC7R diffractometer, ω–2θ scan, 4.0 < 2θ < 130.0°, 2420 reflections measured, 1960 reflections observed [$I > 3\sigma(I)$]. The structure was solved by direct methods (SIR92[4]) and expanded using Fourier techniques (DIRDIF94[5]). The camphor moiety [C(24)–C(33), O(26)] was disordered over three positions with a 43 : 29 : 28 distribution. All non-hydrogen atoms were refined anisotropically except those of the disordered group that were refined as a rigid group isotropically. For this reason, the $R$ value was slightly high. Hydrogen atoms were included but not refined, except those located with the disordered group and the C(23) atom attached to the disordered group, which were ignored. Isotropic temperature factors of the H atoms were set equal to $U_{eq}$ of the bonded C atom. The final cycle of full-matrix least-squares refinement (for 221 parameters) was converged with $R_w$ = 0.099, $R$ = 0.067 (gof = 1.32). For **2**: $C_{14}H_{19}NO_2S$, $M$ = 265.37, tetragonal, $a$ = 8.963(1), $c$ = 34.080(2) Å, $U$ = 2737.7(8) Å$^3$, $T$ = 296 K, space group $P4_32_12$ (no. 96), filtered Cu-Kα radiation, λ = 1.54178 Å, $Z$ = 8, $D_c$ = 1.288 mg m$^{-3}$, $F$(000) = 1136, colourless prism with dimensions 0.40 × 0.40 × 0.10 mm, μ(Cu-Kα) = 2.052 mm$^{-1}$, an empirical absorption correction based on azimuthal scans of several reflections, transmission factors 0.6093–0.9952; Rigaku AFC7R diffractometer, ω–2θ scan, 4.0 < 2θ < 120.0°, 1314 reflections measured, 1137 reflections observed [$I > 3\sigma(I)$]. The structure was solved by direct methods (SIR92) and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined isotropically. The final cycle of full-matrix least-squares refinement (for 240 parameters) was converged with $R$w = 0.051, $R$ = 0.040 (gof = 0.96). S(3)–O(4) distance [1.431(3) Å] is slightly longer than S(3)–O(5) [1.420(3) Å], which can be ascribed to the intermolecular hydrogen bonding between NH and O(4) [N(2)···O(4) 2.955(3) Å]. For **3**: $C_{14}H_{18}FNO_2S$, $M$ = 283.36, orthorhombic, $a$ = 12.704(3), $b$ = 13.518(4), $c$ = 8.263(4) Å, $U$ = 1419.0(6) Å$^3$, $T$ = 152 K, space group $P2_12_12_1$ (no. 19), graphite monochromated Mo-Kα radiation, λ = 0.71069 Å, $Z$ = 4, $D_c$ = 1.326 mg m$^{-3}$, $F$(000) = 600, colourless prism with dimensions 0.32 × 0.23 × 0.17 mm, μ(Mo-Kα) = 0.237 mm$^{-1}$, Rigaku AFC7R diffractometer, ω–2θ scan, 4.0 < 2θ < 55.0°, 1900 reflections measured, 1502 reflections observed [$I > 3\sigma(I)$]. The structure was solved by direct methods (SHELXS86[6]) and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined isotropically. The final cycle of full-matrix least-squares refinement (for 244 parameters) was converged with $R_w$ = 0.045, $R$ = 0.034 (gof = 1.12). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Synthesis of three novel supercharged β,γ-methylene analogues of adenosine triphosphate

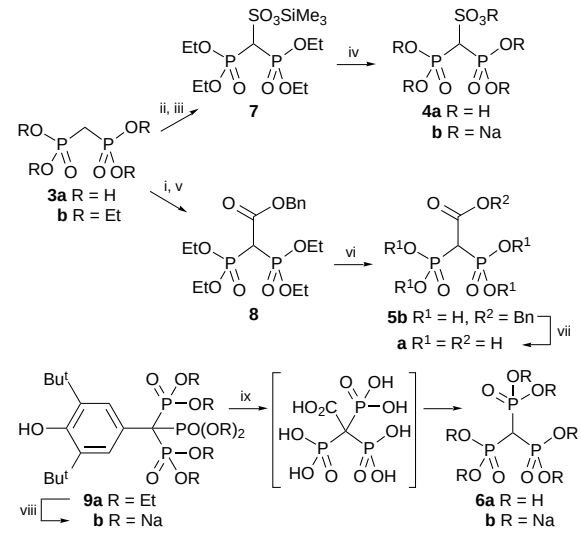
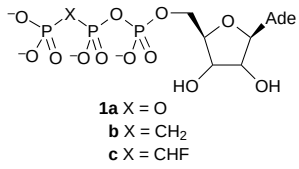
**Xiaohai Liu, Xiu-Rong Zhang and G. Michael Blackburn***

*Krebs Institute, Department of Chemistry, University of Sheffield, Brook Hill, Sheffield, UK S3 7HF*

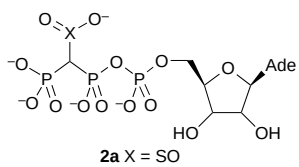


**Three derivatives of methylenebisphosphonic acid containing an additional ionisable acidic function are incorporated into β,γ-bridged derivatives of adenosine triphosphate to give the first examples of supercharged nucleotide analogues 2a–c.**

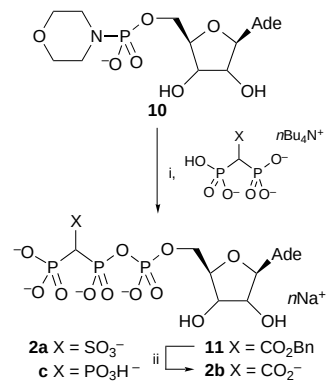
Adenosine triphosphate **1a** has multiple roles in cellular chemistry, among which its function as an energy source is predominant. However, a large variety of intra- and extracellular purinoceptors for adenine nucleotides is currently under intensive investigation and their affinities for nucleotides based on charge and metal ion-binding discrimination is likely to be of critical importance.[1] Also, the known higher affinity (*ca.* 1000-fold) of adenylate kinase for diadenosine 5′,5‴-pentaphosphate ($K_d$ 40 nM) over the corresponding tetraphosphate[2] ($K_d$ 20 μM) can be identified as arising from charge selectivity since the closed form of this enzyme has now been fully characterised in its stable ternary complex with AMP and β,γ-imino-ATP, which embraces six negative charges on phosphates in the reactive site without elongation of the polyphosphate structure.[3]



In previous studies, we have emphasised the significance of generating nucleotide analogues that are both isosteric and isopolar in character[4] with especial emphasis on the use of α-fluorophosphonates to ensure full ionisation of the phosphonate moiety.[5] We here describe supercharged analogues of nucleotides in which additional negative charge is provided without elongation of the polyphosphate chain. Such analogues **2** can be constructed by substituting the β,γ-methylene bridge of AMPPCP **1b** with an anionic function, *e.g.* $SO_3^-$, $CO_2^-$, or $PO_3H^-$. Such analogues will be especially important in the construction of bisubstrate analogues for kinases and related enzymes[2,6] where additional anionic charge cannot be accommodated within the phosphonate framework of simple isopolar nucleotide analogues.



The preparation of such supercharged analogues of ATP and other nucleotides calls for convenient syntheses of derivatives of methylenebisphosphonic acid **3a** having an additional acidic OH function. We have identified 1,1-bis(phosphono)-methanesulfonic acid **4a**, 2,2-bis(phosphono)acetic acid **5a** and the known[7] methanetrisphosphonic acid **6a** as suitable polyanion equivalents to be incorporated into analogues of ATP and other nucleotides by standard methods. We here report syntheses of the first two of these bisphosphonates and an improved synthesis of **6a** along with their condensation with AMP to give three new supercharged analogues of ATP **2a-c**.



1,1-Bis(phosphono)methanesulfonic acid **4a** was prepared by trimethylsilylation[8] of tetraethyl methylenebisphosphonate **3b** and treatment of its anion with trimethylsilyl chlorosulfate in THF at room temperature. Without further purification, the product **7** was treated with an excess of bromotrimethylsilane in $CH_2Cl_2$ in the presence of triethylamine and solvolysed in MeOH to give the pentakis(triethylammonium) salt of 1,1-bis-(phosphono)methanesulfonic acid in 83% yield. This was converted into the free acid by ion exchange chromatography (Dowex-50, $H^+$) (Scheme 1).

[a] NMR at 161.97 MHz (phosphorus) and 400 MHz (proton) in $D_2O$ at pH 7.8. [b] Positive ion FAB-MS data for pentasodium salt $[M + 5Na - 4H]^+$. [c] Ref. 5.

Tetraethyl lithiotrimethylsilylmethylenebisphosphonate (*v.s.*) was reacted with benzyl chloroformate in anhydrous THF to give tetraethyl benzyloxycarbonylmethylenebisphosphonate **8** (43% yield). Treatment of ester **8** with bromotrimethylsilane[9] and methanolysis generated the free phosphonic acid **5b**, which was debenzylated by hydrogenolysis of its cyclohexylamine salt (Pd/C–$H_2$–MeOH) to give the tris(cyclohexyl)ammonium salt of **5a** (Scheme 1).

Hexaethyl (3,5-di-*tert*-butyl-4-hydroxyphenyl)methanetrisphosphonate[10] **9a** was transesterified with excess bromotrimethylsilane in $CH_2Cl_2$, the solvent evaporated and the residue treated with aqueous sodium carbonate, and the pH adjusted to 11 with sodium hydroxide. The sodium salt **9b** was precipitated by addition of MeOH and added to a mixture of hydrogen peroxide (8%, 30 volume strength) in trifluoroacetic acid and the reaction mixture quenched with EtOH and concentrated *in vacuo* to give the hexasodium salt of methanetrisphosphonic acid **6b**. This was converted into the free acid **6a** by ion exchange (Dowex-50, $H^+$) in 28% overall yield. It proved identical in spectroscopic properties to that described by Gross.[7] Evidently, the intermediate 2,2,2-trisphosphonoethanoic acid decarboxylates spontaneously.

The supercharged ATP analogues **2a**–**c** were prepared by condensation of the appropriate *n*-butylammonium salts of the free acids **4a**, **5b** and **6a** with adenosine 5′-phosphoromorpholidate[11] **10**. The free acids **4a**, **5b** and **6a** were treated with tetrabutylammonium hydroxide to pH 8.9, and the resulting tetrabutylammonium salts lyophilised repeatedly from anhydrous pyridine. The resulting dry salts were each reacted with **10** in anhydrous pyridine at room temperature to give the three nucleotide analogues as their tetrabutylammonium salts, purified by DEAE Sephadex chromatography (triethylammonium hydrogen carbonate gradient, pH 7.8). Promotion by 10-camphorsulfonic acid proved very effective for these condensations. The resulting triethylammonium salt products were dissolved in MeOH, from which their sodium salts were precipitated by addition of sodium iodide in propanone to give β,γ-sulfonatomethylene adenosine 5′-triphosphate **2a** (80% yield), β,γ-benzyloxycarbonylmethylene adenosine 5′-triphosphate **11** (75% yield) and β,γ-phosphonomethylene adenosine 5′-triphosphate **2c** (25% yield) as their sodium salts. Catalytic hydrogenolysis (Pd–$BaSO_4$–$H_2$) of **11** removed the benzyl ester function to give β,γ-carboxymethylene adenosine 5′-triphosphate **2b** as its pentasodium salt (61% yield) (Scheme 2).

All three ATP analogues **2a**–**c** were fully characterised by reverse phase high performance liquid chromatography (HPLC), high resolution MS, and $^1$H and $^{31}$P NMR (Table 1). Their phosphorus NMR spectra show AMX spectra for **2a** and **2b** and an $AMX_2$ spectrum for **2c.** The magnitude of the $^2J_{\alpha\beta}$ coupling constants is typical of ATP and its analogues while that for $^2J_{\beta\gamma}$ shows some variation, as is seen for other β,γ-bridged ATP species[5] (Table 1). The two supercharged analogues **2a**,**b** are necessarily mixtures of epimers with respect to the chiral centre in the β,γ-bridge though they are not resolved by HPLC (C-18 reverse phase MeCN–MeOH). The difference between the epimers is manifest most clearly in the $^{31}$P chemical shift for $P_\alpha$ for sulfonic acid **2a** where the signals for $P_\alpha$ in the two isomers are separated by 0.03 ppm. For all of the other phosphorus resonances, this diastereoisomeric separation appears to be not significantly greater than the phosphorus NMR line width (approx. 0.01 ppm). The proton NMR of the adenosine moieties of **2a**–**c** were unexceptional, while the chemical shifts of the methine proton in the β,γ-bridge lie between those for AMPPCP and AMPPCHFP, directly reflecting the increasing electronegativity of the functions: $PO_3H^- < CO_2^- < SO_3^-$ (Table 1). Accordingly, we see a clear need to generate supercharged nucleotides with this methine proton replaced by fluorine and such syntheses are in progress.

The positive ion FAB-MS spectra show a homologous series of peaks of mass increment 22 and having correct accurate masses for $[M + xH^+ + yNa^+]$ where $(x + y = 1)$. The sulfonic acid **2a** showed three to six sodium ions, the carboxylic acid **2b** zero to five sodium ions, and the trisphosphonate **2c** from three to six sodium ions. These data clearly reflect the strong cation binding potential of these nucleotide analogues and data on metal ion and proton affinities will be described elsewhere.

The spectroscopic properties of β,γ-sulfonatomethylene adenosine 5′-triphosphate **2a** most closely approximate to those of β,γ-fluoromethylene adenosine 5′-triphosphate, while it has the added feature of an extra negative charge on the molecule. Syntheses of the corresponding analogues of ADP are in progress and the affinities of various enzymes and receptors for analogues **2a**–**c** are being determined.

We thank the BBSRC for financial support (ROPA/MOLO4558) and Mr Peter Ashton (Birmingham University) for determination of high resolution mass spectra.

# Reversibility of *S*-nitrosothiol formation

**Pablo Herves Beloso† and D. Lyn H. Williams***

*Chemistry Department, University Science Laboratories, South Road, Durham, UK DH1 3LE*

**The nitrosation of thiols is sufficiently reversible to allow, in many cases, the low thiol concentration present at equilibrium to reduce $Cu^{2+}$ and bring about loss of nitric oxide from *S*-nitrosothiols.**

It is now clear that the decomposition of *S*-nitrosothiols in an aqueous buffer to give nitric oxide and the disulfide is brought about by $Cu^{+}$, which in turn is generated by reduction of $Cu^{2+}$ by thiolate ion,[1] or in principle by any other reducing agent. In many cases there is enough free $Cu^{2+}$ present in the aqueous buffer solution for this reaction to take place. Reduction of $Cu^{2+}$ sources where the copper is bound to peptides and proteins also occurs, thus allowing the possibility that these reactions could occur *in vivo*.[2] Currently there is considerable interest in the chemistry/biochemistry of nitrosothiols, since (*a*) they are being examined as possible drugs to effect vasodilation and to reduce platelet aggregation,[3] and (*b*) they are now believed to play an important part in some of the physiological processes involving nitric oxide.[4]

There is a question as to where the thiolate ion comes from, and it has been suggested that enough is present as an impurity, deriving from the nitrosothiol synthesis, whereas it has also been suggested that some partial hydrolysis of the nitrosothiol occurs.[1] We have eliminated the first possibility as a general explanation, by working with solutions of nitrosothiols generated *in situ*, using a very large excess of nitrous acid, when we find that reaction often still occurs.[5] We therefore looked at the possibility that the *S*-nitrosation is a reversible process.

Nitrosation of alcohols is a well-known reversible process in acid solution, [eqn. (1)],[6] and equilibrium constants have been

$$ROH + HNO_2 = RONO + H_2O \quad (1)$$

determined for many alcohols. Some typical values are 3.5 and 1.2 $dm^3\ mol^{-1}$ for methanol and ethanol respectively.[7] A kinetic method for demonstrating this reversibility is by the presence of a positive intercept at [ROH] = 0, when the first-order rate constant ($k_{obs}$) is plotted against [ROH], when reactions are carried out with [ROH] $\gg$ [$HNO_2$]. Equilibrium constants determined in this way[8] are in reasonable agreement with those obtained from direct measurements.[7] Such plots for the nitrosation of thiols showed no measurable intercepts;[9] it was generally assumed by us that the reactions are effectively (*i.e.* from a preparative point of view) irreversible, and this has been rationalised in terms of the difference in nucleophilicities (S > O), important for the forward reaction, and the difference in basicities (O > S), important in the reverse reaction, since *O*- or *S*-protonation occurs. We examined this more carefully in the case of the nitrosation of thiomalic acid. The results are shown in Fig. 1, for reaction at two different acidities. It is clear that there is no measurable intercept at [RSH] = 0. Nevertheless we have analysed solutions of nitrosothiols for thiol content, using Ellman's reagent.[10] Calibration experiments revealed that we were able to measure thiol concentrations in the range $8 \times 10^{-6}$ to $5 \times 10^{-5}$ mol $dm^{-3}$ very readily, from measurements at 412 nm of the absorbance due to the dianion of 2-nitro-5-thiobenzoic acid. All of our calibration measurements gave values for the extinction coefficient at this wavelength which were within 3% of the literature value[10] (14 150 $dm^3\ mol^{-1}\ cm^{-1}$).

Results were obtained for the product of nitrosation of penicillamine ($6.6 \times 10^{-4}$ mol $dm^{-3}$), using stoichiometric ratios of [RSH]:[$HNO_2$] ranging from 1:1 to 1:2. The nitrosation reactions were carried out under mildly acid conditions (*ca*. 0.05 mol $dm^3$ $H^+$), where it is known that reaction is very fast. Analysis for thiol content was carried out at pH 7.27 as described in the literature.[10] At this pH no reactions associated with eqn. (2) will occur. The results are

$$RSH + HNO_2 = RSNO + H_2O \quad (2)$$

presented in Table 1 in the form of the % [RSH] present at the equilibrium position. All of these *S*-nitrosations are very rapid processes. It is clear that thiol remains in all of these solutions, in a quite significant concentration for the 1:1 solution, dropping as expected as we move to the 1:2 mixture. These figures (ignoring the final value, where the concentration is very low and therefore subject to a large uncertainty), give an approximate equilibrium constant (*K*) for eqn. (2) of $3 \times 10^5$ $dm^3\ mol^{-1}$.

Values of *K* of this magnitude would not lead to a measureable intercept for plots such as that shown in Fig. 1, so this kinetic method is obviously not sufficiently sensitive to measure equilibrium constants of this magnitude. We have shown that this is the general situation for the nitrosation of thiols, by determining the equilibrium thiol concentration in a number of other cases. For *S*-nitrosocysteine generated *in situ*, we find 7.8% thiol remains at equilibrium from a 1:1 ratio of reactants (corresponding to an approximate *K* value of $6 \times 10^5$ $dm^3\ mol^{-1}$). The thiol content drops significantly on standing (to a fifth of its value in 1 h), no doubt because of aerial oxidation. Similarly, the nitrosation of thiomalic acid gives

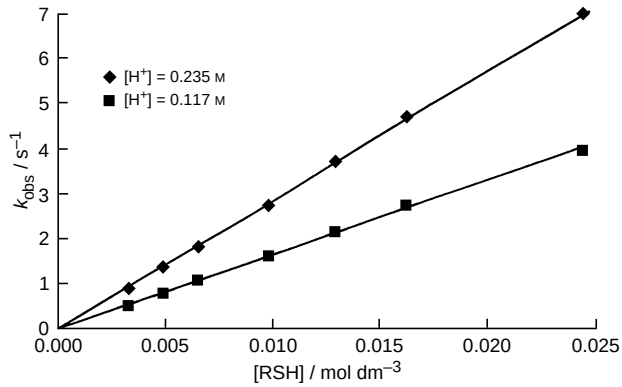

**Fig. 1** Plot of the first order rate constant ($k_{obs}$) *vs* [RSH] for the nitrosation of thiomalic acid by nitrous acid ($1 \times 10^{-4}$ mol $dm^{-3}$) at two different acidities

**Table 1** Percentage thiol remaining at equilibrium in the nitrosation of penicillamine ($6.7 \times 10^{-4}$ mol $dm^{-3}$)

| [RSH]:[$HNO_2$] | % RSH at equilibrium |
|---|---|
| 1:1 | 5.3 |
| 1:1.1 | 4.5 |
| 1:1.2 | 3.2 |
| 1:1.5 | 0.65 |
| 1:2 | 0.08 |

2.0% thiol at equilibrium from a 1 : 1 ratio of reactants, dropping to 0.11% for a 1 : 1.5 ratio, giving a $K$ value of *ca.* $3 \times 10^6$ $dm^3\ mol^{-1}$. Nitrosation of *N*-acetyl penicillamine gave 0.45% thiol from a 1 : 1 reactants ratio. It is not clear why this is so much smaller than that found for penicillamine. A fuller systematic study of the system is underway.

It follows that if *S*-nitrosation of thiols is significantly reversible in this way, then solutions of *S*-nitrosothiols, initially prepared in acid solution, will always contain a small thiol concentration. This will apply to solutions of nitrosothiols made up in any mildly acidic solution, but not presumably to solutions made up in basic solution. Solutions made up (directly in alkaline buffer) from two stable solid nitrosothiols, *S*-nitroso-*N*-acetyl penicillamine (SNAP) and *S*-nitrosoglutathione GSNO, analysed respectively for 0.78 and 0.80% thiol, probably derived from thiol impurity resulting from the incomplete *S*-nitrosation during synthesis. The difficulty in producing nitrosothiol samples totally free from thiol has been reported[11] in the case of GSNO.

Our results provide an explanation as to why reduction of $Cu^{2+}$ by thiolate (in solutions of *S*-nitrosothiols), eqn. (3),

$$2Cu^{2+} + 2RS^- = 2Cu^+ + RSSR \qquad (3)$$

occurs so readily in solutions where it would be expected that there would be no thiolate present. This applies whenever the *S*-nitrosothiol solution is prepared *in situ* from solutions of the thiol and nitrous acid, or in cases where mildly acidic solutions are first made up from solid samples.

We thank the Xunta de Galicia for a Research Training grant to P. H. B., and the EPSRC for a research grant for the purchase of a stopped flow spectrophotometer.

**In contrast to the nitrosyl derivative of iron(II) octaethylporphyrin [Fe(oep)(NO)], the isostructural octaethyltetraazaporphyrin complex [Fe(oetap)(NO)] exhibits fast ligand-promoted nitric oxide dissociation in the presence of pyridine and *N*-methylimidazole.**

Iron(II) nitric oxide complexes of phthalocyanines have been known for over 30 years.[1–3] Although they are closely related to intensively studied porphyrin compounds,[4] they are in general not well characterized and very little is known about their solution reaction chemistry because of their poor solubility. We have begun to systematically explore the reactivity of iron(II) porphyrin nitrosyls and now extend our studies to include soluble iron(II) octaethyltetraazaporphyrins, [Fe(oetap)].[5,6] Herein we describe: (*i*) the synthesis of the nitrosyl derivative of iron(II) octaethyltetraazaporphyrin [Fe(oetap)(NO)] and its characterization by IR, EPR, Mössbauer spectroscopies, electrochemistry and elemental analysis; (*ii*) the structure of [Fe(oetap)(NO)] as determined by single-crystal X-ray diffraction; (*iii*) the comparison of the spectroscopic properties of [Fe(oetap)(NO)] and [Fe(oep)(NO)]; and (*iv*) the markedly different dissociation kinetics of nitric oxide from these two compounds promoted by pyridine and *N*-methylimidazole. Together these results illustrate the effect of the macrocyclic ligand on the properties and reactivities of ferrous nitrosyl complexes.

The iron(II) nitrosyl complexes [Fe(oep)(NO)] and [Fe(oetap)(NO)] are readily prepared under reductive nitrosylation conditions by treating [FeLCl] with nitric oxide in the presence of excess methanol and 2,6-dimethylpyridine.[7]‡ Their characterisation data, Table 1, are typical for paramagnetic five-coordinate iron(II) nitrosyl complexes in which the nitric oxide ligand adopts a bent geometry and the electronic structure is best described as a delocalized {FeNO}$^7$ configuration.[8] The most pronounced difference between [Fe(oep)(NO)] and [Fe(oetap)(NO)] is the potential of the first oxidation couple, {FeNO}$^6$–{FeNO}$^7$, which increases by 350 mV for [Fe(oetap)(NO)], indicating the more electron-withdrawing nature of the nitrogen atoms for the tetraaza derivative compared to the CH units in [Fe(oep)(NO)]. In addition, the larger quadrupolar splitting observed in the Mössbauer spectrum as well as the unusually clear anisotropy and hyperfine coupling observed near $g$ = 2.00 for the low-temperature EPR spectra of [Fe(oetap)(NO)], is indicative of there being a larger ligand field in the [Fe(oetap)(NO)] complex. In the case of the $^{14}$NO derivative two triplets are observed and assigned in the EPR spectrum as $g_z$ = 2.000 with $a_z$ = 17.77 G, and $g_y$ = 2.029, $a_y$ = 16.03 G. The third signal, $g_x$, is presumably part of the low-field shoulder of the overall manifold. The EPR spectra of [Fe(oep)(NO)] and other five-coordinate nitrosyl adducts of iron(II) porphyrins, in general do not exhibit such clear anisotropic signals with well resolved hyperfine coupling in their low-temperature spectra.[9] The decreased core size for the oetap ligand is the best explanation for these macrocyclic effects. In order to rule out aggregation as the origin of these spectroscopic features spectra with tenfold greater and smaller concentrations were measured under identical conditions; the resulting spectra retain all of these features.

Direct support for the interpretation of these spectroscopic results is found in the single-crystal X-ray diffraction structure of [Fe(oetap)(NO)].§ Unlike other related disordered structures, the bent nitrosyl ligand in this complex adopts a single geometry, Fig. 1, with the nitrosyl oriented away from the four ethyl groups on the same face of the macrocycle. In spite of the smaller core size of the tetraazaporphyrin, the {FeNO}$^7$ fragment in this complex adopts a very typical geometry in terms of the Fe–N–O bond angle [143.7(4)°], the iron displacement from the macrocycle [0.308(1) Å], and the dihedral angle N(3)–Fe–N(9)–O(1) [39.6(6)°].[10]

Considering the similarity in the structural and spectroscopic features of [Fe(oetap)(NO)] and [Fe(oep)(NO)], it is surprising to find that nitric oxide dissociation from the former is four orders of magnitude faster when they are treated with coordinating ligands such as pyridine and *N*-methylimidazole, *cf.* Table 1, eqn. (1).

$$[\text{Fe(oetap)(NO)}] + 2\text{L} \rightarrow [\text{Fe(oetap)L}_2] + \text{NO} \qquad (1)$$

The products from these reactions [Fe(oetap)L$_2$][5,6] form isosbestically with the same kinetics in both the presence and absence of dioxygen. However, as shown in Fig. 2, nitric oxide

dissociation from [Fe(oetap)(NO)] exhibits saturation behaviour and at high concentrations of *N*-mim reaches a limiting maximum rate of 0.148 $s^{-1}$. These observations suggest a mechanism which involves rapid equilibrium binding of axial ligand to [Fe(oetap)(NO)] followed by a rate-determining loss of nitric oxide from the six-coordinate intermediate. Thus the observed rates under saturation conditions correspond to nitric oxide dissociation rates as was found for [Fe(obtpp)(NO)].

Nitric oxide is now recognized as an ubiquitous intercellular messenger whose predominant and most well characterized signal transduction pathway involves the up-regulation of soluble guanylate cyclase (sGC) by binding to its iron(II) haem centre.[11] The denitrosylative down-regulation of this key enzyme remains poorly understood, with simple nitric oxide dissociation being frequently discounted due to the generally observed slow rate.[12] Several cases where facile ligand-promoted loss of nitric oxide are now known[10,13] and the factors which control these fundamental transformations are under investigation. The isostructural pair of complexes in this study are significant in that although they have almost identical steric constraints on axial ligand binding, they exhibit dramatic differences in reactivity. These results are clearly directly due to the marked differences in electronic structures of these compounds as shown in their Mössbauer and EPR spectra. Although an exact determination of the electronic structures of these species will require exacting levels of theory, it is clear that coordination of axial ligands populates orbitals with net Fe–NO antibonding character. The challenge is to determine which factors, under direct control of the polypeptide–haem–NO interaction, can also increase the lability of nitric oxide when bound to haem proteins such as sGC.

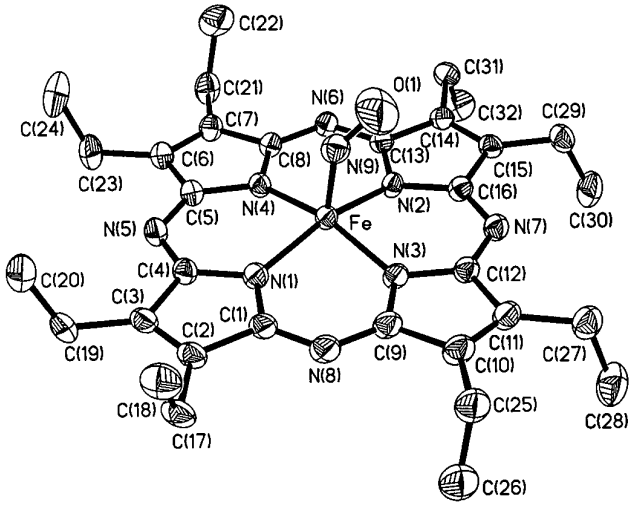

**Fig. 1** Molecular structure of [Fe(oetap)(NO)], with hydrogen atoms omitted for clarity. Important bond lengths (Å) and angles (°): Fe(1)–N(1–4) 1.922–1.941(3), Fe(1)–N(9) 1.721(4), N(9)–O(1) 1.155(5); Fe(1)–N(9)–O(1) 143.7(4).

# Alkene/alkane permselectivities of a carbon molecular sieve membrane

**Hiroyuki Suda* and Kenji Haraya**

*National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba 305, Japan*

**A carbon molecular sieve membrane, whose pore dimension is slightly changed upon mild activation, exhibits excellent permselectivities for alkene/alkane gas pairs.**

Separation of light alkenes/alkanes has been recognized to be a key technology in the petrochemical industry. Propene/propane is a representative example, since propene is an important petrochemical feedstock and useful in the production of many chemicals. Several methods including distillation, adsorption, absorption and membrane separation have been employed for separation of propene from propane.[1] Among them, membrane separation is expected to be superior to other methods, since it is an energy saving process. Up to now, membrane separation of propene from propane has been investigated mainly by using polymeric membranes.[2–4] However, the drawbacks are the relatively lower permselectivity and lack of thermal and chemical stabilities of the polymeric membranes. These have led to further trials to develop thermally and chemically stable inorganic membranes which exhibit a better separation performance for propene/propane.[5,6] One of the candidates is a carbon molecular sieve (CMS) membrane obtained by pyrolysis of a polymeric precursor. The CMS membrane has been extensively studied and shown to have high gas permselectivities, *i.e.* a molecular sieving effect.[7–11] In our previous papers,[12,13] CMS membranes prepared by pyrolysis of both flat and capillary Kapton polyimides had been reported to exhibit the highest gas permselectivities for inorganic gas pairs. Here, we report the excellent propene/propane permselectivity of a CMS membrane whose pore dimension has been slightly expanded.

The original CMS membrane was fabricated by pyrolysis of a Kapton polyimide film (Toray - Du pont Inc.) between graphite blocks at 1273 K for 2 h at a heating rate of 10 K $min^{-1}$ at $10^{-5}$ Torr.[12] The membrane thus obtained was revealed by chemical analysis and IR spectroscopy to consist of almost only carbon. The membrane is essentially X-ray amorphous and was considered to have a turbostratic structure,[14] in which layer-planes of graphite-like structures are dispersed in a non-crystalline material. Because the original membrane has pores of only *ca.* 3.7 Å which are too small for permeation of hydrocarbons such as propene, the membrane was further calcined under mild activation in order to slightly enlarge the pore dimension. The original membrane was heated to 673 K at a heating rate of 10 K $min^{-1}$ under flowing Ar ( > 99.99%, 100 ml $min^{-1}$), and then He ( > 99.995%, 100 ml $min^{-1}$) containing water vapour (*ca*. 20 mmHg). After 10 min the He was replaced by Ar and the sample allowed to cool to room temperature.

Pore size distributions were obtained from analysis of adsorption isotherms at 298 K of probe gas molecules with different kinetic diameters σ[15] ($CO_2$, $C_2H_6$, n-$C_4H_{10}$, i-$C_4H_{10}$) by application of the Dubinin–Astakhov equation [eqn. (1)],[16]

$$W = W_0 \exp[-A/E)^n], A = RT \ln(P_s/P) \quad (1)$$

where $W$ is the pore volume, $A$ is the adsorption potential, $P_s$ is the saturated vapour pressure, $P$ is the equilibrium vapour pressure, $E$ is the characteristic energy of adsorption, and $W_0$ is the limiting micropore volume whose pore size is assumed to be larger than the kinetic diameter of each adsorbate. The samples were degassed at 573 K for 2 h under vacuum prior to each adsorption measurement. The adsorption isotherms obtained for both the CMS membranes before and after the mild activation step revealed that the former adsorbed only the smallest $CO_2$ molecule (σ = 3.3 Å), whereas the latter adsorbed even the larger $C_2H_6$ molecule (σ = 3.9 Å). The results suggest that the mild activation step is effective for the gradual increase of pore dimensions. It was clear from the obtained pore size distributions that the average pore size increased from *ca.* 3.7 to 3.9 Å due to the mild activation step. Fig. 1 demonstrates that larger pores of 4.0–4.3 Å which were not present in the original membrane appear to exist in the modified one.

Permeabilities of selected single gases were measured at 308–373 K with a high-vacuum time-lag method. The permeabilities of inorganic gases for the original CMS membrane were of the order of kinetic gas diameters[15] except for $H_2$ (Fig. 2). The permselectivities measured at 308 K for the

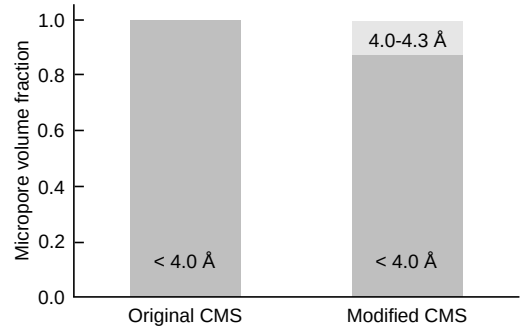

**Fig. 1** Change in micropore volume fraction of each pore size for the original and modified carbon molecular sieve (CMS) membranes

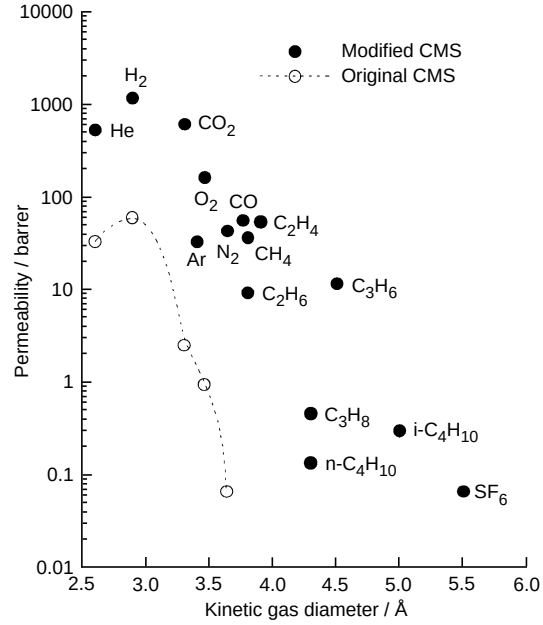

**Fig. 2** Permeabilities of selected gases for the original and modified CMS membranes measured at 373 K. Permeabilities are given in barrer, where 1 barrer = $1 \times 10^{-10}$ $cm^3$ (STP) cm $cm^{-2}$ $s^{-1}$ $(cmHg)^{-1}$.

membrane exceeded 1000 and 100 for $H_2$–$N_2$ and $CO_2$–$N_2$, respectively. These extremely high permselectivities, by which the membrane can discriminate between smaller and larger molecules, were a consequence of a pore dimension suitable for separation of such inorganic gas pairs.

The permeabilities for the modified CMS membrane were 10–700 times higher than those for the untreated membrane mainly due to the enlarged pore dimension. It was also shown from further permeation tests that there is an appreciable permeation of larger hydrocarbons. In particular, the permselectivities for light alkene/alkane gas pairs of the same carbon number were high. Permselectivities for propene/propane, for instance, were $>100$ at 308 K, much higher than previously reported values for polymeric membranes.[2–4] A rather high permselectivity of *ca.* 6 was also obtained at 308 K for ethene/ethane. These rather high permselectivities for the alkene/alkane gas pairs may arise from several factors including size effects, diffusivity and/or sorptivity, and the nature of surface functional groups that can be induced by the modification. A detailed study will now be undertaken on the permeation of hydrocarbons in modified CMS membranes to elucidate the factors leading to high permselectivities.

Considering the drawbacks of polymeric membranes (thermal and chemical instabilities *etc.*), the CMS membrane reported here activated under mild conditions is shown to be a promising candidate for alkene/alkane separation; other candidates for alkene/alkane separation are sol–gel derived inorganic membranes.[5,6] Silica membranes prepared by Asaeda *et al.*[5] exhibited permselectivities of 26 and 75 at 308 K for propene/propane single gas and gas mixtures, respectively, attributed to the selective adsorption of propene. However it appears to be difficult to prepare inorganic membranes which exhibit good propene/propane separation by the sol–gel method.[6]

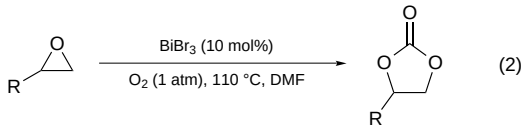
# $BiBr_3$-catalysed formation of cyclic carbonates from epoxides and DMF: a new oxidation reaction with molecular oxygen

**Véronique Le Boisselier, Michèle Postel and Elisabet Dunãch***

*Laboratoire de Chimie Moléculaire, U.R.A. 426 du C.N.R.S., Université de Nice-Sophia Antipolis, Parc Valrose, 06108 Nice Cedex 2, France*

**Cyclic carbonates are obtained in good yields from terminal epoxides and DMF in a $BiBr_3$-catalysed reaction with molecular oxygen as the oxidant.**

In the course of our ongoing research on the use of bismuth(III) derivatives as catalysts in oxidation reactions,[1] we have recently found a new $BiBr_3$-catalysed reaction which provides cyclic carbonates from terminal epoxides and DMF. Cyclic carbonates present interesting applications as polar aprotic solvents and as synthetic intermediates in organic synthesis,[2] and they are also important precursors to polycarbonates and other polymeric materials.[3]



The synthesis of cyclic carbonates from epoxides is generally carried out with carbon dioxide, and various catalysts have been reported for this reaction.[4] To the best of our knowledge, no example in the literature reports the formation of carbonates from epoxides, DMF and $O_2$. Moreover, there has been no report of the use of $BiBr_3$ as the catalyst in oxidation reactions.

We have recently explored new possibilities for $Bi^{III}$ catalysis in the oxidation of epoxides[5] and α-ketols[6] to carboxylic acids by molecular oxygen. With $Bi^{III}$ mandelate[7] as the catalyst in $Me_2SO$, a C–C bond cleavage occurs on the oxirane ring or on the ketol, the carboxylic acids being obtained in 40–65% yield. When $BiBr_3$ was taken as the catalyst (10 mol%) for the oxidation of epoxides in $Me_2SO$ under $O_2$ (1 atm), the corresponding carboxylic acids were also formed. Thus, the reaction of styrene oxide led to benzoic acid in 46% yield [eqn. (1)].

(1)

Interestingly, when the same reaction was carried out in DMF, no oxidative C–C bond cleavage occurred and no carboxylic acid was obtained. The reaction selectively led to the formation of the cyclic carbonate 4-phenyl-1,3-dioxolan-2-one in 56% yield [eqn. (2)]. Thus, the nature of the solvent strongly

(2)

influences the reaction pathway, determining the nature of the reaction products.

The formation of cyclic carbonates from epoxides in DMF–$O_2$ catalysed by $BiBr_3$ appears to be specific to this catalytic system. Thus, when the experiment was carried out with 1,2-epoxydecane as the model epoxide, the corresponding cyclic carbonate was obtained in 70% yield. In the absence of the catalyst, no carbonate was formed. The replacement of $BiBr_3$ by $BiCl_3$ did not afford any carbonate, but led to the synthesis of 2-chloro alcohols (as a mixture of isomers) in 62% yield when 30 mol% $BiCl_3$ was used. It is worth noting that the corresponding bromo alcohols were not isolated in the analogous reaction with $BiBr_3$. Moreover, when $Bi^{III}$ mandelate was used as the catalyst in DMF, no reaction occurred, and the epoxide was quantitatively recovered. The reaction of the epoxide with $CO_2$ catalysed by $BiBr_3$ in refluxing THF did not give any carbonate.

When the reaction of 1,2-epoxydecane in DMF catalysed by $BiBr_3$ was carried out under an inert atmosphere ($N_2$), no carbonate was formed, although some polymerisation of the epoxide occurred. Thus, the presence of molecular oxygen is essential for carbonate formation. The consumption of $O_2$ during the reaction was measured, and reached 1.1 moles of $O_2$ per mole of epoxide at complete conversion (6 h reaction at 110 °C).

A series of epoxides were reacted in DMF under molecular oxygen (1 atm) at 110 °C, with a 10 mol% of $BiBr_3$ [eqn. (2)]. The results concerning the cyclic carbonate formation are presented in Table 1. The reactions were clean and selective, the only isolated products being the cyclic carbonates, the remaining by-products being attributed to epoxide polymerisation.

Aliphatic as well as aromatic terminal epoxides (entries 1–3) afforded the corresponding cyclic carbonates in good yields. An *o*-chlorine substituent on the aromatic ring (entry 4) was compatible with the reaction conditions, although it slowed the reaction rate, probably due to steric hindrance. Benzylic epoxides (entries 5, 6) and epibromohydrin (entry 7) led to the corresponding cyclic carbonates without elimination. No additional intramolecular cyclisation or double bond modification was observed in the reaction of 7,8-epoxyoct-1-ene (entry 8), indicating that carbonate formation does not involve radical intermediates. Several disubstituted epoxides were also tested

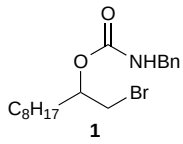


**Table 1** Oxidation of terminal epoxides to cyclic carbonates[a]

| Entry | R | Reaction time/h | Isolated yield of carbonate (%) |
|---|---|---|---|
| 1 | Ph | 7.5 | 56 |
| 2 | $C_8H_{17}$ | 6 | 70 |
| 3 | $C_6H_{13}$ | 8 | 64 |
| 4 | *o*-$ClC_6H_4$ | 31 | 68 (conversion 88%) |
| 5 | $PhOCH_2$ | 24 | 76 |
| 6 | *p*-$OMeC_6H_4OCH_2$ | 30 | 23 |
| 7 | $BrCH_2$ | 7 | 64 |
| 8 | $CH_2{=}CHC_4H_8$ | 31 | 32 (conversion 93%) |

[a] General reaction conditions: anhydrous DMF (5 ml) was stirred in the presence of $BiBr_3$ (134 mg, 0.3 mmol) at 110 °C for 30 min under molecular oxygen (1 atm), followed by the addition of the epoxide (3 mmol). The reaction was followed by GC until complete conversion of the substrate (unless stated). Acidic hydrolysis with aqueous 0.1 M HCl, diethyl ether extraction, drying of the organic layers with $MgSO_4$ and solvent evaporation led to the cyclic cabonates in the yields shown. The products were analysed by GC, $^1H$, $^{13}C$ NMR and mass spectroscopy, and their spectral data compared with those of authentic samples.

but did not afford cyclic carbonates under the same conditions. *trans*-5,6-Epoxydecane led to decane-5,6-dione in 56% yield.

The reaction presumably involves an epoxide ring opening with the incorporation and oxidation of the carbonyl moiety of DMF, the oxidant being $O_2$. 1,2-Diketones are not intermediates in this reaction; the reaction of hexane-3,4-dione did not afford any carbonate. In order to quench the amine residue eliminated from DMF, an equivalent amount of benzoyl chloride was added after the reaction with 1,2-epoxydecane. However, no *N*,*N*-dimethylbenzamide was isolated. In a different experiment, the reaction was carried out in *N*-benzylformamide. The epoxide consumption was slow (72 h) and no cyclic carbonate was formed. We could however isolate the carbamate **1**, arising from the oxidation of the benzylamine residue.†

**1**

Compound **1**, formed in 40% yield and purified by column chromatography, clearly establishes the epoxide–formamide coupling and the oxidation of the formamide group. The presence of a bromide on the less hindered side of the starting epoxide also shows the role of the catalyst in the initial oxirane ring opening. We can assume that an analogue of **1** is likely to be the intermediate in the carbonate formation in DMF. The reaction would be followed by oxygen transfer to the carbamate and ring closure with bromide elimination.

V. L. B. is grateful to the French MESR for a research grant.

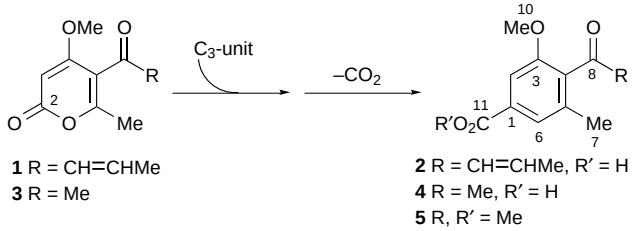
# Biosynthesis of macrophomic acid: plausible involvement of intermolecular Diels–Alder reaction

**Hideaki Oikawa,* Kenji Yagi, Kenji Watanabe, Mamoru Honma and Akitami Ichihara***

*Department of Bioscience and Chemistry, Faculty of Agriculture, Hokkaido University, Sapporo 060, Japan*



**The biosynthetic precursor of the fungal metabolite macrophomic acid 4 from *Macrophoma commelinae* has been studied by feeding experiments and enzymatic conversion from the pyrone 3 to 4 in a cell-free system. Based on the experimental data, a biosynthetic pathway for 4 involving an unprecedented intermolecular Diels–Alder reaction is proposed.**

In 1979 phytotoxin pyrenocine A **1**[1,2] was isolated from *Pyrenochaeta terrestris* by our group, and soon afterwards the structurally related pyrenochaetic acid A **2**[3] was also found from the same fungus. In spite of their striking structural similarity, we were unable to examine their biosynthetic origins due to their scarcity in the culture extracts. Later, Sakurai *et al*. reported that the fungus *Macrophoma commelinae* can convert pyrone **3** to macrophomic acid **4** (Scheme 1).[4,5] To our surprise, this fungus also converted **1** to **2** and its related analogues found in *P. terrestris*. Our continued interest in the biosyntheses of pyrenocines and pyrenochaetic acids prompted us to examine the unusual aromatic ring formation in *M. commelinae*.

Although Sakurai *et al*. established that the whole pyrone skeleton of **3** was directly transformed into benzoic acids with the loss of the C-2 carbon as $CO_2$, the origin of the $C_3$-unit of **4** remained to be established.[4,5] In order to answer this question, we employed several incorporation experiments. Administration of $^{13}C$- or $^{2}H$-labelled precursors to *M. commelinae*, followed by diazomethane treatment of the extracts, afforded methyl ester **5** which was examined by either $^{13}C$ or $^{2}H$ NMR analysis.

When [1-$^{13}$C]-L-serine was administered, an enhancement of the C-11 signal in the $^{13}C$ NMR spectrum of **5** formed in this experiment was observed. Normalization of the enhanced peak indicates an enrichment of 3.4 atom%. Similarly, after administration of [1-$^{13}$C]-L-alanine, high enrichment (6.3 atom%) at C-1 was observed. Since pyruvate is also incorporated without the loss of the C-1 carbon,[5] these data indicate that serine, alanine and pyruvate are converted to a common intermediate which is directly incorporated into **4**.

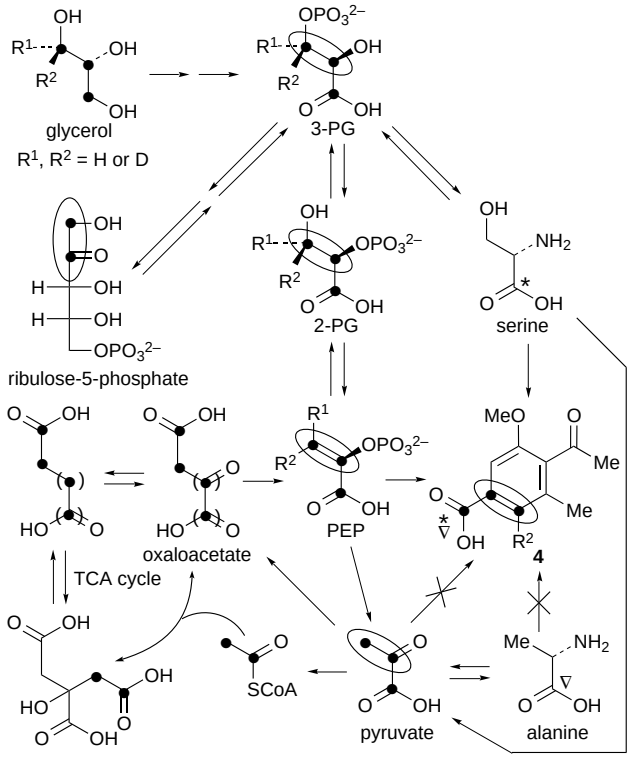
Next, a feeding experiment with [U-$^{13}$C]glycerol was conducted. In the $^{13}C$ NMR spectrum of the methyl ester **5** from the feeding experiment, two doublets at δ 166.5 (C-11, *J* 74.5 Hz) and 124.3 (C-6, *J* 60.3 Hz), and a doublet of doublets at δ 131.3 (C-1, *J* 74.5, 60.3 Hz) were observed. Both the splitting and the enrichment of the resonance show that incorporation of the labels, after the cycling of the $C_3$-unit through the tricarboxylic acid (TCA) and pentose-phosphate (PP) cycles, occurs at significant levels (Table 1). The observed coupling of the C-1 signal establishes the intact incorporation of glycerol.

**Scheme 1**

Administration of (1*RS*, 2*S*)- and (1*RS*, 2*R*)-[1-$^{2}$H]glycerols prepared from 1,2;5,6-di-*O*-isopropylidene-D-mannitol[6,7] to *M. commelinae* was then investigated. As expected, only one signal, assigned to 6-H, was observed at δ 7.36 in the spectra of **5** from both experiments. Enrichment of (2*R*)-[$^{2}$H]-glycerol was estimated to be 3.7%. On the other hand, negligible enrichment of $^{2}H$ (0.23%) was found in the case of (2*S*)-[$^{2}$H]glycerol. The results are explained by the intermediacy of the $C_3$-unit as a (2*R*)-3-phosphoglycerate (3-PG) derivative.

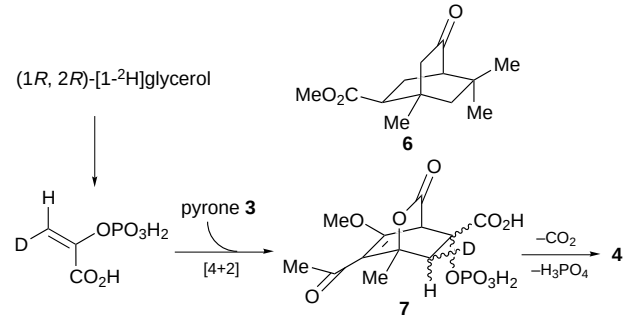
In order to obtain information on the origin of the hydrogen atom at C-6, feeding experiments with specifically $^{2}H$-labelled (1*R*, 2*R*)-[1-$^{2}$H]glycerol (58% ee) and (1*S*, 2*R*)-[1-$^{2}$H]glycerol (59% ee)† were conducted. Analysis of **5** formed in these experiments showed that the $^{2}H$-label at C-6 was retained at a 5.5 times higher level in the case of (1*R*, 2*R*)-glycerol compared with (1*S*, 2*R*)-glycerol. The observed selective labelling indicates that the C–C bond formation between the pyrone **3** and the $C_3$-unit is stereoselective, and that the pathway involves an intermediate which has diastereotopic methylene protons.

Intact incorporation of [U-$^{13}$C]glycerol and retention of the 1-$^{13}C$ label in the feeding experiments of L-serine and L-alanine exclude the possibility that TCA intermediates, *i.e.* oxaloacetate, directly convert into **4**. Among the other possible sources of the $C_3$-precursor, the observed results in the feeding experiment with specifically $^{2}H$-labelled glycerols exclude the possibility of the involvement of pyruvate and alanine as the $C_3$-unit. Experimental evidence in this study leaves the most obvious candidate, PEP, as an intact substrate in the novel aromatic ring formation. Since the previous study suggested that PEP was not incorporated into **4**,[5] we initiated a cell-free study. Using **3** and PEP as substrates, enzymatic formation of **4** in the cell-free system was found.‡§ This finding established that macrophomic acid **4** is formed from the pyrone **3** and PEP by the specific enzyme(s).



For the biosynthesis of macrophomic acid, Sakurai *et al*. proposed an anion-based condensation of **3** and PEP.[5] On the basis of our experimental data, we propose an alternative pathway for the conversion of **3** to **4**, as shown in Scheme 3. In this pathway, an intermolecular inverse-electron-demand Diels–Alder reaction of the pyrone **3** and the dienophile

**Table 1** Incorporation of $^{13}C$- or $^{2}H$-labelled precursors into **5** in *M. commelinae* in the presence of the pyrone **3**



| | | Enrichment | | |
|---|---|---|---|---|
| Entry | Precursor | C-6 | C-1 | C-11 |
| 1 | [1-$^{13}$C]-L-alanine | | | 3.4 |
| 2 | [1-$^{13}$C]-L-serine | | | 6.3 |
| 3 | [U-$^{13}$C]glycerol | 1.9 | 1.6[a] (1.0, 1.9)[b] | 2.9 |
| 4 | (1*RS*, 2*R*)-[1-$^{2}$H]glycerol | 3.7 | | |
| 5 | (1*RS*, 2*S*)-[1-$^{2}$H]glycerol | 0.23 | | |
| 6 | (1*R*, 2*R*)-[1-$^{2}$H]glycerol | 34 | | |
| 7 | (1*S*, 2*R*)-[1-$^{2}$H]glycerol | 7.1 | | |

[a] Enrichment for doublet of doublets. [b] Enrichments for two doublets.

intermediate PEP affords a plausible adduct **7** which is transformed into **4** by successive retro-Diels–Alder reaction and *syn*-elimination of phosphoric acid. Compared with the hypothesis of Sakurai *et al*., our pathway significantly simplifies this unusual conversion. The results in the feeding experiments with (1*R*, 2*R*)- and (1*S*, 2*R*)-[1-$^2$H]glycerols are consistent with the selective retention of $^2$H at C-6 in **5** *via* [3-$^2$H]-PEP. Interestingly, pyrenochaetic acid A **2** was chemically synthesized from pyrenocine A **1** *via* the plausible biomimetic route.[8]

**Scheme 2**

**Scheme 3**

To test this mechanism, the bicyclic compound **6**[9] which mimicked the plausible intermediate **7**, was synthesized. As expected, the intermediate analogue **6** inhibited the enzymatic conversion of **3** (10 μM) and PEP (100 μM) to **4**. The $IC_{50}$ of **6** was determined to be 200 μM. This observation lends further support to our hypothesis, although the anion-based condensation is not rigorously excluded.

Currently, we are working on purifying the enzyme responsible for this unusual biological transformation.

We are grateful to Mr Watanabe and Mrs Fukushi in our department for the acquisition of mass spectra. This work was supported by a Grant-in-Aid from the Ministry of Education, Science, and Culture of Japan.

## Footnotes

† The stereospecifically labelled glycerols were synthesized by Sharpless asymmetric dihydroxylation of deuterium-labelled allyl benzyl ethers. Details will be reported elsewhere.

‡ The crude enzyme was prepared as follows. The mycelium of *M. commelinae* IFO 9570 was cultured under shaking as described by Sakurai *et al*. During preincubation for induction of the desired enzyme, mycelia were collected by filtration and suspended in 50 mM potassium phosphate (0.45% NaCl, pH 7.2) containing a 100 mM DMF solution of pyrone **3** (final concentration 1 mM). This was further incubated under shaking for 3 h. The mycelia were collected by filtration and suspended in the same buffer. The mixture was homogenized with a mortar and pestle. Cell debris was removed by centrifugation (1.207 g, 15 min) and the supernatant was used as a crude enzyme.

§ Reactions were carried out at 30 °C for 4 h in mixtures containing the crude enzyme (1 ml), the pyrone **3** in DMF (10 μl, final concentration 100 μM) and phosphoenolpyruvate in $H_2O$ (10 μl, final concentration 100 μM) in a total volume of 1.02 ml. Denatured enzyme (100 °C, 10 min) was used as a control. HPLC analysis of reaction products was performed with an ODS column (Wakosil-II 5C18, MeCN–$H_2O$, 3 : 2, 1 ml min$^{-1}$, UV 250 nm). Product formation was quantified *via* calibration with a standard. After 4 h, **3** and PEP were completely converted into **4**.

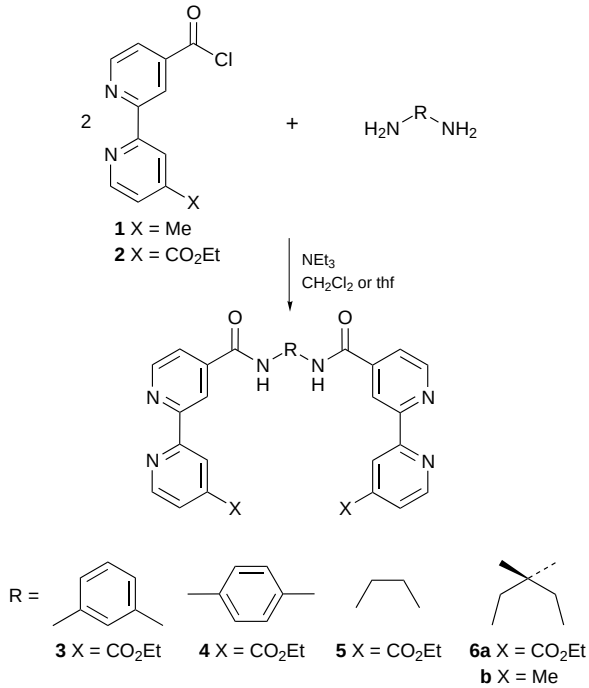
# Novel anion binding selectivity trends exhibited by new dinuclear rhenium(I), ruthenium(II) and osmium(II) bipyridyl cleft-type receptors

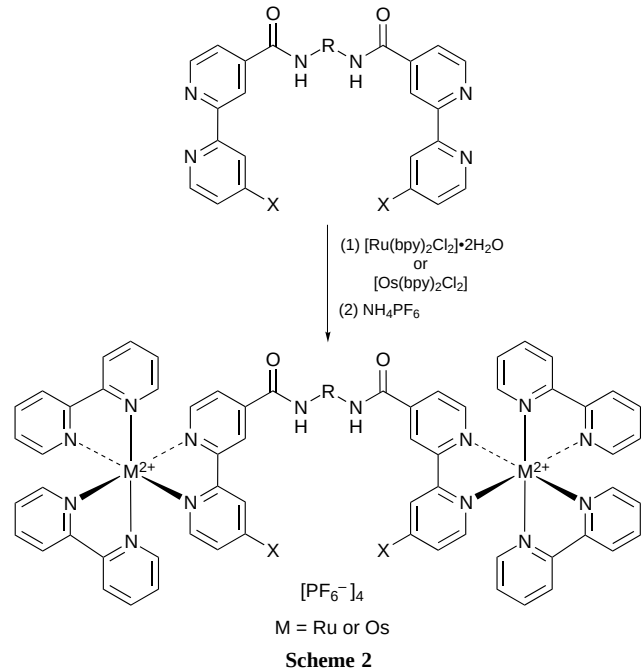
**Paul D. Beer,*[a]† Simon W. Dent,[a] Gerald S. Hobbs[a] and Trevor J. Wear[b]**

[a] *Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR*
[b] *Kodak Ltd, Headstone Drive, Harrow, Middlesex, UK HA1 4TY*



**Novel dinuclear rhenium(I), ruthenium(II) and osmium(II) bipyridyl cleft-type receptor systems exhibit remarkable selectivity for dihydrogenphosphate over halide anions dictated by the nature of the bridging linkage and the transition-metal Lewis-acidic centre.**

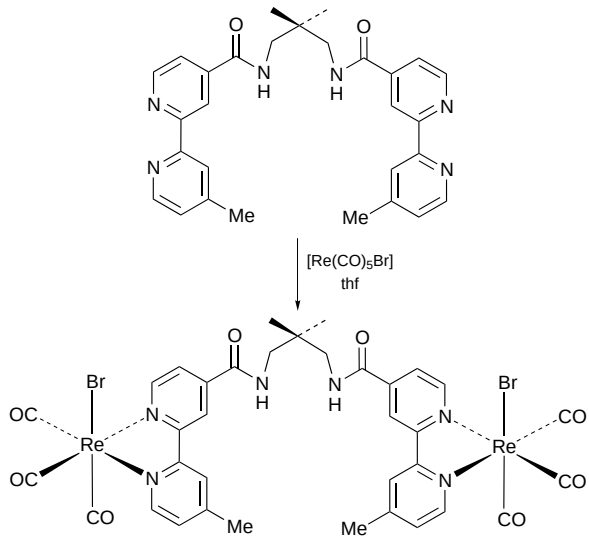
Anions are of crucial importance in many essential chemical and biochemical processes and therefore their binding and recognition is presently the subject of intensive research.[1] To date, a number of research groups have designed and synthesised anion binding reagents that use either favourable hydrogen-bonding interactions alone,[2,3] or hydrogen-bonding interactions in conjunction with electrostatic forces[4–6] to coordinate and, in some instances, sense anions. Examples of the latter which have been particularly successful in this respect are amide containing cobaltocenium[7,8] and ruthenium(II) polypyridyl molecules.[9–11] In an effort to enhance selective anion recognition through the design of new cooperative polymetallic Lewis-acidic systems, we report here the synthesis of novel dinuclear transition-metal bipyridyl, cleft-type receptors whose remarkable selectivity for the dihydrogenphosphate anion over halide anions is profoundly influenced by the nature of the bridging linkage, and the electronic character of the transition-metal Lewis-acidic centre.



The reaction of 4-carboxy-4′-methyl-2,2′-bipyridine[12] or 4-carbonyl-4′-ethoxycarbonyl-2,2′-bipyridine[13] with thionyl chloride afforded the acid chlorides **1** and **2** respectively in quantitative yields. The condensation of 2 equiv. of **1** or **2** with 1 equiv. of diamine in dichloromethane solution afforded the new 'cleft'-type bipyridyl (bpy) ligands **3**–**6** in excellent yields (Scheme 1). The free ligands were chelated to the positively charged $[M(bpy)_2]^{2+}$ fragment (M = Ru, Os) unit by reaction with either 2 equiv. of *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$[14] or *cis*-$[Os(bpy)_2Cl_2]$[15] in ethanol–water–acetic acid. The mixed ruthenium–osmium receptor, Ru–**6b**–Os, was prepared by reaction of ligand **6b** with 1 equiv. of *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$, followed by 1 equiv. of *cis*-$[Os(bpy)_2Cl_2]$. The crude products were purified by column chromatography on Sephadex LH-20 and converted to the hexafluorophosphate salts with an excess of aqueous $NH_4PF_6$ (Scheme 2). The rhenium(I) receptor, Re–**6b**–Re, was prepared by reaction of the free ligand **6b** with 2 equiv. of $[Re(CO)_5Br]$ in thf and purified by recrystallisation from acetone–diethyl ether (Scheme 3).‡

Proton NMR titration experiments with $Cl^-$ and $H_2PO_4^-$ anions were carried out in $(CD_3)_2SO$ solution and revealed significant downfield shifts in the receptors' amide and 3,3′-bpy protons. For example, the amide protons of Ru–**6b**–Ru were perturbed by 0.93 ppm and the 3,3′-bpy protons by 0.84 ppm after the addition of an excess of tetrabutylammonium dihydrogenphosphate. In all cases the resulting titration curves (for example, Fig. 1) suggest complexes with a 1 : 1 receptor : anion stoichiometry are formed in solution. Stability constants were calculated from the titration data using the EQNMR computer program[16] and the values are presented in Table 1.§

Clearly the nature of the bridging linkage has a dramatic influence on the anion binding strength and selectivity these dinuclear cleft-type receptors display. Of particular note is the



**Scheme 1**

**Scheme 2**

remarkable increase in the magnitude of stability constant of $H_2PO_4^-$ that results from simply altering the linkage from *m*-phenylene Ru–**3**–Ru ($K$ = 55 M$^{-1}$) to *p*-phenylene Ru–**4**–Ru ($K$ = 4320 M$^{-1}$), with the halide stability constant values remaining virtually unchanged. In addition, whereas the ethyl-bridged receptor Ru–**5**–Ru forms an extremely weak complex with $H_2PO_4^-$ and is $Cl^-$ selective, the 2,2′-dimethyl-1,3-propane-bridged analogue, Ru–**6a**–Ru forms an extremely strong and selective complex with $H_2PO_4^-$. Comparing Ru–**6a**–Ru and Ru–**6b**–Ru, it is also of interest to note there is a significant 4′-bipyridyl substituent effect, with $H_2PO_4^-$ anions favouring the ester containing receptor and chloride the methyl containing one.

**Scheme 3**

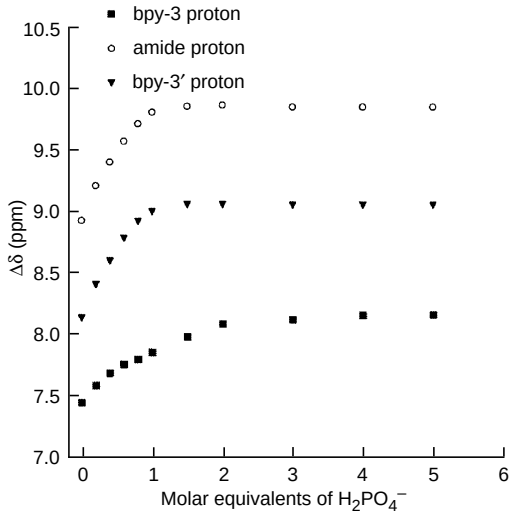


**Fig. 1** $^1$H NMR titration curve of Ru–**6b**–Ru with $NBu_4H_2PO_4$ in $(CD_3)_2SO$

**Table 1** Stability constant data for dinuclear cleft-anion receptors in $(CD_3)_2SO$

| Receptor | $K$ ($Cl^-$)[a,b]/ M$^{-1}$ | $K$ ($Br^-$)[a,b]/ M$^{-1}$ | $K$ ($H_2PO_4^-$)[a,b]/ M$^{-1}$ |
|---|---|---|---|
| Ru–**3**–Ru | 25 | 45 | 55 |
| Ru–**4**–Ru | 55 | 40 | 4320 |
| Ru–**5**–Ru | 70 | 60 | 10 |
| Ru–**6a**–Ru | 245 | 170 | 19700 |
| Re–**6b**–Re | 120 | —[c] | 1820 |
| Ru–**6b**–Ru | 310 | 220 | 15480 |
| Ru–**6b**–Os | 440 | —[c] | 22150 |
| Os–**6b**–Os | 825 | —[c] | > 30000 |

[a] Average for amide and bpy protons. [b] Errors estimated to be < 10%. [c] Not calculated.

Table 1 also demonstrates that the nature of the bipyridyl-coordinated transition-metal centre strikingly dictates the strength and degree of anion recognition selectivity. With both $H_2PO_4^-$ and $Cl^-$ anionic guest species the stability constants increase in magnitude in the order Re–**6b**–Re < Ru–**6b**–Ru < Ru–**6b**–Os < Os–**6b**–Os. From electrostatic considerations it is perhaps not surprising the neutral bis-rhenium(I) receptor forms the relatively weaker anion complexes. However, what is unexpected is the dramatic increase in magnitude of stability constant for the osmium-containing receptors, especially in respect to $H_2PO_4^-$ complexation. This observation suggests the $(bpy)_2Os^{2+}$ moiety is a particularly efficient Lewis-acidic centre to incorporate into this new cleft-type class of transition-metal bipyridyl amide anion receptor.

We thank Kodak Ltd for a studentship (S. W. D.) and Johnson Matthey for the generous loan of ruthenium and osmium salts.

# Design of an SHG-active crystal, 4-iodo-4′-nitrobiphenyl: the role of supramolecular synthons

**Jagarlapudi A. R. P. Sarma,*[a] Frank H. Allen,[b] Vanessa J. Hoy,[c] Judith A. K. Howard,[c] Ram Thaimattam,[d] Kumar Biradha[d] and Gautam R. Desiraju*[d]**

**The crystal structure of 4-iodo-4′-nitrobiphenyl has been determined with packing calculations and the presence of polar and parallel iodo···nitro supramolecular synthons leads to non-centrosymmetry and measurable SHG activity**

We have, in previous publications, described the identification of the I···O mediated, iodo···nitro supramolecular synthon **1** and its use in retrosynthetically guided supramolecular synthesis.[1–3] We conclude from this earlier work that: (*i*) synthon **1** is a polarisation-based structural unit; (*ii*) **1** is reasonably robust and as such it can be employed reliably in the design of new crystal structures. Here, we show that these ideas can be further extended to the design of an organic crystal with the property of second harmonic generation (SHG).

Synthon **1** can be used as a linear extender and so the ribbon structures of 4-iodonitrobenzene **2** and the 1 : 1 complex **3** of 1,4-diiodobenzene and 1,4-dinitrobenzene are not hard to anticipate.[1,2] However, these structures are centrosymmetric and therefore not viable for SHG applications. In **3**, the constituent molecules are themselves centrosymmetric, while in **2** the polar ribbon pattern is stacked in an antiparallel fashion leading to centrosymmetry. This is a general problem and our inability to control tertiary structural features, such as parallel *vs.* antiparallel stacking of polar structural units, is a major challenge in the practice of crystal engineering.

In order to design a non-centrosymmetric crystal, we decided to introduce the iodo and nitro substituents on a biphenyl framework and 4-iodo-4′-nitrobiphenyl **4** was prepared according to literature procedures.[4] While we were reasonably sure that **4** would yield a ribbon structure like **2** and **3**, a twisted and therefore chiral molecular conformation was further anticipated in view of the known structural chemistry of the biphenyls.[5] Finally, it was hoped that the (microscopic) molecular chirality of the twisted biphenyls units would lead to (macroscopic) crystal chirality.[6,7] There is some precedent for this, for in many classes of molecules, chiral sub-structural units (say helices) of the same handedness pack better than those of opposite handedness.[8] In any case, our optimism was furthered when we noted that crystals of **4** were obtained in the *F*-centred orthorhombic system, because the most common space group here, *Fdd*2 is non-centrosymmetric. Crystals of **4** seemingly suitable for X-ray diffraction analysis were obtained by recrystallisation. In fact crystals of two different morphologies were obtained; long needles from benzene and prisms from nitromethane. However, both forms have the same cell parameters and space groups and single-crystal data were collected.†

At this stage, a problem arose. The structure failed to solve despite all reasonable attempts and it was decided to attempt structure solution with packing energy calculations. The Cerius[2] program from molecular simulations was used.[9] The starting points were the experimental unit cell ($a$ = 8.06, $b$ = 18.812, $c$ = 14.364 Å) and the measured crystal density of 1.98 g cm$^{-3}$ which together indicate that $Z$ = 8. Accordingly, the more likely space group is *Fdd*2 with the molecules bisected by [001], the twofold direction. Molecular optimisation with MOPAC[10] (AM1 Hamiltonian) gave a non-planar conformation which was used in the crystal optimisation with the crystal packer module of the Cerius[2] program. The structure rapidly moved into an energy minimum. The molecule was free to rotate about [001] during the minimisation and no effort was made to refine the unit cell. The final structure of **4** is shown in Fig. 1 and the final simulated X-ray powder pattern agrees very well with the experimentally recorded pattern (Fig. 2). In retrospect, it appears that all the crystals chosen for single-crystal data collection were flawed. Even when the coordinates obtained by

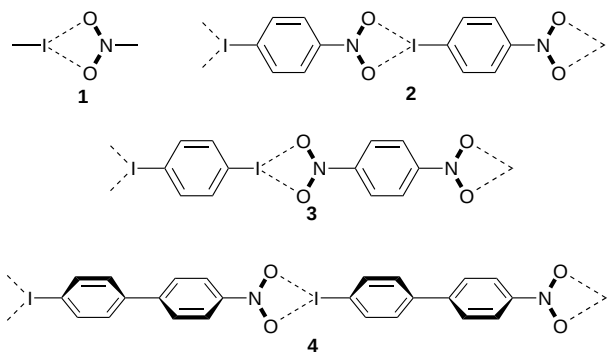

**Fig. 1** Stereoview of a molecular layer of 4-iodo-4′-nitrobiphenyl **4** as obtained by its crystal structure simulation. Notice the parallel arrangement of polar iodo···nitro synthons.

simulation were used in least-squares refinement, such refinements were unsatisfactory. The *R* values routinely fell to below 0.05, but the atomic displacement parameters were generally unacceptable. Alternative disordered or twinned structures in both *Fdd*2 and the alternative *Fddd* were considered but showed no improvement in the fit of the model to the data.

The appearance of the simulated diffraction pattern was found to depend on the assumed particle size along the three crystallographic directions and the value chosen were 300, 600 and 50 Å. These numbers were not picked at random but were obtained from an inspection of Fig. 1. The more numerous herringbone interactions along [100] and [010] were expected to lead to larger values of the particle size in these directions. Yet, the efficacy of the interactions (in effect, the growth rates) appear to be the same along either [100] or [010]. Therefore, noting the relative values of the *a* and *b* parameters, the particle size along [100] was taken, somewhat subjectively, to be half that along [010]. These considerations are important because it was found that the appearance of the spectrum is quite sensitive to the particle size chosen, though naturally the peak positions themselves do not change during these operations.

It may be noted from Fig. 1 that all the iodo···nitro synthons **1** in the structure of **4** are parallel, leading to macroscopic crystal polarity. Preliminary SHG measurements ($Nd^{3+}$/YAG laser, 1064 nm) indicate that crystalline **4** is SHG active. A higher initial activity falls rapidly because of material decomposition in the laser beam and the final activity is in the region of six times that of urea. More interestingly, the calculated molecular hyperpolarisability β is only $4.3 \times 10^{-36}$ esu. This observation hints that the crystal SHG has contributions also from the polarisation-based synthons, **1**. It is important to note that supramolecular synthons as defined previously,[3] not only have structural connotations but also are relevant to crystal properties. Many useful crystal properties are a consequence of molecular and supramolecular structure. It is therefore not surprising that supramolecular hyperpolarisability as manifested in synthons such as **1** is important and should be considered in studies of SHG materials.

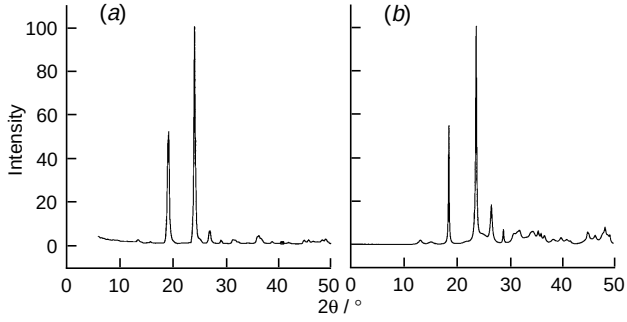

**Fig. 2** Experimental (*a*) and simulated (*b*) X-ray powder spectra of biphenyl **4**. These plots were obtained with the Cerius² program.

This study shows that: (*i*) the principles of supramolecular retrosynthesis may be combined with molecular engineering techniques to obtain non-centrosymmetric crystal structures; (*ii*) supramolecular synthons such as **1** are structural units that are also of relevance in determining the magnitude of SHG activity because they can contribute to supramolecular hyperpolarisability; (*iii*) the use of simulation software is a valuable alternative method of crystal structure determination when single-crystal X-ray diffraction methods prove problematic, and if partial crystallographic information, such as cell parameters and space group, is available.

We thank Molecular Simulations (Cambridge) for their support, Dr D. Narayana Rao and Dr A. Nangia for useful discussions and Mr. Y. Chandrasekhar for carrying out the SHG measurements. R. T. thanks UGC for financial assistance.

**The results of a series of physico-chemical experiments are presented which show that 4-(4-formylphenylethenyl)-1-methylpyridinium methanesulfonate, one example of a styrylpyridinium salt, undergoes a micellar type aggregation as a function of concentration in aqueous solution.**

The photosensitivity of the styrylpyridinium group was first reported by Williams and coworkers,[1,2] subsequently photoreactive styrylpyridinium salts have achieved widespread use in the production of photoresists for screen printing, since their use in this role was first patented by Ichimura and coworkers in 1988.[3,4] The reported mode of action of such salts is by an acid-catalysed aldol condensation reaction with the polymer poly(vinyl alcohol), and subsequently a photoinduced dimerisation, using UV light, of the attached pendant styrylpyridinium groups on adjacent polymer molecules.

Several papers have since been published[5–7] on various aspects of the fundamental photodimerisation reaction of styrylpyridinium, and related compounds, in solution and in the crystal form,[8,9] and of photodimerisation following the solubilisation of these compounds into micellar materials such as aerosol OT[10] but, as far as we are aware, nothing has been reported on the physico-chemical behaviour of such compounds in aqueous solution.

The structure of a molecule of the styrylpyridinium type is such that we considered that unusual aqueous solution behaviour might be expected, thus we report here a series of physico-chemical studies of one such compound, 4-(4-formylphenylethenyl)-1-methylpyridinium methylsulfonate, SbQ, in aqueous solution.

The sample of SbQ was kindly supplied by Sericol plc, purified by a recrystallisation procedure, with a quoted purity of better than 99.5% m/m, which was confirmed by the lack of a minimum in the observed surface tension data. Density measurements were made using previously reported techniques[11] and had a precision of $1 \times 10^{-4}$ kg m$^{-3}$; the microcalorimetric measurements, also using previously reported procedures,[12] had a precision of $1 \times 10^{-7}$ J. Surface tension measurements were undertaken using a drop profile measurement procedure, developed in this laboratory, with a precision of ±0.05 mN m$^{-1}$. Light-scattering measurements were made using a Sofica photogoniometer, model 42 000, modified to use a Uniphase 1 mW He–Ne laser, operating at 543 nm. Vapour-pressure measurements were made with a Knauer vapour-pressure osmometer, standardised against Analar NaCl solutions. Heats of dilution measurements were carried out using an LKB flow microcalorimeter, model 2107-121/127.

The vapour-pressure measurements, obtained at 37 °C, are presented in Fig. 1, where the ratio $\Delta t/c$ represents the difference in temperature between the solvent reference probe and the solution probe at a concentration $c$ in g kg$^{-1}$. The plot shows two linear regions, both with good correlation coefficients of 0.996 and 0.998, intersecting at a concentration value of 1.25% m/m. The intercept of the low range of solution concentrations was utilised in the usual manner to determine a value for the number average molar mass for SbQ of 341, close to the expected value of 335. The difference of slope at the higher concentrations suggests that, above the concentration of 1.25% m/m, some form of aggregation has occurred.

An analysis of the energy of the structure of the SbQ molecule, minimised in water, was performed, using a Hyperchem molecular modelling package, based on MM+ force-field calculations,[13] which produced a very planar structure. Such a structure for the molecule easily allows for the possibility of stacking of the molecules with the hydrophobic regions one above the other, with the aldehyde and NMe groups alternating, to produce an aggregate, shown energy minimised in water for four space-filled SbQ molecules in Fig. 2.

Taking the difference between the intercepts in Fig. 1 for the two concentration regions as being due to the aggregate, this yields a molar mass for the SbQ aggregate of about 2800, suggesting that the aggregate stack consists of about eight monomer units, with a critical concentration for the change of 1.25% m/m, close to 0.04 M

Surface tension measurements, as a function of concentration, for a series of solutions of SbQ, at 25 °C, are shown in Fig. 3; the pattern seen is the classic one for micellisation of a surfactant with the break occurring at about 0.06 M. This evidence therefore suggests that the SbQ aggregate is in fact a stacked rod-like micelle, with a c.m.c. value of 0.04 to 0.06 M, depending on the experimental measurement. The somewhat

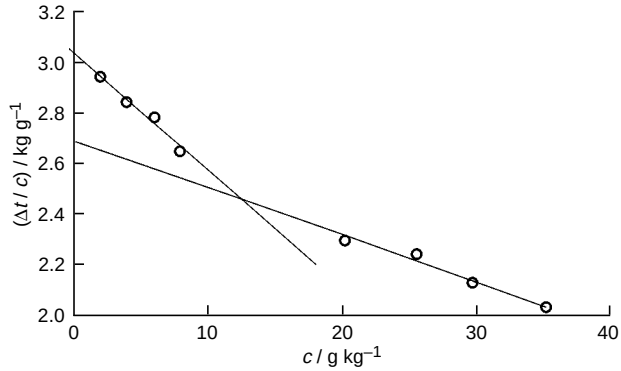

**Fig. 1** Vapour-pressure measurements on solutions of SbQ, at 37 °C, as a function of concentration

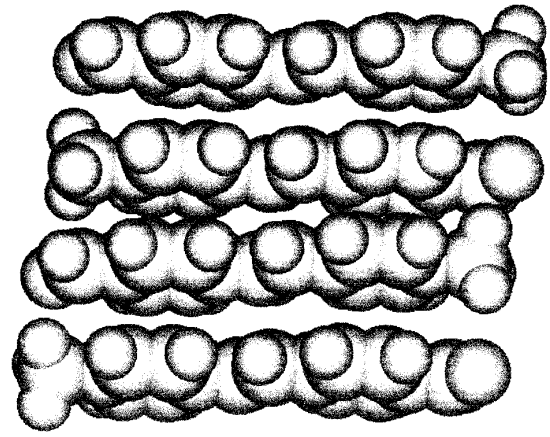

**Fig. 2** Energy-minimised structure of an SbQ aggregate in water

high equilibrium value of the surface tension, at 51 mN $m^{-1}$, is possibly due to the strongly hydrophilic groups present at each end of the molecule.[14]

Values of the apparent molar volume of the SbQ molecule, obtained from the density measurements at 25 °C, are also shown in Fig. 3; the sharp change of slope seen at 0.04 M means that the SbQ molecule adopts a more compact form above this concentration, exactly what might be expected to happen when aggregating to form a micelle. Such a change of slope at the c.m.c. of a surfactant has been reported by Perron *et al.*[15]

Values for the Rayleigh scattering at an angle of 90°, measured at a temperature of 25 °C, as function of concentration, are shown in Fig. 3; the sharp increase in scattering which occurs at concentrations approaching 0.04 M indicates the appearance of larger particles, the micelles in fact.

Heats of dilution measurements, at 25 °C, as a function of the initial concentration of the solution, Fig. 3, also show a sharp change of slope, in this case at 0.035 M, yet again indicating a major change in the solution state of the solute, from monomer to micelle[15] has occurred.

In conclusion, the close correlation between the concentration dependence behaviour of all the experimental measurements is good confirmation of the existence of a monomer–micelle equilibrium in the aqueous solutions of SbQ.

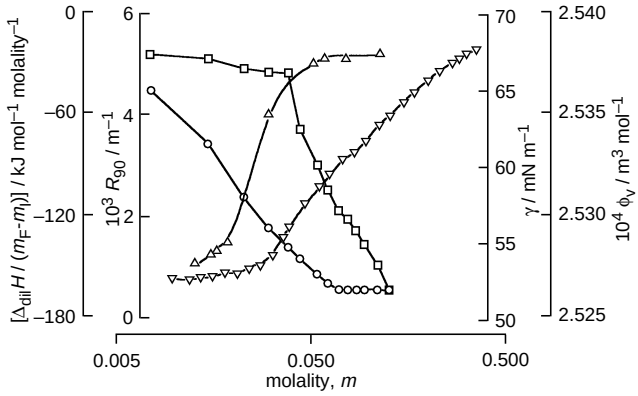

**Fig. 3** Surface tension measurements (○), apparent molar volume values (□), Raleigh scattering values at 90° (△) and heats of dilution (▽) of SbQ solutions at 25 °C, as a function of concentration

The SbQ molecule is one example of quite a large group of styrylpyridinium and styrylquinolinium compounds, all of similar structure; it is therefore very likely that, in general, compounds of this type will exhibit similar micellar behaviour. With regard to the broader implications of this behaviour, we are grateful to one of the referees for drawing our attention to the work of Tiddy *et al.*[16,17] who have reported what may be similar stacked aggregates in dilute aqueous solutions of azo and cyan dyes.

# Remarkable oxygen promotion of the selective reduction of nitric oxide by hydrogen over Au/NaY and Au/ZSM-5 zeolite catalysts

**Tarek M. Salama,† Ryuichiro Ohnishi and Masaru Ichikawa***

*Catalysis Research Center, Hokkaido University, Sapporo 060, Japan*

**A significant enhancement of the selective reduction of nitrogen oxide by $H_2$ is produced in the presence of oxygen over Au/NaY and Au/ZSM-5 catalysts by forming $NO_2$ and $N_2O_4$ intermediates, which are eventually reduced to $N_2$.**

More efficient engine performance would be desirable by using higher air–fuel ratios than those permitted by the 'window' required for conventional three-way catalysts.[1] Thus, there is much interest in the $O_2$-assisted reduction of nitric oxide by hydrocarbons such as methane and propane on Cu/ZSM-5[2] and Pt, Co, Ni and Fe exchanged ZSM-5;[3] however, synergism effected by added oxygen in NO decomposition and reduction with hydrocarbons has not been observed. Although gold has been recognized to be poorly active as a catalyst, Haruta *et al.*[4] have recently found that highly dispersed Au particles on $\alpha$-$Fe_2O_3$ and $Co_3O_4$ exhibit high activity for CO and $H_2$ oxidation at low temperatures. Recently, we reported the catalytic reduction of NO by CO[5] and $H_2$[6] over Au/NaY. Interestingly, the NO + CO reaction did proceed marginally at lower temperatures, *e.g.* 473–623 K, while adding $H_2$ significantly promoted the reaction on Au/NaY, where it assisted N–O dissociation with the formation of the intermediate NCO (with characteristic IR bands at 2280–2240 $cm^{-1}$).[5] The intermediate was converted into $N_2$ and $CO_2$ by interactions with NO in the gas phase. Here, we describe for the first time the remarkable enhancement of the selective reduction of NO by $H_2$ in the presence of oxygen over Au/NaY and Au/ZSM-5. The possible mechanism of $O_2$-assisted NO reduction by $H_2$ was also studied by means of *in situ* FTIR in order to identify the intermediates formed.

Au/NaY (Si/Al = 5.6; Linde, LZY-52, surface area 900 $m^2\ g^{-1}$) and Au/ZSM-5 (Si/Al = 23.8; Tosoh Co. Ltd, surface area 1000 $m^2\ g^{-1}$) samples were prepared by vaporization of $AuCl_3$ (Strem Chemical, 99% purity) into each zeolite, according to the monolayer dispersion technique.[7] The resulting $AuCl_3$ encapsulated in NaY or ZSM-5 was evidently reduced to AuCl by the extraframework hydroxy groups in the zeolites upon thermal treatment in vacuum at 338 K for 24 h. The catalysts contained 5% *m*/*m* Au, according to ICP analysis, and were characterized by EXAFS, XPS and XRD techniques.[7,8]

The catalytic performances in the reduction of nitric oxide by hydrogen in the presence and absence of oxygen were studied at atmospheric pressure in the steady-state flow mode. Four streams of NO–He, $H_2$, $O_2$ and He were supplied by mixing in a chamber using mass flow controller units to obtain a feed-gas mixture of 1375 ppm NO, 1.5% $H_2$ and 0.09–0.7% $O_2$ balanced with He at a total flow rate of 28 ml $min^{-1}$. Each catalyst (100 mg) was charged in a Pyrex glass tubular reactor. The stoichiometry of the feed stream was defined by $S$ = ([NO] +2[$O_2$])/[$H_2$] at zero time. The reactor effluent gas was sampled and analysed by on-line gas chromatography equipped with a thermal conductivity detector, using molecular sieve 5A and porapak-Q columns. Prior to the NO– $H_2$–$O_2$ reaction, the catalyst was reduced in a flowing gas mixture of 10% $H_2$ in He at 623 K. The catalytic activity was expressed in terms of percentage conversion of NO to $N_2$ as a function of the reaction time and $S$.

The selective reduction of NO by $H_2$ into $N_2$ proceeded in the temperature range 373–673 K over Au/NaY and Au/ZSM- 5. As shown in Fig. 1, the NO conversion to $N_2$ was markedly enhanced by 5–10 times by the addition of oxygen (0.2 % *v*/*v*) in the feed stream. Therefore, oxygen in the reaction gas stream plays a synergetic role in the NO–$H_2$ reaction. All the runs showed almost analogous trends of promotion by adding oxygen. The effect is greater on Au/NaY (*a*) than for Au/ZSM-5 (*b*) at the same oxygen level. The data militate against the claim that Cu/ZSM-5 is better than Cu/NaY for the oxygen promotion in NO reduction by hydrocarbons.[9] Control transient response experiments with pulse addition of $O_2$ into an NO–$H_2$ stream revealed that the differences in NO conversions obtained are related to competing reactions of NO and $H_2$ with $O_2$ over the gold catalysts. The oxygen promotion was linearly proportional to the oxygen concentration (0.09–0.21 %). After 2 h reaction time, the oxygen supply was turned off which resulted in a dramatic loss of the NO conversion (Fig. 1).

In the presence of $O_2$, NO reduction by hydrogen selectively goes to $N_2$ formation and neither $NH_3$ nor $N_2O$ were detected over Au/NaY and Au/ZSM-5 catalysts in the effluent stream at the outlet. By contrast, Hastvan *et al.*,[10] have reported for the same reaction over Pd-$MoO_3$/$\gamma$-$Al_2O_3$ catalysts that $NH_3$ and $N_2O$ are the major products. It has also been observed[11] that a better $N_2$ selectivity in the NO reduction by hydrogen is achieved by combining precious metals (Pt, Pd and Rh) and transition-metal oxides on $Al_2O_3$.

To gain insight into the mechanism of oxygen promotion in the selective NO redution by hydrogen, *in situ* FTIR studies were performed over Au/NaY and Au/ZSM-5 samples. *In situ* IR absorption spectra were recorded over the temperature range 474–573 K. A self-supporting wafer was placed in an IR cell

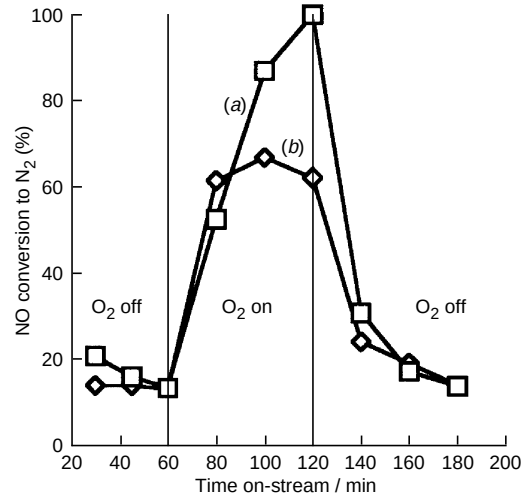

**Fig. 1** NO conversion (mol%) to $N_2$ as a function of time and $O_2$ (0.2% *v*/*v*) switch on–off in the NO (0.14% *v*/*v*)–$H_2$(1.5% *v*/*v*) flow mode reaction (flow rate = 28 ml $min^{-1}$) over Au/NaY (5% mass Au loading) (*a*) and Au/ZSM-5 (5% mass Au loading) (*b*) at 523 K, respectively

equipped with NaCl windows. The sample was reduced in circulating hydrogen (50 Torr) at 473 K before conducting the $NO–H_2–O_2$ reaction at the desired temperature. IR spectra were recorded with a Shimadzu 4100 FT IR double- beam spectrometer with a resolution of 2 $cm^{-1}$.

$^{15}NO_2$ and $^{15}N_2O_4$ were produced by the addition of $O_2$ to $^{15}NO$ (1 : 1 *v*/*v*) at 474 K on Au/ZSM-5. As shown in Fig. 2, after the $NO–O_2$ system reached a steady state [Fig. 2(*a*)], a pair of bands with an intensity ratio of *ca.* 1 : 1 developed at 1780 and 1760 $cm^{-1}$ arising from the stretching mode of monomeric $^{15}N–O$ on $Au^I$ and $Au^IO$, respectively. These bands were similarly assigned by Valyon and Hall[9] in NO chemisorption on Cu/ZSM-5. We did not observe such terminal NO species in the absence of oxygen on the Au/NaY and Au/ZSM-5 samples at identical NO chemisorption conditions. This implies that oxygen acts as a promoter for NO chemisorption on Au. The respective shift to lower wavenumbers (*ca.* 30 $cm^{-1}$) compared to those for $^{14}NO$ at 1811 and 1792 $cm^{-1}$ indicates that they are mononitrosyl species.

After heating the samples to 573 K, the ill resolved doublet bonds assigned to $^{15}N_2O_4$ completely vanished and were replaced by species at 1780 and 1760 $cm^{-1}$ [Fig. 2(*b*)]. The $^{15}NO_2$ bands were also decreased in intensity but to a lesser extent. This leads us to conclude that $^{15}N_2O_4$ together with $^{15}NO_2$ species dissociated back to monomeric NO and NO(O) at higher temperatures. It was previously reported that $NO_2$ dissociates on Au to form coadsorbed $NO_{(a)}$ and $O_{(a)}$ with a kinetic-energy barrier of $E_d \geqslant 17$ kcal mol[12] (1 cal = 4.184 J). The assignments of the observed IR bands associated with nitrogen oxides are summarized in Table 1.

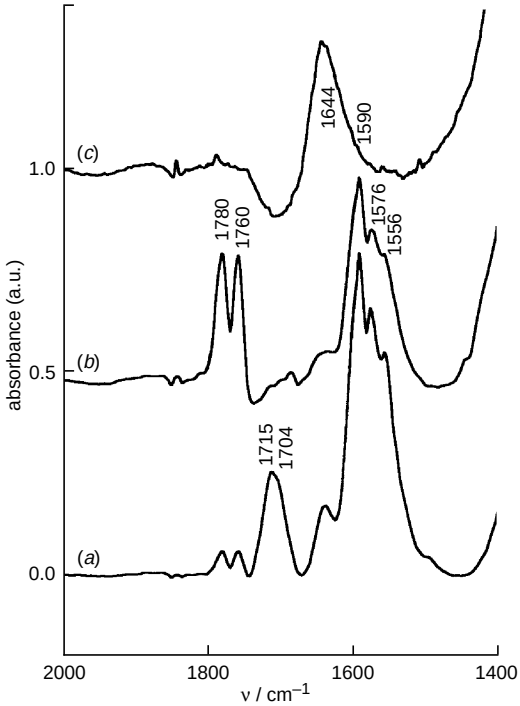

**Fig. 2** *In situ* IR spectra obtained on Au/ZSM-5 (5% Au loading) from (*a*) $^{15}NO$ (40 Torr)–$O_2$ (40 Torr) reaction at 474 K, (*b*) obtained upon increasing the reaction temperature to 573 K for 10 min, and (*c*) after admission of $H_2$ (100 Torr) at 573 K for 20 min

**Table 1** IR bands from the $NO–H_2–O_2$ reaction on Au/ZSM-5 and their assignment

| ν/$cm^{-1}$ | | | | |
|---|---|---|---|---|
| $^{14}NO^a$ | $^{15}NO^a$ | Calc.$^b$ | Assignment | Ref. |

| 1597 | 1556 | 1557 | ⎭ | 14 |

$^a$ NO stretching vibration. $^b$ Calculated using $\nu_{15} = \nu_{14}(\mu_{14}/\mu_{15})$ where $\mu_{14}$ is the reduced mass for $^{14}NO$ and $^{16}O$ and $\mu_{15}$ the reduced mass for $^{15}NO$ and $^{16}O$.

Subsequently, $H_2$ (100 Torr) was admitted to the reacting system [Fig. 2(*c*)], resulting in the complete disappearance of $NO_2$ and $N_2O_4$ species on Au/ZSM-5 with substantial formation of $N_2$ (*m*/*z* 28) and $H_2O$ (band at 1644 $cm^{-1}$). Oxygen promotion in the selective reduction of NO by $H_2$ on Au/NaY and Au/ZSM-5 is proposed to proceed as follows:

$$2NO + 2O_{ads} \xrightarrow[O_2]{\text{very fast}} [2NO_2 \rightleftharpoons N_2O_4]_{ads}$$

$$N_2O_4(NO_2) + 2H_2 \rightarrow N_2 + 2H_2O$$

$$2NO + 2H_2 \rightarrow N_2 + 2H_2O$$

Bands assignable to $N_2O$ and $NH_3$ were not detected by an *in situ* IR experiment in the presence of oxygen even when the reaction took place over a wide range of temperature. Nevertheless, we have previously reported that $N_2O$ and adsorbed $NH_4^+$ were partially detected as by-products due to NO dissociation in the $NO–H_2$ reaction over Au/NaY.[5] Accordingly, the results suggest that oxygen surpresses the dissociation of NO on Au/NaY, while promoting the formation of oxygenated intermediates such as $NO_2$ and $N_2O_4$, which are readily reduced by hydrogen selectively to $N_2$. Moreover, it is noteworthy that the synergism effected in the presence of excess oxygen is produced by inhibiting the sintering of Au due to a facile redox process between $Au^I$ and $Au^0$ in NaY and ZSM-5 even under the reductive $NO–H_2$ atmosphere.

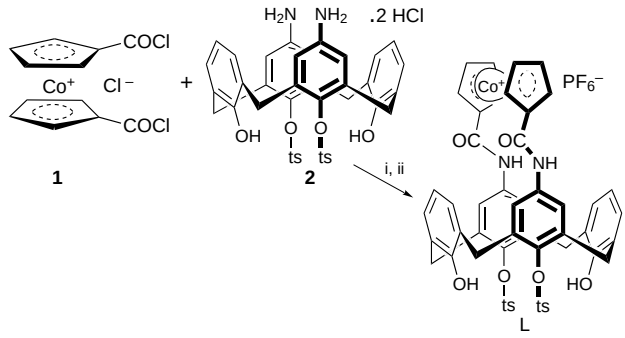
# A new carboxylate anion selective cobaltocenium calix[4]arene receptor



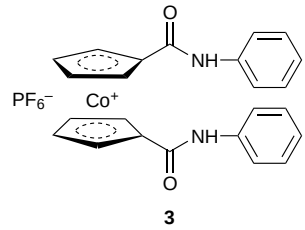
**Paul D. Beer,*[a] Michael G. B. Drew,[b] Dusan Hesek[a] and Kye Chun Nam[a]†**

[a] *Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*
[b] *Department of Chemistry, University of Reading, Whiteknights, PO Box 224, Reading, UK RG6 2AD*

**A new upper-rim cobaltocenium bridged calix[4]arene receptor L is synthesised and by virtue of its unique topology exhibits remarkable carboxylate anion selectivity.**

The synthesis of positively charged or neutral electron-deficient abiotic receptor molecules designed to non-covalently bind[1] and sense[2] anions of biochemical, medical and environmental importance is an area of intense current research activity. As a consequence of their inimitable upper- and lower-rim topologies the calixarenes[3] are attractive host molecules to modify and so create unique cavities for the recognition of target guest species. Although this has been exploited for the recognition of metal cations,[4] in contrast calixarene anion receptors are still relatively rare.[5] We report here the synthesis of a new upper-rim cobaltocenium-bridged calix[4]arene receptor L which by virtue of its topology exhibits remarkable carboxylate anion selectivity.

The condensation of 1,1′-bis(chlorocarbonyl)cobaltocenium chloride **1**[6] with the upper-rim bis-amine-substituted calix[4]-arene derivative **2**[7] in dry acetonitrile in the presence of triethylamine initially gave a crude product which after silica column chromatography and addition of ammonium hexafluorophosphate afforded L as a yellow powder in 38% yield (Scheme 1).



**Scheme 1** *Reagents*: i, MeCN–thf–py; ii, $NH_4PF_6$; ts = $O_2SC_6H_4Me$-*p*

[a] Errors estimated to be ≤10%. [b] Very weak binding, a stability constant value could not be calculated in this solvent.

The anion coordination properties of L were investigated by $^1H$ NMR anion titration experiments in $(CD_3)_2SO$ solution with various tetrabutylammonium halide, nitrate, dihydrogen phos-

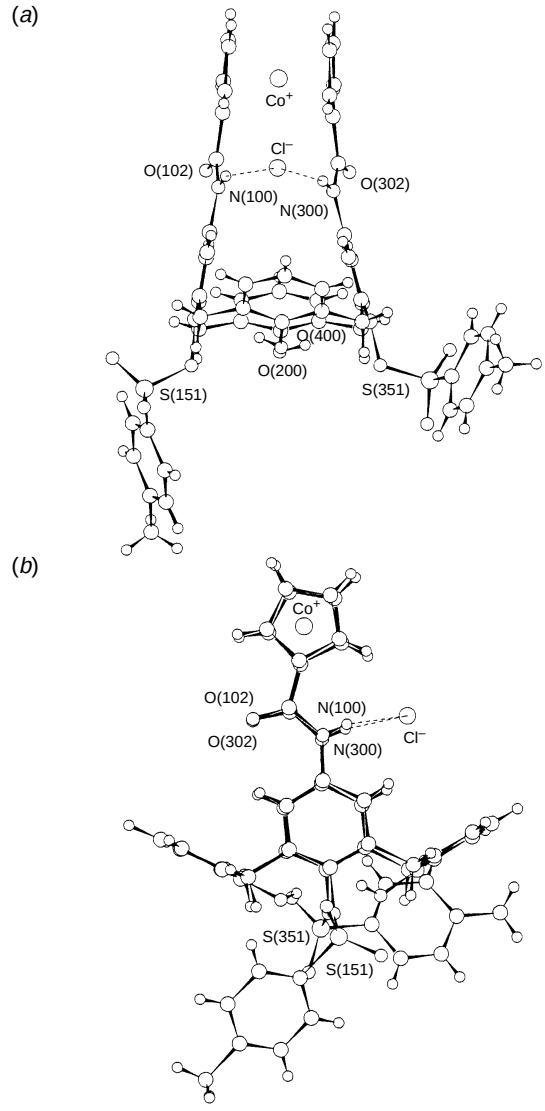

**Fig. 1** Structure of the chloride complex of L

phate, hydrogen sulfate and carboxylate salts. Substantial downfield perturbations of the receptor's amide and cyclopentadienyl protons were observed especially with carboxylate anionic guests, suggesting anion binding is taking place at the upper-rim vicinity of the receptor. It is noteworthy that with benzoate and β-naphthylcarboxylate anions large upfield perturbations of the receptor's aryl calix[4]arene protons of 0.6 ppm were also seen. Stability constants were calculated from the resulting titration curves using EQNMR[8] and these values are presented in Table 1 which includes stability constant data for acyclic receptor **3**. The receptor L exhibits remarkable thermodynamic stability and selectivity preferences for carboxylate anions, in particular for acetate over $H_2PO_4^- \gg NO_3^- > Cl^- > HSO_4^- > Br^-$. In comparison **3** forms a much weaker complex with the acetate anion (Table 1). These novel anion coordination properties may be attributable to the upper-rim rigidly held cobaltocenium bridging unit of L creating a unique and ideal bidentate amide (CO–NH) hydrogen-bond donor environment of complementary topology for recognising bidentate anions such as carboxylates. The X-ray crystal structure of the chloride complex of L corroborates this postulation‡ [Fig. 1(*a*), (*b*)]. As is clearly shown particularly in Fig. 1(*a*) the calix[4]arene has the typical flattened cone conformation with $C_2$ distortion. The angles made by the four phenyl rings and the plane of the four methylene carbon atoms are 106.8, 28.4, 98.9 and 29.8°. The two angles > 90° illustrate that the tops of the two phenyl rings of the calixarene are pulled together so that the cobaltocenium bridge can be formed [Fig. 1(*b*)]. However, despite being attached to the upper rim of the calixarene, the two cyclopentadiene rings are almost coplanar intersecting at an angle of 7.6°. The Co–C distances are in the range 2.04(1)–2.10(1) Å. In addition to the cobaltocenium linkage as shown in the Figure, the two N–H groups form hydrogen bonds to the chloride anion Cl(1)···N(100) 3.287, N(300) 3.298 Å.

[a] Obtained in acetonitrile solution containing 0.1 mol $dm^{-3}$ $NBu_4PF_6$ as supporting electrolyte. [b] Cathodic shift perturbations of cobaltocenium/cobaltocene redox couple of L produced by presence of anions (up to 5 equiv.) added as their tetrabutylammonium salts.

Electrochemical anion recognition studies in acetonitrile solutions reveal L to electrochemically sense carboxylate anions through substantial cathodic shift perturbations of up to $\Delta E$ = 155 mV of the reversible cobaltocenium–cobaltocene redox couple (Fig. 2, Table 2) at 0.85 V. Thus L is a first-generation prototype amperometric selective sensing reagent for carboxylate anionic guest species.

We thank the EPSRC for a postdoctoral fellowship to D. H. and for use of the mass spectrometry service at University College, Swansea. The University of Reading and the EPSRC are gratefully acknowledged for funding towards the crystallographic image-plate system.

# Solvent directed aggregation of a metallocene; structures of $\{[Pb(\eta\text{-}C_5H_5)_2]_3\cdot C_6H_5Me\}_\infty$ and $[Pb(\eta\text{-}C_5H_5)_2]_6$

**Michael A. Beswick, Catherine Lopez-Casideo, Michael A. Paver,* Paul R. Raithby, Christopher A. Russell, Alexander Steiner and Dominic S. Wright***

**The classic zigzagged chain structure of orthorhombic plumbocene, $[Pb(\eta\text{-}C_5H_5)_2]_\infty$, is obtained by crystal growth from the vapour phase; however, crystallisation from toluene results in modification of the conformation of the polymer chain, as observed in the solvate $[Pb(\eta\text{-}C_5H_5)\cdot C_6H_5Me]_\infty$ 1, and cyclisation into hexamers, as seen in the new hexagonal phase $[Pb(\eta\text{-}C_5H_5)_2]_6$ 2.**

We have recently observed that nucleophilic addition of the cyclopentadienide anion ($C_5H_5$) to plumbocene {$[Pb(\eta\text{-}C_5H_5)_2]$} produces a variety of complexes containing mononuclear and linear extended anions of general formulae $[Pb_n(\eta\text{-}C_5H_5)_{2n+1}]^-$.[1] The chain length of the homologue formed depends on the size and nature of the counter cations, and therefore on the lattice energy involved. Accordingly, the reaction of $[Pb(\eta\text{-}C_5H_5)_2]$ with $[Mg(\eta\text{-}C_5H_5)_2]$ in thf produces $[Mg(thf)_6]^{2+}\{[Pb(\eta\text{-}C_5H_5)_3]^-\}_2$ [1c] whereas the same reaction in the presence of 12-crown-4 gives the mixed anion complex $\{[Li(12\text{-crown-}4)_2]^+\}_2[Pb_2(\eta\text{-}C_5H_5)_5]^-[Pb_9(\eta\text{-}C_5H_5)_9]^-$.[1a] The formation of these anions points to the underlying structural flexibility of plumbocene itself. In this respect, two phases of plumbocene have been identified (triclinic and orthorhombic). However, only the orthorhombic polymeric phase $\{[Pb(\eta\text{-}C_5H_5)_2]_\infty\}$, grown from the vapour phase, has been structurally characterised.[2]

With the previous background in mind we have recently embarked on an investigation of the influence of solvation on the structure of plumbocene.[3] We report here that simple crystallisation of orthorhombic plumbocene from toluene solution results in major structural modification of the polymer chain. From such solutions two new complexes, the polymeric toluene solvate $\{[Pb(\eta\text{-}C_5H_5)_2]_3\cdot C_6H_5Me\}_\infty$ **1** and the cyclic molecular phase $[Pb(\eta\text{-}C_5H_5)_2]_6$ **2**, have been characterised.†

Complex **1** has an infinite polymer structure which is qualitatively similar to the orthorhombic form of plumbocene [Fig. 1(*a*)].‡ In both cases the association of the $[Pb(\eta\text{-}C_5H_5)_2]$ monomer units by bridging $\mu\text{-}C_5H_5$ ligands results in trigonal-planar metal environments {av. Cp–Pb–Cp 120.8° in **1**; *cf.* av. 120.0° in orthorhombic $[Pb(\eta\text{-}C_5H_5)_2]$;[2] Cp = centroid of cyclopentadienyl ring}. The pattern of $C_5H_5$–Pb bond lengths in **1** is also similar to that found in orthorhombic $[Pb(\eta\text{-}C_5H_5)_2]$, with a shorter interaction being made to the terminal $C_5H_5$ ligand (av. Pb–Cp 2.50 Å) and two longer interactions being made with the bridging ligands [av. Pb–($\mu$-Cp) 2.75 Å]. However, the presence of toluene solvation within the lattice has a marked effect on the conformation of the polymer chain of **1**. Rather than consisting of a simple two-dimensional zigzagged structure, as is observed in orthorhombic plumbocene, polymer strands of **1** adopt a sinusoidal pattern in order to avoid the interstitial toluene molecules [Fig. 1(*b*)].

Molecules of **2** are composed of six identical $[Pb(\eta\text{-}C_5H_5)_2]$ units which are linked together into a cyclic arrangement (Fig. 2).§ The mode of association of these units and the resulting environments of the metal centres are similar to those found in orthorhombic $[Pb(\eta\text{-}C_5H_5)_2]$ and **1**.[2] However, the monomers of **2** are less affected by their association than in either of the latter. The $[Pb(\eta\text{-}C_5H_5)_2]$ units resemble those found for monomeric plumbocene in the gas phase (Cp–Pb ≈ 2.50 Å and Cp–Pb–Cp 138°),[4] with the Pb centre of each monomer being bonded more closely to two of the $C_5H_5$ ligands [Cp(A)–Pb(1) 2.44 Å, Cp(B)–Pb(1) 2.53 Å and Cp(A)–Pb–Cp(B) 135.3°] than to the $C_5H_5$ ligand of the next monomer unit [Cp(B)···Pb(1b) 3.33 Å]. This pattern of $C_5H_5$–Pb interactions implies that the association of the monomers is extremely loose. The stacking of the $[Pb(\eta\text{-}C_5H_5)_2]_6$ rings results in infinite cylindrical channels through the crystal lattice.

The influence of substituents on the structures of p-block metallocenes is now well established. Increased substitution of the $C_5H_5$ rings with sterically demanding groups generally leads to the formation of oligomeric rather than polymeric species. For example, whereas $[E(\eta\text{-}C_5H_5)]_\infty$ (E = In, Tl)[5] have polymeric structures in the solid state, $[E\{C_5(CH_2Ph)_5\}]$[6] are essentially monomeric. The structural flexibility and subtle influence of the substituents are seen particularly in $[In(\eta\text{-}C_5Me_5)]_6$, which forms loosely associated In···In bonded octahedra in the solid state,[7] and $[Tl\{\eta\text{-}C_5H_3(SiMe_3)_2\text{-}1,3\}]_6$, containing Tl–{$\mu$-$\eta$-$C_5H_3(SiMe_3)_2$-1,3}–Tl linked cyclic molecules related to **2**.[8] Despite its similarity with the structure of the latter, the oligomeric structure of **2** is unique for any unfunctionalised main group metallocene.

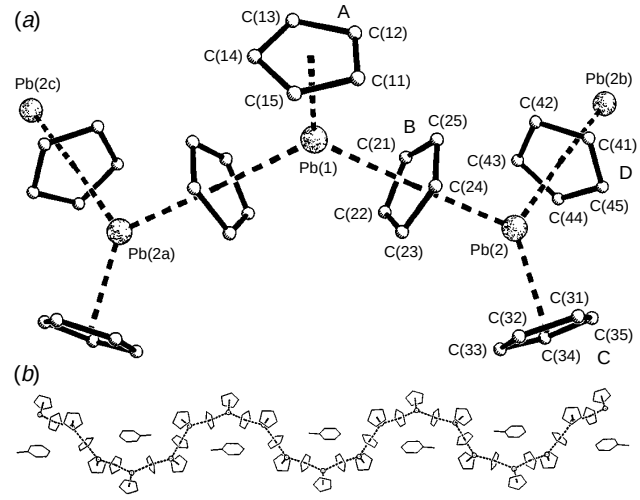

**Fig. 1** (*a*) Asymmetric unit of **1**. Hydrogen atoms have been omitted for clarity. Key bond lengths (Å) and angles (°): Pb(1)–C(11) 2.74(7), Pb(1)–C(12) 2.73(7), Pb(1)–C(13) 2.76(6), Pb(1)–C(14) 2.79(7), Pb(1)–C(15) 2.79(5), Cp(A)–Pb(1) 2.48, Pb(1)–C(21) 3.03(7), Pb(1)–C(22) 3.05(7), Pb(1)–C(23) 2.96(7), Pb(1)–C(24) 2.93(7), Pb(1)–C(25) 2.98(7), Cp(B)–Pb(1) 2.73, Pb(2)–C(21) 3.08(7), Pb(2)–C(22) 3.11(7), Pb(2)–C(23) 3.03(7), Pb(2)–C(24) 2.95(7), Pb(2)–C(25) 2.98(7), Cp(B)–Pb(2) 2.78, Pb(2)–C(31) 2.74(3), Pb(2)–C(32) 2.79(3), Pb(2)–C(33) 2.85(3), Pb(2)–C(34) 2.84(3), Pb(2)–C(35) 2.77(3), Cp(C)–Pb(2) 2.53, Pb(2)–C(41) 3.00(7), Pb(2)–C(42) 3.02(7), Pb(2)–C(43) 3.01(7), Pb(2)–C(44) 2.97(7), Pb(2)–C(45) 2.97(7); Cp(D)–Pb(2) 2.74, av. Cp–Pb–Cp 120.8°, av. Pb–Cp–Pb 175.1, Cp(C)–Pb···Pb–Cp(A) (dihedral) 74.3; Cp represents centroid of $\eta$-$C_5H_5$ ring. (*b*) Polymer structure of **1**.

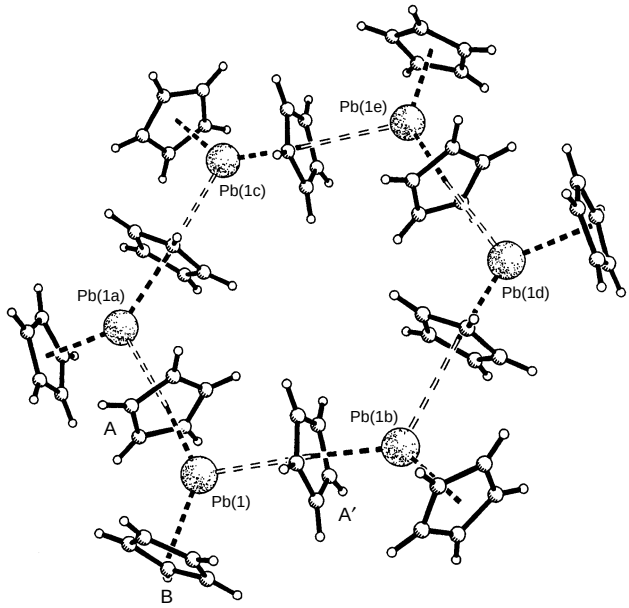

**Fig. 2** Molecular structure of **2** in the solid state. Hydrogen atoms have been omitted for clarity. Key bond lengths (Å) and angles (°): Pb(1)–C(1) 2.76(1), Pb(1)–C(2) 2.86(1), Pb(1)–C(3) 2.88(1), Pb(1)–C(4) 2.79(1), Pb(1)–C(5) 2.71(1), Cp(A)–Pb(1) 2.53, Pb(1)–C(6) 2.79(1), Pb(1)–C(7) 2.78(1), Pb(1)–C(8) 2.69(1), Pb(1)–C(9) 2.64(1), Pb(1)–C(10) 2.71(1), Cp(B)–Pb(1) 2.44, Pb(1)–C(1a,2a,3a,4a,5a) 3.53(2), Cp(A)–Pb(1b) 3.33, Cp(A)–Pb(1)–Cp(B) 135.3, Cp(B)–Pb(1)–Cp(A′) 116.2, Cp(A)–Pb(1)–Cp(A′) 108.5, Pb(1)···Cp(A)–Pb(1b) 179.2, Pb···Pb 5.56, Pb···Pb···Pb 120.0.

The characterisation of **1** and **2** illustrates, for the first time, that non-coordinating solvent interactions can have profound consequences on the conformation and overall structure adopted by a main group metallocene. Similar observations may well be expected for group 13 metallocenes {[E(η-$C_5H_5$)]; E = In, Tl}, for which polymeric structures have been determined for crystals grown from the vapour phase.[5]

## Footnotes

† Orthorhombic [Pb(η-$C_5H_5$)$_2$]$_\infty$ was prepared in the manner described in the literature and purified by sublimation (140 °C, 0.1 atm). Crystallisation from toluene at 5 °C gives a mixture of **1** and **2**. Owing to the composition of this mixture, elemental analysis (C, H) and $^1$H NMR spectroscopy indicate that there is *ca*. toluene molecule to each [Pb(η-$C_5H_5$)$_2$] monomer unit (*i.e.* consistent with largely **1**).

‡ *Crystal data*: **1**, $C_{37}H_{38}Pb_3$, $M$ = 1104.24, orthorhombic space group *Pnma*, $a$ = 16.421(3), $b$ = 24.375(5), $c$ = 8.234(2) Å, $U$ = 3296(1) Å$^3$, $Z$ = 4, λ = 0.710 73 Å, $T$ = 153(2) K, $D_c$ = 2.225 Mg m$^{-3}$, μ(Mo-Kα) = 15.311 mm$^{-1}$. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated crystal[9] of dimensions 0.3 × 0.2 × 0.2 mm using the θ–ω method (8.32 ⩽ 2θ ⩽ 45.06°). Of a total of 2284 reflections collected 2199 were independent. A semi-empirical absorption correction based on ψ-scans was applied (max., min. transmission = 0.981, 0.149). The structure was solved by direct methods and refined by full-matrix least squares on $F^2$ to final values of $R_1$ = 0.102 (for 2195 data with $F > 4\sigma F$) and $wR_2$ = 0.231 (all data) [$R_1 = \Sigma|F_o - F_c|/\Sigma|F_o|$, $wR_2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/\Sigma wF_o^4\}^{0.5}$, $w = 1/[\sigma^2(F_o^2) + (xP)^2 + yP]$, $P = (F_o^2/3)$].[10] Largest peak and hole in the final difference map = 2.968 and −2.958 e Å$^{-3}$. The C atoms were refined isotropically. The $C_5H_5$ rings and toluene molecules were refined as rigid groups. $C_5H_5$(A) is disordered on an inversion centre and $C_5H_5$(D) is disordered on a mirror plane. Hydrogen atoms were set geometrically.

**2**, $C_{60}H_{60}Pb_6$, $M$ = 2024.22, hexagonal, space group $P6cc$, $a$ = 18.058(2), $c$ = 10.219(2) Å, $U$ = 2885.9(7) Å$^3$, $Z$ = 2, λ = 0.710 73 Å, $T$ = 153(2) K, $D_c$ = 2.329 Mg m$^{-3}$, μ(Mo-Kα) = 17.473 mm$^{-1}$. Data were collected on a Siemens-Stoe AED diffractometer using an oil-coated crystal[9] of dimensions 0.15 × 0.24 × 0.24 mm using the θ–ω method (8.40 ⩽ 2θ ⩽ 44.98°). Of a total of 4906 reflections collected 1268 were independent. A semiempirical absorption correction based on ψ-scans was applied (max., min. transmission = 0.953, 0.476). The structure was solved as for **1** to final values of $R_1$ = 0.041 (for 1261 data with $F > 4\sigma F$) and $wR_2$ = 0.124 (all data). Largest peak and hole in the final difference map = 3.118 and −0.749 e Å$^{-3}$. C atoms were refined isotropically and the $C_5H_5$ rings as rigid groups. Hydrogen atoms were set geometrically.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Chiral monolayer of self-assembled Δ-[Os(bpy)$_2$L(Cl)]$^+$ [bpy = 2,2′-bipyridyl, L = 1,2-bis(4-pyridyl)ethane] on a platinum electrode

**Yasuo Inose,[a] Shinobu Moniwa,[a] Akiko Aramata,*[a] Akihiko Yamagishi[b] and Kyaw-Naing[b]**

[a] *Catalysis Research Center, Hokkaido University, Sapporo 060, Japan*
[b] *Graduate School of Science, Hokkaido University, Sapporo 060, Japan*

**A chiral osmium complex, Δ-(2,2′-bipyridyl) [1,2-bis(4-pyridyl)ethane] chloroosmium Δ-[Os(bpy)$_2$L(Cl)]$^+$, is successfully self-assembled at a monolayer molecular level on a clean Pt electrode in non-aqueous solutions; the self-assembled Δ-[Os(bpy)$_2$LCl]$^+$ ions show a phenomenally repulsive interaction with each other on Pt in chiral-field formation and also in the Os$^{II}$–Os$^{III}$ redox reaction, while racemic complexes interact less repulsively with each other.**

Chiral monolayer creation at an electrode interface is a stimulating subject for atomic level surface design. Study of chiral electrode surfaces has been attempted with a cholesteric liquid crystal physically adsorbed on glassy carbon or Pt electrodes.[1] In other work, a chiral metal complex was inserted into a clay mineral by cation exchange leading to a chiral metal complex-modified clay electrode, where the chiral complex was Δ- or Λ-[Ru(phen)$_3$]$^{2+}$ (phen = phenanthroline). Oxidation of racemic [Co(phen)$_3$]$^{2+}$ to Λ-[Co(phen)$_3$]$^{3+}$ on a Δ-[Ru(phen)$_3$]$^{2+}$ modified clay electrode showed chiral performance in a 17% optical yield,[2] and the partial oxidation of phenylcyclohexylsulfide to chiral (*R*)-(+)-phenylcyclohexylsulfoxide on a Λ-[Ru(phen)$_3$]$^{2+}$-modified clay electrode gave a 20% optical yield.[2] The properties of a chiral complex-modified clay in a dispersed colloid form were experimentally and theoretically clarified by Yamagishi *et al.*,[3–5] but the electrochemical features of chiral [Ru(bpy)$_3$]$^{2+}$ in a clay-modified electrode were reported to be different from those in a dispersed form by Villemure and Bard,[6] showing that the electrochemical chirality determination of a metal complex-modified clay electrode is quite complicated and likely to arise from a small fraction of complex ions in defects of layer films of a laminal clay.

Metal electrode modification was carried out by application of a monolayer *via* a thiol RSH on Au in the form of RS–Au, where R contains an electroactive species.[7–9] Recently, an organic thiol with asymmetric carbon, adsorbed on Hg in a self-assembled manner, was reported to show an atomically two-dimensional chiral surface by Mandler and coworkers.[10] As another metal electrode modification, osmium complexes [Os(bpy)$_2$L(Cl)]$^+$ (L = 4,4′-bipyridine or derivatives) were self-assembled onto a Pt electrode through an N atom of bipyridine,[11] and the electrochemical behaviour was examined in aqueous and non-aqueous solutions.[11–15] The electron-transfer mechanism and the adsorption thermodynamics of the osmium complex self-assembled on Pt were discussed in detail since the electron-transfer reaction between the electrode and the complex bound to the electrode is a fairly straightforward system to be theoretically treated for elucidation of electron-transfer processes. An STM image of ordered self-assembled osmium complexes on Pt(111) was successfully observed by Hudson and Abruña,[16] indicating that the self-assembled osmium complexes form a two-dimensional ordered phase on Pt(111). In these reports, the above osmium complexes were synthesized as racemic mixtures of chiral Δ- and Λ-complexes [Fig. 1(*a*), (*b*)], depicted by molecular modelling, and used as a racemic mixture in the following. These lead us to the study of the creation of a chiral electrode interface by self-assembled Δ- or Λ-metal complexes in a monolayer form.

The separation of chiral Δ-(2,2′-bipyridyl) [1,2-bis(4-pyridyl)ethane] chloroosmium hexafluorophosphate [Os(bpy)$_2$L(Cl)]PF$_6$ [L = 1,2-bis(4-pyridyl)ethane] was carried out from racemic [Os(bpy)$_2$L(Cl)]PF$_6$, which was prepared according to ref. 11. The latter was first purified by elution on a 300 mesh alumina column with acetone, and then subjected to anion exchange to give the water-soluble [Os(bpy)$_2$L(Cl)]Cl. Chiral separation from racemic [Os(bpy)$_2$L(Cl)]Cl was conducted at least three times by column treatment on CM Sephadex (Pharmatia) with a potassium antimony (+)-tartrate saturated aqueous solution as the eluting agent to yield the Δ-osmium

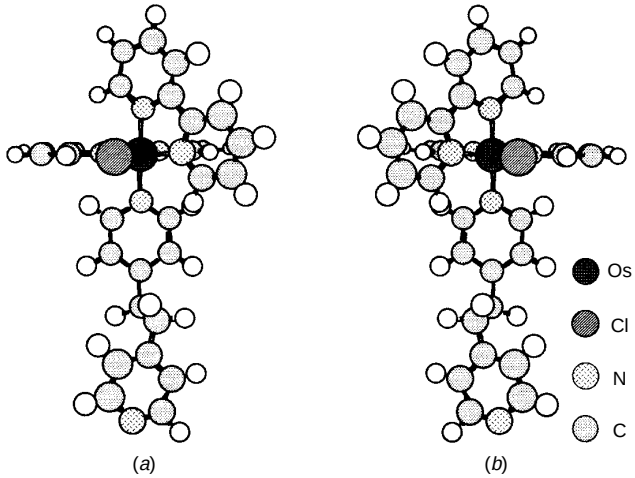

**Fig. 1** Structures of (*a*) Δ- and (*b*) Λ-[Os$^{II}$(bpy)$_2$L(Cl)]$^+$

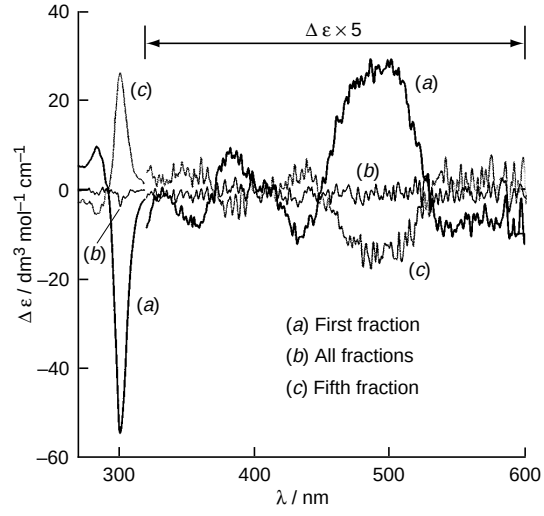

**Fig. 2** Circular dichromism spectra of [Os$^{II}$(bpy)$_2$L(Cl)]$^+$ after chiral separation. First fraction, fifth fraction and all fractions are assumed to be the Δ-, Λ-, and *rac*-species, respectively.

complex as the first of five fractions, since a clear column band separation was not observed. The last fraction containing the Λ-Os complex was also collected. This chiral column separation process also played the role of osmium complex purification. Thus, during the purification process of the racemic osmium complex, all fractions of the column band were collected. The circular dichromism spectra of Δ-, Λ-, and *rac*-complexes are shown in Fig. 2, where we find that the Δε of the first fraction is −55 $dm^3\ mol^{-1}\ cm^{-1}$ at 299 nm, while there is a report that Δε of Λ-$[Os(bpy)_3]^{2+}$ is 400 $dm^3\ mol^{-1}\ cm^{-1}$ at 300 nm.[17] The osmium complexes prepared were stored in a dark cold dry-box before use.

For the monolayer self-assembling procedure, a polycrystalline Pt electrode was inserted into 0.5 mM of Δ- or *rac*-$[Os(bpy)_2L(Cl)]Cl$ in $CH_2Cl_2$ solution for a given time, τ; before this the Pt had been electrochemically polished by cyclic voltammetry (CV) up to 1.2 V (SCE) in perchloric acid solution.

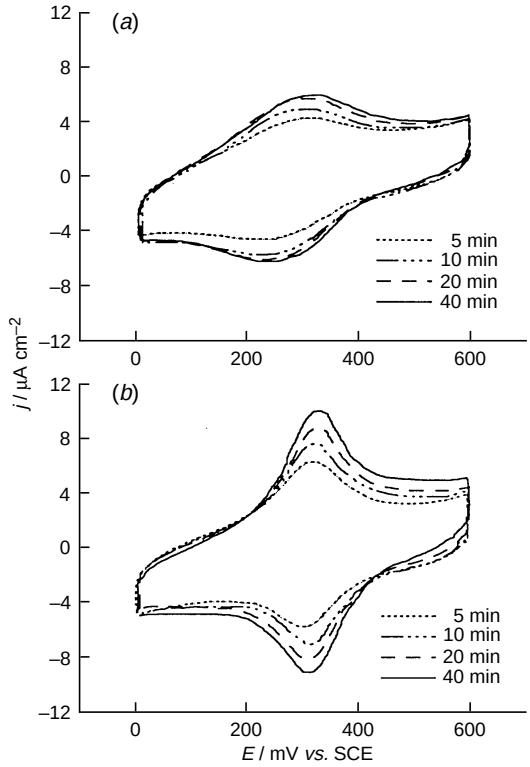

**Fig. 3** CVs of (*a*) Δ- and (*b*) *rac*-$[Os^{II}(bpy)_2L(Cl)]^+$ on a Pt electrode at 0.1 V $s^{-1}$ in 0.05 M TBAP–MeCN solution after Pt was inserted in 0.5 mM Δ- or *rac*-$[Os^{II}(bpy)_2L(Cl)]^+$ for different self-assembling times τ

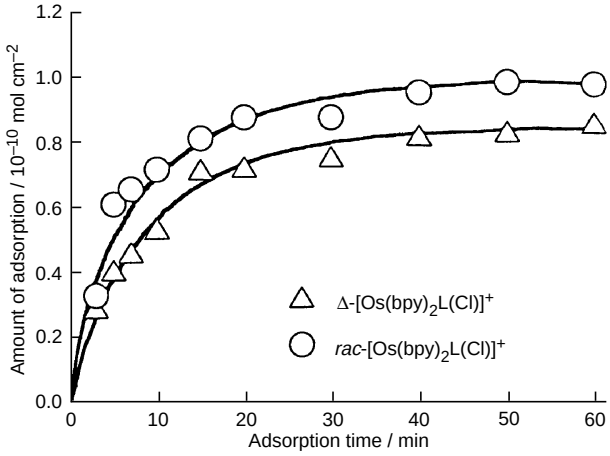

**Fig. 4** Amount of charge of CV peaks of Fig. 3 *vs.* self-assembling adsorption time τ. Ordinate of the amount of the charge densities is expressed in mol $cm^{-2}$.

At each τ, the Pt was subjected to CV measurement at a sweep rate ν of 0.1 V $s^{-1}$ in 0.05 M tetrabutylammonium perchlorate (TBAP) in $Me_2CN$, as shown in Fig. 3, for the electrode reaction of eqn. (1).

$$[Os^{II}(bpy)_2L(Cl)]^+ \rightleftharpoons [Os^{III}(bpy)_2L(Cl)]^{2+} + e \qquad (1)$$

Figs. 3(*a*) and (*b*) are for Δ- and *rac*-osmium complexes, respectively, with τ in the range 5–40 min. The sweep rate dependence of the CV current peak, $j_p$, showed a proportional relation *vs.* ν (at τ = 40 min) when $\nu \leqslant 200$ mV $s^{-1}$, irrespective of whether the electrode was modified by Δ- or *rac*-$[Os(bpy)_2L(Cl)]^+$, as found for a racemic osmium complex in ref. 11. As in that work, the effect of the electron-transfer reaction kinetics on the CV was observed at sweep rates > 100 V $s^{-1}$; the present data are indicative of a quasi-equilibrium state. Remarkable differences of CV characteristics, however, were observed between Δ- and *rac*-$[Os(bpy)_2L(Cl)]^+$ modified Pt electrodes (Fig. 3). Various parameters for the *rac*-Os complex are in good agreement with those of Acevedo and Abruña.[12] Potential differences ($\Delta E$) of anodic and cathodic current peaks are 70 and 30 mV for Δ- and *rac*-modified electrodes, respectively. The peak current height, $j_p$, of the Δ-osmium complex on Pt is roughly half that of the *rac*-osmium complex on Pt with half-height widths of 210 and 120 mV, respectively. The quantity of charge between anodic and cathodic reaction currents is plotted *vs.* τ in Fig. 4, where, at τ = 40 min, the amounts of charge Δ*Q* appear to be saturated at $0.85 \times 10^{-10}$ and $0.95 \times 10^{-10}$ mol $cm^{-2}$ for Δ- and *rac*-modified electrodes respectively, of which the latter amounts to a nearly complete monolayer assuming a cross-section of 1.54 $nm^2$ per molecule of the osmium complex.[11] These results show that a repulsive interaction energy is higher between chiral osmium complexes than between racemic osmium complexes or that a different ordered structure is suggested. The ordered STM structure has been observed for a self-assembled racemic osmium complex on Pt,[16] and the above values suggest that the self-assembled ordered structure should be different for chiral and racemic complexes if chiral complexes also form an ordered monolayer structure.† STM measurements upon the chiral complex self-assembled on Pt are now under way.

## Footnote

† The ordered molecule arrangement depicted in ref. 16 is for chiral complexes.

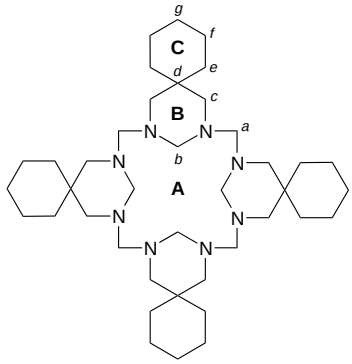
# A tetraspiro nonacyclic compound by condensation of 1,1-bis(aminomethyl)cyclohexane with formaldehyde



**M. Rachel Suissa,*[a,b] Christian Rømming[a] and Johannes Dale[a]**

[a] *Kjemisk Institutt, Universitetet i Oslo, 0315 Oslo, Norway*
[b] *Nesna College, 8700 Nesna, Norway*

**1,1-Bis(aminomethyl)cyclohexane condenses with formaldehyde to precipitate a polymer, which upon heating is readily isomerized to the nonacyclic compound tetraspiro[tetrakis(cyclohexane)-1,5‴′:1′,11‴′:1″, 17‴′:1‴,23‴′-[1,3,7,9,13,15,19,21]octaazapentacyclo[19.3.1.1$^{3,7}$.1$^{9,13}$.1$^{15,19}$]octacosane 1, whose structure has been determined by X-ray analysis and $^{13}$C NMR spectroscopy.**

The term 'strict covalent self assembly' has been defined as 'completely reversible reactions leading to products that are stable at thermodynamic equilibrium'.[1] Condensation of amines with formaldehyde to give multicyclic structures satisfies this criterion if all rings of the structure can obtain a geometry derivable from the diamond lattice. The earliest example is the formation from propane-1,3-diamine and formaldehyde of a pentacyclic octaaza compound, whose central ring is 16-membered.[2] In this laboratory it was shown that it can have two conformations, both of the diamond lattice type.[3] Subsequently, the corresponding product from 2,2-dimethylpropane-1,3-diamine and formaldehyde was also prepared and shown to exist only in the more symmetric ($D_{2d}$) of the two conformations.[4]

If each *gem*-dimethyl group is replaced by a spiro-linked pentamethylene chain, the resulting compound **1** would have four terminal cyclohexane rings (**C**) with high conformational mobility, while the central 16-ring (**A**) with its four laterally fused 6-rings (**B**) would remain rigid. A very special NMR spectroscopic situation can be predicted from the symmetry properties of the expected diamond lattice conformation of **1** as drawn in Fig. 1. The central part (**A** + 4**B**) has two 'vertical' planes of symmetry passing through atoms *b* and *d*, and two 'horizontal' two-fold axes passing through atoms *a*. At room temperature the terminal rings **C** will flip rapidly between the two chair forms to produce by averaging the NMR spectrum of the apparent 'planar' rings, and the molecular $D_{2d}$ symmetry is not destroyed. When the flipping becomes slow at low temperature, the $^{13}$C signal from carbons *c* will split into two, having very different shifts due to the upfield *gauche* interaction when carbons *f* are on the same side of the symmetry plane. The $^{13}$C signals of atoms *f* themselves will however remain unchanged since they will get the same interaction with carbons *c* on either side. Interestingly then, what is going on in ring **C** is not observed in its own spectrum but by 'remote sensing' in the spectrum of ring **B**.

**1**

A modest signal splitting should be expected also for the more distant 'corner' atoms *a* on the two-fold axes, each interacting weakly with two **C** rings. Assuming that the choice of frozen conformation is independent in each *C* ring, three situations are possible for each *a* carbon: the two neighbouring **C** chairs can either both be in the closest position, or one in the closest and one in the distant position (and *vice versa*), or both can be in their distant position. Statistically, this results in the splitting of the $^{13}$C NMR signal of carbon *a* into a triplet with 1 : 2 : 1 intensity.

An analysis in terms of possible species (conformers) can be carried out by looking down on a square projection of ring **A**. Each chair can be oriented clockwise (+) or counterclockwise (−), and if chirality is disregarded, four conformers are possible (Fig. 2). Of these, the conformer ++−−, drawn in full in Fig. 1, was chosen for clarity. The conformer found in the crystal structure is +++− (*vide infra*). The conclusion above that a 1 : 2 : 1 triplet should be expected statistically for carbon *a* in ring **A** is based on the assumption of equal populations of all four conformers.

Compound **1** was prepared as follows: malonodinitrile and 1,5-dibromopentane gave 1,1-dicyanocyclohexane (mp 63 °C, 65%), which by catalytic hydrogenation ($W_2$-Raney nickel, $NH_3$ saturated EtOH, 80 atm., 70 °C) yielded 1,1-bis(amino-

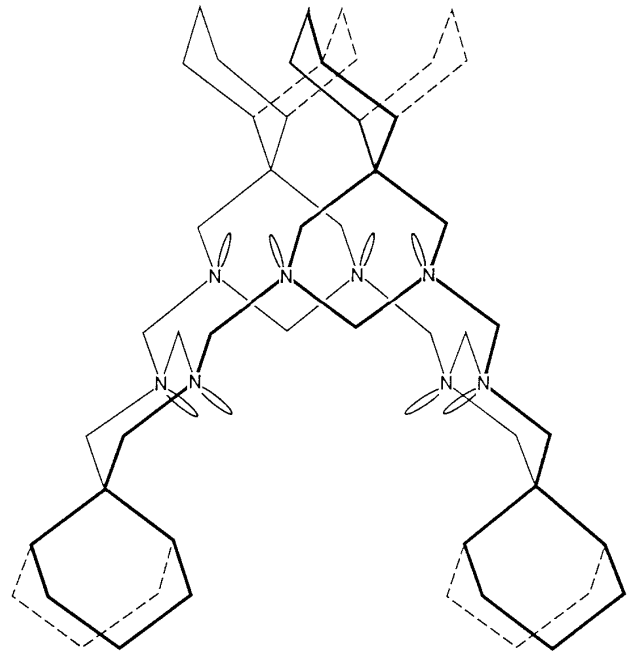


**Fig. 1** The postulated conformation of compound **1**. Both possible chair positions for each **C** ring are shown.

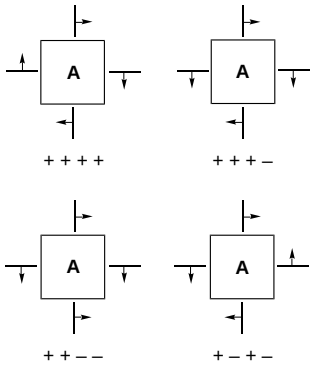

**Fig. 2** The four possible arrangements of rings **C**. The sign (+) represents a clockwise oriented **C** ring and (−) represents a counterclockwise oriented **C** ring.

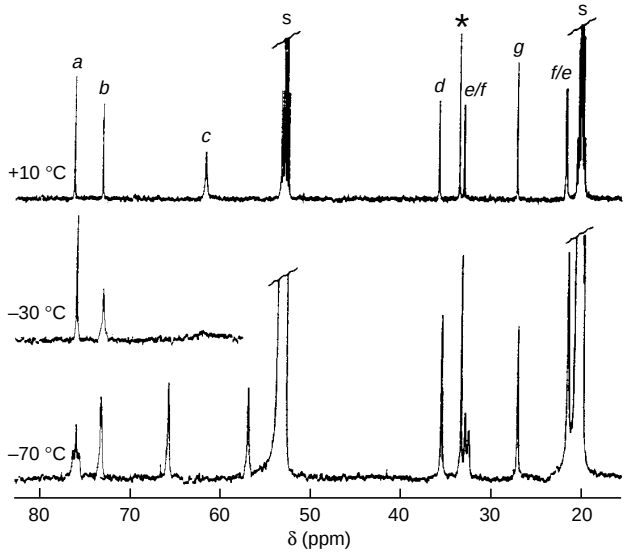

**Fig. 3** 125 MHz $^{13}C$ NMR spectra of **1** in [$^2H_8$]toluene–$CD_2Cl_2$ (1 : 1) at 10, −30 and −70 °C

methyl)cyclohexane as a viscous liquid (80%). Aqueous formaldehyde was dropped into a cooled aqueous solution (*ca.* 0 °C) of this diamine (ratio 2 : 1), causing immediate precipitation of a polymer. The polymer was heated for a few minutes in refluxing dioxane to give compound **1** (mp 215 °C, 100%). It is soluble in most organic solvents and crystallizes from dioxane, $CH_2Cl_2$ or toluene, giving extremely hard crystals; MS (EI, 70 eV) *m/z* 664 ($M^+$), 499 (3/4 M + 1), 333 (1/2 M + 1), 167 (1/4 M + 1), 137, 124, 95, 67, 42; $^{13}C$ NMR (125 MHz in $CD_2Cl_2$, 300 K): δ 76.7 ($C_a$), 73.5 ($C_b$), 62.1 ($C_c$), 36.2 ($C_d$), 33.6 ($C_{e/f}$), 27.6 ($C_g$), 22.2 ($C_{f/e}$).

The $^{13}C$ NMR signals at δ 33.6 and 22.2 (Fig. 3) represent two inner and two outer *e* and *f* carbons, but the splitting is barely visible. After lowering the temperature, the predicted broadening and splitting of the carbon *c* signal at δ 62.1 into a widely separated doublet takes place, while the carbon *a* signal at δ 76.7 splits into a narrow triplet.

The flipping process (or geminal $CH_2$ exchange) of ring **C** could in principle be determined directly by $^1H$ NMR spectroscopy, but this is prevented in practice by complex coupling. Full geminal site exchange of the remaining $CH_2$ groups in ring **A** and **B** would require the passage of much higher barriers, and while at 110 °C clear exchange broadening had started, $T_c$ could not be reached.

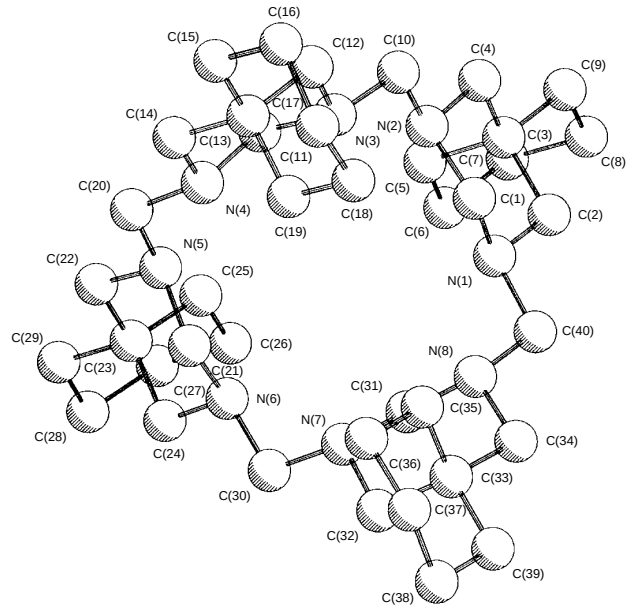

**Fig. 4** PLUTO plot of **1**

The X-ray analysis† of the crystal (Fig. 4) revealed that the unit cell contains four molecules all having the same +++− conformation, possibly chosen to obtain the efficient packing needed to explain the observed unusual hardness of the crystals. The molecules are arranged as two enantiomeric pairs; only one molecule of the pair is shown, the other having disorder in one of the **C** rings due to a 20% population of the +−+− conformer.

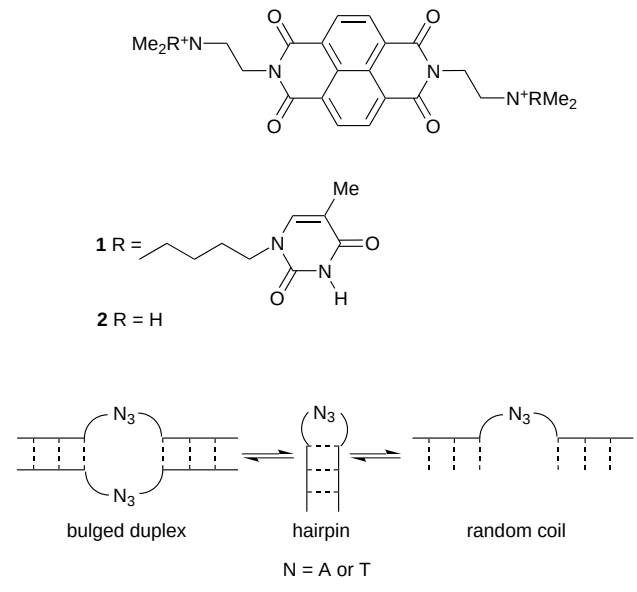
# Selective stabilization of a bulged duplex of d(GCGAAACGC) oligonucleotide by thymine base-substituted naphthalene diimide

**Shigeori Takenaka,*[a] Makoto Yokoyama[b] and Hiroki Kondo[b]**



[a] *Department of Chemical Science and Technology, Kyushu University, Fukuoka 812-81, Japan*
[b] *Department of Biochemical Engineering and Science, Kyushu Institute of Technology, Iizuka 820, Japan*

**A naphthalene diimide carrying thymine moieties at the termini of its substituentsstabilized specifically the bulged duplex of d(GCGAAACGC), which is rarely found under ordinary conditions.**

Nucleic acids have a variety of higher-order structures, such as base bulge and hairpin, which are associated with many biological functions.[1] Compounds recognizing these structures are important for studying nucleic acid structure and can serve as new DNA-targeting agents. Many molecules have been synthesized to exhibit this.[2–10] For example, a macrocyclic bisacridine developed by Lehn and co-workers showed a selective binding to the DNA hairpin of d(GCGAAACGC), named $sA_3$.[10] We have shown that thymine base-substituted naphthalene diimide **1** has a high affinity for polyA.[11] It occurred to us that compound **1** might bind to the hairpin region of $sA_3$ specifically as well, since this oligonucleotide consists of single stranded adenines. Contrary to this expectation, however, **1** produced a bulged duplex rather than a hairpin structure on $sA_3$, as shown in Scheme 1.

In $sA_3$, the bulged structure is in equilibrium with a hairpin. The latter is the predominant species in solution under ordinary conditions, as exemplified by a melting profile in which two transition temperatures were observed.[10] The higher melting temperature ($T_{mH}$) is attributed to intramolecular transition from a hairpin to random coil. The lower melting temperature ($T_{mL}$), which is rarely found and $sA_3$ concentration-dependent, is attributed to intermolecular transition from a bulged duplex to a hairpin.

Fig. 1(*a*) shows the melting curve of $sA_3$ with a major transition temperature at 54 °C due to the collapse of the hairpin structure as described previously.[10] Two transition temperatures appeared at about 18 and 60 °C in the presence of **1**, and the lower temperature transition was raised with an increase in the amount of **1**. Since the absorbance of **1** alone was independent of temperature over the 15–90 °C range, the lower transition temperature was attributed to $T_{mL}$. These data indicated that **1** can stabilize the bulged structure of $sA_3$ specifically, although it stabilized the hairpin structure as well, albeit to a smaller extent [*ca*. 6 °C, compare curves (i) and (ii) in Fig. 1(*a*)]. On the other hand, naphthalene diimide **2**, without thymine moieties, showed a transition curve featuring mainly a rise in the $T_{mH}$ to 80 °C. This behaviour of **2** was largely unaffected by the presence of thymine. Ordinary intercalators insert themselves between adjacent base pairs in double stranded nucleic acids, thus effecting stabilization.[12] This is the case with **2**, where the $T_{mH}$ was raised by 26 °C when compared with the $T_{mH}$ of $sA_3$ alone. In summary, **1** stabilizes the bulged duplex of $sA_3$ much more than its hairpin structure, whereas **2** stabilizes mainly the hairpin structure, as do other ordinary intercalators. This difference arises presumably because **1** can bridge the two DNA strands through hydrogen bonding of its thymines moieties with the adenine moieties of $sA_3$. We estimate that 50 and 10% of $sA_3$ assumes the bulged structure in

**Scheme 1**

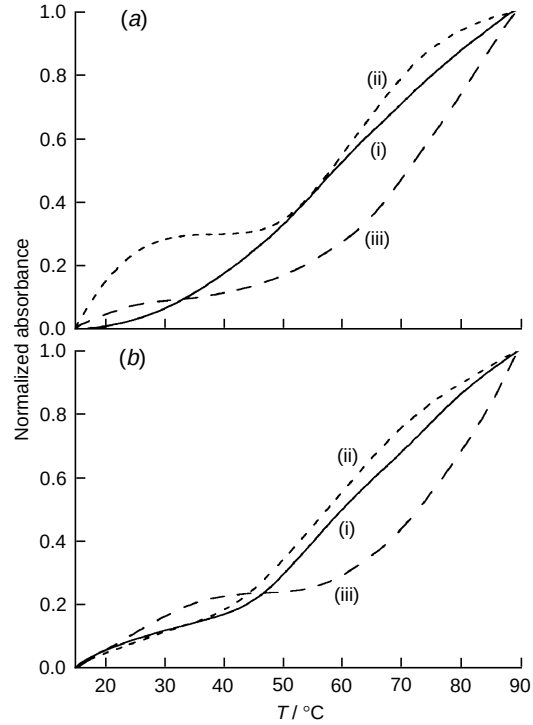


**Fig. 1** Melting profiles for (*a*) $sA_3$ and (*b*) $sT_3$: (i) no additive; (ii) in the presence of **1**; (iii) in the presence of **2**. Carried out in 10 mM MES (2-morpholinoethanesulfonic acid) and 1 mM EDTA (ethylenediaminetetraacetic acid) buffer (pH 6.25); oligonucleotide (in the double strand form) and additive concentration = 5.8 μM.

the presence of an equimolar amount of **1** and **2**, respectively, at 20 °C.

To investigate whether **1** can stabilize the bulged adenines specifically, the melting curve of d(GCGTTTCGC) ($sT_3$) was measured in the absence and presence of **1** or **2** under the same conditions [Fig. 1(*b*)]. This oligonucleotide showed two transition temperatures at *ca*. 15 and 60 °C, which can be attributed to the transition from a bulged duplex to hairpin and from a hairpin to random coil, respectively [(i) in Fig. 1(*b*)]. Neither the bulged duplex nor the hairpin was stabilized by **1**, whereas **2** stabilized the hairpin structure exclusively [(ii) and (iii) in Fig. 1(*b*)]. This result proves that **1** stabilizes the bulged adenines specifically.

The competitive binding to $sA_3$ of **1** and **2** with ethidium bromide was performed by monitoring ethidium fluorescence.

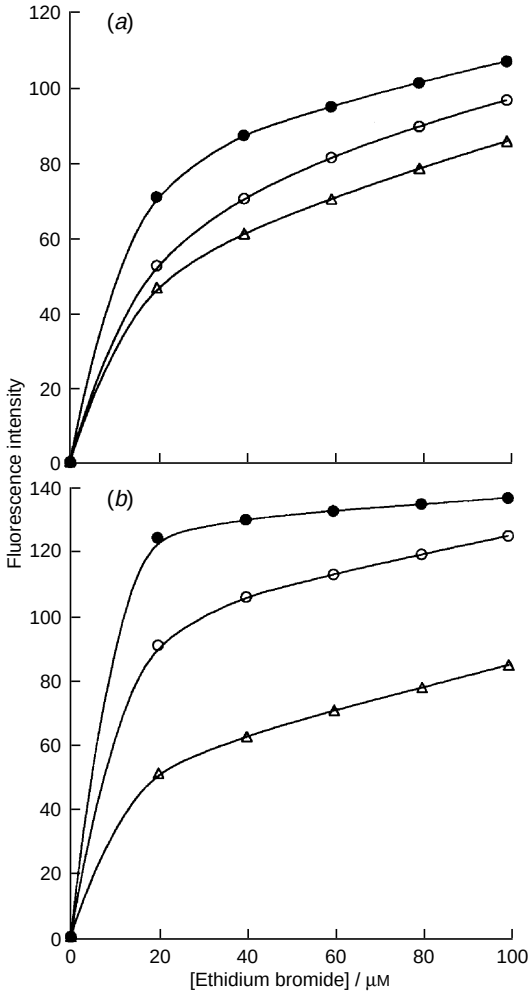

**Fig. 2** Changes in the fluorescence intensity upon addition of ethidium bromide to (*a*) $sA_3$ and (*b*) $sT_3$: (●) no additive; (△) in the presence of **2**; (○) in the presence of **1**. Carried out in 10 mM MES buffer (pH 6.25) containing 0.3% $Me_2SO$ at 20 °C; oligonucleotide (in the double strand form) and additive concentration = 5.8 μM.

Addition of ethidium bromide to $sA_3$ increased the fluorescence intensity at 595 nm ($\lambda_{ex}$ = 546 nm) at 20 °C as a result of binding to DNA as shown in Fig. 2(*a*). The fluorescence of ethidium bromide was suppressed with a mixture of $sA_3$ and **1** or **2**, and the quenching was more pronounced with **2** than with **1** [Fig. 2(*a*)]. On the other hand, **1** was not as effective as **2** in the quenching of the fluorescence of $sT_3$-bound ethidium bromide [Fig. 2(*b*)], demonstrating that the binding of **1** with $sT_3$ is weaker than with $sA_3$, whereas **2** can bind to both $sA_3$ and $sT_3$ equally well.

Since ethidium bromide binds to DNA by intercalation,[13] those intercalators which bind to the double stranded region of DNA compete with ethidium bromide to suppress its fluorescence. It follows therefore that **2** binds mainly to the double stranded region of $sA_3$, whereas **1** is away from such a region and binds mainly to the single stranded loop region. Both the bulge and hairpin structures of $sA_3$ have a loop, but the curvature of the loop is smaller for the bulge. Hence, the naphthalene diimide ring of **1** can stack more effectively with the adenine rings of the bulge. Moreover, since **1** possesses two thymine bases, it can hold together the two strands of $sA_3$ through complementary hydrogen bonding of the thymines with the adenines. We believe that this is the reason why **1** stabilizes the bulged structure of $sA_3$ specifically. Whatever the mechanism, this is the first example of the alteration of the secondary structure of an oligonucleotide using a small molecule.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan.

# Molecular recognition induced aggregation and fusion between vesicles containing lipids bearing complementary hydrogen bonding head-groups

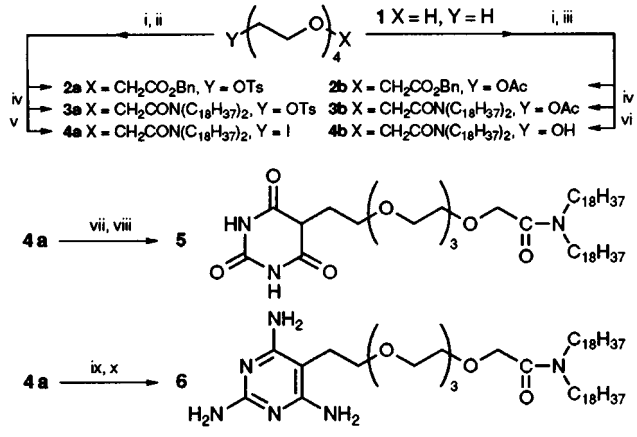
**Valérie Marchi-Artzner,[a] Ludovic Jullien,[a]† Thaddée Gulik-Krzywicki[b] and Jean-Marie Lehn*[a]**

[a] *Laboratoire de Chimie des Interactions Moléculaires, UPR285, Collège de France, 11, Place Marcelin Berthelot, F-75005 Paris, France*

[b] *Centre de Génétique Moléculaire, CNRS, 91190 Gif-sur-Yvette, France*

**Equimolar mixtures of large unilamellar vesicles, obtained from mixtures of egg lecithin and lipids containing complementary hydrogen bonding head-groups (barbituric acid and triaminopyrimidine), aggregate and fuse generating much larger vesicles.**

Molecular recognition research has focussed especially on the selective formation of discrete supermolecules from complementary receptor–substrate pairs.[1] Extension to polymolecular assemblies should allow the recognition-directed generation of well-defined, extended supramolecular entities *via* the introduction of suitable recognition features into the molecular components.



Thus, in previous work from our group, the self-assembly of units bearing complementary hydrogen bonding patterns has been used for generating liquid crystalline phases[2,3] and supramolecular polymers.[3,4] On the other hand, selective interactions take place at molecular layers into which recognition groups have been introduced.[5–7] Further on, molecular recognition may direct processes occuring between discrete polymolecular bodies such as liposomes. Indeed, surface recognition is a basic process controlling the interactions between biological cells.[8] Endowing artificial vesicles with recognition features may provide a means of provoking their interaction and for inducing processes such as aggregation and fusion. In the longer term it should permit the generation of polyvesicular architectures in a controlled fashion, a prerequisite for constructing organized assemblies of vesicles, of interest both as artificial functional nanoarchitectures and as models of biological tissue.

We report here some of our first results on the study of vesicles containing complementary lipids bearing as head groups the barbituric acid (BAR) and triaminopyrimidine (TAP) units which not only interact through three hydrogen bonds, but also, due to their double-faced nature, form self-assembled, extended ribbons.[9] the polymeric character of which is expected to enhance the global adhesion between complementary surfaces. We have previously studied the behavior of electrostatically complementary vesicles bearing opposite charges,[10] and recently the interaction between vesicles containing a biotinylated lipid and streptavidin in solution has been investigated.[11] For this work, we selected the complementary amphiphiles **5** and **6**; they were synthesized according to Scheme 1.‡ In view of the supramolecular organization imposed by hydrogen bonding interaction, a polyoxyethylenic spacer has been introduced in order to provide sufficient orientational freedom to the recognition sites.

Electron microscopy showed that **4b** and 1 : 9 mixtures of **5** or **6** with **4b** form lamellar phases in water under all conditions of vesicle preparation that have been investigated in the present study (detergent removal, sonication or lipid swelling in presence of an alternative electrical field). Large unilamellar vesicles were prepared from 1 : 9 mixtures of **5**, **6** or **4b** and egg lecithin (EPC) either by detergent dialysis[15] or extrusion[16] methods. As indicated by freeze-fracture electron microscopy [Fig. 1(*a*)] and by quasistatic and dynamic light scattering experiments, the size polydispersity of vesicles prepared by extrusion through Nucleopore filters was low, making them suitable to analyse the evolution of the vesicle solution by these techniques. Whereas aqueous suspensions of pure **5**, **6** and **4b** exhibited a sharp signal at 41 ± 1 °C by differential scanning calorimetry (DSC), the 1 : 9 mixtures with EPC did not display any transition, thus suggesting the absence of an extensive lipid segregation within the bilayer.

When identical amounts of weakly light scattering vesicular preparations of **5**-EPC 1 : 9 and **6**-EPC 1 : 9 were mixed, the solution became turbid after a few minutes whereas the appearance of individual preparations remained stable for a week. This observation was quantified by dynamic light scattering measurements (Table 1). The diameters of the starting vesicular suspensions were in the 150 nm range whereas the multimodal mathematical treatment of the data from the final state of the mixture provided an apparent diameter equal to 2000 nm. Considering the relation of size to scattered light intensity, this value can be reasonably assumed to represent the diameter of the largest objects.

In order to define more precisely the nature of the events taking place in these solutions, electron microscopy pictures were recorded at different times after mixing complementary vesicles. First, a rapid aggregation leading to the formation of large clusters of vesicles was observed [Fig. 1(B)]. After 15 min, two different populations of vesicles were visible [Fig. 1(C)]. A few very large vesicles (micrometer range) were surrounded by many smaller ones exhibiting size and morphology close to that of starting preparations. Support for the identification of vesicle fusion as the phenomenon triggering vesicle growth was provided by the observation of singular

events such as the formation of necks between adhering vesicles and budding on large vesicles [Fig. 1(D)].

In the present system, different interactions may contribute to the observed coalescence phenomena. In view of the acidobasic properties of the BAR and TAP lipids leading to the formation of species of opposite charge, an attractive electrostatic interaction may also play a role as observed previously.[10] Furthermore, ion-pairing reinforced hydrogen bonding between BAR and TAP units has been observed.[17] Since polyoxyethyleneglycol is known to promote vesicle fusion, we established that the spacer itself did not do so, since vesicles prepared from 1 : 9 **4b**-EPC mixtures were stable at least for several days. The present experiments consequently suggest that surface recognition *via* complementary hydrogen bonding patterns plays an important role in the events observed. Studies in progress should provide more information about the nature of the interaction between complementary vesicles and about its role in the vesicle fusion event. The intervesicular processes described here represent a first step towards the controlled, recognition-directed construction of organized, functionally integrated assemblies of vesicles leading towards 'tissue-like' artificial entities.

We thank L'OREAL for a graduate fellowship to V. M. A.

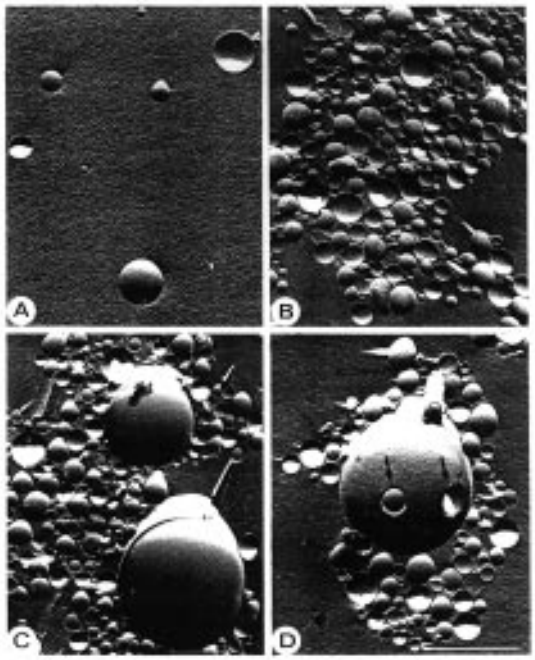

**Fig. 1** Freeze-fracture electron micrographs of the vesicles prepared from 9 : 1 mixtures of egg lecithin and lipids **5** or **6** containing either barbituric acid (BAR) or triaminopyrimidine (TAP) head-groups. (A) Typical image of vesicle preparations containing either BAR or TAP lipids. (B) Equimolar mixture of BAR and TAP vesicles immediately after mixing. (C), (D): the same as (B) but after more than 15 min incubation. Notice the aggregation of vesicles after mixing and the appearance of much larger vesicles after incubation, some of which show vesicle fusion [arrows in (D)]. All photographs are at the same scale; the bar on (D) represents 500 nm.

# Molecular recognition involving multiple cation–π interactions: the inclusion of the acetylcholine trimethylammonium moiety in resorcin[4]arene

**Kazutaka Murayama and Katsuyuki Aoki***

*Department of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 441, Japan*

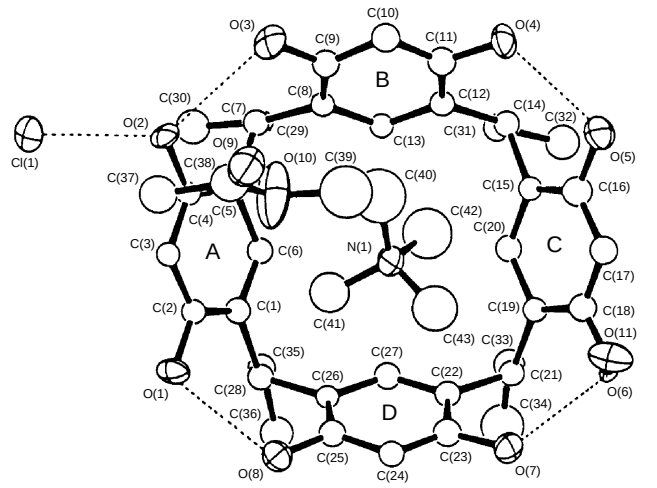
**X-Ray analysis of the molecular complex formed between the neurotransmitter acetylcholine (ACh) and resorcin[4]-arene, ACh$^+$.resorcinarene.Cl$^-$.$H_2O$ shows that the ACh molecule is captured by the macrocyclic resorcinol tetramer through multiple cation–π interactions between the quaternary trimethylammonium group of ACh and the four π-rings of the cavitand.**

The cation–π interaction has attracted much attention because of its chemical,[1–3] biological[1] and theoretical[4] applications. It has been well documented that synthetic macrocyclic compounds comprised of aromatic rings exhibit a strong affinity for quaternary ammonium compounds including the neurotransmitter acetylcholine (ACh).[1a] Particular interest focuses on the origin of the strong molecular association: it has been proposed[1a] that the cationic ammonium group could bind to the π-faces of aromatic rings of its receptor through a cation–π interaction. Although a recent statistical analysis,[5] based on crystal structures from the Cambridge Structural Database, of the interactions between R–N$^+$Me$_3$ cations and phenyl rings demonstrates their preferable occurrence, X-ray evidence for such a cation–π interaction is still lacking† for artificial macrocyclic receptor systems,[1–3,6] involving synthetic ACh receptors.[1a,7] As the continuation of our X-ray investigations on the cation–π interaction,[8] we report here the crystal structure of the molecular complex formed between macrocyclic resorcin[4]arene **1**‡ and ACh, where the quaternary trimethylammonium group of ACh makes close contacts with the four π-rings of **1**. $^1$H NMR spectroscopy confirms that the cation–π interaction also occurs in solution. The biological relevance of the multiple cation–π interactions for the interaction between ACh and acetylcholine esterase (AChE) is suggested.

The ACh–resorcin[4]arene molecular complex was prepared from ACh$^+$.Cl$^-$ (2 mmol) and **1**§ (0.2 mmol) dissolved in ethanol (5 ml)–water (3 ml). The mixture (pH 6) was allowed to stand at room temperature for three weeks after which colourless crystals (plates) formed.¶ 3,3-Dimethylbutyl acetate **2** was synthesized in 83% yield from acetyl chloride (50 mmol) and 3,3-dimethylbutan-1-ol (6 ml, 50 mmol).

Fig. 1 shows the molecular structure of the complex, ACh$^+$.**1**.Cl$^-$.$H_2O$, where **1** is neutral. The most interesting structural feature is the host–guest complexation between **1** and ACh through cation–π interactions, that is, between the quaternary trimethylammonium group of ACh and the multiple π-rings system of the macrocyclic resorcinol tetramer. The choline group makes close contacts through its two methyl groups with the four rings of the bowl-shaped cavitand. To our knowledge, this is the first crystal structure in which ACh shows the cation–π interaction between the trimethylammonium group and the π-electrons of the aromatic ring. The ACh molecule adopts a *gauche* conformation about the choline group due to an N$^+$···O electrostatic interaction [the torsion angle O(10)–C(39)–C(40)–N(1) = −77(5)°], usually observed[9] for the O–C–C–N$^+$ system, and *trans* about the C(38)–O(10) bond [C(37)–C(38)–O(10)–C(39) = −173(2)°]. Furthermore, in the crystal lattice this ACh is capped on its acetyl terminal group by the adjacent resorcinarene molecule (at 3/2 − *x*, 1/2 + *y*, 1/2 − *z*), as shown in Fig. 2. Thus an ACh molecule is captured by two resorcinarene molecules in a head-to-tail arrangement. Interestingly, the polar carboxy oxygen O(9), rather than the apolar methyl group C(37), contacts with the aliphatic ethyl groups tethered to the tail of the cavitand [3.83(3) Å to C(29), 3.80(3) Å to C(31), 3.78(3) Å to C(33) and 3.68(3) Å to C(35)]. The chloride anion forms four hydrogen bonds with the hydroxy oxygen atoms O(1) [Cl···O(1) 3.04(1) Å], O(2) [3.12(1) Å] and O(7) [2.99(2) Å], each oxygen belonging to a different molecule, and a water oxygen atom O(11) [3.24(2) Å], but it does not contact with the cationic choline group of ACh.

The $^1$H NMR spectrum (270 MHz, $CD_3OD$) of the ACh–resorcinarene **1** complex (30 mmol dm$^{-3}$) shows a singlet at δ 2.107 for the *N*-methyl protons of ACh, while the corresponding signal of ACh alone appears at δ 3.215. This upfield shift of 1.108 ppm for the complex is probably due to the aromatic ring-current effect, indicating that the quaternary trimethylammonium group associates preferentially with the π-rings of resorcinarene in solution, where the resorcinarene molecule



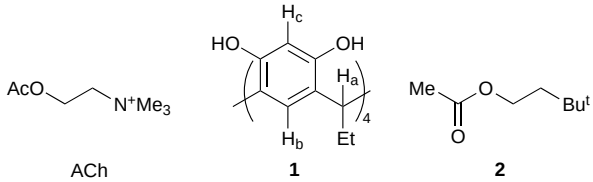


**Fig. 1** Top view of the molecular structure of ACh$^+$.**1**.Cl$^-$.$H_2O$, showing the host–guest complexation between a cyclic resorcinol tetramer and an ACh molecule through cation–π multiple interactions; close contacts (< 3.6 Å): C(41)···C(2) [3.51(4)], C(41)···C(25) [3.56(4)], C(42)···C(12) [3.57(5)], C(42)···C(15) [3.43(5)], C(42)···C(16) [3.54(5)] and C(42)···C(20) [3.48(5) Å]; relevant methyl C···π-centroid distances: C(41)···ring A [3.60], C(41)···ring D [3.87], C(42)···ring B [3.64] and C(42)···ring C [3.36 Å]; relevant methyl C···ring–plane perpendicular distances: C(41)···ring A [3.48], C(41)···ring D [3.59], C(42)···ring B [3.52] and C(42)···ring C [3.31 Å]. Broken lines denote hydrogen bonds.

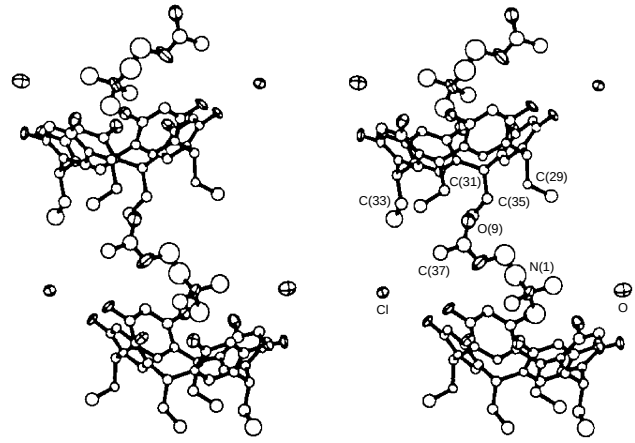

**Fig. 2** Stereoview of a segment of the crystal structure of $ACh^+$.**1**.$Cl^-$.$H_2O$, showing the encapsulation of an ACh molecule between two resorcinarene molecules and close C–H···O contacts between the carboxyl oxygen of ACh and four $CH_2$ moieties tethered to the lower rim of the cavitand

retains the bowl-shaped conformation.‖ In addition, the $^1H$ NMR spectrum (270 MHz, $CD_3OD$) of the solution containing ACh (30 mmol $dm^{-3}$) and resorcinol monomer as noncyclic reference compound in a 1 : 4 molar ratio does not show an appreciable upfield shift of the *N*-methyl protons (δ 3.195) of ACh, showing the importance of the defined structure of **1** in its effective association with ACh, where the preorganized cavity of **1** makes cation–π multiple interactions possible and stabilizes them.

In order to examine more closely the significance of the quaternary trimethylammonium group in the cation–π interaction, a comparative study was undertaken using 3,3-dimethylbutyl acetate **2**, an uncharged compound isosteric to ACh, where the trimethylammonium nitrogen of ACh is replaced with a carbon atom. The $^1H$ NMR spectrum (270 MHz, $CD_3OD$) of the solution containing acetate **2** and resorcinarene **1** (30 mmol $dm^{-3}$; equimolar ratio) and that of **2** alone show only a small upfield shift of 0.052 ppm for the *tert*-butyl protons of **2** in the mixture (δ 0.895 and 0.947, respectively). This indicates that the intensity of interaction between the terminal *tert*-butyl group of **2** and the π-rings of **1** may be minor. Thus it appears again[1a,8] that the cationic nature of the quaternary choline group could be responsible for its preferable association with the π-ring, that is, through cation–π interaction.

In summary, (i) the ACh molecule contacts simultaneously with more than one aromatic ring through multiple cation–π interactions, thus mimicking the ACh binding to AChE. A recent X-ray study[10] has revealed that a total of 14 aromatic residues line the 'active site gorge' of AChE. A biological role of the multiple cation–π interactions might be that simultaneous contacts could promote the gain of total energy for molecular associations which are needed for rapid transport of ACh through the gorge ('aromatic guidance'[10]) and also for the ACh-fixing at the bottom of the gorge. In this regard, the trimethylammonium moiety of ACh, where one positive formal-charge is smeared out over the three methyl groups,[1a] seems to be an excellent device to achieve cation–π multiple interactions. (ii) This study clearly demonstrates that the aromatic system interacts strongly with the cationic choline moiety in preference to the neutral *tert*-butyl group. In order to provide further insights into the significance of the trimethylammonium group of ACh in the cation–π interaction, X-ray and solution studies, by exchanging the $N^+Me_3$ group with $N^+H_nMe_{3-n}$ ($n$ = 1–3), are under way.

## Footnotes

† There have been reported, to our knowledge, two crystal structures[3,11] of host–guest complexes between synthetic macrocycles of aromatic rings and quaternary ammonium compounds: however, in $4Na^+$.(trimethylanilinium$^+$).(*p*-sulfonatocalix[4]arene$^{4-}$).$Cl^-$;[3] the trimethylammonium group is located out of the cavity of the host, and in $(Et_3HN^+)_2$.(tetramethylresorcin[4]arene).$SO_4^{2-}$.4EtOH,[11] no mention is made on the cation–π interaction.

‡ 2,8,14,20-Tetraethyl-4,6,10,12,16,18,22,24-octahydroxycalix[4]arene.

§ Compound **1** was synthesized according to a literature procedure.[12]

¶ *Crystal data* for: $ACh^+$.**1**.$Cl^-$.$H_2O$.$C_{43}H_{58}ClNO_{11}$. $M$ = 800.38, colourless plates, monoclinic, space group $P2_1/n$, $a$ = 12.450(9), $b$ = 21.598(7), $c$ = 15.717(7) Å, β = 95.15(5)°, $U$ = 4209(3) Å$^3$, $Z$ = 4, $D_m$ = 1.265 (measured by flotation in hexane–carbon tetrachloride), $D_c$ = 1.263 g $cm^{-3}$, μ(Mo-Kα) = 1.50 $cm^{-1}$, $T$ = 293 K, $F$(000) = 1712. A Rigaku AFC7R diffractometer with graphite-monochromated Mo-Kα (λ = 0.71069 Å) was used to collect 5847 unique data in the range $4 < 2\theta < 50°$, 1728 data with $I > 3\sigma(I)$ were used in the refinement. The diffraction pattern was in general quite weak and did not extend much beyond 2θ = 40°, mostly due to the small crystal size (0.08 × 0.30 × 0.30 mm) and some disorder of ACh molecules (as noted below). Residuals of $R$ = 0.110 and $R_w$ = 0.117 were obtained after 295 parameters had refined to convergence (TEXSAN), where only Cl, O and N atoms were treated anisotropically while all C atoms isotropically because of limited number of reflection data. The quality-of-fit index is 1.53, and the largest shift/esd = 0.18. High vibrational amplitudes [10–16 Å$^2$] for C(34), O(10), C(37), C(40), C(42) and C(43) of ACh might be due to disorder, that is, these atoms most likely occupy slightly different positions from molecule to molecule (attempts to find alternative chain conformations failed), causing the rather high $R$ values. No attempt to locate the H atoms was made. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/317.

‖ In solution, resorcin[4]arene exists as mixtures of bowl-shaped (crown), saddle, boat and chair conformers.[13] In the ACh-1 system, the equivalency in the NMR spectra of four Ha protons (t, $\delta_H$ 4.175–4.233), four Hb (s, $\delta_H$ 6.248), and four Hc (s, $\delta_H$ 7.262) of **1** indicates that **1** has a symmetric macrocyclic skelton, suggesting **1** to have a bowl-shaped conformation.

# Enhanced binding of a hexacyclic amidine analogue of Hoechst 33258 to the minor groove of DNA: $^1$H NMR and UV melting studies with the decamer duplex d(GGTAATTACC)$_2$

**Clare E. Bostock-Smith,[a] Kevin J. Embrey[b] and Mark S. Searle*[a]**

[a] *Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD*
[b] *Queensland Pharmaceutical Research Institute, Griffith University, Nathan, Brisbane 4111, Australia*

**NMR and UV melting studies with the decamer duplex d(GGTAATTACC)$_2$ show that replacing the *N*-methylpiperazine ring of the DNA minor groove binding agent Hoechst 33258 with a hexacyclic amidine leads to both an increase in duplex stability ($\Delta T_m \approx 7$ °C) and enhanced A–T specific recognition; the amidine NH exchanges slowly with the solvent and has a small temperature coefficient ( < 3 ppb/°C) supporting its involvement in intermolecular hydrogen bonding, however, the data suggest that the ring is flipping rapidly even at 278 K even though the interaction appears to contribute significantly to complex stability.**

The bis-benzimidazole Hoechst 33258 [Fig. 1(*a*), **1**] binds to the minor groove of A–T rich DNA sequences.[1] Specific hydrogen bonding interactions between the benzimidazole NHs and adenine N3/thymine O2 of the DNA bases on the floor of the groove provide key components for binding and recognition; the complex has been studied extensively by NMR[2–6] and X-ray analysis.[7–12] In contrast, the role of the *N*-methylpiperazine ring in the recognition process is less well defined. Its cationic charge clearly contributes to complex stability, while van der Waals contacts are also observed with the floor of the minor groove.[10] However, both the conformation and orientation of the piperazine ring appear to be variable including, in some cases, the observation of preferential binding to G–C regions at the end of A–T tracts of DNA where the wider groove has been proposed to more readily accommodate this bulky substituent.[7,9,11]

One rational approach to the design of new Hoechst analogues with enhanced functional properties is to replace the *N*-methylpiperazine component with one capable of specific hydrogen bond-mediated recognition of the minor groove. Here we describe such an analogue containing a hexacyclic amidine group, Hoechst 43254 **2**. A recent X-ray structure[13] has shown that a Hoechst analogue with a five-membered amidine ring does not have the correct geometry to allow the amidine NH to hydrogen bond to the floor of the minor groove.

Energy minimisation of Hoechst 43254 using MACROMODEL[14] suggests that a twist of *ca*. 20° away from coplanarity is necessary to relieve steric repulsions between amidine NHs and phenyl hydrogens on the adjacent benzimidazole ring. Energy minimisation and molecular dynamics calculations on the DNA complex of **2** (modelled from the X-ray coordinates of the DNA complex of **1** described by Quintana *et al.*[10]) suggest that the ligand should bind with enhanced specificity to the 5′-AATT sequence through the interaction of an amidine NH with the N3 of the second adenine base [see Fig. 1(*b*) *vs*. 1(*c*)]. The twisted conformation of the six-membered amidine ring (*cf*. the five-membered ring) appears to optimise the geometry for such an interaction.

In Fig. 2, UV 'melting' curves for d(GGTAATTACC)$_2$ are shown plotted as absorbance at 260 nm *vs*. temperature at a duplex concentration of 3.2 μM (buffered with 0.01 M sodium phosphate and 0.11 M sodium chloride, pH 7.0). The duplex alone gives a broad melting curve with a $T_m$ of 27 °C. Hoechst 33258 **1** increases the $T_m$ significantly to 45 °C with the melting transition becoming appreciably more cooperative. However, with Hoechst 43254 **2** bound the stabilisation effect is even more pronounced with the $T_m$ rising further to 52 °C ($\Delta T_m \approx$ 7 °C), in good agreement with previous studies with related ligands and other A–T tract duplexes.[15]

In Fig. 3 we show by $^1$H NMR that **2** binds tightly to d(GGTAATTACC)$_2$ and is in slow exchange on the chemical shift time-scale. Binding of the asymmetric ligand lifts the dyad symmetry of the duplex such that the two strands of DNA are non-equivalent in the complex. The high field methyl region (δ 1–1.8) and low field imino proton region of the spectrum (δ 9.0–14.5) of the ligand-free and ligand-bound duplex are illustrated. The number of thymine methyl [(*a*) *vs.* (*b*)] and imino proton resonances from the A–T base pairs [(*c*) *vs.* (*d*)] doubles on ligand binding indicating that the drug is located at a single high affinity site. Generally, the pattern of ligand-induced perturbations to base H6/H8 (major groove) and deoxyribose H1′ resonances (minor groove) are suggestive of a very similar binding location for both **1** and **2** that spans the central AATT site of the decamer duplex (data not shown). Many intermolecular NOEs have so far been identified that support this model.

The $^1$H NMR spectrum of the complex shown in Fig. 3(*d*) also provides evidence for hydrogen bonding interactions between the ligand and minor groove. Downfield shifted resonances are observed for the benzimidazole NHs, one of which is resolved at δ 11.65, the other overlapped at δ 12.74.

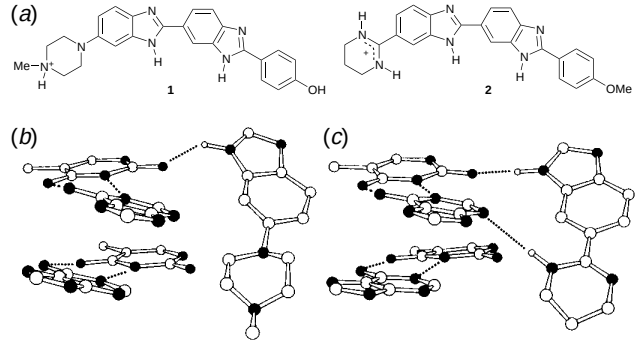

**Fig. 1** (*a*) Structure of Hoechst 33258 **1** and Hoechst 43254 **2**. (*b*) Portion of the X-ray structure of Hoechst 33258 (described by Quintana *et al.*[10]) illustrating the position and orientation of the *N*-methylpiperazine ring in the minor groove. (*c*) Hoechst 43254 complex modelled using the same X-ray coordinates and MACROMODEL software.[14] The ligand structure was energy minimised separately to determine the preferred conformation and orientation of the amidine ring. This conformation was adopted in initial modelling studies of the complex of **2**, keeping all other dihedral angles and ligand–DNA interactions the same as in the X-ray structure. The complex was subsequently energy minimised and subjected to 100 ps of unrestrained room temperature molecular dynamics. The resultant amidine NH → adenine N3 hydrogen bonding distance, which was not added as a constraint, was found to be 2.3 Å.

Both are shifted appreciably further downfield than the corresponding resonances in the complex of Hoechst 33258 with the same DNA sequence (δ 11.02 and 12.03, respectively).[5] Given that both ligands appear to bind similarly to the central AATT binding sequence, we interpret these larger binding shifts for **2** as consistent with stronger electrostatic interactions[16,17] and with overall tighter binding within the minor groove. Thus, introducing a more favourable interaction at the amidine end of the ligand appears to cooperatively enhance other intermolecular interactions at the ligand–DNA interface. Further, the well-resolved resonance at δ 9.39 is assigned to the amidine NH of the bound ligand on the basis of cross-peaks in 2D NOESY spectra to adjacent methylene protons (δ 3.82) on the ring. Identification of this resonance has enabled us to probe the role of the hexacyclic amidine ring in intermolecular interactions. The amidine NH has a small temperature coefficient (< 3 ppb/°C), a very slow rate of exchange (as judged by variable temperature and saturation transfer experiments), and gives a number of intermolecular NOEs that support both its close proximity to the floor of the minor groove, and possible involvement in specific hydrogen bonding with it. It is notable that the amidine NH signal has an integrated intensity equivalent to two protons, indicating that the solvent-exposed and solvent-buried ring NH are equivalent even at 278 K. Averaging of the signals from the C3 and C5 methylene protons adds further weight to the conclusion that in the bound state the ring is undergoing 180° flips (or free rotation) such as to rapidly interchange the environments on either side of the ring. Thus, a proposed hydrogen bond that appears to contribute significantly to complex stability also appears to be a dynamic interaction.

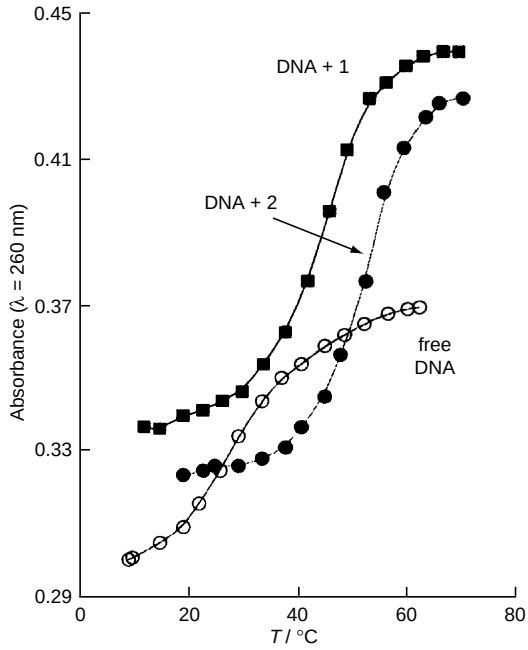

**Fig. 2** UV melting curves for the decamer duplex d(GGTAATTACC)$_2$ with and without bound ligands (**1** and **2**). Errors in $T_m$s were estimated to be less than ±2 °C. Sample concentrations and buffers are indicated in the text. The sample of Hoechst 33258 was purchased from Aldrich, while Hoechst 43254 was kindly provided by Hoechst, Frankfurt, Germany. Both samples were checked by $^1$H NMR and used without further purification. The oligonucleotide duplex was synthesised trityl-on using solid-phase phosphoramidite chemistry and purified by reverse-phase HPLC using 0.1 M triethylammonium acetate (TEAA) buffer and an acetonitrile gradient. The trityl group was removed by treatment with 50% aqueous acetic acid for 1 h at 35 °C and the oligonucleotide finally dialysed to remove TEAA and introduce $Na^+$ as the counter-ion.

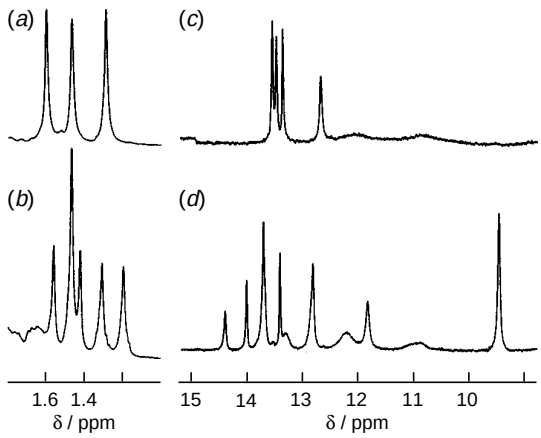

**Fig. 3** $^1$H NMR spectra (500 MHz) of ligand-free DNA (*a*) and (*c*), and of the complex with Hoechst 43254 (*b*) and (*d*), recorded in 90% $H_2O$ solution at 298 K using a 1-1 jump-return pulse sequence to suppress the solvent peak. A spectral width of 24 ppm was employed with a delay of 70 μs to optimise excitation at the position of the imino proton resonances (~ 13 ppm).

We thank the EPSRC for a research studentship to C. E. B. S. K. J. E. was the recipient of an Australian Postgraduate Research Award held at the Victorian College of Pharmacy, Parkville, Victoria, Australia. The Department of Chemistry at the University of Nottingham, the Nuffield Foundation and the Royal Society are gratefully acknowledged for financial support. We thank John Keyte for oligonucleotide synthesis.

# Efficient polymer-supported Sharpless alkene epoxidation catalyst

**Laetitia Canali,[a] Jaana K. Karjalainen,[a] David C. Sherrington[a] and Osmo Hormi[b]**

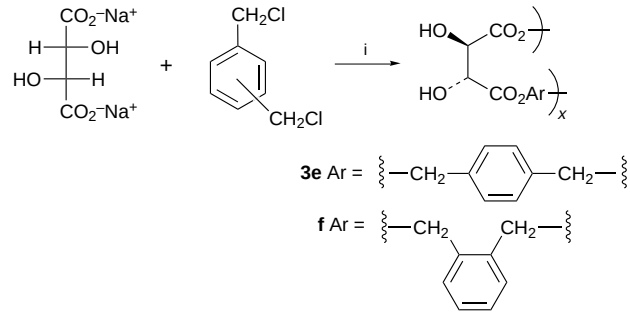
**Linear poly(tartrate ester) ligands provide high chemical yields and enantiomeric excesses in the epoxidation of *trans*-hex-2-en-1-ol using Ti(OPr$^i$)$_4$–*tert*-butyl hydroperoxide.**



The advantages of polymer-supported reactive species are now widely recognised by organic chemists, and increasing exploitation of these systems is occurring both in academic and industrial laboratories.[1] The effective immobilisation of asymmetric catalysts, reagents and auxiliaries is a particularly important methodological target, especially for metal complex-based catalysts. Progress in the area has been reviewed by Hodge[2] and Sherrington.[1] Unfortunately, more often that not the supported systems display levels of induction below those of the corresponding low molecular weight species. However, a notable exception is the Zn-catalysed asymmetric alkylation of aldehydes using $ZnEt_2$ with chiral amino alcohols, where polymer-supported analogues yield very high levels of enantiomeric excess (ee).[3,4] Recently attention has focussed on a number of asymmetric alkene oxidation catalysts. Attempts to immobilise Jacobsen's asymmetric Mn$^{III}$-based alkene epoxidation catalyst[5] have led to polymeric species which offer only relatively low ees in typical reactions.[6,7] However, the results reported by Song *et al.*[8] on the Sharpless asymmetric dihydroxylation of alkenes[9] using catalytic levels of $OsO_4$ with $K_3Fe(CN)_6$–$K_2CO_3$ as secondary oxidant and polymeric alkaloids as the chiral ligand are remarkable, with essentially quantitative asymmetric induction coupled with high chemical yields.

Interestingly, there are no reports of the successful immobilisation of the Sharpless Ti–tartrate ester-based asymmetric alkene epoxidation catalyst, despite this being a relatively long-standing and well used methodology.[10] An early attempt to develop a polymer-supported system by Farrell *et al.*[11] employed a single tartrate ester unit bound to a polystyrene resin. However, the induction achieved (*ca.* 50–60% ee) was only modest. We now report on the synthesis of a group of poly(tartrate ester)s and their use with titanium tetraisopropoxide [Ti(OPr$^i$)$_4$] and *tert*-butyl hydroperoxide (tBHP) as the oxidant in epoxidising *trans*-hex-2-en-1-ol **4** in high chemical yield and good ee.

Poly(tartrate ester)s **3a**–**d** were synthesised from L-(+)-tartaric acid **1** and diols **2** using a standard polycondensation procedure[12] (Scheme 1). Water and unreacted diol were removed by distillation under high vacuum at the end of the reaction. The polymers were extracted with acetone in a Soxhlet apparatus and dried in a vacuum oven (50 °C) for *ca.* 15 h. Poly(tartrate ester)s **3e,f** were synthesised from L-(+)-tartartic acid disodium salt dihydrate dissolved in water and α,α′-dichloroxylene dissolved in $CHCl_3$ by a phase transfer catalysed procedure[13] using tetrabutylammonium bromide hydrate (TBAB) as the catalyst (Scheme 2). The results of polymerisations are shown in Table 1. All the polymers were soluble in $Me_2SO$ and so crosslinking side-reactions involving the secondary OH group on the tartrate residue appear to be absent. The polymers also display a positive optical rotation, and while it is not possible to say that no racemisation of the tartrate residues occurs during polymerisation, the values of the observed

rotations are comparable with those reported[14] for dimethyl L-(+)-tartrate {$[\alpha]_D^{22}$ + 21 (*c* 2.5, $H_2O$)} and for diethyl L-(+)-tartrate {$[\alpha]_D^{20}$ + 8.5 (neat)}.

Polyesters **3a**–**f** were used as ligands in the epoxidation of **4** with $Ti(OPr^i)_4$–tBHP as shown in Scheme 3. Powdered activated 4 Å molecular sieves, polymeric ligand and $Ti(OPr^i)_4$ were first mixed in $CH_2Cl_2$ at −20 °C for 1 h, the tBHP was added and the mixture stirred for a further 1 h at −20 °C before **4** in $CH_2Cl_2$ was added. The reaction was then left to proceed for 3 h at *ca.* −20 °C, when the GC yield was determined. Each reaction mixture was then stored overnight in a freezer before work-up and isolation of pure **5** *via* Kugelrohr distillation. Enantiomeric excess was determined by chiral HPLC using a Chiralcel OB column and hexane–isopropyl alcohol (97.5 : 2.5) as eluent. The results are summarised in Table 2. Generally reactions are fast even at −20 °C with GC yields (3 h) in the range 20–90% depending upon the polymer ligand **3** used. In some instances isolated yields are higher than GC yields because the reactions continue in the freezer overnight. Isolated yields, however, are by no means optimised; pure **5** was isolated simply for optical rotation measurements and considerable scope remains for optimisation. Enantiomeric excesses generally fall in the range 40–80% with a significant dependence on the poly(tartrate ester) employed. Polymer (**3a**) is very poor, and polymer (**3c**) the most effective. The origin of the 'polymer effect' is not clear and may well involve a contribution from solubility and molecular weight variation, and from conformational factors. Polymers **3a** and **3b** are rather insoluble in $CH_2Cl_2$, as is **3c**. However, the latter does form a $CH_2Cl_2$ soluble complex with $Ti(OPr^i)_4$. This led us to prepare **3d** which is itself soluble in $CH_2Cl_2$; however, **3d** gave poorer levels of induction than **3c** under comparable conditions so that solubility alone is not the only factor. Solubility limitations have made molecular weight determination difficult, but two different batches of **3d** yielded $\overline{M}_w$ = 4150 and 4210, with $\overline{M}_w/\overline{M}_N$ = 1.7 (gel permeation chromatography; polystyrene standards in THF). Compound **3d** is therefore oligomeric rather than polymeric, and further work is underway to investigate this parameter. It seems most likely that the active species with simple dialkyl tartrate–$Ti(OPr^i)_4$ are rather complicated, possibly 2 : 2 complexes.[16] The effectiveness of poly(tartrate ester)s may well therefore depend also on the ability of these backbones to assume a conformation which allows maximum opportunity for the formation of such complexes. In this respect, in due course, investigation of poly(tartrate ester)s may well provide useful structural information on the active species themselves.

At the moment we are further optimising these reactions and pursuing the above structural aspects. We are also making crosslinked poly(tartrate ester) gels and immobilising linear poly(tartrate ester)s on supports such as poly(styrenedivinylbenzene) in an attempt to produce highly practical re-usable heterogeneous Sharpless epoxidation catalysts.

We acknowledge funding from the Neste Oy Foundation and the Finnish cultural Foundation. We also appreciate the molecular weight determinations carried out by RAPRA.

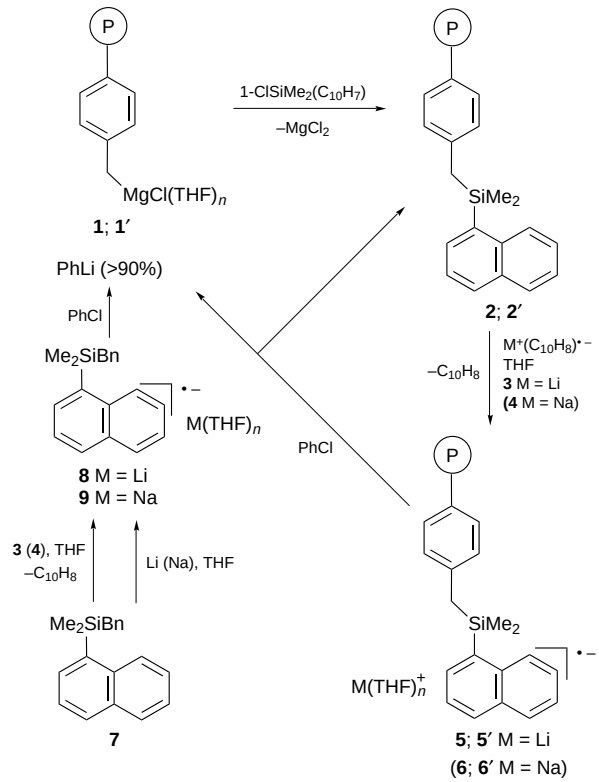
# Polymer supported alkali metal naphthalenides: application in the generation of lithium and sodium reagents

**Tania R. van den Ancker,[a] Graeme R. Hanson,[b] Fu-Chin Lee[a] and Colin L. Raston[c]**

[a] *Faculty of Science and Technology, Griffith University, Nathan, Queensland 4111, Australia*
[b] *Centre for Magnetic Resonance, University of Queensland, St Lucia, Queensland 4072, Australia*
[c] *Department of Chemistry, Monash University, Clayton, Melbourne, Victoria 3168, Australia*



**Polymer supported lithium and sodium naphthalenide complexes are prepared from the reaction of THF solutions of lithium and sodium biphenylide with polystyrene bearing -$CH_2SiMe_2(1\text{-}C_{10}H_7)$ groups, generating highly coloured paramagnetic material, which afford lithium and sodium reagents in high yield when treated with organic halides, nitriles and phosphates.**

Lithium arene radical anion complexes afford organic lithium complexes in high yield;[1] the solutions of these reagents, however, are loaded with the arene by-product. Yus *et al*.[2] have developed a method for the preparation of lithium reagents by the reaction of lithium powder with catalytic amounts of arene (1–2%), resulting in a reduced amount of the by-product. A strategy that completely avoids generating solutions containing the arene is the use of supported lithium reagents. This is developed herein for polymer supported lithium reagents, along with analogous supported sodium reagents, due to their utility in generating lithium and sodium reagents which can be separated from the spent polymer by simple filtration. This work follows from our success in developing synthetically useful polymer[3,4] and silica[5] supported magnesium anthracene. These act as a source of magnesium in the generation of anthracene-free benzylic Grignard reagents.

The naphthalene functionalised polymer **2**; **2′** (Scheme 1) was prepared by the treatment of a THF slurry of the Grignard reagent of chloromethylated polystyrene[3,6] (microporous BIO-RAD S-X1, 1.34 mmol $g^{-1}$ **1** and 4.11 mmol $g^{-1}$ **1′**, 1.0% crosslinked) with an excess of 1-(chlorodimethylsilyl)naphthalene† at 0 °C, in greater than 95% yield based on weight increase (assuming two THF molecules attached to the metal centre), IR studies and analysis for residual chlorine content of $< 0.3$ mmol $g^{-1}$. Solutions of lithium biphenylide **3** in THF (or DME) were added to THF (or DME) slurries of polymers **2**; **2′** resulting in the formation of a red–brown paramagnetic material ($g_{av}$ = 2.0034, 2.0035/THF; $g_{av}$ = 2.0029, 2.0026/DME) of polymer supported lithium naphthalenide **5**; **5′**. Similarly addition of a THF (or DME) solution of sodium biphenylide **4** to THF (or DME) slurries of polymers **2**; **2′** resulted in the formation of a red–brown paramagnetic material ($g_{av}$ = 2.0034, 2.0035/THF; $g_{av}$ = 2.0029, 2.0100/DME) of polymer supported sodium naphthalenide **6**; **6′**. Lithium and sodium biphenylide were chosen as the electron transfer reagents because of the lower reduction potential of biphenyl (−2.70 V *vs*. SCE) relative to that of naphthalene (−2.50 V *vs*. SCE), thus favouring transfer from the biphenyl to naphthalene;[7] the presence of the silyl group on naphthalene in the polymer would further favour electron transfer since silicon stabilises charge by polarisation.[9] No reaction was evident between **2**; **2′** and activated lithium powders.

In an attempt to model the reaction of the functionalised polymers, 1-(benzyldimethylsilyl)naphthalene‡ **7** was prepared. Reaction with lithium or sodium metal yielded a deep green paramagnetic solution of lithium[1-(benzyldimethylsilyl)naphthalene](THF)$_n$ **8**, ($g_{av}$ = 2.0028) and sodium[1-(benzyldimethylsilyl)naphthalene](THF)$_n$ **9**, ($g_{av}$ = 2.0028) respectively (Scheme 1). Complexes **8** and **9** were also prepared by the reaction of **7** with THF solutions of **3** and **4** respectively.

EPR spectra of the polymer supported alkali naphthalenides **5** and **6** were obtained at room temperature in THF. The EPR spectrum of **5** is shown in Fig. 1(*a*), the simulated spectra in Fig. 1(*b*). The spectrum appears as a multiplet ($g_{av}$ = 2.00275) with hyperfine coupling. Extensive simulation using SOPHE[10] indicated the multiplet arises from the coupling of two equivalent lithium atoms [$A(^7\text{Li}) = 2.327(4) \times 10^{-4}$ cm$^{-1}$], four equivalent protons [$A(^1\text{H}) = 1.310(4) \times 10^{-4}$ cm$^{-1}$] and two other equivalent protons [$A(^1\text{H}) = 2.424(4) \times 10^{-4}$ cm$^{-1}$] to a single unpaired electron. Consequently, the EPR spectrum arises from an unpaired electron delocalised over two lithium centres rather than a contact ion pair involving a lithium and a radical anion. Polymer supported magnesium anthracene has radical anion sites with the divalent magnesium accounting for a pair of radicals.[3,4] The EPR spectrum of polymer supported sodium naphthalenide also gave a multiplet with hyperfine coupling, in this case there is a broadening of the signals, resulting in difficulty in the simulation. The broadening may arise from dipole–dipole interaction of the sodium atoms a phenomenon seen in sodium zeolite systems.[11]

**Scheme 1**

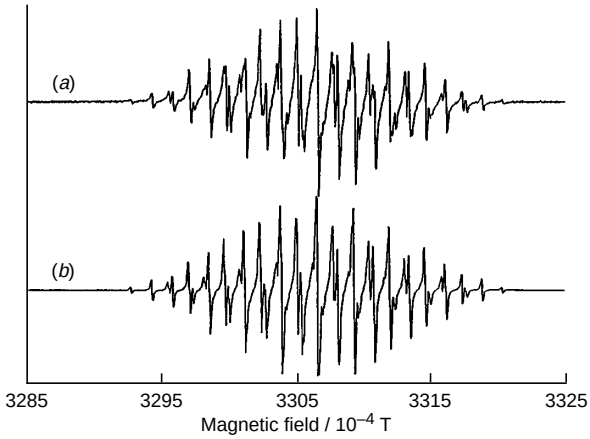


**Fig. 1** EPR spectra of polymer supported lithium naphthalenide **5**: (*a*) experimental (ν = 9.2776 GHz) and (*b*) simulated spectra

Polymer **5**; **5′** affords lithium reagents with a range of organic halides [*e.g.* chlorobenzene, 9-chloroanthracene, 2-(3′-chloropropyl)-2-methyl-1,3-dioxalane, 3-chloro-1-phenylpropan-1-ol], organo nitriles (acetonitrile, benzonitrile) and triorganophosphates [O=P(OR)$_3$, R = Et, Ph] in > 75% yield at *ca.* 0.1 M. These reactions are based on two different methods. The first involves the formation of the organoalkali, which is then quenched to give the desired complex.§ The second reaction involves the quenching of the organoalkali complex *in situ*, in a Barbier-type¶ reaction. Reaction of **8** and **9** with 0.5 equiv. of chlorobenzene or 9-chloroanthracene both gave the corresponding lithium or sodium complexes, respectively.

The spent polymers **2**; **2′** were tested for recycling potential and overall the uptake of lithium from **3** and the yield of lithium reagents obtained differ only slightly over successive cycles. As an example, for three such cycles for **5** the uptake of lithium from **3** was successively 110, 100 and 100% with the corresponding yields of lithiobenzene at 93, 91 and 89% (based on titrations). Each cycle involved quenching **5** with chlorobenzene, separating the polymer and washing it with THF followed by treatment with **3** to regenerate a deep red polymer. Investigations into the use of the sodium naphthalene polymer to generate the sodium reagent of chlorobenzene were also undertaken, with yields of > 80%. This work has also been extended to the use of metal oxide supported complexes.[12]

The main advantages in using polymers **5**; **5′** and **6**; **6′** in generating lithium and sodium reagents, which is possible for a variety of substrates, are that the reactions are high yielding, and the reaction mixtures are free of arene by-products. The ability to recycle the polymers is also noteworthy, as is the fact that the supported polymers offer a means of delivering a small amount of the equivalent of a Group 1 metal.

We thank the Australian Research Council for support of this work.

## Footnotes

† 1-(Chlorodimethylsilyl)naphthalene was prepared by quenching 1-lithionaphthalene with excess dichlorodimethylsilane.[8]

‡ 1-(benzyldimethylsilyl)naphthalene **8** was prepared by the treatment of benzylmagnesium chloride with **2**, in $Et_2O$ in 66% yield (bp 137 °C, 0.5 mmHg, satisfactory spectroscopic and analytical data obtained).

§ In a typical experiment the organic halide in THF was slowly added over 20 min to a THF slurry of the polymer supported lithium naphthalenide at −78 °C. This resulted in the dissipation of the red colour of the polymer supported lithium naphthalenide and the formation of an orange solution. The solution was stirred for a further 1–3 h then filtered to give the arene free organoalkali. In all cases target concentrations of the resulting lithium reagent were close to 0.1 M. For example the lithium reagent of chlorobenzene was generated in > 95% yield (by titration) with quenching by chlorotrimethylsilane affording trimethylsilylbenzene in 90% yield as the exclusive product.

¶ A mixture of the organic halide and electrophile in THF was slowly added over 45 min to a THF slurry of the polymer supported lithium naphthalenide at −30 or 0 °C. This resulted in the dissipation of the red colour and the formation of a pale yellow solution. The resulting solution was then stirred for 15 min, filtered, and the solution hydrolysed and the product extracted into $Et_2O$ and purified by distillation. As an example, benzonitrile gave trimethylsilylbenzene in 75% yield as the only product.

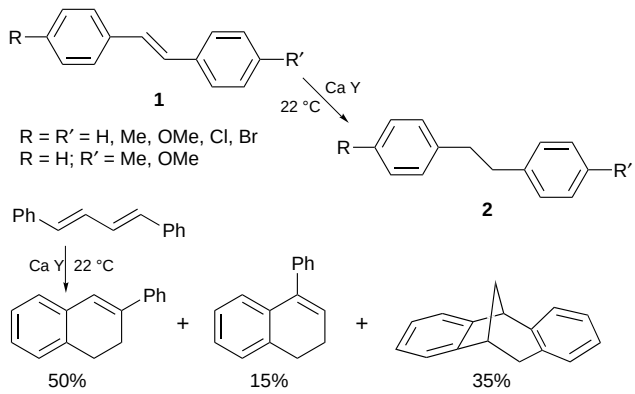
# Zeolite as a reagent and as a catalyst: reduction and isomerization of alkenes by Ca Y

**K. Pitchumani, Abraham Joy, Nicolette Prevost and V. Ramamurthy***

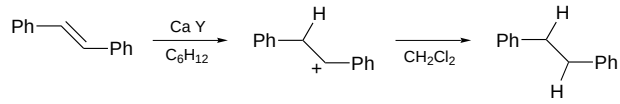


*Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*

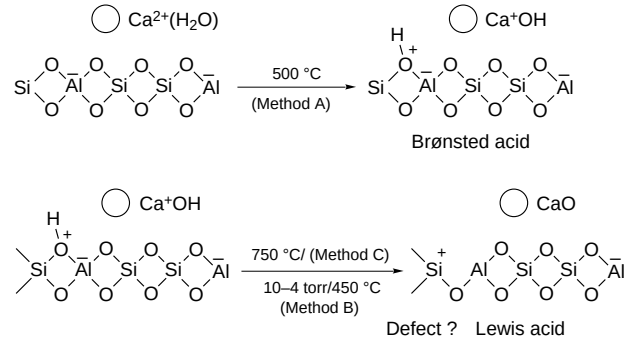
**Depending on the number of Brønsted acid sites present, Ca Y can act either as a reagent and reduce stilbenes to 1,2-diarylethanes or act as a catalyst and isomerize *cis*-stilbenes to the more stable *trans* form; Lewis acid sites generated by the activation process yield radical cations from stilbenes but these do not yield any stable products.**

In spite of its success as an industrial catalyst, the main use of zeolite in the laboratory is still only as a drying agent.[1] Here we show that zeolite can be used to carry out some routine organic transformations. Examples presented illustrate that the characteristics of the zeolite are essentially controlled by its activation procedure.

In this study Ca Y was used.† Since the exact nature of activation determines the behaviour of Ca Y, the activation method is described in detail. In method A, a known amount of the zeolite was placed inside a preheated (*ca*. 500 °C) oven under aerated conditions and activated for *ca*. 10 h. The zeolite was taken out of the oven at that temperature, cooled for *ca*. 2–3 min in the laboratory atmosphere and dropped into a hexane solution of stilbenes **1** (10 mg) after which the resultant slurry was stirred for 1 h. Extraction of the hexane–zeolite slurry with methylene chloride gave the corresponding 1,2-diarylethanes **2** in high yield ( > 90%) (Scheme 1). It is important to note that the reduction is fairly facile, nearly quantitative and is devoid of side reactions.

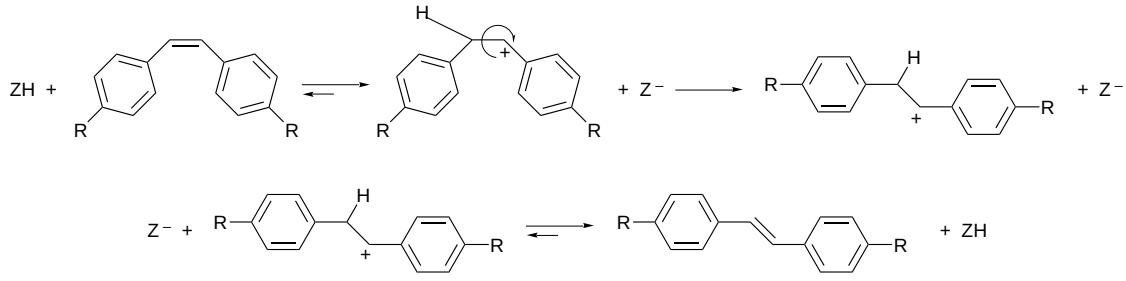


Reduction by Ca Y of a double bond activated by method A was found to be general. For example, 1,1-diphenylethylenes, *p*-methoxystyrene, β-methyl-*p*-methoxystyrene, 1-phenylcyclopentene and 1-phenycyclohexene were reduced to the corresponding hydrocarbons by Ca Y.[2] However, when this reaction was extended to 1,4-diphenylbutadiene, a surprising rearrangement occurred. Addition of Ca Y, activated by method A, to a hexane solution of 1,4-diphenylbutadiene (10 mg), resulted in quantitative conversion to the products shown in Scheme 1. This reaction was exceptionally rapid; the reaction was complete within 5 min of addition. While we are sure that a carbocation is involved in these rearrangements, we are not certain of the details of the mechanism. Work is underway to establish the mechanism.



**Scheme 1**

The proposed mechanism for the reduction of stilbenes is shown in Scheme 2. It is known that activation of Ca Y at 500 °C under aerated conditions generates a large number of Brønsted acid sites within the supercages of the Y zeolite.[1] Formation of $H^+$ has been established to result from the dissociation of water by the strongly polarizing divalent cation $Ca^{2+}$ (Scheme 3). By the use of a combination of Ca Y ($H_2O$), Ca Y ($D_2O$) and deuteriated solvents ($C_6D_{12}$ and $CD_2Cl_2$), we showed that one of the hydrogen atoms comes from a water molecule present within the zeolite before activation and the other from the solvent. The carbocation derived from *p,p*′-dimethoxystilbene was found to be unusually stable. The diffuse reflectance spectrum of Ca Y included with *p,p*′-dimethoxystilbene showed transitions corresponding to the carbocation in the region *ca*. 300–370 nm.[3]



In the second method (method B), the zeolite was activated on a vacuum line at 450 °C. The procedure involved the following steps: a known amount of Ca Y taken in a quartz tube was degassed on a vacuum line at $5 \times 10^{-4}$ Torr for about 2 h. While maintaining the vacuum, the sample was heated to 450 °C at a rate of 20 °C $min^{-1}$ and maintained at 450 °C for *ca*. 10 h. The zeolite was cooled to room temperature and added to a hexane solution of *cis*-**1** and stirred for 3 h. Extraction of the solution gave *trans*-**1** in quantitative yield. Previous studies of alkaline earth cation exchanged zeolites have shown that the condition of activation dictates the generation of Brønsted and Lewis acid sites (Scheme 3).[1] It has been established that activation at higher temperatures ( > 750 °C) or at moderate temperatures ( > 400 °C) under vacuum results mostly in Lewis acid sites; only very few Brønsted acid sites are generated under such conditions. When we used the zeolite activated at 750 °C (method C) only isomerization was observed. Such zeolites failed to reduce the *trans*-**1**. In conclusion, the behaviour of Ca

**Scheme 2**

**Scheme 3**

**Scheme 4**

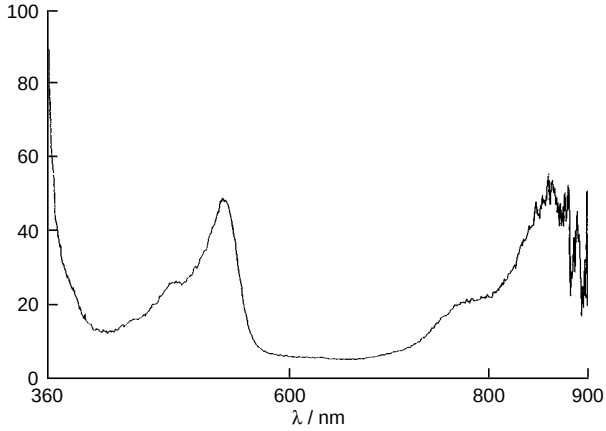


**Fig. 1** Diffuse reflectance spectrum of *p,p′*-dimethoxystilbene included within Ca Y activated at 450 °C under vacuum ($10^{-4}$ Torr)

Y activated by method A was different from the ones activated by methods B and C.

The proposed mechanism for the geometric isomerization of **1** is shown in Scheme 4. The acid–base equilibria represented in Schemes 2 and 4, we propose, are controlled by the number of Brønsted acid sites present in Ca Y. When the number of Brønsted acid sites is disproportionately large when compared to the number of alkene molecules present in a zeolite, the acid–base equilibrium favours the permanent formation of carbocations. These carbocations have a long lifetime and abstract a hydride ion from the solvent to yield **2**. When the number of Brønsted acid sites is relatively small, not enough carbocations are generated to yield significant amounts of **2**. However, when the *cis* isomer is the guest, the protonation results in the conversion of the *cis* isomer to the thermodynamically more stable *trans* form. From the above studies it has become evident that the key to effecting selective *cis* to *trans* isomerization (without reduction) is to control the number of Brønsted acid sites within a zeolite.

In addition to the carbocation, cation radicals were also formed when stilbenes **1** were added to activated Ca Y. The extent of cation radical formation dependent on the method of activaton of Ca Y. While methods B and C gave relatively large amount of radical cations, the method A gave only minor amounts. The diffuse reflectance spectrum displayed in Fig. 1 for *p,p′*-dimethoxystilbene can clearly be identified with the radical cation of the alkene.[4] Consistent with this assignment, EPR signals were observed with the sample. The EPR spectra in all cases were broad and structureless. The radical cations generated spontaneously within Ca Y were stable for several days. Although we rule out Brønsted acid sites as possible electron acceptor sites, we have no knowledge of the nature of the electron acceptor at this time.[5]

We have shown that both carbocations and cation radicals from alkenes can be generated within Ca Y. Further, we have established that by carefully controlling the conditions of activation, one can selectively generate long-lived organic carbocations and cation radicals within such zeolites. We are in the process of identifying the electron acceptor sites within zeolites and the source of hydride ion during the reduction process.

## Footnote

† Ca Y was prepared by exchanging Na Y with calcium nitrate for 12 h at 100 °C. The exchange was repeated four times, the solid filtrate was washed thoroughly with water and dried at 90 °C for *ca.* 16 h. ICP analysis indicated the exchanged zeolite to have a composition of $Si_{138.7}Al_{53.3}Na_{7.5}$-$Ca_{23.3}O_{884}$.

# Catalytic activity of FSM-16 for photometathesis of propene

**Hisao Yoshida,* Koichi Kimura, Yoshitaka Inaki and Tadashi Hattori**

*Department of Applied Chemistry, Graduate School of Engineering, Nagoya University, Nagoya 464-01, Japan*

**Mesoporous silica (FSM-16) catalyses metathesis of propene under photoirradiation at a higher activity than amorphous silica whereas microporous silica crystals (silicalite-1) do not catalyse the reaction.**

Mesoporous silica materials such as MCM-41[1,2] and FSM-16[3,4] attract a great deal of attention as new materials and many applications are expected. Although the application of these materials for catalysis has been widely studied, attention has also been paid to the generation of catalytic activity through the introduction of other metal ions into the silica lattice, but not to the catalytic activity of unmodified mesoporous silica.

Here, we show that unmodified mesoporous silica (FSM-16) has a higher catalytic activity in the photometathesis of propene than does amorphous silica which was recently found to be catalytically active in this reaction.[5] To elucidate structural factors of mesoporous silica in this reaction, we compare the catalytic activities of other forms of $SiO_2$; amorphous silica, microporous crystalline silica (silicalite-1)[6] and high-silica zeolite (dealuminated mordenite).

Amorphous silica (AMS) was prepared by the sol–gel method[7] by hydrolysis of tetraethylorthosilicate (TEOS) followed by calcination at 773 K for 5 h. FSM-16 was prepared essentially in the same manner as described by Inagaki *et al.*[3,4] except that hexadecyltrimethylammonium bromide was used as a template and the resulting material was calcined at 873 K in an $N_2$ atmosphere for 1 h and subsequently in air for 5 h. Silicalite-1 was synthesized from TEOS and tetrapropylammonium bromide (TPABr) by hydrothermal synthesis (433 K, 24 h) followed by washing, drying and calcination at 823 K. Dealuminated mordenite (DM, $SiO_2/Al_2O_3$ = 328) was obtained by extraction (12×) of aluminium using 8 M HCl at 333 K for 24 h[8] from JRC-Z-HM15 (a reference catalyst,[9,10] Catalysis Society of Japan). The structures of the samples were confirmed by XRD and $N_2$ adsorption–desorption isotherms.

Photocatalytic conversion of propene was carried out under irradiation for 1 h using a 250 W Hg lamp in a closed static system (120 ml; propene 100 μmol) at room temperature. The powdered catalyst (200 mg) was spread on the flat bottom (12 $cm^2$) of a quartz reactor irradiated from beneath. Pretreatment of catalyst was performed at 873 K (or 1073 K) in air for 2 h and in the presence of 100 Torr oxygen for 1 h, followed by evacuation at the same temperature. After 1 h reaction, products and unreacted propene were collected with a liquid-$N_2$ trap when the catalyst was under irradiation, and were analysed by GC.

The XRD patterns of the samples pretreated at 873 K and that of silicalite-1 pretreated at 1073 K are shown in Fig. 1. AMS (*a*) showed a very broad diffraction peak at 2θ *ca.* 22°, indicating its amorphous nature. The FSM-16 sample (*b*) exhibited low-angle diffraction peaks at 2θ 2.36, 4.06 and 4.68° and a very broad diffraction peak at 2θ *ca.* 23° as reported,[3,4] indicating that this material has ordered hexagonal mesopores with XRD amorphous walls. Silicalite-1 (*c*) and DM (*d*) were clearly assigned by comparison with their published structures.[6,11] The structures of AMS, FSM-16 and DM were essentially unchanged upon calcination at 1073 K, while silicalite-1 calcined at 1073 K (*e*) gave an XRD pattern resembling that of amorphous silica.

The $N_2$ adsorption isotherms of AMS and FSM-16 were of type IV indicating the presence of mesopores; isotherms of silicalite-1 and DM were of type I, also suggesting microporous structures.

Table 1 shows the catalytic activities of the samples evacuated at 873 K for propene metathesis under photoirradiation. AMS catalysed the metathesis reaction quite slowly, the activity roughly corresponding to that reported previously.[5] By contrast, FSM-16 showed a much higher metathesis activity than AMS. It should be noted that FSM-16 seemed to exhibit a higher specific activity than AMS. This is because the ratio of catalytic activity of FSM-16 to that of AMS is larger than the ratio of BET surface areas (1170 and 580 $m^2\ g^{-1}$ for FSM-16 and AMS, respectively). The $C_2/C_4$ ratio on FSM-16 was close to unity, indicating the metathesis reaction proceeded selectively. In contrast, silicalite-1 showed no activity, indicating its microporous structure is of no advantage under the reaction conditions. DM also give no gaseous products and judging from

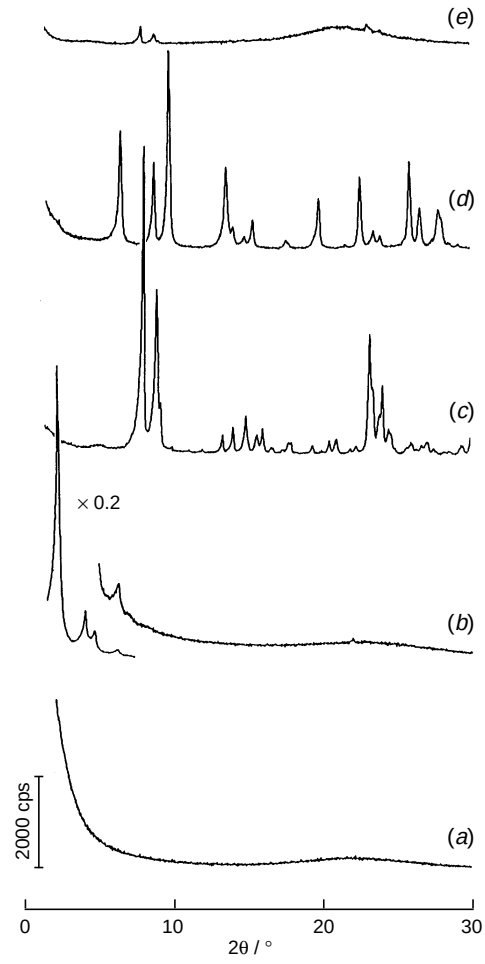

**Fig. 1** XRD patterns of porous silica materials: (*a*) amorphous silica (AMS), (*b*) FSM-16, (*c*) and (*e*) silicalite-1 and (*d*) dealuminated mordenite (DM). Samples (*a*)–(*d*) were calcined at 873 K and (*e*) at 1073 K. The intensity of the low-angle region of (*b*) is reduced to 1/5.

**Table 1** Results of tests for propene photometathesis on silica materials

| Pretreatment temperature/K | Sample | Yield (%) | | | | | Conv. (%) to metathesis | $C_2/C_4$ ratio |
|---|---|---|---|---|---|---|---|---|
| | | $C_2$[a] | *trans*-$C_4$ | *cis*-$C_4$ | 1-$C_4$ | Adsorbed | | |
| 873 | AMS | 1.4 | 1.0 | 0.7 | 0.0 | 1.0 | 3.1 | 0.82 |
| | FSM-16 | 8.2 | 5.7 | 2.8 | 0.3 | 5.8 | 16.9 | 0.94 |

[a] $C_2$ = ethene, $C_4$ = butene. [b] Conversions on amorphous silica and FSM-16 reached equilibrium under the reaction conditions.[5]

the colour of DM after reaction, propene appears to have been adsorbed and polymerized on acid sites of DM.

Upon evacuation at higher temperature (1073 K), the activities of AMS and FSM-16 greatly increased, while DM produced no gaseous products, as shown in Table 1. Activation of amorphous silica upon evacuation at high temperature is in agreement with a previous report.[5]

Upon evacuation at 1073 K the zeolite structure of silicalite-1 was destroyed and became XRD amorphous (BET surface area 7.5 $m^2\ g^{-1}$). This amorphous sample gave no metathesis products even after 30 h reaction.

It is suggested from the results on the catalyst samples evacuated at 873 K that an amorphous phase of silica might be necessary for photometathesis on silica since reaction did not proceed on microporous crystalline silica, but only on amorphous silica (AMS) and on FSM-16 whose walls are amorphous.[2,12] The results on the catalysts evacuated at 1073 K, however, indicated that catalytic activity is governed by the other factors, since amorphous samples produced by evacuation of silicalite-1 showed no activity.

Another distinguishable factor between these samples is the concentration of surface hydroxy groups: microporous crystals have few hydroxy groups, while amorphous silica surfaces such as AMS and FSM-16 would possess a large amount of hydroxy groups, The increase of activity of AMS and FSM-16 evacuated at higher temperature indicates that this process produces active sites on the samples. Therefore it is suggested that sites produced by desorption of hydroxy groups would regulate the activity. For silicalite-1, there are only a small number of hydroxy groups prior to evacuation. Therefore, silicalite-1 evacuated at high temperature possesses few active sites, despite its amorphous surface.

There are two possibilities why FSM-16 exhibits higher activity than AMS. One is that FSM-16 has a larger number of surface hydroxy groups than AMS. The second is that the nature of the active sites differs from that of AMS as a consequence of the characteristic walls of FSM-16 which consist of double $SiO_4$ tetrahedral layers.[13]

In conclusion, the catalytic activity of unmodified mesoporous silica (FSM-16) has been investigated. FSM-16 exhibits higher photocatalytic activity for propene metathesis than amorphous silica. The key point is that FSM-16 has many hydroxy groups on the amorphous walls which constitute the hexagonal mesopore structure. The active sites are proposed to be produced by desorption by hydroxy groups from the amorphous surface of silica.

We thank Mr T. Abe, K. Nishi, T. Ishikura (Nagoya Univ.), S. Inagaki and Dr Y. Fukushima (Toyota Central R & D Labs., Inc.) for their help in the preparation of samples.

# Comparing the acidities of zeolites and SAPOs from first principles

**Rajiv Shah,[a] Julian D. Gale*[b] and Michael C. Payne[a]**

[a] *Cavendish Laboratory (TCM), University of Cambridge, Madingley Road, Cambridge, UK CB3 0HE*
[b] *Department of Chemistry, Imperial College, South Kensington, UK SW7 2AY*

**First-principles density functional calculations using periodic boundary conditions are used to demonstrate that SAPO-34 is less acidic than its aluminosilicate equivalent chabazite, based on the properties of the Brønsted-acid sites and their interaction with basic molecules.**

There is much interest in understanding the nature of microporous solid acid catalysts, which have many important applications in commercial processes. Two of the most commonly studied types of materials in this category are zeolites (aluminosilicates) and silicoaluminophosphates (SAPOs), which result from the substitution of aluminium for silicon and silicon for phosphorus, respectively, within the tetrahedral framework. Such negatively charged defect sites can be counterbalanced by the presence of a proton leading to the formation of Brønsted-acid sites which are believed to be the active sites for catalysis. If we are to gain any insight into the chemistry which occurs within the confines of microporous materials we need to understand the factors which can affect their acidity. In this study the relative acidity of a zeolite and SAPO with the same framework structure is considered, in order to examine the differences made by framework composition.

The question of Brønsted acidity in zeolites has been studied both experimentally,[1,2] and theoretically.[3] However the majority of the theoretical work has used small gas-phase clusters, often without reference to specific materials. More recent work has used periodic boundary conditions to study zeolites.[4] In a previous study[5] we have shown that inclusion of the full zeolite structure is essential if a proper characterisation of the energy surface around the acid site is to be achieved.

The current work uses the same methods to study a SAPO catalyst, allowing a comparison of the properties of these materials with zeolites. Gradient-corrected density functional theory (DFT) is used to calculate the electronic ground-state of the system, expanding the valence electronic wavefunctions in plane-waves upto a 650 eV cut-off and representing the nuclei and core electrons by norm-conserving pseudopotentials.† The framework structure was represented by a single unit cell of the material and periodic boundary conditions. All atoms were allowed to relax freely, except for the constraint of fixed cell shape. The material studied was SAPO-34, structurally analogous to the zeolite chabazite, used for our previous work. SAPO-34 has been observed to be an active catalyst for methanol conversion to hydrocarbons,[8] and so constitutes a realistic model. The structure has twelve tetrahedral sites in the unit cell. For simplicity the case of one Si substitution per unit cell has been considered.

The accuracy of gradient-corrected DFT to represent bonding and structure has been demonstrated by calculations of the lattice parameter of α-quartz and equilibrium bond lengths for a methanol molecule which are within ±1% of experimental values. The gas-phase proton affinity of a methanol molecule has also been reproduced within 1%.[5] The ability of these methods to represent hydrogen bonded systems was shown by Greatbanks *et al.*[9]

Initially we studied just the isolated framework Brønsted acid site. This is confirmed to consist of the proton forming a covalent bond with one of the oxygens around the Si site. A local minimum is found for the proton on any of the four symmetry inequivalent oxygens around the site. The relative energies and some other characteristics of these proton sites are listed in Table 1. The most stable site is O(1), but the difference in energy for O(3) is less than $kT$ at room temperature. The IR frequencies seen for these two sites may correspond to the distinct 3600 and 3625 $cm^{-1}$ O–H bands observed in dehydrated SAPO-34.[2] The range of energies of the sites is less than the 9 kJ $mol^{-1}$ spread seen for the four proton sites in the aluminosilicate chabazite, but it is O(1) which is most stable in both cases.[5] The O–H frequencies are higher and the O–H bond lengths slightly shorter than in the zeolite case. This would be consistent with the SAPO having a higher proton affinity due to a stronger O–H bond. The two bonds formed by the hydroxy group to the rest of the framework are more equal in length than seen in the aluminosilicate, where the bond to the Al is longer than that to Si.

Population analysis techniques[10] have been used to examine the bonding around such an acid site. This shows increasing ionic character around the substituted Si site. The Mulliken charge on the Si (+2.31) is not much higher than that found on substituted Al in zeolites (+2.14). The charges on the surrounding oxygens and hydroxy group are very similar, although the charge on the proton is slightly higher in the zeolite (+0.55) than in the SAPO (+0.53). Hence one would expect the leading term in a multipole expansion of the electrostatic potential to be similar for the zeolite and SAPO. However, the bond populations seen are quite different between the two systems, so higher terms in the expansion would differ. The overlap populations of the two bonds made by the hydroxy group to the framework are more equal in the SAPO (0.29 and 0.24) than in the zeolite (0.16 and 0.38), consistent with the more equal bond lengths.

Although the properties of the isolated Brønsted-acid sites give an indication of the relative O–H bond strengths between the different materials the real test of acidity comes from the interaction between the hydroxy group and a basic adsorbate. This depends not only on the proton affinity but also on the local electrostatic potential which is crucial in stabilising chemisorbed species. Experimentally, weak bases such as CO and $N_2$ are often used to probe acidity by measurement of the shift in

**Table 1** Energies, stretching frequencies and geometry around the O–H group for the four proton sites in SAPO-34. Energies relative to O(1). Values for the most stable site in the zeolite chabazite are also given for comparison. $\nu_{OH}^{harm}$ is the harmonic frequency, and $\nu_{OH}$ the anharmonicity corrected value (using a Morse potential[5])

| | O(1) | O(2) | O(3) | O(4) | Zeolite |
|---|---|---|---|---|---|
| $E$/kJ $mol^{-1}$ | 0 | 5 | 2 | 4 | — |
| $\nu_{OH}^{harm}$/$cm^{-1}$ | 3870 | 3860 | 3860 | 3865 | 3845 |
| $\nu_{OH}$/$cm^{-1}$ | 3610 | 3600 | 3600 | 3605 | 3590 |
| O–H/Å | 0.970 | 0.970 | 0.971 | 0.970 | 0.972 |
| Si–O/Å | 1.762 | 1.741 | 1.747 | 1.777 | 1.697 |
| Al–O/Å | 1.763 | 1.756 | 1.762 | 1.779 | 1.857 |
| Si–O–H/° | 110.6 | 109.0 | 109.3 | 111.0 | 113.5 |
| Al–O–H/° | 116.6 | 116.4 | 115.1 | 117.0 | 111.5 |
| Al–O–Si/° | 132.6 | 133.7 | 134.4 | 131.9 | 134.4 |

their stretching frequency. However, we have chosen to use methanol as a probe molecule because of the interest in the methanol to gasoline conversion process.[11] The adsorption of methanol in zeolites has been previously studied by us,[5] and here we extend this to consider the stable forms for methanol bound to a SAPO acid site. The case of one molecule per acid site was considered. From a number of different starting points the forces on the atoms were used to relax the atoms to the nearest local minimum by a BFGS technique. In the zeolite the geometry shown in Fig. 1 was found, with the proton transferred from the framework to the methanol. For the SAPO case a number of different geometries were found, but in none of these was proton transfer found to be stable. However, the framework O–H bond was lengthened by about 8%, and this hydrogen atom generally formed quite a short hydrogen bond (1.4–1.5 Å) to the methanol oxygen. The most stable geometry, with a binding energy of −77.9 kJ mol$^{-1}$, is illustrated in Fig. 2. Interestingly, although the molecule bridges across the Si site in the same way as it does across Al in zeolites, here the methanol hydrogen forms longer hydrogen bonds to two framework oxygens, rather than just one shorter bond to a single oxygen. Six-ring type geometries of the type found in zeolites were seen, but with the methanol hydrogen forming a single hydrogen bond, about 1.9 Å long, to one of the oxygens adjacent to Si. Such geometries were about 10 kJ mol$^{-1}$ higher in energy.

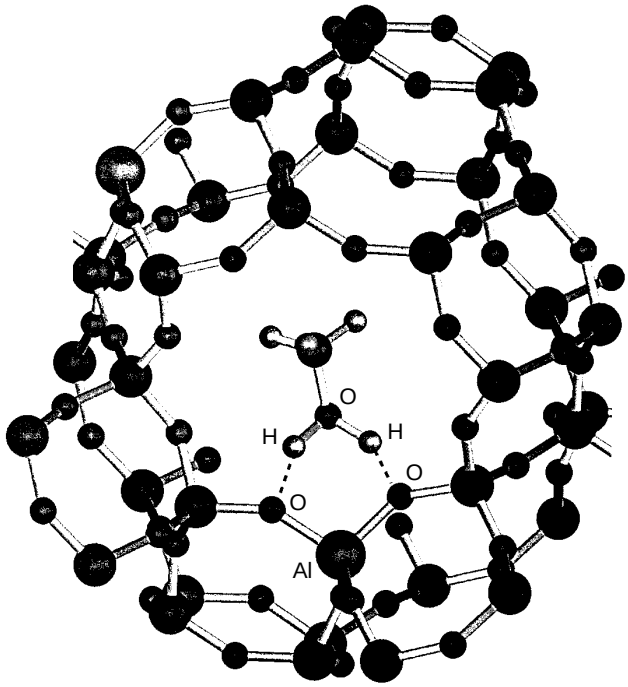

**Fig. 1** Six-ring geometry seen for protonated methanol in chabazite

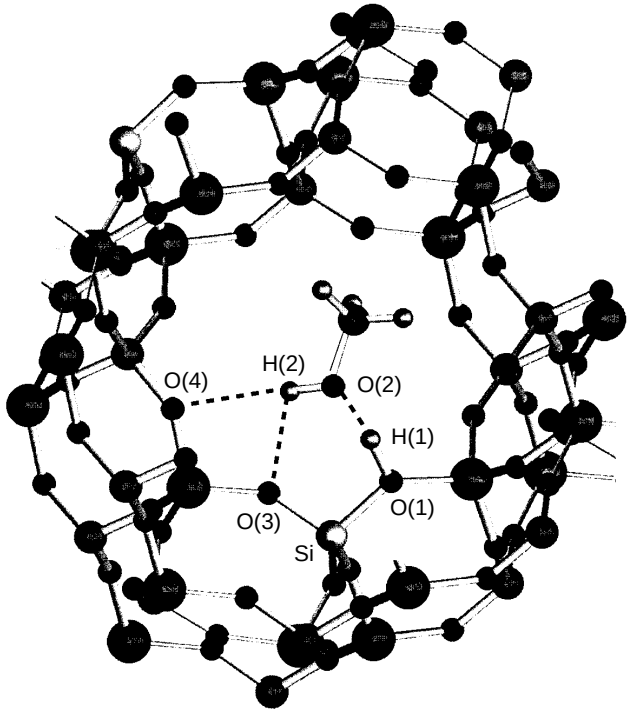

**Fig. 2** The most stable geometry found for methanol bound to acid site of SAPO-34. Selected distances (Å) are O(1)–H(1) 1.06, O(2)–H(1) 1.46, O(2)–H(2) 0.97, O(3)–H(2) 2.36, O(4)–H(2) 2.48.

Our results show that SAPO-34 appears unable to protonate methanol, whereas a zeolite of the same framework topology can. This suggests that, at least for this topology, SAPOs are less acidic than zeolites. This conclusion is different from that of Limtrakul,[12] who suggested SAPOs were more acidic. The differences are probably explained by the very small clusters used in his work, in particular for the SAPO only including one of the oxygens around the Si site while replacing the other oxygens by hydrogen atoms to saturate the edge of the cluster. This meant the only methanol geometry considered was for the molecule to bridge across Al rather Si, which we found to be about 20 kJ mol$^{-1}$ higher in energy. Our finding that at low loading methanol is not protonated in SAPOs, but can be protonated in zeolites, is consistent with the results recently reported by Thursfield and Anderson.[13] The results here have given useful insights into the nature of solid acid catalysts and further work will allow an examination of the IR spectra of adsorbed methanol, and a comparison with the adsorption of other basic molecules such as water, whose structure in SAPO-34 has recently been determined by X-ray crystallography.[2]

Computational work was performed on the Edinburgh Cray T3D, as part of the Materials Chemistry and UKCP consortia. The work of R. S. was supported by EPSRC, and that of J. D. G. by the Royal Society.

# A reductive rearrangement of iron acetylide hydride complexes

**Leslie D. Field,* Adrian V. George,* Elizabeth Y. Malouf, Trevor W. Hambley and Peter Turner**

*School of Chemistry, University of Sydney, NSW 2006, Australia*

**Iron acetylide hydride complexes of the type [Fe(H)(C≡CR)(dmpe)$_2$] [dmpe = 1,2-bis(dimethylphosphino)ethane] react with anions in a methanol solution to form substituted alkenyl complexes; the crystal structure of *trans*-FeN$_3$(CH=CHPh)(dmpe)$_2$] is presented.**

There is current interest in metal acetylide complexes as materials which may be used as components in non-linear optical materials,[1,2] the construction of organometallic polymers[2–4] and as new liquid crystals.[5] Metal σ-acetylide complexes have been prepared by a number of routes including ligand exchange reactions,[4,6] oxidative addition reactions[7,8] and by deprotonation of metal vinylidene complexes.[9]

Acetylide hydride complexes of iron [FeH(C≡CR)L$_4$] have been formed by reaction of a terminal acetylene with a coordinatively unsaturated iron complex [FeL$_4$] (L is usually a phosphine).[8,10] The acetylide hydride complexes of [Fe(PP)$_2$] [PP = 1,2-bis(dimethylphosphino)ethane (dmpe) or 1,2-bis-(diethylphosphino)ethane] are typically reactive, air-sensitive materials but they can be handled and stored as solids under an inert atmosphere.[11] They can be converted to the more stable acetylide chloride derivatives [FeCl(C≡CR)(PP)$_2$] by treatment with dichloromethane or other alkyl halides.‡

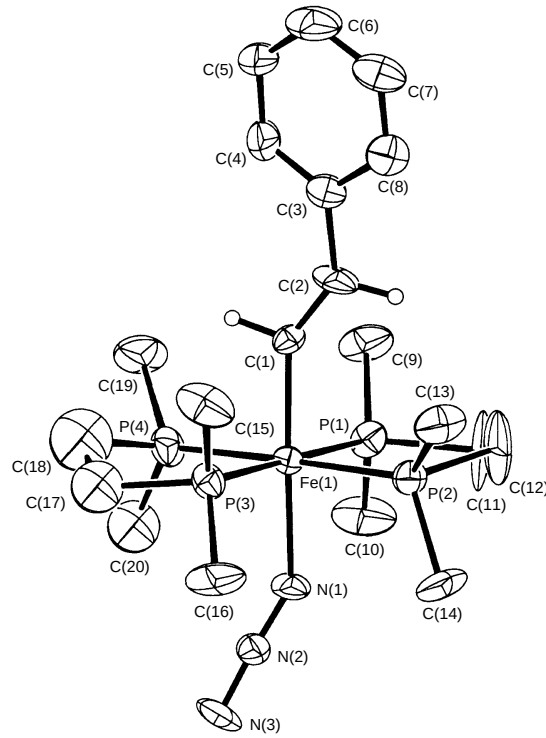
Treatment of the iron acetylide hydride complexes with a chloride, azide or thiocyanate salt in methanol solution, resulted effectively in substitution of the hydride by Cl$^-$, N$_3^-$ or SCN$^-$ with partial reduction of the bound acetylene. Treatment of *trans*-[FeH(C≡CPh)(dmpe)$_2$] **1** with a methanol solution of sodium azide resulted in formation of *trans*-[FeN$_3$(CH=CHPh)(dmpe)$_2$] **2** (Scheme 1).

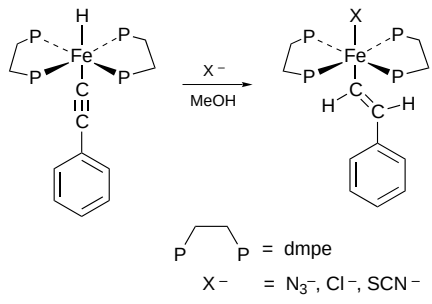
The conversion of **1** to **2** was clean and quantitative and the $^{31}$P NMR spectrum indicated the reaction was complete within 30 min. Removal of the solvent and washing the residue with methanol produced *trans*-[FeN$_3$(CH=CHPh)(dmpe)$_2$] **2** as an orange solid. The $^1$H NMR spectrum exhibited two alkenyl protons (at δ 7.05 and 5.73) with a coupling ($^3J_{HH}$ 16.7 Hz) and this is consistent with a *trans* stereochemistry for the alkene. The vinyl resonance at δ 7.05 also showed coupling to the four equivalent phosphorus ligands ($^3J_{PH}$ 6.9 Hz). An analogous reaction between **1** and chloride or thiocyanate in methanol solvent quantitatively gave *trans*-[FeCl(CH=CHPh)(dmpe)$_2$] **3** and *trans*-[FeSCN-(CH=CHPh)(dmpe)$_2$] **4** respectively.

The crystal structure of **2** (Fig. 1)† confirms that the azide and alkenyl ligands adopt a *trans* configuration about the metal centre and the stereochemistry of the double bond is (*Z*). The three nitrogen atoms of the azide group are approximately collinear (176°) and form an approximate angle of 146° with the equatorial plane containing the metal and the four phosphorus donors.

A likely reaction course for the reduction of the acetylide complexes reported here, involves initial protonation of the σ-bound acetylide ligand at the carbon β to the metal centre to form a vinylidene complex. Metal-to-carbon hydride migration in the vinylidene complex with attack by the anion (Cl$^-$, N$_3^-$ or SCN$^-$) leads to the neutral complexes (Scheme 2).

Protonation (or the addition of other electrophiles) at the β carbon of metal acetylide complexes is well known[12] and the intramolecular hydride migration from the metal to the α carbon





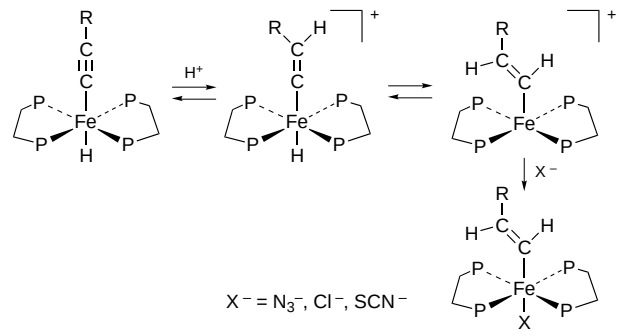


**Fig. 1** ORTEP[20] plot of *trans*-[FeN$_3$(CH=CHPh)(dmpe)$_2$] **2**

**Scheme 1**

**Scheme 2**

of the vinylidene complex is analogous to the mechanism proposed for formation of $\eta^3$-butenyne complexes from metal bis(acetylide)s.[13] The complex *trans*-[FeH(C≡C$C_6H_4$C≡CH)$(dmpe)_2$] **5** which has both metal- and non-metal-bound acetylides reacts with a methanol solution of sodium azide, to give *trans*-[$FeN_3$(CH=C$HC_6H_4$C≡CH)$(dmpe)_2$] **6** as the sole product. Exclusive formation of the vinyl metal product **6** from **5** supports the proposal that an intramolecular metal-to-carbon hydride migration is a key step in the mechanism.

Treatment of analogous ruthenium acetylide hydride complexes with a methanol solution of azide or chloride produces ruthenium alkenyl complexes, presumably by a similar mechanism.[14]

The partial hydrogenation of an acetylene by metal hydride complexes has previously been reported.[15] Reaction of excess phenylacetylene with [$FeH_2(dmpe)_2$] in methanol solution forms a bis(acetylide) complex (*via* an acetylide hydride complex) and 2 equiv. of styrene are produced in the reaction.[16] A reasonable intermediate in the conversion of the acetylide hydride complex to the bis(acetylide) is an acetylide styryl iron complex, [Fe(C≡CPh)(CH=CHPh)$(dmpe)_2$], which would undergo substitution of the styryl group in the presence of excess phenylacetylene to form the bis(acetylide) and free styrene.

The metal-to-carbon hydride migration reported here provides a novel method of reducing metal acetylides to vinyl metal complexes in protic solvents. The reduction is stereospecific and provides an alternative approach for the introduction of the vinyl group into metal complexes.

We gratefully acknowledge financial support from the Australian Research Council.

† *Crystal data* for *trans*-[$FeN_3$(CH=CHPh)$(dmpe)_2$] **2**: $C_{20}H_{39}N_3FeP_4$, $M$ = 501.29, monoclinic, space group $P2_1/c$, $a$ = 23.888(3), $b$ = 9.112(2), $c$ = 35.680(3) Å, β = 95.568(8)°, $Z$ = 12 (three independent complexes), $R$ = 0.055 [3624 $F$, $I > 1.50\sigma(I)$]. Orange acicular crystals of *trans*-[$FeN_3$(CH=CHPh)$(dmpe)_2$] **2** suitable for X-ray diffraction studies were grown by the slow evaporation of a methanol–tetrahydrofuran solution of the complex. A crystal was mounted in a glass capillary, on a Rigaku AFC7R diffractometer equipped with a graphite monochromator. All calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation.[17] Data were reduced and Lorentz, polarisation and absorption corrections (psi scan) were applied. The structure was solved by direct methods[18] and expanded using Fourier techniques.[19]

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/303.

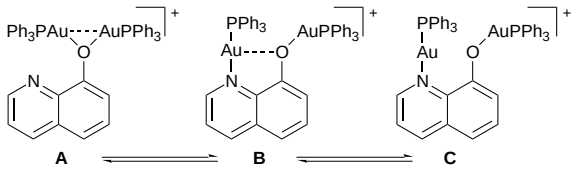
# Dramatic solvent effect on the luminescence of a dinuclear gold(I) complex of quinoline-8-thiolate

**Biing-Chiau Tzeng,[a] Chi-Keung Chan,[a] Kung-Kai Cheung,[a] Chi-Ming Che*[a] and Shie-Ming Peng[b]**



[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*
[b] *Department of Chemistry, National Taiwan University, Taipei, Taiwan*

**The complex $[\{Au(PPh_3)\}_2(8\text{-qnS})]BF_4$ (8-qnS = quinoline-8-thiolate) with intramolecular gold(I)···gold(I) distances of 2.991(2) and 3.081(2) Å in two independent asymmetric units, shows a long-lived emission at 640 nm which is quenched by polar solvents such as acetonitrile and alcohol.**

Study on the solvent and/or medium effect on the occurrence of gold(I)···gold(I) interactions could shed new insight into the molecular self-assembly of gold(I) atoms, which was found to give polynuclear gold(I) compounds with novel structural and electro-optical properties.[1] This is particularly important in understanding the chemistry of gold(I) drugs,[2] where such interaction might occur under biological conditions. Schmidbaur and co-workers had reported an interesting study indicating scrambling of the $[Au(PPh_3)]^+$ units in a solution of the complex (8-quinolinyl)bis[(triphenylphosphine)gold(I)]-oxonium tetrafluoroborate[3] (Scheme 1). Spectroscopic evidence in support of the equilibrium reactions depicted in Scheme 1 only came from $^{31}P$ NMR spectral data of **B**, which revealed two $^{31}P$ signals at low temperature. Herein is described the molecular structures and photophysical properties of $[Au(PPh_3)(8\text{-qnS})]$ (8-qnS = quinoline-8-thiolate) and $[\{Au(PPh_3)\}_2(8\text{-qnS})]BF_4$ indicating an interesting case, whereby a solvent effect on the association of the $[Au(PPh_3)]^+$ units through a bridging sulfur atom could be reflected by a distinct change in emissive properties.

Complexes **1** and **2**$BF_4$† were prepared by modified literature procedures[3,4] and perspective views of their structures‡ are shown in Figs. 1 and 2, respectively. In **1**, the Au(1) atom is two-coordinate, but the measured P(1)–Au(1)–S(1) angle of 163.7(3)° and Au(1)–N(1) distance of 2.627(9) Å suggest a weak Au(1)···N(1) interaction. This is different from the related $[Au(PPh_3)(2\text{-pyS})]$ (2-pyS = pyridine-2-thiolate) complex,[4] where an approximate linear geometry about the Au atom has been found [P–Au–S 177.9(1)°]. In **2**, there are two independent asymmetric units, and the 8-qnS is bonded to 2 nearly equivalent $[Au(PPh_3)]^+$ units through the sulfur atom. The intramolecular gold(I)···gold(I) contacts of 2.991(2) and 3.081(2) Å are longer than those in $[\{Au(PPh_3)\}_4S]^{2+}$ [Au···Au$_{av}$ 2.910(2) Å],[5] but shorter than those values of 3.110(3) Å in $[\{Au(PPh_3)\}_2SR]^+$[6] and 3.299(3) Å in $[\{Au(PPh_3)\}_3S]^+$.[7] It is noted that the mean Au–S–Au angle of 80.6(1)° lies in the range of values found in related complexes[6] which show intramolecular gold(I)···gold(I) interactions.

The absorption spectra of **1** and **2**$BF_4$ measured in dichloromethane and in acetonitrile are shown in Fig. 3. Irrespective of the solvents, complex **1** shows an intense absorption at 386 nm,

**Scheme 1**

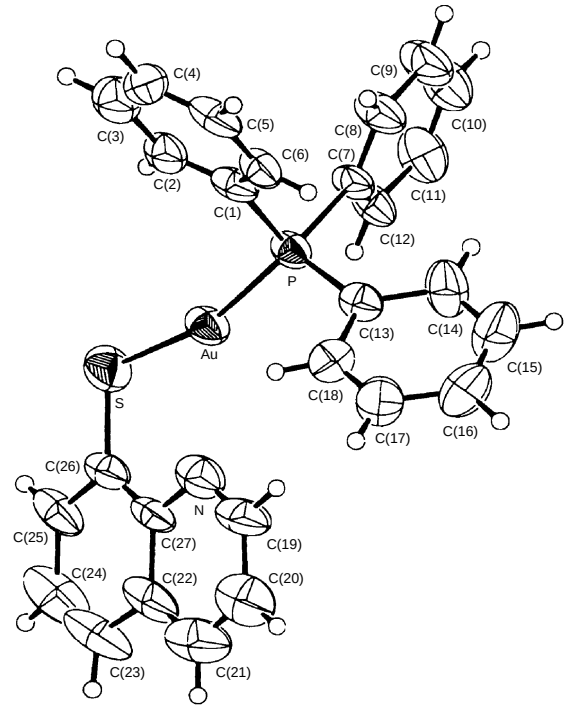


**Fig. 1** A perspective view of $[Au(PPh_3)(8\text{-qnS})]$ (bond lengths in Å, angles in °): Au(1)–S(1) 2.296(8), Au(1)–P(1) 2.248(7); S(1)–Au(1)–P(1) 163.7(3)

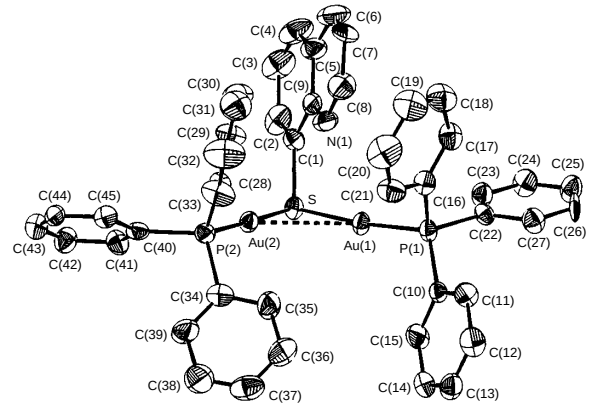

**Fig. 2** A perspective view of $[\{Au(PPh_3)\}_2(8\text{-qnS})]^+$ (bond lengths in Å, angles in °): Au(1A)···Au(2A) 3.081(2), Au(1B)···Au(2B) 2.991(2), Au(1A)–S(1A) 2.343(3), Au(2A)–S(1A) 2.342(3), Au(1A)–P(1A) 2.256(3), Au(2A)–P(2A) 2.268(3), Au(1B)–S(1B) 2.357(3), Au(2B)–S(1B) 2.351(3), Au(1B)–P(1B) 2.253(3), Au(2B)–P(2B) 2.254(3); S(1A)–Au(1A)–P(1A) 174.6(1), S(1A)–Au(2A)–P(2A) 178.6(1), S(1B)–Au(1B)–P(1B) 172.6(1), S(1B)–Au(2B)–P(2B) 169.6(1) (A and B represent two independent asymmetric units)

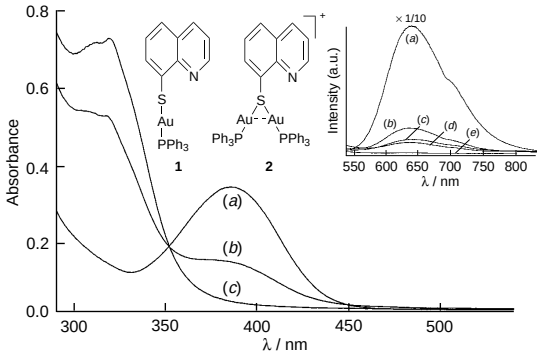

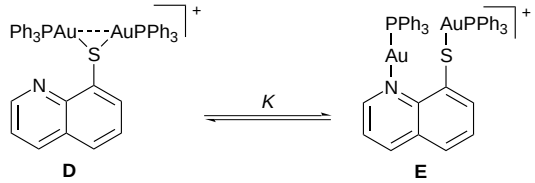

**Fig. 3** The absorption spectra of **1** in $CH_2Cl_2$ (*a*), **2**$BF_4$ in MeCN (*b*) and **2**$BF_4$ in $CH_2Cl_2$ (*c*); complex concentration = $9 \times 10^{-5}$ M. [Insert is the emission spectra of **2**$BF_4$ ($1 \times 10^{-4}$ M) in (*a*) $CH_2Cl_2$, (*b*) thf, (*c*) EtOH, (*d*) MeOH and (*e*) MeCN; excitation at 320 nm].

which is assigned to $S \rightarrow Au^I$ charge transfer (LMCT) transition. For **2**$BF_4$ there is a distinct difference in the spectra measured in dichloromethane and in acetonitrile. In dichloromethane, the complex shows an intense absorption band at *ca*. 320 nm, which is assigned to the $5d(d_{\sigma^*}) \rightarrow 6p(p_\sigma)$ transition modified by gold(I)···gold(I) interation. We suggest that coordinating the electrophilic $[Au(PPh_3)]^+$ unit on the sulfur atom of the [Au(8-qnS)] moiety would blue shift the $S \rightarrow Au^I$ transition and hence explain the apparent blue shift of the spectrum of **2**$BF_4$ from that of **1**. Notably, addition of acetonitrile to a dichloromethane solution of **2**$BF_4$ increases the absorption at *ca*. 386 nm with a concomitant decrease in the absorption at *ca*. 320 nm; the spectral changes with an isosbestic point at 352 nm. Other solvents such as MeOH and EtOH also give similar spectral changes. We rationalize this finding by the following equilibrium reaction (Scheme 2).

**Scheme 2**

Form **E** would be isostructural to form **B** in Scheme 1 and would show no intramolecular gold(I)···gold(I) interaction. Its absorption spectrum, therefore, is anticipated to be similar to that of **1**. Thus the spectral changes shown in Fig. 3 could be rationalized by a decrease in the equilibrium constant *K* (*K* = [**E**]/[**D**]) from acetonitrile to dichloromethane. The scrambling of the $[Au(PPh_3)]^+$ units is very fast on the NMR timescale, since the $^{31}P$ NMR spectrum of an acetonitrile solution of **2**$BF_4$ shows only a single peak (δ 34.12) at room temperature and even at −35 °C (δ 32.97).

The reaction in Scheme 2 could also be shown by emission spectroscopy. In solution, complex **1** shows a very weak emission at 477 nm. Excitation of a dichloromethane solution of **2**$BF_4$ gives a very weak emission at 460 nm and an intense low-energy one with a lifetime of 26 μs at 640 nm (Fig. 3, insert). The low energy emission is absent in **1** and a gold(I)···gold(I) interaction is most probably responsible for it. The excitation spectrum of the 640 nm emission matches with the absorption spectra. The excited state is tentatively assigned to come from the metal-centred $5d(d_{\sigma^*}) \rightarrow 6p(p_\sigma)$ excitation, although mixing with some $S \rightarrow Au$ charge-transfer character in the excited state could not be precluded. Notably, the emission depends on solvent polarity. Polar solvents such as MeCN, MeOH, EtOH and thf were found to quench it with quenching rate constants in the order MeCN > MeOH > EtOH > thf ($k_q = 1.25 \times 10^5$, $0.50 \times 10^5$, $0.32 \times 10^5$ and $0.24 \times 10^5$ $M^{-1}$ $s^{-1}$ respectively). In acetonitrile, the 640 nm emission virtually disappears, whereas it has the highest quantum yield and longest lifetime in dichloromethane. Importantly, addition of dichloromethane to a methanol solution revives the emission. Thus, the decrease in the 640 nm emission in polar solvents is consistent with the UV–VIS absorption data. Because the low-energy emission at 640 nm is associated with a gold(I)···gold(I) interaction, the reaction of Scheme 2 may well explain the apparent solvent-induced quenching of the emission of **2**$BF_4$.

## Footnotes

† *Syntheses*: [Au(PPh$_3$)(8-qnS)] **1**: $NEt_3$ was added dropwise to a methanol solution (15 ml) of quinoline-8-thiol (8-HqnS, 99 mg). A dichloromethane solution of [AuCl(PPh$_3$)] (250 mg) was then added and stirred for 30 min. Then $Ag(CF_3SO_3)$ (130 mg) was added and the insoluble AgCl was filtered. The pale yellow filtrate was reduced to *ca*. 2 ml to give the product (yield = 50%).

[$Au_2$(8-qnS)(PPh$_3$)$_2$] **2**$BF_4$: A solution of Na(8-qnS) was prepared by adding 8-HqnS (99 mg) and NaOMe (30 mg) in $CH_2Cl_2$–MeOH (1 : 1, 25 ml). [AuCl(PPh$_3$)] (500 mg, 25 ml in dichloromethane) was added to the solution, which was stirred for 4 h at room temp. After addition of $NaBF_4$ (60 mg) the pale yellow solution was evaporated to dryness. The resulting solid was extracted with thf (yield = 45%).

‡ *Crystal data*: [Au(PPh$_3$(8-qnS)] **1**: $C_{27}H_{21}AuNPS$, $M$ = 619.47, monoclinic, space group $P2_1/n$, $a$ = 14.632(3), $b$ = 10.424(1), $c$ = 16.360(3) Å, β = 110.08(1)°, $U$ = 2344(1) Å$^3$, $Z$ = 4, $D_c$ = 1.756 g cm$^{-3}$, crystal dimensions 0.2 × 0.15 × 0.25 mm, μ(Mo-Kα) = 64.24 cm$^{-1}$, $F$(000) = 1200. Intensity data were collected on Rigaku AFC7R diffractometer with graphite-monochromated Mo-Kα radiation (λ = 0.7107 Å) using ω–2θ scan mode with $2\theta_{max}$ = 45°. 3489 unique reflections were measured and 1965 reflections with $I > 3\sigma(I)$ were used in the refinement. Refinement of positional and anisotropic thermal parameters for all non-hydrogen atoms (281 variables) converged to $R$ = 0.074 and $R_w$ = 0.090. The final Fourier difference map showed residual extrema in the range of 1.89 to −2.54 e Å$^{-3}$.

[{Au(PPh$_3$)}$_2$(8-qnS)]$BF_4$·0.5thf **2**$BF_4$·0.5thf: $C_{47}H_{40}Au_2BF_4NP_2SO_{0.5}$, $M$ = 1201.58, triclinic, space group $P\bar{1}$, $a$ = 14.049(5), $b$ = 17.319(6), $c$ = 19.623(8) Å, α = 90.09(3), β = 108.72(3), γ = 101.20(3)°, $U$ = 4425(3) Å$^3$, $Z$ = 4, $D_c$ = 1.805 g cm$^{-3}$, crystal dimensions 0.20 × 0.30 × 0.50 mm, μ(Mo-Kα) = 67.28 cm$^{-1}$, $F$(000) = 2300. Intensity data were collected on Enraf-Nonius CAD4 diffractometer with graphite-monochromated Mo-Kα radiation (λ = 0.7107 Å), 11585 unique reflection (2θ < 45°) were measured and 7758 with $I > 2\sigma(I)$ were used in the refinement. Refinement of positional and anisotropic thermal parameters for all non-hydrogen atoms (1046 variables) converged to $R$ = 0.035 and $R_w$ = 0.037. The final Fourier difference map showed residual extrema in the range of 1.34 to −2.34 e Å$^{-3}$.

# Solvent-free oxidation reactions with Ti-MCM-41 and TS-1 catalysts occluded in polydimethylsiloxane (PDMS) membranes

**Ivo Vankelecom,*† Karen Vercruysse, Nancy Moens, Rudy Parton, Jale Sudhakar Reddy and Pierre Jacobs**

*Centre for Surface Chemistry and Catalysis, Faculty of Agricultural and Applied Biological Sciences, Katholieke Universiteit Leuven, Kardinaal Mercierlaan 92, 3001 Leuven, Belgium*

**The incorporation of TS-1 and Ti-MCM-41 catalysts in PDMS is proven to enable the oxidation of hexane and epoxidation of *cis*-cyclooctene, respectively, with high conversions under solvent-free reaction conditions.**

In 1994,[1] we reported a new type of catalytically active membrane, consisting of a FePcY zeolite (ironphthalocyanine occluded in zeolite Y) that was dispersed in a polymeric phase (PDMS). This catalytic system enabled the oxidation of cyclohexane under solvent-free conditions in a counter-current membrane configuration. Furthermore, the new hydrophobic environment of the catalyst created by this PDMS membrane acted as a 'solvent phase' and led to strongly increased conversions.[1–3] Here, we describe two new examples of successful incorporation of oxidation catalysts in PDMS: mesoporous Ti-MCM-41[4] and microporous TS-1,[5] both Ti-containing structures. They are used in the epoxidation of *cis*-cyclooctene and in the oxidation of hexane respectively. A set of reactions have been carried out to demonstrate the influence of the hydrophobic PDMS membrane on the activity of these catalysts with or without any solvent.

Ti-MCM-41 and TS-1 were synthesised following known procedures.[4,6] In the synthesis of Ti-MCM-41 (Ti/Si = 52), 18.8 g Ludox AS-40 (40 mass% colloidal silica in water, Dupont) were mixed with 19.4 g tetraethylammonium hydroxide (TMAOH, 20 mass% in water, Fluka) and 16.1 g cetyltrimetylammonium chloride (CTMACl, 25 mass% in water, Aldrich). After stirring for 15 min, a second portion (32.2 g) of CTMACl was added followed by 3.64 g $Ti(OBu^n)_4$ (99%, Alfa) dissolved in 3.60 g of isopropyl alcohol (99.5%, Aldrich). The complete synthesis was performed in ice-cooled glass containers. After homogenization, the synthesis gel was poured into stainless-steel autoclaves which were placed in a rotating oven at 383 K for 24 h. After synthesis, the autoclaves were cooled and the catalyst was filtered, washed several times, and dried at 333 K over 10 h.

TS-1 (Ti/Si = 50) was prepared by stirring 1.94 g $Si(OEt)_4$ (98%, Aldrich), 0.20 g $Ti(OEt)_4$ (99%, Aldrich) and 20.3 g tetrapropylammonium hydroxide (40 mass% aqueous solution, Fluka) at 330 K under a nitrogen atmosphere over 3 h. The resulting clear solution was poured into a Teflon-lined stainless-steel autoclave which was placed in an oven at 450 K for 24 h. The catalyst was separated by centrifugation and washed several times with deionised water before it was dried at 333 K over 10 h. Both TS-1 and Ti-MCM-41 were calcined at 820 K over 12 h, using a heating rate of 1 K $min^{-1}$.

Before using the TS-1 and Ti-MCM-41 catalysts, they were thoroughly characterised by chemical analysis, XRD, IR and UV–VIS DRS. These characterization techniques indicated that these materials possessed properties similar to those reported in the literature. In the case of Ti-MCM-41, the peaks on the XRD pattern could be indexed on a hexagonal lattice with a pore diameter of 38 Å. Raman and UV–VIS revealed the absence of anatase impurities.

The earlier described method[7] to prepare zeolite-filled membranes could no longer be applied here as the PDMS prepolymer would completely obstruct the mesopores of Ti-MCM-41 during the membrane synthesis. Therefore, a new preparation method, developed by Vankelecom *et al.*,[8] was used in which a partially polymerised network is formed before the catalyst is added. PDMS-prepolymer and crosslinker (General Electric, RTV-615A and B respectively) were mixed in a 10 : 1 ratio. For Ti-MCM-41 containing membranes, a 20 mass% mixture of PDMS in 4-methylpentan-2-one (99.5%, Acros Chimica) was prepolymerised over 1 h at 343 K. When incorporating TS-1, a 15 mass% mixture of PDMS in 4-methylpentan-2-one was stirred at 328 K for 1.5 h. The catalyst was added in a 13 mass% (relative to PDMS) loading in the case of Ti-MCM-41 and in a 17 mass% loading for TS-1. After thorough mixing at room temperature, the suspension was poured into a Petri dish and the solvent was allowed to evaporate overnight. The final curing of the polymer took place in a vacuum oven at 423 K over 1 h. TS-1 and Ti-MCM-41 catalysts embedded in PDMS are denoted as TS-1/PDMS and Ti-MCM-41/PDMS, respectively. *n*-Hexane (10 g) was oxidised in a 100 ml capacity Parr reactor at 373 K using 25 g of a 35 mass% hydrogen peroxide (Acros Chimica) solution in water with 0.25 g TS-1. If a solvent was used in the reaction, 38 g was added to 5 g of hexane, 12 g of hydrogen peroxide and 0.25 g of TS-1. Heptane was used as external standard in the GC analysis of these reactions.

The epoxidation of *cis*-cyclooctene (95%, Aldrich) over Ti-MCM-41 was performed at 330 K in a round-bottomed flask with condensor. 8 g of substrate were reacted with 8.4 g of *tert*-butyl hydroperoxide (70 mass% aqueous solution, Acros Chimica) over 0.2 g of dry Ti-MCM-41. Chlorobenzene (99%, Acros Chimica) was used as external standard for quantitative GC analysis.

The results obtained in the oxidation of *n*-hexane are summarised in Table 1. Under solvent-free reaction conditions,

**Table 1** Oxidation of *n*-hexane with hydrogen peroxide over TS-1 at 373 K

| | No solvent[a] | | Methanol[b] | |
|---|---|---|---|---|
| | TS-1 | TS-1/PDMS | TS-1 | TS-1/PDMS |
| TON[c] | 280 | 870 | 520 | 440 |
| Product distribution (%) | | | | |
| Alcohols | 5 | 9 | 22 | 30 |
| Ketones | 50 | 51 | 70 | 62 |
| Acids | 38 | 38 | 4 | 6 |
| Other[d] | 7 | 3 | 4 | 3 |
| Peroxide efficiency (%)[e] | 26 | 80 | 65 | 59 |
| Peroxide conversion (%)[f] | 99 | 99 | 99 | 92 |

[a] *Reaction conditions*: TS-1 = 0.25 g; substrate = 10 g; $H_2O_2$ (35 mass% in water) = 25 g. [b] *Reaction conditions*: TS-1 = 0.25 g; substrate = 5 g; $H_2O_2$ (35 mass% in water) = 12 g; methanol = 36 g. [c] TON (turnover numbers) after 5 h reaction. [d] Mainly methyl ethers (when using methanol as solvent) and polyfunctional compounds. [e] Peroxide efficiency = 100 × (mmol peroxide utilized in product formation/mmol peroxide consumed). [f] Peroxide conversion = 100 × (mmol peroxide consumed/mmol peroxide at the end of the reaction). The remaining $H_2O_2$ was estimated by titration using a 0.1 M $Ce(SO_4)_2$ solution.

the positive role of the membrane is obvious: the TON (turnover number) is only 280 over TS-1 as compared to 870 over the TS-1/PDMS catalyst. The major products are hexan-2-ol, hexan-3-ol, hexan-2-one and hexan-3-one. By-products, mainly acids, are formed by consecutive oxidation reactions. The very high activity obtained over the membrane-occluded catalyst can be ascribed to the combination of two beneficial effects: (*i*) the hydrophobic nature of the PDMS membrane concentrates the non-polar *n*-hexane around the catalyst particle and (*ii*) the density of the composite membrane makes the incorporated catalyst reside at the interface of both reagent faces, whereas the non-embedded catalyst mainly resides in the aqueous phase at the bottom of the reactor. The conversion of hydrogen peroxide is almost complete in all cases.

When methanol is added as a solvent under comparable conditions, the catalyst powder performs better than the TS-1/PDMS. However, the TON is about halved as compared with TS-1/PDMS under solvent-free conditions. Clearly, the solvent causes a dilution of the reagents. On the other hand, the presence of methanol molecules in the zeolite pores reduces the secondary oxidation reactions by enhancing the removal of the reaction products out of the zeolite pores. Under solvent-free reaction conditions, the residence time of the primary oxidation products in the zeolite pores is higher.

The advantage of a PDMS membrane is further evidenced in the epoxidation of *cis*-cyclooctene with Ti-MCM-41. After only 7 h, 50% of the theoretical maximum conversion is reached, whereas only 8% is converted with the non-membrane resident catalyst a value which hardly exceeds the conversion in a blank reaction.

**Table 2** Epoxidation of *cis* cyclooctene with *tert*-butyl hydroperoxide over Ti-MCM-41 at 330 K[a]

| | Theoretical conversion (%)[b] | | Epoxide selectivity (%)[c] | | Peroxide efficiency (%)[d] | |
|---|---|---|---|---|---|---|
| *t*/h | 7 | 24 | 7 | 24 | 7 | 24 |
| No catalyst | —[e] | 10 | —[e] | 81 | —[e] | 90 |
| Ti-MCM-41 | 8 | 14 | 82 | 81 | 95 | 95 |
| Ti-MCM-41/PDMS | 50 | 72 | 70 | 75 | 97 | 95 |

[a] *Reaction conditions*: Ti-MCM-41 = 0.2 g; substrate = 8.4 g; *tert*-BHP (70 mass% in water) = 4 g. [b] Conversion (%) = 100 × (mmol products formed/mmol *tert*-BHP initially present). [c] Epoxide selectivity (%) = 100 × (mmol epoxide/mmol total products). [d] Per- oxide efficiency (%) = 100 × (mmol *tert*-BHP used in product formation/mmol *tert*-BHP consumed). [e] Not determined.

With these two examples, we have proved the versatility of our earlier reported membrane-occluded catalyst system (FePcY–PDMS). The results confirm that a membrane resident catalyst is able to create an excellent activity under biphasic reaction conditions. However, consecutive oxidation reactions might assume significance as a possible drawback in the absence of a solvent. The application of catalytic membranes in a counter-current membrane reactor might not only reduce this problem, but will most probably further improve the performance of membrane-resident catalysts.

We are grateful to the Belgian Government for the support in the frame of a IUAP-PAI grant on supramolecular Catalysis. R. P. and I. V. thank the Belgian National Fund of Scientific Research (N. F. W. O.) for grants as Post-Doctoral Researchers.

# Perfluorovinyl–metal derivatives: a new one-pot synthesis

**Kulbinder K. Banger, Alan K. Brisdon* and Arti Gupta**

*Department of Chemistry, University of Manchester Institute of Science and Technology, PO Box 88, Manchester, UK M60 1QD*

**The one-pot reaction of the CFC replacement 1,1,1,2-tetrafluoroethane ($CF_3CFH_2$, HFC-134a) with 2 equiv. of butyllithium in diethyl ether at −78 °C followed by the addition of main-group or transition-metal halides results in good yields of the corresponding metal–perfluorovinyl compounds of high purity.**

Although fluorine is capable of replacing hydrogen in many organic systems usually without major structural changes the number of examples of organometallic complexes containing perfluorinated ligands is very much more limited than for the comparable perprotio analogues.[1] Of the examples that do exist in the literature many of the smaller fluorine-containing organic fragments are derived from bromofluorocarbons (BFCs) or chlorofluorocarbons (CFCs). However starting materials like these are currently being phased out under international and national agreements, such as the Montreal Protocol, due to their deleterious effect on the ozone layer. A case in point is the synthesis of perfluorovinyl ($CF_2$=CF–) derivatives which have previously used bromotrifluoroethene as the starting material. This pyrophoric compound is no longer commercially produced which will ultimately result in it being unavailable for pure research applications and thus this route will become obsolete. Very recent work[2] has focused on the use of one of the hydrofluorocarbon replacements for CFCs, 1,1,1,2-tetrafluoroethane ($CF_3CFH_2$, HFC-134a) as an alternative perfluorovinyl source for organic synthesis.

In view of the recent resurgence in interest in the chemistry of organofluorine compounds and in particular their coordination to metal centres to induce C–F bond activation[3] we report the 'one-pot' synthesis of metal perfluorovinyl compounds using HFC-134a as a perfluorovinyl source. The addition of 2 equiv. of *n*-butyllithium to a diethyl ether solution of HFC-134a at −78 °C results in the double deprotonation and elimination of 1 equiv. of lithium fluoride from HFC-134a to generate the $CF_2$=$CF^-Li^+$ reagent **1** in good yields. Compound **1** generated in this way is stable in solution for up to 24 h at this temperature but decomposes rapidly as the temperature is increased above −45 °C. The formation of metal perfluorovinyl complexes is readily achieved by adding concentrated cold diethyl ether or thf solutions of metal halides to the lithium reagent. This immediately results in reaction and the formation of an off-white precipitate of the lithium halide. Multinuclear NMR studies were found to be a convenient method to monitor the progress of these reactions and to determine the degree of perfluorovinyl substitution, prior to work-up procedures. Samples withdrawn from the organic phase of the reaction of $CF_2$=$CF^-Li^+$ and $HgCl_2$ in a 2 : 1 ratio were transferred to NMR tubes and allowed to warm to room temperature. $^{19}$F NMR spectra show replacement of the complex multiplet signals due to HFC-134a at δ −64.9 and −226.5 by three sets of doublets of doublets typical of the AMX pattern previously observed for perfluorovinyl metal complexes[4] each with associated mercury satellite structure. The extent of substitution of the product may also be conveniently determined by NMR, in this case from the $^{199}$Hg NMR spectra which exhibit a triplet of triplets of triplets so confirming unequivocally the product as $[Hg(CF{=}CF_2)_2]_2$ **2**. This compound was isolated as a clear liquid after allowing the reaction mixture to slowly warm to room temperature before being worked up using existing routes.[5] Extraction of the organic phases followed by drying and evaporation of the organic solvents results in the generation of the perfluorovinyl metal compound in good yield (typically > 90%, based on the metal complex).

An analogous reaction using a 1 : 1 ratio of mercury(II) chloride to perfluorovinyllithium reagent generates the mono-substituted complex. NMR studies suggest that a very small amount of bis(perfluorovinyl)mercury is also present (typically < 5%) in the crude product. The relatively high volatility of fluorine-containing compounds coupled with their thermally robust nature means that further purification of the products, if necessary, may often be achieved by distillation or sublimation. For example sublimation of the crude product from the 1 : 1 reaction at 100 °C (20 mmHg) results in an air-stable, white solid which is analytically pure $ClHg(CF{=}CF_2)$ **3**.

Having confirmed that this route may be used successfully to synthesise known perfluorovinyl complexes in high yield the extent of its utility as a general method of introducing the –CF=$CF_2$ moiety into a wide range of substrates was investigated by reaction with a variety of early- and late-transition metal coordination complexes and organometallic compounds. All reactions were carried out in a similar manner to that described above. Confirmation of the identity of the materials synthesised as perfluorovinyl metal complexes was obtained by elemental analysis and spectroscopic measurements.† In all cases $^{19}$F NMR spectra clearly demonstrated three sets of doublets of doublets with the anticipated satellite structure due to coupling with spin-active metal nuclei being evident where appropriate. A summary of these reactions is presented in Fig. 1.

The stability of these complexes is variable, with the majority of these complexes being thermally stable, although decomposition does occur in the presence of water or on extended contact with glassware, however the pentacarbonyl manganese perfluorovinyl complex decomposes rapidly under aqueous conditions.

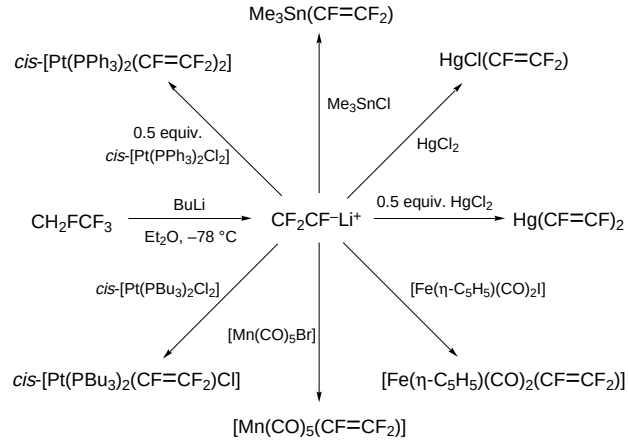

**Fig. 1** Reactions of perfluorovinyllithium, derived from $CF_3CH_2F$, with a variety of metal halides

# Selective complexation and sensitive analysis of charge diffuse cationic species using lipophilic cyclodextrins

**David Parker and Ritu Kataky**

*Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

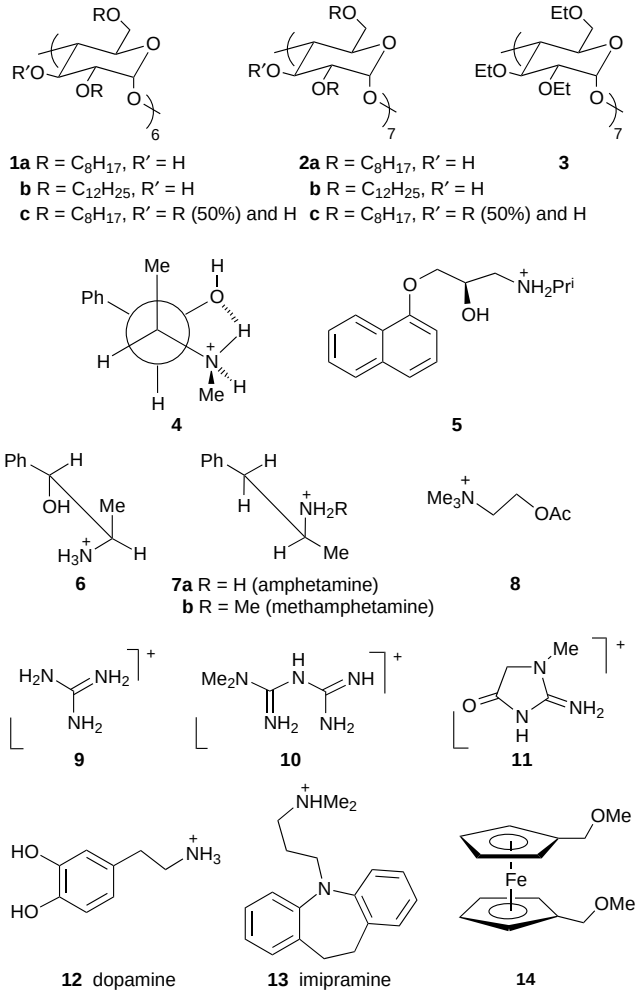
**Lipophilic peralkylated cyclodextrins are useful ionophores for the selective binding of a variety of size-matched charge-diffuse cationic species. Chiral potentiometric sensors may be devised using plasticised membrane electrodes, while voltammetric sensors may be fabricated that allow sub-nanomolar levels of detection of electron-rich aromatic cations. The observation of the binding of size-matched tetraalkylammonium ions has led to the development of sensitive methods of detection for species such as acetylcholine. When lipophilic cyclodextrins are coupled to enzymes in a disposable biosensor, a highly specific method of analysis is achieved giving sub-picomolar levels of detection.**

## Introduction

Classical coordination chemistry focuses on the binding of metal ions by ligands and is an area of research activity that is relatively mature.[1] For example, the principles that govern how a ligand binds to a given ion are well established and selectivity in complexation may be quite accurately predicted from an appreciation of the preference of the ion for a particular type of donor atom, coordination number and geometry. Metal ions are usually charge dense species with large metal–ligand free energies of complexation. On the other hand, many organic cations—such as 'onium ions (of O, P, S and N)—are best considered to be charge diffuse species whose interaction with a ligand or receptor relies upon multiple, weaker binding forces. In the case of ammonium ions for example, the positive charge is usually delocalised over the adjacent carbon and hydrogen atoms. Complexation of such charge diffuse species usually requires both size and shape complementarity between the receptor and the ion and the presence of stabilising hydrogen-bonding interactions. Size and shape complementarity is often associated with a favourable solvophobic interaction, while directed hydrogen-bonding involves the cationic 'onium ion acting as a hydrogen-bond donor to proximate electron-rich acceptors. An early example of such an interaction with a synthetic neutral ionophore involves the complexation of a primary ammonium ion, $R\overset{+}{N}H_3$ with the lone-pairs of $C_3$-related ether oxygen atoms in an 18-crown-6 derivative.[2] Receptors that are rich in π-electron density may also serve as the hydrogen-bond acceptor:[3] in the enzyme acetylcholine esterase the interactions between the cationic $NMe_3$ head group of acetylcholine and the hydrophobic π-electrons of Trp-84 are believed to contribute over 20 kJ $mol^{-1}$ to the overall free energy of binding.[4]

Whilst cation-π interactions are undoubtedly an important binding interaction in supramolecular chemistry, for an $\overset{+}{N}$–CH group as a hydrogen bond donor the interaction with ether oxygens is more energetically favourable. The gas-phase dissociation enthalpies for $\overset{+}{N}Me_4$ with various n and π donors have been measured.[5] The interaction with $H_2O$, MeOH and benzene was considerably weaker than that found for the more polarisable dialkyl ethers, and polyethers gave the highest measured values consistent with multiple additive $\overset{+}{N}$C–H···O interactions. Ionic C–H···O hydrogen bonds are well-documented structurally in the solid-state, and 9 out of 10 of the shortest C–H···O contacts involve $[NCH]^{\delta+}$ as the hydrogen bond donor.[6] Multiple weak C–H···O interactions between alkylammonium ions and size-matched receptors may therefore make a very significant contribution to the overall free-energy of binding of 'onium ions.

## Chiral sensors



Our interest in the binding of charge diffuse organic species was sparked by the challenge of devising an enantioselective ion-selective electrode that exhibited reasonable chemoselectivity for the target ion. If analysis is to be carried out with a membrane-based potentiometric sensor, then a neutral ionophore is required that can reversibly bind the target ion, with fast exchange kinetics, *i.e.* a free energy of activation for exchange between free and bound forms of the analyte of less than, say, 65 kJ $mol^{-1}$. Chemoselectivity in binding the target analyte is important—rejecting competing charge-dense ions for example—and stereoselectivity is also required so that the potential difference that builds up at the aqueous-membrane interface is proportional to the activity of the ion and its enantiomeric purity. Earlier work on chiral sensors had examined certain lipophilic chiral crown ethers as ionophores[2] and although enantioselective sensors for chiral primary amines were defined, chemoselectivity was very modest (severe $Na^+/K^+$ interference) and *N*-alkyl substitution compromised the N–H···O binding interaction.

Given the developing role of alkylated cyclodextrins in GC[7] and HPLC[8] analysis, we were attracted by the possibility of devising lipophilic ionophores by modifying the 2, 3 and 6-OH groups of these chiral host molecules. Initial work therefore focused on the synthesis and characterisation of the lipophilic ionophores[9] and the evaluation of their use as chiral ionophores for size-matched arylammonium ions.[10] A series of alkylated cyclodextrins was prepared, **1**, **2** and **3**, systematically varying the size of the cyclodextrin cavity and the nature of the alkyl chain. α-Cyclodextrin derviatives, comprising six glucose sub-units, define a toroidal cavity that is sufficiently large to include monosubstituted benzene derivatives. The free energy of binding may be attributed to a favourable solvophobic interaction, with inclusion leading to the displacement of relatively 'high-energy' solvent molecules, and to attractive van der Waals' and dispersion forces in the complex. The β- and γ-cyclodextrin analogues containing seven and eight glucose units respectively define a larger cavity suitable for inclusion of larger substrates such as naphthyl derivatives in the former case and tricyclic molecules or ions in the latter.

Stepwise alkylation procedures were devised that allowed preferential 2,6-dialkylation, and the more hindered 3-OH group could be alkylated under more forcing conditions (*e.g.* NaH–THF–18-crown-6–RX). The precise degree of alkylation was assessed by a combination of NMR, reductive depolymerisation–GCMS and direct electrospray mass spectrometric methods[9] and the three independent methods of analysis showed excellent agreement. The per-*O*-ethyl β-cyclodextrin

**3**[11] is perhaps the simplest lipophilic cyclodextrin and is very soluble in non-polar organic solvents and almost completely insoluble in water.

Poly-*O*-octyl-α-cyclodextrin (containing an average of 15.4 octyl groups per cyclodextrin), when incorporated into a plasticised PVC membrane, gave an ion-selective electrode that showed a different response (in slope and in $E°$ values) to the (−)-(1*R*, 2*S*)-ephedrinium ion **4**, compared to its enantiomer and its diastereoisomers, the (+)- or (−)-pseudoephedrinium cations. The electrode could be calibrated to measure the enantiomeric purity of samples of ephedrinium salts (Fig. 1) even in the presence of the pseudo-ephedrinium diastereoisomers.[10] In order to measure the total ephedrinium concentration parallel measurements are needed using an achiral or non-selective ionophore: per-*O*-octyl maltose serves as a suitable ionophore for the latter purpose. Moreover, the electrode response was not significantly impaired by the presence of a simulated clinical electrolyte containing $Na^+$ (150 mM), $K^+$ (4.3 mM), $Ca^{2+}$ (1.26 mM) and $Mg^{2+}$ (0.9 mM), and an overall selectivity coefficient $-\log K^{pot}_{clin}$ of 3.7 was determined. The difference in the free energy of complexation for binding of the ephedrinium enantiomers was only 2.5 kJ $mol^{-1}$ with **1b** and **1c**, but this corresponds to a 26 mV differential response that is sufficient to be measured quite accurately. Using the size-matched β-cyclodextrins **2b** or **2d** as the ionophore, similar experiments were conducted with propranolol **5**, as the analyte. The observed enantiodifferentiation was also about 25 mV or 2.4 kJ $mol^{-1}$, but was sufficient to allow enantiomeric purity determinations to be effected using a calibrated electrode.

## Probing complexation

Complex formation was monitored by NMR methods and by electrospray mass spectrometry, and was probed further by variation of the host and guest structures. Confirmation of the formation of a 1 : 1 complex with ephedrinium or propranolol cations was provided by positive-ion ESMS spectra (Fig. 2), and measurements using pulsed-gradient spin echo $^1H$ NMR methods of the diffusion coefficient of the (+)-ephedrinium ion in the presence and absence of **1b** in $CDCl_3$ were consistent with 1 : 1 complex formation with an equilibrium constant of 137 (288 K).[12] The (−)-enantiomer was bound more weakly and when all of the OH groups in the 3-position were capped with methyl groups both enantiomers bound with the same affinity. Capping of the residual OH groups in the α-cyclodextrin hosts also markedly reduced the enantioselective response of the electrode and its sensitivity to the ephedrinium analyte, highlighting the importance of these groups *either* in rigidifying the CD structure through intramolecular hydrogen bonding *or* in acting as an orienting hydrogen-bond donor to the cationic guest. Variation of the structure of the β-arylammonium ion was also examined: the norephedrinium ion **6** behaved in a parallel manner to ephedrinium, while species lacking the α-hydroxy group—such as the amphetamines **7**—also gave an enantioselective response, suggesting that the configuration of the chiral centre β to the aryl ring was most important in defining enantioselectivity.[10]

Further details of the solution complexation process were provided by measurements of the $^1H$ NMR relaxation rates of the cyclodextrin and of the included ion. Changes in relaxation rate dependent upon which enantiomer was bound by **1c** were observed for both the cyclodextrin and the β-arylammonium ion. The rate of relaxation of the cyclodextrin $H^3$ proton, for example, increased differentially by 1.45 $s^{-1}$ on complexation

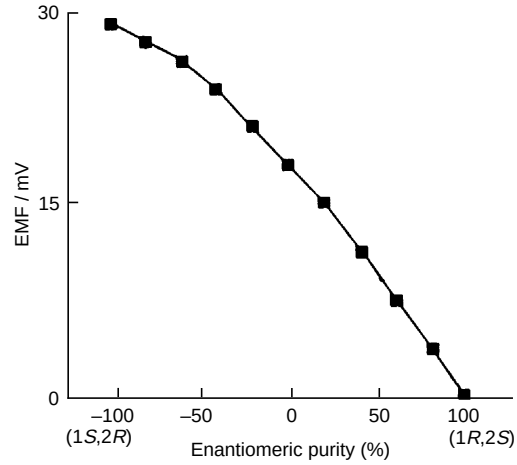


**Fig. 1** Calibrated electrode response for an ISE based on poly-*O*-octyl-α-cyclodextrin with the enantiomeric purity of the ephedrinium analyte (310 K, $I$ = 0.1)

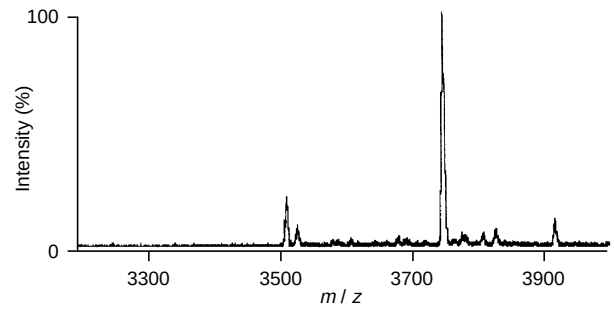

**Fig. 2** Electrospray mass spectrum of the complex formed between 2,6-didodecyl-β-cyclodextrin and (*R*)-propanolol

of (+)-ephedrinium compared to (−)-ephedrinium. It is well known that this proton is oriented towards the centre of the cyclodextrin cavity, and similar (albeit smaller) changes in rate have been observed following inclusion of (+)-Trp by α-cyclodextrin.[13] More marked enantiodependent changes in relaxation rate were measured for the diastereotopic $NH_2$ protons of the guest ephedrinium ion. A model has been proposed that accounts for the observed changes.[10] In the complex of the more strongly bound (+)-ephedrinium ion, the *C*-methyl (in the 2-position) group is oriented away from the H-3 and H-5 protons of the cyclodextrin. With the (−)-enantiomer, in order to avoid an unfavourable steric interaction the complex adopts an alternative structure lacking a stabilising N–H···O hydrogen-bond. Small differences in hydrogen-bonding (*i.e.* one H-bond mismatch) have recently been invoked to explain free-energy differences of the order of 2.5 kJ $mol^{-1}$ in DNA binding to intercalating molecules.[14]

## Binding and detection of 'onium ions

During the course of electrode-response experiments aimed at examining the effect of ionic strength on complexation, we quickly became aware of an *unusual* response in the presence of tetramethylammonium ions, when using poly-*O*-octyl-β- or tri-*O*-octyl-β-cyclodextrin as the membrane ionophore. The *absence* of any response was traced to competitive binding by the alkylammonium ion,[11,15] and 1:1 cyclodextrin: $NR_4^+$ complexes were observed by ESMS (Fig. 3) and were further characterised by $^{14}N$, $^2H$ and $^1H$ NMR measurements.[16] Both $NMe_4^+$ and $NEt_4^+$ have ionic diameters that are matched quite closely in size to a peralkylated cyclodextrin,[17] and complex formation is expected to be driven by a favourable solvophobic interaction and may be aided by multiple, weak $\overset{\delta+}{N}CH\cdots O$ interations.[5,6] This binding interaction allows the lipophilic cyclodextrins to be used as ionophores for the potentiometric detection of a variety of substituted alkylammonium ions (Table 1). Long-chain trimethylammonium ions may be detected sensitively at sub-micellar concentrations, and selectivity over $Na^+/K^+$ was found to reach a maximum at chain lengths that matched those of the alkyl groups in the cyclodextrin receptor.[11] Favourable hydrophobic interactions between alkyl chains may afford an extra stabilising interaction. Indeed, the lipophilic cyclodextrins **1a**, **1b**, **2a** and **2b** themselves form well-defined bilayers at an air–water interface.[18] Calculations of the surface area per molecule in these assemblies suggest that not only are the 'primary' alkyl chains (those bound to the 6-position) directed away from the aqueous phase but also that the chains linked to the 2-position are folded back tightly along the sides of the cyclodextrin. At a clean silicon or gold surface, atomic force microscopic measurements provided clear evidence for aggregation of the lipophilic cyclodextrins and aggregates varying in diameter from 2 to 0.1 μm were observed.[18]

Various other types of charge diffuse cations have been examined as analytes. For example, the strongly basic guanidinium ions such as **9** and **10** may be sensitively detected by potentiometric methods,[19] and the related metabolite creatinine **11** ($pK_a$ = 4.75) may also be assayed, provided that the electrode response is corrected to allow for dissociation of this weak acid.[11] With these hydrogen-bond donating cations, the independence of the observed electrode response to the structure of the sensing cyclodextrin (3-OH *vs.* 3-OR groups, α *vs.* β derivatives) indicated that the primary binding interaction involves $\overset{+}{N}–H\cdots O$ hydrogen-bonding.

Voltammetric methods of analysis, such as differential pulse voltammetry, allow lower concentrations of analytes to be measured, provided that the analyte possesses an accessible redox couple. The catecholamine oxidation of dopamine **12** occurs at +200 mV (*vs.* Ag/AgCl) on a screen-printed carbon electrode that has been coated with 2,3,6-tri-*O*-ethyl-β-cyclodextrin **3**.[20] Dopamine concentrations as low as $10^{-11}$ mol $dm^{-3}$ may be detected in this way, comparing favourably to the levels found in samples of cerebrospinal fluid ($10^{-8}$ mol $dm^{-3}$). The more sterically bulky cation, imipramine—an anti-depressive drug with a toxic level in blood of 5 μg per ml—is more effectively analysed using a sensor incorporating a poly-*O*-octyl-γ-cyclodextrin ionophore. In this case oxidation of the electron-rich aromatic moiety may be monitored by differential pulse voltammetry, and a linear current response was observed in the range $10^{-4}$ to $10^{-9}$ mol $dm^{-3}$ (Fig. 4).

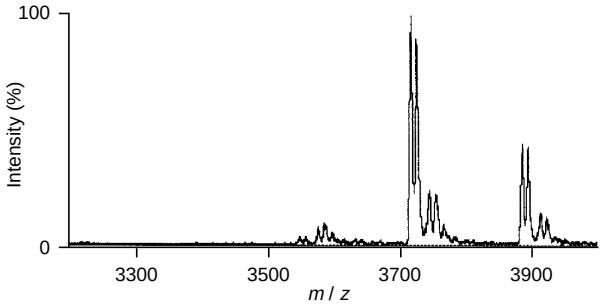

**Fig. 3** Electrospray mass spectrum of the 1:1 complexes between equimolar amounts of $C_{12}H_{25}N(CD_3)_3^+/C_{12}H_{25}NMe_3^+$ and 2,6-didodecyl-β-cyclodextrin ($Pr^iOH$; cone-voltage 30 V)

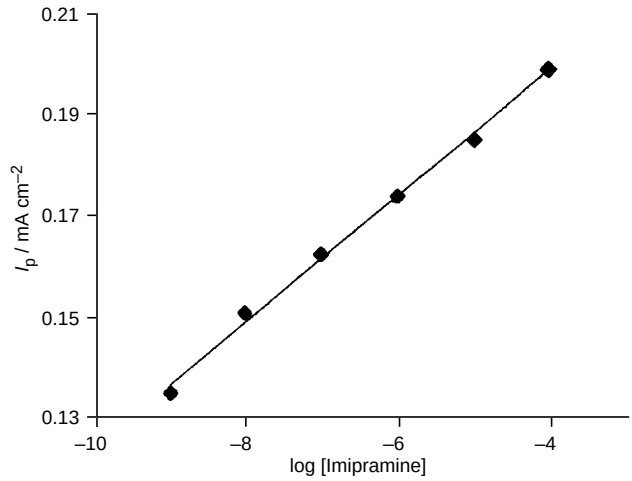
**Table 1** Response of ISEs to alkylammonium cations in the absence and presence of interferent ions using plasticised PVC-based membrane electrodes[a] (310 K)

| Analyte | Ionophore | Slope | Detection limit −log[c]/mol $dm^{-3}$ | $pK_{pot}^{clin}$ |
|---|---|---|---|---|
| $NMe_4^+$ | **1b** | 58.8 | 6.0 | 4.3 |
| $C_{12}H_{25}NMe_3^+$ | **2d** | 61.5 | 6.6 | 5.2 |
| acetylcholine **8**[b] | **1c** | 61.4 | 6.5 | 4.2 |
| choline **9** | **1c** | 61.4 | 6.4 | 3.4 |
| methacholine **10** | **1c** | 60.3 | 6.6 | 4.4 |

[a] $pK^{pot}$ values were determined in a simulated clinical electrolyte (refs. 11,16). [b] Protein interference (*e.g.* 40 g $dm^{-3}$ serum albumin) did not perturb the slope but raised the limit of detection to $10^{-5.1}$ mol $dm^{-3}$.

Whilst lipophilic cyclodextrins are very attractive ionophores for the sensitive detection of a broad spectrum of charge diffuse and size-matched cationic species, their relative lack of specificity needs to be addressed if practicable sensors are to be devised for environmental or clinical applications. For example,



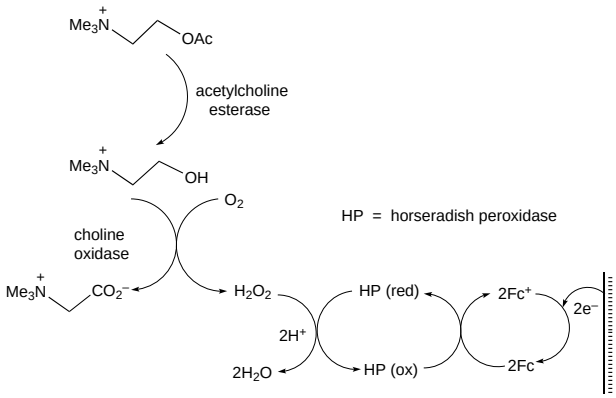


**Fig. 4** Variation of current response, measured by differential pulse voltammetry, with concentration of the tricyclic anti-depressant drug imipramine **13**

while choline and acetyl choline are bound selectively by **1c** or **3**, compared to sodium, potassium, calcium or magnesium, various other cationic aryl species may compete in binding to the cyclodextrin host. By coupling the analysis into an enzymic relay, excellent *specificities* may be achieved with very low limits of detection. Typically biosensors based on this approach have allowed sub-micromolar levels of analytes to be measured, but lower limits of detection have only been achieved if 'preconcentration' techniques are used, *e.g.* microdialysis[21] or HPLC[22] separation. Generally these biosensors are not particularly robust devices that have a limited lifetime.

We have studied recently a biosensor based on the well-established[23] horseradish peroxidase–choline oxidase–acetylcholine esterase relay system (Scheme 1), which is known to allow sub-micromolar levels of acetylcholine to be assayed *via* the relayed amperometric detection of hydrogen peroxide. Using a screen-printed disposable electrode, successive layers were deposited, first the charge shuttle of 1,1′-bis(methoxymethyl)ferrocene **14** then the three enzymes in phosphate buffer and finally a thin encapsulating film of plasticised polyurethane containing 5% by weight of tri-*O*-ethyl-β-cyclodextrin and a lipophilic counterion. The resultant 'dip-type' sensor, after conditioning in aqueous buffer, allows *sub-picomolar* levels of acetylcholine to be measured with negligible interference from compounds such as ascorbic acid, dopamine and atropine (Fig. 5). The electrode was stable to dry storage in air for a period of at least four months and was active in solution for several weeks. Following continuous contact with a $10^{-10}$ mol dm$^{-3}$ solution of acetylcholine, the measured current response had diminished only by 20%. Control experiments

**Scheme 1**

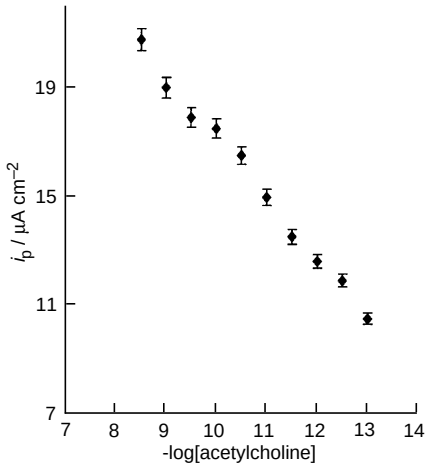

**Fig. 5** Calibration curve for an amperometric enzyme electrode for acetylcholine based on a coated screen printed carbon electrode using the enzyme system, acetylcholine esterase–choline oxidase–horseradish peroxidase encapsulated with a plasticised polyurethane thin film containing 2,3,6-tri-*O*-ethyl-β-cyclodextrin (see Scheme 1)

using an electrode that did not contain, in turn, either the encapsulating thin film or the cyclodextrin derivative have been undertaken. An acetylcholine sensor without the lipophilic anion and the plasticised thin film responded to acetylcholine only at micromolar concentration levels and with nanoamp current levels. The sensor with the cyclodextrin included showed a much improved current response and could be accurately calibrated over a much wider range of substrate concentrations.

The β-cyclodextrin derivative may serve a dual function: not only does it mediate transport of the acetylcholine through the thin polymeric film, but it can also reversibly bind the ferrocene derivative[24] (especially in the ferricenium state) promoting the relay of charge to the electrode. Given that many compounds with widely different uses target the acetylcholine esterase enzyme, *e.g.* organophosphorus pesticides or various chemical warfare agents, then such species may also be detected readily and at low concentration using such a biosensor.[25] More generally, lipophilic cyclodextrins that are designed to bind with some selectivity to other important charge diffuse cations, *e.g.* dopamine, may be coupled into a variety of relayed biosensors and may give excellent specificity and sensitivity in detection.

## Acknowledgements

It is a pleasure to thank the EPSRC for an Advanced Fellowship (R. K.), and the BBSRC for their support of this work.

**David Parker was born in Consett, County Durham. He gained a first class honours degree in Chemistry from Oxford University in 1978 and a DPhil in 1980, working on asymmetric catalysis, under the supervision of Dr John M. Brown in the Dyson Perrins Laboratory. He was a NATO Fellow in 1980/81 working with Professor Jean-Marie Lehn at the Université Louis Pasteur, Strasbourg and was appointed to a Lectureship at Durham University in 1982. He was subsequently promoted to a Senior Lectureship in 1989 and to a Chair in Chemistry in 1992. At present he is the Chairman of the Department of Chemistry at Durham. He was awarded the Hickinbottom Fellowship by the Royal Society of Chemistry in 1988, the Corday Morgan Medal and Prize of the RSC for 1987 and the ICI Research Prize in Organic Chemistry in 1991. In 1996, he gained the Interdisciplinary Award of the RSC and his research interests embrace many aspects of complexation phenomena in solution.**

**Ritu Kataky was born in Shillong, Assam, India and took her degree at the Indian Institute of Technology, New Delhi, India. After lecturing at St. Mary's College, Shillong, she took a PhD under the supervision of Professor Arthur Covington working on ion-selective electrodes in clinical analysis. In 1988 she began a post-doctoral fellowship at Durham University and in 1992 was awarded an EPSRC Advanced Fellowship. Her research interests are in physical aspects of analytical chemistry, focusing on electroanalysis of clinically important species.**

# Self-assembly of tetraalkylammonium salt-stabilized giant palladium clusters on surfaces

**Manfred T. Reetz,* Martin Winter and Bernd Tesche**

*Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim/Ruhr, Germany*

**Nanostructured palladium clusters, stabilized by a monomolecular coat of sufactants $N(C_8H_{17})_4Br$ or $N(C_{18}H_{37})_4Br$, self-assemble on carbon surfaces in an ordered manner with the formation of hexagonal close packed structures.**

Self-assembly of preformed nanostructured transition-metal clusters on solid surfaces in ordered structures constitutes a formidable preparative challenge.[1] Investigations in this field of material science is driven by the prospect of fabricating structurally uniform materials having unique electronic and/or magnetic properties. For example, placing finite-sized clusters onto surfaces in geometrically well defined arrays may open the way to single-electron tunnel devices. Recently we have shown that a variety of nanostructured metal clusters and bimetallic clusters stabilized by tetraalkylammonium salts can be prepared electrochemically in a size-selective manner by correct adjustment of the current density and proper choice of solvent.[2] A combined STM–TEM study revealed that each individual cluster is surrounded by a monomolecular layer of the $NR_4X$ salt.[3] Whereas many TEM studies of $NR_4X$- stabilized metal clusters have been carried out previously in order to determine the average size of the metal core,[2–4] unusual phenomena relating to self-assembly on the surface have not been observed to date. In this paper we describe ordering phenomena involving high purity monodisperse $NR_4X$-stabilized palladium clusters on carbon supports, as observed by transmission electron microscopy.

In all experiments the surfaces upon which the clusters were deposited consisted of carbon support films, produced by means of an impact evaporator, and placed on copper grids (400 mesh $in^{-1}$).[5] Simple dip-coating using solutions of $N(C_4H_9)_4Br$-, $N(C_8H_{17})_4Br$- or $N(C_{18}H_{37})_4Br$-stabilized palladium clusters[2] having average inner core sizes of 2.5, 5.9 and 5.9 nm, respectively, was performed,† followed by TEM analysis. In the case of the $N(C_4H_9)_4Br$-stabilized palladium clusters, the TEM micrographs failed to show any signs of order, irrespective of the conditions used in the dip-coating process. Completely random distributions of clusters on the surface were observed. Similar observations were made upon employing larger sized palladium clusters stabilized by $N(C_4H_9)_4Br$. In complete contrast, the samples stabilized by $N(C_8H_{17})_4Br$ led to high degrees of ordering. The respective clusters self-organize in a hexagonal close packing structure. Interestingly, the system self-assembles in ordered stacks of such layers, these being arranged in almost perfect steps and terraces. High-resolution TEM clearly reveals the first few individual layers (Fig. 1).

Besides the stacks of layers, clear domains of monolayers were obtained, as shown by typical TEM images (Fig. 2). Again hexagonal close packing occurs. The corresponding two-dimensional Fourier-transformed image is shown in Fig. 3. Close inspection of individual clusters at atomic resolution reveals lattice fringes characteristic of face centred cubic (fcc) crystallinity.

Careful analysis of the geometric features of the surface structure reveals some interesting features. We have previously shown by STM measurements that the thickness of the $N(C_8H_{17})_4Br$ protective coat surrounding palladium clusters having different core sizes amounts to 1.2 nm, which is in line with simple force-field calculations (1.1 nm).[3] In the present case assumption of a bilayer between the ordered clusters leads to the prediction that the distance between the centres of the metal cores should amount to 8.3 nm. The observed value of 8.2 nm is in excellent agreement with this expectation, which means

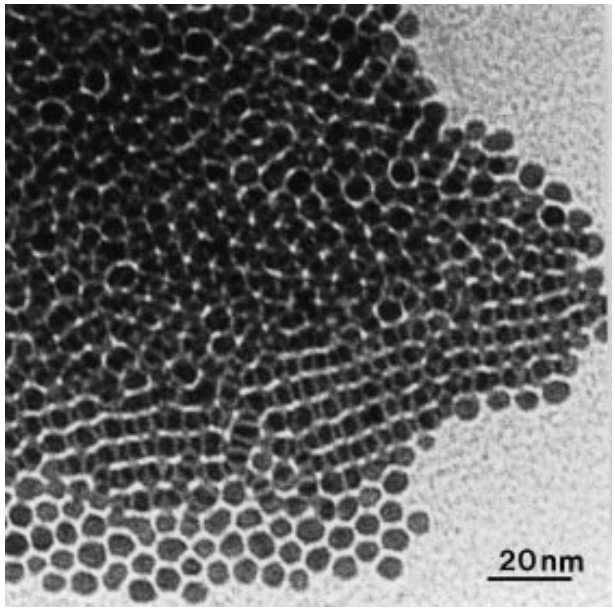

**Fig. 1** Electron micrograph of palladium colloid of the first, second and third monolayer, which are stepwise ordered in a three- dimensional structure after deposition on carbon support films

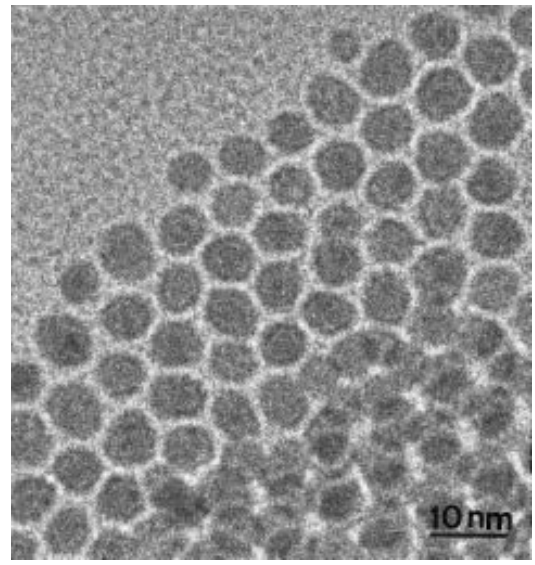

**Fig. 2** Electron micrograph of palladium colloid hexagonal close packed arranged in the first monolayer

that the protective mantles on the surface touch each other without damage or interpenetration. This means that nano-engineering on surfaces should be possible simply by varying the length of the alkyl groups of the ammonium stabilizer. For example, upon using $N(C_{18}H_{37})_4Br$-stabilized palladium clusters having an inner metal core size of 5.9 nm, it is predicted that the average distance between the centres of the clusters should be 10.3 nm. Indeed, upon employing the 5.9 nm sized $N(C_{18}H_{37})_4Br$-stabilized palladium clusters, hexagonal close packing was again observed, the distance between the centres of the clusters this time amounting to 10.2 nm.

An unusual effect was observed in the case of the $N(C_8H_{17})_4Br$-stabilized palladium clusters. A few highly ordered domains were discerned in which hexagonal close packing clearly does not occur (Fig. 4). Although cursory inspection suggests cubic close packing (coordination number four in the two-dimensional layer; twelve in the three-dimensional arrangement), careful analysis reveals that the material is in fact non-close packed. The distance between the centres of the clusters amounts to 6.3 nm. The reason for the formation of such unusual ordered domains is presently unclear. It appears that this molecular structure begins to have the characteristics of a three-dimensional crystalline superlattice (Fig. 4), in which the particles are ordered.

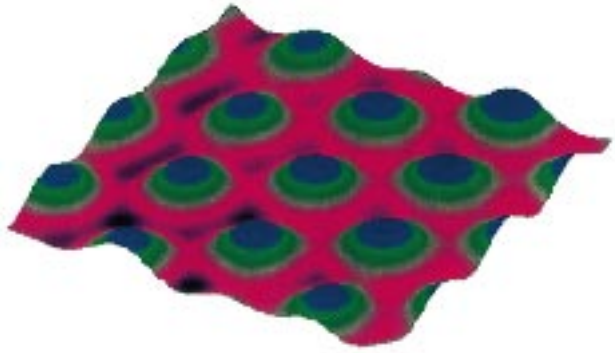

**Fig. 3** Individual hexagonal close packed palladium colloid after digital image processing

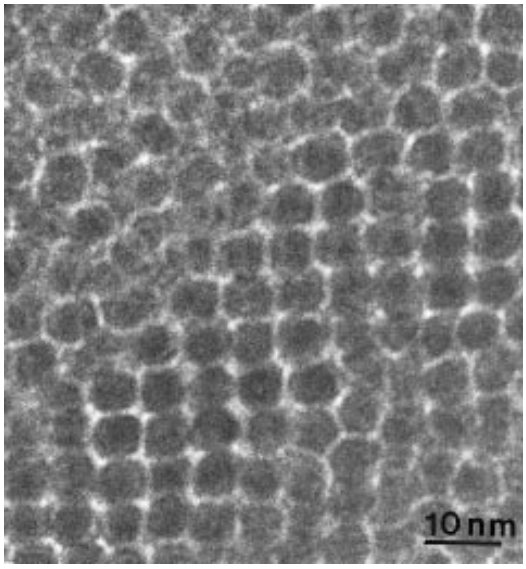

**Fig. 4** Electron micrograph of palladium colloid ordered in a non-closed packed cubic-like arrangement

In summary, we have demonstrated for the first time that certain $NR_4X$-stabilized metal clusters self-organize on supports, forming two-dimensional films and three-dimensional superlattices. By varying the length of the alkyl chains of the ammonium ions, predictable structural ordering is possible. Preliminary experiments show that variation of the palladium cluster core size is another useful parameter which also allows for nanoscale engineering. Extension to other metal clusters and bimetallic analogues as well as the corresponding nanostructured $NR_4X$-stabilized metal oxide clusters[6] should be straightforward.

## Footnote

† A TEM grid (400 mesh $in^{-1}$)[5] was dipped into a $10^{-3}$ M solution of a $NR_4Br$-stabilized palladium cluster[2] in thf for 2–3 s. Following removal from the solution, the grid was dried in air at room temp. for 2–3 h.

# High-intensity, laser-jet photochemistry: photodecarboxylation of 3,3-diphenyl-1*H*,3*H*-naphtho[*cd*][2]pyran-1-one

**R. Marshall Wilson,*[a] K. A. Schnapp,*[b] Martin Glos,[a] Cornelia Bohne*[c] and Andrew C. Dixon[c]**

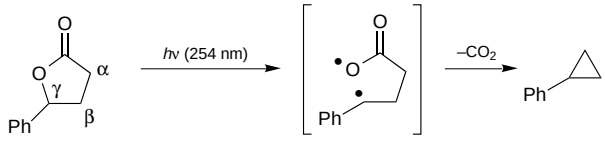
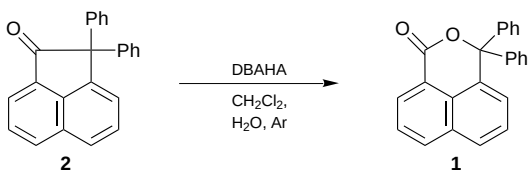
[c] *Department of Chemistry, PO Box 3065, University of Victoria, Victoria, BC, CA 3W8 3V6, Canada*

**The novel photodecarboxylation of an aryl δ-lactone from an upper triplet state is described.**



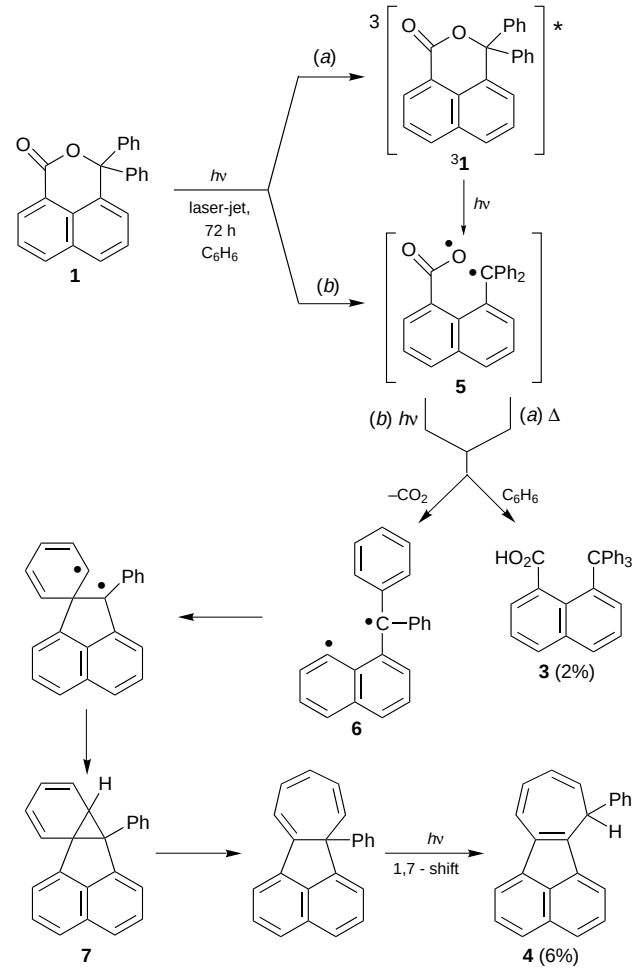
Although the photodecarboxylation of esters is a widely known process, loss of carbon dioxide from lactones is ordinarily a minor pathway in solution phase photochemistry.[1] The majority of cases reported indicate efficient photodecarboxylation requires that an excited aromatic chromophore cleave a benzyl ester bond to form a carboxy radical (Scheme 1).[2] Herein we report the novel high-intensity laser-jet photodecarboxylation of 3,3-diphenyl-1*H*,3*H*-naphtho[*cd*][2]pyran-1-one **1**.

The preparation of **1** in nearly quantitative yield involves the reaction of the ketone **2** with DBAHA [tris(2,4-dibromophenyl)ammonium hexachloroantimonate; Scheme 2] in an unprecedented SET Baeyer–Villiger lactonization.†



When **1** was irradiated under low-intensity conditions (356 nm, Rayonet Photochemical Reactor, $C_6H_6$, Ar, 7 days), no products were observed. However, under high-intensity, laser-jet conditions,[3] two new products were isolated: the carboxylic acid **3**, and the cycloheptatriene **4** (Scheme 3).‡

The mechanism for the formation of photoproducts **3** and **4** might be accounted for by either of two possible pathways [(*a*) and (*b*) in Scheme 3]. Pathway (*a*) involves absorption of a photon by **1** to form $^3$**1**, which upon absorption of a second photon could result in homolytic C–O bond scission to produce **5**, which in turn might lose $CO_2$ thermally to form the novel triarylmethyl biradical **6**. Alternatively, **5** may undergo a most unusual addition to benzene to produce **3**. A second possible pathway (*b*) requires that absorption of the first photon by **1** results in homolytic bond scission to form biradical **5**, which upon the absorption of a second photon produces a biradical excited state that might either react with solvent to form **3** or undergo decarboxylation to produce **6**. In either case, the triarylmethyl biradical **6** apparently cyclizes at the *ipso* position of a phenyl group to form the norcaradiene **7**. The thermally labile **7** undergoes ring opening followed by a photochemically allowed 1,7-phenyl migration to produce the observed cycloheptatriene **4**.[4] Related 1,7-phenyl shifts have been found to be so facile that only the phenyl-shifted final product could be isolated under some conditions.[4b]



The transient absorption spectroscopy of pyranone **1** was examined in order to gain further insight into the mechanism of decarboxylation. Excitation of **1** produced a transient signal ($\lambda_{max}$ = 460 nm, $\tau \geqslant 10$ μs)§ which was independent of solvent (benzene, acetonitrile or cyclohexane). The transient spectrum for **1** was similar to the spectrum determined independently for triplet 1-acetonaphthone, which is expected to be the chromophore with lowest energy in **1**. The transient for **1** was quenched with similar efficiency by $O_2$ and cyclohexa-1,3-diene ($1–3 \times 10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$). These results are consistent with an assignment of the transient of **1** to its triplet state. The biradicals can be ruled out as the transient, since these species would be expected to have shortened lifetimes in cyclohexane due to

**Scheme 1**

**Scheme 2**

**Scheme 3**

hydrogen abstraction from the solvent and probably would not be effciently quenched by cyclohexa-1,3-diene.

Two-laser experiments were performed in order to address the question of whether C–O bond scission occurs from an upper triplet state of **1**.[5]¶ Reactive upper triplet states have been observed for benzil[6] and 1,3-bis(1-naphthyl)propan-2-one.[7] In both of these instances, the first excited triplet state was unreactive, and 'reluctant' reactivity was observed only from upper triplet states. When the triplet of **1** in benzene was further excited at 355 nm, a small but detectable, amount of bleaching was observed within 10 ns following the YAG laser pulse (Fig. 1). The actual amount of bleaching is somewhat larger than shown in Fig. 1, since some triplet was formed by the irradiation of **1** with the 355 nm laser only. The same transient spectra were recorded before and after the irradiation of the triplet by the second laser pulse. This bleaching indicates that **1**[3] is photoreactive and this observation is consistent with pathway (*a*). It is worth noting that the energy of the photolysis (second) laser pulse corresponds to the energy employed in the high-intensity argon laser-jet experiments. When this energy was decreased by irradiating the triplet at 532 nm no bleaching was observed, suggesting that the bleaching quantum yield is dependent on the energy of excitation of the triplet.

Thus, the formation of the high intensity photoproducts **3** and **4** is probably initiated *via* pathway (*a*) (Scheme 3) involving a β-scission[3] in which an excited aromatic ring cleaves the benzyl C–O bond. In previous work,[2a,b] this type of bond was β to an excited phenyl group rather than to an excited naphthyl group. Apparently the higher energy triplet state of a phenyl group (82.5 kcal mol$^{-1}$ for toluene; 1 cal = 4.184 J)[8] leads to direct cleavage of the benzyl C–O bond, while the much lower energy naphthyl triplet state (59.6 kcal mol$^{-1}$ for 1-methyl naphthalene)[8] requires an additional photon to promote it to a higher energy triplet state, from which the benzyl C–O cleavage becomes energetically favourable. Once the decarboxylation has occurred, formation of the cycloheptatriene *via* collapse of **6** to the norcaradiene **7** has precedent in several reactions studied earlier.[4] Finally, it is interesting to note that while high intensity irradiation of the parent ketone **2** might also be expected to form the biradical **6** *via* photodecarbonylation, **2** was found to be photochemically unreactive.

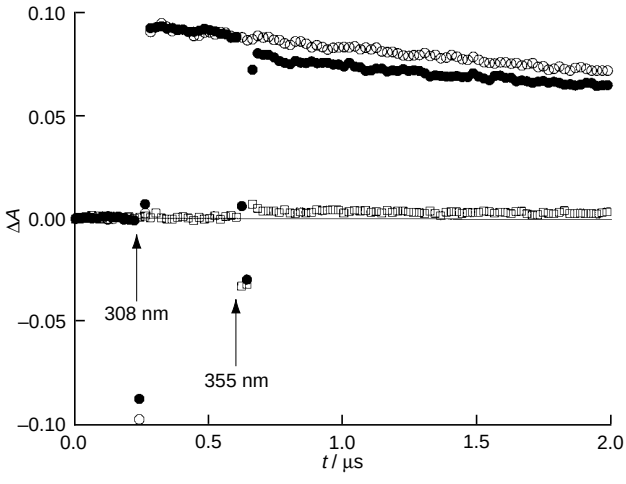


**Fig. 1** Transient signals at 460 nm for the excitation of **1** at (○) 308 nm only, (□) 355 nm only and (●) 308 nm followed by 355 nm

Observed 292.1239.

§ The basic laser flash photolysis system is described in Y. Liao and C. Bohne, *J. Phys. Chem*., 1996, **100**, 734. Since some destruction of **1** was observed, most experiments were performed with a flow cell or the sample was subjected to less than 50 laser shots. The transient lifetime is limited by residual oxygen in the flow cell.

¶ The triplet state was formed by the excitation of **1** with an excimer laser (Lumonics EX-510) at 308 nm. The triplet was monitored at 460 nm, and was irradiated after a suitable delay (Stanford Research Delay Generator, model DG535) by a YAG laser (Spectra Physics GCR-12) at 355 or 532 nm. The excimer laser irradiated the sample at 90° to the monitoring beam, whereas the Yag laser beam irradiated the sample from the front at a small angle with respect to the monitoring beam. The negative Δ*A* values in Fig. 1 correspond to fluorescence of **1** and scattered light.

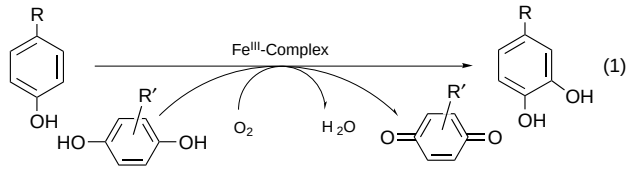
# *ortho*-Hydroxylation of 4-*tert*-butylphenol by nonheme iron(III) complexes as a functional model reaction for tyrosine hydroxylase

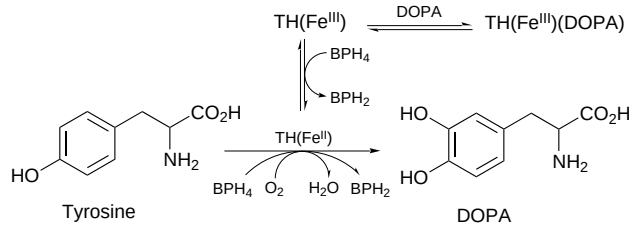


**Takuzo Funabiki,* Tomomasa Yokomizo, Shinko Suzuki and Satohiro Yoshida**

*Department of Molecular Engineering, Graduated School of Engineering, Kyoto University, Kyoto 606-01, Japan*

**Hydroxylation of 4-*tert*-butylphenol to 4-*tert*-butylcatechol is performed by a catecholatoiron(III) complex–hydroquinone–$O_2$ system which mimicks the roles of $Fe^{2+}$ and $Fe^{3+}$ in tyrosine hydroxylase; the *ortho*-hydroxylation of phenols by iron–oxygen active species is suggested.**

Tyrosine hydroxylase (TH) is one of the pteridine-dependent nonheme iron monooxygenases and converts tyrosine to DOPA by hydroxylation with molecular oxygen. Very little is known about not only the active site environment of the enzyme, but also the role of iron in oxygen activation. TH is isolated mostly in the form of $Fe^{3+}$ [TH($Fe^{3+}$), coordinated by DOPA],[1–4] but $Fe^{2+}$ [TH($Fe^{2+}$)] is suggested to be an active species.[1,5–7] Scheme 1[1,3] shows that $Fe^{3+}$ is reduced to an active TH($Fe^{2+}$) by tetrahydropterine ($BPH_4$)[1] and coordinated by catecholamine to give an inert species.[3,4,8,9] The active species has been proposed to be a peroxytetrahydropterin [($BPH_4$)–OOH] rather than an iron–oxygen species.[5,10,11]



In model studies, on the other hand, results suggest that the hydroxylation proceeds *via* an iron—oxygen species in the enzymatic system. Inner-sphere transfer of a peroxo oxygen in $HOC_6H_4O$–$Fe^{III}$–OOR[12] or of the OH ligand in $HOC_6H_4O$–$Fe^{IV}$–OH[13] to the phenolate ligands has been proposed. In the latter case, $Fe^{II}$ complexes such as bis(2,6-dicarboxypyridine)iron(II) and reductants such as PhNHNHPh have been used.[13] Considering that cytochrome P450-type monooxygenations are catalysed by $Fe^{III}$ species, with donation of two electrons and two protons in a catalytic cycle, it is probable that the tyrosine hydroxylase-type *ortho*-hydroxylations are catalysed by $Fe^{III}$ species in the presence of electron and proton donors. In mimicking the processes of reduction of $Fe^{3+}$ to $Fe^{2+}$ by $BPH_4$ and inhibition by coordination of catechol, and in excluding the formation of the ($BPH_4$)–OOH type active species, we have performed hydroxylation of phenol with $O_2$ by iron(III) complexes in the presence of hydroquinones as proton and electron donors [eqn. (1)].

Catecholatoiron complexes formed *in situ*†[14,15] were used as the ferric complex, and 4-*tert*-butylphenol ($Bu^tC_6H_4OH$ **1**) was used as substrate.‡ The effect of four different hydroquinones was studied here: 2,6-di-*tert*-butylhydroquinone (DTBHQ), *tert*-butylhydroquinone (TBHQ), hydroquinone (HQ) and 1,4-dihydroxynaphthalene (DNH). Hydroxylation was performed at 25 °C with $O_2$ (1 atm). In a typical case, the reaction of **1** was started by addition of a MeCN solution (7.5 $cm^3$) of $FeCl_3$ (0.125 mmol) and pyridine (0.25 mmol) to **1** (25 mmol), catechol (0.125–1.25 mmol) and hydroquinone (5.0 mmol).

4-*tert*-Butylcatechol **2** was formed as the sole detectable product from **1**.§ The yield of **2** was greatly dependent on the substituents on catechol: hydroxylation was promoted by electron-withdrawing substituents. Thus, the yield of **2** per mol% Fe decreased in the order: 3,4,5,6-$Cl_4$ (560) > 4-$NO_2$ (410) > 4-Cl (230) > H (120) > 3,5-$Bu^t_2$ (80) > none (*i.e.* without catechol, 52), with [Fe] = [catechol] = 0.125 mmol and [DTBHQ] = 5 mmol. The reverse order was found for the relative rate of consumption of hydroquinones: 3,4,5,6-$Cl_4$ (0.08) < 4-$NO_2$ (0.24) < 4-Cl (0.65) < 3,5-$Bu^t_2$ (0.91) < none (2.18), indicating that electron-withdrawing substituents on catechols, which stabilize the catecholatoiron(III) complexes, are efficient for the *ortho*-hydroxylation of phenols.

It was noticed that after consumption of hydroquinone, **2** was converted to an unidentified polymeric product. As shown in Fig. 1(*a*), this consecutive reaction of **2** was prevented by addition of excess catechol which also, brought about an increase in the yield of **2**. This is probably because the excess catechol effectively controls the competitive coordination of **2**

**Scheme 1**

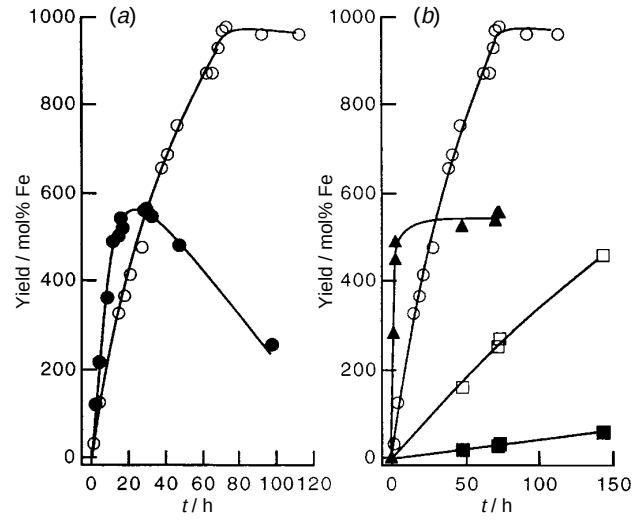


**Fig. 1** Formation of 4-*tert*-butylcatechol from 4-*tert*-butylphenol catalysed by a tetrachlorocatecholatoiron(III) complex under $O_2$ (1 atm). (*a*) Effect of tetrachlorocatechol concentration: [tetrachlorocatechol]:[Fe] = (●) 1 : 1 and (○) 10 : 1, $FeCl_3$ = 0.125 mmol, pyridine = 0.25 mmol, DTBHQ = 5.0 mmol, $Bu^tC_6H_4OH$ = 25 mmol in MeCN (7.5 $cm^3$). (*b*) Effect of different hydroquinones: (○) DTBHQ, (▲) DHN, (□) TBHQ and (■) HQ = 5.0 mmol, tetrachlorocatechol = 1.25 mmol, $FeCl_3$ = 0.125 mmol, pyridine = 0.25 mmol, $Bu^tC_6H_4OH$ = 25 mmol in MeCN (7.5 $cm^3$).

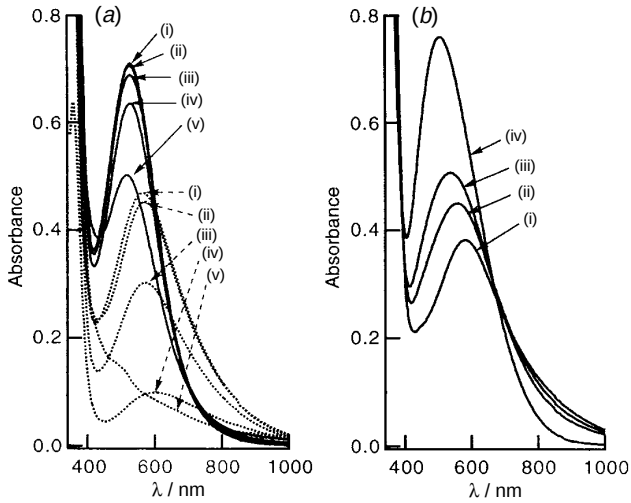
and hydroquinone to $Fe^{III}$. The end of hydroxylation does not mean the deactivation of the active species. The reaction is repeatedly performed by addition of hydroquinone, indicating that the active species is maintained in the form of a catecholatoiron(III) complex.

Hydroxylation is greatly influenced by the hydroquinones. As shown in Fig. 1(*b*), the initial rate of hydroxylation is correlated with the electron-transfer affinity of the hydroquinone (DHN > DTBHQ > TBHQ > HQ), as shown by the decrease in the intensity of the characteristic band of the catecholatoiron(III) complexes [Fig. 2(*a*)]. The rapid quenching of the reaction in spite of the initial rapid formation of **2** is caused by the oxidation of DHN to the corresponding ineffective quinone. Reduction of $Fe^{III}$ to $Fe^{II}$ by hydroquinones was also shown by the formation of a characteristic phenanthrolineiron(II) complex. In the presence of phenanthroline, the hydroxylation does not proceed, indicating that the active iron(II) species is trapped by phenanthroline. The effect of the catecholate ligand on the electron transfer shown in Fig. 2(*a*) indicates that tetrachlorocatecholatoiron(III) is less susceptible to the electron transfer from DTBHQ than the 4-chlorocatecholatoiron(III) complex.

Regardless of the importance of the iron(II) species for hydroxylation, the rapid formation and high yield of **2** was not observed when $FeCl_2$ was used in place of $FeCl_3$ in the tetrachlorocatechol–DTBHQ system. Since $Fe^{2+}$ can be oxidized to an $Fe^{3+}$ species under oxygen, it is difficult to perform the reaction only in the presence of $Fe^{II}$ species, but the result indicates that the $FeCl_3$ system is much better at hydroxylation than the $FeCl_2$ system.

The above results indicate not only that electron transfer to $Fe^{III}$ is essential for hydroxylation, but also that the presence of $Fe^{III}$ species in equilibrium with $Fe^{II}$ is important for the catalytic hydroxylation. This is similar to the participation of both $Fe^{3+}$ and $Fe^{2+}$ in the activity of tyrosine hydroxylase. The most favourable combination of conditions studied here is the use of the tetrachlorocatecholatoiron(III) complex and DTBHQ, which combine to form the most efficient active iron(II) species.

The importance of the presence of $Fe^{III}$ in equilibrium with $Fe^{II}$ suggests the mechanism shown in Scheme 2 for the hydroxylation of phenols. Unlike reactions catalysed by $Fe^{II}$ complexes,[13] the present results suggest that the $Fe^{III}$ species [$(L)Fe^{3+}$] is involved in the catalytic cycle. Support for formation of a free radical intermediate was not found, but addition of triphenylmethane did not affect the reaction. Observation of characteristic LMCT bands at around 600 nm indicated that phenols, including hydroquinones, coordinate to $Fe^{3+}$. Fig. 2(*b*) shows the coordination of phenol to $Fe^{III}$, either together with or replacing a catecholate ligand. The electron-withdrawing substituents on catechol might be effective in making the ferrous as well as ferric centre a better Lewis acid towards the phenolic substrate. It is very likely that the *ortho*-hydroxylation proceeds inside the coordination sphere, but whether the oxygen transfer to phenol proceeds directly *via* a hydroperoxoiron(III) or oxoiron(V) species is a problem to be solved in future.



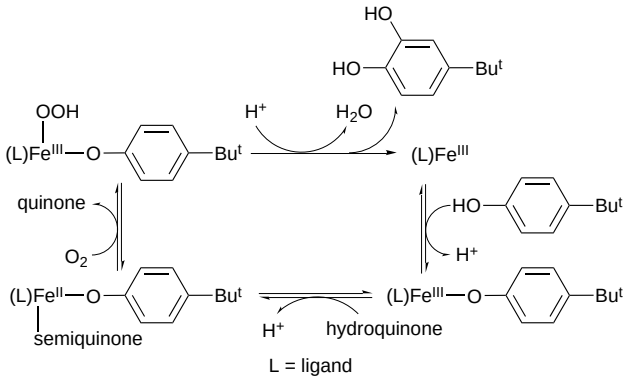


**Fig. 2**(*a*) Visible spectral changes caused by addition of hydroquinones to (- - - - -) tetrachloro- and (——) 4-chloro-catecholatoiron (III) complexes under argon: (i) none, (ii) HQ, (iii) TBHQ, (iv) DTBHQ and (v) DHN. $FeCl_3$ = catechol = 0.025 mmol, hydroquinone = 1.0 mmol, pyridine = 0.05 mmol in MeCN (7.5 $cm^3$). (*b*) Visible changes caused by addition of *tert*-butylphenol to a catecholatoiron (III) complex under argon: (i) $[Bu^tC_6H_4OH]:[catechol]$ = 0 : 1, (ii) 100 : 1, (iii) 250 : 1 (iv) 250 : 0. $FeCl_3$ = catechol = 0.025 mmol, pyridine = 0.05 mmol in MeCN (75 $cm^3$).

**Scheme 2**

## Footnotes

† Formation of three types of catecholatoiron complexes in solution, depending on the catechols used, has been reported:[13,14] $[FeCl(Cat)py_2]$ ($CatH_2$ = 3,5-di-*tert*-butylcatechol), $[FeCl_2(Cat)py]$ ($CatH_2$ = pyrocatechol, 4-methylcatechol, 4-chlorocatechol), $[FeCl_2(Cat)py_2]$ ($CatH_2$ = tetrachlorocatechol).

‡Although chlorophenol is reported to be more reactive than **1**, (ref. 12) we could not detect chlorocatechol in our conditions.

§ No product other than **1** has been detected, indicating that **2** and *tert*-butyl-1,2-benzoquinone **3** are converted to polymeric products.

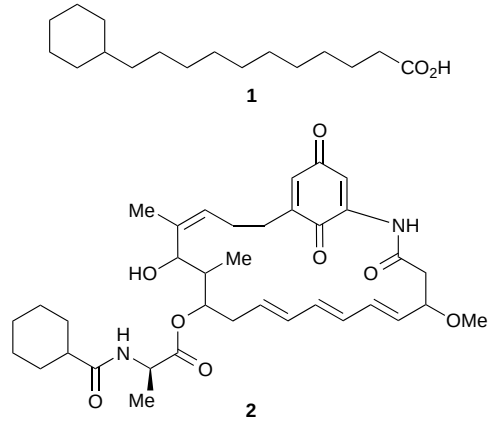
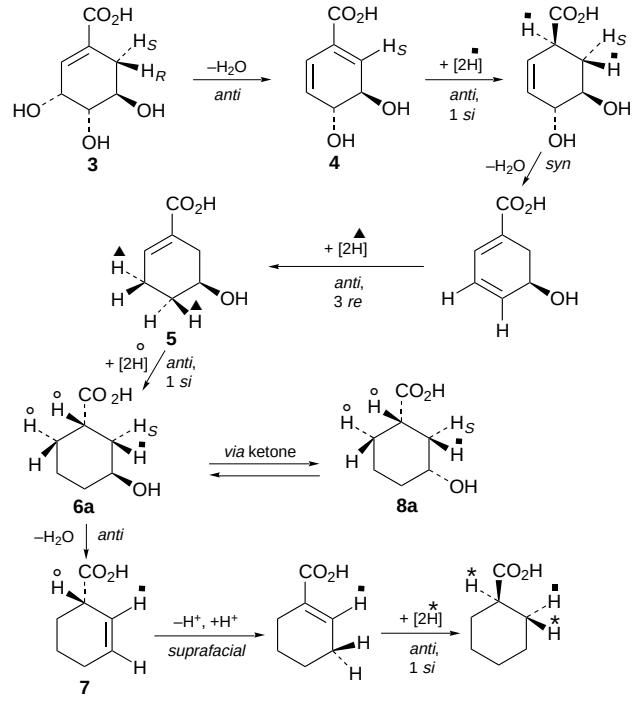
# Biosynthesis of ω-cyclohexyl fatty acids in *Alicyclobacillus acidocaldarius*: the stereochemistry of the initial 1,4-conjugate elimination

**Sandeep Handa and Heinz G. Floss***

*Department of Chemistry, Box 351700, University of Washington, Seattle, Washington 98195-1700, USA*



**The 1,4-conjugate elimination of $H_2O$ from shikimic acid 3, the initial step in the biosynthesis of ω-cyclohexyl fatty acids by the bacterium *Alicyclobacillus acidocaldarius*, has been shown to occur with an overall *anti* stereochemistry *via* loss of the *pro*-6*R* hydrogen of 3.**

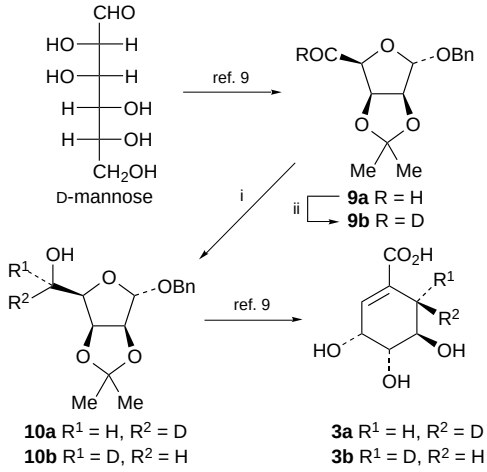


The thermoacidophilic bacterium *Alicyclobacillus acidocaldarius* (formerly *Bacillus acidocaldarius*) produces a series of ω-cyclohexyl fatty acids of which ω-cyclohexylundecanoic acid **1** is the most abundant.[1] It has been suggested that these unusual fatty acids have special physiological importance for the cells at the high temperatures and low pH at which they grow.[2] ω-Cyclohexyl fatty acids have also been isolated from the thermoacidophilic *A. acidoterrestis*[3] and the mesophilic *Curtobacterium pusillum*[4] and in all cases they are believed to arise *via* fatty acid biosynthesis from a cyclohexanecarboxylic acid starter unit (presumably as its coenzyme A thioester). This fully reduced cyclohexanecarboxylate moiety is relatively rare in nature although it is found attached, *via* a D-alanine unit, to the macrocycle of the ansamycin antibiotic ansatrienin A **2** produced by *Streptomyces collinus*.[5]

The biosynthesis of the cyclohexanecarboxylic acid moiety has been studied in *A. acidocaldarius*[6] and *S. collinus*[7] and it has been shown to arise from shikimic acid **3** *via* a series of dehydrations and double bond reductions such that no intermediate is ever aromatic. Previous studies have allowed us to delineate all the steps in the biosynthetic conversion and to establish the stereochemical course for all but one of the metabolic transformations. The biosynthetic pathway, which is common to both organisms, is shown in Scheme 1.

To date, however, the stereochemistry of the initial 1,4-conjugate elimination, resulting in the conversion of shikimic acid **3** to (3*R*,4*R*)-3,4-dihydroxycyclohexa-1,5-dienecarboxylic acid **4** by loss of an unactivated C-6 proton and the C-3 hydroxy group of **3**, has remained elusive. This is primarily due to the fact that both the C-6 protons of **3** are lost in the overall conversion to cyclohexanecarboxylic acid, thus obscuring the stereochemistry of the initial proton loss. This problem was overcome by the isolation of a blocked mutant of *A. acidocaldarius*[8] (designated as mutant 2) which is unable to convert the *trans*-3-hydroxycyclohexanecarboxylic acid intermediate **6a** to cyclohex-2-enecarboxylic acid **7**. This results in the accumulation of **6a**, isolated from the culture medium as its methyl ester **6b**,[6] and lower levels of its C-3 epimer *cis*-3-hydroxycyclohexanecarboxylic acid **8a** (again isolated as the corresponding methyl ester **8b**), postulated to arise from **6a** by a side reaction involving oxidation to the ketone and reduction with opposite stereochemistry.[6] Since both **6a** and **8a** contain the shikimate C-6 proton retained in the initial 1,4-conjugate elimination step, the *A. acidocaldarius* mutant 2 provided a system in which to investigate the stereochemistry of this elimination.

In order to synthesize the stereospecifically deuteriated (6*R*)-(−)-[6-$^2H_1$]shikimic acid **3a** required for these investigations, we decided to employ the route of Fleet,[9] as previously adapted by Zamir *et al.*[10] (Scheme 2). This adaptation allows for the stereospecific labelling to be introduced *via* enzymic reduction of the intermediate aldehyde **9a** (prepared from D-mannose) using horse liver alcohol dehydrogenase coupled to an $NAD^+$ recycling system employing [$^2H_6$]ethanol to supply the deuteride reducing equivalents. The intermediate alcohol **10a** thus produced was then taken through to **3a** as previously described.[9] We were also able use this strategy to synthesise (6*S*)-(−)-[6-$^2H_1$]shikimic acid **3b** *via* the corresponding enzymic reduction of the deuteriated aldehyde **9b** (prepared from **9a** by



**Scheme 1**

an oxidation–reduction sequence) using unlabelled ethanol to supply the reducing equivalents.

With both specifically deuteriated shikimates **3a** and **3b** in hand feeding experiments were carried out with cultures of *A. acidocaldarius* mutant 2. The two accumulated intermediates **6a** and **8a** were isolated as their methyl esters **6b** and **8b**, employing similar conditions and experimental protocols to those previously described.[6] The isolated compounds were subsequently analysed by $^2$H NMR and two of the resulting spectra are shown in Fig. 1.

**Scheme 2** *Reagents*: i, Horse liver alcohol dehydrogenase, $NAD^+$, $C_2D_5OD$ (for **9a**), $C_2H_5OH$ (for **9b**); ii, $NaO_2Cl$, 2-methylbut-2-ene, $Bu^tOH$, $H_2O$, then $CH_2N_2$, $Et_2O$, then $LiAlD_4$, THF, then $Me_2SO$, $(COCl)_2$, $Pr^i_2EtN$, $CH_2Cl_2$

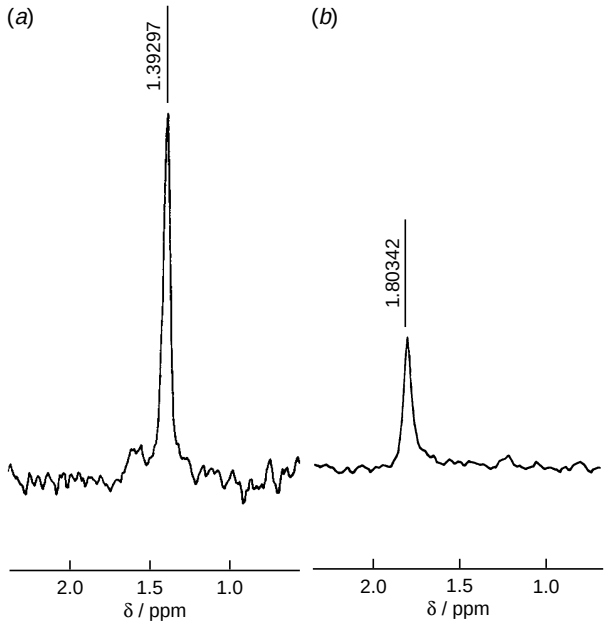


**Fig. 1** Partial 46.07 MHz $^2$H NMR spectra of (*a*) **8b** and (*b*) **6b** from the incorporation of (6*S*)-(−)-[6-$^2H_1$]shikimic acid **3b**. The spectra of **6b** and **8b** obtained from (6*R*)-(−)-[6-$^2H_1$]shikimic acid **3a** showed no signals in this region.

Previous studies[6] had already established that the proton retained in the initial 1,4-conjugate elimination from **3** occupies the *pro*-2*S* position in the acids **6a** and **8a** accumulated by the mutant organism. Furthermore, $^1$H NMR spectra of the corresponding methyl esters **6b** and **8b**, while not allowing definite identification of the signal attributable to this proton, had shown it to lie within a complex set of signals between δ 1.45–1.85 for the *trans*-isomer **6b** and between δ 1.15–1.45 or 1.78–1.96 for the *cis*-isomer **8b**.

Inspection of the $^2$H NMR spectra of **6b** and **8b** isolated from the feeding experiment with (6*S*)-(−)-[6-$^2H_1$]shikimic acid **3b** (Fig. 1) clearly shows that the deuterium label has been retained, giving rise to signals at δ 1.80 and 1.39 for **6b** and **8b**, respectively. The $^2$H NMR spectra of **6b** and **8b** isolated from the experiment with (6*R*)-(−)-[6-$^2H_1$]shikimic acid **3a** showed no discernible signals even after prolonged data accumulation.

Thus the results clearly indicate that it is the *pro*-6*R* hydrogen of shikimate that is lost in the initial 1,4-elimination step in the biosynthesis of cyclohexanecarboxylic acid by *A. acidocaldarius*. The elimination therefore occurs by an overall *anti* mechanism and as such mirrors exactly the analogous 1,4-elimination found in the 'normal' shikimate pathway involving the formation of chorismate from 5-enolpyruvylshikimate 3-phosphate.[11] While previous experiments[12] with *A. acidocaldarius* have shown that chorismate is not an intermediate on the biosynthetic pathway to cyclohexanecarboxylic acid, confirming divergence from the standard shikimate pathway prior to this stage, this new finding suggests that there may be a strong evolutionary relationship between the two metabolic processes, which share the feature of abstraction of an unactivated hydrogen. Additionally it removes the final stereochemical ambiguity of the biosynthetic pathway.

Further work will explore mechanistic aspects of this elimination (*e.g.* whether the hydroxy group is activated by phosphorylation prior to elimination, as is the case in the formation of chorismate) and will examine the stereochemistry of similar reactions in analogous biosynthetic pathways.

This work was supported by the U.S. National Institutes of Health through grant AI20264. We thank Mr Stefan Gröger for recording the NMR spectra.

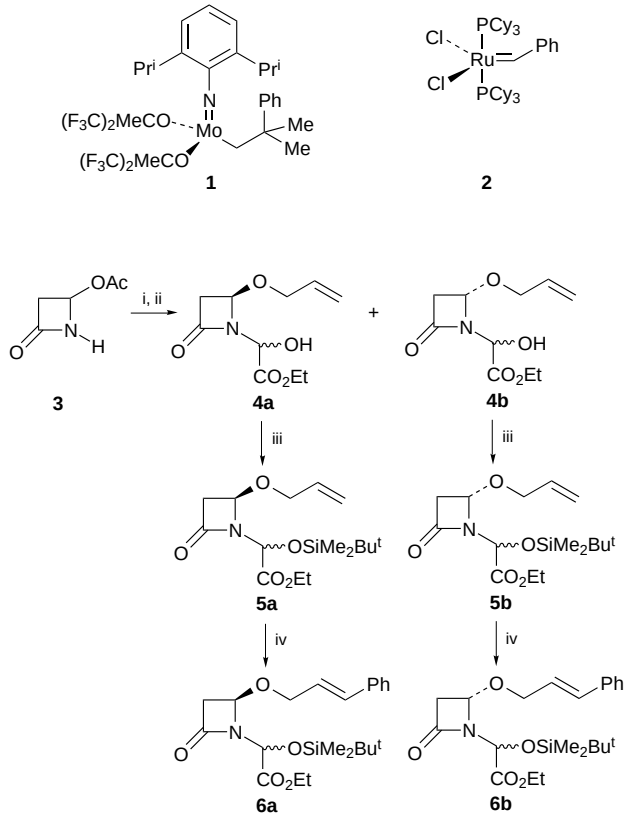
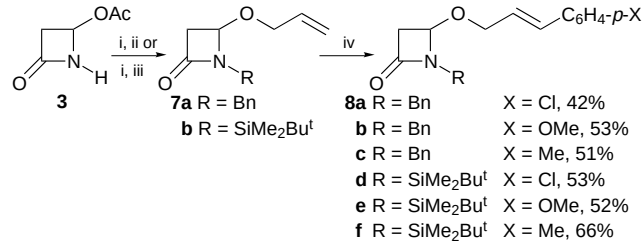
# Highly functionalised monocyclic and bicyclic β-lactams *via* alkene metathesis

**Anthony G. M. Barrett,*[a] Simon P. D. Baugh,[a] Vernon C. Gibson,*[a] Matthew R. Giles,[a] Edward L. Marshall[a] and Panayiotis A. Procopiou[b]**



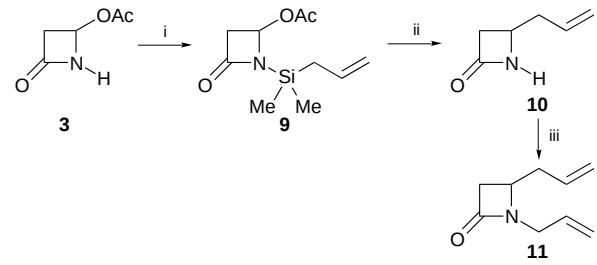
[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*
[b] *Department of Medicinal Chemistry, Glaxo Wellcome Research and Development Ltd, Gunnels Wood Road, Stevenage, Hertfordshire, UK SG1 2NY*

**Both monocyclic and bicyclic β-lactam systems are prepared *via* alkene metathesis reactions using Mo(=CHCPhMe$_2$)(=NC$_6$H$_3$Pr$^i_2$)[(OCMe(CF$_3$)$_2$]$_2$ or Ru(=CHPh)Cl$_2$(PCy$_3$)$_2$.**



The elaboration of carbon skeletons *via* the construction of carbon–carbon bonds represents one of the most important endeavours in synthetic organic chemistry. Transition metal catalysed processes are especially valuable, particularly for the selective transformation of polyfunctional precursors into products of enhanced complexity. The pioneering work of Grubbs has shown that a wide variety of compounds may be synthesised *via* ring-closing metathesis (RCM) procedures[1] using molybdenum **1**[2] and ruthenium **2**[3] based catalysts. Other workers have extended this methodology which is now finding increasing use in synthesis.[4–8] Our group has recently shown that a number of previously unexplored systems are amenable to alkene metathesis.[9,10] In particular we have shown that β-lactams are well tolerated under metathesis conditions furnishing both mono- and bi-cyclic systems alike in good to excellent yields. Herein we report the extension of this work to the synthesis of more highly functionalised β-lactams.

Sequential reaction of the commercially available 4-acetoxyazetidin-2-one **3** with allyl alcohol and ethyl glyoxylate produced the diastereomeric alkenes **4a,b** (Scheme 1) which were separable by chromatography. Protection of **4a** and **4b** with *tert*-butyldimethylchlorosilane gave the metathesis substrates **5a,b**† in quantitative yield. In a similar manner treatment of 4-acetoxyazetidin-2-one **3** with allyl alcohol followed by benzyl bromide or *tert*-butyldimethylchlorosilane gave alkenes **7a** (69%) and **7b** (76%) respectively. Reaction of **5a** with excess styrene (4 equiv.) and a catalytic amount of carbene **1** (1 mol%) in dichloromethane at room temperature for 2 h produced the desired alkene **6a** (79%) (Scheme 1). Similarly epimer **5b** gave **6b** under the same conditions in comparable yield (67%). In all the cross metathesis processes reported herein only the *trans* double bond isomers were observed. We then explored a series of electronically diverse styrenes (*p*-Cl, *p*-OMe, *p*-Me) as the cross metathetic partners of protected β-lactams **7a** and **7b**. The reactions proceeded smoothly in the presence of **1** (1 mol%) to furnish *trans* alkenes **8a**–**f** (42–66%) (Scheme 2).



The synthesis of novel heteroatom-containing β-lactam substrates suitable for RCM were examined next. Following the procedure of Uyeo[11] a modified Sakurai-type reaction was utilised to synthesise 4-allylazetidin-2-one **10** (Scheme 3). Treatment of 4-acetoxyazetidin-2-one **3** with allylchlorodimethylsilane in the presence of an amine base followed by

diastereomer. The novel diene **17** was obtained by sequential treatment of 4-acetoxyazetidin-2-one **3** with prop-2-enethiol and allyl bromide (Scheme 5, 56% over 2 steps). Alkene **19** was synthesised by reaction of 4-acetoxyazetidin-2-one **3** with *N*-tosylallylamine (67%) according to the procedure of Campbell and Connarty[12] followed by *N*-allylation of the resulting β-lactam **18** with allyl bromide (89%).

With the RCM substrates in hand, diene **11** was exposed to a catalytic quantity of ruthenium carbene **2** (5 mol%) in dichloromethane at room temperature. Diene **11** was rapidly converted into the bicyclic [2.4.0]carbacephem **20** in excellent yield (81%) (Scheme 7). In this and the other RCM processes (*vide infra*), only a single product component was evident by TLC analysis. In a similar manner diene **15** was converted into carbacephem **23** in high yield (Scheme 8, 78%). RCM of dienes **17** and **19** proceeded only slowly with ruthenium catalyst **2** (5 mol%) giving bicyclic lactams **21** and **22** in low isolated yield (22 and 36% respectively). However, replacement of the ruthenium catalyst **2** with the molybdenum catalyst **1** (5 mol%) resulted in rapid reactions leading to the isolation of homocephem **21** (78%) and homo-azacephem **22** in excellent yield (91%) (Scheme 7).

In conclusion we have shown that alkene metathesis is an extremely useful synthetic tool for the synthesis of highly functionalised monocyclic β-lactams and a variety of bicyclic β-lactams. The range of heteroatoms tolerated in the ring-closing metathesis reaction (C, O, N and S) suggests that this methodology should be of enormous use for the synthesis of a great range of antibiotics and their derivatives. The azacephem system is of particular interest as this is a relatively unexplored area. Recent work on azapenems has been published by Hegedus[13,14] and our work provides an alternative metal-mediated route to such systems.

# Structure of an amorphous polymer electrolyte, poly(ethylene oxide)$_3$ : LiCF$_3$SO$_3$

**Roger Frech,[a] Sangamithra Chintapalli,[a] Peter G. Bruce[b] and Colin A. Vincent[b]**

[a] *Department of Chemistry and Biochemistry, University of Oklahoma, Norman, Oklahoma 73019, USA*
[b] *School of Chemistry, University of St Andrews, St. Andrews, Fife, UK KY16 9ST*

**The amorphous phase formed on melting the crystalline polymer electrolyte PEO$_3$ : LiCF$_3$SO$_3$ has a short-range structure in which all of the lithium ions are located within the poly(ethylene oxide) helix.**

Polymer electrolytes are compounds formed by the dissolution of salts in polar high molar mass macromolecules which form strong interactions with cations. They form the basis of a new electrochemical technology which includes thin film all-solid-state lithium batteries. Electrolytes based on poly(ethylene oxide), PEO, may form crystalline or amorphous phases. A major advance has recently been made in establishing the structures of crystalline polymer electrolytes, but it is the amorphous materials which exhibit high ionic conductivity and it is therefore their structures which are of particular interest. By combining high-resolution IR spectroscopic studies of both crystalline and amorphous phases with the results of an X-ray diffraction analysis of the crystalline phase, we have established the structure of an amorphous polymer electrolyte consisting of a lithium salt, LiCF$_3$SO$_3$, dissolved in the high molecular mass PEO, such that there are three host oxygen atoms for each Li$^+$ ion present.

The structure of crystalline PEO$_3$ : LiCF$_3$SO$_3$ consists of a parallel array of separate PEO chains each associated with its own set of ions, in which each chain adopts a helical conformation.[1] A single lithium ion is located within each turn of the helix which is coordinated directly by three ether oxygens. The coordination environment around the Li$^+$ ion is completed by two further oxygens, one from each of two CF$_3$SO$_3^-$ anions thus forming a five-coordinate arrangement in an approximate trigonal-bipyramidal geometry. The CF$_3$SO$_3^-$ anions bridge neighbouring lithium ions by donating one of their oxygens to each of two lithiums, while the remaining oxygen of each CF$_3$SO$_3^-$ group is uncoordinated. The CF$_3$ groups sit outside the dimensions of the helix. The crystal structure does not change from −173 °C until the melting point at 179 °C.

In the molten phase there is no long-range order, as is evident from the absence of Bragg peaks.[2] It is clear from a study of vibrational spectra, however, that similar short-range order to that in the crystalline phase persists. Fig. 1 shows the symmetric stretching mode $\nu_s(SO_3)$ as a function of temperature. This mode is known to be affected by both changes in the ionic environment of CF$_3$SO$_3^-$ (*i.e.* by any alteration in neighbouring cation numbers or positions) and by variation in the way 'solvent' is coordinated to neighbouring cations.[3]

Distinct bands which appear in the IR spectra of low molar mass liquid PEO oligomer–LiCF$_3$SO$_3$ solutions in this region have been previously assigned as 'free' ions (1032 cm$^{-1}$), simple ion pairs (1041 cm$^{-1}$) and a more highly associated ionic species described as an ionic aggregate (1050 cm$^{-1}$), following the Raman spectra-based assignments of ref. 3. In the room-temperature IR spectrum of high molecular mass PEO$_3$ : LiCF$_3$SO$_3$ there is only a single band at 1046 cm$^{-1}$. It is seen that apart from the expected increase in bandwidth as the temperature is raised, the frequency shift of the band on melting is $< 1$ cm$^{-1}$.

IR spectra of PEO$_3$ : LiCF$_3$SO$_3$ are shown in Fig. 2 for the CF$_3$ symmetric deformation mode, $\delta_s(CF_3)$, over the temperature range 25–190 °C. This mode is particularly sensitive to variation in the ion association due to a shifting of the electron density between the CF$_3$ and the SO$_3$ ends of the anion as a result of association with a cation.[4] In this spectral region IR bands of oligomer–LiCF$_3$SO$_3$ solutions are assigned as 'free' ions (752 cm$^{-1}$), simple ion pairs (757 cm$^{-1}$), and an aggregate species (763 cm$^{-1}$). We will focus our attention on the $\delta_s(CF_3)$ region because of the more distinct frequency separation of the various triflate ion species in the PEO$_3$ : LiCF$_3$SO$_3$ compounds.

As in the case of $\nu_s(SO_3)$ there is only a single band in Fig. 2, at 760 cm$^{-1}$, which is assigned to the aggregate species. The lowering of this frequency from the value of 763 cm$^{-1}$ which is observed in liquid oligomer–LiCF$_3$SO$_3$ solutions is possibly due to packing effects in the crystalline state, *e.g.* from a decrease in the rotational or reorientational motion of the CF$_3$ groups. Knowledge of the crystal structure permits an unambiguous assignment of the $\nu_s(SO_3)$ mode and the $\delta_s(CF_3)$ mode shown in Figs. 1 and 2, respectively. These vibrational states arise from a CF$_3$SO$_3^-$ ion, two oxygen atoms of which bridge in a monodentate arrangement two Li$^+$ ions that lie adjacent to

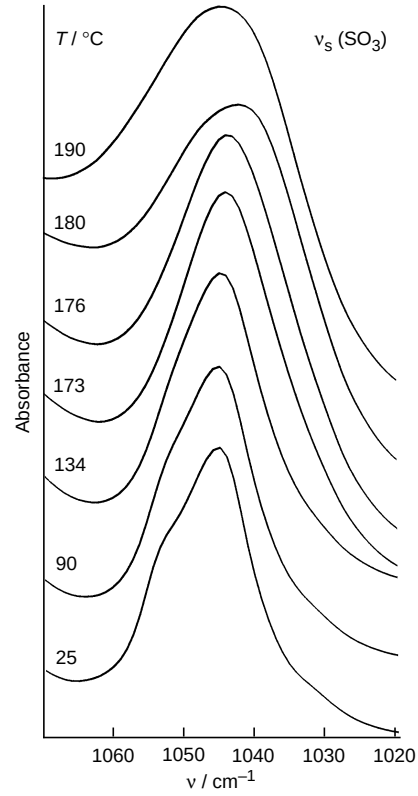

**Fig. 1** Symmetric stretching mode, $\nu_s(SO_3)$, as a function of temperature for poly(ethylene oxide)$_3$ : LiCF$_3$SO$_3$

each other within the polymer helix. Each anion is essentially a $[Li_2CF_3SO_3]^+$ species in terms of the vibrational modes of the $CF_3SO_3^-$ ion. This assignment is consistent with a study of $LiCF_3SO_3$ in acetone and poly(propylene oxide)[5] in which the highest frequency component in the $\nu_s(SO_3)$ spectral region was assigned to the isolated triple ion $[Li_2CF_3SO_3]^+$.

The frequency of the $\delta_s(CF_3)$ band does not change as the temperature is increased up to the onset of melting although thermal broadening of the band is apparent. Above the melting point there is a broad feature centred at 763 $cm^{-1}$, which is the frequency expected for a $[Li_2CF_3SO_3]^+$ species. The question arises: what is the nature of the $[Li_2CF_3SO_3]^+$ species? They cannot be individual, isolated $[Li_2CF_3SO_3]^+$ triple ions as have been previously observed in the oligomer–$LiCF_3SO_3$ solutions with somewhat lower salt concentrations,[6] since the presence of such moieties would necessarily require the presence of 'free' $CF_3SO_3^-$ ions on charge balance considerations. These would in turn give rise to a band at 752–753 $cm^{-1}$, and no absorption can be observed in this region. In principle, the charge balance might also be satisfied by a $[Li(CF_3SO_3)_2]^-$ species, which would be observed spectroscopically at *ca.* 757 $cm^{-1}$. There is indeed a shoulder at 180 °C (but not, apparently, at higher temperatures) which might correspond to such a species, but its intensity is very weak in comparison with the $[Li_2CF_3SO_3]^+$ band and hence is considered to be of minor importance.

Vibrational bands in the 800–1000 $cm^{-1}$ region are due to a mixture of $CH_2$ rocking and C–O stretching and are very sensitive to the local conformation of the polyether backbone.[7] We observe no major shift in the frequency of these modes between the spectrum of the highest temperature crystalline phase and the amorphous phase, suggesting that the basic lithium–polyether backbone interaction does not alter when the crystals melt.

We therefore conclude that the majority species is $[Li_2CF_3SO_3]^+$ and that in the absence of significant quantity of $CF_3SO_3^-$ or $[Li(CF_3SO_3)_2]^-$, this must be present in the amorphous phase largely as part of an extended ionic chain as in the crystal.

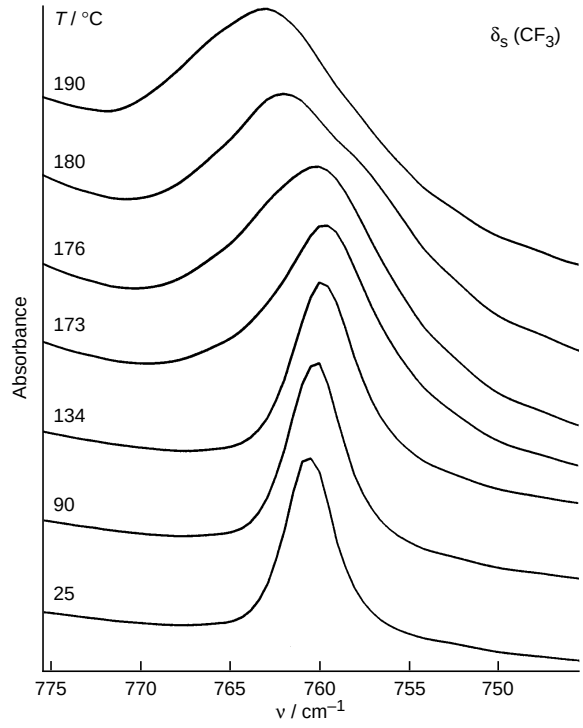

**Fig. 2** Symmetric deformation mode, $\delta_s(CF_3)$, as a function of temperature for poly(ethylene oxide)$_3$ : $LiCF_3SO_3$

It is evident that the structure of the amorphous phase is very similar to that of the crystalline state, with only a loss of long-range order arising from a loss of register between adjacent PEO chains and some disordering in the helical torsion angles. In particular each chain remains intact with its associated ions: *i.e.* every chain is associated with a dedicated set of cations and anions which do not bond to any of the other chains. In this sense each chain forms an isolated, infinitely long, coordination complex. Interchain interactions are only of the dipole–dipole or van der Waals type and are thus of second-order compared with the intrachain interactions. There is no evidence of cation or anion cross-linking between chains.

It seems unlikely, given the absence of interchain ionic cross-links at the high concentration of 3 : 1, that these would be present to any significant extent in amorphous phases with lower salt content. Beginning at a low salt concentration and then increasing the salt content will load each chain with ions and increase the intrachain cross-link density thus reducing segmental motion, raising $T_g$ and suppressing the ionic conductivity, as has been suggested in a recent study based on a detailed analysis of the polymer dynamics by NMR.[8] The consequences of the assertion that interchain cross-links are of minor significance in amorphous polymer electrolytes at higher oxygen/salt ratios (*i.e.* in phases which may be useful in an electrochemical device) will be considered elsewhere.[9]

It is tempting to speculate that the $Li^+$ ions may be transported along the chains while remaining within the helix, as suggested by Armand *et al.*[10] nearly twenty years ago. It is known that the polymer chain dynamics are intimately linked to the ionic motion, and it is therefore likely that the $Li^+$ ions would be 'handed-on' from coil to coil by an appropriate dynamic mode of the polymer, *e.g.* a concertina motion along the axis of the helix. A perfect 3 : 1 structure would have a lithium ion in every coil and conductivity would, as a result, not be possible. However, some defects ($Li^+$ vacancies) are likely which, although below the level that may be detected by the spectroscopic methods, are sufficient to endow the polymer with some conductivity. At lower salt concentrations (*i.e.* higher PEO : salt ratios) there will, of course, be a substantial proportion of $Li^+$ ion vacancies in the PEO coils. It is important to note also that for long-range ion transport (*e.g.* d.c. conductivity) it will be necessary to include interchain lithium ion transfer in the overall mechanism, since as we have argued, there is no significant centre-of-gravity motion of the polymer chains for host molecules above the entanglement limit.

# Highly defined pore size distribution in sol–gel silicate glasses induced by incorporation of an oligomeric siloxane

**Nico A. J. M. Sommerdijk, Ernst R. H. van Eck and John D. Wright***

*Centre for Materials Research, University of Kent, Canterbury, Kent, UK CT2 7NH*

**Doping of sol–gel derived tetramethoxysilane (TMOS) glasses with small amounts of octaphenylcyclotetrasiloxane (OPCTS) induces a remarkably narrow pore size distribution.**

The use of sol–gel techniques for the preparation of silicates employing surfactant aggregates as templates has opened the way to a range of possible applications of these well defined mesoporous materials.[1,2] Using surfactant aggregates displaying hexagonal,[1] cubic,[2] and lamellar[3] phases, highly ordered silicate materials with predefined pores could be obtained. Organically modified alkoxysilane precursors (ormosils) can also be used to modify the pores in sol–gel derived silica materials, but this does not lead to a better definition of the shape and size of the pores.[4,5] However, by the incorporation of non-crosslinking oligosiloxane units of defined size into the inorganic polymer network, better definition of the pore size may be achieved without the use of relatively large quantities of organic materials, and without the need for their removal.

The hydrolytic ring-opening of octaphenylcyclotetrasiloxane (OPCTS) **1** provides well defined ormosil units which may be incorporated into a silicate network. The resulting octaphenyltetrasiloxanediol (OPTSD) units would then provide segments of defined length which could be used to tailor the pore size in these mesoporous materials.

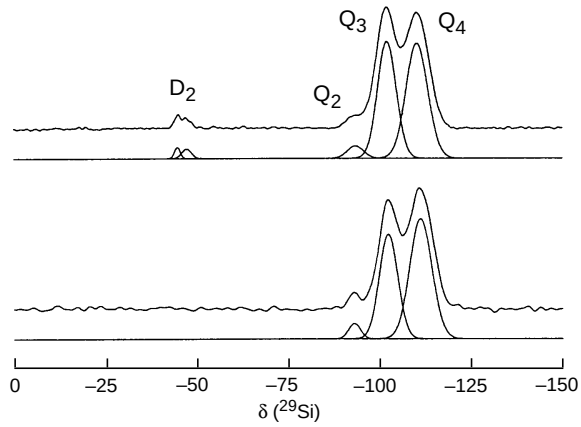
The ring-opening hydrolysis reaction of OPCTS should be carried out preferably in the presence of an excess of prehydrolysed TMOS in order to ensure reaction of the terminal OH groups of OPTSD with the sol–gel network and prevent polysiloxane formation. However, it was not possible to perform this reaction under standard hydrolysis conditions due to precipitation of the apolar OPCTS in aqueous media. This problem was circumvented by adding a 1 : 1 (*v*/*v*) mixture of thf and concentrated hydrochloric acid to a stirred thf solution of TMOS and OPCTS at 50 °C.† Nevertheless, no more than 10 mol% (based on silicon) could be added to the mixture without immediate precipitation. Gelation of the mixture occurred within 2 h and the gel was kept at 50 °C in a sealed vessel for 16 h. After ageing for two weeks at room temperature, small needle-shaped crystals had formed inside the transparent material. The crystalline material was removed by dissolution in thf followed by recrystallisation. Powder diffraction experiments demonstrated that they consisted of OPTSD. The glassy gels were washed with ethanol to remove remaining acid and aged for two more weeks. The diffraction patterns of the powdered ormosil revealed that washing had removed all the crystalline material and that the resulting glass was completely amorphous.

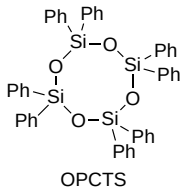
The glasses were transparent. However, drying in air or exposure to water turned them into opaque materials. Glasses prepared without the addition of OPCTS remained transparent upon exposure both to air and water.

The incorporation of ring-opened OPCTS units into the sol–gel network was examined using FTIR and solid-state $^{29}$Si NMR spectroscopy.‡ Comparison of both the FTIR and NMR spectra obtained for the ormosil with those obtained from a reference material prepared without OPCTS revealed that diphenylsiloxane units were incorporated into the new material. Both spectroscopic techniques showed furthermore that the presence of diphenylsiloxane units in the ormosil did not merely arise from entrapped OPTSD, but that it was chemically incorporated in the silica network.

Comparison of the FTIR spectra of the ormosil with those obtained from OPTSD revealed shifts to higher wavenumbers for two of the Si–Ph vibrations, from 741.7 to 744.5 and from 718.2 to 719.3 cm$^{-1}$, respectively,§ indicating restricted conformational motions of the OPTSD units due to incorporation in the silicate network. More concrete evidence was obtained from the solid-state NMR experiments which revealed that condensation with the silicate network must have been complete since the resonance at $\delta$ −39.6, assigned to the terminal $D_1$ unit[6] of OPTSD, was no longer present in the $^{29}$Si NMR spectrum of the ormosil (Fig. 1).¶

The pore size distribution of the ormosil was determined using thermoporometry[7,8] and compared to the pore size distribution found in the reference material. The results presented in Fig. 2 show that the addition of a small amount of OPCTS has a dramatic effect on the porosity of the material. The ormosil has small pores with diameters distributed over a range of 4–10 nm (*i.e.* a distinctly wider range than in the





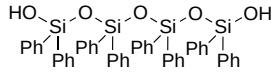


**Fig. 1** $^{29}$Si solid-state NMR spectra of sol–gel glasses prepared from 100% TMOS (lower trace) and from a 96 : 4 mixture (based on Si) of TMOS and OPCTS (upper trace). Gaussian fits are shown below each trace. The spectra were obtained at 59.665 MHz with single-pulse excitation at a MAS frequency of 5.0 kHz using high-power proton decoupling and a relaxation delay of 300 s.

OPCTS

OPTSD

reference compound) and also another type of pores with diameters of approximately 4.5 nm and a very narrow size distribution range. This result shows that incorporation of OPCTS modifies the overall network structure in the host material as well as generating new, sharply defined pore structures.

Remarkably, the $^{29}$Si NMR spectra (Fig. 1) reveal that only 1 mol% of OPTSD is incorporated into the sol–gel network. It is also clear from Fig. 1 that incorporation of OPTSD units causes only a small decrease in the functionality of the Q atoms (the average number of Si–O–Si bonds per Q atom) from 3.503 ± 0.008 to 3.470 ± 0.007. This change is due to an increase in the relative amount of $Q_3$ atoms (from 40 to 45%) and a decrease in $Q_4$ atoms (from 55 to 51%). The number of Si–O–Si links between OPTSD and the silicate network is not sufficient to explain this change in functionality or the dramatic changes in pore size distribution. However, the OPTSD modifies the overall network in other ways (*e.g. via* steric effects) as well as by changes in the type of linkages. Full understanding of these effects requires further experiments using similar modifiers with different substituents, which are in progress.

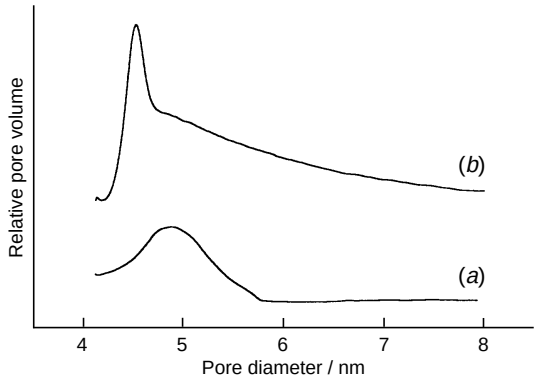

**Fig. 2** Pore size distributions of sol–gel glasses prepared from 100% TMOS (*a*) and from a mixture of TMOS and OPCTS (4% based on Si) (*b*) determined from thermoporometry experiments[7,8]

We would like to thank Drs R. H. Cragg and M. E. Smith for helpful discussions, and gratefully acknowledge the University of Kent for its strong support of NMR facilities.

## Footnotes

† Comparison of powder diffraction patterns of OPCTS before and after hydrolysis indicated that ring opening was complete when the described procedure was applied.

‡ Solid-state $^{29}$Si NMR experiments were performed using a Chemagnetics CMX 300 Infinity spectrometer, using magic angle spinning and proton decoupling.

§ Similar but reversed spectral changes are observed upon ring opening of OPCTS which leads to a shift of the same Si–Ph vibrations from 742.5 to 741.7 and from 720.3 to 718.2 $cm^{-1}$, respectively. These shifts to lower wavenumbers were interpreted as an increase in conformational motion due to a released ring strain.

¶ The notations $D_n$ and $Q_n$ are used to describe the chemical environment of silicon atoms which could form two and four possible Si–O–Si bonds, respectively. The number of bonds actually present is represented by *n*.

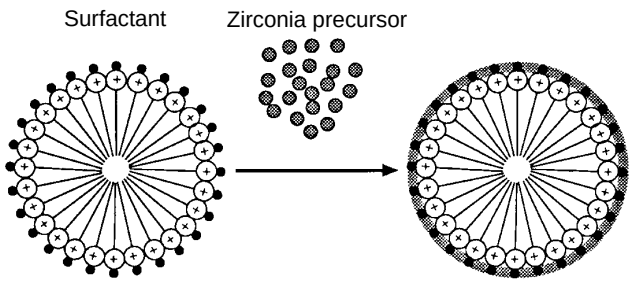
# Amphoteric surfactant templating route for mesoporous zirconia

**Anthony Kim,* Paul Bruinsma, Yuan Chen, Li-Qiong Wang and Jun Liu**

*Pacific Northwest National Laboratory, Richland, Washington, 99352, USA*

**An amphoteric surfactant templating route permits the synthesis of hexagonal mesophases of zirconium compounds by self-assembly of the surfactant and soluble zirconium species in aqueous solution.**



The invention of mesoporous silica molecular sieves[1,2] has generated wide interest in the synthesis of mesoporous materials based on self-assembly of ordered, surfactant/inorganic structures. Routes based on ionic,[1–4] hydrogen,[5,6] and covalent bonding[7–9] between the surfactant and the inorganic have been developed for the synthesis of mesoporous silica and other metal oxides. Previously, mesoporous zirconia has been produced; however, these methods involve expensive alkoxides,[10] rely on sulfate ion to link the surfactant and zirconium,[11,12] or do not involve self-assembly.[13,14] Here, we report a new synthesis route based on self-assembly of a soluble zirconia precursor and an amphoteric surfactant template. The amphoteric surfactant, cocamidopropyl betaine (CAPB), has quaternary ammonium and carboxylate functionalities for the head group and can therefore bond with both negatively and positively charged inorganic species. In contrast to quaternary ammonium surfactant routes,[11,12] CAPB does not require a bridging anion for the formation of the surfactant–Zr complex. CAPB also has the advantage of high solubility over wide ranges of pH and ionic strength[15] and may therefore find use in a variety of syntheses.

The proposed amphoteric surfactant templating route is shown in Scheme 1. Under the low pH conditions of the reaction, the quaternary ammonium group of CAPB is positively charged, and the carboxylate group is initially protonated.[16] Positively charged inorganic species attach to the surfactant by reaction with the carboxyl group. Concurrent surfactant bonding with the inorganic and aggregation of the micellar structures leads to formation of the hexagonal mesophase. The quaternary ammonium group serves two purposes: (*i*) it imparts high solubility for the otherwise insoluble carboxylic acid and (*ii*) it helps to ensure a large head-group area necessary for the formation of the rod-shaped micellar subunits of the hexagonal phase.[17]

The hexagonal mesophase was prepared from zirconyl chloride octahydrate (Aldrich Chemical), cocamidopropyl betaine (Amphosol CG, 30 mass%, Stepan Co.) and water, as follows. CAPB was purified of NaCl by ion exchange to pH = 2.6. Aqueous 0.25 M $ZrOCl_2$ was combined with CAPB until the Zr/CAPB mole ratio was 0.8. After reaction at 70 °C for four days the product was recovered by filtration.

Powder X-ray diffraction (XRD, Cu-K$\alpha$ radiation) of the as-synthesized mesophase (Fig. 1) revealed a primary (100) reflection corresponding to 41 Å and a secondary (110) reflection of the hexagonal phase. Higher order peaks of the hexagonal mesophase were unresolved, in part because of a broad peak centred at 2$\theta$ *ca*. 5.2°. This broad peak suggests that the walls of the mesostructure are made up of amorphous zirconium hydrate, since the peak approximately corresponds to a *d*-spacing of 17 Å, the average distance between zirconium centres in crystalline hydrates.[18] Other evidence for tetrameric species is given by three more broad peaks centred at 2$\theta$ *ca*. 27, 42 and 58° (XRD not shown) which correspond to zirconium tetramers in solution.[19] Transmission electron microscopy (TEM) of as-synthesized mesophase (Fig. 2) confirmed the formation of the hexagonally packed mesostructure. The 42 Å repeat distance from TEM agrees well with $d_{100}$ = 41 Å from XRD.

Bonding between the surfactant and zirconium precursor was probed by solution $^{13}C$ NMR spectroscopy. Betaine [(carboxymethyl)trimethylammonium hydroxide, Aldrich Chemical] was used to model the interactions of the surfactant head-group with zirconium species during the early stages of mesophase formation. The use of betaine in place of CAPB prevented precipitation, allowing the collection of simplified high-resolution solution NMR spectra (Fig. 3). Chemical shifts were referenced to dioxane ($\delta$ 67.4). Betaine on its own [pH adjusted to 1.3 with HCl, Fig. 3(*a*)] showed three distinct peaks: one at $\delta$ 54.00 corresponding to the methyl carbons, one at $\delta$ 63.63 corresponding to the methylene carbon and one at $\delta$ 167.03 corresponding to the carbon of the carboxyl group. Addition of zirconyl chloride [Zr/betaine molar ratio = 1, pH = 1.3, Fig. 3(*b*)] caused peak shifts for the carboxyl carbon ($\delta$ 2.04) and methylene carbon ($\delta$ 1.45). A previous study has shown that the carboxyl carbon peak shifts to lower field upon deprotonation (increasing pH).[20] Since the pH values were the same for the zirconium–betaine and betaine solutions, the significant peak shift is mainly caused by the interaction of the carboxylate

**Scheme 1** Proposed amphoteric surfactant templating route for hexagonal mesophase formation where the carboxylate group provides for the bonding of the surfactant with the inorganic species and the quaternary ammonium group maintains a large head-group area for hexagonal mesophase formation

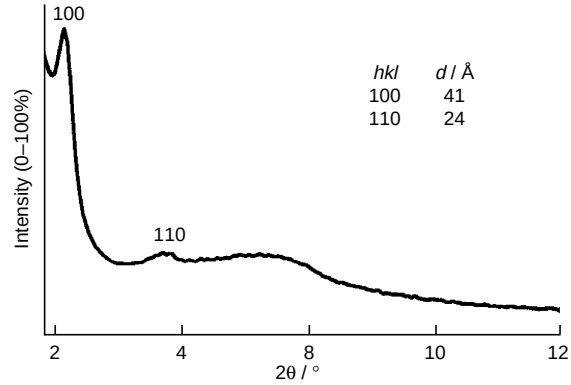


**Fig. 1** Powder X-ray diffraction pattern of the zirconyl chloride hexagonal mesophase showing the 100 and 110 reflections of a hexagonal lattice

group with the zirconium species. Furthermore, bonding between the carboxylate group and zirconium species is supported by a decrease in mobility, as indicated by the broadening of the carboxylate and methylene peaks. Multiple carboxylate peaks suggest a variety of bonding conformations in the betaine–zirconium complex. Peak shifting and broadening of the methyl carbon peak by zirconyl chloride were insignificant, indicating that the quaternary ammonium group does not bond with the zirconium species.

As-synthesized hexagonal mesophases prepared by the amphoteric surfactant templating route showed poor thermal stability. Calcination caused the (100) reflection of the hexagonal mesophase prepared from zirconium sulfate to shift to higher angle, indicating shrinkage of the mesostructure. Concurrently, higher order reflections of the hexagonal mesophase disappeared. Such loss of long-range order occurred as structural water, counter ions, and surfactant were removed simultaneously during calcination. These problems might be solved by innovative methods for removing the surfactant template and condensing the oxide precursors.[8,9] For example, controlled base treatment with NaOH proved to be efficient at removing the counter ions without destroying the mesostructure. Base-treated zirconium sulfate mesophase had surface areas of 130 $m^2\ g^{-1}$ after calcination at 350 °C and 40 $m^2\ g^{-1}$ after calcination at 450 °C, as compared to $< 5\ m^2\ g^{-1}$ for calcined, as-synthesized material.

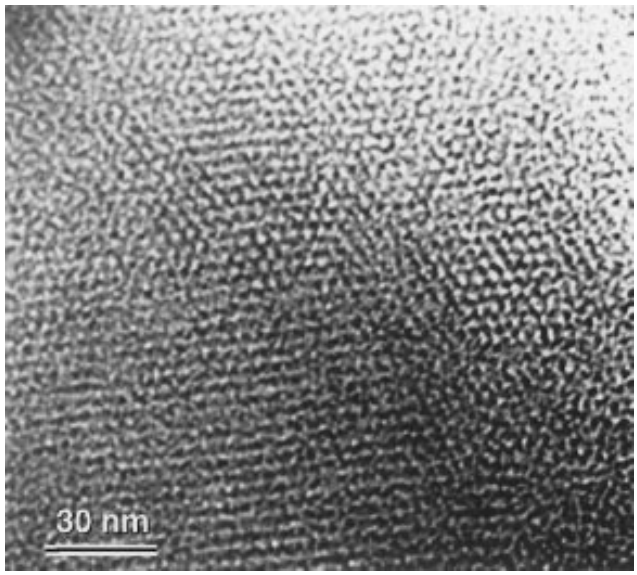

**Fig. 2** Transmission electron micrograph of the zirconyl chloride hexagonal mesophase produced by the amphoteric surfactant templating route showing the 42 Å repeat distance

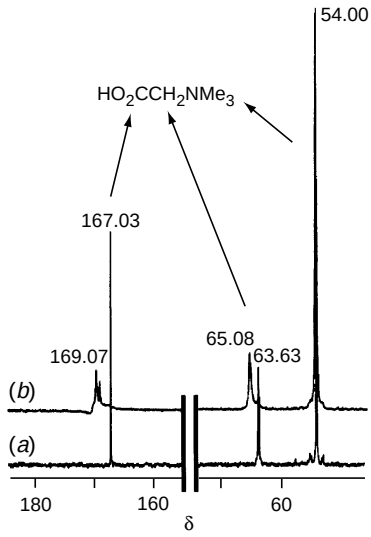

**Fig 3** Solution $^{13}C$ NMR spectra of betaine, pH adjusted to 1.3 (*a*) and of the betaine–zirconyl chloride complex; (*b*) Zr–betaine mole ratio = 1, pH = 1.3

In summary, an amphoteric surfactant templating method has been developed for the self-assembly of hexagonal mesophase zirconium compounds. Cocamidopropyl betaine provides the appropriate head-group area, solubility and chemical bonding to produce a hexagonal mesophase from aqueous solution. The quaternary ammonium group ensures large head-group area and high solubility, while the carboxylate group chemically attaches the precursor to the surfactant. Bifunctional surfactants, such as CAPB, offer new possibilities in mesoporous syntheses, particularly those involving cationic inorganic species.

This work was performed at Pacific Northwest National Laboratory, a multiprogram national laboratory operated by Battelle Memorial Institute for the US Department of Energy under contract DE-AC06-76RLO 1830. The authors greatly appreciate the X-ray diffraction work performed by D. E. McCready.

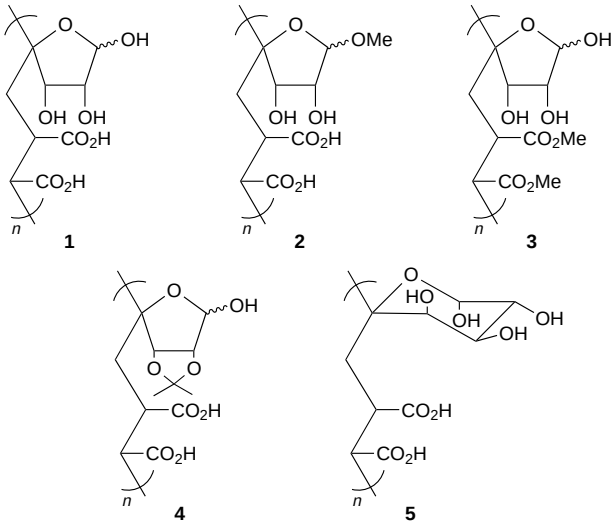
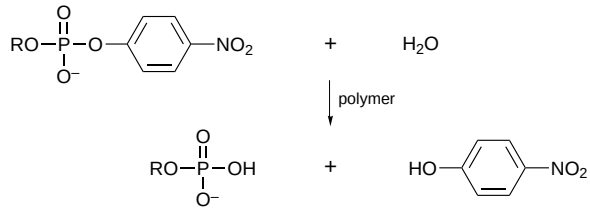
# Synthetic ribofuranose-containing polymers show catalytic activity in the hydrolysis of phosphodiesters



**Man Jung Han,*[a] Kyung Soo Yoo,[a] Tae Joon Cho,[a] Ji Young Chang,[a] Yu Jin Cha[b] and Seok Hyun Nam[b]**



[a] *Department of Applied Chemistry, Ajou University, Suwon 442-749, Republic of Korea*
[b] *Department of Biological Science, Ajou University, Suwon 442-749, Republic of Korea*

**Synthetic polymers containing ribofuranose rings as pendent groups catalyse the cleavage of DNA and the hydrolysis of phosphodiesters with a rate acceleration of $10^3$ compared with that of the uncatalysed reactions.**

In the past three decades there has been great interest in the synthesis of enzyme-like polymers.[1,2] A few synthetic polymers have been found to show catalytic activity; for example, imidazole-containing polymers are reported to catalyse the hydrolysis of phenyl esters.[3,4] While investigating polynucleotide analogues,[5–8] we have found that synthetic ribofuranose-containing polymers show catalytic activity for the hydrolysis of phosphodiesters and the cleavage of oligodeoxyribonucleotides. This is the first example of synthetic polymer catalysis of phosphodiester hydrolysis.

The catalytic activity seemed to be caused by the hydroxy groups on the furanose rings of the polymers. In order to elucidate the structural requirements for the catalytic activity, five polymers were synthesized.† Polymers **1**–**4** contained ribofuranose derivatives, while polymer **5** had pyranose rings in their polymer chains. The number-average molecular weights of polymers **1**–**5** were measured to be 8.4, 13.0, 9.3, 9.5 and 17.0 $\times$ $10^3$ by gel permeation chromatography, respectively. The *vic*-OH groups at C-2′ and C-3′ on the furanose rings of **1**–**3** were in the *cis*-configuration, while the OH groups at C-1′, C-2′, C-3′ and C-4′ on the pyranose ring of **5** were in either the *aeea* or *eaae* conformations. Approximately 30% of the 1′-OH groups of **1** and **3** were in the *cis*-configuration with respect to 2′-OH on the same furanose rings.‡

Hydrolysis rates of ethyl *p*-nitrophenyl phosphate (substrate) were measured in Tris buffers (pH = 7.4, ionic strength = 0.02, KCl) *via* the UV absorption (400 nm) of the *p*-nitrophenol evolved. To check whether any side reaction other than the hydrolysis of the substrate occurred (Scheme 1), the reaction mixtures in the presence of **1** or **3** ([substrate] = $4.67 \times 10^{-4}$ M, [**1**] = [**3**] = $1.62 \times 10^{-5}$ M, pH = 7.4 at 50 °C, 24 h) were examined by $^{31}$P NMR. In both cases only two peaks, at $\delta$ 2.69 for ethyl phosphate and $\delta$ −5.97 for the substrate (relative to phosphoric acid at $\delta$ 0), were observed. The same result was also obtained by liquid chromatography analysis, indicating that the hydrolysis occurred exclusively.

By measuring the hydrolysis rates in the buffer solution alone and in the presence of the monomers (succinic acid and ribofuranose) and the polymers **1**–**5** at 50 °C, it was found that polymers **4** and **5** and the monomers showed no acceleration of the hydrolysis, while **1**, **2** and **3** with *vic*-*cis*-diols on the furanose rings exhibited catalytic activity. These results suggested that the *vic*-*cis*-diols of furanose rings were responsible for the catalytic activity. The *vic*-dicarboxyl groups of the polymers were of little importance for the catalytic activity, as seen in the results of the reactions of **3**, **4** and **5**.

In the hydrolysis, the measured rate ($v_m$) is the sum of the rate of the catalysed reaction ($v_c$) and the uncatalysed reaction ($v_b$) [eqn. (1)]. The value of $v_c$ was therefore obtained from eqn. (2).

$$v_m = v_c + v_b \quad (1)$$

$$v_c = v_m - v_b \quad (2)$$

The initial $v_c$ values were obtained at constant concentrations of **1**, **2** and **3** by changing the substrate concentrations. Michaelis–Menten kinetics for **1**, **2** and **3** were confirmed by performing the double reciprocal plot of Lineweaver and Burk $[v]^{-1}$ (*vs.* $[\text{substrate}]^{-1}$) (Fig. 1), which gave $K_m$ and $V_{max}$. The $k_{cat}$ was obtained from eqn. (3). We assumed that each polymer

$$k_{cat} = V_{max}/[E]_o \quad (3)$$

chain formed one active site, since no significant catalytic activity for the polymers with *M*n's lower than 4000 (PD = 4) was observed. The $k_{cat}$ values were found to be $4.22 \times 10^{-1}$ h$^{-1}$ for polymer **1**, $1.65 \times 10^{-1}$ h$^{-1}$ for **2**, and $9.04 \times 10^{-1}$ h$^{-1}$ for **3**. The $k_{cat}$ of **3** was about $10^3$ higher than that of the uncatalysed reaction ($9.12 \times 10^{-4}$ h$^{-1}$). Polymers **1** and **3** showed higher catalytic activities than **2**, probably because the former polymers contained *ca*. 30% more *vic*-*cis*-diol groups than the latter.

Noncompetitive inhibition was observed by addition of phenylboronic acid ($K_I = 3.33 \times 10^{-4}$ M) and $K_2HPO_4$ ($K_I = 2.38 \times 10^{-4}$ M). Competitive inhibition was found in the presence of acetate ions ($K_I = 6.02 \times 10^{-4}$ M). Both forms of inhibition seemed to occur because the *vic*-*cis*-diols were blocked by formation of hydrogen bonds with the inhibitors.

ssDNA of 30 bases was incubated in a buffer solution in the presence of the polymers, and developed on acrylamide gel

(Fig. 2). The extent of ssDNA cleavage was observed in the order of polymer **3** > polymer **1** > polymer **2**, which was coincident with the $k_{cat}$ of the polymers. Polymers **1**, **2** and **3** containing *vic*-*cis*-diol groups of the furanose ring showed clear DNase activity, while no cleavage was observed in the buffer solution or in the presence of **4** or **5**.

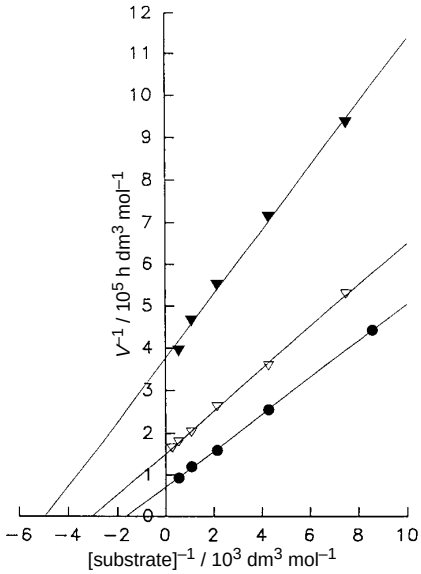


**Fig. 1** The reciprocals of the initial rates as a function of the reciprocals of the substrate concentrations for polymers (▽) **1**, (▼) **2** and (●) **3**: [polymer] = $1.62 \times 10^{-5}$ M in Tris buffer at pH = 7.4, 50 °C, ionic strength = 0.02 (KCl)

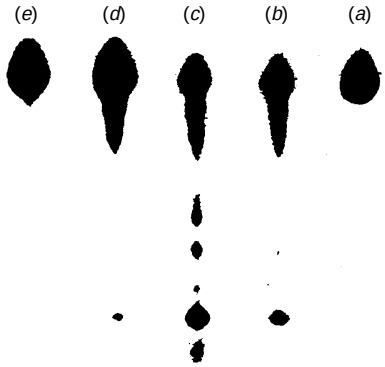

**Fig. 2** Autoradiogram of 7 M urea–8% acrylamide gel electrophoretic analysis of the reaction mixtures. $^{32}$P-Labelled ssDNA of 30 bases, d(CATGGCAAAGCCAGTATACAAATTGTAATA), corresponding to the human foamy virus proviral DNA in position nt. 3634-3611 (ref. 9), was incubated at 37 °C, ionic strength = 0.02 (KCl) and pH = 7.4 (Tris buffer), for 12 h (*a*) with no additive, in the presence of (*b*) polymer **1**, (*c*) polymer **3**, (*d*) polymer **2** and (*e*) polymer **4**. [DNA] = $7.5 \times 10^{-4}$ M, [polymer] = $7.3 \times 10^{-5}$ M. No DNA cleavage was observed in the buffer or in the presence of polymer **4**, while polymers **1**, **2** and **3** catalysed hydrolysis of DNA.

Since no activity was found for the monomer pair, the polymers are likely to form the active sites with a specific conformation. It seems possible that the furanose rings having *vic*-*cis*-diol groups were located inside the active sites, where the phosphodiester substrates were also accommodated. The *vic*-*cis*-diol groups seem to form hydrogen bonds with the two oxygen atoms of the phosphate so as to activate the phosphorus atoms attacked by nucleophiles ($H_2O$). Further investigation of the mechanism is in progress.

## Footnotes

† Copolymerization of 1-*O*-acetyl-5-deoxy-2,3-isopropylidene-D-*erythro*-pent-4-enofuranose with maleic anhydride (molar ratio 1 : 2) in bulk at 90 °C for 13 h in the presence of AIBN (2 mol%) resulted in the alternating copolymer, which was hydrolysed to give **1** using aqueous HCl–dioxane at 97 °C for 24 h and to give **4** using 0.1 M NaOH at room temperature for 24 h. Polymer **1** was esterified with $CH_2N_2$ to give **3**. Polymer **2** was obtained by copolymerization of 1-*O*-methyl-5-deoxy-2,3,-*O*-isopropylidene-D-*erythro*-pent-4-enofuranose with maleic anhydride under the same condition as described above and subsequent hydrolysis of the polymer using formic acid at 107 °C for 13 h. Polymer **5** was synthesized by copolymerization of 6-deoxy-1,2 : 3,4-di-*O*-isopropylidene-α-D-*galacto*-hex-5-enopyranose with maleic anhydride under the same conditions described above and subsequent hydrolysis in 68% formic acid at 100 °C for 13 h.

‡ To determine the configuration of the C-1 atoms of the monomers, 1,2,3-tri-*O*-acetyl-5-*O*-trityl-D-ribofuranose was prepared by tritylation and subsequent acetylation of D-ribose, from which the monomers were also prepared. The configuration of the C-1 atom remained intact during polymerization, and the protection and deprotection reactions of the C-1 hydroxy group. In the α form, the C-1 proton is *cis* with respect to the C-2 proton, while in the β form, the C-1 proton is *trans* with respect to the C-2 proton. In the $^1$H NMR spectrum of 1,2,3-tri-*O*-acetyl-5-*O*-trityl-D-ribofuranose in $CDCl_3$, two peaks appeared at δ 6.54 (d, $J$ = 4 Hz) and 6.22 (s) from the C-1 protons of the α and β forms. The singlet peak at δ 6.22 and the doublet peak at δ 6.54 were assigned to the proton of β form and the proton of α form, respectively, since the angle between the C-1 proton of the α form and the C-2 proton was nearly zero and thus a larger coupling constant was expected. The ratio of the α and β forms was calculated from the peak area ratio.

# Calculated details of a mechanism for conversion of $N_2$ to $NH_3$ at the FeMo cluster of nitrogenase

**Ian Dance**

*School of Chemistry, University of New South Wales, Sydney 2052, Australia*

**Density functional calculations mapping the geometry/energy hypersurface of the $Fe_7MoS_9$(*S*-cysteine)-(homocitrate)(histidine) cluster in nitrogenase and its binding of $N_2$, $H^+$, $e^-$ and N–H intermediates reveal mechanistic details for the formation of $NH_3$.**

The enzyme nitrogenase reduces $N_2$ to $NH_3$ at an $Fe_7MoS_9$(*S*-cysteine)(homocitrate)(histidine) cluster. While the structure of this active site is known in atomic detail, the mechanism for binding, activation, electronation and protonation of $N_2$ is still tantalisingly obscure.[1] In addition to numerous reports of model systems, and commentaries on chemical expectations about mechanism,[2] there are theoretical contributions to investigation of the mechanism which include calculations of $N_2$ binding geometries and electronic structure,[3] and a mechanism supported by density functional calculations has been outlined.[4]

Here I communicate new density functional calculations† mapping the geometry/energy hypersurface of the full cluster, as it binds the reactants $N_2$, $H^+$ (and $e^-$), rearranges the intermediate N–H species, and facilitates the sequential release of $2NH_3$.

Fig. 1 defines the 40 atoms included in the model of the active site. The redox level adopted as the reference state in the following corresponds to a core $[Fe_7Mo]^{22+}$, equivalent to $(Fe^{+2.57})_7Mo^{4+}$. As previously described[4] the protein surrounds favour one undercoordinated $(Fe^3)_4(S^3)_2(S^2)_2$ face‡ ($Fe^{3A}$, $Fe^{3B}$, $Fe^{3C}$, $Fe^{3D}$ in Fig. 1) as the reactive site. Fig. 2 shows three configurations for $N_2$ bound to this site: the lowest energy configuration has the least symmetrical geometry, and is dubbed the oblique arrow configuration. This optimised binding geometry differentiates the proximal N atom ($N^p$) bound to four Fe atoms, and the distal N atom ($N^d$) bound to two Fe atoms.

A characteristic of the oblique arrow configuration is that the distal N atom ($N^d$) is positioned between three of the

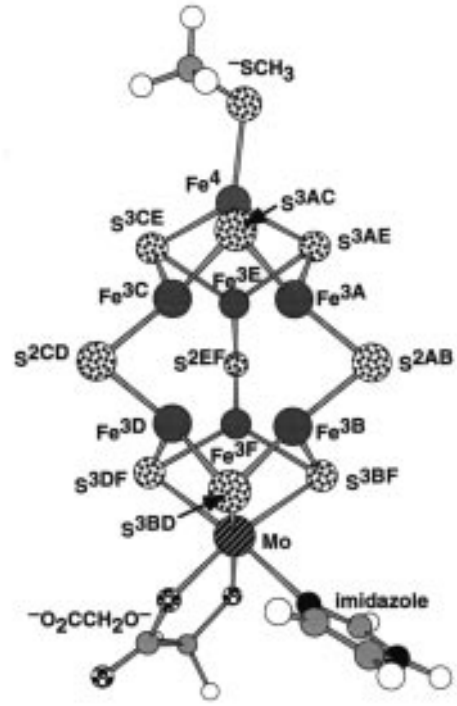

**Fig. 1** The $[Fe_7MoS_9(SCH_3)(imidazole)(O_2CCH_2O)]$ model calculated as the active site of nitrogenase. Numerical superscripts in atom identifiers are coordination numbers: N, black; C, small grey; H, open.

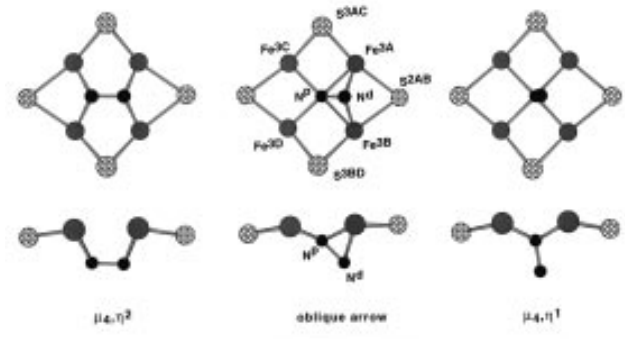

**Fig 2** The $\mu_4,\eta^2$, oblique arrow and $\mu_4,\eta^1$ geometries for $N_2$ bound to the $Fe^{3A}$ $Fe^{3B}$ $Fe^{3C}$ $Fe^{3D}$ face, with relative energies +83, 0, +37 kJ $mol^{-1}$. Other atoms (Fig. 1) included in the energy minimisations are omitted for clarity. In the lowest energy geometry, $N^p$, $N^d$ are proximal and distal to the $Fe_4$ face respectively: $N^p$–$Fe^3$ 1.93–1.98 Å; $N^d$–$Fe^{3A}$,$Fe^{3B}$ 2.07, 2.03 Å; $Fe^{3A}$–$Fe^{3C}$ 2.66, $Fe^{3B}$–$Fe^{3D}$ 2.64 Å, $Fe^{3A}$–$Fe^{3B}$ 2.65 Å, $Fe^{3C}$–$Fe^{3D}$ 2.56 Å.

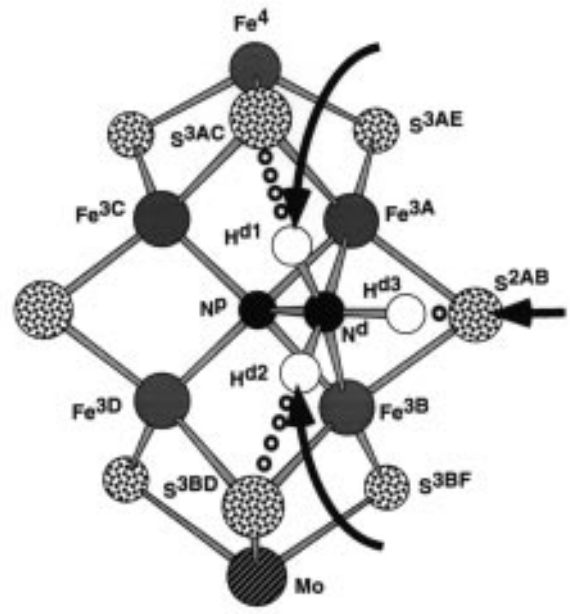

**Fig 3** Location of hydrogen atoms ($H^{d1}$, $H^{d2}$, $H^{d3}$) on $N^d$ prior to dissociation of $N^dH_3$. The rear $Fe^3$ and $S^2$ atoms and the complete coordination of $Fe^4$ and Mo are not shown for reasons of clarity. Open heavy circles show the hydrogen bonds from H to $S^3$ and $S^2$. Heavy arrows show probable trajectories for the three approaching hydrogen atoms (see text).

surrounding S atoms, $S^{2AB}$, $S^{3AC}$, $S^{3BD}$, such that protons on these S atoms are well positioned for transfer to $N^d$. Further, addition of two electrons to the cluster at this stage most affects the electron population at these S atoms: the changes in Mulliken partial charges are *ca.* −0.19 at $S^2$, *ca.* −0.11 at $S^3$, −0.04 at Mo, and *ca.* 0.00 at Fe. Therefore the possibility of reduction and protonation of the distal N atom was investigated by energy minimisation of a structure containing three H atoms between $N^d$ and S, hydrogen bonded to S, as detailed in Fig. 3. The electronic population at this stage was equivalent to addition of $N_2$, $4e^-$ and $3H^+$ relative to the reference state. Energy minimisation caused scission of the N–N bond and dissociation of the distal N atom as $NH_3$: Fig. 4 shows several stages in this dissociation. Because the calculation did not include the surrounding protein and its hydrogen bond acceptor sites, the dissociating $NH_3$ retains its hydrogen bonds to the three S atoms, and inverts during the dissociation; Fig. 4(*d*) also shows a later stage of dissociation after the hydrogen bonds have been broken.

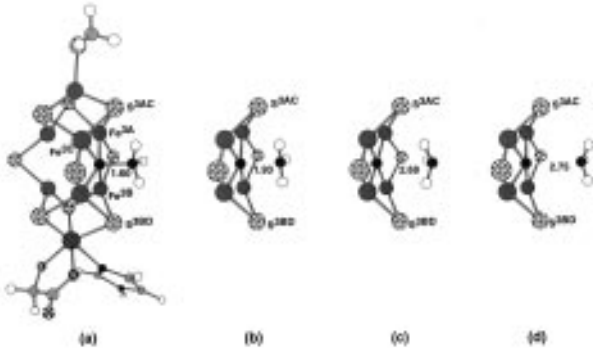

**Fig 4** Side views of four stages in the dissociation of $N^dH_3$, shown fully for stage (*a*) and as the dissociation face only for (*b*)–(*d*). $N^p\cdots N^l$ distances (Å) are marked (the N–N bond length at the beginning of this reaction was 1.28 Å). Relative energies for these intermediates are (*a*) 0, (*b*) −188, (*c*) –368, (*d*) –414 kJ $mol^{-1}$. Stages (*b*) and (*c*) demonstrate the inversion of $NH_3$ due to the strength of the S···H hydrogen bonds, which are broken in stage (*d*).

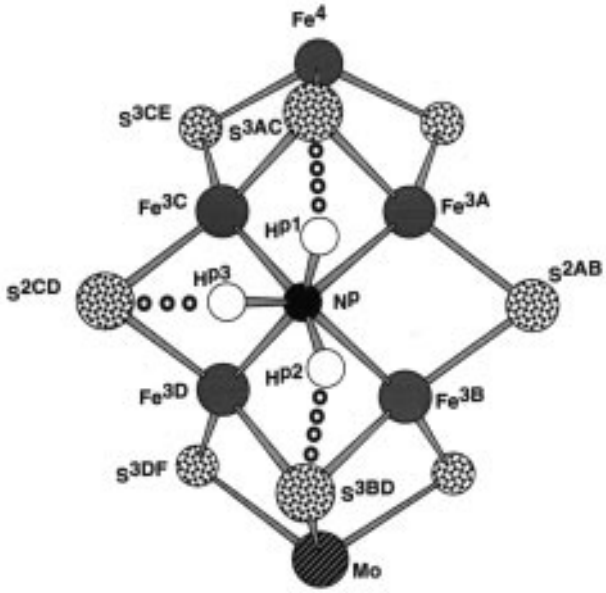

**Fig. 5** Location of hydrogen atoms ($H^{p1}$, $H^{p2}$, $H^{p3}$) on $N^p$ prior to dissociation of $N^pH_3$. The rear $Fe^3$ and $S^2$ atoms and the complete coordination of $Fe^4$ and Mo are not shown for reasons of clarity. Open heavy circles show the hydrogen bonds from H to $S^3$ and $S^2$.

After dissociation of $N^dH_3$ the proximal N atom is left bound to the $Fe_4$ face; the second stage of electronation and protonation of this N atom can also involve the surrounding S atoms, but the geometry is different because $N^p$ is close to the $Fe_4$ face. Fig. 5 shows an intermediate geometry containing three new H atoms associated with $N^p$ and hydrogen bonded to $S^2$ and $S^3$. On energy minimisation with an atom/electron population now corresponding to the reference state + $N_2$ + $6e^-$ + $6H^+$ − $NH_3$, $N^dH_3$ dissociates by sliding around one of the $Fe^3$ atoms.

These results provide the rudiments of a mechanism for binding of $N_2$, proton approach, introduction of electrons, and sequential dissociation of $NH_3$. They reinforce the chemical expectation that undercoordinated $Fe^3$ and $S^2$ atoms play key roles. During the processes described the Fe–Fe, Fe–S and S–Mo distances change as expected according to increases and decreases in coordination. Additional calculations reveal that H atoms can also bridge $Fe^3$–$S^3$ bonds, and that $Fe^3$ atoms as well as the $Fe^3$–$S^3$ bonds can mediate the passage of H atoms from protein to both the distal and proximal N atoms: likely trajectories for H approach to $N^d$ are shown in Fig. 3. Other mechanistic aspects currently being refined involve protonation and/or electronation of $N_2$ *en route* to the oblique arrow configuration, protonation/electronation of $N^p$ while $N^dH_3$ is dissociating, and the coupled formation of $H_2$. Further development will include relevant surrounding protein, which is essential for the ingress of protons and the egress of $NH_3$.

The support of this research by the Australian Research Council is gratefully acknowledged.

## Footnotes

† Calculations used non-local blyp functionals and double numerical basis sets, as implemented in the program DMol (MSI). The accuracy of these methods has been demonstrated by replication of the experimental geometries of related clusters such as $VFe_4S_6(SR)(PR_3)_4$.[5] All models have $C_1$ symmetry.

‡ Numerical superscripts signify coordination numbers.

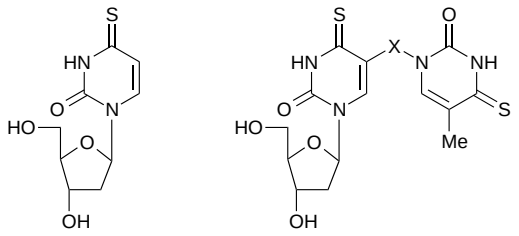
# Site specific photo-crosslinking of single stranded oligonucleotides by a complementary sequence equipped with an internal photoactive probe



**Carole Saintomé,[a,b] Pascale Clivio,[a] Alain Favre,[b] Jean-Louis Fourrey*[a] and Philippe Laugâa[b]**

[a] *Institut de Chimie des Substances Naturelles, CNRS 91198, Gif-sur-Yvette Cedex, France*
[b] *Institut Jacques Monod, CNRS-Université Paris VII, 2 Place Jussieu, 75251 Paris Cedex 05, France*

**The photo-crosslinking behaviour of oligonucleotide constructs, incorporating photoactive residues 1–5 at a defined position, has been examined in the presence of their DNA (14-mer) and RNA (15-mer) complementary targets using a two-fold excess; it revealed a moderate but promising irreversible binding efficiency, the results of which could be anticipated by molecular mechanics in the case of 4.**

There are many instances in which oligodeoxynucleotides (ODN) or nuclease resistant oligonucleotide analogues, conjugated with chemical or photochemical reagents, are utilized as biochemical tools.[1,2] In nucleic acid studies, although simple oligonucleotide binding may not be sufficient to disrupt nucleic acid functions, inactivation will certainly occur if, after specific recognition, a modified oligonucleotide probe has the capacity to undergo irreversible covalent photo-crosslinking to its target.[3] In such probes, a photoactive label is usually introduced at their 5′-terminus, excepted for some examples with psoralens whose applications are specific of AT sites.[4]

Herein, we have examined the photochemical behaviour towards their DNA and RNA targets of strictly complementary constructs having a photoactive nucleoside residue which can be easily placed at a defined position within the sequence. Namely, we have compared the light-induced reactivity of a series of oligonucleotides, containing 4-thiodeoxyuridine ($s^4$dU) **1** with that of their analogues containing the recently synthesized nucleosides **2**–**5** (Fig. 1).[5] The latter have a chain of variable length at the C-5 position of 2′-deoxyuridine which permits the attachment at its other extremity of $N^1$-carboxymethyl-4-thiothymine. It is known that, upon light excitation (UVA, $\lambda_{max} \simeq 330$ nm), such sulfur-substituted pyrimidines (4-thiouracil and 4-thiothymine) undergo covalent bond formation with all the current nucleic bases with a higher preference for thymine.[6,7] In this study, nucleoside **1** and the modified analogues **2**–**5** were incorporated at position 1 (for nucleosides **1** and **4**) or position 7 according to a known synthetic and purification procedure[8] by means of their corresponding phosphoramidites,[5] of 14-mer oligonucleotides designated **Oi**-1 and **Oi**-7 (**i** corresponding to nucleosides **1**–**5** (Fig. 1). Oligonucleotides **Oi**-1 and **Oi**-7 were irradiated in two-fold excess in the presence of their RNA or DNA complements, designated **OR** or **OD** respectively, which had been $^{32}$P-labelled at their 5′-end (Table 1). Denaturing polyacrylamide gel electrophoresis (PAGE) showed formation of interstrand photoproducts manifested by the appearance of slow moving species on the gels, the yields of which were quantified using a phosphorimager. In contrast, there were no such reactions in the dark or with an oligonucleotide sequence unable to anneal to **Oi**-1 and **Oi**-7.

**i** = **1** ($s^4$dU)

**i** = **2**, **X** = $(CH_2)_2CONH(CH_2)_2NHCOCH_2$
**i** = **3**, **X** = $(CH_2)_2CONH(CH_2)_4NHCOCH_2$
**i** = **4**, **X** = $NH(CH_2)_2NHCOCH_2$
**i** = **5**, **X** = $C{\equiv}CCH_2NHCOCH_2$

**Oi**-1 5′d($N_i$ G C C C G T C T G T T G T)3′ with **i** = **1** ($s^4$dU) or **4**

**Oi**-7 5′d(T G C C C G $N_i$ C T G T T G T)3′ with **i** = **1** ($s^4$dU), **2**, **3**, **4** or **5**

**OR** 3′A C G G G C A G A C A A C A G5′

**OD** 3′d(A C G G G C A G A C A A C A )5′

**Fig. 1** Modified nucleosides **i** (i = **1**–**5**) and oligonucleotides **Oi**-1 and **Oi**-7 incorporating **i** at either position 1 or 7 ($N_i$ corresponds to nucleoside **i**). **OR** and **OD** designate the nucleotide sequences of their RNA (15-mer) and DNA (14-mer) complement, respectively. **OR** was obtained by transcription, and contains an extra G in 5′ which gives efficient initiation.

Oligonucleotide **O1**-1 having **1**, the $s^4$dU photoreactive label, placed at its 5′-extremity, exhibited a high photo-crosslinking capacity with both its DNA or RNA target, albeit with a lower efficiency in the latter case (55 *vs*. 33%). However, its analogue **O1**-7 having $s^4$dU at position 7 within the sequence yielded weak (0.5% with DNA) or no detectable (RNA) crosslinks. This indicates that, for a crosslinking reaction to occur, the photoreactive $s^4$dU should be placed at the 5′-dangling end of the duplex and it suggests that the conformational flexibility at this extremity might be higher for a type B DNA helix than for a type A RNA–DNA helix.

When the extended analogue **4** was placed at the 5′-end of the probe, to give **O4**-1, an efficient cross-linking reaction with the complementary target was observed as in the case of **1**. Again, compared to its RNA analogue, the DNA target proved to be more reactive (21 *vs*. 28%). In the **OR** case, the reaction was very selective and covalent bond formation took place with its complementary residue A15, exclusively (for mapping see below).

**Table 1** Crosslinking efficiency, relative yield and position of crosslinks for **Oi**-1 and **Oi**-7

| | Total cross-linking efficiency (%) | | Relative yields (%) and positions of crosslinks with **OR** | | | | |
|---|---|---|---|---|---|---|---|
| Probe | **OD** | **OR** | C3 | C6 | C10 | G11 | A15 |
| **O1**-1 | 53 | 33 | | | | | 100 |
| **O4**-1 | 28 | 21 | | | | | 100 |
| **O1**-7 | 0.5 | 0 | | | | | |
| **O2**-7 | 20 | 8 | | 85 | 6 | 7 | |
| **O3**-7 | 15 | 6 | | 88 | | 12 | |
| **O4**-7 | 10 | 3.5 | | 74[a] | | | |
| **O5**-7 | 22 | 18 | 40 | 60 | | | |

[a] Other crosslinks were not characterized due to their instability.

However, in sharp contrast with **1** at position 7 (Fig. 2), when the extended 2′-deoxyuridine residues **2**–**5** were placed within the sequence at this position, covalent crosslinking occurred with both their complementary **OD** and **OR** (Table 1). As for labels **1** and **4** at position 1, the crosslinking yields are better in the DNA series, varying from 10 to 22%. These moderate yields are not unexpected since the complementary sequences **OD** (DNA) and **OR** (RNA), containing the less reactive A, C and G residues compared to T or U, were chosen intentionally to be in the less favourable conditions for crosslinking.[6] On the other hand, protrusion of the label in the major groove of the double helix, which has the possibility to undergo covalent bonding with proximate intra- or inter-strand residues, could also account for these moderate yields. To examine the relative efficiency of the latter process, 5′ $^{32}$P-labelled **O5**-7 was first irradiated alone. Denaturating PAGE revealed the formation of intrastrand crosslinked species (60% yield) migrating faster than **O5**-7. When a similar experiment was performed with 5′ $^{32}$P-labelled **O5**-7 hybridized to **OR** (two fold excess), it showed a considerable decrease of the fast migrating species (30% yield) together with the appearance of a retarded crosslinked species corresponding to interstrand bridges (22% yield) as revealed by their limited digestion by RNase T1.[9] Interestingly, experiments with **OD** exhibited the same pattern of inter- and intra-strand bridges. Mapping of the exact sites for crosslink formation was carried out using limited alkaline hydrolysis[7c] of the complexes obtained with 5′-end labelled RNA (Fig. 2). The results, given in Table 1, show a preference (74 to 100%) for the residues on the 5′-side of the **OR** target with C6 being preferred (60 to 88%).

Finally, these experimental observations were compared with those predicted by molecular mechanics. A study was undertaken in the case of the **O4**-7–**OR** hybrid in order to determine which residues might participate in inter- and intra-strand photoproduct formation. Model building and computations were performed on a Silicon Graphics Iris 4D/35 equipped with an Evans and Sutherland PS390 graphic device using the SYBYL programme package (Tripos Associates, Saint Louis, Mo). The **O4**-7–**OR** hybrid was built according to the NMR data of Salazar *et al*.,[10] *i.e*. with a C(3′)-*endo* RNA strand and a O(4′)-*endo* DNA strand. The conformational space accessible to the s$^4$T moiety of **4** was explored *via* a systematic search performed along the torsional angles of the linker X (Fig. 1). Residues potentially available for photoaddition were determined through selection of the conformations satisfying both following criteria: (i) a distance of less than 6 Å between the midpoint of the C=S bond of the 4-thiothymine moiety and that of the C(6)=C(5) bond[7g] of the proximal pyrimidines or the midpoint of the C(8)=N(7) bond[11] of the proximal purines, and (ii) an angle between these bonds in the 0 ± 30° (parallel) or 180 ± 30° (antiparallel) ranges. It was found that about 30% of the selected conformations would yield intrastrand crosslinks, while 70% of the selected conformations would yield interstrand crosslinks with residues A5, C6, A7 and G8. When the selection criteria for bond distances and angles were narrowed to 0–4 Å and 0–20° ranges, respectively, the most properly oriented residues appeared to be C6 (50%) and to a lesser extent A7 (21%) and G8 (29%). It is noteworthy that in the case of C6, the plane of the s$^4$T ring is parallel to that of C6, whereas in the case of A7 and G8 it is perpendicular to those of A7 and G8. This might account for the fact that interstrand crosslinking has been detected with a higher preference for C6.

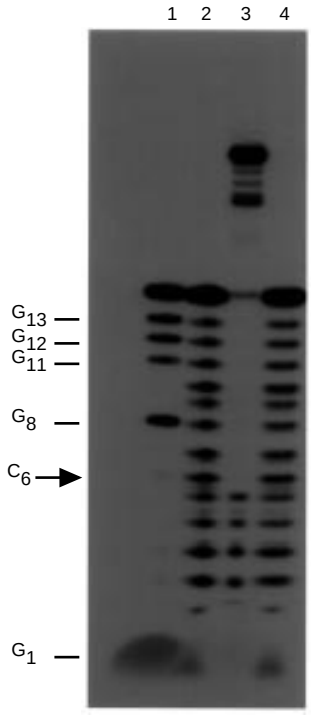


**Fig. 2** Identification of RNA residues involved in crosslinking. Sequencing gel of free and crosslinked **OR**. Lane 1: partial digestion of free **OR** with RNase T1; lanes 2 and 4: limited alkaline hydrolysis of **OR**; lane 3: limited alkaline hydrolysis of the major **OR**–**O4**-7 photoadduct. The spots corresponding to G positions are marked. The arrow points to nucleotide C6 involved in the crosslink.

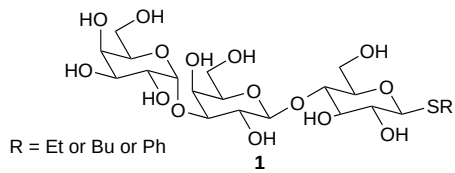
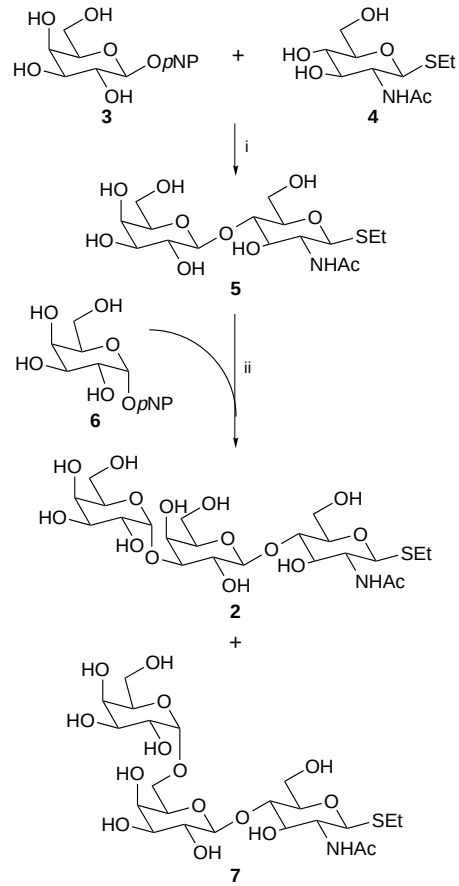
# Glycosidase-catalysed synthesis of oligosaccharides: a one step synthesis of lactosamine and of the linear B type 2 trisaccharide α-D-Gal-(1 → 3)-β-D-Gal-(1 → 4)-β-D-GlcNAcSEt involved in the hyperacute rejection response in xenotransplantation from pigs to man and as the specific receptor for toxin A from *Clostridium difficile*

**Gabin Vic,† Chuong Hao Tran, Michaela Scigelova and David H. G. Crout***



*Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL*

**Sequential use of the β-galactosidase from *Bacillus circulans* and an α-galactosidase from *Aspergillus oryzae* give the linear B trisaccharide 2, identified as the epitope that binds anti-Gal antibodies during pig-to-man xenotransplantation and as the receptor for toxin A from *Clostridium difficile*.**



There is at present a worldwide shortage of organs available for human transplantation. The use of pigs' organs would be a solution to this problem if the hyperacute rejection that occurs after such transplantation could be prevented.[1] Two trisaccharides **1** and **2** bearing the α-D-Gal-(1 → 3)-β-D-Gal terminus have been identified to play a fundamental role in the process of hyperacute xenograft rejection in xenotransplantation from pigs to man.[2] Both of these trisaccharides are specific antigens for the binding of xenoreactive antibodies of the recipient on endothelial cells in the graft which inevitably destroy it within a few hours. Moreover trisaccharide **2** is also known as the receptor for toxin A from *Clostridium difficile* which is the major cause of antibiotic-associated diarrhoea and the causative agent of pseudomembranous colitis (PMC) particularly in elderly patients.[3] The significance of these findings prompted the development of an enzymatic synthesis of these trisaccharides because the application of glycosidases in oligosaccharide synthesis avoids the need for protection-deprotection steps required in non-enzymatic syntheses.

In a previous communication[4] the enzymatic synthesis was described of several derivatives of the linear B type 6 trisaccharide **1** starting from alkyl 1-thio-β-D-lactopyranoside as acceptor and *p*-nitrophenyl α-D-galactopyranoside as donor using the newly discovered α-galactosidase II from *Aspergillus oryzae*.‡ Here we report the synthesis of the linear B type 2 trisaccharide **2** in two enzymatic steps (Scheme 1). The synthesis required first the synthesis of a glycoside **5** of *N*-acetyllactosamine. *N*-Acetylglucosamine has been synthesised using glycosyltransferases. The routes of Wong *et al.*[5] and of Thiem and Wiemann[6] both required the use of six enzymes because, in addition to the galactosyl transferase, an enzyme system for the regeneration of the galactosyl donor, UDP-Gal, was included. In a recent improvement of this procedure, Zervosen and Elling have reduced the number of enzymatic steps required to three by using sucrose synthetase to regenerate UDP-Glc.[7] However, reduction to practice of this scheme required the use of two further enzymes: dTDP-glucose 4,6-dehydratase to synthesise dTDP-6-deoxy-D-*xylo*-4-hexulose required for reactivation of UDP-Glc 4′-epimerase and invertase to hydrolyse the excess of sucrose remaining at the end of the reaction.

The method reported here is based on the use of the β-galactosidase from *Bacillus circulans* which was used by Sakai *et al.* to synthesise *N*-acetyllactosamine from lactose and *N*-acetylglucosamine.[8] Some 1,6-isomer was simultaneously formed and isolation of the product required extensive chromatographic purification. This method has been refined by using the thioethyl glycoside of *N*-acetylglucosamine as acceptor and *p*-nitrophenyl β-D-galactoside as donor. With these substrates the glycosylation was found to proceed with complete regiocontrol for formation of the β 1 → 4 isomer and isolation of the product was also greatly simplified.

**1**

**3** **4** **5** **6** **2** **7**

**Scheme 1** *Reagents*: i, β-galactosidase from *Bacillus circulans*; ii, α-galactosidase II from *Aspergillus oryzae*

Ethyl 1-sulfanyl-(β-D-galactopyranosyl)-(1 → 4)-(2-acetamido-2-deoxy)-*O*-β-D-glucopyranoside **5** was obtained by incubation of *p*-nitrophenyl β-D-galactopyranoside **3** as galactosyl donor and ethyl 1-sulfanyl-(2-acetamido-2-deoxy)-*O*-β-D-glucopyranoside **4**[9] as acceptor using a crude β-galactosidase from *Bacillus circulans*.§ A simple procedure was followed: the donor **3** (0.55 g, 1.82 mmol) and the acceptor **4** (2.96 g, 11.15 mmol) in acetate buffer (pH 5.0, 50 mmol $dm^3$, 37 $cm^3$) were incubated with the crude β-galactosidase (3.8 mg, 7.4 U) at 22 °C for 7 h. After all of the donor has been consumed the reaction was stopped by heating at 100 °C for 5 min. *p*-Nitrophenol was extracted with diethyl ether (4 × 50 $cm^3$) and the aqueous layer was concentrated to a total volume of 12 cm.[3] This was applied in 4 $cm^3$ batches to a Biogel P2 column (120 × 2 cm) which was eluted with $H_2O$ (flow rate 0.6 $cm^3$ $min^{-1}$, fraction 6 $cm^3$) to give the disaccharide **5** in 50% yield (0.39 g). The structure of the product was confirmed by $^1H$ and $^{13}C$ NMR spectroscopy and mass spectrometry.[10]

Synthesis of the trisaccharide glycoside **2** was completed by transfer of the α-D-galactosyl residue (1 → 3) on to the disaccharide **5** using a partially purified α-galactosidase II from *Aspergillus oryzae*. This enzyme accepted *p*-nitrophenyl α-D-galactopyranoside **6** as an α-D-galactosyl donor giving a 1 : 0.9 mixture of the α 1 → 3 and α 1 → 6 linked trisaccharides **2** and **7**. These two trisaccharides were further purified to homogeneity by a combination of Biogel P2 and carbon–Celite column chromatography, and selective enzymatic hydrolysis. Thus donor **6** (79 mg, 0.26 mmol) and the acceptor **5** (0.40 g, 0.93 mmol) in citrate–phosphate buffer (pH 5.0, 50 mmol $dm^3$, 3.12 $cm^3$) were incubated with the partially purified α-galactosidase II (4 U) at 22 °C for 20 h. The reaction was stopped by heating at 100 °C for 5 min, the mixture was diluted with $H_2O$ (15 $cm^3$) and filtered. *p*-Nitrophenol was extracted with diethyl ether (4 × 10 $cm^3$). The aqueous layer was concentrated to 4 $cm^3$ and applied to a Biogel P2 column (120 × 2 cm) which was eluted with $H_2O$ (flow rate 0.6 $cm^3$ $min^{-1}$). The mixture of trisaccharides obtained in 32% overall yield (49 mg) was applied to a carbon–Celite column which was eluted with water–ethanol (75 : 25). The α 1 → 6 linked trisaccharide was eluted in the first fractions and a mixture of α 1 → 3 and a minor β linked trisaccharide were eluted in the following fractions. The presence of this β linked trisaccharide was due to the remaining β-galactosidase activity in the enzymatic preparation. The α 1 → 3 trisaccharide **2** was further purified to homogeneity by selective hydrolysis of the β linked trisaccharide using the β-galactosidase from *Bacillus circulans*¶ to give finally trisaccharide **2** (20 mg). The structure of **2** was confirmed by $^1H$ and $^{13}C$ NMR spectroscopy and mass spectrometry (Table 1). The method described here provides an easy access to this important trisaccharide but was not optimised. This may be realised by using the α-galactosidase II from *Aspergillus oryzae* free from β-galactosidase activity.

We thank the EPSRC and the BBSRC for financial support, Mr I. Katyal for mass spectra and Mrs S. Vic for useful discussions.

**Table 1** Selected $^1H$ NMR data for trisaccharides **2** and **7**[a,b]

| Trisaccharide | 1-H | 1′-H | 1″-H |
|---|---|---|---|
| **2** | 4.61 (d, 10.28) | 4.50 (d, 7.62) | 5.10 (d, 3.65) |
| **7** | 4.65 (d, 10.62) | 4.43 (d, 7.63) | 4.97 (d, 2.98) |

[a] $^1H$ NMR was carried out at 400 MHz using a Bruker AC 400 spectrometer in $D_2O$. [b] [Multiplicity, coupling constant (Hz)].

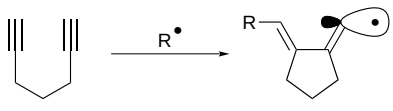
# Synthesis of *p*-tolylsulfonyl-substituted dienes *via* radical cyclization of diynes

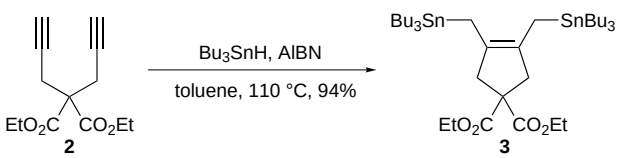
**Stephen Caddick,*[a] Craig L. Shering[a] and Sjöerd N. Wadman[b]**

[a] *The Chemistry Laboratory, University of Sussex, Falmer, Brighton, UK BN1 9QJ*
[b] *GlaxoWellcome, Medicines Research Centre, Gunnels Wood Road, Stevenage, Herts, UK SG1 2NY*



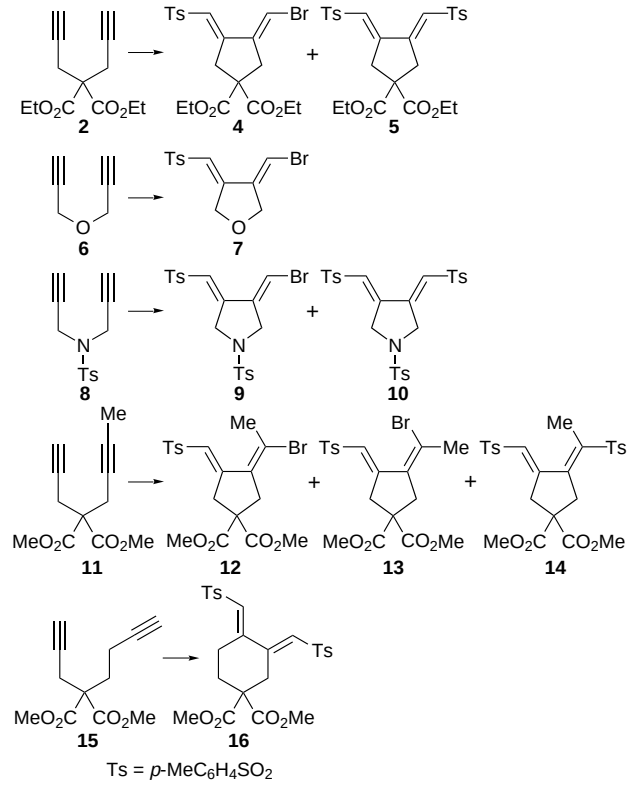
**A novel radical cyclization of hepta-1,6-diynes with toluene-*p*-sulfonyl bromide leads to two new classes of electron deficient sulfonyl dienes.**

The use of radical cyclizations for the synthesis of five-membered rings has become widespread in organic chemistry and radicals are now regarded as useful intermediates in synthesis.[1] The majority of commonly employed methods use tributyltin hydride (TBTH) to induce homolysis of an organic halide or alcohol derivative to generate the reactive carbon-centred radical species. An attractive alternative is to use the addition of a free-radical to a carbon–carbon π bond in order to generate the radical species; this has the advantage of incorporating some additional functional groups into the product. The synthetic utility of this type of approach using enyne and diene systems has been shown. Seminal work by Stork *et al.* has illustrated the synthetic advantages of using alkynes in radical based transformations.[2] Cyclization of diynes has attracted little attention, which is surprising considering the synthetic potential of the resultant diene.[3] Here we present our preliminary investigations relating to this novel type of radical cyclization (Scheme 1).



Our initial work illustrated the nature of the problem associated with the radical cyclization of diynes. Treatment of diyne **2** with TBTH under standard free-radical conditions led to the isolation of the bis(stannane) **3** in good yield[4] (Scheme 2).

This type of symmetrical allylic stannane may well be synthetically useful. However, we were never able to isolate a tin-substituted diene, although we note that, with substrate modification, this may be possible.[5] This reductive process is most likely a reflection of the relative rates of addition of the stannyl radical to an intermediate conjugated diene compared to that to acetylenes.† To address this problem we were attracted to the use of sulfonyl radicals which have, surprisingly, gained little use in synthesis.[6] In a diyne to diene transformation, we postulated that initial addition–cyclization would lead to an electronically deficient π-system; further addition would be disfavoured due to the inherent electrophilic nature of sulfonyl radicals.[7]



We elected to study the reaction of several readily available diynes with toluene-*p*-sulfonyl bromide (TsBr) under standard free-radical conditions (Scheme 3). Table 1 presents the detailed results of these experiments and several features are worthy of note. Entry 2 shows the optimised transformation of **2** to **4**. When the reaction was carried out under reflux the reaction proceeded with diminished yield and selectivity (entry

[c] A stirred benzene solution of excess diyne (*ca.* 0.04 M), TsBr (1 equiv.), AIBN (0.25 equiv.) in a sealed tube (external temp. 63–65 °C) with AIBN added portionwise (0.25 equiv.) every 24 h until reaction complete. [d] A stirred benzene solution of diyne (*ca.* 0.12 M), TsBr (3 equiv.), AIBN (0.4 equiv.) in a sealed tube (external temp. 98–100 °C) with AIBN added portionwise (0.4 equiv.) every 24 h until reaction complete.

1). Substrate **6** was the only precursor from which we isolated the bromo sulfone; we suspect that this is a result of the relatively insoluble nature of the bromide **7** (entry 3). In the synthesis of heterocycles there is no evidence of products derived from β-scission or double bond migration to yield the aromatic furan or pyrrole (entries 3 and 4).[8]

Entry 5 is particularly informative; it demonstrates the regio- and stereo-control which can be associated with reactions of this type.‡ The products appear to be uniquely derived from addition of the *p*-tolylsulfonyl radical to the least hindered end of the alkyne; we attribute this to a reversible addition of sulfonyl radicals to acetylenes. The stereochemical outcome of these reactions may be a consequence of the rapid rate of inversion of vinyl radicals.[9] If so, it is likely that the stereochemical course of a particular reaction could be predicted by comparison of the relative sizes of the bromine atom with other proximal substituents.§

Initially our efforts were directed at maximising the yield of bromo sulfone products and we were surprised by the isolation of the bis(sulfones). We assume that these products result from the further addition of toluene-*p*-sulfonyl bromide to the bromo sulfones followed by loss of bromine under radical or electrocyclic conditions. The bis(sulfones) have some obvious synthetic utility[10] and we decided to examine the prospect of transforming the diynes directly into the bis(sulfones) as the sole product. We found that this was possible with representative diynes **2** and **8** by treatment with excess toluene-*p*-sulfonyl bromide (entries 6 and 7). Using these conditions we were also able to prepare the cyclohexane derivative **16** from **15** in reasonable yield (entry 8).¶

We believe that cyclizations of this type can form the basis for a general synthetic methodology, however, if the bromo sulfones are required it is likely that any given example will require a particular set of reaction conditions. The shelf stable bis(sulfones) are likely to find some utility in synthesis as they are now readily available in good yield from the diyne precursor. The work presented here illustrates for the first time that diynes can be transformed into stable cyclic dienes[11] under radical conditions using toluene-*p*-sulfonyl bromide. The isolation of the bromo sulfone as the major product under appropriate conditions may support the original hypothesis that the electron deficient sulfonyl diene is relatively unreactive toward the electrophilic sulfonyl radical. The incorporation of two useful functional groups in the products derived from this and other toluene-*p*-sulfonyl radical mediated cyclizations is a clear advantage over related tin based transformations. Investigations of the synthetic utility of the two new classes of diene presented here are ongoing.

# Catalytic asymmetric hydroboration–amination

**Elena Fernandez, Mark W. Hooper, Frances I. Knight and John M. Brown***

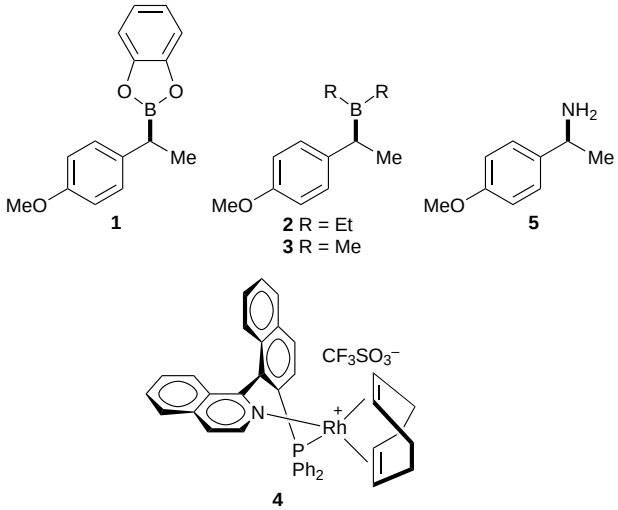
*Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY*

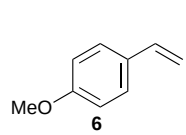
**A one-pot asymmetric synthesis of primary amines from vinylarenes *via* catalytic hydroboration is described.**

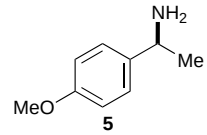
Despite considerable efforts to find alternatives, catecholborane is the most useful borane and rhodium complexes are the most useful catalysts in catalytic hydroboration.[1] Synthetic application of the resulting catecholborane adducts is however limited to oxidation with basic $H_2O_2$, and hence the asymmetric version[2] is in turn limited to the synthesis of secondary alcohols, for which many excellent alternative routes are already available.[3] Given the wealth of functional group transformations that can be performed with alkylboranes,[4] there is an incentive for developing further synthetic outlets for the catalysed case. Our initial efforts were directed to the reaction of isolated 1-phenylethylcatecholboronates† with electrophilic aminating agents such as $ClMgN(Me)OSiMe_3$, and although some success was achieved in controlling enantioselectivity, the chemoselectivity for secondary amine formation over alcohol was moderate.[5]

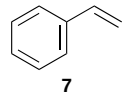
In considering a direct route from alkylcatecholboronates to amines, we were guided by prior results from Brown's research in which alkylboronates, which do not react directly with the standard aminating agent $H_2NOSO_3H$,[6] were converted by a practical, albeit multistep, route into amines *via* the more reactive dialkylborinate esters. In contrast, excess $R_2Zn$ is reported to effect clean transmetallation of a range of dialkylvinylboranes,[7a] trialkylboranes,[7b] alkylboronates and alkyldithioboronates,[7c] thus providing a route to less accessible alkenyl and alkylzinc compounds. Reaction intermediates have not been reported, although it is likely that the trialkylborane is an intermediate in boronate ester transmetallations (*vide infra*).

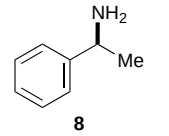
Our own initial experiments were conducted in toluene solution by reacting an isolated sample of catecholboronate ester **1** with 1 equiv. of $Et_2Zn$; we were delighted to observe that a clean and quantitative displacement took place, resulting in the transfer of two ethyl groups to boron to form **2** and removal of the Zn from the reaction medium as an insoluble catecholate.[8] The resulting borane was characterized by $^1H$ NMR [$\delta_H(C_7D_8)$ 1.20 (q), 0.95(t)] and MS (*m/z* 205). Oxidation of the borane **2** under standard conditions ($H_2O_2$, NaOH) demonstrated that the configurational integrity of the stereogenic centre had been maintained. At this point we became aware of an early report that primary alkylcatecholboronates react with 2 equiv. of RMgBr by complete displacement of the catechol residue giving the mixed trialkylborane.[9] In accord with this, complete displacement of catecholate without precipitation was observed when the reaction between MeMgCl and borane **1** was carried

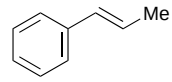


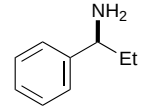


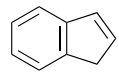


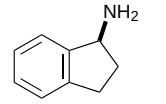


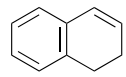


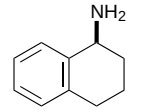


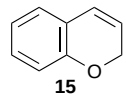


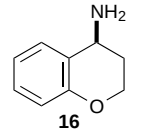


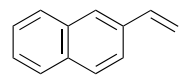












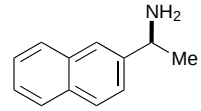


**Table 1** Hydroboration–amination of vinylarenes[a]

| Reactant | Product | Regioselectivity (%)[b] | Isolated yield (%) | Ee (%)[c] |

[a] Hydroboration–amination experiments as per typical protocol (see footnote ‡). [b] Minor component is regioisomeric primary amine. [c] Ees of amines or their acetamides were analysed by GC using a 25 m CHIRALDEX bonded silica column at 140–150 °C, achieving baseline separation in all cases. [d] From isolated organoborane. [e] Not previously obtained in enantiomerically enriched form, $[\alpha]_D^{23}$ −55.21 (*c* 0.36, $CHCl_3$) for acetylamino derivative; configuration assigned by comparison with (*S*)-chroman-4-ol (ref. 16) formed by hydroboration–oxidation. [f] Analysis by $^1H$ NMR using $Eu(tfc)_3$.

out in thf solution, the only product being **3** [$\delta_C$ 13.0 ($J_{BC}$ 82 Hz)].[10] These displacement reactions were also shown to be occur with other arylalkylboronates prepared by catalytic hydroboration of vinylarenes with catecholborane.

With a clean route to enantiomerically enriched trialkylboranes in hand, attention was then turned to developing a synthetically useful amination procedure. It is known that in aminations with $H_2NOSO_3H$, methyl is a poor migrating group,[11] and a protocol was developed accordingly. It was established in an initial experiment that successive addition of 2 equiv. of MeMgCl and 3 equiv. of $H_2NOSO_3H$ to an isolated sample of borane **1** (86% ee) in thf gave amine **5** in 83% ee and 65% yield. Catalytic hydroboration was then carried out for several vinylarenes in thf solution at ambient temperature, employing the rhodium complex of (*S*)-quinap (**4**) in the manner previously described.[12] On completion of the hydroboration reaction, 2 equiv. of MeMgCl (3 M solution in thf) were added followed after 30 min by 3 equiv. of $H_2NOSO_3H$. After stirring for 12 h the amine was isolated either directly, or as its acetamide (MeCOCl) and the ee analysed as described in Table 1. As far as can be determined, the ee values reflect the enantioselectivity of the catalytic hydroboration step, since $H_2O_2$–$OH^-$ oxidation at the trialkylborane stage provides a secondary alcohol whose enantiomeric purity is the same or slightly lower than that of the primary amine (within experimental error). For the acyclic side-chain amines derived from alkenes **6**, **7**, **9** and **17**, the results follow quite closely those observed previously in hydroboration–oxidation, but superior results have been obtained for the slower-reacting dihydronaphthalene **13** and 4-chromene **15** by very careful attention to catalyst purity and freshness, although indene **11** was somewhat inferior. A one-stage asymmetric synthesis of 1-aminotetralin **14** in 97% ee is of potential practical significance.

In summary, we have developed a method for the catalytic asymmetric synthesis of primary amines from alkenes that complements existing methods, which are most commonly based on imine[13] or enamide reduction,[14] or allylic alkylation procedures.[15] The activation of catecholborane adducts offers the possibility of further extending the range of catalytic hydroboration (*e.g.* to Suzuki couplings and other C–C bond forming reactions) and provides an incentive for us to improve the scope and selectivity of the catalytic reaction itself.

We thank the University of Tarragona for leave (to E. F.) and Johnson-Matthey for the loan of rhodium salts. F. I. K. was supported through a Studentship from LINK Asymmetric Synthesis, and we warmly thank Dr A. J. Blacker (Zeneca) for his help and interest. Dr H. Doucet made helpful contributions.

## Footnote

† IUPAC name: *ortho*-phenylene 1-phenylethylboronate.

‡ Freshly prepared complex **4** (4.0 mg, 0.005 mmol, 1.0 mol%) and thf (0.5 ml) were placed in a vial under argon with the alkene (0.5 mmol). Freshly distilled catecholborane (53.3 μl, 59.5 mg, 0.5 mmol) was added with stirring, then left for 1 h. MeMgCl (3 M in thf, 333 μl, 1.0 mmol) was added and the solution stirred for 30 min. The reactant solution was added to predried $H_2NOSO_3H$ (169 mg, 1.5 mmol), with 0.7 ml of thf or diglyme, and stirred under argon for *ca.* 15 h. HCl (1 M, 2 ml) was added, and the mixture poured into $H_2O$ (4 ml). The aqueous layer was extracted with $Et_2O$ (3 × 20 ml) and then was made strongly alkaline with NaOH (1 M, 3 ml). The mixture was then extracted with $Et_2O$ (3 × 20 ml). The $Et_2O$ extracts were combined and dried with magnesium sulfate, and the solvent removed *in vacuo*.

# Copper(II)-templated assembly of tetranuclear grid-like complexes from simple pyridine–pyrazole ligands

**John C. Jeffery, Peter L. Jones, Karen L. V. Mann, Elefteria Psillakis, Jon A. McCleverty,* Michael D. Ward* and Claire M. White**

*School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

**Reaction of $Cu(O_2CMe)_2·H_2O$ with $HL^1$ [3-(2-pyridyl)pyrazole] or $HL^2$ [6-(3-pyrazolyl)-2,2′-bipyridine] and $NH_4PF_6$ followed by crystallisation of the crude products from dmf–ether affords $[Cu_4L^1{}_6(dmf)_2][PF_6]_2$ 1 and $[Cu_4L^2{}_4(dmf)_4][PF_6]_4$ 2 respectively, in which the deprotonated pyrazolyl groups act as bridging ligands and the 2 × 2 grid–like architectures are a result of the preference of the $Cu^{II}$ ions for elongated square-pyramidal coordination geometries.**

Recent developments in the specific, efficient syntheses by self-assembly processes of coordination complexes have afforded a variety of unusual topologies such as molecular helicates, grids, ladders, rings, and boxes.[1–6] Such complexes are of interest not only for their unusual structures and the simple synthetic methods used to prepare them, but also because they allow the preparation of high-nuclearity complexes in which several potentially interacting metal centres are linked in a well defined spatial array.

We describe here the syntheses and structures of the copper(II) complexes of $HL^1$ [3-(2-pyridyl)pyrazole] and $HL^2$ [6-(3-pyrazolyl)-2,2′-bipyridine] in which the above principles have been used to prepare tetranuclear grid-like complexes. These complexes are of particular interest as they show (*i*) how the unusual stereoelectronic preferences of $Cu^{II}$ can be harnessed to assemble complex high-nuclearity structures that are not accessible with other metal ions, and (*ii*) how simple polydentate ligands containing terminal pyrazolyl fragments are appealing components for use in supramolecular chemistry.

$HL^1$ (a known ligand)[7,8] forms simple mononuclear octahedral tris-chelate complexes with $Ni^{II}$ and $Zn^{II}$.[9] We reasoned that this was unlikely with $Cu^{II}$. Reaction of $HL^1$ with $Cu(O_2CMe)_2·2H_2O$ (3 : 2) in methanol at room temperature afforded a clear deep green solution from which a blue–green solid precipitated on addition of $NH_4PF_6$. This was recrystallised from dmf–ether to give crystals of **1**·2 dmf in *ca.* 90% yield. FAB mass spectrometry showed the presence of numerous peaks corresponding to polynuclear species [up to $Cu_4L^1{}_6$] and the elemental analysis was consistent with the empirical formula $[Cu_2L^1{}_3(dmf)][PF_6]$.The crystal structure of **1** (Fig. 1) shows that **1** is in fact $[Cu_4L^1{}_6(dmf)_2][PF_6]_2$.† There are two approximately planar $Cu_2(\mu\text{-}L^1)_2$ units, related by an inversion centre, in which each $[L^1]^-$ acts as a terdentate bridge linking the two metal centres; these units are stacked parallel and face-to-face (mean plane separation 3.2–3.5 Å), with additional

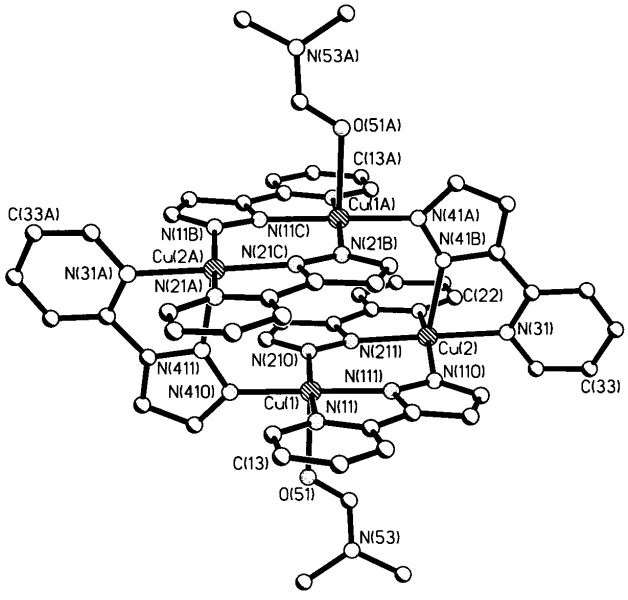

**Fig. 1** Structure of the complex cation of **1**. deprotonated ligands $[L^1]^-$ perpendicular to the two $Cu_2(\mu\text{-}L^1)_2$ planes forming linking 'cross-pieces'. Two of the metals [Cu(1) and Cu(1A)] have additional dmf ligands attached, and therefore have a square-pyramidal $N_4O$ environment in which the O ligands (dmf) are axial; Cu(2) and Cu(2A) have square-pyramidal $N_5$ environments in which one of the pyrazole donor atoms is in the axial position. In every case the axial ligand is significantly further from the metal [Cu(I)–O(51) 2.339(2) Å, Cu(2)–N(411A) 2.198(2) Å] than the four equatorial ligands (lengths in the range 1.97–2.07 Å), in keeping with the requirements of the Jahn–Teller effect.

$HL^2$ was prepared in exactly the same way as $HL^1$,[8] but starting from 6-acetyl-2,2′-bipyridine. $HL^2$ forms simple mononuclear octahedral complexes with many first-row metal ions.[9] Reaction of $HL^2$ with $Cu(O_2CMe)_2\cdot 2H_2O$ (1 : 1) in methanol at room temperature followed by addition of aqueous $NH_4PF_6$ resulted in precipitation of a blue–green solid which was recrystallised from dmf–ether to give crystals of **2**·6dmf in *ca.* 80% yield. Electrospray mass spectrometry indicated the formation of a tetranuclear complex in solution, and the elemental analysis indicated the empirical formula $[Cu(L^2)][PF_6]$, *i.e.* a 1 : 1 metal : ligand ratio. The crystal structure of **2** is in Fig. 2,† and shows that **2** is the tetramer $[Cu_4L^2_4(dmf)_4][PF_6]_4$ and has many structural similarities to **1**. The overall structure is that of a 2 × 2 grid, with two pairs of parallel, stacked $[L^2]^-$ ligands mutually perpendicular to each other. The stacking distances again are in the range 3.2–3.5 Å. Each metal ion is coordinated by the terdentate pocket of one deprotonated ligand $[L^2]^-$, one pyrazole donor atom which is acting as a bridge to a ligand attached to another metal ion, and a dmf ligand. The result is an elongated $N_4O$ square-pyramidal geometry with the dmf ligand in the axial position; the axial bond lengths lie in the range 2.23–2.27 Å, in contrast to the equatorial ones which lie in the range 1.95–2.06 Å. The four metal ions are crystallographically independent but chemically very similar, and the complex has approximate $S_4$ symmetry (*cf.* the $S_2$ axis of **1** implied by its inversion centre).

The grid-like architecture of both complexes is emphasised in Fig. 3. Comparison with the simple mononuclear octahedral complexes that these ligands can also form[9] shows that assembly of these structures is directed principally by the stereoelectronic preference of the $Cu^{II}$ ions for elongated tetragonal geometry: to satisfy this requirement necessitates deprotonation of the pyrazole rings and bridging behaviour of the ligand. These structures are in interesting contrast to other grid- and ladder-like structures in which the necessary mutually perpendicular orientation of ligand strands is achieved by using ligands with bidentate compartments assembling around (pseudo-tetrahedral) $Cu^I$ or $Ag^I$ templates.[3,5,6]

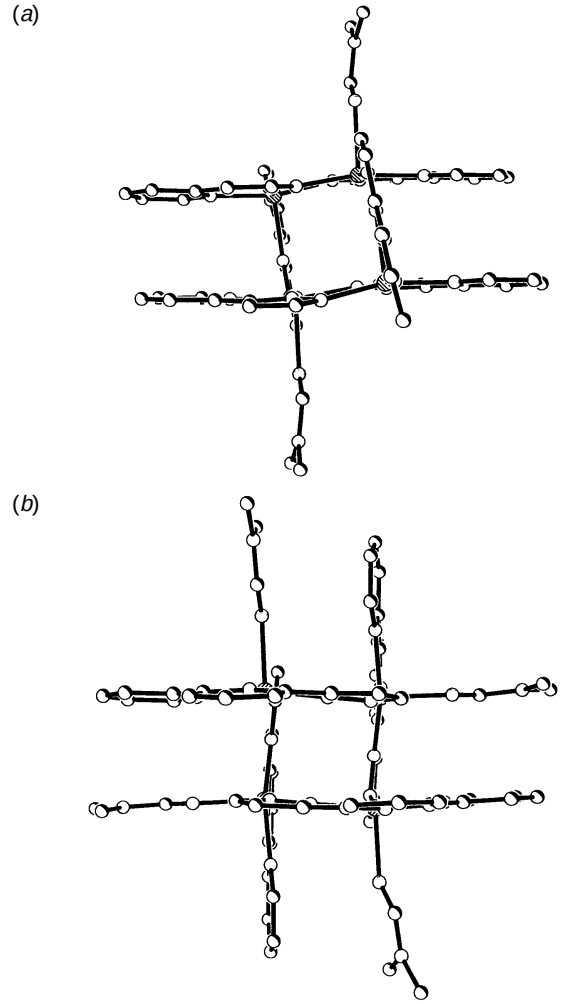

**Fig. 3** Alternative views of the complex cations of **1** (*a*) and **2** (*b*) emphasising the grid-like structure and the aromatic stacking

## Footnote

† *Crystallography*. Suitable crystals were mounted on a Siemens SMART diffractometer (graphite-monochromatised Mo-Kα X-radiation).

**1**·2dmf: $C_{60}H_{64}Cu_4F_{12}N_{22}O_4P_2$, $M$ = 1701.4, green plates, crystal size 0.5 × 0.4 × 0.1 mm; triclinic, space group $P\bar{1}$; $a$ = 10.410(2), $b$ = 13.282(3), $c$ = 14.170(2) Å, α = 85.254(10), β = 70.087(12), γ = 68.15(2)°; $U$ = 1707.5(6) Å$^3$; $Z$ = 1; $D_c$ = 1.655 g cm$^{-3}$; $F(000)$ = 864; μ(Mo-Kα) = 1.373 mm$^{-1}$. 8183 data were collected with $2\theta_{max}$ = 50° at −100 °C, and merged to give 5820 unique data ($R_{int}$ = 0.023).

**2**·6dmf: $C_{82}H_{106}Cu_4F_{24}N_{26}O_{10}P_4$, $M$ = 2450.0, green needles, crystal size 0.7 × 0.15 × 0.1 mm$^3$; monoclinic, space group $P2_1/n$; $a$ = 19.567(2), $b$ = 26.313(3), $c$ = 20.033(2) Å; β = 91.44(1)°; $U$ = 10311(3) Å$^3$; $Z$ = 4; $D_c$ = 1.578 g cm$^{-3}$; $F(000)$ = 5008; μ(Mo-Kα) = 0.987 mm$^{-1}$. 63 226 data were collected with $2\theta_{max}$ = 55° at −100 °C, and merged to give 23 223 unique data ($R_{int}$ = 0.079).

Both structures were solved by direct methods, and refined on all $F^2$ data using the SHELX suite of programs. All non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in calculated positions with fixed isotropic thermal parameters. For **1**·2dmf, $R_1$ = 0.036, $wR_2$ = 0.106. The complex is centrosymmetric so each asymmetric unit contains one half of the complex and one unique dmf molecule. For **2**·6dmf, $R_1$ = 0.079, $wR_2$ = 0.200. Each asymmetric unit contains one complete tetranuclear complex and six independent molecules of dmf. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/323.

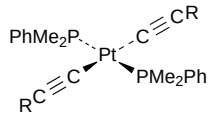
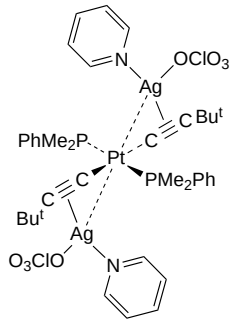
# Rings and linear polymers formed by addition of silver perchlorate to *trans*-[Pt(C≡CR)$_2$(PMe$_2$Ph)$_2$] (R = Bu$^t$, H)

**Shinsaku Yamazaki,*[a] Antony J. Deeming,*[b] Despo M. Speel,[b] David E. Hibbs,[c] Michael B. Hursthouse[c] and K. M. Abdul Malik[c]**



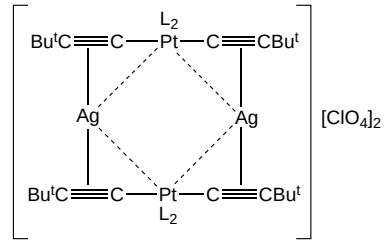
[a] *Chemistry Laboratory, Kochi Gakuen College, 292 Asahi Tenjin-Cho, Kochi 780, Japan*
[b] *Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*
[c] *School of Chemistry and Applied Chemistry, University of Wales, PO Box 912, Cardiff, UK CF1 3TB*

**Addition of AgClO$_4$ to *trans*-[Pt(C≡CR)$_2$(PMe$_2$Ph)$_2$] (R = Bu$^t$, H) gives 1 : 1 adducts of the general formula *trans*-[PtAg(ClO$_4$)(μ-C≡CR)$_2$(PMe$_2$Ph)$_2$] which are cyclic dimers when R = Bu$^t$ (ClO$_4^-$ not coordinated) or linear polymers when R = H (ClO$_4^-$ coordinated to silver).**



*cis*-Dialkynyl complexes of platinum behave as chelating bidentate ligands at copper(I) and silver(I). *cis*-[Pt(CuCl)(C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$] **1** contains Cu coordinated to two alkynes and a chloride ligand and the complexes [Pt$_2$M(C≡CPh)$_4$(dppe)$_2$][BF$_4$] (M = Cu[1], Ag[2]) and *cis*-[Pt$_2$Ag(C≡CPh)$_4$(PPh$_3$)$_4$][ClO$_4$][3] contain Ag or Cu atoms coordinated tetrahedrally to four alkyne groups. Some recent examples of coordination of Pt alkynyl complexes to silver(I)[1–4] and a review by Forniés and Lalinde have appeared.[5]

Attempting to form linear polymers containing M(μ-C≡CR)M′ components, we coupled CuCl with *trans*-[Pt(C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$]. Since the alkynyl ligands are *trans* at platinum, chelation is not possible and the linear polymer [{PtCu$_2$Cl$_2$(C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$}$_n$] with the polymer backbone ···Pt[(μ-C≡CR)CuCl$_2$Cu(μ-RC≡C)Pt]$_n$(μ-C≡CR)··· was obtained.[6] This paper describes our preparation of halide-free polymers with the backbone ···Pt(μ-C≡CR)[Ag(μ-RC≡C)Pt(μ-C≡CR)]$_n$Ag··· composed only of metal and bridging alkynyl ligands.



The complex *trans*-[Pt(C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$] **1a** reacts with AgClO$_4$ (2 mol/mol Pt) in acetonitrile to give *trans*-[PtAg$_2$(MeCN)$_x$(μ-C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$][ClO$_4$]$_2$ **2** (*x* is probably 4) and we have determined the X-ray structure of the corresponding copper complex with *x* = 4.[2] Treatment of **2** with pyridine gave the neutral derivative *trans*-[PtAg$_2$(ClO$_4$)$_2$(py)$_2$(μ-C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$] **3** which was characterised by single-crystal X-ray diffraction.[2] In **3** one silver ion coordinates to each of the two alkynyl ligands and polymerisation is prevented. However, with restricted addition of AgClO$_4$ (1 mol/mol Pt complex) to *trans*-[Pt(C≡CBu$^t$)$_2$(PMe$_2$Ph)$_2$] **1a**, a complex is formed which crystallised from benzene as *trans*-[Pt$_2$Ag$_2$(μ-C≡CBu$^t$)$_4$(PMe$_2$Ph)$_4$][ClO$_4$]$_2$·2C$_6$H$_6$ **4**·2C$_6$H$_6$.† The stoichiometry fits a linear polymer but in this case an alternative cyclic dimer is formed. The X-ray structure was determined at 150(2) K because of crystal degradation at 293 K (see Fig. 1).‡ In contrast to compound **3**, the silver atoms in **4** coordinate on the same face of the Pt coordination plane allowing two square-planar Pt complexes to be glued parallel to each other by two

**1a** R = Bu$^t$
**b** R = H

**3**

**4** (L = PMe$_2$Ph)

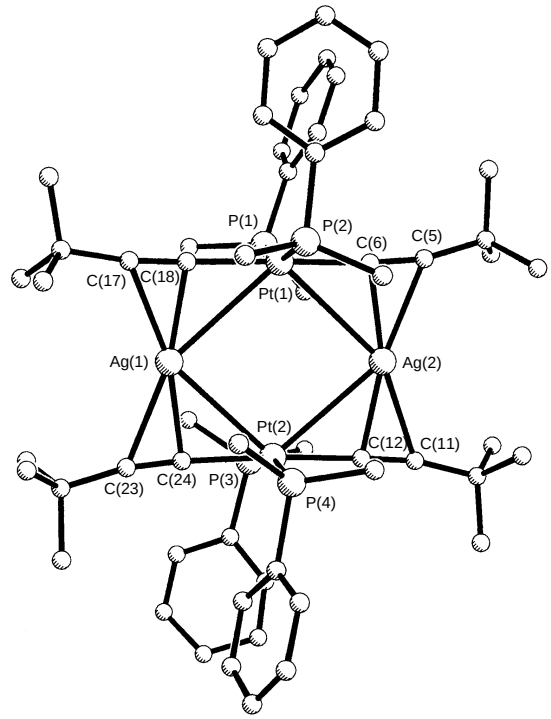


**Fig. 1** Structure of the square dicationic complex in *trans*-[Pt$_2$Ag$_2$(μ-C≡CBu$^t$)$_4$(PMe$_2$Ph)$_4$][ClO$_4$]$_2$·2C$_6$H$_6$ **4**·2C$_6$H$_6$. The non-coordinated perchlorate ions and the benzene molecule are not shown.

$Ag^+$ ions. The perchlorate ions are not coordinated. The $Pt_2Ag_2$ set of atoms is closely planar and approximately square [Pt–Ag distances 3.1960(10), 3.2161(9), 3.2080(9), 3.2683(10) Å; Pt–Ag–Pt angles 86.51(2), 85.44(2)°; Ag–Pt–Ag angles 93.26(2), 94.79(2)°; Pt···Pt 4.3938(9) Å and Ag···Ag 4.7138(9) Å]. The Ag atoms appear to be pulled in towards the centre of the square resulting in shorter contacts with the α than the β alkynyl carbon atoms [av. Ag–$C^{\alpha}$ 2.236 Å, av. Ag–$C^{\beta}$ 2.448 Å] (Fig. 2). Pt···Ag distances up to 2.95 Å have been considered to indicate donor interactions from Pt to Ag but in this case the average Pt···Ag distance of 3.22 Å shows that such interactions must be extremely weak.[7]

The $Bu^t$ groups in **4** are bent away from each other [av. $C^{\alpha}C^{\beta}C(Bu^t)$ 169.1°], as are the tertiary phosphines [P–Pt–P 160.06(8), 163.95(8)°], suggesting that replacement of the $Bu^t$ groups by smaller substituents would allow the cyclic molecules to relax into a tighter configuration. However, addition of $AgClO_4$ (1 mol/mol Pt) to *trans*-[$Pt(C{\equiv}CH)_2(PMe_2Ph)_2$] gives crystals of *trans*-[$PtAg(ClO_4)(\mu\text{-}C{\equiv}CH)_2(PMe_2Ph)_2$] **5**† which, rather than forming a cyclic dimer, gives a linear polymer (X-ray structure, Fig. 3).‡ Relaxation of crowding around Ag has allowed the perchlorate to coordinate to it and the *trans* $PMe_2Ph$ ligands to become closely linear [P–Pt–P 177.2(1)°]. The $Ag^+$ ions still coordinate on the same face of each Pt coordination plane (as in **4** but not **3**) forming a zigzag chain with a perchlorate ion in each cavity along the chain. In addition to the short coordinated Ag–O distance [Ag(1)–O(1) 2.65(1) Å], there are number of $ClO_4^-$-to-chain contacts which might help to stabilize this arrangement. The shortest C≡CH···O contact is too long to be considered a hydrogen bond. [$C^{\beta}$···O 3.56 Å]. Fig. 2 shows the differences in the geometries of $Ag^+$ coordination in compounds **4** and **5**. The $Ag^+$ ion is more closely coordinated to $C^{\alpha}$ than $C^{\beta}$ in **5**, the reverse of the situation in **4**, and Pt···Ag distance are much longer in **5** than in **4**.

We have tried to synthesise analogues of **5** with other counter ions such as $BPh_4^-$ which are too big to fit the cavities or unlikely to coordinate but no crystalline products could be obtained. We have still to assess properly the factors that control the mode of aggregation of [$PtAg(ClO_4)(C{\equiv}CR)_2(PMe_2Ph)_2$] units in complexes of this type.

We thank the Royal Society and the Japan Promotion of Sciences (S. Y.) for support for this collaboration.

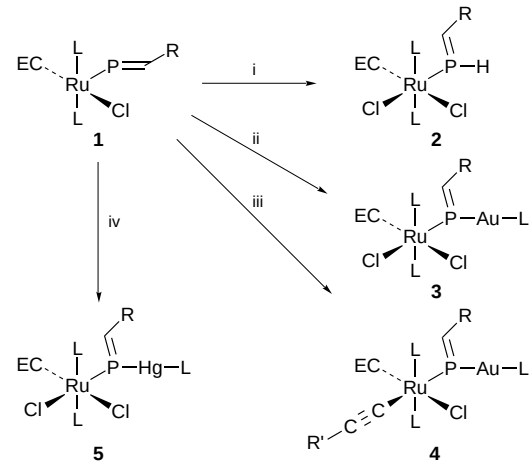
[c] *Chemical Crystallography Laboratory, Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*



**The reaction of $[Ru(P{=}CHBu^t)Cl(CE)(PPh_3)_2]$ (E = O, S) with $[AuX(PPh_3)]$ (X = Cl, $C{\equiv}CC_6H_4Me$-4), $HgCl_2$ or $Hg_2Cl_2$ leads *via* addition of the Au–X or Hg–Cl bonds across the Ru–P linkage to the heterodinuclear phosphaalkene complexes $[Ru\{P(AuPPh_3){=}CHBu^t\}ClX(CE)(PPh_3)_2]$ and $[Ru\{P(HgCl){=}CHBu^t\}Cl_2(CE)(PPh_3)_2]$.**

Mononuclear phosphaalkenyl complexes remain rare.[1] Nevertheless, our recent observation[2] that hydroruthenation of phosphaalkynes provides an exceptionally facile entry into such compounds should presage a substantial broadening of the field. Polynuclear phosphaalkenyl complexes remain unknown, and only one example of a dinuclear complex has been structurally characterised, resulting from the reaction of the kinetically stabilised phosphaalkene $ClP{=}C(SiMe_3)_2$ with Collman's reagent.[3] The remaining examples involve the reactions of $[W\{P{=}C(R)SiMe_3\}(CO)_3(\eta\text{-}C_5H_5)]$ (R = Ph, $SiMe_3$) with $[Fe_2(CO)_9]$, $[Ni(CO)_4]$ or $[AuCl(PPh_3)]$.[4] In these reactions the lone pair of the phosphaalkenyl ligand coordinates to $Fe(CO)_4$, $Ni(CO)_3$ or AuCl fragments *via* a simple dative two-electron interaction. It is this aspect of phosphaalkenyl coordination chemistry with which this report is concerned, in illustrating for the first time the 1,2-addition of metal–halide and metal–carbon bonds across the P–C multiple bond of a phosphaalkenyl complex. This approach converts the three-electron phosphaalkenyl ligand into a formally neutral metallated phosphaalkene (Scheme 1). This has allowed the first structural characterisation of a heterobimetallic phosphaalkenyl complex.

The nucleophilicity of the phosphaalkenyl ligand in the complex $[Ru(P{=}CHBu^t)Cl(CO)(PPh_3)_2]$ **1a** has been recently demonstrated in its reactivity with HCl to provide the phosphaalkene complex $[Ru(HP{=}CHBu^t)Cl_2(CO)(PPh_3)_2]$ **2**.[2] Over the last decade, guided by isolobal considerations the fragment $AuPPh_3^+$ has come to be viewed as the cluster chemist's proton. Within this context, it is therefore noteworthy that the reaction of **1a** with $[AuCl(PPh_3)]$ leads to the smooth and high yield conversion of **1a** to a complex formulated as $[Ru\{P(AuPPh_3){=}CHBu^t\}Cl_2(CO)(PPh_3)_2]$ **3a** on the basis of spectroscopic§ and crystallographic¶ data (Scheme 2, Fig. 1). Most informative amongst the spectroscopic data is the upfield shift of the $^{31}P$ NMR signal associated with the phosphaalkenyl ligand from δ 450.4 in **1a** to δ 319.4 in **3a**. This resonance appears as a double triplet as a result of coupling to the phosphine phosphorus nuclei bound to gold [$J$(PP) 268.5 Hz] and ruthenium [$J$(PP′) 29.6 Hz]. The former suggests an essentially *trans* P–Au–P linkage, whilst the latter is con-

**Scheme 1** Phosphaalkenyl complexes as ligands; $ML_n$ = $Fe(CO)_4$, $Ni(CO)_3$, AuCl; M′L = HgCl, $AuPPh_3$

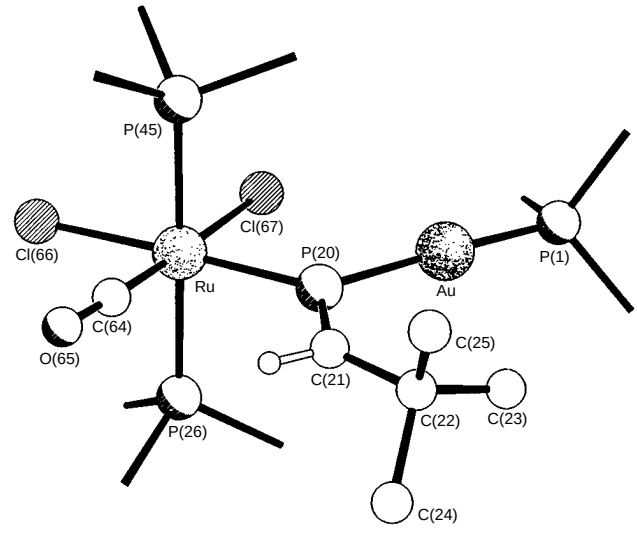

**Fig. 1** Molecular geometry for $[Ru\{P(AuPPh_3){=}CHBu^t\}Cl_2(CO)(PPh_3)_2]$ **3a**; phenyl groups omitted

siderably larger than that found in the precursor **1a** (10.0 Hz). The resonances due to the phosphine ligands both show coupling to the phosphaalkenyl phosphorus, however there is no resolvable coupling between the phosphine resonances consistent with the absence of an Ru–Au bond.

The formulation was confirmed by a single-crystal X-ray diffraction analysis,¶ the results of which are summarised in Fig. 1. The geometry at ruthenium is essentially octahedral with *cis*-interligand angles in the range 87.2(3)–93.0(1)°, whilst the geometry at gold is close to linear [P(1)–Au–P(20) 177.6(1)°]. The two ruthenium chloride distances are 2.481(2) and 2.464(2) Å indicating that the *trans* influence of the phosphaalkenyl ligand is only marginally greater than that of the carbonyl ligand. Interest focusses on the phosphaalkenyl bridge although the novelty of **3a** leaves us with little precedent for comparison. It is noteworthy that the coordination at phosphorus is trigonal [intersubstituent angles in the range 119.7(3)–120.2(3)°], indeed this planarity extends to include Au, P(1), C(22) and the equatorial ruthenium coordination plane [maximum deviation from planarity of 0.085 Å by Cl(66)]. The P(20)–C(21) bond length of 1.664(9) Å is clearly multiple in nature, and comparable to that observed [1.640(4) Å] in [Fe{μ-P=C(SiMe$_3$)$_2$}$_2$(CO)$_6$].[3] The two Au–P distances differ only marginally, with that to the phosphaalkenyl ligand [2.320(2) Å] being the longer of the two. The Ru–P(20) separation of 2.296(2) Å is however *ca*. 0.1 Å shorter than those to the phosphines [P(45) 2.397(2), P(26) 2.413(2) Å], indicating a π-acid role for the phosphaalkenyl ligand when bound to a retrodative metal centre. Finally the *trans* disposition of the ruthenium and the butyl group about the P=C double bond confirms our earlier suggestion that hydroruthenation of P≡CBu$^t$ to provide **1a** occurs in a regiospecifically *trans* manner.

The facility of the addition of [AuCl(PPh$_3$)] to **1a** bodes well for the future elaboration of heterobimetallic phosphaalkenyl complexes by the bridge-assisted methodology. Preliminary results indicate that the gold acetylide [Au(C≡CC$_6$H$_4$Me-4)(PPh$_3$)] also adds across the Ru–P bond to provide the ruthenium acetylide complex [Ru{P(AuPPh$_3$)=CHBu$^t$}(C≡CC$_6$H$_4$Me-4)Cl(CO)(PPh$_3$)$_3$] **4a**§ (Scheme 2). In a similar manner both mercury-(I) and -(II) chloride react with **1** to provide [Ru{P(HgCl)=PHBu$^t$}Cl$_2$(CO)(PPh$_3$)$_2$] **5a**, the former reaction being accompanied by deposition of elemental mercury. Bis(alkynyl)mercurials [Hg(C≡CR)$_2$], however, fail to react with **1a** in contrast to [Au(C≡CC$_6$H$_4$Me-4)(PPh$_3$)]. Similar reactions, and the products [Ru{P(AuPPh$_3$)=CHBu$^t$}XCl(CS)(PPh$_3$)$_2$] [X = Cl **3b**, C≡CC$_6$H$_4$Me-4 **4b**] and [Ru{P(HgCl)=PHBu$^t$}Cl$_2$(CS)(PPh$_3$)$_2$] **5b** are also observed between these reagents and the thiocarbonyl complex [Ru(P=CHBu$^t$)Cl(CS)(PPh$_3$)$_2$] **1b**, obtained from the reaction of [RuHCl(CS)(PPh$_3$)$_3$] and P≡CBu$^t$.

The chemistry described for the complexes **1** illustrates their unusual nature which makes them distinct from other phosphaalkenyl complexes for which the effective atomic number rule holds domain. For such complexes, the linear three-electron (electrophilic at P) or bent one-electron (nucleophilic at P) role of the phosphaalkenyl ligand is distinctly dichotomous. We have previously suggested[2] that the complexes **1** represent a special case: linearisation of the M = P=C linkage, and the attendant reduction of the nucleophilicity of the phosphorus is not apparently favoured by the 15-electron 'RuCl(CE)(PPh$_3$)$_2$' fragment. Such behaviour is typical of formally isoelectronic nitrosyl complexes of the late-transition metals. This leads in the unique case of **1** to the juxtaposition of a nucleophilic phosphaalkenyl phosphorus adjacent to a coordinatively unsaturated ruthenium centre, *i.e.* a 1,2-dipole predisposed to the 1,2-addition of dipolar reagents.

We gratefully acknowledge the generous loan of ruthenium salts by Johnson Matthey Chemicals and the Nuffield Foundation and the Engineering and Physical Sciences Research Council (UK) for financial support and the provision of a diffractometer.

# Generation, entrapment and reactivity of long-lived organic carbocations and radical cations within a supramolecular assembly: Ca Y zeolite

**K. Pitchumani,[a] P. H. Lakshminarasimhan,[a] Nicolette Prevost,[a] D. R. Corbin[b] and V. Ramamurthy*[b]**

[a] *Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*

**Diarylethenes spontaneously form the corresponding radical cations and carbocations upon inclusion within activated Ca Y zeolite; oxygen plays an important role in the generation of the radical cations.**

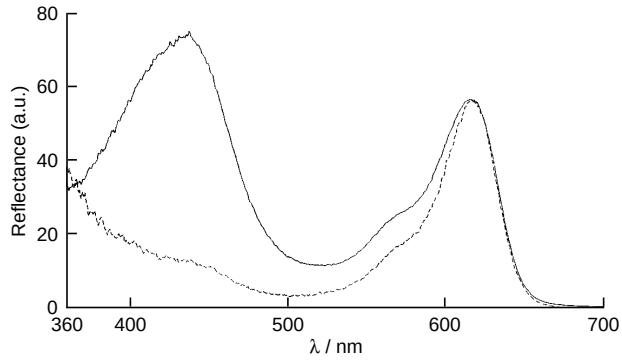
By virtue of their ability to generate carbocations and radical cations, zeolites have been used in a number of catalytic processes.[1] Although the mechanism of carbocation formation is fairly well understood, the potential of such intermediates in routine organic transformations has not been fully realized. On the other hand, no agreement on the mechanism of cation radical generation within zeolites has been reached.[2] This communication addresses these concerns.

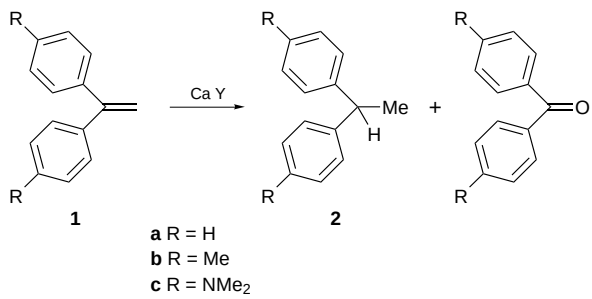
When Ca Y (300 mg) activated at 500 °C under aerated conditions for about 12 h, and cooled to room temperature, was dropped into a cyclohexane solution of 1,1-diphenylethene **1a**, (20 mg 3 ml) a bright green colour developed which, in the slurry, persisted for several weeks.† Extraction of the cyclohexane–zeolite slurry with dichloromethane gave 1,1-diphenylethane **2a** as the single product (Scheme 1). The zeolite residue after extraction was still coloured and remained so for at least 12 h under aerated conditions. When the zeolite turned colourless, it was extracted for a second time with dichloromethane to yield benzophenone. The overall yield of the two products was 90% diphenylethane and 10% benzophenone.

The diffuse reflectance spectra of the zeolite–**1a** complex as formed in cyclohexane, showed two strong absorptions with $\lambda_{max}$ at 432 and 615 nm (Fig. 1). The zeolite residue after the first extraction with dichloromethane showed only a peak at 615 nm. On the basis of literature reports, we assign the 432 nm peak to the $Ph_2C^+Me$ carbocation and the one at 615 nm to the radical cation of **1a**[3,4] The presence of a radical cation in the Ca Y sample is also indicated by EPR spectroscopy.[5] A strong EPR signal with a *g*-value of 2.00235 was obtained.

Ca Y activated in the temperature range 300–600 °C under aerated conditions was found to be ideal for carbocation generation. It has been established in the literature that such conditions of activation lead to the generation of Brønsted acid sites.[6] Through extensive deuteriation experiments, we have established that one of the hydrogens in diphenylethane **2a** (Scheme 1) comes from the water present within the zeolite and the other from dichloromethane which is used to extract the product from the zeolite. Results of the deuteriation experiments are summarized in Scheme 2.

Of the various activation conditions we attempted, Ca Y activated > 400 °C on a vacuum line under reduced pressure ($< 10^{-3}$ Torr) was found to be ideal for the generation of radical cations with minimum interference from carbocations. Two remarkable observations made by us in the case of 1,1-diarylethenes lead us to conclude that oxygen plays an important role in the generation of the radical cation within Ca Y. Inclusion of diphenylethene **1a** into Ca Y activated at 450 °C on a vacuum line and handled under nitrogen atmosphere generated only a very light green colour.‡ However, when oxygen was bubbled into such a solution, a dark green colour resulted and the benzophenone yield was enhanced from 1 to 10%. Enhancement of the yield of the radical cation was also confirmed by the diffuse reflectance spectral data. This observation suggested to us that oxygen is essential for radical cation generation. The following observation made with 4,4′-dimethylaminodiphenylethene **1c** further strengthened our view that oxygen plays a





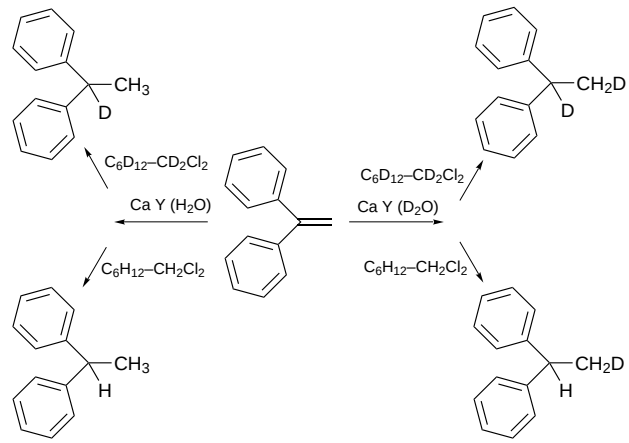


**Fig. 1** Diffuse reflectance spectra of diphenylethene included within activated (500 °C aerated) Ca Y. (—) Soon after the addition of Ca Y to a cyclohexane solution of diphenylethene and (---) after extracting the above solution with $CH_2Cl_2$.

**Scheme 1**

**Scheme 2**

crucial role in the generation of radical cations within zeolites. When 4,4′-dimethylaminodiphenylethene was included within activated Ca Y the corresponding radical cation was generated. The diffuse reflectance spectrum of **1c** within Ca Y is shown in Fig. 2. The blue coloured solid, when degassed on a vacuum line ($< 10^{-3}$ Torr) turned colourless and the diffuse reflectance spectrum no longer contained the peak due to the radical cation at 620 nm. Introduction of air into this sample, most surprisingly, regenerated the blue colour and the peak at 620 nm reappeared in the diffuse reflectance spectrum. This process was reversible for at least six cycles. This remarkable observation lead us to suggest that oxygen is most likely the electron acceptor at least in the case of 4,4′-dimethylaminodiphenylethene. The alkene **1c** was unique in its behaviour in several ways: (*a*) no other alkenes including **1a** and **1b** above showed the reversible behaviour exhibited by **1c**; (*b*) the radical cation from **1c** was generated even in monovalent cation-exchanged (Li, Na, K, Rb and Cs) Y zeolite. All other alkenes gave radical cations only in divalent cation-exchanged Y and in ZSM-5 zeolites.

Recently, Frei and coworkers have exploited the unique feature of divalent cation-exchanged zeolites to stabilize charge-transfer complexes between hydrocarbons and oxygen.[7] In the case of the alkenes used by Frei and coworkers, the permanent charge separation occurs only upon activation by light. However, the alkenes we have investigated, all possessing much lower oxidation potentials[8] than those studied by Frei and coworkers, are oxidized even in the absence of light. Most surprisingly, 4,4'-dimethylaminodiphenylethene, possessing a very low oxidation potential (0.66 V), establishes a reversible oxidation process with oxygen as the acceptor.[9] Absence of such a process with either diphenylethene (1.88 V) or 4,4′-dimethoxydiphenylethene (1.32 V) suggests to us that the acceptor for these alkenes may not be the free oxygen. Further work, in progress, with a series of alkenes with oxidation potential varying between 0.6 and 2.0 V is expected to clarify this aspect of the oxidation of alkenes within Ca Y.

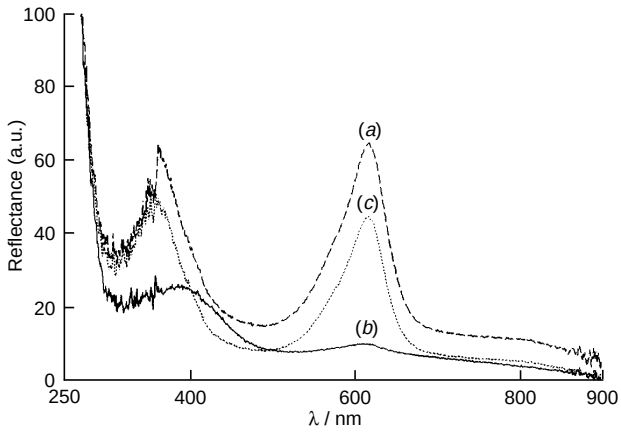

**Fig. 2** Diffuse reflectance spectra of 4,4′-dimethylaminodiphenylethene **1c** included in Ca Y. (*a*) (---) Sample after extraction with dichloromethane under aerated conditions. (*b*) (—) The above sample degassed on a vacuum line and under reduced pressure ($10^{-3}$ Torr). (*c*) (···) Sample (*b*) exposed to air.

The conditions under which radical cations and carbocations can be generated, independent of each other, within Ca Y zeolite have been established. Using this technique we have been able to generate long-lived radical cations and carbocations from a number of alkenes. We are in the process of characterizing the persistent carbocations and radical cations by CP MAS NMR and by EPR respectively. The mechanism of radical cation formation within activated zeolites is also being pursued.

We thank the Division of Chemical Sciences, Office of Basic Energy Sciences, Office of Energy Research, US Department of Energy and NSF-EPSCOR-LBR Center for Photoinduced Processes, Tulane University for support of this program.

## Footnotes

† ICP analysis indicated the zeolite used had the composition $Si_{138.7}Al_{53.3}Na_{7.5}Ca_{23.3}O_{384}$.

‡ Ca Y was placed in a quartz tube and heated at 450 °C under reduced pressure ($5 \times 10^{-4}$ Torr). Nitrogen was adsorbed onto this sample at room temp. and degassed. This process was repeated four times and finally the sample was left under nitrogen overnight. Further handling was done under nitrogen atmosphere. Very light colour formation is consistent with a report [ref. 2(*b*)] that it is difficult to remove strongly adsorbed oxygen from Ca Y.

**Transition metals can be used for shaping and electronically enriching the calix[4]arene cavity; in this approach, the π-basic cavities can be adapted to alkali-metal cation complexation in a very hydrophobic environment and these cations can even be transferred into aliphatic hydrocarbons; the η⁶-arene–alkali-metal cation interaction is structurally elucidated.**

Complexation by transition metals[1,2] can be used as a methodology for shaping[2c] and tuning the binding properties of the calix[4]arene cavity.[3] The present report deals with a simple and general strategy for binding alkali-metal cations inside the calix[4]arene cavity. Solvation of the alkali-metal cations by a π-cavity is a quite remarkable phenomenon, in the context of the role played by the cation–π interactions in chemistry and biology.[4] Typically, complexation of alkali-metal cations is achieved using the chemically modified lower rim of calix[4]arenes, thus rendering complexation outside the cavity, using a set of conventional donor atoms.[3c,5–7]

The metallation of calix[4]arene has been achieved using $NbCl_5$ and $TaCl_5$ and the functionalizable dimers **1**‡ and **2** were obtained as analytically pure crystalline solids.

The reaction of **1** and **2** with alkali-metal phenoxides under the conditions briefly specified in Scheme 1 gave complexes **5**–**12**,‡ which can be considered as alkali-metal cation carriers in hydrophobic environments since they are very soluble in aliphatic hydrocarbons. The formation of **5**–**12** proceeds *via* the intermediacy of the monophenoxo derivatives **3** and **4**, as shown in Scheme 1. Attainment of the thf solvated (**5**–**10**) or unsolvated (**11**, **12**) forms of the alkali-metal cation depends on the reaction solvent. Unexpectedly, the desolvation of **6** and **9** to **11** and **12** was quite easy, thus confirming that the major binding effect of the alkali-metal cation is provided by the calix[4]arene oxygens and the arene rings. X-Ray structural information is available for **1**, **3**, **5**, **6**, **9**, **10** and **11**.§ In particular, we found that complexes **6**, **9** and **10** are isostructural. Structural details are reported only for **9** (see Fig. 1).

**Scheme 1** *Reagents and conditions*: i, toluene, reflux; ii, 1 equiv. NaOPh, thf, room temp.; iii, excess of M*OPh, thf; iv, 1 equiv. of **1** in thf or 1 equiv. of **2** in $C_6H_6$; v, 2 equiv. NaOPh, $C_6H_6$, reflux; vi, azeotropic distillation, $C_6H_{14}$; vii, excess of NaOPh, $C_6H_6$; viii, a single thf is bonded to $Li^+$; ix, NaOPh, thf, room temp.

The two independent molecules A and B have an imposed crystallographic *m* symmetry so in the asymmetric unit of each complex there are two halves of crystallographically independent molecules. The mirror plane runs through the metal atoms and the oxygen atoms O(1) and O(3) bisecting the C(1)–C(4) and C(13)–C(16) rings. An alkali-metal cation is accommodated inside the cavity of the complex interacting with two oxygen atoms of the calixarene [O(2), O(2*)]. Two oxygen atoms from thf complete a planar (for symmetry requirements) coordination around the alkali metal.

As a consequence of the six-coordination of the metal, the calixarene ligand assumes a flattened cone conformation with the opposite C(5)···C(11) and C(3′)···C(11′) rings pushed outward and the opposite C(1)···C(4) and C(13)···C(16) rings inward relative to the cavity of the macrocycle. In both molecules A and B the sodium atom was found to be disordered over two positions (Na and Na′) which lie at a mean distance of 2.102(12) and 2.149(14) Å for molecules A and B respectively, from the reference plane. In both molecules, Na can be considered as η⁶-bonded to the C(1)···C(4) ring [Na···C 3.005(17)–3.415(16) Å, $Na^+$···η⁶-arene(centroid), 2.465(17) Å (molecule A) and 2.924(16)–3.231(16) Å (molecule B)]; $Na^+$ can be considered as η³-bonded to atoms C(13), C(16) and C(13*) of the opposite ring [Na′···C 3.001(16)–3.125(14) Å (molecule A) and 3.168(16)–3.289(15) Å (molecule B)]. The

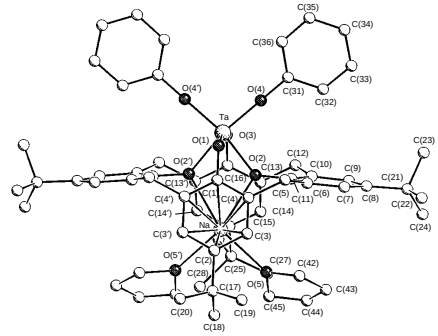

**Fig. 1** A SCHAKAL drawing of complex **6**. Selected interatomic distances (Å) and angles (°): Nb–O(1) 2.015(2), Nb–O(2) 1.969(2), Nb–O(3) 2.016(2), Nb–O(4) 1.975(2), Nb–O(5) 1.901(2), Nb–O(6) 1.896(3), Na–O(1) 2.296(3), Na–O(3) 2.309(3), Na–C(22) 2.975(4), Na–C(23) 3.034(4), Na–C(24) 3.072(4), Na–C(25) 3.047(4), Na–C(26) 2.992(4), Na–C(27) 2.937(4), Na–arene(centroid) 2.666(4); O(5)–Nb–O(6) 98.8(1), O(4)–Nb–O(5) 97.8(1), O(3)–Nb–O(5) 168.2(1), O(3)–Nb–O(4) 83.4(1), O(2)–Nb–O(5) 93.6(1), O(2)–Nb–O(4) 162.7(1), O(2)–Nb–O(3) 82.8(1), O(1)–Nb–O(6) 168.6(1), O(1)–Na–O(3) 65.3(1).

directions of the η bonds are nearly perpendicular to the O(2)O(5)O(2*)O(5*) coordination plane, the dihedral angles between the Na–centroid directions and the normal to the plane are in the range 16.3(2)–17.0(3)°. The sodium atoms are displaced from the coordination plane by 0.440(12) and −0.360(12) Å for Na and Na′ respectively (molecule A) and 0.416(10) and 0.199(14) Å for Na and Na′, respectively (molecule B).

The complexation of alkali-metal cations was achieved by forcing open the calix[4]arene cavity using an appropriate coordination number of the metal.[2c] In the case of **5**–**11**, the negative charge is certainly a determining factor for the binding ability of the cavity. The complexation of the alkali metals by the cavity takes advantage of the cation–π interactions. This has been conveniently revealed by Shinkai *et al.* using mass spectrometry in the case of the alkali-metal cation–calixarene interactions.[8] The structural support for this kind of cation–π interaction comes from the X-ray analyses performed on **5**, **6**, **9**, **10** and **11**. The X-ray analysis revealed, at least in the solid state, how this kind of alkali-metal cation–arene interaction depends on the presence of thf and on the size of the alkali-metal cation. The interaction varies from bis-$\eta^6$-coordination for potassium [$K^+$–$\eta^6$-arene(centroid) 2.742(10), 2.819(10) Å in **10**] to a single $\eta^6$-coordination for sodium [$Na^+$–$\eta^6$-arene(centroid) 2.606(8) Å in **6** and 2.666(4) Å in **11**], to $\eta^3$-coordination for lithium [$Li^+$–$\eta^3$-arene(centroid) 1.98(4) Å in **5**], for the solvated forms of **5**, **6**, **9** and **10**. We should emphasize that, for **11** and **12**, the solvation of the alkali-metal cation is provided mainly by the arene rings. For a comparison of the structural parameters related to alkali-metal cations interacting with aromatic rings we refer to the excellent review by Weiss.[9]

Work is in progress (*i*) to elaborate the strategy for shaping the cavity of calix[4]arene in order to bind organic and inorganic cations inside; (*ii*) to study alkali-metal cation exchange processes; the reaction of **6** with LiCl in thf led, in fact, to the easy displacement of $Na^+$ by $Li^+$ in the cavity; (*iii*) to use these compounds as alkali-metal cation carriers in hydrocarbon media, the calix[4]arene cavity being a very hydrophobic environment.

We thank the Fonds National Suisse de la Recherche Scientifique (Grant No. 20-40268.94) and Ciba-Geigy SA (Basel, Switzerland) for financial support.

## Footnotes

† E-mail: carlo.floriani@icma.unil.ch

‡ *Syntheses*: **1**: $NbCl_5$ (11.065 g, 41.0 mmol) was added to a suspension of calix[4]arene ($H_4L$) (26.58 g, 41.0 mmol) in toluene (200 $cm^3$) and the reaction mixture was refluxed for 14 h. The solvent was removed *in vacuo*, the red residue washed with toluene (150 $cm^3$), and collected (93%). Crystals suitable for X-ray analysis were grown from a saturated thf solution.

**9**: NaOPh (1.22 g, 10.5 mmol) was added to a suspension of $[TaL(Cl)]_2{\cdot}2CH_2Cl_2$ (4.66 g, 2.4 mmol) in thf (100 $cm^3$). The reaction mixture was stirred at room temp. for 12 h, then refluxed for 6 h to give a white suspension. The solid was collected and extracted with the mother-liquors for 30 h. Volatiles were removed *in vacuo* and the solid residue was washed with *n*-hexane (100 $cm^3$), collected and dried *in vacuo* (88%).

**11**: NaOPh (0.91 g, 7.84 mmol) was added to a suspension of **1** (3.32 g, 3.81 mmol) in benzene (150 $cm^3$). The reaction mixture was refluxed for 12 h and the red suspension became a yellow solution. The solvent was removed *in vacuo* and fresh benzene (200 $cm^3$) was added. The mixture was filtered twice, the solvent was concentrated to 10 $cm^3$, and *n*-hexane (200 $cm^3$) was added. Upon concentration of this solution, a yellow solid precipitated and was collected and dried *in vacuo* (77%). Crystal suitable for X-ray analysis were grown by slowly cooling a saturated toluene–hexane solution to 9 °C.

# Activity of carbonaceous deposits in the selective reduction of nitrogen oxides

**Jan Connerton, Richard W. Joyner* and Michael Stockenhuber**

*The Catalysis Research Laboratory, The Nottingham Trent University, Clifton Lane, Nottingham, UK NG11 8NS*

**Carbonaceous deposits, formed on the catalyst Cu/ZSM-5 by interaction at low temperature with propene, NO and oxygen, are characterised spectroscopically and shown to be able to carry out the selective catalytic reduction of NO; rates of reaction, which follow simple kinetics, are lower than in the absence of pre-deposited coke, and the results suggest an inverse correlation between catalyst Brønsted acidity and activity in $NO_x$ reduction.**

The selective reduction of nitrogen oxides by hydrocarbons in the presence of oxygen, using for example Cu/ZSM-5 catalysts, continues to attract attention.[1–5] Much interest now centres on the nature of the nitrogen-containing functionality in the reaction, with spectroscopic support emerging both for oxidised nitrogenous species such as nitro groups,[6,7] and also for reduced species, particularly cyanides.[7–12] Less attention has been paid to the characterisation of the hydrocarbon moieties which must be involved, although it is recognised that long-lived carbonaceous species can be formed within the pores of the zeolite, with possible mechanistic importance, as discussed by ourselves and others.[7,13] Here, we report on the nature and reactivity of hydrocarbon species deliberately deposited on Cu/ZSM-5 catalysts with different metal contents. We have previously shown that nitrogen is released from these deposits by reaction with oxygen[7] and now show that the deposits are also able to activate $NO_x$ directly. The reactivity of the coke towards $NO_x$ is also compared to the steady-state performance of these catalysts.

Catalysts have been prepared from H-ZSM-5 (Si/Al ratio 25) as described previously,[3] using conventional ion-exchange techniques. A range of catalysts from 50 to 130% nominal degree of exchange has been examined. Catalyst performance has been tested in a simple flow-through microreactor, equipped with a chemiluminescent analyser for nitrogen oxides (NOx Box, Signal Instruments Model 4000), and a gas chromatograph. Steady-state reaction conditions comprised 2% oxygen, 1200 ppm propene, 2000 ppm NO, balance helium and GHSV = 30 000 $h^{-1}$; the catalysts were initially activated by heating at 773 K for 1 h in 2% oxygen in helium. IR spectroscopy measurements were carried out in transmission mode using a specially constructed *in situ* vacuum cell which can be heated to > 800 K, and an ATI RS1 Fourier transform spectrometer.

Before studying the behaviour of deposited coke, the steady-state performance of the catalysts was measured, starting at 773 K and gradually reducing the temperature. As in our earlier study,[7] coke was then deposited by exposing the catalyst of interest to the reaction mixture at 473 or 573 K. The IR spectrum of the deposit on a 54% copper exchanged catalyst is shown in Fig. 1. The bands at 2879, 2937 and 2971 $cm^{-1}$ are typical of hydrocarbons adsorbed on acidic zeolites such as H-ZSM-5 and are due to C–H stretching vibrations. It is important to note that the band characteristic of the zeolite's Brønsted acidity (normally observed at *ca*. 3607 $cm^{-1}$) has been suppressed, indicating that these sites have played their expected role in hydrocarbon activation. The intense band at *ca*. 1600 $cm^{-1}$ is assigned to C=C stretching vibrations in adsorbed aromatic molecules, and is characteristic of hydrocarbon deposits on zeolites.[9] It is superimposed on an overtone band associated with the zeolite lattice vibrations. The other important features of the spectrum are the band at 2250 $cm^{-1}$, which it is now accepted is due to cyanide species,[10–12] and bands at 3300 and 3375 $cm^{-1}$. These are nitrogen–hydrogen stretches which probably reflect the presence both of =NH and $–NH_2$ groups, which have not been reported before in this system. Their observation provides important evidence that the organic nitro groups, which are formed first in the sequence of reactions leading to release of nitrogen,[5] can undergo sequential reduction to cyanide [eqn. (1)].

$$–NO_2 \rightarrow –NH–OH \rightarrow –NH_2 \rightarrow =NH \rightarrow \equiv N \qquad (1)$$

The zeolite is unable to activate oxygen at the relatively low temperatures where the hydrocarbon deposit is formed. Coupled with the presence of readily activated propene, the result is an atmosphere which is more strongly reducing than is the case where steady-state reactivity is high, and where the reduction sequence may not progress as far as cyanide.[5]

The reactivity of the carbonaceous deposit in NO reduction in the absence of other hydrocarbons has been studied by exposing it to the same NO–oxygen concentration as was used for steady-state reaction, and heating from 473 to *ca*. 920 K at 10 K $min^{-1}$. The results of experiments with two different catalysts are shown in Fig. 2, which show the instantaneous concentration of $NO_x$ ($NO + NO_2/N_2O_4$) at the reactor exit. In each case the deposit on the catalyst shows significant activity in $NO_x$ reduction, but the maximum of activity for the catalyst with 100% copper exchange occurs at *ca*. 100 K lower temperature than for the catalyst with only 54% exchange. The amount of $NO_x$ converted in each case is, however, rather similar, corresponding to *ca*. 25 mg NO (g catalyst)$^{-1}$. This is the same order of magnitude as that measured for deposited coke in our earlier study,[7] where 30 mg $g^{-1}$ of coke was formed on an overexchanged catalyst tested at 10 000 $h^{-1}$ GHSV. The kinetics of reaction between $NO_x$, oxygen and the carbonaceous deposits can be simply described. Fig. 2 also shows rates of reaction calculated by assuming first-order behaviour in both NO and hydrocarbon concentration, and zero order of reaction in oxygen (which is present in substantial excess throughout). There is very good agreement with experiment for such a simple model, particularly when it is realised that $NO_2$ is a reaction

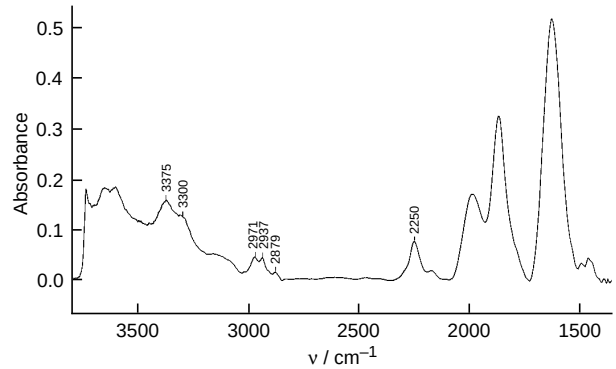

**Fig. 1** IR spectrum of the carbonaceous deposit on a 54% Cu-exchanged catalyst; frequencies of bands discussed in the text are marked

intermediate.[5] In line with the changes in activity, the apparent activation energy of the reaction decreases from *ca*. 92 to 82 kJ mol$^{-1}$ as the copper content of the zeolite is increased.

These results suggest that the presence of too many Brønsted zeolite acid sites inhibits the $NO_x$ reduction reaction. It is known that relatively few Brønsted sites remain in the so-called 'overexchanged' catalysts which are the most active for $NO_x$ reduction.[14] The present study shows that when the catalyst is pre-treated at low temperature in a way that allows the acid sites to have maximum influence in hydrocarbon activation, the result is to produce a hydrocarbonaceous deposit which is of lower activity in $NO_x$ reduction at low temperature than that formed at steady state. Comparison of Fig. 1 with our earlier steady-state results (ref. 3, Fig. 1) shows that the steady-state process occurs more quickly at temperatures up to *ca*. 720 K. Equally, the deposit produced on the catalyst with lower copper content, and therefore higher residual Brønsted acidity, is even less active in NO reduction. There is thus an inverse correlation between Brønsted acidity and catalyst performance. It is still not clear whether the small amount of residual Brønsted acidity which remains in the most active Cu/ZSM-5 catalysts is necessary for the reaction to occur, since it is possible that the Lewis acidity associated with the $Cu^{I}$ sites[14] is sufficient to activate the hydrocarbon species.

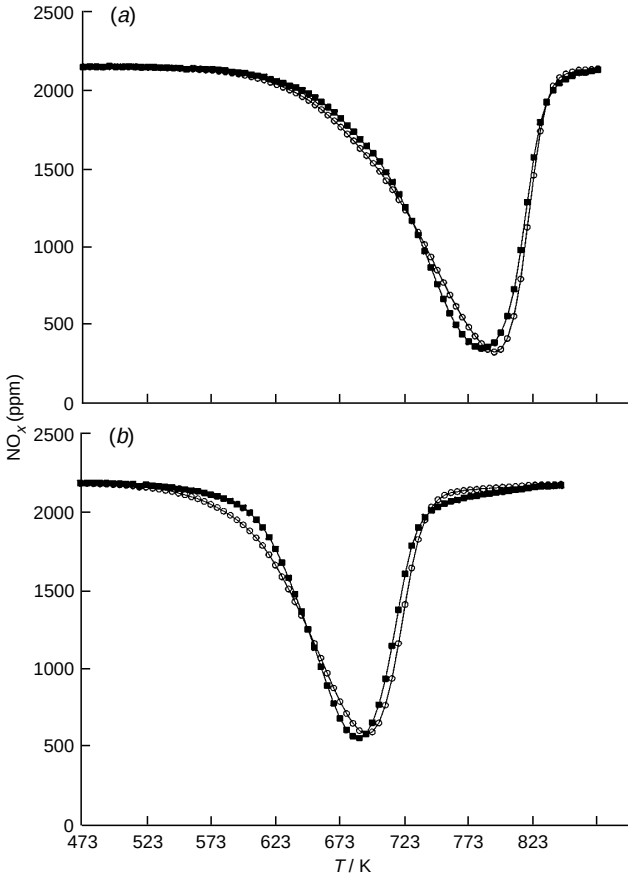

**Fig. 2** (*a*) Observed and calculated $NO_x$ concentration observed during heating at 10 K min$^{-1}$ in NO–oxygen, after the formation of hydrocarbon deposits at 473 K on a 54% Cu-exchanged catalyst as described in the text. (■) Experimental, (○) calculated using the simple model described in the text. (*b*) As (*a*), but for a 100% Cu-exchanged catalyst.

We have had many useful discussions related to this with work with Dr Olga Tkachenko and the late Professor Efim Shpiro, of the Zelinsky Institute of Organic Chemistry, Moscow, and with Drs J. C. Frost, A. Diwell, A. P. Walker and colleagues, of Johnson Matthey Technology Centre. We thank Professor J. A. Lercher for the design of the *in situ* cell for IR spectroscopy developed in his research group. We are grateful to Johnson Matthey PLC for financial support and some analytical assistance, and to EPSRC for financial support.

# Synthesis, molecular structure and NMR spectroscopy of a transition-metal bifluoride complex: formation *via* C–F activation or reaction with $Et_3N{\cdot}3HF$

**Michael K. Whittlesey, Robin N. Perutz,* Bryan Greener and Madeleine H. Moore**

*Department of Chemistry, University of York, York, UK YO1 5DD*

**The bifluoride complex, *trans*-[Ru(dmpe)$_2$(H)(HF$_2$)] (dmpe = Me$_2$PCH$_2$CH$_2$PMe$_2$), is generated by reaction of *cis*-[Ru(dmpe)$_2$H$_2$] either with fluoroarenes (C$_6$F$_6$, C$_6$F$_5$H and others) or by reaction with Et$_3$N·3HF; its solid-state structure, established crystallographically, reveals a Ru(η$^1$-FHF) moiety with a long Ru–F bond and an F···F distance close to that in bifluoride salts, while the presence of the same complex in solution is shown by low-temperature NMR spectra.**

The C–F activation of hexafluorobenzene with transition-metal complexes may take two forms. Simple oxidative addition yields a metal pentafluorophenyl fluoride.[1,2] In a more puzzling process, several metal hydride complexes yield pentafluorophenyl hydride complexes.[2,3] A strong thermodynamic drive for this reaction is provided by the release of hydrogen fluoride, although its fate has not been determined.[4] We show here that the HF can be trapped as a complex of bifluoride, HF$_2$, which can also be accessed by reaction with a mild source of HF, Et$_3$N·3HF.[5] We have been prompted to publish at this stage by the recent report of [Mo(PMe$_3$)$_4$(H)$_2$F(HF$_2$)].[6]

We demonstrated earlier that the reaction of *cis*-[Ru(dmpe)$_2$-H$_2$] **1** (dmpe = Me$_2$PCH$_2$CH$_2$PMe$_2$) with C$_6$F$_6$ at −78 °C generates *trans*-[Ru(dmpe)$_2$(C$_6$F$_5$)H]. Reactions with partially fluorinated arenes yield analogues also arising from C–F activation.[3] In all these reactions, we noted the formation of a second hydride containing species, **2**, which is the subject of this paper. The $^1$H NMR spectrum (293 K) of **2** formed in the reaction of **1** with a twofold excess of C$_6$F$_n$H$_{6-n}$ (*n* = 6, 5, 4, 3) includes two broad singlet resonances at δ 13.8 and −25.8 in [$^2$H$_8$]thf. It is present in a ratio of *ca.*, 1:2 relative to the fluoroaryl hydrides. The $^{31}$P{$^1$H} spectrum shows a broad singlet; there are no resonances in the $^{19}$F NMR spectrum. Although the spectra of **2** were unaffected by running the reaction in an FEP-lined NMR tube, the formation of **2** was completely suppressed by triethylamine (fivefold excess). These observations suggested that **2** is *trans*-[Ru(dmpe)$_2$-(H)(HF$_2$)] formed from the HF released in the C–F activation reactions. A higher yield route to **2** was provided by the reaction of **1** with triethylamine trihydrofluoride.[7] Amine·HF adducts, R$_3$N·*x*HF, represent mild sources of HF which can be handled in solution without special precautions, and which have been employed to synthesise fluoride complexes.[8]

On addition of Et$_3$N·3HF to **1** (< 1 mol Et$_3$N·3HF per mol of **1**, both reagents dissolved in thf) at room temperature, **2** is formed. Although NMR spectra recorded at 293 K suggest that **2** is the single ruthenium-containing product, low-temperature spectra of recrystallised **2** resolve into two sets of resonances. The major species is indeed identified as *trans*-[Ru-(dmpe)$_2$(H)(HF$_2$)] from the full coupling pattern of $^1$H, $^{31}$P and $^{19}$F spectra (Fig. 1, 2).† The NMR spectra are unaffected by heating to 330 K and recooling to *ca.* 200 K. The IR spectrum of **2** (Nujol mull) shows a broad band for the bifluoride ligand at 1690 cm$^{-1}$, in the range reported for bifluoride ion salts.[9]

A suitable single crystal of **2** was obtained by slow evaporation of a thf solution. The structure determined by X-ray crystallography (Fig. 3)‡ showed a bifluoride group, F–H–F, coordinated to ruthenium and lying *trans* to the hydride ligand. The bifluoride bisects the two chelating dmpe groups and is tilted to give a Ru–F···F bond angle of 129.9(3)°. The F···F distance of 2.276(8) Å is very close to that found in bifluoride salts, MHF$_2$ (M = Na, K, NH$_4^+$),[9] or in pyridine·*n*HF,[10] and is significantly shorter (9 e.s.d.s) than the F···F separation of 2.351(8) Å found in [Mo(PMe$_3$)$_4$(H)$_2$F(HF$_2$)].[6] The Ru–F bond length [2.284(5) Å] is longer than in any conventional ruthenium–fluoride complexes (2.01–2.04 Å).[11] Indeed, **2** is a rare example of a complex containing M–H and M–F bonds, and is unique in the octahedral stereochemistry of hydride *trans* to fluorine.[12] Formation of platinum bifluoride complexes in solution has been suggested from $^1$H NMR data.[13] A crystal structure of a niobium dimer with two η$^2$-HF$_2$ groups has been reported but without evidence for this species in solution.[14] The molybdenum bifluoride complex[6] dissociates completely into [Mo(PMe$_3$)$_4$(H)$_2$F$_2$] and HF in solution.

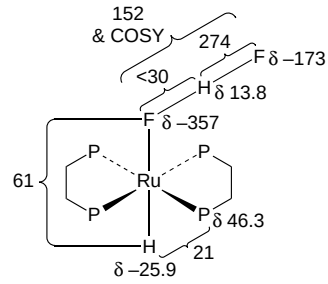

**Fig. 1** Coupling pattern (Hz) and chemical shifts in the low-temperature NMR spectra of *trans*-[Ru(dmpe)$_2$(H)(HF$_2$)] **2**

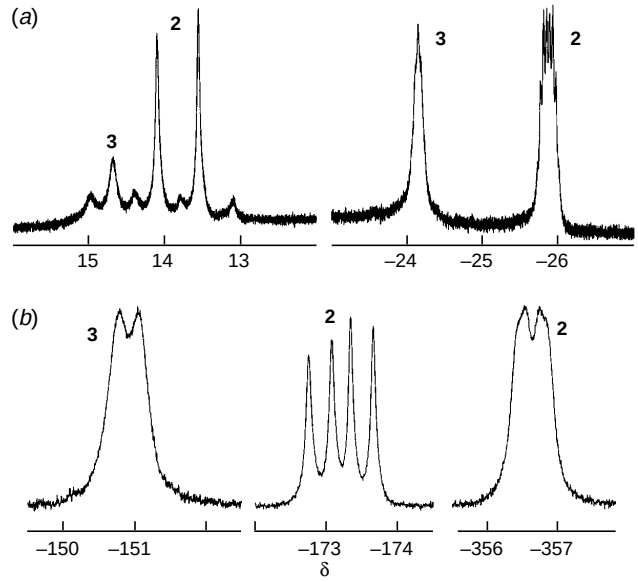

**Fig. 2** (*a*) $^1$H NMR spectrum (500 MHz) of bifluoride and hydride regions of recrystallised **2** in [$^2$H$_8$]thf at 188 K showing the presence of **2** and **3**. (*b*) $^{19}$F NMR spectrum (470 MHz) showing the bifluoride and metal–fluoride regions. The spectra in (*a*) and (*b*) are shown on a common scale in Hz cm$^{-1}$.

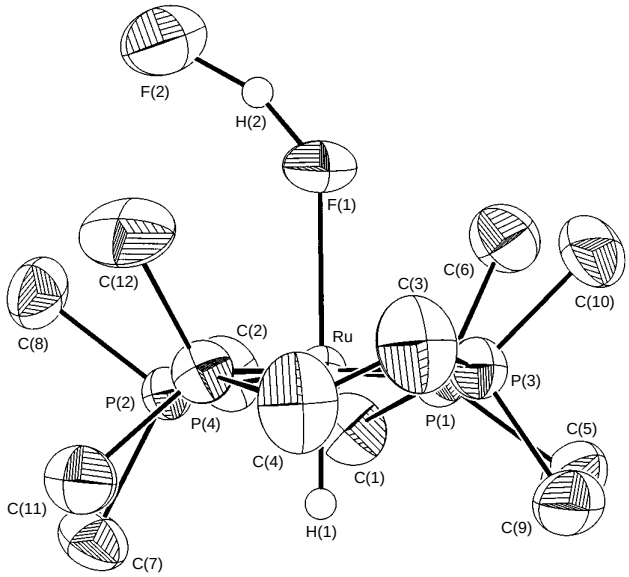

**Fig. 3** ORTEP diagram of the molecular structure of **2** (ellipsoids at 50% level). Principal bond lengths (Å), angles and torsional angles (°): Ru–F(1) 2.284(5), F(1)–F(2) 2.276(8), F(2)–F(1)–Ru 129.9(3), F(2)– F(1)–Ru–P(1) 114.9(4), F(2)–F(1)–Ru–P(2) 31.0(4).

The second species, **3**, observed at 188 K, shows a triplet resonance at δ 14.8 (*J* 145 Hz) in the $^1$H NMR spectrum [Fig. 2(*a*)] and a broad doublet resonance at δ −150.9 [Fig. 2(*b*)] in the $^{19}$F NMR spectrum consistent with the $HF_2^-$ anion.[15] It is identified provisionally as [Ru(dmpe)$_2$-H$^+$][$HF_2^-$].[16]§

A sequence for the formation of the bifluoride hydride that involves an intermediate dihydrogen hydride complex is shown in eqns. (1) and (2) {[Ru] = Ru(dmpe)$_2$}:

$$[Ru]H_2 + HF \longrightarrow [Ru](\eta^2\text{-}H_2)H^+F^- \quad (1)$$

$$[Ru](\eta^2\text{-}H_2)H^+F^- + HF \longrightarrow [Ru](H)(HF_2) + H_2 \quad (2)$$

The HF originates either in $Et_3N{\cdot}3HF$ or in reaction of **1** with fluoroarenes. These experiments show that the bifluoride group, $HF_2$, can be generated in an aprotic organic solvent under mild conditions. The fate of expelled HF in our C–F activation reactions is explained. Taken together with the molybdenum results[6] we may anticipate further bifluoride complexes with the hydrogen atom occupying a range of positions between the two fluorine atoms,¶ which may be probed *via* the values of $J_{HF}$. Our synthetic methods offer new routes to combination of hard and soft ligands as exemplified by *trans*-[Ru(dmpe)$_2$(OH)H], a complex closely related to **2**.[17] The exchange processes in **2** involving coordinated and free bifluoride are under investigation.

We acknowledge financial support from EPSRC and the loan of ruthenium from Johnson Matthey. We wish to thank Drs S. B. Duckett, O. Eisenstein, E. G. Hope and M. G. Partridge and Miss C. L. Higgitt for help and advice.

## Footnotes

† *Spectroscopic data* for *trans*-[Ru(dmpe)$_2$(H)(HF$_2$)], **2**: NMR {500 MHz, [$^2$H$_8$]thf, 188 K}: $^1$H δ −25.86 (dqnt, $^2J_{PH}$ 20.5, $^2J_{FH}$ 61.3 Hz, 1 H, Ru–H), 1.50 (s, 12 H, 4 × CH$_3$), 1.53 (s, 12 H, 4 × CH$_3$), 1.70 (br s, 4 H, 4 × PCH*H*), 1.92 (br s, 4 H, 4 × PC*H*H), 13.83 (d, $^1J_{HF}$ 273.9 Hz, 1 H, HF$_2$). $^{31}$P{$^1$H} δ 46.3(s). $^{19}$F δ −173.1 (dd, $^1J_{HF}$ 273.9, $^2J_{FF}$ 151.5 Hz, 1 F, Ru–F–H–*F*), −356.8 (br d, $^2J_{FF}$ 151.5 Hz, 1 F, Ru–*F*). IR (Nujol): 1690 cm$^{-1}$ ν(HF$_2$). FABMS, *m/z* 403 [Ru(dmpe)$_2$H]$^+$. The C, H analysis fitted [Ru(dmpe)$_2$(H)(F)], probably because of HF loss in the furnace.

‡ *Crystal data* for *trans*-[Ru(dmpe)$_2$(H)(HF$_2$)] **2**: 0.7 × 0.6 × 0.3 mm, $C_{12}H_{34}F_2P_4Ru$, *M* = 441.34, monoclinic, space group $P2_1$, *a* = 9.269(7), *b* = 11.848(8), *c* = 10.126(7) Å, β = 114.40(6)°, *U* = 1012.7(12) Å$^3$, *F*(000) = 456, $D_c$ = 1.447 Mg m$^{-3}$, *Z* = 2, λ(Mo-Kα) = 0.710 69 Å, μ = 1.095 mm$^{-1}$, $R_1[I > 2\sigma(I)]$ = 0.0305, $wR_2$ = 0.0831, GOF = 0.761, *T* = 293 K, 1873 unique reflections out of 1996 reflections measured. Diffractometer: Rigaku AFC6S, 2θ range 5–50°. After initial solution with the TEXSAN software package[18] by direct methods, SHELXL-93[19] was employed for full-matrix least-squares refinement. The hydride hydrogen atom and the bifluoride hydrogen atom were located from the difference map and refined isotropically. While the location of the hydride was unambiguous, that of the bifluoride hydrogen atom was not. All other hydrogen atoms were refined with a 'riding' model. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to CCDC for this material should quote the full literature citation and reference number 183/328.

§ *NMR data* for [Ru(dmpe)$_2$H]$^+$ **3**: NMR {500 MHz, [$^2$H$_8$]thf, 188 K}: $^1$H δ −24.14 (br qnt $^2J_{PH}$ 20.4 Hz, 1 H, Ru–H), (1.00 br s, (4 H, 4 × PCH*H*), 1.46 (s 12 H, 4 × CH$_3$), 1.57 (s 12 H, 4 × CH$_3$), 2.07 (br s, 4 H, 4 × PC*H*H). $^{31}$P{$^1$H} δ 44.5(s). The spectrum in toluene shows very similar chemical shifts and intensity ratio for **2** and **3**, indicating that **3** is not a solvent adduct.

¶ Preliminary effective core potential *ab initio* calculations by F. Maseras and O. Eisenstein confirm the stability of HF bound to *trans*-[Ru(PH$_3$)$_4$(H)F]. They reproduce the F···F and Ru–F distances satisfactorily and place the bifluoride hydrogen 0.25 Å closer to F(2) than F(1) in agreement with the NMR data.

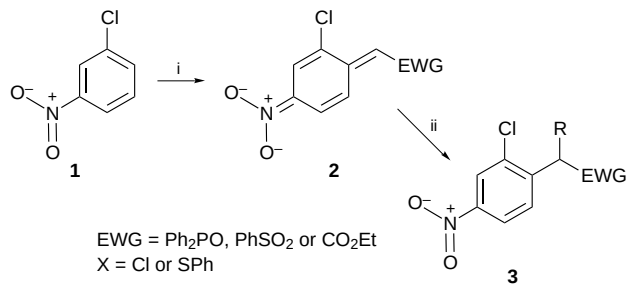
# Asymmetric aromatic vicarious nucleophilic substitution of hydrogen

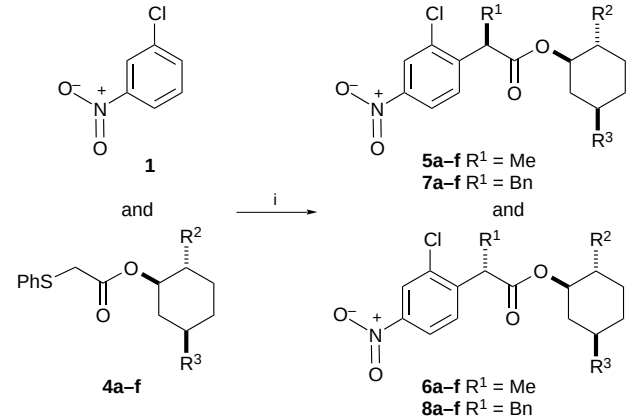
**Mark D. Drew,[a] David A. Jackson,[b] Nicholas J. Lawrence,*[a] John Liddle[a] and Robin G. Pritchard[a]**

[a] *Chemistry Department, University of Manchester Institute of Science and Technology, Manchester, UK M60 1QD*
[b] *ZENECA Process Technology Department, Huddersfield Works, PO Box A38, Leeds Road, Huddersfield, UK HD2 1FF*



**A series of novel one-pot aromatic vicarious nucleophilic substitution of hydrogen/asymmetric alkylation reactions are described; the enolates of several chiral cyclohexyl phenylsulfanylacetates react readily with 3-chloronitrobenzene followed by subsequent stereoselective alkylation.**

The aromatic vicarious nucleophilic substitution[1,2] (VNS) of hydrogen provides a useful route to substituted arenes not readily prepared by electrophilic substitution. We recently reported[3,4] that the anion **2**, the initial product of the reaction between a nitrobenzene and a vicarious nucleophile, can be quenched with a variety of electrophiles (**1** → **3**, Scheme 1). It was clear to us that the relative and absolute stereochemical configuration of the newly created stereogenic centre might be controlled by an appropriate auxiliary incorporated into the nucleophile. Here we report an unprecedented asymmetric variant of this type of one-pot VNS–alkylation reaction which enables the stereocontrolled synthesis of a stereocentre adjacent to an electron deficient aryl group.



We chose to study the VNS reactions of a series of chiral esters **4a**–**f**. Menthol proved to be a poor auxiliary; reaction of the phenylsulfanylacetate **4a** with **1** followed by benzylation gave a 1 : 1 mixture of diastereoisomers in 60% yield. However the VNS–alkylation reaction of phenylsulfanylacetate **4b** derived from (−)-8-phenylmenthol[5] was much more successful. The enolate of **4b** reacted cleanly with 3-chloronitrobenzene **1** in DMF, with substitution taking place solely in the *para* position. Quenching the reaction mixture at −65 °C with a series of alkylating reagents gave moderate to good stereoselectivity.†,‡ Quenching with methyl iodide generated the corresponding diastereoisomeric esters **5b** and **6b** in a ratio of 3 : 1, in good yield. Benzylation proved to be the most diastereoselective reaction, giving the two α-benzylated diastereoisomers **7b** and **8b** in a ratio of 8 : 1 (Scheme 2, Table 1).

*trans*-2-Phenylcyclohexan-1-ol[6] has been extensively used in a wide variety of asymmetric reactions and is often used in place of (−)-8-phenylmenthol, since both enantiomeric forms are available by a variety of methods, most notably *via* asymmetric hydroboration[7] or dihydroxylation–reduction[8] of 1-phenylcylohexene. We therefore decided to apply this auxiliary to our VNS–asymmetric alkylation reaction. The enolate of (−)-*trans*-2-phenylcyclohexyl phenylsulfanylacetate **4c** reacted cleanly with 3-chloronitrobenzene, however no stereoselectivity was obtained upon methylation, while only a poor 2 : 1 diastereoselectivity was observed upon benzylation. We next tested the sterically more demanding esters phenylsulfanylacetates **4d**–**f** prepared from (±)-*trans*-2-biphenyl-, (±)-*trans*-2-(1′-naphthyl)- and (±)-*trans*-2-(2′-naphthyl)cyclohexan-1-ol, which are available *via* cuprate ring-opening of cyclohexene oxide.[9] The alcohols were converted to the phenylsulfanylacetates, reacted with 3-chloronitrobenzene under typical VNS conditions, and quenched with methyl iodide and benzyl bromide at −65 °C.§ The *trans*-2-(2′-naphthyl)cyclohex-1-yl group proved to be the most effective auxiliary, giving a 3 : 1 mixture of diastereoisomers **5f** and **6f** upon methylation and a 4 : 1 mixture of **7f** and **8f** upon benzylation.

Fortunately both products of the VNS reaction of (±)-*trans*-2-(2′-naphthyl)cyclohexyl phenylsulfanylacetate **4f** were crystalline; X-ray crystallography showed the major isomer **7f** to be the (1*RS*,2*SR*,α*RS*) diastereoisomer (Fig. 1).¶,‖ Since both

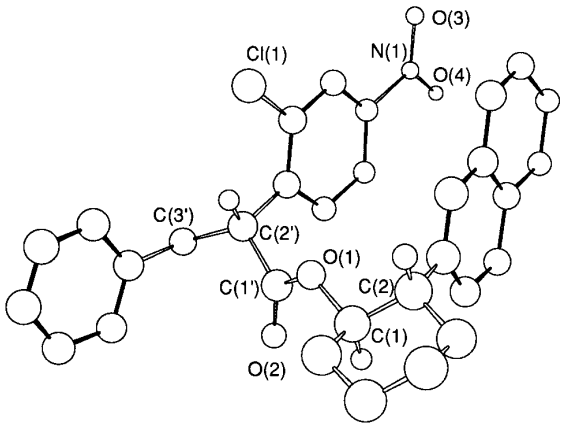
[a] Measured by $^1H$ NMR (300 MHz) analysis of the crude reaction mixture. [b] Similar selectivity was obtained when (−)-**4f** was used. [c] Yields shown in parentheses. The relative stereochemistry of the major diastereoisomer is assigned by analogy to **7b** and **7f**.



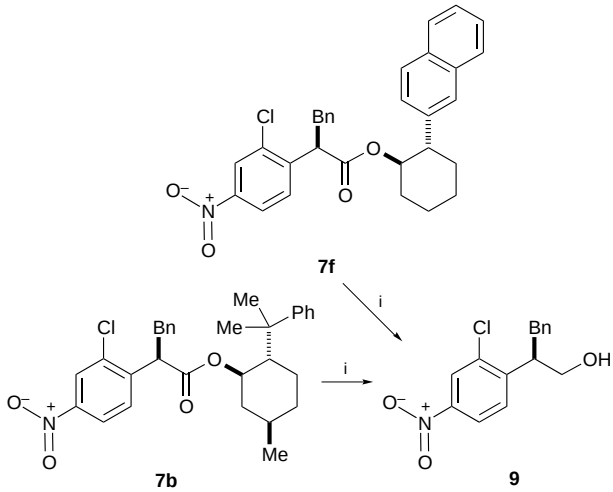


**Fig. 1** X-Ray crystal structure of the diastereoisomer **7f**

**Scheme 3** *Reagents and conditions*: i, DIBALH (2.1 equiv.), THF, room temp.

products **7b** and **8b** from the (−)-8-phenylmenthol derived VNS nucleophile **4b** were oils the alcohol **9**, obtained from DIBALH reduction of **5b**, was compared with that similarly obtained from (−)-*trans*-2-(2′-naphthyl)cyclohexyl phenylsulfanylacetate **4f** (Scheme 3). Enantiomerically pure (−)-*trans*-2-(2′-naphthyl)cyclohexan-1-ol was prepared from 1-(2′-naphthyl)cyclohexene using Sharpless's procedure.[10] The alcohols **9** derived from the two auxiliaries had the same sign of rotation, $[\alpha]_D$ − 36.4 (from **7f**) and $[\alpha]_D$ − 38.2 (from **7b**),** confirming that configuration of the newly created chiral centre in **7b** was also (*R*). It is interesting to note that the sense of stereochemical induction is the same as that reported for the alkylation of the enolate of 8-phenylmenthyl phenylacetate generated by deprotonation with butyllithium.[11]

We thank the EPSRC (CASE award to J. L.) and ZENECA for financial support.

## Footnotes

† Diastereoselectivity was determined by $^1$H NMR spectroscopy (300 MHz). All compounds were fully characterised and gave the expected spectral and analytical data.

‡ *Typical procedure*: To a nitrogen flushed slurry of sodium hydride (2.0 mmol) in dry DMF (3 cm$^3$) at 0 °C was added dropwise a mixture of phenylsulfanylacetate **4** (1 mmol) and 3-chloronitrobenzene (1.1 mmol) in dry DMF (3 cm$^3$). The mixture was allowed to reach room temperature over 2 h then cooled to −65 °C. The alkyl halide (1.0 mmol) was added and the reaction left to reach room temperature. The mixture was poured into dilute hydrochloric acid (20 ml) and extracted with chloroform (3 × 20 cm$^3$). The combined extracts were washed with distilled water, dried (magnesium sulfate) and concentrated *in vacuo*. The diastereoisomeric mixture of esters was separated by chromatography (silica, 1 : 1 chloroform–hexane, v/v).

§ *Selected data* for **7f**: $[\alpha]_D$ −71 (*c* 0.5, $CHCl_3$); $R_f$ 0.45 (silica, 1 : 1, chloroform–hexane, *v/v*); mp 89–91 °C. **Combined crystallographic and IR spectroscopic study of the hydrogen bond network in the synthetic sex steroid mestranol indicates that a C≡C–H···O hydrogen bond can be considerably enhanced if the C≡C–H donor simultaneously accepts an O–H···C≡C interaction.**

It is well known that in arrays of conventional hydrogen bonds such as O–H···O and N–H···O, the strengths of the individual constituents are enhanced by cooperativity effects. Best known is σ-bond cooperativity in chains such as $O^{\delta-}$–$H^{\delta+}\cdots O^{\delta-}$–$H^{\delta+}\cdots O^{\delta-}$–H, where the individual hydrogen bonds enhance each other's strengths by mutual polarisation of the O–H groups.[1] A current topic of hydrogen bond research is directional interactions of the types C–H···Y[2] and X–H··π.[3] In crystal structures, these types of weak hydrogen bonds are often found interconnected with 'normal' or other weak hydrogen bonds, forming motifs that are topologically analogous with conventional hydrogen bond patterns. Several authors have taken this as a manifestation of cooperativity phenomena,[4] although structural analogy alone does not prove such an effect. There are conflicting views that suggest that weak hydrogen bonds are additive in nature, similar to van der Waals contacts.

Here we present a combined structural and spectroscopic study of the crystalline synthetic sex steroid mestranol **1**, which contains a remarkable system of interconnected conventional and non-conventional hydrogen bonds.

The crystal structure† of **1** contains two symmetry-independent molecules of virtually identical conformation‡ (Fig. 1), but which have different intermolecular contacts. A section of the crystal packing is shown in Fig. 2. Symmetry-independent molecules A and B are arranged in a head-to-head fashion, with their hydroxy and ethynyl groups forming a two-dimensional hydrogen bond network. This system of intermolecular interactons is shown in detail in Fig. 3 [only the HC≡C–C(17)–OH moieties are drawn]; geometric data is given in Table 1. The two symmetry-independent ethynyl groups donate antiparallel C≡C–H···O hydrogen bonds of very similar geometries, with C···O separations differing by only 0.035 Å (Table 1). However, these two C≡C–H···O hydrogen bonds have completely different functions in the hydrogen bond array: C≡C(A)–H simultaneously accepts an O–H···π hydrogen bond, and is thereby part of an infinite chain O(B)–H···C≡C(A)–H···O(A′)–H···O(B′)–H *etc.*, for which cooperativity enhancement might be suggested for all participating hydrogen bonds. The other ethynyl residue forms only the isolated hydrogen bond C≡C(B)–H···O(B)–H.

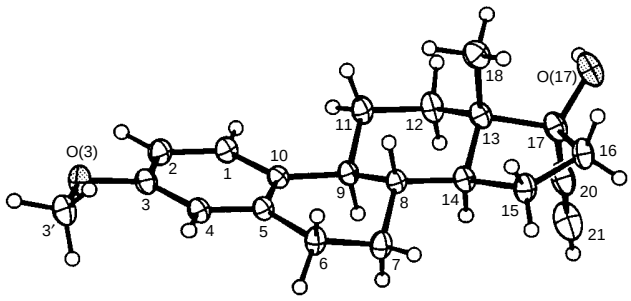

**Fig. 1** Molecular structure and atomic numbering scheme of **1**, molecule A. Oxygen atoms are shaded. Displacement ellipsoids are drawn at the 30% probability level.

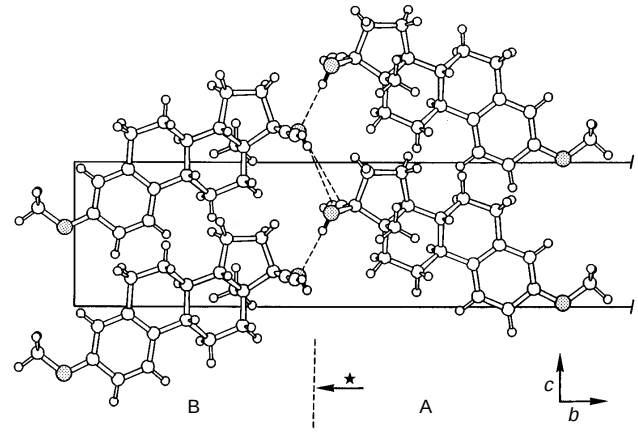

**Fig. 2** Section around $y/b = 1/4$ of the crystal packing. Oxygen atoms are shaded. The arrow marked by a star indicates the projection of Fig. 3.

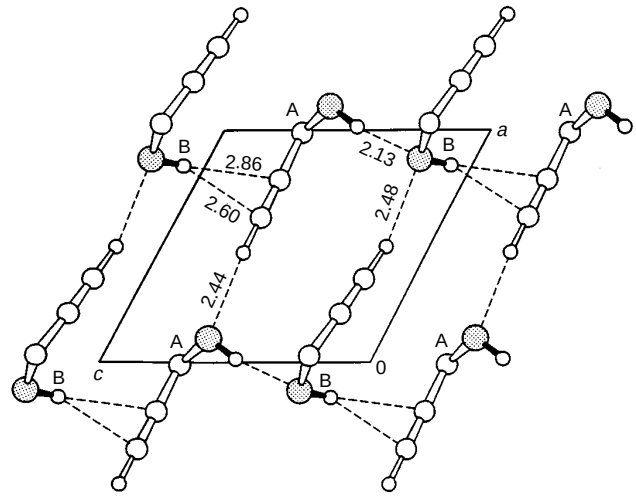

**Fig. 3** Hydrogen bond pattern in a projection perpendicular to Fig. 2. Oxygen atoms are shaded. Normalised H-positions are shown.

The infrared spectra were recorded§ for crystals and a dilute solution of **1** in $CCl_4$ (Table 2 and Fig. 4). As is to be expected, the spectrum shows two distinct O–H and two ≡C–H absorption bands present in the crystal phase, corresponding to the two symmetry-independent molecules. Of the two O–H bands, one is quite narrow and red-shifted by $-90.7$ cm$^{-1}$ compared to the 'free' O–H group in $CCl_4$ solution. This is typical for O–H···π hydrogen bonding, and the band is assigned to O(B)–H. The other O–H absorption band is significantly broader and more intense, and is therefore assigned to the conventionally hydrogen bonding O(A)–H. The two ≡C–H bands are shifted by $-21.3$ and $-59.8$ cm$^{-1}$ compared to free ethynyl groups, both values being indicative of C–H···O hydrogen bonding. Since these two red shifts differ by almost a factor of three, the two C≡C–H···O hydrogen bonds in the crystal must be markedly different despite their similar donor–acceptor separations.

The two C≡C–H···O interactions are formed by chemically identical groups; therefore, the large difference in the corresponding $\nu_{\equiv C-H}$ shifts can only be due to differences in the intermolecular environment. It is straightforward to suggest that the C–H···O interaction in the infinite chain is the stronger one, because it is donated by an ethynyl group which simultaneously accepts an O–H···π interaction. Therefore, the strongly shifted band is assigned to residue A, and the weakly shifted band to residue **B**; the difference is interpreted as a direct consequence of the cooperative effect.¶ This is compatible with spectroscopic investigations on 2-ethynyladamantan-2-ol,[5] where an unusually large $\nu_{\equiv C-H}$ red shift was found for a O–H···C≡C–H···O coupled system; that system, however, contains no non-cooperative C–H···O bonds for comparison.[4c]

These observations show conclusively that C–H···O interactions can be strongly influenced by their environment. The structural and spectral data for **1** are incompatible with the view that C–H···O and X–H·π interactions are too subtle to experience or to generate significant non-additivity effects. This is not relevant only to ethynyl groups. For all other residues that can simultaneously act as C–H donors and π acceptors, similar effects must be expected. A most important example is the phenyl group.

**Table 1** The hydrogen bonds of **1**; M = centroid of C(20)≡C(21) (for normalized H positions with C–H = 1.09 and O–H = 0.98 Å)

| | H···A/Å | D···A/Å | D–H···A (°) |
|---|---|---|---|
| O(17A)–H···O(17B) | 2.13 | 3.098(7) | 170 |
| O(17B)–H···C(20B) | 2.86 | 3.835(6) | 175 |
| O(17B)–H···M(B) | 2.67 | 3.636(7) | 170 |
| O(17B)–H···C(21B) | 2.60 | 3.524(8) | 158 |
| C(21A)–H···O(17A) | 2.44 | 3.443(5) | 153 |
| C(21B)–H···O(17B) | 2.48 | 3.478(5) | 151 |

**Table 2** Stretching frequencies

| Sampling | $\nu_{O-H}$/cm$^{-1}$ | $\nu_{\equiv C-H}$/cm$^{-1}$ |
|---|---|---|
| Dilute solution in $CCl_4$ at r.t. | 3614.0 | 3308.6 |
| Crystal (KBr) at r.t. | 3523.3, 3481.4 | 3287.3, 3248.8 |
| Crystal (KBr) at 92 K[a] | 3505.1, 3471.3 | 3278.9, 3233.8 |
| Shift $\Delta\nu_{cryst-soln}$ at r.t. | −90.7, −132.6 | −21.3, −59.8 |

[a] The low temperature data are not discussed in the text, because no corresponding X-ray crystal structure is available. The increase of the red shifts indicates further strengthening of all hydrogen bonds upon cooling. r.t. = room temperature.

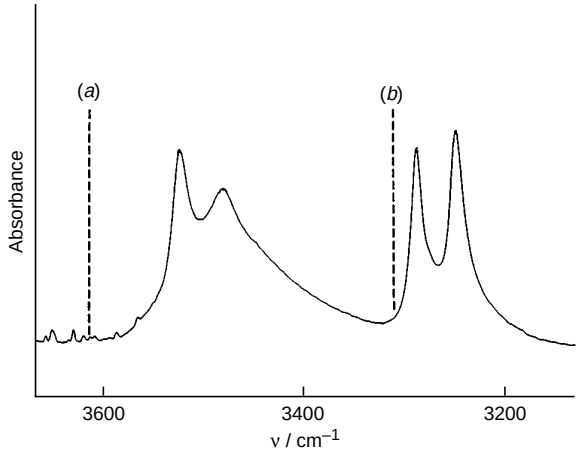

**Fig. 4** Section of the IR absorption spectrum of crystalline **1** at room temp. (KBr); numerical values are listed in Table 2: (*a*) $\nu_{OH}$ in $CCl_4$, (*b*) $\nu_{\equiv C-H}$ in $CCl_4$. The two left bands represent hydrogen bonding O–H, and the two right bands hydrogen bonding C≡CH groups.

Any request to the CCDC for this material should quote the full literature citation and the reference number 182/305.

‡ The steroid skeleton does not significantly differ from 17α-ethynylestradiol as observed in the hemihydrate crystal structure; V. J. van Geerestein, *Acta Crystallogr., Sect. C*, 1987, **43**, 1206.

§ IR spectroscopy: Mattson Research Series spectrophotometer equipped with a DTGS detector. Cryostate Specac P/N 21.000 variable temperature cell. Scanning parameters: region 4000–500 cm$^{-1}$, resolution 2 cm$^{-1}$, 64 scans and triangular apodization.

¶ There is a further difference in the surroundings of the two ethynyl groups: as a consequence of the double-acceptor function of O17(B), there might be electrostatic repulsion between C(21B)–H and O(17A)–H donating hydrogen bonds to O(17B). This could destabilize the C(21B)–H···O interaction, and be responsible for a reduced red shift of $\nu_{C(21B)-H}$. Since the H[C(21B)]···H [O(17A)] distance is rather long (2.80 Å), it is assumed that this interaction is of only secondary importance compared to the O–H··π interaction accepted by the residue A. C(21A)–H does not form such a, possibly unfavourable, contact.

# Dioxygen and carbon monoxide binding in dendritic iron(II)porphyrins

**James P. Collman,*[a] Lei Fu,[a] Adrien Zingg[b] and François Diederich*[b]**

[a] *Department of Chemistry, Stanford University, Stanford, CA 94305, USA*
[b] *Laboratorium für Organische Chemie, ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich, Switzerland*

**Equilibrium $O_2$ and CO binding behaviour of two dendritic iron(II) porphyrin systems is reported.**

Tetrameric haemoglobin (Hb) and monomeric myoglobin (Mb) are haem proteins responsible for dioxygen storage and transport in biological systems. In the deoxy forms of both Hb and Mb the haem iron is bound to a single, 'proximal', axial imidazole resulting in a five-coordinate high-spin ($S$ = 2) $Fe^{II}$; upon oxygenation at the opposite 'distal' face, a diamagnetic $Fe^{III}O_2^-$ complex forms reversibly. The protein superstructure is responsible for the kinetic stabilization of the oxygenated form; amino acid residues on the 'distal' porphyrin face appear to destabilize a competing complex derived from the endogenous toxic CO. Thus the '*M*' value (*i.e.* the ratio of the two equilibrium binding constants $K_{CO}/K_{O_2}$) for Hb and Mb is about 100, small enough that the body can tolerate low, endogenous levels of CO. The 'picket fence' iron(II) model† complex also binds $O_2$ reversibly, exhibiting an $O_2$ affinity about the same as that of Mb; the polar $O_2$ binding cavity kinetically stabilizes the intrinsically bent $O_2$ adduct. In contrast, the linear CO ligand binds very strongly to the 'picket fence' porphyrin; *M* for the T (tense)-state model is 4280.[1] Several subsequent model systems such as 'pocket',[2] 'hybrid',[3] and 'capped'[4] porphyrins effect some distortion of the CO ligand and, as a consequence, *M* is lowered to *ca.* 150; with more hindered cavities, *M* can fall below 1.[5] The detailed interaction between structural distortion and equilibrium affinities of CO remains controversial.[6]

Stabilization of bound $O_2$ is also poorly understood. A distal histidine residue in Hb and Mb forms a weak [stability *ca.* 2 kcal $mol^{-1}$ (1 cal = 4.184 J)] hydrogen bond to the terminal oxygen in the $Fe^{III}O_2^-$ adduct. There have been some attempts to imitate such a hydrogen bond with model iron(II) porphyrins.[7] Some haem proteins have an unusually high $O_2$ affinity; for example in the blood worm *Ascaris*,[8] the $O_2$ affinity is $10^4$-fold higher compared with Hb. One can speculate that a strong hydrogen bond is responsible for this high $O_2$ affinity.

With the recent surge in dendrimer technology,[9] dendritic porphyrins were prepared as synthetic models of globular haem proteins.[10,11] It was shown for aqueous solutions that, in analogy to the protein surroundings in electron transfer proteins, a densely packed dendritic shell around a deeply buried iron haem profoundly influences the redox potential of the biologically relevant $Fe^{III}$–$Fe^{II}$ couple.[10*b*] Recently, Jiang and Aida[11*b*] reported a dendritic iron(II) porphyrin with aryl ether branches which exhibits reversible dioxygen binding. However, in their study, a 1-methylimidazole was used. This ligand is known to form a six-coordinate, low-spin iron(II) complex. This factor complicates any measure of $O_2$ affinity.

Herein we report a gas equilibrium binding study with two dendritic iron(II) porphyrins of first (G1-$Fe^{II}$, $M_r$ = 3956) and second (G2-$Fe^{II}$, $M_r$ = 11296) dendritic generation (Fig. 1). These were prepared from the corresponding free-base dendritic porphyrins[10*b*] *via* metallation with $FeBr_2$ in THF in an inert atmosphere box and subsequently purified chromatographically ($SiO_2$, MeOH–$CH_2Cl_2$).‡ The dendritic iron(II) porphyrins were each dissolved in toluene, 1000 mol equiv. of 1,2-dimethylimidazole (dmim) were added to form the five-coordinate, high-spin iron(II) complex, and the solution was loaded into a tonometer for gas binding studies. The dmim ligand forms only a 1 : 1 high-spin iron(II) adduct obviating the problem of controlling the number of axial ligands. Furthermore, the resulting iron(II) porphyrin is a good model for the lower affinity T-state of Hb.[12]

Gas flow: $O_2$, then $N_2$, then $O_2$ UV–VIS experiments showed reversible $O_2$ binding in toluene solution at 25 °C. Using a tonometer, we measured the $O_2$ and CO equilibrium binding constants ($K_{O_2}$ and $K_{CO}$)[13] for both dendrimers G1-$Fe^{II}$ and G2-$Fe^{II}$. These $P_{1/2}(O_2)$ ( = $1/K_{O_2}$) and $P_{1/2}(CO)$ ( = $1/K_{CO}$) values are displayed in Table 1 compared with those of T-state Hb, the corresponding T-state 'picket fence' model, and of the blood worm *Ascaris.*

It is remarkable that the $O_2$ affinities [$K_{O_2}$ = $1/P_{1/2}(O_2)$] of the dendritic porphyrins are about 1500 times greater than those of T-state Hb; these values approach the high affinity of *Ascaris* (Table 1). The CO affinities of the dendritic porphyrins are lower than those of the 'picket fence' model but are close to the value of Hb in the T-state. The combination of high $O_2$ and low

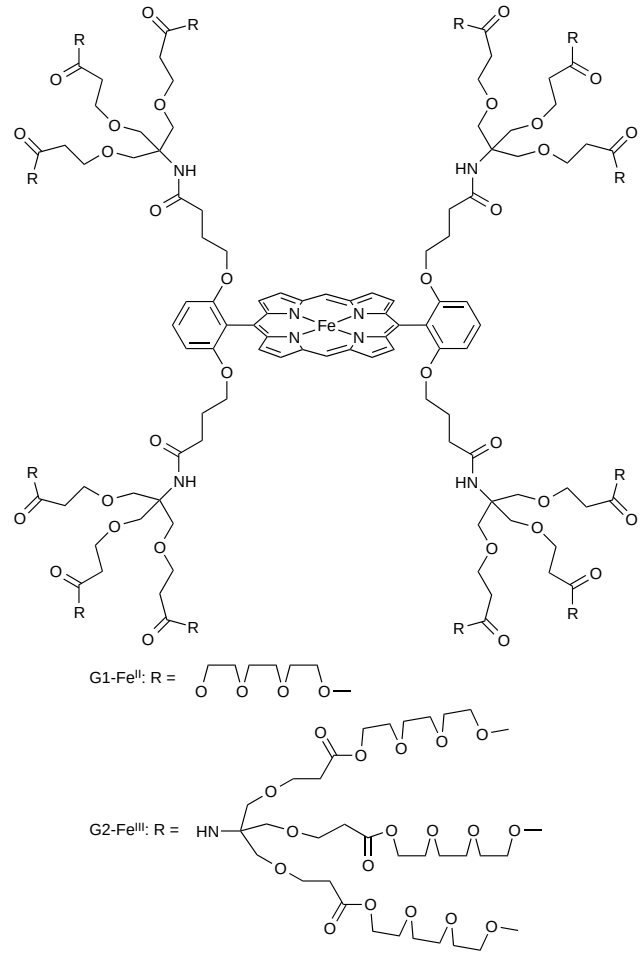

**Fig. 1** Dendritic porphyrins G1-$Fe^{II}$ and G2-$Fe^{II}$

**Table 1** Oxygen and carbon monoxide binding data

| | $P_{1/2}$/Torr | | $M$ $P_{1/2}(O_2)/P_{1/2}(CO)$ |
|---|---|---|---|
| | $O_2$ | CO | |
| Hb (T-state)[a] | 40 | 0.30 | 135[14] |
| Fe (picket fence)/dmim[b] | 38 | 0.0089 | 4280[2b] |
| *Ascaris*[c] | 0.002 | 0.1 | 0.02[8b] |
| G1-$Fe^{II}$/dmim[b] | 0.035 | 0.35 | 0.10 |
| G2-$Fe^{II}$/dmim[b] | 0.016 | 0.19 | 0.08 |

*Conditions*: [a] $H_2O$, pH 7, 25 °C. [b] Toluene, 25 °C. [c] $H_2O$, pH 7, 20 °C. Changing solvent polarity may slightly affect the affinities.[15]

CO affinities yields very low values for *M*. The dendritic *M* values show a trend similar to *Ascaris*.

Why are the $O_2$ affinities so great? These may result from a hydrogen bond to the amide N–H group. Molecular models suggest that the terminal O of bound $O_2$ can form such a hydrogen bond with the NH of the amide group linking together the porphyrin core and the first-generation dendritic branches, but more evidence is needed; studies are in progress. The lower CO affinities may be caused by a congested pocket over the CO binding site much like the sterically distorted model complexes mentioned above.

In conclusion, we have studied two dendrimer-based myoglobin T-state models. Each exhibits reversible $O_2$ and CO binding activities. The measured $O_2$ affinities are about 1500 times higher than those of a haemoglobin and 'picket fence' porphyrin, implying a possible hydrogen bonding between the terminal O of bound $O_2$ and an amide N–H group. In terms of CO affinity, the dendritic model systems are more like Hb than uncapped haem (*e.g.* 'picket fence' porphyrin) suggesting that, as with Hb, bound CO experiences a steric interaction that distorts binding from a favourable linear conformation.

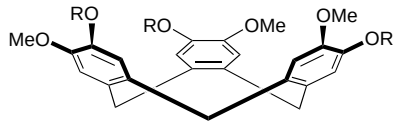
# Qualitative test for supramolecular complexation of $C_{60}$ using a mesoporous silica

**Alexander Drljaca, Christopher Kepert, Leone Spiccia, Colin L. Raston,* Christian A. Sandoval and Thomas D. Smith***



*Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia*

**A new form of mesoporous silica with a surface area of 600 $m^2\ g^{-1}$, mean pore radius of 5.4 nm and total pore volume of 1.9 ml $g^{-1}$ uptakes $C_{60}$ in toluene; on removal of toluene or the addition of fullerene complexing agents the $C_{60}$ undergoes aggregation within the silica, identified by an inter-fullerene resonant transition at *ca*. 450 nm.**

Complexation of $C_{60}$ has been established for a variety of molecules including some hydrophobic calixarenes **1**[1–3] and cyclotriveratrylenes **2**[4,5] and is determined by the dimensions and shape of the cavity of the complexing agent, the nature of the interactions involving the spherical and otherwise non-polarised fullerene within the supermolecule, solvation effects, and fullerene–fullerene interactions.[5] The primary process in complexation of $C_{60}$ is most likely the formation of host–guest species with the resulting polarised fullerene aggregating as part of micelle-like species with a core of fullerenes surrounded by a sheath of host molecules.[5] The host–guest interactions are inherently weak and may not be evident in solution studies using UV–VIS spectroscopy, and where a discrete complex is not isolable, intimate contact between the two species in solution cannot be ruled out.

**1**

**2**

In addressing the difficulties in identifying and encouraging host–guest interactions, we have developed a new amorphous mesoporous silica ($MPSiO_2$) with sufficient pore size to allow mobilisation of $C_{60}$, and large enough to accommodate aggregates of fullerenes and associated host molecules, at least for small aggregates where conventional particle size analysis would be difficult. We show that when this material is loaded with $C_{60}$ it offers a qualitative test for supramolecular complexation of the fullerene, and that devoid of $C_{60}$ is a material for uptake of preformed micelles $\leqslant$5.4 nm in diameter. Other noteworthy features of the new mesoporous silica include: (*i*) the material has a narrow range of mesopores, (*ii*) it is prepared using inexpensive template materials; and (*iii*) its ability to allow solid-state diffusion or diffusion from organic solutions for a range of different classes of compounds including iodine at 293 K, ferrocene, nickelocene, and titanocene dichloride at 400 K, and 2-(2,4-dinitrobenzyl)pyridine at 383 K.[6] Mesoporous silicate (and aluminosilicate) materials containing pores in the range 1.6 to 10.0 nm are prepared by taking advantage of the self-assembling properties of liquid-crystal surfactant molecules,[7] and find application in catalysis. MCM-41 for example is effective for the epoxidation of bulky alkenes,[8,9] although the well defined structural arrangement of its mesopores requires relatively large amounts of liquid-crystal template material, which compromises any catalytic conversion of practical value. A zeolite-related microporous aluminophosphate with one-dimensional pores of diameter 12.5 Å can accommodate $C_{60}$.[10]

$MPSiO_2$ was prepared from sodium silicate, tetraethylammonium bromide, triethanolamine in a mixture of water, dmf and phosphoric acid, with the final product obtained after heating the isolated solid at 823 K:† particle fraction 60–80 mesh, surface area 600 $m^2\ g^{-1}$ with a mean pore radius window limit of 5.4 nm with no evidence of microporosity and a total pore volume of 1.9 ml $g^{-1}$. A sharp IR band at 3740 $cm^{-1}$ shows the presence of silanol groups, which decreased substantially after the adsorption studies. Contact of the magenta toluene solution of $C_{60}$ with $MPSiO_2$ results in magenta colouration of the silica which is retained after air drying, Fig. 1(*a*), but on heating at 320 K to remove the toluene the material changed to yellow, Fig. 1(*b*). This colour change and the associated appearance of a broad new band at 450 nm in the reflectance spectrum, which is ascribed to inter-fullerene resonant transitions, is consistent with disruption of toluene-solvated $C_{60}$ molecules,[11] affording aggregates of $C_{60}$ within the pores of $MPSiO_2$. The band is similar to that found in thin films and aggregates of colloidal $C_{60}$,[11,12] and that for the 1 : 1 complex of $C_{60}$ with **1** (R = Bu$^t$, R′ = H, *n* = 8), which has three fullerenes in the core of the micelle.[13] Contact of the yellow material with toluene restored the magenta colour of toluene-solvated $C_{60}$ in the pores.

Addition of toluene solutions of **1** or **2** to the magenta $MPSiO_2$ solid yields brown–yellow material, with representative reflectance spectra shown in Fig. 2. Except for spectrum

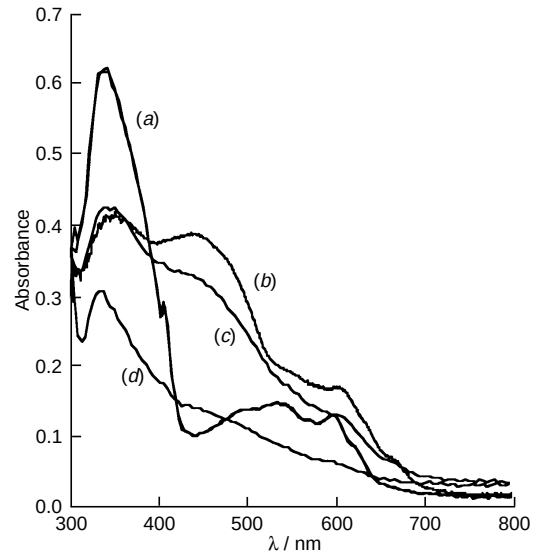


**Fig. 1** UV–VIS reflectance spectra of $MPSiO_2$ after (*a*) uptake of $C_{60}$ in toluene, (*b*) removal of toluene from the solid in (*a*), (*c*) treatment with a 1 : 1 mixture of $C_{60}$ : **2** (R = Me) in toluene and (*d*) treatment with a 1 : 10 mixture of $C_{60}$ : **2** (R = Me) in toluene

(*d*), Fig. 2 (see below), they show a similarly broad new band at *ca*. 450 nm, and is likewise consistent with the formation of aggregates of $C_{60}$, most likely as part of micelle-like structures with the fullerene cores surrounded by host molecules in the pores of $MPSiO_2$. In forming a host–guest interaction the host ligand, L, polarises the fullerene thereby encouraging the formation of aggregates, eqn. (1).[5] The new band is indicative of

$$C_{60} + L \overset{\text{toluene}}{\rightleftharpoons} (C_{60})_n L_x \qquad (1)$$

supramolecular complexation of the fullerene in the pores of the silica and is a qualitative test for host–guest interaction. In addition, we note that some molecules of type **1** and **2** failed to yield isolable host–guest complexes, and failed to show any host–guest interaction in solution, unlike in the pores of $MPSiO_2$, *e.g.* **1** (R = Bu$^t$, R′ = H, *n* = 4), **1** (R = *p*-$C_6H_4OPh$, R′ = Me, *n* = 4), **1** (R = Ph, R′ = Me, *n* = 4) and **2** (R = allyl). However, host–guest interaction is implied by the distinctly different crystal morphology of pure solid $C_{60}$ obtained on evaporation of toluene solutions of the fullerene and host, *e.g.* for **2** (R = allyl) (see below).[5] A toluene solution of $C_{70}$ (red–brown) in contact with $MPSiO_2$ coloured the silica particles red–brown, but in this case there was no marked change in the reflectance spectra on removal of the toluene, or on the addition of host molecules.

Addition of mixtures of $C_{60}$ with a selection of host molecules to $MPSiO_2$ also yielded brown material to varying degrees. A 1 : 1 mixture of $C_{60}$ : **2** (R = Me) gave a similar colour change and spectrum to that of adding the same host to $C_{60}$ already in the pores. However, for a 1 : 10 ratio there was little uptake of fullerene, Fig. 1(*d*), which is consistent with our earlier studies that micelle-like species are being formed under such conditions.[5] The bulk of these must be stable micelles > 5.4 nm in diameter. For **2** (R = allyl) the difference between the 1 : 1 and 1 : 10 mixtures added to the silica is reversed. The 1 : 1 mixture results in little uptake of the fullerene in the pores and thus most of the micelle-like structures are > *ca*. 5.4 nm whereas for the 1 : 10 mixture incorporation of smaller micelles prevails. Electronic spectra of the 1 : 10 solution itself suggests the presence of solvated host–guest species;[5] their intimate contact with the silica in the pores must then encourage fullerene–fullerene interactions.

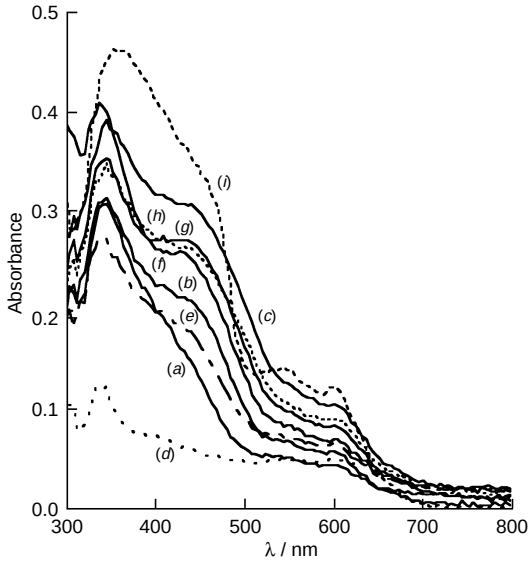

**Fig. 2** UV–VIS reflectance spectra of the solid from Fig. 1(*a*), after treatment with a toluene solution of **1**: (*a*) R = Bu$^t$, R′ = H, *n* = 4; (*b*) R = *p*-$C_6H_4OPh$, R′ = Me, *n* = 4; (*c*) R = Bu$^t$, R′ = H, *n* = 6; (*d*) R = H, R′ = H, *n* = 6; (*e*) R = CPh, R′ = Me, *n* = 4; (*f*) R = Bu$^t$, R′ = H, *n* = 5; (*g*) R = $CH_2Ph$, R′ = H, *n* = 5, (*h*) R = $CH_2Ph$, R′ = Me, *n* = 5, (*i*) R = Bu$^t$, R′ = H, *n* = 8

Unlike other calixarenes, addition of calix[6]arene to the magenta silica results in leaching of the fullerene from the silica, Fig. 2(*d*). However, addition of a mixture of the same calixarene and $C_{60}$ to $MPSiO_2$ gives the inter-fullerene resonant transition. It appears that an excess of the fullerene is required to encourage host–guest interactions/aggregation in the pores and in this context we note that the complex prepared from the calixarene and $C_{60}$ is rich in fullerene, analysing as the 2 : 1 complex.[1] The leaching of the $C_{60}$ by a solution of calix[6]arene may be due to encapsulation of each fullerene by two calixarenes as a toluene-soluble species, and/or the calixarene–fullerene association is more labile than for other calixarenes.

We thank the Australian Research Council for support of this work, and the CSIRO Division of Materials Science and Technology for the measurements of surface area, mean pore radius and pore volume.

## Footnote

† *Synthesis* of $MPSiO_2$: two solutions were prepared: solution A, which contained 30 ml of a stock solution of sodium silicate (density 1.36 g ml$^{-1}$; assay $Na_2O$ 8.55% m/m and $SiO_2$ 27.45% m/m) diluted to 100 ml with water containing 2.0 g of tetraethylammonium bromide, and solution B which consisted of 4 ml of triethanolamine in 10 ml of water to which was added 15 ml of dmf and 6 ml of phosphoric acid (85% m/m). Solution B was added to solution A with rapid stirring which was continued through the formation of a gel which formed within minutes and was allowed to stand overnight. Most of the water content was removed by heating the gel at 383 K for 12 h with stirring of the solid material at hourly intervals. The powdered product was washed successively with portions of hot water (5 × 200 ml) and after drying at 393 K was heated at 823 K in a muffle furnace for 48 h. The organic material was removed within a relatively short time with the longer heating period being required to remove coke which finally gives the white powdered product. After grinding, the particle fraction (60–80 mesh) was isolated and used for uptake of the various compounds.

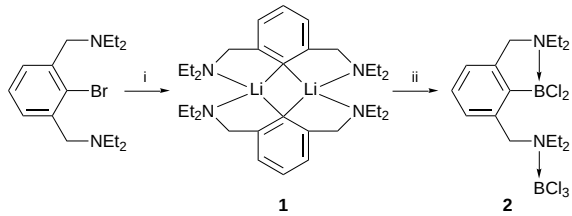
# Different donor binding modes of the pincer ligand 2,6-bis[(diethylamino)-methyl]phenyl: intermolecularly chelating in Li[2,6-$(NEt_2CH_2)_2C_6H_3$] and both mono- and bi-dentate in $BCl_2$\{2-[$BCl_3(NEt_2CH_2)$]-6-$(NEt_2CH_2)C_6H_3$\}

**Robert Schlengermann, Joachim Sieler, Svea Jelonek and Evamarie Hey-Hawkins***



*Institut für Anorganische Chemie der Universität Leipzig, Talstrasse 35, D-04103 Leipzig, Germany*

**The reaction of dimeric Li[2,6-$(NEt_2CH_2)_2C_6H_3$] 1 with $BCl_3$ yields $BCl_2$\{2-[$BCl_3(NEt_2CH_2)$]-6-$(NEt_2CH_2)C_6H_3$\} 2, independent of the stoichiometric ratio (1:1 or 1:2) or reaction conditions (0 °C or boiling hexane).**

The lithium derivatives of monoanionic terdentate ligands 2,6-$(NR_2CH_2)_2C_6H_3$ (R = Me, Et) are valuable starting materials for the preparation of transition-metal or main-group element derivatives.[1] A variety of binding modes to late transition metals, *i.e.* as two-, four- and six-electron donor, have been observed.[2] Intramolecular coordination of the amino group strongly stabilises these compounds.[2] Thus, the intramolecularly stabilised five-coordinate 2,6-[bis(dialkylamino)-methyl]phenyl derivatives $AlX_2$[2,6-$(NMe_2CH_2)_2C_6H_3$] (X = Cl, H),[3] $GaMe_2$[2,6-$(NMe_2CH_2)_2C_6H_3$],[4] $InCl_2$[2,6-$(NEt_2CH_2)_2C_6H_3$],[5] InMe(Cl)[2,6-$(NEt_2CH_2)_2C_6H_3$],[5] $InEt_2$-[2,6-$(NEt_2CH_2)_2C_6H_3$][4] and $InR_2$[2,6-$(NMe_2CH_2)_2C_6H_3$] (R = Me, Et, Pr),[4] are liquids or low-melting solids and far less air-sensitive than trimethyl compounds; they are therefore suitable replacements for MOVPE.[4,5] Of the boron analogues, only the boronic acid derivative $B(OH)_2$[2,6-$(NMe_2CH_2)_2C_6H_3$][6] and the boronates $B(OCH_2CR_2O)$[2,6-$(NMe_2CH_2)_2C_6H_3$] (R = H, Ph),[7] $B(OCH_2CMe_2CH_2O)$[2,6-$(NMe_2CH_2)_2C_6H_3$][8] and $B(OCH_2CHMeO)$[2,6-$(NMe_2CH_2)_2$-$C_6H_3$],[8] which were synthesised from boronic acid and diols, have been reported in the literature. Since base-stabilised arylboron dichloride derivatives would appear to be useful starting materials for the preparation of transition-metal boranediyl complexes,[9] we attempted the preparation of these compounds.

The synthesis and *in situ* reactions of Li[2,6-$(NEt_2CH_2)_2C_6H_3$] **1** have been reported.† **1** (2.0 g, 7.8 mmol) reacts with $BCl_3(OEt_2)$ (15.6 mmol) in hexane (25 ml) at 0 °C to give $BCl_2$\{2-[$BCl_3(NEt_2CH_2)$]-6-$(NEt_2CH_2)C_6H_3$\} **2** in almost quantitative yield, independent of the stoichiometric ratio or reaction conditions (Scheme 1); formation of a $BCl_3$-free product was not observed. This suggests that **2** is the thermodynamically favoured product. In the comparable reaction of **1** with $InCl_3$, $InCl_2$[2,6-$(NEt_2CH_2)_2C_6H_3$] is obtained, in which both amino groups are coordinated to the In atom.[5]

In addition to being indispensable reagents for preparative organometallic and organic chemistry, lithium compounds often exhibit fascinating structures in the solid state.[10] In the compounds studied up to now, the Li atom exhibits a pronounced tendency to interact with electron-rich ligands or donor molecules, or aggregation through electron-deficient Li–C bonds is observed, leading to a large variety of structures.[10] A general principle for the dimerisation of lithium reagents has been described in the literature.[11]

**Scheme 1** *Reagents and conditions*: i, $Bu^nLi$, hexane, 0 °C, 12 h at room temp., 72%; ii, $BCl_3$, hexane, 0 °C, 99%

In the solid state Li[2,6-$(NEt_2CH_2)_2C_6H_3$] **1** consists of dimeric units in which the Li atoms are bonded to the two *ipso*-C atoms of the aryl rings by three-centre–two-electron bonds; the molecule has $C_2$ symmetry (Fig. 1).‡ The tetrahedral coordination of Li is completed by intra- and inter-molecular interactions with one amino group of each aryl ligand. The *ipso*-C atoms, C(1) and C(10), have tetrahedral rather than planar geometry. The structural parameters of **1** are in agreement with those of other structurally characterised dimeric lithium aryls.[12] § The structural data [Li–C, Li···Li, Li–N, bite angle N(2)–Li(1)–C(10) and N(1)–Li(1)–C(1)] as well as the overall structure ($C_2$ symmetry) and geometry of **1** [angle between planes C(1)–C(2a)/$C_2Li_2$ 56.8(1)°, C(10)–C(14a)/$C_2Li_2$ 56.9(2)°, C(1)–C(2a)/C(10)-C(14a) 66.20(8)°] are nearly identical to those of dimeric {2,3,5,6-tetrakis-[(dimethylamino)methyl]phenyl}lithium.[13] Other related lithium derivatives with two intra- and inter-molecularly chelating *ortho* substituents are tetrameric Li[2-$(NMe_2CH_2)C_6H_4$][14] and Li[2,6-$(NMe_2CH_2)_2C_6H_3$],[6,14] which is dimeric according to a molecular mass determination.

Like {Li[2,6-$(NMe_2CH_2)_2C_6H_3$]}$_2$,[14] dimeric **1** has $C_2$ symmetry. Therefore the C–C$H_2$-N and C$H_2$CH$_3$ groups are

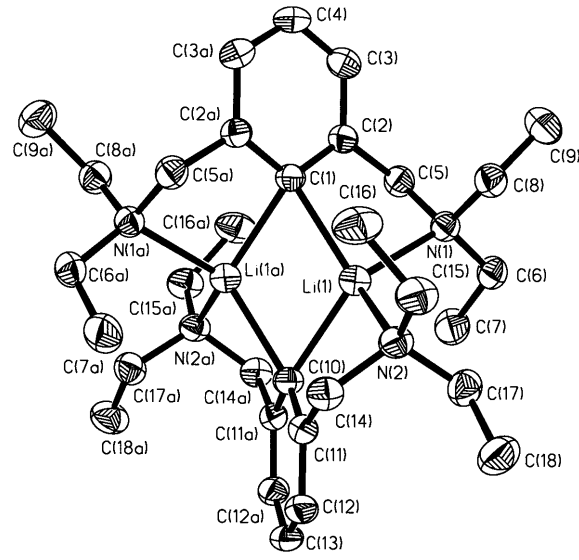


**Fig. 1** Molecular structure of dimeric Li[2,6-$(NEt_2CH_2)_2C_6H_3$] **1** showing the atom numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP).[18] Selected bond lengths (Å) and angles (°): Li(1)–N(1) 2.178(3), Li(1)–N(2) 2.164(3), Li(1)–C(1) 2.228(3), Li(1)–C(10) 2.231(3), Li(1)···Li(1a) 2.483(5); N(2)–Li(1)–N(1) 111.01(12), N(2)–Li(1)–C(1) 134.67(13), N(1)–Li(1)-C(1) 86.07(10), N(2)–Li(1)–C(10) 85.92(10), N(1)–Li(1)–C(10) 134.27(13), C(1)–Li(1)–C(10) 112.32(12), Li(1)–C(1)–Li(1a) 67.73(14), Li(1)–C(10)–Li(1a) 67.62(14), C(2)–C(1)–C(2a) 114.9(2), C(11)–C(10)–C(11a) 114.4(2).

diastereotopic (below 16 °C); above 16 °C they become homotopic as the molecule becomes fluctional ($\Delta G^{\ddagger}$ = 54.6 ± 0.2 kJ mol$^{-1}$).[15]¶

Crystals of **2** were obtained from dichloromethane at −25 °C. The molecular structure of **2** is shown in Fig. 2.‡ In **2**, an arylboron dichloride is intramolecularly stabilised by interaction with one amino group, giving a five-membered B–C–C–C–N ring ($BC_3$ coplanar, N lies 0.5 Å below this plane). This leads to a distorted tetrahedral environment at B(1) [small C(1)–B(1)–N(2) bite angle and large C(1)–B(1)–Cl(1) bond angle]. The structural data of the C–C–C–N–B five-membered ring in **2** are similar to those of B(OCH$_2$CPh$_2$O)[2,6-(NMe$_2$CH$_2$)$_2$C$_6$H$_3$].[7] Due to the coordination number of five in InMe(Cl)[2,6-(NEt$_2$CH$_2$)$_2$C$_6$H$_3$], the C–In–N bite angles are even smaller [72.7(1), 72.3(1)°][5] than in **2** and the boronate. It is well known that $BCl_3$ forms stable adducts with ethers and amines, and the geometry of the $BCl_3$ group which is coordinated by the second amino group in **2** is comparable to that of undistorted tetrahedral $BCl_3$(NMe$_3$).[16] To our knowledge, **2** is the first example where the pincer ligand 2,6-(NEt$_2$CH$_2$)$_2$C$_6$H$_3$ acts as a monodentate ligand towards one molecule and as a bidentate ligand towards another. The only remotely related example is [WL(CO)$_3$(NCMe)] [L = 2-Ph$_3$SnC$_6$H$_4$CH$_2$N(Me)CH$_2$CH$_2$NMe$_2$], in which L exhibits $\eta^2$-N,N′ coordination to W and $\eta^1$-C coordination to Sn.[17]

While the related boronates B(OCH$_2$CR$_2$O)[2,6-(NMe$_2$CH$_2$)$_2$C$_6$H$_3$] (R = H, Ph) are dynamic in solution due to facile exchange of amine ligands,[7] in **2** this process is not possible due to the coordination of one amino group to the (aryl)$BCl_2$ fragment, while the other is coordinated to a $BCl_3$ molecule. Thus, in the proton NMR spectrum of **2** (in [$^2$H$_8$]thf),¶ the non-equivalence of the CC*HH*N (AB system) and NC*HH*CH$_3$ protons (one q for each H of both methylene groups) indicates that the five-membered chelate ring C–C–C–N–B is rigid in solution. For the C-C*H*$_2$N($BCl_3$)(C*H*$_2$CH$_3$)$_2$ group, these are equivalent (one s, one q). The chemical shifts and coupling patterns are solvent dependent.¶

The results presented here show that Li[2,6-(NEt$_2$CH$_2$)$_2$C$_6$H$_3$] **1** is dimeric in the solid state with $C_2$ symmetry. The reaction of **1** with $BCl_3$ yields the novel donor-stabilised arylboron dichloride, $BCl_2${2-[$BCl_3$(NEt$_2$CH$_2$)]-6-(NEt$_2$CH$_2$)C$_6$H$_3$} **2**; a $BCl_3$-free compound was not obtained. We are presently investigating the chemistry of **2** and its use in the preparation of transition-metal boranyl or boranediyl complexes.

We gratefully acknowledge financial support from the Deutsche Forschungsgemeinschaft (R. S.) and the Fonds der Chemischen Industrie; the company Chemetall GmbH has provided a generous donation of lithium alkyls, and Hoechst AG a generous donation of chemicals.

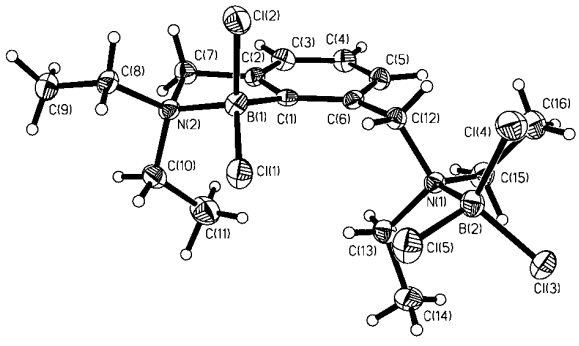

**Fig. 2** Molecular structure of $BCl_2${2-[$BCl_3$(NEt$_2$CH$_2$)]-6-(NEt$_2$CH$_2$)C$_6$H$_3$} **2** showing the atom numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP).[18] Selected bond lengths (Å) and angles (°): B(1)–Cl(1) 1.842(4), B(1)–Cl(2) 1.882(5), B(2)–Cl(3) 1.855(5), B(2)–Cl(4) 1.852(5), B(2)–Cl(5) 1.841(5), B(1)–N(2) 1.649(5), B(2)–N(1) 1.639(5), B(1)–C(1) 1.598(5); C(7)–N(2)–B(1) 103.3(3), C(1)–B(1)–N(2) 100.5(3), C(2)–C(1)–C(6) 119.1(3), C(2)–C(1)–B(1) 107.7(3), C(6)–C(1)–B(1) 132.1(3).

## Footnotes

† Li[2,6-(NEt$_2$CH$_2$)$_2$C$_6$H$_3$] **1** was prepared according to the literature procedure.[4,5] Recrystallisation from hexane gave colourless crystals (72%).

# Spectroscopy with the polarizable solvent diiodomethane

**Fredric M. Menger* and Ana M. Sanchez**

*Department of Chemistry, Emory University, Atlanta, Georgia 30322, USA*

**The polarizable solvent $CH_2I_2$ causes $^1H$ NMR upfield chemical shifts of 1.5 ppm as well as bathochromic shifts of a dye greater than those caused by polar solvents such as methanol.**

Diiodomethane has a density of 3.3, a boiling point of 180 °C and a relative permittivity of 5.3. Its outstanding physical property is, however, a refractive index of 1.748. This compares with 1.333 for water and 1.560 for bromobenzene. Even carbon disulfide (with the highest refractive index among the common solvents) has a value of only 1.628. Refractive indices arise from a light wave's oscillating electric field being countered by a corresponding oscillating field from a molecule's electrons. The velocity of the propagating wave is thereby reduced. Thus, the refractive index of 1.748 for diiodomethane reflects a particularly high electron mobility around the two iodine atoms. More specifically, the longitudinal polarizability for C–I bonds is as much as 9 times greater than for the C–C bond.[1]

Compared to hydrogen-bonding, ion-pairing, charge-transfer and π-stacking, intermolecular polarizability effects on organic compounds are rather poorly understood. The question here, therefore, is how systems are perturbed when embedded in a sea of polarizable electrons as provided by diiodomethane. Judging from its relative permittivity of 5.3, the solvent appears to be apolar in nature. This may be misleading because the dielectric constant, derived from a 'bulk' measurement, fails to depict specific interactions occurring at the molecular level.

One indication that diiodomethane does in fact influence spectral properties comes from an NMR study of $^{129}Xe$ in 46 solvents.[2] Among these solvents, diiodomethane induces by far the largest chemical shift of δ 335. This may be compared to δ 225 for carbon disulfide, δ 248 for iodomethane and δ 196 for water. It was also shown that proton gas-to-liquid NMR shifts for $CH_4$, being a complex function of the refractive indices, is greatest for diiodomethane among several poly-brominated and chlorinated solvents.[3] Diiodomethane has also been used as one of 37 solvents for a study of the visible molecular absorption spectrum of cyanine dyes.[4] A modest red shift of *ca*. 25 nm was observed in switching from methanol to diiodomethane. Molecular absorption bands correlate with $(n^2 - 1)/(2n^2 + 1)$ where $n$ is the refractive index of the solvent.

Before carrying out any spectroscopy, we felt it desirable to obtain a sense of the solubilizing power of diiodomethane. The following compounds are miscible with diiodomethane: acetonitrile, benzene, chloroform, cyclohexene, dioxane, ethanol, ethyl acetate, ethyl ether and tetrahydrofuran. The following are immiscible: bromine, hexane, hexan-1-ol, ethyl vinyl ether and water. Acrylic acid and cyclohexane show modest solubility. In general, aromatic groups seem to help solubilize compounds in diiodomethane.

NMR spectra were obtained with a 500 MHz spectrometer on samples in 5 mm tubes containing 0.14 M solute in $CD_2I_2$. $SiMe_4$ in $CDCl_3$ was used as an external reference. Since no differences were observed between $CD_2I_2$ (Aldrich), (stabilized with copper) and $CD_2I_2$ purified by vacuum distillation, all experiments used the former.

A total of 17 diverse solutes in $CD_2I_2$ were examined by $^1H$ NMR. The vast majority of signals shifted upfield relative to those in $CDCl_3$, by 1.5 ± 0.1 ppm. For example, uncorrected[5] cyclohexene signals shifted from δ 5.58, 1.90 and 1.52 in $CDCl_3$ to δ 4.09, 0.43 and 0.03, respectively, in $CD_2I_2$. Other representative examples from the group of 17 (including an alkene, carboxylic acid, nitrile, ketone *etc*.) are given in Table 1. Since the shifts were more or less uniform regardless of the proton type, there was little simplification of the spectra except in four cases (anisole, phenetole, butyl phenyl ether and thioanisole). These simplifications arose from one proton of a multi-proton multiplet fortuitously shifting slightly differently (*ca*. 0.1 ppm) than the other components. Fig. 1 shows the improved peak resolution of the thioanisole spectrum in $CD_2I_2$ relative to $CDCl_3$. Note that since spectra in $CDCl_3$ and $CCl_4$ are very similar, the observed differences between $CD_2I_2$ and $CDCl_3$ cannot be ascribed to hydrogen-bonding to the latter solvent. A change from $CDCl_3$ to $CD_2I_2$ caused upfield shifts in the $^{13}C$ NMR spectra of less than 1 ppm.

No variation in chemical shift was observed with thioanisole in diiodomethane as the temperature was varied from 10 to 30 °C (6 °C being the freezing point of the solvent). The chemical shifts of the toluene signals in various mixtures of $CD_2I_2$ and $CDCl_3$ were found to be linearly related to the percentage of $CD_2I_2$ in the solvent. All these results point to a nonspecific solvent effect arising from solvent in the aggregate as opposed to definable molecular complexes. Accordingly, it appears that solutes are immersed in a continuum where their spontaneous electric moments create a reaction field in the solvent which, in turn, affects the magnetic shielding at the solute nuclei. Diiodomethane with its high refractive index would be expected to excel in this regard.[6]

Visible spectrophotometry gave more detailed information on the solvation properties of diiodomethane at the molecular level. The experiments used *N*,*N*-dimethindoaniline (phenol blue) dissolved at a concentration of $2 \times 10^{-5}$ M in several solvents including diiodomethane. Phenol blue has a solvent-

**Table 1** $^1H$ NMR chemical shifts in $CDCl_3$ and $CD_2I_2$

| Solute | δ ($CDCl_3$) | δ ($CD_2I_2$) | Δδ/ppm |

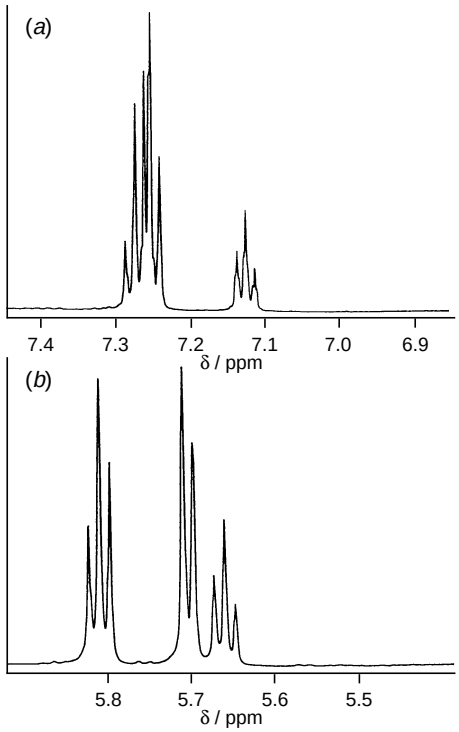
| | 7.277 | 5.811 | 1.466 |
| | 7.053 | 5.599 | 1.545 |

sensitive $\lambda_{max}$, and for this reason it has been widely exploited as a polarity probe.[7] Table 2 lists the absorbance maxima in select solvents ranging in polarity from hexane to water. It is seen that there is a red shift as the solvent becomes more polar. For example, $\lambda_{max}$ shifts from 545 nm in hexane to 654 nm in water. This is traditionally explained by the polar solvents stabilizing the transition dipole which resembles, as a crude model, the dipolar resonance contributor of the dye. The resulting spectral shift, of the dipole-induced dipole type, depends upon both the change in dipole moment of the solute and the refractive index of the solvent. A dispersive interaction is also possible in which a rapidly fluctuating transition moment creates an induced dipole in solvent molecules; this effect likewise depends upon the solvent polarizability and, hence, the refractive index.



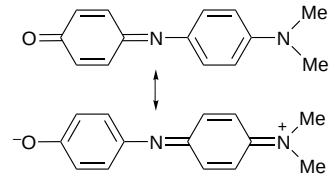


**Fig. 1** $^1$H NMR spectra of the aromatic portion of thioanisole in (*a*) $CDCl_2$ and (*b*) $CD_2I_2$. The simplification in $CD_2I_2$ results from the *ortho*-protons being shifted upfield 0.1 ppm more than the *meta*- and *para*-protons.

**Table 2** Absorbance maxima for phenol blue in several solvents

| Solvent | $\lambda_{max}$/nm |
|---|---|
| Hexane | 545 |
| Benzene | 573 |
| Dimethylformamide | 593.5 |
| Chloroform | 595 |
| Propan-2-ol | 603 |
| Ethanol | 605 |
| Methanol | 607.5 |
| Diiodomethane | 617 |
| Water | 654 |

Diiodomethane adopts a remarkable position in the list of solvents in Table 2. According to our particular reporter dye, only water exceeds diiodomethane in apparent 'polarity'. Even methanol is not quite as polar as diiodomethane. We know of no similar case in which there is such a large disparity between a 'bulk' polarity (as manifested by a relative permittivity of 5.3) and the corresponding 'spectrophotometrically-based' polarity (as manifested by the $\lambda_{max}$ of phenol blue). The shifts with phenol blue are, we presume, so much greater than with cyanine dyes because phenol blue extensively charge-separates in the excited state whereas cyanine dyes merely distribute a cationic charge. Diiodomethane clearly stabilizes transient ionic charge far beyond what is normally expected from an aprotic, and seemingly apolar, solvent.

Diiodomethane would be an interesting solvent with which to carry out kinetic studies, but experimental difficulties have thus far prevented us from doing so. Three problems were encountered: (*a*) insolubility of either the reactant or product in the solvent; (*b*) strong absorbance of the solvent below 400 nm; and (*c*) reactivity of the solvent under the reaction conditions. Information on the ability of polarizable systems to stabilize polar transition states would be particularly useful to those involved in enzyme mechanisms. Methionine, with its polarizable sulfur, frequently resides near active sites with no apparent function.

We thank the National Science Foundation for support of this work.

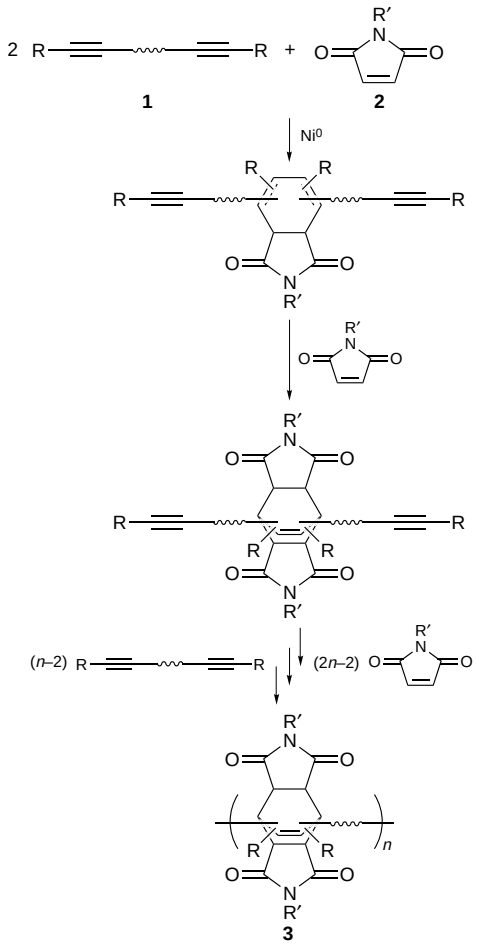
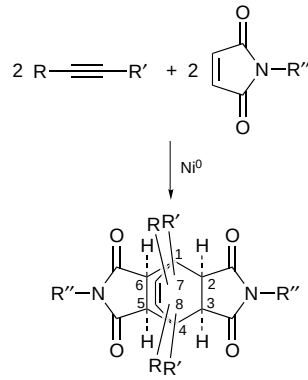
# Nickel(0)-catalysed diyne–maleimide double-cycloaddition copolymerisation to form poly(bicyclo[2.2.2]oct-7-ene)s



**Tetsuo Tsuda,*[a] Akihiko Tobisawa,[b] Haruna Mizuno[b] and Atsushi Takeda[b]**

[a] *Department of Polymer Chemistry, Graduate School of Engineering, Kyoto University, Yoshida, Kyoto 606-01, Japan*
[b] *Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606-01, Japan*

**A nickel(0) catalyst effects the double-cycloaddition copolymerisation of diynes with *N*-substituted maleimides to form poly(bicyclo[2.2.2]oct-7-ene)s.**



Recently we developed a transition metal-catalysed diyne cycloaddition copolymerisation[1] as a useful method of polymer synthesis, in which one molecule of a cycloaddition component such as carbon dioxide, an isocyanate, a nitrile or elemental sulfur reacts with two diyne molecules to afford a cycloaddition copolymer containing a heterocycle in its repeat unit.[2]

Here we report a new type of transition metal-catalysed diyne cycloaddition copolymerisation with an alkene to afford a cycloaddition copolymer containing a carbocycle in its repeat unit, *i.e.* a nickel(0)-catalysed diyne **1**–*N*-substituted maleimide **2** double-cycloaddition copolymerisation to form a poly(bicyclo[2.2.2]oct-7-ene) **3** having a wholly carbon backbone with an imide functionality (Scheme 1). This diyne–maleimide copolymerisation is characterised by a unique process in which two maleimide molecules connect two diyne molecules by double-cycloaddition to generate a copolymer repeat unit containing a bicyclo[2.2.2]oct-7-ene ring *via* nickel(0)-catalysed formation of a cyclohexadiene intermediate. Cycloaddition of two diyne molecules to one maleimide molecule is followed by Diels–Alder cycloaddition with the second maleimide molecule. This diyne–maleimide copolymerisation is based on our recent study of an efficient and chemoselective nickel(0)-catalysed 2 : 2 monoyne–maleimide double-cycloaddition to afford an *exo*,*exo*-bicyclo[2.2.2]oct-7-ene derivative stereoselectively (Scheme 2).[3]

**Scheme 1**

The results of the copolymerisation of 1,4-diethynylbenzene **1ad** with *N*-octylmaleimide **2g** are summarised in Table 1. The reaction was carried out in a 50 ml stainless steel autoclave under nitrogen. When a mixture of **1ad** (0.25 mmol) and **2g** (0.5 mmol) in THF (5 ml) was heated at 90 °C for 20 h in the presence of a $Ni(CO)_2(PPh_3)_2$ catalyst (Ni : **1ad** = 0.1), poly(bicyclo[2.2.2]oct-7-ene) **3adg** with $M_n$ = 27200 and

[a] Conditions: **1ad** (0.25 mmol), THF (5 ml), 20 h, isolation of **3adg** using $CH_2Cl_2$–AcOEt. [b] Molar ratio. [c] Based on 100% conversion of **1ad** to **3adg**. [d] Determined by GPC with polystyrene standards in $CHCl_3$. [e] A $CH_2Cl_2$-insoluble copolymer.

$M_w/M_n$ = 2.1 was obtained in 51% yield by concentration of the resulting reaction mixture under vacuum and by precipitation with $CH_2Cl_2$–AcOEt. Raising the reaction temperature to 110 °C increased the copolymer molecular weight to 34600. A nickel(0) catalyst generated from $Ni(cod)_2$ and 2 equiv. of $PPh_3$ was also effective, but $Ni(cod)_2$ alone gave an insoluble copolymer, probably due to copolymer branching and/or cross-linking[2c] originating from formation of diyne trimer in the copolymer. Compound **3adg** was formed as a pale yellow powder, which was soluble in THF, $CH_2Cl_2$ and $CHCl_3$ but insoluble in AcOEt and diethyl ether. The thermal stability of **3adg** was examined by thermogravimetric analysis (TGA) in air, and $T_{10}$ (the temperature causing a 10% weight loss) was 322 °C.

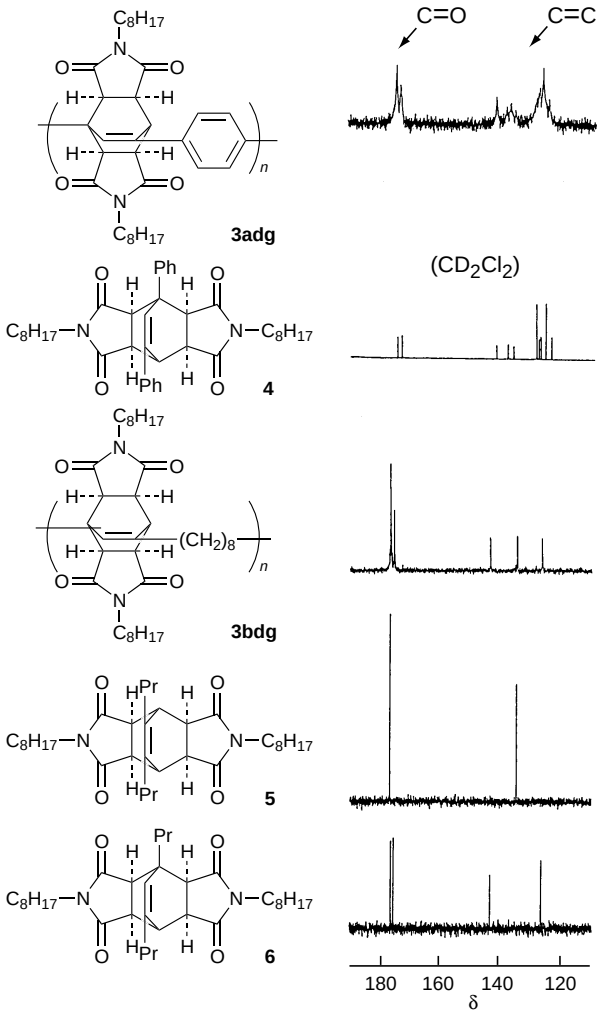

**Fig. 1** $^{13}C$ NMR C=O and C≡C signals of poly(bicyclo[2.2.2]oct-7-ene)s **3adg** and **3bdg** together with model compounds **4**–**6** ($CDCl_3$)

[a] Conditions: **1** (0.25 mmol), $Ni(CO)_2(PPh_3)_2$: **1** = 0.1, THF (2 ml), 20 h, isolation of **3** using $CH_2Cl_2$–hexane. [b] Molar ratio. [c] Based on 100% conversion of **1** to **3**. [d] Determined by GPC with polystyrene standards in $CHCl_3$. [e] Isolation from $CH_2Cl_2$–$Et_2O$.

Copolymerisations of **1ad** with *N*-phenyl- and *N*-ethyl-maleimides **2f** and **2h** gave insoluble copolymers **3adf** and **3adh**. Thus introduction of a longer *N*-alkyl substituent, such as an octyl group, into the maleimide was necessary for the preparation of a soluble poly(bicyclo[2.2.2]oct-7-ene) from **1ad**.

Poly(bicyclo[2.2.2]oct-7-ene) **3adg** was identified by IR, $^1H$ and $^{13}C$ NMR spectroscopy. Comparison of $^{13}C$ NMR C=O and C=C signals of **3adg** and a model compound of the copolymer repeat unit was most informative. The $^{13}C$ NMR C=O and C=C signals of **3adg** were similar to those of model compound **4**,[3] obtained regio- and stereo-selectively by the nickel(0)-catalysed cycloaddition reaction of phenylacetylene with **2g** (Fig. 1). This result confirms that the structure of **3adg** contains an *exo*,*exo*-fused 1,8-phenylene-substituted bicyclo[2.2.2]oct-7-ene ring.

In contrast with the formation of insoluble copolymer **3adf**, dodeca-1,11-diyne **1bd** copolymerised with **2f** to afford soluble copolymer **3bdf**, the difference in solubility being due to the presence of the long alkylene chains (Table 2). Diyne **1bd** copolymerised with **2g** to afford **3bdg** as a colourless resinous solid. The $^{13}C$ NMR C=O and C=C signals of **3bdg** were a superposition of those of two model compounds **5** and **6**,[3] which were obtained stereo- but nonregio-selectively by nickel(0)-catalysed cycloaddition reaction of pent-1-yne with **2g** (Fig. 1). This fact demonstrates the copolymer structure and indicates that **3bdg** has two kinds of repeat units corresponding to **5** and **6**.

Use of a two-fold excess of the maleimide (maleimide : diyne = 4 : 1) did not influence significantly the copolymer yield and molecular weight when compared with the stoichiometric copolymerisation (maleimide : diyne = 2 : 1) (Tables 1 and 2). An internal diyne, tetradeca-3,11-diyne **1ce**, copolymerised with **2f** at 110 °C to afford **3cef**.

Poly(bicyclo[2.2.2]oct-7-ene)s **3adg** and **3bdg** containing two octyl groups per repeat unit have unique rigid and flexible fence-like structures, respectively, and are potentially interesting, as structurally related comb-like polymers are well known and attract considerable attention on account of their specific properties.[4]

This work was partly supported by a Grant-in-Aid for Scientific Research on Priority Areas (Nos. 06227235 and 07216237) from the Ministry of Education, Science, Sports and Culture, Japan.

# The synthesis and structure of $[Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_3Bu^t_2)X]$

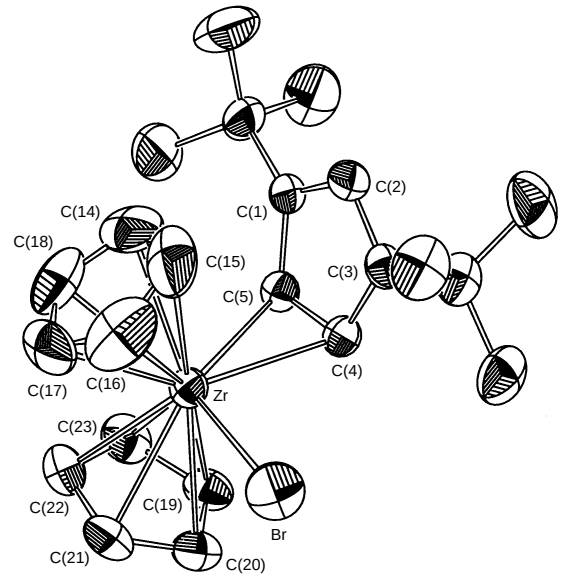
**Marco M. Corradi, David J. Duncalf, Gerard A. Lawless* and Martin P. Waugh**

*The Chemistry Laboratory, School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*

**Reaction of 1 equiv. of $KC_5H_3Bu^t_2$ with $[Zr(\eta\text{-}C_5H_5)_2X_2]$ affords $[Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_3Bu^t_2)X]$ (X = Cl 1, Br 2); the molecular structure, and solid- and solution-state $^{13}C$ NMR data are presented.**

There is considerable interest in the catalysis of alkene polymerisation by Zr-based metallocenes. Overwhelming evidence exists supporting the proposal that cationic 14 electron metallocene alkyls $[Zr(\eta\text{-}C_5H_5)_2R]^+$ are the active species.[1–3] Two steps which are crucial to the proposed mechanism are (*i*) the binding of the alkene to the Zr centre and (*ii*) its subsequent insertion into the Zr–R bond. Given that for ethene the entire insertion process may be as fast as 70–170 fs,[4] it is hardly surprising that no examples of a π complex of an alkene and $[Zr(\eta\text{-}C_5H_5)_2R]^+$ have been structurally characterised, despite the synthesis of an ever increasing number of such cations. We now report that this $\eta^2$ coordination mode is observable when an alkene may act as a three-electron donor. We present as evidence the structure and $^{13}C$ NMR spectroscopic data for **2**.

The reaction of $KC_5H_3Bu^t_2$ with $[Zr(\eta\text{-}C_5H_5)_2X_2]$ in toluene or thf yields **1** and **2** respectively.† The molecular structure of **2** was determined‡ (Fig. 1). The $\eta^2$ coordination mode of the $^-C_5H_3Bu^t_2$ is evident from a comparison of the Zr–C(4) and Zr–C(5) bond lengths [2.490(3), 2.539(3) Å, respectively] with those for Zr–C(1), Zr–C(2) and Zr–C(3) [3.462(4), 3.834(5), 3.368(5) Å, respectively]. Zr, Br, C(4) and C(5) are coplanar to within 0.0165 Å. The M(1)–Zr–C(4) and M(1)–Zr–C(5) angles are 118(3) and 107.7(3)° respectively while the corresponding M(2)–Zr–C(4) and M(2)–Zr–C(5) angles are 108.2(3) and 98.6(3)° respectively. The M(1)–Zr–M(2) angle is unexceptional at 128.6(4). The size and asymmetry of the Zr–C(4) and Zr–C(5) interactions are in good agreement with those calculated for the ethene complex $\{Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_2H_4)Me\}$ (2.50, 2.72 Å).[5] **2** may be formulated as a cyclopentadienyl adduct of a 14-electron Zr cation such as $[Zr(\eta\text{-}C_5H_4Bu^t)_2\{CH_2C(Me)C(Me)C(Me)CH_2\}]$[6] or $[Zr(\eta\text{-}C_5H_4Bu^t)_2\{OCMe_2CH_2CH_2CHCH_2\}]$,[7] [for which the $\eta^2$ Zr–C bond lengths are 2.602(7)–2.759(7) and 2.68(2), 2.89(2) Å respectively]. In this model the resulting anionic charge is delocalised on C(1), C(2) and C(3) (Scheme 1, **a**). The combination of such anionic and cationic centres within a neutral molecule has been recently demonstrated.[8] The high-frequency shifts exhibited in the $^{13}C$ NMR spectra of the β, C(1) and C(3) resonances and the corresponding low-frequency shift for C(2) (δ 170.6 and 87.6 respectively, for **2**) indicate, however, that a cationic formulation for C(1) and C(3) is more appropriate (Scheme 1, **b**–**d**). Thus the $^-C_5H_3Bu^t_2$ groups of **1** and **2** act as three-electron donors to 15-electron Zr centres resulting in 18-electron complexes. A similar bonding model has been previously proposed to account for the $\eta^2$-bonding in $[Ti(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_5)]$.[9] The stability of this coordination mode requires both the availability of a third electron and the concomitant formation of a stable β cationic carbon centre. The Zr–C(4) and Zr–C(5) bond lengths compare well with those reported for the $\eta^2$ coordinated butadiene of $[Zr(\eta\text{-}C_5H_5)_2\{\mu\text{-}(1,2\text{-}\eta^2\text{-}Zr):(4\text{-}\eta^1\text{-}Al)\text{-}C_4H_6\}(\mu\text{-}Cl)AlCl_2]$[10] [2.348(2), 2.510(2) Å] and indenyl groups of the *ansa*-bridged systems $[Zr\{Me_2C(\eta\text{-}C_5H_4)(\eta^2\text{-}C_9H_6)\}(\eta\text{-}C_5H_5)Cl]$ [2.587(8), 2.497(8) Å] and $[Zr\{(CH_2)_5C(\eta\text{-}C_5H_4)(\eta^2\text{-}C_9H_6)\}(\eta\text{-}C_5H_5)Cl]$[11] [2.508(5), 2.564(4) Å]. The latter is characterised by a low-frequency $^{13}C$ NMR shift.§ For $[Zr\{(CH_2)_5C(\eta\text{-}C_5H_5)(\eta^2\text{-}C_9H_6)\}(\eta\text{-}C_5H_5)Cl]$, $[Zr\{Me_2C(\eta\text{-}C_5H_4)(\eta^2\text{-}C_9H_6)\}(\eta\text{-}C_5H_5)Cl]$ and $[Zr(\eta\text{-}C_5H_5)_2\{\mu\text{-}(1,2\text{-}\eta^2\text{-}Zr):(4\text{-}\eta^1\text{-}Al)\text{-}C_4H_6\}(\mu\text{-}Cl)AlCl_2]$ similar shifts have been noted. The long Zr–Br(1), 2.672(1) Å, is also consistent with an 18-electron configuration. A solid-state $^{13}C$ NMR study of **2** confirmed that the $\eta^2$-coordination



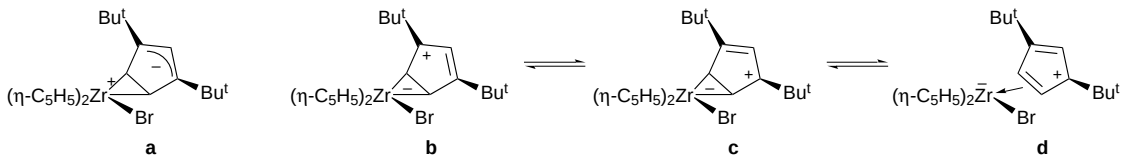


**Fig. 1** The molecular structure of $[Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_3Bu^t_2)Br]$ **2** and atom numbering scheme with selected bond lengths (Å) and angles (°): Zr–C(1) 3.462(4), Zr–C(2) 3.834(5), Zr–C(3) 3.368(5), Zr–C(4) 2.490(5), Zr–C(5) 2.539(3), Zr–Br 2.672(1), Zr–M(1) 2.21(1), Zr–M(2) 2.24(1), M(1)–Zr–C(4) 118.0(3), M(1)–Zr–C(5) 107.7(3), M(2)–Zr–C(4) 108.2(3), M(2)–Zr–C(5) 98.6(3), M(1)–Zr–M(2) 128.6(4), M(1) denotes the centroid of the ring C(14)–C(18), M(2) denotes the centroid of the ring C(19)–C(23)

**Scheme 1** Resonance structures for **2**

mode of the $^{-}C_5H_3Bu^t_2$ group is retained in toluene solution at 243 K, as all $^{13}C$ resonances, C(1)–C(5) are inequivalent. Upon warming to 297 K, however, C(4) and C(5) mutually exchange as do C(1) and C(3). The exchange mechanism may involve either $\eta^2$ to $\eta^1$ or $\eta^2$ to $\eta^5$ rearrangements.¶ We favour the latter for **2**, as the former would be extremely unfavourable sterically due to the β-Bu$^t$ substituents, and the twenty electron count associated with such an $\eta^5$ rearrangement has precedence in $[Zr(\eta\text{-}C_5H_5)_3(\eta^1\text{-}C_5H_5)]$.[12] For non-cyclopentadienyl based $\eta^2$ systems, clearly the former will be of greater importance. A comparison of the $^{13}C$ NMR data for **1** and **2** corroborates the presence of an $\eta^2$ bonding mode for the $^{-}C_5H_3Bu^t_2$ ligand of **1**, also. Initial studies indicate that both **1** and **2** are inactive as ethene polymerisation catalysts although the addition of MAO does produce an active system. Finally, a similar three electron interaction between say, ethene or propene, and a 14-electron Zr centre would sufficiently destabilize the corresponding metallocycle permitting facile insertion into a neighbouring Zr–C bond. Furthermore the tacticity of the resulting polymer would be dependent on the rate of insertion in comparison to the rate of $\eta^2$ to $\eta^1$ exchange.

We thank EPSRC (M. M. C., D. J. D., M. P. W.) for financial support.

## Footnotes

† *Syntheses*: $[Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_3Bu^t_2)Cl]$. To a Schlenk tube containing $[Zr(\eta\text{-}C_5H_5)_2Cl_2]$ (2.84 g, 9.72 mmol) and $KC_5H_3Bu^t_2$ (2.1 g, 9.72 mmol) was added 200 ml of dry, degassed toluene. The reaction mixture was stirred for 72 h during which time a gradual colour change from yellow to dark red was observed. After this time the toluene solution was filtered from the off-white precipitate and the toluene removed *in vacuo* to yield **1** as an orange powder, 85.5% (3.6 g, 8.31 mmol). Recrystallisation of **1** from toluene afforded dark orange platelets unsuitable for single-crystal diffraction. Mp (decomp.) 167–169 °C. $^1H$ NMR ($CDCl_3$, 400.13 MHz) δ 6.05 (s, 10 H) 5.96 [t, 1 H, $^4J(^1H–^1H)$ 1.75 Hz], 5.50 [d, 2 H, $^4J(^1H–^1H)$ 1.75 Hz], 1.28 (s, 18 H); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100.61 MHz) δ 170.2, 115.9 [$^1J(^{13}C–^1H)$ 158 Hz], 113.5 [$^1J(^{13}C–^1H)$ 174 Hz], 88.0 [$^1J(^{13}C–^1H)$ 158 Hz], 34.3, 31.9 [$^1J(^{13}C–^1H)$ 126 Hz].

$[Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_3Bu^t_2)Br]$. To a Schlenk tube containing $[Zr(\eta\text{-}C_5H_5)_2Br_2]$ (0.92 g, 2.41 mmol) in thf (40 ml) was added $KC_5H_3Bu^t_2$ (0.71 g, 3.29 mmol) slurried in thf (50 ml). An immediate colour change from pale yellow to orange was observed. After stirring for a further 12 h the thf was removed *in vacuo* and the resulting orange powder extracted into hexane. The solvent was removed *in vacuo* to yield **2** as an orange powder, 78%, (0.9 g, 1.88 mmol). Recrystallisation of **2** from toluene afforded dark orange platelets suitable for single-crystal diffraction. Mp (decomp) 139.8 °C. $^1H$ NMR ($C_7D_8$, 400.13 MHz) δ 5.96 [t, 1 H, $^4J(^1H–^1H)$ 1.75 Hz], 5.69 (s, 10 H), 5.38 [d, 2 H, $^4J(^1H–^1H)$ 1.75 Hz], 1.33 (s, 18 H); $^{13}C\{^1H\}$ NMR ($C_7D_8$, 100.61 MHz) δ 170.6, 115.9, 112.8, 87.6, 34.4, 31.6; $^{13}C\{^1H\}$ NMR ($C_7D_8$, 100.61 MHz, 243 K) δ 172.6, 169.9, 115.4, 112.8, 93.8, 80.9, 35.2, 34.1, 31.7; $^{13}C\{^1H\}$ CP MAS NMR (100.61 MHz) δ 178, 174, 122, 117, 98, 85, 44, 38, 36.

‡ *Crystal data* $[Zr(\eta\text{-}C_5H_5)_2(\eta^2\text{-}C_5H_3Bu^t_2)Br]$, $C_{30}H_{39}BrZr$. Crystallographic measurements were made on a Siemens three-circle diffractometer equipped with a SMART CCD area detector, using Mo-Kα radiation, λ = 0.71073 Å, 2θ < 57.18°, μ = 2.103 mm$^{-1}$. The heavy atoms were located by the Patterson interpretation of SHELXTL and refined on $F^2$ by a full-matrix least-squares procedure. Anisotropic thermal parameters were used for all non-H atoms. H atoms were given fixed isotropic temperature factors with the positions constrained by the heavy-atom geometry in the refinement. A molecule of toluene is present within the asymmetric unit. $T$ = 220(2) K. Specimen 0.40 × 0.35 × 0.20 mm, $M$ = 570.74, monoclinic, space group $P2_1/n$, $a$ = 11.082(2), $b$ = 10.224(2), $c$ = 21.675(4) Å, β = 96.02(3)°, $U$ = 2442.3(8) Å$^3$, $D_c$ = 1.554 g cm$^{-3}$, μ(Mo-Kα) = 2.103 mm$^{-1}$, $Z$ = 4. For reflections with 1.89 < θ < 28.59°, $R(F)$ = 0.0544 for 4570 observed reflections [$I > 2\sigma(I)$] and $wR(F^2)$ = 0.1162 for all 5724 reflections. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/331.

§ The paramagnetic shift associated with these cations compared with those associated with classical trialkyl carbonium species is diminished due to the resonance stabilisation of the positive charge.

¶ Initial analysis of this lineshape at 298, 273, 253, 243, 233 K yields $\Delta H^‡$ = 66 kJ mol$^{-1}$, $\Delta S^‡$ = 68 J K$^{-1}$ mol$^{-1}$. At 298 K $\Delta G^‡$ = 46 kJ mol$^{-1}$.

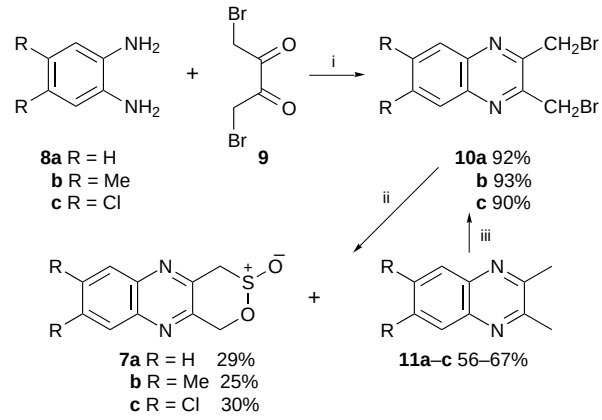
# Quinoxalino-fused sultines and their application in Diels–Alder reactions

**Wen-Sheng Chung* and Jing-Horng Liu**

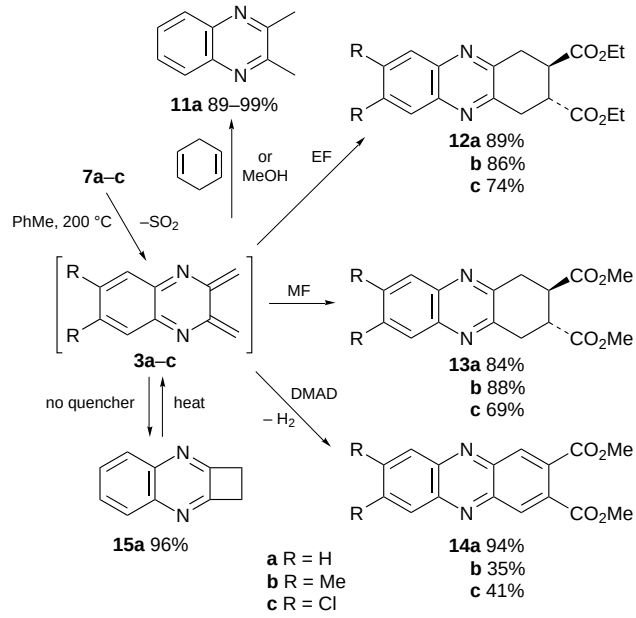
*Department of Applied Chemistry, National Chiao Tung University, Hsinchu, Taiwan 30050, R.O.C.*

**The synthesis of 7,8-disubstituted quinoxalino[2,3-*d*]-[1,2λ⁴]oxathiine 2-oxides 7a–c, precursors for quinoxalino-*o*-quinodimethanes 3a–c, and their application in the Diels–Alder reactions are reported.**



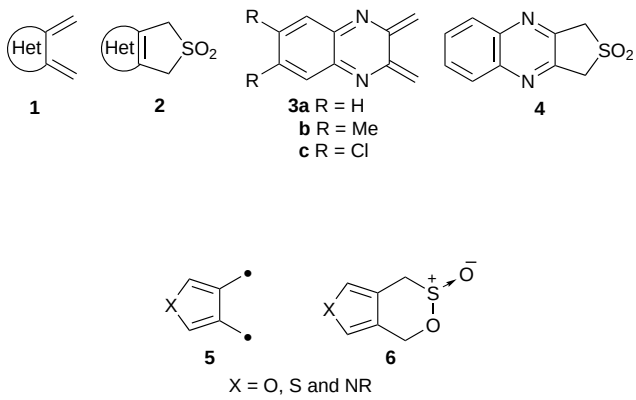
The chemistry of heterocyclic *o*-quinodimethanes **1** has attracted a great deal of attention recently.[1] Various methods for generating these highly reactive dienes have been developed.[2] Among them, cheletropic elimination of $SO_2$ from heteroaromatic-fused 3-sulfolenes **2** has drawn the most attention.[1–3] Quinoxalines are important naturally occurring heterocycles and are usually found to have biological and pharmaceutical activity.[4] Finding an easy, high-yield method for generating quinoxalino-*o*-quinodimethanes **3** is thus of particular interest.

Although Chou *et al*. reported[5] generating quinoxalino-*o*-quinodimethanes **3a** using $SO_2$ extrusion of the quinoxalino-fused sulfolene **4**, all their attempts to isolate the Diels–Alder adducts failed. Recently we described[6] the generation of nonclassical heteroaromatic *o*-quinodimethanes **5** by thermal extrusion of $SO_2$ from corresponding sultines **6**. A significant advantage of using sultines is that their thermolysis occurs at a much lower temperature than that of corresponding sulfolenes.[6–8] We report here our work on the synthesis of quinoxalino-fused sultines **7a**–**c** and their applications in Diels–Alder reactions with alkenes and alkynes.



Previously unknown sultines **7a**–**c** were synthesized in two steps with good yields as shown in Scheme 1. Reaction of the appropriate *o*-diamino-substituted benzene **8** with 1,4-dibromobutane-2,3-dione **9** gave the known 2,3-bis(bromomethyl)quinoxaline **10a**,[9a] 6,7-dimethylquinoxaline **10b**,[4,9b] and 6,7-dichloroquinoxaline **10c**.[4] The desired quinoxalino-fused sultines **7a**–**c**† and by-products **11** were obtained by the use of Rongalite[8] (sodium formaldehyde sulfoxylate) with the corresponding dibromides **10a**–**c**. Although the yields of sultines **7a**–**c** were only *ca*. 30%, fortunately the by-product **11** can be converted back to dibromide **10** *via* *N*-bromosuccinimide bromination,[4b] which makes the syntheses of the sultines more efficient.

The Diels–Alder reactions of quinoxalino-fused sultines **7a**–**c** with several dienophiles are presented in Scheme 2. When heated in toluene (200 °C, sealed tube) in the presence of 3 equiv. of diethyl fumarate (EF) or dimethyl fumarate (MF), the sultines **7a**–**c** all underwent extrusion of $SO_2$ and the resulting quinoxalino-*o*-quinodimethanes **3a**–**c** were intercepted as the 1 : 1 adducts (**12** and **13**) in 69–89% yield. The reactions with dimethyl acetylenedicarboxylate (DMAD) went similarly to 1 : 1 adducts and after loss of $H_2$ gave **14a**–**c** in 35–94% yield.



In the absence of a dienophile, sultine **7a** underwent thermal extrusion of $SO_2$ and formed the cyclobuta[1,2-*b*]quinoxaline **15a** almost quantitatively. In contrast, **15a** was reported[5] to be isolated only in low yield (10%) when the corresponding sulfolene **4** was flash pyrolysed at 500 °C followed by addition of excess *N*-phenylmaleimide (NPM). Thermolysis of **7a** in the presence of methanol or cyclohexa-1,4-diene, on the other hand, gave 2,3-dimethylquinoxaline **11a** in 89–99% yield. Inter-

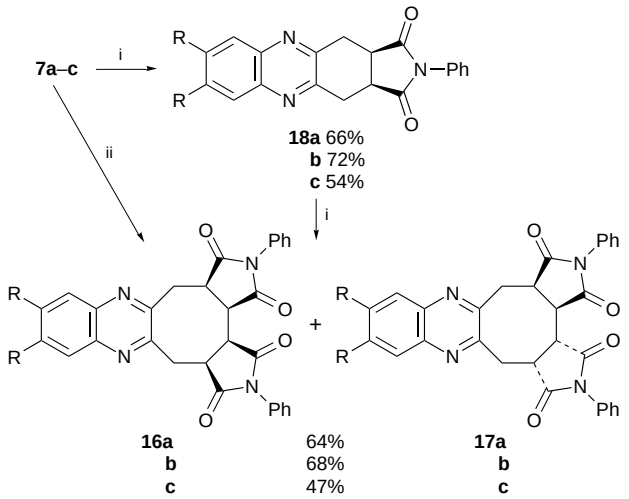
**Scheme 2**



estingly, Diels–Alder adducts (such as **12**–**14a**) were also formed in excellent yield when the cyclobutene **15a** was heated in the presence of dienophiles at 200 °C, indicating that cyclobutene **15a** is also a good precursor of *o*-quinodimethane **3a**.

The reaction of **7a**–**c** with excess NPM at 200 °C gave a pair of new adducts **16** and **17** in 47–68% yields (Scheme 3). These 2 : 1 adducts showed similar spectral characteristics, consistent with the *cis* and *trans* cyclooctaquinoxalines **16** and **17**.‡ When only 1 equiv. of NPM was used, the yield of 1 : 1 adduct **18b** was optimized to 72% and the 2 : 1 adducts (**16** and **17**) were present in only trace amounts. Similar observation of these 2 : 1 adducts in the trapping of pyrimidine *o*-quinodimethanes by NPM has been reported recently by Tomé *et al.*[3a,c] We were, however, surprised to see that different adducts were reported[10] when **10a** was heated with sodium iodide in the presence of NPM, even though this method is generally assumed to give a synthetic equivalent of *o*-quinodimethane **3a**. The real reason for this difference may be just as the authors described:[10] the reaction of **10a** and sodium iodide probably did not involve dehalogenation to give a true *o*-quinodimethane **3a**, but rather the adducts might have been formed by a mechanism involving displacement of a halogen atom by the dienophile.

Thus our results, obtained by pyrolysing 7,8-disubstituted quinoxalino-fused sultines **7a**–**c**, strongly support the formation of quinoxalino-*o*-quinodimethanes **3a**–**c**, which differ from the products formed when sulfolene **4** is pyrolysed, or when **10a** and sodium iodide react.[10] The easily synthesized sultines **7a**–**c** reacted under milder conditions (200 °C) than the corresponding sulfolene **4** (⩾290 °C is required) and their reaction products were different in many cases. When generated in the presence of a dienophile, sultines **7a**–**c** provided elegant synthons for the formation of [4 + 2] cycloadducts. If no trapping agents were used, the sultines gave cyclobuta[1,2-*b*]quinoxaline **15** almost quantitatively, which again is a good precursor of *o*-quinodimethanes **3**. Further work to study the mechanism by laser flash photolysis is in progress.

We thank the National Science Council of the Republic of China for its financial support (Grant No. NSC 85-2113-M-009-002).

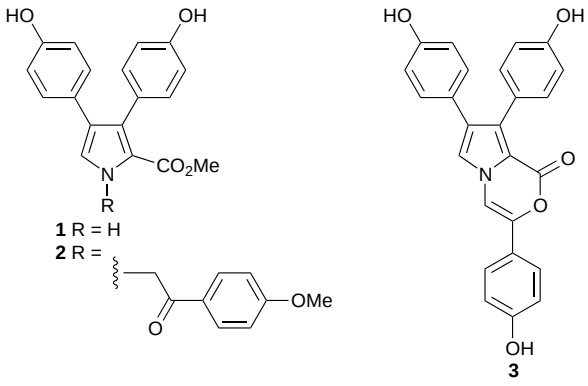
# Convergent syntheses of the pyrrolic marine natural products lamellarin-O, lamellarin-Q, lukianol-A and some more highly oxygenated congeners

**Martin G. Banwell,*[a] Bernard L. Flynn,[a] Ernest Hamel[b] and David C. R. Hockless[a]**



[a] *Research School of Chemistry, Institute of Advanced Studies, The Australian National University, Canberra, ACT 0200, Australia*

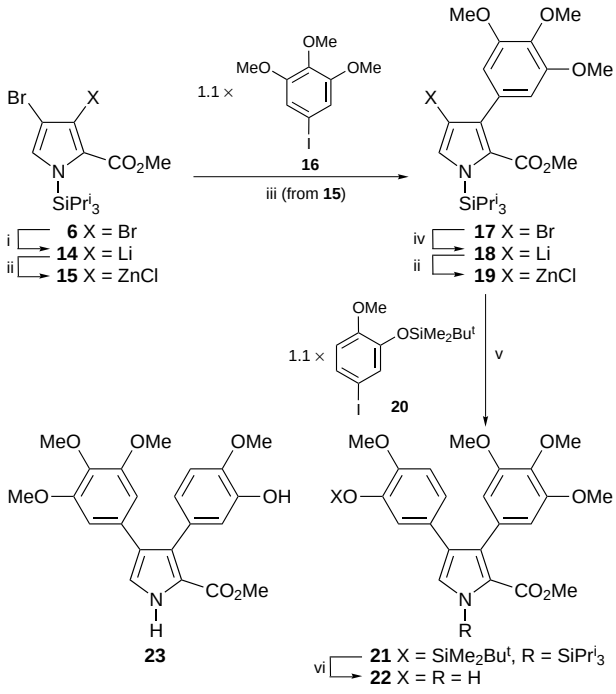
**The marine alkaloids lamellarin-Q 1, lamellarin-O 2 and lukianol-A 3 as well as their more highly oxygenated congeners 22 and 23 are synthesised using Stille, Suzuki or Negishi cross-coupling reactions as the key step.**

Lamellarins A–R,[1–5] lukianols A–B,[6] storniamides A–D,[7] polycitrins A–B[8] and polycitone A[8] are marine natural products that possess a 3,4-diarylated pyrrole 2-carboxylic acid ester or amide moiety as the common structural subunit. These materials have been isolated from widely varying locations and organisms (molluscs, tunicates, sponges) and a number have been shown to possess interesting biological properties. For example, lukianol-A exhibits some activity against a cell line derived from human epidermaoid carcinoma[6] while the penta-*O*-methyl derivative of polycitone A was found to inhibit the growth of SV 40 transformed fibroblast cells at concentrations of 10 μg ml$^{-1}$.[8] Our own interest in such alkaloids stems from the notion that they are configurationally stable structural hybrids of the powerful anti-mitotic agents combretastatin A-4[9] and colchicine[10] and, as such, may represent new classes of compounds that are capable of inhibiting cell division.[11] Despite the foregoing, remarkably little attention has been given to the total synthesis of any of the above-mentioned marine natural products.[12] Consequently, we now report convergent syntheses of the title compounds **1**–**3** as well as two more highly oxygenated and differentially di-arylated congeners. In each case, the key synthetic step involves Stille[13] or Suzuki[14] or Negishi[15] cross-coupling of readily available pyrrole 2-carboxylic acid derivatives with the appropriate aryl stannane, boronic acid or iodide. These steps represent rare examples of the use of palladium-catalysed cross-coupling chemistry for the introduction of carbon-based substituents onto the pyrrole nucleus.[16]

The pivotal dibromopyrrole **6** (Scheme 1) required for all the syntheses was readily prepared from pyrrole itself using procedures developed by Muchowski and co-workers.[17] Thus, the triisopropylsilyl derivative, **4**,[17] of pyrrole was subjected to reaction with 3 molar equiv. of *N*-bromosuccinimide (NBS) in THF at −78 °C. In this manner the tribromo-derivative, **5** (91%, mp 44–46 °C; lit.,[17] mp 46 °C) was obtained. Subjection of this latter compound to reaction with PhLi followed by $ClCO_2Me$ afforded the previously unreported compound **6** (99%). Stille cross-coupling of pyrrole **6** with 2 equiv. of the $Bu^tMe_2Si$ protected stannane **7** using $Pd(PPh_3)_2Cl_2$ as catalyst gave the expected product **8** (66%). Three-fold deprotection of the tris-*O*-silylether **8** using $Bu_4NF$ then afforded lamellarin-Q **1** (98%, mp 227–228 °C) which was spectroscopically identical with the natural product. The synthesis of lamellarin-O followed very similar lines. Thus, compound **6** was desilylated and the resulting pyrrole **9** (99% mp 147–148 °C) coupled with arylstannane **7**. In this manner the two-fold coupling product **10** (66%) was obtained. Reaction of this latter compound with commercially available 2-bromo-4′-methoxyacetophenone in the presence of base then gave the *N*-substituted pyrrole **11** (84%) which was deprotected with $Bu_4NF$ to provide the natural



**Scheme 1** *Reagents and conditions*: i, NBS (3 equiv.), THF, −78 °C, 1 h then 20 °C for 4 h; ii, PhLi (1 equiv.), −78 °C, 0.16 h then $ClCO_2Me$ (1.05 equiv.), −78 to 20 °C, 1 h; iii, $Pd(PPh_3)_2Cl_2$ (10 mol%), 1,4-dioxane, 101 °C, 14 h; iv, $Bu_4NF$ (10 mol% excess), THF, 20 °C, 1 h then 0.5 M aq. HCl; v, *p*-$MeOC_6H_4COCH_2Br$ (3 equiv.), $K_2CO_3$ (5 equiv.), $Bu_4NCl$ (20 mol%), THF, 66 °C, 8 h; vi, $Pd(PPh_3)_4$ (5 mol%), sat. aq. $Na_2CO_3$ (6 equiv.), DMF, 153 °C, 23 h; vii, see ref. 12

product **2** (99%, mp 259–260 °C), the structure of which was confirmed by single-crystal X-ray analysis.†

Two-fold cross-coupling of pyrrole **9** with *p*-$MeOC_6H_4$-$B(OH)_2$ **12**[18] under standard Suzuki conditions afforded compound **13** (78% mp 170–171 °C; lit.,[12] mp 169–171 °C) which has previously been converted, over three steps and in 53% yield, into lukianol A **3** by Fürstner and co-workers.[12] The present work represents a superior synthesis of this natural product since the pivotal intermediate **13** is available in five steps and 69% overall yield from pyrrole by the methods just described while Fürstner's route provides the same material in six steps and *ca*. 15% overall yield.

In carrying out the Stille and Suzuki cross-coupling reactions described above we failed to observe any significant quantities of mono-arylated pyrroles even when shorter reaction times and 1 : 1 stoichiometries were employed. As a consequence, these types of coupling reactions would not seem useful in providing access to differentially di-arylated pyrroles–systems that would be required for the synthesis of the more complex lamellarins and in the preparation of various combretastatin A-4/colchicine hybrids. Such limitations were overcome by regioselective lithiation of compound **6** followed by transmetallation and Negishi cross-coupling reactions as outlined in Scheme 2 for the preparation of differentially diarylated and highly oxygenated pyrroles **22** and **23** (these compounds were chosen as targets because of their structural resemblance to combretastatin A-4). Thus, reaction of compound **6** at −78 °C with PhLi afforded the mono-lithio-derivative **14** which was transmetallated with $ZnCl_2$ to give the organozinc **15**. This last species was, in turn, cross-coupled with the aryl iodide **16**[19] to give the mono-arylated pyrrole **17** (69% from **6**, mp 154–155 °C). Compound **17** was subjected to a further lithiation–transmetallation sequence and intermediate **19** then cross-coupled with aryl iodide **20** (mp 36–38 °C) to give compound **21** (75%, mp 154–156 °C). This latter material was desilylated using $Bu_4NF$ thereby affording the target pyrrole **22** (91%, mp 158–159 °C).

**Scheme 2** *Reagents and conditions*: i, PhLi (1.0 equiv.), THF, −78 °C, 0.25 h; ii, $ZnCl_2$ (1.1 equiv.), THF, −78 to *ca*. 20 °C, 0.25 h; iii, Compound **16** (1.1 equiv.), $Pd(PPh_3)_4$ (5 mol%), THF, 20 °C, 8 h; iv, BuLi (equiv.), THF, −78 °C, 0.02 h; v, Compound **20** (1.1 equiv.), $Pd(PPh_3)_4$ (5 mol%), THF, 20 °C, 8 h; vi, $Bu_4NF$ (2.2 equiv.), THF, 20 °C, 1 h then 0.5 M aq. HCl

An exactly analogous reaction sequence where compound **15** was coupled with aryl iodide **20** and the resulting mono-arylated pyrrole (62%) subjected to metallation and coupling with aryl iodide **16** afforded, after deprotection, the isomeric system **23** (42% from **6**, mp 172–173 °C) the structure of which was confirmed by single-crystal X-ray analysis.†

We thank the Institute of Advanced Studies for financial support including the provision of a post-Doctoral Research Fellowship to B. L. F. Associate Professor R. J. Capon (University of Melbourne) is thanked for providing spectroscopic data on lamellarin-O and -Q.

# $C_{120}O_2$: The first [60]fullerene dimer with cages bis-linked by furanoid bridges

**Andrei Gromov,[a] Sergei Lebedkin,[c] Stephan Ballenweg,[a] Anthony G. Avent,[b] Roger Taylor[b] and Wolfgang Krätschmer*[a]**

[a] *Max-Planck-Institut für Kernphysik, Postfach 103980, D-69029 Heidelberg, Germany*
[b] *The Chemistry Laboratory, University of Sussex, Brighton, UK BNI 9QJ*
[c] *Forschungszentrum Karlsruhe, Institut für Nukleare Festkörperphysik, Postfach 3640, D-76021 Karlsruhe, Germany*

**$C_{120}O_2$ has been prepared, characterised by MALDI–TOF MS, UV–VIS, FTIR, and shown by $^{13}C$ NMR spectroscopy to have $C_{2v}$ symmetry, the [60]fullerene cages being linked by adjacent furanoid rings; thus the structure has a connecting bridge containing a four-membered ring, reminiscent of that conjectured for the [2 + 2] fullerene cycloadduct.**

Recently, we described the preparation and characterisation of $C_{120}O$, the first dimeric fullerene derivative.[1] The structure was subsequently confirmed.[2] As part of our ongoing interest in fullerene oxides, and the search for $C_{119}$ precursors,[3] we prepared and isolated $C_{120}O_2$ by thermolysis of $C_{120}O$.[4] Solid $C_{120}O$ was heated to 400 °C for 1 h at normal pressure in an Ar atmosphere. Under these conditions we observed (i) decay of $C_{120}O$ into $C_{60}$ (up to 60% with respect to the initial $C_{120}O$), (ii) the formation of $C_{120}O_2$ (*ca*. 15%) together with oligomeric oxides $(C_{60})_nO_m$ ($n$ = 3–5; $m$ = 3–9), and (iii) an insoluble uncharacterised residue (*ca*. 10%).[4] $C_{120}O_2$, isolated from the obtained mixture by a two-stage HPLC separation,† is a brown solid, stable under ambient conditions and in solution (HPLC analysis).

The mass spectrum of $C_{120}O_2$ [matrix-assisted laser desorption/ionisation time-of-flight (MALDI–TOF) MS, negative mode of ionisation, matrix 9-nitroanthracene] shows (Fig. 1) the intense molecular ion peak at 1473.3 amu (calculated for $C_{120}O_2$, 1473.32 amu). Weak peaks at 720.2 and 736.6 amu indicate minor fragmentation of $C_{120}O_2$ into $C_{60}$ and $C_{60}O$; a similarly weak peak at 1489.8 amu ($C_{120}O_3$) may indicate oxidation by the matrix under MALDI conditions.

Our initial attempts to obtain a $^{13}C$ NMR spectrum failed due to the low solubility of the substance in $CS_2$. To overcome this problem we produced enriched material with *ca*. 7% $^{13}C$.‡ The $^{13}C$ NMR spectrum is shown in Fig. 2 and consists of two lines in the $sp^3$ region and 27 in the $sp^2$ region (with three coincident peaks).§ The number of lines, and their intensity distribution is consistent with a molecule of $C_{2v}$ symmetry. The two groups of four equivalent $sp^3$-hybridised carbon atoms indicate that each [60]fullerene cage is bis-linked by adjacent furanoid rings.

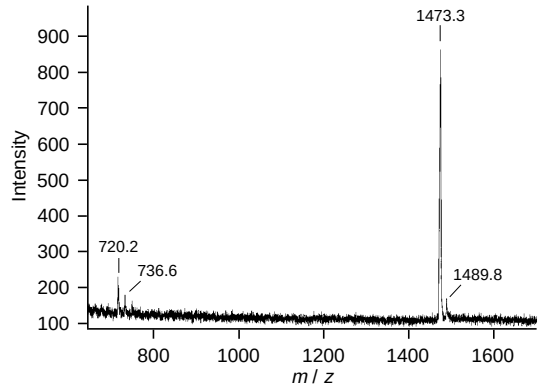

**Fig. 1** MALDI–TOF mass spectrum of $C_{120}O_2$

Thus, the connecting bridge contains a four-membered ring. The four half-intensity $sp^2$ peaks are due to the carbons on one of the $\sigma_v$ planes.

The $^{13}C$ NMR data suggest two most likely structures, in both of which a four-membered ring is part of the linkage between the cages: in one, the two furanoid rings link the cages *via* 6,6 junctions as in the case of $C_{120}O$[1] **1**, whereas the other structure involves 6,5 junctions for this purpose **2** (Fig. 3). Whilst structure **2** has a four-membered ring exactly analogous to that conjectured for photopolymerised fullerenes,[5] **2** may be disputed on two grounds: (i) it contains unfavourable double bonds in pentagons[6] (calculated to destabilise by *ca*. 8.5 kcal $mol^{-1}$ per double bond);[7] (ii) the structure is inappropriate to explain the position in the spectrum of the signals for the on-plane carbons. For structure **2** each on-plane pair is roughly equidistant from the addend, so that four lines in a similar region of the spectrum could be expected. By contrast, in structure **1** one of the pairs is adjacent to the addend site, and is *exo* to a pentagon containing two $sp^3$-hybridised carbons. These latter are less electron-withdrawing than $sp^2$-hybridised carbons and

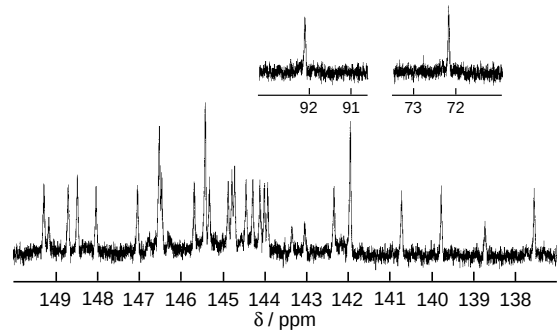

**Fig. 2** $^{13}C$ NMR spectrum of $C_{120}O_2$

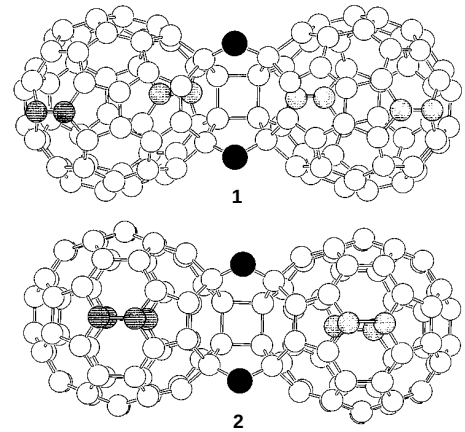

**Fig. 3** Possible structures of $C_{120}O_2$ with $C_{2v}$ symmetry: furan-ring linkage *via* 6,6 junctions **1** or *via* 6,5 junctions **2**. The oxygens are black, and the on-plane carbon pairs are hatched for clarity.

this will therefore induce a dipole in the adjacent double bond, resulting in one carbon (in the pentagon) appearing well upfield, the other carbon correspondingly downfield, as observed. The other on-plane pair is remote from the addend and so should appear at a similar position in the spectrum, also as observed. Lastly, in assigning the structure, we discounted the possibility (i) that all $sp^3$-hybridised carbons are located in one pentagon, implying a substantially larger number of double bonds in pentagons than in **2**; the structure should also have strong repulsive p-orbital interactions from the adjacent oxygens, and (ii) of the locations of the C–C and the C–O–C connections being reversed; this would produce severe strain because the cages would come into almost direct contact.

The UV–VIS spectrum (cyclohexane) resembles that for $C_{120}O$, showing peaks at 224, 256 and 318 nm, and a rather weak band at 422 nm. The FT–IR spectra [KBr for middle IR (MIR), Fig. 4(*a*); polyethylene for far IR (FIR), Fig. 4(*b*)] of $C_{120}O_2$ are compared to that of $C_{120}O$. The $^{13}C$ NMR data suggest that the furanoid bridges in $C_{120}O_2$ and $C_{120}O$ are rather similar and this similarity is also reflected in the IR spectra of both compounds. In the MIR, where the intra-cage vibrations occur, these similarities are especially striking [Fig. 4(*a*)]. However, the inter-cage vibrations of both dimers observable in the FIR show characteristic shifts. $C_{120}O$ exhibits one strong absorption band at 207 $cm^{-1}$ and a weak band at 124 $cm^{-1}$ (very close to 118 $cm^{-1}$ Raman band of photopolymerized [60]fullerene),[5] both of which are probably responsible for the inter-cage stretching modes. The corresponding FIR features of $C_{120}O_2$ occur at *ca*. 260 (line pair) and 161 $cm^{-1}$, and thus are shifted (approximately by a factor of 1.28) in frequency compared to $C_{120}O$. Such a shift indicates the more rigid bridge construction in $C_{120}O_2$, thus confirming the NMR data.

In conclusion, we note that $C_{120}O_2$ is the first characterised compound having a four-membered ring as part of the linkage between the two fullerene cages.

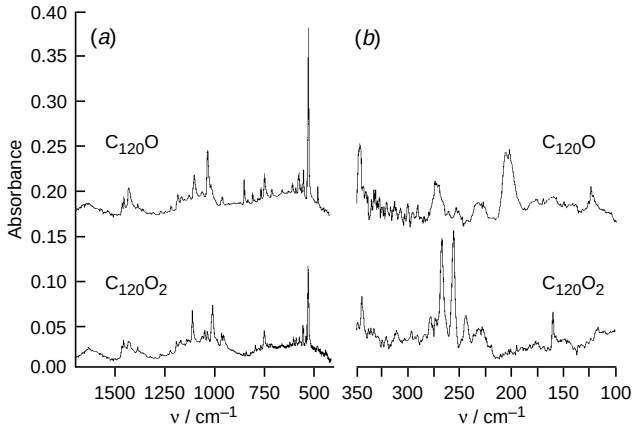

**Fig. 4** (*a*) MIR (KBr, 1 mg of sample) and (*b*) FIR (polyethylene, 20 mg of sample) spectra of $C_{120}O_2$ compared to that of $C_{120}O$. The spectra of $C_{120}O$ are shifted for clarity.

The authors appreciate the support of the Human Capital and Mobility Programme of the EU. A. G., S. B. and W. K. wish to thank the Deutsche Forschungsgemeinschaft and S. L. is grateful to the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie for financial support. The help of Dr G. Monninger and H. Stopka-Ebeler (Max-Planck-Institut für Kernphysik, Heidelberg) in measuring IR spectra, and the skillful assistance of Dr J. Gross (Organisch-Chemisches Institut, Universität Heidelberg) in acquiring mass spectra is greatly acknowledged.

## Footnotes

† $C_{120}O_2$ was first separated from $C_{60}$ and higher mass species using a 250 × 4.6 mm Cosmosil 5PBB column, *o*-dichlorobenzene eluent, flow rate 1.0 ml $min^{-1}$, 150 bar, detection at 340 nm. Final purification was carried out with a 250 × 4.6 mm Cosmosil Buckyprep column, toluene eluent, flow rate 1.0 ml $min^{-1}$, 60 bar, detection at 340 nm. Under these conditions, $C_{120}O_2$ eluted at 18.1 min (*cf.* 7.8 min for $C_{60}$ and 15.8 min for $C_{120}O$).

‡ $^{13}C$-enriched $C_{60}$ was obtained by the standard procedure[8] using graphite rods hollowed out and packed with a mixture of $^{13}C$ enriched powder and regular graphite; the enriched $C_{60}$ was used as starting material for $C_{120}O$ preparation (ref. 1).

§ The $^{13}C$ NMR spectrum [125.76 MHz, $CS_2$–$CDCl_3$ 98 : 2, *ca*. 35 mmol $dm^{-1}$ $Cr(acac)_3$, 60 h, 36 000 scans] exhibits peaks at δ 149.28 (4 C), 149.16 (2 C), 148.70 (4 C), 148.48 (4 C), 148.03 (4 C), 147.04 (4 C), 146.53 (8 C), 146.47 (4 C), 145.69 (4 C), 145.43 (8 C), 145.33 (4 C), 144.88 (4 C), 144.79 (4 C), 144.73 (4 C), 144.46 (4 C), 144.29 (4 C), 144.13 (4 C), 144.02 (4 C), 143.94 (4 C), 143.36 (2 C), 143.06 (2 C), 142.35 (4 C), 141.96 (8 C), 140.73 (4 C), 139.79 (4 C), 138.74 (2 C), 137.58 (4 C), 92.11 (4 C), 72.19 (4 C).

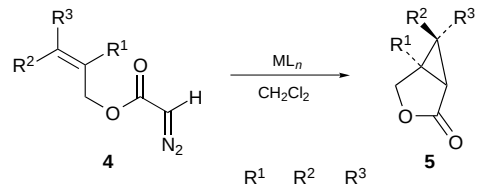
**Enantioselectivity for intramolecular cyclopropanation of allylic diazoacetates shows complementarity in comparisons of chiral Cu$^{I}$, Rh$^{II}$ and Ru$^{II}$ catalysts.**

A broad selection of chiral catalysts for enantioselective cyclopropanation with diazoacetates has been described.[1] The vast majority fall into two structural classes: (i) those, including the appropriately substituted semicorrin[2] and bis-oxazoline[3] complexes of copper(I) and (pybox)$RuCl_2$(ethene),[4] whose chiral ligands are $C_2$-symmetric and (ii) chiral dirhodium(II) carboxamidates whose ligand arrange- ment in these octahedral complexes places two distinguishing ester attachments *cis* to each other.[5] The success of chiral dirhodium(II) carboxamidates, especially dirhodium(II) tetrakis[methyl 2-oxopyrrolidine-5(*R* or *S*)-carboxylates], $Rh_2$(5*R*-MEPY)$_4$ and $Rh_2$(5*S*-MEPY)$_4$ **1a**,[6] for highly enantio-selective intramolecular cyclopropanation of allylic diazoacetates has been described but, surprisingly, these same synthetically useful transformations have not been examined using copper(I) with $C_2$-symmetric ligands nor comprehensively with chiral (pybox)Ru$Cl_2$(ethene). We now present our preliminary results which demonstrate complementarity in enantiocontrol between these diverse catalysts.



Treatment of a selection of allylic diazoacetates (Scheme 1) with 1.0 mol% Cu(OTf)/**2**[7] in $CH_2Cl_2$ resulted in the expected cyclopropanation products **5** in moderate to relatively low isolated yields and with often variable enantiomeric excesses (ee). Dramatic improvements in isolated yields without a corresponding change in enantioselectivity were achieved with the use of Cu(MeCN)$_4$PF$_6$/**2** (Table 1). The air stability and handling ease of Cu(MeCN)$_4$PF$_6$[8] render this copper(I) reagent superior to the universally employed[9] Cu(OTf) for catalytic cyclopropanation reactions. Comparative yields and enantiomeric excesses for $Rh_2$(5*S*-MEPY)$_4$ catalysed reactions (0.1–1.0 mol% **1a**)[5] and for **3** (3–5 mol%) are also given in Table 1. Surprisingly, the absolute configurations of cyclopropane products **5c** and **5d** from catalysis by CuPF$_6$/**2** are opposite to those formed with **3**.

Enantioselectivity in copper(I)/**2** catalysed reactions is higher with allylic diazoacetates that have 2-alkyl (**4e,f**)[10] substituents, and these are the substituents that give the lowest enantioselectivities in $Rh_2$(5*S*-MEPY)$_4$-catalysed reactions. With the (pybox)$RuCl_2$(ethene) catalyst **3**, these diazo substrates did not undergo intramolecular cyclopropanation under a variety of reaction conditions; carbene dimers were the only isolated products. However, use of $Rh_2$(4*S*-MPPIM)$_4$ **1b** instead of $Rh_2$(5*S*-MEPY)$_4$ causes an enormous enhancement in enantiocontrol for **5e** and **5f** as well as for intramolecular cyclopropanation of *trans*-2-hexen-1-yl diazoacetate (**4c**).[11] The preference for higher enantiocontrol with *trans*- disubstituted alkenes **4c** for **3** relative to *cis*-disubstituted systems **4d** with **1a** contrasts with the low % ee values observed for catalysis by CuPF$_6$/**2** of

**1a** Z = $CH_2$
**b** Z = $NCOCH_2CH_2Ph$

[a] Configurational assignment in parentheses (ref. 5). [b] Absolute configuration determined from the X-ray structure of 1-(1-naphthyl)-ethylamide derivative (L. E. Overman, private communication). [c] Configuration assigned by analogy with **5e** and order of elution on a 30 m Chiraldex G-TA column.

either **4c** or **4d**. Thus each of these catalytic systems has unique capabilities for enantio- selection, independent of whether their ligands are $C_2$-symmetric (**2** and **3**) or if they have a *cis*-array of chiral attachments (**1**). However, as is evident from these data, chiral dirhodium(II) carboxamidates are the catalysts of choice for these intramolecular cyclopropanation reactions.

The selectivities for allylic cyclopropanation observed with catalysts **1**–**3** are consistent with the alkene approach trajectories that are depicted by the Newman projections of **6a,b**. In these representations the ligated metal (M) orients the carbon–carbon double bond to a frontside approach to the carbene centre; the backside approach produces the enantiomeric forms. For **6a**, which models selectivity with $Rh_2(MEPY)_4$ catalysts, interaction of $R^1$ with the catalyst face is most pronounced and, appropriate to the high enantiocontrol observed with *cis*-disubstituted allylic diazoacetates, $R^2$ is oriented away from the catalyst (**6b**). High enantiocontrol observed in cyclopropanation reactions of allylic diazoacetates having $R^3$ or $R^1$ groups (*e.g.* with $Cu^I$/**2** or **3**) is consistent with **6b**. However, the absence of cyclopropane products from **4e,f** with **3** suggests that conformation **6a** is required for these substrates, whereas **6b** is operative for **4b–d**. That catalysis by **3** and $CuPF_6$/**2** forms **5c** and **5d** which have opposite configura- tions demands a more subtle explanation than has heretofore been accorded these reactions.

**Scheme 2**

Another comparative measure of selectivity in intramolecular cyclopropanation reactions is regioselection, particularly with **7** which is designed to undergo either γ-lactone formation or macrocyclization (Scheme 2). With $CuPF_6$/**2** macrocycle formation was the predominant intramolecular process (**9**: 87% ee, 43% yield; **8**: 41% ee, 19% yield),[12] whereas only **8** was produced by catalysis with either **1a** (96% ee, 84% yield) or **3** (17% ee, 45% yield). The formation of **8** catalysed by **1a**, $CuPF_6$/**2** and **3** occurred with % ee values and enantiomer configurations that are similar to and predictable from results for **5d** in Table 1.

Support from the National Institutes of Health (GM 46503) and the Robert A. Welch Foundation to M. P. D. is greatly appreciated. We are grateful to L. E. Overman for the information that he provided.

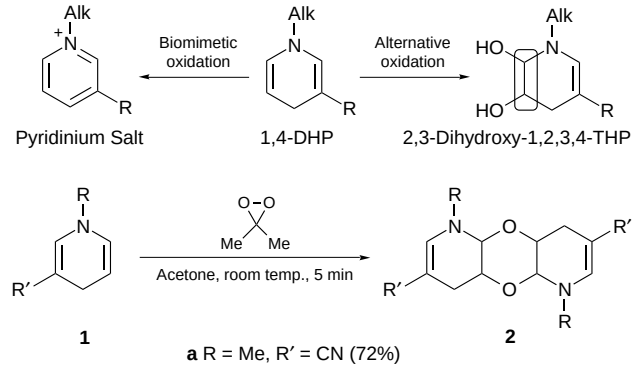
# Non-biomimetic oxidation of 1,4-dihydropyridines†

**Rodolfo Lavilla,* Francisco Gullón, Xavier Barón and Joan Bosch***

*Laboratory of Organic Chemistry, Faculty of Pharmacy, University of Barcelona, 08028 Barcelona, Spain*

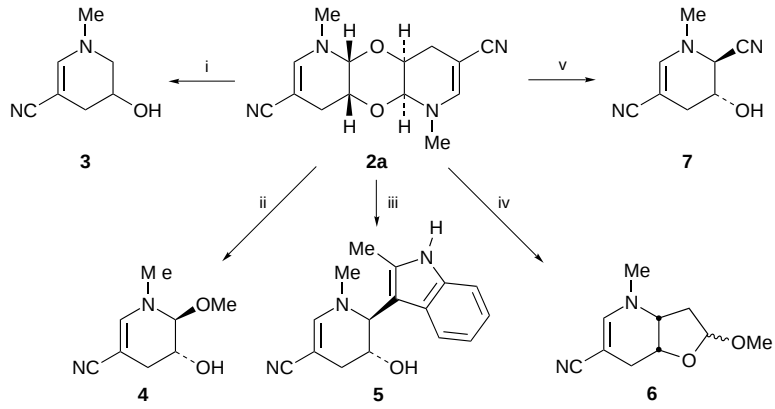
**The reaction between *N*-alkyl-1,4-dihydropyridines and dimethyldioxirane leads to dimeric tetrahydropyridines having oxygen atoms at the 2- and 3-positions in good yields and with good stereocontrol; these compounds are useful iminium ion precursors, and are satisfactorily transformed into 2-substituted 3-hydroxy-1,2,3,4-tetrahydropyridines.**



1,4-Dihydropyridines are interesting compounds and play an important role in synthetic, therapeutic and bioorganic chemistry.[1] New methods for their preparation[2] and transformations have been the subject of research in our laboratory: selective reductions,[3] electrophilic additions[4] and total syntheses of alkaloids[5] have been developed.

Here we report an efficient, mild and selective non-biomimetic oxidation of *N*-alkyl-1,4-dihydropyridines.‡ Although the conversion of these compounds to the corresponding pyridinium salts is a well-established process that has relevant significance in cell metabolism [NAD(P)H is commonly oxidized to $NAD(P)^+$ in many enzyme-assisted reductions], very little is known about 'alternative' dihydropyridine oxidations (*i.e.* epoxidations or dihydroxylations).[6,7] To our knowledge, no synthetically useful reports dealing with this subject have been published. After several unsuccessful attempts to oxidize *N*-alkyl-1,4-dihydropyridines with MCPBA or $OsO_4$, we turned our attention to the use of dimethyldioxirane (DMD), a reagent used in a wide range of functional group transformations,[8] including the oxidation of enamines.[9] It should be mentioned that a chemically related dioxetane was involved in the 'normal' oxidation of a NADH analogue.[10]

The required *N*-methyl-1,4-dihydropyridines **1** were prepared by sodium dithionite reduction of the corresponding pyridinium salts, following published procedures.[11] When dihydropyridines **1** were treated at room temperature with DMD for 5 min, the tricyclic dioxanes **2** were obtained in good yields.§¶ This process can be rationalized by considering the initial epoxidation of the enamine double bond with subsequent ring opening of the oxirane ring to give an iminium ion that undergoes dimerization.



This transformation constitutes the first general, non-biomimetic oxidation of 1,4-dihydropyridines, avoiding the natural oxidation pathway to pyridinium salts. In contrast, the use of dioxiranes generated *in situ* from 2-chlorocyclohexanone or 1,1,1-trifluoroacetone in the presence of stochiometric amounts of Oxone®[12] was not satisfactory, showing the incompatibility of dihydropyridines with strong oxidants like peroxyacids. The major stereoisomers **2** have a centre of symmetry,[13] showing a *cis* stereochemistry for the oxygens at $C_2$–$C_3$ and a *anti* relationship between the two tetrahydropyridine moieties; minor amounts of other isomers were isolated, probably having a *syn* stereochemistry. The stereochemical assignments were based on the coupling constants in the $^1H$ NMR spectra and on $^1H$-$^1H$ COSY, HMQC and NOESY experiments. Dioxanes **2** were stable enough to be chromatographed, spectroscopically characterized and stored indefinitely in the freezer under an inert atmosphere. An additional interest of dimers **2** lies in the fact that they are highly functionalized iminium ion precursors.

A preliminary study of this type of reactivity was undertaken, including the generation of iminium ions under different conditions and their subsequent interaction with nucleophiles. Thus, reduction of **2a** with triethylsilane in the presence of

**a** R = Me, R′ = CN (72%)
**b** R = Me, R′ = $CO_2Me$ (76%)
**c** R = Bn, R′ = CN (69%)
**d** R = Bn, R′ = $CO_2Me$ (60%)

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, $Et_3SiH$, $TiCl_4$, THF, −60 °C, 5 min (95%); ii, MeOH, TFA, 0 °C, 5 min (72%; *cis* isomer 24%); iii, 2-methylindole, TFA, 20 °C, 5 min (60%; *cis* isomer 24%); iv, 1-methoxyethene, $BF_3{\cdot}Et_2O$, THF–$CH_2Cl_2$, −60 °C, 5 min (60%, mixture of isomers at the acetalic carbon); v, $Me_3SiCN$, $TiCl_4$, $CH_2Cl_2$, 0 °C, 5 min (40%; *cis* isomer 27%)

titanium tetrachloride afforded tetrahydropyridinol **3**, whereas TFA-induced addition of methanol gave the 'protected' α-alcoxy tetrahydropyridine **4**. On the other hand, addition of 2-methylindole was achieved under acid catalysis, affording adduct **5** with moderate stereoselectivity. In the latter two reactions, minor amounts of the *cis* isomers were isolated. Addition of methoxyethylene was achieved in the presence of boron trifluoride. In this case, the intramolecular trapping of the resulting carbonium ion by the hydroxy group allowed the formation of the partially reduced furopyridine **6** (ring fusion *cis*) in a one-pot transformation. Finally, $Me_3SiCN$ was added to give α-amino nitrile **7** (epimeric mixture at C-2) in good yield.‖

In conclusion, a useful, mild and selective method for the formal epoxidation of 1,4-dihydropyridines has been developed, and some relevant reactions of the resulting compounds, which act as iminium ion precursors, are reported. These results present interesting possibilities in the study of the chemical reactivity of dihydropyridines, a class of compounds with a significant role in biochemistry and in natural product synthesis (*e.g.* alkaloids and azasugars).

## Footnotes

† Presented in part at the Eigth FECHEM Conference on Heterocycles in Bio-Organic Chemistry, September 1–4, 1996, Villa Olmo, Italy.

‡ The term non-biomimetic is used in a broad sense, meaning that the process involves an oxygen transfer rather than the usual two-electron oxidation observed in nature.

§ All new compounds were characterized by $^1$H and $^{13}$C NMR, IR, UV, MS and HRMS.

¶ *Typical procedure*: A 1.1 fold excess of DMD (0.07 M) in acetone[14] was added to a solution of the dihydropyridine **1a** (1 mmol) in acetone (20 ml) at 0 °C. The progress of the reaction was monitored by TLC. When all the starting material had been consumed (*ca.* 5 min), the solvent was removed under reduced pressure and the residue was chromatographed through neutral alumina ($CH_2Cl_2$–MeOH) to give the corresponding dioxane **2a** (72%). $^1$H NMR (300 MHz, $CD_3OD$) 2.16 (ddd, 1 H, *J* 16.3, 2.7 and 1.5 Hz, H-4), 2.53 (ddd, 1 H, *J* 16.3, 3.7 and 1.9 Hz, H-4), 3.15 (s, 3 H, $CH_3$), 3.83 (m, 1 H, H-3), 4.41 (dd, 1 H, *J* 2.6 and 1.5 Hz, H-2), 6.74 (d, 1 H, *J* 1.9 Hz, H-6); $^{13}$C NMR (75.4 MHz, $CD_3OD$) 24.4 (C-4), 39.3 ($CH_3$), 63.9 (C-3), 70.3 (C-5), 80.4 (C-2), 122.7 (CN), 146.0 (C-6). HRMS (e.i.) *m/z*: calc. 272.1273, found 272.1272.

‖ *Selected spectral data* for **3**: $^1$H NMR (300 MHz, $CDCl_3$) 2.20 (br s, 2 H, H-4 and OH), 2.49 (br d, 1 H, *J* 15.8 Hz, H-4), 2.95 (s, 3 H, $CH_3$), 3.01 (m, 1 H, *J* 12.6, 5.6, 2.5 and 0.9 Hz, H-2), 3.17 (ddd, 1 H, *J* 12.6, 2.6 and 1.1 Hz, H-2), 4.19 (br s, 1 H, H-3), 6.79 (d, 1 H, *J* 0.9 Hz, H-6); $^{13}$C NMR (75.4 MHz, $CDCl_3$): 30.0 (C-4), 42.9 ($CH_3$), 52.9 (C-2), 61.9 (C-3), 69.5 (C-5), 123.0 (CN), 147.5 (C-6). For **4** (major stereoisomer, *trans*): $^1$H NMR (300 MHz, $CDCl_3$) 2.12 (ddd, 1 H, *J* 16.6, 2.2 and 1.3 Hz, H-4), 2.40 (ddd, 1 H, *J* 16.6, 3.8 and 1.9 Hz, H-4), 3.09 (s, 3 H, $NCH_3$), 3.38 (s, 3 H, $OCH_3$), 3.93 (m, 1 H, H-3), 4.07 (dd, 1 H, *J* 3.2 and 1.2 Hz, H-2), 6.77 (dd, 1 H, *J* 2.0 and 1.0 Hz, H-6); $^{13}$C NMR (75.4 MHz, $CDCl_3$): 25.6 (C-4), 42.6 ($NCH_3$), 56.4 ($OCH_3$), 61.8 (C-3), 73.1 (C-5), 89.4 (C-2), 122.1 (CN), 145.2 (C-6). HRMS (e.i.) *m/z*: calc. 168.0899, found 168.0902. For **5** (major stereoisomer, *trans*): $^1$H NMR (300 MHz, $CDCl_3$) 2.33 (dd, 1 H, *J* 15.6 and 6.7 Hz, H-4), 2.43 (s, 3 H, $CH_3$), 2.50 (dd, 1 H, *J* 15.6 and 4.0 Hz, H-4), 2.81 (s, 3 H, $NCH_3$), 4.20 (ddd, 1 H, *J* 6.7, 5.4 and 4.0 Hz, H-3), 4.30 (d, 1 H, *J* 5.4 Hz, H-2), 7.02 (s, 1 H, H-6), 7.07–7.20 (m, 2 H, H-5 and H-6 indole), 7.33 (d, 1 H, *J* 8.0 Hz, H-7 indole), 7.47 (d, 1 H, *J* 7.7 Hz, H-4 indole), 8.10 (br s, 1 H, NH); $^{13}$C NMR (75.4 MHz, $CDCl_3$) 11.8 ($CH_3$), 28.3 (C-4), 40.9 ($NCH_3$), 60.6 (C-2), 66.4 (C-3), 69.2 (C-5), 108.0 (C-3 indole), 110.6 (C-7 indole), 117.8 (C-4 indole), 119.8 (C-6 indole), 120.0 (CN), 121.6 (C-5 indole), 122.2 (C-3a indole), 134.5 (C-2 indole), 136.1 (C-7a indole), 148.5 (C-6). HRMS (e.i.) *m/z*: calc. 267.1372, found 267.1381. For **6** (major stereoisomer): $^1$H NMR (300 MHz, $CDCl_3$): 1.97 (ddd, 1 H, *J* 13.7, 7.5 and 2.9 Hz, H-3), 2.40 (m, 1 H, H-3), 2.47 (m, 2 H, H-7), 2.92 (s, 3 H, $NCH_3$), 3.35 (s, 3 H, $OCH_3$), 3.55 (m, 1 H, H-3a), 4.25 (m, 1 H, H-7a), 5.02 (dd, 1 H, *J* 5.9 and 2.9 Hz, H-2), 6.72 (s, 1 H, H-5); $^{13}$C NMR (75.4 MHz, $CDCl_3$) 25.5 (C-7), 36.6 (C-3), 40.8 ($NCH_3$), 55.4 ($OCH_3$), 57.1 (C-3a), 73.5 (C-7a), 79.9 (C-6), 104.0 (C-2), 123.1 (CN), 147.1 (C-5). HRMS (e.i.) *m/z*: calc. 194.1055, found 194.1060. For **7** (major stereoisomer, *trans*): $^1$H NMR (300 MHz, $CDCl_3$) 2.30 (ddd, 1 H, *J* 16.8, 2.6 and 2.3 Hz, H-4), 2.75 (ddd, 1 H, *J* 16.8, 3.6 and 2.0 Hz, H-4), 3.08 (s, 3 H, $NCH_3$), 3.98 (dd, 1 H, *J* 2.6 and 2.3 Hz, H-2), 4.39 (m, 1 H, H-3), 6.77 (d, 1 H, *J* 2.0 Hz, H-6); $^{13}$C NMR (75.4 MHz, $CDCl_3$) 27.2 (C-4), 41.3 ($NCH_3$), 52.7 (C-2), 63.2 (C-3), 76.3 (C-5), 115.4 (CN), 120.7 (CN), 145.9 (C-6). HRMS (e.i.) *m/z*: calc. 163.0746, found 163.0746.

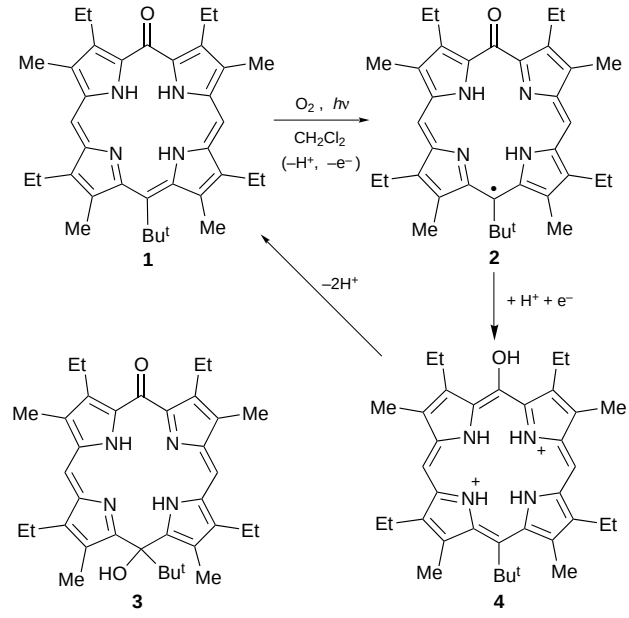
# Stabilization of neutral oxophlorin π-radicals by bulky meso-alkyl groups

**Richard G. Khoury,[a] Laurent Jaquinod,[a] Amy M. Shachter,[b] Nora Y. Nelson[a] and Kevin M. Smith*[a]†**

[a] *Department of Chemistry, University of California, Davis, CA 95616, USA*
[b] *Department of Chemistry, Santa Clara University, Santa Clara, CA 95053, USA*



**The 15-*tert*-butyl-5-oxophlorin 1 forms a stable, neutral π-radical species 2, in high yield; the 13,17-bis-unsubstituted 5-oxophlorin analogue 5, under similar conditions, affords the 15-iso-5-oxophlorin 6 and 15-hydroxy compound 7 (both characterized by X-ray crystallography), the latter demonstrating the trapping of the π-radical by dioxygen.**

The syntheses and chemistry of tetrapyrrole π-free-radicals is one of the few fields of porphyrin chemistry which remains relatively undeveloped. It is also a fact that the preparation of other stable and useful π-radicals are found only infrequently in the literature. Published work on π-radicals has focused on the study of their electronic structure,[1] their use to create charge transfer species in molecular conductors,[2] their use in synthesis[3] and their involvement in biological systems.[4] Compounds such as quinones and related compounds play important roles as mediators in some electron-transfer processes which occur in mitochondria and in chloroplasts. Radicals also react with transition metal ions that have appropriate reduction potentials.[4] In biological systems, haemes in haemoglobin and myoglobin are degraded to bile pigments *via* a key intermediate, suspected to be a meso-oxyporphyrin π-neutral radical or an oxophlorin radical species reacting quickly with $O_2$.[4,5] In 1975, studies by Fuhrhop and co-workers showed that oxophlorins and their metal complexes are oxidized at low potentials yielding fairly unstable neutral π-radicals which underwent a variety of secondary reactions to generate, for instance, 5,15-dioxoporpho-10,20-dimethenes.[6] Examples of radical dimerizations of oxophlorins at the 15-positions[6] led us to believe that the meso-15-position has unique chemical reactivity.[5] We showed that electronic and steric features at the 15-position enable one to exert control over the oxidation potential of the oxophlorin, and direct a novel dimerization process to the 10-position, a phenomenon which has been used for the reversible self-assembly of a cyclic tetra-oxophlorin.[7] In order to further investigate the chemical properties associated with 15-meso-substituents, we targeted 15-*tert*-butyl-5-oxophlorins in the hope that radical formation and stabilization would take place at the 15-position.

MacDonald-type (*i.e.* 2 + 2) condensation of 1,9-diformyl-5-oxodihydrodipyrrin[8] with 5-*tert*-butyl-2,8-diethyl-3,7-dimethyldihydrodipyrrin-1,9-dicarboxylic acid‡ followed by basic treatment resulted in formation of the 15-*tert*-butyl-5-oxophlorin **1** in 43% yield. Exposure of compound **1** to air in $CH_2Cl_2$ and daylight (which accelerated the transformation) afforded the neutral π-radical **2** of 15-*tert*-butyl-5-oxophlorin§ in 90% yield. This compound possesses a Soret band at 410 nm and a typical organic π-radical EPR signal at 3000 G. The magnetic susceptibility of **2**, measured by the NMR Evans method[9] is $\mu_{eff}$ = 2.5 $\mu_B$ at 297 K, indicating that the compound exists entirely in the form of the neutral π-radical.[4]¶ This oxophlorin radical is stable to air for long periods of time in the solid form. It was found to be fairly stable in solution, showing only about 30% decomposition over two weeks in the presence of oxygen (to form 15-*tert*-butyl-15-hydroxy-5-oxophlorin **3**). Addition of acid to a $CH_2Cl$ solution of **2** generated, *via* the readily reduced π-cation porphyrin radical,[10] the diprotonated hydroxyporphyrin **4** (Scheme 1). This reduction–protonation process could be followed by spectrophotometry, which showed clean isobestic points (at $\lambda_{max}$ = 438 and 540 nm), furthermore demonstrating the quantitative radical character of **2**.

Fuhrhop had earlier demonstrated that the spin density distribution in 5-oxophlorin radicals lies predominately on the carbon atom at the 15-position.[6] By analogy, the free radical in **2** is also believed to be localized preferentially at the 15-position where it can be stabilized by hyperconjugation through the *tert*-butyl substituent.

In order to establish the effect of steric congestion upon the radical formation resulting from the interaction of the 15-substituent with abutting groups in the 13- and 17- positions, synthesis of 12,13,17,18-unsubstituted-15-*tert*-butyl-5-oxophlorin **5** was attempted using the same pathway as described for **1**.‖ This synthesis, however, yielded two products neither of which was a π-radical. The first product was characterized as 15-*tert*-butyl-15-iso-5-oxophlorin **6**** and the second was shown to be the 15-*tert*-butyl-15-hydroxy derivative **7**.†† Structure **7** presents evidence for the trapping of the π-radical at the 15-position (presumably by dioxygen) and further indicates the preferential localization of the radical at this position. A 15-peroxo bis(5-oxophlorin) derivative has been proposed earlier by Fuhrhop *et al.*[6a] The molecular structures of **6**‡‡ and **7**‡‡ were confirmed by X-ray crystallography (Fig. 1). Both macrocycles exhibit a slightly ruffled conformation with a mean deviation from there least-squares plane for the 24 core atoms of 0.263 Å for compound **6** and of 0.257 Å for compound **7**. The C=O bond length for structures **6** and **7** are 1.239 and 1.242 Å, respectively, in good agreement with expected C=O bonds lengths. For compound **7** the C–O bond length in the 15-position is 1.455 Å which is also in agreement with expected normal C–O bond lengths.

**Scheme 1**

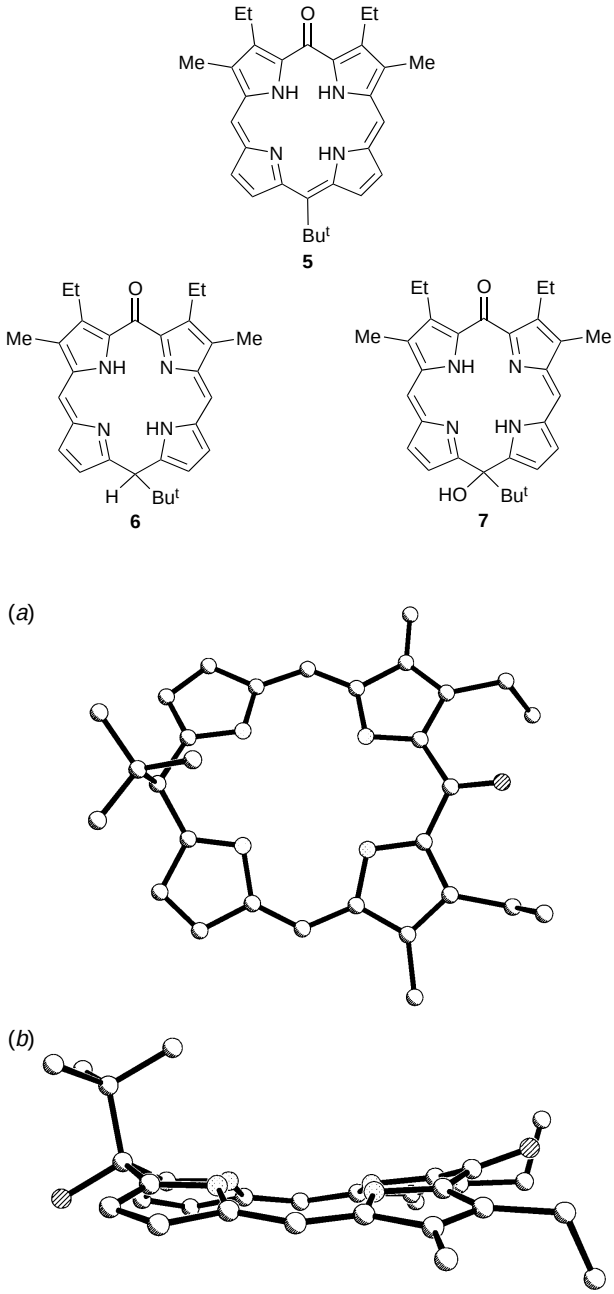


**Fig. 1** Molecular structure of (*a*) 15-*tert*-butyl-15-iso-5-oxophlorin **6** and (*b*) 15-*tert*-butyl-15-hydroxy derivative **7**

‡ Prepared by acidic condensation of trimethylacetaldehyde (TMA) with 2 equiv. of the corresponding α-free-pyrrole benzyl ester (K-10 clay catalyst, $CH_2Cl_2$–TFA (5 : 1), room temp., 4 d, chromatographed on silica gel eluted with $CH_2Cl_2$, deprotection with Pd-C/$H_2$, overall yield 35%).

§ Mp 180–182 °C. UV–VIS $\lambda_{max}(CH_2Cl_2)$/nm 410 (ε 66 700), 628 (11 700), 664 (11 000). $^1$H NMR (300 MHz, $CDCl_3$–[$^2$H]TFA) δ 1.48 (s, 9 H, Bu$^t$), 1.56 (t, 6 H, $CH_2CH_3$), 1.69 (t, 6 H, $CH_2CH_3$), 3.26 (s, 6 H, $CH_3$), 3.43 (s, 6 H, $CH_3$), 3.89 (m, 8 H, $CH_2CH_3$), 10.06 (s, 2 H, meso-H). MS: *m/z* 550.

¶ The magnetic susceptibility of the free radical was determined using Evans method.[9] Paramagnetic shifts of tetramethylsilane were determined for 2-4 × $10^{-3}$ M free radical solutions in chloroform and were obtained on a JEOL GSX 400 MHz ($^1$H NMR) spectrometer. At 24 °C, the molar magnetic susceptibility was 2.6 × $10^{-3}$ $cm^{-3}$ $mol^{-1}$ and the calculated magnetic moment was 2.5 $\mu_B$. Diamagnetic corrections were estimated from Pascal's constants.

‖ The 5-*tert*-butyl-3,7-di-unsubstituted half was prepared by condensation of TMA with 40 equiv. of pyrrole catalysed by TFA.[11]

** Mp 280–285 °C. # Macropolyhedral boron-containing cluster chemistry: isolation and characterization of twenty-one-vertex $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]$

**Pervinder Kaur,[a] Sarath D. Perera,[a]† Tomáš Jelínek,[a,b] Bohumil Stíbr,[b] John D. Kennedy,[a] William Clegg[c] and Mark Thornton-Pett[a]**

[a] *School of Chemistry of the University of Leeds, Leeds, UK LS2 9JT*

[c] *Department of Chemistry of the University of Newcastle, Newcastle-upon-Tyne, UK NE1 7RU*

**Reaction of $B_{20}H_{16}$ with $[ReH_5(PMe_2Ph)_3]$ yields the twenty-one-vertex metallaborane $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]$ which consists of a *closo* twelve-vertex $\{B_{12}\}$ unit and a *nido* eleven-vertex $\{B_{11}\}$ unit fused with a common triangular face, with the $\{(PMe_2Ph)_3HRe\}$ moiety capping *exo* to the *nido* $\{B_{11}\}$ unit with three Re–H–B bonds; an unusual reductive P-phenyl cleavage of a $PMe_2Ph$ moiety to give B-pendant *exo* $PHMe_2$ and *exo* Ph moieties on the open face of the eleven-vertex subcluster is also apparent.**

The extension of the contiguous cluster chemistry of polyhedral boron-containing compounds beyond about fourteen vertices into the so-called 'macropolyhedral' area requires either fusion chemistry of smaller clusters[1] or Aufbau chemistry on pre-formed macropolyhedral species. Aufbau reactions to incorporate metal centres into the two accessible isomers of $B_{18}H_{22}$ yield nineteen- and twenty-vertex metallaboranes,[2,3] but to use this approach for even bigger clusters requires bigger contiguous starting substrates. The next highest known contiguous binary borane, $B_{20}H_{16}$,[4] is very difficult to come by. Its bis(ligand) adduct formation was investigaterd some 30 years ago,[5,6] as well as some related hydrolysis and alcoholysis behaviour,[6] but any further chemistry is unexamined since then. We have now isolated small quantities of $B_{20}H_{16}$ from crude $B_{10}H_{14}$,[7] and here report preliminary results from its reaction with $[ReH_5(PMe_2Ph)_3]$ to generate the large, twenty-one-vertex, contiguous metallaborane $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]$.

Reaction of $[ReH_5(PMe_2Ph)_3]$ (83 mg; 138 μmol) and $B_{20}H_{16}$ (32 mg; 138 μmol) in solution in $C_6H_6$ (7 $cm^3$) at reflux for 60 min, followed by chromatographic separation, revealed several coloured reaction products. Of these, two are identifiable as rhenaborane products in yields that are viable for further examination on this reaction scale. Repeated thin-layer chromatography [silica gel G (Fluka $GF_{254}$), $CH_2Cl_2$–$C_6H_{14}$ mixtures] and repeated recrystallization has now ultimately given one of these, $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]$, as a pure, yellow, crystalline solid [4 mg; 5.5 μmol; 4% ($R_f$ 0.46, $CH_2Cl_2$–$C_6H_{14}$ 80 : 20)]. Crystals suitable for single-crystal X-ray work have been exceedingly difficult to grow. Ultimately (eleven months) one was obtained of suitable size for CCD work (Fig. 1 and schematic cluster structure **I**).‡ The results from the X-ray structural analysis are consistent with the results from NMR spectroscopy of the bulk material.§ The basic cluster structure is based on a *nido* eleven-vertex subcluster and a *closo* twelve-vertex subcluster fused with a common triangular three-boron face (schematics **I** and **II**). This twenty-vertex geometry is similar to those (*a*) of the bis(ligand) adducts of $B_{20}H_{16}$ such as $[B_{20}H_{16}(MeCN)_2]$[5] and (*b*) of $[(PMe_2Ph)_4Pt_2B_{18}H_{16}]$[2] formed *via* oxidative Aufbau from $B_{18}H_{22}$. These three incidences may suggest a particular stability of this twelve-vertex: eleven-vertex *closo* : *nido* structural format. In $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]$ the twenty-first vertex is provided by the capping of a closed triangular three-boron face of the *nido*

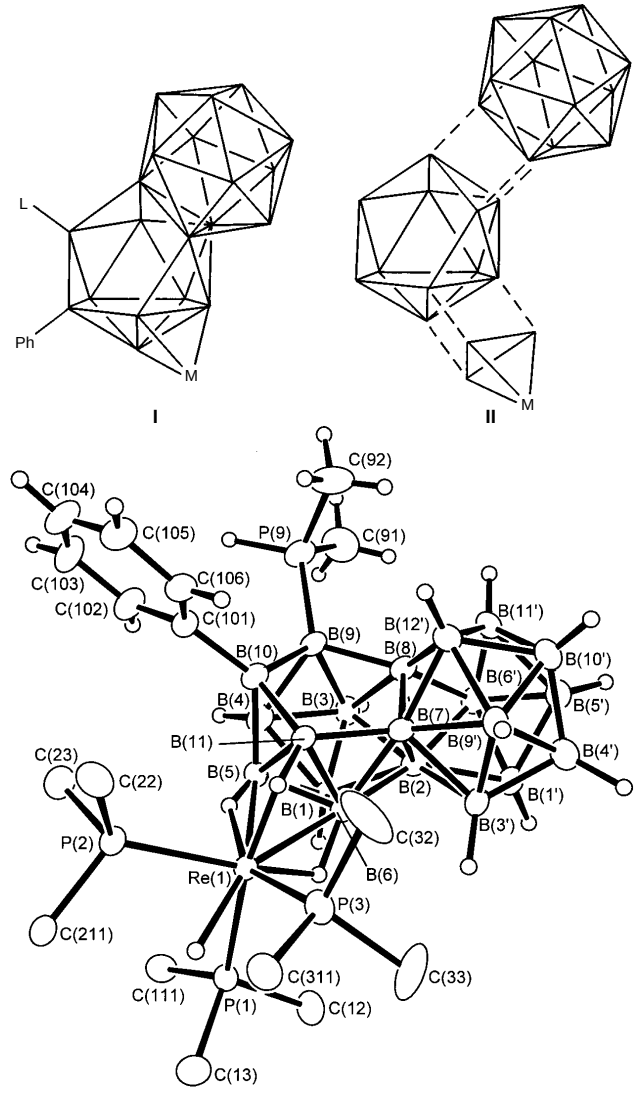

**Fig. 1** ORTEP-type diagram of the molecular structure of $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]$. Selected distances (in Å) are as follows: from Re(1) to P(1) 2.3533(14), to P(2) 2.351(2), to P(3) 2.374(2), to B(5) 2.376(6), to B(6) 2.3561(7) and to B(11) 2.447(6); interboron B(2)–B(7) 1.800(9), B(2)–B(8) 1.772(9), B(7)–B(8) 1.841(10), B(8)–B(9) 1.756(9), B(9)–B(10) 1.736(9), B(10)–B(11) 1.748(9), B(7)–B(11) 1.755(9); B(2)–B(3) is long at 1.991(9), with the other interboron distances in the range 1.712(9)–1.914(9) for the *nido* subcluster and 1.729(11)–1.819(10) for the *closo* subcluster; shorter intercluster distances are B(3)–B(6′) 2.409(10) and B(3′)–B(6) 2.367(9); B(9)–P(9) is 1.888(7) and B(10)–C(101) 1.589(8). Selected angles (in °) at Re(1) are P(1)–P(2) 100.90(5), P(2)–P(3) 104.14(6), P(1)–P(3) 108.52(6), P(1)–H(12) 68.17(4), P(2)–H(12) 64.09(4) and P(3)–H(12) 65.61(4).

eleven-vertex subcluster by a $\{(PMe_2Ph)_3HRe\}$ centre *via* three B–H(*exo*)–Re linkages. This latter type of linkage has predecent in $[(PPh_3)_2ClRuB_{12}H_{11}(NEt_3)]$,[8] and, in Group VII chemistry, $[(CO)_3MnB_8H_{14}]$ and $[(CO)_3MnB_3H_8]$.[9] In sum, the twenty-one-vertex contiguous cluster structure is based upon a triple-cluster unit consisting of a central eleven-vertex $\{B_{11}\}$ *nido* subcluster conjoined by a common three-boron triangular face to a *closo* twelve-vertex $\{B_{12}\}$ subcluster and by a second common three-boron triangular face to a *nido*-type four-vertex $\{ReB_3\}$ subcluster (schematic **II**).

The compound has several other interesting features: (*a*) at twenty-one vertices it is the largest molecular contiguous boron-containing cluster yet characterized; (*b*) the twelve-vertex-*closo* : eleven-vertex-*nido* double-subcluster format with three-atoms-in-common appears to be a stable one; (*c*) the rhenium centre bonds *exo–nido*, rather than *endo* to form a *closo* cluster (there is contemporary interest[10] in this type of boron-to-metal bonding and the factors that may influence it); (*d*) the reductive P–phenyl cleavage of a $PMe_2Ph$ moiety and (*e*) the concomitant phenyl transfer to boron are both very unusual, and the compound may therefore model intermediates for the formation of $[(PH_3)_2(Ph_2PC_6H_4)IrB_9H_7(PPh_3)]$ *via* a so-far unique complete reductive $PAr_3 \rightarrow PH_3$ cleavage,[11] and for the formation of $[(CO)(PPh_3)(PPh_2)Os(PPh_3)PtB_5H_7Ph]$ *via* a phosphorus-to-boron phenyl-group transfer.[12] There is clearly much interesting chemistry to be revealed by the further examination of this and other related twenty-boron systems, and we currently attempt to do this.

Contribution no 57 from the Rez–Leeds Anglo–Czech Polyhedral Collaboration (ACPC). We thank the EPSRC (UK), the Czech Grant Agency, the Academy of Sciences of the Czech Republic, and the Royal Society for support, and Simon Barrett and Jonathan Vessey for assistance with NMR spectroscopy.

‡ *Crystal data* for $[(PMe_2Ph)_3HReB_{20}H_{15}Ph(PHMe_2)]\cdot CHCl_3$: $C_{33}H_{62}B_{20}Cl_3P_4Re$, $M$ = 1091.58 (includes solvent), triclinic, space group $P\bar{1}$, $a$ = 12.8286(9), $b$ = 14.2985(10), $c$ = 15.4090(10) Å, $\alpha$ = 113.369(2)°, $\beta$ = 99.955(2)° $\gamma$ = 93.486(2)°, $U$ = 2529.2(3) Å$^3$, $Z$ = 2, $D_c$ = 1.43 Mg m$^{-3}$, $F(000)$ = 1092, $\mu$ = 2.577 mm$^{-1}$, $T$ = 160 K; crystal size 0.40 × 0.10 × 0.10 mm. 15960 reflections were measured on a Siemens SMART CCD area detector using graphite-monochromated Mo-K$\alpha$ radiation and narrow $\omega$-rotation frames. Data were corrected for absorption empirically using redundant and symmetry equivalent data. The structure was solved by heavy-atom methods[13] and was refined by full-matrix least-squares analysis on $F^2$ using all 11092 unique reflections ($R_{int}$ = 0.0421).[14] $wR = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{\frac{1}{2}}$ = 0.1001 for all data, conventional $R$ [on $F$ values of 9360 reflections with $F_o^2 > 2\sigma(F_o^2)$] = 0.0485, goodness of fit $S$ = 1.134 on all $F^2$ for 610 parameters. All non-hydrogen atoms were refined with anisotropic displacement parameters. Methyl, phenyl and methine hydrogen atoms were constrained to idealised positions with fixed isotropic displacement parameters of $nU_{eq}$ of the parent carbon atom (where $n$ = 1.5 for methyl and 1.2 for phenyl and methine). All other hydrogen atoms were located on Fourier difference syntheses and were freely refined apart from those hydrogen atoms bonded to rhenium which were not refined. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/312.

§ Measured NMR data ($CDCl_3$) as follows (294–297 K) {ordered as $\delta(^{11}B)$ (in ppm rel. $F_3BOEt_3$) [$\delta(^1H)$ (in ppm rel. $SiMe_4$) of directly bound *exo* hydrogen atoms in square brackets]: +23.6 [no *exo*-H], +7.1 [+3.43], *ca.* +0.5 [+2.37], *ca.* +0.5 [+4.08], −1.5 [+2.50], −4.2 [+2.79], −4.7 [−6.53, ReHB bridge], −6.3 [+2.13], −8.0 [+1.96], −11.2 [no *exo*-H], −14.2 [+1.38], −15.0 [+1.54], −17.6 [+2.08], *ca.* −18.0 [no *exo*-H], *ca.* −18.5 [+1.55], *ca.* −18.6 [no *exo*-H], −19.2 [−8.30, ReHB bridge], −28.4 [no *exo*-H], −33.3 [+1.02], −36.2 [−5.66, ReHB bridge]; additionally $\delta(^1H)$(ReH) −6.27 [1 : 2 : 1 t, $^2J(^{31}P–^1H)$(mean) 60 Hz of 1 : 1 d, $^2J(^{31}P–^1H)$ 46 Hz], $\delta(^1H)$(PH) + 4.94 [d, $^1J(^{31}P–^1H)$ 394 Hz of m, $^3J(^1H–C–P–^1H)$(mean) 6 Hz], $\delta(^1H)$(PMe)($PHMe_2$) + 1.23 and +1.38 [for both, $^2J(^{31}P–^1H)$ *ca.* 13 Hz, $^3J(^1H–P–C–^1H)$ *ca.* 6 Hz], $\delta(^1H)$(PMe)($PMe_2Ph$) + 2.07, +1.91, +1.90, +1.77, +1.76 and +1.72 [one tentative, all $^2J(^{31}P–^1H)$ *ca.* 9–10 Hz], $\delta(^{31}P)$ (in ppm rel. 85% $H_3PO_4$) (223 K) −18.3 (sharp), −20.0 (sharp), −20.3 (sharp) and −30.9 (br, $PHMe_2$ group).

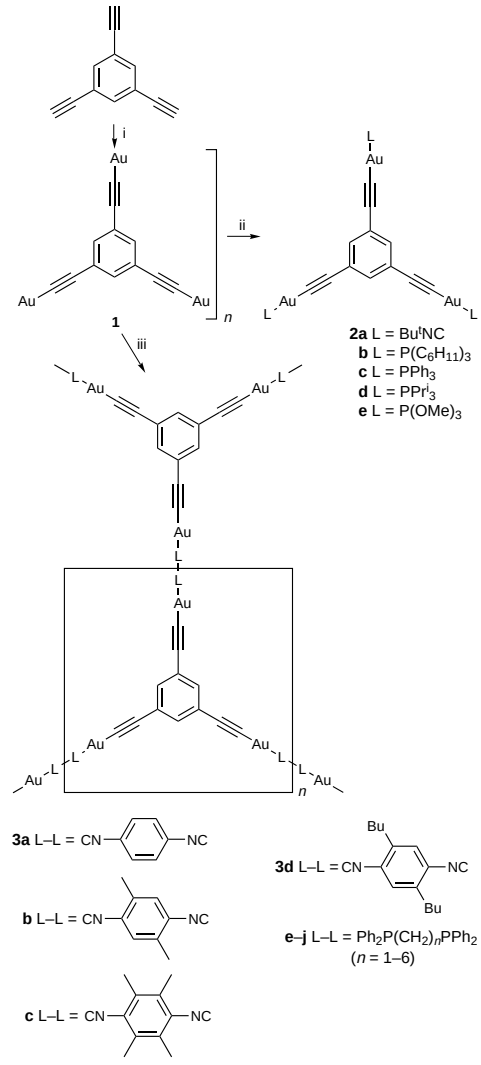
# Trigold triacetylides: polymerization through gold···gold bonding or bridging ligands

**Michael J. Irwin,[a] Ljubica Manojlović-Muir,[b] Kenneth W. Muir,*[b] Richard J. Puddephatt*[a] and Dmitrii S. Yufit[b]**

[a] *Department of Chemistry, University of Western Ontario, London, Canada N6A 5B7*
[b] *Department of Chemistry, University of Glasgow, Glasgow, UK G12 8QQ*

**The new trigold(I) triacetylide $[C_6H_3(C{\equiv}CAu)_3$-1,3,5] reacts with monodentate ligands, L = isocyanide, phosphite or phosphine, to give $[C_6H_3(C{\equiv}CAuL)_3$-1,3,5] complexes which form polymeric solids with intermolecular Au···Au bonding; it also reacts with bidentate ligands to give covalently linked network polymers of the formula $[\{C_6H_3(C{\equiv}CAu)_3$-1,3,5$\}_2(\mu$-L–L$)_3]$, L–L = diisocyanide or diphosphine.**



Linear digold(I) complexes have the interesting tendency to polymerize, either through weak intermolecular gold···gold binding, as in compounds with the chain structure derived from PhC≡C–Au–LL–Au–C≡CPh,[1,2] or through covalent binding of bridging bidentate ligands, as in the linear rigid-rod polymers $(–LL–Au–C{\equiv}C–Ar–C{\equiv}C–Au–)_n$, where L–L = diphosphine or diisocyanide and Ar = 1,4-$C_6H_4$ or a similar spacer group.[2] The former compounds are unique to gold chemistry, while the latter find an analogy in the well known polymers *trans*-$[M(PBu_3)_2(–C{\equiv}C–Ar–C{\equiv}C–)]_n$ (M = Ni, Pd, Pt) and in related complexes[3] whose conjugated structures might lead to materials applications.[4] There is currently much interest in extending this chemistry beyond the one-dimensional polymers, by using trifunctional core molecules, and the triacetylene 1,3,5-triethynylbenzene appears particularly well suited for this purpose.[5,6] In this article we report trigold(I) complexes of the type $[C_6H_3(C{\equiv}C–Au–L)_3]$, which can form loose polymers by intermolecular gold···gold association, as well as covalently linked polymers of the stoichiometry $[\{C_6H_3(C{\equiv}C–Au)_3\}_2(L–L)_3]$.

Reaction of $[AuCl(SMe_2)]$ in tetrahydrofuran–methanol with 1,3,5-triethynylbenzene and sodium acetate as base gave in high yield the insoluble, bright yellow solid $[C_6H_3(C{\equiv}CAu)_3]$ **1** (Scheme 1) which is expected to have a polymeric structure with bridging alkynyl groups.[7] (**CAUTION:** the pure complex **1** detonates easily and should be handled with extreme care and in small quantities only.) Reaction of 3 equiv. of ligand L (L = isocyanide, phosphite or phosphine) with a suspension of **1** in dichloromethane at room temperature yields the soluble complexes $[C_6H_3(C{\equiv}C–Au–L)_3]$ **2** in good yield. Complexes **2** are white or pale yellow, air-stable, analytically pure solids which are soluble in organic solvents. All have been characterized spectroscopically and those with L = $Bu^tN{\equiv}C$ **2a** and $P(OMe)_3$ **2e** by X-ray diffraction as well.† The last two appear to be the first complexes of the $C_6H_3(C{\equiv}C^-)_3$ ligand with any metal, as well as the first trigold triacetylides, to be characterised crystallographically.

The molecular structures of **2a** and **2e**, shown in Fig. 1, are closely similar. Each contains a planar $C_6H_3(C{\equiv}CAuX)_3$ nucleus (X = C or P) which displays approximate $D_{3h}$ symmetry. C–Au–X angles deviate from linearity by 8°.

In the solids of both compounds molecules related by lattice translations are interlinked through weakly attractive Au···Au interactions [3.234(1) Å in **2a**, 3.316(1) Å in **2e**] to form crinkled tapes which extend throughout the crystals (Fig. 1). The gold atoms involved in these interactions [Au(1) and Au(2) in **2a**, Au(1) and Au(3) in **2e**] thereby attain the T-shaped coordination geometry, with Au···Au–X (X = C, P) angles ranging from 73 to 103°.

In **2a** the shortest Au···Au separations between molecular tapes are 3.723(1) Å for Au(1) atoms related by inversion centres and 3.950(1) Å for Au(2) and Au(3) atoms in molecules related by translation along the *a*-axis; in **2e** the two-fold screw axes give rise to intermolecular Au(1)···Au(2) contacts of 3.973(1) Å. Although these inter-tape separations are larger than both the van der Waals diameter of gold (3.60 Å)[8,9] and the range of distances generally regarded as typical of normal $Au^I···Au^I$ attractive interactions (2.90–3.50 Å),[2,8,9] they provide geometrically similar environments for the gold atoms, in which

**Scheme 1** *Reagents*: i, $[AuCl(SMe_2)]$, NaOAc; ii, 3 equiv. L; iii, 1.5 equiv. L–L

the Au···Au–X (X = C, P) angles are 62–120° and the Au···Au···Au angles 135–151°. This directionality of the mutual approach of the gold atoms could be taken as evidence for intertape attractions yielding three-dimensional solids stabilized by cross-linking of ···Au–R–Au···Au–R–Au··· chains [R = $C_6H_3(C{\equiv}C)_3$]. It also appears that weak intermolecular Au···Au interactions leading to the T-shaped geometry, which is considered highly specific for gold(I) complexes,[8] may be a significant factor in driving molecular self-assembly in their solids. It is therefore conceivable that the synthon **A** may prove useful in the design of supramolecular solids with desirable chemical and physical properties.

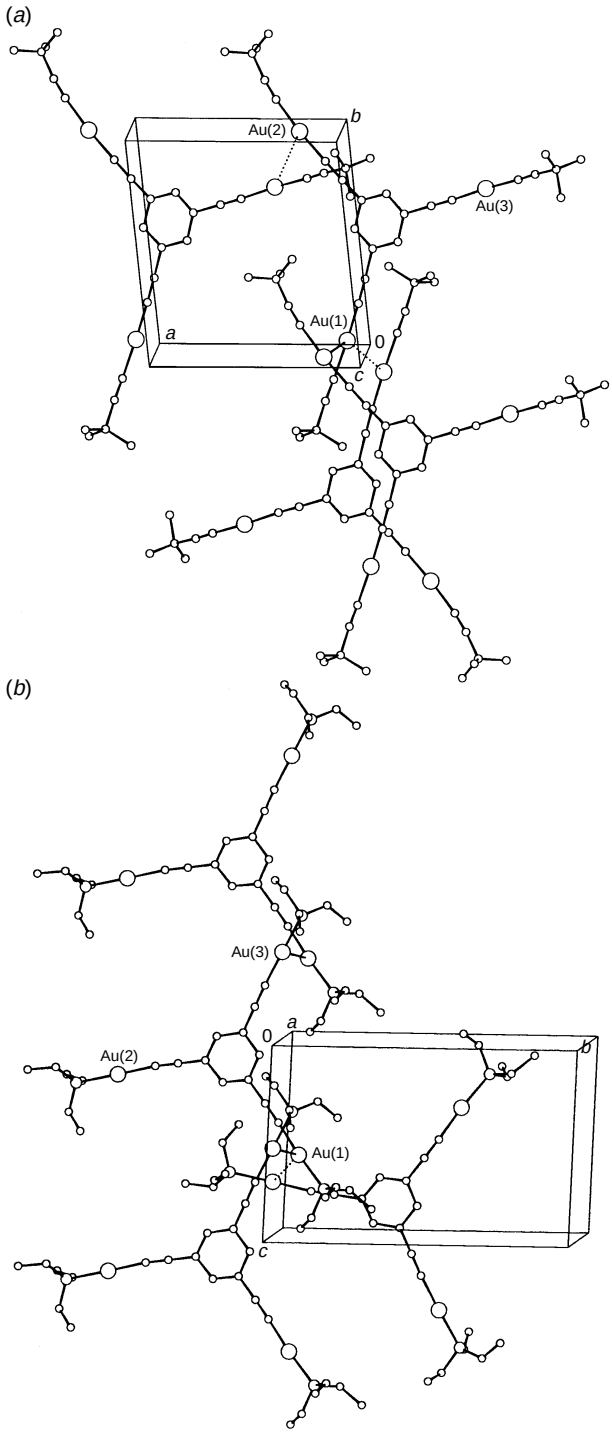


**Fig. 1** (*a*) The crystal structure of 1,3,5-$(Bu^tNCAuC{\equiv}C)_3C_6H_3{\cdot}C_2H_4Cl_2$ **2a**·$C_2H_4Cl_2$, with the solvent molecules omitted for clarity. Labels are shown for the gold atoms in the reference molecule only, the Au···Au interactions within the molecular tapes are shown by full lines, and those involving the gold atoms in different tapes, by dashed lines. Selected interatomic distances (Å) and angles (°): Au(1)–Au(1$^{i}$) 3.723(1), Au(1)–Au(2$^{ii}$) 3.234(1), Au(2)–Au(3$^{iii}$) 3.950(1). The symmetry transformations applied are: i $-x, -y, 1-z$; ii $x, y-1, z$; iii $1+x, y, z$; iv $x, 1+y, z$; (v) $x-1$, y, *z*. (*b*) The crystal structure of 1,3,5-$[(MeO)_3PAuC{\equiv}C]_3C_6H_3$ **2e**. Selected interatomic distances (Å) and angles (°): Au(1)–Au(2$^{i}$) 3.973(1), Au(1)–Au(3$^{ii}$) 3.316(1). The symmetry transformations applied are: i $2-x$, $1/2+y, 1-z$; ii $x, y, 1+x$; (iii) $2-x, -1/2+y, 1-z$; iv $x, y, z-1$. Disorder involving phosphite methoxy groups is not shown for clarity.

Covalently bridged polymers were readily prepared by reaction of **1** (addition) or **2a** (displacement of the $Bu^tN{\equiv}C$ ligands) with bidentate ligands [L–L = diisocyanide CN–Ar–CN, Ar = $C_6H_4$, $C_6H_2Me_2$, $C_6Me_4$, $C_6H_2Bu^t_2$, or diphosphine $Ph_2P(CH_2)_nPPh_2$, $n$ = 1–6] in acetone at room temperature. They precipitated as pale yellow solids which were insoluble in common organic solvents, and analysed as $[\{C_6H_3(C{\equiv}C{-}Au)_3\}_2(L{-}L)_3]_n$ **3**. Their proposed structures (Scheme 1) are supported by comparison of their IR and XPS data with those of the corresponding model compounds **2**.

In summary, the first trigold triacetylide complexes have been prepared and shown to have elegant planar molecular structures with approximate $D_{3h}$ symmetry. They can act as a core of loosely linked polymers formed by weak intermolecular gold···gold binding, or they can react with bidentate ligands to form covalently-linked network polymers.

We thank the NSERC (Canada) and EPSRC (UK) for financial support.

## Footnote

† *Crystallographic data*: **2a**·$C_2H_4Cl_2$: $C_{27}H_{30}Au_3N_3{\cdot}C_2H_4Cl_2$, $M$ = 1086.39, space group $P\bar{1}$, $a$ = 10.340(1), $b$ = 11.539(1), $c$ = 16.444(1) Å, $\alpha$ = 75.01(1), $\beta$ = 80.11(1), $\gamma$ = 81.33(1)°, $U$ = 1855.5(2) Å$^3$, $Z$ = 2.

Intensities were measured at 20 °C with Mo-K$\alpha$ radiation, $\lambda$ = 0.710 73 Å. The mean intensity of three standard reflections decreased by 27% during the experiment. The data were corrected for crystal decomposition and for absorption. Refinement on $F^2$ of 287 parameters, using 5082 observations, converged at $R_1$ = 0.054, $wR_2$ = 0.140 for 2825 reflections with $I > 2\sigma(I)$, $|\Delta\rho| < 1.31$ e Å$^{-3}$. The unit cell contains two molecules of the gold complex, one ordered and one disordered $C_2H_4Cl_2$ solvate molecules.

For **2e**: $C_{21}H_{30}Au_3O_9P_3$, $M$ = 1110.26, monoclinic, space group $P2_1$, $a$ = 0.979(2), $b$ = 15.630(2), $c$ = 10.453(2) Å, $\beta$ = 111.57(2)°, $U$ = 1516.2(5) Å$^3$, $Z$ = 2.

The data were corrected for absorption. Refinement of $F^2$ of 320 parameters using 5242 observations converged at $R_1$ = 0.043, $wR_2$ = 0.080 for 2613 reflections with $I > 2\sigma(I)$, $|\Delta\rho| < 1.43$ e Å$^{-3}$. The Flack absolute structure parameter $\chi$ = −0.015(13). Two oxygen and two carbon atoms of $P(OMe)_3$ ligands are disordered.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/321.

# Excellent effect of lithium-doped sulfated zirconia catalysts for oxidative coupling of methane to give ethene and ethane

**Kazuhisa Murata,* Takashi Hayakawa and Ken-ichi Fujita**

*National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305, Japan*

**Li-doped sulfated zirconia catalysts are found to be effective for oxidative coupling of methane; *ca.* 80% $C_2$ selectivity is attained at 1073 K with 43% $CH_4$ conversion.**

In this decade, much attention has been paid to the conversion of methane into more valuable products under oxidative[1] or non-oxidative[2] conditions. Of many routes, oxidative coupling of methane (OCM) to give $C_2$ hydrocarbons is still one of the most promising choices for direct methane conversion. Generally, research efforts have been directed towards a search for new efficient catalysts and basic metal oxides such as MgO, CaO and $La_2O_3$ are mostly used as catalysts or supports. However, it seems likely that the strong basicities of the catalysts used are not always required.[3]

Here, fairly super-acidic metal oxides were examined as catalyst supports for the OCM reaction and lithium-doped sulfated zirconia systems were found to be excellent candidates for $C_2$ formation.

The catalysts were prepared as follows. Sulfated zirconia was prepared by the conventional two-step method,[4] in which amorphous zirconia was first synthesized by hydrolysing an aqueous $ZrO(NO_3)_2$ solution with ammonia, followed by calcination for 3 h at 573 K. Then, the resulting zirconia (BET surface area = 266 $m^2\ g^{-1}$) was added to $(NH_4)_2SO_4$ solution and evaporated to dryness, accompanied by calcination in air for 3 h at 973 K. The resultant sulfated zirconia (72.8 $m^2\ g^{-1}$) was impregnated with an aqueous solution of alkali- or alkaline earth-metal compounds such as $Li_2CO_3$ in which the alkali-metal content was 5 mass% (the mass percentage is defined as the ratio of Li to $ZrO_2$). This was then evaporated to dryness, drying overnight at 373 K with calcination in air at 873 K for 3 h (the surface area of the resulting catalyst = 7.3 $m^2\ g^{-1}$). The catalytic runs were carried out under atmospheric pressure and in a fixed-bed vertical-flow reactor constructed from a high-purity alumina tube (id = 6 mm) packed with 0.5 g of catalyst and mounted inside a tube furnace. The catalyst was pretreated in nitrogen at 1073 K for 1 h. Then, the reactant gas mixture (15% $CH_4$, 5% $O_2$ and 80% $N_2$, 50 ml $min^{-1}$) was introduced at $W/F$ = 4.1 g cat h $mol^{-1}$. The products were analysed on-line by gas chromatography (GC) equipped with a Syncarbon-S (FID) column for $C_2H_6$, $C_2H_4$, $C_2H_2$, $C_3H_6$ and $C_3H_8$, Porapack Q (2 m) and molecular sieve 5A (2 m) (TCD) columns for $CH_4$, $CO_2$, $H_2O$, $H_2$, $O_2$ and CO and another Porapack Q (1 m) (FID) column for small amounts of higher hydrocarbons such as $C_4H_8$ and benzene.

The major products of the oxidative coupling of methane are ethene, ethane, carbon monoxide and carbon dioxide with only trace amounts of acetylene, but-1-ene and benzene. The results obtained in the various $ZrO_2$ catalysts at 1073 K are presented in Table 1, where data were taken after 30 min of reaction. In the $ZrO_2$ and sulfated $ZrO_2$ catalysts, some reaction took place, carbon oxides being, however, the dominant products and $C_2$ compounds were obtained in only 3% yield. For the Li-doped $ZrO_2$ catalyst without sulfate, the $CH_4$ conversion was almost unaltered, but $C_2$ selectivity (*ca.* 50%) improved slightly. It was found that 80.2% $C_2$ selectivity was achieved at 32.1% $CH_4$ conversion over the Li-doped sulfated $ZrO_2$ catalyst at a $CH_4/O_2$ ratio of 3. This is the first example of the use of solid super-acid-based catalysts for the oxidative coupling of $CH_4$. The $C_2$ yield (34.5%) was improved by the use of a $CH_4/O_2$ ratio of 2,† although the $C_2$ selectivity was slightly decreased. The $C_2$ yield obtained here is found to be considerably better than results reported in the catalysts systems based on basic metal oxides such as MgO.[1] Moreover, at a $CH_4/O_2$ ratio of 9 without diluent, the $C_2$ selectivity was further increased; as high as 85.1% $C_2$ selectivity was attained at 30.7% $CH_4$ conversion,‡ which is desirable from the practical viewpoint. Fig. 1 shows the effects of reaction temperature on the $CH_4$ conversion and the

**Table 1** Catalytic performances for oxidative coupling of methane over Li-promoted sulfated zirconia catalysts[a]

| Catalyst[b] | Conversion (%) | Selectivity[c](%) | | | | | $C_2$ Yield[d](%) |
|---|---|---|---|---|---|---|---|
| | | $C_2H_2$ | $C_2H_4$ | $C_2H_6$ | CO | $CO_2$ | |
| $ZrO_2$ | 16.0 | 0.19 | 11.3 | 6.75 | 64.6 | 16.9 | 2.92 |
| $6\%SO_4^{2-}/ZrO_2$ | 16.8 | 0.27 | 11.7 | 6.29 | 66.2 | 15.3 | 3.06 |
| $5\%Li/ZiO_2$ | 17.2 | 0.62 | 27.2 | 22.9 | 16.4 | 31.9 | 8.74 |
| $5\%Li/6\%SO_4^{2-}/ZrO_2$ | 32.1 | 1.21 | 58.3 | 20.7 | 9.69 | 5.70 | 25.8 |
| $5\%Li/6\%SO_2^{2-}/ZrO_2$[e] | 35.5 | 1.72 | 58.9 | 9.99 | 21.2 | 4.79 | 25.1 |
| $5\%Li/6\%SO_4^{2-}/ZrO_2$[f] | 43.3 | 0.67 | 58.3 | 20.7 | 11.7 | 6.10 | 34.5 |
| $5\%Li/6\%SO_4^{2-}/ZrO_2$[g] | 30.7[h] | 0.62 | 56.8 | 27.7 | 5.36 | 4.27 | 25.7 |

[a] *Reaction conditions*: $T$ = 1073 K, $P$ = 0.1 MPa, total flow = 50 ml $min^{-1}$, reactant gas [$CH_4$ (15%)–$O_2$ (5%)–$N_2$ (80%)]. Results are after 30 min of reaction. [b] The sulfated zirconia was prepared using $(NH_4)_2SO_4$. [c] Conversion and selectivity are based on the amount of methane reacted. [d] $C_2$ yield is obtained from the product of conversion and $C_2$ selectivity, where $C_2$ selectivity is the sum of $C_2H_2$, $C_2H_4$ and $C_2H_6$. [e] The sulfated zirconia was prepared using 0.5 M $H_2SO_4$. [f] Reactant gas [$CH_4$ (10%)–$O_2$ (5%)–$N_2$ (85%)]. [g] Reactant gas [$CH_4$ (90%)–$O_2$ (10%)]. [h] In this run, carbon and hydrogen mass balances were 94 and 92%, respectively: C mass balance = $(2 \times C_2H_6 + 2 \times C_2H_4 + 2 \times C_2H_2 + 3 \times C_3H_6 + 3 \times C_3H_8 + 4 \times C_4H_8 + 5 \times C_5H_{10} + 6 \times$ benzene + $7 \times$ toluene + CO + $CO_2) \times 100/CH_4$ converted. H mass balance = $(3 \times C_2H_6 + 2 \times C_2H_4 + C_2H_2 + 3 \times C_3H_6 + 4 \times C_3H_8 + 4 \times C_4H_8 + 5 \times C_5H_{10}$ + $3 \times$ benzene + $4 \times$ toluene + $H_2$ + $H_2O) \times 100/CH_4$ converted. In other runs the C and H mass balances were also between 90 and 95%. In any run, the remainder of gaseous products must be a very small amount of oxygenates such as methanol. Also, the formation of bulk lithium carbonate during the reaction[9] was not detected by powder X-ray diffraction, the patterns of which remained unchanged before and after reaction. Further study is under way to improve the C and H mass balances.

selectivities under no-diluent conditions. The $CH_4$ conversion and $C_2$ selectivity increased with increasing reaction temperature up to 1073 K, whereas $CO_x$ selectivity decreased. These findings could be explained, at least partly, by a difference in the activation energy between $C_2$ and $CO_x$ formation.[5]

The effect of catalyst components were examined using other acid sources and other alkali metals. In the Li-doped acid-promoted $ZrO_2$ catalysts, the effect of acid precursors other than $(NH_4)_2SO_4$ was in the order: $(NH_4)_2SO_4$ (25.8) > 0.5 M $H_2SO_4$ (25.1) > $NH_4Cl$ (22.9) > trimethyleneborate (22.3) > $(NH_4)_3PO_4$ (19.3) > $NH_4NO_3$ (16.5) > none (8.7). (The values in parentheses represent the $C_2$ yield at 1073 K.) For the Na- and K-doped sulfated $ZrO_2$ catalysts, the $CH_4$ conversion was almost the same as for the Li-doped catalysts, but $C_2$ selectivity decreased to *ca.* 50%, nearly 30% lower than that for the Li-doped catalyst. Over catalysts promoted with 10 mass% of Li, both $CH_4$ conversion and $C_2$ selectivity were slightly reduced and, as a result, the $C_2$ yield decreased to *ca.* 19%.

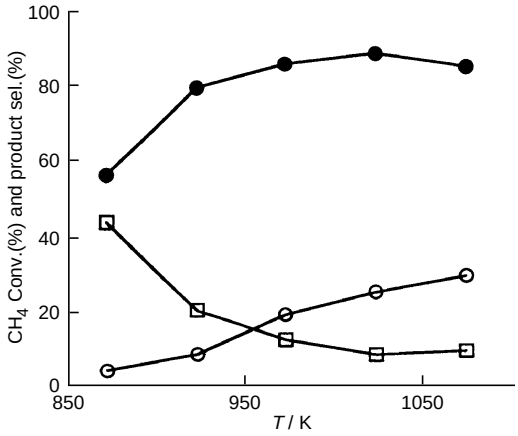

**Fig. 1** Effect of the reaction temperature on the oxidative coupling of methane over 5% Li-doped 6 mass% $SO_4^{2-}/ZrO_2$ catalysts without diluent. *Conditions*: $CH_4$ (90%)–$O_2$ (10%), feed 50 ml $min^{-1}$, catalyst 0.5 g. $CH_4$ conversion (○); selectivities: $C_2$ (●), $CO_x$ (□).

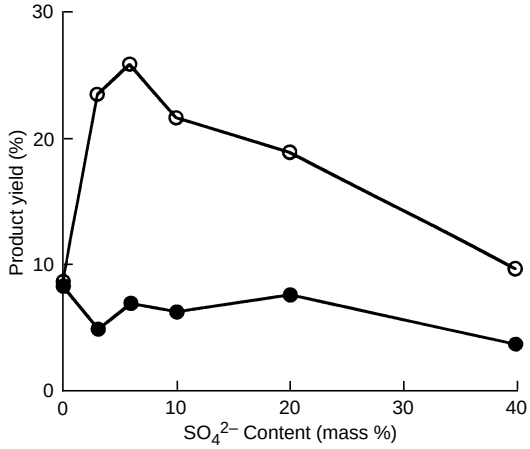

**Fig 2** Effect of sulfate content on the product yields. *Conditions*: $CH_4$ (15%)–$O_2$ (5%)–$N_2$ (80%), feed 50 ml $min^{-1}$, 1073 K. The mass% of sulfate content is defined as the ratio of $SO_4^{2-}$ to $ZrO_2$. Selectivities: $C_2$ (○), $CO_x$ (●).

The effectiveness of the Li-doped sulfated $ZrO_2$ catalysts on the oxidative coupling of $CH_4$ is still not clear. Since the effect of Li doping on MgO support has been already reported,[6] it seems likely that the preparation of sulfated $ZrO_2$ surface is a key step in our catalyst system. In fact, the catalyst performances depend on the sulfate content (Fig. 2) and calcination temperature: a maximum $C_2$ yield is attained over the catalysts which contain 6 mass% sulfate and are calcined at 923–973 K, being closely related to the preparation conditions of sulfated $ZrO_2$ as solid superacids.[7] If so, sulfated metal oxides other than $ZrO_2$[8] might be also effective as supports. We found that, for an Li-doped sulfated $SnO_2$ catalyst,§ 82.4% $C_2$ selectivity at 1073 K is achieved at 30.5% $CH_4$ conversion. Also, a $ZrO_2$ catalyst, impregnated with an aqueous solution containing both $(NH_4)_2SO_4$ and $Li_2CO_3$, followed by calcination in air at 873 K for 3 h, showed much lower reactivity than that prepared by the two-step method. By investigating all these findings, it is concluded that Li doping over a super-acid surface is required for the generation of high catalytic performances for the $ZrO_2$-based OCM reaction reported here.

Further work is in progress not only to carry out reaction on larger experimental scales, but also to elucidate the nature of the Li-doped solid super-acid catalysts.

## Footnotes

† In this run, after reaction for 5 h at 1073 K, methane conversion was decreased (43.3 to 39%), whereas $C_2$ selectivity was slightly increased (79.7 to 82.1%).

‡ In this run, the amount of oxygen required to reach 30.7% $CH_4$ conversion could approximately correspond to that contained in the feedstock, if we assume the following reaction steps including thermal cracking of ethane or ethene to form ethene or acetylene, although further investigation will be required for the reaction scheme. (1) $2CH_4 + 1/2O_2 \rightarrow C_2H_6 + H_2O$, (2) $C_2H_6 \rightarrow C_2H_4 + H_2$, (3) $C_2H_4 \rightarrow C_2H_2 + H_2$, (4) $CH_4 + 3/2O_2 \rightarrow CO + 2H_2O$, (5) $CO + 1/2O_2 \rightarrow CO_2$, (6) $CH_4 + H_2O \rightarrow CO + 3H_2$. In fact, in this run, the expected amount of hydrogen was observed by GC analysis. Also, in a separate experiment using the same catalyst, we confirmed that efficient $C_2H_4$ formation from $C_2H_6$ was observed even at 1023 K in the absence of $O_2$, consistent with a thermodynamical calculation.

§ $SnO_2$ impregnated with 6 mass% $(NH_4)_2SO_4$ was calcined at 873 K for 3 h.

# Hydration structure of $Eu^{III}$ on aqueous ion-exchange resins using laser-induced fluorescence spectroscopy

**Yoshio Takahashi,*[a]†‡ Takaumi Kimura,[b] Yoshiharu Kato,[b] Yoshitaka Minai[a] and Takeshi Tominaga[a]**

[a] *Department of Chemistry, School of Science, University of Tokyo, Hongo, Tokyo 113, Japan*
[b] *Japan Atomic Energy Research Institute (JAERI), Tokai, Ibaraki 310-09, Japan*

***Ca.* 2 and > 5 molecules of hydrated water are removed from the inner sphere of $Eu^{III}$ on strongly and weakly acidic ion-exchange resins, respectively, showing the different mechanisms between ion-exchange reactions occurring on these two types of resins.**

Recently, the hydration structure of metal ions on strongly acidic cation-exchange resins (denoted as SCR) has been investigated by neutron diffraction.[1] However, descriptions on the structures of the exchanged ion have not been fully clarified, despite the wide applications of cation-exchange resins in chemistry and biology.[2] This is perhaps due to difficulties encountered in analysing the adsorbed metal species at a solid–water interface. The present study provides direct information on the hydration structures of $Eu^{III}$ exchanged on SCR and weakly acidic cation-exchange resins (denoted as WCR) obtained through laser-induced fluorescence spectroscopy. This method has the advantages of having high sensitivity and good selectivity for $Eu^{III}$, and can be applied to the current resin system in the presence of an aqueous phase. Moreover, the method is able quantitatively to count the number of hydrated water molecules attached to $Eu^{III}$, unlike neutron diffraction.

The fluorescence lifetime of $Eu^{III}$ ($^5D_0 \rightarrow {}^7F$ manifold) is related to $N_{H_2O}$ (the number of $H_2O$ molecules in the primary coordination sphere of the $Eu^{III}$ ion) due to the energy transfer from the excited state of $Eu^{III}$ to OH vibrations of the hydrated $H_2O$.[3] The method was therefore applied to measure $N_{H_2O}$ values of $Eu^{III}$ in both aqueous and solid phases.[3] In the present study, the method is, for the first time, applied to the study of the hydration structure of $Eu^{III}$ at the solid–water interface.

AG 50WX8 (functional group: $-SO_3^-$; matrix: styrene divinylbenzonate; proton exchange capacity: 2.1 mequiv. $g^{-1}$) and Bio-Rex 70 (functional group: $-CO_2$; matrix: acrylate; proton exchange capacity: 3.5 mequiv. $g^{-1}$) purchased from Bio-Rad Lab., Inc. were used as the SCR and WCR samples, respectively. Linear poly(4-styrenesulfonic) acid (PSS) and linear polyacrylic acid (PAA) purchased from Aldrich were also employed. The concentrations of polyelectrolytes (SCR, WCR, PSS and PAA) and $Eu^{III}$ are listed in Fig. 1. The pH and supporting electrolyte concentration ($C_s$) were adjusted by addition of small amounts of NaOH or $HClO_4$ and $NaClO_4$ respectively. An aqueous solution of $Eu^{III}$ with no polyelectrolyte was also prepared (WP system). These solutions (or suspensions in the resin systems) were aged overnight prior to the subsequent procedures. The distribution of $Eu^{III}$ between the aqueous and solid phases was measured using a $^{152}Eu$ tracer after centrifugation at 3000 rpm for 1 min. The solution or suspension contained in a quartz cell and magnetically stirred was exposed to light (395 nm) from a dye laser giving rise to the excitation of $Eu^{III}$ ($^7F_0 \rightarrow {}^5L_6$). The decay curve for the emission at 615 nm was measured by a photomultiplier and recorded with a digital oscilloscope coupled with a personal computer.

The relation of $N_{H_2O}$ with the lifetimes $\tau_{H_2O}$ and $\tau_{D_2O}$ measured in the $H_2O$ and $D_2O$ systems, respectively, is as follows:[3]

$$N_{H_2O} = 1.05\,(1/\tau_{H_2O} - 1/\tau_{D_2O})/ms^{-1} \quad (1)$$

For SCR, WCR, PSS and PAA systems, $\tau_{D_2O}$ values were 1.10, 1.98, 3.00 and 3.05 ms, respectively. These $\tau_{D_2O}$ values allow us to evaluate $N_{H_2O}$ from the luminescence lifetime measurement data [eqn. (1)] and results are shown in Fig. 1 It is seen that $N_{H_2O}$ of the europium(III) aqua complex is 9.[3]

In the WP system, the $N_{H_2O}$ decreases from the $N_{H_2O}$ of $Eu^{III}$ (aq) which indicates the formation of inorganic complexes of $Eu^{III}$ such as $Eu(CO_3)^+$, $Eu(OH)^{2+}$ or $Eu(OH)_2^+$ between pH 6 and 7.5.[4] When pH > 7.5, the $^{152}Eu$ experiments shows that $Eu^{III}$ formed inorganic colloids or precipitates.[4] Formation of such inorganic colloids or precipitates of $Eu^{III}$ made its lifetime very short due to the non-radiative energy transfer among the neighbouring $Eu^{III}$ in the colloids or precipitates.[5] In this pH region therefore, $N_{H_2O}$ of $Eu^{III}$ in the WP system apparently becomes much greater than 9. Such short lifetime values were not observed in the polyelectrolyte systems; therefore inorganic colloidal species were not formed, and all the $Eu^{III}$ is completely complexed with the polyelectrolytes.

In the WCR system, $Eu^{III}$ was shown from $^{152}Eu$ experiments to be adsorbed at pH > 4. $N_{H_2O}$ decreased abruptly at pH *ca.* 3.5 due to the initiation of ion exchange. The $N_{H_2O}$ value in the WCR system decreased gradually from 3.5 to 2.5 between pH 4 and 9, in a manner similar to the PAA system. This decrease suggests that more carboxylates are bound to $Eu^{III}$ with increasing pH accompanied with an increasing degree of ionization of WCR or PAA.[6]

In the SCR system, $Eu^{III}$ was adsorbed at pH > 0.5 at which $N_{H_2O}$ of the adsorbed $Eu^{III}$ on SCR was *ca.* 7.5. The exchanged $Eu^{III}$ ion on WCR releases five to seven molecules of hydrated

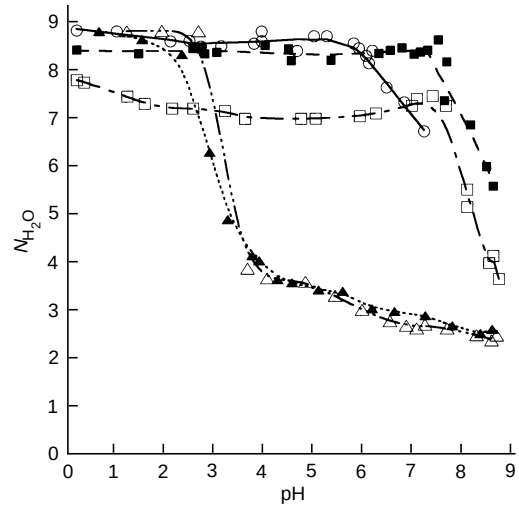

**Fig. 1** pH dependence of $N_{H_2O}$ in the SCR (□), WCR (△), PSS (■), PAA (▲) and WP (○) systems. Total concentration of $Eu^{III}$ is $2 \times 10^{-4}$ M. SCR and WCR systems: 4.0 g of AG 50WX8 and 10 g of Bio-Rex 70 suspended in 1 $dm^3$ water, respectively; PSS and PAA systems: aqueous solutions of polystyrenesulfonic acid (8.3 g $dm^{-3}$) and polyacrylic acid (3.0 g $dm^{-3}$), respectively; WP system: $Eu^{III}$ in water without added polyelectrolyte.

water, while only one or two water molecules are released when adsorbed on SCR. This indicates that the hydration structure of $Eu^{III}$ ion is much more affected by WCR than SCR. The present result suggests different mechanisms between the ion-exchange reactions in the SCR and WCR systems: the hydrated $Eu^{III}$ ion interacts with SCR, whereas the dehydrated $Eu^{III}$ ion interacts with WCR. Reports on the selectivities in the ion exchange of alkali, alkaline earth, and lanthanoid elements concludes that a metal ion with a larger ionic radius is more readily exchanged on SCR for metal ions having the same charge showing that hydrated ions interacts with SCR.[2] By contrast, WCR adsorbs a smaller ion more effectively, showing that the metal ion forms an inner-sphere complex with WCR.[2] The present results on the hydration structure of $Eu^{III}$ have provided spectroscopic evidence for the different mechanisms of ion-exchange reactions on SCR and WCR, as has been suggested by thermodynamic data.[2]

In the PSS and SCR systems at higher pH region, $N_{H_2O}$ begins to decrease at pH *ca.* 7.5. In contrast, in the absence of the polyelectrolytes (WP system), the decrease of $N_{H_2O}$ was observed at pH > 6 due to the formation of inorganic complexes, as described earlier. This shows that the $Eu^{III}$ ion was exchanged on PSS or SCR as a free hydrated ion accompanied by removal of the hydroxide or carbonate ligand at pH between 6 and 7.5. When pH > 7.5, the $N_{H_2O}$ values in the PSS and SCR systems decreased with an increase in pH. This indicates that the complex ion of europium(III) hydroxide or carbonate [*e.g.*, $Eu(CO_3)^+$, $Eu(OH)^{2+}$ or $Eu(OH)_2^+$] is directly adsorbed on PSS and SCR at these pH values.

Although it is suggested that the hydrated ion interacts with SCR, the $N_{H_2O}$ value of the adsorbed $Eu^{III}$ on SCR was less than that of $Eu^{3+}$ (aq). This shows that the SCR affects the hydration structure of $Eu^{III}$ to some extent. On the other hand, the $N_{H_2O}$ value of $Eu^{III}$ complexed with PSS (linear polyelectrolyte analogue of SCR) was similar to that of the aqua complex. On comparing the $N_{H_2O}$ values in the SCR and PSS systems, it is thought that the cross-linked structure of SCR may be responsible for its influence on the hydration structure of $Eu^{III}$. This is compatible with the result of neutron diffraction study[1] on the hydration structure of ion-exchanged $Ni^{2+}$ and $Li^+$, showing that a sulfonate group penetrates into the primary hydration sphere of these ions.

As $C_s$ (concentration of supporting electrolyte, $NaClO_4$) increases up to 1.0 M, $N_{H_2O}$ values in the WCR and SCR systems remained almost constant (Fig. 2). This was also found to be the case for the WP system in the $C_s$ region.[7] However, $N_{H_2O}$ values in the PAA (linear polyelectrolyte of acrylate) system decreased. This is perhaps due to change in conformation, since the shape of PAA was folded as a result of shielding the repulsive forces between the dissociated carboxylate groups with the supporting cations.[8] This suggests that network structures of WCR and SCR resins are more rigid than the linear structure of PAA.

This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas 'New Development of Rare Earth Complexes' No. 08220212 from the Ministry of Education, Science, Sports, and Culture.

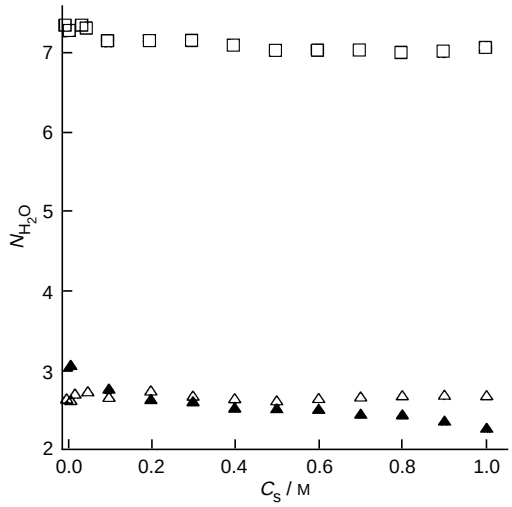

**Fig. 2** Dependence of $N_{H_2O}$ upon $C_s$ in the SCR (□), WCR (△) and PAA (▲) systems. Experimental conditions were similar to those for Fig. 1.

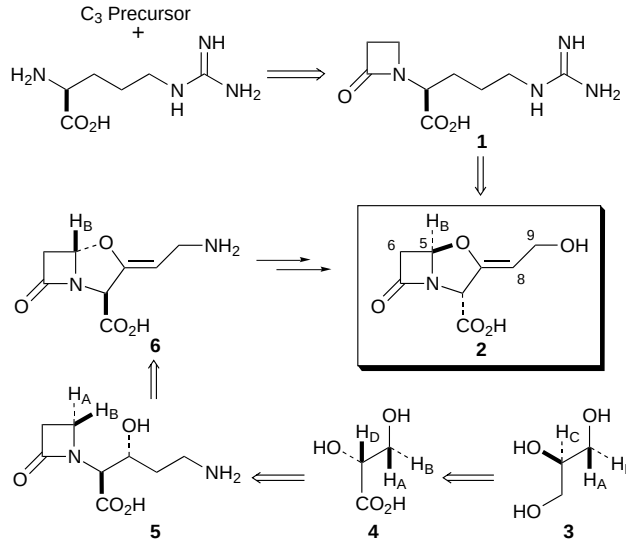
# The fate of [2,3,3-$^2H_3$, 1,2-$^{13}C_2$]-D,L-glycerate in clavulanic acid biosynthesis

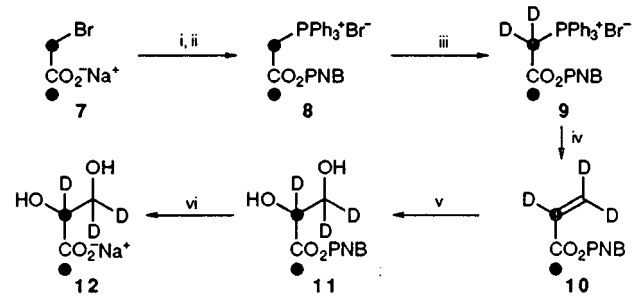
**Janos Pitlik and Craig A. Townsend***

*Department of Chemistry, The Johns Hopkins University, Baltimore, Maryland 21218, USA*



**The hydrogen at C-2 of glycerate is lost in the biosynthesis of clavulanic acid.**

Elusive to experiment and mechanistic understanding has been the biosynthesis of the 4-membered ring of deoxyguanidinoproclavaminic acid **1**, the first β-lactam-containing intermediate in the anabolic pathway to clavulanic acid **2**.[1] These three carbons are known to be derived efficiently from glycerol **3**, accompanied by the loss of $H_C$.[2,3] Subsequent radiochemical experiments with samples of this $C_3$-carbohydrate bearing tritium stereospecifically at the *pro*-(*R*) hydroxymethylene established that chiral information was delivered through the entire biosynthetic pathway to clavulanic acid **2** such that the (1*R*,2*S*)-hydrogen ($H_A$) of **3** is lost while $H_B$ is incorporated in **2** at C-5.[4] Similarly, in the clavaminate synthase-catalysed cyclization/dehydration of proclavaminic acid **5** to clavaminic acid **6** it was determined that formation of the oxazolidine ring involved specific replacement of the 4′*S*-label ($H_A$) with substrate oxygen (retention of configuration).[5] Finally, the demonstration that both $H_A$ and $H_B$ are retained from glycerol **3** to proclavaminic acid **5** allowed important deductions to be made about the cryptic formation of the β-lactam ring. Generation of the azetidinone N–C-4′ bond takes place with (*a*) loss of the glycerol oxygen, (*b*) no net change in oxidation state at this methylene carbon and, (*c*) overall retention of configuration,[6] unlike monocyclic β-lactam formation in nocardicin[7] and, presumably, the monobactams. Lastly, the stereochemical inversion that takes place between clavaminic acid **6** and clavulanic acid **2** must occur with retention of $H_B$.



The complete loss of $H_C$ from glycerol **3**, but the retention of both $H_A$ and $H_B$ into proclavaminic acid **5** followed by their stereospecific loss and retention, respectively, into clavulanic acid **2** point to the intervention of conventional glycolytic metabolism, *e.g.* to glycerate **4**, prior to uptake into the β-lactam biosynthetic pathway. Earlier whole-cell studies revealed that [2-$^3$H, 1-$^{14}$C]-D-glycerate gave efficient incorporation of carbon label into the β-lactam ring (95–100%) of clavulanic acid, but only 4–11% of the tritium could be accounted for in the molecule by chemical degradation, principally at C-6 and C-8.[3] Given the inherent inaccuracies of low radioactivity in this technically difficult double label experiment, we have re-examined the fate of the glycerate C-2 hydrogen by a methodologically distinct means.

The experiment to test the retention or loss of H-2 was designed to use two $^{13}$C-labels as internal measures of intact and absolute carbon utilization and then multiple deuterium labels to monitor changes at H-2 knowing that one of the glycerate H-3 hydrogens would be cleanly retained in clavulanic acid **2**. Thus, (±)-[2,3,3-$^2H_3$, 1,2-$^{13}C_2$]glycerate **12** (Scheme 2) was prepared as follows. [1,2-$^{13}C_2$]Bromoacetate **7** was converted to its crystalline *p*-nitrobenzyl (PNB) ester and treated with $PPh_3$ to form the phosphonium salt **8**. Facile ylide formation in $D_2O$ allowed rapid exchange at the C-2 methylene followed by Wittig reaction with deuterioformaldehyde in $D_2O$[8,9] in the presence of anhydrous $K_2CO_3$ yielded *p*-nitrobenzyl [2,3,3-$^2H_3$, 1,2-$^{13}C_2$]acrylate **10** in excellent yield. Sharpless dihydroxylation[10,11] gave PNB glycerate **11**. Hydrogenolysis in the presence of $NaHCO_3$ and reverse-phase HPLC purification (Partisil 10 ODS 3, 25 × 250 mm, $H_2O$ elution) provided the desired quintuply labelled sodium glycerate **12** in nearly 60% overall yield. $^{13}C\{^1H\}$ NMR analysis of the product [Fig. 1(*a*)] displayed the expected carboxyl resonance as a clean doublet ($^1J_{CC}$ = 54.2 Hz) while the corresponding doublet for C-2 was further split into a pair of 1 : 1 : 1 triplets owing to the directly bound deuterium ($^1J_{CD}$ = 22.1 Hz) and broadened slightly by the adjacent C-3 deuteria.

Cultures (2.0 l) of *Streptomyces clavuligerus* (ATCC 27064) were grown as previously described (500 ml/4 l flask).[12] After 48 h, **12** (2.0 mmol/l) was administered in equal portions to the fermentations under sterile conditions. After an additional 96 h, the clavulanic acid produced was isolated by adsorption onto carbon, conversion to its *p*-bromobenzyl ester and purification by silica gel chromatography (40 mg).[2,13] Careful $^{13}C\{^1H\}$ NMR analysis of this product showed the natural abundance singlet for the β-lactam carbonyl, C-7, flanked by a doublet ($^1J_{CC}$ = 38.9 Hz) indicating 0.80–0.85% intact incorporation of the multiply labeled glycerate carbon skeleton [Fig. 1(*b*)].

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, PNB–OH, EDC, DMAP, $CH_2Cl_2$, room temp., 3 h, 95%; ii, $PPh_3$, THF–$CH_2Cl_2$, room temp., 24 h; iii, $D_2O$, room temp., 24 h; iv, $D_2CO$ in $D_2O$, $K_2CO_3$, 24 h, 80% for 3 steps; v, Bu$^t$OOH, cat. $OsO_4$, $Et_4NOAc$, acetone, 0 °C to room temp., 6 h, 85%; vi, $H_2$, 10% Pd–C, $NaHCO_3$, $H_2O$–THF, room temp., 24 h, then RP–HPLC, 92%

Centred upfield at δ 46.39, the natural abundance peak for C-6 could be found flanked by upfield α- and α/β-shifted doublets.[14] That marked by (▲) corresponds to $^{13}C$ at C-6 paired to $^{13}C$ at C-7 and $^{2}H$-label at C-5 (α- and β-heavy isotopes; $\Delta\delta$ = 0.144 ppm). This species represents 80% fully intact incorporation of **12**. The second, smaller doublet (●) is due to doubly $^{13}C$-labelled molecules, but having $^{1}H$ at C-5 (α-heavy isotope; $\Delta\delta$ = 0.019 ppm). While this 20% of incorporated precursor seems high, it is an artifact[4] of cummulative isotope effects[15] that discriminate against $^{2}H$-labelled molecules, but let the very small proportion of [$^{1}H$,$^{13}C$]-labelled precursor and intermediate molecules pass more swiftly along the pathway. These observations notwithstanding, notably absent is a 1 : 1 : 1 triplet corresponding to deuterium directly bound to C-6 and a concommitant β-isotope shift detectable in the doublet for C-7. In an attempt to establish an upper bound for incorporation of deuterium at C-6, a $^{2}H\{^{1}H\}$ NMR spectrum was recorded (data not shown). Deuterium label at C-5 was easily observed and, while some minor secondary incorporation at C-9 could be detected, none was seen at C-6. Within the limits of the NMR methods used, we place the possible level of deuterium incorporation at C-6 from each of these NMR experiments at < 0.05%.

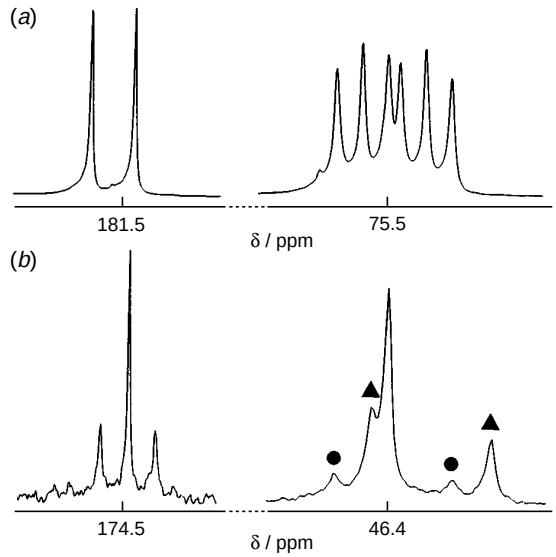


**Fig. 1** Partial $^{13}C\{^{1}H\}$ NMR spectra at 100 MHz of (*a*) [2,3,3-$^{2}H_3$, 1,2-$^{13}C_2$]-D,L-glycerate **12** in $D_2O$, referenced to DSS; (*b*) biosynthetically enriched *p*-bromobenzyl clavulanate in $CDCl_3$, referenced to $SiMe_4$, 21 000 transients

We are led to conclude from these data that $^{2}H$-2 is lost from **12** upon incorporation into clavulanic acid. There is a caveat, however remote, that H-2, unlike H-3, is labile among the intermediates of glycolysis despite the use of a triglyceride-based medium to favour gluconeogenesis.[3,12] The possibility exists that the metabolic flux among these intermediates is so great relative to the rate of entry into the biosynthetic pathway that the C-2 deuterium has exchanged for hydrogen before detectable incorporation at C-6 can occur. This proviso aside, the loss of H-2 from glycerate imposes new limitations on the mechanism of β-lactam formation in clavulanic acid biosynthesis, a process whose full understanding has thus far resisted experimental enquiry.

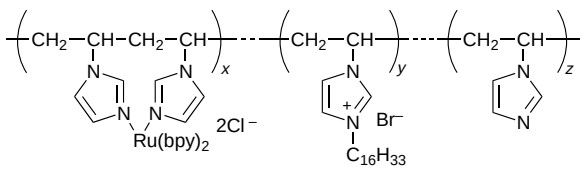
# Hydrogen generation using water-insoluble polymer-bound ruthenium(II) complexes

**Masahiro Suzuki, Satoshi Kobayashi, Mutsumi Kimura, Kenji Hanabusa and Hirofusa Shirai***



*Department of Functional Polymer Science, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386, Japan*

**Water-insoluble free-standing films of partially quaternized poly(1-vinylimidazole)-bound ruthenium(II) complexes are prepared, and photoinduced hydrogen generation is observed with light irradiation (λ > 440 nm) of aqueous solutions containing the polymer-bound ruthenium(II) complex film, methyl viologen, triethanolamine and bis(2,2′-bipyridine)platinum(II).**

Tris(2,2′-diimine)ruthenium(II) complexes have attracted much attention as photosensitizers for application to solar-energy conversion.[1–3] In particular, tris(2,2′-bipyridine)ruthenium(II), $[Ru(bpy)_3]^{2+}$, has been widely employed as a photocatalyst for water cleavage and used as a photosensitizer in many hydrogen generation systems.[4–7] Metallopolymers, in which ruthenium(II) complexes are coordinated to poly(4-vinylpyridine) and poly(1-vinylimidazole), have been investigated, and applications to polymer catalysts, photosensitizers, and molecular diodes have been proposed.[8–10] However, there are no reports on the application of these photosensitizers to photoinduced hydrogen generation.

Recently, we have reported the preparation of partially quaternized poly(1-vinylimidazole)-bound ruthenium(II) complexes [Ru(QPIm)] and their films, and luminescence quenching and photosensitized charge separation using Ru(QPIm)s as photosensitizers.[11–13] These results indicated that Ru(QPIm)s and their films are sufficiently capable of utilization as photosensitizers. In this work, hydrogen generation using Ru(QPIm)s as photosensitizers was investigated in methanol–water and water.

The polymer photosensitizers were prepared according to the literature[11] and the structures were confirmed by $^1$H NMR and absorption spectroscopies (Fig. 1). The polymer films were prepared by casting from methanol solution, and the measured thicknesses were 0.182 mm for $C_{16}$RuQPIm-25 and 0.184 mm for $C_{16}$RuQPIm-44. 1,1′-Dimethyl-4,4′-bipyridinium ($MV^{2+}$) and 1,1′-dioctyl-4,4′-bipyridinium ($C_8V^{2+}$) were used as acceptors. Triethanolamine (TEA) was used as a sacrificial donor and bis(2,2′-bipyridine)platinum(II) $[Pt(bpy)_2]^{2+}$ was used as the catalyst for hydrogen evolution, respectively. Hydrogen generation was performed at 25 °C with light irradiation by a 300 W slide projector under an argon atmosphere. Light with λ < 440 nm was cut off by a Toshiba Y-44 filter.

| Polymers | *x* | *y* | *z* |
|---|---|---|---|
| $C_{16}$RuQPIm-25 | 0.0033 | 0.2531 | 0.7436 |
| $C_{16}$RuQPIm-44 | 0.0033 | 0.4404 | 0.5563 |

**Fig. 1** Chemical structure of Ru(QPIm)

Fig. 2 shows the relationship between hydrogen generation and irradiation time for Ru(QPIm)s in methanol–water (9 : 1 *v*/*v*) and RuQPIm films in aqueous solution.

The amount of generated hydrogen for $C_{16}$RuQPIm-25 was larger than that for $C_{16}$RuQPIm-44. This is attributed to electrostatic repulsion between viologen species and quaternized imidazolium residues and steric hindrance of alkyl side-chains.

Compared with $MV^{2+}$ systems, hydrogen generation for $C_8V^{2+}$ systems was lower. We have already reported that viologens with long alkyl groups show van der Waals interactions with alkyl side-chains on the polymer backbone.[11,12] After electron transfer from the photoexcited ruthenium(II) complex to $MV^{2+}$ in the polymer domain, the $MV^{\cdot+}$ species formed quickly diffuse into the bulk solution and readily react with the Pt catalyst. However, the $C_8V^{\cdot+}$ species barely diffuse into the bulk solution due to interaction with the polymer, leading to the inhibition of reaction with the positively charged Pt catalyst; consequently, hydrogen generation decreases.

In Ru(QPIm) film systems, 0.46 and 0.36 ml of hydrogen was evolved for $C_{16}$RuQPIm-25/$MV^{2+}$ and $C_{16}$RuQPIm-44/$MV^{2+}$, respectively, while hydrogen evolution was scarcely observed in the $C_8V^{2+}$ systems. During light irradiation, the colour of reaction solution and polymer film do not change, indicating that the $MV^{\cdot+}$ species formed react rapidly with the platinum catalyst. For $C_8V^{2+}$ systems, however, the colour of the polymer film changes from orange to deep blue (but the solution is

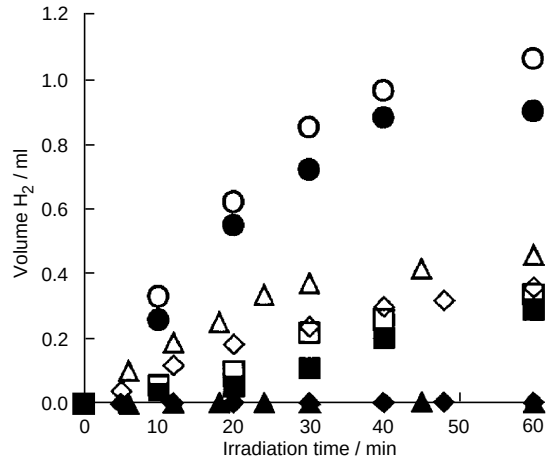


**Fig. 2** Hydrogen generation upon light irradiation of methanol–water (9 : 1 *v*/*v*) containing $5.0 \times 10^{-5}$ mol dm$^{-3}$ Ru(QPIm), $5.0 \times 10^{-3}$ mol dm$^{-3}$ viologen, 0.1 mol dm$^{-3}$ TEOA, and $3.0 \times 10^{-3}$ mol dm$^{-3}$ platinum catalyst for $C_{16}$RuQPIm-25/$MV^{2+}$ (○), $C_{18}$RuQPIm-44/$MV^{2+}$ (□), $C_{16}$RuQPIm-25/$C_8V^{2+}$ (●), $C_{16}$RuQPIm-44/$C_8V^{2+}$ (■), $C_{16}$RuQPIm-25film/$MV^{2+}$ (△), $C_{16}$RuQPIm-44film/$MV^{2+}$ (◇), $C_{16}$RuQPIm-25film/$C_8V^{2+}$ (▲) and $C_{16}$RuQPIm-44film/$C_8V^{2+}$ (◆)

unchanged), which indicates that a charge separation reaction occurs and the $C_8V^{\cdot+}$ species scarcely react with the platinum catalyst. In a previous paper,[13] we reported that $C_8V^{2+}$ species are adsorbed on the surface of the polymer film and only adsorbed $C_8V^{2+}$ species react with photoexcited ruthenium(II) complexes. Considering this fact, the present results can be explained as follows. After electron transfer from the photoexcited ruthenium(II) complex to the $MV^{2+}$ species on the surface of the polymer, the $MV^{\cdot+}$ species formed diffuse into the bulk solution and react with the platinum catalyst, leading to hydrogen generation. On the other hand, $C_8V^{2+}$ species are adsorbed on the surface of the polymer film and the charge separation takes place only on the film surface. Therefore, no evolution of hydrogen is observed since the adsorbed $C_8V^{\cdot+}$ species do not react with the positively charged platinum catalyst. Quantum yields for $H_2$ formation are summarized in Table 1.

**Table 1** Maximum amount of generated hydrogen and quantum yields for hydrogen generation for solution and film systems

| | $H_2$[a]/ml | $\phi(H_2)$ |
|---|---|---|
| In MeOH–$H_2O$ | | |
| $C_{16}$RuQPIm-25/$MV^{2+}$ | 1.01 | 0.026 |
| $C_{16}$RuQPIm-25/$C_8V^{2+}$ | 0.34 | 0.025 |
| $C_{16}$RuQPIm-44/$MV^{2+}$ | 0.91 | 0.022 |
| $C_{16}$RuQPIm-44/$C_8V^{2+}$ | 0.29 | 0.018 |
| In aqueous solution (film) | | |
| $C_{16}$RuQPIm-25/$MV^{2+}$ | 0.46 | 0.015 |
| $C_{16}$RuQPIm-25/$C_8V^{2+}$ | 0.36 | 0.014 |
| $C_{16}$RuQPIm-44/$MV^{2+}$ | < 0.01 | < 0.001 |
| $C_{16}$RuQPIm-44/$C_8V^{2+}$ | < 0.01 | < 0.001 |

[a] Irradiation for 1 h.

The present results demonstrate that partially quaternized poly(1-vinylimidazole)-bound ruthenium(II) complex films can be used for a photoinduced hydrogen generation reaction as new polymer-solid photosensitizers. Furthermore, it is found that the high efficiency of charge separation does not necessarily bring about high efficiency of hydrogen generation in the present systems. A detailed investigation on the hydrogen generation is now in progress in our laboratory.

# A novel diaminoborate ligand system derived from 1,8-diaminonaphthalene and 9-BBN: preparation of titanium and zirconium complexes and crystal structure of the titanium complex

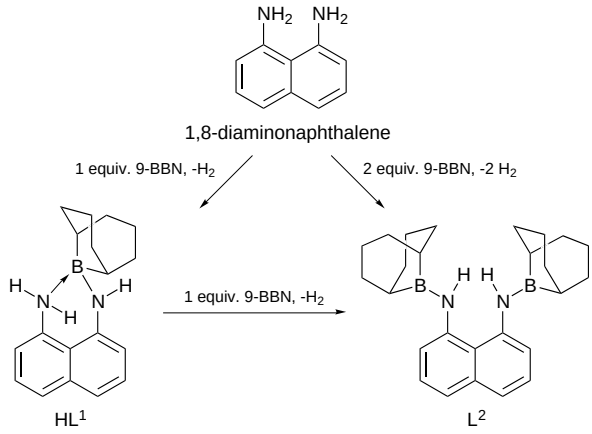
**Galia Bar-Haim, Romem Shach and Moshe Kol*†**

*School of Chemistry, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel-Aviv University, Tel-Aviv 69978, Israel*

**1,8-Diaminonaphthalene reacts selectively with 1 equiv. of 9-BBN to form a bridging amine–aminoborane, and with 2 equiv. of 9-BBN to form a non-bridging bis(aminoborane); these aminoboranes give rise to a novel diaminoborate (4e,1−) ligand system by reactions with dimethylamides of titanium and zirconium.**

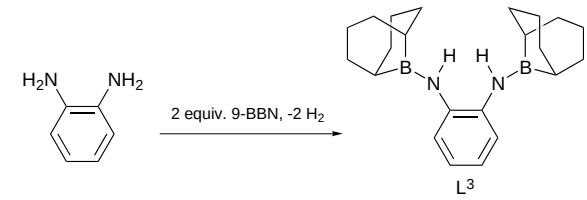
The search for new ligand systems, and especially ones that could replace the (6e,1−) cyclopentadienyl type ligands, is a major area of research in current inorganic and organometallic chemistry. Most progress has been achieved with ligands based on nitrogen donors like trispyrazolylborate,[1] benzamidinate,[2] silyl amide,[3] boryl amide[4] and others.[5] A major aspect in designing of such ligands, other than their electronic character, is their steric effects on the metal environment. In this report we describe a novel boron nitrogen ligand derived *via* two routes from 1,8-diaminonaphthalene and 9-BBN, and its complexes with titanium and zirconium.

Aniline was reported to react with 9-borabicyclo[3.3.1]-nonane (9-BBN) to form the corresponding *B*-phenylamino-9-BBN with evolution of hydrogen gas.[6] We found that 1,8-diaminonaphthalene can react with 9-BBN, with evolution of hydrogen gas, to form two isolable products, depending on the molar ratio of the reactants: addition of exactly 1 equiv. of 9-BBN to 1,8-diaminonaphthalene results in highly selective formation of an amine–aminoborane, $HL^1$, whereas addition of 2 equiv. of 9-BBN to 1,8-diaminonaphthalene yields a bis-(aminoborane), $L^2$, quantitatively. Adding 1 equiv. of 9-BBN to isolated $HL^1$ produces $L^2$ in high yield as well (Scheme 1). When stored and handled under dry nitrogen at room temperature, $HL^1$ and $L^2$ are stable for months.



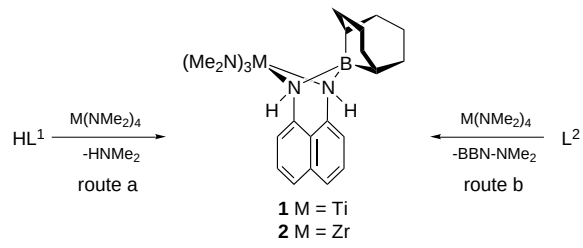
$^1$H, $^{13}$C and $^{11}$B NMR indicate that $HL^1$ is *pseudo*-$C_{2v}$-symmetrical on the NMR timescale, with the boron atom bridging between the two nitrogen atoms.‡ The three N–H protons appear as a sharp singlet in the $^1$H NMR spectrum even at −50 °C. These data are consistent with a fast dynamic process in which the bridging 9-BBN unit is rocking between the two faces of the naphthalene ring, while the three N–H protons rapidly equilibrate between the two nitrogen atoms.

On the other hand, the two boron atoms in $L^2$ are three-coordinate according to $^{11}$B NMR spectroscopy, *i.e.* they are not bridging between the two nitrogen atoms. Three peaks for six aromatic protons indicate a symmetrical naphthalene system. Two peaks for four bridgehead carbons of the two 9-BBN units indicate a high barrier to rotation of the 9-BBN groups around the B–N bonds attributed to $p_\pi$–$p_\pi$ interactions.§



Interestingly, related aromatic diamines do not exhibit the same high selectivity in formation of an amine–aminoborane. Thus, reaction between 1,2-phenylenediamine and 2 equiv. of 9-BBN gave a bis(aminoborane), $L^3$, quantitatively, whose spectral properties are analogous to those of $L^2$ (Scheme 2).¶ However, reaction between 1,2-phenylenediamine and 1 equiv. of 9-BBN gave an inseparable mixture of products.

$HL^1$ reacted cleanly with tetrakis(dimethylamino)titanium in an amine elimination reaction giving $[TiL^1(NMe_2)_3]$ **1** and dimethylamine. **1** was isolated in high yield as an orange crystalline solid upon evaporation of the solvent and recrystallisation from diethyl ether–pentane at −35 °C. Tetrakis-(dimethylamino)zirconium reacted similarly yielding $[ZrL^1(NMe_2)_3]$ **2** as a white crystalline solid after a similar work-up (Scheme 3, route a). **1** and **2** exhibit almost identical NMR spectra that indicate that, in solution, $L^1$ is a (4e,1−) symmetrical chelating diaminoborate-type ligand.‖



The X-ray crystal structure of the titanium complex **1** showed that the chelating diaminoborate ligand effectively blocks one face of the metal (Fig. 1).** The main structural feature is an almost perfectly symmetrical Ti–N–B–N four-membered ring, having B–N and Ti–N bond lengths of 1.60 and 2.29 Å, respectively, and N–B–N and N–Ti–N bond angles of 94.4 and 61.4°, respectively.

**Scheme 1**

**Scheme 2**

**Scheme 3**

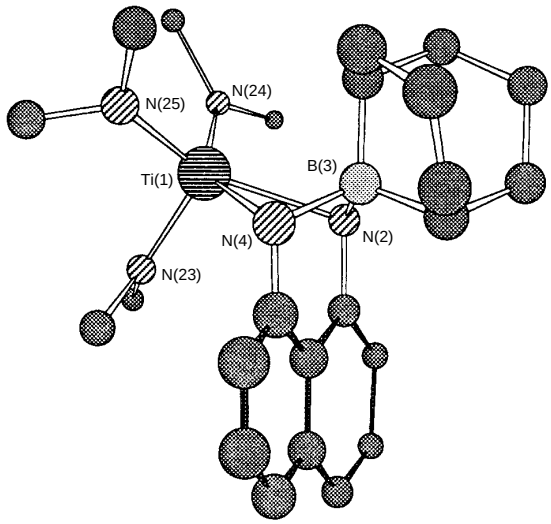


**Fig. 1** Molecular structure of [TiL$^1$(NMe$_2$)$_3$] **1**. Hydrogen atoms omitted for clarity. Selected distances (Å) and angles (°): Ti(1)–N(2) 2.302(3), Ti(1)–N(4) 2.282(4), Ti(1)–N(23) 1.874(3), Ti(1)–N(24) 1.927(5), Ti(1)–N(25) 1.912(3), B(3)–N(2) 1.586(7), B(3)–N(4) 1.604(5); N(2)–Ti(1)–N(4) 61.4(1), N(2)–B(3)–N(4) 94.4(4), Ti(1)–N(2)–B(3) 88.0(2), Ti(1)–N(4)–B(3) 88.3(3).

Several reports describing systems that include M–N–B–N four-membered rings have appeared (M = Ge, Sn, Ti, Zr, Cr).[7] However, in those cases the N–B–N unit either forms a (4e,2−) ligand, or it is a part of a larger heterocyclic system. The system we describe herein is the first case of a (4e,1−) diaminoborate ligand system, to the best of our knowledge. Unlike other (4e,1−) ligands, such as benzamidinate or acetylacetonate, the diaminoborate ligand consists of tetrahedral atoms rather than trigonal-planar atoms close to the metal centre. Since tetrahedral atoms are inherently more sterically demanding than trigonal-planar atoms, close control of the metal environment can be achieved by proper substitutions in this ligand system.

The *N,N′*-bis(trimethylsilyl) derivative of 1,8-diaminonaphthalene acts as a (4e,2−) ligand.[8] Considering the B–Si diagonal relationship one may expect that L$^2$ would act as a chelating (4e,2−) bis(borylamide) ligand[4] by double deprotonation. However, this was not the case. Instead, L$^2$ reacted cleanly with tetrakis(dimethylamino)-titanium and -zirconium to yield the diaminoborate complexes **1** and **2**, respectively, accompanied by 9-BBN–NMe$_2$ as a by-product[9] (Scheme 3, route b). The driving force for this unprecedented transformation is, apparently, the stability of the boron-bridged structure, in the 1,8-diaminonaphthalene skeleton.

Proximity effects have a strong effect on chemical reactivity in 1,8-disubstituted naphthalenes.[10] We think that the selective formation of HL$^1$ and of the (4e,1−) metal complexes of L$^1$ (**1** and **2**) are a result of such effects. We are currently investigating these effects as well as the reactivity of the novel diaminoborate complexes.

‡ HL$^1$ was prepared on a 20 mmol scale by adding 1 equiv. of 9-BBN in hexanes to a solution of 1,8-diaminonaphthalene in ether under nitrogen, and stirring at room temp. until hydrogen evolution ceased (*ca*. 30 min). The light yellow solid that precipitated was washed with ether and dried to give pure HL$^1$ in *ca*. 95% yield: $^1$H NMR ($C_6D_6$, 200 MHz) δ 0.58 (br s, 2 H, CH), 1.60–2.20 (m, 12 H, 6 $CH_2$), 4.06 (s, 3 H, NH), 6.12 (d, 2 H, *J* 8 Hz), 7.08 (t, 2 H, *J* 8 Hz), 7.24 (d, 2 H, *J* 8 Hz). $^{13}$C{$^1$H} NMR ([$^2H_8$]thf, 50.4 MHz) δ 24.4 (CH), 27.3 ($CH_2$), 33.2 ($CH_2$), 113.4 (CH), 120.6 (CH), 128.3 (CH). $^{11}$B NMR ($C_6D_6$, 115.5 MHz) δ −1.7.

§ L$^2$ was prepared on a 10 mmol scale, by adding 2 equiv. of 9-BBN in hexanes to a solution of 1,8-diaminonaphthalene in ether under nitrogen, and stirring at room temp. until hydrogen evolution ceased (*ca*. 30 min). Removing the solvents under vacuum yielded white crystalline L$^2$ quantitatively: $^1$H NMR ($C_6D_6$, 200 MHz) δ 1.29–1.95 (m, 14 H), 6.92 (s, 2 H, NH), 7.04 (d, 2 H, *J* 8 Hz), 7.15 (t, 2 H, *J* 8 Hz), 7.44 (d, 2 H, *J* 8 Hz). $^{13}$C{$^1$H} NMR ($C_6D_6$ 50.4 MHz) δ 22.9 (CH), 28.1 (CH), 24.4 ($CH_2$), 33.8 ($CH_2$), 34.4 ($CH_2$), 126.2 (CH), 123.6 (CH), 126.3 (CH). $^{11}$B NMR ($C_6D_6$, 115.5 MHz) δ 49.9.

¶ L$^3$: $^1$H NMR ($C_6D_6$, 200 MHz) δ 1.30–2.04 (m, 14 H), 5.67 (s, 2 H, NH), 7.02 (m, 2 H), 7.23 (m, 2 H); $^{13}$C{$^1$H} NMR ($C_6D_6$, 50.4 MHz) δ 23.2, 28.0 (CH), 24.5, 34.0, 34.8 ($CH_2$), 125.3, 125.9 (CH); $^{11}$B NMR ($C_6D_6$, 115.5 MHz) δ 51.6.

‖ [TiL$^1$(NMe$_2$)$_3$] **1**: $^1$H NMR ($C_6D_6$, 200 MHz) δ 0.63 (br s, 1 H, CH), 0.67 (br s, 1 H, CH), 1.75–2.20 (m, 12 H, 6 $CH_2$), 2.84 (s, 18 H), 4.11 (s, 2 H, NH), 6.39 (d, 2 H, *J* 7 Hz), 7.13 (t, 2 H, *J* 7 Hz), 7.20 (d, 2 H, *J* 7 Hz). $^{11}$B NMR ($C_6D_6$, 115.5 MHz) δ −2.8. [ZrL$^1$(NMe$_2$)$_3$] **2**: $^1$H NMR ($C_6D_6$, 200 MHz) δ 0.69 (br s, 2 H, CH), 1.68–2.11 (m, 12 H, 6 $CH_2$), 2.69 (s, 18 H) 3.99 (s, 2 H, NH), 6.37 (d, 2 H, *J* 7 Hz), 7.08 (t, 2 H, *J* 7 Hz), 7.22 (d, 2 H, *J* 7 Hz). $^{11}$B NMR ($C_6D_6$, 115.5 MHz) δ −4.4.

** *Crystal data* for $C_{24}H_{40}BN_5Ti$, *M* = 457.32, monoclinic, space group $P2_1/a$, *a* = 15.649(4), *b* = 18.949(2), *c* = 18.404(3) Å, β = 111.72(2)°, *U* = 5070(2) Å$^3$, *Z* = 8, $D_c$ = 1.198 g cm$^{-3}$, λ(Mo-Kα) 0.71073 Å, $2\theta_{max}$ = 45.96°. Data were collected on an Enraf-Nonius CAD4 diffractometer using an orange crystal mounted in a sealed glass capillary at room temperature. Of a total of 6245 collected reflections, 6027 were unique ($R_{int}$ = 0.0387). The structure was solved by direct methods. The final cycle of full-matrix least-squares refinement was based on 6027 observed reflections ($I > 0$) and 571 variable parameters and converged with unweighted and weighted agreement factors of $R$ = 0.0995, $R_w$ = 0.1391 for the entire data. GOF = 1.010. Residual electron densities: +0.20, −0.29 e Å$^{-3}$.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/314.

# Structure determination from sparse data: geometries of the monohalogenophosphines

**Bruce A Smart and David W. H. Rankin***

*Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

**Use of restraints calculated *ab initio* allows the refinement of the structures of the halogenophosphines, $PH_2X$ (X = F, Cl, Br, I), from published rotation constants.**

It is well known that combining experimental information obtained from methods such as gas-phase electron diffraction, rotational spectroscopy and liquid-crystal NMR spectroscopy in least-squares refinements yields more accurate structures than can be obtained using any one method alone.[1] The development of very fast and inexpensive computers has also made it practicable to utilise information calculated *ab initio* to improve the quality of molecular structures. Until recently, where experimental information was insufficient to determine the values of some parameters, normal practice was to fix them at values calculated *ab initio*.[2] This procedure is less than ideal, first because a fixed parameter is tacitly assumed to be absolutely correct and so its effect on other refining parameters cannot be gauged and, secondly, because unrealistically low standard deviations for correlated parameters can result.

We have recently described a method for assigning uncertainties to *ab initio* data, allowing theoretical information to be entered into structure refinements as predicate observations or flexible restraints (the SARACEN method).[3] A sensible choice of uncertainties can be obtained either by performing a graded series of calculations in which the basis set and level of correlation is systematically varied, or by consideration of the known accuracy of calculations at the highest level. The original aim of the SARACEN method was to enhance electron diffraction studies, giving complete molecular structures which were previously inaccessible. The method can also be used with rotation constants, providing a quick and relatively inexpensive way of extracting structural information from small sets of data. It is thus related to the 'diagnostic least-squares' method,[4] with the very important distinction that the restraints are now based on high-level calculations, instead of being more or less inspired guesses.

Recent reports of the rotation constants of the unstable monohalogenophosphines, $PH_2F$,[4,5] $PH_2Cl$,[5,6] $PH_2Br$[6,7] and $PH_2I$,[6,8] have provided an ideal opportunity to demonstrate the utility of this technique, leading to structures of these important molecules.

A graded series of *ab initio* molecular orbital calculations was undertaken to provide values and uncertainties used in structural refinements and to obtain vibrational corrections for conversion from the $B_0$ to $B_z$ structural type.† Calculated molecular geometries for the monohalogenophosphines are reported in Table 1.

Most parameters were insensitive to the adopted theoretical method, a notable exception being the phosphorus–halogen distances, which require the use of large polarisation sets. For

[a] Distances in pm, angles in degrees. [b] Experimental geometry from ref. 20. [c] Molecular geometry not calculated at this level.

example, when the basis set is improved from 6-311G** to 6-311G(2df,2p) at the MP2 level of theory the P–F bond in $PH_2F$ is shortened by more than 2 pm. An analogous effect is found for the heavier $PH_2X$ compounds and has previously been observed for $PF_3$.[19] In all four compounds predictions of the P–H bond lengths proved to be far less sensitive to changes in the adopted theoretical method, with improvements beyond 6-31G**/MP2 having little effect on the value of this parameter. The H–P–X and H–P–H angles were found to be sensitive only to the inclusion of diffuse functions and a large polarisation set, although these effects are small and act in opposing directions.

Values chosen for use in SARACEN refinements were those calculated at the QZ3P(f,d)/MP2 level, corrected to allow for small differences between $r_e$ and $r_z$ structural types. Conservative estimates of uncertainties of geometric parameters were made in accordance with the level of convergence achieved with respect to improvements in the theoretical treatment. Uncertainties of 2.0 and 1.0 pm were used for P–X and P–H bonds while the two angle parameters were assigned uncertainties of 1.0°. Corrections of 1.5(2) and 0.5(2) pm for $r_z$ minus $r_e$ were adopted for the P–H and P–X bond lengths while angle corrections were 0.0(2)°, based on comparisons of the two structural types previously reported for $PH_3$ and $PF_3$.[20,21]

All rotation constants were converted from $B_0$ to $B_z$ structural type using vibrational corrections obtained from scaled 6-31G**/MP2 force fields, before inclusion in least-squares refinements. Uncertainties of 10% were attached to all corrections. In all cases values of rotation constants for the refined structures fell within about one standard deviation of the corrected values.

Flexible restraints derived from *ab initio* calculations were used for all four parameters in refinements for each molecule. In each case molecular parameters ($r_e$) refined to values which fell within one standard deviation of the flexible restraint (see Table 1). The refined e.s.d.s for the P–X and P–H bond lengths were found to be much smaller than the uncertainties used for the predicate observations, suggesting that most of the information about these refined parameters is derived from experimental information. The e.s.d.s of angles were much closer to the uncertainties of the restraints, indicating that less information about these parameters is provided by the rotation constants. In particular, the standard deviation of the X–P–H angle is as high as 0.7° in the case of $PH_2Cl$, indicating that this parameter is poorly defined by experimental information.

The structure of the $–PH_2$ unit in the monohalogenophosphines was found to be surprisingly independent of the attached halogen. The P–H bond lengths in the four compounds fell across a range of just a few tenths of a pm, while the H–P–H bond angles were indistinguishable. Increasing the size of the halogen results in slight narrowing of the X–P–H angle. Our final structures for $PH_2X$ molecules (where X = F, Cl, Br) are in good agreement with recent results based on more extensive experimental data (see Table 1).[22,23] This method therefore provides acceptable structural parameters, making optimum use of a restricted data set to yield a full structure.

We thank the EPSRC for the provision of the Edinburgh *ab initio* facilities (grant GR/K/04194). We are grateful to Dr J. Demaison for very helpful discussions, and for his willingness to provide us with results prior to publication.

## Footnote

† All calculations were carried out on a DEC Alpha APX 1000 workstation using the Gaussian 94 program.[9] Geometry optimisations and vibrational frequencies were calculated from analytic first and second derivatives respectively, with bond lengths and angles converging to at least 0.01 pm or 0.01°. Geometries for all molecules were calculated using the standard 6-31G**[10–12] and 6-311G**[13–14] basis sets at the SCF and MP2 levels of theory. The iodine basis sets used in 6-31G** and 6-311G** calculations are due to Dunning and Sadlej, respectively.[15,16] To explore the effects of diffuse functions and a larger polarisation set on the molecular geometry additional calculations were carried out at the 6-311+G**/MP2 and 6-311G(2df,2pd)/MP2 levels. For the fluorine, chlorine and bromine compounds the effects of more complete correlation treatments were investigated at the MP3, MP4SDQ and QCISD levels. Final geometry optimisations for all $PH_2X$ molecules were performed at the MP2 level of theory using a QZ3P(f,d) basis set due to Huzinaga,[17,18] comprising 7s3p1d/4s3p1d (H), 15s10p3d1f/10s5p3d1f (F), 18s13p3d1f/13s8p3d1f (P, Cl), 20s14p11d1f/14s10p7d1f (Br) and 24s19p16d1f/18s14p12d1f (I) basis sets. Vibrational frequency calculations were performed at the 6-31G**/MP2 level to obtain harmonic force fields, which were scaled by 0.95 and 0.90 for bond stretches and angle bends respectively before being used to obtain predictions of vibrational corrections for rotational constants.

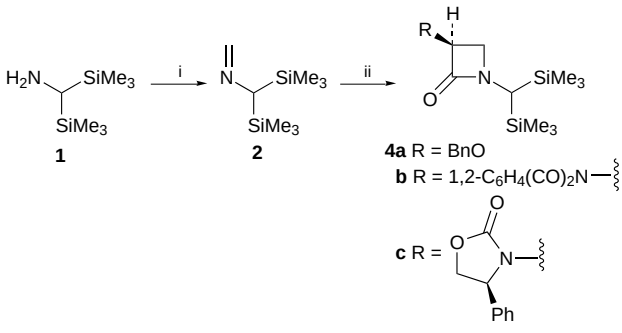
# *N*-Methylidene[bis(trimethylsilyl)methyl]amine: the first isolable and stable monomeric methanimine allowing thermal [2 + 2] cycloadditions with ketenes

**Claudio Palomo,* Jesus M. Aizpurua, Marta Legido and Regina Galarza**



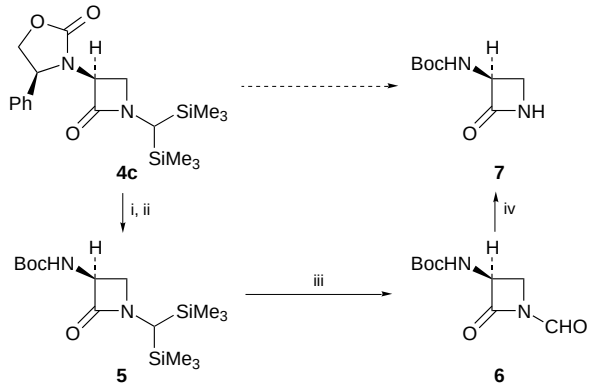
*Departamento de Química Orgánica, Facultad de Química, Universidad del Pais Vasco, Aptdo 1072, 20080 San Sebastián, Spain*

***N*-Methylidene[bis(trimethylsilyl)methyl]amine acts as a stable methanimine synthon [$CH_2$=NH] equivalent in [2 + 2] cycloadditions to ketenes, generated from acid chlorides and triethylamine, to provide 4-unsubstituted β-lactams in a single step.**

Although the chemistry of the C=N double bond has been extensively exploited over the years, reactions with formaldehyde imines have been virtually ignored.[1] Two main reasons have contributed to this fact: on the one hand the inaccessibility of monomeric methanimine in the condensed state[2] and, on the other hand, their great instability caused by spontaneous tri- or oligo-merization.[3] A very limited number of investigations have been conducted to address this problem. For example, Barluenga's group[4] has demonstrated that both *N*-methylenearyl- and *N*-methylenealkyl-amines are stable at −60 °C and can be generated *in situ* by the reaction of organometallic reagents with *N*-(alkoxymethyl)arylamines and *N*-alkyl-*N*-(alkylthiomethyl)ammonium chlorides, respectively. Independently to this group, Overman *et al.*[5] has also revealed that formaldehyde imines can be produced in solution, generally at −70 °C, from the reaction of *N*-(cyanomethyl)amines with strong bases. Although these authors also noticed the low temperature trapping of such methyleneamine species with carbon nucleophiles, no report on the reactivity of a methanimine species withstanding higher temperature reaction conditions has been published to date.

Here we report the chemical behaviour of some ketenes of interest in the context of β-lactam antibiotic chemistry,[6] (Scheme 1) towards the first isolable and stable methanimine,[7] easily prepared by the simple mixing of 33% formaldehyde aqueous solution and the readily available *C,C*-bis(trimethylsilyl)methylamine **1**.[8,†] To establish the correct reaction conditions for the expected [2 + 2] cycloaddition reaction, Table 1, we investigated the behaviour of imine **2** towards benzyloxyketene generated *in situ* from the carboxylic acid chloride **3a** and triethylamine. As entries 1 and 2 show, only poor yields of the expected β-lactam were obtained when the reactions were performed either at low temperature or under reflux of $CH_2Cl_2$ but, interestingly, the chromatographic analysis (GC–MS) of the reaction mixtures after 16 h revealed the presence of important quantities of unreacted imine **2** (typically 30–35%) surviving these reaction conditions. After several runs increasing the temperature by changing the solvent and using two- and four-fold excesses of the acid chloride **3a** (entries 3 and 4) a reasonable 62% yield of the isolated β-lactam **4a** was obtained after column chromatography. In view of this result, we next examined the suitability of this approach to the construction of the 3-amino 4-unsubstituted azetidin-2-one ring owing to its importance as a key structural element for the development of β-lactam antibiotics.[6] Actually, comparatively good yields of **4b** (65%, mp 207–209 °C) and **4c** {75%, mp 150–151 °C, $[\alpha]_D^{25}$ +89.6 (*c* 1.0, $Cl_2CH_2$)} could be reached, without the need for an excess acid chloride, by simply performing the reaction in refluxing benzene or chloroform as solvents (entries 5 and 6). This result contrasts with the fact that the cycloaddition between the Evans–Sjögren acid chloride **3c** and methanimine trimers, derived from benzylamine and trimethylsilylmethylamine, under the reported conditions[9] only affords traces of the expected β-lactams ( < 15%) together with major amounts of 3-[(4*S*)-2-oxo-4-phenyloxazolidin-3-yl]-acetic acid. In addition, the total asymmetric induction observed during the single step convergent formation of the β-lactam **4c**‡ was unaffected by the reaction temperature (entries 6 and 7), and it was particularly noteworthy when compared with the limited diastereomeric excesses achieved in comparable approaches reported to date.[10]

On the other hand, because the easy cleavage of the bis(trimethylsilyl)methyl moiety was fundamental in β-lactams **4** finding synthetic applications, we tried several deprotection methods using compound **5** {mp 124–126 °C, $[\alpha]_D^{25}$ +13.6 (*c* 1.0, $Cl_2CH_2$)} as a model, Scheme 2. This compound was easily obtained in 70% yield through the oxazolidinone moiety cleavage[11] and further *N*-Boc protection of the resulting free amino derivative. After screening our previously reported method[12] we found that exposure of **5** to the action of



**Scheme 1** *Reagents and conditions*: i, 30% HCHO (1.2 equiv.), $H_2O$, room temp., 20 h, 75%; ii, $RCH_2COCl$ **3a**–**c**, $NEt_3$, for conditions, see Table 1

**Table 1** Cycloaddition reaction of methanimine **2** with alkoxy- and amidoketenes derived from acyl chlorides **3**

| Entry | Product **4** | Conditions[a] Solvent; *T*/°C; *t*/h | Yield (%)[b] |
|---|---|---|---|
| 1 | **a** | $CH_2Cl_2$; −78 → 20; 16 | 28 |
| 2 | **a** | $CH_2Cl_2$; 0 → 40; 16 | 30 |
| 3 | **a** | $CHCl_3$; 0 → 80[c]; 2 | 39 |

| 5 | **b** | $C_6H_6$; 0 → 80; 16 | 65 |
| 6 | **c** | $C_6H_6$; 0 → 80; 16 | 75[e] |
| 7 | **c** | $CH_2Cl_2$; −78 → 20; 16 | 33[e] |

[a] Unless otherwise stated, the acid chloride (1.2 equiv.) was added to the imine **2** (1 equiv.) and triethylamine (2.4 equiv.) at the first temperature, and the reaction mixture was then stirred at the second temperature for the indicated time. [b] Yields of pure isolated products after column chromatography (silica gel, hexanes). [c] A twofold excess of the acid chloride and triethylamine was used. [d] The acid chloride (4.0 equiv.) was dropwise added to the imine **2** (1 equiv.) and triethylamine (8.0 equiv.) at reflux temperature. [e] Product obtained as single stereoisomer.

**Scheme 2** *Reagents and conditions*: i, Li (6 equiv.), THF, Bu$^t$OH, $NH_3$ (10 : 1 : 33), −78 °C, 10 min, then 1 M HCl, 5 min, 70%; ii, $(Boc)_2O$, room temp., 3 h; iii $(NH_4)_2Ce(NO_3)_6$, MeCN, $H_2O$, room temp., 3 h, 84%; iv, $NaHCO_3$, $Na_2CO_3$, $Me_2CO$, $H_2O$, room temp., 2 h, 78%

cerium(IV) ammonium nitrate in acetonitrile–water furnished the intermediate formyl derivative **6** [mp 134–136 °C, $[\alpha]_D^{25}$ −17.7 (*c* 1.0, $Cl_2CH_2$)] in a clean and high-yielding (90%) reaction. Further exposure of **6** to *N*-deformylation under usual conditions[12,13] afforded **7** [mp 172–174 °C, $[\alpha]_D$ −18.4 (*c* 1.0, MeOH), lit.,[14] mp 171–172 °C], which was identical in all respects to that previously described. Therefore, the bis-(trimethylsilyl)methyl group must be considered as a new protecting group for β-lactam synthesis.[15]

This work was supported by Basque Government (Project PI 95/93) and, in part, by Basque Country University (EHU/UPV : 170.215-EB147/94). A grant from Ministerio de Educacion y Ciencia (Spanish Government) to M. L. is gratefully acknowledged.

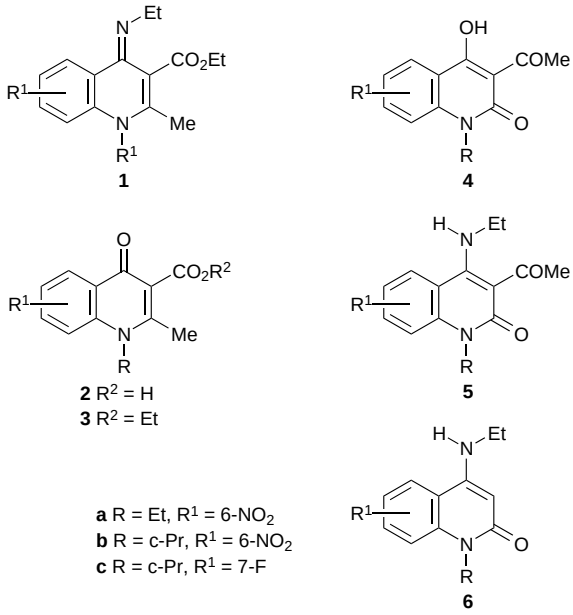
# Novel production of quinol-2(1*H*)-one derivatives from quinol-4(1*H*)-one derivatives

**Theodorus van Es[a] and Benjamin Staskun*[b]**

[a] *Department of Biochemistry and Microbiology, Cook College, Rutgers, The State University of New Jersey, 08903-0231, USA*
[b] *Department of Chemistry, University of the Witwatersrand, Johannesburg, South Africa*



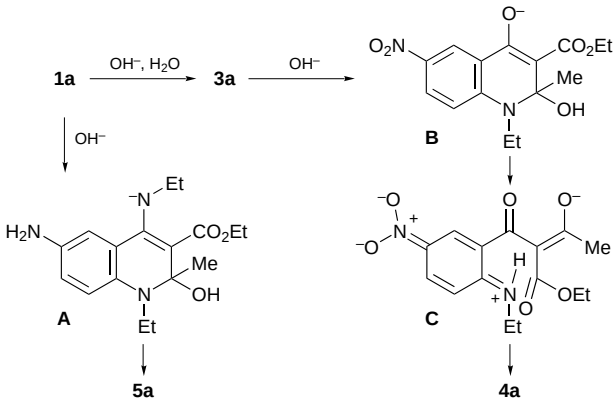
**Certain 1-alkyl-4-ethylimino-1,4-dihydro-2-methylquinoline-3-carboxylates transform in alkaline solution to give a variety of 1-alkylquinol-2(1*H*)-one derivatives by competitive C-2 attack by hydroxide followed by rearrangement.**

The venerable and extensive field of quinoline chemistry contains numerous and diverse molecular transformations.[1] Here we report the first examples, as far as we are aware, of a quinol-4(1*H*)-one derivative transforming to a quinol-2(1*H*)-one derivative. Alkaline hydrolysis of the recently available ethyl 1-ethyl- or 1-cyclopropyl-4-ethylimino-1,4-dihydro-2-methylquinoline-3-carboxylate **1** in most cases afforded the expected corresponding 4-oxoquinoline-3-carboxylic acid **2** *via* the intermediate ester **3**. However, the saponification of 1-ethyl-6-nitro substituted imine **1a**†‡ was accompanied by a rearrangement which yielded unexpected quinol-2(1*H*)-ones as major products. Thus with very dilute alkali the alkali-soluble 3-acetyl-1-ethyl-4-hydroxy-6-nitroquinol-2(1*H*)-one **4a**‡ (isomeric with the anticipated acid **2a**) and alkali-insoluble 3-acetyl-1-ethyl-4-ethylamino-6-nitroquinol-2(1*H*)-one **5a**‡ were obtained, while with a greater amount of NaOH **4a** and alkali-insoluble 1-ethyl-4-ethylamino-6-nitroquinol-2(1*H*)-one **6a**‡ were obtained (Table 1). The 1-cyclopropyl-6-nitro imine **1b** similarly gave the corresponding compounds **4b**, **5b** and **6b**, respectively. The relative proportions of the aforementioned products varied with the NaOH concentration and the reaction conditions (Table 1). An indication that the rearrangement is not restricted to imine **1** bearing a 6-$NO_2$ group was shown with the 1-cyclopropyl-7-fluoro substituted **1c** which in aqueous $(Me)_4NOH$–dioxane mixture (to minimise nucleophilic displacement of the fluorine) formed 3-acetyl-1-cyclopropyl-7-fluoro-4-hydroxyquinol-2(1*H*)-one **4c** and the expected quinoline-3-carboxylic acid **2c**.

Of mechanistic significance were the findings that on alkaline hydrolysis (i) even ethyl 1-ethyl-1,4-dihydro-2-methyl-6-nitro-4-oxoquinoline-3-carboxylate **3a** furnished 3-acetyl-4-hydroxyquinol-2(1*H*)-one **4a** (together with the expected 4-oxoquinoline-3-carboxylic acid **2a**) and (ii) 4-ethylaminoquinol-2(1*H*)-one **5a** converted to **4a**, the latter of which was not obtained from acid **2a**.

A tentative rationale based on the available evidence which accounts for the conversion **1** → **4**, **5** and **6** is outlined in Scheme 1 (with imine **1a**): Competitive attachment of $OH^-$ at C-2 of **1a** and at C-2 of 4-oxo ester **3a** (generated from **1a** by conventional hydrolysis of the imine function) gives rise to alcohol intermediates **A** and **B**, respectively. Ring-opening of **B** to a species such as **C** (depicted as a resonance contribution) followed on by an intramolecular *N*-acylation of the ester function in **C** results in **4a**. Similar events stemming from intermediate **A** result in enamine **5a**. The latter substance may subsequently undergo competitive hydrolysis of the 3-acetyl group to yield **6a**, and of the 4-ethylamino function to give **4a**.

It would appear from these preliminary results and the mechanistic analysis that electron-withdrawing group substituted substrates would be especially prone to this rearrange-



**a** R = Et, $R^1$ = 6-$NO_2$
**b** R = c-Pr, $R^1$ = 6-$NO_2$
**c** R = c-Pr, $R^1$ = 7-F

**Table 1** Production of quinol-2(1*H*)-one derivatives from quinol-4(1*H*)-one derivatives

| Substrate | R | $R^1$ | Amount/ mmol‡ | Method§ | Product(s)[a] (% yield)[b] |
|---|---|---|---|---|---|
| **1a** | Et | 6-$NO_2$ | 1 | A | **4a**(10), **5a**(63) |
| | | | 1 | B | **4a**(66), **5a**(15) |
| | | | 10 | C | **4a**(54), **6a**(35) |
| **1b** | cyclo-$C_3H_5$ | 6-$NO_2$ | 1 | A | **5b** (*ca.* 10)[c] |
| | | | 10 | C | **4b**(61), **6b**(35) |
| **1c** | cyclo-$C_3H_5$ | 7-F | 7.2 | D | **4c**( > 6%), **2c**(38%) |
| **3a** | Et | 6-$NO_2$ | 0.28 | E | **4a** (*ca.* 18%), **2a** (*ca.* 54%) |

[a] The products after purification [silica gel, benzene–acetone (4 : 1), followed by crystallisation] were fully characterised from their $^1$H NMR ($CDCl_3$) spectra (supplemented on occasion by NOE experiments) and accurate mass measurements (HRMS). [b] Crude. [c] Separated from alkali-insoluble co-product **6b** (silica gel, benzene–acetone, 4 : 1).

**Scheme 1**

ment, and that the reaction could be extrapolated to include the 2-demethylated analogues of **1** and **3**. Work is currently underway to optimise yields, identify other $R^1$ substituents in **1** and **3** which favour the rearrangement and to evaluate the synthetic utility of the finding.

In summary, we describe a novel 4-ethyliminoquinoline ⟶ quinol-2(1*H*)-one conversion reaction which leads to products of potential pharmacological interest,[2] and draw attention to the possibility, hitherto unforeseen, of rearrangements having occurred in certain cases during the numerous literature saponifications of 4-oxoquinoline-3-carboxylic esters.

We are grateful to Dr L. Carlton for conducting the NOE experiments and for helpful discussion, and to Mrs S. Heiss for the acquisition of NMR spectra. B. S. thanks the University of the Witwatersrand for financial support.

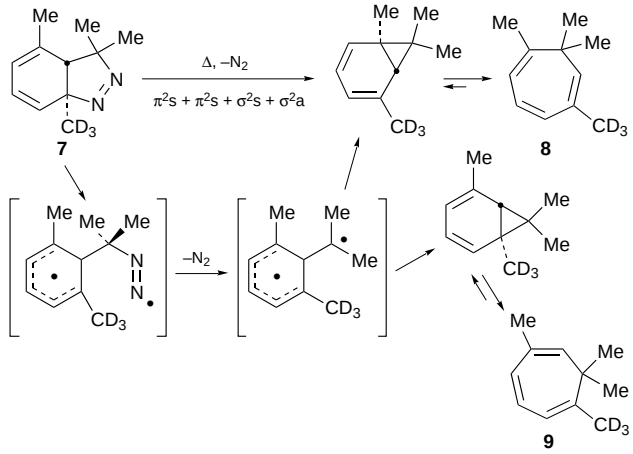
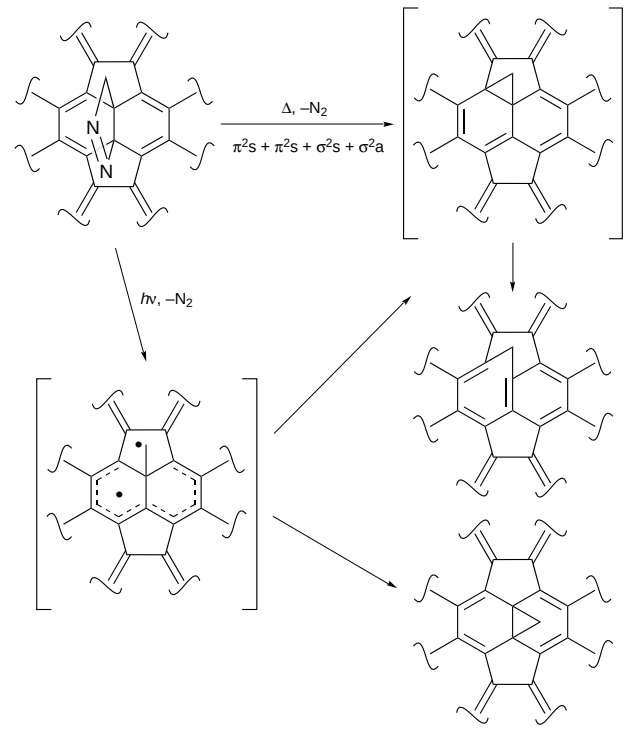
**Repeated treatment of the $C_{2v}$-symmetrical $C_{60}$ pentakis-adducts 1a,b with diazomethane provided with high regioselectively the novel heptakis- 5 and octakis-adducts 4a,b *via* hexakis-adducts 3a,b; an orbital symmetry-controlled reaction mechanism for the thermal dinitrogen extrusion from the pyrazoline intermediates in the addition of diazomethane to fullerenes is proposed.**

The 1,3-dipolar cycloaddition of diazomethane to $C_{60}$ or $C_{70}$ occurs at 6-6-bonds (bonds at the junction between two 6-membered rings) under formation of isolable pyrazoline derivatives.[1,2] Photolysis of these intermediates under $N_2$-extrusion provides an isomeric mixture of methanofullerenes, namely 6-6-closed ones, in which the 6-6-bond is bridged in a cyclopropane-type fashion, and 6-5-open ones, in which the methano group bridges the open junction between a 6- and 5-membered ring,[2] similar to the bonding in 1,6-methano-[10]annulene.[3] In contrast, thermolysis of the pyrazolines proceeds with high regioselectivity and yields 6-5-open adducts almost exclusively.[1,2a,c] As part of our research on higher adducts of $C_{60}$,[4] we became interested in exploring whether diazomethane would still add to highly functionalised carbon spheres of considerably reduced electrophilicity[4c] and dienophile character and whether the product distribution obtained by $N_2$-extrusion from the intermediate pyrazolines would be similar to that observed for the parent fullerenes. The $C_{2v}$-symmetrical pentakis-adducts **1a** and **1b**[4b] (Scheme 1) were chosen as starting materials in these investigations since their reactivity is limited to a single 6-6-bond in pseudo-octahedral position.[5] Addition to this bond is particularly favourable since it generates a residual fullerene π-chromophore consisting of eight stable benzenoid ring sub-structures.[6] Here, we report the stepwise addition of diazomethane to **1a**,**b** under formation of novel hexakis- to octakis-adducts of $C_{60}$ and propose a mechanism for the $N_2$-extrusion from the intermediate pyrazolines to give methanofullerenes.



Reaction of **1a**,**b** with $CH_2N_2$ (*ca*. 60-fold excess) in $CHCl_3$ at 0 °C afforded the corresponding yellow, $C_s$-symmetrical pyrazolines **2a**,**b** in high yields (Scheme 1).† Upon heating to reflux in $CCl_4$, $N_2$-extrusion led to the orange-coloured, $C_1$-symmetrical 6-5-open methanofullerenes **3a**,**b** in nearly quantitative yield. Treatment of **3a**,**b** with $CH_2N_2$ (*ca*. 40-fold excess) in $CHCl_3$ at 0 °C gave within 15 min the yellow–orange, $C_1$-symmetrical octakis-adducts **4a**,**b** in an astonishing 90% yield. A further reaction of **4a**,**b** with additional diazomethane was not observed. When **3b** was reacted with $CH_2N_2$ (*ca*. 20-fold excess) for 10 min in $CH_2Cl_2$ at −80 to −60 °C, followed by quenching of the excess reagent with AcOH at −60 °C and workup at room temperature, heptakis-adduct **5** was directly obtained. Neither in the formation of **4a**,**b** nor in the preparation of **5** were pyrazoline intermediates observed. When pyrazoline **2a** was photolysed, the $C_{2v}$-symmetrical hexakis-adduct **6** and the $C_1$-symmetrical regioisomer **3a** were obtained in *ca*. 1 : 1 ratio and a combined yield of 15%. The isomeric mixture could not be separated by column chromatography. Therefore, **6** was purified by adding $CH_2N_2$ at 0 °C to the mixture in $CH_2Cl_2$ which transformed **3a** into octakis-adduct **4a** while leaving **6** unchanged. Chromatographic purification ($SiO_2$, $CH_2Cl_2$) was subsequently feasible, yielding **6** as a bright yellow solid. Thus, the reaction of diazomethane with pentakis-adducts **1a** ultimately yielded similar products to those observed in the addition to $C_{60}$: diazomethane added to the 6-6-bond and



**Scheme 1** *Reagents and conditions*: i, $CH_2N_2$ (*ca*. 60 equiv.), $CHCl_3$, 0 °C, 1.5 h; 71% (**2a**), 93% (**2b**); ii, $CCl_4$, reflux, 15 min; 93% (**3a**, **b**); iii, *h*ν (Hg medium pressure lamp, 250 W), $C_6D_6$, $c$ = 9.6 mmol dm$^{-3}$, $T$ = 5–10 °C, 8 min, 15% (**6** and **5a** in *ca*. 1 : 1 ratio); iv, excess $CH_2N_2$ (*ca.* 40 equiv.), $CHCl_3$, 0 °C, 15 min; 90% (**4a, b**); v, $CH_2N_2$ (*ca*. 20 equiv.), $CH_2Cl_2$, −80 to −60 °C, 10 min, then excess HOAc, −60 °C, and workup at 20 °C; 79% (**3**)

photolysis of **2a** gave a mixture of 6-6-closed **6** and 6-5-open **3a** methanofullerenes, whereas thermolysis exclusively provided the 6-5-open derivative **3a**. None of the isomeric 6-6-closed methanofullerene **6** was detected in the $^1$H NMR spectrum of the crude thermolysis product.

According to semiempirical PM3 calculations,[4a,7] the 6-6-closed methanofullerene **6** is 2.1 kcal mol$^{-1}$ (1 cal = 4.184 J) more stable than the 6-5-open isomer **3a**. The preferred formation of the thermodynamically less stable product suggested that thermolysis proceeded under kinetic control, and one of us (F. G. K.) recognised the close analogy of the $N_2$-elimination of diazomethane–fullerene adducts to 6-5-open methanofullerenes to the previously reported $N_2$-elimination from diazoalkane–toluene adducts (Scheme 2).[8] Starting from **7**, thermolysis provides in an orbital symmetry controlled [$\pi^2$s + $\pi^2$s + $\sigma^2$s + $\sigma^2$a] rearrangement with high regioselectivity

**Scheme 2** Proposed mechanism for the thermal and photochemical $N_2$-extrusion from diazoalkane adducts of toluene

**Scheme 3** Proposed mechanism for the thermal and photochemical $N_2$-extrusion from diazalkane adducts of fullerenes (shown only in part)

cycloheptatriene **8**, resulting from ring-opening of the intermediate norcaradiene. In contrast, photolysis of **7** presumably proceeds *via* a diradical mechanism, leading to a mixture of **8** and isomeric **9**. We propose a similar mechanism (Scheme 3) to explain the product distribution obtained during thermolysis and photolysis of diazomethane–fullerene adducts. Even the surprising formation of **5** and **4a**,**b** can be rationalized by this mechanism. A 1,3-dipolar cycloaddition of diazomethane to **3a**,**b** or **5** is followed by rapid, regioselective, concerted $N_2$-elimination and valence bond isomerisation. It might also be responsible for the analogous preference of azide adducts of $C_{60}$ to thermally form 6-5-open azafullerenes.[9]

Support from the Swiss National Science Foundation is gratefully acknowledged.

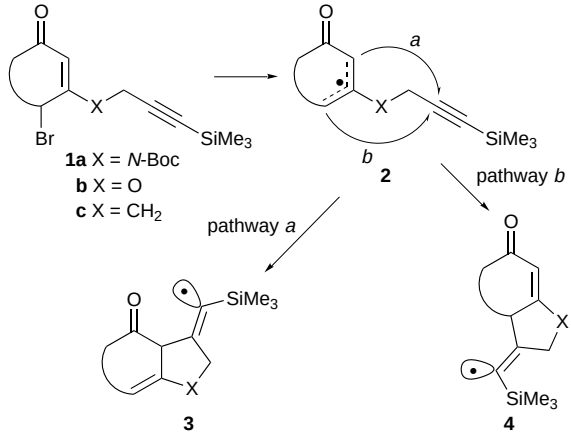
# Radical cyclization reactions of 4-bromo vinylogous-esters, vinylogous-amides and enones

**Chin-Kang Sha,* Wei-Hong Tseng, Kuan-Tsau Huang, Kuan-Miao Liu, Herng-Yih Lin and San-Yan Chu***

*Department of Chemistry, National Tsing Hua University, Hsinchu 300, Taiwan, R.O.C.*



**Radicals generated from 4-bromo vinylogous-esters, vinylogous-amides and enones cyclize to a tethered acetylene side-chain preferentially at the γ-position; theoretical calculations of the spin density of the radicals and the relative stability of the radical intermediates are performed to rationalize the experimental observations.**

Radical reactions have emerged as one of the most useful synthetic methodologies in the formation of carbon–carbon bonds.[1] Previously we have described intramolecular cyclization reactions of α-ketone[2] and α-enone[3] radicals. As an extension to our work in this area, we investigated the intramolecular cyclization reactions of allylic enone radicals **2**, Scheme 1. Both from theoretical and experimental points of view, it is of special interest to discover whether radicals **2**, generated from 4-bromo cycloalkenones **1**, would cyclize at the α- or γ-position due to delocalization of the radical. Here we report the preliminary results of this investigation.

Vinylogous-esters **5** and **8** and vinylogous-amides **11**, **14** and **17** were prepared by literature methods.[4] Thus, 3-trimethylsilylprop-2-yn-1-ol[5] was condensed with cyclohexane-1,3-dione and cyclopentane-1,3-dione to afford vinylogous-esters **5** and **8**. Condensation of 3-trimethylsilylpropynylamine[6] with the corresponding cycloalkane-1,3-diones, followed by reaction with di-*tert*-butyl dicarbonate and 4-dimethylaminopyridine gave *tert*-butoxycarbonyl (Boc) protected vinylogous-amides **11**, **14** and **17**. Enones **21** and **24** were synthesized by treatment of the corresponding 3-ethoxycycloalkenones with 4-trimethylsilylbut-3-ynylmagnesium bromide followed by treatment with dilute HCl.[7] Bromination of **5**, **8**, **11**, **14**, **17**, **21** and **24** with *N*-bromosuccinimide (NBS) and AIBN in refluxing $CCl_4$ afforded the corresponding 4-bromo compounds **6**, **9**, **12**, **15**, **18**, **22** and **25**. Radical cyclizations were then carried out using tin hydride,[2] the results of which are summarized in Table 1. 4-Bromo vinylogous-esters and vinylogous-amides cyclized in acceptable yields. 4-Bromo enone **22** underwent radical cyclization with some difficulty to give both the cyclized product **23** and the reduction product **21** in equal amounts. 4-Bromo enone **25** did not cyclize to **26** but gave only the reduction product **24**. In general, radicals generated from 4-bromo cyclohexenones **6**, **12** and **22** were found to cyclize in better yields than the radicals generated from 4-bromo cyclopentenones **9**, **15** and **25**. However, it is interesting to note that most of radical cyclizations occurred at the γ-carbon. Only in entry 5, the radical generated from compound **18** with a highly hindered γ-position cyclized both at the γ- and α-positions to give **19** and **20** (1 : 2.5). Exocyclic double bonds formed after cyclization were isomerised into conjugated systems under the reaction condition (entries 1, 2 and 4, Table 1). In entry 6, the enone double bond was deconjugated after cyclization to give **23**.

To understand this unusual regioselectivity of radical cyclization at the γ-carbon, we performed PM3 calculations[8] on model radical systems **27** and **28**. Spin densities at the α- and γ-positions, expressed as the square of atomic orbital coefficients in SOMO, are 0.34 and 0.49 for **27**, and 0.33 and 0.53 for **28**. For the reaction under kinetic control, these coefficients are in accordance with the experimental observations. It is noteworthy that HOMO electron densities at the α- and γ-positions of the corresponding anionic species **29** are 0.47 and 0.32, which are opposite to the radical species. It is well known that reactions of anion **29** usually occur at the α-position.[9] We also calculated the relative stability of intermediates **30** and **31** which were formed *via* the α- or γ-cyclization (pathway *a* or *b* in Scheme 1). We found that **31** is 4.5 kcal $mol^{-1}$ (1 cal = 4.184 J) more stable than **30**. This probably reflects that cyclization at the γ-position, maintaining the conjugate enone π system in the transition state, is the pathway having the lower activation energy.

We gratefully acknowledge a grant (NSC 85-2113-M-007-016) from the National Science Council of the Republic of China.

# The first observation of 'NMR-invisible phosphorus' in cobalt-substituted aluminophosphate molecular sieves

**L. Canesson and A. Tuel***

*Institut de Recherches sur la Catalyse, C.N.R.S. 2 av. A. Einstein, 69626 Villeurbanne Cedex, France*

**A spin-echo mapping technique is used to record the total $^{31}$P NMR signal of CoAPO molecular sieves for which a large proportion of phosphorus nuclei are not accessible by conventional NMR techniques.**

Framework substitution of divalent cations for aluminium in aluminophosphate molecular sieves ($MeAPO_4$) has been a matter of interest over the last years as it provides AlPO materials with interesting properties in catalytic reactions.[1,2] Therefore, it is of prime importance to have an extensive characterisation of these catalysts, and to determine the nature and location of the metal ions within the channels and cavities of the structure. Among all the spectroscopic techniques that can be used, solid-state NMR is very attractive as both $^{31}$P and $^{27}$Al nuclei possess a natural abundance of 100%. It is expected that substitution of divalent cations for aluminium modifies the chemical shift of neighbouring $^{31}$P nuclei, as observed in $^{29}$Si NMR spectra of zeolites with aluminium incorporation. Up to now, the method has been successfully applied for the study of the environment of phosphorus nuclei in magnesium-substituted aluminophosphates MAPOs.[3–5] However, as far as paramagnetic transition-metal cations like $Co^{2+}$ are concerned, conventional NMR sequences cannot be applied. NMR signals are broadened and numerous spinning side-bands are observed, due to various interactions between cobalt and phosphorus nuclei.[6] The presence of these side-bands as well as the decrease in both the $T_1$ and $T_2$ relaxation times of $^{31}$P nuclei has sometimes been considered as a proof for the framework cobalt siting.[7] However, such modifications are also observed in Co-impregnated aluminophosphates, which makes the discrimination between framework and non-framework cobalt almost impossible with this technique. Peeters *et al.*[8] have shown that, when cobalt is incorporated into the AlPO framework, phosphorus nuclei in the first and third coordination spheres around the metal cannot be detected by NMR and become 'NMR-invisible'.

We report here for the first time a method that allowed us to observed these so-called 'NMR-invisible phosphorus' nuclei and to record the total $^{31}$P NMR spectrum of CoAPO materials. The method is based on a spin-echo mapping technique that has been successfully applied for the characterisation of paramagnetic VPO catalysts.[9,10] Schematically, the method consists of recording a series of spectra using a Hahn echo sequence at different irradiation frequencies. For each spectrum, the intensity is corrected taking into account the relaxation of the magnetisation before acquisition of the signal. The total NMR signal is then obtained by addition of all individual spectra. Tong[11] has recently shown that, under specific conditions, the spectrum obtained by spin-echo mapping could reproduce the real line shape. Therefore, it was possible to make quantitative measurements by comparing the NMR intensities with those of pure AlPO-5. All experiments were carried out on a Bruker DSX 400 spectrometer operating at 161.9 MHz. The 90° pulse was 3 μs and the defocalisation time between the 90 and 180° pulses in the echo sequence was 20 μs. All CoAPO molecular sieves were synthesised following literature procedures.

Fig. 1 compares the $^{31}$P NMR spectra of CoAPO-50 obtained under various conditions. Almost no signal is observed under MAS conditions, due to the high Co content in the sample (11 mass% Co). With a Hahn echo, a broad signal is observed at δ *ca.* −20 (ref. $H_3PO_4$), the intensity of which corresponds to < 10% of the total amount of phosphorus in the material. This shows that > 90% of $^{31}$P nuclei are not detected under these conditions. Using the spin-echo mapping technique, a very broad signal is observed between δ *ca.* 0 and 10 000. The integrated intensity of the obtained spectrum corresponds to 98% of the phosphorus atoms present in the sample, which shows that the total signal has been recorded. In fact, most of the signal (*ca.* 85%) is shifted towards low fields, which is the reason why it could not be observed using conventional echo sequences. The invisibility of $^{31}$P nuclei is thus not due to very fast relaxation processes but to the fact that the signal cannot be observed when the irradiation frequency is centred on δ 0. As for VPO catalysts, the shift probably results from an electron–nuclear dipolar-plus contact term between the electrons of $Co^{2+}$ and $^{31}$P nuclei. We have already reported that the frequency shift is proportional to a fractional contribution of the unpaired electron spin to the $^{31}$P nucleus.[10] In order to obtain more information about the nature and the assignments of the NMR

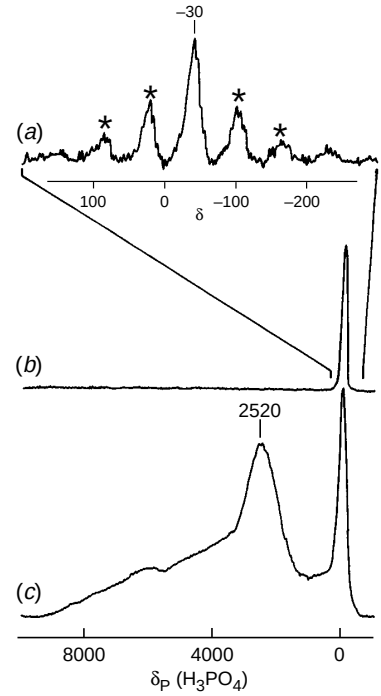

**Fig. 1** $^{31}$P NMR spectra of CoAPO-50. (*a*) $^{31}$P MAS spectrum. Pulse length: 2 μs, recycle delay: 20 s, spinning rate: 10 kHz. 1600 scans were accumulated (asterisks denote spinning side-bands). (*b*) Spectrum obtained with a Hahn echo sequence with the irradiation frequency at 0 Hz. (*c*) Spin-echo mapping spectrum obtained by addition of 22 spectra. For each individual spectrum, 1800 FIDs were accumulated.

signals, we have recorded the spectrum of DAF-2, a cobalt phosphate made of alternating $CoO_4$ and $PO_4$ tetrahedra.[12] The signal is composed of a broad peak at δ *ca*. 9500 and corresponds to P atoms surrounded exclusively by four Co atoms. As the shift is proportional to the electron density of $Co^{2+}$ on the $^{31}P$ nucleus, it is expected that it will depend on the number of Co atoms in the first coordination sphere around P. Therefore, we can suggest that the signal observed between δ *ca*. 500 and 10 000 corresponds to P atoms with at least one Co in the first coordination sphere, whilst the peak at δ *ca*. 0 corresponds to P(4A1) species. This was confirmed by studying a series of CoAPO molecular sieves with various Co contents. The relative intensity of the signal above δ 500 increases with the Co content but, in all cases, integration of the spectrum indicates that all phosphorus atoms were detected (Table 1). More details about the evolution of the line shape and intensity with the amount of Co incorporated will be given in a forthcoming paper.

CoAPO-50 clearly shows a distinct NMR peak at δ *ca*. 2500 which corresponds to approximately one quarter of the shift observed for DAF-2. We can thus assume that this line corresponds to P(1Co,3Al) units. Unfortunately, NMR lines are very broad and deconvolution of the signal into several lines corresponding to P(*n*Co, 4 − *n*Al) is not trivial. However, our assumption was supported by the study of samples containing low amounts of cobalt, like CoAPO-34 (2.95 mass% Co) or CoAPO-5 (3.05 mass% Co). For these samples, if we assume a random distribution of Co in the lattice, the relative contribution of P(2Co,2Al) species is expected to be negligible compared to that of P(1Co,3Al). Experimentally, spectra are essentially composed of two lines centred around δ 0 and 2500 without significant contribution above δ 5000. Moreover, we found that the relative intensity of the signal at δ 0 could be directly correlated with the Co content in the various samples, which makes the method very interesting not only for observing the total $^{31}P$ NMR signal but also to estimate the chemical composition. The line shape is slightly modified upon calcination of CoAPO materials in air (Fig. 2). As a general trend, we have noticed that the intensity in the range δ 500–1500 increases upon calcination whilst that above δ 2500 decreases, but the total intensity remained unchanged. As the observed shift strongly depends on the geometry and electronic density around P atoms, such modifications might be explained by changes in bond angles and lengths or by partial oxidation of $Co^{II}$ to $Co^{III}$ species upon calcination. Indeed, oxidation is expected to reduce the electronic density on the phosphorus nuclei and thus to decrease the observed NMR shift as already reported for VPO.[9]

Finally, we have studied a CoAPO-5 sample (10 mass% Co) obtained by impregnation of calcined AlPO-5 with cobalt(II) nitrate followed by calcination in air at 500 °C. As previously reported,[8] numerous spinning side bands are observed in the MAS NMR spectrum and $T_1$ and $T_2$ relaxation times considerably decrease with respect to pure AlPO-5. However, no signal is detected in the range δ 500–10 000 using the spin-echo mapping technique. This strongly suggests that the presence of an NMR signal in this region is characteristic of the incorporation of Co in the AlPO framework. The presence of Co–O–P bridges is probably necessary to delocalise the unpaired electrons of the metal on $^{31}P$ nuclei.

All these experiments show that the spin-echo mapping technique is a rapid and very powerful method to characterise CoAPO molecular sieves and to prove the incorporation of the metal in the framework. A detailed attribution of the different signals as well as the possibility of applying the method to the characterisation of other transition-metal substituted molecular sieves is in progress.

**Table 1** Percentage of phosphorus nuclei observed by $^{31}P$ NMR in various samples

| Sample | Co (mass%) | $I_E$ (%)[a] | $I_{SEM}$ (%)[b] |
|---|---|---|---|
| CoAPO-50 | 11.7 | 9.5 | 98 |
| CoAPO-46 | 7.9 | 17 | 103 |
| CoAPO-39 | 2.95 | 71 (65[c]) | 101 (97[c]) |
| CoAPO-5 | 3.05 | 67 (66[c]) | 99 (102[c]) |

[a] $I_E$ is the percentage of $^{31}P$ nuclei detected using a Hahn echo with irradiation frequency at 0 Hz. [b] $I_{SEM}$ is the percentage of $^{31}P$ nuclei detected with the spin-echo mapping technique. [c] Values obtained on calcined samples.

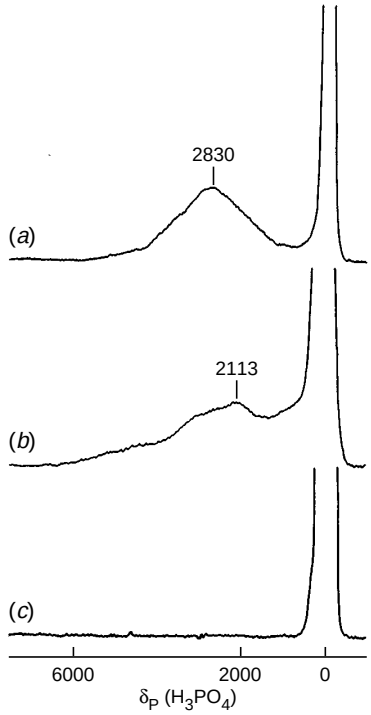

**Fig. 2** $^{31}P$ NMR spectra by spin-echo mapping of as-synthesised CoAPO-5 (*a*), calcined CoAPO-5 (*b*) and cobalt impregnated AlPO-5 (*c*)

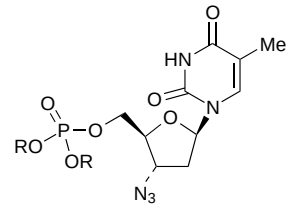
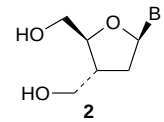
# Synthesis of the first homo-3′,5′-cyclic nucleotide



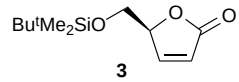
**Jayne H. M. Gould and John Mann***

*Department of Chemistry, Reading University, Whiteknights, Reading, UK RG6 6AD*

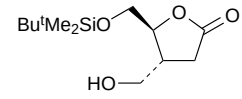


**Syntheses of 2′,3′-dideoxy-3′-hydroxymethylcytidine-6′-diphenylphosphate and the corresponding 5′,6′-cyclicphenylphosphate from 5(*S*)-*tert*-butyldimethylsilyloxymethylfuran-2(5*H*)-one are achieved.**

In the search for drugs with activity against HIV reverse transcriptase, novel analogues of the natural nucleosides have always been the most popular targets for synthesis. Recent discoveries include biologically potent L-series nucleosides[1] and variously protected phosphates like **1**, which are prodrugs of AZT.[2] Our synthesis of 2′,3′-dideoxy-3′-hydroxymethyl nucleosides of general structure **2** demonstrated that the cytidine derivative (B = cytosine) and 5-fluorocytidine derivative (B = 5-fluorocytosine) had particularly potent activity against a range of viruses,[3] and this encouraged us to try to prepare the monophosphate and cyclic phosphate derivatives for biological evaluation. Here we describe the successful attainment of these goals.



We have previously described the photoinduced addition of methanol to 5(*S*)-*tert*-butyldimethylsilyloxymethylfuran-2(5*H*)-one **3** to produce adduct **4**,[4] but for the present work this reaction was carried out on the 30 g scale with yields in the range 45–50%. Protection of the free hydroxy as its benzoate ester **5a** allowed selective reduction of the lactone (disiamyl borane in THF) and derivatisation of the resultant lactols to yield the anomeric acetates **6a** (overall yield 52%). These were reacted with bis-trimethysilylcytosine in the presence of tin(IV) chloride to yield the protected nucleoside analogue **7a** as a *ca.* 1 : 1 anomeric mixture, which could not be separated by flash chromatography. Selective removal of the benzoate was



**1** R = subst. aryl or $RCOSCH_2CH_2$

possible using base (1% NaOH in MeOH) and the free hydroxy was selectively phosphorylated using a modification of the method of Uchiyama *et al*.[5] This involved reaction of the nucleoside with 1 equiv. of *tert*-butylmagnesium chloride in the presence of diphenylphosphorochloridate to produce the desired 6′-diphenylphosphate **8** (63% yield). We had hoped to convert this compound into the cyclic phosphate **9**, but despite considerable efforts, this goal eluded us.

We thus turned our attention to the bis-silylated adduct **5b** which was reduced (DIBAL-H) and derivatised to provide lactol esters **6b** and thence the protected nucleoside anomers **7b** (52% overall). Protection of the free amino group of the cytosine as its 2-(*p*-nitrophenyl)ethyl carbamate[6] yielded the fully-protected nucleoside anomers **10**, and to our delight the anomers could now be separated (with relative ease) by flash chromatography. (Indeed we have used this protecting group to facilitate separation of anomeric mixtures of several substituted cytidines.) The silyl ether groups of these individual anomers were now removed (toluene-*p*-sulfonic acid in MeOH) and the resultant diols **11** were reacted in pyridine with bis(benzotriazolyl)phenyl phosphate[7] (from 2 equiv. of 1-hydroxybenzotriazole and phenylphosphodichloridate in the presence of triethylamine), to produce the desired cyclic phosphates **12** (35% α and 31% β after chromatography.† The α-anomer was more easily recrystallised than the β-anomer, and an X-ray crystallographic study confirmed the structure of this compound.‡ Finally, the carbamate group was removed from the β-anomer using triethylamine to yield the novel homo-cyclic nucleotide **13**,§ which was submitted for biological evaluation. We had hoped that the compound would act as a prodrug from compound **2** (B = cytosine), a compound with good activity against several viruses.[3] It did in fact show modest activity against HIV-1 ($EC_{50}$ 350 μmolar) and is presently being evaluated in other systems.

All of the reactions as far as compound **11** have been carried out routinely on the half-gram scale (though the cyclic phosphate formation has only been accomplished thus far on the 100 mg scale). One obvious extension of this work is to replace the phenyl group with other aryl groups or by *S*-acyl-2-thioethyl groups as in prodrugs like **1**, in an attempt to improve the bioavailability of the compounds. However, given the pivotal importance of cyclic-3′,5′-AMP and -GMP in biological processes, a more urgent task is to extend this methodology to the purine series in order to make homologues of these very important compounds.

J. G. thanks the MRC for a studentship under the AIDS Initiative Programme and we thank Dr Naheed Mahmood (MRC) for the (ongoing) biological evaluation. We are also very grateful for the advice given by Professor Colin Reese and for the numerous FAB mass spectra provided by the EPSRC Mass Spectrometry Centre at the University of Swansea.

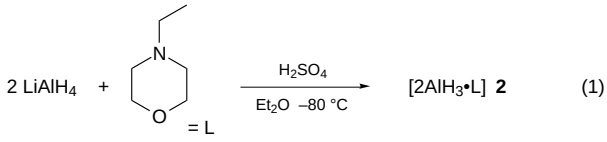
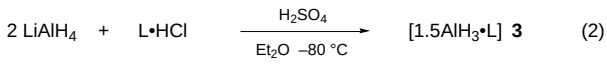
# Self-assembling polymeric mixed donor (O/N) *N*-ethylmorpholine adducts of alane ($AlH_3$)

**Philip C. Andrews,[a] Colin L. Raston,*[a] Brian W. Skelton[b] and Allan H. White[b]**



[a] *Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia*
[b] *Department of Chemistry, The University of Western Australia, Nedlands, W. A., Australia 6907*



**The 2:3 and 1:2 stoichiometric reactions of *N*-ethyl morpholine with the $Et_2O$ adduct of $AlH_3$, prepared from $LiAlH_4$ and $H_2SO_4$ in $Et_2O$ at −80 °C, afford alane-rich hydride-bridged polymers exhibiting a range of bonding modes of Lewis bases to $AlH_3$ including unprecedented mono Al···H hydride bridging.**

Lewis-base adducts of alane ($AlH_3$) are important precursors in CVD production of thin films.[1] The stability of such compounds and hence ease of decomposition is often determined by the nature of the Lewis bases present. Attempts at rationalising the stability of such complexes has led to a great deal of solid-state structural information on N-amine and P-phosphine stabilised adducts, for example $AlH_3{\cdot}2$quinuclidine, $AlH_3{\cdot}2NMe_3$ and $AlH_3{\cdot}PBu^t_3$ which are monomeric five- or four-coordinate species, dimeric $[AlH_3{\cdot}NMe_2(CH_2Ph)]_2$ with weak hydride bridging and thus five-coordinate metal centres, and polymeric $[AlH_3{\cdot}tmen]_\infty$ and $[AlH_3{\cdot}Pr^i_2PCH_2CH_2PPr^i_2]_\infty$ which have polydentate ligands associated with five-coordinate metal centres.[2] In contrast the only structurally authenticated alane derivatives involving Lewis bases donating through an O atom are $AlH_3{\cdot}2$thf, $[AlH_2(\mu\text{-}H{\cdot}thf)]_2$[3] and the mixed-donor complex $[AlH_3{\cdot}$*N*-methylmorpholine$]_\infty$ **1**.[4] Such complexes are important since they give insight into the possible decomposition processes for alane and gallane ($GaH_3$), Lewis-base adducts in the presence of air and/or moisture where simple O-complexation at the metal centre is likely to be the primary process for decomposition, as well as how such adducts bind to oxidised silica surfaces.[5]

Herein, we report the synthesis and crystal structures of two alane adducts of *N*-ethylmorpholine (L): namely $[2AlH_3{\cdot}L]_\infty$ **2** and $[1.5AlH_3{\cdot}L]_\infty$ **3**. The compounds spontaneously self-assemble into one- or two-dimensional polymeric structures with head-to-head hydride bridging and/or two O-donating groups to the same metal centre. This has implications for building even more complex systems for polydentate donor ligands in general. In addition, a new structural type for alane has been established, and overall both structures taken together summarise the structural variety found for all other characterised Lewis base adducts of alane and gallane.

Complexes **2** and **3** were prepared as shown in reactions (1) and (2).† In reaction (1) the *N*-ethylmorpholine is

added immediately on cooling to −80 °C an $Et_2O$ solution of alane preformed from sulfuric acid (98%) and an $Et_2O$ solution of $LiAlH_4$. In reaction (2) the hydrochloride salt of the morpholine is present together with the $LiAlH_4$ in $Et_2O$ prior to the addition of the sulfuric acid. The use of the hydrochloride salt in reaction (2) is important in finely controlling the stoichiometry of the reaction. Therefore an $L : AlH_3{\cdot}xEt_2O$ ratio of 1:2 for **2** and 1:1.5 for **3** is ensured. Colourless crystals of both **2** and **3** are obtained at −30 °C from an $Et_2O$ solution, although the colourless rhomboidal crystals of **3** were also obtained from *in vacuo* sublimation. Both sets of crystals are stable at room temperature with **2** melting with gas evolution *in vacuo* at 66–67 °C and finally decomposing to metal at *ca*. 137 °C, and **3** decomposing > 150 °C.

Due to the quadrupolar $^{27}Al$ nucleus the only meaningful information from the NMR studies was the relative chemical shifts of the $AlH_3$ protons, giving a relatively broad singlet, and the protons and $^{13}C$ in the complexed *N*-ethylmorpholine.

The solid-state structures of **2** and **3** are shown in Figs. 1 and 2 respectively.‡ Both structures are polymeric crystallising in the space group $P\bar{1}$, albeit showing significant differences: **2** forms a polymeric chain due to the linking of discrete N and O bound $AlH_3$ units *via* hydride bridging, while this is also a feature of **3** there are several other important additional features which give rise to a two-dimensional net-like structure. The repeating unit in **3** consists of four L moieties and two lots of three different types of $AlH_3$ units giving in total three different trigonal-bipyramidal Al environments. One Al centre behaves in a similar fashion to that as seen in **2**. However the two other

Al centres which are both five-coordinate help form the two-dimensional structure through the formation of single Al–H hydride bridging, which is unprecedented for alane species. The Al which is bound by two O atoms contributes a $H^{\delta-}$ while it is the N-bound Al centre which provides the electropositive metal centre, thus achieving five-coordination. It is interesting that the polymer **1**, which is formed from the 1 : 1 reaction of $LiAlH_4$ with the hydrochloride salt of *N*-methylmorpholine (L′·HCl) gives a simpler asymmetric unit in compliance with the stoichiometry of the reaction; repeating $AlH_3$·L′ with each five-coordinate Al centre bound by both O and N from different morpholine moieties and with no intermolecular hydride bridging and with the donor ligands arranged head-to-tail rather than head-to-head as seen in **2** and **3**. In complete contrast the 1 : 1 L′ adduct of trimethylaluminium shows no Al–O bonding although it is observed in the 2 : 1 adduct which forms a monomer.

The reaction of $AlH_3$ in $Et_2O$ with 4-(2-chloroethyl)morpholine hydrochloride affords the *N*-ethylmorpholine adduct, $[(AlH_3)(AlClH_2)\cdot L]_\infty$ **4**, which exhibits another variation in the polymeric framework, containing features of both **2** and **3**.†‡ Essentially it has the same hydrogen-bonded backbone as **2** but the cross-linking features of **3** with the close electrostatic interactions being between the bis O-bound Al (on which hydride/chloride exchange has occurred between the $AlH_3$ and $NCH_2CH_2Cl$ units) and Cl instead of Al···H.

The variety in structural motifs contained within **2** and **3** are clearly seen from an analysis of the bond lengths and angles. In **2** the Al–O bonds are relatively short, 1.993(3) Å, in comparison to the longer bonds of 2.172 and 2.034 Å in **3** and 2.19(2) Å in **1** reflecting the lower covalent interactions at the Al centre {*cf.* also the mono [1.967(2) Å] and bis [av. 2.066(3) Å] thf adducts of alane cited above}. In **3** the O–Al–O bond angle bisecting the trigonal-planar $AlH_3$ unit is almost linear at 174.7(1)°. The intermolecular $Al_2\cdots H_2$ distances of 2.11(3) and 1.93(3) Å in **2** and 2.13(3) Å in **3** are significantly longer than those within the $AlH_3$ units, 1.47(2)–1.58(6) Å. The N–Al···H–Al polymer linking bonds in **3** are longer again at 2.29(3) Å. All the Al–N distances are comparable with those found in related amine–alane adducts.

The use of ethereal solutions of alane by-passes the typical, and as yet unfavourable, ligand substitution reactions with $AlH_3\cdot NMe_3$ for forming exclusively O-donor ligand bound complexes. It also allows for the possibility of determining the relative stability of the Lewis-base O-donating species in comparison with their amine or phosphine stabilised analogues.

We thank the Australian Research Council for support of this work.

## Footnotes

† **2**. The $Et_2O$ complex of $AlH_3$ was generated *in situ* at −80 °C from the reaction of $LiAlH_4$ (0.46 g, 12 mmol) with $H_2SO_4$ (98%, 0.59 g, 6.12 mmol) in $Et_2O$ (30 ml). Almost immediately *N*-ethylmorpholine (0.69 g, 6 mmol) was added dropwise while the reaction mixture was stirred. This was then allowed to warm slowly to room temp. and stirred for a further 2 h. The white suspension was filtered leaving a clear $Et_2O$ solution from which rhomboidal colourless crystals were obtained at −30 °C (1.4 g, 73%). Alternatively a white powder can be formed on quick removal of $Et_2O$ from the clear solution and sublimed *in vacuo* to give the same rhomboidal crystals. Melting with gas evolution at 66–67 °C, further gas evolution from 94 °C until decomposition to metal at *ca*. 137 °C. $^1$H NMR (300 MHz, 25 °C, $C_6D_6$) δ 4.14 (s, AlH), 3.62 (m, $OCH_2$), 2.15 (m, $NCH_2$), 0.87 (t, $CH_3$), $^{13}$C NMR (75.5 MHz, 25 °C, $C_6D_6$) δ 63.16, 54.84, 52.87, 8.81. Anal. required (found) C, 41.14 (41.48); H, 10.93 (10.98); N, 8.00 (8.13)%.

**3**. $H_2SO_4$ (98%, 0.38 g, 3.90 mmol) was added dropwise to a stirred reaction mixture of *N*-ethylmorpholine hydrochloride (L·HCl) (0.61 g, 4 mmol) and $LiAlH_4$ (0.30 g, 8 mmol) in $Et_2O$ (25 ml) at −80 °C. This was allowed to stir and warm slowly to room temp. at which point it was stirred for a further 2 h. The white suspension was filtered and the clear $Et_2O$ solution cooled to −30 °C at which temperature fine colourless crystals of **3** were obtained (0.43 g, 62%); decomp. > 151 °C, $^1$H NMR (300 MHz, 25 °C, $C_6D_6$) δ 4.15 (s, AlH), 3.65 (m, $OCH_2$), 2.20 (m, $NCH_2$), 0.85 (t, $CH_3$), $^{13}$C NMR (75.5 MHz, 25 °C, $C_6D_6$) δ 63.25, 54.77, 52.91, 8.91. Anal: required (found) C 44.99 (41.88), H 11.01 (11.06), N 8.74 (8.51)%.

**4**. This was prepared from the reaction of 2 equiv. of $LiAlH_4$ and 1 equiv. of 4-(2-chloroethyl)morpholine hydrochloride in $Et_2O$ at −80 °C. Large colourless crystals were grown from the filtered clear ether solution at 4 °C, mp 123 °C.

‡ *Crystal structure determinations* (CAD4 diffractometer, crystals mounted in capillaries): **2**. $C_6H_{19}Al_2NO$, $M$ = 175.2, triclinic, space group $P\bar{1}$, $a$ = 11.941(6), $b$ = 7.021(3), $c$ = 6.963(3) Å, α = 101.68(3), β = 98.29(4), γ = 103.27(4)°, $U$ = 544.1 Å$^3$. $D_c$ ($Z$ = 2) = 1.069 g cm$^{-3}$, $F$(000) = 192. $\mu_{Mo}$ = 2.2 cm$^{-1}$, specimen: 0.27 × 0.18 × 0.15 mm, $A^*_{min,\ max}$ = 1.03, 1.04. $2\theta_{max}$ = 50°, final $R$, $R_w$ = 0.044, 0.042. $N_0$ = 1301 'observed' [$I > 3\sigma(I)$] reflections out of $N$ = 1905 unique.

**3**. $C_{12}H_{35}Al_3N_2O_2$, $M$ = 320.4. Triclinic, space group $P\bar{1}$, $a$ = 15.388(4), $b$ = 10.233(5), $c$ = 6.676(3) Å, α = 73.15(4), β = 77.95(4), γ = 81.62(4)°, $U$ = 980 Å$^3$, $D_c$ ($Z$ = 2) = 1.086 g cm$^{-3}$, $F$(000) = 352. $\mu_{Mo}$ = 1.9 cm$^{-1}$, specimen: 0.50 × 0.49 × 0.48 mm (no correction), $2\theta_{max}$ = 55°, final $R$, $R_w$ = 0.049, 0.051, $N$ = 2625, $N_0$ = 1868.

**4**. $C_{12}H_{34}Al_3ClO_2N_2$, $M$ = 354.8 triclinic, space group $P\bar{1}$, $a$ = 12.964(7), $b$ = 12.447(6), $c$ = 6.887(2) Å, α = 83.54(3), β = 77.30(4), γ = 71.06(4)°. $U$ = 1003 Å$^3$, $D_c$ ($Z$ = 2) = 1.18 g cm$^{-3}$, $F$(000) = 384. $\mu_{Mo}$ = 3.2 cm$^{-1}$, specimen: 0.55 × 0.50 × 0.40 mm (no correction), $2\theta_{max}$ = 50°, final $R$, $R_w$ = 0.055, 0.062. $N$ = 3512, $N_0$ = 2655. Refinement abnormalities, including a significant difference map residue, were modelled in terms of disorder of Cl(1) to either side of Al(3), populations of Cl(1,1′) being ($x$, 1 − $x$) $x$ = 0.840(3). Hydrogen atoms were refined in ($x$, $y$, $z$, $U_{iso}$)$_H$ leaving an effectively featureless final difference map (max. residue 0.45 e Å$^{-3}$). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/327.

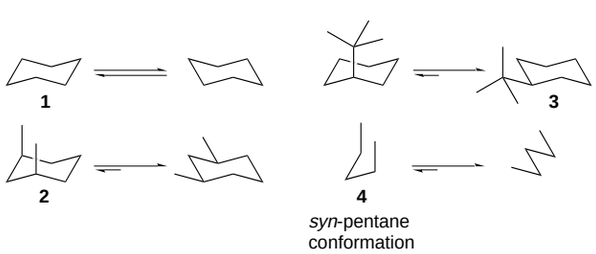
# Open chain compounds with preferred conformations[1]

**Richard Göttlich, B. Colin Kahrs, Joachim Krüger and Reinhard W. Hoffmann***

*Fachbereich Chemie der Philipps-Universität Marburg, Hans-Meerwein-Strasse, 35032 Marburg, Germany*

**The shape of a flexible molecule, *i.e.* the preferred conformation of a multi-substituted alkyl chain, may be controlled by the nature and location of the pendant substituents. Steric interactions between those substituents themselves as well as the main chain, or sterically demanding end-groups, can be used to realize conformation design of flexible molecules.**

## Introduction



Compounds may be described in terms of a molecular backbone and of the functional groups attached to it. The distance and spatial arrangement of the functional groups frequently defines the activity of biologically active compounds. In cases of flexible, open chain compounds, it is the conformational space of the molecular backbone that limits and defines the possible distance between the functional groups attached. Definite arrangements may prevail, if the backbone of the molecule shows a marked conformational preference.

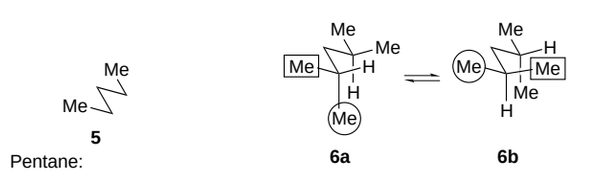
For instance, extended hydrogen bonding networks lead in polypeptides and proteins to the secondary and tertiary structure. Oligosaccharides composed of pyranoses have more defined spatial structures than saccharides composed of furanoses due to the conformational preferences of six membered rings. In polypropionate natural products steric interactions between the pendant methyl groups may restrict the conformational space and lead to oligo-conformational systems.[2] At the present time, when the design of peptidomimetics, artificial receptors and synthetic hosts is of interest, the properties of molecular backbones, especially their conformational properties, merit more detailed consideration. It is important to recognize the principles that render segments of a flexible molecular backbone mono-conformational, and to identify typical substructures of backbones, which populate to more than 90% a single conformation.

Well known examples are the 'conversion' of a bi-conformational cyclohexane nucleus **1** into a monoconformational situation by 1,3-*cis* disubstitution (*cf.* **2**) or by attachment of a conformational anchor, *e.g.* a *tert*-butyl group, *cf.* **3** (Scheme 1). One should keep in mind that the molecules **2** and **3** are still conformationally fully flexible. It is only that a single conformation predominates substantially.

Commonly, this effect is ascribed to the destabilization of one conformer by 1,3-diaxial interactions, which are a special case of the (destabilizing) *syn*-pentane interaction, *cf.* **4**. *syn*-Pentane interactions between two $CH_2$ groups result in a destabilization of *ca.* 3 kcal mol$^{-1}$ (1 cal = 4.184 J).[3,4,5] The avoidance of *syn*-pentane interactions is thus a powerful tool to reduce the number of low energy conformations of open chain compounds.[2,5] While pentane **5** is multiconformational, having five low energy conformations $E_r \leqslant 3.0$ kcal,[3] placement of substituents, *e.g.* methyl residues, in the 2,4 positions leads to 2,4-dimethylpentane **6**. The latter is 'bi-conformational' having only two low energy conformations **6a** and **6b** (Scheme 2). All other diamond lattice-type conformations are destabilized by *syn*-pentane interactions. Likewise, placement of substituents in the 2,4,6,8-positions of longer hydrocarbon chains will substantially reduce the number of low energy conformations available, creating bi-conformational situations in each dimethylpentane subsegment.

Placement of further substituents on the particular segment will not necessarily lead to a mono-conformational situation, since the additional *syn*-pentane interactions generated now affect all of the remaining low energy conformations. Different approaches towards reaching mono-conformational entities are the topic of this present account.

**Scheme 1**

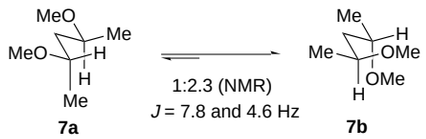


## Heteroatoms as pending substituents

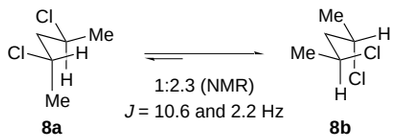
In 2,4-dimethylpentane **6** the two methyl groups within each pair of end groups are identical. Hence, the conformers **6a** and **6b** are enantiomorphous, *i.e.* isoenergetic. The two conformers of **6** are formally interconverted by a +120° rotation about one skeletal bond and a −120° rotation about the other one. Considering an individual methyl group, *e.g.* the squared one, it has no *gauche* interactions in conformer **6a** and one gauche interaction in **6b**. If the end groups (squared or circled) in **6** were different, the energetic degeneracy would be lifted. On replacement of the squared methyl group by a group of smaller size, as measured *e.g.* by the *A*-value, the conformer equilibrium should be shifted towards **6b**.

The $^1$H–$^1$H vicinal coupling constants recorded for 2,4-dimethoxypentane[6] **7** or 2,4-dichloropentane[7] **8** document the expected shift in the conformer equilibrium; the conformer **b** (with the larger methyl group in the extended chain position) being preferred (Scheme 3).

The analysis of the conformer equilibria in such bi-conformational situations rests on the determination of vicinal coupling constants. The coupling constants between two individual hydrogens, *e.g.* $H_a$ and $H_b$ in **9** differ for the two conformers (Scheme 4).



The measured coupling constant is the weighted time average over the conformer population. If, for example, **9a** and **9b** are present in a 1 : 1 ratio, an average coupling constant of about 6–7 Hz should be observed. Any bias of the equilibrium towards one side leads to a divergence of the coupling constants. By



**Scheme 2**

comparison of the measured coupling constants with those calculated[8] for the individual conformers, the position of the equilibrium can be estimated.

At this point some general remarks are appropriate: We restrict our discussion to diamond lattice-type conformers. By this we imply backbone conformations with dihedral angles of 180 ± 15° or 60 ± 15°. If a conformation involving a *syn*-pentane interaction relaxes into the nearest energy minimum, this usually results in a skewed backbone conformation with dihedral angles of 90 ± 15°. These conformers are generally ⩾ 3 kcal higher in energy[9] than the lowest energy conformer. For this reason these skewed conformers contribute little to the overall conformer population and are not further considered here. Experimental information regarding the position of conformer equilibria derives from vicinal $^1H–^1H$ coupling constants between protons along the backbone of the molecule. The accuracy of these coupling constants obtained from first order multiplets in the $^1H$ NMR spectra is around ±0.1 Hz. If higher order multiplets have to be simulated, as is the case for all $C_2$-symmetrical structures such as **10** (Scheme 5), the coupling constants are accurate to about ±0.2 Hz. The experimental coupling constants are the weighted average of those of the populated conformers. In order to estimate the position of the conformer equilibrium for the bi-conformational backbone segments the coupling constants for the individual conformers have to be calculated. This is done by minimizing the individual conformer structures by the MM3* force field implemented in the MACROMODEL program.[8] This program also has a routine by which vicinal coupling constants are predicted for a given structure based on Karplus relationships. This routine makes provision for changes in the magnitude of coupling constants due to electronegative substituents on the backbone.[10] Clearly, coupling constants predicted this way will not be better than ±0.2 Hz. It is obvious that equating[11] experimental coupling constants with ±0.2 Hz accuracy with calculated coupling constants with ±0.2 Hz accuracy can give only a crude estimate of the conformer population. Nevertheless, the conformer population estimated this way agrees by and large with those calculated by MM3. Since it is not our aim to determine conformer populations accurately, but rather to identify substitution patterns that lead to a biased conformer equilibrium, the approach delineated above is sufficient for that purpose.

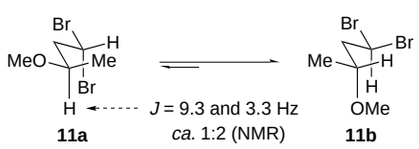
$J_{a,b}$ = small
$J_{a,c}$ = large

**Scheme 4**

**10a** **10b**



**Scheme 5**

The bias in the conformer equilibrium of the dimethoxy compound **7** can be attributed to a difference in effective size of a methoxy group *vs*. a methyl group—*cf* the *A*-values: Me = 1.74, MeO = 0.60. However, the conformer population depends not only on the differences in the van der Waals radii, but also on the restrictions in conformational space experienced by the methoxy group. This concerns both the energy and the number of the local C–C–O–$CH_3$ rotamers. The number of low energy rotamers for **7a** is 9 and for **7b** it is 4, giving more statistical weight to **7a**. The latter term affecting the conformer population of the backbone in **7** can be eliminated by tying the methoxy group into a ring. This is achieved by going from the dimethoxy compound **7** to the bis(tetrahydropyranyl)-methane **10**. In doing so, the methyl groups of **7** are also changed to $CH_2R$ groups. But the latter should have no effect on the conformer equilibrium, since the R residue, being held in a ring, does not lead to any additional gauche interactions in either conformer **10a** or **10b**. When comparing the conformer equilibria of **7** and **10**, it becomes apparent that the equilibrium of **10** lies considerably more on the **b** side, as judged by the $^1H$ NMR coupling constants.[1] The situation in **10** probably reflects the true difference in effective size between an ether oxygen and a methylene group.

Our goal was to convert a bi-conformational situation as found in **6** into a mono-conformational one, as approximated by **10**. The key was to replace one of the 'methyl groups' in **6**, *e.g.* the squared one by a group of different size than the remaining circled group. For a broader study on how the effective sizes of two groups effect the conformer population, we wanted to avoid $C_2$-symmetric systems, such as **7** or **10**, and turned to derivatives of 1,1-dibromobutane such as **11** (Scheme 6). In doing so we use a dibromomethyl group as a conformational lock to secure a bi-conformational situation and we determine than, to what extent the differences in effective size, *e.g.* of a methoxy and a methyl group, shift the conformer population toward a mono-conformational situation. In fact, the coupling constant of the hydrogen α to the oxygen substituent in **11** revealed a noticeable shift of the conformer equilibrium towards **11b**.

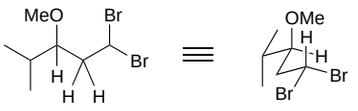
Increasing the size of the methyl group in **11**—the latter prefers to go into the sterically less encumbered chain end position—to an isopropyl group results in only a negligeable change in the conformer equilibrium, as seen from the coupling constants of **12** (Scheme 7). The small difference between a methyl and isopropyl group in such a system is also evident from the coupling constants recorded for **13**.[12] A sizeable effect is, however, attained when going to a *tert*-butyl group, as seen for **14**.

When changes are made at the oxygen substituent, the effect of tying the methoxy group into a ring can also be picked up within the dibromomethyl series, *cf*. the differences in coupling constants between **11** and **15** (Scheme 8). A change of the methoxy group in **12** to a trimethylsilyloxy group in **16** has, on the other hand, only a small effect. Thus, a trimethylsilyloxy group is hardly larger than a methoxy group as viewed from the dibromomethyl reporter unit.

**11a** **11b**

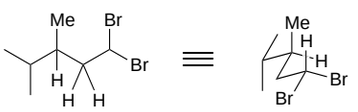
**Scheme 6**

## End-group control of conformation



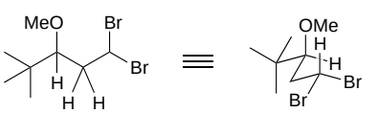
Coming back to the starting point **6**: when one replaces the squared methyl group in **6** by a really space-demanding substituent one should populate just the conformer **6a**. This is realized by going from **11** to **14**. The sizeable effect of the *tert*-butyl end group on the conformer population as seen for **14** has long been known as the *tert*-butyl effect,[13] according to which a *trans*-conformation is induced in structures such as **17** at the bond indicated (Scheme 9). Any other diamond lattice conformation around this bond would lead to *syn*-pentane interactions.

Hence, a combination of the structural elements **17** and **6**, as in compound **18**, should induce a t,g$^+$-conformation[14] as shown. In fact, a high tendency to adopt a single conformation has been reported for this compound by Luisi[15] based on measurements of the molecular rotation.



A more intricate situation of end-group control is seen in the examples **19** and **20** (Scheme 10). Obviously, steric bulk is not all that counts. In **19** and **20** an α-methoxyisobutyl residue is considered as the end group for the neighbouring bi-conformational segment. Since this segment is no longer symmetrically substituted, there are two sets of coupling constants, one large and one small in each. For the sake of simplicity we quote in Scheme 10 only the average value of the large coupling constants on the one side and of the small ones on the other side.

To evaluate the effect of the α-methoxyisobutyl group on the conformation of the C3–C4 bond (which in turn controls the conformation of the C4–C5 bond) in **19** and **20** we may consider just the number of low energy conformations which are free of *syn*-pentane interactions: For **19** there are three such conformations: (2,3g$^+$ 3,4t); (2,3t, 3,4t); and (2,3t 3,4g$^-$). Thus, in the bi-conformational segment C3 to C5, the 3,4t conformers are favoured by 2 : 1 over the 3,4g conformers according to this simplified analysis. The $^1$H NMR coupling constants indicate a 1.5 : 1 preference for the t conformation in this segment.



When going to **20** the situation is markedly different: there is only one conformer, the (2,3t 3,4t) conformer, which is free of *syn*-pentane interactions. Hence, compound **20** should have only one low energy conformation, the one shown, a fact that is reflected in the strong difference of the coupling constants recorded for **20**.[16] This effect can be used to selectively exert local conformation control in more extended molecular backbones such as **21** (Scheme 11).[17]

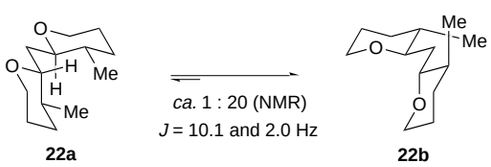
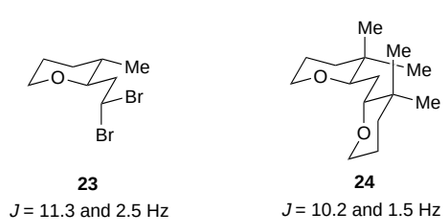
### sp²-Hybridized substituents

sp²-Hybridized end groups, such as vinyl, phenyl and methoxycarbonyl are, on the other hand, slimmer than a $CH_2R$ group. Therefore, in bi-conformational situations the former groups should be preferentially found in those positions, which are subject to the higher number of gauche interactions. This has been tested with a number of model compounds (Scheme 12).[16]

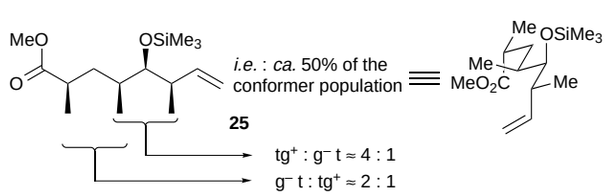


As can be seen from the coupling constants, the effects caused by a single sp²-hybridized substituent are rather small; $\Delta G$ values which affect the conformer equilibrium, do not exceed *ca*. 0.5 kcal mol$^{-1}$.

### Conformation design



Many of the effects described above, which bias a bi-conformatonal towards a mono-conformational situation, are small or not far-reaching. For this reason effective conformation design to attain mono-conformational situations in larger molecular backbones would have to rely on the combination of several control elements. The introduction of polar repulsions, of hydrogen bonding networks, or of situations that profit from the attractive gauche effect,[18] would obviously offer additional strategies. At the present stage of the development of the field, we were interested to see how far one could go simply by using the effects discussed in the previous sections.



**Scheme 12**

**Scheme 13**

**Scheme 14**

**Scheme 15**

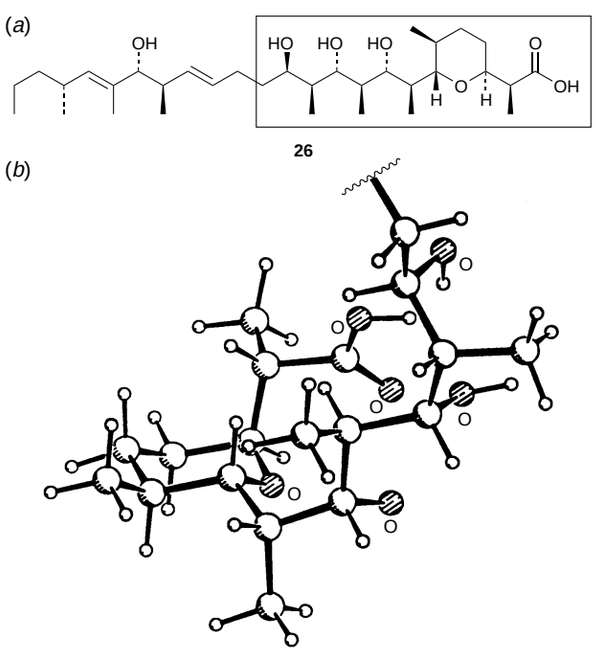
For example, in the case of **10**, introduction of two methyl groups to give **22** should reinforce the conformational preference. The two methyl groups in **22** have been strategically placed in the equatorial position to selectively destabilize the conformer **22a** by *syn*-pentane interactions between the methyl group and the backbone each relative to the conformer **22b** (Scheme 13).[1]

The same effect is seen[19] on comparison of the conformational preference of compound **23** with that of **15**. Since an essentially mono-conformational situation is already reached in compounds **22** and **23** by these tools, introduction of further methyl groups as in **24** has only a minor effect (Scheme 14).[1]

The effects that may be attained by multiple substitution of a chain with sp²-hybridized substituents are less striking. Nevertheless, the coupling constants recorded for **25**[16] indicate that about 50% of the total conformer population has a central g$^-$ttg$^+$ conformation (Scheme 15).

The various principles mentioned above are clearly manifest in nature's conformation design as illustrated by zincophorin **26**,[20] a natural ligand conformationally preorganized to complex $Zn^{2+}$. Inspection of part of its crystal structure lets one read nature's conformations design (Fig. 1).

The awareness of these and other factors, which render backbones of flexible molecules oligo- or mono-conforma-



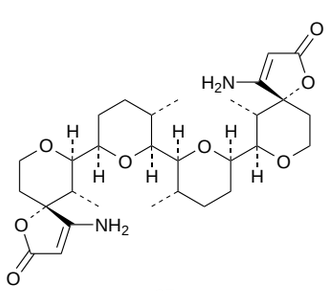


**Fig. 1** (*a*) Structure of zincophorin with fragment highlighted, and (*b*) partial crystal structure of highlighted fragment

tional, is obviously important for contemporary drug design and the design of tailor-made host molecules. This has recently been demonstrated by W. C. Still[21] with the synthesis of artificial ligands such as **27**.

# Cyano adduct-anions of [60]fullerene observed by electrospray mass spectrometry

**George Khairallah and J. Barrie Peel***

*School of Chemistry, La Trobe University, Bundoora, Victoria 3083, Australia*

**Negative-ion electrospray mass spectrometry of $C_{60}$–$CN^-$ solutions are used to study the cyano adduct-anions of [60]fullerene, revealing three abundant species, namely $C_{60}(CN)_n^-$, $n$ = 1, 3, 5, with $C_{60}(CN)^-$ as the dominant anion.**

The nucleophilic addition reactions of [60]fullerene demonstrate its behaviour as an electron deficient polyalkene.[1] Thus $C_{60}$ undergoes amination reactions such as with triethylamine,[2] where the intermediate radical anion, $C_{60}^{\cdot -}$, is thought to be involved. The $C_{60}$ reaction with cyanide anion[3] forms the mono-adduct anion, $C_{60}(CN)^-$, as a soluble salt. Electrospray mass spectrometry (ESMS) examining both positive and negative ions has been demonstrated as a powerful technique in the study of fullerenes and their adducts. The study of $C_{60}$ and $C_{70}$ anions by negative-ion ESMS,[4] led to observation of higher fullerene anions.[5] Tagged fullerenes[6] and polyamine adducts of $C_{60}$[7] have been studied by positive-ion ESMS, and the methoxylated anions of $C_{60}$ and $C_{70}$ by negative-ion ESMS.[5,8]

It has been noted that electrospray response varies according to source design as well as instrument conditions,[8] which offers an explanation for the different spectra observed for the methoxylated anions of $C_{60}$ by Wilson and Wu[8] and by Hiraoka and coworkers.[5] The former observed only the even-electron species, $C_{60}(OMe)_n^-$, $n$ = 1, 3, 5, which are the more likely long-lived anions in solution, as confirmed by semi-empirical theoretical studies.[9] By contrast the latter workers observed one odd-electron species, $C_{60}(OMe)_2^{\cdot -}$, as well.[5] It is possible that this ion results from collision-induced dissociation of the stable higher ions within the electrospray source. However an electrospray source can also behave as an electrochemical cell,[10,11] and $C_{60}^{\cdot -}$ is observed in the ESMS of $C_{60}$ solutions.[11] Hence the odd-electron species $C_{60}(OMe)_2^{\cdot -}$ is possibly resulting from electron attachment (reduction) of neutral $C_{60}(OMe)_2$.

We have used the reaction of $C_{60}$ (MER Corporation) in dry 1,2-dichlorobenzene with NaCN in dry DMF to provide various solutions for examination by ESMS. Mass spectra were obtained with a VG BioQ triple-quadrupole system (VG Biotech, Altrincham, UK). The freshly prepared mixtures, which contained $C_{60}$ total concentrations of *ca*. 0.5 mmol dm$^{-3}$ and NaCN of *ca*. 5–100 mmol dm$^{-3}$, were injected directly into the spectrometer using a Rheodyne injector incorporating a 50 mm$^3$ loop. The mobile phase used was 1 : 1 propan-2-ol–water as recommended for its proven negative-ion sensitivity.[12] A flow rate of 5 mm$^3$ min$^{-1}$ was used and spectra were acquired in the negative-ion mode with the nozzle/skimmer (cone) voltage of 40 V. Scanning was from *m/z* 700–900, with 25 scans being signal-averaged over a 120 s period to produce each mass spectrum.

Visual observation of typical $C_{60}$–$CN^-$ solutions showed an initial olive green colour which changed progressively over a period of around an hour through dirty brown shades to a brown–yellow colour. The ESMS data presented here were obtained for solutions up to 1 h following mixing.

Typical spectra measured for various $CN^-$ concentrations and at various times, Fig. 1, exhibit strong peaks in the 740–800 *m/z* range. The three peaks located at *m/z* values of 746, 798 and 850 indicate the presence of the even-electron cyano adduct-anions $C_{60}(CN)_n^-$ $n$ = 1, 3, 5. At higher resolution each peak clearly demonstrates the appropriate isotope ratios based on natural $^{12}C/^{13}C$ as illustrated for the 746 peak in Fig. 2. The four discernible isotopes of $C_{60}(CN)^-$, of *m/z* 746, 747, 748 and 749, have theoretical relative abundances of 100 : 68 : 23 : 5. However the peak at 772, of *m/z* corresponding to the odd-electron $C_{60}(CN)_2^{\cdot -}$ species, as also shown in Fig. 2, exhibits an isotope distribution revealing 0.5 amu spacings, contrary to this formula. This pattern is suggestive of a doubly-charged ion containing two $C_{60}$ units, and our conjecture is that it is an ion–molecule complex, namely $C_{60}(CN)_4^{2-}.C_{60}$. This is supported by our observation that $C_{60}(CN)_4^{2-}$ at *m/z* 412 is also present in some $C_{60}$–$CN^-$ solutions.[13] Likewise the 824 peak is probably due to the analogous $C_{60}(CN)_8^{2-}.C_{60}$ species.

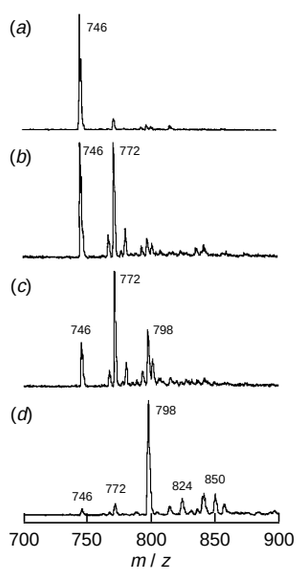

**Fig. 1** Negative-ion electrospray mass spectra for *m/z* = 700–900 of $C_{60}$–$CN^-$ solutions (*a*) [$CN^-$] = *ca*. 5 mmol dm$^{-3}$, (*b*) [$CN^-$] = *ca*. 50 mmol dm$^{-3}$ at 25 min, (*c*) [$CN^-$] = *ca*. 50 mmol dm$^{-3}$ at 50 min, and (*d*) [$CN^-$] = *ca*. 100 mmol dm$^{-3}$

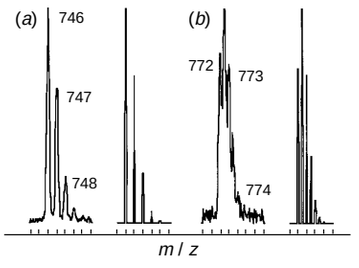

**Fig. 2** Comparison of experimental and theoretical $^{12}C/^{13}C$ isotope distributions for the negative-ion mass spectra of (*a*) $C_{60}(CN)^-$ and (*b*) $C_{60}(CN)_4^{2-}.C_{60}$

The spectra of fresher and lower concentration solutions are dominated by $C_{60}(CN)^-$ in agreement with the observation of this species as the intermediate in the reactions described by Majid *et al.*[3] For older and more concentrated solutions the relative abundance of $C_{60}(CN)_3^-$ increases and then $C_{60}(CN)_5^-$ likewise, with all three ($n$ = 1, 3, 5) present in some cases in comparable amounts. There are various other weak peaks in this mass region, and these can be assigned to species containing oxygen indicative of some degree of oxidation.

A comparison with the ESMS data reported[5,8] for $C_{60}(OMe)_n^-$ shows that the same even-electron species ($n$ = 1, 3, 5) are dominant. However the $C_{60}^{\cdot -}$ observed in the $C_{60}$–$OMe^-$ mixtures is not observed here with the $C_{60}(CN)_n^-$ species.

The results of semi-empirical molecular orbital calculations obtained using the AM1 approximation with the MOPAC program[14] are presented in Table 1. On the basis of earlier calculations[9] on the $OMe^-$ adducts the likely isomers for the $C_{60}(CN)_n^-$ ($n \geqslant 2$) species are relatively few in number. An analysis of the charge distribution for $C_{60}(CN)^-$ shows that the negative charge is located mostly on and near the CN group, analogous to the case of $C_{60}OMe^-$.[9] So for the higher isomers the structures with reasonably localized CN groups should adequately support the excess negative charge in their vicinity.

The calculated ionization energies and heats of formation, and the derived mean binding energies per CN of the chosen isomeric structures for each $C_{60}(CN)_n^-$ for $n$ = 1, 3, 5 are given in Table 1. The latter parameters offer a simple quantitative comparison of the relative stabilities of the respective anion species.

**Table 1** MOPAC/AM1 results for selected isomers of $C_{60}(CN)_n^-$, $n$ = 1, 3, 5; calculated ionization energies, IE (in eV) and heats of formation, $\Delta H_f$ with mean binding energies per CN, $\Delta H_b$ (kJ mol$^{-1}$)

| Molecule | Structure[a] | IE | $\Delta H_f$ | $\Delta H_b$[b] |
|---|---|---|---|---|
| $C_{60}$ | | 9.64 | 4072 | |
| $C_{60}^{\cdot -}$ | | 3.31 | 3771 | |
| $CN^-$ | | 3.13 | 184 | |
| $C_{60}(CN)^-$ | | 4.99 | 3817 | 439 |
| $C_{60}(CN)_3^-$ | 1,4,11- | 5.37 | 3950 | 197 |
| | 1,4,55- | 5.13 | 3994 | 182 |
| | 1,4,15- | 5.19 | 4016 | 175 |
| $C_{60}(CN)_5^-$ | 1,4,11,15,30- | 6.09 | 4042 | 157 |
| | 1,2,39,57,60- | 5.31 | 4169 | 131 |
| | 1,4,39,53,57- | 5.31 | 4176 | 130 |

[a] The numbering system used is that given in ref. 15. [b] $\Delta H_b$ is given by $\Delta H/n$ for the reaction $C_{60} + n\ CN^- \rightarrow C_{60}(CN)_n^-$.

Since the ionization energies (IEs) of the anions are significantly positive and increasing with increasing $n$, it is not surprising that the strong ionic environment is able to support the negative charge state of these species. So $C_{60}^{\cdot -}$, with its much lower calculated IE of 3.31 eV, is not supported in this environment, while $C_{60}(CN)^-$ with its higher IE of 4.99 eV is present at moderate $CN^-$ concentration. Hence the favoured isomers of $C_{60}(CN)_3^-$ and $C_{60}(CN)_5^-$ with their higher IEs of 5.37 and 6.09 eV, respectively, are formed at higher $CN^-$ concentration and over time. However the $CN^-$ concentration may not be high enough to produce the $C_{60}(CN)_7^-$ species, possibly because of an unfavourable equilibrium with $C_{60}(CN)_6$, which, with a structure likely to be the same as $C_{60}Cl_6$,[15] is expected to be the most stable of the neutral species considered. Overall these results show good correspondence with the ESMS observation of the dominance of $C_{60}(CN)^-$ represented in the spectra of Fig. 1.

We thank J. C. Traeger and I. M. thomas for assistance with the ESMS measurements, and the Australian Research Council for financial support.

# Aqueous-phase p$K_a$ of the methyl group in acetic acid

**Joseph J. Grabowski**

*Department of Chemistry, University of Pittsburgh, Pittsburgh, PA, 15260, USA*

**The gas-phase acidity of the α-hydrogens of acetic acid and the aqueous-phase p$K_a$ of ethyl acetate are combined with other literature values in a thermodynamic cycle to provide the aqueous-phase p$K_a$ of the methyl group of acetic acid as 22.7 ± 1.0 and the p$K_a$ of the enol of acetic acid as 3.3 ± 1.0.**

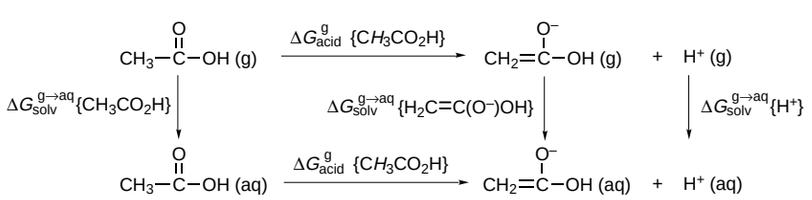
Enolate anions of carboxylic acids are postulated as intermediates in a number of biologically important reactions that include addition,[1] racemization[2] and elimination processes.[3] Despite their importance and the attempts to understand how such energetic species could be stabilized,[4] little is known about α-C–H acidities in carboxylic acids including the prototypical acetic acid itself. Arguable exceptions are limited to compounds with special structural features that provide kinetic or thermodynamic stabilization[5,6] or those that can be generated as products from the decay of reactive intermediates produced by laser flash photolysis.[7]

An alternative strategy for determining an aqueous phase p$K_a$ is to translate a gas-phase acidity into its condensed-phase counterpart by using an appropriate thermochemical cycle such as that for acetic acid shown in Scheme 1.[8] Knowing any four of the five parameters in Scheme 1 allows one to obtain the missing thermochemical value. This approach has been used to determine hydration enthalpies of alkyl ammonium[9] and aliphatic carboxylate ions,[8,10] and takes advantage of recently determined, accurate gas-phase basicities[11,12] or acidities.[13]

Several distinct advantages over conventional approaches are realized for p$K_a$ determinations *via* Scheme 1. First, gas-phase acidities can be accurately determined across the full range of acidities, and in a well-defined common environment (*i.e.* the gas-phase), while condensed-phase values are easily and accurately determined only in water. Second, all gas-phase acidities, by their very nature, are for the direct ionization process depicted in the top equation of Scheme 1 and do not require any consideration for ion-pairing or other aggregation effects. Third, the control accessible to modern gas-phase ion chemistry techniques allows nearly equal ability to measure absolute acidities of two or more different types of protons in the same molecule, a process more difficult to address in the condensed-phase.

Recent determinations of the gas-phase acidity of the α-C–H of acetic acid[14,15] and the p$K_a$ of ethyl acetate as a carbon acid in aqueous solution[16] can now be combined with other calorimetric data from the literature, as described below, to provide a direct evaluation of the aqueous phase p$K_a$ of the less acidic proton in acetic acid. Inspection of Scheme 1 provides the necessary equation with which to evaluate the aqueous-phase ionization energy of acetic acid as a carbon acid, $\Delta G^{aq}_{acid}\{CH_3CO_2H\}$ [eqn. (1)]. (All thermochemical values are summarized in Table 1.)

$$\Delta G^{aq}_{acid}\{CH_3CO_2H\} = \Delta G^{g}_{acid}\{CH_3CO_2H\} - \Delta G^{g\rightarrow aq}_{solv}\{CH_3CO_2H\} + \Delta G^{g\rightarrow aq}_{solv}\{H^+\} + \Delta G^{g\rightarrow aq}_{solv}\{H_2C{=}C(O^-)OH\} \quad (1)$$



Several years ago we discovered that gas-phase deprotonation of acetic acid by hydroxide and other bases led to competitive proton abstraction from the O and C sites;[14] bracketing studies in both directions led to the determination that $\Delta G^{g}_{acid}\{CH_3CO_2H\}$ = 361.2 kcal mol$^{-1}$ (1 cal = 4.184 J). Additional proton abstraction studies of the monoenolate anion of acetic acid prepared by a fluorodesilylation reaction are entirely consistent with this value.[15]

Free energies of hydration of many neutrals are available in the literature[17–19] and simple unknown values can be estimated to within an accuracy of better than 0.25 kcal mol$^{-1}$.[19] For acetic acid, $\Delta G^{g\rightarrow aq}_{solv}\{CH_3CO_2H\}$ is −6.70 kcal mol$^{-1}$, an experimental value reproduced to within 0.1 kcal mol$^{-1}$ by group contributions.[19]

Prior uses of the thermochemical cycle in Scheme 1 have variously considered the free energy of hydration of the proton[20,21] to be well established,[22] at −259.5 kcal mol$^{-1}$, as well as the 'object of much dispute',[8] at −262.4 kcal mol$^{-1}$. While this value is critical for determining absolute energies of solvation for anions, as previously demonstrated, it is completely unimportant herein because the value appears in eqn. (1) and in estimating $\Delta G^{g\rightarrow aq}_{solv}\{H_2C{=}C(O^-)OH\}$ and therefore cancels. Thus, while the value used by Wilson and co-workers[8] is adopted for Table 1, it is important to recognize that changing this solvation energy will have no effect on the p$K_a$ that is derived.

To date, the major hindrance in using Scheme 1 to estimate p$K_a$ values has been the lack of reliable anion hydration energies; this is the situation for the monoenolate anion of acetic acid. Scheme 1, therefore, is most commonly used when both gas and aqueous-phase acidities are known, to derive ion energies of hydration.[8,10,22] By using Scheme 1 to determine the free energy of hydration of the enolate anion for methyl acetate, and using this value to estimate the energy of hydration of the monoenolate anion of acetic acid, one can overcome two problems at once: namely, the uncertainty in the absolute hydration energy of the proton and the unknown hydration energy of the monoenolate anion of acetic acid.

Rearranging eqn. (1) for methyl acetate and to determine an anion hydration energy, requires: p$K_a\{CH_3CO_2CH_3\}$ = 25.6 (assumed to be identical to ethyl acetate[16]) or $\Delta G^{aq}_{acid}\{CH_3CO_2CH_3\}$ = 34.9 kcal mol$^{-1}$;

**Scheme 1**

$\Delta G^{g}_{acid}\{CH_3CO_2CH_3\}$ = 365.1 kcal mol$^{-1}$ and[13] $\Delta G^{g\rightarrow aq}_{solv}\{CH_3CO_2CH_3\}$ = −3.32 kcal mol$^{-1}$.[19] Combining these values with the hydration energy of the proton provides $\Delta G^{g\rightarrow aq}_{solv}\{H_2C{=}C(O^-)OCH_3\}$ = −71.1 kcal mol$^{-1}$. If we assume the hydration energy of the monoenolate anion of acetic acid is equal to that of the enolate anion of methyl acetate plus a correction term for the mutation of a methyl group into a hydrogen, then the hydration energy of the proton drops out of consideration for the p$K_a\{CH_3CO_2H\}$ determination.

The remaining question concerns the correction term. Inspection of Table 1 reveals that $CH_3CO_2H$ has a more negative solvation free energy than $CH_3CO_2CH_3$ by 3.4 kcal mol$^{-1}$. Likewise, literature data[19] for propanoic acid *vs.* methyl propanoate, butanoic acid *vs.* methyl butanoate and methanol *vs.* dimethyl ether shows that mutating a methyl into a hydrogen enhances solvation free energy in each case by 3.42 ± 0.15 kcal mol$^{-1}$. Using this value as the correction term therefore allows us to predict $\Delta G^{g\rightarrow aq}_{solv}\{H_2C{=}C(O^-)OH\}$ = −74.54 kcal mol$^{-1}$. Using this latter value, the aqueous C–H acidity of acetic acid thus derived (Scheme 1, Table 1) is p$K_a\{CH_3CO_2H\}$ = 22.7. More complex corrections might have been required if the monoenolate anion of acetic acid possessed an internal hydrogen bond in the gas-phase. However, high level *ab initio* calculations clearly demonstrate the lack of such an interaction.[15,23]

A consideration of the approach used to derive the p$K_a$ shows that the error in the derived value is determined by the error in four terms. Relative gas-phase acidities are good to better[24] than 1.0 kcal mol$^{-1}$ while relative solvation energies have an estimated error of 0.1 kcal mol$^{-1}$. The stated error for the p$K_a$ of ethyl acetate is 0.5 p$K_a$ units (± 0.7 kcal mol$^{-1}$) and little extra error will result from the assumption of equivalent p$K_a$ values for methyl and ethyl acetates. The standard deviation for the four sets of literature examples used to derive an average $\delta\Delta G^{g\rightarrow aq}_{solv}$ for mutation of a methyl group into a hydrogen is 0.15 kcal mol$^{-1}$. Thus the best estimate is p$K_a\{CH_3CO_2H\}$ = 22.7 ± 1.0.

The p$K_a$ value derived here is entirely consistent with the oft-cited value of 24 that is obtained from an extrapolation of a correlation of ionization rate to p$K_a$s[25] and may be compared to the p$K_a\{CH_3COCH_3\}$[26] = 19.27, p$K_a${α-hydroxy-α-phenylacetic acid}[7] = 22 and p$K_a\{CH_3COSCH_2CH_3\}$[27] = 21.0. Combination of p$K_a\{CH_3CO_2H\}$ = 22.7 with p$K_E$ = 19.4 (where $K_E$ is the equilibrium constant for formation of the enol from the keto tautomer)[28–30] leads to the prediction that p$K_a\{H_2C = C(OH)_2\}$ = 3.3 (±1.0).[16]

In summary, an approach has been outlined that allows one to determine p$K_a$ values in aqueous solution by hydrating the reaction for the corresponding gas-phase value. This approach is limited by the availability and accuracy of the necessary thermochemical values. Even the simplest 'thermochemical literature history' reveals a constant refinement and improvement in accuracy as time and experimental methodologies progress. All values used in this work are, therefore, summarized in Table 1. In the event that one of the values used to derive this p$K_a$ is refined in the future, one simply needs to replace that value in Table 1 and thereby derive the new and presumably more accurate p$K_a$. For comparison, the hydration energy of acetate ion and acetone enolate are also included in Table 1; these values were obtained using a method analogous to that in Scheme 1.

Acknowledgment is made to the National Science Foundation for financial support for this work and to Professors Chris Cramer and Chris Maricondi for valuable discussion.

**Table 1** Free energies and p$K_a$s (at 298 K) used and derived in this work[a]

| | $CH_3CO_2CH_3$ | $CH_3CO_2H$ | $CH_3COCH_3$ | $CH_3CO_2H$ |
|---|---|---|---|---|
| Gas-phase acid data[b] | 365.1 | 361.2[c] | 361.9 | 341.5 |
| Neutral solvation data[d] | −3.32 | −6.70 | −3.85 | −6.70 |
| $H^+$ Solvation data[e] | −262.4 | −262.4 | −262.4 | −262.4 |
| Aqueous acidity data | | | | |
| p$K_a$ | 25.6[f] | 22.7[g] | 19.27[i] | 4.76 |
| $\Delta G^{aq}_{acid}$ | 34.91[g] | 31.0[b] | 26.28[g] | 6.49[g] |
| Anion solvation data | −71.12[h] | −74.52[i] | −77.09[h] | −79.3[h] |

[a] All values except p$K_a$'s are in kcal mol$^{-1}$. [b] All gas-phase acidities are obtained from ref. 13 unless noted. [c] Ref. 14. [d] All neutral free energies of hydration are obtained from ref. 19. [e] Derived from the $\Delta H$ and $\Delta S$ values cited in ref. 8. Note that while this value is crucial for deriving absolute solvation energies using gas- and aqueous-phase acidities, the p$K_a$ derived for the methyl position of acetic acid is insensitive to this value as discussed in the text. [f] Assumed to the same as ethyl acetate and obtained from ref. 16. [g] Derived from $\Delta G = -RT\ln K_a$. [h] Derived from the other values in this Table and a consideration of Scheme 1. [i] Ref. 24. [j] See text.

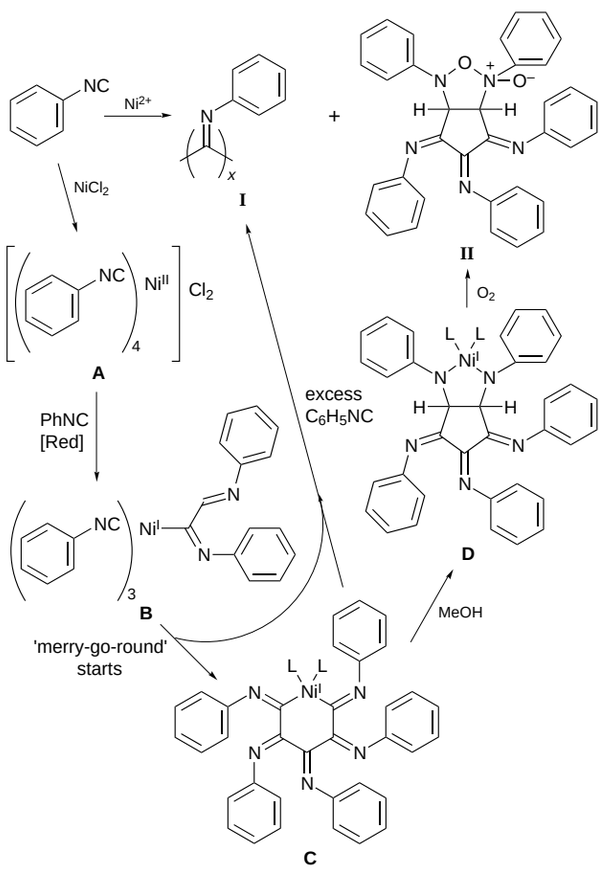
# Isolation and characterization of a unique heterocyclic ring system from nickel-ion catalysed polymerization of phenylisocyanide

**William B. Euler,* Jiun-Tang Huang, Misoo Kim, Lynne Spencer and William Rosen***

*Department of Chemistry, 51 Lower College Road, University of Rhode Island, Kingston, RI 02881, USA*

**Nickel-ion catalysed polymerization of phenylisocyanide (PhNC) produces the expected major product, poly(*N*-phenyliminomethylene), and a minor product of low molecular mass with a structure that gives insight into the mechanism of polymerization.**

The nickel(II) catalysed polymerization of isocyanide derivatives has been formulated as producing helical structures by a process described as a 'merry-go-round mechanism'.[1] Intermediates that seem to confirm this proposed mechanism[2] have been isolated and the structures of these characterized nickel(II) complexes have been established.[3] Recently, Deming and Novak[4] have challenged the assumption that $Ni^{II}$ is the active catalytic centre; their data implicating $Ni^{I}$ as the centre around which the helical polymers are constructed.



In the hopes of taking advantage of the interesting helical polymers that can be produced when isocyanide derivatives are catalytically polymerized, we embarked upon a study of the polymerization process as applied to phenylisocyanide (PhNC). As part of these studies we reported that the 'as-prepared' poly(*N*-phenyliminomethylene) **I**[5] is indeed substantially helical when first formed mechanistically but that dissolution of **I** in a non-polar solvent leads to an unravelling of the helical conformation. Our conclusion from this study, along with speculation in the literature,[6] is that the 'merry-go-round mechanism' is applicable initially but subsequent processing of the resultant helical polymers is liable to lead to non-helical structures if the side-chain group is not sterically demanding.[7]

As part of our initial investigation we reported[5] that polymer **I** is always accompanied by a low molecular mass component which is produced in very low yield when the polymerization is carried out in methanol as described.† We have now characterized the low molecular mass component from the polymerization of PhNC, structure **II** in Scheme 1, and this leads to some interesting conclusions concerning the polymerization mechanism. Structure **II** is unique[8] in the chemical literature‡ and allows us to speculate on the 'merry-go-round mechanism'[1] and its application when $Ni^{I}$ is the active catalytic centre.[4]

Preparation of the 'as-prepared' polymer **I** and GPC analysis of this polymer has been described elsewhere.[5] The bulk of the soluble product consisted of a polymer with $M_n \approx 2000$ and broad polydispersity but GPC always showed a low molecular mass band whose intensity was dependent upon the method of polymerization; those preparations done under a blanket of $N_2$ had a much more pronounced low molecular mass peak than those done under ambient air. Isolation of this low molecular mass fraction from the GPC column led to a colourless, crystalline solid with mp 263.5–264 °C. From preparations that yielded 2 g of the 'as-prepared' polymer **I** we were able to isolate about 20 mg of **II** when a blanket of $N_2$ was employed during the reaction.

The isolated crystalline solid **II** was structurally characterized by high-resolution mass spectrometry and $^1H$ and $^{13}C$ NMR and IR spectra. The high-resolution mass spectrum, using $NH_4^+$ in the LSIMS mode, yielded an $(M+H)^+$ molecular ion with $m/z$ = 550.22353 which most closely fits the molecular formula $C_{35}H_{27}N_5O_2$.§ The $^1H$ NMR spectrum displays 27 protons of which 23 resonate as a complex multiplet centred at δ 7.25 while the remainder resonate as doublets at δ 5.89 (1H, $J$ = 2 Hz), 6.03 (2H, $J$ = 7 Hz) and 6.52 (1H, $J$ = 2 Hz). The $^{13}C$ NMR spectrum exhibits 35 signals with peaks at δ 166.0, 151.5 and 150.5 assigned to imine carbons, those at δ 146.2, 144.2, 140.8, 138.1 and 135.0 are assigned to *ipso* carbons on the phenyl rings, 25 peaks between δ 130.2 and 119.2 are associated with *o*-, *m*- and *p*-carbons on the phenyl rings, and two at δ 74.6 and 67.0 which are assigned to saturated bridgehead carbons.¶ The $^1H$–$^{13}C$ HETCOR spectrum connects the δ 5.89 proton to the δ 74.6 carbon and the δ 6.52 proton to the δ 67.0 carbon.‖ The $^1H$–$^{13}C$ COLOC (long-range HETCOR) correlates the δ 5.89 proton with both the δ 151.5 and 166.0 carbons and the δ 6.52 proton with both the δ 150.5 and 151.5 carbons. Finally, the IR spectrum shows a strong absorption at 1668 $cm^{-1}$ assigned to an imine stretching mode. The spectral information is compatible with structure **II**.

The mechanism that is implied by the isolation of **II** accommodates both the 'merry-go-round'[1] concept and the idea that $Ni^{I}$ is the active catalytic centre,[4] as indicated in Scheme 1. Initiation of the process begins with the formation of **A**[3] and if an amine nucleophile is present, and a sterically hindered

**Scheme 1**

isocyanide derivative is being polymerized, then a nickel(II)–carbene intermediate can be isolated.[9] However, in the absence of a good nucleophile (such as an amine), attack by the reducing isocyanide (in excess) should lead to the intermediate **B** which contains a nickel(I) carboiminoyl diradical moiety rather than a nickel(II) carbene moiety.[9] The intermediate **B** can initiate the 'merry-go-round' for which the activation barrier is very low and the polymerization proceeds until either $O_2$ terminates the reaction or isocyanide is depleted. Under anaerobic conditions the chain-growth process is slowed[4] because of an increased activation barrier that leads through **C** to products (again, the presence or absence of an excess of isocyanide determines the ultimate course of reaction). The enhanced stability of **C** may be due to the fact that the pentamer corresponds to the first turn of a $4_1$ helix and this puts the fifth monomer in a geometry to readily coordinate to the metal. From **C**, when either depletion of isocyanide or anaerobic conditions dictate the course, the solvent (MeOH) acts as a reducing agent which leads to an intermediate such as **D**, which should be isolable. Once $O_2$ is introduced into the system, intermediate **D** is quickly oxidized to **II** and the $Ni^{II}$ regenerated.**

We thank the US Army Research Office for financial support for this work under grant number DAAL03-92-G-0391.

## Footnotes

† *Polymer preparation*: PhNC was added to a stirred solution of anhydrous $NiCl_2$ in MeOH, either under a blanket of $N_2$ or in contact with air, and the mixture was stirred for one week. A solid precipitate began to form after a short time and polymerization was virtually complete within one or two days but the odour of PhNC was still present so that stirring was always continued for one week. The solid precipitate was removed by filtration, washed thoroughly with MeOH, dried, and analysed by GPC.[5]

‡ An unstable intermediate (2,3,5-triphenyltetrahydro-1,2,5-oxadiazole-*N*-oxide) having a similar structure to **II** has been isolated[8] but little spectral information is available for it. Compound **II** shows some decomposition after several months but is much more stable than intermediates reported in the literature.[8]

§ The observed *m*/*z* value of 550.22353 for $(M + H)^+$ deviates from the calculated value for $C_{35}H_{28}N_5O_2^+$ of 550.22370 by $< 0.73$ ppm. Anal. Calc. for $C_{35}H_{27}N_5O_2$ C, 76.48; H, 4.95; N, 12.74. Found, C, 76.08; H, 5.14; N, 12.37%.

¶ A DEPT spectrum confirmed the assignment of the quaternary carbons.

‖ Based on the size of the coupling constant, the ring fusion seems to be in the *cis* conformation. MM2 calculations show that the *cis* isomer is of lower energy than the *trans* isomer, supporting this conclusion.

** We have noted that the amount of **II** produced is approximately the same as the molar amount of $NiCl_2$ used to initiate the catalysis, but how intermediate **C** evolves into intermediate **D** is still unclear. We have been unable to isolate either **C** or **D** and we have been unable to characterize the oxidation product derived from the presumed reducing agent, methanol.

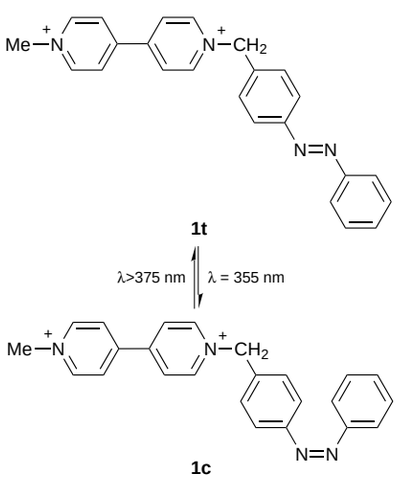
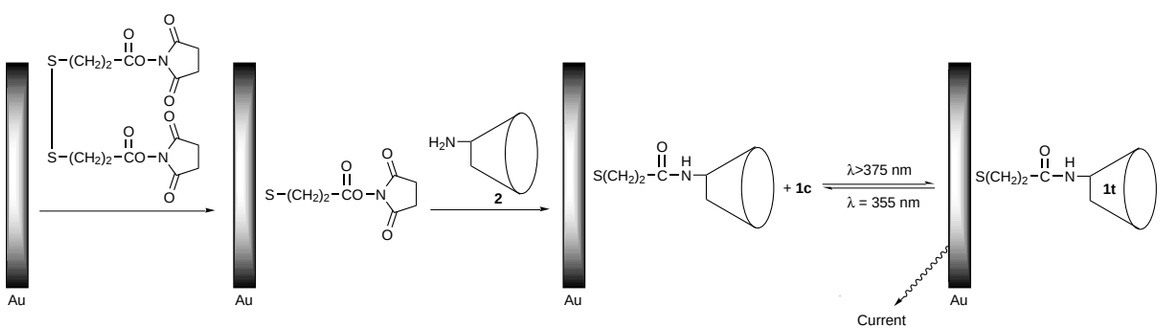
# A β-amino-cyclodextrin monolayer-modified Au electrode: a command surface for the amperometric and microgravimetric transduction of optical signals recorded by a photoisomerizable bipyridinium–azobenzene diad

**Michal Lahav, Koodali T. Ranjit, Eugenii Katz and Itamar Willner***



*Institute of Chemistry and the Farkas Center for Light-Induced Processes, The Hebrew University of Jerusalem, Jerusalem 91904, Israel*

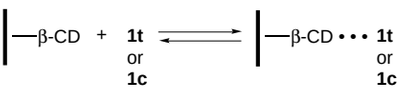


**A β-amino-cyclodextrin monolayer assembled onto Au electrodes acts as an active interface for the electrochemical and microgravimetric transduction of optical signals recorded by a bipyridinium–azobenzene diad.**

Molecular electronic and optoelectronic devices are the subject of recent extensive research efforts.[1,2] Electrical triggering of molecular functions and physical transduction of the activated chemical functionality provide the grounds for molecular electronic systems.[3,4] Photonic or optical triggering of molecular functions and transduction of the light-activated chemical functionality represent the basic features of molecular optoelectronics.[5,6] Photochemical activation of the formation or dissociation of donor–acceptor complexes in the presence of photoisomerizable electron acceptors[7] or light-induced molecular isomerization into a redox-active photoisomer state[5] allows the spectroscopic or electrical transduction of the recorded optical signals. To design molecular electronic or optoelectronic devices integration of the molecular assembly with a transducing element (surface) is essential. Functionalized monolayers assembled onto electrode surfaces were applied as active interfaces for sensing,[8] concentration of redox-active compounds[9] and discrimination of molecular redox activities at electrode surfaces.[10] Recently, the assembly of functionalized photoisomerizable monolayers onto electrode surfaces enabled the amperometric and piezoelectric transduction of optical signals recorded by the monolayer.[11–13] Here, we report on the use of a β-amino-cyclodextrin monolayer-modified Au electrode as a command surface for electrochemical transduction of optical signals, recorded by *N*-methyl-*N*′-[1-phenylazobenzyl]-4,4′-bipyridinium **1**.

*N*-Methyl-*N*′-[1-phenylazobenzyl]-4,4′-bipyridinium exhibits reversible photoisomerizable properties. Irradiation of *trans*-*N*-methyl-*N*′-[1-phenylazobenzyl]-4,4′-bipyridinium **1t**, λ = 355 nm, yields the *cis* isomer **1c**† and further irradiation of **1c**, λ > 375 nm, regenerates the **1t** state. The two photoisomers reveal different association features to **2**. The association constants of **1t** and **1c** to **2** were determined spectroscopically by following the absorbance changes at λ = 420 nm, and correspond to $K_a$ = 1700 and 180 M$^{-1}$, respectively.

A primary monolayer of thiopropionic acid-active ester was assembled onto the electrode followed by coupling β-amino-cyclodextrin[14] **2** to the functionalized surface (Scheme 1).[15] The **2**-functionalized monolayer electrode acts as a command interface for the amperometric or microgravimetric quartz crystal microbalance (QCM) transduction of optical signals recorded by the photoisomerizable diad **1**.‡ Fig. 1 shows the cyclic voltammograms of **1t** and **1c** in the presence of the **2**-modified electrode. A high amperometric response corresponding to the one-electron reduction of the bipyridinium redox-active unit is observed for **1t** while the redox wave for **1c** is substantially lower.§ The peak currents of the redox waves of **1t** and **1c** show a linear relation with the scan rates ($i \propto \nu$ for $\nu \leqslant 3$ V s$^{-1}$) implying that the redox waves originate from surface-confined redox-active species. Control experiments at a bare Au electrode reveal that **1t** and **1c** yield under the same conditions identical, very weak, redox waves. The enhanced electrical responses of the photoisomerizable diad in the presence of the **2**-monolayer-modified electrode are attributed to its concentration at the electrode interface by association to



**Scheme 1** Assembly of the **2** monolayer onto Au surfaces

the cyclodextrin cavity. The photoisomer **1t** exhibits high affinity for **2** and yields a high amperometric response. The photoisomer **1c** exhibits a low association constant to the receptor sites and results in a low redox signal. Coulometric analysis of the redox waves of **1t** and **1c** implies surface coverages of the functionalized cyclodextrin by **1t** and **1c** that correspond to $2.7 \times 10^{-11}$ and $1.5 \times 10^{-11}$ mol cm$^{-2}$, respectively. These values are consistent with the surface coverages evaluated by the microgravimetric experiments. By reversible photoisomerization of the diad between the states **1t** and **1c**, cyclic high and low amperometric signals are transduced from the system (inset, Fig. 1).

Microgravimetric analysis of the association of **1t** to the **2** interface and the dissociation of **1c** from the functionalized monolayer using a quartz crystal microbalance provides a further means for the electronic transduction of the recorded optical signals.[16] The Au electrodes associated with a quartz crystal (9 MHz) were modified by the **2** monolayer as described in Scheme 1. Fig. 2 shows the crystal frequency changes upon its interaction with **1c** and **1t** [curves (*a*) and (*b*), respectively]. A high frequency change of $\Delta f = -11 \pm 1$ Hz is observed for **1t**, while a substantially lower frequency change, $\Delta f = -5 \pm 0.5$, is detected for **1c**. These results clearly demonstrate that **1t** associates to the **2** receptor interface while **1c** reveals a substantially lower affinity for the monolayer electrode. From the frequency changes observed upon interaction of photoisomers **1t** and **1c** with the **2**-monolayer electrode, and by the application of the Sauerbrey equation [eqn. (1), where $\Delta f$ is the crystal frequency change upon changing the crystal mass by $\Delta m$, and $A$ is the surface area], the surface densities of **1t** and **1c** on the monolayer electrode are estimated to be $2.8 \times 10^{-11}$ and $1.3 \times 10^{-11}$ mol cm$^{-2}$, respectively.¶ By cyclic photoisomerization of the diad between the states **1t** and **1c**, reversible high- and low-frequency changes of the modified quartz crystal are observed [Fig. 2 (inset)].

$$\Delta f = (-2.3 \times 10^{-6}) f_0^2 (\Delta m/A) \quad (1)$$

(2)

In conclusion, we have demonstrated that the β-amino-cyclodextrin-modified Au electrodes or piezoelectric crystals provide active interfaces for electronic transduction of optical signals recorded by the photoisomerizable electroactive bipyridinium–azobenzene diad **1**.

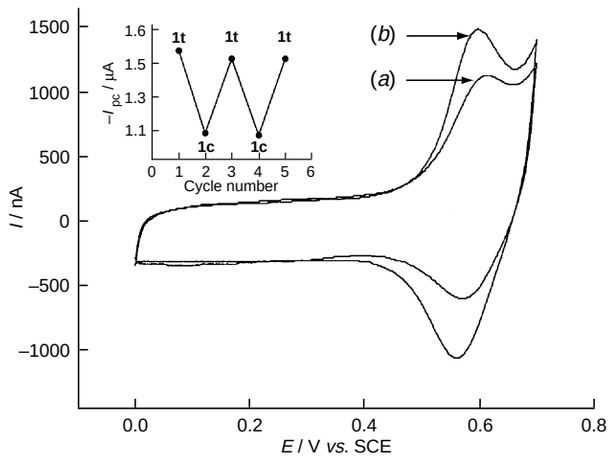


**Fig. 1** Cyclic voltammograms of (*a*) [**1c**] = $1 \times 10^{-6}$ M and (*b*) [**1t**] = $1 \times 10^{-6}$ M in 0.01 M phosphate buffer, pH = 10.8, scan rate 100 mV s$^{-1}$, $T$ = 25 °C. Inset: Cyclic cathodic responses of the **2**-monolayer electrode measured at 0.6 V upon reversible photoisomerization of the diad between **1t** and **1c**, respectively.

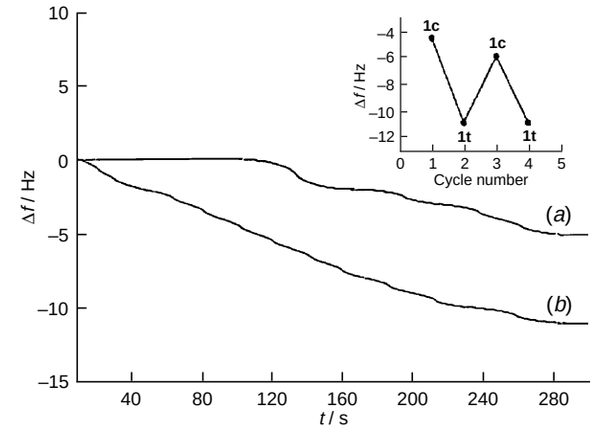

**Fig. 2** Frequency changes of the **2**-modified quartz crystal upon interaction with: (*a*) [**1c**] = $3 \times 10^{-6}$ M; (*b*) [**1t**] = $3 \times 10^{-6}$ M. Inset: cyclic frequency changes of the crystal upon reversible photoisomerization of the diad between state **1c** and **1t**, respectively. Frequencies are measured after 300 s of interaction of the crystal with the respective isomer. Experiments were performed in an aqueous environment.

## Footnotes

† A photostationary state corresponding to 92% of **1c** is formed.
‡ Microgravimetric QCM analysis of the modified monolayer indicates a surface coverage of $(4.7 \pm 0.1) \times 10^{-10}$ mol cm$^{-2}$ of β-amino-CD.
§ As the **1c** state represents a photostationary state where *ca*. 8% of **1t** is present (*ca*. 90 nA) of the total current response of **1c** (1.12 μA) is attributed to residual **1t** in the system.
¶ By following the frequency changes of the β-amino-CD modified crystal at different bulk concentrations of **1t** and **1c**, the association constants of the two photoisomers to the monolayer receptor sites, [eqn. (2)] were estimated to be $K_a$(**1t**) = 7000 M$^{-1}$ and $K_a$(**1c**) = 3000 M$^{-1}$.

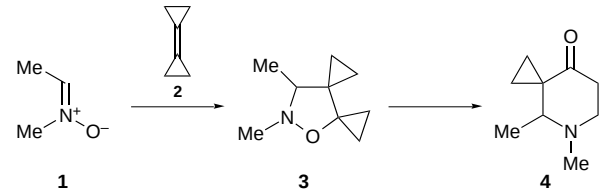
**The domino cycloaddition–thermal rearrangement of nitrile oxides and methylenespiro[2.2]pentane gives 5-azaspiro-[2.5]oct-6-en-8-one derivatives; with a nitrone the process complements the one using bi(cyclopropylidene) for the synthesis of α-spiro cyclopropanated heterocyclic ketones.**

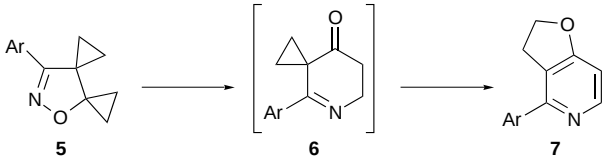
We have recently reported on the 'domino' cycloaddition–rearrangement process involving 1,3-dipoles such as nitrones **1** or nitrile oxides and bi(cyclopropylidene) **2**.[1] The process, essentially 'one pot', led to new 5-azaspiro[2.5]octan-8-ones **4** with high selectivities and in good yields (Scheme 1). Some of these spirocyclopropanated heterocycles also showed interesting biological activity, as they were found to cleave a DNA plasmid.[2]

However, isoxazolines **5**, derived by addition of **2** to nitrile oxides under the rearrangement conditions did not give the analogous derivatives **6**, instead affording exclusively the 2-substituted dihydrofuro[2,3-*c*]pyridine derivatives **7**[1] due to a non-selective rearrangement of both cyclopropane units in **5** under the required thermolytic conditions (Scheme 2).



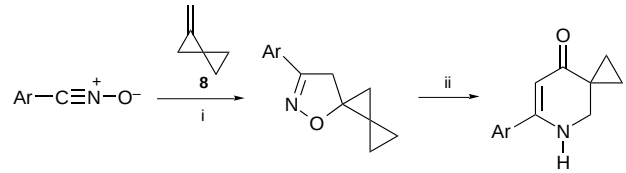
We now report the synthesis of 6-substituted 5-azaspiro-[2.5]oct-6-en-8-ones **11** by a different approach, utilising methylenespiro[2.2]pentane **8** as the dipolarophile (Scheme 3).

Methylenespiro[2.2]pentane **8**,[3,4] easily available from methylenecyclopropane[4a] or by thermal isomerization of bi(cyclopropylidene),[4b] has already been used in [2+1] addition processes for the synthesis of triangulanes.[5] The cycloaddition of benzonitrile oxide **9a**, generated slowly *in situ* at room temperature from the corresponding hydroximoyl chloride, to **8** afforded the isoxazoline **10a** in 64% yield with high regioselectivity, while the stable 2,4,6-trimethylbenzonitrile oxide **9b** gave the corresponding adduct **10b** quantitatively. Compared to bi(cyclopropylidene) **2**,[1] methylenespiro-[2.2]pentane **8** showed higher reactivity towards nitrile oxides, as demonstrated by the milder conditions required for the reaction with the stable nitrile oxide **9b** and the considerable decrease in formation of the undesired side-product generated by dimerization of the unstable nitrile oxide **9a**.

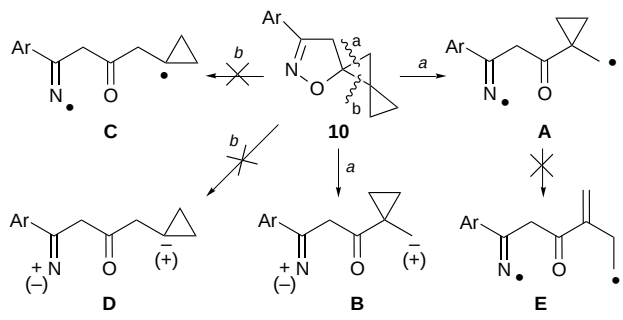


Isoxazolines **10** underwent thermal rearrangement more easily than their counterparts (**5**) from bi(cyclopropylidene)[1] and provided the ketones **11**, which contained a spiro-cyclopropane ring on the pyridone structure (Scheme 3). The structural assignment was based on the observation of characteristic signals in the NMR spectra for the C=C–C=O system, the olefinic proton and the methylene group adjacent to nitrogen. The higher lability of compounds **6** (Scheme 2), where the cyclopropane ring did not survive the rearrangement conditions, can be ascribed to the double spiro-conjugated cyclopropane ring.[6]

The highly regioselective opening of the spiro cyclopropane ring in **10** is noteworthy. This selectivity is opposite to that obtained when the process was applied to alkyl or aryl-substituted methylenecyclopropanes.[7] If a homolytic N–O bond cleavage is involved, as indicated by previous observations,[7a] this selectivity can be explained by the higher preference for the route (*a*) (Scheme 4) with ring opening to the diradical intermediate **A**, where the disubstituted cyclopropane carbon maintains the $sp^3$-like hybridization lost in intermediate **C** (Scheme 4).



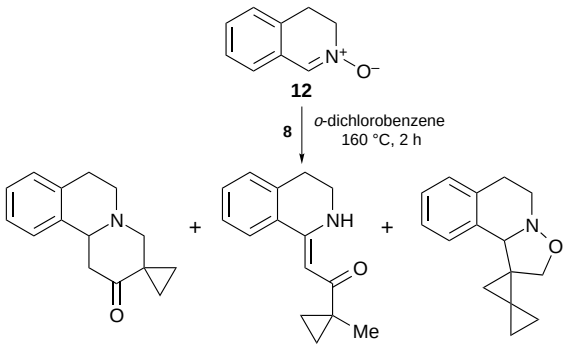
However, cyclopropyl methyl radicals **A** are known to rearrange readily to homoallylic radicals **E**,[8] which would eventually lead to products not observed in our process. This high regio- and chemo-selectivity, therefore, cannot rule out the



**Scheme 1**

**Scheme 2**

**Scheme 3** *Reagents and conditions* for **9a**: i, $C_6H_6$, room temp. 16 h, 64%; ii, *o*-dichlorobenzene, 160 °C, 14 h, 70%; for **9b**: i, $C_6H_6$, 60 °C, 4 h, 95%; ii, mesitylene, 163 °C, 4 h, 92%



**Scheme 4**

presence of zwitterionic intermediates such as **B** in the rearrangement of isoxazolines **10**, although a solvent effect on the process could not be observed. Further investigations are required to assess the origin of the high regio- and chemoselectivity observed.

With nitrones the process suffers from low selectivity. For example, heating a solution of nitrone **12** and **8** in *o*-dichlorobenzene at 160 °C for 2 h in a 'one pot' process gives the ketone **13** (30%) as well as the enaminone **14** and the regioisomeric cycloadduct **15** (Scheme 5).[1,5*a*,7] The regioselectivity of the cyclopropane opening was confirmed, but, as expected, besides the product of diradical coupling (**13**), a 1,5-hydrogen shift in the intermediate diradical led to the open-chain isomer **14**, as the major product.[7]

The authors are indebted to CRUI-Italy (Conferenza dei Rettori delle Università Italiane) and the German Academic Exchange Service (DAAD) for partial financial support of this project within the Vigoni Program. This work was also supported by the Fonds der Chemischen Industrie as well as by BASF, Bayer and Degussa AG (gifts of chemicals).

**$^{19}F$ chemical shift variations of *p*-fluoroacetophenone adsorbed on a MFI zeolite show that this compound is a promising probe for measurements of zeolite acidity strength.**

Zeolites are used as acid catalysts in important industrial processes such as the cracking of hydrocarbons in refineries. 'Direct' methods (IR spectroscopy and $^{1}H$ NMR of OH groups)[1–3] and methods using probe molecules (titration, calorimetric measurements, NMR of adsorbed bases, *etc.*)[4–6] have been employed to study zeolite acidity properties. However, the evaluation of the acidity strength of these materials still represents a real difficulty. In this work, the use of $^{19}F$ MAS NMR using a new probe molecule is presented.

The $^{19}F$ nucleus is very interesting for NMR studies with a nuclear spin $I$ of 1/2, a natural abundance of 100%, a high detection sensitivity (83% relative to H), and a large chemical shift range. The principle of the method we propose is to relate the chemical shift of the $^{19}F$ nucleus in the adsorbed probe molecule to the strength of the acid sites in the zeolite. This paper presents preliminary results on the adsorption of *p*-fluoroacetophenone on MFI. This organic compound is a good indicator of zeolite acidity strength because it contains a functionality whose $pK_{BH^+}$ value (−6.2)[7] falls in the acidity strength range of zeolites.[9] $^{19}F$ chemical shift variation as a function of acidity strength has been determined for *p*-fluoroacetophenone by Taft and Levins[7] and found to vary from δ −107.0 (Hammett acidity function: $H_0$ = 0) to δ −79.4 ($H_0$ = −11) with a shift of 4.9 ppm per $H_0$ unit near its $pK_{BH^+}$.

Prior research shows that $^{19}F$ NMR of alkaline probe molecules has made pH measurements in biological systems[9] possible. Nicholas *et al.*[10] studied adsorption of *p*-fluoroaniline and *p*-fluoronitrobenzene in zeolites. However, they could only determine the boundaries of the acidity strength for the MFI and FAU zeolites under study.

MFI zeolites were prepared in fluoride media in our laboratory.[11] Acid zeolites with Si/Al ratios of 35.5 and 55 [HZSM-5(35.5), HZSM-5(55)] and a non-acid purely siliceous MFI zeolite [HZSM-5(∞)] were calcined up to 823 K for 6 h under ambient atmosphere. Under these calcination conditions no residual $F^-$ (δ *ca.* −64) is observed in the $^{19}F$ MAS NMR spectra. After hydration, the zeolite samples were mounted in glass tubes with a bed depth of 5 mm and heated to 673 K at a heating rate of 15 K $h^{-1}$ *in vacuo*. At this temperature, samples were evacuated for 20 h at a pressure of $10^{-1}$ Pa. After cooling, samples were exposed to a saturated vapour of dehydrated *p*-fluoroacetophenone. After adsorption, samples were transferred into the NMR rotor in an argon atmosphere. $^{19}F$ MAS NMR spectra (reference $CFCl_3$) were recorded at 282.4 MHz on a Bruker MSL-300 with a 4 mm Doty probe (pulse length of 4 μs for the π/2 pulse, recycle delay of 6 or 10 s, spinning rate of 7–8 kHz).

Fig. 1 shows the spectra thus obtained for two days adsorption realized at room temperature. The amount of adsorbed *p*-fluoroacetophenone was determined by comparison of $^{19}F$ MAS NMR spectra with that of a known amount of an as-synthesized uncalcined MFI zeolite with no aluminium prepared in fluoride medium[11] which contains $4F^-$ ions per unit cell (Table 1). The maximum loading of the probe molecule in the zeolite structure based on geometric constraints alone is eight species per unit cell.

The narrow peak ($\Delta\nu_{1/2}$ = 375 Hz) which appears at δ −106.6 for HZSM-5(∞) [Fig. 1(*a*)] has a chemical shift

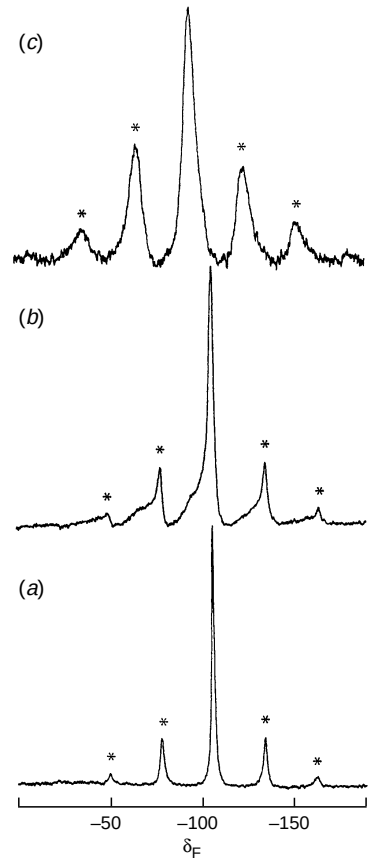

**Fig. 1** $^{19}F$ MAS NMR spectra of (*a*) HZSM-5(∞), (*b*) HZSM-5(55) and (*c*) dehydrated HZSM-5(35.5) treated with *p*-fluoroacetophenone for 2 days at room temperature; * MAS side-bands

**Table 1** Concentration of bridging OH (framework aluminium as determined by $^{27}Al$ MAS NMR) and *p*-fluoroacetophenone (as determined by $^{19}F$ MAS NMR)

| | Concentration in species per unit cell | |
|---|---|---|
| Sample | Bridging OH (framework aluminium) | *p*-Fluoroacetophenone |
| HZSM-5(35.5) | 2.3 | 1.6 |
| HZSM-5(55) | 1.7 | 4.0 |
| HZSM-5(∞) | — | 1.5 |

which is practically identical to that of *p*-fluoroacetophenone molecules in the liquid state (δ −107.0). Furthermore, the symmetrical shape of the signal indicates that fluorinated molecules have no preferential orientation and the small linewidth suggests a high mobility. We assign the peak at δ −106.6 to *p*-fluoroacetophenone molecules involved in weak interactions with this non-acidic zeolite framework.

When the Si/Al ratio decreases to 55, we distinguish different fluorinated molecules populations [Fig. 1(*b*)]. The first corresponds to a relatively narrow ($\Delta\nu_{1/2}$ = 845 Hz) peak situated at δ −106.6. By analogy with the HZSM-5(∞) [Fig. 1(*a*)] this is attributed to molecules which are in weak, interaction with the zeolite framework. The two other populations correspond to broader peaks ($\Delta\nu_{1/2}$ = 1740 and 1630 Hz) situated at lower fields (δ −95.3 and −100.5 respectively). The relative areas of various fluorinated species [δ −95.3 (23.3%), δ −100.5 (16.9%), *ca*. −106.6 (59.3%)] show that for four adsorbed fluorinated molecules per unit cell, the amount of *p*-fluoroacetophenone associated with the peaks situated at δ −95.3 and −100.5 represents 1.6 molecules per unit cell. This value corresponds approximately to the number of zeolite acid sites (Table 1). From the chemical shift values determined by Taft and Levins,[7] it can be deduced that these molecule populations are in interaction with acid sites which have a strength $H_0$ of −6.4 (δ −95.3) and $H_0$ −5.4 (δ −100.5). The increase in linewidths could be related to a decrease of the mobility of fluorinated molecules which reveals a stronger interaction with the zeolite framework. However, many interactions, such as homonuclear dipolar interactions (F–F), heteronuclear dipolar interactions (F–H, F–Al), chemical shift anisotropy, magnetic susceptibility and/or chemical exchange could contribute to the increase in linewidth. A more detailed study will be published elsewhere. Furthermore, measurement of areas corresponding to *p*-fluoroacetophenone molecules in strong interaction with acid sites and *p*-fluoroacetophenone in weak interaction with zeolite framework [Fig. 1(*b*)] shows that this method is quantitative.

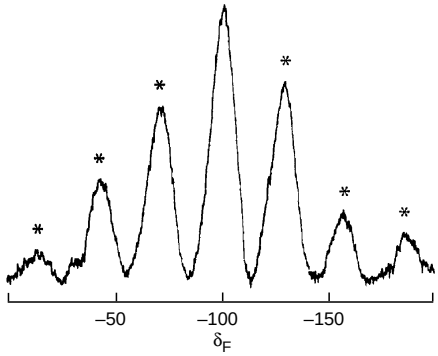

**Fig. 2** $^{19}$F MAS NMR spectrum of hydrated HZSM-5(35.5) treated with *p*-fluoroacetophenone for 15 days at room temperature; * MAS side-bands

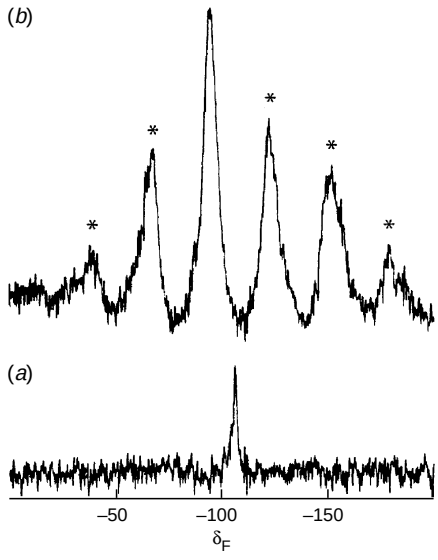

**Fig. 3** $^{19}$F MAS NMR spectra of (*a*) dehydrated HZSM-5(∞) and (*b*) HZSM-5(35.5) treated with *p*-fluoroacetophenone for 70 h at 423 K; * MAS side-bands

In the HZSM-5(35.5) sample, the $^{19}$F MAS NMR spectrum reveals only one broad peak ($\Delta\nu_{1/2}$ = 1830 Hz) situated at δ −95.6 [Fig. 1(*c*)]. Analysises (Table 1) show that there are fewer adsorbed fluorinated molecules than zeolite acid sites. At such an Si/Al ratio, most acid sites in the MFI zeolite structure should be accessible. The main reason for this low adsorption rate may be the blocking up of the channels by molecules in interaction with acid sites because channels are not blocked prior to adsorption of *p*-fluoroacetophenone (*n*-hexane adsorption rate at 298 K is 11.6%).

On partially hydrated HZSM-5(35.5) (3–8%) loaded with *p*-fluoroacetophenone, we observed only one broad peak ($\Delta\nu_{1/2}$ = 3340 Hz) situated at δ −100.2 ($H_0$ −5.4) (Fig. 2). This is indicative of a decrease of acidity induced by water molecules which react with zeolite acid sites[12] and level their acidity. Chemical shift exchange between water and *p*-fluoroacetophenone molecules, and important dipolar interactions between F and H of $H_2O$ and $H_3O^+$ chemical species may induce the increase in linewidth.

When adsorption on dehydrated zeolites is realized at 423 K (Fig. 3) only a few *p*-fluoroacetophenone molecules are trapped inside HZSM-5(∞) unlike HZSM-5(35.5). In the latter, strong zeolite acid sites related to aluminium interact with *p*-fluoroacetophenone and the thermal energy is not high enough at 423 K to break these interactions.

In conclusion, this work shows that *p*-fluoroacetophenone acts as a quantitative acidity strength indicator *via* $^{19}$F MAS NMR. The $^{19}$F chemical shift value allows the acidity strength to be determined, whereas the area of the signal can be related to the number of acid sites. However, we can foresee several limitations to this method. In aluminium-rich zeolites, the adsorption of a probe molecule might prevent another molecule to reach an acid site close to the first one. In some structures, small cavities could be inaccessible to the *p*-fluoroacetophenone molecules, whereas in structures with only one-dimensional channels, the adsorption of such a molecule could prevent others to progress inside the channels. All these limits are also encountered by reacting molecules when zeolites are used as catalysts.

We thank Professor J. L. Guth for valuable discussions.

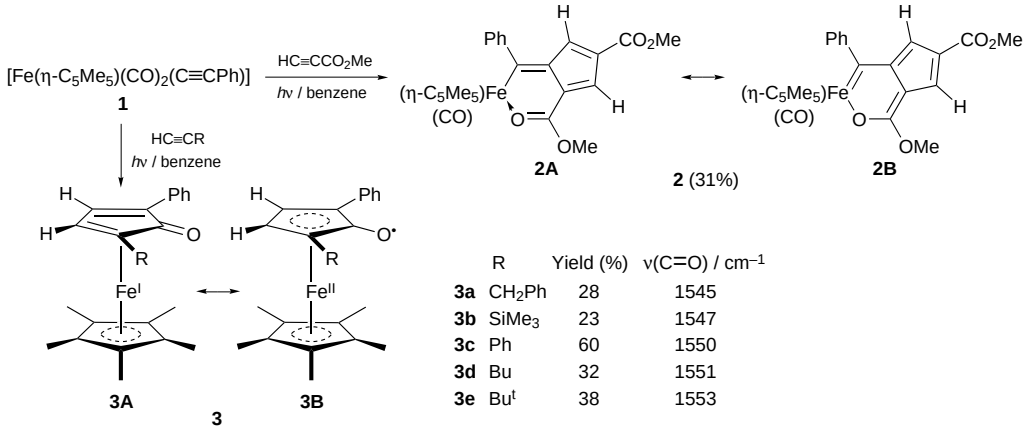
# Photochemical C–C coupling reaction of an iron acetylide complex $[Fe(\eta^5\text{-}C_5Me_5)(CO)_2(C{\equiv}CPh)]$ with alk-1-ynes (RC≡CH) leading to cyclic compounds including paramagnetic iron(I) cyclopentadienone complexes $[Fe(\eta^5\text{-}C_5Me_5)(\eta^4\text{-}2\text{-}Ph\text{-}5\text{-}R\text{-}C_5H_2O)]$

**Munetaka Akita,* Masako Terada and Yoshihiko Moro-oka***

*Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226, Japan*



**Photolysis of $[Fe(\eta^5\text{-}C_5Me_5)(CO)_2(C{\equiv}CPh)]$ with methyl propynoate which bears a coordinating substituent ($CO_2Me$) affords a metallabicyclic compound incorporating two molecules of the alkyne, whereas the reaction with alk-1-ynes (RC≡CH) bearing a non-coordinating substituent (R = alkyl, Ph, $SiMe_3$) produces paramagnetic 17e iron(I)-cyclopentadienone complexes $[Fe(\eta^5\text{-}C_5Me_5)(\eta^4\text{-}2\text{-}Ph\text{-}5\text{-}R\text{-}C_5H_2O)]$.**

C–C coupling reactions of alkynes have been realized by the action of a transition-metal species.[1] One versatile transformation is insertion into an M–C bond leading to oligomeric or polymeric conjugated systems.[2] In a previous paper, we reported the photochemical dimerization of iron acetylides $[Fe(\eta\text{-}C_5Me_5)(CO)_2(C{\equiv}CR)]$ (R = H, Ph), giving dinuclear complexes with an enyne ligand.[3] The study reveals that, when a C≡C group is introduced into the coordination sphere of the acetylide complex, insertion takes place quite readily. Herein we disclose photochemical reactions of the phenylacetylide complex with alk-1-ynes leading to cyclic products including iron(I) cyclopentadienone complexes.[4]

Irradiation of a benzene solution of $[Fe(\eta\text{-}C_5Me_5)(CO)_2(C{\equiv}CPh)]$ **1**[5] with a high-pressure mercury lamp in the presence of methyl propynoate (5 equiv.) afforded a red–brown complex **2** in 31% yield (Scheme 1). The NMR spectrum of the mononuclear complex **2**† showed two MeO signals [$\delta_H(CDCl_3)$ 3.74, 3.80] and revealed the incorporation of two molecules of the alkyne. The bicyclic structure of **2** has been determined by X-ray crystallography (Fig. 1)‡ and the contribution of a carbene structure **2B** in addition to the dominant resonance structure **2A** is evident as indicated by the structural parameters as well as the spectroscopic data {$\delta_C$(C2) 280.7 (s), $\nu$[C(23)=O(3)] 1600 $cm^{-1}$}.

In contrast to the reaction with alk-1-yne bearing a coordinating substituent ($CO_2R$) mentioned above, the photochemical reaction with alk-1-ynes (RC≡CH) bearing a non-coordinating substituent (R) afforded air-stable orange products **3** (R = $CH_2Ph$ **a**, $SiMe_3$ **b**, Ph **c**, Bu **d**, $Bu^t$ **e**) after separation by alumina column chromatography. The striking features of **3** are (*i*) paramagnetism, (*ii*) loss of the $\nu$(C≡O) absorption, and (*iii*) the appearance of an IR absorption around 1550 $cm^{-1}$ (KBr) which is assignable to a $\nu$(C=O) vibration. Complex **3** has been characterized as a 17e iron(I) cyclopentadienone complex, $[Fe(\eta\text{-}C_5Me_5)(\eta^4\text{-}2\text{-}Ph\text{-}5\text{-}R\text{-}C_5H_2O)$, on the basis of the results of X-ray crystallography of the $SiMe_3$ and Ph derivatives **3b**,**c**.§ A view of **3c** is shown in Fig. 2. The Fe–C(1) distance [2.22(1) Å] is substantially longer than the Fe–C(2)–(5) distances [2.090(9), 2.029(9), 2.028(9), 2.075(9) Å; suggesting that the cyclopentadienone ring C(1)–(5) is coordinated to the Fe centre essentially in an $\eta^4$-mode (**3A**) [C(1)–C(2) 1.43(1), C(1)–C(5) 1.48(1), C(2)–C(3) 1.42(1), C(3)–C(4) 1.50(1), C(4)–C(5) 1.42(1) Å], like an $\eta^4$-diene ligand. However, the considerably elongated C(1)–O bond [1.26(1) Å] and the lowered wavenumber of the $\nu$(C=O) vibration (Scheme 1) are indicative of a minor contribution of the iron(II) $\eta^5$-cyclopentadienoxyl structure (**3B**), where the unpaired electron is localized on the oxygen atom and the Fe centre attains an 18e configuration. The cyclopentadienone ring is located virtually parallel to the $C_5Me_5$ ring [Fe–C($C_5Me_5$) 2.06–2.10(1) Å], and the two Ph groups at the 2 and 5 positions are arranged almost coplanar with the central five-membered ring to extend the conjugated $\pi$ system.

A possible formation mechanism of **2** and **3** is summarized in Scheme 2. Initial photodecarbonylation followed by coordination of the alk-1-yne gives an $\eta^2$-alkyne intermediate **4**. Subsequent insertion of the C≡C moiety into the Fe–C≡ bond with the orientation of the substituent directing toward the metal centre gives an ynenyl species **5**. In the case of the reaction with methyl propynoate, a sequence of (*i*) further insertion of the acetylene substrate **6**, (*ii*) insertion of the terminal PhC≡C part into the Fe–C($sp^2$) bond, and (*iii*) coordination of the ester C=O moiety would give **2**. On the other hand, the reaction of

| | R | Yield (%) | ν(C=O) / $cm^{-1}$ |
|---|---|---|---|
| **3a** | $CH_2Ph$ | 28 | 1545 |
| **3b** | $SiMe_3$ | 23 | 1547 |
| **3c** | Ph | 60 | 1550 |
| **3d** | Bu | 32 | 1551 |
| **3e** | $Bu^t$ | 38 | 1553 |

**Scheme 1**

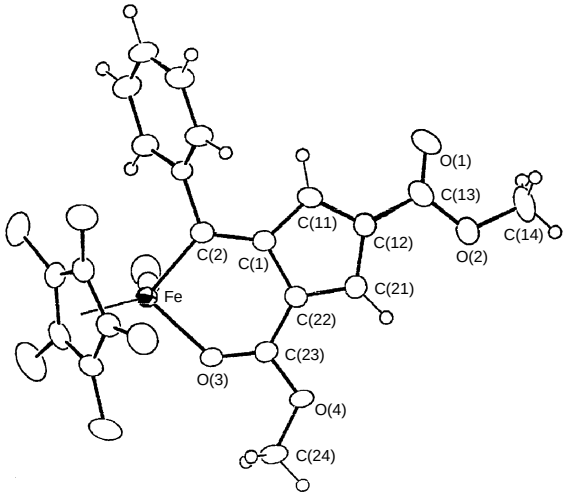


**Fig. 1** Molecular structure of **2** with thermal ellipsoids drawn at the 30% probability level. Selected bond distances (Å): Fe–C(2) 1.922(4), Fe–O(3) 1.995(3), C(2)–C(1) 1.406(6), C(1)–C(11) 1.435(6), C(1)–C(22) 1.451(6), C(11)–C(12) 1.379(6), C(12)–C(21) 1.428(6), C(21)–C(22) 1.365(6), C(22)–C(23) 1.427(6), C(23)–O(3) 1.234(5), C(13)–O(1) 1.197(6).

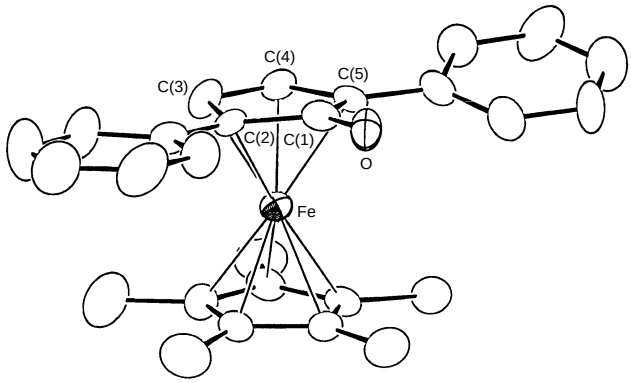

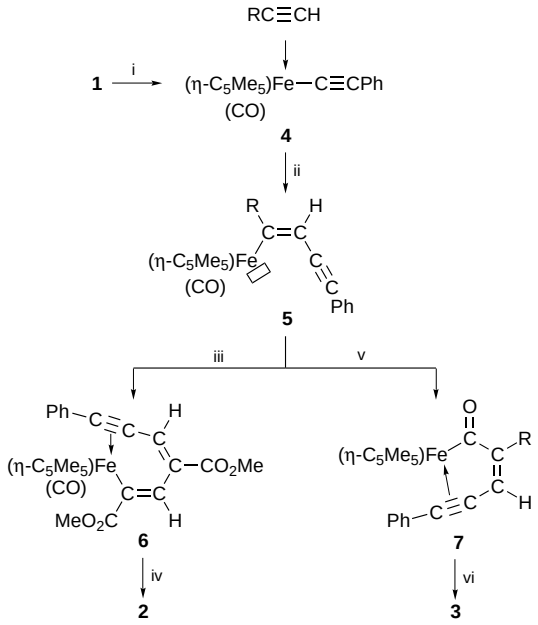

**Fig. 2** An overview of **3c** with thermal ellipsoids drawn at the 30% probability level

**Scheme 2** i, Photodecarbonylation and coordination of RC≡CH; ii, insertion of alk-1-yne; iii, insertion of a second molecule of alk-1-yne; iv, insertion of the PhC≡C part and coordination of the ester C=O group; v, CO insertion; vi, PhC≡C insertion and H abstraction

alk-1-yne with a non-coordinating substituent follows CO insertion of the ynenyl moiety to form the acyl intermediate **7**. Successive ring closure *via* C≡C insertion and H abstraction from the reaction medium gives the cyclopentadienone complex **3**. The reaction pathways may depend on the nucleophilicity of the α-carbon atom of the ynenyl group in **5** as well as the coordinating ability of the alk-1-yne substituent (R).

In summary, a C≡C functional group incorporated in a metal coordination sphere readily inserts into the M–C≡ bond to form a conjugated system *via* C–C coupling. The obtained 17e species **3**, which can be viewed as a dehydrogenated form of the classical hydroxyferrocene or a paramagnetic counterpart of well known cyclopentadienone complexes,[4] belongs to a rare class of iron(I) compounds.[6] Despite the paramagnetic character, **3** is air stable and passes through an alumina column. A study on the physical properties and reactivity of **3** is now under way.

# A versatile route to $[Ru_3(CO)_{11}(alkyne)]$ complexes

**Silvio Aime,*† Walter Dastrù, Roberto Gobetto, Luciano Milone and Alessandra Viale**

*Dipartimento di Chimica Inorganica, Chimica Fisica e Chimica dei Materiali, V. Pietro Giuria 7, 10125 Torino, Italy*

**Alkynes react at low temperature with $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ to afford the novel $[Ru_3(CO)_{11}(alkyne)]$ complexes, which correspond to the first stage of the coordination of alkynes to metal clusters and are the precursors of the previously reported $[Ru_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}alkyne)]$ derivatives.**

Although the reactions between alkynes and trimetallic carbonyl clusters $[M_3(CO)_{12}]$ (M = Fe, Ru, Os) have been under intense scrutiny in the last two to three decades and a large number of derivatives have been characterized,[1] no report has yet appeared on derivatives corresponding to the first step of alkyne coordination, *i.e.* to $[M_3(CO)_{11}(alkyne)]$ species containing an alkyne ligand coordinated in a $\eta^2$-mode to a single metallic centre. It is reasonable to think that the lack of observation of these compounds is an indication of their instability and their prompt transformation to $[M_3(CO)_x(alkyne)]$ derivatives:[2,3] [eqn. (1); M = Fe, $x$ = 9; M = Ru, Os, $x$ = 10].

$$[M_3(CO)_{12}] + \text{alkyne} \xrightarrow{-CO} [M_3(CO)_{11}(\text{alkyne})] \xrightarrow{-CO} [M_3(CO)_x(\text{alkyne})] \quad (1)$$

Thus the thermally activated dissociation of CO ligands from $[M_3(CO)_{12}]$ occurs at temperatures which appear to be too high to allow the observation of detectable amounts of $[M_3(CO)_{11}(alkyne)]$ derivatives.

A way to overcome this problem lies in the possibility of forming the coordinatively unsaturated '$Ru_3(CO)_{11}$' species at low temperature and then to allow its reaction *in situ* with the alkyne ligand.

Some years ago, Keister and coworkers[4] reported that $[Ru_3H(\mu\text{-}H)(CO)_{11}]$, in the presence of carbon monoxide, decomposes cleanly to $[Ru_3(CO)_{12}]$ (97% isolated yield). They also showed that the kinetics of this conversion are first order in $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ and independent of CO concentration. The proposed mechanism consists of the reductive elimination of $H_2$ (through a three-centre transition state) leading to the formation of the coordinatively unsaturated '$Ru_3(CO)_{11}$' intermediate.

On the basis of this background information, we thought that $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ may represent an interesting 'lightly stabilized' derivative[5] for carrying out substitution reactions at low temperature.

The reaction between $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ and acetylene was carried out directly in the NMR tube, in $CD_2Cl_2$ at 183 K. After few minutes the $^1H$ NMR spectrum of the reaction mixture shows two doublets at $\delta$ 8.45 and 5.97 ($^3J_{HH}$ 8.6 Hz) assigned to $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$, and two singlets at $\delta$ 5.42 and 1.80 assigned to free $C_2H_4$‡ and $C_2H_2$ respectively. The $^{13}C$ NMR spectrum at 183 K of the reaction mixture obtained by using a $^{13}CO$-enriched sample of $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ is shown in Fig. 1. In the spectrum there are eleven carbonyl resonances of equal intensity at $\delta$ 215.0, 196.1, 194.9, 193.8, 193.1, 191.1, 190.1, 189.0, 188.4, 187.8 and 185.9.

As we approach ambient temperature, we observe that the transformation of $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$ to $[Ru_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}C_2H_2)]$ takes place as clearly assessed from both $^1H$ and $^{13}C$ NMR spectroscopy.[3] The observation of distinct $^1H$ and $^{13}C$ resonances for all the ligands present in $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$ is indicative of a 'frozen' asymmetric structure in which the acetylene occupies an axial coordination site. The observation of a carbonyl resonance significantly downfield shifted ($\delta$ 215.0) is reminiscent of a semi-bridging ligand which 'disperses' excess of charge to a neighbouring metallic centre. This may be an indication of the occurrence of some interaction of the acetylene ligand with a second ruthenium centre as shown in Fig. 2. The source of molecular asymmetry would then arise from a partial alignment of the alkyne ligand along one of the metal–metal bonds and this arrangement anticipates to some extent the coordination geometry found in $[Ru_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}alkyne)]$.[3]

An estimation of the distance between the two hydrogens in the alkyne moiety was obtained by measuring the $^1H$ NMR relaxation times at 213 K. Both hydrogens show the same $T_1$ value of 1.6 s. On the assumption that the relaxation pathway is largely dominated by the dipolar contribution, the $r_{HH}$ distance can be determined by eqn. (2):[6]

$$\frac{1}{T_1} = \frac{3}{2}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\gamma_H^4 \hbar^2 \tau_c}{r^6} \quad (2)$$

where $\mu_0$ is the magnetic susceptibility in a vacuum, $\gamma_H$ is the gyromagnetic value for a proton and $\tau_c$ is the molecular reorientational time of the complex. Since $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$ and $[Ru_3(CO)_{12}]$ have very similar molecular sizes, we used a value of 172 ps for $\tau_c$ at 213 K as evaluated from a recent NMR relaxation study of $[Ru_3(CO)_{12}]$.[7] The obtained $r_{HH}$ distance is 2.48 Å. On the basis of a carbon–carbon distance of

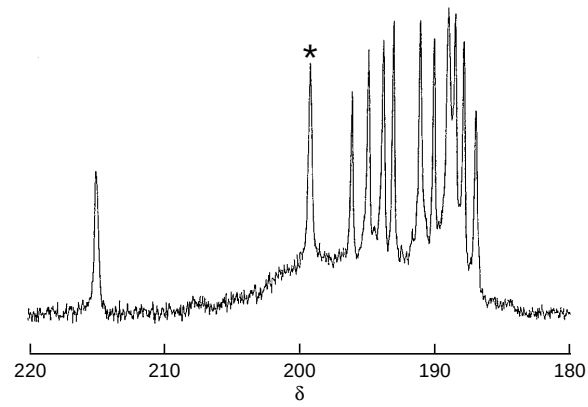

**Fig. 1** $^{13}C\{^1H\}$ NMR spectrum of a $^{13}CO$ enriched sample of $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]\{CD_2Cl_2$, 183 K; * is assigned to $[Ru_3(CO)_{12}]\}$

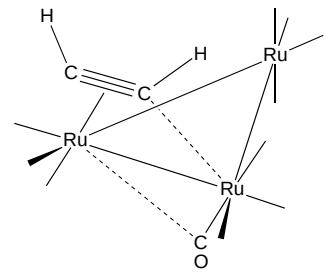

**Fig. 2** Proposed structure for $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$

1.27 Å (as found for mononuclear systems containing an $\eta^2$-bonded acetylene molecule[8]) and a carbon–hydrogen distance of 1.1 Å an average value of 123.5° for the H–C–C angle was obtained.

Analogous results were obtained when $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ was reacted with substituted acetylenes. In the case of phenylacetylene only one of the two possible isomers of $[Ru_3(CO)_{11}(\eta^2\text{-}HC_2Ph)]$ was detected as clearly established by the single resonance for the acetylenic proton observed at $\delta$ 6.18 in the NMR spectrum.

In summary the results herein reported show that $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ may represent a useful starting material for the synthesis of $[Ru_3(CO)_{11}L]$ derivatives where L may be an alkyne as well as a number of other two-electron donor ligands. This novel synthetic route to $[Ru_3(CO)_{11}L]$ species may also provide useful insights into the further development of the cluster–surface analogy,[9] since the first stages of the chemisorption processes are probably represented by the interaction of Lewis-base substrates at single metallic centres followed by the eventual set-up of multicentre bonding schemes.

We thank Ministero dell' Università e della Ricerca Scientifica e Tecnologica (MURST) and the Consiglio Nazionale delle Ricerche (Comitato 03) for financial support.

## Footnotes

† E-mail: aime@ch.unito.it

‡ The detection of $C_2H_4$ seems to imply that the reactivity of $[Ru_3H(\mu\text{-}H)(CO)_{11}]$ could not be limited to the loss of $H_2$ to give '$Ru_3(CO)_{11}$'. Another mechanism involving intermediates like $[Ru_3H_2(C_2H_2)(CO)_{11}]$ and $[Ru_3H(CHCH_2)(CO)_{11}]$ which react with $C_2H_2$ to yield $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$ and $C_2H_4$ may occur. However, it has been observed that $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$ is also formed in the reaction between $[Ru_3(CO)_{11}(NCMe)]$ and $C_2H_2$ at room temperature {even if it can be detected only in small amounts as it rapidly transforms to $[Ru_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}C_2H_2)]$}.[10] As MeCN is known to be a good leaving group, this observation supports the view that $[Ru_3(CO)_{11}(\eta^2\text{-}C_2H_2)]$ may be formed *via* the intermediate '$Ru_3(CO)_{11}$' species.

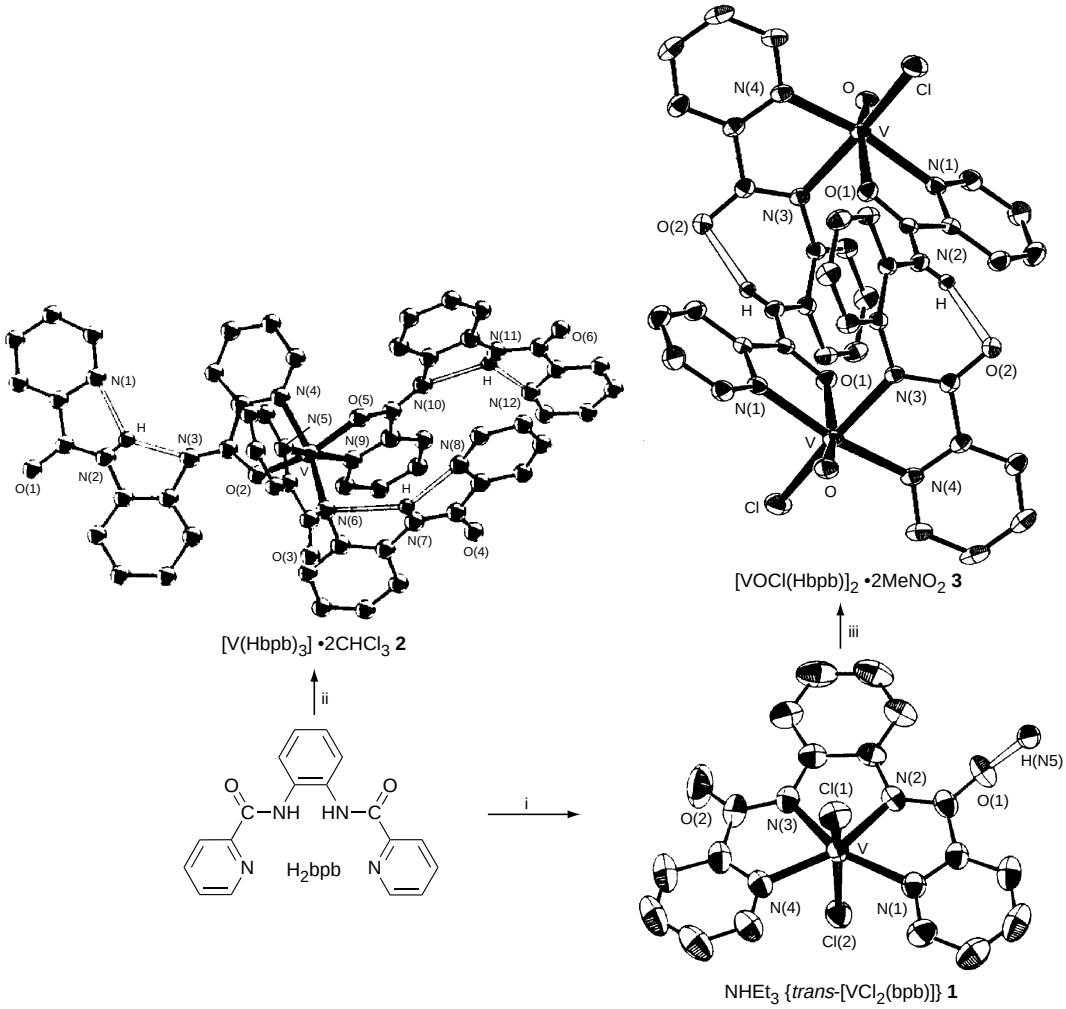
# Novel vanadium(III/IV) compounds with the diamidate ligand 1,2-bis(2-pyridinecarboxamide)benzene ($H_2$bpb)



**Antonis T. Vlahos,[a] Themistoklis A. Kabanos,*[a] Catherine P. Raptopoulou[b] and Aris Terzis[b]**

[a] *Department of Chemistry, Section of Inorganic and Analytical Chemistry, University of Ioannina, 45 110 Ioannina, Greece*
[b] *NRPCS Demokritos, Institute of Materials Science, 15 310 Agia Paraskevi Attikis, Greece*

**Reaction of the diamidate ligand $H_2$bpb with $VCl_3$ depending on the base affords either the compound $NHEt_3${*trans*-$[V^{III}Cl_2(bpb)]$} 1 or $[V^{III}(Hbpb)_3]\cdot 2CHCl_3$ 2; aerial oxidation–hydrolysis of 1 gives the dimeric species $[VOCl(Hbpb)]_2\cdot 2MeNO_2$ 3; the X-ray crystal structures of 1, 2 and 3 are reported.**

Vanadium is a bioessential element,[1] but its role in biological systems is not yet well understood. The synthesis as well as the structural and spectroscopic characterization of low molecular mass model complexes of the biologically important oxidation states (+II to +V) of vanadium will help in making further progress in the elucidation of the biological role of vanadium.

Currently our group[2a] in parallel with others[2b] have embarked on a study of the interaction of vanadium with the amide(peptide) functionality, –NHCO–, which is a potential metal-ion binding site in biomolecules. Herein we wish to report the synthesis and structural characterization of vanadium(III) and oxovanadium(IV) compounds, $NHEt_3${*trans*-$[V^{III}Cl_2(bpb)]$} **1**, $[V^{III}(Hbpb)_3]\cdot 2CHCl_3$ **2** and $[V^{IV}OCl(Hbpb)]_2\cdot 2MeNO_2$ **3** (Scheme 1). The structure of **1** is the first example of a vanadium(III) centre that is bound by two deprotonated amidate nitrogens, while the structures of **2** and **3** are the first examples of vanadium(III/IV) centres with simultaneous ligation of a deprotonated amide nitrogen and of an amide oxygen from two different amide functionalities.

**Scheme 1** Synthesis and X-ray crystal structures of complexes **1**, **2** and **3**. *Conditions*: i, $VCl_3$, $NEt_3$, toluene; ii, $VCl_3$, $NH_3$, toluene; iii, $CH_3NO_2$, air. Selected interatomic distances (Å): for **1**, V–N(3) 1.996(2), V–N(2) 2.016(2), V–N(4) 2.136(2), V–N(1) 2.141(2), V–Cl(1) 2.350(1), V–Cl(2) 2.357(1). For **2**, V–O(5) 1.936(3), V–O(2) 1.974(3), V–N(6) 2.011(4), V–N(9) 2.114(4), V–N(5) 2.118(4), V–N(4) 2.186(4). For **3**, V–Cl 2.355(1), V–O 1.587(2), V–N(3) 2.086(2), V–N(4) 2.115(2), V–N(1) 2.145(2), V–O(1) 2.217(2).

Refluxing a mixture of vanadium(III) chloride (1.30 mmol), $H_2$bpb (1.30 mmol) and triethylamine (6.50 mmol) in dry toluene under argon for 14 h yielded the mononuclear brick red complex **1** and $NHEt_3Cl$ [eqn. (1)].

$$VCl_3 + H_2bpb + 2NEt_3 \rightarrow NHEt_3\{trans[VCl_2(bpb)]\} + NHEt_3Cl \quad (1)$$

**1**

By layering diethyl ether into a chloroform solution of **1** and $NHEt_3Cl$ brick-red crystals of complex **1** (yield 20%) suitable for X-ray structure analysis† were obtained. Because the solubilities of complex **1** and $NHEt_3Cl$ were almost identical in various organic solvents **1** could not be separated from $NHEt_3Cl$ and so gaseous ammonia (bubbling) was substituted for triethylamine whereupon crystals of **2** were obtained in a very low yield (5%) (this is under further investigation). When a nitromethane solution of **1** was exposed to the atmosphere the dimeric species **3** is formed as green crystals (yield 80%).

As shown in Scheme 1, the structure of complex **1** exhibits distorted octahedral coordination at the vanadium centre. The two chlorine atoms are *trans* and the angle Cl(1)–V–Cl(2) is bisected by the plane defined by the four nitrogen atoms of the ligand $bpb^{2-}$. The mean $V–N_{amide}$ bond length [2.006(2) Å] is slightly longer (0.024 Å) than the only other known vanadium(III)–amidate distance[2a] and this might be due to the stronger, dianionic ligand set in complex **1**, which results in a lower effective charge on the vanadium(III) centre and therefore longer V–N distances. The bond lengths to N(1) [2.141(2) Å] and N(4) [2.136(2) Å] the pyridine nitrogens lie at the lower limit of $V–N_{py}$ distances seen in the literature.[2a,3] The V–Cl bond lengths [V–Cl(1) 2.350(1), V–Cl(2) 2.357(1) Å] are in the range expected for vanadium(III) complexes.[2a,4] Comparison of the structure of complex **1** described herein with its iron analogue,[5] *i.e.* $NHEt_3\{trans$-$[FeCl_2(bpb)]\}\cdot MeCN$, reveals a close similarity, except that there is a small reduction in the average V–N bond length (*ca.* 0.04 Å) [V–N (av.) 2.07(8), Fe–N (av.) 2.11(1) Å] that results in a slight increase of the *cis*-bite angles of the vanadium complex.

The structure of complex **3** (Scheme 1) consists of discrete dimers. The vanadium(IV) centres are related by a centre of symmetry. In this dimeric species, each vanadium has a distorted octahedral environment and is bonded to two pyridine nitrogens, one amidic oxygen, one amidic nitrogen (from two bridging $\mu_2$-$\eta^4$-$Hbpb^-$ ligands), to a chlorine atom and to an oxo group. The ligated pyridine nitrogens are *trans* to each other and the amidic oxygen is *trans* to the oxo ligand. The V=O and the V–Cl (the chlorine atom is *cis* to the oxo group) bond lengths of 1.587(2) A and 2.355(1) Å, respectively, are in good agreement with those reported in the literature for octahedral oxovanadium(IV) compounds.[6,7] The $V–O_{amide}$ bond distance [2.217(2) Å] is almost identical with the only other known vanadium(IV)–amidate O distance[6] [2.206(1) Å], while the $V–N_{amide}$ bond [2.086(2) Å] is substantially longer (*ca.* 0.09 Å) than the mean $V–N_{amide}$ distance [2.00(1) Å] for various oxovanadium(IV)–amidate compounds,[2] and this might be due to the substantial deviation from planarity of the bridging ligand $Hbpb^-$. Compound **3**, unlike the double-helical complexes of Constable *et al.*,[8] resembles instead the non-helical dimer of Williams and coworkers.[9]

While the formation of **1** is straightforward, the reasons for the preferential formation of **2** when ammonia is substituted for triethylamine are not at all clear. The vanadium atom in **2** is coordinated to three singly deprotonated chelated rings ($\eta^2$-$Hbpb^-$) in a distorted octahedral coordination, environment with two different modes of coordination, *i.e.* $N_{py},O_{am}$ (two chelate rings) and $N_{py},N_{am}$ (one chelate ring). One might expect a tris-chelate vanadium(III) complex through pyridine and deprotonated amide nitrogen atoms, since the deprotonated amides normally coordinate *via* N.[10] To this general trend there are only two other exceptions.[11,12] Steric hindrance, or strong preference of the vanadium(III) centre for oxygen ligation might be an explanation for amidate-O ligation and not deprotonated amidate-N ligation in two chelate rings of **2** (theoretical calculations are under way).

We gratefully acknowledge support of this research by the Greek General Secretariat of Research and Technology (Grant No. 1807/95) and Mrs F. Masala for typing the manuscript of this paper.

# Low-temperature water–gas shift reaction over gold deposited on $TiO_2$

**Hiroaki Sakurai,*† Atsushi Ueda, Tetsuhiko Kobayashi and Masatake Haruta**

*Osaka National Research Institute, AIST, Midorigaoka 1, Ikeda, Osaka 563, Japan*

**Gold exhibits very high catalytic activities, comparable with that of a conventional $Cu/ZnO/Al_2O_3$ catalyst, for forward and reverse water–gas shift reactions when supported on titanium oxide by the deposition–precipitation method.**

The water–gas shift reaction is used as one of the important industrial processes to adjust the $CO/H_2$ ratio for methanol synthesis and to produce $H_2$ for ammonia synthesis. For this reaction, two kinds of catalysts are commercially used.[1] One is a high-temperature shift catalyst, which is based on iron oxide structurally promoted with chromium oxide and is used in the temperature range 583–723 K and at 2.5–3.5 MPa. Another is a low-temperature shift catalyst composed of copper, zinc oxide and alumina, and is used between 483 and 513 K. Recently, Andreeva *et al*. reported that Au deposition enhances the catalytic activity of iron oxide for the water–gas shift reaction.[2,3] The activity is comparable with that of a conventional copper catalyst. Here, we report a novel and more active catalyst, Au deposited on $TiO_2$, which contains neither copper nor iron oxide, but exhibits low-temperature activities both for the forward and reverse water–gas shift reactions.

The catalysts were prepared by deposition–precipitation (DP) of gold hydroxide from $HAuCl_4$ on titanium dioxide powder (P25, Japan Aerosil Co.).[4] To obtain fine gold particles, magnesium citrate solution was added during preparation.[5,6] The catalyst was finally calcined in air at 673 K. Gold loading in the starting solutions is expressed as atom% [100Au/(Au+M) for $Au/M_xO_y$]. For comparison, other gold and copper catalysts were prepared by coprecipitation (Cop) and impregnation (Imp) methods.

Table 1 shows the catalyst parameters and some kinetic data under forward water–gas shift conditions. Other than Au catalysts, a commercial $Cu/ZnO/Al_2O_3$ catalyst (Catalysts and Chemicals Inc., Far East) was examined for comparison. The reactant gas containing CO (1%), $H_2O$ (2%) and He (balance) was fed at a space velocity of 12 600 $h^{-1}$ ml (g cat)$^{-1}$ and under a pressure of 0.1 MPa, and the introduction of $H_2O$ was carried out using a micro-feeder or by bubbling. At 373 K, CO conversion was < 20% and much lower than the equilibrium conversion (99.97%), therefore, the reaction rate, TOF, and activation energy were calculated around this temperature. The catalysts tested were stable during catalytic activity measurements and the change of CO conversion during 2.5 h was less than < 0.5%. In the calculation of TOF for supported metal catalysts, generally, the number of exposed metal atoms is determined by titration using CO and $H_2$. In the case of supported gold, the titration method is not applicable because of the lack of irreversible stoichiometric adsorption of these molecules on the surface of gold. The number of gold atoms exposed to the surface was thus simply calculated from the mean diameter of the gold particle. The shape of the gold particles deposited on the $TiO_2$ surface was well defined and hemispherical by TEM observation.[4]

**Table 1** Catalytic activity of supported gold catalysts for the water–gas shift reaction[a]

| Catalyst[b] | $D_{metal}$[c] /nm | Rate at 373 K/mol $s^{-1}$ (g cat)$^{-1}$ | TOF at 373 K/$s^{-1}$ | $E_a$/kJ $mol^{-1}$ |
|---|---|---|---|---|
| $Au/TiO_2$(DP, 3.4%)[d] | 4.4 | $1.0 \times 10^{-7}$ | $7.9 \times 10^{-4}$ | 46 |
| $Au/TiO_2$(DP, 5%)[d] | — | $1.4 \times 10^{-7}$ | — | 45 |
| $Au/TiO_2$(DP, 10%)[d] | 4.4 | $3.0 \times 10^{-7}$ | $9.2 \times 10^{-4}$ | 31 |
| $Au/TiO_2$(Cop, 33%)[d] | 2.8 | $6.4 \times 10^{-8}$ | $5.6 \times 10^{-5}$ | 47 |
| $Au/Fe_2O_3$(Cop, 5%) | 3.3 | $2.2 \times 10^{-8}$ | $9.1 \times 10^{-5}$ | 52 |
| $Au/Al_2O_3$(Cop, 5%) | 3.7 | $3.4 \times 10^{-8}$ | $1.1 \times 10^{-4}$ | 24 |
| Au/ZnO(Cop, 5%) | 4.9 | $9.0 \times 10^{-9}$ | $5.7 \times 10^{-5}$ | 34 |
| $Cu/ZnO/Al_2O_3$[e] | 13.4 | $1.2 \times 10^{-7}$ | $2.0 \times 10^{-4}$ | 53 |

[a] Reactant gas CO(1%)–$H_2O$(2%)–He(balance); SV = 12 600 $h^{-1}$ ml (g cat)$^{-1}$; pressure 0.1 MPa. [b] DP, deposition–precipitation; Cop, coprecipitation, Au loading in atom%. [c] Calculated from XRD by using Scherrer's equation. [d] Addition of magnesium citrate during preparation. [e] Commercial catalyst, with Cu content of 42 atom% by XRF analysis.

Particle sizes of Au and Cu given in Table 1 were calculated from the XRD data. The titania powder P25 is composed of both anatase and rutile. Because the broad diffraction peaks for gold overlapped with these diffraction lines, the diffraction profile of $TiO_2$ itself was mathematically subtracted from the profile of $Au/TiO_2$, and then the Au particle size was calculated by using Scherrer's equation. It was found that Au was deposited on the oxide surface with diameters < 5 nm.

Among gold catalysts (Table 1), $Au/TiO_2$ showed the highest reaction rates. While the reaction rate at 373 K increased with increasing Au loading for a series of $Au/TiO_2$ catalysts prepared by the deposition–precipitation method, $Au/TiO_2$ prepared by coprecipitation showed a lower rate despite the higher metal loading and the smallest gold particle sizes. This may be attributed to differences in exposure of gold particles on the surface and the crystalline nature of $TiO_2$ depending on the preparation method. The activation energies listed in Table 1, except for $Au/Al_2O_3$ and Au/ZnO, are close to the reported values for $Cu/Al_2O_3$ (55.6 kJ $mol^{-1}$) and $Au/Al_2O_3$ (48.8 kJ $mol^{-1}$), both prepared by incipient wetness impregnation.[7] However, the reaction rate and turnover frequency were very different depending on the preparation method. The TOF reported for $Au/Al_2O_3$(Imp) was only 1/342 that of the value for $Cu/Al_2O_3$(Imp).[7] On the other hand, $Au/Al_2O_3$(Cop) was more active and had half of the TOF of the $Cu/ZnO/Al_2O_3$ catalyst. The activities of $Au/TiO_2$ (DP) were much more striking. The rates of reaction at 373 K were comparable and the TOF was more than 4 times higher than that of $Cu/ZnO/Al_2O_3$. Although this comparison is not made under industrial reaction conditions and the lifetime (the commercial Cu catalyst has a lifetime of *ca*. 2–4 years by adding the alumina component[1]) has not yet been examined, the results clearly show that gold is potentially as active as copper, when highly dispersed on suitable support oxide.

Fig. 1 shows the activities of gold catalysts under the reverse water–gas shift conditions. The reactant gas mixture $CO_2$(23%)– $H_2$(67%)–Ar(balance) was passed through the catalyst bed at a space velocity of 3000 $h^{-1}$ ml (g cat)$^{-1}$ and under a pressure of 0.1 or 5 MPa. Catalytic activities are expressed by $k$ defined as $[CO][H_2O]/[CO_2][H_2]$. The concentration of each component was calculated from analytical data and the material balance equations.[8] Au on $TiO_2$ and $Al_2O_3$ showed higher activities than $Au/Fe_2O_3$, and the most active $Au/TiO_2$ reached thermodynamic equilibrium at a temperature as low as 423 K at 5 MPa. However, $Au/TiO_2$ and $Cu/TiO_2$

prepared by impregnation methods were only poorly active, and did not reach equilibrium even at 673 K.

As reported previously, these gold catalysts produce methanol, methane and other hydrocarbons under such high- pressure conditions, and the product selectivity greatly differs depending on the nature of the oxide supports.[8–10] When the total pressure was decreased from 5 to 0.1 MPa, the activity decreased as shown in Fig. 1, however, CO selectivities were very much improved. For example, $Au/TiO_2$ produced methanol, methane and CO with selectivities of 4, 10 and 86%, respectively, at 523 K and 5 MPa, CO selectivity reached values > 99% at 0.1 MPa.

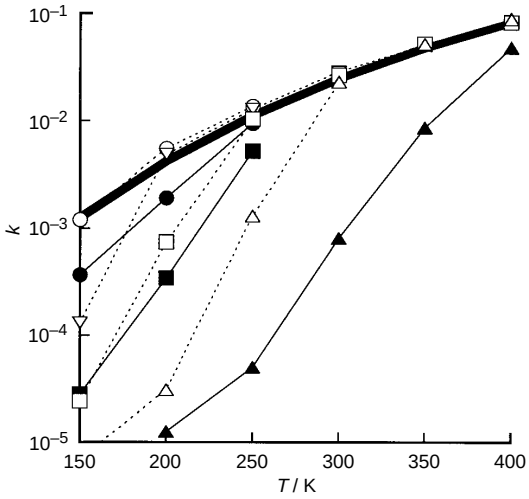

**Fig. 1** Catalytic activities of supported gold catalysts for the reverse water–gas shift reaction. Reactant gas mixture $CO_2$(23%)–$H_2$(67%)–Ar(balance); SV = 3000 $h^{-1}$ ml (g cat).$^{-1}$ Activities are expressed in terms of $k$ at a total pressure of 5 MPa over (○) $Au/TiO_2$ (DP, 2 atom%), (▽) $Au/Al_2O_3$ (Cop, 5 atom%), (□) $Au/Fe_2O_3$ (Cop, 5 atom%), (△) Au/ZnO (Cop, 5 atom%) and 0.1 MPa over (●) $Au/TiO_2$ (DP, 2 atom%), (■) $Au/Fe_2O_3$ (Cop, 5 atom%), (▲) Au/ZnO (Cop, 5%). The thick continuous line shows the thermodynamic equilibrium limit.

Gold deposited on $TiO_2$ is known to exhibit very high activity for CO oxidation to $CO_2$ even below 273 K.[4,5] $CO_2$ formation is further enhanced when moisture is added to the reactant mixture of CO and air.[11] This enhancement is not due to the shift reaction of CO and water because the shift activity is almost zero at 273 K under the conditions used here.

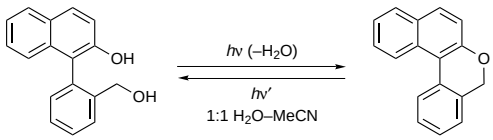
# Photocyclization of a 1,1′-bisnaphthalene: planarization of a highly twisted biaryl system after excited state ArOH dissociation

**Yijian Shi and Peter Wan***

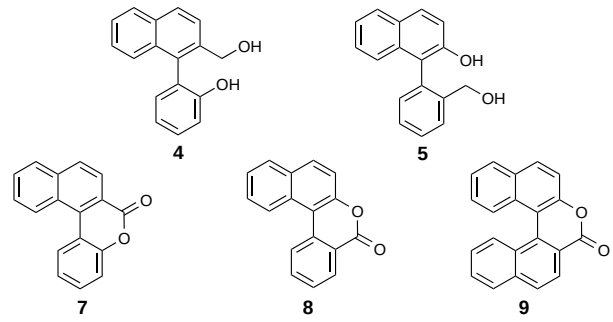
*Department of Chemistry, Box 3065, University of Victoria, Victoria, British Columbia, Canada V8W 3V6*

**Photolysis of the highly twisted 1,1′-bisnaphthalene 6 gives the much more planar dinaphthopyran 10 with high quantum yield (Φ = 0.17) in aqueous MeCN, demonstrating that the expected enhanced electronic communication between the connected aromatic rings of biaryls in $S_1$ is sufficient to drive thermally unfavourable reactions requiring initial planarization of these biaryl systems.**



Twisted ground state structures of biphenyls and biaryls in general become much more planar when electronically excited.[1] However, this phenomenon has been utilized only on a limited basis to design or induce new photochemistry.[2] We demonstrated several years ago that photolysis of twisted (dihedral angle of 72°) 2-(2′-hydroxyphenyl)benzyl alcohol **1** in aqueous solution or in 100% MeCN gave the essentially planar 5*H*-dibenzo[*b*,*d*]pyran **3** *via* the proposed *o*,*o*′-biphenyl quinone methide **2** with high quantum efficiency (Φ up to 0.5) [eqn. (1)].[2c,d] We wondered whether the reaction could be

**1** **2** **3** (1)



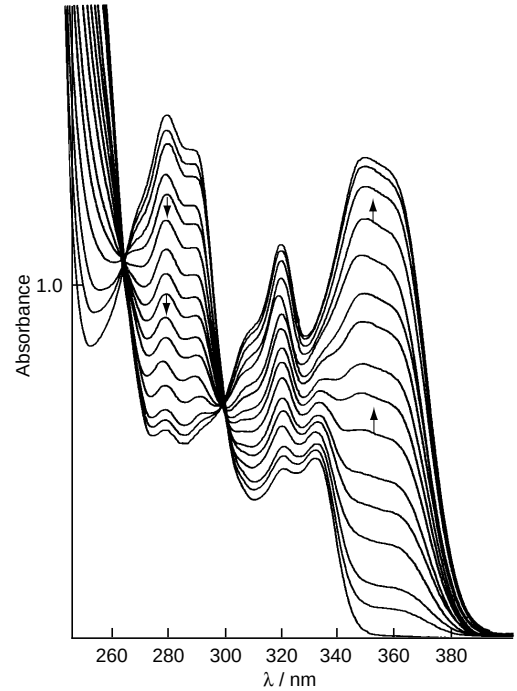
extended to binaphthyls and related compounds since large biaryls are of interest in a variety of areas including supramolecular chemistry where photoflexible systems are useful as photoswitches,[3] and as ligands in catalysis design.[4] Since 1,1′-binaphthyls are more twisted than biphenyls in general due to the additional steric interactions from introduction of two additional benzene rings, the notion that electronically excited binaphthyls can undergo extensive twisting to a more planar form even under these additional constraints would be relevant chemical information for use in supramolecular chemistry where large torsional motions are of intrinsic value in molecular switching.

Biarylmethyl alcohols **4**–**6** were made *via* LAH reduction of the corresponding lactones **7**–**9**, which were synthesized according to method of Bringmann *et al*.[5] All of **4**–**6** were smoothly converted to their corresponding pyrans on photolysis in MeCN or aqueous MeCN at 254 nm [*e.g.* eqn. (2)].† Shown

**6** **10** (2)

in Fig. 1 is the UV–VIS spectra for conversion of **6** to pyran **10** in 1 : 1 $H_2O$–MeCN at 254 nm showing the clean conversion to almost 100% **7**, with Φ = 0.17. Photolysis of the pyran **10** at > 350 nm resulted in > 50% conversion back to **6** illustrating the reversibility of the photoreaction. Although reaction of **5** was clean and reversible, the quantum yield for cyclization (Φ ≈ 0.04) was substantially lower than observed for **4** and **6** (*vide infra*). Molecular mechanics calculations of **5** and **6** and an X-ray crystal structure‡ of **4** showed that these biaryls are highly twisted with dihedral angles approaching 90°. However, the corresponding pyran products are much more planar. For example, the dihedral angle for **10** (the most non-planar of the pyrans products) is 37° from X-ray crystallography.‡ Thus, these photocyclizations involve a very substantial twisting motion to planarity on the excited state surface. Moreover, the photoreversibility of the reaction shows that there is an equally substantial twisting motion out of planarity in the ring opening reaction, which formally requires conrotatory motion of the orbitals involved (a photochemically induced electrocyclic ring opening). Indeed, the degree of twisting motion displayed in these systems on photolysis approach those observed for *cis*–*trans* photoisomerization of alkenes.

**4** **5** **7** **8** **9**



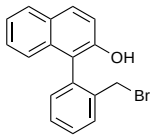


**Fig. 1** UV–VIS traces of conversion of **6** to **10** on photolysis of at 254 nm in 1 : 1 $H_2O$–MeCN. Each trace taken after about 5–20 s irradiation in a UV cuvette.

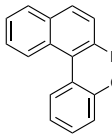
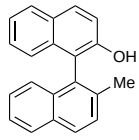
Bromide derivative **11** was photolyzed in 1 : 1 $H_2O$–MeCN and gave **10** in > 90% yield ($\Phi \approx 0.35$) along with a dramatic decrease in the pH of the aqueous solution (from pH 7 to 2.6) indicating that these binaphthyl systems can also photo release strong acid concurrent with geometric change [eqn. (3)]. The



**11**

$$\xrightarrow[\text{1:1 } H_2O\text{–MeCN}]{h\nu} \mathbf{10} + \text{HBr} \qquad (3)$$



additional fact that **11** was found to be thermally stable to 125 °C makes these systems potentially useful for the photodeprotection of esters and related functional groups by making the required naphthylmethyl derivatives from bromide **11**.

The twisting motion of biaryls towards planarity on the excited state surface has been generally rationalized[2a,6] by noting that the coefficients of the two carbons joining the two aryl rings in the LUMO have the same sign whereas they have opposite sign in the HOMO. Thus population of the LUMO on electronic excitation causes an increase in the π-bond strength joining the two aryl groups; hence a twisting motion to a more planar structure.

However, simple twisting of the two aryl rings to a more planar geometry on electronic excitation does not completely explain why these compounds cyclize and lose water. Additional chemical steps are required, *viz.* dissociation of the hydroxynaphthalene (or phenol) proton and loss of hydroxide ion from the arylmethyl (benzylic) position to form the corresponding biaryl naphthoquinone methide. In our first report of this type of reaction[2c] [eqn. (1)], we were not able to address whether twisting took place before proton dissociation from the phenol or *vice versa*, or that they took place together, although it was clear that the phenolate ion in the excited state was the reactive species. We now report that a better understanding is available for **4**–**6**. We have studied the fluorescence behaviour of model compounds **12** and **13** (for **4** and **6**, whose fluorescence were too weak for proper study due to their high photoreactivity for cyclization) and **5** (which is sufficiently fluorescent), and found that there is a correlation

**12**

**13**

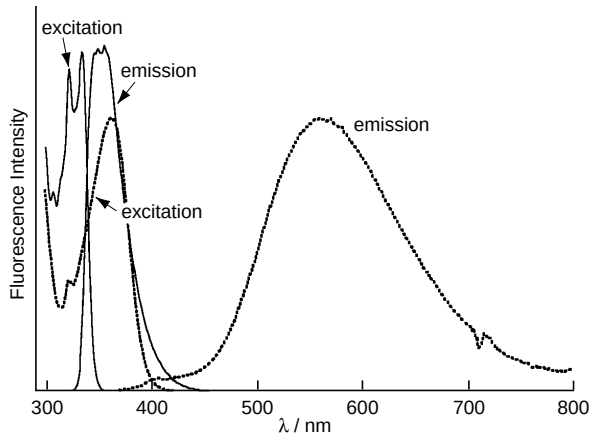


**Fig. 2** Fluorescence excitation and corrected emission spectra of **13** in 100% MeCN (solid lines) and in 1 : 1 MeCN–0.01 mol $dm^{-3}$ NaOH (dashed lines). The measured Stokes shifts are 1700 and 7500 $cm^{-1}$ for the protonated (ArOH) and naphthoate ($ArO^-$) forms of **13**, respectively.

between the amount of observed Stokes shift (a useful measure of the degree of change in geometry between the Franck–Condon and the fluorescent states)[1] and the quantum efficiency of cyclization.

All of **5**, **12** and **13** display only a modest Stokes shift in 100% MeCN (*ca.* 1700 $cm^{-1}$, Fig. 2) where the fluorescence is from the protonated form. This implies that the degree of twisting of the excited protonated phenol or naphthol is insignificant. However, when their fluorescence spectra were taken in pH 12 (excitation of the phenolate or naphthoate forms), the Stokes shifts of the emission from the deprotonated forms were substantial for **12** and **13** (*ca.* 7500–8000 $cm^{-1}$) (Fig. 2) but much less for **5** (*ca.* 3000 $cm^{-1}$). We can conclude that these systems twist to become more planar only after (adiabatic) excited state deprotonation. That is, the mechanism for cyclization must involve initial adiabatic deprotonation from the twisted (Franck–Condon) structure followed by twisting to a more planar form, which then loses hydroxide ion from the arylmethyl position to generate the required (naphtho)quinone methide intermediate. The much lower quantum yield of cyclization observed for **5** is most likely due to the lesser degree in which this system is capable of twisting (to the more planar form) after deprotonation although the exact reasons for this is unknown at this time. A possible explanation we are currently investigating is that there is a dependence of the degree of twisting and the amount of available electron density to the $ArCH_2OH$ moiety from the electronically excited $ArO^-$ ring. We believe the above new results and improved understanding of the reaction mechanism will help us design supramolecular systems which can incorporate these chromophores for use as photoactivatable systems.

We acknowledge support of this research by the Natural Sciences and Engineering Research Council (NSERC) of Canada.

## Footnotes

† Oxygen had no measurable effect on these photocyclizations. The fluorescence results reported here and previously[2c,d] indicate that these are most likely reactions from the singlet excited state. Although we have not been able to directly observe the proposed *o,o′*-biaryl quinone methides by nanosecond laser flash photolysis (presumably due to their very short lifetimes), we have observed[2d] similar quinone methides when they cannot cyclize to the corresponding pyrans. This argues in favour of a photocyclization mechanism *via* such intermediates rather than, for example, simple displacement of the hydroxide of the methylene carbon by the phenol oxygen.

‡ Details of the X-ray crystal structure analyses will be published in due course.

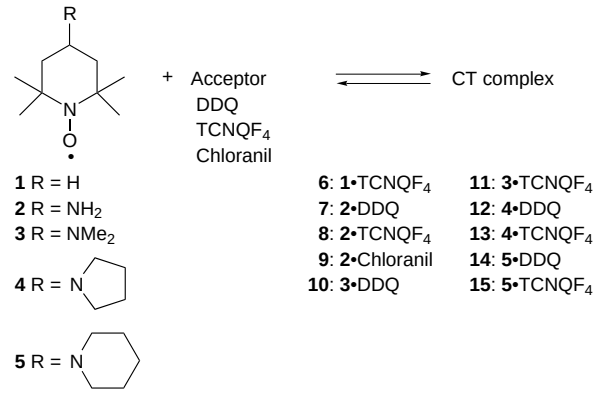
**TEMPO (2,2,6,6-tetramethylpiperidinyloxy) radical 1 and its derivatives 2–5 are found to form charge-transfer complexes with some acceptors such as $TCNQF_4$ (2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane) or DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone) being isolated as solid substances.**

The development of new molecular magnetic materials, especially organomagnetic materials is current interest and a number of compounds carrying stable radicals as the key building blocks have been prepared and their magnetic behaviour has been elucidated in recent years.[1] In the course of our study for the development of new organomagnetic compounds, we have been interested in preparing some donor or acceptor molecules carrying stable radicals, especially TEMPO radicals, and the charge-transfer (CT) complexes derived therefrom to build up and to arrange the spins in the solid state/crystal structures.[2] Here we report that some TEMPO radicals themselves are able to form CT complexes with appropriate acceptors, that is to say, TEMPO radicals can act as donors to form CT complexes which can be isolated as solids.

When TEMPO radical **1** was treated with an equimolecular amount of $TCNQF_4$ in acetonitrile, the resulting deep-blue solid was confirmed by elemental analysis to be the 1 : 1 complex **6**. Moreover, bands corresponding to the $TCNQF_4$ radical anion, at 856 and 753 nm in acetonitrile were clearly observed in the visible absorption spectrum of **6** and the lower wavenumber of νCN (νCN 2190 $cm^{-1}$) observed in its IR spectrum compared with the neutral acceptor ($TCNQF_4$: νCN 2237 $cm^{-1}$) was also consistent with the formation of the CT complex **6** (Table 1).† To our knowledge, this is a rare example of a isolated charge-transfer complex in which a radical acts as a donor (Scheme 1).[3,4]‡

**Table 1** Summary of magnetic data of **1**–**5** as well as complexes **6**–**15**



| Compound | Magnetic interaction | $\theta^a$/K |
|---|---|---|

| **13** | antiferromagnetic | −0.3 |
| **14** | antiferromagnetic | −6.2[c] |
| **15** | antiferromagnetic | −0.9 |

[a] Fitting for Curie–Weiss rule. [b] *Cf.* ref. 5 in text. [c] Short-range order is suggested from the susceptibility data in this case.

A magnetic susceptibility measurement on **6** was carried out on a polycrystalline sample using a SQUID susceptometer in the temperature range 2–300 K. It was found from the data that while TEMPO **1** itself shows antiferromagnetic interactions with a Weiss constant θ of −3.0 K,[5] a drastic decrease of magnetic susceptibility was observed in complex **6** suggesting a strong tendency for singlet formation between the radical centres.§

An X-ray analysis of single crystals of **6** grown by recrystallization from acetone gave confirmative structural elucidation of the complex as shown in Fig. 1.¶ Relatively small bond alternation in each $TCNQF_4$ molecule of the complex **6** suggests the delocalization of π electrons on the whole molecule upon formation of the radical anion (Fig. 1, upper).[6] It is apparent from Fig. 1 that both donors and acceptors form segregated column structures along the *a*-axis with a zigzag structure in the latter. The following features are also disclosed from the analysis. (*i*) The nearest O···O distance found is that between donor molecules in the column which amounts to 6.99 Å. (*ii*) The interplanar stacking distance between $TCNQF_4$ molecules is *ca*. 6.99 Å. Partial insertion with some slipping of another $TCNQF_4$ molecule results in the zigzag column structure. (*iii*) The nearest distance between oxygen of a donor molecule and a $TCNQF_4$ molecule is that of O(1)···F(2) of 2.78 Å (Fig. 1, upper), somewhat shorter than the sum of the van der Waals radii of each atom. The magnetic behaviour of the complex would then be interpreted as follows: the charge accepted by the $TCNQF_4$ species is from TEMPO radicals which leads to the formation of oxoammonium ions, *i.e.* TEMPO is converted into $TEMPO^+$ resulting a singlet while the loss of the spins of $TCNQF_4$ radical anions is supposed to be derived from their columnar structure as described above.

Following the results obtained above, we then prepared a series of similar CT complexes derived from 4-amino-TEMPO

**Scheme 1**

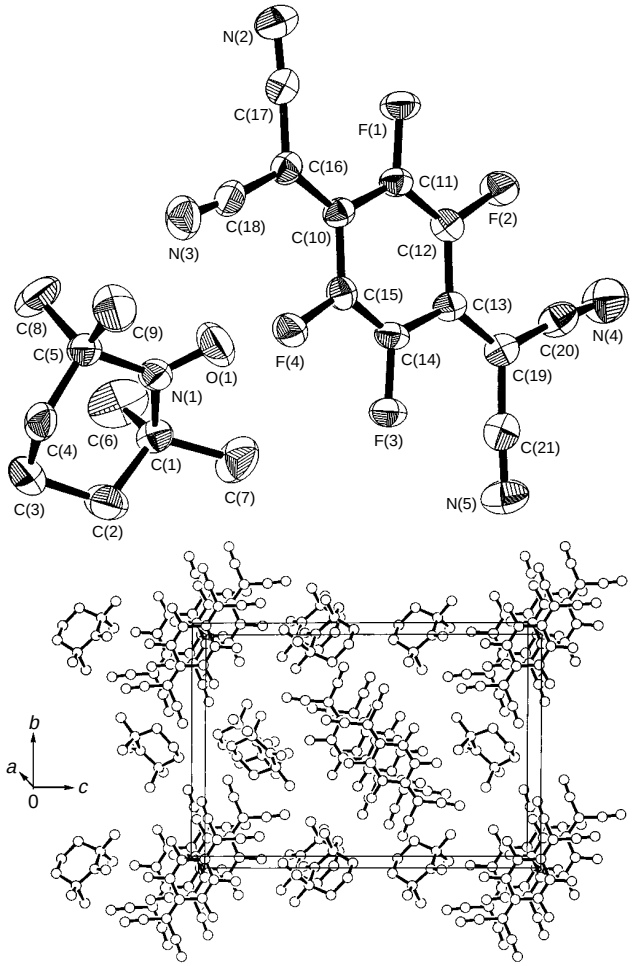

**Fig. 1** Upper: structure of **6**. Lower: crystal structure of **6** viewed almost along the *a* axis. Selected interatomic distances (Å) and angles (°): O(1)–N(1) 1.195(5), N(1)–C(1) 1.526(6), N(1)–C(5) 1.531(6), O(1)–N(1)–C(1) 117.6(5), O(1)–N(1)–C(5) 117.2(5), C(1)–N(1)–C(5) 125.2(5), C(10)–C(11) 1.423(6), C(11)–C(12) 1.350(7), C(12)–C(13) 1.418(7), C(13)–C(14) 1.416(7), C(14)–C(15) 1.340(7), C(10)–C(15) 1.414(7), C(10)–C(16) 1.407(7), C(13)–C(19) 1.398(7).

**2** and its alkylated derivatives **3**–**5** (Scheme 1) having stronger electron-donating ability than **1**.[4]‖ The latter radicals (**3**–**5**) were prepared by the reductive amination of 4-oxo-TEMPO with alkyl amines using sodium cyanoborohydride as a reducing reagent and those radicals **2**–**5** gave complexes with weaker acceptors than $TCNQF_4$, *e.g.* DDQ or chloranil. As summarized in Table 1, acceptor-dependent antiferromagnetic or ferromagnetic interactions were suggested in each complex on the basis of their Weiss constants, *e.g.* for the complexes prepared from 4-amino-TEMPO **2**, weak ferromagnetic interactions were suggested in the DDQ complex **7** or chloranil complex **9** ($\theta$ = 0.1 K for both) while antiferromagnetic interactions were suggested in the $TCNQF_4$ complex ($\theta$ = −1.0 K). Among other complexes prepared from 4-alkylated amino-TEMPO derivatives **3**–**5**, short-range antiferromagnetic spin order in the very low-temperature region was suggested for the complex **14** as depicted in Fig. 2.

In summary, we have prepared a series of CT complexes **6**–**15** based on TEMPO radicals having variable and acceptor-dependent magnetic behaviour. The TEMPO–$TCNQF_4$ complex **6** was structurally elucidated by X-ray analysis to rationalize its low magnetic susceptibility.

Because the CT complexes could be easily prepared from simple nitroxyl radicals and acceptors and because the finding described above may be possibly applied to a variety of hitherto known nitroxyls, it would be expected to enrich sources of novel

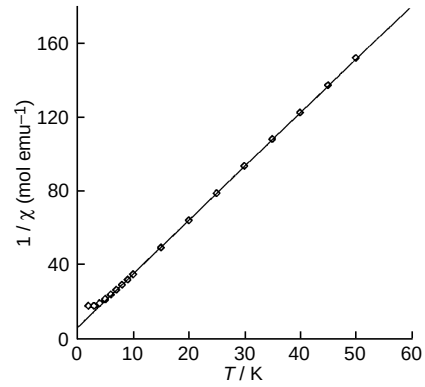

**Fig. 2** Temperature dependence of 1/χ below 50 K for complex **14**. The straight line was drawn to show deviation from Curie–Weiss behaviour in the lower temperature region.

organomagnetic materials and further studies to prepare related complexes and their single crystals are now under way.

This research was supported by a Grant-in-Aid for Scientific Research on Priority Area 'Molecular Magnetism' (No. 228/04242104) from the Ministry of Education, Science and Culture, Japan and a Scientific Research Grant from The Foundation of Himeji Institute of Technology, which are gratefully acknowledged.

## Footnotes

† In the EPR spectrum of **6**, triplet absorptions due to the nitroxy radical were observed in acetone solution, suggesting partial dissociation of the complex in the solution.

‡ Independently and almost at the same time, Sugawara and coworkers have prepared and isolated a charge-transfer complex based on *p*-dimethylamino-nitronyl nitroxide and chloranil.

§ The Curie constant *C* for **6** was very low with a value of $1.57 \times 10^{-3}$ emu K $mol^{-1}$.

# Hydrothermal synthesis of an iron silicate with layered structure

**Ramesh B. Borade and Abraham Clearfield**

*Department of Chemistry, Texas A&M University, College Station, TX 77840, USA*

**A method is provided for the synthesis of a crystalline layered iron silicate using a particular reaction gel composition containing an organic directing agent and possessing significant quantities of iron (Si/Fe = 38.6) in trivalent oxidation state; the present layered iron silicate has a structure related to kenyaite and/or silica-X.**

Kenyaite is a hydrous sodium silicate mineral first found in the lake beds of Lake Magadi in Kenya.[1] Synthetic forms of similar silicates using potassium instead of sodium ions, with layered structures, were subsequently prepared.[2–5] Synthetic kenyaite has the chemical formula $K_2Si_{20}O_{41}{\cdot}xH_2O$. The intercalation behaviour of this material was used to establish its layered structure. The crystal structure of kenyaite remains unknown at present. The layered silicate, identified as silica-X, was first reported by Heidemann.[6] Silica-X was synthesized hydrothermally using silicic acid and KOH solution at 175 °C for 3–10 days,[6,7] Attempts made by Greenwood,[8] to synthesize silica-X using silicic acid and $Na^+$, $Mg^{2+}$ and $NH_4^+$ cations instead of $K^+$, were unsuccessful. However, the synthesis of silica-X using diaquat-4 halide[9] and of kenyaite using poly-(diethyldiallylammonium chloride)[5] as a structure-directing template is reported in the literature. Incorporation of Al in kenyaite or silica-X by synthetic routes was also achieved.[5,9] Comparison of X-ray powder diffraction patterns of silica-X with kenyaite suggests that these materials are closely related to each other. Here, we report the synthesis of an iron silicate with a kenyaite/silica-X type structure using hexamethyleneimine (HMI) as template.

A typical procedure to synthesize the iron containing layered silicate is as follows. Solution A was obtained by adding appropriate quantities of water and the nitrogen-containing template to a sodium silicate solution (27% $SiO_2$, 14% NaOH and 69% water, Aldrich). Solution B was prepared by dissolving iron(III) sulfate [$Fe_2(SO_4)_3{\cdot}5H_2O$, Fluka] in water. Then, solution B was added (dropwise addition) to A. The addition of the $Fe_2(SO_4)_3{\cdot}5H_2O$ solution is a crucial step. Slow addition produces a lemon-coloured solution and fast addition produced a red–brown mixture. When addition was complete, the mixture was stirred for another 20 min. Finally, conc. $H_2SO_4$ (98%, EM Science) was added to adjust the final pH of the mixture. The final mixture was a lemon-coloured turbid solution with the chemical formula: 20–40 $SiO_2$ : 1 $Fe_2O_3$ : 9.8 $Na_2O$ : 13.7 HMI : 1360 $H_2O$ : 9.8 $H_2SO_4$. This solution was then transferred into stainless-steel autoclaves of 300 ml capacity, which were heated at 150 °C for 15 days without stirring. The resultant solid product was recovered by filtration and washed with demineralized hot water. This product is denoted as as-made kenyaite. The Na-form of the sample was prepared by air calcination of the as-made sample at 540 °C for 4 h. This material was repeatedly ion-exchanged with 5 M ammonium chloride solution at 80 °C to obtain the $NH_4$-form of kenyaite. The H-form was obtained by calcination of the $NH_4$-form in air at 400 °C for 2 h. Using this procedure, highly crystalline iron silicate samples with input $SiO_2/Fe_2O_3$ ratios of 20–40 were obtained.

The X-ray powder diffraction pattern was obtained on a Rigaku Ru200 automated powder diffractometer using Cu-Kα radiation (λ = 1.5418 Å). The XRD pattern, presented in Fig. 1, is similar to kenyaite and or silica-X type materials. Scanning electron micrographs of the iron silicate (Fig. 2) show spherical

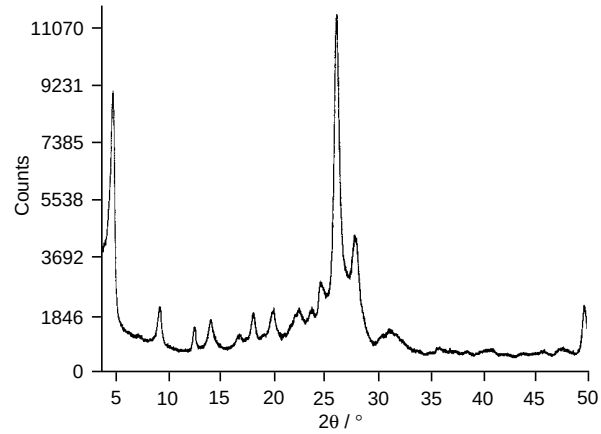

**Fig. 1** X-Ray powder diffraction pattern of iron-containing kenyaite (as-made)

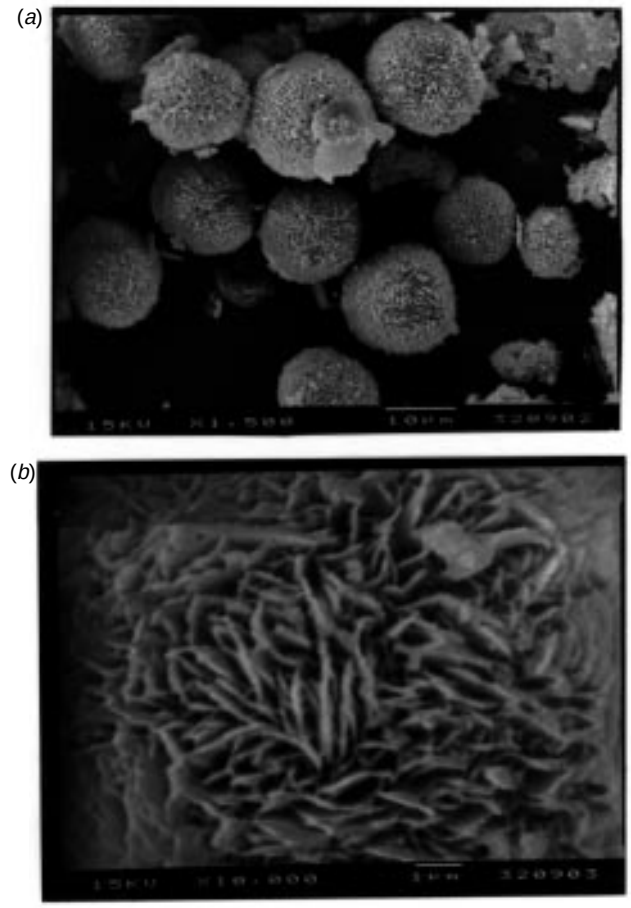

**Fig. 2** Scanning electron micrographs of iron-containing kenyaite at different magnifications

particles 5–15 μm in diameter. The spherical aggregates are made up of a variety of thin stacked crystals in rosette form. This platelet morphology is very similar to those of kenyaite[5] and ferrierite type materials.[10,11] After calcination at 540 °C for 4 h, the peak at 3.25 Å disappeared completely and all peaks were shifted towards lower *d* values. The relative shift in *d* values was significant for the first two peaks. For kenyaite, Eugster[1] indexed these two peaks as 001 and 002 reflections, assuming tetragonal symmetry. In as-synthesized iron silicate these 00*l* reflections appear at 20.2 and 10.1 Å and in the calcined sample at 17.6 and 8.8 Å. Similar observations have been made by Schwieger *et al.*[5] for kenyaite. TGA experiments were carried out using a DuPont (Model 951) thermal analyser. About 20 mg of the sample was placed in a quartz bucket and heated in a nitrogen–oxygen atmosphere at a heating rate of 10 °C $min^{-1}$. The TGA curve clearly showed three mass losses. The first step (25–200 °C) is due the desorption of water and the second (200–600 °C) and third steps (600–950 °C) are due to desorption/decomposition of the organic template and dehydroxylation of iron silicate, respectively. The (Na + organic)/(Si + Fe) ratio in as-made kenyaite is 0.073/1. The mass loss associated with each step was 4.7, 6.6 and 4.0%, respectively. That the third step is indeed due to dehydroxylation and not due to the residual carbon was confirmed by carrying out additional TGA experiments with $Na^+$ and $H^+$ forms of kenyaite containing no template. The chemical composition and sorption capacity of iron silicate are reported in Table 1. The constancy in the Si/Fe ratio before and after ion exchange indicates that Fe is not present in occluded form or in ion-exchangeable sites. Sorption data presented in Table 1 suggest that the iron silicate of the present study sorbs water as well as *n*-hexane in amounts 3–4 times greater than silica-X.[9] The measured $N_2$ BET surface area of the iron silicate was 170 $m^2$ $g^{-1}$.

The presence of most of the Fe in the trivalent oxidation state and indeed situated in the layered silicate framework position is confirmed by studying the O 1s XPS and EPR spectra of iron silicate. The surface Si/Fe ratio determined by XPS was 32.8 and by bulk chemical analysis 38.9 for the Na-form of the iron silicate indicating a somewhat inhomogeneous Fe distribution and/or the presence of a small amount of extraframework iron oxidic species on the surface of the sample. In addition, the O 1s XPS spectra (not shown) gave a main peak at 532.4 eV and a shoulder at 530.7 eV corresponding to oxygen species associated with the silicate framework and extraframework iron oxidic species, respectively. The relative area contribution due to the shoulder peak to the main O 1s peak was *ca*. 13%. When the Na-form of the iron silicate was exchanged with $NH_4Cl$ the relative contribution of the O 1s shoulder peak to the main peak reduced to 7%, indicating that there are some iron oxidic species that can be washed away by $NH_4^+$ treatment. Since the Na/Fe ratio was close to 1 in the Na-form of the material, the possibility of the presence of Fe in an ion-exchangeable site is less likely. It is obvious that these excess Fe species must be occluded iron oxidic/hydroxidic species. The formation of such small amounts of extraframework iron oxidic species during the synthesis of iron-containing zeolites was previously observed.[12–14] X-Band EPR spectra were obtained at room temperature using a Bruker ER-200 D spectrometer. The spectrum shown in Fig. 3 shows four signals at $g = 2.0$, *ca*. 2.9, 4.3 and 9.6. The signal at $g = 4.3$ in conjunction with the signal at $g = 9.6$ is commonly assigned to incorporation of $Fe^{3+}$ on a strongly distorted rhombic site.[15–18] The signal at $g = 2.8$ has been assigned to Fe as iron oxidic or hydroxidic phases. This is consistent with the O 1s XPS results. The signal at $g = 2.0$ may be due to framework or non-framework $Fe^{3+}$ species.[15] These two species can be distinguished by EPR by conducting dehydration–rehydration studies with the same sample. Thus, an EPR study in combination with XPS clearly shows the presence of most of the $Fe^{3+}$ in framework positions. The FTIR spectra of chemisobed $NH_3$ revealed the formation of $NH_4^+$ ions (*ca*. 1460 $cm^{-1}$) with Brønsted-acid sites indirectly suggesting that Fe is present in the framework position.[19]

To summarize, synthesis of an iron silicate with a kenyaite and/or silica-X type material using a hexamethyleneimine template is reported.

The authors acknowledge with thanks the R. A. Welch Foundation for partial support of this study under grant No. A673.

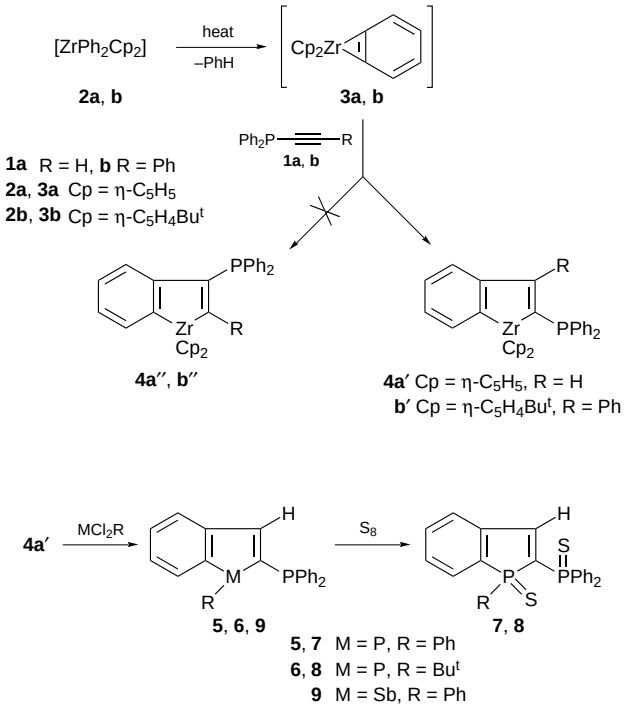
# Stereoselective synthesis of 2-phosphino-1-zirconaindenes and related 2-phosphinophospholes and stiboles

**Y. Miquel,[a] A. Igau,[a] B. Donnadieu,[a] J.-P. Majoral,*[a] L. Dupuis,[b] N. Pirio[b] and P. Meunier*[b]**



[a] *Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cedex, France*
[b] *Laboratoire de Synthèse et d'Electrosynthèse Organométalliques associé au CNRS (UMR 5632), Université de Bourgogne, Faculté des Sciences Gabriel, 6 boulevard Gabriel, 21000 Dijon, France*

**2-Phosphinophospholes and stiboles are prepared from the reaction of benzynezirconocene with alkynylphosphines followed by addition either of dichlorophosphines or a dichlorostibene.**

The development of new and practical methods of stereoselective synthesis of main-group element derivatives is currently among the major objectives of a number of research groups throughout the world. Our ongoing investigations concern the study of interactions between group IV element and main-group element species[1] and are focused on the discovery of new methodologies of ring formation, opening or expansion but also on the preparation of ligands which have been regarded as laborious to prepare by conventional means.

The present report deals with an efficient synthesis of substituted zirconaindene compounds and their use as starting reagents for the formation of a variety of 2-phosphinophospholes and of a 2-phosphinostibole. Indeed phospholes[2] continue to attract considerable attention because of their use in different fields (*e.g.* catalysis, coordination chemistry) and therefore there is a need to diversify ways of preparation of these useful phosphorus heterocycles as well as the nature of these derivatives. To the best of our knowledge only one report described the preparation of a 2-thiophosphinophosphole which was obtained *via* a sequence of reactions involving metallation of the 1-phenyl-3,4-dimethyl-2-thiophosphole followed by addition of diphenylchlorophosphane.[3]

Treatment of the alkynylphosphine **1a** with [$ZrPh_2(\eta\text{-}C_5H_5)_2$] **2a** in benzene at 80 °C for 6 h leads to the formation of a phosphinozirconaindene **4a** arising from insertion of the carbon–carbon triple bond of **1a** into a zirconium–carbon bond of the transient benzyne zirconocene **3a**. The reaction gave rise to only one phosphorus species as indicated by $^{31}P$ NMR spectroscopy (**4a**, δ 6.9) (Scheme 1). **4a** was further characterized by $^{1}H$ and $^{13}C$ NMR† but the spectroscopic data did not distinguish between the two possible structures for **4a**: the 2-phosphinozirconaindene form **4a′** or the 3-phosphinozirconaindene form **4a″**. In order to have a better knowledge of the structure of **4a**, exchange reactions with phenyl or *tert*-butyl dichlorophosphanes were attempted. Addition of these dichlorophosphanes $RPCl_2$ to a solution of **4a** in thf afforded the phosphinophosphol derivatives **5** (R = Ph) or **6** (R = $Bu^t$) (Scheme 1). $^{31}P$ NMR spectra exhibit as expected two doublets [**5**, δ −14 ($PPh_2$), 10.6 (PPh); **6**, δ −12 ($PPh_2$), 3.7 ($PBu^t$)] with a large $^{2}J_{PP}$ of 50 Hz for **5** and 52 Hz for **6**. Compounds **5** and **6** were fully characterized as their disulfide adducts **7** and **8** {**7**, δ($^{31}P$) 39.2 [$P(S)Ph_2$], 51.4 [P(S)Ph], $^{2}J_{PP}$ 24.7 Hz; **8**, δ ($^{31}P$) 38.9 [$P(S)Ph_2$],† 78.6 [$P(S)Bu^t$], $^{2}J_{PP}$ 24.9 Hz}. Confirmation of the identity of **8** was achieved by a single-crystal X-ray study‡ which shows that the 2- and not the 3-substituted thiophosphole

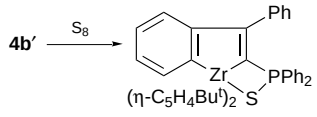
Selected bond lengths (Å) and angles (°): P(1)–C(1) 1.831(3), P(1)–C(9) 1.814(3), C(1)–C(2) 1.340(4), C(2)–C(3) 1.468(4), C(3)–C(9) 1.391(4), P(2)–C(1) 1.804(3); C(1)–P(1)–C(9) 91.4(1), P(1)–C(1)–C(2) 109.2(2), P(1)–C(1)–P(2) 130.7(2).



was formed. A molecule of **8** is shown in Fig. 1 and important bond lengths and angles are summarized.

Therefore these results clearly demonstrate that the 2-phosphinozirconaindene form **4a′** is selectively prepared when the acetylenic phosphane **1a** is treated with the benzynezirconocene **3a**.

A similar exchange reaction involving **4a′** and phenyldichlorostibene led to the formation of the corresponding 2-phosphinostibole **9** [δ ($^{31}$P) −2] (Scheme 1).

Remarkably such a stereoselective synthesis of 2-phosphinophospholes was also observed with more hindered acetylenic phosphanes such as **1b** and more hindered diphenylzirconocenes such as [$ZrPh_2(\eta\text{-}C_5H_4Bu^t)_2$] **2b**.

Indeed treatment of **1b** with **2b** affords exclusively the complex **4b′** [δ ($^{31}$P) −27.1]. Addition of $S_8$ to **4b′** led to the corresponding sulfide **10** [δ ($^{31}$P) 34.3]† (Scheme 2). Successful X-ray diffraction analysis of a single crystal of **10**‡ shows several interesting features (Fig. 2). First, it corroborates that, here also, the insertion reaction of the benzynezirconocene **3b** into the carbon–carbon triple bond of **1b** is stereoselective and leads to an α-substituted zirconaindene. Secondly the structure reveals an interaction between zirconium and sulfur. The Zr–S distance is 2.797(1) Å, and compares well, for example, with the Zr–S bond lengths found in compounds with a chelating dithiocarbamate ligand such as [$ZrCl(S_2CNEt_2)(\eta\text{-}C_5H_5)_2$] [Zr–S 2.635(2), 2.723(2) Å].[4,5]

**10**

**Scheme 2**

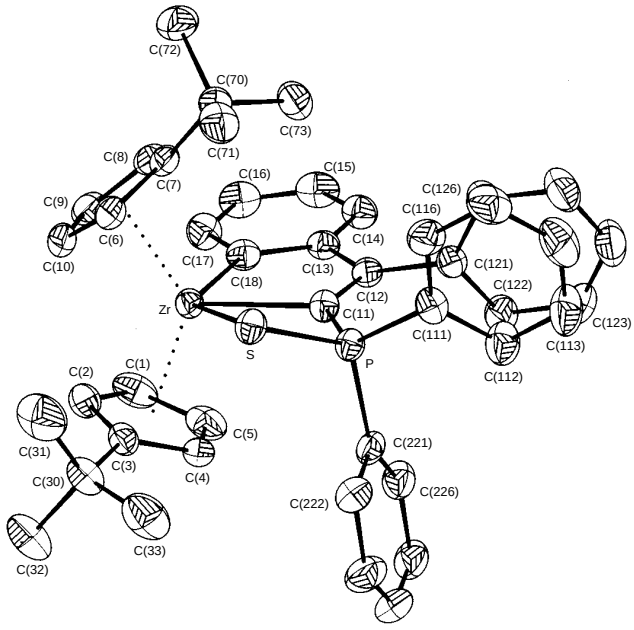


**Fig. 2** Molecular structure of **10** with crystallographic numbering scheme. Selected bond lengths (Å) and angles (°): P–S 2.005(1), P–C(1) 1.749(3), S–Zr 2.797(1), Zr–C(1) 2.490(4), Zr–C(8) 2.580(3), C(8)–C(3) 1.391(4), C(3)–C(2) 1.406(5), C(1)–C(2) 1.389(6), Zr–C(1)–P 106.4(2), Zr–S–P 85.4(4).

As a consequence the P–S bond length is found to be slightly larger [2.005(1) Å] than those generally observed for thiophosphoryl groups (1.93–1.95 Å). Indeed, the P–S bond length lies in between those of a single and a double P–S bond.

In conclusion, we have discovered a new and easy approach to the synthesis of 2-phosphinophospholes and a related 2-phosphinostibole. The remarkable stereoselectivity in these reactions arises from the strong interaction between the phosphorus lone pair in **1a** or **1b** and zirconium in **3a** or **3b**. Such an interaction has been already demonstrated to be the driving force in many reactions involving phosphorus and zirconium.[6]

## Footnotes

† Satisfactory analytical and/or spectral data were obtained for all new compounds. *Selected spectroscopic data* for compounds **8** and **10**. For **8**: DCIMS, *m/z* 439 ([M + 1]$^+$, 100%). NMR: $\delta_H$ ($C_6D_6$) 1.06 [d, $^3J$(HP) 18.2 Hz, 9 H, $CH_3$], 6.80–7.14 (m, 8 H, $CH_{Ph}$), 7.45 (m, 1 H, $CH_{Ph}$), 7.80 [dd, $^2J$(HP) 35.5, $^3J$(HP) 17.6 Hz, 1 H, CH], 8.18, 8.24, 8.50, 8.58 (m, 1 H, $CH_{Ph}$); $\delta_C$ 136.1 [dd, $^1J$(CP) 27.5, $^1J$(CP) 66.3 Hz, PCP], 138.1 [dd, $^1J$(CP) 78.9, $^3J$(CP) 3.2 Hz, CPBu$^t$], 140.9 [dd, $J$(CP) 17.2, $J$(CP) 22.0 Hz, CCPBu$^t$], 157.1 [dd, $^2J$(CP) 10.2, $^2J$(CP) 6.2 Hz, CH].

For **10**: DCIMS, *m/z* 727 ([M + 1]$^+$, 100%). NMR: $\delta_H$ ($C_6D_6$) 1.14 (s, 18 H, $C_5H_4Bu^t$), 5.75 (m, 4 H, $C_5H_4Bu^t$), 5.87, 6.16 (2 pseudo q, 4 H, $C_5H_4Bu^t$), 6.68 (m, 1 H, $CH_{Ar}$), 6.86–6.90 (m, 3 H, $CH_{Ar}$), 6.96–6.99 (m, 1 H, $CH_{Ar}$), 7.04–7.07 (m, 2 H, $CH_{Ar}$), 7.13–7.16 (m, 1 H, $CH_{Ar}$), 7.26–7.30 (m, 4 H, $CH_{Ar}$), 7.36–7.41 (m, 6 H, $CH_{Ar}$), 7.45–7.46 (m, 1 H, $CH_{Ar}$); $\delta_C$ 154.7 [d, $^2J$(CP) 6.3 Hz, ZrC=*C*Ph], 154.8 [d, $^1J$(CP) 33.3 Hz, ZrCP], 170.5 [d, $^3J$(CP) 5.5 Hz, ZrC=*C*], 194.2 [d, $^3J$(CP) 6.5 Hz, ZrC].

‡ Crystal data recorded on an IPDS STOE diffractometer using a φ rotation scan, Mo-Kα radiation was used (λ = 0.710 73 Å). For **8**: $C_{24}H_{24}P_2S_2{\cdot}0.5C_6H_6$, crystal dimensions 0.50 × 0.37 × 0.25 mm, monoclinic, space group *I*2/*a*, *a* = 19.156(4), *b* = 10.131(2), *c* = 28.391(6) Å, β = 109.50(2)°, *U* = 5193.8 Å$^3$; $D_c$ = 1.22 g cm$^{-3}$, μ = 3.29 cm$^{-1}$, number of reflections collected 16191, number of independent reflections 4100 ($R_m$ = 0.049), *R* = 0.0429, $R_w$ = 0.0445, GOF = 1.04.

For **10**: $C_{44}H_{35}PSZr$, crystal dimensions 0.60 × 0.50 × 0.50 mm, monoclinic, space group $P2_1/c$, *a* = 12.247(2), *b* = 19.746(4), *c* = 15.970(1) Å, β = 106.41(1)°, *U* = 3704.8 Å$^3$; $D_c$ = 1.31 g cm$^{-3}$, μ = 4.16 cm$^{-1}$, number of reflections collected 23721, number of independent reflections 4163 ($R_m$ = 0.047), *R* = 0.0314, $R_w$ = 0.0364, GOF = 0.8.

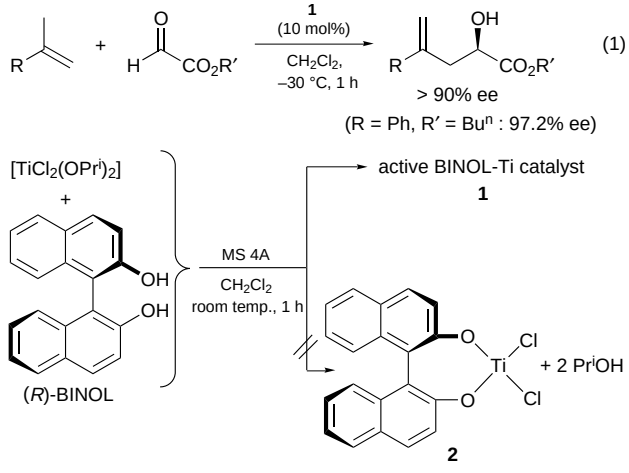
# Anomalous role of molecular sieves 4A in the preparation of a binaphthol-derived active $\mu_3$-oxo titanium catalyst

**Masahiro Terada,[a] Yousuke Matsumoto,[a] Yoshiyuki Nakamura[b] and Koichi Mikami*[a]**

[a] *Department of Chemical Technology, Tokyo Institute of Technology, Meguro-ku, Tokyo 152, Japan*
[b] *Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Midori-ku, Yokohama 27, Japan*

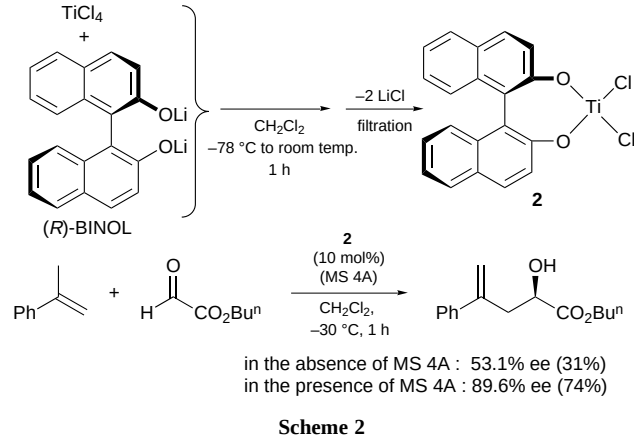
**The active species of binaphthol-derived titanium catalyst 1, which is used as an efficient catalyst for glyoxylate–ene reactions, is primarily composed of a $\mu_3$-oxo ($Ti_3O$) species, for which the molecular sieves 4A employed in the catalyst preparation act as a $H_2O$ donor.**

Recently, much attention has been focused on the development of chiral Lewis-acid catalysts for a variety of carbon–carbon bond forming reactions.[1] We have already reported the asymmetric glyoxylate–ene reaction catalysed by the chiral titanium complex **1** prepared from optically pure binaphthol (BINOL) and $[TiCl_2(OPr^i)_2]$ in the presence of molecular sieves (MS) 4A [Scheme 1, eqn. (1)].[2] The MS 4A employed in the catalyst preparation has been proven to serve as a catalyst for the ligand-exchange reaction.[2a] Thus, the structure of the active titanium catalyst is assumed to be the BINOL-derived titanium dichloride **2**. Herein we report that, by elucidating the significant role of MS 4A,[3,4] the active species of the chiral titanium catalyst **1** is not the dichlorotitanium complex **2** but a $\mu_3$-oxo species ($Ti_3O$) on the basis of $^{17}O$ NMR and elemental analyses (Scheme 1).



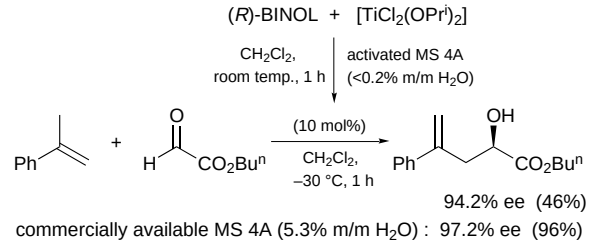
As shown in Scheme 2, it can be confirmed that the dichlorotitanium complex **2**, prepared from $TiCl_4$ and BINOL dilithium salt in dichloromethane according to the preparative procedure of dichlorotitanium 3,3′-dimethylbinaphthoxide,[5] is probably not the active species in the glyoxylate–ene reaction; the dichlorotitanium complex **2** only gives the ene product in low yield along with a low % ee.† By contrast, treatment of **2** with commercially available MS 4A‡ without activation significantly increases the chemical yield along with a higher level of % ee. These results reveal that the MS 4A converts the pre-catalyst **2** into the active BINOL–Ti catalyst **1**.

In order to elucidate the role of MS 4A to give the active catalyst **1**, the chiral titanium catalyst was prepared from BINOL and $[TiCl_2(OPr^i)_2]$ in the presence of highly activated (320 °C, < 0.05 mmHg, 12 h) and, hence, dehydrated MS 4A (< 0.2% m/m $H_2O$).[7] Inspection of the data in Scheme 3 reveals, in turn, a significant role of an 'unactivated' MS 4A; a quite low chemical yield is observed by using activated MS 4A. In contrast, titanium complex prepared in the presence of commercially available and unactivated MS 4A following our original procedure[2a,c] gives the ene product in high chemical yield with a high level of enantioselectivity. From gravimetric analysis of the $H_2O$ content in the unactivated MS 4A, the commercially available MS 4A employed in the catalyst preparation[2] is found to contain 5.3% m/m $H_2O$.§ These results, coupled with the catalytic activity, imply that $H_2O$ thus contained in MS 4A is important in giving the active BINOL–Ti catalyst **1**.¶



In order to obtain evidence for the involvement of $H_2O$ in the active catalyst **1**, we next turned our attention to the $^{17}O$ NMR analysis of the active BINOL–Ti catalyst **1**. An analytical sample of **1** was prepared from BINOL and $[TiCl_2(OPr^i)_2]$ in the presence of MS 4A doped with $H_2{}^{17}O$ [5.3% m/m $H_2{}^{17}O$ (10 atom% enriched)]. The $^{17}O$ NMR spectrum of the active BINOL–Ti catalyst **1** in $[^2H_8]$toluene reveals peaks only in the $\mu_3$-oxo ($Ti_3O$) region (δ 520–590).‖

Furthermore, elemental analysis of **1** reveals only a low amount of Cl (Found: Ti, 11.4; Cl, 0.6%; Cl/Ti = 0.07. Calc. for **2**: Ti, 11.9; Cl; 17.6%). These results strongly suggest that the MS 4A not only serves as an $H_2O$ donor to hydrolyse the titanium pre-catalyst but also as a base to trap HCl.



In summary, we have uncovered that the MS 4A, despite being a desiccant, serves anomalously as a $H_2O$ donor towards

**Scheme 1**

**Scheme 2**

**Scheme 3**

a titanium pre-catalyst and also acts as a base to trap HCl to give the active BINOL–Ti catalyst **1**. We have further disclosed by $^{17}O$ NMR spectroscopy that the active BINOL–Ti catalyst **1** is composed of $\mu_3$-oxo species.

## Footnotes

† In our previous report,[2] the dichlorotitanium complex **2** prepared in ether according to Reetz's procedure[6] exhibits high levels of enantioselectivity (93% ee). However, in our hands, the reproducibility of the enantioselectivity is poor ranging from 37 to 93% ee.

‡ Molecular sieve 4A, powder (catalogue no. 23,366-8) was purchased from Aldrich.

§ Quite recently,[8] the amount of $H_2O$ content externally introduced in MS 4A was reported to affect the % ee in an asymmetric Diels–Alder reaction catalysed by the BINOL-derived chiral titanium complex **1** prepared according to our modified procedure.[2d]

¶ Binaphthoxytitanium diisopropoxide **3**, which was prepared from $[Ti(OPr^i)_4]$ and BINOL with azeotropic removal of isopropyl alcohol and recrystallization, exhibited only low catalytic activity (12% yield), but after treatment with unactivated MS 4A, gives high chemical yield (98%) and enantioselectivity (97.3% ee) to suggest that MS 4A also acts as a $H_2O$ donor for **3**.

‖ The oxygen chemical shifts of titanium(IV) polyoxo–alkoxides have been reported to be strongly dependent on the titanium bridging mode; $\mu_3$-oxo ($Ti_3O$) and $\mu$-oxo ($Ti_2O$) oxygens have chemical shifts at $\delta$ 450–650 and 650–850, respectively.[9]

# β-*trans*-$[N_4\{P(Ph)(C_6H_{11}N)\}_4]^{4-}$; a tetraanionic ligand system exhibiting two separated tetradentate coordination sites of concave-shaped cavities

**Alexander Steiner* and Dominic S. Wright**

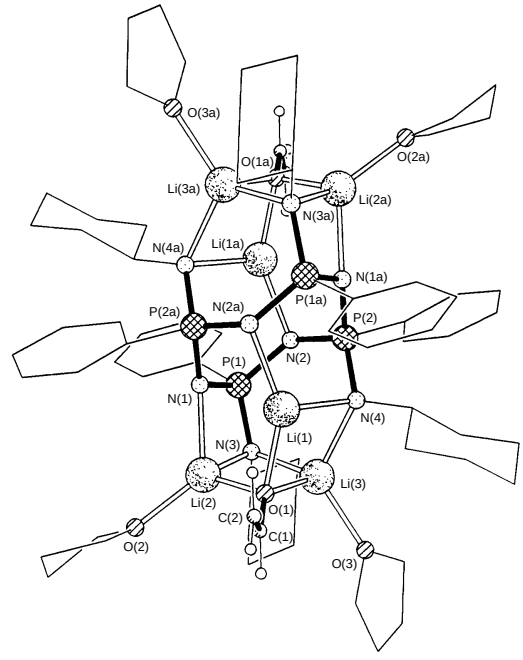
*Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

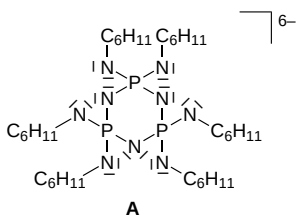
**β-*trans*-$[N_4\{P(Ph)(C_6H_{11}NH)\}_4]$ can be deprotonated at all four N–H functions with BuLi in toluene yielding $Li_4\{$β-*trans*-$[N_4\{P(Ph)(C_6H_{11}NH)\}_4]\}$, using an excess of BuLi in the presence of thf, the lithium enolate co-complex $Li_6\{$β-*trans*-$[N_4\{P(Ph)(C_6H_{11}N)\}_4](CH_2{=}CHO)_2\}\cdot 4$thf is formed, in which the tetraanionic ligand β-*trans*-$[N_4\{P(Ph)(C_6H_{11}N)\}_4]^{4-}$ exhibits two separated coordination sites; both act in a tetradentate way and form concave-shaped cavities.**

Multianionic ligand systems have scarcely been investigated in metallo-organic coordination chemistry.[1] Their high reactivity and low solubility, due to their exceptional high polarity, limit their synthetic applications in aprotic solvents. Recently we discovered, that highly charged ligand systems can be stabilized by introducing cyclophosphazene backbones into the ligand cores as shown in the hexaanionic $[N_3P_3(C_6H_{11}N)_6]^{6-}$ **A** ($C_6H_{11}$ = cyclohexyl).[2] Its structural and spectroscopic features suggest, that the negative charge is stabilised by delocalisation from the terminal amido onto the central ring-nitrogen functions. The dimeric lithium complex $Li_{12}[N_3P_3(CyN)_6]_2\cdot 4$thf **1** (Cy = $C_6H_{11}$) is soluble in aprotic solvents and therefore a potential transfer reagent for introducing this ligand system into a wide range of diverse metal complexes. In systems such as **A**, where there is an extensive surface of donating N-centres, a variety of metal coordination modes is expected. This paper is concerned with manipulating the ligand sphere of these systems by partial substitution of donating centres with organic substituents. The introduction of non-coordinating substituents should provide steric control and therefore a specific design of the ligand surface. Consequently the overall equatorial arrangement of the phosphorus-bonded phenyl substituents in the novel tetraanionic ligand system β-*trans*-$[N_4\{P(Ph)(C_6H_{11}N)\}_4]^{4-}$ **B**, presented here, should provide a sterically controlled separation of coordination sites within this ligand system.

The β-*trans* isomer of 2,4,6,8-tetraphenyl-2,4,6,8-tetrakis(cyclohexylamino)cyclotetraphosphazene **1** can be obtained with retention of configuration by the aminolysis reaction of the corresponding nongeminal tetrachlorotetraphenylcyclotetraphosphazene[3] with cyclohexylamine in the presence of triethylamine in diethyl ether in 50% yield. Further reaction with 4 equiv. of BuLi in toluene gives almost quantitatively the tetrametallated derivative $Li_4\{$β-*trans*-$[N_4\{P(Ph)(CyN)\}_4]\}$ **2**. Carrying out the reaction in thf by using an excess of BuLi yielded a colourless crystalline material, which was suitable for X-ray structure analysis‡ and could be identified as $Li_6\{$β-*trans*-$[N_4\{P(Ph)(C_6H_{11}N)\}_4](CH_2{=}CHO)_2\}\cdot 4$thf **3**. The presence of two equivalents of lithium enolate in **3** is derived from the reaction of excess BuLi with thf. However, this is a common decomposition pathway of thf in the presence of strong bases and inclusion of $CH_2{=}CHOLi$, caused by fragmentation of thf, has been reported recently.[4]

The molecular structure of **3** exhibits $C_i$ symmetry and is composed of the centrally arranged tetraanionic ligand encapsulated by two triangular $Li_3$ faces, each capped by an O-donor function of the monoanionic enolate moieties (Fig. 1). The equatorial configuration of all four phenyl substituents and the overall axial arrangement of the cyclohexylamido substituents at the puckered chair-shaped $P_4N_4$ ring separate the donating ligand surface into two coordination spheres. Both form concave-shaped cavities, due to the shielding arrangement of the surrounding organic substituents, and act in a tetradentate way *via* two terminal and two ring-nitrogen centres. Fig. 2 illustrates the central core of **3**, which approximately can be described as three interlocked distorted hexagonal prisms, in which the central one is surrounded by the $P_4N_4$ ring. Each N(r)-function (r = ring) coordinates one and each N(t)-function (t = terminal) coordinates two Li centres, resulting in three different coordination patterns towards the three crystallo-





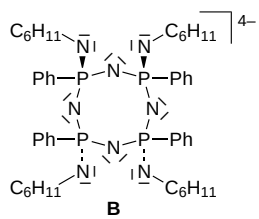


**Fig. 1** Molecular structure of **3**. Selected bond lengths (Å) and angles (°): P(1)–N(1) 1.626(6), P(1)–N(2) 1.635(6), P(1)–N(3) 1.624(6), P(2)–N(2) 1.603(6), P(2)–N(4) 1.622(6), P(2)–N(1a) 1.660(6), Li(1)–N(2a) 2.07(1), Li(1)–N(4) 2.10(1), Li(1)–O(1) 1.94(1), Li(2)–N(1) 2.08(1), Li(2)–N(3) 2.06(1), Li(2)–O(1) 1.91(1), Li(2)–O(2) 1.96(1), Li(3)–N(3) 2.09(1), Li(3)–N(4) 2.08(1), Li(3)–O(1) 2.02(1), Li(3)–O(3) 2.06(1), O(1)–C(1) 1.339(9), C(1)–C(2) 1.28(1); N(1)–P(1)–N(2) 112.9(3), N(1)–P(1)–N(3) 103.0(3), N(2)–P(1)–N(3) 119.5(3), N(2)–P(2)–N(1a) 110.0(3), N(2)–P(2)–N(4) 111.5(3), N(4)–P(2)–N(1a) 115.9(3), P(1)–N(1)–P(2a) 124.0(3) P(1)–N(2)–P(2) 127.6(4), O(1)–C(1)–C(2) 128.9(9). Atoms labelled a are generated by a centre of inversion.

graphically independent Li centres; while Li(1) and Li(3) can be seen as parts of two different six-membered heterocycles [Li(1)–N(r)–P–N(r)–P–N(t) and Li(3)–N(t)–P–N(r)–P–N(t)], Li(2) is chelated by a N(r)–P–N(t) unit. Four- and six-membered heterocyclic P–N ring-systems containing s-block metals were observed also in the presence of monoanionic linear phosphazene ligands.[5] All Li centres in **3** are further saturated by an enolate O-function, in addition Li(2) and Li(3) are coordinated by thf donor molecules, resulting in trigonal-planar [Li(1)] and tetrahedral [Li(2) and Li(3)] metal environments.

Structural parameters of the central $P_4N_8$ unit are comparable with those of the $P_3N_9$ unit in **1** and suggest an equal distribution of the negative charge onto all eight N-functions. As observed in **1** there is no significant difference in bond lengths from the phosphorus atoms toward the ring [av. P–N(4) 1.63 Å] and those toward the terminally located nitrogen centres [av. P–N(t) 1.62 Å]. On the other hand, neutral amino-substituted cyclophosphazenes exhibit significantly shorter P–N-ring bond distances compared to their terminal located counterparts, as illustrated in the structurally related β-*trans*-$[N_4\{P(Ph)(MeNH)\}_4]$ [P–N(r) 1.60 Å, P–N(t) 1.68 Å (av.)].[3b]

Ligand systems such as **A** and **B** show that there is a vast potential in multianionic ligand systems. Coordination mode and charge can be varied by formal successive substitution of donating centres with steric organic groups, thus introducing a specific design of the ligand surface. It would be interesting to investigate the nature of delocalisation of the negative charge throughout the P–N cores and its influence on coordination behaviour. There is also the possibility that anion **B** could accommodate two mixed-valent metal centres in its separate cavities, interacting electronically *via* the P–N core.[6]

We thank Dr J. M. Rawson for providing a sample of $[N_4\{P(Ph)Cl\}_4]$. A. S. gratefully acknowledges the EU Human Capital and Mobility Program for a research fellowship.

# A cluster model for the catalytic hydrogenation of CFCs and the synthesis and structural characterisation (when X = Br) of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}X)_3(PBu^t_3)_4]$ (X = Cl, Br)

**Ramón Vilar, Simon E. Lawrence, D. Michael P. Mingos* and David J. Williams**

*Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*

**The syntheses, characterisation and crystal structure (when X = Br) of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}X)_3(PBu^t_3)_4]$ (X = Cl, Br) are reported; the $\mu_3$-CF moiety is hydrogenated to $CFH_3$ under mild conditions and serves as a model for the heterogeneous hydrogenation of CFCs to HCFCs.**

The cluster–surface analogy has a long history which can be traced back to Muetterties pioneering work.[1] Molecular clusters with coordinated organic fragments have proved to be invaluable for providing definitive spectroscopic data which have been used to identify analogous species on metal surfaces.[2] The study of such systems on clean and well defined metal surfaces has implications for understanding the heterogeneous catalysed transformations of organic feedstocks. The lack of reactivity of molecular clusters, specifically catalytic reactivity, has, however, limited the development of the cluster–surface analogy.

Alkylidyne ligands have been extensively studied when coordinated to group 8 and 9 metals.[3,4] However, fluoromethylidyne cluster compounds have been structurally characterised only for iron[5–7] and molybdenum.[8] Recently, $[Pd_4(\mu_3\text{-}CH)(\mu\text{-}Cl)_3(PBu^t_3)_4]$, the first example of a palladium methylidyne cluster, has been described and structurally characterised.[9] Herein we report the syntheses of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}X)_3(PBu^t_3)_4]$ (X = Cl **1**, Br **2**) and the first structural characterisation of a palladium $\mu_3$-CF cluster. Interestingly the CF group of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ is readily cleaved when the cluster is reacted with $H_2$ under mild conditions.

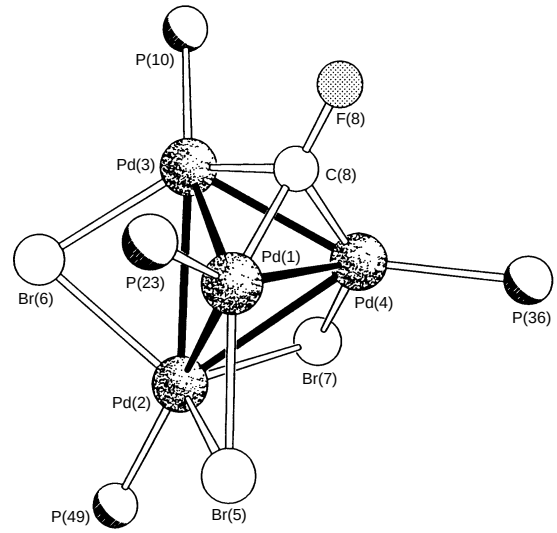
When 1 mol equiv. of $[Pd_2(dba)_3]\cdot C_6H_6$, 2 mol equiv. of $PBu^t_3$ and 0.5 mol equiv. of $CFCl_3$ were reacted in toluene for 6 h the reaction mixture turned dark brown. The solvent was removed under reduced pressure and the crude product was recrystallised from toluene–acetone at 4 °C to give $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ **1** as dark green crystals. The formulation of this product was confirmed on the basis of IR, $^{31}P\{^1H\}$ NMR, $^{19}F$ NMR, FABMS and elemental analyses.†

A solution of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ in toluene was treated with 3 mol equiv. of LiBr in acetone for 4 h and $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Br)_3(PBu^t_3)_4]$ **2** was obtained. After removing the solvents under reduced pressure the remaining dark green solid was extracted with benzene and crystals of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Br)_3(PBu^t_3)_4]$ were obtained from benzene–acetone after cooling to 4 °C overnight. The formulation was confirmed by the IR, $^{31}P\{^1H\}$ NMR, $^{19}F$ NMR, FABMS and analytical data.‡ A single-crystal X-ray analysis§ of compound **2** has confirmed that the cluster has a structure similar to that previously reported for $[Pd_4(\mu_3\text{-}CH)(\mu\text{-}Cl)_3(PBu^t_3)_4]$.[9] It consists of a tetrahedral cluster with a face-capping fluoromethylidyne ligand. The molecular structure (Fig. 1) demonstrates that the chlorine atoms of the starting material have been substituted by three bromine atoms, whilst retaining the effective $C_{3v}$ symmetry of the metal cluster skeleton. The Pd–Pd bonds in the cluster are in the range 2.727(2)–3.123(2) Å compared with 2.668(1)–3.143(1) Å in the analogous $[Pd_4(\mu_3\text{-}CH)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ cluster compound.

The presence of the $\mu_3$-CF capping ligand in these clusters is interesting in terms of the cluster–surface analogy. It is known that palladium black and palladium supported in alumina may be used as heterogeneous catalysts for the hydrogenation of chloroflurocarbons (CFCs) to hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs).[11] Recently these reactions have taken on considerable industrial importance because of the need for HFCs as possible substitutes for the ozone-damaging CFCs. However, to our knowledge only heterogeneous catalytic processes for converting CFCs to HCFCs have been reported.[12] $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ derived from $CFCl_3$ may be converted to $CFH_3$ homogeneously under mild conditions and therefore provides an effective model for such a process.

A solution of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ in toluene was reacted with $H_2$–$NEt_3$ and 4 mol equiv. of $PBu^t_3$ under mild conditions (at STP). The products formed in this reaction were $[Pd(PBu^t_3)_2]$, $[HNEt_3]Cl$ and $CFH_3$ (in > 50% yield after 2 h as detected by gas chromatography).¶ No other volatile fluorocarbon compounds were detected by gas chromatography. $[Pd(PBu^t_3)_2]$ was detected using $^{31}P\{^1H\}$ NMR, by its characteristic resonance at δ 85.5[13] and monitoring its signal indicated that the reaction was complete after 4 h. This confirms that a $\mu_3$-CF moiety, derived by an oxidative-addition process from $CFCl_3$, may be hydrogenated to $CFH_3$ under mild conditions.

When the hydrogenation reaction was repeated using the mononuclear compound $[Pd(PBu^t_3)_2]$, generated *in situ* from $[Pd_2(dba)_3]$ and $PBu^t_3$, with an excess of $CFCl_3$ {50 : 1 relative



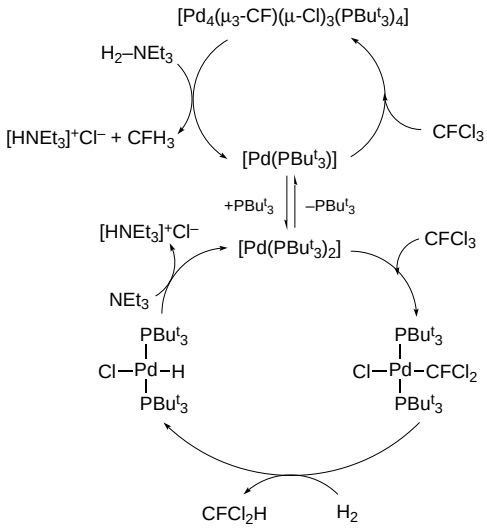


**Fig. 1** The molecular structure of the cluster $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Br)_3(PBu^t_3)_4]$ showing the numbering used (the phosphine substituents are omitted for clarity). Important bond lengths (Å): Pd(1)–C(8) 1.94(2), Pd(3)–C(8) 1.96(2), Pd(4)–C(8) 1.96(2), Pd(1)–Br(5) 2.524(3), Pd(2)–Br(5) 2.668(3), Pd(2)–Br(6) 2.666(3), Pd(2)–Br(7) 2.639(3), Pd(3)–Br(6) 2.531(3), Pd(4)–Br(7) 2.529(2), Pd(1)–P(23) 2.397(5), Pd(2)–P(49) 2.361(5), Pd(3)–P(10) 2.403(6), Pd(4)–P(36) 2.392(5), Pd(1)–Pd(2) 3.112(2), Pd(1)–Pd(3) 2.727(2), Pd(1)–Pd(4) 2.729(2), Pd(2)–Pd(3) 3.097(2), Pd(2)–Pd(4) 3.123(2), Pd(3)–Pd(4) 2.731(2), C(8)–F(8) 1.36(2).

to $[Pd_2(dba)_3]$}, the only hydrogenation product observed was $CFCl_2H$. Complete conversion of the $CFCl_3$ to $CFCl_2H$ required 24 h. No traces of $CFH_3$ or any other gas were detected, suggesting that the cluster $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ plays an essential role in the hydrogenation of $CFCl_3$ to $CFH_3$.

Although the formation of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ from $CFCl_3$ and its subsequent hydrogenation provides an illustration of how $CFCl_3$ may be hydrogenated to $CFH_3$ on a metal surface, the cluster compound itself is not an effective homogeneous catalyst. When $H_2$ was bubbled through a solution of $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Cl)_3(PBu^t_3)_4]$ in toluene in the presence of $NEt_3$ and with a 50-fold excess of $CFCl_3$, the gases produced were identified as $CFH_3$ and $CFCl_2H$ with a ratio of $CFCl_3H/CFH_3$ of *ca*. 2.3. $^{31}P\{^1H\}$ NMR data confirmed that the cluster had fragmented during this reaction.

Scheme 1 summarises plausible mechanistic cycles involving the reactions for the mono- and tetra-nuclear palladium compounds. Although in the absence of hydrogen the formation of the tetranuclear cluster with the $\mu_3$-CF group proceeds at a sufficient rate to compete with the formation of the simple oxidative-addition products, the hydrogenation step proceeds more quickly for the mononuclear product than for the tetranuclear compound leading to the formation of $CFCl_2H$ in addition to $CFH_3$. Attempts are currently being made to use variations in the ligands to change the relative rates of the competing cycles and thereby improve the selectivity of the catalytic hydrogenation process.

We thank CONACYT and ORS for scholarships to R. V., EPSRC for financial support to S. E. L., BP plc for endowing D. M. P. M.'s chair and ICI for providing reference samples of $CFCl_2H$ and $CFH_3$.

† *Selected data* for **1**: yield 18%. (Found C, 42.4; H, 7.4. $C_{49}H_{108}Cl_3FP_4Pd_4$ requires C, 42.9; H, 7.9%). $^{31}P\{^1H\}$ NMR ([$^2H_6$]benzene) δ 103.4 (q), 68.6 (dd); $^{19}F$ NMR ([$^2H_6$]benzene) δ 111.0 [dq, $^3J$(PP) 132.2, $^3J$(PF) 39.7, $^4J$(PF) 8.5 Hz]. IR ν(C–F) 1052 $cm^{-1}$.

‡ *Selected data* for **2**: yield 61%. (Found C, 40.9; H, 6.8 $C_{49}H_{108}Br_3FP_4Pd_4\cdot0.75C_6H_6\cdot0.75Me_2CO$ requires C, 41.0; H, 7.1%). $^{31}P\{^1H\}$ NMR ([$^2H_6$]benzene) δ 117.0 (q), 70.5 (dd); $^{19}F$ NMR ([$^2H_6$]benzene) δ 116.0 [dq, $^3J$(PP) 173.0, $^3J$(PF) 40.1, $^4J$(PF) 11.0 Hz]. The metathesis reaction of **1** to **2** was monitored at different reaction times by $^{31}P\{^1H\}$ and $^{19}F$ NMR spectroscopy. The asymmetric mixed-halogen clusters $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Br)(\mu\text{-}Cl)_2(PBu^t_3)_4]$ **3** and $[Pd_4(\mu_3\text{-}CF)(\mu\text{-}Br)_2(\mu\text{-}Cl)(PBu^t_3)_4]$ **4** were identified as intermediates, suggesting that the substitution reaction takes place sequentially.

§ *Crystal data* for **1**: $C_{49}H_{108}Br_3FP_4Pd_4\cdot0.75Me_2CO\cdot0.75C_6H_6$, $M$ = 1607.7, monoclinic, space group $C2/c$; $a$ = 25.989(4), $b$ = 25.529(4), $c$ = 24.216(4) Å, β = 118.77(1)°; $U$ = 14083(4) Å$^3$, $Z$ = 8, $D_c$ = 1.517 g $cm^{-3}$; μ(Mo-Kα) = 2.833 $mm^{-1}$; $F(000)$ = 6524. Data were measured on a Siemens P4/PC diffractometer with graphite-monochromated Mo-Kα radiation using ω scans. The structure was solved by direct methods and the non-hydrogen atoms of the cluster refined anisotropically by full-matrix least-squares based on $F^2$ to give $R_1$ = 0.0783, $wR_2$ = 0.1446 (SHELXTL)[10] for 3824 unique observed reflections ($|F| > 4\sigma|F_o|$, $2\theta \leqslant 50°$) and 609 parameters. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/330.

¶ *Selected data for chromatographic studies*: the chromatographic studies were performed in a Perkin Elmer 8500-GC with an FID detector and a Carbopack B/5% Fluorocol column special to detect fluorinated compounds. The oven temperature was set to 60 °C, the detector to 250 °C and the injection temperature to 200 °C. The carrier gas ($N_2$) flow rate was adjusted to 25 ml $min^{-1}$. Samples: 200 μl of sample (gases produced in the reaction) was injected using a gas-tide syringe. The assignment of the peaks was made by comparison with standards of $CFH_3$, $CFCl_2H$ and $CFCl_3$ at the same temperature and flow rate conditions.

# Optical control over $Pb^{2+}$ binding to a crown ether-containing chromene

**Mark T. Stauffer, David B. Knowles, Carrie Brennan, Lance Funderburk, Fu-Tyan Lin and Stephen G. Weber***

*Department of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260 USA*

**Naphthochromene 1 binds $Pb^{2+}$ in the dark, and the complex is photodissociated by a novel mechanism.**

Metal-ion chelation by crown ethers has been the subject of intense investigation by researchers[1] for over thirty years. Functionalization of crown ethers[2] leads to pH, redox, and photochemical control over metal-ion binding. Several reports of metal-ion chelation by crown ether groups coupled to photochromic azobenzenes,[2] spiropyrans,[3] and spirooxazines[4] have appeared in the literature. Binding strategies described include the 'butterfly'[2] configuration (*i.e.* a crown ether attached to each end of azobenzene) and use of ionic 'caps'.[2–4] We present here a crown ether-containing chromene that binds $Pb^{2+}$ in the dark, with dissociation of $Pb^{2+}$ upon irradiation with near-UV light. The process is photoreversible. We monitor $Pb^{2+}$ binding by observing the changes in the cathodic reduction of $Pb^{2+}$. To our knowledge, there are no published accounts of metal-ion binding using photochromic chromenes. In metal-binding azobenzenes,[2] spiropyrans,[3] and spirooxazines,[4] the binding affinity is controlled by light through its influence on the chelator's geometry and/or the large increase in donor strength of the pyran oxygen following cleavage of the spiro carbon–oxygen bond. In contrast, compound **1** functions by taking advantage of the decrease in electron donor strength on ligating heteroatoms that can also stabilize, by electron donation, the positive charge created following photolysis.

Compound **1** was synthesized from 1-phenyl-1-(3,4-benzo-1,4,7,10,13-pentaoxacyclopentadeca-3-ene)prop-2-yn-1-ol and β-naphthol under acidic conditions, and purified by re-crystallization (mp 83 °C). Perchlorate salts, benzo-15-crown-5, and methanol (MeOH) were used as received. Simultaneous photochemistry and square-wave voltammetry of solutions of $Pb^{2+}$ and **1** [MeOH–$H_2O$ (9 : 1)–$5.0 \times 10^{-2}$ mol $dm^{-3}$ $LiClO_4$] were carried out at amalgamated Au in a 1 mm quartz cuvette. Square-wave voltammetry of solutions of $Pb^{2+}$ and benzo-15-crown-5 was performed at amalgamated Au in a conventional three-electrode electrochemical cell, in the same medium used for the photoelectrochemistry.

We used the model compound benzo-15-crown-5 to study the effect of $Pb^{2+}$ binding by a crown ether upon the voltammetry of $Pb^{2+}$ (Fig. 1). In the absence of benzo-15-crown-5, we observed reduction of free $Pb^{2+}$ (−346 mV *vs.* Ag/AgCl). Increasing the concentration of benzo-15-crown-5 in solution caused the $Pb^{2+}$ reduction peak to shift and decrease in intensity, indicative of binding of $Pb^{2+}$ by benzo- 15-crown-5. We carried out competitive binding between $Pb^{2+}$ and $Na^+$, in the presence of an excess of $Na^+$, to confirm that the decrease in the $Pb^{2+}$ reduction wave upon addition of benzo-15-crown-5 was due to binding of $Pb^{2+}$ by the crown ether. Addition of $7.0 \times 10^{-2}$ mol $dm^{-3}$ $NaClO_4$ to a solution containing $1.83 \times 10^{-5}$ mol $dm^{-3}$ $Pb^{2+}$ and $1.0 \times 10^{-2}$ mol $dm^{-3}$ benzo-15-crown-5 yielded the reduction wave (*ca.* −420 mV, *vs.* Ag/AgCl) for free $Pb^{2+}$ during voltammetry of this solution. Thus, the change in the voltammetry of $Pb^{2+}$ observed in Fig. 1 was due to binding by the crown ether.

Compound **1** ($\lambda_{max}$ = 284, 302, 346, 358 nm) yields a visible band ($\lambda_{max}$ = 476 nm) during irradiation with 300–400 nm light. Photoswitching of **1** in the presence of $Pb^{2+}$ (Fig. 2) reveals that **1** is fairly photostable. Voltammetry of **1** in the dark

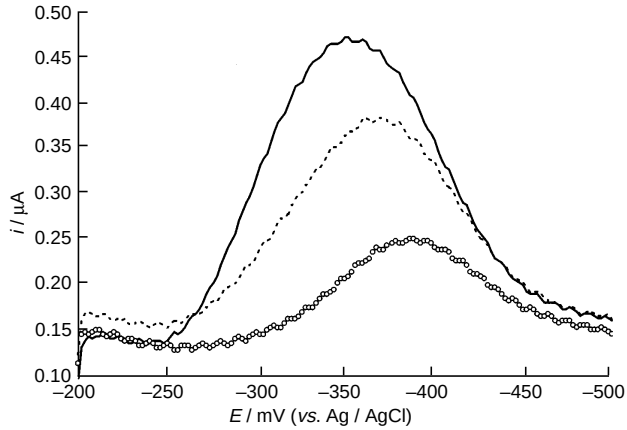

**Fig. 1** Cathodic reduction of $4.0 \times 10^{-5}$ mol $dm^{-3}$ $Pb^{2+}$ in MeOH–$H_2O$ (9 : 1) containing 0.1 mol $dm^{-3}$ $LiClO_4$ in the absence and presence of excess benzo-15-crown-5. (——) $4.0 \times 10^{-5}$ mol $dm^{-3}$ $Pb^{2+}$; (---) $9.6 \times 10^{-3}$ mol $dm^{-3}$ benzo-15-crown-5 added; (ooo) $3.3 \times 10^{-2}$ mol $dm^{-3}$ benzo-15-crown-5 added.

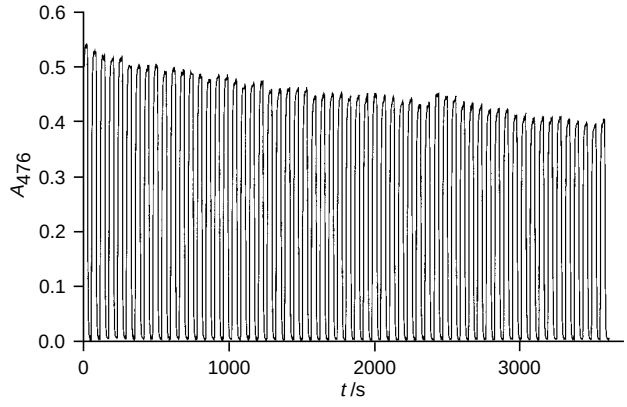

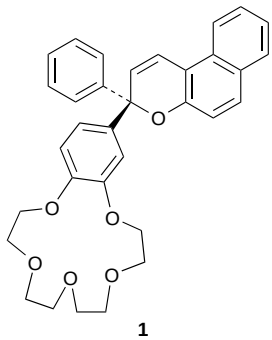

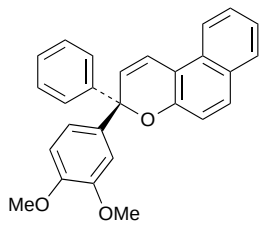

**Fig. 2** Photoswitching of $4.93 \times 10^{-4}$ mol $dm^{-3}$ **1** in the presence of $5.39 \times 10^{-3}$ mol $dm^{-3}$ $Pb^{2+}$, in MeOH–$H_2O$ (9 : 1) containing $5 \times 10^{-2}$ mol $dm^{-3}$ $LiClO_4$. Each cycle consists of 30 s irradiation with 300–400 nm light, followed by 30 s irradiation with > 420 nm light.

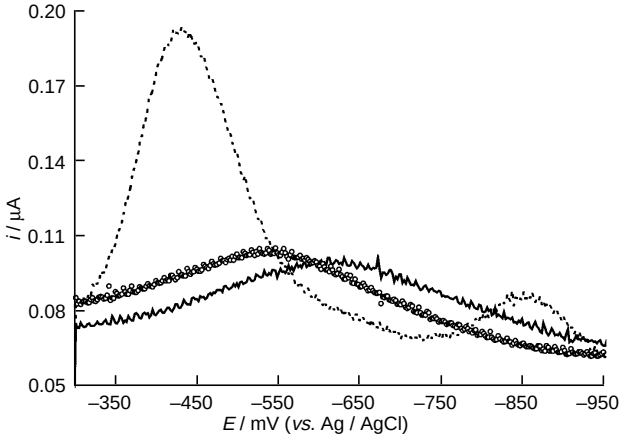
**1**

**2**

or during illumination yields no waves in the −300 to −1000 mV region. Fig. 3 illustrates the results of our photoelectrochemical studies of $Pb^{2+}$ in the presence of **1**. In the dark, we do not see the wave at *ca.* −400 mV (*vs.* Ag) corresponding to reduction of free $Pb^{2+}$. Instead, we observe a very broad wave at *ca.* −600 mV, indicating that the $Pb^{2+}$ binds to the crown ether. Upon irradiation with 300–400 nm light, we obtain the wave (*ca.* −420 mV, *vs.* Ag) for reduction of free $Pb^{2+}$, showing that the $Pb^{2+}$–crown complex has dissociated due to photoisomerization of **1** (Scheme 1). Irradiation with > 420 nm light yields the same result observed in the dark, indicating the $Pb^{2+}$ binds again to **1**. $^1$H and $^{13}$C NMR spectroscopies† of **1** upon addition of $Pb^{2+}$ (2 : 1 $Pb^{2+}$: **1** in $CD_3CN$) in the dark give further



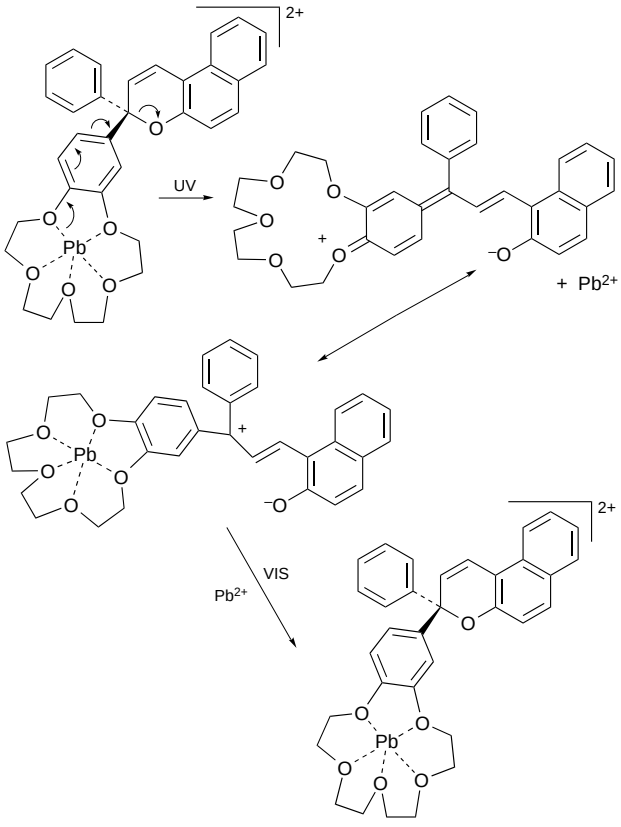


**Fig. 3** Photoelectrochemistry of $5.8 \times 10^{-5}$ mol dm$^{-3}$ $Pb^{2+}$ + $2 \times 10^{-3}$ mol dm$^{-3}$ **1** in MeOH–$H_2O$ (9 : 1) containing $5 \times 10^{-2}$ mol dm$^{-3}$ $LiClO_4$. (——) dark; (---) UV photolysis; (ooo) visible photolysis.

**Scheme 1**

evidence of binding by $Pb^{2+}$. For $^1$H NMR, the crown ether methylene proton resonances are in the region δ 3.73–4.33 with $Pb^{2+}$ *cf.* δ 3.56–4.00 in the absence of $Pb^{2+}$. Resonance shifting and line broadening occur in both $^1$H and $^{13}$C NMR spectra of **1** in the presence of $Pb^{2+}$.

Further evidence suggests that the $Pb^{2+}$ binds to the crown ether moiety. In the dark, we observe the same trend for cathodic reduction of $Pb^{2+}$ in the presence of a large excess of **1** (Fig. 3) as that in excess benzo-15-crown-5 (Fig. 1). In each case, the reduction potential of $Pb^{2+}$ becomes more negative upon addition of the crown ethers. Control experiments involving the dimethoxylated analogue of **1** (*i.e.*, **2**) show no indication of $Pb^{2+}$ binding. We observe no shift in the $Pb^{2+}$ reduction peak potential upon addition of **2** in the dark. Also, $^1$H and $^{13}$C NMR spectroscopies† reveal no changes in the chemical shifts and shapes of the resonances of **2** upon addition of $Pb^{2+}$ in the dark, indicating that $Pb^{2+}$ does not bind to **2**.

Unlike previously designed crowned photochromics,[2–4] in which UV photolysis enhances the cation-binding abilities of the ligands through the creation of additional binding sites or geometry changes, UV-induced photoisomerization of **1** causes open **1** to lose its cation-binding ability due to withdrawal of electron density from the crown ether moiety (Scheme 1). Kimura *et al.*[5] observe a similar occurrence for $Na^+$ bound to a crowned malachite green leuconitrile. The difference between **1** and Kimura's[5] leuconitrile is that the coordination by **1** is photoreversible. There is a significant technical advantage to exerting optical control over metal-ion binding in this manner. The system using the photochromic chelator (*e.g.* sensor or extractor) functions in the dark, and only needs to be exposed to light, with consequent photodegradation, for brief periods of forced dissociation.

We gratefully acknowledge the financial support of the Office of Naval Research.

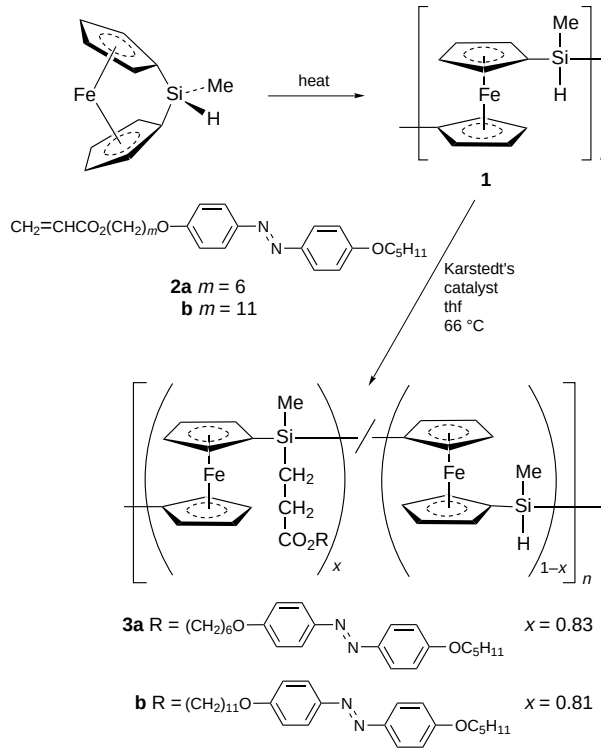
# Novel calamitic side-chain metallomesogenic polymers with ferrocene in the backbone: synthesis and properties of thermotropic liquid-crystalline poly(ferrocenylsilanes)

**Xiao-Hua Liu,[a] Duncan W. Bruce*[b] and Ian Manners*[a]**



[a] *Department of Chemistry, University of Toronto, 80 St. George Street, Toronto M5S 3H6, Ontario, Canada*
[b] *Department of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD*

**Novel thermotropic, metallomesogenic polymers with a poly(ferrocenylsilane) main chain and 4-pentoxy-4′-hydroxyhexanoxyazobenzene or 4-pentoxy-4′-hydroxy-undecyloxyazobenzene acrylate side chains have been prepared; each material displays a nematic mesophase.**

The study of the incorporation of metals into the structures of low molar mass liquid crystals with the aim of accessing novel physical properties is now a well established area of materials chemistry.[1,2] Metallomesogenic polymers are particularly attractive as they have the potential to combine the advantageous properties of polymers (*e.g.* excellent mechanical properties, low thermal expansion, and excellent processability) with those of transition-metal complexes (*e.g.* colour, polarizability, magnetic characteristics).[3,4] Ferrocene units are of considerable interest as components of liquid-crystalline (LC) materials due to their high thermal stability, tunable redox characteristics and their structural variability which might lead to intriguing effects on mesophase morphology.[5] A range of low molecular mass calamitic (rod-like) systems can be prepared by monosubstitution or by 1,2-, 1,3- or 1,1′-disubstitution of the ferrocene nucleus.[6] Several examples of calamitic side-chain metallomesogenic polymers with ferrocene in the side-group structure are known.[7] For example, thermotropic ferrocene-containing side-chain LC polymers have been prepared from ferrocene-containing monomers.[7a,b] Ferrocene-containing side chain LC polymers where the liquid crystallinity is derived from the organic mesomorphic monomers have also been reported.[7c] Although main-chain, LC polymers with ferrocene in the backbone are more common (*e.g.* main-chain polyester incorporating ferrocene units substituted at 1,1′-positions[8]) these are limited to materials in which the ferrocene units are a significant distance apart, making the exploitation of cooperative interactions between the iron atoms difficult. Here, we report on the synthesis and thermal properties of the first side-chain metallomesogenic polymers with ferrocene units in the main chain. These materials were prepared by the functionalization of poly(ferrocenylmethylhydrosilane) and represent the first well characterized, liquid-crystalline poly(ferrocenylsilanes).

Recent work has shown that high molar mass poly(ferrocenylsilanes) are accessible *via* the ring-opening polymerization of silicon-bridged [1]ferrocenophane precursors.[9] To prepare side-chain LC poly(ferrocenylsilanes) a hydrosilylation strategy was used. First, poly(ferrocenylmethylsilane) **1** was synthesized by thermal ring-opening polymerization of the appropriate [1]ferrocenophane precursor.[10] Secondly, azobenzene-based mesogens, **2a** and **2b**,† were then attached to the backbone of polymer **1** *via* a platinum-catalysed hydrosilylation reaction (Scheme 1). Analysis of the orange polymers **3a** and **3b** by $^1$H NMR gave a hydrosilylation yield of $>80\%$ for both polymers, although a significant amount of unreacted Si–H bonds was present in the resulting polymers, as indicated by IR and by $^{29}$Si and $^1$H NMR spectroscopy.‡

The mesomorphic behaviour of the azobenzene derivatives and the polymers was investigated by a combination of differential scanning calorimetry (DSC) and polarized optical microscopy. Thus, on heating, polymer **3b** underwent a glass transition at 35 °C followed by melting at 53 °C; polymer **3a** underwent a coincident glass transition and melting event at 36 °C (Fig. 1). Following melting, a birefringent phase was found which was readily identified as corresponding to a

**Scheme 1**

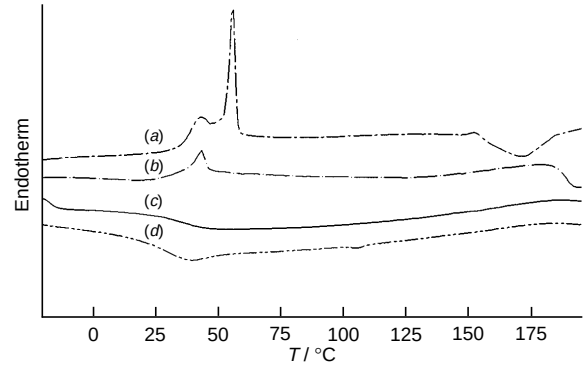


**Fig. 1** Differential scanning calorimetry thermograms of polymers **3a** and **3b** (10 °C min$^{-1}$); (*a*) the first heating of **3b**, (*b*) the first heating of **3a**, (*c*) the first cooling of **3a**, (*d*) the first cooling of **3b**

nematic phase on account of the characteristic 'flashing' seen when the sample was subject to mechanical stress (although the 'flashing' was, of course, much slower than that normally observed in low molar mass systems on account of the much higher viscosity of the polymer). Thus, the polymers melted at much lower temperature than the free azobenzene groups and by comparing the transition temperature of the two liquid-crystal polymers **3a** and **3b**, it is apparent that as the number of carbon atoms in the flexible spacer is increased, the melting point increases. On further heating, the nematic phase was found to persist above 250 °C, by which time decomposition of the sample was becoming rapid. By DSC, **3a** and **3b** showed broad exothermic transitions at 185 and 153 °C, which did not correspond to any event observable by microscopy, and which we therefore suppose represented the onset of decomposition. The nature of the decomposition is, however, unclear at present, as neither the parent, unfunctionalized polymer, nor the free azobenzene fragments decomposed below 300 °C. On cooling, **3a** and **3b** did not recrystallize. Table 1 shows the transition types, temperatures, molecular mass data and $^{29}$Si NMR chemical shifts.

In conclusion, we have reported the synthesis and mesogenic properties of two novel calamitic thermotropic side-chain LC polymers containing ferrocene in the backbone. The optical microscopy showed a well defined texture for the nematic phase. These functionalized poly(ferrocenylmethylsilanes) represent the first examples of calamitic thermotropic side-chain LC polymers with ferrocene units in the backbone, and in particular, it is interesting to note that whereas the precursor mesogen **2a** is not liquid-crystalline, mesophase stabilization is apparent in polymer **3a**. This synthetic route offers ample opportunities for structural variations and we are exploring these and the properties of the materials in detail. Of particular interest[11] is the study of the liquid-crystal properties in the three oxidation states accessible for these materials (neutral, oxidised at alternate iron sites, and fully oxidised).[9]

We thank the University of Sheffield for the award of a Postgraduate Scholarship to Xiao-Hua Liu, and Ron Rulkens for assistance in synthesis of the starting polymer **1**. I. M. thanks the Natural Science and Engineering Research Council of Canada (NSERC) for funding and the Alfred P. Sloan Foundation for a Research Fellowship (1994–1998), and D. W. B. thanks the University of Exeter for support.

**Table 1** Molecular masses, $^{29}$Si NMR, thermal transition temperatures and assignments for **1**, **2a**, **2b** and the metallomesogenic polymers **3a** and **3b**

| Compound | $M_w$[a] | $M_n$[a] | PDI[a] | δ($^{29}$Si)[b] | Transition[c] | $T$/°C |
|---|---|---|---|---|---|---|
| **1** | $2.1 \times 10^5$ | $9.6 \times 10^4$ | 2.2 | −20.3 | $T_g$ | 9 |
| **2a** | | | | | K–I | 89 |
| **2b** | | | | | K–I | 96 |
| | | | | | (I–N) | (84) |
| | | | | | $(N–S)_A$ | (82) |
| **3a** | $3.8 \times 10^4$ | $1.4 \times 10^4$ | 2.7 | −20.3 | $T_g$ | *ca.* 30 |
| | | | | −4.5 | K–N | *ca.* 36 |
| | | | | | N–d | > 250[d] |
| **3b** | $4.2 \times 10^4$ | $1.7 \times 10^4$ | 2.5 | −20.3 | $T_g$ | 35 |
| | | | | −4.5 | K–N | 53 |
| | | | | | N–d | > 250[d] |

[a] Estimated by gel permeation chromatography (GPC) in thf using polystyrene standards, PDI = $M_w/M_n$. [b] $^{29}$Si NMR spectra were recorded in $CDCl_3$. [c] The transition temperatures were measured by DSC at 10 °C min$^{-1}$. Notation: crystal (K), glass transition ($T_g$), smectic A ($S_A$), nematic (N), and isotropic (I) phases, and decomposition temperature (d). [d] DSC suggests that decomposition begins around 185 °C for **3a** and around 153 °C for **3b**, although 250 °C represents a temperature at which it becomes rapid.

## Footnotes

† The synthesis of **2a** and **2b** was achieved in five steps from *p*-acetamidophenol. The steps involved reaction with i, *n*-$C_5H_{11}Br$; ii, $H^+$–$H_2O$; iii, phenol, HCl and $NaNO_2$; iv, $HO(CH_2)_mBr$ and v, $CH_2CHCOCl$. Both compounds gave satisfactory IR, $^1$H and $^{13}$C NMR and mass spectra.

‡ **3a**: The catalyst [$Pt_2\{(\eta\text{-}CH_2{=}CHSiMe_2)O\}_3$] (4 mg) in xylenes (20 μl) was added to a mixture of polymer **1** (0.3 g, 1.32 mmol) and compound **2a** (0.58 g, 1.32 mmol) in dry thf (100 ml). The reaction mixture was heated to reflux and $^1$H NMR was used to follow the hydrosilylation reaction. After three days $^1$H NMR showed that a small amount of unreacted Si–H bonds still existed. The product was purified by precipitation into hexanes twice. An orange coloured polymer was obtained. Yield 0.55 g (63%). $^1$H NMR (200 MHz, $CDCl_3$): δ 0.4–0.65 (br m, 6 H, C*H*$_3$SiCH$_2$ and C*H*$_3$SiH), 0.85–1.1 (m, 5 H, C*H*$_3$CH$_2$ and SiCH$_2$), 1.25 −1.95 [br m, 14 H, $(CH_2)_7$], 2.34 (br s, 2 H, $CH_2CO_2$), 4.0–4.2 (br m, 22 H, $C_5H_4$, C*H*$_2$OPh and $CO_2CH_2$), 4.9 (br s, 1 H, SiH), 6.95–7.1 (d, 4 H, Ph), 7.85–8.0 (d, 4 H, Ph). $^{13}$C NMR (50 MHz, $CDCl_3$): δ −3.9, −2.7, 11.4, 14.1, 22.5, 25.6, 26.0, 28.2, 28.7, 28.9, 29.1, 29.3, 29.4, 29.5, 31.5, 64.6, 67.9, 68.3, 71.5, 72.9, 73.0, 114.6, 124.2, 146.9, 161.0, 174.8. $^{29}$Si NMR (79 MHz, $CDCl_3$) δ 4.5 ($SiCH_2$), −20.3 (SiH, $^1J_{SiH}$ 51 Hz). The hydrosilylation yield was confirmed by $^1$H NMR.

**3b** was synthesised by using the same method as **3a**. Similar analytical data were obtained.

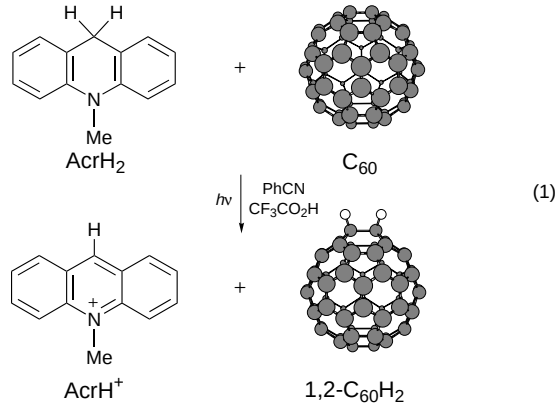
# Selective two-electron reduction of $C_{60}$ by 10-methyl-9,10-dihydroacridine *via* photoinduced electron transfer



**Shunichi Fukuzumi,*[a] Tomoyoshi Suenobu,[a] Shuichiro Kawamura,[a] Akito Ishida[a] and Koichi Mikami*[b]**

[a] *Department of Applied Chemistry, Faculty of Engineering, The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565, Japan*

[b] *Department of Chemical Technology, Tokyo Institute of Technology, Meguro-ku, Tokyo 152, Japan*

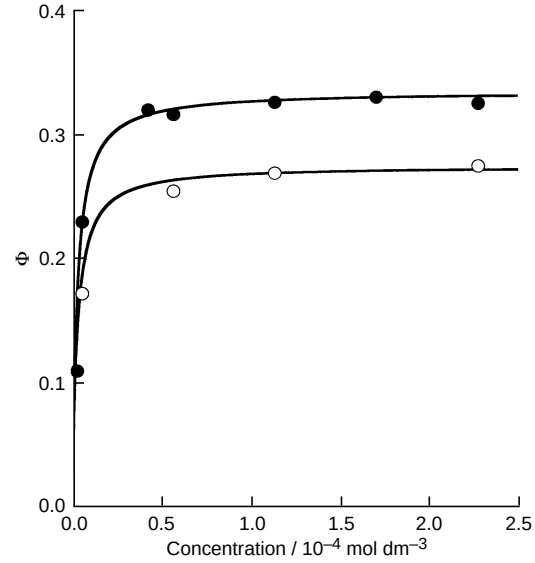
**The selective two-electron reduction of $C_{60}$ to 1,2-dihydro[60]fullerene is attained *via* photoinduced electron transfer from 10-methyl-9,10-dihydroacridine to the triplet excited state of $C_{60}$ in the presence of trifluoroacetic acid in benzonitrile under irradiation of visible light.**

The preparation of dihydro[60]fullerene ($C_{60}H_2$) has recently attracted considerable interest, since it is the simplest $C_{60}$ hydrocarbon derivative.[1,2] The reduction of $C_{60}$ has so far been achieved by the use of strong reductants such as $BH_3$, which yield not only $C_{60}H_2$ but also polyhydride mixtures ($C_{60}H_{2n}$, $n$ = 2 and 3).[1,2] Thus, the use of relatively mild reductants to achieve the selective reduction of $C_{60}$ to $C_{60}H_2$ is desirable. However, $C_{60}$ in the ground state has proved extremely difficult to reduce with mild reductants. We report herein the selective two-electron reduction of $C_{60}$ by a mild hydride donor, 10-methyl-9,10-dihydroacridine ($AcrH_2$), *via* photoinduced electron transfer from $AcrH_2$ to the triplet excited state of $C_{60}$ ($^3C_{60}{}^*$) in the presence of trifluoroacetic acid in benzonitrile (PhCN) to yield 1,2-$C_{60}H_2$ selectively [eqn. (1)].

The hydride donor $AcrH_2$ and its deuteriated analogue 10-methyl[9,9-$^2H_2$]acridine ($AcrD_2$) were prepared as previously described.[3] To a solution of $C_{60}$ (10.1 mg, 0.014 mmol) in deaerated PhCN (50 ml) was added $AcrH_2$ (2.7 mg, 0.014 mmol) and $CF_3CO_2H$ (0.014 mmol), and the solution was irradiated with a Xe lamp equipped with a UV-cut filter ($\lambda$ < 540 nm) for 30 min. After evaporation of PhCN under reduced pressure, the residue was separated by washing with MeCN and centrifuged to give 1,2-$C_{60}H_2$ exclusively in 70% yield.† In the dark, however, no reaction occurred even at high temperatures (*e.g.* 373 K). No appreciable amount of polyadducts was obtained even after a prolonged irradiation time under the present experimental conditions. The $^1$H NMR signal at $\delta$ 5.91 (s, 2H) of 1,2-$C_{60}H_2$ (400 MHz, in $C_6D_6$) agrees well with that reported previously.[1] The visible spectrum exhibits an absorption maximum at $\lambda_{max}$ = 434 nm, which is known to be characteristic of a 1,2-monoadduct resulting from 1,2-addition to a 6–6 bond.[2] Theoretical investigation also indicates that 1,2-$C_{60}H_2$ is the most stable form among 23 different regioisomers.[4]

When the photoreduction of $C_{60}$ by $AcrH_2$ is carried out in the presence of NaI, the reaction is strongly inhibited. Since NaI is a well-known triplet quencher,[5] the photoreduction of $C_{60}$ probably proceeds *via* $^3C_{60}{}^*$, which is quenched by NaI to retard the photoreduction. In fact, the lifetime of the transient $^3C_{60}{}^*$ triplet–triplet (T–T) absorption at $\lambda_{max}$ = 740 nm is significantly reduced by the presence of $AcrH_2$. The bimolecular quenching rate constant ($k_q$) of $^3C_{60}$* by $AcrH_2$ was determined to be 4.3 × $10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$ from the decay kinetics of transient T–T absorption at 740 nm following excitation at 355 nm. The quantum yields ($\Phi$) were also determined from an increase in absorbance due to 1,2-$C_{60}H_2$ by using a ferrioxalate actinometer[6] under irradiation of monochromatized light of $\lambda$ = 546 nm. The $\Phi$ value for the photoreduction of $C_{60}$ by $AcrH_2$ in PhCN increases with an increase in the concentration of $AcrH_2$ to reach a limiting value ($\Phi_\infty$) as shown in Fig. 1. From the dependence of $\Phi$ on [$AcrH_2$] is obtained the quenching constant $K_{obs}$ ( = $k_{obs}\tau_T$), which is converted to the rate constant ($k_{obs}$) for the reaction of $^3C_{60}$* with $AcrH_2$ (5.0 × $10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$) by using $\tau_T$ for $^3C_{60}$* (32 μs) in PhCN.[7] The $k_{obs}$ value agrees with a $k_q$ value (4.3 × $10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$) determined independently (*vide supra*). Such an agreement confirms that the photoreduction of $C_{60}$ proceeds *via* the triplet excited state.

The free energy change of the photoinduced electron transfer from $AcrH_2$ to $^3C_{60}$* is negative ($\Delta G^0_{et}$ = −32 kJ mol$^{-1}$) judging from the fact that the one-electron oxidation potential of $AcrH_2$ ($E^0_{ox}$ *vs.* SCE = 0.81 V)[8] is lower than the one-electron reduction potential of $^3C_{60}$* ($E^0_{red}$ *vs.* SCE = 1.14 V).[9] In such



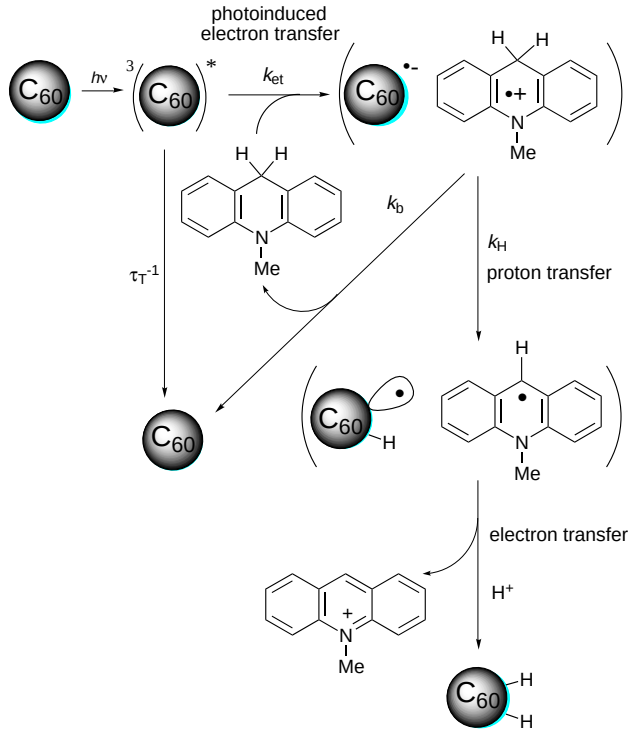


**Fig. 1** Dependence of the quantum yield on the concentration of $AcrH_2$ and $AcrD_2$ for the photoreduction of $C_{60}$ (2.8 × $10^{-4}$ mol dm$^{-3}$) by ● $AcrH_2$ and ○ $AcrD_2$ in the presence of $CF_3CO_2H$ (5.6 × $10^{-4}$ mol dm$^{-3}$) in PhCN at 298K.

a case the electron transfer rate constant ($k_{et}$) may reach the diffusion-limited value in PhCN ($5.6 \times 10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$),[9] which agrees with both the $k_{obs}$ and $k_q$ values (*vide supra*). Thus, the photoreduction of $C_{60}$ by $AcrH_2$ may proceed *via* photoinduced electron transfer from $AcrH_2$ to $^3C_{60}$* ($k_{et}$) as shown in Scheme 1. The photoinduced electron transfer gives the radical ion pair in competition with the decay to the ground state ($k_T = \tau_T^{-1}$). Since $AcrH_2^{\cdot+}$ is known to be a very strong acid,[8] proton transfer from $AcrH_2^{\cdot+}$ to $C_{60}^{\cdot-}$ ($k_H$) may occur in the radical ion pair in competition with the back electron transfer to the reactant pair ($k_b$), to give $C_{60}H^{\cdot}$, which is converted to 1,2-$C_{60}H_2$ by fast electron transfer from $AcrH^{\cdot}$ in the presence of $CF_3CO_2H$. By applying the steady-state approximation to the reactive species, $^3C_{60}$* and the radical ion pair in Scheme 1, the dependence of $\Phi$ on [$AcrH_2$] can be derived as given by eqn. (2), which agrees with the observed dependence of $\Phi$ on

$$\Phi = (k_H/(k_H + k_b))k_{et}\tau_T[AcrH_2]/(1 + k_{et}\tau_T[AcrH_2]) \quad (1)$$

**Scheme 1**

[$AcrH_2$] in Fig. 1. The limiting quantum yield $\Phi_\infty$ corresponds to $k_H/(k_H + k_b)$. Thus, the $\Phi_\infty$ value being smaller than unity (0.33) may be ascribed to the competition of the proton transfer process ($k_H$) with the back electron transfer process ($k_b$). The existence of a protonation step following the photoinduced electron transfer is confirmed by the observed deuterium isotope effect in the limiting quantum yield ($\Phi^\infty_H/\Phi^\infty_D = 1.2$ in Fig. 1) when $AcrH_2$ is replaced by the deuteriated compound ($AcrD_2$). In contrast, no kinetic isotope effect was observed for the rate constant of electron transfer.

Alternatively, $C_{60}^{\cdot-}$ produced in the initial photoinduced electron transfer from $AcrH_2$ to $C_{60}$ could be protonated by the acid, and hydrogen transfer from $AcrH_2^{\cdot+}$ to $C_{60}H^{\cdot}$ gives the final products. However, no increase in the quantum yield was observed with an increase in the amount of $CF_3CO_2H$. In addition, the reduction potential of $C_{60}$ was not affected by the presence of $CF_3CO_2H$ in PhCN, as previously observed.[10] Thus, the protonation of $C_{60}^{\cdot+}$ probably occurs *via* $AcrH_2^{\cdot+}$ in the radical ion pair rather than *via* $CF_3CO_2H$ (Scheme 1).

## Footnote

† The yield was determined by HPLC equipped with an analytical 'Buckyclutcher I' column (Regis, Morton Grove, IL). A hexane– toluene mixture was used as eluent with a flow rate of 2 ml min$^{-1}$. The product was monitored at 434 nm with a UV-VIS detector.

# Synthesis, crystal structure and rearrangement of a methylene(ylene)-phosphorane containing a $CH_2$-moiety at an $sp^2$-hybridized phosphorus(v) centre

**Bernd Schinkels, Alexander Ruban, Martin Nieger and Edgar Niecke***

*Anorganisch-Chemisches-Institut der Universität Bonn, Gerhard Domagk Str.1, D-53121 Bonn, Germany*

**The reaction of the iminophosphane, $(Me_3Si)_3C–P=N–Mes^*$, with $Me_2S=CH_2$ affords the first methylenephosphorane containing a $CH_2$ moiety at an $sp^2$-hybridized phosphorus(v) centre; the crystal structure as well the rearrangement of which is reported.**

Methylenephosphoranes **I**, which may be formally regarded as a phosphane stabilized methylene ($CH_2$), are well established[1] and their chemistry with respect to organic and organometallic syntheses has long been known.[2]

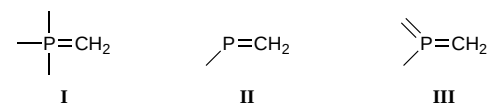
In contrast, only one kinetically stable derivative of a methylenephosphane,[3] **II**, is known so far in which the $CH_2$ moiety is linked to a phosphinidene unit. Methylene(ylene)-phosphoranes **III**, which also contain an $sp^2$-hybridized phosphorus centre as in **II** but with phosphorus(v) are known so far only as transient species, and their existence has only been inferred from trapping experiments.[4] Here we report the synthesis and X-ray structure of the first example of a stable derivative of a methylenephosphorane of the type **III** (Fig. 1).

In a typical experiment, a THF solution of the iminophosphane, $(Me_3Si)_3CP=NMes^*$, **1** [obtained by the treatment of $ClP=NMes^*$[5] with an equimolar quantity of $LiC(SiMe_3)_3$ in THF at −78 °C†] was added under stirring to an equimolar quantity of $Me_2S=CH_2$ in THF at −40 °C.

The solvent was removed under vacuum and the residue was taken up in 40 ml of hexane. The LiI present was removed by filtration and the filtrate concentrated and the resulting residue recrystallized from hexane to give **2** as pale colourless crystals (82.6% yield).

Compound **2** was shown to be a monomer from the observation of the molecular ion in the high-resolution mass spectrum at *m/z* 534 (6%). The formation of an imino(methylene)phosphorane and not of the valence isomeric azaphosphirane[6] is readily demonstrated by the low field $^{31}P$ NMR chemical shift (δ 157.8), while the lowest field signal in the $^{13}C$ NMR spectrum (δ 64.2, $^1J_{CP}$ 108.2 Hz) manifests the existence of a methylene carbon atom attached to a phosphorus(v) centre. The direct proximity of two chemical inequivalent hydrogens attached to this atom (d δ 3.07; dd 3.38, $^2J_{PH}$ 14.1, $^2J_{HH}$ 7.7 Hz) unambiguously proves the presence of a $>P=CH_2$ moiety (Scheme 1).

The new methylenephosphorane **2** was conclusively characterized by X-ray crystallography‡ for which suitable crystals were obtained from hexane at room temperature (Fig. 2). As in all structurally investigated bis(ylene)phosphoranes,[7] the central phosporus atom exhibits a trigonal planar environment (sum of the angles at P = 360°). The methylene carbon atom, both the hydrogen atoms bonded to it, and the atoms P(1)–N(1)–C(12) are almost planar (mean deviation from plane = 0.005 Å). The aryl substituent at N(1) is approximately orthogonal to the central π-bond system (the angle between the plane P(1)–N(1)–C(1)–C(2) and the aryl plane is 89°) and in an *E*-configuration relative to the $(Me_3Si)_3C$ substituent at P(1), as is found in the iminophosphane **1** (Scheme 1). As compared to known imino(methylene)phosphoranes,[8] the P(1)–N(1)-bond length [1.556(2) Å] in **2** is elongated which may be interpretated in terms of the small P(1)–N(1)–C(12) angle [121.2(2)°], whereas the P(1)–C(1) distance [1.612(3) Å] is significantly shorter. Other bond lengths and angles do not show any peculiarities.



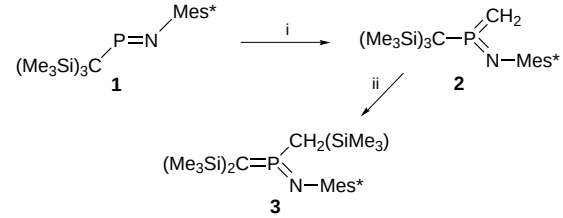


**Fig. 1**

While compound **2** is stable at ambient temperatures it easily isomerizes by heating a toluene solution of **2** at about 100 °C to give the corresponding imino(methylene)phosphorane **3**, which was isolated by recrystallization from non-polar solvents as a colourless powder (84.7% yield). The isomerization **2** → **3** by [1,3] silyl migration in the C–P=C triad results in chemical equivalence and the shielding of the two hydrogens atoms, as shown by $^1H$ NMR, (δ 2.0, $^2J_{PH}$ 16.1 Hz), which reflects the change in hybridization from $sp^2$ to $sp^3$. Furthermore the three equivalent silyl groups in **2** split into a set of three resonances in **3**. The tricoordinated phosphorus(v) centre maintains the characteristic low field shift in the $^{31}P$ NMR spectrum (δ 129.5), whereby the chemical shift of the methylene carbon in the $^{13}C$ NMR spectrum (δ 68.3, $^1J_{PC}$ 43.1 Hz) falls in the same spectral

# Formation of a novel $Re_3$(μ-ethyne) cluster and the possible involvement of Re=Re electrons in the bonding

**Wei-Wei Zhuang and David M. Hoffman***

*Department of Chemistry, University of Houston, Houston, TX 77204, USA*

**The homoleptic neopentoxide cluster $[Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6]$ reacts with ethyne to give a novel adduct having ethyne bridged perpendicular to one edge of a $Re_3$ triangle and with substituted alkynes to yield alkenyl clusters and pivaldehyde.**

The chemistry of $[Re_3(\mu\text{-}X)_3X_6]$ clusters, which have a robust triangular $Re_3$ core with three Re–Re double bonds, is characterized primarily by reactions involving X substitution or transformation, ligand adduct formation and, in a few cases, cluster breakdown.[1] Herein we report the formation of a novel ethyne adduct derived from a $[Re_3(\mu\text{-}X)_3X_6]$ cluster, $[Re_3(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7(\mu\text{-}HCCH)]$, which may be best described as a dimetallatetrahedrane.

The homoleptic neopentoxide cluster $[Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6]$, synthesized by the same method used to prepare $[Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6]$,[2] reacts in hot hexane with 10 equiv. of ethyne (closed flask heating at 50 °C for 12 h) to give $[Re_3(OCH_2Bu^t)_9(HCCH)]$. The product was isolated in 61% yield as green crystals from a cold saturated hexane solution. A single-crystal X-ray crystallographic analysis shows that ethyne bridges perpendicularly to one edge of a $Re_3$ triangle (Fig. 1).† The ethyne-bridged Re–Re bond is slightly longer (0.021 Å) than the neopentoxide-bridged bond, and both distances are significantly longer than the Re–Re distances in $[Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6]$ [av. 2.368 (1) Å][3] and other $Re_3$ alkoxide clusters.[2,4,5] The C–C bond distance [1.414(33) Å] is between those of a single and double bond but the large e.s.d. indicates the distance should be interpreted with caution. The Re–C distances are close to those found, for example, in $[Re_3Me_9(PPhEt_2)_2]$,[6] and the Re–$O_t$ distances are normal. The bridging neopentoxide is 0.2 Å closer to Re(1) than Re(2).

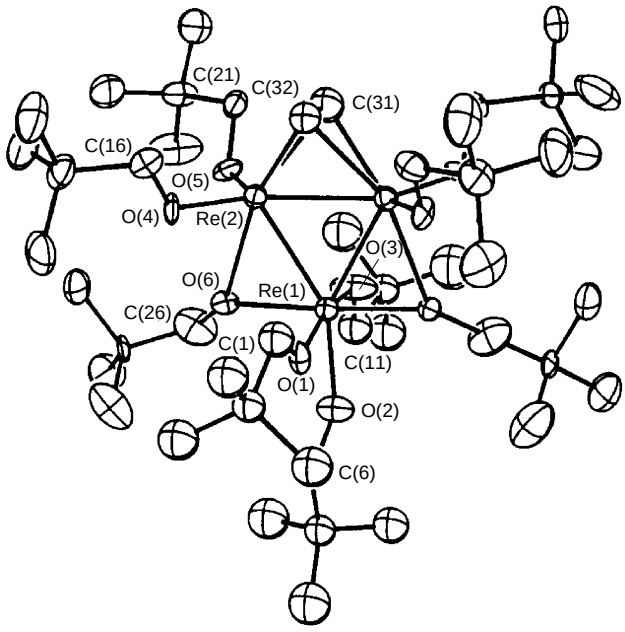

**Fig. 1** View of the $[Re_3(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7(\mu\text{-}HCCH)]$ molecule showing the atom numbering scheme. Only one orientation of each disordered group is shown. Bond lengths (Å) and angles (°): Re(1)–Re(2) 2.496(1), Re(1)–O(1) 1.895(13), Re(1)–O(2) 2.025(16), Re(1)–O(3) 1.912(14), Re(1)–O(6) 1.990(11), Re(2)–Re(2′) 2.517(2), Re(2)–O(4) 1.910(10), Re(2)–O(5) 1.902(10), Re(2)–O(6) 2.203(10), Re(2)–C(31) 2.143(22), Re(2)–C(32) 2.155(18), C(31)–C(32) 1.414(33); O(1)–Re–O(2) 84.1(6), O(1)–Re–O(3) 165.6(6), O(6)–Re–O(6′) 175.1(6), O(4)–Re(2)–O(5) 111.6(5), O(6)–Re(2)–O(4) 82.5(4), O(6)–Re(2)–O(5) 83.7(4).

The room-temperature $^1H$ NMR spectrum of $[Re_3(OCH_2Bu^t)_9(HCCH)]$ is fully consistent with the solid-state structure. The coupling constants associated with the ethyne ligand were obtained for $[Re_3(OCH_2Bu^t)_9(H^{13}C^{13}CH)]$ from proton and carbon-13 spectra, which each consisted of one-half of an expected AA′XX′ pattern in the ethyne region. Two of the four constants, $^1J_{CH}$ = 210 Hz and $^2J_{CH}$ = 4.5 Hz, were determined analytically from the spectrum,[7] and the other two, $^1J_{CC}$ = 23–26 Hz and $^3J_{HH}$ = 0–3 Hz, were obtained by a combination of analytical methods and spectrum simulations. The small one-bond $^{13}C$–$^{13}C$ coupling constant (*cf.* $^1J_{CC}$ = 172 Hz for ethyne)[8] suggests there is substantial electron transfer from the Re=Re bonds to the coordinated ethyne. The observed $^1J_{CC}$ is comparable, in fact, to those for $[M_2(OR)_6(py)_n(\mu\text{-}C_2H_2)]$ complexes (M = Mo, 23–28 Hz; M = W, 10–19 Hz), which have been described as closely approaching the dimetallatetrahedrane description on the basis of structural, theoretical, spectroscopic and reactivity studies.[9] The lengthening of the Re–Re bonds in the adduct compared to the parent cluster is also consistent with the dimetallatetrahedrane model.

Steric factors are important in the formation of the ethyne adduct. The reactions of $[Re_3(OCH_2Bu^t)_9]$ with MeCCMe, $Me_3CCH$ and PhCCPh, for example, all give alkenyl products and pivaldehyde [eqn. (1)]. Analogous products were observed previously in reactions between $[Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6]$ and alkynes, including ethyne.[4] The proposed mechanism for formation of the alkenyl products in these systems is alkoxide β-hydrogen elimination from $[Re_3(\mu\text{-}OR)_3(OR)_6]$ to give the terminal hydride cluster $[Re_3H(\mu\text{-}OR)_3(OR)_5]$, and subsequent trapping of the hydride by alkyne.

$$[Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6] + RCCR' \xrightarrow[50\ °C]{C_6D_6} [Re_3(\mu\text{-}OCH_2Bu^t)_3\{\eta^1\text{-}CR{=}C(H)R'\}(OCH_2Bu^t)_5] + Bu^tC(O)H \quad (1)$$

(R = R′ = Me, Et or Ph; R = H, R′ = $Bu^t$)

To summarize, $[Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6]$ and ethyne react to give $[Re_3(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7(\mu\text{-}HCCH)]$, a triangular cluster in which ethyne bridges perpendicularly to a Re–Re edge. There are a few low-valent transition-metal alkyne clusters having cores resembling that in $[Re_3(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7(\mu\text{-}HCCH)]$,[10,11] but there appear to be no other mid- or high-valent examples. The ethyne in $[Re_3(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7(\mu\text{-}HCCH)]$ is substantially reduced as judged by the long C–C bond and small $^{13}C$–$^{13}C$ coupling constant, suggesting there is electron transfer from the Re=Re bonds to the ethyne. Although this appears to be the first example of this type of internal electron-transfer behaviour in the $[Re_3(\mu\text{-}X)_3X_6]$ system, it is a common feature in the chemistry of mid-

valent early transition-metal multiply bonded compounds. Two prototypical examples are the reactions of triply bonded $[M_2(OR)_6]$ (M = Mo, W) compounds with CO and alkynes to form, respectively, alkylidene- and dimetallatetrahedrane-like $[M_2(OR_6)(\mu\text{-CO})]$ and $[M_2(OR)_6(\mu\text{-alkyne})]$ complexes. In contrast to the reaction between ethyne and $[Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6]$, reactions involving substituted alkynes give pivaldehyde and alkenyl clusters *via* a proposed hydride intermediate.

We thank the Robert A. Welch Foundation for financial support and Dr J. Korp for his technical assistance with the X-ray crystallographic analysis of $[Re_3(OCH_2Bu^t)_9(HCCH)]$.

## Footnote

† *Crystal data* for $[Re_3(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7(\mu\text{-HCCH})]$ at −50 °C, $C_{47}H_{101}O_9Re_3\cdot 2CH_2Cl_2$, dark olive green plate, 0.12 × 0.40 × 0.45 mm, $M$ = 1538.94, monoclinic, space group $P2_1/m$, $a$ = 11.879(2), $b$ = 22.847(5), $c$ = 12.004(2) Å, β = 95.46(1)°, $U$ = 3243 Å$^3$, $Z$ = 2, $D_c$ = 1.58 g cm$^{-3}$, μ(Mo-Kα) = 58.7 cm$^{-1}$. Data were collected on a Nicolet R3m/V diffractometer with graphite-monochromated Mo-Kα radiation (λ = 0.710 73 Å) in the ω scan mode. Lorentz and polarization corrections as well as an empirical absorption correction based on ten reflections having χ values between 70 and 90° were applied to the data. A total of 5023 reflections were collected in the range $4 < 2\theta < 48°$; 3452 unique reflections with $I > 3\sigma(I)$ were used in the structure solution. Three of the neopentoxide groups [C(1), C(6), C(11)] were treated as independently rotating rigid bodies because of disorder. Two significant areas of residual electron density were noted on the mirror plane which were indicative of a severe positional disorder of the entire molecule, and these were refined as partial Re atoms having a total of 3% occupancy. $R(F)$ = 0.061; $R_w(F)$ = 0.054 where $w = [\sigma(F)]^{-2}$.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/338.

# Chromogenic reagent for mercury based on Kemp's acid imide

**Zhen-He Wang,[a] Takuji Hirose,*[a] Bruce W. Baldwin[a] and Yanyan Yang[b]**

[a] *National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba, Ibaraki 305, Japan*
[b] *Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

**Kemp's acid imide type chromogenic reagent showed a significant colour change with excellent selectivity for $Hg^{II}$ over other transition- and heavy-metal ions.**

Recently, we reported that Kemp's acid imides were useful carriers for the transport of various metal ions.[1,2] Amongst these carriers, the aromatic Kemp's acid imide **2** had an especially high transport ability and efficiency for $Hg^{II}$. By substituting a chromogenic moiety in place of the *n*-butyl group of **2**, a molecular sensor for mercury was constructed. Here, we present an excellent chromogenic reagent **1**, which is different from the usual reagents having either sulfur atoms or a macrocyclic structure,[3–5] for $Hg^{II}$ with high selectivity over other transition- and heavy-metal ions.

Chromophore **1** was synthesized in 59% yield in the same manner as **2** by the reaction of Kemp's triacid anhydride acid chloride and *N*,*N*-dimethyl-4,4′-azodianiline **3**.[6] Characterization of **1** was accomplished using $^1H$ and $^{13}C$ NMR spectroscopy, high-resolution mass spectrometry, and elemental analysis. UV–VIS spectra were measured on a Jasco V-550 spectrophotometer in acetonitrile containing 0.01 mol $dm^{-3}$ $LiClO_4$ as electrolyte; a large excess of $LiClO_4$ did not affect the spectra of **1** under these conditions. A 1.00 cm optical pathlength quartz cell, stirred magnetically, and thermostatted at 25.0 ± 0.2 °C, was used in the spectral measurements.

The titration experiments were carried out using $3.00 \times 10^{-5}$ mol $dm^{-3}$ of chromophore **1**, with the addition of 0.0–10.0 mol equiv. of $Hg(ClO_4)_2$. After the addition of an acetonitrile solution of $Hg(ClO_4)_2$, the yellow chromophoric solution ($\lambda_{max}$ = 418 nm) dramatically changed colour to red with the appearance of a new peak ($\lambda_{max}$ = 519 nm), as shown in Fig. 1. As clearly seen upon the addition of $Hg^{II}$ from 0.0 to 10.0 mol equiv. the original absorption band ($\lambda_{max}$ = 418 nm) intensity decreased, while the new absorption band ($\lambda_{max}$ = 519 nm) intensity increased. The two absorption bands, with an isosbestic point at 462 nm, indicated an equilibrium between at least two species. The simplest case would involve two species present in solution, assumed to be the chromophore itself ($\lambda_{max}$ = 418 nm), and the complex ($\lambda_{max}$ = 519 nm) in a 1 : 1 (and/or 2 : 2) chromophore : metal ratio. The 1 : 1 (and/or 2 : 2) complex was also proposed by $^{13}C$ NMR titration of **2**.[1] Moreover, **1** showed a significant response to $Hg^{II}$ cation at concentrations as low as $4.0 \times 10^{-6}$ mol $dm^{-3}$. Assuming 1 : 1 complexation of $Hg^{II}$, the stability constant derived from the absorption spectral data was $8.0 \times 10^4$ $dm^3$ $mol^{-1}$.

The same experiments were also carried out using different metals, and the results summarized in Table 1. Clearly, **1** is the most sensitive to $Hg^{II}$ among the transition- and heavy-metal ions studied. The sensitivities of $Zn^{II}$ and $Cd^{II}$ with respect to $Hg^{II}$ are 1/75 and < 1/7500, respectively. It is very interesting that **1** has high selectivity towards highly toxic mercury over the biologically important zinc cation.[7] Although the detectable concentration limit of **1** was not as low as dithizone,[4] which is the usual chromogenic reagent for mercury, its selectivity for mercury was very high, even though it contains no sulfur atom unlike most other mercury selective chromophores.[3,4] The high selectivities (sensitivities) shown in Table 1 show that no preorganization of a suitable cavity seems to be necessary for ideal complexation as discussed by Lerchi *et al*.[3] The selectivity is similar to that previously reported in the transport results of imide **2**.[1] The only unusual phenomenon was observed in the

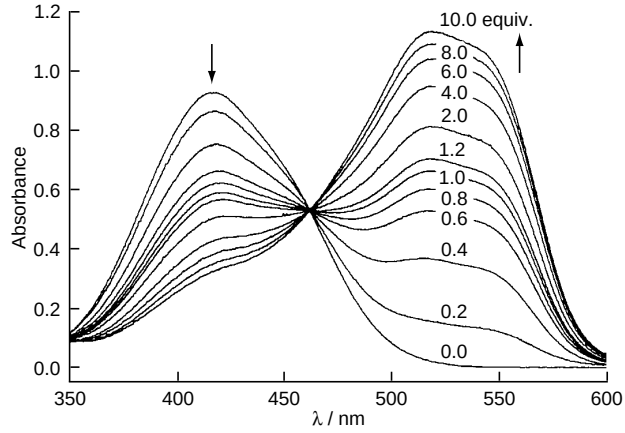

**Fig. 1** UV–VIS spectra of **1** ($3.00 \times 10^{-5}$ mol $dm^{-3}$) and upon incremental addition of $Hg(ClO_4)_2$ in MeCN containing 0.01 mol $dm^{-3}$ $LiClO_4$ as electrolyte

**Table 1** Detection limits (mol $dm^{-3}$) of **1**[a]

| Metal ion[b] | $10^4c$/mol $dm^{-3}$ | Selectivity ([M]/[Hg]) |
|---|---|---|
| $Hg^{II}$ | 0.040 | 1.0 |
| $Cd^{II}$ | > 300 | > 7500 |
| $Zn^{II}$ | 3.0 | 75 |
| $Co^{II}$ | 9.0 | 230 |
| $Ni^{II}$ | 30 | 750 |
| $Cu^{II}$ | 0.15 | 3.8 |
| $Pb^{II}$ | 0.12 | 3.0 |
| $Ag^{I}$ | 16 | 400 |

[a] $3.00 \times 10^{-5}$ mol $dm^{-3}$ in MeCN containing 0.01 mol $dm^{-3}$ $LiClO_4$ as electrolyte at 25.0 ± 0.2 °C. [b] The counter anion was $ClO_4^-$ except for $Cd(NO_3)_2$.

**2** **3** **1** R = $NMe_2$ **4** R = $NO_2$

UV–VIS spectra in titration with $Cu^{II}$. In this case, in addition to the new absorption band ($\lambda_{max}$ = 519 nm), another ($\lambda_{max}$ = 610 nm) also appeared (not shown). The maximum absorbance at 519 nm was reached upon the addition of 1 mol equiv. of $Cu^{II}$. However, further addition of $Cu^{II}$ decreased the 519 nm absorption and increased the new absorption at 610 nm until 2.0 mol equiv. of $Cu^{II}$ was added. We propose that this new absorption band arises from the interaction between excess $Cu^{II}$ and the dimethylamino group of chromophore **1**, as a consequence of the higher affinity of $Cu^{II}$ for nitrogen compared to other metal cations investigated.

The time-dependent spectra of **1** and **3** in the presence of 1 mol equiv. $Hg^{II}$ were taken over a period of 5–60 min to elucidate the spectroscopic features of chromophore **1**. These spectra showed that although **3** showed large absorbance changes with time, no spectral change was observed for **1** under the same conditions. In other words, there was no time dependence for the interaction of $Hg^{II}$ cation and chromophore **1**.

In order to investigate the mechanism of colour change, hydrochloric acid and sodium hydroxide solution were used in place of $Hg^{II}$, the complexation of Kemp′s acid imide **2** with $Na^{I}$ is very weak[2] while the spectrum of the 1 : 1 chromophore–HCl solution was exactly the same as that of the 1 : 1 chromophore–$Hg^{II}$ solution. This meant **1** was also a good molecular sensor for acid. On the other hand, when an NaOH solution was put into the above solution, the absorption at 519 nm decreased, and disappeared upon addition of 1 equiv. of NaOH. This suggested that protonation played a very important role in changing the colour. A plausible mechanism for the colour change is that when transition- or heavy-metal ions are added to the chromophoric solution, the carboxylic acid proton is removed during complex formation, and that this proton binds to the azo group, changing the conjugate feature of **1**, while the dimethylamino group acts as an electron donating group aiding protonation. This mechanism of the colour change is different from other ionizable cyclic or bicyclic molecular sensors.[5] To obtain further evidence, the nitro-substituted derivative **4** was also prepared. Since the nitro group acts as an electron attracting group which decreases the electronic density at the azo group, the released proton cannot interact with the azo group to change the conjugate feature of **4**, such that, as predicted, no colour change occurred even in the presence of excess metal ion.

In summary, a novel Kemp's acid imide **1** was prepared as a chromogenic reagent for $Hg^{II}$. The selectivity of **1** for $Hg^{II}$ was very high over that of other transition- and heavy-metal ions such as $Co^{II}$, $Ni^{II}$, $Cu^{II}$, $Zn^{II}$, $Cd^{II}$, $Pb^{II}$ and $Ag^{I}$. The mechanism of the colour change was demonstrated as being due to the formation of a complex in 1 : 1 (and/or 2 : 2) chromophore : metal ratio after the addition of the transition- or heavy-metal ion to the chromophoric solution. The complexation causes proton transfer from the carboxyl group to the azo group, changing the colour of the original chromophore **1**.

# Non-linear optical properties of the inorganic cluster $[(\eta\text{-}C_5H_5)CoFe_2SSe(CO)_6]$

**Sudeep Banerjee,[a] G. Ravindra Kumar,*[a]† Pradeep Mathur*[b]‡ and P. Sekar[b]**

[a] *Tata Institute of Fundamental Research, Homi Bhabha Road, Mumbai 400 005, India*
[b] *Department of Chemistry, Indian Institute of Technology, Powai, Mumbai 400 076, India*

**Non-linear refraction and absorption have been studied in a mixed-metal, mixed chalcogenide cluster. The cluster displays optical limiting significantly superior to that displayed by $C_{60}$.**

The relentless search for materials with good non-linear optical response has led to impressive strides in understanding existing materials as well as the design and synthesis of new types of molecules.[1] In particular, there has been great interest in finding better non-linear media for the process of optical limiting.[2] Organic systems like dyes, porphyrins and fullerenes have been explored in considerable detail.[2–4] Some transition-metal cluster compounds have also been investigated for their potential for response comparable to or exceeding that of $C_{60}$.[5–8]

Cluster compounds which contain one or more bridging chalcogen ligands have recently been attracting considerable attention.[9] It is possible to design the construction of certain classes of mixed-metal clusters in which different combinations of chalcogen ligands can be incorporated.[10] Recently we have synthesised and structurally characterised the first example of a mixed-metal cluster containing both S and Se ligands $[(\eta\text{-}C_5H_5)CoFe_2(CO)_6(\mu_3\text{-}S)(\mu_3\text{-}Se)]$.[11] Here, we report on its optical limiting characteristics. Among the key requirements for a good optical limiter are (*a*) large transmission at low intensities followed by low transmission at high intensities and (*b*) a low threshold for the onset of non-linear attenuation of the input beam.[2] We show that, on both these counts, the present cluster displays superior performance compared to other materials.

The linear absorption spectrum of a solution of $[(\eta\text{-}C_5H_5)CoFe_2SSe(CO)_6]$ in *n*-hexane is shown in Fig. 1. There is weak absorption in the visible and near-IR regions. Commonly used laser wavelengths (Nd-YAG, dye and diode) exist in these regions and hence limiting applications are important here. The non-linear optical properties of the solution were measured by the *Z*-scan technique[12] at 1064 and 532 nm using an Nd-YAG laser emitting 35 ps pulses at a 10 Hz repetition rate. Typical *Z*-scans are shown in Fig. 2. The large peak to valley difference (nearly 40%) in the closed aperture case [Fig. 2(*a*)] indicates considerable non-linear refraction and the occurrence of the peak at positive *z* indicates positive non-linearity or self-focussing. The non-linear refraction coefficient $\gamma$ can be extracted from the difference in transmission between the peak and the valley.[12] Table 1, which summarises the experimental parameters and the extracted non-linear coefficients, indicates that our $\gamma$ value at 532 nm is two orders of magnitude larger than the values reported by Shi and coworkers for other inorganic clusters at the same wavelength.[13] The $\gamma$ at 1064 nm for our

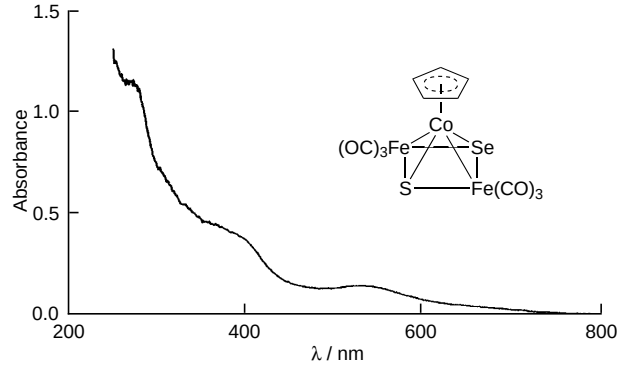

**Fig. 1** Linear absorption spectrum of $[(\eta\text{-}C_5H_5)CoFe_2SSe(CO)_6]$ in *n*-hexane. The inset shows the structure of this cluster.

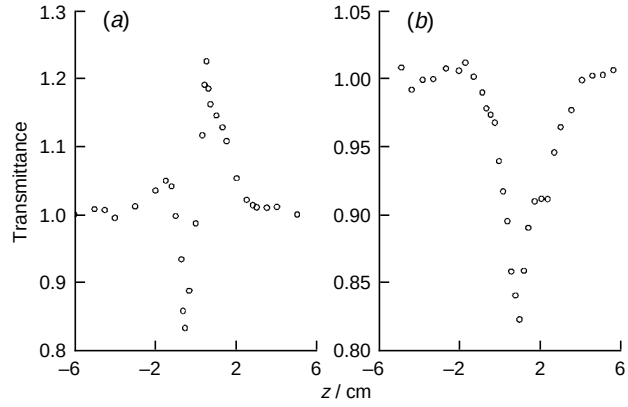

**Fig. 2** Results of a *Z*-scan at 532 nm. A lens with 50 cm focal length was used, giving a focussed spot radius of about 25 μm. The sign convention for *z* is as defined in ref. 12. $z = 0$ is the focus. The fluence at focus is 0.80 J cm$^{-2}$. (*a*) Non-linear refraction, (*b*) non-linear absorption.

**Table 1** Experimentally determined values for $[(\eta\text{-}C_5H_5)CoFe_2SSe(CO)_6]$ and those reported for other materials. The maximum (at focus) intensity in our *Z*-scan experiment was 23 GW cm$^{-2}$, corresponding to a maximum fluence of 0.8 J cm$^{-2}$. The sample concentration was 50 μmol ml$^{-1}$; $\gamma$ is the non-linear refractive index coefficient (see ref. 12). $F_t$ is the limiting threshold fluence at 532 nm

| Material | $\gamma$ (532 nm)/ m$^2$ W$^{-1}$ | $\gamma$ (1064 nm)/ m$^2$ W$^{-1}$ | $F_t$ (with ap.)/ J cm$^{-2}$ | $F_t$ (no. ap.)/ J cm$^{-2}$ | Ref. |
|---|---|---|---|---|---|
| $[(\eta\text{-}C_5H_5)CoFe_2SSe(CO)_6]$ | $2.7 \times 10^{-14}$ | $-5.8 \times 10^{-18}$ | $2.1 \times 10^{-3}$ | $11.0 \times 10^{-3}$ | This work |
| $C_{60}$ | $-9 \times 10^{-17}$ | — | — | $175 \times 10^{-3}$ | 14, 15 |
| $[MoOS_3(CuNCS)_3]^{2-}$ | $-2.3 \times 10^{-16}$ | — | — | 7.0 | 13, 16 |
| $[Mo_8O_8Cu_{12}S_{24}]^{4-}$ | $-3.5 \times 10^{-16}$ | — | — | — | 13 |
| $[Cu_4(SPh)_6]^{2-}$ | $5.0 \times 10^{-17}$ | — | — | — | 13 |

cluster is also of a significant magnitude (no other data exist for a comparison to be made at this wavelength). Note that the sign of the non-linearity changes at 1064 nm, where the non-linear refraction is found to be due to self-defocussing. Moving on to the open aperture data [Fig. 2(*b*)], it is evident that there is non-linear absorption, indicated by the dip in the transmission as the sample is moved towards the focus. The non-linear absorption of about 16% at the maximum fluence of 0.80 J $cm^{-2}$, is significant considering the low fluence levels we have used. The solvent *n*-hexane did not give any signals. It is also clear from Table 1 that the $\gamma$ is considerably superior to that measured for $C_{60}$.[14]

The significant non-linear refraction as well as non-linear absorption displayed by this cluster have been used to design optical limiters with and without apertures. Fig. 3 shows the measurements of transmission at 532 nm as a function of input energy density (fluence) with an aperture of 1 mm in the output beam. The input pulse was focussed by a lens with a focal length of 50 cm. The concentration of the sample was adjusted such that the transmission of the limiter at low fluences is quite large (80%). The transmission starts decreasing as the input increases to a fluence of 1.0 mJ $cm^{-2}$ (28 MW $cm^{-2}$) and comes down to 30% at 3.5 mJ $cm^{-2}$. The onset of non-linear transmission in other inorganic clusters has been found to occur at values that are two orders of magnitude larger than that for the present cluster.[7] The benchmark limiting material, $C_{60}$, also shows onset of non-linear transmission at 80 mJ $cm^{-2}$.[15] The threshold for limiting,[2] defined as the fluence at which the transmission decreases to half of the value at low input fluences, is found to be 2.1 mJ $cm^{-2}$ for our cluster. This value is about 250 times smaller than the smallest value obtained for other inorganic clusters studied recently.[16] Even without an aperture (the open aperture case), our limiting threshold is 11 mJ $cm^{-2}$, which is a factor of over 45 times smaller compared to the other clusters[16] and about 15 times smaller than that for $C_{60}$. An additional advantage of our cluster is that it has a large transmission at low input intensities, a characteristic required for an ideal optical limiter.

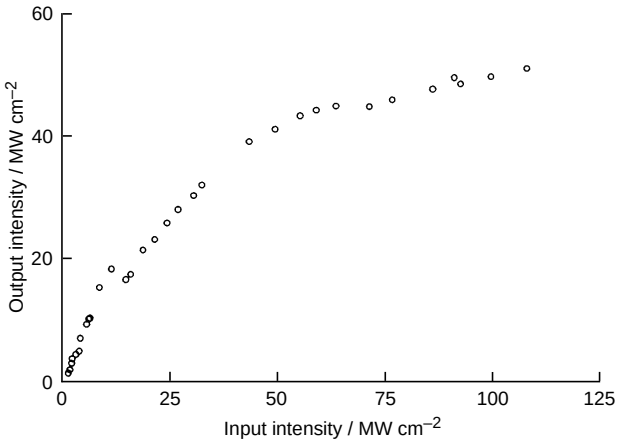

**Fig. 3** Output–input characteristics of a solution of the cluster in *n*-hexane at 532 nm with an aperture of 1 mm in the transmitted beam. Linear (low intensity) transmission of the limiter was 80%. The sample was contained in a 1 mm path length quartz curvette.

In conclusion, we have shown that the mixed-metal, mixed chalcogenide cluster [($\eta$-$C_5H_5$)$CoFe_2SSe(CO)_6$] displays large optical non-linearity. We have demonstrated that it has optical limiting characteristics which are considerably superior to $C_{60}$ and other recently investigated inorganic clusters.

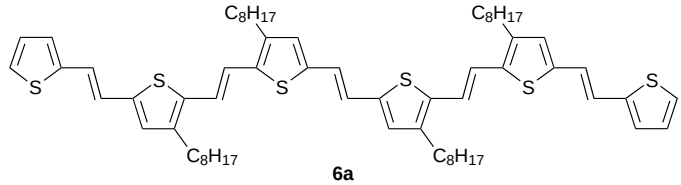
# Extensively π-conjugated soluble oligothienylenevinylenes

**El Hadj Elandaloussi, Pierre Frère* and Jean Roncali***

*Ingénierie Moléculaire et Matériaux Organiques, CNRS UMR 6501, Université d'Angers, 2 Bd Lavoisier, F-49045 Angers, France*

**Soluble oligothienylenevinylenes are synthesized; the longest oligomers exhibit small bandgaps and can be oxidized to the dication by a two-electron transfer.**

Conjugated oligomers are subject to considerable current interest related to their potential applications in diodes,[1] field-effect transistors,[2] light-emitting diodes,[3] or molecules for non-linear optics (NLO).[4] From a fundamental viewpoint, π-conjugated oligomers are widely investigated as models for the electronic and electrochemical properties of the parent polymers.[5] While these two fields of research have been extensively developed for thiophene oligomers (nTs),[1–5] oligothienylenevinylenes (nTVs) have attracted less attention. Due to the presence of ethylene linkages, nTVs are expected to exhibit less rotational disorder and lower aromatic character than nTs and hence enhanced electron delocalization. Although advantage has been taken of these efficient electron-transmission properties for the design of NLO molecules,[6] attempts to prepare nTVs of well defined structure have remained scarce.[7] Thus, Nakayama and Fujimori synthesized nTVs containing up to seven thiophene rings,[7b] but their electrochemical properties were not analysed.



Here, we report preliminary results on the synthesis of the first examples of alkyl substituted nTVs, that are also the longest ever reported. The solubility of these nTVs allowed the analysis of their electrochemical properties providing a first evidence for direct two-electron generation of a dication on a conjugated oligomer.

Oligomers containing two (**2a**,**b**), four (**4a**,**b**) and eight thiophene rings (**8a**,**b**) have been synthesized from 3-octylthiophene and 3,4-dibutylthiophene using an iterative strategy involving formylation of a nTV of degree *n* followed by McMurry dimerization. Compounds **6a** and **10b** were prepared by double Wittig–Horner alkenation of the appropriate dialdehyde and with thienylmethylphosphonate (TP), while **6b** was prepared from 3,4-dibutyl-2,5-thiophenedicarbaldehyde by

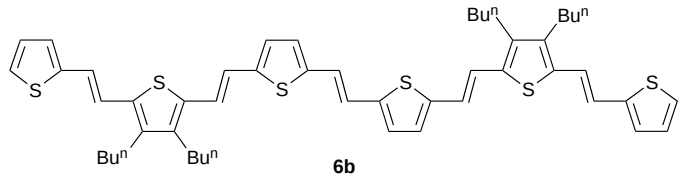


**Table 1** Electrochemical[a] and optical[b] data for nTVs

| Compound | $E_{pa_1}$ | $E_{pa_2}$ | $E_{pa_2} - E_{pa_1}$ | $\lambda_{max}$/nm | $\Delta E^c$/eV |

double Wittig–Horner alkenation with TP followed by monoformylation and McMurry coupling.

Table 1 lists the main electrochemical and optical data of the new nTVs. Due to the +I effect of the two butyl chain, nTVs **b** show lower oxidation potentials and absorb at longer wavelengths than nTVs **a**. The CV of **2a** and **2b** shows two irreversible oxidation waves with peak potentials $E_{pa1}$ and $E_{pa2}$ around 1.00 and 1.30–1.40 V corresponding to the successive generation of the radical cation and dication. Extension of the conjugation length in **4a**,**b** and **6a**,**b** leads to a negative shift of the peak potentials and to a decrease of their difference $E_{pa2} - E_{pa1}$ indicative of a weaker coulombic repulsion between positive charges in the dication. In parallel, both oxidation waves become reversible. For **8a**,**b**, the dication is formed directly through a single-step two-electron transfer. Furthermore, two additional reversible one-electron waves occur around 0.80 and 1.00 V showing that the system can be charged up to the tetracationic state (Fig. 1). Further chain extension to **10b** produces a further decrease of $E_{pa1}$ to 0.43 V. However, the combined effects of chain extension and of the absence of alkyl chains on the terminal thiophenes produce a dramatic decrease of the solubility.

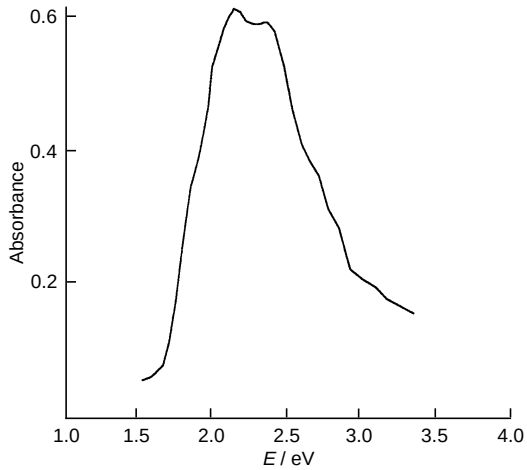

**Fig. 2** Optical spectrum of a film of **8a** cast from a $CH_2Cl_2$ solution

Although two-electron oxidations have already been reported,[8] it is to our knowledge the first time that such a process is observed for oligomers based on the repetition of a single basic unit. This result suggests that soluble nTVs could be of great interest for modelling bipolarons in conjugated polymers.

The solution optical spectra of all nTVs exhibit a well defined vibronic fine structure consistent with an all *trans* rigid geometry. Optical data (Table 1) show that chain extension leads to the expected red shift of $\lambda_{max}$ which reaches 586 nm for **10b** while the HOMO–LUMO gap ($\Delta E$) decreases to 1.72 eV. The optical spectrum of a solution-processed film of **8a** (Fig. 2) reveals the persistence of the vibronic fine structure and a bandgap of *ca.* 1.70 eV. This value, slightly smaller than that of the parent poly(thienylenevinylene) (PTV),[9] suggests that for PTV prepared by thermal elimination the mean conjugation length is limited to *ca.* 8 TV units. On the other hand, the steady decrease of $\Delta E$ with chain extension and the absence of saturation observed for both series of nTVs strongly suggest that longer nTVs could exhibit even lower gaps. Further support to this conclusion is provided by the extrapolation of the plot of $\Delta E$ *vs.* the reciprocal number of conjugated carbons for nTVs **b** which leads to a predicted bandgap of 1.45 eV for PTV.

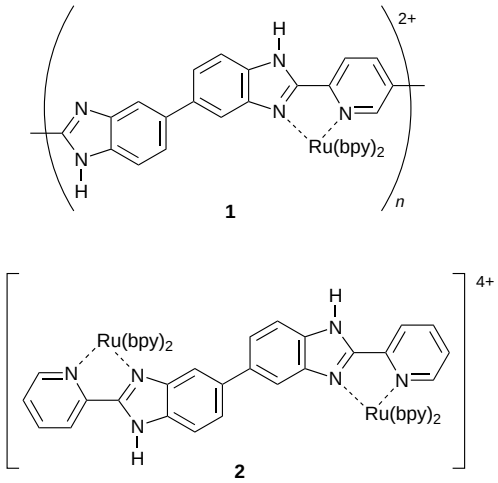
# A conjugated polymer/redox polymer hybrid with electronic communication between metal centres

**Colin G. Cameron and Peter G. Pickup***

*Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7*

**Enhanced electrochemical charge transport rates in a conjugated metallopolymer formed by complexation of $[Ru(2,2'\text{-bpy})_2]^{2+}$ moieties to donor N-atoms in the backbone of a benzimidazole-based polymer provide strong evidence for electronic communication between metal centres.**

In the study of electrodes coated with electroactive polymers,[1,2] a clear distinction has been made between 'conducting polymers' whose redox sites are delocalised over a conjugated π system, and 'redox polymers' which have localised redox sites. Although redox polymers based on transition-metal complexes have many potential advantages in applications such as electrocatalysis and electronic devices, the development of commercial applications has been much more successful for conducting polymers.[3,4] There could therefore be significant opportunities for the exploitation of transition-metal centres in conducting polymers. Indeed, there has been much work in this area,[5] but in most cases the complex has been electronically isolated from the conjugated polymer backbone by saturated linkages. The few examples which involve direct electronic interaction between the conjugated polymer and the complex have demonstrated novel electronic, electrochemical and catalytic properties.[6–10]



We report here a benzimidazole-based conjugated polymer with coordinated $Ru(bpy)_2^{2+}$ moieties (**1**, bpy = 2,2′-bipyridine). The Ru redox centres are coordinated to nitrogen atoms in the conjugated backbone of the polymer, providing direct electronic communication between the complex and the polymer. Work on an analogous binuclear complex (**2**) has indicated that there is a weak electronic interaction between adjacent Ru centres, which can be increased by removal of the imidazole proton.[11] These interactions are manifested most strikingly in polymer **1** by a high, pH-dependent electron transport rate.

Polymer **1** was prepared following standard literature procedures for the preparation of polybenzimidazoles[12] and $[Ru(bpy)_2L]^{2+}$ complexes[13] (glycerol was used as the solvent for complexation). Gel permeation chromatography indicated that the molar mass of the ruthenium-complexed polymer was $> 50\,000$ g mol$^{-1}$. Elemental analysis indicated that *ca*. 60% of the bidentate pyridine–benzimidazole sites were occupied. Polymer films were deposited on Pt disc electrodes by evaporation of acetonitrile–water (12 : 1).

Fig. 1 shows cyclic voltammograms of a film of **1** in acetonitrile containing acid or base. The formal potentials are close to values reported for the dimer complex **2**. The shift in potential with increasing pH is due to deprotonation of the imidazole ring.

Fig. 2 shows complex impedance plots for similar films in basic (*a*) and acidic (*b*) electrolyte solutions. In each case the impedance was measured at the formal potential. These impedance data are typical for a redox polymer film on an electrode and the electron diffusion coefficient ($D_e$) can be obtained from the difference between the high-frequency intercept ($R_{high}$) and the low-frequency limiting real impedance ($R_{low}$): $D_e = d^2/[3(R_{low} - R_{high})C_{lf}]$, where $d$ is the film thickness and $C_{lf}$ is the low-frequency capacitance.[14] Values of $d$ were obtained from the surface coverage, determined from a slow voltammogram, using a ruthenium site concentration of 1.6 M based on the dry density of similar materials.[15] Although this concentration is an estimate, it does not compromise the validity of our conclusions because (*a*) it is the same value used to obtain $D_e$ values for the comparison material, poly-$[Ru(bpy)_2(vpy)_2]^{2+}$ (vpy = 4-vinylpyridine),[16] and (*b*) it is unlikely to be significantly overestimated, since the Ru site concentration in a $[Ru(bpy)_3][PF_6]_2$ crystal is only 1.75 M.[17] $D_e$ values obtained from impedance measurements on **1** in acidic and basic acetonitrile were $6 \times 10^{-9}$ and $1 \times 10^{-8}$ cm$^2$ s$^{-1}$, respectively. For comparison, $D_e$ for poly-$[Ru(bpy)_2(vpy)_2]^{3+/2+}$ in acetonitrile is *ca*. $7 \times 10^{-10}$ cm$^2$ s$^{-1}$.[16]

In both acidic and basic media, electron transport is significantly faster in **1** than in poly-$[Ru(bpy)_2(vpy)_2]^{3+/2+}$, suggesting enhanced electronic communication between Ru centres. $D_e$ is higher in the basic solution than in the acidic solution, consistent with the known increase in electron

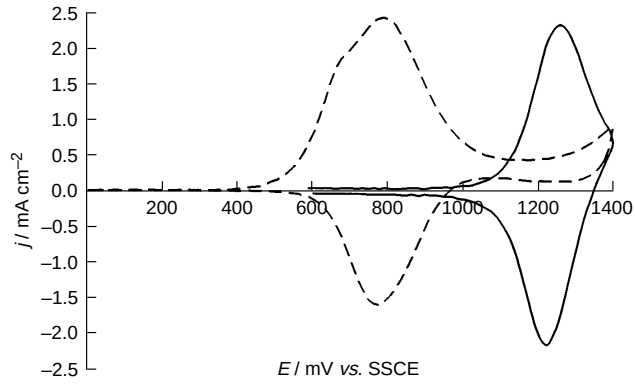


**Fig. 1** Cyclic voltammograms (100 mV s$^{-1}$) of a Pt electrode (0.0052 cm$^2$) coated with a thin ($\Gamma_{Ru} = 3.6 \times 10^{-8}$ mol cm$^{-2}$) film of **1** in 0.1 M $NEt_4ClO_4$–MeCN containing *ca*. 5 mM $NBu_4OH$ (---) or *ca*. 50 mM $HClO_4$ (—)

delocalization between Ru centres connected by a benzimidazole bridge.[11] Furthermore, $D_e$ values for **1** were found to decrease with time spent at high potentials in the basic electrolyte (*i.e.* during impedance measurements or cyclic voltammetry), consistent with the expected deactivation (over-oxidation) of the conjugated polymer backbone.[18] As far as we know, the $D_e$ value obtained for **1** in basic acetonitrile is the highest value yet reported for a Ru–bpy based redox polymer.[19]

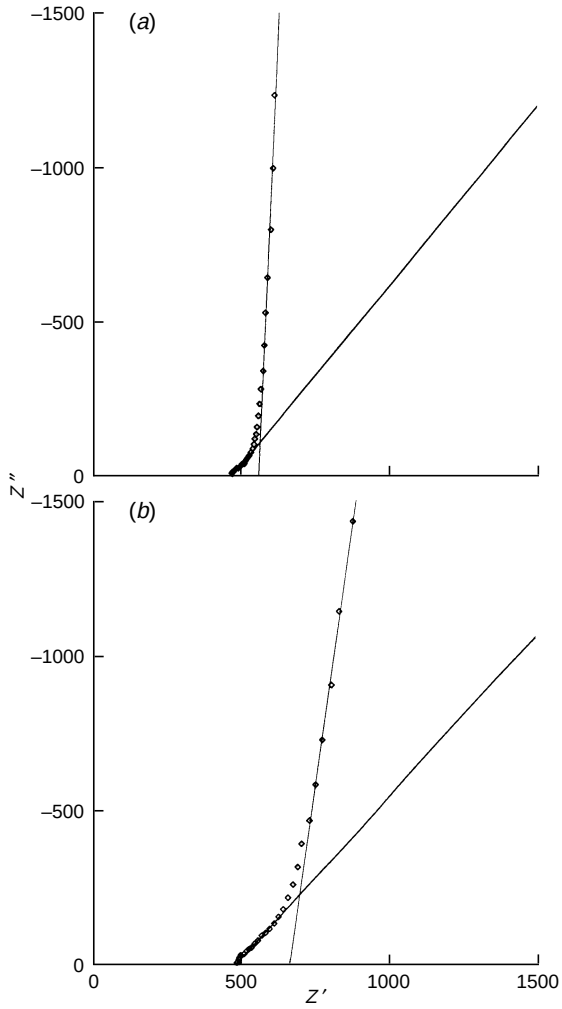

**Fig. 2** Complex plane impedance plots for Pt electrodes (0.0052 $cm^2$) coated with thin films of **1** in 0.1 M $NEt_4ClO_4$–MeCN containing (*a*) *ca.* 5 mM $NBu_4OH$ ($\Gamma_{Ru} = 1.5 \times 10^{-8}$ mol $cm^{-2}$) or (*b*) *ca.* 50 mM $HClO_4$ ($\Gamma_{ru} = 1.4 \times 10^{-8}$ mol $cm^{-2}$). Lines show extrapolations to the real axis intercepts, $R_{high}$ and $R_{low}$.

These results provide conclusive evidence that the conjugated polybenzimidazole backbone of **1** is involved in electron transfer between Ru sites. Since the Ru-free polymer does not exhibit electrochemical activity in the potential region of the Ru formal potential in either medium studied, electron transport is presumably facilitated by an electronic interaction between metal centres through the polymer backbone, rather than by hopping *via* the polymer backbone. This type of long-range, multi-metal centre interaction could provide the basis for useful electrocatalytic and electronic materials.

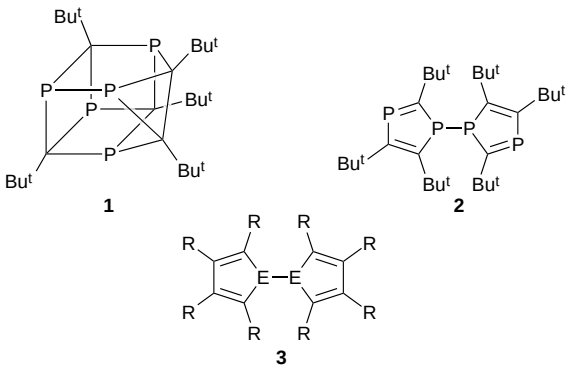
# Synthesis, crystal and molecular structure of a novel organoantimony cage compound, $C_4Bu^t_4P_4Sb_2$

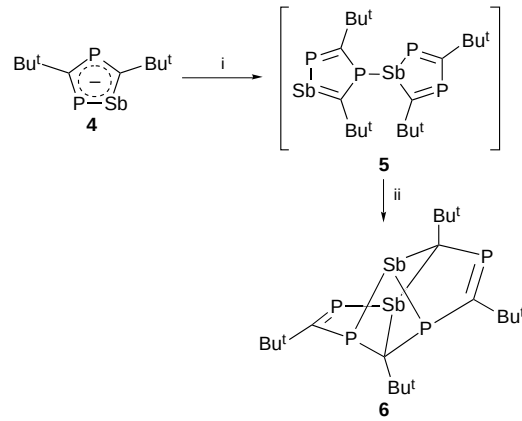
**Steven J. Black, Matthew D. Francis and Cameron Jones*†**

*Department of Chemistry, University of Wales, Swansea, Singleton Park, Swansea, UK SA2 8PP*

**The reaction of the hetero-ring anion $[P_2SbC_2Bu^t_2]^-$ with $FeCl_3$ affords the organoantimony cage compound, $C_4Bu^t_4P_4Sb_2$, *via* a proposed oxidative coupling reaction; the X-ray crystal structure of the cage displays weak intermolecular interactions.**



The chemistry of organophosphorus cage compounds is a rapidly expanding area that derives its current importance from the remarkable similarities such compounds show to their hydrocarbon cage counterparts.[1] Several synthetic routes to these compounds have been developed but the oxidative coupling of polyphospholyl ions is the route most relevant to the work described here.[2] For example, Nixon and coworkers have reported that the treatment of a 1:1 mixture of the ions $[1,2,4\text{-}P_3C_2Bu^t_2]^-$–$[1,3\text{-}P_2C_3Bu^t_3]^-$ with $FeCl_3$ leads to low yields of the cage, $P_5C_5Bu^t_5$ **1**, *via* an unknown mechanism.[3] The formation of organophosphorus cage compounds *via* oxidative coupling reactions can be blocked if the reacting polyphospholyl ion is sufficiently sterically protected, as is the case in the reaction of $[1,3\text{-}P_2C_3Bu^t_3]^-$ with $[RuCl_2(\eta^4\text{-}C_8H_{12})]_n$ which yields **2** among other products.[4] Moreover, the absence of any known uncoordinated poly-arsolyl, -stibolyl or -bismolyl anions precludes the existence of heavier group 15 element organometallic cages derived from oxidative coupling reactions. However, coupling of their monosubstituted counterparts is known to yield compounds of the type **3**, which can possess solid-state intermolecular interactions (E = Sb, Bi) that impart thermochromic properties to these species.[5]



We have recently developed a high-yielding synthetic route to the diphosphastibolyl ring anion $[P_2SbC_2Bu^t_2]^-$ **4**,[6] which we have incorporated into a range of organometallic complexes, *viz*. $[Ru(\eta^5\text{-}C_5R_5)(\eta^5\text{-}P_2SbC_2Bu^t_2)]$ (R = H, Me),[7] $[M(\eta^5\text{-}P_2SbC_2Bu^t_2)(\eta^4\text{-}C_8H_{12})]$ (M = Rh, Ir) and $[Co(\eta^5\text{-}P_2SbC_2Bu^t_2)(\eta^4\text{-}P_2SbC_2HBu^t_2)]$.[8] Our interests have now extended to an examination of the formation of organometallic cages *via* oxidative coupling reactions of **4**. The results of these investigations are reported herein.

Treatment of a dme solution of $FeCl_3$ with 1 equiv. of $[Li(tmeda)_2]$ **4** (Scheme 1) leads to the formation of the air- and moisture-stable cage compound, $C_4Bu^t_4P_4Sb_2$ **6** (mp 82 °C decomp.), in good yield (61%) after chromatographic work-up (Kieselgel, hexane). Compound **6** can also be prepared in lower yields by the reactions of $[Li(tmeda)_2]$ **4** with either $InCl_3$, $PbCl_2$ or $SbF_3$. It seems likely that the reaction mechanism involves an initial coupling to give the intermediate, **5**, which then undergoes a [4 + 2] cycloaddition reaction to give the final product, **6**. If this is so, it is surprising that the coupling occurs through the most sterically hindered heterocentre on one of the rings, *i.e.* the P centre adjacent to two *tert*-butyl substituted C centres. It is also surprising that only one set of enantiomers is formed despite the numerous isomers that are possible if the coupling reaction were to occur through any of the heterocentres on each ring and if there was no specificity to the possible subsequent cycloaddition reactions.

The spectroscopic data‡ for **6** support its proposed structure. Its $^{31}P\{^1H\}$ NMR spectrum is pseudo-first order and has been successfully simulated as an AMNX spin system with four inequivalent phosphorus resonances; two at low field ($P_A$, $P_X$) in the region consistent with phosphaalkenes, and two in the higher field saturated phosphorus region ($P_M$, $P_N$). The lowest field signal (δ 363.4) shows considerable broadening which suggests it arises from the low-coordinate phosphorus centre, P(1), adjacent to the quadrupolar antimony centre, Sb(1). This would necessitate the highest field signal (δ −18.6) to originate from P(2) due to its two-bond coupling (28 Hz) to P(1). The assignment of the remaining signals, P(4) (δ 356.5) and P(3) (δ 32.5) logically follows. Interestingly, there is a very large two-bond coupling (137 Hz) between P(2) and P(3). This is perhaps best explained as a through space coupling which results from the very short intramolecular P(2)–P(3) distance (*vide infra*). Both the $^1H$ and $^{13}C$ NMR spectra of **6** are as expected and highlight four inequivalent *tert*-butyl groups. The mass spectrum of **6** exhibits a molecular-ion peak with the correct isotopic distribution.

The molecular structure of **6**§ is depicted in Fig. 1. All bond lengths within the structure are normal for single bonded interactions except those for P(1)–C(2) [1.681(4) Å] and P(4)–C(12) [1.689(4) Å] which are consistent with localised

**Scheme 1** *Reagents and conditions*: i, $FeCl_3$, dme, 18 h, 25 °C; ii, [4 + 2] cycloaddition

P–C double bonds. Compound **6** contains the first example of a structurally characterised diphosphastibacyclobutane fragment [Sb(2)–P(3)–C(1)–P(2)] which has very short cross-ring P···P (2.822 Å) and Sb···C (3.024 Å) distances which are well within the sum of the van der Waals radii (3.8 and 4.04 Å respectively[9]) for these atom combinations. There are also two polyhetero six-membered rings within the structure [P(1)=C(2)–P(2)–Sb(2)–C(11)–Sb(1) and P(4)=C(12)–P(3)–C(1)–Sb(1)–C(11)] which are also the first examples of such heterocyclic fragments. Another feature of the structure of **6** became evident from an examination of its cell packing diagram (Fig. 2) which shows the molecules to be linked in infinite one-dimensional arrays through weak intermolecular interactions [Sb(2)···P(1) 3.621(6) Å, P(2)···P(1) 3.652(5) Å] which are less than the sum of the van der Waals radii of the atoms involved [Sb–P (4.1 Å), P–P (3.8 Å)].

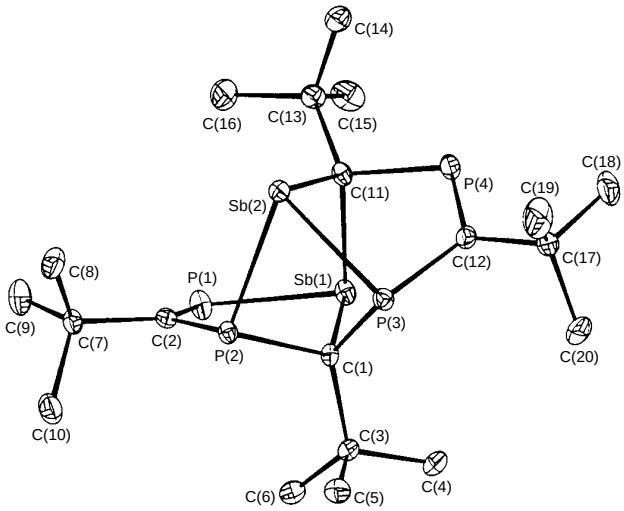


**Fig. 1** Molecular structure of $C_4Bu^t_4P_4Sb_2$ **6**. Selected bond lengths (Å) and angles (°): Sb(1)–C(1) 2.200(4), Sb(1)–C(11) 2.223(4), Sb(1)–P(1) 2.531(1), Sb(2)–C(11) 2.221(4), Sb(2)–P(3) 2.516(1), Sb(2)–P(2) 2.529(1), P(1)–C(2) 1.681(4), P(2)–C(2) 1.827(4), P(2)–C(1) 1.874(4), P(3)–C(12) 1.852(4), P(3)–C(1) 1.925(4) P(4)–C(12) 1.689(4), P(4)–C(11) 1.844(4), C(1)–Sb(1)–C(11) 88.7(1), C(1)–Sb(1)–P(1) 91.6(1), C(11)–Sb(1)–P(1) 98.5(1); C(11)–Sb(2)–P(3) 82.6(1), C(11)–Sb(2)–P(2) 96.2(1), P(3)–Sb(2)–P(2) 68.0(4), C(2)–P(1)–Sb(1) 98.8(1), C(2)–P(2)–C(1) 107.6(2), C(2)–P(2)–Sb(2) 104.1(1), C(1)–P(2)–Sb(2) 85.6(1), C(12)–P(3)–C(1) 109.2(2), C(12)–P(3)–Sb(2) 94.7(1), C(1)–P(3)–Sb(2) 84.9(1), P(2)–C(1)–P(3) 95.9(2), P(2)–C(1)–Sb(1) 107.0(2), P(3)–C(1)–Sb(1) 111.8(2), P(1)–C(2)–P(2) 124.9(2), P(4)–C(11)–Sb(2) 107.9(2), P(4)–C(11)–Sb(1) 97.1(2), Sb(2)–C(11)–Sb(1) 109.2(2), P(4)–C(12)–P(3) 121.8(2).

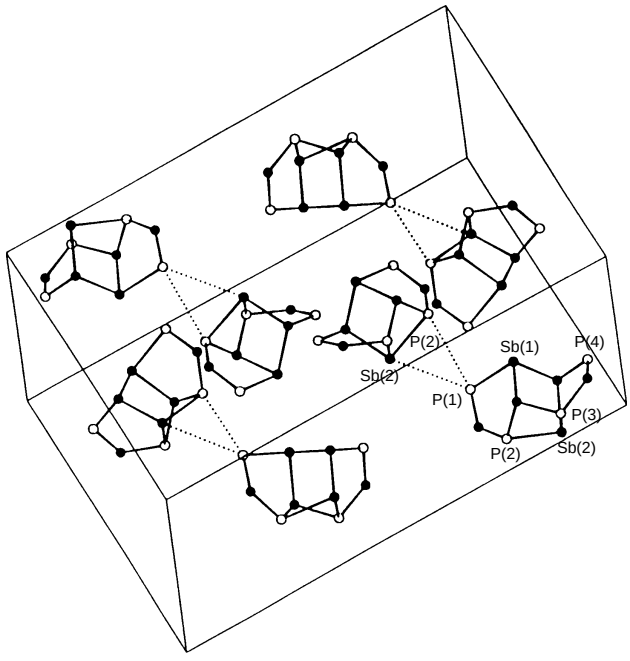

**Fig. 2** Unit-cell diagram for $C_4Bu^t_4P_4Sb_2$ **6** showing intermolecular interactions. *tert*-Butyl groups omitted for sake of clarity

We have recently discovered that the highly strained cage compound **6** undergoes facile intramolecular rearrangement reactions, either in solution (even at −30 °C) or when treated with transition-metal fragments, *e.g.* $[W(CO)_5]$. The results of these investigations will be presented in a later publication.

We gratefully acknowledge financial support from The Leverhulme Trust (S. J. B.) and The Nuffield Foundation. We also thank Professor M. B. Hursthouse and Mr D. E. Hibbs (EPSRC Crystallography Service, Cardiff) for the X-ray data collection and many helpful discussions.

‡ *Spectroscopic data* for **6**: $^1$H NMR (250 MHz, $C_6D_6$, $SiMe_4$) δ 1.16 (s, 9 H, Bu$^t$), 1.28 (s, 9 H, Bu$^t$), 1.48 (s, 9 H, Bu$^t$), 1.62 (s, 9 H, Bu$^t$); $^{13}$C NMR (100.6 MHz, $C_6D_6$) δ 30.7 (dd, C*C*H$_3$, $^3J_{PC}$ 7.5, 7.8 Hz), 31.8 (dd, C*C*H$_3$, $^3J_{PC}$ 11.4, 10.0 Hz), 32.7 (dd, C*C*H$_3$, $^3J_{PC}$ 6.0, 9.1 Hz), 36.3 (d, C*C*H$_3$, $^3J_{PC}$ 10.4 Hz), 38.6 (d, *C*CH$_3$, $^2J_{PC}$ 16.2 Hz), 42.1 (dd, *C*CH$_3$, $^2J_{PC}$ 22.0, 21.0 Hz), 46.2 (dd, *C*CH$_3$, $^2J_{PC}$ 14.9, 12.6 Hz), 47.7 (dd, *C*CH$_3$, $^2J_{PC}$ 12.1, 14.2 Hz), 79.0 (ddd, PCP, $^1J_{PC}$ 50, 51, $^3J_{PC}$ 8 Hz), 90.5 (d, SbCP, $^1J_{PC}$ 65 Hz), 212.0 (ddd, PCP, $^1J_{PC}$ 77, 74, $^3J_{PC}$ 10.1 Hz), 240.2 (ddd, PCP, $^1J_{PC}$ 89, 87, $^3J_{PC}$ 9.6 Hz); $^{31}$P{$^1$H} NMR (101.4 MHz, $C_6D_6$) δ −18.6 (dd, P$^2$, $^2J_{P2,3}$ 137, $^2J_{P1,2}$ 28 Hz), 32.5 (dd, P$^3$, $^2J_{P2,3}$ 137, $^2J_{P3,4}$ 31 Hz), 356.5 (d, P$^4$, $^2J_{P3,4}$ 31 Hz), 363.4 (d, P$^1$, $^2J_{P1,2}$ 28 Hz); CIMS (70 kV) 645 (MH$^+$, 8%), 523 (MH$^+$ − Sb, 10%), 169 (Bu$^t$CPCBu$^{t+}$, 15%), 57 (Bu$^{t+}$, 100%). Suitable analytical data were obtained.

‡ *Crystal data* for **6**: $C_{20}H_{36}P_4Sb_2$, $M$ = 643.87, orthorhombic, space group *Pbca*, $a$ = 12.9730(5), $b$ = 19.0530(7), $c$ = 21.052(2) Å, $U$ = 5203.5(6) Å$^3$, $Z$ = 8, $D_c$ = 1.644 g cm$^{-3}$, $F(000)$ = 2544, μ = 23.26 cm$^{-1}$, crystal 0.23 × 0.31 × 0.18 mm, radiation Mo-Kα (λ = 0.710 69 Å), 150(2) K.

All crystallographic measurements were made using a FAST area detector diffractometer. The structure was solved by direct methods and difference synthesis and refined on $F^2$ by full-matrix least squares using all unique data. All non-hydrogen atoms are anisotropic with H atoms included in calculated positions (riding model). Final $wR$ (on $F^2$) and $R$ (on $F$) were 0.0647 and 0.0446 for all data. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/336.

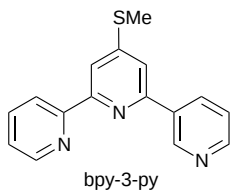
# Self-assembly of supramolecular boxes

**Michael J. Hannon,* Claire L. Painting and William Errington**



*Department of Chemistry, University of Warwick, Gibbet Hill Road, Coventry, UK CV4 7AL*

**Supramolecular boxes are prepared from a dinucleating ligand and redox-active metal centres incorporated into the cavity framework without the need for ancillary ligands to block coordination sites on the metal; crystal structures of copper(I) and cadmium(II) cage structures of 4-thiomethyl-6-(3-pyridyl)-2,2′-bipyridine are reported.**

There is much interest in the use of the supramolecular synthetic approach to assemble large molecular aggregates.[1] The metallosupramolecular approach has enjoyed particular success and nanoscale arrays containing up to 15 components have been assembled.[2] Following the elegant work of Fujita *et al*.[3] and others[4] we were drawn to the assembly of supramolecular species containing cavities as they represent readily prepared analogues of organic macrocycles. As described by Fujita *et al*., a square-shaped cyclophane analogue results from mixing the pre-prepared complex $[Pd(en)(NO_3)_2]$ with the bis-monodentate ligand 4,4′-bipyridine.[3] In this reaction the ethylenediamine ligand acts as a blocking ligand sealing up two coordination sites on the palladium centre. In the absence of blocking ligands polymeric arrays result.[8]

We reasoned that, with judicious design, it should be possible to assemble boxes from ligands incorporating chelating units. The incorporation of chelating units into the framework is desirable as it should (*a*) remove the need for ancillary blocking ligands and (*b*) permit the incorporation of a more varied selection of metal ions into the cage arrays. Using our design, cage structures might be assembled in a single self-assembly process involving simple mixing of metals and ligands rather than the stepwise approach, involving pre-preparation of the blocked metal complex, inherent in the previous work.[3,4] Such a design requires the preparation of ligands which contain two coordination sites, linked in such a fashion that they cannot both coordinate to the same metal ion. Moreover the position of the link must lead logically to the formation of a defined closed structure when metal ions coordinate to the ligand, and the closed structure that results must contain an aryl-linked cavity. The coordination sites used might be either two polydentate sites or one polydentate and one monodentate site. We have chosen to initiate our studies with the latter and wish to report our preliminary results in this area.

Following our design, we have prepared the substituted terpyridine ligand 4-thiomethyl-6-(3″-pyridyl)-2,2′-bipyridine (bpy-3-py). This ligand is constrained by its connectivity to act as a dinucleating ligand, presenting a didentate binding site to one metal ion and a monodentate to the other. The ligand was prepared in good yield (64%) in a one-pot Potts[5] reaction of 3,3-bis(methylthio)-1-(2′-pyridinyl)prop-2-en-1-one with the potassium enolate of 3-acetylpyridine, followed by ring closure with ammonium acetate.

bpy-3-py

Warming methanolic or acetonitrilic solutions of the ligand with 1 equiv. of copper(I) salts $[Cu(MeCN)_4]X$ (X = $PF_6$, $BF_4$) leads to the rapid formation of red solutions from which red–brown salts of formula $[Cu_2(bpy\text{-}3\text{-}py)_2(MeCN)_2]X_2$ are isolated on cooling. Mass spectrometric analysis (FAB) shows the presence of dinuclear $M_2L_2$ and $M_2L_2X$ peaks consistent with this formulation. Cyclic voltammetric analysis of acetonitrilic solutions of the complexes shows a single reversible oxidation at +0.13 V (*vs*. $Fc–Fc^+$) consistent with copper(I) in an $N_4$ coordination environment.[6] More importantly this implies that there are not two different types of copper(I) centre present in the molecule. The absorption spectra of acetonitrilic solutions of the complexes show charge-transfer bands centred at 537 ($\varepsilon$ = 1300) and 426 nm (2300 $M^{-1}$ $cm^{-1}$), which are also consistent with an $N_4$ coordination set containing polypyridyl units.[6] The $^1H$ NMR spectra of $CD_3CN$ solutions of the salts show the expected number of resonances in the aromatic region and the presence of a single thiomethyl resonance. The spectra are slightly broadened at room temperature, most probably as a result of 'ring-wobbling' processes similar to those that we have previously observed[6,7] in other oligopyridine assemblies.

Recrystallisation of the hexafluorophosphate salt from acetonitrile solution by the slow diffusion of diethyl ether afforded deep red crystals, the structure of which has been determined† and which is shown in Fig. 1. As anticipated the bpy-3-py ligand bridges between two metal centres. Each copper(I) centre is bound to a bipyridyl unit from one ligand and a pyridyl from the other, resulting in the formation of a dimeric $M_2L_2$ species. The pseudo-tetrahedral coordination sphere of the metal centre is completed by an acetonitrile solvent molecule. The metal–ligand bond lengths and angles are unremarkable and the intermetallic Cu···Cu distance is 5.178(1) Å. The pyridyl and bipyridyl binding domains are twisted with respect to each other [dihedral angle 50.26(13)°] and a cavity between the pyridyl units of the two ligands results. This twisting is anticipated; indeed we have previously used it to generate double-helical complexes.[6] In this case the twisting results in the aromatic rings defining the desired aryl-lined cavity.

The cage structure furnishes each metal ion with only three donor atoms (one from the pyridyl unit of one ligand and two from the bipyridyl of the ligand). The box structure is

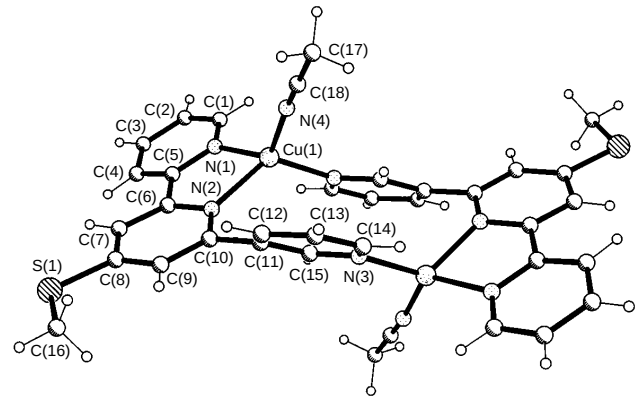


**Fig. 1** Crystal and molecular structure of the cation $[Cu_2(bpy\text{-}3\text{-}py)_2(MeCN)_2]^{2+}$

nevertheless formed with the tetrahedral copper(I) ion. We have therefore investigated whether the structure might also be supported by metal ions with a higher coordination number requirement.

Reaction of a methanolic solution of the ligand with cadmium(II) acetate gives a pale green solution from which beautiful green blocks crystallise on the addition of methanolic ammonium hexafluorophosphate. On isolation the crystals rapidly lose solvent to give an apple-green solid. An X-ray crystallographic study has been undertaken on the crystalline material† and the structure is shown in Fig. 2. Once again a dimeric $M_2L_2$ cage structure is formed with the ligand bridging between the two metal centres and each cadmium(II) ion bound to a pyridyl group from one ligand and a bipyridyl unit from the other ligand. The twisting about the aryl–aryl bonds between the pyridyl and bipyridyl units [dihedral angle 55.40(13)°] again results in the desired aryl-lined cavity. In contrast to the pseudo-tetrahedral copper(I) cations the cadmium(II) dications occupy a pseudo-octahedral environment. The remaining coordination sites are completed by a didentate acetate ligand and a methanol solvent molecule. The two cadmium centres are separated by 5.6788(8) Å.

The structure may be contrasted with the polymeric species obtained from mixing cadmium(II) salts with 4,4′-bipyridine.[8] While the reaction of $[Pd(en)(NO_3)_2]$ with 4,4′-bipyridine gives rise to a molecular square, the reaction of the cadmium(II) metal salt, which does not contain a blocking ethylenediamine ligand, gives rise to a polymeric array of squares. As anticipated, the introduction of the chelating unit within our system does lead to the formation of the box structure, rather than a polymeric array.

We have thus established a novel ligand which allows us to form metallosupramolecular cage species with a variety of metal ions without the need for ancillary ligands which deliberately block coordination sites. We are also applying the principles learnt in this study to the development of polymeric arrays ('crystal engineering') and will address our studies in that area in a subsequent paper.

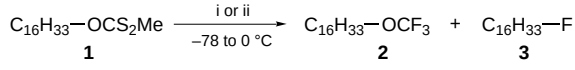
# Oxidative desulfurization–fluorination of alkanol xanthates. Control of the reaction pathway to fluorination or trifluoromethoxylation

**Kiyoshi Kanie, Yoichiro Tanaka, Masaki Shimizu, Manabu Kuroboshi† and Tamejiro Hiyama***

*Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama, Kanagawa 226, Japan*

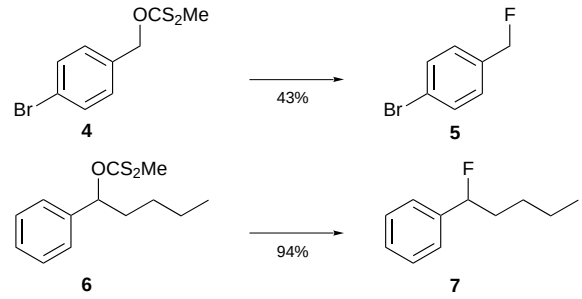
**The reagent consisting of 70% HF–py (py = pyridine) and a halonium oxidant converts R–$OCS_2Me$ into either R–$OCF_3$ (R = primary) or R–F (R = secondary, tertiary or benzylic) whereas the 50% HF–py system converts R–$OCS_2Me$ (R = secondary) into R–$OCF_3$.**

Exploitation of novel and efficient fluorination reactions has been the subject of extensive research,[1] because organofluorine compounds very often play key roles in material and pharmaceutical science. The oxidative desulfurization–fluorination reaction[2] recently disclosed by us transforms the xanthates derived from phenols and primary alkanols to the corresponding trifluoromethyl ethers.[3] To achieve this transformation, a readily available reagent system consisting of hydrogen fluoride and 30% pyridine (70% HF–py)[4] and a halonium oxidant is extremely effective.



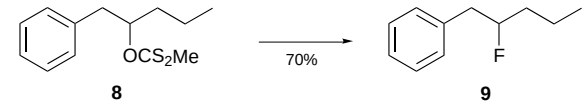
Very recently, Motherwell and his co-workers reported that the xanthates of primary and secondary alkanols were converted into the corresponding fluorides by means of 4-methyl(difluoroiodo)benzene ($TolIF_2$).[5] This paper, indicating that the xanthates of primary alkanols gave different products, prompted us to study in more detail the oxidative desulfurization–fluorination of the xanthates of various secondary and tertiary alkanols. Herein we report that R–$OCS_2Me$ (R = primary) could be converted into R–$OCF_3$, whereas R–$OCS_2Me$ (R = secondary, tertiary or benzylic) was fluorinated to give R–F. Furthermore, we also found that 50% HF–py could convert R–$OCS_2Me$ (R = secondary) into the corresponding R–$OCF_3$ with R–F being undetected. According to the presented method, secondary alkyl trifluoromethyl ethers are prepared for the first time from the corresponding alcohols.

To compare the selectivity of the reagent 70% HF–py–$X^+$ with $TolIF_2$, we first chose *O*-hexadecyl *S*-methyl dithiocarbonate **1** for the model substrate. Upon treatment with $TolIF_2$, **1** was reportedly converted into 1-fluorohexadecane **3** in 48% yield.[5] When **1** was treated with 1,3-dibromo-5,5-dimethylhydantoin (DBH, 3.0 mol) and 70% HF–py (80 mol) in dichloromethane at −78 to 0 °C for 1 h, 1-trifluoromethoxyhexadecane **2** was isolated in 95% yield, and no trace of **3** could be detected. To confirm the difference between the two reagents, we used bis(trifluoroacetoxy)iodobenzene (3.0 mmol) in place of DBH; trifluoromethyl ether **2** was obtained again as the sole product in 67% yield (Scheme 1) Thus, the reagent system consisting of 70% HF–py and an oxidant exhibits unique reactivity, contrasting sharply to $TolIF_2$, and the reaction pathway appears to be governed by a fluorinating agent rather than by an oxidant.

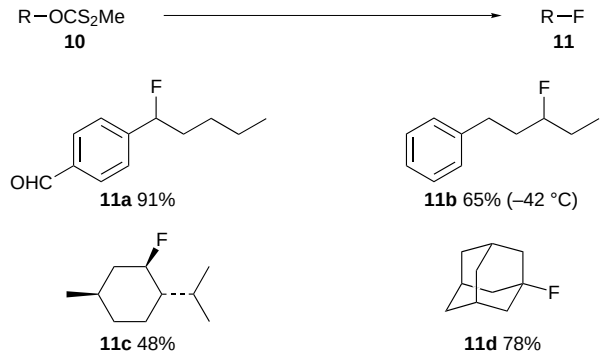


In contrast to the xanthates of primary alcohols, those of benzylic, secondary or tertiary alcohols underwent the fluorination reaction under the standard oxidative desulfurization–fluorination conditions. Examples are the reactions of the benzylic xanthates **4**‡ and **6**; both gave fluorination products **5** and **7**, respectively (Scheme 2).

Xanthate **8** also was successfully fluorinated to give **9** in 70% yield using *N*-iodosuccinimide (NIS) as the oxidant (Scheme 3). With DBH, bromination of the phenyl ring accompanied the fluorination reaction.§



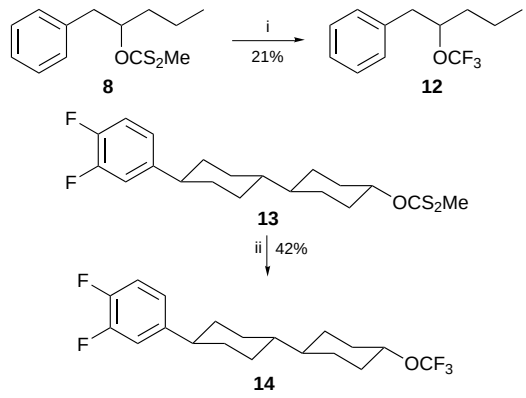
The fluorination conditions were applied to the xanthates derived from secondary or tertiary alcohols. The isolated yield is shown below the formula of each product (Scheme 4). As readily seen, both secondary and tertiary alkyl fluorides could be prepared in good yields.¶ The xanthate of menthol gave **11c** as an isolable single product. Although the reaction appears to have proceeded with retention of configuration, we consider **11c** was produced through a carbocationic intermediate. Similar stereochemical results are reported with other fluorination reagents.[5,6]



**Scheme 1** *Reagents and conditions*: i, 70% HF–py, DBH, **2** 95%; ii, 70% HF–py, $PhI(OCOCF_3)_2$, **2** 67%

**Scheme 2** *Reagents and conditions*: 70% HF–py (40 mol), DBH (3.0 mol), $CH_2Cl_2$, −78 to 0 °C, 1 h

**Scheme 3** *Reagents and conditions*: 70% HF–py (20 mol), NIS (3.0 mol), $CH_2Cl_2$, −42 °C, 1 h



**Scheme 4** *Reagents and conditions*: 70% HF–py (40 mol), NIS (3.0 mol), $CH_2Cl_2$, −78 to 0 °C, 0.5–1 h

The fluorination reaction may be attributed to an easy elimination of the $–OCS_2Me$ group from secondary and tertiary aliphatic xanthates under the acidic conditions, followed by the subsequent fluoride attack at the resulting electrophilic carbon to complete the fluorination. Hence we envisaged that, if the acidity of the reaction conditions was controlled by proper choice of the reagent system, we could switch the reaction pathway to the trifluoromethyl ether formation. Thus, we used 50% HF–py as the fluorinating reagent that was prepared by dilution of 70% HF–py with pyridine. Indeed, xanthate **8** afforded the corresponding trifluoromethyl ether **12** in 21% yield by treatment with 50% HF–py (40 mol) and *N*-bromosuccinimide (NBS, 5.0 mol) at −78 to 0 °C for 30 min (Scheme 5).‖ Herein no trace of alkyl fluoride **9** could be detected. Furthermore, xanthate **13** was also converted into the corresponding trifluoromethyl ether **14** in 42% yield.

In conclusion, the reagent system consisting of 70% HF–py and a halonium ion oxidant is extremely effective for the conversion of $R–OCS_2Me$ (R = alkyl) into either $R–OCF_3$ (R = primary) or R–F (R = benzylic, secondary or tertiary), depending on the structure of the substrate. In particular, the xanthates of primary alcohols give trifluoromethyl ethers in striking contrast to the reaction with $TolIF_2$. The difference may be attributed to the difference between the reactive species involved.[5,6] Furthermore, the synthesis[7] of secondary alkyl trifluoromethyl ethers is achieved with a readily adjustable reagent system consisting of 50% HF–Py and NBS. Thus, the reaction pathway to secondary alkyl fluoride or to trifluoromethyl ether is controlled simply by an appropriate choice of the fluorination reagent starting with the same substrate.

The present work is partially supported financially by a grant from the Asahi Glass Foundation and by a Grant-in-Aid (No. 07405042) for Scientific Research (A) from the Ministry of Education, Science, Sports and Culture.

**Scheme 5** *Reagents and conditions*: i, 50% HF–py (40 mol), NBS (5.0 mol), $CH_2Cl_2$, −78 to 0 °C, 0.5 h; ii, 50% HF–py (40 mol), NBS (5.0 mol), $CH_2Cl_2$, 0 °C, 1 h

## Footnotes

† Present address: Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushima-naka, Okayama 700, Japan.

‡ To obtain the product in high yield, 40 mol of 70% HF–py was enough. When 80 mol of 70% HF–py was used, halogenation of the aromatic moiety simultaneously took place, and a mixture of monobromo, dibromo and tribromo derivatives resulted.

§ When 40 mol of 70% HF–py was used, iodination of the phenyl group occurred to some extent.

¶ A procedure for the synthesis of 4-(1-fluoropentyl)benzaldehyde **11a** is representative. To a suspension of NIS (1.5 mmol) in dichloromethane (2.5 ml) were added 70% HF–py[4] (0.5 ml, 2.2 mmol, 20 mmol of $F^-$) and *O*-{1-(4-formylphenyl)pentyl} *S*-methyl dithiocarbonate (0.5 mmol) at −78 °C. The mixture was stirred at 0 °C for 1 h, poured into a pH = 10 buffer solution ($NaHCO_3$, $NaHSO_3$ and NaOH) and extracted with diethyl ether three times. The combined ethereal layers were dried over $MgSO_4$, filtered and concentrated under reduced pressure. Flash column chromatography on silica gel (hexane–$Et_2O$, 20 : 1) afforded **11a** in 91% yield.

‖ A procedure for the preparation of trifluoromethyl ether **12** is as follows. To a suspension of NBS (5.0 mmol) in dichloromethane (2.5 ml) was added pyridine (0.46 ml); subsequently 70% HF–py (1.0 ml, 4.4 mmol, 40 mmol of $F^-$) was slowly added dropwise at −78 °C, and the resulting mixture was stirred at room temp. for 5 min and then recooled to −78 °C. A dichloromethane (2.5 ml) solution of xanthate **8** (1.0 mmol) was added dropwise to the suspension at −78 °C. The resulting mixture was stirred at 0 °C for 30 min, poured into a pH = 10 buffer solution ($NaHCO_3$, $NaHSO_3$ and NaOH) and extracted with diethyl ether three times. The combined ethereal layers were dried over $MgSO_4$, filtered and concentrated under reduced pressure. Flash column chromatography on silica gel (cyclohexane) afforded 1-phenylpent-2-yl trifluoromethyl ether **12** in 21% yield.

** Under the similar conditions, trifluoromethyl ethers of β-cholestanol and 1-phenylpentan-3-ol were prepared in 24 and 16% yield, respectively.

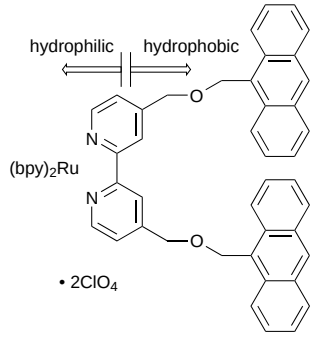
# Directional photochemical processes with an amphiphilic anthraceno–ruthenium complex in dihexadecyl phosphate vesicles

**Joe Otsuki,*[a] Naotoshi Okuda,[b] Takeyuki Amamiya,[b] Koji Araki[a] and Manabu Seno[b]**



[a] *Institute of Industrial Science, University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106, Japan*
[b] *College of Science and Technology, Nihon University, 1-8-14 Kanda Surugadai, Chiyoda-ku, Tokyo 101, Japan*

**Excitation of an amphiphilic anthraceno–ruthenium complex, which serves as an antenna-sensitizer complex, leads to two kinds of anthracene triplet states, one of which is bleached by a hydrophilic acceptor and the other by a hydrophobic acceptor in dihexadecyl phosphate vesicles; the latter process is directional from the surface to the interior of the bilayer membrane.**

Numerous model studies have appeared on photo-induced electron-transfer systems across vesicle membranes, since vesicles have been considered to be useful in providing desirable microheterogeneous environments for the charge separation processes required in photosynthesis.[1] However, nearly all studies involve diffusional processes of redox-active components and the organization of components is thus limited. O'Brien and coworkers recently addressed this problem and reported some systems in which components are partitioned selectively in various parts of the membrane.[2] Another approach would be to connect the components covalently and incorporate them into vesicles with a defined direction by rational design of the hydrophobic–hydrophilic balance. There are only a few reports on covalently linked chromophores in vesicles[3] in spite of the fact that the covalent approach has been met with great success in elucidating factors determining the rate of electron transfer in homogeneous solutions.[4,5] Here we report on vectorial processes effected by a covalently linked anthraceno–ruthenium complex **1** in dihexadecyl phosphate (DHP) vesicles.

The $[Ru(bpy)_3]^{2+}$–anthracene system was chosen as the covalently linked photoactive centre because the intramolecular triplet energy transfer process of a related compound from the ruthenium centre to the anthracene unit is well documented and its excited-state lifetime is longer than that of $[Ru(bpy)_3]^{2+}$ itself.[6] The antenna-sensitizer complex **1**, which has two anthracenes on one of the bipyridine ligands, is designed so that half of the molecule (Ru centre) is hydrophilic, whereas the other half including anthracene is hydrophobic.

The bis-anthracene ligand was prepared from 9-anthracenemethanol and 4,4′-bis(bromomethyl)-2,2′-bipyridine[7] with KOH in $Me_2SO$ (64%, mp 184–185 °C). The complexation of this ligand with *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$[8] followed by the addition of $NaClO_4$ provided **1** (80%, mp 175–179 °C). *N*,*N*′-Didodecylpyromellitimide **2** was prepared from pyromellitic anhydride and 1-aminododecane in refluxing dmf (82%, mp 156.5–158.5 °C).†

**1**

The absorption spectrum of **1** is nearly the superposition of $[Ru(bpy)_3]^{2+}$ and 9-anthracenemethanol, thus the intramolecular electronic interaction in the ground state is negligible. On the other hand, emission properties of **1** are totally different from the model compounds as shown in Table 1.‡ Upon excitation of **1** at 455 or 470 nm, the emission intensity from the metal-to-ligand charge transfer (MLCT) state is diminished by a factor of 20 from that of $[Ru(bpy)_3]^{2+}$. It was established by Meyer and coworkers[8] that the quenching is caused by the intramolecular triplet energy transfer to anthracene (An). Although anthracenemethanol also quenches the emission from $[Ru(bpy)_3]^{2+}$ in DHP vesicles, the intramolecular quenching in **1** is more efficient. The fluorescence from $^1$An is diminished by a factor of 100 in the vesicular solution. The loss of emission may be caused by an enhanced rate for $^1$An to $^3$An intersystem crossing facilitated by the spin–orbit coupling due to the heavy-atom effect of ruthenium.[8] Indeed, the transient absorption spectrum§ after excitation at 337 nm coincides with that of $^3$An (data not shown). According to these observations, it is concluded that excitation, either to MLCT or to $^1$An, leads to $^3$An.

The triplet anthracene in **1** in vesicular solution decays by two exponential processes of comparative amplitudes with lifetimes of 3 and 13 μs [Fig. 1(*a*)], whereas the decay in MeCN is single exponential ($\tau$ = 150 μs). In the presence of 0.2 mM of methyl viologen ($MV^{2+}$), which is known to adsorb on the surface of DHP vesicles,[10] only the longer lifetime component is bleached, while the shorter one is unaffected, as shown in Fig. 1(*b*).

An acceptor with alkyl chains, **2**, was prepared aiming at being incorporated in bilayer membranes, which was indeed confirmed by gel permeation chromatography. Electron-transfer quenching of the MLCT state by the imide should be possible on the basis of redox potentials {−0.84 V for $[*Ru(bpy)_3]^{2+/3+}$[11] and −0.71 V for the diimide[1−/0][12] *vs.* SCE}. However, the emission intensity of $[Ru(bpy)_3]^{2+}$ adsorbed on the vesicle surface is unaltered by up to *ca.* 50 μM of **2**. Hence, **2** must be separated from the ruthenium complex on the membrane surface and so located in the hydrophobic part of the bilayer membrane. In sharp contrast to the case with $MV^{2+}$,

**Table 1** Relative emission intensities[a]

| | MeCN | | DHP vesicles | |
|---|---|---|---|---|
| $\lambda_{ex}$/nm | 455 | 364 | 470 | 366 |
| $\lambda_{em}$/nm | 610 | 410 | 630 | 415 |
| **1** | 0.05 | 0.09 | 0.06 | 0.01 |
| $[Ru(bpy)_3]^{2+}$, AnMeOH | 1.07 | 0.96 | 0.16 | 0.32 |
| $[Ru(bpy)_3]^{2+}$ | 1 | — | 1 | — |
| AnMeOH | — | 1 | — | 1 |

[a] The concentrations of Ru units were 3 and 30 μM, while those of An units were 6 and 60 μM in MeCN and in vesicle dispersions, respectively. AnMeOH = 9-anthracenemethanol.

transient absorption of **1** with **2** (10 μM) in DHP vesicles shows that the shorter-lifetime component is completely bleached [Fig. 1(*c*)], suggesting electron transfer from $^3$An to **2**,¶ whereas the longer-lifetime component is not affected at all.

To summarize, there are two types of $^3$An in DHP vesicles with different lifetimes, the longer-lifetime component being located near the surface of the membrane and bleached by $MV^{2+}$, while the shorter-lifetime component is located deeper in the membrane and bleached by the diimide (Fig. 2).‖ In the latter process, the photochemical events proceed directionally from the initial excitation of the ruthenium centre on the membrane surface to the final bleaching by the imide in the hydrophobic region in the membrane. Thus it is demonstrated that the covalent approach is useful to effect directional processes across the interface.

This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture. The authors acknowledge Professor K. Horie and Dr T. Yamashita of the University of Tokyo for help in establishing the photolysis system. Part of the photolysis equipment was made by S. Furuya and T. Shinohara of the Central Workshop of our Institute.

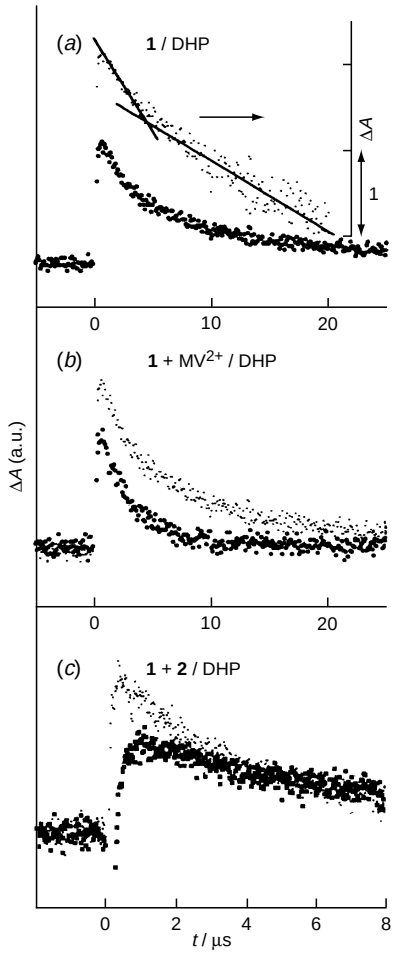


**Fig. 1** (*a*) Transient absorption decay of **1** incorporated in DHP vesicles at 418 nm following excitation at 337 nm. The logarithm plot is also shown. (*b*) The transient absorption in the presence of $MV^{2+}$. (*c*) The transient absorption in the presence of **2**. In (*b*) and (*c*), the decay curve without an acceptor is also shown for comparison by small dots. The experimental conditions are the same as in Table 1.

‡ DHP vesicles were prepared according to a reported procedure.[9] Incorporation of the respective components was confirmed by passing the vesicle solution through Sephadex G50 and observing the coelution of vesicles and the components. Samples were substituted by Ar prior to measurements.

§ Laser flash photolysis experiments were conducted using a home- made system including an $N_2$ laser as the excitation source and a Xe lamp as the monitor light.

¶ We were unable to detect any direct evidence of $\mathbf{2}^-$ probably due to its small concentration and fast (< 0.2 μs with our instrumentation) back electron transfer. Bleaching by energy transfer is unlikely, since the triplet energy of the diimide (2.54 eV for *N*,*N*′-dimethylpyromellitimide[13]) is much larger than that of anthracene (1.85 eV).[8]

‖ It is not clear whether the two $^3$An species belong to the same molecule (as implied in Fig. 2) or to different molecules.

# Iodine intercalation in the oxide-ion conductor $BaBi_8O_{13}$

**Darren P. Scarfe, Sai Bhavaraju and Allan J. Jacobson***

*Department of Chemistry and Texas Center for Superconductivity, University of Houston, Houston, TX 77204-5641, USA*

**The intercalation compound $I_3BaBi_8O_{13}$ forms on reaction of iodine with the layered oxide-ion conductor $BaBi_8O_{13}$; the location of iodine within the structure and the ac conductivity of the iodine intercalated phase are described.**

Intercalation reactions of neutral molecules with neutral layered host lattices are restricted to a few guest–host combinations.[1] In insulating host lattices, host–guest interactions include hydrogen bonding, for example in formamide–kaolinite intercalation compounds,[2] and coordination of a base to a metal centre in pyridine–$VOPO_4$.[3] In conducting host lattices, intercalation of neutral molecules is usually accompanied by oxidation of the host lattice and reduction of the guest species. The formation of graphite intercalation compounds with bromine and arsenic pentafluoride are among the most studied examples of neutral molecule intercalation reactions that proceed by this mechanism.[4] A closely related recent example was provided by the observation of iodine intercalation in bismuth cuprate high $T_c$ superconductors, for example, $Bi_2Sr_2CaCu_2O_8$.[5] Iodine is intercalated by direct reaction with the oxide to form a stage 1 structure with iodine located between the double Bi–O sheets and the composition $IBi_2Sr_2CaCu_2O_8$. The nature of the intercalated iodine species remains controversial though the preponderance of the evidence from Raman, XPS, and XAS measurements suggests that the intercalated species is $I_3^-$ charge balanced by the formation of holes in the $CuO_2$ planes.[6–12] Here, we describe a new example of the intercalation of iodine into the layered bismuth oxide host lattice, $BaBi_8O_{13}$. In this case, the host lattice is a good oxide ion conductor but is electronically insulating.

The composition $BaBi_8O_{13}$ is part of the solid solution series observed in the $Bi_2O_3$–BaO phase diagram between *ca*. 20 to 25 mole% BaO that is characterized by a rhombohedral layer structure.[13] The same layered structure type is also observed in the $Bi_2O_3$–MO (M = Ca, Sr) systems.[14] Each macrolayer is composed of a slab built of octahedrally coordinated (Ba,Bi)–O units sandwiched between two planar hexagonal Bi–O sheets. The structure of each complex layer can be related to that of fluorite and is distinctly different from the structure of the square-planar BiO layers in $Bi_2Sr_2CaCu_2O_8$. In each rhombohedral unit cell of $BaBi_8O_{13}$ (space group $R\bar{3}m$) three interlayer spaces are located between the hexagonal Bi–O sheets (a significant fraction of the oxygen atoms in the Bi–O layers are missing). The macrolayers are held together by van der Waals forces and there are no interlayer ions in the pristine host lattice. The rhombohedral phase has been studied in detail because of its very high oxide ion conductivity.[13–19] Two previous structural studies have investigated possible oxygen transport pathways and have suggested that migration *via* the empty interlayer sites is important in the anionic conduction mechanism.[16,19] In this study, we have synthesized the new intercalation compound $I_3BaBi_8O_{13}$ and measured its ac conductivity. The conductivity difference between the host and the intercalated lattice gives further insight into the conductivity mechanism.

The host material was prepared by reaction of a stoichiometric mixture of $Bi_2O_3$ and $Ba(NO_3)_2$ with repeated grinding and annealing at 710 °C in air. The lattice parameters of the single-phase product ($BaBi_8O_{13}$) were determined from the powder X-ray diffraction (XRD) pattern shown in Fig. 1(*a*) [*a* = 3.984(1), *c* = 28.491(2) Å]. Iodine intercalation was carried out by reaction of single-phase $BaBi_8O_{13}$ with $I_2$ (4–5 molar excess) in a sealed evacuated (*ca*. 50 mTorr) Pyrex tube for 1–5 d. The optimum conditions for intercalation were investigated by varying reaction temperatures from 50 to 350 °C and analysing the reaction products by XRD. The yellow colour of the starting material changes to brown on intercalation. For temperatures ≤150 °C, the XRD patterns showed no reaction between the host material and excess iodine. Reactions at temperatures ≥300 °C resulted in a decomposition of the starting materials to $BiI_3$ and other unidentified impurity phases. XRD patterns of samples reacted at 150–275 °C showed the formation of a single-phase layered iodine intercalated compound [Fig. 1(*b*)]. Electron microprobe analysis (EMPA‡) was used to determine the stoichiometry of the reaction product. Analyses of elemental composition and the backscattered electron images indicated the formation of a single-phase product with an average composition $I_{3.10}Ba_{0.98}Bi_{8.06}O_{13.42}$.‡ The stability of the iodine intercalated phase was studied by thermogravimetric analysis (TGA) under flowing $N_2$ saturated with water at 298 K using a TA 2950 Instrument. TGA and XRD showed that the iodine intercalated structure is stable up to temperatures of *ca*. 450 °C, although this is accompanied by the evolution of 1.3 moles of iodine. Above 650 °C the host material is the majority phase observed together with small

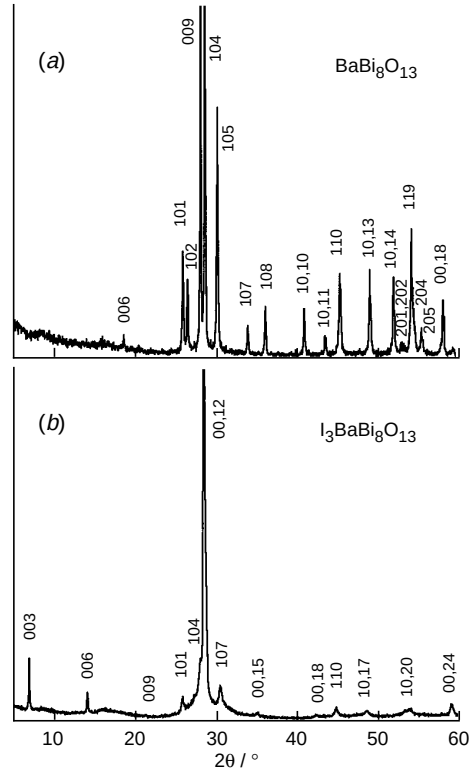

**Fig. 1** Powder X-ray diffraction patterns for (*a*) the host compound $BaBi_8O_{13}$ and (*b*) the iodine intercalated phase $I_3BaBi_8O_{13}$

amounts of unidentified impurity phases. Single-phase host material is obtained only after heating at 700 °C for 10 h. In agreement with the EMPA data, the weight loss given by TGA indicates an iodine content of 3.15(2).

The X-ray diffraction data for the iodine intercalation compound [Fig. 1(*b*)] show several (*h*0*l*) and a well defined series of (00*l*) reflections. The mixed reflections are weak relative to the (00*l*) series most probably due to a combination of preferred orientation effects and some stacking disorder. We note that the observed (*h*0*l*) reflections obey rhombohedral absences suggesting that the layer stacking sequence is preserved. The *a* axis expands from 3.984(1) to 4.01(1) Å on intercalation. The X-ray data show no evidence of any superstructure.

The positions of the (00*l*) reflections were used to determine the *c* axis of the intercalation compound. A value of $c$ = 38.46(5) Å was obtained corresponding to an increase of 9.97 Å per unit cell assuming that the rhombohedral symmetry is preserved. Each unit cell contains three layers and therefore each iodine layer expands the *c* axis by *ca*. 3.32 Å. Refinement of the intensities of the observed (00*l*) reflections was used to confirm a structural model in which the intercalated iodine species form a stage 1 compound with a monolayer of iodine located in the van der Waals gap mid-way between the Bi–O layers. In the refinement, the Ba, Bi and O atom positions were fixed at positions corresponding to the host structure. A scale factor, iodine atom *z* coordinate, occupancy and thermal parameters were refined. The best fit to the data gave an iodine stoichiometry of 3.12(4) corresponding to approximately one iodine atom intercalated into each interlayer space within the unit cell of the host material. Because only a limited number of mixed reflections are observed, the nature and the arrangement of iodine species within the *ab* plane is not yet known. Further studies on single crystal samples are in progress.

Conductivity measurements were made using a two-probe ac impedance technique in the temperature range 260–440 °C. The conductivities of the pristine host material and the iodine intercalated phase are shown in Fig. 2 in the form of an Arrhenius plot. The conductivity of the intercalated phase is approximately 1.5–2 orders of magnitude lower than the host material. The lower conductivity supports previous suggestions that oxide-ion conductivity involves the participation of interlayer sites. At higher temperatures, the difference between the conductivities of the two materials decreases possibly due to the increase in the number of vacant interlayer sites available to oxide ions as iodine is removed from the structure. A larger value of the activation energy due to the migration of oxide ions *via* intralayer sites is a further possibility.

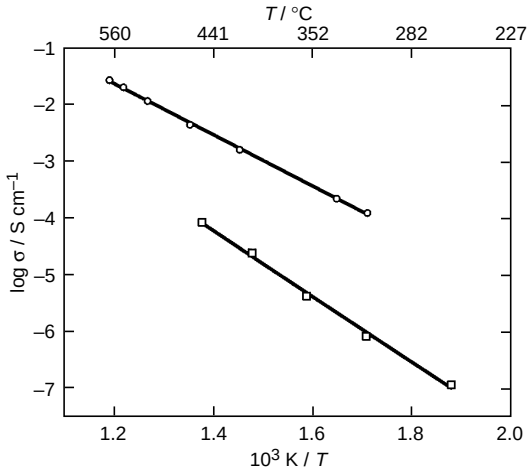

**Fig. 2** Ac conductivity *vs.* $10^3/T$ for $BaBi_8O_{13}$ (○) and $I_3BaBi_8O_{13}$ (□)

At present, the nature of the intercalated iodine species (*e.g.* $I_3^-$, $I^-$, $I_2$), and its structural arrangement within the *ab* plane are not known. Further studies are required in order to determine the nature of the host–guest interactions and the extent of charge transfer in this new example of an intercalation compound formed by reaction of a neutral guest species with a neutral insulating host lattice. Iodine intercalation experiments in compounds with different Bi : Ba ratios and in the related rhombohedral phases in which Ba is substituted with Sr, Ca or La are in progress.

We thank the Robert A. Welch Foundation and the Texas Center for Superconductivity for support of this work.

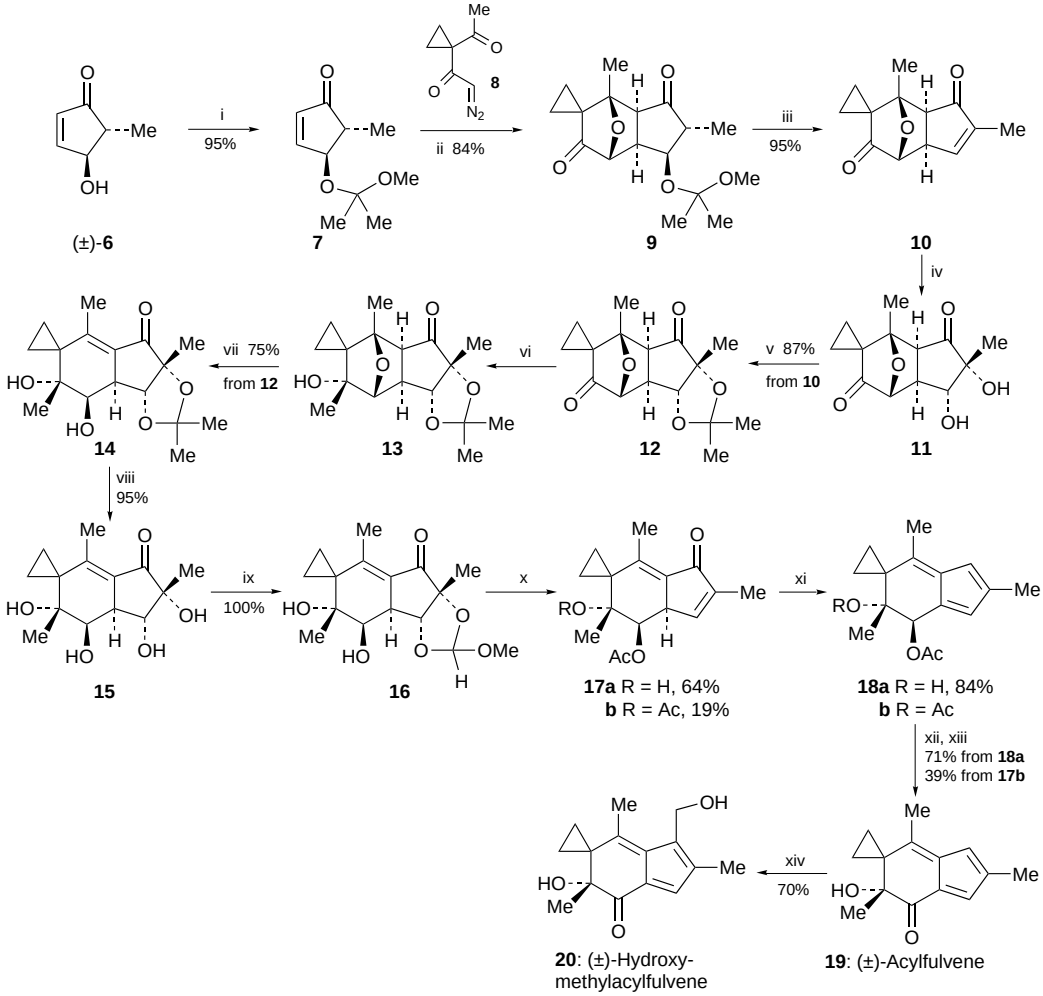
# Total synthesis of hydroxymethylacylfulvene, an antitumour derivative of illudin S



**Trevor C. McMorris,*[a] Yi Hu,[a] Jian Yu[a] and Michael J. Kelner[b]**

[a] *Department of Chemistry and Biochemistry, University of California, San Diego, La Jolla, CA 92093, USA*
[b] *Department of Pathology, University of California, San Diego, La Jolla, CA 92093, USA*

**(±)-Hydroxymethylacylfulvene is synthesized in 14 steps from 4-hydroxy-5-methyl-2-cyclopenten-1-one and 1-acetyl-1-(diazoacetyl)cyclopropane in 15% overall yield.**

Acylfulvenes are a new class of potent antitumour compounds derived from the toxic sesquiterpene illudin S **1**.[1,2] The latter and illudin M **2** are produced in cultures of the basidiomycete *Omphalotus illudens*.[3] These two compounds also possess antitumour activity but were found to have poor therapeutic indices when tested *in vivo*, particularly in solid tumour systems. Studies on the mechanism of toxicity of illudins have led to the preparation of illudin derivatives with greatly improved therapeutic indices compared to the parent compounds. Thus first generation analogue dehydroilludin M **3**[4] showed better efficacy against metastatic MV 522 lung carcinoma xenografts (established in 4-week old athymic

**Scheme 1** *Reagents and conditions*: i, 2-Methoxypropene, $POCl_3$, room temp., 12 h; ii, $Rh_2(OAc)_4$, $CH_2Cl_2$, DMF, reflux, 1.5 h; iii, KOH–MeOH, room temp., 1 h; iv, $OsO_4$, NMO, THF, $H_2O$, room temp., 24 h; v, dimethoxypropane, *p*-TsOH, MeCN, room temp., 10 h; vi, MeMgCl, THF, −78 °C, 2.5 h; vii, KOH–MeOH, 80 °C, 2 h; viii, Dowex resin, $H^+$ form, MeOH, room temp., 12 h; ix, $HC(OMe)_3$, *p*-TsOH, room temp., 2 h; x, $Ac_2O$, reflux, 1.5 h; xi, $CeCl_3·7H_2O$, $NaBH_4$, MeOH–THF (1 : 3), 0 °C to room temp., 5% HCl; xii, $LiAlH_4$, diethyl ether; xiii, Dess–Martin reagent, $CH_2Cl_2$, room temp., 1 h; xiv, $(CH_2O)_n$, $H_2SO_4$, $H_2O$–acetone, room temp., 20 h

Balb/c nu/nu mice) than nine known anticancer agents including cisplatin, cytoxan and paclitaxel. Its efficacy was comparable to that of mitomycin C.[5] The efficacy of second generation analogue acylfulvene **4** exceeded that of dehydroilludin M and mitomycin C.[6] Although these compounds prolonged lifespan in the MV 522 model, they did not induce regression of the primary tumour implants. However, a third generation analogue hydroxymethylacylfulvene (HMAF) **5** caused complete tumour regression in all animals at the maximum tolerated dose of 10 mg $Kg^{-1}$ (iv or ip) three times per week for three weeks. This resulted in an increase in life span of more than 150%.[7] HMAF has also been found to exhibit outstanding activity against breast, colon and skin cancer cell lines derived from human tumours. This compound is now undergoing clinical trials.[8]

HMAF can be prepared readily from acylfulvene **4**, with paraformaldehyde in dilute $H_2SO_4$ solution in 73% yield, or directly from illudin S. However, the total synthesis of acylfulvenes remains a very desirable objective, because it will make available a variety of analogues for structure–activity investigations. The synthesis of (±)-hydroxymethylacylfulvene has been accomplished as follows.

(±)-4-Hydroxy-5-methylcyclopent-2-enone (±)-**6**†[9] was converted to the acetal **7** (2-methoxypropene, $POCl_3$). The latter and rhodium acetate were added to dichloromethane containing dimethylformamide. A solution of diazoketone **8**[10] in dichloromethane was added slowly to the refluxing solution.[10,11] The intermediate carbonyl ylide underwent a 1,3-dipolar cycloaddition reaction with the cyclopentenone to form the adduct **9** in 84% yield, isolated as one enantiomeric pair. Compound **9** was sensitive to base and was converted in high yield (95%) to cyclopentenone **10** with methanolic KOH at room temperature. Further base treatment of **10**, in an attempt to cleave the oxygen bridge, led to extensive decomposition. Because of the electrophilicity of the cyclopropyl ring and reactivity of the unsaturated ketone, many other efforts also failed to give the desired oxygen bridge-opened compound. The double bond was therefore masked by forming diol **11** with $OsO_4$, NMO in THF at room temperature. Diol **11** was converted to the acetonide **12** with dimethoxypropane and *p*-TsOH (87% for two steps). Regioselective reaction of **12** with methylmagnesium chloride (THF, −78 °C) afforded the Grignard product **13**. Treatment of **13** with 10% KOH–MeOH at 80 °C for 2 h cleaved the oxygen bridge giving the diol **14** (75% for the two steps). The acetonide was next hydrolysed (Dowex resin, $H^+$ form, MeOH, 12 h) giving the tetraol **15** (95%).[12] Compound **15** was converted to the orthoester **16** (trimethyl orthoformate, *p*-TsOH, room temp.) and the latter was heated in acetic anhydride (reflux, 1.5 h).[13] A mixture of mono- and di-acetate (**17a** 64%, **17b** 19%) was obtained. Reduction of **17a** with $NaBH_4$, $CeCl_3 \cdot 7H_2O$ in THF and methanol gave an unstable product and the hydroxy group was eliminated on work up yielding the fulvene **18a** (84%). Reduction of the acetate **18a** ($LiAlH_4$, diethyl ether, room temp., 10 min) followed by oxidation of the resulting alcohol with Dess–Martin reagent[14a,b] yielded (±)-acylfulvene **19** (71%) as a yellow gum. Diacetate **17b** could also be converted similarly to **19** (40%). Finally, (±)-hydroxymethylacylfulvene **20** was obtained from **19** following the known procedure.[2]

The spectral properties of (±)-hydroxymethylacylfulvene **20** and (±)-acylfulvene **19** were identical to those of the hydroxymethylacylfulvene and acylfulvene derived from illudin S.

This investigation was supported by MGI Pharma Inc., Minnetonka, Minnesota, USA.

## Footnote

† The new compounds **6**–**20** were fully characterised by spectroscopic data including HRMS.

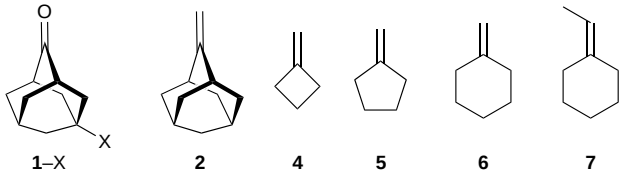
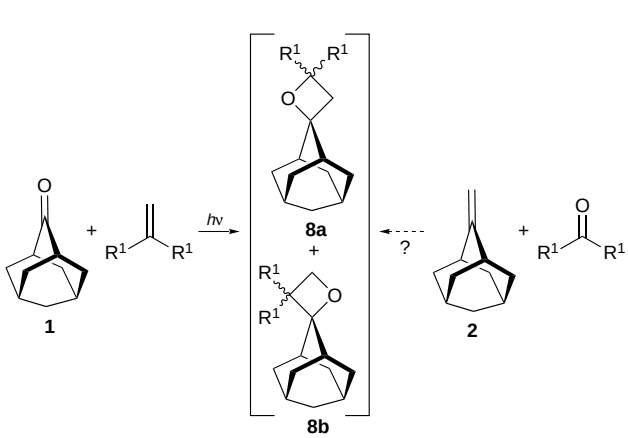
# Photochemistry of acetone in the presence of exocyclic olefins: an unexpected competition between the photo-Conia and Paternò–Büchi reactions



**Wen-Sheng Chung* and Chia-Chin Ho**

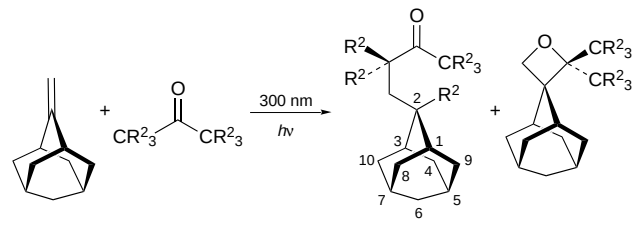


*Department of Applied Chemistry, National Chiao Tung University, Hsinchu, Taiwan 30050, ROC*

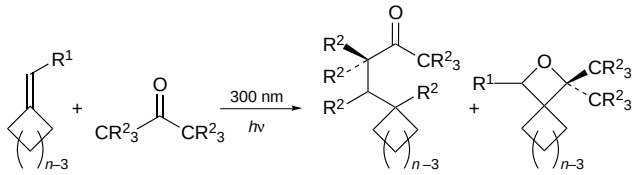
**When irradiated in the presence of several exocyclic olefins, acetone undergoes homoalkylation with the olefins to form a series of 4-cycloalkylbutan-2-ones (with quantum yields of 0.14 ± 0.01) rather than exhibiting the expected Paternò–Büchi reaction; in contrast, the photolysis of perdeuteriated acetone gave both types of products.**

Carbonyl group photochemistry has been covered in many excellent reviews and books over the last four decades.[1] It has long been known that when irradiated in the presence of olefins, aliphatic ketones undergo the Paternò–Büchi reaction,[2] Norrish type I or Type II reactions,[2,3] the former of which gives oxetane products, and the latter, pinacols, alcohols and hydrocarbon dimers. In some rare cases they may also lead to ene-reaction products.[4] Results other than those described above have been reported[5] but the reports have long been ignored.[1] For example, the photochemistry of acetone with norbornene was reported[5a] to proceed by chain addition of acetonyl radicals to norbornene, a process analogous to the addition of cyclohexanone to oct-1-ene[5b] and to cyclohexene.[5c] The same outcome, when obtained thermochemically, is known as the Conia reaction.[6] Thus, we shall call the latter reactions photo-Conia reactions.

In the course of studying face selectivity in the photocycloaddition reaction of 5-substituted adamantan-2-ones **1**–Xs, we have used many different olefins with nitrile or alkoxy substituents and have found that they all give oxetane products in excellent yields.[7] It is of interest to know whether the photocycloaddition occurs when **1**–X is replaced with methyleneadamantane **2** and the olefin is replaced with a ketone (Scheme 1). It is also surprising to note that the photochemistry of ketones in the presence of exocyclic olefins has not been systematically studied.[1] We report here the photochemistry of acetone **3a** with methyleneadamantane **2** and a series of exocyclic alkenes, *e.g.* methylenecyclobutane **4**, methylenecyclopentane **5**, methylenecyclohexane **6** and ethylidenecyclohexane **7**.



**Scheme 1**



Irradiation at 300 nm of a degassed solution of 0.1 g of **2** in 20 ml spectrograde acetone **3a** at room temp. for 12 h leads to the formation of a novel photo-Conia[6] adduct **9** as a major product† (52% isolated yield), some oxetane **10** (5%), and many other minor reaction products (each less than 5% as determined by GC) (Scheme 2). The major product was first identified as a 1 : 1 adduct by GC–MS which indicated a molecular ion peak at *m/z* 206. If oxetane **10** were the major product, ring metathesis fragments[3b,7] would have been observed in the mass spectrum, *e.g. m/z* at 176 ($M^+ - HCOH$) and 148 (**2**), however, the major peaks were observed at *m/z* 191 ($M^+ - Me$), 188 ($M^+ - H_2O$) and 163 ($M^+ - COMe$). This observation along with information from $^1H$ and $^{13}C$ NMR spectra (*vide infra*) confirmed structure **9** as the major product.

It has been reported[7,8] that hydrogen on the carbon α to the oxygen of an oxetane ring has a chemical shift of δ 4–5, whereas hydrogen on the β-carbon atom has a chemical shift of δ 2.5–3.6. The $^1H$ NMR spectrum of **9** had a triplet at δ 2.38 for hydrogens α to carbonyl and a singlet at δ 2.12 for Me, which is incompatible with an oxetane structure. One expects to see only singlet oxetane ring protons no matter whether the oxetane is **8a** or **10**. The $^{13}C$ NMR and DEPT signals of the major product included 7 lines for adamantane and one methyl at δ 29.80, two methylene carbons at δ 26.57 and 42.04 due to the 3,4-carbons of adamant-4-ylbutan-2-one, and a quaternary carbon at δ 209.63 due to carbonyl carbon, which provide further evidence for the photo-Conia product **9**.

In order to determine the proton source on C-2 of product **9**, we also irradiated **2** in deuteriated [$^2$H]acetone **3b** for comparison. The ratio of photo-Conia product to oxetane **9**/**10** was about 11 in acetone, but about 2 (**11** : **12**) in [$^2H_6$]acetone. Comparing the $^1H$ NMR spectra of **11** with **9**, three dramatic changes are observed: (i) the triplet at δ 2.38 for hydrogens α-to carbonyl, (ii) the singlet at δ 2.12 for Me, and (iii) the multiplet at δ 1.55 for proton at C-2 had all disappeared. These deuteriated acetone **3b** results indicate that the proton at C-2 was abstracted from acetone. Note that oxetane **12** has now been isolated in good yield, but was only trace when acetone **3a** was used. The large deuterium isotope effect observed implies that

**Scheme 2**

**Scheme 3**

a C–H bond cleavage was involved in the transition state of this novel photo-Conia reaction.

Note that the photo-Conia reaction of **2** occurs only in neat acetone and deuteriated acetone, but not in other organic solvents such as acetonitrile, benzene and cyclohexane. Compound **2** would also neither react photochemically in dilute acetone solutions (≤1 mol $dm^{-3}$ in organic solvents), nor would it react with acetone in the dark. In order to explore the scope of this photo-Conia reaction, we also photolysed **2** in acetophenone, benzophenone and butan-2-one for 24 h. No reaction was found in the aryl ketones. Although the photo reaction in butan-2-one revealed evidence of formation of some Conia-type products under GC–MS analysis, they were too complex to be isolated.

We then turned our attention to the variation of **2** into a series of exocyclic olefins **4**–**7**. The photolysis of methylenecyclobutane **4**, methylenecyclopentane **5** and methylenecyclohexane **6** in acetone gives photo-Conia products **13**–**15** as the only isolable products (Scheme 3).† Due to many possible secondary photochemical reactions, the yields from methylenecyclobutane **4** and methylenecyclopentane **5** are poor. Nevertheless, methylenecyclohexane **6** gave the homo-alkylation product **15** as the major product in 60% yield. The expected oxetane product from the Paternò–Büchi reaction was detected in trace by GC–MS but was not isolated. On the other hand, when a trisubstituted olefin such as **7** was photolysed in acetone, adducts **16** and **17** were obtained as a 1 : 1 mixture. The Paternò–Büchi reaction product **19** became dominant when **7** was photolysed in deuteriated acetone **3b**. The quantum yields for the photo-Conia reaction products of **2** and **6** in acetone (*i.e.* Φ for **9** and **15**) were determined‡ to be 0.15 and 0.13, respectively.

Kharasch[5b,9] suggested that in the reaction of aldehydes with terminal olefins to form ketones, it is the acyl radical [R(O=)C·] that attacks the olefin. Acetone[5a] or cyclohexanone[5b,c] undergoing Type I cleavage would not, however, explain the observed photo-Conia products. Our results may be explained as follows: the rate-determining step involves an α-hydrogen abstraction of acetone by another excited acetone to give an α-keto radical,[5c] which is then added further to a molecule of exocyclic olefin. In deuteriated acetone **3b**, the C–D bond cleavage step is hampered with respect to that of a C–H bond, thus the Paternò–Büchi reaction is comparable. Although the mechanism of this photo-Conia reaction is still unclear at present, it provides a novel and good-yield method for homoalkylation,[11] which has long been neglected in carbonyl photochemistry.

We thank the National Science Council of the Republic of China for its financial support (Grant No. NSC 84-2113-M-009-002).

## Footnotes

† Satisfactory spectral data were obtained for all products. *Selected data* for **9**: colourless oil; $^1$H NMR (300 MHz, $CDCl_3$), δ 2.38 (2 H, t, *J* 8.7 Hz), 2.12 (3 H, s) and 1.85–1.44 (17 H, m); $^{13}$C NMR (75.4 MHz, $CDCl_3$), δ 209.63 (C=O), 43.96 (CH), 42.04 ($CH_2$), 39.06 ($CH_2$), 38.25 ($CH_2$), 31.66 (CH), 31.43 ($CH_2$), 29.80 (Me), 28.17 (CH), 27.93 (CH) and 26.57 ($CH_2$); *m/z* 206 ($M^+$, 2), 191 (5), 188 (24), 163 (20), 148 (100%), 106 (36) and 92 (52); (Found: $M^+$ 206.1674. $C_{14}H_{22}O$ requires 206.1671). For **11**: colourless oil; $^1$H NMR, δ 1.88–1.81 (6 H, m), 1.72–1.65 (8 H, m) and 1.52–1.48 (2 H, m); $^{13}$C NMR, δ 210.04 (C=O), 43.95 (CD), 38.98 ($CH_2$), 38.27 ($CH_2$), 31.60 (CH), 31.45 ($CH_2$), 31.33 ($CH_2$), 28.18 (CH), 27.97 (CH) and 26.48 ($CH_2$); *m/z* 212 ($M^+$, 3), 194 (22), 192 (5), 166 (10), 148 (100%), 92 (48) and 80 (40); (Found: $M^+$ 212.2054. $C_{14}H_{16}OD_6$ requires 212.2047). For **12**: colourless oil, $^1$H NMR, δ 4.19 (2 H, s), 2.30 (2 H, br s) and 1.82–1.60 (12 H, m); $^{13}$C NMR, δ 87.87 ($C_q$), 75.59 ($CH_2$), 49.52 ($C_q$), 37.07 ($CH_2$), 34.65 ($CH_2$), 34.35 ($CH_2$), 32.07 (CH), 26.79 (CH) and 26.55 (CH); *m/z* 212 ($M^+$, 31), 194 (100%), 182 (95), 148 (7), 135 (28) and 65 (36). For **15**: colourless oil; $^1$H NMR, δ 2.44 (2 H, t, *J* 7.8 Hz), 2.14 (3 H, s), 1.71–1.63 (5 H, m), 1.50–1.43 (2 H, m), 1.26–1.15 (4 H, m) and 0.93–0.86 (2 H, m); $^{13}$C NMR, δ 209.58 (C=O), 41.26 ($CH_2$), 37.12 (CH), 32.99 ($CH_2$), 31.10 ($CH_2$), 29.73 (Me), 26.42 ($CH_2$) and 26.13 ($CH_2$); *m/z* 154 ($M^+$, 15), 136 (11), 96 (77), 81 (65) and 55 (100%); (Found: $M^+$ 154.1361. $C_{10}H_{18}O$ requires 154.1358).

‡ We used *trans*-stilbene as an actinometer when taking the quantum yield for its *trans* to *cis* isomerization as 0.32 at 300 nm light and measured the quantum yield for **9** and **15**. For the use of this actinometer see ref. 10.

# Unexpected structure of 1,3-diphenyl-2-azaallylpotassium–*N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine: infinite, zigzag chains of alternating cations and two distinct types of anion, one azaallyl bonded, the other allyl bonded

**Philip C. Andrews,[a] David R. Armstrong,[a] William Clegg,[b] Fiona J. Craig,[a] Lorraine Dunbar[a] and Robert E. Mulvey*[a]**

[a] *Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK G1 1XL*
[b] *Department of Chemistry, University of Newcastle, Newcastle-upon-Tyne, UK NE1 7RU*

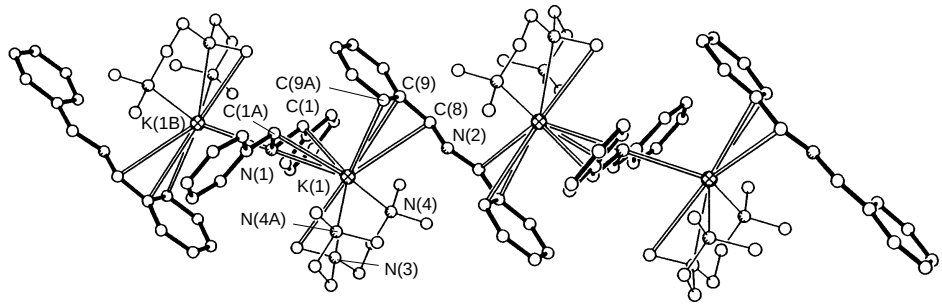
**[{[PhC(H)⋯N⋯C(H)Ph]$^-$K$^+$·pmdeta}$_\infty$] adopts a novel crystal structure exhibiting separate η$^3$-C⋯N⋯C and η$^3$-C⋯C⋯C ligating modes, surprisingly leaving one electronegative N centre not bonded to K$^+$; reaction of the azaallyl K with its parent imine PhC(H)=NCH$_2$Ph in toluene affords the interesting, metal-free, chiral product PhC(H)=NCH(Ph)CH(Ph)N(H)CH$_2$Ph.**

With numerous studies devoted to the structural chemistry of synthetically important lithium organic derivatives having taken place since the early sixties,[1] attention is now turning to their more reactive, and less easily handled, heavier congeners.[2] One recent report[3] focused on the structure of the 1,3-diphenyl-2-azaallyl anion–potassium ion pair [{PhC(H)⋯N⋯C(H)Ph}$^-$K$^+$] in the presence of 18-crown-6: a simple discrete monomer with the anion η$^2$-C,N-bonded to the cation. Previously we had described the structure of the pmdeta-ligated sodium analogue [{PhC(H)⋯N⋯C(H)Ph}$^-$Na$^+$],[4]† which is also monomeric, though its anion is only N-bonded to the smaller Na$^+$ cation. Given this background, the crystal structure of the potassium analogue, [{[PhC(H)⋯N⋯C(H)Ph]$^-$K$^+$·pmdeta}$_\infty$] **1**, revealed herein, is novel on three counts: first, it is a polymer as opposed to a monomer; second, the anion engages in unique η$^3$–C⋯N⋯C interactions with K$^+$; third, and most significantly, a second type of anion–cation coordination is present, remarkable for not involving the central highly electronegative N atom, but the adjacent *o*-C⋯*ipso*-C⋯α-C units. The existence of the previously reported bis-solvated variant [{PhC(H)⋯N⋯C(H)Ph}$^-$K$^+$·2pmdeta}] **2**,[5] a suspected monomer,‡ makes these findings all the more intriguing. We also demonstrate the synthetic value of the azaallyl potassium system in reporting an addition reaction which produces the interesting chiral compound PhC(H)=NCH(Ph)CH(Ph)N(H)CH$_2$Ph **3**.

The aforementioned crown complex was prepared by deprotonating the imine PhC(H)=NCH$_2$Ph with KH in a 12 h long reflux procedure.[3] However, our alternative method for generating the azaallyl potassium ion pair starting from dibenzylamine can be accomplished in minutes (Scheme 1). As discussed in depth elsewhere,[5] mechanistically this process appears to involve also the imine and KH, but as short-lived intermediates, of enhanced reactivity. Originally we thought that only bis-adduct **2** was affordable by this method, as 2 equiv. of pmdeta were necessary to achieve complete dissolution of the initially formed dibenzylamidopotassium. But it transpires that hot toluene mixtures containing 1 equiv. of pmdeta, when filtered through Celite to remove fine solids, afford solutions that on cooling deposit some crystalline **1** mixed with **2**.§

The crystal structure of **1**¶ consists of infinite chains of contacted ions, the salient feature of which is the two distinct types of bridging-anion (Fig. 1). These lie approximately perpendicular to each other (87.7°). Predictably, type 1 ligates through the central azaallyl C(1)⋯N(1)⋯C(1A) unit. More surprisingly, type 2 ligates through the off-centre allyl C(8)–C(9)–C(9A) unit, leaving N(2) not bonded to K(1); this N atom lies 3.648 Å from two adjacent K$^+$ ions. Both types use their delocalised π systems to bridge to pairs of K$^+$ cations, disposed on either side of the planar PhC(H)NC(H)Ph frameworks. Chelating tridentate triamine ligands complete the coordination of the cations. Two-fold disorder of each type of anion limits the precision of the structure. Nevertheless, it is still discernible that the metal–anion contacts are decidedly shorter for type 1 than for type 2 (by about 0.35 Å on average), and

**Scheme 1**



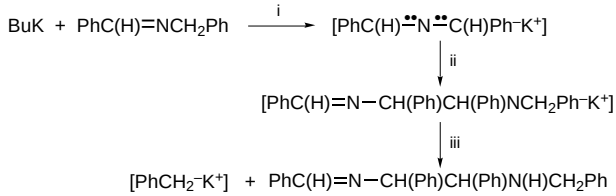


**Fig. 1** Section of the infinite chain structure of **1** with labelling of selected atoms. Hydrogen atoms are omitted for clarity and only one disorder component of each anion is shown. Key dimensions (Å): K(1)–N(1) 2.996(2), K(1)–C(1) and K(1)–C(1A) 2.930(6), K(1)–C(8) 3.366(7), K(1)–C(9) and K(1)–C(9A) 3.268(5), K(1)–N(3) 2.868(5), K(1)–N(4) and K(1)–N(4A) 2.889(4), N(1)–C(1) 1.513(6), N(2)–C(8) 1.347(10), K(1)···N(2) 3.648(3). Symmetry operators: A *x*, 1 − *y*, *z*; B 1 − *x*, 1 − *y*, 1 − *z*.

linked to this, that the C⋯N bonds in the former have substantially less double bond character than those in the latter. This implies that the structure is primarily dictated by strong metal-to-azaallyl anion (electrostatic) bonding, the steric characteristics of which permit the loose attachment of the allyl fragment of another anion [the 'loose' K–C bonds are slightly longer than those producing the polymeric arrangement in the benzyl structure mentioned below, which lie in the range 3.150–3.265 Å; while the strong cation–anion interaction is considerably shorter, and is more representative of that in the monomeric crown analogue described above (3.044 Å)]. The observation that a second pmdeta molecule can readily displace one of the two anions from the coordination sphere of the cation (*i.e.* as in **2**), supports this interpretation. In a search for comparable structures to **1**, [{$PhCH_2K$·pmdeta·0.5toluene}$_\infty$][6] stands out in view of its zigzag polymeric set-up and two distinct multihapto anion–$K^+$ coordinations; however, the similarity is only superficial as it contains a single type of anion, and one devoid of a heteroatom (*i.e.* incapable of offering a seat of high electron density). Pyridyl-substituted [$K(2\text{-}C_5H_4N)CHPPh_2CHPPh_2$·2thf][7] is also noteworthy in exhibiting a 1-azaallyl (N⋯C⋯C) unit (**1** displays a 2-azaallyl alternative).

Preliminary studies probing the chemistry of the azaallyl–K ion pair have uncovered the interesting reaction sequence shown in Scheme 2. A second equivalent of imine gives the addition product which appears to metallate toluene. Chiral product **3** with no K present, crystallises from solution, its identity being unambiguously established by a $^1$H NMR spectrum.‖ The yield of **3** still needs to be optimised, but it is significant that it is also found in reactions containing a 1 : 1, BuK : imine stoichiometry. Earlier it was reported that the reaction between the azaallyl and [$ZrCl_2(\eta\text{-}C_5H_5)_2$] yielded [$Zr(\eta^2\text{-PhCH-N-CH(Ph)CH(Ph)-N=CPh-}\eta^1)(\eta\text{-}C_5H_5)_2$][3] the coupling of the azaallyl moieties was ascribed to an oxidative addition process in which $Zr^{IV}$ is reduced to $Zr^{II}$ then oxidised back to $Zr^{IV}$. The implication of our new finding is that similar coupling processes can occur even without the mediation of a transition-metal redox centre.

We thank the EPSRC for its continuing financial support (studentship to F. J. C. and research equipment to W. C.) and Dr Daniel R. Baker (Solvay Interox) for many helpful discussions.

## Footnotes

† pmdeta = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine.

‡ An attempted crystal structure determination confirmed the monomeric nature and bis-pmdeta solvation; however, the quality of the data was poor and not of a publishable standard.

§ The relative amounts of **1** and **2** appear variable and inconsistent, though **2** generally predominates. As our efforts to separate this mixture have so far failed, we are unable to give an absolute yield of **1**. However, the possibility that **1** is a rogue crystal can be ruled out as the unit-cell parameters of a number of crystals (from repeated syntheses of **1**), have been checked and found to conform to those reported here.

¶ *Crystal data* for **1**: $C_{23}H_{35}KN_4$, $M$ = 406.65, monoclinic, space group $C2/m$, $a$ = 11.1901(8), $b$ = 17.6135(13), $c$ = 12.6609(10) Å, β = 107.272(2)°, $U$ = 2382.9(3) Å$^3$, $Z$ = 4, $D_c$ = 1.134 g cm$^{-3}$, μ = 0.24 mm$^{-1}$ (Mo-Kα, λ = 0.710 73 Å), $T$ = 160 K. 6177 Reflections were measured on a Siemens SMART CCD area detector diffractometer, yielding 2165 unique reflections ($2\theta_{max}$ = 50° , $R_{int}$ = 0.0207). The structure was solved by direct methods and refined on $F^2$ values with anisotropic atomic displacement parameters, constrained hydrogen atoms, and twofold disorder across 2/*m* ($C_{2h}$) positions for both independent anions. Final $R^1$ = $\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]^{\frac{1}{2}}$ = 0.1938 for all data, conventional $R$ = 0.0861 for $F$ values of 1846 reflections with $F_o^2 > 2\sigma(F_o^2)$, goodness of fit = 1.103 for all $F^2$ values and 173 refined parameters; extremes of difference map +0.29 and −0.85 e Å$^{-3}$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Crystal engineering of inorganic/organic composite solids: the structure-directing role of aromatic ammonium cations in the synthesis of the 'step'-layered molybdenum oxide phase [4,4′-$H_2$bpy][$Mo_7O_{22}$]·$H_2O$

**Pamela J. Zapf,[a] Robert C. Haushalter*[b] and Jon Zubieta*[a]**

[a] *Department of Chemistry, Syracuse University, Syracuse, NY 13244, USA*
[b] *NEC Research Institute, 4 Independence Way, Princeton, NJ 08540, USA*

**The hydrothermal reaction of $MoO_3$, Mo metal, $NiCl_2$ and 4,4′-bipyridine yields a step-layered molybdenum oxide [4,4′-$H_2$bpy)][$Mo_7O_{22}$]·$H_2O$, a material structurally related to layered $MoO_3$.**

Among the inorganic materials enjoying widespread contemporary interest, the metal oxide-based solid phases occupy a prominent position by virtue of their applications to catalysis, sorption, molecular electronics, energy storage, optical materials and ceramics.[1,2] The evolution of metal oxide chemistry is critically dependent on the synthesis of new solids possessing unique structures and properties.[3] While the synthesis of solid-state materials remains a challenge,[4,5] the techniques of hydrothermal synthesis, in combination with the structure-directing properties of organic components, may be exploited in the isolation of metastable inorganic/organic composites which retain the structural elements of the synthetic precursors.[6,7] The cooperative assembly of metal oxide/organic phases has been demonstrated by the recent reports of novel one-dimensional molybdenum oxide polymers, incorporating organoammonium cations.[8,9] More significantly, we have demonstrated that incorporation of organoammonium or amine-ligated transition- or post-transition-metal cations situated between mixed-valence vanadium oxide layers yields materials structurally related to $V_2O_5$, with the degree of reduction and condensation within the layers reflected in the charge per volume ratio of the interlamellar cation. In addition to functioning as structure-directing cations or as components of complex cations, organoamines may serve as multifunctional ligands, forming an integral part of the covalent skeleton of the solid. While crystal 'engineering' based on transition-metal coordination to appropriate ligands has evolved dramatically since the seminal work of Robson and Hoskins,[10,11] applications to metal oxides have remained largely unexplored. We have shown recently that 4,4′-bipyridine may be incorporated into metal oxide phases as a ligand serving to buttress the inorganic layers, as illustrated by [$MoO_3$(4,4′-bpy)$_{0.5}$].[12] It was anticipated that under more acidic reaction conditions, protonation of the aromatic amine would provide an aromatic ammonium cation which would serve as a structure-directing template by virtue of the interplay of hydrophobic/hydrophilic interactions[13] and of multipoint hydrogen bonding between the cation and the metal oxide scaffolding of the composite.

The title compound [4,4′-$H_2$bpy][$Mo_7O_{22}$]·$H_2O$ (**1**·$H_2O$) was prepared as colourless rhombs in 10–15% yield in the hydrothermal reaction of $MoO_3$, Mo (250 mesh), 4,4′-bipyridine, $NiCl_2$ and $H_2O$ in the mole ratio 5 : 1 : 2 : 2 : 300 at 200 °C for 93 h in a Parr acid-digestion bomb.

Under the acidic conditions of the reaction, the pyridyl nitrogen atoms are protonated, precluding coordination to the oxide skeleton and resulting in incorporation of the organic component as the bipyridinium dication.

As shown in Fig. 1, the structure of **1**·$H_2O$† consists of the molybdenum oxide layers, separated by an interlamellar region populated by [4,4′-$H_2$bpy]$^{2+}$ cations and $H_2O$ molecules of crystallization. The inorganic subunit of **1**·$H_2O$ is both structurally and compositionally related to the layered oxide $MoO_3$. In a formal sense, **1**·$H_2O$ may be considered to derive from $MoO_3$ through intercalation of [4,4′-$H_2$bpy]$^{2+}$ cations and water, requiring the addition of an oxide anion to the inorganic framework to achieve charge compensation. Since charge/volume considerations result in one bipyridinium cation for seven molybdenum oxide sites, compound **1**·$H_2O$ may be reformulated as [4,4′-$H_2$bpy][$(MoO_3)_7O$]·$H_2O$ to reflect its relationship to the $MoO_3$ parent.

However, while the $[Mo_7O_{22}]_n^{2n-}$ layers are constructed from edge- and corner-sharing {$MoO_6$} octahedra as observed for $MoO_3$,[14] the consequences of adding one $O^{2-}$ group every seven molybdenum sites are manifested in a layer structure significantly different from that adopted by $MoO_3$. The $MoO_3$ layer is constructed from linear ribbons, two polyhedra thick, of edge-sharing {$MoO_6$} octahedra; adjacent ribbons are linked through corner-sharing to produce the layer structure. Consequently, each Mo site in $MoO_3$ displays three triply bridging, two doubly bridging, and one terminal oxo group.

In contrast to the planar layers adopted by $MoO_3$, the oxide layers of **1**·$H_2O$ are distinctly stepped. Examinations of the detailed structure of the layers of **1**·$H_2O$ reveals a motif again based on ribbons of edge-sharing {$MoO_6$} octahedra. However, as shown in Fig. 2, the ribbon executes a 90° turn and shifts one polyhedral length along the *b*-direction at the 'step' juncture at every seventh Mo site. Adjacent ribbons are again linked through corner-sharing interactions, but in such a fashion as to produce three distinct {$MoO_6$} sites. The molybdenum centres Mo(2) and Mo(3) exhibit bonding patterns essentially identical to that observed for $MoO_3$: each projects a single terminal oxo

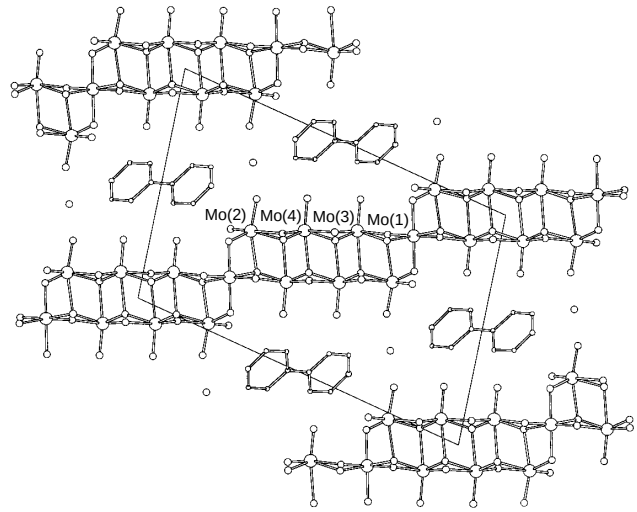

**Fig. 1** A view of the structure of **1**·$H_2O$, showing the $[Mo_7O_{22}]_n^{2n-}$ inorganic layers and the $H_2O$ molecules and $[C_{10}H_{80}N_2]^{2+}$ cations occupying the interlamellar regions

group to either surface of the metal oxide layers and participates in three triply bonding oxo interactions within the ribbon and two doubly bonding oxo linkages to adjacent ribbons. On the other hand, the Mo(4) site is constrained by the folding of the ribbon to provide a second terminal oxo unit, which projects into the 'step' domain of the metal oxide network and adopts the conventional *cis* configuration with respect to the terminal oxo group directed toward the interlamellar region. The most unusual coordination site is occupied by Mo(1) which exhibits only doubly and triply bridging oxo groups and provides the locus of the dislocation of the layer structure of **1**·$H_2O$ with respect to the parent $MoO_3$ structure.

There is an extensive hydrogen-bonding network formed among the $-NH^+$ groups of the bipyridinium cations, the waters of crystallization, and the *cis* terminal oxo groups of Mo(4). This extensive hydrogen-bonding motif causes water and the organic component to be released only at elevated temperatures. Thermogravimetric analysis of **1**·$H_2O$ at a heating rate of 10 °C $min^{-1}$ under $N_2$ revealed no mass loss until 170 °C when release of water commences. The organic component is not removed until *ca*. 250–300 °C.

There has been considerable interest in $MoO_3$ for its catalytic properties in the oxidation of methanol to formaldehyde[15] and for its intercalation properties,[16] for example, intercalation of hydrogen from oxide bronzes of the $H_xMoO_3$ family with applications to electrochromic displays and proton mobility in solids.[17] Oxide **1**·$H_2O$ represents a new class of organically based molybdenum oxides which are different from those obtained from intercalation reactions.[18] The structural modifications of composite metal oxide/organic solids may be realized by introducing organic components as ligands, tethers or structure-directing cations, roles which reflect hydrophobic–hydrophilic interactions and/or multipoint directional hydrogen bonding. Thermal removal of the organic templates from these materials may lead to new metal oxides, with different physical properties and selectivities with respect to interactions with organic substrates. The characterization of the thermal decomposition products of **1**·$H_2O$ is in progress, and their structures and physical properties will be presented in future publications.

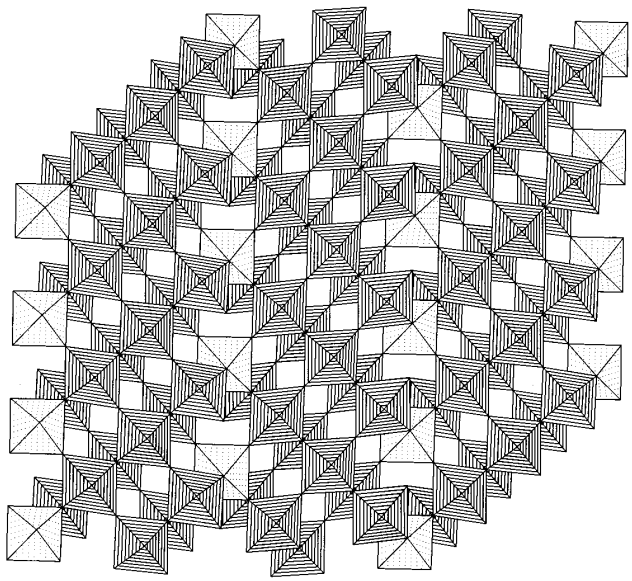

**Fig. 2** A polyhedral representation of the $[Mo_7O_{22}]_n^{2n-}$ layer. The stippled polyhedra represent the Mo(1) sites which provide the location of the dislocations in the **1**·$H_2O$ structure with respect to the parent $MoO_3$ structure.

The work at Syracuse University was funded by NSF grant CHE9318824.

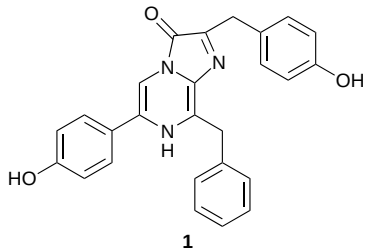
# Highly efficient and flexible total synthesis of coelenterazine

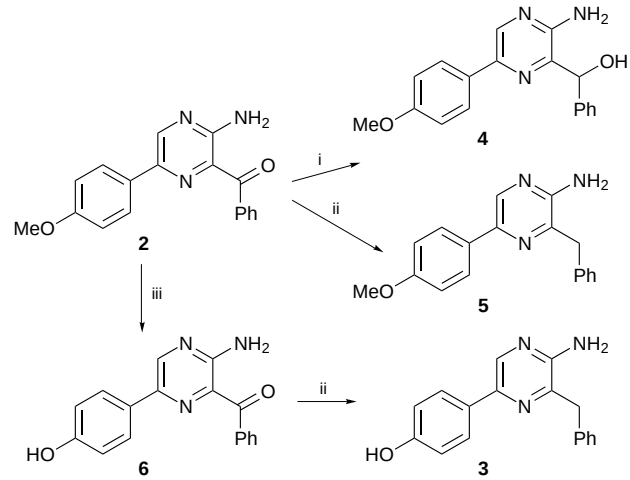


**Martine Keenan, Keith Jones* and Frank Hibbert**

*Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS*

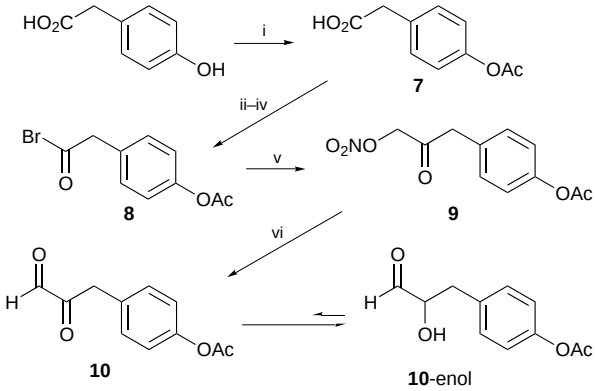
**A new total synthesis of the bioluminescent chromophore coelenterazine 1 is described.**

Coelenterazine **1** found in the jellyfish *Aequorea victoria* was the second imidazopyrazine-based chromophore to be isolated from luminescent marine organisms.[1] Its structure was determined in 1974[2] and it has been synthesised using an approach developed by Kishi[3] in which the fully-substituted pyrazine ring is synthesised by a condensation reaction between an α-amino nitrile and an α-nitroso ketone. In the jellyfish, coelenterazine is bound covalently to a protein which is activated to bioluminescence by reaction with calcium ions. The fact that the protein has been cloned and over-expressed means that a very sensitive system for the detection of calcium ions within cells is available.[4] In addition, the gene for this protein has recently been suggested to be an ideal reporter of gene expression.[5] Both these techniques require the addition of coelenterazine itself to the system in order to observe the desired luminescence. In addition coelenterazine on its own undergoes chemiluminescence with superoxide anion and this has been used as an assay of respiratory burst in neutrophils.[6] These wide-ranging analytical uses make coelenterazine a sought-after molecule for both medical and molecular biological use. Our interest in this area arose from a desire to couple the useful luminescent properties of coelenterazine, with a metal-binding site in the same molecule to explore the possibility of luminescent detection of specific metals. To achieve this goal, we needed a flexible, high-yielding synthesis of coelenterazine which could be adapted to incorporate suitable metal-binding sites. We chose to adopt a different strategy to the Kishi synthesis and start with the pyrazine ring intact to allow late introduction of the substituents.



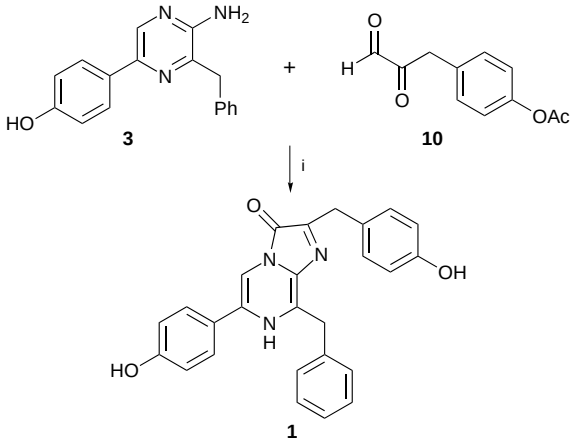
We recently reported the synthesis of the aminopyrazine **2** involving as a key step the formation of the aryl–heteroaryl bond by a high yielding Suzuki coupling reaction between a bromopyrazine and 4-methoxyphenylboronic acid.[7] We further demonstrated that this coupling could give a range of aryl-substituted pyrazines in excellent yield by varying the boronic acid. In order to convert this compound into the desired aminopyrazine **3** representing the southern hemisphere of coelenterazine, two transformations were required, namely reduction of the ketone to a methylene unit and deprotection of the methyl ether (Scheme 1). A two-step procedure was explored involving reduction of the ketone to the alcohol **4** in 60% yield using $NaBH_4$ in MeOH for 15 min.[8] However, reduction of the alcohol **4** with a variety of reagents ($Et_3SiH$ and $CF_3CO_2H$,[9] $ZnBr_2$ and $NaBH_3CN$[10] and radical-based deoxygenation[11]) failed to give any trace of **3**. Reduction of the ketone *via* the alcohol was abandoned and direct reduction to the alkane was investigated. After the failure of a number of methods, a Wolff–Kishner reduction of **2** was explored. Reaction of **2** with hydrazine hydrate and KOH in ethylene glycol at 240 °C for 3 h[12] gave an extremely insoluble red compound, the mass spectrum of which indicated reduction had occurred to give some **5**. However, the insolubility of this material led us to believe that **5** was a minor component and that extensive decomposition had occurred. Consequently, we decided to deprotect the methyl ether prior to reduction of the ketone moiety. Cleavage of methyl aryl ethers has been reported under a variety of conditions but the only successful deprotection of **2** was achieved using ethanethiolate in DMF at 100 °C for 10 h.[13] This gave phenol **6** as a brown solid (mp 176–177 °C) in 81% yield. Finally we were gratified to find that exposure of **6** to the Wolff–Kishner conditions as described above gave the aminopyrazine **3** as a powdery yellow solid (mp 220–222 °C) in 84% yield. This compound was readily purified by chromatography and was fully characterised.

**1**



In order to complete the synthesis of coelenterazine, a suitable α-keto aldehyde representing the northern hemisphere was required. After exploring a variety of dithiane-based routes to this compound, we settled on the route shown in Scheme 2.[14] Acetylation of the phenol group in 4-hydroxyphenylacetic acid was carried out in 84% yield using NaOAc in $Ac_2O$. Formation of the acid chloride ($SOCl_2$) and reaction with $CH_2N_2$ gave the α-diazo ketone in high yield. This was not isolated but was reacted with dry HBr to give the bromomethyl ketone **8** in 89% overall yield from **7**. Reaction of the rather sensitive **8** with $AgNO_3$ in MeCN overnight gave the nitrate ester **9** as a colourless solid (mp 65–70 °C) in 98% yield. Finally, reaction of **9** with NaOAc in $Me_2SO$ at room temperature for 25 min gave the α-keto aldehyde **10** in 88% yield as a colourless solid (mp 134–136 °C). Interestingly, NMR studies on **10** indicated that it exists entirely in the enol form in a range of solvents.

The stage was now set for the condensation of **3** and **10** which should lead directly to coelenterazine.[14,15] Model condensations



**Scheme 1** *Reagents and conditions*: i, $NaBH_4$, MeOH, 0 °C, 15 min; ii, hydrazine hydrate, KOH, ethanediol, 240 °C 3 h; iii, EtSH, NaH, DMF, 100 °C, 10 h

using the methoxy analogue of the acetoxy α-keto aldehyde **10** had proceeded in poor yield and subsequent cleavage of the methyl ether had proven impossible. The choice of the acetate group for protection of the phenol in the α-keto aldehyde unit was in order to allow deprotection to the phenol to occur under the acidic conditions of the coupling reaction. Reaction of **3** and **10** in EtOH containing conc. HCl and water for 4.5 h at 80 °C in the dark gave coelenterazine **1** as a methanol-soluble orange–brown solid (mp 177 °C, lit.,[14] 175–178 °C) in 62% yield after chromatography. This material forms brilliant yellow-coloured solutions which are both light- and air-sensitive but is relatively stable as a solid. The spectral properties of **1** agreed with those reported in the literature.[3,14] This new, highly convergent synthesis of coelenterazine involves 14 steps in total, although there are only 8 linear steps, and proceeds in 25% overall yield from commercially available 2-chloropyrazine. We are now in a position to prepare a wide range of analogues and explore their chemical and luminescent properties.

**Scheme 2** *Reagents and conditions*: i, NaOAc, $Ac_2O$, reflux, 2 h; ii, $SOCl_2$ (excess), room temp., 12 h; iii, $CH_2N_2$, $Et_2O$, 0 °C, 90 min; iv, dry HBr, 0 °C, 30 min; v, $AgNO_3$, MeCN, room temp., 12 h; vi, NaOAc·3 $H_2O$, $Me_2SO$, room temp., 25 min

**Scheme 3** *Reagents and conditions*: i, EtOH, conc. HCl, 80 °C, 4.5 h with light and air excluded

We thank the BBSRC for a studentship (M. K.) and Professor F. McCapra for useful discussions.

# Reaction of 1,8-diazabicyclo[5.4.0]undec-8-ene with methyl 3,5-dinitrobenzoate and 1,3,5-trinitrobenzene

**James K. Sutherland**

*Chemistry Department, University of Manchester, UK M13 9PL*

**1,8-Diazabicyclo[5.4.0]undec-8-ene (DBU) undergoes a double addition reaction with the title compounds forming crimson 2-aminoindole derivatives.**

In the course of examining the complexation of 3,5-dinitrobenzoates of cholic acids with a variety of compounds it was observed that with DBU a red colour rapidly developed in $CHCl_3$ and that, after some time, stable red compounds were formed. In order to determine whether these reactions were solely a function of the complexing ability of the cholic esters or due to the dinitrobenzoate function, methyl 3,5-dinitrobenzoate was treated in $CHCl_3$ or EtOAc with DBU whereupon deep red solutions were formed with the colour intensity increasing for up to 2 d. Chromatography yielded starting material and two orange compounds. The less polar orange compound (19%) was shown by spectroscopy† to have structure **1**. The structure of the more polar product was assigned by spectroscopy.‡ Assuming that DBU is also acting as a C-nucleophile in forming this product, structure **3** was assigned.

DBU reacts in a similar manner with 1,3,5-trinitrobenzene to give **2** (11%).§

A scheme to account for the formation of **1** and **3** is the initial reaction giving the Meisenheimer complexes **4** and **5** (the original red colour formed on mixing) from the ester and DBU acting as a C-nucleophile,¶ followed by oxidation of the adducts to form the aryl compounds **6** and **7**; *ipso* displacement of the nitro group of **6** would then give the indole **1** whilst **7** cyclises to form the isoquinolone **3** (Scheme 1). There are a number of examples of DBU reacting as a C- and N-nucleophile,[1] but the order in which reaction occurs is not clear; in the current example DBU appears to be acting initially as a C-nucleophile.

1,3-Dimethylpiperidino-2-indole is reported[2] to absorb at $\lambda_{max}$/nm 230 (ε 25 400), 290 (9300) and 296 (8950) thus the introduction of the electron accepting $NO_2$ and $CO_2Me$ groups effects a large bathochromic shift of *ca*. 180 nm, presumably due to the donating power of both nitrogens of the enediamine system.

I thank Dr G. A. Morris for valuable discussions.

# A trisbipyridine tripodal ligand as toluene gelator. Phase transition-triggered binding of iron(II)

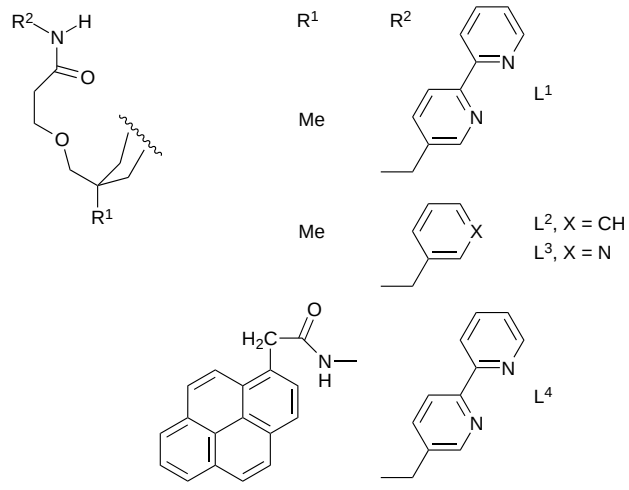
**Jean-Ernest Sohna Sohna and Frédéric Fages***

*Photophysique et Photochimie Moléculaire (URA 348 CNRS), Université de Bordeaux I, 351 Cours de La Libération, 33405 Talence Cedex, France*

**The formation of a physical gel with toluene is reported for a trisbipyridine ligand which exhibits iron(II) binding properties triggered by the gel-to-liquid phase transition.**

During the course of investigations on the synthesis of new molecular receptors for transition-metal ions,[1] we discovered that the trisbipyridine ligand $L^1$ exhibited unanticipated solvent gelation properties.†

At room temperature, a solution of ligand $L^1$ in toluene is entirely transformed into a highly viscous thermoreversible gel. In a typical gelation experiment, a 1 mg sample of $L^1$ ($M_W$ = 838) was added to 1 $cm^3$ of toluene in a test tube, and the mixture was either heated or sonicated at room temperature until total dissolution. The resulting solution was allowed to stand undisturbed for *ca*. 2 h at room temperature. The obtained transparent gel mass could be inverted without any flow, and remained stable for several months in a stoppered tube. Using 2 mg of $L^1$, the gelation of the same volume of toluene was effected in only a few minutes. One molecule of the gel-forming tripodal molecule can therefore bind up to 8000 molecules of toluene. We determined $T_{gel}$ of $L^1$ by the spectroscopic turbidity method. We measured the absorbance at 600 nm of a gel {[$L^1$] = 1.15 mg $g^{-1}$} prepared in a 10 mm optical cell. A value of 72 ± 1 °C was obtained by raising the temperature of the sample at a rate of 1 °C $min^{-1}$.



It was also found that 1 : 4 (molar ratio) $CH_2Cl_2$–diethyl ether and 2 : 3 $CH_2Cl_2$–*tert*-butyl methyl ether solvent mixtures could be gelated quite effectively {[$L^1$] = 1.2 mg $g^{-1}$}. $L^1$ did not form gels with cyclohexane, pentane, methanol, $Me_2SO$, dichloromethane, chloroform, nitrobenzene, or *o*-xylene. The structurally related compounds $L^2$–$L^4$ did not gelate toluene.‡

Over the last few years, the ability of several classes of low molecular-mass organic molecules to promote physical gelation of organic solvents has been reported.[2] This phenomenon has been explained on the basis of gelator molecules self-aggregation, which produces a three-dimensional network encaging solvent molecules.[2,3] van der Waals interactions and/or hydrogen bonding were invoked to account for supramolecular network formation. The FTIR spectrum (KBr) of a xerogel, obtained by the slow evaporation of toluene from a gel sample, was compared to that of $L^1$ crystallized from methanol. Bands at 3281 (NH), 1636 (amide I), and 1548 $cm^{-1}$ (amide II) $cm^{-1}$ were observed in the spectrum of the xerogel, whereas the corresponding bands in the spectrum of $L^1$ obtained from methanol were found at 3424, 3284, 1649 and 1556 $cm^{-1}$. This data are indicative of an enhanced manifestation of hydrogen-bonding interactions in the former sample relative to the latter. While intramolecular hydrogen bonds were shown to prevail in solution for a series of related tripod-like molecules incorporating amido linkages in each of the tripod chains,[4] it is very likely that gelation of the apolar toluene solvent by $L^1$ could rather result from molecular self-aggregation through extensive intermolecular hydrogen bonding. The bipyridine subunits might play a specific role in the assembling process leading to gelation, although, as yet, this remains undemonstrated.§

A great variety of complexing agents containing three 2,2′-bipyridine chelating units have been synthesized previously and were shown to exhibit a strong affinity towards first-row transition-metal cations ($M^{2+}$).[5] Especially, some receptors bearing pendent 2,2′-bipyridyl-5-ylmethyl arms were found to form extremely stable $[M(bipy)_3]^{2+}$ complexes in solution.[6] Consistently, $[FeL^1]^{2+}$, prepared by reaction of $L^1$ with 1 mol equiv. of $FeCl_2{\cdot}4H_2O$, was observed to be quite stable in aqueous media, and could be isolated by addition of an excess of potassium hexafluorophosphate. Its VIS spectrum in acetone ($\lambda_{max}$ = 520 nm, $\varepsilon_{max}$ = 7220 $dm^3\ mol^{-1}\ cm^{-1}$) was very close to that of $[Fe(bipy)_3]^{2+}$ and of iron(II) complexes[6] of related ligands. The formation of the 1 : 1 complex in methanol ([$L^1$] < $10^{-5}$ mol $dm^{-3}$) was confirmed spectrophotometrically by the method of continuous variations (Job plot).

Shinkai's group reported previously the case of a cholesterol-based gelator bearing a crown ether moiety. The gelation ability of this system was shown to respond to alkali-metal cations.[7] To our knowledge, $L^1$ is the first example of a molecular receptor for transition-metal ions endowed with solvent gelation properties. A gelled toluene solution of ligand $L^1$ showed drastically reduced complexation ability towards iron(II) salts.

When 0.5 $cm^3$ of water was carefully deposited at the top of a toluene gel sample prepared in a 10 mm diameter test-tube from 0.5 $cm^3$ of toluene {[$L^1$] = 1.2 mg $g^{-1}$), we observed that (*i*) the aqueous phase, despite being denser, occupied the upper layer and (*ii*) the biphasic system remained stable indefinitely. When the same experiment was carried out with water containing an excess of $Fe(SO_4){\cdot}7H_2O$, the gel mass was similarly unaltered after 24 h. As compared to the blank experiment, only a slight modification of the shape of the interface layer between gelled toluene and isotropic water was noticed. Furthermore, the latter phase slowly turned pink, probably due to the extraction of some ligand molecules from the gel into the isotropic water phase driven by complexation equilibria. When the system was heated above $T_{gel}$, the gel collapsed, which led to mixing and the inversion of toluene and water, with, simultaneously, a deep red colouring of the aqueous

solution. VIS absorption spectroscopy indicated that the total amount of ligand $L^1$ initially dissolved in toluene was then transferred to water as the iron(II) chelate. In the blank experiment, $L^1$ was not extracted into water.

Polymer gels that can take up or release molecules upon phase transition are of considerable interest for a wide range of applications.[8] The properties of the new gelator $L^1$ could lead to the development of supramolecular devices for applications.

We are grateful to the CNRS, the Université de Bordeaux I and La Région Aquitaine for financial support.

## Footnotes

† Compound $L^1$ was prepared by a simple two-step procedure. 1,1,1-Tris-(carboxyethoxymethyl)ethane was activated *via* DCC-mediated condensation with *N*-hydroxysuccinimide to give the corresponding active triester. The latter was reacted in dmf with 3.3 mol equiv. of 5-aminomethyl-2,2′-bipyridine to afford $L^1$ (white solid) in 80% yield. Mp 91 °C, $^1$H NMR ($CD_3OD$): δ 0.80 (s, 3 H), 2.45 (t, 6 H), 3.25 (s, 6 H), 3.65 (t, 6 H), 4.45 (s, 6 H), 7.4 (m, 3 H), 7.8 (m, 6 H), 8.25 (m, 6 H), 8.60 (m, 6 H). Satisfactory elemental analyses and mass spectrometry data were obtained.

‡ $L^2$–$L^4$ were characterized by proton NMR spectroscopy and mass spectrometry. The synthesis of $L^4$, together with its metal cation binding and photophysical studies, will be published elsewhere.

§ $L^2$ and $L^3$ do not gelate. Furthermore, we also noticed the conspicuous propensity of a series of related molecular systems symmetrically substituted with two or three 5-amidomethyl-2,2′-bipyridine moieties to aggregate strongly even in polar solvents.

# Water-soluble poly(4,7,10,13-tetraoxatetradecylmethylsilane): enhanced yield and improved purity *via* polymerization using graphite-potassium ($C_8K$) as reducing agent

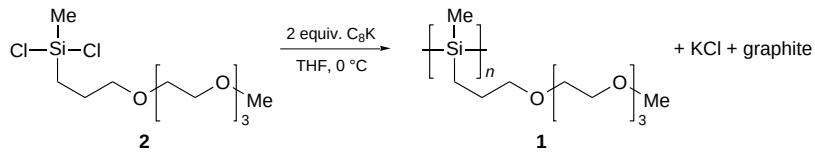
**Thomas J. Cleij, Stellar K. Y. Tsang and Leonardus W. Jenneskens*†**

*Debye Institute, Department of Physical Organic Chemistry, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands*

**Application of graphite-potassium ($C_8K$, THF, 0 °C), instead of convential Wurtz-type coupling conditions (Na, toluene, 110 °C), as reducing agent for the preparation of non-ionic, watersoluble poly(4,7,10,13-tetraoxatetradecylmethylsilane) 1 gives a markedly enhanced yield as well as a high molecular weight polymer of high purity.**

Polysilanes, *viz*. polysilylenes, exhibit (photo)physical and electronic properties of interest for application in materials science.[1] Although with the conventional Wurtz-type coupling conditions (Na, toluene, 110 °C) a number of polysilanes with alkyl and/or aryl substituents have been prepared, a drawback is that the severe polymerization conditions impair the use of monomers with functionalized side chains.[2] Hence, introduction of, for example, ionic groups has to be achieved by side chain functionalization after polymerization.[2–4] Notwithstanding using the conventional Wurtz-type coupling procedure, polysilanes containing ether linkages in their side chains[5] and, more recently, the first non-ionic water-soluble polysilanes possessing oligo(oxyethylene) side chains have become available,[6,7] albeit in low yields. Moreover, especially in the case of the non-ionic water-soluble polysilanes, their remarkable solubility in common organic solvents as well as water hampered their purification by simple (repeated) precipitation. High molecular weight material had to be separated from low molecular weight impurities (*vide infra*) by laborious preparative size exclusion chromatography (SEC). Hence as shown for poly(4,7,10,13-tetraoxatetradecylmethylsilane) **1**,[6,7] isolated yields varied considerably (**1**; $\ll$ 1.0[7] up to 11%[6]). This is unfortunate, since polar polysilanes in general attract attention due to their propensity to Langmuir film formation at the air–water interface[2,3] and their potential application in (self)-assembly.[8]

Here we report that with graphite-potassium ($C_8K$),[9] instead of Na, as reducing agent, non-ionic, water-soluble **1** is accessible in a markedly enhanced yield. Furthermore, the high molecular weight fraction isolated by preparative SEC is shown to possess considerably improved purity (Scheme 1). The choice of $C_8K$ was based on reported results for poly(methylphenylsilane)[10] and poly(phenylsilyne).[11] $C_8K$ was shown to be applicable at subambient temperature and to be compatible with a wide range of solvents.‡ Hence in contrast to the conventional Wurtz-type coupling procedure (Na, toluene, 110 °C), polymerization *via* the $C_8K$ route requires considerably less severe conditions.



To establish the suitability of $C_8K$ for the preparation of **1**, the monomer 4,7,10,13-tetraoxatetradecylmethyldichlorosilane **2**[6] was polymerized under various conditions.§ Initial experiments revealed that both the formation of **1** as well as its final yield are strongly dependent on the ratio $C_8K$ : **2**, reaction temperature and duration of polymerization, respectively. In THF, the high molecular weight polymer **1** was only obtained with a ratio $C_8K$ : **2** of 2 and a reaction temperature of 0 °C. No **1** could be identified if either excess $C_8K$ (ratio $C_8K$ : **2** > 2) was used or in polymerizations executed with *ca*. 2 equiv. $C_8K$ at $T > 0$ °C. To determine optimal polymerization conditions the effect of reaction time was studied in more detail (Table 1). The data show that for optimal formation of **1** a reaction time of 2–2.5 h is required (Table 1, entry 3). Longer reaction times lead to degradation of **1** (Table 1, entries 4 and 5, SEC). Under optimized conditions similar molecular weight distributions were found as those reported previously for **1** (Wurtz-type coupling reaction; Table 1, entry 6; $M_w$ *ca*. 1.5 × 10[4]).[6] In contrast to results reported for poly(methylphenylsilane) prepared *via* the $C_8K$ route,[10] no polymer **1** could be extracted from the graphite phase after filtration.

After preparative SEC, polymer **1** was isolated in yields ranging from 20 to 35%. This is a considerable enhancement with respect to the yields obtained using conventional Wurtz-type coupling conditions (**1**; $\ll$ 1.0[7] up to 11%[6]). $^{29}$Si NMR analysis only gave the characteristic silicon backbone resonance at δ −31.4 (Table 1, entry 3 and Fig. 1). The absence of resonances attributable to end-groups and/or siloxane moieties indicates that **1** prepared using $C_8K$ after purification by preparative SEC is completely free from low-molecular weight material (*vide infra*). This is supported by $^1$H and $^{13}$C NMR

**Table 1** Salient features of **1** obtained *via* the $C_8K$ route ($C_8K$ : **2** = 2.0, THF, 0 °C) with different reaction times after purification by preparative SEC.§¶

| Entry | *t*/h | Yield (%) | $M_w$ × 10$^{-3}$ [a] | $M_w$/$M_n$ [b] | $\lambda_{max}$/nm [c] | ε(Si–Si)/10$^3$ dm$^3$ mol$^{-1}$ cm$^{-1}$ [c] |
|---|---|---|---|---|---|---|
| 1 | 1.0 | 30 | 6.9 | 1.3 | 300 | 1.6 |
| 2 | 1.5 | 34 | 10.7 | 1.5 | 301 | 2.1 |
| 3 | 2.0 | 22 | 14.0 | 1.9 | 304 | 4.8 |
| 4 | 2.5 | 33 | 14.4 | 2.0 | 304 | 2.4 |
| 5 | 3.0 | 18 | 8.8 | 1.6 | 301 | 3.2 |
| 6 [d] | 2.0 | 11 | 15.1 | 1.4 | 299 | 1.8 |

[a] Molecular weight distributions determined with analytical SEC (UV detection λ 300 nm, polystyrene standards). [b] Polydispersity [see footnote (*a*)]. [c] Solvent MeCN. [d] Prepared using conventional Wurtz-type coupling conditions.[6]

**2** **1**

**Scheme 1**

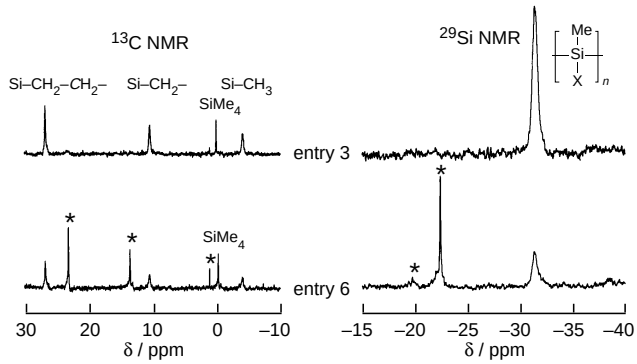


**Fig. 1** $^{13}C$ and $^{29}Si$ NMR spectra of **1** prepared using either $C_8K$ [THF, 0 °C (entry 3)] or conventional Wurtz-type coupling conditions [Na, toluene, 110 °C (entry 6)]. Peaks marked with * are due to impurities such as cyclosiloxanes‖ and low molecular weight oligomers (for X see Scheme 1).

spectroscopy (Fig. 1, $^{13}C$ NMR).¶ While for **1** prepared *via* the conventional Wurtz-type coupling reaction broad and split $^1H$ NMR signals were observed for the $SiCH_3$, $SiCH_2$ and $SiCH_2CH_2$ moieties,[6] discrete resonances, similar to those reported for poly(γ-methoxypropylmethylsilane),[5] were found for **1** prepared using $C_8K$.¶

Additional evidence for the improved purity of **1** prepared *via* the $C_8K$ method was obtained from its UV spectrum. The $\lambda_{max}$ value at *ca*. 300 nm ($\sigma \rightarrow \sigma^*$ transition) in combination with the increase of the extinction coefficient ε are in agreement with the presence of only a high molecular weight polymer (Table 1; entries 2–5 *vs*. entry 6).[1,6]

$^{29}Si$ NMR and FAB-MS of the low molecular weight fractions indicate that they mainly consist of cyclosiloxanes [$D_n$ with $n$ = 3, 4 and 5], which apparently are formed during work-up.‖ This result differs from that found for the low molecular weight fractions for **1** prepared using conventional Wurtz-type coupling conditions. In that case the low molecular weight fraction primarily consists of cyclosilanes (five- and six-membered) and cyclosiloxanes [$D_n$ with $n$ = 4 and 5].[6]‖

‡ It is noteworthy that it was recently reported that the yield of poly(methylphenylsilane) prepared using $C_8K$ (THF, −78 to 25 °C) appears to be sensitive to the addition of a co-solvent such as 1,2-dimethoxyethane.[13]

§ All polymerizations were carried out in dried glassware under an Ar atmosphere. In a typical experiment, 4,7,10,13-tetraoxatetradecylmethyldichlorosilane (**2**, 1.66 g, 5.2 mmol) was slowly added *via* a syringe to a suspension of THF (10 ml) and $C_8K$ [prepared by stirring graphite (1.00 g, 83.2 mmol) and potassium (0.41 g, 10.4 mmol) for 1 h at 150 °C][9] cooled at 0 °C. After the appropriate reaction time (see Table 1) the reaction mixture was quenched by adding MeOH (2 ml) followed by filtering off the graphite and precipitated KCl. To the filtrate a solution of $KHCO_3$ (0.5 g) in water (30 ml) was added to neutralize dissolved HCl and to prevent polymer degradation. After removal of solvents *in vacuo* the oily residue was redissolved in $CH_2Cl_2$ (30 ml) and the precipitated $KHCO_3$ as well as additional KCl were removed by filtration. The filtrate was concentrated *in vacuo* and the high molecular weight polymer fraction was subsequently isolated by preparative SEC (Biobeads SX-1, eluent $CH_2Cl_2$). Polysilane **1** was characterized with analytical SEC, DSC, TGA, UV, $^1H$, $^{13}C$ and $^{29}Si$ NMR spectroscopy.¶

¶ Polysilane **1** prepared using $C_8K$ possesses improved purity compared to **1** obtained with the conventional Wurtz-type coupling procedure (Fig. 1).[6] $^1H$ NMR (300.13 MHz, $CDCl_3$) $\delta_H$ 0.26 (br, 3 H), 0.77 (br, 2 H), 1.60 (br, 2 H) and 3.38–3.66 (br, 17 H); $^{13}C$ NMR (75.47 MHz, $CDCl_3$) $\delta_C$ −4.1, 10.4, 26.8, 59.0, 70.1, 70.5, 70.6, 72.0 and 74.4; $^{29}Si$ NMR (59.63 MHz, $CDCl_3$) $\delta_{Si}$ −31.4.

‖ Cyclosiloxanes $D_n$ {$\overline{[–Si(R^1R^2)–O–]_n}$ with $R^1$=$R^2$=Me} possess $^{29}Si$ NMR chemical shifts at δ −8.93, −20.00 and −22.62 for $n$ = 3, 4 and 5, respectively. For the low molecular weight fractions isolated from the crude reaction mixture $^{29}Si$ NMR chemical shifts at δ −11.94 and −12.32, −21.06 and −22.0 assigned to $D_3$, $D_4$ and $D_5$ species, respectively, were found.[12] This assignment is corroborated by FAB-MS.

# Modelling the active sites of heterogeneous titanium epoxidation catalysts using titanium silasequioxanes: insight into specific factors that determine leaching in liquid-phase processes

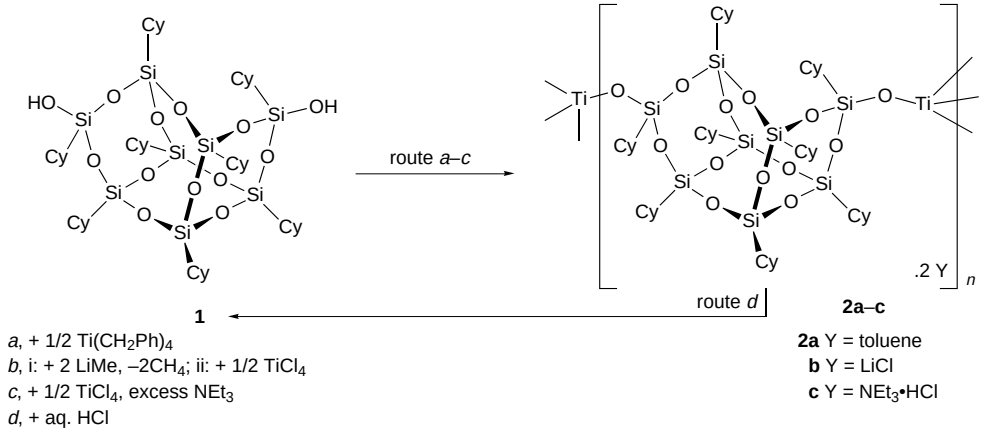
**Hendrikus C. L. Abbenhuis,* Simon Krijnen and Rutger A. van Santen**

*Schuit Institute of Catalysis, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands*

**Active catalysts for the epoxidation of alkenes by *tert*-butyl hydroperoxide are provided by silasesquioxane titanium(IV) derivatives; a non-leaching catalyst, not prone to irreversible protic cleavage of its siloxy functions by the oxidizing agent, contains a terdentate silasesquioxane ligand.**

In the current search for non-leaching heterogeneous liquid-phase oxidation catalysts detailed studies of how the catalytically active metal species are bonded to the support are rare. Often, more attention is paid to the performance of the catalyst, rather than to the fundamental question whether the catalyst is truly heterogeneous or not. In order to approach this problem at a molecular level, we report here on epoxidations catalysed by titanium silasesquioxanes. In these silasesquioxanes, the titanium is incorporated *via* spatially oriented siloxy bonds (Ti–O–Si) which structurally resemble surface sites that have been purportedly identified on silica surfaces.

Heterogeneous titanium catalysts are very important in oxidation processes but at the same time have been reported to undergo some leaching in liquid-phase applications. For instance, the highly active Shell titanium/silica epoxidation catalyst[1,2] becomes only truly heterogeneous after a certain time on stream.[3] Similar materials, that are currently being reported as the result of grafting silica[4] or MCM-41 mesoporous silica[5] with titanium derivatives, or even novel titanosilicates,[6] might therefore be only partially heterogeneous when applied in liquid-phase oxidation reactions.



The silasesquioxane **1** (Scheme 1) possesses a well defined structure which includes two reactive, isolated hydroxy groups that occupy '*exo*' positions above nearby $Si_4O_4$ rings, that are part of an interdigitated $Si_8O_{11}$ skeleton. Several functionalizations of **1** have already been achieved *via* clean silanol centred reactions and were in most cases reported to leave the silasesquioxane skeleton intact.[7–9] Recently, we reported on the construction of a very active, truly heterogeneous catalyst from **1** for Diels–Alder reactions of enones.[10]

We found that, in toluene, the silanol groups present in **1** easily react with tetrabenzyltitanium (Scheme 1, route *a*), resulting in concomitant formation of toluene and a pale yellow titaniumsilasesquioxane gel **2a** that occludes the entire volume of the solvent used. When subjected to prolonged centrifugation (20 min at 900 g), the gel releases toluene until a toluene/silasesquioxane mass ratio of *ca.* 18 is reached. Upon drying *in vacuo*, the gel collapses into a powder, yielding **2a** free of solvent in 90% yield. The swelling capacity of the dried titaniumsilasesquioxane gel **2a** for toluene is reduced to approximately 0.5 ml $g^{-1}$.

Related titaniumsilasesquioxane gels were also prepared from the building block **1** involving reactions with titanium tetrachloride and a base (Scheme 1, routes *b* and *c*). As a result of these synthetic methods, the gels obtained contain enclosed lithium chloride or $[NHEt_3]Cl$.

The silanol-mediated functionalizations that lead to the formation of the silasesquioxane gels **2** are straightforward and find precedent in the well exploited silanol-centred reactivity of the related silasesquioxane $(C_6H_{11})_7Si_7O_9(OH)_3$.[11] Powder reflection UV–VIS measurements on **2a–c** show the onset of significant UV absorption only below 350 nm, with a maximum at 220–240 nm. This indicates that in **2a–c** the titanium centres exist as four-coordinate titanium(IV) siloxy units.

Analysis of the titaniumsilasesquioxane gels **2** by single-pulse 79.5 MHz $^{29}Si$ MAS NMR provides a method to establish the degree of silanol functionalization during their formation. Upon substitution, the originally lower field resonance of the silanol silicon atoms at δ −58.9 shifts towards the higher field part of the spectrum where the other silasesquioxane silicon resonances are already found (δ −65 to −75). Comparison of the integrals over the two distinct parts of the spectra indicates that the fraction of remaining silanol units in the titanium gels **2a–c** is, typically, 0.05 (*cf.* 0.25 in the silasesquioxane **1**), *i.e. ca.* 80% of the silanol units of the starting material **1** have been functionalized in the gel-forming process.

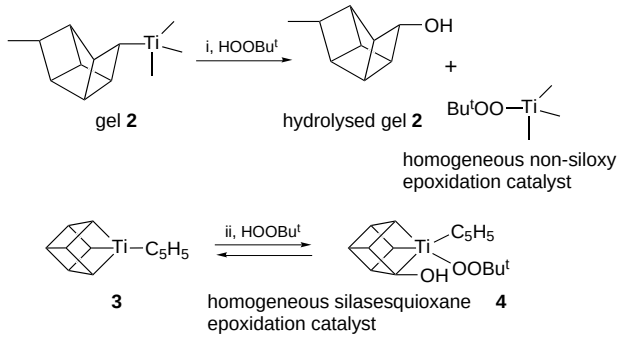
**Scheme 1** Synthetic routes to the titaniumsilasesquioxane gels **2a–c** (Cy = cyclohexyl)

Interestingly, when any of the gels **2** are subjected to acid hydrolysis followed by organic work-up, the silasesquioxane **1** can be recovered in near to quantitative yield (Scheme 1, route *d*). From this observation, it can be concluded that the silanol deprotonations involved in the formation of the gels **2** do not induce any change in the silasesquioxane framework.

The titanium silasesquioxane gels **2** efficiently catalyse the epoxidation of alkenes under mild conditions (see Table 1). In a typical reaction equimolar amounts of alkene and *tert*-butyl hydroperoxide (TBHP) were reacted over the catalyst (*ca.* 1 mol% Ti with respect to the substrates) in hexane at 50 °C. Though for the reactions studied, the silasesquioxane gels **2** were reasonable to good catalysts, attempts to filter the catalyst off during epoxidation, and thus to stop the reaction, met with complications which were indicative of severe leaching of catalytically active species from the titanium gels. Interestingly, NMR studies showed that during epoxidation, rapid hydrolysis of the gel by TBHP occurs resulting in the quantitative reformation of the silasesquioxane **1** and concomitant formation of non-siloxy titanium species that are catalytically active.

An essential feature of several of the proposed mechanisms of alkene epoxidation by titanium silicalites involves hydrolysis of a titanium siloxy function in a four-coordinate active site.[12–15] For the titanium gel **2**, such a hydrolysis step would lead to rapid degeneration of the material since the titanium siloxy units (Ti–O–Si) result here from functionalization of isolated silanol groups, the silasesquioxane being a bifunctional monodentate ligand (Scheme 2, route i). This would therefore imply that silasesquioxane titanium species where the silasesquioxane can bind to titanium as a multidentate ligand are more robust epoxidation catalysts.

In order to verify this hypothesis, we have tested the activity of the known silasesquioxane complex **3**, that has a terdentate silasesquioxane ligand,[8,16] for similar alkene epoxidations (Table 1). Interestingly, complex **3** turned out to be an epoxidation catalyst that is effective at low concentration and which selectively produces alkene oxides in high yield with good peroxide economy. Especially the somewhat difficult epoxidation of oct-1-ene is catalysed more effectively by **3**. The same catalytic performance was found for **3** that was repeatedly recrystallized from toluene–acetonitrile, which seems to exclude the possibility that undetected trace impurities in **3** are responsible for the observed catalytic activity. It is likely that due to multidentate silasesquioxane coordination, **3** does not hydrolyse irreversibly during epoxidation reactions (Scheme 2, route ii); in fact, the complex is even stable in 1 M aq. HCl! Under catalytic conditions, complex **3** can be easily monitored by $^{1}H$ and $^{13}C$ NMR, it's cyclopentadienyl unit providing a convenient and sensitive NMR probe. From these NMR experiments it could be concluded that after *ca.* 100 turnovers, complex **3** is still the only observable silasesquioxane species present and that it does not lose the cyclopentadienyl ligand during epoxidation catalysis. These findings are consistent with a mechanism for alkene epoxidation in which reversible hydrolysis of a titanium siloxy function occurs. In our opinion, these observations support the mechanism of heterogeneous alkene epoxidation by titanium silicalites proposed by Clerici, Ingallina, Sheldon and Van Doorn.[12–15]



In conclusion, we have shown that new titanium-containing silasesquioxane gels effectively catalyse the epoxidation of alkenes by TBHP under mild conditions. The active catalyst, however, is a soluble, non-siloxy titanium species. Alternatively, the titanium complex **3**, that contains a terdentate silasesquioxane ligand, has excellent performance in the same epoxidations. In this case, the catalysis occurs exclusively through titanium siloxy complexes. As such, liquid-phase, silica-supported titanium epoxidation catalysts are predicted to be accessible and active in many cases but will be truly heterogeneous only when stringent conditions are met. More work on the structural characterization of the titanasilasesquioxane gels as well on their use in catalysis is currently in progress together with experimental work on the heterogenization of complex **3**.

The research of H. C. L. A. has been made possible by a fellowship of the Royal Netherlands Academy of Arts and Sciences (KNAW). S. K. thanks the Netherlands Institute for Catalysis Research (NIOK) for financial support.

**Table 1** Epoxidation of alkenes with TBHP catalysed titanasilasesquioxanes[a]

| Catalyst | Alkene | *t*/h | Conv. (%) | Selectivity in alkene (%) |
|---|---|---|---|---|
| **2a** | Oct-1-ene | 24 | 15 | 60 |
| **2b** | Oct-1-ene | 24 | 25 | 60 |
| **3** | Oct-1-ene | 24 | 80 | 80 |
| **2a** | Cyclooctene | 4 | 50 | > 95 |
| **2b** | Cyclooctene | 4 | 90 | > 95 |
| **3** | Cyclooctene | 3 | 90 | > 95 |
| **2a** | Norbornylene | 4 | 60 | > 95 |
| **2b** | Norbornylene | 3.5 | 90 | > 95 |
| **3** | Norbornylene | 3 | 90 | > 95 |

[a] All reactions were performed using equimolar amounts (1.6 mmol) of alkene and dried *tert*-butyl hydrogen peroxide (1.6 mmol) in hexane (1.0 ml). Reactions were performed at 50 °C in sealed vials that were magnetically stirred using 25 mg of catalyst. Conversions and yields were determined by $^{1}H$ NMR spectroscopy.

**Scheme 2** Schematic representation of the reaction of silasesquioxane titanium species with TBHP rendering species capable of alkene epoxidation: i, the irreversible hydrolysis of the silasesquioxane gels **2** and ii, the reversible hydrolysis of a silasesquioxane complex (the lines in the cube-type ligands represent Si–O–Si, with cyclohexyl units at the corners)

# Vectorial transfer of electronic energy in rod-like ruthenium–osmium dinuclear complexes

**Francesco Barigelletti,[a] Lucia Flamigni,[a] Jean-Paul Collin[b] and Jean-Pierre Sauvage[b]**

[a] *Istituto FRAE-CNR, Via P. Gobetti 101, 40129 Bologna, Italy*
[b] *Laboratoire de Chimie Organo-Minerale, Université Louis Pasteur, Faculté de Chimie, 1 rue Blaise Pascal, F-67008, Strasbourg, France*

**Dinuclear complexes containing ruthenium and osmium-based bis-terpyridyl chromophoric termini are prepared and their luminescence properties investigated. The two chromophoric units are connected by 1,4-phenylenes only, or phenylene and bicyclooctane spacers. In this way complete control of the geometry of the dinuclear complexes is achieved and these rigid species resemble molecular rods or girders featuring intermetal distances in the range 11–24 Å. The Ru → Os transfer of electronic excitation is energetically allowed and we have studied the effect on this process both of the intermetal separation and the electronic properties of the spacers. The main conclusions are that the phenylene spacers are very efficient in transmitting the intermetal electronic communication but an important role is also played by the spatial localization of the metal-to-ligand charge-transfer excited states involved in the excitation-transfer process.**

## Introduction

The study of vectorial photoinduced processes is of great importance in large-size molecular assemblies that combine light-sensitive components and molecular functionalities for carrying out useful functions (artificial photochemical molecular devices, PMD[1]). Basically, these molecular assemblies can be obtained either by action of weak intermolecular forces[2] or by covalently linking molecular subunits.[3] The latter approach may lead to the building up of very large species where the spatial organization of the active components is provided by suitable bridging ligands, BLs. Thus, in the presence of properly arranged energy gradients for intercomponent energy- or electron-transfer steps, light absorption may drive the intercomponent processes sought for. For instance, bearing in mind the mimicry of natural systems, investigated systems include high-nuclearity light-harvesting assemblies[4] and di-, tri- or multi-partite systems for performing charge separation.[5] In all cases, the BL is expected not only to provide the spatial organization of the active components but also to be responsible for a certain amount of electronic interaction between them. Clearly, it is of importance to achieve control of the electronic factor in order to tune the various kinetic steps and ensure an efficient energy cascade.

Systems convenient for study are those in which the BLs contain a variable number of identical molecular subunits. This allows the construction of series of compounds in which (*i*) the distance between the active components is gradually varied and, as a consequence, (*ii*) the electronic interaction between them is modulated. We survey here results for relatively simple but geometrically well defined dinuclear species (Figs. 1 and 2).† These contain ruthenium- and osmium-based centres (the photochemically active units[6]), connected by bischelating BLs. In the cases illustrated here, the bridges contain (*i*) terpyridyl-[7,8] or bipyridylbenzene-like[9] chelating sites; the external ligand being 4′-*p*-tolylterpyridine in each case, and (*ii*) a spacer S that includes phenylene and bicyclooctane units. The employed BLs allow a high degree of geometric control of the dinuclear species because the metal centres are kept at fixed distances and are linearly aligned with BL.

We will only be concerned with intramolecular (intercomponent) processes because in dilute solutions (concentration *ca.* $10^{-5}$ mol $dm^{-3}$) intermolecular processes do not take place within the considered timescales. Recent reports deal with the behaviour of BLs which include spacers like cyanide,[10] ethenyl,[11] ethenylbenzene,[12] ethenylbicyclooctane,[13] ethynylbenzene,[14] ethynylbicyclooctane[15] and polyenes.[16] These BLs are capable of providing a high degree of rigidity to the dinuclear species. We will not concern ourselves with a close comparison between our and other results;[17–19] instead we will only briefly comment on problems arising with dinuclear complexes where the ruthenium- and osmium-based photoactive units employ a tris-bipyridine instead of the bis-terpyridine-type coordination discussed here.

## Synthetic strategies

The strategy employed for the synthesis of Ru–BL–Os dinuclear complexes starts with the synthesis of the symmetrical BLs (terpyridyl- or dipyridylbenzene-type ligand). Two successive steps with the suitable precursor (Ru or Os) afford the heterodinuclear complexes. In fact, the key step is the preparation of the mononuclear ruthenium complex bearing a free coordination site. The yield for this reaction can be optimized by using an excess of bridging ligand *vs.* the labile solvated ruthenium precursor, $[Ru(ttp)(Me_2CO)_3]^{2+}$. All the compounds reported here were isolated as $PF_6^-$ salts and characterized by $^1H$ NMR and FABMS.

The terpyridyl-type BLs were prepared by homocoupling of the appropriate terpyridine units either following the method reported by Constable and Ward,[20] or by the method of Kröhnke[21] in the case of the series with the tpy–$ph_n$–tpy BLs. Suzuki's cross-coupling procedure[22] was used for the bis-terpyridine BL incorporating the bicyclo[2.2.2]octane spacer, tpy–ph–bco–ph–tpy.

The bis-cyclometallating dipyridylbenzene BLs were also prepared by reductive coupling or Suzuki's cross-coupling reaction utilizing 1-bromo-3,5-dipyridylbenzene as the building block.[23] This latter compound was prepared by a palladium-catalysed C–C coupling procedure based on aromatic stannanes.[24]

## The experimental approach

In our systems, the lowest-lying excited energy levels centred on the ruthenium- and osmium-based active components are triplet states of metal-to-ligand charge-transfer (MLCT) nature.[6] These excited levels can be populated by absorption of visible light. In order to observe the Ru → Os electronic energy transfer we have performed both steady-state and time-resolved measurements.[7–9] Unfortunately, selective excitation of the donor is not possible and in the former case we have excited the Ru–BL–Os dinuclear species corresponding to an isosbestic point for the absorption of the ruthenium- and osmium-based

reference complexes. In this way 50% of the excited dinuclear species will have excitation centred on the ruthenium-based chromophore and 50% will have excitation centred on osmium-based chromophores [eqn. (1)].

$$2\ \text{Ru–BL–Os} + h\nu \rightarrow \text{*Ru–BL–Os} + \text{Ru–BL–*Os} \quad (1)$$

The ruthenium- and osmium-based luminescence spectra fall in different wavelength regions and with steady-state luminescence spectroscopy it has been possible to monitor the quenching of the ruthenium-based luminescence and sensitization of the osmium-based luminescence, owing to the Ru → Os transfer of the excitation energy [eqn. (2)].

$$\text{*Ru–BL–Os} \rightarrow \text{Ru–BL–*Os} \quad (2)$$

The same information has been obtained by employing time-resolved spectroscopic methods. In this case we have monitored the lifetime of the excited ruthenium-based unit (the energy donor), $\tau$, in the dinuclear complex, with respect to the lifetime of the excited reference compound, $\tau_o$, and derived the energy transfer rate, $k$ [eqn. (3)].

$$k = \frac{1}{\tau} - \frac{1}{\tau_0} \quad (3)$$

In some cases it has also been possible to observe time-resolved sensitization of the osmium-based component, followed by its decay.[8]

## Transfer of electronic excitation energy

From the spectroscopic properties of the ruthenium- and osmium-based components,[6–9] it is possible to see that the Ru → Os transfer of electronic excitation energy [eqn. (2)] is exoergonic. This transfer takes place according to the exchange (Dexter)[25] mechanism, whereas the Coulombic (Förster)[26] mechanism has been found to be negligible.[7,9]

The exchange mechanism may be conveniently visualized as a simultaneous double electron exchange between the donor and the acceptor partners.[27] On this basis, it is possible to follow a classical approach that parallels that for non-adiabatic electron transfer.[28] Thus, in the weak interaction limit between involved centres, the Dexter energy transfer can be cast in terms of thermodynamic quantities [eqn. (4)].

$$k = \nu \exp(-\Delta G^{\ddagger}/RT) \quad (4a)$$

$$\nu = \frac{2H^2}{h}\left(\frac{\pi^3}{\lambda RT}\right)^{1/2} \quad (4b)$$

$$\Delta G^{\ddagger} = \frac{\lambda}{4}\left(1 + \frac{\Delta G^0}{\lambda}\right)^2 \quad (4c)$$

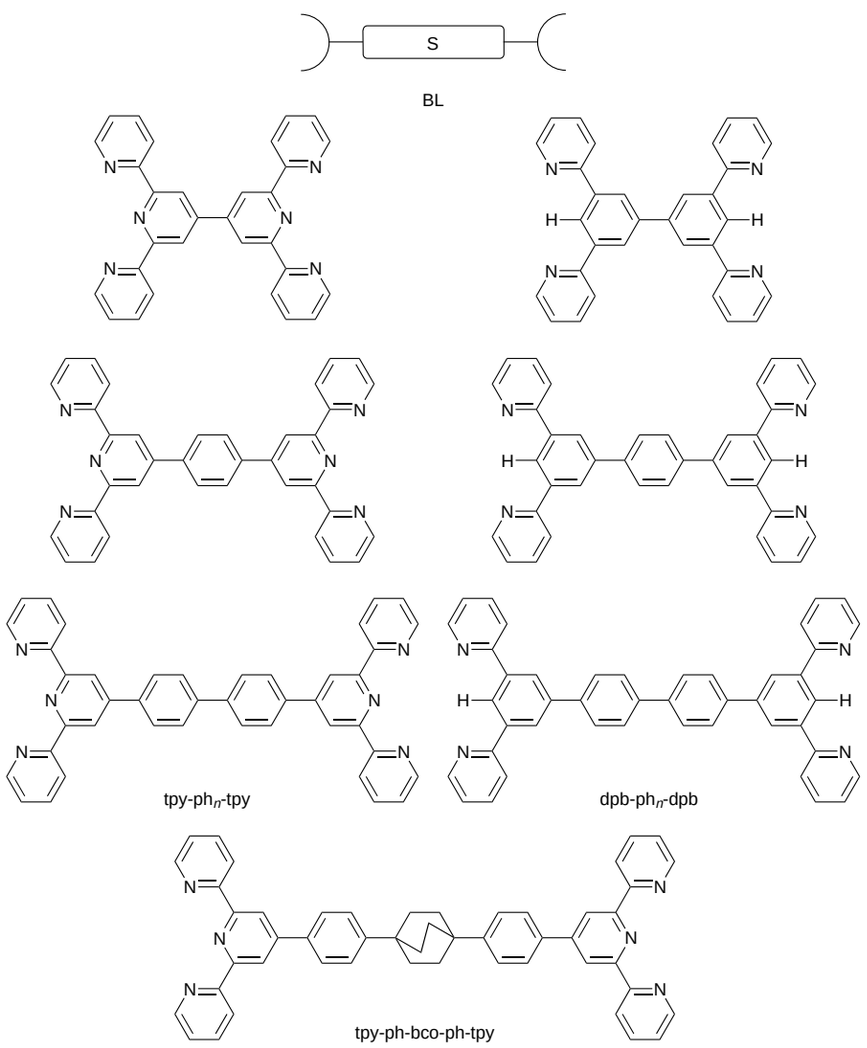

**Fig. 1** The employed bridging ligands, BLs: tpy–ph$_n$–tpy is a series of bis-tpy BLs containing phenylene spacers, $n$ = 0–2; dpb–ph$_n$–dpb is a series of bis-dipyridylbenzene BLs containing phenylene spacers, $n$ = 0–2 (in the Ru–BL–Os complexes, these latter BLs are dianions); and tpy–ph–bco–ph–tpy is a BL where a bicyclooctane unit has been interposed between two phenylene groups

In these equations ν is a frequency factor, λ is the reorganization energy, $H$ is the intercomponent electronic interaction energy and $\Delta G^{\ddagger}$ and $\Delta G^0$ are the activation energy and the free energy change, respectively, for the transfer of excitation energy. The free energy change is evaluated from the maxima of the emission bands of the donor and acceptor reference compounds, as measured at 77 K.[6–9] For the osmium-based complexes, the reorganization energy, $\lambda^{Os}$, may be estimated from the Stokes shift of absorption and emission spectra, $2\lambda^{Os}$ = SS.[29] For structurally similar ruthenium- and osmium-based complexes, it is usually assumed that $\lambda^{Ru} = \lambda^{Os}$.[9,13] Table 1 collects estimates for $\Delta G^0$ and λ values concerned with some structurally similar ruthenium- and osmium-based couples of reference complexes.

From Table 1, it can be seen that electronic excitation transfer between the selected donor and acceptor couples occurs under nearly activationless conditions since $\Delta G^0 \approx -\lambda$ [eqn. (4a–c)]. Thus the double electron exchange is expected to be governed by electronic factors. Under these conditions, the distance dependence of the interaction energy, $H$, can be described by eqn. (5).

$$H = H_0 \exp(-\beta d_{MM}) \quad (5)$$

where $d_{MM}$ indicates the distance between the metal centres, β is an attenuation factor and $H_0$ is the interaction energy at intercomponent orbital contact.

### Energy transfer in the series of complexes containing the tpy–ph$_n$–tpy BLs

Pertinent photophysical data for the [(ttp)Ru(tpy–ph$_n$–tpy)Os(tpy)]$^{4+}$ series of complexes are collected in Table 2. For these complexes, the $d_{MM}$ intermetal distance changes from 11 to 20 Å, depending on $n$. The excited Ru(ttp)$_2^{2+}$ chromophore exhibits a room-temperature lifetime $\tau$ = 0.95 ns in acetonitrile. Thus, because of the competition with intrinsic deactivation of the ruthenium-based component, only Ru → Os processess occurring with rates $k > 10^9$ s$^{-1}$ are expected to take place. Actually, the transfer of energy was found to occur with $k > 10^{10}$ s$^{-1}$ even for $n$ = 2 and one concludes that the polyphenylene bridge behaves as an extremely good energy transducer over the remarkable intermetal separation of 20 Å.[7] Interposition of a bicyclooctane (bco) unit in [(ttp)Ru(tpy–ph–bco–ph–tpy)Os(tpy)]$^{4+}$ leads to an intermetal separation of 24 Å, and results in a dramatic decrease of the energy transfer rate, $k = 4.4 \times 10^6$ s$^{-1}$ as measured at 77 K,[8] Table 2. To some extent, this effect is due to the increased intermetal distance, however a major role must be ascribed to the electronically insulating properties of the bco saturated group. This group breaks the ππ* frame of molecular orbitals centred on the phenylene units and only provides less efficient σσ* orbitals for the transmission of the intermetal interaction.

### Energy transfer in the series of complexes containing the dpb–ph$_n$–dpb biscyclometallating BLs

The dinuclear complexes that contain these dianionic BLs exhibit the same geometrical properties as the previous series, with distances between the metal centres ranging from 11 to 20 Å, depending on the size of the phenylene spacer.[9] For the cyclometallated series, the rate of Ru → Os energy transfer proved to be much lower than for the structurally identical series seen in the previous section. Thus, at room temperature no energy transfer was observed, despite the fact that the excited [Ru(ttp)(dpb)]$^+$ chromophore exhibits a lifetime $\tau_o$ = 4.5 ns in

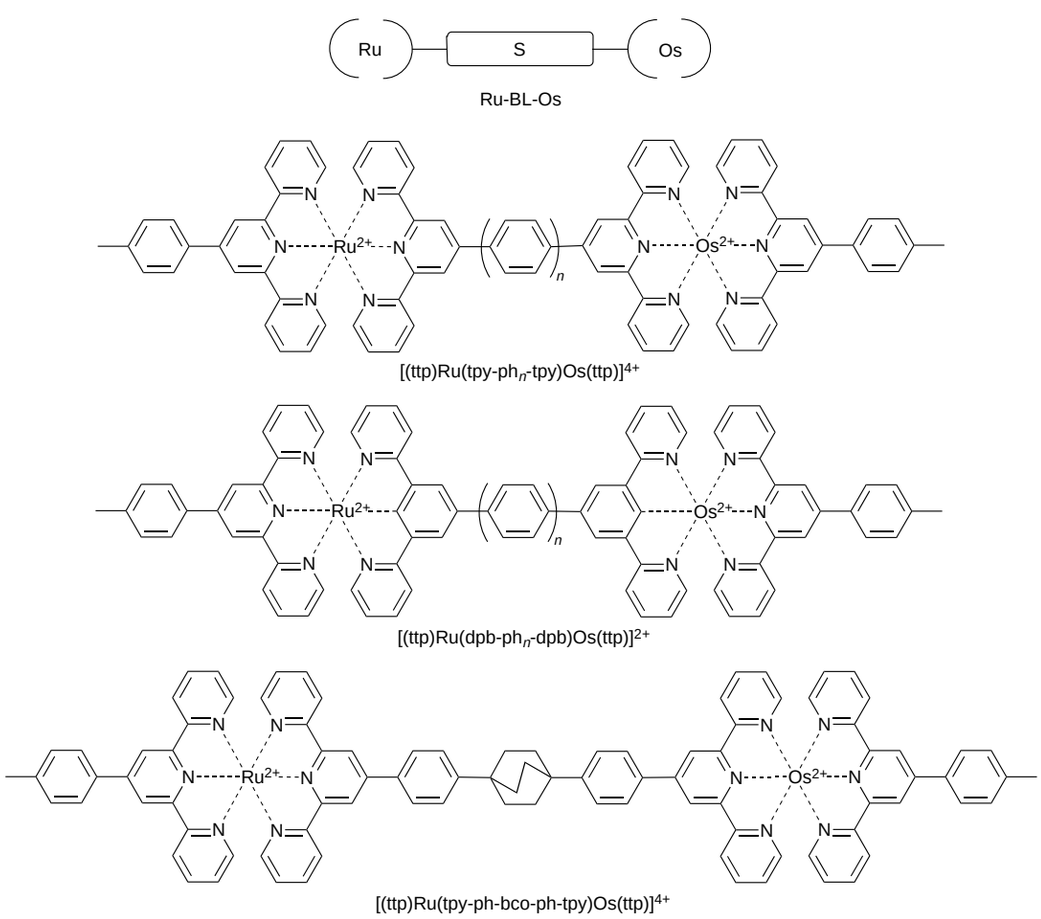

**Fig. 2** The Ru–BL–Os dinuclear complexes

acetonitrile, *i.e.* significantly longer than that of its $[Ru(ttp)_2]^{2+}$ homologue ($\tau_o$ = 0.95 ns). As a consequence, it was necessary to monitor the process at 77 K, where the intrinsic deactivation of the excited $[Ru(ttp)(dpb)]^+$ species is sufficiently slow, $\tau_o$ = 496 ns, Table 2. The Ru → Os energy- transfer rates for the $[(ttp)Ru(dpb–ph_n–dpb)Os(ttp)]^{2+}$ series were obtained both according to the steady-state approach outlined above (in this case we used 550 or 514 nm light excitation so as to excite 40 and 60% of the ruthenium- and osmium-based chromophores, respectively), and by time-resolved experiments [eqn. (3)]. As one can see from Table 2, the energy-transfer rate is affected to a large degree by the presence of the phenylene spacers and it was possible to draw a sizeable attenuation factor $\beta$ = 0.33 Å$^{-1}$ [eqn. (5)] for the phenylene units.[9]

**Table 1** Parameters for Ru → Os electronic energy transfer[a]

| Reference donor | Reference acceptor | $\Delta G^{0\,b}$/eV | $\lambda^c$/eV | Ref. |
|---|---|---|---|---|
| $[(ttp)Ru(ttp)]^{2+}$ | $[(ttp)Os(ttp)]^{2+}$ | −0.25 | 0.15 | 7 |
| $[(ttp)Ru(dpb)]^+$ | $[(ttp)Os(dpb)]^+$ | −0.18 | 0.15 | 9 |
| $[(bpy)_2Ru(bpy)]^{2+}$ | $[(bpy)_2Os(bpy)]^{2+}$ | −0.38 | 0.40 | 13 |

[a] See eqn. (4a–c), solvent is acetonitrile, butyronitrile or dmf–$CH_2Cl_2$ (9 : 1). [b] Estimated from luminescence band maxima of the reference donor and acceptor complexes at 77 K. [c] Estimated from Stokes shifts for the acceptor complex.

### Electronic properties of the chromophores in the $[(ttp)Ru(tpy–ph_n–tpy)Os(ttp)]^{4+}$ and $[(ttp)Ru(dpb–ph_n–dpb)Os(ttp)]^{2+}$ series

For the two series of complexes, which are geometrically identical (see Fig. 2), there is a difference of orders of magnitude in the Ru → Os energy-transfer rate, Table 2. As the energy-transfer step is nearly activationless in both cases, a minor rôle is played by nuclear (reorganization) factors [eqn. (4a–c)] whereas a possible explanation relies on a different role of the electronic factor.

A pictorial description of the energy-transfer process for the two smallest members of the two series is provided in Fig. 3. Here we emphasize the spatial properties of the ruthenium- and osmium-centred MLCT states involved in the excitation transfer. In particular (*a*) for the case of the tpy–tpy BL the MLCT excited states are described with the promoted electron residing on the tpy fragment of BL, and (*b*) for the dpb–$dpb^{2-}$ BL the promoted electron is placed on the external ttp ligand. Actually, in the former case the tpy–tpy bridging ligand is a better electron acceptor with respect to the ttp terminal ligand because of electronic delocalization[7] and in the latter case the ttp terminal ligand is a better electron acceptor than the dianionic dpb–$dpb^{2-}$ BL.[9]

Fig. 3 describes the Ru → Os simultaneous double electron exchange in terms of a metal–metal hole transfer (HT) and a ligand–ligand electron transfer (ET).[30] Clearly, HT occurs over identical distances in the two series (for the same *n*, $d_{HT} = d_{MM}$)

**Table 2** Photophysical results and Ru → Os energy-transfer rates[a]

| | | 293 K | | | 77 K | | | |
|---|---|---|---|---|---|---|---|---|
| | $d_{MM}$/Å | $\tau_0{}^b$/ns | $\tau^b$/ns | $k^c$/s$^{-1}$ | $\tau_o{}^b$/ns | $\tau^b$/ns | $k^c$/s$^{-1}$ | Ref. |
| $[(ttp)Ru(ttp)]^{2+}$ | | 0.95 | | | 9100 | | | 7 |
| $[(ttp)Ru(tpy–tpy)Os(ttp)]^{4+}$ | 11 | | < 0.03 | > $10^{10}$ | | < 0.03 | > $10^{10}$ | 7 |
| $[(ttp)Ru(tpy–ph–tpy)Os(ttp)]^{4+}$ | 15.5 | | < 0.03 | > $10^{10}$ | | < 0.03 | > $10^{10}$ | 7 |
| $[(ttp)Ru(tpy–ph–ph–tpy)Os(ttp)]^{4+}$ | 20 | | < 0.03 | > $10^{10}$ | | < 0.03 | > $10^{10}$ | 7 |
| $[(ttp)Ru(tpy–ph–bco–ph–tpy)Os(ttp)]^{4+}$ | 24 | | 0.95 | —[d] | | 220 | $4.4 \times 10^6$ | 8 |
| $[(ttp)Ru(dpb)]^+$ | | 4.5 | | | 496 | | | |
| $[(ttp)Ru(dpb–dpb)Os(ttp)]^{2+}$ | 11 | | 0.35 | $2.6 \times 10^9$ | | 0.72 | $1.4 \times 10^9$ | 9 |
| $[(ttp)Ru(dpb–ph–dpb)Os(ttp)]^{2+}$ | 15.5 | | 3.5 | $6.3 \times 10^7$ | | 42 | $2.2 \times 10^7$ | 9 |
| $[(ttp)Ru(dpb–ph–ph–dpb)Os(ttp)]^{2+}$ | 20 | | 4.9 | $< 2.2 \times 10^7$ | | 178 | $3.6 \times 10^6$ | 9 |

[a] Solvent is acetonitrile, butyronitrile or dmf–$CH_2Cl_2$ (9 : 1). [b] Lifetimes of the ruthenium-based chromophore. [c] $k = (1/\tau) - (1/\tau_o)$. [d] No energy transfer takes place at room temperature.

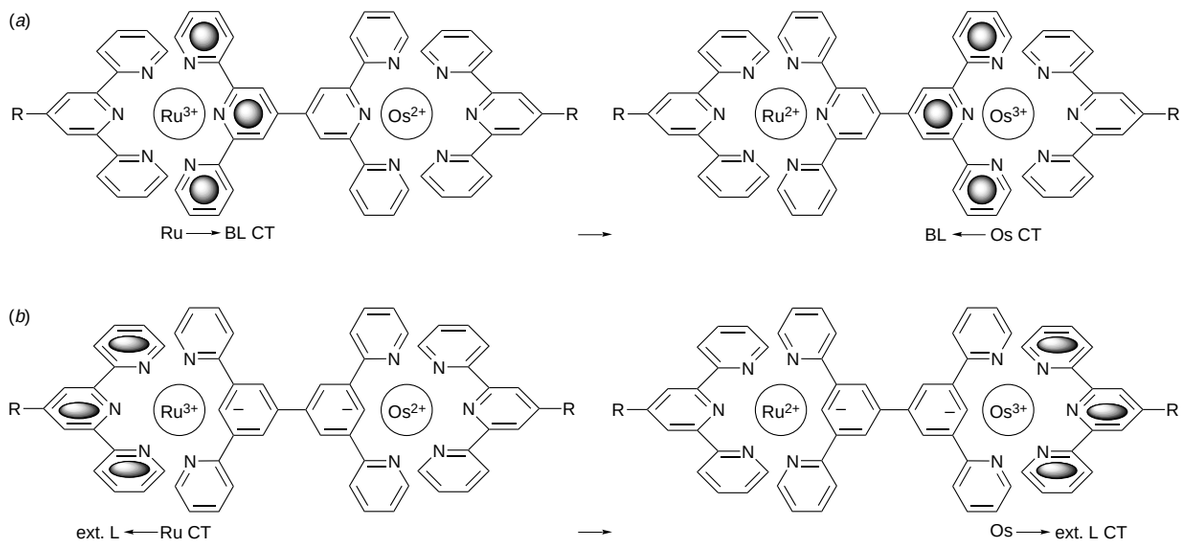

**Fig. 3** Spatial properties of the MLCT excited states involved in the Ru → Os excitation-transfer step for $[(ttp)Ru(tpy–tpy)Os(ttp)]^{4+}$ (*a*) and $[(ttp)Ru(dpb–dpb)Os(ttp)]^{2+}$ (*b*); R = 4′-*p*-tolyl. The shaded areas indicate localization regions for the promoted electron of the MLCT excited state: M → BL (*a*) and M → external L (*b*).

and is thought to involve the available highest- occupied molecular orbitals (HOMOs) of the bridge.[31] In contrast, ET involves the chelating sites of BL for case (*a*), $d_{ET} < d_{MM}$, and the external ligands for case (*b*), $d_{ET} > d_{MM}$. Thus ET occurs in remarkably different conditions in the two series, both in terms of intercentre spatial separation and of electronic coupling. The latter point may be appreciated by noting that around each metal centre the external ligand system is arranged perpendicularly with respect to the chelating site belonging to the bridge (Fig. 3). Given that ET occurs by involving the available lowest $\pi^*$ unoccupied molecular orbitals (LUMOs, which are ligand-centred), the electron travelling from one external ligand to the opposite external ligand will cross at least two regions where the $\pi$ orbital systems are perpendicularly arranged. In this case therefore, one expects a low electronic coupling for the ligand–ligand ET. In conclusion, it seems possible that the difference in energy-transfer rates between the two series is mainly ascribable to a different rôle of the electronic factor for the two cases.

## Future developments

One limitation in the development of larger species for the study of long-range vectorial energy transfer is related to the lifetime of the excited donor, the ruthenium-based chromophore. This happens because the energy-transfer process, which becomes slower and slower with increasing size of the bridge, is in direct competition with intrinsic deactivation of the excited donor. Actually, long-lived ruthenium-based chromophores with the tris-bpy coordination ($\tau \approx$ hundreds of ns)[6] are employed in building dinuclear and higher nuclearity complexes.[30,32] Unfortunately, this latter type of coordination results in some geometric disadvantages with respect to that based on the bis-tpy coordination. For the purpose of illustration, Fig. 4 depicts some geometrical properties of such a complex, $[(bpy)_2Ru(bpy–S–bpy)Os(bpy)_2]^{4+}$, where S includes double bonds and a bicyclooctane unit.[13] Because of the properties of the tris-bpy coordination, the bpy–S–bpy BL is not linearly aligned with the metal centres (and with the peripheral ligands). In addition, because of rotations around single bonds, the intermetal separation is 17 Å as an average, with an uncertainty estimated at ±1 Å.

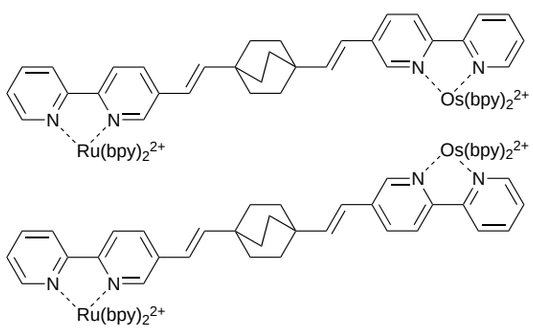

**Fig. 4** Two possible nuclear configurations resulting from the use of the tris-bpy coordination in a $[(bpy)_2Ru(bpy–S–bpy)Os(bpy)_2]^{4+}$ dinuclear complex: there is no linear alignment along the M–BL–M axis and the intermetal distance is subject to some uncertainty

For the building up of new dinuclear complexes there may be different strategies. One useful approach is to combine the electronic properties of the tris-bpy arrangement and the geometrical properties of a perfectly aligned, more symmetric bridge. An example of such type of approach is illustrated in Fig. 5. In this species, the $Ru(bpy)_2(phen)^{2+}$ chromophore exhibits a long-lived excitation, $\tau$ = 145 ns, and the phen–adamantane–phen BL ensures the sought-for alignment of the various components, with a fixed intermetal separation of 21 Å.[33]

Another useful approach may be based on the improvement of the spectroscopic properties of Ru–tpy type fragments by appending suitable groups at the 4′ position of the external tpy ligand. Actually, by using both electron-withdrawing and attracting appended groups[34] or groups that affect electronic delocalization over the tpy fragment[14] it has been possible to obtain long-lived Ru–tpy type units. Also, the use of protonable appended sites to the Ru–tpy chromophore may be of interest.[35] Literature examples of these possible approaches are illustrated in Fig. 6.

## Conclusions

In order to develop molecular assemblies it is of obvious importance to gain control of the energetic and geometric factors. Our studies show that, for assemblies incorporating ruthenium– and osmium–terpyridine type and related cyclometallated analogues, the additional possibility exists of a fine

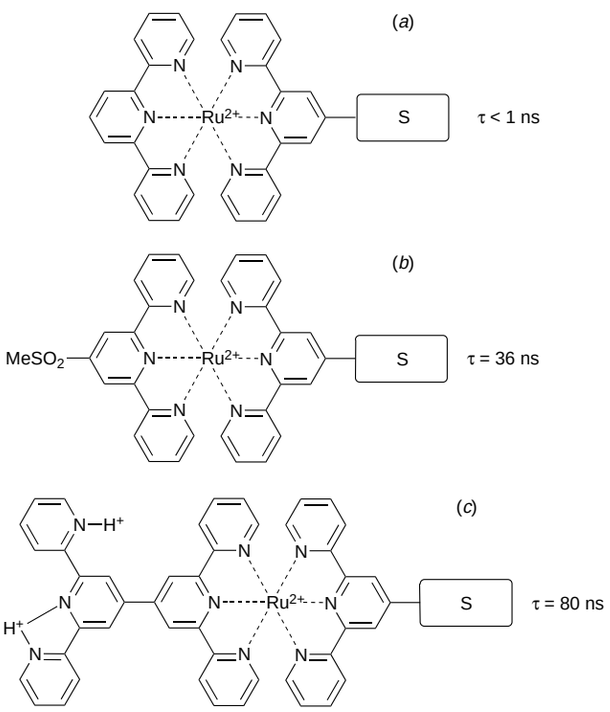

**Fig. 6** Perturbation of the basic $Ru(tpy)_2^{2+}$ chromophore (*a*),[7] may result in long-lived excited states centred on the ruthenium-based unit: (*b*) ref. 34 and (*c*) ref. 35. The diagrams show various Ru–tpy chromophores linked to a spacer for incorporation in dinuclear complexes.

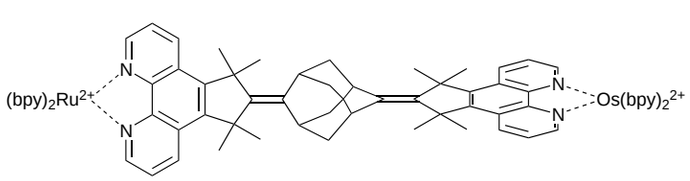

**Fig. 5** A linear alignment of the metals and the BL results from the use of the phen–adamantane–phen BL;[33] the metal centres are at a fixed separation of 21 Å

modulation of photoinduced intermetal processes which is based on control of the spatial distribution of the metal-to-ligand charge-transfer excited states involved in the processes. We have performed our studies by employing cyclometallating analogues of the terpyridine ligand but a similar approach is likely to work with other types of ligand fragments. In principle, our results indicate ways for substantial manipulation of rates of energy transduction along molecular rods.

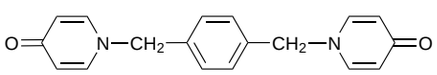
# Diversity of linking modes by *N*,*N*′-*p*-phenylenedimethylenebis(pyridin-4-one) [*p*-XBP4] in the novel 'linked lantern' framework complex $\{[Nd_2(p\text{-XBP4})_6(H_2O)_4](p\text{-XBP4})(H_2O)_3(ClO_4)_6\}_n$

**David M. L. Goodgame, Stephan Menzer, Amanda M. Smith and David J. Williams**



*Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*

**The title compound has a complex framework structure in which pairs of Nd atoms are linked by four *p*-XBP4 ligands to form 'lanterns' which are further connected by interwoven Nd–(*p*-XBP4)–Nd bridges, and yet again by non-coordinated *p*-XBP4 molecules hydrogen bonded to aqua ligands on the Nd centres.**

The field of supramolecular chemistry has undergone a veritable explosion of activity opening up a wide diversity of themes and applications.[1] A particularly interesting topic within this field is the use of the 'self-assembly' process for the formation of, for example, macrocycles, catenanes and cages and the range of approaches for achieving these objectives has very recently been reviewed.[2] We have shown that a particularly versatile ligand for forming such materials is *N*,*N*′-*p*-phenylenedimethylenebis(pyridin-4-one) (**I**, *p*-XBP4). It has the ability to form interwoven metallomacrocyclic networks[3,4] and also to bring pairs of metal ions into close proximity within these arrays by forming μ-O atom bridges.[3] Further studies with **I** have produced an extensive range of lanthanide (Ln) compounds with unusual stoichiometries;[5] examples include $Ln_4(p\text{-XBP4})_7(NO_3)_{12}\cdot 4H_2O$ (Ln = La–Eu), $Ln_2(p\text{-XBP4})_3(NO_3)_6\cdot 2H_2O$ (Ln = Gd–Yb) and $Ln_2(p\text{-XBP4})_7(ClO_4)_6\cdot 7H_2O$ (Ln = La, Nd, Sm, Gd). In view of our previous observations of the propensity for **I** to generate novel structures with transition-metal ions, the non-integral stoichiometries of the lanthanide compounds pointed to the formation of yet further types of framework arrays. Full X-ray characterisation of most of these compounds has been hindered by their formation only as poorly crystalline powders. However X-ray quality crystals have been obtained for $Nd_2(p\text{-XBP4})_7(ClO_4)_6\cdot 7H_2O$ **1**,† and the structural study‡ of this reveals not only a particularly novel framework array but also a new type of networking role for **I**.

This analysis reveals that each neodymium atom is eight coordinate (Fig. 1) being bound to one oxygen atom from each of six different *p*-XBP4 ligands [Nd–O in the range 2.373(4)–2.433(4) Å] and to two aqua ligands with Nd–O(aqua) distances of 2.551(4) and 2.639(4) Å. The coordination geometry around each neodymium atom is essentially bicapped trigonal prismatic with O(21) and O(91) as the capping atoms. There are four different *p*-XBP4 ligand geometries (A, B, C and D)§ in the structure, and, although all the *p*-XBP4 ligands act as bridges, they do so in three quite different ways.

Pairs of adjacent neodymium centres are directly bridged by four *p*-XBP4 ligands, two each of types A and B (shown in red in Fig. 2), forming a 'pumpkin'- or 'lantern'-like oblate spheroidal 'box', with a Nd···Nd separation of 11.9 Å and with distances between the centroids of the opposite pairs of *p*-$C_6H_4$ rings of *ca*. 14 Å, thereby producing an effective cage volume

**I** (*p*-XBP4)

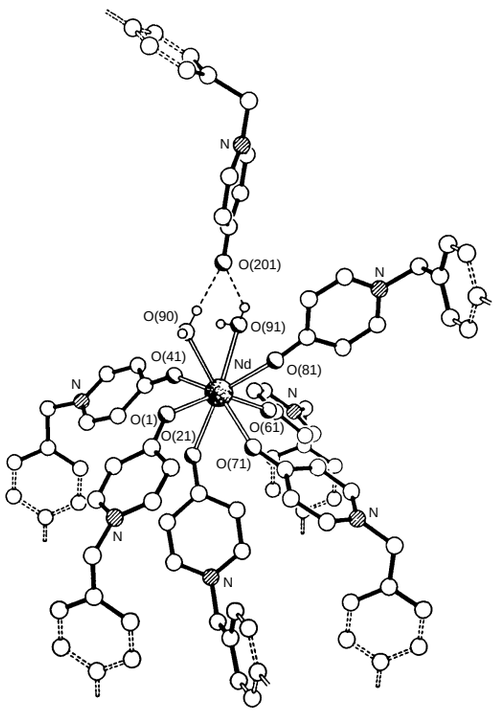


**Fig. 1** The neodymium coordination environment in **1** showing also the hydrogen bonding of part of a D-type *p*-XBP4 molecule to the aqua ligands

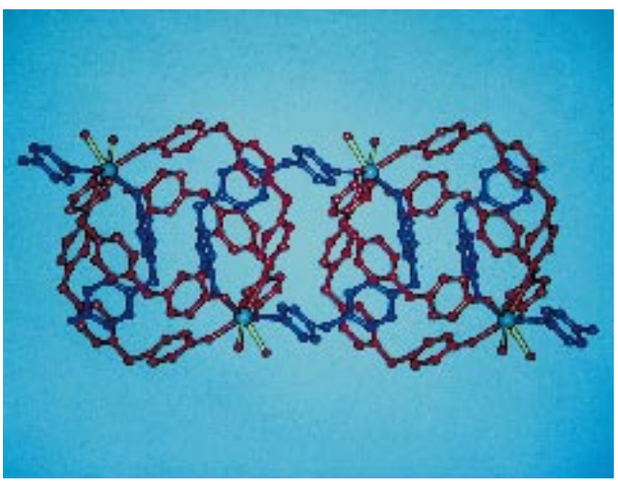

**Fig. 2** Part of one of the covalently linked chains of 'lanterns' formed by **1** in the solid state. Ligands of types A and B are shown in red and the interpenetrating C-type linkages are shown in blue.

of *ca*. 1260 Å$^3$. The 'surfaces' of these globular lanterns comprise sets of 34-membered metallocycles which are sufficiently large to permit the interweaving capability of **I** to operate. Pairs of type C ligands (shown in blue in Fig. 2) are initially directed into the central cavity but then fold and pass through the centres of the rings that form the opposite lantern faces and, by interpenetrating adjacent lanterns, form a further set of 34-membered macrocycles and link them into chains.

Pyridinone rings from the type C ligands form π–π stacked pairs within the central cavity of each lantern (Fig. 2) (mean interplanar separation of 3.37 Å and centroid–centroid distance of 3.66 Å). There is a further strong π–π interaction between pairs of pyridinone rings of type B ligands of adjacent lanterns (mean interplanar separation of 3.34 Å and centroid–centroid distance of 3.73 Å).

The solid-state structure of **1** also reveals a further type of bridging role for the *p*-XBP4 molecule not seen hitherto. The chains of lanterns are connected into sheets by cross-struts comprising non-coordinated *p*-XBP4 molecules of type D *via* strong hydrogen bonds between each of the carbonyl oxygen atoms and the pairs of aqua ligands bonded to each neodymium centre (Fig. 3).¶ The resulting voids within each sheet, *i.e.* between the D-type molecules, are occupied by the perchlorate ions, water molecules of solvation and the lantern-like spheroids of offset adjacent sheets.

The 'superstructure' described above demonstrates the ability of the *p*-XBP4 molecule to act, not only as a unit for the self-assembly of complex networks by virtue of its versatile ligand coordination behaviour, but also as an efficient hydrogen-bonding acceptor, thereby extending its crystal engineering potential.

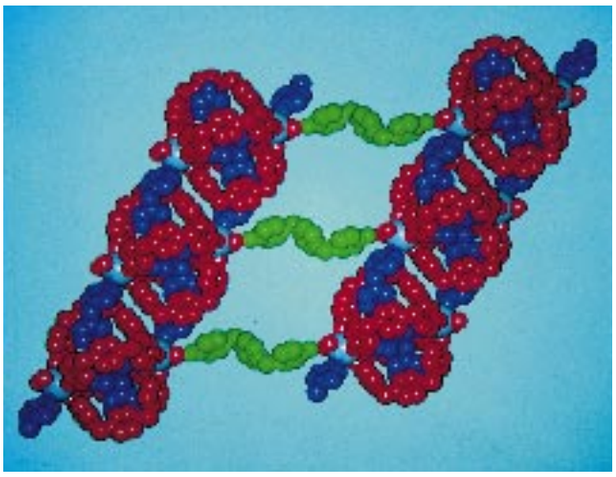

**Fig. 3** The linking of adjacent chains *via* hydrogen bonds from the aqua ligands to D-type *p*-XBP4 molecules (shown in green)

We thank the EPSRC for a Research Studentship (to A. M. S.), the BBSRC for a postdoctoral fellowship (to S. M.) and the Wolfson Foundation for equipment.

## Footnotes

† Pale mauve crystals of **1** were obtained in 43% yield by slow (2 weeks) evaporation of a solution of $Nd(ClO_4)_3{\cdot}6H_2O$ (0.04 mmol) and **I**·$4H_2O$ (0.2 mmol) in a mixture of methanol (6 cm$^3$), acetonitrile (4 cm$^3$) and water (1 cm$^3$). Satisfactory analyses were obtained.

‡ *Crystal data*: $C_{63}H_{63}Cl_3N_7NdO_{22.5}$ **1**, crystal dimensions 0.10 × 0.16 × 0.17 mm, triclinic, space group $P\bar{1}$, $a$ = 14.083(2), $b$ = 15.754(2), $c$ = 17.519(2) Å, α = 67.01(1), β = 73.51(1), γ = 69.08(1)°, $U$ = 3294.8(6) Å$^3$, $Z$ = 2, $M$ = 1528.8, $D_c$ = 1.541 g cm$^{-3}$, λ = 0.710 73 Å, μ(Mo-Kα) = 0.993 mm$^{-1}$, $T$ = 293 K, Siemens P4/PC diffractometer, graphite-monochromated Mo-Kα radiation, ω scans. The structure was solved by the heavy-atom method and was refined anisotropically, on $F^2$ data, using the SHELXTL program package (version 5.03)[6] to $R_1$ = 0.0454, $wR_2$ = 0.1168 for 7016 independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, 2θ = 3.5–45.0°]. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/351.

§ In type A ligands, the pyridinone rings have a skewed open-book conformation with respect to the central *p*-$C_6H_4$ rings, whereas in type B the geometry is closer to orthogonal. The type C ligands have their pyridinone rings oriented so that one is essentially orthogonal to the central *p*-$C_6H_4$ ring whilst the other is in an open-book conformation. Type D molecules have their pyridinone rings in an *anti* open-book arrangement.

¶ The O(aqua)···O(*p*-XBP4) distances are 2.65 and 2.70 Å and the O···O(*p*-XBP4)···O angle [O(90)···O(201)···O(91)] is 67.6°, with associated H···O and O–H···O distances and angles of 1.76 Å, 174° and 1.92 Å, 144° respectively.

# A tetranuclear neodymium cage which tightly binds sodium carbonate molecules

**Glen B. Deacon,*[a] Tiecheng Feng,[a] David C. R. Hockless,[b] Peter C. Junk,[a] Brian W. Skelton[b] and Allan H. White[b]**

[a] *Chemistry Department, Monash University, Clayton, Victoria 3168, Australia*
[b] *Department of Chemistry, University of Western Australia, Nedlands, WA 6907, Australia*

**The complexes $[Na_2Nd_4L_4(CO_3)L'_4]$ [$H_3L$ = (*o*-$HOC_6H_4CH{=}NCH_2)_2CHOH$, L′ = tetrahydrofuran or $L'_2$ = 1,2-dimethoxyethane] have novel cage structures in which $Nd_4O_{12}N_8$ bowl-shaped frameworks of $Nd_4L_4$ molecules entrap solvated $Na_2CO_3$ molecules within the cavity of the bowl.**

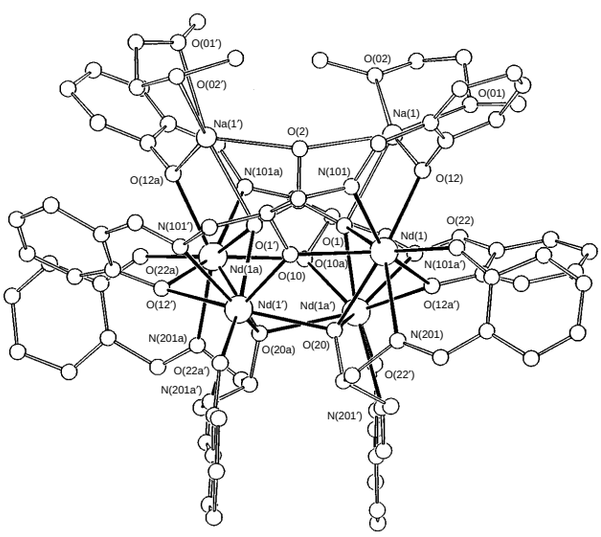
Lanthanoid alkoxide cage complexes are of great interest,[1] but aryloxide analogues are much less common. Some rare examples are based on the 4-methylphenoxide ion and include $[Na_3La_2(\mu_4\text{-}OAr)_3(\mu\text{-}OAr)_6(thf)_5]$, (thf = tetrahydrofuran, Ar = 4-$MeC_6H_4$).[2] Cage complexes have the capacity to act as hosts for a variety of guest species,[3] and there is a current focus on incorporation of anionic species, *e.g.* environmentally important contaminants such as phosphate.[4] The Schiff-base ligand (*o*-$HOC_6H_4CH{=}NCH_2)_2CHOH$ ($H_3L$), which is known to give bimetallics for d-block metals,[5] has the potential, on deprotonation to $L^{3-}$, to form mixed aryloxo–alkoxo cages with lanthanoid metals. We now report the synthesis and structure of a tetranuclear neodymium cage based on this ligand. This host tightly encapsulates solvated sodium carbonate within the cavity of the cluster, and a novel binding mode of $CO_3^{2-}$ is observed.

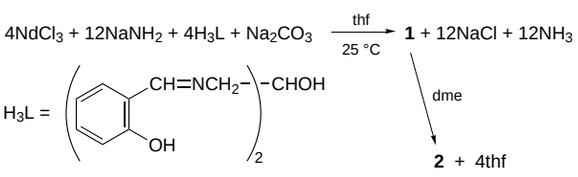
Reaction of anhydrous $NdCl_3$, $H_3L$, sodium amide and sodium carbonate in thf at room temperature (Scheme 1) resulted in triple deprotonation of the ligand and gave a blue solution from which was isolated air- and moisture-sensitive pink $[Na_2Nd_4L_4(CO_3)(thf)_4]$ **1**, in good yield.† Recrystallisation of **1** from 1,2-dimethoxyethane (dme) yielded the air- and moisture-sensitive pink complex $[Na_2Nd_4L_4(CO_3)(dme)_2]\cdot 1.5$ dme, **2**·1.5 dme.†

A synthesis in the absence of sodium carbonate gave a product with analytical composition $NdL(thf)_2$ which could not be crystallized in a form suitable for X-ray studies nor were the solubility properties suitable for characterization in solution.

The molecular structures of both **1** and **2** (Fig. 1), established by X-ray crystallography,‡ feature a tetranuclear, bowl-shaped, cage $[Nd_4L_4]$ with quasi-twofold symmetry. Within the cavity of the cage resides a multiply anchored, solvated sodium carbonate molecule, $Na_2CO_3L'_4$ (L′ = thf or $L'_2$ = dme). One carbonate oxygen bridges two sodium atoms, whilst each of the others bridges one sodium and two neodymium atoms. The carbonate coordination appears unique in combining $\mu_6$-bridging with chelation to two of the bridged atoms (**I**). This contrasts the known simple $\mu_6$-bridging[6] for the unique $CO_3^{2-}$ in the centre of $[(VO)_6(\mu_6\text{-}CO_3)(\mu\text{-}CO_3)_3(OH)_9]^{5-}$, and the recently observed $\mu_9$-bridging in a lithium siloxane complex.[7] Each sodium is five-coordinate, being bound not only by the chelating carbonate and thf or dme, but also by a bridging aryloxide oxygen of the cage (see below). Thus, sodium carbonate is securely bonded to the cage.

The $Nd_4L_4$ cage contains square-antiprismatic eight-coordinate neodymium atoms with Nd(1) and Nd(1a) of **2** different from Nd(1′) and Nd(1a′) (Fig. 1). The former are coordinated by two imide nitrogens, one $\eta^1$- and two $\mu$-aryloxide (NdONd and NdONa) oxygens, one $\mu_3$- and one $\mu$-alkoxide oxygen, and a $\mu_3$-carbonate oxygen ($ONd_2Na$). By contrast, the latter pair are





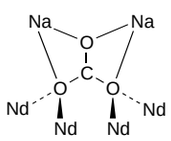


**Fig. 1** Molecular projection of $[Na_2Nd_4L_4(CO_3)(dme)_2]$ **2** normal to the quasi-twofold axis; hydrogen atoms have been omitted for clarity. Selected bond distances (Å): Nd–($\eta^1$-OAr), Nd(1)–O(22) 2.24(3), Nd(1a)–O(22a) 2.32(3), Nd(1′)–O(22a′) 2.35(2), Nd(1a′)–O(22′) 2.22(2); M–($\mu$-OAr), Nd(1)–O(12) 2.26(1), Nd(1)–O(12a′) 2.57(2), Nd(1a)–O(12a) 2.34(1), Nd(1a)–O(12′) 2.61(2), Nd(1′)–O(12′) 2.42(2), Nd(1a′)–O(12a′) 2.39(2), Na(1)–O(12) 2.34(3), Na(1′)–O(12a) 2.25(3); M–($\mu$-OCH), Nd(1)–O(10) 2.40(1), Nd(1a)–O(10a) 2.34(2), Nd(1′)–O(10) 2.36(2), Nd(1a′)–O(10a) 2.43(2); M–($\mu_3$-OCH), Nd(1)–O(20) 2.54(2), Nd(1a)–O(20a) 2.57(1), Nd(1′)–O(20) 2.47(1), Nd(1′)–O(20a) 2.46(2), Nd(1a′)–O(20) 2.49(2), Nd(1a′)–O(20a) 2.48(1); Na–($\mu$-$OCO_2$), Na(1)–O(2) 2.37(2), Na(1′)–O(2) 2.35(2); M–($\mu_3$-$OCO_2$), Nd(1)–O(1) 2.51(2), Nd(1a)–O(1′) 2.48(2), Nd(1′)–O(1′) 2.56(1), Nd(1a′)–O(1) 2.51(1), Na(1)–O(1) 2.56(1), Na(1′)–O(1′) 2.50(1); Nd–N, 2.51(2)–2.63(2); Na–O(dme), 2.48(2)–2.60(2). Selected bond angles (°) O(1)–C(1)–O(1′) 123(1), O(1)–C(1)–O(2) 117(2), O(1′)–C(1)–O(2) 120(2).

**Scheme 1**

**I**

coordinated by two nitrogens, one $\eta^1$- and one $\mu$-(NdONd)-aryloxide oxygen, one $\mu$- and two $\mu_3$-alkoxide oxygens and a $\mu_3$-carbonate oxygen.

The deprotonated ligands are bridging pentadentate and bind to each of two Nd atoms with three donor atoms, and to a further Nd by one donor atom. However, two ligands have $\mu_3$-alkoxo donors [O(20) or O(20a)] and two $\eta^1$-aryloxide oxygens whereas the other two contain $\mu$-alkoxo donors [O(10) or O(10a)], and two $\mu$-aryloxide oxygens.

The Nd–OAr distances (Fig. 1) feature short bonds to the $\eta^1$-bonded oxygens and the $\mu$-oxygens bridging to sodium, whilst the Nd–O(Ar)–Nd bonds are significantly longer for Nd(1,1a) but only marginally longer for Nd(1′,1a′). The Nd–($\eta^1$-O) bond lengths are comparable with those of La–($\eta^1$-OAr) of seven-coordinate lanthanum in the rare aryloxo cluster $NMe_4[Na_2La_2(\mu_4\text{-OAr})(\mu_3\text{-OAr})_2(\mu\text{-OAr})_4(\eta^1\text{-OAr})_2(thf)_5]$, (Ar = 4-$MeC_6H_4$).[2] (The effect of the higher coordination number of **2** offsets that of the smaller lanthanoid radius.) For Nd(1, 1a), Nd–($\mu$-OCH) distances are markedly shorter than Nd–($\mu_3$-OCH), whereas these distances differ less for Nd(1′, 1a′) (Fig. 1). However, the range is similar to that for previously reported Nd–($\mu$ or $\mu_3$-OR) bonds (*e.g.* R = $CH_2Bu^t$, $CHPr^i_2$).[1,8] Average Na–($\mu$-OAr) distances are somewhat longer than those of four-coordinate $[Na\{OC_6H_2(CF_3)_3\text{-}2,4,6\}(thf)_2]_2$[9] as is reasonable for the coordination number difference. Nd–O–$CO_2$ distances are comparable with those in the eight-coordinate Nd cage, $[Nd_8(thd)_8(H_2O)_2(\mu\text{-}Bu^tCO_2)_6(\mu_3\text{-}OH)_6(\mu_6\text{-}CO_3)_2]$, (thd = 2,2,6,6-tetramethylheptane-3,5-dionate).[10] Although there is considerable variation in the Na–$OCO_2$ distances (Fig. 1), this can be attributed to the expected difference between bonding to $\mu$- and $\mu_3$-bridged oxygens. Moreover, a similar range has been observed for 'strongly bonded' Na–($\mu$-O) in $[Na_3\{Ru_2(CO_3)_4\}\cdot 6H_2O]_n$.[11] The Nd···Nd separations [3.803(3)–3.844(4) Å] are not much larger than the sum (3.63 Å)[12] of the six-coordinate metal radii encouraging our planned investigation of the magnetic properties to explore possible Nd···Nd interactions.

We have also recently prepared and crystallographically characterized other complexes which incorporate the $Nd_4L_4$ stoichiometry. These include $[Na_5Nd_4L_4(OH)(OMe)_4(HOMe)(dme)_3]$, which contains the $Nd_4L_4$ cage in a different arrangement and encapsulates NaOH and NaOMe molecules.[13] This indicates the cage can be prepared independently of $Na_2CO_3$ and will accommodate other species.

We are grateful to the Australian Research Council for support of this work.

## Footnotes

† All operations were carried out under an atmosphere of purified $N_2$ or Ar because of the extreme sensitivity of the compounds to air and moisture. **1**: a mixture of $NdCl_3$ (0.50 g, 2.0 mmol), $H_3L$ (0.59 g, 2.0 mmol), $NaNH_2$ (0.40 g, 8.0 mmol) and $Na_2CO_3$ (0.20 g, 1.7 mmol) in thf (50 ml), was rapidly stirred at ambient temperature for 48 h, whereupon a light blue solution and a white precipitate was produced. After filtration, concentration and addition of a small amount of pentane (*ca*. 5 ml), dichroic light pink crystals of **1** deposited on prolonged standing (yield 66%) (Found: C, 47.4, H, 4.5, N, 5.5, Nd, 28.2, Na, 1.9%. $C_{85}H_{92}N_8Na_2Nd_4O_{19}$ requires C, 47.4, H, 4.3, N, 5.2, Nd, 26.8, Na, 2.1%). IR (Nujol): 1629vs, 1596s, 1550m, 1538s, 1347s, 1323s, 1302s, 1245w, 1218m, 1193m, 1145s, 1124m, 1107w, 1063m, 1040s, 1026s, 965w, 896m, 865m, 848w, 791w, 756s, 738s, 702m, 646w, 592m $cm^{-1}$. $\lambda_{max}$ (thf)/nm ($\varepsilon$/$dm^3$ $mol^{-1}$ $cm^{-1}$): 575 (213), 582 (209), 737 (130).

**2**: complex **1** was recrystallised from dme, and dichroic light pink crystals of **2** were obtained on prolonged standing (Found: C, 46.4, H, 4.8, N, 5.4%. $C_{83}H_{95}N_8Na_2Nd_4O_{22}$ requires C, 45.7, H, 4.4, N, 5.1%). IR (Nujol): 1627vs, 1596s, 1540m, 1341m, 1322m, 1290m, 1193w, 1146w, 1125w, 1057w, 1028m, 974w, 896w, 865w, 851w, 789w, 758s, 738m, 728m, 694w, 624w, 588w $cm^{-1}$. $\lambda_{max}$ (thf)/nm ($\varepsilon$/$dm^3$ $mol^{-1}$ $cm^{-1}$): 528 (78), 577 (100), 583 (115), 737 (93), 756 (89).

‡ *Crystallographic data*: **2**: air-sensitive pink crystals, $C_{83}H_{95}N_8Na_2Nd_4O_{22}$, $M$ = 2179.8, monoclinic, space group $P2_1/c$, $a$ = 25.90(1), $b$ = 22.88(2), $c$ = 15.331(6) Å, $\beta$ = 90.89(4)°; $2\theta_{max}$ = 45°. $N$ (unique) = 10733; $N_0$ [$I > 3\sigma(I)$; absorption corrected] = 4197. $R$, $R_w$ = 0.066, 0.052. Anisotropic thermal parameter refinement for Nd, Na, O, N; $(x, y, z, U_{iso})_H$ included at constrained estimates. Abnormal features: high thermal motion on the ether ligands.

**1** (a less satisfactory result): $C_{85}H_{92}N_8Na_2Nd_4O_{19}$, $M$ = 2152.7, modelled as orthorhombic; space group *Pnca*, $a$ = 25.30(3), $b$ = 23.67(1), $c$ = 15.077(5) Å; $2\theta_{max}$ = 40°. $N$, $N_o$ = 4868, 2773. $R$, $R_w$ = 0.092, 0.097. (Nd, Na anisotropic) with similar connectivity to **2** which it predates. The result of **2** raises the possibility that **1** is actually isomorphous, pseudo-orthorhombic, with monoclinic $\beta$ = 90°; no further adequately crystalline material has been forthcoming to pursue the point further.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/345.

# Photoreduction of carbon dioxide by metal phthalocyanine adsorbed Nafion membrane

**J. Rajan Premkumar and Ramasamy Ramaraj***

*School of Chemistry, Madurai Kamaraj University, Madurai-625 021, India*

**Formic acid is photosynthesised from carbon dioxide upon reduction by metal phthalocyanines adsorbed onto a Nafion membrane (photocatalyst) in acidic aqueous solution containing triethanolamine as a hole scavenger.**

The rise of carbon dioxide ($CO_2$) concentration in the atmosphere because of the 'greenhouse effect' has now become a global environmental issue. In this context, the reduction of $CO_2$ into other useful chemicals has attracted much attention.[1,2] Electrochemical reduction of $CO_2$ has been reported using modified electrodes[2–4] while its photochemical reduction has been reported using semiconductor colloids[5] and metal complexes[6] in homogeneous solution. The development of more efficient photocatalysts in the solid phase is desirable for the efficient multielectron photoreduction of $CO_2$. Catalysts immobilized in Nafion membranes are particularly advantageous due to their spatial separation from the solution phase which normally contains very many species. In the present investigation, we have used metal phthalocyanines (MPCs) adsorbed into a Nafion membrane for the photocatalytic reduction of $CO_2$. The MPC film behaves as p-type material.[7] The dopant/electron acceptor, $CO_2$, diffuses into the phthalocyanine matrix which is adsorbed in the Nafion membrane. The presence of such defect sites is a fundamental prerequisite for a good performance of the MPC film in photovoltaic/photoelectrochemical cells and for their electrical conductivity as well as photoconductivity.[7,8]

MPCs [cobalt(II) phthalocyanine (CoPC), zinc(II) phthalocyanine (ZnPC)] and Nafion membrane (type 115, 1100 equiv. wt., thickness 0.13 mm) were purchased from Aldrich. The Nafion membrane (1 $cm^2$) was pretreated by boiling in concentrated $HNO_3$ followed by washing with distilled water.[9] The MPC-adsorbed Nafion membrane was prepared by immersing the membrane in a solution containing a known concentration of CoPC or ZnPC in dmf. Then the MPC-adsorbed Nafion membrane (represented as Nf/CoPC or Nf/ZnPC) was washed and dipped in distilled water. The CoPC and ZnPC were adsorbed irreversibly and the amounts of CoPC and ZnPC adsorbed into the Nafion membrane were determined by measuring the changes in absorbance of CoPC and ZnPC in solution before and after dipping the Nafion membrane.[10] The Nf/MPC membrane was characterized by absorption and emission spectra. Fig. 1 shows the surface morphology of the

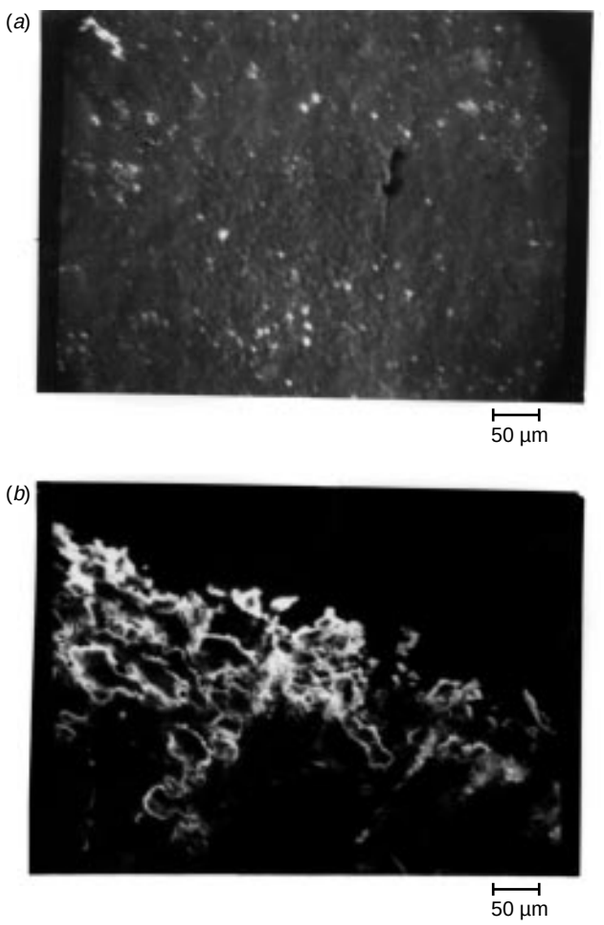

**Fig. 1** SEM photographs of (*a*) Nafion and (*b*) Nf/CoPC membranes

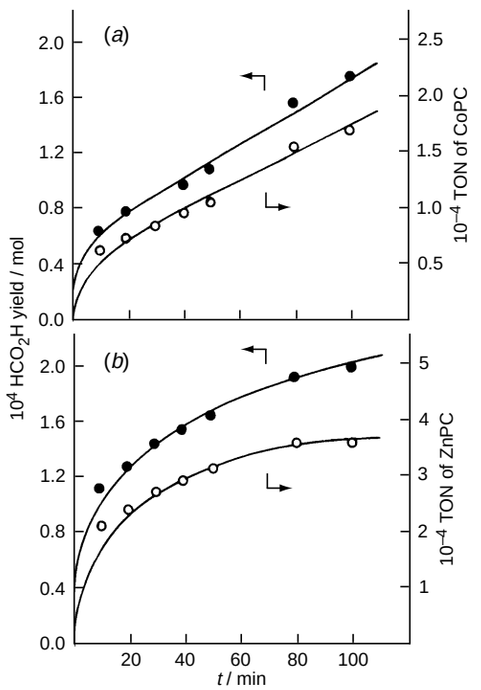

**Fig. 2** Yield of formic acid and turnover number (TON) of (*a*) Nf/CoPC and (*b*) Nf/ZnPC (1 $cm^2$ area Nafion membrane) at different light irradiation times (*t*). Adsorbed amounts: (*a*) $2.046 \times 10^{-8}$ mol CoPC and (*b*) $1.057 \times 10^{-8}$ mol ZnPC.

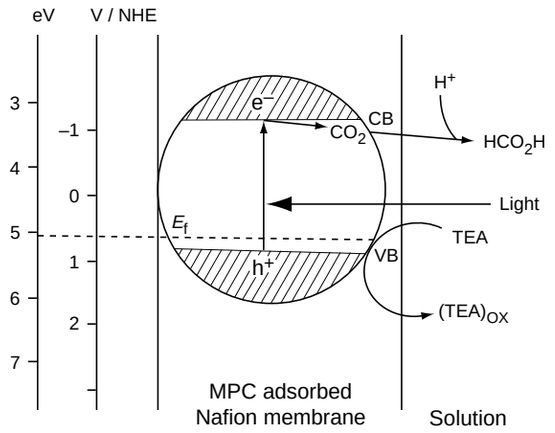
Nafion and Nf/CoPC membranes recorded using a scanning electron microscope (SEM) (Hitachi S-450). Adsorption of CoPC into the Nafion membrane [Fig. 1(*b*)] is evident when compared to the SEM of a blank Nafion membrane [Fig. 1(*a*)]. The adsorbed CoPC then agglomerates into larger deposits.

The prepared Nf/MPC was used for photocatalytic reduction of $CO_2$. The Nf/CoPC and Nf/ZnPC were dipped into a photolysis cell containing a $CO_2$-saturated aqueous solution of triethanolamine (TEA) (0.1 mol $dm^{-3}$) and $HClO_4$ (0.1 mol $dm^{-3}$) and then irradiated with visible light. A 500 W tungsten–halogen lamp was used as the light source with a water filter cell (6 cm pathlength with Pyrex glass windows) and a Pyrex-glass filter to cut off IR and UV radiation. The distance between the light source and the Nafion membrane was 40 cm. After 10–100 min of irradiation the cell solution was tested for formic acid, formaldehyde and oxalic acid using HPLC (Shimadzu, LC-8A modular HPLC system, reverse-phase column (ODS), 70% methanol mobile phase) and spectrophotometric methods.[4,11] Formic acid alone was detected as the $CO_2$ reduction product. The yields of formic acid formed at different light irradiation times at Nf/CoPC and Nf/ZnPC were determined and the corresponding turnover numbers (TONs) of CoPC and ZnPC are shown in Fig. 2. The TONs of MPCs were obtained using the relation 2 × (mol of formic acid produced/mol of MPC in Nafion membrane). The TON of ZnPC was higher than that of CoPC (Fig. 2). This may be due to the greater interaction of ZnPC with $CO_2$ than that of CoPC with $CO_2$. The axial coordinating ability of other central metals is relatively lower when compared to ZnPC.[7,12] The experiments were repeated several times and reproducible results were obtained. The Nf/MPC membrane was found to be very stable for weeks and was reused in the experiments.

In the absence of any one of the reaction components (visible light, MPC, TEA, $H^+$ and $CO_2$) formic acid was not observed. The p-type semiconductor nature of MPC film has already beenreported[7,8] and the probable photocatalytic reactions are given below [eqns. (1)–(3)]:



$$\text{MPC} + h\nu \longrightarrow \text{MPC*}\ (e^-_{CB} + h^+_{VB}) \quad (1)$$

$$2\ \text{TEA} + 2\ h^+_{VB} \longrightarrow 2\ (\text{TEA})_{ox} \quad (2)$$

$$CO_2 + 2\ e^-_{CB} + 2\ H^+ \longrightarrow HCO_2H \quad (3)$$

where $e^-_{CB}$ and $h^+_{VB}$ denote an electron in the conduction band and a positive hole in the valence band of the Nf/MPC system, respectively.

In the bulk of the Nf/MPC film, $CO_2$ plays an active role as a dopant of the p-type phthalocyanine. For MPCs, in the intrinsic case, the width of the bandgap in a slip-stack orientation of adjacent molecules is *ca*. 2.0 eV.[8] Light irradiation results in an $S_0 \rightarrow S_1$ transition, *i.e.* the formation of MPC* located about 0.2 eV below the conduction band edge. The ionized intermediates $MPC^{\cdot+}$ and $CO_2^{\cdot-}$ are formed by electron transfer. It is assumed that in a semiconductor catalyst, the photoexcited electrons in the more negative conduction band have the greater ability to reduce $CO_2$ in solution (Scheme 1). It is also reasonable to assume that the field in the microenvironmental sites as well as the highly acidic nature of the Nafion membrane[13,14] accelerate further the $CO_2$ reduction process. Investigations on the role of the MPC catalyst in the Nafion membrane in the selective production of formic acid by $CO_2$ reduction are under way.

**Scheme 1** Schematic illustration of the photocatalytic reduction of carbon dioxide at MPC adsorbed in a Nafion membrane. The circle describes the semiconducting nature of the adsorbed MPC Nafion membrane. MPC = CoPC or ZnPC, TEA = triethanolamine, CB = conduction band, VB = valence band and $E_F$ = Fermi level.

Generous financial support from the Department of Science and Technology (DST) and the Council of Scientific and Industrial Research (CSIR) is gratefully acknowledged. J. P. acknowledges the CSIR for a Senior Research Fellowship. We thank Professor G. Kulandaivelu for his help in recording SEM images.

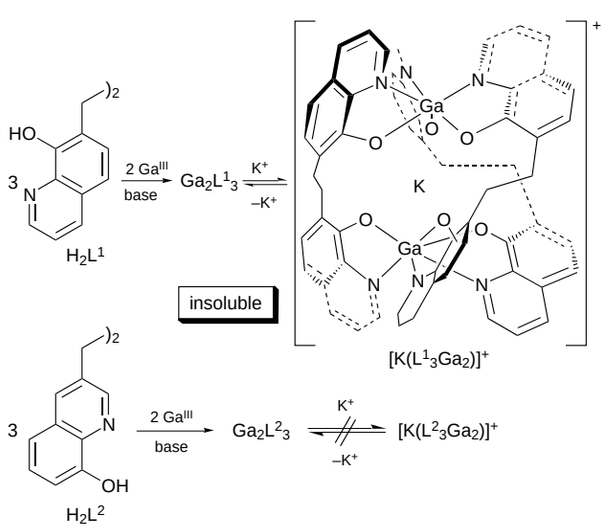
# Solubilization of a self-assembled metallocryptand by addition of $K^+$

**Markus Albrecht* and Oliver Blau**

*Institut für Organische Chemie, Universität Karlsruhe, Richard-Willstätter-Allee, D-76131 Karlsruhe, Germany*

**The insoluble self-assembled neutral coordination compound $Ga_2L^1_3$ can be solubilized by binding of $K^+$ if the ligand $H_2L^1$ with internal oxygen atoms is used.**

Helicates are formed in spontaneous self-assembly processes from linear oligo-donor ligands and appropriate metal ions. If nitrogen donors are used, cationic[1] or neutral[2] complexes are obtained, while oxygen donor ligands lead to anionic supramolecular species.[3,4] In recent studies we could show that anionic helicates, which are formed from alkyl-bridged dicatecholate ligands and titanium(IV) ions, are able to bind alkali-metal counter ions in a cryptate-type fashion.[4]



To investigate the cation binding ability of neutral self-assembled metallo-supramolecular hosts[5] we synthesized the ethylene-bridged di(8-hydroxyquinoline) ligands $H_2L^1$ and $H_2L^2$.[6] Upon formation of dinuclear triple-stranded complexes with metal ions $M^{3+}$ either a cryptand-type compound $M_2L^1_3$ with internal oxygen atoms or a cage molecule $M_2L^2_3$ without internal donor atoms should be obtained. The latter is not able to bind alkali-metal cations in its interior.[7]

To prove this hypothesis we performed the reaction of $H_2L^1$ or $H_2L^2$ (3 equiv.) with $Ga(NO_3)_3{\cdot}H_2O$ (2 equiv.) in the presence of sodium carbonate (3 equiv.) as base in methanol (Scheme 1). Heating overnight afforded yellow solids in quantitative yields. The compounds were insoluble in common solvents but elemental analysis shows the composition $Ga_2L_3{\cdot}xH_2O$ ($L^1$, $x$ = 8; $L^2$, $x$ = 7).†

If $Ga_2L^1_3$ is suspended in $(CD_3)_2SO$ and a large excess of potassium chloride or potassium chlorate is added and the sample is heated to 160 °C, the solution starts to turn yellow. The $^1H$ NMR spectrum (500 MHz, 296 K, Fig. 1) reveals the signals of the ligating moieties of $L^1$ at δ 8.67 (dd, *J* 1.0, 8.4 Hz), 7.94 (dd, *J* 1.0, 4.8 Hz), 7.76 (d, *J* 8.4 Hz), 7.62 (dd, *J* 4.8, 8.4 Hz), and 7.31 (d, *J* 8.4 Hz). Resonances of diastereotopic protons of the alkyl spacer at δ 3.08 (m) and 2.69 (m) show the presence of chiral metal complex units. Corresponding $^{13}C$ NMR signals (125 MHz, 296 K) are observed at δ 153.5 (C), 144.8 (CH), 141.2 (CH), 136.1 (C), 132.0 (CH), 128.2 (C), 125.7 (C), 121.7 (CH), 112.5 (CH) and 31.0 ($CH_2$). In accordance with our earlier work on related dinuclear catecholate–titanium systems the compound should adopt the chiral helicate[4] and not the achiral *meso*-helicate[8] structure.

Preparation of $Ga_2L^1_3$ in the presence of a large amount of potassium chloride (70 equiv.) leads to a yellow precipitate from methanol which is soluble in $(CD_3)_2SO$ and gives rise to an NMR spectrum as discussed above. FAB(+) mass spectrometry [Fig. 2, 3-nitrobenzyl alcohol (3-NBA) matrix] confirms that a cationic species $[K(L^1_3Ga_2)]^+$ is obtained. At high molar masses exclusively the peak of $[K(L^1_3Ga_2)]^+$ can be observed (*m/z* 1121, correct isotopic pattern). An analytically pure sample of $[K(L^1_3Ga_2)]Cl{\cdot}8H_2O$† was obtained by washing the solid material with a small amount of water. Extracting $[K(L^1_3Ga_2)]Cl$ with a large amount of water leads to the removal of KCl to give the insoluble neutral complex $Ga_2L^1_3$. Upon heating of $[K(L^1_3Ga_2)]Cl$ in $(CD_3)_2SO$ no dynamic behaviour can be observed by NMR spectroscopy up to 430 K indicating a remarkable configurational stability of the complex.[3,8]

$[K(L^1_3Ga_2)]Cl$ can be crystallized from dmf–diethyl ether. Preliminary results of an X-ray structure analysis[9] unambiguously show that the complex in the solid state adopts a helical structure and that the $K^+$ ion is located in the interior of the dinuclear gallium cryptand.

**Scheme 1** Preparation of $Ga_2L^1_3$, $[K\subset(L^1_3Ga_2)]Cl$ and $Ga_2L^2_3$

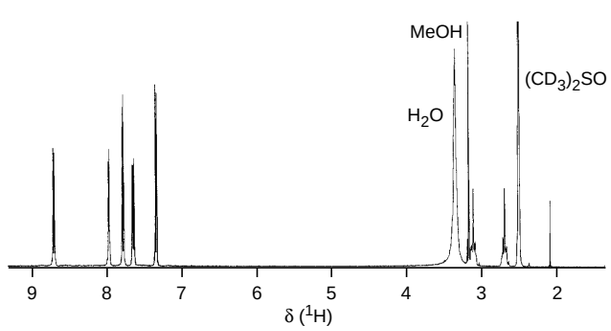


**Fig. 1** $^1H$ NMR spectrum of $[K\subset(L^1_3Ga_2)]Cl$ in $(CD_3)_2SO$

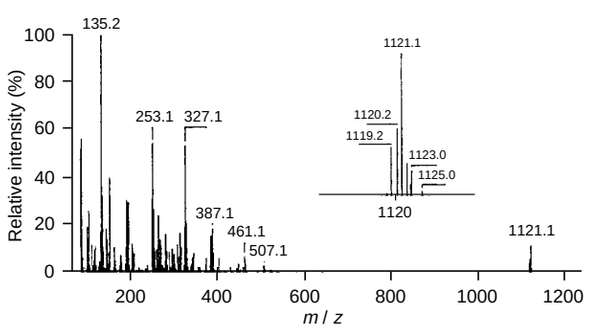

**Fig. 2** Positive FAB mass spectrum of $[K\subset(L^1Ga_2)]Cl$ (3-NBA matrix)

Due to the lack of internal oxygen donors, $Ga_2L^2_3$ is not solubilised by addition of potassium cations and heating to 160 °C. No endohedral complex with the alkaline-metal cation is formed in this case.

To summarise, we introduced a new ligand $H_2L^1$ for metallo-supramolecular chemistry which upon coordination to $Ga^{III}$ forms the neutral insoluble complex $Ga_2L^1_3$. Addition of potassium salts leads to the soluble inclusion compound $[K\subset(L^1_3Ga_2)]Cl$. By contrast, no soluble material can be obtained by addition of $K^+$ to the ligand $H_2L^2$, which does not possess internal oxygen atoms. Future work will focus on the nature of the insoluble coordination compound $Ga_2L^1_3$ and on its behaviour in the presence of different metal cations.

This work was supported by the Deutsche Forschungsgemeinschaft.

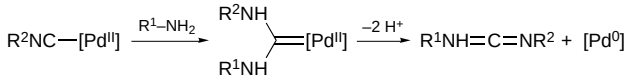
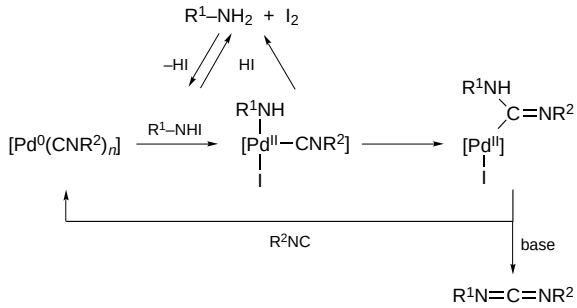
# *N*,*N*-Dialkylcarbodiimide synthesis by palladium-catalysed coupling of amines with isonitriles

**Ilan Pri-Bar[a] and Jeffrey Schwartz*[b]**



[a] *Radiochemistry Department, Rotem Industries Ltd., Beer-Sheva, 84190, Israel*
[b] *Department of Chemistry, Princeton University, Princeton, New Jersey, 08544-1009, USA*

**Catalytic condensation of amines and isonitriles can be accomplished efficiently at 100 °C using a palladium complex catalyst, oxygen, and iodine to give *N*,*N*-dialkylcarbodiimides.**



We recently reported[1] that $I_2$ can promote the homogeneous carbonylation of amines to urethanes using a palladium complex catalyst in an alcohol,† and we suggested that an *N*-iodoamine intermediate was involved. Isonitriles are isoelectronic with carbon monoxide, and we now wish to report that amines will condense with isonitriles, under conditions similar to those noted for amine carbonylation, to give good yields of *N*,*N*-dialkylcarbodiimides. This $I_2$-promoted reaction provides an alternative to conventional syntheses of carbodiimides which are accomplished *via* phosgenation of thiourea,[2] thermal coupling of isocyanates (for which synthesis also entails phosgene),[3] or catalytic dehydration of ureas.[4] Furthermore, this new route, which uses $O_2$, seems advantageous compared with another palladium complex catalysed procedure that uses silver oxide as a stoichiometric oxidant.[5]

$$R^1NH_2 + R^2NC \xrightarrow[I_2,\ O_2]{\text{Pd cat.}} R^1N{=}C{=}NR^2 + H_2O$$

**Scheme 1**

**Scheme 2**

**Scheme 3**

In a typical procedure (Scheme 1), palladium acetate (22 mg, 0.1 mmol), iodine (50 mg, 0.2 mmol), and anhydrous sodium carbonate (320 mg, 3.0 mmol) were placed in a pressure vessel. Cyclohexylamine (0.11 ml, 1.0 mmol) and cyclohexyl isocyanide (0.1 ml, 0.8 mmol) were dissolved in acetonitrile (10 ml) and added to the reaction mixture which was then pressurized with $O_2$ (40 psi) and heated to 100 °C for 3 h. The initially deep-red reaction mixture turned yellow–orange; no Pd black precipitation was observed. (There was no obvious reaction rate dependence on $O_2$ pressure.) The mixture was cooled to ambient temperature, depressurized, filtered, and analysed by GC. Carbodiimide isolation was accomplished by evaporative removal of solvent and residual amine, followed by vacuum distillation. Representative results are given in Table 1.

As shown in Table 1, aliphatic amines give some carbodiimide when $O_2$ is used as the sole oxidizing reagent (entries 2, 7). This may derive from a process (Scheme 2) which is similar to that reported[5] for a palladium complex-catalysed carbodiimide synthesis *via* a palladium(II) carbene complex; here, $O_2$ replaces $Ag_2O$ as the oxidant. Indeed, the initial rate of carbodiimide synthesis increases with increasing $O_2$ pressure. However, in the absence of iodine, the carbodiimide product undergoes subsequent hydrolysis to the urea.

We have proposed[1] that oxidative addition of an *in situ* generated *N*-iodoamine intermediate to a low-valent palladium species occurs in the context of carbamate synthesis.‡ Donor substituents could contribute to the stability of such oxidized amine intermediates and, by concentration enhancement, favour overall reaction with $Pd^0$. Relative rates for amine carbonylation were: *p*-$Me_2NC_6H_4NH_2$ > *p*-$MeOC_6H_4NH_2$ ≫ $PhNH_2$ > *p*-$ClC_6H_4NH_2$ > *p*-$MeO_2CC_6H_4NH_2$; aliphatic amines were

[a] Carbodiimide yield determined by GC; yield based on added isonitrile. [b] An unknown byproduct was also formed; no urea was produced. [c] Dicyclohexyl urea was also formed (10%) in the absence of $I_2$. [d] Reaction performed in neat amine. [e] No $Na_2CO_3$ added. [f] Di-*tert*-butyl urea was also formed (30%) in the absence of $I_2$. [g] Sym = *N*,*N*-di-*tert*-butylcarbodiimide; asym = *N*-*tert*-butyl-*N*-*n*-butylcarbodiimide.

the most reactive. Carbodiimide synthesis was slower than carbonylation for each amine investigated, and only aliphatic amines and *p*-methoxyaniline were especially reactive.§ Highest yields of carbodiimide were realized when excess amine was employed (Table 1, entries 4, 5, 6). A mechanistic alternative for the $I_2$-enhanced pathway involves oxidative addition of the *N*-iodoamine to a palladium(0) isonitrile complex,¶ which may be rate determining, or reversible. In this latter proposal (Scheme 3), migratory 'insertion' of the amido ligand‖ could be rate determining, and relative rates for insertion** *vs*. reversion to the starting amine would contribute to the overall success of the synthetic procedure, as would the presence of base, such as carbonate or excess amine. The preferred formation of the asymmetrical carbodiimide from a mixture of *tert*-butylamine and *n*-butylamine and *tert*-butyl isocyanide (Table 1, entry 9) is likely sterically controlled.

## Footnotes

† For example, palladium acetate (22 mg, 0.1 mmol), iodine (254 mg, 1.0 mmol), $Na_2CO_3$ (276 mg, 2.0 mmol), aniline (92 mg, 1.0 mmol), methanol (10 ml) 50 psi CO; 100 °C; 30 min yields methyl phenylcarbamate (74%).

‡ Aniline treated with $I_2$ under carbonylation reaction conditions (ref. 1), but in the absence of Pd or $O_2$, gave azobenzene (15%), consistent with the intermediate formation of *N*-iodoaniline.

§ A small amount of carbodiimide was produced, as determined by GC–MS, by reaction between *p*-$ClC_6H_4NH_2$ and $C_6H_{11}NC$.

¶ For oxidative addition to $(RNC)_2Pd^0$, see L. Malatesta, *J. Chem. Soc*., 1955, 3924. Relative rate trends for oxidative addition of a series of *N*-iodoamines to either $(RNC)_2Pd^0$ or $Pd^0(CO)_n$ species could be similar.

‖ Deprotonation of a palladium(II)-coordinated amine to give an amido complex has been reported using strong bases such as disilylamide (J. Louie, F. Paul and J. F. Hartwig, *Organometallics*, 1996, **15**, 2794) or *tert*-butoxide (see, for example, R. A. Widenhoefer and S. L. Buchwald, *Organometallics*, 1996, **15**, 3534). No similarly strong base is present in the system described herein.

** The rate of alkyl group 'insertion' in a $Pd^{II}(RNC)$ complex increases with increasing nucleophilicity of the migrating carbon. See S. Otsuka and K. Ataka, *J. Chem. Soc., Dalton Trans*., 1976, 327. Relative rates for amido group insertion might also follow this trend.

# Photochemical host–guest interaction in $Tb^{3+}$ and $Eu^{3+}$ ion-exchanged $K_{2-x}H_xTi_2O_5$ layered oxides

**Akihiko Kudo* and Eichi Kaneko**

*Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162, Japan*

**Luminescence of $Eu^{3+}$ and $Tb^{3+}$ intercalated in $K_{2-x}H_xTi_2O_5$ layered oxides is observed by exciting the layered titanate host indicating that the energy transfer *via* electron–hole trapping from the layered host to the guest in the interlayers occurred.**

Energy- and electron-transfer processes have been studied using various types of organic and inorganic host–guest materials. This phenomenon is especially important for rare-earth phosphors doped in inorganic bulk materials.[1] Ion-exchangeable layered oxides with structural regularity are one of the interesting host materials. Applications of the layered oxides to photochemistry, materials chemistry *etc.* have been extensively investigated.[2] The photochemical interaction in energy- and electron-transfer processes between oxide layers (hosts) and substances in interlayers (guests) is of particular interest from the viewpoint of the development of new host–guest systems. Recently, the host–guest interaction in the luminescent properties of $[Ru(bpy)_3]^{2+}$ intercalated in layered titanates and niobates has been reported.[3] Here, the photochemical host–guest interaction induced by the excitation of layered oxide hosts is revealed by the photoluminescence properties of $K_{2-x}H_xTi_2O_5$ layered oxides exchanged with rare-earth metal ions.

$K_2Ti_2O_5$ was synthesized by melting a mixture of $TiO_2$ (Kanto Chemicals, 99.0%) and $K_2CO_3$ (Kanto Chemicals) at 1270 K for 1 h in air using a platinum crucible.[4,5] $H^+$- and $Ln^{3+}$-exchanged derivatives were prepared in aqueous $LnCl_3$ (0.02 M, 40 ml) containing 1 g of $K_2Ti_2O_5$ powder. About 50% of $K^+$ in $K_2Ti_2O_5$ can easily be exchanged with $H^+$ even in distilled water.[5] Therefore, the $H^+$-exchange should partly take place during the ion-exchange reactions in aqueous $LnCl_3$ solutions; the trivalent rare-earth metal ion-exchanged derivatives are denoted $K_{2-x-3y}H_xLn_yTi_2O_5$. The compositions of the ion-exchanged derivatives were determined by EDX (Kevex, DeltaPlus). Photoluminescence was measured for powdered samples at room- and liquid-nitrogen-temperatures using a quartz cell and a fluorometer (Spex, Fluoromax™).

Fig. 1 shows the emission spectra of $H^+$-, $Eu^{3+}$- and $Tb^{3+}$-exchanged $K_{2-x}H_xTi_2O_5$ obtained by excitation at 320 nm at 77 K. The compositions of obtained materials were $K_{0.7}H_{1.3}Ti_2O_5$, $K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$ and $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$, respectively. A broad emission band was observed at 520 nm for $K_{0.7}H_{1.3}Ti_2O_5$ although an emission band was observed at 420 nm by excitation at 270 nm for $K_2Ti_2O_5$.[6] Such a shift by $H^+$-exchange in emission spectra has also been observed for layered potassium niobates.[7] It is noteworthy that the emission comes from the host of two-dimensional titanate sheets. For $K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$ and $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$, the host emission was partly quenched and emission of the rare-earth metal ions was observed ($Eu^{3+}$, $^5D_0 \rightarrow {}^7F_{1,2}$; $Tb^{3+}$, $^5D_4 \rightarrow {}^7F_{4,5,6}$). Moreover, the ratios of luminescence intensities of $Eu^{3+}$ and $Tb^{3+}$ to those of the hosts were increased by increasing the degree of ion exchange.

Fig. 2 shows the excitation spectra of the ion-exchanged derivatives at 77 K. A broad excitation band with an onset at 350 nm was observed for $K_{0.7}H_{1.3}Ti_2O_5$. For $K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$ and $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$, broad excitation bands with onsets at 350 nm were observed in addition to the peaks due to direct excitation of the rare-earth metal ions (360, 376 and 393 nm for $Eu^{3+}$, 367 and 377 nm for $Tb^{3+}$). Especially for $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$, the intensity of the broad band was larger than that of the direct excitation of $Tb^{3+}$. These broad bands were similar to that for $K_{0.7}H_{1.3}Ti_2O_5$. Luminescence of $K_{0.7}H_{1.3}Ti_2O_5$ was not observed at 300 K because non-radiative transitions in titanate layers and/or electron transfer quenching by $H^+$ in interlayers occurred. At 300 K, only the peaks due to the direct excitation of $Eu^{3+}$ and $Tb^{3+}$ were observed for the $K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$ and $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$ powder but broad bands were not obtained. Moreover, such a band was not obtained in the excitation spectrum of an aqueous $Tb^{3+}$ solution. From these results, it was concluded that the broad band was due to the excitation of titanate layers. Accordingly, the

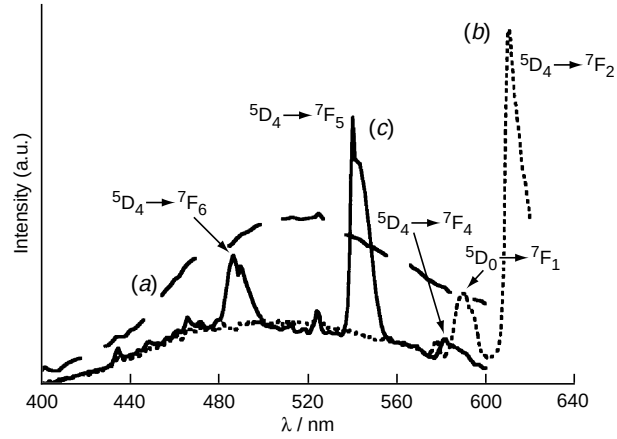

**Fig. 1** Emission spectra of (*a*) $K_{0.7}H_{1.3}Ti_2O_5$, (*b*) $K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$ and (*c*) $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$ at 77 K obtained by excitation at 320 nm

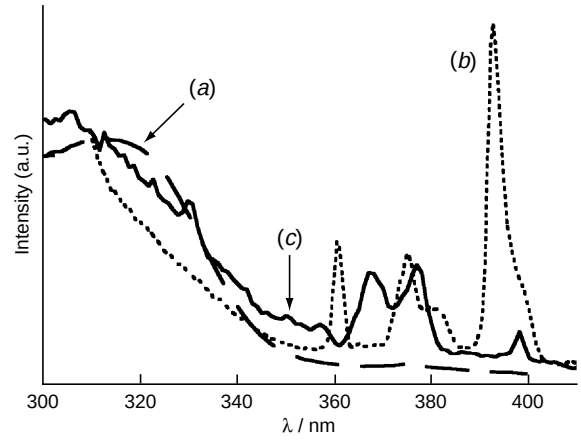

**Fig. 2** Excitation spectra of (*a*) $K_{0.7}H_{1.3}Ti_2O_5$ (monitored at 520 nm), (*b*) $K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$ (monitored at 591.5 nm) and (*c*) $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$ (monitored at 541.5 nm) at 77 K

emission spectra in Fig. 1 which had been obtained by excitation at 320 nm were due to the host excitation.

The absorption spectra of $Pr^{3+}$, $Sm^{3+}$, $Eu^{3+}$, $Tb^{3+}$, $Dy^{3+}$ and $Er^{3+}$ ions more or less overlap with the host emission spectra.[8] Therefore, the resonant energy transfer would have been possible energetically for all the rare-earth metal ion-exchanged derivatives. Unexpectedly, however, only $Eu^{3+}$ and $Tb^{3+}$ showed luminescence by the host excitation even though the amounts of rare-earth metal ions exchanged were similar in all samples ($K_{0.60}H_{1.2}Eu_{0.04}Ti_2O_5$, $K_{0.58}H_{1.4}Pr_{0.02}Ti_2O_5$, $K_{0.85}H_{1.0}Tb_{0.05}Ti_2O_5$, $K_{1.2}H_{0.68}Sm_{0.04}Ti_2O_5$, $K_{0.57}H_{1.4}Dy_{0.02}Ti_2O_5$ and $K_{0.64}H_{1.3}Er_{0.03}Ti_2O_5$). Only the host emission was observed for the $K_{0.58}H_{1.4}Pr_{0.02}Ti_2O_5$, $K_{1.2}H_{0.68}Sm_{0.04}Ti_2O_5$, $K_{0.57}H_{1.4}Dy_{0.02}Ti_2O_5$ and $K_{0.64}H_{1.3}Er_{0.03}Ti_2O_5$ powders indicating the lack of the energy transfer from the host layer to the guest ion. $Eu^{3+}$ and $Tb^{3+}$ can easily assume other oxidation numbers such as $Eu^{2+}$ and $Tb^{4+}$. Therefore, the present result can be explained as follows; electrons and holes produced by host excitation in titanate layers can be trapped by $Eu^{3+}$ and $Tb^{3+}$ located in interlayers, respectively, and holes and electrons successively can recombine at their ions resulting in the luminescence, *i.e.* electrons and holes act as carriers of the excitation energy. Photocatalytic reactions proceed at interlayers of $K_{2-x}H_xTi_2O_5$[9] indicating that the electrons and holes can actually be transferred to substances in the interlayers. The energy levels of the conduction and valence bands of the titanate layers would satisfy the redox reactions of $Eu^{3+}$ and $Tb^{3+}$ judging from the band structures of various titanates.[10,11]

In conclusion, in the $K_{2-x-3y}H_xLn_yTi_2O_5$ layered oxide system, $Eu^{3+}$ and $Tb^{3+}$ in interlayers showed luminescence upon excitation of the titanate layers. This observation indicates energy-transfer processes *via* electron–hole trapping from layered titanate hosts to guests in interlayers. The present study demonstrates the energy transfer in two-dimensional systems by probing luminescence of guests of rare-earth metal ions. This will be of particular interest as the novel photochemical host–guest system in which the direct excitation of stable layered oxide hosts plays an important role.

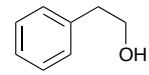
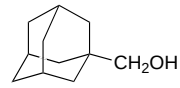
# Scandium(III) or lanthanide(III) triflates as recyclable catalysts for the direct acetylation of alcohols with acetic acid

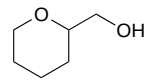
**Anthony G. M. Barrett* and D. Christopher Braddock**

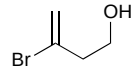
*Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London UK SW7 2AY*

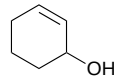
**Scandium(III) or lanthanide(III) triflates are found to efficiently catalyse the direct acetylation of primary, secondary or tertiary alcohols with acetic acid; the catalyst can be recovered quantitatively and re-used with no loss of activity.**

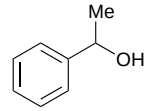


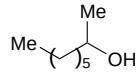


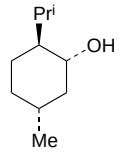


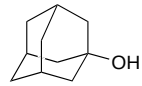


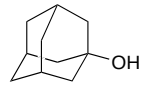












Esterification of carboxylic acids and the acylation of alcohols are fundamental processes in organic chemistry.[1,2] The direct acylation of alcohols with carboxylic acids, the Fischer esterification, can be brought about with mineral acids or sulfonic acids where the only by-product is water, *i.e.* formally an atom economic process.[3] However, the reaction is reversible and typically large excesses of either the alcohol or acid are required. Alternatively, Fischer esterifications can be driven to completion by azeotropic removal of water. However the use of strong mineral acids leads to highly acidic waste streams posing an environmental problem for industrial processes.

In order to circumvent the problem of equilibria, typically acylation of alcohols is performed with activated acyl groupings such as (mixed) acid anhydrides or acid chlorides with a stoichiometric quantity of amine base in the presence of basic catalysts such as 4-dimethylaminopyridine or 4-pyrrolidinopyridine.[2,4] These acylations work extremely well, but from an atom economic standpoint are found wanting when compared to the Fischer esterification. Acylation of alcohols can also be brought about by the action of Lewis acidic reagents in conjunction with carboxylic acids, but the Lewis acid is destroyed in the work-up procedure.[5] Similarly, Lewis acids are known to activate acid anhydrides for the acylation of alcohols,[6] but the conversion is inherently wasteful since half of every acid anhydride molecule is lost as a carboxylic acid. Furthermore, from an industrial point of view, and tonne for tonne, anhydrides are significantly more expensive than the corresponding carboxylic acid.

Lanthanides have found increasing use as mild and selective reagents in organic synthesis.[7] In particular, scandium(III) or lanthanide(III) trifluoromethanesulfonates (triflates)[8] have been used to good effect as Lewis acids in Diels–Alder,[9] allylation,[10] Friedel–Crafts[11] and Mukaiyama aldol[12,13] reactions. Many of these publications stress the ability of the catalyst to function effectively in protic media.[13,14] Indeed, for the Mukaiyama reaction the optimum solvent system was found to be aqueous THF, the catalyst recycled *via* aqueous work up and used repeatedly with little detriment to rate or yield.[13] Recently the catalytic use of scandium(III) triflate has been described for the acylation of alcohols with acid anhydrides, or with carboxylic acids in the presence of 1.5 equiv. of *p*-nitrobenzoic anhydride.[15,16] In a similar vein, the methanolysis of methoxyacetates with ytterbium(III) triflate has also been reported.[17] The compatibility of lanthanide(III) triflate salts with water and other protic solvents and yet their apparent ability to function as strong Lewis acids is somewhat paradoxical. We sought to harness this water tolerant Lewis acidity and have instigated a program in the area of clean technology using lanthanide(III) triflates for atom economic transformations.† In the course of our investigations we found that these lanthanide salts were active acylation catalysts. Herein we report the direct acylation of primary, secondary and tertiary alcohols using acetic acid in the presence of a catalytic quantity of scandium(III) or lanthanide(III) triflates. The use of acetic acid rather than acetic anhydride or acetyl chloride is both economically and environmentally advantageous. Furthermore, the catalysts are readily recyclable *via* a simple aqueous work-up.

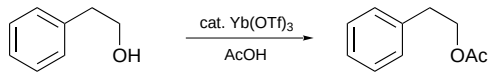
[a] 1 mmol of alcohol in 2 ml HOAc, except entry 10 (1 mmol in 5 ml HOAc) and entry 11 (1 mmol in 25 ml HOAc). [b] GC–MS determination. [c] After flash chromatography on silica gel.

The experimental procedure for these acetylations is remarkably simple, requiring neither dry glassware nor inert atmospheres: a catalytic quantity of lanthanide(III) salt (5–10 mol%) was added to a stirred solution of the alcohol (1 mmol) in acetic acid (2 ml). In the case of primary alcohols the reactions can be run at room temperature: quantitative acetylation occurs over 24 h and a range of functional groups can be tolerated (Table 1, entries 1–5). In the control experiments with no lanthanide(III) salts only small quantities of the alcohols were converted to their acetates over the same reaction time. Alternatively, the reaction can be carried out at higher temperature and acetylation is essentially complete in the time taken to bring the reaction mixture to reflux. For simple secondary alcohols somewhat elevated temperatures are required for acceptable reaction times, and again quantitative acetylation occurred (Table 1, entries 6–9). It is of interest to note that no elimination adducts were observed. Cyclohex-2-enol, an allylic alcohol, was acetylated remarkably quickly, the reaction being complete within 1 h at room temperature, while in the corresponding control experiment only traces of the acetate were detected after 24 h (Table 1, entry 5). Acetylation of adamantan-1-ol, an extremely bulky tertiary alcohol, was somewhat less successful (Table 1, entries 10 and 11). However a remarkable rate acceleration was observed and the equilibrium position was obtained in less than 0.5 h in refluxing acetic acid in the presence of a catalytic quantity of scandium(III) triflate.



Partition work-up with $CH_2Cl_2$ and water leads to the isolation of the acetylated alcohols which are essentially single components by standard analytical techniques ($^1H$ and $^{13}C$ NMR) and require no further purification (primary and secondary alcohols). The aqueous phase containing both the catalyst and acetic acid can be evaporated under reduced pressure to furnish the lanthanide(III) salt as a white solid which can be recycled and used repeatedly without loss of activity (Table 2).‡

Of the metal triflates examined in this study, scandium(III) triflate was found to be the most effective. The lanthanide(III) triflates were less active but ytterbium(III) triflate was appreciably more effective than lanthanum, praeseodymium or europium triflates (Table 3).

In conclusion, we have demonstrated the use of scandium(III) or lanthanide(III) triflates for the acetylation of alcohols using acetic acid only as the acetyl source and where the catalyst is readily recovered and re-used. This underscores the use of lanthanide salts as environmentally acceptable catalysts for atom economic transformations.

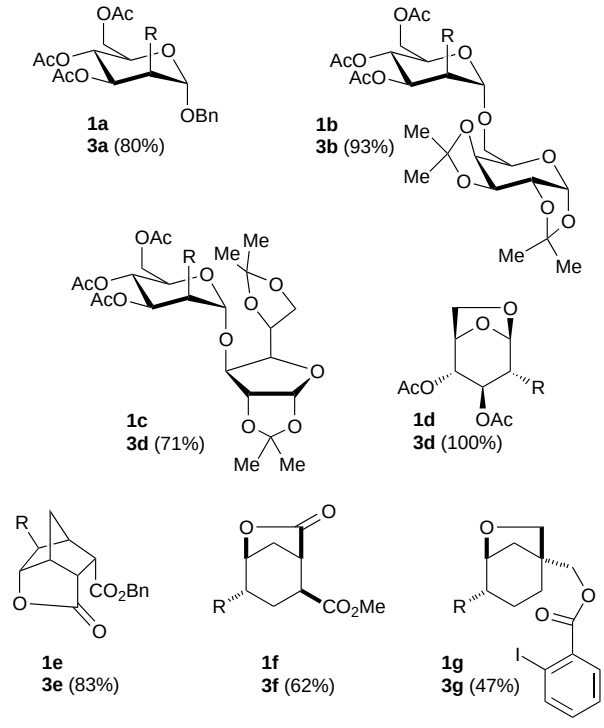
# New reductive deiodination reaction by hydrogen atom transfer from cyclohexane

**Jean Boivin,[a] Béatrice Quiclet-Sire,[b] Laure Ramos[a] and Samir Z. Zard*[a,b]**



[a] *Laboratoire de Synthèse Organique associé au CNRS, Ecole Polytechnique, 91128 Palaiseau, France*
[b] *Institut de Chimie des Substances Naturelles, CNRS, 91198 Gif-Sur-Yvette, France*

**Secondary iodides flanked by one or more inductive electron-withdrawing groups can be reduced *via* a radical chain reaction involving a hydrogen atom transfer from cyclohexane, the process being triggered by a small amount of an initiator such as dilauroyl peroxide.**

Although organoiodine compounds are seldom found in nature and are therefore rarely synthetic targets themselves, they are nevertheless very useful intermediates in organic synthesis in general.[1] Iodides are not only starting materials in a wide variety of organometallic transformations: the introduction of an iodine atom is often an integral part of the creation of another bond, as in the iodo-lactonisation reaction and other related processes.[2] When introduced in this way, and after its task has been accomplished, the iodine atom must then often be reductively removed. The most generally employed reagent for this purpose is tributylstannane, used either in stoichiometric amounts or, when possible, regenerated *in situ* by an auxiliary reducing agent such as sodium borohydride or cyanoborohydride.[3,4] Other procedures include catalytic hydrogenation, reduction with dissolving metals or low valent metal salts and, in some cases, with complex hydrides.[4] Apart perhaps from catalytic hydrogenation, most of these methods are not generally applicable to iodides derived from iodo-lactonisation since they usually cause either reductive opening of the lactone ring or reduce the lactone itself. We now report a new radical chain process where reduction is achieved by an unusual hydrogen atom transfer from cyclohexane.

The reaction of iodides with radicals is a fast and reversible process, the equilibrium lying normally to the side of the most stable radical. This important property is the basis of the Kharasch-type atom transfer reactions, which have been elegantly exploited in organic synthesis in recent years.[5] It seemed that if an *unstabilised* secondary radical generated from the corresponding iodide and rendered electrophilic by one or more inductively electron-withdrawing groups (represented by a β-acetoxy group in **1**) present in the vicinity, then it should be possible to establish the chain process outlined in Scheme 1. The key, and rate determining, step is the hydrogen abstraction from cyclohexane.[6] This process is not normally efficient with ordinary aliphatic radicals, allowing cyclohexane to be used for example as solvent in replacement of the more toxic benzene.[6] However, when the radical has electrophilic character then the hydrogen abstraction rate is promoted by favourable polar factors.[7] The requirement for secondary radicals that are not stabilised by resonance comes from a need to make the process nearly thermoneutral (and preferably slightly exothermic) rather than strongly endothermic. With primary iodides, the hydrogen abstraction step (step B) would be even more favoured, but the subsequent iodine transfer equilibrium (step A) would shift to the wrong side.

This conjecture was reduced to practice as shown by the examples (and yields) compiled in Fig. 1. The reaction is performed in the following way: a solution of the iodide in cyclohexane (0.1 M) is heated to reflux under an inert atmosphere for 20–30 min and dilauroyl peroxide (typically 17 mol% with respect to the iodide, but this amount can be decreased or increased depending on the scale and purity of the iodide) is added in one portion to the deoxygenated reaction mixture. After heating for 2–3 h (TLC monitoring), the solution is concentrated under partial vacuum and the residue purified by column chromatography. The concomitant formation of cyclohexyl iodide was confirmed by GC–MS analysis of the reaction mixture. Carbohydrate-derived iodides are ideal substrates since the presence of several carbon–oxygen bonds around the radical centre make them especially electrophilic. It is worth

**Scheme 1**

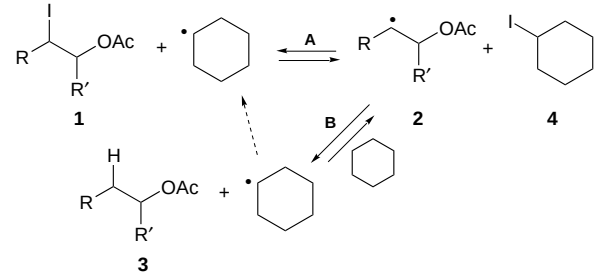


**Fig. 1** Reduction of iodides **1a–g** (R = I) into **3a–g** (R = H)

pointing out that all the substrates were constructed using either an iodo-etherification or an iodo-lactonisation reaction,[2,8] both powerful processes that introduce at the same time the iodide and an electron-withdrawing group. For example, **1b** and **1c** were made by reacting tri-*O*-acetyl-D-glucal with a 1,2:3,4-di-*O*-isopropylidene-D-galactopyranose or diacetone-D-glucose in the presence of iodosuccinimide.[8]

The importance of the electron-withdrawing group is shown by the behaviour of iodo lactones **1e** and **1f** and iodo ether **1g**. These compounds contain only one electron-attracting group next to the incipient radical centre, in contrast to the carbohydrate examples; consequently, the reaction required more dilauroyl peroxide (up to 37%). In the case of the cyclic iodo ether **1g** the yield was modest, reflecting the poorer electron-withdrawing ability of the ether linkage. Moreover, when a *mixture* of both **1f** and **1g** was subjected to the reaction conditions, lactone **1f** reacted much faster (about 5 times), as ascertained by GC–MS monitoring of the reaction. It is interesting to note that the aromatic iodide in **1g** remains largely unaffected. In fact, this competition experiment reveals aspects of selectivity that could be exploited in synthesis, and work aimed at exploring such possibilities is under way.

The present process represents a convenient and inexpensive method for reducing an important class of iodides. A number of useful and commonly encountered functional groups are tolerated. From a more fundamental point of view, it strengthens the notion that it is polar[7] and not steric effects[9] that play a predominant role in the so-called β-C–O bond effect discovered Barton and his collaborators[10] several years ago. It was noted at the time that xanthates derived from carbohydrates underwent deoxygenation more smoothly and sometimes at a lower temperature than simpler derivatives when exposed to tributyltin hydride.

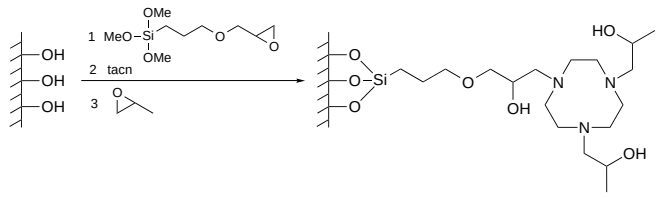
**A convenient immobilisation of triazacyclononane ligands on a glycidylated surface leads to a new group of active, heterogeneous manganese epoxidation catalysts.**

The catalytic activity of complexes of Mn and 1,4,7-triazacyclononane (tacn) type ligands in oxidation catalysis has only recently been unveiled.[1] Working in the right solvent and temperature conditions can greatly improve epoxidation activity and selectivity, although both catalytic parameters are also largely influenced by the nature of the substituents on the nitrogen atoms.[2] We now exploit this knowledge in devising an easy procedure for covalently anchoring Mn–tacn complexes on a mesoporous MCM-41 support material. Considerable research has been devoted to the covalent anchoring of first-row transition-metal catalysts, but most of this work concentrated on porphyrins. These are heterogenised on inorganic carriers *via* substitution at the periphery of the macrocycle, or *via* a coordinative bond with a covalently attached axial ligand.[3] While some non-haem transition-metal complexes have been covalently attached to the MCM-41 surface,[4] there seem to be few reports on the catalytic activity of these systems. We now report that our anchoring of tacn on a glycidylated support provides a heterogeneous catalyst in which the catalytic activity of the Mn–tacn core is well preserved.

The mesoporous, siliceous MCM-41 material was synthesised by a slightly modified literature procedure.[5] Its quality was established by XRD and by sorption measurements. In the surface modification, the dried surface of MCM-41 was first reacted with (3-glycidyloxypropyl)trimethoxysilane in dry toluene.† IR spectroscopy shows that the reaction of the silanol groups ($\nu_{OH}$ *ca.* 3745 $cm^{-1}$) is almost complete. Next tacn is added and reacts selectively with the glycidyloxypropyl (GP) residue, producing a 3-propoxy-2-hydroxypropyl substituent on the tacn macrocycle. This type of oxirane opening is well known from the preparation of 2-hydroxyalkyl-substituted tacn ligands.[6] In a third step, the remaining secondary amine groups of the anchored tacn are further functionalised, for instance through reaction with propylene oxide (Scheme 1). Careful Soxhlet extractions after the surface modification ensure that only covalently attached ligands reside on the host material. The different steps in the build-up at the surface were followed by $^{13}C$ MAS NMR, and by thermal analysis. For instance, after reaction with the glycidylating agent, the MAS NMR spectrum shows peaks at δ 73.4, 50, 44, 23 and 9, which is in close agreement with the peaks of the glycidyloxypropyltrimethoxysilane precursor. Only the $CH_2Si$ resonance is slightly shifted downfield (from δ 5.26 to 9) as a result of the surface bonding. Loadings with tacn were determined with thermogravimetric analysis; a typical loading is 0.4 mmol tacn per gram of modified MCM-41. Porosity measurements indicate that the pore volume with a radius under 20 Å substantially decreases after anchoring of the tacn (from 1.62 to 0.98 ml $g^{-1}$). For the sake of comparison, tacn was also anchored on a silica, glycidylated *via* the same method (Sil-GP–tacn); a commercial chloropropyl functionalised silica was also reacted with tacn (Sil-P–tacn).



The metal-binding properties of the functionalised surfaces were thoroughly characterized by EPR spectroscopy. Therefore the materials were doped with a small amount of $Mn^{2+}$ or $Cu^{2+}$ probe ions, corresponding to 10% of the estimated metal binding capacity.‡ The EPR parameters of $Cu^{2+}$ are highly sensitive to the composition of the primary coordination sphere, and can be used to distinguish between mono- and bis-chelated complexes [Table 1 and Fig. 1(*a*)–(*c*)].[7] In a $Cu^{2+}$ doped MCM-GP–tacn, $Cu^{2+}$ binds selectively on the bound ligand, and not on the siliceous surface. At low $Cu^{2+}$ concentrations, bis-complexes are formed. This shows that the mobility of the bound ligands and the surface coverage are sufficiently high to allow an interaction between neighbouring attached ligands. At contrast, not only bis- but also mono-complexes are observed with the $Cu^{2+}$ doped Sil-P–tacn sample. This proves that the metal binding sites are more isolated in this material. In the case of $Mn^{2+}$–MCM-GP–tacn, the selective metal binding to the ligand is evidenced by the appearance of 'non-central' lines in the X-band EPR spectrum [Fig. 1(*d*)].[8,9]

Most importantly, the catalytic activity of Mn–tacn is preserved intact after this mild anchoring procedure. Before reaction, a solution of $MnSO_4$ (8 μmol) was reacted for 1 h with the heterogenised ligand (20 mg) under an $N_2$ atmosphere. Subsequently the alkene (1 mmol) and $H_2O_2$ (2 mmol, diluted in the organic solvent in a 1 : 1 mass ratio) were added, bringing the oxidant : alkene : Mn ratio to 250 : 125 : 1. Results are given in Table 2. Especially encouraging are the high epoxide selectivities (up to 90%) obtained for styrene and cyclohexene

**Table 1** EPR parameters of crystalline and supported Cu–tacn complexes

| Complex | $g_{\parallel}$ | $\lvert A_{\parallel}\rvert$ [a] | $g_{\perp}$ |
|---|---|---|---|
| $Cu^{2+}$ on MCM-41 | 2.409 | 131 | 2.08 |
| $Cu^{2+}$ on Sil-P–tacn | 2.289 | 159 | 2.05–2.06 |
| | 2.223 | 181 | 2.05–2.06 |
| $Cu^{2+}$ on MCM-GP–tacn | 2.229 | 176 | 2.05 |
| $[Cu(tacn)Br_2]$[b] | 2.278 | 158 | 2.050 |
| $[Cu(tacn)_2]$ $[Cu(CN)_3]$[b] | 2.229 | 177 | 2.055 |

**Scheme 1**

with an Mn–MCM-GP–tacn modified with propylene oxide. This means that radical reactions are unimportant in product formation. In the particular case of styrene oxidation in methanol, the epoxide is further converted *via* acid catalysis into phenylacetaldehyde and phenylethanediol. As the siliceous MCM-41 is not acidic, the low pH of aqueous $H_2O_2$ may well be at the basis of these reactions. A typical turnover number for reactions in methanol is 50. Somewhat lower turnover numbers were obtained with other solvents such as acetone and acetonitrile, but epoxide selectivities were higher. The glycidylation approach is not limited to the MCM support. Thus a considerable activity was obtained with tacn, anchored on a glycidylated silica surface. The catalytic data prove that for tacn anchoring, the newly proposed glycidylation approach is clearly more successful than the more traditional approach *via* substitution of a silica-bound chloropropyl chain.

Summarizing, our work presents to our knowledge the first example of a catalytically active, non-aromatic Mn complex which is covalently heterogenised on an inorganic support. The reaction of the glycidyl residue with tacn is not only a very facile anchoring step; the opening of the oxirane ring by tacn also creates a hydroxy group which can assist in the metal binding.

We thank the Belgian Government for supporting this work in the framework of an I.U.A.P. project. Y. V. S. R. and D. D. V. thank K.U. Leuven and FWO (Belgium) for post-doctoral fellowships. T. B. acknowledges funding from the US Department of Energy.

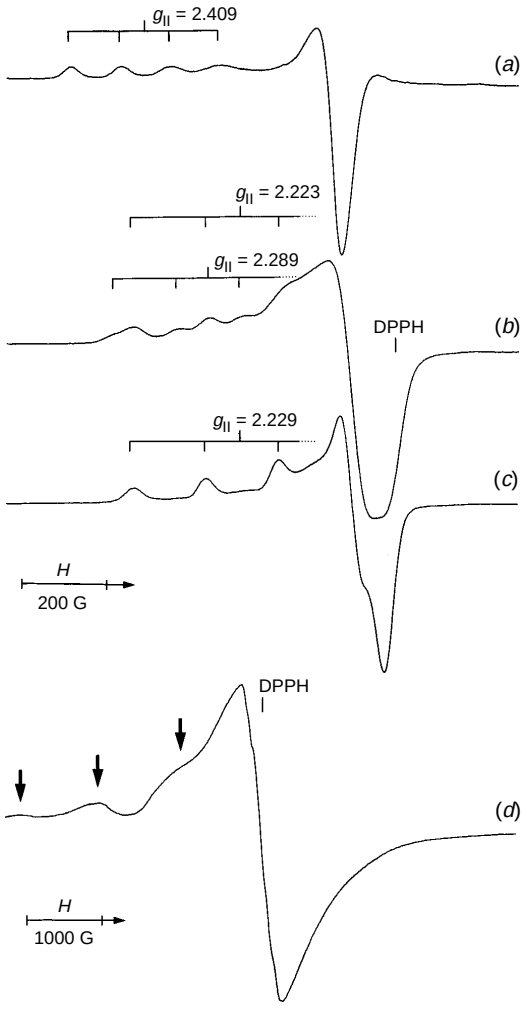

**Fig. 1** X-Band EPR spectra (130 K) of $Cu^{2+}$, adsorbed on (*a*) siliceous MCM-41, (*b*) Sil-P–tacn, (*c*) MCM-GP-tacn; (*d*) is the spectrum, recorded at 293 K under $N_2$, of $Mn^{2+}$ on MCM-GP–tacn. The clear non-central transitions (indicated by arrows) prove a strong distortion of the $Mn^{2+}$ coordination symmetry from spherical and thus coordination of $Mn^{2+}$ by a surface-bound tacn macrocycle.

**Table 2** Catalytic activity of complexes of Mn and tacn, covalently anchored on silica carriers[a]

| Substrate | Catalyst | Solvent | T.O.[b] | Selectivity[c] |
|---|---|---|---|---|
| Styrene | MCM-GP–tacn | Acetone | 4.1 | 87 (88) |
| | MCM-GP–tacn[d] | Acetone | 16 | 87 (90) |
| | MCM-GP–tacn[d] | Methanol | 52 | 24 (76) |

[a] *Reaction conditions*: 1 mmol of substrate, 2 mmol of aqueous 35% $H_2O_2$, 20 mg of support with the covalently attached ligand, 8 μmol of $MnSO_4$, 1 g of solvent, 1 h, 273 K. [b] T.O. = turnover number, *i.e.* moles of epoxide and epoxide-derived products $h^{-1}$ (mole Mn)$^{-1}$. [c] Epoxide selectivity. Numbers within parentheses includes products directly derived from the epoxide, *e.g.* phenylacetaldehyde and phenylethanediol in the case of styrene. [d] Modified with propylene oxide.

## Footnotes

† 1.0 ml (4.5 mmol) of 3-glycidyloxypropyltrimethoxysilane (Fluka) was added to 3.0 g of a freshly calcined MCM-41 in 25 ml of dry toluene and refluxed for 24 h in an $N_2$ atmosphere. After reaction the resulting solid was filtered, washed thoroughly with toluene and methanol and subjected to toluene Soxhlet extraction. The oxirane ring on the glycidylated support (1 g) was opened with tacn (80 mg) in toluene (50 ml, 50 °C, 24 h). 2-Hydroxypropyl substituents were introduced by adding an excess of propylene oxide in ethanol (293 K, 10 h). For anchoring on silica supports, analogous procedures were adopted. Silica was from Fluka (70–230 mesh) and 3-chloropropyl silica was from Aldrich (230–400 mesh).

‡ For the EPR measurements, 0.1 g of the functionalised support was stirred for 2 h in 4 ml of a 1 mM $MnSO_4{\cdot}H_2O$ or $CuSO_4{\cdot}5H_2O$ solution in methanol–water (9 : 1), and collected by filtration. For Mn, an inert atmosphere was used. The metal concentration was limited to avoid dipolar line broadening.

# X-Ray structure of the 1 : 1 complex of a tripodal receptor and *cis*-cyclohexane-1,3,5-tricarboxylic acid

**Pablo Ballester,[a] Antoni Costa,[a] Pere M. Deyà,[a] Ghislain Deslongchamps,[b] Daniel Mink,[b] Andreas Decken,[b] Rafael Prohens,[a] Salvador Tomàs[a] and Manuel Vega[a]**

[a] *Departament de Química, Universitat de les Illes Balears, 07071 Palma de Mallorca, Spain*
[b] *Department of Chemistry, University of New Brunswick, Fredericton, N.B., E3B 6E2, Canada*

**The X-ray crystal structure of the 1 : 1 complex of a tripodal abiotic receptor and *cis*-cyclohexane-1,3,5-tricarboxylic acid is reported; the 1 : 1 complex is devoid of $C_3$-symmetry and packs into a multi-columnar self-assembly.**

Two years ago, some of us reported[1] the synthesis and binding properties of the tripodal receptor **1**, designed to bind tricarboxylic acids.[2] The receptor **1** shows high selectivity[3] for binding *cis*-cyclohexane-1,3,5-tricarboxylic acid **2** (Fig. 1) and forms a very stable complex with it in chloroform solution. Molecular modeling studies[4] suggested that two different $C_3$-symmetric geometries, **3a** and **3b**, were possible for the binding of triacid **2** by receptor **1**. In both cases, six intermolecular hydrogen bonds could form between the three carboxylic acids of the guest and the three amidopyridine 'arms' of the receptor.

ROESY[5] $^1$H NMR studies of the complex in $CHCl_3$ revealed intermolecular contacts that agreed with a predominance in solution of the '*endo*'† supramolecular complex **3a**. Slow diffusion of cyclohexane into a 1 : 1 solution of **1** and **2** in $CH_2Cl_2$ produced colourless plates that were relatively unstable when removed from the mother liquor. After numerous attempts to obtain a suitable dataset, the X-ray crystal structure was solved,‡ revealing that **2** is docked into the receptor *via* six intermolecular hydrogen bonds (Fig. 2). This structure shows a complex geometry which is in general agreement with the solution structure **3a** proposed previously based on NMR data. However, the triacid complex does not possess the anticipated $C_3$-symmetry axis. The O···N distances for all six hydrogen-bonded interactions are different, ranging from 2.612 (0.010) to 2.739 (0.010) Å (N···HO) and from 2.854 (0.010) to 2.910 (0.010) Å (O···HN). The dihedral angles about the carboxy–cyclohexyl single bonds vary by as much as 94°. The asymmetry is also evident in the three propyl chains, where two are in different *anti* conformations while the third chain is *gauche*. Deviation from $C_3$-symmetry undoubtedly arises from the presence of disordered cyclohexane, which was found to be present at an occupancy less than 1 in the difference map.

Further inspection of the crystal packing reveals a columnar motif. The 1 : 1 complexes stack on top of each other in an alternating top-to-top and bottom-to-bottom fashion and form columnar supramolecular arrangements (Fig. 3). The bottom-to-bottom interaction involves π–π interaction[6] between the two central benzene rings of the receptor in a perfect face-to-face geometry separated by *ca*. 3.9 Å. The absolute stereochemistry of the complexes alternates within a single column. Thus, any two adjacent complexes within a column (whether top-to-top or bottom-to-bottom) form a perfectly centrosymmetric dimer, a direct consequence of the $C_2/c$ space group in which the complex crystallizes.

The columnar structures pack in parallel fashion to form palisade-like sheets, which are stabilized by antiparallel π–π

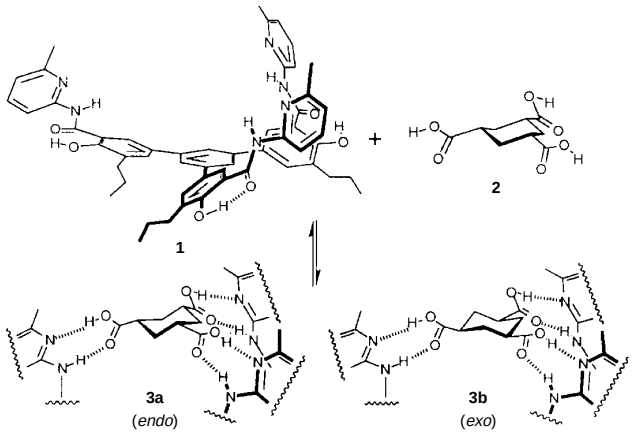

**Fig. 1** Possible binding geometries for the 1 : 1 complex of **1** and **2**

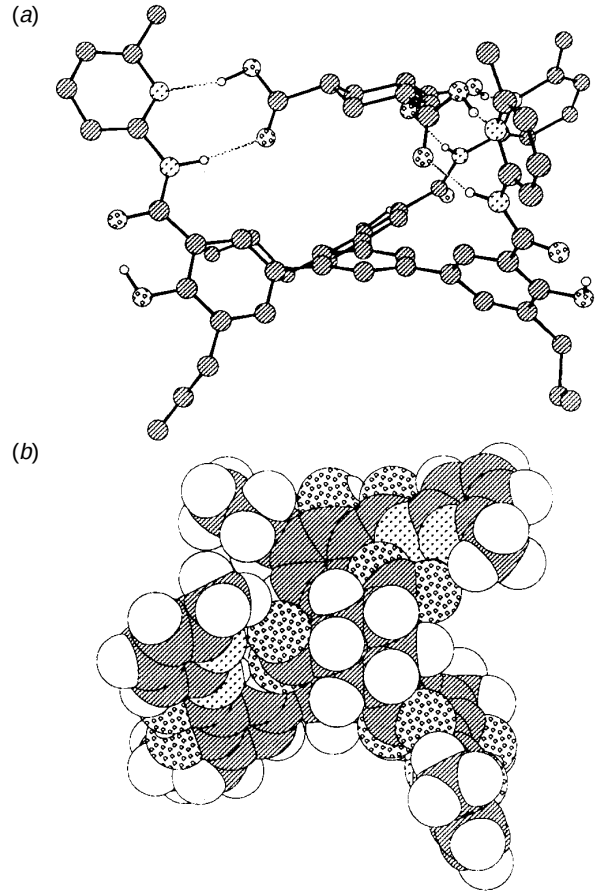

**Fig. 2** X-Ray structure of 1 : 1 complex between **1** and **2**: (*a*) side view (only polar hydrogens in calculated positions are shown, dotted lines indicate intermolecular hydrogen bonds) and (*b*) top view of a CPK representation

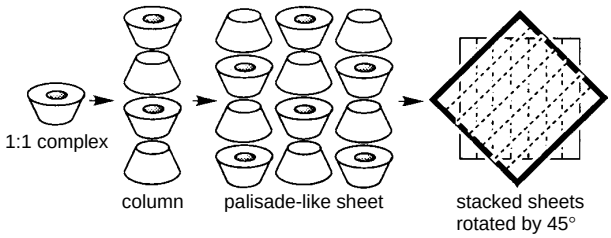

**Fig. 3** Schematic crystal packing of the 1 : 1 complex

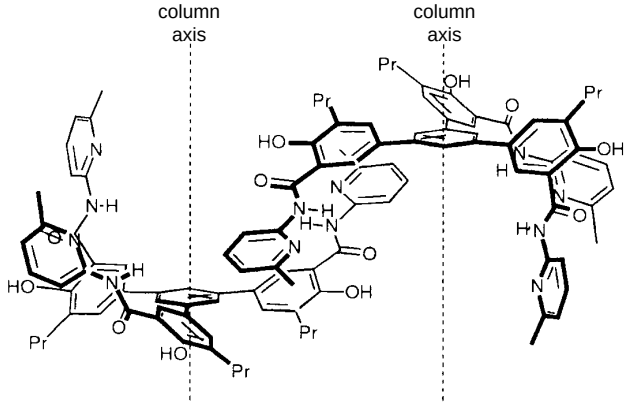

**Fig. 4** Antiparallel π-stacking between arylamidopyridine arms

stacking between arylamidopyridine 'arms' from adjacent columns (Fig. 4). The sheets stack on top of each other to complete the packing and are rotated with respect to each other by about 45°. Attempts at the X-ray characterization of other supramolecular complexes of triacids are under way, including *trans*-cyclohexane-1,3,5-tricarboxylic acid, and we will report on these findings in due course.

We thank the DGICYT (Project PB92-0251), NSERC and NATO (SRG 930949) for financial support. We are most grateful to Dr T. Stanley Cameron (Dalhousie University, Halifax, Canada) for acquisition of the X-ray data.

## Footnotes

† The terms '*endo*' and '*exo*' refer to the orientation of the three equatorial carboxy groups of **2** with respect to the receptor cavity.

‡ *Crystal data* for $C_{54}N_6O_6H_{54}\cdot C_9O_6H_{12}\cdot 0.5\ C_6H_{12}$: $M$ = 1141.30, crystallizes from dichloromethane–cyclohexane as colourless plates; crystal dimensions 0.25 × 0.25 × 0.08 mm, monoclinic, $a$ = 32.562(6), $b$ = 14.825(8), $c$ = 27.201(4) Å, β = 105.93(1)°, $U$ = 12626(8) Å$^3$, $Z$ = 8, $D_c$ = 1.201 g cm$^{-3}$, space group $C2/c$, $F(000)$ = 4848. Three-dimensional, room-temperature X-ray data were collected in the range 33 to 60° in 2θ on a Rigaku AR5F diffractometer by the θ–2θ scan method using Cu-Kα radiation; 9388 independent reflections ($R_{int}$ = 0.054 on $F^2$) were collected. The structure was solved by direct methods and refined by full-matrix least-squares methods on $F^2$. Hydrogen atoms were included in calculated positions and refined using a riding model. Refinement converged at a final $R1$ = 0.0741 ($wR2$ = 0.2098 for all 9326 data, 747 parameters, mean and maximum δ/σ 0.003, 0.043), with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density −0.307 and 0.549 e Å$^{-3}$. A weighting scheme $w = 1/[\sigma^2(F_0^2) + (0.030P)^2 + (0.00P)]$ where $P = [\max(F_0^2, 0) + 2F_c^2]/3$ was used in the latter stages of the refinement. Complex scattering factors were taken from the software package.[7]

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/344.

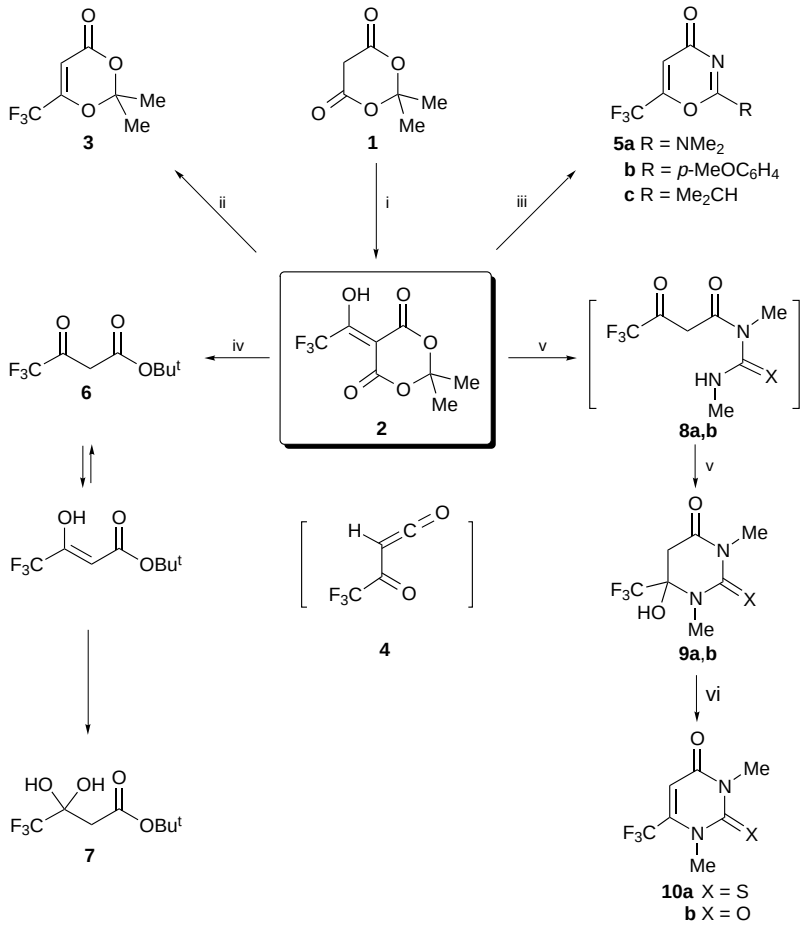
# Convenient preparation of trifluoroacetyl Meldrum's acid and its use as a building block for trifluoromethyl-containing compounds



**Yasuo Morita, Rika Kamakura, Masaki Takeda and Yutaka Yamamoto***

*Tohoku College of Pharmacy, 4-4-1 Komatsushima, Aoba-ku, Sendai 981, Japan*

**Trifluoroacetyl Meldrum's acid is conveniently prepared and applied to the synthesis of trifluoromethyl-containing compounds.**

Building block approaches are currently of major interest for the construction of biologically significant trifluoromethyl-containing organic compounds.[1] Additionally, acylketenes are reactive intermediates that have been widely used in organic synthesis.[2] In this context, trifluoroacetylketene will serve as one of the most useful building blocks. However, only a few publications have appeared concerning trifluoromethyl-containing acyl ketenes, which are generated *in situ* by the thermolysis of 4*H*-1,3-dioxin-4-one[3] or by the trifluoroacetylation of ketene.[4] Acyl Meldrum's acids[5] (5-acyl-2,2-dimethyl-1,3-dioxane-4,6-dione) also behave as a precursor of acylketene. Here we describe our preliminary findings on the simple preparation of trifluoroacetyl Meldrum′s acid and its successful application to the preparation of trifluoromethyl-containing compounds such as 6-trifluoromethyl-2*H*,4*H*-1,3-dioxin-4-one, *tert*-butyl trifluoroacetoacetate, 6-trifluoromethyl-4*H*-1,3-oxazin-4-ones and 6-trifluoromethyl (thio)uracil derivatives.†
